Abstract

We introduce a new dynamic data structure for maintaining the strongly connected components (SCCs) of a directed graph (digraph) under edge deletions, so as to answer a rich repertoire of connectivity queries. Our main technical contribution is a decremental data structure that supports sensitivity queries of the form “are u and v strongly connected in the graph G \ w?”, for any triple of vertices u, v, w, while G undergoes deletions of edges. Our data structure processes a sequence of edge deletions in a digraph with n vertices in O(mn log n) total time and O(n² log n) space, where m is the number of edges before any deletion, and answers the above queries in constant time. We can leverage our data structure to obtain decremental data structures for many more types of queries within the same time and space complexity. For instance for edge-related queries, such as testing whether two query vertices u and v are strongly connected in G \ e, for some query edge e.

As another important application of our decremental data structure, we provide the first nontrivial algorithm for maintaining the dominator tree of a flow graph under edge deletions. We present an algorithm that processes a sequence of edge deletions in a flow graph in O(mn log n) total time and O(n² log n) space. For reducible flow graphs we provide an O(mn)-time and O(m + n)-space algorithm. We give a conditional lower bound that provides evidence that these running times may be tight up to subpolynomial factors.

1 Introduction

Dynamic graph algorithms have been extensively studied for several decades, and many important results have been achieved for dynamic versions of fundamental problems, including connectivity, 2-edge and 2-vertex connectivity, minimum spanning tree, transitive closure, and shortest paths (see, e.g., the survey in [14]). We recall that a dynamic graph problem is said to be **fully dynamic** if it involves both insertions and deletions of edges, **incremental** if it only involves edge insertions, and **decremental** if it only involves edge deletions.

The decremental strongly connected components (SCCs) problem asks us to maintain, under edge deletions in a directed graph $G$, a data structure that given two vertices $u$ and $v$ answers whether $u$ and $v$ are strongly connected in $G$. We extend this problem to sensitivity queries of the form “are $u$ and $v$ strongly connected in the graph $G \setminus w$?”, for any triple of vertices $u, v, w$, i.e., we additionally allow the query to temporarily remove a third vertex $w$. We show that this extended decremental SCC problem can be used to answer fast a rich repertoire of connectivity queries, and we present a new and efficient data structure for the problem. In particular, our data structure for the extended decremental SCC problem can be used to support edge-related queries, such as maintaining the strong bridges of a digraph, testing whether two query vertices $u$ and $v$ are strongly connected in $G \setminus e$, reporting the SCCs of $G \setminus e$, or the largest and smallest SCCs in $G \setminus e$, for any query edge $e$. Furthermore, using our framework, it is possible to maintain the 2-vertex-and 2-edge-connected components of a digraph under edge deletions. All of these extensions can be handled with the same time and space bounds as for the extended decremental SCC problem. (Most of these reductions have been deferred to the full version of the paper.)

A naive approach to solving the extended decremental SCC problem is to maintain separately the SCCs in every subgraph $G \setminus w$ of $G$, for all vertices $w$. After an edge deletion we then update the SCCs of all these $n$ subgraphs, where $n$ is the number of vertices in $G$. If we simply perform a static recomputation after each deletion, then we, for example, obtain decremental algorithms with $O(m^2n)$ total time and $O(n^2)$ space by recomputing the SCCs in each $G \setminus w$ [37] or $O(m^2 + mn)$ total time and $O(m + n)$ space by constructing a more suitable static connectivity data structure [22], respectively. Here $m$ denotes the initial number of edges. The current fastest (randomized) decremental SCC algorithm by Chechik et al. [10] trivially gives $O(mn^{3/2} \log n)$ total update time and $O(mn)$ space for our extended decremental SCC problem.

The main technical contribution of this paper is a data structure for the extended decremental SCC problem with $O(mn \log n)$ total update time that uses $O(n^2 \log n)$ space, and that answers queries in constant time. We obtain this data structure by extending Łącki’s decremental SCC algorithm [30]. His algorithm maintains the SCCs of a graph under edge deletions by recursively decomposing the SCCs into smaller and smaller subgraphs. We therefore refer to his data structure as an SCC-decomposition. His total update time is $O(mn)$ and the space used is $O(m + n)$. We observe that the naive algorithm based on SCC-decompositions can be implemented in such a way that most of the work performed is redundant. We obtain our data structure by merging $n$ SCC-decompositions into one joint data structure, which we refer to as a joint SCC-decomposition. Our data structure, like that of Łącki, is deterministic. Using completely different techniques, Georgiadis et al. [21] showed how to answer the same sensitivity queries in $O(mn)$ total time in the incremental setting, i.e., when the input digraph undergoes edge insertions only.

The extended SCC problem is related to the so-called fault-tolerant model. Here, one wishes to preprocess a graph $G$ into a data structure that is able to answer fast certain
sensitivity queries, i.e., given a failed vertex \( w \) (resp., failed edge \( e \)), compute a specific property of the subgraph \( G \setminus w \) (resp., \( G \setminus e \)) of \( G \). Our data structure supports sensitivity queries when a digraph \( G \) undergoes edge deletions, which gives an aspect of decremental fault-tolerance. This may be useful in scenarios where we wish to find the best edge whose deletion optimizes certain properties (fault-tolerant aspect) and then actually perform this deletion (decremental aspect). This is, e.g., done in the computational biology applications considered by Mihalák et al. [32]. Their recursive deletion-contraction algorithm repeatedly finds the edge of a strongly connected digraph whose deletion maximizes quantities such as the number of resulting SCCs or minimizes their maximum size.

As another important application of our joint SCCs data structure, we provide the first nontrivial algorithm for maintaining the dominator tree of a flow graph under edge deletions. A flow graph \( G = (V, E, s) \) is a directed graph with a distinguished start vertex \( s \in V \), w.l.o.g. containing only vertices reachable from \( s \). A vertex \( w \) dominates a vertex \( v \) (\( w \) is a dominator of \( v \)) if every path from \( s \) to \( v \) includes \( w \). The immediate dominator of a vertex \( v \), denoted by \( d(v) \), is the unique vertex that dominates \( v \) and is dominated by all dominators of \( v \). The dominator tree \( D \) is a tree with root \( s \) in which each vertex \( v \) has \( d(v) \) as its parent. Dominator trees can be computed in linear time [2, 7, 8, 23]. The problem of finding dominators has been extensively studied, as it occurs in several applications, including program optimization and code generation [12], constraint programming [34], circuit testing [4], theoretical biology [1], memory profiling [31], fault-tolerant computing [5, 6], connectivity and path-determination problems [16, 17, 19, 18, 25, 27, 28, 29], and the analysis of diffusion networks [24].

