Abstract
A noticeable fraction of Algorithms papers in the last few decades improve the running time of well-known algorithms for fundamental problems by logarithmic factors. For example, the $O(n^2)$ dynamic programming solution to the Longest Common Subsequence problem (LCS) was improved to $O(n^2/\log^2 n)$ in several ways and using a variety of ingenious tricks. This line of research, also known as the art of shaving log factors, lacks a tool for proving negative results. Specifically, how can we show that it is unlikely that LCS can be solved in time $O(n^2/\log^3 n)$?

Perhaps the only approach for such results was suggested in a recent paper of Abboud, Hansen, Vassilevska W. and Williams (STOC’16). The authors blame the hardness of shaving logs on the hardness of solving satisfiability on boolean formulas (Formula-SAT) faster than exhaustive search. They show that an $O(n^2/\log^{1000} n)$ algorithm for LCS would imply a major advance in circuit lower bounds. Whether this approach can lead to tighter barriers was unclear.

In this paper, we push this approach to its limit and, in particular, prove that a well-known barrier from complexity theory stands in the way for shaving five additional log factors for fundamental combinatorial problems. For LCS, regular expression pattern matching, as well as the Fréchet distance problem from Computational Geometry, we show that an $O(n^2/\log^{7+\varepsilon} n)$ runtime would imply new Formula-SAT algorithms.

Our main result is a reduction from SAT on formulas of size $s$ over $n$ variables to LCS on sequences of length $N = 2^{n/2} \cdot s^{1+o(1)}$. Our reduction is essentially as efficient as possible, and it greatly improves the previously known reduction for LCS with $N = 2^{n/2} \cdot s^c$, for some $c \geq 100$.

Tighter Connections Between Formula-SAT and Shaving Logs

Vassilevska Williams for helpful discussions regarding regular expressions. We also thank an anonymous reviewer for ideas leading to shaving off a second log-factor for FORMULA-PAIR.

1 Introduction

Since the early days of Algorithms research, a noticeable fraction of papers each year shave log factors for fundamental problems: they reduce the best known upper bound on the time complexity from $T(n)$ to $T(n)/\log^c n$, for some $c > 0$. While in some cases a cynic would call such results “hacks” and “bit tricks”, there is no doubt that they often involve ingenious algorithmic ideas and suggest fundamental new ways to look at the problem at hand. In his survey, Timothy Chan calls this kind of research “The Art of Shaving Logs” [37]. In many cases, we witness a race of shaving logs for some problem, in which a new upper bound is found every few months, without giving any hints on when this race is going to halt. For example, in the last few years, the upper bound for combinatorial Boolean Matrix Multiplication dropped from $O(n^3/\log^2 n)$ [16], to $O(n^3/\log^{2.25} n)$ [20], to $O(n^3/\log^3 n)$ [38], and most recently to $O(n^3/\log^4 n)$ [99]. Perhaps the single most important missing technology for this kind of research is a tool for proving lower bounds.

Consider the problem of computing the Longest Common Subsequence (LCS) of two strings of length $n$. LCS has a simple $O(n^2)$ time dynamic programming algorithm [93, 46]. Several approaches have been utilized in order to shave log factors such as the “Four Russians” technique [16, 61, 74, 23, 58], utilizing bit-parallelism [10, 47, 62], and working with compressed strings [48, 54]. The best known upper bounds are $O(n^2/\log^2 n)$ for constant size alphabets [74], and $O(n^2 \log \log n/\log^2 n)$ for large alphabets [58]. But can we do better? Can we solve LCS in $O(n^2/\log^3 n)$ time? While the mathematical intrigue is obvious, we remark that even such mild speedups for LCS could be significant in practice. Besides its use as the diff operation in Unix, LCS is at the core of highly impactful similarity measures between biological data. A heuristic algorithm called BLAST for a generalized version of LCS (namely, the Local Alignment problem [87]) has been cited more than sixty thousand times [14]. While such heuristics are much faster than the near-quadratic time algorithms above, they are not guaranteed to return an optimal solution and are thus useless in many applications, and biologists often fall back to (highly optimized implementations of) the quadratic solutions, see, e.g. [71, 72].

How would one show that it is hard to shave logs for some problem? A successful line of work, inspired by NP-hardness, utilizes “fine-grained reductions” to prove statements of the form: a small improvement over the known runtime for problem A implies a breakthrough algorithm for problem B, refuting a plausible hypothesis about the complexity of B. For example, it has been shown that if LCS can be solved in $O(n^{2-\varepsilon})$ time, where $\varepsilon > 0$, then there is a breakthrough $(2−\delta)^n$ algorithm for CNF-SAT, and the Strong Exponential Time Hypothesis (SETH, defined below) is refuted [2, 29]. Another conjecture that has been used to derive interesting lower bounds states that the 3-SUM problem cannot be solved in $O(n^{2-\varepsilon})$ time. It is natural to ask: can we use these conjectures to rule out log-factor improvements for problems like LCS? And even more optimistically, one might hope to base the hardness of LCS on a more standard assumption like $P \neq NP$. Unfortunately, we can formally prove that these assumptions are not sharp enough to lead to any consequences for log-factor improvements, if only Turing reductions are used. In Section 3 we prove the

---

2 3-SUM asks, given a list of $n$ numbers, to find three that sum to zero. The best known upper bound is $O(n^2(\log \log n)^2/\log n)$ for real numbers [59, 53, 56] and $O(n^2(\log \log n/\log n)^2)$ for integers [21].
following theorem which also shows that an $O(f(n)/\log^c(f(n)))$ time algorithm for problem A cannot imply, via a fine-grained reduction, an $O(g(n)^{1-\varepsilon})$ algorithm for problem B, unless B is (unconditionally) solvable in $O(g(n)^{1-\delta})$ time.

Theorem 1.1 (Informally). If for some $c > 0$ there is a fine-grained reduction proving that LCS is not in $O(n^2/\log^c n)$ time unless SETH fails, then SETH is false.

