Contents

Preface
Jarosław Byrka and Raghu Meka 0:ix

RANDOM

Extractor Lower Bounds, Revisited
Divesh Aggarwal, Siyao Guo, Maciej Obremski, João Ribeiro, and Noah Stephens-Davidowitz 1:1–1:20

A Simpler Strong Refutation of Random k-XOR
Kwangjun Ahn 2:1–2:15

Iterated Decomposition of Biased Permutations via New Bounds on the Spectral Gap of Markov Chains
Sarah Miracle, Amanda Pascoe Streib, and Noah Streib 3:1–3:21

Improved Explicit Hitting-Sets for ROABPs
Zeyu Guo and Rohit Gurjar 4:1–4:16

Almost Optimal Testers for Concise Representations
Nader H. Bshouty 5:1–5:20

Palette Sparsification Beyond $(\Delta + 1)$ Vertex Coloring
Noga Alon and Sepehr Assadi 6:1–6:22

On Hitting-Set Generators for Polynomials That Vanish Rarely
Dean Doron, Amnon Ta-Shma, and Roei Tell 7:1–7:23

Polynomial Identity Testing for Low Degree Polynomials with Optimal Randomness
Markus Bläser and Anurag Pandey 8:1–8:13

Bounds for List-Decoding and List-Recovery of Random Linear Codes
Venkatesan Guruswami, Ray Li, Jonathan Mosheiff, Nicolas Resch, Shashwat Silas, and Mary Wootters 9:1–9:21

Is It Possible to Improve Yao's XOR Lemma Using Reductions That Exploit the Efficiency of Their Oracle?
Ronen Shaltiel 10:1–10:20

Balanced Allocation on Dynamic Hypergraphs
Catherine Greenhill, Bernard Mans, and Ali Pourmiri 11:1–11:22

The GaussianSketch for Almost Relative Error Kernel Distance
Jeff M. Phillips and Wai Ming Tai 12:1–12:20

A Fast Binary Splitting Approach to Non-Adaptive Group Testing
Eric Price and Jonathan Scarlett 13:1–13:20

Maximum Shallow Clique Minors in Preferential Attachment Graphs Have Polylogarithmic Size
Jan Dreier, Philipp Kuinke, and Peter Rossmanith 14:1–14:13

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2020).
Editors: Jarosław Byrka and Raghu Meka
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

On Nonadaptive Security Reductions of Hitting Set Generators
Shuichi Hirahara and Osamu Watanabe 15:1–15:14

Testable Properties in General Graphs and Random Order Streaming
Artur Czumaj, Hendrik Fichtenberger, Pan Peng, and Christian Sohler 16:1–16:20

Multicriteria Cuts and Size-Constrained k-Cuts in Hypergraphs
Calvin Beideman, Karthekeyan Chandrasekaran, and Chao Xu 17:1–17:21

On Testing and Robust Characterizations of Convexity
Eric Blais and Abhinav Bommireddi 18:1–18:15

Distributed Testing of Graph Isomorphism in the CONGEST Model
Reut Levi and Moti Medina 19:1–19:24

Reaching a Consensus on Random Networks: The Power of Few
Linh Tran and Van Vu 20:1–20:15

Time-Space Tradeoffs for Distinguishing Distributions and Applications to Security of Goldreich's PRG
Sumegha Garg, Pravesh K. Kothari, and Ran Raz 21:1–21:18

Streaming Verification for Graph Problems: Optimal Tradeoffs and Nonlinear Sketches
Amit Chakrabarti, Prantar Ghosh, and Justin Thaler 22:1–22:23

Disjointness Through the Lens of Vapnik–Chervonenkis Dimension: Sparsity and Beyond
Anup Bhattacharya, Sourav Chakraborty, Arijit Ghosh, Gopinath Mishra, and Manaswi Paraashar 23:1–23:15

Testing Data Binnings
Clément L. Canonne and Karl Wimmer 24:1–24:13

Chernoff Bound for High-Dimensional Expanders
Tali Kaufman and Ella Sharakanski 25:1–25:22

Vector-Matrix-Vector Queries for Solving Linear Algebra, Statistics, and Graph Problems
Cyrus Rashtchian, David P. Woodruff, and Hanlin Zhu 26:1–26:20

Almost Optimal Distribution-Free Sample-Based Testing of k-Modality
Dana Ron and Asaf Rosin 27:1–27:19

When Is Amplification Necessary for Composition in Randomized Query Complexity?
Shalev Ben-David, Mika Göös, Robin Kothari, and Thomas Watson 28:1–28:16

On Multilinear Forms: Bias, Correlation, and Tensor Rank
Abhishek Bhrushundi, Prahladh Harsha, Pooya Hatami, Swastik Kopparty, and Mrinal Kumar 29:1–29:23

On the List Recoverability of Randomly Punctured Codes
Ben Lund and Aditya Potukuchi 30:1–30:11

APPROX

On Perturbation Resilience of Non-Uniform k-Center
Sayan Bandyapadhyay 31:1–31:22

Low-Rank Binary Matrix Approximation in Column-Sum Norm
Fedor V. Fomin, Petr A. Golovach, Fahad Panolan, and Kirill Simonov 32:1–32:18

Pinning down the Strong Wilber 1 Bound for Binary Search Trees
Parinya Chalermsook, Julia Chuzhoy, and Thatchaphol Saranurak 33:1–33:21

Revisiting Alphabet Reduction in Dinur's PCP
Venkatesan Guruswami, Jakub Opršal, and Sai Sandeep 34:1–34:14

L_p Pattern Matching in a Stream
Tatiana Starikovskaya, Michal Svagerka, and Przemysław Uznański 35:1–35:23

Computing Bi-Lipschitz Outlier Embeddings into the Line
Karine Chubarian and Anastasios Sidiropoulos 36:1–36:21

Online Minimum Cost Matching with Recourse on the Line
Nicole Megow and Lukas Nölke 37:1–37:16

Hardness of Approximation of (Multi-)LCS over Small Alphabet
Amey Bhangale, Diptarka Chakraborty, and Rajendra Kumar 38:1–38:16

On Approximating Degree-Bounded Network Design Problems
Xiangyu Guo, Guy Kortsarz, Bundit Laekhanukit, Shi Li, Daniel Vaz, and Jiayi Xian 39:1–39:21

Permutation Strikes Back: The Power of Recourse in Online Metric Matching
Varun Gupta, Ravishankar Krishnaswamy, and Sai Sandeep 40:1–40:20

How to Cut a Ball Without Separating: Improved Approximations for Length Bounded Cut
Eden Chlamtáč and Petr Kolman 41:1–41:17

On the Facility Location Problem in Online and Dynamic Models
Xiangyu Guo, Janardhan Kulkarni, Shi Li, and Jiayi Xian 42:1–42:23

Nearly Optimal Embeddings of Flat Tori
Ishan Agarwal, Oded Regev, and Yi Tang 43:1–43:14

A Tight $(3/2 + \varepsilon)$ Approximation for Skewed Strip Packing
Waldo Gálvez, Fabrizio Grandoni, Afrouz Jabal Ameli, Klaus Jansen, Arindam Khan, and Malin Rau 44:1–44:18

Learning Lines with Ordinal Constraints
Bohan Fan, Diego Ihara, Neshat Mohammadi, Francesco Sgherzi, Anastasios Sidiropoulos, and Mina Valizadeh 45:1–45:15

Improved Circular k-Mismatch Sketches
Shay Golan, Tomasz Kociumaka, Tsvi Kopelowitz, Ely Porat, and Przemysław Uznański 46:1–46:24

On Guillotine Separability of Squares and Rectangles
Arindam Khan and Madhusudhan Reddy Pittu 47:1–47:22

Maximizing Throughput in Flow Shop Real-Time Scheduling
Lior Ben Yamin, Jing Li, Kanthi Sarpatwar, Baruch Schieber, and Hadas Shachnai 48:1–48:18

Maximizing the Correlation: Extending Grothendieck's Inequality to Large Domains
Dor Katzelnick and Roy Schwartz 49:1–49:18

Streaming Complexity of SVMs
Alexandr Andoni, Collin Burns, Yi Li, Sepideh Mahabadi, and David P. Woodruff 50:1–50:22

On the Parameterized Approximability of Contraction to Classes of Chordal Graphs
Spoorthy Gunda, Pallavi Jain, Daniel Lokshtanov, Saket Saurabh, and Prafullkumar Tale 51:1–51:19

Online Coloring of Short Intervals
Joanna Chybowska-Sokół, Grzegorz Gutowski, Konstanty Junosza-Szaniawski, Patryk Mikos, and Adam Polak 52:1–52:18

Approximating Requirement Cut via a Configuration LP
Roy Schwartz and Yotam Sharoni 53:1–53:16

Parametrized Metrical Task Systems
Sébastien Bubeck and Yuval Rabani 54:1–54:14

A Constant Factor Approximation for Capacitated Min-Max Tree Cover
Syamantak Das, Lavina Jain, and Nikhil Kumar 55:1–55:13

An Extension of Plücker Relations with Applications to Subdeterminant Maximization
Nima Anari and Thuy-Duong Vuong 56:1–56:16

Approximating Star Cover Problems
Buddhima Gamlath and Vadim Grinberg 57:1–57:19

On the Approximability of Presidential Type Predicates
Neng Huang and Aaron Potechin 58:1–58:20

An Approximation Algorithm for the MAX-2-Local Hamiltonian Problem
Sean Hallgren, Eunou Lee, and Ojas Parekh 59:1–59:18

Better and Simpler Learning-Augmented Online Caching
Alexander Wei 60:1–60:17

A 4/3-Approximation Algorithm for the Minimum 2-Edge Connected Multisubgraph Problem in the Half-Integral Case
Sylvia Boyd, Joseph Cheriyan, Robert Cummings, Logan Grout, Sharat Ibrahimpur, Zoltán Szigeti, and Lu Wang 61:1–61:12

Improved Multi-Pass Streaming Algorithms for Submodular Maximization with Matroid Constraints
Chien-Chung Huang, Theophile Thiery, and Justin Ward 62:1–62:19

Polylogarithmic Approximation Algorithm for k-Connected Directed Steiner Tree on Quasi-Bipartite Graphs
Chun-Hsiang Chan, Bundit Laekhanukit, Hao-Ting Wei, and Yuhao Zhang 63:1–63:20

Weighted Maximum Independent Set of Geometric Objects in Turnstile Streams
Ainesh Bakshi, Nadiia Chepurko, and David P. Woodruff 64:1–64:22

Preface

This volume contains the papers presented at the 23rd International Conference on Approximation Algorithms for Combinatorial Optimization Problems (APPROX 2020) and the 24th International Conference on Randomization and Computation (RANDOM 2020), which due to the travel restrictions related to COVID-19 were organized as parallel virtual conferences during August 17–19, 2020.

APPROX focuses on algorithmic and complexity issues surrounding the development of efficient approximate solutions to computationally difficult problems, and was the 23rd in the series. RANDOM is concerned with applications of randomness to computational and combinatorial problems, and was the 24th in the series. Prior to 2003, APPROX took place in Aalborg (1998), Berkeley (1999), Saarbrücken (2000), Berkeley (2001), and Rome (2002), while RANDOM took place in Bologna (1997), Barcelona (1998), Berkeley (1999), Geneva (2000), Berkeley (2001), and Harvard (2002). Since 2003, APPROX and RANDOM have been collocated, taking place in Princeton (2003), Cambridge (2004), Berkeley (2005), Barcelona (2006), Princeton (2007), Boston (2008), Berkeley (2009), Barcelona (2010), Princeton (2011), Boston (2012), Berkeley (2013), Barcelona (2014), Princeton (2015), Paris (2016), Berkeley (2017), Princeton (2018), and Boston (2019).

Topics of interest for APPROX and RANDOM are: approximation algorithms, hardness of approximation, small space, sub-linear time and streaming algorithms, online algorithms, approaches that go beyond worst case analysis, distributed and parallel approximation, embeddings and metric space methods, mathematical programming methods, spectral methods, combinatorial optimization, algorithmic game theory, mechanism design and economics, computational geometric problems, approximate learning, design and analysis of randomized algorithms, randomized complexity theory, pseudorandomness and derandomization, random combinatorial structures, random walks/Markov chains, expander graphs and randomness extractors, probabilistic proof systems, random projections and embeddings, error-correcting codes, average-case analysis, smoothed analysis, property testing, and computational learning theory.

The volume contains 34 contributed papers, selected by the APPROX Program Committee out of 67 submissions, and 30 contributed papers, selected by the RANDOM Program Committee also out of 67 submissions. We would like to thank all of the authors who submitted papers, the members of the Program Committees, and the external reviewers. We are grateful for the guidance of the steering committees: Klaus Jansen, Samir Khuller, Monaldo Mastrolili, and László Végh for APPROX, and Oded Goldreich, Cris Moore, Anup Rao, Omer Reingold, Dana Ron, Ronitt Rubinfeld, Amit Sahai, Ronen Shaltiel, Alistair Sinclair, and Paul Spirakis for RANDOM.

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2020).

Program Committees

APPROX

Nikhil Bansal	CWI & TU Eindhoven
Jarosław Byrka (chair)	University of Wrocław
Andreas Emil Feldmann	Charles University in Prague
Naveen Garg	IIT Delhi
Anupam Gupta	Carnegie Mellon
Pasin Manurangsi	Google Research
Evangelos Markakis	AUEB, Athens
Nicole Megow	University of Bremen
Marcin Mucha	University of Warsaw
Harald Räcke	TU Munich
Laura Sanità	TU Eindhoven & University of Waterloo
Chaitanya Swamy	University of Waterloo
Jakub Tarnawski	Microsoft Research
Anke van Zuylen	William and Mary
David Williamson	Cornell University

RANDOM

Nima Anari	Stanford University
Eshan Chattopadhyay	Cornell University
Gil Cohen	Tel Aviv University
Parikshit Gopalan	VmWare Research
Prahladh Harsha	Tata Institute of Fundamental Research
Sam Hopkins	University of California, Berkeley
Valentine Kabanets	Simon Fraser University
Gautam Kamath	University of Waterloo
Tali Kaufman	Bar-Ilan University
Yin-Tat Lee	University of Washington
Sepideh Mahabadi	TTI Chicago
Raghu Meka	UCLA, PC chair
Jelani Nelson	University of California, Berkeley
Ryan O'Donnell	Carnegie Mellon University
Ilya Razenshteyn	Microsoft Research
Barna Saha	University of California, Berkeley
Tselil Schramm	Stanford University
Madhu Sudan	Harvard University
Avishay Tal	University of California, Berkeley
Eric Vigoda	Georgia Tech University
Mary Wootters	Stanford University

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2020).
Editors: Jarosław Byrka and Raghu Meka

Abstract

We revisit the fundamental problem of determining seed length lower bounds for strong extractors and natural variants thereof. These variants stem from a "change in quantifiers" over the seeds of the extractor: While a strong extractor requires that the average output bias (over all seeds) is small for all input sources with sufficient min-entropy, a *somewhere* extractor only requires that there *exists* a seed whose output bias is small. More generally, we study what we call *probable* extractors, which on input a source with sufficient min-entropy guarantee that a large enough fraction of seeds have small enough associated output bias. Such extractors have played a key role in many constructions of pseudorandom objects, though they are often defined implicitly and have not been studied extensively.

Prior known techniques fail to yield good seed length lower bounds when applied to the variants above. Our novel approach yields significantly improved lower bounds for somewhere and probable extractors. To complement this, we construct a somewhere extractor that implies our lower bound for such functions is tight in the high min-entropy regime. Surprisingly, this means that a random function is far from an optimal somewhere extractor in this regime. The techniques that we develop also yield an alternative, simpler proof of the celebrated optimal lower bound for strong extractors originally due to Radhakrishnan and Ta-Shma (SIAM J. Discrete Math., 2000).

1 Introduction

Strong seeded extractors are central objects in pseudorandomness that have found many applications in theoretical computer science and cryptography. Informally speaking, a function $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ is a strong extractor if for every source X of sufficiently high min-entropy it holds that the average bias of $\mathsf{Ext}(X,i)$ over the seeds $i \in [D]$ is small. More precisely, we have the definition below. Throughout this paper, we focus on single-bit output extractors since lower bounds in this setting immediately imply lower bounds for any m-bit output extractor.

▶ **Definition 1.1** ((k,ε)-strong extractor). *For $\varepsilon < 1/2$, a function $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ is said to be a (k,ε)-*strong extractor *if*

$$\mathop{\mathbb{E}}_{i \leftarrow [D]} [\Delta(\mathsf{Ext}(X,i); U_1)] \leq \varepsilon \tag{1}$$

for every (n,k)-source[1] X, where $i \leftarrow [D]$ means i is uniformly distributed over $[D]$, and

$$\Delta(\mathsf{Ext}(X,i); U_1) = |\Pr[\mathsf{Ext}(X,i) = 1] - 1/2|$$

is the bias of $\mathsf{Ext}(X,i)$.

A fundamental parameter when studying strong extractors is the number of seeds D. Ideally, one would like to construct strong extractors with D as small as possible. However, there exist lower bounds on D depending on n, k, and ε. Nisan and Zuckerman [21] showed that every strong extractor must use $D = \Omega\left(\frac{n-k}{\varepsilon}\right)$ seeds. Later, in a seminal work, Radhakrishnan and Ta-Shma [22] improved the lower bound above to[2]

$$D = \Omega\left(\frac{n-k}{\varepsilon^2}\right). \tag{2}$$

Notably, this turns out to be tight. In fact, a random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ with $D = C \cdot \frac{n-k}{\varepsilon^2}$ seeds, for a sufficiently large constant $C > 0$, is a (k,ε)-strong extractor with high probability. An alternative proof of (2) for a limited range of k was given by Bar-Yossef, Kumar, and Sivakumar [3], based on the connection between extractors and averaging samplers [27] and sampling lower bounds.

[1] See Definition 2.3.
[2] The lower bound in (2) also holds for "non-strong" extractors, i.e., functions $F : \{0,1\}^n \times [D] \to \{0,1\}^{d+1}$ such that $F(X, U_{[D]}) \approx_\varepsilon U_{d+1}$, where $d = \log D$. Note that in this case the lower bound only holds for output length at least $d+1$; otherwise, one can just output the uniformly random seed.

At the opposite end of the spectrum lies another well-known pseudorandom object, called a *somewhere extractor*. While a strong extractor has small average bias, all we require of a somewhere extractor is that its *minimum* bias over all seeds is small. More precisely, we have the following definition.

▶ **Definition 1.2** ((k,ε)-somewhere extractor)**.** *For $\varepsilon < 1/2$, a function* $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ *is said to be a* (k,ε)-somewhere extractor *if for every (n,k)-source X it holds that*

$$\min_{i\in[D]} \Delta(\mathsf{Ext}(X,i);U_1) \leq \varepsilon.$$

Somewhere extractors arise in a number of different contexts. In fact, many of the most important applications of strong extractors (e.g., in the construction of multi-source extractors) actually only require these potentially weaker objects. Given the complete picture we have of strong extractors, it is natural to wonder what kind of bounds we can prove on the number of seeds D for a somewhere extractor Ext.

A simple averaging argument on the preimage sizes of Ext shows that $D > n - k$, but it is possible to improve on this lower bound. If one considers somewhere extractors with m output bits, then [2] showed that a connection to dispersers leads to the lower bound

$$D = \Omega\left(\frac{n-k}{\varepsilon + 2^{-m}}\right). \tag{3}$$

While (3) was good enough in the context of [2], it is quite unsatisfactory in general for two reasons: First, it is trivial for small m (e.g., in our setting, where $m = 1$). Second, even for larger m, it does not scale with ε below 2^{-m}. In the 1-bit output setting, which is the hardest for lower bounds, the best known lower bound is given in [2] as

$$D = \Omega\left(n - k + \log\left(1/\varepsilon\right)\right).$$

On the other hand, as we show in this work, a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ is a (k,ε)-somewhere extractor with non-negligible probability only when $D = \Omega\left(\frac{n-k}{\varepsilon^2}\right)$ (we discuss this in more detail below). Therefore, in contrast with strong extractors, there is a large gap between upper and lower bounds on the number of seeds required by somewhere extractors, leaving open the exciting possibility of better constructions.

One may also wonder whether the strong extractor lower bound techniques from [21, 22] can be adapted to yield better lower bounds for somewhere extractors. However, it is not clear how this can be done, since these techniques are fundamentally tailored for dealing solely with the average bias as in Definition 1.1. Overall, current techniques seem incapable of yielding a sharp, unconditional analysis of somewhere extractors.

1.1 Our contributions

In this work, we develop a novel approach towards proving lower bounds on the number of seeds required by natural variants of strong extractors. We highlight our main results here.

1.1.1 Improved lower bounds for somewhere extractors

We significantly improve the lower bound for (k,ε)-somewhere extractors. More precisely, we prove the following result.

▶ **Theorem 1.3.** *Every (k,ε)-somewhere extractor* $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ *must have*

$$D \geq \frac{\ln 2}{2} \cdot \frac{n-k}{\varepsilon}. \tag{4}$$

Recall that the previous best lower bound was $D = \Omega(n - k + \log(1/\varepsilon))$. Observe also that the lower bound in (4) is a factor of ε smaller than the one in (2) for strong extractors. Remarkably, we construct a (simple) (k, ε)-somewhere extractor that shows (4) is *tight* in the high min-entropy regime.

▶ **Theorem 1.4.** *For every $\varepsilon \geq \frac{1}{2(1+2^k)}$, there exists a (k, ε)-somewhere extractor* $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ *with*

$$D = \frac{2^{n-k-1}}{\varepsilon} + 1.$$

▶ Remark 1.5. We note that there are no (k, ε)-somewhere extractors with $\varepsilon < \frac{1}{2(1+2^k)}$. To see this, consider an (n, k)-source X uniformly distributed over a set of size $2^k + 1$. Then, for every i, $\Pr[\mathsf{Ext}(X, i) = 1] = \frac{C}{2^k+1}$ for some integer $C \geq 0$, and so $\mathsf{Ext}(X, i)$ has bias $\left|\frac{C}{2^k+1} - \frac{1}{2}\right| = \left|\frac{C - 2^{k-1} - 1/2}{2^k+1}\right| \geq \frac{1}{2(1+2^k)}$

In particular, Theorem 1.4 shows that (4) is tight up to a constant factor when $n - k$ is constant.

On the other hand, the existential result for strong extractors immediately implies that a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ with $D = C \cdot \frac{n-k}{\varepsilon^2}$ for a large enough constant $C > 0$ is a (k, ε)-somewhere extractor with high probability. Interestingly, we show that this probabilistic argument is tight up to a constant factor, in the sense that a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ must have $D = \Omega\left(\frac{n-k}{\varepsilon^2}\right)$ in order to be a (k, ε)-somewhere extractor with non-negligible probability for essentially all regimes of k and ε. Given the above, we conclude that a random function is far from an optimal (k, ε)-somewhere extractor in the high min-entropy regime. This provides a rare example where an explicit construction actually yields a significantly better extractor than a random function (at least for some parameters), and highlights a qualitative difference with strong extractors.

To be more precise, we show the following.

▶ **Theorem 1.6.** *For large enough n, suppose that $k \leq n - 400$, $2^{-0.24(n+k)} \leq \varepsilon \leq c$ for a sufficiently small constant $c > 0$, and*

$$D \leq \frac{n-k}{400 \cdot \varepsilon^2}.$$

Then, a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ is not *a (k, ε)-somewhere extractor with probability at least $1 - 2^{-2^{\Omega(n)}}$.*

1.1.2 Simple proof of the optimal lower bound for strong extractors

In the setting of strong extractors, we give an alternative proof of the tight lower bound (2). Our proof is much simpler than those due to Radhakrishnan and Ta-Shma [22] and Bar-Yossef, Kumar, and Sivakumar [3]. To be precise, we prove the following result.

▶ **Theorem 1.7.** *For every $n, k, \varepsilon > 0$ satisfying $n - k \geq 39$ and every (k, ε)-strong extractor* $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ *it holds that*

$$D \geq \frac{\ln 2}{18} \cdot \frac{n-k}{\varepsilon^2}.$$

1.1.3 Generalizing somewhere extractors and lower bounds

Finally, we initiate the systematic study of a meaningful generalization of somewhere extractors and also obtain significantly improved lower bounds in that setting, as discussed below. A somewhere extractor Ext can be generalized in a natural way by requiring that some fraction of the seeds of Ext yield an unbiased output, instead of only a single seed. This leads to the following definition.

▶ **Definition 1.8** ((k, ε, δ)-probable extractor)**.** *For $\varepsilon < 1/2$, a function $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ is said to be a (k, ε, δ)-*probable extractor *if*

$$\Pr_{i \leftarrow [D]}[\Delta(\mathsf{Ext}(X, i); U_1) > \varepsilon] < \delta$$

for every (n, k)-source X.

We note that probable extractors have been defined explicitly before, but not studied in depth, in [23, 6]. Observe that a (k, ε)-somewhere extractor corresponds to a $(k, \varepsilon, \delta = 1)$-probable extractor. Moreover, a (k, ε)-strong extractor lies somewhere between a $(k, \varepsilon/2, \varepsilon/2)$-probable extractor and a $(k, \sqrt{\varepsilon}, \sqrt{\varepsilon})$-probable extractor. More generally, every (k, ε)-strong extractor is a $(k, \varepsilon/\delta, \delta)$-probable extractor for every $\delta > 0$ by Markov's inequality. On the other hand, we also have that every (k, ε, δ)-probable extractor is a $(k, \varepsilon + \delta)$-strong extractor.

Given our previous discussion, a natural question to ask about probable extractors is the following:

How do ε and δ influence the number of seeds D?

Our work leads to a better understanding of this behavior. Similarly to what was already discussed in [6], by separating the maximum fraction of "bad" seeds δ and the maximum bias of the "good" seeds ε, we are able to explore the explicit influence that each of these parameters has on the number of seeds. Such a fine-grained analysis is not possible, for example, in the case of strong extractors, since those properties are essentially merged into a single global error parameter.

Besides being interesting on its own, there are practical motivations for the question above. In fact, several constructions of multi-source extractors make use of (k, ε)-strong extractors in scenarios where a $(k, \varepsilon/\delta, \delta)$-probable extractor would suffice with δ much larger than ε. The reason for this is simply that no better constructions of $(k, \varepsilon/\delta, \delta)$-probable extractors are known. However, it could be a priori possible to design a $(k, \varepsilon/\delta, \delta)$-probable extractor requiring much fewer seeds than a (k, ε)-strong extractor. In turn, this would lead to simpler constructions of, and improved parameters for, several multi-source extractors. We expand on this in Section 1.2.

1.1.4 Lower bounds for probable extractors

Lower bounds on the number of seeds required by probable extractors can be derived directly from lower bounds for both strong and somewhere extractors. Combining (2) with the fact that every (k, ε, δ)-probable extractor is a $(k, \varepsilon + \delta)$-strong extractor immediately leads to the lower bound

$$D = \Omega\left(\frac{n-k}{(\varepsilon+\delta)^2}\right).$$

However, note that the bound above becomes trivial whenever one of ε or δ is large.

To achieve a stronger bound, we observe that a (k, ε, δ)-probable extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ must be a (k, ε)-somewhere extractor when restricted to the first δD seeds. Therefore, any lower bound L for the number of seeds of (k, ε)-somewhere extractors immediately implies the lower bound $D \geq L/\delta$ for any (k, ε, δ)-probable extractor. Combining this with Theorem 1.3 leads to the following result.

▶ **Theorem 1.9.** *Let* $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ *be a* (k, ε, δ)*-probable extractor. Then, it holds that*

$$D \geq \frac{\ln 2}{2} \cdot \frac{n-k}{\varepsilon \cdot \delta}. \tag{5}$$

The lower bound in (5) significantly improves upon all previous bounds over a large range of (ε, δ), namely when $\delta \gg \varepsilon$ or $\varepsilon \gg \delta$. On the other hand, we show that a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ with $D = O\left(\frac{n-k}{\varepsilon^2 \cdot \delta}\right)$ is a (k, ε, δ)-probable extractor with high probability. It remains an open problem to close the gap between this upper bound and Theorem 1.9 in general. While we know from our previous discussion that the lower bound in Theorem 1.9 is tight for $\delta = 1$ and $n - k = O(1)$, the behavior might change substantially for other parameters.

Given the gap between the bounds above, it is natural to ask whether a different probabilistic argument could be used to show that a uniformly random function using fewer seeds is a (k, ε, δ)-probable extractor with high probability. As before, we can easily extend Theorem 1.6 to the setting of probable extractors to show the answer to the question above is negative. Namely, we have the following result, which shows that our probabilistic construction is tight up to a constant factor.

▶ **Theorem 1.10.** *For any* $\delta = \delta(n) \in (0, 1]$ *and large enough* n*, suppose that* $k \leq n - 400$*,* $2^{-0.24(n+k)} \leq \varepsilon \leq c$ *for a sufficiently small constant* $c > 0$*, and*

$$D \leq \frac{n-k}{400 \cdot \varepsilon^2 \cdot \delta}.$$

Then, a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ *is* not *a* (k, ε, δ)*-probable extractor with probability at least* $1 - 2^{-2^{\Omega(n)}}$*.*

1.2 Applications of somewhere- and probable- extractors

Besides the works we have already discussed, several others have either implicitly or explicitly used probable extractors. Many constructions of seeded and multi-source extractors [26, 20, 25, 24, 15, 17, 16, 9, 18, 19, 6, 8], along with some constructions of dispersers [5] and non-malleable and affine extractors [7, 19], use probable extractors (or slight variants of probable extractors) in their constructions.

In the literature, the output of the probable extractor (concatenated over all D seeds) is usually called a *somewhere-random source with D rows*. The time complexity of the resulting extractor constructions depends linearly on the complexity of enumerating the D seeds of the probable extractor being used. This poses a problem because, even now, the best explicit probable extractor we know of for a single weak source is simply a strong extractor. For such constructions, the lower bound in (2) applies, and so extra assumptions must be made or parameters must be worsened in order to ensure that seed enumeration can be done efficiently.

We present concrete examples of the compromise above. Some works settle for a large overall $1/\mathrm{poly}(n)$ error of the resulting extractor to get around the seed enumeration problem [24, 15, 17, 16, 19]. On another front, many works use extra independent weak sources with enough min-entropy as input to generate somewhere-random sources with fewer rows [4, 5, 9, 18, 19, 7, 6, 8]. Moreover, the addition of a short uniformly random seed to

achieve this goal has also been considered [20]. Many works above can be interpreted as constructing several types of randomness extractors for somewhere-random sources (called *mergers*), a problem which was first studied by Ta-Shma [26]. Other works that have studied mergers include [25, 28, 12, 11, 13, 10].

Prior to this work, we could not rule out a (k, ε, δ)-probable extractor for δ much larger than ε with much fewer seeds than a (k, ε)-strong extractor. Given the discussion above, this would lead not only to extractors with improved parameters, but also to conceptually simpler constructions, since many tools and assumptions were introduced to deal with the fact that somewhere-random sources generated by strong extractors have rather many rows. Our results preclude this possibility.

Finally, we note that many of the applications above still work if one considers an extractor that outputs *convex combinations* of somewhere-random sources from (n, k)-sources instead. Our lower bounds do not apply to this weaker setting. Therefore, we do not rule out the existence of methods of generating a convex combination of somewhere-random sources from one weak source requiring fewer seeds. Our results show that, without considering convex combinations, one cannot do *too much* better than the naive and globally used method of enumerating over the seeds of a strong extractor (although, surprisingly, we show that a polynomial improvement in $1/\varepsilon$ *is* possible). We leave it as an interesting open problem to extend our new techniques and bounds to the setting of convex combinations.

1.3 Technical overview

In this section, we provide a more detailed account of our contributions.

1.3.1 The high-level approach

Our extractor lower bounds can be unified under a common high-level approach. Fix an arbitrary function $F : \{0,1\}^n \times [D] \to \{0,1\}$. Our goal is to relate the number of seeds D to some measure of the bias of F over all seeds, depending on the type of extractor we are dealing with. For the remainder of this section, we focus on somewhere extractors and the minimum bias. However, everything is equally applicable to strong extractors simply by replacing minimum bias by average bias.

To prove a lower bound on D, we must show the existence of an input (n, k)-source X such that $P = (F(X, 1), F(X, 2), \ldots, F(X, D))$ is sufficiently biased. We do this by constructing the output distribution P directly, rather than trying to find an input distribution X that maps to P.

Throughout the remainder of this paper, we write

$$F(x) = (F(x, 1), F(x, 2), \ldots, F(x, D)) \in \{0,1\}^D.$$

Then, for F and fixed k, we construct a distribution $P = (P_1, P_2, \ldots, P_D)$ over $\{0,1\}^D$ such that the following two conditions hold.

1. There exists an (n, k)-source X such that $F(X) = P$;
2. It holds that[3]

$$\min_{i \in [D]} \Delta(P_i; U_1) \geq \alpha,$$

where α is some quantity depending on n, k, and D.

If F is a (k, ε)-somewhere extractor, the two conditions above imply that $\varepsilon \geq \alpha$. This relationship then yields a lower bound on D.

[3] In the case of strong extractors, this condition is replaced by $\mathbb{E}_{i \leftarrow [D]}[\Delta(P_i; U_1)] \geq \alpha$.

The main novelty of our approach lies in the design of the output distribution P. The distribution $A = F(U_n)$ takes on a special role in our construction of good choices of P. We begin by showing that the first condition above automatically holds provided P satisfies a simple constraint related to A, which is detailed in the following lemma (below and throughout the paper, we write $X(x)$ for the probability that a random variable/distribution X takes on value x).

▶ **Lemma 1.11.** *There exists an (n,k)-source X such that $F(X) = P$ if*

$$P(a) \le 2^{n-k} A(a) \tag{6}$$

for all $a \in \{0,1\}^D$.

Proof. It is enough to consider the source $X \in \{0,1\}^n$ that picks each $x \in \{0,1\}^n$ with probability

$$X(x) = 2^{-n} \cdot \frac{P(F(x))}{A(F(x))}.$$

First, by (6) it follows that $X(x) \le 2^{-n} \cdot 2^{n-k} = 2^{-k}$ for every x. Moreover, using the fact that $A(a) = 2^{-n} \cdot |F^{-1}(a)|$, it is easy to see that X is a valid probability distribution and $F(X) = P$. ◀

▶ Remark 1.12. *It is easy to see that such an (n,k)-source exists if* and only if (6) *holds. However, in this work, we only need the implication in one direction.*

We construct distributions P implicitly in terms of the distribution $A = F(U_n)$. In fact, Lemma 1.11 shows it is enough to restrict our attention to distributions P that can be written as

$$P(a) = A(a) \cdot f(a)$$

for some non-negative function f satisfying $f(a) \le 2^{n-k}$ for all $a \in \{0,1\}^D$. As discussed in the following sections, careful choices of f lead to good lower bounds on D with streamlined derivations.

1.3.2 Improved lower bound for somewhere and probable extractors

We employ the high-level approach detailed in Section 1.3.1 to obtain improved lower bounds for probable extractors. Namely, we prove Theorem 1.3, which states that every (k,ε)-somewhere extractor must have $D \ge \frac{\ln 2}{2} \cdot \frac{n-k}{\varepsilon}$. In turn, this easily implies Theorem 1.9 for general (k,ε,δ)-probable extractors.

Let $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ be an arbitrary (k,ε)-somewhere extractor. In order to prove Theorem 1.3 via the high-level approach from Section 1.3.1, we consider the family of distributions $\overline{P}_z$ parameterized by $z \in \{0,1\}^D$ defined as

$$\overline{P}_z(a) = \frac{1}{C_z} \cdot A(a) \cdot \prod_{i=1}^{D} [1 + (-1)^{a_i + z_i} \gamma], \quad a \in \{0,1\}^D,$$

where $A = \mathsf{Ext}(U_n)$, $\gamma \in (0,1)$ is a parameter of our choice, and C_z is the normalizing factor.

We choose $z^\star$ which maximizes C_z over all $z \in \{0,1\}^D$, and consider $P = \overline{P}_{z^\star}$. In particular, this choice implies that $C_{z^\star} \ge 1$, which allows us to take $\gamma = \Theta\left(\frac{n-k}{D}\right)$ while still satisfying (6). It remains to lower bound $\Delta(P_i; U_1)$ for every $i \in [D]$ appropriately. The product structure of the family of distributions we consider makes it amenable to a Fourier-analytic approach, which we employ to show that for every $i \in [D]$ we have

$$\Delta(P_i; U_1) = \Omega(\gamma) = \Omega\left(\frac{n-k}{D}\right).$$

This yields the desired lower bound on D. More details can be found in Section 3.

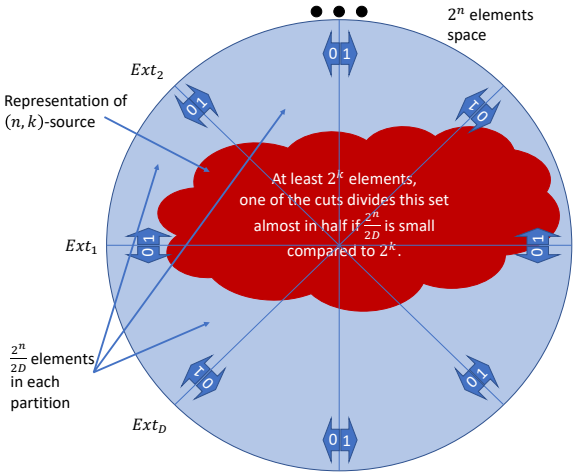

Figure 1 An illustration of the (k, ε)-somewhere extractor that shows our lower bound is tight in the high min-entropy regime.

1.3.3 Tight upper bound for somewhere extractors

We design a somewhere extractor that shows our lower bound for (k, ε)-somewhere extractors is tight (up to a multiplicative constant) in the high min-entropy regime where $n - k = O(1)$. More precisely, we prove Theorem 1.4, which states that there exists a (k, ε)-somewhere extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ with $D = \frac{2^{n-k-1}}{\varepsilon} + 1$ for all non-trivial ε.

This is accomplished by showing that the function $\mathsf{Ext} : [N] \times \{0, 1, \ldots, E\} \to \{0,1\}$, with $E = \frac{2^{n-k-1}}{\varepsilon}$ and $N = 2^n$, defined as

$$\mathsf{Ext}(x, i) = \mathsf{sign}[(x + i) \mod 2E], \quad i = 0, 1, \ldots, E \tag{7}$$

is a (k, ε)-somewhere extractor. In (7), we see $x \mod 2E$ as an integer in $\{-E, \ldots, E-1\}$, and define $\mathsf{sign}(y) = \mathbf{1}_{\{y \geq 0\}}$. Intuitively, this simple function yields a good somewhere extractor because the functions $\mathsf{Ext}(\cdot, i)$ "transition smoothly" from $\mathsf{Ext}(\cdot, 0)$ to its opposite, $\mathsf{Ext}(\cdot, E) = 1 - \mathsf{Ext}(\cdot, 0)$, as shown in Figure 1.

In more detail, given an (n, k)-source X, we wish to prove that there is a seed i such that $\Delta(\mathsf{Ext}(X, i); U_1) \leq \varepsilon$. In order to show this, we will look at how the quantities

$$\Delta_i = \Pr[\mathsf{Ext}(X, i) = 1] - \Pr[\mathsf{Ext}(X, i) = 0], \quad i = 0, 1, \ldots, E$$

behave. The desired result follows if we show that $|\Delta_i| \leq 2\varepsilon$ for some i. In turn, this holds because the Δ_i's satisfy two simple properties. First, we have $\Delta_0 = -\Delta_E$. Second, when going from $\mathsf{Ext}(\cdot, i-1)$ to $\mathsf{Ext}(\cdot, i)$, by our choice of parameters at most $4\varepsilon \cdot 2^k$ elements of $[N]$ go from 1 to 0, and vice-versa. This implies that $|\Delta_i - \Delta_{i-1}| \leq 4\varepsilon$. Combining the two properties above immediately ensures the existence of $i^\star$ such that $|\Delta_{i^\star}| \leq 2\varepsilon$, as desired. For more details, see Section 4.

1.3.4 Simpler proof of the optimal lower bound for strong extractors

In this section, we discuss our alternative, simpler proof of the optimal lower bound on the number of seeds for strong extractors, originally obtained by Radhakrishnan and Ta-Shma [22]. Namely, we prove Theorem 1.7, which states that every (k, ε)-strong extractor must have $D \geq \frac{\ln 2}{18} \cdot \frac{n-k}{\varepsilon^2}$ when $n - k \geq 39$.

As before, we follow the high-level approach introduced in Section 1.3.1. However, we consider a different family of distributions. Fix an arbitrary (k, ε)-strong extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$, and let $A = \mathsf{Ext}(U_n)$. Then, for $z \in \{0,1\}^D$ and $t \leq D$ define the distribution

$$\overline{P}_{z,t}(a) = \frac{1}{C_{z,t}} \cdot A(a) \cdot \mathbf{1}_{\{\|z-a\|_1 \leq t\}}, \quad a \in \{0,1\}^D,$$

where $C_{z,t}$ is the normalizing factor. The desired result now follows via two simple combinatorial arguments, which guarantee that (i) for an appropriate $t = D/2 - \Theta(\sqrt{(n-k)D})$, there exists a choice of z such that $P = \overline{P}_{z,t}$ satisfies (6), and (ii) the average bias of every distribution $\overline{P}_{z,t}$ is at least $1/2 - t/D = \Omega\left(\sqrt{(n-k)/D}\right)$. More details can be found in Appendix B.

1.3.5 Probabilistic constructions and lower bounds for random functions

We study for which values of D it holds that a uniformly random function $F : \{0,1\}^n \times [D] \to \{0,1\}$ is a (k, ε, δ)-probable extractor with non-negligible probability. To show an upper bound, we consider a connection between probable extractors and strong *two-source* extractors, and then invoke well-known existential results for the latter.[4] This shows that, under a mild constraint on k, ε, and δ, a uniformly random function is a (k, ε, δ)-probable extractor with probability at least, say, 0.99 when $D = C \cdot \frac{n-k}{\varepsilon^2 \cdot \delta}$ for a sufficiently large constant $C > 0$.

We complement the upper bound in the previous paragraph via Theorem 1.10, which states that a uniformly random function with $D \leq \frac{n-k}{400 \cdot \varepsilon^2 \cdot \delta}$ is *not* a (k, ε, δ)-probable extractor with probability at least $1 - 2^{-2^{\Omega(n)}}$. This means that our probabilistic construction above is tight up to a constant factor. Similarly to Section 1.3.2, to prove this result it suffices to focus our attention on somewhere extractors. We consider a source $X \in \{0,1\}^n$ uniformly distributed over a set $\mathcal{X}_F$ defined as

$$\mathcal{X}_F = \{x \in \{0,1\}^n : \|F(x)\|_1 \leq t\}$$

for an appropriate $t = D/2 - \Theta(\sqrt{(n-k)D})$. Then, we show X satisfies two properties: First, by a Chernoff bound, it holds that $|\mathcal{X}_F| \geq 2^k$ with very high probability over the choice of F, and hence X is an (n, k)-source with very high probability. Second, we show that, again with very high probability, we have $\Delta(F(X, i); U_1) > \varepsilon$ simultaneously for all $i \in [D]$. These two properties immediately imply that F is not a (k, ε)-somewhere extractor with high probability. More details can be found in the full version of this paper [1].

1.4 Open questions

Besides the natural problem of improving upon our lower bounds in general, our work leaves open other interesting avenues for further research.:

- Consider the special case of $(k, \varepsilon, \varepsilon)$-probable extractors. In this setting, the best lower bounds only yield $D = \Omega\left(\frac{n-k}{\varepsilon^2}\right)$, while the probabilistic method requires $D = \Omega\left(\frac{n-k}{\varepsilon^3}\right)$ to work with non-negligible probability. We believe $D = \Theta\left(\frac{n-k}{\varepsilon^3}\right)$ is the correct answer, and it would be very interesting to prove (or disprove) this claim, as it showcases different behavior than (k, ε, δ)-probable extractors for $\delta \gg \varepsilon$;

[4] More direct approaches do not seem to work because the set of sources from which a somewhere extractor successfully extracts is not necessarily convex.

- Show the existence of a (k, ε)-somewhere extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ using $D = O\left(\frac{n-k}{\varepsilon}\right)$ seeds. This would extend the tightness of our lower bound for somewhere extractors below the high min-entropy regime;
- Extend our (k, ε)-somewhere extractor from Section 1.3.3 to output $m > 1$ bits with (roughly) the same number of seeds;
- Extend our lower bounds to the setting where one is allowed to output convex combinations of somewhere-random sources from one (n, k)-source (see Section 1.2).

1.5 Organization

We introduce basic notions and results that are useful throughout our work in Section 2. The proofs of our extractor lower bounds are presented in Section 3 and Appendices A and B. The matching upper bound on the number of seeds of somewhere extractors can be found in Section 4. Probabilistic constructions of probable extractors, along with lower bounds on the number of seeds of uniformly random functions are discussed in the full version [1].

2 Preliminaries

2.1 Notation

Random variables and distributions are usually denoted by uppercase letters such as X, Y, and Z. When context allows, we may confuse a random variable with its associated distribution. We write $X(x)$ for the probability that X equals x, and denote the support of X by $\mathsf{supp}(X)$. The uniform distribution over $\{0,1\}^n$ is denoted by U_n. We write $i \leftarrow S$ to mean that i is sampled uniformly at random from the set S. For a distribution X, we write $x \sim X$ to denote x is sampled according to X. Given an event E, the indicator of E is denoted by $\mathbf{1}_{\{E\}}$. The expected value of a random variable X is denoted by $\mathbb{E}[X]$ or $\mathbb{E}_{x\sim X}[x]$. Sets are usually denoted by uppercase letters such as S and T. The set $\{1, 2, \ldots, D\}$ is denoted by $[D]$. We will usually identify a set S with its characteristic vector, so that we write $S_i = 1$ if and only if $i \in S$. We write $S + T$ for the symmetric difference between two sets S and T (i.e., the modulo 2 sum of their characteristic vectors). We denote the base-2 logarithm by log and the natural logarithm by ln. We write $\|x\|_p$ for the p-norm of a vector x. The inner product between two vectors x and y over some field is denoted by $\langle x, y\rangle$.

2.2 Probability theory

In this section, we introduce some basic notions and results from probability theory.

▶ **Definition 2.1** (Statistical distance). *Given two distributions X and Y over a set $\mathcal{X}$, the* statistical distance between X and Y, *denoted by $\Delta(X;Y)$, is defined as*

$$\Delta(X;Y) = \max_{S\subseteq\mathcal{X}} |\Pr[X \in S] - \Pr[Y \in S]| = \frac{1}{2}\sum_{x\in\mathcal{X}} |X(x) - Y(x)| .$$

*We say that X and Y are ε-*close*, also written $X \approx_\varepsilon Y$, if $\Delta(X;Y) \le \varepsilon$.*

▶ **Definition 2.2** (Min-entropy). *Given a distribution X over $\mathcal{X}$, the* min-entropy of X, *denoted by $\mathbf{H}_\infty(X)$, is defined as*

$$\mathbf{H}_\infty(X) = -\log\left(\max_{x\in\mathcal{X}} X(x)\right).$$

▶ **Definition 2.3** ((n,k)-source)**.** *A distribution X supported on $\{0,1\}^n$ is said to be an* (n,k)-source *if $\mathbf{H}_\infty(X) \geq k$. An (n,k)-source is said to be* flat *if it is uniformly distributed over a subset of $\{0,1\}^n$ of size 2^k.*

The several notions of extractors that we focus on in this work were already covered in Definitions 1.1, 1.2, and 1.8 in Section 1.

Later on, we will exploit the well-known (and not difficult to prove) fact that the Chernoff bound is tight (up to constants in the exponent).

▶ **Lemma 2.4** (Inverse Chernoff bound, see, e.g., [14, Lemma 4, Part 1 with $p = 1/2$])**.** *Suppose $\gamma, D > 0$ are such that $\gamma \leq 1/2$ and $\gamma^2 D \geq 6$, and let Z denote a binomial distribution with D trials and success probability $1/2$. Then,*

$$2^{-D} \cdot \sum_{i=0}^{(1-\gamma)D/2} \binom{D}{i} = \Pr\left[Z \leq \frac{(1-\gamma)D}{2}\right] \geq \exp\left(-\frac{9\gamma^2 D}{2}\right).$$

2.3 Basic boolean functional analysis

In this section, we briefly discuss basic notions from the analysis of boolean functions that we will use later on.

Given a set $S \subseteq [n]$, the Fourier character $\chi_S : \{0,1\}^n \to \{-1,1\}$ is defined as

$$\chi_S(x) = (-1)^{\langle x,s\rangle},$$

where s is the characteristic vector of S (i.e., $s_i = 1$ if and only if $i \in S$). The characters χ_S satisfy $\chi_S(x+y) = \chi_S(x) \cdot \chi_S(y)$ and form an orthonormal basis of the space of functions $f : \{0,1\}^n \to \mathbb{R}$. Consequently, every such function f has a unique Fourier expansion

$$f(x) = \sum_{S \subseteq [n]} \widehat{f}(S) \cdot \chi_S(x),$$

where $\widehat{f}(S) = \mathbb{E}_{x \leftarrow \{0,1\}^n}[f(x) \cdot \chi_S(x)]$ is the Fourier coefficient of f on S.

3 A lower bound for probable extractors

In this section, we follow the high-level approach described in Section 1.3.1 to prove Theorem 1.3, which we restate here for convenience. By the discussion in Section 1.3.2, this result immediately implies the more general Theorem 1.9 for probable extractors.

▶ **Theorem 1.3.** *Every (k,ε)-somewhere extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ must have*

$$D \geq \frac{\ln 2}{2} \cdot \frac{n-k}{\varepsilon}. \tag{4}$$

Fix a (k,ε)-somewhere extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$, and let $A = \mathsf{Ext}(U_n)$. For $z \in \{0,1\}^D$, consider the (unnormalized) distribution P_z defined as

$$P_z(a) = A(a) \cdot \prod_{i=1}^{D} [1 + (-1)^{a_i + z_i}\gamma] = A(a) \sum_{S \subseteq [D]} \chi_S(a+z)\gamma^{|S|} \tag{8}$$

for $a \in \{0,1\}^D$, where $\gamma = (g/D)\ln 2$ and $g = n - k$ is the min-entropy gap. The second equality in (8) holds because for every $S \subseteq [D]$ we have

$$\mathop{\mathbb{E}}_{a\leftarrow\{0,1\}^D}\left[\prod_{i=1}^{D}[1+(-1)^{a_i+z_i}\gamma]\cdot\chi_S(a)\right]=\prod_{i=1}^{D}\mathop{\mathbb{E}}_{a_i\leftarrow\{0,1\}}[(1+(-1)^{a_i+z_i}\gamma)\cdot(-1)^{a_i\cdot S_i}]$$
$$=\prod_{i\in S}\gamma(-1)^{z_i}$$
$$=\gamma^{|S|}\cdot\chi_S(z).$$

Observe that $0<\gamma<1$ since we know $D>g>0$. To see this, note that, if $D\le g$, a simple averaging argument guarantees there is $a\in\{0,1\}^D$ with $|\mathsf{Ext}^{-1}(a)|\ge 2^k$. This implies there is an (n,k)-source X such that $\mathsf{Ext}(X)$ is constant. We can then define the normalizing constant

$$C_z=\sum_{a\in\{0,1\}^D}P_z(a)>0,$$

and we set

$$\overline{P}_z(a)=\frac{P_z(a)}{C_z}.$$

We will fix $z^\star$ to be a choice of z that maximizes C_z, and we let

$$P=\overline{P}_{z^\star}.$$

Note that P is a distribution over $\{0,1\}^D$. We denote the distribution of its i-th coordinate by P_i.

3.1 Proof of Theorem 1.3

Our goal now is twofold: First, we must ensure that

$$P(a)\le 2^g A(a)\quad\forall a\in\{0,1\}^D. \tag{9}$$

Second, we wish to show that

$$\min_{i\in[D]}\Delta(P_i;U_1)\ge\gamma/2. \tag{10}$$

Since Ext is a (k,ε)-somewhere extractor, from (9) and (10) it follows that $\varepsilon\ge\gamma/2$. By the choice of γ above this immediately implies Theorem 1.3.

▶ **Lemma 3.1.** *Condition* (9) *holds for the choice of* $z^\star$ *and* γ *above.*

Proof. First, since $z^\star=\arg\max_z C_z$, we have

$$C_{z^\star}\ge\mathop{\mathbb{E}}_{z\leftarrow\{0,1\}^D}[C_z]=\sum_{a\in\{0,1\}^D}\mathop{\mathbb{E}}_{z\leftarrow\{0,1\}^D}[P_z(a)]=\sum_{a\in\{0,1\}^D}A(a)=1.$$

Therefore, it suffices to show that

$$\prod_{i=1}^{D}[1+(-1)^{z_i^\star+a_i}\gamma]\le 2^g.$$

for every $a\in\{0,1\}^D$. This follows immediately from the fact that

$$(1+\gamma)^D=\left(1+\frac{g\ln 2}{D}\right)^D\le\exp(g\ln 2)=2^g.$$ ◀

▶ **Lemma 3.2.** *We have*

$$\min_{i\in[D]} \Delta(P_i; U_1) \geq \gamma/2.$$

Proof. In order to show the desired inequality, it suffices to prove that

$$\left| \mathop{\mathbb{E}}_{a\sim P}[\chi_{\{i\}}(a)] \right| \geq \gamma \tag{11}$$

for every $i \in [D]$. For any $T \subseteq [D]$ and $z \in \{0,1\}^D$, we have

$$\begin{aligned} C_z \cdot \mathop{\mathbb{E}}_{a\sim P_z}[\chi_T(a)] &= \sum_{a\in\{0,1\}^D} P_z(a)\cdot\chi_T(a) \\ &= \sum_{a\in\{0,1\}^D} \left[A(a) \sum_{S\subseteq[D]} \chi_S(a+z)\gamma^{|S|} \right] \cdot \chi_T(a) \\ &= \sum_{S\subseteq[D]} \chi_S(z)\gamma^{|S|} \sum_{a\in\{0,1\}^D} A(a)\cdot\chi_S(a)\cdot\chi_T(a) \\ &= 2^D \sum_{S\subseteq[D]} \chi_S(z)\gamma^{|S|}\cdot\widehat{A}(S+T), \end{aligned} \tag{12}$$

where the second equality follows from (8), the third equality is true because $\chi_S(a+z) = \chi_S(a)\cdot\chi_S(z)$, and the last equality holds since $\chi_S(a)\cdot\chi_T(a) = \chi_{S+T}(a)$ and by the definition of $\widehat{A}(S+T)$.

For $i \in [D]$ and $b \in \{0,1\}$, define

$$a_b = 2^D \sum_{S\subseteq[D]:S_i=b} \chi_S(z^\star)\gamma^{|S|}\cdot\widehat{A}(S).$$

By setting $T = \emptyset$ and $z = z^\star$, from (12) we obtain

$$C_{z^\star} = C_{z^\star}\cdot \mathop{\mathbb{E}}_{a\sim P}[\chi_\emptyset(a)] = a_0 + a_1. \tag{13}$$

Moreover, setting $T = \{i\}$ and $z = z^\star$ in (12) leads to

$$\begin{aligned} C_{z^\star}\cdot \mathop{\mathbb{E}}_{a\sim P}[\chi_{\{i\}}(a)] &= 2^D \sum_{S\subseteq[D]} \chi_S(z^\star)\gamma^{|S|}\cdot\widehat{A}(S+\{i\}) \\ &= 2^D \sum_{S':=S+\{i\}\subseteq[D]} \chi_{S'+\{i\}}(z^\star)\gamma^{|S'+\{i\}|}\cdot\widehat{A}(S') \\ &= \chi_{\{i\}}(z^\star)\cdot\gamma\cdot 2^D \sum_{S'\subseteq[D]:S'_i=0} \chi_{S'}(z^\star)\cdot\gamma^{|S'|}\widehat{A}(S') \\ &\quad + \frac{\chi_{\{i\}}(z^\star)}{\gamma}\cdot 2^D \sum_{S'\subseteq[D]:S'_i=1} \chi_{S'}(z^\star)\cdot\gamma^{|S'|}\widehat{A}(S') \\ &= \chi_{\{i\}}(z^\star)\left(a_0\gamma + \frac{a_1}{\gamma}\right). \end{aligned} \tag{14}$$

Combining (14) with (13) implies that

$$\left| \mathop{\mathbb{E}}_{a\sim P}[\chi_{\{i\}}(a)] \right| = \left| \frac{a_0\gamma + a_1/\gamma}{a_0 + a_1} \right|. \tag{15}$$

To conclude the proof, we show that $a_1 \geq 0$. Coupled with (15), this yields (11) because then we have

$$|a_0\gamma + a_1/\gamma| \geq \gamma(a_0 + a_1) = \gamma|a_0 + a_1|,$$

where the inequality follows from $a_1 \geq 0$ and the fact that $0 < \gamma < 1$ (recall that $D > g > 0$), and the equality holds because $a_0 + a_1 = C_{z^\star} > 0$.

It remains to show that $a_1 \geq 0$. Let $e_i \in \{0,1\}^D$ be the vector that is 1 at i and 0 elsewhere, and set $z' = z^\star + e_i$. Then, by (12) with $T = \emptyset$ and $z = z' = z^\star + e_i$ we have

$$\begin{aligned} C_{z'} &= 2^D \sum_{b\in\{0,1\}} \sum_{S\subseteq[D]:S_i=b} \chi_S(z^\star + e_i)\gamma^{|S|} \cdot \widehat{A}(S) \\ &= 2^D \sum_{b\in\{0,1\}} (-1)^b \sum_{S\subseteq[D]:S_i=b} \chi_S(z^\star)\gamma^{|S|} \cdot \widehat{A}(S) \\ &= a_0 - a_1, \end{aligned}$$

where the second equality follows from the multiplicative property of χ_S and the fact that $\chi_S(e_i) = (-1)^{S_i}$. Since $z^\star = \arg\max_z C_z$, we conclude that $a_0 + a_1 = C_{z^\star} \geq C_{z'} = a_0 - a_1$, and thus $a_1 \geq 0$. ◀

In Appendix A, we present an alternative proof of Lemma 3.2 which was suggested to us by an anonymous reviewer.

4 Matching upper bound for somewhere extractors

In this section, we prove Theorem 1.4, which we restate here.

▶ **Theorem 1.4.** *For every $\varepsilon \geq \frac{1}{2(1+2^k)}$, there exists a (k,ε)-somewhere extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ with*

$$D = \frac{2^{n-k-1}}{\varepsilon} + 1.$$

Combining this result with Theorem 1.3 in the high min-entropy regime (i.e., $n-k = O(1)$) immediately leads to the following corollary.

▶ **Corollary 4.1.** *The minimum number of seeds required for a (k,ε)-somewhere extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ when $n - k = O(1)$ is $D = \Theta(1/\varepsilon)$.*

It is instructive to compare Corollary 4.1 with analogous results for strong extractors and dispersers, since somewhere extractors lie between the two. With respect to dispersers, the optimal number of seeds in the high min-entropy regime is also $\Theta(1/\varepsilon)$ [22]. Moreover, this is achieved by a uniformly random function with high probability. For strong extractors, the optimal number of seeds is $\Theta(1/\varepsilon^2)$, again achieved by a uniformly random function with high probability. Remarkably, by Corollary 4.1 the optimal number of seeds for (1-bit output) somewhere extractors is $\Theta(1/\varepsilon)$, matching the behavior of dispersers. On the other hand, by Theorem 1.6, a uniformly random function requires $D = \Theta(1/\varepsilon^2)$ to be a (k,ε)-somewhere extractor with non-negligible probability, similarly to strong extractors!

We now proceed to define and analyze the relevant (k,ε)-somewhere extractor Ext that proves Theorem 1.4. In this section, it will be useful to identify the set of inputs $\{0,1\}^n$ with the set of integers $[N]$ for $N = 2^n$. For any N and D, we define the function $\mathsf{Ext} : [N] \times \{0,1,\ldots,E\} \to \{0,1\}$ for $E = \frac{2^{n-k-1}}{\varepsilon}$ via the simple expression

$$\mathsf{Ext}(x,i) = \mathsf{sign}[(x+i) \mod 2E]. \tag{16}$$

In (16), we interpret $(x+i) \mod 2E$ as an integer in $\{-E, -E+1, \ldots, E-1\}$ and $\mathsf{sign}(y) = \mathbf{1}_{\{y\geq 0\}}$.

4.1 Proof of Theorem 1.4

In order to prove the desired statement for the choice of Ext above, we need to show that for every (n,k)-source X there is $i = 0,1,\ldots,E$ such that

$$\Delta(\mathsf{Ext}(X,i);U_1) = \frac{1}{2}|\Pr[\mathsf{Ext}(X,i)=1] - \Pr[\mathsf{Ext}(X,i)=0]| < \varepsilon.$$

Fix an arbitrary (n,k)-source X. For each seed $i = 0,1,\ldots,E$, define

$$\Delta_i = \Pr[\mathsf{Ext}(X,i)=1] - \Pr[\mathsf{Ext}(X,i)=0].$$

The Δ_i's satisfy two important properties. First, observe that

$$\Delta_0 = -\Delta_E \tag{17}$$

since

$$\mathsf{sign}(x \mod 2E) = 1 - \mathsf{sign}[(x+E) \mod 2E]$$

for every x. Second, for every $i \in [E]$ it holds that

$$|\Delta_i - \Delta_{i-1}| \leq 2^{-k} \cdot \left\lceil \frac{N}{2E} \right\rceil = 2^{-k} \cdot \lceil \varepsilon 2^k \rceil \leq 4\varepsilon. \tag{18}$$

To see that (18) holds, it suffices to note that (i) there are at most $\lceil \frac{N}{2E} \rceil = \lceil \varepsilon 2^k \rceil$ integers $x \in [N]$ such that $\mathsf{Ext}(x,i-1) = 0$ but $\mathsf{Ext}(x,i) = 1$ and vice-versa, (ii) $X(x) \leq 2^{-k}$ for every integer x, and (iii) we have $\varepsilon \geq \frac{1}{2(1+2^k)}$. Finally, combining (17) and (18) ensures the existence of $i^\star$ such that $|\Delta_{i^\star}| \leq 2\varepsilon$. Therefore, we have

$$\Delta(\mathsf{Ext}(X,i^\star);U_1) \leq \varepsilon.$$

A Alternative proof of Lemma 3.2

In this section, we present an alternative proof of Lemma 3.2 that was suggested to us by an anonymous reviewer.

Recall that we defined $P = \frac{P_{z^\star}}{C_{z^\star}}$ for $z^\star = \arg\max_z C_z$, where for arbitrary $z \in \{0,1\}^D$ we defined

$$P_z(a) = A(a) \cdot \prod_{i=1}^{D} [1 + (-1)^{z_i + a_i}\gamma]$$

with $A = \mathsf{Ext}(U_n)$, and

$$C_z = \sum_{a \in \{0,1\}^D} P_z(a).$$

Observe that P is a distribution over $\{0,1\}^D$, and we defined P_i as the distribution of its i-th coordinate. Then, our goal is to show that for every $i \in [D]$ we have

$$\Delta(P_i; U_1) \geq \gamma/2.$$

Equivalently, we must show that

$$|P_i(0) - P_i(1)| \geq \gamma \tag{19}$$

for all $i \in [D]$.

Consider an arbitrary $i \in [D]$. Then, we have

$$C_{z^\star} = (1 + (-1)^{z_i^\star}\gamma)S_0 + (1 - (-1)^{z_i^\star}\gamma)S_1$$

for

$$S_b = \sum_{a : a_i = b} A(a) \prod_{j \neq i} [1 + (-1)^{z_j^\star + a_j}], \quad b \in \{0,1\}.$$

We proceed by cases.

- $z_i^\star = 0$: Then, it holds that $S_0 \geq S_1$. Indeed, if $S_0 < S_1$, we claim that $z^\star$ does not maximize C_z, a contradiction. To see this, consider $z_i' = z^\star + e_i$. Then, we would have

$$\begin{aligned} C_{z'} &= (1-\gamma)S_0 + (1+\gamma)S_1 \\ &> (1+\gamma)S_0 + (1-\gamma)S_1 \\ &= C_z. \end{aligned}$$

As a result, we can compute

$$P_i(0) - P_i(1) = \frac{(1+\gamma)S_0 - (1-\gamma)S_1}{(1+\gamma)S_0 + (1-\gamma)S_1} \geq \gamma,$$

which follows by elementary algebra, using the fact that $S_0 \geq S_1$ and $0 < \gamma < 1$. This implies (19), as desired.

- $z_i^\star = 1$: The proof follows analogously, but symmetrically, to the previous case. First, in this case we have $S_1 \geq S_0$. Then, we have

$$P_i(1) - P_i(0) = \frac{(1+\gamma)S_1 - (1-\gamma)S_0}{(1+\gamma)S_1 + (1-\gamma)S_0} \geq \gamma,$$

again by elementary algebra, since $S_1 \geq S_0$ and $0 < \gamma < 1$. This implies (19), which concludes the proof.

B A lower bound for strong extractors

In this section, we prove Theorem 1.7 via the high-level approach in Section 1.3.1. This yields a different, simpler proof of the optimal lower bound on the number of seeds of (k, ε)-strong extractors, originally obtained by Radhakrishnan and Ta-Shma [22]. We restate Theorem 1.7 here for convenience.

▶ **Theorem 1.7.** *For every $n, k, \varepsilon > 0$ satisfying $n - k \geq 39$ and every (k, ε)-strong extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$ it holds that*

$$D \geq \frac{\ln 2}{18} \cdot \frac{n-k}{\varepsilon^2}.$$

Fix a (k, ε)-strong extractor $\mathsf{Ext} : \{0,1\}^n \times [D] \to \{0,1\}$, and let $A = \mathsf{Ext}(U_n)$. For $z \in \{0,1\}^D$ and $t \leq D$, define the (unnormalized) distribution $P_{z,t}$ over $\{0,1\}^D$ as

$$P_{z,t}(a) = A(a) \cdot \mathbf{1}_{\{\|z-a\|_1 \leq t\}}.$$

The associated normalizing factor $C_{z,t}$ is given by

$$C_{z,t} = \sum_{a \in \{0,1\}^D} P_{z,t}(a) = A(B_t(z)),$$

where $B_t(z)$ denotes the Hamming ball of radius t centered at z and $A(B_t(z)) = \sum_{a \in B_t(z)} A(a)$ denotes its measure under A. Provided that $A(B_t(z)) > 0$, we can then define the normalized distribution $\overline{P}_{z,t}$ by

$$\overline{P}_{z,t}(a) = \frac{P_{z,t}(a)}{C_{z,t}}.$$

B.1 Proof of Theorem 1.7

Taking into account Section 1.3.1, in order to prove Theorem 1.7 we will show, via two easy lemmas, that $P = \overline{P}_{z^\star,t^\star}$ for appropriate choices $z^\star$ and $t^\star$ satisfies

$$P(a) \leq 2^g A(a) \quad \forall a \in \{0,1\}^D \tag{20}$$

and

$$\mathop{\mathbb{E}}_{i \leftarrow [D]}[\Delta(P_i; U_1)] = \frac{1}{D} \left\| \mathop{\mathbb{E}}_{a \sim P}[a] - (1/2, \ldots, 1/2) \right\|_1 \geq c\sqrt{g/D}, \tag{21}$$

where $g = n - k$ is the entropy gap, $c = \sqrt{\frac{\ln 2}{18}}$, and P_i denotes the distribution of the i-th coordinate of P. Properties (20) and (21) imply there is an (n, k)-source X such that $\mathsf{Ext}(X) = P$, and so $\varepsilon \geq c\sqrt{g/D}$. This immediately yields the desired lower bound on D.

▶ **Lemma B.1.** *For $c = \sqrt{\frac{\ln 2}{18}}$ and $C = 39$, if $g = n - k \geq C$, there exists $z^\star \in \{0,1\}^D$ such that* (20) *is satisfied for $t^\star = D/2 - c\sqrt{gD}$.*

Proof. Note that (20) is equivalent to

$$A(B_{t^\star}(z^\star)) \geq 2^{-g}.$$

Moreover, a simple averaging argument (based on the fact that every $y \in \{0,1\}^D$ belongs to the same number of Hamming balls) implies there is $z^\star$ such that $A(B_{t^\star}(z^\star)) \geq 2^{-D} \cdot V_{t^\star}$ (recall $V_{t^\star}$ denotes the volume of a Hamming ball of radius $t^\star$). Fix this choice of $z^\star$. From the choice of c and C above, and since $D > g \geq C$, by the inverse Chernoff bound (Lemma 2.4 with $\gamma = 2c\sqrt{g/D}$) we have

$$2^{-D} \cdot V_{t^\star} \geq \exp\left(-18c^2 g\right) = 2^{-g}$$

for $t^\star = D/2 - c\sqrt{gD}$. ◀

By considering the shifted extractor $\overline{\mathsf{Ext}}(x) = \mathsf{Ext}(x) + z^\star$, without loss of generality we can assume that $z^\star = 0$. Then, we have the following result.

▶ **Lemma B.2.** *For $t = D/2 - \alpha$, it holds that*

$$\left\| \mathop{\mathbb{E}}_{a \sim \overline{P}_{0,t}} [a] - (1/2, \ldots, 1/2) \right\|_1 \geq \alpha.$$

Proof. Note that $\mathbb{E}_{a \sim \overline{P}_{0,t}}[a]$ is a convex combination of elements of $\mathsf{supp}(\overline{P}_{0,t})$. Since $\mathsf{supp}(\overline{P}_{0,t}) \subseteq B_t(0)$, it follows that

$$\left\| \mathop{\mathbb{E}}_{a \sim \overline{P}_{0,t}} [a] \right\|_1 \leq t.$$

Moreover, it holds that $\|(1/2, \ldots, 1/2)\|_1 = D/2$. Consequently, by the triangle inequality we have

$$\left\| \mathop{\mathbb{E}}_{a \sim \overline{P}_{0,t}} [a] - (1/2, \ldots, 1/2) \right\|_1 \geq D/2 - t = \alpha.$$ ◀

Combining Lemmas B.1 and B.2 immediately yields (20) and (21).

A Simpler Strong Refutation of Random k-XOR

Kwangjun Ahn
Department of EECS, Massachusetts Institute of Technology, Cambridge, MA, USA
kjahn@mit.edu

Abstract

Strong refutation of random CSPs is a fundamental question in theoretical computer science that has received particular attention due to the long-standing gap between the information-theoretic limit and the computational limit. This gap is recently bridged by Raghavendra, Rao and Schramm where they study sub-exponential algorithms for the regime between the two limits. In this work, we take a simpler approach to their algorithms and analyses.

1 Introduction

Refutation of random instances of constraint satisfaction problems (random CSPs) is one of the central questions in theoretical computer science with numerous applications. Among many predicates (types of constraints), this paper considers the XOR predicate and studies the strong refutation of the corresponding random CSP. In fact, Allen, O'Donnell and Witmer [2] demonstrate that one can use strong refutation algorithms for random XOR to refute random CSPs with other predicates[1]. In particular, we consider:

▶ **Definition 1** (Random k-XOR). *A* ***random k-XOR*** *with probability p (or equivalently, at density pn^{k-1}) refers to a set $\Phi = \{C_S\}$ of k-XOR constraints over n variables $x \in \{\pm 1\}^n$ obtained as per the following procedure:*

1. *First sample each of the n^k possible k-tuples with probability p independently.*
2. *For each sampled $S = (s_1, s_2, \ldots, s_k) \in [n]^k$, include a k-XOR constraint $C_S : \prod_{i=1}^k x_{s_i} = \eta_S$, where η_S is i.i.d. Rademacher random variable.*

For an assignment $x \in \{\pm 1\}^n$, let $P_\Phi(x)$ be the fraction of constraints satisfied by x.

▶ Remark 2. One can alternatively consider a model where we sample subsets of size k instead of k-tuples (there will be $\binom{n}{k}$ possible subsets in total). However, as noted in [2], the precise details of the random model are not relevant to the results to follow. For simplicity, we follow the prior works [2, 7] and consider the above k-tuple model throughout the paper.

[1] For instance, it is demonstrated that one can refute random k-SAT by reducing it to strong refutations of random ℓ-XOR for $\ell = 1, 2, \ldots, k$.

Under this random k-XOR model, we study the strong refutation problem. To motivate the problem, it is a consequence of standard concentration inequalities that when the density is of $\omega(1)$ (i.e., $pn^{k-1} = \omega(1)$), with high probability, no assignment can satisfy more than a $1/2 + o(1)$ fraction of the constraints. Hence, it is a natural algorithmic question to ask whether one can certify such a fact. More specifically, we consider:

▶ **Definition 3** (Strong refutation). *For a quantity $\alpha = \omega(1)$, an algorithm which takes a k-XOR instance and outputs a quantity $\widehat{P_\Phi}$ is said to strongly refute random k-XOR at density α if it satisfies:*

1. *For any k-XOR instance Φ, $P_\Phi(x) \le \widehat{P_\Phi}$ for all assignments $x \in \{\pm 1\}^n$.*
2. *For a random k-XOR instance Φ with density α, $\widehat{P_\Phi} = 1/2 + o(1)$ with high probability.*

However, the question of developing strong refutation algorithms for the density $\omega(1)$ turns out to be rather intractable. More specifically, the best known guarantees are obtained from spectral methods [2, 3] which require the density to be $\widetilde{\Omega}(n^{k/2-1})$. This computational limit of $\widetilde{\Omega}(n^{k/2-1})$ (also known as *spectral threshold*) is significantly larger than the information-theoretic threshold of $\omega(1)$, and this gap has been conjectured to be fundamental.

Recently, to bridge the gap, Raghavendra, Rao and Schramm investigate sub-exponential refutation algorithms below the spectral threshold [7]. Their results constitute a smooth trade-off between the density and the time complexity required for certifying unsatisfiability. More specifically, their algorithm parametrized by d achieves the following performance: For all $\delta \in [0, 1)$, their algorithm with $d = n^\delta$ finds a certificate at density $\widetilde{\Omega}\left(n^{(k/2-1)(1-\delta)}\right)$ in time $\exp(\widetilde{O}(n^\delta))$. At $\delta \approx 0$, their result recovers the polynomial-time strong refutation result at the spectral threshold, while at $\delta \approx 1$, their result recovers an exponential-time strong refutation at the information-theoretic threshold.

This beautiful result, however, relies on an intricate analysis spanning over 20 pages as well as technical complications in algorithm steps, raising a question of whether one can simplify the analysis as well as the algorithm. This work addresses this question as follows:

1. This work simplifies the key technical component of the analysis in [7] (Section 4). More specifically, the spectral norm analysis [7, Theorem 4.4] is significantly simplified in this work relying on more elementary combinatorial arguments.
2. In addition, for even k, this work also simplifies their refutation algorithm by modifying the technical preprocessing step (Section 5). At a high level, the previous work requires $O(d)$ spectral norm computations of the matrix of size $n^{O(d)\times O(d)}$, whereas the approach in this paper only requires a *single* computation.

As a byproduct of our simpler approach, the theoretical guarantee in this paper comes with less technical conditions and enjoys better refutation performances.

2 Preliminary: spectral strong refutation algorithms

To set the stage for our main result, we first briefly review the spectral refutation algorithms in the prior works [5, 2, 3] that achieve the spectral threshold. For illustrative purpose, we focus throughout on the case when k is even; indeed, the odd k case follows similarly modulo some extra "tricks" to reduce it to the even case (see e.g. [2, Appendix A.2] for details).

We first represent the strong refutation problem as the problem of certifying an upper bound on a polynomial.

▶ **Definition 4** (Constraints tensor). *Given a set of constraints Φ consisting of m constraints $C_{S_1}, \dots, C_{S_m}$, the* constraints tensor *of Φ is a n^k tensor $\boldsymbol{T}^\Phi$ defined as $\boldsymbol{T}^\Phi_S = \eta_{S_a}$ if $S = S_a$ for some $a = 1, \dots, m$ and $\boldsymbol{T}^\Phi_S = 0$ otherwise.*

▶ **Definition 5** (Constraints polynomial). *Given a set of constraints* Φ*, the* constraints polynomial *of* Φ *is a* k*-degree homogeneous polynomial* f^Φ *defined as* $f^\Phi(x) := \langle \boldsymbol{T}^\Phi, x^{\otimes k}\rangle$.

Having the above definitions, it is straightforward to verify the following identity:

$$2m \cdot \left(P_\Phi(x) - \frac{1}{2}\right) = \sum_{\ell=1}^{m} \eta_{(i_\ell,j_\ell)} x_{i_\ell} x_{j_\ell} = \langle \boldsymbol{T}^\Phi, x^{\otimes k}\rangle = f^\Phi(x)$$

$$\iff P_\Phi(x) = \frac{1}{2} + \frac{1}{2m} \cdot f^\Phi(x)\,. \tag{1}$$

Having established (1), the strong refutation problem turns into the problem of certifying a good upper bound on the constraints polynomial:

$$\max_{x\in\{\pm 1\}^n} P_\Phi(x) \le \frac{1}{2} + o(1) \iff \max_{x\in\{\pm 1\}^n} f^\Phi(x) = o(m)\,. \tag{2}$$

Now, the key idea of the spectral refutation is to certify an upper bound on the constraints polynomial by first computing a *matrix representation* of the polynomial and then computing the spectral norm of the matrix. We first formally define matrix representations:

▶ **Definition 6** (Matrix representation [1, Section 9]). *We say an* $n^{k/2} \times n^{k/2}$ *matrix* M *is a matrix representation of a degree-*k *homogeneous polynomial* f *if we have* $f(x) = (x^{\otimes k/2})^\top M x^{\otimes k/2}$*. Here and below, we use* $x^{\otimes k/2}$ *to denote its vector flattening*[2].

If we have a matrix representation M of the constraints polynomial f^Φ, one can certify an upper bound by computing the spectral norm of the matrix representation:

$$\max_{x\in\{\pm 1\}^n} f^\Phi(x) = \max_{x\in\{\pm 1\}^n} (x^{\otimes k/2})^\top M x^{\otimes k/2} \le n^{k/2} \|M\|\,, \tag{3}$$

where the inequality follows since $\left\|x^{\otimes k/2}\right\| = \sqrt{n^{k/2}}$.

Having (3), it is now crucial to find a matrix representation that results in a small spectral norm. It turns out that to achieve the spectral threshold, a simple matrix representation suffices. Let us denote by $\boldsymbol{M}^\Phi$ the natural $n^{k/2} \times n^{k/2}$ flattening of the constraints tensor $\boldsymbol{T}^\Phi$. Certainly $\boldsymbol{M}^\Phi$ is a matrix representation, and hence, its symmetrization is also a matrix representation:

▶ **Definition 7** (Symmetric matrix representation). $S^\Phi := \frac{1}{2}[\boldsymbol{M}^\Phi + (\boldsymbol{M}^\Phi)^\top]$.

Indeed, it follows from a standard result in random matrix theory that the symmetric matrix representation S^Φ constructed from random k-XOR has the spectral norm $o(m)$ with high probability as soon as the density is above the spectral threshold, i.e., $\alpha = \widetilde{\Omega}(n^{k/2-1})$ (see e.g. [2, Appendix A.1] for precise details).

Thus far, we present the spectral refutation algorithms in the prior arts that achieve the spectral threshold. Now, we move on to the result due to Raghavendra, Rao and Schramm [7]. It turns out that for strong refutation below the spectral threshold, one needs to rely on a higher-order symmetry. This will be the subject of the next section.

3 Higher-order symmetry for refutation below spectral threshold

In this section, we discuss the approach based on a higher-order symmetry due to Raghavendra, Rao and Schramm [7]. We remark that a similar technique was independently developed by Bhattiprolu, Guruswami and Lee [4] under the context of finding an upper bound certificate of the tensor injective norm.

[2] More formally, we regard $x^{\otimes k/2}$ as a vector of dimension $nk/2$ rather than as a $n^{k/2}$ tensor.

3.1 Higher-order type-symmetric matrix representation

To illustrate the main idea, we first define the types of the entries:

▶ **Definition 8** (Histogram tuples). *Let* $\mathsf{hist}(I)$ *be the* n*-tuple* $(\alpha_1, \ldots, \alpha_n)$ *such that* α_i *is the number of times* i *appears in* I*, i.e., the histogram of the tuple* I*. Let* $\mathsf{hist}(I)! := \prod_{i=1}^{n} (\alpha_i)!$*, where* $0! = 1$ *by convention.*

▶ **Definition 9** (Types of entries). *Given a matrix representation* M *of a constraints polynomial* f^Φ*, we say two entries* $M_{I,J}$ *and* $M_{I',J'}$ *have the same* type *if* $\mathsf{hist}(I) = \mathsf{hist}(I')$ *and* $\mathsf{hist}(J) = \mathsf{hist}(J')$*, i.e., for all* $i \in [n]$*, the number of* i*'s appearing in* I *(resp.* J*) is equal to that in* I' *(resp.* J'*) .*

With this definition, one can easily notice that the entries of the same type corresponds to the coefficient of the same monomial in f^Φ. Now the key idea of [7] is to consider a matrix representation which distributes the coefficient of a monomial in f^Φ *equally* across the corresponding type of entries. It turns out that such a matrix representation has small spectral norm, resulting in a better refutation certificate.

▶ **Definition 10** (Type-symmetric matrix representation). *We say a matrix representation is type-symmetric if the entries of the same type have the same value.*

To maximize the gain from a type-symmetric matrix representation, [7] indeed considers a higher order matrix representation, which amounts to working with $(f^\Phi)^d$ instead of f^Φ for some $d > 1$ at the cost of increased computational complexity. Given a type-symmetric matrix representation $\boldsymbol{R}^{\Phi,d}$ of $(f^\Phi)^d$ (we defer the formal definition to Definition 13), we have $f^\Phi(x)^d = (x^{\otimes kd/2})^\top \boldsymbol{R}^{\Phi,d} x^{\otimes kd/2}$ from which one can conclude

$$\max_{x \in \{\pm 1\}^n} f^\Phi(x) = n^{k/2} \cdot \max_{x \in \frac{1}{\sqrt{n}} \cdot \{\pm 1\}^n} \left[(x^{\otimes kd/2})^\top \boldsymbol{R}^{\Phi,d} x^{\otimes kd/2} \right]^{1/d} \leq n^{k/2} \cdot \left\| \boldsymbol{R}^{\Phi,d} \right\|^{1/d} . \quad (4)$$

However, as mentioned in [7, Section 4], it turns out that the inequality in (4) is not tight enough for the desired result. To overcome this issue, [7] suggested the technique of removing high multiplicity rows/columns. This will be the subject of the next subsection.

3.2 Overcoming challenge with trimming rows/columns

Before getting into the technique in [7], let us first discuss why the inequality in (4) is not tight. The main reason for the looseness is the fact that the left hand side of the inequality is the maximum over the specific unit vectors of the form $\frac{1}{\sqrt{n}} \cdot \{\pm 1\}^n$, while the spectral norm certificate finds the maximum over all unit vectors. In particular, if the maximum of the spectral norm is achieved by a sparse vector, this certificate would no longer provide a good upper bound.

To cope with this issue, [7] employs the *trimming* step, in which they remove rows and columns of $\boldsymbol{R}^{\Phi,d}$ corresponding to index tuples with high multiplicities, i.e., I's such that coordinate values of $\mathsf{hist}(I)$ are large. This technical step indeed results in a better spectral norm bound as we shall see in Section 4.2.

3.3 Technical challenge of the approach in Raghavendra-Rao-Schramm

However, it turns out that analyzing this higher-order method with the trimming step is rather technical:

1. Note that the construction of symmetric matrix representation results in a rather complicated dependency structure across entries, making it hard to analyze its spectral norm. Indeed, the spectral norm analysis [7, Theorem 4.4] constitutes the main technical component of the analysis in [7].
2. Moreover, it turns out that justifying the validity of the trimming step also requires some technical modification of the algorithm together with an additional careful analysis. At a high level, these complications arise due to the fact that the trimmed matrix is no longer a matrix representation of the constraints polynomial. In particular, their approach requires computations of $O(d)$ spectral norms of matrices of size $n^{O(d)\times O(d)}$.

We will address the above challenges in order in the subsequent sections.

4 A simpler spectral norm analysis

In this section, we provide a simpler spectral norm analysis of the symmetric matrix representation. As we mentioned in the previous section, the symmetric matrix representation has an intricate dependency structure between entries and hence the standard tools such as matrix Chernoff bound [8] does not apply. Hence, we need to rely on more direct analysis based on the trace power method:

▶ **Proposition 11** (Trace power method). *Let $n, \ell \in \mathbb{N}$, let $c \in \mathbb{R}$, and let M be a symmetric $n \times n$ random matrix. Then,*

$$\mathbb{E}\operatorname{Tr}(M^{2\ell}) \le \beta \implies \Pr\left(\|M\| \ge c \cdot \beta^{1/2\ell}\right) \ge 1 - c^{-2\ell}.$$

Proof. The proof follows from the fact that $\|M\|^{2\ell} = \left\|M^{2\ell}\right\| \le \operatorname{Tr}(M^{2\ell})$ together with Markov's inequality. ◀

Hence, to come up with a probabilistic upper bound on the spectral norm, one need to bound the trace power term. However, in contrast to well-known settings in random matrix theory, our matrix of interest M has $kd/2$-tuples for its row/column indices, which renders computing the trace power term more complicated. In particular, for an integer ℓ, the trace power term can be represented as

$$\sum_{I^{(1)},\dots,I^{(2\ell)} \in [n]^{kd/2}} \mathbb{E}\left[\prod_{j=1}^{2\ell} M_{I^{(j)},I^{(j+1)}}\right], \tag{5}$$

where indices are read modulo-2ℓ, i.e., $I_{2\ell+1}$ denotes I_1. As a warm-up, we first analyze the symmetric matrix representation, i.e. $M = \boldsymbol{R}^{\Phi,d}$.

4.1 Warm-up: analysis for higher-order type-symmetric matrix

In this section we apply the trace power method to $M = \boldsymbol{R}^{\Phi,d}$ as a warm-up. Let us first formally define $\boldsymbol{R}^{\Phi,d}$. To that end, we first recall the symmetric matrix representation S^{Φ}. By its definition (Definition 7), S^{Φ} is a $n^{k/2} \times n^{k/2}$ symmetric random matrix with independent mean-zero entries taking values in $[-1, 1]$. Now, let $S^{\Phi,d}$ be the d-th Kronecker power of S^{Φ}, i.e., for $k/2$-tuples $U_1, \dots, U_d$ and $V_1, \dots, V_d$,

$$S^{\Phi,d}_{(U_1,\dots,U_d),(V_1,\dots,V_d)} = S^{\Phi}_{U_1,V_1} \times S^{\Phi}_{U_2,V_2} \times \cdots \times S^{\Phi}_{U_d,V_d}. \tag{6}$$

Now, the symmetric matrix representation is obtained from $S^{\Phi,d}$ by replacing each entry with the average of the entries of the same type as the corresponding entry. To formally define, we begin with some notations:

▶ **Definition 12** (Permutations). *For each positive integers n, q and $I = (i_1, \dots, i_q) \in [n]^q$, let $\mathbb{S}_q$ be the set of permutations on $[q]$. For a permutation $\pi \in \mathbb{S}_q$ and a subtuple $U = (i_{j_1}, \dots, i_{j_\ell})$ of I, let $\pi(U) := (i_{\pi(j_1)}, \dots, i_{\pi(j_\ell)})$.*

Now based on these notations, we formally define $\boldsymbol{R}^{\Phi,d}$ as follows:

▶ **Definition 13** (Higher-order symmetric matrix representation). *For an even integer k and $d \geq 1$, $\boldsymbol{R}^{\Phi,d}$ is an $n^{kd/2 \times kd/2}$ matrix representation of $(f^\Phi)^d$ defined as*

$$\boldsymbol{R}^{\Phi,d}_{I,J} = \frac{1}{|\mathbb{S}_{kd/2}|^2} \sum_{\pi,\sigma \in \mathbb{S}_{kd/2}} S^{\Phi,d}_{\pi(I),\sigma(J)} \,. \tag{7}$$

Now having the formal definition of $\boldsymbol{R}^{\Phi,d}$, one can write the trace power term (5) as follows (where we write each $kd/2$-tuple as $I^{(\cdot)} = (U_1^{(\cdot)}, U_2^{(\cdot)}, \dots, U_d^{(\cdot)})$):

$$\begin{aligned} &\frac{1}{|\mathbb{S}_{kd/2}|^{4\ell}} \cdot \sum_{\substack{I^{(j)} \in [n]^{kd/2} \\ j=1,\dots,2\ell}} \sum_{\substack{\pi_j,\sigma_j \in \mathbb{S}_{kd/2} \\ j=1,\dots,2\ell}} \mathbb{E}\left[\prod_{j=1}^{2\ell} S^{\Phi,d}_{\pi_j(I^{(j)}),\sigma_j(I^{(j+1)})}\right] \\ =&\frac{1}{|\mathbb{S}_{kd/2}|^{4\ell}} \cdot \sum_{\substack{I^{(j)} \in [n]^{kd/2} \\ j=1,\dots,2\ell}} \sum_{\substack{\pi_j,\sigma_j \in \mathbb{S}_{kd/2} \\ j=1,\dots,2\ell}} \mathbb{E}\left[\prod_{j=1}^{2\ell} \prod_{s=1}^{d} S^{\Phi}_{\pi_j(U_s^{(j)}),\sigma_j(U_s^{(j+1)})}\right], \end{aligned} \tag{8}$$

Although (8) looks quite complicated, note that one can actually simplify it further.

▶ **Definition 14** (Partition of the index set according equality). *Given $\{I^{(j)}\}$, $\{\pi_j\}$ and $\{\sigma_j\}$ $(j = 1, \dots, 2\ell)$, we define $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})$ to be the partition of the index set $\mathcal{I} := \{(j, s) \,:\, j = 1, \dots, 2\ell, s = 1, \dots, d\}$ according to the equivalence relation $(j, s) \sim (j', s')$ if and only if $(\pi_j(U_s^{(j)}), \sigma_j(U_s^{(j+1)})) = (\pi_{j'}(U_{s'}^{(j')}), \sigma_{j'}(U_{s'}^{(j'+1)}))$ or $(\pi_j(U_s^{(j)}), \sigma_j(U_s^{(j+1)})) = (\sigma_{j'}(U_{s'}^{(j'+1)}), \pi_{j'}(U_{s'}^{(j')}))$. We denote by $|\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})|$ the number of equivalence classes in the partition.*

Since S^Φ is a symmetric random matrix with mean zero entries, it follows that the summand in (8) corresponding to $\{I^{(j)}\}$, $\{\pi_j\}$ and $\{\sigma_j\}$ is equal to zero if the partition $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})$ contains an equivalence class of odd size.

Hence, in order to have a nonzero summand, every equivalence class of the partition $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})$ must have even size.

▶ **Definition 15.** *Given $\{I^{(j)}\}$, $\{\pi_j\}$ and $\{\sigma_j\}$ $(j = 1, \dots, 2\ell)$, we say the partition of the index set $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})$ is called an* even *partition if all of its equivalence classes have even size.*

When $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})$ is even, since each entry of S^Φ is in $[-1, 1]$, one can easily upper bound the summand of (8) explicitly in terms of the number of equivalence classes in $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\})$:

$$\mathbb{E}\left[\prod_{j=1}^{2\ell} \prod_{s=1}^{d} S^{\Phi}_{\pi_j(U_s^{(j)}),\sigma_j(U_s^{(j+1)})}\right] \leq p^{|\mathsf{Par}(\{I^{(j)}\},\{\pi_j\},\{\sigma_j\})|} \,. \tag{9}$$

Using the upper bound (9), and grouping the trace power term so that each group contains the summand corresponding to the same partition, we obtain

$$(8) \le \frac{1}{\left|\mathbb{S}_{kd/2}\right|^{4\ell}} \sum_{\mathcal{Q}:\ \text{even}} \left[p^{|\mathcal{Q}|} \cdot \mathsf{Num}(\mathcal{Q})\right], \tag{10}$$

where $\mathsf{Num}(\mathcal{Q}) := \left|\left\{(\{I^{(j)}\},\{\pi_j\},\{\sigma_j\}) \ :\ \mathsf{Par}(\{I^{(j)}\},\{\pi_j\},\{\sigma_j\}) = \mathcal{Q}\right\}\right|$. Therefore, to upper bound the trace power term, one needs to upper-estimate $\mathsf{Num}(\mathcal{Q})$ for each $\mathcal{Q}$. Although the counting $\mathsf{Num}(\mathcal{Q})$ looks complicated, the symmetry saves the day.

▶ **Definition 16.** *Num*$(\mathcal{Q} \mid \{\pi_j\}) := \left|\left\{(\{I^{(j)}\},\{\sigma_j\}) \ :\ \mathsf{Par}(\{I^{(j)}\},\{\pi_j\},\{\sigma_j\}) = \mathcal{Q}\right\}\right|$.

First, one can easily verify the following based on a simple symmetry argument (here Id denotes the identity permutation in $\mathbb{S}_{kd/2}$):

▷ Claim 17. $\mathsf{Num}\left(\mathcal{Q} \mid \{\mathsf{Id}\}\right) = \mathsf{Num}\left(\mathcal{Q} \mid \{\pi_j\}\right)$ for any $\{\pi_j\}$.

Proof. See Section A.1. ◁

Due to Claim 17, it follows that:

$$\mathsf{Num}\left(\mathcal{Q}\right) = \left|\mathbb{S}_{kd/2}\right|^{2\ell} \cdot \mathsf{Num}\left(\mathcal{Q} \mid \{\mathsf{Id}\}\right). \tag{11}$$

Hence, with this argument, we reduce the problem of counting triples $(\{I^{(j)}\},\{\pi_j\},\{\sigma_j\})$ into the problem of counting pairs $(\{I^{(j)}\},\{\sigma_j\})$. Now let us further reduce the problem. To that end, we first define:

▶ **Definition 18.** *We say a collection of index tuples* $\{I^{(j)}\}$ *is* $\mathcal{Q}$-valid *if there exist* $\{\sigma_j\}$ *such that* $\mathsf{Par}(\{I^{(j)}\},\{\mathsf{Id}\},\{\sigma_j\})$ *is equal to* $\mathcal{Q}$.

▷ Claim 19. For any $\mathcal{Q}$-valid $\{I^{(j)}\}$, there are at most $(kd/2)^{k|\mathcal{Q}|/2} \cdot \prod_{j=1}^{2\ell} \mathsf{hist}(I^{(j)})!$ different $\{\sigma_j\}$'s such that $\mathsf{Par}\left(\{I^{(j)}\},\{\mathsf{Id}\},\{\sigma_j\}\right) = \mathcal{Q}$.

Proof. The proof is based on an elementary counting argument. See Section A.2. ◁

Due to Claim 19, now we have:

$$\mathsf{Num}\left(\mathcal{Q}\right) = \left|\mathbb{S}_{kd/2}\right|^{2\ell} \cdot (kd/2)^{k|\mathcal{Q}|/2} \cdot \sum_{\{I^{(j)}\}\ :\ \mathcal{Q}\text{-valid}} \left[\prod_{j=1}^{2\ell} \mathsf{hist}(I^{(j)})!\right]. \tag{12}$$

Putting this back to (10), we obtain the following result:

▶ **Theorem 20.** *For even* k *and* $d \ge 1$*, let* $\boldsymbol{R}^{\Phi,d}$ *be the* $n^{kd/2 \times kd/2}$ *higher-order symmetric matrix representation (Definition 13) of random* k*-XOR. Then, the following upper bound on the trace power term holds:*

$$\mathbb{E}\,\mathrm{Tr}((\boldsymbol{R}^{\Phi,d})^{2\ell}) \le \frac{1}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{\mathcal{Q}:\ even} \left[\left(p(kd/2)^{k/2}\right)^{|\mathcal{Q}|} \cdot \sum_{\substack{\{I^{(j)}\}\ :\\ \mathcal{Q}\text{-}valid}} \left[\prod_{j=1}^{2\ell} \mathsf{hist}(I^{(j)})!\right]\right].$$

Having established Theorem 20, one can slightly modify the proof to handle the trimmed matrix from Section 3.2. This will be the focus of the next subsection.

4.2 A simpler spectral norm analysis of the trimmed matrix from Raghavendra-Rao-Schramm

Having established Theorem 20, which explicitly characterizes the upper bound on the trace power term in terms of $\mathsf{hist}(I^{(j)})!$'s, one can now quantitatively understand the trimming technique due to Raghavendra, Rao and Schramm [7]. In particular, we will shortly demonstrate that our Theorem 20 recovers the main technical result [7, Theorem 4.4]. This is remarkable as our proof is much simpler than the original proof in [7].

The problem with the upper bound in Theorem 20 is that the value $\mathsf{hist}(I^{(j)})!$ could be in general large. For instance, if $I^{(j)}$ is the $kd/2$-tuple consisting only of index 1, then $\mathsf{hist}(I^{(j)})! = (kd/2)!$, which turns out to be too large for our desired result. Now having observed this, one can now see how the trimming preprocessing of [7] helps reduce the spectral norm: by removing rows/columns corresponding to the index tuples with high multiplicities, one can significantly reduce the upper bound. More formally, following [7], if we remove the rows/columns corresponding to the index tuples I's such that $\mathsf{hist}(I)$ has a coordinate value larger than $10 \log n$, we have the following:

▶ **Corollary 21.** *For even k and $d \geq 1$, let $\boldsymbol{R}^{\Phi,d,\mathrm{trim}}$ be the $n^{kd/2 \times kd/2}$ matrix obtained from the $\boldsymbol{R}^{\Phi,d}$ (Definition 13) by removing all rows/columns I's such that $\mathsf{hist}(I)$ has a coordinate value larger than $10 \log n$. Assume that $d^{k/2-1} n^{k/2} p > 1$. Then, the following spectral norm bound holds with probability at least $1 - n^{-2}$:*

$$\left\| \boldsymbol{R}^{\Phi,d,\mathrm{trim}} \right\|^{1/d} \leq c \cdot \frac{e^{3k/4} \cdot 10^{5k/2}}{(k/2)^{k/4}} \cdot \frac{n^{k/4} p^{1/2}}{d^{(k-2)/4}} \cdot \log^{5k/2+1} n \,.$$

for some absolute constant $c > 0$.

▶ Remark 22. Although we focus on the even k case throughout the proof for simplicity, we note that a similar argument applies to the case of odd k following the "tricks" [7, Section 4.2] based on Cauchy Schwartz inequality. Consequently, our proof technique provides a simpler proof of the main technical statement for the odd k case [7, Theorem 4.13]

Proof of Corollary 21. From Theorem 20, we have the following upper bound on the trace power term:

$$\mathbb{E}\,\mathrm{Tr}((\boldsymbol{R}^{\Phi,d,\mathrm{trim}})^{2\ell}) \leq \frac{1}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{\mathcal{Q}\colon \text{ even}} \left[\left(p(kd/2)^{k/2} \right)^{|\mathcal{Q}|} \cdot \sum_{\substack{\{I^{(j)}\} \,:\\ \mathcal{Q}\text{-valid}}} \left[\prod_{j=1}^{2\ell} \mathsf{hist}(I^{(j)})! \right] \right] .$$

On the other hand, due to the trimming procedure, each coordinate value of the tuple $\mathsf{hist}(I^{(j)})$ is upper bounded by $10 \log n$, from which we have the following upper bound on the $\mathsf{hist}(I^{(j)})!$:

$$\mathsf{hist}(I^{(j)})! \leq ((10 \log n)!)^{kd/2} \leq (10 \log n)^{5kd \log n} \leq n^{5kd \log(10 \log n)} \,.$$

The trimming step gives us an uniform upper bound on $\mathsf{hist}(I^{(j)})!$, and hence, it suffices to upper bound the number of $\mathcal{Q}$-valid $\{I^{(j)}\}$'s:

▷ Claim 23. For any even partition $\mathcal{Q}$, there are at most $n^{k(|\mathcal{Q}|+d)/2}$ $\mathcal{Q}$-valid $\{I^{(j)}\}$'s.

Proof. The proof is elementary. See Section A.3. ◁

Due to Claim 23, the upper bound on the trace power term becomes:

$$\mathbb{E}\,\mathrm{Tr}((\boldsymbol{R}^{\Phi,d,\mathrm{trim}})^{2\ell}) \le \frac{n^{5kd\log(10\log n)}}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{\mathcal{Q}:\ \text{even}} \left[\left(p(kd/2)^{k/2}\right)^{|\mathcal{Q}|} \cdot n^{k(|\mathcal{Q}|+d)/2}\right]$$
$$= \frac{n^{5kd\log(10\log n)+kd/2}}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{M=1}^{d\ell} \left[N_M \cdot \left(p(nkd/2)^{k/2}\right)^{M}\right], \tag{13}$$

where N_M is the number of even partitions of size M and we have $M \le d\ell$ in the range of summation since an even partition has size at most $d\ell$. Thus, the last ingredient is to bound the number of even partitions:

▷ Claim 24. $N_M \le \binom{2d\ell}{M} \cdot M^{2d\ell-M}$ for all $1 \le M \le d\ell$.

Proof. The first term in the upper bound accounts for the number of different ways of choosing M representative indices in $\mathcal{I}$, and the second term counts the number of different ways of assigning the other indices to the M representative elements. ◁

Due to Claim 24, the upper bound (13) becomes:

$$\frac{n^{5kd\log(10\log n)+kd/2}}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{M=1}^{d\ell} \left[\binom{2d\ell}{M} \cdot M^{2d\ell-M} \cdot \left(p(nkd/2)^{k/2}\right)^{M}\right]. \tag{14}$$

Having established (14), the rest of the proof is straightforward calculations. We first upper bound each term in the above summand as follows: (i) $\binom{2d\ell}{M} \le 2^{2d\ell}$, (ii) $M^{2d\ell-M} \le (d\ell)^{2d\ell-M} \le d^{2d\ell-M}\ell^{2d\ell}$, and (iii) $\left((kdn/2)^{k/2}p\right)^{M} \le \left((dn)^{k/2}p\right)^{M} \cdot (k/2)^{kd\ell/2}$. Then, the summand in (14) is upper bounded by

$$2^{2d\ell} \cdot d^{2d\ell-M}\ell^{2d\ell} \cdot (k/2)^{kd\ell/2} \left((dn)^{k/2}p\right)^{M} = (2\ell)^{2d\ell}(k/2)^{kd\ell/2} \cdot d^{2d\ell} \left(d^{k/2-1}n^{k/2}p\right)^{M}.$$

Using this upper bound, it follows that

$$(14) \le \frac{(2\ell)^{2d\ell}(k/2)^{kd\ell/2}n^{5kd\log(10\log n)+kd/2}d^{2d\ell}}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \cdot \sum_{M=1}^{d\ell} \left(d^{k/2-1}n^{k/2}p\right)^{M}$$
$$\le \frac{(2\ell)^{2d\ell}(k/2)^{kd\ell/2}e^{kd\ell}n^{5kd\log(10\log n)+kd/2}d^{2d\ell}}{(kd/2)^{kd\ell}} \cdot d\ell \cdot \left(d^{k/2-1}n^{k/2}p\right)^{d\ell}, \tag{15}$$

where the inequality follows from the facts that $|\mathbb{S}_{kd/2}|^{2\ell} = ((kd/2)!)^{2\ell} \ge (\frac{kd/2}{e})^{kd\ell}$ ($\because n! \ge (n/e)^n$) and $d^{k/2-1}n^{k/2}p > 1$. Reorganizing terms in (15), we obtain

$$(2\ell)^{2d\ell+1}e^{kd\ell}(k/2)^{-kd\ell/2}d^{-kd\ell/2+d\ell+1}n^{kd\ell/2+5kd\log(10\log n)+kd/2}p^{d\ell}.$$

Invoking Proposition 11 and using the fact that $f(x) = x^{1/x}$ is bounded on $[1,\infty)$, $\|M\|^{1/d}$ is upper bounded by

$$c \cdot (2\ell)e^{k/2}(k/2)^{-k/4}d^{-k/4+1/2}n^{k/4+5k\log(10\log n)/(2\ell)+k/(4\ell)}p^{1/2}$$

with probability at least $1 - e^{-2\ell}$ for some absolute constant $c > 0$. Choosing $\ell = \log n$, we complete the proof. ◀

Thus far, we have addressed the first challenge in Section 3.3 by developing a simpler spectral norm analysis of the type-symmetric representation as well as the trimmed matrix. Now, we move on to the second challenge: as mentioned in Section 3.3, the trimmed matrix $\boldsymbol{R}^{\Phi,d,\mathrm{trim}}$ is no longer a matrix representation of $(f^{\Phi})^d$, it requires additional non-trivial modifications of the algorithm steps as well as analysis.

5 A simpler spectral refutation with re-scaling entries

In this section, we address the second challenge from Section 3.3 and develop a simpler spectral refutation algorithm. Our main idea is to re-scale the rows/columns of $\boldsymbol{R}^{\Phi,d}$. To describe our re-scaling step, we first revisit the upper bound from Theorem 20:

$$\mathbb{E}\,\mathrm{Tr}((\boldsymbol{R}^{\Phi,d})^{2\ell}) \le \frac{1}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{\mathcal{Q}:\text{ even}} \left[\left(p(kd/2)^{k/2}\right)^{|\mathcal{Q}|} \cdot \sum_{\substack{\{I^{(j)}\}:\\ \mathcal{Q}\text{-valid}}} \left[\prod_{j=1}^{2\ell} \mathsf{hist}(I^{(j)})! \right] \right]. \tag{16}$$

As we have discussed in Section 4.2, we need to cancel out the $\mathsf{hist}(I^{(j)})!$ terms in the bound to reduce the spectral norm. Our approach is to appropriately re-scale $\boldsymbol{R}^{\Phi,d}$ so that one can remove the $\prod_{j=1}^{2\ell}\mathsf{hist}(I^{(j)})!$ terms in the upper bound (16). In particular, if we divide the (I,J)-th entry of $\boldsymbol{R}^{\Phi,d}$ by $\sqrt{\mathsf{hist}(I)!\cdot\mathsf{hist}(J)!}$, the $\prod_{j=1}^{2\ell}\mathsf{hist}(I^{(j)})!$ term will be exactly canceled out by the re-scaling. More formally, we define the following vector and its corresponding diagonal matrix:

▶ **Definition 25** (Re-scaling factors). *Let* hist *be an* $n^{kd/2}$*-dimensional vector whose* I*-th coordinate is defined as* $\mathsf{hist}_I := \sqrt{\mathsf{hist}(I)!}$ *for each* $I \in [n]^{kd/2}$*. We define* D_{hist} *to be an* $n^{kd/2}\times n^{kd/2}$ *diagonal matrix whose* (I,I)*-th entry is defined as* hist_I*.*

Using Definition 25, one can precisely achieve the re-scaling discussed above as follows:

▶ **Definition 26** (Re-scaled matrix representation). $\boldsymbol{R}^{\Phi,d,\mathsf{rescale}} := D_{\mathsf{hist}}^{-1}\cdot\boldsymbol{R}^{\Phi,d}\cdot D_{\mathsf{hist}}^{-1}$.

Then, following the same proof as that of Corollary 21, one can prove the following spectral norm bound:

▶ **Corollary 27.** *For even* k *and* $d\ge 1$*, let* $\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}$ *be the* $n^{kd/2\times kd/2}$ *matrix obtained from the* $\boldsymbol{R}^{\Phi,d}$ *by re-scaling the rows/columns as per* (26)*. Assume that* $d^{k/2-1}n^{k/2}p>1$*. Then, the following spectral norm bound holds with probability at least* $1-n^{-2}$*:*

$$\left\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\right\|^{1/d} \le c\cdot\frac{e^{3k/4}}{(k/2)^{k/4}}\cdot\frac{n^{k/4}p^{1/2}}{d^{(k-2)/4}}\cdot\log n\,.$$

for some absolute constant $c>0$*.*

▶ Remark 28. Note that the spectral norm bound in Corollary 27 is better than the bound due to the trimming step (Corollary 21). This improvement actually leads to a better strong refutation guarantee as we shall see in Theorem 32. Also see Section 6 for an extensive comparison with [7].

Proof. Due to the re-scaling factor, following the proof of Theorem 20, we obtain the following bound on the trace bower term without the $\prod_{j=1}^{2\ell}\mathsf{hist}(I^{(j)})!$ term:

$$\mathbb{E}\,\mathrm{Tr}((\boldsymbol{R}^{\Phi,d,\mathsf{rescale}})^{2\ell}) \le \frac{1}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{\mathcal{Q}:\text{ even}} \left[\left(p(kd/2)^{k/2}\right)^{|\mathcal{Q}|} \cdot \sum_{\substack{\{I^{(j)}\}:\\ \mathcal{Q}\text{-valid}}} [1] \right].$$

Now due to Claims 23 and 24, one can further upper bound the trace power term by

$$\frac{n^{kd/2}}{\left|\mathbb{S}_{kd/2}\right|^{2\ell}} \sum_{M=1}^{d\ell} \left[\binom{2d\ell}{M} \cdot M^{2d\ell-M} \cdot \left(p(nkd/2)^{k/2}\right)^{M} \right], \tag{17}$$

which is better than (14) by a multiplicative factor of $n^{5kd\log(10\log n)}$. Now, following the exact same calculations as in the proof of Corollary 21 and choosing $\ell = \log n$, one can easily notice that the improvement by a multiplicative factor of $n^{5kd\log(10\log n)}$ results in an improvement in the final bound by a multiplicative factor of $n^{5k\log(10\log n)/(2\ell)} = n^{5k\log(10\log n)/(2\log n)} = (10\log n)^{5k/2}$, which completes the proof. ◀

With this re-scaled matrix $\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}$, one can also easily come up with a valid certificate for strong refutation (Definition 3):

▶ **Proposition 29.** *For any k-XOR instance Φ and assignment $x \in \{\pm 1\}^n$, we have*

$$\left|P_\Phi(x) - \frac{1}{2}\right| \le \frac{1}{2m}\left[\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\| \cdot \left(\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)!\right)\right]^{1/d}.$$

In other words, $\frac{1}{2} + \frac{1}{2m}[\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\| \cdot (\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)!)]^{1/d}$ is a valid certificate for strong refutation.

Proof. First, since $\boldsymbol{R}^{\Phi,d}$ is a matrix representation of $(f^\Phi)^d$, we have

$$f^\Phi(x)^d = (x^{\otimes kd/2})^\top \boldsymbol{R}^{\Phi,d} x^{\otimes kd/2}.$$

Hence, it follows that

$$\begin{aligned} f^\Phi(x)^d &= (D_{\mathsf{hist}} x^{\otimes kd/2})^\top \cdot D_{\mathsf{hist}} D_{\mathsf{hist}}^{-1} \cdot \boldsymbol{R}^{\Phi,d} \cdot D_{\mathsf{hist}}^{-1} D_{\mathsf{hist}} \cdot x^{\otimes kd/2} \\ &= (D_{\mathsf{hist}} x^{\otimes kd/2})^\top \cdot \boldsymbol{R}^{\Phi,d,\mathsf{rescale}} \cdot D_{\mathsf{hist}} x^{\otimes kd/2}. \end{aligned}$$

Consequently, we have

$$|f^\Phi(x)^d| \le \left\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\right\| \cdot \left\|D_{\mathsf{hist}} x^{\otimes kd/2}\right\|^2 = \left\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\right\| \cdot \left(\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)!\right),$$

where the equality is due to the fact that $x^{\otimes kd/2}$ is an $n^{kd/2}$-dimensional vector with coordinates equal to ± 1. Therefore, the proposition follows thanks to the identity (1), which reads $P_\Phi(x) = \frac{1}{2} + \frac{1}{2m} \cdot f^\Phi(x)$. ◀

Hence, in order to guarantee that the certificate from Proposition 29 works, our last ingredient is to show that the term $(\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)!)$ is not too large compared to $\left\|x^{\otimes kd/2}\right\|^2 = n^{kd/2}$.

▶ **Proposition 30.** *For even k and $d \ge 1$,*

$$\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)! = \frac{(kd/2+n-1)!}{(n-1)!} = (kd/2+n-1)(kd/2+n-2)\cdots n.$$

In particular, if $d \le n$, we have $\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)! \le (k/2+1)^{kd/2} n^{kd/2}$.

Proof. We first group the terms in the summation according to the value of $\mathsf{hist}(I)$:

$$\sum_{I\in[n]^{kd/2}} \mathsf{hist}(I)! = \sum_{\substack{(s_1,s_2,\ldots,s_n)\in(\mathbb{Z}_{\ge 0})^n: \\ \sum_i s_i = kd/2}} \sum_{\substack{I\in[n]^{kd/2}: \\ \mathsf{hist}(I)=(s_1,s_2,\ldots,s_n)}} \prod_{i=1}^n (s_i)!. \tag{18}$$

For each $(s_1, s_2, \ldots, s_n) \in (\mathbb{Z}_{\geq 0})^n$, there are $\frac{(kd/2)!}{\prod_{i=1}^n (s_i)!}$ different I's such that $\mathsf{hist}(I) = (s_1, s_2, \ldots, s_n)$. Hence, the right hand side of (18) becomes

$$\sum_{\substack{(s_1,s_2,\ldots,s_n)\in(\mathbb{Z}_{\geq 0})^n: \\ \sum_i s_i = kd/2}} (kd/2)! = (kd/2)! \cdot \left| \left\{ (s_1, s_2, \ldots, s_n) \in (\mathbb{Z}_{\geq 0})^n : \sum_i s_i = kd/2 \right\} \right| .$$

It is a simple enumerative combinatorics (c.f. stars and bars argument) to show that the number of feasible $(s_1, \ldots, s_n)$'s is equal to $\binom{kd/2+n-1}{n-1} = \binom{kd/2+n-1}{kd/2}$. Therefore, the summation is equal to

$$\binom{kd/2+n-1}{kd/2} \cdot (kd/2)! = (kd/2+n-1)(kd/2+n-2)\cdots n\,,$$

which completes the proof. ◀

Combining what we have obtained thus far, one can consider the following simpler refutation algorithm based on re-scaling entries:

Algorithm 1 A simpler strong refutation algorithm with parameter d for even k.

Input: A k-XOR instance Φ on n variables consisting of m clauses $C_{S_1}, \ldots, C_{S_m}$ for distinct tuples $S_1, \ldots, S_m \in [n]^k$ and a parameter $d \in \mathbb{N}$.

1. Construct a higher-order symmetric matrix representation $\boldsymbol{R}^{\Phi,d}$ based on the k-XOR instance Φ as per Definition 13.
2. Compute $\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}$ as per Definition 26.

Output: $\widehat{P_\Phi} := \frac{1}{2} + \frac{1}{2m} \left\| \boldsymbol{R}^{\Phi,d,\mathsf{rescale}} \right\|^{1/d} \cdot \left(\frac{(kd/2+n-1)!}{(n-1)!} \right)^{1/d}$.

▶ Remark 31. A similar idea of re-scaling rows/columns with diagonal matrices to obtain a better certificate also appeared in the MAXCUT literature; see e.g. [6, Theorem 2.2].

▶ **Theorem 32.** *Let $d \leq n$ be positive integers and k be an even integer. For any instance Φ of k-XOR, the output $\widehat{P_\Phi}$ of Algorithm 1 satisfies $|P_\Phi(x) - \frac{1}{2}| \leq \widehat{P_\Phi} - \frac{1}{2}$ for any $x \in \{\pm 1\}^n$. Assume further that Φ is an instance of random k-XOR with probability p (Definition 1). If $p \cdot d^{k/2-1} n^{k/2} > 1$, the following bound holds with probability at least $1 - O(n^{-1})$ for some absolute constant $c > 0$:*

$$\widehat{P_\Phi} - \frac{1}{2} \leq c \cdot \frac{\log n}{\sqrt{d^{k/2-1} n^{k/2} p}} \cdot \frac{e^{3k/4} \cdot (k/2+1)^{k/2}}{(k/2)^{k/4}} .$$

In particular, Algorithm 1 with parameter d certifies with high probability that $P_\Phi(x)$ is equal to $1/2 \pm o(1)$ for any $x \in \{\pm 1\}^n$ whenever $n^{k-1} p = \omega((n/d)^{k/2-1} \log^2 n)$.

Proof. First from Proposition 29, we have

$$\left| P_\Phi(x) - \frac{1}{2} \right| \leq \frac{1}{2m} \left[\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\| \cdot \left(\sum_{I \in [n]^{kd/2}} \mathsf{hist}(I)! \right) \right]^{1/d} = \widehat{P_\Phi} - \frac{1}{2}\,, \tag{19}$$

where the equality is due to Proposition 30. Hence the first part of the theorem is proved. As for the second part, it follows from Corollary 27 and Proposition 30 that with probability at least $1 - O(n^{-2})$:

$$\left[\|\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}\| \cdot \left(\sum_{I \in [n]^{kd/2}} \mathsf{hist}(I)! \right) \right]^{1/d} \leq c \cdot \frac{n^{3k/4} p^{1/2}}{d^{(k-2)/4}} \log n \cdot \frac{e^{3k/4} \cdot (k/2+1)^{k/2}}{(k/2)^{k/4}} \tag{20}$$

for some absolute constant $c > 0$. Next, it follows from a standard concentration inequality (e.g. Chernoff bound) that with probability at least (say) $1 - n^{-10}$, $m \geq pn^k/2$. Putting these bounds back to (19), we obtain

$$\begin{aligned} \left| P_\Phi(x) - \frac{1}{2} \right| &\leq \frac{1}{pn^k} \cdot c \cdot \frac{n^{3k/4} p^{1/2}}{d^{(k-2)/4}} \log n \cdot \frac{e^{3k/4} \cdot (k/2+1)^{k/2}}{(k/2)^{k/4}} \\ &= c \cdot \frac{\log n}{\sqrt{d^{k/2-1} n^{k/2} p}} \cdot \frac{e^{3k/4} \cdot (k/2+1)^{k/2}}{(k/2)^{k/4}}, \end{aligned}$$

and hence, the second part of the theorem also follows. ◀

6 Comparison with Raghavendra-Rao-Schramm

We compare Algorithm 1 with the refutation algorithm of Raghavendra, Rao and Schramm [7]. First, the algorithm steps in this paper is simpler than that of [7]. As we have discussed earlier, the trimming step in the algorithm of [7] causes some technical complications as the resulting matrix is no longer a matrix representation of $(f^\Phi)^d$. Indeed, their algorithm first constructs matrices of size $n^{kj/2} \times n^{kj/2}$ for $j \in [\delta d, d]$ and computes the spectral norms of those matrices to design a refutation certificate; see [7, Section 4.1.1] for details. This is in stark contrast with Algorithm 1 which only computes the spectral norm of a *single* matrix $\boldsymbol{R}^{\Phi,d,\mathsf{rescale}}$ of size $n^{kd/2} \times n^{kd/2}$. In addition, while their certificate requires non-trivial analysis [7, Section 4.1.1] to guarantee its validity, the validity of our certificate $\widehat{P_\Phi}$ readily follows as we saw in Proposition 29.

As a result of the simpler approach in this paper, the theoretical guarantee in this paper comes with less technical conditions and enjoys a better refutation guarantee as well as density requirement. More specifically, unlike the guarantee in [7], our main theorem does not require a technical condition like $d \log n = O(n)$. Moreover, the density requirement for strong refutation reads $n^{k-1}p = \omega((n/d)^{k/2-1} \log^{2k} n)$ in [7], which is worse than that of this paper by a poly-logarithmic factor (recall that the requirement in Theorem 32 reads $n^{k-1}p = \omega((n/d)^{k/2-1} \log^2 n)$). Lastly, even when the density requirement is fulfilled, their refutation guarantee reads $\frac{1}{2} + \gamma + o(1)$ for some constant $\gamma > 0$ that depends on a hyperparameter in the trimming step. On the other hand, this constant γ does not appear in the refutation guarantee of this paper.

7 Conclusion

In this paper, we establish a simpler approach to strong refutation of random k-XOR below the spectral threshold. Our simplification is two-fold. First, we provide a simpler spectral norm analysis of the certificate matrix of the previous work [7] (Section 4). Second, we develop a simple strong refutation algorithm for the even k case (Section 5). Thanks to our simpler approach, our main result (Theorem 32) enjoys a better theoretical guarantee under less assumptions. It is important to note that a recent work by Wein, El Alaoui and

Moore also establishes a simpler strong refutation algorithm for random even k-XOR [9, Theorem F.1] with a different approach. Given the successful simplifications for the even k case, it would be interesting to see if one can come up with a simpler strong refutation algorithm for the odd k case.

A Deferred proofs of claims

A.1 Proof of Claim 17

Proof. Recall that Claim 17 reads $\mathsf{Num}\left(\mathcal{Q} \mid \{\mathsf{Id}\}\right) = \mathsf{Num}\left(\mathcal{Q} \mid \{\pi_j\}\right)$ for any $\{\pi_j\}$. Let us arbitrarily fix a collection of permutations $\{\pi_j\}$. The main observation is that for any $\{I^{(j)}\}$ and $\{\sigma_j\}$, we have $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\}) = \mathsf{Par}(\{\pi_j(I^{(j)})\}, \{\mathsf{Id}\}, \{\sigma_j \circ \pi_j^{-1}\})$. This is a straightforward consequence of Definition 14. Hence, there is an one-to-one correspondence between the collection of pairs $(\{I^{(j)}\}, \{\sigma_j\})$ such that $\mathsf{Par}(\{I^{(j)}\}, \{\pi_j\}, \{\sigma_j\}) = \mathcal{Q}$ and the collection such that $\mathsf{Par}(\{I^{(j)}\}, \{\mathsf{Id}\}, \{\sigma_j\}) = \mathcal{Q}$. This concluded the proof. ◀

A.2 Proof of Claim 19

Proof. We first restate Claim 19: for any $\mathcal{Q}$-valid$\{I^{(j)}\}$, there are at most $(kd/2)^{k|\mathcal{Q}|/2} \cdot \prod_{j=1}^{2\ell} \mathsf{hist}(I^{(j)})!$ different $\{\sigma_j\}$'s such that $\mathsf{Par}\left(\{I^{(j)}\}, \{\mathsf{Id}\}, \{\sigma_j\}\right) = \mathcal{Q}$.

We bound the number of feasible $\{\sigma_j\}$'s as we go through the index set $\mathcal{I} = \{(j, s) \ : \ j = 1, \ldots, 2\ell, s = 1, \ldots, d\}$ in the lexicographical order, i.e., $(1, 1)$, $(1, 2)$, $\ldots$, $(1, d)$, $(2, 1)$, $\ldots$ and so on. As we read the indices in such an order, we call an index (j, s) *new* if $(U_s^{(j)}, \sigma_j(U_s^{(j+1)}))$ is not equivalent to the previously appeared indices. Consider the indices $(j, 1), (j, 2), \ldots, (j, d)$ for a fixed $j \in [2\ell]$. We consider two different scenarios:

1. First, suppose that all indices $(j, 1), (j, 2), \ldots, (j, d)$ are old. Then it should be the case that for each $m = 1, \ldots, kd/2$, $\sigma_j(m)$ is chosen so that the $\sigma_j(m)$-th coordinate of $I^{(j+1)}$ respects the previous appeared equivalent index. Having observed this, it readily follows that there are $\mathsf{hist}(I^{(j+1)})!$ different choices for $\sigma_j(1), \ldots \sigma_j(kd/2)$ considering the permutation.

2. Now, suppose that there are $d_{\text{new}}^{(j)}$ new indices among $(j,1),(j,2),\dots,(j,d)$. For simplicity, assume that $U_{j,1},\dots,U_{j,d_{\text{new}}^{(j)}}$ are new. Choosing the values $\sigma_j(1),\sigma_j(2),\dots,\sigma_j(kd_{\text{new}}^{(j)}/2)$ arbitrarily, there are at most

$$(kd/2)(kd/2-1)\cdots(kd/2-kd_{\text{new}}^{(j)}/2+1) \le (kd/2)^{kd_{\text{new}}^{(j)}/2}$$

different choices for $\sigma_j(1),\sigma_j(2),\dots,\sigma_j(kd_{\text{new}}/2)$. A similar counting to previous case yields that for the remaining values there are at most $\mathsf{hist}(I^{(j+1)})!$ different choices.

Taking a product over all j's, we complete the proof since $\sum_{m=1}^{2\ell} d_{\text{new}}^{(m)} = |\mathcal{Q}|$. ◀

A.3 Proof of Claim 23

Proof. Let $\mathcal{Q}$ be an even partition. We count the number of possible $\mathcal{Q}$-valid $\{I^{(j)}\}$'s. First, let us choose $I^{(1)}$ arbitrarily. Note that there are $n^{kd/2}$ different ways of choosing I_1. Now, consider $I_2,\dots,I_{2\ell}$. Similar to the proof of Claim 19, we will bound the number of feasible choices s we go through the index set $\mathcal{I} = \{(j,s) \ : \ j=1,\dots,2\ell, s=1,\dots,d\}$ in the lexicographical order. Again, we call an index (j,s) *new* if $(\pi_j(U_s^{(j)}),\sigma_j(U_s^{(j+1)}))$ is not equivalent to the previously appeared indices.

Note that we only need to consider new indices because the tuples of old indices are fully determined by their previous appearance. We begin with the tuples $(1,1),(1,2),\dots,(1,d)$. Whenever we encounter a new tuple, say $(U_s^{(1)},\sigma_1(U_s^{(2)}))$, we only need to specify $\sigma_1(U_s^{(2)})$ since $I^{(1)}$ is already fully specified. Hence, there are at most $n^{kd_{\text{new}}^{(1)}/2}$ different ways of choosing $I^{(2)}$, where $d_{\text{new}}^{(1)}$ is the number of new indices among $(1,1),(1,2),\dots,(1,d)$. By similar arguments, inductively for $j=2,3,\dots,2\ell$, there are at most $n^{kd_{\text{new}}^{(j)}/2}$ different ways of choosing $I^{(j)}$. Taken collectively, we obtain the result since $\sum_{j=1}^{2\ell} d_{\text{new}}^{(j)} = |\mathcal{Q}|$. ◀

Iterated Decomposition of Biased Permutations via New Bounds on the Spectral Gap of Markov Chains

Abstract

In this paper, we address a conjecture of Fill [Fill03] about the spectral gap of a nearest-neighbor transposition Markov chain $\mathcal{M}_{\text{nn}}$ over biased permutations of $[n]$. Suppose we are given a set of input probabilities $\mathcal{P} = \{p_{i,j}\}$ for all $1 \leq i, j \leq n$ with $p_{i,j} = 1 - p_{j,i}$. The Markov chain $\mathcal{M}_{\text{nn}}$ operates by uniformly choosing a pair of adjacent elements, i and j, and putting i ahead of j with probability $p_{i,j}$ and j ahead of i with probability $p_{j,i}$, independent of their current ordering.

We build on previous work [25] that analyzed the spectral gap of $\mathcal{M}_{\text{nn}}$ when the particles in $[n]$ fall into k classes. There, the authors iteratively decomposed $\mathcal{M}_{\text{nn}}$ into simpler chains, but incurred a multiplicative penalty of n^{-2} for each application of the decomposition theorem of [23], leading to an exponentially small lower bound on the gap. We make progress by introducing a new complementary decomposition theorem. We introduce the notion of ϵ-orthogonality, and show that for ϵ-orthogonal chains, the complementary decomposition theorem may be iterated $O(1/\sqrt{\epsilon})$ times while only giving away a constant multiplicative factor on the overall spectral gap. We show the decomposition given in [25] of a related Markov chain $\mathcal{M}_{\text{pp}}$ over k-class particle systems is $1/n^2$-orthogonal when the number of particles in each class is at least $C \log n$, where C is a constant not depending on n. We then apply the complementary decomposition theorem iteratively n times to prove nearly optimal bounds on the spectral gap of $\mathcal{M}_{\text{pp}}$ and to further prove the first inverse-polynomial bound on the spectral gap of $\mathcal{M}_{\text{nn}}$ when k is as large as $\Theta(n/\log n)$. The previous best known bound assumed k was at most a constant.

1 Introduction

For $n \in \mathbb{N}$, the problem of generating permutations of $[n] = \{1, 2 \ldots, n\}$ at random is foundational in the history of computer science [19]. Markov chains for sampling permutations arise in a variety of contexts, including self-organizing lists [17, 30], card shuffling [2, 32], and search engines [5]. The spectral gap of a Markov chain provides a measure of the rate of convergence to stationarity, which is crucial to the efficiency of Markov chain algorithms for sampling.

Suppose we are given a set of input probabilities $\mathcal{P} = \{p_{i,j}\}$ for all $1 \leq i, j \leq n$ with $p_{i,j} = 1 - p_{j,i}$. A natural Markov chain $\mathcal{M}_{\text{nn}}$ over permutations operates by uniformly choosing a pair of adjacent elements, i and j, and putting i ahead of j with probability $p_{i,j}$ and j ahead of i with probability $p_{j,i}$, independent of their current ordering. We call $\mathcal{M}_{\text{nn}}$ the *nearest-neighbor* transposition chain.

The Markov chain $\mathcal{M}_{\text{nn}}$ was among the first Markov chains studied in terms of its computational efficiency for sampling [1, 10, 9]. Its spectral gap has been studied extensively, both in the uniform and biased settings [3, 4, 8, 10, 32].

A central question is under what conditions the spectral gap of $\mathcal{M}_{\text{nn}}$ is an inverse polynomial in n, which implies a polynomial time bound on the *mixing time*, or the time until the chain will be "close" to its stationary distribution. We say $\mathcal{P}$ is *positively biased* if $p_{i,j} \geq 1/2$ for all $i < j$. It is easy to see that this condition is necessary (see, e.g. [4]); however, it is not sufficient, as demonstrated in [4].

In 2003, Fill [13, 14] introduced the following monotonicity conditions: $p_{i,j+1} \geq p_{i,j}$ for all $1 \leq i < j \leq n-1$ and $p_{i-1,j} \geq p_{i,j}$ for all $2 \leq i < j \leq n$. He conjectured that if $\mathcal{P}$ is positively biased and monotone, then the spectral gap of $\mathcal{M}_{\text{nn}}$ is an inverse polynomial in n, and moreover that the smallest spectral gap is attained at the uniform distribution.

Despite significant work on this subject, Fill's conjecture remains mostly open after more than 15 years. In the uniform case, there is a clever path coupling argument that achieves tight bounds on the mixing time [32]. Various papers [3, 4] have identified different classes of $\mathcal{P}$ for which $\mathcal{M}_{\text{nn}}$ may cleverly be viewed as the direct product of simpler independent Markov chains, and thus may be analyzed easily in terms of those chains. In [3], the authors proved a bound of $O(n^2)$ on the mixing time of $\mathcal{M}_{\text{nn}}$ in the case that $p_{i,j} = p$ for all $i < j$, and in [4] the authors considered the case that $p_{i,j}$ depends only on the smaller of i and j.

Among the positively biased, monotone distributions that have proven to be challenging to analyze are those arising in the context of self-organizing lists, where each element i has a frequency w_i of being requested, and then moved ahead one in the list; in this case, $p_{i,j} = w_i/(w_i + w_j)$. The Markov chain $\mathcal{M}_{\text{nn}}$ was termed a "gladiator chain" in this case by Haddadan and Winkler [16].

Figure 1 An example of a 4-class permutation and corresponding 4-particle process, with $n = 7$.

It is instructive to consider *k-classes* [25], where $[n]$ is partitioned into k classes and particles from class i and class j interact with a fixed probability $\overline{p}_{i,j}$[1]. When $k = n$, this captures the general setting. In this context, $\mathcal{M}_{\text{nn}}$ can be seen as having dual duties: *whisking*,

[1] The bar in the notation indicates that we have re-indexed the probabilities by class.

which uniformly mixes particles of the same type[2], and *sifting*, which mixes particles of different types in together [16]. As the mixing properties of the uniform chain are well-understood, it is sufficient to analyze the sifting operation in isolation [16, 25]. By discarding moves between particles in the same class, we are left with a linear k-particle process that maintains elements within each particle class in fixed relative orders (and therefore we may drop their individual labels and re-index, identifying all elements from class i with the label i, as is done in Figure 1).

In this paper, we use the version of the k-particle process introduced in [25], called $\mathcal{M}_{\text{pp}}$, which is also allowed to make certain non-adjacent transpositions – it may swap i and j if all elements between them are smaller than both i and j. This simplifies our analysis, and as in [25], we compensate by using comparison techniques [9, 28] when evaluating the spectral gap of $\mathcal{M}_{\text{nn}}$.

The *bias* towards having a particle of type i ahead of a particle of type j is $\overline{q}_{i,j} = \overline{p}_{i,j}/\overline{p}_{j,i}$. We say that the bias is *bounded* if there exists a constant $q > 1$ such that $\overline{q}_{i,j} \geq q$ for all $i < j$. After a series of papers [16, 25], it was shown that the spectral gap of $\mathcal{M}_{\text{pp}}$ is at least $\Omega(n^{-2(k-1)})$ for positively biased, monotone, and bounded distributions. These results apply to the gladiator chain (self-organizing lists) with k distinct frequencies. In fact, the result in [25] requires only *weak monotonicity*, and not full monotonicity. Weak monotonicity in the setting of k-classes is defined as follows.

▶ **Definition 1** ([4]). *If $\mathcal{P}$ forms a k-class, then $\mathcal{P}$ is weakly monotonic if properties 1 and either 2 or 3 are satisfied.*

1. $\overline{p}_{i,j} \geq 1/2$ *for all* $1 \leq i < j \leq k$, *and*
2. $\overline{p}_{i,j+1} \geq \overline{p}_{i,j}$ *for all* $1 \leq i < j \leq k-1$ *or*
3. $\overline{p}_{i-1,j} \geq \overline{p}_{i,j}$ *for all* $2 \leq i < j \leq k$.

The aforementioned results are based on a natural decomposition of $\mathcal{M}_{\text{pp}}$ into simpler chains, but not as a direct product. To get a bound on the overall spectral gap, the authors of [25] used the decomposition theorem of [23], which bounds the spectral gap of a Markov chain in terms of the spectral gaps of the simpler Markov chains. Unfortunately, one incurs an extra factor of n^{-2} each time it is applied in this setting, and in [25] it is applied iteratively $k-2$ times. Thus, this produced a bound on the spectral gap of $\Omega(n^{-2(k-1)})$, which is an inverse polynomial only for constant k.

To make this iterated decomposition scheme work for larger k requires a stronger decomposition theorem, and that is the main focus of the present paper. We introduce a new decomposition theorem that allows us to achieve nearly optimal bounds of $\Omega(n^{-2})$ on the spectral gap of $\mathcal{M}_{\text{pp}}$ for bounded k-classes, as long as the number of particles of each type is at least $C_q \log n$ (where C_q is a constant depending on the minimum bias q; i.e. not depending on n). We believe this new decomposition theorem is of independent interest and will have other applications.

1.1 The decomposition method

The decomposition method was first introduced by Madras and Randall [21], and has been subsequently used and modified to produce the first polynomial time bounds on the spectral gaps of many interesting Markov chains [6, 7, 11, 12, 15, 16, 18, 22, 23, 24, 26, 27]. Suppose $\mathcal{M}$ is a finite, ergodic Markov chain that is reversible and has stationary distribution π.

[2] We use the terms "type" and "class" interchangeably.

Let $\Omega = \cup_{i=1}^{r} \Omega_i$ be a partition of the state space of $\mathcal{M}$ and γ_i be the spectral gap of $\mathcal{M}$ restricted to Ω_i. The disjoint decomposition theorem of [23] states that the spectral gap γ of $\mathcal{M}$ satisfies $\gamma \geq \frac{1}{2}\gamma_{\min}\bar{\gamma}$, where $\gamma_{\min} = \min_i \gamma_i$ and $\bar{\gamma}$ is the spectral gap of a certain *projection* chain over states $[r]$.

There has been significant effort towards improving the decomposition technique by providing stronger bounds in special cases [7, 12, 15, 18, 22, 23, 26, 27]. While γ may indeed be on the order of $\gamma_{\min}\bar{\gamma}$ – one example is the random walk on the path, decomposed into two smaller paths – there are instances in which it may instead satisfy the much larger bound $\gamma \geq c\min\{\gamma_{\min}, \bar{\gamma}\}$, for some constant c. The simplest such example is the direct product of two independent Markov chains [4, 12]; in this case, $c = 1$.

Tight bounds are especially important when applying the decomposition method iteratively, as was done in [25]. At each level of the induction, $\bar{\gamma} = \Theta(n^{-2})$, so the original bound of [23] yields $\gamma = \Omega(n^{-2(n-1)})$ for the final iteration. Even a bound of the form $\gamma \geq c\min\{\gamma_{\min}, \bar{\gamma}\}$, such as the one in [26], would introduce a factor of c for each application, and would thus yield a bound that is an inverse exponential in n if $c < 1$ is constant. The bounds in [18] are iterable in some cases, but $\mathcal{M}_{\text{pp}}$ does not satisfy those conditions.

1.2 Our results

In this paper, we develop a new decomposition framework that yields iterable bounds for a new class of Markov chains. Among our results, we present a complementary decomposition theorem, which achieves a tight bound on γ without appealing to a bound on the gap $\bar{\gamma}$ of the projection chain, but rather the minimum gap $\tilde{\gamma}_{\min}$ of certain *complementary restrictions* $\tilde{P}_1, \tilde{P}_2, \ldots, \tilde{P}_{\tilde{r}}$. We first consider the simple setting where the state space Ω can be seen as a product space, i.e. $\Omega = \Omega_1 \times \Omega_2$. In other words, for each $a \in \Omega_1$ and each $b \in \Omega_2$, there is a unique $\sigma = (a, b) \in \Omega$. This setting is similar to the direct product of independent Markov chains, but the transition probabilities are not necessarily independent. We define a restriction chain P_a for each $a \in \Omega_1$ that fixes a and operates only on the second coordinate. Similarly, we define a complementary restriction chain $\tilde{P}_b$, which fixes b and operates only on the first coordinate. Recall π is the stationary distribution of $\mathcal{M}$. We write $\pi(a) = \sum_{b\in\Omega_2} \pi(a, b)$ and $\pi(b) = \sum_{a\in\Omega_1} \pi(a, b)$. Define

$$r(a, b) = \frac{\pi(a, b)}{\pi(a)\pi(b)}.$$

The function $r(a, b)$ allows us to capture the degree of dependence between a and b. Let

$$\epsilon = \sum_{(a,b)\in\Omega} \pi(a, b) \left(\sqrt{r(a, b)} - 1/\sqrt{r(a, b)}\right)^2. \tag{1}$$

We say a decomposition satisfying the equality above is ϵ-orthogonal.

▶ **Theorem 2.** *For any ϵ-orthogonal decomposition of Markov chain $\mathcal{M}$ on product space Ω,*

$$\gamma(\mathcal{M}) \geq \min\{\gamma_{\min}, \tilde{\gamma}_{\min}\} \left(1 - \sqrt{\epsilon}\right)^2.$$

This bound can be iterated t times with only a constant overhead, as long as $\sqrt{\epsilon} \leq 1/t$. We note that parts of the proof of this theorem are similar to a "multi-decomposition" result of Destainville [7], which we discuss in Section 5. There we also present several generalizations of Theorem 2, which apply beyond the product space setting.

Favorably, analysis of ϵ-orthogonality requires only a comparison between two stationary distributions and not an analysis of the dynamics of any Markov chain. When $\mathcal{M}$ is a direct product of independent Markov chains, we have that $r(a,b) = 1$ for all pairs $a \in \Omega_1$ and $b \in \Omega_2$ and the decomposition is 0-orthogonal, leading to the bound $\gamma \geq \min\{\gamma_{\min}, \tilde{\gamma}_{\min}\}$, as expected. However, we do not require a strong pointwise bound on $r(a,b)$. The notion of ϵ-orthogonality captures the *average* value of $r(a,b)$, and allows us to achieve tight bounds on γ even when the constituent Markov chains are only *nearly* independent. Indeed, it is possible to prove ϵ is very small even if $r(a,b)$ is far from 1 for pathological pairs a and b, as long as it is close to 1 on average. Importantly, this holds even though the elements in this "bad" space are visited polynomially often.

Armed with our new decomposition theorem, we use the iterated decomposition in [25] to achieve nearly optimal bounds on the spectral gap of the k-particle process $\mathcal{M}_{\text{pp}}$. We prove that this decomposition is $1/n^2$-orthogonal at each level of the decomposition. Thus, we may apply Theorem 2 iteratively k times to get a bound of $\Omega(n^{-2})$ on the spectral gap $\gamma(\mathcal{M}_{\text{pp}})$. This bound is optimal up to constants. More formally, let $N^* = \max\left\{\frac{\log(6n^2)+\log((1+q)/(q-1))}{\log((1+q)/2)}, \frac{\log^2(14)}{\log^2(2q/(1+q))}\right\} =: C_q \log n$, and let c_i denote the number of particles of type i, for $1 \leq i \leq k$. We prove the following.

▶ **Theorem 3.** *If the probabilities $\mathcal{P}$ are weakly monotonic and bounded and $c_i \geq 2N^*$ for all $1 \leq i \leq k$, then the spectral gap γ of the chain $\mathcal{M}_{pp}$ satisfies $\gamma = \Omega(n^{-2})$.*

4131124131342

Figure 2 At level 2 of the decomposition, all particles of type 1 are in fixed positions, and the underlined particle 2 may swap with the 3 to its left or the 4 immediately to its right.

The iterated decomposition works as follows. At the ith level of the decomposition, all particles of type less than i are in fixed positions, and particles of larger type are allowed to swap across these (this is the reason for allowing these non-adjacent transpositions); see Figure 2. This decomposition is designed to exploit the hypothesis that the movement of the particles of type i is nearly independent of the relative order of the particles of type bigger than i. The tool of ϵ-orthogonality allows us to make this intuition precise. We define the complementary restriction chains to contain the moves involving only particles of type bigger than i, and we define the restriction chains to contain moves between particles of type i and particles of larger type. We prove that this decomposition is $1/n^2$-orthogonal if the number of particles of type $i+1$ is large enough. Indeed, the highest probability configuration is the one in which particles are sorted by class, with all particles of smaller type appearing before particles of larger type. Thus, having many particles of type $i+1$ ensures that a typical configuration will not have a particle of type i after a particle of type at least $i+2$, as this requires many transpositions from the highest probability configuration, and each costs a factor of at least the minimum bias q; see Figure 3. Note that such "bad" configurations are polynomially suppressed, but not exponentially suppressed.

1223123111213341314344 4

Figure 3 A "typical" configuration at level 2 has no 2's appearing after any $j \geq 4$.

We use Theorem 3 and comparison techniques to prove the following result for $\mathcal{M}_{\text{nn}}$.

▶ **Theorem 4.** *If the probabilities $\mathcal{P}$ are weakly monotonic and form a bounded k-class with at least $2N^*$ particles in each class, then $\gamma(\mathcal{M}_{nn}) = \Omega(n^{-7})$.*

This is the first inverse-polynomial bound on the spectral gap of $\mathcal{M}_{\text{nn}}$ for monotone bounded k-classes for k as large as $\Theta(n/\log n)$. This is a significant improvement over the previous result which was inverse polynomial only for constant k [23]. Theorem 4 also leads to a bound of $O(n^9)$ on the mixing time of $\mathcal{M}_{\text{nn}}$ under the same conditions.

1.3 Outline

The layout of the paper is as follows. In Section 2, we begin with some notation and terminology. In Section 3, we give details on Theorem 2 and illustrate its use by applying it to the one-dimensional Ising model. In Section 4, we apply Theorem 2 to the biased permutation problem. In Section 5, we generalize the notion of ϵ-orthogonality to non-product spaces and present a more general complementary decomposition theorem that applies to all ϵ-orthogonal decompositions. We also present a classical decomposition theorem that generalizes some results of [18] and show how our decomposition theorems relate to previous results. Finally, we give a brief summary of the proof techniques for the decomposition theorems. Appendix A provides even more detail concerning the proofs of the decomposition theorems, whereas the complete proofs appear in the full version of the paper.

2 Preliminaries

We assume $\mathcal{M}$ is an ergodic Markov chain over a finite state space Ω with transition matrix P. We also assume $\mathcal{M}$ is reversible and has stationary distribution π; that is, it satisfies the *detailed balance* condition: for all $\sigma, \tau \in \Omega$, $\pi(\sigma)P(\sigma,\tau) = \pi(\tau)P(\tau,\sigma)$. Notationally, we write $\pi(S) = \sum_{\sigma\in S}\pi(\sigma)$ for any set $S \subseteq \Omega$.

Let $\Omega = \cup_{i=1}^{r}\Omega_i$ be a partition of the state space into r pieces. For each $i \in [r]$, define $P_i = P(\Omega_i)$ as the restriction of P to Ω_i which rejects moves that leave Ω_i. Formally, P_i is defined as follows: if $\sigma \neq \tau$ and $\sigma, \tau \in \Omega_i$ then $P_i(\sigma,\tau) = P(\sigma,\tau)$; if $\sigma \in \Omega_i$ then $P_i(\sigma,\sigma) = 1 - \sum_{\tau\in\Omega_i,\tau\neq\sigma} P_i(\sigma,\tau)$. The Markov chain $\mathcal{M}_i$ with transition matrix P_i is called a *restriction* Markov chain, and its state space is Ω_i. Let π_i be the normalized restriction of π to Ω_i; i.e. $\pi_i(S) = \pi(S \cap \Omega_i)/\pi(\Omega_i)$ for any $S \subseteq \Omega$. The chain $\mathcal{M}_i$ is ergodic, reversible, and has stationary distribution π_i.

We will be interested in decomposing P into the part that performs restriction moves and the part that performs all other moves. Define $\tilde{P}$ to be the transition matrix of the Markov chain defined by rejecting moves from σ to τ if σ and τ are within the same Ω_i. The matrix $\tilde{P}$ defines a *complementary* partition $\Omega = \cup_{j=1}^{\tilde{r}}\tilde{\Omega}_j$, where each $\tilde{\Omega}_j$ is a maximal subset of Ω that is connected by $\tilde{P}$. For each $j \in [\tilde{r}]$, define the *complementary restriction* $\tilde{P}_j = P(\tilde{\Omega}_j)$ as the restriction of P to $\tilde{\Omega}_j$ which rejects moves that leave $\tilde{\Omega}_j$. The complementary restriction $\tilde{P}_j$ is also ergodic, reversible, and its stationary distribution is the normalized restriction of π to $\tilde{\Omega}_j$, which we call $\tilde{\pi}_j$. Notice that the complementary restrictions are defined by the decomposition $P_1, P_2, \ldots, P_r$.

The efficiency of a Markov chain $\mathcal{M}$ is a function of its spectral gap, denoted $\gamma(\mathcal{M})$, which is defined as the difference of 1 and the second largest eigenvalue of its transition matrix. Letting $\gamma_i = \gamma(\Omega_i)$ and $\tilde{\gamma}_j = \gamma(\tilde{\Omega}_j)$, the complementary decomposition theorem, Theorem 2, is proven by analyzing the spectral gaps $\gamma_{\min} = \min_i \gamma_i$ and $\tilde{\gamma}_{\min} = \min_j \tilde{\gamma}_j$. Note that if some restriction or complementary restriction has a single element, its spectral gap is taken to be 1.

3 Complementary decomposition theorem

In this section, we show how to apply our new complementary decomposition theorem by considering a few simple examples. Recall $r(a,b) = \pi(a,b)/(\pi(a)\pi(b))$ and

$$\epsilon = \sum_{(a,b)\in\Omega} \pi(a,b)\left(\sqrt{r(a,b)} - 1/\sqrt{r(a,b)}\right)^2.$$

Theorem 2 states that the spectral gap γ of $\mathcal{M}$ satisfies $\gamma \geq \min\{\gamma_{\min}, \tilde{\gamma}_{\min}\}(1-\sqrt{\epsilon})^2$. A simple application of Theorem 2 is to a Markov chain $\mathcal{M}$ that is the direct product of two Markov chains $\mathcal{M}_1$ and $\mathcal{M}_2$. It is easy to see that $r(a,b) = 1$ for all a, b, and so this proves $\gamma(\mathcal{M}) = \min\{\gamma(\mathcal{M}_1), \gamma(\mathcal{M}_2)\}$. By iterating on $\tilde{\gamma}_{\min}$, we can immediately prove the following well-known result.

▶ **Corollary 5.** *If $\mathcal{M}$ is the direct product of Markov chains $\{\mathcal{M}_i\}$, then $\gamma(\mathcal{M}) = \min_i \gamma(\mathcal{M}_i)$.*

3.1 One-dimensional Ising model

As a second introductory example prior to our main application, we consider the one-dimensional Ising model. Here each configuration $\sigma \in \Omega$ is an assignment of a "spin" (either +1 or -1) to each of n vertices connected to form a line; see Figure 4. Let $\lambda = e^{-\beta}$, where $\beta > 0$ represents inverse temperature. We are interested in sampling from the Gibbs distribution given by $\pi(\sigma) = e^{-\beta H(\sigma)}/Z$, where the Hamiltonian $H(\sigma)$ is the number of edges whose endpoints have different spins and Z is the normalizing constant $\sum_{\sigma\in\Omega} e^{-\beta H(\sigma)}$, also called the *partition function*. (See [20] for background on the ferromagnetic Ising model.)

Consider the Glauber dynamics Markov chain $\mathcal{M}_{\text{gd}}$.

Glauber Dynamics $\mathcal{M}_{\text{gd}}$

`Starting at any configuration` σ^0`, iterate the following:`

- At time t, choose a vertex $1 \leq i \leq n$ uniformly at random.
- Set the spin of vertex i to $+1$ with probability $p = (\pi(\sigma^{t,i\leftarrow +}))/(\pi(\sigma^{t,i\leftarrow +}) + \pi(\sigma^{t,i\leftarrow -}))$ where $\sigma^{t,i\leftarrow +}$ is identical to σ^t with the spin of vertex i set to $+1$ (or -1 for $\sigma^{t,i\leftarrow -}$).
- Otherwise, set the spin of vertex i to -1 with probability $1-p$.

For simplicity, we will assume that n is a power of 2. To apply our theorem, we decompose the state space by breaking configurations in half along the middle edge; again, see Figure 4. Transitions that fix the signs on the left are part of the restriction chains, and transitions that fix signs on the right are part of the complementary restriction chains. Thus, our restrictions and complementary restrictions are both $1 \times n/2$ Ising models for which we can readily apply induction. Let a be the assignment of signs to the left $n/2$ vertices and b be the signs of the right $n/2$ vertices. It is straightforward to see $\sigma = (a,b)$ gives a unique configuration and that the state space is a product space. However, $\mathcal{M}_{\text{gd}}$ is not a direct product of independent Markov chains on a and b because the probability of changing a sign of either of the middle two vertices ($n/2$ or $n/2+1$) depends on the sign of the other middle vertex. In order to apply Theorem 2, we first analyze $r(a,b) = \pi(a,b)/(\pi(a)\pi(b))$ and subsequently ϵ. The techniques used here are similar to, but simpler than, those used Section 4.

Define $\lambda = e^{-\beta}$. Let $w(a) = \lambda^{H(a)}$, where $H(a)$ is the number of edges in a (the left half) with disagreeing signs. Analogously, define $w(b) = \lambda^{H(b)}$. Let $c_{ab} = \lambda$ if the middle signs disagree and $c_{ab} = 1$ otherwise. Thus $\pi(a,b) = w(a)w(b)c_{ab}/Z$. Let $\Omega^* \subset \Omega$ be the configurations where the middle two vertices agree. Define $Z_A = \sum_a w(a)$ and $Z_B = \sum_b w(b)$.

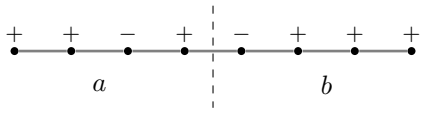

Figure 4 An example configuration of the one-dimensional Ising model.

