Counting Solutions to Polynomial Systems via Reductions*

Richard Ryan Williams

Abstract

This paper provides both positive and negative results for counting solutions to systems of polynomial equations over a finite field. The general idea is to try to reduce the problem to counting solutions to a single polynomial, where the task is easier. In both cases, simple methods are utilized that we expect will have wider applicability (far beyond algebra).

First, we give an efficient deterministic reduction from approximate counting for a system of (arbitrary) polynomial equations to approximate counting for one equation, over any finite field. We apply this reduction to give a deterministic poly(n, s, log p)/ε²-time algorithm for approximately counting the fraction of solutions to a system of s quadratic n-variate polynomials over $\mathbb{F}_p$ (the finite field of prime order p) to within an additive $\varepsilon$ factor, for any prime $p$. Note that uniform random sampling would already require $\Omega(s/\varepsilon^2)$ time, so our algorithm behaves as a full derandomization of uniform sampling. The approximate-counting algorithm yields efficient approximate counting for other well-known problems, such as 2-SAT, NAE-3SAT, and 3-Coloring. As a corollary, there is a deterministic algorithm (with analogous running time) for producing solutions to such systems which have at least $\varepsilon p^n$ solutions.

Second, we consider the difficulty of exactly counting solutions to a single polynomial of constant degree, over a finite field. (Note that finding a solution in this case is easy.) It has been known for over 20 years that this counting problem is already NP-hard for degree-three polynomials over $\mathbb{F}_2$; however, all known reductions increased the number of variables by a considerable amount. We give a subexponential-time reduction from counting solutions to k-CNF formulas to counting solutions to a degree-$k O(k)$ polynomial (over any finite field of $O(1)$ order) which exactly preserves the number of variables. As a corollary, the Strong Exponential Time Hypothesis (even its weak counting variant #SETH) implies that counting solutions to constant-degree polynomials (even over $\mathbb{F}_2$) requires essentially $2^n$ time. Similar results hold for counting orthogonal pairs of vectors over $\mathbb{F}_p$.

1 Introduction

A canonical problem in pseudorandomness is:

Given a class $C$ of Boolean circuits, is there a deterministic and efficient method for approximately counting the fraction of satisfying assignments to any circuit from $C$?

By uniformly random sampling Θ(1/ε²) inputs to a given circuit, we can easily obtain an additive ε-approximation to the fraction of satisfying assignments, with high probability. Thus the above problem amounts to deterministically achieving what trivial random sampling can provide in a natural setting, with the target of reaching \( \text{poly}(n)/\epsilon^2 \) time (or perhaps even better in some cases where randomness can also achieve more, such as approximately counting knapsack solutions [20]).

The general problem of finding such algorithms has been studied for decades. Of most relevance to this paper are the prior results for \( AC^0 \) circuits [2, 30, 8], for CNF/DNF of bounded or unbounded width [28, 23, 32, 21], and for \( \mathbb{F}_q \) polynomials of constant degree [29, 6, 7, 33]. Approximate counting algorithms with only a \( 1/\epsilon^2 \) dependence in the running time are not known for any of these problems except in the case of degree-two polynomials, where one can exactly count solutions over a finite field in polynomial time (see the Preliminaries). We would like to “lift” this nice algorithm to more expressive representations.

In the first part of this paper, we study approximate counting for an NP-hard problem in algebra:

**Counting Solutions to Multivariate Quadratic Systems \((#MQS)\)**

**Given:** A system of degree-two polynomials over \( \mathbb{F}_p[x_1, \ldots, x_n] \), for some prime \( p \)

**Output:** The number of solutions to the system.

The decision version of \#MQS (“is there a solution?”) is well-known to be NP-hard, and is of interest in several theoretical and practical areas (see [27] for references). With regards to approximating \#MQS, the best deterministic algorithm in the literature is due to Viola [33], who gave a pseudorandom generator for fooling a degree-\( d \) polynomial with seed length at least \( d \log n + 2d^2 \log(1/\epsilon) \). Since the Fourier spectrum of the AND function has low \( \ell_1 \)-norm (see for example [9]), a pseudorandom generator for a single polynomial extends to a system of polynomials, yielding a deterministic approximation algorithm for the fraction of \#MQS solutions with running time \( \text{poly}(n) \cdot \epsilon^{-8} \).

### Approximately Solving \#MQS

The first main result of this paper is that the \( 1/\epsilon^2 \) dependence of the random sampling algorithm for \#MQS can be matched in a deterministic way.

▶ **Theorem 1.** For every prime \( p \), there is a deterministic algorithm running in \( \text{poly}(n, s, \log p)/\epsilon^2 \) time for approximately counting the fraction of solutions to a system of \( s \) quadratic equations in \( n \) variables over \( \mathbb{F}_p \).

As a corollary, one can also efficiently and deterministically find solutions to any system of quadratic equations, provided there are many solutions:

▶ **Corollary 2.** For every prime \( p \), there is a deterministic algorithm running in \( \text{poly}(n, s, \log p)/\epsilon^2 \) time which, given any system of \( s \) quadratic equations in \( n \) variables over \( \mathbb{F}_p \), with at least \( \epsilon p^s \) solutions, outputs a solution.

Recalling that more common counting problems such as \#2-SAT and \#NAE-3-SAT can easily be expressed as an instance of \#MQS with no increase in the number of variables, Theorem 1 implies improved approximation algorithms (in terms of \( \epsilon \)) for those problems as well: the best known approximate counting algorithm for general \( k \)-SAT is that of Trevisan [32] which has an \( 1/\epsilon k^{2^k \ln(4)} \) dependence in the running time. (Note that Viola’s
PRG is slightly faster in terms of $\varepsilon$.) For a non-binary example, the 3-coloring problem can be represented as a system of quadratic polynomials over $\mathbb{F}_3$ (for each edge $(i,j)$ in your graph, include a polynomial $P(x_i, x_j)$ which is 0 if and only if $x_i \neq x_j$). In general, constraint satisfaction problems over a prime-order domain and two variables per constraint are handled by Theorem 1.

