Abstract

Given a point set $S = \{s_1, \ldots, s_n\}$ in the unit square $U = [0,1]^2$, an anchored square packing is a set of $n$ interior-disjoint empty squares in $U$ such that $s_i$ is a corner of the $i$th square. The reach $R(S)$ of $S$ is the set of points that may be covered by such a packing, that is, the union of all empty squares anchored at points in $S$.

It is shown that $\text{area}(R(S)) \geq \frac{1}{2}$ for every finite set $S \subset U$, and this bound is the best possible. The region $R(S)$ can be computed in $O(n\log n)$ time. Finally, we prove that finding a maximum area anchored square packing is NP-complete. This is the first hardness proof for a geometric packing problem where the size of geometric objects in the packing is unrestricted.

1 Introduction

Let $S = \{s_1, \ldots, s_n\}$ be a set of $n$ points in the unit square $U = [0,1]^2$. We say that a square $q$ is empty if no point in $S$ lies in the interior of $q$, and $q$ is anchored at a point $s$ if one of its four corners is $s$. An anchored square packing for $S$ is a set $Q = \{q_1, \ldots, q_a\}$ of interior-disjoint axis-aligned empty squares that lie in $U$ such that $q_i$ is anchored at $s_i$ for $i = 1, \ldots, n$. A lower-left anchored square packing is an anchored square packing in which $s_i$ is the lower-left corner of $q_i$, for $i = 1, \ldots, n$ [2]. No polynomial-time algorithm is known for...
computing the maximum area of an anchored square packing for a given point set $S$; the problem admits a PTAS using a reduction to the maximum weight independent set problem (MWIS) [1]. The empty squares anchored at $S$ do not always cover $U$ entirely (Fig. 1(a)). For finding a maximum anchored square packing for $S$, it suffices to consider the subset of $U$ that can be reached by anchored empty squares. Specifically, we define the reach of $S$, denoted $R(S)$, as the union of all axis-aligned empty squares contained in $U$ and anchored at some point in $S$.

For computing the reach $R(S)$, we can take the union of all maximal empty squares anchored at the points in $S$, as follows. For $i = 1, \ldots, n$, let $q_i^1$ be the maximal axis-aligned empty square in $U$ whose lower-left corner is $s_i$, and similarly define $q_i^2$, $q_i^3$, and $q_i^4$ where $s_i$ is the upper-left, upper-right, and lower-right corner, respectively. We say that a point $s \in S$ blocks a square $q_i^j$ if $s$ is incident to the top or right edge of $q_i^j$. Similarly, $s$ blocks $q_i^j$ if $j = 2$ (resp., 3, 4) and $s$ is incident to the bottom or right edges of $q_i^j$ (resp., bottom or left edges, or top or left edges of $q_i^j$). It is now clear that $R(S) = \bigcup_{i=1}^n \bigcup_{j=1}^4 q_i^j$.

**Summary of Results.** We prove that for every finite set $S \subset U$, the area of $R(S)$ is at least $\frac{1}{2}$, and this bound is the best possible (Section 2). This settles in the affirmative a conjecture by Balas et al. [1]. We show how to compute $R(S)$ in $O(n \log n)$ time where $n = |S|$ (Section 3). We also show that finding the maximum area anchored square packing for a given point set $S$ is NP-complete (Section 4). This is the first NP-hardness result for a geometric packing problem, where the size of the geometric objects in the packing is unrestricted. We conclude with related open problems (Section 5).

**Motivation and Related Previous Work.** Geometric packing and covering problems have a long and revered history, going back to Kepler’s problem about the densest packing of congruent balls in Euclidean space. In a classical packing problem, we are given a container region $C$, and a set $O$ of geometric objects, and we wish to find a maximum subset $O' \subset O$ such that congruent copies (or translates) of the objects in $O'$ fit in $C$ without overlap.

Anchored variants, where each geometric object needs to contain a given point (anchor) initially emerged in VLSI design, where the anchors represent the endpoints of wires. Allen Freedman [15] conjectured that for every finite set $S \subset [0,1]^2$, which contains the origin (i.e., $0 \in S$), there is a lower-left anchored rectangle packing of area at least $\frac{1}{2}$. This lower bound would match an easy upper bound construction, where $n$ points are equally distributed on the diagonal. The current best lower bound is 0.091 [6].
More recently, a broad family of anchored packing problems were proposed in the context of map labelling, where the anchors represent cities in a map, and axis-aligned rectangles represent labels [7, 8, 9, 10, 12, 13, 16]. Variants of the problem require the anchor to be at a corner, at a side, or anywhere in the rectangle, and the objective is to maximize the number of labels that can be packed in the map. Many of these problems are known to be NP-complete. However, in all previous reductions, the label boxes have a finite number of possible sizes [7, 12, 16] or bounded size [8].

In this paper, we consider the variant of Freedman’s problem: We need to place an axis-aligned square at each anchor, and the sizes of the squares are not given in advance. Our objective is to maximize the total area of an anchored square packing. Balas et al. [1] showed that a greedy strategy finds an $\frac{n}{2^2}$-approximation, and a reduction to MWIS yields a PTAS that achieves an $(1 - \epsilon)$-approximation in time $n^{O(1/\epsilon)}$. It is known that the number of maximum-area square anchored packings may be exponential in $n$ [2].