For any fixed a, we have $\sum_{b:(a,b)\in\Omega^*} w(b) = \sum_{b:(a,b)\notin\Omega^*} w(b) = \frac{1}{2}Z_B$, since we can swap spins on all vertices in b to obtain a unique configuration $b' \in \Omega \setminus \Omega^*$ with $w(b') = w(b)$. Thus, we have

$$Z = \sum_{(a,b)\in\Omega^*} w(a)w(b) + \lambda \sum_{(a,b)\notin\Omega^*} w(a)w(b) = (1+\lambda) \sum_{(a,b)\in\Omega^*} w(a)w(b) = \frac{(1+\lambda)Z_A Z_B}{2}.$$

We consider two different cases for $r(a,b)$ depending on whether the sign of the middle two vertices agree. First consider the case where $(a,b) \in \Omega^*$. Here we have

$$\pi(a) = \sum_{b'} \pi(a,b') = \sum_{b':(a,b')\in\Omega^*} \frac{w(a)w(b')}{Z} + \lambda \sum_{b':(a,b')\notin\Omega^*} \frac{w(a)w(b')}{Z} = \frac{w(a)(1+\lambda)Z_B}{2Z},$$

and similarly $\pi(b) = w(b)(1+\lambda)Z_A/(2Z)$. Therefore

$$r(a,b) = \frac{\pi(a,b)}{\pi(a)\pi(b)} = \frac{4Zw(a)w(b)c_{ab}}{w(a)w(b)(1+\lambda)^2 Z_A Z_B} = \frac{2}{1+\lambda}.$$

The next case is almost identical except that $c_{ab} = \lambda$, so we have for $(a,b) \notin \Omega^*$ that $r(a,b) = 2\lambda/(1+\lambda)$.

Next we use our analysis of $r(a,b)$ to bound ϵ. First notice that since $\sum_{(a,b)\in\Omega^*} \pi(a,b) + \sum_{(a,b)\notin\Omega^*} \pi(a,b) = 1$ and $\sum_{(a,b)\notin\Omega^*} \pi(a,b) = \lambda \sum_{(a,b)\in\Omega^*} \pi(a,b)$, we have that $\sum_{(a,b)\in\Omega^*} \pi(a,b) = 1/(1+\lambda)$ and $\sum_{(a,b)\notin\Omega^*} \pi(a,b) = \lambda/(1+\lambda)$. This yields

$$\begin{aligned}\epsilon &\leq \sum_{(a,b)\in\Omega^*} \pi(a,b)(\sqrt{r(a,b)} - 1/\sqrt{r(a,b)})^2 + \sum_{(a,b)\notin\Omega^*} \pi(a,b)(\sqrt{r(a,b)} - 1/\sqrt{r(a,b)})^2 \\ &= \frac{1}{1+\lambda}\left(\sqrt{\frac{2}{1+\lambda}} - \sqrt{\frac{1+\lambda}{2}}\right)^2 + \frac{\lambda}{1+\lambda}\left(\sqrt{\frac{2\lambda}{1+\lambda}} - \sqrt{\frac{1+\lambda}{2\lambda}}\right)^2 = \left(\frac{1-\lambda}{1+\lambda}\right)^2\end{aligned}$$

Applying the complementary decomposition theorem (Theorem 2) gives the following recurrence: $\gamma_n \geq \gamma_{n/2}\left(\frac{2\lambda}{1+\lambda}\right)^2$. Since the base case has gap $\Omega(n^{-1})$, this solves to $\gamma_n = \Omega(n^{-c})$ for $c = 1 + 2\log_2\left(\frac{1+\lambda}{2\lambda}\right)$. Note that while this does not give a tight bound, the constant c is strictly better than the constant given by [18] and, unlike earlier decomposition approaches, we have not incurred an extra factor of n with each application of the decomposition theorem.

3.2 Ising model on bounded degree trees

As in [18], our proof for the one-dimensional Ising model can be easily generalized to trees with constant maximum degree r. A straightforward induction shows that such a tree T on n vertices has an edge whose deletion cuts T into two components, each with size at least $n/(r+1)$. We let a represent the spins on one component and b the spins on the other. At each level of the induction, we compute $r(a,b)$ and ϵ using arguments similar to those in Section 3.1 to get $\gamma_n = \Omega(n^{-c})$ for $c = 1 + 2\log_{(r+1)/r}\left(\frac{1+\lambda}{2\lambda}\right)$.

4 Application to permutations

In this section, we apply the complementary decomposition theorem, Theorem 2, to the problem of sampling biased permutations. We give an overview of the proof of Theorem 4 which bounds the spectral gap of the following nearest-neighbor Markov chain over S_n, the permutations of $[n]$. The complete details are provided in the full version of the paper.

The Nearest Neighbor Markov chain $\mathcal{M}_{\text{nn}}$

`Starting at any permutation` σ^0`, iterate the following:`

- At time $t \geq 0$, choose a position $1 < i \leq n$ uniformly at random in permutation σ^t.
- With probability $p_{\sigma^t(i),\sigma^t(i-1)}/2$, exchange the elements $\sigma^t(i)$ and $\sigma^t(i-1)$ to obtain σ^{t+1}.
- Otherwise, do nothing so that $\sigma^{t+1} = \sigma^t$.

The chain $\mathcal{M}_{\text{nn}}$ connects the state space S_n and has the following stationary distribution (see e.g., [4]):

$$\pi_{\text{nn}}(\sigma) = \prod_{i<j:\sigma(i)>\sigma(j)} \frac{p_{\sigma(i),\sigma(j)}}{p_{\sigma(j),\sigma(i)}} Z_{\text{nn}}^{-1} = \prod_{i<j:\sigma(i)>\sigma(j)} q_{\sigma(i),\sigma(j)} Z_{\text{nn}}^{-1}$$

where Z_{nn} is a normalizing constant and $q_{\sigma(i),\sigma(j)} = \frac{p_{\sigma(i),\sigma(j)}}{p_{\sigma(j),\sigma(i)}}$.

We consider the special case of k-classes where $[n]$ is partitioned into k classes $C_1, C_2, \ldots, C_k$, and assume elements in class C_i interact with elements in class C_j with the same probability. That is, if $i_1, i_2 \in C_i$ and $j_1, j_2 \in C_j$ then $p_{i_1,j_1} = p_{i_2,j_2}$. In this case we define $\overline{p}_{i,j}$ to be this shared probability for classes C_i and C_j (the bar indicates that we have reindexed the set of probabilities by the classes) and we say that $\mathcal{P}$ forms a *k-class*. Note that $\overline{p}_{i,i}$ is assumed to be $1/2$, so that $\mathcal{M}_{\text{nn}}$ swaps elements within the same class with probability $1/2$. When $k = n$, the k-class assumption does not lose any generality, but this structure allows us to simplify the problem by considering $k < n$, as was done in [25, 16].

Define $\overline{q}_{i,j} = \overline{p}_{i,j}/\overline{p}_{j,i}$ to be the *bias* towards having a particle of type i ahead of a particle of type j. We say that $\mathcal{P}$ is *bounded* if there exists a constant $q > 1$ such that $\overline{q}_{i,j} \geq q$ for all $1 \leq i < j \leq k$. The constant q is called the *minimum bias*. We prove the following.

▶ **Theorem 4.** *If the probabilities $\mathcal{P}$ are weakly monotonic and form a bounded k-class with at least $2N^*$ particles in each class, then $\gamma(\mathcal{M}_{nn}) = \Omega(n^{-7})$.*

The chain $\mathcal{M}_{\text{nn}}$ samples over S_n using these probabilities, and in particular the order of elements within each class approaches the uniform distribution. The spectral gap of this uniform sampling is well-understood and may be analyzed separately. The complete analysis can be found in the full version of the paper. In order to isolate the biased moves, we define a new Markov chain $\mathcal{M}_{\text{pp}}$ that eliminates swaps within each class. As $\mathcal{M}_{\text{pp}}$ maintains a fixed order on particles within each class, it makes sense to relabel each element of $[n]$ by the index of the class it is in. That is, we let $c_i = |C_i|$ and we consider a linear array of length n with c_i particles labeled i for each $1 \leq i \leq k$. We call this a k-particle system for the given set $\{c_i\}$, and the Markov chain $\mathcal{M}_{\text{pp}}$ is called a k-particle process. We view the new state space as the set Ω of k-particle systems for $\{c_i\}$.

The Markov chain $\mathcal{M}_{\text{pp}}$ over k-particle systems also allows certain non-adjacent transpositions. In particular, we let a particle of type i and a particle of type j swap across particles of type less than i and j. More formally, the chain $\mathcal{M}_{\text{pp}}$ is defined as follows.

The particle process Markov chain $\mathcal{M}_{\text{pp}}$

`Starting at any` k`-particle system` σ^0`, iterate the following:`

- At time t, choose a position $1 \le i \le n$ and direction $d \in \{L, R\}$ uniformly at random.
- If $d = L$, find the largest j less than i with $\sigma^t(j) \ge \sigma^t(i)$ (if one exists). If $\sigma^t(j) > \sigma^t(i)$, then with probability $1/2$, exchange $\sigma^t(i)$ and $\sigma^t(j)$ to obtain σ^{t+1}.
- If $d = R$, find the smallest j with $j > i$ and $\sigma^t(j) \ge \sigma^t(i)$ (if one exists). If $\sigma^t(j) > \sigma^t(i)$, then exchange $\sigma^t(i)$ and $\sigma^t(j)$ to obtain σ^{t+1} with probability

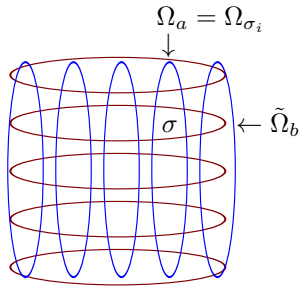
$$\frac{1}{2}\,\overline{q}_{\sigma_t(j),\sigma_t(i)} \prod_{i<l<j} \overline{q}_{\sigma_t(j),\sigma_t(l)}\overline{q}_{\sigma_t(l),\sigma_t(i)}.$$

- With all remaining probability, $\sigma^{t+1} = \sigma^t$.

The chain $\mathcal{M}_{\text{pp}}$ connects the space Ω and has the stationary distribution (see e.g., [4])

$$\pi(\sigma) = \prod_{i<j:\sigma(i)>\sigma(j)} \frac{\overline{p}_{\sigma(i),\sigma(j)}}{\overline{p}_{\sigma(j),\sigma(i)}} Z^{-1} = \prod_{i<j:\sigma(i)>\sigma(j)} \overline{q}_{\sigma(i),\sigma(j)} Z^{-1}$$

where Z is a normalizing constant and $\overline{q}_{\sigma(i),\sigma(j)} = \frac{\overline{p}_{\sigma(i),\sigma(j)}}{\overline{p}_{\sigma(j),\sigma(i)}}$.



Recall the definition of weakly monotonic from Section 1. We will assume that property (2) holds. If instead property (3) holds, then as described in [25] we would modify $\mathcal{M}_{\text{pp}}$ to allow swaps between elements of different particle types across elements whose particle types are larger (instead of smaller) and modify the induction so that at each step σ_i restricts the location of particles larger than i (instead of smaller).

We prove the following bound on the spectral gap of $\mathcal{M}_{\text{pp}}$. Then, using comparison techniques [9, 28], we prove the bound on the spectral gap of $\mathcal{M}_{\text{nn}}$ given in Theorem 4. The details of this comparison argument can be found in the full version of the paper.

▶ **Theorem 3.** *If the probabilities $\mathcal{P}$ are weakly monotonic and bounded and $c_i \ge 2N^*$ for all $1 \le i \le k$, then the spectral gap γ of the chain $\mathcal{M}_{pp}$ satisfies $\gamma = \Omega(n^{-2})$.*

The proof of Theorem 3 uses the same inductive technique as [25], where at each level of the induction we fix the locations of particles in one less particle class. For $i \ge 0$, let σ_i represent a fixed location of the particles of type $1, 2, \ldots, i$ (σ_0 represents no restriction); for example, in Figure 5, we set $\sigma_2 = 12_1_2_1_\ _$, where "_" represents locations that can be filled with particles of type 3 or higher. We consider the chain $\mathcal{M}_{\sigma_i}$ whose state space Ω_{σ_i} is the set of all k-particle systems σ where the elements with type in $[i]$ are consistent with σ_i. The moves of $\mathcal{M}_{\sigma_i}$ are those moves from $\mathcal{M}_{\text{pp}}$ that do not involve an element of type at most i. We prove by induction that $\mathcal{M}_{\sigma_i}$ has spectral gap $\Omega(n^{-2}(1-1/n)^{2(k-2-i)})$ for all choices of σ_i. To be clear, we assume that the spectral gap of $\mathcal{M}_{\sigma_i}$ are bounded for all σ_i by induction, and then prove our bound on the spectral gap of $\mathcal{M}_{\sigma_{i-1}}$. To start, we show that $\Omega_{\sigma_{i-1}}$ is a product space, which is required to apply Theorem 2.

Let A consist of all 2-particle systems with c_i particles of type i and $\sum_{j=i+1}^{k} c_j$ particles of type "_"; A is in bijection with staircase walks by mapping each i to a step right and each "_" to a step down, as in Figure 6. Let B consist of all $k-i$ particle systems with c_j particles of type j for all $i+1 \le j \le k$. Our goal is to show that the set of permutations σ consistent with σ_{i-1} on particles of type at most $i-1$ is in bijection with $A \times B$. To this end, we can write $\sigma = (a, b)$, where $a \in A$ is the 2-particle system obtained from σ_i by removing particles of type less than i (see Figure 5), as those particles are in a fixed position for all of $\Omega_{\sigma_{i-1}}$.

$$\begin{aligned} \sigma_2 &= 12_1_2_1_\ _ \\ \sigma_3 &= 1231_2_13_ \\ a &= 3_\ _3_ \\ b &= 454 \\ \sigma &= 123142513 4 \end{aligned}$$

Figure 5 The state space $\Omega_{\sigma_{i-1}}$ decomposed, with $i = 3$.

Next, define $b \in B$ to be the restriction of σ to elements of type bigger than i. For the other direction, given any (a, b) pair, it is clear that there is a unique $\sigma \in \Omega_{\sigma_{i-1}}$ corresponding to that pair.

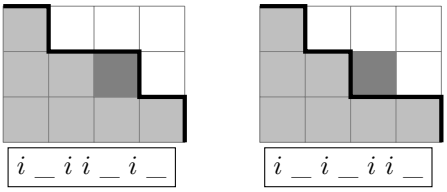


Figure 6 An exclusion process on staircase walks operates by adding or removing a square.

We next describe the decomposition. Note that the moves of $\mathcal{M}_{\sigma_i}$ fix an $a \in A$ and perform (j_1, j_2) transpositions, where $j_1, j_2 > i$; i.e. they operate exclusively on B. Thus, the Markov chain $\mathcal{M}_{\sigma_i}$ is a restriction of $\mathcal{M}_{\sigma_{i-1}}$ with state space Ω_a. On the other hand, the remaining moves of $\mathcal{M}_{\sigma_{i-1}}$ are (i, j) transpositions for $j > i$. These are the complementary restrictions; these moves fix a $b \in B$ and operate on A, so we label the state space of this Markov chain $\tilde{\Omega}_b$. As these moves fix the relative order of all particles of type bigger than i, the complementary restriction chains can be seen as bounded exclusion processes on particles of type i with particles of type bigger than i. Bounded generalized biased exclusion processes operate on staircase walks as in Figure 6, where every square has a different bias but they are all bounded by some q. These processes were analyzed in [25]. We prove the following lemma in the full version of the paper.

▶ **Lemma 6.** *The complementary restrictions at each level of the induction are bounded generalized biased exclusion processes with spectral gap* $\Omega(n^{-2})$.

The chain $\mathcal{M}_{\sigma_{i-1}}$ is not the direct product of the chains on A and B because, e.g., for $(a, b) \in A \times B$, $P((a, b), (a', b))$ depends on b. However, we show that the above decomposition is $1/n^2$-orthogonal by bounding $r(a, b)$. We define "good" a's to be those with fewer than $N^* = C_q \log n$ inversions and "good" b's to be those with fewer than N^* inversions involving particles of type $i + 1$. Thus, as there are at least $2N^*$ particles of type $i + 1$, then (a, b) has no inversions between i and j for $j > i + 1$ when a and b are both good. For such pairs, $r(a, b)$ is very close to 1. For all other pairs we show $r(a, b)\pi(\Omega_a \cap \tilde{\Omega}_b)$ is small. By viewing b as a staircase walk on particles of type $i + 1$ with particles of any higher type, we see that for either a or b, the probability it is bad is smaller than the weighted sum of all biased exclusion processes with more than N^* inversions (equivalently, area N^* under the curve). We prove the following lemma in the full version of the paper.

▶ **Lemma 7.** *For any biased exclusion process with minimum bias constant $q > 1$, the total weight of staircase walks with area larger than N^* satisfies*

$$\sum_{\sigma: N(\sigma) \geq N^*} q^{-N(\sigma)} \leq \frac{1}{6n^2}.$$

This allows us to prove the following.

▶ **Lemma 8.** *If the probabilities $\mathcal{P}$ are weakly monotonic and bounded with $c_i \geq 2N^*$ for all $1 \leq i \leq k$, then at each step of the induction we have a $1/n^2$-orthogonal decomposition.*

We illustrate the main ideas of the proof of Lemma 8 here in the simplified $k = 3$ case (the details are deferred to the full version). In this case, there is no recursion but instead just a single application of the decomposition theorem. The restriction chains of $\mathcal{M} = \mathcal{M}_{\sigma_0}$ are the set $\{\mathcal{M}_{\sigma_1}\}$, which fix all elements in class C_1. The stationary distribution of $\mathcal{M}$ is

$$\pi(\sigma) = Z^{-1} \prod_{\substack{i<j: \\ \sigma(i)>\sigma(j)}} \overline{q}_{\sigma(i),\sigma(j)}, \tag{2}$$

where Z is a normalizing constant.

Let $w(a)$ and $w(b)$ be the parts of this product that depend only on a and only on b, respectively, and let $w(a, b)$ be a correction factor that depends on both a and b. Let $t_{1,3}$ (respectively, $t_{1,2}$ and $t_{2,3}$) denote the number of inversions in σ between a 1 and a 3 (respectively a 1 and a 2 and a 2 and a 3). For example, let $\sigma = 111221312323$, which has stationary probability $Z^{-1}(\overline{q}_{1,2})^4(\overline{q}_{2,3})^3(\overline{q}_{1,3})$. Then $a = 111_\ _1_1_\ _\ _\ _\ b = 2232323$. From b we find that $t_{2,3} = 3$ and $w(b) = (\overline{q}_{2,3})^3$; more generally, define $w(b)$ to be the product $(\overline{q}_{2,3})^{t_{2,3}}$. From a, we can see that there are five inversions involving 1, but the number of those that are inversions with a 3 versus a 2 depends on b as well. Ignoring this for a moment, we define $w(a)$ to be the product $(\overline{q}_{1,2})^{t_{1,2}+t_{1,3}}$. In our example, $w(a) = (\overline{q}_{1,2})^5$. Since we have made the false assumption that there were no inversions between a 1 and a 3 in σ, we need a correction factor $w(a, b) = (\overline{q}_{1,3}/\overline{q}_{1,2})^{t_{1,3}}$. With these definitions, it is clear that $\pi(\sigma) = Z^{-1}w(a)w(b)w(a, b)$.

A key idea in the proof of Lemma 8 is that if a and b are both good, then $t_{1,3} = 0$ – indeed, the total number of inversions is less than $2N^*$ and the number of 2's is at least $2N^*$ – and thus the correction factor $w(a, b) = 1$, implying $\pi(a, b) \approx \pi(a)\pi(b)$. Moreover, the probability that a or b is bad is very small, so these pairs (a, b) do not contribute much to the sum in Equation 1.

To make the above statements precise is somewhat technical. Deferring details to the full version, we now give a bit more intuition. Define $Z_A = \sum_a w(a)$, $Z_B = \sum_b w(b)$, and $\epsilon_1 = 1/(6n^2)$. We show that $\sum_{a \text{ bad}} w(a) \leq \epsilon_1$ and $\sum_{b \text{ bad}} w(b) \leq \epsilon_1/Z_B$. Thus, we find $Z_A \approx \sum_{a \text{ good}} w(a)$ and $Z_B \approx \sum_{b \text{ good}} w(b)$, and moreover $Z = \sum_{a,b} w(a)w(b)w(a, b) \approx Z_A Z_B$. We show that when a and b are both good, $\pi(a) \approx w(a)Z_B/Z$ and $\pi(b) \approx w(b)Z_A/Z$. Thus, when a and b are both good, $r(a, b) = \frac{\pi(a,b)}{\pi(a)\pi(b)} \approx \frac{Z}{Z_A Z_B} \approx 1$. This allows us to show

$$\sum_{\substack{a \text{ good} \\ b \text{ good}}} \pi(a, b) \left(\sqrt{r(a, b)} - \frac{1}{\sqrt{r(a, b)}} \right)^2 \leq 5\epsilon_1^2.$$

We must also consider the case that either a or b is bad. In this case, we show that the weight of these configurations is so small that it overcomes the fact that $w(a, b)$ and $r(a, b)$ may be exponentially small. We use the loose bound

$$\sum_{a \text{ or } b \text{ bad}} \pi(a,b)\left(\sqrt{r(a,b)} - \frac{1}{\sqrt{r(a,b)}}\right)^2 \leq \sum_{a \text{ or } b \text{ bad}} \pi(a)\pi(b) + \sum_{a \text{ or } b \text{ bad}} \frac{\pi(a,b)^2}{\pi(a)\pi(b)}.$$

The summation on the left is bounded by $\Pr(a \text{ bad}) + \Pr(b \text{ bad}) \leq 2\epsilon_1/(1-\epsilon_1)$. The summands in the summation on the right are products of conditional probabilities. We use the law of total probability to bound that summation by $\sum_{a \text{ bad}} w(a) + \sum_{b \text{ bad}} w(b)/(1-\epsilon_1) \leq \epsilon_1 + \epsilon_1/(1-\epsilon_1)$. Putting this all together, we have, for $\epsilon_1 \leq .225$,

$$\sum_{a,b} \pi(a,b)\left(\sqrt{r(a,b)} - \frac{1}{\sqrt{r(a,b)}}\right)^2 \leq 5\epsilon_1^2 + \epsilon_1 + \frac{3\epsilon_1}{1-\epsilon_1} \leq 6\epsilon_1 = 1/n^2.$$

This shows that the decomposition is $1/n^2$-orthogonal.

5 Generalizations and comparison with other theorems

In Sections 5.1 and 5.2, we present several generalizations of Theorem 2 and compare these results with related prior work. Our decomposition theorems fall into two categories: complementary decomposition theorems that rely on the notion of ϵ-orthogonality between the restrictions and complementary restrictions, and more classical decomposition theorems based on the projection Markov chain. In Section 5.3, we summarize the proofs, with more details given in Appendix A.

5.1 Generalized complementary decomposition theorems

Theorem 2 generalizes easily to non-product spaces. Define $r(i,j) = \pi(\Omega_i \cap \tilde{\Omega}_j)/(\pi(\Omega_i)\pi(\tilde{\Omega}_j))$, for any $1 \leq i \leq r, 1 \leq j \leq \tilde{r}$. We say that $\{\Omega_i\}$ and $\{\tilde{\Omega}_j\}$ is an ϵ-orthogonal decomposition of $\mathcal{M}$ if

$$\epsilon = \sum_{(i,j)} \pi(\Omega_i \cap \tilde{\Omega}_j)(\sqrt{r(i,j)} - 1/\sqrt{r(i,j)})^2.$$

▶ **Theorem 9.** *For any ϵ-orthogonal decomposition of $\mathcal{M}$, $\gamma(\mathcal{M}) \geq \min\{\gamma_{\min}, \tilde{\gamma}_{\min}\}\left(1 - \sqrt{\epsilon}\right)^2$.*

We use Theorem 10 to prove Theorem 9, which in turn implies Theorem 2.

▶ **Theorem 10.** $\gamma(\mathcal{M}) \geq \min_{x \perp \sqrt{\pi}, \|x\|=1} \gamma_{\min}\|x^\perp\|^2 + \tilde{\gamma}_{\min}\|\tilde{x}^\perp\|^2$.

Here, $x^\perp$ and $\tilde{x}^\perp$ are orthogonal projections of a vector x onto the complement of the eigenspace of the top eigenvectors of certain matrices (defined in Section A.4) containing the P_i's and $\tilde{P}_j$'s, respectively. This theorem is similar to a special case of the main result in [7]. Destainville [7] introduced a "multi-decomposition" scheme that uses m different partitions of Ω. In Destainville's result, $\|x^\perp\|^2 + \|\tilde{x}^\perp\|^2$ is replaced by a function of the norm of a "multi-projection" operator Π. Bounding these norms is essential, as the Markov chain $\mathcal{M}$ can require exponential time to mix even if all of the restrictions and complementary restrictions are polynomially mixing[3].

[3] Indeed, the introduction of the projection chain in [21] was a key insight to the original decomposition theorem.

Unfortunately, bounding these norms can be challenging. Destainville [7] bounds the norm of the projection Π by the spectral gap of a smaller matrix $\bar{\Pi}$. In some cases, this gap can be analyzed directly, or even computationally for particular problem instances. However, for very complex distributions such as the distribution over biased permutations we consider here, it can be challenging to find the spectral gap of $\bar{\Pi}$. We believe one of our main contributions is the definition of ϵ-orthogonality, a concrete combinatorial quantity that may be easier to analyze. This approach is particularly useful when the chain decomposes into pieces that are nearly independent, as in the setting of Theorem 2.

5.2 Classical decomposition theorems

The disjoint decomposition theorem of [23] states that the spectral gap γ of $\mathcal{M}$ satisfies $\gamma \geq \frac{1}{2}\gamma_{\min}\bar{\gamma}$, where, as we recall from Section 1, $\gamma_{\min} = \min_i \gamma_i$ and $\bar{\gamma}$ is the spectral gap of a projection chain over states $[r]$. Jerrum, Son, Tetali, and Vigoda [18] considered two quantities related to the spectral gap: the Poincaré and log-Sobolev constants. There, the authors defined a parameter $T = \max_i \max_{\sigma\in\Omega_i} \sum_{\tau\in\Omega\setminus\Omega_i} P(\sigma,\tau)$, which can be seen as the maximum probability of escape from one part of the partition in a single step of P, and used it to produce a bound on the order of the minimum gap when T is on the order of $\bar{\gamma}$. They also provided improved bounds when another parameter η is close to zero; this requires a pointwise regularity condition. More recently, Pillai and Smith [26] introduced other conditions in order to directly bound the mixing time by a constant times the maximum of the mixing times of the projection and the restrictions.

The techniques developed for proving the complementary decomposition theorems introduced in this paper can be further applied to prove the following "classical"-style decomposition theorem.

▶ **Theorem 11.** *Let* $\rho = \sqrt{2T/\bar{\gamma}}$. *Then* $\gamma(\mathcal{M}) \geq \min_{p^2+q^2=1} \gamma_{\min} q^2 + \bar{\gamma}\left(q\rho - p\right)^2$.

We state a more general version of this theorem, Theorem 17, in Section A.3. This bound allows us to rederive several known classical decomposition theorems.

▶ **Corollary 12.** *Assume* $\mathcal{M}$ *is lazy. Then* $\gamma \geq \gamma_{\min}\bar{\gamma}/3$.

In fact, one can show that the constant is $1/2$ if $\gamma_{\min}, \bar{\gamma} \leq 1/2$ (which is a common situation) or $\delta_2 \geq 1/2$ (δ_2 is defined in Section A.2). In Corollary 13 we show that Theorem 11 can be seen as a generalization of Theorem 1 of [18], except that it instead bounds the spectral gap.

▶ **Corollary 13.** $\gamma \geq \min\left\{\frac{\bar{\gamma}}{3}, \frac{\gamma_{\min}\bar{\gamma}}{3T+\bar{\gamma}}\right\}$.

In particular, if $T/\bar{\gamma}$ is a constant, then we get within a constant of the minimum gap as well. Theorem 11 produces slightly improved bounds over Corollary 13 when $T \approx \bar{\gamma} \ll \gamma_{\min}$.

5.3 Summary of the proofs of the decomposition theorems

Our proofs are elementary and use only basic facts from linear algebra about eigenvalues and eigenvectors. We have chosen to assume the Markov chains are discrete and finite to keep the proofs as accessible as possible. We utilize the following standard characterization of the second largest eigenvalue λ of a symmetric matrix A with top eigenvector v:

$$\lambda = \max_{x\perp v} \frac{\langle x, xA\rangle}{\|x\|^2} = \max_{x\perp v:\|x\|=1} \langle x, xA\rangle. \tag{3}$$

For a general reversible Markov chain with transition matrix P, we apply Equation 3 to a symmetric matrix $A = A(P)$ that has the same eigenvalues as P.

We apply the Vector Decomposition Method from the expander graph literature (see, e.g. [29, 31]), and decompose the vector x into $x^{\perp} + x^{\parallel}$, where $x^{\parallel}$ is parallel to the top eigenvector of each restriction matrix. The intuition of this method is that if a particular distribution is far from stationarity, then it will either be far from stationarity on some part of the partition or on the projection, and therefore applying P brings us closer to stationarity. The benefit of this approach is that it allows us to quantify the independence of the restriction chains with the projection or complementary restriction chains. Using Equation 3, for any $x \perp v$, we need to bound

$$\langle x, xA\rangle = \langle x^{\perp}, x^{\perp}A\rangle + \langle x^{\parallel}, x^{\parallel}A\rangle + 2\langle x^{\perp}, x^{\parallel}A\rangle. \tag{4}$$

It is easy to bound $\langle x^{\perp}, x^{\perp}A\rangle$ and $\langle x^{\parallel}, x^{\parallel}A\rangle$ using ideas from other decomposition results [18, 23]. The term $\langle x^{\perp}, x^{\parallel}A\rangle$ determines whether the decomposed Markov chain is nearly the direct product of two independent Markov chains $\mathcal{M}_1$ and $\mathcal{M}_2$, in which case $\langle x^{\perp}, x^{\parallel}A\rangle \approx 0$ and $\gamma(\mathcal{M}) \approx \min\{\gamma(\mathcal{M}_1), \gamma(\mathcal{M}_2)\}$, or whether they are far from independent, in which case $\langle x^{\perp}, x^{\parallel}A\rangle$ is large and $\gamma(\mathcal{M}) = \Theta(\gamma_{\min}\bar{\gamma})$. The key to our decomposition proofs lies in our bounds on $\langle x^{\perp}, x^{\parallel}A\rangle$, which are different for our complementary decomposition theorems than they are for our classical decomposition theorems. More details are provided in the appendix.

A Proofs of the decomposition theorems

In this section, we provide illustrate the main ideas of the proofs of the decomposition theorems. Some details are deferred to the full version of the paper. First, in Section A.1, we introduce some notation and terminology which will be useful for the proofs. Several parts

are common to all of the proofs, so we present those parts in Section A.2. In Section A.3, we prove our classical decomposition theorem, Theorem 11. Finally, in Section A.4, we prove our complementary decomposition theorems, Theorems 2, 9, and 10.

A.1 Preliminaries

We first fix some notation and terminology. We write I_n to mean the $n \times n$ identity matrix. The symbol $\otimes$ is used for tensor product. We write $(v)_i$ to mean the i^{th} coordinate of a vector v. The second largest eigenvalue of P_i will be denoted λ_i, and $\lambda_{\max} = \max_i \lambda_i$. The "top eigenvector" of a matrix will be the eigenvector corresponding to the eigenvalue of largest absolute value.

Define $\bar{P}$ to be the aggregated transition matrix on the state space $[r]$ defined by $\bar{P}(i,j) = \pi(\Omega_i)^{-1} \sum_{\sigma\in\Omega_i, \tau\in\Omega_j} \pi(\sigma)P(\sigma,\tau)$. Then $\bar{P}$ is the transition matrix of a reversible Markov chain $\bar{\mathcal{M}}$ with stationary distribution $\bar{\pi}$ defined by $\bar{\pi}(i) := \pi(\Omega_i)$. We call $\bar{\mathcal{M}}$ the *projection* chain.

It is useful to decompose the matrix P into the part that performs restriction moves and the part that performs all other moves. Define $\hat{P}$ as the block diagonal $|\Omega| \times |\Omega|$ matrix with the P_i matrices along the diagonal; i.e. $\hat{P}$ is obtained from P by rejecting moves between different parts of the partition. Define $\tilde{P}$ to be the transition matrix of the Markov chain defined by rejecting moves from σ to τ if σ and τ are within the same Ω_i. Then $(\hat{P}+\tilde{P})(\sigma,\tau) = P(\sigma,\tau)$ unless $\sigma = \tau$, and $(\hat{P}+\tilde{P})(\sigma,\sigma) = P(\sigma,\sigma)+1$, since each move of P gets rejected in exactly one of $\hat{P}$ or $\tilde{P}$ (and of course the probability of transitioning from a state is 1). Therefore, we have $P = \hat{P} + \tilde{P} - I_{|\Omega|}$.

Note that for any pair $\sigma, \tau \in \Omega$, the transitions (σ,τ) and (τ,σ) are either both nonzero in $\tilde{P}$ or both zero in $\tilde{P}$. Thus $\tilde{P}$ is itself the disjoint union of a set of ergodic, reversible Markov chains $\tilde{P}_1, \tilde{P}_2, \ldots, \tilde{P}_{\tilde{r}}$ on state spaces $\tilde{\Omega}_1, \tilde{\Omega}_2, \ldots, \tilde{\Omega}_{\tilde{r}}$. We call these chains *complementary restrictions*.

In order to prove our decomposition results, we wish to apply Equation 3 to P. However, since P may not be symmetric, we appeal to the following symmetrization technique that appears in [20, p. 153]. Given P with stationary distribution π, define a matrix $A := A(P)$ by $A(\sigma,\tau) := \pi(\sigma)^{1/2}\pi(\tau)^{-1/2}P(\sigma,\tau)$. A is similar to P (i.e. they have the same eigenvalues), but is symmetric, so we can infer a bound on the second eigenvalue of P by applying Equation 3 to A. It is easy to check that the top eigenvector of A is $\sqrt{\pi}$, which is the vector with entries $\sqrt{\pi(\sigma)}$ for any $\sigma \in \Omega$.

We apply this same symmetrization technique to other matrices as well. For $i \in [r]$ we let $A_i := A(P_i)$ and for $i \in [\tilde{r}]$ we let $\tilde{A}_i := A(\tilde{P}_i)$. We then write $\hat{A}$ to mean the $|\Omega| \times |\Omega|$ matrix with $\hat{A}(\sigma,\tau) = A_i(\sigma,\tau)$ if $\sigma,\tau \in \Omega_i$ for some $i \in [r]$, and zero otherwise. Analogously, we write $\tilde{A}$ to mean the $|\Omega| \times |\Omega|$ matrix with $\tilde{A}(\sigma,\tau) = \tilde{A}_i(\sigma,\tau)$ if $\sigma,\tau \in \tilde{\Omega}_i$ for some $i \in [\tilde{r}]$, and zero otherwise. It is important to note that $\hat{A} \neq A(\hat{P})$ and $\tilde{A} \neq A(\tilde{P})$. This allows us to write $A = \hat{A} + \tilde{A} - I_{|\Omega|}$.

▶ **Proposition 14.** *The matrix A satisfies $A = \hat{A} + \tilde{A} - I_{|\Omega|}$.*

Let $\mu_1 \geq \mu_2 \geq \ldots \geq \mu_{|\Omega|}$ be the eigenvalues of $\tilde{A}$ with corresponding eigenvectors $v_1, v_2, \ldots, v_{|\Omega|}$. As $\tilde{A}$ is symmetric, the real spectral theorem tells us that its eigenvectors form an orthonormal basis of $\mathbb{R}^{|\Omega|}$. We consider the basis representations $x^{\perp} = \sum_i a_i^{\perp} v_i$ and $x^{\parallel} = \sum_i a_i^{\parallel} v_i$. More generally, for any $v \in \mathbb{R}^{|\Omega|}$, we write $v = \sum_i a_i v_i$ for some constants $a_1, a_2, \ldots, a_{|\Omega|} \in \mathbb{R}$. Also, $\|v\|^2 = \sum_i a_i^2 \|v_i\|^2$, and $v\tilde{A} = \sum_i a_i \mu_i v_i$.

A.2 Key ideas and lemmas for the proofs

We wish to apply Equation 3 to A. Recall that $\sqrt{\pi}$ is the top eigenvector of A. Let $x \in \mathbb{R}^{|\Omega|}$ with $x \perp \sqrt{\pi}$ and $\|x\| = 1$. We will decompose x into two vectors $x^{\|}$ and $x^{\perp}$ as follows (note: this is similar to the vector decomposition used for the Zig Zag Product in [29]). For any $i \in [r]$, let $x_i \in \mathbb{R}^{|\Omega_i|}$ be the vector defined by $x_i(\sigma) = x(\sigma)$ for all $\sigma \in \Omega_i$. Then $x = \sum_i e_i \otimes x_i$. We further decompose x_i into $x_i^{\|}$, the part that is parallel to $\sqrt{\pi_i}$, and $x_i^{\perp}$, the part that is perpendicular to $\sqrt{\pi_i}$; recall that $\sqrt{\pi_i}$ is the top eigenvector of A_i. Finally, define $x^{\|}, x^{\perp} \in \mathbb{R}^{|\Omega|}$ by $x^{\|} = \sum_i e_i \otimes x_i^{\|}$ and $x^{\perp} = \sum_i e_i \otimes x_i^{\perp}$. Hence $x = \sum_i e_i \otimes x_i = x^{\|} + x^{\perp}$. Define $\tilde{x}^{\|}$ and $\tilde{x}^{\perp}$ analogously.

As described in Section 5.3, we will bound $\langle x, xA\rangle$ via Equation 4:

$$\langle x, xA\rangle = \langle x^{\perp}, x^{\perp}A\rangle + \langle x^{\|}, x^{\|}A\rangle + 2\langle x^{\perp}, x^{\|}A\rangle.$$

We need the following simple proposition.

▶ **Lemma 15.** *The following holds:* $x^{\|}A = x^{\|}\tilde{A}$.

Applying Lemma 15, Equation 4 becomes

$$\langle x, xA\rangle = \langle x^{\|}, x^{\|}\tilde{A}\rangle + 2\langle x^{\perp}, x^{\|}\tilde{A}\rangle + \langle x^{\perp}, x^{\perp}(\hat{A} + \tilde{A} - I_{|\Omega|})\rangle.$$

For ease of notation, we define the following quantities:

$$\delta_1 = \frac{\langle x^{\perp}, x^{\perp}\hat{A}\rangle}{\|x^{\perp}\|^2},\ \delta_2 = \frac{\langle x^{\perp}, x^{\perp}\tilde{A}\rangle}{\|x^{\perp}\|^2},\ \delta_3 = \frac{\langle x^{\|}, x^{\|}\hat{A}\rangle}{\|x^{\|}\|^2},\ \delta_4 = \frac{\langle x^{\|}, x^{\|}\tilde{A}\rangle}{\|x^{\|}\|^2}.$$

Plugging these in, we have

$$\langle x, xA\rangle = \delta_4\|x^{\|}\|^2 + 2\langle x^{\perp}, x^{\|}\tilde{A}\rangle + (\delta_1 + \delta_2 - 1)\|x^{\perp}\|^2. \tag{5}$$

Bounding δ_1 and δ_4 is straightforward, and borrows many of the ideas from classical decomposition results. If $x^{\|}\tilde{A}$ were orthogonal to $x^{\perp}$, then doing so would be sufficient to proving a strong decomposition theorem. However, this is not true in general, so we must also bound $\langle x^{\perp}, x^{\|}\tilde{A}\rangle$. Our two types of theorems do so in different ways, which are presented in Sections A.3 and A.4.

The next lemma makes concrete the intuition that if a particular distribution is far from stationarity, then it will either be far from stationarity on some restriction – in which case $\hat{A}$ will bring it closer to stationarity (as in part 1) – or on the projection – in which case $\tilde{A}$ will bring it closer to stationarity (as in part 2). The proof is straightforward from the definitions.

▶ **Lemma 16.** *With the above notation,*
1. $\delta_1 \le \lambda_{\max}$.
2. $\delta_4 \le \bar{\lambda}$.

A.3 Classical decomposition theorems

In this section, we will prove Theorem 17, which is a generalization of Theorem 11.

▶ **Theorem 17.** *Let* $\rho = \sqrt{(1-\delta_2)/\bar{\gamma}}$. *Then* $\gamma(\mathcal{M}) \ge \min_{p^2+q^2=1} \gamma_{\min} q^2 + \bar{\gamma}\left(q\rho - p\right)^2$.

With the technology developed in Section A.2, there is one critical piece remaining to prove Theorem 17, which is to bound the cross terms generated by applying the matrix $\tilde{A}$ to $x^{\|}$.

▶ **Lemma 18.** *With the above notation,* $|\langle x^\perp, x^\parallel \tilde{A}\rangle| \leq \sqrt{(1-\delta_4)(1-\delta_2)}\|x^\parallel\|\|x^\perp\|$.

The proof appears in the full version.

Finally, we are ready to prove Theorem 17.

Proof of Theorem 17. Let $x \in \mathbb{R}^{|\Omega|}$ with $x \perp \sqrt{\pi}$ and $\|x\| = 1$. By Equation 3, $\gamma(\mathcal{M}) \geq 1 - \langle x, xA\rangle$. Applying Lemma 15 and the definitions of δ_1, δ_4, and δ_2, Equation 4 becomes

$$\begin{aligned}\langle x, xA\rangle &= \langle x^\parallel, x^\parallel \tilde{A}\rangle + 2\langle x^\perp, x^\parallel \tilde{A}\rangle + \langle x^\perp, x^\perp(\hat{A} + \tilde{A} - I_{|\Omega|})\rangle \\ &= \delta_4\|x^\parallel\|^2 + 2\langle x^\perp, x^\parallel \tilde{A}\rangle + (\delta_1 + \delta_2 - 1)\|x^\perp\|^2. \end{aligned} \tag{6}$$

Applying Lemma 18, we have

$$\gamma(\mathcal{M}) \geq 1 - (\delta_4\|x^\parallel\|^2 + 2\sqrt{(1-\delta_4)(1-\delta_2)}\|x^\parallel\|\|x^\perp\| + (\delta_1 + \delta_2 - 1)\|x^\perp\|^2).$$

Rearranging terms and using the fact that $1 = \|x\|^2 = \|x^\perp\|^2 + \|x^\parallel\|^2$, we have

$$\gamma(\mathcal{M}) \geq \min_{x^\perp \sqrt{\pi}:\|x\|=1} (1-\delta_1)\|x^\perp\|^2 + \left(\sqrt{1-\delta_2}\|x^\perp\| - \sqrt{1-\delta_4}\|x^\parallel\|\right)^2. \tag{7}$$

By setting $q = \|x^\perp\|$ and $p = \|x^\parallel\|$, we immediately get

$$\gamma(\mathcal{M}) \geq \min_{p^2+q^2=1} (1-\delta_1)q^2 + \left(\sqrt{1-\delta_2}q - \sqrt{1-\delta_4}p\right)^2.$$

Using a bit of calculus one may show that the expression on the right is minimized when $(1-\delta_1)$ is minimized, when $(1-\delta_2)$ is maximized and when $(1-\delta_4)$ is minimized. By Lemma 16, $(1-\delta_1) \geq \gamma_{\min}$ and $(1-\delta_2) \geq \bar{\gamma}$. Therefore, we have

$$\gamma(\mathcal{M}) \geq \min_{p^2+q^2=1} \gamma_{\min}q^2 + \left(q\sqrt{1-\delta_2} - p\sqrt{\bar{\gamma}}\right)^2. \qquad ◀$$

The statement of Theorem 17 is admittedly technical. However, from it we may derive several corollaries, as listed in Section 5. It is simple to show that Theorem 11 follows from Theorem 17 by noticing that $\delta_2 \geq 1 - 2T$.

We do not currently have a comparison between our Theorem 11 and Corollary 2 of [18], which requires a pointwise bound of π_i^j. However, see Remark 19 which shows that their result would not be sufficient for our application to permutations.

▶ **Remark 19.** It is worth pointing out that the decomposition of $\mathcal{M}_{\sigma_{i-1}}$ that we described in Section 4 does not satisfy the regularity conditions of [18] needed to obtain a better bound. For any $\upsilon \in \Omega_j$, define

$$\pi_j^{j'}(\upsilon) = \pi_j(\upsilon)\frac{\sum_{\upsilon' \in \Omega_{j'}} P(\upsilon, \upsilon')}{\bar{P}(j, j')}.$$

We need to bound $\pi_j^{j'}(\upsilon)/\pi_j(\upsilon)$ for any j, j', and $\upsilon \in \Omega_j$. For example, let $\sigma_2 =$ 12_11111_2_1_ _ and $\sigma_3 =$ 12311111_231_ _. Notice that the two permutations $\upsilon_1 =$ 12311111423156 and $\upsilon_2 =$ 12311111523146 are in the same restriction Ω_j (i.e. they are both consistent with σ_3). They each have a single move to $\Omega_{j'}$: the move of swapping the first 3 with the 4 (in the case of υ_1) or 5 (in the case of υ_2). However, the probability of these moves differ by a factor of $(\overline{q}_{4,3}/\overline{q}_{5,3})(\overline{q}_{4,1}/\overline{q}_{5,1})^5$, as there are five 1's between them. In principle, there could be order n smaller numbers between the two numbers we are swapping. Thus, $\pi_j^{j'}(\upsilon)/\pi_j(\upsilon)$ cannot be uniformly bounded to within $1 \pm \eta$ unless η is exponentially large.

A.4 Complementary decomposition theorems

Next we use the technology developed in Section A.3 to prove Theorem 10. Recall that $\mu_1 \geq \mu_2 \geq \ldots \geq \mu_{|\Omega|}$ are the eigenvalues of $\tilde{A}$ with corresponding eigenvectors $v_1, v_2, \ldots, v_{|\Omega|}$, and that for any $v \in \mathbb{R}^{|\Omega|}$, we write $v = \sum_i a_i v_i$ for some constants $a_1, a_2, \ldots, a_{|\Omega|} \in \mathbb{R}$. Also, $\|v\|^2 = \sum_i a_i^2 \|v_i\|^2$, and $v\tilde{A} = \sum_i a_i \mu_i v_i$. Define the set $S = \{i : \mu_i = 1\}$. Let $\tilde{\delta}_1 = \frac{\langle \tilde{x}^\perp, \tilde{x}^\perp \tilde{A} \rangle}{\|\tilde{x}^\perp\|^2}$. Now we can make an explicit statement about the gap of $\mathcal{M}$; notice the equality in Equation 8.

▶ **Theorem 10.**

$$\gamma(\mathcal{M}) = \min_{x \perp \sqrt{\pi}, \|x\|=1} (1-\delta_1)\|x^\perp\|^2 + (1-\tilde{\delta}_1)\|\tilde{x}^\perp\|^2. \tag{8}$$

In particular,

$$\gamma(\mathcal{M}) \geq \min_{x \perp \sqrt{\pi}, \|x\|=1} \gamma_{\min}\|x^\perp\|^2 + \tilde{\gamma}_{\min}\|\tilde{x}^\perp\|^2. \tag{9}$$

Proof. Notice $\tilde{\delta}_1 \|\tilde{x}^\perp\|^2 = \sum_{i \in S} \mu_i (a_i^\perp + a_i^\parallel)^2$. Thus,

$$(1-\tilde{\delta}_1)\|\tilde{x}^\perp\|^2 = \sum_i (1-\mu_i)(a_i^\perp + a_i^\parallel)^2 = (1-\delta_2)\|x^\perp\|^2 + (1-\delta_4)\|x^\parallel\|^2 - 2\langle x^\perp, x^\parallel \tilde{A}\rangle.$$

On the other hand, from Equation 6, we have

$$1 - \langle x, xA\rangle = (1-\delta_1)\|x^\perp\|^2 + (1-\delta_2)\|x^\perp\|^2 + (1-\delta_4)\|x^\parallel\|^2 - 2\langle x^\perp, x^\parallel \tilde{A}\rangle.$$

Thus, for all $x \perp \sqrt{\pi}$ with norm 1, we have

$$1 - \langle x, xA\rangle = (1-\delta_1)\|x^\perp\|^2 + (1-\tilde{\delta}_1)\|\tilde{x}^\perp\|^2.$$

Applying Equation 3, we get Equation 8. To get Equation 9, we apply Lemma 16, which yields $1 - \delta_1 \geq 1 - \lambda_{\max} = \gamma_{\min}$. An analogous statement to Lemma 16 holds for $\tilde{\delta}_1$, and shows $1 - \tilde{\delta}_1 \geq \tilde{\gamma}_{\min}$. ◀

It remains to prove Theorem 9. By Theorem 10, if $\gamma_{\min}$ and $\tilde{\gamma}_{\min}$ are not too small, it suffices to show that $\|x^\perp\|^2$ and $\|\tilde{x}^\perp\|^2$ cannot both be small. To this end, we further decompose $x^\perp$ and $\tilde{x}^\parallel$ based on the eigenvectors of $\tilde{A}$. Define $S = \{i : \mu_i = 1\}$ and vectors $x_{11} = \sum_{i \in S} a_i^\parallel v_i$ and $x_{12} = \sum_{i \notin S} a_i^\parallel v_i$. Similarly, let $x_{21} = \sum_{i \in S} a_i^\perp v_i$ and $x_{22} = \sum_{i \notin S} a_i^\perp v_i$. Notice $\tilde{x}^\parallel = x_{11} + x_{21}$ and $\tilde{x}^\perp = x_{12} + x_{22}$, so that the vectors in each row (respectively, column) of the following table sum to the vector in its row (respectively, column) label.

	$\tilde{x}^\parallel$	$\tilde{x}^\perp$
$x^\parallel$	x_{11}	x_{12}
$x^\perp$	x_{21}	x_{22}

The vectors within each row are orthogonal, as they are in the span of eigenvectors with distinct eigenvalues. However, the vectors within each column are not necessarily orthogonal.

The idea of the proof of Theorem 9 is that if $\|x_{11}\|$ is small, then $\|x^\perp\|^2 + \|\tilde{x}^\perp\|^2$ is large. The following lemma states that ϵ-orthogonality is sufficient to guarantee $\|x_{11}\|$ is small.

▶ **Lemma 20.** *Let ϵ be as defined in Equation 1. Then $\|x_{11}\|^2 \leq \epsilon$.*

Proof. Recall x_{11} is the projection of $x^{\|}$ onto the top eigenvectors of $\tilde{A}$. The top eigenvectors of $\tilde{A}$ are precisely the set of all $\sqrt{\tilde{\pi}_j}$ for $j \in [\tilde{r}]$. Therefore,

$$x_{11} = \sum_j \frac{\langle x^{\|}, \sqrt{\tilde{\pi}_j}\rangle}{\|\sqrt{\tilde{\pi}_j}\|^2}\sqrt{\tilde{\pi}_j}.$$

As the eigenvectors of $\tilde{A}$ are an orthonormal basis, we have

$$\|x_{11}\|^2 = \sum_j \langle x^{\|}, \sqrt{\tilde{\pi}_j}\rangle^2.$$

For any $j \neq j' \in [\tilde{r}]$ and any $\sigma \in \tilde{\Omega}_{j'}$, $\sqrt{\tilde{\pi}_j(\sigma)} = 0$ and for $i \in [r]$, $\tilde{\pi}_j(\Omega_i \cap \tilde{\Omega}_j) = \pi(\Omega_i \cap \tilde{\Omega}_j)/\pi(\tilde{\Omega}_j)$. Therefore,

$$\langle x^{\|}, \sqrt{\tilde{\pi}_j}\rangle = \sum_i \sum_{\sigma\in\Omega_i} x^{\|}(\sigma)\sqrt{\tilde{\pi}_j(\sigma)} = \sum_i \alpha_i \sum_{\sigma\in\Omega_i\cap\tilde{\Omega}_j} \sqrt{\pi_i(\sigma)\tilde{\pi}_j(\sigma)} = \sum_{i\in[r]} \alpha_i \frac{\pi(\Omega_i\cap\tilde{\Omega}_j)}{\sqrt{\pi(\Omega_i)\pi(\tilde{\Omega}_j)}}. \tag{10}$$

Since $x \perp \sqrt{\pi}$ and $x^{\perp} \perp \sqrt{\pi}$ by definition, it follows that $x^{\|} \perp \sqrt{\pi}$ as well. This implies that $\alpha \perp \sqrt{\tilde{\pi}}$, as

$$0 = \langle x^{\|}, \sqrt{\pi}\rangle = \sum_i \alpha_i \sum_{\sigma\in\Omega_i} \sqrt{\pi_i(\sigma)\pi(\sigma)} = \sum_i \alpha_i \sum_{\sigma\in\Omega_i} \frac{\sqrt{\pi(\sigma)}}{\sqrt{\pi(\Omega_i)}}\sqrt{\pi(\sigma)} = \sum_i \alpha_i \sqrt{\pi(\Omega_i)}, \tag{11}$$

and this final term is equal to $\sum_i \alpha_i\sqrt{\tilde{\pi}_i} = \langle \alpha, \sqrt{\tilde{\pi}}\rangle$. Multiplying Equation 11 by $\pi(\tilde{\Omega}_j)$ and subtracting it from Equation 10, we have

$$\langle x^{\|}, \sqrt{\tilde{\pi}_j}\rangle = \sum_{i\in[r]} \alpha_i \left(\frac{\pi(\Omega_i\cap\tilde{\Omega}_j)}{\sqrt{\pi(\Omega_i)\pi(\tilde{\Omega}_j)}} - \sqrt{\pi(\Omega_i)\pi(\tilde{\Omega}_j)} \right) = \langle \alpha, V_j\rangle,$$

where

$$V_j(i) := \left(\frac{\pi(\Omega_i\cap\tilde{\Omega}_j)}{\sqrt{\pi(\Omega_i)\pi(\tilde{\Omega}_j)}} - \sqrt{\pi(\Omega_i)\pi(\tilde{\Omega}_j)} \right) = \sqrt{\pi(\Omega_i\cap\tilde{\Omega}_j)}(\sqrt{r(i,j)} - 1/\sqrt{r(i,j)}).$$

By the Cauchy-Schwartz inequality and the fact that $\|\alpha\| = \|x^{\|}\| \leq \|x\| = 1$, we have $\langle \alpha, V_j\rangle \leq \|\alpha\|\|V_j\| = \|V_j\|$. Therefore we get,

$$\|x_{11}\|^2 = \sum_j \langle x^{\|}, \sqrt{\tilde{\pi}_j}\rangle^2 \leq \sum_j \|V_j\|^2 = \sum_{i,j} \pi(\Omega_i\cap\tilde{\Omega}_j)(\sqrt{r(i,j)} - 1/\sqrt{r(i,j)})^2. \quad \blacktriangleleft$$

To prove Theorem 9 from Theorem 10, we must show that if $\|x_{11}\|^2 \leq \epsilon$, then $\|x^{\perp}\|^2 + \|\tilde{x}^{\perp}\|^2 \geq (1-\sqrt{\epsilon})^2$. As the sum of the squared norms of the vectors in the above table is 1, it is reasonable to expect that if $\|x_{11}\|^2$ is small, then $\|x^{\perp}\|^2 + \|\tilde{x}^{\perp}\|^2$ is large. However, this is not as straightforward as one might expect, as the vectors within each column are not necessarily orthogonal, so we may have $\|\tilde{x}^{\perp}\|^2 < \|x_{12}\|^2 + \|x_{22}\|^2$. The proof is deferred to the full version of this paper.

Improved Explicit Hitting-Sets for ROABPs

Abstract

We give improved explicit constructions of hitting-sets for *read-once oblivious algebraic branching programs* (ROABPs) and related models. For ROABPs in an unknown variable order, our hitting-set has size polynomial in $(nr)^{\frac{\log n}{\max\{1,\log\log n-\log\log r\}}}d$ over a field whose characteristic is zero or large enough, where n is the number of variables, d is the individual degree, and r is the width of the ROABP. A similar improved construction works over fields of arbitrary characteristic with a weaker size bound.

Based on a result of Bisht and Saxena (2020), we also give an improved explicit construction of hitting-sets for *sum of several ROABPs*. In particular, when the characteristic of the field is zero or large enough, we give polynomial-size explicit hitting-sets for sum of constantly many log-variate ROABPs of width $r = 2^{O(\log d/\log\log d)}$.

Finally, we give improved explicit hitting-sets for polynomials computable by width-r ROABPs in any variable order, also known as *any-order ROABPs*. Our hitting-set has polynomial size for width r up to $2^{O(\log(nd)/\log\log(nd))}$ or $2^{O(\log^{1-\epsilon}(nd))}$, depending on the characteristic of the field. Previously, explicit hitting-sets of polynomial size are unknown for $r = \omega(1)$.

1 Introduction

Polynomial identity testing (PIT) is one of the fundamental problems in the area of derandomization. The problem asks whether a given multi-variate polynomial is identically zero. For example, the polynomial $(x+y)(x-y)-x^2-y^2$ is identically zero. The input to the problem can be given as an algebraic formula or circuit or other algebraic computation models like arithmetic branching programs or determinant of a symbolic matrix. The problem is not known to be polynomial-time solvable. One way to test zeroness could be to check whether the coefficient of each monomial is zero in the polynomial. However, for a given circuit or branching program, it might take exponential time (in the input size) to compute coefficients.

On the other hand, there is a simple (polynomial time) randomized algorithm to test zeroness of a given polynomial: just evaluate the input circuit at a random point and see if the evaluation is nonzero. It is known that a nonzero polynomial evaluated at a random

[1] Part of this work was done while the first author was a postdoc at IIT Kanpur.

point from gives a nonzero value with high probability [14, 6, 22, 20]. More precisely, for an n-variate polynomial of degree d, if you evaluate it at a random point from S^n for some subset $S \subseteq \mathbb{F}$, then the probability of the evaluation being zero is at most $d/|S|$. The polynomial identity testing question can be asked over any field, however as this randomized algorithm suggests, in case of finite characteristic we need to take a large enough field extension.

To obtain a deterministic polynomial time algorithm for the polynomial identity testing has been a long open question. Such an algorithm is known only for some special cases, for example, read-once oblivious arithmetic branching programs (ROABP) (for more such cases, see [21, 18, 19]). Deterministic identity testing for ROABPs has been widely studied in the last decade. One reason for such an interest in this special case is that it can be considered as an algebraic analogue of the RL vs. L question. An ROABP is a product of matrices $f = \beta^\top f_1 f_2 \cdots f_n \gamma$ where $\beta, \gamma \in \mathbb{F}^{r\times 1}$ and $f_i \in \mathbb{F}^{r\times r}[x_{\pi(i)}]$ is a matrix with entries being polynomials in the variable $x_{\pi(i)}$ for each $1 \leq i \leq n$ for some permutation $\pi\colon [n] \to [n]$. The permutation π is said to be the variable order of the ROABP.

Raz and Shpilka [16] gave the first polynomial time algorithm to test whether a given ROABP computes a nonzero polynomial. PIT is also studied in the so-called black-box model, where one does not have access to the circuit/ABP computing the polynomial. Instead, one has to construct an explicit hitting-set – a set of points with the guarantee that every nonzero polynomial in the class of interest gives a nonzero evaluation on at least one of the points in the set. Here, by *explicit* we mean that every point in the hitting-set should be computable in polynomial time. Forbes and Shpilka [9] first gave a quasi-polynomial size explicit hitting-set for ROABPs, when the variable order is known. In subsequent works [8, 1], a quasi-polynomial size explicit hitting-set was also constructed for the unknown order case. Constructing a polynomial-size explicit hitting-set for ROABPs remains a challenging open question. This situation is somewhat similar to that for pseudorandom generators (PRG) for log-space computation. There are no PRGs known with the optimal seed length, i.e. $O(\log n)$, but are known with close to optimal seed length i.e., $O(\log^2 n)$ [13, 12, 15].

There has been a sequence of work in last few years which improve the hitting-set construction for ROABPs with respect to various parameters. There are usually three parameters associated with ROABPs, its length or depth n, which is same as the number of variables, the individual degree d – maximum degree of any variable, and the width r – the size of the matrices involved in the product. The hitting-set of [9] and of [1] both had size $(ndr)^{O(\log n)}$, for the cases of known and unknown variable orders, respectively. For the known order case slightly better results are known. The first paper [9] also gave a bound of $(ndr)^{O(\log n/\max\{1,\log\log n - \log\log r\})}$, which is better when the width r is relatively small. For the small width case, another improved bound of $ndr^{\log n}$ was obtained by [10], when the field characteristic is zero or large enough.

A special class of polynomials, which is known to have better hitting-sets, is called any-order ROABPs. These are polynomials that have small-width ROABPs in every possible variable order. Any-order ROABPs generalize commutative ROABPs[2] and diagonal circuits [17]. Building upon the techniques of [8], an explicit hitting-set of size $(ndr)^{O(\log\log r)}$ for any-order ROABPs was obtained in [10].

A more general model, namely, sum of constantly many ROABPs was considered by [11]. As is known for ROABPs, they could give a polynomial time algorithm for sum of constantly many ROABPs in the white-box case and also a quasi-polynomial size explicit hitting-set. More precisely, for a sum of c ROABPs, their hitting-set size is $(ndr)^{O(c\cdot 2^c \log(ndr))}$.

[2] We say an ROABP is commutative if its output does not change under any permutation of the matrices involved in the product. The usage of "commutative ROABP" is slightly different in [8], which actually refers to any-order ROABPs in this paper.

Recently, Bisht and Saxena [3] considered PIT for ROABP and sum of ROABPs in the small variate regime. For a sum of c ROABPs, they gave a hitting-set of size $\text{poly}(r^{n3^c}, d^c)$, which also means a hitting-set of size $\text{poly}(r^n, d)$ for an ROABP. These results are better than those of [11] and [1] respectively, when $n = O(\log(rd))$ and $r = O(1)$.

In this work we give improved explicit hitting-sets for ROABPs (unknown order), sum of several ROABPs (small variate regime) and any-order ROABPs with respect to various parameters. Though, we are still away from a polynomial size hitting-set, one important feature of our results is a better dependence on the degree parameter d. In particular, for unknown order and any-order ROABPs, our dependence on d is only polynomial instead of quasi-polynomial (when field characteristic is zero/large). This is somewhat analogous to a recent result for read-once boolean branching programs [4], where they construct a hitting-set of size quasi-polynomial in length and width, but the dependence on the error parameter $1/\epsilon$ is nearly-polynomial.

1.1 Our Results

We now state our main theorems, which give improved explicit constructions of hitting-sets for ROABPs in an unknown order, sum of several ROABPs, and any-order ROABPs.

1.1.1 ROABPs in an Unknown Order

We have the following result for general ROABPs in an unknown order.

▶ **Theorem 1.** *Let $\mathcal{C}$ be the family of polynomials $f \in \mathbb{F}[x_1, x_2, \ldots, x_n]$ computed by ROABPs of length n, width r and individual degree d in an unknown order. If $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > d$, then there exists an explicit hitting-set for $\mathcal{C}$ of size polynomial in*

$$M(n, r, d) := d \cdot (nr)^{\frac{\log n}{\max\{1, \log\log n - \log\log r\}}}.$$

In arbitrary characteristic, there exists an explicit hitting-set for $\mathcal{C}$ of size polynomial in

$$M'(n, r, d) := \begin{cases} (nr)^{\log n} d & nd \leq r^2, \\ (nd)^{\frac{\log n}{\log\log(nd) - \log\log r}} & r^2 < nd < r^n, \\ nd & nd \geq r^n. \end{cases}$$

Comparison with Previous Work. In all cases, our bounds are strictly better than the previous best bound of $(ndr)^{O(\log n)}$ [1] for unknown order ROABPs. In particular, our dependence on the individual degree d is better. Our bounds are also better than known order case results of [9]. Recall that they had an explicit hitting-set of size $(ndr)^{O(\log n)}$, and for small r, they had an explicit hitting-set of size $(ndr)^{O(\log n/\max\{1, \log\log n - \log\log r\})}$ (not explicitly written, but follows from [9, Theorem 3.24]). These results are subsumed by Theorem 1. In fact, we follow the same idea in [9] of merging $k \geq 2$ parts of the ROABP at each level of the recursion. We note our construction has two advantages compared with [9]:

- Theorem 1 applies to ROABPs in an *unknown* order, while it is not clear how to achieve the same using the construction in [9]. The requirement that the hitting-set works in an unknown order is crucial for the model of the sum of several ROABPs which is discussed below.
- When $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > d$, our size bound depends only polynomially on the individual degree bound d, which gives much smaller hitting-sets compared with [9] if $n, r \ll d$.

The hitting-set constructed in [3, Lemma 9] for $\mathcal{C}$ of size $\text{poly}(r^n, d)$ is also subsumed by our result. When $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > d$, Theorem 1 improves this by giving an explicit hitting-set of size $M(n, r, d) \leq \text{poly}((nr)^{\log n}, d)$. In particular, in the log-variate case $n = O(\log(rd))$ considered in [3], they can achieve a $\text{poly}(n, r, d)$-size hitting-set only when $r = O(1)$, while we can achieve the same for r up to $2^{O(\log d/ \log\log d)}$. In arbitrary characteristic, we obtain a worse size bound $M'(n, r, d)$, which still subsumes [3, Lemma 9].[3]

Finally, in comparison with the hitting-set of [10, Theorem 3.6] of size $\text{poly}(n^{\log r}, d)$ for *known* order ROABPs, our bound of $M(n, r, d)$ is weaker. In particular, they give polynomial-size hitting-sets when the width r is constant. However, their result is not known to be extendible to ROABPs in an unknown order.

1.1.2 Sum of Several ROABPs

The paper [3] studied the problem of constructing hitting-sets for the sum of several (log-variate) ROABPs and established a reduction from this problem to constructing hitting-sets for ROABPs in an unknown order. Using this reduction, we obtain the following result for the model of sum of several ROABPs.

▶ **Theorem 2.** *Let $\mathcal{C}$ be the family of polynomials $f \in \mathbb{F}[x_1, x_2, \ldots, x_n]$ computed by the sum of c ROABPs of length n, width $r \geq 2$ and individual degree d in unknown and possibly different orders.*

1. *If $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > d$, there exists an explicit hitting-set for $\mathcal{C}$ of size polynomial in $2^{cn} \cdot M(n, (2r)^{3^c}, d)^c$ where $M(\cdot, \cdot, \cdot)$ is as in Theorem 1. In particular, the hitting-set has size $\text{poly}(d)$ when $c = O(1)$, $n = O(\log d)$ and $r = 2^{O(\log d/ \log\log d)}$.*
2. *In arbitrary characteristic, there exists an explicit hitting-set for $\mathcal{C}$ of size polynomial in $2^{cn} \cdot M'(n, (2r)^{3^c}, d)^c$ where $M'(\cdot, \cdot, \cdot)$ is as in Theorem 1.*

The paper [3] constructed an explicit hitting-set of size $\text{poly}(r^{n3^c}, d^c)$ for $\mathcal{C}$, which has size $\text{poly}(d)$ when $n = O(\log d)$ and c, r are constants. This result is subsumed by our Theorem 2 (2) since $M'(n, r, d)$ is bounded by $\text{poly}(n, r^n, d)$. Moreover, when $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > d$, our Theorem 2 (1) yields a $\text{poly}(d)$-size hitting-set for $n = O(\log d)$, $c = O(1)$ and $r = 2^{O(\log d/ \log\log d)}$ (instead of constant r).

1.1.3 Any-Order ROABPs

Recall that any-order ROABPs are polynomials that have small-width ROABPs in every possible variable order. We obtain the following result for any-order ROABPs.

▶ **Theorem 3.** *Let $\mathcal{C}$ be the family of polynomials $f \in \mathbb{F}[x_1, x_2, \ldots, x_n]$ computed by ROABPs of length n, width r and individual degree d in any order.*

1. *If $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > n^4(d+1)^2$, then there exists an explicit hitting-set for $\mathcal{C}$ of size $\text{poly}(n, r^{\log\log r}, d)$. In particular, the hitting-set has size $\text{poly}(n, d)$ for $r = 2^{O(\log(nd)/ \log\log(nd))}$.*
2. *In arbitrary characteristic, there exists an explicit hitting-set for $\mathcal{C}$ of size*

$$\text{poly}(r^{\log\log r}, (nd)^{1+\frac{\log\log r}{\max\{1, \log\log(nd) - \log\log r\}}}).$$

So the hitting-set has size $\text{poly}(n, d)$ for $r = 2^{O(\log^{1-\epsilon}(nd))}$ and any constant $0 < \epsilon < 1$.

---

[3] We note that [3, Lemma 9] is proved using ideas different from ours. To directly see that our bound subsumes the bound $\text{poly}(r^n, d)$ when $r^2 < nd < r^n$, write $nd = r^{n^{1/e}}$ with $1 < e < \log n$ and note $M'(n, r, d) = (nd)^{\frac{\log n}{\log\log(nd) - \log\log r}} = r^{en^{1/e}} = r^{O(n)}$.

The previous best explicit construction of hitting-sets for any-order ROABPs [10] has size $(ndr)^{O(\log\log r)}$, which is superpolynomial for width $r = \omega(1)$. Our hitting-set has polynomial size for r up to $2^{O(\log(nd)/\log\log(nd))}$ or $2^{O(\log^{1-\epsilon}(nd))}$ depending on the characteristic of $\mathbb{F}$.

1.2 Proof Techniques

We prove our results by combining the analyses in previous work [8, 1, 10, 11, 3] with the following ideas.

(1) Low-Degree Concentration via Random Shift. Randomly shifting a multivariate polynomial is an important and common technique in polynomial identity testing for ROABPs and related models. For example, it was used in [2, 8, 1, 10, 11, 7] to achieve rank concentration of polynomials. We use a simple version of this technique, applied only to univariate polynomials: View the layers of a width-r ROABP as univariate polynomials $f_1(x_1), f_2(x_2), \ldots, f_n(x_n)$ with matrix-valued coefficients. We preprocess these polynomials by performing the shift $f_i(x_i) \mapsto f_i(x_i + \alpha)$ simultaneously for $i = 1, 2, \ldots, n$ with randomly chosen $\alpha \in \mathbb{F}$.

Assuming $\mathrm{char}(\mathbb{F})$ is zero or large, a standard argument shows that with high probability, each of the new polynomials $f_i(x_i + \alpha)$ is *low-degree concentrated* in the sense that its coefficient span, which has dimension $\ell_i \leq r^2$, is spanned by the coefficients of the ℓ_i monomials with the lowest degrees. This is useful when the width r is much smaller than the degree bound d of the polynomials, as it allows us to reduce d to r^2 in the analysis.

We remark that a generalization of this technique was developed in [7], where it was shown that a (pseudo-)random shift achieves *low-cone concentration* for multivariate polynomials [7, Theorem 2]. We only need the special case for univariate polynomials, which is classical and uses the nonsingularity of the Wronskian matrix.

(2) Merging Multiple Parts at Each Level of the Recursion. Explicit hitting-sets for ROABPs of size $(ndr)^{O(\log n)}$ were constructed in [9, 1], which may be seen as analogues of the PRG constructions in [13] and [12] for read-once branching programs. Roughly speaking, these hitting-sets are recursively constructed as follows: Divide the ROABP into two parts, construct a hitting-set for each part recursively, and then merge them at the cost of increasing the size by a factor polynomial in ndr. The size of the final hitting-set is $(ndr)^{O(\log n)}$ as the recursion tree has depth $O(\log n)$.

A slightly better construction was also given in [9] for ROABPs of small width. The idea is to merge k parts of the ROABP at each level of the recursion, where k is possibly greater than two. We use the same idea in this paper but replace the construction in [9] by the one in [1], which has the advantage of working for ROABPs in an unknown order. The cost incurred at each level of the recursion is bounded by $\mathrm{poly}(n, d, r^k)$ while there are $O(\log n/\log k)$ levels. When $\mathrm{char}(\mathbb{F})$ is zero or large, the cost incurred at each level may be improved to $\mathrm{poly}(n, r^k)$ by using the idea (1) above. We then choose the optimal k according to the parameters n, r and d.

(3) Reducing the Number of Variables via Hashing. In [8, 10], hitting-sets for any-order ROABPs are constructed in two steps: The first step is to explicitly construct a small set $T \subseteq \mathbb{F}^n$ such that for some $s = (s_1, s_2, \ldots, s_n) \in T$, performing the shift $x_i \mapsto x_i + s_i$ achieves *low-support concentration* for any-order ROABPs. The second step is to convert an any-order ROABP with low-support concentration into a short ROABP.

In [8], the cost of the first step (i.e., the size of T) is polynomial in n and $d^{\log r}$. This was later improved to $(ndr)^{O(\log\log r)}$ in [10]. In this paper, we further improve the cost to $\mathrm{poly}(n, r^{\log\log r}, d)$ when $\mathrm{char}(\mathbb{F})$ is zero or large. In arbitrary characteristic, we obtain a worse bound which still improves those in [8, 10]. See Theorem 16 for details.

One crucial idea used in [8, 10] (which originates from [2]) is that for any-order ROABPs, low-support concentration is a "local" property. Namely, in order to achieve low-support concentration of n-variate any-order ROABPs, it suffices to achieve it when restricting to every subset of ℓ variables, where $\ell = O(\log r)$. In this paper, we use a construction similar to the one in [10] except that we further exploit the locality by using hash functions. This has the effect of reducing n to $\mathrm{poly}(\log r)$ in the analysis, which leads to the improvement.

Organization of the Paper. Preliminaries and notations are given in Section 2. Theorem 1 and 2 are proved in Section 3. Theorem 3 is proved in Section 4. Finally, some open problems are listed in Section 5.

2 Preliminaries

Notations. Let $\mathbb{N} := \{0, 1, 2, \dots\}$ and $\mathbb{N}^+ := \{1, 2, \dots\}$. Denote $\{1, 2, \dots, n\}$ by $[n]$. The cardinality of a set S is denoted by $|S|$. Denote by $\log a$ the logarithm of a with base two.

Let $\mathbb{F}$ be a field. Throughout this paper, we always assume $|\mathbb{F}|$ is large enough. This can be guaranteed by replacing $\mathbb{F}$ with an extension field if necessary. We often write $\mathbf{x}$ as a shorthand for a list of variables $x_1, x_2, \dots, x_n$. For $\mathbf{a} = (a_1, a_2, \dots, a_n) \in \mathbb{N}^n$, write $\mathbf{x}^\mathbf{a}$ for the monomial $\prod_{i=1}^n x_i^{a_i}$. The *support* of $\mathbf{x}^\mathbf{a}$ is $\mathrm{supp}(\mathbf{x}^\mathbf{a}) := \{i \in [n] : a_i > 0\}$. The set of all monomials in $x_1, x_2, \dots, x_n$ is denoted by $\mathcal{M}(x_1, x_2, \dots, x_n)$ or $\mathcal{M}(\mathbf{x})$.

For an algebra $\mathbb{A}$ over $\mathbb{F}$, write $\mathbb{A}[\mathbf{x}]$ for the ring of polynomials in the variables $\mathbf{x}$ with coefficients in $\mathbb{A}$. For $f \in \mathbb{A}[\mathbf{x}]$ and a monomial $m = \mathbf{x}^\mathbf{a}$, denote by $\mathrm{coef}_f(m) \in \mathbb{A}$ the coefficient of m in f. The linear span of a set $T \subseteq \mathbb{A}$ over $\mathbb{F}$ is denoted by $\mathrm{span}\, T$. The *coefficient span* of $f \in \mathbb{A}[\mathbf{x}]$ is $\mathrm{span}(f) := \mathrm{span}\{\mathrm{coef}_f(m) : m \text{ is a monomial in } f\}$.

More generally, for an extension field $\mathbb{K}$ of $\mathbb{F}$, denote by $\mathbb{A} \otimes_\mathbb{F} \mathbb{K}$ the tensor product of $\mathbb{A}$ and $\mathbb{K}$ over $\mathbb{F}$, which is an algebra over $\mathbb{K}$, i.e., $\mathbb{A} \otimes_\mathbb{F} \mathbb{K}$ is obtained from $\mathbb{A}$ by extending the field of scalars from $\mathbb{F}$ to $\mathbb{K}$. For $f \in (\mathbb{A} \otimes_\mathbb{F} \mathbb{K})[\mathbf{x}]$ and a monomial $m = \mathbf{x}^\mathbf{a}$, again denote by $\mathrm{coef}_f(m) \in \mathbb{A} \otimes_\mathbb{F} \mathbb{K}$ the coefficient of m in f. The linear span of a set $T \subseteq \mathbb{A} \otimes_\mathbb{F} \mathbb{K}$ over $\mathbb{K}$ is denoted by $\mathrm{span}_\mathbb{K} T$. The coefficient span of $f \in (\mathbb{A} \otimes_\mathbb{F} \mathbb{K})[\mathbf{x}]$ over $\mathbb{K}$ is $\mathrm{span}_\mathbb{K}(f) := \mathrm{span}_\mathbb{K}\{\mathrm{coef}_f(m) : m \text{ is a monomial in } f\}$.

Let $r \in \mathbb{N}^+$ be a parameter. From now on, we fix $\mathbb{A}$ to be $M_{r\times r}(\mathbb{F})$, the algebra of $r \times r$ matrices over $\mathbb{F}$, even though statements in this paper often hold over other algebras as well. So $\mathbb{A} \otimes_\mathbb{F} \mathbb{K}$ is simply $M_{r\times r}(\mathbb{K})$, the algebra of $r \times r$ matrices over $\mathbb{K}$.

Rank Concentration. We need the following definitions about rank concentration.

▶ **Definition 4.** *Let $f \in \mathbb{A}[\mathbf{x}] = \mathbb{A}[x_1, x_2, \dots, x_n]$ be a polynomial over $\mathbb{A}$. For a set $S \subseteq \mathcal{M}(\mathbf{x})$ of monomials, we say f is* concentrated on S *if* $\mathrm{span}(f) = \mathrm{span}\{\mathrm{coef}_f(m) : m \in S\}$. *For $\ell \in \mathbb{N}$, we say f is* ℓ-support concentrated *if it is concentrated on $S = \{\mathbf{x}^\mathbf{a} : |\mathrm{supp}(\mathbf{x}^\mathbf{a})| < \ell\}$. Similarly, we say f is* ℓ-degree concentrated *if it is concentrated on $S = \{\mathbf{x}^\mathbf{a} : \deg(\mathbf{x}^\mathbf{a}) < \ell\}$.*

More generally, for an extension field $\mathbb{K}$ of $\mathbb{F}$, we say $f \in (\mathbb{A} \otimes_\mathbb{F} \mathbb{K})[\mathbf{x}]$ is concentrated on S over $\mathbb{K}$, ℓ-support concentrated *over $\mathbb{K}$, or* ℓ-degree concentrated *over $\mathbb{K}$ if f satisfies the corresponding property above with* $\mathrm{span}(f)$ *and* $\mathrm{span}\{\mathrm{coef}_f(m) : m \in S\}$ *replaced by* $\mathrm{span}_\mathbb{K}(f)$ *and* $\mathrm{span}_\mathbb{K}\{\mathrm{coef}_f(m) : m \in S\}$ *respectively.*

We use low-degree concentration of f only for univariate polynomials f in this paper.

Hitting-Sets. We say a set $\mathcal{H} \subseteq \mathbb{F}^n$ is a *hitting-set* for a nonzero polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$ if there exists $\alpha \in \mathcal{H}$ such that $f(\alpha) \neq 0$. We say $\mathcal{H} \subseteq \mathbb{F}^n$ is a hitting-set for a class of polynomials $\mathcal{C} \subseteq \mathbb{F}[x_1, \ldots, x_n]$ if $\mathcal{H}$ is a hitting-set for every nonzero polynomial in $\mathcal{C}$.

ROABPs. A *read-once oblivious arithmetic branching program* (ROABP) in the order $x_1, \ldots, x_n$ is a weighted directed graph $\mathcal{B}$ with $n+1$ layers of vertices $\{V_0, V_1, \ldots, V_n\}$ together with a start node s and an end node t. All the edges are from s to V_0, V_{i-1} to V_i for $i \in [n]$, or V_n to t.

For $i \in [n]$, the weight of an edge e from V_{i-1} to V_i is a univariate polynomial $w_e \in \mathbb{F}[x_i] \subseteq \mathbb{F}[\mathbf{x}]$. The weights of the edges e from s to V_0 and those from V_n to t are constants (i.e, $w_e \in \mathbb{F}$). We define the weight of a path in $\mathcal{B}$ from s to t to be the product of the weights of the edges on that path. The polynomial computed by $\mathcal{B}$ is the sum of the weights of the paths in $\mathcal{B}$ from s to t.

Let $r = \max\{|V_i| : i \in [n]\}$. We say $\mathcal{B}$ has *length*[4] n and *width* r. We say $\mathcal{B}$ has *individual degree* d if $\deg(w_e) \leq d$ for $e \in E(\mathcal{B})$. By adding dummy vertices, we may always assume each layer V_i of $\mathcal{B}$ has exactly r vertices. The polynomial f computed by $\mathcal{B}$ can be represented as a product of matrices $f = \beta^\top f_1 f_2 \cdots f_n \gamma$ where $\beta, \gamma \in \mathbb{F}^{r \times 1}$ and $f_i \in \mathbb{A}[x_i]$ for $i \in [n]$ with $\mathbb{A} = M_{r \times r}(\mathbb{F})$.

Let $c > 0$ be a large enough constant. Throughout the paper, we always assume the length n of an ROABP is at least c and the width r is at least two, which is fine since explicit hitting-sets of polynomial size for ROBAPs are easy to construct when $n < c$ or $r = 1$. These assumptions are made to avoid technicalities in boundary cases (e.g. $\log \log r$ is undefined when $r = 1$). Similarly, we always assume the individual degree bound d is at least c by replacing d with $\max\{d, c\}$ if necessary.

Unknown-Order and Any-Order ROABPs. The above definition of ROABPs is given with respect to the variable order $x_1, x_2, \ldots, x_n$. More generally, we say an ROABP has an *unknown order* or is an *unknown-order ROABP* if it has the variable order $x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}$ where π is an arbitrary permutation of $[n]$.

Let $\mathcal{C}$ be a class of unknown-order ROABPs. We say $f \in \mathbb{F}[\mathbf{x}]$ is computed by ROABPs in $\mathcal{C}$ *in any order* (or simply an *any-order ROABP* in $\mathcal{C}$) if for every permutation π of $[n]$, f is computed by an ROABP in $\mathcal{C}$ that has the variable order $x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}$. In this paper, $\mathcal{C}$ will be the class of unknown-order ROABPs of length n, width r and individual degree d for some n, r and d.

We also say a polynomial $f \in \mathbb{A}[\mathbf{x}]$ over $\mathbb{A}$ is computed by ROABPs of length n, width r and individual degree d in any order if for any permutation π of $[n]$, we can write $f = f_1 f_2 \cdots f_n$ such that $f_i \in \mathbb{A}[x_{\pi(i)}]$ is a univariate polynomial of degree at most d in $x_{\pi(i)}$ where $\mathbb{A} = M_{r \times r}(\mathbb{F})$.

3 Hitting-Sets for ROABPs

In this section, we give an explicit construction of hitting-sets for ROABPs in an unknown order. Then we prove Theorem 1 and Theorem 2.

[4] The length is also called the *depth* and equals the number of variables.

3.1 Low-Degree Concentration by Random Shift

We start with the following lemma, which states that random shift achieves low-degree concentration with high probability.

▶ **Lemma 5.** *Suppose* $\mathrm{char}(\mathbb{F}) = 0$ *or* $\mathrm{char}(\mathbb{F}) > d \in \mathbb{N}$. *Let* $f \in \mathbb{A}[x]$ *be a univariate polynomial of degree* d. *Let* $\ell = \dim_{\mathbb{F}}(\mathrm{span}(f)) \leq \dim_{\mathbb{F}} \mathbb{A} = r^2$. *Then for all but at most* $d\ell$ *choices of* $\alpha \in \mathbb{F}$, $f(x+\alpha)$ *is* ℓ*-degree concentrated.*

Proof. Using the fact that all the $\ell \times \ell$ minors of the Wronskian matrix $W = \left[\binom{i}{j}\right]_{0 \leq i \leq d, 0 \leq j < \ell}$ are nonzero when $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > d$, it can be shown that $f(x+t)$ is ℓ-degree concentrated over $\mathbb{F}(t)$, where t is an indeterminate. We omit the proof of this claim but note it is a special case of [7, Theorem 2] applied to univariate polynomials.

View $\mathbb{A}$ as a vector space over $\mathbb{F}$. As $f(x+t)$ is ℓ-degree concentrated, the matrix formed by the ℓ vectors $\mathrm{coef}_{f(x+t)}(1), \mathrm{coef}_{f(x+t)}(x), \ldots, \mathrm{coef}_{f(x+t)}(x^{\ell-1}) \in \mathbb{A}$ has a nonzero $\ell \times \ell$ minor $g(t)$. Note $g(t)$ is a polynomial in t of degree at most $d\ell$. So for all but at most $d\ell$ choices of α, we have $g(\alpha) \neq 0$. For such α, the vectors $\mathrm{coef}_{f(x+\alpha)}(1), \mathrm{coef}_{f(x+\alpha)}(x), \ldots, \mathrm{coef}_{f(x+\alpha)}(x^{\ell-1})$ are linearly independent and hence span the space $\mathrm{span}(f) = \mathrm{span}(f(x+\alpha))$. So $f(x+\alpha)$ is ℓ-degree concentrated. ◀

We use Lemma 5 to preprocess the univariate polynomials f_i in an ROABP so that they are r^2-degree concentrated: Suppose $f_1 \in \mathbb{A}[x_1], f_2 \in \mathbb{A}[x_2] \ldots, f_n \in \mathbb{A}[x_n]$ are univariate polynomials of degree at most d. Let $S \subseteq \mathbb{F}$ such that $|S| > ndr^2$. By Lemma 5 and the union bound, there exists $\alpha \in S$ such that $f_i(x_i + a)$ is r^2-degree concentrated for $i \in [n]$.

▶ Remark. Lemma 5 may not hold if $0 < \mathrm{char}(\mathbb{F}) \leq d$. For example, let $a, b \in \mathbb{A}$ be linearly independent over a field $\mathbb{F}$ of characteristic $p > 0$. Let $f(x) = ax^d + b$ where $d \geq p$ is a power of p. Then $f(x+\alpha) = ax^d + \alpha^d a + b$ is not ℓ-degree concentrated for $\alpha \in \mathbb{F}$ and $\ell \leq d$.

3.2 Basis Isolation

A *weight assignment* of the variables $x_1, x_2, \ldots, x_n$ is a map $w : \{x_1, x_2, \ldots, x_n\} \to \mathbb{N}$. Extend w to a map $w : \mathcal{M}(\mathbf{x}) \to \mathbb{N}$ on the set $\mathcal{M}(\mathbf{x})$ of monomials by $w(\mathbf{x}^{\mathbf{a}}) := \sum_{i=1}^{n} w(x_i)a_i$ for $\mathbf{x}^{\mathbf{a}} = \prod_{i=1}^{n} x_i^{a_i} \in \mathcal{M}(\mathbf{x})$.

One basic tool we need is the following explicit construction of weight assignments that separate polynomially many monomials.

▶ **Lemma 6** ([1, Lemma 4, restated])**.** *For* $n, s, \ell \in \mathbb{N}^+$ *and* $0 < \epsilon < 1$, *there exist weight assignments* $w_1, w_2, \ldots, w_N : \{x_1, x_2, \ldots, x_n\} \to [N \log N]$, *where* $N = \mathrm{poly}(n, s, \log \ell, \epsilon^{-1})$, *such that for any* s *monomials* $m_1, m_2, \ldots, m_s \in \mathcal{M}(\mathbf{x})$ *of individual degree less than* ℓ, *all but at most* ϵ*-fraction of* w_i *among* $w_1, w_2, \ldots, w_N$ *separate these monomials, i.e.,* $w_i(m_j) \neq w_i(m_{j'})$ *for* $j, j' \in [s]$ *with* $m_j \neq m_{j'}$. *The weight assignments* $w_1, w_2, \ldots, w_N$ *can be computed in time polynomial in* N.

We are interested in weight assignments that have the property of *basis isolation*, introduced in [1].

▶ **Definition 7** (basis isolating weight assignment [1])**.** *For a polynomial* $f \in \mathbb{A}[\mathbf{x}]$, *we say* $w : \{x_1, x_2, \ldots, x_n\} \to \mathbb{N}$ *is a* basis isolating weight assignment *for* f *if there exists a set* $S \subseteq \mathcal{M}(\mathbf{x})$ *of monomials whose coefficients in* f *form a basis of* $\mathrm{span}(f)$, *such that*

1. $w(m) \neq w(m')$ *for distinct* $m, m' \in S$, *and*
2. $\mathrm{coef}_f(m) \in \mathrm{span}\{\mathrm{coef}_f(m') : m' \in S,\ w(m') < w(m)\}$ *for* $m \in \mathcal{M}(\mathbf{x}) \setminus S$.

The following lemma states that, if w is a basis isolating weight assignment, then the variable substitution map $x_i \mapsto y^{w(x_i)}$ preserves the nonzeroness of polynomials. This makes basis isolating weight assignments a very useful tool for PIT.

▶ **Lemma 8** ([1, Lemma 6]). *Let $f(\mathbf{x}) \in \mathbb{A}[\mathbf{x}]$, $\beta, \gamma \in \mathbb{F}^r$, and $g(\mathbf{x}) = \beta^\top f(\mathbf{x})\gamma \in \mathbb{F}[\mathbf{x}]$. Suppose $w : \{x_1, x_2, \ldots, x_n\} \to \mathbb{N}$ is a basis isolating weight assignment for $f \in \mathbb{A}[\mathbf{x}]$. Then $g(\mathbf{x}) = 0$ iff $g(y^{w(x_1)}, y^{w(x_2)}, \ldots, y^{w(x_n)}) = 0$.*

Explicit Construction. We use the following explicit construction of basis isolating weight assignments for ROABPs, which is a k-ary generalization of the one in [1].

Let $n, \ell \in \mathbb{N}^+$, $k \in \{2, \ldots n\}$ and $\epsilon \in (0, 1)$ where n is a power of k. Let $u = \log n / \log k \in \mathbb{N}$. Let $N = \text{poly}(n, s, \log \ell, \epsilon^{-1})$ and $w_1, w_2, \ldots, w_N$ be as in Lemma 6 with respect to the parameters n, s, ℓ, ϵ, where $s = \max\{\ell, r^{2k}\}$. Let $h = n\ell N \log N$. For $\mathbf{t} = (t_1, t_2, \ldots, t_u) \in [N]^u$, define the weight assignment $w_{\mathbf{t}} : \{x_1, x_2, \ldots, x_n\} \to [N \log N h^u]$ by

$$w_{\mathbf{t}}(x_i) = \sum_{j=1}^{u} w_{t_j}(x_i) h^{u-j}.$$

So $w_{\mathbf{t}}$ is a linear combination of $w_{t_1}, w_{t_2}, \ldots, w_{t_u}$, where w_{t_j} is multiplied by h^{u-j} for $j \in [u]$. If $u = 0$ (i.e., $n = 1$), define $w_{\mathbf{t}}(x_1) = 1$ instead for the unique element $\mathbf{t} \in [N]^u$.

▶ **Lemma 9.** *Let $\pi : [n] \to [n]$ be a permutation. Let $f = \prod_{i=1}^{n} f_i$ where $f_i \in \mathbb{A}[x_{\pi(i)}]$ is ℓ-degree concentrated for $i \in [n]$. Then for all but at most ϵ'-fraction of $\mathbf{t} \in [N]^u$, $w_{\mathbf{t}}$ is a basis isolating weight assignment for f, where $\epsilon' = \frac{(n-1)\epsilon}{k-1}$.*

Proof. We prove the lemma for the case $(x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}) = (x_1, x_2, \ldots, x_n)$. The same proof works for arbitrary variable orders since the monomial separation property of w_i as asserted in Lemma 6 is closed under any permutation of the variables $x_1, x_2, \ldots, x_n$.

The proof is done by induction on $u = \log n / \log k$.

Base case: Suppose $u = 0$, i.e., $n = 1$. We want to prove that the weight assignment $w_{\mathbf{t}}$ defined by $w_{\mathbf{t}}(x_1) = 1$ is basis isolating for $f = f_1$. Choose the set of monomials $S \subseteq \mathbb{F}[x_1]$ in the following greedy way: Start with $S = \emptyset$ and enumerate $i = 0, 1, 2 \ldots$. For each i, add x^i to S whenever $\text{coef}_{f_1}(x_i) \notin \text{span}\{\text{coef}_{f_1}(m) : m \in S\}$. Continue this process until $\text{span}\{\text{coef}_{f_1}(m) : m \in S\} = \text{span}(f)$. Then $w_{\mathbf{t}}$ and S satisfy Definition 7. So $w_{\mathbf{t}}$ is a basis isolating weight assignment for $f = f_1$.

Inductive step: Suppose $u > 0$, and assume the claim holds for $u' = u-1$. Let $n' = n/k = k^{u'}$. Divide $[n]$ into k blocks $B_1, B_2, \ldots, B_k$, where $B_i = \{(i-1)n'+1, (i-1)n'+2, \ldots, in'\}$. For $i \in [k]$, let $f^{(i)} = \prod_{j \in B_i} f_j = \prod_{j=(i-1)n'+1}^{in'} f_j$. So $f = \prod_{i=1}^{k} f^{(i)}$.

Let $\epsilon'' = \frac{(n'-1)\epsilon}{k-1}$. By the induction hypothesis and the union bound, for all but at most $k\epsilon''$-fraction of $\mathbf{t} = (t_1, t_2, \ldots, t_{u-1}) \in [N]^{u-1}$, $w_{\mathbf{t}}$ is a basis isolating weight assignment for $f^{(1)}, f^{(2)}, \ldots, f^{(k)}$. Fix such $\mathbf{t}$. For $i \in [k]$, let $S_i \subseteq \mathcal{M}(x_j : j \in B_i)$ be a set of monomials in the variables x_j with $j \in B_i$ such that $w_{\mathbf{t}}$, S_i and $f^{(i)}$ satisfy the conditions in Definition 7. Then $|S_i| \leq \dim_{\mathbb{F}} \text{span}(f^{(i)}) \leq \dim_{\mathbb{F}} \mathbb{A} = r^2$ for $i \in [k]$.

▷ Claim 10. The monomials in $S_1, S_2, \ldots, S_k$ have individual degree less than ℓ.

Proof of Claim 10. Assume to the contrary that some S_i contains a monomial m whose degree in some variable x_j is $d \geq \ell$. Write $m = x_j^d \bar{m}$ where $\bar{m}$ does not depend on x_j. As f_j is ℓ-degree concentrated, we have $\text{coef}_{f_j}(x_j^d) \in \text{span}\{\text{coef}_{f_j}(x_j^a) : 0 \leq a < \ell\}$. Using the fact $f^{(i)} = \prod_{j \in B_i} f_j$ and $f_j \in \mathbb{A}[x_j]$ for $j \in S_i$, we see

$$\text{coef}_{f^{(i)}}(m) \in \text{span}\{\text{coef}_{f^{(i)}}(x_j^a \bar{m}) : 0 \leq a < \ell\} \subseteq \text{span}\{\text{coef}_{f^{(i)}}(m') : w_{\mathbf{t}}(m') < w_{\mathbf{t}}(m)\}.$$

But, from (2) of Definition 7, we know that for any $m' \in \mathcal{M}(x_j : j \in B_i) \setminus S_i$,

$$\text{coef}_{f^{(i)}}(m') \in \text{span}\{\text{coef}_{f^{(i)}}(m'') : m'' \in S_i,\ w_{\mathbf{t}}(m'') < w_{\mathbf{t}}(m')\}.$$

From the above two containments we get that

$$\text{coef}_{f^{(i)}}(m) \in \text{span}\{\text{coef}_{f^{(i)}}(m'') : m'' \in S_i,\ w_{\mathbf{t}}(m'') < w_{\mathbf{t}}(m)\}.$$

This contradicts the fact that the coefficients of the monomials in S_i form a basis of $\text{span}(f_i)$ (Definition 7). ◁

Let $T := \{\prod_{i=1}^{k} m_i : m_i \in S_i \text{ for } i \in [k]\}$. Then $\text{span}\{\text{coef}_f(m) : m \in T\} = \text{span}(f)$. Note $|T| = \prod_{i=1}^{k} |S_i| \le r^{2k} \le s$, and T consists of monomials of individual degree less than ℓ. By Lemma 6, for all but at most ϵ-fraction of $t_u \in [N]$, w_{t_u} separates the monomials in T. Fix such t_u and let $\mathbf{t}' = (t_1, t_2, \ldots, t_u) = (\mathbf{t}, t_u)$.

For $m \in T$, as the individual degree of m is less than ℓ, we have $0 \le w_{t_u}(m) < n\ell N \log N = h$. By definition, $w_{\mathbf{t}'}(m) = w_{t_u}(m)$ if $u = 1$ and $w_{\mathbf{t}'}(m) = w_{\mathbf{t}}(m)h + w_{t_u}(m)$ if $u > 1$. In either case, we have $w_{\mathbf{t}'}(m) \neq w_{\mathbf{t}'}(m')$ whenever $w_{t_u}(m) \neq w_{t_u}(m')$ for $m, m' \in T$. Therefore, the weight assignment $w_{\mathbf{t}'}$ also separates the monomials in T.

Next, we choose a subset $S \subseteq T$ of monomials such that $w_{\mathbf{t}'}$, S, and f satisfy the conditions in Definition 7. Initially, let $S = \emptyset$. Choose $m \in T$ with the minimum weight $w_{\mathbf{t}'}(m)$ such that $\text{coef}_f(m) \notin \text{span}\{\text{coef}_f(m') : m' \in S\}$, and add m to S. Note m is unique as $w_{\mathbf{t}'}$ separates the monomials in T. Repeat this step until $\text{span}\{\text{coef}_f(m) : m \in S\}$ equals $\text{span}\{\text{coef}_f(m) : m \in T\} = \text{span}(f)$.

We check that $w_{\mathbf{t}'}$, S and f satisfy the conditions in Definition 7. The set $\{\text{coef}_f(m) : m \in S\}$ is a basis of $\text{span}(f)$ by our choice of S. As $w_{\mathbf{t}'}$ separates the monomials in $T \supseteq S$, Condition (1) of Definition 7 holds. We now prove that Condition (2) also holds.

▷ Claim 11. $\text{coef}_f(m) \in \text{span}\{\text{coef}_f(m') : m' \in S,\ w_{\mathbf{t}'}(m') < w_{\mathbf{t}'}(m)\}$ for $m \in \mathcal{M}(\mathbf{x}) \setminus S$.

Proof of Claim 11. We prove the claim by induction on $w := w_{\mathbf{t}'}(m)$. The claim is vacuously true for $w < 0$ (since this is impossible). Now suppose $w \ge 0$ and the claim holds for $w' < w$. If $m \in T$, the claim holds by our choice of S. So assume $m \notin T$. Write $m = \prod_{i=1}^{k} m_i$ where m_i is a monomial in the variables in B_i. As $m \notin T$, there exists $i \in [k]$ such that $m_i \notin S_i$. Assume $i = 1$ (the other cases are similar). By the choice of S_1, we have

$$\begin{aligned}\text{coef}_{f^{(1)}}(m_1) &\in \text{span}\{\text{coef}_{f^{(1)}}(m_1') : m_1' \in S_1,\ w_{\mathbf{t}}(m_1') < w_{\mathbf{t}}(m_1)\} \\ &\subseteq \text{span}\{\text{coef}_{f^{(1)}}(m_1') : m_1' \in S_1,\ w_{\mathbf{t}'}(m_1') < w_{\mathbf{t}'}(m_1)\}.\end{aligned}$$

where the second step holds since $w_{t_u}(m_1') < n\ell N \log N = h$ for $m_1' \in S_1$, which in turn holds by Claim 10. Therefore

$$\begin{aligned}\text{coef}_f(m) &\in \text{span}\{\text{coef}_f(m_1' m_2 \cdots m_k) : m_1' \in S_1,\ w_{\mathbf{t}'}(m_1') < w_{\mathbf{t}'}(m_1)\} \\ &\subseteq \text{span}\{\text{coef}_f(m') : m' \in \mathcal{M}(\mathbf{x}), w_{\mathbf{t}'}(m') < w_{\mathbf{t}'}(m)\}.\end{aligned}$$

Consider a monomial $m' \in \mathcal{M}(\mathbf{x})$ satisfying $w_{\mathbf{t}'}(m') < w_{\mathbf{t}'}(m)$. By the induction hypothesis, either $m' \in S$, or $\text{coef}_f(m')$ is in the span of the coefficients of those monomials in S with weight strictly less than $w_{\mathbf{t}'}(m') < w_{\mathbf{t}'}(m)$. It follows that $\text{coef}_f(m) \in \text{span}\{\text{coef}_f(m') : m' \in S, w_{\mathbf{t}'}(m') < w_{\mathbf{t}'}(m)\}$. ◁

By the union bound, for all but at most ϵ'-fraction of $\mathbf{t}' = (t_1, \ldots, t_u) \in [N]^u$, where $\epsilon' = k\epsilon'' + \epsilon = \frac{(n-1)\epsilon}{k-1}$, $w_{\mathbf{t}'}$ is a basis isolating weight assignment for f. This completes the proof for the inductive step. ◀

Let $\epsilon = 1/n$. Then the maximum values of the weight assignments $w_{\mathbf{t}}$ constructed above are polynomial in h^u with $h = \mathrm{poly}(n, \ell, r^k)$ and $u = \log n / \log k$, which suggests that we should choose $k = \Theta(\log(n\ell)/\log r)$. However, as $k \in \{2, \ldots, n\}$, we have to choose $k = 2$ (resp. $k = n$) when $\log(n\ell)/\log r$ is subconstant (resp. superlinear in n). This yields the following theorem.

▶ **Theorem 12.** *Let $\mathcal{C}$ be the family of polynomials $f = \beta^\top f_1 f_2 \cdots f_n \gamma$ computed by ROABPs of length n, width r and individual degree d in an unknown order, where each f_i is ℓ-degree concentrated. Then there exists an explicit hitting-set for $\mathcal{C}$ of size polynomial in $M_0(n, r, d, \ell)$, where*

$$M_0(n,r,d,\ell) := \begin{cases} (nr)^{\log n} d & n\ell \le r^2, \\ (n\ell)^{\frac{\log n}{\log\log(n\ell) - \log\log r}} d & r^2 < n\ell < r^n, \\ n\ell d & n\ell \ge r^n. \end{cases}$$

Proof. Choose

$$k = \begin{cases} 2 & n\ell \le r^2, \\ \log(n\ell)/\log r & r^2 < n\ell < r^n, \\ n & n\ell \ge r^n. \end{cases}$$

By adding dummy variables, we may assume n is a power of k. Let $\epsilon = 1/n$. Construct the weight assignment $w_{\mathbf{t}} : \{x_1, x_2, \ldots, x_n\} \to [N \log N h^u]$ for $\mathbf{t} \in [N]^u$ as above, where $N = \mathrm{poly}(n, s, \log \ell, \epsilon^{-1})$, $s = \max\{\ell, r^{2k}\}$, $h = n\ell N \log N$, and $u = \log n / \log k$.

Consider $0 \neq f = \beta^\top f_1 f_2 \cdots f_n \gamma \in \mathcal{C}$. By Lemma 9, there exists $\mathbf{t} \in [N]^u$ such that $w_{\mathbf{t}}$ is a basis isolating weight assignment for $f_1 f_2 \cdots f_n \in \mathbb{A}[\mathbf{x}]$, which implies that $g_{w_{\mathbf{t}}}(y) := f(y^{w_{\mathbf{t}}(x_1)}, \ldots, y^{w_{\mathbf{t}}(x_n)}) \neq 0$ by Lemma 8. As $g_{w_{\mathbf{t}}}(y)$ is univariate, any subset of $\mathbb{F}$ of size $\deg(g_{w_{\mathbf{t}}}) + 1 \le N \log N h^u n d + 1$ is a hitting-set for $g_{w_{\mathbf{t}}}$. Enumerating all $\mathbf{t} \in [N]^u$, we obtain an explicit hitting-set for $\mathcal{C}$ of size at most $N^u(N \log N h^u n d + 1)$, which is polynomial in $M_0(n, r, d, \ell)$. ◀

Theorem 1 follows easily from Theorem 12.

Proof of Theorem 1. Note degree-d polynomials are trivially $(d+1)$-degree concentrated. The second part of Theorem 1 (the claim for arbitrary characteristic) then follows from Theorem 12 with $\ell = d + 1$.

Moreover, when $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > d$, we may preprocess the polynomials f_i using Lemma 5 so that they are r^2-degree concentrated. The first part of Theorem 1 then follows from Theorem 12 with $\ell = r^2$. ◀

3.3 Sum of Several ROABPs

Using the reduction in [3], we may extend Theorem 1 to the model of sum of several ROABPs and prove Theorem 2. Here we only sketch the proof as it is the same as the proof in [3] except for some small adjustments.

Proof sketch of Theorem 2. Choose a function $M^*(n, r, d) \ge \mathrm{poly}(n, r, d)$ such that we have explicit hitting-sets of size at most $M^*(n, r, d)$ for the family of polynomials computed by ROABPs of length n, width r and individual degree d in an unknown order. By Theorem 1, we may choose $M^*(n, r, d)$ to be polynomial in $M(n, r, d)$ when $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > d$ and polynomial in $M'(n, r, d)$ in arbitrary characteristic.

Fix n and d. It was shown in the proof of [3, Lemma 14] (and the proof of [3, Lemma 12]) that for $c \geq 1$ and $r \geq 2$, one can explicitly construct a set $\mathcal{S}$ of ring homomorphisms $\Psi : \mathbb{F}[x_1, x_2, \ldots, x_n] \to \mathbb{F}[t]$ satisfying the following properties ($\mathcal{C}$ is the class of sum of c ROABPs):

- If $0 \neq f \in \mathcal{C}$, there exists $\Psi \in \mathcal{S}$ such that $\Psi(f) \neq 0$.
- For $f \in \mathcal{C}$ and $\Psi \in \mathcal{S}$, the degree of $\Psi(f)$ is at most $S(c, r)$, where $S(1, r) \leq M^*(n, r, d)$ and

$$S(c, r) \leq \text{poly}(M^*(n, r, d)) \cdot S(c - 1, 2r^3) \tag{1}$$

  for $c \geq 2$.
- The time complexity of computing $\mathcal{S}$ is at most $T(c, r)$, where $T(1, r) \leq \text{poly}(M^*(n, r, d))$ and

$$T(c, r) \leq n2^n \cdot \text{poly}(M^*(n, r, d)) \cdot T(c - 1, 2r^3) \tag{2}$$

  for $c \geq 2$. In particular, the size of $\mathcal{S}$ is bounded by $T(c, r)$.

Solving the recursive relations (1) and (2) above gives $S(c, r) \leq \text{poly}(M^*(n, (2r)^{3^c}, d)^c)$ and $T(c, r) \leq \text{poly}(2^{cn}, M^*(n, (2r)^{3^c}, d)^c)$.

For $f \in \mathcal{C}$ and $\Psi \in \mathcal{S}$, any subset of $\mathbb{F}$ of size $S(c, r)+1$ is a hitting-set for $\Psi(f)$ since $\Psi(f)$ is a univariate polynomial of degree at most $S(c, r)$. Enumerating all possible $\Psi \in \mathcal{S}$, we obtain an explicit hitting-set for $\mathcal{C}$ of size at most $T(c, r)(S(c, r) + 1)$, which is polynomial in $2^{cn} \cdot M(n, (2r)^{3^c}, d)^c$ when $\text{char}(\mathbb{F}) = 0$ or $\text{char}(\mathbb{F}) > d$ and polynomial in $2^{cn} \cdot M'(n, (2r)^{3^c}, d)^c$ in arbitrary characteristic. ◀

4 Hitting-Sets for Any-Order ROABPs

In this section, we prove Theorem 3 by giving an explicit construction of hitting-sets for any-order ROABPs.

4.1 Low-Support Concentration

Following [8, 10], we first achieve low-support concentration by shifting the variables. The basic tool is the following lemma.

▶ **Lemma 13** ([11, Lemma 5.2]). *Suppose $w : \mathbf{x} \to \mathbb{N}$ is a basis isolating weight assignment for $f = \prod_{i=1}^{n} f_i \in \mathbb{A}[\mathbf{x}]$. Then $f(x_1 + y^{w(x_1)}, x_2 + y^{w(x_2)}, \ldots, x_n + y^{w(x_n)})$ is $\lceil \log(r^2 + 1) \rceil$-support concentrated over $\mathbb{F}(y)$.*

The next lemma states that low-support concentration is a "local" property for any-order ROABPs.

▶ **Lemma 14** ([2, 8, 10]). *Let $\ell < n$. Let $\mathbf{s} = (s_1, s_2, \ldots, s_n) \in \mathbb{K}^n$ where $\mathbb{K}$ is an extension field of $\mathbb{F}$. Suppose for any distinct $i_1, i_2 \ldots, i_\ell \in [n]$ and $f_1 \in \mathbb{A}[x_{i_1}], f_2 \in \mathbb{A}[x_{i_2}], \ldots, f_\ell \in \mathbb{A}[x_{i_\ell}]$ of degree at most d, the product $f_1(x_{i_1} + s_{i_1}) f_2(x_{i_2} + s_{i_2}) \cdots f_\ell(x_{i_\ell} + s_{i_\ell})$ is ℓ-support concentrated over $\mathbb{K}$. Then for $f(\mathbf{x}) \in \mathbb{A}[\mathbf{x}]$ computed by ROABPs of length n, width r and individual degree d in any order, $f(\mathbf{x} + \mathbf{s})$ is ℓ-support concentrated over $\mathbb{K}$.*

Explicit Construction. Let $\mathbb{K} = \mathbb{F}(y, z, t)$, where y, z and t are indeterminates. We construct $\mathbf{s} \in \mathbb{F}[y, z, t]^n$ such that the shift $\mathbf{x} \mapsto \mathbf{x} + \mathbf{s}$ achieves low-support concentration over $\mathbb{K}$ for polynomials computed by any-order ROABPs. The construction is as follows.

- Let $\ell = r^2$ if $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > d$. Otherwise let $\ell = d + 1$.
- Choose sufficiently large $\bar{n} = \mathrm{poly}(\log r)$ and let $\mathcal{H} = \{h : [n] \to [\bar{n}]\}$ be an explicit family of hash functions of size $\mathrm{poly}(n, \log r)$ such that for any $T \subseteq [n]$ of size $\lceil \log(r^2+1) \rceil$, there exists $h \in \mathcal{H}$ that maps T injectively to $[\bar{n}]$. Such an explicit family $\mathcal{H}$ can be constructed using pairwise independence [5].
- Using Lemma 9, construct a set $\mathcal{S}$ of weight assignments $w : \{u_1, u_2, \ldots, u_{\bar{n}}\} \to \mathbb{N}$ of the variables $u_1, u_2, \ldots, u_{\bar{n}}$ such that for any permutation $\pi : [\bar{n}] \to [\bar{n}]$ and polynomials $f_1 \in \mathbb{A}[u_1], f_2 \in \mathbb{A}[u_2], \ldots, f_{\bar{n}} \in \mathbb{A}[u_{\bar{n}}]$ of degree at most d that are ℓ-degree concentrated, there exists a basis isolating weight assignment in $\mathcal{S}$ for $\prod_{i=1}^{\bar{n}} f_{\pi(i)}$.
- Fix an injective map $\psi : \mathcal{S} \times \mathcal{H} \to \mathbb{F}$. For $(w, h) \in \mathcal{S} \times \mathcal{H}$, construct the polynomial $p_{w,h}(z) \in \mathbb{F}[z]$ of degree $|\mathcal{S} \times \mathcal{H}| - 1$ by interpolation such that for $(w', h') \in \mathcal{S} \times \mathcal{H}$,

$$p_{w,h}(\psi(w', h')) = \begin{cases} 1 & (w', h') = (w, h) \\ 0 & (w', h') \neq (w, h). \end{cases}$$

- Define $\mathbf{s} = (s_1, s_2, \ldots, s_n) \in \mathbb{F}[y, z, t]^n$ by $s_i(y, z, t) = t + \sum_{(w,h) \in \mathcal{S} \times \mathcal{H}} y^{w(u_{h(i)})} p_{w,h}(z)$ for $i \in [n]$. So $s_i(y, \psi(w, h), t) = t + y^{w(u_{h(i)})}$ for $i \in [n]$ and $(w, h) \in \mathcal{S} \times \mathcal{H}$.

The main difference between the above construction and the one in [10] is the use of hash functions, which has the effect of reducing the number of variables from n to $\bar{n} = \mathrm{poly}(\log r)$ in the analysis.

▶ **Lemma 15.** *Suppose $f \in \mathbb{A}[\mathbf{x}]$ is computed by ROABPs of length n, width r and individual degree d in any order. Then $f(\mathbf{x} + \mathbf{s})$ is $\lceil \log(r^2+1) \rceil$-support concentrated over $\mathbb{K} = \mathbb{F}(y, z, t)$.*

Proof. The lemma is trivial if $n < \lceil \log(r^2 + 1) \rceil$. So assume $n \geq \lceil \log(r^2 + 1) \rceil$. Let $n' = \lceil \log(r^2+1) \rceil$. Consider distinct $i_1, i_2 \ldots, i_{n'} \in [n]$ and $f_1 \in \mathbb{A}[x_{i_1}], f_2 \in \mathbb{A}[x_{i_2}], \ldots, f_{n'} \in \mathbb{A}[x_{i_{n'}}]$ of degree at most d. By Lemma 14, it suffices to prove that

$$g := \prod_{j=1}^{n'} f_j(x_{i_j} + s_{i_j}) \in (\mathbb{A}[y, z, t])[\mathbf{x}] \subseteq (\mathbb{A} \otimes_{\mathbb{F}} \mathbb{K})[\mathbf{x}]$$

is n'-support concentrated over $\mathbb{K}$.

Fix $h \in \mathcal{H}$ such that h maps $\{i_1, \ldots, i_{n'}\}$ injectively to $[\bar{n}]$. Note that there exists $\alpha \in \mathbb{F}$ such that for $j \in [n']$, $f_j(x_{i_j} + \alpha)$ is ℓ-degree concentrated: If $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > d$, then $\ell = r^2$ and this claim follows from Lemma 5. Otherwise, $\ell = d + 1$ and this claim holds trivially. Fix such α.

Let $f^*(u_1, u_2, \ldots, u_{\bar{n}}) := \prod_{j=1}^{n'} f_j(u_{h(i_j)} + \alpha) \in \mathbb{A}[u_1, u_2, \ldots, u_{\bar{n}}]$. By the choice of $\mathcal{S}$, there exists a basis isolating weight assignment $w : \{u_1, u_2, \ldots, u_{\bar{n}}\} \to \mathbb{N}$ in $\mathcal{S}$ for f^*. Fix such w. By Lemma 13, $f^*(u_1 + y^{w(u_1)}, \ldots, u_{\bar{n}} + y^{w(u_{\bar{n}})}) = \prod_{j=1}^{n'} f_j(u_{h(i_j)} + y^{w(u_{h(i_j)})} + \alpha)$ is n'-support concentrated over $\mathbb{F}(y)$. Substituting $u_{h(i_j)}$ with x_{i_j} for $j \in [n']$, we see that

$$g^* := \prod_{j=1}^{n'} f_j(x_{i_j} + y^{w(u_{h(i_j)})} + \alpha) \in (\mathbb{A}[y])[\mathbf{x}] \subseteq (\mathbb{A} \otimes_{\mathbb{F}} \mathbb{F}(y))[\mathbf{x}]$$

is n'-support concentrated over $\mathbb{F}(y)$.

Let $g_0 = \prod_{j=1}^{n'} f_j(x_{i_j})$. As $g_0(\mathbf{x} + \alpha) = g^*|_{y=0}$, we have $\mathrm{span}_{\mathbb{F}(y)}(g_0) = \mathrm{span}_{\mathbb{F}(y)}(g_0(\mathbf{x} + \alpha)) \subseteq \mathrm{span}_{\mathbb{F}(y)}(g^*)$. On the other hand, note the coefficients of g^* can be written as linear combinations of those of g_0 over $\mathbb{F}(y)$. So $\mathrm{span}_{\mathbb{F}(y)}(g^*) \subseteq \mathrm{span}_{\mathbb{F}(y)}(g_0)$. It follows that $\mathrm{span}_{\mathbb{F}(y)}(g^*) = \mathrm{span}_{\mathbb{F}(y)}(g_0)$. Also note $\mathrm{span}_{\mathbb{K}}(g) = \mathrm{span}_{\mathbb{K}}(g_0)$ since $g(\mathbf{x}) = g_0(\mathbf{x} + \mathbf{s})$.

Let $D := \dim_{\mathbb{F}}(\mathrm{span}(g_0))$. We have $D = \dim_{\mathbb{F}(y)}(\mathrm{span}_{\mathbb{F}(y)}(g_0)) = \dim_{\mathbb{F}(y)}(\mathrm{span}_{\mathbb{F}(y)}(g^*))$ and $D = \dim_{\mathbb{K}}(\mathrm{span}_{\mathbb{K}}(g_0)) = \dim_{\mathbb{K}}(\mathrm{span}_{\mathbb{K}}(g))$. As g^* is n'-support concentrated over $\mathbb{F}(y)$, there exist $m_1, m_2, \ldots, m_D \in \mathcal{M}(\mathbf{x})$ of support size less than n' such that the coefficients $\mathrm{coef}_{g^*}(m_1), \mathrm{coef}_{g^*}(m_2), \ldots, \mathrm{coef}_{g^*}(m_D)$ are linearly independent. Also note $g^* = g|_{z=\psi(w,h),t=\alpha}$, which implies $\mathrm{coef}_{g^*}(m_i) = \mathrm{coef}_g(m_i)|_{z=\psi(w,h),t=\alpha}$ for $i \in [D]$. Therefore, the coefficients $\mathrm{coef}_g(m_1), \mathrm{coef}_g(m_2), \ldots, \mathrm{coef}_g(m_D)$ are also linearly independent. It follows that g is n'-support concentrated over $\mathbb{K}$, as desired. ◀

▶ **Theorem 16.** *Let $\mathbf{s} = (s_1, \ldots, s_n) \in \mathbb{F}[y,z,t]^n$ be as above. Let $T \subseteq \mathbb{F}$ be a large enough set with*

$$|T| = \begin{cases} \mathrm{poly}(n, r^{\log\log r}, d) & \mathrm{char}(\mathbb{F}) = 0 \text{ or } \mathrm{char}(\mathbb{F}) > d \\ \mathrm{poly}(n, r^{\log\log r}, d^{1+\frac{\log\log r}{\max\{1, \log\log d - \log\log r\}}}) & \text{otherwise.} \end{cases}$$

Suppose $f \in \mathbb{A}[\mathbf{x}]$ is computed by ROABPs of length n, width r and individual degree d in any order. Then there exists $(a,b,c) \in T^3$ such that $f(\mathbf{x}+\mathbf{s}(a,b,c)) \in \mathbb{A}[\mathbf{x}]$ is $\lceil \log(r^2+1) \rceil$-support concentrated.

Proof. We know $|\mathcal{H}| = \mathrm{poly}(n, \log r)$. If $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > d$, then $|\mathcal{S}|$ and the maximum value of every $w \in \mathcal{S}$ are bounded by $\mathrm{poly}(M(\bar{n}, r, d)) = \mathrm{poly}(r^{\log\log r}, d)$. Otherwise they are bounded by $\mathrm{poly}(M'(\bar{n}, r, d)) \leq \mathrm{poly}(r^{\log\log r}, d^{1+\frac{\log\log r}{\max\{1, \log\log d - \log\log r\}}})$. The degree of each $s_i \in \mathbb{F}[y,z,t]$ is polynomial in $|\mathcal{S}|$, $|\mathcal{H}|$ and $\max\{w(u_i) : w \in S, i \in [\bar{n}]\}$.

Let $D = \dim_{\mathbb{F}}(\mathrm{span}(f))$. By Lemma 15, $f(\mathbf{x}+\mathbf{s})$ is $\lceil \log(r^2+1) \rceil$-support concentrated over $\mathbb{K}$. So there exist monomials $m_1, m_2 \ldots, m_D \in \mathcal{M}(\mathbf{x})$ of support size less than $\lceil \log(r^2+1) \rceil$ and individual degree at most d such that $\mathrm{coef}_{f(\mathbf{x}+\mathbf{s})}(m_1), \mathrm{coef}_{f(\mathbf{x}+\mathbf{s})}(m_2), \ldots, \mathrm{coef}_{f(\mathbf{x}+\mathbf{s})}(m_D)$ are linearly independen over $\mathbb{K}$. Therefore, the matrix formed by these coefficients (viewed as vectors over $\mathbb{K}$) has a nonzero $D \times D$ minor $g \in \mathbb{K}$. Note g is a polynomial in y, z, t whose degree is polynomial in n, r, d and the degrees of the polynomials $s_i \in \mathbb{F}[y,z,t]$. By the Schwartz-Zippel-DeMillo-Lipton lemma, for large enough T whose size is as in Theorem 16, there exists $(a,b,c) \in T^3$ such that $g(a,b,c) \neq 0$. For such (a,b,c), the coefficients $\mathrm{coef}_{f(\mathbf{x}+\mathbf{s}(a,b,c))}(m_1), \mathrm{coef}_{f(\mathbf{x}+\mathbf{s}(a,b,c))}(m_2), \ldots, \mathrm{coef}_{f(\mathbf{x}+\mathbf{s}(a,b,c))}(m_D)$ span the coefficient span of f, which implies that $f(\mathbf{x}+\mathbf{s}(a,b,c))$ is $\lceil \log(r^2+1) \rceil$-support concentrated. ◀

4.2 Converting Low-Support Concentrated Any-Order ROABPs into Short ROABPs

Our next step follows that in [8, 10], which converts any-order ROABPs with low-support concentration into short ROABPs. In particular, we need the following lemma proved in [8].

▶ **Lemma 17** ([8, Lemma 7.6, restated]). *Let $\mathcal{C}$ be the set of polynomials $f \in \mathbb{F}[\mathbf{x}]$ computed by ROABPs of length n, width r and individual degree d in any order such that f has a monomial m with a nonzero coefficient and $|\mathrm{supp}(m)| < \ell$. Then for some $n' = O(\ell^2)$, there exists an explicit set $S \subseteq (\mathbb{F}[y_1, y_2, \ldots, y_{n'}])^n$ of size $\mathrm{poly}(n,r,d)$ satisfying the following condition: For any $f \in \mathcal{C}$, there exists $(\phi_1, \phi_2, \ldots, \phi_n) \in S$ such that $f(\phi_1, \phi_2, \ldots, \phi_n) \in \mathbb{F}[y_1, y_2, \ldots, y_{n'}]$ is a nonzero polynomial computed by ROABPs of length n', width r and individual degree $n^4(d+1)^2$ in any order.*

Now we are ready to prove Theorem 3.

Proof of Theorem 3. Consider $0 \neq f \in \mathcal{C}$. Regard $f \in \mathbb{F}[\mathbf{x}]$ as an element of $\mathbb{A}[\mathbf{x}] \cong M_{r\times r}(\mathbb{F}[\mathbf{x}])$ such that the $(1,1)$-th entry of the corresponding matrix is f and the other entries are zero. Then f, regarded as an element of $\mathbb{A}[\mathbf{x}]$ this way, is also computed by ROABPs of length n, width r and individual degree d in any order. Let $\mathbf{s} = (s_1, s_2, \ldots, s_n) \in \mathbb{F}[y,z,t]^n$

and $T \subseteq \mathbb{F}$ be as in Theorem 16. By Theorem 16, there exists $(a,b,c) \in T^3$ such that $f^*(\mathbf{x}) := f(\mathbf{x}+\mathbf{s}(a,b,c))$ is $\lceil \log(r^2+1) \rceil$-concentrated. As $f \neq 0$, this implies that $f^*(\mathbf{x})$ has a monomial m with a nonzero coefficient and $|\mathrm{supp}(m)| < \lceil \log(r^2+1) \rceil$.

Let $S \subseteq (\mathbb{F}[y_1, y_2, \ldots, y_{n'}])^n$ be the set in Lemma 17 with $\ell = \lceil \log(r^2+1) \rceil$. By Lemma 17, there exists $\phi = (\phi_1, \phi_2, \ldots, \phi_n) \in S$ such that $f^*(\phi_1, \phi_2, \ldots, \phi_n)$ is a nonzero polynomial computed by ROABPs of length n', width r and individual degree $n^4(d+1)^2$, where $n' = O((\log r)^2)$.

Finally, use Theorem 1 to construct an explicit hitting-set $\mathcal{H}$ for

$$f^*(\phi_1, \phi_2, \ldots, \phi_n) = f(\phi_1 + s_1(a,b,c), \phi_2 + s_2(a,b,c), \ldots, \phi_n + s_n(a,b,c)).$$

Then $\mathcal{H}_{a,b,c,\phi} := \{(\phi_1(\alpha) + s_1(a,b,c), \phi_2(\alpha) + s_2(a,b,c), \ldots, \phi_n(\alpha) + s_n(a,b,c)) : \alpha \in \mathcal{H}\}$ is a hitting-set for f. We do not know the correct $(a,b,c) \in T^3$ and $\phi \in S$ but may just enumerate all the possible choices and then take the union of $\mathcal{H}_{a,b,c,\phi}$. When $\mathrm{char}(\mathbb{F}) = 0$ or $\mathrm{char}(\mathbb{F}) > n^4(d+1)^2$, the size of the final hitting-set we obtain is polynomial in

$$\begin{aligned} |T|^3 \cdot |S| \cdot M(n', r, n^4(d+1)^2) &= \mathrm{poly}(n, r^{\log\log r}, d) \cdot \mathrm{poly}(n, r, d) \cdot M(n', r, n^4(d+1)^2) \\ &= \mathrm{poly}(n, r^{\log\log r}, d). \end{aligned}$$

In arbitrary characteristic, the size of the final hitting-set is polynomial in

$$\begin{aligned} &|T|^3 \cdot |S| \cdot M'(n', r, n^4(d+1)^2) \\ &= \mathrm{poly}(n, r^{\log\log r}, d^{1+\frac{\log\log r}{\max\{1, \log\log d - \log\log r\}}}) \cdot \mathrm{poly}(n, r, d) \cdot M'(n', r, n^4(d+1)^2) \\ &= \mathrm{poly}(r^{\log\log r}, (nd)^{1+\frac{\log\log r}{\max\{1, \log\log(nd) - \log\log r\}}}). \end{aligned}$$

◀

5 Open Problems

We list some open problems.

- The results we have obtained in positive characteristics are worse than those in characteristic zero, due to the issue that random shift may fail to achieve low-degree concentration in positive characteristics. Is it possible to close the gaps between characteristic zero and characteristic $p > 0$?
- In characteristic $p > 0$, are there explicit hitting-sets of polynomial size for any-order ROABPs of length n, width r and individual degree d when $r, d = 2^{O(\log n / \log\log n)}$? The following issue prevents us from obtaining such a result: In Lemma 17, the substitution map $f \mapsto f(\phi_1, \phi_2, \ldots, \phi_n)$ increases the individual degree from d to $n^4(d+1)^2$. Thus an application of Lemma 17 forces the new individual degree to be at least $\mathrm{poly}(n)$ even if we start with $d = n^{o(1)}$.
- It was shown in [7] that in characteristic zero, explicit hitting-sets of size $\mathrm{poly}(s)$ exist for log-variate diagonal circuits of size s. It is a natural question to ask if this result can be extended to commutative or any-order log-variate ROABPs of width $\mathrm{poly}(s)$ and individual degree $\mathrm{poly}(s)$.

Almost Optimal Testers for Concise Representations

Nader H. Bshouty
Department of Computer Science, Technion, Haifa, Israel
bshouty@cs.technion.ac.il

Abstract

We give improved and almost optimal testers for several classes of Boolean functions on n variables that have concise representation in the uniform and distribution-free model. Classes, such as k-Junta, k-Linear, s-Term DNF, s-Term Monotone DNF, r-DNF, Decision List, r-Decision List, size-s Decision Tree, size-s Boolean Formula, size-s Branching Program, s-Sparse Polynomial over the binary field and functions with Fourier Degree at most d.

The approach is new and combines ideas from Diakonikolas et al. [24], Bshouty [13], Goldreich et al. [32], and learning theory. The method can be extended to several other classes of functions over any domain that can be approximated by functions with a small number of relevant variables.

Acknowledgements I am extremely grateful to Oded Goldreich for very helpful discussions and comments and for allowing me to include his overview of the first tester in the paper (Section 2). I am also grateful to the reviewers of the earlier version of the manuscript for their helpful comments.

1 Introduction

Property testing of Boolean function was first considered in the seminal works of Blum, Luby and Rubinfeld [12] and Rubinfeld and Sudan [46] and has recently become a very active research area. See for example, [2, 4, 5, 6, 8, 9, 13, 15, 16, 17, 18, 19, 20, 21, 24, 27, 31, 33, 36, 37, 41, 40, 43, 47] and other works referenced in the surveys and books [29, 30, 44, 45].

A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is said to be k-junta if it depends on at most k coordinates. The class k-Junta is the class of all k-juntas. The class k-Junta has been of particular interest to the computational learning theory community [10, 11, 14, 23, 34, 38, 42]. A problem closely related to learning k-Junta is the problem of learning and testing subclasses C of k-Junta and classes C of Boolean functions that can be approximated by k-juntas [9, 11, 25, 17, 24, 32, 33, 43]. In both testing and learning we are given black-box query access to a Boolean function f. In learning, for $f \in C$, we need to learn, with high probability, a hypothesis h that is ϵ-close to f. In testing, for any Boolean function f, we need to distinguish, with high probability, the case that f is in C versus the case that f is ϵ-far from every function in C.

In the *uniform-distribution property testing* (and learning) model, the distance between Boolean functions is measured with respect to the uniform distribution. In the *distribution-free property testing*, [32], (and learning [48]) the distance between Boolean functions is measured with respect to an arbitrary and unknown distribution $\mathcal{D}$ over $\{0,1\}^n$. In the

distribution-free model, the testing (and learning) algorithm is allowed (in addition to making black-box queries) to draw random $x \in \{0,1\}^n$ according to the distribution $\mathcal{D}$. This model is studied in [13, 22, 26, 28, 35, 39].

1.1 Results

In Table 1, we list all the previous results and our results in this paper. In the table, $\tilde{O}(T)$ stands for $O(T \cdot Poly(\log T))$, U and D stand for uniform and distribution-free models, resp., and Exp and Poly stand for exponential and polynomial time, resp.

It follows from the lower bounds of Saglam [47], that our query complexity is almost optimal (up-to log-factor) for the classes k-Junta, k-Linear, k-Term, s-Term DNF, s-Term Monotone DNF, r-DNF (r constant), Decision List, r-Decision List (r constant), size-s Decision Tree, size-s Branching Programs and size-s Boolean Formula.

1.2 Notations

In this subsection, we give some notations that we use throughout the paper.

Denote $[n] = \{1, 2, \ldots, n\}$. For $S \subseteq [n]$ and $x = (x_1, \ldots, x_n)$ we denote $x(S) = \{x_i | i \in S\}$. For $X \subset [n]$ we denote by $\{0,1\}^X$ the set of all binary strings of length $|X|$ with coordinates indexed by $i \in X$. For $x \in \{0,1\}^n$ and $X \subseteq [n]$ we write $x_X \in \{0,1\}^X$ to denote the projection of x over coordinates in X. We denote by 1_X and 0_X the all-one and all-zero strings in $\{0,1\}^X$, respectively. When y is a variable then $z = (y)_X$ is the all y string with coordinates indexed by $i \in X$, i.e., $z_i = y$ for all $i \in X$. When we write $x_I = 0$ we mean $x_I = 0_I$. For $X_1, X_2 \subseteq [n]$ where $X_1 \cap X_2 = \emptyset$ and $x \in \{0,1\}^{X_1}, y \in \{0,1\}^{X_2}$ we write $x \circ y$ to denote their concatenation, i.e., the string in $\{0,1\}^{X_1 \cup X_2}$ that agrees with x over coordinates in X_1 and agrees with y over coordinates in X_2. For $X \subseteq [n]$ we denote $\overline{X} = [n] \backslash X = \{x \in [n] | x \notin X\}$. For a function $f : \{0,1\}^k \to \{0,1\}$, $x \in \{0,1\}^n$ and $X = \{i_1, \ldots, i_k\} \subseteq [n]$ where $i_1 < i_2 < \cdots < i_k$, when we write $f(x_X)$ we mean $f(x_{i_1}, \ldots, x_{i_k})$.

Given $f, g : \{0,1\}^n \to \{0,1\}$ and a probability distribution $\mathcal{D}$ over $\{0,1\}^n$, we say that f is *ϵ-close to g with respect to $\mathcal{D}$* if $\mathbf{Pr}_{x \in \mathcal{D}}[f(x) \neq g(x)] \leq \epsilon$, where $x \in \mathcal{D}$ means x is chosen from $\{0,1\}^n$ according to the distribution $\mathcal{D}$. We say that f is *ϵ-far from g with respect to $\mathcal{D}$* if $\mathbf{Pr}_{x \in \mathcal{D}}[f(x) \neq g(x)] \geq \epsilon$. For a class of Boolean functions C, we say that f is *ϵ-far from every function in C with respect to $\mathcal{D}$* if for every $g \in C$, f is ϵ-far from g with respect to $\mathcal{D}$. We will use U to denote the uniform distribution over $\{0,1\}^n$ or over $\{0,1\}^X$ when X in clear from the context.

For a distribution $\mathcal{D}$ over $\{0,1\}^n$ and $X \subset [n]$, we denote by $\mathcal{D}_X$ the distribution $\mathcal{D}$ projected on the coordinates X. That is, the distribution of x_X when $x \in \mathcal{D}$.

For a Boolean function f and $X \subset [n]$, we say that X is an *influential set* of f if there are $a, b \in \{0,1\}^n$ such that $f(a) \neq f(b_X \circ a_{\overline{X}})$. We call the pair (a, b) (or just a when $b = 0$) a *witness* of f for the influential set X. When $X = \{i\}$ then we say that x_i is an *influential variable* of f and a is *a witness* of f for x_i. Obviously, if X is influential set of f then $x(X)$ contains at least one influential variable of f.

We say that the Boolean function $f : \{0,1\}^n \to \{0,1\}$ is a *literal* (*dictatorship* and *anti-dictatorship*, resp.) if $f \in \{x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}\}$ where $\overline{x}$ is the negation of x ($f \in \{x_1, \ldots, x_n\}$ and $f \in \{\overline{x_1}, \ldots, \overline{x_n}\}$, resp.).

Let C be a class of Boolean functions $f : \{0,1\}^n \to \{0,1\}$. We say that C is *symmetric* if for every permutation $\pi : [n] \to [n]$ and every $f \in C$ we have $f_\pi \in C$ where $f_\pi(x) := f(x_{\pi(1)}, \cdots, x_{\pi(n)})$. We say that C is *closed under zero projection* (resp. *closed under one projection*) if for every $f \in C$ and every $i \in [n]$, $f(0_{\{i\}} \circ x_{\overline{\{i\}}}) \in C$ (resp. $f(1_{\{i\}} \circ x_{\overline{\{i\}}}) \in C$). We say it is closed under zero-one projection if is closed under zero and one projection.

Table 1 A table of the results. In the table, $\tilde{O}(T)$ stands for $O(T \cdot poly(\log T))$, U and D stand for uniform and distribution-free models, resp., and Exp and Poly stand for exponential and polynomial time, resp.

2 Overview of the Distribution-Free Tester

2.1 Preface

Our approach refers to testing properties that are (symmetric) sub-classes C of k-juntas; that is, $f : \{0,1\}^n \to \{0,1\}$ has the property if there exists a function $f' : \{0,1\}^k \to \{0,1\}$ that belongs to a predetermined class C' of functions (over k-bit strings) such that $f(x) = f'(x_\Gamma)$

for some k-subset Γ. Our new approach builds upon the "testing by implicit sampling" approach of Diakonikolas et al. [24], while extending it from the case of uniform distribution to the case of arbitrary unknown distributions (i.e., the distribution-free model).

This allows us to present (almost optimal) *distribution-free* testers for classes of properties that are sub-classes of k-juntas, which correspond to classes of k-bit long Boolean functions.

While we follow Diakonikolas et al. [24] in considering learning algorithms for the underlying classes, our approach is also applicable to testing algorithms (see [30, Sec. 6.2]).

Let us again spell out our task. For a class C of n-bit long Boolean functions and a proximity parameter ϵ, given samples from an unknown distribution $\mathcal{D}$ and oracle access to a function $f : \{0,1\}^n \to \{0,1\}$, we wish to distinguish the case that $f \in C$ from the case that f is ϵ-far from C. Recall that C is a (symmetric) class consisting of a symmetric subclass of k-juntas C'; that is, $f \in C$ if and only if there exists a k-subset $\Gamma \subset [n]$ and $f' \in C'$ such that $f(x) = f'(x_\Gamma)$, where $x_{\{i_1,\ldots,i_k\}} = (x_{i_1}, \ldots, x_{i_k})$. Actually, we also assume that C' is closed under zero projection.

2.2 A Bird's Eye View

The basic strategy is to consider a random partition of $[n]$ to $r = O(k^2)$ parts, denoted $(X_1, \ldots, X_r)$, while relying on the fact that, whp, each X_i contains at most one influential variable. Assuming that $f \in C$, first we determine a set I of at most k indices such that $\cup_{i\in[n]\setminus I} X_i$ contains no "significantly influential" variables of f. Suppose that $f' : \{0,1\}^k \to \{0,1\}$, $f' \in C'$, is a function that corresponds to the tested function $f : \{0,1\}^n \to \{0,1\}$, and that $I \subset [n]$ is indeed the collection of all sets that contain influential variables. The crucial ingredient is devising a method that allows to generate samples of the form $(x', f'(x'))$, when given samples of the form $(x, f(x))$ (for $x \in \mathcal{D}$). We stress that we cannot afford to find the influential variables, and so this method works without determining these locations. Using this method, we can test whether f' belongs to the underlying class C'; hence, we test f by implicitly sampling the projection of $\mathcal{D}$ on the (unknown) influential variables.

The method employed by Diakonikolas et al. [24] only handles the uniform distribution (i.e., the case that $\mathcal{D}$ is uniform over $\{0,1\}^n$), and so it only yields testers for the standard testing model (rather than for the distribution-free testing model). Furthermore, their method as well as the identification of the set I rely heavily on the notion of influence of sets, where the influence of a set S of locations on the value of a function is defined as $\Pr_{x',x''\in\{0,1\}^n : x'_S = x''_S}[f(x') \neq f(x'')]$. However, this notion refers to the uniform distribution (over $\{0,1\}^n$) and does not seem adequate for the distribution-free context (e.g., for[1] $f(x) = x_1 + x_2$ we may get $\Pr_{x',x''\in\mathcal{D} : x'_1 = x''_1}[f(x') \neq f(x'')] = 0$).

We use a different way of identifying the set I and for generating samples for the underlying function f'. Loosely speaking, we identifies I as the set of indices i for which $f(1_{X_i} \circ 0_{\overline{X_i}}) \neq f(0^n)$, where (recall that) $1_S \circ 0_{\overline{S}}$ is a string that is 1 on the locations in S and is 0 on other locations. (*Be warned that this description is an over-simplification*!) This means that for every $i \in I$ and $x \in \{0,1\}^n$, the value of x at the influential variable in the set X_i (a variable whose location is unknown to us!), equals $f(x') + f(0^n)$ where $x' = x_{X_i} \circ 0_{\overline{X}_i}$, i.e., $x'_j = x_j$ if $j \in X_i$ and $x'_j = 0$ otherwise.[2] Note that the foregoing holds when $f \in C$; in

[1] The addition operation in this paper is over the binary field F_2.

[2] Indeed, if $\tau(i) \in X_i$ is the index of the (unique) influential variable that resides in the set X_i, then

$$f(x') = x_{\tau(i)} \cdot f(1_{X_i} \circ 0_{\overline{X_i}}) + (x_{\tau(i)} + 1) \cdot f(0^n) = x_{\tau(i)} + f(0^n)$$

since $f(1_{X_i} \circ 0_{\overline{X_i}}) + f(0^n) = 1$.

general, we can test whether $x \mapsto f(x') + f(0^n)$ is close to a dictatorship (under the uniform distribution) and reject otherwise, whereas if the mapping is close to a dictatorship, we can self-correct it.

To sample the distribution $\mathcal{D}_\Gamma$, where Γ is the influential variables in $X_I = \cup_{i\in I} X_i$, we sample $\mathcal{D}$ and determine the value of the influential variable in each set X_i, for $i \in I$. Queries to the function f' are answered by querying f such that the query $y = y_1 \cdots y_k$ is mapped to the query $\texttt{ext}(y)$ such that[3] $\texttt{ext}(y)_j = y_i$ if j belongs to the i^{th} set in the collection I (and $\texttt{ext}(y)_j = 0$ if $j \in [n] \setminus X_I$). Effectively, we query the function $F : \{0,1\}^n \to \{0,1\}$ defined as $F(x) = f(\texttt{ext}(x_\Gamma))$, and this makes sense provided that F is close to f (under the distribution $\mathcal{D}$). To test the latter hypothesis condition, we sample $\mathcal{D}$ and for each sample point x we compare $f(x)$ to $F(x)$, where here we again use the ability to determine the value of the influential variable in each set. Specifically, $\texttt{ext}(x_\Gamma)$ is computed by determining the value of x_Γ (without knowing Γ), and using our knowledge of $(X_i)_{i\in I}$.

We warn that the foregoing description presumes that we have correctly identified the collection I of all sets containing an influential variable. This leaves us with two questions: The first question is, how do we identify the set I. (Note that the influence of a variable may be as low as 2^{-k}, whereas we seek algorithms of poly(k)-complexity.) The solution (to be presented in Section 2.3.1) will be randomized, and will have one-sided error; specifically, we may fail to identify some sets that contain influential variables, but will never include in our collection sets that have no influential variables. Consequently, $f(1_{X_i} \circ 0_{\overline{X_i}}) \neq f(0^n)$ may not hold for some $i \in I$, and (over-simplifying again) we shall seek instead some $v^{(i)} \in \{0,1\}^n$ such that $f(v^{(i)}) \neq f(w^{(i)})$, where $w^{(i)} = v^{(i)}_{X_i} \circ 0_{X_i}$ (i.e., $w^{(i)}_j = v^{(i)}_j$ if $j \in [n] \setminus X_i$ and $w^{(i)}_j = 0$ otherwise). Second, as before, for every $i \in I$ and $x \in \{0,1\}^n$, we wish to determine the value in x of the influential variable in the set X_i (a variable whose location is unknown to us!). This is done by observing that if $f \in C$ then this value equals $f(x') + f(v^{(i)}) + 1$ where $x' = x_{X_j} \circ v^{(i)}_{\overline{X_j}}$ (i.e., $x'_j = x_j$ if $j \in X_i$ and $x'_j = v^{(i)}_j$ otherwise).[4] Again, we need to test whether $x \mapsto f(x') + f(v^{(i)}) + 1$ is a dictatorship, and use self-correction.

2.3 The Actual Tester

As warned, the above description is an over-simplification, and the actual way in which the set I is identified and used is more complex.

We fix a random partition of $[n]$ to $r = O(k^2)$ parts, denoted $(X_1, \ldots, X_r)$. If $f \in C$, then, with high probability, each X_i contains at most one influential variable, denoted $\tau(i)$. We assume that this is the case when providing intuition throughout this section.

2.3.1 Stage 1: Finding I and corresponding $v^{(i)}$

Our goal is to find a collection I of at most k sets such that the function h_I is $\epsilon/3$-close to f (w.r.t distribution $\mathcal{D}$), where h_I is defined as $h_I(x) = f(x_{X_I} \circ 0_{\overline{X_I}})$ and $X_I = \cup_{i\in I} X_i$. In addition, for each $i \in I$, we seek a witness $v^{(i)}$ for the fact that f depends on some variable in X_i; that is, $f(v^{(i)}) \neq f(w^{(i)})$ for some $v^{(i)}$ that differ from $w^{(i)}$ only on X_i.

---

[3] Notice that $\texttt{ext}(y) = 0_{\overline{X_I}} \circ \left(\underset{i\in I}{\circ} (y_i)_{X_i} \right)$ - Here $(y)_X = 1_X$ if $y = 1$ and 0_X if $y = 0$.

[4] Indeed, if $\tau(i) \in X_i$ is the index of the (unique) influential variable that resides in the set X_i, then

$$f(x') = x_{\tau(i)} \cdot f(v^{(i)}) + (x_{\tau(i)} + 1) \cdot f(w^{(i)}) = x_{\tau(i)} + f(v^{(i)}) + 1$$

since $f(v^{(i)}) + f(w^{(i)}) = 1$.

The procedure

We proceed in iterations, starting with $I = \emptyset$.

1. We sample $\mathcal{D}$ for $O(1/\epsilon)$ times, trying to find $u \in \mathcal{D}$ such that $f(u) \neq h_I(u)$.
   (Note that if $I = \emptyset$, then $h_I(u) = f(0^n)$. In general, we seek u such that $f(u) \neq f(u_{X_I} \circ 0_{\overline{X_I}})$.
   If no such u is found, then we set $h = h_I$ and proceed to Stage 2. In this case, we may assume that h_I is $\epsilon/3$-close to f (w.r.t $\mathcal{D}$).
2. Otherwise (i.e., $f(u) \neq h_I(u)$), we find an $i \in [m] \setminus I$ and $v^{(i)}$ such that $h_I(v^{(i)}) \neq h_{I\cup\{i\}}(v^{(i)})$, which means that X_i contains an influential variable and $v^{(i)}$ is the witness for the sensitivity that we seek. We set $I \leftarrow I \cup \{i\}$ and proceed to the next iteration.
   (We find this i by binary search that seeks i and S such that $h_{I\cup S\cup\{i\}}(u) \neq h_{I\cup S}(u)$, which means that $v^{(i)}$ equals u in locations outside S and is zero on S.)[5]

Once the iterations are suspended (due to not finding u), we reject if $|I| > k$, and continue to the Stage 2 otherwise. Recall that in the latter case $h = h_I$ is $\epsilon/3$-close to f (w.r.t $\mathcal{D}$).

Note that if $f \in C$, then I contains only sets that contain variables of the k-junta, and so we never reject in this stage. In general, if $i \in I$, then $h_{I\setminus\{i\}}(v^{(i)}) \neq h_I(v^{(i)})$, which implies that $f(x') \neq f(x'')$, where x' and x'' differ only on X_i (e.g., $x''_{X_I} = v^{(i)}_{X_I}$ and $x''_j = 0$ if $j \notin X_I$).

2.3.2 Stage 2: Extracting the value of an influential variable

Given a collection I as found in Stage 1 (and a sensitivity witness $v^{(i)}$ for each $i \in I$), let $h = h_I$ and recall that h is close to f w.r.t $\mathcal{D}$. For each $i \in I$, given $x \in \{0,1\}^n$, we wish to determine the value of x at the influential variable that resides in X_i.

For each $i \in I$, we define $\nu_i : \{0,1\}^{|X_i|} \to \{0,1\}$ such that $\nu_i(z) = h_I(y)$, where $y_{X_i} = z$ and $y_{\overline{X_i}} = v^{(i)}_{\overline{X_i}}$. Suppose that $f \in C$, and recall that $\tau(i) \in X_i$ denotes the location of the influential variable in X_i. Let $\sigma(i)$ denote the index of $\tau(i)$ in X_i (i.e., the $\sigma(i)^{\text{th}}$ element of X_i is $\tau(i)$). Then, in this case, ν_i is either a dictatorship or an anti-dictatorship. In particular, if ν_i is a dictatorship, then $\nu_i(z) = z_{\sigma(i)}$ (and otherwise $\nu_i(z) = z_{\sigma(i)} + 1$).

For each $i \in I$, we test whether ν_i is a dictatorship or anti-dictatorship, where testing is w.r.t the uniform distribution over $\{0,1\}^{|X_i|}$. Note that we also check whether ν_i is a dictatorship or anti-dictatorship. If the tester (run with proximity parameter 0.1) fails, we reject. Otherwise (i.e., if we did not reject), we can compute ν_i via self-correction on h_I; that is, to compute ν_i at z, we select $u \in \{0,1\}^{|X_i|}$ at random, and return $\nu_i(z+u) + \nu_i(u)$, which (w.h.p.) equals $(z+u)_{\sigma(i)} + u_{\sigma(i)} = z_{\sigma(i)}$.

Hence, we always continue to Stage 3 if $f \in C$, and whenever we continue to Stage 3 we can compute all ν_i (for $i \in I$) via self-correction.

2.3.3 Stage 3: Emulating a tester of C'

Recall that when reaching this stage, we may assume that $h = h_I$ is $\epsilon/3$-close to f (w.r.t $\mathcal{D}$). Also recall that $h_I(x)$ depends only on x_{X_I}, where $X_I = \cup_{i\in I} X_i$, and that by Stage 2 we may assume that $\nu_i(z) = z_{\sigma(i)}$ (for every $i \in I$ and almost all z). In light of the forgoing, we define $F : \{0,1\}^n \to \{0,1\}$ such that $F(x) = h(x')$ where $x'_{X_i} = (x_{\sigma(i)}, \ldots, x_{\sigma(i)})$ (i.e.,

[5] By Step 1, we have $h_{S'\cup I}(u) \neq h_{S''\cup I}(u)$, for $S' = [n] \setminus I$ and $S'' = \emptyset$, and in each iteration we cut $S' \setminus S''$ by half while maintaining $h_{S'\cup I}(u) \neq h_{S''\cup I}(u)$.

$x'_j = (x_{X_i})_{\sigma(i)} = x_{\tau(i)}$ if $j \in X_i$)[6] and $x'_j = 0$ otherwise. (Indeed, if $f \in C$, then $F(x) = h(x)$, since $h(y)$ depends only on $(y_{\tau(i)})_{i \in I}$. Using hypothesis that C' (and so C) is closed under zero projection, it follows that $F \in C$.)

We observe that if F is $\epsilon/3$-close (w.r.t $\mathcal{D}$) to both h and C, then f must be ϵ-close to C (since f is $\epsilon/3$-close to h). Hence, we test both these conditions. Specifically, using our ability to sample $\mathcal{D}$, query f, and determine the value of the influential variables in X_I, we proceed as follows:

1. Test whether $F = h$, where testing is w.r.t the distribution $\mathcal{D}$ and proximity parameter $\epsilon/3$.

   This is done by taking $O(1/\epsilon)$ samples of $\mathcal{D}$, and comparing the values of F and h on these sample points. Recall that $h(u) = h_I(u) = f(u_{X_I} \circ 0_{\overline{X_I}})$.

   The value of F on u is determined as follows.

   a. For every $i \in I$, if ν_i is a dictatorship, then set v_i to equal the self-corrected value of $\nu_i(u_{X_i})$, where ν_i is as defined in Stage 2. Otherwise (i.e., when ν_i is an anti-dictatorship), we set v_i to equal the self-corrected value of $\nu_i(u_{X_i}) + 1$.

   b. Return the value $h(u')$, where $u'_j = v_i$ if $j \in X_i$ and $u'_j = 0$ otherwise.

   Indeed, $F = h$ always passes this test, whereas F that is $\epsilon/3$-far from h (w.r.t $\mathcal{D}$) is rejected w.h.p.
2. Test whether F is in C, where testing is w.r.t the distribution $\mathcal{D}$ and proximity parameter $\epsilon/3$. This is done by testing whether F' is in C, where $F'(z) = F(x)$ such that $x_j = z_i$ if j is in the i^{th} set in the collection I, and $x_j = 0$ otherwise. Here we use a distribution-free tester, and analyze it w.r.t the distribution $\mathcal{D}_I$. Toward this end, we need to samples $\mathcal{D}_I$ as well as answer queries to F', where both tasks can be performed as in the prior step. Recall that if $f \in C$, then $F \in C$, and this test will accept (w.h.p.), whereas if F is $\epsilon/3$-far from C the test will reject (w.h.p.).

We conclude that if we reached Stage 3 and $f \in C$ (resp., f is ϵ-far from C), then we accept (resp., reject) w.h.p.