The key to Theorem 1 is a reduction from approximate counting for a system of degree-$d$ polynomials to approximate counting for a single polynomial:

\begin{quote}
\textbf{Theorem 3.} For all primes $p$, integers $d > 0$, and $\varepsilon \in (0, 1)$, there exists a deterministic $\text{poly}(n, s, \log p)$-time reduction from approximately counting solutions to systems of degree-$d$ equations over $\mathbb{F}_p$ to within an $\varepsilon$ factor, to approximately counting solutions to one degree-$d$ equation over $\mathbb{F}_p$ to within a $\Theta(\varepsilon^3/s^2)$ factor.
\end{quote}

Theorem 3 is appealing for several reasons.\footnote{Note that over the real numbers, it is easy to reduce a system of polynomial equations $\{p_i(x_1, \ldots, x_n) = 0\}$ of degree $d$ to a single equation of degree $2d$, by simply taking the sum of squares of the $p_i$. This is not useful for us, since (1) it does not work over a finite field and (2) in order for the approximation algorithm to work, we need a reduction that does not increase the degree.}

First, it is somewhat surprising at first glance. For example, detecting feasibility of a system of quadratic polynomials (over any field) is NP-hard, but detecting the feasibility of only one such polynomial is trivial. Thus in some cases, our reduction efficiently reduces an NP-hard problem to an easy one — but only for the task of approximate counting.

Second, the proof is extremely simple in hindsight. The central idea consists of applying the known constructions of small-biased sets in just the right way to solve the problem. We also show how such sets yield new schemes for approximating the intersection of a set family.

Third, Theorem 3 is extremely generic, in comparison with its application (Theorem 1): it works for any polynomial system of any degree.

Theorem 1 follows from applying the reduction of Theorem 3 and an exact counting algorithm for $\#\text{MQS}$ instances with only one equation. We certainly do not obtain a pseudorandom generator in this way, but we do get a considerably different perspective on approximate counting in this domain. (We also do not use any algebraic geometry tools, which often appear in the literature on counting solutions to polynomial systems.)

\section{SETH-Hardness of Exactly Counting Roots of One O(1)-Degree Polynomial}

Complementing the above approximation algorithm, we use similar ideas to give a strong hardness reduction for exactly counting solutions (zeros) of degree-$d$ polynomials over a finite field of constant order, for constant $d > 2$. Finding a solution to such a polynomial is not hard: by a variant of the Schwartz-Zippel-DeMillo-Lipton lemma (see for example [36]), a not-identically-zero polynomial $p$ of degree-$d$ is nonzero on at least a $1/2^{\frac{d}{2}}$-fraction of points in $\{0, 1\}^n$, so it is easy to find a nonzero of $p$ with randomness over any small field. (It is also easy to find a zero of $p$ in $\{0, 1\}^n$ as well, by considering the polynomial $1 - p^q - 1$ where $q$ is the order of the field.)

Ehrenfeucht and Karpinski [17] showed that the solution-counting problem is already NP-hard for a single degree-3 polynomial over $\mathbb{F}_2$. However, all reductions from $k$-SAT to the counting problem (to our knowledge) increased the number of variables by a polynomial
factor; in the worst case, $\Omega(n)$ new variables are introduced. Here we give a much improved reduction in terms of the number of variables, sacrificing a bit in the degree:

- **Theorem 4.** Let $q$ be a prime power and $\varepsilon > 0$ be arbitrarily small. There is an $O(q^n)$-time deterministic reduction from $\#k$-SAT instances with $n$ variables to the problem of counting roots to a $\mathbb{F}_q$-polynomial of degree $q(k/\varepsilon)^{O(k)}$ with $n$ variables.

In fact, the proof of Theorem 4 provides a subexponential-time reduction from the problem of exactly counting solutions to systems of $O(n)$ degree-$k$ equations to that of exactly counting the zeros of one polynomial of degree $q(k/\varepsilon)^{O(k)}$, similarly to how Theorem 3 gives a polynomial-time reduction from approximate counting a degree-$k$ system to approximate counting for a single degree-$k$ polynomial. The high-level structure of the two reductions are similar as well: both reductions output a linear combination of the outputs of their oracle calls. However, the actual oracle calls themselves are quite different. Theorem 3 uses small-biased sets to construct a polynomial number of oracle calls, and obtain an approximate solution count; Theorem 4 uses a multiplication trick so that the number of oracle calls is only subexponential, while preserving the exact count. (The multiplication trick is the reason why the degree of the underlying polynomials increases to $q(k/\varepsilon)^{O(k)}$.)

From Theorem 4, it follows that the Strong Exponential Time Hypothesis (even its counting variant $\#\text{SETH}$) predicts that for all $\varepsilon > 0$, there is a constant $d_\varepsilon > 2$ such that counting Boolean solutions to degree-$d_\varepsilon$ polynomials (even over $\mathbb{F}_2$) cannot be done in $(2 - \varepsilon)^n$ time.

Under $\#\text{ETH}$ (the hypothesis that counting 3-SAT solutions requires $2^{\Omega(n)}$ time), it is known (for example) that counting the number of independent sets of size $n/3$ in an $n$-node graph requires $2^{\Omega(n)}$ time [24], $\#2$-SAT requires $2^{\Omega(n)}$ time [15], the permanent of $n \times n$ Boolean matrices requires $2^{\Omega(n)}$ [15], and counting the number of perfect matchings in graphs with $m$ edges requires $2^{\Omega(m)}$ time [14]. The reductions proving these conditional lower bounds generally introduce a minor (linear) increase in the relevant parameter $n$. Theorem 4 gives a tight lower bound for counting solutions to polynomials, under $\text{SETH}$.

