aleksandrs.belovs@lu.lv

Abstract
We study quantum algorithms working on classical probability distributions. We formulate four different models for accessing a classical probability distribution on a quantum computer, which are derived from previous work on the topic, and study their mutual relationships.

Additionally, we prove that quantum query complexity of distinguishing two probability distributions is given by their inverse Hellinger distance, which gives a quadratic improvement over classical query complexity for any pair of distributions.

The results are obtained by using the adversary method for state-generating input oracles and for distinguishing probability distributions on input strings.

Acknowledgements Most of all I would like to thank Anrás Gilyén for the suggestion to work on this problem. I am also grateful to Frédéric Magniez, Shalev Ben-David, and Anurag Anshu for useful discussions, as well as to anonymous reviewers for their comments. Part of this research was performed while at the Institute for Quantum Computing in Waterloo, Canada. I would like to thank Ashwin Nayak for hospitality.

1 Introduction

It is customary for a quantum algorithm to receive its input and produce its output in the form of a classical string of symbols, quantized in the form of an oracle. This is purely classical way to store information, and, given intrinsic quantum nature of quantum algorithms, this might be not the best interface for many tasks. Moreover, even classical algorithms make use of other interfaces as well. For instance, classical algorithms can receive and produce samples from some probability distribution. In this paper we study quantum algorithms working with classical probability distributions.

1.1 Models

We analyse previously used models of accessing classical probability distributions by quantum algorithms. We prove and conjecture some relations between them. We give more detail in Section 3, but for now let us very briefly introduce the models.

In one of the models, used in, e.g., [16, 18, 27, 25], the probability distribution is encoded as a frequency of a symbol in a given input string, which the quantum algorithm accesses via the standard input oracle. In another model, e.g., [17, 2, 6], the input probability distribution
Quantum Algorithms for Classical Probability Distributions

is given through a quantum oracle that prepares a state in the form \( \sum_{a} \sqrt{p_a} |a\rangle \). Finally, one more model, used in [26, 20, 19], is similar but with additional state tensored with each \( |a\rangle \).

This is the latter model that we champion in this paper. We find this model particularly relevant because of our belief that an input oracle should be easily interchangeable with a quantum subroutine, see discussion in [26]. It is relatively easy to see what it means for a quantum algorithm to output a probability distribution: just measure one of the registers of its final state. The latter model precisely encompasses all such subroutines. We conjecture that this model is equivalent to the first model, see also [19], where a similar conjecture is made.

1.2 Distinguishing two Probability Distributions

Additionally, we study the problem of distinguishing two probability distributions. This might be the most fundamental problem one can formulate in these settings. Given two fixed probability distributions \( p \) and \( q \), and given an input oracle encoding one of them, the task is to detect which one, \( p \) or \( q \), the oracle encodes. To the best of our knowledge, this particular problem has not been studied in quantum settings, although similar problems of testing the distance between two distributions [16] and testing whether the input distribution is equal to some fixed distribution [18] have been already studied.

Classically one needs \( \Theta(1/ d_{H}(p, q)^2) \) samples to solve this problem for any \( p \) and \( q \), where \( d_{H} \) stands for Hellinger distance. This result is considered “folklore”, see, e.g. [7, Chapter 4]. We prove that for any \( p \) and \( q \) and for any of the models of access described above, query complexity of this problem is \( \Theta(1/ d_{H}(p, q)) \). This constitutes quadratic improvement over classical algorithm for any pair of distributions \( p \) and \( q \). Moreover, our algorithm also admits a simple low-level implementation, which is efficient assuming the distributions \( p \) and \( q \) can be efficiently processed.

1.3 Techniques

Our main technical tool for proving the upper bound is the version of the adversary bound for state-generating oracles, which is a special case of the adversary bound for general input oracles [11]. It is stated in the form of a relative \( \gamma_2 \)-norm and generalises the dual formulation of the general adversary bound [28, 29] for function evaluation, as well as for other problems [5, 24]. The dual adversary bound has been used rather successfully in construction of quantum algorithms, as in terms of span programs and learning graphs [9, 23, 13, 8, 22], as in an unrelated fashion [10, 4]. Our work gives yet another application of these techniques for construction of quantum algorithms.