## 2 The Minimum Area of the Reach

In this section, we prove $area(R(S)) \geq \frac{1}{2}$ for every set $S$ of $n$ points in $U = [0, 1]^2$ (Theorem 12). Note that this bound is the best possible for all $n \in \mathbb{N}$. Indeed, if $S$ is the one-element set $S = \{(\frac{1}{2}, 0)\}$, then $area(R(S)) = \frac{1}{2}$; see Fig. 1(b). By placing $n$ points in an $\epsilon$-neighborhood of $(\frac{1}{2}, 0)$ in $U$, we see that for every $\epsilon > 0$ and every $n \in \mathbb{N}$, there exists a set $S$ of $n$ points in $U$ such that $area(R(S)) < \frac{1}{2} + \epsilon$. Note that in this construction all maximal anchored squares are disjoint from the top side of $U$. Under this constraint, the upper bound $\frac{1}{2}$ is always attained.

We call a point set $S$ trivial if $R(S)$ is disjoint from one of the sides of $U$. The following lemma shows that $area(R(S)) \geq \frac{1}{2}$ for trivial instances.

**Lemma 1.** If $R(S)$ does not touch one of the sides of $U$, then $area(R(S)) \geq \frac{1}{2}$.

**Proof.** Without loss of generality, $R(S)$ does not touch the top side of $U$. Let $s = (x, y)$ be a point in $S$ with maximum $y$-coordinate. Consider the maximal empty squares whose lower-left and lower-right corners are at $s$. Since these squares do not touch the top side of $U$, and $s$ has maximum $y$-coordinate, they touch the left and right side of $U$, respectively. Consequently, their combined area is $x^2 + (1 - x)^2 \geq (\frac{1}{2})^2 + (\frac{1}{2})^2 = \frac{1}{2}$. Hence $area(R(S)) \geq \frac{1}{2}$, as claimed.

**Remark.** We do not know of any nontrivial point set $S$ that attains the lower bound $area(R(S)) \geq \frac{1}{2}$. Our best lower bound construction for nontrivial instances yields $\frac{1}{2}$; see Fig. 1(c).

**Outline.** In the remainder of Section 2, we consider nontrivial instances $S \subset U$. A gap is a connected component of $U \setminus R(S)$, i.e., of the complement of the reach. Section 2.1 presents basic properties of $R(S)$ and its gaps; Section 2.2 classifies the possible gaps into five types, and Section 2.3 presents a charging scheme in which we define for every gap $C$ a region $RC \subset R(S)$ such that $area(C) \leq area(R_C)$, and the regions $R_C$ are pairwise interior-disjoint. Summation over all gaps yields $area(U \setminus R(S)) \leq \sum_C area(R_C) \leq area(R(S))$, consequently $area(R(S)) \geq \frac{1}{2} area(U) = \frac{1}{2}$.
2.1 Properties of the Reach and its Gaps

Lemma 2. For every finite set \( S \subset U \), the reach \( R(S) \) is connected.

**Proof.** Let \( S \subset U \) be a finite set, and let \( c_0 = (\frac{1}{2}, \frac{1}{2}) \) denote the center of \( U \). We show that for each \( s \in S \), there is an empty square \( Q_s \) anchored at \( s \) that contains \( c_0 \) whose boundary contains a segment \( s' \in S \) such that \( \|s' - c_0\|_\infty < \|s - c_0\|_\infty \) (i.e., \( s' \) is closer to \( c_0 \) than \( s \)). This implies that \( Q_s \) (hence \( R(S) \)) contains a line segment from \( s \) to \( c_0 \) or to \( s' \). Consequently, \( R(S) \) contains a polyline from every \( s \in S \) to \( c_0 \). By the definition of \( R(S) \), this further implies that \( R(S) \) contains a polyline between any two points in \( R(S) \).

It remains to prove the claim. Let \( s \in S \). We may assume without loss of generality that \( x(s) \leq y(s) \leq \frac{1}{2} \), hence \( \|s - c_0\|_\infty = \frac{1}{2} - x(s) \). Let \( Q_s \) be the maximal empty square whose lower-left corner is \( s \). Refer to Fig. 2(a). If \( c_0 \in Q_s \), then our proof is complete. Otherwise, the side length of \( Q_s \) is \( a_s < \frac{1}{2} - x(s) \), and there is a point \( s' \) in the right or the top side of \( Q_s \). The anchor \( s' \) lies in the interior of the \( L_\infty \)-ball of radius \( \frac{1}{2} - x(s) \) centered at \( c_0 \), hence \( \|s' - c_0\|_\infty < \|s - c_0\|_\infty \), as claimed. <br />

Lemma 3. For every point \( p \in U \setminus R(S) \), there exists a point \( r \in \partial U \) such that the line segment \( pr \) is horizontal or vertical; and \( pr \subset U \setminus R(S) \).

**Proof.** Let \( p \in U \setminus R(S) \), and let \( Q \) be the maximal empty axis-aligned square centered at \( p \). Refer to Fig. 2(b). The boundary of this square, \( \partial Q \), intersects \( S \) or \( \partial U \), otherwise \( Q \) would not be maximal.

First assume that \( \partial Q \) contains a point \( s \in S \). Without loss of generality, we may assume that \( x(p) \leq x(s) \) and \( y(p) \leq y(s) \). Since \( Q \) is empty, the maximal anchored square with upper-right corner at \( s \) contains \( p \), hence \( p \in R(S) \), contradicting our assumption that \( p \notin R(S) \).

