Abstract
We consider the $k$-Median problem on planar graphs: given an edge-weighted planar graph $G$, a set of clients $C \subseteq V(G)$, a set of facilities $F \subseteq V(G)$, and an integer parameter $k$, the task is to find a set of at most $k$ facilities whose opening minimizes the total connection cost of clients, where each client contributes to the cost with the distance to the closest open facility. We give two new approximation schemes for this problem:

- **FPT Approximation Scheme**: for any $\varepsilon > 0$, in time $2^{O\left(\frac{k}{\varepsilon} \log\left(\frac{k}{\varepsilon} - 1\right)\right)} \cdot n^{O(1)}$ we can compute a solution that has connection cost at most $(1 + \varepsilon)$ times the optimum, with high probability.

- **Efficient Bicriteria Approximation Scheme**: for any $\varepsilon > 0$, in time $2^{O\left(\frac{\varepsilon}{\log(\varepsilon - 1)}\right)} \cdot n^{O(1)}$ we can compute a set of at most $(1 + \varepsilon)k$ facilities whose opening yields connection cost at most $(1 + \varepsilon)$ times the optimum connection cost for opening at most $k$ facilities, with high probability.

As a direct corollary of the second result we obtain an EPTAS for Uniform Facility Location on planar graphs, with same running time.

Our main technical tool is a new construction of a “coreset for facilities” for $k$-Median in planar graphs: we show that in polynomial time one can compute a subset of facilities $F_0 \subseteq F$ of size $k \cdot (\log n/\varepsilon)^{O(\varepsilon^{-3})}$ with a guarantee that there is a $(1 + \varepsilon)$-approximate solution contained in $F_0$.

1 Introduction

We study approximation schemes for classic clustering objectives, formalized as follows. Given an edge-weighted graph $G$ together with a set $C$ of vertices called clients, a set $F$ of vertices called candidate facilities, and an opening cost open $\in \mathbb{R}_{\geq 0}$, the Uniform Facility Location problem asks for a subset of facilities (also called centers) $D \subseteq F$ that minimizes
the cost defined as $|D| \cdot \text{open} + \sum_{c \in C} \min_{f \in D} \text{dist}(c, f)$. In the Non-uniform Facility Location variant, the opening costs may vary between facilities.

We also consider the related $k$-Median problem, where the tuple $(G, F, C)$ comes with a hard budget $k$ for the number of open facilities (as opposed to the opening cost open). That is, the problem asks for a set $D \subseteq F$ of size at most $k$ that minimizes the connection cost $\sum_{c \in C} \text{dist}(c, D)$. Note that Uniform Facility Location can be reduced to $k$-Median by guessing the number of open facilities in an optimal solution.

Facility Location and $k$-Median model in an abstract way various clustering objectives appearing in applications. Therefore, designing approximation algorithms for them and their variants is a vibrant topic in the field of approximation algorithms. For Non-uniform Facility Location, a long line of work [1, 15, 22, 16] culminated with the 1.488-approximation algorithm by Li [18]. On the other hand, Guha and Khuller [13] showed that the problem cannot be approximated in polynomial time within factor better than 1.463 unless $\text{NP} \subseteq \text{DTIME}[n^{O((\log \log n) \cdot \log \log n)}]$, which gives almost tight bounds on the best approximation factor achievable in polynomial time. For $k$-Median, the best known approximation ratio achievable in polynomial time is 2.67 due to Byrka et al. [3], while the lower bound of 1.463 due to Guha and Khuller [13] holds here as well.

Given the approximation hardness status presented above, it is natural to consider restricted metrics. In this work we consider planar metrics: we assume that the underlying edge-weighted graph $G$ is planar.

It was a long-standing open problem whether Facility Location admits a polynomial-time approximation scheme (PTAS) in planar metrics. For the uniform case, this question has been resolved in affirmative by Cohen-Addad et al. [8] in an elegant way: they showed that local search of radius $O(1/\varepsilon^2)$ actually yields a $(1 + \varepsilon)$-approximation, giving a PTAS with running time $n^{O(1/\varepsilon^2)}$. This approach also gives a PTAS for $k$-Median with a similar running time, and works even in metrics induced by graphs from any fixed proper minor-closed class.

Very recently, Cohen-Addad et al. [9] also gave a PTAS for Non-uniform Facility Location in planar metrics using a different approach. Roughly, the idea is to first apply Baker layering scheme to reduce the problem to the case when in all clusters (sets of clients connected to the same facility) in the solution, all clients are within distance between 1 and $r$ from the center, for some constant $r$ depending only on $\varepsilon$. This case is then resolved by another application of Baker layering scheme, followed by a dynamic programming on a hierarchichal decomposition of the graph using shortest paths as balanced separators.

Both the schemes of [8] and of [9] are PTASes: they run in time $n^{g(\varepsilon)}$ for some function $g$. It is therefore natural to ask for an efficient PTAS (EPTAS): an approximation scheme with running time $f(\varepsilon) \cdot n^{O(1)}$ for some function $f$. Such an EPTAS was given by Cohen-Addad [5] for $k$-Means in low-dimensional Euclidean spaces; this is a variant of $k$-Median where every client contributes to the connection cost with the square of its distance from the closest open facility. Here, the idea is to apply local search as in [8], but to use the properties of the metric to explore the local neighborhood faster. Unfortunately, this technique mainly relies on the Euclidean structure (or on the bounded doubling dimension of the input) and seems hard to lift to the general planar case. Also the techniques of [9] are far from yielding an EPTAS: essentially, one needs to use a logarithmic number of portals at every step of the final dynamic programming in order to tame the accumulation of error through log $n$ levels of the decomposition. Recently, a near-linear time EPTAS was given by Cohen-Addad et al. [6] for $k$-median, $k$-means and non-uniform facility location where the input points lie in a metric of bounded doubling dimension. This result is obtained using a randomized dissection of the metric, a technique that is not available for planar inputs.