Our upper bound naturally follows from the analysis of the \( \gamma_2 \)-norm optimisation problem associated with the task. We also compare our techniques with more standard ones involving quantum rejection sampling and amplitude amplification in the spirit of [20] and show that our techniques give a slightly better result.

As for the lower bound, we make use of the version of the adversary bound from [12]. This is a simple generalisation of the primal version of the general adversary bound [21] for function evaluation, and it is tailored for the task we are interested in: distinguishing two probability distributions on input strings. Our lower bound is surprisingly simple and gives a very intuitive justification of the significance of Hellinger distance for this problem.
2 Preliminaries

We mostly use standard linear-algebraic notation. We use ket-notation for vectors representing quantum states, but generally avoid it. We use $A^*$ to denote conjugate operators (transposed and complex-conjugated matrices). For $P$ a predicate, we use $1_P$ to denote 1 if $P$ is true, and 0 if $P$ is false. We use $[n]$ to denote the set $\{1, 2, \ldots, n\}$.

It is unfortunate that the same piece of notation, $\oplus$, is used both for direct sum of matrices and direct sum of vectors, which is in conflict with each other if a vector, as it often does, gets interpreted as a column-matrix. Since we will extensively use both these operations in this paper, let us agree that $\boxplus$ denotes direct sum of vectors, and $\oplus$ always denotes direct sum of matrices. Thus, in particular, for $u, v \in \mathbb{R}^m$, we have

$$u \boxplus v = \begin{pmatrix} u_1 \\ \vdots \\ u_m \\ v_1 \\ \vdots \\ v_m \end{pmatrix} \quad \text{and} \quad u \oplus v = \begin{pmatrix} u_1 & 0 \\ \vdots & \vdots \\ u_m & 0 \\ 0 & v_1 \\ \vdots & \vdots \\ 0 & v_m \end{pmatrix}.$$}

We often treat scalars as $1 \times 1$-matrices which may be also thought as vectors.

2.1 Relative $\gamma_2$-norm

In this section, we state the relative $\gamma_2$-norm and formulate some of its basic properties. All the results are from [11].

**Definition 1 (Relative $\gamma_2$-norm).** Let $X_1, X_2, Z_1$ and $Z_2$ be vector spaces, and $D_1$ and $D_2$ be some sets of labels. Let $A = \{A_{xy}\}$ and $\Delta = \{\Delta_{xy}\}$, where $x \in D_1$ and $y \in D_2$, be two families of linear operators: $A_{xy} : Z_2 \to Z_1$ and $\Delta_{xy} : X_2 \to X_1$. The relative $\gamma_2$-norm,

$$\gamma_2(A|\Delta) = \gamma_2(A_{xy} | \Delta_{xy})_{x \in D_1, y \in D_2},$$

is defined as the optimal value of the following optimisation problem, where $\Upsilon_x$ and $\Phi_y$ are linear operators,

$$\begin{align*}
\text{minimise} & \quad \max \left\{ \max_{x \in D_1} \| \Upsilon_x \|^2, \max_{y \in D_2} \| \Phi_y \|^2 \right\} \\
\text{subject to} & \quad A_{xy} = \Upsilon_x^*(\Delta_{xy} \otimes I_W) \Phi_y \quad \text{for all } x \in D_1 \text{ and } y \in D_2; \\
& \quad W \text{ is a vector space, } \quad \Upsilon_x : Z_1 \to X_1 \otimes W, \quad \Phi_y : Z_2 \to X_2 \otimes W. 
\end{align*}$$

(1a) (1b) (1c)

This is a generalisation of the usual $\gamma_2$-norm, also known as Schur (Hadamard) product operator norm [14].