**Hardness for Counting Orthogonal Vectors over $\mathbb{F}_p$**

Let $p$ be any (small) prime. To demonstrate the range of the simple ideas in our reductions, we also use them to show that exactly counting pairs of $O(\log n)$-dimensional vectors with inner product zero modulo $p$ (among a given set of $n$ vectors) requires $n^{2-o(1)}$ time under $\text{SETH}$. This follows from the theorem:

- **Theorem 5.** Let $p$ be prime, and let $\ell \in [1,d]$ be an integer dividing $d$. There is an $\tilde{O}(n \cdot \ell^{d/\ell} \cdot p^\ell)$-time reduction from $\#\text{OV}$ with $n$ vectors in $d$ dimensions to $p^\ell$ instances of $\#\text{OV}_p$, each with $n$ vectors in $\ell^{2d/\ell} + 1$ dimensions.

- **Corollary 6.** Let $\varepsilon > 0$ be sufficiently small. There is an $\tilde{O}(n^{1+\varepsilon} \cdot p^{O(\varepsilon)})$-time reduction from $\#\text{OV}$ with $n$ vectors in $c \log n$ dimensions to $n^c$ instances of $\#\text{OV}_p$, each with $n$ vectors in $O(p^{c/\varepsilon} \log(n))$ dimensions.

---

2 The Strong Exponential Time Hypothesis [12] (SETH) states that for every $\varepsilon > 0$, there is a $k > 2$ such that $k$-SAT cannot be solved in $(2 - \varepsilon)^n$ time; it is a vast strengthening of $P \neq \text{NP}$ and a mild strengthening of ETH [25] which states that there is an $\varepsilon > 0$ such that 3-SAT cannot be solved in $(1 + \varepsilon)^n$ time. The “counting variant” $\#\text{SETH}$ states the same strong lower bound for the problem of counting the number of solutions to a $k$-SAT instance.
This reduction is in stark contrast with the fact that detecting a pair of vectors with inner product zero modulo $p$ can be accomplished in nearly-linear time when the vectors have $n^{o(1)}$ dimension [35]. One can either view this result as evidence that the counting problem is hard, or as (yet) another angle towards refuting SETH.

2 Preliminaries

Exact counting for degree-two equations

Our approximate counting algorithm will use the fact that the exact counting problem for a single degree-two equation over a finite field $\mathbb{F}_q$ is polynomial-time solvable:

▶ Theorem 7 (Woods [37], p.6). For every prime power $q$, there is a deterministic $n^3 \cdot \text{poly}(\log q)$-time algorithm for counting the number of solutions to a given degree-two polynomial over $\mathbb{F}_q$.

Ehrenfeucht and Karpinski [17] covered the case of $\mathbb{F}_2$, and showed that exact counting for a degree-three polynomial is already $\text{NP}$-hard. Cai, Chen, Lipton, and Lu [10] gave an algorithm for the counting problem that works over $\mathbb{Z}_m$, for any fixed integer $m > 1$. Woods remarks that his algorithm essentially follows from placing the matrices defining the degree-two polynomial in Jordan canonical form, in which case the number of solutions can be more-or-less read off from the form obtained.

Small-bias sets

For our approximation algorithm, we need explicit constructions of small sets of vectors which closely approximate the uniform distribution of vectors, with respect to inner products over a finite field.

▶ Definition 8. A set $S \subseteq \mathbb{F}_q^n$ is $\varepsilon$-biased if for all $u \in \mathbb{F}_q^n$ and $r \in \mathbb{F}_q$,

$$\left| \Pr_{v \in S} [\langle u, v \rangle = r] - \Pr_{v \in \mathbb{F}_q^n} [\langle u, v \rangle = r] \right| \leq \varepsilon.$$

(Note that sometimes a more general definition is given, involving the characters of $\mathbb{F}_p^n$, but the above simple condition is implied by it. See [18].) The following simple consequences of being $\varepsilon$-biased will be important:

- $\Pr_{v \in S} [\langle \vec{0}, v \rangle = 0] = 1$, where $\vec{0}$ is the all-zeroes vector.
- For all $u \neq \vec{0}$ and $r \in \mathbb{F}_q$, $\Pr_{v \in S} [(u, v) = r] \in (1/q - \varepsilon, 1/q + \varepsilon)$.

We also use deterministic explicit constructions of $\varepsilon$-biased sets over $\mathbb{F}_p$, for every prime $p$.

▶ Theorem 9 ([4, 18, 5]). For every prime $p$, and every $\varepsilon \in (0, 1/p^n)$, there is a $\text{poly}(n, \log p)/\varepsilon^2$-time constructible set of vectors $S \subseteq \mathbb{F}_p^n$ of cardinality $O(n^2/\varepsilon^2)$ that is $\varepsilon$-biased.

It will be important that the $\varepsilon$-dependencies in the above theorem are only $1/\varepsilon^2$, but this can be achieved. For example, the constructions based on linear feedback shift registers of [4] (which are easily generalized to $\mathbb{F}_p$, see [18]) take all vectors $x, y \in \mathbb{F}_p^n$, where $d = \log_p(n/\varepsilon)$ and $y$ corresponds to the coefficient vector of a monic irreducible $\mathbb{F}_p$-polynomial of degree $d$. The $n$-length vector $\nu_{x,y}$ of the $\varepsilon$-biased set $S$ is generated by repeatedly computing inner products of $y$ with vectors made up of previously computed inner products, up to $n$ times.
To construct this set \( S \), the main difficulty is constructing the \( y \)'s, which we can do by enumerating all monic \( \mathbb{F}_p \)-polynomials of degree \( d \), and throwing out those with non-trivial divisors. Rabin’s test for irreducibility ([31]) would take \( O(d^2 \cdot \text{poly}(\log n, \log p)) \) time. There are \( O(n/e) \) such polynomials to enumerate, and since \( e \geq 1/p^a \) we have \( d \leq O(n) \), so this step takes \( O(n^3/e) \cdot \text{poly}(\log n, \log p) \) time. The remaining list of monic irreducible polynomials (paired up with all possible vectors \( x \in \mathbb{F}_p^d \)) forms our \( \varepsilon \)-biased \( S \), and each component of each \( n \)-length vector \( v_{x,y} \) in \( S \) is just an inner product of two known \( d \)-length vectors. The running time of this construction is therefore \( O(n^4/e^2) \) (omitting \( \text{poly}(\log p) \) factors).

