Abstract

We consider clustering problems with *non-uniform lower bounds and outliers*, and obtain the *first approximation guarantees* for these problems. We have a set \mathcal{F} of facilities with lower bounds $\{L_i\}_{i \in \mathcal{F}}$ and a set \mathcal{D} of clients located in a common metric space $\{c(i, j)\}_{i, j \in \mathcal{F} \cup \mathcal{D}}$, and bounds k, m . A feasible solution is a pair $(S \subseteq \mathcal{F}, \sigma : \mathcal{D} \mapsto S \cup \{\text{out}\})$, where σ specifies the client assignments, such that $|S| \leq k$, $|\sigma^{-1}(i)| \geq L_i$ for all $i \in S$, and $|\sigma^{-1}(\text{out})| \leq m$. In the *lower-bounded min-sum-of-radii with outliers* (LBkSRO) problem, the objective is to minimize $\sum_{i \in S} \max_{j \in \sigma^{-1}(i)} c(i, j)$, and in the *lower-bounded k-supplier with outliers* (LBkSupO) problem, the objective is to minimize $\max_{i \in S} \max_{j \in \sigma^{-1}(i)} c(i, j)$.

We obtain an approximation factor of 12.365 for LBkSRO, which improves to 3.83 for the non-outlier version (i.e., $m = 0$). These also constitute the *first approximation bounds* for the min-sum-of-radii objective when we consider lower bounds and outliers *separately*. We apply the primal-dual method to the relaxation where we Lagrangify the $|S| \leq k$ constraint. The chief technical contribution and novelty of our algorithm is that, departing from the standard paradigm used for such constrained problems, we obtain an $O(1)$ -approximation *despite the fact that we do not obtain a Lagrangian-multiplier-preserving algorithm for the Lagrangian relaxation*. We believe that our ideas have broader applicability to other clustering problems with outliers as well.

We obtain approximation factors of 5 and 3 respectively for LBkSupO and its non-outlier version. These are the *first approximation results* for k -supplier with *non-uniform* lower bounds.

1 Introduction

Clustering is an ubiquitous problem arising in applications in various fields such as data mining, machine learning, image processing, and bioinformatics. Many of these problems involve finding a set S of at most k “cluster centers”, and an assignment σ mapping an underlying set \mathcal{D} of data points located in some metric space $\{c(i, j)\}$ to S , to minimize

some objective function; examples include the *k-center* (minimize $\max_{j \in \mathcal{D}} c(\sigma(j), j)$) [20, 21], *k-median* (minimize $\sum_{j \in \mathcal{D}} c(\sigma(j), j)$) [9, 22, 25, 6], and *min-sum-of-radii* (minimize $\sum_{i \in \mathcal{S}} \max_{j: \sigma(j)=i} c(i, j)$) [15, 11] problems. Viewed from this perspective, clustering problems can often be viewed as *facility-location* problems, wherein an underlying set of clients that require service need to be assigned to facilities that provide service in a cost-effective fashion. Both clustering and facility-location problems have been extensively studied in the Computer Science and Operations Research literature; see, e.g., [27, 29] in addition to the above references.

We consider clustering problems with (non-uniform) *lower-bound requirements* on the cluster sizes, and where a bounded number of points may be designated as *outliers* and left unclustered. One motivation for considering lower bounds comes from an *anonymity* consideration. In order to achieve data privacy, [28] proposed an anonymization problem where we seek to perturb (in a specific way) some of (the attributes of) the data points and then cluster them so that every cluster has at least L identical perturbed data points, thus making it difficult to identify the original data from the clustering. As noted in [2, 1], this anonymization problem can be abstracted as a lower-bounded clustering problem where the clustering objective captures the cost of perturbing data. Another motivation comes from a facility-location perspective, where (as in the case of *lower-bounded facility location*), the lower bounds model that it is infeasible or unprofitable to use services unless they satisfy a certain minimum demand (see, e.g., [26]). Allowing outliers enables one to handle a common woe in clustering problems, namely that data points that are quite dissimilar from any other data point can often disproportionately (and undesirably) degrade the quality of *any* clustering of the *entire* data set; instead, the outlier-version allows one to designate such data points as outliers and focus on the data points of interest.

Formally, adopting the facility-location terminology, our setup is as follows. We have a set \mathcal{F} of facilities with lower bounds $\{L_i\}_{i \in \mathcal{F}}$ and a set \mathcal{D} of clients located in a common metric space $\{c(i, j)\}_{i, j \in \mathcal{F} \cup \mathcal{D}}$, and bounds k, m . A feasible solution chooses a set $S \subseteq \mathcal{F}$ of at most k facilities, and assigns each client j to a facility $\sigma(j) \in S$, or designates j as an outlier by setting $\sigma(j) = \text{out}$ so that $|\sigma^{-1}(i)| \geq L_i$ for all $i \in S$, and $|\sigma^{-1}(\text{out})| \leq m$. We consider two clustering objectives: minimize $\sum_{i \in S} \max_{j: \sigma(j)=i} c(i, j)$, which yields the *lower-bounded min-sum-of-radii with outliers* (LBkSRO) problem, and minimize $\max_{i \in S} \max_{j: \sigma(j)=i} c(i, j)$, which yields the *lower-bounded k-supplier with outliers* (LBkSupO) problem. We refer to the non-outlier versions of the above problems (i.e., where $m = 0$) as LBkSR and LBkSup respectively.

Our contributions. We obtain the *first* results for clustering problems with *non-uniform lower bounds and outliers*. We develop various techniques for tackling these problems using which we obtain *constant-factor approximation guarantees* for LBkSRO and LBkSupO. Note that we need to ensure that none of the *hard* constraints involved here – at most k clusters, non-uniform lower bounds, and at most m outliers – are violated, which is somewhat challenging.

We obtain an approximation factor of 12.365 for LBkSRO (Theorem 7, Section 2.2), which improves to 3.83 for the non-outlier version LBkSR (Theorem 6, Section 2.1). These also constitute the *first* approximation results for the min-sum-of-radii objective when we consider: (a) lower bounds (even uniform bounds) but no outliers (LBkSR); and (b) outliers but no lower bounds. Previously, an $O(1)$ -approximation was known only in the setting where there are *no lower bounds and no outliers* (i.e., $L_i = 0$ for all i , $m = 0$) [11].

For the k -supplier objective (Section 3), we obtain an approximation factor of 5 for LBkSupO (Theorem 16), and 3 for LBkSup (Theorem 15). These are the *first* approximation

results for the k -supplier problem with non-uniform lower bounds. Previously, [1] obtained approximation factors of 4 and 2 respectively for $\text{LB}k\text{SupO}$ and $\text{LB}k\text{Sup}$ for the special case of *uniform* lower bounds and when $\mathcal{F} = \mathcal{D}$ (often called the k -center version). Complementing our approximation bounds, we prove a factor-3 hardness of approximation for $\text{LB}k\text{Sup}$ (Theorem 17), which shows that our approximation factor of 3 is optimal for $\text{LB}k\text{Sup}$.

Our techniques. Our main technical contribution is an $O(1)$ -approximation algorithm for $\text{LB}k\text{SRO}$ (Section 2.2). Whereas for the non-outlier version $\text{LB}k\text{SR}$ (Section 2.1), one can follow an approach similar to that in [11] for the min-sum-of-radii problem without lower bounds or outliers, the presence of outliers creates substantial difficulties whose resolution requires various novel ingredients. As in [11], we view $\text{LB}k\text{SRO}$ as a k -ball-selection (k -BS) problem of picking k suitable balls (see Section 2) and consider its LP-relaxation (P_2). Let OPT denote its optimal value. Following the Jain-Vazirani (JV) template for k -median [22], we move to the version where we may pick any number of balls but incur a fixed cost of z for each ball we pick. The dual LP (D_2) has α_j dual variables for the clients, which “pay” for (i, r) pairs (where (i, r) denotes the ball $\{j \in \mathcal{D} : c(i, j) \leq r\}$). For $\text{LB}k\text{SR}$ (where $m = 0$), as observed in [11], it is easy to adapt the JV primal-dual algorithm for facility location to handle this fixed-cost version of k -BS: we raise the α_j s of uncovered clients until all clients are covered by some fully-paid (i, r) pair (see PDAlg). This yields a so-called *Lagrangian-multiplier-preserving* (LMP) 3-approximation algorithm: if F is the primal solution constructed, then $3 \sum_j \alpha_j$ can pay for $\text{cost}(F) + 3|F|z$; hence, by varying z , one can find two solutions F_1, F_2 for nearby values of z , and combine them to extract a low-cost k -BS-solution.

