Abstract

For a given binary relation of finite trees, we consider the synthesis problem of deciding whether there is a deterministic top-down tree transducer that uniformizes the relation, and constructing such a transducer if it exists. A uniformization of a relation is a function that is contained in the relation and has the same domain as the relation. It is known that this problem is decidable if the relation is a deterministic top-down tree-automatic relation. We show that it becomes undecidable for general tree-automatic relations (specified by non-deterministic top-down tree automata). We also exhibit two cases for which the problem remains decidable. If we restrict the transducers to be path-preserving, which is a subclass of linear transducers, then the synthesis problem is decidable for general tree-automatic relations. If we consider relations that are finite unions of deterministic top-down tree-automatic relations, then the problem is decidable for synchronous transducers, which produce exactly one output symbol in each step (but can be non-linear).

1 Introduction

A uniformization of a (binary) relation is a function that selects for each element in the domain of the relation a unique image that is in relation with this element. Originally, uniformization has been studied in set theory, where the complexity of a class of definable relations is related with the complexity of uniformizations for these relations (see [18] for results of this kind). The basic uniformization question for a class \( C \) of relations is whether each relation from \( C \) has a uniformization in \( C \).

Automata provide a natural framework for defining relations (over words or trees), and uniformization problems in this setting have been studied since the early days of automata theory. Word relations defined by asynchronous finite automata [8], also called rational relations, were first shown to have rational uniformizations in [13, Theorem 3] (with many alternative and simplified proofs following later). For relations of infinite words that are accepted by synchronous finite automata, or equivalently definable in monadic second-order logic (MSO) over the structure consisting of natural numbers equipped with the successor relation, the uniformization property is shown in [19]. Over infinite trees, the uniformization property fails for MSO definable relations (corresponding to synchronous tree automata) [10, 2], while it has been shown recently that uniformization is possible for synchronous

relations over finite trees [14, 4]. These relations defined by synchronous automata are usually referred to as automatic, \( \omega \)-automatic, tree-automatic and \( \omega \)-tree-automatic relations (for finite words, infinite words, finite trees, and infinite trees, respectively).

In a more algorithmic setting, uniformization is often referred to as synthesis: The relation is viewed as a specification between inputs and outputs, and the function is supposed to be realized by a device that produces the output while processing the input. This means, that the class for the uniformizations is usually different from the class of the specifications, and the problem of interest is now the decision problem whether a given relation admits a uniformization in the desired class.

The classical setting, originating from Church's synthesis problem [3], is the one of infinite words. The specification is given by an \( \omega \)-automatic relation (originally in MSO), and the question is whether it can be uniformized by a synchronous sequential transducer that produces, letter by letter, an infinite output word while reading an infinite input word. The seminal paper of Büchi and Landweber [1] shows the decidability of this problem, and has been extended later to uniformizations by asynchronous sequential transducers [12, 11]. A detailed study of the synthesis of sequential transducers for asynchronous automata on finite words is provided in [6].

Our aim is to study these uniformization questions for relations over finite trees. Tree automata are used in many fields, for example as a tool for analyzing and manipulating rewrite systems or XML Schema languages (see [7]). Tree transformations that are realized by finite tree transducers thus become interesting in the setting of translations from one document scheme into another [17]. As class for the uniformizations we consider deterministic top-down tree transducers (D\( \downarrow \)TTs), which are a natural extension of sequential transducers on words. A first result in this setting was obtained in [16], where we show that it is decidable whether a tree-automatic relation that is defined by a deterministic top-down tree automaton (D\( \downarrow \)TA) can be uniformized by a D\( \downarrow \)TT. A representation of the specification by a deterministic automaton model is essential in many synthesis algorithms for automata. A standard approach is to build a game in which the two players produce input and output. The aim of the output player is to ensure that the pair of input and output produced along a play satisfies the specification. This property is ensured in the game by simulating a deterministic automaton for the specification on the moves of the players. A winning strategy for the output player then corresponds to a uniformizer.

In this paper, we show that the synthesis problem for D\( \downarrow \)TT from nondeterministic tree-automatic relations is indeed undecidable, showing that the nondeterminism does not only destroy the game theoretic approach (as sketched above) but makes the problem intractable in general. On the positive side, we prove two decidability results for restricted classes of uniformizers and specifications:

1. For nondeterministic tree-automatic relations uniformization by path-preserving D\( \downarrow \)TTs is decidable. Intuitively, we call a D\( \downarrow \)TT path-preserving if every node of the output tree is produced from a node of the input tree that is above or below the output node (this implies that each path-preserving D\( \downarrow \)TT is in particular linear). For this class of uniformizers we can adapt the game theoretic approach by using guidable automata [5, 15] instead of deterministic automata for the specification.

2. If we restrict the specifications to unions of D\( \downarrow \)TAs with disjoint domain, we obtain decidability for uniformizations by synchronous D\( \downarrow \)TTs. We call a D\( \downarrow \)TT synchronous if it produces one output symbol in each transition (but the transitions can be non-linear). While this is a rather specific result, it is the first decidability result for synthesis of transducers in which the synthesized transducer may need to be non-linear.
The paper is structured as follows. In Section 2 we fix some basic definitions and terminology. In Section 3 we show undecidability for synthesis of D1TTs from tree-automatic specifications, and the decidability results are presented in Section 4.

2 Preliminaries

Words and trees. The set of natural numbers containing zero is denoted by \(\mathbb{N}\). For a set \(S\), the powerset of \(S\) is denoted by \(2^S\). An alphabet \(\Sigma\) is a finite non-empty set of letters. A finite word is a finite sequence of letters. The set of all finite words over \(\Sigma\) is denoted by \(\Sigma^*\). The length of a word \(w \in \Sigma^*\) is denoted by \(|w|\), the empty word is denoted by \(\varepsilon\). For \(w = a_1 \ldots a_n \in \Sigma^*\) for some \(n \in \mathbb{N}\) and \(a_1, \ldots, a_n \in \Sigma\), let \(w[i]\) denote the \(i\)th letter of \(w\), i.e., \(w[i] = a_i\). Furthermore, let \(w[i, j]\) denote the infix from the \(i\)th to the \(j\)th letter of \(w\), i.e., \(w[i, j] = a_i \ldots a_j\). We write \(u \subseteq w\) if there is some \(v\) such that \(w = uv\) for \(u, v \in \Sigma^*\).

A ranked alphabet \(\Sigma\) is an alphabet where each letter \(f \in \Sigma\) has a rank \(rk(f) \in \mathbb{N}\). The set of letters of rank \(i\) is denoted by \(\Sigma_i\). A tree domain \(\mathsf{dom}\) is a non-empty finite subset of \((\mathbb{N} \setminus \{0\})^*\) such that \(\mathsf{dom}\) is prefix-closed and for each \(u \in (\mathbb{N} \setminus \{0\})^*\) and \(i \in \mathbb{N} \setminus \{0\}\) if \(ui \in \mathsf{dom}\), then \(uj \in \mathsf{dom}\) for all \(1 \leq j < i\). We speak of \(ui\) as successor of \(u\) for each \(u \in \mathsf{dom}\) and \(i \in \mathbb{N} \setminus \{0\}\).