In particular, the dynamic dominator problem arises in various applications, such as data flow analysis and compilation [11, 15]. Moreover, the results of Italiano et al. [27] imply that dynamic dominators can be used for dynamically testing 2-vertex connectivity, and for maintaining the strong bridges and strong articulation points of digraphs. The decremental dominator problem appears in the computation of maximal 2-connected subgraphs in digraphs [25, 29, 13]. The problem of updating the dominator relation has been studied for a few decades (see, e.g., [3, 9, 11, 20, 33, 35, 36]). For the incremental dominator problem, there are algorithms that achieve total \( O(mn) \) running time for processing a sequence of edge insertion in a flow graph with \( n \) vertices, where \( m \) is the number of edges after all insertions [3, 11, 20]. Moreover, they can answer dominance queries, i.e., whether a query vertex \( u \) dominates another query vertex \( v \), in constant time. Prior to our work, the best of our knowledge, no decremental algorithm with total running time better than \( O(m^2) \) was known for general flow graphs. In the special case of reducible flow graphs (a class that includes acyclic flow graphs), Cicerone et al. [11] achieved an \( O(mn) \) update bound for the decremental dominator problem. Both the incremental and the decremental algorithms of [11] require \( O(n^2) \) space, as they maintain the transitive closure of the digraph.

Our algorithm is the first to improve the trivial \( O(m^2) \) bound for the decremental dominator problem in general flow graphs. Specifically, our algorithm can process a sequence of edge deletions in a flow graph with \( n \) vertices and initially \( m \) edges in \( O(mn \log n) \) time and \( O(n^2 \log n) \) space, and after processing each deletion can answer dominance queries in constant time. For the special case of reducible flow graphs, we give an algorithm that matches the \( O(mn) \) running time of Cicerone et al. while improving the space usage to \( O(m + n) \). We remark that the reducible case is interesting for applications in program optimization since one notion of a “structured” program is that its flow graph is reducible. (The details about this result appear in the full paper.) Finally, we complement our results with a conditional lower bound, which suggests that it will be hard to substantially improve our update bounds. In particular, we prove that there is no incremental nor decremental algorithm for maintaining
the dominator tree (or more generally, a dominance data structure) that has total update time $O((mn)^{1-\epsilon})$ (for some constant $\epsilon > 0$) unless the OMv Conjecture [26] fails. The same lower bound applies to the extended decremental SCC problem. Unlike the update time, it is not clear that the $O(n^2 \log n)$ space used by our joint SCC-decomposition is near-optimal. We leave it as an open problem to improve this bound.

Further Notation and Terminology. For a given directed graph $G = (V, E)$, we denote the set of vertices by $V(G) = V$ and the set of edges by $E(G) = E$. We let $|E| = m$ and $|V| = n$. Two vertices $u$ and $v$ are strongly connected in $G$ if there is a path from $u$ to $v$ and a path from $v$ to $u$. $G$ is strongly connected if every vertex is reachable from every other vertex. The strongly connected components (SCCs) of $G$ are its maximal strongly connected subgraphs. The reverse graph of a graph $G$, denoted by $G^R$, is the graph obtained after reversing the direction of all edges in $G$. For a strongly connected graph $H$, we say that deleting an edge $e$ breaks $H$, if $H \setminus e$ is not strongly connected.

An edge (resp., a vertex) of $G$ is a strong bridge (resp., a strong articulation point) if its removal increases the number of SCCs. An edge $e$ (resp., a vertex $v$) is a separating edge (resp., a separating vertex) for two vertices $u$ and $v$ if $u$ and $v$ are not strongly connected in $G \setminus e$ (resp., in $G \setminus v$). Two vertices $u$ and $v$ are 2-edge connected (2-vertex connected) if there are two edge-disjoint paths (internally vertex-disjoint paths) between $u$ and $v$. We denote by $G^R$ the reverse graph of $G$, i.e., the graph which has the same vertices as $G$ and contains an edge $e^R = (v, u)$ for every edge $e = (u, v)$ of $G$.

## 2 A Data Structure for Maintaining Joint SCC-Decompositions

For a given initial graph $G$, the decremental SCC problem asks us to maintain a data structure that allows edge deletions and can answer whether (arbitrary) pairs $(u, v)$ of vertices are in the same SCC. The goal is to update the data structure as quickly as possible while answering queries in constant time. In this paper we present a data structure for the extended decremental SCC problem in which a query provides an additional vertex $w$ and asks whether $u$ and $v$ are in the same SCC when $w$ is deleted from $G$. We maintain this information under edge deletions, and our data structure relies on Łącki’s SCC-decomposition [30] for doing so.

### 2.1 Review of Łącki’s SCC Decomposition

An SCC-decomposition recursively partitions the graph $G$ into smaller strongly connected subgraphs. This generates a rooted tree $T$, whose root $r$ represents the entire graph, and where the subtree rooted at each node $\phi$ represents some vertex-induced strongly connected subgraph $G_\phi$ (we refer to vertices of $T$ as nodes to distinguish $T$ from $G$). Every non-leaf node $\phi$ is a vertex of $G_\phi$, and the children of $\phi$ correspond to SCCs of $G_\phi \setminus \phi$. The concept was introduced by Łącki [30] and slightly extended by Chechik et al. [10]. We adopt the notation from [10].

**Definition 1** (SCC-decomposition). Let $G = (V, E)$ be a strongly connected graph. An SCC-decomposition of $G$ is a rooted tree $T$, whose nodes form a partition of $V$. For a node $\phi$ of $T$ we define $G_\phi$ to be the subgraph of $G$ induced by the union of all descendants of $\phi$ (including $\phi$). Then, the following properties hold:

- Each internal node $\phi$ of $T$ is a single-element set. (In this case, we sometimes abuse notation and assume that $\phi$ is the vertex itself.)
Let $\phi$ be any internal node of $T$, and let $H_1, \ldots, H_t$ be the SCCs of $G_\phi \setminus \phi$. Then the node $\phi$ has $t$ children $\phi_1, \ldots, \phi_t$, where $G_{\phi_i} = H_i$ for all $i \in \{1, \ldots, t\}$.