Note that it also does not suffice to simply make SETH stronger by postulating a higher running time lower bound for CNF-SAT, since superpolynomial improvements are known for this problem [81, 34, 49, 8]. Similarly, we cannot base a study of log-factor improvements on the APSP conjecture, since superlogarithmic improvements are known for APSP [97]. (However, 3SUM could be a candidate to base higher lower bounds on, since only log-factor improvements are known [59, 53, 56, 21], see Section A of the full version for a discussion.)

Thus, in a time when super-linear lower bounds for problems like LCS are far out of reach, and our only viable approach to obtaining such negative results is reductions-based, we are left with two options. We could either leave the study of log-factor improvements in limbo, without a technology for proving negative results, or we could search for natural and convincing assumptions that are more fine-grained than SETH that could serve as the basis for the negative results we desire. Such assumptions were recently proposed by Abboud, Hansen, Vassilevska Williams and Williams [3]. The authors blame the hardness of shaving logs on the hardness of solving satisfiability on boolean formulas (Formula-SAT) faster than exhaustive search, by polynomial factors (which are log-factors in the runtime), a task for which there are well known “circuit lower bound” barriers in complexity theory. They show that an $O(n^2/\log^{1000} n)$ algorithm for LCS would imply a major advance in circuit lower bounds. In the final section of this paper, we give a more detailed argument in favor of this approach. Whether one should expect it to lead to tight barriers, i.e. explaining the lack of $O(n^2/\log^3 n)$ algorithms for LCS or any other natural problem, was completely unclear.

The Machine Model

We use the Word-RAM model on words of size $\Theta(\log n)$, where there is a set of operations on words that can be performed in time $O(1)$. Most papers do not fix the concrete set of allowed operations, and instead refer to “typical Boolean and arithmetic operations”. In this paper, we choose a set of operations $P$ that is robust with respect to changing the word size: For any operation $\circ \in P$, given two words $a, b$ (of size $\Theta(\log n)$) we can compute $a \circ b$ in time $(\log n)^{1+o(1)}$ on a Word RAM with word size $\Theta(\log \log n)$ and operation set $P$. In other words, if we split $a, b$ into $\Theta(\log n/\log \log n)$ words of size $\Theta(\log \log n)$ then $a \circ b$ can still be computed very efficiently.

This robustness in particular holds for the following standard set of operations: initializing a cell with a constant, bitwise AND, OR, NOT, shift, addition, subtraction, multiplication, and division with remainder (since multiplication and division have near-linear time algorithms).

The results in this paper will get gradually weaker as we relax the restriction on near-linear time per operation to higher runtimes, however, even with this restriction, to the best of our knowledge this model captures all log shaving results in the literature (on the “standard” Word RAM model without fancy word operations).

---

3 In [3] the authors focus on SAT on Branching Programs (BPs) rather than formulas, but due to standard transformations between BPs and formulas, the two problems are equivalent up to polynomial factors. Focusing on Formula-SAT will be crucial to the progress we make in this paper.
A boolean formula over $n$ input variables can be viewed as a tree in which every leaf is marked by an input variable or its negation and every internal node or gate represents some basic boolean operation. Throughout this introduction we will only talk about deMorgan formulas, in which every gate is from the set \{\&, v\}. The size of the formula is defined to be the number of leaves in the tree.

In the Formula-SAT problem we are given a formula $F$ of size $s$ over $n$ inputs, and we have to decide whether there is an input $\{0, 1\}^n$ that makes it output 1. A naive algorithm takes $O(2^s \cdot n)$ time, since evaluating the formula on some input takes $O(s)$ time. Can we do better? We will call a SAT algorithm non-trivial if it has a runtime at most $O(2^n \cdot s^{\varepsilon})$, for some $\varepsilon > 0$.

It seems like a clever algorithm must look at the given formula $F$ and try to gain a speedup by analyzing it. The more complicated $F$ can be, the harder the problem becomes. Indeed, Dantsin and Hirsch [49] survey dozens of algorithms for SAT on CNF formulas which exploit their structure. For $k$-CNF formulas of size $s$ there are $2^n s/2^{\Omega(n/k)}$ time algorithms (e.g. [81]), and for general CNF formulas the bound is $2^n s/2^{\Omega(n/\log \Delta)}$ where $\Delta = s/n$ is the clause-to-variable ratio [34, 49, 8]. The popular SETH [66, 35] essentially says that this is close to optimal, and that there is no $2^n s/2^{\Omega(n)}$ algorithm for CNF-SAT. For arbitrary deMorgan formulas, the upper bounds are much worse. A FOCS'10 paper by Santhanam [84] and several recent improvements [41, 43, 42, 70, 91] solve Formula-SAT on formulas of size $s = n^{3-16\varepsilon}$ in time $2^n s^{O(1)/2^{n^{\varepsilon}}}$, which is non-trivial only for $s = o(n^3)$, and going beyond cubic seems extremely difficult. This leads us to the first barrier which we will transform into a barrier for shaving logs.

▶ Hypothesis 1.2. There is no algorithm that can solve SAT on deMorgan formulas of size $s = n^{3+\Omega(1)}$ in $O(2^n s^{\varepsilon})$ time, for some $\varepsilon > 0$, in the Word-RAM model.

Perhaps the main reason to believe this hypothesis is that despite extensive algorithmic attacks on variants of SAT (perhaps the most extensively studied problem in computer science) over decades, none of the ideas that anyone has ever come up with seem sufficient to refute it. Recent years have been particularly productive in non-trivial algorithms designed for special cases of Circuit-SAT [84, 86, 64, 35, 98, 22, 40, 67, 63, 44, 83, 57] (in addition to the algorithms for deMorgan formulas above) and this hypothesis still stands.