2.4 Digest: Our approach vs the original one [24]

Our new approach differs from the original approach of Diakonikolas et al. [24] in two main aspects:

1. In [24], sets that contain influential variables are identified according to their influence, which is defined with respect to the uniform distribution. This definition seems inadequate when dealing with arbitrary distributions. Instead, we identify such a set by searching for two assignments that differ only on this set and yield different function values. The actual process is iterative and places additional constraints on these assignments (as detailed in Section 2.3.1).
2. In [24], given an assignment to the function, the value of the unique influential variable that resides in a given set S is determined by approximating the influence of two subsets of S (i.e., the subsets of locations assigned the value 0 and 1, respectively). In contrast, we determines this value by defining an auxiliary function, which depends on the unknown influential variable, and evaluating this function (via self-correction w.r.t the uniform distribution (!); see Section 2.3.2).

[6] In general, $\tau(i)$ denotes the location in $[n]$ of the $\sigma(i)^{\text{th}}$ element of X_i.

2.5 The Model

In this subsection, we define the testing and learning models.

In the testing model, we consider the problem of testing a Boolean function class C in the uniform and distribution-free testing models. In the distribution-free testing model (resp. uniform model), the algorithm has access to a Boolean function f via a black-box that returns $f(x)$ when a string x is queried. We call this query *membership query* (MQ_f or just MQ). The algorithm also has access to unknown distribution $\mathcal{D}$ (resp. uniform distribution) via an oracle that returns $x \in \{0,1\}^n$ chosen randomly according to the distribution $\mathcal{D}$ (resp. according to the uniform distribution). We call this query *example query* ($\mathrm{ExQ}_{\mathcal{D}}$ (resp. ExQ or ExQ_U)).

A *distribution-free testing algorithm*, [32], (resp. *testing algorithm*) $\mathcal{A}$ for C is an algorithm that, given as input a distance parameter ϵ and the above two oracles to a Boolean function f,

1. if $f \in C$ then $\mathcal{A}$ outputs "accept" with probability at least $2/3$.
2. if f is ϵ-far from every $g \in C$ with respect to the distribution $\mathcal{D}$ (resp. uniform distribution) then $\mathcal{A}$ outputs "reject" with probability at least $2/3$.

We will also call $\mathcal{A}$ *a tester (or ϵ-tester) for the class C* and an algorithm for *ϵ-testing C*.

We say that $\mathcal{A}$ is *one-sided* if it always accepts when $f \in C$; otherwise, it is called *two-sided* algorithm. The *query complexity of $\mathcal{A}$* is the maximum number of queries $\mathcal{A}$ makes on any Boolean function f.

In the learning models, C is a class of representations of Boolean functions rather than a class of Boolean functions. Therefore, we may have two different representations in C that are logically equivalent. In this paper, we assume that this representation is verifiable; that is, given a representation g, one can decide in polynomial time on the length of this representation if $g \in C$.

A *distribution-free proper learning algorithm* (resp. proper learning algorithm under the uniform distribution) $\mathcal{A}$ for C is an algorithm that, given as input an accuracy parameter ϵ, a confidence parameter δ and an access to both MQ_f for the *target function* $f \in C$ and $\mathrm{ExQ}_{\mathcal{D}}$, with unknown $\mathcal{D}$, (resp. ExQ or ExQ_U), with probability at least $1-\delta$, $\mathcal{A}$ returns $h \in C$ that is ϵ-close to f with respect to $\mathcal{D}$ (resp. with respect to the uniform distribution). This model is also called *proper PAC-learning with membership queries* under any distribution (resp. under the uniform distribution) [3, 48].

3 The Distribution-Free Tester

In this section, we sketch the proof of the tester from Section 2.

For a class C of n-bit long Boolean functions and a set $Y = \{y_1, \ldots, y_q\}$ we define $C^*(Y)$ the class of all q-bit long Boolean functions $f(y_1, \ldots, y_q) = g(y_1, \ldots, y_q, 0, \ldots, 0)$ where $g \in C$. We define $C(Y) \subseteq C^*(Y)$ the class of $f \in C(Y)$ that depends on all the variables in Y. That is, all the variables in Y are influential.

Our main result is

▶ **Theorem 1.** *Let C be a class of n-bit long Boolean functions that is symmetric subclass of k-Junta and is closed under zero projection. Suppose for every $Y = \{y_1, \ldots, y_q\}$ with $q \leq k$, there is a tester T_Y for q-bit Boolean function F such that*

1. *T_Y is a polynomial time two-sided distribution-free (resp. uniform-distribution) adaptive ϵ-tester*
2. *If $F \in C(Y)$ then, with probability at least $1-\delta$, T_Y accepts.*

3. *If F is ϵ-far from every function in $C^*(Y)$ w.r.t $\mathcal{D}$ then, with probability at least $1-\delta$, T_Y rejects.*
4. *T_Y makes $M(\epsilon,\delta)$ MQs and $Q(\epsilon,\delta)$ $ExQ_{\mathcal{D}}$ (resp. ExQ_U).*

Then

1. *There is a polynomial time two-sided distribution-free adaptive algorithm for ϵ-testing C that makes*

$$\tilde{O}\left(M(\epsilon/12,1/24)+kQ(\epsilon/12,1/24)+\frac{k}{\epsilon}\right)$$

   queries.
2. *(resp. There is a polynomial time two-sided uniform-distribution adaptive algorithm for ϵ-testing C that makes*

$$\tilde{O}\left(M(\epsilon/12,1/24)+Q(\epsilon/12,1/24)+\frac{k}{\epsilon}\right)$$

   queries.)

Using Goldreich et. al [32], reduction of testing to proper learning we get

▶ **Theorem 2.** *Let C be a class of n-bit long Boolean functions that is symmetric subclass of k-Junta and is closed under zero projection. Suppose for every $Y=\{y_1,\ldots,y_q\}$ with $q\le k$, there is a polynomial time proper learning algorithm that learns $C^*(Y)$ using $M(\epsilon,\delta)$ MQs and $Q(\epsilon,\delta)$ $ExQ_{\mathcal{D}}$s (resp. ExQ_Us). Then*

1. *There is a polynomial time two-sided distribution-free adaptive algorithm for ϵ-testing C that makes*

$$\tilde{O}\left(M(\epsilon/12,1/24)+kQ(\epsilon/12,1/24)+\frac{k}{\epsilon}\right)$$

   queries.
2. *(resp. There is a polynomial time two-sided uniform-distribution adaptive algorithm for ϵ-testing C that makes*

$$\tilde{O}\left(M(\epsilon/12,1/24)+Q(\epsilon/12,1/24)+\frac{k}{\epsilon}\right)$$

   queries.)

Before we give the proof sketch, we give some applications.

3.1 Some Applications

***k*-Junta:** For the class $C=k$-Junta, $C^*(Y)=q$-Junta and since f is q-bit Boolean function $f\in C^*(Y)$ and the tester T_Y can just returns accept. Then $M=Q=0$ and we get a distribution-free tester for k-Junta that makes $\tilde{O}(k/\epsilon)$.

***k*-Linear:** For the class $C=k$-Linear, the sum (over F_2) of at most k variables, we have $C(Y)=\{y_1+y_2+\cdots+y_q\}$. If f is ϵ-far from $C^*(Y)$ then it is ϵ-far from $y_1+y_2+\cdots,y_q$. We can distinguish between $g=y_1+y_2+\cdots+y_q$ and a function that is ϵ-far from g with $O(1/\epsilon)$ $\mathrm{ExQ}_{\mathcal{D}}$. Then $M=0$ and $Q=O(1/\epsilon)$. So we get a distribution-free tester for k-Linear that makes $O(k/\epsilon)$ queries.

***k*-Term:** For the class $C = k$-Term, the conjunction of at most k literals, we have $C(Y) = \{z_1 \wedge z_2 \wedge \cdots \wedge z_q \mid z_i \in \{y_i, \overline{y_i}\}\}$. The tester T_Y asks $O(1/\epsilon)$ $\mathrm{ExQ}_{\mathcal{D}}$. If for all the strings f is zero then the tester accept. Otherwise, there is a string a such that $f(a) = 1$. Then $z_i = y_i$ if $a_i = 1$ and $z_i = \overline{y_i}$ if $a_i = 0$. Then as above, it tests if f is ϵ-far from $z_1 \wedge z_2 \wedge \cdots \wedge z_q$ and we get a distribution-free tester for k-Term that makes $O(k/\epsilon)$ queries.

***s*-term monotone *r*-DNF:** For the class s-term monotone r-DNF (a DNF that contains at most s r-Terms), in the full paper, we give an algorithm that properly learns this class in polynomial time and makes $O(s/\epsilon)$ $\mathrm{ExD}_{\mathcal{D}}$ and $O(rs\log(ns))$ MQs. Since the number of influential variables in any s-term monotone r-DNF is at most sr we have $q \leq k = sr$. Therefore the class $C^*(Y)$ $(n = q \leq sr)$ can be properly learned using $O(s/\epsilon)$ $\mathrm{ExD}_{\mathcal{D}}$ and $O(rs\log(rs))$ MQs. By Theorem 2 we get

▶ **Theorem 3.** *For any $\epsilon > 0$, there is a polynomial time two-sided distribution-free adaptive algorithm for ϵ-testing s-Term Monotone r-DNF that makes $\tilde{O}(rs^2/\epsilon)$ queries.*

In the full paper, we also show that

▶ **Theorem 4.** *For any $\epsilon > 0$, there is a polynomial time two-sided distribution-free adaptive algorithm for ϵ-testing s-Term Unate[7] r-DNF that makes $\tilde{O}(rs^2/\epsilon)$ queries.*

3.2 Proof Sketch

Algorithm 1 A distribution-free tester for subclasses C of k-Junta.

Tester$C(f, \mathcal{D}, \epsilon)$
Input: Oracle that accesses a Boolean function f and $\mathcal{D}$.
Output: If any one of the procedures rejects
then "reject", otherwise, "accept"

1. $(X, V, I) \leftarrow$**ApproxTarget**$(f, \mathcal{D}, \epsilon, 1/3)$.
2. Define $h(x) = f(x_X \circ 0_{\overline{X}})$.
3. **TestSets**(h, X, V, I).
4. Define F
5. **Close**$fF(f, \mathcal{D}, \epsilon, 1/15)$
6. Run T_Y on F
7. Accept

We now sketch the proof of Theorem 1. See the full proof in [13]. The tester is **Tester**C in Algorithm 1. First, **Tester**C calls the procedure **ApproxTarget**, in Algorithm 2. This procedure executes the first stage of the tester. See Subsection 2.3.1. The reason that here the procedure is more complex is because, for learning classes of unate functions the procedure in Algorithm 1 returns witnesses for $h(x) = f(x_{X_I} \circ 0_{\overline{X_I}})$ and not for f (as in Subsection 2.3.1). So those witnesses also give us the unateness of each variable in the function. This is, for example, how we get the result in Theorem 4.

Throughout the paper we denote $X = X_I$ and $h(x) = f(x_X \circ 0_{\overline{X}})$. In [13] we prove the following. The proof sketch is in Subsection 2.3.1.

[7] The function f is unate if there is a such that $f(x + a)$ is monotone.

Algorithm 2 A procedure that finds influential sets $\{X_i\}_{i\in I}$ of f and a witness $v^{(i)}$ for each influential set X_i for $h := f(x_{X_I} \circ 0_{\overline{X_I}})$ where $X_I = \cup_{i\in I} X_i$. Also, whp, h is $(\epsilon/3)$-close to the target.

ApproxTarget$(f, \mathcal{D}, \epsilon, c)$
Input: Oracle that accesses a Boolean function f and
an oracle that draws $x \in \{0,1\}^n$ according to the distribution $\mathcal{D}$.
Output: Either "reject" or (X_I, V, I)

Partition $[n]$ **into** r **sets**
1. Set $r = 2k^2$.
2. Choose uniformly at random a partition $X_1, X_2, \ldots, X_r$ of $[n]$

Find a close function and influential sets
3. Set $X_I = \emptyset$; $I = \emptyset$; $V = \emptyset$; $t(X_I) = 0$.
4. Repeat $M = 3k\ln(15k)/\epsilon$ times
5. Choose $u \in \mathcal{D}$.
6. $t(X_I) \leftarrow t(X_I) + 1$
7. If $f(u_{X_I} \circ 0_{\overline{X_I}}) \neq f(u)$ then
8. $W \leftarrow \emptyset$.
9. $(\ell, w^{(\ell)}) \leftarrow$ Binary Search to find a new influential set X_ℓ using u and $u_{X_I} \circ 0_{\overline{X_I}}$ and a string
10. $w^{(\ell)} \in \{0,1\}^n$ such that $f(w^{(\ell)}) \neq f(w^{(\ell)}_{\overline{X_\ell}} \circ 0_{X_\ell})$;
11. $X_I \leftarrow X_I \cup X_\ell$; $I \leftarrow I \cup \{\ell\}$.
12. If $|I| > k$ then Output("reject").
13. $W = W \cup \{w^{(\ell)}\}$.
14. Choose $w^{(r)} \in W$.
15. If $f(w^{(r)}_{X_I} \circ 0_{\overline{X_I}}) \neq f(w^{(r)}_{X_I \setminus X_r} \circ 0_{\overline{X_I} \cup X_r})$ then $W \leftarrow W \setminus \{w^{(r)}\}$; $v^{(r)} \leftarrow w^{(r)}_{X_I} \circ 0_{\overline{X_I}}$; $V \leftarrow V \cup \{v^{(r)}\}$; If $W \neq \emptyset$ then Goto 14
16. Else If $f(w^{(r)}_{X_I} \circ 0_{\overline{X_I}}) \neq f(w^{(r)})$ then $u \leftarrow w^{(r)}$; Goto 9
17. Else $u \leftarrow w^{(r)}_{\overline{X_r}} \circ 0_{X_r}$; Goto 9
18. $t(X_I) = 0$.
19. If $t(X_I) = c\ln(15k)/\epsilon$ then Output(X_I, V, I).

▶ **Lemma 5.** *Consider steps 1-2 in the* ***ApproxTarget****. If f is a k-junta then, with probability at least $2/3$, for each $i \in [r]$, the set $x(X_i) = \{x_j | j \in X_i\}$ contains at most one influential variable of f.*

▶ **Lemma 6.** *If* ***ApproxTarget*** *does not reject then it outputs (X, V, I) that satisfies*
1. $q = |I| \leq k$.
2. *For every $\ell \in I$, $v^{(\ell)}_{\overline{X}} = 0$ and $f(v^{(\ell)}) \neq f(0_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$. That is, $v^{(\ell)} \in V$ is a witness of $h(x) = f(x_X \circ 0_{\overline{X}})$ for X_ℓ .*
3. *Each $x(X_\ell)$, $\ell \in I$, contains at least one influential variable of $h(x) = f(x_X \circ 0_{\overline{X}})$.*
4. *With probability at least $14/15$*

$$\boldsymbol{Pr}_{u\in\mathcal{D}}[h(x) \neq f(x)] \leq \epsilon/3.$$

▶ **Lemma 7.** *If f is k-junta and each $x(X_i)$ contains at most one influential variable of f then*

1. ***ApproxTarget*** *outputs (X, V, I).*
2. *Each $x(X_\ell)$, $\ell \in I$, contains exactly one influential variable in $h(x) = f(x_X \circ 0_{\overline{X}})$.*
3. *For every $\ell \in I$, $h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}}) = f(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is a literal.*

▶ **Lemma 8.** *The procedure **ApproxTarget** makes $O((k \log k)/\epsilon) = \tilde{O}(k/\epsilon)$ queries.*

The tester then defines $h(x) = f(x_X \circ 0_{\overline{X}})$. Now, since $\mathbf{Pr}_{u \in \mathcal{D}}[h(x) \neq f(x)] \leq \epsilon/3$ it is enough to distinguish between h is in C and h that is $(2\epsilon/3)$-far from every function in C with respect to $\mathcal{D}$.

The tester then moves to the second stage. See Subsection 2.3.2. First, it calls the procedure **TestSets**. See Algorithm 3 in Appendix A. The procedure tests if every $h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is close to a literal. In the procedure, $\mathbf{UniformJunta}(g, k, \epsilon, \delta)$ is Blais's uniform-distribution one-sided tester [7] for k-Junta. For $k = 1$ it tests whether g is a literal or constant function or ϵ-far from any literal and constant function with respect to the uniform distribution.

The following is very easy to prove

▶ **Lemma 9.** *We have*

1. *If h is k-junta and each $x(X_i)$ contains at most one influential variable of f then **TestSets** returns "OK".*
2. *If for some $\ell \in I$, $h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is $(1/30)$-far from every literal with respect to the uniform distribution then, with probability at least $1 - (1/15)$, **TestSets** rejects.*
3. *The procedure **TestSets** makes $O(k)$ queries.*

This test does not give $\tau(i)$ (the index of the influential variable in X_i) but the fact that $h(x_{X_i} \circ v^{(i)}_{\overline{X_i}})$ is close to $x_{\tau(i)}$ or $\overline{x_{\tau(i)}}$ can be used to find the value of $u_{\tau(i)}$ in every assignment $u \in \{0,1\}^n$ without knowing $\tau(i)$. The latter is done, whp, by the procedure **RelVarValues** that uses self-correction. See Algorithm 4 in Appendix A. We have

▶ **Lemma 10.** *We have*

1. *If h is k-Junta and each $x(X_i)$ contains at most one influential variable of h then **RelVarValues** outputs z such that $z_\ell = w_{\tau(\ell)}$ where $h(x_{X_\ell} \circ 0_{\overline{X_\ell}}) \in \{x_{\tau(\ell)}, \overline{x_{\tau(\ell)}}\}$.*
2. *If for every $\ell \in I$ the function $h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is $(1/30)$-close to a literal in $\{x_{\tau(\ell)}, \bar{x}_{\tau(\ell)}\}$ with respect to the uniform distribution, where $\tau(\ell) \in X_\ell$, and **RelVarValues** does not reject then, with probability at least $1 - \delta$, we have: For every $\ell \in I$, $z_\ell = w_{\tau(\ell)}$.*
3. *The procedure **RelVarValues** makes $O(k \log(k/\delta))$ queries.*

Proof. Since $\nu_i(x) = h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is $(1/30)$-close to a literal in $\{x_{\tau(\ell)}, \bar{x}_{\tau(\ell)}\}$ we have that for a uniform random string z, with probability at least $1/15$ we have $\nu(x + z) + \nu(z) = x_{\tau(\ell)}$. If we repeat this test $O(\log(k/\delta))$ times for every $\ell \in I$, we get a success probability $1 - \delta$. Since $|I| \leq k$, **RelVarValues** makes $O(k \log(k/\delta))$ queries. ◀

We collect all the above events that happens with high probability in the following

▶ **Assumption 11.** *For the rest of this section we assume*

1. *If $f \in C$ then*
   - *$h(x) = f(x_X \circ 0_{\overline{X}}) \in C$.*
   - *Each $x(X_\ell)$, $\ell \in I$ contains exactly one influential variable.*
   - *For every $\ell \in I$, $f(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is a literal in $\{x_{\tau(\ell)}, \overline{x_{\tau(\ell)}}\}$.*

2. *If f is ϵ-far from every function in C then*
   - *$h(x) = f(x_X \circ 0_{\overline{X}})$ is $(\epsilon/3)$-close to f with respect to $\mathcal{D}$ and therefore $h(x)$ is $(2\epsilon/3)$-far from every function in C with respect to $\mathcal{D}$.*
   - *For every $\ell \in I$, $f(x_{X_\ell} \circ v_{\overline{X_\ell}}^{(\ell)})$ is $(1/30)$-close to a literal in $\{x_{\tau(\ell)}, \bar{x}_{\tau(\ell)}\}$ with respect to the uniform distribution.*
3. *For any u, we can get $(u_{\tau(\ell)})_{\ell \in I}$ using $\tilde{O}(k)$ queries.*

We are getting now to the third stage. See Subsection 2.3.3. For a function $f \in C$ we define $\mathrm{Rel}(f)$, the set of all influential variables of f. Let $q = |I|$ and $\Gamma := \{\tau(\ell_1), \ldots, \tau(\ell_q)\}$. Notice that, with the above assumption, if $h \in C$ then $\mathrm{Rel}(h) = \Gamma$. We define the class $C(\Gamma)$ (resp. $C^*(\Gamma)$), the set of functions in C with $\mathrm{Rel}(f) = \{x_\gamma \mid \gamma \in \Gamma\}$ (resp. $\mathrm{Rel}(f) \subseteq \{x_\gamma \mid \gamma \in \Gamma\}$). Since C is symmetric and closed under zero projection $C(\Gamma)$ (resp. $C^*(\Gamma)$) is the set of all functions $f(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)}, 0, 0, \ldots, 0)$ where $f \in C$ and $\mathrm{Rel}(f) = \{x_1, \ldots, x_q\}$ (resp $\mathrm{Rel}(f) \subseteq \{x_1, \ldots, x_q\}$). We recall that, for $Y = \{y_1, \ldots, y_q\}$, $C(Y)$ (resp. $C^*(Y)$) are the set of all functions $f(y_1, \ldots, y_q, 0, 0, \ldots, 0)$ where $f \in C$ and $\mathrm{Rel}(f) = \{x_1, \ldots, x_q\}$ (resp. $\mathrm{Rel}(f) \subseteq \{x_1, \ldots, x_q\}$).

Let $F(y_1, \ldots, y_q) = h(z)(= f(z))$ where $z = (y_1)_{X_{\ell_1}} \circ \cdots \circ (y_q)_{X_{\ell_q}} \circ 0_{\overline{X}}$. That is, for every $\ell_i \in I$, $j \in X_{\ell_i}$ we have $z_j = y_i$ and for every $j \in \overline{X}$ we have $z_j = 0$. Then, by Assumption 11, it is easy to prove that (see Subsection 2.3.3)

▶ **Lemma 12.** *We have*

1. *If $h \in C$ then $F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)}) = h$.*
2. *If $h \in C$ then $F(y_1, \ldots, y_q) \in C(Y)$.*
3. *If h is $2\epsilon/3$-far from every function in C with respect to D then either*
   a. *h is $\epsilon/3$-far from $F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)})$ with respect to $\mathcal{D}$,*
   or,
   b. *$F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)})$ is $\epsilon/3$-far from every function in C with respect to $\mathcal{D}$.*

Therefore, we need to do two tests. The first is to distinguish between $h = F$ and h that is $\epsilon/3$-far from F w.r.t $\mathcal{D}$. The second is to distinguish between $F \in C$ and F that is $\epsilon/3$-far from every function in C w.r.t $\mathcal{D}$.

The following result shows that we can query $F(y_1, \ldots, y_q)$ and for every $x \in \{0,1\}^n$ we can extract x_Γ. So, in particular, we can get a sample according to $\mathcal{D}_\Gamma$ and query $F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)})$. The proof is immediate (See Appendix A)

▶ **Lemma 13.** *For the function F we have*

1. *Given $(y_1, \ldots, y_q)$, computing $F(y_1, \ldots, y_q)$ can be done with one query to f.*
2. *Given $x \in \{0,1\}^n$ and δ, there is an algorithm that makes $O(k \log(k/\delta))$ queries and, with probability at least $1 - \delta$, either discovers that $f \notin C$ and then reject or computes $x_\Gamma = (x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)})$ and $F(x_\Gamma)$.*
3. *There is a polynomial time algorithm that makes $O(k \log(k/\delta))$ queries and with probability at least $1 - \delta$ returns a string u in $\{0,1\}^q$ according to the distribution $\mathcal{D}_\Gamma$ and $F(u)$.*
4. *There is a polynomial time algorithm that makes one query and returns a string u in $\{0,1\}^q$ according to the uniform distribution and $F(u)$.*

We now give the procedure **Close**fF that tests whether $h(x) = f(x_X \circ 0_{\overline{X}})$ is $(\epsilon/3)$-far from F with respect to $\mathcal{D}$. See Algorithm 5 and the proof in Appendix A.

▶ **Lemma 14.** *For any ϵ, a constant δ, and (X, V, I) that satisfies Assumption 11, procedure **Close**fF makes $O((k/\epsilon)\log(k/\epsilon)) = \tilde{O}(k/\epsilon)$ queries and*

1. *If $f \in C$ then **Close**fF returns OK.*
2. *If $h(x)$ is $(\epsilon/3)$-far from F with respect to $\mathcal{D}$ then, with probability at least $1-\delta$, **Close**fF rejects.*

The second test is to distinguish between $F \in C$ and F that is $\epsilon/3$-far from C w.r.t the distribution $\mathcal{D}$.

Consider the tester T_Y in Theorem 1. If $h(x) = F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)}) \in C$ then, by Assumption 11, since each $x(X_\ell)$, $\ell \in I$, contains exactly one influential variable, $F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)}) \in C(\Gamma)$. Therefore $F = F(y_1, \ldots, y_q) \in C(Y)$. If $F(x_{\tau(\ell_1)}, \ldots, x_{\tau(\ell_q)})$ is $\epsilon/3$-far from every function in C w.r.t $\mathcal{D}$, then it is $\epsilon/3$-far from every function in $C^*(\Gamma)$ w.r.t $\mathcal{D}_\Gamma$. Therefore, $F = F(y_1, \ldots, y_q)$ is $\epsilon/3$-far from every function in $C^*(Y)$ w.r.t $\mathcal{D}_\Gamma$. Therefore, T_Y can be used for the second test of $F(x_\Gamma) \in C$ vs. $\epsilon/3$ far from every function in C.

Now by, Lemma 13, every MQ to F can be simulated with one MQ to f and every $\mathrm{ExQ}_{\mathcal{D}_\Gamma}$ can be simulated with $O(k \log(k/\delta'))$ $\mathrm{ExQ}_{\mathcal{D}}$ queries and have success probability $1-\delta'$. Since T_Y asks $Q(\epsilon, \delta)$ queries, we need $O(k \log(kQ(\epsilon, \delta)/\delta))$ $\mathrm{ExQ}_{\mathcal{D}}$ to have success $1-\delta$ for all the queries. When $\mathcal{D}$ is uniform then, by Lemma 13, every ExQ_{U_Γ} can be simulated with one query to MQ.

Notice that the success probability in all the procedures above is $1-\delta$ for any constant δ. By choosing $\delta = 1/20$ for each procedure, we get a tester with confidence of at least $2/3$. By Lemmas 8, 9 and the above analysis the query complexity of the tester is as stated in Theorem 1.

4 The Second Tester: Uniform-Distribution Tester for Classes that are Close to k-Junta w.r.t the Uniform Distribution

The second tester in this paper tests classes that are close to k-Junta w.r.t the uniform distribution, that is, for every $f \in C$ and every ϵ, there is k such that every function in C is ϵ-close to some function in k-Junta.

To understand the intuition behind the second tester, we demonstrate it for testing s-term DNF, the class of DNF with at most s terms. This class is close to $(s \log(s/\epsilon))$-Junta. This is because, for every s-term DNF and every ϵ, the function g that results by removing the terms of size greater than or equal to $\log(s/\epsilon)$ in f is ϵ-close to f and $g \in (s \log(s/\epsilon))$-Junta.

Let f be an s-term DNF. Since, for ϵ-testing, the variables that are influential in f are variables in terms of size $d = O(\log(s/\epsilon))$, there are at most $k = sd = O(s \log(s/\epsilon))$ influential variables in f. Suppose we uniformly at random distribute the variables of f into $r = 10k$ bins $X_1, \ldots, X_r$. The influential variables falls into at most k bins. We call those bins influential bins. Terms in f of size greater than d, with high probability, $d/2$ of their variables falls into the uninfluential bins.

We try as before to find the influential bins, but this time, we use uniform random strings in our search. This is because, when we use uniform random strings, with high probability, all the large terms in f are equal zero for those strings, and therefore, no uninfluential bin is found by the search procedure.

We find enough influential bins such that if we substitute a random assignment in the variables of the uninfluential bins, w.h.p., we get a function H that is $\epsilon/4$-close to f. The next key idea is: as we said before, if we have a large term in f, then with high probability, many of its variables fall into the uninfluential bins. So when we substitute a random assignment for the variables in the uninfluential bins, with high probability, the large terms in f vanish in H. Therefore, with high probability, H is $\epsilon/4$ close to f and contains small terms (terms of size at most $d = O(\log(s/\epsilon))$. Since H is s-term d-DNF, it is a function in sd-Junta, and we can use the first tester to test H.

See more details in Appendix B.

A The Procedures of the First Tester

Proof of Lemma 13.

Proof. *1* is immediate since $F(y_1,\ldots,y_q) = f(z)$ where $z = (y_1)_{X_{\ell_1}} \circ \cdots \circ (y_q)_{X_{\ell_q}} \circ 0_{\overline{X}}$. To prove *2*. We run **RelVarValues**(x, X, V, I, δ). If it rejects then, by Lemma 10, $f \notin C$. Otherwise, by Lemma 10, with probability at least $1-\delta$, the procedure outputs z where for every ℓ, $z_\ell = x_{\tau(\ell)}$. Then using *1* we compute $F(z)$. Since by Lemma 10, **RelVarValue** makes $O(k\log(k/\delta))$ queries, the result follows. Now 3 and 4 follows immediately from 1 and 2. ◀

Algorithm 3 A procedure that tests if for all $\ell \in I$, $h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}})$ is (1/30)-close to some literal with respect to the uniform distribution.

TestSets(h, X, V, I)
Input: Oracle that accesses a Boolean function f and (X, V, I).
Output: Either "reject" or "OK"

1. For every $\ell \in I$ do
2. If **UniformJunta**$(h(x_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}}), 1, 1/30, 1/15)$="reject"
3. then Output("reject")
4. Choose $b \in \{0,1\}^n$ uniformly at random
5. If $h(b_{X_\ell} \circ v^{(\ell)}_{\overline{X_\ell}}) = h(\overline{b_{X_\ell}} \circ v^{(\ell)}_{\overline{X_\ell}})$ then Output("reject")
6. Return "OK"

Algorithm 4 A procedure that takes as input (X, V, I) and a string $w \in \{0,1\}^n$ and, with probability at least $1 - \delta$, returns the values of $w_{\tau(i)}$, $i \in I$, where $h(x_{X_i} \circ v^{(i)}_{\overline{X_i}})$ is (1/30)-close to one of the literals in $\{x_{\tau(i)}, \overline{x_{\tau(i)}}\}$ with respect to the uniform distribution.

RelVarValues(w, X, V, I, δ)
Input: Oracle that accesses a Boolean function h, (X, V, I) and $w \in \{0,1\}^n$.
Output: Either "reject" or returns for every $\ell \in I$, the value, $z_\ell = w_{\tau(\ell)}$ where $x_{\tau(\ell)}$ is one of the influential variables of $h(x_X \circ 0_{\overline{X}})$ in $x(X_\ell)$

1. For every $\ell \in I$ do
2. For $\xi \in \{0,1\}$ set $Y_{\ell,\xi} = \{j \in X_\ell | w_j = \xi\}$.
3. Set $G_{\ell,0} = G_{\ell,1} = 0$;
4. Repeat $t = \ln(k/\delta)/\ln(4/3)$ times
5. Choose $b \in \{0,1\}^n$ uniformly at random;
6. If $h(b_{Y_{\ell,0}} \circ b_{Y_{\ell,1}} \circ v^{(\ell)}_{\overline{X_\ell}}) \neq h(\overline{b_{Y_{\ell,0}}} \circ b_{Y_{\ell,1}} \circ v^{(\ell)}_{\overline{X_\ell}})$ then $G_{\ell,0} \leftarrow G_{\ell,0} + 1$
7. If $h(b_{Y_{\ell,1}} \circ b_{Y_{\ell,0}} \circ v^{(\ell)}_{\overline{X_\ell}}) \neq h(\overline{b_{Y_{\ell,1}}} \circ b_{Y_{\ell,0}} \circ v^{(\ell)}_{\overline{X_\ell}})$ then $G_{\ell,1} \leftarrow G_{\ell,1} + 1$
8. If $(\{G_{\ell,0}, G_{\ell,1}\} \neq \{0, h\})$ then Output("reject")
9. If $G_{\ell,0} = t$ then $z_\ell \leftarrow 0$ else $z_\ell \leftarrow 1$
10. Output("$\{z_\ell\}_{\ell \in I}$")

Algorithm 5 A procedure that tests whether $h(x)$ is $(\epsilon/3)$-far from F with respect to $\mathcal{D}$.

Close$fF(f, \mathcal{D}, \epsilon, \delta)$
Input: Oracle that accesses a Boolean function f and $\mathcal{D}$.
Output: Either "reject" or "OK"

1. Repeat $t = (3/\epsilon)\ln(2/\delta)$ times
2. Choose $u \in \mathcal{D}$.
3. $z \leftarrow$**RelVarValue**$(u, X, V, I, \delta/(2t))$.
4. If $h(u) \neq F(z)$ then Output("reject")
5. Return "OK".

Proof of Lemma 14.

Proof. If $f \in C$ then, by Lemma 12, $F(u_\Gamma^{(i)}) = h(u)$ for every i. By Lemma 10 and Assumption 11, $z^{(i)} = u_\Gamma^{(i)}$ for all i, and therefore **Close**fF returns OK.

Suppose now $h(x)$ is $(\epsilon/3)$-far from F with respect to $\mathcal{D}$. By *2* in Lemma 13, **RelVarValue** makes $O(kt\log((kt)/\delta))$ queries and computes $F(u_\Gamma^{(i)})$, $i = 1, \ldots, t$, with failure probability at most $\delta/2$. Then the probability that it fails to reject is at most $(1-\epsilon/3)^t \le \delta/2$. This gives the result.

Therefore, **Close**fF makes $O((k/\epsilon)\log(k/\epsilon))$ queries and satisfies *1* and *2*. ◀

B Classes that are Close to k-Junta

We now give more details. The tester first runs the procedure **Approx**C in Algorithm 6. This procedure is similar to the procedure **ApproxTarget**. It randomly uniformly partitions the variables to $r = 4c^2(c+1)s\log(s/\epsilon)$ disjoint sets $X_1, \ldots, X_r$ and finds influential sets $\{X_i\}_{i\in I}$. Here c is a large constant. To find a new influential set, it chooses two random uniform strings $u, v \in \{0,1\}^n$ and verifies if $f(u_X \circ v_{\overline{X}}) \neq f(u)$ where X is the union of the influential sets that it has found thus far. If $f(u_X \circ v_{\overline{X}}) \neq f(u)$ then the binary search finds a new influential set.

In the binary search for a new influential set, the procedure defines a set X' that is equal to the union of half of the sets in $\{X_i\}_{i\notin I}$. Then either $f(u_{X\cup X'} \circ v_{\overline{X'}}) \neq f(u)$ or $f(u_{X\cup X'} \circ v_{\overline{X'}}) \neq f(u_X \circ v_{\overline{X}})$. Then it recursively does the above until it finds a new influential set X_ℓ.

It is easy to see that if f is s-term DNF then, whp, for all the terms T in f of size at least $c^2\log(s/\epsilon)$, for all the random uniform strings u, v chosen in the algorithm and for all the strings z generated in the binary search, $T(u_X \circ v_{\overline{X}}) = T(u) = T(z) = 0$. Therefore, when f is s-term DNF, the procedure, whp, runs as if there are no terms of size greater than $c^2\log(s/\epsilon)$ in f. This shows that, whp, each influential set that the procedure finds contains at least one variable that belongs to a term of size at most $c^2\log(s/\epsilon)$ in f. Therefore, if f is s-term DNF, the procedure, whp, does not generate more than $c^2 s\log(s/\epsilon)$ influential sets. If the procedure finds more than $c^2 s\log(s/\epsilon)$ influential sets then, whp, f is not s-term DNF and therefore it rejects.

Let R be the set of all the variables that belong to the terms in f of size at most $c^2\log(s/\epsilon)$. The procedure returns $h(x) = f(x_X \circ w_{\overline{X}})$ for random uniform w where X is the union of the influential sets $X = \cup_{i\in I} X_i$ that is found by the procedure. If f is s-term DNF then since $r = 4c^2(c+1)s\log(s/\epsilon)$ and the number of influential sets is at most $c^2 s\log(s/\epsilon)$, whp, at least $(1/2)c\log(s/\epsilon)$ variables in each term of f that contains at least $c\log(s/\epsilon)$ variables not in R falls outside X in the partition of $[n]$. Therefore, for random uniform w, whp, terms T in f that contains at least $c\log(s/\epsilon)$ variables not in R satisfies $T(x_X \circ w_{\overline{X}}) = 0$ and therefore, whp, are vanished in $H = f(x_X \circ w_{\overline{X}})$. Thus, whp, H contains all the terms that contains variables in R and at most $cs\log(s/\epsilon)$ variables not in R. Therefore, whp, H contains at most $c(c+1)s\log(s/\epsilon)$ influential variables. From this, and using similar arguments as for the procedure **ApproxTarget** in the previous subsection, we prove that, **Approx**C makes at most $\tilde{O}(s/\epsilon)$ queries and

1. If f is s-term DNF then, whp, the procedure outputs X and w such that
   - $H = f(x_X \circ w_{\overline{X}})$ is s-term DNF[8].
   - The number of influential variables in $H = f(x_X \circ w_{\overline{X}})$ is at most $O(s\log(s/\epsilon))$.

[8] So in this case we need the class to be closed under zero-one projection.

2. If f is ϵ-far from every s-term DNF then the procedure either rejects or outputs X and w such that, whp, $H = f(x_X \circ w_{\overline{X}})$ is $(3\epsilon/4)$-far from every s-term DNF.

We can now run **Tester**C (with $3\epsilon/4$) on H from the previous subsection for testing C^* where C^* is the set of s-term DNF with $k = O(s \log(s/\epsilon))$ influential variables.

Algorithm 6 A procedure that removes variables from f that only appear in large size terms.

Algorithm Approx$C(f, \epsilon)$
Input: Oracle that accesses a Boolean function f and ϵ
Output: Either "$X \subseteq [n], w \in \{0,1\}^n$" or "reject"

Partition $[n]$ **into** r **sets**
1. Set $r = 8sc\log(s/\epsilon)$.
2. Choose uniformly at random a partition $X_1, X_2, \ldots, X_r$ of $[n]$

Find a close function and influential sets
3. Set $X = \emptyset$; $I = \emptyset$; $t(X) = 0$; $k = 3ms$
4. Repeat $M = 400k\ln(100k)/\epsilon$ times
5. Choose w and u uniformly at random from $\{0,1\}^n$;.
6. $t(X) \leftarrow t(X) + 1$
7. If $f(u_X \circ v_{\overline{X}}) \neq f(u)$ then
8. Binary Search to find a new influential set X_ℓ; $X \leftarrow X \cup X_\ell$; $I \leftarrow I \cup \{\ell\}$.
9. If $|I| > k$ then output "reject" and halt.
10. $t(X) = 0$.
11. If $t(X) = 400\ln(100k)/\epsilon$ then
12. Sample w uniformly at random from $\{0,1\}^n$;
13. Output$(X, w, H = f(x_X \circ w_{\overline{X}}))$.

Palette Sparsification Beyond $(\Delta + 1)$ Vertex Coloring

Sepehr Assadi
Department of Computer Science, Rutgers University, Piscataway, NJ, USA

Abstract

A recent *palette sparsification theorem* of Assadi, Chen, and Khanna [SODA'19] states that in every n-vertex graph G with maximum degree Δ, sampling $O(\log n)$ colors per each vertex independently from $\Delta + 1$ colors almost certainly allows for proper coloring of G from the sampled colors. Besides being a combinatorial statement of its own independent interest, this theorem was shown to have various applications to design of algorithms for $(\Delta + 1)$ coloring in different models of computation on massive graphs such as streaming or sublinear-time algorithms.

In this paper, we focus on palette sparsification beyond $(\Delta + 1)$ coloring, in both regimes when the number of available colors is much larger than $(\Delta+1)$, and when it is much smaller. In particular,

- We prove that for $(1 + \varepsilon)\Delta$ coloring, sampling only $O_\varepsilon(\sqrt{\log n})$ colors per vertex is sufficient and necessary to obtain a proper coloring from the sampled colors – this shows a separation between $(1 + \varepsilon)\Delta$ and $(\Delta + 1)$ coloring in the context of palette sparsification.
- A natural family of graphs with chromatic number much smaller than $(\Delta + 1)$ are triangle-free graphs which are $O(\frac{\Delta}{\ln \Delta})$ colorable. We prove a palette sparsification theorem tailored to these graphs: Sampling $O(\Delta^\gamma + \sqrt{\log n})$ colors per vertex is sufficient and necessary to obtain a proper $O_\gamma(\frac{\Delta}{\ln \Delta})$ coloring of triangle-free graphs.
- We also consider the "local version" of graph coloring where every vertex v can only be colored from a list of colors with size proportional to the degree $\deg(v)$ of v. We show that sampling $O_\varepsilon(\log n)$ colors per vertex is sufficient for proper coloring of any graph with high probability whenever each vertex is sampling from a list of $(1 + \varepsilon) \cdot \deg(v)$ arbitrary colors, or even only $\deg(v) + 1$ colors when the lists are the sets $\{1, \ldots, \deg(v) + 1\}$.

Our new palette sparsification results naturally lead to a host of new and/or improved algorithms for vertex coloring in different models including streaming and sublinear-time algorithms.

1 Introduction

Given a graph $G(V, E)$, let $n := |V|$ be the number of vertices and Δ denote the maximum degree. A proper c-coloring of G is an assignment of colors to vertices from the palette of colors $\{1, \ldots, c\}$ such that adjacent vertices receive distinct colors. The minimum number of colors needed for proper coloring of G is referred to as the chromatic number of G and is denoted by $\chi(G)$. An interesting variant of graph coloring is *list-coloring* whereby every vertex v is given a set $S(v)$ of available colors and the goal is to find a proper coloring of G such that the color of every v belongs to $S(v)$. When this is possible, we say that G is list-colorable from the lists S.

It is well-known that $\chi(G) \leq \Delta + 1$ for every graph G; the algorithmic problem of finding such a coloring – the $(\Delta + 1)$ coloring problem – can also be solved via a text-book greedy algorithm. Very recently, Assadi, Chen, and Khanna [5] proved the following **palette sparsification theorem** for the $(\Delta + 1)$ coloring problem: Suppose for every vertex v of a graph G, we *independently* sample $O(\log n)$ colors $L(v)$ uniformly at random from the palette $\{1, \ldots, \Delta + 1\}$; then G is almost-certainly list-colorable from the sampled lists L.

The palette sparsification theorem of [5], besides being a purely graph-theoretic result of its own independent interest, also had several interesting algorithmic implications for the $(\Delta + 1)$ coloring problem owing to its "sparsification" nature: it is easy to see that by sampling only $O(\log n)$ colors per vertex, the total number of edges that can ever become monochromatic while coloring G from lists L is with high probability only $O(n \cdot \log^2 n)$; at the same time we can safely ignore all other edges of G. This theorem thus reduces the $(\Delta + 1)$ coloring problem, in a *non-adaptive* way, to a list-coloring problem on a graph with (potentially) much smaller number of edges.

The aforementioned aspect of this palette sparsification is particularly appealing for the design of *sublinear algorithms* – these are algorithms which require computational resources that are substantially smaller than the size of their input. Indeed, one of the interesting applications of this theorem, proven (among other things) in [5], is a randomized algorithm for the $(\Delta + 1)$ coloring problem that runs in $\widetilde{O}(n\sqrt{n})$[1] time; for sufficiently dense graphs, this is faster than even reading the entire input once!

Palette sparsification in [5] was tailored to the $(\Delta + 1)$ coloring problem. Motivated by the ubiquity of graph coloring problems on one hand, and the wide range of applications of this palette sparsification result on the other hand, the following question is natural:

What other graph coloring problems admit (similar) palette sparsification theorems?

This is precisely the question we study in this work from both upper and lower bound fronts.

1.1 Our Contributions

We consider palette sparsification beyond $(\Delta + 1)$ coloring: when the number of available colors is much larger than $\Delta + 1$, when it is much smaller, and when the number of available colors for vertices depend on "local" parameters of the graph.

$(1 + \varepsilon)\Delta$ Coloring. The palette sparsification theorem of [5] is shown to be tight in the sense that on some graphs, sampling $o(\log n)$ colors per vertex from $\{1, \ldots, \Delta + 1\}$, results in the sampled list-coloring instance to have no proper coloring with high probability. We prove that in contrast to this, if one allows for a larger number of available colors, then indeed we can obtain a palette sparsification with asymptotically smaller sampled lists.

[1] Here and throughout the paper, we use the notation $\widetilde{O}(f) := O(f \cdot \text{polylog}(f))$ to suppress log-factors.

▶ **Result 1** (Informal – Formalized in Theorem 5). *For any graph $G(V,E)$, sampling $O_\varepsilon(\sqrt{\log n})$ colors per vertex from a set of size $(1+\varepsilon)\Delta$ colors with high probability allows for a proper list-coloring of G from the sampled lists.*

Result 1, combined with the lower bound of [5], provides a separation between $(\Delta+1)$ coloring and $(1+\varepsilon)\Delta$ coloring in the context of palette sparsification. We also prove that the bound of $\Theta(\sqrt{\log n})$ sampled colors is (asymptotically) optimal in Result 1.

To prove Result 1, we unveil a new connection between palette sparsification theorems and some of the classical list-coloring problems in the literature. In particular, several works in the past (see, e.g. [31, 20, 32] and [3, Proposition 5.5.3]) have studied the following question: Suppose in a list-coloring instance on a graph G, we define the c-degree of a vertex-color pair (v,c) as the number of neighbors of v that also contain c in their list; what conditions on maximum c-degrees and minimum list sizes imply that G is list-colorable from such lists?

Palette sparsification theorems turned out to be closely related to these questions as the sampled lists in these results can be viewed through the lens of these list-coloring results. In particular, Reed and Sudakov [32] proved that in the above question if the size of each list is larger than the maximum c-degree by a $(1+o(1))$ factor, then G is always list-colorable. The question here is then whether or not the lists sampled in Result 1 satisfy this condition with high probability. The answer turns out to be *no* as sampling only $O(\sqrt{\log n})$ colors does not provide the proper concentration needed for this guarantee. Despite this, we show that one can still use [32] to prove Result 1 with a more delicate argument by applying [32] to carefully chosen subsets of the sampled lists.

$O(\frac{\Delta}{\ln \Delta})$ Coloring of Triangle-Free Graphs. Even though $\chi(G)$ in general can be $\Delta+1$, many natural families of graphs have chromatic number (much) smaller than $\Delta+1$. One key example is the set of triangle-free graphs which are $O(\frac{\Delta}{\ln \Delta})$ colorable by a celebrated result of Johansson [21] (which was recently simplified and improved to $(1+o(1))\cdot\frac{\Delta}{\ln\Delta}$ by Molloy [24]; see also [29, 8]). We prove a palette sparsification theorem for these graphs.

▶ **Result 2** (Informal – Formalized in Theorem 6). *For any triangle-free graph $G(V,E)$, sampling $O(\Delta^\gamma+\sqrt{\log n})$ colors per vertex from a set of size $O_\gamma(\frac{\Delta}{\ln\Delta})$ colors with high probability allows for a proper list-coloring of G from the sampled lists.*

Unlike Result 1 of our paper and the theorem of [5], in this result we also have a dependence of Δ^γ on the number of sampled colors (where the exponent depends on the number of available colors). We prove that this dependence is also necessary (Proposition 8).

The proof of Result 2 is also based on the aforementioned connection to list-coloring problems based on c-degrees. However, unlike the case for Result 1, here we are not aware of any such list-coloring result that allows us to infer Result 2. As such, a key part of the proof of Result 2 is exactly to establish such a result. Our proof for the corresponding list-coloring problem is by the probabilistic method and in particular a version of the so-called "Rödl Nibble" or the "semi-random method"; see, e.g. [33, 26]. Similar to previous work on coloring triangle-free graphs, the main challenge here is to establish the desired concentration bounds. We do this following the approach of Pettie and Su [29] in their distributed algorithm for coloring triangle-free graphs.

We shall note that our proofs of Results 1 and 2 are almost entirely disjoint from the techniques in [5] and instead build on classical work on list-coloring problems in graph theory.

Coloring with Local Lists Size. Finally, we consider a coloring problem with "local" list sizes where the number of available colors for vertices depends on a local parameter, namely their degree as opposed to a global parameter such as maximum degree.

▶ **Result 3** (Informal – Formalized in Theorem 12). *For any graph $G(V, E)$, sampling $O_\varepsilon(\log n)$ colors for each vertex v with degree $\deg(v)$ from a set $S(v)$ of $(1+\varepsilon)\cdot\deg(v)$ arbitrary colors or only $\deg(v)+1$ colors when the lists are the sets $\{1,\ldots,\deg(v)+1\}$, allows for a proper coloring of G from the sampled colors.*

Coloring problems with local lists size have been studied before in both the graph theory literature, e.g. in [14, 11] for coloring triangle-free graphs (and as pointed out by [14], the general idea goes all the way back to the notion of degree-choosability in one of the original list-coloring papers [16]), and theoretical computer science, e.g. in [13].

To be more precise, the first part of Result 3 refers to the standard $(1+\varepsilon)\deg$ *list*-coloring problem and the second part corresponds to the so-called $(\deg+1)$ coloring problem introduced first (to our knowledge) in the recent work of Chang, Li, and Pettie [13] (see also [4] for an application of this problem). We remark that the $(\deg+1)$ coloring problem is a generalization of the $(\Delta+1)$ coloring problem and hence our Result 3 generalizes that of [5] (although we build on many of the ideas and tools developed in [5] for $\Delta+1$ coloring).

Our proof of Result 3 takes a different route than Results 1 and 2 that were based on list-coloring and instead we follow the approach of [5] for $(\Delta+1)$ coloring. A fundamental challenge here is that the graph decomposition for partitioning vertices into sparse and dense parts that played a key role in [5] is no longer applicable to the $(\deg+1)$ coloring problem. We address this by "relaxing" the requirements of the decomposition and develop a new one that despite being somewhat "weaker" than the ones for $(\Delta+1)$ coloring in [18, 13, 5] (themselves based on [30]), takes into account the disparity between degrees of vertices in the $(\deg+1)$ coloring problem. Similar to [5], we then handle "sparse"[2] and dense vertices of this decomposition separately but unlike [5], here the main part of the argument is to handle these "sparse" vertices and the result for the dense part follows more or less directly from [5].

We conclude this section by noting that our proof for $(1+\varepsilon)\deg$-list coloring problem also immediately gives a palette sparsification result for obtaining a $(1+\varepsilon)\kappa$-list coloring with sampling $O_\varepsilon(\log n)$ colors, where κ is the degeneracy of the graph. This problem was studied very recently in the context of sublinear or "space conscious" algorithms by Bera, Chakrabarti, and Ghosh [7] who also proved, among other interesting results, that $(\kappa+1)$ coloring cannot be achieved via palette sparsification – our result thus complements their lower bound. We postpone the details of this result to the full version of the paper.

1.2 Implication to Sublinear Algorithms for Graph Coloring

As stated earlier, one motivation in studying palette sparsification is in its application to design of sublinear algorithms. As was shown in [5], these theorems imply sublinear algorithms in various models in "almost" a black-box way (see Section 5 for details). For concreteness, in this paper, we stick to their application to the two canonical examples of streaming and sublinear-time algorithms. We only note in passing that exactly as in [5], our results also imply new algorithms in models such as massively parallel computation (MPC) or distributed/linear sketching; see also [12, 7] for more recent results on graph coloring problems in these and related models.

[2] Technically speaking, this decomposition allows for vertices that are neither sparse nor dense and are key to extending the decomposition from $(\Delta+1)$ coloring to $(\deg+1)$ coloring.

Table 1 A sample of our sublinear algorithms as corollaries of Results 1, 2, and 3, and the previous work in [5] and [7] (for brevity, we assume ε, γ are constants). All streaming algorithms here are *single-pass* and all sublinear-time algorithms except for $(1+\varepsilon)\kappa$ coloring are *non-adaptive*.

Problem	Graph Family	Streaming	Sublinear-Time	Source
$(\Delta+1)$ Coloring	General	$O(n \log^2 n)$ space	$\widetilde{O}(n^{3/2})$ time	[5]
$(1+\varepsilon)\kappa$ Coloring	κ-Degenerate	$O(n \log n)$ space	$\widetilde{O}(n^{3/2})$ time	[7]
$O_\gamma(\frac{\Delta}{\ln \Delta})$ Coloring	Triangle-Free	$O(n \cdot \Delta^\gamma)$ space	$O(n^{3/2+\gamma})$ time	our work
$(1+\varepsilon)$ deg List-Coloring	General	$O(n \cdot \log^2 n)$ space	$\widetilde{O}(n^{3/2})$ time	our work
(deg +1) Coloring	General	$O(n \cdot \log^2 n)$ space	$\widetilde{O}(n^{3/2})$ time	our work

Our results in this part appear in Section 5. Table 1 presents a summary of our sublinear algorithms and the directly related previous work (even though our Result 1 implies a separation between $(\Delta+1)$ and $(1+\varepsilon)\Delta$ coloring, the resulting sublinear algorithms from Result 1 are subsumed by the previous work in [7] and hence are omitted from Table 1).

Sublinear Algorithms from Graph Partitioning. Motivated by our results on sublinear algorithms for triangle-free graphs, we also consider sublinear algorithms for coloring other "locally sparse" graphs such as K_r-free graphs, locally r-colorable graphs, and graphs with sparse neighborhood. We give several results for these problems through a general algorithm based on the graph partitioning technique (see, e.g. [12, 27, 28, 7]). Our results in this part are presented in Appendix B.

2 Preliminaries

Notation. For any integer $t \geq 1$, we define $[t] := \{1, \ldots, t\}$. For a graph $G(V, E)$, we use $V(G) := V$ and $E(G) := E$ to denote the vertex-set and edge-set respectively. For a vertex $v \in V$, $N_G(v)$ denotes the neighborhood of v in G and $\deg_G(v) := |N_G(v)|$ denotes the degree of v (when clear from the context, we may drop the subscript G). For a vertex-set $U \subseteq V$, $G[U]$ denotes the induced subgraph of G on U. When there are lists of colors $S(v)$ given to vertices v, we use the term ***c*-degree** of v to mean the number of neighbors u of v of with color c in their list $S(u)$ and denote this by $\deg_S(v, c)$. We use the term "with high probability" (w.h.p.) for an event to mean that the probability of this event happening is at least $1 - 1/n^c$ where c is a sufficiently large constant.

List-Coloring with Constraints on Color-Degrees. We use the following result of Reed and Sudakov [32] on list-coloring of graphs with constraints on c-degrees of vertices.

▶ **Proposition 4** ([32]). *For every $\varepsilon > 0$ there exists a $d_0 := d_0(\varepsilon)$ such that for all $d \geq d_0$ the following is true. Suppose $G(V, E)$ is a graph with lists $S(v)$ for every $v \in V$ such that:*

1. *for every vertex v, $|S(v)| \geq (1+\varepsilon) \cdot d$, and*
2. *for every vertex v and color $c \in S(v)$, $\deg_S(v, c) \leq d$ (recall that $\deg_S(v, c)$ denotes the c-degree of v which is the number of neighbors u of v with color $c \in S(u)$).*

Then, there exists a proper coloring of G from these lists.

A weaker version of this result obtained by replacing $(1+\varepsilon)$ above with some absolute constant appeared earlier in [31] (see also [3, Proposition 5.5.3] and [20]).

3 Two New Palette Sparsification Theorems

We present our new palette sparsification theorems in Result 1 and Result 2 in this section. We postpone the proof of the optimality of Result 1 (the lower bound on sampled-list sizes) to the full version of the paper as it is a basic argument. Instead we give the more interesting proof of the optimality of Result 2 in almost full details in this section.

3.1 Palette Sparsification for $(1+\varepsilon)\Delta$ Coloring

We start with our improved palette sparsification theorem for $(1+\varepsilon)\Delta$ coloring.

▶ **Theorem 5.** *For every $\varepsilon \in (0, 1/2)$, there exists an integer $n(\varepsilon) \geq 1$ such that the following is true. Let $G(V,E)$ be any graph with $n \geq n(\varepsilon)$ vertices and maximum degree Δ, and define $C := C(\varepsilon) = (1+\varepsilon)\cdot\Delta$. Suppose for every vertex $v \in V$, we independently sample a set $L(v)$ of colors of size $\ell := \left(10\sqrt{\log n}/\varepsilon^{1.5}\right)$ uniformly at random from colors $\{1,\ldots,C\}$. Then, with high probability, there exists a proper coloring of G from lists $L(v)$ for every $v \in V$.*

We shall note that in contrast to Theorem 5, it was shown in [5] that for the more stringent problem of $(\Delta+1)$ coloring, sampling $\Omega(\log n)$ colors per vertex is necessary. As such, Theorem 5 presents a separation between these two problems in palette sparsification.

Proof of Theorem 5

The proof of this theorem is by showing that the lists sampled for vertices can be adjusted so that they satisfy the requirement of Proposition 4; we then apply this proposition to obtain a list-coloring of G from the sampled lists.

Recall that $\deg_L(v,c)$ is the c-degree of vertex v in lists L. For every $c \in L(v)$,

$$\mathbb{E}\left[\deg_L(v,c)\right] := \sum_{u \in N(v)} \mathbb{P}\left(u \text{ samples } c \text{ in } L(u)\right) \leq \Delta \cdot \frac{\ell}{C} = \frac{\ell}{1+\varepsilon}. \tag{1}$$

Now *if* $\deg_L(v,c)$ was concentrated enough so that $\max_{v,c} \deg_L(v,c) = (1-\Theta(\varepsilon))\cdot\ell$, we would have been done already: by Proposition 4, there is always a proper coloring of G from such lists (take the parameter d to be $\max_{v,c}\deg_L(v,c)$ and so size of each list is $(1+\Theta(\varepsilon))d$). Unfortunately however, it is easy to see that as $\ell = \Theta(\sqrt{\log n})$ in general no such concentration is guaranteed.

We fix the issue above by showing existence of a *subset* $\widehat{L}(v)$ of each list $L(v)$ such that these new lists can indeed be used in Proposition 4. The argument is intuitively as follows: the probability that $\deg_L(v,c)$ deviates significantly from its expectation is $2^{-\Theta(\ell)} = 2^{-\Theta(\sqrt{\log n})}$ by a simple Chernoff bound. Moreover, the probability that $\Omega(\sqrt{\log n})$ colors in $L(v)$ all deviate from their expectation can be bounded by $\left(2^{-\Theta(\sqrt{\log n})}\right)^{\Omega(\sqrt{\log n})}$ (ignoring dependency issues for the moment). This probability is now $n^{-\Theta(1)}$, enough for us to take a union bound over all vertices. As such, by removing some fraction of the colors from the list of each vertex, we can satisfy the c-degree requirements for applying Proposition 4 and conclude the proof. We now formalize this.

We say that a color $c \in L(v)$ is *bad* for v iff $\deg_L(v,c) > (1+\varepsilon/2)\cdot\mathbb{E}\left[\deg_L(v,c)\right]$. As the choice of color c for each vertex $u \in N(v)$ is independent, by Eq (1) and Chernoff bound (Proposition 28),

$$\mathbb{P}\left(\deg_L(v,c) > (1+\varepsilon/2)\cdot\mathbb{E}\left[\deg_L(v,c)\right]\right) \leq \exp\left(-\frac{\varepsilon^2}{12}\cdot\frac{\ell}{1+\varepsilon}\right). \tag{2}$$

Define $\mathsf{bad}(v)$ as the number of colors c in $L(v)$ that are bad for vertex v. We note that by the sampling process in Theorem 5, conditioning on some colors being bad for v can only reduce the chance of the remaining colors being bad for v. As such, by Eq (2),

$$\begin{aligned}\mathbb{P}\left(\mathsf{bad}(v) \geq \varepsilon/4 \cdot \ell\right) &\leq \binom{\ell}{\varepsilon/4 \cdot \ell} \cdot \exp\left(-\frac{\varepsilon^2}{12} \cdot \frac{\ell}{1+\varepsilon}\right)^{\varepsilon \cdot \ell/4} \\ &\leq 2^{\ell} \cdot \exp\left(-\frac{\varepsilon^3}{72} \cdot \ell^2\right) \leq \exp\left(-20 \log n\right).\end{aligned}$$

(by the choice of $\ell = 10\sqrt{\log n}/\varepsilon^{1.5}$ and as $\varepsilon < 1/2$ is sufficiently smaller than n)

By a union bound over all n vertices, with high probability, for every vertex v, $\mathsf{bad}(v) \leq \varepsilon \cdot \ell/4$. We let $\widehat{L}(v)$ to be a subset of $L(v)$ obtained by removing all bad colors from $L(v)$. For any $c \in \widehat{L}(v)$:

$$\deg_{\widehat{L}}(v,c) \leq \deg_{L}(v,c) \leq (1+\varepsilon/2) \cdot \frac{\ell}{1+\varepsilon} \leq (1-\varepsilon/3) \cdot \ell. \qquad \text{(for } \varepsilon < 1/2\text{)}$$

On the other hand, as $\mathsf{bad}(v) \leq \varepsilon \cdot \ell/4$, we have $\left|\widehat{L}(v)\right| \geq (1-\varepsilon/4) \cdot \ell$. As such, by Proposition 4 (as ε is a constant with respect to ℓ), we can list-color G from lists $\widehat{L}$ and consequently also L, finalizing the proof. ◀

3.2 Palette Sparsification for Triangle-Free Graphs

We now prove a palette sparsification theorem for triangle-free graphs.

▶ **Theorem 6.** *Let $G(V,E)$ be any n-vertex triangle-free graph with maximum degree Δ. Let $\gamma \in (0,1)$ be a parameter and define $C := C(\gamma) = \left(\frac{9\Delta}{\gamma \cdot \ln \Delta}\right)$. Suppose for every vertex $v \in V$, we independently sample a set $L(v)$ of size $b \cdot (\Delta^{\gamma} + \sqrt{\log n})$ uniformly at random from colors $\{1,\ldots,C\}$ for an appropriate absolute positive constant b. Then, with high probability there exists a proper coloring of G from lists $L(v)$ for every vertex $v \in V$.*

It is known that there are triangle-free graphs with chromatic number $\Omega(\frac{\Delta}{\ln \Delta})$ [10] (In fact this bound holds even for graphs with arbitrarily large girth not only girth > 3). Theorem 6 then shows that one can match the chromatic number of these graphs asymptotically by sampling a small number of colors per vertex (almost as small as $O(\Delta^{o(1)} + \sqrt{\log n})$).

Proof of Theorem 6

As we already saw in the proof of Theorem 5, looking at the sampled lists $L(v)$ of vertices as a list-coloring problem with constraints on c-degrees can be quite helpful in proving the corresponding palette sparsification result. We take the same approach in proving Theorem 6 as well. However, unlike for $(1+\varepsilon)\Delta$ coloring, to the best of our knowledge, no such list-coloring results (with constraints on c-degrees *instead* of maximum degree) are known for coloring triangle-free graphs. Our main task here is then exactly to prove such a result formalized as follows.

▶ **Proposition 7.** *There exists an absolute constant d_0 such that for all $d \geq d_0$ the following holds. Suppose $G(V,E)$ is a triangle-free graph with lists $S(v)$ for every $v \in V$ such that:*

1. *for every vertex v, $|S(v)| \geq 8 \cdot \frac{d}{\ln d}$, and*
2. *for every vertex v and color $c \in S(v)$, $\deg_S(v,c) \leq d$.*

Then, there exists a proper coloring of G from these lists.

We give the proof of Theorem 6 assuming Proposition 7 here. The proof of Proposition 7 itself is technical and detailed and thus even though interesting on its own, we opted to postpone it to the full version to preserve the flow of the paper here.

Proof of Theorem 6. We prove this theorem with the weaker bound of $O(\Delta^\gamma + \log n)$ (as opposed to $O(\Delta^\gamma + \sqrt{\log n})$) for the number of sampled colors. The extension to the improved bound with $O(\sqrt{\log n})$ dependence is exactly as in the proof of Theorem 5 and is thus omitted.

Let $\ell := (\Delta^\gamma + 100 \ln n)$ and suppose each vertex samples ℓ colors from $\{1, \ldots, C\}$ for $C := C(\gamma) = \left(\frac{9\Delta}{\gamma \cdot \ln \Delta}\right)$. Let $p := \ell / C$ which is equal to the probability that any vertex v samples a particular color in $L(v)$. We have,

$$\mathbb{E}\left[\deg_L(v, c)\right] = \sum_{u \in N(v)} \mathbb{P}\left(u \text{ samples } c \text{ in } L(u)\right) \leq p \cdot \Delta.$$

Note that as $p \cdot \Delta \geq p \cdot C = \ell \geq 100 \ln n$, a simple application of Chernoff bound plus union bound ensures that, for every vertex v and color c, $\deg_L(v, c) \leq (1.1) \cdot p\Delta$ with high probability. In the following, we condition on this event.

Let $d := (1.1) \cdot p\Delta$. By the above conditioning, c-degree of every vertex $v \in V$ is at most d. In order to apply Proposition 7 to graph G with lists L, we only need to prove that $\ell \geq \frac{8d}{\ln d}$. We prove that in fact $\ell \cdot \ln \ell \geq 8d$ which implies the desired bound as $\ell = p \cdot C \leq p \cdot \Delta \leq d$. We have,

$$\ell \cdot \ln \ell \geq (p \cdot C) \cdot \ln\left(\Delta^\gamma\right) = p \cdot \left(\frac{9\Delta}{\gamma \cdot \ln \Delta}\right) \cdot \gamma \cdot \ln \Delta = 9 \cdot p\Delta > 8d.$$

(as $\Delta^\gamma < \ell = p \cdot C$ and by the choice of C)

The proof now follows from applying Proposition 7 to lists L. ◀

Asymptotic Optimality of the Bounds in Theorem 6

We now prove the optimality of Theorem 6 up to constant factors.

▶ **Proposition 8.** *There exists a distribution on n-vertex graphs with maximum degree $\Delta = \Theta(n^{1/3})$ such that for every $\gamma < 1/16$ and $C := C(\gamma) = \frac{\Delta}{16\gamma \cdot \ln \Delta}$ the following is true. Suppose we sample a graph $G(V, E)$ from this distribution and then for each vertex $v \in V$, we independently pick a set $L(v)$ of colors with size Δ^γ uniformly at random from colors $\{1, \ldots, C\}$; then, with high probability there exists no proper coloring of G wherein the color of every vertex $v \in V$ sis chosen from $L(v)$.*

Let $\mathcal{G}_{n,p}$ denote the Erdős-Rényi distribution of random graphs on n vertices in which each edge is chosen independently with probability p. Define the following distribution $\mathcal{G}_{n,p}^{-K_3}$ on triangle-free graphs: Sample a graph G from $\mathcal{G}_{n,p}$, then remove *every* edge that was part of a triangle originally. Clearly, the graphs output by $\mathcal{G}_{n,p}^{-K_3}$ are triangle-free. Throughout this section, we take $p = \Theta(n^{-2/3})$ (the choice of the constant will be determined later).

We prove Proposition 8 by considering the distribution $\mathcal{G}_{n,p}^{-K_3}$. However, we first present some basic properties of distribution $\mathcal{G}_{n,p}$ needed for our purpose. The proofs are simple exercises in random graph theory and can be found in the full version of the paper. In the following, let $t(G)$ denote the number of triangles in G and $\alpha(G)$ denote the maximum independent set size, and recall that $\Delta(G)$ denotes the maximum degree of G.

▶ **Lemma 9.** *For $G \sim \mathcal{G}_{n,p}$, $\mathbb{E}\left[t(G)\right] \leq (np)^3$, and $t(G) \leq (1 + o(1))\,\mathbb{E}\left[t(G)\right]$ w.h.p.*

▶ **Lemma 10.** *For $G \sim \mathcal{G}_{n,p}$, $\mathbb{E}\left[\alpha(G)\right] \leq \frac{3 \cdot \ln(np)}{p}$, and $\alpha(G) \leq \frac{3 \cdot \ln(np)}{p}$ w.h.p.*

▶ **Lemma 11.** *For $G \sim \mathcal{G}_{n,p}$, $\Delta(G) \leq 2np$ w.h.p.*

Proof of Proposition 8. Let $p := \frac{1}{3} \cdot (n)^{-2/3}$ for this proof and consider the distribution $\mathcal{G}_{n,p}^{-K_3}$. Moreover, let $\mathcal{L}$ denote the distribution of lists of colors sampled for vertices. By Lemma 11, the maximum degree of $G \sim \mathcal{G}_{n,p}$ and consequently $G \sim \mathcal{G}_{n,p}^{-K_3}$ is at most $\widetilde{\Delta} := 2np$ with high probability. Throughout the following argument, we condition on this event. This can only change the probability calculations by a negligible factor (that we ignore for the simplicity of exposition). This way, the number of colors sampled in $\mathcal{L}$ can be assumed to be at most $C := \frac{\widetilde{\Delta}}{16\gamma \cdot \ln \widetilde{\Delta}}$. We further use $q := \widetilde{\Delta}^{\gamma}/C$ to denote the probability that a color c is sampled in list $L(v)$ of a vertex v.

For a graph $G(V, E) \sim \mathcal{G}_{n,p}^{-K_3}$ and lists $L \sim \mathcal{L}$, let $V_1, \ldots, V_C$ be a collection of subsets of V (not necessarily disjoint) where for every $c \in [C]$, V_c denotes the vertices v that sampled the color c in their list $L(v)$. As each color is sampled with probability q by a vertex, and the choices are independent across vertices, a simple application of Chernoff bound ensures that with high probability, $|V_c| \leq 2q \cdot n$ for all c. We also condition on this event in the following (and similarly as before ignore the negligible contribution of this conditioning to the probability calculations below).

Let δ denote the probability of "error" i.e., the event that the sampled colors do not lead to a proper coloring of the graph. An averaging argument implies that there exists a fixed set of lists $L \sim \mathcal{L}$ such that for G sampled from $\mathcal{G}_{n,p}^{-K_3}$, the error probability of L on G is at most δ. Fix such a choice of L in the following. We will show that $\delta = 1 - o(1)$.

Recall that $G \sim \mathcal{G}_{n,p}^{-K_3}$ is chosen independent of the lists L (by definition of palette sparsification). For any graph G, define:

- $\mu_L(G) := \max_{(U_1,\ldots,U_C)} \sum_{c=1}^{C} |U_c|$ where all U_c's are *disjoint*, each $U_c \subseteq V_c$, and $G[U_c]$ is an independent set.

As we have fixed the choice of the lists L, the function $\mu_L(\cdot)$ is fixed at this point and its value only depends on G. A necessary condition for G to be colorable from the lists L is that $\mu_L(G) = n$. This is because (i) any proper coloring of G from lists L necessarily induces an independent set inside each V_c; (ii) these independent sets are disjoint and hence we can take them as a feasible solution $(U_1, \ldots, U_C)$ to $\mu_L(G)$; (iii) these independent sets cover all vertices of G. Our task is now to bound the probability that $\mu(G) = n$ to lower bound δ.

Firstly, we can switch from the distribution $\mathcal{G}_{n,p}^{-K_3}$ to $\mathcal{G}_{n,p}$ using the following equation (recall that $t(G)$ denotes the number of triangles):

$$\mathop{\mathbb{E}}_{G \sim \mathcal{G}_{n,p}^{-K_3}} [\mu_L(G)] \leq \mathop{\mathbb{E}}_{H \sim \mathcal{G}_{n,p}} [\mu_L(H) + 3 \cdot t(H)]\,. \tag{3}$$

This is because any graph $G \sim \mathcal{G}_{n,p}^{-K_3}$ is obtained by removing edges of every triangle in a graph $H \sim \mathcal{G}_{n,p}$ and removing these edges can only increase the total size of a collection of *disjoint* independent sets (namely, the value of μ_L) by the number of vertices in the triangles (in fact, by at most two vertices from each triangle). We can upper bound the second-term in Eq (3) using Lemma 9. We now bound the first term. In the following, let $n_c := |V_c|$ for $c \in [C]$. We have,

$$\mathop{\mathbb{E}}_{H\sim\mathcal{G}_{n,p}}[\mu_L(H)] \leq \mathop{\mathbb{E}}_{H\sim\mathcal{G}_{n,p}}\left[\sum_{c=1}^{C}\alpha(H[V_c])\right],$$

(by removing the disjointness condition between sets U_c's we can only increase value of $\mu_L(H)$)

$$= \sum_{c=1}^{C}\mathop{\mathbb{E}}_{H_c\sim\mathcal{G}_{n_c,p}}[\alpha(H_c)]$$

(by linearity of expectation and as for every $c\in[C]$, $H[V_c]$ is sampled from $\mathcal{G}_{n_c,p}$)

$$\leq \sum_{c=1}^{C}\frac{3\cdot\ln(n_c p)}{p} \qquad \text{(by Lemma 10)}$$

$$\leq C\cdot\frac{3\cdot\ln(2qn\cdot p)}{p} \qquad \text{(as we conditioned on } n_c\leq 2q\cdot n\text{)}$$

$$= \frac{\widetilde{\Delta}}{16\gamma\cdot\ln\widetilde{\Delta}}\cdot\frac{3\cdot\ln(q\cdot\widetilde{\Delta})}{(\widetilde{\Delta}/2n)} \qquad \text{(by definitions of } C \text{ and } \widetilde{\Delta}\text{)}$$

$$= \frac{6n}{16}\cdot\frac{\ln(q\cdot\widetilde{\Delta})}{\ln(\widetilde{\Delta}^{\gamma})} \qquad \text{(by a simple re-arranging of terms)}$$

$$< \frac{6n}{8}. \qquad \text{(as } \ln\left(q\cdot\widetilde{\Delta}\right)=\ln\left(\widetilde{\Delta}^{\gamma}\cdot 16\gamma\cdot\ln\widetilde{\Delta}\right)<2\ln\left(\widetilde{\Delta}^{\gamma}\right)\text{)}$$

Plugging this in Eq (3) together with Lemma 9 to bound the second term, implies that:

$$\mathop{\mathbb{E}}_{G\sim\mathcal{G}_{n,p}^{-K_3}}[\mu_L(G)] \leq \frac{6n}{8}+3\cdot(\frac{n^{1/3}}{3})^3 < \frac{7n}{8}.$$

Finally, by Lemmas 9 and 10, $\mu_L(G)<n$ w.h.p. This implies that $\delta=1-o(1)$ as needed. ◀

4 A Local Version of Palette Sparsification

We now give a "local version" (see, e.g. [14, 11]) of the palette sparsification theorem.

▶ **Theorem 12.** *Let $G(V,E)$ be any n-vertex graph and assume each vertex $v\in V$ is given a list $S(v)$ of colors. Suppose for every vertex $v\in V$, we independently sample a set $L(v)$ of colors of size ℓ uniformly at random from colors in $S(v)$. Then,*
1. *if $S(v)$ is* any arbitrary set *of $(1+\varepsilon)\cdot\deg(v)$ colors and $\ell=\Theta(\varepsilon^{-1}\cdot\log n)$ for $\varepsilon>0$,*
2. *or if $S(v)=\{1,\ldots,\deg(v)+1\}$ and $\ell=\Theta(\log n)$,*

then, with high probability, there exists a proper coloring of G from lists $L(v)$ for $v\in V$.

The main part of the proof of Theorem 12 is Part 2 as the proof of the first part follows almost directly from this proof. However, we start with a standalone proof of Part 1 for intuition and then sketch the proof of Part 2, which involves the bulk of our effort.

Proof of Theorem 12 – Part 1. Fix any $\varepsilon>0$ and suppose we sample $\ell:=\frac{10}{\varepsilon}\cdot\ln n$ colors $L(v)$ from $S(v)$ for every vertex $v\in V$. Consider the following process:

1. Iterate over vertices v in an *arbitrary* order and for each vertex v, let $N^{<}(v)$ denote the neighbors of v that appear before v in this ordering.
2. For each vertex v, if there exists a color $c(v)$ in $L(v)$ that is not used to color any vertex $u\in N^{<}(v)$, color v with $c(v)$. Otherwise **abort**.

We argue that this procedure will terminate with high probability without having to **abort**. This ensures that G is colorable from sampled lists L, thus proving Part 1 of Theorem 12.

$$\begin{aligned}\mathbb{P}(\textbf{abort}) &\leq \sum_v \mathbb{P}\left(L(v) \text{ is a subset of colors chosen for } N^{<}(v)\right) && \text{(by union bound)}\\ &\leq \sum_v \left(\frac{|N^{<}(v)|}{|S(v)|}\right)^{\ell} \leq n \cdot \left(\frac{\deg(v)}{(1+\varepsilon)\cdot\deg(v)}\right)^{\ell} \leq n\cdot(1-\varepsilon/2)^{\ell} \\ &&& \text{(by the sampling without replacement procedure of Theorem 12)}\\ &\leq n\cdot\exp\left(-\frac{\varepsilon}{2}\cdot\frac{10}{\varepsilon}\cdot\ln n\right) = n^{-4}. && \text{(by the choice of } \ell)\end{aligned}$$

This concludes the proof of Part 1 of Theorem 12. ◀

Proof Sketch of Theorem 12 – Part 2. In order to prove the second part of Theorem 12, we follow the approach of [5] for $(\Delta+1)$ coloring problem. The key difference is that the graph decomposition of the graph into *sparse* and *dense* parts that played a key role in [5] is no longer applicable to $(\deg+1)$ coloring. In the following, we first give a new graph decomposition tailored to $(\deg+1)$ coloring and states its main properties as well as its differences with similar decompositions for $(\Delta+1)$ coloring in [18, 13, 5] (themselves based on [30]). The next step is then to show that this decomposition, even though "weaker" than the one for $(\Delta+1)$ coloring, still has enough structure to carry out the proof for $(\deg+1)$ coloring along the lines of the one for $(\Delta+1)$ coloring in [5] with the main difference being on how we handle the "sparse" vertices.

A Graph Decomposition for $(\deg+1)$ Coloring. Let $\varepsilon \in (0,1)$ be a parameter. We define the following structures for any graph $G(V,E)$.

▶ **Definition 13.** *We say that an induced subgraph K of G is an **ε-almost-clique** iff:*
1. *For every $v \in K$, $\deg_G(v) \geq (1-8\varepsilon)\cdot\Delta(K)$ where we define $\Delta(K) := \max_{v\in K}\deg_G(v)$;*
2. *$(1-\varepsilon)\cdot\Delta(K) \leq |V(K)| \leq (1+8\varepsilon)\cdot\Delta(K)$;*
3. *Any vertex $v \in K$ has at most $8\varepsilon\cdot\Delta(K)$* non-neighbors *(in G)* inside *K;*
4. *Any vertex $v \in K$ has at most $9\varepsilon\cdot\Delta(K)$* neighbors *(in G)* outside *K.*

Definition 13 can be seen as a natural analogue of (Δ,ε)-almost-cliques defined in [5]. The main difference is that instead of having dependence on the global parameter Δ in a (Δ,ε)-almost-clique of [5], our ε-almost-cliques only depend on $\Delta(K)$ which is a $(1+\Theta(\varepsilon))$-approximation of the degree of every vertex in K (thus can be much smaller than Δ).

▶ **Definition 14.** *We say a vertex $v \in G$ is **ε-sparse** iff there are at least $\varepsilon^2\cdot\binom{\deg(v)}{2}$* non-edges *in the neighborhood of v.*

Again, Definition 14 is a natural analogue of sparse vertices in [5, 18, 13] by replacing the dependence on Δ with $\deg(v)$ instead.

▶ **Definition 15.** *We say a vertex $v \in G$ is **ε-uneven** iff for* at least $\varepsilon\cdot\deg(v)$ *neighbors u of v, we have* $\deg(v) < (1-\varepsilon)\cdot\deg(u)$.

Roughly speaking, a vertex v is considered uneven if it has a "sufficiently large" number of neighbors with "sufficiently larger" degree than v. Definition 15 is tailored specifically to $(\deg+1)$ coloring problem and does not have an analogue in [5, 18, 13] for $(\Delta+1)$ coloring. We prove the following decomposition result using the definitions above.

▶ **Lemma 16** (Graph Decomposition for $(\deg+1)$ Coloring). *For any sufficiently small $\varepsilon > 0$, any graph $G(V, E)$ can be partitioned into $V := V^{\mathsf{uneven}} \sqcup V^{\mathsf{sparse}} \sqcup K_1 \sqcup \ldots \sqcup K_k$ such that:*

1. *For every $i \in [k]$, the induced subgraph $G[K_i]$ is an ε-almost-clique;*
2. *Every vertex in V^{sparse} is $(\varepsilon/2)$-sparse;*
3. *Every vertex in V^{uneven} is $(\varepsilon/4)$-uneven.*

The key difference of Lemma 16 with prior decompositions for $(\Delta+1)$ coloring in [30, 5, 18, 13] is the introduction of V^{uneven} that captures vertices with "sufficiently large" higher degree neighbors. Allowing for such vertices is (seemingly) crucial for this type of decomposition that depends on the local degrees of vertices as opposed to maximum degree[3]. We postpone the proof of this lemma to the full version of the paper.

Coloring the Graph Using the Decomposition. For the rest of the proof, fix a decomposition of the graph $G(V, E)$ with some sufficiently small **absolute constant** $\varepsilon > 0$ (taking $\varepsilon = 10^{-4}$ would certainly suffice). In the following, we show that we can handle both V^{uneven} and V^{sparse} vertices first, and then color the almost-cliques using a result of [5] almost in a black-box way. As such, the main difference between our work and [5] (beside the decomposition) is in the treatment of vertices in $V^{\mathsf{uneven}} \cup V^{\mathsf{sparse}}$.

As in [5], the proof consists of two parts. We first show that $V^{\mathsf{uneven}} \cup V^{\mathsf{sparse}}$ can be colored from the sampled lists, and then show how to color each almost-clique given any arbitrary coloring of vertices outside the almost-clique. Before we move on, we make an assumption (without loss of generality) that is used in our concentration bounds.

▶ **Assumption 17.** *We may and will assume that degree of every vertex is at least $D_{\mathsf{min}} := \alpha \cdot \varepsilon^{10} \cdot \log n$ for some sufficiently large **absolute constant** $\alpha > 0$. This is without loss of generality as by sampling $\Theta(\log n)$ colors, any vertex with lower degree will have $L(v) = S(v)$ and hence we can greedily color these vertices after finding a coloring of the rest of the graph.*

Step one. The main part of the argument is the following lemma.

▶ **Lemma 18.** *Suppose for every vertex $v \in V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}$, we sample a set $L(v)$ of $\Theta(\varepsilon^{-6} \cdot \log n)$ colors independently and uniformly at random from $S(v) := \{1, \ldots, \deg(v) + 1\}$. Then, with high probability, the induced subgraph $G[V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}]$ can be properly colored from the sampled lists.*

We construct the coloring of Lemma 18 in two steps. The first step is to create "excess" colors on vertices, reducing the problem essentially to $(1 + \varepsilon)\deg$ coloring, and then using the simple argument for the proof of Part 1 of Theorem 12) to finalize this case as well. One important bit is that the first step of this argument should be done *simultaneously* for both V^{uneven} and V^{sparse}. We now sketch some the key ideas of the proof.

For the proof of Lemma 18, we need to partition vertices in V^{sparse} and V^{uneven} further in order to be able to handle the disparity in degree of vertices. As such, we define:

- $\psi := \varepsilon^2/32$: a parameter used throughout the definitions in this part for ease of notation.
- V^{small}: Let $\text{Small}(v) := \{u \in N(V) : \deg(u) < d_{\mathsf{small}}(v)\}$ where $d_{\mathsf{small}}(v) := \psi \cdot \deg(v)$. We define $V^{\mathsf{small}} \subseteq V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}$ as all vertices v with $|\text{Small}(v)| \geq 2d_{\mathsf{small}}(v)$.
- V^{large}: Let $\text{Large}(v) := \{u \in N(v) : \deg(u) > d_{\mathsf{large}}(v)\}$ where $d_{\mathsf{large}}(v) := 2\deg(v)$. We define $V^{\mathsf{large}} \subseteq V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}$ as all vertices v with $|\text{Large}(v)| \geq \psi \cdot \deg(v)$.[4]

[3] For instance, consider a vertex of degree d that is incident to d vertices of a $2d$-clique. Such a vertex is neither sparse (its neighborhood is a clique), nor belongs to an almost-clique for small $\varepsilon < 1$.

[4] We remark that the change in the place where ψ used in the two definitions above is intentional and not a typo.

As stated earlier, the goal of our first step is to construct excess colors for vertices. As it will become evident shortly, vertices in V^{small} actually do not need require having excess colors to begin with (roughly speaking, after coloring their very "low degree" neighbors in $\text{Small}(v)$, we are anyway left with many excess colors). Hence, we ignore these vertices in the first step altogether and handle them directly in the second one. Another important remark about the first step is that even though its goal is to color only $V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}$ (minus V^{small}), we assume *all* vertices of the graph (including almost-cliques) participate in its coloring procedure. This is only to simplify the math and after this step we simply *uncolor* all vertices that are not in $V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}$.

Creating Excess Colors. We start with the following coloring procedure as our first step:

Algorithm 1 FirstStepColoring: A procedure for finding a (partial) coloring of $G[V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}]$.

1. Iterate over vertices of V in an arbitrary order.
2. For every vertex v, **activiate** v w.p. $p_{\mathtt{active}} := \psi/16 \ \ (= \Theta(\varepsilon^2))$.
3. For every activated vertex v, pick a color $c_1(v)$ uniformly at random from $L(v)$ and if $c(v)$ is not used to color any neighbor of v so far, **color** v with $c_1(v)$.

We shall note right away that distribution of $c_1(v)$ for every vertex v in FirstStepColoring is simply uniform over $S(v)$. For any vertex $v \in V$, let $S_1(v)$ denote the list of available colors $S(v)$ after removing the colors assigned to neighbors of v in this procedure. Similarly, let $\deg_1(v)$ denote the degree of v after removing the colored neighbors of v. We show that $S_1(v)$ is "sufficiently larger" than $\deg_1(v)$ for all vertices in $V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}} \setminus V^{\mathsf{small}}$. Formally,

▶ **Lemma 19.** *There exists an absolute constant $\alpha \in (0,1)$ such that with high probability, for every $v \in V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}} \setminus V^{\mathsf{small}}$, we have $|S_1(v)| \geq \deg_1(v) + \alpha \cdot \varepsilon^6 \cdot \deg(v)$.*

The proof of of this lemma is given in three parts, each for coloring one of the sets V^{uneven}, V^{large} and $V^{\mathsf{sparse}} \setminus (V^{\mathsf{small}} \cup V^{\mathsf{large}})$ separately. The first two have an almost identical proof and are based on a novel argument – the third part uses a different argument which on a high level is similar to the approach of [5] (and [15, 18, 13], all rooted in an earlier work of [25]) for coloring sparse vertices (according to a global definition of sparse based on Δ), although several new challenges has to be addressed there as well.

▶ **Lemma 20.** *W.h.p. for all $v \in V^{\mathsf{uneven}}$: $|S_1(v)| \geq \deg_1(v) + \alpha \cdot \varepsilon^4 \cdot \deg(v)$.*

Proof. Let $\theta := (\varepsilon/4)$ and recall that all vertices in V^{uneven} are θ-uneven by Lemma 16. Fix a vertex v in V^{uneven} and let $U(v)$ be the neighbors u of v where $\deg(v) < (1-\theta) \cdot \deg(u)$. As v is θ-uneven $|U(v)| \geq \theta \cdot \deg(v)$. For any $u \in U(v)$, let $S_{\mathsf{ext}}(u) = S(u) \setminus S(v)$ denote the set of colors that are available (originally) to u but not to v. For $s_{\mathsf{ext}}(u) := |S_{\mathsf{ext}}(u)|$, we have,

$$s_{\mathsf{ext}}(u) = \deg(u) - \deg(v) \geq \deg(u) - (1-\theta) \cdot \deg(u) = \theta \cdot \deg(u). \tag{4}$$

We say that a vertex $u \in U(v)$ is *good* iff u is colored from $S_{\mathsf{ext}}(u)$ by FirstStepColoring. Let $n_{\mathsf{good}}(v)$ denote the number of good neighbors of v. It is easy to see that $|S_1(v)| \geq \deg_1(v) + n_{\mathsf{good}}(v)$ as colors of good vertices are not removed from $S(v)$. Our goal is to lower bound $n_{\mathsf{good}}(v)$ then. Define the following two events:

- $\mathcal{E}_{\mathsf{active}}$: For every vertex $u \in V$, the number of active neighbors of u, denoted by $\deg_{\mathsf{active}}(u)$, is between $(p_{\mathtt{active}}/2) \cdot \deg(u)$ and $(2p_{\mathtt{active}}) \cdot \deg(u)$.
- $\mathcal{E}^U_{\mathsf{active}}(v)$: The set $U^{\mathsf{active}}(v)$ of *active* vertices in $U(v)$ has size at least $(p_{\mathtt{active}}/2) \cdot \theta \cdot \deg(v)$.

By our Assumption 17 and a simple application of Chernoff bound, both event $\mathcal{E}_{\mathsf{active}}$ and $\mathcal{E}^{U}_{\mathsf{active}}(v)$ hold with high probability (recall the lower bound on size of $U(v)$) above. Note that both these events are only a function of the probability of activating each vertex and independent of choice of lists L. Hence, in the following we condition on these events (and all coins tosses for activation probabilities) and only consider the randomness with respect to choices in L.

Let $u_1, \ldots, u_k$ for $k := (p_{\mathtt{active}}/2) \cdot \theta \cdot \deg(v)$ be the first k vertices in $U^{\mathsf{active}}(v)$ according to the ordering of FirstStepColoring. Let $\mathcal{R}(u_i)$ denote all the random choices that govern whether u_i will be good or not. Note that by the time we process u_i at most $\deg_{\mathsf{active}}(u_i)$ colors from $S(u_i)$ may have been assigned to neighbors of u_i. Even if all of these colors are adversarially chosen to be in $S_{\mathsf{ext}}(u_i)$, the number of colors that if chosen by u_i make u_i a good vertex is at least:

$$s_{\mathsf{ext}}(u_i) - \deg_{\mathsf{active}}(u_i) \geq \theta \cdot \deg(u_i) - (2p_{\mathtt{active}}) \cdot \deg(u_i) > (\theta/2) \cdot \deg(u_i).$$
(by Eq (4) and event $\mathcal{E}_{\mathsf{active}}$, respectively and since $p_{\mathtt{active}} = \Theta(\varepsilon^2) < \theta/4$)

Even conditioned on everything else, this choice is only a function of $c_1(u_i)$ chosen uniformly at random from $S(u_i)$. As such,

$$\mathbb{P}\left(u_i \text{ is good} \mid \mathcal{R}(u_1), \ldots, \mathcal{R}(u_{i-1})\right) \geq \frac{(\theta/2) \cdot \deg(u_i)}{\deg(u_i)+1} \geq (\theta/3).$$

This implies that (i) $\mathbb{E}\left[n_{\mathsf{good}}(v)\right] \geq (\theta/3) \cdot k$ and (ii) the distribution of good vertices among first k vertices in $U^{\mathsf{active}}(v)$ stochastically dominates the binomial distribution $\mathcal{B}(k, \theta/3)$. By a basic concentration of binomial distributions (say by using Chernoff bound in Proposition 28):

$$\mathbb{P}\left(n_{\mathsf{good}}(v) < (\theta/6) \cdot k\right) \leq \exp\left(-\Theta(1) \cdot \theta \cdot k\right) = \exp\left(-\Theta(1) \cdot \varepsilon^4 \cdot \log n\right) \ll n^{-10}.$$
(by the choice of $\theta = \Theta(\varepsilon)$, $p_{\mathtt{active}} = \Theta(\varepsilon^2)$, k, and Assumption 17)

As $k = \Theta(\varepsilon^3 \cdot \deg(v))$ and $\theta = \Theta(\varepsilon)$, we obtain that w.h.p. $n_{\mathsf{good}}(v) \geq \Theta(\varepsilon^4) \cdot \deg(v)$. ◀

The following lemma has a similar proof as Lemma 20 and is postponed to the full version.

▶ **Lemma 21.** *W.h.p. for all $v \in V^{\mathsf{large}}$: $|S_1(v)| \geq \deg_1(v) + \alpha \cdot \varepsilon^4 \cdot \deg(v)$.*

Finally, the following lemma also has a relatively standard proof by-now and is postponed to the full version.

▶ **Lemma 22.** *Wh.p. for all $v \in V^{\mathsf{sparse}} \setminus (V^{\mathsf{small}} \cup V^{\mathsf{large}})$: $|S_1(v)| \geq \deg_1(v) + \alpha \cdot \varepsilon^6 \cdot \deg(v)$.*

Lemma 19 now follows directly from Lemmas 20, Lemma 21 and 22 and a union bound.

Exploiting Excess Colors. For the second step, consider the following procedure:

Algorithm 2 SecondStepColoring: A procedure for finishing the proper coloring of $G[V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}]$.

1. Iterate over uncolored vertices $v \in V^{\mathsf{sparse}} \cup V^{\mathsf{uneven}}$ in an *arbitrary* order and for each vertex v, let $N^{<}(v)$ denote the neighbors of v that appear before v in this ordering *plus* all neighbors of v that have been colored in the first step.
2. For each vertex v, if there exists a color in $L(v)$ that is not used to color any vertex $u \in N^{<}(v)$, color v with this color. Otherwise **abort**.

It is immediate that if SecondStepColoring does not **abort**, we find a proper coloring using the sampled colors in lists L. We can prove that **abort** happens with a small probability (the proof is postponed to the appendix).

▶ **Lemma 23.** *W.h.p.* SecondStepColoring *does* not **abort**.

Lemma 18 now follows from Lemmas 19 and 23 and a union bound.

Step two. In the second part of the proof, we are left with the coloring of almost-cliques from the sampled lists *after* fixing the colors of remaining vertices. This is done by the following lemma. This lemma is a simple generalization of a result of [5] for $(\Delta+1)$ coloring and the proof is via a simple "reduction" to the proof of the original lemma of [5].

Recall the definition of an ε-almost-cliques K in Definition 13. For a vertex $v \in K$, we define out-deg(v) as the number of neighbors of v that are outside K. Note that by definition of ε-almost-cliques, out-deg$(v) \leq 9\varepsilon \cdot \Delta(K)$. We prove the following lemma in the full version.

▶ **Lemma 24.** *Let K be an ε-almost-clique in G according to Definition 13 for some sufficiently small $\varepsilon > 0$ and define $\Delta(K) := \max_{v \in K} \deg(v)$. Suppose for every vertex $v \in K$, we* adversarially *pick a set $\overline{S}(v)$ of size at most* out-deg$(v) \leq 9\varepsilon \cdot \Delta(K)$ *from colors $\{1, \ldots, \deg(v)+1\}$. If for every vertex $v \in V$, we sample a set $L(v)$ of $\Theta(\varepsilon^{-1} \cdot \log n)$ colors independently from the set of colors $\{1, \ldots, \deg(v)+1\}$, then, with high probability, the induced subgraph $G[K]$ can be properly colored from the lists $L(v) \setminus \overline{S}(v)$ for $v \in C$.*

Proof of Theorem 12 – Part 2. We fix a decomposition of the graph G according to Lemma 16 for some sufficiently small absolute constant $\varepsilon > 0$ (taking $\varepsilon = 10^{-4}$ would certainly suffice). Lemma 18 allows us to argue that with high probability, all vertices except for almost-cliques in the decomposition can be properly colored using the sampled lists. We fix such a coloring of those vertices. We then iterate over almost-cliques one by one, and invoke Lemma 24 to each almost-clique K_i by letting $\overline{S}(v)$ for every $v \in K_i$ to be the set of colors used so far in this process for coloring neighbors of v outside this almost-clique. This allows us to color this almost-clique in a way that its coloring can be extended to the partial coloring computed so far (with high probability). Iterating over all almost-cliques this way and using a union bound finalizes the proof. ◀

5 Sublinear Algorithms from Palette Sparsification

In this section, we describe some applications of our palette sparsification theorems to sublinear algorithms following the work of [5]. In the following, we give the definition of each of the two models of streaming algorithms and sublinear-time algorithms formally, followed by the resulting algorithms from palette sparsification for each one separately.

Streaming Algorithms. In the streaming model, edges of the graph are presented one by one to an algorithm that can make one or a few passes over the input and use a limited memory to process the stream and has to output the answer at the end of the last pass. In this paper, we only consider *single-pass* streaming algorithms. We can obtain the following algorithms from Results 1, 2, and 3.

▶ **Corollary 25.** *There exists randomized single-pass streaming algorithms for finding each of the following colorings with high probability:*

- *a $(1+\varepsilon)\Delta$ coloring of any general graph with $O_\varepsilon(n \log n)$ space;*
- *an $O(\frac{\Delta}{\gamma \cdot \ln \Delta})$ coloring of any triangle-free graph with $\widetilde{O}(n \cdot \Delta^{2\gamma})$ space;*
- *a $(1+\varepsilon)\deg$-list coloring of any general graph with $O_\varepsilon(n \cdot \log^2 n)$ space;*
- *a $(\deg+1)$ coloring of any general graph with $O(n \cdot \log^2 n)$ space.*

The streaming algorithms in Corollary 25 are basically as follows: we sample the colors in L at the beginning of the stream and throughout the stream whenever an edge (u, v) is presented, we check whether $L(u) \cap L(v) = \emptyset$ or not; if not we store this edge explicitly. At this point, obtaining the first two algorithms in Corollary 25 from Results 1 and 2 is straightforward (see also [5]). However, the results for the latter two parts does not immediately follow from the argument for other two (or the one in [5]). This is due to the fact that both $(1 + \varepsilon)\deg$ and $(\deg +1)$ problems are "local" problems with dependence on deg instead of Δ. We postpone the proof of this corollary to the full version of the paper. We conclude this part by noting that our results can be extended to dynamic streams where edges can be both inserted to and deleted from the stream by increasing the space of the algorithm with polylog(n) factors as was done in [5].

Sublinear-Time Algorithms. When designing sublinear-time algorithms, it is crucial to specify the data model as the algorithm cannot even read the entire input once. We assume the standard query model for sublinear-time algorithms on general graphs (see, e.g., [17, Chapter 10]). In this model, we have the following three types of queries (i) what is the degree of a vertex v; (ii) what is the i-th neighbor of a given vertex v; and (iii) whether a given pair of vertices (u, v) are neighbor to each other or not. We say an algorithm is *non-adaptive* if it asks all its queries in parallel in one go.

We can obtain the following algorithms from Results 1, 2, and 3.

▶ **Corollary 26.** *There exists randomized non-adaptive sublinear-time algorithms for finding each of the following colorings with high probability:*

- *a* $(1 + \varepsilon)\Delta$ *coloring of any general graph in* $\widetilde{O}_\varepsilon(n^{3/2})$ *time;*
- *an* $O(\frac{\Delta}{\gamma \cdot \ln \Delta})$ *coloring of any triangle-free graph in* $\widetilde{O}(n^{3/2+2\gamma})$ *time;*
- *a* $(1 + \varepsilon)\deg$*-list coloring of any general graph in* $\widetilde{O}(n^{3/2})$ *time;*
- *a* $(\deg +1)$ *coloring of any general graph in* $\widetilde{O}(n^{3/2})$ *time.*

The sublinear-time algorithms in Corollary 26 are again based on finding the edges of the conflict-graph E_{conflict} using $\widetilde{O}(\min\{n\Delta, n^2/\Delta\})$ queries for the case of $(1+\varepsilon)\Delta$ coloring and $\widetilde{O}(\min\{n\Delta, n^2/\Delta^{1-2\gamma}\})$ queries for triangle-free graphs. This can be done using the simple approach of [5] but as before that does not work for the last two parts. As such, in the full version of the paper, we give another simple way for finding edges of the conflict-graph using a small number of queries, and conclude the proof of Corollary 26.

A Probabilistic Tools

We use the following standard probabilistic tools.

▶ **Proposition 27** (Lovász Local Lemma – symmetric form; cf. [3]). *Let $\mathcal{E}_1, \ldots, \mathcal{E}_n$ be n events such that each event $\mathcal{E}_i$ is mutually independent of all other events besides at most d, and $\mathbb{P}(\mathcal{E}_i) \leq p$ for all $i \in [n]$. If $e \cdot p \cdot (d+1) \leq 1$ (where $e = 2.71...$), then $\mathbb{P}\left(\wedge_{i=1}^{n} \overline{\mathcal{E}_i}\right) > 0$.*

▶ **Proposition 28** (Chernoff-Hoeffding bound; cf. [3]). *Let $X_1, \ldots, X_n$ be n independent random variables where each $X_i \in [0, b]$. Define $X := \sum_{i=1}^{n} X_i$. Then, for any $t > 0$,*

$$\mathbb{P}\left(|X - \mathbb{E}[X]| > t\right) \leq 2 \cdot \exp\left(-\frac{2t^2}{n \cdot b^2}\right).$$

Moreover, for any $\delta \in (0, 1)$,

$$\mathbb{P}\left(|X - \mathbb{E}[X]| > \delta \cdot \mathbb{E}[X]\right) \leq 2 \cdot \exp\left(-\frac{\delta^2 \cdot \mathbb{E}[X]}{3b}\right).$$

A function $f(x_1, \ldots, x_n)$ is called *c-Lipschitz* iff changing any single x_i can affect the value of f by at most c. Additionally, f is called *r-certifiable* iff whenever $f(x_1, \ldots, x_n) \geq s$, there exists at most $r \cdot s$ variables $x_{i_1}, \ldots, x_{i_{r \cdot s}}$ so that knowing the values of these variables certifies $f \geq s$.

▶ **Proposition 29** (Talagrand's inequality; cf. [26]). *Let $X_1, \ldots, X_n$ be n independent random variables and $f(X_1, \ldots, X_n)$ be a c-Lipschitz function; then for any $t \geq 1$,*

$$\mathbb{P}\left(|f - \mathbb{E}[f]| > t\right) \leq 2 \exp\left(-\frac{t^2}{2c^2 \cdot n}\right).$$

Moreover, if f is additionally r-certifiable, then for any $b \geq 1$,

$$\mathbb{P}\left(|f - \mathbb{E}[f]| > b + 30c\sqrt{r \cdot \mathbb{E}[f]}\right) \leq 4 \exp\left(-\frac{b^2}{8c^2 r\, \mathbb{E}[f]}\right).$$

B Sublinear Algorithms from Graph Partitioning

In this appendix, we deviate from our theme of palette sparsification and consider another technique for designing sublinear algorithms for graph coloring. A simple technique that lies at the core of various algorithms for graph coloring in different models is *random graph partitioning* (see, e.g. [27, 28, 19, 12, 7]). While the exact implementation of this technique varies significantly from one application to another, the basic idea is as follows: Partition the vertices of the graph G randomly into multiple parts $V_1, \ldots, V_k$, then color the induced subgraphs $G[V_1], \ldots, G[V_k]$ separately using disjoint palettes of colors for each subgraph. The hope is that each subgraph $G[V_i]$ has become "simpler enough" so that it can be colored "easily" with a "small" palette of colors.

We apply the same basic idea in this section. To state our result, we need some definitions first. We say that a family $\mathcal{G}$ of graphs is *hereditary* iff for every $G \in \mathcal{G}$, every induced subgraph of G also belongs to $\mathcal{G}$, namely, $\mathcal{G}$ is closed under vertex deletions.

▶ **Definition 30.** *Let $\mathcal{G}$ be a hereditary family of graphs and $\zeta : \mathbb{N}^+ \to \mathbb{N}^+$ be a non-decreasing function. We say that $\mathcal{G}$ is **ζ-colorable** iff every graph G in $\mathcal{G}$ is $\zeta(\Delta)$-colorable, where $\Delta := \Delta(G)$ denotes the maximum degree of G.*

For instance, the family of all graphs is an ζ-colorable family for the function $\zeta(\Delta) = \Delta+1$, and triangle-free graphs are ζ-colorable for $\zeta(\Delta) = O(\frac{\Delta}{\ln \Delta})$.

▶ **Theorem 31.** *Let $\mathcal{G}$ be a ζ-colorable family of graphs (see Definition 30) and $G(V, E)$ be an n-vertex graph with maximum degree Δ in $\mathcal{G}$. For the parameters*

$$\varepsilon > 0, \qquad 1 \leq k \leq \frac{\varepsilon^2 \cdot \Delta}{9 \ln n}, \qquad C := C(\varepsilon, k) = k \cdot \zeta\Big((1+\varepsilon) \cdot \frac{\Delta}{k}\Big),$$

suppose we partition V into k sets $V_1, \ldots, V_k$ uniformly at random; then with high probability G can be C-colored by coloring each $G[V_i]$ with a distinct palette of size C/k.

The proof of this theorem is by simply showing that the maximum degree of each graph $G[V_i]$ is sufficiently small, itself a simple application of Chernoff bound. As such, we postpone it to the full version of the paper.

B.1 Sublinear Algorithms from Theorem 31

As before, we only focus on streaming and query algorithms in this section. Table 2 contains a summary of our results in this part. In the following two algorithms, the parameters C and k are the same as in Theorem 31.

Algorithm 3 Streaming Algorithms from Theorem 31.

1. At the beginning, sample a random k-partitioning of the vertices into $V_1, \ldots, V_k$.
2. Throughout the stream, store any edge that belongs to one of the graphs $G[V_i]$.
3. At the end, use the stored subgraphs to find a C-coloring of G by coloring each $G[V_i]$ with a distinct palette of size C/k.

Using this algorithm and Theorem 31, we obtain the following corollary (proven formally in the full version).

Table 2 A sample of our sublinear algorithms obtained as corollaries of Theorem 31. All the streaming algorithms here are *single-pass* and all the sublinear-time algorithms are *non-adaptive*.

# of Colors	Graph Family	Streaming	Sublinear-Time
$O(\frac{\Delta}{\gamma \cdot \ln \Delta})$	Triangle-Free	$O(n\Delta^{2\gamma})$ space	$\widetilde{O}(n^{3/2+2\gamma})$ time
$O(\frac{\Delta \ln\ln \Delta}{\gamma \cdot \ln \Delta})$	K_r-Free	$O(n\Delta^{2\gamma})$ space	$\widetilde{O}(n^{3/2+\Theta(\gamma)})$ time
$O(\frac{\Delta}{\gamma \ln \Delta} \cdot \ln r)$	Locally r-Colorable	$O(n\Delta^{2\gamma})$ space	$\widetilde{O}(n^{3/2+2\gamma})$ queries
$O(\frac{\Delta}{\gamma \ln\ln n} \cdot \ln r)$	Locally r-Colorable	$O(n\Delta^{2\gamma})$ space	poly(n) time
$O(\frac{\Delta}{\ln(1/\delta)})$	δ-Sparse-Neighborhood	$O(n/\delta)$ space	$\widetilde{O}(n^{3/2} \cdot \text{poly}(1/\delta))$ time

▶ **Corollary 32.** *Let $\mathcal{G}$ be a ζ-colorable family of graphs (Definition 30). There exists a randomized streaming algorithm that makes a single pass over any graph G from $\mathcal{G}$ with maximum degree Δ, and for any setting of parameters:*

$$\varepsilon > 0, \qquad 1 \leq k \leq \frac{\varepsilon^2 \cdot \Delta}{9 \ln n}, \qquad C := C(\varepsilon, k) = k \cdot \zeta\Big((1+\varepsilon) \cdot \frac{\Delta}{k}\Big),$$

with high probability computes a proper C-coloring of G using $O(n \cdot \frac{\Delta}{k})$ space.

Algorithm 4 Query Algorithms from Theorem 31.

1. Sample a random k-partitioning of the vertices into $V_1, \ldots, V_k$.
2. Obtain the subgraphs $G[V_1], \ldots, G[V_k]$ using the following procedure:
   - If $\Delta > n/k$, then non-adaptively query all pairs of vertices u, v where both u, v belong to the same V_i (using pair queries);
   - Otherwise, non-adaptively query all neighbors of all vertices u (using neighbor queries).
3. Find a C-coloring of G by coloring each $G[V_i]$ with a distinct palette of size C/k (with no further access to G).

Again, using this algorithm and Theorem 31, we obtain the following corollary (proven formally in the full version).

▶ **Corollary 33.** *Let $\mathcal{G}$ be a ζ-colorable family of graphs (Definition 30). There exists a randomized non-adaptive algorithm that given query access to any graph G from $\mathcal{G}$ with maximum degree Δ, for any setting of parameters:*

$$\varepsilon > 0, \qquad 1 \leq k \leq \frac{\varepsilon^2 \cdot \Delta}{9 \ln n}, \qquad C := C(\varepsilon, k) = k \cdot \zeta\Big((1+\varepsilon) \cdot \frac{\Delta}{k}\Big),$$

with high probability computes a proper C-coloring of G using $\min\big\{O(n\Delta) + O(n^2/k)\big\}$ queries.

We conclude this section with some important remarks about Corollaries 32 and 33.

▶ Remark 34 (Runtime of our algorithms). We did not state the runtime of our algorithms in this section and focused primarily on space and query complexity of algorithms, respectively.

This is because in both cases, the runtime of the algorithm crucially depends on the runtime of the coloring algorithm for finding a ζ-coloring of each subgraph $G[V_i]$ which is specific to the family $\mathcal{G}$ (and ζ) and thus not known a-priori.

Nevertheless, for **almost all** our applications to specific families of graphs (with one exception), **the runtime of the algorithms is also sublinear in the input size**.

B.2 Particular Implications of Theorem 31

We now list the applications of Theorem 31 and Corollaries 32 and 33 to different families of "locally sparse" graphs that are colorable with much fewer than $(\Delta+1)$ colors.

Triangle-Free Graphs

As stated earlier, triangle-free graphs admit an $O(\frac{\Delta}{\ln \Delta})$ coloring. This was first proved by Johansson [21] by showing an upper bound of $9\frac{\Delta}{\ln \Delta}$ on the chromatic number of these graphs[5]. The leading constant was then improved to 4 by Pettie and Su [29] and very recently to $1+o(1)$ by Molloy [24] matching the result of Kim for graphs of girth 5 [23]. Moreover, Molloy's result implies an $\widetilde{O}(n\Delta^2)$ time algorithm for finding such a coloring.

Note that triangle-free graphs form a hereditary family of graphs and aforementioned results imply that they are $\zeta_{\textsf{tri-free}}$-colorable for $\zeta_{\textsf{tri-free}}(\Delta) = O(\frac{\Delta}{\ln \Delta})$. As such, Corollaries 32 and 33 imply the following algorithms for any $\gamma \in (0, 1/2)$ as small as $\Theta(\frac{\ln\ln\Delta}{\ln\Delta})$:

- **Streaming Model:** A randomized single-pass $\widetilde{O}(n^{1+\gamma})$ space algorithm for $O(\frac{\Delta}{\gamma \ln \Delta})$ coloring of triangle-free graphs. The post-processing time of this algorithm is $\widetilde{O}(n \cdot \Delta^{\gamma})$.
- **Query Model:** A randomized non-adaptive $\widetilde{O}(n^{3/2+\gamma})$-query algorithm for $O(\frac{\Delta}{\gamma \ln \Delta})$ coloring of triangle-free graphs. The runtime of this algorithm is also $\widetilde{O}(n^{3/2+2\gamma})$.

Both results above are proved by picking $\varepsilon = \Theta(1)$ and $k = \Theta(\Delta^{1-\gamma})$, thus obtaining a C-coloring:

$$C = C(\varepsilon, k) = k \cdot \zeta_{\textsf{tri-free}}\Big(\Theta(\Delta/k)\Big) = O(k) \cdot \frac{\Delta/k}{\ln(\Delta/k)} = O(\frac{\Delta}{\ln \Delta^{\gamma}}) = O(\frac{\Delta}{\gamma \ln \Delta}).$$

K_r-Free Graphs

For any fixed integer $r \geq 1$, we refer to any graph that does not contain a copy of the K_r, namely, the clique on r vertices, as a K_r-free graph. Johansson proved that any K_r-free graph admits an $O(\frac{\Delta \ln\ln\Delta}{\ln\Delta})$ coloring [22] and gave an $O(n \cdot \text{poly}(\Delta))$ time algorithm for finding it[6]. This result was very recently simplified (and extended to r beyond a fixed constant) by Molloy [24] (however the latter result does not imply an efficient algorithm).

Similar to the case of triangle-free graphs, combining these results with Corollaries 32 and 33 imply the following algorithms for any $\gamma \in (0, 1/2)$ as small as $\Theta(\frac{\ln\ln\Delta}{\ln\Delta})$:

- **Streaming Model:** A randomized single-pass $\widetilde{O}(n^{1+\gamma})$ space algorithm for $O(\frac{\Delta \ln\ln\Delta}{\gamma \ln\Delta})$ coloring of K_r-free graphs. The post-processing time of this algorithm is $O(n^{1+\Theta(\gamma)})$.
- **Query Model:** A randomized non-adaptive $\widetilde{O}(n^{3/2+\gamma})$-query algorithm for $O(\frac{\Delta \ln\ln\Delta}{\gamma \ln\Delta})$ coloring of K_r-free graphs. The runtime of this algorithm is also $O(n^{3/2+\Theta(\gamma)})$.

[5] This result of Johansson was never published – see [26, Chapter 13] for a lucid presentation of the original proof.

[6] This result of Johansson was also never published – see [6] for a streamlined version of this proof.

Graphs with r-Colorable Neighborhoods

For any fixed integer $r \geq 1$, we say that a graph G is locally r-colorable iff neighborhood of every vertex in G is r-colorable. Johansson also proved that r-colorable graphs admits an $O(\frac{\Delta}{\ln \Delta} \cdot \ln r)$ coloring [22]; see [6] for a proof and also an algorithm that finds such a coloring in $\text{poly}(n \cdot 2^{\Delta})$ time (which uses, as a subroutine, a result of [9]).

It is easy to see that locally r-colorable graphs also form a hereditary family. Consequently, as before, Corollaries 32 and 33 imply the following for any $\gamma \in (0, 1/2)$ as small as $\Theta(\frac{\ln \ln \Delta}{\ln \Delta})$:

- **Streaming Model:** A randomized single-pass $\widetilde{O}(n^{1+\gamma})$ space algorithm for $O(\frac{\Delta}{\gamma \ln \Delta} \cdot \ln r)$ coloring of locally r-colorable graphs. The post-processing time of the algorithm is $\text{poly}(n \cdot 2^{\Delta^{\gamma}})$.
- **Query Model:** A randomized non-adaptive $\widetilde{O}(n^{3/2+\gamma})$-query algorithm for $O(\frac{\Delta}{\gamma \ln \Delta} \cdot \ln r)$ coloring of locally r-colorable graphs. The runtime of this algorithm is also $\text{poly}(n \cdot 2^{\Delta^{\gamma}})$.

Graphs with δ-Sparse Neighborhoods

For any $\delta \in (0, 1)$, we say a graph $G(V, E)$ has a δ-sparse neighborhood iff the total number of edges in the neighborhood of any vertex v (i.e., edges between neighbors of v) is at most $\delta \cdot \Delta^2$ (not to be confused with Definition 14 for ε-sparse vertices, albeit the two definitions are equivalent for Δ-*regular* graphs by setting $\delta = (1 - \varepsilon^2)$). Alon, Krivelevich and Sudakov [2] proved that any graph G with maximum degree Δ and δ-sparse neighborhood admits an $O(\frac{\Delta}{\log (1/\delta)})$ coloring and that this is tight for all admissible values of δ and Δ.

We note that unlike all other families of graphs considered in this section, the family of sparse-neighborhood graphs is *not* a hereditary family. As such, we cannot readily apply Theorem 31 (and hence Corollaries 32 and 33). However, we can modify the proof of Theorem 31 slightly to apply to this case as well (see the full version).

▶ **Lemma 35.** *For any $\delta \in (0, 1)$, let $G(V, E)$ be an n-vertex graph with maximum degree Δ and δ-sparse neighborhoods. For the parameters*

$$1 \leq k \leq \frac{\delta \cdot \Delta}{9 \cdot \ln n}, \qquad C := \Theta(\frac{\Delta}{\ln (1/\delta)}),$$

suppose we partition V into k sets $V_1, \ldots, V_k$ uniformly at random; then with high probability G can be C-colored by coloring each $G[V_i]$ with a distinct palette of size C/k.

Similar to Corollaries 32 and 33, this in turn implies the following algorithms:

- **Streaming Model:** A randomized single-pass $\widetilde{O}(n/\delta)$ space algorithm for $O(\frac{\Delta}{\ln (1/\delta)})$ coloring of graphs with δ-sparse neighborhoods. The post-processing time is $\widetilde{O}(n \cdot \text{poly}(1/\delta))$.
- **Query Model:** A randomized non-adaptive $\widetilde{O}(n^{3/2}/\delta)$-query algorithm for $O(\frac{\Delta}{\ln (1/\delta)})$ coloring of graphs with δ-sparse neighborhoods. The runtime of the algorithm is $\widetilde{O}(n^{3/2} \cdot \text{poly}(1/\delta))$

On Hitting-Set Generators for Polynomials That Vanish Rarely

Abstract

The problem of constructing hitting-set generators for polynomials of low degree is fundamental in complexity theory and has numerous well-known applications. We study the following question, which is a relaxation of this problem: Is it easier to construct a hitting-set generator for polynomials $p\colon \mathbb{F}^n \to \mathbb{F}$ of degree d if we are guaranteed that the polynomial vanishes on at most an $\varepsilon > 0$ fraction of its inputs? We will specifically be interested in tiny values of $\varepsilon \ll d/|\mathbb{F}|$. This question was first considered by Goldreich and Wigderson (STOC 2014), who studied a specific setting geared for a particular application, and another specific setting was later studied by the third author (CCC 2017).

In this work our main interest is a *systematic study of the relaxed problem*, in its general form, and we prove results that significantly improve and extend the two previously-known results. Our contributions are of two types:

- Over fields of size $2 \leq |\mathbb{F}| \leq \text{poly}(n)$, we show that the seed length of any hitting-set generator for polynomials of degree $d \leq n^{.49}$ that vanish on at most $\varepsilon = |\mathbb{F}|^{-t}$ of their inputs is at least $\Omega\left((d/t) \cdot \log(n)\right)$.
- Over $\mathbb{F}_2$, we show that there exists a (non-explicit) hitting-set generator for polynomials of degree $d \leq n^{.99}$ that vanish on at most $\varepsilon = |\mathbb{F}|^{-t}$ of their inputs with seed length $O\left((d-t) \cdot \log(n)\right)$. We also show a polynomial-time computable hitting-set generator with seed length $O\left((d-t) \cdot \left(2^{d-t} + \log(n)\right)\right)$.

In addition, we prove that the problem we study is closely related to the following question: "Does there exist a small set $S \subseteq \mathbb{F}^n$ whose degree-d closure is very large?", where the degree-d closure of S is the variety induced by the set of degree-d polynomials that vanish on S.

Acknowledgements We are grateful to an exceptionally helpful anonymous reviewer, who pointed us to the work of Nie and Wang [33] and to follow-up works, suggested an alternative proof strategy for the lower bound in the special case of prime fields (the alternative proof for this special case appears in the full version), and helped improve our initial results.

1 Introduction

Let $\mathcal{P}_{n,q,d}$ denote the set of all polynomials $\mathbb{F}^n \to \mathbb{F}$ of total degree d over the field of size $q = |\mathbb{F}|$. We think of n as sufficiently large, and of the degree d and the field size q as functions of n. For simplicity, throughout the paper we assume that $d < n$.[1]

A fundamental problem in complexity theory is that of constructing *hitting-set generators for low-degree polynomials*. Recall that a Hitting-Set Generator (HSG) for $\mathcal{P}_{n,q,d}$ is a function $H\colon \{0,1\}^\ell \to \mathbb{F}^n$ such that for every non-zero polynomial $p \in \mathcal{P}_{n,q,d}$ there exists $s \in \{0,1\}^\ell$ satisfying $p(H(s)) \neq 0$ (see Definition 11); in other words, every non-zero polynomial $p \in \mathcal{P}_{n,q,d}$ does not vanish on at least one element in the *hitting-set* $S = \left\{H(s)\colon s \in \{0,1\}^\ell\right\}$. The two main measures of efficiency for HSGs are the seed length ℓ (equivalently, the size of the hitting-set S as a multiset) and the computational complexity of H as a function (i.e., the computational complexity of generating an element of the hitting-set S given its index s).

A standard linear-algebraic argument yields a lower bound of $\Omega\left(d \cdot \log\left(n/d\right)\right)$ on the seed length of any HSG for $\mathcal{P}_{n,q,d}$, and a standard probabilistic argument shows that there *exists* a HSG for $\mathcal{P}_{n,q,d}$ with matching seed length $O\left(d \cdot \log(n/d) + \log\log(q)\right)$ (see Fact 14 and Fact 15). Naturally, the probabilistic upper-bound does not guarantee that the function H is *efficiently-computable*. Thus, the main open problem concerning HSGs for $\mathcal{P}_{n,q,d}$ is to construct efficiently-computable HSGs with seed length that matches the known lower bound. This well-known problem (as well as a variant that refers to *pseudorandom generators* as in Definition 13) has attracted a significant amount of attention over the years; see, e.g., [32, 29, 26, 25, 9, 10, 8, 27, 43, 28, 12, 35], and the related survey by Viola [42].

Several years ago, Goldreich and Wigderson [18, Section 5] considered a *relaxed version* of the foregoing problem. In general terms, what they asked is the following:

> Does the HSG problem become easier if we are guaranteed that the polynomial *vanishes rarely* (i.e., has very few roots)?

Note that, intuitively, we expect that the relaxed problem will indeed be easier: This is both since there are less polynomials that vanish rarely (than arbitrary polynomials), and since for any such polynomial p, almost all inputs will "hit" p.

In their original paper, Goldreich and Wigderson considered a specific instance of this problem, geared for a particular application (see Section 1.2 for details). In this paper our goal is to *study the relaxed problem in and of itself, in a systematic and general way*. Our motivation for doing so is three-fold. First, this is a special (and potentially-easy) case of the classical HSG problem, and thus constitutes a potential path to make progress on the classical problem. Secondly, the relaxed question is of independent interest as part of the broad study of *quantified derandomization*, which was initiated in the original work of Goldreich and Wigderson [18] (see also, e.g., [40, 11, 14]). And thirdly, as polynomial-based

[1] Most of our results also carry on to the setting of $d > n$, albeit with less "clean" parametrizations.

constructions are ubiquitous in complexity theory, any progress in our understanding of structured classes of polynomials or in related HSG constructions may be valuable for other explicit constructions.

To be more formal, denote by $\mathcal{P}_{n,q,d,\varepsilon}$ the set of polynomials $p \in \mathcal{P}_{n,q,d}$ such that $\Pr_{x\in\mathbb{F}^n}[p(x)=0] \leq \varepsilon$; that is, $\mathcal{P}_{n,q,d,\varepsilon}$ is the set of degree-d polynomials that *vanish rarely*, where the notion of "rarely" is parametrized by the parameter ε. The two main questions we consider in this context are:

- **The combinatorial question:** What is the minimal size of a hitting-set for $\mathcal{P}_{n,q,d,\varepsilon}$? Equivalently, we ask what is the minimal seed length of any HSG for $\mathcal{P}_{n,q,d,\varepsilon}$. This question is combinatorial since it refers to the *existence* of a HSG, regardless of its computational complexity.
- **The computational question:** For which values of $\varepsilon > 0$ can we construct a HSG for $\mathcal{P}_{n,q,d,\varepsilon}$ with small seed length that will be *efficiently-computable*? In other words, can we simultaneously optimize not only the seed length but also the *computational complexity* of HSGs for $\mathcal{P}_{n,q,d,\varepsilon}$?

1.1 Context and Previous Work

Let us first delineate some trivial values for ε. To do so, first recall that we expect a random polynomial to vanish on q^{-1} of its inputs. Now, by the Schwartz-Zippel lemma, any non-zero $p \in \mathcal{P}_{n,q,d}$ has at most an $\varepsilon = d/q$ fraction of roots; this bound is quite good when q is large compared to d, and in general, for arbitrary d and q, any non-zero polynomial vanishes on at most $1-\delta$ of its inputs, where $\delta \geq q^{-d/(q-1)}$ denotes the relative distance of the Reed-Muller code of degree d over $\mathbb{F}_q$. Therefore, the value $\varepsilon = 1-\delta$ represents the general case (i.e., the case of hitting *any* non-zero polynomial). Remarkably, we also have a minimal non-zero value that ε can have: By a theorem of Warning [45], every polynomial in $\mathbb{F}_q^n \to \mathbb{F}_q$ of degree d that vanishes *somewhere* vanishes on at least a q^{-d} fraction of its inputs. Therefore, hitting polynomials that vanish on $\varepsilon < q^{-d}$ fraction of their inputs is trivial, since such polynomials have no zeroes. It will be useful to denote $\varepsilon = q^{-t}$ from now on.

Figure 1 The two extremal values of ε (i.e., $\varepsilon = q^{-d}$ and $\varepsilon = 1-\delta$) and the expected $\varepsilon = q^{-1}$ for a random polynomial. (The parameter δ denotes the relative distance of the corresponding q-ary Reed-Muller code $RM(n,d)$.)

Referring to the combinatorial question, the standard probabilistic argument mentioned before shows there exists a HSG for $\mathcal{P}_{n,q,d,\varepsilon}$ with seed length $O(\log\log(|\mathcal{P}_{n,q,d,\varepsilon}|))$. Thus, the combinatorial question is intimately connected to the long-standing open problem of determining the *weight distribution of the Reed-Muller code*, i.e., *counting* the number of polynomials in $\mathcal{P}_{n,q,d}$ that vanish on precisely $\varepsilon > 0$ of their inputs, for every $\varepsilon > 0$. The latter problem has been studied since the late 60's (see, e.g., [4, 22]), but is currently settled only for $d = 2$ (see [37, 31]). Only recently have general results been obtained for $d > 2$, and the bounds in these results are asymptotic (rather than precise bounds) and hold only over $\mathbb{F}_2$ (see [24, 1]). More generally, this problem is a special case of the well-known problem of studying weight distributions of (classes of) linear codes, which is typically tackled using weight enumerator polynomials (for relevant background see, e.g., [30, Chapter 5]). Note, however, that the weight distribution problem is more general, since it refers to all non-trivial values of $\varepsilon > 0$, whereas in our setting we focus only on tiny values of ε.

Another related line of works focuses on structural properties of *biased polynomials*. Fixing a polynomial $p\colon \mathbb{F}^n \to \mathbb{F}$ and looking at the distribution over $\mathbb{F}$ that is obtained by evaluating p at a random point, we can ask whether this distribution is close to uniform, or whether it is far from uniform, in which case we call the polynomial biased. A sequence of works showed that biased polynomials are very "structured", in the sense that they can be determined by a relatively-small number of polynomials of lower degree (see [19, 23, 21, 5, 7, 6]). Our setting is much more specific than the setting in these works, since their assumption is only that the polynomial is *biased*, whereas our assumption is that the polynomial is biased in a very specific manner (i.e., one output-value has tiny weight $\varepsilon > 0$). Thus, the results in these works typically do not seem sufficiently strong to be useful in our more specific setting.[2]

Goldreich and Wigderson [18, Section 5], who were motivated by a specific application in circuit complexity (derandomization of $\mathcal{AC}^0[\oplus]$), constructed a polynomial-time computable HSG for the setting of $q = 2$ and $\varepsilon = 2^{-(d-O(1))} = O(2^{-d})$ (for details see Section 1.2). Thus, they gave an upper-bound for the *computational question*, which holds only for $\mathbb{F}_2$ polynomials with extremely few roots. In a subsequent work by the third author [40], two combinatorial lower bounds were proved for the setting of $q = \text{poly}(n)$ and $\varepsilon = q^{-O(1)}$ (again, for details see Section 1.2). Thus, the subsequent work showed lower bounds for the *combinatorial question*, which hold only for polynomials over $\mathbb{F}_{\text{poly}(n)}$ with a relatively-large number of roots (i.e., only mildly less roots than the expected value of $\varepsilon = q^{-1}$). In both previous works, ad-hoc arguments were used to obtain the corresponding results.

1.2 Our Main Results

Our first main result is a general lower bound for the combinatorial problem. For context, in [40] it was shown that when $q = \text{poly}(n)$, any HSG for $\mathcal{P}_{n,d,q,q^{-O(1)}}$ requires a seed of length $\Omega(d^{\Omega(1)} \cdot \log(n/d^{\Omega(1)}))$; and any HSG with constant density[3] for $\mathcal{P}_{n,d,q,q^{-1}}$ requires a seed of length $\Omega(d \cdot \log(n/d))$. Thus, both previous lower bounds referred to the setting of $q = \text{poly}(n)$ and of $\varepsilon = q^{-O(1)}$ (i.e., $t = O(1)$).

The following result shows a lower bound that is both significantly stronger, and – more importantly – applies to a far broader parameter setting. In particular, the following result applies to a general $q \leq \text{poly}(n)$ and to values of $\varepsilon = q^{-t}$ almost up to the extreme value of $\varepsilon = q^{-d}$, and gives a lower bound of $\Omega((d/t) \cdot \log(n))$:

▶ **Theorem 1** (lower bound over general fields). *For every constant $c > 1$ there exists a constant $\gamma > 0$ such that the following holds. For every $n, q, d, t \in \mathbb{N}$ such that $2 \leq q \leq n^c$ is a prime power, $d \leq n^{.49}$, and $t \leq \gamma \cdot d$, any HSG for $\mathcal{P}_{n,q,d,q^{-t}}$ requires a seed of length $\Omega\left((d/t) \cdot \log(n)\right)$.*

Let us parse the meaning of the lower bound in Theorem 1. For comparison, recall that there exists a HSG for all polynomials of degree $d \leq n^{.49}$ with seed length $O(d \cdot \log(n))$. Theorem 1 tells us that the relaxation of only requiring to "hit" polynomials that vanish with probability q^{-t} can "buy" a factor of at most $1/t$ in the seed length. In particular, there does not exist a significantly smaller hitting-set for polynomials that vanish with probability $q^{-O(1)}$. Perhaps surprisingly, this is also true for polynomials that vanish with probability $q^{-d^{o(1)}}$ (since the lower bound remains almost linear in $d \cdot \log(n)$). Only for polynomials that vanish with probability $q^{-d^{\Omega(1)}}$ does our lower bound imply that a significantly smaller

[2] One exception is the field $\mathbb{F}_2$, in which the notions of bias and of "vanish rarely" converge. Indeed, the proofs of our results for $\mathbb{F}_2$ use insights developed in this sequence of works.

[3] A hitting-set S for a class $\mathcal{P}$ has density $\varepsilon > 0$ if for every $p \in \mathcal{P}$ it holds that $\Pr_{s \in S}[p(s) \neq 0] \geq \varepsilon$.

hitting-set *might* exist; and at an "extreme" value of $q^{-\Omega(d)}$, our lower bound does not rule out a polynomial-sized hitting-set. For technical statements that include various extensions and improvements of Theorem 1 (and in particular also hold for polynomials of higher degree $n^{.49} < d \leq \gamma \cdot n$), see Section 5.[4]

Now, still referring to the combinatorial question, we observe that a result of Kaufmann, Lovett, and Porat [24], which upper-bounds the *number* of biased $\mathbb{F}_2$ polynomials (i.e., analyzes the weight distribution of the Reed-Muller code over $\mathbb{F}_2$), yields a corresponding existential upper-bound. Specifically:

▶ **Theorem 2** (upper-bound over $\mathbb{F}_2$, following [24]). *Let $n, d, t \in \mathbb{N}$ where $d > t$. Then, there exists a (non-explicit) hitting-set for $\mathcal{P}_{n,2,d,2^{-t}}$ with seed length $O\left((d-t) \cdot \log(\frac{n}{d-t})\right)$.*

Note that while the lower bound in Theorem 1 holds for any finite field, the upper bound in Theorem 2 holds only over $\mathbb{F}_2$. Nevertheless, comparing Theorem 1 and Theorem 2 (for $\mathbb{F} = \mathbb{F}_2$ and $d \leq n^{.49}$) reveals that there is still a *significant gap* between the upper-bound and the lower-bound: The lower bound is of the form $(d/t) \cdot \log(n)$, whereas the existential upper bound is of the form $(d-t) \cdot \log(n)$. For example, the lower bound indicates that there *might* exist a significantly smaller hitting-set for the relaxed problem when $t = d^{\Omega(1)}$, whereas the existential upper bound is significantly better than the one for the original problem only for $t = d - d^{\Omega(1)}$.

Our last main result is computational and shows an *explicit* construction of a HSG. As mentioned above, Goldreich and Wigderson [18] constructed a polynomial-time computable HSG with seed length $O(\log(n))$ that "hits" polynomials $\mathbb{F}_2^n \to \mathbb{F}_2$ of degree d that vanish on $O(2^{-d})$ of their inputs (for any $d \in \mathbb{N}$). We prove a significantly more general result, by constructing an explicit HSG for $\mathcal{P}_{n,2,d,2^{-t}}$ for any $t < d - O(1)$:

▶ **Theorem 3** (explicit upper-bound over $\mathbb{F}_2$). *Let $n \in \mathbb{N}$ be sufficiently large, and let $d > t+4$ be integers. Then, there exists a polynomial-time computable HSG for $\mathcal{P}_{n,2,d,2^{-t}}$ with seed length $O\left((d-t) \cdot \left(2^{d-t} + \log(\frac{n}{d-t})\right)\right)$.*

Note that the original result from [18] is the special case of Theorem 3 when $t = d - O(1)$. Also note that the seed length of the explicit HSG from Theorem 3 depends exponentially on $d-t$, whereas the seed length of the non-explicit HSG from Theorem 2 depends linearly on $d-t$. We also comment that the result is actually slightly stronger, and asserts that for any $r \in \mathbb{N}$ there exists a polynomial-time computable HSG for $\bigcup_d \mathcal{P}_{n,2,d,q^{d-r}}$ with seed length $O(r \cdot (2^r + \log(n/r)))$; that is, for every r there is a *single* HSG that works for *all degrees* d with $t = d - r$.

Below, in Table 1, we present an informal summary of the main results mentioned above, and compare them to previously-known results.

1.3 The Connection to Small Sets With Large Degree-d Closures

In addition to our lower-bounds and upper-bounds for the problem of HSGs for polynomials that vanish rarely, we also tie this problem to the study of a clean and elegant algebraic question; namely, to the study of the degree-d closure of a set $S \subseteq \mathbb{F}^n$, which was recently initiated by Nie and Wang [33].

[4] In these technical results, the $\log(n)$ term in the lower bound in Theorem 1 is replaced by a more complicated term that depends on d and on t, for example $\log(n^{.99} \cdot (t/d))$.

Table 1 An informal summary of our results and comparison to previous results.

	Seed length		Field Size	ε
Lower bounds				
[40]	$\Omega(d^{\Omega(1)} \cdot \log(n/d^{\Omega(1)}))$		$q = \text{poly}(n)$	$q^{-O(1)}$
Theorem 1	$\Omega((d/t) \cdot \log n)$	$(d \leq n^{.49})$	$2 \leq q \leq \text{poly}(n)$	q^{-t}
Theorem 23	$\Omega((d/t) \cdot \log(n^{.99} \cdot t/d))$	$(d/t \lessapprox q \cdot n^{.01})$	$2 \leq q \leq \text{poly}(n)$	q^{-t}
Upper bounds				
[18]	$O(\log n)$	(explicit)	$q = 2$	$2^{-d+O(1)}$
Theorem 2	$O((d-t)\log(\frac{n}{d-t})$	(non-explicit)	$q = 2$	2^{-t}
Theorem 3	$O((d-t) \cdot (2^{d-t} + \log(\frac{n}{d-t}))$	(explicit)	$q = 2$	2^{-t}

Using terminology from algebraic geometry, the degree-d closure of a set $S \subseteq \mathbb{F}^n$ is a finite-degree analogue of the Zariski closure of S, and is defined as the variety induced by the set of degree-d polynomials $\mathbb{F}^n \to \mathbb{F}$ that vanish on S. In more detail, let us first define the degree-d ideal of S to be $\mathcal{I}^{(d)}(S) = \{p \in \mathcal{P}_d : \forall s \in S, p(s) = 0\}$, where $\mathcal{P}_d$ is the set of degree-d polynomials $\mathbb{F}^n \to \mathbb{F}$.[5] Then, the degree-$d$ closure of S is defined by:

$$\texttt{Cl}^{(\texttt{d})}(S) = \{x \in \mathbb{F}^n : \forall p \in \mathcal{I}^{(d)}(S), p(x) = 0\}.$$

As an example, observe that the degree-d closure of any $d+1$ points on a fixed line in $\mathbb{F}^n$ contains the entire line. As another example, recall that the closure of any Kakeya set in $\mathbb{F}_q^n$ with respect to homogeneous degree-$(q-1)$ polynomials is the entire domain $\mathbb{F}_q^n$ (this was proved by Dvir [16, Section 3] towards showing that any Kakeya set is necessarily of size at least $\binom{q+n-1}{n}$).

Following the latter example, it is natural to ask whether there exists a *very small* set $S \subseteq \mathbb{F}^n$ whose degree-d closure is *very large*. An initial observation towards answering this question is that a set $S \subseteq \mathbb{F}^n$ has *maximal* degree-d closure (i.e., $\texttt{Cl}^{(\texttt{d})}(S) = \mathbb{F}^n$) if and only if S is a hitting-set for degree-d polynomials. (This is since in both cases, the only degree-d polynomial that vanishes on S is the zero polynomial.)

▶ **Observation 4** (maximal closure $\iff$ hitting-set)**.** *A set $S \subseteq \mathbb{F}^n$ is a hitting-set for (all) degree-d polynomials* if and only if $\left|\texttt{Cl}^{(\texttt{d})}(S)\right| = q^n$.

Loosely speaking, the main result of Nie and Wang [33] extends Observation 4 by showing that that for any $S \subseteq \mathbb{F}^n$ it holds that $\left|\texttt{Cl}^{(\texttt{d})}(S)\right| \leq \frac{|S|}{\binom{n+d}{d}} \cdot |\mathbb{F}|^n$. The meaning of this result is that, while there exist sets of size $|S| = \binom{n+d}{d}$ whose degree-d closure is $\mathbb{F}^n$, the degree-d closure of smaller sets decreases by a factor of at least $\frac{|S|}{\binom{n+d}{d}}$.[6]

[5] Note that $\mathcal{I}^{(d)}(S)$ is not an actual ideal in the ring of n-variate polynomials over $\mathbb{F}$, since multiplying $p \in \mathcal{I}^{(d)}(S)$ by another polynomial does not necessarily preserve the degree of p.

[6] Another result along these lines was recently proved by Beelen and Datta [3], who showed a tight upper-bound on the size of the variety induced by *any* subspace of degree-d polynomials (rather than only for varieties induced by a subspace of the form $\mathcal{I}^{(d)}(S)$ for some $S \subseteq \mathbb{F}^n$).

We take another approach to extending Observation 4, by establishing a connection between the study of small sets with large closures and the study of HSGs for polynomials that vanish rarely. Specifically, we show two-way implications between the statement that S is a hitting-set generator for polynomials *that vanish rarely*, and the statement that S has *large closure*. In more detail, we relate hitting-sets for polynomials that vanish with probability q^{-t} to sets with closure of size q^{n-t}:

▶ **Theorem 5** (small sets with large closures versus hitting-sets for polynomials that vanish rarely). *Let $\mathbb{F}$ be a field of size q, let $n \in \mathbb{N}$ and $t < d < n$, and let $S \subseteq \mathbb{F}^n$. Then,*

1. *If $\left|\mathtt{Cl}^{(\mathtt{d})}(S)\right| > q^{n-t}$, then S is a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$.*
2. *If S is a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$, then $\left|\mathtt{Cl}^{(\mathtt{d}/2(\mathtt{t}+1))}(S)\right| > \frac{1}{2} \cdot q^{n-t}$.*

Notice that Theorem 5 does not show a complete equivalence between the two notions, since in the second item the closure refers to degree $d/2t$ rather than to degree d. Thus, intuitively, Theorem 5 asserts that constructing a small set with a large degree-d closure is at least as hard as constructing a hitting-set for polynomials that vanish rarely; and while it also gives a converse reduction (in the second item), it is nevertheless possible that constructing a hitting-set for polynomials that vanish rarely is an easier problem. We also remark that the first item in Theorem 5 is almost immediate, whereas the second item requires more work (see Appendix C for details).

Lastly, we comment that one can obtain an upper-bound on the size of $\mathtt{Cl}^{(\mathtt{d})}(S)$ for small sets $S \subseteq \mathbb{F}^n$ by combining the first item in Theorem 5 with our lower bound from Theorem 1. (This is since the former asserts that sets with closure of size q^{n-t} are hitting-sets for $\mathcal{P}_{n,q,d,q^{-t}}$, whereas the latter asserts that any such hitting-set must be large.) However, the bounds obtained in this way are not stronger than the known bounds proved in [33]. For more details see Appendix C.

2 Overview of Our Techniques

2.1 Combinatorial Lower Bounds From Low-Degree Dispersers

The proofs of our lower bounds on HSGs for polynomials that vanish rarely rely on a *complexity-theoretic* approach, rather than on a direct algebraic analysis. Specifically, we reduce the problem of constructing HSGs for *arbitrary* polynomials to the problem of constructing HSGs for polynomials that *vanish rarely*; since we already know lower bounds for the former, we obtain lower bounds for the latter.

Specifically, given an arbitrary non-zero polynomial $p_0 \colon \mathbb{F}^m \to \mathbb{F}$, we will use a form of "error-reduction" for polynomials (akin to error-reduction for probabilistic algorithms; see below) to obtain another polynomial $p \colon \mathbb{F}^n \to \mathbb{F}$ such that:

1. The polynomial p vanishes rarely.
2. Any non-zero input for p can be mapped into a small list of inputs for p_0 that contains a non-zero input for p_0.

To define p, fix a (k,δ)-disperser $\mathsf{Disp} \colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$, for appropriate parameters k and δ that we will determine in a moment.[7] Then, p is the result of the following procedure: Given $z \in \mathbb{F}^n$, compute the 2^ℓ inputs $\{\mathsf{Disp}(z,i)\}_{i \in \{0,1\}^\ell}$, evaluate p_0 at each of these inputs, and output the disjunction of these evaluations; that is:

$$p(z) = \bigvee_{i \in \{0,1\}^\ell} p_0\left(\mathsf{Disp}(z,i)\right).$$

[7] A (k,δ)-disperser $\mathsf{Disp} \colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$ is a function such that for every $T \subseteq \mathbb{F}^m$ satisfying $|T|/|F|^m \geq \delta$, for all but at most 2^k of the inputs $z \in \mathbb{F}^n$ there exists $i \in \{0,1\}^\ell$ such that $\mathsf{Disp}(z,i) \in T$.

The disperser Disp has the property that for every set $T \subseteq \mathbb{F}^m$ of density at least δ it holds that $\Pr_{z\in\mathbb{F}^n}[\forall i\ \mathsf{Disp}(z,i) \notin T] \leq \varepsilon = 2^k/q^n$. We take T to be the set of elements in $\mathbb{F}^n$ on which p_0 does not vanish, and take δ to be the density of T (i.e., δ is the distance of the corresponding Reed-Muller code); we also let $k = (n-t)\cdot\log(q)$. Then, the polynomial p vanishes on at most an $\varepsilon = 2^k/q^n = q^{-t}$ fraction of its inputs. Also, any non-zero input $z \in \mathbb{F}^n$ for p can be mapped to a list of 2^ℓ inputs $\{x_i = \mathsf{Disp}(z,i)\}_{i\in\{0,1\}^\ell}$ for p_0 such that for some $i \in \{0,1\}^\ell$ it holds that $p_0(x_i) \neq 0$, as we wanted.

The reduction above shows that if there exists a HSG with seed length s for polynomials $\mathbb{F}^n \to \mathbb{F}$ of degree $d = \deg(p)$ that vanish with probability ε, then there exists a corresponding HSG with seed length $s + \ell$ for all non-zero polynomials $\mathbb{F}^m \to \mathbb{F}$ of degree $d_0 = \deg(p_0)$. The known lower bound on the latter, which asserts that $s + \ell = \Omega(d_0 \cdot \log(m/d_0))$, yields a corresponding lower bound on the former.

While this is indeed our main idea, it unfortunately does not quite work as-is. The main challenge is that the reduction above incurs *significant overheads* that crucially deteriorate the lower bound. Most importantly, the *degree* of the polynomial increases (from $d_0 = \deg(p_0)$ to $d = \deg(p)$), and the number of variables also increases (from m to n); this affects us since we are interested in a lower bound as a function of n and d, whereas our lower bound is a function of m and d_0. Moreover, the lower bound deteriorates by an additive factor of ℓ, since each non-zero input $z \in \mathbb{F}^n$ for p yields 2^ℓ inputs for p_0, one of which is guaranteed to be non-zero. Thus, we want to modify the reduction above, in order to minimize the blowup in the degree and in the number of variables, and also minimize the seed length ℓ of the disperser.

A coding-theoretic perspective

One can view the procedure described above as amplifying the *weight* (i.e., the fraction of non-zero coordinates) of a codeword in the Reed-Muller code. At first glance, this task seems similar to the task of amplifying the *distance* of linear error-correcting codes; in particular, the disperser-based technique described above is technically reminiscent of the well-known distance amplification technique of Alon *et al.* [2].[8] However, the crucial difference is that we are interested in amplifying the weight to be much larger than $1 - 1/q$, and indeed our resulting subcode (of polynomials that vanish rarely) is a small and non-linear subcode of the Reed-Muller code. Moreover, as explained above, we will be particularly interested in the degree blow-up, which is a parameter specific to polynomial-based codes.

Warm-up: The setting of $d \ll q$

For simplicity, let us assume that $q = \mathrm{poly}(n)$ and that $d \leq n^{.99}$. In this case the fraction δ of non-zeroes of p_0 is very close to one and we only need Disp to be a $(k, .99)$-disperser for $k = (n-t)\cdot\log(q)$.

Note that to compute p at an input $z \in \mathbb{F}^n$, we wish to compute $\mathsf{Disp}_i(z) = \mathsf{Disp}(z,i)$ as a function of z for each *fixed* value i of the seed. Since we want p to have degree as low as possible, we are interested in objects that we call low-degree dispersers: Informally, a disperser $\mathsf{Disp}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$ has low degree if for any $i \in \{0,1\}^\ell$ and $j \in [m]$, the polynomial $q_{i,j}(z) = \mathsf{Disp}(z,i)_j$ (i.e., $q_{i,j}(z)$ is the j^{th} output element of $\mathsf{Disp}(z,i)$ as a function of z)

[8] The main differences are that we will use a specific disperser that is different from theirs, to minimize the degree blow-up; and that we handle alphabet reduction differently (using an `OR` function instead of code concatenation), since our target weight is much larger than $1 - 1/q$.

has low degree (see Definition 16 and Definition 17). Note that in our argument we only need the *existence* of a low-degree disperser (i.e., we do not need the low-degree disperser to be efficiently computable); however, the dispersers that are obtained via naive probabilistic arguments do not have low degree.

Fortunately, in the current "warm-up" setting we can get a good (albeit non-optimal) lower bound even using the "naive disperser" that just performs uniform sampling: That is, the disperser that treats its input $z \in \mathbb{F}^n$ as n/m substrings of length m, and treats its seed as an index $i \in [n/m]$, and outputs the i^{th} substring of length m in z. Note that this disperser is *linear* (i.e., has degree one), since for a fixed seed, each output element is a projection of a corresponding input element.

We do encounter one other problem in implementing our idea in this setting, which is the degree blow-up that comes from the fact that p computes the OR function on the outputs of the disperser (recall that the OR function of 2^ℓ inputs has maximal degree $(q-1)\cdot 2^\ell$). To circumvent this problem, we replace the OR function with a multivalued OR function. Specifically, observe that in the reduction above it suffices that on any non-zero input $y \in \mathbb{F}^{2^\ell}$, the OR function will output *some* non-zero element (rather than map any non-zero y to $1 \in \mathbb{F}$). In contrast to the OR function, there exists a multivalued OR function of 2^ℓ elements with degree roughly 2^ℓ (see Proposition 10).

Working out the precise parameters, this approach transforms any p_0 of degree d_0 into a corresponding p of degree $d = d_0 \cdot 2^\ell = d_0 \cdot t \cdot \log(q)$, and for every $t \leq d/O(\log(q))$ implies a lower bound of $\Omega(d_0 \cdot \log(m/d_0)) - \ell = \Omega(d/t)$ on the seed length of HSGs for polynomials that vanish with probability q^{-t}. To improve this lower bound to match the bound stated in Theorem 1, we use a disperser that is better than the naive one, and utilize the techniques that are outlined below (see Section 5).

The more challenging setting of $d \gg q$

Observe that in the argument above we "paid" for the seed length ℓ of the disperser *twice*: One loss was a blow-up of 2^ℓ in the degree (since the multivalued OR function has degree 2^ℓ), and the other loss was that the lower bound on the seed length of the HSG decayed additively in ℓ (because our reduction maps any non-zero input for p to a list of 2^ℓ inputs for p_0). Also note that the first loss decreases the lower bound itself, whereas the second loss limits the values of t to which the lower bound applies (to ones for which $\ell \ll d_0 \cdot \log(m/d_0)$).

When $d \gg q$ these two losses may deteriorate our lower bound much more severely than in the "warm-up" setting. This is because when q was large we instantiated the disperser with the parameter $\delta = \Omega(1)$, and hence its seed length was relatively small, whereas in our current setting the value of $\delta = q^{-d_0/(q-1)}$ may be much smaller.[9]

In the special case when $\mathbb{F}$ is a *prime field*, this problem can be overcome by starting not from a lower bound for hitting all degree-d_0 polynomials, but rather from a lower bound for hitting a large subcode of the corresponding Reed-Muller code (i.e., a subcode with dimension linear in $\binom{m+d_0}{d_0}$) that still has distance $\Omega(1)$; see [15, Appendix B] for details. To overcome the problem also over non-prime fields, we show a general method that, regardless of the disperser, *allows us to "pay" only an $O(t)$ factor in the degree blow-up*, instead of the 2^ℓ factor. This method does not prevent the additive loss of ℓ in the seed length, and we will explain how this additive loss affects us in the end of the current section.

[9] To demonstrate the problem, note that over fields of constant size, even a disperser with optimal parameters would yield a quadratic degree blow-up, regardless of t; that is, $d \geq 2^\ell \cdot d_0 \geq 2^{\log(t\cdot\log(q)/\delta)} \cdot d_0 = \Omega_q((d_0)^2 \cdot t)$, compared to the previous blow-up of $d = \Omega_q(d_0 \cdot t)$ when we had $\delta = \Omega(1)$.

To explain this method, fix a disperser, and recall that our goal is to "hit" the set $\mathrm{G} \subseteq \mathbb{F}^n$ of inputs z such that for some $i \in \{0,1\}^\ell$ it holds that $p_0(\mathsf{Disp}(z,i)) \neq 0$ (since any $z \in \mathrm{G}$ maps to 2^ℓ inputs, one of which "hits" the original polynomial p_0). We think of the polynomial p above as a test of its input $z \in \mathbb{F}^n$ that distinguishes between G and $\mathbb{F}^n \setminus \mathrm{G}$ (i.e., p vanishes precisely on $\mathbb{F}^n \setminus \mathrm{G}$). Our initial approach to hit G was to construct a HSG for the test p, which would output some $z \in \mathrm{G}$.

The key observation is that constructing a HSG for p is an "overkill". Specifically, to hit G, *we can replace the test p by a distribution $\mathbf{p}$ over tests that distinguishes between* G *and* $\mathbb{F}^n \setminus \mathrm{G}$*, with high probability*, and still deduce that any HSG for the tests in the support of $\mathbf{p}$ outputs some $z \in \mathrm{G}$. That is, we replace the test p for G by a $\mathsf{randomized\ test}$ $\mathbf{p}$ for G such that the polynomials in the support of $\mathbf{p}$ have lower degree than p, and show that "hitting" the polynomials in the support of $\mathbf{p}$ still allows us to "hit" G. Moreover, since $\mathbf{p}$ "tests" a *dense* set G with small error, by an averaging argument almost all of the polynomials in the support of $\mathbf{p}$ *vanish rarely*; thus, it suffices to "hit" only the polynomials in the support of $\mathbf{p}$ that vanish rarely.