A (finite \(\Sigma\)-labeled) tree is a pair \(t = (\mathsf{dom}_t, \mathsf{val}_t)\) with a mapping \(\mathsf{val}_t : \mathsf{dom}_t \to \Sigma\) such that for each node \(u \in \mathsf{dom}_t\) the number of successors of \(u\) is a rank of \(\mathsf{val}_t(u)\). The height \(h\) of a tree \(t\) is the length of its longest path, i.e., \(h(t) = \max\{|u| \mid u \in \mathsf{dom}_t\}\). The set of all \(\Sigma\)-labeled trees is denoted by \(\mathcal{T}_\Sigma\). A subset \(T \subseteq \mathcal{T}_\Sigma\) is called tree language over \(\Sigma\).

A subtree \(t_u\) of a tree \(t\) at node \(u\) is defined by \(\mathsf{dom}_{t_u} = \{v \in \mathbb{N}^* \mid uv \in \mathsf{dom}_t\}\) and \(\mathsf{val}_{t_u}(v) = \mathsf{val}_t(uv)\) for all \(v \in \mathsf{dom}_{t_u}\). In order to formalize concatenation of trees, we introduce the notion of special trees. A special tree over \(\Sigma\) is a tree over \(\Sigma \cup \{\circ\}\) such that \(\circ\) occurs exactly once at a leaf. Given \(t \in \mathcal{T}_\Sigma\) and \(u \in \mathsf{dom}_t\), we write \(t[\circ/u]\) for the special tree that is obtained by deleting the subtree at \(u\) and replacing it by \(\circ\). Let \(\mathcal{S}_\Sigma\) be the set of special trees over \(\Sigma\). For \(t \in \mathcal{S}_\Sigma\) and \(s \in \mathcal{T}_\Sigma\) or \(s \in \mathcal{S}_\Sigma\) let the concatenation \(t \cdot s\) be the tree that is obtained from \(t\) by replacing \(\circ\) with \(s\).

Let \(X_n\) be a set of \(n\) variables \(\{x_1, \ldots, x_n\}\) and \(\Sigma\) be a ranked alphabet. We denote by \(\mathcal{T}_\Sigma(X_n)\) the set of all trees over \(\Sigma\) which additionally can have variables from \(X_n\) at their leaves. We define \(X_0\) to be the empty set, the set \(\mathcal{T}_\Sigma(\emptyset)\) is equal to \(\mathcal{T}_\Sigma\). Let \(X = \bigcup_{n \geq 0} X_n\). A tree from \(\mathcal{T}_\Sigma(X)\) is called linear if each variable occurs at most once. For \(t \in \mathcal{T}_\Sigma(X_n)\) let \(t[x_1 \leftarrow t_1, \ldots, x_n \leftarrow t_n]\) be the tree that is obtained by substituting each occurrence of \(x_i \in X_n\) by \(t_i \in \mathcal{T}_\Sigma(X)\) for every \(1 \leq i \leq n\).

A tree from \(\mathcal{T}_\Sigma(X_n)\) such that all variables from \(X_n\) occur exactly once and in the order \(x_1, \ldots, x_n\) when reading the leaf nodes from left to right, is called \(n\)-context over \(\Sigma\). Given an \(n\)-context, the node labeled by \(x_i\) is referred to as \(i\)th hole for every \(1 \leq i \leq n\). A special tree can be seen as a 1-context, a tree without variables can be seen a 0-context. If \(C\) is an \(n\)-context and \(t_1, \ldots, t_n \in \mathcal{T}_\Sigma(X)\) we write \(C[t_1, \ldots, t_n]\) instead of \(C[x_1 \leftarrow t_1, \ldots, x_n \leftarrow t_n]\).

Tree automata. We fix our notations. For a detailed introduction to tree automata see e.g. [9] or [7]. Let \(\Sigma = \bigcup_{i=0}^n \Sigma_i\) be a ranked alphabet. A non-deterministic top-down tree automaton (an N\(\Sigma\)TA) over \(\Sigma\) is of the form \(\mathcal{A} = (Q, \Sigma, Q_0, \Delta)\) consisting of a finite set of states \(Q\), a set \(Q_0 \subseteq Q\) of initial states, and \(\Delta \subseteq \bigcup_{i=0}^n (Q \times \Sigma_i \times Q^i)\) is the transition relation. For \(i = 0\), we identify \(Q \times \Sigma_i \times Q^i\) with \(Q \times \Sigma_0\). Let \(t\) be a tree and \(\mathcal{A}\) be an N\(\Sigma\)TA, a run of \(\mathcal{A}\) on \(t\) is a mapping \(\rho : \mathsf{dom}_t \to Q\) compatible with \(\Delta\), i.e., \(\rho(\varepsilon) \in Q_0\) and for each...
node $u \in \text{dom}_t$ with $i \geq 0$ successors $(\rho(u), \text{val}_t(u), \rho(u1), \ldots, \rho(u_i)) \in \Delta$. A tree $t \in T_{\Sigma}$ is accepted if, and only if, there is a run of $A$ on $t$. The tree language recognized by $A$ is $T(A) = \{ t \in T_{\Sigma} \mid A$ accepts $t \}$. A tree language $T \subseteq T_{\Sigma}$ is called regular if $T$ is recognizable by a non-deterministic top-down tree automaton.

A top-down tree automaton $A = (Q, \Sigma, Q_0, \Delta)$ is deterministic (a DT$A$) if the set $Q_0$ is a singleton set and for each $f \in \Sigma_i$ and each $q \in Q$ there is at most one transition $(q, f, q_1, \ldots, q_i) \in \Delta$. However, non-deterministic and deterministic top-down automata are not equally expressive. It is effectively decidable whether a regular tree language is top-down deterministic [9].

In Section 4.1 we use guidable tree automata [15]. The concept of guidable tree automata is that another tree automaton can act as a guide, meaning that a tree automaton $B$ can guide a tree automaton $A$ if an accepting run of $B$ on a tree $t$ can be translated deterministically into an accepting run of $A$ on $t$.

Formally, an $\text{N} \upharpoonright \text{TA} A$ can be guided by an $\text{N} \upharpoonright \text{TA} B$ if there is a mapping $g : Q_A \times \Delta_B \rightarrow \Delta_A$ such that $g(q, (p, a, p_1, \ldots, p_i)) = (q, a, q_1, \ldots, q_i)$ for some $q_0, \ldots, q_i \in Q_A$, and for every accepting run $\rho$ of $B$ over a tree $t$, $g(\rho)$ is an accepting run of $A$ over $t$, where $g(\rho) = \rho'$ is the unique run such that $\rho'(\epsilon) = g(\epsilon)$, and for all $u \in \text{dom}_t : (\rho'(u), \text{val}_t(u), \rho'(1u), \ldots, \rho'(ui)) = g(\rho'(u), (\rho(u), \text{val}_t(u), \rho(u1), \ldots, \rho(ui)))$. An $\text{N} \upharpoonright \text{TA} A$ is called guidable if it can be guided by every $\text{N} \upharpoonright \text{TA} B$ such that $T(B) \subseteq T(A)$.