A well-known “circuit lower bounds” barrier seems to be in the way for refuting Hypothesis 1.2: can we find an explicit boolean function that cannot be computed by deMorgan formulas of cubic size? Functions that require formulas of size $\Omega(n^{1.5})$ [89] and $\Omega(n^2)$ [69] have been known since the 60’s and 70’s, respectively. In the late 80’s, Andreev [15] proved an $\Omega(n^{2.5})$ which was later gradually improved to $\Omega(n^{2.55})$ by Nisan and Wigderson [65] and to $\Omega(n^{2.63})$ by Paterson and Zwick [79] until Håstad proved his $n^{3-o(1)}$ lower bound in FOCS’93 [60] (a recent result by Tal improves the $n^{o(1)}$ term [90]). All these lower bound results use the “random restrictions” technique, first introduced in this context by Subbotovskaya in 1961 [89], and it is known that a substantially different approach must be taken in order to go beyond the cubic barrier. What does this have to do with Formula-SAT algorithms? Interestingly, this same “random restrictions” technique was crucial to all the non-trivial Formula-SAT algorithms mentioned above. This is not a coincidence, but only one out of

---

4 Some works on SAT algorithms used this term for runtimes of the form $2^{n \cdot \text{poly}(s)}/n^{o(1)}$. In our context, we need to be a bit more fine-grained.
the many examples of the intimate connection between the task of designing non-trivial algorithms for SAT on a certain class $F$ of formulas or circuits and the task of proving lower bounds against $F$. This connection is highlighted in many recent works and in several surveys [85, 78, 96]. The intuition is that both of these tasks seem to require identifying a strong structural property of functions in $F$. There is even a formal connection shown by Williams [95], which in our context implies that solving Formula-SAT on formulas of size $O(n^{3.1})$ in $O(2^{n^c/n^{10}})$ time (which is only slightly stronger than refuting Hypothesis 1.2) is sufficient in order to prove that there is a function in the class $\mathbf{E}^{NP}$ that cannot be computed by formulas of size $O(n^{3.1})$ (see [3] for more details). This consequence would be the first polynomial progress on the fundamental question of worst case formula lower bounds since Håstad’s result.

1.1 Our Results: New Reductions

Many recent papers have reduced CNF-SAT to fundamental problems in P to prove SETH-based lower bounds (e.g. [80, 82, 6, 4, 27, 18, 7, 1, 33, 5, 19, 75, 39]). Abboud et al. [3] show that even SAT on formulas, circuits, and more, can be efficiently reduced to combinatorial problems in P. In particular, they show that Formula-SAT on formulas of size $s$ over $n$ inputs can be reduced to an instance of LCS on sequences of length $N = O(2n^2/s^{1000})$. This acts as a barrier for shaving logs as follows. A hypothetical $O(N^2/\log^\omega N)$ time algorithm for LCS can be turned into an algorithm for Formula-SAT in time

$$n^{1+o(1)} \cdot (2^{n^2/s^{1000}})^{2/(\log 2^\Theta(n))} c = O(2^n \cdot s^{2000}/n^{c-1}),$$

which for a large enough $c \geq 2001$ would refute Hypothesis 1.2. The first $n^{1+o(1)}$ factor in the runtime comes from the jump from $n$ to $N = 2^n$ and our Word-RAM machine model: whenever the LCS algorithm wants to perform a unit-cost operation on words of size $\Theta(\log N)$ (this is much more than the word size of our SAT algorithm which is only $\Theta(\log \log N)$), the SAT algorithm can simulate it in $(\log N)^{1+o(1)} = n^{1+o(1)}$ time in the Word-RAM model with words of size $\Theta(\log n)$.

Our main result is a much more efficient reduction to LCS. For large but constant size alphabets, we get a near-linear dependence on the formula size, reducing the $s^{1000}$ factor to just $s^{1+o(1)}$.

**Theorem 1.3.** Formula-SAT on formulas of size $s$ on $n$ inputs can be reduced to an instance of LCS on two sequences over an alphabet of size $\sigma$ of length $N = 2^{n^2/\log \log \sigma}$, in $O(N)$ time.

Thus, if LCS on sequences of length $N$ and alphabet of size $\omega(1)$ can be solved in $O(N^2/\log^\omega N)$ time, then Formula-SAT can be solved in $2^n \cdot (2^{n^2/\log^\omega n})^{1+o(1)}$ time. Recall that the known upper bound for LCS is $O(n^2/\log^c n)$ for any constant alphabet size, with $c = 2$, and we can now report that the barrier of cubic formulas stands in the way of improving it to $c > 7$ (see Corollary 1.6 below).

The novelty in the proof of Theorem 1.3 over [3] is discussed in Section 2. As an alternative to Theorem 1.3, in Section D of the full version we present another reduction to LCS which is much simpler than all previously known reductions, but uses a larger alphabet.

**Fréchet Distance**

An important primitive in computational geometry is to judge how similar are two basic geometric objects, such as polygonal curves, represented as sequences of points in $d$-dimensional Euclidean space. Such curves are ubiquitous, since they arise naturally as trajectory data of
Tighter Connections Between Formula-SAT and Shaving Logs

moving objects, or as time-series data of stock prices and other measures. The most popular similarity measure for curves in computational geometry is the Fréchet distance, also known as dog-leash-distance. For formal definitions see Section F of the full version. The Fréchet distance has found many applications (see, e.g., [76, 26, 30]) and developed to a rich field of research with many generalizations and variants (see, e.g., [11, 17, 13, 51, 36, 45, 32, 50, 73, 68]).

This distance measure comes in two variants: the continuous and the discrete. A classic algorithm by Alt and Godau [12, 55] computes the continuous Fréchet distance in time $O(n^2 \log n)$ for two given curves with $n$ vertices. The fastest known algorithm runs in time $O(n^2 (\log \log n)^2 / \log n)$ for the discrete Fréchet distance, the original algorithm has running time $O(n^2)$ [52], which was improved to $O(n^2 \log \log n / \log n)$ by Agarwal et al. [9]. Their algorithm runs in time $O(n^2 \log \log n / \log^2 n)$ for the decision version. It is known that both versions of the Fréchet distance are SETH-hard [27]. However, this does not rule out log factor improvements. In particular, no reduction from versions of SETH on formulas or branching programs is known.

In this paper we focus on the decision version of the discrete Fréchet distance (which we simply call “Fréchet distance” from now on). We show that Fréchet distance suffers from the same barriers for shaving logs like LCS. In particular, this reduction allows us to base the usual $\Omega(n^2 - \epsilon)$ lower bound on a weaker assumption than SETH, such as NC-SETH (see the discussion in [3]). This is the first NC-SETH hardness for a problem that does not admit alignment gadgets (as in [29]).