More accurately, let us instantiate our disperser with $k = (n-2t) \cdot \log(q)$, instead of $k = (n-t) \cdot \log(q)$, such that the density of G is $1 - q^{-2t}$ (this is to allow for some slackness in the parameters). Then, the following holds:

▶ **Lemma 6** (informal; see Appendix A)**.** *Assume that there exists a distribution $\boldsymbol{p}$ over polynomials $\mathbb{F}^n \to \mathbb{F}$ such that for every $z \in \mathrm{G}$ it holds that $\Pr[\boldsymbol{p}(z) \neq 0] \geq 1 - q^{-2t}$ and for every $z \notin \mathrm{G}$ it holds that $\Pr[\boldsymbol{p}(z) = 0] = 1$. Further assume that every polynomial in the support of $\boldsymbol{p}$ has degree $O(d \cdot t)$. Then, any hitting-set for polynomials of degree $O(d \cdot t)$ that vanish on at most $2q^{-t}$ of their inputs contains some $z \in \mathrm{G}$.*

Our construction of the specific distribution $\mathbf{p}$ that we use is simple: Starting from the construction of p above, instead of taking an $\mathtt{OR}$ of the evaluations of p_0 on the entire output-set of the disperser (i.e., on all seeds), we *sample from the seeds of the disperser*. More accurately, to sample a polynomial $f \sim \mathbf{p}$, we uniformly sample $2t$ vectors $a^{(1)}, ..., a^{(2t)} \in \mathbb{F}^{2^\ell}$, and output the polynomial

$$f(z) = \mathtt{OR}_{j \in [2t]} \left(\sum_{i \in 2^\ell} a_i^{(j)} \cdot p_0(\mathsf{Disp}(z,i)) \right).$$

To see why this distribution works, observe that if $z \in \mathrm{G}$ then a random $\mathbb{F}$-linear sum of the elements $\{\mathsf{Disp}(x,i)\}_{i \in \{0,1\}^\ell}$ will be non-zero with probability $1 - 1/q$, whereas if $z \notin \mathrm{G}$ then such a sum will be zero, with probability one. Thus, a random polynomial in $\mathbf{p}$ computes the disjunction of $2t$ such random sums, and it is straightforward to see that its "error probability" is q^{-2t} and its degree is $O(d_0 \cdot t)$ (assuming that the disperser is linear). Using Lemma 6, any HSG for polynomials of degree $O(d_0 \cdot t)$ that vanish on at most q^{-2t} of their inputs outputs some $z \in \mathrm{G}$. We therefore reduced the problem of constructing a HSG for p_0 to the problem of constructing a HSG for polynomials of degree $d = O(d_0 \cdot t)$ that vanish on at most q^{-2t} of their inputs.

The last missing piece is that we need a concrete disperser to instantiate the argument with, and the parameters of the disperser will determine the lower bound that we get. Furthermore, recall that we are losing an additive factor of ℓ in the lower bound, and thus any lower bound that we get using this approach applies only to values of t such that $\ell \ll d_0 \cdot \log(m/d_0)$. Specifically, the approach above gives the following lemma (for simplicity, we state it only for linear dispersers):

▶ **Lemma 7** (linear dispersers yield lower bounds on HSGs for polynomials that vanish rarely; informal, see Corollary 20). *Let $d_0 < m$ be integers, let $\mathbb{F}$ be a field of size q, and let $t \in \mathbb{N}$. Assume that for $k = (n-2t)\cdot\log(q)$ and $\delta = q^{-d_0/(q-1)}$ there exists a linear (k,δ)-disperser $\mathsf{Disp}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$. Then, for $d = 4d_0 \cdot t$, if $\ell \leq \frac{d}{8t}\cdot\log(mt/d)$, then the seed length for any HSG for $\mathcal{P}_{n,q,d,2q^{-t}}$ is $\Omega\left((d/t)\cdot\log\left(mt/d\right)\right)$.*

Note that to get a good lower bound using Lemma 7 we want a *linear* disperser $\mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q^m$ for large min-entropy $k = (n-2t)\cdot\log(q)$ that has small seed length ℓ and large output length m.[10] In particular, if there exists a *linear* disperser with *optimal* parameters, then a lower bound of $\Omega((d/t)\cdot\log(nt/d))$ would follow for essentially all settings of the parameters (see Corollary 21).

Our lower bounds, which include Theorem 1 and various extensions and are presented in Section 5, are proved by instantiating Lemma 7 with specific useful dispersers. In a gist, Theorem 1 and some extensions are proved using a linear disperser that we obtain by modifying the extractor by Shaltiel and Umans [36]; the original extractor works over the binary alphabet, and we modify it to a linear disperser over an arbitrary field $\mathbb{F}_q$ (see Appendix B for details). Another extension of Theorem 1, which applies only to fields of constant size, is proved using a linear disperser that is based on the recent construction of "linear 1-local expanders" by Goldreich [17], following Viola and Wigderson [44].

2.2 Explicit Upper Bound Over $\mathbb{F}_2$

To construct the explicit HSG for polynomials $\mathbb{F}_2^n \to \mathbb{F}_2$ that vanish rarely in Theorem 3 we generalize a construction of [18], by extending a proof approach from [40]. In high-level, we reduce the problem of constructing a HSG for polynomials that vanish rarely to the problem of constructing a PRG for arbitrary *low-degree polynomials*, and then use the explicit PRG of Viola [43] for low-degree polynomials.

In more detail, we say that a polynomial $p\colon \mathbb{F}_2^n \to \mathbb{F}_2$ is approximated by a distribution $\mathbf{h}$ over polynomials $h\colon \mathbb{F}_2^n \to \mathbb{F}_2$ if for every $x \in \mathbb{F}_2^n$ it holds that $\Pr_h[\mathbf{h}(x) = p(x)] \geq .99$. Our first step is to show that any polynomial $p \in \mathcal{P}_{n,2,d,q^{-t}}$ can be approximated by a distribution $\mathbf{h}$ over polynomials of degree $d-t$. To do so, let $\Delta_a(p)$ be the directional derivative of p in direction $a \in \mathbb{F}_2^n$ (i.e., the function $\Delta_a p(x) = p(x+a)+p(x)$). We sample $h \sim \mathbf{h}$ by uniformly sampling $\vec{a} = a^{(1)},\ldots,a^{(k)} \in \mathbb{F}_2^n$, where $k = t - O(1)$, and outputting the polynomial $h_{\vec{a}} = \Delta_{a^{(k)}}\Delta_{a^{(k-1)}}\ldots\Delta_{a^{(1)}}(p) + 1$; that is, we derive p in k random directions, and "negate" the output.

Note that indeed $\deg(h_{\vec{a}}) = d - t + O(1)$. Now, for any fixed $x \in \mathbb{F}_2^n$ and non-empty $S \subseteq [k]$, the probability over $\vec{a}$ that $p\left(x + \sum_{i\in S} a^{(i)}\right) = 1$ is at least $1 - 2^{-t}$ (since p vanishes with probability at most 2^{-t}, and $x + \sum_{i\in S} a^{(i)}$ is uniform in $\mathbb{F}_2^n$). Thus, by a union bound, with probability at least .99 over the choice of $\vec{a}$, for every non-empty $S \subseteq [k]$ it holds that $p\left(x + \sum_{i\in S} a^{(i)}\right) = 1$. In this case, we have that $h_{\vec{a}}(x) = \sum_{S\subseteq[k]} p\left(x + \sum_{i\in S} a^{(i)}\right) + 1 = p(x) + (2^k - 1) + 1 = p(x)$. Hence, the distribution $\mathbf{h}$ also has the property that for every $x \in \mathbb{F}_2^n$ it holds that $\Pr[\mathbf{h}(x) = p(x)] \geq .99$.

Our next observation is similar to the "randomized tests" technique mentioned in Section 2.1: We show that if a distribution $\mathbf{h}$ over low-degree polynomials approximates p, then a pseudorandom generator for the polynomials in the support of $\mathbf{h}$ (with sufficiently small constant error) also "hits" p. Combining the two claims, we get a reduction from the

[10] Moreover, since our error $\delta = q^{-d_0/(q-1)}$ might be large, we want good dependency of the parameters ℓ and m on the error δ.

problem of constructing a HSG for $\mathcal{P}_{n,2,d,q^{-t}}$ to the problem of constructing a PRG (with small constant error) for arbitrary polynomials of degree $d-t+O(1)$. Thus, the PRG of Viola [43] for such polynomials, which uses a seed of length $O((d-t)\cdot(2^{d-t}+\log(n)))$, is also a HSG for $\mathcal{P}_{n,2,d,2^{-t}}$.

The proofs of Theorem 2 and Theorem 3 appear in the full version (see [15, Section 5]).

On the tightness of the reduction above

Recall that there is a gap between the seed length of the explicit HSG above and the seed length of the *non-explicit* HSG from Theorem 2, which is $O\left((d-t)\cdot\log(\frac{n}{d-t})\right)$. We note that to close this gap, one does not need to improve the *reduction* detailed above, but only the *explicit PRG for arbitrary polynomials* (i.e., Viola's construction). Specifically, if there exists an explicit PRG for all polynomials of degree $d'=d-t+O(1)$ with seed length $O(d'\cdot\log(n/d'))$ (matching the non-explicit upper-bound for such PRGs), then the reduction above yields a HSG for $\mathcal{P}_{n,2,d,2^{-t}}$ with seed length $O((d-t)\cdot\log(n/(d-t)))$.

3 Preliminaries

We denote random variables by boldface. For an alphabet Σ and $n\in\mathbb{N}$, we denote the uniform distribution over Σ^n by $\mathbf{u}_n$, where Σ will be clear from context.

3.1 Polynomials Over Finite Fields

We consider multivariate polynomials over a finite field. A polynomial $p\colon\mathbb{F}^n\to\mathbb{F}$ of degree d can be viewed as a codeword in the corresponding Reed-Muller code; thus, if p is non-zero, then the relative distance of the corresponding Reed-Muller code, which is stated below, lower bounds the fraction of inputs on which p does not vanish.

▶ **Theorem 8** (distance of the Reed-Muller code; see, e.g., [20]). *For any $d,q\in\mathbb{N}$, let $a=\lfloor d/(q-1)\rfloor$ and $b=d \pmod{q-1}$. The relative distance of the Reed-Muller code of degree d over alphabet q is $\delta_{RM}(d,q)=q^{-a}\cdot(1-b/q)\geq q^{-d/(q-1)}$.*

The $\mathtt{OR}\colon\mathbb{F}^k\to\mathbb{F}$ function maps any non-zero input $z\in\mathbb{F}^k\setminus\{0^k\}$ to $1\in\mathbb{F}$, and maps 0^k to zero. We consider a generalization of this function, which we call *multivalued OR*; a multivalued OR function maps any non-zero $z\in\mathbb{F}^k\setminus\{0^k\}$ to *some* non-zero element (i.e., different non-zero inputs may yield different outputs), while still mapping 0^k to zero. That is:

▶ **Definition 9** (multivalued OR functions). *For any finite field $\mathbb{F}$, we say that a polynomial $\mathtt{mvOR}\colon\mathbb{F}^k\to\mathbb{F}$ is a multivalued OR function if $\mathtt{mvOR}(0^k)=0$, but $\mathtt{mvOR}(x)\neq 0$ for every $x\neq 0^k$.*

For a fixed field $\mathbb{F}$ there are many different k-variate multivalued OR functions. Indeed, the standard $\mathtt{OR}$ function is a multivalued OR function, but it has maximal degree $k\cdot(q-1)$ as a polynomial. We will need k-variate multivalued OR functions that are of much lower degree (i.e., degree approximately k); such functions can be constructed relying on well-known techniques in algebraic geometry (see [40, Proposition 7.3] for the construction, and see e.g. [13, Exercise 8] for a reference to the well-known underlying techniques):

▶ **Proposition 10** (low-degree multivalued OR function). *Let $\mathbb{F}$ be a finite field and let $k\in\mathbb{N}$. Then, there exists a multivalued OR function $\mathtt{mvOR}\colon\mathbb{F}^k\to\mathbb{F}$ that is computable by a polynomial of degree less than $2k$.*

3.2 Hitting-Set Generators

We recall the standard definitions of hitting-set generators (HSGs), of hitting-set generators and of pseudorandom generators (PRGs). Recall that HSGs for a class of polynomials need to produce a set of inputs such that any polynomial from the class evaluates to *non-zero* on some input in the set. That is:

▶ **Definition 11** (hitting-set generator). *Fix a field $\mathbb{F}$, and let $d, n \in \mathbb{N}$. A function $H\colon \{0,1\}^\ell \to \mathbb{F}^n$ is a hitting-set generator for a set of functions $\mathcal{P} \subseteq \{\mathbb{F}^n \to \mathbb{F}\}$ if for every non-zero function $p \in \mathcal{P}$ there exists $s \in \{0,1\}^\ell$ satisfying $p(H(s)) \neq 0$. In this case, the set $S = \{H(s) : s \in \{0,1\}^\ell\}$ is called a hitting-set for $\mathcal{P}$.*

▶ **Definition 12** (explicit hitting-set generators). *Let $\ell, q, d\colon \mathbb{N} \to \mathbb{N}$, let $\{\mathbb{F}_{q(n)}\}_{n\in\mathbb{N}}$ such that for every $n \in \mathbb{N}$ it holds that $\mathbb{F}_{q(n)}$ is a field of size $q(n)$, and let $H = \{H_n\colon \{0,1\}^{\ell(n)} \to \mathbb{F}_{q(n)}^n\}$ such that for every $n \in \mathbb{N}$ it holds that H_n is a hitting-set generator for polynomials of degree $d(n)$. We say that H is polynomial-time computable if there exists an algorithm that gets as input $s \in \{0,1\}^\ell$ and outputs $H_n(s)$ in time $\mathrm{poly}(\ell, \log(q), n)$.*

The standard definition of PRGs for polynomials in $p\colon \mathbb{F}^n \to \mathbb{F}$ that we will use is as follows. Consider the distribution over $\mathbb{F}$ that is obtained by uniformly choosing $x \in \mathbb{F}^n$ and outputting $p(x)$, and the distribution over $\mathbb{F}$ that is obtained by choosing a seed s for a PRG G and outputting $p(G(s))$. We require that the statistical distance between the two distributions is small. That is:

▶ **Definition 13** (pseudorandom generator). *Fix a field $\mathbb{F}$, let $d, n \in \mathbb{N}$, and let $\rho > 0$. A function $G\colon \{0,1\}^\ell \to \mathbb{F}^n$ is a pseudorandom generator with error ρ for polynomials of degree d if for every polynomial $p\colon \mathbb{F}^n \to \mathbb{F}$ of degree at most d it holds that*

$$\sum_{\sigma\in\mathbb{F}} \left| \Pr_{s\in\{0,1\}^\ell}[p(G(s)) = \sigma] - \Pr_{x\in\mathbb{F}^n}[p(x) = \sigma] \right| \leq \rho.$$

An alternative standard definition of PRGs for polynomials requires that the "character distance" $\left|\mathbb{E}_{x\in\mathbb{F}^n}[\mathsf{e}^{p(x)}] - \mathbb{E}_x[\mathsf{e}^{p(G(s))}]\right|$ will be small, where e is any (fixed, non-trivial) character of $\mathbb{F}$. The "character distance" and the statistical distance are equivalent, up to a multiplicative factor of $\sqrt{q-1}$ (see [27, Lemma 2.4]).

Lastly, we recall the standard lower bound on the size of hitting-sets for polynomials of degree d and state the complementary upper-bound that is obtained by a standard probabilistic argument. (For proofs see [15, Section 3].)

▶ **Fact 14** (lower bound on the size of hitting-sets for linear subspaces). *Let $\mathbb{F}$ be a finite field, let $n \in \mathbb{N}$, and let $\mathcal{C} \subseteq \{\mathbb{F}^n \to \mathbb{F}\}$ be a linear subspace of dimension $D = \dim(\mathcal{C})$. Then, any hitting-set for $\mathcal{C}$ has at least D points. In particular, for any $d < n$, any hitting-set for degree-d polynomials $\mathbb{F}^n \to \mathbb{F}$ has size at least $\binom{n+d}{d}$, and correspondingly the seed length of any hitting-set generator for such polynomials is at least $d \cdot \log(n/d)$.*

▶ **Fact 15** (upper bound on the size of hitting-sets). *Let $\mathbb{F}$ be a finite field, let $n \in \mathbb{N}$, and let $d < n$. Then, there exists a (non-explicit) hitting-set generator for polynomials $\mathbb{F}^n \to \mathbb{F}$ of degree d with seed length $O(d \cdot \log(n/d) + \log\log(q))$.*

3.3 Dispersers and Extractors

We recall the definition of dispersers $\mathsf{Disp}\colon [N] \times \{0,1\}^\ell \to [M]$, where we identify the domain N with the vector space $\mathbb{F}^n$ and the range M with the vector space $\mathbb{F}^m$.

▶ **Definition 16** (disperser). *Let $\mathbb{F}$ be a finite field of size $q = |\mathbb{F}|$. A function* $\mathsf{Disp}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$ *is a (k,δ)-disperser if for every $T \subseteq \mathbb{F}^m$ of size $|T| \geq \delta \cdot q^m$, the probability over $x \in \mathbb{F}^n$ that for all $i \in \{0,1\}^\ell$ it holds that $\mathsf{Disp}(x,i) \notin T$ is less than $2^k/q^n$. The value ℓ is the seed length of the disperser.*[11]

In this work we are interested in dispersers that can be computed by low-degree polynomials. Specifically, we require that for each fixed seed $s \in \{0,1\}^\ell$ and output index $i \in [m]$, the function that maps any $z \in \mathbb{F}^n$ to the i^{th} output of Disp at z with seed s (i.e., $z \mapsto \mathsf{Disp}(z,s)_i$) has low degree as a polynomial $\mathbb{F}^n \to \mathbb{F}$.

▶ **Definition 17** (degree of a disperser). *We say that a disperser* $\mathsf{Disp}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$ *has degree d if for every fixed $s \in \{0,1\}^\ell$ and $i \in [m]$, the polynomial $p_{s,i}\colon \mathbb{F}^n \to \mathbb{F}$ defined by $p_{s,i}(z) = \mathsf{Disp}(z,s)_i$ is of degree at most d. If $d = 1$, then we say the disperser is linear.*

Recall that there are two standard dispersers that are linear: The naive disperser, which treats its input $z \in \mathbb{F}^n$ as a list of samples from $\mathbb{F}^m$ and its seed as an index of a sample in this list; and the subspace sampler, which treats its input as the description of an affine subspace in $\mathbb{F}^m$ and its seed as an index of an element in the subspace. Nevertheless, these dispersers have disadvantages (small output length and large seed length, respectively), and in our results we will use more sophisticated linear dispersers (see Section 5 for details).

Alternatively, one can verify that Definition 16 is equivalent to the following definition: Disp is a (k,δ)-disperser if for any random variable $\mathbf{x} \sim \mathbb{F}^n$ with min-entropy[12] k, the support of $\mathsf{Disp}(\mathbf{x}, \mathbf{u}_\ell)$ covers at least $(1-\delta)q^m$ elements from $\mathbb{F}^m$. Although dispersers will be our main pseudorandom object, we will sometimes work with the stronger notion of an *extractor*. While in dispersers we only care about covering almost all of $\mathbb{F}^m$, in extractors we want to do it *uniformly*, i.e., we require $\mathsf{Ext}(\mathbf{x}, \mathbf{u}_\ell)$ to be δ-close to the uniform distribution $\mathbf{u}_m$ over $\mathbb{F}^m$. Formally:

▶ **Definition 18** (extractor). *Let $\mathbb{F}$ be a finite field of size $q = |\mathbb{F}|$. A function* $\mathsf{Ext}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$ *is a (k,δ)-extractor if for every random variable $\boldsymbol{x} \sim \mathbb{F}^n$ with min-entropy k it holds that $\mathsf{Ext}(\boldsymbol{x}, \boldsymbol{u}_\ell)$ is δ-close to $\boldsymbol{u}_m$. The value ℓ is the seed length of the extractor.*

As the support size of a distribution which is δ-close to $\mathbf{u}_m$ is at least $(1-\delta)q^m$, any (k,δ)-extractor is readily a (k,δ)-disperser.

4 Lower Bounds from Low-Degree Dispersers

In this section we prove general results that use low-degree dispersers to reduce hitting arbitrary polynomials to hitting polynomials that vanish rarely (and thus deduce lower bounds for the latter); this follows the high-level explanations that were presented in Section 2.1. The following proposition specifies the reduction itself, and the subsequent corollary specifies the lower bounds that we can obtain using the reduction.

▶ **Proposition 19** (reducing hitting polynomials to hitting polynomials that vanish rarely by sampling from the seeds of a disperser). *Let $m, d_0 \in \mathbb{N}$, let $\mathbb{F}$ be a field of size q, and let $\delta = \delta_{RM}(d_0, q)$. For $k < \log(q^n)$, let $\varepsilon = 2^k/q^n$, let $\rho < 1-\varepsilon$, and let $r = \log_q(1/\rho)$. Assume that:*

[11] In this work we take the *hitter* view of a disperser, which is equivalent to the following standard definition of dispersers: For every random variable $\mathbf{x} \sim \mathbb{F}^n$ with min-entropy k, $\mathsf{Disp}(\mathbf{x}, \mathbf{u}_\ell)$ has support size at least $(1-\delta)q^m$.

[12] A random variable $\mathbf{x}$ has min-entropy k if for every $x \in \mathsf{supp}(\mathbf{x})$ is holds that $\Pr[\mathbf{x} = x] \leq 2^{-k}$.

1. *There exists a* (k,δ)*-disperser* $\mathsf{Disp}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$ *of degree* $d_{\mathsf{Disp}} \in \mathbb{N}$.
2. *There exists a hitting-set* $W \subseteq \mathbb{F}^n$ *for polynomials* $\mathbb{F}^n \to \mathbb{F}$ *of degree* $d = 2d_0 \cdot r \cdot d_{\mathsf{Disp}}$ *that vanish on at most* $\sqrt{\rho+\varepsilon}$ *of their inputs.*

Then, there exists a hitting-set $W_0 \subseteq \mathbb{F}^m$ *for polynomials* $\mathbb{F}^m \to \mathbb{F}$ *of degree* d_0 *such that* $|W_0| \leq |W| \cdot 2^\ell$.

Proof. For $L = 2^\ell$, let $W_0 = \{\mathsf{Disp}(z,i) : z \in W, i \in [L]\}$. We will prove that W_0 is a hitting-set for polynomials $\mathbb{F}^m \to \mathbb{F}$ of degree d_0.

To do so, fix any non-zero polynomial $f\colon \mathbb{F}^m \to \mathbb{F}$ of degree d_0. Let $V = \{x \in \mathbb{F}^m : f(x) = 0\}$ be the set of points on which f vanishes, and let $\mathrm{G} = \{z \in \mathbb{F}^n : \exists i \in [L], \mathsf{Disp}(z,i) \notin V\}$ be the set of inputs $z \in \mathbb{F}^n$ for Disp such that for some $i \in [L]$ it holds that f does not vanish on $\mathsf{Disp}(z,i)$. Note that G has density at least $1-\varepsilon$; this is the case since $|V|/q^m \leq 1-\delta$ (and recall that δ is the distance of the corresponding Reed-Muller code and f is non-zero), and since Disp is a (k,δ)-disperser.

Note that W_0 is a hitting-set for f if and only if $\Pr_{z\in W}[z \in \mathrm{G}] > 0$. We will prove that $\Pr_{z\in W}[z \in \mathrm{G}] > 0$ using Lemma 22. To construct the distribution $\mathbf{p}$ over polynomials in $\mathbb{F}^n \to \mathbb{F}$ needed for the hypothesis of the lemma, fix a multivalued OR polynomial $\mathtt{mvOR}\colon \mathbb{F}^r \to \mathbb{F}$ of degree less than $2r$ as in Proposition 10. Then, sampling $p \sim \mathbf{p}$ is equivalent to the following random process:

> Uniformly and independently choose $\alpha^{(1)}, ..., \alpha^{(r)} \in \mathbb{F}^L$, and output the polynomial $p(z) = \mathtt{mvOR}\left(\sum_{i\in[L]} \alpha_i^{(1)} \cdot f(\mathsf{Disp}(z,i)), ..., \sum_{i\in[L]} \alpha_i^{(r)} \cdot f(\mathsf{Disp}(z,i))\right)$.

Note that each $p \sim \mathbf{p}$ has degree less than $d = d_{\mathsf{Disp}} \cdot d_0 \cdot 2r$. Also note that for any $z \notin \mathrm{G}$ we have that $\Pr[\mathbf{p}(z) = 0] = 1$, whereas for any $z \in \mathrm{G}$ we have that $\Pr[\mathbf{p}(z) \neq 0] \geq 1 - q^{-r} = 1 - \rho$. Using Lemma 22 and the hypothesis that W is a hitting-set for polynomials that vanish on at most $\sqrt{\rho+\varepsilon}$ of their inputs, we deduce that $\Pr_{z\in W}[z \in \mathrm{G}] > 0$, as we wanted. ◀

Using the reduction from Proposition 19, and relying on the unconditional lower bound from Fact 14, we obtain the following result, which uses low-degree dispersers to deduce lower bounds on HSGs for polynomials that vanish rarely:

▶ **Corollary 20** (a lower bound by sampling from the seeds of a disperser)**.** *Let* $m, d_0 \in \mathbb{N}$ *such that* $d_0 < m$*, let* $\mathbb{F}$ *be a field of size* q*, and let* $\delta = \delta_{RM}(d_0, q)$*. For* $t \in \mathbb{N}$ *and* $k = (n-2t)\cdot\log(q)$*, assume that there exists a linear* (k,δ)*-disperser* $\mathsf{Disp}\colon \mathbb{F}^n \times \{0,1\}^\ell \to \mathbb{F}^m$*. Then, any hitting-set* $W \subseteq \mathbb{F}^n$ *for polynomials in* $\mathbb{F}^n \to \mathbb{F}$ *of degree* $d = 4d_0 \cdot t$ *that vanish on at most* $\sqrt{2} \cdot q^{-t}$ *of their inputs has size at least* $\binom{m+d_0}{d_0} \cdot 2^{-\ell}$*. In particular, the seed length for any such hitting-set is at least*

$$\Omega\left(\frac{d}{t} \cdot \log\left(\frac{m \cdot t}{d}\right)\right),$$

provided that $t \leq \frac{\log(mt/d)}{8\ell} \cdot d$.

Proof. We use Proposition 19 with the parameter values $\varepsilon = \rho = q^{-2t} \leq 1/4$ (such that $r = 2t$) and $d_{\mathsf{Disp}} = 1$, and rely on the fact that any hitting-set $W_0 \subseteq \mathbb{F}^m$ for all polynomials $\mathbb{F}^m \to \mathbb{F}$ of degree d_0 has size at least $\binom{m+d_0}{d_0}$ (i.e., on Fact 14). The seed length (in bits) for sampling from the hitting-set is thus at least $d_0 \cdot \log(m/d_0) - \ell = \frac{d}{4t} \cdot \log(4mt/d) - \ell \geq \Omega((d/t) \cdot \log(mt/d)$, where the last inequality is due to the hypothesis that $\frac{d}{4t} \cdot \log(mt/d) \geq 2\ell$. ◀

Finally, note that if there exists a linear (k,δ)-disperser $\mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q^m$ with optimal parameters, then we get a lower bound of $\Omega((d/t)\cdot\log(nt/d))$ for essentially all settings of the parameters. That is:

▶ **Corollary 21** (lower bounds assuming an optimal linear disperser)**.** *Assume that for every $n,q,k\in\mathbb{N}$ and $\delta>0$ there exists a* linear (k,δ)*-disperser* $\mathsf{Disp}\colon \mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q^m$ *where $\ell = \log(n\cdot\log(q)-k)+\log(1/\delta)+O(1)$ and $m\cdot\log(q) = k+\ell-\log\log(1/\delta)-O(1)$. Then, for every constant $c>1$ there exists a constant $\gamma>0$ such that the following holds.*

Let $n,q,d,t\in\mathbb{N}$ such that $q\le 2^{n^c}$, and $d<n/2$, and $t\le\gamma\cdot n$, and $\frac{q-1}{\log(q)}\cdot\log(nt/d)\ge 1/\gamma$. Then, the seed length of any HSG for $\mathcal{P}_{n,q,d,\sqrt{2}\cdot q^{-t}}$ is at least $\Omega\left(\frac{d}{t}\cdot\log\left(\frac{n\cdot t}{d}\right)\right)$.

Proof. Let $d_0 = d/4t$, and let $a = d_0/(q-1)$ such that $\delta = \delta_{RM}(d_0,q) \ge q^{-a}$. When instantiating the hypothesized linear disperser with parameters n and $k=(n-2t)\cdot\log(q)$ and $\delta = q^{-a}$, it has seed length $\ell = O(\log(t\cdot\log(q)) + (d/4t)\cdot(\log(q)/(q-1)))$ and output length $m=\Omega(n)$. Relying on Corollary 20, we get a lower bound of $\Omega\left((d/t)\cdot\log(n\cdot(t/d))\right)$, assuming that $d_0<m$ (which holds since we assumed that $d<n/2$) and that $t\le\frac{\log(nt/d)}{8\ell}\cdot d$. Thus, we just need to verify the latter condition.

We verify the condition by a case analysis. The first case is when $t\ge\sqrt{d/4(q-1)}$, which implies that the seed length is $\ell = O(\log(t\cdot\log(q)))$. The condition in this case holds since $\log(nt/d)=\Omega(\log(n))$ and $q\le 2^{\mathrm{poly}(n)}$, which implies that $\frac{\log(nt/d)}{8\ell}=\Omega(1)$. The second case is when $t<\sqrt{d/4(q-1)}$, which implies that the seed length is $\ell = O((d/t)\cdot\log(q)/(q-1))$. The condition in this case holds if and only if $\frac{q-1}{\log(q)}\cdot\log(nt/d)$ is larger than a sufficiently large constant, which is our hypothesis. ◀

5 Lower Bounds Over General Finite Fields

In this section we describe our lower bounds on the seed length of HSGs for polynomials that vanish rarely, which are proved by instantiating the approach from Section 4 with specific dispersers that are suitable for the corresponding parameter settings.

We prove three incomparable lower bounds. Our first and main lower bound is a generalization of Theorem 1. This lower bound is of the form $\Omega((d/t)\cdot\log(n^{1-\Omega(1)}t/d))$, and holds under complicated conditions on the degree d and on t; in particular, for $d\le n^{.49}$ as in Theorem 1, it holds for all values of t up to $\Omega(d)$. For details see Theorem 23 in Appendix B.

Our two additional lower bounds, which are detailed and proved in the full version (see [15, Section 6.3]), hold in more specific settings than the foregoing lower bound, but have advantages over this bound. The first of the two lower bounds holds only when $d\le q$ (i.e., when the corresponding Reed-Muller code has distance $\Omega(1)$); this lower bound is of the same form as in Theorem 23, but holds for higher degrees up to $d\le n^{1-\Omega(1)}$ without complicated conditions on d and t. The second lower bound holds only over fields of constant size; this lower bound is of the stronger form $\Omega((d/t)\cdot\log(nt/d))$,[13] and holds for degrees d up to $\Omega(n)$, but only for value of $t\lessapprox\sqrt{d}$.

A Randomized Tests

The proofs of both our upper bounds and of our lower bounds relies on a general observation that we explain here. The observation is essentially from [40, Sections 2.1 & 4], following a proof idea from [10].

Assume that we want to deterministically *find* an element in a set $\mathrm{G} \subseteq \mathbb{F}^n$. A standard way to do so is to show that G can by decided by a simple algorithm p (e.g., p is a low-degree polynomial), which we think of as a *simple test*. Then, a hitting-set generator for p outputs an element in G. Our goal now is to find an element in G using a hitting-set generator for tests that are *simpler* than p. The basic observation is that if G can be decided, with high probability, by a *distribution* $\boldsymbol{p}$ *over simple tests*, then a hitting-set generator with small density for the tests in the *support* of $\mathbf{p}$ outputs an element in G (see [40, Observation 2.1]). The advantage is that instead of constructing a deterministic test p we can now construct a *randomized test* $\boldsymbol{p}$, whose complexity is potentially lower than that of p; that is, the complexity of the tests in the support of the distribution $\mathbf{p}$ may be lower than the complexity of the deterministic test p.

The observation above can be extended in various ways (see [40] for details), and we will apply it in two specific settings. In the first setting, which is useful for our lower bound proofs, the set G is dense (i.e., $\Pr_{x\in\mathbb{F}^n}[x \in \mathrm{G}] \geq .99$), and can be decided by a distribution $\mathbf{p}$ over polynomials with small "one-sided" error (i.e., every $x \in \mathrm{G}$ is accepted with high probability, and every $x \notin \mathrm{G}$ is rejected with probability one). We show that in this case, any hitting-set generator for the polynomials in the support of $\mathbf{p}$ that *vanish rarely* outputs an element in G (and this holds without any density requirement from the HSG).

▶ **Lemma 22** (randomized tests). *Let $\varepsilon, \rho > 0$ such that $\varepsilon + \rho < 1$, and let $\mathrm{G} \subseteq \mathbb{F}^n$ be such that $\Pr_{x\in\mathbb{F}^n}[x \in \mathrm{G}] \geq 1 - \varepsilon$. Assume that there exists a distribution $\boldsymbol{p}$ over polynomials $p\colon \mathbb{F}^n \to \mathbb{F}$ such that:*

1. *For every fixed $x \in \mathrm{G}$ it holds that $\Pr[\boldsymbol{p}(x) \neq 0] \geq 1 - \rho$.*
2. *For every fixed $x \notin \mathrm{G}$ it holds that $\Pr[\boldsymbol{p}(x) = 0] = 1$.*

Let $\boldsymbol{w}$ be a distribution over $\mathbb{F}^n$ such that for every $p\colon \mathbb{F}^n \to \mathbb{F}$ in the support of $\boldsymbol{p}$ that vanishes on at most a $\sqrt{\rho + \varepsilon}$ fraction of its inputs there exists $w \sim \boldsymbol{w}$ such that $p(w) \neq 0$. Then, there exists $w \sim \boldsymbol{w}$ such that $w \in \mathrm{G}$.

We give the proof of Lemma 22 in the full version of the paper (see [15, Section 4]).

In the second setting, which is useful for our upper-bound proof (see [15, Section 5]), we want to "fool" a polynomial $p\colon \mathbb{F}^n \to \mathbb{F}$ using a pseudorandom generator for polynomials that are simpler than p (e.g., they are of lower degree). This is indeed possible if there is a distribution $\mathbf{h}$ over polynomials that are simpler than p such that for every fixed $x \in \mathbb{F}^n \to \mathbb{F}$ it holds that $\Pr[\mathbf{h}(x) = p(x)]$ is high. We defer the details of the second setting to the full version (see [15, Section 4]).

B The Main Lower Bound: Proof of Theorem 1

In this section we prove lower bounds that hold also when the degree is much larger than the field size (i.e., $d \gg q$). Specifically, we will prove the following, more general version of Theorem 1:

▶ **Theorem 23** (a lower bound using the Shaltiel-Umans linear disperser; a more general version of Theorem 1). *For any two constants $\gamma > 0$ and $\gamma' > 0$ there exists a constant $\gamma'' > 0$ such that the following holds. Let $n, d, t, q \in \mathbb{N}$ such that $q \leq n^{1/\gamma'}$ is a prime power, $d \leq n/4$, and:*

- *(essentially all values of $\varepsilon = q^{-t}$) $t \leq \gamma'' \cdot \frac{\log(nt/d)}{\log(n)} \cdot d$.*
- *(auxiliary condition that holds for typical settings) $\frac{q-1}{\log(q)} \cdot \log(nt/d) \geq 1/\gamma''$.*
- *(main condition: d/t is upper-bounded) $d/t \leq \gamma'' \cdot \min\left\{\frac{q-1}{\log(q)} \cdot n^{\gamma}, n^{1-(\gamma+\gamma')}\right\}$.*

Then, the seed length of any HSG for $\mathcal{P}_{n,q,d,\sqrt{2}\cdot q^{-t}}$ is at least $\Omega\left(\frac{d}{t} \cdot \log\left(\frac{n^{1-(\gamma+\gamma')}\cdot t}{d}\right)\right)$.

To deduce Theorem 1 from Theorem 23, note that if we are willing to assume that $d \leq n^{.49}$, then we can choose $\gamma = .499$ and $\gamma' > 0$ that is sufficiently small, and the three conditions in Theorem 23 hold for every $q \leq n^{1/\gamma'}$ and $t \leq \gamma'' \cdot d$.

To prove Theorem 23 we will instantiate Corollary 20 with a linear disperser that we will construct relying on the extractor of Shaltiel and Umans [36]. Recall that [36] constructed an extractor $\mathsf{Ext}\colon \{0,1\}^n \times \{0,1\}^\ell \to \{0,1\}^m$ by first constructing what they called a q-ary extractor, whose output lies in a field of size $\mathrm{poly}(n)$ and only satisfies a relatively-weak unpredictability requirement, and then transforming the q-ary extractor to a standard extractor over the binary alphabet (the transformation follows an idea of Ta-Shma, Zuckerman, and Safra [39]).

We want to construct a low-degree disperser $\mathsf{Disp}\colon \mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q$ where the field $\mathbb{F}_q$ is of size much smaller than $\mathrm{poly}(n)$ (i.e., $q \leq n^{\gamma'}$ for some small constant $\gamma' > 0$). To do so, we take as a starting-point their construction of a q_0-ary extractor from [36], where $q_0 = \mathrm{poly}(n)$, and then generalize their transformation of q_0-ary extractors to standard extractors (and in particular dispersers) such that the resulting extractor is both over the field $\mathbb{F}_q$, rather than over a binary alphabet, and linear.

Towards presenting the construction, let us first recall the definition of q_0-ary extractors and the main construction of such objects from [36].

▶ **Definition 24** (q_0-ary extractor). *For $n, k, m, \ell \in \mathbb{N}$ and $\rho > 0$, and a prime power $q_0 \in \mathbb{N}$, we say that $\mathsf{Ext}_0\colon \mathbb{F}_{q_0}^n \times \{0,1\}^\ell \to \mathbb{F}_{q_0}^m$ is a (k,ρ) q_0-ary extractor if for every random variable $\boldsymbol{x}$ over $\mathbb{F}_{q_0}^n$ with min-entropy at least k, and every $i \in [m]$, and every function $P\colon \mathbb{F}_{q_0}^{i-1} \to \mathbb{F}_{q_0}^{\rho^{-2}}$, it holds that $\Pr_{x\sim\boldsymbol{x},u\sim\boldsymbol{u}_\ell}[P(\mathsf{Ext}_0(x,u)_1, ..., \mathsf{Ext}_0(x,u)_{i-1}) \ni \mathsf{Ext}_0(x,u)_i] \leq \rho$.*

▶ **Theorem 25** ([36, Theorem 4.5, Item 1]). *There exists a universal constant $c > 1$ such that the following holds. Let $n_0, q_0, k, m, r, h \in \mathbb{N}$ and $\rho > 0$ such that q_0 is a prime power, and the following inequalities hold:*

1. *(sufficiently large auxiliary parameters h and r) $n_0 \leq \binom{h+r-1}{r}$.*
2. *(sufficiently large field) $q_0 \geq c \cdot \frac{(h\cdot r)^2}{\rho^4}$.*
3. *(sufficiently small output length) $m \leq \frac{k - \log(1/\rho)}{c\cdot h\cdot r\cdot \log(q_0)}$.*

Then, there exists an $r \times r$ matrix A over $\mathbb{F}_{q_0}$ such that the following holds. Let $\mathsf{Ext}_0\colon \mathbb{F}_{q_0}^{n_0} \times \{0,1\}^{r\cdot\log(q_0)} \to \mathbb{F}_{q_0}^m$ be defined by $\mathsf{Ext}_0(x,v) = p_x(A^1\cdot v) \circ p_x(A^2\cdot v) \circ ... \circ p_x(A^m \cdot v)$, where v is interpreted as an element in $\mathbb{F}_{q_0}^r$, and $p_x\colon \mathbb{F}_{q_0}^r \to \mathbb{F}_{q_0}$ is the r-variate polynomial of total degree $h-1$ whose coefficients are specified by x. Then, Ext_0 is a (k,ρ) q_0-ary extractor.

Note that in [36] the input of the extractor is represented in binary and interpreted as n_0 elements in $\mathbb{F}_q$, whereas in Theorem 25 we considered the input as n_0 elements in $\mathbb{F}_q$. The two formulations are equivalent, since a random variable over $\mathbb{F}_{q_0}^{n_0}$ has min-entropy k if and only if the corresponding random variable over $\{0,1\}^{n_0 \cdot \log(q_0)}$ has min-entropy k. Also note that [36, Lemma 4.4] showed that A can be constructed in time $q_0^{O(r)}$ (by an exhaustive search over the field $\mathbb{F}_{(q_0)^r}$), and deduced that the extractor is efficiently computable; however, we will not use this property of the extractor.

We now present the transformation of q_0-ary extractors to standard extractors whose inputs and outputs are vectors over $\mathbb{F}_q$, where $q \ll q_0$; as mentioned above, the proof, given in the full version, generalizes an idea from [39]. The intuition for this transformation is the following. Consider the output distribution of a q_0-ary extractor as consisting of blocks of elements from $\mathbb{F}_q$, where each block represents a single element from $\mathbb{F}_{q_0}$; by definition, the output distribution of a q_0-ary extractor is "next-element unpredictable", and hence the distribution of elements from $\mathbb{F}_q$ is a *block source* (see, e.g., [41, Section 6.3.1]). Following Nisan and Zuckerman [34], we compose the q_0-ary extractor with a strong extractor over $\mathbb{F}_q$ that outputs a single element (and maps each block to a single element) and obtain an extractor over $\mathbb{F}_q$. We will specifically use a single-output extractor that is obtained from a *linear list-decodable code* (see, e.g., [38, Claim 4.1]), relying on well-known constructions of such codes.[14]

▶ **Proposition 26** (transforming a q_0-ary extractor into a standard extractor over $\mathbb{F}_q$)**.** *Let $\rho > 0$, let q be a prime power, let $q_0 = q^\Delta$ for some $\Delta \in \mathbb{N}$, and let $\mathfrak{C}\colon \mathbb{F}_q^\Delta \to \mathbb{F}_q^\Delta$ be a $(1 - 1/q - \rho, \rho^{-2})$-list-decodable code. Assume that $\mathsf{Ext}_0\colon \mathbb{F}_{q_0}^{n_0} \times \{0,1\}^{\ell_0} \to \mathbb{F}_{q_0}^m$ is a (k,ρ) q_0-ary extractor. Let $\mathsf{Ext}\colon \mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q^m$, where $n = n_0 \cdot \Delta$ and $\ell = \ell_0 + \log(\bar{\Delta})$, be defined by*

$$\mathsf{Ext}(x,(y,j)) = \mathfrak{C}(\mathsf{Ext}_0(\hat{x},y)_1)_j \circ \ldots \circ \mathfrak{C}(\mathsf{Ext}_0(\hat{x},y)_m)_j \ ,$$

where $\hat{x} \in \mathbb{F}_{q_0}^{n_0}$ is the vector that is represented by $x \in \mathbb{F}_q^{n_0 \cdot \Delta}$. Then, Ext is a $(k, 2qm \cdot \rho)$-extractor.

We now combine Theorem 25 and Proposition 26 to obtain a linear (k,δ)-disperser $\mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q^m$ with output length $m = k/n^{\Omega(1)}$ and seed length $\ell = O(\log(n/\delta))$. We provide the proof in the full version of the paper.

▶ **Theorem 27** (an adaptation of the Shaltiel-Umans extractor to a linear disperser over general finite fields)**.** *For any two constants $\gamma, \gamma' > 0$ the following holds. Let $n, k, q \in \mathbb{N}$ such that $k \geq n^{\gamma+\gamma'}$ and $q \leq n^{1/\gamma'}$, and let $\delta \geq 2^{-n^\gamma + \log(2qn)}$. Then, there exists a linear (k,δ)-disperser $\mathsf{Disp}\colon \mathbb{F}_q^n \times \{0,1\}^\ell \to \mathbb{F}_q^m$, where $\ell = O_{\gamma'}(\log(n/\delta))$ and $m = \Omega_{\gamma'}\left(k/n^{\gamma+\gamma'}\right)$.*

Finally, we deduce our lower bound from Theorem 23 using Corollary 20 with the linear disperser from Theorem 27.

Proof of Theorem 23. Let $d_0 = d/4t$, and let $a = d_0/(q-1)$ such that $\delta = \delta_{RM}(d_0, q) \geq q^{-a}$. We instantiate the linear disperser from Theorem 27 with parameters n and $k = (n-2t)\cdot\log(q)$ and $\delta = q^{-a} \geq 2^{-n^\gamma + \log(2qn)}$, and with the parameters $\gamma > 0$ and $\gamma' > 0$. The conditions of Theorem 27 hold due to our hypotheses that $d/t \leq \gamma'' \cdot \frac{q-1}{\log(q)} \cdot n^\gamma$ (which implies that

[14] In fact, since in our case the output of the q_0-ary extractor is not only unpredictable but also unpredictable by predictors that output a *list* of elements, we use a simpler proof that does not go through the notion of strong extractors.

$\delta \geq 2^{-n^{\gamma}+\log(2qn)}$) and that $d \leq n/4$ (which implies that $k = \Omega(n)$). For these parameters, the disperser has seed length $\ell = O(\log(n/\delta)) = O(\log(n) + (d/4t) \cdot (\log(q)/(q-1)))$ and output length $m = \Omega(n^{1-(\gamma+\gamma')})$.

Relying on Corollary 20, we get a lower bound of $\Omega\left((d/t) \cdot \log(n^{1-(\gamma+\gamma')} \cdot (t/d))\right)$, assuming that $d_0 < m$ (which holds since $d/4t < \gamma'' \cdot n^{1-(\gamma+\gamma')}$) and that $t \leq \frac{\log(nt/d)}{8\ell} \cdot d$. Thus, we just need to verify the latter condition.

We verify the condition by a case analysis. The first case is when $\log(n) > \frac{d\log(q)}{4t(q-1)}$, which implies that the seed length is $\ell = O(\log(n))$; then, the condition that we want holds due to our hypothesis $t \leq \gamma'' \cdot \frac{\log(nt/d)}{\log(n)} \cdot d$. In the second case we have that $\frac{d\log(q)}{4t(q-1)} \geq \log(n)$, which implies that the seed length is $\ell = O\left(\frac{d\log(q)}{t(q-1)}\right)$; then, the condition holds since we assumed that $\frac{q-1}{\log(q)} \cdot \log(nt/d) \geq 1/\gamma''$. ◀

C Small Sets With a Large Degree-d Closure

In this section we establish a connection between the study of HSGs for polynomials that vanish rarely, and the study of small sets with large degree-d closures, which was recently initiated by Nie and Wang [33]. To do so let us first define the degree-d closure of a set $S \subseteq \mathbb{F}^n$:

▶ **Definition 28** (degree-d closure). *Let $\mathbb{F}$ be a finite field, and let $n, d \in \mathbb{N}$. Then, for any $S \subseteq \mathbb{F}^n$, we define the degree-d closure of S, denoted $\mathtt{Cl}^{(\mathtt{d})}(S)$, by $\mathtt{Cl}^{(\mathtt{d})} = \{x \in \mathbb{F}^n : \forall p \in \mathcal{I}(S), p(x) = 0\}$, where $\mathcal{I}(S) = \{p : \mathbb{F}^n \to \mathbb{F} : \deg(p) = d \wedge \forall s \in S, p(s) = 0\}$.*

We now restate and prove Theorem 5, which shows two reductions. Loosely speaking, we show that any set with degree-d closure of size q^{n-t} is a hitting-set for polynomials that vanish with probability at most q^{-t}; and we show that any hitting-set for polynomials that vanish with probability at most q^{-t} has degree-d' closure of size $q^{n-t}/2$, for d' that is not much smaller than d.

▶ **Theorem 5** (small sets with large closures versus hitting-sets for polynomials that vanish rarely). *Let $\mathbb{F}$ be a field of size q, let $n \in \mathbb{N}$ and $t < d < n$, and let $S \subseteq \mathbb{F}^n$. Then,*

1. *If $\left|\mathtt{Cl}^{(\mathtt{d})}(S)\right| > q^{n-t}$, then S is a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$.*
2. *If S is a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$, then $\left|\mathtt{Cl}^{(\mathtt{d}/2(\mathtt{t}+1))}(S)\right| > \frac{1}{2} \cdot q^{n-t}$.*

Proof. For the first statement, let $S \subseteq \mathbb{F}^n$ be such that $\left|\mathtt{Cl}^{(\mathtt{d})}(S)\right| > q^{n-t}$. Then, every degree-$d$ polynomial that vanishes on S also vanishes on more than q^{n-t} of the inputs. It follows that S is a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$.

For the second statement, for $d' = d/2(t+1)$, assuming that $\left|\mathtt{Cl}^{(\mathtt{d}')}(S)\right| \leq \frac{1}{2} \cdot q^{n-t}$, we construct a degree-$d$ polynomial that vanishes on S and that vanishes on at most q^{n-t} inputs in $\mathbb{F}^n$ (and it follows that S is not a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$).

To construct the polynomial, let $T_1 = \mathbb{F}^n \setminus \mathtt{Cl}^{(\mathtt{d}')}(S)$. Note that for every $x \in T_1$ there exists a degree-d' polynomial p_x that vanishes on S, but does not vanish at x. We can thus construct a collection $\mathcal{P}_1$ of degree-d' polynomials such that for every $x \in T_1$ there exists a corresponding $p_x \in \mathcal{P}_1$ satisfying $p_x(x) \neq 0$. (Indeed, a single polynomial might "cover" two distinct inputs, i.e. $p_x = p_y$ for $x \neq y$.)

Now, consider the distribution $\mathbf{p}_1$ over polynomials $\mathbb{F}^n \to \mathbb{F}$ that is defined by

$$\mathbf{p}_1(z) = \sum_{x \in T_1} \mathbf{c}_x \cdot p_x(z),$$

where the coefficients $\mathbf{c}_x$ are uniformly and independently chosen in $\mathbb{F}$. Note that $\mathbf{p}_1$ is supported by polynomials of degree d' that vanish on S. Also note that for any fixed $z \in T_1$ we have that

$$\begin{aligned}\Pr[\mathbf{p}_1(z)=0] &= \Pr\left[\sum_{x\in T_1}\mathbf{c}_x\cdot p_x(z)=0\right] \\ &= \mathop{\mathbb{E}}_{\{c_x\}_{x\in T_1\setminus\{z\}}}\left[\Pr\left[\mathbf{c}_z\cdot p_z(z)=-\sum_{x\in T_1\setminus\{z\}}c_x\cdot p_x(z)\right]\right],\end{aligned}$$

which equals $1/q$ since $p_z(z)\neq 0$. Therefore, there exists a fixed polynomial p of degree d' that vanishes on S and on at most $1/q$ of the inputs in T_1.

We now repeat this step t additional times, while maintaining the invariant that for every $x \in T_i$ there exists a polynomial $p_x \in \mathcal{P}_i$ such that $p_x(x)\neq 0$. Specifically, for $i=2,...,t+1$, we let $T_i = T_{i-1}\cap\{x\in T_i : p_{i-1}(x)=0\}$ and $\mathcal{P}_i = \mathcal{P}_{i-1}\setminus\{p_{i-1}\}$. Note that $|T_i|\leq |T_{i-1}|/q$, and that for every $x\in T_i$ there exists $p_x\in\mathcal{P}_i$ such that $p_x(x)\neq 0$. We again define a distribution $\mathbf{p}_i(z)=\sum_{x\in T_i}\mathbf{c}_x\cdot p_x(z)$, and using the same argument as above, we deduce that there exists a fixed polynomial p_i of degree d' that vanishes on S and on at most $1/q$ of the inputs in T_i.

After $t+1$ steps we obtain $t+1$ polynomials $p_1,...,p_{t+1}$ of degree d' that vanish on S such that $\left|\{x\notin \mathtt{Cl}^{(\mathtt{d})}(S) : \forall i\in[t], p_i(x)=0\}\right| \leq |T_1|/q^{t+1}\leq \frac{1}{2}\cdot q^{-t}$. Let $p\colon \mathbb{F}^n\to\mathbb{F}$ be the multivalued OR of $p_1,...,p_{t+1}$, defined by $p(x)=\mathtt{mvOR}(p_1(x),...,p_t(x))$. Note that $\deg(p)<2(t+1)\cdot d'=d$, and that p vanishes on S. Thus, denoting $\delta=\left|\mathtt{Cl}^{(\mathtt{d}')}(S)\right|/q^n\leq\frac{1}{2}\cdot q^{-t}$, we have that

$$\Pr_{x\in\mathbb{F}^n}[p(x)=0]=\delta+(1-\delta)\cdot q^{-(t+1)}<q^{-t}.$$

which implies that $p\in\mathcal{P}_{n,q,d,q^{-t}}$. Hence, S is not a hitting-set for $\mathcal{P}_{n,q,d,q^{-t}}$. ◀

As mentioned in Section 1.3, we can obtain an upper-bound on the size of $\mathtt{Cl}^{(\mathtt{d})}(S)$ for any sufficiently-small set S, by combining Theorem 23 and the first item of Theorem 5. Specifically, we can deduce that for every $2\leq q\leq \mathrm{poly}(n)$ and $d\leq n^{.49}$ and $t\leq\gamma\cdot d$ (where $\gamma>0$ is a sufficiently small constant), any set S of size $|S|\leq n^{\gamma\cdot(d/t)}$ satisfies $\left|\mathtt{Cl}^{(\mathtt{d})}(S)\right|\leq q^{n-t}$. However, this corollary is superseded by the upper-bound of [33], who showed that for any $S\subseteq\mathbb{F}^n$ it holds that $\left|\mathtt{Cl}^{(\mathtt{d})}(S)\right|\leq\frac{|S|}{\binom{n+d}{d}}\cdot q^n$.

Indeed, since the problem of constructing small sets with large degree-d closures is at least as hard as the problem of constructing HSGs for polynomials that vanish rarely (due to the first item of Theorem 5), it might be inherent that a direct lower bound on the former problem is stronger than a lower bound that is obtained via a reduction from the latter problem.

Polynomial Identity Testing for Low Degree Polynomials with Optimal Randomness

Abstract

We give a randomized polynomial time algorithm for polynomial identity testing for the class of n-variate poynomials of degree bounded by d over a field $\mathbb{F}$, in the blackbox setting.

Our algorithm works for every field $\mathbb{F}$ with $|\mathbb{F}| \geq d+1$, and uses only $d \log n + \log(1/\epsilon) + O(d \log \log n)$ random bits to achieve a success probability $1-\epsilon$ for some $\epsilon > 0$. In the low degree regime that is $d \ll n$, it hits the information theoretic lower bound and differs from it only in the lower order terms. Previous best known algorithms achieve the number of random bits (Guruswami-Xing, CCC'14 and Bshouty, ITCS'14) that are constant factor away from our bound. Like Bshouty, we use Sidon sets for our algorithm. However, we use a new construction of Sidon sets to achieve the improved bound.

We also collect two simple constructions of hitting sets with information theoretically optimal size against the class of n-variate, degree d polynomials. Our contribution is that we give new, very simple proofs for both the constructions.

1 Introduction

We investigate algorithms for the problem of Polynomial Identity testing (PIT). Given a polynomial in some implicit representation, it asks whether the polynomial is identically zero or not. It is a fundamental problem in algorithms and complexity theory. It has found applications in algorithm design, for example in algorithms for perfect matching in graphs [17, 36, 39], for primality testing [2, 3, 4], for equivalence testing of read once branching programs [13], and for multi-set equality testing [14], and also in complexity theory, for example, in establishing some major results related to interactive proofs and probabilistically-checkable proofs [38, 9, 8, 7, 45]. In fact, it has also been discovered that an algorithm for polynomial identity testing is intimately connected with complexity theoretic lower bounds [31, 1].

In order to formalize the algorithmic problem of polynomial identity testing, it is important to specify the representation in which the polynomial is given. One possibility is that the polynomial is given as a blackbox, which means that the algorithm is restricted to using the given representation of the given polynomial only as an oracle. That is, the algorithm is only allowed to query the values of the polynomial at points of its choice. Apart from that, the algorithm only knows that the given polynomial comes from some particular class of polynomials. The other possibility is that the algorithm is also allowed to look into the representation. In this case, if the polynomial is given as a list of coefficients, the problem becomes trivial. The problem remains interesting in the case when the polynomial is given in some succinct representation, for example, either as a determinant of a given symbolic matrix, as an algebraic branching program, or more generally, as some arithmetic circuit.

It is known that randomness is necessary for a polynomial time blackbox PIT algorithm (see for example [35]). The challenge thus in this case is to find polynomial time algorithms that use optimal amount of randomness. Randomness is not known to be essential in the setting when the polynomial is given as an arithmetic circuit. In fact, it is popularly believed that there do exist polynomial time algorithms for this version of PIT which do not use randomness. More generally, it is believed that in the regime of efficient computation, randomization is not essential, that is, the complexity classes P and BPP are equal (see [30]). In this case, the challenge is to come up with a deterministic algorithm. A lot of progress has happened over the years towards both the challenges [18, 35, 32, 12, 10, 28, 27, 24, 23, 22, 6, 11, 2, 33, 15, 37, 29], however the problems are still far from the complete solution. For a history on the progress on polynomial identity testing, we refer the readers to [47, 42, 43].

In this work, we are interested in blackbox polynomial identity testing. We will focus our attention to the case when the underlying field is a finite field. More precisely, we are interested in the following computational problem.

▶ **Problem 1.** *Let $(\mathbb{F}_q, n, d)$ denote the class of multivariate polynomials over $\mathbb{F}_q$ in n variables with degree bounded by d* [1] *with $q \geq d+1$. Given a polynomial $p \in (\mathbb{F}_q, n, d)$ as a blackbox and a parameter $\epsilon > 0$, decide whether p is an identically zero polynomial in randomized $poly(n, d)$ time with success probability $1 - \epsilon$.*

We are interested in algorithms for Problem 1 which minimize the number of random bits needed to solve it. In the next subsection we discuss some previous works on the problem that are relevant to this article. While mentioning these works, we will assume the error bound ϵ to be some inverse polynomial in (nd), and we will focus only on algorithms that run in $poly(n, d)$ time under this assumption.

1.1 Previous works on Problem 1

A lot of randomized algorithms are known for PIT in the blackbox setting. The first one is the algorithm due to Schwartz-Zippel-DeMillo-Lipton [2] [44, 49, 21]. It uses $\sum_{i=1}^{n} \log(d_i + 1) + n \log n + 1$ random bits. Then came the algorithm by Lewin and Vadhan [35] which used $\sum_{i=1}^{n} \lceil \log d_i \rceil$ random bits, where d_i refers to the degree of the given polynomial with respect to the variable x_i. Using the Kronecker substitution, Agrawal and Biswas [2] gave a test with $\lceil \sum_{i=1}^{n} \log(d_i + 1) \rceil$ random bits, while Bläser-Hardt-Steurer [12] extended their Kronecker substitution based test to work for asymptotically smaller fields by using $\sum_{i=1}^{n} \log(d_i + 1) + \tilde{O}(\sqrt{\sum_{i=1}^{n} \log(d_i + 1)})$ random bits.

[1] in this paper, unless stated otherwise, degree always refers to the total degree

[2] In their paper [21], DeMillo-Lipton work with the total degree. However, implicitly, the analysis of their algorithm only assumes the individual degrees to be bounded by d.

These works achieve optimal number of random bits in the regime where individual degrees of $x_1, \ldots, x_n$ are bounded by $d_1, \ldots, d_n$ respectively. In that regime, a simple dimension argument shows a lower bound of $\log(\prod_{i=1}^{n}(d_i+1)) - \log T(n, d_1, \ldots, d_n)$, where $T(n, d_1, \ldots, d_n)$ denotes the number of queries made to the blackbox [35, Theorem 7.1]. Thus, when $T(n, d_1, \ldots, d_n)$ is $poly(n)$ bounded, we get a $(1 - o(1)) \sum_{i=1}^{n} \log(d_i + 1)$ lower bound on the number of random bits needed. However, when we are in the setting as given in Problem 1, that is, when only a bound on the total degree is given, the number of random bits used by these methods are asymptotically similar to that of Schwartz-Zippel-DeMillo-Lipton i.e. $\Omega(n \log d)$, which is far from optimal in the regime where $d \ll n$. In this regime, again using a simple dimension argument (see [35, Theorem 7.1] and Lemma 9), we have the following lower bound:

▶ **Fact 1.** *Any blackbox identity testing algorithm against $(\mathbb{F}_q, n, d)$, $q \geq d+1$ which makes $T(n,d)$ queries to the blackbox and succeeds with probability $1-\epsilon$ uses at least $\log(\binom{n+d}{d}) + \log(1/\epsilon) - \log T(n,d)$ random bits.*

Applying Stirling's approximation on $\binom{n+d}{d}$ in the above when $d = o(n)$ gives $\log(\binom{n+d}{d}) = (1+o(1))d\log(\frac{n+d}{d}) = d\log n + o(d\log n)$ [20]. Plugging this in above, with $T(n,d) = (nd)^{O(1)}$, we get the lower bound of $d\log n + \log(1/\epsilon) + o(d\log n)$.[3]

Moving on to the previous works when $d \ll n$, several algorithms are known that actually do achieve the $O(d \log n)$ random bits. For instance, Klivans-Spielman [32], Bogdanov [15], Shpilka-Volkovich generator [46], Lu [37], Guruswami-Xing [29] and finally Bshouty [16] (also see Cohen-Ta-Shma [19]). However, except for [29] and [16], all of them require the field size to be superlinear in d/ϵ as a pre-condition for the algorithm. Moreover, in all of these algorithms including the ones in Bshouty [16] and Guruswami-Xing [29], the number of random bits used is $\geq 2d \log n$.

1.2 Our contributions and methods

From the above, we can see that in the low-degree regime, the number of random bits needed by all the previously discovered algorithms, is away from the information theoretically optimal bound at least by a constant multiplicative factor. We take up the challenge and solve it. We give an algorithm that matches the information theoretic lower bound differing from it only in the lower order terms.

More precisely, we show the following:

▶ **Theorem 1.** *Given a polynomial $f \in (\mathbb{F}_q, n, d)$ with $q \geq d+1$ as a blackbox, and a parameter $\epsilon > 0$, there exists a randomized $poly(n,d)$ time algorithm which uses $d\log n + \log(1/\epsilon) + O(d \log\log n)$ random bits and outputs whether f is an identically zero polynomial with success probability $1-\epsilon$.*

Starting point of our algorithm is an algorithm given in Bshouty [16]. He used the so-called Sidon sets (discussed in Section 2.1) for polynomial identity testing by using them to reduce the problem to the univariate setting while preserving the nonzeroness. He then used the obvious randomized algorithm for the obtained univariate polynomial. This, however, requires the field-size to be large. He gets around this problem by inventing the concepts of testers (discussed in Section 2.2). Informally, testers take a point α from a field $\mathbb{F}$ and map it to a bunch of points in a smaller subfield of $\mathbb{F}$, while maintaining the property that if $f(\alpha) \neq 0$, then f will evaluate to a nonzero value on at least one of the points given by the tester.

[3] this is what we refer to as the information theoretic lower bound in this article

He used two constructions for Sidon sets for this purpose. One of them is not known to be poly time constructible, while the other, which is poly time constructible is factor 2 away from the information theoretic lower bound. To overcome this, we use a new, elementary construction of Sidon sets that is mentioned in Timothy Gowers' weblog [26] (presented in Section 2.1).

Our second contribution is aesthetic in nature. We first remind the readers that a hitting set against a class $\mathcal{P} \subseteq \mathbb{F}[x_1, \ldots, x_n]$ is a set of point $\mathcal{H} \subseteq \mathbb{F}^n$ such that no nonzero polynomial in $\mathcal{P}$ evaluates to zero on all the points in $\mathcal{H}$. We present two simple constructions of information theoretically optimal hitting sets (i.e. of size $\binom{n+d}{d}$) against $(\mathbb{F}, n, d)$ with $|\mathbb{F}| \geq d+1$ that are, at least implicitly, present in the literature. We extract them out and give very simple and neat proofs for both. The first construction (presented in Section 3.1) is essentially the set of exponent vectors of all the monomials spanning $(\mathbb{F}, n, d)$. This works when $\{0, 1, \ldots, d\} \subseteq \mathbb{F}$. The second construction (presented in Section 3.2) says that taking all the intersection points of n-sized subsets of a set of $n+d$ hyperplanes in general position also forms a hitting set against $(\mathbb{F}, n, d)$ of optimal size.

In the rest of the paper, $(\mathbb{F}, n, d)$ (resp. $(\mathbb{F}_q, n, d)$) denotes the class of n-variate polynomials with degree bounded by d over $\mathbb{F}$ (resp. $\mathbb{F}_q$). For a natural number $d \in \mathbb{N}$, $[d]$ denotes the set $\{1, \ldots, d\}$.

2 Polynomial Identity Testing with optimal randomness

In this section, we present our main result. We first describe the main component of the proof, that is, the construction of Sidon sets in Section 2.1, and then describe the way to reduce the field size in Section 2.2. We finally give our algorithm and the proof for our main theorem in Section 2.3.

2.1 Sidon Sets

A set $\mathcal{S} := \{s_1, s_2, \ldots, s_n\} \subset \mathbb{Z}_{\geq 0}$ is said to be a Sidon B_d set if every element in the set $d\mathcal{S} := \{s_{i_1} + s_{i_2} + \ldots + s_{i_d} \mid \forall k \in [d], s_{i_k} \in \mathcal{S}\}$ are distinct up to rearrangements of the summands. We also have a stronger notion: we call $\mathcal{S}$ to be Sidon $B_{\leq d}$ set if the sums $\{s_{i_1} + s_{i_2} + \ldots + s_{i_r},\ r \leq d \mid \forall k \in [r], s_{i_k} \in \mathcal{S}\}$ are distinct up to rearrangements of the summands. For our purposes, the stronger notion of Sidon $B_{\leq d}$ set when $d \ll n$ will be useful. We are interested in constructions that minimize the size of the maximum element of $\mathcal{S}$ and are $poly(n, d)$ time constructible.

Sidon sets and its variants have a long history in mathematics and several explicit constructions are known. We refer the readers to a survey by Kevin O'Bryant [40].

In complexity theory, explicit Sidon set constructions have also been used, for example, by Bshouty for constructions of hitting sets for black box polynomial identity testing [16], and by Kumar and Volk for matrix factorization lower bounds [34].

Bshouty uses two constructions for polynomial identity testing. The first construction uses discrete log and is not known to be poly time constructible [16, Lemma 59]. The second construction is poly time constructible, but the value of the maximum element is $(2nd)^{2d}$ [16, Lemma 60]. This $2d$ in the exponent makes this construction suboptimal for our purposes because the resulting randomized PIT algorithm will have $\geq 2d \log n$ random bits, which is factor 2 away from the information theoretic bound in low degree regime which is the regime of interest in this paper.

This motivated us to look for constructions that are both polynomial time constructible and also give rises to PIT algorithm with optimal randomness. That is when we stumbled across the weblog of Timothy Gowers about the so-called dense Sidon sets [26] where he describes the idea of a construction by Imre Z. Ruzsa [41] that scales up for our purposes too.

In its core, the construction is based on the fundamental theorem of arithmetic. Informally, when we take a set of primes and consider two different multi-subsets of them. Then the product of elements will be different for the two multi-subsets. Now taking logarithm of products convert them to sums. These simple facts along with the mean value theorem constitute the ingredients of the proof of the construction. We give the construction now.

▶ **Theorem 2.** *For every n, d, there exists a poly(n, d) time constructible Sidon $B_{\leq d}$ set $S_{n,d} := \{b_1, \ldots, b_n\} \subset \mathbb{N}$ with $b_1 < b_2 < \cdots < b_n$, with $b_n \leq \lceil (d+1) \cdot (2n \log n)^d \cdot \log(2n \log n) \rceil$.*

Proof. We take the first n primes $p_1, \ldots, p_n$. By prime number theorem, we know that $p_n < n(\log n + \log \log n) < 2n \log n$. Let $I, J \subseteq \{1, \ldots, n\}$ be multisets, where $|I|, |J| \leq d$, $I \neq J$. By the fundamental theorem of arithmetic, we have $\prod_{i \in I} p_i \neq \prod_{j \in J} p_j$. Without loss of generality, we can assume that $\prod_{i \in I} p_i < \prod_{j \in J} p_j$, that is, $\prod_{i \in I} p_i \leq \prod_{j \in J} p_j + 1$. Now applying the mean value theorem on the function $f(x) = \log x$ in the interval $[a, b]$ with $a := \prod_{i \in I} p_i$ and $b := \prod_{j \in J} p_j$, we get that

$$\sum_{j \in J} \ell_j - \sum_{i \in I} \ell_i = \frac{1}{c} \left(\prod_{j \in J} p_j - \prod_{i \in I} p_i \right), \text{ for some } c \in (a, b), \text{ where } \ell_k := \log p_k.$$

The numerator in the RHS of the equation is at least 1, while the denominator is upper bounded by $b = \prod_{j \in J} p_j$. Thus, we have

$$\sum_{j \in J} \ell_j - \sum_{i \in I} \ell_i \geq \frac{1}{\prod_{j \in J} p_j}. \tag{1}$$

Thus, if we choose the set to be set of logarithm of the first n primes, we do get, that for distinct multi-subsets of size at most d, the sum of elements are also distinct. However, clearly, the elements and their differences will not be all integers. But the above calculation is suggestive of what the set should be. Note that in Equation (1), the denominator of the RHS, that is, $\prod_{j \in J} p_j$ is upper bounded by $(2n \log n)^d$, Thus,

$$\sum_{j \in J} (d+1) \cdot \ell_j \cdot (2n \log n)^d - \sum_{i \in I} (d+1) \cdot \ell_i \cdot (2n \log n)^d \geq d + 1$$

Now, if we consider the set $\mathcal{S}_{n,d}$ of size n with elements being positive integers $b_k := \lceil (d+1) \cdot \ell_k \cdot (2n \log n)^d \rceil$ of size n, we have that $\sum_{j \in J} b_j - \sum_{i \in I} b_i > 0$. Thus, $\mathcal{S}_{n,d}$ is a Sidon $B_{\leq d}$ set.

It only remains to argue that the construction can be done in $poly(n, d)$ time. We need to show that all the $b_k = \lceil (d+1) \cdot \log p_k \cdot (2n \log n)^d \rceil$ are $poly(n, d)$ time constructible, It is known that the first n primes are easily constructible, for example, by using Sieve of Eratosthenes which takes $O(n \log \log n)$ time. The other functions like log and powering function are also known to be efficiently computable to the desired precision. ◀

We now present the concept useful for transferring a polynomial identity testing algorithm over a large field to an algorithm for a small subfield of it.

2.2 Testers

The notion of testers is also crucial for our algorithm. They were introduced by Bshouty in [16]. He also used it for several applications including in the setting of blackbox PIT. We will be using it in the same fashion as he did i.e. to reduce the field size of the blackbox PIT set that we would be using for the algorithm. We present the definition of testers restricted to the setting that we need. He defined it for a more general setting.

▶ **Definition 3.** *Let $\mathbb{F}_q$ be a finite field with q elements and let $\mathbb{F}_{q^{t_1}}$ and $\mathbb{F}_{q^{t_2}}$ be two field extensions of $\mathbb{F}_q$ viewed as $\mathbb{F}_q$-algebras with $t_1 \geq t_2$, and let $\mathcal{P} \subseteq \mathbb{F}_q[x_1, \ldots, x_n]$ be a class of multivariate polynomials. Let $L = \{\ell_1, \ldots, \ell_\nu\}$ be a set of maps $\mathbb{F}_{q^{t_1}}^n \to \mathbb{F}_{q^{t_2}}^n$. For $f \in \mathcal{P}$, we denote by fL the map $\mathbb{F}_{q^{t_1}}^n \to \mathbb{F}_{q^{t_2}}^\nu$ defined as: for $\boldsymbol{a} \in \mathbb{F}_{q^{t_1}}^n$, $(fL)(\boldsymbol{a}) = (f(\ell_1(\boldsymbol{a})), \ldots, f(\ell_\nu(\boldsymbol{a})))$. We say that L is an $(\mathcal{P}, \mathbb{F}_{q^{t_1}}, \mathbb{F}_{q^{t_2}})$-tester if for every $\boldsymbol{a} \in \mathbb{F}_{q^{t_1}}^n$ and $f \in \mathcal{P}$ we have*

$$(fL)(\boldsymbol{a}) = \boldsymbol{0} \implies f(\boldsymbol{a}) = 0.$$

The size of the tester L is defined as $|L| = \nu$, the number of maps constituting L.

So, essentially, a tester L for the class of polynomials $\mathcal{P}$ is a set of maps from a field to its subfield such that for every point on which a polynomial $f \in \mathcal{P}$ evaluates to a nonzero value, the tester gives a set of points in the subfield such that the polynomial evaluates to a nonzero value on at least one of the points given by the tester.

Hence a tester is very useful for reducing a blacbox PIT set over a bigger field to a blackbox PIT set over a smaller field while incurring a blowup by the size of the tester. Bshouty [16] also gave many constructions of testers against several classes of multivariate polynomials which helped him achieve constructions of hitting sets which are optimal with respect to the field size and the size of hitting sets.

The tester that is relevant to our purposes which we will be using as a blackbox has the following property. For a proof we refer the readers to [16].

▶ **Lemma 4** ([16], Theorem 40)**.** *Let $\mathcal{P} := (\mathbb{F}_q, n, d) \subseteq \mathbb{F}_q[x_1, \ldots, x_n]$ denote the class of n-variate, degree d polynomials over $\mathbb{F}_q$, with $q \geq d + 1$. Then, for every n, d, t, there exists a $(\mathcal{P}, \mathbb{F}_{q^t}, \mathbb{F}_q)$-tester L of size $O(d^5 t)$ that can be constructed in $poly(n, d, t)$ time.*

The above lemma clearly suggests a strategy for construction of blackbox PIT sets: first design a blackbox PIT set over a large extension field and then reduce the field size to $d + 1$ using the tester promised by the above lemma.

2.3 The algorithm: Proof of Theorem 1

In this section, we present our randomized algorithm for polynomial identity testing and prove Theorem 1.

Before we prove the theorem, we state a simple lemma about univariate polynomials that we will need in the proof.

▶ **Lemma 5.** *Let $f \in \mathbb{F}_q[x]$ be a nonzero univariate polynomial whose degree is bounded by d. Let $\mathbb{F}_{q^t}$ be an extension field of $\mathbb{F}_q$ such that $|\mathbb{F}_{q^t}| \geq d/\epsilon$ and $\boldsymbol{a}$ is sampled uniformly at random from $\mathbb{F}_{q^t}$, then $f(\boldsymbol{a}) \neq 0$ with probability $1 - \epsilon$.*

Lemma 5 follows from the folklore theorem that a univariate polynomial of degree d over a field $\mathbb{F}_q$ has at most d roots in any field extension $\mathbb{F}_{q^t}$ of $\mathbb{F}_q$.

We are now ready to prove Theorem 1.

▶ **Theorem 6** (Theorem 1 restated)**.** *Given a polynomial $f \in (\mathbb{F}_q, n, d)$ with $q \geq d + 1$ as a blackbox or as a $poly(n, d)$-sized arithmetic circuit, and $\epsilon > 0$, there exists a randomized $poly(n, d)$ time algorithm which uses $d \log n + \log(1/\epsilon) + O(d \log \log n)$ random bits and succeeds with probability $1 - \epsilon$.*

Proof. Suppose we are given a polynomial $f \in (\mathbb{F}_q, n, d)$ as a blackbox. To test whether the given polynomial is an identically zero polynomial or not, our algorithm works as follows:

Step 1. Construct Sidon set: Given n, d, we construct a Sidon $B_{\leq d}$ set $\mathcal{S}_{n,d} = \{b_1, \ldots, b_n\}$ using the construction in Theorem 2.

Step 2. Pick a random point from large field: We pick a random point α from the field $\mathbb{F}_{q^t}$ with $t = \lceil \log_q((b_n d)/\epsilon) \rceil$.

Step 3. Construct the tester: Next we construct a $(\mathcal{P}, \mathbb{F}_{q^t}, \mathbb{F}_q)$-tester, $L = \{\ell_1, \ldots, \ell_\nu\}$, for $\mathcal{P} = (\mathbb{F}_q, n, d)$ and $t = \lceil \log_q((b_n d)/\epsilon) \rceil$ using the construction promised by Lemma 4.

Step 4. Reduce the field size by testers: We then apply the tester L on $(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_{q^t}^n$ to get the set of points $\ell_1(\alpha^{b_1}, \ldots, \alpha^{b_n}), \ldots, \ell_\nu(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_q^n$.

Step 5. Evaluate: We evaluate f on $\ell_1(\alpha^{b_1}, \ldots, \alpha^{b_n}), \ldots, \ell_\nu(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_q^n$. If f evaluates to zero on $\ell_k(\alpha^{b_1}, \ldots, \alpha^{b_n})$, for every $k \in 1, \ldots, \nu$, we output that f is an identically zero polynomial. Otherwise we output that f is not a zero polynomial.

We now show the correctness of the above algorithm. The Sidon $B_{\leq d}$ set $\mathcal{S}_{n,d} = \{b_1, \ldots, b_n\}$, $b_1 < b_2 < \cdots < b_n$ and $b_n = \lceil (d+1) \cdot (2n \log n)^d \cdot \log(2n \log n) \rceil$ from Theorem 2 is used to reduce the problem to the univariate case. It is also $poly(n, d)$ time constructible. By the definition of Sidon $B_{\leq d}$ set in Section 2.1, it follows that for distinct multi-subsets of $\mathcal{S}_{n,d}$, the sum of elements will also be distinct. Thus, the map $(x_1, x_2, \ldots, x_n) \mapsto (x^{b_1}, x^{b_2}, \ldots, x^{b_n})$ maps the monomials of the degree at most d in the variables $x_1, \ldots, x_n$ to distinct univariate monomials in x. In particular, every nonzero polynomial $f \in (\mathbb{F}_q, n, d)$ maps to a nonzero polynomial $g \in (\mathbb{F}_q, 1, b_n d)$. Thus, g is a polynomial of degree bounded by $b_n d$.

Now, by Lemma 5, on a randomly chosen point α from the extension field $\mathbb{F}_{q^t}$ with $|\mathbb{F}_{q^t}| \geq (b_n d)/\epsilon$, g will evaluate to a nonzero value with probability $\geq 1 - \epsilon$. Hence, f will evaluate to a non-zero value on $(\alpha^{b_1}, \ldots, \alpha^{b_n})$ with probability $\geq 1 - \epsilon$. The number of random bits needed is $\log((b_n d)/\epsilon) = \log b_n + \log d + \log(1/\epsilon) = d \log n + O(d \log \log n) + \log(1/\epsilon)$ as claimed.

Finally we use an $((\mathbb{F}_q, n, d), \mathbb{F}_{q^t}, \mathbb{F}_q)$-tester from Lemma 4 on $(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_{q^t}^n$ to get the set of points $\ell_1(\alpha^{b_1}, \ldots, \alpha^{b_n}), \ldots, \ell_\nu(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_q^n$. By Lemma 4, the number of points $\nu = O(d^5 t) = O(d^5(\log(b_n d) + \log(1/\epsilon))) = O(d^6(\log n + \log 1/\epsilon))$ and time to construct the tester is $poly(n, d, t) = poly(n, d, \log 1/\epsilon)$. By the definition of testers from Definition 3, for a nonzero polynomial $f \in (\mathbb{F}_q, n, d)$, if $f(\alpha^{b_1}, \ldots, \alpha^{b_n}) \neq 0$, then at least one of $f(\ell_1(\alpha^{b_1}, \ldots, \alpha^{b_n})), \ldots, f(\ell_\nu(\alpha^{b_1}, \ldots, \alpha^{b_n}))$ also evaluates to a nonzero value. Thus, we get the desired result. ◀

▶ Remark 7. When $d = o(\log n)$, we can get an improvement on the number of random bits from $d \log n + d \log \log n +$ lower order terms (as in Theorem 1) to $d \log n + d \log d +$ lower order terms. This can be achieved by adapting an idea due to Goldwasser-Grossman [25, Lemma 8] that they used to construct weight assignments to get unique min-weight perfect matching. Their idea suggests a map $(x_1, x_2, \ldots, x_n) \mapsto (x^{b_1}, x^{b_2}, \ldots, x^{b_n})$, where $b_i = [i]_p + (pd)[i^2]_p + (pd)^2[i^3]_p + \cdots + (pd)^d[i^{d+1}]_p$, where $[x]_p$ denotes the number between 0 and $p-1$ which is equal to x modulo p, and p is a prime number greater than n. This map can replace the map due to Sidon Sets in the Step 1 from the above proof, while the rest of the algorithm and the proof remains the same. As in the above proof of Theorem 1, the number of random bits needed equals $\log b_n + \log d + \log(\frac{1}{\epsilon})$ which becomes $d \log n + d \log d +$ lower order terms. For the correctness of this map, we refer the reader to the proof of Lemma 8 in [25].

▶ Remark 8. Our algorithm works for fields of zero characteristic as well. In fact, whenever the field size is already larger than $(b_n d)/\epsilon$, we do not need Step 3 and Step 4, and we can directly evaluate f on $(\alpha^{b_1}, \ldots, \alpha^{b_n})$ in Step 5. Thus, we have an algorithm for blackbox polynomial identity testing which uses information theoretically optimal number of random bits for all fields $\mathbb{F}$ with $|\mathbb{F}| \geq d + 1$.

3 Optimal Hitting sets

In this section, we describe a few optimal hitting sets, i.e. the ones that exactly matches with the lower bound against the class of n-variate polynomials with total degree bounded by d. The authors are excited about these proofs because of their simplicity and elegance.

We first begin by stating the straight-forward folklore lower bound.

▶ **Lemma 9.** *For any hitting set $\mathcal{H}$ against the class n-variate polynomials with total degree bounded by d over a field $\mathbb{F}$, we have $|\mathcal{H}| \geq \binom{n+d}{d}$.*

This follows by the fact that the set of all n-variate polynomials with total degree bounded by d over a field $\mathbb{F}$ forms a vector space of dimension $\binom{n+d}{d}$. This is true because the number of monomials supported on n-variables with total degree bounded by d is $\binom{n+d}{d}$, and they form the basis for the vector space as they are all $\mathbb{F}$-linearly independent, and all polynomials in the set can be represented as an $\mathbb{F}$-linear combination of them. Thus, in the worst case, one needs to query f on at least $\binom{n+d}{d}$ points.

We now consider a very popular construction which is suboptimal for our purposes.

Construction 0 – Schwartz-Zippel-DeMillo-Lipton lemma: As a consequence of the Lemma [44, 49, 21], for $(\mathbb{F}, n, d)$, one gets the hitting set $\mathcal{H}_0 := S^n$ where $S \subseteq \mathbb{F}$, with $|S| = d + 1$, which is the grid of size $(d+1)^n$. We point out that this is optimal when we are considering the set of n-variate polynomials with *individual degrees* of each variable bounded by d, by a similar argument as in Lemma 9. However, this is not optimal for $(\mathbb{F}, n, d)$ where we bound the *total degree*. Especially when $d \ll n$, the gap is huge.

Thus, it makes sense to investigate optimal hitting sets for $(\mathbb{F}, n, d)$. In what follows, we present two such constructions for the hitting set. They were both, at least implicitly, already present in the literature. We also believe that other constructions can be found without much effort. However our predilection towards these constructions and our new proofs is purely aesthetic.

3.1 Construction 1: The set of exponent vectors

The lower bound tells that any hitting set $\mathcal{H}$ should have size at least $\binom{n+d}{d}$. Now this $\binom{n+d}{d}$ comes from the number of monomials in n variables of degree at most d. Very interestingly, when $\{0, 1, \ldots, d\} \subseteq \mathbb{F}$, these monomials also suggest a set of points of size $\binom{n+d}{d}$ that can be seen as a potential hitting set: simply collect all the exponent vectors of all the monomials in a set, viewing them as points in $\mathbb{F}^n$, that is, the suggested set is $\mathcal{H}_1 := \{(x_1, \ldots, x_n) \in \{0, 1, \ldots, d\}^n \mid x_1 + x_2 + \cdots + x_n \leq d\}$. The above construction obviously requires that $\mathbb{F}^n$ indeed contains $\mathcal{H}_1$ as a subset. Surprisingly to some, and beautifully to the authors, this indeed works. This was shown by Bshouty [16, Lemma 77] using Combinatorial Nullstellensatz [5].

In this work, we give a direct inductive proof which we found with Mrinal Kumar. It bypasses the combinatorial nullstellensatz and flows along the lines of the proof of Schwartz-Zippel-DeMillo-Lipton lemma. We are suprised that we did not find this proof somewhere in the literature.

▶ **Theorem 10.** *If $\{0, 1, \ldots, d\} \subseteq \mathbb{F}$, then the set $\mathcal{H}_1 := \{(x_1, \ldots, x_n) \in \{0, 1, \ldots, d\}^n \mid x_1 + x_2 + \cdots + x_n \leq d\}$, is a hitting set for $(\mathbb{F}, n, d)$.*

Proof. Consider the integral grid $\mathcal{G} := \{0, 1, \dots d\}^n$ with $|\mathcal{G}| = (d+1)^n$. Now the statement of the theorem can be rephrased as: for every nonzero polynomial $f \in (\mathbb{F}, n, d)$, there exists a point $g \in \mathcal{G}$ with its ℓ_1-norm $\|g\|_1 \leq d$, such that $f(g) \neq 0$. We use this as our induction hypothesis and prove it by induction on the number of variables n.

For $n = 1$, that is the univariate case, this holds true because every degree d polynomial has at most d zeros. Suppose the hypothesis holds for $n-1$. For the inductive step, write a nonzero $f \in (\mathbb{F}, n, d)$ as a univariate in x_n as $f = \sum_{i=1}^{d'} P_i(x_1, \dots, x_{n-1}) x_n^i$, where d' is the maximum degree of f in x_n and $P_i(x_1, \dots, x_{n-1})$ are the coefficients coming from $\mathbb{F}[x_1, \dots, x_{n-1}]$. Now consider $P_{d'}(x_1, \dots, x_{n-1})$ which is the coefficient of the highest degree term in x_n. If f is a nonzero polynomial, then so is $P_{d'}(x_1, \dots, x_{n-1})$. Also, $\deg(P_{d'})$ is bounded by $d - d'$. By the induction hypothesis, there is a point s' in the grid $\mathcal{G}' := \{0, 1, \dots, d - d'\}^{n-1}$ with $\|s'\|_1 \leq d - d'$ such that $P_{d'}(s') \neq 0$. Now we fix $x_1, \dots, x_{n-1}$ to the values as given by s'. Now $P_{d'}$ restricted to the assignment s' is a univariate polynomial in x_n of degree d'. Thus, setting x_n to a value in $\{0, 1, \dots d'\}$ gives a point on which f evaluates to nonzero. The ℓ_1 norm of the point is at most $(d - d') + d' = d$. ◀

We now give another construction which we find beautiful.

3.2 Construction 2: Intersection of hyperplanes in general position

The construction is as follows: In the projective space $\mathbb{P}^n(\mathbb{F})$ over a field $\mathbb{F}$, with $|\mathbb{F}| \geq d + 1$, take a collection $\mathcal{C}$ of $n + d$ hyperplanes in general position i.e. every size n subsets of $\mathcal{C}$ intersect in a point, whereas no size $n + 1$ subset of $\mathcal{C}$ intersect. Now all intersection points of n-sized subset of $\mathcal{C}$ gives the desired hitting set.

We now mention a standard explicit family of hyperplanes in general position.

▶ **Example 11.** Take hyperplanes $H_1, \dots, H_{n+d}$ in the projective space $\mathbb{P}^n$ where H_i is given by the equation $t_i^1 x_1 + t_i^2 x_2 + \cdots + t_i^n x_n + x_{n+1} = 0$, where $t_i \in \mathbb{F}$. Then, $H_1, \dots, H_{n+d}$ are hyperplanes in general position.

Itaï Ben Yaacov [48] considers hyperplanes in general position and gives an algebraic proof of a generalized Vandermonde Identity in higher dimension. What his identity implies is that taking all intersection points of n-sized subsets of $n+d$ hyperplanes in general position gives a hitting set for $(\mathbb{F}, n, d)$.

In order to state his result, we need some notations. Let $M_{p\times q}(\mathbb{F})$ denote the set of all $p \times q$ matrices over $\mathbb{F}$. He defines the following three maps. It useful to think that the $(n+1) \times m$ matrix Q is denoting the family of m hyperplanes, say $\mathcal{H}_m$ in $\mathbb{P}^n$, i.e. the entries of each column correspond to the coefficients of a hyperplane.

- **i)** $\mu : M_{(n+1)\times m}(\mathbb{F}) \to M_{(n+1)\times \binom{m}{n}}(\mathbb{F})$ sends an $(n+1) \times m$ matrix Q to a matrix P whose entries are all the minors of Q of order n. Note that a lexicographic ordering on the chosen sequence of rows and columns of Q induces an ordering on the minors as well. By Cramer's rule from linear algebra, P is precisely the matrix of intersection points of all n-sized subsets of $\mathcal{H}_m$, where each column of Q has the coordinates of an intersection point as its entries.
- **ii)** $\delta : M_{(n+1)\times m}(\mathbb{F}) \to \mathbb{F}$ sends an $(n+1) \times m$ matrix Q to the product of all its minors of order $n + 1$.
- **iii)** $\nu_r : M_{(n+1)\times m}(\mathbb{F}) \to M_{\binom{n+r}{n}\times m}(\mathbb{F})$ applies the Veronese map on each column i.e. for each column, it applies all the n-variate degree r monomials on the entries of the column. Assume an ordering (say, inverse lexicographical ordering) on the monomials.

We are now ready to quote the generalized Vandermonde identity in higher dimension.

▶ **Theorem 12** ([48], Theorem 1.4)**.** *Let R be a commutative ring. $n \leq m \in \mathbb{N}$, and let Q be a $(n+1) \times m$ matrix over R. Then $\nu_{m-n}\mu Q$ is a square matrix of order $\binom{m}{n}$, and the following Vandermonde identity of order m in dimension n holds:*

$$\det(\nu_{m-n}\mu Q) = (\delta Q)^n$$

Then the above theorem with $m = n + d$, implies that if $(\delta Q) \neq 0$, which is the algebraic condition for the $n + d$ hyperplanes to be in general position, then $\det(\nu_{n+d-n}\mu Q) \neq 0$. Now $\nu_{m-n}\mu Q$ is the matrix with Veronese map applied on the intersection points of n-sized subsets of m hyperplanes. Normalizing the coordinates by the last coordinate gives us the points in the affine setting with the Veronese maps essentially applying all the monomials of degree at most d on the points. Thus, $\det(\nu_d \mu Q) \neq 0$ means that the set of intersection points form a hitting set against $(\mathbb{F}, n, d)$.

We now present a direct, simple, geometric proof of the construction which we found with Raimund Seidel.

▶ **Theorem 13.** *Let $H_1, \ldots, H_{n+d}$ be hyperplanes in general position. If $f \in (\mathbb{F}, n, d)$ vanishes on all the points obtained by intersecting all n-sized subsets of $\{H_1, \ldots, H_{n+d}\}$, then f is an identically zero polynomial.*

Proof. We prove the above statement by induction on the number of variables n. The base case $n = 1$ is the univariate case and the hyperplanes become $d+1$ points, and the statement of the lemma reduces to f vanishing on $d+1$ points. Thus, the statement holds in this case because a degree d univariate polynomial that vanishes on $d+1$ points is an identically zero polynomial.

Suppose that the statement holds for the number of variables up to $n-1$, and we assume an $f \in (\mathbb{F}, n, d)$ that vanishes on all the intersection points of n-sized subsets of $\{H_1, \ldots, H_{n+d}\}$. The assumption, in particular, implies that f restricted to the hyperplane H_1 vanishes on all the intersection points of $(n-1)$-sized subsets of $\{H_2, \ldots, H_{n+d}\}$. However, note that f restricted to H_1 reduces to an $(n-1)$-variate case and hence we can apply the induction hypothesis and conclude that f restricted to H_1 is identically zero. Doing the same for all the hyperplanes, we get that f restricted to all the hyperplanes $H_1, \ldots, H_{n+d}$ is identically zero. It remains to conclude that f is indeed identically zero. For this, restrict f to a generic line ℓ. Note that $H_1, \ldots, H_{n+d}$ all intersect ℓ at distinct points. Thus, f restricted to ℓ is a univariate which vanishes on $n + d$ points, hence f restricted to a generic ℓ is identically zero. Hence f is identically zero. ◀

Note that an explicit construction corresponding to Theorem 13 can be obtained using the family given in Example 11.

Revision Notice

This is a revised version of the eponymous paper appeared in the proceedings of APPROX/RANDOM 2020 (LIPIcs, volume 176, https://www.dagstuhl.de/dagpub/978-3-95977-164-1, published in August, 2020), in which the proof of Theorem 6 is corrected. The proof in the previous version did not work, because the tester map constructed in Step 3, was incorrectly applied to $\alpha \in \mathbb{F}_{q^t}$, to get the points $\ell_1(\alpha), \ldots, \ell_\nu(\alpha) \in \mathbb{F}_q$, on which $f(x^{b_1}, x^{b_2}, \ldots, x^{b_n})$ was finally evaluated. In this revised version, the tester map is applied on $(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_{q^t}^n$ instead, to get the points $\ell_1(\alpha^{b_1}, \ldots, \alpha^{b_n}), \ldots, \ell_\nu(\alpha^{b_1}, \ldots, \alpha^{b_n}) \in \mathbb{F}_q^n$, on which $f(x_1, \ldots, x_n)$ is finally evaluated.

Abstract

A family of error-correcting codes is list-decodable from error fraction p if, for every code in the family, the number of codewords in any Hamming ball of fractional radius p is less than some integer L that is independent of the code length. It is said to be list-recoverable for input list size ℓ if for every sufficiently large subset of codewords (of size L or more), there is a coordinate where the codewords take more than ℓ values. The parameter L is said to be the "list size" in either case. The capacity, i.e., the largest possible rate for these notions as the list size $L \to \infty$, is known to be $1 - h_q(p)$ for list-decoding, and $1 - \log_q \ell$ for list-recovery, where q is the alphabet size of the code family.

In this work, we study the list size of *random linear codes* for both list-decoding and list-recovery as the rate approaches capacity. We show the following claims hold with high probability over the choice of the code (below q is the alphabet size, and $\varepsilon > 0$ is the gap to capacity).

- A random linear code of rate $1 - \log_q(\ell) - \varepsilon$ requires list size $L \geq \ell^{\Omega(1/\varepsilon)}$ for list-recovery from input list size ℓ. This is surprisingly in contrast to completely random codes, where $L = O(\ell/\varepsilon)$ suffices w.h.p.
- A random linear code of rate $1 - h_q(p) - \varepsilon$ requires list size $L \geq \lfloor h_q(p)/\varepsilon + 0.99 \rfloor$ for list-decoding from error fraction p, when ε is sufficiently small.
- A random *binary* linear code of rate $1 - h_2(p) - \varepsilon$ is list-decodable from *average* error fraction p with list size with $L \leq \lfloor h_2(p)/\varepsilon \rfloor + 2$. (The average error version measures the average Hamming distance of the codewords from the center of the Hamming ball, instead of the maximum distance as in list-decoding.)

The second and third results together precisely pin down the list sizes for binary random linear codes for both list-decoding and average-radius list-decoding to three possible values.

Our lower bounds follow by exhibiting an explicit subset of codewords so that this subset – or some symbol-wise permutation of it – lies in a random linear code with high probability. This uses a recent characterization of (Mosheiff, Resch, Ron-Zewi, Silas, Wootters, 2019) of configurations of codewords that are contained in random linear codes. Our upper bound follows from a refinement of the techniques of (Guruswami, Håstad, Sudan, Zuckerman, 2002) and strengthens a previous result of (Li, Wootters, 2018), which applied to list-decoding rather than average-radius list-decoding.

1 Introduction

In coding theory, one is interested in the combinatorial properties of sets $\mathcal{C} \subseteq \mathbb{F}_q^n$.[1] Such a set $\mathcal{C}$ is called a *code* of *length* n over the *alphabet* $\mathbb{F}_q$, and the elements $c \in \mathcal{C}$ are called *codewords*.

List-decoding, introduced by Elias and Wozencraft in the 1950's [10, 44], is such a combinatorial property. For $p \in [0,1]$ and integer $L \geq 1$, we say that a code $\mathcal{C} \subseteq \mathbb{F}_q^n$ is (p, L)-*list-decodable* if, for all $z \in \mathbb{F}_q^n$,

$$|\{c \in \mathcal{C} : \delta(c, z) \leq p\}| < L,$$

where $\delta(x, y) = \frac{1}{n}|\{i : x_i \neq y_i\}|$ denotes relative Hamming distance. That is, $\mathcal{C}$ is list-decodable if not too many codewords of $\mathcal{C}$ live in any small enough Hamming ball. In this paper, we are interested in the trade-offs between p, L, and the rate of the code $\mathcal{C}$. The *rate* R of $\mathcal{C}$ is defined as $R = \frac{\log_q |\mathcal{C}|}{n}$. The rate lies in the interval $[0, 1]$, and larger is better.

Variations of list-decoding

In this work, we consider standard list-decoding along with two variations.

The first variation is a strengthening of list-decoding known as *average-radius list-decoding*. A code $\mathcal{C}$ is (p, L)-*average-radius list-decodable* if for any set $\Lambda \subseteq \mathcal{C}$ of size L and $z \in \mathbb{F}_q^n$,

$$\frac{1}{L}\sum_{c \in \Lambda} \delta(c, z) \geq p.$$

[1] Here and throughout the paper, $\mathbb{F}_q$ denotes the finite field with q elements. In this we work only consider linear codes, so we always assume that the alphabet is a finite field.

It is not hard to see that (p, L)-average-radius list-decodability implies (p, L)-list-decodability, and this stronger formulation has led to stronger lower bounds than are achievable otherwise [22]. In addition to stronger lower bounds, average-radius list-decoding – essentially replacing a maximum with an average in the definition of list-decoding – is a natural concept, and it has helped establish connections between list-decoding and compressed sensing [7].

The second variation, known as *list-recovery,* is a version where the "noise" is replaced by uncertainty about each symbol of the received word z. Formally, we say that a code $\mathcal{C}$ is (ℓ, L)-*list-recoverable* if for any sets $S_1, \ldots, S_n \subseteq \mathbb{F}_q$ with $|S_i| \leq \ell$ for all i,

$$|\{c \in \mathcal{C} : c_i \in S_i \, \forall i\}| < L.$$

List-recovery was originally used as a stepping-stone to list-decoding and unique-decoding (e.g., [17, 18, 19, 20]) but it has since become a useful primitive in its own right, with applications beyond coding theory [31, 38, 13, 28, 8].

Pinning down the output list size

We are motivated by the problem of pinning down the output list size L for (average-radius) list-decoding and for list-recovery. For all three of these problems, given q and p (respectively, q and ℓ), there exists an *optimal rate*, denoted R^*. Namely, R^* is the largest rate so that, for any $\varepsilon > 0$, there are q-ary codes of rate $R^* - \varepsilon$ and arbitrarily large length, which are (p, L)-(average-weight)-list-decodable (resp. (ℓ, L)-list-recoverable), for some $L(q, p, \varepsilon)$ (resp. $L(q, \ell, \varepsilon)$). Importantly, L must not depend on the length of the code. The *list-decoding capacity theorem* gives the dependence of R^* on q and p (resp. q and ℓ): $R^* = 1 - h_q(p)$ for both standard and average-radius list-decoding, [11, 45] and $R^* = 1 - \log_q(\ell)$ for list-recovery (e.g., [42]).

We are interested in the trade-off between the list size L, the parameters p, q, ℓ of the problem, and this gap ε; we refer to ε as the *gap to capacity.* Pinning down the list size L is an important problem. For example, for many of the algorithmic applications within coding theory, the list size represents a bottleneck on the running time of an algorithm that must check each item in the list before pruning it down [20, 9, 26, 27, 21]. For applications in pseudorandomness, for example to expanders or extractors, the list size corresponds to the expansion or to the amount of entropy in the input, respectively, and it is of interest to precisely pin down these quantities.

We make progress on pinning down the output list sizes for the case of *random linear codes.* A random linear code is a uniformly random subspace of $\mathbb{F}_q^n$ of certain dimension. The list-decodability of random linear codes has been well studied for many reasons [45, 15, 7, 43, 40, 42, 34]. First, it is a natural mathematical question that studies the interplay between two fundamental notions in $\mathbb{F}_q^n$: subspaces and Hamming balls. Second, there are constructions of codes which use random linear codes (and their list-decodability) as a building block [20, 24, 30, 29], and improvements in the parameters of random linear codes will lead to improvements in these constructions as well. Third, random linear codes can be seen as one way to partially derandomize completely random codes; this is especially motivating in the binary (or fixed alphabet) case, where we do not know of any explicit constructions of optimally list-decodable codes, linear or otherwise.

1.1 Contributions

Our main results are improved bounds on the list size of random linear codes. We defer the formal theorem statements until after we have set up notation, but we informally summarize our results here. Below, we consider codes of *rate* $R^* - \varepsilon$, where as above we use R^* to denote best achievable rate for each particular problem.

(1) **Lower bound on the list size for list-recovery of random linear codes.** We show that if a random linear code of rate $R^* - \varepsilon$ is list-recoverable with high probability with input list sizes ℓ and output list size L, then we must have $L = \ell^{\Omega(1/\varepsilon)}$. This is in contrast to completely random codes, for which the output list size is $L = O(\ell/\varepsilon)$ with high probability.
This gap between random linear codes and completely random codes demonstrates that in some sense zero-error list-recovery behaves more like *erasure-list-decoding* [14] than it does like list-decoding with errors. Such a gap is present between general and linear codes in erasure list-decoding, but as we see below, there is no such gap for list-decoding from errors.
Our result extends to the setting of list-recovery with erasures as well. The formal theorem statement and proof can be found in Section 3.

(2) **Better lower bounds on the list size for list-decoding random linear codes.** We show that if a q-ary random linear code of rate $R^* - \varepsilon$ is list-decodable with high probability up to radius p with an output list size of L, then we must have $L \geq \left\lfloor \frac{h_q(p)}{\varepsilon} + 0.99 \right\rfloor$. By [34], this result is tight for list-decoding of binary random linear codes up to a small additive factor. As an immediate corollary, $L \geq \left\lfloor \frac{h_q(p)}{\varepsilon} + 0.99 \right\rfloor$ for *average-radius* list-decoding of random linear codes as well, and, as we will see below, this is also tight for binary random linear codes, up to a small additive factor. We conjecture that the leading constant $h_q(p)$ is also correct for $q > 2$.
Previous work [22] has established that $L = \Omega(1/\varepsilon)$, but to the best of our knowledge this is the first work that pins down the leading constant. In particular, [22] shows that, in the situation above, we have $L \geq c_{p,q}/\varepsilon$, where $c_{p,q}$ is a constant that goes to zero as p goes to $1 - 1/q$. In contrast, we show below that the leading constant is at least $h_q(p)$, which goes to 1 as p goes to $1 - 1/q$.
The formal theorem statement and proof can be found in Section 4.

(3) **Completely pinning down the list size for average-radius list-decoding of binary random linear codes.** We prove a new upper bound on the *average-radius* list-decodability of binary random linear codes, which matches our lower bound, even up to the leading constant. More precisely, we show that with high probability, a random binary linear code of rate $R^* - \varepsilon$ is *average-radius* list-decodable up to radius p with $L \leq \lfloor h_2(p)/\varepsilon \rfloor + 2$.
Such a bound was known for standard list-decoding [34], but our upper bound holds even for the stronger notion of average-radius list-decoding, and improves the additive constant by 1.[2] In particular, this shows that for both list-decoding and average-radius list-decoding of binary random linear codes, the best possible L is concentrated on at most three values: $\lfloor h_q(p)/\varepsilon \rfloor + 2$, $\lfloor h_q(p)/\varepsilon \rfloor + 1$ and $\lfloor h(p)/\varepsilon + 0.99 \rfloor$. This tight concentration demonstrates the sharpness of our upper and lower bound techniques.
The formal theorem statement and proof can be found in Section A.

1.2 Overview of techniques

In this section, we give a brief overview of our techniques.

Lower bounds

To illustrate the techniques for our lower bounds, we warm up with a back-of-the-envelope calculation which suggests why the "right" answer for our result (1) above is $\ell^{\Omega(1/\varepsilon)}$.

[2] Under our definition of list-decoding, [34] show (p, L) list-decodability with $L = \lfloor h(p)/\varepsilon \rfloor + 3$.

Consider a random linear code $\mathcal{C} \subset \mathbb{F}_q^n$, of rate $R = 1 - \log_q(\ell) - \varepsilon$, where $\varepsilon \in (0, \frac{1}{2})$. That is, $\mathcal{C}$ is the kernel[3] of a uniformly random matrix sampled from $\mathbb{F}_q^{(1-R)n \times n}$. Suppose that ℓ is a prime power, and $q = \ell^t$ for some $t \geq 2$. Thus, $\mathbb{F}_\ell$ is a sub-field of $\mathbb{F}_q$. Let D be an integer slightly smaller than $\frac{1}{2\varepsilon}$ and let $L = \ell^D \geq \ell^{\Omega(1/\varepsilon)}$. We claim that $\mathcal{C}$ is unlikely to be (ℓ, L)-list-recoverable.

Given a matrix $M \in \mathbb{F}_q^{n \times D}$, we write $M \subseteq \mathcal{C}$ ("$\mathcal{C}$ contains M") to mean that each of the columns of M is a codeword in $\mathcal{C}$.

Let $\mathcal{M}$ denote the set of all full-rank matrices $M \in \mathbb{F}_q^{n \times D}$ that have the following property: for every row M_i of M there exists some $x_i \in \mathbb{F}_q^*$ such that all entries of M_i belong to the set $x_i \cdot \mathbb{F}_\ell$.

We will show that $\mathcal{M}$ is *bad* and *abundant*. By *bad* we mean that a linear code containing a matrix from $\mathcal{M}$ cannot be (ℓ, L)-list-recoverable. We say that $\mathcal{M}$ is *abundant* (for the rate R) if a random linear code of rate R is likely to contain at least one matrix from $\mathcal{M}$. Clearly, the combination of these properties means that $\mathcal{C}$ is unlikely to be (ℓ, L)-list-recoverable.

We first prove that $\mathcal{M}$ is bad. Assume that $\mathcal{C}$ contains some matrix $M \in \mathcal{M}$. By linearity of the code, $\mathcal{C}$ also contains every vector of the form Mu, for $u \in \mathbb{F}_q^D$. In particular, consider the set of vectors $B := \left\{Mu \mid u \in \mathbb{F}_\ell^D\right\} \subseteq \mathcal{C}$. Observe that $\mathcal{C}$ cannot be (ℓ, L)-list-recoverable, since B is a "bad list" for list-recoverability with these parameters: First, since M has full-rank, B is of cardinality $\ell^D = L$. Now, given $i \in [n]$, we need to show that there exists a subset $S_i \subseteq \mathbb{F}_q$ with $|S_i| = \ell$, such that $v_i \in S_i$ for all $v \in B$. We take S_i to be the set $x_i \cdot \mathbb{F}_\ell$, which contains all entries of the row M_i. For $j \in [D]$, write $M_{i,j} = x_i \cdot w_j$ ($w_j \in \mathbb{F}_\ell$), and let $v = Mu$ for some $u \in \mathbb{F}_\ell^D$. Then

$$v_i = \sum_{j=1}^{D} M_{i,j} u_j = x_i \cdot \left(\sum_{j=1}^{D} w_j \cdot u_j \right) \in x_i \cdot \mathbb{F}_\ell,$$

and we conclude that $\mathcal{M}$ is bad.

Showing that $\mathcal{M}$ is abundant is harder, and at this stage we only provide some intuition for this fact. Let us compute the expected number of matrices $M \in \mathcal{M}$ that are contained in $\mathcal{C}$. First, we estimate the cardinality of $\mathcal{M}$. One may generate a matrix in $\mathcal{M}$ by choosing each of its rows in an essentially independent fashion.[4] Choosing a row amounts to choosing one of $\frac{q-1}{\ell-1}$ sets of the form $x \cdot \mathbb{F}_\ell$ ($x \in \mathbb{F}_q^*$) and then taking each entry to be an element of that set. Accounting for multiple counting of the all-zero row, the number of possible rows is thus $\frac{q-1}{\ell-1} \cdot (\ell^D - 1) + 1$, which we approximate as $q \cdot \ell^{D-1}$. Thus, $|\mathcal{M}| \approx (q \cdot \ell^{D-1})^n$. Next, it is not hard to see that a random linear code contains a given matrix of rank r with probability $q^{-(1-R) \cdot r \cdot n}$. Consequently, for $M \in \mathcal{M}$, we have $\Pr[M \subseteq \mathcal{C}] = q^{-(1-R)Dn}$. Therefore,

$$\begin{aligned} \mathbb{E}\left|\{M \in \mathcal{M} : M \subseteq \mathcal{C}\}\right| &= |\mathcal{M}| q^{-(1-R)Dn} \approx \left(q \cdot \ell^{D-1}\right)^n \cdot q^{-(1-R)Dn} \\ &= \left(\ell^{-1} \cdot q^{1-\varepsilon D}\right)^n = \ell^{(-1+t(1-\varepsilon D))n}, \end{aligned}$$

where, the penultimate equality is due to substituting $1 - \log_q(\ell) - \varepsilon$ for R. Finally, since $t \geq 2$ and $D < \frac{1}{2\varepsilon}$, the right-hand side of the above is $\ell^{\Omega(n)}$. Thus, in expectation, $\mathcal{C}$ contains many "bad" lists for list-recovery.

---

[3] This is one of several natural models for a random linear code. Another possible model is taking a uniformly random subspace of dimension Rn. It is not hard to see that the total variation distance between these distributions is exponentially small. In particular, our model yields a code of dimension exactly Rn with probability $1 - \exp(-\Omega(n))$.

[4] We say "essentially" since the resulting matrix might not have full rank, but this happens with negligibly small probability.

Of course, this back-of-the-envelope calculation does *not* yield the result advertised above. It might be the case that, even though the expected number of $M \in \mathcal{M}$ so that $M \subseteq \mathcal{C}$ is large, the probability that such an M exists is still small. In fact, as [37] shows, there are simple examples where this does happen. Thus, proving that $\mathcal{M}$ is abundant requires more work.

A standard approach to show that $\mathcal{M}$ is abundant would be via the second-moment method. Recently, [37] gave a general theorem which encompasses second-moment calculations in this context. In particular, they showed that there is essentially only one reason that a set $\mathcal{M}$ might not be abundant: there exists some matrix $A \in \mathbb{F}_q^{D \times D'}$, such that the set $\{MA \mid M \in \mathcal{M}\}$ is small. If this occurs, we say that $\mathcal{M}$ is *implicitly rare*.[5] They used this result to study the list-decodability of random Low-Density Parity-Check codes, but we can use their result to do our second moment calculation. We show that our example of $\mathcal{M}$ above[6] is not implicitly rare, by showing that there is no such linear map A. This establishes that the back-of-the-envelope calculation is in fact correct. Appealing to the machinery of [37], rather than applying the second moment method from scratch, allows us to get tighter constants with slightly less work, and gives a more principled approach to our lower bounds; indeed, our result (2) follows the same outline.

The intuition for our second result (2) is similar: we give an example of a class $\mathcal{M}$ which is *bad* for list-decoding and *abundant.* We define $\mathcal{M}$ as follows: Let $u \in \mathbb{F}_q^D$ be a random vector with independent $\text{Bernoulli}_q(p)$ entries, namely, each entry is 0 with probability $1-p$, and chosen uniformly from $\mathbb{F}_q^*$ with probability p. Let x be uniformly sampled from $\mathbb{F}_q$. Let τ denote the distribution (over $\mathbb{F}_q^D$) of the random vector $u + x \cdot 1_D$. Finally, define $\mathcal{M}$ to be the set of all matrices $M \in \mathbb{F}_q^{n \times D}$, such that a uniformly sampled row of M has the distribution τ. As before, we show that $\mathcal{M}$ is abundant by showing that $\mathcal{M}$ is not implicitly rare and using the result of [37].

Upper bounds

Our argument for our upper bound result (3) closely follows that of [34], which itself builds on the argument of [16]. The argument imagines building the random linear code one dimension at a time and uses a potential function to show that, so long as we do not add too many dimensions, no ball intersects the code too much. We now provide an informal overview of our approach, specifically comparing and contrasting it with the arguments of Guruswami, Håstad, Sudan and Zuckerman [16]; and Li and Wootters [34].

Let $R = 1 - h(\rho) - \varepsilon$ and put $k := Rn$ (which we assume for exposition is an integer). Note that sampling a random linear code of rate R is the same as sampling $b_1, \ldots, b_k \in \mathbb{F}_2^n$ independently and uniformly at random and outputting $\text{span}\{b_1, \ldots, b_k\}$. Consider the "intermediate" codes $\mathcal{C}_i = \text{span}\{b_1, \ldots, b_i\}$; [34] (following [16]) define a potential function $S_{\mathcal{C}_i}$ and endeavor to show that $S_{\mathcal{C}_i}$ does not grow too quickly. The work [16] demonstrated that this holds in expectation; the work [34] improved their argument to show that it holds with high probability. In both cases the potential function is such that it is easy to show that, so long as $S_{\mathcal{C}}$ is $O(1)$, the code $\mathcal{C}$ is list-decodable.

The potential function in these works keeps track of the radius p list-size at each vector $x \in \mathbb{F}_2^n$, that is, the cardinalities $|\{c \in \mathcal{C}_i : \delta(x, c) \leq p\}|$ for $i = 1, \ldots, k$, and shows that so long as i is not too large all these cardinalities remain at most L. For average-radius list-decoding, we instead keep track of a sort of "weighted" list size, where codewords that

[5] The term "implicitly rare" is used by the first version of [37], available at `https://arxiv.org/abs/1909.06430v1`.

[6] More precisely, we study an example similar to this one; the example above was slightly tweaked to simplify the exposition for this back-of-the-envelope explanation.

are very close x are weighted more heavily. We can reuse much of the analysis from [34] to demonstrate that on the k-th step the potential function is still bounded by a constant (in fact, it is at most 2). The real novelty in our argument is a demonstration that, assuming this potential function is small, the code is indeed (p, L)-average-radius list-decodable. This step is more involved than the argument in [16, 34] to establish (p, L)-list-decodability.

1.3 Related work

We now highlight some related work. In what follows, ε is always the "gap-to-capacity", i.e., if the capacity for a particular problem is R^*, then the result concerns codes of rate $R^* - \varepsilon$.

Lower bounds for list sizes of arbitrary codes

It is known that a typical (i.e., uniformly random) list-decodable code of rate $R^* - \varepsilon$ has list size $L = \Theta(1/\varepsilon)$, and a natural question to ask is whether *every* code requires a list of size $L = \Omega(1/\varepsilon)$. Blinovsky ([5, 4]) showed that lists of size $\Omega_p(\log(1/\varepsilon))$ are necessary for list-decoding a code of rate $R^* - \varepsilon$. Later, Guruswami and Vadhan [25] considered the high-noise regime where $p = 1 - 1/q - \eta$ and showed that lists of size $\Omega_q(1/\eta^2)$ are necessary. Finally, Guruswami and Narayanan [22] showed that for *average-radius* list-decoding, the list size must be $\Omega_p(1/\sqrt{\varepsilon})$.

Existing lower bounds for random linear codes

For the special case of random linear codes, Guruswami and Narayanan [22] showed that lists of size $c_{p,q}/\varepsilon$ are necessary. The constant $c_{p,q}$ is not explicitly computed (and in fact relies on a constant from [15] which we discuss below), but one can deduce from the proof that if p tends to $1 - 1/q$ then $c_{p,q}$ will tend to 0. Their lower bound follows from a second moment method argument, i.e., they consider a certain random variable X whose positivity is equivalent to the failure of a random linear code to be list-decodable, and then show that $\mathrm{Var}(X) = o(\mathbb{E}[X])^2$. In this sense our approach is similar to theirs, because we rely on results from [37] which themselves are proved using a second moment method. However, we are able to get stronger results (in the sense that our leading constant does not decay as $p \to 1 - 1/q$, and moreover is optimal for binary codes). One of the reasons may be the notion of "implicit rareness" from [37], which provides a useful characterization of the lists contained in a random linear code.

The work [22] also established lower bounds on list-decoding random linear codes from *erasures*. While we do not discuss list-decoding from erasures in this work (except in the sense that erasure list-recovery is a generalization of list-decoding from erasures), this result is relevant to our work because [22] established an exponential lower bound of the form $L \geq \exp(\Omega(1/\varepsilon))$, in contrast to the list size $O(1/\varepsilon)$ that is attained by uniformly random codes. Thus, our results suggest that (zero-error) list-recovery behaves more like list-decoding from erasures than from errors, at least with respect to the list size of random (linear) codes.

Existing upper bounds for random linear codes

We now turn our attention to upper bounds on list sizes for random linear codes. A long line of works [45, 16, 15, 7, 43, 40, 42, 34] has studied this problem, and we highlight the most relevant results now. Zyablov and Pinsker [45] showed that random linear codes of rate $R^* - \varepsilon$ have lists of size at most $q^{1/\varepsilon}$.[7] Guruswami, Håstad, Sudan and Zuckerman [16] first

[7] For list-recovery with input lists of size ℓ, the argument of [45] shows that the list size is at most $q^{\ell/\varepsilon}$. Furthermore, their results for list-decoding also apply to average-radius list-decoding.

showed the existence of capacity-achieving binary linear codes with lists of size $O(1/\varepsilon)$. Li and Wootters [34] revisited their techniques and showed that in fact random linear codes of rate $R^* - \varepsilon$ have lists of size $O(1/\varepsilon)$ with high probability; moreover they computed the constant coefficient in the big-Oh notation. However, neither of these results apply to either average-radius list-decoding or to list-recovery. As discussed above in Section 1.2, our new upper bound is the result of an improvement of the techniques of [34], which extends their result to average-radius list-decoding.

As for larger alphabets, Guruswami, Håstad and Kopparty [15] showed that there exists a constant $C_{p,q}$ for which random linear codes are $(p, C_{p,q}/\varepsilon)$-list-decodable with high probability. Unfortunately, if p tends to $1 - 1/q$ then this constant tends to infinity. To address this, an ongoing line of works [7, 43, 41, 42] has studied the list-decodability of random linear codes in the "high-noise regime" where p is close to $1 - 1/q$; these results also apply to average-radius list-decodability. These results imply that for binary random linear codes, when $p = 1 - 1/q - \Theta(\sqrt{\varepsilon})$, random linear codes with rate $R^* - \varepsilon$ are average-radius list-decodable with list sizes $O(1/\varepsilon)$. However, the constant hiding in the big-Oh is not correct (in particular, the authors do not see how to make it smaller than 2). Moreover, these results only hold in a particular parameter regime for p and ε, and degrade as the alphabet size grows.

As for list-recovery, a result by Rudra and Wootters [42] guarantees that random linear codes with rate $R^* - \varepsilon$ over sufficiently large alphabets $\mathbb{F}_q$ have lists of sizes at most $(q\ell)^{O(\log(\ell)/\varepsilon)}$. To the best of our knowledge, no lower bounds were known.

Relevant results for other ensembles of codes

Lastly, we discuss some other results concerning other code ensembles. First of all, recent work of [37] shows that a random code from Gallager's ensemble of LDPC codes [12] achieves list-decoding capacity with high probability. More generally, they show that random LDPC codes have similar combinatorial properties to random linear codes, including list-decoding, average-radius list-decoding, and list-recovery. As part of their approach, they develop techniques to characterize the lists that appear in a random linear code with high probability, which we utilize for our work.

Finally, we note that there are no known explicit constructions of list-decodable codes of rate $R^* - \varepsilon$ which achieve a list size even of $O(1/\varepsilon)$. Over large alphabets, the best explicit constructions of capacity-achieving list-decodable or list-recoverable codes have list sizes at least $(1/\varepsilon)^{\Omega(1/\varepsilon)}$ (e.g., [33, 32]). Further, if one insists on *binary* codes, or even codes over alphabets of size independent of ε, we do not know of *any* explicit constructions of list-decodable codes with rate approaching R^*.

Two-point concentration

We showed that the optimal list size L of a random linear code is concentrated on at most three values for both list-decoding and average-radius list-decoding: $\lfloor h(p)/\varepsilon \rfloor + 2$, $\lfloor h(p)/\varepsilon \rfloor + 1$, and, if the value is different, $\lfloor h(p)/\varepsilon + 0.99 \rfloor$.

In [34, Theorem 2.5], it was also shown that the optimal list size of a *completely* random binary code is concentrated on two or three values for list-decoding. This type of concentration is also well studied in graph theory, where it is known that in Erdős-Rényi graphs, a number of graph parameters are concentrated on two values. Examples include the clique number (size of the largest clique) [36, 6], the chromatic number [35, 2, 1], and the diameter [39].

1.4 Discussion and open problems

In this work, we have made progress on pinning down the output list sizes for (average-radius) list-decoding and list-recovery for random linear codes. Before we continue with the technical portion of the paper, we highlight some open questions and future directions.

- We showed that random linear codes of rate $1 - h_q(p) - \varepsilon$ are not (p, L)-list-decodable for $L \sim \frac{h_q(p)}{\varepsilon}$. We conjecture this lower bound is tight, i.e. that random linear codes of rate $1 - h_q(p) - \varepsilon$ are (p, L)-(average-radius) list-decodable for $L = \frac{h_q(p)}{\varepsilon}(1 + o(1))$, where the $o(1) \to 0$ as $\varepsilon \to 0$. Our Theorem 14 (and earlier in [34] for list-decoding) shows it is true for $q = 2$, and we conjecture this is true for larger q.
- Our results show that list-decoding and average-radius list-decoding have essentially the same output list sizes over binary alphabets, for random linear codes. It would be interesting to extend this to larger alphabets, or even to more general families of codes. This is especially interesting given that there is an exponential gap in the best known lower bounds (on the list-size for arbitrary codes) between list-decoding and average-radius list-decoding for general codes.
- We have used different techniques for our upper and lower bounds. However, we think it is an interesting direction to use the characterization of [37] – which we used to prove our lower bounds – to prove upper bounds as well. This would entail showing that every sufficiently bad list is implicitly rare.
- Finally, we note that our lower bounds for list-recovery rely on the field $\mathbb{F}_q$ being an extension field (that is, $q = p^t$ for some $t > 1$). It is an interesting question whether or not an exponential lower bound also holds over prime fields. We note that other lower bounds on list-decoding and list-recovery for Reed-Solomon codes also apply only to extension fields [23, 3]; perhaps all of these bounds taken together are evidence that better list-decodability may be possible in general over prime fields.

1.5 Organization

In Section 2 we set up notation and formally state the results of [37] that we build on for our lower bounds. In Section 3 we state and sketch the proof of our lower bound on list-recovery of random linear codes. In Section 4 we state and sketch the proof of our lower bound on the list-decodability of random linear codes. In Appendix A we state and prove our upper bound on the list-decodability of random linear codes.

2 Preliminaries

In this section, we set notation and introduce the notions and results from [37] that we need for our lower bounds.

2.1 Notation

Unless otherwise specified, all logarithms are base 2. We use the notation $\exp(x)$ to mean e^x. For an integer a, we define $[a] := \{1, \ldots, a\}$. For a vector $x \in \mathbb{F}_q^A$ and $I \subset [A]$, we use $x_I \in \mathbb{F}_q^{|I|}$ to denote the vector $(x_i)_{i \in I}$ with coordinates from I in increasing order. We use $\mathbf{1}_D$ to denote the all ones vector of length D.

We use several notions from information theory. Define the q-ary entropy $h_q : [0,1] \to [0,1]$ by

$$h_q(x) \stackrel{\text{def}}{=} x \log_q(q-1) - x \log_q x - (1-x)\log_q(1-x) \tag{1}$$

We assume $q = 2$ if q is omitted from the subscript.

For a random variable X with domain $\mathcal{X}$, we use $H(X)$ to denote the *entropy* of X:

$$H(X) = -\sum_{x \in \mathcal{X}} \Pr_X(x) \log(\Pr_X(x)).$$

For a probability distribution τ, we may also use $H(\tau)$ to denote the entropy of a random variable with distribution τ.

Let X be a random variable supported on $\mathcal{X}$ and Y be a random variable supported on $\mathcal{Y}$. We define the *conditional entropy* of Y given X as

$$H(Y|X) = -\sum_{x \in \mathcal{X}, y \in \mathcal{Y}} p(x,y) \log \frac{p(x,y)}{p(x)}.$$

It is easy to check that $H(X) - H(X|Y) = H(Y) - H(Y|X)$ and we call this the *mutual information* $I(X;Y)$:

$$I(X;Y) = H(X) - H(X|Y) = H(Y) - H(Y|X)$$

For random variables X, Y, Z, we define the *conditional mutual information* $I(X;Y|Z)$ by

$$I(X;Y|Z) = H(X|Z) - H(X|Y,Z) = H(Y|Z) - H(Y|X,Z)$$

Conditional entropy, mutual information, and conditional mutual information satisfy the *data processing inequality:* for any function f supported on the domain of Y, we have

$$H(X|f(Y)) \geq H(X|Y) \quad \text{and} \quad I(X;Y) \geq I(X;f(Y)) \quad \text{and} \quad I(X;Y|Z) \geq I(X;f(Y)|Z).$$

We also use *Fano's inequality*, which states that if X is a random variable supported on $\mathcal{X}$ and Y is a random variable supported on $\mathcal{Y}$, and if $f : \mathcal{Y} \to \mathcal{X}$ is a function and $p_{err} = \Pr_{X,Y}[f(Y) \neq X]$

$$H(X|Y) \leq h(p_{err}) + p_{err} \cdot \log(|\mathcal{X}| - 1)$$

We define

$$H_q(X) \stackrel{\text{def}}{=} \frac{H(X)}{\log q}, \qquad I_q(X;Y) = \frac{I(X;Y)}{\log q}.$$

and similarly for conditional entropy and conditional mutual information.

For a distribution τ on $\mathbb{F}_q^L$ and a matrix $A \in \mathbb{F}_q^{L' \times L}$, we define the distribution $A\tau$ on $\mathbb{F}_q^{L'}$ in the natural way by

$$\Pr_{A\tau}(x) = \sum_{\{y \in \mathbb{F}_q^L \,:\, Ay = x\}} \Pr_\tau(y),$$

namely, $A\tau$ is the distribution of the random vector Ay, where $y \sim \tau$.

We have defined list-decoding, average-radius list-decoding, and list-recovery in the introduction. We will in fact consider a more general version of list-recovery, which also tolerates erasures:

▶ **Definition 1** (List-recovery from erasures)**.** *A code $C \subset \mathbb{F}_q^n$ is (α, ℓ, L)*-list-recoverable from erasures *if the following holds. Let $S_1, \ldots, S_n \subset \mathbb{F}_q$ be lists so that $|S_i| \leq \ell$ for at least αn values of i. Then*

$$|\{c \in \mathcal{C} \,:\, \forall i \in [n], c_i \in S_i\}| < L.$$

We take $\alpha = 1$ if it is omitted.

2.2 Tools from [37]

As discussed in Section 1.2, for our lower bounds we use tools from the recent work [37]. We work with matrices $M \in \mathbb{F}_q^{n \times L}$ ($L \in \mathbb{N}$), where we view the columns of M as potential codewords in $\mathcal{C}$. We use the notation "$M \subseteq \mathcal{C}$" to mean that the columns of M are all contained in $\mathcal{C}$.

We group together sets of such matrices M according to their row distribution.

▶ **Definition 2** (τ_M, $\dim(\tau)$, $\mathcal{M}_{n,\tau}$)**.** *Given a matrix $M \in \mathbb{F}_q^{n \times L}$, the empirical row distribution defined by the rows of M over $\mathbb{F}_q^L$ is called the type τ_M of M. That is, τ_M is the distribution so that for $v \in \mathbb{F}_q^L$,*

$$\Pr_{\tau_M}(v) = \frac{|\{i \,:\, \textit{the } i\textit{'th row of } M \textit{ is equal to } v\}|}{n}.$$

For a distribution τ on $\mathbb{F}_q^L$, we use $\dim(\tau)$ to refer to $\dim(\mathrm{span}(\mathrm{supp}(\tau)))$. We use $\mathcal{M}_{n,\tau}$ to refer to the set of all matrices in $\mathbb{F}_q^{n \times L}$ which have empirical row distribution τ.

▶ Remark 3. We remark that for some distributions τ over $\mathbb{F}_q^L$, the set $\mathcal{M}_{n,\tau}$ may be empty due to $n \cdot \Pr_\tau(v)$ not being an integer. For such τ we can define $\mathcal{M}_{n,\tau}$ to consist of matrices M with either $\lfloor n \cdot \Pr_\tau(v) \rfloor$ or $\lceil n \cdot \Pr_\tau(v) \rceil$ copies of v. This has a negligible effect on the analysis as we always take n to be sufficiently large compared to other parameters, so for clarity of exposition we ignore this technicality.

Given $M \in \mathcal{M}_{n,\tau}$, note that $\mathcal{M}_{n,\tau}$ consists exactly of those matrices obtained by permuting the rows of M. In particular, since the *random linear code* model is invariant to such permutations, all of the matrices in $\mathcal{M}_{n,\tau}$ have the same probability of being contained in $\mathcal{C}$.

As discussed in Section 1.2, we prove a lower bound by exhibiting a distributions τ over $\mathbb{F}_q^L$ such that the corresponding set $\mathcal{M}_{n,\tau}$ is both *bad* and *abundant*. When $\mathcal{M}_{n,\tau}$ satisfies these properties, we say that τ itself is, respectively, *bad* and *abundant*.

The work [37] characterizes which distributions τ satisfy the *abundance* property, namely, which classes $\mathcal{M}_{n,\tau}$ are likely to have at least one of their elements appear (as a matrix) in a random linear code of a given rate. To motivate the definition below, suppose that the distribution τ has low entropy: $H_q(\tau) < \gamma \cdot \dim(\tau)$ for some $\gamma \in (0,1)$. This implies that the class $\mathcal{M}_{n,\tau}$ is not too big: more precisely, it is not hard to see that $|\mathcal{M}_{n,\tau}| \leq q^{H_q(\tau) \cdot n} \leq q^{\gamma \dim(\tau) n}$. Using a calculation like we did in Section 1.2, we see that, since $\mathcal{M}_{n,\tau}$ is not very large, it is unlikely for a random linear code of rate less than $1 - \gamma$ to contain a matrix from $\mathcal{M}_{n,\tau}$.

However, this is not the only reason that $\mathcal{M}_{n,\tau}$ might be unlikely to appear in a random linear code. As is shown in [37], it could also be because a random output of τ, subject to some linear transformation (perhaps to a space of smaller dimension), has low entropy. We call such distributions *implicitly rare:*

▶ **Definition 4** (γ-implicitly rare)**.** *We say that a distribution τ over $\mathbb{F}_q^L$ is* γ-implicitly rare *if there exists a full-rank linear transformation $A : \mathbb{F}_q^L \to \mathbb{F}_q^{L'}$ where $L' \leq L$ such that*

$$H_q(A\tau) < \gamma \cdot \dim(A\tau)$$

Observe that by taking A to be the identity map, we recover the case where τ itself has low entropy. Furthermore, note that every matrix in $\mathcal{M}_{n,A\tau}$ has all of its columns contained in the column-span of some matrix in $\mathcal{M}_{n,\tau}$. This implies that if no matrix in $\mathcal{M}_{n,A\tau}$ lies in a code, then no matrix in $\mathcal{M}_{n,\tau}$ lies in the code. Thus, abundance of the distribution $A\tau$ implies abundance of τ.

For an illustrative example of an implicitly rare distribution, we refer the reader to [37, Example 2.5]. Specifically, the example provides a case where for some full-rank matrix A, we have $H_q(A\tau)/\dim(A\tau) > H_q(\tau)/\dim(\tau)$.

Essentially, [37] shows that a row distribution τ is likely to appear in a random linear code (namely, τ satisfies the abundance property) if and only if it is *not* implicitly rare. The following theorem follows from Lemma 2.7 in [37].[8]

▶ **Theorem 5** (Follows from Lemma 2.7 in [37]). *Let $R \in (0,1)$ and fix $\eta > 0$. Let τ be a $(1-R-\eta)$-implicitly rare distribution over $\mathbb{F}_q^L$ ($L \in \mathbb{N}$), and let $\mathcal{C}$ be a random linear code of rate R. Then*

$$\Pr[\exists M \in \mathcal{M}_{n,\tau} : M \subseteq \mathcal{C}] \leq q^{-\eta n}$$

Conversely, suppose that τ is not $(1-R+\eta)$-implicitly rare. Then

$$\Pr[\exists M \in \mathcal{M}_{n,\tau} : M \subseteq \mathcal{C}] \geq 1 - n^{O_{L,q}(1)} \cdot q^{-\eta n} \ .$$

The first part of the theorem follows from a natural first-moment method argument, while the second part follows from the analogous second-moment argument. We emphasize that it is important that we allow arbitrary full-rank linear transformations $A : \mathbb{F}_q^L \to \mathbb{F}_q^{L'}$ in Definition 4: if we only allowed A to be the identity map, the second part of the theorem would be false.

3 Lower bounds for list-recovery with erasures

Our main result in this section is the following.

▶ **Theorem 6.** *Fix $0 \leq \rho < 1$. Fix a prime power $\ell \geq 2$ and an integer $t \geq 2$, and let $q = \ell^t$. Fix $0 < \varepsilon \leq \frac{1-\rho}{20t}$ and let $L = \ell^{\lceil \frac{1-\rho}{20\varepsilon} \rceil}$. For $n \in \mathbb{N}$, let $\mathcal{C} \subseteq \mathbb{F}_q^n$ denote a random linear code of rate $R := 1 - (\rho + (1-\rho)\log_q(\ell)) - \varepsilon$. Then the probability of $\mathcal{C}$ being $(1-\rho, \ell, L)$-erasure list-recoverable is at most $q^{-\Omega(n)}$.*

We will prove Theorem 6 below, after we build up the necessary building blocks. As discussed in Sections 1.2 and 2, to prove Theorem 6 we seek a distribution τ that is both is *bad* and *abundant*. That is, $\mathcal{C}$ should likely contains some matrix from $\mathcal{M}_{n,\tau}$, and the corresponding codewords should yield a counterexample to the list-recoverability of $\mathcal{C}$. We will describe our choice of τ in Definition 7; we will show that it is bad in Proposition 8; and finally we will show that it is not implicitly rare (and hence abundant by Theorem 5) in Lemma 9.

Our construction of the distribution τ follows similar lines to that in Section 1.2.

▶ **Definition 7** (The bad distribution τ for list-recovery lower bounds). *Fix ρ, ℓ, t, q as in Theorem 6. Let $D \geq t$ be a positive integer. Let $\mathbb{F}_\ell$ be a subfield of $\mathbb{F}_q$, where $q = \ell^t$ and $t \geq 2$. Let $\alpha_1, \ldots, \alpha_{(q-1)/(\ell-1)}$ be a set so that $\alpha_i \mathbb{F}_\ell^*$ are disjoint cosets of $\mathbb{F}_\ell^*$ partitioning $\mathbb{F}_q^*$. Let $L = \ell^D$. Let $G \in \mathbb{F}_\ell^{L \times D}$ be the matrix whose rows are all of the distinct elements of $\mathbb{F}_\ell^D$.*

Let σ be the distribution that with probability $1-\rho$ returns $\alpha_i u$ for (i,u) uniform in $\left\{1, \ldots, \frac{q-1}{\ell-1}\right\} \times \mathbb{F}_\ell^D$; and with probability ρ returns a uniformly random element of $\mathbb{F}_q^D$.

Let τ be the distribution given by Gv for $v \sim \sigma$.

[8] This is also given as Theorem 2.2 in the first version of [37], available at `https://arxiv.org/abs/1909.06430v1`.

To motivate this construction, consider first the $\rho = 0$ case. Now consider a matrix $M \in \mathbb{F}_q^{n \times L}$ that has row distribution given by τ. If we ignore the coefficients α_i, the columns of M span a D-dimensional subspace of $\mathbb{F}_\ell^n$. In particular, they are *bad,* in the sense that each coordinate of these codewords are contained in a list of size ℓ (namely, $\mathbb{F}_\ell$). Moreover, as soon as any D linearly independent columns of M are contained in $\mathcal{C}$, all of the columns of M are contained in $\mathcal{C}$; this suggests that it's relatively likely (compared to, say, a random matrix in $\mathbb{F}_q^{L \times n}$) that $M \subseteq \mathcal{C}$. These properties don't change when we multiply by the coefficients α_i: each coordinate is now contained in some list $\alpha_i \mathbb{F}_\ell$ rather than $\mathbb{F}_\ell$ (notice that the fact that the α_i are coset representatives means that all of these possible lists are disjoint, other than zero), and it's still just as likely that $M \subseteq \mathcal{C}$. However, by throwing these multiples α_i into the mix, we have increased the size of $\mathcal{M}_{n,\tau}$, making τ more *abundant.* In particular, note that, over all choices of (i, u), the value $\alpha_i u$ is distinct except when $u = 0$. Thus, τ has entropy close to the entropy of the uniform distribution on (i, u), so $H_q(\tau) \approx \log_q(q\ell^{D-1}) \approx D(\log_q(\ell) + \frac{1}{D})$. Using a similar idea, we can estimate the entropy of $A\tau$ for all matrices A, showing that τ is *not* $\log_q(\ell) + \frac{1}{10D}$ implicitly rare, implying that it is abundant.

To generalize to the $\rho > 0$ case, the construction essentially "frees" a ρ fraction of the coordinates relative to the $\rho = 0$ case. This further increases the size of $\mathcal{M}_{n,\tau}$ (making τ even more abundant), while still maintaining the badness property for list-recovery with a ρ fraction of erasures.

▶ **Proposition 8** (τ is bad). *Let τ be as in Definition 7. Let $\mathcal{C} \subseteq \mathbb{F}_q^n$, and let $M \in \mathcal{M}_{n,\tau}$. If $M \subseteq \mathcal{C}$, then $\mathcal{C}$ is not $(1-\rho, \ell, L)$-list-recoverable.*

Proof. Suppose that $M \subseteq \mathcal{C}$. Let $w_1, w_2, \ldots, w_n \in \mathbb{F}_q^L$ be the rows of M. It suffices to show that there are input lists $S_1, \ldots, S_n$ so that $w_j \in S_j^L$ for all $j \in [n]$, and so that for at least $(1-\rho)n$ values of $j \in [n]$, we have $|S_j| \leq \ell$. Recall that each row w_j of M is of the form Gv_j where a $(1-\rho)$ fraction of the v_j are of the form $\alpha_{i_j} \cdot u_j$ for $(i_j, u_j) \in [(q-1)/(\ell-1)] \times \mathbb{F}_\ell^D$, and a ρ fraction of the v_j are arbitrary vectors in $\mathbb{F}_q^D$.[9]

In the first case, set $S_j = \alpha_{i_j} \cdot \mathbb{F}_\ell$. Because the elements of G are all in $\mathbb{F}_\ell$, all the coordinates of $w_j = Gv_j = \alpha_{i_j} G u_j$ lie in S_j. Moreover by definition $|S_j| \leq \ell$. In the second case, set $S_j = \mathbb{F}_q$. By definition all the coordinates of $w_j \in \mathbb{F}_q^L$ lie in $S_j = \mathbb{F}_q$.

This completes the proof. ◀

Next, we claim that τ is not implicitly rare, which will imply that τ is abundant. Due to space constraints, the proof is omitted.

▶ **Lemma 9** (τ is abundant). *Let τ be as in Definition 7. Then τ is* not

$$\left(\rho + (1-\rho)\log_q(\ell) + \frac{1-\rho}{10D}\right)\text{-implicitly rare.}$$

We now show how to use Proposition 8 and Lemma 9 to prove Theorem 6.

Proof of Theorem 6. Let $0 < \varepsilon \leq \frac{1-\rho}{20t}$. Let τ be as in Definition 7, choosing $D = \lceil \frac{1-\rho}{20\varepsilon} \rceil$. By our choice of ε, we indeed have $D \geq t$. Lemma 9 shows that τ is *not* $(\rho + (1-\rho)\log_q(\ell) + \frac{1-\rho}{10D})$-implicitly rare. By choice of D, we have $\frac{1-\rho}{10D} > \varepsilon$. From Theorem 5 with $\eta = \frac{1-\rho}{10D} - \varepsilon$, we see that for any sufficiently large n, a random code of rate

[9] As per Remark 3, we may ignore the rounding issue that ρn may not be an integer. This is without loss of generality, as we may replace τ with a very similar distribution so that a $\lceil \rho n \rceil$ fraction of the v_j are arbitrary in $\mathbb{F}_q^D$, and adjust all parameters by a term that is $o(1)$ as $n \to \infty$.

$$\left(1-\left(\rho+(1-\rho)\log_q(\ell)+\frac{1-\rho}{10D}\right)\right)+\eta=1-\left(\rho+(1-\rho)\log_q(\ell)\right)-\varepsilon$$

contains ℓ^D codewords given by a matrix $M \in \mathcal{M}_{n,\tau}$ with probability at least $1-q^{\Omega(\varepsilon n)}$. By Proposition 8, if this occurs, then $\mathcal{C}$ is not $(1-\rho,\ell,L)$-list-recoverable. ◀

4 Lower bounds for list-decoding with errors

Our main theorem in this section is the following.

▶ **Theorem 10.** *Fix a prime power q, fix $p \in (0, 1-\frac{1}{q})$, and fix $\delta \in (0,1)$. There exists $\varepsilon_{p,q,\delta} > 0$ such that for all $\varepsilon \in (0, \varepsilon_{p,q,\delta})$ and n sufficiently large, a random linear code in $\mathbb{F}_q^n$ of rate $1-h_q(p)-\varepsilon$ is not $\left(p, \left\lfloor \frac{h_q(p)}{\varepsilon} - \delta \right\rfloor\right)$-list-decodable with probability $1-q^{-\Omega(n)}$.*

Our proof of Theorem 10 below follows the same outline as the proof of Theorem 6 above. We first define a bad distribution τ in Definition 11; then we will show that it is bad in Proposition 12; then we will show that it is not implicitly rare (and hence abundant by Theorem 5) in Lemma 13. Finally we will prove Theorem 10 from these pieces.

Below, we let $\text{Bernoulli}_q(p)$ be the distribution that returns $0 \in \mathbb{F}_q$ with probability $1-p$ and any other element of $\mathbb{F}_q$ with probability $\frac{p}{q-1}$.

▶ **Definition 11** (The bad distribution τ for list-decoding lower bounds)**.** *Let $p \in (0, 1-\frac{1}{q})$ and $\delta > 0$. Choose $L > 0$. Define the distribution τ on $\mathbb{F}_q^L$ as the distribution of the random vector $u + \alpha \mathbf{1}_L$, where $u \sim \text{Bernoulli}_q(p)^L$, and α is sampled independently and uniformly from $\mathbb{F}_q$.*

First, we observe that τ is indeed bad, in the sense that it provides a counter-example to list-decodability.

▶ **Proposition 12** (τ is bad)**.** *Let τ be as in Definition 11. Let $\mathcal{C} \subseteq \mathbb{F}_q^n$ and let $M \in \mathcal{M}_{n,\tau}$. If $M \subseteq \mathcal{C}$, then $\mathcal{C}$ is not (p,L)-list-decodable.*

Proof. Let $M \in \mathcal{M}_{n,\tau}$. We want to show that the columns of M all lie in a single ball of radius pn.

By definition of τ and $\mathcal{M}_{n,\tau}$, we may write the j-th row of M as $u^{(j)} + \alpha_j \mathbf{1}_L$, so that the empirical distribution of the pairs $(u^{(j)}, \alpha_j)_{1 \le j \le n}$ is $\text{Bernoulli}_q(p)^L \times \text{Uniform}(\mathbb{F}_q)$.[10]

For any $i \in [L]$, the number of $j \in [n]$ such that $M_{i,j} = u_i^{(j)} + \alpha_j \neq \alpha_j$ is exactly the number of times $u_i^{(j)} \neq 0$, which is pn, since $u_i^{(j)}$ is distributed as $\text{Bernoulli}_q(p)$. Thus, each column $M_{i,*}$ of M has distance at most pn from the word $(\alpha_1, \ldots, \alpha_n)$, so that any code containing M has L codewords in a ball of radius pn and hence is not (p,L)-list-decodable. ◀

Next, we claim that τ is appropriately implicitly rare for large enough L. Due to space constraints, the proof is omitted.

▶ **Lemma 13.** *Let $p \in (0, 1-\frac{1}{q})$ and let $\delta > 0$. There exists $L_{p,q,\delta}$ such that, for $L \ge L_{p,q,\delta}$, the distribution τ given in Definition 11 is not $\left(h_q(p) + \frac{h_q(p)}{L+\delta}\right)$-implicitly rare.*

[10] This is without loss of generality: if not, as per Remark 3, we can associate pairs with rows so that the empirical distribution is close to $\text{Bernoulli}_q(p)^L \times \text{Uniform}(\mathbb{F}_q)$ up to an additive factors that are $o(1)$ as $n \to \infty$. After adjusting parameters, this has a negligible effect on the analysis and final result.

We now show how to use Proposition 12 and Lemma 13 to prove Theorem 10.

Proof of Theorem 10. Let $L_{p,q,\delta/2}$ be as in Lemma 13 and choose $\varepsilon_{p,q,\delta} \stackrel{\text{def}}{=} \frac{h_q(p)}{L_{p,q,\delta/2}+1}$. Fix $\varepsilon < \varepsilon_{p,q,\delta}$. Let $L = \left\lfloor \frac{h_q(p)}{\varepsilon} - \delta \right\rfloor$. Let τ be as in Definition 11 with this choice of L. By Lemma 13, as $L \geq L_{p,q,\delta/2}$, τ is not $\left(h_q(p) + \frac{h_q(p)}{L+\delta/2}\right)$-implicitly rare. Thus, as $\varepsilon \leq \frac{h_q(p)}{L+\delta} < \frac{h_q(p)}{L+\delta/2}$, there is some constant $c_{p,q,\varepsilon} > 0$ so that τ is not $(h_q(p) + \varepsilon + c_{p,q,\varepsilon})$-implicitly rare.

Then Theorem 5 with $\eta = c_{p,q,\varepsilon}$ tells us that, for n sufficiently large, a random linear code of rate $1 - (h_q(p) + \varepsilon + c_{p,q,\varepsilon}) + c_{p,q,\varepsilon} = 1 - h_q(p) - \varepsilon$ contains L codewords given by some matrix $M \in \mathcal{M}_{n,\tau}$ with probability at least $1 - q^{-\Omega_{p,q,\varepsilon}(n)}$.

Finally, Proposition 12 implies that $\mathcal{C}$ is not (p, L)-list-decodable. Our choice of L proves the theorem. ◀

A Upper bounds for average-radius list-decoding over $\mathbb{F}_2$

In this section we prove the following theorem. Recall that we abbreviate $h(p) = h_2(p)$.

▶ **Theorem 14.** *Let $n \in \mathbb{N}$. Let $p \in (0, \frac{1}{2})$ and $R = 1 - h(p) - \varepsilon$, where $0 < \varepsilon < 1 - h(p)$. Let $L = \lfloor \frac{h(p)}{\varepsilon} + 2 \rfloor$. Then, a random linear code $\mathcal{C} \leq \mathbb{F}_2^n$ of rate R is (p, L)-average-radius list-decodable with probability $1 - 2^{-\Omega_{p,\varepsilon}(n)}$.*

Recall from the introduction that, following the techniques in [16] and [34], we imagine sampling independent and uniform vectors $b_1, \ldots, b_k$ and constructing the "intermediate" random linear codes $\mathcal{C}_i = \text{span}\{b_1, \ldots, b_i\}$. A potential function based argument is used to show that, with high probability, each of these intermediate codes is indeed (p, L)-average-radius list-decodable; in particular, this is true for $\mathcal{C}_k$.

Before discussing our potential function, we first briefly review the techniques of [16] and [34]; in particular, we describe the potential function they use. First, for a code $\mathcal{C}$ and a vector $x \in \mathbb{F}_2^n$, we define

$$L_{\mathcal{C}}(x) := |\{c \in \mathcal{C} : \delta(x, c) \leq p\}| \ .$$

In [16], the authors define

$$S_{\mathcal{C}} := \frac{1}{2^n} \sum_{x \in \mathbb{F}_2^n} 2^{\varepsilon n L_{\mathcal{C}}(x)}$$

and observe that, for any $b_1, \ldots, b_i \in \mathbb{F}_2^n$,

$$\mathop{\mathbb{E}}_{b_{i+1} \sim \mathbb{F}_2^n} \left[S_{\mathcal{C}_i + \{0, b_{i+1}\}} \right] = S_{\mathcal{C}_i}^2 \ ,$$

where we recall $\mathcal{C}_i = \mathrm{span}\{b_1, \ldots, b_i\}$.[11] That is, the potential function squares in expectation, so the probabilistic method guarantees that we can choose some b_{i+1} for which $S_{\mathcal{C}_{i+1}} \le S_{\mathcal{C}_i}^2$. Thus, for some choice of $b_1, \ldots, b_k$, one has $S_{\mathcal{C}_k} \le (S_{\{0\}})^{2^k}$.

In [34], the definition of $S_{\mathcal{C}}$ is slightly modified:

$$S_{\mathcal{C}} := \frac{1}{2^n} \sum_{x \in \mathbb{F}_2^n} 2^{\frac{\varepsilon n L_{\mathcal{C}}(x)}{1+\varepsilon}} \ .$$

This little bit of extra room allows to show that, in fact, with high probability over the choice of b_{i+1}, $S_{\mathcal{C}_i + \{0, b_{i+1}\}} \le S_{\mathcal{C}_i}^2$. By a union bound, it follows that with high probability, $S_{\mathcal{C}_k} \le (S_{\{0\}})^{2^k}$.

In either case, to conclude the proof, one observes the bound[12] $S_{\{0\}} \le 1 + 2^{-n(1-h(p)-\varepsilon)}$ and then uses

$$S_{\mathcal{C}_k} \le (S_{\{0\}})^{2^k} \le (1 + 2^{-n(1-h(p)-\varepsilon)})^{2^k} \le \exp 2^{k-n(1-h(p)-\varepsilon)} \le O(1)$$

for k chosen as above.

A.1 Alterations for average-radius list-decoding

While this argument analyzes the (absolute-radius) list-decodability of random linear codes very effectively, it is not immediately clear how to generalize the argument to study average-radius list-decodability. We now introduce the additional ideas we need to derive Theorem 14. We will fix a threshold parameter $\lambda \in (p, \frac{1}{2})$ for which $h(\lambda) < 1 - R = h(p) + \varepsilon$, to be determined later, and define

$$\eta \stackrel{\mathrm{def}}{=} 1 - R - h(\lambda).$$

We define the function $M_{R,\lambda} : [0,1] \to \mathbb{R}$ by

$$M_{R,\lambda}(\gamma) := \begin{cases} 1 - R - h(\gamma) & \text{if } \gamma < \lambda \\ 0 & \text{if } \gamma \ge \lambda \end{cases} .$$

▶ Remark 15. One can think of this quantity as a sort of "normalized entropy change" up to the threshold λ. Recalling that $1 - R = h(p) + \varepsilon$, if $\gamma < \lambda$, then

$$M_{R,\lambda}(\gamma) \approx \frac{1}{n} \left(h(p) - h(\lambda) \right) \approx \log \left(\frac{|B^n(p)|}{|B^n(\gamma)|} \right),$$

where $B^n(p)$ denotes the Hamming ball in $\mathbb{F}_2^n$ of radius p. Hence, $M_{R,\lambda}(\gamma)$ is something like a normalized "surprise" an observer would experience if they are expecting a random vector of weight $\le p$ and see a vector of weight $\le \gamma$.

[11] Here and throughout, for two subsets $A, B \subseteq \mathbb{F}_2^n$, we denote $A + B = \{a + b : a \in A, b \in B$. Thus, $\mathcal{C}_i + \{0, b_{i+1}\} = \mathcal{C}_{i+1}$.

[12] Actually, for the potential function in [34], one has $S_{\{0\}} \le 1 + 2^{-n(1-h(p)-\frac{\varepsilon}{1+\varepsilon})}$, but this difference does not matter for the conclusion.