The presence of outliers in $\text{LB}k\text{SRO}$ significantly complicates things. The natural adaptation of the primal-dual algorithm is to now stop when at least $|\mathcal{D}| - m$ clients are covered by fully-paid (i, r) pairs. But now, the dual objective involves a $-m \cdot \gamma$ term, where $\gamma = \max_j \alpha_j$, which potentially cancels the dual contribution of (some) clients that pay for the last fully-paid (i, r) pair, say f . Consequently, we *do not obtain an LMP-approximation*: if F is the primal solution we construct, we can only say that (roughly) $3(\sum_j \alpha_j - m \cdot \gamma)$ pays for $\text{cost}(F \setminus f) + 3|F \setminus f|z$ (see Theorem 8 (ii)). In particular, this means that *even if the primal-dual algorithm returns a solution with k pairs, its cost need not be bounded*, an artifact that never arises in $\text{LB}k\text{SR}$ (or k -median). This in turn means that by combining the two solutions F_1, F_2 found for $z_1, z_2 \approx z_1$, we only obtain a solution of cost $O(\text{OPT} + z_1)$ (see Theorem 10).

Dealing with the case where $z_1 = \Omega(\text{OPT})$ is technically the most involved portion of our algorithm (Section 2.2.2). We argue that in this case the solutions F_1, F_2 (may be assumed to) have a very specific structure: $|F_1| = k + 1$, and every F_2 -ball intersects at most one F_1 -ball, and vice versa. We utilize this structure to show that either we can find a good solution in a suitable neighborhood of F_1 and F_2 , or F_2 itself must be a good solution.

We remark that the above difficulties (i.e., the inability to pay for the last “facility” and the ensuing complications) also arise in the k -median problem with outliers. We believe that our ideas also have implications for this problem and should yield a much-improved approximation ratio for this problem. (The current guarantee is a large (unspecified) constant [12].)

For the k -supplier problem, $\text{LB}k\text{SupO}$, we leverage the notion of skeletons and pre-skeletons defined by [14] in the context of *capacitated k -supplier with outliers*, wherein facilities have capacities instead of lower bounds limiting the number of clients that can be assigned to them. Roughly speaking, a skeleton $F \subseteq \mathcal{F}$ ensures there is a low-cost solution (F, σ) . A pre-skeleton satisfies some of the properties of a skeleton. We show that if F is a pre-skeleton,

then either F is a skeleton or $F \cup \{i\}$ is a pre-skeleton for some facility i . This allows one to find a sequence of facility-sets such that at least one of them is a skeleton. For a given set F , one can check if F admits a low-cost assignment σ , so this yields an $O(1)$ -approximation algorithm.

Related work. There is a vast literature on clustering and facility-location (FL) problems (see, e.g., [27, 29]); we limit ourselves to work that is relevant to LBkSRO and LBkSupO.

The only prior work on clustering problems to incorporate both lower bounds *and* outliers is by Aggarwal et al. [1]. They obtain approximation ratios of 4 and 2 respectively for LBkSupO and LBkSup with *uniform* lower bounds, which they consider as a means of achieving anonymity. They also consider an alternate *cellular clustering* (CellC) objective and devise an $O(1)$ -approximation algorithm for lower-bounded CellC with uniform lower bounds, and mention that this can be extended to an $O(1)$ -approximation for lower-bounded CellC with outliers.

More work has been directed towards clustering problems involving outliers *or* lower bounds (but not both). Charikar et al. [10] consider (among other problems) the outlier-versions of the uncapacitated FL, k -supplier and k -median problems. They devise constant-factor approximations for the first two problems, and a bicriteria approximation for the k -median problem with outliers. They also proved a factor-3 approximation hardness result for k -supplier with outliers. This nicely complements our factor-3 hardness result for k -supplier with lower bounds but no outliers. Chen [12] obtained the first true approximation for k -median with outliers via a sophisticated combination of the primal-dual algorithm for k -median and local search that yields a large (unspecified) $O(1)$ -approximation. Cygan and Kociumaka [14] consider the *capacitated k -supplier with outliers* problem, and devise a 25-approximation algorithm. We leverage some of their ideas in developing our algorithm for LBkSupO.

Lower-bounded clustering and FL problems remain largely unexplored and ill-understood. Besides LBkSup (which has also been studied in Euclidean spaces [16]) another such FL problem that has been studied is *lower-bounded facility location* (LBFL) [23, 19], wherein we seek to open facilities (which have lower bounds) and assign each client j to an open facility $\sigma(j)$ so as to minimize $\sum_{j \in \mathcal{D}} c(\sigma(j), j)$. Svitkina [30] obtained the first true approximation for LBFL, achieving an $O(1)$ -approximation; the $O(1)$ -factor was subsequently improved by [3]. Both results apply to LBFL with uniform lower bounds, and can be adapted to yield $O(1)$ -approximations to the k -median variant (where we may open at most k facilities).

Doddi et al. [15] introduced the min-sum-of-diameters objective, which is closely related to the min-sum-of-radii objective (the former is at most twice the latter). Charikar and Panigrahi [11] devised the first (and current-best) $O(1)$ -approximation algorithms for these problems, obtaining approximation ratios of 3.53 and 7.06 for the radii and diameter problems respectively. Various other results are known for specific metric spaces and when $\mathcal{F} = \mathcal{D}$, such as Euclidean spaces [18, 7] and metrics with bounded aspect ratios [17, 5].

The k -supplier and k -center (i.e., k -supplier with $\mathcal{F} = \mathcal{D}$) objectives have a rich history of study. Hochbaum and Shmoys [20, 21] obtained optimal approximation ratios of 3 and 2 for these problems respectively. Capacitated versions of k -center and k -supplier have also been studied: [24] devised a 6-approximation for uniform capacities, [13] obtained the first $O(1)$ -approximation for non-uniform capacities, and this $O(1)$ -factor was improved to 9 in [4].

Finally, our algorithm for LBkSRO leverages the template based on Lagrangian relaxation and the primal-dual method to emerge from the work of [22, 8] for the k -median problem.

2 Minimizing sum of radii with lower bounds and outliers

Recall that in the *lower-bounded min-sum-of-radii with outliers* (LBkSRO) problem, we have a facility-set \mathcal{F} and client-set \mathcal{D} located in a metric space $\{c(i, j)\}_{i, j \in \mathcal{F} \cup \mathcal{D}}$, lower bounds $\{L_i\}_{i \in \mathcal{F}}$, and bounds k and m . A feasible solution is a pair $(S \subseteq \mathcal{F}, \sigma : \mathcal{D} \mapsto S \cup \{\text{out}\})$, where $\sigma(j) \in S$ indicates that j is assigned to facility $\sigma(j)$, and $\sigma(j) = \text{out}$ designates j as an outlier, such that $|S| \leq k$, $|\sigma^{-1}(i)| \geq L_i$ for all $i \in S$, and $|\sigma^{-1}(\text{out})| \leq m$. The cost $\text{cost}(S, \sigma)$ of such a solution is $\sum_{i \in S} r_i$, where $r_i := \max_{j \in \sigma^{-1}(i)} c(i, j)$ denotes the *radius* of facility i ; the goal is to find a solution of minimum cost. We use LBkSR to denote the non-outlier version where $m = 0$.