The goal of this work is to circumvent these difficulties and give an EPTAS for Uniform Facility Location in planar metrics.
Our results. Our main technical contribution is the following theorem. In essence, it states that when solving $k$-Median on a planar graph one can restrict the facility set to a subset of size $k \cdot (\varepsilon^{-1} \log n)^{O(\varepsilon^{-3})}$, at the cost of losing a multiplicative factor of $(1 + \varepsilon)$ on the optimum connection cost. This can be seen as the planar version of the classic result by Matoušek [20] who showed that for Euclidean metrics of dimension $d$, it is possible to reduce the number of candidate centers to $\text{poly}(k)\varepsilon^{-O(d)}$ at the cost of losing a multiplicative factor of $(1 + \varepsilon)$ on the optimum connection cost (through the use of coresets as well). For general metrics, obtaining such a result seems challenging, since this would imply a $(1 + \varepsilon)$-approximation algorithm with running time $f(k, \varepsilon)n^{O(1)}$, which would contradict Gap-ETH [7].

From now on, by with constant probability we mean with probability at least $1/2$; this can be boosted by independent repetition.

**Theorem 1.** Given a $k$-Median instance $(G, F, C, k)$, where $G$ is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized polynomial time compute a set $F_0 \subseteq F$ of size $k \cdot (\varepsilon^{-1} \log n)^{O(\varepsilon^{-3})}$ satisfying the following condition with constant probability: there exists a set $D_0 \subseteq F_0$ of size at most $k$ such that for every set $D \subseteq F$ of size at most $k$ it holds that $\sum_{u \in C} \min_{c \in D_0} \text{dist}(u, c) \leq (1 + \varepsilon) \sum_{u \in C} \min_{c \in D} \text{dist}(u, c)$.

A direct corollary of Theorem 1 is a fixed-parameter approximation scheme for the $k$-Median problem in planar graphs. This continues the line of work on fixed-parameter approximation schemes for $k$-median and $k$-means in Euclidean spaces [12, 17], where the goal is to design an algorithm running in time $f(k, \varepsilon) \cdot n^{O(1)}$ for a computable function $f$.

**Corollary 2.** Given a $k$-Median instance $(G, F, C, k)$, where $G$ is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized time $2^{O(k\varepsilon^{-3} \log (k\varepsilon^{-1}))} \cdot n^{O(1)}$ compute a solution $D \subseteq F$ that has connection cost at most $(1 + \varepsilon)$ times the minimum possible connection cost with constant probability.

**Proof.** Apply the algorithm of Theorem 1 and let $F_0 \subseteq F$ be the obtained subset of facilities. Then run a brute-force search through all subsets of $F_0$ of size at most $k$ and output one with the smallest connection cost. Thus, the running time is

\[
(k \cdot (\varepsilon^{-1} \log n)^{O(\varepsilon^{-3})})^k \cdot n^{O(1)} \leq 2^{O(k\varepsilon^{-3} \log (k\varepsilon^{-1}))} \cdot (\log n)^{O(k \varepsilon^{-3})} \cdot n^{O(1)}
\]

which is at most $2^{O(k\varepsilon^{-3} \log (k\varepsilon^{-1}))} \cdot n^{O(1)}$ since $(\log n)^d \leq 2^{O(d \log d)} \cdot n^{O(1)}$: if $n \leq 2^d$ then $(\log n)^d \leq d^d \leq 2^{O(d \log d)}$, and if $n > 2^d$ then $(\log n)^d \leq 2 \sqrt{\log n \log \log n} \leq n^{O(1)}$.

Using Theorem 1 we can also give an efficient bicriteria PTAS for $k$-Median in planar graphs. This time, the proof is more involved and uses the local search techniques of [5].

**Theorem 3.** Given a $k$-Median instance $(G, F, C, k)$, where $G$ is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized time $2^{O((\varepsilon^{-3} \log (\varepsilon^{-1})) k)} \cdot n^{O(1)}$ compute a set $D \subseteq F$ of size at most $(1 + \varepsilon)k$ such that its connection cost is at most $(1 + \varepsilon)$ times the optimum cost for solutions of size $k$ with constant probability.

A direct corollary of Theorem 3 is an efficient PTAS for Uniform Facility Location in planar graphs.

**Theorem 4.** Given a Uniform Facility Location instance $(G, F, C, \text{open})$, where $G$ is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized time $2^{O((\varepsilon^{-3} \log (\varepsilon^{-1})) k)} \cdot n^{O(1)}$ compute a solution $D \subseteq F$ that has total cost at most $(1 + \varepsilon)$ times the optimum cost with constant probability.
Proof. Iterate over all possible choices of \( k \) being the number of facilities opened by the optimum solution, and for every \( k \) invoke the algorithm of Theorem 3 for the \( k \)-Median instance \((G, F, C, k)\). From the obtained solutions output one with the smallest cost. ▷

Note that the approach presented above fails for the non-uniform case, where each facility has its own, distinct opening cost.

In this extended abstract we focus on proving the main result, Theorem 1. The proof of Theorem 3, on which Theorem 4 also relies, is fully deferred to the full version of the paper [10].

Our techniques. The first step in the proof of Theorem 1 is to reduce the number of relevant clients using the coreset construction of Feldman and Langberg [11]. By applying this technique, we may assume that there are at most \( k \cdot \mathcal{O}(\varepsilon^{-2} \log n) \) clients in the instance, however they are weighted: every client \( c \) is assigned a nonnegative weight \( \omega(c) \), and it contributes to the connection cost of any solution with \( \omega(c) \) times the distance to the closest open facility in the solution.