For a linear code $\mathcal{C} \leq \mathbb{F}_2^n$ and $x \in \mathbb{F}_2^n$ we define

$$L_{\mathcal{C},R,\lambda}(x) := \sum_{y \in \mathcal{C}} M_{R,\lambda}(\delta(x,y)).$$

This is intuitively the "smoothed-out" list-size of x, where nearby codewords are weighted more heavily than far away codewords, and the weighting is given by the "entropy change" implied by the distance from x to y.

Next, we define

$$A_{\mathcal{C},R,\lambda}(x) := 2^{\frac{nL_{\mathcal{C},R,\lambda}(x)}{1+\eta}} \quad \text{and} \quad S_{\mathcal{C},R,\lambda} := \frac{1}{2^n} \sum_{x \in \mathbb{F}_2^n} A_{\mathcal{C},R,\lambda}(x).$$

The quantity $S_{\mathcal{C},R,\lambda}$ is the potential function we analyze.

A.2 Proof of Theorem 14

In this subsection we prove Theorem 14. The quantities R and λ (and hence $\eta = 1-R-h(\lambda)$) will be fixed throughout – although the precise value of λ will be determined later – and so we will suppress their dependence and simply write $M(x)$, $L_{\mathcal{C}}(x)$, $A_{\mathcal{C}}(x)$ and $S_{\mathcal{C}}$.

First, we observe that the following analog of [34, Lemma 3.2] holds. The proof is a simple adaptation of theirs (which in turn follows [16]).

▶ **Lemma 16.** *For all $\mathcal{C} \leq \mathbb{F}_2^n$ and $b \in \mathbb{F}_2^n$,*

$$L_{\mathcal{C}+\{0,b\}}(x) \leq L_{\mathcal{C}}(x) + L_{\mathcal{C}}(x+b), \tag{2}$$

$$A_{\mathcal{C}+\{0,b\}}(x) \leq A_{\mathcal{C}}(x) \cdot A_{\mathcal{C}}(x+b). \tag{3}$$

Moreover, equality holds if and only if $b \notin \mathcal{C}$.

Next, we bound $S_{\{0\}}$. We have

$$S_{\{0\}} \leq 1 + 2^{-n} \sum_{\substack{x \in \mathbb{F}_2^n \\ \mathrm{wt}(x) \leq \lambda}} 2^{\frac{n \cdot (1-R-h(\mathrm{wt}(x)))}{1+\eta}} \leq 1 + \sum_{i=0}^{\lfloor \lambda n \rfloor} 2^{-n\left(1-h(i/n)-\frac{h(\lambda)+\eta-h(i/n)}{1+\eta}\right)}.$$

As this sum is dominated by its last term, we deduce

$$S_{\{0\}} \leq 1 + (\lambda n) 2^{-n\left(1-h(\lambda)-\frac{\eta}{1+\eta}\right)}. \tag{4}$$

From here, we can combine Lemma 16 and (4) to deduce

▶ **Lemma 17.** *Let $p \in (0, \frac{1}{2})$ and $R = 1 - h(p) - \varepsilon$ for $0 < \varepsilon < 1 - h(p)$. Let $\mathcal{C}_{Rn} \leq \mathbb{F}_2^n$ be a random linear code of rate R. Then $S_{\mathcal{C}_{Rn}} \leq 2$ with probability at least $1 - \exp(-\Omega_\eta(n))$.*

The proof of this lemma is completely analogous to that of [34, Lemma 3.3]. One only needs to be careful about the growth rate of $S_{\mathcal{C}}$. In particular, this proof crucially uses that η is positive. We again choose vectors $b_1, \ldots, b_{Rn}$ independently and uniformly at random. If $\mathcal{C}_i = \mathrm{span}\{b_1, \ldots, b_i\}$, we need "in expectation" that $S_{\mathcal{C}_i} \leq 1 + 2^{-\Omega(n)}$ for all i for the error bounds to succeed. As we expect the $o(1)$ term to roughly double, we need $2^{Rn} \cdot (S_{(0)} - 1) = 2^{-n(\eta - \frac{\eta}{1+\eta})} \leq 2^{-\Omega_\eta(n)}$.

Thus, in order to conclude Theorem 14, we are simply required to demonstrate that $S_{\mathcal{C}} \leq 2$ implies that $\mathcal{C}$ is (p, L)-average-radius list-decodable: this is the crux of our contribution. The main lemma we require is the following.

▶ **Lemma 18.** *Let $\mathcal{C} \leq \mathbb{F}_2^n$ be a linear code of rate R such that $S_{\mathcal{C}} \leq 2$. Then, for all $x \in \mathbb{F}_2^n$ and $D \subseteq \mathcal{C} \cap B(x, \lambda)$, it holds that*

$$\sum_{y \in D} h(\delta(x,y)) \geq (|D| - 1 - \eta)(1-R) - \frac{1+\eta}{n}.$$

Proof. First, observe that for any $x \in \mathbb{F}_2^n$,

$$L_{\mathcal{C}}(x) \geq \sum_{y \in D} ((1-R) - h(\delta(x,y))) = |D|(1-R) - \sum_{y \in D} h(\delta(x,y))$$

$$\text{so} \qquad \log A_{\mathcal{C}}(x) \geq n \frac{|D|(1-R) - \sum_{y \in D} h(\delta(x,y))}{1+\eta}. \tag{5}$$

Next, as $\delta(x,y) = \delta(x+z, y+z)$ for any $z \in \mathbb{F}_2^n$, we have, for any $x \in \mathbb{F}_2^n$ and $c \in \mathcal{C}$, that $L_{\mathcal{C}}(x) = L_{\mathcal{C}}(x+c)$ and hence $A_{\mathcal{C}}(x) = A_{\mathcal{C}}(x+c)$. Thus, $\max_{x \in \mathbb{F}_2^n} A_{\mathcal{C}}(x)$ is attained at at least $|\mathcal{C}|$ different values of x, so

$$S_{\mathcal{C}} = \frac{1}{2^n} \sum_{x \in \mathbb{F}_2^n} A_{\mathcal{C}}(x) \geq \frac{1}{2^n} \cdot |\mathcal{C}| \cdot \max_{x \in \mathbb{F}_2^n} A_{\mathcal{C}}(x) = 2^{-(1-R)n} \cdot \max_{x \in \mathbb{F}_2^n} A_{\mathcal{C}}(x).$$

Combining this with (5), we have, for any $x \in \mathbb{F}_2^n$,

$$\begin{aligned} 1 &\geq \log S_{\mathcal{C}} \geq -(1-R)n + \log\left(A_{\mathcal{C}}(x)\right) \\ &\geq n \cdot \left(-(1-R) + \frac{|D|(1-R) - \sum_{y \in D} h(\delta(x,y))}{1+\eta} \right) \\ &= n \cdot \frac{(|D| - 1 - \eta)(1-R) - \sum_{y \in D} h(\delta(x,y))}{1+\eta}. \end{aligned}$$

Rearranging yields the lemma. ◀

We may now conclude Theorem 14.

Proof of Theorem 14. Since $L = \lfloor \frac{h(p)}{\varepsilon} + 2 \rfloor > \frac{h(p)}{\varepsilon} + 1 = \frac{1-R}{\varepsilon}$, there exists $\eta > 0$ small enough so that for all sufficiently large n

$$L > \frac{1 - R + \eta + \frac{1+\eta}{n}}{\varepsilon - \eta}. \tag{6}$$

Thus, we define λ so that η (which we defined as $\eta = 1 - R - h(\lambda)$) satisfies (6). Let $\mathcal{C}$ be a random linear code of rate R. Due to Lemma 17, the conclusion of Lemma 18, holds with probability $1 - 2^{-\Omega_\eta(n)}$ for $\mathcal{C}$. It remains to show that, assuming n is sufficiently large, any code $\mathcal{C}$ satisfying the conclusion of Lemma 18 is (p, L)-average-radius list-decodable.

Let $x \in \mathbb{F}_2^n$ and $\Lambda \subseteq \mathcal{C}$ such that $|\Lambda| = L$; our goal is to show that, for all such x and Λ,

$$\frac{1}{L} \sum_{y \in \Lambda} \delta(x,y) > p. \tag{7}$$

Let

$$D = \{y \in \Lambda : \delta(x,y) \leq \lambda\}$$

and define

$$h^*(\alpha) = \begin{cases} h(\alpha) & \text{if } \alpha \leq \frac{1}{2} \\ 1 & \text{if } \alpha > \frac{1}{2} \end{cases}.$$

Now,

$$\sum_{y\in\Lambda} h^*(\delta(x,y)) \geq \sum_{y\in D} h(\delta(x,y)) + (L-|D|)h(\lambda) \tag{8}$$

$$\geq (|D|-1-\eta)(1-R) + (L-|D|)(1-R-\eta) - \frac{1+\eta}{n} \tag{9}$$

$$= (1-R)\cdot(L-1) - \eta\cdot(1-R) - \eta\cdot(L-|D|) - \frac{1+\eta}{n}$$

$$\geq (1-R)\cdot(L-1) - \eta\cdot(L+1) - \frac{1+\eta}{n}$$

$$= (1-R)L - (1-R) - \eta\cdot(L+1) - \frac{1+\eta}{n}$$

$$= Lh(p) - (1-R) - (L+1)\eta + L\varepsilon - \frac{1+\eta}{n} \tag{10}$$

$$= Lh(p) - (1-R+\eta) + L(\varepsilon-\eta) - \frac{1+\eta}{n}$$

$$> Lh(p). \tag{11}$$

Here, Inequality (8) holds because $h^*(\alpha) > h(\lambda)$ for all $\alpha > \lambda$; Inequality (9) is the conclusion of Lemma 18; Equality (10) follows from the fact that $R = 1 - h(p) - \varepsilon$; and Inequality (11) follows from (6). Thus, we deduce

$$\frac{1}{L}\sum_{y\in\Lambda} h^*(\delta(x,y)) > h(p). \tag{12}$$

Since h^* is concave,

$$h^*\left(\frac{1}{L}\sum_{y\in\Lambda}(\delta(x,y))\right) \geq \frac{1}{L}\sum_{y\in\Lambda} h^*(\delta(x,y)),$$

and so (7) follows from (12), the monotonicity of h^* and the fact that $h^*(p) = h(p)$. ◀

Is It Possible to Improve Yao's XOR Lemma Using Reductions That Exploit the Efficiency of Their Oracle?

Abstract

Yao's XOR lemma states that for every function $f : \{0,1\}^k \to \{0,1\}$, if f has hardness $2/3$ for $P/poly$ (meaning that for every circuit C in $P/poly$, $\Pr[C(X) = f(X)] \leq 2/3$ on a uniform input X), then the task of computing $f(X_1) \oplus \ldots \oplus f(X_t)$ for sufficiently large t has hardness $\frac{1}{2} + \epsilon$ for $P/poly$.

Known proofs of this lemma cannot achieve $\epsilon = \frac{1}{k^{\omega(1)}}$, and even for $\epsilon = \frac{1}{k}$, we do not know how to replace $P/poly$ by $\mathrm{AC}^0[\mathrm{PARITY}]$ (the class of constant depth circuits with the gates $\{\mathrm{AND},\mathrm{OR},\mathrm{NOT},\mathrm{PARITY}\}$ of unbounded fan-in).

Recently, Grinberg, Shaltiel and Viola (FOCS 2018) (building on a sequence of earlier works) showed that these limitations cannot be circumvented by *black-box reductions*. Namely, by reductions $\mathrm{Red}^{(\cdot)}$ that given oracle access to a function D that violates the conclusion of Yao's XOR lemma, implement a circuit that violates the assumption of Yao's XOR lemma.

There are a few known reductions in the related literature on worst-case to average case reductions that are *non-black box*. Specifically, the reductions of Gutfreund, Shaltiel and Ta Shma (Computational Complexity 2007) and Hirahara (FOCS 2018)) are "class reductions" that are only guaranteed to succeed when given oracle access to an oracle D from some efficient class of algorithms. These works seem to circumvent some black-box impossibility results.

In this paper we extend the previous limitations of Grinberg, Shaltiel and Viola to class reductions, giving evidence that class reductions cannot yield the desired improvements in Yao's XOR lemma. To the best of our knowledge, this is the first limitation on reductions for hardness amplification that applies to class reductions.

Our technique imitates the previous lower bounds for black-box reductions, replacing the inefficient oracle used in that proof, with an efficient one that is based on limited independence, and developing tools to deal with the technical difficulties that arise following this replacement.

1 Introduction

Yao's XOR Lemma is a fundamental and celebrated result in complexity theory, that is extensively studied (from various aspects) and has found many applications. See [9] for a survey article.

▶ **Definition 1** (The XOR function). *Given a $f : \{0,1\}^k \to \{0,1\}$, and a number t, we define $f^{\oplus t} : \{0,1\}^{t \cdot k} \to \{0,1\}$, as follows: Given $y \in \{0,1\}^{t \cdot k}$, we view y as $(y_1, \ldots, y_t) \in (\{0,1\}^k)^t$, and define:*

$$f^{\oplus t}(y) = f(y_1) \oplus \ldots \oplus f(y_t)$$

Let U_k denote the uniform distribution on k bit strings. Loosely speaking, Yao's XOR lemma says that if a function f is "mildly hard one average" on input $X \leftarrow U_k$, then as t increases, computing $f^{\oplus t}$ on input $Y \leftarrow U_{tk}$, becomes "very hard on average".

▶ **Lemma 2** (Yao's XOR lemma, for poly-size circuits). *For every $f : \{0,1\}^k \to \{0,1\}$, and $t \leq \text{poly}(k)$ such that $t = \omega(\log k)$:*

If, for every $\text{poly}(k)$ size circuit C, $\Pr_{X \leftarrow U_k}[C(X) = f(X)] < \frac{2}{3}$,

Then, for every constant c, and every $\text{poly}(k)$ size circuit D, $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] < \frac{1}{2} + \frac{1}{k^c}$.[1]

One weakness of Yao's XOR lemma, is that it cannot be used to conclude a statement in which the "hardness on average" $\frac{1}{2} + \frac{1}{k^c}$ is replaced by $\frac{1}{2} + \frac{1}{k^{\omega(1)}}$. This holds, even if the number of repetitions t is increased from slightly larger than $\log k$ (as is the case in Lemma 2) to the maximal choice of $t = \text{poly}(k)$. Specifically, the following question is wide open:

▶ **Open problem 3** (Yao's XOR lemma for subpolynomial error?). *Is it true that for every $f : \{0,1\}^k \to \{0,1\}$, taking $t = \omega(\log k)$ (or even the maximal choice of $t = \text{poly}(k)$) it holds that:*

If, for every $\text{poly}(k)$ size circuit C, $\Pr_{X \leftarrow U_k}[C(X) = f(X)] < \frac{2}{3}$,

Then, for every $\text{poly}(k)$ size circuit D, $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] < \frac{1}{2} + \frac{1}{k^{\omega(1)}}$,

Another weakness of Yao's XOR Lemma is that known proofs fail to prove Yao's XOR lemma when replacing *P/poly* with many interesting constant depth circuit classes. An especially frustrating case is the class $\text{AC}^0[\text{PARITY}]$ of poly-size constant depth circuits over the gates $\{\text{AND,OR,NOT,PARITY}\}$ of unbounded fan-in. There are known lower bounds showing explicit functions that have hardness $\frac{2}{3}$ for $\text{AC}^0[\text{PARITY}]$ (or even $\frac{1}{2} - o(1)$ hardness for circuits of depth d and size $2^{k^{\Omega(1/d)}}$ [25, 28]) but lower bounds with hardness $\frac{1}{2} - \frac{1}{k}$ are unknown. This is a twenty five year old barrier that prevents us from "using the hybrid argument" when constructing pseudorandom generators for $\text{AC}^0[\text{PARITY}]$ (and related classes). This barrier limits the best known pseudorandom generators for $\text{AC}^0[\text{PARITY}]$ (and related classes) [6] to very poor seeds (See [6] for a discussion of this limitation). Specifically, the following question is wide open:

▶ **Open problem 4** (Yao's XOR lemma for constant depth circuits?). *Let G be the set of gates $\{\text{AND,OR,NOT,PARITY}\}$ of unbounded fan-in. Is it true that for every $f : \{0,1\}^k \to \{0,1\}$, taking $t = \omega(\log k)$ (or even the maximal choice of $t = \text{poly}(k)$) it holds that:*

If, for every $\text{poly}(k)$ size, constant-depth circuit C with gates in G, $\Pr_{X \leftarrow U_k}[C(X) = f(X)] < \frac{2}{3}$,

Then, for every $\text{poly}(k)$ size, constant-depth circuit D, with gates in G, $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] < \frac{1}{2} + \frac{1}{k}$,

[1] Naturally, in order to make this asymptotic statement precise, one needs to consider an infinite sequence of functions $\{f_k\}$ with growing input length (so that terms like "poly-size", "$\omega(\log k)$", and "constant" are well defined). We allow ourselves to be imprecise, as a more general, and quantitatively precise statement of Yao's XOR lemma is given below in Lemma 5.

1.1 Proofs of Yao's Lemma as (nonuniform) black-box reductions

Before discussing the best known proofs of Yao's XOR Lemma, let us state the lemma more precisely, in a more general and quantitative form. The next formulation is achieved using Impagliazzo's proof of Yao's XOR lemma [18, 9] together with the quantitative improvement of Klivans and Servedio [21] of Impagliazzo's hard-core lemma [18].

▶ **Lemma 5** (Yao's XOR lemma, General version). *There exist a constant c, and a polynomial p, such that for every $f : \{0,1\}^k \to \{0,1\}$, every $\epsilon, \delta > 0$, and every $t \geq c \cdot \frac{\log(1/\epsilon)}{\delta}$, setting $q = c \cdot \frac{\log(1/\delta)}{\epsilon^2}$, we have that:*

If, for every circuit C of size $s \geq p(t,k,q)$, $\Pr_{X \leftarrow U_k}[C(X) = f(X)] < 1 - \delta$,

Then, for every circuit D of size $s' = \frac{s}{q}$, $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] < \frac{1}{2} + \epsilon$.

The special case of Lemma 2 is obtained by taking s to be a polynomial in k, and $\delta = \frac{1}{3}$. In order to reduce the number of live parameters, we recommend that the reader focuses on these choices on a first reading. We point out that s' (which is the size of D) is smaller by a factor of $q = \Omega(\frac{1}{\epsilon^2})$, than s (which is the size of C). This implies that $s' \leq O(\epsilon^2 \cdot s)$, implying that $\epsilon \geq \Omega(\frac{1}{\sqrt{s}})$, and it is impossible to get $\epsilon < \frac{1}{s}$ with current proofs. (This is a more quantitative way to state the phenomenon in open problem 3).

All known proofs of Yao's XOR lemma work by *reduction*. That is, the proof shows a reduction that transforms a circuit D such that $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] \geq \frac{1}{2} + \epsilon$, into a circuit C such that $\Pr_{X \leftarrow U_k}[C(X) = f(X)] \geq 1 - \delta$. All known proofs are "nonuniform black-box reductions", meaning that they provide a reduction (namely an oracle circuit $\mathrm{Red}^{(\cdot)}(x, \alpha)$ where x is an input, and α is an "advice string") and the circuit C is obtained by $C(x) = \mathrm{Red}^D(x, \alpha)$ where α is an "nonuniform advice string" that may depend on f and D.[2] This is made precise in the next definition.

▶ **Definition 6** (Nonuniform black-box reduction for Yao's XOR lemma). *Let $\epsilon, \delta > 0$, and let k, t, a be integers. A $(\frac{1}{2} + \epsilon) \to (1 - \delta)$* black-box reduction for Yao's XOR lemma *(with input length k, t repetitions and advice length a) is an oracle circuit $\mathrm{Red}^{(\cdot)}(x, \alpha)$, where $x \in \{0,1\}^k$ and $\alpha \in \{0,1\}^a$, such that for every $f : \{0,1\}^k \to \{0,1\}$, the following holds:*

For every function $D : \{0,1\}^{tk} \to \{0,1\}$, such that $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] \geq \frac{1}{2} + \epsilon$,

there exists $\alpha \in \{0,1\}^a$, such that $\Pr_{X \leftarrow U_k}[\mathrm{Red}^D(X, \alpha) = f(X)] \geq 1 - \delta$.

The version of Yao's XOR lemma stated in Lemma 5, follows by showing the following reduction:

▶ **Lemma 7** (Known black-box reductions for Yao's XOR lemma). *There exist a constant c, and a polynomial p, such that for every integer k, every $\epsilon, \delta > 0$ such that $1 - \delta > \frac{1}{2} + \epsilon$, and every $t \geq c \cdot \frac{\log(1/\epsilon)}{\delta}$, there is a $(\frac{1}{2} + \epsilon) \to (1 - \delta)$ black-box reduction $\mathrm{Red}^{(\cdot)}(x, \alpha)$ for Yao's XOR lemma with input length k, t repetitions, and advice length a such that:*

- *R makes at most $q = c \cdot \frac{\log(1/\delta)}{\epsilon^2}$ queries to its oracle.*
- *R is an oracle circuit of size $r = p(t,k,q)$, (and in particular, $a \leq r$).*
- *R is an oracle circuit of constant depth d over the gates $\{AND, OR, NOT\}$ of unbounded fan-in and also uses one majority gate with fan-in q.*

[2] There is a formal connection between "black box hardness amplification" and list-decodable error correcting code [29], see for example the discussion in [27, 10]. Using this connection, it is known that black-box reductions for Yao's XOR lemma, must be nonuniform and use an advice string if $1 - \delta > \frac{1}{2} + \epsilon$ and $\epsilon < \frac{1}{4}$.

In order to understand the limitations that prevent known proofs from solving the aforementioned open problems, it is instructive to see how Lemma 5 follows from Lemma 7. Specifically, assume (for contradiction) that Lemma 5 does not hold and let D be a circuit of size s' that is violating the conclusion. By Lemma 7, there exists $\alpha \in \{0,1\}^a$, such that the circuit $C(x) = \mathrm{Red}^D(x,\alpha)$ computes $f(X)$ with success $1-\delta$ on $X \leftarrow U_k$. The size of C is bounded by $s = r + a + q \cdot s' \geq q \cdot s'$, and the obtained circuit C has depth at least d, and needs to compute majority on q bits. Summing up:

- The number of queries q made by the reduction is a lower bound on $\frac{s}{s'}$, meaning that $s' \leq \frac{s}{q}$ and as the known reductions have $q \geq \frac{1}{\epsilon^2}$ we cannot expect $\epsilon < \frac{1}{\sqrt{s}}$, and cannot solve open problem 3.
- The fact that the best known reductions requires a majority gate on $q \geq \frac{1}{\epsilon}$ inputs, means that we need to assume hardness against a class that can perform this computation. For $\epsilon = 1/k$, Razborov's lower bound [25] (see also [24]) shows that for every depth d', majority on k bits, cannot be computed by circuits of depth d' and size $2^{k^{\Omega(1/d')}}$ over the gates $\{\text{AND},\text{OR},\text{NOT},\text{PARITY}\}$, explaining why current reductions cannot solve open problem 4.

Limitations on black-box reductions

A sequence of works [32, 27, 12, 3, 2] culminating in [10], shows that known black-box reductions for Yao's XOR lemma must suffer from the limitations above: They require $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$ queries, and require computing majority on input length $\Omega(\frac{1}{\epsilon})$.[3]

1.2 Class reductions

On a closer examination, black-box reductions seem to be an overkill for the task of proving Yao's XOR lemma. For proving Yao's XOR lemma, we don't need $\mathrm{Red}^{(\cdot)}$ to succeed given oracle access to *every* function D such that $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] \geq \frac{1}{2} + \epsilon$. It is sufficient that Red succeeds only given oracle access to functions D that are *efficiently computable* and belong to the class $\mathcal{D}$ of circuits with size s' (if we're in the setup of open problem 3) and size s' with constant depth (if we're in the setup of open problem 4).

This motivates a notion of *class reduction* (suggested for example in [14]) in which reductions are only required to succeed if given oracle access to a function D that belongs to some class $\mathcal{D}$ of "efficient circuits", and do not need to succeed when given oracle access to a function D that does not belong to $\mathcal{D}$. The definition of *class $\mathcal{D}$ reduction* below is identical to definition 6 with the single exception (that is underlined for emphasis) being that we only require the reduction to succeed when given oracle access to a function D from the class $\mathcal{D}$.

▶ **Definition 8** (Nonuniform class reduction for Yao's XOR lemma)**.** *Let $\epsilon, \delta > 0$ and let k, t, a be integers, and let $\mathcal{D}$ be some class of functions $D : \{0,1\}^{tk} \to \{0,1\}$. A $(\frac{1}{2}+\epsilon) \to (1-\delta)$* class $\mathcal{D}$ reduction for Yao's XOR lemma *(with input length k, t repetitions and advice length a) is an oracle circuit $\mathrm{Red}^{(\cdot)}(x,\alpha)$, where $x \in \{0,1\}^k$ and $\alpha \in \{0,1\}^a$, such that for every $f : \{0,1\}^k \to \{0,1\}$, the following holds:*

For every function $D : \{0,1\}^{tk} \to \{0,1\}$ in the class $\mathcal{D}$, such that $\Pr_{Y \leftarrow U_{tk}}[D(Y) = f^{\oplus t}(Y)] \geq \frac{1}{2} + \epsilon$,

there exists $\alpha \in \{0,1\}^a$, such that $\Pr_{X \leftarrow U_k}[\mathrm{Red}^D(X,\alpha) = f(X)] \geq 1 - \delta$.

[3] More formally, saying that $\mathrm{Red}^{(\cdot)}$ "requires computing majority on input length $\Omega(1/\epsilon)$" means that every such reduction $\mathrm{Red}^{(\cdot)}$ can be transformed into a circuit (with no oracle) of roughly the same size and depth as $\mathrm{Red}^{(\cdot)}$ for computing the majority function on inputs of length $\Omega(\frac{1}{\epsilon})$.

Note that a black-box reduction is a special case of a class reduction where $\mathcal{D}$ is the class of all boolean functions on tk bits. This raises the following questions:

1. Are there reductions in the literature that are class reductions but not black-box reductions?
2. Can class reductions circumvent the limitations on black-box reductions and solve open problem 3 or open problem 4?

The answer to the first question is affirmative in the sense that there are at least two examples that we are aware of, where a worst-case to average case amplification is proven by a reduction that is not black-box. Furthermore, in both cases, the reduction is a class reduction, and there is strong evidence that it cannot be made black-box.

The first example is a worst-case hardness to average case hardness tradeoff for SAT (with respect to a distribution sampled in quasipolynomial time) by Shaltiel, Gutfreund and Ta-Shma [13] (see also a related work [4, 11, 14]). The correctness of the reduction of [13] relies on the efficiency of the oracle and the term "class reduction" was suggested by Gutfreund and Ta-Shma [14]. It was also argued in [14] that limitations on black-box reductions proven by Bogdanov and Trevisan [5] can be extended to the scenario studied in [13], and show that if the class reduction of [13] (which is non-adaptive) could be made also black-box, then co-NP has nondeterministic circuits of quasipolynomial size.

Another example is Hirahara's recent worst-case to average case reductions for variants of MCSP and MINKT [17]. These reductions are non-black-box, in the sense that their correctness relies on the efficiency of their oracle. The aforementioned work of Bogdanov and Trevisan [5] shows that if these reductions can be made black-box, then these problems are in co-NP/poly, which is not known, and is false, if these problems are NP-complete. See [17] for an elaborate discussion of consequences of the existence of such black-box reductions.

1.3 Our results: limitations on class reductions for Yao's XOR lemma

In this paper we give evidence that the answer to the second question above is negative. We extend the aforementioned limitations of [10] on black-box reductions for Yao's XOR lemma to *class reductions* for any $\mathcal{D}$ of that contains circuits that have polynomial size and constant depth over the gates $\{\text{AND},\text{OR},\text{NOT},\text{PARITY}\}$ with unbounded fan-in. To the best of our knowledge, this is the first example of proving limitations on class reductions in this setup. Our results are stated formally in the next theorem.[4]

▶ **Theorem 9** (Limitations on class reductions for Yao's XOR lemma). *There exist constants $\delta_0 > 0$, $\nu > 0$, $d_0 > 1$ and a polynomial p such that: Let $\mathrm{Red}^{(\cdot)}(x,\alpha)$ be a $(\frac{1}{2}+\epsilon) \to (1-\delta)$ class $\mathcal{D}$ reduction for Yao's XOR lemma, with input length k, t repetitions and advice length a. Assume that:*

- *$\mathrm{Red}^{(\cdot)}$ is a size r oracle circuit, that makes at most q queries.*
- *The class $\mathcal{D}$ contains circuits of size $p(r)$ and depth d_0 over the gates $\{\text{AND},\text{OR},\text{NOT},\text{PARITY}\}$ of unbounded fan-in.*
- *$t, a, \frac{1}{\epsilon}, \frac{1}{\delta} \leq r \leq 2^{\nu \cdot k}$ and $\delta \leq \delta_0$.*

Then the following holds:

[4] We remark that any circuit of size r over the gates $\{\text{AND},\text{OR},\text{NOT},\text{PARITY}\}$ with unbounded fan-in, cannot use fan-in larger than r, and therefore can be simulated by a circuit of size $O(r^2)$ over the standard gates $\{\text{AND},\text{OR},\text{NOT}\}$ with bounded fan-in. This allows us to state our results in a way that captures both circuits of small depth (using gates with unbounded fan-in) and circuits that use the standard gates with bounded fan-in.

- $\text{Red}^{(\cdot)}$ *requires many queries, specifically:* $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$.
- $\text{Red}^{(\cdot)}$ *requires majority, specifically: if in addition to the size restriction on* Red*, we also have that* $\text{Red}^{(\cdot)}$ *is an oracle circuit of depth* d *over a set of gates* G *that contains the gates* $\{$AND,OR,NOT,PARITY$\}$ *of unbounded fan-in, then the majority function over* $\Omega(\frac{1}{\epsilon})$ *bits can be computed by a circuit of size* $\text{poly}(r)$ *and depth* $O(d)$ *over the set of gates* G.

What kind of reductions are ruled out by this result?

Theorem 9 achieves exactly the same limitations on *class reductions* for Yao's XOR lemma as the limitations of [10] for *black-box reductions*. This is achieved for any class $\mathcal{D}$ that contains small circuits with constant depth over the gates $\{$AND,OR,NOT,PARITY$\}$ of unbounded fan-in, which is exactly the classes that come up if one wants to use class reductions to solve open problems 3 and 4. This shows that a class reduction cannot circumvent the known limitations on black-box reductions, and additional ideas are needed for solving open problems 3 and 4.

More specifically, for the purpose of solving open problem 3 one wants a $(\frac{1}{2} + \frac{1}{k^{\omega(1)}}) \to \frac{2}{3}$ class $\mathcal{D}$ reduction $\text{Red}^{(\cdot)}$ for Yao's XOR lemma, of size $\text{poly}(k)$, for the class $\mathcal{D}$ of all circuits of size $\text{poly}(k)$. This is ruled out by our lower bound on the number of queries. For the purpose of solving open problem 4 one wants a $(\frac{1}{2} + \frac{1}{k}) \to \frac{2}{3}$ class $\mathcal{D}$ reduction for Yao's XOR lemma, of size $\text{poly}(k)$ and constant depth over the gates $G = \{$AND,OR,NOT,PARITY$\}$, for the class $\mathcal{D}$ of all circuits of size $\text{poly}(k)$ and constant depth over the gates G. This is ruled out by our results that $\text{Red}^{(\cdot)}$ requires majority on inputs of length $\Omega(k)$, and Razborov's lower bound [25] showing that this cannot be done by circuits of depth d' and size $2^{k^{\Omega(1/d)}}$.

A potential weakness of our impossibility results, is that they require that the class $\mathcal{D}$ has circuits of size larger than the reduction (although it is allowed that $\mathcal{D}$ contains only circuits of smaller depth than the reduction). This allows a scenario in which for every polynomial p_1, there exists a larger polynomial p_2 such that there is a $(\frac{1}{2} + \frac{1}{k^{\omega(1)}}) \to \frac{2}{3}$ class $\mathcal{D}_{p_1}$ reduction Red_{p_1} of size $p_2(k)$ for the class $\mathcal{D}_{p_1}$ of circuits of size $p_1(k)$ (but not for the class of circuits of size $p(p_2(k))$ where p is the polynomial in Theorem 9). This is sufficient for solving open problem 3 and is not ruled out by our impossibility results.

An optimistic view is that this may point us to the kind of reductions we need to design, in order to solve the aforementioned open problems. We remark however that the aforementioned reduction by Hirahara [17] *does not* need to assume that the oracle is weaker than the reduction. (The reduction of [13] involves a more complicated scenario where there is also a third entity which is the samplable distribution, and so, it is arguable whether the reduction is more powerful than the oracle).

Theorem 9 is weaker than the results of [10] in the sense that the limitations of [10] apply not only to Yao's XOR lemma, but to *any* hardness amplification technique. More precisely, in the results of [10] one can replace $f^{\oplus t}$ by any other function f' over $n = 2^{o(k)}$ bits, with the same limitations. Our approach cannot give such a general result, but can be extended as follows:

Extension to any efficient hardness amplification construction

Our results immediately extend to any function f' over $n = 2^{o(k)}$ bits such that f' can be efficiently computed given access to f. More precisely, in Theorem 9 one can replace occurrences of the parameter t by n, and the theorem extends to any function f' such that there exists an oracle circuit $\text{Con}^{(\cdot)}$ of size $\text{poly}(r)$, and constant depth over the gates $\{$AND,OR,NOT,PARITY$\}$ of unbounded fan-in, such that $f' = \text{Con}^f$. Moreover, if we omit the restriction that $\text{Con}^{(\cdot)}$ has constant depth, then the theorem holds with respect to any class $\mathcal{D}$ that contains circuits of size $p(r)$.

Extension to hardness amplification based on sufficiently explicit linear codes

Using ideas from [32], our results also extend to the case of $\delta = 2^{-2k}$ (which captures worst-case to average case hardness amplification) for functions f' over $n = 2^{o(k)}$ bits, such that:

$$f'(y) = \sum_{x \in \{0,1\}^k} f(x) \cdot g(x,y),$$

where the sum is taken in the field $\mathbb{F}_2$, and $g : \{0,1\}^k \times \{0,1\}^n \to \{0,1\}$ can be computed by circuits of size $\text{poly}(r)$ and depth d over the set G of gates.

This definition of f' corresponds to "hardness amplification by a linear map". More specifically, we can view g as a matrix A of order $2^k \times 2^n$ over $\mathbb{F}_2$ by $A_{x,y} = g(x,y)$, and view the truth tables of the functions f, f' as vectors over $\mathbb{F}_2$ of dimension 2^k, 2^n, respectively. In this interpretation, the definition of f' above, says that $f' = f \cdot A$, for a matrix A in which the entry $A_{x,y}$ can be efficiently computed given x, y.

Many worst-case to average-case hardness amplification results in the literature choose f' so that the truth table f' is obtained by applying an error correcting code on the truth table of f. (It was observed in [29] that there is a formal connection between black-box reductions for hardness amplification, and list-decodable error correcting codes, see for example [10] for a discussion). Typical choices of this error correcting code are linear codes (most commonly Reed-Muller concatenated with Hadamard) and our results apply to this scenario, with the weaker conclusion that $q = \Omega(\frac{\log r}{\epsilon^2})$, and the same conclusion for the case of majority.

Perspective

Limitations for black-box reductions are extensively studied in various settings in complexity theory and cryptography. In order to prove impossibility results on black-box reduction, it is sufficient to show the existence of an oracle D (*that does not need to be efficient*) on which the reduction cannot succeed.

Many impossibility results and limitations in the literature strongly utilize the ability to choose an oracle D that is not efficient. One notable example is the aforementioned results of Bogdanov and Trevisan [5] (that build on earlier work of Feigenbaum and Fortnow [7]). Indeed, this is why these limitations do not apply to class reductions like the aforementioned results [13, 17].

This work puts an emphasis on whether or not the oracle D that one designs when showing a black-box impossibility result, can be made efficient, and demonstrates that achieving this, has the additional benefit of also ruling out class reductions.

1.4 Some more related work

It is beyond the scope of this paper to survey the vast literature on Yao's XOR lemma and hardness amplification. The reader is referred to [9] for a survey on Yao's XOR lemma, and to [32, 27, 10] for detailed discussions on the more general problem hardness amplification.

A significant advantage of Yao's XOR lemma (over some other suggested methods of hardness amplification) is that the "construction" $f' = f^{\oplus t}$ can be computed very efficiently, when given oracle access to f. A line of work (that is orthogonal to studying the complexity of *reductions* for hardness amplification) is interested in the complexity of *constructions* yielding hardness amplification. This line of work is mostly interested in starting from worst-case hard functions (which correspond to $\delta < 2^{-k}$) and aims to design (or prove impossibility results for) efficient constructions $\text{Con}^{(\cdot)}$ for which one can prove that if f has hardness $1 - \delta$, then $f' = \text{Con}^f$ has hardness $\frac{1}{2} + \epsilon$. (See e.g., [30, 31, 23, 15] for further discussion).

In this orthogonal line of work, there are examples of *constructions* which are non-black-box, and utilize specific properties of the function f (for example that $f \in \text{NP}$ or that f is a low degree polynomial). This is a different form of "non-black-box" than the one studied in this paper, and it is interesting to combine the two orthogonal directions.

There is a large body of work on proving black-box impossibility results in cryptography. This study was initiated by Impagliazzo and Rufich [19] and is concerned both with issues that are related to black-box constructions and to black-box reductions. See for example the discussion in Reingold, Trevisan and Vadhan [26] for a taxonomy of various notions.

2 Technique and a road map for proof

Our results are obtained by carefully examining the argument of the black-box impossibility result of [10], replacing the inefficient oracle with an efficient one, and handling the technical difficulties arising from this modification.

In this section we survey our technique, and give a roadmap of the proof of Theorem 9. We assume the setup of Theorem 9. Specifically, let $\text{Red}^{(\cdot)}(x,\alpha)$ be a $(\frac{1}{2}+\epsilon) \to (1-\delta)$ class $\mathcal{D}$ reduction for Yao's XOR lemma, with input length k, t repetitions and advice length a, which satisfies the requirements of the theorem. Let r be the size of Red and let d (which is not necessarily a constant) be the depth of Red. Our goal is to show that $\text{Red}^{(\cdot)}$ requires many queries, and that $\text{Red}^{(\cdot)}$ requires majority.

Let $f : \{0,1\}^k \to \{0,1\}$ be some function that we choose later, and let $n = tk$ be the input length of $f^{\oplus t}$. We start by surveying the approach of of the previous papers (which only handle *black-box* reductions rather than *class* reductions).

2.1 The approach of [32, 27]

We first introduce the following notation.

▶ **Definition 10** (Random sequences/functions). *For a number $0 \le p \le 1$, and an integer q, we define a distribution Noise^q_p over $\{0,1\}^q$ which consists of q i.i.d. bit variables $\mathsf{Noise}^q_p(1),\ldots,\mathsf{Noise}^p_q(q)$ where each of them has probability p to be one. This notation also allows us to view Noise^q_p as a distribution over functions from $[q]$ to $\{0,1\}$.*

Following [32, 27] (and as done in later works [12, 10]) our plan is to show that a $(\frac{1}{2}+\epsilon) \to (1-\delta)$ reduction $\text{Red}^{(\cdot)}(x,\alpha)$ that makes q queries, can be transformed into a (distribution) over circuits $T : \{0,1\}^q \to \{0,1\}$ with no oracle (that have roughly the same size and depth as Red) that distinguishes $\mathsf{Noise}^q_{1/2-2\epsilon}$ from $\mathsf{Noise}^q_{1/2}$. We will prove the following lemma (which we call the "zoom lemma").

▶ **Lemma 11** (Zoom lemma). *Under the assumption of Theorem 9, for every $x \in \{0,1\}^k$, there exists a circuit T_x over q bits, with size $\text{poly}(r)$ and depth $O(d)$ over the set of gates G, such that:*

- $\Pr_{X \leftarrow U_k}[T_X(\mathsf{Noise}^q_{1/2-2\epsilon}) = 1] \ge 1 - 2\delta$.
- $\Pr_{X \leftarrow U_k}[T_X(\mathsf{Noise}^q_{1/2}) = 1] \le \frac{1}{2} + \frac{1}{200}$.

Shaltiel and Viola [27] (see also [22]) showed that Theorem 9 follows from Lemma 11. This is formally stated and explained in Section A.[5]

[5] On an intuitive level, the connection between the consequence of the zoom lemma and the consequence of Theorem 9 is that the "best way" to distinguish $\mathsf{Noise}^q_{1/2-2\epsilon}$ from $\mathsf{Noise}^q_{1/2}$ is to check whether the

In the remainder of this section, we prove Lemma 11 modulo some other lemmas and claims, that are stated in this section, and proven in later sections of the paper.

2.2 The oracle used for black-box reductions

Lemmas that are similar to the zoom lemma are at the heart of earlier results [27, 12, 10] on *black-box* reductions, and we would like to imitate the argument working with *class* reductions. Let us start by explaining the oracle used in previous works.

Specifically, let us set $N = 2^n$ and identify the set $[N]$ with the set $\{0,1\}^n$ (so that we can think of Noise_p^N as a function $\mathsf{Noise}_p^N : \{0,1\}^n \to \{0,1\}$). We consider the following two (distributions over) oracles $D : \{0,1\}^n \to \{0,1\}$.

- $D_{1/2-2\epsilon}(y) = f^{\oplus t}(y) \oplus \mathsf{Noise}_{1/2-2\epsilon}^N(y)$
- $D_{1/2}(y) = f^{\oplus t}(y) \oplus \mathsf{Noise}_{1/2}^N(y)$.

▶ **Definition 12.** *We say that a function $D : \{0,1\}^n \to \{0,1\}$ is* useful*, if there exists an $\alpha \in \{0,1\}^a$ such that $\Pr_{X \leftarrow U_k}[\mathrm{Red}^D(X,\alpha) = f^{\oplus t}(X)] \geq 1 - \delta$.*

In the oracle $D_{1/2}$, the noise $\mathsf{Noise}_{1/2}^N(y)$ is uniform and completely masks out the information in $f^{\oplus t}(y)$. Intuitively, this means that the oracle $D_{1/2}$ isn't useful for the reduction. On the other hand, a Chernoff bound shows that w.h.p. over choosing $h \leftarrow \mathsf{Noise}_{1/2-2\epsilon}^N$, we have that $|\{y \in \{0,1\}^n : h(y) = 1\}| \leq (\frac{1}{2} - \epsilon) \cdot N$. This gives that w.h.p. over choosing $D \leftarrow D_{1/2-2\epsilon}$, we have that $\Pr_{Y \leftarrow U_n}[D(Y) = f^{\oplus t}(Y)] \geq \frac{1}{2} + \epsilon$.

If Red is a $(\frac{1}{2} + \epsilon) \to (1 - \delta)$ *black-box* reduction, then by definition, this implies that every such good D is useful. The proof of [32, 27] then proceeds to transform a *black-box* reduction Red into the circuits T_x required from Lemma 11. We will elaborate on this argument shortly.

Our plan is to imitate this argument when Red is not necessarily a *black-box reduction*, and is only guaranteed to be a *class* reduction. Using this weaker assumption, we are not guaranteed that w.h.p. $D \leftarrow D_{1/2-2\epsilon}$ is useful. This is because we are not guaranteed that w.h.p. $D \leftarrow D_{1/2-2\epsilon}$ belongs to the class $\mathcal{D}$, and the reduction does not need to succeed if $D \notin \mathcal{D}$.

2.3 Using limited independence to obtain efficient oracles

We would like to make the oracle $D_{1/2-2\epsilon}$ efficiently computable by small circuits, so that it belongs to $\mathcal{D}$. This presents two difficulties:

1. $f^{\oplus t}$ is harder to compute than f (and f is assumed to be hard).
2. $\mathsf{Noise}_{1/2-2\epsilon}^N$ is a random function, and w.h.p. requires circuits of exponential size.

In order to circumvent the first problem we use an idea from [32] and will choose the function $f : \{0,1\}^k \to \{0,1\}$ in the following way:

▶ **Lemma 13.** *There exist constants c_1 such that for every constant c_2, there exists a function $f : \{0,1\}^k \to \{0,1\}$ such that:*

- *For every circuit $B : \{0,1\}^k \to \{0,1\}$ of size r^{c_2}, $\Pr_{X \leftarrow U_k}[B(X) = f(X)] \leq \frac{1}{2} + \frac{1}{200}$.*
- *f can be computed by a DNF of size $r^{c_1 \cdot c_2}$.*

fraction of ones is below or above $\frac{1}{2} - \epsilon$. This is similar in spirit to majority over inputs of length $\Omega(1/\epsilon)$, and it can be shown that majority on length $\Omega(1/\epsilon)$ can be reduced to this task. A Chernoff bound shows that $q = O(\frac{\log(1/\delta)}{\epsilon^2})$ is sufficient to distinguish between the two distributions with confidence $1 - \delta$, and it can be shown that such a confidence requires $q = \Omega(\frac{\log(1/\delta)}{\epsilon^2})$.

Proof. By a standard counting argument, there exists a constant c_1 such that for every constant c_2, setting $m = c_1 \cdot c_2 \cdot \log r$, there exists a function $g : \{0,1\}^m \to \{0,1\}$ such that for every circuit B of size $2^{m/c_1} = r^{c_2}$, $\Pr_{X \leftarrow U_m}[B(X) = g(X)] \leq \frac{1}{2} + \frac{1}{200}$. By choosing $\nu > 0$ to be sufficiently small as a function of c_2, we can get that $m \leq k$. The function $f : \{0,1\}^k \to \{0,1\}$ is the function that given $x \in \{0,1\}^k$ applies g on the first m bits of x. ◀

We choose f by the lemma, where c_2 is a constant that we choose later. With this choice we have that:

▶ **Corollary 14.** *The function $f^{\oplus t}$ can be computed by circuits of size* $\mathrm{poly}(r)$ *and constant depth over the gates* $\{$AND,OR,NOT,PARITY$\}$ *of unbounded fan-in.*

▶ Remark 15 (Replacing $f^{\oplus t}$ by a different target function f'). Corollary 14 is the only place in the proof where we use specific properties of $f^{\oplus t}$. The corollary holds for every function $f' : \{0,1\}^n \to \{0,1\}$ for which there exists an oracle circuit $\mathrm{Con}^{(\cdot)}$ of size $\mathrm{poly}(r)$ and constant depth over the gates $\{$AND,OR,NOT,PARITY$\}$ of unbounded fan-in, such that $f' = \mathrm{Con}^f$. This means that our results hold for every such function f'. Furthermore, if Con does not have constant depth, then Corollary 14 gives a size bound on f', and this is sufficient to show the lower bound on number of queries with respect to the class $\mathcal{D}$ of circuits of size $p(r)$.

Corollary 14 takes care of the first difficulty above. It says that $f^{\oplus t}$ can be computed by circuits in the class $\mathcal{D}$. We would like to replace $\mathsf{Noise}^N_{1/2-2\epsilon}$ by a (distribution) over efficient circuits in $\mathcal{D}$. Our approach is to replace $\mathsf{Noise}^N_{1/2-2\epsilon}$ (which consists of N independent bits) by a distribution which is ℓ-wise independent, for $\ell = \mathrm{poly}(r)$.

▶ **Definition 16** (ℓ-wise independence with bias p)**.** *A sequence $R_1, \ldots, R_N$ of bit random variables is ℓ-wise independent with bias p, if $R_1, \ldots, R_N$ are ℓ-wise independent, and for every $i \in [N]$, $\Pr[R_i = 1] = p$.*

We will rely on the following theorem by Gutfreund and Viola [16] (which is usually stated for $p = \frac{1}{2}$ but immediately extends to every rational $p = \frac{a}{b}$ as stated below:)

▶ **Theorem 17** ([16])**.** *Let $N = 2^n$. For every integers $\ell \leq N$ and $a \leq b$, setting $p = \frac{a}{b}$, there exists a distribution H^ℓ_p over circuits $h : \{0,1\}^n \to \{0,1\}$ of size* $\mathrm{poly}(n, \ell, b)$ *and depth $O(1)$ (over the gates* $\{$AND,OR,NOT,PARITY$\}$ *of unbounded fan-in) such that the distribution obtained by choosing $h \leftarrow H^\ell_p$ and considering $(h(1), \ldots, h(N))$, is ℓ-wise independent with bias p.*[6]

We will assume w.l.o.g. that $\frac{1}{\epsilon}$ is an integer, and set $\ell = p_0(r)$ for a polynomial p_0 that we will specify later. We define the following two (distributions over) oracles $D : \{0,1\}^n \to \{0,1\}$, in which we replace the independent bits of Noise^N by ℓ-wise independent bits:[7]

---

[6] We remark that the result of Gutfreund and Viola [16] is significantly stronger. More specifically, for our purposes it suffices that there is a family H of ℓ-wise independent hash functions $h : \{0,1\}^n \to \{0,1\}^b$, such that every h can be computed by the type of circuits claimed above. The result of Gutfreund and Viola gives a stronger bound on the size of H, and also shows that there is a *uniform* circuit that given the "index of h" and an input x, computes $h(x)$.

[7] Replacing fully independent oracles by limited independence oracles, and arguing that black-box procedures with few queries cannot tell the difference, is a common approach in proving black-box impossibility results, originating from the work of Goldreich and Krawczyk [8]. It should be noted that even when ignoring the issue of class reductions, and focusing on black-box reductions, we are considering reductions which are *nonuniform*. Nonuniform reductions get an advice string α that depends on the choice of the oracle. Loosely speaking, this may give them information about the "seed" used to generate the limited independence oracle. This creates technical difficulties that do not occur when reductions are uniform.

- $D^{\ell}_{1/2-2\epsilon}(y) = f^{\oplus t}(y) \oplus H^{\ell}_{1/2-2\epsilon}(y)$
- $D^{\ell}_{1/2}(y) = f^{\oplus t}(y) \oplus H^{\ell}_{1/2}(y)$.

We now have that every D in the support of $D^{\ell}_{1/2-2\epsilon}$ has size $r^{c_1 \cdot c_2} + \mathrm{poly}(n, \ell, 1/\epsilon)$ which can be bounded by $p(r)$ for some polynomial p. Furthermore, each such D has constant depth over the set of gates $\{\text{AND},\text{OR},\text{NOT},\text{PARITY}\}$. This gives that every such D is sufficiently efficient, and belongs to the class $\mathcal{D}$.

This will allow us to imitate the argument for black box reductions. Specifically, by Chebyshev's inequality, with probability at least $1 - \frac{1}{\epsilon^2 2^n} \geq \frac{1}{2}$ over choosing $h \leftarrow H^{\ell}_{1/2-2\epsilon}$, we have that $|\{y \in \{0,1\}^n : h(y) = 1\}| \leq (\frac{1}{2} - \epsilon) \cdot N$. This means that with probability at least half over choosing $D \leftarrow D^{\ell}_{1/2-2\epsilon}$, we have that $\Pr_{Y \leftarrow U_n}[D(Y) = f^{\oplus t}(Y)] \geq \frac{1}{2} + \epsilon$. As Red is a $(\frac{1}{2} + \epsilon) \to (1 - \delta)$ class $\mathcal{D}$ reduction, and every such good D belongs to $\mathcal{D}$, we get that:

▷ Claim 18. $\Pr_{h \leftarrow H^{\ell}_{1/2-2\epsilon}}[(f^{\oplus t} \oplus h) \text{ is useful}] \geq \frac{1}{2}$.

2.4 A more general fixed set lemma

We will now proceed in a similar manner to [27, 10]. Specifically, let Advice be a function that given a useful D, produces an advice string α such that $\Pr_{X \leftarrow U_k}[\mathrm{Red}^D(x, \alpha) = f^{\oplus t}(y)] \geq 1 - \delta$ (such an α exists by definition). For every $\alpha \in \{0,1\}^a$, let A_α be the event

$$A_\alpha = \{h : \{0,1\}^n \to \{0,1\} : (f^{\oplus t} \oplus h) \text{ is useful, and } \mathsf{Advice}(f^{\oplus t} \oplus h) = \alpha\}.$$

By averaging over the 2^a advice strings we obtain that:

▷ Claim 19. There exists $\alpha' \in \{0,1\}^a$ s.t. $\Pr_{h \leftarrow H^{\ell}_{1/2-2\epsilon}}[h \in A_{\alpha'}] \geq \frac{1}{2} \cdot 2^{-a} = 2^{-(a+1)}$.

Let $R = H^{\ell}_{1/2-2\epsilon}$ and $Z = (R | R \in A_{\alpha'})$, following [27, 10] we would like to argue that (in some sense to be explained below) for every $x \in \{0,1\}^k$, $\mathrm{Red}^{(\cdot)}(x, \alpha')$ does not distinguish between the oracle $f^{\oplus t} \oplus Z$ (in which bits can be correlated in complicated ways) and the oracle $f^{\oplus t} \oplus R$ (in which bits are ℓ-wise independent). Note that for every $x \in \{0,1\}^k$, and $h : \{0,1\}^n \to \{0,1\}$, we can think of $\mathrm{Red}^{f^{\oplus t} \oplus h}(x, \alpha')$ as a decision tree (that depends on x) that makes q queries to (the truth table of) h.

With this intuition in mind, we will prove the following lemma (which generalizes a "fixed set lemma" proven in [10] for the special case where the random variables $R_1, \ldots, R_N$ are independent).

▶ **Lemma 20** (A more general fixed set lemma)**.** *Let N, a and q be integers, and let $R = (R_1, \ldots, R_N)$ be some distribution, let $A \subseteq \{0,1\}^N$ be an event such that $\Pr[R \in A] \geq 2^{-a}$, and let $Z = (R | R \in A)$. For every $\eta > 0$, there exists a set $B \subseteq [N]$ of size $b \leq O(a \cdot q/\eta)$, and $v \in \{0,1\}^B$ in the support of Z_B, such that for $R' = (R | R_B = v)$ and $Z' = (Z | Z_B = v) = (R | R_B = v, R \in A)$, and every q-query decision tree P, $P(R')$ and $P(Z')$ are η-close.*[8]

Loosely speaking, the proof works by showing that if there exists a q-query decision tree that distinguishes R from Z, then by fixing the variables on some path of that tree, one obtains a distribution R' such that $\Pr[R' \in A] \geq \Pr[R \in A] \cdot (1 + \eta)$. We apply this argument iteratively (using R' as R) until there does not exist a q query decision tree that distinguishes

[8] Two distributions X, Y over the same domain S are η-close if for every $A \subset S$, $|\Pr[X \in A] - \Pr[Y \in A]| \leq \eta$.

R from Z. In each iteration, $\Pr[R \in A]$ increases by a factor of $1+\eta$, and as this probability cannot be larger than one, this process has to stop after $O(a/\eta)$ steps. By then, we have fixed no more than $O(qa/\eta)$ of the variables. The full proof of Lemma 20 appears in Section 4.[9]

We now continue with the proof of Lemma 11. We apply Lemma 20 on $R = H^{\ell}_{1/2-2\epsilon}$ and the event A'_{α}, using $\eta = \delta$, and let Z, R', Z', B, v and b be as in the lemma. It follows that for every $x \in \{0,1\}^k$, the random variables $\mathrm{Red}^{f^{\oplus t} \oplus R'}(x, \alpha')$ and $\mathrm{Red}^{f^{\oplus t} \oplus Z'}(x, \alpha')$ are δ-close. As this holds for every fixed $x \in \{0,1\}^k$, this also holds for an independently chosen $X \leftarrow U_k$, and we obtain that:

$$\Pr[\mathrm{Red}^{f^{\oplus t} \oplus R'}(X, \alpha') = f(X)] \geq \Pr[\mathrm{Red}^{f^{\oplus t} \oplus Z'}(X, \alpha') = f(X)] - \delta.$$

The support of Z' is contained in $A_{\alpha'}$, and so, for every h in the support of Z', $(f^{\oplus t} \oplus h)$ is useful (with the advice string α') and we get that:

$$\Pr_{X \leftarrow U_k}[\mathrm{Red}^{f^{\oplus t} \oplus Z'}(X, \alpha') = f(X)] \geq 1 - \delta. \tag{1}$$

Combining this with the previous inequality, gives that:

$$\Pr[\mathrm{Red}^{f^{\oplus t} \oplus R'}(X, \alpha') = f(X)] \geq 1 - 2\delta. \tag{2}$$

The advantage of (2) over (1) is that we have replaced Z' (in which the bits of $Z'([N] \setminus B)$ can be correlated in complicated ways) with R', where $R'([N] \setminus B)$ is $(\ell - b)$-wise independent. This will allow us to relate this oracle to $\mathsf{Noise}^q_{1/2-2\epsilon}$ and prove the zoom lemma.

2.5 Constructing the circuits for the zoom lemma

In order to construct the circuits required for the zoom lemma, we define the following oracle circuit.

▶ **Definition 21.** *We define an oracle circuit $E^{(\cdot)}(x)$ as follows: On input x and oracle h, $E^h(x)$ simulates* $\mathrm{Red}^{(\cdot)}(x, \alpha')$. *Whenever* Red *makes a query y to its oracle, R acts as follows: if $y \notin B$, then R makes the query y to h, and returns $f^{\oplus t}(y) \oplus h(y)$ to* Red. *If $y \in B$, then R returns $f^{\oplus t}(y) \oplus v(y)$ to* Red. *The output of R is the output of* Red *at the end of this simulation.*

With this definition, it is possible to show that:

▶ **Lemma 22.** *By choosing the constant c_2 and the polynomial p_0 to be sufficiently large, we get that:*

- $\Pr[E^{H^q_{1/2-2\epsilon}}(X) = f(X)] \geq 1 - 2\delta$.
- $\Pr[E^{H^q_{1/2}}(X) = f(X)] \leq \frac{1}{2} + \frac{1}{200}$.
- *For every $x \in \{0,1\}^k$, there exists a circuit $T_x : \{0,1\}^q \to \{0,1\}$ of size* $\mathrm{poly}(r)$ *and depth $O(d)$ over the gates G, such that for every $0 \leq p \leq 1$, $T_x(\mathsf{Noise}^q_p) = E^{H^q_p}(x)$.*

We note that this lemma immediately implies Lemma 11. The proof of Lemma 22 appears in Section 3, and is similar in spirit to earlier work [27, 12, 10]. It is in fact significantly simpler, as in this paper, we have the additional advantage that $f^{\oplus t}$ has circuits of size $\mathrm{poly}(r)$ and constant depth.

---

[9] The proof of the fixed set lemma given in [10] also uses an iterative argument: It shows that the existence of a q-query decision tree gives rise to a new distribution Z where the entropy of Z is increased. It is then argued that the iterative process has to stop before (as the entropy of Z is upper bounded by N). This limits the earlier proofs to distributions R where $Z = (R|R \in A)$ has very high entropy, which isn't the case for our choice of oracle.

Organization of the paper

We prove Lemma 22 in Section 3. In Section 4 we prove the more general fixed set lemma (that is Lemma 20). In Appendix A we state and survey the results of [27] showing that the zoom lemma implies the main theorem. In Appendix B we explain how to extend the argument to sufficiently explicit linear codes.

3 Proof of Lemma 22

In this section we prove Lemma 22. We start by proving the first item. Note that $b = O(qa/\delta)$ is bounded by some polynomial in r. We are allowed to choose the polynomial p_0 to be sufficiently large so that $\ell = p_0(r)$ satisfies $(\ell - b) \geq q$. This gives that the $N - b$ coordinates of $R'([N] \setminus B)$ are $(\ell - b)$-wise independent (because R' was obtained by fixing b indices of R which is ℓ-wise independent). The fact that $R'([N] \setminus B)$ are q-wise independent, and that E answers queries in B using v, gives that for every $x \in \{0,1\}^k$, the q queries made by $E^{H^q_{1/2-2\epsilon}}(x)$ are distributed exactly like the queries of $\mathrm{Red}^{f^{\oplus t} \oplus R'}(x, \alpha')$, meaning that:

$$\Pr[E^{H^q_{1/2-2\epsilon}}(x) = f(x)] = \Pr[\mathrm{Red}^{f^{\oplus t} \oplus R'}(x, \alpha') = f(x)].$$

This immediately means that for an independent $X \leftarrow U_k$:

$$\Pr[E^{H^q_{1/2-2\epsilon}}(X) = f(X)] = \Pr[\mathrm{Red}^{f^{\oplus t} \oplus R'}(X, \alpha') = f(X)].$$

We have already seen in (2) that:

$$\Pr[\mathrm{Red}^{f^{\oplus t} \oplus R'}(X, \alpha') = f(X)] \geq 1 - 2\delta,$$

and this gives the first item.

For the second item, we note that if $E^{H^q_{1/2}}$ makes a query $y \notin B$, then it obtains a uniform coin, and the coins obtained on different queries are independent. Recall that on queries $y \in B$, E answers the queries without consulting the oracle. This means that we can simulate $E^{H^q_{1/2}}(x)$ by a randomized circuit $\bar{C}$ that on input x, simulates E and answers queries $y \notin B$ by random coins. It follows that for every $x \in \{0,1\}^k$:

$$\Pr[E^{H^q_{1/2}}(x) = f(x)] = \Pr[\bar{C}(x) = f(x)].$$

This immediately means that for an independent $X \leftarrow U_k$:

$$\Pr[E^{H^q_{1/2}}(X) = f(X)] = \Pr[\bar{C}(X) = f(X)].$$

There exists some fixing for the random coins of $\bar{C}$ such that the obtained (deterministic) circuit C satisfies $Pr[C(X) = f(X)] \geq \Pr[\bar{C}(X) = f(X)]$. The circuit C is hardwired with this choice of random coins, and with α', B, v, and $f^{\oplus t}(B)$. (A crucial observations is that C does not need to compute $f^{\oplus t}$ for $y \notin B$). Overall, this is a circuit of size r^c for some constant c, and by choosing the constant c_2 from to be a larger constant, and using Lemma 13, we have that:

$$\Pr[E^{H^q_{1/2}}(X) = f(X)] \leq \Pr[C(X) = f(X)] \leq \frac{1}{2} + \frac{1}{200}.$$

This proves the second item.

For the third item, we note (once again) that for every p, and for every $x \in \{0,1\}^k$, the distribution of the q answers that $E^{H^q_p}$ obtains from its oracle is distributed like Noise^q_p. This means that for every x, we can construct a circuit T_x that on input Noise^q_p simulates $E^{H^q_p}(x)$,

using its i'th input to answer the i'th query of E. The circuit T_x is hardwired with α', B and v. Unlike the circuit C from the second item, T_x needs to compute $f^{\oplus t}$ on each of the q queries. This can be done using Corollary 14. Overall, T_x is a circuit of size $\text{poly}(r)$ (this time the polynomial is larger than r^{c_2}) and depth $O(d)$ (because on every oracle call of Red, T_x may have to compute $f^{\oplus t}$ (which takes constant depth according to Corollary 14).[10]

4 The fixed set lemma for ℓ-wise independence

In this section we prove Lemma 20. The proof will iteratively applying the following lemma.

▶ **Lemma 23.** *Let $R = (R_1, \ldots, R_N)$ be a distribution, let $A \subseteq \{0,1\}^N$ be an event, and let $Z = (R|R \in A)$. If there exists a q-query decision tree P such that $|\Pr[P(R) = 1] - \Pr[P(Z) = 1]| > \eta$ then there exists $Q \subset [N]$ of size q and $v \in \{0,1\}^Q$ in the support of Z_Q, such that*

$$\Pr[R \in A | R(Q) = v] > (1 + \eta) \cdot \Pr[R \in A].$$

Proof. Let P be a q-query decision tree, and assume w.l.o.g. (by complementing P if necessary) that $\Pr[P(Z) = 1] - \Pr[P(R) = 1] > \eta$. A path in the decision tree corresponds to a subset $Q \subset [N]$ of the q variables queried on the path, and a string $v \in \{0,1\}^q$ of the answers. For every such path, let $path_{Q,v} : \{0,1\}^N \to \{0,1\}$ be the function that evaluates to 1 on input $r = (r_1, \ldots, r_N)$ if $r(Q) = v$ (meaning that the tree P takes the path (Q, v) on input r). Let S be the set of all pairs (Q, v) corresponding to paths of P that answer 1. The path taken by a decision tree is unique, and therefore, for any distribution R on $\{0,1\}^N$, we have that:

$$\Pr[P(R) = 1] = \sum_{(Q,v) \in S} \Pr[path_{Q,v}(R) = 1].$$

▷ Claim 24. There exists a path $(Q, v) \in S$ such that:

$$\Pr[path_{Q,v}(Z) = 1] > (1 + \eta) \cdot \Pr[path_{Q,v}(R) = 1].$$

Proof of claim. This is because otherwise:

$$\begin{aligned}
\Pr[P(Z) = 1] &= \sum_{(Q,v) \in S} \Pr[path_{Q,v}(Z) = 1] \\
&\leq (1 + \eta) \cdot \sum_{(Q,v) \in S} \Pr[path_{Q,v}(R) = 1] \\
&= (1 + \eta) \cdot \Pr[P(R) = 1] \\
&\leq \Pr[P(R) = 1] + \eta.
\end{aligned}$$

◁

[10] Our proof of Lemma 22 relies on the fact that $f^{\oplus t}$ has small constant depth circuits. This allows us to simplify the argument used by some of the previous work [27, 12, 10] which wasn't allowed to assume that the target function $f' = f^{\oplus t}$ can be computed by a small constant depth circuit. The proofs in [27, 12, 10] need to resort to different arguments (and this creates additional difficulties if Red makes adaptive calls to its oracle, meaning that the queries that $\text{Red}^{(\cdot)}(x, \alpha')$ makes are not a function of x and α', and may also depend on previous answers). However, using a clever hybrid argument of [12] and additional ideas explained in [10], it is possible to conclude that T_x has depth $O(d)$ *without* relying on the fact that f' is computable by constant depth circuits. This argument allows choosing f' where $f' = \text{Con}^f$ for an oracle circuit Con that has size $\text{poly}(r)$, but does not necessarily has constant depth, and this gives the aforementioned extension of Theorem 9 to this setup, which now holds for every class $\mathcal{D}$ that contains circuits of size $\text{poly}(r)$.

In particular, the event $\{R(Q) = v\}$ occurs with positive probability, and it follows that:

$$\begin{aligned}\Pr[R \in A | R(Q) = v] &= \frac{\Pr[R \in A \cap R(Q) = v]}{\Pr[R(Q) = v]} \\ &= \frac{\Pr[R \in A] \cdot \Pr[R(Q) = v | R \in A]}{\Pr[path_{Q,v}(R) = 1]} \\ &= \frac{\Pr[R \in A] \cdot \Pr[Z(Q) = v]}{\Pr[path_{Q,v}(R) = 1]} \\ &= \frac{\Pr[R \in A] \cdot \Pr[path_{Q,v}(Z) = 1]}{\Pr[path_{Q,v}(R) = 1]} \\ &> (1+\eta) \cdot \Pr[R \in A].\end{aligned}$$

◀

We are now ready to prove Lemma 20.

Proof of Lemma 20. We consider the following iterative process: At step i, we have:

- A distribution $R^{(i)}$ over $\{0,1\}^N$.
- A set $B^{(i)} \subseteq [N]$.
- $v^{(i)} \in \{0,1\}^{B^{(i)}}$.

We will assume that the following invariant is satisfied:

- $B^{(i)}$ is of size $i \cdot q$.
- $\Pr[R^{(i)} \in A] \geq 2^{-a} \cdot (1+\eta)^i$.
- $R^{(i)}(B^{(i)}) = v^{(i)}$ (with probability one).

Note that the assumption in the lemma fulfills this invariant for $i = 0$ with $R^{(0)} = R.$ and $B^{(0)} = \emptyset$.

At step i, we define $\bar{R} = R^{(i)}([N] \setminus B^{(i)})$. As $R^{(i)}$ is fixed on $B^{(i)}$, we can think of A as an event that only observes the indices in $[N] \setminus B^{(i)}$. More formally, there is an event $\bar{A} \subseteq \{0,1\}^{[N] \setminus B^{(i)}}$ such that $R^{(i)} \in A$ iff $\bar{R} \in \bar{A}$, and

$$\Pr[\bar{R} \in \bar{A}] = \Pr[R^{(i)} \in A] \geq 2^{-a} \cdot (1+\eta)^i.$$

Let $\bar{Z} = (\bar{R} | \bar{R} \in \bar{A})$. If the conclusion of Lemma 20 does not hold with respect to $B^{(i)}, v^{(i)}$, then there exists a q-query decision tree P that distinguishes $R^{(i)}$ from $(R^{(i)} | R^{(i)} \in A)$, with advantage η, and as the two distributions agree on the queries in $B^{(i)}$, we conclude that P distinguishes $\bar{R}$ from $\bar{Z}$ with the same advanatge. We apply Lemma 23 on $\bar{R}$ and $\bar{A}$, and conclude that there exists $Q \subseteq [N] \setminus B^{(i)}$ and $v \in \{0,1\}^Q$ such that

$$\Pr[\bar{R} \in \bar{A} | \bar{R}(Q) = v] > (1+\eta) \cdot \Pr[\bar{R} \in \bar{A}] \geq 2^{-a} \cdot (1+\eta)^{i+1}.$$

We set:

- $B^{(i+1)} = B^{(i)} \cup Q$.
- $v^{(i+1)}$ to be the "concatenation of $v^{(i)}$ and v". More precisely, for $y \in B^{(i)}$, $v_y^{(i+1)} = v_y^{(i)}$ and for $y \in Q$, $v_y^{(i+1)} = v_y$.
- $R^{(i+1)} = (R^{(i)} | R^{(i)}(Q) = v)$. (Note that by definition $B^{(i)} \cap Q = \emptyset$).

We now observe that the invariant is maintained in step $i+1$. Specifically:

- $|B^{(i+1)}| = |B^{(i)}| + q = i \cdot q + q = (i+1) \cdot q$.
- $\Pr[R^{(i+1)} \in A] = \Pr[R^{(i)} \in A | R^{(i)}(Q) = v] = Pr[\bar{R} \in \bar{A} | \bar{R}(Q) = v] \geq 2^{-a} \cdot (1+\eta)^{i+1}$.
- By definition, $R^{(i+1)}(B^{(i+1)}) = v^{(i+1)}$ with probability one.

Therefore, if this process fails to deliver the lemma after i steps, then the invariant is maintained at the end of step i, and in particular, $\Pr[R^{(i)} \in A] \geq 2^{-a} \cdot (1+\eta)^i$. However, this is impossible for $i > \frac{a}{\log(1+\eta)} = \Theta(a/\eta)$, and so, this process has to deliver the lemma within this number of steps. We obtain that the lemma follows with $b = |B| \leq O(\frac{qa}{\eta})$. ◀

5 Conclusion and open problems

Class reductions are known to bypass some limitations on black-box reductions (as explained in Section 1.2). This work demonstrates that it is sometimes possible to extend limitations on black-box reductions to class reductions. Studying the power of class reductions may promote our understanding of how to bypass limitations on black-box reductions. We now mention some more specific open problems:

- Unlike the results of [10], our results do not hold for any construction of target functions f' from f. Is it possible to extend our results to this general setting?
- In Theorem 9, the class $\mathcal{D}$ contains circuits that are polynomially larger than the size of the the reduction. Is it possible to extend our limitations on class reductions with respect to a classes $\mathcal{D}$ of circuits smaller than the circuit size of the reduction?
- Yao's XOR lemma states that *for every* function f, if f is somewhat hard, then $f^{\oplus t}$ is very hard. It makes sense to focus on some specific choice for a somewhat hard function f and prove and improved result for this specific function. If we prove such an assertion by reduction, we can allow the reduction to be tailored to the specific function f, and do no need to require that the reduction performs on any function f, but only on the chosen one. This type of reductions was termed "function specific" by Artemenko and Shaltiel [3], who proved limitations on nonuniform black-box functions specific reductions. It is interesting to understand whether function specific class reductions can circumvent the limitations proven in this paper. We remark that our proof technique indeed relies on the fact that the reduction is not function specific, and must work for *any* function f. This allows us to choose f with specific properties that are useful for our argument.

A Showing that the main theorem follows from the zoom lemma

In this section we show that Theorem 9 follows from Lemma 11. This follows by the earlier work of Shaltiel and Viola [27] which we now explain.

A.1 Consequences distinguishing noise $\frac{1}{2}$ from $(\frac{1}{2} - 2\epsilon)$

The next lemma shows that distinguishing between $\mathsf{Noise}^q_{1/2-2\epsilon}$ and $\mathsf{Noise}^q_{1/2}$ requires many queries.

▶ **Lemma 25** ([32, 27]). *For every $\epsilon, \delta > 0$, such that $\delta < 0.4$, if $T : \{0,1\}^q \to \{0,1\}$ satisfies:*

- $\Pr[T(\mathsf{Noise}^q_{1/2-2\epsilon}) = 1] \geq 1 - \delta$.
- $\Pr[T(\mathsf{Noise}^q_{1/2}) = 1] \leq 0.51$.

Then, $q = \Omega(\frac{\log \frac{1}{\delta}}{\epsilon})$.

The next lemma essentilly shows that distinguishing between $\mathsf{Noise}^q_{1/2-2\epsilon}$ and $\mathsf{Noise}^q_{1/2}$ requires majority on $\Omega(1/\epsilon)$ bits. A technicality is that for this conclusion it is not sufficient to distinguish $\mathsf{Noise}^q_{1/2-2\epsilon}$ from $\mathsf{Noise}^q_{1/2}$, and one needs circuits that distinguish $\mathsf{Noise}^q_{1/2-\frac{2}{j}}$ from $\mathsf{Noise}^q_{1/2}$ for every integer j between 1 and $\log(1/\epsilon)$. This complication is in some sense necessary (see discussion in [27]).

▶ **Lemma 26** ([32, 27]). *For every $\epsilon, \delta > 0$, such that $\delta < 0.4$, and $\frac{1}{\epsilon}$ is an integer. If $T_1, \ldots, T_{\frac{1}{\epsilon}}$ are circuits over q bits, with size $s \geq q$ and depth d (over some set of gates G that includes the standard set $\{\text{AND}, \text{OR}, \text{NOT}\}$ with unbounded fan-in) and for every $j \in [\frac{1}{\epsilon}]$, we have that:*

- $\Pr[T_j(\mathit{Noise}^q_{1/2-\frac{2}{j}}) = 1] \geq 1 - \delta$.
- $\Pr[T_j(\mathit{Noise}^q_{1/2}) = 1] \leq 0.51$.

Then, there exists a circuit A that computes the majority function over $\Omega(\frac{1}{\epsilon})$ bits, and A has size $s \cdot \mathrm{poly}(\frac{1}{\epsilon})$ and depth $d + O(1)$ over the same set of gates G.

A.2 Finishing up

We now have have all the tools to prove that Theorem 9 follows from Lemma 11. We will assume w.l.o.g. that $\frac{1}{\epsilon}$ is an integer. We first observe that a $(\frac{1}{2} + \epsilon) \to (1 - \delta)$ class $\mathcal{D}$ reduction for Yao's XOR lemma, is in particular a $(\frac{1}{2} + \frac{1}{j}) \to (1 - \delta)$ class $\mathcal{D}$ reduction for Yao's XOR lemma, for every $j \in [\frac{1}{\epsilon}]$.

This means that for every $j \in [\frac{1}{\epsilon}]$, we can apply Lemma 11 choosing the parameter ϵ to be $\epsilon = \frac{1}{j}$, and for each such j and $x \in \{0,1\}^k$ we obtain a circuit T^j_x over q bits with size $\mathrm{poly}(r)$ and depth $O(d)$ over the set of gates G such that:

- $\Pr_{X \leftarrow U_k}[T^j_X(\mathsf{Noise}^q_{1/2-\frac{2}{j}}) = 1] \geq 1 - 2\delta$.
- $\Pr_{X \leftarrow U_k}[T^j_X(\mathsf{Noise}^q_{1/2}) = 1] \leq \frac{1}{2} + \frac{1}{200}$.

Applying Markov's inequality to the second item of the lemma, we obtain that there exists a constant $\beta > 0$ such that for every j, for a β fraction of $x \in \{0,1\}^k$,

$$\Pr[T^j_x(\mathsf{Noise}^q_{1/2}) = 1] \leq 0.51.$$

Applying Markov's inequality to the first item of the lemma, we obtain that for every j, for a $1 - \beta/2$ fraction of $x \in \{0,1\}^k$,

$$\Pr[T^j_x(\mathsf{Noise}^q_{1/2-\frac{2}{j}}) = 1] \leq 1 - \frac{4 \cdot \delta}{\beta} \leq 1 - \frac{4 \cdot \delta_0}{\beta}.$$

Together, this gives that for every j, there exists $x \in \{0,1\}^k$ that satisfies both inequalities. Theorem 9 now follows directly from Lemma 25 and Lemma 26, by choosing the constant $\delta_0 > 0$ to be sufficiently small.[11]

B Extending the argument to sufficiently explicit linear codes

We now prove the extension of our results to sufficiently explicit linear codes which is stated in Section 1.3. More specifically, we will prove a version of Theorem 9 that assumes that $\delta = 2^{-2k}$ and replace replace $f^{\oplus t}$ by a function $f' : \{0,1\}^n \to \{0,1\}$ defined by:

$$f'(y) = \sum_{x \in \{0,1\}^k} f(x) \cdot g(x,y),$$

where the sum is taken in the field $\mathbb{F}_2$, and $g : \{0,1\}^k \times \{0,1\}^n \to \{0,1\}$ can be computed by circuits of size $\mathrm{poly}(r)$ and depth d over the set G of gates.

This argument is based on a trick by Viola [32] that we can incorporate into our framework. We will modify the proof of Lemma 11 so that it holds in this setting, the modified version of Theorem 9 will follow from Lemma 11 just as before.

We start by replacing the function f of Lemma 13 with a sightly different function:

[11] The argument above is wasteful, and leads to a rather small constant $\delta_0 > 0$. We remark that with a more careful argument, we could have chosen δ_0 to be any constant smaller than $\frac{1}{2}$, and even allow it to approach $\frac{1}{2}$. More specifically, a more careful analysis can allow $\delta_0 = \frac{1}{2} - O(\log(1/\epsilon))$.

▶ **Lemma 27.** *There exist constants c_1 such that for every constant c_2, there exists a function $f : \{0,1\}^k \to \{0,1\}$ such that there exists $m \leq c_1 \cdot c_2 \cdot \log r$ such that:*

- *For every circuit $B : \{0,1\}^k \to \{0,1\}$ of size r^{c_2}, $\Pr_{X \leftarrow U_m}[B(X \circ 0^{k-m}) = f(X \circ 0^{k-m})] \leq \frac{1}{2} + \frac{1}{200}$.*
- *f can be computed by a DNF of size $r^{c_1 \cdot c_2}$.*

Proof. We repeat the proof of Lemma 13, but this time we take $f(x)$ to be the following function: Let x' denote the first m bits of x and x'' denote the remaining $k-m$ bits. We define $f(x)$ to be $g(x')$ if $x'' = 0^{k-m}$ and zero otherwise. ◀

On a random $X \leftarrow U_k$, $\Pr[f(X) = 0] \geq 1 - 2^{k-m} = 1 - 2^{-\Omega(k)}$. Therefore, it is very easy to compute f with success probability $1 - 2^{-\Omega(k)}$ by simply answering zero. However, by Lemma 27 it is hard for circuits of size r^{c_2} to compute f with success probability 1, or equivalently success probability $1 - \delta$ for $\delta = 2^{-2k}$. This is why this approach can only succeed for very small δ.

With this choice, we can get a corollary that is analogous to Corollary 14.

▶ **Corollary 28.** *The function f' can be computed by circuits of size* $\mathrm{poly}(r)$ *and constant depth over the gates* $\{$AND,OR,NOT,PARITY$\}$ *of unbounded fan-in.*

Proof. The function f' is defined by:

$$f'(y) = \sum_{x \in \{0,1\}^k} f(x) \cdot g(x,y).$$

The sum ranges over 2^k choices of x. However, for our function f, except for $\mathrm{poly}(r)$ of these x (the ones for which the second part of x is $k-m$ zeros) all the remaining x have $f(x) = 0$. This, together with the requirement on g, gives the required result. ◀

The proof proceeds as in Section 2, with the following modifications:

- For $\delta = 2^{-2k} < 2^{-k}$, Red is a $(\frac{1}{2} + \epsilon) \to 1$ reduction. This means in particular that if D is useful, then there exists $\alpha \in \{0,1\}^a$ such that $\Pr_{X \leftarrow U_m}[\mathrm{Red}^D(X \circ 0^{k-m}, \alpha) = f(X \circ 0^{k-m})] = 1$.
- We set $\delta' = \frac{1}{r}$ and will replace some occurrences of δ in the earlier argument by δ'. This is done because the choice of $\delta = 2^{-2k}$ does not satisfy the requirement that $\frac{1}{\delta} \leq r$ made in Theorem 9. Specifically, the requirement that $\frac{1}{\delta} \leq r$ was used to argue that when we apply Lemma 20 with $\eta = \delta$, the size of the set B (which is polynomial in $\frac{1}{\eta}$) is polynomial in r. In order to obtain a set B of size $\mathrm{poly}(r)$ we will now choose $\eta = \delta'$.
- In Section 2.4 we argued that for an independent $X \leftarrow U_k$:

  $$\Pr[\mathrm{Red}^{f^{\oplus t} \oplus R'}(X, \alpha') = f(X)] \geq \Pr[\mathrm{Red}^{f^{\oplus t} \oplus Z'}(X, \alpha') = f(X)] - \delta.$$

  With our modifications we get that for an independent $X \leftarrow U_m$:

  $$\Pr[\mathrm{Red}^{f' \oplus R'}(X \circ 0^{k-m}, \alpha') = f(X \circ 0^{k-m})] \geq \Pr[\mathrm{Red}^{f^{\oplus t} \oplus Z'}(X, \alpha') = f(X)] - \delta'.$$

- This allows us to continue the argument, replacing occurrences of $X \leftarrow U_k$ by $X \circ 0^{k-m}$ for $X \leftarrow U_m$, and occurrences of δ by δ'.
- When we finish the proof and obtain a lower bound of $q = \Omega(\frac{\log(1/\delta')}{\epsilon^2}) = \Omega(\frac{\log r}{\epsilon^2})$ as required. The result on majority is not affected by replacing δ by δ'.

Balanced Allocation on Dynamic Hypergraphs

Abstract

The balls-into-bins model randomly allocates n sequential balls into n bins, as follows: each ball selects a set D of $d \geqslant 2$ bins, independently and uniformly at random, then the ball is allocated to a least-loaded bin from D (ties broken randomly). The *maximum load* is the maximum number of balls in any bin. In 1999, Azar et al. showed that, provided ties are broken randomly, after n balls have been placed the *maximum load*, is $\log_d \log n + \mathcal{O}(1)$, with high probability. We consider this popular paradigm in a dynamic environment where the bins are structured as a *dynamic hypergraph*. A dynamic hypergraph is a sequence of hypergraphs, say $\mathcal{H}^{(t)}$, arriving over discrete times $t = 1, 2, \ldots$, such that the vertex set of $\mathcal{H}^{(t)}$'s is the set of n bins, but (hyper)edges may change over time. In our model, the t-th ball chooses an edge from $\mathcal{H}^{(t)}$ uniformly at random, and then chooses a set D of $d \geqslant 2$ random bins from the selected edge. The ball is allocated to a least-loaded bin from D, with ties broken randomly. We quantify the dynamicity of the model by introducing the notion of *pair visibility*, which measures the number of rounds in which a pair of bins appears within a (hyper)edge. We prove that if, for some $\varepsilon > 0$, a dynamic hypergraph has pair visibility at most $n^{1-\varepsilon}$, and some mild additional conditions hold, then with high probability the process has maximum load $\mathcal{O}(\log_d \log n)$. Our proof is based on a variation of the witness tree technique, which is of independent interest. The model can also be seen as an adversarial model where an adversary decides the structure of the possible sets of d bins available to each ball.

1 Introduction

The standard balls-into-bins model is a process that randomly allocates m sequential balls into n bins, where each ball chooses a set D of d bins, independently and uniformly at random, then the ball is allocated to a least-loaded bin from D (with ties broken randomly). When $m = n$ and $d = 1$, it is well known that at the end of process the maximum number of balls

at any bin, the *maximum load*, is $(1 + o(1))\frac{\log n}{\log \log n}$, with high probability. Surprisingly, Azar et al. [2] showed that for this d-choice process with $d \geqslant 2$, provided ties are broken randomly, the maximum load exponentially decreases to $\log_d \log n + \mathcal{O}(1)$. This phenomenon is known as the *power of d choices*. The multiple-choice paradigm has been successfully applied in a wide range of problems from nearby server selection, and load-balanced file placement in the distributed hash table, to the performance analysis of dictionary data structures (e.g., see [21]). In the classical setting, all $\binom{n}{d}$ sets of d bins are available to each ball. However, in many realistic scenarios such as cache networks, peer-to-peer or cloud-based systems, the balls (requested files, jobs, items,..) have to be allocated to bins (servers, processors,...) that are close to them, in order to minimize the access latencies. On the other hand, the lack of perfect randomness stimulates the de-randomization of the d-choice process, which also requires the study of non-uniform distributions over choices (e.g. [1, 6, 7, 11]). Hence in many settings, allowing all possibilities for the set D of d bins is costly, and may not be practical. This motivates the investigation of the effect of distributions of the set D on the maximum load. In this regard, Kenthapadi and Panigrahy [13] proposed *balanced allocation* on graphs, where bins form the vertices of a Δ-regular graph and each ball chooses an edge of the graph uniformly at random. The ball is then placed in an endpoint of the selected edge with smaller load (ties are broken randomly). Kenthapadi and Panigrahy showed that the maximum load is $\Theta(\log \log n)$ if and only if $\Delta = n^{\Omega(1/\log \log n)}$. Here, one may see that the possibilities for the set D (the two chosen bins) is restricted to the set of $n\Delta/2$ edges of the graph. In the standard balls-into-bins model with $d = 2$, the underlying graph is a complete graph (all $\binom{n}{2}$ edges present). Following the study of balls-into-bins with related choices, Godfrey [12] utilized hypergraphs to model the structure of bins. In this model, each ball picks a random edge of a given hypergraph that contain $\Omega(\log n)$ bins and the hypergraph satisfies some mild conditions. Then, the ball is allocated to a least-loaded bin contained in the edge, with ties broken randomly. Godfrey showed that the maximum load is constant. Balanced allocation on graphs and hypergraphs has been further studied in [3, 4, 17, 18]. In the aforementioned works, either the underlying graph is fixed during the process or, in the hypergraph setting, the number d of choices satisfies $d = \Omega(\log n)$. However, in many real-world systems the structure may change over time, and probing the load of $\Omega(\log n)$ bins might be a costly task. Seeking a more realistic model, this paper studies the d-choice process in dynamic graphs and hypergraphs, where $2 \leqslant d = o(\log n)$.

Balanced allocation on dynamic hypergraphs can also be seen as an adversarial model, where the set D of potential choices is proposed by an adversary (environment) whose goal is to increase the maximum load. Here we want to understand the conditions under which the balanced allocation on dynamic (hyper)graphs still benefits from the effect of the power of d choices.

1.1 Our Results

We propose balanced allocation algorithms on different dynamic environments, namely dynamic graph and hypergraph models. In order to measure the dynamicity, we introduce the notion of *pair visibility*. For a pair $\{i, j\}$ of distinct vertices, the *visibility* of $\{i, j\}$, denoted by $\texttt{vis}(i, j)$, is the number of rounds $t \in \{1, \ldots, n\}$ such $\{i, j\}$ is contained in the edge chosen at round t. (A more formal definition is given below.) When ball i is placed into a bin, the *height* of ball i is the number of balls that were allocated to the bin before ball i. We say that event E_n holds with high probability (w.h.p.) if $\mathbf{Pr}[\mathsf{E}_n] \geqslant 1 - n^{-c}$ for every constant $c > 0$.

Balanced Allocation on Dynamic Hypergraphs

Write $[n] = \{1, \dots, n\}$ to be the set of n bins. A hypergraph $\mathcal{H} = ([n], \mathcal{E})$ is *s-uniform* if $|H| = s$ for every $H \in \mathcal{E}$. For every integer $n \geqslant 1$, let $s = s(n)$ be an integer such $2 \leqslant s \leqslant n$. A *dynamic s-uniform hypergraph*, denoted by $(\mathcal{H}^{(1)}, \mathcal{H}^{(2)}, \dots, \mathcal{H}^{(n)})$, is a sequence of s-uniform hypergraphs $\mathcal{H}^{(t)} = ([n], \mathcal{E}_t)$ with vertex set $[n]$. The edge sets $\mathcal{E}_t$ may change with t. A hypergraph is *regular* if every vertex is contained in the same number of edges.

In this paper, we are interested in the following properties which dynamic hypergraphs may satisfy. We refer to these properties as the *balancedness*, *visibility*, and *size* properties. The balancedness property is adapted from [3, 12].

Balancedness: Let H_t denote a randomly chosen edge from $\mathcal{E}_t$. If there exists a constant $\beta \geqslant 1$ such that $\mathbf{Pr}[i \in H_t] \leqslant \beta s/n$ for every $1 \leqslant t \leqslant n$ and each bin $i \in [n]$, then the dynamic hypergraph $(\mathcal{H}^{(1)}, \dots \mathcal{H}^{(n)})$ is β-balanced. A dynamic hypergraph is balanced if it is β-balanced for some constant $\beta \geqslant 1$. Every regular hypergraph is 1-balanced.

Visibility: For every pair of distinct vertices $\{i, j\} \subset [n]$, the visibility of $\{i, j\}$ is

$$\mathtt{vis}(i, j) = |\{t \in \{1, 2, \dots, n\} \mid \{i, j\} \subset H \in \mathcal{E}_t\}|.$$

If there exists a constant $\varepsilon \in (0, 1)$ such that $\mathtt{vis}(i, j) \leqslant sn^{1-\varepsilon}$ for all pairs $\{i, j\} \subseteq [n]$ of distinct bins then the dynamic hypergraph $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ is ε-visible. A dynamic hypergraph satisfies the visibility property if it is ε-visible for some constant $\varepsilon \in (0, 1)$.

Size: If $s = \Omega(\log n)$ and there exists a positive constant $c_0 \geqslant 1$ such that $|\mathcal{E}_t| \leqslant n^{c_0}$ for every $t \geqslant 1$, then the dynamic hypergraph $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ satisfies the c_0-size property. A dynamic hypergraph satisfies the size property if it satisfies the c_0-size property for some constant $c_0 \geqslant 1$.

▶ **Definition 1** (Balanced Allocation on Dynamic Hypergraphs). *Suppose that $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ is an s-uniform hypergraph and fix $d = d(n)$ with $2 \leqslant d = o(\log n)$ and $d \leqslant s$. The balanced allocation algorithm on $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ proceeds in rounds $(t = 1, 2, \dots, n)$, sequentially allocating n balls to n bins. In round t, the t-th ball chooses an edge H_t uniformly at random from $\mathcal{E}_t$, then it randomly chooses a set D_t of d bins from H_t (without repetition) and allocates itself to a least-loaded bin from D_t, with ties broken randomly.*

▶ **Theorem 2.** *Let $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ be a dynamic s-uniform hypergraph which satisfies the balancedness, ε-visibility and size properties. Fix $d = d(n)$ such that $2 \leqslant d = o(\log n)$. There exists $\Theta(n) \leqslant m \leqslant n$ such that after the balanced allocation process on $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ has allocated m balls, the maximum load is $\log_d \log n + \mathcal{O}(1/\varepsilon)$ with high probability. Moreover, for every fixed positive integer γ with $\gamma m \leqslant n$, after allocating γm balls the maximum load is at most $\gamma(\log_d \log n + \mathcal{O}(1/\varepsilon))$, w.h.p..*

▶ Remark 3. In our result we only consider the case where $d = o(\log n)$, because when $d = \Omega(\log n)$, a constant upper bound is obtained by [12]. The size property is mainly assumed for technical reasons. For instance, $|\mathcal{E}_t| \leqslant \mathrm{poly}(n)$ is not necessary. Roughly speaking, balanced allocation on a dynamic hypergraph with large $|\mathcal{E}_t|$ resembles the standard balls-into-bins process. So it might be possible that having more structural information about a dynamic hypergraph would enable us to extend our result to allow an arbitrary number of edges $|\mathcal{E}_t|$. Another possible extension of Theorem 2 would be to allow s to be a function of d.

Proof Technique. The proof of our main result (i.e., Theorem 2) is based on the witness tree technique, which has been applied in [1, 11, 13, 16, 20]. The standard 2-choice process simulates a random graph process, where any 2-element subset of bins chosen by a ball can be viewed as a random edge chosen from a complete graph. Kenthapadi and Panigrahi [13] replaced the underlying complete graph by a dense graph, say G, and each ball chooses a random edge from the graph. In this model, after allocating all n balls, the union of the chosen random edges builds a random subgraph of G. They showed that, with high probability, there does not exist a connected and random subgraph of size $\Omega(\log n)$ whose nodes (bins) each contain a constant number of balls. A rooted spanning tree contained in the subgraph is the witness structure. Now, if the maximum load is higher than a certain threshold, then a deterministic construction yields the witness graph, which is a rooted tree. Thus, the maximum load is bounded from above by the threshold. In this work, although we follow the same steps as [13], the witness structure is not as straightforward since the underlying structure is a dynamic hypergraph, $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$, and each ball chooses $d \geqslant 2$ bins. Here, the witness structure is a d-uniform hypergraph, say $H = (V, E)$, where (1) each node (bin) in V contains a constant number of balls, (2) $|V| = \Omega(\log n)$ and (3) H has an expansion property which means there is an ordering of the hyperedges of H so that with respect to this ordering, all but a constant number of hyperedges only shares one bin with the union of the preceding hyperedges. Applying the visibility condition we conclude that, with high probability, there does not exist a structure satisfying these three properties. Assuming a maximum load higher than a certain threshold, we recursively build the witness structure and the proof follows.

The following theorem presents a lower bound for the maximum load attained by the balanced allocation on some dynamic hypergraphs in terms of ε-visibility.

▶ **Theorem 4.** *Let $s = s(n) = n^{\varepsilon}$, where $\varepsilon \in (0, 1)$ is an arbitrary small real number. There exists a dynamic s-uniform hypergraph, say $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$, which satisfies the balancedness condition and (trivially) satisfies the ε-visibility condition. Let $2 \leqslant d \leqslant s$ be any integer which is constant. Suppose that the balanced allocation process on $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ has allocated n balls, then the maximum load is at least $\min\{\Omega(1/\varepsilon), \Omega(\log n/\log\log n)\}$ with high probability.*

Balanced Allocation on Dynamic Graphs

A dynamic graph is a special case of a dynamic hypergraph, where $s = s(n) = 2$ for all n. Write $(G^{(1)}, \ldots, G^{(n)})$ to denote a dynamic graph, where $G^{(t)} = ([n], E_t)$ for $t = 1, 2, \ldots, n$. Theorem 2 does not cover the case of graphs ($s = 2$), due to the size property. We will prove a result on balanced allocation for regular dynamic graphs.

▶ **Definition 5** (Balanced Allocation on Dynamic Graphs)**.** *Suppose that $(G^{(1)}, \ldots, G^{(n)})$ is a regular dynamic graph on vertex set $[n]$. The balanced allocation algorithm on $(G^{(1)}, \ldots, G^{(n)})$ proceeds in rounds $(t = 1, \ldots, n)$. In each round t, the t-th ball chooses an edge of $G^{(t)}$ uniformly at random, and the ball is then placed in one of the bins incident to the edge with a lesser load, with ties broken randomly.*

Say that the dynamic graph is *regular* if $G^{(t)}$ is Δ_t-regular for some positive integer Δ_t and all $t = 1, 2, \ldots, n$. For every pair of distinct bins $\{i, j\} \subset [n]$, we will assume that the visibility $\texttt{vis}(i, j)$ satisfies

$$\texttt{vis}(i, j) = |\{t \in \{1, 2, \ldots, n\} \mid \{i, j\} \in E_t\}| \leqslant 2n^{1-\varepsilon}$$

for some constant $\varepsilon \in (0, 1)$. This property is called ε-visibility.

▶ **Theorem 6.** *Let $(G^{(1)}, \dots, G^{(n)})$ be a regular dynamic graph which satisfies the ε-visibility condition, for some $\varepsilon \in (0,1)$. Suppose that the balanced allocation process on $(G^{(1)}, \dots, G^{(n)})$ has allocated n balls. Then the maximum load is at most $\log_2 \log n + \mathcal{O}(1/\varepsilon)$, with high probability.*

The proof, which can be found in Section 4, is again based on the witness tree technique. We remark that Theorem 6 can be extended to the case where the dynamic graph is *almost regular*, meaning that the ratio of the minimum and maximum degree of $G^{(t)}$ is bounded above by an absolute constant for $t = 1, \dots, n$.

Dynamic Graphs and Hypergraphs with Low Pair Visibility

In order to show the ubiquity of the visibility condition, we will describe some dynamic graphs with low pair visibility. One can easily construct a dynamic hypergraph from a dynamic graph by considering the r-neighborhood of each vertex of the t-th graph as a hyperedge in the t-th hypergraph, for $t = 1, \dots, n$.

- Dynamic Cycle. For $t = 1, \dots, n$ define the edge set

$$E_t = \{\{i,j\} \subset \{0, \dots, n-1\} \mid j = i + \lceil t/\sqrt{n} \rceil \pmod n \text{ or } i = j + \lceil t/\sqrt{n} \rceil \pmod n\},$$

where calculations are performed modulo n (that is, in the additive group $\mathbb{Z}_n$). In modular addition, for every pair $\{i,j\} \subset \{0, \dots, n-1\}$, the equation $i = j + k \pmod n$ has at most one solution $1 \leqslant k \leqslant \sqrt{n}$ and hence

$$\texttt{vis}(i,j) = |\{t \in \{1,2,\dots,n\} \mid \{i,j\} \in E_t\}| \leqslant \sqrt{n}.$$

Now $C^{(t)} = (\{0,1,\dots,n-1\}, E_t)$ is 2-regular, so it is either a Hamilton cycle or a union of two or more disjoint cycles (depending on whether t and n are coprime). By Theorem 6, the maximum load attained by the algorithm on $\{C^{(t)}, t = 1, \dots, n\}$ is at most $\log_2 \log n + \mathcal{O}(1)$. The analysis of the balanced allocation algorithm on Δ-regular graphs given by Kenthapadi and Panigrahy [13] showed that the balanced allocation process on arbitrary Δ-regular graphs has maximum load $\Theta(\log \log n)$ only when $\Delta = n^{\Omega(1/\log \log n)}$. By contrast, here each $C^{(t)}$ has degree at most 2, but the visibility condition keeps the maximum load as low as the standard two-choice process.

▶ Remark 7. By Theorem 6, w.h.p., the balanced allocation process on the dynamic cycle achieves the maximum load at most $\log_2 \log n + \mathcal{O}(1)$. Since $|E_t| = n$ for $t = 1, \dots, n$, each ball requires $\log_2 n$ random bits. However, in the standard power-of-two-choices process, each ball chooses two independent and random bins, which requires $2 \log n$ random bits. Therefore, the dynamic cycle can be used to reduce (by half) the number of random bits required in the standard two-choice process.

- Dynamic Modular Hypergraph. Suppose that n is a prime number and fix $s = s(n)$ such that $\log n \leqslant s \leqslant n^{1/5}$. (Here n is large enough so that this range is non-empty.) For $t = 1, \dots, n$, let $k_t = \lceil \sqrt{n} \rceil + \lceil \frac{t}{n^{3/4}} \rceil$ and for each $\alpha \in \mathbb{Z}_n$ define

$$H_t(\alpha) = \{\, \alpha + jk_t \pmod n \mid j = 0, 1, \dots, s-1 \,\}.$$

Then $H_t(\alpha)$ is a subset of $\mathbb{Z}_n$ of size s, as n is prime. Now for each $t = 1, \dots, n$ we define the dynamic s-uniform hypergraph $\mathcal{H}^{(t)} = (\mathbb{Z}_n, \mathcal{E}_t)$, where $\mathcal{E}_t = \{H_t(\alpha) \mid \alpha \in \mathbb{Z}_n\}$. Then $\mathcal{H}^{(t)}$ is s-regular, and hence 1-balanced, and it satisfies the 1-size property as $|\mathcal{E}_t| = n$.

Suppose that $\{\beta_1, \beta_2\} \subset H_t(\alpha)$ for some $\alpha \in \mathbb{Z}_n$, with $\beta_1 \neq \beta_2$. Then there exists $j_1, j_2 \in \{0, \ldots, s-1\}$ such that $\beta_1 = \alpha + j_1 k_t \pmod n$ and $\beta_2 = \alpha + j_2 k_t \pmod n$. Thus, $\beta_2 - \beta_1 = (j_2 - j_1) k_t \pmod n$. Note that j_1, j_2 must be distinct as β_1, β_2 are distinct. Next suppose that $k_{t_1} \neq k_{t_2}$ for some $t_1, t_2 \in \{1, \ldots, n\}$, and take any $j_1, j_2 \in \{1, \ldots, s-1\}$. By definition of k_t and working in $\mathbb{Z}$, we see that

$$1 \leqslant |j_2 k_{t_2} - j_1 k_{t_1}| \leqslant (s-1)\big(\lceil \sqrt{n} \rceil + \lceil n^{1/4} \rceil\big) < n,$$

and it follows that

$$j_1 k_{t_1} \neq j_2 k_{t_2} \pmod n. \tag{1}$$

Finally, suppose that some distinct β_1, β_2 satisfy $\{\beta_1, \beta_2\} \subset H_{t_1}(\alpha) \cap H_{t_2}(\alpha)$ where $k_{t_1} \neq k_{t_2}$. Then $\beta_2 - \beta_1 = j k_{t_1} \pmod n$ for some $j_1 \in \{1, \ldots, s-1\}$, and $\beta_2 - \beta_1 = j_2 k_{t_2} \pmod n$ for some $j_2 \in \{1, \ldots, s-1\}$, but this contradicts (1). Therefore, by definition of k_t, for every $\{\beta_1, \beta_2\} \subset \mathbb{Z}_n$, we have

$$\texttt{vis}(\beta_1, \beta_2) = |\{t \in \{1, 2, \ldots, n\} \mid \{\beta_1, \beta_2\} \subset H_t(\alpha) \text{ for some } \alpha \in \mathbb{Z}_n\}| \leqslant \mathcal{O}(n^{3/4}).$$

- Stationary Geometric Mobile Network. Consider an R-dimensional torus $\Gamma(n, R)$, which is a graph whose vertex set is the Cartesian product of $\mathbb{Z}_\ell^R = \mathbb{Z}_\ell \times \ldots \times \mathbb{Z}_\ell$, where $\ell = n^{1/R} \in \mathbb{Z}$, and two vertices $(x_1, \ldots, x_R)$ and $(y_1, \ldots, y_R)$ are connected if for some $j \in \{1, 2 \ldots, R\}$ $x_j = y_j \pm 1 \bmod n$ and for all $i \neq j$ we have $x_i = y_i$. Let π be the stationary distribution of the following random walk on $\Gamma(n, R)$: at each step, the walker stays at the current vertex with probability p, and otherwise chooses a neighbour randomly and moves to that neighbour. The transition probability from vertex u to a neighbouring vertex w is $(1-p)/(2R)$, where $2R$ is the degree of vertex u in $\Gamma(n, R)$. Now place n agents on vertices of $\Gamma(n, R)$ independently, each according to the distribution π. At each time step, each agent independently performs a step of the random walk described above (For random walks on a torus we refer the interested reader to [15]). For every pair of distinct agents a and b, let $d_t(a, b)$ denote the Manhattan distance (in Γ) of the locations of a and b at time t. For a given $r \geqslant 1$, we define the *communication graph process* $\{G_r^{(t)} \mid t = 0, 1, \ldots\}$ over the set of agents, say A, so that for every $t \geqslant 0$, agents a and b are connected if and only if $d_t(a, b) \leqslant r$. The model has been thoroughly studied when $R = 2$ in the context of information spreading [9]. We present the following result regarding the pair visibility of the communication graph process, proved in Appendix B.

▶ **Proposition 8.** *Fix $r = r(n) = n^{o(1)}$. Also let $\{G_r^{(t)} = (A, E_t) \mid 1 \leqslant t \leqslant n\}$ be the communication graph process defined on an R-dimensional torus $\Gamma(n, R)$. Then there exists constant $\varepsilon > 0$ such that for every pair of agents, say $\{a, b\} \subset A$,*

$$\texttt{vis}(a, b) = |\{t \in \{1, 2, \ldots, n\} \mid \{a, b\} \in E_t\}| = \mathcal{O}(n^{1-\varepsilon}).$$

1.2 Related Works

As we discussed, in the standard balls-into-bins, each ball picks a set of d choices from n bins, independently and uniformly at random. One of the first algorithms considering a different distribution over the bins is called *always-go-left* proposed by Vöcking [20]. In this algorithm, the bins are partitioned into d groups of size n/d and each ball picks one random bin from each group. The ball is then allocated to a least-loaded bin among the chosen bins, with ties broken in favor of the bin from the least-indexed group. The algorithm uses exponentially smaller number of choices and achieve a maximum load of $\frac{\log \log n}{d \phi_d} + \mathcal{O}(1)$,

where $1 \leqslant \phi_d \leqslant 2$ is an specified constant. Byers et al. [5] studied a model, where n bins are uniformly at random placed on a geometric space. Then each ball, in turn, picks d locations in the space. Corresponding to these d locations, the ball probes the load of d bins that have the minimum distance from the locations. The ball then allocates itself to one of the d bins with minimum load. In this scenario, the probability that a location close to a bin is chosen depends on the distribution of other bins in the space and hence there is not a uniform distribution over the potential choices. Here, the authors showed the maximum load is $\log_d \log n + \mathcal{O}(1)$. Later on, Kenthapadi and Panigrahy [13] proposed a graphical balanced allocation in which bins are interconnected as a s-regular graph and each ball picks a random edge of the graph. It is then placed in one of its endpoints with a smaller load. This allocation algorithm results in a maximum load of $\log \log n + \mathcal{O}\left(\frac{\log n}{\log(s/\log^4 n)}\right) + \mathcal{O}(1)$. Godfrey [12] studied balanced allocation on hypergraphs where each ball probes the bins contained in a random edge of size $\Omega(\log n)$. In [3, 12], the balanced allocation process on hypergraphs was studied where number of choices is $d = \Omega(\log n)$. The analysis involves the second moment method (Chernoff bounds), and lower bound on d is needed in order to achieve concentration. Hence it is unlikely that the techniques of [3,12] can be extended to the range $d = o(\log n)$. Peres et al. [17] also considered balanced allocation on graphs where the number of balls m can be much larger than n (i.e., $m \gg n$) and the graph is not necessarily regular and dense. Then, they established upper bound $\mathcal{O}(\log n/\sigma)$ for the gap between the maximum and the minimum loaded bin after allocating m balls, where σ is the edge expansion of the graph. Bogdan et al. [4] studied a model where each ball picks a random vertex and performs a local search from the vertex to find a vertex with local minimum load, where it is finally placed. They showed that when the graph is a constant degree expander, the local search guarantees a maximum load of $\Theta(\log \log n)$. Pourmiri [18] substitutes the local search by non-backtracking random walks of length $\ell = o(\log n)$ to sample the choices and then the ball is allocated to a least-loaded bin. Provided the underlying graph has sufficiently large girth and ℓ, he showed the maximum load is a constant. In the context of hashing (e.g., [1, 11]), authors apply the witness graph techniques to analyze the maximum load in the balls-into-bins process where the bins are picked based on tabulation.

2 Balanced Allocation on Dynamic Hypergraphs

In this section we establish an upper bound for the maximum load attained by the balanced allocation on hypergraphs (i.e., Theorem 2). In order to analyze the process let us first define a *conflict graph*. We write D_t for the set of d bins chosen by the t-th ball, and sometimes refer to D_t as the *d-choice* of the t-th ball. We will slightly abuse the notation and write $D_u \cap D_t$, $D_u \cup D_t$ to denote the set of common bins, and the union of bins, chosen by balls u and t, respectively.

▶ **Definition 9** (Conflict Graph). *For $m = 1, \ldots, n$, the conflict graph $\mathcal{C}_m$ is a simple graph with vertex set $\{D_1, D_2, \ldots, D_m\}$. Vertices D_u and D_t are connected by an edge in $\mathcal{C}_m$ if and only if $D_u \cap D_t \neq \emptyset$ (that is, the d-choices of the t-th ball and the u-th ball contain a common bin).*

We say a subgraph of $\mathcal{C}_m$ with vertex set $\{D_{t_1}, \ldots, D_{t_k}\}$ is *c-loaded* if every bin in $D_{t_1} \cup D_{t_2} \cup \cdots \cup D_{t_k}$ has at least c balls.

Our analysis will involve a useful combinatorial object, called an *ordered tree*. An ordered tree is a rooted tree, together with a specified ordering of the children of every vertex. Recall that $\frac{1}{k+1}\binom{2k}{k}$ is the k-th Catalan number, which counts numerous combinatorial objects,

including the number of ways to form k balanced parentheses. It is well known [19] that ordered trees with $k-1$ edges are counted by the $(k-1)$-th Catalan number, leading easily to the following proposition.

▶ **Proposition 10.** *The number of k-vertex ordered trees is $\frac{1}{k}\binom{2k-2}{k-1} \leqslant 4^{k-1}$.*

More information regarding the enumeration of trees can be found in [14].

The following blue-red coloring will be very helpful in our analysis.

▶ **Definition 11** (Blue-red coloring). *Given $m \in \{1, 2, \ldots, n\}$, suppose that $T \subset \mathcal{C}_m$ is a rooted and ordered k-vertex tree contained in $\mathcal{C}_m$. Let the vertex set of T be $\{D_{t_1} \ldots, D_{t_k}\}$, where D_{t_1} is the root. Perform depth-first search starting from the root, respecting the specified order of each vertex. For $i = 1, \ldots, k$, let $D(i) \in \{D_{t_1} \ldots, D_{t_k}\}$ be the vertex which is the i-th visited vertex in the depth-first search. Then $D(1) = D_{t_1}$ is the root. for $j = 1, \ldots, k$. We now define a blue-red coloring $col : \{D(2), \ldots, D(k)\} \to \{blue, red\}$ as follows. For $i = 2, \ldots, k$,*

$$col(D(i)) = \begin{cases} blue & \text{if } |(\cup_{j=1}^{i-1} D(j)) \cap D(i)| = 1, \\ red & \text{if } |(\cup_{j=1}^{i-1} D(j)) \cap D(i)| \geqslant 2. \end{cases}$$

The following key lemma presents a upper bound for the probability that a certain tree can be found as a subgraph of $\mathcal{C}_m$.

▶ **Lemma 12** (Key Lemma). *Let $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ be a dynamic s-uniform hypergraph which satisfies the β-balanced, ε-visibility and c_0-size properties. Suppose that $c > 0$ is an arbitrary constant and $k = C \log n$ for some constant $C \geqslant 1$. There exists $\Theta(n) \leqslant m \leqslant n$ such that the probability that $\mathcal{C}_m$ contains a c-loaded k-vertex tree with r red vertices in its blue-red colouring is at most*

$$n^{c_0+3} \exp\{4k \log(2\beta d) - r\varepsilon \log(n)/2 - c(d-1)(k-r-1)\}.$$

Moreover, with high probability, $r = \mathcal{O}(1/\varepsilon)$.

The proof, presented in Section 3, involves an extension of the witness tree technique. This method might be of independent interest in the study of random hypergraphs.

We now explain how to recursively build a witness graph if there exists a bin whose load is higher than a certain threshold. The *minimum load* of D_t is the number of balls in the least-loaded bin in D_t (the set of d choices of D_t). Clearly, if ball t is placed at height h then D_t has minimum load at least h.

Construction of the Witness Graph

Suppose that there exists a bin with load $\ell + c + 1$. Let R be the d-choice corresponding to the ball at height $\ell + c$ in this bin. Then the minimum load of R is $\ell + c$. We start building the witness tree in $\mathcal{C}_m$ whose root is R. For every bin $i \in R$, consider the ℓ balls in bin i at height $\ell + c - j$, for $j = 1, \ldots, \ell$, and let $D^i_{t_j}$ be the d-choice corresponding to the ball in bin i with height $\ell + c - j$. These ℓ balls exist as the minimum load of R is $\ell + c$. We refer to set $\{D^i_{t_j} \mid i \in R,\ 1 \leqslant j \leqslant \ell\}$ as the set of *children* of R, where the minimum load of $D^i_{t_j}$ is $\ell + c - j - 1$. All children of R are connected to R in $\mathcal{C}_m$. Order the children of R arbitrarily, then blue-red colour the first level of the tree (the children of R). Recall that a vertex is colored by blue if it only shares one bin with its predecessors in the ordering. So a blue d-choice contains $d-1$ bins that have not appeared in previous d-choices (with respect to depth-first search, respecting the fixed ordering). We call these $d-1$ bins *fresh*.

Next, consider each blue vertex of the tree (if any), and recover the d-choices corresponding to balls that are placed in fresh bins with height at least c. Then, blue-red color the children of those d-choices, with respect to an arbitrary ordering. This recursion will continue until either there are no balls remaining with height at least c, or there are no blue vertices. For $j = 1, \dots, \ell$, let $f(\ell - j)$ denote the number of d-choices that the recursive construction gives, when the d-choice for the root has minimum load $\ell + c - j - 1$. Provided all vertices are colored blue, the recursive construction continues until no ball remains with height at least c. Therefore, a simple calculation shows that

$$f(\ell) \geqslant (d-1)(f(\ell-1) + f(\ell-2) + \cdots + f(0) + 1),$$

where $f(0) = 1$. Solving the above recursive formula shows that $f(\ell) \geqslant 2(d-1)d^{\ell-1} \geqslant d^{\ell}$.

Proof of Theorem 2. Let $(\mathcal{H}^{(1)}, \dots, \mathcal{H}^{(n)})$ be a dynamic hypergraph which satisfies the β-balanced, ε-visibility and c_0-size properties. By Lemma 12, there exists $\Theta(n) = m \leqslant n$ such that the following holds with high probability: after m balls have been allocated by the balanced allocation process, if $T \subseteq \mathcal{C}_m$ is a c-loaded tree with k vertices and T is blue-red coloured according to some arbitrary ordering of the children of each vertex, then the number r of red vertices satisfies $r = \mathcal{O}(1/\varepsilon)$. So we are able to find a constant $c_2 \geqslant 0$ such that, with high probability, $r < c_2 \cdot d$.

Now suppose that after allocating m balls, there is a ball at height $\ell + c_1 + c_2 + 1$. This implies that there is a d-choice, denoted by R, whose minimum load is at least $\ell + c_1 + c_2 + 1$. Let us consider all balls placed in the bins contained in R with height at least $\ell + c_1 + 1$. Recover the corresponding d-choices for these balls, say $D_1, D_2, \dots, D_w$, then colour them blue-red with respect to the root R and an arbitrary ordering of the children of each vertex. Since $w \geqslant c_2 \cdot d$, w.h.p., there are $b \geqslant 1$ blue vertices and $w - b$ red vertices. We now consider every blue vertex $D_t \in \{D_1, D_2, \dots, D_w\}$ as a root and start the recursive construction of the witness graph. Assuming that the number of red vertices is strictly less than $c_2 \cdot d < w$, it follows that at least one recursive construction (with root D_i) does not produce any red vertex. Moreover, the recursion from D_i gives a c_1-loaded tree with at least $k = d^{\ell}$ vertices. We take $\ell = \log_d \log n$, so that $k = \log n$. Another application of Lemma 12 implies that a c_1-loaded k-vertex tree with no red vertices exists with probability at most

$$\begin{aligned} n^{c_0+3} \exp\{4k \log(2\beta d) - c_1(d-1)(k-1)\} &\leqslant \exp\left\{\left(c_0 + 4 + 4\log(2\beta d) - c_1(d-1)\right)\log n\right\} \\ &\leqslant \exp\left\{\left(c_0 + 4 + 4\log(4\beta) - c_1\right)\log n\right\}, \end{aligned}$$

using the fact that $2 \leqslant d = o(\log n)$ and $k = \log n$. Setting c_1 to be a large enough positive constant, we conclude that with high probability the maximum load is at most

$$\log_d \log n + \mathcal{O}(1) + c_2 = \log_d \log n + \mathcal{O}(1/\varepsilon),$$

where $c_2 = \mathcal{O}(1/\varepsilon)$. This proves the first statement of Theorem 2.

In order to prove the second statement of Theorem 2 we show the sub-additivity of the balanced allocation algorithm. We want to prove that for every constant integer $\gamma \geqslant 1$ with $\gamma m \leqslant n$, after allocating γm balls, the maximum load is at most $\gamma(\log_d \log n + \mathcal{O}(1/\varepsilon))$, with high probability. First assume that $2m \leqslant n$ and suppose that the algorithm has allocated m balls to $\mathcal{H}^{(t)}, t = 1, \dots, m$ and let $\ell^* \leqslant \log_d \log n + \mathcal{O}(1)$ denote its maximum load. We now consider two independent balanced allocation algorithms, say $\mathcal{A}$ and $\mathcal{A}_0$, on two dynamic hypergraphs starting from step m. These dynamic hypergraphs are $(\mathcal{H}^{(m)}, \dots, \mathcal{H}^{(n)})$ and $(\mathcal{H}_0^{(m)}, \dots, \mathcal{H}_0^{(n)})$, where $\mathcal{H}_0^{(t)}$ is an identical copy of $\mathcal{H}^{(t)}$ for $t = m, \dots, n$. Moreover, we assume that in round m, all bins contained in $\mathcal{H}_0^{(m)}$ have exactly ℓ^* balls. Let us couple

algorithm $\mathcal{A}$ on $\mathcal{H}^{(t)}$ and algorithm $\mathcal{A}_0$ on $\mathcal{H}_0^{(t)}$. Write $V = [n]$ for the set of n bins. To do so, the coupled process allocates a pair of balls to bins as follows: for $t = m+1, \ldots, 2m$, the coupling chooses a one-to-one labeling function $\sigma_t : V \to \{1, 2, \ldots, n\}$ uniformly at random, where V is the ground set of both hypergraphs (i.e, set of n bins) and $\{1, 2, \ldots, n\}$ is a set of labels. Next, the coupling chooses D_t randomly from $\mathcal{H}^{(t)}$. Let D'_t denote the same set of d bins as D_t in $\mathcal{H}_0^{(t)}$. Algorithm $\mathcal{A}$ allocates ball $t+1$ to a least-loaded vertex of D_t, and algorithm $\mathcal{A}_0$ allocates ball $t+1$ to a least-loaded vertex of D'_t, with both algorithms breaking ties in favour of the vertex v with the smallest load and minimum label $\sigma_t(v)$. Note that algorithm $\mathcal{A}$ is a faithful copy of the balanced allocation process on $(\mathcal{H}^{(m)}, \ldots, \mathcal{H}^{(n)})$, and algorithm $\mathcal{A}_0$ is a faithful copy of the balanced allocation process on $(\mathcal{H}_0^{(m)}, \ldots, \mathcal{H}_0^{(n)})$, respectively. (This follows as σ_t is chosen uniformly at random.) Let X_i^t and Y_i^t, $m+1 \leqslant t \leqslant 2m$, denote the load of bin i in $\mathcal{H}^{(t)}$ and $\mathcal{H}_0^{(t)}$, respectively. We prove by induction that for every integer $m \leqslant t \leqslant 2m$ and $i \in V$ we have

$$X_i^t \leqslant Y_i^t. \tag{2}$$

The inequality holds when by the assumption that $Y_i^m = \ell^*$ for every $i \in V$. Let us assume that for every t', $t' \leqslant t \leqslant 2m$, Inequality (2) holds, then we will show it for $t+1$. Let $i \in D_{t+1}$ and $j \in D'_{t+1}$ denote the vertices (bins) that receive a ball in step $t+1$. We now consider two cases:

- **Case 1:** $X_i^t < Y_i^t$. Since algorithm $\mathcal{A}$ allocated ball $t+1$ to bin i, it follows that

  $$X_i^t + 1 = X_i^{t+1} \leqslant Y_i^t \leqslant Y_i^{t+1}.$$

  So, Inequality (2) holds for $t+1$ and every bin $i \in V$.
- **Case 2:** $X_i^t = Y_i^t$. Since D'_{t+1} is a copy of D_{t+1}, we have $j \in D_{t+1}$ and $i \in D'_{t+1}$. We know that no vertex (bin) in D_{t+1} has smaller load than i, and no vertex (bin) in D'_{t+1} has smaller load than j. Hence

  $$X_i^t \leqslant X_j^t \leqslant Y_j^t \leqslant Y_i^t,$$

  where the middle inequality follows from the inductive hypothesis (2) for bin j. So by assumption of this case we obtain $X_i^t = X_j^t = Y_j^t = Y_i^t$. If $i \neq j$ and $\sigma_{t+1}(j) < \sigma_{t+1}(i)$, then it contradicts the fact that ball $t+1$ is allocated to bin i by algorithm $\mathcal{A}$. Similarly, if $\sigma_{t+1}(j) > \sigma_{t+1}(i)$, then it contradicts the fact that algorithm $\mathcal{A}_0$ allocated ball t to bin j. Therefore $i = j$ and hence

  $$X_i^{t+1} = X_i^t + 1 = Y_i^t + 1 = Y_i^{t+1}.$$

Thus, in both cases, Inequality (2) holds for every $t \geqslant 0$. By applying the first part of the theorem, with high probability, using algorithm $\mathcal{A}_0$ to allocate m balls to the dynamic hypergraph $(\mathcal{H}_0^{(m)}, \ldots, \mathcal{H}_0^{(2m)})$ results in maximum load

$$\ell^* + \log_d \log n + \mathcal{O}(1/\varepsilon) \leqslant 2(\log_d \log n + \mathcal{O}(1/\varepsilon))$$

in $\mathcal{H}_0^{(2m)}$. Therefore, by Inequality (2), after using algorithm $\mathcal{A}$ to allocate m balls to the dynamic hypergraph $(\mathcal{H}^{(m)}, \ldots, H^{(n)})$, with high probability the maximum load in $\mathcal{H}^{(2m)}$ is at most $2(\log_d \log n + \mathcal{O}(1/\varepsilon))$. Applying the union bound, we conclude that after allocating γm balls, where $\gamma m \leqslant n$, the maximum load is at most $\gamma(\log_d \log n + \mathcal{O}(1/\varepsilon))$, with high probability. This completes the proof of Theorem 2. ◀

3 Appearance Probability of a Certain Structure

In this section we work towards a proof of Lemma 12. First we will give some useful definition and prove some helpful results. The definition was introduced in [18].

▶ **Definition 13.** *Suppose that $\mathcal{A}$ is an allocation algorithm that sequentially allocates n balls into n bins according to some mechanism. For a given constant $\alpha > 0$, and for $\Theta(n) = m \leqslant n$, we say that $\mathcal{A}$ is (α, m)-uniform if for every ball $1 \leqslant t \leqslant m = \Theta(n)$ and every bin $i \in [n]$,*

$$\mathbf{Pr}\left[\text{ ball } t \text{ is allocated to bin } i \text{ by } \mathcal{A} \mid \text{balls } 1, 2, \ldots, t-1 \text{ have been allocated by } \mathcal{A}\right] \leqslant \frac{\alpha}{n}.$$

In the above definition, we condition on the allocations of balls $1, \ldots, t-1$ into bins made by $\mathcal{A}$.

The following result will be proved in Appendix C.

▶ **Lemma 14.** *Fix $d = d(n)$ with $2 \leqslant d = o(\log n)$. Suppose that the dynamic s-uniform hypergraph $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ satisfies the balancedness and size properties. There exists $m = \Theta(n)$ with $m < n$ such that with probability at least $1 - n^{-2}$, the edge H_t chosen by the t-th ball contains at least $s/2$ empty vertices for $t = 1, \ldots, m$.*

Using this result we can prove that the balanced allocation process is uniform on dynamic hypergraphs.

▶ **Lemma 15** (Uniformity Lemma)**.** *Fix $d = d(n)$ with $2 \leqslant d = o(\log n)$ and suppose that for some constant $\beta \geqslant 1$, the s-uniform dynamic hypergraph $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ satisfies the β-balanced and size properties, with $d \leqslant s$. Then there exists a constant $\alpha = \alpha(\beta)$, which depends only on β, and there exists $m = \Theta(n)$ with $m < n$, such that the balanced allocation process on $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ is (α, m)-uniform. Specifically, we may take $\alpha = 44\beta$.*

Proof. Fix $m = m(n)$ to equal the m provided by Lemma 14. For $t = 1, \ldots, m$, let D_t be the d-element subset of H_t that is chosen by the t-th ball. Define the indicator random variable $\mathbb{I}_t$ as follows:

$$\mathbb{I}_t := \begin{cases} 1 & \text{if } D_t \text{ contains at least } d/6 \text{ empty vertices,} \\ 0 & \text{otherwise.} \end{cases}$$

Let us fix an arbitrary bin i and then define $A(t, i)$ to be the event that the t-th ball is allocated to vertex i. (The first $t-1$ balls have already been allocated, as the balanced allocation process never fails.) Observe that if $i \notin D_t$ then $\mathbf{Pr}\left[A(t,i)\right] = 0$. It follows that

$$\begin{aligned} \mathbf{Pr}\left[A(t,i)\right] &= \mathbf{Pr}\left[A(t,i) \mid i \in D_t \text{ and } \mathbb{I}_t = 1\right] \cdot \mathbf{Pr}\left[i \in D_t \text{ and } \mathbb{I}_t = 1\right] \\ &\quad + \mathbf{Pr}\left[A(t,i) \mid i \in D_t \text{ and } \mathbb{I}_t = 0\right] \cdot \mathbf{Pr}\left[i \in D_t \text{ and } \mathbb{I}_t = 0\right]. \end{aligned}$$

Now there are at least $d/6$ empty vertices on D_t when $\mathbb{I}_t = 1$, so

$$\mathbf{Pr}\left[A(t,i) \mid i \in D_t \text{ and } \mathbb{I}_t = 1\right] \leqslant 6/d.$$

It follows that

$$\begin{aligned} \mathbf{Pr}\left[A(t,i)\right] &\leqslant (6/d)\ \mathbf{Pr}\left[i \in D_t \text{ and } \mathbb{I}_t = 1\right] + \mathbf{Pr}\left[i \in D_t \text{ and } I_t = 0\right] \\ &\leqslant (6/d)\ \mathbf{Pr}\left[i \in D_t\right] + \mathbf{Pr}\left[\mathbb{I}_t = 0 \mid i \in D_t\right] \cdot \mathbf{Pr}\left[i \in D_t\right]. \end{aligned} \tag{3}$$

In order to have $i \in D_t$, first an edge containing i must be selected, and then the chosen d-element subset of that edge must contain i. By the β-balancedness property,

$$\mathbf{Pr}\left[i \in D_t\right] \leqslant \frac{\beta s}{n} \cdot \frac{\binom{s-1}{d-1}}{\binom{s}{d}} \leqslant \frac{\beta}{n}.$$

Using the above inequality, we simplify Inequality (3) as follows:

$$\mathbf{Pr}\left[A(t,i)\right] \leqslant \frac{6\beta}{n} + \frac{\beta d}{n}\,\mathbf{Pr}\left[\mathbb{I}_t = 0 \mid i \in D_t\right].$$

If $d \leqslant 6$ then the above inequality immediately implies that $\mathbf{Pr}\left[A(t,i)\right] \leqslant 12\beta/n$. This completes the proof when $d \leqslant 6$. For the remainder of the proof we assume that $d \geqslant 7$, and prove that

$$\mathbf{Pr}\left[\mathbb{I}_t = 0 \mid i \in D_t\right] \leqslant \hat{c}/d \tag{4}$$

for some absolute constant $\hat{c} > 0$. From this, we see that $\mathbf{Pr}\left[A(t,i)\right] \leqslant \alpha/n$ where $\alpha = \beta(6+\hat{c})$. As i was an arbitrary bin, this proves that the process is (α, m)-uniform.

Let $\mathcal{F}$ be the event that H_t contains at least $s/2$ empty vertices for all $t = 1, \ldots, m$. By Lemma 14, we have $\mathbf{Pr}\left[\mathcal{F}\right] \geqslant 1 - n^{-2}$. Then

$$\begin{aligned}
&\mathbf{Pr}\left[\mathbb{I}_t = 0 \mid i \in D_t\right] \\
&= \mathbf{Pr}\left[\mathbb{I}_t = 0 \mid (i \in D_t) \text{ and } \mathcal{F}\right] \cdot \mathbf{Pr}\left[\mathcal{F}\right] + \mathbf{Pr}\left[\mathbb{I}_t = 0 \mid (i \in D_t) \text{ and } \neg\mathcal{F}\right] \cdot \mathbf{Pr}\left[\neg\mathcal{F}\right] \\
&\leqslant \mathbf{Pr}\left[\mathbb{I}_t = 0 \mid (i \in D_t) \text{ and } \mathcal{F}\right] + n^{-2} \leqslant \mathbf{Pr}\left[\mathbb{I}_t = 0 \mid (i \in D_t) \text{ and } \mathcal{F}\right] + 1/d.
\end{aligned} \tag{5}$$

Let X be the random variable that counts the number of empty bins of a random $(d-1)$-element subset of $H_t \setminus \{i\}$, conditioned on the event that "$(i \in D_t)$ and $\mathcal{F}$" holds. Then X is a hypergeometric random variable with parameters $(s-1, K, d-1)$, where K is the number of empty bins contained in $H_t \setminus \{i\}$. Thus

$$\mathbf{E}\left[X\right] = \frac{(d-1)K}{s-1} \quad \text{and} \quad \mathbf{Var}\left[X\right] \leqslant \frac{(d-1)K}{s-1} \leqslant d.$$

Then $\mathbf{E}\left[X\right] > d/3$, since $K \geqslant s/2 - 1$ when $i \in D_t$ and $\mathcal{F}$ holds (and using the size property $s = \Omega(\log n)$) and the fact that $d \geqslant 7$). Therefore

$$\begin{aligned}
&\mathbf{Pr}\left[\mathbb{I}_t = 0 \mid (i \in D_t) \text{ and } \mathcal{F}\right] \\
&\leqslant \mathbf{Pr}\left[X < d/6\right] \leqslant \mathbf{Pr}\left[\left|X - \mathbf{E}\left[X\right]\right| \leqslant \mathbf{E}\left[X\right]/2\right] < \frac{4\,\mathbf{Var}\left[X\right]}{\mathbf{E}\left[X\right]^2} \leqslant \frac{36d}{d^2} = \frac{36}{d},
\end{aligned}$$

using Chebychev's inequality. Substituting the above upper bound in Inequality (5) establishes (4) with $\hat{c} = 38$, which completes the proof. ◀

We are ready to prove Lemma 12.

▶ **Lemma 16** (Restatement of Lemma 12). *Fix $d = d(n)$ with $2 \leqslant d = o(\log n)$. Let $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ be a dynamic hypergraph which satisfies the β-balanced, ε-visibility and c_0-size properties. Suppose that $c \geqslant 44\beta\mathrm{e}^2$ is a sufficiently large constant, and let $k = C\log n$ for some constant $C \geqslant 1$. There exists $\Theta(n) \leqslant m \leqslant n$ such that the probability that $\mathcal{C}_m$ contains a c-loaded k-vertex tree is at most*

$$\exp\left\{4k\log(2\beta d) - c(d-1)(k-r-1) + \left(c_0 + 3 - r\varepsilon/2\right)\log(n)\right\}$$

where r is the number of red vertices in the blue-red coloring of the tree. Moreover, with high probability, if $\mathcal{C}_m$ contains any such tree then $r = \mathcal{O}(1/\varepsilon)$.

Proof. Fix $m = m(n)$ to equal the m provided by Lemma 15. There are at most 4^k ordered trees with k vertices. (Proposition 10). Fix such a tree, say T, and label the vertices $\{1, 2, \ldots, k\}$ such that vertex i is the i-th new vertex visited when performing depth-first search in T starting from the root, and respecting the given ordering. In particular, the root of T is vertex 1. Next, we will assign a d-choice to the root vertex of T, as a first step in describing trees which may be present in the witness graph $\mathcal{C}_m$. Let x count the number of possible d-choices that can be assigned to the root of T. Then

$$x \leqslant \binom{s}{d} \cdot \left| \bigcup_{t=1}^{m} \mathcal{E}_t \right| \cdot m \leqslant \binom{s}{d} \cdot n^{c_0+2},$$

where the last inequality follows from the size property and the inequality $m \leqslant n$. Therefore, there are x possibilities for the root and hence there are at most $4^k \cdot \binom{s}{d} \cdot n^{c_0+2}$ ordered trees with the specified root. Fix an arbitrary d-choice D_t as the root for T.

Next we fix an arbitrary function $\mathrm{col} : \{2, \ldots, k\} \to \{\text{blue}, \text{red}\}$, that gives a blue-red coloring of $2, \ldots, k$. In what follows we establish an upper bound for the probability that $\mathcal{C}_m$ contains the blue-red colored tree $T \subset \mathcal{C}_m$, (according to Definition 11). Let $q_1(t)$ be the probability that the t-th ball chooses the root of T (that is, that the d-choice made by the t-th ball corresponds to the root of T). Then

$$\sum_{t=1}^{m} q_1(t) \leqslant \sum_{t=1}^{m} \frac{1}{\binom{s}{d}} \leqslant \frac{n}{\binom{s}{d}}, \tag{6}$$

because H contains $\binom{s}{d}$ distinct d-element sets for for every $H \in \mathcal{E}_t$. For every $t = 2, \ldots, k$, define $q_i(t, \mathrm{col}(i))$ to be the probability that the t-th ball chooses the i-th vertex of the tree (i.e., i) with $\mathrm{col}(i)$. If $\mathrm{col}(i)$ is red then D_t must share at least two bins with $\cup_{j=1}^{i-1} D_{t_j}$, while if $\mathrm{col}(i)$ is blue then D_t only shares one bin with its parent. For every $i = 2, \ldots, k$, let us derive an upper bound on $q_i(t, \text{blue})$. Here, the i-th vertex share one bin with its parent in T, say D_{t_j}. Now D_{t_j} has d bins and by the balancedness property we get

$$\mathbf{Pr}\left[D_{t_j} \cap H_t \neq \emptyset\right] \leqslant \sum_{i \in D_{t_j}} \mathbf{Pr}\left[i \in H_t\right] \leqslant \frac{\beta d s}{n},$$

where H_t is the edge chosen by ball t from $\mathcal{H}^{(t)}$, uniformly at random. Suppose that for some $a \geqslant 1$ we have $|D_{t_j} \cap H_t| = a \leqslant d$. Then the total number of d-element subsets of H_t which share only one bin with D_{t_j} is $a\binom{s-a}{d-1} \leqslant d\binom{s-1}{d-1}$. Thus, we get

$$\sum_{t=1}^{m} q_i(t, \text{blue}) \leqslant \sum_{t=1}^{m} \frac{\beta d s}{n} \cdot d \frac{\binom{s-1}{d-1}}{\binom{s}{d}} = \sum_{t=1}^{m} \frac{\beta d^3}{n} \leqslant \beta d^3, \tag{7}$$

because $m \leqslant n$.

Next, for every $i = 2, \ldots, k$, and every $t = 2, \ldots, m$, we need an upper bound on $q_i(t, \text{red})$. If the i-th vertex of the tree is the set D_t and is coloured red, then D_t is a d-element set of bins which shares at least two bins with $\cup_{j=1}^{i-1} D_{t_j}$. One of these bins belongs to the (known) parent, and the other belongs to $D_{t_1} \ldots, D_{t_{i-1}}$. So if U is the number of choices for this pair of bins, then

$$U \leqslant d \cdot (i-1)d \leqslant kd^2. \tag{8}$$

Let $\{p_1, p_2 \ldots, p_U\}$ be the set of such pairs of bins. For $J = 1, \ldots, U$, write $A(p_J, t)$ for the event that the pair p_J is contained in a randomly chosen edge of $\mathcal{E}_t$. Observe that if $p_J \subset D_t$ then $A(p_J, t)$ holds. Then, by the balancedness property we have

$$
\begin{aligned}
&\mathbf{Pr}\left[p_J \subset D_t\right] \\
&= \mathbf{Pr}\left[p_J \subset D_t \mid A(p_J,t)\right] \cdot \mathbf{Pr}\left[A(p_J,t)\right] \\
&\leqslant \mathbf{Pr}\left[p_J \subset H_t\right] \cdot \frac{\binom{s-2}{d-2}}{\binom{s}{d}} \cdot \mathbf{Pr}\left[A(p_J,t)\right] \\
&\leqslant \mathbf{Pr}\left[p_J \cap H_t \neq \emptyset\right] \cdot \frac{\binom{s-2}{d-2}}{\binom{s}{d}} \cdot \mathbf{Pr}\left[A(p_J,t)\right] \\
&\leqslant \frac{2\beta s}{n} \cdot \frac{\binom{s-2}{d-2}}{\binom{s}{d}} \cdot \mathbf{Pr}\left[A(p_J,t)\right] = \frac{2\beta d(d-1)}{(s-1)n}\ \mathbf{Pr}\left[A(p_J,t)\right],
\end{aligned}
$$

as $\binom{s-2}{d-2}$ is the number of d-element subsets of H_t which contain the pair p_J. Then

$$
q_i(t,\mathrm{red}) \leqslant \sum_{J=1}^{U} \frac{2\beta d(d-1)}{(s-1)n}\ \mathbf{Pr}\left[A(p_J,t)\right].
$$

Note that by (8) we have $U \leqslant kd^2$ and hence,

$$
\sum_{t=1}^{m} q_i(t,\mathrm{red}) \leqslant \sum_{J=1}^{U}\sum_{t=1}^{n} \frac{2\beta d(d-1)}{(s-1)n}\ \mathbf{Pr}\left[A(p_J,t)\right] \leqslant \sum_{J=1}^{U} \frac{2\beta d(d-1)}{(s-1)n}\ \mathtt{vis}(p_J) \leqslant \frac{2\beta k d^4}{n^{\varepsilon}}. \tag{9}
$$

The final inequality follows from the visibility property, using the fact that $d < s$.

Write $\mathrm{col}^{-1}(\mathrm{blue})$ for the set of blue vertices in T, and similarly for $\mathrm{col}^{-1}(\mathrm{red})$. Then

$$
|\mathrm{col}^{-1}(\mathrm{red})| + |\mathrm{col}^{-1}(\mathrm{blue})| = k-1.
$$

Suppose that $(t_1,\ldots,t_k)$ is the sequence of balls that are going to select vertices $1,2,\ldots,k$ of T. By applying (6), (7) and (9), we find that the probability that the edges of the colored tree T appears in $\mathcal{C}_m$ at times $(t_1,\ldots,t_k)$, and the corresponding sets $D_{t_1},\ldots,D_{t_k}$ consistent with chosen blue-red coloring scheme, is at most

$$
\begin{aligned}
&\sum_{(t_1,\ldots,t_k)} \left\{ q_1(t_1) \prod_{i=2}^{k} q_i(t_i,\mathrm{col}(i)) \right\} \leqslant \left(\sum_{t=1}^{m} q_1(t) \right) \prod_{2=1}^{k} \left(\sum_{t=1}^{m} q_i(t,\mathrm{col}(i)) \right) \\
&\leqslant \frac{n}{\binom{s}{d}} \left(\prod_{i\in\mathrm{col}^{-1}(\mathrm{blue})} \sum_{t=1}^{m} q_i(t,\mathrm{blue}) \right) \left(\prod_{i\in\mathrm{col}^{-1}(\mathrm{red})} \sum_{t=1}^{m} q_i(t,\mathrm{red}) \right) \\
&\leqslant \frac{n}{\binom{s}{d}} \left(\beta d^3\right)^{|\mathrm{col}^{-1}(\mathrm{blue})|} \left(\frac{2\beta k d^4}{n^{\varepsilon}} \right)^{|\mathrm{col}^{-1}(\mathrm{red})|} \leqslant \frac{n\beta^k d^{4k}}{\binom{s}{d}} \left(\frac{2k}{n^{\varepsilon}} \right)^{|\mathrm{col}^{-1}(\mathrm{red})|}.
\end{aligned} \tag{10}
$$

There are at most 2^{k-1} coloring functions and $4^k \mathrm{poly}(n)\binom{s}{d}$ rooted and ordered trees. So by the upper bound (10), together with the union bound over all colored ordered trees, we obtain

$$
\begin{aligned}
&\mathbf{Pr}\left[\ \mathcal{C}_m \text{ contains a valid blue-red colored } k\text{-vertex tree with } r \text{ red vertices }\right] \\
&\leqslant 4^k 2^{k-1} \cdot n^{c_0+2} \binom{s}{d} \cdot \frac{n\,\beta^k d^{4k}}{\binom{s}{d}} \left(\frac{2k}{n^{\varepsilon}} \right)^{r} \\
&\leqslant n^{c_0+3} \cdot (2\beta d)^{4k} \cdot n^{-r\varepsilon/2} \leqslant \exp\left(4k\log(2\beta d) + (c_0+3-r\varepsilon/2)\log n\right),
\end{aligned} \tag{11}
$$

using $k = \mathcal{O}(\log n)$ for the penultimate inequality.

Let $b = k - r - 1$ be the number of blue vertices and let $D_{s_1}, \dots, D_{s_b}$ be the sorted list of blue vertices such that $s_1 < s_2 < \cdots < s_b$. Then, by the definition of blue-red coloring, for every $j = 1, \dots, b$ we have $|(\cup_{g=1}^{j-1} D_{s_g}) \cap D_{s_j}| \leqslant 1$. This implies that

$$y = |\cup_{j=1}^{k} D_{t_j}| \geqslant |\cup_{j=1}^{b} D_{s_j}| \geqslant (d-1)b = (d-1)(k-1-r),$$

since $\{s_1, \dots, s_b\} \subseteq \{t_1, \dots, t_k\}$. Applying Lemma 15 implies that the balanced allocation is (α, m)-uniform, where $\alpha = 44\beta$, say. Hence for any $c \geqslant 44\beta \mathrm{e}^2$, the probability that each bin in $\cup_{j=1}^{k} D_{t_j}$ is allocated at least c balls (that is, the tree T is c-loaded) is at most

$$\binom{m}{cy} \left(\frac{\alpha y}{n}\right)^{cy} \leqslant \left(\frac{\mathrm{e}m}{cy}\right)^{cy} \left(\frac{\alpha y}{n}\right)^{cy} \leqslant \left(\frac{\mathrm{e}\alpha}{c}\right)^{cy} \leqslant \mathrm{e}^{-c(d-1)(k-r-1)},$$

where the last inequality follows from $m \leqslant n$ and the fact that $c > \alpha \mathrm{e}^2$. Since balls are independent from each other, we can multiply the above inequality by (11) to show that the probability that $\mathcal{C}_m$ contains a c-loaded k-vertex tree with r red vertices is at most

$$\exp\Big\{4k\log(2\beta d) - c(d-1)(k-r-1) + \big(c_0 + 3 - r\varepsilon/2\big)\log n\Big\}, \tag{12}$$

proving the first statement of the lemma. Finally, suppose that $r\varepsilon \to \infty$ as $n \to \infty$. Then the upper bound in (12) can be written as

$$\begin{aligned}&\exp\Big\{\big(4\log(2\beta d) - c(d-1)\big)k + \mathcal{O}(\log n) + o(r \cdot \log n) - (r\varepsilon/2)\log n\Big\}\\ &\leqslant \exp\Big\{\mathcal{O}(\log n) + o(r \cdot \log n) - (r\varepsilon/2)\log n\Big\}.\end{aligned}$$

Since $r\varepsilon \to \infty$, this term dominates and the probability that $\mathcal{C}_m$ contains a blue-red coloured tree with r red vertices tends to zero. Therefore, if such a tree is present in $\mathcal{C}_m$ then $r = \mathcal{O}(1/\varepsilon)$ with high probability. This completes the proof. ◀

4 Balanced Allocation on Dynamic Graphs

In this section we show an upper bound for maximum load attained by the balanced allocation on regular dynamic graphs (i.e., Theorem 6). Suppose that the balanced allocation process has allocated n balls to the dynamic regular graph $(G^{(1)}, \dots, G^{(n)})$. Define the *conflict graph* $\mathcal{C}_n$ formed by the edges selected by the n balls. The vertex set of $\mathcal{C}_n$ is the set $[n]$ of bins, and the loads of these bins are updated during the process.

Given a tree T which is a subgraph of $\mathcal{C}_n$, and vertices u, v of the tree, if $\{u, v\}$ is an edge of $\mathcal{C}_n$ then we say it is a *cycle-producing edge* with respect to the tree T. The name arises as adding this edge to the tree would produce a cycle, which may be a 2-cycle if the edge $\{u, v\}$ is already present in T. For a positive integer $c > 0$, a subgraph of $\mathcal{C}_n$ is called *c-loaded* if each vertex (bin) contained in the subgraph has load at least c. The following proposition presents some properties of connected components of $\mathcal{C}_n$.

▶ **Proposition 17.** *Let $(G^{(1)}, \dots, G^{(n)})$ be a regular dynamic graph on vertex set $[n]$ which is ε-visible. Let that $\mathcal{C}_n$ be the conflict graph obtained after allocating n balls using the balanced allocation process. Then for every given constant $c > 0$, with probability at least $1 - n^{-c}$, every $12(c+1)$-loaded connected component of $\mathcal{C}_n$ contains strictly fewer than $\log n$ vertices. Moreover, the number of cycle-producing edges in the component is at most $2(c+1)/\varepsilon$.*

We will prove the proposition in Appendix D. We now explain how to recursively build a witness graph, provided there exists a bin whose load is higher than a certain threshold.

Construction of the Witness Graph

Let us start with a bin, say r, with $\ell + c$ balls. Clearly, if a ball is in bin r at height h then the other bin it chose, as part of the balanced allocation procedure, had load at least h. Starting from bin (vertex) r, let us recover all ℓ edges corresponding to the balls that were placed in r with height at least c. Thus, the alternative bin choices have loads at least $\ell + c - 1, \ldots, c$, respectively. These ℓ bins are all neighbours of r in $\mathcal{C}_n$, and we refer to them as the children of r. Next, we recover the edges corresponding to balls placed in the children of r at height at least c. Recursively, we continue until there is no ball remaining at height c or more. For every $i = 1, \ldots, \ell$, let $f(\ell - i)$ denote the number of vertices generated by the recursive construction, starting with a bin which contains $\ell - i + c$ balls. Assume for the moment that, for each vertex with load at least c, the recursive procedure always gives produces distinct children. Then

$$f(\ell) \geqslant f(\ell - 1) + f(\ell - 2) + \ldots + f(0) + 1,$$

where $f(0) = 1$. A simple calculation shows that $f(\ell) \geqslant 2^\ell$. Thus, the recursive procedure gives a c-loaded tree with at least 2^ℓ vertices, under the assumption that the children of each vertex considered by the recursion are all distinct.

We may now prove our main result on dynamic regular graphs.

Proof of Theorem 6. We want to show that after n balls have been allocated to the dynamic regular graph $(G^{(1)}, \ldots, G^{(n)})$, which satisfies the ε-visibility property, the maximum load is at most $\log_2 \log n + \mathcal{O}(1/\varepsilon)$ with high probability.

Let $c > 0$ be a given constant. By the second statement of Proposition 17, with probability at least $1 - n^{-c}$, the number of cycle-producing edges in a given component of $\mathcal{C}_n$ is at most $c_2 = 2(c+1)/\varepsilon$. For a contradiction, suppose that there exists a bin, say r, which has at least $\ell + c_1 + c_2 + 1$ balls, where $c_1 = 12(c+1)$. Consider $c_2 + 1$ balls in r at height at least $\ell + c_1$. The children of r in $\mathcal{C}_n$ are the bins $r_1, r_2, \ldots, r_{c_2+1}$ (which might not be distinct), which were the alternative choice of these $c_2 + 1$ balls. Each of these children r_i has load at least $\ell + c_1$. We start the recursive construction at each child r_i of r. Assuming that this component of $\mathcal{C}_n$ contains at most c_2 cycle-producing edges, it follows that for at least one child r_i of r, the recursive procedure gives distinct children for each vertex which is a descendent of r_i. Hence we obtain a c_1-loaded tree which has 2^ℓ vertices. Substituting $\ell = \log_2 \log n$ and applying the first statement of Proposition 17, we conclude that with probability at least $1 - n^{-c}$ such a structure does not exist in $\mathcal{C}_n$. This contradiction shows that with high probability, the maximum load after n balls have been allocated is at most $\log_2 \log n + \mathcal{O}(1/\varepsilon)$. ◀

A Proof of Theorem 4

Proof. Let $G = ([n], E)$ denote a s-regular graph that does not contain any 4-cycle, where $s = n^{\varepsilon}$. It is worth mentioning that there are several explicit families of s-regular graphs with girth $\log_s n$ (e.g., see [10]). For each $i \in [n]$, let $N(i)$ be set of vertices adjacent to i.

Also, let $\mathcal{H} = ([n], \{N(i), i = 1, \ldots, n\})$ denote a hypergraph obtained from G. We consider the s-uniform dynamic hypergraph $(\mathcal{H}, \mathcal{H}, \ldots, \mathcal{H})$. Clearly, for every $\{i, j\} \subset [n]$ we have that

$$\texttt{vis}(i, j) \leqslant n \leqslant sn^{1-\varepsilon}$$

Therefore, the dynamic hypergraph is ε-visible. Fix an integer d such that $2 \leqslant d \leqslant s$ and d is constant. Since G does not contain any 4-cycle, we deduce that every d-subset of vertices only appears in at most one hyperedge of $\mathcal{H}$. Therefore, the probability that a d-subset is chosen by any ball is $1/(n\binom{s}{d})$. Let $D = \{i_1, i_2, \ldots, i_d\} \subset [n]$ be an arbitrary set of d vertices contained in some hyperedge of $\mathcal{H}$. Let $X(D, k)$ be an indicator random variable taking one if at least k balls choose D and zero otherwise. Then we have that

$$\mathbf{Pr}\left[X(D, k) = 1\right] = \binom{n}{k}\left(\frac{1}{n\binom{s}{d}}\right)^k$$

Also let $Y_k = \sum_D X(D, k)$ denote the number of d-subsets that are chosen by at least k balls. By linearity of expectation we have that

$$\mathbf{E}\left[Y_k\right] = \sum_D \mathbf{E}\left[X(D, k)\right] = n\binom{s}{d}\binom{n}{k}\left(\frac{1}{n\binom{s}{d}}\right)^k \geqslant n\left(\frac{s^{-d}}{k}\right)^k = n\left(\frac{n^{-d\varepsilon}}{k}\right)^k, \tag{13}$$

where the last inequality follows from $\binom{n}{k} \geqslant (\frac{n}{k})^k$ and $\binom{s}{d} < s^d$. In what follows we show that with high probability there exists k such that $Y_k \geqslant 1$. Suppose that $d\varepsilon = \Theta(1)$, then if we set $k = 1$, then there is a d-subset which is picked by at least one ball and hence $Y_1 \geqslant 1$. If $(\log\log n)/(3\log n) < d\varepsilon$ and $d\varepsilon = o(1)$, then by setting $k = 1/(6d\varepsilon)$ we have $k < (\log n)/(2\log\log n) < \log n$ and

$$\mathbf{E}\left[Y_k\right] \geqslant nk^{-k}n^{-kd\varepsilon} \geqslant n(\log n)^{-\log n/(2\log\log n)}n^{-1/6} = n^{1/3} = \omega(\log n).$$

Moreover, if $d\varepsilon \leqslant \log\log n/(3\log n)$, then by letting $k = \log n/(2\log\log n)$ we get that

$$\mathbf{E}\left[Y_k\right] \geqslant nk^{-k}n^{-kd\varepsilon} \geqslant n(\log n)^{-\log n/(2\log\log n)}n^{-1/6} = n^{1/3} = \omega(\log n).$$

Therefore, there exists $k = \min\{\Omega(1/\varepsilon), \Omega(\log n/\log\log n)\}$ so that $\mathbf{E}\left[Y_k\right] = \omega(\log n)$. As the number of balls is n, it is easy to observe that for a given k, the random variables $X(D, k)$ are negatively correlated. Application of the Chernoff bound for negatively correlated random variable implies that

$$\mathbf{Pr}\left[Y_k \leqslant \mathbf{E}\left[Y_k\right]/2\right] \leqslant \exp(-\mathbf{E}\left[Y_k\right]/8) = \exp(-\omega(\log n)).$$

It follows that there exists a d-subset D which is chosen by at least k balls and hence there is at least one bin in D whose load is at least k/d. ◀

B Proof of Proposition 8

In this section we prove Proposition 8. First we restate a useful theorem from [8].