3 Approximating \#MQS: Reduction and Algorithm

We begin with the proof of Theorem 3, which reduces the counting problem for a system of equations to the counting problem for a single equation.

Let \( S = \{v_1, \ldots, v_m\} \subseteq \mathbb{F}_p^d \) be an \( \varepsilon \)-biased set of vectors. Let \( \{p_1(y) = 0, \ldots, p_s(y) = 0\} \) be a system of degree-\( d \) equations over \( \mathbb{F}_p \) in \( n \) variables, and let \( A \subseteq \mathbb{F}_p^n \) be the set of solutions to the system. For each \( i = 1, \ldots, m \), define the polynomial

\[
P_i(y) = \sum_j v_i[j] \cdot p_j(y).
\]

We observe two distinct properties of solutions and non-solutions to the original system:

(a) Every \( y \in A \) is a solution of the equation \( P_i(y) = 0 \) and not of the equation \( P_i(y) = 1 \), for all \( i = 1, \ldots, m \). This follows because for all \( y \in A \), \( p_1(y) = \cdots = p_s(y) = 0 \).

(b) For every \( y \not\in A \), there are integers \( N_0, N_1 \in [m(1/p - \varepsilon), m(1/p + \varepsilon)] \) such that \( y \) is a solution to \( N_0 \) of the \( m \) equations \( P_i(y) = 0 \) and is a solution to \( N_1 \) of the \( m \) equations \( P_i(y) = 1 \). To see this, note that for \( y \not\in A \), the vector \( u = [p_1(y), \ldots, p_s(y)] \) is not all-zeroes. Thus for any \( r \in \mathbb{F}_p \) we have \( \Pr_{y \in [m]}[\langle u, v_i \rangle = r] \in (1/p - \varepsilon, 1/p + \varepsilon) \), because \( S \) is \( \varepsilon \)-biased.

Given the ability to count solutions to one degree-\( d \) equation, here is an algorithm for approximately counting solutions to a system of equations:

1. Construct the \( \varepsilon \)-biased set \( S = \{v_1, \ldots, v_m\} \subseteq \mathbb{F}_p^d \).
2. Count the number of solutions to the equation \( P_i(y) = 0 \), for all \( i = 1, \ldots, m \).
   
   Let \( Z \) be the sum of all these numbers.
3. Count the number of solutions to the equation \( P_i(y) = 1 \), for all \( i = 1, \ldots, m \).
   
   Let \( O \) be the sum of all these numbers.
4. Output \((Z - O)/m \).

Now we analyze the algorithm. Let \( Z_i \) (respectively, \( O_i \)) be the number of solutions to the equation \( P_i(y) = 0 \) (respectively, \( P_i(y) = 1 \)), for all \( i, \ldots, m \). Our algorithm outputs the quantity:

\[
\frac{1}{m} \left( \sum_i Z_i - \sum_i O_i \right).
\]

By property (a), every \( y \in A \) contributes 1 to the sum \( \frac{1}{m} \sum_i Z_i \), and contributes 0 to the sum \( \sum_i O_i \). By property (b), every \( y \not\in A \) contributes a value \( z_y \in [1/p - \varepsilon, 1/p + \varepsilon] \) to the
sum $\frac{1}{m} \sum_i Z_i$, and contributes a value $o_y \in [1/p - \varepsilon, 1/p + \varepsilon]$ to the sum $\frac{1}{m} \sum_i O_i$. We can therefore re-express (1) as:

$$\frac{1}{m} \left( \sum_i Z_i - \sum_i O_i \right) = |A| + \sum_{y \not\in A} (z_y - o_y).$$

Given the bounds on $z_y$’s and $o_y$’s, we can easily upper-bound and lower-bound (1):

$$|A| + \sum_{y \not\in A} (z_y - o_y) \leq |A| + \sum_{y \not\in A} ((1/p + \varepsilon) - (1/p - \varepsilon)) = |A| + |A| \cdot 2\varepsilon$$

and

$$|A| + \sum_{y \not\in A} (z_y - o_y) \geq |A| + \sum_{y \not\in A} ((1/p - \varepsilon) - (1/p + \varepsilon)) = |A| - |A| \cdot 2\varepsilon.$$

It follows that the algorithm outputs a number that approximates the fraction of solutions to within $\pm 2\varepsilon$.

Moreover, observe that to obtain an approximate answer, we do not need an exact algorithm for counting solutions to one equation: if our algorithm for one equation always outputs approximations that are within $\varepsilon/(2m)$ of the exact count, then each of the $2m$ $Z_i$ and $O_i$ terms will be computed to within an $\varepsilon/(2m)$ factor, and the output will still be within $\pm 3\varepsilon$ of the exact fraction. This completes the proof of Theorem 3.

To obtain the final algorithm (Theorem 1) for approximately computing $\#\text{MQS}$, we simply apply Theorem 7 to count the number of satisfying assignments to a single quadratic equation over $\mathbb{F}_p$ in $n^3 \cdot \text{poly}(\log p)$ time. Using this algorithm in the above reduction, we get an approximate counting algorithm running in time $O(s^2/\varepsilon^2 \cdot (n^3 + s) + t(s, 1/\varepsilon, p))$, where $t(s, 1/\varepsilon, p)$ is the time needed to construct an $\varepsilon$-biased set over $\mathbb{F}_p^n$. This completes the proof of Theorem 1.

### 3.1 A succinct approximate inclusion-exclusion

The reduction of Theorem 3 works by approximately representing the cardinality of the intersection of $s$ equations by a linear combination of cardinalities on single $\mathbb{F}_p$-equations. Along the lines of the work of Linial and Nisan [26] on approximate inclusion-exclusion via low-degree polynomials over the reals, the ideas of Theorem 3 imply a variant of the inclusion-exclusion principle. However, unlike Linial and Nisan, our approximation of the cardinality of the intersection has only polynomially many terms.