It will be convenient to consider a relaxation of LBkSRO that we call the *k-ball-selection* (*k-BS*) problem, which focuses on selecting at most k balls centered at facilities of minimum total radius. More precisely, let $B(i, r) := \{j \in \mathcal{D} : c(i, j) \leq r\}$ denote the ball of clients centered at i with radius r . Let $c_{\max} = \max_{i \in \mathcal{F}, j \in \mathcal{D}} c(i, j)$. Let $\mathcal{L}_i := \{(i, r) : |B(i, r)| \geq L_i\}$, and $\mathcal{L} := \bigcup_{i \in \mathcal{F}} \mathcal{L}_i$. The goal in *k-BS* is to find a set $F \subseteq \mathcal{L}$ with $|F| \leq k$ and $|\mathcal{D} \setminus \bigcup_{(i, r) \in F} B(i, r)| \leq m$ so that $\text{cost}(F) := \sum_{(i, r) \in F} r$ is minimized. (When formulating the LP-relaxation of the *k-BS*-problem, we equivalently view \mathcal{L} as containing only pairs of the form $(i, c(i, j))$ for some client j , which makes \mathcal{L} finite.) It is easy to see that any LBkSRO-solution yields a *k-BS*-solution of no greater cost. The key advantage of working with *k-BS* is that we do not explicitly consider the lower bounds (they are folded into the \mathcal{L}_i s) and we do not require the balls $B(i, r)$ for $(i, r) \in F$ to be disjoint. While a *k-BS*-solution F need not directly translate to a feasible LBkSRO-solution, one can show that it does yield a feasible LBkSRO-solution of cost at most $2 \cdot \text{cost}(F)$. We prove a stronger version of this statement in Lemma 1. In the following two sections, we utilize this relaxation to devise the *first* constant-factor approximation algorithms for for LBkSR and LBkSRO. To our knowledge, our algorithm is also the first $O(1)$ -approximation algorithm for the outlier version of the min-sum-of-radii problem *without* lower bounds.

We consider an LP-relaxation for the *k-BS*-problem, and to round a fractional *k-BS*-solution to a good integral solution, we need to preclude radii that are much larger than those used by an optimal solution. We therefore “guess” the t facilities in the optimal solution with the largest radii, and their radii, where $t \geq 1$ is some constant. That is, we enumerate over all $O((|\mathcal{F}| + |\mathcal{D}|)^{2t})$ choices $F^O = \{(i_1, r_1), \dots, (i_t, r_t)\}$ of t (i, r) pairs from \mathcal{L} . For each such selection, we set $\mathcal{D}' = \mathcal{D} \setminus \bigcup_{(i, r) \in F^O} B(i, r)$, $\mathcal{L}' = \{(i, r) \in \mathcal{L} : r \leq \min_{p=1, \dots, t} r_p\}$ and $k' = k - |F^O|$, and run our *k-BS*-algorithm on the modified *k-BS*-instance $(\mathcal{F}, \mathcal{D}', c, \mathcal{L}', k', m)$ to obtain a *k-BS*-solution F . We translate $F \cup F^O$ to an LBkSRO-solution, and return the best of these solutions. The following lemma, and the procedure described therein, is repeatedly used to bound the cost of translating $F \cup F^O$ to a feasible LBkSRO-solution. We call pairs $(i, r), (i', r') \in \mathcal{F} \times \mathbb{R}_{\geq 0}$ *non-intersecting*, if $c(i, i') > r + r'$, and *intersecting* otherwise. Note that $B(i, r) \cap B(i', r') = \emptyset$ if (i, r) and (i', r') are non-intersecting. For a set $P \subseteq \mathcal{F} \times \mathbb{R}_{\geq 0}$ of pairs, define $\mu(P) := \{i \in \mathcal{F} : \exists r \text{ s.t. } (i, r) \in P\}$.

► **Lemma 1.** *Let $F^O \subseteq \mathcal{L}$, and $\mathcal{D}', \mathcal{L}', k'$ be as defined above. Let $F \subseteq \mathcal{L}$ be a *k-BS*-solution for the *k-BS*-instance $(\mathcal{F}, \mathcal{D}', c, \mathcal{L}', k', m)$. Suppose for each $i \in \mu(F)$, we have a radius $r'_i \leq \max_{r: (i, r) \in F} r$ such that the pairs in $U := \bigcup_{i \in \mu(F)} (i, r'_i)$ are non-intersecting and $U \subseteq \mathcal{L}'$. Then there exists a feasible LBkSRO-solution (S, σ) with $\text{cost}(S, \sigma) \leq \text{cost}(F) + \sum_{(i, r) \in F^O} 2r$.*

2.1 Approximation algorithm for LBkSR

We now present our algorithm for the non-outlier version, LBkSR, which introduces many of the ideas underlying our algorithm for LBkSRO (Section 2.2). Let O^* be the cost of an optimal

solution to the given $\text{LB}k\text{SR}$ instance. For each selection $(i_1, r_1), \dots, (i_t, r_t)$ of t pairs, we do the following. We set $\mathcal{D}' = \mathcal{D} \setminus \bigcup_{p=1}^t B(i_p, r_p)$, $\mathcal{L}' = \{(i, r) \in \mathcal{L} : r \leq R^* := \min_{p=1, \dots, t} r_p\}$, $k' = k - t$, and consider the k -BS-problem of picking a min-cost set of at most k' pairs from \mathcal{L}' whose corresponding balls cover \mathcal{D}' (but our algorithm $k\text{-BSAlg}$ will return pairs from \mathcal{L}). Consider the following natural LP-relaxation (P_1) of this problem, and its dual (D_1) .

$$\begin{array}{ll}
\min & \sum_{(i,r) \in \mathcal{L}'} r \cdot y_{i,r} \quad (P_1) \\
\text{s.t.} & \sum_{(i,r) \in \mathcal{L}': j \in B(i,r)} y_{i,r} \geq 1 \quad \forall j \in \mathcal{D}' \\
& \sum_{(i,r) \in \mathcal{L}'} y_{i,r} \leq k' \quad (1) \\
& y \geq 0.
\end{array}
\quad
\begin{array}{ll}
\max & \sum_{j \in \mathcal{D}'} \alpha_j - k' \cdot z \quad (D_1) \\
\text{s.t.} & \sum_{j \in B(i,r) \cap \mathcal{D}'} \alpha_j - z \leq r \quad \forall (i,r) \in \mathcal{L}' \\
& \alpha, z \geq 0.
\end{array}
\quad (2)$$

Let OPT denote the common optimal value of (P_1) and (D_1) . As in the JV-algorithm for k -median, we Lagrangify constraint (1) and consider the unconstrained problem where we do not bound the number of pairs we may pick, but we incur a fixed cost z for each pair (i, r) that we pick (in addition to r). It is easy to adapt the JV primal-dual algorithm for facility location [22] to devise a simple *Lagrangian-multiplier-preserving* (LMP) 3-approximation algorithm for this problem (see PDAlg and Theorem 3). We use this LMP algorithm within a binary-search procedure for z to obtain two solutions F_1 and F_2 with $|F_2| \leq k' < |F_1|$, and show that these can be “combined” to extract a k -BS-solution F of cost at most $3.83 \cdot OPT + O(R^*)$. This combination step is more involved than in k -median. The main idea here is to use the F_2 solution as a guide to merge some F_1 -pairs. We cluster the F_1 pairs around the F_2 -pairs and setup a *covering-knapsack problem* whose solution determines for each F_2 -pair (i, r) , whether to “merge” the F_1 -pairs clustered around (i, r) or select all these F_1 -pairs (see step B2). Finally, we add back the pairs $(i_1, r_1), \dots, (i_t, r_t)$ selected earlier and apply Lemma 1 to obtain an $\text{LB}k\text{SR}$ -solution. As required by Lemma 1, to aid in this translation, our k -BS-algorithm returns, along with F , a suitable radius $\text{rad}(i)$ for every facility $i \in \mu(F)$. This yields a $(3.83 + \epsilon)$ -approximation algorithm (Theorem 6).