▶ **Theorem 18** ([8, Theorem 3]). *Let M be an ergodic Markov chain with finite state space Ω and stationary distribution π. Let $T = T(\varepsilon)$ be its ε-mixing time for $\varepsilon < 1/8$. Let $(Z_1, \ldots, Z_t)$ denote a t-step random walk on M starting from an initial distribution ρ on Ω (that is, Z_1 is distributed according to ρ). For some positive constant μ and every $i \in [t]$, let $f_i : \Omega \to [0, 1]$ be a weight function at step i such that the expected weight $\mathbf{E}_\pi\left[f_i(v)\right] = \sum_{v\in\Omega}\pi(v)f_i(v)$ satisfies $\mathbf{E}_\pi\left[f_i(v)\right] = \mu$ for all i. Define the total weight of the walk $(Z_1, ..., Z_t)$ by $X = \sum_{i=1}^t f_i(Z_i)$. Write $||\rho||_\pi = \sqrt{\sum_{x\in\Omega}\rho_x^2/\pi_x}$. Then there exists some positive constant c (independent of μ and ε) such that for all $\alpha \geqslant 0$,*

1. $\mathbf{Pr}\left[X \geqslant (1+\alpha)\mu t\right] \leqslant c||\rho||_\pi \, \mathrm{e}^{-\alpha^2\mu t/72T}$ *for* $0 \leqslant \alpha \leqslant 1$.
2. $\mathbf{Pr}\left[X \geqslant (1+\alpha)\mu t\right] \leqslant c||\rho||_\pi \, \mathrm{e}^{-\alpha\mu t/72T}$ *for* $\alpha > 1$.
3. $\mathbf{Pr}\left[X \leqslant (1-\alpha)\mu t\right] \leqslant c||\rho||_\pi \, \mathrm{e}^{-\alpha^2\mu t/72T}$ *for* $0 \leqslant \alpha \leqslant 1$.

Proof of Proposition 8. Let Ω be the vertex set of the R-dimensional torus $\Gamma(n, R)$ and let a and b denote two arbitrary agents. By definition of the communication graph process, agents a and b are initially placed on two randomly chosen vertices of Γ, say u_0 and v_0. Note that u_0 and v_0 are independently chosen according to the stationary distribution π of the random walk on $\Gamma(n, R)$. Now consider the trajectory of agents a and b, which give two independent random walks $u_0, u_1, \ldots$ and $v_0, v_1, \ldots$ on $\Gamma(n, R)$. Defining $X_t = (u_t, v_t)$ for $t = 0, 1, \ldots$ gives a finite, ergodic Markov chain with stationary distribution (π, π) on $\Omega \times \Omega$. For every $t \geqslant 0$, define $f(X_t) = f(u_t, v_t)$ to equal 1 if $d(u_t, v_t) \leqslant r$, and equal 0 otherwise, where $d(\cdot, \cdot)$ is the Manhattan distance for the given grid. Let u_t^1 and v_t^1 denote the projection of the random walks u_t and v_t onto the 1-dimensional torus $\Gamma(n^{1/R}, 1)$, respectively, defined by taking the first component of each of the random walks on $\Gamma(n, R)$. Then $X_t^1 = (u_t^1, v_t^1)$ is an ergodic Markov chain on $\Gamma(n^{1/R}, 1)$, and its initial distribution is stationary. We may also define $f(u_t^1, v_t^1)$ to be 1 if $d(u_t^1, v_t^1) \leqslant r$, and 0 otherwise. By the Manhattan distance property, if $f(u_t, v_t) = 1$ then $f(u_t^1, v_t^1) = 1$. Therefore,

$$\mathtt{vis}(a, b) = \sum_{t=0}^{n} f(X_t) \leqslant \sum_{t=0}^{n} f(X_t^1).$$

Set $\delta = \min\{1/4, 1/R\}$. Let t_0 be the first time when $d(u_{t_0}^1, v_{t_0}^1) \leqslant n^\delta$. Consider a moving window W of length $2n^\delta + 1$, which contains the locations of $u_{t_0}^1$ and $v_{t_0}^1$. At time t_0, the vertices covered by W are labelled in increasing order, with the leftmost vertex labelled $-n^\delta$ and the rightmost vertex labelled $n^\delta - 1$. The window W stays at its initial location as long as no agent hits a border of W (vertices labelled $-n^\delta$ or n^δ), or the middle vertex of W (labelled 0). Let b be the first agent that hits a border or the centre of W. From this time on, b and W are coupled so that they both move and/or stay, simultaneously. (If b moves left then W also moves left, for example.) Each time the window W moves, a vertex $u \in \Gamma_1$ is no longer covered by W and a new vertex, $w \in \Gamma_1$, becomes covered by w. The new vertex w is assigned the label of vertex u. This process always labels the vertices covered by W by $\{-n^{\delta-1}, \ldots, n^\delta - 1\}$, and the movement of agent b over these labeled vertices simulates a random walk on the additive group $\mathbb{Z}_{2n^\delta+1}$. Define

$$S = \{1 \leqslant t \leqslant n \mid u_t^1 \text{ and } v_t^1 \in W\}.$$

Assume that $S \neq \emptyset$ and define the chain $Y_t = (u_t^1, v_t^1), t \in S$. Then Y_t can be considered as an ergodic Markov chain of length $|S| \leqslant n$ over $\mathbb{Z}_{2n^\delta-1}$, or equivalently, as a Markov chain on a $(2n^\delta + 1)$-cycle. By the proposition assumption we have $r = \mathcal{O}(n^{o(1)}) < n^\delta$, and so

$$\mathtt{vis}(a, b) = \sum_{t=0}^{n} f(X_t) \leqslant \sum_{t=0}^{n} f(X_t^1) \leqslant \sum_{t \in S} f(Y_t) \leqslant \sum_{t=0}^{n} f(Y_t).$$

The chain Y_t converges to stationary distribution (π, π), where π is the uniform distribution of a random walk on a $(2n^\delta + 1)$-cycle. It follows that for all $t = 0, 1, \ldots$ we have $\mathbf{E}_{(\pi,\pi)}\left[f(Y_t)\right] = \mu = \Theta(r/n^\delta)$, independently of t. It is well-known [15] that the ε-mixing time of the random walk on a $(2n^\delta + 1)$-cycle is $\mathcal{O}(n^{2\delta} \log(1/\varepsilon))$. If ρ is the initial distribution Y_0, then we have that $||\rho||_\pi \leqslant \mathcal{O}(n^\delta)$. Applying Theorem 18 implies that

$$\mathbf{Pr}\left[\sum_{t=1}^{n} f(Y_t) \geqslant \mu \cdot n\right] = \mathcal{O}(n^\delta)\mathrm{e}^{-\Theta(rn^{1-3\delta})} = n^{-\omega(1)}.$$

Therefore, with probability $1 - n^{-\omega(1)}$,

$$\texttt{vis}(a,b) \leqslant \sum_{t=0}^{n} f(Y_t) = \mathcal{O}(rn^{1-\delta}) = \mathcal{O}(n^{1-\delta+o(1)}) = \mathcal{O}(n^{1-\varepsilon}),$$

taking $\varepsilon = \delta/2$, say. Taking the union bound over all pairs of agents completes the proof. ◀

C Proof of Lemma 14

Berenbrink et al. [3] proposed an allocation algorithm $\mathcal{B}$ such that for $t = 1, 2, \ldots$, the t-th ball chooses an edge of $\mathcal{H}^{(t)} = ([n], \mathcal{E}_t), t = 1, \ldots$, uniformly at random, say H_t. The ball is then allocated to an empty vertex (bin) of H_t, with ties broken randomly. If H_t does not contain an empty bin then the process fails. The next lemma follows directly from [3, Lemmas 4, 5].

▶ **Lemma 19.** *Suppose that the dynamic s-uniform hypergraph $(\mathcal{H}^{(1)}, \ldots, \mathcal{H}^{(n)})$ satisfies the balancedness and size properties. There exists $m = \Theta(n)$ such that with probability at least $1 - n^{-2}$, algorithm $\mathcal{B}$ successfully allocates m balls and there are at least $s/2$ empty vertices in H_t for $t = 1, \ldots, m$.*

We now apply the above result to prove Lemma 14.

Proof of Lemma 14. We apply a coupling technique between the balanced allocation process on a dynamic hypergraph and $\mathcal{B}$.

Let us first consider an identical copy of the set of bins, called B. The coupled process sequentially allocates a ball to a pair of bins. In round $t = 1, \ldots, m$, the t-th ball chooses an edge of $\mathcal{H}^{(t)}$ uniformly at random, say H_t. Let H'_t be the corresponding set of bins, chosen from B. Then the first ball is allocated to a bin, say i, contained in H_t according the balanced allocation. If $i \in H'_t$ is empty then the second ball is allocated to bin $i \in H'_t$ as well. If $i \in H'_t$ is not empty then the second ball is allocated to an empty bin from H'_t, with ties are broken randomly. If there is no empty bin in H'_t then the coupling fails. Note that H_t and H'_t have the same set of bins but may have different loads. Observe that the coupled process allocates balls to bins from B according to $\mathcal{B}$. Next we show that for $t = 1, \ldots, m$,

$$\textsc{Empty}(H_t) \geqslant \textsc{Empty}(H'_t), \tag{14}$$

where $\textsc{Empty}(H)$ denotes the number of empty bins contained in H. For a contradiction, assume that there is a first time t_1 such that $\textsc{Empty}(H'_{t_1}) > \textsc{Empty}(H_{t_1})$. Then there is vertex $i \in H'_{t_1}$ which is empty, while $i \in H_{t_1}$ has a ball at height zero: this is ball t_0, say, where $1 \leqslant t_0 \leqslant t_1$. This implies that the coupled process has allocated ball t_0 to bin $i \in H_{t_1}$, but it has not allocated any ball to bin $i \in H'_{t_1}$, since i was empty until round t_1. This contradicts the definition of the coupled process. So Inequality (14) holds for $t = 1, \ldots, m$. Applying Lemma 19 yields that there exists $m = \Theta(n)$ such that for $t = 1, \ldots, m$, $\textsc{Empty}(H_t) \geqslant \textsc{Empty}(H'_t) \geqslant s/2$. ◀

D Proof of Proposition 17

In this subsection we will prove two lemmas and then combine them to establish the proposition. The lemmas and their proofs are inspired by [13, Lemma 2.1 and 2.2]. Recall that a subgraph of $\mathcal{C}_n$ is c-loaded if every vertex (bin) in the subgraph has load at least c.

▶ **Lemma 20.** *Let k be a positive integer and let $c_1 > 0$. The probability that conflict graph $\mathcal{C}_n$ contains a c_1-loaded connected component with k vertices is at most $n \cdot 8^k \cdot \left(\frac{2\mathrm{e}}{c_1}\right)^{c_1 k}$. Moreover, by setting $c_1 = 12(c+1)$, we conclude that with probability at least $1 - n^{-c}$, the conflict graph $\mathcal{C}_n$ does not contain a c_1-loaded tree with at least $\log n$ vertices.*

Proof. A connected component in $\mathcal{C}_n$ with k vertices contains a spanning tree with k vertices. By Proposition 10, there are at most 4^{k-1} ordered trees with k vertices. For every ordered tree, we can choose its root in n ways, as we have n bins (vertices). Hence there are at most $n \cdot 4^{k-1}$ rooted and ordered trees. Let us fix an arbitrary ordered tree T with a specified root. Also let $(t_1, \ldots, t_{k-1})$ denote an arbitrary sequence of rounds, where $t_i \in \{1, \ldots, n\}$ is the round when the i-th edge of the ordered tree T is chosen. Notice that in an ordered tree with specified root, the i-th edge always connects the i-th child to its parent, and the parent is already known to us. Therefore, to build the tree, the i-th edge of the tree must be chosen from edges of $G^{(t_i)}$ that are adjacent to the known parent. This implies that the algorithm chooses the i-th edge of T in round t_i with probability $\frac{\Delta_{t_i}}{n\Delta_{t_i}/2} = \frac{2}{n}$. Since balls are independent from each other, the tree T is constructed at the given times $(t_1, \ldots, t_{k-1})$ with probability

$$\left(\frac{2}{n}\right)^{k-1}. \tag{15}$$

On the other hand, ball t is allocated to a given bin with probability at most $\Delta_t/(n\Delta_t/2) = 2/n$. Therefore, the probability that T is c_1-loaded is at most

$$\binom{n}{ck}\left(\frac{2k}{n}\right)^{c_1 k} \leqslant \left(\frac{\mathrm{e}n}{c_1 k}\right)^{c_1 k}\left(\frac{2k}{n}\right)^{c_1 k} = \left(\frac{2\mathrm{e}}{c_1}\right)^{c_1 k}, \tag{16}$$

where we used the fact that $\binom{n}{c_1 k} \leqslant \left(\frac{\mathrm{e}n}{c_1 k}\right)^{c_1 k}$. Since balls are independent, one can multiply (15) by (16) and derive an upper bound for the probability that T is constructed at the given times and is c-loaded. Taking the union bound over all rooted ordered trees and time sequences gives

$$\begin{aligned} n4^{k-1} \sum_{(t_1,\ldots,t_{k-1})} \left\{\left(\frac{2}{n}\right)^{k-1}\left(\frac{2\mathrm{e}}{c_1}\right)^{c_1 k}\right\} &\leqslant n4^{k-1}n^{k-1} \cdot \left\{\left(\frac{2}{n}\right)^{k-1}\left(\frac{2\mathrm{e}}{c_1}\right)^{c_1 k}\right\} \\ &= n8^{k-1}\left(\frac{2\mathrm{e}}{c_1}\right)^{c_1 k}, \end{aligned}$$

proving the first statement of the lemma. By setting $c_1 = 12(c+1)$ and $k = \log n$ in the above formula, we infer that the probability that $\mathcal{C}_n$ contains a c_1-loaded tree with $\log n$ vertices is at most

$$n8^{k-1}\left(\frac{2\mathrm{e}}{c_1}\right)^{c_1 k} < n2^{3k}2^{-12(c+1)k} \leqslant n2^{-ck-9k} \leqslant n^{-c},$$

completing the proof. ◀

▶ **Lemma 21.** *Suppose that the conflict graph $\mathcal{C}_n$ contains a c-loaded k-vertex tree T, where $c > 4\mathrm{e}$ is any constant and k is a positive integer. Let p denotes the number of cycle-producing edges (with respect to T) which have been added between vertices in this tree during the allocation process. Then $p < 2(c+1)/\varepsilon$ with probability at least $1 - n^{-c}$.*

Proof. For a given connected component of k vertices, there are at most $\binom{k}{2}$ edges whose addition may produce a cycle. This includes edges already present in the component, as an edge with multiplicity 2 (double edge) forms a 2-cycle. Thus, the p edges can be chosen in $\binom{k}{2}^p < k^{2p}$ ways. Let $\{e_1, e_2, \ldots, e_p\}$ denote a set of p cycle-producing edges (some of these may create 2-cycles). Also let $(t_1, \ldots, t_p)$ denote a sequence of rounds, where $t_i \in \{1, \ldots, n\}$ is the round in which the t_i-th ball picks edge e_i. For each round $t = 1, 2, \ldots, n$ and $i = 1, \ldots, p$, let us define $\mathbb{I}_t(e_i)$ to equal 1 if $e_i \in E_t$, and 0 otherwise. It is easy to see that

$$\mathbf{Pr}\left[\text{ball } t \text{ picks edge } e_i \text{ of } G^{(t)}\right] = \frac{\mathbb{I}_t(e_i)}{|E_t|}.$$

Now $\texttt{vis}(e_i) = \sum_{t=1}^{n} \mathbb{I}_t(e_i)$ for $i = 1, \ldots, p$. Using this, and the fact that $|E_t| \geqslant n/2$ for each t (since $G^{(t)}$ is regular with degree at most 1), the probability that $e_1, e_2, \ldots, e_p$ are chosen is at most

$$\sum_{(t_1,\ldots,t_p)} \left\{ \prod_{i=1}^{p} \frac{\mathbb{I}_{t_i}(e_i)}{E_{t_i}} \right\} \leqslant \prod_{i=1}^{p} \left\{ \sum_{t=1}^{n} \frac{\mathbb{I}_t(e_i)}{E_t} \right\} \leqslant \prod_{i=1}^{p} \frac{4\,\texttt{vis}(e_i)}{n} \leqslant \left(\frac{4n^{1-\varepsilon}}{n}\right)^p = \left(\frac{4}{n^\varepsilon}\right)^p. \quad (17)$$

Moreover, applying Lemma 20 shows that the probability that $\mathcal{C}_n$ contains a c-loaded k-vertex tree is at most

$$n \cdot 8^k \cdot \left(\frac{2\mathrm{e}}{c}\right)^{ck} \leqslant n \cdot 2^{-k}, \quad (18)$$

as $c \geqslant 4\mathrm{e}$. So, with high probability, $\mathcal{C}_n$ does not contain any c-loaded tree with at least $(\log n)^2$ vertices. Now assume that $k < (\log n)^2$. Combining (17) and (18), and taking the union bound over all choices for a set of p edges, we find that the probability that a c-loaded k-vertex tree contains p cycle-producing edges is at most

$$k^{2p} \cdot \left(\frac{4}{n^\varepsilon}\right)^p \cdot n \cdot 2^{-k} = \left(\frac{4 \cdot k^2}{n^\varepsilon}\right)^p \cdot n \cdot 2^{-k} \leqslant n^{-\varepsilon p/2} \cdot n \cdot 2^{-k}, \quad (19)$$

where the inequality holds as $k < (\log n)^2$. Therefore the probability that $p = \lceil 2(c+1)/\varepsilon \rceil$ cycle-producing edges are present is at most n^{-c}. We conclude that $p < 2(c+1)/\varepsilon$ with probability at least $1 - n^{-c}$. ◀

Proof of Proposition 17. Combining the Lemmas 20 and 21 establishes the proposition. ◀

The GaussianSketch for Almost Relative Error Kernel Distance

Abstract

We introduce two versions of a new sketch for approximately embedding the Gaussian kernel into Euclidean inner product space. These work by truncating infinite expansions of the Gaussian kernel, and carefully invoking the RecursiveTensorSketch [Ahle et al. SODA 2020]. After providing concentration and approximation properties of these sketches, we use them to approximate the kernel distance between points sets. These sketches yield almost $(1+\varepsilon)$-relative error, but with a small additive α term. In the first variants the dependence on $1/\alpha$ is poly-logarithmic, but has higher degree of polynomial dependence on the original dimension d. In the second variant, the dependence on $1/\alpha$ is still poly-logarithmic, but the dependence on d is linear.

1 Introduction

Kernel methods are a pillar of machine learning and general data analysis. These approaches consider classic problems such as PCA, linear regression, linear classification, k-means clustering which at their heart fit a linear subspace to a complex data set. Each of the methods can be solved by only inspecting the data via a dot product $\langle x, p\rangle$. Kernel methods, and specifically the "kernel trick," simply replaces these Euclidean dot products with a non-linear inner product operation. The two most common inner products are the polynomial kernel $K_z(x,p) = (\langle x,p\rangle + 1)^z$ and the Gaussian kernel $K(x,p) = \exp(-\|x-p\|^2)$.

The "magic" of the kernel method works mainly because of the existence of a reproducing kernel Hilbert space (RKHS) $\mathcal{H}_K$ associated with any positive definite (p.d.) kernel [43] K. It is a function space, so for any data point $x \in \mathbb{R}^d$, there is a mapping $\phi : \mathbb{R}^d \to \mathcal{H}_K$ so $\phi(x) = K(x,\cdot)$. Since $\phi(x)$ is a function with domain $\mathbb{R}^d$, and each "coordinate" of $\phi(x)$ is associated with another point $p \in \mathbb{R}^d$, there are an infinite number of "coordinates," and $\mathcal{H}_K$ can be infinite dimensional. However, since $\langle \phi(x), \phi(p)\rangle_{\mathcal{H}_K} = K(x,p)$, this embedding does not ever need to be computed, we can simply evaluate $K(x,p)$. And life was good.

However, at the dawn of the age of big data, it became necessary to try to explicitly, but approximately, compute this map ϕ. Kernel methods typically start by computing and then analyzing the $n \times n$ gram matrix K_X where $(K_X)_{i,j} = K(x_i, x_j)$ for a data sets X

of size n. As n became huge, this became untenable. In a hallmark paper, Rahimi and Recht [37] devised random Fourier features (RFFs) for p.d. kernels (with max value 1, e.g., Gaussians) that compute a random map $\tilde{\phi} : \mathbb{R}^d \to \mathbb{R}^{\tilde{D}}$ so $\langle \tilde{\phi}(x), \tilde{\phi}(p) \rangle$ is an unbiased estimate of $K(x, p)$, and with probability at least $1 - \delta$ has error $|K(x, p) - \langle \tilde{\phi}(x), \tilde{\phi}(p) \rangle| \leq \varepsilon$. For just one pair of points they require $\tilde{D} = O((1/\varepsilon^2) \log(1/\delta))$, or for all comparisons among n points $\tilde{D}_n = ((1/\varepsilon^2) \log(n/\delta))$, or for any points in a region Λ of volume $\mathsf{vol}(\Lambda) \leq V$, then $\tilde{D}_V = ((1/\varepsilon^2) \log(V/\delta))$.

However, relative-error-preserving RKHS embeddings for p.d. kernels are impossible without some restriction on the size n or domain Λ of the data. Consider n data points each far from each other so any pair $x, p \in \mathbb{R}^d$ satisfies $K(x, p) < 1/n$. In any relative-error-approximate embedding $\hat{\phi} : \mathbb{R}^d \to \mathbb{R}^{\hat{D}}$, each point must be virtually orthogonal to all other points, and hence $\Omega(n)$ dimensions are required [28].

Instead, to obtain (almost) relative-error results in big data sets, researchers have relied on other approaches such as sampling [45], exploiting structure of p.d. Gram matrices [34], devising modified RFFs for regularized kernel regression [9], or building data structures for kernel density estimate queries [12].

The kernel distance and data set embeddings. To address these difficulties, we first turn our attention from the inner product $\langle \phi(x), \phi(p) \rangle_{\mathcal{H}_K} = K(x, p)$ in the RKHS to the natural distance it implies. Before stating this distance, we generalize the inner product to point sets $P \subset \mathbb{R}^d$ (which extends naturally to probability distributions μ_P with domain $\mathbb{R}^d$). We treat P as a discrete probability distribution with uniform $1/|P|$ weight on each point. This can be represented in $\mathcal{H}_K$ as $\Phi(P) = \frac{1}{|P|} \sum_{x \in P} \phi(x)$, known as the kernel mean [33]. Indeed, for any query point $p \in \mathbb{R}^d$, the inner product $\langle \Phi(P), \phi(p) \rangle_{\mathcal{H}_K} = \frac{1}{|P|} \sum_{x \in P} K(x, p)$ is precisely the kernel density estimate at p. For two point sets $P, Q \subset \mathbb{R}^d$ we define $\kappa(P, Q) = \frac{1}{|P|} \frac{1}{|Q|} \sum_{x \in P} \sum_{y \in Q} K(p, q) = \langle \Phi(P), \Phi(Q) \rangle_{\mathcal{H}_K}$.

Now the kernel distance [36, 26] (alternatively known as the current distance [23] or maximum mean discrepancy [24, 39]) is defined

$$\mathtt{D}_K(P, Q) = \|\Phi(P) - \Phi(Q)\|_{\mathcal{H}_K} = \sqrt{\kappa(P, P) + \kappa(Q, Q) - 2\kappa(P, Q)}.$$

Under a slightly restricted class of kernels (a subset of p.d. kernels), called *characteristic* kernels [42], this distance is a metric. These include the Gaussian kernels which we focus on hereafter. This distance looks and largely acts like Euclidean distance; indeed, restricted to any finite-dimensional subspace, it is equivalent to Euclidean distance.

In data analysis and statistics, kernel mean is a compact way to represent a point set distribution. One can also use kernel distance to compare different point set as opposed to more expensive measure such as Wasserstein distance. In practice, there are various applications such as hypothesis test and geometric search (see section 4 for detail discussion) that use kernel distance as a core component. We suggest the reader refer to [38, 40] for more details on the statistical perspective of kernel distance. Therefore, making computation of the kernel distance scalable by a kernel distance embedding is of significant importance for those downstream applications. More generally, one can view oblivious kernel distance embedding as special case of oblivious subspace embedding for RKHS [32, 2], which gives a stronger guarantee than a subspace in the RKHS is preserved within relative error. However, many application of kernel distance do not require such a strong guarantee, which generally attain worse results (see below for more detail comparison).

So a natural question to ask is if this distance is preserved within relative error via some approximate lifting. Clearly RFFs guarantee additive ε-error. However, relate this problem to the Johnson-Lindenstrauss (JL) Lemma [25]: JL describe a family of random projections

from a high-dimensional space to a D'-dimensional space which preserve $(1+\varepsilon)$-relative error on Euclidean distance, again with $D' = O((1/\varepsilon^2)\log(n/\delta))$ for any $\binom{n}{2}$ pairs of distances, succeed with probability $1-\delta$, but only guarantees additive error on inner products.

Moreover, it is possible to apply the JL Lemma to create such an approximate embedding. First for any set of n points X, we can create $n \times n$ Gram matrix K_X (that is positive definite), and decompose it to $K_X = B_X B_X^T$. Then each row $(B_X)_i$ in B_X is the n-dimensional vector representation of the ith data point, and the Euclidean distance $\|(B_X)_i - (B_X)_j\|_2$ is the kernel distance between data points i and j [31, 8]. Then we can apply JL on these rows $\{(B_X)_i\}$ to obtain such an approximate embedding. However, this embedding is not oblivious to the data (necessary for many big data settings like streaming) and still requires $\Omega(n^2)$ time just to create the Gram matrix, not to mention the time for decomposition.

Another recent approach [14] analyzed RFFs for this task, and shows that these approximate embeddings do guarantee relative error on the kernel distance, but only between each pair of points $x, p \in \mathbb{R}^d$ (e.g., so $\frac{\|\hat{\phi}(x)-\hat{\phi}(p)\|}{\mathtt{D}_K(x,p)} \in (1 \pm \varepsilon)$), and as we describe next many downstream analysis tasks require the distance preserved between point *sets*. Alternatively, if we assume $\mathtt{D}_K^2(P,Q) > \alpha$, then standard RFFs can provide a relative error guarantee using $\tilde{D} = O(\frac{1}{\varepsilon^2\alpha^2}\log\frac{1}{\delta})$. However, such a large factor in α is undesirable, since typically $\alpha \ll \varepsilon$.

Our Results. We provide two sketches $G : \mathbb{R}^d \to \mathbb{R}^D$ for the Gaussian kernel, improving on work of Rahimi and Recht [37] and Avron et al. [9], which achieves almost relative error for kernel distance. Let $F(X) = \frac{1}{|X|}\sum_{x\in X} G(x)$ extend the sketch to point sets $X \subset \mathbb{R}^d$. Then we show that for two point sets $P, Q \subset \mathbb{R}^d$

$$\left|\mathtt{D}_K^2(P,Q) - \|F(P) - F(Q)\|^2\right| \leq \varepsilon \mathtt{D}_K^2(P,Q) + \alpha.$$

As we can always reduce the dimension $G : \mathbb{R}^d \to \mathbb{R}^D$ using JL to about $D = 1/\varepsilon^2$, we focus on reducing the runtime dependence, in particular the dependence on α.

In the first sketch (the GaussianSketch) to process a single point with $G(x)$ it takes $O\left(\frac{d^2}{\varepsilon^2}\log\frac{d}{\varepsilon} + ds\right)$ time, with $s = \Theta\left(\frac{\log(d\exp(dL^2)/\alpha)}{\log(\frac{1}{L^2}\log(d\exp(dL^2)/\alpha))}\right)$, where L describes the (L_∞) radius of the domain containing X. So the dependence on $1/\alpha$ is less than a single logarithmic term.

The second sketch (the GaussianSketchHD) is useful when the dimension d is potentially large (it turns out to be very similar to a recent sketch in [2], but our analysis is different). Then the runtime to compute $G(x)$ is $O\left(\frac{s^3}{\varepsilon^2}\log\frac{s}{\varepsilon} + s^2 d\right)$ where $s = \Theta\left(\frac{\log(4\exp(2R^2)/\alpha)}{\log(\frac{1}{R^2}\log(4\exp(2R^2)/\alpha))}\right)$, and R is the (L_2) domain radius. Now the dependence on $1/\alpha$ is still poly-logarithmic, but the dependence on dimension d is linear.

For example, we can set $\alpha = n^{-C_1}$, $R = C_2\sqrt{\log n}$ and $L = C_3\sqrt{\log n}$ for some absolute constant C_1, C_2, C_3. In low dimension, we have $s = \Theta(\frac{\log n}{\log d})$ and the running time is $O(\frac{d^2}{\varepsilon^2}\log\frac{d}{\varepsilon} + \frac{d\log n}{\log d})$. In high dimension, we have $s = \Theta(\log n)$ and the running time is $O\left(\frac{1}{\varepsilon^2}\log^3 n\log(\log n/\varepsilon) + d\log^2 n\right)$.

Implications. Several concrete applications work direfctly on this kernel distance between point sets. First, the kernel two-sample test [24, 33] is a non-parametric way to perform hypothesis tests between two empirical distributions; simply, the null hypothesis of them being drawn from the same distribution is rejected if the kernel distance is sufficiently large. While the sketched kernel two-sample test has proven effective under additive error [48], when the significance threshold is $\Theta(1/n)$, the RFF-based solutions require time $O(n^2)$, no better than brute force; but setting ε constant and $\alpha = 1/n$, our sketches provide near-linear or almost-linear time runtimes. Second, devising a Locality Sensitive Hash (LSH) between

point sets (or geometrically-aware LSH for probability distributions) has lacked a great general solution. Despite progress in special cases (e.g., for polygons [13], curves [18]), more general distances between geometric distributions, like Earth-Mover distance require $\Omega(\log s)$ distortion on a domain with at least s discrete points [7]. In general, an LSH requires relative error to properly provide $(1+\varepsilon)$-approximate nearest neighbor results. In Section 4 we specify how our new almost relative-error embeddings for the kernel distance provide efficient solutions for these applications.

Furthermore, this embedding can be composed with a Johnson-Lindenstrauss-type embedding [25, 3, 4, 1, 46] to create an overall oblivious embedding of dimension roughly $O(\frac{1}{\varepsilon^2}\log\frac{1}{\delta})$, that is with no dependence on $1/\alpha$ or d (or n or domain radius L or R in the *for each* setting), and roughly the same guarantees.

1.1 Comparison to Other Recent Work on Large Data and Kernels

Recent related works on kernel approximation do not provide our guarantees; we survey here work that addresses similar problems, and often require similar sets of error parameters.

Approximated KDEs. Charikar and Siminelakis [12] describe a data structure of size $n\hat{D}$ and query time $\hat{D}$, which answers $\kappa(P,t)$ queries within $(1+\varepsilon)$-relative error as long as $\kappa(P,t)>\alpha$; it requires $\hat{D}=O(\frac{1}{\varepsilon^2}\frac{1}{\sqrt{\alpha}}\log\frac{1}{\delta}e^{O(\log^{2/3} n\log\log n)})$. However, this cannot argue much about how large $\mathtt{D}_K(P,Q)$ has to be for this to achieve relative error on the kernel distance since it could be $\mathtt{D}_K(P,Q)$ is small but $\kappa(P,t)$ and $\kappa(P,P)$ are both large. Moreover, its guarantees only work for a single point set P with point queries t, not for two or more points sets P,Q, as we argue many downstream data analysis tasks require.

Approximated kernel regression. Avron et al. [9] modify the RFF embeddings using different sampling probability related to the statistical leverage in the kernel space. This approximates a λ-regularized kernel regression problem, creating a $\tilde{D}$-dimensional embedding; that is for an $n\times n$ gram matrix K_X, and a regularization parameter λ it creates a $n\times\tilde{D}$ matrix Z so $(1-\varepsilon)(K_X+\lambda I_n)\preceq ZZ^*+\lambda I_n\preceq(1+\varepsilon)(K_X+\lambda I_n)$, using $\tilde{D}=O(\frac{1}{\varepsilon^2}(L^d\log^{d/2}(n/\lambda)+\log^{2d}(n/\lambda))\log(s_\lambda(K)/\delta))$. Following our forthcoming methods for analysis, one can modify this result to $(1+\varepsilon)$-approximate the kernel distance, with an additive α term, with an embedding of dimension $D=O\left(\frac{1}{\varepsilon^2}(L^d\log^{d/2}\frac{n}{\alpha}+\log^{2d}\frac{n}{\alpha})\log\frac{n}{\delta}\right)$.

Also, Ahle et al. [2] recently showed that one can create such $\tilde{D}$-dimensional embedding where $\tilde{D}=O(\frac{1}{\varepsilon^2}(R^2+\log\frac{n}{\varepsilon\lambda})^5 s_\lambda(K_X))$ in $O(\frac{1}{\varepsilon^2}(R^2+\log\frac{n}{\varepsilon\lambda})^6 s_\lambda(K_X))$ time for each data point. Again, in our setting, one can interpret this result as $(1+\varepsilon)$-approximate the kernel distance, with an additive α term, in $O(\frac{1}{\varepsilon^2}(R^2+\log\frac{n}{\varepsilon\alpha})^6 s_\alpha(K_X))$ time.

Compared to our bounds (adapted to our problem using our techniques), these depend on n and s_λ (ours do not), the low-d one is exponential in d (ours is polynomial), and the other powers are larger.

Approximate Kernel PCA. Suppose we are given a data set $X=\{x_1,\ldots,x_n\}\subset\mathbb{R}^d$, and want to find a low rank (rank k) approximation of $X_\phi=\{\phi(x_1),\phi(x_2),\ldots,\phi(x_n)\}\in\mathcal{H}_K$. In particular, this can be described concretely in the context of the Gram matrix K_X and its decomposition $B_X B_X^T$. Given any $n\times m$ matrix M, let $[M]_k$ be its best rank-k approximation. A natural question is to find a rank-k matrix $\tilde{K}_X$ so

$$\left\|K_X-\tilde{K}_X\right\|_F^2\leq(1+\varepsilon)\left\|K_X-[K_X]_k\right\|_F^2.$$

While most previous work [19, 30, 22, 41, 44] has focused on providing absolute (or additive) error bounds. For instance, they showed roughly $\|K_X - \tilde{K}_X\|_F^2 \leq \|K_X - [K_X]_k\|_F^2 + \varepsilon n$ using e.g., Nyström sampling and RFFs. More recently, Musco and Woodruff [35] for p.d. Gram matrices K_X show how to efficiently find $\tilde{K}_X$ with relative error. This only requires $O(nk^{\omega-1} \cdot \mathsf{poly}(\log n/\varepsilon))$ inspections of entries of K_X, where $\omega < 2.373$ is the matrix multiplication exponent. This is not data oblivious, and uses properties of the p.d. matrix, so it does not provide an embedding sketch.

A closely related problem is approximate kernel PCA problem which is to find a $n \times k$ orthonormal matrix V so that

$$\|B_X - VV^T B_X\|_F^2 \leq (1+\varepsilon)\|B_X - [B_X]_k\|_F^2.$$

The RKHS basis V, provides a compact and non-linear set of attributes to describe a complex data set X, and has many uses in analyzing complex data which lacks strong linear correlations. Musco and Woodruff [34] provide an algorithm with runtime $O(\mathsf{nnz}(X)) + \tilde{O}(n^{\omega+1.5}(\frac{k}{\sigma_{k+1}\varepsilon^2})^{\omega-1.5})$; which has polynomial dependence on $1/\sigma_{k+1}$. They leave open whether this can be removed or reduced while maintaining only roughly $\mathsf{nnz}(X)$ dependence on X. The matrix V returned by their algorithm can be used to approximate the matrix K_X by writing $B_X P B_X^T$ where P is the projection onto the row span of $VV^T B_X$.

Our techniques can be combined with the a sketch for the polynomial kernel [10] to explicitly solve for V so

$$\|B_X - VV^T B_X\|_F^2 \leq (1+\varepsilon)\|B_X - [B_X]_k\|_F^2 + \alpha.$$

with similar dimensions required for approximating the kernel distance; the s parameter increases roughly by $\log n/\log\log n$. This is detailed in Appendix A. If the data size n has a known bound, then this provides an oblivious sketch for this almost relative error kernel PCA problem. Moreover, replacing the σ_{k+1} with $\varepsilon\alpha$, it almost answers the kernel PCA $\mathsf{nnz}(X)$ question of Musco and Woodruff [34] – however our algorithm does not depend on the number-of-non-zeros of X through our sketches, so we leave as an open question if our sketches $G(x)$, particular the GaussianSketchHD or similar, can be generated in time $O(\mathsf{nnz}(x)\mathsf{polylog}(1/\alpha) + n\mathsf{poly}(k, 1/\varepsilon, \log(1/\alpha))$.

2 The GaussianSketch and its Properties

In this section we describe our new sketches for approximate mapping from $\mathbb{R}^d$ to an RKHS associated with a Gaussian kernel. They are based on the RecursiveTensorSketch of Ahle et al. [2], so we first review its properties.

The RecursiveTensorSketch. We first introduce RecursiveTensorSketch hash family [2]. Given positive integers n, m and k, RecursiveTensorSketch$_{n,m,k}$ is the family of hash functions $T : \mathbb{R}^{n^k} \to \mathbb{R}^m$ as constructed in [2]. This hash family will be used to construct our main sketch and has the following guarantee [2]: suppose $u, v \in \mathbb{R}^{n^k}$ and picking $m = O(\frac{k}{\varepsilon^2})$, then the expectation $\mathsf{E}(\langle T(u), T(v)\rangle) = \langle u, v\rangle$ and the variance $\mathsf{Var}(\langle T(u), T(v)\rangle) \leq \frac{\varepsilon^2}{10}\|u\|^2\|v\|^2$. Moreover, the running time of computing $T(x)$ for any $x \in \mathbb{R}^{n^k}$ is $O(km\log m + kn)$.

The GaussianSketch. Now, we can define the hash family of the first sketch for the Gaussian kernel GaussianSketch. Given a vector $x \in \mathbb{R}^d$ and a positive integer s, we first define d vectors $y_x^{(1)} \dots, y_x^{(d)} \in \mathbb{R}^s$ such that ith coordinate of $y_x^{(j)}$ is $\exp(-x_j^2)\sqrt{\frac{2^{i-1}}{(i-1)!}}x_j^{i-1}$. Given an integer m, define GaussianSketch$_{m,s}$ to be the family of hash functions that if G is in it, then $G(x) = T(y_x^{(1)} \otimes \cdots \otimes y_x^{(d)})$ where T is randomly chosen from RecursiveTensorSketch$_{s,m,d}$.

Here, $x \otimes y$ is Kronecker product. Namely, given $x \in \mathbb{R}^p$ and $y \in \mathbb{R}^q$, $x \otimes y$ is a pq dimensional vector indexed by two integers i, j where $i = 1, \dots, p$ and $j = 1, \dots, q$ such that $(x \otimes y)_{i,j} = x_i \cdot y_j$. For notational convenience, we extend Kronecker product when p and q are infinity. Namely, given $\{x_i\}_{i=1}^{\infty}$ and $\{y_j\}_{j=1}^{\infty}$ are infinite sequences, $x \otimes y$ is also an infinite sequence indexed by two positive integers i, j such that $(x \otimes y)_{i,j} = x_i \cdot y_j$. Also, denote $x^{\otimes k} = x \otimes x^{\otimes k-1}$ and $x^{\otimes 0} = 1$.

The rationale for the GaussianSketch comes from the following infinite expansion of the Gaussian kernel. Define $\bar{y}_x^{(j)}$ (for $j \in [d]$) as the infinite dimensional analog of $y_x^{(j)}$ with its ith coordinate as $\exp(-x_j^2)\sqrt{\frac{2^{i-1}}{(i-1)!}}x_j^{i-1}$.

▶ **Lemma 1.** *For $x, p \in \mathbb{R}^d$*

$$\begin{aligned}
&\exp(-\|x-p\|^2) \\
&= \sum_{j_1=0}^{\infty} \cdots \sum_{j_d=0}^{\infty} \left(\exp(-\|x\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}x_i^{j_i}\right)\right)\left(\exp(-\|p\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}p_i^{j_i}\right)\right) \\
&= \left\langle \bar{y}_x^{(1)} \otimes \cdots \otimes \bar{y}_x^{(d)}, \bar{y}_p^{(1)} \otimes \cdots \otimes \bar{y}_p^{(d)} \right\rangle.
\end{aligned}$$

Proof.

$$\begin{aligned}
&\exp(-\|x-p\|^2) \\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\exp(2\langle x, p\rangle) \\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\prod_{i=1}^{d}\exp(2x_ip_i) \\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\prod_{i=1}^{d}\left(\sum_{j=0}^{\infty}\frac{1}{j!}(2x_ip_i)^j\right) \quad \text{by Taylor expansion of } \exp(\cdot) \\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\sum_{j_1=0}^{\infty}\cdots\sum_{j_d=0}^{\infty}\left(\prod_{i=1}^{d}\frac{1}{j_i!}(2x_ip_i)^{j_i}\right) \\
&= \sum_{j_1=0}^{\infty} \cdots \sum_{j_d=0}^{\infty} \left(\exp(-\|x\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}x_i^{j_i}\right)\right)\left(\exp(-\|p\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}p_i^{j_i}\right)\right) \\
&= \left\langle \bar{y}_x^{(1)} \otimes \cdots \otimes \bar{y}_x^{(d)}, \bar{y}_p^{(1)} \otimes \cdots \otimes \bar{y}_p^{(d)} \right\rangle.
\end{aligned}$$

◀

Note that the Gaussian sketch takes as input one element of these inner products, but trimmed so that each $\bar{y}_x^{(j)}$ is trimmed to $y_x^{(j)}$ (without the $\bar{}$ marker) that only has s terms each.

The GaussianSketchHD. We can also define another hash family of sketches for the Gaussian kernel GaussianSketchHD, which works better for high dimension d, but will have worse dependence on other error and domain parameters. For $j = 1, \dots, s$, it will use T_j

as randomly chosen from RecursiveTensorSketch$_{d,m_j,j-1}$. Given a vector $x \in \mathbb{R}^d$, a positive integer s, and s positive integers $m_1, \ldots, m_s$, define GaussianSketchHD$_{m_1,\ldots,m_s,s}$ to be the family of hash functions that if G is in it, then $G(x) \in \mathbb{R}^m$ with $(m_{j-1}+1)$th coordinate to m_jth coordinate be $\sqrt{\frac{2^{j-1}}{(j-1)!}}\exp(-\|x\|^2)T_j(x^{\otimes j-1}) = T_j(z_x^{(j)}) \in \mathbb{R}^{m_j}$ where $z_x^{(j)} = \sqrt{\frac{2^{j-1}}{(j-1)!}}\exp(-\|x\|^2)x^{\otimes j-1} \in \mathbb{R}^{d^{j-1}}$ and $m = \sum_{j=1}^s m_j$. Denote z_x the $\frac{d^s-1}{d-1}$ dimensional vector where the first coordinate is $z_x^{(1)}$, the next d coordinates are $z_x^{(2)}$, the next d^2 coordinates are $z_x^{(3)}$, and so on. The GaussianSketchHD uses the following, a different infinite expansion of the Gaussian kernel (also explored by Cotter et al. [17]).

▶ **Lemma 2.** *For $x, p \in \mathbb{R}^d$,*

$$\exp(-\|x-p\|^2) = \sum_{i=0}^{\infty}\left\langle \exp(-\|x\|^2)\sqrt{\frac{2^i}{i!}}x^{\otimes i}, \exp(-\|p\|^2)\sqrt{\frac{2^i}{i!}}p^{\otimes i}\right\rangle = \sum_{i=0}^{\infty}\left\langle z_x^{(i)}, z_p^{(i)}\right\rangle$$

Proof.

$$\begin{aligned}
&\exp(-\|x-p\|^2)\\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\exp(2\langle x,p\rangle)\\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\sum_{i=0}^{\infty}\frac{1}{j!}(2\langle x,p\rangle)^j && \text{by Taylor expansion of } \exp(\cdot)\\
&= \exp(-\|x\|^2)\exp(-\|p\|^2)\sum_{i=0}^{\infty}\frac{2^j}{j!}\langle x^{\otimes j}, p^{\otimes j}\rangle\\
&= \sum_{j=0}^{\infty}\left\langle \exp(-\|x\|^2)\sqrt{\frac{2^j}{j!}}x^{\otimes j}, \exp(-\|p\|^2)\sqrt{\frac{2^i}{j!}}p^{\otimes j}\right\rangle
\end{aligned}$$

◀

2.1 Concentration Bounds for GaussianSketch and GaussianSketchHD

The sketches will inherit the concentration properties of the RecursiveTensorSketch. Similar observations were recently observed by Ahle et al. [2]. Consider a weighted set of elements $X \subset \mathbb{R}^d$ with weights α_x for $x \in X$, and we use the general concentration bounds for these under the GaussianSketch.

▶ **Lemma 3** ([2]). *Let G be a randomly chosen hash function in GaussianSketch$_{m,s}$ with $m = O\left(\frac{d}{\varepsilon^2}\right)$. Let $v = \sum_{x\in X}\alpha_x y_x^{(1)} \otimes \cdots \otimes y_x^{(d)}$, then $\mathsf{E}\left[\left\|\sum_{x\in X}\alpha_x G(x)\right\|^2\right] = \|v\|^2$ and $\mathsf{Var}\left[\left\|\sum_{x\in X}\alpha_x G(x)\right\|^2\right] \le \frac{\varepsilon^2}{10}\|v\|^4$ and hence with probability at least 9/10 we have $\left|\left\|\sum_{x\in X}\alpha_x G(x)\right\|^2 - \|v\|^2\right| \le \varepsilon\|v\|^2$.*

If G is randomly chosen from GaussianSketchHD$_{m_1,\ldots,m_s,s}$, then $G(x) = Sz_x$, where S is a $m \times \frac{d^s-1}{d-1}$ random matrix (recall $m = \sum_{j=1}^s m_j$) so, for the $(m_{i-1}+1)$th row to the m_ith row, and the $(\frac{d^{i-1}-1}{d-1}+1)$th column to the $\frac{d^i-1}{d-1}$th column forms a matrix S_i where $T_i(z_x^{(i)}) = S_i z_x^{(i)}$, and the rest of entries are zero.

▶ **Lemma 4** ([2]). *Suppose A, B has $\frac{d^s-1}{d-1}$ columns. Denote A_i and B_i be ith row of A and B respectively. By taking $m_i = O\left(\frac{i}{\varepsilon^2}\right)$, we have $\mathbf{Pr}\left[\left\|AB^T - AS^TSB^T\right\|_F^2 \le \varepsilon^2\|A\|_F^2\|B\|_F^2\right] \ge 1-\delta$.*

2.2 Truncation Bounds for GaussianSketch and GaussianSketchHD

These sketches are effective when it is useful to analyze the effect of sketching a large data set X of size n, and we desire to show the cumulative measured across all pairs of elements. For each sketch we expand these infinite sums, and determine the truncation parameter s so the sum of terms past s have a bounded effect.

In our analysis, we will use the following inequality which follows by standard calculus analysis, for any $\eta > 0$,

$$\sum_{j=s}^{\infty} \frac{\eta^j}{j!} \leq \frac{\left(\sup_{y\in[-\eta,\eta]} \exp(y)\right)\eta^s}{s!} \leq \frac{\exp(\eta)\eta^s}{s!} \tag{1}$$

The following expression also arises in our analysis.

▶ **Lemma 5.** *For $\xi, a, b > 0$, setting $s = \Theta\left(\frac{\log \frac{\xi\cdot a}{\alpha}}{\log\left(\frac{1}{b}\log\frac{\xi\cdot a}{\alpha}\right)}\right)$ then the we have $\xi \cdot a\left(\frac{b}{s}\right)^s \leq \alpha$.*

Proof. By setting $\frac{s}{b} = C\frac{\gamma}{\log\gamma}$ for some large constant C where $\gamma = \frac{1}{b}\log\frac{\xi a}{\alpha}$, we have

$$\frac{s}{b}\log\frac{s}{b} = C\frac{\gamma}{\log\gamma}\log\left(C\frac{\gamma}{\log\gamma}\right) = \gamma\cdot C\left(1 + \frac{\log C}{\log\gamma} - \frac{\log\log\gamma}{\log\gamma}\right) \geq \gamma = \frac{1}{b}\log\frac{\xi a}{\alpha}.$$

Now, if we rearrange the inequality then $\xi \cdot a\left(\frac{b}{s}\right)^s \leq \alpha$. ◀

Consider a point set $X = \{x^{(1)}, x^{(2)}, \ldots, x^{(n)}\} \subset \mathbb{R}^d$, denote K_X as the $n \times n$ matrix with $(K_X)_{i,j} = \exp(-\left\|x^{(i)} - x^{(j)}\right\|^2)$. First truncate K_X using Lemma 1 to obtain the $n \times n$ matrix $K^{\mathsf{GS}}_{X,s}$ with

$$\begin{aligned}
&(K^{\mathsf{GS}}_{X,s})_{i,j} \\
&= \sum_{j_1=0}^{s-1}\cdots\sum_{j_d=0}^{s-1}\left(\exp(-\left\|x^{(i)}\right\|^2)\left(\prod_{a=1}^{d}\sqrt{\frac{2^{j_a}}{j_a!}}(x_a^{(i)})^{j_a}\right)\right) \\
&\qquad\qquad \cdot\left(\exp(-\left\|x^{(j)}\right\|^2)\left(\prod_{a=1}^{d}\sqrt{\frac{2^{j_a}}{j_a!}}(p_a^{(j)})^{j_a}\right)\right)
\end{aligned}$$

▶ **Lemma 6.** *Suppose $X \subset \mathbb{R}^d$ so for all $x^{(i)} \in X$ has $\left\|x^{(i)}\right\|_\infty \leq L$ for some $L > 0$. Given a vector $w \in \mathbb{R}^n$ with $\left(\sum_{i=1}^n |w_i|\right)^2 \leq \xi$, we have*

$$w^T(K_X - K^{\mathsf{GS}}_{X,s})w \leq \left(\sum_{i=1}^n |w_i|\right)^2 d\exp(2dL^2)\left(\frac{2eL^2}{s}\right)^s \leq \alpha,$$

where the last $\leq \alpha$ inequality follows from setting $s = s_{L,d,\alpha} = \Theta\left(\frac{\log\frac{\xi\cdot d\exp(2dL^2)}{\alpha}}{\log\left(\frac{1}{2eL^2}\log\frac{\xi\cdot d\exp(2dL^2)}{\alpha}\right)}\right)$.

Proof. From Lemma 1, we have

$$\begin{aligned}
&(K_X - K^{\mathsf{GS}}_{X,s})_{i,j} \\
&= \sum_{\substack{j_1,\ldots,j_d \\ \text{one of } j_b \geq s}}\left(\exp(-\left\|x^{(i)}\right\|^2)\left(\prod_{a=1}^{d}\sqrt{\frac{2^{j_a}}{j_a!}}(x_a^{(i)})^{j_a}\right)\right) \\
&\qquad\qquad \cdot\left(\exp(-\left\|x^{(j)}\right\|^2)\left(\prod_{a=1}^{d}\sqrt{\frac{2^{j_a}}{j_a!}}(x_a^{(j)})^{j_a}\right)\right)
\end{aligned}$$

Then we can analyze these in aggregate with respect to a test vector z. The first line uses the fact that a matrix A (for instance with $A = K_X - K^{\mathsf{GS}}_{X,s}$) written as $\sum_j (\sum_{x_i \in X} \psi_j(x_i))(\sum_{x'_i \in X} \psi_j(x'_i))$ can be simplified $w^T A w = \sum_j (\sum_{x_i \in X} w_i \psi_j(x_i))^2$.

$$
\begin{aligned}
& w^T (K_X - K^{\mathsf{GS}}_{X,s}) w \\
&= \sum_{\substack{j_1,\ldots,j_d \\ \text{one of } j_b \geq s}} \left(\sum_{i=1}^n w_i \exp(-\left\|x^{(i)}\right\|^2) \left(\prod_{a=1}^d \sqrt{\frac{2^{j_a}}{j_a!}} (x_a^{(i)})^{j_a} \right) \right)^2 \\
&\leq \sum_{b=1}^d \sum_{\substack{j_1,\ldots,j_d \\ j_b \geq s}} \left(\sum_{i=1}^n w_i \exp(-\left\|x^{(i)}\right\|^2) \left(\prod_{a=1}^d \sqrt{\frac{2^{j_a}}{j_a!}} (x_a^{(i)})^{j_a} \right) \right)^2 && \text{by union bound} \\
&\leq \sum_{b=1}^d \sum_{\substack{j_1,\ldots,j_d \\ j_b \geq s}} \left(\sum_{i=1}^n |w_i| \left(\prod_{a=1}^d \sqrt{\frac{2^{j_a}}{j_a!}} L^{j_a} \right) \right)^2 && \text{assuming } \left\|x^{(i)}\right\|_\infty \leq L \\
&\leq \left(\sum_{i=1}^n |w_i| \right)^2 \left(\sum_{b=1}^d \sum_{\substack{j_1,\ldots,j_d \\ j_b \geq s}} \left(\prod_{a=1}^d \frac{(2L^2)^{j_a}}{j_a!} \right) \right)
\end{aligned}
$$

The term $\sum_{b=1}^d \sum_{\substack{j_1,\ldots,j_d \\ j_b \geq s}} \left(\prod_{a=1}^d \frac{(2L^2)^{j_a}}{j_a!} \right)$ can be expressed as the follows.

$$
\begin{aligned}
& \sum_{b=1}^d \sum_{\substack{j_1,\ldots,j_d \\ j_b \geq s}} \left(\prod_{a=1}^d \frac{(2L^2)^{j_a}}{j_a!} \right) \\
&= \sum_{b=1}^d \left(\sum_{j_1=0}^\infty \frac{(2L^2)^{j_1}}{j_1!} \right) \cdots \left(\sum_{j_b=s}^\infty \frac{(2L^2)^{j_b}}{j_b!} \right) \cdots \left(\sum_{j_d=0}^\infty \frac{(2L^2)^{j_d}}{j_d!} \right) \\
&= \sum_{b=1}^d \left(\prod_{\substack{a=1 \\ a \neq b}}^d \exp(2L^2) \right) \left(\sum_{j_b=s}^\infty \frac{(2L^2)^{j_b}}{j_b!} \right) \\
&\leq \sum_{b=1}^d \left(\exp((d-1)2L^2) \right) \frac{\exp(2L^2)(2L^2)^s}{s!} && \text{by (1)} \\
&= \frac{d \exp(2dL^2)(2L^2)^s}{s!} \\
&\leq d \exp(2dL^2) \left(\frac{2eL^2}{s} \right)^s && \text{by the fact } s! \geq \left(\frac{s}{e} \right)^s
\end{aligned}
$$

Thus, we have

$$
\begin{aligned}
w^T (K_X - K^{\mathsf{GS}}_{X,s}) w &\leq \left(\sum_{i=1}^n |w_i| \right)^2 \left(\sum_{b=1}^d \sum_{\substack{j_1,\ldots,j_d \\ j_b \geq s}} \left(\prod_{a=1}^d \frac{(2L^2)^{j_a}}{j_a!} \right) \right) \\
&\leq \left(\sum_{i=1}^n |w_i| \right)^2 d \exp(2dL^2) \left(\frac{2eL^2}{s} \right)^s \\
&\leq \alpha
\end{aligned}
$$

where the last inequality follows Lemma 5 using $\xi = (\sum_{i=1}^n |w_i|)^2$, $a = d \exp(2dL^2)$ and $b = 2eL^2$. ◀

Now truncate K_X based on Lemma 2 to obtain $K^{\mathsf{HD}}_{X,s}$ with

$$(K^{\mathsf{HD}}_{X,s})_{i,j} = \sum_{a=0}^{s-1} \left\langle \exp(-\left\|x^{(i)}\right\|^2)\sqrt{\frac{2^a}{a!}}(x^{(i)})^{\otimes a}, \exp(-\left\|x^{(j)}\right\|^2)\sqrt{\frac{2^a}{a!}}(x^{(j)})^{\otimes a} \right\rangle$$

▶ **Lemma 7.** *Define $\Lambda^d_R = \{x \in \mathbb{R}^d \mid \|x\|_2 \le R\}$. For a point set $X \subset \Lambda^d_R$, and a vector $w \in \mathbb{R}^n$ with $(\sum_{i=1}^n |w_i|)^2 \le \xi$, we have*

$$w^T(K_X - K^{\mathsf{HD}}_{X,s})w \le \left(\sum_{i=1}^n |w_i|\right)^2 \exp(2R^2)\left(\frac{2eR^2}{s}\right)^s \le \alpha$$

where the last $\le \alpha$ inequality follows from setting $s = s_{R,\alpha} = \Theta\left(\frac{\log \frac{\xi\cdot\exp(2R^2)}{\alpha}}{\log\left(\frac{1}{2eR^2}\log\frac{\xi\cdot\exp(2R^2)}{\alpha}\right)}\right)$.

Proof. From Lemma 2, we have

$$(K_X - K^{\mathsf{HD}}_{X,s})_{i,j} = \sum_{a=s}^{\infty} \left\langle \exp(-\left\|p^{(i)}\right\|^2)\sqrt{\frac{2^a}{a!}}(p^{(i)})^{\otimes a}, \exp(-\left\|p^{(j)}\right\|^2)\sqrt{\frac{2^a}{a!}}(p^{(j)})^{\otimes a} \right\rangle$$

Then we can analyze these in aggregate with respect to a test vector z. The first line uses the fact that a matrix A (for instance with $A = K_X - K^{\mathsf{HD}}_{X,s}$) written as $\sum_j(\sum_{x_i\in X}\psi_j(x_i))(\sum_{x'_i\in X}\psi_j(x'_i))$ can be simplified $w^TAw = \sum_j(\sum_{x_i\in X} w_i\psi_j(x_i))^2$.

$$\begin{aligned}
&w^T(K_X - K^{\mathsf{HD}}_{X,s})w \\
&= \sum_{a=s}^{\infty}\left\|\sum_{i=1}^n w_i \exp(-\left\|x^{(i)}\right\|^2)\sqrt{\frac{2^a}{a!}}(x^{(i)})^{\otimes a}\right\|^2 \\
&\le \sum_{a=s}^{\infty}\left(\sum_{i=1}^n |w_i|\left\|\exp(-\left\|x^{(i)}\right\|^2)\sqrt{\frac{2^a}{a!}}(x^{(i)})^{\otimes a}\right\|\right)^2 \\
&\le \sum_{a=s}^{\infty}\left(\sum_{i=1}^n |w_i|\sqrt{\frac{2^a}{a!}}R^a\right)^2 && \text{assuming } \left\|x^{(i)}\right\| \le R \\
&= \left(\sum_{i=1}^n |w_i|\right)^2\left(\sum_{a=s}^{\infty}\frac{(2R^2)^a}{a!}\right) \\
&\le \left(\sum_{i=1}^n |w_i|\right)^2\frac{\exp(2R^2)(2R^2)^s}{s!} && \text{by (1)} \\
&\le \left(\sum_{i=1}^n |w_i|\right)^2\exp(2R^2)\left(\frac{2eR^2}{s}\right)^s && \text{by the fact } s! \ge \left(\frac{s}{e}\right)^s \\
&\le \alpha
\end{aligned}$$

where the last inequality follows Lemma 5 using $\xi = \left(\sum_{i=1}^n |w_i|\right)^2$, $a = \exp(2R^2)$ and $b = 2eR^2$. ◀

3 Application to the Gaussian Kernel Distance

Let $K : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ be Gaussian kernel. Namely, for any $x, y \in \mathbb{R}^d$, $K(x,y) = \exp(-\|x-y\|^2)$. Given two point sets $P, Q \subset \mathbb{R}^d$, one can define a similarity function $\kappa(P,Q) = \frac{1}{|P|}\frac{1}{|Q|}\sum_{x\in P}\sum_{y\in Q}K(x,y)$ and a squared kernel distance

$$\mathtt{D}^2_K(P,Q) = \kappa(P,P) - 2\kappa(P,Q) + \kappa(Q,Q).$$

We make the important observation that the above formulation is equivalent to the following form which will be much simpler to fit within our framework:

$$\mathtt{D}_K^2(P,Q) = \sum_{x\in P\cup Q}\sum_{y\in P\cup Q}\beta_x\beta_y\exp(-\|x-y\|^2)$$

where β_x is $\frac{1}{|P|}$ if $x\in P$ and $-\frac{1}{|Q|}$ if $x\in Q$.

We now express $\mathtt{D}_K^2(P,Q)$ as the infinite sum using Lemma 1.

$$\begin{aligned}
&\mathtt{D}_K^2(P,Q)\\
&= \sum_{x\in P\cup Q}\sum_{y\in P\cup Q}\beta_x\beta_y\exp(-\|x-y\|^2)\\
&= \sum_{x\in P\cup Q}\sum_{y\in P\cup Q}\beta_x\beta_y\sum_{j_1=0}^{\infty}\cdots\sum_{j_d=0}^{\infty}\left(\exp(-\|x\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}x_i^{j_i}\right)\right)\\
&\qquad\qquad\cdot\left(\exp(-\|y\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}y_i^{j_i}\right)\right)\\
&= \sum_{j_1=0}^{\infty}\cdots\sum_{j_d=0}^{\infty}\left(\sum_{x\in P\cup Q}\beta_x\exp(-\|x\|^2)\left(\prod_{i=1}^{d}\sqrt{\frac{2^{j_i}}{j_i!}}x_i^{j_i}\right)\right)^2\\
&= \left\|\sum_{x\in P\cup Q}\beta_x\bar{y}_x^{(1)}\otimes\cdots\otimes\bar{y}_x^{(d)}\right\|^2,
\end{aligned}$$

where each $\bar{y}_x^{(j)}$ is an infinite dimension vector with ith coordinate $\exp(-x_j^2)\sqrt{\frac{2^{i-1}}{(i-1)!}}x_j^{i-1}$.

▶ **Theorem 8.** *For any $\varepsilon, R, \alpha > 0$, let G be randomly chosen from $\textsc{GaussianSketch}_{m,s}$ with $m = O\left(\frac{d}{\varepsilon^2}\right)$ and $s = \Theta\left(\frac{\log\frac{4d\exp(2dL^2)}{\alpha}}{\log\left(\frac{1}{2eL^2}\log\frac{4d\exp(2dL^2)}{\alpha}\right)}\right)$. Let $\Omega_L^d = \{x\in\mathbb{R}^d \mid \|x\|_\infty \le L\}$. Define a mapping function F from any $X\subset\Omega_L^d$ so $F(X) = \sum_{x\in X}G(x)$, which is a vector in $\mathbb{R}^m$. Then for any $P,Q\subset\Omega_L^d$ with probability at least $9/10$*

$$\left|\|F(P)-F(Q)\|^2 - \mathtt{D}_K^2(P,Q)\right| \le \varepsilon\mathtt{D}_K^2(P,Q) + \alpha.$$

The mapping $G:\mathbb{R}^d\to\mathbb{R}^m$ can be computed in $O\left(\frac{d^2}{\varepsilon^2}\log\frac{d}{\varepsilon} + ds\right)$ time.

Proof. To analyze the GaussianSketch, we need to account for error from two sources: from the RecursiveTensorSketch (using Lemma 3) and parameter m, and from the truncation of the Taylor expansion at s (using Lemma 6). In this case we analyze the following infinite expansion

$$\mathtt{D}_K^2(P,Q) = \left\|\sum_{x\in P\cup Q}\beta_x\bar{y}_x^{(1)}\otimes\cdots\otimes\bar{y}_x^{(d)}\right\|^2,$$

where each $\bar{y}_x^{(j)}$ is an infinite dimension vector with ith coordinate $\exp(-x_j^2)\sqrt{\frac{2^{i-1}}{(i-1)!}}x_j^{i-1}$.

Let $v = \sum_{x\in P\cup Q}\beta_x\bar{y}_x^{(1)}\otimes\cdots\otimes\bar{y}_x^{(d)}$. Then by Lemma 3 by setting $m = O(d/\varepsilon^2)$ we have with probability at least $9/10$ that

$$\left|\left\|\sum_{x\in P\cup Q}\beta_x G(x)\right\|^2 - \|v\|^2\right| \le \varepsilon\|v\|^2.$$

Next note that $(\sum_{x\in P\cup Q}|\beta_x|)^2 \leq 4 = \xi$. So by Lemma 6 the truncation by only s terms can be accounted for as

$$\mathtt{D}_K^2(P,Q) - \|v\|^2 = \beta^T\left(K_{P\cup Q} - K^{\mathsf{GS}}_{P\cup Q,s}\right)\beta \leq 4d\exp(2dL^2)\left(\frac{2eL^2}{s}\right)^2 \leq \alpha,$$

where $K_{P\cup Q}$ and $K^{\mathsf{GS}}_{P\cup Q,s}$ are defined as in Lemma 6 with $X = P\cup Q$.

Combining these together we have

$$(1-\varepsilon)\left(\mathtt{D}_K^2(P,Q)-\alpha\right) \leq (1-\varepsilon)\|v\|^2 \leq |F(P)-F(Q)| \leq (1+\varepsilon)\|v\|^2 \leq (1+\varepsilon)\mathtt{D}_K^2(P,Q).$$

and hence as desired

$$\left|\|F(P)-F(Q)\|^2 - \mathtt{D}_K^2(P,Q)\right| \leq \varepsilon\mathtt{D}_K^2(P,Q)+\alpha.$$

Recall that the running time of G for mapping a point is

$$O(dm\log m + ds) = O\left(\frac{d^2}{\varepsilon^2}\log\frac{d}{\varepsilon} + ds\right). \qquad \blacktriangleleft$$

Using the Gaussian Sketch HD for high dimensions. We first express $\exp(-\|x-y\|^2)$ as another infinite sum using Lemma 2. Starting with $\mathtt{D}_K^2(P,Q) = \sum_{x\in P\cup Q}\sum_{y\in P\cup Q}\beta_x\beta_y\exp\left(-\|x-y\|^2\right)$ where β_x is $\frac{1}{|P|}$ if $x\in P$ and $-\frac{1}{|Q|}$ if $x\in Q$, we have

$$\begin{aligned}\mathtt{D}_K^2(P,Q) &= \sum_{x\in P\cup Q}\sum_{y\in P\cup Q}\beta_x\beta_y\left\langle \exp(-\|x\|^2)\sqrt{\frac{2^i}{i!}}x^{\otimes i}, \exp(-\|y\|^2)\sqrt{\frac{2^i}{i!}}y^{\otimes i}\right\rangle \\ &= \sum_{i=0}^{\infty}\left\|\sum_{x\in P\cup Q}\beta_x\exp(-\|x\|^2)\sqrt{\frac{2^i}{i!}}x^{\otimes i}\right\|^2.\end{aligned}$$

▶ **Theorem 9.** *For any $\varepsilon, R, \alpha > 0$, let G be randomly chosen from $\textsc{GaussianSketchHD}_{m_1,\ldots,m_s,s}$ with $m_i = O\left(\frac{i}{\varepsilon^2}\right)$ and $s = \Theta\left(\frac{\log\frac{4\exp(2R^2)}{\alpha}}{\log\left(\frac{1}{2eR^2}\log\frac{4\exp(2R^2)}{\alpha}\right)}\right)$. Let $\Lambda_R^d = \{x\in\mathbb{R}^d \mid \|x\|_2 \leq R\}$. Define a mapping function F from any $X\subset\Lambda_L^d$ so $F(X) = \sum_{x\in X}G(x)$, which is a vector in $\mathbb{R}^m$ where $m = \sum_{i=1}^s m_i$. Then for any $P,Q\subset\Lambda_R^d$ with probability at least $9/10$*

$$\left|\|F(P)-F(Q)\|^2 - \mathtt{D}_K^2(P,Q)\right| \leq \varepsilon\mathtt{D}_K^2(P,Q)+\alpha.$$

The mapping $G:\mathbb{R}^d\to\mathbb{R}^m$ can be computed in $O(\frac{s^3}{\varepsilon^2}\log\frac{s}{\varepsilon} + s^2d)$ time.

Proof. Suppose $G(x)\in\mathbb{R}^m$ with $(m_{i-1}+1)$th coordinate to m_ith coordinate be $\sqrt{\frac{2^{i-1}}{(i-1)!}}\exp(-\|x\|^2)T_i(x^{\otimes i-1})$. Here, T_i is randomly chosen from $\textsc{RecursiveTensorSketch}_{d,m_i,i-1}$ for $i = 1,\ldots,s$.

We first need to invoke Lemma 4 to inherit the appropriate concentration bounds from the RecursiveTensorSketch. We use $t\times\frac{d^s-1}{d-1}$ matrices A and B as just row vectors with $t=1$, and let $A=B$. In particular, define this single row as $z = \sum_{x\in P\cup Q}\beta_x[z_x^{(1)}, z_x^{(2)},\ldots,z_x^{(s)}]$, then the conclusion of Lemma 4 is that with probability at least $1-\delta$

$$\left|\|z\|^2 - \left\|\sum_{x\in P\cup Q}\beta_x G(x)\right\|^2\right|^2 = \left\|\|z\|^2 - zS^TSz^T\right\|_F^2 \leq \varepsilon^2\|z\|^4.$$

So by Lemma 7 the truncation by only s terms can be accounted for as

$$\mathtt{D}_K^2(P,Q) - \|z\|^2 = \beta^T(K_{P\cup Q} - K^{\mathsf{HD}}_{P\cup Q,s}))\beta \leq 4d\exp(2dL^2)(2eL^2/s)^2 \leq \alpha,$$

where $K_{P\cup Q}$ and $K^{\mathsf{HD}}_{P\cup Q,s}$ are defined as in Lemma 7 with $X = P \cup Q$.

Combining these together we have

$$(1-\varepsilon)(\mathtt{D}_K^2(P,Q) - \alpha) \leq (1-\varepsilon)\|z\|^2 \leq \|F(P) - F(Q)\|^2 \leq (1+\varepsilon)\|z\|^2 \leq (1+\varepsilon)\mathtt{D}_K^2(P,Q).$$

and hence as desired

$$\left|\|F(P) - F(Q)\|^2 - \mathtt{D}_K^2(P,Q)\right| \leq \varepsilon\mathtt{D}_K^2(P,Q) + \alpha.$$

Recall that the running time of G for mapping a point is $O(\sum_{i=1}^s im_i \log m_i + id) = O(\sum_{i=1}^s \frac{i^2}{\varepsilon^2}\log\frac{i}{\varepsilon} + id) = O(\frac{s^3}{\varepsilon^2}\log\frac{s}{\varepsilon} + s^2 d)$. ◀

4 Extensions and Data Analysis Implications

There are many data analysis applications where useful sketched bounds almost immediately follow from this new embedding. Before we begin, we start by improving the dimensionality of the embedding with a simple post-processing. We can applying a Johnson-Lindenstrauss-type embedding [25, 3, 4, 1] to the m-dimensional space to obtain $O(1/\varepsilon^2)$-dimensional space that, with constant probability, preserves the distance of a pair of point sets. Furthermore, we can use median trick to boost the success probability to $1-\delta$ by running $O(\log\frac{1}{\delta})$ independent copies. For applications in kernel two-sample hypothesis testing and nearest neighbor searching, setting δ depends on the number of queries q we make, for instances the bounded number needed for k-means clustering [16], now applied to kernel k-means. These results are useful for reducing the *storage space* of data representations. Recall that the running time of JL embedding from m-dimensional space to ρ-dimensional space is $O(m\log\rho + \rho^2)$ [3, 4].

4.1 Kernel Two-Sample Test

The kernel two-sample test [24] is a "non-parametric" hypothesis test between two probability distributions represented by finite samples P and Q; let $n = |P \cup Q|$. Then this test simply calculates $\mathtt{D}_K(P,Q)$, and if the value is large enough it rejects the null hypothesis that P and Q represent the same distribution. Since its introduction a few year ago it has seen many applications and relations; see the recent 140 page survey [33]. Zhao and Deng [48] proposed to speed this test up for large sets using RFFs which improves runtime and in some cases even statistical power. While several improvements are suggested [47] including using FastFood [29], these all only provide additive ε-error.

Consider $P \sim \mu_P$ and $Q \sim \mu_Q$. If $\mu_P = \mu_Q$, then empirical distributions P, Q may have $\mathtt{D}_K(P,Q) = \Theta(1/n)$. Hence distinguishing the case of $\mu_P = \mu_Q$ from them not being equal would either require additive error $\varepsilon = \Theta(1/n)$, or relative $(1+\varepsilon)$-error with a minimum $\Theta(1/n)$ additive error. RFFs would require $\Theta(1/\varepsilon^2) = \Theta(n^2)$ dimensions, so one may just as well compute $\mathtt{D}_K(P,Q)$ exactly in $O(n^2)$ time. In our approach, we can set ε to be a constant (say $\varepsilon = 0.2$) and α to be $\Theta(1/n)$. Assuming a constant region diameter, the total running time is $O\left(\frac{n\log n}{\log\log n}\right)$ in the low dimensional case (by Theorem 8) or $O\left(\frac{n\log^2 n(\log n + d)}{\log^2\log n}\right)$ in the high dimensional case (by Theorem 9).

Another way to determine if $\mathtt{D}_K(P,Q)$ should estimate P and Q as distinct, is to run permutation tests. That is for some large number (e.g., $q = 1000$) of trials, select two sets P_j, Q_j iid from $P \cup Q$, of size $|P|$ and $|Q|$ respectively. For each generated pair we calculate

(or estimate using Theorem 8 or Theorem 9) the value of $\mathtt{D}_K(P_j, Q_j)$, and then use the 95th-percentile of these values as a threshold. Note since each P_j, Q_j is drawn from the same domain as P, Q, then the guarantees on the accuracy of the featurized estimate carries over directly even under a large q number of permutations.

4.2 LSH for Point Sets, Geometric Distributions

The new results also allow us to immediately design LSH and nearest neighbor structures for the kernel distance by relying on standard Euclidean LSH [6]. Building a search engine for low-dimensional shapes [21] has long been a goal in computational geometry and geometric modeling. A difficulty arises in that many of the best-known shape distance measures require an alignment (e.g., Frechet [20, 5] or earth movers [11]) which creates many challenges in designing LSH-type procedures. Some methods have been designed, but with limitations, e.g., on point set size for earth mover distance [7] or number of segments in curves for discrete Frechet [18]. The kernel distance provides an alternative distance for shapes, low-dimensional distributions, or curves [26]; it can encode normals or tangents as well to encode direction information of curves [23]. That is, given two shapes composed of (or approximated by) point sets P_i, P_j, the distance between the shapes is simply $\mathtt{D}_K(P_i, P_j)$.

Given a family of point sets $\mathcal{P} = \{P_1, P_2, \ldots, P_N\}$ such that each $P_i \subset \mathbb{R}^d$ has size at most n, an ε-approximate nearest neighbor of a query point set Q is a point set $\hat{P} \in \mathcal{P}$ so that $\mathtt{D}_K(\hat{P}, Q) \leq (1+\varepsilon)\min_{P_j \in \mathcal{P}} \mathtt{D}_K(P_j, Q)$. Here, we assume that $\mathtt{D}_K(P_i, P_j) \geq \alpha'$ for any $i \neq j$. For $\varepsilon \leq 1/2$, we can embed each P_j to $F(P_j) \in \mathbb{R}^D$, and then invoke the key result from Andoni and Indyk [6] for a c'-approximate nearest neighbor, so the total error factor is $c'(1+\varepsilon)$. Overall, we can retrieve a c-approximate nearest neighbor (setting $c = c'(1+\varepsilon)$) to a query $Q \subset \mathbb{R}^d$ with $O(DN^{1/c^2+o(1)})$ query time after using $O(DN^{1+1/c^2+o(1)})$ space and $O(DN^{1+1/c^2+o(1)} + N(\frac{n \log \frac{1}{\varepsilon\alpha'}}{\log\log \frac{1}{\varepsilon\alpha'}} + \frac{1}{\varepsilon^2}\log\frac{1}{\varepsilon}))$ preprocessing when d is small or $O(DN^{1+1/c^2+o(1)} + Nn(\frac{\log^2 \frac{1}{\varepsilon\alpha'}(\log \frac{1}{\varepsilon\alpha'} + d)}{\varepsilon^2 \log^2 \log \frac{1}{\varepsilon\alpha'}}))$ preprocessing when d is large, both assuming a data region with constant diameter.

A Gaussian Kernel PCA

Let k be a positive integer and $\varepsilon > 0$. Avron et al. [10] provide the following algorithm. Suppose S and T are randomly chosen from $\text{RecursiveTensorSketch}_{s,m,d}$ and $\text{RecursiveTensorSketch}_{s,r,d}$ respectively where $m = \Theta(d(k^2 + \frac{k}{\varepsilon}))$ and $r = \Theta(\frac{dm^2}{\varepsilon^2})$. Given n vectors $v^{(1)}, \ldots, v^{(n)} \in \mathbb{R}^{s^d}$, compute $n \times m$ matrix M with ith row as $S(v^{(i)})$ and $n \times r$ matrix N that ith row as $T(v^{(i)})$. Let U be the orthonormal basis for column space of M and W be $m \times k$ matrix containing top k left singular vector of $U^T N$. Finally, return $V = UW$. This algorithm has the following guarantee.

▶ **Lemma 10** ([10] with straightforward modification). *Given a n-by-s^d matrix A, a positive integer k and $\varepsilon > 0$. The above algorithm that has rows of A as input returns a matrix V such that*

$$\left\|A - VV^T A\right\|_F^2 \leq (1+\varepsilon)\left\|A - [A]_k\right\|_F^2$$

where $[A]_k$ is the best rank-k approximation of A.

Now, we can directly modify the above algorithm into our context for rank-k Gaussian low-rank approximation. Given a point set $X = \{x_1, \ldots, x_n\} \subset \mathbb{R}^d$ and a positive integer s. Suppose G and H are randomly chosen from $\textsc{GaussianSketch}_{m,s}$ and $\textsc{GaussianSketch}_{r,s}$ respectively. Recall that $m = \Theta(d(k^2 + \frac{k}{\varepsilon}))$ and $r = \Theta(\frac{dm^2}{\varepsilon^2})$. Compute the $n \times m$ matrix M with ith row as $G(x_i)$ and $n \times r$ matrix N with ith row as $H(x_i)$. Let U be the orthonormal basis for column space of M and W be $m \times k$ matrix containing top k left singular vector of $U^T N$. Finally, return $V = UW$.

▶ **Theorem 11.** *Let $\varepsilon, L, \alpha > 0$ and $s = \Theta\left(\frac{\log \frac{4n^2 d \exp(2dL^2)}{\alpha}}{\log\left(\frac{1}{2eL^2}\log \frac{4n^2 d\exp(2dL^2)}{\alpha}\right)}\right)$. For $\Omega_L^d = \{x \in \mathbb{R}^d \mid \|x\|_\infty \leq L\}$ and $X \subset \Omega_L^d$, and let A_X be a pd matrix with elements $(A_X)_{i,j} = K(x_i, x_j) = \exp(-\|x_i - x_j\|^2)$ for $x_i, x_j \in X$ and factorization $A_X = B_X B_X^T$. Then with constant probability*

$$\left\|B_X - VV^T B_X\right\|_F^2 \leq (1+\varepsilon)\left\|B_X - [B_X]_k\right\|_F^2 + \alpha.$$

The runtime to compute V is $O\left(nds + n\frac{d^4(k^2+\frac{k}{\varepsilon})^3}{\varepsilon^2}\right)$.

Proof. Let $v_x^{(i)}$ be a vector in $\mathbb{R}^s$ with jth coordinate to be $\exp(-x_i^2)\sqrt{\frac{2^{j-1}}{(j-1)!}}x_i^{j-1}$ for any $x \in \mathbb{R}^d$.

By Lemma 10, taking A_s as an $n \times s^d$ matrix with ith row as $v_{x_i}^{(1)} \otimes \cdots \otimes v_{x_i}^{(d)}$. We have

$$\left\|A_s - VV^T A_s\right\|_F^2 \leq (1+\varepsilon)\left\|A_s - [A_s]_k\right\|_F^2$$

From Lemma 6, $v^T(B_X B_X^T - A_s A_s^T)v \leq \left(\sum_{i=1}^n |v_i|\right)^2 d\exp(2dL^2)\left(\frac{2eL^2}{s}\right)^s \leq \alpha/n$. To see this expression is at most α/n, first observe that columns of V are orthonormal, and therefore, the norm of each row of $I - VV^T$ is at most 2. Hence, $\left(\sum_{i=1}^n |v_i|\right)^2 \leq 4n$. Then the choice of s and Lemma 5 with $\xi = 4n^2$, $a = d\exp(2dL^2)$ and $b = 2eL^2$ complete this derivation.

We now have

$$\begin{aligned}
\left\|B_X - VV^T B_X\right\|_F^2 &= \mathsf{Tr}((I - VV^T)B_X B_X^T (I - VV^T)^T) \\
&\leq \left\|A_s - VV^T A_s\right\|_F^2 + \mathsf{Tr}((I - VV^T)(B_X B_X^T - A_s A_s^T)(I - VV^T)^T) \\
&\leq \left\|A_s - VV^T A_s\right\|_F^2 + \alpha
\end{aligned}$$

On the other hand, by Lemma 1, $B_X B_X^T - A_s A_s^T$ is still positive definite. Therefore,

$$\begin{aligned}
&\|A_s - [A_s]_k\|_F^2 \\
&= \left\|A_s - UU^T A_s\right\|_F^2 \quad \text{where } U \text{ is the matrix of top-}k \text{ left singular vectors of } A_s \\
&\leq \left\|A_s - U'U'^T A_s\right\|_F^2 \quad \text{where } U \text{ is the matrix of top-}k \text{ left singular vectors of } B_X \\
&= \|B_X - [B_X]_k\|_F^2 - \mathsf{Tr}((I - U'U'^T)(B_X B_X^T - A_s A_s^T)(I - U'U'^T)) \\
&\leq \|B_X - [B_X]_k\|_F^2 \quad \text{recall that } B_X B_X^T - A_s A_s^T \text{ is positive definite}
\end{aligned}$$

We can plug in everything.

$$\begin{aligned}\left\|B_X - VV^T B_X\right\|_F^2 &\leq \left\|A_s - VV^T A_s\right\|_F^2 + \alpha \\ &\leq \|A_s - [A_s]_k\|_F^2 + \alpha \\ &\leq \|B_X - [B_X]_k\|_F^2 + \alpha.\end{aligned}$$

To see the running time, it takes $O(d(s + m\log m))$ to compute $G(\cdot)$ and $O(d(s + r\log r))$ time to compute $H(\cdot)$, and hence n times as much to compute matrices M and N. We can compute the basis U of M in $O(nm^2)$ time, and the projection $U^T N$ in $O(nrm)$ time. The basis W takes $O(rm^2)$ time, and the final low rank basis $V = UW$ takes $O(nmk)$ time. Thus the total runtime is $O(nd(s + m\log m + r\log r) + nm^2 + nrm + rm^2 + nmk) = O(nd(s + rm))$ using that $r > m^2 > k^4$ that $m > \log r$, and assuming $n > r$. Now using $m = O(d(k^2 + k/\varepsilon))$ and $r = O(dm^2/\varepsilon^2) = O(d^3(k^4 + k^2/\varepsilon^2)/\varepsilon^2)$ and we have a total time of $O\left(nds + n\frac{d^4(k^2+\frac{k}{\varepsilon})^3}{\varepsilon^2}\right)$. ◀

Gaussian Low Rank Approximation with Gaussian Sketch HD in High Dimensions. Now, we can also modify the above algorithm into our context for rank-k Gaussian low-rank approximation in another way. Given a point set $X = \{x_1, \ldots, x_n\} \subset \mathbb{R}^d$ and a positive integer s. Suppose G and H are randomly chosen from $\textsc{GaussianSketchHD}_{m_1,\ldots,m_s,s}$ and $\textsc{GaussianSketchHD}_{r_1,\ldots,r_s,s}$ respectively. Here, $m_i = \Theta(i(k^2 + \frac{k}{\varepsilon}))$ and $r_i = \Theta(\frac{im^2}{\varepsilon^2})$ where $m = \sum_{i=1}^{s} m_i$. Compute the $n \times m$ matrix M with ith row as $G(x_i)$ and $n \times r$ matrix N with ith row as $H(x_i)$. Let U be the orthonormal basis for column space of M and W be $m \times k$ matrix containing top k left singular vector of $U^T N$. Finally, return $V = UW$.

Note that a hash function in GaussianSketchHD is not directly applying a hash function in RecursiveTensorSketch. Therefore, Lemma 10 cannot be directly applied. However, we can still exploit the structure of it in order to prove the same lemma.

As Avron et al. [10] suggest, it is generally possible by combining Lemma 4 and arguments in [10, 15, 27]. We have the following lemma. Here, denote A_s is a $n \times \frac{d^s-1}{d-1}$ matrix that ith row as z_{x_i} for given point set $X = \{x_1, x_2 \ldots, x_n\} \subset \mathbb{R}^d$.

▶ **Lemma 12.** *Given a point set $X \subset \mathbb{R}^d$, a positive integer k and $\varepsilon > 0$. The above algorithm returns a matrix V such that*

$$\left\|A_s - VV^T A_s\right\|_F^2 \leq (1+\varepsilon)\|A_s - [A_s]_k\|_F^2$$

where $[A]_k$ is the best rank-k approximation of A.

Before getting into Lemma 12, the following lemma from [10] which is implied by Lemma 4 would be helpful.

▶ **Lemma 13** ([10] implied by Lemma 4 with straightforward modification)**.** *For any positive integer k', given any $\frac{d^s-1}{d-1} \times k'$ matrix B with orthonormal columns, we have $\left\|B^T S^T SB - I\right\|_2 \leq \varepsilon$. Here, S is randomly chosen from $\textsc{GaussianSketchHD}_{n_1,\ldots,n_s,s}$ where $n_i = \frac{ik'^2}{\varepsilon^2}$.*

Proof. (of Lemma 12)

In the proof of Theorem 3.1 from [15], the only properties of S used are

- Given any $\frac{d^s-1}{d-1} \times k$ matrix B with orthonormal columns, we have $\left\|B^T S^T SB - I\right\|_2 \leq \varepsilon_0$ for some constant $\varepsilon_0 > 0$
- For any two matrices A, B with $\frac{d^s-1}{d-1}$ columns, $\left\|AB^T - AS^T SB^T\right\|_F \leq \sqrt{\frac{\varepsilon}{k}}\|A\|_F\|B\|_F$

The first property can be shown by Lemma 13 since we pick $m_i = \Omega(ik^2)$ and the second property can be shown by Lemma 4 since we pick $m_i = \Omega(\frac{ik}{\varepsilon})$. Also, Theorem 3.1 of [15] implies Lemma 4.2 of [15] which means there is a matrix Z such that $\|UZ - A_s\|_F \leq (1+\varepsilon)\|A_s - [A_s]_k\|_F$ in our context. Combining Lemma 4.3 of [15], we have

$$\left\|U[U^T A_s] - A_s\right\|_F \leq (1+\varepsilon)\|A_s - [A_s]_k\|_F \tag{2}$$

Now, Lemma 13 implies Lemma 2.1 from [27] and further implies

$$\left\|WW^T U^T A_s - A_s\right\|_f \leq (1+\varepsilon)\|A_s - [A_s]_k\|_F \tag{3}$$

by setting k' in Lemma 13 be m and picking $r_i = \Theta(\frac{3^i m^2}{\varepsilon^2})$. Using equation (2) and (3) in the proof of Theorem 1.1 from [27], we have our conclusion $\left\|A_s - UWW^T U^T A_s\right\|_F^2 = \left\|A_s - VV^T A_s\right\|_F^2 \leq (1+\varepsilon)\|A_s - [A_s]_k\|_F^2$. ◀

▶ **Theorem 14.** *Let $\varepsilon, R, \alpha > 0$ and $s = \Theta\left(\frac{\log \frac{4n^2\exp(2R^2)}{\alpha}}{\log\left(\frac{1}{2eR^2}\log\frac{4n^2\exp(2R^2)}{\alpha}\right)}\right)$. For $\Lambda_R^d = \{x \in \mathbb{R}^d \mid \|x\|_2 \leq R\}$ and $X \subset \Lambda_R^d$, and let A_X be a pd matrix with elements $(A_X)_{i,j} = K(x_i, x_j) = \exp(-\|x_i - x_j\|^2)$ for $x_i, x_j \in X$ and factorization $A_X = B_X B_X^T$. Then with constant probability*

$$\left\|B_X - VV^T B_X\right\|_F^2 \leq (1+\varepsilon)\|B_X - [B_X]_k\|_F^2 + \alpha.$$

The runtime to compute V is $O(nds^2 + n\frac{3^{4s}(k^2+\frac{k}{\varepsilon})^3}{\varepsilon^2})$.

Proof. By Lemma 12, we have

$$\left\|A_s - VV^T A_s\right\|_F^2 \leq (1+\varepsilon)\|A_s - [A_s]_k\|_F^2.$$

From Lemma 7, $v^T(B_X B_X^T - A_s A_s^T)v \leq \left(\sum_{i=1}^n |v_i|\right)^2 \exp(2R^2)\left(\frac{2eR^2}{s}\right)^s \leq \alpha/n$ with our setting of s as long as $\left(\sum_{i=1}^n |v_i|\right)^2 \leq 4n$. Indeed the columns of V are orthonormal, so the norm of each row of $I - VV^T$ is at most 2, and thus $\left(\sum_{i=1}^n |v_i|\right)^2 \leq 4n$.

We now have

$$\begin{aligned}
\left\|B_X - VV^T B_X\right\|_F^2 &= \mathsf{Tr}((I - VV^T)B_X B_X^T (I - VV^T)^T) \\
&\leq \left\|A_s - VV^T A_s\right\|_F^2 + \mathsf{Tr}((I - VV^T)(B_X B_X^T - A_s A_s^T)(I - VV^T)^T) \\
&\leq \left\|A_s - VV^T A_s\right\|_F^2 + n \cdot (\alpha/n)
\end{aligned}$$

Also by Lemma 2, $B_X B_X^T - A_s A_s^T$ is still positive definite. Therefore,

$$\begin{aligned}
&\|A_s - [A_s]_k\|_F^2 \\
&= \left\|A_s - UU^T A_s\right\|_F^2 \qquad \text{where } U \text{ is the matrix of top-}k \text{ left singular vectors of } A_s \\
&\leq \left\|A_s - U'U'^T A_s\right\|_F^2 \qquad \text{where } U' \text{ is the matrix of top-}k \text{ left singular vectors of } B_X \\
&= \|B_X - [B_X]_k\|_F^2 - \mathsf{Tr}((I - U'U'^T)(B_X B_X^T - A_s A_s^T)(I - U'U'^T)) \\
&\leq \|B_X - [B_X]_k\|_F^2 \qquad \text{recall that } B_X B_X^T - A_s A_s^T \text{ is positive definite}
\end{aligned}$$

We can plug in everything.

$$\begin{aligned}
\left\|B_X - VV^T B_X\right\|_F^2 &\leq \left\|A_s - VV^T A_s\right\|_F^2 + \alpha \\
&\leq \|A_s - [A_s]_k\|_F^2 + \alpha \\
&\leq \|B_X - [B_X]_k\|_F^2 + \alpha
\end{aligned}$$

To see the running time, it takes $O(\sum_{i=1}^{s} i(d + m_i \log m_i))$ to compute $G(\cdot)$ and $O(\sum_{i=1}^{s} i(d + r_i \log r_i))$ time to compute $H(\cdot)$. Using that $r_i > m_i^2 > k^4$ and $m_i > 1/\varepsilon$ then it takes less time to compute $H(\cdot)$ than $G(\cdot)$, and this runtime is $O(ds^2 + s^2 r_s \log r_s) = O(ds^2 + s^2 r \log r)$ since the r_i values are exponentially increasing in i, and so $r_s = O(r)$ for $r = \sum_{i=1}^{s} r_i$. The time to compute M and N is n time longer.

We can compute the basis U of M in $O(nm^2)$ time, and the projection $U^T N$ in $O(nrm)$ time – this step is the post-sketch bottlneck. The basis W takes $O(rm^2)$ time, and the final low rank basis $V = UW$ takes $O(nmk)$ time. Thus the total runtime is $O(n(ds^2 + s^2 r \log r) + nm^2 + nrm + rm^2 + nmk) = O(n(ds^2 + rm))$ using that $r > m^2 > k^4$ that $m > s^2 \log r$, and assuming $n > r$. Now using $m = O(s^2(k^2 + k/\varepsilon))$ and $r = O(sm^2/\varepsilon^2) = O(s^3(k^4 + k^2/\varepsilon^2)/\varepsilon^2)$ and we have a total time of $O(nds^2 + ns^4(k^2 + \frac{k}{\varepsilon})^3/\varepsilon^2)$. ◀

A Fast Binary Splitting Approach to Non-Adaptive Group Testing

Abstract

In this paper, we consider the problem of noiseless non-adaptive group testing under the for-each recovery guarantee, also known as probabilistic group testing. In the case of n items and k defectives, we provide an algorithm attaining high-probability recovery with $O(k \log n)$ scaling in both the number of tests and runtime, improving on the best known $O(k^2 \log k \cdot \log n)$ runtime previously available for any algorithm that only uses $O(k \log n)$ tests. Our algorithm bears resemblance to Hwang's adaptive generalized binary splitting algorithm (Hwang, 1972); we recursively work with groups of items of geometrically vanishing sizes, while maintaining a list of "possibly defective" groups and circumventing the need for adaptivity. While the most basic form of our algorithm requires $\Omega(n)$ storage, we also provide a low-storage variant based on hashing, with similar recovery guarantees.

1 Introduction

Group testing is a classical statistical problem with a combinatorial flavor [4, 19, 20], and has recently regained significant attention following new applications [14, 18, 25], connections with compressive sensing [26, 27], and most recently, utility in testing for COVID-19 [28, 42, 45]. The goal is to identify a defective (or infected) subset of items (or individuals) based on a number of suitably-designed tests, with the binary test outcomes indicating whether or not the test includes at least one defective item.

In both classical studies and recent works, considerable effort has been put into the development of group testing algorithms achieving a given recovery criterion with a near-optimal number of tests [1, 3, 5, 11, 15, 16, 20, 33, 35, 36, 39], and many solutions are known with decoding time linear or slower in the number of items. In contrast, works seeking to further reduce the decoding time have only arisen more recently [9, 10, 12, 30, 31, 34, 37]; see Section 1.2 for an overview.

In this paper, we present a non-adaptive group testing algorithm that guarantees high-probability recovery of the defective set with $O(k \log n)$ scaling in both the number of tests and the decoding time in the case of n items and k defectives. By comparison, the best

previous decoding time alongside $O(k \log n)$ tests was $O(k^2 \log k \cdot \log n)$ [9], with faster algorithms incurring suboptimal $O(k \log k \cdot \log n)$ scaling in the number of tests [10,34]. By a standard information-theoretic lower bound [4, Sec. 1.4], the $O(k \log n)$ scaling in the number of tests is optimal whenever $k \leq n^{1-\Omega(1)}$.

Before outlining the related work and contributions in more detail, we formally introduce the problem.

1.1 Problem Setup

We consider a set of n items indexed by $\{1, \dots, n\}$, and let $S \subset \{1, \dots, n\}$ be the set of defective items. The number of defectives is denoted by $k = |S|$; this is typically much smaller than n, so we assume that $k \leq \frac{n}{2}$. For clarity of exposition, we will present our algorithm and analysis for the case that k is known, but these will trivially extend to the case that only an upper bound $\overline{k} \geq k$ is known, and $\overline{k}$ replaces k in the number of tests and decoding time.

A sequence of t tests $X^{(1)}, \dots, X^{(t)}$ is performed, with $X^{(i)} \in \{0,1\}^n$ indicating which items are in the i-th test, and the resulting outcomes are $Y^{(i)} = \bigvee_{j \in S} X_j^{(i)}$ (i.e., 1 if there is any defective item in the test, 0 otherwise). We focus on the non-adaptive setting, in which all tests $X^{(1)}, \dots, X^{(t)}$ must be designed prior to observing any outcomes.

We consider a for-each style recovery guarantee, in which the goal is to develop a randomized algorithm that, for any fixed defective set S of cardinality k, produces an estimate $\widehat{S}$ satisfying $\mathbb{P}[\widehat{S} \neq S] \leq \delta$ for some small $\delta > 0$ (typically $\delta \to 0$ as $n \to \infty$). In our algorithm, only the tests $\{X^{(i)}\}_{i=1}^t$ will be randomized, and the decoding algorithm producing $\widehat{S}$ from the test outcomes will be deterministic.

1.2 Related Work

The existing works on group testing vary according to the following defining features [4, 20]:

- **For-each vs. for-all guarantees.** In *combinatorial (for-all) group testing*, one seeks to construct a test design that guarantees the recovery of *all* defective sets up to a certain size. In contrast, in *probabilistic (for-each) group testing*, the test design may be randomized, and the algorithm is allowed some non-zero probability of error.
- **Adaptive vs. non-adaptive.** In the *adaptive* setting, each test may be designed based on all previous outcomes, whereas in the *non-adaptive setting*, all tests must be chosen prior to observing any outcomes. The non-adaptive setting is often preferable in practice, as it permits the tests to be performed in parallel.
- **Noiseless vs. noisy.** In the *noiseless* setting, the test outcomes are perfectly reliable, whereas in *noisy settings*, some tests may be flipped according to some probabilistic or adversarial noise model.

As outlined in the previous subsection, our focus is on the for-each guarantee, non-adaptive testing, and noiseless tests, but for comparison, we also discuss other variants in this section.

By a simple counting argument, even in the least stringent scenario of noiseless adaptive testing and the for-each guarantee, $\Omega\big(k \log \frac{n}{k}\big)$ tests are required for reliable recovery [6, 36]. In the noiseless adaptive setting, the classical generalized binary splitting algorithm of Hwang [29] matches this bound with sharp constant factors, and attains the stronger for-all guarantee. More recently, $O(k \log n)$ adaptive tests and decoding time were shown to suffice under the for-each guarantee in the presence of random noise [10].

Table 1 Overview of existing noiseless non-adaptive group testing results with $\text{poly}(k \log n)$ decoding time under the for-each guarantee, with n items and k defectives.

Reference	Number of tests	Decoding time	Construction
SAFFRON [34]	$O(k \cdot \log k \cdot \log n)$	$O(k \log k)$[1]	Randomized
GROTESQUE [10]	$O(k \cdot \log k \cdot \log n)$	$O(k \cdot \log k \cdot \log n)$	Randomized
Inan *et al.* [30]	$O\big(k \cdot \log n \cdot \log \frac{\log n}{\log k}\big)$	$O\big(k^3 \cdot \log n \cdot \log \frac{\log n}{\log k}\big)$	Explicit
BMC [9]	$O(k \log n)$	$O(k^2 \cdot \log k \cdot \log n)$	Randomized
This Paper	$O(k \log n)$	$O(k \log n)$	Randomized

In the non-adaptive setting with the for-each guarantee, a recent of result of [2] shows that n tests are required to attain asymptotically vanishing error probability as $n \to \infty$ with $k = \lfloor \beta n \rfloor$, for arbitrarily small $\beta > 0$. Thus, $O(k \log \frac{n}{k})$ scaling (with a universal implied constant) is impossible; see also [16]. On the other hand, $O(k \log n)$ tests do suffice, and this scaling is equivalent to $O(k \log \frac{n}{k})$ in the regime $k \leq n^{1-\Omega(1)}$. Early works achieved this for the scaling regime $k = O(1)$ [5, 35, 36], and a variety of more recent works considered more general k [1, 5, 15, 16, 33, 35, 36, 39], particularly under "unstructured" random test designs such as i.i.d. Bernoulli [3, 5, 39] and near-constant tests-per-item [15, 33]. In fact, following the recent work of Coja-Oghlan et al. [16], the precise constants for non-adaptive group testing have been nailed down in the regime $k \leq n^{1-\Omega(1)}$, with the algorithm for the upper bound requiring $\Omega(n)$ decoding time.

Since non-adaptive algorithms with $\text{poly}(k \log n)$ decoding time under the for-each guarantee are particularly relevant to the present paper, we provide a summary of the existing works in Table 1. We separate our discussion according to whether or not each algorithm attains $O(k \log n)$ scaling in the number of tests, as we believe this to be a particularly important desiderata in practice when tests are expensive:

- SAFFRON and GROTESQUE both use $O(k \log k \cdot \log n)$ tests, which is suboptimal by a $\log k$ factor. In particular, SAFFRON's decoding time is as low as $O(k \log k)$ in the word-RAM model.[1] While storage requirements were not a significant point of focus in the existing works, we also note (for later comparison) that SAFFRON only requires $O(k \log k \cdot \log n)$ bits of storage; see Appendix A for details.
- In the regime $k = \Theta(n^\alpha)$ with fixed $\alpha \in (0, 1)$, Inan et al. [30] attain $O(k^3 \log n)$ decoding time with $O(k \log n)$ tests, whereas the number of tests becomes suboptimal in sparser regimes such as $k = \text{poly}(\log n)$. The best previous decoding time for an algorithm that only uses $O(k \log n)$ tests is $O(k^2 \log k \cdot \log n)$, via bit-mixing coding (BMC) [9]. To our knowledge, all other existing algorithms succeeding with $O(k \log n)$ tests incur $\Omega(n)$ decoding time [1, 5, 15, 16, 33, 35, 36, 39].

Our main theoretical contribution is to provide an algorithm that attains $O(k \log n)$ scaling in both the number of tests and decoding time, as well as using distinct algorithmic ideas from the existing works (see Section 2.1 for discussion). In particular, among the algorithms using $O(k \log n)$ tests, ours reduces the dependence on k in the decoding time from quadratic to linear.

[1] The decoding time of SAFFRON is typically stated as $O(k \log k \cdot \log n)$, but can be $O(k \log k)$ in the word-RAM model of computation, where the test outcomes are stored as $O(k \log k)$ words of length $\log_2 n$ each; see Appendix A for details.

It is worth noting that the works [9, 10, 30, 34] also extend their guarantees to noisy settings, and the approach in [30] has the additional advantage of using an *explicit* test design, i.e., the test vectors $X^{(1)}, \dots, X^{(t)}$ can be constructed deterministically in time polynomial in n and t. Although noisy and/or de-randomized variants of our algorithm may be possible, this is deferred to future work.[2]

In addition, [34] demonstrated that $O\big(k \log n \cdot \log \frac{1}{\epsilon}\big)$ tests suffice for SAFFRON in the case that one is only required to identify a fraction $1 - \epsilon$ of the defectives, as opposed to the entire defective set. Thus, $O(k \log n)$ scaling is maintained for approximate recovery with constant $\epsilon > 0$, but not for the more common requirement of exact recovery.

While we have focused our discussion on the for-each setting, the first $\text{poly}(k \log n)$-time non-adaptive group testing algorithms were for the more stringent for-all setting [12, 31, 37]. The strength of the for-all guarantee comes at the expense of requiring significantly more tests, e.g., see [23] for an $\Omega\big(\min\big\{k^2 \frac{\log n}{\log k}, n\big\}\big)$ lower bound. An $O(k^2 \log n)$ upper bound on the number of tests was originally attained with $\Omega(n)$ decoding time, [22, 38], and more recently with $\text{poly}(k \log n)$ decoding time [31, 37]. The earlier work of [12] attained $\text{poly}(k \log n)$ decoding time under a list decoding recovery criterion, and also allowed for adversarial noise in the test outcomes.

1.3 Summary of Results

Before summarizing our main results, we briefly highlight that our algorithmic techniques are distinct from the existing works summarized above (see Section 2.1 for further details), and are more closely related to the adaptive binary splitting approach of Hwang [29]. We first test large groups of items together, placing each group into a single randomly-chosen test among a sequence of $O(k)$ tests. We then "split" these groups into smaller sub-groups, while using the $O(k)$ test outcomes to eliminate those known to be non-defective. This process is repeated (with the elimination step ensuring that the number of groups under consideration does not grow too large) until a superset of S is found. This superset is shown to be of size $O(k)$ with high probability, and S is deduced from this superset via a final sequence of $O(k \log k)$ tests (similar ideas to this final step have appeared in works such as [12, 37]). Despite the sequential nature of this procedure, the tests can be performed non-adaptively.

Our first main result is informally stated as follows; see Theorem 1 for a formal statement.

▶ **Main Result 1** (Algorithmic Guarantees – Informal Version). *There exists a non-adaptive group testing algorithm that, for any constant $c > 0$, succeeds with probability $1 - O(k^{-c})$ using $O(k \log n)$ tests and $O(k \log n)$ decoding time, and requires $O(n \log^2 k)$ bits of storage.*

Main Result 1 uses $\Omega(n)$ storage to record the random choices of tests the items are included in. For our second main result, we consider a low-storage variant in which the tests are instead allocated using hash functions. In this case, the precise decoding time and storage guarantees depend on the properties of the hash family used. The following theorem informally states the guarantee resulting from $O(\log k)$-wise independent hashing using the classical hash family of Wegman and Carter [44]; see Theorem 11 for a formal and more general statement.

▶ **Main Result 2** (Algorithmic Guarantees with Reduced Storage – Informal Version). *There exists a non-adaptive group testing algorithm that, for any constant $c > 0$, succeeds with probability $1 - O\big(\frac{\log n}{k^c}\big)$ using $O(k \log n)$ tests and $O(k \log k \cdot \log n)$ decoding time, and requires $O(k \log n + \log k \cdot \log^2 n)$ bits of storage.*

[2] Our analysis can easily be adapted to handle false positive tests, but handling false negative tests appears to require more significant changes and a slightly increased decoding time.

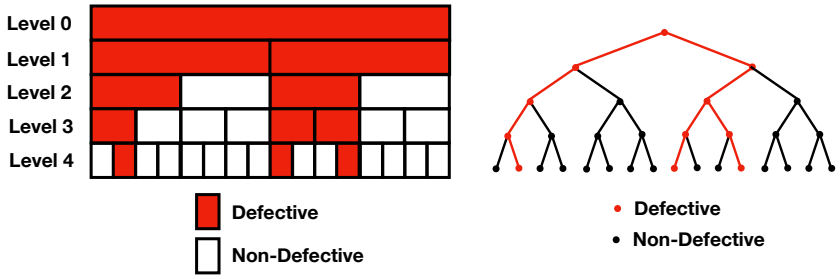

Figure 1 Example structure of groups of items that are tested together when $n = 16$ and $k = 3$ (Left), and the corresponding tree representation (Right). Leaves correspond to single items, and nodes at the higher levels correspond to groups of items.

2 Non-Adaptive Binary Splitting Algorithm

In this section, we introduce our algorithm, and state and prove our main result giving guarantees on its correctness, number of tests, decoding time, and storage. For simplicity of notation, we assume throughout the analysis that k and n are powers of two. Our algorithm only requires an upper bound on the number of defectives, and hence, any other value of k can simply be rounded up to a power of two. In addition, the total number of items n can be increased to a power of two by adding "dummy" non-defective items.

2.1 Description of the Algorithm

We propose an algorithm that works with a tree structure, as illustrated in Figure 1. On the left of the figure, we have $1 + \log_2 n$ levels, with the top level containing all items, the second level containing two groups with half the items each, and so on, with each level "splitting" the previous levels' groups in half until the final level containing individual items. The ordering of items is inconsequential for our analysis and results provided that the two children of a given node can be identified in constant time, so for convenience we assume the natural order.[3] For $\ell = 0, \dots, \log_2 n$, the j-th group at the ℓ-th level is denoted by $G_j^{(\ell)} \subseteq \{1, \dots, n\}$, and we observe that for fixed ℓ, there are 2^ℓ groups $G_1^{(\ell)}, \dots, G_{2^\ell}^{(\ell)}$ of cardinality $\frac{n}{2^\ell}$ each.

We consider the binary tree representation in Figure 1 (Right), in which each node corresponds to a group of items (e.g., the root corresponds to the set of all items, and the leaves correspond to individual items). The levels of the tree are indexed by $\ell = 0, \dots, \log_2 n$. Our algorithm works down the tree one level at a time, keeping a list of *possibly defective* (PD) nodes, and performing tests to obtain such a list at the next level, while ideally keeping the size of the list small (e.g., $O(k)$). When we perform tests at a given level, we treat each node as a "super-item"; including a node in a test amounts to including all of the items in the corresponding group $G_j^{(\ell)}$. While this may appear to naturally lead to an adaptive algorithm, we can in fact perform all of the tests non-adaptively.

If we were to test nodes at the root or the early levels, they would almost all return positive, and hence not convey significant information. We therefore let the algorithm start at the level $\ell_{\min} = \log_2 k$, and we consider the following test design:

[3] Alternatively, one may use a dyadic splitting approach: Assign each item a unique $(\log_2 n)$-bit string, and first split according to the first bit, then the second bit, and so on.

- For each $\ell = \log_2 k, \dots, \log_2 n - 1$, form a sequence of Ck tests (for some $C > 0$ to be selected later), and for each $j = 1, \dots, 2^\ell$, choose a single such test uniformly at random, and place all items from $G_j^{(\ell)}$ into that test.
- For the final level $\ell = \log_2 n$, each $G_j^{(\ell)} = \{j\}$ is a singleton. In this case, we form $C' \log k$ sequences of $2k$ tests (for some $C' > 0$). For each item, and each of the $C' \log k$ sequences of tests, we place the item in one of the $2k$ corresponding tests, chosen uniformly at random.

This creates a total of $t = Ck \log_2 \frac{n}{k} + 2C'k \log k = O(k \log n)$ tests.

Upon observing the t non-adaptive test outcomes, the decoder forms an estimate $\widehat{S}$ of the defective set via the following procedure:

- Initialize $\mathcal{G}^{(\ell_{\min})} = \{G_j^{(\ell_{\min})}\}_{j=1}^k$, where $\ell_{\min} = \log_2 k$;
- Iterate the following for $\ell = \log_2 k, \dots, \log_2 n - 1$:
  - For each group $G \in \mathcal{G}^{(\ell)}$, check whether the single test corresponding to that group is positive or negative. If positive, then add both children of G (see Figure 1) to $\mathcal{G}^{(\ell+1)}$.
- Let the estimate $\widehat{S}$ of the defective set be the (singleton) elements of $\mathcal{G}^{(\log_2 n)}$ that are not included in any negative test among the $2C'k \log k$ tests at the final level.

Comparisons with existing methods

Our algorithm is distinct from existing sublinear-time non-adaptive group testing algorithms, which are predominantly based on code concatenation [31,37] or related methods that encode item indices' binary representations directly into the test matrix [8, 10, 34]. In fact, in the context of group testing, our approach is perhaps most reminiscent of the *adaptive* algorithm of Hwang [29] (see also [4, 20]), which identifies one defective at a time using binary splitting, removing each defective from consideration after it is identified. By keeping track of the multiple defective nodes simultaneously and allowing a small number of false positives up to the final level, we are able to exploit similar ideas without requiring adaptivity.

Beyond group testing and binary splitting, this recursive tree-structured approach is also reminiscent of ideas used in sketching algorithms, such as dyadic tree recovery for count-min sketch [17]. Our particular approach – maintaining a superset at each level, and relying on a lack of false negatives – is most similar to the pyramidal reconstruction method for compressive sensing under the earth mover's distance [32].

A nearly identical algorithm to ours was given independently in the concurrent work of [13], with similar theoretical guarantees. In addition, [13] observes that since the total number of non-discarded nodes in the algorithm is $O\big(k \log \frac{n}{k}\big)$ with overwhelming probability (see Lemma 6 below), one can take a union bound over the $\binom{n}{k}$ possible defective sets to attain *list recovery* in the combinatorial (for-all) setting. This idea allows the authors of [13] to attain a variety of other results, including in the related problems of heavy hitters and compressive sensing. In the context of probabilistic (for-each) group testing, some slight advantages of our analysis include (i) proving that the first batch of tests leads to $O(k)$-size list recovery rather than $O\big(k \log \frac{n}{k}\big)$-size, thus circumventing the need for a third batch of tests, and (ii) only requiring $O(\log k)$-wise independence in our low-storage variant based on hashing (see Section 3), rather than $O\big(k \log \frac{n}{k}\big)$-wise independence (albeit at the expense of a higher error probability).

2.2 Algorithmic Guarantees

In the following, we provide the formal version of Main Result 1. Here and subsequently, we assume a word-RAM model of computation; for instance, with n items and t tests, it takes constant time to read a single integer in $\{1, \dots, n\}$ from memory, perform arithmetic operations on such integers, fetch a single test outcome indexed by $\{1, \dots, t\}$, and so on.

▶ **Theorem 1** (Algorithmic Guarantees). *Let S be a fixed (defective) subset of $\{1,\dots,n\}$ of cardinality k. For any constant $c>0$, there exist choices of C and C' such that the group testing algorithm described in Section 2.1 satisfies the following with probability $1-O(k^{-c})$:*

- *The returned estimate $\widehat{S}$ equals S;*
- *The algorithm runs in time $O(k\log n)$;*
- *The algorithm uses $O(n(\log k)^2)$ bits of storage.*

In addition, the number of tests scales as $O(k\log n)$.

We note that the success probability approaches one as $n\to\infty$ in any asymptotic regime satisfying $k=\omega(1)$, but not in the regime $k=O(1)$; the same is true in the existing works listed in Table 1, with the exception of [9]. In addition, it is straightforward to improve the success probability to $1-e^{-\Omega(k)}-O(n^{-c})$ by using $O(\log n)$ (rather than $O(\log k)$) sequences of $2k$ tests at the final level.

Theorem 1 is proved in the remainder of the section. We emphasize that our focus is on scaling laws, and we make no significant effort to optimize the underlying constant factors.

2.3 Analysis

Throughout the analysis, the defective set S will be fixed but otherwise arbitrary, and we will condition on fixed placements of the defective items into tests (and hence, fixed test outcomes). The test placements of the non-defective items are independent of those of the defectives, and our analysis will hold regardless of which particular tests the defectives were placed in. We use $\mathbb{P}[\cdot\,|\,\mathcal{T}_S]$ to represent this conditioning, and we refer to $\mathcal{T}_S$ as the defective test placements. In addition, for the tree illustrated in Figure 1, we refer to nodes containing defective items as defective nodes, to all other nodes as non-defective nodes, and to the set of defective nodes as the defective (sub-)tree.[4]

We begin with the following simple lemma.

▶ **Lemma 2** (Probabilities of Non-Defectives Being in Positive Tests). *Under the test design described in Section 2.1, the following holds at any given level $\ell=\log_2 k,\dots,\log_2 n-1$: Conditioned on any defective test placements $\mathcal{T}_S$, any given non-defective node at level ℓ has probability at most $\frac{1}{C}$ of being placed in a positive test.*

Proof. Since there are k defective items, at most k nodes at a given level can be defective, and since each node is placed in a single test, at most k tests out of the Ck tests at the given level can be positive. Since the test placements are independent and uniform, it follows that for any non-defective node, the probability of being in a positive test is at most $\frac{1}{C}$. ◀

In view of this lemma, when starting at any non-defective child of any given defective node (or alternatively, starting at a non-defective node at level $\ell_{\min}$), we can view any further branches down the non-defective sub-tree as "continuing" (i.e., the two children remain "possibly defective") with probability at most $\frac{1}{C}$. Hence, we have the following.

▶ **Lemma 3** (Probability of Reaching a Non-Defective Node). *Under the setup of Lemma 2, any given non-defective node having Δ non-defective ancestor nodes is reached (i.e., all of its ancestor nodes are placed in positive tests, so the node is considered possibly defective) with probability at most $\left(\frac{1}{C}\right)^{\Delta}$.*

We will use the preceding lemmas to control the following two quantities:

[4] Since we start at level $\ell_{\min}=\log_2 k$, this could more precisely be considered as a forest.

- N_{total}, the total number of non-defective nodes that are reached in the sense of Lemma 3;
- N_{leaf}, the number of non-defective leaf nodes that are reached, and thus are still considered possibly defective by the final level.

It will be useful to upper bound N_{total} for the purpose of controlling the overall decoding time, and to upper bound N_{leaf} for the purpose of controlling the number of items considered at the final level.

2.3.1 Bounding N_{total} and N_{leaf} on average

We first present two lemmas bounding the averages of N_{total} and N_{leaf}, and then establish high-probability bounds.

▶ **Lemma 4** (Bounding N_{total} on Average). *For any $C \geq 4$ and any defective test placements $\mathcal{T}_S$, we have*

$$\mathbb{E}[N_{\text{total}} \,|\, \mathcal{T}_S] \leq 6k \log_2 \frac{n}{k}. \tag{1}$$

Proof. Since the tree is binary, each defective node can have at most 2^i non-defective descendants appearing exactly i levels further down the tree; such descendants correspond to $\Delta = i - 1$ in Lemma 3. Since there are at most $k \log_2 \frac{n}{k}$ defective nodes, it follows that there are at most $\big(k \log_2 \frac{n}{k}\big) 2^{\Delta+1}$ non-defective nodes with Δ non-defective ancestors and at least one defective ancestor. Similarly, there are at most k non-defective nodes at level $\ell_{\min} = \log_2 k$, each of which has at most 2^Δ non-defective nodes appearing Δ levels later.

Since Lemma 3 demonstrates a probability $\big(\frac{1}{C}\big)^\Delta$ of being reached for a given number Δ of non-defective ancestors, it follows that

$$\mathbb{E}[N_{\text{total}} \,|\, \mathcal{T}_S] \leq \Big(k \log_2 \frac{n}{k}\Big) \sum_{\Delta=0}^{\log_2 \frac{n}{k} - 1} 2^{\Delta+1} \Big(\frac{1}{C}\Big)^\Delta + k \sum_{\Delta=0}^{\log_2 \frac{n}{k}} 2^\Delta \Big(\frac{1}{C}\Big)^\Delta. \tag{2}$$

Hence, the assumption $C \geq 4$ gives

$$\mathbb{E}[N_{\text{total}} \,|\, \mathcal{T}_S] \leq \Big(2k \log_2 \frac{n}{k}\Big) \sum_{\Delta=0}^{\log_2 \frac{n}{k} - 1} 2^{-\Delta} + k \sum_{\Delta=0}^{\log_2 \frac{n}{k}} 2^{-\Delta} \leq 6k \log_2 \frac{n}{k}, \tag{3}$$

where we used $\sum_{\Delta=0}^{\infty} 2^{-\Delta} = 2$ and $\log_2 \frac{n}{k} \geq 1$ (for $k \leq \frac{n}{2}$). ◀

▶ **Lemma 5** (Bounding N_{leaf} on Average). *For any $C \geq 4$ and any defective test placements $\mathcal{T}_S$, we have*

$$\mathbb{E}[N_{\text{leaf}} \,|\, \mathcal{T}_S] \leq 6k. \tag{4}$$

Proof. Again using the fact that each defective node can have at most 2^i descendants appearing i levels further down the tree, we find that there are at most $k 2^{\Delta+1}$ leaf nodes with Δ non-defective ancestors and at least one defective ancestor. In addition, a leaf having only non-defective ancestors corresponds to $\Delta = \log_2 \frac{n}{k}$ in Lemma 3 (since $\ell_{\min} = \log_2 k$), and to handle this case, we trivially upper bound he number of leaves by n. Hence, for $C \geq 4$, we have similarly to (3) that

$$\mathbb{E}[N_{\text{leaf}} \,|\, \mathcal{T}_S] \leq 2k \sum_{\Delta=0}^{\log_2 \frac{n}{k} - 1} 2^\Delta \Big(\frac{1}{C}\Big)^\Delta + n \Big(\frac{1}{C}\Big)^{\log_2 \frac{n}{k}} \leq 6k. \tag{5}$$

◀

2.3.2 Bounding N_{total} with high probability

In this subsection, we prove the following.

▶ **Lemma 6** (High-Probability Bound on N_{total})**.** *For any $C \geq 16$, conditioned on any defective test placements $\mathcal{T}_S$, we have $N_{\text{total}} = O\big(k \log \frac{n}{k}\big)$ with probability $1 - e^{-\Omega(k \log \frac{n}{k})}$.*

To prove this result, we make use of Lemmas 2 and 4, along with the following auxiliary result written in generic notation.

▶ **Lemma 7** (Sub-Exponential Behavior in a Branching Process)**.** *Consider an infinite-depth binary tree in which each node is independently assigned a value $\{0, 1\}$ with probability q of being 1, and let N be the number of nodes whose ancestors are all marked as 1. Then, when $q \leq \frac{1}{16}$, we have all $n > 0$ that $\mathbb{P}[N = n] \leq 2^{-(n-1)}$.*

Proof. We make use of branching process theory [24, Ch. XII], in particular noting that N equals the *total progeny* [21] when the initial population size is 1 (i.e., the root) and the distribution of the number of children per node is given by

$$P_X(0) = 1 - q, \quad P_X(2) = q, \quad P_X(x) = 0, \forall x \notin \{0, 2\}. \tag{6}$$

The results we use from branching process theory are expressed in terms of the generative function $M_X(s) = \mathbb{E}[s^X]$, which is given by

$$M_X(s) = (1 - q) + qs^2. \tag{7}$$

It is evident in our case that $N < \infty$ with probability one provided that $q < \frac{1}{2}$, and one way to formally prove this is to utilize the general result that the *extinction probability* $\mathbb{P}[N < \infty]$ equals one provided that the smallest root of $s = M_X(s)$ is $s = 1$ [24, Sec. XII.4].

We utilize an exact expression for the distribution of N for general branching processes [21] (specialized to the case that the initial population size is one):

$$\mathbb{P}[N = n] = \frac{1}{n} m_{n-1}^{(n)}, \tag{8}$$

where $m_{n-1}^{(n)}$ is computed according to the expansion

$$\big(M_X(s)\big)^n = \sum_{j=0}^{\infty} m_j^{(n)} s^j. \tag{9}$$

Substituting our expression (7) for $M_X(s)$ on the left-hand side, we find that $(M_X(s))^n = \big((1 - q) + qs^2\big)^n$, which equals $\sum_{i=0}^{n} \binom{n}{i} (1 - q)^{n-i} (qs^2)^i$ by a binomial expansion. Hence, we obtain $m_{n-1}^{(n)} = 0$ for even-valued n, and for odd-valued n we substitute $i = \frac{n-1}{2}$ to obtain

$$m_{n-1}^{(n)} = \binom{n}{\frac{n-1}{2}} (1 - q)^{\frac{n+1}{2}} q^{\frac{n-1}{2}} \tag{10}$$

$$\leq 2(2\sqrt{q})^{n-1}, \tag{11}$$

where we applied $\binom{n}{\frac{n-1}{2}} \leq 2^n = 2 \cdot 2^{n-1}$ and $(1 - q)^{\frac{n+1}{2}} \leq 1$.

Substituting (11) into (8), we obtain

$$\mathbb{P}[N = n] \leq \frac{2}{n} \big(\sqrt{4q}\big)^{n-1} \mathbb{1}\{n \text{ is odd}\}. \tag{12}$$

This implies $\mathbb{P}[N = n] \leq 2^{-(n-1)}$ when $q \leq \frac{1}{16}$ and $n \geq 2$, and the same trivially holds when $n = 1$. ◀

The condition $\mathbb{P}[N = n] \le 2^{-(n-1)}$ in Lemma 7 implies that N is a sub-exponential random variable, and the same trivially follows for a branching process that only runs up to a certain depth (number of generations). In the group testing setup of Lemma 6, we are adding together $O\big(k \log \frac{n}{k}\big)$ independent copies of such random variables (each corresponding to a different non-defective sub-tree) to get N_{total}. As a result, we can apply a standard concentration bound for sums of independent sub-exponential random variables [43, Prop. 5.16] to obtain

$$\mathbb{P}[N_{\text{total}} \ge \mathbb{E}[N_{\text{total}} \,|\, \mathcal{T}_S] + t \,|\, \mathcal{T}_S] \le e^{-\Omega(\min\{t^2/(k \log_2 \frac{n}{k}), t\})}, \tag{13}$$

from which Lemma 6 follows by setting $t = \Theta\big(k \log_2 \frac{n}{k}\big)$ and using $\mathbb{E}[N_{\text{total}} \,|\, \mathcal{T}_S] = O\big(k \log_2 \frac{n}{k}\big)$ (see Lemma 4). The condition $C \ge 16$ coincides with $q \le \frac{1}{16}$ in Lemma 7.

2.3.3 Bounding N_{leaf} with high probability

In this subsection, we prove the following.

▶ **Lemma 8** (High-Probability Bound on N_{leaf})**.** *For any $C \ge 12$, conditioned on any defective test placements $\mathcal{T}_S$, we have $N_{\text{leaf}} = O(k)$ with probability $1 - e^{-\Omega(k)}$.*

We again use Lemma 2, along with the following auxiliary results written in generic notation.

▶ **Lemma 9** (Tail Bound on Binary Tree Paths)**.** *Consider a binary tree of height h in which each node is independently assigned a value $\{0, 1\}$ with probability q of being 1, and let N_h be the number of leaf nodes that have a path of 1's back to the root (including both endpoints). Then $\mathbb{P}[N_h \ge t] \le 4^{-(h+t)}$ for any integer $t \ge 1$.*

Proof. We use a proof by induction. The base case is $h = 1$, in which case we have $\mathbb{P}[N_h > 2] = 0$, $\mathbb{P}[N_h = 2] = \frac{1}{q^3}$, and $\mathbb{P}[N_h \ge 1] \le \frac{2}{q^2}$ by the union bound. These bounds satisfy the claim of the lemma due to the assumption $q \le \frac{1}{12}$.

Now fix $h \ge 2$ and suppose that the claim is true for height $h - 1$. Let L and R be the number of leaf nodes reached in the left and right sub-trees of the root, and observe that

$$\mathbb{P}[N_h \ge t] \le \sum_{j=0}^{t} \mathbb{P}[L \ge j \cap R \ge t - j] \tag{14}$$

$$= \mathbb{P}[L \ge t] + \mathbb{P}[R \ge t] + \sum_{j=1}^{t-1} \mathbb{P}[L \ge j \cap R \ge t - j]. \tag{15}$$

Applying the induction hypothesis, we find that the first two terms are at most $q4^{-(h-1+t)} = 4q \cdot 4^{-(h+t)}$, and for $1 \le j \le t-1$, we have $\mathbb{P}[L \ge j \cap R \ge t-j] \le q \cdot 4^{-(h-1+j)} \cdot 4^{-(h-1+t-j)} = 16q \cdot 4^{-(2h+t)}$, where the multiplications by q correspond to the root node being marked as 1. Substituting back into (15) gives

$$\mathbb{P}[N_h \ge t] \le 8q4^{-(h+t)} + 16qt4^{-(2h+t)}. \tag{16}$$

We may assume that $t \le 2^h$, since for $t > 2^h$ we trivially have $\mathbb{P}[N_h \ge t] = 0$. Hence, the above bound simplifies to

$$\mathbb{P}[N_h \ge t] \le 8q4^{-(h+t)} + 16q4^{-(h+t)}2^{-h} \le 4^{-(h+t)}, \tag{17}$$

since $h \ge 2$ implies $2^{-h} \le \frac{1}{4}$, and we have assumed $q \le \frac{1}{12}$. ◀

▶ **Lemma 10** (Sub-Exponential Behavior for Binary Tree Paths). *Under the setup of Lemma 9, N_h satisfies $\mathbb{E}[e^{\lambda N_h}] \le 1 + 4^{-h}$ for $\lambda \le \log 2$. In addition, for any integer $h_{\max} \ge 1$, if $N_1, \dots, N_{h_{\max}}$ are independent random variables with the same distribution as N_h for the specified height, then $N = \sum_{h=1}^{h_{\max}} N_h$ satisfies $\mathbb{E}[e^{\lambda N}] \le 2$ for $\lambda \le \log 2$.*

Proof. We seek to upper bound $\mathbb{E}[e^{\lambda N_h}] = \sum_{t=0}^{\infty} \mathbb{P}[N_h = t] e^{\lambda t}$. Separating out the $t = 0$ term and applying Lemma 9, we obtain $\mathbb{E}[e^{\lambda N_h}] \le 1 + \sum_{t=1}^{\infty} 4^{-(h+t)} e^{\lambda t} = 1 + 4^{-h} \sum_{t=1}^{\infty} e^{(\lambda - \log 4)t} = 1 + 4^{-h} \cdot \frac{e^{\lambda}}{4 - e^{\lambda}}$ for $\lambda \in [0, \log 4)$. In particular, if $\lambda \le \log 2$, then $\mathbb{E}[e^{\lambda N_h}] \le 1 + 4^{-h}$.

For the second part, we again consider $\lambda \le \log 2$, and use the independence assumption to write $\mathbb{E}[e^{\lambda N}] = \prod_{h=1}^{h_{\max}} \mathbb{E}[e^{\lambda N_h}] \le \prod_{h=1}^{h_{\max}} \left(1 + 4^{-h}\right) \le e^{\sum_{h=1}^{h_{\max}} 4^{-h}} \le e^{1/3} \le 2$. ◀

We now consider the following decomposition of N_{leaf}:

$$N_{\text{leaf}} = N'_{\text{leaf}} + N''_{\text{leaf}}, \tag{18}$$

where N'_{leaf} counts the reached non-defective leaf nodes having at least one defective ancestor, and N''_{leaf} counts the reached non-defective leaf nodes having all non-defective ancestors. In the case of a single defective item (i.e., $k = 1$), we claim that N'_{leaf} has the same distribution as $2N$, with N given in Lemma 10 for a suitably-chosen value of $h_{\max}$ and $q = \frac{1}{2}$. To see this, we identify the leaf nodes in Lemma 10 with nodes at the *second-last* level of the tree illustrated in Figure 1, and observe that the factor of 2 arises since every such node produces two children at the final level (hence contributing to N'_{leaf}) when placed in a positive test.

In the case of k defective items, some care is needed, as the relevant sets of leaves associated with the k defective paths may overlap, potentially creating complicated dependencies between the associated random variables. However, if we take the definition of N in Lemma 10 and remove some leaves from the count, the quantity $\mathbb{E}[e^{\lambda N}]$ can only decrease further, so the conclusion $\mathbb{E}[e^{\lambda N}] \le 2$ remains valid. Hence, by counting any overlapping leaves only once (in an otherwise arbitrary manner), we can form k independent random variables $N^{(1)}, \dots, N^{(k)}$ satisfying $2 \sum_{i=1}^{k} N^{(i)} \overset{\text{d}}{=} N'_{\text{leaf}}$ and $\mathbb{E}[e^{\lambda N^{(i)}}] \le 2$. In addition, since there are k nodes at level $\ell_{\min} = \log_2 k$, we can similarly form $k' \le k$ independent random variables $N^{(k+1)}, \dots, N^{(k+k')}$ satisfying $\sum_{i=k+1}^{k+k'} N^{(i)} \overset{\text{d}}{=} N''_{\text{leaf}}$ and $\mathbb{E}[e^{\lambda N^{(i)}}] \le 2$.

Thus, by (18), N_{leaf} is the sum of at most $2k$ independent sub-exponential random variables. Again applying a standard concentration bound [43, Prop. 5.16], it follows that

$$\mathbb{P}[N_{\text{leaf}} \ge \mathbb{E}[N_{\text{leaf}} \,|\, \mathcal{T}_S] + t \,|\, \mathcal{T}_S] \le e^{-\Omega(\min\{t^2/k, t\})}, \tag{19}$$

from which Lemma 8 follows upon setting $t = \Theta(k)$ and using the fact that $\mathbb{E}[N_{\text{leaf}} \,|\, \mathcal{T}_S] = O(k)$ (see Lemma 5).

2.3.4 Analysis of the final level

Recall that at the final level, we perform $C' \log k$ independent sequences of $2k$ tests, with each item being randomly placed in one test in each sequence. We study the error probability conditioned on the high-probability event that $N_{\text{leaf}} = O(k)$ (see Lemma 8)

For a given non-defective item and a given sequence of $2k$ tests, the probability of colliding with any defective item is at most $\frac{1}{2}$, similarly to Lemma 2. Due to the $C' \log k$ repetitions, for any fixed $c' > 0$, there exists a choice of C' yielding $O(k^{-c'})$ probability of a given non-defective appearing only in positive tests. By a union bound over the $N_{\text{leaf}} = O(k)$ non-defectives at the final level, we find that the estimate $\widehat{S}$ equals S with (conditional) probability $1 - O(k^{1-c'})$.

2.3.5 Number of tests, error probability, decoding time, and storage

The claims of Theorem 1 are established as follows:

- *Number of tests:* As stated in Section 2.1, the number of tests is $t = Ck\log_2\frac{n}{k} + 2C'k\log k$, which behaves as $O\big(k\log\frac{n}{k} + k\log k\big) = O(k\log n)$.
- *Error probability*: The concentration bounds on N_{leaf} and N_{total} (see Lemmas 6 and 8) hold with probability $1 - e^{-\Omega(k)}$ and $1 - e^{-\Omega(k\log\frac{n}{k})}$ respectively, and we treat their complements as error events. These terms are dominated by the final stage, which incurs $O(k^{1-c'})$ failure probability; setting $c' = c+1$ gives the $O(k^{-c})$ behavior stated in Theorem 1.
- *Decoding time*: We claim that conditioned on the the high-probability events $N_{\text{total}} = O\big(k\log\frac{n}{k}\big)$ and $N_{\text{leaf}} = O(k)$, the decoding time is $O\big(k\log\frac{n}{k} + k\log k\big) = O(k\log n)$. The first term comes from considering all levels except the last, since it takes $O(1)$ time to check whether each node associated with N_{total} is in a positive or negative test. While N_{total} only counts the non-defective nodes, the number of defective nodes also trivially behaves as $O\big(k\log\frac{n}{k}\big)$. At the last level, for each of the $k + N_{\text{leaf}} = O(k)$ relevant leaf nodes, we perform $O(\log k)$ such checks for a total time of $O(k\log k)$.
- *Storage*: At the ℓ-th level, we need to store 2^ℓ integers indicating the test associated with each of the 2^ℓ nodes. Hence, excluding the last level, we need to store $\sum_{\ell=\log_2 k}^{\log_2 n-1} 2^\ell = O(n)$ integers in $\{1,\dots,2k\}$, or $O(n\log k)$ bits. Similarly, the $O(\log k)$ independent sequences of tests at the final level amount to storing $O(n\log k)$ integers, or $O(n(\log k)^2)$ bits. In addition, under the high-probability event $N_{\text{total}} = O\big(k\log\frac{n}{k}\big) = O(k\log n)$, the storage of the possibly defective set requires $O(k\log n)$ integers, or $O(k\log^2 n)$ bits. Since $k \le n$, this is no higher than $O(n\log^2 k)$.

3 Storage Reductions via Hashing

A notable weakness of Theorem 1 is that the storage required at the decoder is higher than linear in the number of items. In this section, we present a variant of our algorithm with considerably lower storage that attains similar guarantees to Theorem 1.

The idea is to interpret the mappings $\{1,\dots,2^\ell\} \to \{1,\dots,Ck\}$ at each level as hash functions. Since the high storage in Theorem 1 comes from explicitly storing the corresponding $2^\ell = O(n)$ values, the key to reducing the overall storage is to use lower-storage hash families. The reduced storage comes at the expense of reduced independence between different hash values (e.g., only r-wise independence for some $r \ll n$), and the proof of Theorem 1 utilizes full independence. The modified algorithm in this section uses $\Theta(\log k)$-wise independent hash families, and we leave open the question of whether similar recovery guarantees can be attained with only $O(1)$-wise independence.

A second modification to the algorithm is that in order to attain the behavior $O(k^{-c})$ in the error probability similarly to Theorem 1, we consider the use of $\widetilde{C} \ge 1$ independent repetitions at each level $\ell = \ell_{\min},\dots,\log_2 n - 1$, in the same way that we already used repetitions at the final level. This means that at each level, there are $\widetilde{C}$ sequences of Ck tests (each with a different and independent hash function), and a node is only considered to be possibly defective at a given level if *all* of its associated $\widetilde{C}$ tests are positive.

▶ Remark. This idea of using low-storage hash functions is reminiscent of the Bloom filter data structure [7]. A direct approach to transferring Bloom filters to group testing is to perform $L = O(\log n)$ hashes of each item into one of $t = O(k\log n)$ tests, and then estimate the defective set to be the set of items only included in positive tests [4, Sec. 1.7]. By checking the L test outcomes associated with each item, the defective set can be identified with low

storage (depending on the hash family properties) under the preceding scaling laws. However, a drawback of this direct approach is that checking all items separately takes $\Omega(n)$ time. Our algorithm circumvents this via the binary splitting approach.

3.1 Statement of Result

With the above-described modifications to the algorithm, we have the following counterpart to Theorem 1, which formalizes and generalizes Main Result 2.

▶ **Theorem 11** (Algorithmic Guarantees with Reduced Storage). *Let S be a fixed (defective) subset of $\{1,\dots,n\}$ of cardinality k. For any constant $c > 0$, there exist choices of C, $\widetilde{C}$, and C' such that the above-described group testing algorithm adapted from Section 2.1, with a $\Theta(\log k)$-wise independent hash family and $\widetilde{C}$ independent repetitions per level, yields the following with probability at least $1 - O\big(\frac{\log n}{k^c}\big)$:*

- *The returned estimate $\widehat{S}$ equals S;*
- *The algorithm runs in time $O(\mathsf{T}_{\text{hash}} k \log n)$, where T_{hash} is the evaluation time for one hash value;*
- *The algorithm uses $O(k \log n + \mathsf{S}_{\text{hash}} \log n)$ bits of storage, where S_{hash} is the number of bits of storage required for one hash function.*

In addition, the number of tests scales as $O(k \log n)$.

We briefly discuss some explicit values that can be attained for T_{hash} and S_{hash}. Supposing that n, k, and C are powers of two, we can adopt the classical approach of Wegman and Carter [44] and consider a random polynomial over the finite field $\mathrm{GF}(2^m)$, where $m \in \{\log_2 k, \dots, \log_2 n\}$ (depending on the level). In this case, one attains r-wise independence while storing r elements of $\mathrm{GF}(2^m)$ (or $O(r \log n)$ bits), and performing $O(r)$ additions and multiplications in $\mathrm{GF}(2^m)$ to evaluate the hash. As a result, with $r = \Theta(\log k)$, we get

$$\mathsf{T}_{\text{hash}} = O(\log k), \qquad \mathsf{S}_{\text{hash}} = O(\log k \cdot \log n) \tag{20}$$

under the assumption that operations in $\mathrm{GF}(2^m)$ can be performed in constant time. Hence, Theorem 11 gives $O(k \log k \cdot \log n)$ decoding time and $O(k \log n + \log k \cdot \log^2 n)$ storage. Different trade-offs can also be attained using more recent hash families that can attain r-wise independence with an evaluation time significantly less than r [40, 41].

The error probability of $O\big(\frac{\log n}{k^c}\big)$ is slightly worse than the $O(k^{-c})$ scaling of Theorem 1; in particular, $o(1)$ error probability is only guaranteed when $k = (\log n)^{\Omega(1)}$. We expect that this requirement could be avoided via a refined analysis, e.g., by characterizing the behavior of the random variables N_{total} and N_{leaf} used in the proof of Theorem 1. In addition, the following variants of Theorem 11 can already be attained with almost no additional effort:

- We can allow $c = \omega(1)$ in the statement of Theorem 11, but at the expense of the number of tests and decoding time increasing by a multiplicative $\Theta(c)$ factor.
- It is straightforward to show that $\mathbb{E}[N_{\text{total}}] = O\big(k \log \frac{n}{k}\big)$ and $\mathbb{E}[N_{\text{leaf}}] = O(k)$, and one can use Markov's inequality to deduce that $N_{\text{total}} = O\big(k^{1+c} \log \frac{n}{k}\big)$ and $N_{\text{leaf}} = O(k^{1+c})$ with probability $1 - O(k^{-c})$. For any constant $c > 0$, this approach leads to $O(k^{-c})$ error probability with $O(k \log n)$ tests, but the decoding time increases to $O(\mathsf{T}_{\text{hash}} k^{1+c} \log n)$, and the storage increases to $O(k^{1+c} \log^2 n + \mathsf{S}_{\text{hash}} \log n)$.

In the remainder of the section, we provide the proof of Theorem 11.

3.2 Analysis

3.2.1 Auxiliary variance calculation (case $\widetilde{C} = 1$)

We first study the case $\widetilde{C} = 1$ (i.e., no repetitions), as the case $\widetilde{C} > 1$ will then follow easily.

Recall that the algorithm maintains an estimate of the possibly defective (PD) set at each level. We will give conditions under which the size of this set remains at $O(k)$ throughout the course of the algorithm. For $\ell = \ell_{\min} = \log_2 k$, we trivially have at most $k \le 4k$ PD items. We will use an induction argument to show that every level has at most $4k$ PD items, with high probability.

Consider two non-defective nodes indexed by u, v at a given level ℓ having $k' \le k$ defective nodes, let $\mathcal{D}_u, \mathcal{D}_v$ denote the respective events of hashing into a test containing one or more defectives, and let D_u, D_v be the corresponding indicator random variables. The dependence of these quantities on ℓ is left implicit. We condition on all of the test placements performed at the earlier levels, accordingly writing $\mathbb{E}_\ell[\cdot]$ and $\mathrm{Var}_\ell[\cdot]$ for the conditional expectation and conditional variance. In accordance with the above induction idea, we assume that there are at most $4k$ PD nodes at level ℓ.

▶ **Lemma 12** (Mean and Variance Bounds)**.** *Under the preceding setup and definitions, if there are at most $4k$ PD nodes at level ℓ, then we have the following when $\widetilde{C} = 1$ and $C \ge 8$:*

$$\mathbb{E}_\ell\left[\sum_u D_u\right] \le \frac{k}{2} \tag{21}$$

$$\mathrm{Var}_\ell\left[\sum_u D_u\right] = c_{\mathrm{var}} k, \tag{22}$$

where the sums are over all non-defective PD nodes at the ℓ-th level, and $c_{\mathrm{var}} > 0$ is a universal constant.

The proof is given in Appendix B. Given this result, we easily deduce the following.

▶ **Lemma 13.** *For $\widetilde{C} = 1$ and $C \ge 8$, conditioned on the ℓ-th level having at most $4k$ possibly defective (PD) nodes, the same is true at the $(\ell+1)$-th level with probability $1 - O\big(\frac{1}{k}\big)$.*

Proof. Among the PD nodes at the ℓ-th level, at most k are defective, amounting to at most $2k$ children at the next level. By Lemma 12 and Chebyshev's inequality, with probability $1 - O\big(\frac{1}{k}\big)$, at most k non-defective nodes are marked as PD, thus also amount to at most $2k$ additional children at the next level, for a total of $4k$. ◀

3.2.2 Analysis of the error probability

At the first level $\ell = \log_2 k$, we trivially have $k \le 4k$ possibly defective (PD) nodes. For $\widetilde{C} = 1$, using Lemma 13 and an induction argument, the same follows for all levels simultaneously with probability at least $1 - O(k^{-1} \log n)$. For $\widetilde{C} > 1$, we note that since we have $\widetilde{C}$ repetitions at each level and only keep the nodes whose tests are *all* positive, the $1 - O(k^{-1})$ behavior becomes $1 - O(k^{-\widetilde{C}})$ due to the independence of the repetitions. Hence, the expression $1 - O(k^{-1} \log n)$ for $\widetilde{C} = 1$ generalizes to $1 - O\big(k^{-\widetilde{C}} \log n\big)$.

The analysis of the final level in Section 2.3.4 did not rely on $h(\cdot)$ being a fully independent hash function, but rather, only relied on a collision probability of $\frac{1}{2k}$ between any two given items. Since this condition still holds for any pairwise (or higher) independent hash family, we immediately deduce the same conclusion: Conditioned on the final level having $O(k)$ nodes marked as possibly defective, and by choosing C' appropriately in the algorithm description, we attain $O(k^{1-c'})$ error probability at this level for any fixed $c' > 0$.

Combining the above and setting $\widetilde{C} = c$ and $c' = 1 + c$, we attain the desired scaling $O(k^{-c} \log n)$ in the theorem statement.

3.2.3 Number of tests, decoding time, and storage

The remaining claims of Theorem 11 are established as follows:

- *Number of tests:* The number of tests is the same as in the fully independent case, possibly with a modified implied constant if $\widetilde{C} > 1$ and/or a different choice of C is used.
- *Decoding time*: The analysis of the decoding time is similar to the fully independent case (see Section 2.3.5), but each hash takes T_{hash} time to compute. Hence, the decoding time is $O\big(\mathsf{T}_{\text{hash}} k \log n\big)$.
- *Storage*: We use $O(1)$ hash functions at each level except the last, and $O(\log k)$ hash functions at the final level, for a total of $O\big(\log \frac{n}{k} + \log k\big) = O(\log n)$, requiring $O(\mathsf{S}_{\text{hash}} \log n)$ storage. In addition, under the high-probability event that there are $O(k)$ possibly defective nodes at each level, their storage requires $O(k)$ integers, or $O(k \log n)$ bits. Hence, the total storage is $O(k \log n + \mathsf{S}_{\text{hash}} \log n)$.

4 Conclusion

We have presented a novel non-adaptive group testing algorithm ensuring high-probability (for-each) recovery with $O(k \log n)$ scaling in both the number of tests and decoding time. In addition, we presented a low-storage variant with similar guarantees depending on the hash family used. An immediate open question for this variant is whether similar guarantees hold for $O(1)$-wise independent hash families. In addition, even for the fully independent version, it would be of significant interest to develop a variant that is robust to random noise in the test outcomes (see Footnote 2 on Page 4).

A Discussion on the SAFFRON Algorithm

While the SAFFRON algorithm [34] is based on sparse-graph codes, we find it most instructive to compare against the simplified singleton-only version [4, Sec. 5.4], as the more sophisticated version does not attain better scaling laws (though it may attain better constant factors).

Singleton-only SAFFRON is briefly outlined as follows. One forms $O(k \log k)$ "bundles" of tests of size $2\log_2 n$ each, and assigns each item to any given bundle with probability $O\big(\frac{1}{k}\big)$. If a given item is assigned to a given bundle, then its $(\log_2 n)$-bit description is encoded into the first $\log_2 n$ tests (i.e., the item is included in the test if and only if its bit description contains a 1 at the corresponding location), and its bit-wise complement is encoded into the last $\log_2 n$ tests. The following decoding procedure ensures the identification of any defective item for which there exists a bundle in which it is included without any other defective items:

- For each bundle, check whether the first $\log_2 n$ test outcomes equal the bit-wise negation of the second $\log_2 n$ outcomes.
- If so, add the item with bit representation given by the first $\log_2 n$ outcomes into the defective set estimate.

Due to the first step, the second step will never erroneously be performed on a bundle without defective items, nor on a bundle with multiple defective items.

In [34], a decoding time of $O(k \log k \cdot \log n)$ is stated under the assumption that reading the $2 \log_2 n$ bits takes $O(\log n)$ time. However, if the associated $2 \log_2 n$ tests are stored in memory as two "words" of length $\log_2 n$ each, then a word-RAM model of computation only incurs $O(1)$ time per bundle, or $O(k \log k)$ time overall.

We also note that SAFFRON only requires $O(k \log k \cdot \log n)$ bits of storage, amounting to negligible storage overhead beyond the test outcomes themselves. This is because the only item indices stored are those added to the estimate of the defective set, and there are at most k such indices (or $k \log_2 n$ bits) due to the fact that SAFFRON makes no false positives.

B Proof of Lemma 12 (Mean and Variance Bounds)

For ease of notation, we leave the subscripts $(\cdot)_\ell$ implicit throughout the proof, but the associated conditioning is understood to apply to all probabilities, expectations, variance terms, and so on.

We first prove (21). The event $\mathcal{D}_u$ occurs if u is hashed into the same bin as any of the $k' \le k$ defective nodes. Since we are hashing into $\{1, \dots, Ck\}$ and the hash family is (at least) pairwise independent, each collision occurs with probability $\frac{1}{Ck}$. Hence, by the union bound, u is in a positive test with probability at most $\frac{1}{C}$, and (21) follows from the assumption that there are at most $4k$ PD nodes and $C \ge 8$.

As for (22), we first characterize $\mathrm{Cov}[D_u, D_v]$, writing

$$\begin{aligned} \mathrm{Cov}[D_u, D_v] &= \mathbb{E}[D_u D_v] - \mathbb{E}[D_u]\mathbb{E}[D_v] && (23)\\ &= \mathbb{P}[\mathcal{D}_u \cap \mathcal{D}_v] - \mathbb{P}[\mathcal{D}_u]\mathbb{P}[\mathcal{D}_v] && (24)\\ &= \mathbb{P}[\mathcal{D}_u] + \mathbb{P}[\mathcal{D}_v] - \mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v] - \mathbb{P}[\mathcal{D}_u]\mathbb{P}[\mathcal{D}_v]. && (25) \end{aligned}$$

We proceed by bounding $\mathbb{P}[\mathcal{D}_u]$ (the same bound holds for $\mathbb{P}[\mathcal{D}_v]$) and $\mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v]$ separately.

Probability of the individual event

Fix a non-defective node u. Let $h(\cdot)$ denote the random hash function with output values in $\{1, \dots, Ck\}$, and for each defective node indexed by $i \in \{1, \dots, k'\}$ (where k' is the total number of defective nodes at the level under consideration), let B_i be the "bad" event that $h(i) = h(u)$. We apply the inclusion-exclusion principle, which is written in terms of the following quantities for $j = 1, \dots, k'$:

$$T_j = \sum_{1 < i_1 < \dots < i_j < k'} \mathbb{P}[B_{i_1} \cap \dots \cap B_{i_j}]. \tag{26}$$

If the hash function is $(j+1)$-wise independent, this simplifies to

$$T_j = \binom{k'}{j} \left(\frac{1}{Ck}\right)^j. \tag{27}$$

Hence, if the hash function is $(j_{\max}+1)$-wise independent for some $j_{\max}$, then the inclusion-exclusion principle gives

$$\mathbb{P}[\mathcal{D}_u] = \mathbb{P}\Big[\bigcup_{i=1,\dots,k'} B_i\Big] \tag{28}$$

$$\leq \sum_{j=1}^{j_{\max}} (-1)^{j+1} T_j \tag{29}$$

$$= \sum_{j=1}^{j_{\max}} \binom{k'}{j} (-1)^{j+1} \Big(\frac{1}{Ck}\Big)^j \tag{30}$$

for odd-valued $j_{\max}$, and the reverse inequality for even-valued $j_{\max}$. Using the fact that $\sum_{j=1}^{k'} \binom{k'}{j}(-1)^{j+1}\big(\frac{1}{Ck}\big)^j = 1 - \big(1-\frac{1}{Ck}\big)^{k'}$, we can write (30) as

$$\mathbb{P}[\mathcal{D}_u] \leq 1 - \Big(1-\frac{1}{Ck}\Big)^{k'} - \sum_{j_{\max}+1}^{k'} \binom{k'}{j} (-1)^{j+1} \Big(\frac{1}{Ck}\Big)^j. \tag{31}$$

The final term can then be bounded as follows in absolute value:

$$\Big|\sum_{j_{\max}+1}^{k'} \binom{k'}{j} (-1)^{j+1} \Big(\frac{1}{Ck}\Big)^j\Big| \leq \sum_{j_{\max}+1}^{k'} \binom{k'}{j} \Big(\frac{1}{Ck}\Big)^j \tag{32}$$

$$\leq \sum_{j_{\max}+1}^{\infty} \Big(\frac{1}{C}\Big)^j \tag{33}$$

$$= \frac{(1/C)^{j_{\max}+1}}{1-1/C}, \tag{34}$$

where (33) uses $\binom{k'}{j} \leq (k')^j$ and $k' \leq k$, and (34) applies the geometric series formula. Assuming $C \geq 2$, we can further upper bound the above expression by $(1/C)^{j_{\max}}$, and hence by any target value δ_0 provided that $j_{\max} \geq \log_C \frac{1}{\delta_0}$. Recall also that (31) is reversed for even-valued $j_{\max}$, so loosening the preceding requirement to $j_{\max} \geq \lceil \log_C \frac{1}{\delta_0} \rceil + 1$ gives

$$1 - \Big(1-\frac{1}{Ck}\Big)^{k'} - \delta_0 \leq \mathbb{P}[\mathcal{D}_u] \leq 1 - \Big(1-\frac{1}{Ck}\Big)^{k'} + \delta_0. \tag{35}$$

Since u is arbitrary, the same bound also holds for $\mathbb{P}[\mathcal{D}_v]$.