We now examine the Voronoi diagram induced in the input graph \( G \) by the clients: vertices of \( G \) are classified into cells according to the closest client. This Voronoi diagram has one cell per every client, thus it can be regarded as a planar graph with \(|C|\) faces, where each face accommodates one cell. To formally define the Voronoi diagram, and in particular the boundaries between neighboring cells, we use the framework introduced by Marx and Pilipczuk [19] and its extension used in [21].

Consider now all the spokes in the diagram, where a spoke is the shortest path connecting the center of a cell (i.e. a client) with a branching node of the diagram incident to the cell (which is a face of \( G \)). Removing all the spokes and all the branching nodes from the plane divides it into diamonds, where each diamond is delimited by four spokes, called further the perimeter of the diamond. See Figure 1 for an example. Since the diagram is a planar graph with \(|C|\) faces, there are \( \mathcal{O}(|C|) = k \cdot \mathcal{O}(\varepsilon^{-2} \log n) \) diamonds altogether. Moreover, since no diamond contains a client in its interior, whenever \( P \) is a path connecting a client with a facility belonging to some diamond \( \Delta \), \( P \) has to cross the perimeter of \( \Delta \).

Now comes the key and most technical part of the proof. We very carefully put \( \mathcal{O}(\varepsilon^{-2} \log n) \) portals on the perimeter of each diamond. The idea of placement is similar to that of the resolution metric used in the QPTAS for Facility Location. Namely, on a spoke \( Q \) starting at client \( c \) we put portals at distance \( 1, (1 + \varepsilon), (1 + \varepsilon)^2, \ldots \) from \( c \), so that the further we are on the spoke from \( c \), the sparser the portals are. As a diamond is delimited by four spokes, we may thus use only \( \mathcal{O}(\varepsilon^{-2} \log n) \) portals per diamond, while the cost of snapping a path crossing \( Q \) to the portal closest to the crossing point can be bounded by \( \varepsilon \) times the distance from the crossing point to \( c \).

For a facility \( f \) in a diamond \( \Delta \), we define the profile of \( f \) as follows. For every spoke \( Q \) in the perimeter of \( \Delta \), we look at the closest portal \( \pi \) from \( f \) on \( Q \). We record approximate (up to \( (1 + \varepsilon) \) multiplicative error) distances from \( f \) to \( \pi \) and \( \mathcal{O}(\varepsilon^{-3}) \) neighboring portals, as well as the distance to the client endpoint of the spoke \( Q \). The crux lies in the following fact: for every two facilities \( f, f' \) in \( \Delta \) with the same profile, replacing \( f \) with \( f' \) increases the connection cost of any client \( c \) connected to \( f \) only by a multiplicative factor of \( (1 + \varepsilon) \).

Hence, for every profile in every diamond it suffices to keep just one facility with that profile. Since there are \( k \cdot \mathcal{O}(\varepsilon^{-2} \log n) \) diamonds and \( \mathcal{O}(\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})} \) possible profiles in each of them, we keep at most \( k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})} \) facilities in total. This proves Theorem 1.

For the proof of Theorem 3, we first apply Theorem 1 to reduce the number of facilities to \( k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})} \). Then we again inspect the Voronoi diagram, but now induced by the facilities. Having contracted every cell to a single vertex, we compute an \( \tau \)-division of the
obtained planar graph to cover it with regions of size \( r = (\varepsilon^{-1} \log n)^{O(\varepsilon^{-3})} \) so that only \( O(\varepsilon)k \) facilities are on boundaries of the regions. We open all the facilities in all the boundaries — thus exceeding the quota for open facilities by \( O(\varepsilon)k \) — run the PTAS of Cohen-Addad et al. [8] in each region independently, and at the end assemble regional solutions using a knapsack dynamic programming. Since within each region there are only polylogarithmically many facilities, each application of the PTAS actually works in time \( f(\varepsilon) \cdot n^{O(1)} \).

2 Preliminaries on Voronoi diagrams and coresets

In this section we recall some tools about Voronoi diagrams in planar graphs and coresets that will be used in the proof of Theorem 1. We will consider undirected graphs with positive edge lengths embedded in a sphere, with the standard shortest-paths metric \( \text{dist}(u, v) \) for \( u, v \in V(G) \). Contrary to the previous section, the metric is defined on the vertex set of \( G \) only, i.e., we do not consider \( G \) as a metric space with points in the interiors of edges. For \( X, Y \subseteq V(G) \), we denote \( \text{dist}(X, Y) = \min_{x \in X, y \in Y} \text{dist}(x, y) \) and similarly we define \( \text{dist}(u, X) = \min_{v \in X} \text{dist}(u, v) \).

Recall that for a set \( D \subseteq V(G) \) of open facilities and a set \( C \subseteq V(G) \), we define the connection cost as

\[
\text{conn}(D, C) = \sum_{v \in C} \text{dist}(v, D).
\]

If the input is additionally equipped with opening costs \( \text{open}: F \to \mathbb{R}_{\geq 0} \), then the opening cost of \( D \) is defined as \( \sum_{w \in D} \text{open}(w) \).

2.1 Voronoi diagrams in planar graphs

We now recall the construction of Voronoi diagrams and related notions in planar graphs used by Marx and Pilipczuk [19]. The setting is as follows. Suppose \( G \) is an \( n \)-vertex simple graph embedded in a sphere \( \Sigma \) whose edges are assigned nonnegative real lengths. We consider the shortest path metric in \( G \): for two vertices \( u, v \), their distance \( \text{dist}(u, v) \) is equal to the smallest possible total length of a path from \( u \) to \( v \). We will assume that \( G \) is triangulated (i.e. every face of \( G \) is a cycle of length 3), for this may always be achieved by triangulating the graph using edges of infinite weight.