An SCC-decomposition of a graph $G$ that is not strongly connected is a collection of SCC-decompositions of the SCCs of $G$. We say that $T$ is a partial SCC-decomposition when the leaves of $T$ are not required to be singletons.

Observe that for each node $\phi$, the graph $G_\phi$ is strongly connected. Moreover, the subtree of $T$ rooted at $\phi$ is an SCC-decomposition of $G_\phi$. Also, for a leaf $\phi$ we have that $\phi = V(G_\phi)$.

To build an SCC-decomposition $T$ of a strongly connected graph $G$ we pick an arbitrary vertex $v$, put it in the root of $T$, then recursively build SCC-decompositions of SCCs of $G \setminus \{v\}$ and make them the children of $v$ in $T$. Note that since the choice of $v$ is arbitrary, there are many ways to build an SCC-decomposition of the same graph. Łącki [30] (and Chechik et al. [10]) introduced a procedure $\text{Build-SCC-Decomposition}(G, S)$ that takes as input a set of vertices $S$ and returns a partial SCC-decomposition whose internal nodes are the vertices of $S$, i.e., these vertices are picked first and therefore appear at the top of the constructed tree. We refer to the vertices in $S$ as internal nodes and the remaining nodes as external nodes. Note that all external nodes appear in the leaves of $T$, while internal nodes can be both leaves and non-leaves. This distinction is helpful when describing our algorithm.

Łącki [30] showed that the total initialization and update time under edge deletions of an SCC-decomposition is $O(m\gamma)$, where $\gamma$ is the depth of the decomposition.

## 2.2 Towards a Joint SCC-Decomposition

Recall that the extended decremental SCC problem asks us to maintain under edge deletions a data structure for a graph $G$ such that we can answer whether $u$ and $v$ are strongly connected in $G \setminus \{w\}$ when given $u, v, w \in V(G)$. A naive algorithm does this by maintaining $n$ SCC-decompositions, each with a distinct vertex $w$ as its root. The children of $w$ in an SCC-decomposition that has $w$ as its root are then exactly the SCCs of $G \setminus \{w\}$. Hence, $u$ and $v$ are in the same SCC if and only if they appear in the same subtree below $w$. The total update time of this data structure is however $O(mn^2)$, which is undesirable. With a more refined approach, we improve the time bound to $O(mn \log n)$.

Observe that the external nodes of a partial SCC-decomposition $T$ produced by the procedure $\text{Build-SCC-Decomposition}(G, S)$ exactly correspond to the SCCs of $G \setminus S$. This is true regardless of the order in which vertices from $S$ are picked by the procedure. If two SCC-decompositions are built using the same set $S$, but with vertices being picked in a different order, then the nodes below $S$ represent the same SCCs, which means that they can be shared by the two SCC-decompositions. Our algorithm is based on this observation. We essentially construct the $n$ SCC-decompositions of the naive algorithm described above such that large parts of their subtrees are shared, and such that we do not need to maintain multiple copies of these subtrees. The idea is to partition the set $S$ into two subsets $S_1$ and $S_2$ of equal size (we assume for simplicity that $n$ is a power of 2), and then construct half of the SCC-decompositions with $S_1$ at the top and the other half with $S_2$ at the top. The procedure is repeated recursively on the top part of both halves. We refer to the bottom part, i.e., nodes that are not from $S_1$ and $S_2$, respectively, as the extension of the top part. Note that we eventually get a distinct vertex as the root of each of the $n$ SCC-decompositions. The following definition formalizes the idea.

**Definition 2 (Joint SCC-decomposition).** A joint SCC-decomposition $J$ is a recursive structure. It is either a regular SCC-decomposition $T$ (the base case), or a pair of joint SCC-decompositions $J_1, J_2$ with the same set of internal nodes $S$ and a shared set of external nodes.
Decremental Data Structures for Connectivity and Dominators

Input: A graph $G$ and a set of vertices $S \subseteq V(G)$
Output: A balanced joint SCC-decomposition $J = (J_1, J_2, S, \Phi)$ of $G$ on $S$.

1. if $|S| = 1$ then
   2. return $T = \text{BUILD-SCC-DECOMPOSITION}(G, S)$.
3. end
4. Let $S_1$ and $S_2$ be the first and second half of $S$, respectively, and let $\Phi$ be an empty list.
5. foreach $i \in \{1, 2\}$ do
   7. foreach external node $\phi$ of $J_i$ do
      8. Compute $T_\phi = \text{BUILD-SCC-DECOMPOSITION}(G_\phi, \phi \cap S)$.
      9. Add each external node of $T_\phi$ to $\Phi$, if it is not already there.
   10. end
   11. end
   12. return $J = (J_1, J_2, S, \Phi)$

Figure 1 Build-Joint-SCC-Decomposition($G, S$).

$\Phi$. In the second case we refer to $J$ as the tuple $(J_1, J_2, S, \Phi)$. A joint SCC-decomposition $J = (J_1, J_2, S, \Phi)$ is balanced on $S$ if it has one of the following two properties:
1. $S$ is a singleton and $J$ is a regular (partial) SCC-decomposition $T$ with the vertex from $S$ as root and no other internal nodes (the base case).
2. $S$ can be partitioned into two equally sized halves $S_1$ and $S_2$, and $J$ consists of two joint SCC-decompositions $J_1 = (J_{1,1}, J_{1,2}, S_1, \Phi_1)$ and $J_2 = (J_{2,1}, J_{2,2}, S_2, \Phi_2)$ that are balanced on $S_1$ and $S_2$, respectively. Also, each external node $\phi$ in $\Phi_1$ and $\Phi_2$ is extended with an associated SCC-decomposition $T_\phi$ for $G_\phi$ whose internal nodes are those of $\phi \cap S$.

The combined set of external nodes of $T_\phi$ for all $\phi \in \Phi_1$ is equal to the combined set of external nodes of $T_{\phi'}$ for all $\phi' \in \Phi_2$, and these nodes are the external nodes $\Phi$ of $J$.