We can now assume that \( \partial Q \) intersects \( \partial U \). Without loss of generality, \( \partial Q \cap \partial U \) lies in the bottom side of both \( Q \) and \( U \). Let \( r \in \partial Q \cap \partial U \) be a point vertically below \( p \) (see Fig. 2(c) for an example). Suppose that segment \( pr \) intersects \( R(S) \). Then some point \( x \in pr \) lies in a square \( Q' \) anchored at a point \( s \in S \). Since \( Q \) is empty, the anchor \( s \) lies outside of \( Q \), and so the side length of \( Q' \) is at least half of that of \( Q \), i.e., the side length of \( Q' \) is at least \( |pr| \). However, then \( y(s) \geq |pr| \), and the square \( Q' \) contains the segment \( pr \), contradicting our assumption that \( p \notin R(S) \). Therefore there is no such point \( x \in pr \), and \( pr \subset U \setminus R(S) \), as claimed.
Corollary 4. The reach is simply connected.

Proof. By Lemma 2, $R(S)$ is connected. Suppose that $R(S)$ is not simply connected. Then there is a gap $C \subset U \setminus R(S)$ such that $\partial C \subset R(S)$. Let $p \in \text{int}(C)$ be an arbitrary point in the interior of $C$. By Lemma 3, there is a point $r \in \partial U$ such that $pr \subset U \setminus R(S)$, which implies $r \in \partial C$, contradicting our assumption $\partial C \subset R(S)$. Therefore $R(S)$ is simply connected, as required.

2.2 Classification of Gaps

In this section we classify the possible shapes of the gaps in $U \setminus R(S)$ for nontrivial instances. To simplify our analysis, we assume that $S \subset \text{int}(U)$ and no two points in $S$ have the same $x$- or $y$-coordinates. This assumption is justified by the following lemma.

Lemma 5. If $\text{area}(R(S)) \geq \frac{1}{2}$ for every finite point set $S \subset U$ such that $S \subset \text{int}(U)$ and no two points in $S$ have the same $x$- or $y$-coordinates, then $\text{area}(R(S)) \geq \frac{1}{2}$ for every finite point set $S \subset U$.

Proof. Let $S \subset U$ be a finite point set that contains a point in $\partial U$ or two points with the same $x$- or $y$-coordinate. Let $\varepsilon_0$ be minimum positive difference between $x$- and $y$-coordinates of points in $S$. For every $\varepsilon \in (0, \varepsilon_0/2)$, translate each point in $S$ by a random vector of length at most $\varepsilon$ into $\text{int}(U)$. The resulting point set $S_\varepsilon$ lies in $\text{int}(U)$ and have distinct $x$- and $y$-coordinates with probability 1; the side length of each maximal anchored square may increase by at most $2\varepsilon$, but could decrease substantially. Consequently, $\text{area}(R(S_\varepsilon)) \leq \text{area}(R(S)) + 4\varepsilon$, hence $\lim_{\varepsilon \to 0} \text{area}(R(S_\varepsilon)) \leq \text{area}(R(S))$. ▶

We distinguish a corner gap, which is incident to a corner of $U$; and a side gap, which is adjacent to exactly one side of $U$. We show that every gap is bounded by $\partial U$ and by squares anchored at up to three points in $S$. We define five types of gaps (two types of corner gaps and three types of side gaps). Each type is defined together with an empty rectangle $B \subset U$ and 1–3 anchors on the boundary of $B$. In each case, the gap is determined by the maximal empty squares that lie entirely in $B$ and are anchored at points in $S \cap B$.

We describe each type modulo the symmetry group of $U$ (i.e., the dyhedral group $D_4$). Specifically, we restrict ourselves to corner gaps incident to the lower-left corner of $U$, and side gaps adjacent to the bottom side of $U$. Reflection in the line $x = y$ (resp., $x = \frac{1}{2}$) maintains corner gaps incident to the origin (resp., side gaps along the bottom side of $U$); and we describe only one variant modulo reflection.

1. Let $0 < c < b < 1$. If $B = [0, b] \times [0, b + c]$ is empty and $s_1 = (b, c) \in S$, then the squares anchored at $s_1$ form a corner gap $[0, b - c] \times [0, c]$. See Fig. 3(a).

![Figure 3](image-url) (a) A corner gap of type 1. (b–d) Corner gaps of type 2.
Let $0 < a < b < 1$ and $0 < c < d < 1$ such that $c < b$ and $d < b + c$. If $B = [0, b] \times [0, d]$ is empty and $s_1 = (b, c), s_2 = (a, d) \in S$, then the squares anchored at $s_1$ and $s_2$ form a corner gap $[0, b - c] \times [0, \min(c, d - a, d - b + a)] \cup [0, \min(a, b - c, b - d + c)] \times [0, d - a]$. See Fig. 3(b–d).

Let $0 < a < b < 1$ and $0 < c, d < 1$ with $\max(c, d) < b - a$. If $B = [a, b] \times [0, \min(c, d) + (b - a)]$ is empty and $s_1 = (a, c), s_2 = (b, d) \in S$, then the squares anchored at $s_1$ and $s_2$ form a side gap $[a + c, b - d] \times [0, \min(c, d)]$. See Fig. 4(a).

Let $0 < a < b < 1$ and $0 < c < d < 1$ with $b - a < d$. If $B = [a, b + d] \times [0, d]$ is empty and $s_1 = (a, c), s_2 = (b, d) \in S$, then the squares anchored at $s_1$ and $s_2$ form a side gap $[a + c, b - d + a]$ and lie in the exterior of the defining box $B$ of $C$. Consequently, $C$ is bounded by $\partial U$ and some empty squares anchored at points in $S \cap B$.

**Lemma 6.** Every gap $C$ of type 1–5 is disjoint from all empty squares that are anchored at points in $S$ and lie in the exterior of the defining box $B$ of $C$. Consequently, $C$ is bounded by $\partial U$ and some empty squares anchored at points in $S \cap B$.