While our approach is similar to the one in [11] for the min-sum-of-radii problem *without* lower bounds (although our combination step is notably simpler), an important distinction that arises is the following. In the absence of lower bounds, the ball-selection problem k -BS is *equivalent* to the min-sum-of-radii problem, but (as noted earlier) this is no longer the case when we have lower bounds since in k -BS we do not insist that the balls we pick be disjoint. Moving from overlapping balls in a k -BS-solution to an $\text{LB}k\text{SR}$ -solution incurs, in general, a factor-2 blowup in the cost, but we avoid this blowup by exploiting the structure of the k -BS-solution obtained and carefully merging in the pairs $(i_1, r_1), \dots, (i_t, r_t)$ (see Lemma 1). It is interesting that our approximation factor is quite close to the approximation factor (of 3.53) achieved in [11] for the min-sum-of-radii problem without lower bounds.

We now describe our algorithm in detail and analyze it. We describe a slightly simpler $(6.183 + \epsilon)$ -approximation algorithm below (Theorem 2). We sketch the ideas behind the improved approximation ratio at the end of this section and defer the details to the full version.

▶ Algorithm 1.

Input: An LBkSR-instance $\mathcal{I} = (\mathcal{F}, \mathcal{D}, \{L_i\}, \{c(i, j)\}, k)$, parameter $\epsilon > 0$.

Output: A feasible solution (S, σ) .

A1. Let $t = \min\{k, \lceil \frac{1}{\epsilon} \rceil\}$. For each set $F^O \subseteq \mathcal{L}$ with $|F^O| \leq t$, do the following.

A1.1. Set $\mathcal{D}' = \mathcal{D} \setminus \bigcup_{(i,r) \in F^O} B(i, r)$, $\mathcal{L}' = \{(i', r') \in \mathcal{L} : r' \leq R^* = \min_{(i,r) \in F^O} r\}$, $k' = k - |F^O|$.

A1.2. If (P_1) is infeasible, then reject this guess and move to the next set F^O . If $\mathcal{D}' \neq \emptyset$, run k -BSAlg($\mathcal{D}', \mathcal{L}', k', \epsilon$) to obtain $(F, \{\text{rad}(i)\}_{i \in F})$; else set $(F, \text{rad}) = (\emptyset, \emptyset)$.

A1.3. Apply the procedure in Lemma 1 taking $r'_i = \text{rad}(i)$ for all $i \in \mu(F)$ to obtain (S, σ) .

A1. Among all the solutions (S, σ) found in step A1, return the one with smallest cost.

▶ Algorithm k -BSAlg($\mathcal{D}', \mathcal{L}', k', \epsilon$).

Output: $F \subseteq \mathcal{L}$ with $|F| \leq k'$, a radius $\text{rad}(i)$ for all $i \in \mu(F)$.

B1. Binary search for z .

B1.1. Set $z_1 = 0$ and $z_2 = 2k'c_{\max}$. For $p = 1, 2$, let $(F_p, \{\text{rad}_p(i)\}, \alpha^p) \leftarrow \text{PDAI}(\mathcal{D}', \mathcal{L}', z_p)$, and let $k_p = |F_p|$. If $k_1 \leq k'$, stop and return $(F_1, \{\text{rad}_1(i)\})$. We prove in Theorem 3 that $k_2 \leq k'$; if $k_2 = k'$, stop and return $(F_2, \{\text{rad}_2(i)\})$.

B1.2. Repeat the following until $z_2 - z_1 \leq \delta_z = \frac{\epsilon OPT}{3^n}$, where $n = |\mathcal{F}| + |\mathcal{D}|$. Set $z = \frac{z_1 + z_2}{2}$. Let $(F, \{\text{rad}(i)\}, \alpha) \leftarrow \text{PDAI}(\mathcal{D}', \mathcal{L}', z)$. If $|F| = k'$, stop and return $(F, \{\text{rad}(i)\})$; if $|F| > k'$, update $z_1 \leftarrow z$ and $(F_1, \text{rad}_1, \alpha^1) \leftarrow (F, \text{rad}, \alpha)$, else update $z_2 \leftarrow z$ and $(F_2, \text{rad}_2, \alpha^2) \leftarrow (F, \text{rad}, \alpha)$.

B2. Combining F_1 and F_2 . Let $\pi : F_1 \mapsto F_2$ be any map such that (i', r') and $\pi(i', r')$ intersect $\forall (i', r') \in F_1$. (This exists since every $j \in \mathcal{D}'$ is covered by $B(i, r)$ for some $(i, r) \in F_2$.) Define star $\mathcal{S}_{i,r} = \pi^{-1}(i, r)$ for all $(i, r) \in F_2$ (see Fig. 1). Solve the following *covering-knapsack LP*.

$$\begin{aligned} \min \quad & \sum_{(i,r) \in F_2} \left(x_{i,r}(2r + \sum_{(i',r') \in \mathcal{S}_{i,r}} 2r') + (1 - x_{i,r}) \sum_{(i',r') \in \mathcal{S}_{i,r}} r' \right) & \text{(C-P)} \\ \text{s.t.} \quad & \sum_{(i,r) \in F_2} (x_{i,r} + |\mathcal{S}_{i,r}|(1 - x_{i,r})) \leq k', \quad 0 \leq x_{i,r} \leq 1 \quad \forall (i, r) \in F_2. \end{aligned}$$

Let x^* be an extreme-point optimal solution to (C-P). The variable $x_{(i,r)}$ has the following interpretation. If $x_{i,r}^* = 0$, then we select all pairs in $\mathcal{S}_{i,r}$. Otherwise, if $\mathcal{S}_{i,r} \neq \emptyset$, we pick a pair in $(i', r') \in \mathcal{S}_{i,r}$, and include $(i', 2r + r' + \max_{(i'',r'') \in \mathcal{S}_{i,r} \setminus \{(i',r')\}} 2r'')$ in our solution. Notice that by expanding the radius of i' to $2r + r' + \max_{(i'',r'') \in \mathcal{S}_{i,r} \setminus \{(i',r')\}} 2r''$, we cover all the clients in $\bigcup_{(i'',r'') \in \mathcal{S}_{i,r}} B(i'', r'')$. Let F' be the resulting set of pairs.

B3. If $\text{cost}(F_2) \leq \text{cost}(F)$, return (F_2, rad_2) , else return $(F', \{\text{rad}_1(i)\}_{i \in \mu(F')})$.

▶ Algorithm PDAI($\mathcal{D}', \mathcal{L}', z$).

Output: $F \subseteq \mathcal{L}$, radius $\text{rad}(i)$ for all $i \in \mu(F)$, dual solution α .

P1. Dual-ascent phase. Start with $\alpha_j = 0$ for all $j \in \mathcal{D}'$, \mathcal{D}' as the set of *active clients*, and the set T of *tight pairs* initialized to \emptyset . We repeat the following until all clients become inactive: we raise the α_j s of all active clients uniformly until constraint (2) becomes tight for some (i, r) ; we add (i, r) to T and mark all active clients in $B(i, r)$ as inactive.

P2. Pruning phase. Let T_I be a maximal subset of non-intersecting pairs in T picked by a greedy algorithm that scans pairs in T in non-increasing order of radius. Note that for each $i \in \mu(T_I)$, there is exactly one pair $(i, r) \in T_I$. We set $\text{rad}(i) = r$, and $r_i = \max\{c(i, j) : j \in B(i', r'), (i', r') \in T, r' \leq r, (i', r') \text{ intersects } (i, r) \text{ ((i', r') could be (i, r))}\}$. Let $F = \{(i, r_i)\}_{i \in \mu(T_I)}$. Return $F, \{\text{rad}(i)\}_{i \in \mu(T_I)}$, and α .