▶ Theorem 1.4. Formula-SAT on formulas of size $s$ on $n$ inputs can be reduced to an instance of the Fréchet distance on two curves of length $N = O(2^{n/2} \cdot s)$, in $O(N)$ time.

Regular Expression Pattern Matching

Our final example is the fundamental Regular Expression Pattern Matching problem: Decide whether a given regular expression of length $m$ matches a substring of a text of length $n$. Again, there is a classical $O(mn)$ algorithm [92], and the applicability and interest in this problem resulted in algorithms shaving log factors; the first one by Myers [77] was improved by Bille and Thorup [24] to time $O(mn / \log^{1.5} n)$. Recently, Backurs and Indyk proved an $n^{2-o(1)}$ SETH lower bound [19], and performed an impressive study of the exact time complexity of the problem with respect to the complexity of the regular expression. This study was essentially completed by Bringmann, Grønlund, and Larsen [28], up to $n^{o(1)}$ factors. In Section E of the full version we show that this problem is also capable of efficiently simulating formulas and thus has the same barriers as LCS and Fréchet distance.

▶ Theorem 1.5. Formula-SAT on formulas of size $s$ on $n$ inputs can be reduced to an instance of Regular Expression Pattern Matching on text and pattern of length $N = O(2^{n/2} \cdot s \log s)$ over a constant size alphabet, in $O(N)$ time.

Consequences of the Cubic Formula Barrier

We believe that SAT on formulas can be tightly connected to many other natural problems in P. As we discuss in the next section, such reductions seem to require problem-specific engineering and are left for future work. The main point of this paper is to demonstrate the possibility of basing such ultra fine-grained lower bounds on one common barrier. Our conditional lower bounds are summarized in the following corollary, which shows that current log-shaving algorithms are very close to the well-known barrier from complexity theory of cubic formula lower bounds.
Corollary 1.6. For all $\varepsilon > 0$, solving any of the following problems in $O(n^2 / \log^{7+\varepsilon} n)$ time refutes Hypothesis 1.2, and solving them in $O(n^2 / \log^{17+\varepsilon} n)$ time implies that $\text{E}^{\text{NP}}$ cannot be computed by non-uniform formulas of cubic size:

- LCS over alphabets of size $\omega(1)$
- The Fréchet distance on two curves in the plane
- Regular Expression Pattern Matching over constant size alphabets.

The main reason that our lower bounds above are not tight (the gap between 2 and 7) is that we need to start from SAT on cubic size formulas rather than linear size ones, due to the fact that clever algorithms do exist for smaller formulas. We remark that throughout the paper we will work with a class of formulas we call $F_1$ (see Section 2 below), also known as bipartite formulas, that are more powerful than deMorgan formulas yet our reduction to LCS can support them as well. This makes our results stronger, since $F_1$-Formula-SAT could be a harder problem than SAT on deMorgan formulas. In fact, in an earlier version of the paper we had suggested the hypothesis that $F_1$-Formula-SAT does not have non-trivial algorithms even on linear size formulas. This stronger hypothesis would give higher lower bounds. However, Avishay Tal (personal communication) told us about such a non-trivial algorithm for formulas of size up to $n^{2-O(1)}$ using tools from quantum query complexity. We are optimistic that one could borrow such ideas or the “random restrictions” technique from SAT algorithms in order to shave more logs for combinatorial problems such as LCS. This is an intriguing direction for future work.

## 2 Technical Overview and the Reduction to LCS

We first define the class of formulas $F_1$. A formula $F$ of size $s$ over $n$ variables $x_1, \ldots, x_n$ is in the class $F_1$ iff it has the following properties. The gates in the first layer (nodes in the tree whose children are all leaves) compute arbitrary functions $C : \{0,1\}^{n/2} \rightarrow \{0,1\}$, as long as $C$ can be computed in $2^{o(n)}$ time and all children of a gate are marked with variables in $\{x_1, \ldots, x_{n/2}\}$ or with variables in $\{x_{n/2+1}, \ldots, x_n\}$ but not with both. W.l.o.g. we can assume that the inputs are only connected to nodes in the first layer. The gates in the other layers compute deMorgan gates, i.e., OR and AND gates. The size of $F$ is considered to be the number of gates in the first layer. Since $F$ is a formula and thus has fanout 1, our size measure is up to constant factors equal to the total number of all gates except the inputs. Note that the complexity of the functions in the first layer and their number of incoming wires, i.e. the number of leaves in the tree, do not count towards the size of $F$.

All the reductions from SAT to problems in P mentioned in the introduction start with a split-and-list reduction to some “pair finding” problem. In the SETH lower bounds, CNF-SAT is reduced to the Orthogonal-Vectors problem of finding a pair $a \in A, b \in B, A, B \subseteq \{0,1\}^d$ that are orthogonal [94]. When starting from Formula-SAT, we get a more complex pairfinding problem. In Section B of the full version we show a simple reduction from SAT on formulas from the class $F_1$ (which contains deMorgan formulas) to the following problem.

**Definition 2.1 (Formula-Pair Problem).** Given a deMorgan formula over $2m$ variables $F = F(x_1, \ldots, x_m, y_1, \ldots, y_m)$ (each appearing once in $F$), and two sets of vectors $A, B \subseteq \{0,1\}^m$ of size $n$, decide if there is a pair $a \in A, b \in B$ such that $F(a_1, \ldots, a_m, b_1, \ldots, b_m) = \text{true}$.

In Section B of the full version we show a Four-Russians type algorithm that solves Formula-Pair in $O(n^2m / \log^2 n)$ time, and even when $m = |F| = (\log n)^{1+o(1)}$ no $O(n^2 / \log^{1+\varepsilon} n)$ upper bound is known. By our reduction, such an upper bound would
imply a non-trivial algorithm for SAT on formulas from \( \mathcal{F} \). Moreover, Hypothesis 1.2 implies that we cannot solve FORMULA-PAIR in \( O(n^2 / \log^2 n) \) time, for \( m = (\log n)^{3 + \Omega(1)} \). In the next sections, we reduce FORMULA-PAIR to LCS, from which Theorem 1.3 follows. A simpler reduction using much larger alphabet size can be found in Section D of the full version.