Tree-automatic relations are defined by using tree automata over a product alphabet. For nodes that belong only to one of the trees one uses a padding symbol. Formally, let $\Sigma, \Gamma$ be ranked alphabets and let $\Sigma_\perp = \Sigma \cup \{ \perp \}$, $\Gamma_\perp = \Gamma \cup \{ \perp \}$, where $\perp$ is a new symbol with rank 0. For an $i$-ary symbol $f \in \Sigma_\perp$ and a $j$-ary symbol $g \in \Gamma_\perp$, let $rk((f, g)) = \max\{i, j\}$.

The convolution of $(t_1, t_2)$ with $t_1 \in T_{\Sigma}$, $t_2 \in T_{\Gamma}$ is the $\Sigma \times \Gamma$-labeled tree $t = t_1 \otimes t_2$ defined by $\text{dom}_t = \text{dom}_{t_1} \cup \text{dom}_{t_2}$, and $\text{val}_t(u) = (\text{val}^I_{t_1}(u), \text{val}^I_{t_2}(u))$ for all $u \in \text{dom}_t$, where $\text{val}^I_{t_1}(u) = \text{val}_{t_1}(u)$ if $u \in \text{dom}_{t_1}$ and $\text{val}^I_{t_1}(u) = \perp$ otherwise for $i \in \{1, 2\}$. As a special case, given $t \in T_{\Sigma}$, we define $\perp \otimes \perp$ to be the tree with $\text{dom}_{\perp \otimes \perp} = \text{dom}_t$, and $\text{val}_{\perp \otimes \perp}(u) = (\text{val}_t(u), \perp)$ for all $u \in \text{dom}_t$. Analogously, we define $\perp \otimes t$. We define the convolution of a tree relation $R \subseteq T_{\Sigma} \times T_{\Gamma}$ to be the tree language $T_R := \{ t_1 \otimes t_2 \mid (t_1, t_2) \in R \}$.

We call a (binary) relation $R$ tree-automatic if there exists a regular tree language $T$ such that $T = T_R$. For ease of presentation, we say a tree automaton $A$ recognizes $R$ if it recognizes the convolution $T_R$ and denote by $R(A)$ the induced relation $R$.

A uniformization of a relation $R \subseteq X \times Y$ is a function $f_R : X \rightarrow Y$ such that $(x, f_R(x)) \in R$ for all $x \in \text{dom}(R)$. We are interested in uniformizations of tree-automatic relations by deterministic top-down tree transducers.

Tree transducers. We consider top-down tree transducers, which read the tree from the root to the leaves and produce finite output trees in each step that are attached to the already produced output (see [7] for an introduction to tree transducers).

A top-down tree transducer (a DT$T$) is of the form $T = (Q, \Sigma, \Gamma, q_0, \Delta)$ consisting of a finite set of states $Q$, a finite input alphabet $\Sigma$, a finite output alphabet $\Gamma$, an initial state $q_0 \in Q$, and $\Delta$ is a finite set of transition rules of the form $q(f(x_1, \ldots, x_i)) \rightarrow w[q_1(x_{j_1}), \ldots, q_n(x_{j_n})]$, or $q(x_1) \rightarrow w[q_1(x_1), \ldots, q_n(x_1)](\epsilon$-transition), where $f \in \Sigma_i$, $w$ is an $n$-context over $\Gamma$, $q_1, \ldots, q_n \in Q$ and variables $x_{j_1}, \ldots, x_{j_n} \in X_i$. A deterministic top-down tree transducer (a DT$T$) has no $\epsilon$-transitions and no two rules with the same left-hand side.

A configuration of a top-down tree transducer is a triple $c = (t, t', \varphi)$ of an input tree $t \in T_{\Sigma}$, an output tree $t' \in T_{\Gamma \cup Q}$ and a function $\varphi : D_{t'} \rightarrow \text{dom}_{t'}$, where $\text{val}_{t'}(u) \in \Gamma_i$ for each $u \in \text{dom}_{t'}$ with $i > 0$ successors, and
Consider the set \( R \) of states. For each leaf \( u \) on the top-down tree, let \( \varphi_0(u) = \varepsilon \). Then \( \varphi_0 \) extends to \( \varphi \) on all \( T \) by \( \varphi(u) = v \cdot j_i \) if \( u = u_i.v \) with \( u_i \) being the ith hole in \( v \).

Furthermore, let \( \rightarrow_T \) be the reflexive and transitive closure of \( \rightarrow_T \) and \( \rightarrow_T^\varphi \) the reachability relation for \( \rightarrow_T^\varphi \) in \( n \) steps. From here on, let \( \varphi_0 \) always denote the mapping \( \varphi_0(\varepsilon) = \varepsilon \). A configuration \( (t, q_0, \varphi_0) \) is called initial configuration of \( T \) on \( t \). A configuration \( c = (t, t', \varphi) \) is said to be reachable in a computation of \( T \) on \( t \), if \( c_0 \rightarrow_T \cdots \rightarrow_T^\varphi c \), where \( c_0 \) is the initial configuration of \( T \) on \( t \). The relation \( R(T) \) induced by a top-down tree transducer \( T \) is \( R(T) = \{(t, t') \in T_S \times T_T \mid (t, q_0, \varphi_0) \rightarrow_T^\varphi (t', \varphi) \} \). For a (special) tree \( t \in T_S \), or \( t \in T_G \) let \( T(t) \subseteq T_G \cup Q \) be the set of final transformed outputs of a computation of \( T \) on \( t \), that is the set \( \{t' \mid (t, q_0, \varphi_0) \rightarrow_T^\varphi (t', \varphi) \text{ s.t. there is no successor configuration of } (t', \varphi) \} \). Note, we explicitly do not require that the final transformed output is a tree over \( \Gamma \). In the special case that \( T(t) \) is a singleton set \( \{t'\} \), we also write \( T(t) = t' \). The class of relations definable by \( \downarrow T \) is called the class of top-down tree trans formations.

**Example 1.** Let \( \Sigma \) be a ranked alphabet given by \( \Sigma_2 = \{f\} \), \( \Sigma_1 = \{g, h\} \), and \( \Sigma_0 = \{a\} \). Consider the \( \downarrow T \) given by \( \{q\} \), \( \Sigma, \Sigma, \{a\} \), \( \Delta \) with \( \Delta = \{q(a) \rightarrow a, q(g(x)) \rightarrow q(x), f(h(x_1)) \rightarrow h(q(x_1)), q(f(x_1), x_2) \rightarrow f(q(x_1), q(x_2))\} \).