**Proof.** In each of the five cases, $\partial B \cap \text{int}(U)$ is covered by empty squares anchored at the points in $S$ that define $C$. More precisely, each point in $\partial B \cap \text{int}(U)$ lies in an empty square anchored at a point in $S \cap \partial B$ blocked by some point in $S \cap \partial B$ or $\partial U \cap \partial B$. For $s_1 \in S$ lying in the exterior of $B$, let $Q_i$ be a square anchored at $s_i$. If $Q_i$ intersects $B$, then its interior intersects $\partial B \cap \text{int}(U)$, hence it intersects a square $Q_j$ anchored at some $s_j \in \partial B$ and blocked by some point $p_j \in S \cap \partial B$ or $\partial U \cap \partial B$. Since $\text{int}(Q_i)$ contains neither $s_j$ nor $p_j$, we have $Q_i \cap B \subset Q_j$, and so $Q_i$ is disjoint from the gap $C$, as claimed.

We prove the following classification result for the gaps in the full paper.

**Lemma 7.** Every gap of a nontrivial instance is of one of the five types defined above.

It is now easy to check that the following properties hold for all five types of gaps.

**Corollary 8.**

(i) Each gap is either a rectangle incident to a side of $U$, or the union of two rectangles incident to the same side of $U$ (which we call an L-shaped gap).

(ii) Every edge $uv$ of a gap is contained in either $\partial U$ or a maximal anchored rectangle. Consequently, the square built on the side $uv$ outside of the gap lies either outside of $U$ or in $R(S)$.

We say that a point $p \in \partial U$ is a lead if it is a vertex of a maximal anchored square $q^t$, and $ps_t$ is a diagonal of $q^t$. We observe that one or two vertices of a gap along $\partial U$ is a lead.
Corollary 9.
- If $C$ is a rectangular gap, then at least one endpoint of $C \cap \partial U$ is a lead,
- otherwise both endpoints of $C \cap \partial U$ are leads.

### 2.3 Charging Scheme

For every gap $C$, we define a region $R_C \subset R(S)$; and then we show that $\text{area}(R_C) \geq \text{area}(C)$ and the regions $R_C$ are pairwise interior-disjoint.

For ease of exposition, we subdivide every L-shaped side gap $C$ into two rectangles $C = C_1 \cup C_2$, then define interior-disjoint regions $R_{C_1}$ and $R_{C_2}$, and let $R_C := R_{C_1} \cup R_{C_2}$. Specifically, let $C^*$ be a set of regions that contains: (1) all corner gaps, (2) all rectangular side gaps, and (3) for each L-shaped side gap $C$, the two interior-disjoint rectangles $C_1$ and $C_2$, such that $C = C_1 \cup C_2$ and both $C_1$ and $C_2$ have a common side with $\partial U$ (see Fig. 5 for an example). By Corollary 9, at least one vertex of every rectangle in $C^*$ is a lead, and two vertices of every L-shaped corner gap in $C^*$ are leads.

We are now ready to define a region $R_C$ for each region $C \in C^*$.

- Let $C = (a, b, c, d)$ be a rectangle in $C^*$. Assume w.l.o.g. that $bc$ is contained in the bottom side of $U$, and $c$ is a lead (a symmetric construction applies if $bc$ is contained in another side of $U$ or $b$ is the only lead). Refer to Fig. 6(a). Let $\ell_1$ and $\ell_2$ be lines of slope 1 passing through $a$ and $c$, respectively. Let $p_1$ be the intersection of $\ell_1$ with the vertical line through $cd$, and let $p_2$ be the intersection of $\ell_2$ with the horizontal line through $da$. Let $z_1$ (resp., $z_2$) be the intersection point of $\ell_2$ (resp., $\ell_1$) with the line of slope $-1$ passing through $p_1$ (resp., $p_2$). Then $R_C$ is the smaller pentagon out of $(a, d, c, z_1, p_1)$ and $(a, d, c, p_2, z_2)$.

- Let $C = (a, b, c, d, e, f)$ be a L-shaped corner gap in $C^*$. Assume w.l.o.g. that $b$ is the lower-left corner of $U$. By Corollary 9, both $a$ and $c$ are leads. Refer to Fig. 6(b). Let $\ell_1$ and $\ell_2$ be lines of slope 1 passing through $a$ and $c$, respectively. Let $p_1, p_2 \in S$ be the anchors on $\ell_1$ and $\ell_2$, respectively (which exist since both $a$ and $c$ are leads). Let $z_1$ (resp., $z_2$) be the intersection point of line $\ell_2$ (resp., $\ell_1$) with the line of slope $-1$ passing through $p_1$ (resp., $p_2$). Then $R_C$ is the smaller heptagon out of $(a, f, e, d, c, z_1, p_1)$ and $(a, f, e, d, c, p_2, z_2)$.

Lemma 10. For every $C \in C^*$, we have:

- (P1) $R_C \subseteq R(S)$,
- (P2) int($R_C$) does not contain any anchors, and
- (P3) $\text{area}(C) \leq \text{area}(R_C)$.

Proof. The region $C \in C^*$ is either a gap or a rectangle within an L-shaped side gap; Fig. 6(b). Let $C^*$ be the gap that contains $C$, and $B$ the box defining the gap $C^*$. For all five types of gaps, int($B$) does not contain any anchor, and $B \setminus C^* \subset R(S)$. By Corollaries 8(ii) and 9, the points $p_1$ and $p_2$ lie in $B$. Consequently, $R_C \subset B$, hence $R_C \subset B \setminus C^*$. This confirms (P1) and (P2).