**Theorem 2.2.** FORMULA-PAIR on formulas of size \( s \) and lists of size \( n \) can be reduced to an instance of LCS on two strings over alphabet of size \( \sigma \geq 2 \) of length \( O(n \cdot s^{1 + O(1 / \log \log \sigma)}) \), in linear time.

The reduction constructs strings \( x, y \) and a number \( \rho \) such that LCS\((x, y) \geq \rho \) holds if and only if the given Formula-Pair instance \( (F, A, B) \) is satisfiable. The approach is similar to the reductions from Orthogonal-Vectors to sequence alignment problems (e.g. \([6, 27, 18, 2, 29]\)). The big difference is that our formula \( F \) can be much more complicated than a CNF, and so we will need more powerful gadgets. Sequence gadgets that are able to simulate the evaluation of deMorgan formulas were (implicitly) constructed in \([3]\) with a recursive approach. Our main contribution is an extremely efficient implementation of such gadgets with LCS.

The main part of the reduction is to construct gate gadgets: for any vectors \( a, b \in \{0, 1\}^m \) and any gate \( g \) of \( F \), we construct strings \( x(g, a) \) and \( y(g, b) \) whose LCS determines whether gate \( g \) evaluates to true for input \((a, b) \) to \( F \) (see Section 2.1). Once we have this, to find a pair of vectors \( a \in A, b \in B \) satisfying \( F \), we combine the strings \( x(r, a), y(r, b) \), constructed for the root \( r \) of \( F \), using a known construction of so-called alignment gadgets \([2, 29]\) from previous work (see Section C.1 of the full version).

Let us quickly explain how \([3]\) constructed gate gadgets and the main ideas that go into our new construction. There are two kinds of gadgets, corresponding to the two types of gates in \( F \): AND and OR gates. Since the AND gadgets will be relatively simple, let us consider the OR gadgets. Fix two inputs \( a, b \), and let \( g = (g_1 \lor g_2) \) be an OR gate, and assume that we already constructed gate gadgets for \( g_1, g_2 \), namely \( x_1 = x(g_1, a), y_1 = y(g_1, b), x_2 = x(g_2, a), y_2 = y(g_2, b) \) so that for \( i \in \{1, 2\} \) we have that LCS\((x_i, y_i) \) is large if the gate \( g_i \) outputs true on input \((a, b) \), and it is smaller otherwise. In \([3]\), these gadgets were combined as follows. Let \( \beta \) be an upper bound on the total length of the gadgets \( x_i, y_i \). We add a carefully chosen padding of 0’s and 1’s, so that any optimal matching of the two strings will have to match either \( x_1, y_1 \) or \( x_2, y_2 \) but not both.

\[
\begin{align*}
x &::= 0^{4\beta} x_1 1^{\beta} x_2 0^{4\beta} \\
y &::= y_1 1^{\beta} 0^{4\beta} 1^{\beta} y_2
\end{align*}
\]

One then argues that, in any optimal LCS matching of \( x, y \), the \( 0^{4\beta} \) block of \( y \) must be matched either left or right. If it’s matched left, then the total score will be equal to \( 4\beta + \beta + \text{LCS}(x_2, y_2) \) while if it’s matched right, we will get \( 4\beta + \beta + \text{LCS}(x_1, y_1) \). Thus, LCS\((x, y) \) is determined by the OR of \( g_1, g_2 \). The blowup of this construction is a multiplicative factor of 11 with every level of the formula, and the length of the gadget of the root will end up roughly \( 1^{\text{depth}(F)} \). To obtain our tight lower bounds, we will need to decrease this blowup to \( 1 + \varepsilon_\sigma \) at every level, where \( \varepsilon_\sigma \) goes to 0 when the alphabet size \( \sigma \) tends to infinity. With the above construction, decreasing the length of the padding will allow the optimal LCS matching to cheat, e.g. by matching \( y_1 \) to both \( x_1 \) and \( x_2 \), and no longer corresponding to the OR of \( g_1, g_2 \).

Our first trick is an ultra-efficient OR gadget in case we are allowed unbounded alphabet size. We take \( x_1, y_1 \) and transform all their letters into a new alphabet \( \Sigma^n \), and we take \( x_2, y_2 \) and transform their letters into a disjoint alphabet \( \Sigma^{\rho n} \). Then our OR gadget does not
require any padding at all:
\[ x := x_1 \ x_2 \]
\[ y := y_2 \ y_1 \]

The crossing structure of this construction means that any LCS matching that matches letters from \(x_1\), \(y_1\) cannot also match letters from \(x_2, y_2\), and vice versa, while the disjoint alphabets make sure that there can be no matches between \(x_1, y_2\) or \(x_2, y_1\). With such gadgets we can encode a formula of size \(s\) with \(O(s)\) letters, for details see Section D of the full version.

But how would such an idea work for constant size alphabets? Once we allow \(x_1\) and \(y_2\) to share even a single letter, this argument breaks. Natural attempts to simulate this construction with smaller alphabets, e.g. by replacing each letter with a random sequence, do not seem to work, and we do not know how to construct such an OR gadget with a smaller alphabet in a black box way. The major part of our proof will be a careful examination of the formula and the sub-gadgets \(g_1, g_2\) in order to reduce the alphabet size to a large enough constant, while using padding that is only \(1 + \varepsilon\sigma\) times the length of the sub-gadgets. We achieve this by combining this crossing gadget with a small padding that will reuse letters from alphabets that were used much deeper in the formula, and we will argue that the noise we get from recycling letters is dominated by our paddings, in any optimal matching.

We remark that the reduction of [3] can be implemented in a generic way with any problem that admits alignment gadgets as defined in [29], giving formula-gadgets of size \(s^{O(1)}\). The list of such problems includes LCS and Edit-Distance on binary strings. However, Fréchet Distance falls outside the alignment gadgets framework of [29] and no reduction from Formula-SAT was known before. In Section F of the full version we prove such a reduction by a significant boosting of the SETH-lower bound construction of [27]. In order to reduce the alphabet size to a large enough constant, while using padding that is only \(1 + \varepsilon\sigma\) times the length of the sub-gadgets. We achieve this by combining this crossing gadget with a small padding that will reuse letters from alphabets that were used much deeper in the formula, and we will argue that the noise we get from recycling letters is dominated by our paddings, in any optimal matching.