The procedure BUILD-JOINT-SCC-DECOMPOSITION($G, S$) describes how we build a balanced joint SCC-decomposition. $G$ is the graph that we wish to decompose, and $S$ is the set of vertices that we wish to place at the top. Initially $S$ is the set of all vertices. The following lemma bounds the number of SCC-decompositions that make up a joint balanced SCC-decomposition. The lemma is proved by observing that the number of SCC-decompositions constructed by BUILD-JOINT-SCC-DECOMPOSITION($G, S$) is given by the recurrence $g(s) = 2g(s/2) + 2$ when $s > 1$ and $g(s) = 1$ otherwise, where $s = |S|$.

Lemma 3. A balanced joint SCC-decomposition for a graph $G$ with $n$ vertices consists of $O(n)$ SCC-decompositions.

Lemma 4. Let $J = (J_1, J_2, S, \Phi)$ be a balanced joint SCC-decomposition of a graph $G$ such that $S = V(G)$. Then the total number of nodes of $J$ is $O(n \log n)$, where $n = |V(G)|$.

Proof. The proof is by induction. Our induction hypothesis says that the total number of internal nodes of a balanced joint SCC-decomposition $J = (J_1, J_2, S, \Phi)$, counting not only $S$ but also recursively the number of internal nodes of $J_1$ and $J_2$, is $|S| \cdot (1 + \log |S|)$.

In the base case, $J$ is an SCC-decomposition with a single internal node, and the induction hypothesis is clearly satisfied. For the induction step we count separately the total number of internal nodes of $J_1 = (J_{1,1}, J_{1,2}, S_1, \Phi_1)$ and $J_2 = (J_{2,1}, J_{2,2}, S_2, \Phi_2)$, and add the number of internal nodes of the SCC-decompositions $T_\phi$ for $\phi \in \Phi_1$ and $\phi \in \Phi_2$, i.e., the extensions
of $J_1$ and $J_2$ to $S$. Since $|S_1| = |S_2| = |S|/2$, it follows from the induction hypothesis that both $J_1$ and $J_2$ have $\left\lceil \frac{|S|}{2} \log |S| \right\rceil$ internal nodes in total. The internal nodes of $T_\phi$ for $\phi \in \Phi_1$ are exactly $S_2$, and the internal nodes of $T_\phi$ for $\phi \in \Phi_2$ are exactly $S_1$. Hence the number of internal nodes in the extensions are $|S_1| + |S_2| = |S|$. It follows that the total number of internal nodes of $J$ is $|S| \cdot (1 + \log |S|)$ as desired.

It remains to count the external nodes of $J$. Note that external nodes of $J_1$ and $J_2$ correspond to internal nodes of $J$, i.e., they are roots of the SCC-decompositions that extend $J_1$ and $J_2$. Therefore there are at most as many external nodes inside the recursion as there are internal nodes in total. There are $O(n)$ external nodes in the extensions of $J_1$ and $J_2$ to $S$, and we conclude that the total number of nodes when $S = V(G)$ is at most $O(n \log n)$.

Recall that an SCC-decomposition of depth $\gamma$ can be initialized in time $O(n \gamma)$ [30]. Since the depth of an SCC-decomposition is at most the number of internal nodes plus one, and since Lemma 4 shows that the total number of nodes in a joint SCC-decomposition is $O(n \log n)$, it follows that the combined depth of all the SCC-decompositions that make up a joint SCC-decomposition is at most $O(n \log n)$, which proves the following lemma.

Lemma 5. The procedure \textsc{Build-Joint-SCC-Decomposition}(\(G, S\)) constructs a joint SCC-decomposition in time $O(n \log n)$.

To answer queries for the extended decremental SCC problem in constant time, we also construct and maintain an $n \times n$ matrix $A$ such that $A[u, w]$ is the index of the SCC of $G \setminus \{w\}$ that contains $u$. Two vertices $u$ and $v$ are in the same SCC of $G \setminus \{w\}$ if and only if $A[u, w] = A[v, w]$. To avoid cluttering the pseudo-code we describe separately how $A$ is maintained. In \textsc{Build-Joint-SCC-Decomposition}(\(G, S\)) we initialize $A$ in the base case when we compute an SCC-decomposition $T$ for a singleton $S = \{w\}$. Indeed, in this case $w$ is the root of $T$, and the external nodes are exactly the SCCs of $G \setminus \{w\}$. Hence, for every vertex $u \in V(G) \setminus \{w\}$ we set $A[u, w]$ to the index of the SCC it is part of in $G \setminus \{w\}$.

Note that storing the matrix $A$ takes space $O(n^2)$. The time spent initializing $A$ is however dominated by the other work performed by the algorithm.

2.3 Deleting Edges from a Joint SCC-Decomposition

We next show how to maintain a joint SCC-decomposition under edge deletions. It is again instructive to consider the work performed by the naïve algorithm that maintains $n$ SCC-decompositions with distinct roots. If these are constructed as described in Section 2.2, then the SCC-decompositions will share many identical subtrees, and the work performed on these subtrees will be the same. In the joint SCC-decomposition such subtrees are shared, but otherwise the work performed is the same as the work performed for individual SCC-decompositions. We therefore use Łącki’s algorithm [30] to delete edges from the individual SCC-decompositions, and we introduce a new procedure for handling the interface between the SCC-decompositions. We next briefly sketch Łącki’s algorithm (see also [10, 30]).

Recall that each node $\phi$ of an SCC-decomposition $T$ represents a strongly connected subgraph $G_\phi$ induced by the vertices in the subtree rooted at $\phi$. If $\phi$ is an internal node of $T$, then the children of $\phi$ are the SCCs of $G_\phi \setminus \phi$. Łącki uses the following two operations to compactly represent edges among $\phi$ and its children.

Definition 6. Let $G$ be a graph. The condensation of $G$, denoted by \textsc{Condense}(\(G\)), is the graph obtained from $G$ by contracting all its SCCs into single vertices. Let $v \in V(G)$. By \textsc{Split}(\(G, v\)) we denote the graph obtained from $G$ by splitting $v$ into two vertices: $v_{in}$ and $v_{out}$. The in-edges of $v$ are connected to $v_{in}$ and the out-edges to $v_{out}$.
The two operations are often used together, and to simplify notation we use the shorthand $G^\mathrm{con}_v = \text{CONDENSE}(\text{SPLIT}(G,v))$. The graph $G^\mathrm{con}_v$ is stored with every internal node $\phi$ of the SCC-decomposition $T$. This introduces at most three copies of every vertex $v$ of $G$: The two vertices $v_{\text{in}}$ and $v_{\text{out}}$ in $G^\mathrm{con}_v$, and possibly a third vertex in the condensed graph of the parent of $v$ in $T$. Moreover, every edge $(u,v)$ appears in exactly one condensed graph, namely that of the lowest common ancestor of $u$ and $v$ in $T$, which we denote by $\text{LCA}(u,v)$. The combined space used for storing all the condensed graphs is thus $O(m+n)$.