Probability of the union of two events

We can decompose $\mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v]$ as follows:

$$\mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v] = \Big(1-\frac{1}{Ck}\Big)\mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v \,|\, h(u) \neq h(v)] + \frac{1}{Ck}\mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v \,|\, h(u) = h(v)] \tag{36}$$

$$= \mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v \,|\, h(u) \neq h(v)] + O\Big(\frac{1}{k}\Big). \tag{37}$$

Hence, we focus on the case $h(u) \neq h(v)$ in the following. Similar to the above, let B'_i be the "bad" event that $h(i) \in \{h(u), h(v)\}$, and define

$$T'_j = \sum_{1<i_1<\dots<i_j<k'} \mathbb{P}[B'_{i_1} \cap \dots \cap B'_{i_j} \,|\, h(u) \neq h(v)]. \tag{38}$$

If the hash function is $(j+2)$-wise independent, this simplifies to

$$T'_j = \binom{k'}{j}\Big(\frac{2}{Ck}\Big)^j, \tag{39}$$

where the factor of two comes from the possibility of colliding with either u or v. Following the same argument as above, we find that if (i) $j_{\max} \geq \lceil \log_{C/2} \frac{1}{\delta_0} \rceil + 1$, (ii) $C \geq 4$, and (iii) the hash function is $(j_{\max}+2)$-wise independent, then the following analog of (35) holds:

$$1 - \Big(1 - \frac{2}{Ck}\Big)^{k'} - \delta_0 \leq \mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v \,|\, h(u) \neq h(v)] \leq 1 - \Big(1 - \frac{2}{Ck}\Big)^{k'} + \delta_0. \tag{40}$$

Combining and simplifying

Setting $\delta_0 = \frac{1}{k}$ and combining the above findings, we deduce that for a $\Theta(\log k)$-wise independent hash,

$$\mathbb{P}[\mathcal{D}_u] = 1 - \Big(1 - \frac{1}{Ck}\Big)^{k'} + O\Big(\frac{1}{k}\Big), \tag{41}$$

$$\mathbb{P}[\mathcal{D}_u \cup \mathcal{D}_v] = 1 - \Big(1 - \frac{2}{Ck}\Big)^{k'} + O\Big(\frac{1}{k}\Big). \tag{42}$$

The idea in the following is to approximate $1 - \frac{\nu}{Ck} \approx e^{-\frac{1}{Ck}}$ for $\nu = 1, 2$, and substitute into (25). To make this more precise, we use the fact that $k' \leq k$ to write

$$\Big(1 - \frac{1}{Ck}\Big)^{k'} = \Big(e^{-\frac{1}{Ck} + O\left(\frac{1}{k^2}\right)}\Big)^{k'} \tag{43}$$

$$= e^{-\frac{k'}{Ck} + O\left(\frac{1}{k}\right)} \tag{44}$$

$$= e^{-\frac{k'}{Ck}} + O\Big(\frac{1}{k}\Big). \tag{45}$$

Applying a similar argument to $\big(1 - \frac{2}{Ck}\big)^{k'}$ and substituting into (25), we obtain

$$\mathrm{Cov}[D_u, D_v] = 2\Big(1 - e^{-\frac{k'}{Ck}}\Big) - \Big(1 - e^{-\frac{2k'}{Ck}}\Big) - \Big(1 - e^{-\frac{k'}{Ck}}\Big)^2 + O\Big(\frac{1}{k}\Big) \tag{46}$$

$$= O\Big(\frac{1}{k}\Big), \tag{47}$$

since the first three terms cancel upon expanding the square. The proof is concluded by writing

$$\mathrm{Var}\Big[\sum_u D_u\Big] = \sum_u \mathrm{Var}[D_u] + \sum_{u \neq v} \mathrm{Cov}[D_u, D_v] = O(k) \tag{48}$$

since $\mathrm{Var}[D_u] \leq \mathbb{E}[D_u] \leq \frac{1}{C}$, and there are at most $4k$ values of u by assumption.

Maximum Shallow Clique Minors in Preferential Attachment Graphs Have Polylogarithmic Size

Abstract

Preferential attachment graphs are random graphs designed to mimic properties of real word networks. They are constructed by a random process that iteratively adds vertices and attaches them preferentially to vertices that already have high degree. We prove various structural asymptotic properties of this graph model. In particular, we show that the size of the largest r-shallow clique minor in G_m^n is at most $\log(n)^{O(r^2)}m^{O(r)}$. Furthermore, there exists a one-subdivided clique of size $\log(n)^{1/4}$. Therefore, preferential attachment graphs are asymptotically almost surely somewhere dense and algorithmic techniques developed for structurally sparse graph classes are not directly applicable. However, they are just barely somewhere dense. The removal of just slightly more than a polylogarithmic number of vertices asymptotically almost surely yields a graph with locally bounded treewidth.

1 Introduction

Large scale complex networks occur for example in the context of social-, biological, and technical networks. Even though these are vastly different environments, all these networks follow the same common laws. Many models [18, 23, 19, 8, 20] have been proposed that aim to mimic complex networks. The most prominent model might be the *preferential attachment graph model* (also called Barabási–Albert model) [3]. These graphs are created by a random process that iteratively adds new vertices and randomly connects them to already existing ones. Every time a new vertex is added, it is connected to the remaining graph via m random edges. Thereby, the probability that an edge from the new vertex to another vertex v is drawn is proportional to the current degree of v (see Section 2.3 for a more rigorous definition). The vertices are denoted by $v_1, v_2, v_3, \ldots$ in order of insertion. We denote the preferential attachment graph with n vertices and nm edges by G_m^n.

This process creates a certain imbalance: The degree of low-degree vertices is unlikely to increase and the degree of high-degree vertices is likely to increase even further. This so called "the rich get richer"-effect has has been widely recognized as a reasonable explanation

of the heavy tailed degree distribution of real networks. The preferential attachment model is particularly interesting from the point of mathematical analysis because of its simple formulation and interesting characteristics.

1.1 Previous Results

There exists a wide range of results on the asymptotic structure of preferential attachment graphs (for an overview see [31]). The radius of these graphs has been shown to be logarithmic [5, 12], which means they exhibit small world behavior [1, 21]. Various aspects of their degrees have been studied [13, 2, 24, 29, 28]. In particular, the degree distribution follows a power-law with exponent three [6]. However, unlike many real networks [32, 30], preferential attachment graphs have a vanishing clustering coefficient [7]. This result has been obtained by bounding the number of certain subgraphs in preferential attachment graphs. For example, the expected number of triangles or l-cycles in G_m^n has been shown to be $\log(n)^{\Theta(1)}$ for fixed l and m [7], which is lower than what is to be expected in real networks [22].

1.2 Our Results

In this work, we obtain new insights to the clustering behavior of preferential attachment graphs. We show that there is a cluster centered around a logarithmic number of tightly connected hubs that has previously not been discussed. On the other hand, removing these central hubs asymptotically yields a graph in which every r-neighborhood is a tree with at most one extra edge. In particular, at most two neighbors of a vertex are connected. This drastically bounds the local clustering coefficient. In summary, we show that the first logarithmically many vertices are the main source of structural complexity in preferential attachment graphs and removing them yields a locally extremely sparse graph.

We prove these results one by one. At first, we show that preferential attachment graphs contain one-subdivisions of cliques of logarithmic size. A one-subdivision is the graph obtained by replacing every edge with a path of length two.

▶ **Theorem 9.** *There exists a constant c such that for $m, n \in \mathbf{N}$, $m \geq 2$, $n \geq c$, the preferential attachment graph G_m^n contains a one-subdivided clique of size at least $\log(n)^{1/4}$ with a probability of at least $1 - e^{-\log(n)^{1/4}/c}$.*

Graph classes which contain subdivided cliques of logarithmic size cannot for example be planar or have bounded treewidth. In fact, they are *somewhere dense*, as we will discuss later on. The previous theorem is complemented by showing that removing the first polylogarithmically many vertices of a preferential attachment graph leaves a graph with a locally extremely sparse, tree-like structure.

▶ **Corollary 13.** *There exists a constant c such that for $l, n, m \in \mathbf{N}^+$ and $b = \lceil \log(n)^{cl^2} m^{cl} \rceil$ the graph $G_m^n[v_{b+1}, \ldots, v_n]$ contains a.a.s. no subgraph with up to l vertices and more edges than vertices.*

Forbidding subgraphs with more edges than vertices is quite restrictive. The previous statement states that for a fixed m, removing $\log(n)^{O(l^2)}$ vertices leads asymptotically to a graph in which all connected subgraphs with l vertices have either l or $l-1$ edges, i.e., they are either a tree or a tree with one extra edge. This means for example that the removal of $\log(n)^{O(1)}$ vertices yields asymptotically a graph with no cliques of size four. It also yields the following statement about tree-like neighborhoods in preferential attachment graphs.

▶ **Theorem 16.** *There exists a constant c such that for $r, n, m \in \mathbf{N}^+$ and $b = \lceil \log(n)^{cr^2} m^{rc} \rceil$, a.a.s. every r-neighborhood of $G_m^n[v_{b+1}, \dots, v_n]$ is either a tree or a tree with one additional edge.*

1.3 Sparsity

An often observed property of real networks is a relatively low average degree. For example in a social network, the vast majority of members only has relatively few neighbors, especially compared to the set of all potential neighbors. This leads us to a concept called *structural sparsity* [25]. Sparsity has been deeply studied and has lead to many interesting results. In particular, there exists a large body of work focusing on algorithmic applications of sparsity (for example [4, 9, 14, 16, 17]). Many graph problems that are hard for general graphs become easier on structurally sparse graph classes.

Sparsity is not a property of single graphs, but a property of graph classes. An important cornerstone of sparsity theory are *nowhere dense* and *somewhere dense* graph classes introduced by Nešetřil and Ossona de Mendez [25]. These graph classes are defined using *shallow topological clique minors*. A graph G contains an r-shallow topological clique minor of size k if a subgraph of G is isomorphic to a graph obtained by subdividing a k-clique up to $2r$ times. The size of the largest r-shallow topological clique minor of a graph G is denoted by $\omega(G \mathbin{\widetilde{\nabla}} r)$. A graph class is nowhere dense if for every radius r and every graph G in the graph class, $\omega(G \mathbin{\widetilde{\nabla}} r) \leq f(r)$ for some function $f(r)$ independent of the graph size. Conversely, if $\omega(G \mathbin{\widetilde{\nabla}} r)$ is unbounded for some r, the graph class is said to be somewhere dense. Every graph class is either nowhere or somewhere dense. For a rigorous definition of these two concepts see Section 2.4.

Nowhere dense graph classes generalize many different sparse graph properties such as bounded degree, planarity, bounded treewidth, bounded genus or bounded expansion [25]. An important algorithmic result is that every problem definable in first-order logic can be solved in almost linear time on nowhere dense graph classes [16]. On the other hand, somewhere density defines for many problems a natural barrier in tractability. The model checking problem for first-order logic on monotone somewhere dense graph classes is AW[$*$]-complete and therefore as hard as on general graphs [16].

In order to lift deep algorithmic results for sparse graph classes to random graphs, people started analyzing which random graph models are somewhere or nowhere dense *in the limit*. Roughly speaking, a random graph model is asymptotically almost surely (a.a.s.) nowhere dense if for large graphs $\omega(G \mathbin{\widetilde{\nabla}} r)$ is with probability one bounded by some function $f(r)$ independent of the graph size and a.a.s. somewhere dense if it is with probability one unbounded. If a random graph model is a.a.s. nowhere dense it is not a.a.s. somewhere dense, and vice versa. However, it is possible that a random graph model is neither a.a.s. somewhere nor a.a.s. nowhere dense. Again, for more details see Section 2.4.

Erdős–Rényi graphs, random intersection graphs, Chung–Lu graphs, and the configuration model have been classified with respect to a.a.s. somewhere and nowhere density [26, 10, 15]. This has lead directly to efficient algorithms on random graphs. Preferential attachment graphs are known not to be a.a.s. nowhere dense [10] but a complete classification remained open. In this work, we show that shallow topological clique minors have polylogarithmic size and therefore that the preferential attachment model is a.a.s. somewhere dense.

▶ **Theorem 1.** *Let $r \in \mathbf{N}^+$, $m \geq 2$. Then a.a.s. $\log(n)^{1/4} \leq \omega(G_m^n \mathbin{\widetilde{\nabla}} r) \leq \log(n)^{O(r^2)} m^{O(r)}$. In particular G_m^n is a.a.s. somewhere dense.*

This is a direct consequence of Theorem 9 and Theorem 15. Our result implies that algorithmic techniques developed for nowhere dense graph classes do not directly transfer to preferential attachment graphs. However, shallow topological clique minors have only polylogarithmic size. Hence, preferential attachment graphs are "just barely" somewhere dense. In particular, the removal of few vertices places the random graph model a.a.s. in a very sparse graph class, where all connected subgraphs of bounded diameter are "tree-like." Note that locally bounded treewidth implies nowhere denseness [25].

▶ **Theorem 17.** *Let $m \in \mathbf{N}^+$ and $g(n)\colon \mathbf{N} \to \mathbf{N}$ be a function with $g(n) = \omega(1)$. If we remove the first $\log(n)^{g(n)}$ vertices from G_m^n the remaining graph has a.a.s. locally bounded treewidth.*

2 Preliminaries

2.1 Graph Notation

We use common graph theory notation [11]. Furthermore, an *r-neighborhood* is an induced subgraph with radius at most r.

2.2 Probabilities and Random Graph Models

In this work, a random graph model (such as the preferential attachment model) is a sequence $\mathcal{G} = (\mathcal{G}_n)_{n\in\mathbf{N}}$, where $\mathcal{G}_n$ is a probability distribution over undirected simple graphs with n vertices (this means graphs have no self-loops or multi-edges). In slight abuse of notation, we also write $\mathcal{G}_n$ for the random variable which is distributed according to $\mathcal{G}_n$. This way, we can lift graph notation to notation for random variables of graphs: For example edge set and clique number of a random graph $\mathcal{G}_n$ are represented by random variables $E(\mathcal{G}_n)$ and $\omega(\mathcal{G}_n)$.

2.3 The Preferential Attachment Graph Model

In this work we focus on the *preferential attachment random graph model* which we describe in this subsection. It has been ambiguously defined in the original article by Barabási and Albert [3]. The model generates random graphs by iteratively inserting new vertices and edges. It depends on a parameter, usually denoted by m, which indicates the number of edges attached to each newly created vertex. We follow the rigorous definition of Bollobás et al. [6]: For a fixed parameter m the random process is defined by starting with a single vertex and iteratively adding vertices, thereby constructing a sequence of graphs $\bar{G}_m^1, \bar{G}_m^2, \ldots, \bar{G}_m^t$, where $\bar{G}_m^t$ has t vertices and mt edges (of which some may be self-loops). We define $d_m^t(v)$ to be the degree of vertex v in the graph $\bar{G}_m^t$. The random process for $m = 1$ works as follows. A random graph is started with one vertex v_1 that has exactly one self-loop. This graph is $\bar{G}_1^1$. We then define the graph process inductively: Given $\bar{G}_1^{t-1}$ with vertex set $\{v_1, \ldots, v_{t-1}\}$, we create $\bar{G}_1^t$ by adding a new vertex v_t together with a single edge from v_t to v_i, where i is chosen at random from $\{1, \ldots, t\}$ with

$$\Pr[i = s] = \begin{cases} \dfrac{d_1^{t-1}(v_s)}{2t-1} & 1 \le s \le t \\ \dfrac{1}{2t-1} & s = t. \end{cases}$$

This means we add an edge to a random vertex with a probability proportional to its degree at the time.

For $m > 1$, the process can be defined by merging sets of m consecutive vertices in $\bar{G}_1^{mt}$ to single vertices in $\bar{G}_m^t$ [6]. Let $v'_1, \dots, v'_{mt}$ be the vertices of $\bar{G}_1^{mt}$. The graph $\bar{G}_m^t$ with vertices $v_1, \dots, v_t$ is constructing by merging $v'_{(i-1)m+1}, \dots, v'_{im}$ into a single vertex v_i. The graph $\bar{G}_m^t$ is a multigraph. The number of edges between vertices v_i and v_j in $\bar{G}_m^t$ equals the number of edges between the corresponding sets of vertices in $\bar{G}_1^{mt}$. Self-loops are allowed. We obtain a simple random graph G_m^n from $\bar{G}_m^n$ by removing all self-loops and replacing multiple edges with a single edge.

2.4 Sparsity

At first, we define nowhere and somewhere density as a property of *graph classes* and then lift the notation to *random graph models*. There are various equivalent definitions and we use the most common definition based on shallow topological minors.

▶ **Definition 2** (Shallow topological minor [27]). *A graph H is an r-*shallow topological minor *of a graph G if a graph obtained from H by subdividing every edge up to $2r$ times is isomorphic to a subgraph of G. The set of all r-shallow topological minors of a graph G is denoted by $G \mathbin{\widetilde{\nabla}} r$. We define the maximum clique size over all shallow topological minors of G as*

$$\omega(G \mathbin{\widetilde{\nabla}} r) = \max_{H \in G \mathbin{\widetilde{\nabla}} r} \omega(H).$$

▶ **Definition 3** (Nowhere dense, somewhere dense [25]). *A graph class $\mathcal{G}$ is* nowhere dense *if there exists a function f, such that for all r and all $G \in \mathcal{G}$, $\omega(G \mathbin{\widetilde{\nabla}} r) \leq f(r)$. A graph class $\mathcal{G}$ is* somewhere dense *if for all functions f there exists an r and a $G \in \mathcal{G}$, such that $\omega(G \mathbin{\widetilde{\nabla}} r) > f(r)$.*

Observe that a graph class is somewhere dense if and only if it is not nowhere dense. We lift these notions to random graph models using the following two definitions.

▶ **Definition 4** (a.a.s. nowhere dense, a.a.s. somewhere dense). *A random graph model $\mathcal{G}$ is* a.a.s. nowhere dense *if there exists a function f such that for all r*

$$\lim_{n \to \infty} \Pr[\omega(\mathcal{G}_n \mathbin{\widetilde{\nabla}} r) \leq f(r)] = 1.$$

A random graph model $\mathcal{G}$ is a.a.s. somewhere dense *if for all functions f there is an r such that*

$$\lim_{n \to \infty} \Pr[\omega(\mathcal{G}_n \mathbin{\widetilde{\nabla}} r) > f(r)] = 1.$$

While for graph classes the concepts are complementary, a random graph model can be *neither* a.a.s. somewhere dense *nor* a.a.s. nowhere dense (e.g., if the random graph model is either the empty or the complete graph, both with a probability of $1/2$).

3 Lower Bounds

In this section we show that preferential attachment graphs are a.a.s. somewhere dense. We do so by analyzing the probability that a preferential attachment graph of size n contains a one-subdivided clique of size at least $k = \log(n)^{1/4}$ as a subgraph. Let this probability be p_n. We show that $\lim_{n \to \infty} p_n = 1$. The proof works as follows: We start with a small preferential attachment graph and pick a set of k vertices with high degree. These will be the principal vertices of the one-subdivided clique. We then add vertices to the graph according to the

preferential attachment process. A one-subdivided clique of size k arises if for every pair of principal vertices v and w, a new vertex u is added that is adjacent to both v and w. We show that after $n = k^4 2^{k^3}$ vertices have been inserted, with high probability there is at least one connecting vertex for every pair of principal vertices.

We now describe an urn experiment that illustrates for a pair of principal vertices v,w the probability that a new vertex u is connected to both u and v. This experiment has no connection to Pólya Urns and is solely used for illustrative purposes. The experiment consists of multiple rounds. In the ith round (we assume $i \geq 10$), we define an urn containing i balls, where $\sqrt{\lceil i \rceil}$ balls are red, $\sqrt{\lceil i \rceil}$ balls are blue, and the rest is black. In each round we draw two balls uniformly at random from the urn. The experiment succeeds if we draw a red and a blue ball in the same round. It is easy to see that the probability of success in the ith round equals $2(\sqrt{\lceil i \rceil}/i)^2$. We observe that eventually the experiment succeeds because

$$1 - \prod_{i=10}^{\infty} \left(1 - 2\Big(\frac{\sqrt{i}}{i}\Big)^2\right) = 1.$$

This experiment behaves similarly to the process of connecting two principal vertices. Two principal vertices are connected in round i if the vertex v_i is connected to both principal vertices. The expected degree of the first vertex in a preferential attachment graph of size i is proportional to $\sqrt{i}$. If we (naively) assume that the degrees of u and v at time i are at all times exactly $\sqrt{i}$ then a new vertex throws an edge to v or w with probability proportional to $\sqrt{i}/i$ and is connected to both with probability roughly $2(\sqrt{i}/i)^2$. Therefore, the probability that in the ith step a new vertex u connects both v and w is proportional to the probability that in the ith round of the urn experiment a red and a blue ball is drawn. Using similar arguments we show in this section that the success probability of building a one-subdivided clique also is high.

If we however alter the urn experiment and assume that in the ith round there are only about $\sqrt{i}/\log(i)$ red or blue balls we cannot guarantee success because

$$1 - \prod_{i=10}^{\infty} \left(1 - 2\Big(\frac{\sqrt{i}/\log(i)}{i}\Big)^2\right) \neq 1.$$

This means if the expected value of the degrees were just a logarithmic factor smaller then our proof would not work. This suggests that preferential attachment graphs are "just barely" a.a.s. somewhere dense. This also means we need lower bounds which guarantee that the degrees of our principal vertices are not much smaller than their expected value, e.g., at most a constant factor off. Bounds which guarantee a factor of $1/\log(i)$ would not be sufficient.

Unfortunately the probability distribution of the degree of a vertex is only well centered around its expected value if its initial degree is already large (Proposition 5). We therefore use Lemma 6 to find in a graph of size k^4 with high probability k vertices with a degree of roughly k. These vertices will be our principal vertices. For large k, their degree is centered closely around its expected value for our technique to work.

In our proof of Theorem 9 we argue that with high probability for every pair of principal vertices there will eventually be a vertex which is connected to both. One may try to prove this by showing that with high probability the degrees of the principal vertices are well centered at all times of the random process (roughly $\sqrt{i}$ in the ith round for every i) and then showing that the probability that the principal vertices will be connected under this condition is high. However, it is highly non-trivial to bound the probability that an edge is inserted during the preferential attachment process under the condition that something else will happen *afterwards*. Therefore this approach does not work easily. It is much easier to

condition under events that happen *before* in the random process. We therefore analyze the random process over time and *interleave* the concentration bounds of the principal vertices with bounds on the event that a new vertex connects a pair of principal vertices. This interleaved analysis works as follows: Let B_i be the event that the degree of the principal vertices is at least half their expected degree at time step i of the random process. We prove B_i to be likely. For j slightly larger than i, one can easily obtain a good bound on the probability that a new edge of the jth vertex is connected to a principal vertex under the assumption B_i. Our calculations work in a way where whenever we assume a new event B_i the small probability $\Pr[\bar{B}_i]$ is added to our failure probability (see Lemma 8). So if we were to assume all events $B_i, B_{i+1}, B_{i+2}, \dots$ our bound quickly becomes meaningless as the sum $\Pr[\bar{B}_i] + \Pr[\bar{B}_{i+1}] + \Pr[\bar{B}_{i+2}] + \cdots$ quickly becomes larger than one. But if we assume exponentially spaced events $B_i, B_{2i}, B_{4i}, B_{8i}, \dots$ our bound on the failure probability stays small enough and new vertices are still likely to be connected to our principal vertices, allowing us to show in Theorem 9 that G_2^n contains a large one-subdivided clique.

The results of this section build upon the following concentration bound for vertex degrees. We define $d_m^n(S) = \sum_{v \in S} d_m^n(v)$ as the summed degree of S in G_m^n.

▶ **Proposition 5** ([13], Theorem 19). *For $t, m, d \in \mathbf{N}^+$, $0 < \varepsilon \leq 1/2$, $S \subseteq \{v_1, \dots, v_t\}$ with $\Pr[d_m^t(S) = d] \neq 0$ and $d \geq \log(\log(3tm))\varepsilon^{-200}$*

$$\Pr\left[(1-\varepsilon)\sqrt{\frac{n}{t}}d < d_m^n(S) < (1+\varepsilon)\sqrt{\frac{n}{t}}d \text{ for all } n \geq t \;\middle|\; d_m^t(S) = d\right] \geq 1 - e^{-\varepsilon^{200}d}.$$

This bound is strong if the initial degree $d_m^t(S)$ is large. At first, we show that there are some vertices which have a reasonably high degree after a short number of steps.

▶ **Lemma 6.** *There exists a constant c such that for $k, m \in \mathbf{N}$, $k \geq c$ with probability at least $1 - ke^{-k/c}$ there exists a set of vertices $X \subseteq \{v_1, \dots, v_{k^2}\}$, $|X| = k$ such that $d_m^{k^4}(x) \geq mk/2$ for all $x \in X$.*

Proof. We partition the first k^2 vertices into k sets of k vertices. Let S be one of these sets. Since $|S| = k$ and every vertex has at least degree m, we know that $d_m^{k^2}(S) \geq mk$. Therefore

$$\Pr\left[d_m^{k^4}(S) \leq \frac{1}{2}mk^2\right] \leq \sum_{d=mk}^{\infty} \Pr\left[d_m^{k^2}(S) = d\right] \cdot \Pr\left[d_m^{k^4}(S) \leq \frac{1}{2}\sqrt{\frac{k^4}{k^2}}d_m^{k^2}(S) \;\middle|\; d_m^{k^2}(S) = d\right].$$

Since $k \geq c$, we can choose c sufficiently large to always guarantee $c \geq 2^{200}$ and $mk \geq 2^{200}\log\log(mk^2)$. Using $t = k^2$, $n = k^4$, and $\varepsilon = 1/2$, Proposition 5 bounds the term above by at most

$$\sum_{d=mk}^{\infty} \Pr\left[d_m^{k^2}(S) = d\right] \cdot e^{-\varepsilon^{200}d} \leq e^{-k/c}.$$

With a probability of at least $1 - ke^{-k/c}$ each of the k sets have at time k^4 a total degree of at least $mk^2/2$ by the union bound. We define x_i to be the vertex in the ith set that has the highest degree after k^4 steps. Since the set contains k vertices, x_i has a degree of at least $mk/2$. We set $X = \{x_1, \dots, x_k\}$. ◀

We now bound the probability that two principal vertices v_a, v_b become connected under the condition that they have high degree.

▶ **Lemma 7.** *We consider the preferential attachment process with $m \geq 2$. Let $k \in \mathbf{N}$ and $a, b \leq k^4$. Let B_i be the event that $d_m^i(v_a), d_m^i(v_b) \geq m\sqrt{i}/4k$. Let $A_{j,i}$ with $k^4 < j \leq i$ be the event that the first two edges of at least one of the vertices $v_j, \ldots, v_i$ are incident to v_a and v_b, respectively. Then $\Pr[\bar{A}_{i+1,2i} \mid \bar{A}_{j,i}, B_i] \leq e^{-\frac{1}{256k^2}}$ for $k^4 \leq i$ and $j \leq i$.*

Proof. Let $u > 0$. $\Pr[A_{i+u,i+u} \mid B_i]$ is the probability that vertex v_{i+u} is adjacent to both v_a and v_b under the condition that v_a and v_b have degree at least $m\sqrt{i}/4k$ at some earlier time i. When vertex v_{i+u} is inserted, the random process draws $m \geq 2$ edges from v_{i+u} to earlier vertices. The probability that some vertex is chosen equals its degree divided by the total number of edges in the graph at this time. The degree of v_a and v_b is at least $m\sqrt{i}/4k$ at this point in time. Also there is a total of at most $2(i+u)m$ edges in the graph. We can therefore bound

$$\Pr[A_{i+u,i+u} \mid B_i] \geq \Big(\frac{m\sqrt{i}/4k}{2(i+u)m}\Big)^2 = \Big(\frac{\sqrt{i}}{8(i+u)k}\Big)^2.$$

The same argument holds if we additionally assume some of the earlier vertices not to be adjacent to both v_a and v_b. Let $j < i$. Then

$$\Pr[A_{i+u,i+u} \mid \bar{A}_{j,i+u-1}, B_i] \geq \Big(\frac{\sqrt{i}}{8(i+u)k}\Big)^2.$$

We now consider the probability that no vertex in a sequence of vertices is adjacent to both v_a and v_b. The chain rule yields

$$\begin{aligned}\Pr[\bar{A}_{i+1,2i} \mid \bar{A}_{j,i}, B_i] &= \prod_{u=1}^{i} \Pr[\bar{A}_{i+u,i+u} \mid \bar{A}_{j,i+u-1}, B_i] \\ &\leq \prod_{u=1}^{i} \Big(1 - \Big(\frac{\sqrt{i}}{8(i+u)k}\Big)^2\Big) \\ &\leq \Big(1 - \Big(\frac{\sqrt{i}}{16ik}\Big)^2\Big)^i \leq \Big(1 - \frac{1}{256ik^2}\Big)^i \leq e^{-\frac{1}{256k^2}}.\end{aligned}$$

◀

Imagine a sequence of events $\mathcal{A}_0, \ldots, \mathcal{A}_{l-1}$ such that a preferential attachment graph contains a large subdivided clique if any one of these events occurs. This means it is sufficient to show that the probability $\Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{l-1}]$ is small. Assume we can only bound the probability of event $\bar{\mathcal{A}}_i$ under the condition $\mathcal{B}_i$. The following technical observation gives a good approximation of $\Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{l-1}]$ if the events $\mathcal{B}_i$ have a high probability.

▶ **Lemma 8.** *Let $\mathcal{A}_0, \ldots, \mathcal{A}_l, \mathcal{B}_0, \ldots, \mathcal{B}_l$ be events. Then*

$$\Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_l] \leq \sum_{0=1}^{l} \Pr[\bar{\mathcal{B}}_i] + \prod_{0=1}^{l} \Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1} \cap \mathcal{B}_i].$$

Proof. Let $i \leq l$. We apply the chain rule and the law of total probability. Then

$$\begin{aligned}\Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_i] &= \Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1}] \Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1}] \\ &= \Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1}] \Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1} \cap \mathcal{B}_i] \Pr[\mathcal{B}_i] \\ &\quad + \Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1}] \Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1} \cap \bar{\mathcal{B}}_i] \Pr[\bar{\mathcal{B}}_i] \\ &\leq \Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1}] \Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1} \cap \mathcal{B}_i] + \Pr[\bar{\mathcal{B}}_i].\end{aligned}$$

We can now recursively apply this inequality, and use an upper bound of 1 for all factors in front of $\Pr[\mathcal{B}_1], \ldots, \Pr[\mathcal{B}_l]$ when expanding the product, to get our claim. ◀

We now use Lemma 6 and Lemma 7 to prove the main result of this section.

▶ **Theorem 9.** *There exists a constant c such that for $m, n \in \mathbf{N}$, $m \geq 2$, $n \geq c$, the preferential attachment graph G_m^n contains a one-subdivided clique of size at least $\log(n)^{1/4}$ with a probability of at least $1 - e^{-\log(n)^{1/4}/c}$.*

Proof. Let $k \in \mathbf{N}$. We choose $n = k^4 2^{k^3}$ which implies $k \geq \log(n)^{1/4}$ for $k \geq 2$. We will prove this theorem by showing that k vertices in G_m^n are with high probability pairwise connected by a path of length two and thereby span a one-subdivided clique.

We know that if a vertex has high degree early on then their degree will be centered closely around its expected values in the future (Proposition 5). Let us therefore assume there is a set of vertices $X \subseteq \{v_1, \ldots, v_{k^2}\}$, $|X| = k$ such that $d_m^{k^4}(x) \geq mk/2$ for all $x \in X$. We call these vertices principal vertices. Since $n \geq c$, we have $k \geq \log(c)^{1/4}$. We can choose the constant c high enough such that according to Lemma 6 these principal vertices exist with a probability of at least $1 - ke^{-k/c}$.

Let us fix a pair of principal vertices v_a, v_b and show that with high probability there is a vertex that is adjacent to both v_a and v_b. The higher the degree of v_a and v_b the higher the probability that a new vertex is adjacent. As in Lemma 7, we define for $i \geq k^4$, B_i to be the event that $d_m^i(v_a), d_m^i(v_b) \geq m\sqrt{i}/4k$. Again using $k \geq \log(c)^{1/4}$, we can assume c large enough to guarantee $mk/2 \geq \log(\log(3k^4 m))2^{200}$. Since we have $d_m^{k^4}(v_a) \geq mk/2$, Proposition 5 states with $t = k^4$, $\varepsilon = 1/2$ and $d \geq mk/2$

$$\Pr\left[d_m^i(v_a) < \frac{m\sqrt{i}}{4k} = \frac{1}{2}\sqrt{\frac{i}{k^4}}mk/2\right] \leq e^{-\varepsilon^{200}mk/2} = e^{-|\Omega(k)|}.$$

This yields $\Pr[\bar{B}_i] = e^{-|\Omega(k)|}$. We further define $A_{j,i}$ with $k^4 < j \leq i$ to be the event that the first two edges of at least one of the vertices $v_j, \ldots, v_i$ is adjacent to both v_a and v_b. We will show that v_a and v_b have a connecting vertex in G_m^n by showing that $\Pr[\bar{A}_{k^4+1,n}]$ converges to zero. We divide our vertices from $k^4 + 1$ to $n = k^4 2^{k^3}$ into k^3 windows which double in size. For $0 \leq i < k^3$ we set $\bar{\mathcal{A}}_i = \bar{A}_{k^4 2^i + 1, k^4 2^{i+1}}$ and $\mathcal{B}_i = B_{k^4 2^i}$. Lemma 7 states $\Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1} \cap \mathcal{B}_i] \leq e^{-\frac{1}{256k^2}}$. By Lemma 8

$$\begin{aligned}
\Pr[\bar{A}_{k^4+1,n}] = \Pr[\bar{A}_{k^4+1,k^4 2^{k^3}}] &= \Pr[\bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{k^3-1}] \\
&\leq \sum_{i=0}^{k^3-1} \Pr[\bar{\mathcal{B}}_i] + \prod_{i=0}^{k^3-1} \Pr[\bar{\mathcal{A}}_i \mid \bar{\mathcal{A}}_0 \cap \cdots \cap \bar{\mathcal{A}}_{i-1} \cap \mathcal{B}_i] \\
&\leq \sum_{i=0}^{k^3-1} e^{-|\Omega(k)|} + \prod_{i=0}^{k^3-1} e^{-\frac{1}{256k^2}} \\
&\leq k^3 e^{-|\Omega(k)|} + e^{-\frac{k^3}{256k^2}} = k^3 e^{-|\Omega(k)|}.
\end{aligned}$$

This means that in G_m^n the probability that there exists a vertex which connects the principal vertices v_a and v_b is at least $1 - k^3 e^{-|\Omega(k)|}$. According to the union bound, the probability that for all $\binom{k}{2}$ pairs of principal vertices there exists a vertex which connects them is bounded by $1 - \binom{k}{2} k^3 e^{-|\Omega(k)|}$. In Lemma 7, only the first two edges of the connecting vertex are considered. Therefore each connecting vertex may only connect a single pair of principal vertices. This means every pair of principal vertices has a unique connecting vertex, i.e., the principal vertices span a one-subdivided clique with probability $1 - \binom{k}{2} k^3 e^{-|\Omega(k)|}$.

So far, all our calculations were based on the assumption that there are k principal vertices with reasonably high degree in the beginning. According to Lemma 6, the probability that k such vertices do not exist is at most $ke^{-k/c}$. So by law of total probability, we can add this error probability to the conditional bound to get an unconditional bound. This means that G_m^n contains no one-subdivided k clique with a probability of at most

$$\binom{k}{2}k^3e^{-|\Omega(k)|} + ke^{-k/c} = e^{-|\Omega(\log(n)^{1/4})|}. \qquad \blacktriangleleft$$

We can restate Theorem 9 as a lower bound on 1/2-shallow clique minors.

▶ **Corollary 10.** *Let $m \geq 2$. Then a.a.s. $\omega(G_m^n \mathbin{\widetilde{\nabla}} \frac{1}{2}) \geq \log(n)^{1/4}$. In particular, G_m^n is a.a.s. somewhere dense.*

4 Upper Bounds

In this section we prove polylogarithmic upper bounds on the density of shallow topological minors in preferential attachment graphs. In fact, we even show that it is sufficient to remove a polylogarithmic number of vertices to make these graphs look locally almost like trees. Our results are based on the following proposition that bounds the probability of edges occurring between fixed vertices.

▶ **Proposition 11** ([13], Lemma 10). *Let $n, m \in \mathbf{N}^+$, $n \geq 2$ and $E \subseteq \binom{v_1,\dots,v_n}{2}$. Then*

$$\Pr[E \subseteq E(G_m^n)] \leq \log(n)^{O(|E|)^2} m^{2|E|} \prod_{v_x v_y \in E} 1/\sqrt{xy}.$$

The main work is spend in Lemma 12, where we bound for $l, b \in \mathbf{N}$ the expected number of dense subgraphs of size l after removing the first b vertices of the graph. This is done by summing over all potential vertex sets $\binom{v_{b+1},\dots,v_n}{l}$ of a dense subgraph and using the previous proposition to bound the probability that these vertices induce a graph with many edges. This bound is quite strong and flexible, but its dependence on five parameters b, l, k, n, m makes it a bit unwieldy. We simplify it to obtain statements abound the size of r-shallow minors or the density of local regions.

▶ **Lemma 12.** *Let $b, l, k, n, m \in \mathbf{N}^+$ with $n \geq 2$. The expected number of subgraphs of $G_m^n[v_{b+1}, \dots, v_n]$ with at most l vertices and k more edges than vertices is at most $\log(n)^{O(l+k)^2} m^{O(l+k)} b^{-k}$.*

Proof. Let H be a graph with at most l vertices and k more edges than vertices. Let p be the expected number of subgraphs of $G_m^n[v_{b+1}, \dots, v_n]$ that are isomorphic to H. We want to find an upper bound for p. We iteratively remove every degree-one vertex from H. The resulting graph H' still has at most l vertices and k more edges than vertices. Let p' the expected number of subgraphs of $G_m^n[v_{b+1}, \dots, v_n]$ isomorphic to H'. Since H' is a subgraph of H, we have $p \leq p'$.

Let $V(H') = \{u_1, \dots, u_\gamma\}$ with $\gamma \leq l$ and let $\delta_1, \dots, \delta_\gamma$ be the degree sequence of $V(H')$. We state two inequalities that we will use later. Inequality (1) follows from $\delta_i \geq 2$ and (2) holds since the number of edges in H' is $\gamma + k = \sum_{i=1}^{\gamma} \delta_i/2$.

$$\sum_{y_i=b+1}^{n} \frac{1}{\sqrt{y_i}^{\delta_i}} \leq \int_b^n \frac{1}{\sqrt{x}^{\delta_i}} dx \leq 2b^{1-\delta_i/2} \log n \tag{1}$$

$$\sum_{i=1}^{\gamma} (-\delta_i/2 + 1) = -k \tag{2}$$

For integers $b < x_1, \dots, x_\gamma \leq n$, we consider an embedding of H' into the graph $G_m^n[v_{b+1}, \dots, v_n]$ that maps u_i to v_{x_i} (for $1 \leq i \leq \gamma$). According to Proposition 11, the probability that this embedding of H' is a subgraph of G_m^n is at most

$$\log(n)^{O(l+k)^2} m^{O(l+k)} \prod_{i=1}^{\gamma} \frac{1}{\sqrt{x_i}^{\delta_i}}.$$

We use the union bound over all valid embeddings, (1), and (2) to bound

$$\begin{aligned}
p \leq p' &\leq \sum_{x_1=b+1}^{n} \cdots \sum_{x_\gamma=b+1}^{n} \log(n)^{O(l+k)^2} m^{O(l+k)} \prod_{i=1}^{\gamma} \frac{1}{\sqrt{x_i}^{\delta_i}} \\
&= \log(n)^{O(l+k)^2} m^{O(l+k)} \sum_{x_1=b+1}^{n} \frac{1}{\sqrt{x_1}^{\delta_1}} \cdots \sum_{x_\gamma=b+1}^{n} \frac{1}{\sqrt{x_\gamma}^{\delta_\gamma}} \\
&\overset{(1)}{\leq} \log(n)^{O(l+k)^2} m^{O(l+k)} \prod_{i=1}^{\gamma} 2b^{1-\delta_i/2} \log(n) \\
&\overset{(2)}{\leq} \log(n)^{O(l+k)^2} m^{O(l+k)} 2^\gamma \log(n)^\gamma b^{-k} \leq \log(n)^{O(l+k)^2} m^{O(l+k)} b^{-k}.
\end{aligned}$$

For an arbitrary but fixed graph H with at most l vertices and k more edges than vertices we have bounded the expected number of valid embeddings p. There are at most 2^{l^2} graphs with l vertices. Therefore, the expected number of subgraphs of $G_m^n[v_{b+1}, \dots, v_n]$ with at most l vertices and k more edges than vertices is at most $2^{l^2} \log(n)^{O(l+k)^2} m^{O(l+k)} b^{-k} = \log(n)^{O(l+k)^2} m^{O(l+k)} b^{-k}$. ◀

The following corollary simplifies the last lemma by choosing the specified value for b.

▶ **Corollary 13.** *There exists a constant c such that for $l, n, m \in \mathbf{N}^+$ and $b = \lceil \log(n)^{cl^2} m^{cl} \rceil$ the graph $G_m^n[v_{b+1}, \dots, v_n]$ contains a.a.s. no subgraph with up to l vertices and more edges than vertices.*

▶ **Lemma 14.** *There is a constant c such that for all $r, n, m \in \mathbf{N}^+$ and $b = \lceil \log(n)^{cr^2 l^2} m^{crl} \rceil$, $G_m^n[v_{b+1}, \dots, v_n]$ contains a.a.s. no r-shallow topological minor of a graph with l vertices and more edges than vertices.*

Proof. If a graph contains an r-shallow topological minor of a graph with l vertices and more edges than vertices then it also contains a subgraph with at most $(2r+1)(l+1)$ vertices and more edges than vertices. Using this observation, this lemma follows directly from Corollary 13. ◀

▶ **Theorem 15.** *Let $r, n, m \in \mathbf{N}^+$. Every r-shallow topological clique minor in G_m^n has a.a.s. size at most $\log(n)^{O(r^2)} m^{O(r)}$.*

Proof. The previous lemma with $l = 4$ and $b = \lceil \log(n)^{16cr^2} m^{4cr} \rceil$ means that the graph $G_m^n[v_{b+1}, \dots, v_n]$ contains a.a.s. no r-shallow clique minor of size four. Since adding the vertices $v_1, \dots, v_b$ to the graph can increase the size of the maximum r-shallow topological clique minor by at most b, we immediately obtain this result. ◀

▶ **Lemma 16.** *There is a constant c such that for all $r, n, m \in \mathbf{N}^+$ and $b = \lceil \log(n)^{cr^2} m^{cr} \rceil$, a.a.s. every r-neighborhood of $G_m^n[v_{b+1}, \dots, v_n]$ is either a tree or a tree with one additional edge.*

Proof. Assume an r-neighborhood which is a tree with two or more additional edges. We build a breadth-first spanning tree T of the r-neighborhood with root v and radius r. We pick two edges a_1, a_2 and b_1, b_2 which are not in T. Now there are unique paths of length at most $2r+1$ in T between v and a_1, a_2, b_1, b_2. The two edges together with these four paths describe a graph with at most $4(2r+1)$ vertices and one more edge than vertices. The statement now follows from Corollary 13. ◀

▶ **Theorem 17.** *Let $m \in \mathbf{N}^+$ and $g(n)\colon \mathbf{N} \to \mathbf{N}$ be a function with $g(n) = \omega(1)$. If we remove the first $\log(n)^{g(n)}$ vertices from G_m^n the remaining graph has a.a.s. locally bounded treewidth.*

Proof. Let $G_m'^n$ be the graph obtained by removing the first $\log(n)^{g(n)}$ many vertices from G_m^n and let c be the constant from Lemma 16. For every $r \in \mathbf{N}$ there exists an $f(r)$ such that for $n \geq f(r)$, $G_m'^n$ was obtained by removing at least the first $\lceil \log(n)^{cr^2} m^{rc} \rceil$ vertices. Then by Lemma 16, a.a.s. every r-neighborhood of $G_m'^n$ is either a tree or a tree with an additional edge and therefore has treewidth at most 2. If $n \leq f(r)$ then trivially every r-neighborhood of $G_m'^n$ has treewidth at most $f(r)$. Thus, $G_m'^n$ a.a.s. has locally bounded treewidth. ◀

5 Conclusion

In our analysis of preferential attachment graphs we obtained a logarithmic lower bound on the size of shallow clique minors, that implies that preferential attachment graphs are a.a.s. somewhere dense. This implies that algorithmic techniques developed for nowhere dense graph classes are not directly applicable to preferential attachment graphs. This is complemented by matching polylogarithmic upper bounds. We further observed that the removal of a polylogarithmic number of vertices makes the graph locally extremely sparse. Real networks however, do not have this extremely sparse structure after removal of very few vertices. Our results therefore yield further evidence that the preferential attachment process alone is not sufficient to explain the structure of complex networks.

Abstract

One of the central open questions in the theory of average-case complexity is to establish the equivalence between the worst-case and average-case complexity of the Polynomial-time Hierarchy (PH). One general approach is to show that there exists a PH-computable hitting set generator whose security is based on some NP-hard problem. We present the limits of such an approach, by showing that there exists no exponential-time-computable hitting set generator whose security can be proved by using a nonadaptive randomized polynomial-time reduction from any problem outside $\mathsf{AM} \cap \mathsf{coAM}$, which significantly improves the previous upper bound $\mathsf{BPP}^{\mathsf{NP}}$ of Gutfreund and Vadhan (RANDOM/APPROX 2008 [14]). In particular, any security proof of a hitting set generator based on some NP-hard problem must use either an adaptive or non-black-box reduction (unless the polynomial-time hierarchy collapses). To the best of our knowledge, this is the first result that shows limits of black-box reductions from an NP-hard problem to some form of a distributional problem in DistPH.

Based on our results, we argue that the recent worst-case to average-case reduction of Hirahara (FOCS 2018 [18]) is inherently non-black-box, without relying on any unproven assumptions. On the other hand, combining the non-black-box reduction with our simulation technique of black-box reductions, we exhibit the existence of a "non-black-box selector" for GapMCSP, i.e., an efficient algorithm that solves GapMCSP given as advice two circuits one of which is guaranteed to compute GapMCSP.

1 Introduction

The technique of reductions is one of central tools in complexity theory. In order to show that a computational task A is easier than another computational task B, it suffices to design a (black-box) reduction, i.e., the algorithm that solves A given oracle access to B. Most reductions of complexity theory are *black-box*. That is, the correctness of a reduction can be established without assuming any computational efficiency of the oracle. Black-box reductions are quite powerful and led us to, for instance, the discovery of thousands of NP-complete problems computationally equivalent to each other. However, a line of work

© Shuichi Hirahara and Osamu Watanabe;

has exhibited limits of black-box reductions: Black-box reductions are too general to resolve several important open questions. We herein continue the study of black-box reductions especially in the context of the construction of a hitting set generator.

A *hitting set generator* γ-secure against a class $\mathcal{C}$ is a family of functions $G = \{G_\ell : \{0,1\}^{s(\ell)} \to \{0,1\}^\ell\}_{\ell\in\mathbb{N}}$ such that no $\mathcal{C}$-algorithm can γ-avoid G; here we say that an algorithm R *γ-avoids* G if R rejects every string in the image of G, and R accepts at least a γ-fraction of all inputs of length ℓ for every $\ell \in \mathbb{N}$. By default, we assume $\gamma := 1/4$ and we say that R *avoids* G if R $(1/4)$-avoids G. A typical approach for constructing a hitting set generator is to design a black-box reduction that reduces some computationally hard task to the task of avoiding a hitting set generator.

In fact, there have been already several known proof techniques that are not black-box. Impagliazzo and Wigderson [27] constructed a hitting set generator based on the uniform hardness assumption that $\mathsf{EXP} \neq \mathsf{BPP}$. Their security proof of the hitting set generator is not a (black-box) reduction from the task of solving EXP to the task of avoiding the hitting set generator; they crucially exploited the fact that there exists an efficient algorithm that avoids the hitting set generator. Trevisan and Vadhan [36] and Gutfreund and Vadhan [14] showed that the security reduction of [27] is inherently non-black-box in some senses. More recently, building on [10, 22], Hirahara [18] applied the proof techniques for constructing a hitting set generator to the context of average-case complexity, and presented the first non-black-box worst-case to average-case reduction within NP.

Given the fact that there are already non-black-box proof techniques, why should we study the limits of black-box reductions? We highlight several points:

1. Black-box reductions are *more general* and *useful* than non-black-box reductions. Therefore, it is desirable to have a black-box reduction when it is possible; studying limits of black-box reductions enables us to identify when one can hope to construct a black-box reduction.
   For example, Impagliazzo and Wigderson [27] showed that $\mathsf{EXP} \not\subseteq \mathsf{BPP}$ implies that BPP can be derandomized in *sub-exponential* time (on most inputs, for infinitely many input lengths). This is shown by a non-black-box reduction, and it is not known whether the result can be generalized to a "high-end" result: does $\mathsf{EXP} \not\subseteq \mathsf{BPSUBEXP}$ imply that BPP can be derandomized in *quasi-polynomial* time? On one hand, Trevisan and Vadhan [36] used a black-box reduction and provided a positive answer to this question when EXP is replaced with PSPACE. On the other hand, Gutfreund and Vadhan [14] showed that a (mildly adaptive) black-box reduction cannot be used to prove the "high-end" result for EXP.
2. Studying limits of black-box reductions can inspire new black-box reductions. Inspired by this work, Hirahara [21, 20] subsequently presented new constructions of black-box reductions to Kolmogorov complexity, which were previously conjectured to be impossible.
3. Surprisingly, in some cases, the proof techniques for showing limits of black-box reductions can be combined with non-black-box reductions. We will show that one of our new algorithms for simulating black-box reductions can be combined with a non-black-box reduction of [18] (under some assumptions), and present a new structural property of an approximation version of the Minimum Circuit Size Problem (MCSP [28]).

As a main result of this paper, we show that any security proof of a hitting set generator based on some NP-hard problem must use either an adaptive or non-black-box reduction. This is the first limit of black-box worst-case to average-case reductions from NP-hard problems to some form of a distributional problem in DistPH.

Due to the connection to several research areas such as average-case complexity, black-box reductions, and derandomization, it is not easy to describe the literature in few words; we thus review the literature in the subsequent two sections. In Section 2, we review the theory of average-case complexity and state our main results. In Section 3, we review the non-black-box reduction of [18], present some applications of our results, and describe our proof techniques. Due to the space limitation, details are omitted in this version; see the full version of the paper.

2 Average-Case Complexity

2.1 Background

One of the central open questions in the theory of average-case complexity [29] is to establish the equivalence between the worst-case and average-case complexity of NP.

▶ **Open Question 1.** *Does* $\mathsf{DistNP} \subseteq \mathsf{AvgP}$ *imply* $\mathsf{NP} = \mathsf{P}$*?*

Here DistNP is the class of distributional problems $(L, \mathcal{D})$ (i.e., a pair of a problem and its input distribution) such that $L \in \mathsf{NP}$ and $\mathcal{D}$ is an efficiently samplable distribution. AvgP is the class of distributional problems that admit an errorless heuristic polynomial-time scheme [8] (also known as an "average-case polynomial-time algorithm"). Here, for $L \subseteq \{0,1\}^*$ and $\mathcal{D} = \{\mathcal{D}_m\}_{m \in \mathbb{N}}$, a distributional problem $(L, \mathcal{D})$ is said to be in AvgP if there exists an algorithm M such that, for every $m \in \mathbb{N}$, given an input x in the support of D_m, and a parameter $\delta > 0$,

1. $M(x, \delta)$ halts in time $\mathsf{poly}(m, 1/\delta)$,
2. $M(x, \delta)$ outputs either the correct answer $L(x)$ or $\perp$ ("I don't know"), and
3. the probability that $M(x, \delta)$ outputs $\perp$ over a choice of $x \sim \mathcal{D}_m$ is at most δ.

Open Question 1 is of particular importance from the perspective of cryptography: Average-case hardness of NP is a prerequisite for constructing secure complexity-theoretic cryptographic primitives such as one-way functions (OWFs). Thus resolving Open Question 1 is an important step towards building cryptographic primitives whose security is based on more plausible assumptions (e.g., the worst-case hardness of NP).

There has been a line of work showing that Open Question 1 cannot be resolved by using either relativizing proof techniques [26], black-box worst-case-to-average-case reductions [11, 9, 2, 7, 6], or error-correcting codes [37].

For large enough complexity classes such as PSPACE and EXP, there is a general technique for converting any worst-case hard function f to some two-sided-error average-case hard function $\mathrm{Enc}(f)$ based on error-correcting codes [35, 36]. Here, the encoded function $\mathrm{Enc}(f)$ is computable in EXP or PSPACE given oracle access to f; thus, the worst-case and average-case complexity of such large complexity classes are known to be equivalent. Viola [37] showed limits of such an approach: $\mathrm{Enc}(f)$ cannot be computed in PH^f; thus, the proof technique of using error-correcting codes is not sufficient to resolve Open Question 1 as well as the following weaker open question:

▶ **Open Question 2.** *Does* $\mathsf{DistPH} \subseteq \mathsf{AvgP}$ *imply* $\mathsf{PH} = \mathsf{P}$ *(or, equivalently,* $\mathsf{NP} = \mathsf{P}$*)?* [1]

[1] We mention in passing that Pavan, Santhanam, and Vinodchandran [32] made some progress, by proving that $\mathsf{DistP}^{\mathsf{NP}} \subseteq \mathsf{AvgP}$ implies $\mathsf{NP} = \mathsf{P}$, under the implausible assumption that $\mathsf{NP} \subseteq \mathsf{P/poly}$.

Note that Open Question 2 is an easier question than Open Question 1, since $\mathsf{PH} = \mathsf{P}$ is known to be equivalent to $\mathsf{NP} = \mathsf{P}$. In fact, this well-known equivalence between $\mathsf{PH} = \mathsf{P}$ and $\mathsf{NP} = \mathsf{P}$ is shown by using a non-black-box reduction technique[2]; as we will explain later, this is one reason why all the previous limits of black-box reductions [11, 9, 2, 7, 6] fail to explain the difficulty of resolving Open Question 2. In this work, we present the first limit of black-box reduction techniques for resolving Open Question 2, thereby clarifying what kind of proof techniques are useful. We emphasize that, while Viola's result [37] excludes the construction of error-correcting codes within PH, it does not show limits of black-box worst-case to average-case reduction techniques such as Ajtai's reduction [1].

One general approach for constructing an (errorless) average-case hard function is to make use of a hitting set generator. Indeed, a hitting set generator G secure against polynomial-time algorithms naturally induces a hard distributional problem in DistNP^G: Consider the distributional problem $(\mathrm{Im}(G), \mathcal{U})$, i.e., the distributional problem of checking whether an input x is in the image of G, where x is randomly chosen from the uniform distribution $\mathcal{U}$. Since the number of YES instances of $\mathrm{Im}(G)$ is small under the uniform distribution, any errorless heuristic algorithm must reject a large fraction of NO instances, which gives rise to an algorithm that avoids G. To summarize:

▶ **Fact 3** (Implicit in [18]). *Suppose there exists a hitting set generator $G := \{G_\ell \colon \{0,1\}^{\ell-1} \to \{0,1\}^\ell\}_{\ell\in\mathbb{N}}$ that is $1/4$-secure against polynomial-time algorithms. Then, $\mathsf{DistNP}^G \not\subseteq \mathsf{AvgP}$. In particular, when G is computable in PH, we obtain $\mathsf{DistPH} \not\subseteq \mathsf{AvgP}$.*

Fact 3 suggests an approach for resolving Open Question 2: Try to construct a PH-computable hitting set generator whose security is based on the worst-case hardness of NP. How do we compare this approach with the technique based on error-correcting codes [37]? Our approach is *more general*, because, given a two-sided-error average-case hard function $\mathrm{Enc}(f)$, one can construct a pseudorandom generator $G = \{G_\ell \colon \{0,1\}^{\ell-1} \to \{0,1\}^\ell\}_{\ell\in\mathbb{N}}$ defined as $G_\ell(z) := (z, \mathrm{Enc}(f)(z))$ for a seed $z \in \{0,1\}^{\ell-1}$ [38].

In order to construct a secure hitting set generator based on the hardness of a problem L, we need to argue that, if there exists an efficient algorithm that avoids G, then L can be solved efficiently. A typical way to establish such an implication is to design *black-box reductions* from L to a distinguisher for a hitting set generator. Specifically, for a candidate hitting set generator G, a reduction M is said to be a black-box reduction from L to any γ-avoiding oracle R for G if, for every input x and any oracle R that γ-avoids G, M computes L on input x under the oracle R.

Gutfreund and Vadhan [14] initiated the study of limits of such a black-box reduction, motivated by the question on whether derandomization is possible under uniform assumptions (e.g., [27, 36]). They showed that any polynomial-time randomized nonadaptive black-box reductions to any oracle avoiding an exponential-time-computable hitting set generator G can be simulated in $\mathsf{BPP}^{\mathsf{NP}}$. Unfortunately, their upper bound is too weak to deduce any limit of the approach on Open Question 2 since $\mathsf{NP} \subseteq \mathsf{BPP}^{\mathsf{NP}}$. Similarly, it is impossible to deduce any limit of the approach on Open Question 1, because the upper bound becomes trivial when G is polynomial-time-computable.

[2] Indeed, if the reduction is black-box, we should have $\mathsf{PH} \subseteq \mathsf{P}^{\mathsf{NP}}$, which means that PH collapses.

2.2 Our Results: Limits of Security Proof of Hitting Set Generators

We significantly improve the upper bound of [14] to $\mathsf{AM} \cap \mathsf{coAM}$. We also show upper bounds of $\mathsf{NP/poly} \cap \mathsf{coNP/poly} \cap \mathsf{S}_2^{\mathsf{NP}}$ even if G is not computable.

To state our results formally, let $\mathsf{BPP}_{\|}^R$ denote the class of languages solvable by a randomized polynomial-time machine with nonadaptive oracle access to R.[3] In the definition of a black-box reduction M to any γ-avoiding oracle R, the reduction M is not allowed to depend on R. However, we will show that the existence of a randomized nonadaptive black-box reduction from L to any γ-avoding oracle R is equivalent to saying that $L \in \mathsf{BPP}_{\|}^R$ for every oracle R that γ-avoids R.[4] In light of this, the result of Gutfreund and Vadhan [14] can be stated as $\bigcap_R \mathsf{BPP}_{\|}^R \subseteq \mathsf{BPP}^{\mathsf{NP}}$, where the intersection is taken over all oracles R that γ-avoid an exponential-time computable function G. Our main result improves $\mathsf{BPP}^{\mathsf{NP}}$ to $\mathsf{AM} \cap \mathsf{coAM}$:

▶ **Theorem 4** (Main). *Let $G = \{G_\ell : \{0,1\}^{s(\ell)} \to \{0,1\}^\ell\}_{\ell \in \mathbb{N}}$ be any (not necessarily computable) family of functions and $\gamma\colon \mathbb{N} \to [0,1)$ be a parameter such that*

- *there exists a constant $\epsilon > 0$ such that $s(\ell) \leq (1-\epsilon)\ell$ for all large $\ell \in \mathbb{N}$, and*
- *there exists a constant $c > 0$ such that $\gamma(\ell) \leq 1 - \ell^{-c}$ for all large $\ell \in \mathbb{N}$.*

Then,

$$\bigcap_R \mathsf{BPP}_{\|}^R \quad \subseteq \quad \mathsf{NP/poly} \cap \mathsf{coNP/poly} \cap \mathsf{S}_2^{\mathsf{NP}},$$

where the intersection is taken over all oracles R that γ-avoids G. Moreover, if G can be computed in time $2^{O(\ell)}$, then we also have

$$\bigcap_R \mathsf{BPP}_{\|}^R \quad \subseteq \quad \mathsf{AM} \cap \mathsf{coAM}.$$

At the core of Theorem 4 is the following two types of algorithms simulating black-box reductions: One is an $\mathsf{S}_2^{\mathrm{p}}$-type algorithm that simulates any query $q \stackrel{?}{\in} R$ of length at most $\Theta(\log n)$, and the other is an $\mathsf{AM} \cap \mathsf{coAM}$-type algorithm that simulates any query $q \stackrel{?}{\in} R$ of length at least $\Theta(\log n)$. In particular, if G is exponential-time computable, the $\mathsf{S}_2^{\mathrm{p}}$-type algorithm can be replaced with a polynomial-time algorithm and obtain the $\mathsf{AM} \cap \mathsf{coAM}$ upper bound.

Theorem 4 shows that there exists no hitting set generator whose security can be based on the hardness of some NP-hard problem via a nonadaptive reduction (unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$). In particular, the approach for Open Question 2 by constructing a PH-computable hitting set generator based on an NP-hard problem must use either an adaptive or non-black-box reduction.

It is worthy of note that Theorem 4 is almost tight from several perspectives: First, it is impossible to extend Theorem 4 to the case of *adaptive* reductions (unless $\mathsf{PSPACE} = \mathsf{AM}$). Indeed, Trevisan and Vadhan [36] constructed an exponential-time-computable pseudorandom generator based on the intractability of some PSPACE-complete problem, and its security reduction is adaptive and black-box in the sense of Theorem 4. Second, our $\mathsf{S}_2^{\mathrm{p}}$-type algorithm for simulating short queries is completely tight when G is a universal Turing machine. Third, it is possible to construct a hitting set generator based on the hardness of SZK (Statistical

[3] The subscript $\|$ stands for parallel queries.

[4] We state our results in the latter way because this makes our impossibility results stronger. The proof of the equivalence can be found in the full version of the paper.

Zero Knowledge), which is one of the best lower bound on $\mathsf{AM} \cap \mathsf{coAM}$; thus, the $\mathsf{AM} \cap \mathsf{coAM}$ upper bound of Theorem 4 cannot be significantly improved. (The details can be found in the full version of the paper.)

2.3 Related Work: Limits of Worst-case to Average-case Reductions within NP

To the best of our knowledge, Theorem 4 is *the first result* that shows limits of black-box reductions from an NP-hard problem to (some form of) a distributional problem in DistPH. In order to explain this in more detail, we review the previous work on limits of worst-case to average-case reductions within NP.

A natural approach for establishing the equivalence between the worst-case and average-case complexity of NP is by means of black-box reductions. That is, it is sufficient for resolving Open Question 1 to design a reduction that solves some NP-hard problem L, using oracle access to an errorless heuristic algorithm M that solves some distributional problem in DistNP. A line of work has been devoted to explaining why such a black-box reduction technique is too general to establish a worst-case to average-case connection for an NP-complete problem.

Building on the work of Feigenbaum and Fortnow [11], Bogdanov and Trevisan [9] showed that if a worst-case problem L is reducible to some distributional problem in DistNP via a nonadaptive black-box randomized polynomial-time reduction, then L must be in $\mathsf{NP/poly} \cap \mathsf{coNP/poly}$. This in particular shows that the average-case hardness of NP cannot be based on the worst-case hardness of an NP-complete problem using such a reduction technique (unless the polynomial-time hierarchy collapses [39]). Akavia, Goldreich, Goldwasser and Moshkovitz [2, 3] showed that, in the special case of a nonadaptive reduction to the task of inverting a one-way function, the upper bound of [9] can be improved to $\mathsf{AM} \cap \mathsf{coAM}$, thereby removing the advice "/poly". Bogdanov and Brzuska [7] showed that even an adaptive reduction to the task of inverting a size-verifiable one-way function cannot be used for any problem outside $\mathsf{AM} \cap \mathsf{coAM}$. Applebaum, Barak, and Xiao [6] studied black-box reductions to PAC learning, and observed that the technique of [2] can be applied to (some restricted type of) a black-box reduction to the task of inverting an auxiliary-input one-way function (AIOWF), which is a weaker primitive than a one-way function. We summarize the limits of black-box reductions (depicted by $\rightarrow$) as well as known implications (depicted by $\Longrightarrow$) in Figure 1.

Compared to the previous results on the limits of black-box worst-case-to-average-case reductions within NP, a surprising aspect of Theorem 4 is that it generalizes to any function G that may not be computable (and this is a key property for obtaining the limits of the approach on Open Question 2). Indeed, almost all the previous results [11, 9, 2, 6] crucially exploit the fact that a verifier can check the correctness of a certificate for an NP problem; thus a dishonest prover can cheat the verifier only in one direction by not providing a certificate for a YES instance. In our simulation algorithms, a verifier cannot compute G and thus cannot prevent dishonest provers from cheating in this way. At a high level, our technical contributions are to overcome this difficulty by combining the ideas of Gutfreund and Vadhan [14] with the techniques developed in [11, 9].

Is it possible to directly deduce some limits of an approach on Open Question 2 from the previous results [11, 9]? No! Recall that, in order to resolve Open Question 2, it suffices to establish a reduction from an NP-complete problem to DistPH (using the non-black-box equivalence between $\mathsf{P} = \mathsf{NP}$ and $\mathsf{P} = \mathsf{PH}$). The results of [11, 9] crucially rely on the fact that a YES instance of DistNP is verifiable in polynomial time. If we would like to simulate

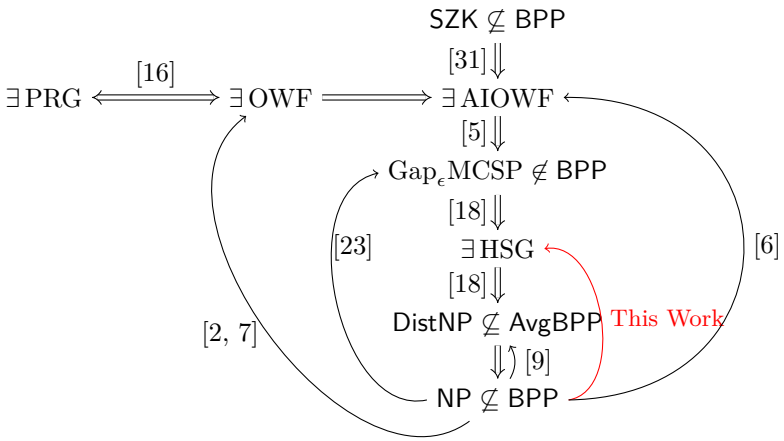

Figure 1 Average-case complexity and limits of black-box reductions. "$A \to B$" means that there is no black-box (or oracle-independent) reduction technique showing "$A \Rightarrow B$" under reasonable complexity theoretic assumptions. The security of all cryptographic primitives is with respect to an almost-everywhere polynomial-time randomized adversary.

a black-box reduction to DistNP^A for some oracle A, the simulation protocol of Feigenbaum and Fortnow [11] runs in $\mathsf{NP}^A/\mathsf{poly} \cap \mathsf{coNP}^A/\mathsf{poly}$. Thus, in order to simulate a reduction to $\mathsf{Dist}\Sigma_2^{\mathrm{p}} \subseteq \mathsf{DistPH}$, the upper bound becomes $\mathsf{NP}^{\mathsf{NP}}/\mathsf{poly} \cap \mathsf{coNP}^{\mathsf{NP}}/\mathsf{poly}$, which trivially contains NP.

It is also worthy of note that Theorem 4 improves some aspects of all the previous results about limits of black-box reductions within NP. Compared to [9], our results show that the advice "/poly" is not required to simulate black-box reductions to any oracle avoiding an exponential-time-computable hitting set generator. Compared to [2, 6], our results are "improvement" on their results in the sense that the existence of auxiliary-input one-way functions implies the existence of hitting set generators; on the other hand, since the implication goes through the *adaptive* reduction (from the task of inverting a one-way function to a distinguisher for a PRG) of [16], technically speaking, our results are incomparable with their results.[5] Similarly, our results conceptually improve the result of [23], but these are technically incomparable, mainly because the implication goes through the non-black-box reduction of [18].

3 In Search of Inherently Non-Black-Box Reduction Techniques

Hirahara [18] presented the first non-black-box worst-case to average-case reduction within NP, which is the motivation for this work. Building on [10, 22], Hirahara [18] presented a (nonadaptive) reduction from Gap$_\epsilon$MCSP to a distinguisher for a polynomial-time-computable hitting set generator $G^{\mathsf{int}} = \{G^{\mathsf{int}}_{2^n} \colon \{0,1\}^{\widetilde{O}(2^{\delta n})} \to \{0,1\}^{2^n}\}_{n \in \mathbb{N}}$. Here, G^{int} is a "circuit

[5] We emphasize that we concern the nonadaptivity of reductions used in the security proof of pseudorandom generators. Several simplified constructions of pseudorandom generators G^f from one-way functions f (e.g., [25, 15]) are nonadaptive in the sense that G^f can be efficiently computed with nonadaptive oracle access to f; however, the security reductions of these constructions are adaptive because of the use of Holenstein's uniform hardcore lemma [24]. Similarly, the reduction of [16, Lemma 6.5] is adaptive. (We note that, in the special case when the degeneracy of a one-way function is efficiently computable, the reduction of [16] is nonadaptive.)

interpreter": a function that takes a description of a circuit of size $2^{\delta n}$ and outputs its truth table. For a constant $\epsilon > 0$, $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ denotes the problem of approximating the minimum circuit size of a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ within a factor of $2^{(1-\epsilon)n}$, given the truth table of f. Rudich [33] conjectured that $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ cannot be solved in $\mathsf{coNP/poly}$ (even in the sense of average-case complexity). Therefore, the reduction of [18] is indeed non-black-box under Rudich's conjecture, as otherwise it contradicts the limits of black-box reductions (such as Theorem 4 and [9]).

Here we pose the following question:

> Are the reductions of [18] *inherently* non-black-box? Or should we regard it as an approach for refuting Rudich's conjecture?

On one hand, the proofs of [18] seem to yield only non-black-box reductions, in the sense that the efficiency of an oracle is crucially exploited. On the other hand, if the reduction from $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ to DistNP could be made black-box, by using our coAM simulation protocol of black-box reductions (i.e., Theorem 4), we would obtain $\mathrm{Gap}_\epsilon\mathrm{MCSP} \in \mathsf{coAM} \subseteq \mathsf{coNP/poly}$, which refutes Rudich's conjecture.

In order to answer the question, it is desirable to clarify a fundamental obstacle to applying the simulation techniques of black-box reductions to the reductions of [18], without relying on any unproven assumption.

3.1 Hirahara's Reduction is Unconditionally Non-Black-Box

Based on Theorem 4, we can argue that the reductions of [18] are inherently non-black-box in a certain formal sense. The reason is that the idea of [18] can be applied to not only time-bounded Kolmogorov complexity but also any other types of Kolmogorov complexity, including *resource-unbounded* Kolmogorov complexity. Therefore, if this generalized reduction could be made black-box, then (as outlined below) by Theorem 4 we would obtain a finite-running-time algorithm $\mathsf{S}_2^{\mathsf{NP}}$ that approximates resource-unbounded Kolmogorov complexity, which is a contradiction *unconditionally*.

More specifically, fix any universal Turing machine U, and regard it as a hitting set generator $U = \{U_\ell : \{0,1\}^{\ell/2} \to \{0,1\}^\ell\}_{\ell\in\mathbb{N}}$. That is, U_ℓ takes an input (M, x) of length $\ell/2$, simulates the Turing machine M on input x, and outputs $M(x)$ if the length of the output $M(x)$ is exactly ℓ; otherwise, U_ℓ outputs 1^ℓ.

▷ Claim 5. Suppose that there exists a computable oracle R that avoids U. Then, there exists a randomized polynomial-time nonadaptive R-oracle algorithm that approximates $\mathrm{K}_U(x)$.

Proof Sketch. The idea of the non-black-box reduction of [18] is as follows: Given an input $x \in \{0,1\}^n$, take any construction of a pseudorandom generator $G^x\colon \{0,1\}^{\ell/4} \to \{0,1\}^\ell$ based on a worst-case hard function $x\colon \{0,1\}^{\log n} \to \{0,1\}$.[6] For example, we can use the Nisan-Wigderson generator [30] combined with some error-correcting codes. The reduction estimates $p := \mathbb{E}_z[R(G^x(z))]$ by sampling, and accepts if and only if p is small.

The correctness is proved as follows: If $\mathrm{K}_U(x) \le \ell/5$, then $\mathrm{K}_U(G^x(z)) \le |z| + \mathrm{K}_U(x) \ll \ell/2$ for a large enough ℓ; thus $p = 0$. Conversely, if $p \approx 0$, then by using the security proof of G^x, we obtain a small R-oracle Turing machine that outputs x; thus $\mathrm{K}^R_U(x) \le \mathsf{poly}(\ell, \log n)$; in particular, *by using the assumption that R is computable*, we obtain $\mathrm{K}_U(x) \le \mathsf{poly}(\ell, \log n)$. Therefore, the reduction distinguishes the YES instances x such that $\mathrm{K}_U(x) \le \ell/5$ and the NO instances x such that $\mathrm{K}_U(x) > \mathsf{poly}(\ell, \log n)$. ◁

[6] Here we identify a function with its truth table.

Observe that, in the proof above, we crucially used the assumption that R is computable. Can we avoid the assumption and generalize Claim 5 for any R that avoids U? In other words, is there a black-box reduction from approximating $\mathrm{K}_U(x)$ to the task of avoiding U? If it is the case, Theorem 4 implies that approximating $\mathrm{K}_U(x)$ can be done in $\mathsf{S}_2^{\mathsf{NP}}$, which contradicts the undecidability of Kolmogorov complexity. Therefore, we conclude that the reduction of Claim 5 is inherently non-black-box.

3.2 Applications: Non-Black-Box Selector for GapMCSP

As explained in the previous subsection, the non-black-box reductions of [18] cannot be combined with Theorem 4 *unconditionally*. However, we show that our simulation protocol of black-box reductions can be combined with the non-black-box reductions *conditionally*, which constitutes a new structural property of GapMCSP – the existence of a "non-black-box selector."

▶ **Theorem 6** (GapMCSP Has a "Non-Black-Box Selector"). *For any constant $\epsilon > 0$, there exist some constant $\delta > 0$ and a randomized polynomial-time algorithm that takes as advice two circuits one of which is guaranteed to solve* $\mathrm{Gap}_\epsilon\mathrm{MCSP}$ *and solves* $\mathrm{Gap}_\delta\mathrm{MCSP}$ *with high probability.*

A *selector* for a problem L is an efficient algorithm that solves L given oracle access to two oracles one of which is guaranteed to solve; thus, it "selects" the correct answer from the two oracles. The notion of selector exactly characterizes the class of languages for which advice of logarithmic length can be removed [17]. The selector of Theorem 6 is non-black-box in the sense that it requires to take as advice two polynomial-size circuits instead of black-box access to two oracles.

The main building block of the non-black-box selector is our $\mathsf{S}_2^{\mathrm{p}}$-type simulation algorithm of Theorem 4. Recall that $\mathsf{S}_2^{\mathrm{p}}$ is a proof system where two competing provers, one of which is guaranteed to be honest, try to convince a polynomial-time verifier. In our $\mathsf{S}_2^{\mathrm{p}}$ simulation algorithm of black-box reductions, for each $i \in \{0,1\}$, the ith prover sends a set R_i; the honest prover sends a set R_i that avoids a hitting set generator G. Then a verifier obtains an oracle $R_0 \cap R_1$ that avoids G, to which the reduction is guaranteed to work.

Theorem 6 is proved by combining this $\mathsf{S}_2^{\mathrm{p}}$-type simulation algorithm with the non-black-box reductions of [10, 18].[7] The reason why we can combine the non-black-box reductions with our $\mathsf{S}_2^{\mathrm{p}}$-type simulation algorithm is that the non-black-box reduction of [18] is, in fact, a *size-restricted black-box reduction* [14]. This is a black-box reduction which works correctly when an oracle can be computed by a polynomial-size circuit. Our $\mathsf{S}_2^{\mathrm{p}}$-type simulation algorithm can simulate the size-restricted black-box reduction under the assumption that there exists a polynomial-size circuit that avoids a hitting set generator.

In contrast, we were not able to combine our $\mathsf{AM} \cap \mathsf{coAM}$ algorithm of Theorem 4 with the non-black-box reductions under similar conditions. We leave it as an interesting open question, which could have an application to fixed-polynomial circuit lower bounds (e.g., [34]).

▶ **Open Question 7** ("Non-Black-Box Instance Checkability" of GapMCSP). *Prove that* $\mathrm{MCSP} \in \mathsf{P/poly}$ *(or* $\mathsf{NP} \subseteq \mathsf{P/poly}$*) implies* $\mathrm{Gap}_\epsilon\mathrm{MCSP} \in \mathsf{coAM}$ *for some constant $\epsilon > 0$.*

[7] There is an alternative proof based on the search-to-decision reduction of GapMCSP given by Carmosino, Impagliazzo, Kabanets, and Kolokolova [10]. However, we choose to present the proof by combining the $\mathsf{S}_2^{\mathrm{p}}$-type simulation algorithm with the non-black-box reductions in order to highlight the difference between Theorem 6 and Open Question 7.

3.3 Our Techniques

We outline our proof strategy for Theorem 4 below. Suppose that we have some reduction M from L to any oracle R that avoids a hitting set generator G. Fix any input $x \in \{0,1\}^*$, and let $\mathcal{Q}_x$ denote the query distribution that a reduction makes on input x. We focus on the case when the length of each query is larger than $\Theta(\log n)$, and explain the proof ideas for showing $L \in \mathsf{AM} \cap \mathsf{coAM}$.

As a warm-up, consider the case when the support $\mathsf{supp}(\mathcal{Q}_x)$ of $\mathcal{Q}_x$ is small (i.e., $|\mathsf{supp}(\mathcal{Q}_x) \cap \{0,1\}^\ell| \ll 2^\ell$ for all large $\ell \in \mathbb{N}$). In this case, we can define an oracle R_1 so that $R_1 := \{0,1\}^* \setminus \mathsf{supp}(\mathcal{Q}_x) \setminus \mathrm{Im}(G)$; this avoids the hitting generator G because $R_1 \cap \mathrm{Im}(G) = \varnothing$ and the size of $R_1 \cap \{0,1\}^\ell$ is at least $2^\ell - |\mathsf{supp}(\mathcal{Q}_x)| - |\mathrm{Im}(G_\ell)| \gg 2^{\ell-1}$ for all large $\ell \in \mathbb{N}$. Therefore, it is guaranteed that the reduction M computes L correctly under the oracle R_1; we can simulate the reduction by simply answering all the queries by saying "No" (since $q \notin R_1$ for every $q \in \mathcal{Q}_x$); hence $L \in \mathsf{BPP}$.

In general, we cannot hope that $\mathsf{supp}(\mathcal{Q}_x)$ is small enough. To generalize the observation above, let us recall the notion of α-heaviness [9]: We say that a query q is *α-heavy* (with respect to $\mathcal{Q}_x$) if the query q is α times more likely to be sampled under $\mathcal{Q}_x$ than the uniform distribution on $\{0,1\}^{|q|}$; that is, $\Pr_{w \sim \mathcal{Q}_x}[w = q] \geq \alpha 2^{-|q|}$. Now we define our new oracle $R_2 := \{0,1\}^* \setminus \{\, q \in \{0,1\}^* \mid q\colon \alpha\text{-heavy} \,\} \setminus \mathrm{Im}(G)$, which can again be shown to avoid G because the fraction of α-heavy queries is at most $1/\alpha$ $(\ll 1)$.

The problem now is that it is difficult to simulate the new oracle R_2; it appears that, given a query q, we need to test whether $q \stackrel{?}{\in} \mathrm{Im}(G)$, which is not possible in $\mathsf{AM} \cap \mathsf{coAM}$. However, it turns out that it is not necessary to test it, as we explain next: Observe that the size of $\mathrm{Im}(G)$ is very small; it is at most $2^{s(\ell)}$ $\left(\ll 2^\ell\right)$. Thus, the probability that a query q is in $\mathrm{Im}(G)$ and q is not α-heavy (i.e., q is rarely queried) is at most $\alpha \cdot 2^{s(\ell)-\ell}$, where ℓ denotes the length of q. As a consequence, the reduction cannot "distinguish" the oracle R_2 and a new oracle $R_3 := \{0,1\}^* \setminus \{\, q \in \{0,1\}^* \mid q\colon \alpha\text{-heavy} \,\}$; hence, we can simulate the reduction if, given a query q, we can decide whether $q \stackrel{?}{\in} R_3$ in $\mathsf{AM} \cap \mathsf{coAM}$.

This task, however, still appears to be difficult for $\mathsf{AM} \cap \mathsf{coAM}$; indeed, at this point, Gutfreund and Vadhan [14] used the fact that the approximate counting is possible in $\mathsf{BPP}^{\mathsf{NP}}$, and thereby simulated the oracle R_3 by a $\mathsf{BPP}^{\mathsf{NP}}$ algorithm.

Our main technical contribution is to develop a way of simulating the reduction to R_3. First, note that the lower bound protocol of Goldwasser and Sipser [13] enables us to give an AM certificate for α-heaviness; we can check, given a query q, whether q is $\alpha(1+\epsilon)$-heavy or α-light for any small error parameter $\epsilon > 0$. Thus, we have an AM protocol for $\{0,1\}^* \setminus R_3$ for every query q (except for the queries that are α-heavy and $\alpha(1+\epsilon)$-light).

If, in addition, we had an AM protocol for R_3, then we would be done; however, it does not seem possible in general. The upper bound protocol of Fortnow [12] performs a similar task, but the protocol can be applied only for a limited purpose: we need to keep the randomness used to generate a query $q \sim \mathcal{Q}_x$ from being revealed to the prover. When the number of queries of the reduction is limited to 1, we can use the upper bound protocol in order to give an AM certificate for R_3; on the other hand, if the reduction makes two queries $(q_1, q_2) \sim \mathcal{Q}_x$, we cannot simultaneously provide AM certificates of the upper bound protocol for *both* q_1 and q_2, because the fact that q_1 and q_2 are sampled *together* may reveal some information about the private randomness. To summarize, the upper bound protocol works only for the *marginal* distribution of each query, but does not work for the *joint* distribution of several queries.

Still, the upper bound protocol is useful for extracting some information about *each* query. For example, the heavy-sample protocol of Bogdanov and Trevisan [9] (which combines the lower and upper bound protocol and sampling) estimates, in $\mathsf{AM} \cap \mathsf{coAM}$, the probability that a query q sampled from $\mathcal{Q}_x$ is α-heavy. This protocol enables us to estimate the probability that $q \in R_3$ over the choice of $q \sim \mathcal{Q}_x$.

The probability that $q \in R_3$ is useful for simulating the reduction M. Feigenbaum and Fortnow [11] developed an $\mathsf{AM} \cap \mathsf{coAM}$ protocol that simulates a nonadaptive reduction to an NP oracle R, given as advice the probability that a query q is in R. We generalize this protocol for the case when the oracle R is solvable by AM on average:

▶ **Theorem 8** (Generalized Feigenbaum–Fortnow Protocol; informal)**.** *Suppose that M is a randomized polynomial-time nonadaptive reduction to an oracle R whose queries are distributed according to $\mathcal{Q}_x$ on input $x \in \{0,1\}^n$, and that R is solvable by AM on average (i.e., there exists an AM protocol Π_R such that, with probability $1 - 1/\mathsf{poly}(n)$ over the choice of $q \sim \mathcal{Q}_x$, the protocol Π_R computes R on input q). Then, there exists an $\mathsf{AM} \cap \mathsf{coAM}$ protocol Π_M such that, given a probability $p^* \approx \Pr_{q \sim \mathcal{Q}_x}[q \in R]$ as advice, the protocol Π_M simulates the reduction M with probability at least $1 - 1/\mathsf{poly}(n)$.*

Let R denote the complement of R_3, i.e., $R := \{\, q \in \{0,1\}^* \mid q\colon \alpha\text{-heavy} \,\}$. Using the generalized Feigenbaum–Fortnow protocol, we simulate the reduction M to R as follows. Firstly, we use the heavy-sample protocol of [9] in order to estimate $p^* \approx \Pr_{q \sim \mathcal{Q}_x}[q\colon \alpha\text{-heavy}]$. Secondly, using the lower bound protocol of [13], we argue that R can be solved by some AM-protocol Π_R on average. Lastly, we use the protocol of Theorem 8 to simulate M. The details can be found in the full version of the paper.

We mention in passing the difficulty of Open Question 7, i.e., the reason why we were not able to combine our $\mathsf{AM} \cap \mathsf{coAM}$-type simulation algorithm with the non-black-box reduction *even conditionally*: The non-black-box reduction outlined in Subsection 3.1 reduces the promise problem whose YES instance consists of $\mathrm{K}_U(x) \leq \ell/5$ and NO instance consists of $\mathrm{K}_U^R(x) > \mathsf{poly}(\ell, \log n)$ to an oracle R. In order to make sure that the promise problem is non-trivial, it is important that R does not depend on x. On the other hand, in our simulation algorithm, we need to choose an oracle R_x depending on the input x, which potentially makes the promise problem trivial. (For example, $\mathrm{K}_U^{R_x}(x)$ may be always close to 0.)

3.4 Subsequent Work

Inspired by this work, Allender's conjectures [4] were refuted under the plausible assumptions about the exponential-time hierarchy [21, 20]. Moreover, it turned out that the stretch of a hitting set generator construction is important. In [20], it was shown that there exists a function $G = \{G : \{0,1\}^{n - O(\log n)} \to \{0,1\}^n\}_{n \in \mathbb{N}}$ such that $\mathsf{NEXP} \cup \mathsf{coNEXP} \subseteq \mathsf{BPP}_{\|}^R$ for any oracle R that avoids G. This result bypasses our limits of black-box reductions (Theorem 4) because G extends its seed by a small amount of $O(\log n)$ whereas Theorem 4 requires that G extends its seed by a constant factor. In [19], the approximation quality of non-black-box reductions of [18] is improved. Moreover, based on the improvement, it is shown that, under the assumption that $\mathsf{DistPH} \subseteq \mathsf{AvgP}$, the time-bounded SAT-oracle Kolmogorov complexity of a string x is equal to the time-bounded Kolmogorov complexity of x up to an additive term of $O(\log n)$, for any string $x \in \{0,1\}^n$.

Abstract

We consider the fundamental question of understanding the relative power of two important computational models: *property testing* and *data streaming*. We present a novel framework closely linking these areas in the setting of *general graphs* in the context of constant-query complexity testing and constant-space streaming. Our main result is a generic *transformation* of a one-sided error property tester in the random-neighbor model with constant *query* complexity into a one-sided error property tester in the streaming model with constant *space* complexity. Previously such a generic transformation was only known for *bounded-degree* graphs.

1 Introduction

We consider the fundamental question of understanding the relative power of two important computational models: *property testing* and *data streaming*. We present a novel framework closely linking these areas in the setting of *general graphs* in the context of constant-query complexity testing and constant-space streaming. We first provide a new analysis of constant-query property testers (in the random-neighbor model, see Definition 6) for general graphs

and develop the framework of canonical testers for general graphs. Then, using the concept of canonical testers, we provide a generic *transformation* of a one-sided error property tester in the random-neighbor model with constant *query* complexity into a one-sided error property tester in the streaming model with constant *space* complexity.

Property testing. A fundamental task in the study of big networks/graphs is to efficiently analyze their structural properties. For example, we may want to know if a graph is well-connected, has many natural clusters, has many copies (instances) of some specific sub-structures, etc. Given that modern networks are large, often consisting of millions and billions of nodes (web graph, social networks, etc.), the task of analyzing their structure has become recently more and more challenging, and the running-time efficiency of this task is becoming of critical importance. The framework of *property testing* has been developed to address some of these challenges, aiming to trade the efficiency with the accuracy of the output, with the goal of achieving very fast algorithms.

In (graph) property testing, one of the main challenges is to characterize properties that are testable with a constant number of queries in various computational models. Typically, a tester has query access to a graph (e.g., random vertices or neighbors of a vertex for graphs), and its goal is to determine if the graph satisfies a certain property (e.g., is well-clusterable) or is far from having such a property (e.g., is "far" from any graph being well-clusterable; see, e.g., [18, 19, 20, 39]). To be precise, we define testers as follows. Given a property Π, a tester for Π is a (possibly randomized) algorithm that is given a proximity parameter ε and oracle access to the input graph G. If G satisfies property Π, then the algorithm must accept with probability at least $\frac{2}{3}$. If G is ε-far from Π, then the algorithm must reject with probability at least $\frac{2}{3}$. If the algorithm is allowed to make an error in both cases, we say it is a *two-sided error tester*; if, on the contrary, the algorithm always gives the correct answer when G satisfies the property, we say it is a *one-sided error tester*. Further details of the model depend on the data representation. In the main model considered in this paper, *property testing for general graphs*, we will consider the *random neighbor oracle access* to the input graph (cf. Definition 6), which allows to query a random neighbor of any given vertex[1]. In our model, we will say that G is ε-far from a property Π if any graph that satisfies Π differs from G on at least $\varepsilon|E(G)|$ edges. To analyze the performance of a tester, we will measure its quality in term of its *query complexity*, which is the number of oracle queries it makes.

In the past, a large body of research has focused on the analysis of various graph properties in different graph models, for example, leading to a precise characterization of all properties that can be tested with constant query complexity [1, 3] in the so-called dense model (graphs with $\Theta(n^2)$ edges), and some partial results for bounded-degree graph models (see, e.g., [5, 13, 17, 18, 20, 21, 35]). However, our understanding of the model of general graphs, graphs where each vertex can have arbitrary degree, is still rather limited. We have seen some major advances in testing graph properties for general graphs, including the results of Parnas and

[1] Our model is in contrast with the other two widely used property testing models for graphs with arbitrarily large maximum degree: In the *adjacency list model* [36, 30], the algorithm can perform both *neighbor queries* (i.e., for the i-th neighbor of any vertex v such that $i \leq \deg(v)$), and the *degree queries* (i.e., for the degree $\deg(v)$ of any vertex v); In the *general graph model*, the algorithm is allowed to perform *vertex-pair queries* (i.e., for the existence of an edge between any two vertex pair u, v), in addition to neighbor and degree queries [28, 2, 18]. Still, we believe that the *random neighbor oracle model* considered in this paper is the most natural model of computations in the property testing framework in the context of very fast algorithms, especially those performing $O(1)$ queries. We note however, that our analysis can be generalized to other models of general graphs (cf. the full version).

Ron [36], Kaufman et al. [28], Alon et al. [2], Czumaj et al. [11, 14] (see also the survey in [18, Chapter 10]). The main challenge of the study in the model of general graphs is a lack of good characterization of testable properties and of a good algorithmic toolbox for the problems in this model. Still, the importance of the general graph model and lack of major advances have been widely acknowledged in the property testing community. For example, it is recognized that the general graph model is "most relevant to computer science applications" and "designing testers in this model requires the development of algorithmic techniques that may be applicable also in other areas of algorithmic research" (see [18, Chapter 10.5.3]).

Graph streaming algorithms. One important way of processing large graphs in modern data analysis is to design *graph streaming algorithms* (see, e.g., [31, 34]). A graph streaming algorithm obtains the input graph as a stream of edges in some order and its goal is to process and analyze the input stream in order to compute some basic characteristics about the input graph. For example, we want to know whether the graph is connected, or bipartite, or to know its approximate maximum matching size. Following the mainstream research in data streaming, we focus on algorithms that make only a *single pass* over the graph stream. Since in the single pass model every edge is seen only once, the central complexity measure of data streaming algorithms is the amount of space used to store information about the graph, with the golden standard in streaming being *sublinear space*. Unfortunately, it is known that for many natural graph problems sublinear space $o(n)$ is not possible when the edges are arriving in a single pass and in arbitrary order, where n is the number of vertices of the input graph [23].

There have been several approaches to cope with this inherent limitation of the streaming setting for graph problems. While some of the early works in graph streaming algorithms approached this challenge by allowing more than one pass over the input, the single-pass model is still considered to be the most interesting and the most natural scenario for streaming algorithms. The $\Omega(n)$ space lower bound (e.g., for testing if the graph is connected or estimating the size of transitive closure [23]) led to a significant number of papers designing semi-streaming algorithms, which are algorithms using $O(n \operatorname{polylog}(n))$ space, so only slightly larger than linear in the number of vertices (see the survey [31]). This model leads to sublinear algorithms for dense graphs, where m, the number of edges, is $\omega(n \operatorname{polylog}(n))$. For the very natural setting of *sparse graphs*, semi-streaming algorithms are useless, since with $O(n \operatorname{polylog}(n))$ space one can store the entire input graph (all arriving edges). Therefore, one can trivially solve any graph problem. Some works consider special classes of graphs. For example, it is known how to approximate the matching size within a constant factor in polylogarithmic space for planar graphs or graphs with bounded arboricity (see, e.g., [15, 10, 32, 6]).

Another, central approach to address the linear space lower bounds for graph streaming problems that recently received increasing attention is the *random-order streaming model*, where the edges arrive in random order, i.e., in the order of a uniformly random permutation of the edges (see, e.g., [8, 26, 29, 31, 33, 37, 4, 27, 9, 16]). The assumption about uniformly random or near-uniformly random ordering is very natural and can arise in many contexts. One might also use the random-order streaming model to justify the success of some heuristics in practice, even though there exists strong space lower bound for (the worst case of) the problem. Furthermore, some recent advances have shown that some problems that are hard for adversarial streams can be solved with small space in the random order model. For example, Konrad et al. [29] gave single-pass semi-streaming algorithms for maximum matching for bipartite and general graphs with approximation ratio strictly larger than $\frac{1}{2}$ in the random

order semi-streaming model. Kapralov et al. [26] gave a polylogarithmic approximation algorithm in polylogarithmic space for estimating the size of maximum matching of an unweighted graph in one pass over a random order stream. It is not known if such trade-offs between approximation ratios and space complexity are possible in the adversarial order model. Finally, [37] showed that in the random-order streaming model, even with constant space, one can approximate the number of connected components of the input graph within an additive error of εn, the size of a maximum independent set in planar graphs within a multiplicative factor of $1+\varepsilon$, and the weight of a minimum spanning tree of a connected input graph with small integer edge weights within a multiplicative factor of $1+\varepsilon$. However, for the first and third problems in adversarial order streams, there exist $n^{1-O(\varepsilon)}$ space lower bounds [24]. While these results demonstrate the strength of the random-order streaming model, Chakrabarti et al. [8] proved that $\Omega(n)$ space is needed for any single pass algorithm for graph connectivity in the random-order streaming model, almost matching the optimal $\Omega(n \log n)$ space lower bound in the adversarial order model [40]. This poses a central open question in the area of graph streaming algorithms, of *characterizing graph problems which can be solved with small, sublinear space in the random-order streaming model.*

The main goal of our paper in the context of streaming algorithms, is to address this task and to enlarge the class of graph problems known to be solvable with *small space* in the *random order streaming* model in a *single pass*. Our main focus is on the most challenging scenario: of achieving *constant space*[2].

1.1 Basic Definitions and Overview of Our Results

In this paper, we extend the approach recently introduced by Monemizadeh et al. [33] (see also [37]) to demonstrate a *close connection between streaming algorithms and property testing* in the most general setting of *general graphs*. Monemizadeh et al. [33] show that for *bounded-degree graphs*, any graph property that is constant-query testable in the adjacency list model can be tested with constant space in a single pass in random order streams. In this paper, we show that similar results hold also for general graphs. To this end, we design a novel framework of canonical testers for all constant-query testers for general graphs and apply it to design a generic method of transforming any constant-query tester (with one-sided error) for graph properties into a constant-space tester (with one-sided error) in the random-order streaming model.

We consider the *random neighbor* query oracle model for general graphs, which allows the algorithm to query a random neighbor of any specified vertex (cf. Definition 6).

▶ **Definition 1** (Property testers in the random-neighbor model). *Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be a graph property, where Π_n is a property of graph of n vertices. We say that* Π is testable with query complexity *q, if for every ε and n, there exists an algorithm (called* tester*) that makes at most $q = q(n,\varepsilon)$ oracle queries, and with probability at least $\frac{2}{3}$, accepts any n-vertex graph satisfying* Π*, and rejects any n-vertex graph that is ε-far from satisfying* Π*. If $q = q(\varepsilon)$ is a function independent of n, then we call* Π constant-query testable*. If the tester always accepts graphs that satisfy* Π*, we say that it has* one-sided error*. Otherwise, we say the tester has* two-sided error*.*

[2] Throughout the entire paper, we will count the size of the *space in words* (assuming that a single word can store any single ID of a vertex or of an edge), i.e., space bounds have to be multiplied by $O(\log n)$ to obtain the number of bits used. With this in mind, we use term *constant space* to denote space required to store a constant number of words, or IDs, that is, $O(\log n)$ bits.

We notice that the definition above is generic and can be applied to any of the query oracle models (see e.g. [18]). However, since our main query oracle model is the random-neighbor model, only for that model we will use the terminology from Definition 1 without a direct reference to the query oracle model. We first present *canonical testers* in this model. In order to do so, we introduce a process called *q-random BFS* (q-RBFS) starting with any specified vertex v, i.e., a BFS of depth q that is restricted to visiting at most q random neighbors for every vertex (see Definition 7). We call the subgraph obtained by a q-RBFS a *q-bounded disc*. Our first result is informally stated as follows.

▶ **Theorem 2** (informal; cf. Theorem 10). *If a property $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ is testable with $q = q(\varepsilon)$ queries in the random-neighbor model, then it can also be tested by a canonical tester that*
1. *samples q' vertices;*
2. *performs q'-RBFS from each sampled vertex;*
3. *accepts if and only if the explored subgraph does not contain any (forbidden) graph $F \in \mathcal{F}$,*

where q' depends only on q, and $\mathcal{F}$ is a family of rooted graphs such that each graph $F \in \mathcal{F}$ is the union of q' many q'-bounded discs.

We remark that similar canonical testers have been given for dense graphs [22], bounded-degree graphs and digraphs [21, 12]. Actually, our proof for the above theorem heavily builds upon [21, 12], though our analysis requires some extensions to deal with general graphs (of possibly unbounded degree). To formally state our result regarding testing graph properties in streaming, we introduce the following definition.

▶ **Definition 3** (Property testers in the streaming model). *Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be a graph property, where Π_n is a property of graph of n vertices. We say that Π is testable with space complexity q, if for every ε and n, there exists an algorithm that performs a single pass over an edge stream of an n-vertex graph G, uses $q = q(n, \varepsilon)$* words *of space, and with probability at least $\frac{2}{3}$, accepts G satisfying Π, and rejects G that is ε-far from satisfying Π. If $q = q(\varepsilon)$ is a function independent of n, then we call Π* constant-space testable*. If the tester always accepts the property, then we say that the property can be tested with* one-sided error*. Otherwise, we say the tester has* two-sided error*.*

Our main result and our main technical contribution is the *transformation* of a one-sided error property tester in the random-neighbor model with constant *query* complexity into a one-sided error property tester in the streaming model with constant *space* complexity.

▶ **Theorem 4** (Main Theorem). *Every graph property Π that is constant-query testable with one-sided error in the random-neighbor model is also constant-space testable (space measured in words) with one-sided error in the random order graph streams.*

Applications. We believe that the main contribution of our paper is the general transformation presented in Theorem 4. However, we admit that the number of properties testable with one-sided error with a constant number of queries in the random-neighbor model is rather limited. Still, we can apply our transformation to, for example, the property of being (s, t)-disconnected (i.e., there is no path between s and t), see, e.g., [41][3]. Furthermore, our

[3] The constant-query tester from [41] performs degree queries and neighbor queries, but it is straightforward to simulate it in the random-neighbor model. Indeed, the algorithm in [41] only needs to repeatedly perform a constant-length random walks from s and reject if only if one path from s to t is found. Such an algorithm can be trivially simulated in the random-neighbor model, as each step of a random walk just needs to query one random neighbor of the current vertex.

transformation actually holds when the input graph is restricted to come from a certain class of graphs such as planar graphs, minor-free graphs, or bounded-degree graphs. Since bipartiteness in planar graphs (or minor-free graphs) is testable in the random-neighbor model [11], it is also one-sided error testable in random order streams in constant space; notice that this result stands in contrast to the $n^{1-O(\varepsilon)}$ space lower bound for *adversarial order streams* for (property) testing bipartiteness in planar graphs [24]. Further, recent constant-query complexity testing of H-freeness in planar or minor-free graphs [14] shows that also testing H-freeness is one-sided error testable in random order streams in constant space.

Furthermore, our techniques can also be used to transform any constant-query tester (with one-sided error) in the *random neighbor/edge model* (cf. the full version) to the random-order streaming model, where the random neighbor/edge model allows to sample an edge uniformly at random. Therefore, for example, since the property of being P_k-free (there is no path of length k) is constant-query testable in the random neighbor/edge model with one-sided error [25], P_k-freeness is also constant-space testable with one-sided error in the random order graph streams. Similarly, it is not hard to see that the property of being d-bounded (the maximum degree is at most d) is constant-query testable in the random neighbor/edge model[4], and therefore this property too is constant-space testable with one-sided error in the random order graph streams.

The contribution of our paper goes beyond just establishing a connection between property testing and streaming. While the concept of canonical testers has been used in graph property testing before (cf. [22, 21, 12]), our study and characterization of canonical testers for general graphs (Theorem 2 and Theorem 10) is new. We believe that this study will shed light on our understanding of constant-query testable graph properties and will lead to new results for property testing in general graphs. For example, Czumaj and Sohler [14] recently used our canonical testers as a tool in their proof of a complete characterization of constant-query testable properties in general planar graphs [14] after a preliminary version of this work appeared.

1.2 Challenges and Techniques

The result about constant-space streaming algorithms for bounded-degree graphs by Monemizadeh et al. [33] is obtained by noting that any constant-query complexity tester basically estimates the distribution of local neighborhoods of the vertices (see, e.g., [12, 18, 21]) and emulating any such algorithm on a random order graph stream using constant space. Unfortunately, this approach inherently relies on the assumption that the input graph is of bounded degree. This limitation comes from two ends: on one hand, there has not been known any versatile description of testers for constant-query testable graph properties of general graphs, and on the other hand, the streaming approach from [33] relies on a breadth-first-search-like graph exploration that is possible (with constant space) only when the input graph has no high-degree vertices. A follow-up paper [37] made the first attempt to address the challenge of dealing with general degrees, and considered some problems in which one can *ignore* high degree vertices (e.g., for approximating the number of connected components or the size of a maximum independent set in planar graphs).

[4] If G is ε-far from the property, then at least $\Omega(\varepsilon|E|)$ edges are incident to a node with degree at least $d+1$. Thus, we can simply sample a constant number of edges and check if either of its endpoints has degree at least $d+1$.

One important reason why the earlier approaches have been failing for the model of general graphs, without bounded-degree assumption, was our lack of understanding of constant-query complexity testers in general graphs and the lack of techniques to appropriately emulate off-line algorithms allowing many high-degree vertices. In this paper, we advance our understanding on both of these challenges.

A general and simple canonical tester. To derive a canonical tester for constant-query testable properties in the random-neighbor model, we introduce the process *q-random BFS* (q-RBFS): it starts from any specified vertex v, and then performs a BFS-like exploration of depth q that is restricted to visiting at most q random neighbors at each step (see Definition 7 for the formal definition). We call the subgraph obtained by a q-RBFS a *q-bounded disc*. With the notion of q-RBFS and q-bounded discs, we are able to transform every constant-query tester for properties of general graphs into a *canonical tester* that works as follows: it samples q random vertices, performs a q-RBFS from each sampled vertex, and rejects if and only if the (non-induced) subgraph it has seen (which is a union of q-bounded discs) is isomorphic to some member of a family $\mathcal{F}$ of forbidden subgraphs (see Theorems 2 and 10). Furthermore, such a canonical tester preserves one-sided error, while the query complexity blows up exponentially. We believe that the exponential blow-up is necessary, even for bounded-degree graphs, as adaptivity is essential for property testing in sparse graphs [38, 7]. This is in contrast to the dense graph model for property testing, in which a quadratic blow-up of the query complexity of canonical testers was known [22].

Canonical testers provide us a systematic view of the behavior of constant-query testers in the random-neighbor model. They further tell us that in order to test a constant-query testable property Π, it suffices to estimate the probability that some forbidden subgraph in $\mathcal{F}$ is found by a q-RBFS starting from a randomly sampled vertex. Slightly more formally, we define the *reach probability* of a subgraph $F \in \mathcal{F}$ to be the probability that a q-RBFS starting from a uniformly chosen vertex v sees a graph that is isomorphic to F. In particular, if we can estimate these reach probabilities in random order streams, then we can also test Π accordingly.

The problem with this approach is that it is hard to estimate the reach probabilities of subgraphs in $\mathcal{F}$. The main challenge here is that a forbidden subgraph $F \in \mathcal{F}_n$ may be the union of more than two or more subgraphs obtained from different q-RBFS that may intersect with each other.

A refined canonical tester. To cope with the challenge mentioned above of estimating the reach probabilities of subgraphs in $\mathcal{F}$, we decompose each forbidden subgraph $F \in \mathcal{F}_n$ into all possible sets of intersecting q-bounded discs whose union is F and then try to recover F from these sets. In order to recover F from such a decomposition, we have to identify and monitor *vertices that are contained in more than one q-bounded disc of F*.

We refine the analysis of the canonical tester and separate the q-bounded discs explored by each q-RBFS and keep track of their intersections (cf. Theorem 17). We first observe that for every input graph G and every ε, there exists a *small fixed set* $V_\alpha \subseteq V$ of all vertices whose probability to be visited by a random q-RBFS from a random vertex exceeds some small threshold α (depending on q and ε, but independent of n). In other words, with constant probability, the subgraphs explored by multiple q-RBFS in the canonical tester will only overlap on vertices from V_α. Furthermore, we prove that the degree of all vertices in V_α is at least linear (in n), and with constant probability, two random q-RBFS subgraphs will not share any edge. Since V_α has constant size, each q-bounded disc can be viewed as a

colored q-bounded disc *type* such that each vertex in V_α is assigned a unique color from a constant-size palette. This way, it is possible to reversibly decompose each $F \in \mathcal{F}_n$ into a multiset of colored q-bounded disc types (actually, there may be many such multisets for each F): since the q-bounded discs that are explored by different q-RBFS intersect only at vertices in V_α, F is obtained by identifying vertices of the same color. See Figure 1 in Appendix A for an example.

These properties are crucial to describe the forbidden subgraphs in terms of the graphs seen by the q many q-RBFS that the canonical tester performs and a *constant-size* description of their interaction, i.e., how they overlap.

Simulation in the streaming. In the streaming, in order to simulate q-RBFS, it is natural to consider the following procedure called StreamCollect (q-SC, see Algorithm 2 in Appendix B) to explore the subgraph surrounding any specified vertex. That is, it maintains a connected component C that initially contains only the start vertex. Whenever it reads an edge that connects to the current C and the augmented component may be observed by a run of q-RBFS, it adds the edge to C.

Note that one important feature of random order streams is that we would see the right exploration (as in the query model) with constant probability, while it is challenging to verify if the subgraph we collected from the stream is indeed the right exploration (cf. [33, 37] for a more detailed discussion). In our setting, as we mentioned, another technical difficulty is to analyze whether subgraphs found by running the stream procedure multiple times *intersect* in exactly the same way as the q-bounded discs that are found by q-RBFS.

With the refined canonical tester, which specifies how different q-RBFS procedures intersect, we are able to *simulate one-sided error constant-query testers* in the random-neighbor model for general graphs in the *random-order streaming model*. Since the considered property Π is one-sided error testable in the random-neighbor model, it suffices to detect a forbidden subgraph F in the family $\mathcal{F}$ corresponding to Π with constant probability. That is, it suffices to show that if the graph is far from having the property, then for any forbidden subgraph H that can be reached by the canonical tester with probability p, it can also be detected by *multiple* StreamCollect subroutines with probability at least cp for some suitable constant c.[5]

In order to do so, we first decompose the forbidden subgraphs that characterize the property into colored subgraphs, where each subgraph corresponds to a run of q-RBFS and vertices in V_α are colored with a unique color. Then, we prove that for a sufficiently large sample of vertices, the q-SC subroutines starting from these sampled vertices will collect, for each colored subgraph H, at least as many instances of H as the canonical property tester sees. Suppose that the input graph is far from the property. Since the subgraphs observed by the canonical tester intersect only at vertices in V_α, i.e., colored vertices, with constant probability, it is possible to stitch a forbidden subgraph by identifying vertices of the same color in the analysis.

[5] Note that this is not sufficient for simulating two-sided error testers. Let us take the property connectivity (which is 2-sided error testable in random-neighbor model) for example. If the input graph is a path on n vertices, then a q-RBFS will detect a forbidden subgraph (i.e., a path of constant length that is not connected to the rest) corresponding to connectivity with small constant probability, while a q-SC might see a forbidden subgraph with high constant probability. That is, in order to test connectivity, we need to be able to approximate the *frequencies* of the forbidden subgraphs, for which our current techniques fail.

The analysis of this procedure is two-fold. First, we show that if a single run of q-RBFS from v sees a certain colored q-bounded disc type with probability p (where the colored vertices are V_α), then a single run of q-SC from v sees this disc type with probability cp for some suitable constant c (see Corollary 20).

The second step (which is the main technical part) is to show that if the probability that a q-RBFS from a random vertex sees a colored q-bounded disc type Δ is p, then with constant probability, for a sufficiently large sample set S, the calls to q-SC from vertices in S will also see a q-bounded disc type Δ, even though there are intersections from different q-SCs (see Lemma 21). Then we can show that if the input graph is far from the property, with constant probability, we can stitch the colored q-bounded discs to obtain a forbidden subgraph $F \in \mathcal{F}$ (see Theorem 4).

Finally, we remark that colors are only used in the analysis as the streaming algorithm can identify intersections of multiple q-SC by the vertex labels. However, the colors are crucial to the analysis: without colors, we cannot guarantee that the q-bounded disc types found by multiple q-SCs can be stitched in the same way as the q-bounded disc types found by q-RBFS. Here is an example: Consider some constant-query testable property Π such that the set of forbidden subgraphs $\mathcal{F}$ contains a graph F that is not a subgraph of any single q-bounded disc type (i.e, it is the union of at least two intersecting q-bounded disc types). For the sake of illustration, a concrete example is provided in Figure 2 in Appendix A. In order to reject, the canonical property tester needs to find at least two intersecting q-bounded discs such that their union contains F as a subgraph. However, even if we bound, for each *uncolored* q-bounded disc type Δ, the probability that q-SC finds Δ by some constant fraction of the probability that q-RBFS finds Δ, this is not sufficient to conclude that the probability that multiple q-SCs find a copy of F is bounded by a constant fraction of the probability that multiple q-RBFS find a copy of F. The reason is that q-SC might only find copies of Δ that are not intersecting, while q-RBFS might tend to find copies of Δ that intersect. Again, see Figure 2 for an example. Therefore, we need to preserve, for each q-bounded disc type Δ, the information which of the corresponding vertices in the input graph are likely to be contained in more than one q-RBFS for the analysis.

2 Preliminaries

Let $G = (V, E)$ be an undirected graph. We will assume that the vertex set V of G is $[n] = \{1, \ldots, n\}$, and we let $\deg(v)$ denote the degree of $v \in V$. Sometimes, we use $V(G)$ to denote the vertex set V of G and $E(G)$ to denote the edge set E of G. We let $\mathcal{S}(G)$ denote the input stream of edges that defines G. In this paper, we consider streaming algorithms for random order streams, i.e., the input stream $\mathcal{S}(G)$ to our algorithm is drawn uniformly from the set of all permutations of E. We are interested in *streaming algorithms that have constant space complexity* in the size of the graph, where we count the size of the space in words, i.e., space bounds have to be multiplied by $O(\log n)$ to obtain the number of bits used, see also Footnote 2.

A graph G is called a *rooted* graph if at least one vertex in G is marked as *root*. Let us define the notion of a root-preserving isomorphism.

▶ **Definition 5.** *Given two rooted graphs H_1 and H_2, a* root-preserving isomorphism *from H_1 to H_2 is a bijection $f : V(H_1) \to V(H_2)$ such that 1) if u is the root of $V(H_1)$ then $f(u)$ is the root of $V(H_2)$, and 2) that $(u, v) \in E(H_1)$ if and only if $(f(u), f(v)) \in E(H_2)$. If there is a root-preserving isomorphism from H_1 to H_2 then we say that H_1 is root-preserving isomorphic to H_2 and denote it by $H_1 \simeq H_2$.*

3 Canonical Constant-Query Testers in General Graphs

In this section, we present our main result on the *canonical testers for constant-query testable properties in general graphs*. After starting with some basic definitions, we will present two canonical testers for constant-query testable properties in general graphs. Our first canonical tester is of a general form (see Section 3.2) and our second tester (see Theorem 17 in Section 3.3) is slightly more refined, allowing for a more natural use later in the setting of streaming algorithms in Section 5.

We note that in this paper we focus on one specific model of access to the input graph, the *random-neighbor model*. It is possible to extend some of our analysis (of canonical testers) to some other graph access models, though (cf. the full version).

3.1 Random BFS and Bounded Discs

Property testing in query oracle model. Since we consider general graphs, without any bounds for vertex degrees, we have to carefully define the access provided to the input graph in the property testing framework. The access to the input graph is given by *queries* to an *oracle* representing the graph. There have been several oracles considered in the literature for general graphs, but our main focus is on the *random-neighbor model*, which we consider to be natural for graphs with unbounded degree, especially in the context of properties testable with a constant number of queries.

▶ **Definition 6** (Random-neighbor model)**.** *In the* random-neighbor model*, an algorithm is given $n \in \mathbb{N}$ and access to an input graph $G = (V, E)$ by a query oracle, where $V = [n]$. The algorithm may ask queries based on the entire knowledge it has gained by the answers to previous queries. The* random neighbor query *specifies a vertex $v \in V$ and the oracle returns a vertex that is chosen i.u.r. (independently and uniformly at random) from the set of all neighbors of v.*

Notice that in the random-neighbor model, since $V = [n]$, the algorithm can also trivially select a vertex from V i.u.r. We believe that the random-neighbor model is the most natural model of computations in the property testing framework in the context of very fast algorithms (especially those of constant query complexity), and therefore our main focus is on that model. However, we want to point out that some of our results are sufficiently general to apply to a larger variety of the query oracle models, though we will not elaborate about it here (cf. the full version).

We describe the first canonical testers of all constant-query testers (in the random-neighbor model) for general graphs, both, for one-sided and two-sided errors. With this canonization, we can model all graph properties testable with a constant number of queries using *canonical testers*; see Theorems 10 and 17 for formal statements.

To formalize our canonical testers for all constant-query testers in the random-neighbor model, we will use the following two definitions of constrained random BFS-like graph exploration and of bounded discs.

We begin with the definition of a q-RBFS process, which starts at some vertex and explores its neighborhood in a BFS-like fashion, conditioned on a bound of the depth and the breadth of the exploration (see Definition 7 for formal definition and Algorithm 1 in Appendix B for the detailed implementation).

▶ **Definition 7** (q-random BFS)**.** *Let $q > 0$ be an integer and G be a simple graph. For any vertex $v \in V(G)$, the* q-random BFS *(abbreviated as* q-RBFS*) explores a random subset of the q-neighborhood of v in G iteratively as follows. First, it initializes a queue $Q = \{v\}$*

and a graph $H = (\{v\}, \emptyset)$. Then, in every iteration, it pops a vertex u from Q and samples q random neighbors $s_{u,1}, \ldots, s_{u,q}$ of u. For every edge $e = \{u, s_{u,i}\}$, it adds $s_{u,i}$ and the directed edge $(u, s_{u,i})$ to H. Furthermore, if $s_{u,i}$ has distance less than q from v in H and $s_{u,i}$ has not been added to Q before, $s_{u,i}$ is appended to Q. When Q is empty, all edges in H are made undirected (without creating parallel edges) and H is returned.

Any output of q-RBFS algorithms can be described in a static form using the concept of bounded discs.

▶ **Definition 8** (q-bounded disc). *For a given $q \in \mathbb{N}$, graph $G = (V, E)$, and vertex $v \in V$, a* q-bounded disc of v in G *is any subgraph H of G that is rooted at v and can be returned by $\textsc{RandomBFS}(G, v, q)$. In this case, vertex v is called a* root *of the q-bounded disc H and the maximum distance from v to any other vertex in H is called the* radius *of H.*

All q-bounded discs that are root-preserving isomorphic form an equivalence class.

▶ **Definition 9** (q-bounded disc type). *Let H be a q-bounded disc. The equivalence class of H with respect to $\simeq$, i. e., the existence of a root-preserving isomorphism (see Definition 5), is called the q-bounded disc type of H.*

3.2 Canonical Testers: A General Version

Now we present the proof of our first main result. We show that any tester with query complexity $q = q(\varepsilon, n)$ in the random-neighbor model can be simulated by a *canonical tester* that samples $q' = O(q)$ vertices and rejects if and only if the union of the subgraphs induced by the q'-RBFS from the sampled vertices belongs to some family of forbidden graphs.

▶ **Theorem 10** (Canonical tester). *Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be a graph property that can be tested in the random-neighbor model with query complexity $q = q(\varepsilon, n)$ and error probability at most $\frac{1}{3}$. Then for every ε, there exists an infinite sequence $\mathcal{F} = (\mathcal{F}_n)_{n\in\mathbb{N}}$ such that for every $n \in \mathbb{N}$,*

- *$\mathcal{F}_n$ is a set of rooted graphs such that each graph $F \in \mathcal{F}_n$ is the union of q' many q'-bounded discs;*
- *the property Π_n on n-vertex graphs can be tested with error probability at most $\frac{1}{3}$ by the following canonical tester:*
  1. *sample q' vertices i.u.r. and mark them roots;*
  2. *for each sampled vertex v, perform a q'-RBFS starting at v;*
  3. *reject if and only if the explored subgraph is root-preserving isomorphic to some $F \in \mathcal{F}_n$,*

where $q' = cq$ for some constant $c > 1$. The query complexity of the canonical tester is $q^{O(q)}$. Furthermore, if $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ can be tested in the random-neighbor model with one-sided error, then the resulting canonical tester for Π has one-sided error too, i.e., the tester always accepts graphs satisfying Π.

3.3 Canonical Testers Revisited: Identifying Vertices in the Intersecting Discs

Theorem 10 provides us a canonical way of testing constant-query testable properties (in the random-neighbor model) by relating the tester to a set of forbidden subgraphs $\mathcal{F}_n$ for every $n \in \mathbb{N}$. However, as we mentioned in Section 1, it is hard to directly use Theorem 10 to design and analyze our streaming testers due to the intersections of q-RBFS. In order to tackle this difficulty, we decompose each forbidden subgraph $F \in \mathcal{F}_n$ into all possible sets of intersecting q-bounded discs whose union is F. In order to recover F from such a decomposition, we have to identify and monitor *vertices that are contained in more than one q-bounded disc of F.*

Identifying vertices with large reach probability. Now we prove that with constant probability the q-bounded discs found by q-RBFS will only intersect on a *small* set of vertices V_α and the discs will not intersect on any edge.

We begin with a useful definition on the probability of reaching a vertex from a q-RBFS.

▶ **Definition 11.** *For each vertex v, the* reach probability $r(v) := r_q(v)$ *of v is the probability that a q-RBFS starting at a uniformly randomly chosen vertex reaches v.*

In the following lemma, we give an upper bound on the size of the set of vertices with constant reach probability, which also implies that with constant probability, the number of vertices visited by at least two q-RBFS that the canonical tester performs is small. For any α, $0 \leq \alpha \leq 1$, we let $V_\alpha := \{v \in V : r(v) \geq \alpha\}$. For a fixed q, let $c_j := \sum_{i=0}^{j} q^i = \frac{q^{j+1}-1}{q-1}$.

▶ **Lemma 12.** *For any $0 < \alpha < 1$, it holds that $|V_\alpha| \leq \frac{c_q}{\alpha}$.*

We further show that with high probability, two q-RBFS starting from vertices chosen i.u.r. will not share an edge (i.e., will not visit the same edge).

▶ **Lemma 13.** *Let $0 < \alpha \leq 1$. Let $n \geq \frac{qc_q}{\alpha^2}$. Let u, v be two randomly chosen vertices. Let H_u and H_v denote the subgraphs visited by two q-RBFS starting at u and v, respectively. Then with probability at least $1 - qc_q \cdot 2\alpha$, no edge will be contained in both H_u and H_v.*

Colored q-bounded disc types. To identify vertices in V_α, we assign them unique colors for the analysis. We call a disc *r-colored* if in addition to uncolored vertices in the disc, some vertices in the disc may be colored with at most r colors, each color being used at most once. Two colored q-bounded disc types Δ_1 and Δ_2 (cf. Definition 9) are called to be isomorphic to each other, denoted by $\Delta_1 \simeq \Delta_2$, if there is a root-preserving isomorphism f from Δ_1 to Δ_2 that also preserves the colors, i.e., if and only if $u \in V(\Delta_1)$ is colored with color c, then $f(u) \in \Delta_2$ is colored with color c.

▶ **Definition 14.** *Let $q > 0$ be an integer. We let $\mathcal{H}_q := \{\Delta_1, \cdots, \Delta_N\}$ denote the set of all possible r-colored q-bounded disc types, where N is the total number of such types.*

For any given colored q-bounded disc type, we have the following definition on the probability of seeing such a disc type from a q-RBFS.

▶ **Definition 15** (Reach probability of colored q-bounded disc types)**.** *Let $G = (V, E)$ be a graph with n vertices such that each vertex in V_α is assigned to a unique color. Let $\Delta \in \mathcal{H}_q$ be a colored q-bounded disc type. The* reach probability of Δ in G *is the probability that a q-RBFS from a random vertex in G reveals a graph that is (root- and color-preserving) isomorphic to Δ, that is* $\mathrm{Reach}_G(\Delta) := \Pr_{v \sim V, BFS}[\textsc{RandomBFS}(G, v, q) \simeq \Delta]$.

For a given vertex v, the reach probability of Δ from v in G is the probability that a q-RBFS from v in G induces a graph that is (root- and color-preserving) isomorphic to Δ, that is $\mathrm{Reach}_G(v, \Delta) := \Pr_{BFS}[\textsc{RandomBFS}(G, v, q) \simeq \Delta]$.

Recall from Definition 8 that a q-bounded disc of v in G is any subgraph H of G that is rooted at v and can be returned by $\textsc{RandomBFS}(G, v, q)$. In order to estimate the reach probability of a colored q-bounded disc type, we consider for each starting vertex v, the set of all possible colored q-bounded discs, denoted $\mathcal{C}_v$, that one can see from a q-RBFS from v.

▶ **Definition 16** (Reach probability of a colored q-bounded disc)**.** *Let $G = (V, E)$ be a graph in which all vertices in V_α are uniquely colored. Let v be a vertex in G. A* colored q-bounded disc *of v is a q-bounded disc of v in G in which all vertices in V_α colored. We let $\mathcal{C}_v$ denote*

the set of all possible colored q-bounded discs of v.[6] *For any fixed colored q-bounded disc $C \in \mathcal{C}_v$ of v, the reach probability of C from v is the probability that a q-RBFS from v sees exactly C, that is,* $\mathrm{Reach}_G(v, C) := \Pr_{BFS}[\textsc{RandomBFS}(G, v, q) = C]$.

By our definition, the q-RBFS from a vertex v in the colored graph G (with vertices in V_α colored) will return exactly one colored q-bounded disc of v. For each colored q-bounded disc type Δ, we let $\mathcal{C}_v(\Delta)$ denote the subset of $\mathcal{C}_v$ which contains all colored q-bounded discs of v that are isomorphic to Δ. Therefore, we have the following observation: $\mathrm{Reach}_G(v, \Delta) = \sum_{D \in \mathcal{C}_v(\Delta)} \mathrm{Reach}_G(v, D)$.

Canonical testers with distinguished vertices in the intersecting discs. Now, we give a refined characterization of the family of forbidden subgraphs corresponding to any constant-query testable property in general graphs, which establishes the basis of our framework for transforming the canonical constant-query testers in the random-neighbor model to the random-order streaming model.

In our next theorem, we will consider partially vertex-colored graphs and q-bounded discs: we color each vertex in V_α with a unique color from a palette of size $|V_\alpha|$. Recall from Lemma 12 that $|V_\alpha| \leq \frac{c_q}{\alpha}$. We obtain canonical testers of constant-query testable properties by *forbidden colored q-bounded discs* instead of *forbidden subgraphs* (that can be composed of more than a single q-bounded disc). See Figure 1 in Appendix A for an example.

▶ **Theorem 17.** *Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be a graph property that is testable with query complexity $q = q(\varepsilon)$. Let $\alpha \leq \frac{1}{24q'c_{q'}}$, where q' is the number from Theorem 10 for a canonical tester with error probability $1/6$. There is an infinite sequence $\mathcal{F}' = (\mathcal{F}'_n)_{n\in\mathbb{N}}$ such that for any $\epsilon > 0$, $n \geq \frac{q'c_{q'}}{\alpha^2}$, the following properties hold:*

- *$\mathcal{F}'_n$ is a set of graphs, and for each graph $F \in \mathcal{F}'_n$, there exists at least one multiset S of q' many $c_{q'}/\alpha$-colored and rooted q'-bounded disc types such that 1) the disc types are pairwise edge-disjoint, and 2) the graph obtained by identifying all vertices of the same color in the bounded discs of S is isomorphic to F.*
- *For any n-vertex graph $G = (V, E)$ such that each vertex in V_α is colored uniquely, let $S_{q'}$ denote the set of q' subgraphs obtained by performing q'-RBFS starting at q' vertices sampled i.u.r. Then,*
  - *if $G \in \Pi_n$, with probability at least $\frac{2}{3}$, there is no $F \in \mathcal{F}'_n$ such that F is isomorphic to a graph from $S_{q'}$,*
  - *if G is ε-far from Π_n, with probability at least $\frac{2}{3}$, there exists $F \in \mathcal{F}'_n$ such that F is isomorphic to a graph from $\simeq S_{q'}$,*

  where the probability is taken over the randomness of $S_{q'}$.

Furthermore, if Π can be tested with one-sided error, then for $G \in \Pi_n$, with probability 1, there is no $F \in \mathcal{F}'_n$ such that $F \simeq S_{q'}$.

4 Estimating the Reach Probabilities in Random Order Streams

Given a canonical tester $\mathcal{T}$ for a property Π that is constant-query testable in the random-neighbor model, we transform it into a random-order streaming algorithm as follows. Recall from Theorem 10 that $\mathcal{T}$ explores the input graph by sampling vertices uniformly at random and running q-RBFS for each of these vertices. Only if the resulting subgraph contains an

[6] Note that the number $|\mathcal{C}_v|$ of colored q-bounded discs of v can be a polynomial of n.

instance of a forbidden subgraph from a family $\mathcal{F}$, it rejects. It seems natural to define a procedure like q-RBFS for random order streams, namely a procedure StreamCollect($\mathcal{S}(G), v, q$) (q-*SC*), and let the streaming algorithm reject only if the union of all q-SC contains an instance of a graph from $\mathcal{F}$. However, this raises a couple of issues.

It seems hard to analyze the union of the subgraphs obtained by q-SC and relate it to the union of subgraphs observed by q-RBFS because the interference between two q-SC is quite different from the interference of two q-RBFS. Therefore, we use Theorem 17, which roughly says that we can decompose each forbidden subgraph into colored q-bounded disc types. This leads to the following idea: First, we prove that for any colored q-bounded disc type Δ, if q-RBFS finds an instance of Δ in the input graph with probability p (where colors correspond to intersections of multiple RBFS), then q-SC finds an instance of Δ with probability cp for some suitable constant c. Then, we prove that if S is a sufficiently large set of vertices sampled uniformly at random, for each colored q-bounded disc type Δ, the fraction of q-bounded discs found by q-SCs started from S that are isomorphic to Δ is bounded from below by the probability that a q-RBFS from a random vertex sees a colored q-bounded disc that is isomorphic to Δ. Finally, in the next section, we conclude that if q-RBFS finds a forbidden subgraph $F \in \mathcal{F}$ with probability p, then the fraction of q-SC also finds this subgraph with probability cp (for some suitable constant c) because it will find the corresponding colored q-bounded discs that assemble F.

Collecting a q-Bounded Disc in a Stream. In our streaming algorithm, we need to collect a q-bounded disc from a vertex v. We do this in a natural and greedy way: We start with a graph $H = (U, F)$ with $U = \{v\}$ and $F = \emptyset$. Then whenever we see an edge (u, w) from the stream that is connected to our current graph H and adding (u, w) to H does not violate the q-bounded radius of H, and the degree of u or the degree of w in H is still less than q^{2q}, we add it to F (and possibly add one of its endpoints to U); otherwise, we simply ignore the edge. Note that the algorithm does not assign colors to the subgraphs it explores. The procedure StreamCollect is formally defined in Algorithm 2 in Appendix B.

Relation of One q-SC and One q-RBFS. In the following, we show that for any vertex v, and any colored q-bounded disc C of v, the probability of collecting C from v by running StreamCollect on a random order edge stream is at least a constant factor of the probability of reaching C from v by running a q-RBFS on G. The statements in this subsection hold for a single run of q-SC.

We emphasize that the coloring does not need to be explicitly given. It is sufficient if it can be applied when random access to the graph is given. In particular, we may assign each vertex in V_α a unique color. This enables us to identify the vertices where multiple q-RBFS may intersect, which is crucial to apply Theorem 17 later.

▶ **Lemma 18.** *Let G be a vertex-colored graph. There exists a constant $c_*(q)$ depending on q, such that for any colored q-bounded disc C of G, it holds that the probability (over $\mathcal{S}(G)$) that StreamCollect($\mathcal{S}(G), v, q$) contains C is at least $c_*(q) \cdot \mathrm{Reach}_G(v, C)$.*

The following lemma performs the step from q-bounded discs to q-bounded disc *types*.

▶ **Lemma 19.** *Let Δ be a fixed colored q-bounded disc type. Let $X_{v,\Delta}$ denote the indicator variable that StreamCollect from v collects a subgraph that contains a colored q-bounded disc of v that is isomorphic to Δ. Let Y_v denote the indicator variable that RandomBFS from v sees a colored q-bounded disc of v that is isomorphic to Δ. Then it holds that $\mathrm{E}_{\mathcal{S}(G)}[X_{v,\Delta}] \geq c_*(q) \cdot \mathrm{E}_{RBFS}[Y_v]$, where $c_*(q)$ is the constant from Lemma 18.*

Now we consider the probability of seeing a colored q-disc type Δ. Note that $\mathrm{E}_{\mathcal{S}(G)}[X_{v,\Delta}] = \Pr_{\mathcal{S}(G)}[\text{StreamCollect}(\mathcal{S}(G), v, q)$ contains a subgraph F with $F \simeq \Delta]$. Furthermore, it holds that $\mathrm{E}_{RBFS}[Y_v] = \mathrm{Reach}_G(v, \Delta)$. Thus, we have the following lemma.

▶ **Corollary 20.** *For any colored q-bounded disc type Δ, the probability (over $\mathcal{S}(G)$) that* StreamCollect*$(\mathcal{S}(G),v,q)$ contains a subgraph F with $F \simeq \Delta$ is at least $c_*(q) \cdot \mathrm{Reach}_G(v, \Delta)$.*

Relation of Multiple q-SCs and q-RBFS. In the above, we related a single run of q-RBFS and a single run of q-SC. In particular, Corollary 20 states that if a q-RBFS starting from v finds some colored q-bounded disc type Δ with probability p, q-SC finds the same type Δ with probability $\Omega(p)$. However, the forbidden subgraphs that the property tester aims to find may be composed of more than one q-bounded disc. Therefore, we need to prove that if multiple runs of q-RBFS find q-bounded disc types $\Delta_1, \ldots, \Delta_k$ whose union contains an instance of a forbidden subgraph $F \in \mathcal{F}'_n$, then multiple runs of q-SC will find $\Delta_1, \ldots, \Delta_k$ with probability $\Omega(p)$.

We now show our main technical lemma on estimating the reach probability of q-bounded disc types in random order streams. Again, the coloring of vertices in G is implicit and only used for the analysis.

▶ **Lemma 21.** *Let $G = (V, E)$ be a graph defined by a random order stream and let all vertices in V_α be colored. Let $q > 0$ be an integer and let $c'_q := \sum_{i=0}^{q+1} q^{2qi}$. Let $\delta > 0$, and let S denote a set of vertices that are chosen uniformly, where $s := |S| \geq \max\left\{\frac{1}{20\sqrt{\alpha q^{2q} \cdot c'_q}}, \frac{5000|\mathcal{H}_q|}{c_*(q)\delta^3}\right\}$, $\alpha := \frac{c_*(q)^4\delta^8}{10^9|\mathcal{H}_q|^2 q^{2q} c'_q}$. Let $\mathcal{J} := \{H_v : H_v =$ StreamCollect$(\mathcal{S}(G), v, q), v \in S\}$ denote the set of colored q-bounded discs collected by* StreamCollect *from vertices in S. For each type $\Delta \in \mathcal{H}_q$, let X_Δ denote the number of graphs H in $\mathcal{J}$ such that H contains a subgraph F with $F \simeq \Delta$.*

Then it holds that with probability at least $1 - \frac{1}{100}$, for each type $\Delta \in \mathcal{H}_q$, $q_\Delta := \frac{1}{c_*(q)} \cdot \frac{X_\Delta}{s} \geq \mathrm{Reach}_G(\Delta) - \delta$, where $c_*(q)$ is a constant from Corollary 20.

5 Testing Graph Properties in Random Order Streams

Now we transform constant-query property testers (with one-sided error) into constant-space streaming property testers, and prove Theorem 4. The main idea is to explore the streamed graph by StreamCollect and look for the forbidden subgraphs in $\mathcal{F}_n$ that characterize Π (see Theorem 10). However, in the underlying analysis, we use the (reversible) decomposition of the forbidden subgraphs in $\mathcal{F}_n$ into $\mathcal{F}'_n$ (see Theorem 17) to prove the following: if $\mathcal{T}$ finds the colored q-bounded discs $\Delta_1, \ldots, \Delta_k$ that compose a forbidden subgraph $F \in \mathcal{F}'_n$ with probability p, then the streaming tester will find at least as many copies of $\Delta_1, \ldots, \Delta_k$ as $\mathcal{T}$ (see Lemma 21) and can stitch F from these copies. With these tools at hand, we can incorporate our analysis from previous sections to complete the proof of Theorem 4 (see Appendix C).

6 Conclusions

We gave the first canonical testers for all constant-query testers in the random-neighbor model for general graphs and show that one can emulate any constant-query tester with one-sided error in this query model in the random-order streaming model with constant space. Our transformation between constant-query testers and streaming algorithms with constant space provides a strong and formal evidence that property testing and streaming algorithms are very closely related. Our results also work for any restricted class of general graphs and other query models, e.g., random neighbor/edge model. It follows that many properties are constant-space testable (with one-sided error) in random order streams, including (s,t)-disconnectivity, being d-bounded degree, k-path-freeness of general graphs and bipartiteness and H-freeness of planar (or minor-free) graphs.

A Missing Illustrations from Section 1

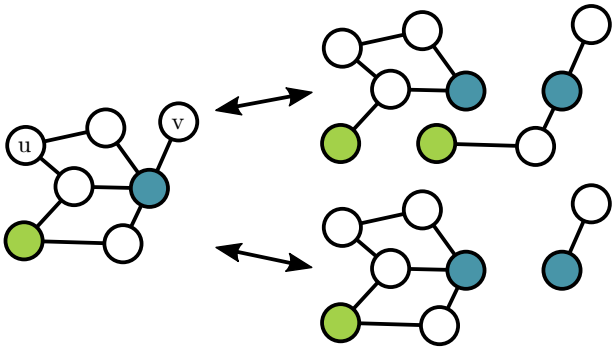

Figure 1 Consider the graph on the left, which can be decomposed into colored 3-bounded disc types (which are rooted at u and v in this example) in more than one way. However, it is always possible to recover the original graph by identifying vertices of the same color. Furthermore, every mapping is bijective because every color is assigned at most once per disc. If the colored vertices correspond to the vertices in V_α, every forbidden graph $F \in \mathcal{F}_n$ from Theorem 10 corresponds to a decomposition into edge-disjoint colored q-bounded discs $F' \in \mathcal{F}'_n$ in Theorem 17, which intersect only at colored vertices.

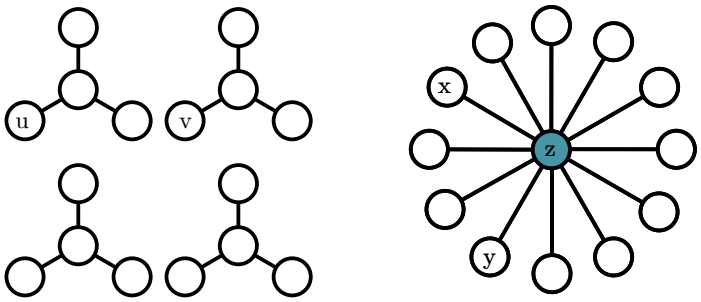

Figure 2 The above graph, which is composed of 3-stars and a $\omega(1)$-star with root z and which should be thought of as a subgraph of some larger graph, illustrates the need for colors in our analysis of the streaming property tester. Although the 2-bounded discs of u, v x and y are all 3-stars (with constant probability over the randomness of the neighbor queries), exploring u and v by q-RBFS does not result in finding a 6-star, while it is likely to find a 6-star by exploring x and y. Even if we prove that the probability that a q-SC finds uncolored 3-stars is lower bounded by some constant fraction of the probability that q-RBFS finds uncolored 3-stars, we still cannot rule out that q-SC might tend to find leaves of the small stars (like u and v) while q-RBFS tends to find leaves of the big star (like x and y). Observe that here, z is the only vertex that is likely contained in two different q-RBFS due to its high degree.

B Missing Pseudocodes from Section 3 and 4

The pseudocodes for the q-random BFS and for collecting a q-bounded disc from a vertex in stream are given below.

Algorithm 1 q-random BFS.

function RandomBFS(G, v, q)
  $Q \leftarrow$ empty queue; enqueue(Q, v)
  $\forall w \in V : \ell[w] \leftarrow \infty$
  $\ell[v] \leftarrow 0$
  $H \leftarrow (\{v\}, \emptyset)$ with v as root
  while Q not empty **do**
    $u \leftarrow$ pop element from Q
    for $1 \leq i \leq q$ **do**
      $s_{u,i} \leftarrow$ query oracle for random neighbor of u
      add vertex $s_{u,i}$ and edge $(u, s_{u,i})$ to H
      if $(\ell[u] < q - 1) \wedge (\ell[s_{u,i}] = \infty)$ **then**
        $\ell[s_{u,i}] \leftarrow \ell[u] + 1$
        enqueue$(Q, s_{u,i})$
  return undirected H without parallel edges
end function

Algorithm 2 Collecting a q-bounded disc from a vertex in stream.

function StreamCollect$(\mathcal{S}(G), v, q)$
  $U \leftarrow \{v\}$
  $\forall u \in V : d_u \leftarrow 0, \ell_u \leftarrow \infty$
  $\ell_v \leftarrow 0; F \leftarrow \emptyset$
  $H = (U, F)$ with v marked as root
  for $(u, w) \leftarrow$ next edge in the stream **do**
    if $(\{u, w\} \cap U \neq \emptyset)$ **then**
      if $(u \in U \Rightarrow (\ell_u < q \wedge d_u < q^{2q}) \vee (w \in U \Rightarrow (\ell_w < q \wedge d_w < q^{2q}))$ **then**
        $U \leftarrow U \cup \{u, w\}$
        $F \leftarrow F \cup (u, w)$
        $d_u \leftarrow d_u + 1; d_w \leftarrow d_w + 1$
        $\ell_u \leftarrow \min(\ell_u, \ell_w + 1); \ell_w \leftarrow \min(\ell_w, \ell_u + 1)$
  return H
end function

C Missing Proofs from Section 5

Proof of Theorem 4. We let $q_0 = q_0(\varepsilon)$ denote the query complexity of Π. Let $n = |V|$. We present our testing algorithm. Let $q = c \cdot q_0$ for some constant c from Theorem 10. Let $\alpha = \frac{c_*(q)^4 \delta^8}{10^9 |\mathcal{H}_q|^2 q^{2q} c'_q}$, where $c'_q = \sum_{i=0}^{q+1} q^{2qi}$, and $\delta = \frac{1}{200|\mathcal{H}_q|}$. If $n \leq n_0 := \frac{qc_q}{\alpha^2}$, then we simply store the whole graph. If $n > n_0$, we proceed as follows. Let $\mathcal{F}_n$ be the set of forbidden subgraphs that characterize Π as stated in Theorem 10. We sample $s \geq \max\{\frac{1}{20\sqrt{\alpha q^{2q} \cdot c'_q}}, \frac{5000|\mathcal{H}_q|}{c_*(q)\delta^3}\}$ vertices $S \subseteq V$ and run StreamCollect$(\mathcal{S}(G), v, q)$ for each $v \in S$ to obtain a subgraph $H_v = (V_v, E_v)$ of G. If $H = \cup_{v \in S} H_v$ contains a forbidden subgraph $F \in \mathcal{F}_n$, the tester rejects, otherwise it accepts. See Algorithm 3 for details.

Algorithm 3 Testing graph property Π in random order stream.

function StreamTest($\mathcal{S}(G), n, \varepsilon, \mathcal{F}_n$)
  $S \leftarrow$ sample s vertices u.a.r. from V
  for all $v \in S$ **do**
    $H_v \leftarrow (V_v, E_v) =$ StreamCollect($\mathcal{S}(G), v, q$)
  $H \leftarrow (\cup_v V_v, \cup_v E_v)$
  if there exists $F \in \mathcal{F}_n$ such that H contains a subgraph F **then**
    Output **Reject**
  else
    Output **Accept**
end function

The space complexity of the algorithm is $s \cdot q_0^{O(q_0)} = O_{q_0}(1)$ words. For the correctness of the algorithm, we note that for any property Π that is constant-query testable with one-sided error, then with probability 1, we will not see any $F \in \mathcal{F}'_n$ if the graph G satisfies Π.

On the other hand, if G is ε-far from satisfying Π, then by Theorem 17, with probability at least $\frac{2}{3}$, the subgraph S_q spanned by the union of q-bounded discs rooted at q uniformly sampled vertices from G will span a subgraph that is isomorphic to some $F \in \mathcal{F}'_n$. Note that, in contrast to the algorithm above, the analysis uses the decomposition of forbidden subgraphs in $\mathcal{F}_n$ into colored q-discs given by Theorem 17. The key idea is to use the q-bounded discs that StreamCollect collects and the implicit colors (which are not observed by StreamCollect, but can be used in the analysis to identify vertices in V_α) to stitch forbidden subgraphs from $\mathcal{F}'_n$ that are discovered by RandomBFS. We prove that with sufficient probability, for each colored q-bounded disc Δ, StreamCollect finds at least as many copies of Δ as RandomBFS, and therefore, it can reproduce the same types of forbidden subgraphs from $\mathcal{F}'_n$.

By Markov's inequality and the union bound, the probability that at least one q-RBFS in the canonical tester for Π will return a colored q-bounded disc that is isomorphic to a disc Δ' such that $\mathrm{Reach}_G(\Delta') < 2\delta = \frac{1}{100|\mathcal{H}_q|}$ is at most $\frac{1}{100}$. Let $\mathcal{D}$ be the set of all colored q-bounded discs Δ such that $\mathrm{Reach}_G(\Delta) \geq 2\delta$.

By Lemma 21, with probability at least $1 - \frac{1}{100}$, for every $\Delta \in \mathcal{D}$, the number of graphs H_v obtained by StreamCollect that contain a subgraph isomorphic to Δ is at least $100|\mathcal{H}_q| \cdot \mathrm{Reach}_G(\Delta) \geq 1$. By (implicitly) coloring all vertices in V_α, it follows from Theorem 17 that H contains a forbidden subgraph from $\mathcal{F}'_n$ with probability $1 - \frac{1}{100} - \frac{1}{100} > \frac{2}{3}$. ◀

Multicriteria Cuts and Size-Constrained k-Cuts in Hypergraphs

Abstract

We address counting and optimization variants of multicriteria global min-cut and size-constrained min-k-cut in hypergraphs.

1. For an r-rank n-vertex hypergraph endowed with t hyperedge-cost functions, we show that the number of multiobjective min-cuts is $O(r2^{tr}n^{3t-1})$. In particular, this shows that the number of parametric min-cuts in constant rank hypergraphs for a constant number of criteria is strongly polynomial, thus resolving an open question by Aissi, Mahjoub, McCormick, and Queyranne [1]. In addition, we give randomized algorithms to enumerate all multiobjective min-cuts and all pareto-optimal cuts in strongly polynomial-time.
2. We also address node-budgeted multiobjective min-cuts: For an n-vertex hypergraph endowed with t vertex-weight functions, we show that the number of node-budgeted multiobjective min-cuts is $O(r2^r n^{t+2})$, where r is the rank of the hypergraph, and the number of node-budgeted b-multiobjective min-cuts for a fixed budget-vector $b \in \mathbb{R}^t_+$ is $O(n^2)$.
3. We show that min-k-cut in hypergraphs subject to constant lower bounds on part sizes is solvable in polynomial-time for constant k, thus resolving an open problem posed by Queyranne [11]. Our technique also shows that the number of optimal solutions is polynomial.

All of our results build on the random contraction approach of Karger [12]. Our techniques illustrate the versatility of the random contraction approach to address counting and algorithmic problems concerning multiobjective min-cuts and size-constrained k-cuts in hypergraphs.

1 Introduction

Cuts and partitioning play a central role in combinatorial optimization and have numerous theoretical as well as practical applications. We consider multicriteria cut problems in hypergraphs. Let $G = (V, E)$ be an n-vertex hypergraph and $c_1, \ldots, c_t : E \to \mathbb{Z}_+$ be t non-negative hyperedge-cost functions, where t is a constant. The cost of a subset F of hyperedges under criterion $i \in [t]$ is $c_i(F) := \sum_{e \in F} c_i(e)$. For a positive integer k, a subset

of hyperedges that crosses a k-partition $(U_1, \ldots, U_k)$ of the vertex set is said to be a k-cut. We refer to a 2-cut simply as a cut. We recall that the rank of a hypergraph G is the size of the largest hyperedge in G (the rank of a graph is 2).

Since we have several criteria, there may not be a single cut that is best for all criteria. In multicriteria optimization, there are three important notions to measure the quality of a cut: (i) parametric min-cuts, (ii) pareto-optimal cuts, and (iii) multiobjective min-cuts. A cut F is a *parametric min-cut* if there exist positive multipliers $\mu_1, \ldots, \mu_t \in \mathbb{R}_+$ such that F is a min-cut in the hypergraph G with hyperedge costs given by $c_\mu(e) := \sum_{i=1}^{t} \mu_i c_i(e)$ for all $e \in E$. A cut F *dominates* another cut F' if $c_i(F) \leq c_i(F')$ for every $i \in [t]$ and there exists $i \in [t]$ such that $c_i(F) < c_i(F')$. A cut F is *pareto-optimal* if it is not dominated by any other cut. For a budget-vector $b \in \mathbb{R}_+^{t-1}$, a cut F is a *b-multiobjective min-cut* if $c_i(F) \leq b_i$ for every $i \in [t-1]$ and $c_t(F)$ is minimum subject to these constraints. A cut F is a *multiobjective min-cut* if there exists a non-negative budget-vector $b \in \mathbb{R}_+^{t-1}$ for which F is a b-multiobjective min-cut. These three notions satisfy the following relationship with the containment being possibly strict (see the full version of this paper for a proof [4]):

$$\text{Parametric min-cuts} \subseteq \text{Pareto-optimal cuts} \subseteq \text{Multiobjective min-cuts}. \tag{1}$$

There is also a natural notion of min-cuts under node-weighted budget constraints. Let $w_1, \ldots, w_t : V \to \mathbb{R}_+$ be vertex-weight functions and $c : E \to \mathbb{R}_+$ be a hyperedge-cost function. For a budget-vector $b \in \mathbb{R}_+^t$, a subset $F \subseteq E$ of hyperedges is a *node-budgeted b-multiobjective min-cut* if $F = \delta(U)$ for some subset $\emptyset \neq U \subsetneq V$ with $\sum_{u \in U} w_i(u) \leq b_i$ for all $i \in [t]$ and $c(F)$ is minimum among all such subsets of E. A cut F is a *node-budgeted multiobjective min-cut* if there exists a non-negative budget-vector b for which F is a node-budgeted b-multiobjective min-cut. In this work, we address the following natural questions concerning multiobjective min-cuts and min-k-cuts:

1. Multiobjective min-cuts: Is the number of multiobjective min-cuts at most strongly polynomial?
2. Node-budgeted multiobjective min-cuts: Is the number of node-budgeted multiobjective min-cuts at most strongly polynomial?
3. Size-constrained min-k-cut: For fixed positive integers k and $s_1, \ldots, s_k$ (all constants), a vertex-weight function $w : V \to \mathbb{Z}_+$, and a hyperedge-cost function $c : E \to \mathbb{R}_+$, can we compute a k-cut F with minimum $c(F)$ subject to the constraint that F is the set of hyperedges crossing some k-partition $(U_1, \ldots, U_k)$ of V where $\sum_{u \in U_i} w(u) \geq s_i$ for every $i \in [k]$ in polynomial-time? Is the number of optimal solutions strongly polynomial?

Previous Work. For single criterion, a classic result of Dinitz, Karzanov, and Lomonosov [7] shows that the number of min-cuts in an n-vertex graph is $O(n^2)$ (also see Karger [12]). The same upper bound was shown to hold for constant-rank hypergraphs by Kogan and Krauthgamer [14] and for arbitrary-rank hypergraphs by Chekuri and Xu [6] and by Ghaffari, Karger, and Panigrahi [8] via completely different techniques. For $t = 2$ criteria in graphs, Mulmuley [15] showed an $O(n^{19})$ upper bound on the number of parametric min-cuts. For t criteria in constant-rank hypergraphs, Aissi, Mahjoub, McCormick, and Queyranne [1] showed that the number of parametric min-cuts is $\tilde{O}(m^t n^2)$, where m is the number of hyperedges, using the fact that the number of approximate min-cuts in constant-rank hypergraphs is polynomial. Karger [13] improved this bound to $O(n^{t+1})$ by a clever and subtle argument based on his random contraction algorithm; we will describe his argument later. Karger also constructed a graph that exhibited $\Omega(n^{t/2})$ parametric min-cuts.

Armon and Zwick [3] showed that all pareto-optimal cuts in graphs can be enumerated in pseudo-polynomial time. For $t = 2$ criteria in constant-rank hypergraphs, Aissi et al [1] showed an upper bound of $\tilde{O}(n^5)$ on the number of pareto-optimal cuts – this was the first result showing a strongly polynomial upper bound. Aissi et al raised the question of whether the number of pareto-optimal cuts is strongly polynomial for a constant number t of criteria in constant-rank hypergraphs (or even in graphs). Note that, by containment relationship (1), answering our first question affirmatively would also answer their open question. On a related note, Aissi, Mahjoub, and Ravi [2] designed a random contraction based algorithm to solve the b-multiobjective min-cut problem in graphs. The correctness analysis of their algorithm also implies that the number of b-multiobjective min-cuts in graphs for a fixed budget-vector $b \in \mathbb{R}_+^{t-1}$ is $O(n^{2t})$. We emphasize the subtle, but important, distinction between the number of b-multiobjective min-cuts for a fixed budget-vector b and the number of multiobjective min-cuts.