In a quantum algorithm with general input oracles, the input oracle performs some unitary operation $O$ on some fixed Hilbert space. The algorithm can execute either $O$ or its inverse $O^{-1}$ on some register. Each execution counts as one query. It is known that $O$ is equal to one $O_x$ out of a set of possible input unitaries, where $x$ ranges over some set $D$ of labels. If $O = O_x$, the algorithm has to perform a unitary $V_x$ on some specified part of its work-space. The algorithm knows in advance all possible $O_x$ and which $V_x$ corresponds to each $O_x$, but it does not know which $O_x$ it is given in a specific execution. The adversary bound corresponding to this problem is $\gamma_2(V_x - V_y | O_x - O_y)_{x, y \in D}$. This bound is semi-tight: it is a lower bound on the exact version of the problem and an upper bound on the approximate version.
The $\gamma_2$-norm formalism is modular in the sense that the general task of implementing a unitary can be replaced by something more specific. For instance, assume that our task is to evaluate a function $f(x)$. Then the adversary bound reads as $\gamma_2(1_{f(x)\neq f(y)} | O_x - O_y)_{x,y\in D}$. In this case, the bound is tight: it is also a lower bound on the approximate version of the problem.

As another example, consider the standard input oracle $O_x$ encoding a string $x \in [q]^n$. It works as $O_x: |i\rangle |0\rangle \mapsto |i\rangle |x_i\rangle$, which can be seen as a direct sum of oracles performing transformation $|0\rangle \mapsto |x_i\rangle$. Using the modular approach, the corresponding adversary bound becomes $\gamma_2^2(1_{f(x)\neq f(y)} | \bigoplus_j 1_{x_j\neq y_j})_{x,y\in D^2}$, where $\bigoplus$ stands for direct sum of matrices (resulting in a diagonal matrix). This is equivalent to the usual version of dual adversary for function evaluation (up to a constant factor).

Now we consider state-generating input oracles. This is the version we will use further in the paper. Assume that $c_0 = |0\rangle$ is orthogonal to $\mathbb{C}^m$, thus the operator $O$ above works in $\mathbb{C}^{m+1}$.

The corresponding $\gamma_2$-object can be defined in two alternative ways:

$$L_\psi = \psi e_0^* + c_0 \psi^* \quad \text{or} \quad L_\psi = \psi \oplus \psi^*.$$  

In the second expression, $\psi$ is an $m \times 1$-matrix and $\psi^*$ is a $1 \times m$-matrix, the resulting matrix being of size $(m + 1) \times (m + 1)$. In the case of a function-evaluation problem, the corresponding adversary bound is $\gamma_2^2(1_{f(x)\neq f(y)} | L_{\psi_x} - L_{\psi_y})_{x,y\in D}$.

Let us also state the version of the adversary bound for the decision problem with state-generating input oracles. This is the version we will use further in the paper. Assume we have a collection of states $\psi_x \in \mathcal{X}$ for $x \in D_0$, and a collection of states $\psi_y \in \mathcal{X}$ for $y \in D_1$. The task is to distinguish the two classes of states. Let $D = D_0 \cup D_1$. Using the general case, we obtain the following version of the adversary bound.

**Theorem 2.** The quantum query complexity of the decision problem with state-generating oracles as above is equal to $\gamma_2(1 | L_{\psi_x} - L_{\psi_y})_{x\in D_0, y\in D_1}$ up to a constant factor.

An explicit optimisation problem for $\gamma_2^2(1 | L_{\psi_x} - L_{\psi_y})_{x\in D_0, y\in D_1}$ is given by

$$\begin{align*}
\text{minimise} & \quad \max_{x\in D} \left(\|u_x\|^2 + \|v_x\|^2\right) \\
\text{subject to} & \quad \langle v_z, (\psi_x - \psi_y) \otimes u_y \rangle + \langle (\psi_x - \psi_y) \otimes u_x, v_y \rangle = 1 \quad \forall x \in D_0, y \in D_1; \\
& \quad u_z \in W, \quad v_z \in \mathcal{X} \otimes W \quad \forall z \in D.
\end{align*}$$

This result follows from general results of [11], see the full version of the paper, where we also give a stand-alone implementation and analysis of the corresponding quantum algorithm.