To simplify the discussion, here we consider just the case of $\mathbb{F}_2$, and consider unions instead of intersections. Over $\mathbb{F}_2$, we will demonstrate how a small-bias set lets us “approximately” express the cardinality of a union of a set collection as a short linear combination of cardinalities of what one might call “oddtersections” of sub-collections of sets.

Let $(x \mod 2) : \mathbb{Z} \rightarrow \{0, 1\}$ map integers to bits in the natural way. In Theorem 3, we are effectively using a representation of the AND function as a short linear combination of PARITY functions (see, for instance, Alon and Bruck [3]). Below is a representation of the OR function (which is analogous):

**Lemma 10.** For all $n \in \mathbb{N}$ and $\varepsilon \in (0, 1)$, there is a $(\text{poly}(n)/\varepsilon^2)$-time constructible collection of subsets $S_1, \ldots, S_m \subseteq [n]$, with $m \leq O(n^3/\varepsilon^2)$, such that for every $x \in \{0, 1\}^n$,

$$\left| \left( \bigvee_{i=1}^n x_i \right) - \sum_{i=1}^m \frac{2}{m} \left( \sum_{j \in S_i \mod 2} x_j \right) \right| \leq \varepsilon. \quad (2)$$
Proof. Let \( S = \{ S_1, \ldots, S_m \} \subseteq [n] \) be a set family whose corresponding indicator vectors in \( \{0, 1\}^n \) form an \((\varepsilon/2)\)-biased set. By Theorem 9, we can take \( m \leq O(n^2/\varepsilon^2) \). Observe:

- If \((x_1, \ldots, x_n) = 0\) then for all \( i = 1, \ldots, m \), \( (\sum_{j \in S_i} x_j \mod 2) = 0 \), so \( \sum_{i=1}^m \frac{2}{m} \).

- If \((x_1, \ldots, x_n) \neq 0\) then by properties of \((\varepsilon/2)\)-biased sets, the number of \( i \in [m] \) such that \( \sum_{j \in S_i} x_j \neq |S_i| \mod 2 \) is in the interval \([m/2 - \varepsilon m/2, m/2 + \varepsilon m/2]\). So in this case,

\[
\sum_{i=1}^m \frac{2}{m} \left( \sum_{j \in S_i} x_j \mod 2 \right) \in \left[ \frac{2}{m} \cdot \left( \frac{m - \varepsilon m}{2} \right), \frac{2}{m} \cdot \left( \frac{m + \varepsilon m}{2} \right) \right] = [1 - \varepsilon, 1 + \varepsilon].
\]

This completes the proof. \(\square\)

Let \( A_1, \ldots, A_k \) be any sets over a finite universe \( U \), and define their \textit{odd intersection} to be

\[ \bigoplus_i A_i = \{ x \in U \mid x \text{ appears in an odd number of the } A_i's \}. \]

The upshot of Lemma 10 is that we can write:

\[
\left| \bigcup_i A_i \right| \approx \varepsilon \sum_{i=1}^m \frac{1}{m} \left| \bigoplus_{j \in S_i} A_j \right|,
\]

where the \( \approx \) means that the two quantities are within \( \varepsilon |U| \) of each other. (Note that \( \bigcup_i A_i \) is the sum over all \( y \in U \) of \( \bigvee_{i=1}^k \mathbf{1}_{y \in A_i} \), where \( \mathbf{1}_{y \in A_i} = 1 \) if \( y \in A_i \), and 0 otherwise. Invoking (2) on each term in this sum, we obtain the right-hand side of (3) to within an additive \( \pm \varepsilon |U| \) factor.) Thus we can approximately represent the cardinality of a union of sets in a sparse way, as “oddities” of various sub-collections. It seems likely that this observation has more applications. For example, equation (3) immediately implies that we can reduce approximate counting for \( k \)-DNF formulas (with additive error) to approximate counting for degree-\( k \) polynomials over \( \mathbb{F}_2 \) (with additive error), by letting \( A_i \) be the set of satisfying assignments to the \( i \)-th clause of a DNF.

### 3.2 Producing a solution when there are many

Given Theorem 1, one can obtain a deterministic algorithm for producing a solution to a quadratic system given that it has many solutions, using a self-reducibility argument.\(^3\)

\[ \text{Reminder of Corollary 2.} \quad \text{For every prime } p, \text{ constant } k \text{, and fraction } \varepsilon \in [1/p^n, 1], \text{ there is a deterministic algorithm running in } poly(n, s, \log p)/\varepsilon^2 \text{ time which, given any system of } s \text{ quadratic equations in } n \text{ variables over } \mathbb{F}_p \text{ with at least } \varepsilon p^n \text{ solutions, outputs a solution.} \]

\[ \text{Proof.} \quad \text{Suppose we are given a system over the variables } x_1, \ldots, x_n \text{ with } S \geq \varepsilon \cdot p^n \text{ solutions, where } \varepsilon \geq 1/p^n. \]

\(^3\) This reduction is apparently folklore. See also Goldreich [19, Theorem 3.5] for a generic reduction from “search-to-decision” in this setting.
For each $a \in \mathbb{F}_p$, assign $x_1 := a$ in all equations of the system, and run the polynomial-time approximate counting algorithm of Theorem 1 with error parameter $\alpha := \varepsilon/(2n)$. Let $x_1 := a_1$ be the assignment that yields the largest count from the algorithm. (If the count returned is zero for all $a \in \mathbb{F}_p$, return fail.) Analogously, set the variables $x_2 := a_2, \ldots, x_{n-k} := a_{n-k}$ one at a time, for $k = 2 \log_p(1/\varepsilon)$, always taking the assignment that yields the largest count. Finally, try all $p^k = p^{2\log_p(1/\varepsilon)} \leq 1/\varepsilon^2$ assignments on the remaining $k$ variables, and return any solution found.