To delete an edge $(u,v)$, Łącki [30] locates $\phi = \text{LCA}(u,v)$, and deletes $(u',v')$ from $G^\mathrm{con}_\phi$, where $u'$ and $v'$ are the vertices whose subtrees contain $u$ and $v$. (He uses $O(m)$ space to store a pointer from every edge $(u,v)$ to $\text{LCA}(u,v)$, enabling him to find the lowest common ancestor in constant time.) To preserve connectivity, he then checks whether $u'$ and $v'$ have non-zero out- and in-degrees, respectively, in $G^\phi$. If this is not the case, then he repeatedly removes vertices with out- or in-degree zero and their adjacent edges from $G^\phi$. All such vertices can be located, starting from $u'$ and $v'$, in time that is linear in the number of edges adjacent to the removed vertices. The corresponding children of $\phi$ are then moved up one level in $T$ and made siblings of $\phi$. They are also inserted into $G^\mathrm{con}_{\text{par}(\phi)}$, where $\text{par}(\phi)$ is the parent of $\phi$, and their edges and the edges of $\phi$ in $G^\mathrm{con}_{\text{par}(\phi)}$ are updated correspondingly. This can again be done in time linear in the number of edges in the original graph that are adjacent to vertices in the subtrees that are moved. The procedure is then repeated in $G^\mathrm{con}_{\text{par}(\phi)}$. Since every vertex increases its level at most $\gamma$ times, where $\gamma$ is the initial depth of $T$, it follows that the total update time of the algorithm is at most $O(m\gamma)$.

We let $\text{DELETE-EDGE-FROM-SCC-DECOMPOSITION}(T,u,v)$ be the procedure for deleting an edge $(u,v)$ from an SCC-decomposition $T$. We also denote the recursive procedure for moving nodes $\phi_1,\ldots,\phi_k$ from being children of $\phi$ to being siblings of $\phi$ in $T$ after an edge $(u,v)$ is deleted by $\text{FIX-SCC-DECOMPOSITION}(T,u,v,\phi,\{\phi_1,\ldots,\phi_k\})$. Both procedures return the resulting SCC-decomposition, or a collection of SCC-decompositions in case the graph is not strongly connected. (The pseudo-code appears in the full version of the paper.)

In a joint SCC-decomposition, vertices and edges may appear in multiple nodes as part of smaller SCC-decompositions. We therefore need to find every occurrence of the edge that we wish to delete. We introduce a procedure $\text{DELETE-EDGE}(J,u,v)$ that does that by recursively searching through the nested joint SCC-decompositions and deleting $(u,v)$ from the relevant SCC-decompositions. The procedure also handles the interface between SCC-decompositions. Note that deleting $(u,v)$ from an SCC-decomposition $T$ may cause the SCC corresponding to the root $\phi$ of $T$ to break. The procedure $\text{DELETE-EDGE-FROM-SCC-DECOMPOSITION}(T,u,v)$ will in this case return a collection of SCC-decompositions $\{T_1,\ldots,T_k\}$, one for each new SCC. Suppose $J = (J_1,J_2,S,\Phi)$. If $T$ extends $J_1$ (resp. $J_2$), then it is an SCC-decomposition of the subgraph $G_\phi$ associated with some external node $\phi$ of $J_1$ (resp. $J_2$). $\phi$ is then itself a leaf of an SCC-decomposition $T'$ in $J_1$ (resp. $J_2$). Moreover, when the SCC corresponding to $\phi$ breaks, then this leaf must be split into multiple leaves of $T'$, one for each new SCC. Note however that the levels in $T'$ of the involved vertices do not change after the split. We therefore cannot change the work performed when splitting $\phi$ to the analysis by Łącki [30].

Let $\phi_1,\ldots,\phi_k$ be the roots of the SCC-decompositions $T_1,\ldots,T_k$ that are created when the deletion of $(u,v)$ breaks the SCC $G_{\phi}$. As mentioned above, we need to replace $\phi$ in $T'$ by $\phi_1,\ldots,\phi_k$, which means that $\phi_1,\ldots,\phi_k$ should replace $\phi$ in $G^\mathrm{con}_{\text{par}(\phi)}$, where $\text{par}(\phi)$ is the parent of $\phi$ in $T'$. To efficiently reconnect $\phi_1,\ldots,\phi_k$ in $G^\mathrm{con}_{\text{par}(\phi)}$ we identify the vertex $\phi_1$ whose associated graph $G_{\phi_1}$ has the most vertices, and we then scan through all the vertices in the other graphs $G_{\phi_2},\ldots,G_{\phi_{k-1}},G_{\phi_{k+1}},\ldots,G_{\phi_k}$ and reconnect their adjacent edges in $G^\mathrm{con}_{\text{par}(\phi)}$ when relevant. The work performed is exactly the same as when Łącki
fixes an SCC-decomposition after an edge is removed. We can therefore call \textsc{Fix-SCC-

decomposition}(T',u,v,\phi,\{\phi_1,\ldots,\phi_{i-1},\phi_{i+1},\ldots,\phi_k\}). Note that this makes \phi_i take over
the role of \phi. Also note that we provide the procedure with the end-points \(u\) and \(v\) of the edge
that was deleted, since \(u\) and \(v\) are used as starting points for the search for disconnected
vertices when propagating the update further up the tree.

Finally, observe that splitting the leaf \(\phi\) of the SCC-decomposition \(T'\) may propagate
all the way to the root of \(T'\) and break the SCC corresponding to \(T'\). We therefore use a
recursive procedure, \textsc{Split-Leaf}(J,u,v,\phi,\{\phi_1,\ldots,\phi_k\}), to perform the split. Here \(u\) and \(v\)
are again the end-points of the edge that was deleted.

\begin{theorem}
The total update time spent by \textsc{Delete-Edge}(J,u,v) in order to maintain
a balanced joint SCC-decomposition under edge deletions is \(O(mn\log n)\).
\end{theorem}

\textbf{Proof.} We only sketch the proof, and refer to the full paper for additional details.