### 3 Models

In this section we formally define four different models how a quantum algorithm can access a classical probability distribution $p = (p_a)_{a \in A}$. These models were briefly explained in the introduction. We would like to understand relations between them, and, ideally, prove some equivalences between them.

---

A standard input oracle encoding a string $x \in A^n$ for some relatively large $n$, where $p_a$ is given as the frequency of $a$ in $x$:

$$p_a = \frac{1}{n} \left| \{i \mid x_i = a \} \right|.$$ 

A standard input oracle encoding a string $x \in A^n$ for some relatively large $n$, where each $x_i$ is drawn independently at random from $p$.

A quantum procedure that generates the state

$$\mu_p = \sum_a \sqrt{p_a} |a\rangle \otimes |\psi_a\rangle,$$ (3)

where $\psi_a$ are arbitrary unit vectors.

A quantum procedure that generates a state of the form

$$\sum_a \sqrt{p_a} |a\rangle|\psi_a\rangle = \sum_a \sqrt{p_a} \psi_a,$$ (4)

As mentioned in the introduction, model (i) is used in [16, 18, 27, 25]. It has a downside that the probabilities $p_a$ must be multiples of $1/n$. All other models are free from this assumption.

Model (ii) seems like the most obvious way to encode probability distribution as a classical string, which a quantum algorithm can later gain access to. Up to our knowledge, this model has not been previously used. It has a downside that the distribution $p$ is encoded as a probability distribution over possible input strings, which is not usual for quantum algorithms. The acceptance probability of the quantum algorithm depends both on the randomness introduced by the algorithm and the randomness in the input.

Model (iii) is the one used in [17, 2, 6]. And model (iv) is used in [26, 20, 19]. Both of these two models assume that the input oracle prepares a quantum state, which again is not very common for quantum algorithms.

▶ Proposition 3. We have the following relations between these models.

(a) Models (i) and (ii) are equivalent assuming $n$ is large enough. More precisely, no quantum algorithm can distinguish models (i) and (ii) encoding the same probability distribution unless it makes $\Omega(n^{1/3})$ queries.

(b) Model (iv) is more general than model (i). This means that any algorithm working in model (iv) can be turned into an algorithm working in model (i) with the same query complexity.

(c) Model (iv) is strictly more general than model (iii). This means there exist problems where model (iii) allows substantially smaller query complexity than model (iv).

Proof. We leave (a) for the end of the proof, and let us start with (b). Note that using one query to the input oracle of model (i), it is possible to prepare that state

$$\frac{1}{\sqrt{n}} \sum_i |i\rangle |x_i\rangle = \sum_{a \in A} \left[ \frac{1}{\sqrt{n}} \sum_i |i\rangle \right] \otimes |a\rangle,$$ 

which is a legitimate input state in model (iv) if one swaps the registers.

Now let us prove (c). It is obvious that model (iv) is more general than model (iii). To prove that (iii) cannot simulate (iv), consider the collision problem [15]. In this problem, a function $f : [n] \to [n]$ is given, and one has to distinguish whether $f$ is 1-to-1 or 2-to-1. In terms of model (i), this boils down to distinguishing a probability distribution $p$ which is uniform on $[n]$ from a probability distribution $q$ which is uniform on half of $[n]$. 

![Image]
In model (iii), this problem can be solved in $O(1)$ queries because the state $\mu_p$ as in (3) has inner product $1/\sqrt{2}$ with all $\mu_q$. On the other hand, by [1, 3], quantum query complexity of this problem in model (i) is $\Omega(n^{1/3})$. As model (iv) is more general than model (i), this gives the required lower bound.