■ **Figure 1** An example of stars formed by F_1 and F_2 where $F_1 = \{u_1, u_2, \dots, u_{11}\}$ and $F_2 = \{v_1, v_2, \dots, v_6\}$ depicted by squares and circles, respectively.

Analysis. We prove the following result.

► **Theorem 2.** For any $\epsilon > 0$, Algorithm 1 returns a feasible LBkSR-solution of cost at most $(6.1821 + O(\epsilon))O^*$ in time $n^{O(1/\epsilon)}$.

We first prove that PDAIlg is an LMP 3-approximation algorithm, i.e., its output (F, α) satisfies $\text{cost}(F) + 3|F|z \leq 3 \sum_{j \in \mathcal{D}'} \alpha_j$. (Theorem 3). Utilizing this, we analyze k -BSAAlg, in particular, the output of the combination step B2, and argue that k -BSAAlg returns a feasible solution of cost at most $(6.183 + O(\epsilon)) \cdot \text{OPT} + O(R^*)$ (Theorem 5). For the right choice of F^O , combining this with Lemma 1 yields Theorem 2.

► **Theorem 3.** Suppose PDAIlg(\mathcal{D}' , \mathcal{L}' , z) returns $(F, \{\text{rad}(i)\}, \alpha)$. Then

- (i) the balls corresponding to F cover \mathcal{D}' ;
- (ii) $\text{cost}(F) + 3|F|z \leq 3 \sum_{j \in \mathcal{D}'} \alpha_j \leq 3(\text{OPT} + k'z)$;
- (iii) $\{(i, \text{rad}(i))\}_{i \in \mu(F)} \subseteq \mathcal{L}'$, is a set of non-intersecting pairs, $\text{rad}(i) \leq r_i \leq 3R^* \forall i \in \mu(F)$;
- (iv) if $|F| \geq k'$ then $\text{cost}(F) \leq 3 \cdot \text{OPT}$; if $|F| > k'$, then $z \leq \text{OPT}$. (Hence, $k_2 \leq k'$ in step B1.1.)

Let $(F, \{\text{rad}(i)\}) = k$ -BSAAlg(\mathcal{D}' , \mathcal{L}' , k' , ϵ). If k -BSAAlg terminates in step B1, then $\text{cost}(F) \leq 3 \cdot \text{OPT}$ due to part (ii) of Theorem 3, so assume otherwise. Let $a, b \geq 0$ be such that $ak_1 + bk_2 = k'$, $a + b = 1$. Let $C_1 = \text{cost}(F_1)$ and $C_2 = \text{cost}(F_2)$. Recall that $(F_1, \text{rad}_1, \alpha^1)$ and $(F_2, \text{rad}_2, \alpha^2)$ are the outputs of PDAIlg for z_1 and z_2 respectively.

► **Claim 4.** We have $aC_1 + bC_2 \leq (3 + \epsilon)\text{OPT}$.

► **Theorem 5.** k -BSAAlg(\mathcal{D}' , \mathcal{L}' , k' , ϵ) returns a feasible solution $(F, \{\text{rad}(i)\})$ with $\text{cost}(F) \leq (6.183 + O(\epsilon)) \cdot \text{OPT} + O(R^*)$ where $\{(i, \text{rad}(i))\}_{i \in \mu(F)} \subseteq \mathcal{L}'$ is a set of non-intersecting pairs.

Proof. The radii $\{\text{rad}(i)\}_{i \in \mu(F)}$ are simply radii obtained from some execution of PDAIlg, so $\{(i, \text{rad}(i))\}_{i \in \mu(F)} \subseteq \mathcal{L}'$ and comprises non-intersecting pairs. If k -BSAAlg terminates in step B1, we have a better bound on $\text{cost}(F)$. If not, and we return F_2 , the cost incurred is C_2 .

Otherwise, we return the solution F' found in step B2. Since (C-P) has only one constraint in addition to the bound constraints $0 \leq x_{i,r} \leq 1$, the extreme-point optimal solution x^* has at most one fractional component, and if it has a fractional component, then $\sum_{(i,r) \in F_2} (x_{i,r}^* + |\mathcal{S}_{i,r}|(1 - x_{i,r}^*)) = k'$. For any $(i, r) \in F_2$ with $x_{i,r}^* \in \{0, 1\}$, the number of pairs we include is exactly $x_{i,r}^* + |\mathcal{S}_{i,r}|(1 - x_{i,r}^*)$, and the total cost of these pairs is at most the contribution to the objective function of (C-P) from the $x_{i,r}^*$ and $(1 - x_{i,r}^*)$ terms. If x^* has a fractional component $(i', r') \in F_2$, then $x_{i',r'}^* + |\mathcal{S}_{i',r'}|(1 - x_{i',r'}^*)$ is a positive integer. Since we include at most one pair for (i', r') , this implies that $|F'| \leq k'$. The cost of the pair we include is at most $15R^*$, since all $(i, r) \in F_1 \cup F_2$ satisfy $r \leq 3R^*$. Therefore, $\text{cost}(F') \leq \text{OPT}_{\text{C-P}} + 15R^*$. Also, $\text{OPT}_{\text{C-P}} \leq 2bC_2 + (2b + a)C_1 = 2bC_2 + (1 + b)C_1$, since setting $x_{i,r} = b$ for all $(i, r) \in F_2$ yields a feasible solution to (C-P) of this cost.

So when we terminate in step B3, we return a solution F with $\text{cost}(F) \leq \min\{C_2, 2bC_2 + (1+b)C_1 + 15R^*\}$. We show that $\min\{C_2, 2bC_2 + (1+b)C_1\} \leq 2.0607(aC_1 + bC_2)$ for all $a, b \geq 0$ with $a + b = 1$. Combining this with Claim 4 yields the bound in the theorem. ◀

Proof. Proof of Theorem 2 It suffices to show that when the selection $F^O = \{(i_1, r_1), \dots, (i_t, r_t)\}$ in step A1 corresponds to the t facilities in an optimal solution with largest radii, we obtain the desired approximation bound. In this case, we have $R^* \leq \frac{O^*}{t} \leq \epsilon O^*$ and $OPT \leq O^* - \sum_{p=1}^t r_p$. Combining Theorem 5 and Lemma 1 then yields the theorem. ◀

Improved approximation ratio. The improved approximation ratio comes from a better way of combining F_1 and F_2 in step B2. We observe that the dual solutions α^1 and α^2 are component-wise close to each other (we can control the closeness by controlling δ_z). Thus, we may essentially assume that if $T_{1,I}, T_{2,I}$ denote the tight pairs yielding F_1, F_2 respectively, then every pair in $T_{1,I}$ intersects some pair in $T_{2,I}$, because we can augment $T_{2,I}$ to include non-intersecting pairs of $T_{1,I}$. This yields dividends when we combine solutions as in step B2, because we can now ensure that if $\pi(i', r') = (i, r)$, then the pairs of $T_{2,I}$ and $T_{1,I}$ yielding (i, r) and (i', r') respectively intersect, which yields an improved bound on $c_{i,i'}$. This yields an improved approximation of 3.83 for the combination step, and hence for the entire algorithm.