The time spent by \textsc{Delete-Edge}(J,u,v) consists of three parts: checking whether
\(\{u,v\} \subseteq V(G_\phi)\) for some \(\phi \in \Phi\), the work performed while deleting edges from SCC-
decompositions, and the work performed by \textsc{Split-Leaf}(J_i,u,v,\phi,\{\phi_1,\ldots,\phi_k\}), for \(i \in \{1,2\}\). To check in constant time whether \(\{u,v\} \subseteq V(G_\phi)\), we maintain for each SCC-
decomposition \(T\) an array on the vertices of the original graph \(G\), such that \(T(v) = \text{True}\) if \(v\) appears in \(T\), and \(T(v) = \text{False}\) otherwise. Storing these arrays takes up \(O(n^2)\) space,
and they are updated when the SCC of the root of an SCC-decomposition breaks.

Recall that Łącki [30] showed that the total initialization and update time of an SCC-
decomposition is \(O(m\gamma)\), where \(\gamma\) is the depth of the decomposition. By Lemma 4, the
total number of nodes of the SCC-decompositions in \(J\) is \(O(n \log n)\), and therefore the
combined depth of the SCC-decompositions is also \(O(n \log n)\). It follows that the time spent
on \textsc{Delete-Edge-from-SCC-decomposition}(T_\phi,u,v) is bounded by \(O(mn \log n)\).

It remains to analyze the time spent on \textsc{Split-Leaf}(J_i,u,v,\phi,\{\phi_1,\ldots,\phi_k\}). Recall that
\textsc{Split-Leaf} identifies the node \(\phi_i\) that contains the most vertices from \(G\), and then breaks
off \(\phi_1,\ldots,\phi_{i-1},\phi_{i+1},\ldots,\phi_k\) from \(\phi\). This means that \(\phi\) is turned into \(\phi_i\), and that we do not
scan through edges adjacent to vertices in \(\phi_i\). Since a split therefore moves vertices to
new nodes of at most half the size, each vertex \(v\) can only be moved \(O(\log n)\) times in
one particular SCC-decomposition \(T\) by \textsc{Split-Leaf}. Each move takes time proportional
to the number of edges adjacent to \(v\), so the total time spent splitting leaves of \(T\) is at
most \(O(m \log n)\). Since, by Lemma 3, there are only \(O(n)\) SCC-decompositions in \(J\), it
follows that the total time spent splitting leaves is \(O(mn \log n)\). Furthermore, the time
spent by \textsc{Split-Leaf} on fixing SCC-decompositions can be charged to the depth reduction
of the vertices that are moved, and this part of the analysis is therefore the same as for
\textsc{Delete-Edge-from-SCC-decomposition}(T_\phi,u,v).

Recall that we also maintain a matrix \(A\) for answering queries, where \(A[u,w]\) is the index
of the SCC of \(G \setminus \{v\}\) that contains \(u\). We again update \(A\) when we make changes to the
topmost SCC-decompositions that each only contain a single internal node, i.e., when such a
root \(\phi\) gets a new child, or when \(G_\phi\) breaks into multiple SCCs. The time spent updating
\(A\) is dominated by the rest of the work that is performed by our algorithm, where we scan
through all edges adjacent to vertices whose SCC is changed.

As described briefly in Section 2.3, Łącki’s SCC-decomposition can be implemented such
that is uses \(O(m+n)\) space [30]. Since a balanced joint SCC-decomposition consists of \(O(n)\)
SCC-decompositions (Lemma 3), it follows that a naive implementation of our data structure
uses \(O(mn)\) space. In the full version of the paper we show how to obtain an alternative
bound of \(O(n^2 \log n)\). Doing so requires two observations:
After an edge \((u', v')\) is deleted from a condensed graph \(G_{\phi}^{con}\), the vertex \(u'\) has a path to \(\phi_{in}\) if and only if \(u'\) has non-zero out-degree, and there is a path from \(\phi_{out}\) to \(v'\) if and only if \(v'\) has non-zero in-degree. Instead of storing the edges of the condensed graphs we therefore store the in- and out-degrees of the vertices. To visit all neighbors of a vertex \(u'\) in \(G_{\phi}^{con}\), we then collect from the original graph \(G\) all edges adjacent to vertices in the subgraph of \(u'\), and we check for each edge whether the other end-point is part of \(G_{\phi}^{con}\) and which vertex of \(G_{\phi}^{con}\) it goes to. To do so we store pointers between the vertices of \(G\) and the vertices of the condensed graphs that they are part of. Since a joint SCC-decomposition contains \(O(n \log n)\) nodes this takes \(O(n^2 \log n)\) space.

Since a joint SCC-decomposition contains \(O(n \log n)\) nodes in total, we have time to visit all the nodes of an SCC-decomposition \(T\) when searching for the lowest common ancestor of two vertices \(u\) and \(v\). This is done in a bottom-up fashion. We therefore do not need to store a pointer from every edge \((u, v)\) to \(\text{LCA}(u, v)\).

## 3 Applications

In this section we exploit the decremental joint SCC-decomposition to design decremental algorithms for various connectivity notions defined with respect to vertex or edge failures.

### Maintaining Decrementeally the Dominator Tree.

We show how to maintain a dominator tree \(D\) of a flow graph \(G\), rooted at a starting vertex \(s\). We denote by \(d(v)\) the parent of \(v\) in \(D\). We first produce a flow graph \(G_s\) from \(G\) by adding an edge from each vertex \(v \in V \setminus s\) to \(s\). The addition of those edges has the following property. If a vertex \(u\) is not strongly connected to \(s\) in \(G_s\) then there is no path from \(s\) to \(u\) in \(G\). Conversely, if a vertex \(u\) is not strongly connected to \(s\) in \(G_s\), while \(s\) and \(u\) are strongly connected in \(G_s\), then all paths from \(s\) to \(u\) in \(G\) contain \(v\). That is, \(v\) is a dominator of \(u\) in \(G\).