Given Theorem 1, it is clear that the algorithm runs in the desired time. Now we turn to correctness. The algorithm began with a guarantee of $S$ solutions. At least one setting of the variable $x_1$ yields a system on $n-1$ variables with at least $S/p$ solutions. So after setting $x_1$ to maximize the number of solutions returned by the algorithm, the number of solutions in the remaining $(n-1)$-variable system is at least $S_1 = S/p - \alpha \cdot p^{n-1}$. Similarly, after setting $x_1$ and $x_2$ appropriately, the number of solutions in the remaining system on $n-2$ variables is at least

$$S_2 = S_1/p - \alpha \cdot p^{n-2} = S/p^2 - \alpha \cdot p^n - \alpha \cdot p^{n-2} = S/p^2 - 2\alpha \cdot p^{n-2}.$$  

After setting $x_1, \ldots, x_i$ for $i = 1, \ldots, n$, we are inductively guaranteed that the number of remaining solutions in the system is at least

$$S_i = S_{i-1}/p - \alpha \cdot p^{n-i} = S/p^i - \alpha \cdot i \cdot p^{n-i}.$$  

For $i = n - 2 \log_p(1/\varepsilon)$, the number of solutions remaining is at least

$$\varepsilon p^n/p^i - \alpha \cdot i \cdot p^{n-i} \geq \varepsilon \cdot p^{2\log_p(1/\varepsilon)} - \alpha \cdot np^{2\log_p(1/\varepsilon)} \geq (\varepsilon - \alpha n) \cdot 1/\varepsilon^2.$$  

For $\alpha = \varepsilon/(2n)$, the number of solutions remaining after setting $x_1, \ldots, x_i$ is at least $1/\varepsilon^2 \cdot (\varepsilon/2) \geq 1/(2\varepsilon)$, i.e., the number is non-zero. Therefore the algorithm returns a solution, if there are at least $\varepsilon p^n$ solutions.

4 From Counting $k$-SAT to Counting Roots to Polynomials of $O(1)$-Degree

Reminder of Theorem 4. Let $q$ be a prime power and $\varepsilon > 0$ be arbitrarily small. There is an $O(q^n)$-time deterministic reduction from $\#k$-SAT instances with $n$ variables to the problem of counting roots to a $\mathbb{F}_q$-polynomial of degree $q(k/\varepsilon)^{O(k)}$ with $n$ variables.

Imagining $q$ and $k$ as fixed constants, and $\varepsilon$ as a tiny parameter, we obtain a $2^{O(cn)}$ time reduction from $\#k$-SAT on $n$ variables to counting roots of an $\mathbb{F}_q$-polynomial on $n$ variables of degree $\text{poly}(1/\varepsilon)$.

Proof. Let $\varepsilon > 0$ be arbitrarily small. We are given a $k$-CNF formula $F$ in $n$ variables $x_1, \ldots, x_n$, and we want to reduce it to a single low-degree polynomial. We will in fact reduce the counting problem for $F$ to a (sub-exponential) number of calls to counting roots of a single low-degree polynomial.

First, by the Sparsification Lemma [25, 11] (the counting version of which appears in [15]), we may assume without loss of generality that the $k$-CNF formula $F$ has at most $m \leq (k/\varepsilon)^{O(k)} n$ clauses, with $2^{O(n)}$-time overhead.

Second, we can express $F$ as a system of $m$ polynomial equations in the obvious way, where each equation contains at most $k$ variables (and therefore each equation has degree at
most $k$). For all $i = 1, \ldots, n$, add the degree-two equations $x_i \cdot (1 - x_i) = 0$ to the system (these equations simply force all solutions to be Boolean). Call the overall system of $m + n$ equations $G$, and note the number of solutions to $G$ equals the number of SAT assignments to $F$.

Arbitrarily partition $G$ into $\varepsilon n$ subsystems of equations $G_1, \ldots, G_{\varepsilon n}$, where each subsystem has at most $(k/\varepsilon)^{O(k)}$ equations. Our next move is to write each $G_j$ as a single polynomial over the finite field $F_q$. More precisely, given that $G_j$ contains the $t = (k/\varepsilon)^{O(k)}$ equations

$$p_1(x_1, \ldots, x_n) = 0, \ldots, p_t(x_1, \ldots, x_n) = 0,$$

define the $(q-1)(k/\varepsilon)^{O(k)}$-degree polynomial

$$P_j(x_1, \ldots, x_n) := 1 - \prod_{i=1}^{t}(1 - p_i(x_1, \ldots, x_n)^{q-1}).$$

Note that for all $(a_1, \ldots, a_n) \in F_q^n$, $P_j(a_1, \ldots, a_n) = 0$ if and only if $p_i(a_1, \ldots, a_n) = 0$ for each $i$ with $1 \leq i \leq t$. Furthermore, since each $p_i$ has at most $k$ variables, there are at most $kt$ variables in $P_j$. So by repeatedly applying the identity $x^q = x$, over $F_q$, it takes no more than $q^{O(kt)} \leq q^{(k/\varepsilon)^{O(k)}}$ time to express the polynomial $P_j$ as a sum of monomials, for all $j = 1, \ldots, \varepsilon n$.

Finally, we wish to exactly count the number of solutions to the system

$$P_1(x_1, \ldots, x_n) = 0, \ldots, P_{\varepsilon n}(x_1, \ldots, x_n) = 0 \quad (4)$$

where each $P_j$ has $(k/\varepsilon)^{O(k)}$ variables and degree at most $q(k/\varepsilon)^{O(k)}$. Here, we reason similarly to the earlier approximate counting algorithm (namely, the reduction of Theorem 3), except instead of using small-biased sets of size polynomial in $n$, we simply use all $q^n$ possible linear combinations of the $P_j$’s to exactly count.