► **Theorem 6.** *For any $\epsilon > 0$, our algorithm returns a feasible LBkSR-solution of cost at most $(3.83 + O(\epsilon))O^*$ in time $n^{O(1/\epsilon)}$.*

2.2 Approximation algorithm for LBkSRO

We now build upon the ideas in Section 2.1 to devise an $O(1)$ -approximation algorithm for the outlier version LBkSR. The high-level approach is similar to the one in Section 2.1. We again “guess” the t (i, r) pairs F^O corresponding to the facilities with largest radii in an optimal solution, and consider the modified k -BS-instance $(\mathcal{D}', \mathcal{L}', k', m)$ (where $\mathcal{D}', \mathcal{L}', k'$ are defined as before). If the LP-relaxation below, (P_2) , for the k -BS-problem is infeasible, we move on to the next guess. Otherwise, we design a primal-dual algorithm for the Lagrangian relaxation of the k -BS-problem where we are allowed to pick any number of pairs from \mathcal{L}' (leaving at most m uncovered clients) incurring a fixed cost of z for each pair picked, utilize this to obtain two solutions F_1 and F_2 , and combine these to extract a low-cost solution. However, the presence of outliers introduces various difficulties both in the primal-dual algorithm and in the combination step. Consider the following LP-relaxation of the k -BS-problem and its dual.

$$\begin{array}{ll}
 \min & \sum_{(i,r) \in \mathcal{L}'} r \cdot y_{i,r} \quad (P_2) \\
 \text{s.t.} & \sum_{(i,r) \in \mathcal{L}' : j \in B(i,r)} y_{i,r} + w_j \geq 1 \quad \forall j \in \mathcal{D}' \\
 & \sum_{(i,r) \in \mathcal{L}'} y_{i,r} \leq k', \quad \sum_{j \in \mathcal{D}'} w_j \leq m \\
 & y, w \geq 0.
 \end{array}
 \quad
 \begin{array}{ll}
 \max & \sum_{j \in \mathcal{D}'} \alpha_j - k' \cdot z - m \cdot \gamma \quad (D_2) \\
 \text{s.t.} & \sum_{j \in B(i,r) \cap \mathcal{D}'} \alpha_j - z \leq r \quad \forall (i,r) \in \mathcal{L}' \\
 & \alpha_j \leq \gamma \quad \forall j \in \mathcal{D}' \\
 & \alpha, z, \gamma \geq 0.
 \end{array}
 \quad (3)$$

Let OPT denote the optimal value of (P_2) . The natural modification of the earlier primal-dual algorithm PDA1g is to now stop the dual-ascent process when the number of active clients is at most m and set $\gamma = \max_{j \in \mathcal{D}'} \alpha_j$. This introduces the significant complication

that one may not be able to pay for the $r + z$ -cost of non-intersecting tight pairs selected in the pruning phase by the dual objective value $\sum_{j \in \mathcal{D}'} \alpha_j - m \cdot \gamma$, since clients with $\alpha_j = \gamma$ may be needed to pay for the $r + z$ -cost of the last tight pair $f = (i_f, r_f)$ but their contribution gets canceled by the $-m \cdot \gamma$ term. This issue affects us in various guises. First, we no longer obtain an LMP-approximation for the unconstrained problem since we have to account for the $(r + z)$ -cost of f separately. Second, unlike Claim 4, given solutions F_1 and F_2 obtained via binary search for $z_1, z_2 \approx z_1$ respectively with $|F_2| \leq k' \leq |F_1|$, we now only obtain a fractional k -BS-solution of cost $O(OPT + z_1)$. While one can modify the covering-knapsack-LP based procedure in step B2 of k -BSAlg to combine F_1, F_2 , this only yields a good solution when $z_1 = O(OPT)$. The chief technical difficulty is that z_1 may however be much larger than OPT . Overcoming this obstacle requires various novel ideas and is the key technical contribution of our algorithm. We design a second combination procedure that is guaranteed to return a good solution when $z_1 = \Omega(OPT)$. This requires establishing certain structural properties for F_1 and F_2 , using which we argue that one can find a good solution in the neighborhood of F_1 and F_2 .

We now detail the changes to the primal-dual algorithm and k -BSAlg in Section 2.1, and analyze them to prove the following theorem.

► **Theorem 7.** *There exists a $(12.365 + O(\epsilon))$ -approximation algorithm for LBkSRO that runs in time $n^{O(1/\epsilon)}$ for any $\epsilon > 0$.*

Modified primal-dual algorithm $\text{PDAI}^0(\mathcal{D}', \mathcal{L}', z)$. This is quite similar to PDAI (and we again return pairs from \mathcal{L}). We stop the dual-ascent process when there are at most m active clients. We set $\gamma = \max_{j \in \mathcal{D}'} \alpha_j$. Let $f = (i_f, r_f)$ be the last tight pair added to the tight-pair set T , and $B_f = B(i_f, r_f)$. We sometimes abuse notation and use (i, r) to also denote the singleton set $\{(i, r)\}$. For a set P of (i, r) pairs, define $\text{uncov}(P) := \mathcal{D}' \setminus \bigcup_{(i,r) \in P} B(i, r)$. Note that $|\text{uncov}(T \setminus f)| > m \geq |\text{uncov}(T)|$. Let Out be a set of m clients such that $\text{uncov}(T) \subseteq Out \subseteq \text{uncov}(T \setminus f)$. Note that $\alpha_j = \gamma$ for all $j \in Out$.

The pruning phase is similar to before, but we only use f if necessary. Let T_I be a maximal subset of non-intersecting pairs picked by greedily scanning pairs in $T \setminus f$ in non-increasing order of radius. For $i \in \mu(T_I)$, set $\text{rad}(i)$ to be the unique r such that $(i, r) \in T_I$, and let r_i be the smallest radius ρ such that $B(i, \rho) \supseteq B(i', r')$ for every $(i', r') \in T \setminus f$ such that $r' \leq \text{rad}(i)$ and (i', r') intersects $(i, \text{rad}(i))$. Let $F' = \{(i, r_i)\}_{i \in \mu(T_I)}$. If $\text{uncov}(F') \leq m$, set $F = F'$. If $\text{uncov}(F') > m$ and $\exists i \in \mu(F')$ such that $c(i, i_f) \leq 2R^*$, then increase r_i so that $B(i, r_i) \supseteq B_f$ and let F be this updated F' . Otherwise, set $F = F \cup f$ and $r_{i_f} = \text{rad}(i_f) = r_f$. We return $(F, f, Out, \{\text{rad}(i)\}_{i \in \mu(F)}, \alpha, \gamma)$.

► **Theorem 8.** *Let $(F, f, Out, \{\text{rad}(i)\}, \alpha, \gamma) = \text{PDAI}^0(\mathcal{D}', \mathcal{L}', z)$. Then:*

- (i) $\text{uncov}(F) \leq m$;
- (ii) $\text{cost}(F \setminus f) + 3|F \setminus f|z - 3R^* \leq 3(\sum_{j \in \mathcal{D}'} \alpha_j - m\gamma) \leq 3(OPT + k'z)$;
- (iii) $\{(i, \text{rad}(i))\}_{i \in \mu(F)} \subseteq \mathcal{L}'$, is a set of non-intersecting pairs, $\text{rad}(i) \leq r_i \leq 3R^* \forall i \in \mu(F)$;
- (iv) if $|F \setminus f| \geq k'$ then $\text{cost}(F) \leq 3 \cdot OPT + 4R^*$, and if $|F \setminus f| > k'$ then $z \leq OPT$.

Modified algorithm k -BSAlg $^0(\mathcal{D}', \mathcal{L}', k', \epsilon)$. We again use binary search to find solutions F_1, F_2 and extract a low-cost solution from these. The only changes to step B1 are as follows. We start with $z_1 = 0$ and $z_2 = 2nk'c_{\max}$; for this z_2 , one can argue PDAI^0 returns at most k' pairs. We stop when $z_2 - z_1 \leq \delta_z := \frac{\epsilon OPT}{3n2^n}$. We do not stop even if PDAI^0 returns a solution (F, \dots) with $|F| = k'$ for some $z = \frac{z_1 + z_2}{2}$, since Theorem 8 is not strong enough to bound $\text{cost}(F)$ even when this happens! If $|F| > k'$, we update $z_1 \leftarrow z$ and the F_1 -solution;

otherwise, we update $z_2 \leftarrow z$ and the F_2 -solution. Thus, we maintain that $k_1 = |F_1| > k'$, and $k_2 = |F_2| \leq k'$.