We maintain decrementally a joint SCC-decomposition of \(G_s\) in a total of \(O(mn \log n)\) time and \(O(n^2 \log n)\) space. Therefore, for each vertex \(v\) we maintain the SCCs in \(G \setminus v\). Let \(v \neq s\): after the SCC containing \(s\) in \(G \setminus v\) breaks, all the vertices that are not in the new SCC that contains \(s\) are dominated from \(v\) in \(G\). We can report the newly dominated vertices from \(v\) in \(G\) in time proportional to their number. Therefore, after each edge deletion we need to process a batch \(N\) of incoming new dominance relations \(N(v) = \{u_1, \ldots, u_k\}\), where \(u_1, \ldots, u_k\) are dominated by \(v\) in \(G\). We can process a batch of updates \(N\) in two phases as follows. For each vertex \(u \neq s\) we keep a counter \(\text{depth}(u)\) of the number of vertices that dominate \(u\). For each dominance relation \(N(v) \in N\), we increase \(\text{depth}(u)\) for each \(u \in N(v)\). After this first phase ends, all vertices have updated counters. Then the new parent of each vertex \(u\) in \(D\) is the vertex with the largest counter among \(d(u)\) (i.e., the parent of \(u\) in \(D\) before the edge insertion) and all vertices \(v\) such that \(u \in N(v)\) and \(N(v) \in N\).

Now we bound the total time required to maintain the dominator tree. The running time of the above procedure, during the whole sequence of deletions, is bounded by the total size of all the sets \(N(v)\). Note that any vertex can appear in a specific \(N(v)\) set at most once during the deletion sequence. Hence, the total size of all the sets \(N(v)\) is \(O(n^2)\).

**Lemma 8.** The dominator tree of a directed graph \(G\) with start vertex \(s\) can be maintained decrementally in \(O(m n \log n)\) total update time and \(O(n^2 \log n)\) space, where \(m\) is the number of edges in the initial graph and \(n\) is the number of vertices.

### Maintaining Decrementeally the Strong Bridges of the Graph.

Let \(G\) be strongly connected: its strong bridges can be computed efficiently from a dominator tree \(D\) of \(G\) and a
dominator tree $D^R$ of $G^R$, both rooted at the same start vertex $s$. We present a randomized algorithm that maintains such a pair of dominator trees in each SCC of a digraph in $O(mn \log n)$ total expected time, and $O(n^2 \log n)$ space. This allows us to maintain the set of strong bridges of a digraph in the same (expected) running time and space.

**Maintaining Decrementally the 2-Edge-Connected Components.** In this section we show how to maintain the 2-edge-connected components of directed graphs. Two vertices $w$ and $z$ are 2-edge-connected if and only if there is no edge $e$ such that $w$ and $z$ are not strongly connected in $G \setminus e$. A 2-edge-connected component is a maximal subset $B \subseteq V$, such that $w$ and $z$ are 2-edge-connected, for all $w, z \in B$. Therefore, a simple-minded algorithm for computing the 2-edge-connected components is the following. We start with the trivial partition $P$ of the vertices that is equal to the set of SCCs of the graph. For every strong bridge $e$, we compute the SCCs $C_1, \ldots, C_k$ of $G \setminus e$ and we refine the maintained partition $P$ according to the partition induced by the SCCs $C_1, \ldots, C_k$. After performing all refinements on $P$ two vertices are in the same set if and only if we did not find an edge that separates them, which is exactly the definition of 2-edge-connected components.

Our algorithm is a dynamic version of the aforementioned simple-minded algorithm. That is, we maintain the SCCs of $G \setminus e$, for each strong bridge $e$, and refine the maintained partition $P$ whenever we identify that $P$ no longer contains the 2-vertex-connected components of $G$. We do this as follows. Assume that a component $C \in P$ contains vertices in different SCCs of $G \setminus e$, for some $e$. Let $C_1, C_2, \ldots, C_k$ be the SCCs in $G \setminus e$. We replace $C$ by $\{C \cap C_1\}, \ldots, \{C \cap C_k\}$. These refinements can be easily performed in $O(n)$ time, and therefore we spend total time $O(n^2)$ for all refinements throughout the algorithm.

In order to make our algorithm efficient we need to specify how to detect whether two 2-edge-connected vertices appear in different SCCs in $G \setminus e$, for some edge $e$. Whenever an SCC $C$ in $G \setminus e$, breaks into $k$ SCCs $C_1, \ldots, C_k$, for all SCCs $C_i$ except the largest one we examine whether the components $C \in P$ containing subsets of vertices of $C_i$ are entirely contained in $C_i$. We develop machinery that allows us to list all vertices in the resulting SCCs $C_1, \ldots, C_k$ except the largest one, in time proportional to their number. The details can be found in the full paper. Each vertex can appear at most $\log n$ times in an SCC of $G \setminus e$, for some strong bridge $e$, that is not the largest after a big SCC breaks. This implies that we spend $O(n \log n)$ time for each graph $G \setminus e$ on testing whether an edge deletion leaves two (previously) 2-edge-connected vertices in different SCCs in $G \setminus e$, for some edge $e$. We show that at most $O(n)$ strong bridges can appear throughout any sequence of edge deletions. Thus we spend $O(n^2 \log n)$ time in total.

► **Lemma 9.** The 2-edge-connected components of a digraph $G$ can be maintained decrementally in $O(mn \log n)$ total expected time against an oblivious adversary, using $O(n^2 \log n)$ space, where $m$ is the number of edges in the initial graph and $n$ is the number of vertices.

### Conditional Lower Bound

In the following we give a conditional lower bound for the partially dynamic dominator tree problem. We show that there is no incremental or decremental algorithm for maintaining the dominator tree that has total update time $O((mn)^{1-\epsilon})$ (for some constant $\epsilon > 0$) unless the OMv Conjecture [26] fails. This also holds for algorithms that do not explicitly maintain the tree, but are able to answer parent-queries. Formally, we prove the following statement.

► **Theorem 10.** For any constant $\delta \in [0, 1/2]$ and any $n$ and $m = \Theta(n^{1/(1-\delta)})$, there is no algorithm for maintaining a dominator tree under edge deletions/insertions allowing queries...
of the form “is $x$ the parent of $y$ in the dominator tree” that uses polynomial preprocessing time, total update time $u(m,n) = (mn)^{1-\epsilon}$ and query time $q(m) = m^{3-\epsilon}$ for some constant $\epsilon > 0$, unless the $\text{OMv}$ conjecture fails.