For each \( t \in T_S \) the transducer deletes all occurrences of \( g \) in \( t \). Consider \( t := f(g(h(a)), a) \). A possible sequence of configurations of \( T \) on \( t \) is \( c_0 \rightarrow_T^\varphi c_5 \) such that \( c_0 := (t, q, \varphi_0(\varepsilon) = \varepsilon, c_1 := (t, q, q), q(\varphi_1) \) with \( \varphi_1(1) = 1, \varphi_1(2) = 2, c_2 := (t, q, q, q), \varphi_2(1) = 11, \varphi_2(2) = 22, c_3 := (t, \varphi_2(2), q, q), \varphi_3(1) = 11, c_4 := (t, \varphi_2(2), q, q), \varphi_4(11) = 111, \) and \( c_5 := (t, f(h(a)), a, a) \). A visualization of this sequence is shown in Figure 1.

We consider two restricted types of top-down tree transducers. The first type are transducers with bounded (output) delay. Intuitively, delay occurs in a computation of a transducer if there is a difference between the number of produced output symbols and read input symbols. If the output is behind this is called output delay. More formally, in a configuration \( (t, t', \varphi) \) occurs delay \( d \) w.r.t. a node \( u \in D_T \) if the absolute value of \( |\varphi(u)| - |u| \)
equals $d$. We speak of output delay if $|\varphi(u)| - |u|$ is a positive integer. We say the delay (resp. output delay) in a $\downarrow\text{TT}$ $\mathcal{T}$ is bounded by $k$, if there is a $k \in \mathbb{N}$ such that for every reachable configuration $c$ of $\mathcal{T}$ the maximal delay (resp. output delay) that occurs in $c$ is at most $k$. We speak of synchronous $\downarrow\text{TT}$s if the delay is bounded by 0.

Consider $\mathcal{T}$ from Example 1 and the configuration sequence of $\mathcal{T}$ given in Example 1. In $c_2$ occurs output delay 1 resp. 0 w.r.t. node 1 resp. 2 of the output tree. It is easy to see that the transducer has unbounded output delay, because it deletes all occurrences of $g$ in an input tree.

The second restricted type of top-down tree transducer concerns the ability to copy and swap subtrees. A $\downarrow\text{TT}$ is linear if all the trees in the transitions are linear. In Section 4.1, we consider a special case of linear $\downarrow\text{TT}$s called path-preserving. Intuitively, a $\downarrow\text{TT}$ is said to be path-preserving if in every computation the read input and correspondingly produced output are always on the same path, i.e., every node of the output tree is produced from a node of the input tree that is above or below the output node. More formally, in every reachable configuration $(t,t',\varphi)$ of the transducer it holds either $u \in \varphi(u)$ or $\varphi(u) \subseteq u$ for every node $u \in D_\nu$. We refer to this kind of $\downarrow\text{TT}$s as $\text{P}_\downarrow\text{TT}$s for short.

### 3 Undecidability Results

**Theorem 2.** It is undecidable whether a given tree-automatic relation has a uniformization by a deterministic top-down tree transducer.

**Proof Sketch.** We give a reduction from the halting problem for Turing machines (TM). Given a TM $M$, our goal is to describe a tree-automatic specification $R_M$ which can only be realized by a deterministic top-down tree transducer if $M$ does not halt on the empty input tape. In order to save space, we draw trees from left to right rather than from top to bottom. For explaining the idea, we provide for a given Turing machine a specification $S$ and a uniformizer $\theta$ and a $\downarrow\text{TT}$-realizable transformation $\theta$ such that $\theta$ uniformizes $S$ if, and only if, $M$ does not halt on the empty tape. For the full proof, the specification and the uniformizer have to be adapted such that $\theta$ becomes the only candidate for uniformizer of $S$, which then implies the undecidability of the existence of a uniformizer.

In the following, we explain the simple versions of $S$ and $\theta$. Let $Q_M$ denote the state set of $M$, $q_0$ denote the initial state of $M$, and $\Gamma_M$ denote the tape alphabet of $M$. We can represent a configuration $c$ of $M$, as a unary tree, i.e., as a string, of the form $u_1 - \cdots - u_k - q - v_1 - \cdots - u_l$, where $u_1, \ldots, u_k, v_1, \ldots, v_l \in \Gamma_M$, $u_1 \cdots u_k v_1 \cdots v_l$ is the content of the tape of $M$, $q \in Q_M$ is the current control state of $M$, and the head of $M$ is on $v_1$.

We start with the first step. Concerning the specification $S$, we are interested in pairs $(t,t')$ of trees over $Q_M \cup \Gamma_M \cup \{f,a\}$ which have the form

\[
\begin{pmatrix}
  f & f & \cdots & f & a \\
  c_0 & c_1 & \cdots & c_n & k_1 & k_2 & \cdots & k_m
\end{pmatrix},
\]

where $m \geq n$, each $c_i$ (resp. $k_i$) is a configuration of $M$, $c_0$ is the initial configuration of $M$ on the empty tape and $c_n$ is a halting configuration of $M$. Note that the numbering of the $c_i$ starts with 0 and the numbering of the $k_i$ with 1, this is intended. Such a pair of trees is part of the specification $S$ if it additionally satisfies the following: There is an $i \in \{0, \ldots, n-1\}$ such that $\text{succ}(c_i) \neq k_{i+1}$, where $\text{succ}(c_i)$ is the successor configuration of $c_i$.

The specification $S$ is tree-automatic. Note that for a pair $(t,t')$ of the correct form, the configurations $c_i$ and $k_{i+1}$ overlap for each $i \in \{0, \ldots, n-1\}$ in $t \otimes t'$. A tree-automaton can guess a branch and verify that $\text{succ}(c_i) \neq k_{i+1}$ holds.

Now, we consider the function $\theta: \text{dom}(S) \to T_{Q_M \cup \Gamma_M \cup \{f,a\}}$ defined by
Assuming that a transducer is only given input trees that have the desired form, this function is realizable by a deterministic top-down tree transducer, e.g., by some transducer that produces no output in the first step, continues at the right child and then simply copies the rest of the input tree.

Assume that $M$ does not halt on the empty input tape and consider an input tree $t \in \text{dom}(S)$, then there are configurations $c_i$ and $c_{i+1}$ such that $c_{i+1}$ is not the successor configuration of $c_i$. The transformation $\theta$ yields $c_{i+1} = k_{i+1}$, it follows that $\text{succ}(c_i) \neq k_{i+1}$, i.e., $(t, \theta(t)) \in S$. Conversely, assume that $M$ halts on the empty input tape. Consider an input tree $t \in \text{dom}(S)$ such that $c_0c_1 \cdots c_n$ is the halting configuration sequence. It follows that $k_{i+1} = \text{succ}(c_i) = c_{i+1}$ for all $i \in \{0, \ldots, n - 1\}$, i.e., $(t, \theta(t)) \notin S$. Clearly, $S$ is uniformized by $\theta$ if, and only if, $M$ does not halt on the empty input tape.