In the remainder of this section we present the details of the reduction to LCS. Some missing proofs can be found in Section C of the full version.

### 2.1 Implementing Gates

Fix vectors \(a, b \in \{0, 1\}^m\) (where \(2m\) is the number of inputs to \(F\)). In this section we prove the following lemma which demonstrates our main construction.

> **Lemma 2.3.** For any sufficiently large \(\sigma > 0\) let \(\tau = (\log \sigma)^{1/4}\). We can inductively construct, for each gate \(g\) of \(F\), strings \(x(g) = x(g, a)\) and \(y(g) = y(g, b)\) over alphabet size \(5\sigma^2\) and a number \(\rho(g)\) such that for \(L(g) := LCS(x(g), y(g))\) we have (1) \(L(g) \leq \rho(g)\) and (2) \(L(g) = \rho(g)\) if and only if gate \(g\) evaluates to true on input \((a, b)\) to \(F\). Moreover, we have \(|x(g)| = |y(g)| = n(g) \leq 6\tau \cdot |F_0|(1 + 7/\tau)^{\text{depth}(F_0)}\), where \(F_0\) is the subformula of \(F\) below \(g\).

In this construction, we use disjoint size-5 alphabets \(\Sigma_1, \ldots, \Sigma_{\sigma^2}\), determining the total alphabet size as \(5\sigma^2\). Each gate \(g\) is assigned an alphabet \(\Sigma_{f(g)}\). We fix the function \(f\) later.

In the following, consider any gate \(g\) of \(F\), and write the gate alphabet as \(\Sigma_{f(g)} = \{0, 1, 2, 3, 4\}\). For readability, we write \(x = x(g)\) and similarly define \(y, n, L, \rho\). If \(g\) has fanin 2, write \(g_1, g_2\) for the children of \(g\). Moreover, let \(x_1 = x(g_1)\) and similarly define \(y_1, n_1, L_1, \rho_1\) and \(x_2, y_2, n_2, L_2, \rho_2\).
Input Gate

The base case is an input bit $a_i$ to $F$ (input bits $b_j$ are symmetric). Interpreting $a_i$ as a string of length 1 over alphabet $\{0, 1\}$, note that $\text{LCS}(a_i, 1) = a_i$. Hence, the strings $x = a_i$ and $y = 1$, with $n = \rho = 1$, trivially simulate the input bit $a_i$.

AND Gates

Consider an AND gate $g$ and let $\beta := [(n_1 + n_2)/\tau^2]$. We construct strings $x, y$ as

$$x := x_1 \beta^{x_2} \quad \text{and} \quad y := y_1 \beta^{y_2}$$

\[\textbf{Lemma 2.4.} \] If $\text{LCS}(x_2, y_1), \text{LCS}(x_1, y_2) \leq \beta/4$ and the symbols 0, 1 appear at most $\beta/16$ times in each of $x_1, x_2, y_1$, and $y_2$, then we have $L = \text{LCS}(x, y) = 2\beta + L_1 + L_2$.

Later we will choose the gate alphabets $\Sigma_f(y_i)$ such that the preconditions of the above lemma is satisfied. Setting $\rho := 2\beta + \rho_1 + \rho_2$ we thus inductively obtain (1) $L \leq \rho$ and (2) $L = \rho$ if and only if $g_1$ and $g_2$ both evaluate to true. Thus, we correctly simulated the AND gate $g$. It remains to prove the lemma.

\[\textbf{Proof.} \] Clearly, we have $L \geq \text{LCS}(x_1, y_1) + \text{LCS}(0^\beta, 0^\beta) + \text{LCS}(1^\beta, 1^\beta) + \text{LCS}(x_2, y_2) = 2\beta + L_1 + L_2$. For the other direction, consider any LCS $z$ of $x, y$. If $z$ does not match any symbol of the left half of $x$, $x_10^\beta$, with any symbol of the right half of $y$, $1^\beta y_2$, and it does not match any symbol of the right half of $x$, $1^\beta x_2$, with any symbol of the left half of $y$, $y_10^\beta$, then we can split both strings in the middle and obtain $L = |z| \leq \text{LCS}(x_10^\beta, y_10^\beta) + \text{LCS}(1^\beta x_2, 1^\beta y_2)$. Greedy suffix/prefix matching now yields $L \leq (\text{LCS}(x_1, y_1) + \beta) + (\beta + \text{LCS}(x_2, y_2)) = 2\beta + L_1 + L_2$.

In the remaining case, there is a matching from some left half to some right half. By symmetry, we can assume that there is a matching from the left half of $x$ to the right half of $y$. We can moreover assume that $z$ matches a symbol of $x_1$ with a symbol of $1^\beta y_2$, since the case that $z$ matches a symbol of $y_2$ with a symbol of $x_10^\beta$ is symmetric. Now no symbol in $0^\beta$ in $x$ can be matched with a symbol in $0^\beta$ in $y$. We obtain a rough upper bound on $L = |z|$ by summing up the LCS length of all remaining $4 \cdot 4 - 1 = 15$ pairs of a part $x' \in \{x_1, 0^\beta, 1^\beta, x_2\}$ in $x$ and a part $y' \in \{y_1, 0^\beta, 1^\beta, y_2\}$ in $y$. This yields $L \leq L_1 + L_2 + \beta + 2 \cdot \beta/4 + 8 \cdot \beta/16 = 2\beta + L_1 + L_2$, finishing the proof. \[\blacksquare\]