Further, we assume that shortest paths are unique in \( G \) and that finite distances between distinct vertices in \( G \) are pairwise different: for all vertices \( u, v, u', v' \) with \( u \neq v, u' \neq v' \) and \( \{u, v\} \neq \{u', v'\} \), we have \( \text{dist}(u, v) \neq \text{dist}(u', v') \) or \( \text{dist}(u, v) = \text{dist}(u', v') = +\infty \). This can be achieved by adding small perturbations to the edge lengths. Since we never specify degrees of polynomials in the running time of our algorithms, we may ignore the additional complexity cost incurred by the need of handling the perturbations in arithmetic operations.

Voronoi diagrams and their properties. Suppose that \( S \) is a subset of vertices of \( G \). First, define the Voronoi partition: for a vertex \( p \in S \), the Voronoi cell \( \text{Cell}_S(p) \) is the set of all those vertices \( u \in V(G) \) whose distance from \( p \) is smaller than the distance from any other vertex \( q \in S \); note that ties do not occur due to the distinctness of distances in \( G \). Note that \( \{\text{Cell}_S(p)\}_{p \in S} \) is a partition of the vertex set of \( G \). For each \( p \in S \), let \( T(p) \) be the union of

\footnote{In [19] a more general setting is considered where objects inducing the diagram are connected subgraphs of \( G \) instead of single vertices. We will not need this generality here.}
shortest paths from vertices of \( \text{Cell}_S(p) \) to \( p \); recall here that shortest paths in \( G \) are unique. Note that, due to the distinctness of distances in \( G \), \( T(p) \) is a spanning tree of the subgraph of \( G \) induced by the cell \( \text{Cell}_S(p) \).

The diagram \( \text{Vor}_S \) induced by \( G \) is a multigraph constructed as follows. First, take the dual \( G^* \) of \( G \) and remove all edges dual to the edges of all the trees \( T(p) \), for \( p \in S \). Then, exhaustively remove vertices of degree 1. Finally, for every maximal 2-path (i.e., path with internal vertices of degree 2), say with endpoints \( u \) and \( v \), we replace this path by the edge \( uv \); note that this creates a loop at \( u \) in case \( u = v \). The resulting multigraph \( \text{Vor}_S \) is the Voronoi diagram induced by \( S \). Note that the vertices of \( \text{Vor}_S \) are faces of \( G \); for clarity we shall call them branching nodes. Furthermore, \( \text{Vor}_S \) inherits an embedding in \( \Sigma \) from the dual \( G^* \), where an edge \( uv \) that replaced a maximal 2-path \( P \) is embedded precisely as \( P \), i.e., as the concatenation of (the embeddings of) the edges comprising \( P \). From now on we will assume this embedding of \( \text{Vor}_S \).

We recall several properties of \( \text{Vor}_S \), observed in \cite{19}. ▶ Lemma 5 (Lemmas 4.4 and 4.5 of \cite{19}). The diagram \( \text{Vor}_S \) is a connected and 3-regular multigraph embedded in \( \Sigma \), which has exactly \( |S| \) faces, \( 2|S| - 4 \) branching nodes, and \( 3|S| - 6 \) edges. The faces of \( \text{Vor}_S \) are in one-to-one correspondence with vertices of \( S \): each \( p \in S \) corresponds to a face of \( \text{Vor}_S \) that contains all vertices of \( \text{Cell}_S(p) \) and no other vertex of \( G \).

**Spokes and diamonds.** We now introduce further structural elements that can be distinguished in the Voronoi diagram, see Figure 1 for reference. The definitions and basic observations presented below are taken from Pilipczuk et al. \cite{21}, and were inspired by the Euclidean analogues due to Har-Peled \cite{14}.

An **incidence** is a triple \( \tau = (p,u,f) \) where \( p \in S \), \( f \) is a branching node of the diagram \( \text{Vor}_S \), and \( u \) is a vertex of \( G \) that lies on \( f \) (recall that \( f \) is a triangular face of \( G \)) and belongs to \( \text{Cell}_S(p) \). The **spoke** of the incidence \( \tau \), denoted \( \text{Spoke}(\tau) \), is the shortest path in \( G \) between \( p \) and \( u \). Note that all the vertices of \( \text{Spoke}(\tau) \) belong to \( \text{Cell}_S(p) \).

Let \( e = f_1f_2 \) be an edge of the diagram \( \text{Vor}_S \), where \( f_1, f_2 \) are branching nodes (possibly \( f_1 = f_2 \) if \( e \) is a loop in \( \text{Vor}_S \)). Further, let \( p_1 \) and \( p_2 \) be the vertices from \( S \) that correspond to faces of \( \text{Vor}_S \) incident to \( e \) (possibly \( p_1 = p_2 \) if \( e \) is a bridge in \( \text{Vor}_S \)). Suppose for a moment that \( f_1 \neq f_2 \). Then, out of the three edges of \( f_1 \) (these are edges in \( G \)) there is
Consequently, the intersection of diamonds of two different edges of \( e \) edges of the branching nodes (considered as interiors of faces on the intersection of their perimeters. We rely on the following result of Feldman and Langberg [11].

That is, every client \( u \) of a client set in a \( k \)-Median instance, the (weighted) connection cost is defined as

\[
\text{conn}(D, \omega) = \sum_{v \in C} \text{dist}(v, D) \cdot \omega(v).
\]

That is, every client \( v \) is assigned a weight \( \omega(v) \) with which it contributes to the objective function. The support of a weight function \( \omega \) is defined as \( \text{supp}(\omega) = \{ v \in C \mid \omega(v) > 0 \} \). From now on, whenever we speak about a \( k \)-Median instance without specified client weight function, we assume the standard function assigning each client weight 1.