However, the specification $S$ does not suffice to enforce that this kind of transformation is the only possible uniformizer. This can be achieved by extending the alphabet and the specification.

From the undecidability proof one can derive that the uniformization problems remain undecidable if we restrict the $D^{\downarrow}_{\text{TT}}$s, as stated in the following two theorems. Together with the decidability result from Section 4.1 this gives an almost complete picture of the frontier between decidability and undecidability (for the case of all tree-automatic relations as specifications, and subclasses of $D^{\downarrow}_{\text{TT}}$s as uniformizers).

\begin{itemize}
  \item **Theorem 3.** It is undecidable whether a given tree-automatic relation has a uniformization by a linear deterministic top-down tree transducer with delay bounded by 1.
  \item **Theorem 4.** It is undecidable whether a given tree-automatic relation has a uniformization by a synchronous deterministic top-down tree transducer.
\end{itemize}

4 Decidability Results

In the previous section we have seen that the uniformization problem for general tree-automatic specifications is undecidable. In order to regain decidability of the uniformization problem for non-deterministic top-down specifications we present two approaches. In Section 4.1, we consider general non-deterministic top-down specifications and restrict the uniformizer, whereas in Section 4.2 we consider a restricted class of non-deterministic top-down specifications and ask whether there is a synchronous uniformizer.

4.1 Path-preserving uniformization

In this section, we consider general non-deterministic tree relations and restrict the uniformizer; we are looking for a uniformization by a deterministic path-preserving top-down transducer. We solve the following uniformization problem.

\begin{itemize}
  \item **Theorem 5.** It is decidable whether a given tree-automatic relation has a uniformization by a deterministic path-preserving top-down tree transducer.
\end{itemize}

In the following we show that deciding whether a general non-deterministic top-down tree relation has a path-preserving uniformization reduces to deciding the winner in a safety game between two players. We show that the use of guidable tree automata [15] for the specifications makes it feasible to adapt a decision procedure presented in [16], where the
uniformization problem for deterministic top-down tree relations was reduced to deciding
the winner in a safety game.

Before we present the decision procedure, we need to fix some notations. Given \( \Sigma = \bigcup_{i=0}^{m} \Sigma_i \), let \( \text{dir}_\Sigma = \{1, \ldots, m\} \) be the set of directions compatible with \( \Sigma \). For \( \Sigma = \bigcup_{i=0}^{n} \Sigma_i \), the set \( \text{Path}_\Sigma \) of labeled paths over \( \Sigma \) is defined inductively by:
- \( \varepsilon \) is a labeled input path and each \( f \in \Sigma \) is a labeled input path,
- given a labeled input path \( \pi = x \cdot f \) with \( f \in \Sigma_i \) (\( i > 0 \)) over \( \Sigma \), then \( \pi \cdot jg \) with \( j \in \{1, \ldots, i\} \) and \( g \in \Sigma \) is a labeled input path.

For \( \pi \in \text{Path}_\Sigma \), we define the path \( \text{path}(\pi) \in \text{dir}_\Sigma^* \) and the word \( \text{labels}(\pi) \in \Sigma^* \) induced by \( \pi \) inductively by:
- if \( \pi = \varepsilon \) or \( \pi = f \), then \( \text{path}(\varepsilon) = \text{path}(f) = \varepsilon \), \( \text{labels}(\varepsilon) = \varepsilon \) and \( \text{labels}(f) = f \),
- if \( \pi = x \cdot jf \) with \( j \in \text{dir}_\Sigma \), \( f \in \Sigma \), then \( \text{path}(\pi) = \text{path}(x) \cdot j \), \( \text{labels}(\pi) = \text{labels}(x) \cdot f \).

The length \( || \pi || \) of a labeled path over \( \Sigma \) is the length of the word induced by its path, i.e., \( ||\pi|| = |\text{labels}(\pi)| \).

For \( \pi \in \text{Path}_\Sigma \) let \( T^\pi_x := \{ t \in T^\pi_{\Sigma} \mid \text{val}_x(\text{path}(\pi)[1, (i-1)]) = \text{labels}(\pi)[i] \text{ for } 1 \leq i \leq ||\pi|| \} \) be the set of trees \( t \) over \( \Sigma \) such that \( \pi \) is a prefix of a labeled path through \( t \). For a tree-automatic relation \( R \subseteq T_\Sigma \times T_\Sigma \) recognized by an \( \mathbb{N} \uparrow \mathcal{T} A \), \( \pi \in \text{Path}_\Sigma \) and \( q \in Q_A \) let \( R^\pi := \{(t, t') \in R \mid t \in T^\pi_x \} \) and \( R^0_q := \{(t, t') \in R(A_q) \mid t \in T^\pi_x \} \).

Since we consider labeled paths through trees, it is convenient to define the notion
of convolution also for labeled paths. For a labeled path \( x \in \text{Path}_\Sigma \) with \( ||x|| > 0 \), let \( \text{dom}_x := \{ u \in \text{dir}_\Sigma \mid u \subseteq \text{path}(x) \} \) and \( \text{val}_x : \text{dom}_x \rightarrow \Sigma \), where \( \text{val}_x(u) = \text{labels}(x)[i] \) if \( u \in \text{dom}_x \) with \( |u| = i + 1 \). Let \( x \in \text{Path}_\Sigma \), \( y \in \text{Path}_\Sigma \) with \( \text{path}(y) \subseteq \text{path}(x) \) or \( \text{path}(x) \subseteq \text{path}(y) \), then the convolution of \( x \) and \( y \) is \( x \otimes y \) defined by \( \text{dom}_{x \otimes y} = \text{dom}_x \cup \text{dom}_y \), and \( \text{val}_{x \otimes y}(u) = (\text{val}_x^{-1}(u), \text{val}_y^{-1}(u)) \) for all \( u \in \text{dom}_{x \otimes y} \), where \( \text{val}_x^{-1}(u) = \text{val}_x(u) \) if \( u \in \text{dom}_x \) and \( \text{val}_x^{-1}(u) = \bot \) otherwise, analogously defined for \( \text{val}_y^{-1}(u) \).

Furthermore, it is useful to relax the notion of runs to labeled paths. Let \( x \in \text{Path}_\Sigma \), \( y \in \text{Path}_\Sigma \) such that \( x \otimes y \) is defined, i.e., \( \text{path}(y) \subseteq \text{path}(x) \) or \( \text{path}(x) \subseteq \text{path}(y) \). We define the run of \( A \) on \( x \otimes y \) such that it maps all nodes from \( \text{dom}_{x \otimes y} \) as well as all nodes that are a direct successor of a node from \( \text{dom}_{x \otimes y} \) to a state of \( A \). Formally, let the (partial) run of \( A \) on \( x \otimes y \) be the partial function \( \rho : \text{dir}_\Sigma \rightarrow Q_A \) such that \( \rho(\varepsilon) = q_0^A \), and for each \( u \in \text{dom}_{x \otimes y} \) if \( q := \rho(u) \) is defined and there is a transition \( (q, \text{val}_{x \otimes y}(u), q_1, \ldots, q_k) \in \Delta_A \), then \( \rho(u) = q_j \) for all \( j \in \{1, \ldots, i\} \). Let \( \text{path}(x \otimes y) = v \) and \( i \in \text{dir}_\Sigma \). Shorthand, we write \( A : q_0^A \xrightarrow{x \otimes y}{\text{val}_{x \otimes y}(v)} q_i \), if \( q := \rho(vi) \) is defined. We write \( A : q_0^A \xrightarrow{x \otimes y}{\text{val}_{x \otimes y}(v)} \Delta_A \) to indicate that the (partial) run \( \rho \) of \( A \) on \( x \otimes y \) is accepting.