To prove (a), we show that if one can distinguish models (i) and (ii), one can distinguish a random function from a random permutation, and the result follows from the lower bound of $\Omega(n^{1/3})$ for this task from [30]. Indeed, let $p$ be a probability distribution and let $y$ be a fixed string encoding $p$ as in model (i). Let $\sigma: [n] \to [n]$ be a function, and consider the input string $x$ given by $x_i = y_{\sigma(i)}$, which can be simulated given oracle access to $\sigma$ (as the string $y$ is fixed). If $\sigma$ is a random permutation, then $x$ is a uniformly random input string from model (i). If $\sigma$ is a random function, then $x$ is distributed as in model (ii).

## 4 Distinguishing Two Probability Distributions

Recall the definition of Hellinger distance between two probability distributions $p$ and $q$ on the same space $A$:

$$d_H(p, q) = \sqrt{\frac{1}{2} \sum_{a \in A} (\sqrt{p_a} - \sqrt{q_a})^2}.$$ 

Up to a constant factor, it equals $\|\mu_p - \mu_q\|$ and $1 - \langle \mu_p, \mu_q \rangle$, where $\mu_p$ and $\mu_q$ are as in (3).

In this section, we prove the following result:

▶ **Theorem 4.** For any two probability distributions $p$ and $q$ on the same space $A$, and any model of accessing them from Section 3, the quantum query complexity of distinguishing $p$ and $q$ is

$$\Theta\left(\frac{1}{d_H(p, q)}\right).$$

Note that this is quadratically better than complexity of the best classical algorithm for every choice of $p$ and $q$. Note also that for this problem model (iii) is equal in strength to the remaining models.

The proof of main involves proving lower and upper bounds in all four models, but, luckily, we can use relations from Proposition 3. The outline of the proof is as follows. We prove upper bound in model (iv), which implies upper bounds in all other models as model (iv) is the most general of them. As for the lower bounds, we prove it for model (ii), which implies lower bounds in models (i) and (iv). For model (iii), we prove the lower bound independently. As a bonus, we prove an upper bound in model (iii) as a warm-up for the upper bound in model (iv).

In most of the proofs, we will use $\alpha$ for the angle between the vectors $\mu_p$ and $\mu_q$. Note that

$$\alpha = \Theta(\|\mu_p - \mu_q\|) = \Theta(d_H(p, q)).$$
4.1 Analysis in Model (iii)

In this section, we analyse the problem in model (iii).

\[ \text{Claim 5.} \text{ Quantum query complexity of distinguishing probability distributions } p \text{ and } q \text{ in model (iii) is } \Theta(1/d_H(p, q)). \]

**Proof.** Let us start with the upper bound. Let \( O \) be the input oracle, and let \( U \) be a unitary that maps \( |\mu_p\rangle \) into \( |0\rangle \) and \( |\mu_q\rangle \) into \( \cos \alpha |0\rangle + \sin \alpha |1\rangle \). Now use quantum amplitude amplification on the unitary \( UO \) amplifying for the value \( |1\rangle \). The algorithm can be also made exact using exact quantum amplitude amplification.

Now let us prove the lower bound. Let \( O_p \) be the input oracle exchanging \( |0\rangle \) and \( |\mu_p\rangle \) and \( O_q \) exchange \( |0\rangle \) and \( |\mu_q\rangle \). Simple linear algebra shows \( ||O_p - O_q|| = O(\alpha) \). Let \( A^O \) be a query algorithm making \( t \) queries to \( O \) and distinguishing \( O_p \) from \( O_q \). Then,

\[ ||A^{O_p} - A^{O_q}|| \leq t||O_p - O_q|| = O(t\alpha). \]

As this must be \( \Omega(1) \), we get that \( t = \Omega(1/\alpha) \).

4.2 Upper Bound in Model (iv)

The aim of this section is to prove the following claim.

\[ \text{Claim 6.} \text{ Quantum query complexity of distinguishing probability distributions } p \text{ and } q \text{ in model (iv) is } O(1/d_H(p, q)). \]

We prove this claim by constructing a feasible solution to (2). In the full version of the paper, we explain how to implement this algorithm time-efficiently and give a comparison to an algorithm using more typical techniques.