The essence of coresets is that one can find weight functions with small support that well approximate the original instance. Given a \( k \)-Median instance \((G, F, C, k)\) (without weights) and an accuracy parameter \( \varepsilon > 0 \), a coreset is a weight function \( \omega \) such that for every set \( D \subseteq F \) of size at most \( k \), it holds that

\[
|\text{conn}(D, C) - \text{conn}(D, \omega)| \leq \varepsilon \cdot \text{conn}(D, C).
\]

We rely on the following result of Feldman and Langberg [11].

- Proposition 6. Consider removing all the spokes (considered as curves on \( \Sigma \)) and all the branching nodes (considered as interiors of faces on \( \Sigma \)) of the diagram \( \text{Vor}_S \) from the sphere \( \Sigma \). Then \( \Sigma \) breaks into \( 3|S| - 6 \) regions that are in one-to-one correspondence with edges of \( \text{Vor}_S \): a region corresponding to the edge \( e \) is the interior of the diamond \( \text{Diam}(e) \). Consequently, the intersection of diamonds of two different edges of \( \text{Vor}_S \) is contained in the intersection of their perimeters.

- Lemma 7. Let \( p \in S \) and \( u \) be a vertex of \( G \) belonging to the diamond \( \text{Diam}(e) \) for some edge \( e \) of \( \text{Vor}_S \). Then every path in \( G \) connecting \( u \) and \( p \) intersects the perimeter of \( \text{Diam}(e) \).

### 2.2 Coresets

In most our algorithms, the starting point is the notion of a coreset and a corresponding result of Feldman and Langberg [11]. To this end, we need to slightly generalize the notion of a client set in a \( k \)-Median instance. A client weight function is a function \( \omega: C \rightarrow \mathbb{R}_{\geq 0} \). Given a set \( D \subseteq F \) of open facilities, the (weighted) connection cost is defined as
Theorem 8 (Theorem 15.4 of [11]). Given a $k$-Median instance $(G, F, C, k)$ with $n = |V(G)|$ and accuracy parameter $\varepsilon > 0$, one can in randomized polynomial time find a weight function $\omega$ with support of size $O(k\varepsilon^{-2} \log n)$ that is a coreset with constant probability.

We note that Ke Chen [4] gave a construction of a strong coreset with support of size $O(k^2\varepsilon^{-2} \log n)$ that is much simpler than the later construction of Feldman and Langberg [11]. By using this construction instead, we would obtain a weaker version of Theorem 1, with a bound on $|F_0|$ that is quadratic in $k$ instead of linear. This would be perfectly sufficient to derive an FPT approximation scheme as in Corollary 2, but for Theorem 3 we will vitally use the stronger statement. A construction of coresets with similar size guarantees, but maintainable in the streaming model, has been proposed by Braverman et al. [2].

3 Facility coreset for $k$-Median in planar graphs

In this section we give a coreset for centers for the $k$-MEDIAN problem, that is, we prove Theorem 1. We shall focus on the following lemma, which in combination with Theorem 8 yields Theorem 1.

Lemma 9. Given a $k$-Median instance $(G, F, C, k)$ with a weight function $\omega$ and an accuracy parameter $\varepsilon > 0$, one can in polynomial time compute a set $F_0 \subseteq F$ of size $|\text{supp}(\omega)| \cdot (\varepsilon^{-1} \log |V(G)|)^O(\varepsilon^{-3})$ satisfying the following condition with constant probability: there exists a set $D_0 \subseteq F_0$ of size at most $k$ such that for every set $D \subseteq F$ of size at most $k$ it holds that $\text{conn}(D_0, \omega) \leq (1 + \varepsilon) \cdot \text{conn}(D, \omega)$.

Before we proceed, let us verify that Theorem 8 and Lemma 9 together imply Theorem 1. Given an instance $(G, F, C, k)$ of $k$-MEDIAN, we first apply Theorem 8 to obtain a coreset $\omega$ with support of size $O(k\varepsilon^{-2} \log n)$. Next, we pass this coreset to Lemma 9, thus obtaining a set $F_0 \subseteq F$ of size $k \cdot (\varepsilon^{-1} \log n)^O(\varepsilon^{-3})$. Let $D_0$ be the subset of $F_0$ of size at most $k$ that minimizes $\text{conn}(D_0, \omega)$. Then using the approximation guarantees of Theorem 8 and Lemma 9, for any $D \subseteq F$ we have

$$\text{conn}(D_0, C) \leq (1 + \varepsilon)\text{conn}(D_0, \omega) \leq (1 + \varepsilon)^2\text{conn}(D, \omega) \leq (1 + \varepsilon)^3\text{conn}(D, C).$$

It remains to rescale $\varepsilon$. Hence, for the rest of this section we focus on proving Lemma 9.

Let $I = (G, F, C, k)$ be an input $k$-MEDIAN instance with a weight function $\omega$, where $G$ is planar. Let $\varepsilon > 0$ be an accuracy parameter and without loss of generality assume that $\varepsilon < 1/4$. Let $n = |V(G)|$ and $m = |E(G)|$. Without loss of generality assume that $n = \Theta(m)$.

We assume that $G$ is embedded in a sphere $\Sigma$ and apply the necessary modifications explained in the beginning of Section 2.1 to fit into the framework of Voronoi diagrams. Denote $S = \text{supp}(\omega)$. We compute the Voronoi partition $\text{Cell}_S$ induced by $S$ and the Voronoi diagram $\text{Vor}_S$ induced by $S$. By Proposition 6, $\text{Vor}_S$ has $O(|S|)$ vertices, faces, and edges.