We explicitly state a simple lemma that is used in several places.

\textbf{Lemma 6 ([16])}. Given a \( \downarrow \mathcal{T} A \) and a state \( q \) of \( A \), the following properties are decidable:
1. \( \forall t \in T_{\Sigma} : t \otimes \bot \in T(A_q) \),
2. \( \exists t' \in T_{\Gamma} : \bot \otimes t' \in T(A_q) \),
3. \( \exists t' \in T_{\Gamma} : \forall t \in T_{\Sigma} : t \otimes t' \in T(A_q) \).

Towards the decision procedure, we consider the relationship between the delay a
transducer introduces and uniformizability. Intuitively, if a specification is uniformized by
a transducer such that the uniformizer introduces long delays between outputs, then only
one path in an input tree is relevant in order to determine an output tree. We express this
property by introducing the term path-recognizable function, meaning that there is a \( \mathbb{D} \uparrow \mathcal{T} T \)
that first deterministically reads a path from the root to a leaf in an input tree and then outputs a matching output tree. Note that such a uniformizer is always path-preserving.

Formally, we say a relation $R \subseteq T_S \times T_T$ is uniformizable by a path-recognizable function, if there exists a $D_1\Gamma$TT $T$ that uniformizes $R$ such that $\Delta_T$ only contains transitions of the following form:

1. $q(f(x_1, \ldots, x_i)) \rightarrow q'(x_j)$, or
2. $q(a) \rightarrow t$,

where $f \in \Sigma_i$, $i > 0$, $a \in \Sigma_0$, $q, q' \in Q_T$ and $j \in \{1, \ldots, i\}$ and $t \in T_T$.

This notion was introduced in [16], where it was shown to be decidable whether a top-down deterministic relation can be uniformized by a path-recognizable function. Using guidable automata, the result carries over to general tree-automatic relations.

**Theorem 7.** It is decidable whether a given tree-automatic relation can be uniformized by a path-recognizable function.

Given a specification, we can show that there exists a computable bound with the following property: If it is necessary for a $D_1\Gamma$TT to introduce delay that exceeds the bound in order to satisfy the specification, then either the remaining specification has a simple uniformization by a path-recognizable function, which is decidable by the above theorem, or is not $D_1\Gamma$TT-uniformizable.

Towards the definition of the game, we need one more notion. We introduce a relation that contains state transformations of a given specification automaton that a labeled path segment in an input tree to (partially) determine a matching output tree. Formally, let $x \in \text{Path}_S$, $y \in \text{Path}_T$ and $i \in \text{dir}_S$ such that $x \otimes y$ is defined. We define the relation $\tau_{x\otimes y} \subseteq Q_A \times Q_A$ such that $(q, q') \in \tau_{x\otimes y}$ if there is a partial run $\rho_q$ of $A_q$ on $x \otimes y$ with $A_q : q \xrightarrow{x \otimes y} i \quad q'$ and for each $u_j$ with $u \in \text{dom}_{x \otimes y}$, $u_j \not\subseteq \text{path}(x \otimes y)i$, and $j \in \{1, \ldots, \text{rk}((\text{val}_T^+)(u), \text{val}_T^+(u)))\}$ holds

- if $r := \rho_q(u_j)$ and $j \leq \text{rk}(\text{val}_T^+(u)), \text{rk}(\text{val}_T^+(u))$, then there exists $t' \in T_T$ such that $t \otimes t' \in T(A_r)$ for all $t \in T_S$, and
- if $r := \rho_q(u_j)$ and $\text{rk}(\text{val}_T^+(u)) < j \leq \text{rk}(\text{val}_T^+(u))$, then $t \otimes \perp \in T(A_r)$ for all $t \in T_S$, and
- if $r := \rho_q(u_j)$ and $\text{rk}(\text{val}_T^+(u)) < j \leq \text{rk}(\text{val}_T^+(u))$, then there exists $t' \in T_T$ such that $\perp \otimes t' \in T(A_r)$.

Lemma 6 implies that it is decidable whether $(q, q') \in \tau_{x\otimes y}$. Basically, if $q$ is in the domain of $\tau_{x\otimes y}$, then there exists a fixed (partial) output tree $s' \in S_T^{\perp \otimes}$ such that for each input tree $t \in T_S \cap \text{dom}(T(A_q))$ there exists some $t' \in T_T$ such that $t \otimes (s' \cdot t') \in T(A_q)$.

Now, we are ready to show that the uniformization problem posed in this section reduces to deciding the winner in a safety game, provided that the specification is given by a guidable automaton. The game is played between $\text{In}$ and $\text{Out}$ on a game graph parameterized by $k$, where $\text{In}$ can follow any path from the root to a leaf in an input tree such that $\text{In}$ plays one input symbol at a time. $\text{Out}$ can either react with an output symbol, or delay the output a bounded number of times (at most $2k$ times) and react with a direction in which $\text{In}$ should continue with his input sequence. As stated after Theorem 7, when the output delay increases to a computable bound, then uniformization is either impossible or can be realized by a path-recognizable function ($\text{Out}$ then wins automatically, see o4. in the construction below). To make the decision procedure sound, the parameter $k$ has to be chosen as this bound.

Given a tree-automatic relation $R \subseteq T_S \times T_T$, we assume its domain to be deterministic, otherwise no deterministic $\Gamma$TT can recognize the domain. Let $R$ be recognized by a guidable
Uniformization for Tree-Automatic Relations and Top-Down Tree Transducers

N|TA A and let dom( R) be recognized by a D↓TA B. Formally, the game graph $G_{\mathcal{A},\mathcal{B}}^k$ is constructed as follows.

- $V_{\text{in}} = \{(p,q,\pi j) \in Q_{\mathcal{B}} \times Q_{\mathcal{A}} \times \text{Path}_{\mathcal{B}} \cdot \text{dir}_{\mathcal{B}} | \| \pi \| \leq 2k + 1, \pi \in \text{Path}_{\mathcal{B}}, j \in \text{dir}_{\mathcal{B}}\} \cup Q_{\mathcal{B}} \times Q_{\mathcal{A}}$ is the set of vertices of player In including the initial vertex $\{(q_0^B, q_0^A)\}$.