To prove (P3), we distinguish two cases. First assume that $C$ is an $x \times y$ rectangle. Let $T$ be an isosceles right triangle whose hypotenuse has length $x + y$. It is easy to check that $\text{area}(C) \leq \text{area}(T)$. Indeed, $\text{area}(T) = \frac{1}{2}(x + y)^2 = \frac{1}{2} \left( \frac{x^2}{2} + xy + \frac{y^2}{2} \right) \geq xy = \text{area}(C)$.
By definition, $R_C$ contains a triangle congruent to $T$, consequently area($C$) ≤ area($T$) ≤ area($R_C$), as claimed.

Next assume that $C \in C^*$ is an L-shaped corner gap; Fig. 6(b). Assume that $C$ is formed by three interior-disjoint axis-aligned rectangles defined by diagonals $ae$, $be$, and $ce$. Let their dimensions respectively be $x \times y$, $x \times z$, and $w \times z$. Let $T_1$ and $T_2$ be isosceles right triangles whose hypotenuses are of length $x + y$ and $w + z$, respectively. Let $T_3$ and $T_4$ be isosceles right triangles whose legs are of length $x$ and $z$, respectively. By definition, $R_C$ contains interior-disjoint triangles congruent to $T_1$, $T_2$, $T_3$, and $T_4$: the hypotenuses of the respective triangles are in the same supporting lines as $ef$, $ed$, $ap_1$, and $ep_2$ respectively. Using the same argument as in the previous case, we can show that area($T_1$) and area($T_2$) are, respectively, greater or equal than the areas of the $x \times y$ and $w \times z$ rectangles. It remains to show that area($T_3$) + area($T_4$) is greater or equal than the area of the $x \times z$ rectangle. By definition, we have area($T_3$) + area($T_4$) = $\left(\frac{x^2}{2} + \frac{z^2}{2}\right) \geq xz$ for all $x, z > 0$.

We prove that the regions $R_C$, $C \in C^*$, are pairwise interior-disjoint in the full paper.

\begin{itemize}
  \item \textbf{Lemma 11.} For every two regions $C, C' \in C^*$, $C \neq C'$, we have int($R_C$) \cap int($R_{C'}$) = \emptyset.
  \item \textbf{Theorem 12.} For every finite set $S \subset U$, we have area($R(S)$) $\geq \frac{1}{2}$, and this bound is the best possible.
\end{itemize}

\textbf{Proof.} By Lemma 5, it suffices to prove the lower bound when $S \subset \text{int}(U)$ and no two points in $S$ have the same $x$- or $y$-coordinate. For all gaps $C \subset U \setminus R(S)$, we have defined interior-disjoint regions $R_C \subset R(S)$ such that area($C$) ≤ area($R_C$). Consequently, $\sum_C \text{area}(C) \leq \sum_C \text{area}(R_C) \leq \text{area}(R(S))$, which immediately yields area($R(S)$) = $1 - \sum_C \text{area}(C) \geq 1 - \text{area}(R(S))$, and area($R(S)$) $\geq 1/2$, as claimed. This bound is the best possible: the point set $S = \{(\frac{1}{2}, 0)\}$ attains area($R(S)$) = $\frac{1}{2}$.

\section{Algorithm for Computing the Reach}

In this section, we show how to compute efficiently the reach of a given point set.

\begin{itemize}
  \item \textbf{Theorem 13.} For a set $S \subset U$ of $n$ points, $R(S)$ can be computed in $O(n \log n)$ time.
\end{itemize}
Recall that, for a set \( S = \{s_1, \ldots, s_n\} \), the reach is defined as a union of \( 4n \) squares, 
\[
R(S) = \bigcup_{i=1}^{n} \bigcup_{j=1}^{4} q_i^j,
\]
where \( q_i^1 \) is the maximal axis-aligned empty square in \( U \) whose lower-left corner is \( s_i \), and \( q_i^2, q_i^3, q_i^4 \) are defined similarly where \( s_i \) is the upper-left, upper-right, and lower-right corner, respectively. Since any two squares cross in at most two points, the \( 4n \) squares \( q_i^j \) (\( i = 1, \ldots, n \) and \( j = 1, \ldots, 4 \)) form a pseudo-circle arrangement. It is well known that the union of \( O(n) \) pseudo-circles has \( O(n) \) vertices [11]. The union of \( 4n \) axis-aligned squares can be computed by a sweep-line algorithm in \( O(n \log n) \) time [3].

We note that Bentley’s sweep-line algorithm can compute the area of the union of \( n \) axis-aligned rectangles in \( O(n \log n) \) time (without computing the union itself, which may have \( \Theta(n^2) \) complexity). Computing the volume of the union of axis-aligned hyper-rectangles in \( \mathbb{R}^d \) is known as Klee’s measure problem, and the current best algorithms [4] for \( d \geq 3 \) run in \( O(n^{d/2}) \) time in general, and in \( O(n^{(d+1)/3} \log(n)) \) time for hypercubes (see also [17]).