For every $\beta \in F_q^n$, suppose we count the number of zeroes to the polynomial

$$Q_\beta(x_1, \ldots, x_n) := \sum_{j=1}^{\varepsilon n} \beta_j \cdot P_j(x_1, \ldots, x_n)$$

and suppose we count the number of solutions to the polynomial $R_\beta := 1 - Q_\beta$. Note for all $\beta$, the degree of $Q_\beta$ is at most $q(k/\varepsilon)^{O(k)}$. We want to show that a linear combination of these $O(q^n)$ zero-counts will tell us the number of solutions to the original $k$-CNF $F$.

Suppose $(a_1, \ldots, a_n) \in F_q^n$ is a solution to the system $G$. Then it is also a solution to the system $(4)$. Hence $P_j(a_1, \ldots, a_n) = 0$ for all $j$, and therefore $Q_\beta(a_1, \ldots, a_n) = 0$ for all $\beta \in F_q^n$. That is, $(a_1, \ldots, a_n)$ is a zero for all $q^n$ polynomials $Q_\beta$, and is never a zero for any $R_\beta$.

On the other hand, if $(a_1, \ldots, a_n) \in F_q^n$ is not a solution to $G$, then $P_j(a_1, \ldots, a_n) \neq 0$ for some $j$. So we can think of each $Q_\beta(a_1, \ldots, a_n)$ as the inner product of the vector $\beta$ with a fixed non-zero vector. Therefore in this case, $Q_\beta(a_1, \ldots, a_n) = 0$ for exactly $q^n/q$ polynomials $Q_\beta$, and $R_\beta(a_1, \ldots, a_n) = 0$ for exactly $q^n/q$ polynomials $R_\beta$.

Combining these observations, we conclude that

$$\frac{(\text{total number of zeros to all } Q_\beta) - (\text{total number of zeros to all } R_\beta)}{q^n}$$

equals the number of solutions to $G$. So we can solve $\#k$-$\text{SAT}$ by making $O(q^n)$ calls to counting solutions to a single degree-$q(k/\varepsilon)^{O(k)}$ polynomial over $F_q$. (Note that by tweaking $\varepsilon$ slightly, we can write the number of calls as $O(2^n)$.)
We observe that the proof of Theorem 4 also provides a subexponential-time reduction from

exact counting for a system of $O(n)$ degree-$O(1)$ equations
to

exact counting for one degree-$O(1)$ equation.

(Referring back to the proof, even if each $p_i$ depended on all $n$ variables but had degree only $k$, each polynomial $P_i$ would have $n$ variables and degree at most $q(k/\varepsilon)^{O(k)}$, so it would take at most $n^{q(k/\varepsilon)^{O(k)}}$ time to expand each $P_i$ into a sum of monomials.) To compare, Theorem 3 gave a polynomial-time reduction for the respective approximation versions (but from a degree-$k$ system to a single degree-$k$ polynomial).

4.1 A consequence for fine-grained counting complexity

The reduction method in the proof of Theorem 4 extends nicely to results on the fine-grained counting complexity of simple polynomial-time problems. Here we demonstrate this claim on the problem of counting the number of orthogonal pairs among a set of Boolean vectors:

**#Orthogonal Vectors (#OV)**

Given: vectors $v_1, \ldots, v_n, w_1, \ldots, w_n \in \{0, 1\}^d$

Output: The number of pairs $(i, j)$ such that $\langle v_i, w_j \rangle = 0$.

Note that #OV is trivially solvable in $O(n^2d)$ time, although faster algorithms are known for certain ranges of $d$ [22, 13]. The detection problem OV (determining if there is at least one orthogonal pair) is widely studied. Finding a significantly faster algorithm for OV will already be challenging, as it is known that (for example) a $n^{1.9} \cdot 2^{o(d)}$ time algorithm for OV would contradict SETH [34]. A minor variant of OV studies the problem modulo a fixed prime $p$:

**Orthogonal Vectors Mod p (OVp)**

Given: vectors $v_1, \ldots, v_n, w_1, \ldots, w_n \in \mathbb{F}_p^d$

Decide: Are there $i, j$ such that $\langle v_i, w_j \rangle = 0 \mod p$?

Williams and Yu [35] showed that OVp is apparently much easier than OV for constant $p$: it is solvable in $O(n \cdot d^{p-1})$ time.

One can similarly define #OVp, in which the task is to count the number of $i, j$ such that $\langle v_i, w_j \rangle = 0 \mod p$. Recently, Dell and Lapinskas [16] show how to use the algorithm for OVp to approximately compute #OVp efficiently. In particular, they show that for any $\varepsilon > 0$, given an #OVp instance with number of solutions $N$, one can output a value $v$ such that $|v - N| \leq \varepsilon N$ in $\tilde{O}(\varepsilon^{-4n} \cdot d^{p-1})$ time.

Interestingly, a minor modification of Theorem 4 shows that exactly computing #OVp is as hard as #OV itself:

**Reminder of Theorem 5.** Let $p$ be prime, and let $\ell \in [1, d]$ be an integer that divides $d$. There is an $\tilde{O}(n \cdot \ell^{2^{d/\ell}} \cdot p^{\ell})$-time reduction from #OV with $n$ vectors in $d$ dimensions to $p^\ell$ instances of #OVp, each with $n$ vectors in $\ell^{2^{d/\ell} + 1}$ dimensions.
Proof. The idea of the reduction is analogous to Theorem 4, except we need to be slightly more abstract in our construction. We start with vectors \( v_1, \ldots, v_n, w_1, \ldots, w_n \in \{0,1\}^d \), and we want to compute \#OV on them. Partition the components of all vectors into \( \ell \) parts, where each part has \( d/\ell \) components. For each vector \( v_i \), let \( v_{i,1}, \ldots, v_{i,\ell} \in \{0,1\}^{d/\ell} \) be its decomposition into parts; define vectors \( w_{i,j} \) similarly.