- $V_{\text{Out}} = \{(p,q,\pi) \in Q_{\mathcal{B}} \times Q_{\mathcal{A}} \times \text{Path}_{\mathcal{B}} | \| \pi \| \leq 2k + 1\}$ is the set of vertices of player Out.

- From a vertex of In the following moves are possible:
  1. $(p,q,\pi j) \to (p,q,\pi j')$ for each $f \in \Sigma$ such that $B$: $p \xrightarrow{\pi j} p'$ and there exists $(p',f,p_1,\ldots,p_i) \in \Delta_{\mathcal{B}}$ if $\| \pi \| < 2k + 1$ (delay; In chooses the next input symbol)
  2. $\{(p_1,q_1),\ldots,(p_n,q_n)\} \to (p_j,q_j,f)$ for each $f \in \Sigma$ such that there is $(p_j,f,p_j^1,\ldots,p_j^k) \in \Delta_{\mathcal{B}}$ and each $j \in \{1,\ldots,n\}$ (no delay; In chooses the next direction and input symbol)

- From a vertex of Out the following moves are possible:
  1. $(p,q,f) \xrightarrow{\tau} \{(p_1,q_1),\ldots,(p_i,q_i)\}$ if there is $r = (q,(f,g),q_i,\ldots,q_n) \in \Delta_{\mathcal{A}}$,
     $(p,f,p_1,\ldots,p_i) \in \Delta_{\mathcal{B}}, f \in \Sigma$ is i-ary, $g \in \Sigma_{\perp}$ is j-ary, $n = \max\{i,j\}$, and if $j > i$ there exist trees $t_{i+1},\ldots,t_j \in T_{\mathcal{B}}$ such that $\perp \otimes t_l \in T(A_{\mathcal{A}})$ for all $i < l \leq j$.
     (no delay; Out applies a transition; Out can pick out trees for all directions where the input has ended; In can continue from the other directions)

Note, if $f \in \Sigma_0$, i.e., the input symbol is a leaf, then the next reached vertex is $\emptyset \in V_{\text{in}}$, which is a terminal vertex.

- $(p,q,f) \xrightarrow{\tau} \{(p_1,q_1),\ldots,(p_i,q_i)\}$ if there is $r = (q,(f,g),q_i,\ldots,q_n) \in \Delta_{\mathcal{A}}$ such that $(q,q_j) \in \tau_{f,j,g}$ and $(p,f,p_1,\ldots,p_i) \in \Delta_{\mathcal{B}}$.
     (delay; Out applies a transition, removes the leftmost input symbol and advances in direction of the labeled path ahead; Out can pick out trees for all divergent directions)

- $(p,q,\pi j) \to (p,q,\pi j')$ for each $j' \in \{1,\ldots,i\}$ for $f \in \Sigma$, if $\| \pi j f \| < k + 1$.
     (Out delays and chooses a direction from where In should continue)

- $(p,q,\pi) \to (p,q,\pi)$ if $R^k_{\pi}$ is uniformizable by a path-recognizable function.
     (Out stays in this vertex and wins)

Note that the game graph can effectively be constructed, because Lemma 6 and Theorem 7 imply that it is decidable whether the edge constraints are satisfied.

The desired winning condition expresses that player Out loses the game if the input can be extended, but no valid output can be produced. This is represented in the game graph by a set of bad vertices $B$ that contains all vertices of Out with no outgoing edges. If one of these vertices is reached during a play, Out loses the game. Thus, we define $\mathcal{G}_{\mathcal{A},\mathcal{B}}^k = (G_{\mathcal{A},\mathcal{B}}^k, V \setminus B)$ as safety game for Out.

The following two lemmata show that from the existence of a winning strategy a top-down tree transducer that uniformizer the relation can be obtained and vice versa.

Lemma 8. Given $k$, if Out has a winning strategy in $\mathcal{G}_{\mathcal{A},\mathcal{B}}^k$, then $R$ is $D\downarrow PTT$-uniformizable.

The key idea in order to lift the proof in [16] from deterministic to general non-deterministic specifications is, given a guidable automaton for the specification, to turn a uniformizer into a guide for the specification automaton in order to construct a winning strategy.

Lemma 9. If $R$ is $D\downarrow PTT$-uniformizable, then Out has a winning strategy in $\mathcal{G}_{\mathcal{A},\mathcal{B}}^k$, where $k$ is a number effectively computable from $\mathcal{A}$.

As a consequence of Lemmata 8 and 9 and the fact that a winning strategy for Out in $\mathcal{G}_{\mathcal{A},\mathcal{B}}^k$ can effectively be computed, together with the fact that for each tree-automatic relation a guidable $N\downarrow TA$ can effectively be constructed, see [15], we immediately obtain Theorem 5.
4.2 Union of top-down deterministic specifications

In this section, we assume that \( R \subseteq T_S \times T_T \) is given as the union \( \bigcup_{i=1}^{n} R_i \) of \( n \) relations with pairwise disjoint domains, where each \( R_i \) is recognized by a \( D_{TA} A_i \) and its domain is recognized by a \( D_i TA B_i \). Furthermore, we assume that the domain of the relation is \( D_{TA} \)-recognizable, otherwise there exists no uniformization by a deterministic top-down tree transducer.

\[ \text{Example 10.} \] Let \( \Sigma \) be an input alphabet given by \( \Sigma_1 = \{ h \} \) and \( \Sigma_0 = \{ c, d \} \) and let \( \Gamma \) be an output alphabet given by \( \Gamma_2 = \{ f \} \), \( \Gamma_1 = \{ h \} \) and \( \Gamma_0 = \{ c, d \} \). We consider the relation \( R \subseteq T_S \times T_T \) defined by \( \{(h(t), f(t, t')) \mid t, t' \in T_S \text{ such that } t \text{ and } t' \text{ have the same leaf symbol} \} \).

This specification can be obtained by the union of two deterministic top-down specifications, one specification for each leaf symbol. Clearly, a deterministic top-down transducer can realize the specification by producing \( f(t, t') \) for a unary input tree \( h(t) \), e.g., by starting with \( q_0(h(x_1)) \rightarrow f(q(x_1), q(x_1)) \). However, there is no linear synchronous uniformizer for \( R \), because in the first step a linear \( D_{TA} \) would have to pick for either the right or the left subtree an output tree with a fixed leaf symbol. As the actual leaf symbol of the input tree is yet unknown it is not possible to fix a correct output tree.

We provide a decision procedure for the following problem.

\[ \text{Theorem 11.} \] It is decidable whether the union of \( D_i TA \)-recognizable relations with pairwise disjoint \( D_{TA} \)-recognizable domains has a uniformization by a synchronous deterministic top-down tree transducer.

We show that the existence of a synchronous uniformizer for such a relation is a regular property over infinite trees that can be checked by a parity tree automaton. For an introduction to parity tree automata, see e.g. [20]. We define a regular infinite tree, given as the unfolding of a finite graph, such that each vertex of the infinite tree represents a node in an input tree together with a set of output nodes produced from this input node. Since the uniformizer might be non-linear, output at different positions in the output tree can depend on the same position in the input tree. Our construction bounds the number of required output choices by making the choice only depending on the state transition that the current output sequences together with the input sequence induces.