OR Gates

Consider an OR gate $g$ and again let $\beta := [(n_1 + n_2)/\tau^2]$. We first make the LCS target values equal by adding $4|\rho_1 - \rho_2|$ to the shorter of $x_2/y_2$ and $x_1/y_1$, i.e., we set $x'_1 := 4^{\max(0, \rho_2 - \rho_1)}x_1$ and similarly $y'_1 := 4^{\max(0, \rho_2 - \rho_1)}y_1$, $x'_2 := 4^{\max(0, \rho_1 - \rho_2)}x_2$, $y'_2 := 4^{\max(0, \rho_1 - \rho_2)}y_2$. Note that the resulting strings satisfy $L'_1 := \text{LCS}(x'_1, y'_1) \leq \rho' := \max\{\rho_1, \rho_2\}$ and $L'_2 := \text{LCS}(x'_2, y'_2) \leq \rho'$ if and only if $g_1$ evaluates to true, and similarly $L'_2 := \text{LCS}(x'_2, y'_2) \leq \rho'$ and $L'_2 = \rho'$ if and only if $g_2$ evaluates to true. We construct the strings $x, y$ as

$$x := 0^\beta x'_1 2^\beta 3^\beta x'_2 0^\beta 1^\beta \quad \text{and} \quad y := 2^\beta 3^\beta y'_1 0^\beta 1^\beta 2^\beta 3^\beta$$

\[\textbf{Lemma 2.5.} \] If $\text{LCS}(x_2, y_1), \text{LCS}(x_1, y_2) \leq \beta/8$ and the symbols 0, 1, 2, 3 appear at most $\beta/48$ times in each of $x_1, x_2, y_1$, and $y_2$, then $L = \text{LCS}(x, y) = 4\beta + \max\{L'_1, L'_2\}$.
Later we will choose the gate alphabets $\Sigma_{f(g)}$ such that the preconditions of the above lemma is satisfied. Setting $\rho := 4\beta + \rho' = 4\beta + \max\{\rho_1, \rho_2\}$ we thus inductively obtain (1) $L \leq \rho$ and (2) $L = \rho$ if and only if at least one of $g_1$ and $g_2$ evaluates to true, so we correctly simulated the OR gate $g$. The proof of the Lemma is in Section C of the full version.

Analyzing the Length

Note that the above constructions inductively yields strings $x(g), y(g)$ simulating each gate $g$. We inductively prove bounds for $n(g)$ and $\rho(g)$. See Section C of the full version.

- **Lemma 2.6.** We have $n(g) \leq 6\sigma \cdot |F_g|(1 + 7/7\tau)^{\text{depth}(F_g)}$ and $\rho(g) \leq 6|F_g|(1 + 7/7\tau)^{\text{depth}(F_g)}$ for any gate $g$, where $F_g$ is the subformula of $F$ below $g$.

Fixing the Gate Alphabets

Now we fix the gate alphabet $\Sigma_{f(g)}$ for any gate $g$. Again let $\Sigma_{(i,j)}$, $i, j \in [\sigma]$, be disjoint alphabets of size 5, and let $\Sigma := \bigcup_{i,j} \Sigma_{(i,j)}$. For any gate $g$ of $F$, we call its distance to the root the height $h(g)$. For any $h$, order the gates with height $h$ from left to right, and let $i(g)$ be the index of gate $g$ in this order, for any gate $g$ with height $h$. Note that $(h(g), i(g))$ is a unique identifier of gate $g$. We define $f(g) := (h(g) \mod \sigma, i(g) \mod \sigma)$, i.e., we set the gate alphabet of $g$ to $\Sigma_{f(g)} = \Sigma_{(h(g) \mod \sigma, i(g) \mod \sigma)}$. Note that the overall alphabet $\Sigma$ has size $5\sigma^2$. Recall that we set $\tau := (\log \sigma)^{1/4}$.

It remains to show that the preconditions of Lemmas 2.4 and 2.5 are satisfied. Specifically, consider a gate $g$ with children $g_1, g_2$. As before, let $x, y, n$ be the strings and string length constructed for gate $g$, and let $x_i, y_i, n_i$ be the corresponding objects for $g_i$, $i \in \{1, 2\}$. We need to show:

1. LCS($x_2, y_1$), LCS($x_1, y_2$) $\leq (n_1 + n_2)/(8\sigma^2)$, and
2. each $c \in \Sigma_{f(g)}$ appears at most $(n_1 + n_2)/(48\sigma^2)$ times in each of $x_1, x_2, y_1$, and $y_2$.

We call a gate $g'$ in the subformula $F_g$ d-deep if $h(g') \geq h(g) + d$, and d-shallow otherwise.

For each symbol $c$ in $x$ or $y$ we can trace our construction to find the gate $g'$ in $F_g$ at which we introduced $c$ to $x$ or $y$. In other words, each symbol in $x, y$ stems from some gate $g'$ below $g$.

First consider (2). Observe that all symbols in $x, y$ stemming from $\sigma$-shallow gates do not belong to the gate alphabet $\Sigma_{f(g)}$, since the function $f(g')$ has $(h(g') \mod \sigma)$ as the first component, which repeats only every $\sigma$ levels. Thus, if a symbol $c \in \Sigma_{f(g)}$ occurs in $x$ or $y$, then this occurrence stems from a $\sigma$-deep gate. We now argue that only few symbols in $x, y$ stem from deep gates. For any $d > 0$, let $N_d$ be the number of symbols in $x$ (or, equivalently, $y$) stemming from $d$-deep gates. Note that $N_d$ is equal to the total string length $\sum_{g'} n(g')$, summed over all gates $g'$ in $F_g$ with height $h(g') = h(g) + d$. Observe that our construction increases the string lengths in each step by at least a factor $1 + 1/\tau^2$, i.e., $N_d \geq (1 + 1/\tau^2)N_{d+1}$ holds for any $d$. It follows that $N_0 \leq N_1/(1 + 1/\tau^2)\sigma^{-1} = (n_1 + n_2)/(1 + 1/\tau^2)\sigma^{-1}$. Hence, each symbol in $\Sigma_{f(g)}$ appears at most $(n_1 + n_2)/(1 + 1/\tau^2)\sigma^{-1}$ times in each of $x_1, x_2, y_1, y_2$. Since $\tau = (\log \sigma)^{1/4}$, we have $1 + 1/\tau^2)\sigma^{-1} = 2\delta(\sigma/\sqrt{\log \sigma}) \geq 48\sqrt{\log \sigma} = 48\sigma^2$ for sufficiently large $\sigma$. This proves (2).