Let \( \psi \) and \( \phi \) be some vectors encoding \( p \) and \( q \), respectively, as in model (iv). That is,

\[ \psi = \sum_a \sqrt{p_a} \psi_a, \quad \text{and} \quad \phi = \sum_a \sqrt{q_a} \phi_a, \]

where \( \psi_a \) and \( \phi_a \) are some normalised vectors. Our goal is to come up with a feasible solution to (2) with \( \psi \) and \( \phi \) replaced by \( \psi \) and \( \phi \).

We first analyse a pair of vectors \( \sqrt{p_a}\psi_a \) and \( \sqrt{q_a}\phi_a \) for a fixed \( a \). We would like to get a construction in the spirit of (2) that “erases” directions \( \psi_a \) and \( \phi_a \), and only depends on the norms \( \sqrt{p_a} \) and \( \sqrt{q_a} \). One way is to use the following identity:

\[ \left\langle \sqrt{p_a}\psi_a, \sqrt{q_a}\phi_a - \sqrt{q_a}\phi_a \right\rangle + \left\langle \sqrt{p_a}\psi_a - \sqrt{q_a}\phi_a, \sqrt{q_a}\phi_a \right\rangle = p_a - q_a. \tag{5} \]

We combine this identity over all \( a \), add weights \( c_a \), and re-normalise:

\[ \left\langle \sum_a c_a \sqrt{p_a} \psi_a, (\psi - \phi) \cdot \sqrt{\sum_a c_a^2 p_a} \right\rangle + \left\langle (\psi - \phi) \cdot \sqrt{\sum_a c_a^2 q_a}, \sum_a c_a \sqrt{q_a} \phi_a \right\rangle = \sum_a c_a (p_a - q_a), \]

which gives

\[ \gamma_2 \left( \sum_a c_a (p_a - q_a) \right) I_{\psi} - I_{\phi} \leq \sqrt{\sum_a c_a^2 p_a} + \sqrt{\sum_a c_a^2 q_a}. \]
Dividing by \( \sum_a c_a(p_a - q_a) \), we get that complexity of distinguishing \( p \) from \( q \) is at most
\[
O \left( \frac{\sqrt{\sum_a c_a^2 p_a} + \sqrt{\sum_a c_a^2 q_a}}{\sum_a c_a(p_a - q_a)} \right) .
\]
(6)

Using triangle inequality
\[
\sum_a c_a^2 (\sqrt{p_a} + \sqrt{q_a})^2 \leq \sqrt{\sum_a c_a^2 p_a} + \sqrt{\sum_a c_a^2 q_a} \leq 2 \sqrt{\sum_a c_a^2 (\sqrt{p_a} + \sqrt{q_a})^2},
\]
so (6) is equivalent to
\[
O \left( \frac{\sum_a c_a^2 (\sqrt{p_a} + \sqrt{q_a})^2}{\sum_a c_a(p_a - q_a)} \right) .
\]

Now it is easy to see that it is minimised to
\[
O \left( \frac{1}{\sqrt{\sum_a (\sqrt{p_a} - \sqrt{q_a})^2}} \right) = O \left( \frac{1}{d_H(p,q)} \right)
\]
when \( c_a = (\sqrt{p_a} - \sqrt{q_a})/(\sqrt{p_a} + \sqrt{q_a}) \).

### 4.3 Lower Bound in Model (ii)

We use the following version of the adversary lower bound from [12].