For each \( j = 1, \ldots, \ell \), make a \( 2^{d/\ell} \)-bit vector \( a_{i,j} \) which has a 1 in the component corresponding to the \( d/\ell \)-bit vector \( v_{i,j} \), and 0s in all other components. Also for each \( j = 1, \ldots, \ell \), make a \( 2^{d/\ell} \)-bit vector \( b_{i,j} \) which has a 1 for each \( d/\ell \)-bit vector \( x \) such that \( \langle x, w_{i,j} \rangle \neq 0 \), and 0s everywhere else. (This is similar to “embedding 3” of Ahle, Pagh, Razenshteyn and Silvestri [1, Lemma 3.]) Taking the vectors

\[
a_i := (a_{i,1}, \ldots, a_{i,\ell}) \in \{0,1\}^{2^{d/\ell}}, \quad b_i := (b_{i,1}, \ldots, b_{i,\ell}) \in \{0,1\}^{2^{d/\ell}},
\]

over all \( i = 1, \ldots, n \), we have \( \langle v_i, w_j \rangle = 0 \) if and only if \( \langle a_i, b_j \rangle = 0 \). Furthermore, notice that for all \( j = 1, \ldots, \ell \), \( \langle a_{i,j}, b_{i,j} \rangle \in \{0,1\} \), so for all primes \( p \) and for all \( j \), we have \( \langle a_{i,j}, b_{i,j} \rangle \equiv 0 \pmod{p} \) if and only if \( \langle a_{i,j}, b_{i,j} \rangle \equiv 0 \pmod{p} \).

We now build \( 2p^\ell \) instances of \#OV as follows. For every \( \beta \in \mathbb{F}_p^\ell \), construct the \( 2n \) vectors

\[
a_i^\beta = (\beta_1 a_{i,1}, \ldots, \beta_\ell a_{i,\ell}), \quad b_i := (b_{i,1}, \ldots, b_{i,\ell}),
\]

and let \( N_\beta \) be the number of pairs \( \langle a_i^\beta, b_i \rangle \) which are orthogonal modulo \( p \), for all \( i, i' = 1, \ldots, n \). Also construct

\[
c_i^\beta = (1, \beta_1 a_{i,1}, \ldots, \beta_\ell a_{i,\ell}), \quad d_i := (1, b_{i,1}, \ldots, b_{i,\ell}),
\]

and let \( M_\beta \) be the number of pairs \( \langle c_i^\beta, d_i \rangle \) which are orthogonal modulo \( p \). Our algorithm for \#OV outputs the quantity

\[
\sum_{\beta \in \mathbb{F}_p^\ell} (N_\beta - M_\beta)/p^\ell.
\]

It is easy to see that this reduction has the desired running time and number of oracle calls. We need to show that the reduction outputs the correct number of orthogonal pairs. For an orthogonal pair \( v_i, w_j \) in the original instance, we know that \( \langle a_i, b_j \rangle = 0 \), and therefore \( \langle a_{i,j}, b_{i,j} \rangle = 0 \) for all \( j \). So for every vector \( \beta \), \( \langle a_i^\beta, b_i \rangle = 0 \pmod{p} \) as well. That is, every orthogonal pair \( v_i, w_j \) is counted \( p^\ell \) times in the sum \( \sum_\beta (N_\beta - M_\beta) \).

For an non-orthogonal pair \( v_i, w_j \), we know that \( \langle a_{i,j}, b_{i,j} \rangle \neq 0 \) for some \( j \). In particular, recalling that all \( \langle a_{i,j}, b_{i,j} \rangle \) are either 0 or 1, we have that the \( \ell \)-dimensional vector

\[
ab_{i,j} = (\langle a_{i,1}, b_{i,1} \rangle, \ldots, \langle a_{i,\ell}, b_{i,\ell} \rangle)
\]

is not the all-zero vector over \( \mathbb{F}_p \). Observing that

\[
\langle a_i^\beta, b_j \rangle = (\beta, ab_{i,j}) \pmod{p}
\]

and

\[
\langle c_i^\beta, d_j \rangle = 1 + (\beta, ab_{i,j}) \pmod{p},
\]

it follows that there are exactly \( p^\ell - 1 \) choices of \( \beta \) for which \( \langle a_i^\beta, b_j \rangle \equiv 0 \pmod{p} \), and \( p^{\ell-1} \) choices of \( \beta \) for which \( \langle c_i^\beta, d_j \rangle \equiv 0 \pmod{p} \). Therefore every non-orthogonal pair has a net contribution of zero to the sum \( \sum_\beta (N_\beta - M_\beta)/p^\ell \).

\[\triangleright\]

4 Note [1] use the fact that \( \langle a_i, b_j \rangle \in \{0,1, \ldots, \ell \} \) to give a non-trivial inapproximability result for computing the maximum inner product between two vector sets.
Setting $\ell := \lceil \varepsilon \log_p(n) \rceil$ for tiny $\varepsilon > 0$, we obtain:

**Reminder of Corollary 6.** Let $\varepsilon > 0$ be sufficiently small. There is an $\tilde{O}(n^{1+\varepsilon} \cdot p^{O(\varepsilon/\varepsilon)})$-time reduction from $\#OV$ with $n$ vectors in $\log n$ dimensions to $n^\varepsilon$ instances of $\#OV_p$, each with $n$ vectors in $O(p^{\varepsilon/\varepsilon} \log(n))$ dimensions.

Therefore an algorithm for counting orthogonal-mod-2 pairs in $n^{1.9} \cdot 2^{o(d)}$ time would yield a similar algorithm for counting orthogonal pairs, refuting SETH.

**Acknowledgements.** I am grateful to the Simons Institute at UC Berkeley for inviting me to the workshop on “Proving and Using Pseudorandomness” in Spring 2017. There, I got a chance to think more carefully about the ideas in the approximate counting algorithm. I also thank the reviewers of SOSA for some helpful comments, and Holger Dell for telling me about his work on approximate counting; the conversation prompted me to work out the details for Theorem 5.