For (1), remove all $\log(\sigma)$-deep symbols from $x_1$ and $y_2$ to obtain strings $x'_1, y'_2$. Note that we removed exactly $N_{\log \sigma}$ symbols from each of $x_1, y_2$. This yields LCS($x_1, y_2$) $\leq 2N_{\log \sigma} + LCS(x'_1, y'_2)$. For $x'_1, y'_2$, we claim that any $\log(\sigma)$-shallow gates $g_1 \neq g_2$ in $F_g$ have disjoint alphabets $\Sigma_{f(g_1)}, \Sigma_{f(g_2)}$. Indeed, if $h(g'_1) \neq h(g'_2)$ then since the first component $(h(g') \mod \sigma)$ of $f(g')$ repeats only every $\sigma$ levels we have $f(g'_1) \neq f(g'_2)$. If $h(g'_1) = h(g'_2) := h,$
then note that each gate $g'$ in height $h$ has a unique label $\ell(g') \mod \sigma$, since there are $\sigma$ such labels and there are at most $2^{h-h(g')} \leq \sigma$ gates with height $h$ in $F'$. Hence, $x_1'$ and $y_2'$ use disjoint alphabets, and we obtain $LCS(x_1', y_2') = 0$. Thus, $LCS(x_1, y_2) \leq 2N_{\log \sigma}$. As above, we bound $N_{\log \sigma} \leq (n_1 + n_2)/(1 + 1/\tau^2)\log^{\sigma-1}$, so that $LCS(x_1, y_2) \leq 2(n_1 + n_2)/(1 + 1/\tau^2)\log^{\sigma-1}$. Since $\tau = (\log \sigma)^{1/4}$, we have $(1 + 1/\tau^2)\log^{\sigma-1}/2 = 2\Omega(\sqrt{\log \sigma}) \geq 8\sqrt{\log \sigma} = 8\tau^2$ for sufficiently large $\sigma$. This yields (1), since the strings $x_2, y_1$ are symmetric, finishing the proof of Lemma 2.3.

Finalizing the Proof

Let us sketch how we complete the proof of Theorem 2.2. The full details are in Section C.1 of the full version. First, for all vectors $a \in A, b \in B$ we construct gate gadgets for the output gate of the formula, i.e. formula gadgets, by invoking Lemma 2.3. Then we combine all these gadgets by applying a standard alignment gadget [2, 29] to get our final sequences of length $O(n|F|/(1 + 7/\tau)^{\text{depth}(F)})$ and with alphabet of size $O(\sigma^2)$. The LCS of the final sequence will be determined by the existence of a satisfying pair. Since a priori the depth of $F$ could be as large as $|F|$, the factor $(1 + 7/\tau)^{\text{depth}(F)}$ in our length bound is not yet satisfactory. Thus, as a preprocessing before the above construction, we decrease the depth of $F$ using a depth-reduction result from Bonet and Buss [88, 25]: for all $k \geq 2$ there is an equivalent formula $F'$ with depth at most $(3k \ln 2) \log |F|$ and size $|F'| \leq |F|^{1 + 1/(1 + \log (k - 1))}$. Choosing the parameters correctly, we get final sequences of length $O(n|F|^{1 + O(1/\log \log \sigma)})$.

3 On the Limitations of Fine-Grained Reductions

With the increasingly complex web of reductions and conjectures used in the “Hardness in P” research, one might oppose to our use of nonstandard assumptions. Why can’t we base the hardness of shaving logs on one of the more established assumptions such as SETH, or even better, on $P \neq NP$? We conclude the paper with a proof that such results are not possible if one is restricted to fine-grained reductions, which is essentially the only tool we have in this line of research.

Let $A$ be a problem with best known upper bound of $T_A(n)$ on inputs of size $n$, and let $B$ be a problem with best known upper bound of $T_B(n)$ on inputs of size $n$. Throughout this section we assume that these runtime are non-decreasing functions, such as $2^n$ or $n^2$. A fine-grained reduction from “solving $A$ in time $T_A(n)/g(n)$” to “solving $B$ in time $T_B(n)/f(n)$” proves that improving $T_B(n)$ to $T_B(n)/f(n)$ improves $T_A$ to $T_A(n)/g(n)$. Formally, it is an algorithm $X$ that solves $A$ and it is allowed to call an oracle for problem $B$, as long as the following bound holds. Let $n_i$ be the size of the instance in the $i$th call to problem $B$ that our algorithm performs, where $i \leq t$ for some value $t$, and let $T_X(n)$ be the runtime of $X$ excluding the time it takes to answer all the instances of problem $B$. It must be that $T_X(n) + \sum_{i=1}^t T_B(n_i)/f(n_i) \leq T_A(n)/g(n)$. This is a natural adaptation of the definition of fine-grained reductions from previous works, where the improvements were restricted to be by polynomial factors. We can now give a formal version of Theorem 1.1 from the introduction.

**Theorem 3.1.** If for some $c, \varepsilon > 0$ and all $k \geq 2$ there is a fine-grained reduction from solving $k$-SAT in time $\text{poly}(n, m)2^n/2^{\varepsilon n}$ to solving LCS in time $O(n^2/\log^c n)$, then SETH is false.

**Proof.** Assume there was a fine-grained reduction from $k$-SAT to LCS as above. This means that there is an algorithm $X$ for $k$-SAT that makes $t$ calls to LCS with instances of size $n_1, \ldots, n_t$ such that $T_X(n) + \sum_{i=1}^t n_i^2/\log^c n_i = O(\text{poly}(n, m)2^n/2^{\varepsilon n})$. But then consider
algorithm $X'$ which simulates $X$ and whenever $X$ makes a call to the LCS oracle with an instance of size $n_i$, our algorithm will execute the known quadratic time solution for LCS. Let $n_{\text{max}}$ be the size of the largest instance we call, and note that $n_{\text{max}} < 2^n$. Simple calculations show that $X'$ solves $k$-SAT and has a running time of $T_{X'}(n) + \sum_{i=1}^{t} n_i^2 = O(\text{poly}(n,m)2^n/2^{\epsilon n})$ for all $k$, refuting SETH.