Distance levels. We first compute an $O(1)$-approximate solution $\tilde{D} \subseteq F$ using the algorithm given by Feldman and Langberg [11, Theorem 15.1]; this algorithm outputs an $O(1)$-approximate solution with constant probability. Let us scale all the edge lengths in $G$ by the same ratio so that

$$\text{conn}(\tilde{D}, \omega) = |S|/\varepsilon.$$  \hspace{1cm} (1)

Next, we assign length $+\infty$ to every edge of length larger than $\text{conn}(\tilde{D}, \omega)$; clearly, they are not used in the computation of the connection cost of an optimum solution. Without loss of
generality we assume that all the distances between vertices in \( G \) are finite: otherwise we can split the instance into a number of independent ones, compute a suitable set \( F_0 \) for each of them and take the union.

The next step is to assign levels to distances in the graph. For any \( c \in [0, +\infty) \), define the level of \( c \), denoted \( \text{level}(c) \), to be the smallest nonnegative integer \( \ell \) such that \( c < (1 + \varepsilon)^\ell \).

Note that \( \text{level}(c) = 0 \) if and only if \( c < 1 \). Let \( L = 1 + \text{level}(m \cdot \text{conn}(D, \omega)) \), then we have

\[
\text{level}(\text{dist}(u, v)) \in \{0, 1, \ldots, L - 1\} \quad \text{for all } u, v \in V(G).
\]

Observe that since \( m = \Theta(n) \), by (1) we have

\[
L \leq O(\varepsilon^{-1} \log(m|S|/\varepsilon)) \leq O(\varepsilon^{-2} \log n).
\] (2)

**Portals and profiles.** Let \( \tau = (p, u, f) \) be an incidence in \( \text{Vor}_S \). Let \( d(\tau) = \text{dist}(p, u) \) and let \( \ell(\tau) = \text{level}(d(\tau)) \); note that \( \text{Spoke}(\tau) \) has length exactly \( d(\tau) \). For every integer \( i \in \{1, \ldots, \ell(\tau)\} \), we define the portal \( p(\tau, i) \) as a vertex on \( \text{Spoke}(\tau) \) at distance exactly \( (1 + \varepsilon)^{\ell-i} \) from \( p \); we subdivide an edge an create a new vertex to accommodate \( p(\tau, i) \) if necessary. Furthermore, we add also a portal \( p(\tau, 0) = p \). Since \( \ell(\tau) = \text{level}(d(\tau)) \leq L \), there are at most \( L \) portals on the spoke \( \text{Spoke}(\tau) \).

Consider a diamond \( \text{Diam}(e) \) induced by some edge \( e \) of \( \text{Vor}_S \), and a vertex \( v \) in \( \text{Diam}(e) \). Recall that the perimeter of \( \text{Diam}(e) \) consists of spokes \( \text{Spoke}(\tau_{i,j}) \) for four incidence \( \tau_{i,j} \), where \( i, j \in \{1, 2\} \). The profile of a vertex \( w \) belonging to the diamond \( \text{Diam}(e) \) consists of the following information, for all \( \tau \in \{\tau_{i,j} : i, j \in \{1, 2\}\} \):

1. The minimum index \( \lambda \in \{0, 1, \ldots, \ell(\tau)\} \) satisfying

\[
\text{dist}(p(\tau, \lambda), p) > \varepsilon \cdot \text{dist}(p(\tau, \lambda), w),
\]

where \( p = p(\tau, 0) \) is the vertex of \( S \) involved in \( \tau \). If no such index exists, we set \( \lambda = \ell(\tau) \).

2. Letting

\[
I = \{(0) \cup \{\ell : |\ell - \lambda| \leq 1/\varepsilon^3\}\} \cap \{0, 1, \ldots, \ell(\tau)\},
\]

the profile records the value of \( \ell(\text{dist}(w, p(\tau, \ell))) \) for all \( \ell \in I \).

Whenever speaking about a vertex \( w \) and incidence \( \tau \), we use \( \lambda(\tau, w) \) and \( I(\tau, w) \) to denote \( \lambda \) and \( I \) as above. We note that in total there are only few possible profiles.

\( \triangleright \) **Claim 10.** The number of possible different profiles of vertices in \( \text{Diam}(e) \) is \( L^{O(\varepsilon^{-3})} \).

**Proof.** Since \( 0 \leq \ell(\tau) \leq L \) for every incidence \( \tau \), there are at most \( L^4 \) choices for the four values \( \lambda(\tau_{i,j}, w) \) for \( i, j \in \{1, 2\} \). Further, we have \( |I(\tau_{i,j}, w)| \leq O(\varepsilon^{-3}) \), so there are at most \( L^{O(\varepsilon^{-3})} \) choices for the values \( \ell(\text{dist}(w, p(\tau_{i,j}, \ell))) \) for \( i, j \in \{1, 2\} \) and \( \ell \in I(\tau_{i,j}, w) \).

For future reference, we state the key property of profiles: having the same profile implies having approximately same distances to the profiles with indices in \( I \).