The main change is in the way solutions F_1, F_2 are combined. We adapt step B2 to handle outliers (procedure \mathcal{A} in Section 2.2.1), but the key extra ingredient is that we devise an alternate combination procedure \mathcal{B} (Section 2.2.2) that returns a low-cost solution when $z_1 = \Omega(OPT)$. We return the better of the solutions output by the two procedures. Combining Theorem 9 with Lemma 1 (for the right selection of $t(i, r)$ pairs) yields Theorem 7.

► **Theorem 9.** k -BSAlg $^\circ(\mathcal{D}', \mathcal{L}', k', \epsilon)$ returns a solution (F, rad) with $\text{cost}(F) \leq (12.365 + O(\epsilon)) \cdot OPT + O(R^*)$ where $\{(i, \text{rad}(i))\}_{i \in \mu(F)} \subseteq \mathcal{L}'$ comprises non-intersecting pairs.

2.2.1 Combination subroutine $\mathcal{A}((F_1, \text{rad}_1), (F_2, \text{rad}_2))$

As in step B2, we cluster the F_1 -pairs around F_2 -pairs in stars. However, unlike before, some $(i', r') \in F_1$ may remain *unclustered* and we may not pick (i', r') or some pair close to it. Since we do not cover all clients covered by F_1 , we need to cover a suitable number of clients from $\text{uncov}(F_1)$. We again setup an LP to obtain a suitable collection of pairs, which is now a 2-dimensional covering knapsack LP, and use the structure of an extreme-point optimal solution to extract from it a good collection of pairs.

► **Theorem 10.** We can obtain a solution $(F, \{\text{rad}(i)\}_{i \in \mu(F)})$ to the k -BS-problem with $\text{cost}(F) \leq (6.1821 + O(\epsilon))(OPT + z_1) + O(R^*)$ where $\{(i, \text{rad}(i))\}_{i \in \mu(F)} \subseteq \mathcal{L}'$ is a set of non-intersecting pairs.

2.2.2 Subroutine

$\mathcal{B}((F_1, f_1, \text{Out}_1, \text{rad}_1, \alpha^1, \gamma^1), (F_2, f_2, \text{Out}_2, \text{rad}_2, \alpha^2, \gamma^2))$

Subroutine \mathcal{A} in the previous section yields a low-cost solution only if $z_1 = O(OPT)$. We complement subroutine \mathcal{A} by now describing a procedure that returns a good solution when z_1 is large. We assume in this section that $z_1 > (1 + \epsilon)OPT$. Then $|F_1 \setminus f_1| \leq k'$ (otherwise $z \leq OPT$ by part (iv) of Theorem 8), so $|F_1 \setminus f_1| \leq k' < |F_1|$, which means that $k_1 = k' + 1$ and $f_1 \in F_1$. Hence, $\alpha_j^1 = \gamma^1$ for all $j \in B_{f_1} \cap \mathcal{D}'$. We utilize the following *continuity lemma*, which is essentially Lemma 6.6 in [11]; we include a proof in the full version of the paper.

► **Lemma 11.** Let $(F_p, \dots, \alpha^p, \gamma^p) = \text{PDAlg}^\circ(\mathcal{D}', \mathcal{L}', z_p)$ for $p = 1, 2$, where $0 \leq z_2 - z_1 \leq \delta_z$. Then, $\|\alpha_j^1 - \alpha_j^2\|_\infty \leq 2^n \delta_z$ and $|\gamma^1 - \gamma^2| \leq 2^n \delta_z$. Thus, if (3) is tight for some $(i, r) \in \mathcal{L}'$ in one execution, then $\sum_{j \in B(i, r) \cap \mathcal{D}'} \alpha_j^p \geq r + z - 2^n \delta_z$ for $p = 1, 2$.

First, we take care of some simple cases. If there exists $(i, r) \in F_1 \setminus f_1$ such that $|\text{uncov}(F_1 \setminus \{f_1, (i, r)\} \cup (i, r + 12R^*))| \leq m$, then set $F = F_1 \setminus \{f_1, (i, r)\} \cup (i, r + 12R^*)$. We have $\text{cost}(F) = \text{cost}(F_1 \setminus f_1) + 12R^* \leq 3 \cdot OPT + 15R^*$ (by part (ii) of Theorem 8). If there exist pairs $(i, r), (i', r') \in F_1$ such that $c(i, i') \leq 12R^*$, take r'' to be the minimum $\rho \geq r$ such that $B(i', r') \subseteq B(i, \rho)$ and set $F = F_1 \setminus \{(i, r), (i', r')\} \cup (i, r'')$. We have $\text{cost}(F) \leq \text{cost}(F_1 \setminus f_1) + 13R^* \leq 3 \cdot OPT + 16R^*$. In both cases, we return $(F, \{\text{rad}_1(i)\}_{i \in \mu(F)})$.

So we assume in the sequel that neither of the above apply. In particular, all pairs in F_1 are well-separated. Let $AT = \{(i, r) \in \mathcal{L}' : \sum_{j \in B(i, r) \cap \mathcal{D}'} \alpha_j^1 \geq r + z_1 - 2^n \delta_z\}$ and $AD = \{j \in \mathcal{D}' : \alpha_j^1 \geq \gamma^1 - 2^n \delta_z\}$. By Lemma 11, AT includes the tight pairs of $\text{PDAlg}^\circ(\mathcal{D}', \mathcal{L}', z_p)$ for both $p = 1, 2$, and $\text{Out}_1 \cup \text{Out}_2 \subseteq AD$. Since the tight pairs T_2 used for building solution F_2 are almost tight in $(\alpha^1, \gamma^1, z_1)$, we swap them in and swap out pairs from F_1 one by one while maintaining a feasible solution. Either at some point, we will

be able to remove f , which will give us a solution of size k' , or we will obtain a bound on $\text{cost}(F_2)$. The following lemma is our main tool for bounding the cost of the solution returned.

► **Lemma 12.** *Let $F \subseteq \mathcal{L}'$, and $T_F = \{(i, r'_i)\}_{i \in \mu(F)}$ where $r'_i \leq r$ for each $(i, r) \in F$. Suppose $T_F \subseteq AT$ and consists of non-intersecting pairs. If $|F| \geq k'$ and $|AD \setminus \bigcup_{(i,r) \in F} B(i, r)| \geq m$ then $\text{cost}(T_F) \leq (1 + \epsilon)OPT$. Moreover, if $|F| > k'$ then $z_1 \leq (1 + \epsilon)OPT$.*

Define a mapping $\psi : F_2 \rightarrow F_1 \setminus f_1$ as follows. Note that any $(i, r) \in F_2$ may intersect with at most one F_1 -pair: if it intersects (i', r') , $(i'', r'') \in F_1$, then we have $c(i', i'') \leq 12R^*$. First, for each $(i, r) \in F_2$ that intersects with some $(i', r') \in F_1$, we set $\psi(i, r) = (i', r')$. Let $M \subseteq F_2$ be the F_2 -pairs mapped by ψ this way. For every $(i, r) \in F_2 \setminus M$, we arbitrarily match (i, r) with a *distinct* $(i', r') \in F_1 \setminus \psi(M)$. We claim that ψ is in fact a one-one function.