Under this conditional lower bound, the running time of our algorithm is optimal up to sub-polynomial factors. We give the reduction for the decremental version of the problem. Hardness of the incremental version follows analogously.

In the online Boolean matrix-vector problem we are first given a Boolean $n \times n$ matrix $M$ to preprocess. After the preprocessing, we are given a sequence of pairs of $n$-dimensional Boolean vectors $v^{(1)}, \ldots, v^{(n)}$ one by one. For each $1 \leq t \leq n$, we have to return the result of the matrix-vector multiplication $Mv^{(t)}$ before we are allowed to see the next vector $v^{(t+1)}$. The $\text{OMv}$ Conjecture states that there is no algorithm that computes each matrix-vector product correctly (with high probability) and in total spends time $O(n^{3-\epsilon})$ for some constant $\epsilon > 0$.

We will not use the $\text{OMv}$ problem directly as the starting point of our reduction. Instead we consider the following $\gamma$-$\text{OuMv}$ problem (for a fixed $\gamma > 0$) and parameters $n_1, n_2, \text{and } n_3$ such that $n_1 = \lfloor n_2^{\gamma} \rfloor$: We are first given a Boolean $n_1 \times n_2$ matrix $M$ to preprocess. After the preprocessing, we are given a sequence of pairs of $n_1$-dimensional Boolean vectors $(u^{(1)}, v^{(1)}), \ldots, (u^{(n_2)}, v^{(n_2)})$ one by one. For each $1 \leq t \leq n_2$, we have to return the result of the Boolean vector-matrix-vector multiplication $(u^{(t)})^\top Mv^{(t)}$ before we see the next pair of vectors $(u^{(t+1)}, v^{(t+1)})$. It has been shown \cite{26} that under the $\text{OMv}$ Conjecture, there is no algorithm for this problem with polynomial preprocessing time and total processing time $O(n_1^{3-\epsilon}n_2^{1-\gamma}n_3^{1-\epsilon})$ such that all $\epsilon_i$ are $\geq 0$ and at least one $\epsilon_i$ is a constant $> 0$.

We now give the reduction from the $\gamma$-$\text{OuMv}$ problem with $\gamma = \delta/(1-\delta)$ to the decremental dominator tree problem. In the following we denote by $v_i$ the $i$-th entry of a vector $i$ and by $M_{i,j}$ the entry at row $i$ and column $j$ of a matrix $M$.

Consider an instance of the $\gamma$-$\text{OuMv}$ problem with parameters $n_1 = m^{1-\delta}$, $n_2 = m^\delta$, and $n_3 = m^{1-\delta}$. We preprocess the matrix $M$ by constructing a graph $G^{(0)}$ with the set of vertices $V = \{s, x_1, \ldots, x_{n_3}, x_{n_3+1}, y_1, \ldots, y_{n_1}, z_1, \ldots, z_{n_2}\}$ and the following edges: (1) an edge $(s, x_1)$, and, for every $1 \leq t \leq n_3$, an edge $(x_t, x_{t+1})$, (2) for every $1 \leq j \leq n_2$, an edge $(t, z_j)$, (3) for every $1 \leq t \leq n_3$ and every $1 \leq i \leq n_1$, an edge $(x_i, y_i)$, and (4) for every $1 \leq i \leq n_1$ and every $1 \leq j \leq n_2$, an edge $(y_i, z_j)$ if and only if $M_{i,j} = 1$.

Whenever the algorithm is given the next pair of vectors $(u^{(t)}, v^{(t)})$, we first create a graph $G^{(t)}$ by performing the following edge deletions in $G^{(t-1)}$: If $t \geq 2$, we first delete all outgoing edges of $x_{t-1}$, except the one to $x_t$. Then, for any value of $t$, for every $i$ such that $u_i^{(t)} = 0$ we delete the edge from $x_t$ to $y_i$. Thus, for every $1 \leq i \leq n_1$, there will be an edge from $x_t$ to $y_i$ in $G^{(t)}$ if and only if $u_i^{(t)} = 1$. Having created $G^{(t)}$, we now, for every $j$ such that $v_j^{(t)} = 1$, check whether $x_t$ is the parent of $z_j$ in the dominator tree. If this is the case for at least one $j$ we return that $(u^{(t)})^\top Mv^{(t)}$ is $1$, otherwise we return $0$.

The correctness of our reduction follows from the following lemma.

\textbf{Lemma 11.} For every $1 \leq t \leq n$, the $j$-th entry of $(u^{(t)})^\top M$ is $1$ if and only if $x_t$ is the immediate dominator of $z_j$ in $G^{(t)}$.

Note that $(u^{(t)})^\top Mv^{(t)}$ is $1$ if and only if there is a $j$ such that both the $j$-th entry of $u^{(t)} M$ as well as the $j$-th entry of $v^{(t)}$ are $1$. Furthermore, $x_t$ is the parent of $z_j$ in the dominator tree if and only if $x_t$ is an immediate dominator of $z_j$ in the current graph. Therefore the lemma establishes the correctness of the reduction.

The initial graph $G^{(0)}$ has $n := \Theta(n_1 + n_2 + n_3) = \Theta(m^\delta + m^{1-\delta})$ vertices and $\Theta(n_1n_2 + n_2n_3) = \Theta(m)$ edges. The total number of parent-queries is $O(n_1n_3) = m^{2(1-\delta)}$. Suppose the total update time of the decremental dominator tree algorithm is $O(u(m,n)) =$
\((mn)^{1-\epsilon}\) and its query time is \(O(q(m)) = m^{\delta-\epsilon}\). Using the reduction above, we can thus solve the \(\gamma\text{-OuMv}\) problem for the parameters \(n_1, n_2, n_3\) with polynomial preprocessing time and total update time \(O(u(m, n) + m^{2(1-\delta)q(m)}) = O(u(m, m^{1-\delta}) + m^{2(1-\delta)q(m)}) = O(m^{2-\delta-\epsilon})\). Since \(n_1 n_2 n_3 = m^{2-\delta}\), this means we would get an algorithm for the \(\gamma\text{-OuMv}\) problem with polynomial preprocessing time and total update time \(O(u_1^{1-\epsilon_1}u_2^{1-\epsilon_2}n_3^{1-\epsilon_3})\) where at least one \(\epsilon_i\) is a constant \(> 0\). This contradicts the \(\text{OMv}\) Conjecture.