Before we formally define the finite graph, we describe its components. Recall, \( R = \bigcup_{i=1}^{n} R_i \), where \( R_i \) is recognized by a \( D_{TA} A_i \) and \( dom(R) \) is recognized by a \( D_{TA} D \). The graph keeps track of the state of \( D \) on the input, and the states of \( A_1, \ldots, A_n \) on the produced output. For the latter we use vectors with \( n \) elements. We define a function \( \lambda \) that returns the \( \ell \)th element of a vector, for each \( 1 \leq \ell \leq n \). Let \( L \) denote such a vector, then \( \lambda_{\ell}(L) \) stores the information w.r.t. \( A_\ell \). We model that read input and produced output can be on the same or on divergent paths as follows: In case that input and output are on the same path, \( \lambda_{\ell}(L) \) is the state of \( A_\ell \) on the combined input sequence and output sequence. In case that the output is mapped to a divergent path, \( \lambda_{\ell}(L) \) is a set of states of \( A_\ell \) that is obtained by combining all possible input sequences with the produced output sequence. Now we are ready to formally define the graph \( G \):

\[ \begin{align*}
&\text{From a vertex } v \text{ of the form } (p, \{L_1, \ldots, L_m\}) \text{, where } p \text{ is a state of } D \text{ and each } L_j \text{ is a vector of states resp. sets of states over } A_1, \ldots, A_n \text{, the following edges exist:} \\
&v \rightarrow (v, f) \text{ if there is } (p, f, p_1, \ldots, p_k) \in \Delta_D \quad \text{(edges for every possible input symbol)} \\
&\text{An edge } ((p, \{L_1, \ldots, L_m\}), f) \overset{\alpha_1 \cdots \alpha_m}{\rightarrow} ([p_1, Q_1], \ldots, (p_n, Q_n)) \text{ defining output choices } \\
&\alpha_1, \ldots, \alpha_m \text{ exists if } (p, f, p_1, \ldots, p_k) \in \Delta_D \text{ and the following conditions hold:} \\
&\text{for each } L_j \text{ an output } o_j \text{ consisting of one symbol and directions to continue is chosen) }
\end{align*} \]
the set \( Q_d \) is constructed as follows for each \( 1 \leq d \leq i \):
- if for output \( o_j = g(x_{j_1}, \ldots, x_{j_p}) \) there is \( k \in \{1, \ldots, r\} \) with \( j_k = d \),
  (the \( k \)th child of the output \( o_j \) depends on the \( d \)th child of the input)
we add a vector \( V_k \) to \( Q_d \), where the component \( \lambda^V(V_k) \) referring to \( A_k \) is build up from \( \lambda^L(L_j) \) and \( o_j \) as follows:
- if \( \lambda^L(L_j) \in Q_{A_i} \), say \( q \in Q_{A_i} \), (input and output are at the same position)
  and there is \( (q_1, f, g, q_1, \ldots, q_{\max}(rk(f), rk(g))) \in \Delta_{A_i} \),
  then \( \lambda^V(V_k) = \{q_k\} \) otherwise. (input and output continue in divergent directions)
  (the corresponding transition in \( A_k \) is applied)
- if \( \lambda^L(L_j) \in 2^{\Delta_{A_i}} \), (input and output are on divergent paths)
  then set \( \lambda^L(V_k) \) to \( \emptyset \) and for each \( q \in \lambda^L(L_j) \) and each \( f' \in \Sigma \) such that there is \( (q, f', g, q_1, \ldots, q_{\max}(rk(f'), rk(g))) \in \Delta_{A_i} \), add \( q_k \) to \( \lambda^V(V_k) \).
  (all possibly reachable states in \( A_k \) are collected)
- From \([v_1, \ldots, v_i]\) an edge to \( v_j \) exists for all \( 1 \leq j \leq i \). (edges to all directions)
- The initial vertex is \((p_0, \{L\})\), where \( L = [q_0^{A_1}, \ldots, q_0^{A_i}] \) and \( p_0 \) is the initial state of \( D \).

Now that we have defined \( G \), we consider the unfolding \( H \) of \( G \) which is a regular infinite tree. Consequently, each vertex of \( H \) is associated with a labeled path, interpreted as an input sequence \( \pi \), and additionally it is associated with a bounded number of labeled paths, interpreted as output sequences produced by a transducer while reading the input sequence \( \pi \). Note that different vertices of \( H \) may represent the same input sequence, but differ in the associated output sequences. This is a regular infinite tree that has the desired property, namely, each input sequence together with a (sufficiently large) number of possible output sequences is represented in the tree.

Our goal is to construct a parity tree automaton, whose tree language is non-empty iff \( R \) has a uniformization by a synchronous deterministic top-down tree transducer. The idea is to annotate \( H \) with an output strategy \( \sigma \). The strategy selects for each node of the form \((v, f)\) with \( f \in \Sigma \) one child, i.e., \( \sigma \) fixes an output choice. Let \( H^\sigma \) denote the tree \( H \) with annotations encoding \( \sigma \). Given \( H^\sigma \) and some input tree \( t \in dom(R) \), the output choices defined by \( \sigma \) identify a unique output tree that a \( D_\uparrow \)TT can produce while reading \( t \). For an input tree \( t \), let \( \sigma(t) \) denote the corresponding output tree. The strategy \( \sigma \) corresponds to a uniformizer if for all \( t \in dom(R) \) holds that \( (t, \sigma(t)) \in R \). The following lemma shows that the set of trees \( H^\sigma \) such that \( \sigma \) corresponds to a uniformizer is a regular set of trees.

**Lemma 12.** There exists a parity tree automaton \( C \) that accepts exactly those trees \( H^\sigma \) such that \((t, \sigma(t)) \in R \) for all \( t \in dom(R) \).

The next lemma shows that the uniformization problem posed in this section reduces to deciding the emptiness problem for \( C \). It directly implies Theorem 11 because emptiness of parity tree automata is decidable (see [20]).

**Lemma 13.** The tree language \( T(C) \) is non-empty if, and only if, \( R \) has a uniformization by a synchronous deterministic top-down tree transducer.

## 5 Conclusion

We have considered uniformization of tree-automatic relations by \( D_\uparrow \)TTs. Using the subclasses of bounded-delay, linear, and path-preserving \( D_\uparrow \)TTs, we have obtained an almost complete picture of the frontier between decidability and undecidability. We have also presented a class
of tree-automatic relations for which the uniformization problem is decidable but requires, in
general, non-linear uniformizers.

As further research questions it would be interesting to extend the class of specifications
beyond those of tree-automatic relations. In [6] decidability results for word transformations
have been obtained for deterministic rational relations, and for uniformization questions in
which the delay of the uniformizer is related to the one of the specification. We plan to study
extensions of these ideas from words to trees.