► **Lemma 13.** *Every $(i, r) \in F_1 \setminus f_1$ intersects with at most one F_2 -pair.*

Let F'_2 be the pairs $(i, r) \in F_2$ such that if $(i', r') = \psi(i, r)$, then $r' < r$. Let $P = F'_2 \cap M$ and $Q = F'_2 \setminus M$. For every $(i', r') \in \psi(Q)$ and $j \in B(i', r')$, we have $j \in \text{uncov}(F_2) \subseteq AD$ (else (i', r') would lie in $\psi(M)$). Starting with $F = F_1 \setminus f_1$, we iterate over $(i, r) \in F'_2$ and do the following. Let $(i', r') = \psi(i, r)$. If $(i, r) \in P$, we update $F \leftarrow F \setminus (i', r') \cup (i, r + 2r')$ (so $B(i, r + 2r') \supseteq B(i', r')$), else we update $F \leftarrow F \setminus (i', r') \cup (i, r)$. Let $T_F = \{(i, \text{rad}_1(i))\}_{(i,r) \in F \cap F_1} \cup \{(i, \text{rad}_2(i))\}_{(i,r) \in F \setminus F_1}$. Note that $|F| = k'$ and $\text{uncov}(F) \subseteq AD$ at all times. Also, since (i, r) intersects only (i', r') , which we remove when (i, r) is added, we maintain that T_F is a collection of non-intersecting pairs and a subset of $AT \subseteq \mathcal{L}'$. This process continues until $|\text{uncov}(F)| \leq m$, or when all pairs of F'_2 are swapped in. In the former case, we argue that $\text{cost}(F)$ is small and return $(F, \{\text{rad}_1(i)\}_{(i,r) \in F \cap F_1} \cup \{\text{rad}_2(i)\}_{(i,r) \in F \setminus F_1})$. In the latter case, we show that $\text{cost}(F'_2)$, and hence $\text{cost}(F_2)$ is small, and return (F_2, rad_2) .

► **Lemma 14.**

- (i) *If the algorithm stops with $|\text{uncov}(F)| \leq m$, $\text{cost}(F) \leq (9 + 3\epsilon)OPT + 18R^*$.*
- (ii) *If case (i) does not apply, then $\text{cost}(F_2) \leq (3 + 3\epsilon)OPT + 9R^*$.*
- (iii) *The pairs corresponding to the radii returned are non-intersecting, and a subset of \mathcal{L}' .*

3 Minimizing the maximum radius with lower bounds and outliers

The *lower-bounded k -supplier with outliers* (LBkSupO) problem is the min max-radius version of LBkSRO. The input and the set of feasible solutions are the same as in LBkSRO: the input is an instance $\mathcal{I} = (\mathcal{F}, \mathcal{D}, \{c(i, j)\}, \{L_i\}, k, m)$, and a feasible solution is $(S \subseteq \mathcal{F}, \sigma : \mathcal{D} \mapsto S \cup \{\text{out}\})$ with $|S| \leq k$, $|\sigma^{-1}(i)| \geq L_i$ for all $i \in S$, and $|\sigma^{-1}(\text{out})| \leq m$. The cost of (S, σ) is now $\max_{i \in S} \max_{j \in \sigma^{-1}(i)} c(i, j)$. The case $m = 0$ is called the *lower-bounded k -supplier* (LBkSup) problem, and the setting where $\mathcal{D} = \mathcal{F}$ is often called the *k -center* version.

Let τ^* denote the optimal value; note that there are only polynomially many choices for τ^* . As is common in the study of min-max problems, we reduce the problem to a “graphical” instance, where given some value τ , we try to find a solution of cost $O(\tau)$ or deduce that $\tau^* > \tau$. We construct a bipartite unweighted graph $G_\tau = (V_\tau = \mathcal{D} \cup \mathcal{F}_\tau, E_\tau)$, where $\mathcal{F}_\tau = \{i \in \mathcal{F} : |B(i, \tau)| \geq L_i\}$, and $E_\tau = \{ij : c(i, j) \leq \tau, i \in \mathcal{F}_\tau, j \in \mathcal{D}\}$. Let $\text{dist}_\tau(i, j)$ denote the shortest-path distance in G_τ between i and j , so $c(i, j) \leq \text{dist}_\tau(i, j) \cdot \tau$. We say that an assignment $\sigma : \mathcal{D} \mapsto \mathcal{F}_\tau \cup \{\text{out}\}$ is a *distance- α assignment* if $\text{dist}_\tau(j, \sigma(j)) \leq \alpha$ for every client j with $\sigma(j) \neq \text{out}$. We call such an assignment feasible, if it yields a feasible LBkSupO-solution, and we say that G_τ is feasible if it admits a feasible distance-1 assignment. It is not hard to see that given $F \subseteq \mathcal{F}_\tau$, the problem of finding a feasible

distance- α -assignment $\sigma : \mathcal{D} \mapsto F \cup \{\text{out}\}$ in G_τ (if one exists) can be solved by creating a network-flow instance with lower bounds and capacities.

Observe that an optimal solution yields a feasible distance-1 assignment in G_{τ^*} . We devise an algorithm that for every τ , either finds a feasible distance- α assignment in G_τ for some constant α , or detects that G_τ is not feasible. This yields an α -approximation algorithm since the smallest τ for which the algorithm returns a feasible LBkSupO-solution must be at most τ^* . We obtain Theorems 15 and 16 via this template, and complement these via a hardness result (Theorem 17) showing that our approximation factor for LBkSup is tight.

► **Theorem 15.** *There is a 3-approximation algorithm for LBkSup.*

► **Theorem 16.** *There is a 5-approximation algorithm for LBkSupO.*

► **Theorem 17.** *It is NP-hard to approximate LBkSup within a factor better than 3.*

Finding a distance-5 assignment for LBkSupO. The goal is to find a set $F \subseteq \mathcal{F}_\tau$ of at most k centers that are close to the centers in $F^* \subseteq \mathcal{F}_\tau$ for some feasible distance-1 assignment $\sigma^* : \mathcal{D} \mapsto F^* \cup \{\text{out}\}$ in G_τ . If centers in F do not share a neighbor in G_τ , then clients in $N(i)$ can be assigned to i for each $i \in F$ to satisfy the lower bounds.

► **Definition 18** ([14]). Given the graph G_τ , a set $F \subseteq \mathcal{F}$ is called a *skeleton* if it satisfies the following properties.

- (a) (*Separation property*) For $i, i' \in F$, $i \neq i'$, we have $\text{dist}_\tau(i, i') \geq 6$;
- (b) There exists a feasible distance-1 assignment $\sigma^* : \mathcal{D} \mapsto F^* \cup \{\text{out}\}$ in G_τ such that
 - (*Covering property*) For all $i^* \in F^*$, $\text{dist}_\tau(i^*, F) \leq 4$, where $\text{dist}_\tau(i^*, F) = \min_{i \in F} \text{dist}_\tau(i^*, i)$.
 - (*Injection property*) There exists $f : F \mapsto F^*$ such that $\text{dist}_\tau(i, f(i)) \leq 2$ for all $i \in F$.

If F satisfies the separation and injection properties, it is called a *pre-skeleton*.

► **Lemma 19.** *Let F be a pre-skeleton in G_τ . Define $U = \{i \in \mathcal{F}_\tau : \text{dist}_\tau(i, F) \geq 6\}$ and let $i = \arg \max_{i' \in U} |N(i')|$. Then, either F is a skeleton, or $F \cup \{i\}$ is a pre-skeleton.*

Suppose $F \subseteq \mathcal{F}_\tau$ is a skeleton and satisfies the properties with respect to a feasible distance-1 assignment (F^*, σ^*) . The separation property ensures that the neighbor sets of any two locations $i, i' \in F$ are disjoint. The covering property ensures that F^* is at distance at most 4 from F , so there are at least $|\mathcal{D}| - m$ clients at distance at most 5 from F . Finally, the injection and separation properties together ensure that $|F| \leq k$. Thus, if F is a skeleton, then we can obtain a feasible distance-5 assignment $\sigma : \mathcal{D} \mapsto F \cup \{\text{out}\}$.

If G_τ is feasible, then \emptyset is a pre-skeleton. A skeleton can have size at most k . So using Lemma 19, we can find a sequence \mathcal{F}' of at most $k + 1$ subsets of \mathcal{F}_τ by starting with \emptyset and repeatedly applying Lemma 19 until we either have a set of size k or the set U in Lemma 19 is empty. By Lemma 19, if G_τ is feasible then one of these sets must be a skeleton. So for each $F \in \mathcal{F}'$, we check if there exists a feasible distance-5 assignment $\sigma : \mathcal{D} \mapsto F \cup \{\text{out}\}$, and if so, return (F, σ) . Otherwise we return that G_τ is not feasible.