**Theorem 7.** Assume \( A \) is a quantum algorithm that makes \( T \) queries to the input string \( x = (x_1, \ldots, x_n) \in D \), with \( D = A^n \), and then either accepts or rejects. Let \( P \) and \( Q \) be two probability distributions on \( D \), and \( p_x \) and \( q_y \) denote probabilities of \( x \) and \( y \) in \( P \) and \( Q \), respectively. Let \( s_P \) and \( s_Q \) be acceptance probability of \( A \) when \( x \) is sampled from \( P \) and \( Q \), respectively. Then,
\[
T = \Omega \left( \min_{j \in [n]} \frac{\delta_P \Gamma \delta_Q - \tau(s_P, s_Q) \| \Gamma \|}{\| \Gamma \circ \Delta_j \|} \right),
\]
(7)

for any \( D \times D \) matrix \( \Gamma \) with real entries. Here, \( \delta_P [x] = \sqrt{p_x} \) and \( \delta_Q [y] = \sqrt{q_y} \) are unit vectors in \( \mathbb{R}^D \); for \( j \in [n] \), the \( D \times D \) matrix \( \Delta_j \) is defined by \( \Delta_j [x,y] = 1_{x,y} = y \neq y_j \); and
\[
\tau(s_P, s_Q) = \sqrt{s_p s_Q} + \sqrt{(1 - s_p)(1 - s_Q)} \leq 1 - \frac{|s_P - s_Q|^2}{8}.
\]
(8)

In our case, \( \delta_P = \mu_p^\otimes n \) and \( \delta_Q = \mu_q^\otimes n \). We construct \( \Gamma \) as a tensor power \( G^\otimes n \), where \( G \) is an \( A \times A \) matrix satisfying
\[
G \mu_q = \mu_p, \quad \| G \| = 1, \quad \text{and} \quad \| G \circ \Delta \| \text{ is as small as possible,}
\]
where \( \Delta \) is the \( A \times A \) matrix given by \( A[a,b] = 1_{a 
eq b} \). Then,
\[
\delta_P \Gamma \delta_Q = \| \Gamma \| = 1, \quad \text{and} \quad \| \Gamma \circ \Delta_j \| = \| G \circ \Delta \|,
\]
and \( \text{adv} \) gives the lower bound of \( \Omega(1/\| G \circ \Delta \|) \).
We construct $G$ as follows. Recall that $\alpha$ is the angle between $\mu_q$ and $\mu_p$. Then, $G$ is rotation by the angle $\alpha$ in the plane spanned by $\mu_q$ and $\mu_p$ and homothety with coefficient $\cos \alpha$ on its orthogonal complement. That is, in an orthonormal basis where the first two vectors span the plane of $\mu_q$ and $\mu_p$, we have

$$G = \begin{pmatrix}
\cos \alpha & -\sin \alpha & 0 & \cdots & 0 \\
\sin \alpha & \cos \alpha & 0 & \cdots & 0 \\
0 & 0 & \cos \alpha & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & \cos \alpha
\end{pmatrix}.$$ 

Clearly, $G \mu_q = \mu_p$ and $\|G\| = 1$. Let $G' = G - \cos \alpha I$. We have

$$\|G \circ \Delta\| = \|G' \circ \Delta\| \leq 2\|G'\| = 2\sin \alpha = O(d_H(p, q)).$$

For the inequality we used that $\gamma_2(\Delta) \leq 2$, see [24, Theorem 3.4]. This gives the required lower bound.

5 Summary and Future Work

In this paper we considered quantum algorithms dealing with classical probability distributions. We identified four different models, and proved various relations between them. We conjecture that models (i), (ii) and (iv) are equivalent.

Also, we considered the problem of distinguishing two probability distributions and obtained precise characterisation of its quantum query complexity in all four models in terms of Hellinger distance between the probability distributions. The complexity turned out to be exactly quadratically smaller than the classical complexity of this problem for all pairs of distributions.

We showed that the corresponding algorithm can be implemented efficiently given that the probability distributions $p$ and $q$ can be handled efficiently. We also compared our algorithm with a more standard approach using rejection sampling and amplitude estimation.

This raises a number of interesting open problems. The first one is to prove or disprove the conjecture that models (i) and (iv) are equivalent. Another interesting problem is to come up with a nice $\gamma_2$-characterisation of probability distribution oracles like gamma2StatePreparing characterises state-generating oracles. Unfortunately, we do not have any hypothesis of how this characterisation might look like. Finally, we would be interested in further quantum algorithms based on techniques of Section 4.2.