\( \triangleright \) **Claim 11.** Suppose \( w \) and \( w' \) are two vertices of \( \text{Diam}(e) \) that have the same profile. Then for each \( \tau \in \{\tau_{i,j} : i, j \in \{1, 2\}\} \) and \( \ell \in I(\tau, w) \), we have

\[
\text{dist}(w', p(\tau, \ell)) \leq (1 + \varepsilon)^{\ell} \cdot \text{dist}(w, p(\tau, \ell)) + 1.
\]

**Proof.** Let \( \ell = \text{level}(\text{dist}(w, p(\tau, \ell))) = \text{level}(\text{dist}(w', p(\tau, \ell))) \), as recorded in the common profile. If \( \ell = 0 \), then \( \text{dist}(w', p(\tau, \ell)) < 1 \) and we are done. Otherwise, \( \text{dist}(w, p(\tau, \ell)) \) and \( \text{dist}(w', p(\tau, \ell)) \) are both contained in the interval \( [(1 + \varepsilon)^{\ell-1}, (1 + \varepsilon)^{\ell}] \). This interval has length \( \varepsilon \cdot (1 + \varepsilon)^{\ell-1} \leq \varepsilon \cdot \text{dist}(w, p(\tau, \ell)) \), hence the claim follows. \( \triangleright \)
Construction of the set \( F_0 \). We now construct the set \( F_0 \) as follows: for every diamond \( \text{Diam}(e) \) and every possible profile in \( \text{Diam}(e) \), include in \( F_0 \) one facility with that profile (if one exists). Since there are \( O(|S|) \) diamonds, by Claim 10 and (10) we have

\[
|F_0| \leq O(|S|) \cdot L^{O(\varepsilon^{-3})} = |\text{supp}(\omega)| \cdot (\varepsilon^{-1} \log n)^{O(\varepsilon^{-3})},
\]
as claimed. It remains to prove that \( F_0 \) has the claimed approximation properties.

For every facility \( w \in F \), pick a diamond \( \text{Diam}(e) \) containing \( w \) and let \( f(w) \) to be the facility \( f(w) \in F_0 \cap \text{Diam}(e) \) that has the same profile as \( w \). Fix a solution \( D^* \subseteq F \) with \( |D^*| \leq k \) minimizing \( \text{conn}(D^*, \omega) \). Let \( D_0 = \{ f(w) : w \in D^* \} \). Clearly, \( |D_0| \leq |D^*| \leq k \). To finish the proof of Lemma 9 it suffices to show that

\[
\text{conn}(D_0, \omega) \leq (1 + O(\varepsilon))\text{conn}(D^*, \omega).
\]

To this end, consider any client \( v \in S = \text{supp}(\omega) \) and let \( w \in D^* \) be the facility in \( D^* \) serving \( v \), that is, \( \text{dist}(v, w) = \text{dist}(v, D^*) \). To show (3), it suffices to prove that

\[
\text{dist}(v, f(w)) \leq (1 + O(\varepsilon))\text{dist}(v, w) + O(1).
\]

Indeed, by summing (4) through all \( v \in S \) and using (1) we obtain

\[
\text{conn}(D_0, \omega) \leq (1 + O(\varepsilon))\text{conn}(D^*, \omega) + O(1) \cdot |S|
\]

\[
\leq (1 + O(\varepsilon))\text{conn}(D^*, \omega) + O(\varepsilon) \cdot \text{conn}(\tilde{D}, \omega) \leq (1 + O(\varepsilon))\text{conn}(D^*, \omega),
\]

where the last inequality is due to \( \tilde{D} \) being an \( O(1) \)-approximate solution.

Hence, from now on we focus on proving (4). Let \( \text{Diam}(e) \) be the diamond containing \( w \) and \( f(w) \). Consider the shortest path \( P \) from \( w \) to \( v \) in \( G \). By Lemma 7, the path \( P \) intersects the perimeter of the diamond \( \text{Diam}(e) \). Let \( u \) be the vertex on the perimeter of \( \text{Diam}(e) \) that lies on \( P \) and, among such, is closest to \( w \) on \( P \). Since \( P \) is a shortest path, the length of the subpaths of \( P \) between \( v \) and \( u \) and between \( u \) and \( w \) equal \( \text{dist}(v, u) \) and \( \text{dist}(u, w) \), respectively, and in particular \( \text{dist}(v, w) = \text{dist}(v, u) + \text{dist}(u, w) \).

We now observe that to prove (4), it suffices show the following.

\[
\text{dist}(u, f(w)) \leq \text{dist}(u, w) + O(\varepsilon)\text{dist}(v, w) + O(1).
\]

Indeed, assuming (5) we have

\[
\text{dist}(v, f(w)) \leq \text{dist}(v, u) + \text{dist}(u, w) \leq \text{dist}(v, u) + \text{dist}(u, w) + O(\varepsilon)\text{dist}(v, w) + O(1) = \text{dist}(v, w) + O(\varepsilon)\text{dist}(v, w) + O(1).
\]

Hence, from now on we focus on proving (5).

Let \( \tau_{i,j} \) for \( i, j \in \{1, 2\} \), be the four incidences involved in the diamond \( \text{Diam}(e) \). Since \( u \) lies on the perimeter of \( \text{Diam}(e) \), actually \( u \) lies on \( \text{Spoke}(\tau) \), where \( \tau = \tau_{i,j} \) for some \( i, j \in \{1, 2\} \). Let \( p = p(\tau, 0) \) be the vertex of \( S \) involved in the incidence \( \tau \). Since \( u \in \text{Cell}_S(p) \) while \( v \in S \), we have that \( \text{dist}(u, p) \leq \text{dist}(u, v) \). Consequently, we have \( \text{dist}(u, w) \leq \text{dist}(v, w) \) and \( \text{dist}(u, p) \leq \text{dist}(v, w) \), so to prove (5) it suffices to prove the following:

\[
\text{dist}(u, f(w)) \leq \text{dist}(u, w) + O(\varepsilon)(\text{dist}(u, w) + \text{dist}(u, p)) + O(1).
\]

Let \( p_u = p(\tau, i) \) be the portal on the subpath of \( \text{Spoke}(\tau) \) between \( u \) and \( p \) that is closest to \( u \). Intuitively, \( p_u \) is a good approximation of \( u \) and distances from \( p_u \) are almost the same as distances from \( u \). As this idea will be repeatedly used in this sequel, we encapsulate it in a single claim.
Claim 12. Suppose for some vertices $x$ and $y$ we have
\[ \text{dist}(p_u, x) \leq A \cdot \text{dist}(p_u, y) + B, \]
for some $A, B$. Then
\[ \text{dist}(u, x) \leq A \cdot \text{dist}(u, y) + (A + 1) \varepsilon \cdot \text{dist}(u, p) + (A + 1). \]