It remains to compute the \( 4n \) anchored maximal empty squares \( q_i^1 \). We focus on the \( n \) lower-left anchored squares \( q_i^1 \) (\( i = 1, \ldots, n \)), the other three types can be computed analogously. For every \( i = 1, \ldots, n \), the lower-left corner of \( q_i^1 \) is \( s_i \), and its left or top side contains another anchor or a point in \( \partial U \); we say that this point is the blocker of \( q_i^1 \). For each \( i \), we find a first point that may block the square \( q_i^1 \) on the left and on the top side, independently. The blocker of \( q_i^1 \) is the points closest to \( s_i \) in \( L_\infty \) norm. We continue with the details. We define two wedges with apex at the origin: Let \( W^L = \{(x, y) \in \mathbb{R}^2 : 0 < y < x\} \) and \( W^T = \{(x, y) \in \mathbb{R}^2 : 0 < x < y\} \); see Fig. 7(b–c). The Minkowski sums \( W_i^L := s_i + W^L \) and \( W_i^T := s_i + W^T \) are the translates of these wedges with apex at \( s_i \). Let \( r_i \) be a point of minimum \( x \)-coordinate in \( W_i^L \cap (S \cup \partial U) \); and let \( t_i \) be a point of minimum \( y \)-coordinate in \( W_i^T \cap (S \cup \partial U) \). Then the blocker of \( q_i^1 \) is either \( r_i \) or \( t_i \), whichever is closer to \( s_i \) in \( L_\infty \) norm.

For every \( i = 1, \ldots, n \), we find points \( r_i \) and \( t_i \), independently. Consider the points \( r_i \in W_i^R \), for \( i = 1, \ldots, n \) (the case of the points \( t_i \in W_i^T \) is analogous). We use a data structure originally developed for computing \( \Theta \)-graphs in the context of geometric spanners by Narasimhan and Smid [14, Section 4.1.2]. They developed the following dynamic data structure for \( n \) points in the plane:

**Lemma 14** ([14], Lemma 4.1.9). Let \( H \) be a nonvertical line through the origin. There is a data structure that maintains a set \( P \) of \( n \) points in the plane and supports the following queries: (i) \( \text{MINBELOW}(p) \): Given a query point \( p \in P \), compute a point with the minimum \( x \)-coordinate among all points in \( P \) that are below \( p + H \); (ii) insert a point into \( P \); (iii) delete a point from \( P \). The data structure has \( O(n) \) space, \( O(n \log n) \) preprocessing time, and \( O(\log n) \) query time.

![Figure 7](image-url)
\textbf{Corollary 15.} Given a point set \( S = \{s_i : i = 1, \ldots, n\} \subset U \), the points \( r_i \) and \( t_i \) \((i = 1, \ldots, n)\) can be computed in \( O(n \log n) \) time. Consequently, the squares \( q_i^1 \) can also be computed in \( O(n \log n) \) time.

\textbf{Proof.} Assume that \( S \) is sorted in decreasing order by their \( y \)-coordinates. We use the data structure in Lemma 14 with the line \( H : y = x \) as follows. Initially \( P = \emptyset \). For \( i = 1, \ldots, n \), we insert \( s_i \) into \( P \). If \( \text{MinBelow}(s_i) \) returns a point in \( P \), then let this be \( r_i \); otherwise let \( r_i \) be the point in the right side of \( U \) that has the same \( y \)-coordinate as \( s_i \). Since \( P \) contains all points in \( S \) whose \( y \)-coordinates are greater or equal to that of \( s_i \), if wedge \( W_i^R \) contains any anchor, then \( \text{MinBelow}(s_i) \) returns one with the minimum \( x \)-coordinate. This shows that \( r_i \) is computed correctly for all \( i = 1, \ldots, n \).

The points \( t_i \) \((i = 1, \ldots, n)\) can be computed analogously in \( O(n \log n) \) time. In \( O(1) \) additional time for each \( i = 1, \ldots, n \), we can compare \( r_i \) and \( t_i \), find the blocker of \( q_i^1 \), and determine the maximal anchored square \( q_i^1 \).

\textbf{Proof of Theorem 13.} By a repeated application of Corollary 15, we can compute all \( 4n \) anchored squares \( q_i^1 \) \((i = 1, \ldots, n; j = 1, \ldots, 4)\). As noted above, a sweep-line algorithm can compute the union \( R(S) = \bigcup_{i=1}^{n} \bigcup_{j=1}^{4} q_i^1 \) in \( O(n \log n) \) time. This completes the proof. \( \square \)

\section{NP-Hardness of Maximum-Area Anchored Square Packings}

We now prove that the maximum-area anchored square packing problem is NP-complete. We define the decision version of the problem as follows. Instead of the unit square \( U \), we ask whether there is a maximal square packing of area \( W \) with integer coordinates, we ask whether there is an anchored square packing of area \( W \).

We prove NP-hardness by a reduction from \textsc{Planar-Monotone-3SAT} (described below). For every instance of \textsc{Planar-Monotone-3SAT}, we construct an instance \( S \subset \{0, W\}^2 \). We say that an anchored empty square is \textit{forced} if every packing of area \( W^2 \) contains it. An anchor in \( S \) is \textit{forced} if it is the anchor of a forced square; otherwise it is \textit{free}. A forced square \( A \) and its anchor \( s \in S \) form a \textit{forced pair} \((A, s)\). We construct an instance in which the two instances are equivalent, we shall argue that a set of squares and anchors are forced. In an intermediate step, we assume that \( \mathcal{F} = \{(A_i, s_i) : i = 1, \ldots, f\} \) is a set of forced square-anchor pairs, and we would like to show that another square-anchor pair \((A, s)\) is also forced. Let \( P = U \setminus \bigcup_{i=1}^{f} A_i \) be the complement of the forced squares in \( \mathcal{F} \). By construction, \( P \) is an orthogonal polygon (possibly with holes). An anchor \( s \) is \textit{undecided} if there is no forced pair \((A, s)\) anchored at \( s \) in \( \mathcal{F} \) (i.e., \( s \) is either free or its forced pair is not in \( \mathcal{F} \)).