Proof. By the choice of $p_u$ we have
\[ \text{dist}(p_u, p) \leq \text{dist}(u, p) \leq (1 + \varepsilon) \text{dist}(p_u, p) + 1, \]
so \( \text{dist}(u, p_u) \leq \varepsilon \cdot \text{dist}(u, p) + 1 \). Therefore, we have
\[
\text{dist}(u, x) \leq \text{dist}(p_u, x) + \text{dist}(p_u, u) \leq A \cdot \text{dist}(p_u, y) + B + \text{dist}(p_u, u)
\leq A \cdot (\text{dist}(u, y) + \text{dist}(p_u, u)) + B + \text{dist}(p_u, u)
\leq A \cdot \text{dist}(u, y) + B + (A + 1) \cdot \varepsilon \cdot \text{dist}(u, p) + (A + 1),
\]
as claimed.
\[\boxed{}\]

Since $w$ and $f(w)$ have the same profile, we may denote \( \lambda = \lambda(\tau, w) = \lambda(\tau, f(w)) \) and \( I = I(\tau, w) = I(\tau, f(w)) \). Further, let $p_\lambda = p(\tau, \lambda)$ We now consider a number of cases depending on the relative values of $\iota$ and $\lambda$, with the goal on proving that (6) holds in each case. See Figure 2 for an illustration.

**Middle case: $\iota \in I$.** As profiles of $w$ and $f(w)$ are the same and $\iota \in I$, by Claim 11 we have
\[ \text{dist}(p_u, f(w)) \leq (1 + \varepsilon) \text{dist}(p_u, w) + 1. \]
It suffices now to apply Claim 12 to infer inequality (6).

**Close case: $\iota < \lambda - 1/\varepsilon^3$.** Since $\iota < \lambda - 1/\varepsilon^3$, by the choice of $\lambda$ we have
\[ \text{dist}(p_u, p) \leq \varepsilon \cdot \text{dist}(p_u, w). \]
By applying Claim 12, we infer that
\[ \text{dist}(u, p) \leq \varepsilon \cdot \text{dist}(u, w) + (1 + \varepsilon) \varepsilon \cdot \text{dist}(u, p) + O(1) \leq \varepsilon \cdot \text{dist}(u, w) + \text{dist}(u, p)/2 + O(1), \]

![Figure 2](image-url)
which entails
\[
\text{dist}(u, p) \leq 2 \varepsilon \cdot \text{dist}(u, w) + \mathcal{O}(1).
\]

Since \(0 \in I\) and the profiles of \(w\) and \(f(w)\) are equal, by Claim 11 we have
\[
\text{dist}(p, f(w)) \leq (1 + \varepsilon) \cdot \text{dist}(p, w) + 1.
\]

By combining the last two inequalities, we conclude that
\[
\begin{align*}
\text{dist}(u, f(w)) & \leq \text{dist}(u, p) + \text{dist}(p, f(w)) \\
& \leq \text{dist}(u, p) + (1 + \varepsilon) \text{dist}(p, w) + 1 \\
& \leq \text{dist}(u, p) + (1 + \varepsilon) \text{dist}(u, w) + 1 \\
& \leq (1 + \mathcal{O}(\varepsilon)) \text{dist}(u, w) + \mathcal{O}(1).
\end{align*}
\]

Thus, inequality (6) holds in this case.

**Far case: \(\iota > \lambda + 1/\varepsilon^3\).** By the definition of \(\lambda\) and since \(\iota > \lambda + 1/\varepsilon^3\), we have in particular \(\lambda < \ell(\tau)\) and hence
\[
\varepsilon \cdot \text{dist}(p_\lambda, w) < \text{dist}(p_\lambda, p).
\]

On the other hand, we have
\[
\text{dist}(p, p_\lambda) = (1 + \varepsilon)^{\lambda - \iota} \text{dist}(p, p_u) \leq (1 + \varepsilon)^{-1/\varepsilon^3} \text{dist}(p, p_u) \leq \varepsilon^2 \cdot \text{dist}(p, p_u),
\]

where the last step follows from Bernoulli’s inequality. By combining the above two inequalities we obtain
\[
\text{dist}(p_\lambda, w) \leq \varepsilon \cdot \text{dist}(p, p_u),
\]

implying
\[
\text{dist}(p, w) \leq \text{dist}(p, p_\lambda) + \text{dist}(p_\lambda, w) \leq (\varepsilon + \varepsilon^2) \cdot \text{dist}(p, p_u) \leq 2 \varepsilon \cdot \text{dist}(p, p_u) \leq 2 \varepsilon \cdot \text{dist}(p, u).
\]

As before, by Claim 11 we have \(\text{dist}(p, f(w)) \leq (1 + \varepsilon) \text{dist}(p, w) + 1\) due to \(0 \in I\), hence
\[
\begin{align*}
\text{dist}(u, f(w)) & \leq \text{dist}(u, p) + \text{dist}(p, f(w)) \\
& \leq (\dist(u, w) + \text{dist}(p, w)) + (1 + \varepsilon) \text{dist}(p, w) + 1 \\
& \leq \dist(u, w) + (2 + \varepsilon) \cdot \dist(u, p) + 1 \\
& \leq \dist(u, w) + \mathcal{O}(\varepsilon) \text{dist}(u, p) + \mathcal{O}(1).
\end{align*}
\]

We conclude that inequality (6) holds in this case.

As the case investigation presented above covers all the possibilities, the proof of Lemma 9 is complete, so we have also proved Theorem 1.