We show (Lemma 16) that the following two properties each imply that the pair \((A, s)\) is forced (given that all pairs in \( \mathcal{F} \) are forced). We define both properties for the orientations shown in Fig. 8, but they generalize to all other orientations obtained through the symmetry group of \( U \). Let \( s \in S \), and let \( A \) be a maximal empty square anchored at \( s \) such that \( \text{int}(A) \subset P \). Without loss of generality, assume that \( s \) is the upper-right corner of \( A \).

1. The lower-left corner of \( A \) is a convex vertex of \( P \) and there is no undecided anchor in the closure of the bottom and left edges of \( A \).
2. The lower-left corner of $A$ is a convex vertex of $P$, the side length of $A$ is greater than 1, and the bottom edge of $A$ is contained in $\partial P$. There is a unique undecided anchor $s' \in \partial A$ located one unit above the lower-left corner of $A$. There is no undecided anchor one unit to the right of $s$ or to the right of the lower-right corner of $A$.

Lemma 16. Given a set of forced pairs $F = \{(A_i, s_i) : i = 1 \ldots, f\}$, if a pair $(A, s)$ has properties 1 or 2, then $(A, s)$ is a forced pair.

Proof. Suppose, to the contrary, that there is a anchored square packing $Q$ of area $W^2$ that does not use the square $A$ anchored at $s$. Let $B \subseteq A$ be the unit square incident to the lower-left corner of $A$. Since all anchors have integer coordinates, every empty square containing $B$ is also contained in $A$. If a pair $(A, s)$ has property 1, apart from $A$, no such empty square has a corner at an undecided anchor and, hence, $B$ cannot be covered. If a pair $(A, s)$ has property 2, $B$ must be covered by a square anchored at its upper-left corner, which is undecided by hypothesis. Hence, $B \in Q$. Let $B'$ be a unit square with integer coordinates to the right of $B$. Then the maximal empty square in $P \setminus B$ containing $B'$ satisfies property 1, but that there is no point at its upper-right corner. In this case, $B'$ is not covered.

Theorem 17. It is NP-hard to compute the maximum area anchored square packing of a given set $S$ of $n$ anchors with integer coordinates in a square $U = [0, W]^2$.

Proof. We reduce from Planar-Monotone-3SAT which is NP-complete [5]. An instance of such problem consists of a boolean formula $\Phi$ in 3CNF with $n$ variables $\{x_1, \ldots, x_n\}$ and $m$ clauses, and a planar rectilinear drawing of the a bipartite graph of $\Phi$. The drawing given by an Planar-Monotone-3SAT instance represents variables and clauses by rectangles, and edges by vertical line segments. It has the additional property that the rectangles of variables (and only variables) intersect the line $y = 0$ and the rectangles of clauses lies in the upper (resp., lower) half-plane contain only positive (resp., negative) literals. A literal is called negative if it is the negation of a variable, and positive otherwise. We need to decide whether we can satisfy all $m$ clauses, each of which is a disjunction of three literals.

For a given instance of Planar-Monotone-3SAT, we construct an instance $S \subset [0, W]^2$ of the maximal area anchored square packing problem, and then show that the two instances are equivalent. We first modify the rectilinear graph of the Planar-Monotone-3SAT instance in the following way. Replace each rectangle by a cycle along its boundary and denote by $G$ the resulting geometric graph. Delete the left, right, and the top (resp., bottom) edges of the rectangles representing positive (resp., negative) clauses. Each clause is now represented by a horizontal segment (a path of length 2 in $G$). We designate the middle vertex of this path, which has degree 3, as a clause vertex. For each cycle in $G$ that represents a variable, delete the right vertical edges, and designate the left vertical edge as a variable edge. All remaining edges in $G$ called wires and all remaining vertices of degree 3 are called split vertices. We orient the wires such that they form directed paths from the variable edges to clause vertices. Assume that the feature size of the resulting rectilinear graph is 1 and the
side length of a minimum enclosing axis-aligned square is $k$. We set $W = 48k + 48$ and let $U = [0, W]^2$. Scale up the drawing by a factor of 48 and place it in $U$ so that every vertex is at distance at least 24 from $\partial U$.

We tile $U$ with orthogonal polygons. Every tile is congruent to one of the tiles shown in Fig. 9. We call these tiles gadgets: (a) is a filler gadget, (b–c) are wire gadgets, (d–g) are turn gadgets, (h) is a split gadget, and (i) is a clause gadget. The filler gadget is a $12 \times 12$ square, all other tiles are constructed from a $12 \times 12$ square by possibly adding or deleting $1 \times 2$ rectangular features in two or three side of the squares. In a tiling of $[0, W]^2$, each such feature matches a feature of an adjacent tile. Choose a tile for each variable that contains part of the variable edge and add the anchors shown in Fig. 9(b) (only the star contained in the $12 \times 12$ square is added). Do the same for split and clauses using the tiles shown in Fig. 9(h) and (i), respectively. Connect the gadgets as they are connected in the original drawing using wires and turns. The directions of the wires attached to split and clause gadgets are indicated by blue arrows in Fig. 9. For all remaining tiles, we use filler gadgets with one anchor. This completes the description of the instance $S \subset [0, W]^2$.

We now prove that a Planar-Monotone-3SAT instance admits a positive solution if and only if the corresponding point set $S \subset [0, W]^2$ admits an anchored square packing of area $W^2$. 
Assume that the Planar-Monotone-3SAT instance admits a positive solution. We show that the corresponding instance \( S \subset [0, W]^2 \) admits an anchored square packing of area \( W^2 \). Choose every orange square in each gadget assigning its anchor as the origin of the arrow contained in it (as shown in Fig. 9). For each of the \( n \) wire gadgets placed on variable edges, if the corresponding variable is assigned \textit{true} (resp., \textit{false}) add all blue squares assigning its anchor as the only point on its bottom (resp., top) edge. Every connected component formed by blue squares represents a path of wires. We say that a wire is \textit{positive} if it is in the upper half of \( U \) and its corresponding variable is assigned \textit{true}, or if it is in the lower half of \( U \) and its corresponding variable is assigned \textit{false}. A wire is \textit{negative} otherwise. If a wire is positive (resp., negative), assign the corner that is behind (resp., ahead of) the blue square as its anchor, considering the direction of the wire. For split gadgets connected to positive wires assign the top-left corner of the red square as its anchor. For negative wires, the red square is reached by four equal squares as shown in Fig. 10. Since there exists at least one positive wire connected to a clause vertex, there will be at least one point in a corner of the red square in the clause gadget that has not yet been assigned a square. We complete the square packing by adding such a square with a corresponding anchor. Since the anchored squares cover all gadgets, the overall area of the square packing is \( W^2 \).

Assume that the anchored square packing instance \( S \subset [0, W]^2 \) admits a positive solution (of area \( W^2 \)). Recall that \( [0, W]^2 \) is tiled with gadgets. Sort them in lexicographic order by the coordinates of their lower-left corners (i.e., the first gadget is incident to the origin). We use Lemma 16 to prove the following property for each gadget:

\[ \text{Property (i).} \] If the left and bottom boundaries are part of the perimeter of a forced polygon \( P \) and contain no free anchor relative to \( P \) except for the points shown by a star, then (i.a) every orange and blue square shown in Fig. 9 in the corresponding gadget is forced; and (i.b) if \( P' \) is the union of \( P \) and the orange and blue squares inside the gadget, then there is no free anchor relative to \( P' \) on the boundary of the gadget except for points shown by a star.

Initially, in every gadget, we can determine at least one pair of a forced square and a corresponding forced anchor using Lemma 16. Fig. 11 shows the result of recursively adding a forced square into the forced polygon, and applying Lemma 16 to another pair until there

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{forced_squares_anchors.png}
\caption{Forced squares and anchors.}
\end{figure}
are no more forced pairs in the gadget. We now show that all blue squares are forced. In each case, we can take the lower-left blue square and conclude that if the square packing covers it entirely, then it is covered by a square anchored at one of its corners. After we add this square to the forced polygon \( P \), the same argument holds for every lower-left blue square not in \( P \). Consequently, all blue squares are forced. The remaining orange squares are forced by recursively applying Lemma 16. Then, if property (i) is satisfied, every gadget satisfies (i.a) and (i.b). Property (i) is trivially satisfied for the lower-left gadget and inductively satisfied by assuming that all gadgets to the left and below satisfy (i.a) and (i.b).

We now show how to convert a square packing of area \( W^2 \) into a solution of the Planar-Monotone-3SAT instance. Wire gadgets have two points indicates by a star: one that is ahead and one behind using the direction of the wire (recall that the direction points from the variable edge to the clause). A wire gadget that does not use the star that is ahead in its direction as an anchor for one of the squares contained in it is called positive. A wire gadget is called negative otherwise. For all wire gadgets satisfying (i.a) and (i.b), if a star is not used as an anchor for a square in the gadget, then the other point marked by a star must be used as anchor in this gadget. This implies that, for a pair of adjacent wire gadgets, if the one ahead in the wire direction is positive, so is the other gadget. Now assume that one of the outputs of the split gadget satisfying (i.a) and (i.b) is connected to a positive gadget. A point in the middle of an edge of the red square in Fig. 11(h) must be used as an anchor of a blue square. Then, the only way to cover all the red area is to use a single square anchored at its upper-left corner. Therefore, the wire connected to the input of the split gadget must also be positive. Finally, assume that the red square in a clause gadget that satisfies (i.a) and (i.b) (see Fig. 11(i)) is covered. Then, it must be anchored at one of its corners. If it is anchored at the upper-left (resp., bottom-left, bottom-right) corner, then the star at the top (resp., left, bottom) of the gadget is used as an anchor of a blue square in this gadget. Therefore, it must be adjacent to a positive wire. Combining all arguments, we set a variable true if its first wire gadget (that was placed on the variable edge) is positive and false otherwise, and then this assignment will satisfy the boolean formula of the Planar-Monotone-3SAT instance.

\[\text{\Leftrightarrow}\]

5 Open Problems

We have shown that at least half of the area of the unit square \( U = [0,1]^2 \) can be reached by empty squares anchored at \( S \) for any finite set \( S \subset U \), and this bound is the best possible. We have also given the first NP-hardness proof for a packing problem over geometric objects of arbitrary sizes. Our results raise several intriguing open problems. Does our result generalize to higher dimensions, that is, is there a lower bound for the maximal volume covered by empty hypercubes anchored at a finite set of points in \([0,1]^d\) for \( d > 2\)? Axis-aligned squares are balls in \( L_\infty\)-norm: Over all finite sets \( S \) of anchors in a unit-diameter ball \( U \) in \( L_p\)-norm, \( p \geq 1 \), what is the maximum area of a packing of \( L_p\)-balls that each contain an anchor? Is there a polynomial-time algorithm for computing the minimum area lower-left anchored square packing for a given set \( S \) of \( n \) points in the unit square \([0,1]^2\)? Is it NP-hard to compute the maximum area anchored rectangle packing of a given set \( S \subset [0,1]^2 \)? For the last two problems, simple greedy strategies achieve constant-factor approximations [6], and a QPTAS is available for rectangles and a PTAS for squares [1].