Node-budgeted multiobjective min-cut has a rich literature extending nicely to submodular functions. For graphs, Armon and Zwick [3] gave a polynomial-time algorithm to find a minimum valued cut with at most b vertices in the smaller side. Goemans and Soto [9] addressed the more general problem of minimizing a symmetric submodular function $f : 2^V \to \mathbb{R}$ over a downward-closed family $\mathcal{I}$. Recall that the hypergraph cut function is symmetric submodular and the family of vertex subsets satisfying node-weighted budget constraints is in fact downward-closed. Goemans and Soto extended Queyranne's submodular minimization algorithm to enumerate all the $O(n)$ minimal minimizers in $\mathcal{I}$ using $O(n^3)$ oracle calls to the function f and the family $\mathcal{I}$. Their result implies that the number of minimal minimizers is $O(n)$, but it is straightforward to see that the total number of minimizers could be exponential. For the special case of node-budgeted multiobjective min-cuts in graphs, Aissi, Mahjoub, and Ravi [2] gave a faster algorithm than that of Goemans and Soto – their algorithm is based on random contraction, runs in $\tilde{O}(n^2)$-time, and shows that the number node-budgeted b-multiobjective min-cuts in graphs for a fixed budget-vector $b \in \mathbb{R}_+^t$ is $O(n^2)$.

For size-constrained min-k-cut, if we allow arbitrary sizes (i.e., arbitrary lower bounds), then the problem becomes NP-hard even for $k = 2$ as it captures the well-studied min-bisection problem in graphs. If we consider constant sizes but arbitrary k, then the problem is again NP-hard in graphs [10]. So, our focus is on constant k and constant sizes. Guinez and Queyranne [11] raised size-constrained min-k-cut with unit vertex-weights as a subproblem towards resolving the complexity of the submodular k-partitioning problem. In submodular k-partitioning, we are given a submodular function $f : 2^V \to \mathbb{R}$ (by value oracle) and a fixed constant integer k (e.g., $k = 2, 3, 4, 5, \ldots$) and the goal is to find a k-partition $(U_1, \ldots, U_k)$ of the ground set V so as to minimize $\sum_{i=1}^{k} f(U_i)$. The complexity of even special cases of this problem are open: e.g., if the submodular function f is the cut function of a given hypergraph, then its complexity is unknown.[1] Guinez and Queyranne showed surprisingly strong non-crossing properties between optimum solutions to size-constrained $(k-1)$-partitioning (constant size lower bounds on the parts) and optimum solutions to k-partitioning. This motivated them to study the size-constrained min-k-cut problem in hypergraphs for unit vertex-weights as a special case. They showed that size-constrained min-k-cut for unit vertex-weights is solvable in polynomial-time in constant-rank hypergraphs

[1] We note that if the submodular function f is the cut function of a given hypergraph, then the submodular k-partition problem is not identical to hypergraph k-cut as the two objectives are different. However, if the submodular function is the cut function of a given graph, then the submodular k-partition problem coincides with the graph k-cut problem which is solvable in polynomial-time.

(with exponential run-time dependence on the rank) and mention the open problem of designing an algorithm for it in arbitrary-rank hypergraphs. The size-constrained min-k-cut problem for unit sizes (i.e., all size lower-bounds $s_1, \ldots, s_k$ are equal to one) is known as the hypergraph k-cut problem. The hypergraph k-cut problem was shown to admit a polynomial-time algorithm only recently [5] via a non-uniform random contraction algorithm.

1.1 Our Contributions

Our high-level contribution is in showing the versatility of the random contraction technique to address algorithmic and counting problems concerning multiobjective min-cuts and size-constrained min-k-cuts in hypergraphs. All of our results build on the random contraction technique with additional insights.

Our first result is a strongly polynomial upper bound on the number of multiobjective min-cuts in constant-rank hypergraphs.

▶ **Theorem 1.1.** *The number of multiobjective min-cuts in an r-rank, n-vertex hypergraph G with t hyperedge-cost functions is $O(r2^{rt}n^{3t-1})$.*

We emphasize that our upper bound is over all possible non-negative budget-vectors (in contrast to the number of b-multiobjective min-cuts for a fixed budget-vector b). Theorem 1.1 and Proposition 1 imply that the number of pareto-optimal cuts in constant-rank hypergraphs is $O(n^{3t-1})$ and hence, is strongly polynomial for constant number of criteria. This answers the main open question posed by Aissi, Mahjoub, McCormick, and Queyranne [1]. We also design randomized polynomial time algorithms to enumerate all multiobjective min-cuts and all pareto-optimal cuts in constant-rank hypergraphs (see Section A.3). Independent of our work, Rico Zenklusen has also shown Theorem 1.1. We learned after submission of this work that his approach leads to *deterministic* polynomial time algorithms to enumerate all multiobjective min-cuts and all pareto-optimal cuts in constant-rank hypergraphs.

Given the upper bound in Theorem 1.1, a discussion on the lower bound is in order. We recall that Karger [13] constructed a graph with t edge-cost functions that exhibited $\Omega(n^{t/2})$ parametric min-cuts. This is also a lower bound on the number of pareto-optimal cuts and multiobjective min-cuts by (1). We improve this lower bound for pareto-optimal cuts by constructing a graph with t edge-cost functions that exhibits $\Omega(n^t)$ pareto-optimal cuts (see Section A.4). Our instance also exhibits the same lower bound on the number of b-multiobjective min-cuts for a fixed budget-vector b.

Our next result is an upper bound on the number of node-budgeted multiobjective min-cuts and node-budgeted b-multiobjective min-cuts.

▶ **Theorem 1.2.** **1.** *The number of node-budgeted multiobjective min-cuts in an r-rank, n-vertex hypergraph with t vertex-weight functions is $O(r2^r n^{t+2})$.*

2. *For a fixed budget-vector $b \in \mathbb{R}^t_+$, the number of node-budgeted b-multiobjective min-cuts in an n-vertex hypergraph with t vertex-weight functions is $O(n^2)$.*

We draw the reader's attention to the distinction between the two parts in Theorem 1.2. The first part implies that the number of node-budgeted multiobjective min-cuts is strongly polynomial in constant-rank hypergraphs for constant number of vertex-weight functions. The second part implies that the number of node-budgeted b-multiobjective min-cuts for any fixed budget-vector $b \in \mathbb{R}^t_+$ is strongly polynomial in arbitrary-rank hypergraphs for any number t of vertex-weight functions.

Our final result shows that the size-constrained min-k-cut problem can be solved in polynomial time for constant k and constant sizes (in arbitrary-rank hypergraphs).

▶ **Theorem 1.3.** *Let $k \geq 2$ be a fixed positive integer and let $1 \leq s_1 \leq s_2 \leq \ldots \leq s_k$ be fixed positive integers. Let G be an n-vertex hypergraph with hyperedge-cost function $c : E \to \mathbb{R}_+$. Then, there exists a polynomial-time algorithm that takes (G, c) as input and returns a fixed w-weighted s-size-constrained min-k-cut for any choice of vertex-weight function $w : V \to \mathbb{Z}_+$ with probability $\Omega\left(\frac{1}{n^{2\sigma_{k-1}+1}}\right)$, where $\sigma_{k-1} := \sum_{i=1}^{k-1} s_i$.*

Theorem 1.3 resolves an open problem posed by Guinez and Queyranne [11]. A structural consequence of Theorem 1.3 is that the number of size-constrained min-k-cuts (over all possible node-weight functions $w : V \to \mathbb{Z}_+$) in a given hypergraph is polynomial for constant sizes and constant k.

We refer the reader to Table 1 for a comparison of known results and our contributions.

Table 1 Text in gray refers to known results while text in black illustrates results from this work. Here, t denotes the number of criteria (i.e., the number of hyperedge-cost/vertex-weight functions), r denotes the rank of the hypergraph, and n denotes the number of vertices.

1.2 Technical Overview

As mentioned earlier, all our results build on the random contraction technique introduced by Karger [12] to solve the global min-cut problem in graphs. Here, a *uniform* random edge of the graph is contracted in each step until the graph has only two nodes; the set of edges between the two nodes is returned as the cut. Karger showed that this algorithm returns a fixed global min-cut with probability $\Omega(n^{-2})$. As a consequence, the number of min-cuts in an n-vertex graph is $O(n^2)$. The algorithm extends naturally to r-rank hypergraphs, however the naive analysis will only show that the algorithm returns a fixed global min-cut with probability $\Omega(n^{-r})$. Kogan and Krauthgamer [14] introduced an LP-based analysis thereby showing that the algorithm indeed succeeds with probability $\Omega(2^{-r}n^{-2})$. As a consequence, the number of global min-cuts in constant-rank hypergraphs is also $O(n^2)$.

In a recent work, Karger observed that uniform random contraction can also be used to bound the number of parametric min-cuts in constant-rank hypergraphs. We describe his argument for graphs since two of our theorems build on it. Suppose we fix the multipliers

$\mu_1, \ldots, \mu_t$ in the parametric min-cut problem, then a fixed min c_μ-cost cut can be obtained with probability $\Omega(n^{-2})$ by running the random contraction algorithm with respect to the edge-cost function c_μ. Karger suggested an alternative viewpoint of the execution of the algorithm for the edge-cost function c_μ. For simplicity, we assume parallel edges instead of costs, i.e., $c_i(e) \in \{0, 1\}$ for every edge e and every criterion $i \in [t]$. Let E_i be the set of edges with non-zero weight in the i'th criterion. The execution of the random-contraction algorithm wrt c_μ can alternatively be specified as follows: a permutation π_i of the edges in E_i for each $i \in [t]$ and an *interleaving* indicating at each step whether the algorithm contracts the next edge from π_1 or π_2 or ... or π_t. Critically, the sequences π_i for every $i \in [t]$ can be assumed to be uniformly random. Thus, we can move all randomness upfront, namely pick a uniform random permutation π_i for each criterion $i \in [t]$. Now, instead of returning one cut, we return the collection of cuts produced by contracting along all possible interleavings. This modified algorithm no longer depends on the specific multipliers $\mu_1, \ldots, \mu_t$ and hence, a parametric min-cut for any fixed choice of multipliers $\mu_1, \ldots, \mu_t$ will be in the output collection with probability at least $\Omega(n^{-2})$. It remains to bound the number of interleavings since that determines the number of cuts in the returned collection: the crucial observation here is that the number of interesting interleavings is only n^{t-1}. This is because interleaved contractions produce the same final graph as performing a certain number of contractions according to π_1 (until the number of vertices is n_1 say), then a certain number of contractions based on π_2 (until the number of vertices is n_2 say), and so on. So, the order of contractions becomes irrelevant and only the number of vertices $n_1, \ldots, n_t$ are relevant. Overall, this implies that the number of parametric min-cuts is $O(n^{t+1})$. We emphasize that this *interleaving argument* relies crucially on the basic random contraction algorithm picking edges to contract according to a *uniform distribution* (allowing the permutations $\pi_1, \ldots, \pi_t$ to be uniform random permutations).

Next, we describe our approach underlying the proof of Theorem 1.1, but for graphs. In order to bound the number of multiobjective min-cuts through the interleaving argument, we first need a random-contraction based algorithm to solve the b-multiobjective min-cut problem. Indeed, Aissi, Mahjoub, and Ravi [2] designed a random-contraction based algorithm to solve the b-multiobjective min-cut problem in graphs. Their algorithm proceeds as follows: Let $U_0 := \emptyset$ and for each $i \in [t-1]$, let U_i be the set of vertices $u \in V - \cup_{j=1}^{i-1} U_j$ for which $c_i(\delta(u)) > b_i$ (known as the set of i-infeasible vertices), and let $U_t := V - \cup_{j=1}^{t-1} U_j$. In each step, they pick $i \in [t]$ with probability proportional to the number of i-infeasible vertices (i.e., $|U_i|$) and pick a random edge e among the ones incident to U_i with probability proportional to $c_i(e)$, contract e, and repeat. Unfortunately, this algorithm does not have the *uniform distribution* that is crucially necessary to apply Karger's interleaving argument. To introduce uniformity to the distribution, we modify this algorithm in two ways:

1. At each step we deterministically choose the criterion i corresponding to the largest U_i (as opposed to picking i randomly with probability proportional to $|U_i|$).
2. Next, we choose a uniform random edge e from among all edges in the graph with probability proportional to $c_i(e)$ (as opposed to picking an edge only from among the edges incident to U_i). We contract this chosen edge e.

These two features bring a *uniform distribution* property to the algorithm, which in turn, allows us to apply the interleaving argument. With these two features, we show that the algorithm returns a fixed b-multiobjective min-cut for a fixed budget-vector b with probability $\Omega(n^{-2t})$. Armed with the two features, we move all randomness upfront using the interleaving argument. As a consequence, we obtain that the total number of multiobjective min-cuts (irrespective of the choice of budget-vector b) is $O(n^{3t-1})$. For constant-rank hypergraphs, we

perform an LP-based analysis of our algorithm for b-multiobjective min-cut (thus, extending Kogan and Krauthgamer's analysis) to arrive at the same success probability. The interleaving argument for constant-rank hypergraphs proceeds similarly.

We emphasize that the interleaving argument does not extend to arbitrary-rank hypergraphs. This is because, the random contraction based algorithm that we know for arbitrary-rank hypergraphs crucially requires non-uniform contractions (the next hyperedge to contract is chosen from a distribution that depends on the current sizes of all hyperedges), so we cannot assume that the permutations $\pi_1, \pi_2, \ldots, \pi_t$ are uniformly random. Consequently, we do not even know if the number of parametric min-cuts in a hypergraph is at most strongly polynomial. Another interesting open question here is whether the b-multiobjective min-cut problem in hypergraphs is solvable in polynomial-time even for $t = 2$ criteria. We have arrived at hypergraph instances (with large rank) for which Aissi, Mahjoub, and Ravi's approach (as well as our modified approach) will never succeed, even with non-uniform random contractions.

Next, we outline the proof of Theorem 1.2. The approach is to again design a random-contraction algorithm that returns a fixed node-budgeted b-multiobjective min-cut with probability $\Omega(n^{-2})$ (in both constant-rank and arbitrary-rank hypergraphs). Such an algorithm would imply the second part of the theorem immediately while the first part would follow if we can apply an interleaving-like argument (i.e., the designed algorithm performs uniform random contractions). Our approach is essentially an extension of the approach by Goemans and Soto who suggested contracting the infeasible vertices together (a vertex u is infeasible if $w_i(u) > b_i$ for some $i \in [t]$. Aissi, Mahjoub, and Ravi show that doing this additional step after each random contraction step returns a fixed node-budgeted b-multibjective min-cut with probability $\Omega(n^{-2})$ in graphs. Our main contribution is showing that this additional "contracting infeasible vertices together" step in conjunction with (1) uniform random contractions for constant-rank hypergraphs and (2) non-uniform random contractions for arbitrary hypergraphs succeeds with the required probability. Next, a naive interleaving-like argument can be applied for constant-rank hypergraphs to conclude that the number of node-budgeted multiobjective min-cuts is $O(n^{t+3})$. We improve this to $O(n^{t+2})$ with a more careful argument.

Finally, we outline our approach for Theorem 1.3. Guinez and Queyranne address size-constrained k-cut in constant-rank hypergraphs for unit vertex-weights by performing uniform random contractions until the number of nodes in the hypergraph is close to $\sum_{i=1}^{k} s_i$ at which point they return a uniform random cut. Their success probability has exponential dependence on the rank. The key technical ingredient to bring down the exponential dependence on rank is the use of non-uniform contractions. For the special case of unit sizes and unit vertex-weights (i.e., the hypergraph k-cut problem), Chandrasekaran, Xu, and Yu [5] introduced an explicit non-uniform distribution that leads to a success probability of $\Omega(n^{-2(k-1)})$. Our algorithm extends the non-uniform distribution to arbitrary but constant sizes (as opposed to just unit sizes), yet without depending on vertex-weights. Our analysis takes care of the vertex-weight function through weight tracking, i.e., by declaring the weight of a contracted node to be the sum of the weight of the vertices in the hyperedge being contracted. We note that our algorithm's success probability when specialized to the case of unit vertex-weights and unit sizes is weaker than the success probability of the algorithm by Chandrasekaran, Xu, and Yu (by a factor of n). We leave it as an open question to improve this. On the other hand, our algorithm has the added advantage that it does not even take the vertex-weight function w as input and yet succeeds in returning a w-vertex-weighted s-size-constrained k-cut for any choice of w with inverse polynomial probability.

Organization. In Section 2, we bound the number of multiobjective min-cuts (and prove Theorem 1.1). Due to page limit, we give efficient algorithms to enumerate all multiobjective min-cuts and all pareto-optimal cuts, and present lower bounds on the number of pareto-optimal cuts and the number of b-multiobjective min-cuts in the appendix. In Section 3, we give an algorithm to solve size-constrained min-k-cut, thereby proving Theorem 1.3. Due to page limit, we defer the details of node-budgeted multiobjective min-cuts and a proof of Theorem 1.2 to the full version of the paper [4].

1.3 Preliminaries

We define the random contraction procedure that is central to all of our algorithms. Let $G = (V, E)$ be a hypergraph, and let $U \subseteq V$ be a set of vertices in G. We define G *contract* U, denoted G/U, to be a hypergraph on the vertex set $(V \setminus U) \cup \{u\}$, where u is a newly introduced vertex. The hyperedges of G/U are defined as follows. For each hyperedge $e \in E$ of G, such that $e \not\subseteq U$, G/U has a corresponding hyperedge e', where $e' := e$ if $e \subseteq V \setminus U$ and $e' := (e \setminus U) \cup \{u\}$ otherwise. If w is a vertex-weight function for G, then we will also use w as a vertex-weight function for G/U. We define the weight of the newly introduced vertex u as $w(u) := \sum_{v \in U} w(v)$.

We will need the following lemma that will be used in the analysis of two of our algorithms. We refer the reader to the full version of this paper for the proof.

▶ **Lemma 1.4.** *Let r, γ, n be positive integers with $n \geq \gamma \geq r + 1 > 2$. Let $f : \mathbb{N} \to \mathbb{R}_+$ be a positive-valued function defined over natural numbers. Then, the optimum value of the linear program (LP_1) defined below is* $\min_{2 \leq j \leq r}(1 - \frac{j}{\gamma - r + j}) f(n - j + 1)$.

$$\underset{x_2,\ldots,x_r,y_2,\ldots,y_r}{\textit{minimize}} \quad \sum_{j=2}^{r} (x_j - y_j) f(n - j + 1) \tag{LP_1}$$

$$\textit{subject to} \quad 0 \leq y_j \leq x_j \ \forall j \in \{2, \ldots, r\} \tag{2}$$

$$\sum_{j=2}^{r} x_j = 1 \tag{3}$$

$$\gamma \sum_{j=2}^{r} y_j \leq \sum_{j=2}^{r} j \cdot x_j \tag{4}$$

2 Multiobjective Min-Cuts and Pareto-Optimal Cuts

In this section, we give upper and lower bounds on the number of multiobjective min-cuts and pareto-optimal cuts and prove Theorem 1.1.

Let $G = (V, E)$ be an r-rank hypergraph and let $c_1, \ldots, c_t : E \to \mathbb{R}_+$ be cost functions on the hyperedges of G. For a subset F of hyperedges, we will use $c_i(F)$ to denote $\sum_{e \in F} c_i(e)$. For a subset U of vertices, we will use $\overline{U}$ to denote $V \setminus U$ and $\delta(U)$ to denote the set of hyperedges that intersect both U and $\overline{U}$. For a vertex v, we will use $\delta(v)$ to denote $\delta(\{v\})$. A subset F of hyperedges is a cut if there exists a partition $(U, \overline{U})$ such that $F = \delta(U)$. We refer the reader to Section 1 for the definitions of b-multiobjective min-cuts, multiobjective min-cuts, and pareto-optimal cuts.

We begin with a randomized algorithm for the b-multiobjective min-cut problem in Section 2.1. We take an alternative viewpoint of this randomized algorithm in Section 2.2 to prove Theorem 1.1. Since all pareto-optimal cuts are multiobjective min-cuts, Theorem 1.1

also implies that the number of pareto-optimal cuts in an r-rank n-vertex hypergraph G with t hyperedge-cost functions is $O(r2^{rt}n^{3t-1})$. In Section A.3, we give randomized polynomial-time algorithms to enumerate all pareto-optimal cuts and all multiobjective min-cuts. In Section A.4, we show a lower bound of $\Omega(n^t)$ on the number of pareto-optimal cuts and on the number of b-multiobjective min-cuts.

2.1 Finding b-Multiobjective Min-Cuts

In this section, we design a randomized algorithm for the b-multiobjective min-cut problem, which is formally defined below. We use Algorithm 1. We summarize its correctness and run-time guarantees in Theorem 2.1.

b-Multiobjective Min-Cut
Given: A hypergraph $G = (V, E)$ with hyperedge-cost functions $c_1, \ldots, c_t : E \to \mathbb{R}_+$ and a budget-vector $b \in \mathbb{R}_+^{t-1}$.
Goal: A b-multiobjective min-cut.

Algorithm 1 b-Multiobjective Min-Cut.

b-Multiobjective-Min-Cut(G, r, t, c, b):

Input: An r-rank hypergraph $G = (V, E)$, hyperedge-cost functions $c_1, \ldots, c_t : E \to \mathbb{R}_+$ and a budget-vector $b \in \mathbb{R}_+^{t-1}$.

If $|V| \leq rt$:
  $X \leftarrow$ a random subset of V
  return $\delta(X)$
For $i = 1, \ldots, t-1$:
  $U_i \leftarrow \{v \in V \setminus (\bigcup_{j=1}^{i-1} U_j) \colon c_i(\delta(v)) > b_i\}$
$U_t \leftarrow V \setminus \bigcup_{j=1}^{t-1} U_j$
$i \leftarrow \arg\max_{j \in [t]} |U_j|$
$e \leftarrow$ a random hyperedge chosen according to $\Pr[e = e'] = \frac{c_i(e')}{c_i(E)}$
$G' \leftarrow G/e$
Return b-Multiobjective-Min-Cut(G', r, t, c, b)

▶ **Theorem 2.1.** *Let $G = (V, E)$ be an r-rank n-vertex hypergraph with hyperedge-cost functions $c_1, \ldots, c_t : E \to \mathbb{R}_+$ and let $b \in \mathbb{R}_+^{t-1}$ be a budget-vector. Let F be an arbitrary b-multiobjective min-cut. Then, Algorithm 1 outputs F with probability at least Q_n, where*

$$Q_n := \begin{cases} \frac{1}{2^{rt}} & \text{if } n \leq rt, \text{ and} \\ \frac{2t+1}{2^{rt}(rt+1)} \binom{n-t(r-2)}{2t}^{-1} & \text{if } n > rt. \end{cases}$$

Moreover, the algorithm can be implemented to run in polynomial time.

Proof. We note that sets U_i can be computed in polynomial time, and the algorithm recomputes them at most n times. Random contraction can also be implemented in polynomial time, and therefore the overall run-time of the algorithm is polynomial.

We now bound the correctness probability by induction on n. For the base case, we consider $n \leq rt$. In this case, the algorithm returns $\delta(X)$ for a random $X \subseteq V$. There are 2^n possible values for X, and $F = \delta(X)$ for at least one of them. Thus, the probability that the algorithm returns F is at least $\frac{1}{2^n} \geq \frac{1}{2^{rt}} = Q_n$.

Next, we prove the induction step. Suppose $n > rt$. We will need the following claim whose proof appears in the appendix.

▷ Claim 2.2. The algorithm outputs F with probability at least the optimum value of the following linear program.

$$\begin{aligned} \underset{x_2,\ldots,x_r,y_2,\ldots,y_r}{\text{minimize}} \quad & \sum_{j=2}^{r}(x_j - y_j)Q_{n-j+1} && (LP_2)\\ \text{subject to} \quad & 0 \le y_j \le x_j \ \forall j \in \{2,\ldots,r\} \\ & \sum_{j=2}^{r} x_j = 1 \\ & |U_i| \sum_{j=2}^{r} y_j \le \sum_{j=2}^{r} j \cdot x_j \end{aligned}$$

Let U_i be a the largest among the sets $U_1, \ldots, U_t$ that the algorithm generates when executed on input (G, r, t, c, b). Claim 2.2 tells us that the algorithm outputs F with probability at least the optimum value of the linear program (LP_2) from the claim.

The linear program (LP_2) is exactly the linear program (LP_1) from Lemma 1.4 with $\gamma = |U_i|$ and $f(n) := Q_n$. To apply Lemma 1.4, we just need to show that $n \ge |U_i| \ge r + 1$. We recall that U_i is the largest of the t sets that the algorithm constructs. Each of these sets is a subset of V, so we can conclude that $|U_i| \le |V| = n$. We also know from the the construction of the sets $U_1, \ldots, U_t$ that they partition V. This means that $\sum_{j=1}^{t} |U_j| = n$. Since U_i is the largest of the sets, we must have $|U_i| \ge \frac{n}{t}$. Since $n > rt$, this means $|U_i| \ge \frac{rt+1}{t} > r$. Thus $|U_i| > r$, and since r and $|U_i|$ are integers, we conclude that $|U_i| \ge r + 1$. Therefore, we can apply Lemma 1.4 with $\gamma = |U_i|$ to conclude that

$$\Pr[\text{Algorithm returns the cut } F] \ge \min_{2 \le j \le r} \left(1 - \frac{j}{|U_i| - r + j}\right) Q_{n-j+1}.$$

The following claim completes the proof of the theorem. Its proof appears in the appendix. ◀

▷ Claim 2.3. For every $j \in \{2, \ldots, r\}$, we have $\left(1 - \frac{j}{|U_i|-r+j}\right) Q_{n-j+1} \ge Q_n$.

2.2 Finding Multiobjective Min-Cuts

In this section, we present Algorithm 2, which does *not* take a budget-vector as input, yet outputs any multiobjective min-cut (for any choice of budget-vector) with inverse polynomial probability. This is accomplished by returning a collection of cuts.

In contrast to Algorithm 1, all of the randomness in Algorithm 2 (except for the selection of a random cut in the base case) occurs upfront through the selection of a permutation of the hyperedges. Theorem 2.4 summarizes the guarantees of Algorithm 2.

▶ **Theorem 2.4.** *Let G be an r-rank, n-vertex hypergraph with t hyperedge-cost functions. Then, a fixed multiobjective min-cut F is in the collection returned by Algorithm 2 with probability $\frac{\Omega(n^{-2t})}{r2^{rt}}$. Moreover, the algorithm outputs at most n^{t-1} cuts.*

Proof. We begin by showing the second part of the theorem. The algorithm outputs at most one cut for each choice of $n_1, \ldots, n_{t-1} \in [n]$ (or just one cut if $|V| \le rt$). Hence, it outputs at most n^{t-1} cuts.

We now argue that the algorithm retains the same success probability as Algorithm 1, for any fixed budget-vector b.

Algorithm 2 Multiobjective Min-Cut.

Multiobjective-Min-Cut$(G, r, t, c_1, \ldots, c_t)$:

Input: An r-rank hypergraph $G = (V, E)$ and hyperedge-cost functions $c_1, \ldots, c_t : E \to \mathbb{R}_+$.

If $|V| \leq rt$:
  Pick a random subset X of V and return $\delta(X)$
For $i = 1, \ldots, t$:
  $E_i \leftarrow \{e \in E \colon c_i(e) > 0\}$
  $\pi_i \leftarrow$ a permutation of E_i generated by repeatedly choosing a not yet chosen hyperedge e with probability proportional to $c_i(e)$
$R \leftarrow \emptyset$
For each sequence $n_1, \ldots n_t$ with $n \geq n_1 \geq n_2 \geq \cdots \geq n_{t-1} \geq n_t = rt$:
  $G' \leftarrow G$
  For $i = 1, \ldots, t$:
    While $|V(G')| > n_i$:
      $e \leftarrow$ the first hyperedge from π_i that is still present in G'
      $G' \leftarrow G'/e$
  $X \leftarrow$ a random subset of $V(G')$
  Add $\delta(X)$ to R if it is not already present
Return R

Suppose $n \leq rt$. Then both Algorithm 2 and Algorithm 1 return $\delta(X)$ for a random subset X of the vertices of G. Thus, for any cut F, the two algorithms have the same probability of returning F. Henceforth, we assume $n > rt$.

We will view Algorithm 1 from a different perspective. In that algorithm, whenever we contract a hyperedge e, we choose, for some $i \in [t]$, a hyperedge according to the probability distribution $\Pr[e = e'] = \frac{c_i(e')}{c_i(E)}$. In particular, the choice of i depends on which contractions have been made so far, but the choice of a particular hyperedge, given the choice of i, does not depend on our previous contractions, except for the fact that we do not contract hyperedges which have already been reduced to singletons. We note that allowing the contraction of singletons would not change the success probability of the algorithm.

Therefore, we could modify Algorithm 1 so that it begins by selecting permutations $\pi_1, \ldots, \pi_t$ of $E_1, \ldots, E_t$ (where $E_i = \{e \in E \colon c_i(e) > 0\}$) as in Algorithm 2, and then whenever the algorithm asks to contract a random hyperedge with probability proportional to its weight under c_i, we instead contract the next hyperedge from π_i which is still present in the current hypergraph. This modification does not change at any step the probability that a particular hyperedge is the next contraction of a non-singleton hyperedge, and therefore the success probability of the algorithm remains exactly the same.

Viewing Algorithm 1 in this way, we note that when we reach the base case of $n \leq rt$, we will have contracted the first m_i hyperedges of each π_i, for some $m_1, \ldots, m_t \in \{0, \ldots |E|\}$. The crucial observation now is that interleaved contractions can be separated. That is, if we know m_i for every $i \in [t]$, the order in which we do the contractions is irrelevant: we will get the same resulting hypergraph if we contract the first m_1 hyperedges from π_1, then contract the first m_2 hyperedges from π_2, and so on up through the first m_t hyperedges from π_t instead of the interleaved contractions. Let n_1 be the number of vertices in the hypergraph obtained after contracting the first m_1 hyperedges from π_1, subsequently, let n_2 be the number of vertices in the hypergraph obtained after contracting the first m_2 hyperedges from π_2 and so on.

When we view Algorithm 1 in this way, it is only the choice of the values $n_1, \ldots, n_t$ that depends on the budgets, while the choice of the permutation π_i does not depend on the budgets. Algorithm 2 is running exactly the version of Algorithm 1 that we have just described, except that instead of choosing $n_1, \ldots, n_t$ based on the budgets, it simply tries all possible options (which will certainly include whichever $n_1, \ldots, n_t$ Algorithm 1 would use for the given input budget-vector).

Therefore for every fixed choice of budget-vector b, and every fixed b-multiobjective min-cut F, the probability that F is in the collection R output by the algorithm is at least as large as the probability that F is the cut output by Algorithm 1. By Theorem 2.1, this probability is $\frac{\Omega(n^{-2t})}{r2^{rt}}$, as desired. ◀

We derive Theorem 1.1 from Theorem 2.4 now.

▶ **Theorem 1.1.** *The number of multiobjective min-cuts in an r-rank, n-vertex hypergraph G with t hyperedge-cost functions is $O(r2^{rt}n^{3t-1})$.*

Proof. Let x be the number of multiobjective min-cuts in G. By Theorem 2.4, the expected number of multiobjective min-cuts output by our algorithm Multiobjective Min-Cut (i.e., Algorithm 2) is $(x/r2^{rt})\Omega(n^{-2t})$. Theorem 2.4 also tells us that the algorithm outputs at most n^{t-1} cuts. Therefore, $x = r2^{rt} \cdot O(n^{3t-1})$. ◀

3 Size-Constrained Min-k-Cut in Arbitrary-Rank Hypergraphs

In this section, we consider the problem of finding a minimum cost k-cut subject to constant lower bounds on the weights of the partition classes and prove Theorem 1.3. Throughout this section, we assume that k is a constant. We focus on the cardinality case (i.e., unit-cost variant) for the sake of simplicity of exposition and mention that our algorithm also extends to arbitrary non-negative hyperedge costs.

We begin by formally defining the terminology. Let $G = (V, E)$ be a hypergraph. For a partition $X = (X_1, \ldots, X_k)$ of V, we define $\delta(X)$ to be the set of hyperedges that intersect at least two parts of X. For a weight function $w : V \to \mathbb{Z}_+$, we call (G, w) a *vertex-weighted hypergraph*. We now define our main object of study, namely size-constrained minimum cuts.

▶ **Definition 3.1.** *Let $G = (V, E)$ be a hypergraph, $w : V \to \mathbb{Z}_+$ be a vertex-weight function, $k \geq 2$ be an integer, and $s \in \mathbb{Z}_+^k$ be a size-vector. A k-partition X of V is an* s-size-constrained k-partition *if $w(X_i) \geq s_i$ for every $i \in [k]$. A set of hyperedges $F \subseteq E$ is an* s-size-constrained k-cut *if $F = \delta(X)$ for some s-size-constrained k-partition X. An s-size-constrained k-cut of minimum cardinality is said to be an* s-size-constrained min-k-cut.

The following is the central problem of interest in this section.

s-Size-Constrained Min-k-Cut
Given: A vertex-weighted hypergraph (G, w), a positive integer k, and a size-vector $s \in \mathbb{Z}_+^k$.
Goal: An s-size-constrained min-k-cut.

We give a random contraction based algorithm for this problem. Given a hypergraph $G = (V, E)$ and a size-constraint vector $s \in \mathbb{Z}_+^k$, let $n = |V|$. We define $\sigma_j := \sum_{i=1}^{j} s_i$, and $\alpha_e := \frac{\binom{n-|e|}{\sigma_{k-1}}}{\binom{n}{\sigma_{k-1}}}$. With these definitions, we solve s-size-constrained min-k-cut using Algorithm 3. We prove Theorem 1.3 using this algorithm.

Algorithm 3 s-Size-Constrained Min-k-Cut.

s-Size-Constrained-Min-k-Cut(G, k, s):

Input: An n-vertex hypergraph $G = (V, E)$, an integer $k \geq 2$ and size-constraint vector $s = (s_1, \ldots, s_k) \in \mathbb{Z}_+$

If $n \leq \max\{2\sigma_{k-1}, \sigma_k\}$
  Pick a random k-partition X of V and return $\delta(X)$
$S \leftarrow$ a random subset of V of size $2\sigma_{k-1}$
$X_i \leftarrow \emptyset$ for $i \in \{1, \ldots, k\}$
For each $v \in S$:
  Pick a random integer $i \in \{1, \ldots, k\}$ and add v to X_i
$X_k \leftarrow X_k \cup (V \setminus S)$
$X \leftarrow (X_1, \ldots, X_k)$
If X is a k-partition of V:
  $R \leftarrow \delta(X)$
Else:
  $R \leftarrow E$
Compute $\alpha_e := \frac{\binom{n-|e|}{\sigma_{k-1}}}{\binom{n}{\sigma_{k-1}}}$ for every $e \in E$
If $\alpha_e = 0$ for every hyperedge $e \in E(G)$:
  Return R
$e \leftarrow$ a random hyperedge of G chosen with probability proportional to α_e
$R' \leftarrow$ s-Size-Constrained-Min-k-Cut$(G/e, k, s)$
Return R with probability $\frac{1}{n}$ and R' with probability $\frac{n-1}{n}$

▶ **Theorem 1.3.** *Let $k \geq 2$ be a fixed positive integer and let $1 \leq s_1 \leq s_2 \leq \ldots \leq s_k$ be fixed positive integers. Let G be an n-vertex hypergraph with hyperedge-cost function $c : E \to \mathbb{R}_+$. Then, there exists a polynomial-time algorithm that takes (G, c) as input and returns a fixed w-weighted s-size-constrained min-k-cut for any choice of vertex-weight function $w : V \to \mathbb{Z}_+$ with probability $\Omega\left(\frac{1}{n^{2\sigma_{k-1}+1}}\right)$, where $\sigma_{k-1} := \sum_{i=1}^{k-1} s_i$.*

Proof. We consider Algorithm 3. We first analyze its run-time. Each recursive call reduces the number of vertices in the hypergraph. Thus, the algorithm makes at most n recursive calls. Apart from the recursion steps, the algorithm only selects random partitions and performs contractions, both of which can be implemented to run in polynomial time.

Now we analyze the success probability. Let $\mathcal{G}_n$ be the set of all vertex-weighted n-vertex hypergraphs which contain an s-size-constrained k-cut. For a vertex-weighted hypergraph (G, w), let $M(G, w)$ be the set of all s-size-constrained min-k-cuts in (G, w). Define

$$q_n := \min_{(G,w)\in\mathcal{G}_n} \min_{F\in M(G,w)} \Pr[\text{Algorithm returns } F \text{ on input } (G, w, k, s)], \text{ and}$$

$$Q_n := \begin{cases} \left(k^{\max\{2\sigma_{k-1},\sigma_k\}}\right)^{-1} & \text{if } n \leq \max\{2\sigma_{k-1}, \sigma_k\}, \text{and} \\ \left(k^{\max\{2\sigma_{k-1},\sigma_k\}} n\binom{n}{2\sigma_{k-1}}\right)^{-1} & \text{if } n > \max\{2\sigma_{k-1}, \sigma_k\}. \end{cases}$$

We note that $Q_n = \Omega(k^{-\sigma_{k-1}-\sigma_k} n^{-2\sigma_{k-1}-1})$, so it suffices to show that $q_n \geq Q_n$ for all $n \geq k$ (for smaller n, there are no k-cuts).

We proceed by induction on n. Let F be an s-size-constrained min-k-cut in (G, w). Let Y be an s-size-constrained k-partition with $F = \delta(Y)$. We assume that $|Y_1| \leq |Y_2| \leq \cdots \leq |Y_k|$. This assumption is without loss of generality because we can relabel the parts of an s-size-constrained k-partition so that they are in increasing order of size and the resulting partition will still be an s-size-constrained k-partition (since we have assumed that the size vector s is in increasing order).

For the base case, suppose $n \leq \max\{2\sigma_{k-1}, \sigma_k\}$. In this case, the algorithm returns $\delta(X)$ where X is a k-partition of V chosen uniformly at random. Since $F = \delta(Y)$, the probability that $F = \delta(X)$ for the X randomly chosen by the algorithm is at least $\Pr[X = Y]$. The number of k-partitions of V is at most k^n, the number of ways to assign each of the n vertices to one of k labeled sets. Thus, $\Pr[X = Y] \geq k^{-n} \geq k^{-max(2\sigma_{k-1}, \sigma_k)} = Q_n$.

Now we will prove the inductive step. Assume that $n > \max\{2\sigma_{k-1}, \sigma_k\}$. By the inductive hypothesis, we have $q_{n'} \geq Q_{n'}$ for all $n' \in \{k, \ldots, n-1\}$. We will show that $q_n \geq Q_n$.

Suppose $|Y_k| \geq n - 2\sigma_{k-1}$. Let T be an arbitrary subset of Y_k of size $n - 2\sigma_{k-1}$. Consider the set S chosen by the algorithm. The probability that S is equal to $V - T$ is $\binom{n}{2\sigma_{k-1}}^{-1}$. Next, consider the sets X_i created by the algorithm. The probability that $X_i = Y_i$ for every $i \in [k]$ conditioned on $S = V - T$, is $k^{-2\sigma_{k-1}}$. Thus, the probability that the k-partition X obtained in the algorithm is identical to Y is at least $k^{-2\sigma_{k-1}}\binom{n}{2\sigma_{k-1}}^{-1}$. Since the last step of the algorithm returns $R = \delta(X)$ with probability $1/n$, it follows that the algorithm returns F with probability at least $\left(nk^{\max\{2\sigma_{k-1}, \sigma_k\}}\binom{n}{2\sigma_{k-1}}\right)^{-1} = Q_n$.

Henceforth, we assume that $|Y_k| < n - 2\sigma_{k-1}$. We will call a hyperedge *large* if it contains at least $n - 2\sigma_{k-1}$ vertices. Since Y_k is the largest part of the k-partition Y, every large hyperedge must be contained in the k-cut F. In particular, if $\alpha_e = 0$ for a hyperedge e, then $\binom{n-|e|}{\sigma_{k-1}} = 0$, which implies that $n - |e| < \sigma_{k-1}$, and hence e is large and consequently, e cannot be in F.

Next, suppose that $\alpha_e = 0$ for every hyperedge e. Then every hyperedge is a large hyperedge and therefore, $F = E$. In this case, the algorithm will return R. We note that $R = E$ if X is not a k-partition. We lower bound the probability that X is not a k-partition now. If all vertices in S are assigned to X_k, then X is not a k-partition. The probability that all vertices in S are assigned to X_k is $k^{-2\sigma_{k-1}}$. Thus, the probability that the algorithm returns $F = R = E$ is at least $k^{-2\sigma_{k-1}} \geq Q_n$.

Henceforth, we assume that $\alpha_e > 0$ for some hyperedge $e \in E$. This means that the algorithm will contract some hyperedge and then recurse on the resulting hypergraph. Let e' be a random variable for the hyperedge chosen to be contracted. Let w' be the weight function defined on the vertices of G/e' as follows: $w'(v) := w(v)$ for each $v \in V \setminus e'$ and $w'(v) := \sum_{u \in e'} w(u)$ when v is the new vertex resulting from the contraction. If $e' \notin F$, then F will be an s-size-constrained min-k-cut in $(G/e', w')$. Therefore, we have that $\Pr[R' = F \text{ on input } (G, k, s)]$

$$
\begin{aligned}
&= \sum_{e \in E \setminus F} \Pr[e' = e] \cdot \Pr[\text{Algorithm returns } F \text{ on input } (G/e, k, s)] \\
&\geq \sum_{e \in E \setminus F} \frac{\alpha_e}{\sum_{f \in E} \alpha_f} \cdot q_{n-|e|+1}.
\end{aligned}
$$

Let e be a hyperedge that is not in the k-cut F. Then, e cannot be a large hyperedge and hence, $|e| < n - 2\sigma_{k-1}$. Consequently, $n - |e| + 1 > 2\sigma_{k-1} + 1 \geq k$. Therefore, by applying the induction hypothesis, we have $q_{n-|e|+1} \geq Q_{n-|e|+1}$. Hence,

$$\Pr[R' = F \text{ on input } (G,k,s)] \geq \frac{1}{\sum_{f\in E}\alpha_f}\sum_{e\in E\setminus F}\alpha_e \cdot Q_{n-|e|+1}.$$

We need the following two claims. We prove Claim 3.2 in the full version of this paper, and we defer the proof of Claim 3.3 to complete the proof of the theorem.

▷ Claim 3.2. For every hyperedge $e \in E \setminus F$, we have $\alpha_e Q_{n-|e|+1} \geq \frac{nQ_n}{n-1}$.

▷ Claim 3.3. $\frac{|E\setminus F|}{\sum_{f\in E}\alpha_f} \geq 1$.

By Claim 3.2, we have that $\Pr[R' = F \text{ on input } (G,k,s)]$

$$= \frac{1}{\sum_{f\in E}\alpha_f}\sum_{e\in E\setminus F}\alpha_e \cdot Q_{n-|e|+1} \geq \frac{1}{\sum_{f\in E}\alpha_f}\sum_{e\in E\setminus F}\frac{nQ_n}{n-1} = \frac{|E\setminus F|}{\sum_{f\in E}\alpha_f}\cdot\frac{nQ_n}{n-1}.$$

Thus, Claim 3.3 implies that

$$\Pr[R' = F \text{ on input } (G,k,s)] \geq \frac{nQ_n}{n-1}.$$

Finally, we note that since we have assumed $n > \max\{2\sigma_{k-1}, \sigma_k\}$ and $\alpha_e > 0$ for some e, the probability that the algorithm returns R' is $(n-1)/n$. Thus, we conclude that $\Pr[\text{Algorithm returns } F] \geq Q_n$. ◀

Proof of Claim 3.3. Let $Z = (Z_1, \ldots, Z_k)$ be a random k-partition obtained by picking disjoint sets $Z_1, \ldots, Z_{k-1}$ with $|Z_i| = s_i$ and setting $Z_k = V \setminus \bigcup_{i=1}^{k-1} Z_i$. Since $n > \sigma_k$ and every vertex has weight at least 1, the k-partition Z is an s-size-constrained k-partition. Therefore, $|\delta(Z)|$ is an upper bound on $|F|$. In particular, $|F| \leq \mathbb{E}(|\delta(Z)|) = \sum_{e\in E}\Pr(e \in \delta(Z))$. Negating the inequality and adding $|E|$ to both sides gives

$$\begin{aligned}|E\setminus F| &\geq \sum_{e\in E}(1-\Pr(e\in\delta(Z))) = \sum_{e\in E}\Pr(e\notin\delta(Z)) = \sum_{e\in E}\sum_{i=1}^{k}\Pr(e\subseteq Z_i)\\ &\geq \sum_{e\in E}\frac{\binom{n-|e|}{\sigma_{k-1}}}{\binom{n}{\sigma_{k-1}}} = \sum_{e\in E}\alpha_e.\end{aligned}$$

◁

▶ Remark. Since our algorithm does not even take the vertex-weights as input, it could trivially be extended to handle a version of the problem where we have multiple weight functions on the vertices (as in the previous sections) each with their own minimum sizes. If we have t vertex-weight functions, $w_1, \ldots, w_t : V \to \mathbb{Z}_+$ and each function w_j has an associated list of lower bounds $s_{j,1}, \ldots, s_{j,k}$, then we can find a min-k-cut satisfying all of these lower-bound constraints with at least inverse polynomial probability by simply running our algorithm with $s_i = \max_{j\in[t]} s_{j,i}$ for every $i \in [t]$.

4 Conclusion and Open problems

In this work, we illustrated the versatility of the random contraction technique by addressing multicriteria versions of min-cut and size-constrained min-k-cut problems. There are several interesting open questions in this area. We conclude by stating a few: (1) For the number of pareto-optimal cuts and multiobjective min-cuts, there is still a gap between our lower

bound (which is $\Omega(n^t)$) and our upper bound (which is $O(n^{3t-1})$). Can we improve either of these bounds? We believe that improving our bounds for the number of b-multiobjective min-cuts for a fixed budget-vector $b \in \mathbb{R}_+^{t-1}$ would be a first-step towards this goal. (2) We gave a polynomial-time algorithm to solve the b-multiobjective min-cut problem in constant-rank hypergraphs. How about arbitrary-rank hypergraphs? Is the b-multiobjective min-cut problem in arbitrary rank hypergraphs (even for $t = 2$ criteria) solvable in polynomial-time or is it NP-hard?

A Appendix

A.1 Proof of Claim 2.2

Proof of Claim 2.2. Since $n > rt$, when the algorithm is executed on G it will contract a randomly chosen hyperedge and recurse. Let e' be the random hyperedge chosen by the algorithm. If $e' \notin F$, then F will still be a b-multiobjective min-cut in G/e'. We observe that G/e' is a hypergraph with $n - |e'| + 1$ vertices and the rank of G/e' is at most the rank of G. Therefore, if $e' \notin F$, then the algorithm will output F with probability at least $Q_{n-|e'|+1}$.

Let $i \in [t]$ be the index of the cost function chosen by the algorithm. Let

$$E_j := \{e \in E \colon |e| = j\},$$
$$x_j := \Pr[e' \in E_j] = \frac{c_i(E_j)}{c_i(E)}, \text{ and}$$
$$y_j := \Pr[e' \in E_j \cap F] = \frac{c_i(E_j \cap F)}{c_i(E)}.$$

We note that E_j is the set of hyperedges of size j, x_j is the probability of picking a hyperedge of size j to contract, and y_j is the probability of picking a hyperedge of size j from F to contract. We know that

$$\Pr[\text{Algorithm returns the cut } F] \geq \sum_{j=2}^{r} (x_j - y_j) Q_{n-j+1}. \tag{5}$$

The values of x_j and y_j will depend on the structure of G. However we can deduce some relationships between them. Since $0 \leq c_i(E_j \cap F) \leq c_i(E_j)$ for every $j \in \{2, \ldots, r\}$, we know that

$$0 \leq y_j \leq x_j \text{ for every } j \in \{2, \ldots, r\}. \tag{6}$$

Moreover, x_j is the probability of picking a hyperedge of size j. Hence,

$$\sum_{j=2}^{r} x_j = 1. \tag{7}$$

Next, we show that for every $i \in [t]$ and every $v \in U_i$, we have

$$c_i(F) \leq c_i(\delta(v)). \tag{8}$$

If $i < t$, then $c_i(F) \leq b_i < c_i(\delta(v))$ for every $v \in U_i$. Let $i = t$. We recall that F is a b-multiobjective min-cut. Since every cut induced by a single vertex in U_t satisfies all of the budgets, no such cut can have a better c_t-cost than F, so again $c_i(F) \leq c_i(\delta(v))$ for every $v \in U_i$.

From inequality (8), we conclude that

$$c_i(F) \leq \frac{\sum_{v \in U_i} c_i(\delta(v))}{|U_i|} \leq \frac{\sum_{v \in V} c_i(\delta(v))}{|U_i|} = \frac{\sum_{e \in E} |e| c_i(e)}{|U_i|} = \frac{\sum_{j=2}^{r} j \cdot c_i(E_j)}{|U_i|}.$$

Therefore

$$\sum_{j=2}^{r} y_j = \Pr[e' \in F] = \frac{c_i(F)}{c_i(E)} \leq \frac{1}{|U_i|} \sum_{j=2}^{r} j \cdot x_j.$$

Thus, we have that

$$|U_i| \sum_{j=2}^{r} y_j \leq \sum_{j=2}^{r} j \cdot x_j. \tag{9}$$

The minimum value of our lower bound in equation (5) over all choices of x_j and y_j that satisfy inequalities (6), (7), and (9) is a lower bound on the probability that the algorithm outputs F. ◁

A.2 Proof of Claim 2.3

Proof of Claim 2.3. Let $j \in \{2, \ldots, r\}$. The given inequality is equivalent to $\frac{Q_{n-j+1}}{Q_n} \geq \frac{|U_i|-r+j}{|U_i|-r}$. Since U_i is the largest among $U_1, \ldots, U_t$ which together partition V, we have $|U_i| \geq \frac{n}{t}$. Consequently, $\frac{|U_i|-r+j}{|U_i|-r} = 1 + \frac{j}{|U_i|-r} \leq 1 + \frac{jt}{n-rt}$. Therefore, it suffices to prove that $\frac{Q_{n-j+1}}{Q_n} \geq 1 + \frac{jt}{n-tr}$. We case on the value of $n-j+1$.

1. Suppose that $n - j + 1 > rt$. Then, we have

$$\frac{Q_{n-j+1}}{Q_n} = \frac{\binom{n-t(r-2)}{2t}}{\binom{n-j+1-t(r-2)}{2t}} = \prod_{\ell=0}^{2t-1} \frac{n-t(r-2)-\ell}{n-j+1-t(r-2)-\ell}. \tag{10}$$

We consider two sub-cases based on the value of j.

a. Suppose that $j > 2t$. Then, we observe that

$$\begin{aligned}
\prod_{\ell=0}^{2t-1} \frac{n-t(r-2)-\ell}{n-j+1-t(r-2)-\ell} &\geq \left(\frac{n-t(r-2)}{n-j+1-t(r-2)}\right)^{2t} \\
&= \left(1 + \frac{j-1}{n-j+1-t(r-2)}\right)^{2t} \\
&\geq 1 + \frac{2t(j-1)}{n-j+1-t(r-2)} \\
&\geq 1 + \frac{jt+(j-2)t}{n-rt} \\
&\geq 1 + \frac{jt}{n-rt}.
\end{aligned}$$

We use $j > 2t$ in the second to last inequality and $j \geq 2$ in the final inequality.

b. Suppose that $j \leq 2t$. Then we can cancel additional terms from the the right hand side of equation (10) to obtain that

$$\begin{aligned}
\prod_{\ell=0}^{2t-1} \frac{n-t(r-2)-\ell}{n-j+1-t(r-2)-\ell} &= \prod_{\ell=0}^{j-2} \frac{n-t(r-2)-\ell}{n-tr-\ell} \\
&\geq \left(\frac{n-t(r-2)}{n-tr}\right)^{j-1} \\
&= \left(1 + \frac{2t}{n-rt}\right)^{j-1} \\
&\geq 1 + \frac{2t(j-1)}{n-rt} \\
&\geq 1 + \frac{jt}{n-rt}.
\end{aligned}$$

Thus, in either subcase, our desired inequality holds.

2. Suppose that $n - j + 1 \leq rt$. Now the expression for Q_{n-j+1} is different. Since we still know that $n \geq rt + 1$ and $j \leq r$, we conclude that

$$\begin{aligned}\frac{Q_{n-j+1}}{Q_n} &= \frac{(rt+1)\binom{n-t(r-2)}{2t}}{2t+1} \\ &\geq \frac{(rt+1)\binom{rt+1-t(r-2)}{2t}}{2t+1} \\ &= rt+1 \\ &\geq 1+jt \\ &\geq 1+\frac{jt}{n-rt}.\end{aligned}$$

Thus, our desired inequality holds in all cases. ◁

A.3 Enumerating Multiobjective Min-Cuts and Pareto-Optimal Cuts

In this section, we give algorithms to enumerate all multiobjective min-cuts and pareto-optimal cuts in polynomial time.

We first give a polynomial time algorithm to enumerate all multiobjective min-cuts. We execute our algorithm for Multiobjective Min-Cut (i.e., Algorithm 2) a sufficiently large number of times so that it succeeds with high probability (i.e., with probability at least $1 - 1/n$): In particular, executing it $r^2 t 2^{rt} O(n^{2t} \log n)$ many times gives us a collection $\mathcal{C}$ that is a superset of the collection $\mathcal{C}_{MO}$ of multiobjective min-cuts with high probability. Moreover, the size of the collection $\mathcal{C}$ is $r^2 t 2^{rt} O(n^{3t-1} \log n)$. We can prune $\mathcal{C}$ to identify $\mathcal{C}_{MO}$ in polynomial-time as follows: remove every cut $F \in \mathcal{C}$ for which there exists a cut $F' \in \mathcal{C}$ with $c_t(F') < c_t(F)$ and $c_i(F') \leq c_i(F)$ for every $1 \leq i \leq t-1$.

Next, we give a polynomial time algorithm to enumerate pareto-optimal cuts. By containment relation (1), it suffices to identify all pareto-optimal cuts in the collection $\mathcal{C}$. For this, we only need a polynomial-time procedure to verify if a given cut F is pareto-optimal. Algorithm 4 gives such a procedure. It essentially searches for a cut that dominates the given cut F by running our algorithm for b-Multiobjective Min-Cut with t different budget-vectors.

Algorithm 4 Verify pareto-optimality of a given cut.

Verify-Pareto-Optimality$(G, r, t, c_1, \ldots, c_t, F)$:
Input: An r-rank hypergraph $G = (V, E)$, cost functions $c_1, \ldots, c_t : E \to \mathbb{R}_+$, and a cut F in G

For $i = 1, \ldots, t$:
  $\vec{c} \leftarrow (c_1, \ldots c_{i-1}, c_{i+1}, \ldots, c_t, c_i)$
  $\vec{b} \leftarrow (c_1(F), \ldots, c_{i-1}(F), c_{i+1}(F), \ldots, c_t(F))$
  For $j = 1, \ldots, r2^{rt}O(n^{2t}\log(n))$:
    $F' \leftarrow b$-Multiobjective-Min-Cut$(G, r, t, \vec{c}, \vec{b})$
    If F' is a b-multiobjective cut in $(G, \vec{c})$ and $c_i(F') < c_i(F)$:
      Return FALSE
Return TRUE

▶ **Theorem A.1.** *Given an r-rank, n-vertex hypergraph G with t hyperedge-cost functions and a cut F in G, if F is a pareto-optimal cut, then Algorithm 4 returns TRUE, and if F is*

not a pareto-optimal cut, then the algorithm returns FALSE with high probability. Moreover, the algorithm can be implemented to run in polynomial time.

Proof. The run-time of the algorithm is polynomial because our algorithm for b-Multiobjective Min-Cut (i.e., Algorithm 1) is a polynomial-time algorithm. Algorithm 4 returns false only if it finds a cut that dominates the input cut F. If F is pareto-optimal, no such cut will exist, and therefore the algorithm will return true.

Next, suppose the input cut F is not pareto-optimal. Then F must be dominated by some other cut F'. Let $i \in [t]$ be such that $c_i(F') < c_i(F)$ (such an i is guaranteed to exist by the definition of domination). Let b be a budget-vector of the costs of F under the cost functions other than c_i and let c' be c with c_i moved to the end of the vector of cost functions. Then F will not be a b-multiobjective min-cut in (G, c'), since F' also satisfies b, but has a lower c_i-cost.

Therefore, any b-multiobjective min-cut will dominate F (since it will also satisfy b and cannot have higher c_i cost than F'). Thus, if any of our $r2^{rt}n^{2t}\log(n)$ calls to our algorithm for b-Multiobjective-Min-Cut (i.e., Algorithm 1) for this value of i returns a multiobjective min-cut, then the algorithm will return false. By Theorem 2.1, our algorithm for b-Multiobjective Min-Cut returns a b-multiobjective min-cut with probability $\frac{1}{r2^{rt}}\Omega(\frac{1}{n^{2t}})$. Therefore, if we run this algorithm $r2^{rt}O(n^{2t}\log(n))$ times, a b-multiobjective min-cut will be returned at least once with high probability, and our algorithm will correctly return false. ◀

A.4 Lower Bounds

In this section we discuss lower bounds on the number of distinct pareto-optimal cuts in n-vertex hypergraphs. Karger gave a family of graphs with $n^{t/2}$ parametric min-cuts [13]. We recall that every parametric min-cut is a pareto-optimal cut by the containment relation (1). Thus, $n^{t/2}$ is also a lower bound on the number of pareto-optimal cuts in n-vertex hypergraphs. To the best of the authors' knowledge, this is the best lower bound on the number of pareto-optimal cuts that is known in the literature. We give an $\Omega(n^t)$ (for constant t) lower bound on the number of pareto-optimal cuts in a graph. Our lower bound construction is different from that of Karger.

▶ **Theorem A.2.** *For all positive integers t and n such that $n \geq t+2$, there exists an n-vertex graph G with associated edge-cost functions $c_1, \ldots, c_t : E(G) \to \mathbb{R}_+$ such that G has at least $\left(\frac{n-2}{t}\right)^t$ distinct pareto-optimal cuts.*

Proof. For fixed n and t, construct a graph G as follows. The graph G has two special vertices u and v. The rest of the vertices are used to form t distinct paths between u and v with each path consisting of at least $\lfloor\frac{n-2}{t}\rfloor + 1 > \frac{n-2}{t}$ distinct edges. We assign edge costs as follows: If e is an edge in the i'th path, then $c_i(e) = 1$, while $c_j(e) = 1/(t+1)$ for every $j \in [t] \setminus \{i\}$. See Figure 1 for an example. We will show that any cut which contains exactly one edge from each path is pareto-optimal. The number of such cuts is at least $\left(\frac{n-2}{t}\right)^t$, since each path has at least $(n-2)/t$ edges, so this will suffice to prove the theorem.

We observe that any cut contains either exactly one edge from each path or at least two edges from some path. Any cut F which contains exactly one edge from each path will have $c_i(F) = 2t/(t+1)$ for every $i \in [t]$. Any cut F' that contains at least two edges from some path $i \in [t]$ will have $c_i(F') = 2 > 2t/(t+1)$. Therefore no cut which contains two edges from the same path can dominate a cut which contains exactly one edge from each path. Furthermore, if two different cuts each contain exactly one edge from all paths, then they both have the same cost under every cost function, and thus neither can dominate the other. We conclude that every cut which contains exactly one edge from each path is pareto-optimal. ◀

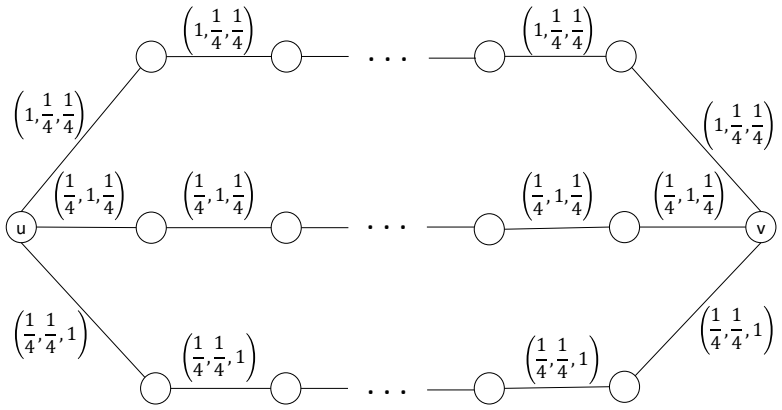

Figure 1 An illustration of our lower bound construction for $t = 3$.

▶ Remark A.3. The lower bound from Theorem A.2 is still significantly smaller than the $O(n^{3t-1})$ upper bound from Theorem 1.1. We believe that this gap comes from the slack in the analysis of our randomized algorithms.

▶ Remark A.4. We note that the construction in Theorem A.2 also shows that there exists a budget-vector $b \in \mathbb{R}_+^{t-1}$ such that the number of b-multiobjective min-cuts is $\Omega(n^t)$: consider budget values $b_i = (2t)/(t+1)$ for every $i \in [t-1]$. We emphasize that since not every multiobjective min-cut is pareto-optimal, this lower bound does not imply the one from Theorem A.2. Since distinct pareto-optimal cuts need not be b-multiobjective min-cuts for the same vector b, the bound in Theorem A.2 does not immediately imply this bound either.

On Testing and Robust Characterizations of Convexity

Abstract

A body $K \subset \mathbb{R}^n$ is convex if and only if the line segment between any two points in K is completely contained within K or, equivalently, if and only if the convex hull of a set of points in K is contained within K. We show that neither of those characterizations of convexity are robust: there are bodies in $\mathbb{R}^n$ that are far from convex – in the sense that the volume of the symmetric difference between the set K and any convex set C is a constant fraction of the volume of K – for which a line segment between two randomly chosen points $x, y \in K$ or the convex hull of a random set X of points in K is completely contained within K except with exponentially small probability. These results show that any algorithms for testing convexity based on the natural line segment and convex hull tests have exponential query complexity.

1 Introduction

A *body* is a subset of $\mathbb{R}^n$ that is compact – i.e., closed and bounded – and has a non-empty interior. A body $K \subset \mathbb{R}^n$ is *convex* if for every two points $x, y \in K$ and every parameter λ in the range $[0, 1]$, the point $z = \lambda x + (1 - \lambda)y$ is also in K. The *geometric convexity testing* problem is a formalization of the following property testing problem:

> How efficiently can we distinguish convex bodies from those that are far from convex?

The geometric convexity testing problem was first studied by Rademacher and Vempala [18], who formalized the problem as follows. A body $K \subset \mathbb{R}^n$ is *ϵ-far from convex* for some $\epsilon > 0$ if for every convex body $C \subset \mathbb{R}^n$, the volume of the symmetric difference of K and C is bounded below by $\mathrm{Vol}(K \triangle C) \geq \epsilon \,\mathrm{Vol}(K)$. Following the standard framework of property testing [20, 12], we can then define an *ϵ-tester for convexity* to be a bounded-error randomized algorithm that distinguishes convex bodies from bodies that are ϵ-far from convex. We consider testers that access an unknown body $K \subset \mathbb{R}^n$ via the following two standard oracles:

Membership oracle. Given as input a point $x \in \mathbb{R}^n$, the oracle returns "yes" if and only if $x \in K$.

Random oracle. The oracle returns a point x drawn uniformly at random from K.

© Eric Blais and Abhinav Bommireddi;
licensed under Creative Commons License CC-BY

The measure of complexity of ϵ-testers of convexity that we examine is the minimum number of queries to either of these oracles that they require, and the main open question is whether there exists an ϵ-tester of convexity of bodies in $\mathbb{R}^n$ that has query complexity that is polynomial in both n and $1/\epsilon$. Three natural testers have been proposed and studied previously with the aim of answering this question.

I. Approximation tester

Rademacher and Vempala [18] showed that there is an ϵ-tester for convexity of bodies in $\mathbb{R}^n$ with query complexity $q = (cn/\epsilon)^n$ for some constant $c > 0$. This tester is obtained via the natural *testing by learning* approach [12]. With q queries to the random oracle for K, we obtain a set S of points whose convex hull C satisfies $\mathrm{Vol}(K \triangle C) < \frac{\epsilon}{2}\mathrm{Vol}(K)$ with high probability when K is convex and (by definition) always satisfies $\mathrm{Vol}(K \triangle C) \geq \epsilon\,\mathrm{Vol}(K)$ when K is ϵ-far from convex. A tester can then distinguish between these two cases with $O(1/\epsilon)$ queries to the random and membership oracles for K.

However, any ϵ-tester for convexity that follows the testing by learning approach must have query complexity exponential in n, since any algorithm that learns a convex set C which satisfies $\mathrm{Vol}(K \triangle C) \leq \epsilon\,\mathrm{Vol}(K)$ for some unknown convex body $K \subset \mathbb{R}^n$ must have query complexity $2^{\Omega(\sqrt{n}/\epsilon)}$ [13]. (In fact, a number of queries that is exponential in n is required even just for estimating the volume of K [2, 11].) So a completely different approach is required if we aim to test convexity of high-dimensional bodies more efficiently.

II. Line segment tester

The definition of convex bodies immediately suggests a simple *line segment test* for convexity: draw two points $x, y \in K$ using the random oracle for K, pick a parameter $\lambda \in [0, 1]$ according to some distribution, and use the membership oracle to determine if the point $z = \lambda x + (1 - \lambda)y$ is in K. If K is convex, this test will always pass, and conversely when K is ϵ-far from convex then there must exist some points x, y, z for which this test does not pass.

A natural idea for constructing an ϵ-tester for convexity is to simply run the line segment test multiple times and accept if and only if each test passes. But Rademacher and Vempala [18] showed that the resulting tester cannot have query complexity that is polynomial in *both* n and $1/\epsilon$. More precisely, they showed that there is a body $K \subset \mathbb{R}^n$ which is $\Omega(\frac{1}{n^2})$-far from convex but for which the line segment $\overline{xy}$ joining two points x and y drawn uniformly at random from K satisfies $\Pr[\overline{xy} \not\subseteq K] = 2^{-\Omega(n)}$.

The counter-example of Rademacher and Vempala, however, does not rule out the possibility that there exists an ϵ-tester of convexity with query complexity polynomial in n when ϵ is a constant. Our first result rules out this possibility as well, showing that the query complexity of testers obtained from the line segment test must be exponential in n for all $\epsilon \leq \frac{1}{8}$.

▶ **Theorem 1.1.** *There exists a body $K \subset \mathbb{R}^n$ that is $\frac{1}{8}$-far from convex for which*

$$\Pr_{x,y \in K}\left[\overline{xy} \not\subseteq K\right] = 2^{-\Omega(n)}. \tag{1}$$

Theorem 1.1 has another interpretation that is independent of property testing: it says that the line segment characterization of convexity is not *robust*: while it is true that only convex bodies satisfy $\overline{xy} \in K$ for every $x, y \in K$, there are bodies that are far from convex where $\overline{xy} \in K$ still holds for "most" points in K.

III. Convex hull tester

For any $m \geq 1$, the *convex hull* of a set $X = \{x^{(1)}, \ldots, x^{(m)}\}$ of m points in $\mathbb{R}^n$ is

$$\mathrm{conv}\Big(X\Big) := \left\{ y : \exists \lambda_1, \ldots, \lambda_m \geq 0, \sum_{i=1}^{m} \lambda_i = 1 \text{ s.t. } y = \sum_{i=1}^{m} \lambda_i x^{(i)} \right\},$$

the set of points that can be obtained by taking a convex combination of the points in X. A natural extension of the line segment test is the *convex hull test*: for some $m \geq 2$, draw a set X of m points from K using the random oracle, draw a point z from $\mathrm{conv}(X)$ according to some distribution, and check whether z is in K. When $m = 2$, the convex hull test is equivalent to the line test which, as we have seen above, cannot lead to an efficient tester for convexity. For $m \geq 3$, however, it is possible that it leads to much more efficient testing algorithms. Indeed, Berman, Murzabulatov, and Raskhodnikova [6, 5] showed that in a slightly different property testing model, the convex hull test can be used to test convexity with a number of queries that is polynomial in $1/\epsilon$ in the two-dimensional setting where $K \subset \mathbb{R}^2$. (See also [19, 7] for related results.)

Our next and main result rules out the possibility of obtaining an efficient tester for convexity in the high-dimensional setting using the convex hull test by showing that the convex hull characterization is not robust, even when taking the convex hull of an *exponential* (in the dimension n) number of points.

▶ **Theorem 1.2.** *There exist a body $K \subset \mathbb{R}^n$ that is $\frac{1}{8}$-far from convex and a constant $c > 0$ such that a set $X = \{x^{(1)}, \ldots, x^{(m)}\} \in K$ of $m = 2^{cn}$ points drawn uniformly and independently at random from K satisfies*

$$\Pr_X \Big[\mathrm{conv}(X) \not\subseteq K\Big] = 2^{-\Omega(n)}.$$

Theorem 1.2 shows that any ϵ-tester for convexity built on the convex hull test must have query complexity $2^{\Omega(n)}$. It also relates to a conjecture of Rademacher and Vempala [18]: they conjecture that when $K \subset \mathbb{R}^n$ is ϵ-far from convex and $x, y, z \in K$ are drawn uniformly at random from K, then the intersection of K with the two-dimensional subspace spanned by x, y, and z is non-convex with probability at least $\Omega(\epsilon/n)$. Theorem 1.2 shows that it is impossible to strengthen the conjecture by replacing the subspace spanned by $\{x, y, z\}$ with the convex hull of these points, since in that case the resulting statement is false.

1.1 Proof overview

Theorems 1.1 and 1.2 are established constructively. The construction that achieves the bounds promised in the theorems is obtained by taking the union of two truncated cones, as pictured in Figure 1. The main technical component of the proof of the theorems lies in the task of showing that, contrary to what our low-dimensional intuition might suggest, the union of two truncated cones is far from being convex, even when the radius at the point of intersection of both cones is very close to the maximum radius of both truncated cones. The construction is defined precisely and is shown to be far from convex in Section 3.

The proof of Theorem 1.1 is completed in Section 4.1, where we show that with high probability the line segment joining two points drawn uniformly at random from the union of two truncated cones is contained within the body. We then build on this result in Section 4.2 to show that the convex hull of $m \geq 2$ points drawn uniformly from that body is also contained within the body with high probability.

1.2 Discussion

Testing convexity efficiently

Our results do not rule out the possibility that convexity of high-dimensional sets can be tested with a number of queries to random and membership oracles that is polynomial in n and $1/\epsilon$, but they do show that new algorithmic techniques that go beyond convex hull testing are required if such an efficient convexity tester exists. To determine which additional techniques might be useful in obtaining such an efficient convexity tester (or ruling out their existence), it might be instructive to point out that the body constructed in Section 3 is in fact very easy to distinguish from convex bodies. One way to do this is to notice that the union of truncated cones has poor *expansion*: if we take a random walk from a point within one of the two truncated cones, with high probability it will remain within the same truncated cone. By contrast, a random walk in a convex body quickly converges to a distribution that is close to uniform in the body. Is it possible to efficiently test if an unknown body is expanding or far from it? And is it also possible to efficiently distinguish convex sets from expanding sets that are far from convex? Affirmative answers to both of these questions – for any reasonable formalization of the expansion testing problem – would likely lead to a new efficient tester for convexity; the question of testing expansion of high-dimensional sets also appears to be worth studying for independent interest as well.

Testing convexity over the Gaussian distribution

There is another formalization of the geometric convexity testing problem in which we measure the distance to convexity in terms of of the Gaussian distribution on $\mathbb{R}^n$. Chen, Freilich, Servedio, and Sun [10] studied *sample-based* testers for convexity in this model – testers that have access to the membership oracle but can only observe its responses to points drawn from the Gaussian distribution. They showed that all such sample-based testers for convexity have exponential sample complexity. Could the construction introduced in this paper be extended to show a similar bound for the query complexity of a wider class of testers in the same setting? Such results do not follow immediately from the current work since the argument showing that the union of truncated cones is far from convex does not hold in the Gaussian distribution setting.

Testing convex functions

Another problem that has received a considerable amount of attention in the property testing literature, starting with the work of Parnas, Ron, and Rubinfeld [17], is that of testing the convexity of *functions* [8, 4, 9, 3]. There is a close connection between convexity of sets and convexity of functions. Namely, a function $f : \mathbb{R}^n \to \mathbb{R}$ is convex if and only if its epigraph is a convex set in $\mathbb{R}^{n+1}$. The definitions of distance to convexity, however, make the problems of testing convex functions and testing convex sets quite different in general. Nonetheless, as Berman, Raskhodnikova, and Yaroslavtsev [8] pointed out, the two problems are closely connected when we consider the testing of convex functions under the ℓ_1 norm, and it would be interesting to see if the techniques or results introduced here could yield any progress on the problem of testing convex functions with a polynomial number of queries. (See [8, 22] for more details on this problem.)

2 Preliminaries

We use standard notions and results regarding high-dimensional convex sets. For general introductions to the topic and to algorithmic implications, see [1, 15, 16, 14, 21].

2.1 Convex bodies and slices

The *distance* between two bodies $A, B \in \mathbb{R}^n$ is defined to be

$$\mathrm{dist}(A, B) = \mathrm{Vol}(A \triangle B) = \mathrm{Vol}(A \setminus B) + \mathrm{Vol}(B \setminus A),$$

the measure of the symmetric difference of the two bodies. We will repeatedly use the following simple lower bound on the distance of two bodies.

▶ **Proposition 2.1.** *The distance between two bodies $A, B \subset \mathbb{R}^n$ is bounded below by*

$$\mathrm{dist}(A, B) \geq \max\big\{\mathrm{Vol}(A) - \mathrm{Vol}(B), \mathrm{Vol}(B) - \mathrm{Vol}(A)\big\}.$$

Furthermore, equality holds whenever $A \subseteq B$ or $B \subseteq A$.

Proof. The distance between A and B is bounded below by

$$\mathrm{dist}(A, B) = \mathrm{Vol}(A \setminus B) + \mathrm{Vol}(B \setminus A) \geq \max\{\mathrm{Vol}(A \setminus B), \mathrm{Vol}(B \setminus A)\}.$$

The lower bound then follows from the observation that $\mathrm{Vol}(A \setminus B) = \mathrm{Vol}(A) - \mathrm{Vol}(A \cap B) \geq \mathrm{Vol}(A) - \mathrm{Vol}(B)$ and, similarly, that $\mathrm{Vol}(B \setminus A) \geq \mathrm{Vol}(B) - \mathrm{Vol}(A)$. Finally, when $A \subseteq B$, then $\mathrm{Vol}(A \setminus B) = 0$ and $\mathrm{Vol}(B \setminus A) = \mathrm{Vol}(B) - \mathrm{Vol}(A)$, as $\mathrm{Vol}(A \cap B) = \mathrm{Vol}(A)$ so equality holds. Similarly, equality also holds when $B \subseteq A$. ◀

Much of our analysis in Section 3 is concerned with various slices of a high-dimensional body. To make this notion precise, for each $t \in \mathbb{R}$ we define

$$H_t = \{x \in \mathbb{R}^n : x_1 = t\}$$

to be the hyperplane of all points with first coordinate value t. The corresponding halfspaces are denoted by $H_{\leq t} = \{x \in \mathbb{R}^n : x_1 \leq t\}$ and $H_{\geq t} = \{x \in \mathbb{R}^n : x_1 \geq t\}$. The t-th *slice* of a body $A \subset \mathbb{R}^n$ is

$$A_t = A \cap H_t = \{x \in A : x_1 = t\}.$$

For $t_1 \leq t_2 \in \mathbb{R}$, we also define $A_{[t_1,t_2]} = A \cap H_{\geq t_1} \cap H_{\leq t_2}$ to be the set of points in A with first coordinate between t_1 and t_2.

A fundamental property of the slices of a convex body is that the $(n-1)$-th root of their volumes is a concave function.

▶ **Brunn's Theorem.** *For any convex body $C \subset \mathbb{R}^n$, the function $t \mapsto \mathrm{Vol}_{n-1}(C_t)^{\frac{1}{n-1}}$ is concave on its support.*

2.2 High-dimensional balls and cones

We use $B_n(x, r) = \{y \in \mathbb{R}^n : \|y - x\| \leq r\}$ to denote the ball of radius r around a point $x \in \mathbb{R}^n$. We use $B(r)$ as a shorthand for $B_n(o, r)$, and $B_{n-1}(r)$ for $B_{n-1}(o, r)$, where o is the origin. Similarly, we use $S_n(x, r) = \{y \in \mathbb{R}^n : \|y - x\| = r\}$ to denote the sphere of radius r around a point $x \in \mathbb{R}^n$. We will use the following standard approximation on the volume of the ball.

▶ **Proposition 2.2.** *The volume of ball $B(r) \subset \mathbb{R}^n$ with radius r is*

$$\mathrm{Vol}(B(r)) = r^n \cdot \frac{\pi^{\frac{n}{2}}}{\Gamma(\frac{n}{2}+1)} = r^n \cdot \frac{1}{\sqrt{\pi n}}\left(\frac{2\pi e}{n}\right)^{\frac{n}{2}} \cdot (1 + O(n^{-1})),$$

where Γ is Euler's gamma function.

We also use the following standard concentration inequality for high-dimensional balls. (See, e.g., [1].)

▶ **Proposition 2.3.** *Let $x \in \mathbb{R}^n$ be drawn uniformly at random from $B(r)$. Then*

$$\Pr\left[|x_1| \geq \tfrac{r}{100}\right] \leq 2^{-\Omega(n)}.$$

▶ **Definition 2.4.** *Let $H \subset \mathbb{R}^n$ be a hyperplane, $S \subset H$ be an $(n-1)$-dimensional convex body, and $x \in \mathbb{R}^n \setminus H$ be a point. The* cone *with x as vertex and S as base is the convex hull of x with the body S;*

$$\mathrm{cone}(x, S) = \mathrm{conv}(x \cup S).$$

We use the following result on the volume of cones.

▶ **Proposition 2.5.** *Let $H \subset \mathbb{R}^n$ be a hyperplane, $S \subset H$ be an $(n-1)$-dimensional convex body, and $x \in \mathbb{R}^n \setminus H$ be a point at a distance $h = \min_{y \in H} \|x - y\|$ from the hyperplane H. Then the volume of the cone is*

$$\mathrm{Vol}(\mathrm{cone}(x, S)) = \frac{h}{n}\mathrm{Vol}_{n-1}(S).$$

▶ **Definition 2.6.** *A* truncated cone *is the convex hull of two balls $B_{n-1}((t_1, 0 \ldots, 0), r_1) \subset H_{t_1}$ and $B_{n-1}((t_2, 0 \ldots, 0), r_2) \subset H_{t_2}$, $\mathrm{conv}(B_{n-1}((t_1, 0 \ldots, 0), r_1) \cup B_{n-1}((t_2, 0 \ldots, 0), r_2))$.*

3 Union of truncated cones

Theorems 1.1 and 1.2 are both established by analyzing a construction obtained by taking the union of two truncated cones. We describe this construction in Section 3.1. The main technical component of the proofs is in Section 3.2, where we show that the union of truncated cones is far from convex.

3.1 Description of the union of truncated cones D

The body $D \subset \mathbb{R}^n$ that will show the non-robustness of the line and convex hull definition is defined as follows. First, let $d > 0$ be some distance parameter. This distance parameter does not affect the results in the following sections; the reader may fix $d = 1$ for simplicity.

Let B_L, B_R, and B_O be three $(n-1)$-dimensional balls in the hyperplanes H_{-d}, H_d, and H_0, respectively. We define the balls B_L and B_R to have radius 1.1 each and be centered on the points $(-d, 0, 0, \ldots, 0)$ and $(d, 0, 0, \ldots, 0)$, respectively, while B_O has radius 1 and is centered at the origin. Define the body D to be the union of the truncated cones $\mathrm{conv}(B_L, B_O)$ and $\mathrm{conv}(B_O, B_R)$,

$$D = \mathrm{conv}(B_L, B_O) \cup \mathrm{conv}(B_O, B_R).$$

The definition of the body D is illustrated in Figure 1.

One of the basic properties of the body D that we will use in later sections is that a point drawn uniformly at random from D will have a large value in its first coordinate with high probability.

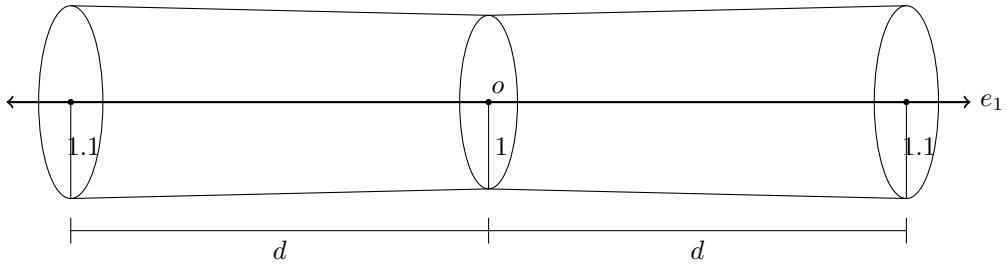

Figure 1 The body D obtained by taking the union of two truncated cones.

▶ **Proposition 3.1.** *Let $x = (x_1, \ldots, x_n)$ be drawn uniformly at random from D. Then*

$$\Pr\left[|x_1| \leq \frac{d}{2}\right] = 2^{-\Omega(n)}.$$

Proof. Using the formula in Proposition 2.5 for the volume of a cone, the volume of the body D is bounded below by

$$\begin{aligned}\mathrm{Vol}(D) = 2\,\mathrm{Vol}(D_{[0,d]}) &= 2\Big(\frac{11d}{n}\,(1.1)^{n-1}\,\mathrm{Vol}_{n-1}\big(B_{n-1}(1)\big) \\ &\qquad - \frac{10d}{n}\,(1)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1))\Big) \\ &\geq \frac{2d}{n}\,(1.1)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1)).\end{aligned}$$

Similarly, the volume of the body $D_{[-\frac{d}{2},\frac{d}{2}]}$ is bounded above by

$$\begin{aligned}\mathrm{Vol}(D_{[-\frac{d}{2},\frac{d}{2}]}) = 2\,\mathrm{Vol}(D_{[0,\frac{d}{2}]}) &= 2\Big(\frac{10.5d}{n}\,(1.05)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1)) \\ &\qquad - \frac{10d}{n}\,(1)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1))\Big) \\ &\leq \frac{21d}{n}\,(1.05)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1)).\end{aligned}$$

Therefore, the probability that the absolute value of the first coordinate of the point is less than or equal to $\frac{d}{2}$ is bounded by

$$\Pr\left[|x_1| \leq \frac{d}{2}\right] = \frac{\mathrm{Vol}(D_{[-\frac{d}{2},\frac{d}{2}]})}{\mathrm{Vol}(D)} \leq \frac{\frac{21d}{n}\,(1.05)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1))}{\frac{2d}{n}\,(1.1)^{n-1}\,\mathrm{Vol}_{n-1}(B_{n-1}(1))} \leq \frac{1}{2^{\Omega(n)}}.$$ ◀

3.2 D is far from convex

In this section, we prove that the body D is $\frac{1}{8}$-far from convex. We prove this in three steps. First, we show that the closest convex body to D must be symmetric about the axis $e_1 = (1, 0, 0, \ldots, 0)$. Next, we prove that if the closest convex body is symmetric about e_1, then it has to be a truncated cone. Finally, we prove that every truncated cone is $\frac{1}{8}$-far from our body D.

3.2.1 A partial converse to Brunn's Theorem

The first step in the proof – showing that the closest convex body to D must be symmetric – uses Brunn's Theorem as well as the following partial converse result.

▶ **Lemma 3.2.** *Let $K \subset \mathbb{R}^n$ be a body such that for each $t \in \mathbb{R}$ the slice K_t is an $(n-1)$ dimensional ball and the function $t \mapsto \mathrm{Vol}_{n-1}(K_t)^{\frac{1}{n-1}}$ is concave on its support. Then K is convex.*

Proof. Assume for the sake of contradiction that K is a non-convex body that satisfies the conditions of the theorem. Then there exist points $x, y \in K$ and $0 \leq \lambda \leq 1$ such that the point $z = \lambda x + (1-\lambda)y \notin K$.

Let $r : \mathbb{R} \to \mathbb{R}$ be the function defined by setting $r(t)$ to be the radius of the $(n-1)$-dimensional ball with volume $\mathrm{Vol}_{n-1}(K_t)$. By applying the formula for volume of the ball from Proposition 2.2, we have that

$$r(t) = \frac{\Gamma(\frac{n-1}{2}+1)^{\frac{1}{n-1}}}{\sqrt{\pi}} \mathrm{Vol}_{n-1}(K_t)^{\frac{1}{n-1}}.$$

Since the function $t \mapsto \mathrm{Vol}_{n-1}(K_t)^{\frac{1}{n-1}}$ is concave, the function r is concave as well.

The concavity of r and the fact that $x, y \in K$ imply that

$$r(z_1) = r(\lambda x_1 + (1-\lambda)y_1) \geq \lambda r(x_1) + (1-\lambda) r(y_1) \geq \lambda \sqrt{\sum_{2 \leq i \leq n} x_i^2} + (1-\lambda)\sqrt{\sum_{2 \leq i \leq n} y_i^2}.$$

The fact that $z \notin K$ also implies that

$$r(z_1) < \sqrt{\sum_{2 \leq i \leq n} z_i^2} = \sqrt{\sum_{2 \leq i \leq n} (\lambda x_i + (1-\lambda)y_i)^2}.$$

But by the convexity of Euclidean norm and Jensen's inequality, $\sqrt{\sum_{2 \leq i \leq n} (\lambda x_i + (1-\lambda)y_i)^2}$ $\leq \lambda \sqrt{\sum_{2 \leq i \leq n} x_i^2} + (1-\lambda)\sqrt{\sum_{2 \leq i \leq n} y_i^2}$ so the last two inequalities yield the desired contradiction. ◀

3.2.2 Symmetry of the closest convex body

A body $K \subset \mathbb{R}^n$ is *symmetric* about $e_1 = (1, 0, 0, \ldots, 0)$ if for every point $x \in K$, all points $y \in \mathbb{R}^n$ that satisfy $x_1 = y_1$ and $\sum_{i=2}^n x_i^2 = \sum_{i=2}^n y_i^2$ are also in K. In other words, a body K is symmetric about e_1 if it is invariant under rotations about the axis e_1. We use a standard symmetrization argument to prove that the closest convex body to D is symmetric about e_1.

▶ **Lemma 3.3.** *There exists a closest convex body to D that is symmetric about e_1.*

Proof. Fix C to be any convex body which minimizes $\mathrm{dist}(D, C)$. C should be contained between H_{-d} and H_d, otherwise we can truncate C and get a convex body closer to D. Let C^s be the body where for every $t \in \mathbb{R}$, the slice C_t^s of the body is an $(n-1)$-dimensional ball centered at $(t, 0, 0, \ldots, 0)$ and has volume $\mathrm{Vol}_{n-1}(C_t^s)$ equal to the volume of the slice C_t of C. By this construction, C^s is symmetric about e_1. To complete the proof, we need to show that it satisfies $\mathrm{dist}(D, C^s) \leq \mathrm{dist}(D, C)$ and that it is convex.

We first establish the inequality $\mathrm{dist}(D, C^s) \leq \mathrm{dist}(D, C)$. The distance between D and C is

$$\mathrm{dist}(D, C) = \int_{t=-d}^{d} \mathrm{dist}(D_t, C_t)\,\mathrm{d}t = \int_{t=-d}^{d} \mathrm{Vol}_{n-1}(D_t \triangle C_t)\,\mathrm{d}t.$$

By Proposition 2.1, for every $t \in \mathbb{R}$, the volume of the symmetric difference between the slices D_t and C_t is bounded below by

$$\mathrm{Vol}_{n-1}(D_t \triangle C_t) \geq \max\Big\{\mathrm{Vol}_{n-1}(C_t) - \mathrm{Vol}_{n-1}(D_t), \mathrm{Vol}_{n-1}(D_t) - \mathrm{Vol}_{n-1}(C_t)\Big\}.$$

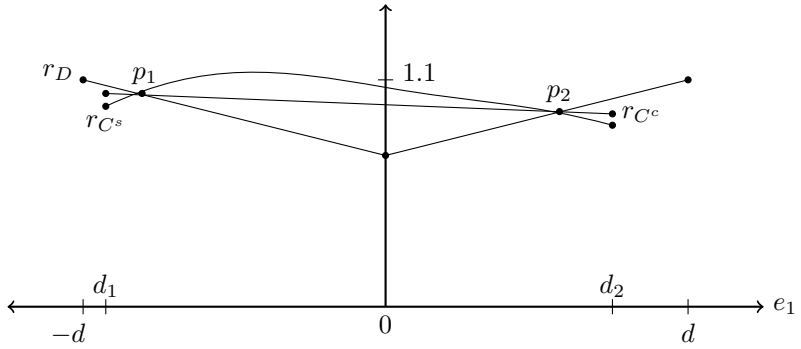

Figure 2 Illustration of the radius functions r_D, r_{C^s}, and r_{C^c} and of the points p_1 and p_2 in the proof of Lemma 3.5.

Since $\mathrm{Vol}_{n-1}(C_t) = \mathrm{Vol}_{n-1}(C_t^s)$, we then obtain

$$\mathrm{dist}(D,C) \geq \int_{t=-d}^{d} \max\left\{\mathrm{Vol}_{n-1}(C_t^s) - \mathrm{Vol}_{n-1}(D_t), \mathrm{Vol}_{n-1}(D_t) - \mathrm{Vol}_{n-1}(C_t^s)\right\} \mathrm{d}t.$$

Both D_t and C_t^s are balls with the same center, so one is a strict subset of the other and so we can apply the equality condition of Proposition 2.1 to obtain

$$\mathrm{dist}(D,C) \geq \int_{t=-d}^{d} \mathrm{Vol}_{n-1}(D_t \triangle C_t^s)\,\mathrm{d}t = \int_{t=-d}^{d} \mathrm{dist}(D_t, C_t^s)\,\mathrm{d}t = \mathrm{dist}(D, C^s),$$

as we wanted to show.

We now complete the proof of the lemma by showing that C^s is convex. From Brunn's Theorem, the function $t \mapsto \mathrm{Vol}_{n-1}(C_t)^{\frac{1}{n-1}}$ is concave on its support. And from the construction we have that $\mathrm{Vol}_{n-1}(C_t^s)^{\frac{1}{n-1}} = \mathrm{Vol}_{n-1}(C_t)^{\frac{1}{n-1}}$. Hence, the function $t \mapsto \mathrm{Vol}_{n-1}(C_t^s)^{\frac{1}{n-1}}$ is also concave on its support and by Lemma 3.2, the body C^s is convex. ◀

3.2.3 The closest convex body is a truncated cone

We now show that the closest symmetric convex body to D is a truncated cone. The proof of this claim uses the following standard result about the separation of convex and concave functions.

▶ **Lemma 3.4.** *Fix any $d_1 \leq d_2 \in \mathbb{R}$. Let $f : [d_1, d_2] \to \mathbb{R}$ be a convex function and $g : [d_1, d_2] \to \mathbb{R}$ be a concave function such that $\forall t \in [d_1, d_2]$, $f(t) \geq g(t)$. Then there exists an affine function $h : [d_1, d_2] \to \mathbb{R}$ such that $g(t) \leq h(t) \leq f(t)$ for all $t \in [d_1, d_2]$.*

Proof. The proof follows from the fact that any two convex sets have a separating hyperplane. Let $S_1 = \{(t,x) : t \in [d_1, d_2], x \geq f(t)\}$ and $S_2 = \{(t,x) : t \in [d_1, d_2], x \leq g(t)\}$. The sets S_1 and S_2 are convex and their separating hyperplane corresponds to the function h. ◀

▶ **Lemma 3.5.** *The closest convex body to D that is symmetric about e_1 is a truncated cone.*

Proof. Let C^s be a convex body that is symmetric about e_1 and minimizes $\mathrm{dist}(D, C^s)$. We will construct a truncated cone C^c that is also symmetric about e_1 and satisfies $\mathrm{dist}(D, C^c) \leq \mathrm{dist}(C^s, D)$.

Define the functions $r_D, r_{C^s} : \mathbb{R} \to \mathbb{R}$ where $r_D(t)$ and $r_{C^s}(t)$ are the radii of the $(n-1)$-dimensional balls D_t and C^s_t, respectively. Let d_1 be the infimum of t for which $r_{C^s}(t) > 0$ and d_2 be the supremum of t for which $r_{C^s}(t) > 0$. Note that $-d \le d_1 < d_2 \le d$ since the body C^s is contained between the hyperplanes H_{-d}, H_d.

We define an affine function $r_{C^c} : [d_1, d_2] \to \mathbb{R}$. We further define C^c to be the body whose slices C^c_t are $(n-1)$-dimensional balls of radius $r_{C^c}(t)$, for $t \in [d_1, d_2]$. Clearly C^c is a truncated cone. We define r_{C^c} differently for different cases mentioned below. In Case 1 we define it directly and in Cases 2, 3 we define two values a_1, a_2. The affine function $r_{C^c} : [d_1, d_2] \to \mathbb{R}$ corresponding to the values a_1, a_2 is defined by the line joining the points $p_1 = (a_1, r_D(a_1)), p_2 = (a_2, r_D(a_2))$. See Figure 2 for an illustration of this construction.

- **Case 1: $\forall t \in (d_1, d_2)$, $r_{C^s}(t) \le r_D(t)$**
  Since r_D is convex and r_{C^s} is concave, from Lemma 3.4, there exists an affine function $r_{C^c} : [d_1, d_2] \to \mathbb{R}$ such that $r_D(t) \ge r_{C^c}(t) \ge r_{C^s}(t)$ for all $t \in [d_1, d_2]$.
- **Case 2: $\forall t \in (d_1, d_2)$, $r_{C^s}(t) > r_D(t)$**
  Let $a_1 = d_1$, $a_2 = d_2$.
- **Case 3:** $\exists t_1, t_2 \in [d_1, d_2]$ such that $r_{C^s}(t_1) \le r_D(t_1)$ and $r_{C^s}(t_2) > r_D(t_2)$
  This case be further divided into three sub-cases.
  - **Case 3a:** $r_{C^s}(d_1) \le r_D(d_1)$ and $r_{C^s}(d_2) \le r_D(d_2)$
    In this case since r_{C^s} is concave and r_D is convex the curves have exactly two points of intersection. Let a_1, a_2 be the values of t where the curves intersect.
  - **Case 3b:** $r_{C^s}(d_1) \le r_D(d_1)$ and $r_{C^s}(d_2) > r_D(d_2)$
    In this case since r_{C^s} is concave and r_D is convex the curves have exactly one point of intersection. Let a_1 be the value of t where the curves intersect and let $a_2 = d_2$.
  - **Case 3c:** $r_{C^s}(d_1) > r_D(d_1)$ and $r_{C^s}(d_2) \le r_D(d_2)$
    In this case since r_{C^s} is concave and r_D is convex the curves have exactly one point of intersection. Let a_2 be the value of t where the curves intersect and let $a_1 = d_1$.

Since the function r_{C^c} is affine, it is also concave and so by Lemma 3.2 the body C^c is convex. To complete the proof, we need to show that $\mathrm{dist}(D, C^c) \le \mathrm{dist}(D, C^s)$ in all three cases.

By definition, the distance between D and C^s is

$$\mathrm{dist}(D, C^s) = \mathrm{Vol}(D \setminus C^s) + \mathrm{Vol}(C^s \setminus D) = \int_{-d}^{d} \mathrm{Vol}_{n-1}(D_t \setminus C^s_t) + \mathrm{Vol}_{n-1}(C^s_t \setminus D_t)\,\mathrm{d}t.$$

For Case 1, since D, C^s, C^c are symmetric about e_1 and $r_D(t) \ge r_{C^c}(t) \ge r_{C^s}(t)$ for every $t \in [d_1, d_2]$,

$$\begin{aligned}
\mathrm{dist}(D, C^s) &= \int_{-d}^{d_1} \mathrm{Vol}_{n-1}(D_t)\,\mathrm{d}t + \int_{d_1}^{d_2} \mathrm{Vol}_{n-1}(D_t) \\
&\qquad\qquad - \mathrm{Vol}_{n-1}(C^s_t)\,\mathrm{d}t + \int_{d_2}^{d} \mathrm{Vol}_{n-1}(D_t)\,\mathrm{d}t \\
&\ge \int_{-d}^{d_1} \mathrm{Vol}_{n-1}(D_t)\,\mathrm{d}t + \int_{d_1}^{d_2} \mathrm{Vol}_{n-1}(D_t) \\
&\qquad\qquad - \mathrm{Vol}_{n-1}(C^c_t)\,\mathrm{d}t + \int_{d_2}^{d} \mathrm{Vol}_{n-1}(D_t)\,\mathrm{d}t \\
&= \mathrm{dist}(D, C^c).
\end{aligned}$$

For Cases 2 and 3, for $t \in (d_1, a_1) \cup (a_2, d_2)$, the ball D_t contains the ball C^s_t. Conversely, for every $t \in [a_1, a_2]$, C^s_t contains D_t. And for $t \in (-d, d_1) \cup (d_2, d)$ the ball C^s_t has zero radius Hence, the distance between D and C^s is

$$\begin{aligned}\operatorname{dist}(D, C^s) = &\int_{d_1}^{a_1} \operatorname{Vol}_{n-1}(D_t) - \operatorname{Vol}_{n-1}(C^s_t)\,\mathrm{d}t + \int_{a_1}^{a_2} \operatorname{Vol}_{n-1}(C^s_t) - \operatorname{Vol}_{n-1}(D_t)\,\mathrm{d}t \\ &+ \int_{a_2}^{d_2} \operatorname{Vol}_{n-1}(D_t) - \operatorname{Vol}_{n-1}(C^s_t)\,\mathrm{d}t + \int_{-d}^{d_1} \operatorname{Vol}_{n-1}(D_t)\,\mathrm{d}t \\ &+ \int_{d_2}^{d} \operatorname{Vol}_{n-1}(D_t)\,\mathrm{d}t.\end{aligned}$$

For every $t \in (d_1, a_1) \cup (a_2, d_2)$, we have that $r_D(t) \geq r_{C^c}(t) \geq r_{C^s}(t)$. And for every $t \in (a_1, a_2)$, we have the reverse inequalities $r_D(t) \leq r_{C^c}(t) \leq r_{C^s}(t)$. Therefore,

$$\begin{aligned}\operatorname{dist}(D, C^s) &\geq \int_{d_1}^{a_1} \operatorname{Vol}_{n-1}(D_t) - \operatorname{Vol}_{n-1}(C^c_t)\,\mathrm{d}t + \int_{a_1}^{a_2} \operatorname{Vol}_{n-1}(C^c_t) - \operatorname{Vol}_{n-1}(D_t)\,\mathrm{d}t \\ &\quad + \int_{a_2}^{d_2} \operatorname{Vol}_{n-1}(D_t) - \operatorname{Vol}_{n-1}(C^c_t)\,\mathrm{d}t + \int_{-d}^{d_1} \operatorname{Vol}_{n-1}(D_t)\,\mathrm{d}t \\ &\quad + \int_{d_2}^{d} \operatorname{Vol}_{n-1}(D_t)\,\mathrm{d}t \\ &= \operatorname{Vol}(D \setminus C^c) + \operatorname{Vol}(C^c \setminus D) = \operatorname{dist}(D, C^c).\end{aligned}$$

◀

3.2.4 Every truncated cone is far from D

As the last step in the proof that D is far from convex, we show that it is far from every truncated cone.

▶ **Lemma 3.6.** *Every truncated cone is $\frac{1}{8}$-far from D.*

Proof. Let C^c be a truncated cone. Without loss of generality let the truncated cone have larger radius towards the left side. We consider the two cases where $\operatorname{Vol}(C^c_{[0,d]}) \leq \frac{1}{2}\operatorname{Vol}(D_{[0,d]})$ and where $\operatorname{Vol}(C^c_{[0,d]}) > \frac{1}{2}\operatorname{Vol}(D_{[0,d]})$ separately.

Case 1: $\operatorname{Vol}(C^c_{[0,d]}) \leq \frac{1}{2}\operatorname{Vol}(D_{[0,d]})$.

In this case, Proposition 2.1 and the case condition yield

$$\operatorname{Vol}(D \triangle C^c) \geq \operatorname{Vol}(D_{[0,d]} \triangle C^c_{[0,d]}) \geq \operatorname{Vol}(D_{[0,d]}) - \operatorname{Vol}(C^c_{[0,d]}) \geq \frac{1}{2}\operatorname{Vol}(D_{[0,d]}) = \frac{1}{4}\operatorname{Vol}(D).$$

Case 2: $\operatorname{Vol}(C^c_{[0,d]}) \geq \frac{1}{2}\operatorname{Vol}(D_{[0,d]})$

In this case, if $C^c_{[-d,-\frac{d}{2}]} = \emptyset$, then from Proposition 3.1

$$\operatorname{Vol}(D \triangle C^c) \geq \operatorname{Vol}(D_{[-d,-\frac{d}{2}]} \triangle C^c_{[-d,-\frac{d}{2}]}) = \operatorname{Vol}(D_{[-d,-\frac{d}{2}]}) \geq \frac{1}{4}\operatorname{Vol}(D).$$

If $C^c_{[-d,-\frac{d}{2}]} \neq \emptyset$, then using the fact that C^c is a truncated cone with larger radius on the left side we get

$$\operatorname{Vol}(C^c_{[-\frac{d}{2},\frac{d}{2}]}) \geq \operatorname{Vol}(C^c_{[0,d]}) \geq \frac{1}{2}\operatorname{Vol}(D_{[0,d]}) \geq \frac{1}{4}\operatorname{Vol}(D).$$

Then Proposition 2.1 implies that

$$\begin{aligned}\mathrm{Vol}(D \triangle C^c) &\geq \mathrm{Vol}(D_{[-\frac{d}{2},\frac{d}{2}]} \triangle C^c_{[-\frac{d}{2},\frac{d}{2}]}) \geq \mathrm{Vol}(C^c_{[-\frac{d}{2},\frac{d}{2}]}) - \mathrm{Vol}(D_{[-\frac{d}{2},\frac{d}{2}]}) \\ &\geq \frac{1}{4}\mathrm{Vol}(D) - \mathrm{Vol}(D_{[-\frac{d}{2},\frac{d}{2}]}).\end{aligned}$$

From Proposition 3.1, we also have that $\mathrm{Vol}(D_{[-\frac{d}{2},\frac{d}{2}]})$ is exponentially smaller than $\mathrm{Vol}(D)$. Hence,

$$\mathrm{Vol}(D \triangle C_C) \geq \frac{1}{4}\mathrm{Vol}(D) - o\big(\mathrm{Vol}(D)\big) \geq \frac{1}{8}\mathrm{Vol}(D). \qquad \blacktriangleleft$$

Putting our last three lemmas together completes the proof of the main result from this section.

▶ **Theorem 3.7.** *The body D is $\frac{1}{8}$-far from convex.*

▶ Remark 3.8. In fact, the above argument shows that D is $(\frac{1}{4} - o(1))$-far from convex. With more careful calculations, it is possible to show that D is $(\frac{1}{2} - o(1))$-far from convex. This result is tight, since the body D is $(\frac{1}{2} - o(1))$-close to the convex body obtained by deleting the right half of D and extending the truncated cone in the left half to d.

4 Proofs of Theorems 1.1 and 1.2

We complete the proofs of Theorems 1.1 and 1.2 in this section. The proof of Theorem 1.1 is completed in Section 4.1, where we show that a line segment connecting two points drawn at random from the body is contained within the body with high probability. In Section 4.2, we generalize this result to show that the convex hull of a set of points picked uniformly at random lies inside the body with high probability.

4.1 Non-robustness of the line characterization

We are now ready to prove Theorem 1.1 by showing that when two points x and y are drawn uniformly at random from D, then with high probability the line segment $\overline{xy}$ that connects x to y is completely contained within D.

▶ **Lemma 4.1.** *When $x, y \in D$ are drawn uniformly at random from D, then the line segment $\overline{xy}$ that joins x and y satisfies*

$$\Pr\left[\overline{xy} \not\subseteq D\right] = 2^{-\Omega(n)}.$$

Proof. Let $x = (\alpha, x_2, \ldots, x_n)$ and y be drawn independently and uniformly at random from D. By the symmetry of D with respect to reflection on the axis e_1, we can assume without loss of generality that $\alpha \leq 0$. Furthermore, since D is symmetric with respect to rotations around e_1, we can also assume that $x_2 \geq 0$ and rest of the $x_i = 0$. Hence, without loss of generality let $x = (\alpha, x_2, 0, 0, \ldots, 0)$ and let $y = (\beta, y_2, \ldots, y_n)$.

If $\beta \leq 0$, then both x and y lie in the same half of D, and that half is a convex set so the line segment $\overline{xy}$ is contained in D.

Consider the case now where $\beta > 0$. By Proposition 3.1, with probability $1 - 2^{-\Omega(n)}$ we have $\alpha \leq -d/2$ and $\beta \geq d/2$. Furthermore, for any given β since $(y_2, \ldots, y_n)$ is uniformly distributed over an $(n-1)$-dimensional ball of radius at most 1.1, from Proposition 2.3 we have that $\Pr[|y_2| \leq \frac{1}{10}] = 1 - 2^{-\Omega(n)}$. In the rest of the proof, assume that all three

inequalities $\alpha \leq -\frac{d}{2}$, $\beta \geq \frac{d}{2}$, and $|y_2| \leq \frac{1}{10}$ hold. We will show that in this case, the line passes through the center slice D_0 and, therefore, the line segment $\overline{xy}$ is contained in D, thus completing the proof of the theorem.

Consider the point $z = \frac{|\alpha|}{|\alpha|+|\beta|}(\beta, y_2, \ldots, y_n) + \frac{|\beta|}{|\alpha|+|\beta|}(\alpha, x_2, 0, 0, \ldots, 0)$. The point z lies in the hyperplane H_0. We want to show that it is contained in the slice D_0 or, equivalently, that $\|z\|^2 \leq 1$. By definition,

$$\begin{aligned}\|z\|^2 &= \left(\frac{1}{|\alpha|+|\beta|}\right)^2 \left(|\alpha| y_2 + |\beta| x_2\right)^2 + \left(\frac{|\alpha|}{|\alpha|+|\beta|}\right)^2 \sum_{i=3}^{n-1} y_i^2 \\ &= \left(\frac{|\beta| x_2}{|\alpha|+|\beta|}\right)^2 + \left(\frac{1}{|\alpha|+|\beta|}\right)^2 2|\alpha||\beta| x_2 y_2 + \left(\frac{|\alpha|}{|\alpha|+|\beta|}\right)^2 \sum_{i=2}^{n} y_i^2.\end{aligned}$$

Since x and y are in D, then $\sum_{i=2}^{n} y_i^2 \leq (1.1)^2$ and $x_2 \leq 1.1$. And we have that $y_2 \leq 0.1$. Substituting these bounds into the above expression, we obtain

$$\begin{aligned}\|z\|^2 &\leq \left(\frac{1.1|\beta|}{|\alpha|+|\beta|}\right)^2 + \left(\frac{1}{|\alpha|+|\beta|}\right)^2 .22|\alpha||\beta| + \left(\frac{1.1|\alpha|}{|\alpha|+|\beta|}\right)^2 \\ &= (1.1)^2 - 2.2|\alpha||\beta| \left(\frac{1}{|\alpha|+|\beta|}\right)^2.\end{aligned}$$

Defining $\delta = |\alpha|/|\beta|$, the above equation simplifies to $\|z\|^2 \leq 1.21 - 2.2\frac{\delta}{(1+\delta)^2}$. Since $|\alpha|$ and $|\beta|$ are both in the range $[\frac{d}{2}, d]$, then $\delta \in [\frac{1}{2}, 2]$. The minimum value of the function $\frac{\delta}{(1+\delta)^2}$ in the interval $[\frac{1}{2}, 2]$ is $\frac{2}{9}$, so $\|z\|^2 \leq 1.21 - 2.2 \cdot \frac{2}{9} \leq 1$. ◀

Theorem 1.1 follows immediately from Theorem 3.7 and Lemma 4.1.

4.2 Non-robustness of the convex hull characterization

In this section, we complete the proof of Theorem 1.2 by combining Lemma 4.1 with the following structural result about the body D.

▶ **Lemma 4.2.** *For any finite set $X \subset D$, if the line connecting any two points $x, y \in X$ satisfies $\overline{xy} \subseteq D$, then*

$$\mathrm{conv}(X) \subseteq D.$$

Proof. We prove the claim by induction on the number of points in X. The base case where $|X| = 2$ is trivially true. For the base case where $|X| = 3$, let $X = \{x, y, z\}$ be any set that satisfies $\overline{xy}, \overline{xz}, \overline{yz} \subseteq D$. We can assume without loss of generality that $x, y \in D_{\geq 0}$. If $z \in D_{\geq 0}$ as well, then $\mathrm{conv}(X) \subseteq D$ since $D_{\geq 0}$ is a convex set. Let us now consider the case where $z \in D_{<0}$. Note that a line joining two points $a \in D_{\leq 0}, b \in D_{\geq 0}$ is contained in the body if and only if $\overline{ab} \cap D_0 \neq \emptyset$. From this observation, we get that $\overline{xz} \cap D_0 \neq \emptyset$ and $\overline{yz} \cap D_0 \neq \emptyset$. Define $x' = \overline{xz} \cap D_0$ and $y' = \overline{yz} \cap D_0$. Let w be any point on the line $\overline{xy}$ and define $w' = \overline{zw} \cap H_0$. Since $w \in \overline{xy}$, we have that $w' \in \overline{x'y'}$. Since $x', y' \in D_0$ and D_0 is convex, we must also have that $w' \in D_0$, and so $\overline{zw} \subseteq D$. Since every point in the convex hull of X is on the line $\overline{zw}$ for some $w \in \overline{xy}$, this means that $\mathrm{conv}(X) \subseteq D$.

For the induction step, we assume that the claim is true for all sets with at most k points for some fixed $k \geq 2$. Fix any set $X \subseteq D$ with $k+1$ elements such that every line $\overline{xy}$ connecting $x, y \in X$ is contained in D. We want to show that $\mathrm{conv}(X) \subseteq D$.

Let $x \in X$ be an element for which there exists $y \in X$ that satisfies $x_1 y_1 \geq 0$, i.e x, y are in the same half of D. Such an element x is guaranteed to exist since $|X| \geq 3$. Without loss of generality, assume $x \in D_{\leq 0}$. Define $X_k = X \setminus \{x\}$. By the induction hypothesis, we must have that $\text{conv}(X_k) \subseteq D$. Furthermore, if every $x' \in \text{conv}(X_k)$ satisfies $\overline{x'x} \subseteq D$, then $\text{conv}(X) = \text{conv}(x \cup X_k) \subseteq D$. To complete the proof, let us now assume that there exists $x' \in \text{conv}(X_k)$ for which $\overline{x'x} \not\subseteq D$ and show that this leads to a contradiction.

Define $X_1 = \{y : y \in X_k \cap D_{\leq 0}\}$ and $X_2 = X_k \setminus X_1$. By our choice of x, $|X_1| \geq 1$ and so $|X_2| \leq k-1$. And since $x' \in \text{conv}(X_k) = \text{conv}(X_1 \cup X_2)$, there exist two points $x'' \in \text{conv}(X_1)$ and $x''' \in \text{conv}(X_2)$ such that $x' \in \overline{x''x'''}$. We have $\overline{xx''} \subseteq D$ as $x, x'' \in D_{\leq 0}$ and $D_{\leq 0}$ is convex. And $\overline{xx'''} \subseteq D$ because $\text{conv}(\{x\} \cup X_2) \subseteq D$ from the induction hypothesis. Finally, since $x'', x''' \in \text{conv}(X_k)$ we also have that $\overline{x''x'''} \subseteq D$. Hence, the three points x, x'', x''' satisfy $\overline{xx''} \subseteq D$, $\overline{xx'''} \subseteq D$, and $\overline{x''x'''} \subseteq D$. Therefore, from the induction hypothesis on the set $\{x, x'', x'''\}$, $\text{conv}(x, x'', x''') \subseteq D$. This implies $\overline{xx'} \subseteq D$, which is a contradiction. Therefore, $\text{conv}(X) = \text{conv}(\{x\} \cup X_K) \subseteq D$. ◀

There exists a small constant $c > 0$ such that if we pick $m = 2^{cn}$ points, X, uniformly at random then the probability that $\forall x, y \in X$, $\overline{xy} \subset D$ is greater than $1 - \frac{1}{2^{\Omega(n)}}$. We get this by applying a union bound on Lemma 4.1. This combined with Lemma 4.2 completes the proof of Theorem 1.2.

Abstract

In this paper we study the problem of testing graph isomorphism (GI) in the CONGEST distributed model. In this setting we test whether the distributive network, G_U, is isomorphic to G_K which is given as an input to all the nodes in the network, or alternatively, only to a single node.

We first consider the *decision* variant of the problem in which the algorithm should distinguish the case where G_U and G_K are isomorphic from the case where G_U and G_K are not isomorphic. Specifically, if G_U and G_K are not isomorphic then w.h.p. at least one node should output reject and otherwise all nodes should output accept. We provide a randomized algorithm with $O(n)$ rounds for the setting in which G_K is given only to a single node. We prove that for this setting the number of rounds of any deterministic algorithm is $\tilde{\Omega}(n^2)$ rounds, where n denotes the number of nodes, which implies a separation between the randomized and the deterministic complexities of deciding GI. Our algorithm can be adapted to the semi-streaming model, where a single pass is performed and $\tilde{O}(n)$ bits of space are used.

We then consider the *property testing* variant of the problem, where the algorithm is only required to distinguish the case that G_U and G_K are isomorphic from the case that G_U and G_K are *far* from being isomorphic (according to some predetermined distance measure). We show that every (possibly randomized) algorithm, requires $\Omega(D)$ rounds, where D denotes the diameter of the network. This lower bound holds even if all the nodes are given G_K as an input, and even if the message size is unbounded. We provide a randomized algorithm with an almost matching round complexity of $O(D + (\epsilon^{-1} \log n)^2)$ rounds that is suitable for dense graphs (namely, graphs with $\Omega(n^2)$ edges).

We also show that with the same number of rounds it is possible that each node outputs its mapping according to a bijection which is an *approximate* isomorphism.

We conclude with simple simulation arguments that allow us to adapt centralized property testing algorithms and obtain essentially tight algorithms with round complexity $\tilde{O}(D)$ for special families of sparse graphs.

1 Introduction

Testing graph isomorphism is one of the most fundamental computational problems in graph theory. A pair of graphs G and H are isomorphic if there is a bijection that maps the nodes of G to the nodes of H such that every edge of G is mapped to an edge of H and likewise for non-edges. Currently, it is not known whether there exists an efficient algorithm for this problem and in fact it is one of the few natural problems which is a candidate for being in NP-intermediate, that is, neither in P nor NP-complete. In order to obtain efficient algorithms for this problem, various restrictions and relaxations were considered (e.g. [34, 30]). This problem has been extensively studied also in other computational models such as parallel computation models [29, 41, 10, 32, 46, 35, 24, 9] and in the realm of property testing in which the main complexity measure is the query complexity [17, 43, 25, 42, 38, 3].

In the context of distributive models such as the CONGEST [44] and the LOCAL [40] models, the main complexity measure is the round complexity and the computational power is usually considered to be unbounded. Therefore in these models the complexity of the problem may change dramatically. While there seem to be many sensible settings, one of the simplest settings of the problem for distributive models is to test for isomorphism between the distributed network, G_U, and a known graph, G_K, which is given as an input to all the nodes in the network, or alternatively, only to a subset of the nodes [1]. The requirement from the algorithm is that if G_K and G_U are isomorphic, then with high probability [2] all nodes should output accept and that at least one node should output reject otherwise.

Since the property of being isomorphic to a specific graph is inherently global, intuitively we expect the round complexity to be $\Omega(D)$ where D denotes the diameter of the network (even for the case in which G_K is given as an input to all the nodes in the network). As we show, this intuition is correct even for the LOCAL model, in which there is no bound on the message size. Therefore, in the LOCAL model, it is not possible to improve over the trivial algorithm that collects the entire information on the network at a single node in $O(D)$ rounds and tests for graph isomorphism in a centralized manner. In the CONGEST model, in which the message-size is bounded by $O(\log n)$, where n denotes the number of nodes in the network, implementing this trivial solution may require $O(n^2)$ rounds. This leads to the obvious question whether is it possible to obtain round complexity which is better than $O(n^2)$ in the CONGEST model.

Another interesting question is whether we can obtain better bounds if we relax the decision problem (as considered in the realm of *property testing*) such that the algorithm is only required to distinguish between pairs of graphs which are isomorphic and pairs of graphs which are *far* from being isomorphic (according to some predetermined distance measure).

In this setting we define the problem as follows. Let G_U be the distributed network and let m denote the number of edges in the network or an upper bound on this number. We say that a pair of graphs are ϵ-far from being isomorphic if ϵm edges need to be deleted/inserted in order to make the graphs isomorphic, where m denotes the number of edges in the network. An adversarially chosen node, r, receives as an input the graph G_K and a proximity parameter $\epsilon \in (0, 1)$. The requirement from the algorithm is as follows. If G_K and G_U are isomorphic, then w.h.p. all nodes should output accept. If G_K and G_U are ϵ-far from being isomorphic, then w.h.p. at least one node should output no.

[1] This formulation in which G_K is a parameter falls into the category of massively parameterized problems and is also considered in the setting of property testing [17, 25].

[2] We say that an algorithm succeed with high probability, if it succeeds with probability at least $1 - 1/n^c$ for any constant c (without changing the round complexity asymptotically).

1.1 Our Results

In this section we outline our results. We further elaborate on our results in the next sections. In all that follows, unless explicitly stated otherwise, when we refer to distributed algorithms, we mean in the CONGEST model.

A Decision Algorithm and a Lower Bound for the Decision Problem. For the (exact) decision problem we provide a randomized one-sided error algorithm that runs in $O(n)$ rounds and succeeds with high probability (see Theorem 15). The algorithm works even for the setting in which G_K is given only to a single node (that may be chosen adversely). For this setting we prove that any deterministic algorithm requires $\tilde{\Omega}(n^2)$ rounds, which implies a separation between the randomized and the deterministic complexity of the decision problem (see Theorem 17 in Appendix A). We note that our algorithm can be adapted to the semi-streaming model [15] in which it uses $\tilde{O}(n)$ bits of space and performs only one pass (see Theorem 16).

A Lower Bound for the Property Testing Variant. For property testing algorithms we show that even under this relaxation $\Omega(D)$ rounds are necessary even for constant ϵ and constant error probability. This lower bound holds even in the LOCAL model, for two-sided error algorithms, and even if all the nodes receive G_K as an input (see Theorem 18 in Appendix A). It also holds for dense graphs, namely, when $m = \Theta(n^2)$ and for sparse graphs, that is when $m = \Theta(n)$.

A Property Testing Algorithm and Computation of Approximate Isomorphism. We provide a distributed two-sided error property testing algorithm that runs in $O(D + (\epsilon^{-1} \cdot \log n)^2)$ rounds and succeeds with high probability for the case that $m = \Theta(n^2)$, implying that our result is tight up to an additive term of $(\epsilon^{-1} \cdot \log n)^2$ (see Theorem 1). This algorithm works even in the setting in which G_K is given only to a single node. We note that the graphs that are constructed for the lower bound for the exact variant are dense and have a constant diameter. Therefore for these graphs, the property testing algorithm runs in only $O((\epsilon^{-1} \cdot \log n)^2)$ rounds (while the decision algorithm runs in $O(n)$ rounds).

If G_K is given to all the nodes and the graphs are indeed isomorphic then we show that we can also approximately recover the isomorphism with the same round complexity as of testing. Specifically, each node v outputs $g(v)$ where g is a bijection such that the graph $g(G_U)$, namely the graph in which we re-name the nodes according to g, is ϵ-close to G_K.

Simulation Arguments and their application to special families of sparse graphs. Finally, we show, by simple simulation arguments, that it is possible to obtain essentially tight algorithms with $\tilde{O}(D)$ round complexity for special families of sparse graphs by adapting centralized property testing algorithms. In particular, these algorithms apply for bounded-degree minor-free graphs and general outerplanar graphs (see Appendix B) .

1.2 The Decision Algorithm

As described above, a naive approach for testing isomorphism to G_K is to gather the entire information on the network at a single node and then to test for isomorphism in a centralized manner. By the brute-force approach, we may go over all possible bijections between the nodes of the graphs and test for equality between the corresponding graphs. Our algorithm follows this approach with the difference that it only gathers a compressed version of the

network as in the algorithm of Abboud et al. [2] for the Identical Subgraph Detection problem. The idea of their algorithm is to reduce the problem of testing if two graphs are equal to the problem of testing equality between a pair of binary strings. From the fact that the test for equality has a one-sided error, namely it never rejects identical graphs, it follows that our algorithm never rejects isomorphic graphs. To ensure that our algorithm is sound we amplify the success probability of the equality test by repeating the test $\Theta(n)$ times and, as a result, obtain a total round complexity of $O(n)$.

1.3 A Lower Bound for the Decision Problem

We reduce Set-Equality to the problem of deciding isomorphism in the setting in which only a single node receives G_K as an input (as it is the case for our upper bound). The idea is to construct a graph $G_{x,y}$ over n nodes for every pair of strings $x, y \in \{0,1\}^k$ where $k = \Theta(n^2)$ such that $G_{x,y}$ is isomorphic to $G_{x',y'}$ if and only if $x = x'$ and $y = y'$. Let x and y denote the input of Alice and Bob, respectively. In the reduction, G_K is known to Alice and is taken to be $G_{x,x}$. Alice and Bob simulate the distributed algorithm on the graph $G_{x,y}$, which by construction is isomorphic to $G_{x,x}$ if and only if $x = y$, as desired. This reduction yields a lower bound of $\Omega(n^2/\log n)$ rounds for any deterministic algorithm.

1.4 A High-Level Description of the Property Testing Algorithm

Our algorithm closely follows the approach taken by Fischer and Matsliah [17] for testing graph isomorphism in the dense-graph model [26] with two sided-error. However, in order to obtain a round complexity which only depends poly-logarithmically in n (rather than a dependency of $\tilde{O}(\sqrt{n})$ as the query complexity in [17]), we need to diverge from their approach as described next.

1.4.1 The Algorithm of Fischer-Matsliah

The algorithm of Fischer-Matsliah receives as an input a graph G_K (over n vertices), referred to as the known graph, and an oracle access to the adjacency matrix of a graph G_U, referred to as the unknown graph. It also receives the proximity parameter ϵ. The algorithm begins with picking, u.a.r., a sequence of $s = \text{poly}(\epsilon^{-1}, \log(n))$ nodes from the unknown graph. The selection of these nodes induces labels for each node in the graph as follows. The label of each node v is a string of s bits where the i-th bit indicates whether v is a neighbor of the i-th node in the sequence. This labeling scheme guarantees that, with high probability, only "similar" nodes, that is, nodes with similar sets of neighbors, might have identical labels. It is not hard to see that if the graphs are isomorphic, then given that we managed to map the nodes in the sequence according to the isomorphism, both graphs should have the same frequency over labels. More surprisingly, it is shown by Fischer and Matsliah that if the nodes in the sequence are mapped according to the isomorphism then it is possible to extend this mapping on-the-fly and obtain, roughly speaking, an approximate isomorphism. In particular, they showed that as long as each node in the graph is mapped to a node with the same label in the other graph (with respect to the mapped sequence), then the obtained function is close to being an isomorphism. This is due to the fact that nodes which are too "different" are likely to have different labels and the fact that similar nodes are exchangeable. Given a candidate for the approximate isomorphism, the problem is then reduced to testing closeness of graphs. Therefore, if the graphs are isomorphic then by going over all possible mappings of the selected sequence (there are only quasi-polynomially many ways to map

these nodes) and for each such partial mapping obtaining a candidate by extending the partial mapping as described above, one should be able to obtain a candidate that passes the test, namely a function, f, which is close to being an isomorphism. On the other hand, if the graphs are far from being isomorphic then by definition any bijection gives two graphs which are far from each other. Therefore, these two cases can be distinguished by approximating the Hamming distance of the corresponding adjacency-matrices. In turn, this can be done by selecting random locations (that is, potential edges) and checking the values of both matrices in these locations. Since constructing f entirely would be too costly, one needs to be able to generate f on-the-fly. A crucial point is that its generation can not depend on the selection of the random locations. In other words, its generation should be query-order-oblivious. To this end, in the algorithm of Fischer-Matsliah they first test if the distributions over the labels are close. If so, they can safely generate f on-the-fly while ensuring that there is only little dependency between f and the queries the algorithm makes to f. This is done by simply mapping a node v to a random node in G_K that have the same label as v. [3] The query complexity of testing identity of distributions, which is $\Theta(\sqrt{n})$ [4, 45, 28, 5], dominates the query complexity of the algorithm [4]. As shown in [17], in the centralized setting this algorithm is essentially tight.

1.4.2 Our Algorithm

In the CONGEST model, by straight-forward simulation arguments it follows that one can simulate the algorithm of Fischer-Matsliah in $\tilde{O}(D + \sqrt{n})$ rounds by collecting the answers to the queries of the algorithm at a single node and simulating the centralized algorithm (see Claim 19). A crucial observation for improving this bound is that nodes that have the same label also have at least one neighbor in common (with the only exception of the all-zero label), therefore they can be coordinated by one of their common neighbors. Moreover, it is possible to obtain both samples and access to the frequencies of the labels via these coordinators. Our algorithm proceeds as follows. As in [17] a sequence C of s random nodes is selected and is sent to the entire network (in $O(D)$ rounds). Each node figures out its label and broadcasts this label to its neighbors. The node r, that received G_K as an input, selects a random set of potential edges $(i_1, j_1), \ldots, (i_k, j_k)$, where $k = \text{poly}(\log n, \epsilon^{-1})$. It then broadcasts this set to the entire network. For each potential edge, the information whether it is an actual edge in the network is sent to r. For each label of a node in $I = \{i_1, j_1, \ldots, i_k, j_k\}$, the corresponding coordinator sends to r the frequency of this label. From this point the rest of the computation is done centrally at r. We say that a sequence, P, of nodes in G_K is *good* with respect to C and I if it induces the same frequency of labels as C when restricted to labels of nodes in I. The node r goes over all possible mappings of C to the known graph and looks for good sequences (with respect to C and I). For every good sequence, P, r generates a function f on-the-fly: on query v, f maps v to a random node in V_K which is still unmatched and has the same label as v (w.r.t. P). As we show, from the fact that the sequence is good it follows that f is query-order-oblivious. Let $f(G_U)$ denote the graph obtained from G_U after applying f on V_K. As in the algorithm of Fischer-Matsliah, if the graphs are isomorphic and the sequence P is the mapping of C according to the isomorphism, then $f(G_U)$ is guaranteed

[3] The little dependency between f and the queries that the algorithm makes to f comes from the fact that the frequencies of labels of the two graphs are not necessarily identical as they are only guaranteed to be close (w.h.p.).

[4] In fact, in [17] the failure probability of the test for testing identity of distributions needs to be negligible and consequently the query complexity of this test is $\tilde{\Theta}(\sqrt{n})$.

to be (w.h.p.) ϵ-close to G_K. The set of potential edges is then used to approximate the distance between G_K and $f(G_U)$. This allows us to obtain a significant improvement in the round complexity (over the straight-forward simulation), in terms of n, from $\tilde{O}(\sqrt{n})$ to $O(\log^2 n)$.

1.5 High-level Approach for Computing an Approximate Isomorphism

As described in the previous section, if the graphs are isomorphic then w.h.p. the algorithm finds a sequence P that corresponds to a bijection f such that $f(G_U)$ is guaranteed to be (w.h.p.) ϵ-close to G_K. The algorithm accesses f only on a small set of random locations. It is tempting to try to output $f(v)$ for every v in the network. Assume now that every node in the network knows G_K. If the sequence P is indeed the mapping of C according to an isomorphism then the following naive approach should work. Each coordinator can independently map to V_K the nodes that are assigned to it according to their labels. However, it might be the case that P is not the mapping of C according to any isomorphism (although it passed the test). In particular it might be that it is not good with respect to C and V_U (recall that P is good w.r.t. C and I). In this case we may want the coordinators of the nodes to be coordinated such that they exchange the mapping of nodes with "overflow" and "underflow" labels (that is, labels that are more/less frequent in G_U than in G_K, respectively). Since there might be $O(n)$ labels, such coordination might cause too much congestion. To this end we cluster the labels according to their most significant bit and assign a single coordinator to each cluster. Since there are only $\text{poly}(\epsilon^{-1}, \log(n))$ many clusters, these coordinators can coordinate without causing too much congestion as long as they do not need to communicate too much information. The naive approach of sending the IDs of the nodes that are still un-matched is too costly as there might be a small but a constant fraction of such nodes. Alternatively, we show how the matching of these nodes can be coordinated such that each coordinator sends only $O(\log n)$ bits. In particular, each coordinator sends a number that indicates by how much it is "under-flowing" or "overflowing". Each coordinator with an under-flow reserve a set of nodes in V_K that are reserved to be the image of nodes that are assigned to other coordinators. The set of reserved nodes can be determined by the above-mentioned numbers (i.e., the numbers which indicate the under-flows and over-flows of the coordinators). Moreover, we show that each coordinator with an over-flow can determine which nodes are reserved to be the image of its over-flowing nodes. We prove that the resulting mapping, g, is close enough to f in the sense that the distance between $g(G_U)$ and $f(G_U)$ is small. We prove the latter by coupling g and f and showing that they agree on the mapping of most nodes as long as these nodes have enough neighbors (and if they do not, then their contribution to the distance between $g(G_U)$ and $f(G_U)$ has to be small).

1.6 A Lower Bound for the Property Testing Variant

We prove that for any D there exists a family of graphs with diameter $\Theta(D)$ such that any distributed two-sided error property testing algorithm for testing isomorphism on this family of graphs requires $\Omega(D)$ rounds. In the construction we start with a pair of graphs G_1 and G_2 that have diameter $O(D)$ which are far from being isomorphic. The graph G_U is then defined to be composed of G_1 and G_2 and a path of length $\Theta(D)$ that connects the two graphs. Roughly speaking, the idea is to argue that for round complexity which is at most D/c, where c is some absolute constant, the nodes in G_U which belong to the side of G_1 cannot distinguish the case in which the network is composed of two graphs which are isomorphic to G_1 (connected by a path). Likewise for the nodes that belong to the side of

G_2 (that cannot distinguish the case in which the network is composed of two graphs which are isomorphic to G_2). It then follows that the algorithm must err. In the detailed proof, which appears in the appendix, there are some technicalities that need to be addressed in order to prove that the above argument still holds when the nodes may use randomness, port numbers and IDs.

1.7 Related work

In this section we overview results in distributed decision and property testing in the CONGEST model. We also overview related results in centralized property testing.

Distributed Decision. There is a large body of algorithms and lower bounds for the *subgraph detection problem*: given a fixed graph H, and an input graph G, the task is to decide whether G contains a subgraph which is isomorphic to H. The subgraphs considered include: paths [36], cycles [36, 19, 12], triangles [31, 1, 8], cliques [11, 12, 6]. Abboud et al. [2, Sec. 6.2] considered the *identical subgraph detection problem*. In this problem the graph's nodes are partitioned into two equal sets. The task is to decide whether the induced graphs on these two sets are identical w.r.t. to a fixed mapping between the nodes of these two sets. They showed an $\Omega(n^2)$ lower bound on the number of rounds of any deterministic algorithm and a randomized algorithm that performs $O(D)$ rounds which succeeds w.h.p.

Distributed Property Testing for Graph Problems. Distributed property testing was initiated by Censor-Hillel et al. [7]. In particular, they designed and analyzed distributed property testing algorithms for: triangle-freeness, cycle-freeness, and bipartiteness. They also proved a logarithmic lower bound for the latter two properties. While they mainly focus on the bounded degree model and the general model they also studied the dense model[5]. In this model they showed that for a certain class of problems, any centralized property testing algorithm can be emulated in the distributed model such that number of rounds is q^2 where q denotes the number of queries made by the centralized tester. Fraigniaud et al. [23] studied distributed property testing of excluded subgraphs of size 4 and 5. Since the appearance of the above papers, there was a fruitful line of research in distributed property testing for various properties, mainly focusing on properties of whether a graph excludes a fixed sub-graph [22, 20, 21, 14, 13, 18]. Other problems on graphs such as testing planarity, and testing the conductance were studied in [39, 16], respectively.

Centralized Property Testing. Fischer and Matsliah [17] studied the graph isomorphism problem in the dense-graph model [26].[6] They considered four variations of the Graph Isomorphism testing problem: (1) one-sided error, where one of the graphs is known, and there is a query access to the graph which is tested, i.e., the tested graph is "unknown", (2) one-sided error, where there is a query access for both graphs, i.e., both graphs are unknown, (3) two-sided error, where one graph is known, (4) two sided error, where both graphs are unknown. For the first three variants Fischer and Matsliah [17] showed (almost)

[5] In centralized property testing, these models describe the distance measure as well as how the input graph is represented. In the distributive setting the difference between the models is only in the distance measure. The access to the input graph (which is the underlying network) is clearly the same in all models.

[6] In the dense-graph model, a graph G is considered to be ϵ-far from a property Π if the symmetric difference between its edge set to the edge set of any graph in Π is greater than $\epsilon|V(G)|^2$.

matching lower and upper bounds of, respectively: (1) $\tilde{O}(n)$, $\Omega(n)$, (2) $\tilde{O}(n^{3/2})$, $\Omega(n^{3/2})$, and (3) $\tilde{O}(n^{1/2})$, $\Omega(n^{1/2})$, where n is the number of vertices of each input (known or unknown) graph. For the fourth variant they showed an upper-bound of $\tilde{O}(n^{5/4})$ and a lower-bound of $\Omega(n)$. Onak and Sun [43] improved the upper bound of the fourth case to $O(n) \cdot 2^{\tilde{O}\left(\sqrt{\log n}\right)}$ by bypassing the distribution testing reduction that was used by [17]. Property testing of graph isomorphism was also considered in the bounded-degree model [27][7]. Goldreich [25] proved that the query complexity of any property testing algorithm is at least $\tilde{\Omega}(n^{1/2})$, for the variant in which one graph is known, and $\tilde{\Omega}(n^{2/3})$ when both graphs are unknown. Newman and Sohler [42] provide an algorithm for minor-free graphs with degree bounded by $d = O(1)$ (this class includes for example bounded degree planar graphs) whose query complexity is independent of the size of the graph. Moreover, they showed that any property is testable in this class of graphs with the same query complexity. Kusumoto and Yoshida [38], and Babu, Khoury, and Newman [3] considered testing of isomorphism between graphs which are forests and outerplanar in the general model [33][8], respectively. They both proved an upper bound of $\operatorname{poly}\log n$ and a lower bound of $\Omega(\sqrt{\log n})$ was shown in [38]. Moreover, they proved that any graph property is testable on these family of graphs with $\operatorname{poly}\log n$ queries.

2 The Algorithm for Testing Isomorphism in Dense Graphs

In this section, we describe and analyze the distributed algorithm for testing graph isomorphism in dense graphs. We begin with several useful definitions and observations, followed by the listing Algorithm 1 and the proof of its correctness (which follows from Lemma 11 and Lemma 12). Finally we discuss in more details how the algorithm is implemented in the CONGEST model.

We establish the following theorem.

▶ **Theorem 1.** *There exists a distributed two-sided error property testing algorithm for testing isomorphism (of dense graphs) that runs in $O(D + (\epsilon^{-1}\log n)^2)$ rounds in the CONGEST model. The algorithm succeeds with high probability.*

2.1 Definitions and Notation

We shall use the following definitions in our algorithm and in its analysis.

Let G be a graph and let $C = (c_1, \ldots, c_s)$ be a sequence of s nodes from $V(G)$.

▶ **Definition 2** ([17])**.** *For every node $v \in V(G)$, the C-label of v in G, denoted by $\ell_C^G(v)$, is a string of s bits defined as follows:*

$$\ell_C^G(v)_i = 1 \Leftrightarrow c_i \in N_G(v)\,,$$

where $N_G(v)$ denotes the neighbors of v in G.

For the graphs we consider, $G = (V, E)$, we assume $V \subseteq [|V|^c]$ for some absolute constant $c \geq 1$. In particular we assume that there is a total order defined on V. We use the $\triangle$-operator to denote both the symmetric difference between two sets and when applied on

[7] In the bounded-graph model, a graph G with maximum degree d, is considered to be ϵ-far from a property Π if the symmetric difference between its edge set to the edge set of any graph in Π is greater than $\epsilon d|V(G)|$

[8] In the general-graph model, a graph G, is considered to be ϵ-far from a property Π if the symmetric difference between its edge set to the edge set of any graph in Π is greater than $\epsilon|E(G)|$.

graphs it denotes the Hamming distance between the corresponding adjacency matrices. We assume that the columns and rows of the adjacency matrices are ordered according to the order on the vertices.

▶ **Definition 3** ([17]). *For $\beta \in (0,1]$, we say that C is β-separating if for every pair of nodes u, v such that $|\triangle(N(u), N(v))| \geq \beta n$ it holds that u and v have different C-labels in G.*

▶ **Definition 4** (inverse of ℓ_C^G). *For a label $x \in \{0,1\}^s$, define $S_C^G(x) \triangleq \{v \in V(G) : \ell_C^G(v) = x\}$. Namely, $S_C^G(x)$ is the set of nodes in G for which the C-label is x.*

Let G and H be a pair of graphs such that $|V(G)| = |V(H)|$. The following definitions are defined with respect to a pair of sequences of $s \geq 1$ nodes from $V(G)$ and $V(H)$, $C_G = (c_1^G, \ldots, c_s^G)$ and $C_H = (c_1^H, \ldots, c_s^H)$, respectively.

We next define what we mean by saying that the mapping of a function $f : V(G) \to V(H)$ is consistent w.r.t. the labels of C_G and C_H.

▶ **Definition 5.** *For $f : V(G) \to V(H)$ which is a bijection, we say that f is* (C_G, C_H)-label-consistent *if the following holds:*

1. *f maps C_G to C_H: $f(c_i^G) = c_i^H$ for every $i \in [s]$.*
2. *The label of a node and its image is the same: $\ell_{C_G}^G(v) = \ell_{C_H}^H(f(v))$ for every $v \in V(G)$.*

For $f : V(G) \to V(H)$ and a sequence $C = (c_1, \ldots, c_s)$, we define $f(C)$ to denote $(f(c_1), \ldots, f(c_s))$ and $f(G)$ to denote the graph whose nodes are $V(H)$ and its edge set is $\{\{f(u), f(v)\} : \{u, v\} \in E(G)\}$.

We next observe that if G and H are isomorphic then for any sequence C and any function f which is an isomorphism between G and H, f is consistent w.r.t. C and $f(C)$.

▶ **Observation 1.** *If G and H are isomorphic and π is an isomorphism from $V(G)$ to $V(H)$ then for every sequence of nodes , C, from $V(G)$, π is $(C, \pi(C))$-label consistent. In particular, $|S_C^G(x)| = |S_{\pi(C)}^H(x)|$ for every $x \in \{0,1\}^s$.*

If f is not an isomorphism then it might be the case that it is not consistent w.r.t. C and $f(C)$. We next define a weaker notion of consistency which is being maximally-label-consistent.

▶ **Definition 6.** *We say that a function $f : V(G) \to V(H)$ is* maximally (C_G, C_H)-label-consistent *if the following holds:*

1. *f is a bijection.*
2. *f maps C_G to C_H: $f(c_i^G) = c_i^H$ for every $i \in [s]$.*
3. *For every $x \in \{0,1\}^s$ such that $|S_{C_G}^G(x)| = |S_{C_H}^H(x)|$, f maps the elements of $S_{C_G}^G(x)$ to the elements of $S_{C_H}^H(x)$.*

▶ **Definition 7.** *For a pair of graphs G and H, we say that a function, $f : V(G) \to V(H)$,* ϵ-approximates isomorphism *if f is a bijection and $f(G)$ is ϵ-close to H.*

See Figure 1 for illustration for the definitions in this section.

2.2 Distributed Algorithm Description

The listing of the distributed algorithm appears in Algorithm 1. The detailed description of the distributed implementation of Algorithm 1 appears in Section 2.4.

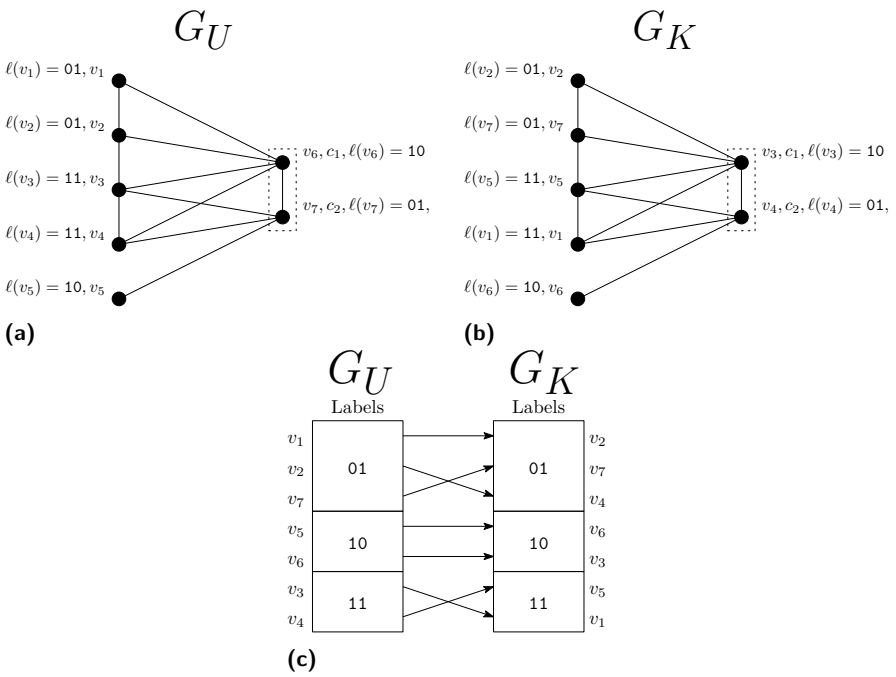

Figure 1 The unknown G_U and known G_K graphs are depicted in Sub-figure 1a, and 1b, respectively. The C sequence consists of the nodes $c_1 = v_6$ and $c_2 = v_7$. Hence, the label of a node v is a binary string $\ell_C^{G_U} = (b_2, b_1) \in \{0,1\}^2$, where $b_i = 1 \Leftrightarrow c_i \in N(v)$, and the same for G_K. In the figures, we removed the super (sub) scripts as they are clear from the context. The induced labels are depicted next to the node number. Note that all the nodes have a neighbor in C, hence the label class 00 is empty. In Sub-figure 1c two tables are depicted: (1) label assignment to the nodes of G_U, and (2) label assignment to the nodes of G_K. The order of which the nodes are presented is according to the (single) isomorphism function between the two graphs. One can observe that the number of nodes per each corresponding label-classes, e.g., a buckets, is the same, as well as buckets which have the same msb bit, e.g., a cluster of labels. A random bijection that preserves the bucket of labels is depicted by the arrows. We show in Thm. 13 that such a bijection yields graphs which are close to being isomorphic.

2.3 Correctness of the Distributed Testing Algorithm

In this subsection we prove the correctness of our algorithm. We begin with a couple of claims and lemmas that we use in our proof. Missing proofs are deferred to Appendix C.

The proof of the following claim appears in [17]. The proof of Lemma 9 can be derived from the proof of Lemma 4.11 in [17] (for the sake of completeness we provide both proofs in the appendix).

▷ Claim 8 ([17]). For $\beta \in (0,1]$ and a sequence, C, of $s = \Theta(\log(n/\delta)/\beta)$ nodes, chosen uniformly at random, C is β-separating with probability at least $1 - \delta$.

▶ **Lemma 9** ([17]). *Let G and H be isomorphic graphs and let π be an isomorphism between them. For any C that is an ϵ-separating sequence of nodes of G and for any f that is $(C, \pi(C))$-label-consistent it holds that $\Delta(f(G), H) \leq \epsilon n^2$.*

The following claim is implied directly from the multiplicative Chernoff's bound.

▷ Claim 10. Let G and H be two graphs such that $V(G) = V(H)$. Then by querying the adjacency-matrices of G and H in $\Theta(\log(1/\delta)/\epsilon)$ random entries it is possible to distinguish between the case that $\Delta(G,H) > \epsilon n^2$ from the case that $\Delta(G,H) \leq \epsilon n^2/2$ with probability at least $1 - \delta$.

Algorithm 1 Testing Isomorphism: The distributed network is $G_U = (V_U, E_U)$.

Input: A "known" graph, $G_K = (V_K, E_K)$ and a proximity parameter ϵ are given as an input to a single node r (may be chosen adversarially).

Output: with high probability, all nodes output yes if G_K is isomorphic to G_U and no otherwise.

1 Compute a BFS tree, T, in G_U rooted at r.

2 Pick, u.a.r., a sequence of $s \triangleq \Theta(\epsilon^{-1} \log |V_U|)$ nodes in G_U. Let $C \triangleq (c_1, \ldots, c_s)$ denote this sequence.

3 Each node $v \in V(G_U)$ computes its label, $\ell_C^{G_U}(v) \in \{0,1\}^s$, according to C and its neighbors in G_U (see Definition 2), and sends this label to its neighbors.

4 The node r picks a sequence of $t \triangleq \Theta(\epsilon^{-1} \log(|V_K|^s))$ pairs of nodes, $A = ((i_1, j_1), \ldots, (i_t, j_t))$, u.a.r. from $V_U \times V_U$. Let $I \triangleq \{i_1, j_1, \ldots, i_t, j_t\}$.

5 For every $e \in A$, r sends e down the BFS tree and learns whether $e \in E_U$ or not. Similarly, for every $v \in I$, it learns $\ell_C^{G_U}(v)$, i.e., the C-label of v in G_U.

6 For each sequence, $P = (p_1, \ldots, p_s)$, of s nodes from V_K, r proceeds as follows:

1. For every $i \in [s]$, verify that $\ell_C^{G_U}(c_i) = \ell_P^{G_K}(p_i)$. If not, then reject P as a candidate and proceed to the next sequence.
2. For every $v \in I$, let ℓ denote $\ell_C^{G_U}(v)$. Check if $|S_C^{G_U}(\ell)| = |S_P^{G_K}(\ell)|$. If not, then reject P as a candidate and proceed to the next sequence.
3. Pick uniformly at random a function f from the set of all functions that are maximally (C, P)-label-consistent (see Definition 6).
4. Compute the number of edges in A which are non-edges in $f(A)$ and vice-versa. That is, the number of edges $(i_k, j_k) \in A$ such that $(i_k, j_k) \in E_U$ and $(f(i_k), f(j_k)) \notin E_K$, or $(i_k, j_k) \notin E_U$ and $(f(i_k), f(j_k)) \in E_K$). If it is at most $(3\epsilon)|A|/2$ then **return** yes.

If all sequences, P, failed to pass the previous step then **return** no.

▶ **Lemma 11.** *If G_U is isomorphic to G_K then Algorithm 1 accepts with high probability.*

Proof. Assume G_U is isomorphic to G_K and let $\pi : V(G_U) \to V(G_K)$ denote an isomorphism from G_U to G_K. Since the algorithm goes over every sequence P of s nodes from V_K, it also checks $\pi(C)$. By Observation 1, the probability that $\pi(C)$ passes Step 2 is 1. By Claim 8, with high probability, C is $(\epsilon/2)$-separating (see Definition 3). By Lemma 9, if C is $(\epsilon/2)$-separating, then $f(G_U)$ is $(\epsilon/2)$-close to $\pi(G_U) = G_K$. If $f(G_U)$ is $(\epsilon/2)$-close to G_K, then by Claim 10, with high probability $\pi(C)$ passes Step 4. Therefore by the union bound, the algorithm accepts with high probability. ◀

▶ **Lemma 12.** *If G_U is ϵ-far from being isomorphic to G_K then Algorithm 1 rejects with high probability.*

Proof. Assume G_U is ϵ-far from being isomorphic to G_K. We claim that with high probability, any sequence P, fails to pass Step 6. We show this by bounding the probability that a fixed P passes Step 6 and then apply the union bound over all possible sequences. Fix a sequence P and assume that P passes Step 2 (otherwise we are done). Let f be the corresponding f from Step 3 (that is chosen at random). Since G_U is ϵ-far from being isomorphic to G_K, by definition, $\Delta(f(G_U), G_K) \geq \epsilon n^2$. Recall that f is chosen uniformly at random from the set of functions that are maximally (C, P)-label-consistent. By Construction the selection of f is independent of the selection of A. Therefore we can apply Claim 10 on Step 4 as A is a

set of potential edges chosen uniformly at random and, in particular, independently from the random coins in which we use to select f. By Claim 10, P succeeds to pass Step 4 with probability at most $1/|V_K|^{s+c}$ for any absolute constant c. Thus, the lemma follows by a union bound over all possible sequences, as their number is bounded by $|V_K|^s$. ◀

2.4 A Detailed Description of the Distributed Implementation of Algorithm 1

In this section we provide a detailed description of the distributed implementation of our algorithm. We focus on steps for which the implementation is not straightforward and analyze their round complexity. In particular, we focus on Steps 2,6.2,6.3-6.4.

Step 2: Selecting s Nodes u.a.r. In Appendix C.4 we describe a simple procedure to select s nodes uniformly at random (which is a kind of folklore). The round complexity of this procedure is $D + s$.

Step 6.2: Computing the Size of $S_C^{G_U}(\ell)$. Clearly, r can compute $S_P^{G_K}(\ell)$ for any label ℓ as r knows P and G_K. Therefore, in order to describe the implementation of Step 2 it suffices to explain how r can obtain $|S_C^{G_U}(\ell)|$.

We begin with the special case of $\ell = (0, \ldots, 0)$. The nodes in G_U that have this label are nodes that are not adjacent to any one of the nodes in C. Their number can be computed in $O(D)$ rounds by summing it up the BFS tree as follows. Assume w.l.o.g. that every node knows its layer in the BFS-tree. In the first round, every node that is in the last layer (which is also a leaf) sends 1 up to its parent if its C-label is $(0, \ldots, 0)$. In the next round, all nodes in the next layer sum up the received numbers and add 1 if their C-label is $(0, \ldots, 0)$. They send this number up to their parents and so on until we get to the root.

Consider a label ℓ for which at least one bit is 1. Let $\mathrm{msb}(\ell)$ denote the maximum i such that $\ell_i = 1$. Since the node $c_{\mathrm{msb}(\ell)}$ is connected to all nodes whose C-label is ℓ, it can compute their total number (recall that in Step 3 every node sends its C-label to all its neighbors) and send it to the root. Therefore, by a pipelining argument, the root can obtain $|S_C^{G_U}(\ell)|$ for every ℓ which is a C-label of a node in I in $O(D + |I|) = O(D + (\epsilon^{-1} \log n)^2)$ rounds.

Steps 6.3-6.4: Accessing f. Recall that we require from f to be chosen u.a.r. from the set of all functions that are maximally (C, P)-label-consistent (see Definition 6). Recall that f is only evaluated on nodes in I but at the same time its selection has to be independent of A (and I). In particular, the selection of f should be independent of the queries we make to f. To this end, the root verifies the following:

1. In Sub-step 1 of Step 6 it verifies that for the selected sequences, C and P, corresponding nodes have matching labels. Namely, $\ell_C^{G_U}(c_i) = \ell_P^{G_K}(p_i)$ for every $i \in [s]$.
2. In Sub-step 2 of Step 6 it verifies that $|S_C^{G_U}(\ell)| = |S_P^{G_K}(\ell)|$ for every ℓ which is a C-label of a vertex in I.

If both conditions hold, then it follows that by mapping the nodes in $S_C^{G_U}(\ell)$ to the nodes in $S_P^{G_K}(\ell)$ u.a.r. and independently from the mapping of all other nodes (except for the mapping of C to P which is already determined) for every ℓ such that $|S_C^{G_U}(\ell)| = |S_P^{G_K}(\ell)|$, we are in fact accessing f which is drawn according to the desired distribution. Therefore the root r simply maps every $v \in I$ to a uniform node $u \in V_K$ such that: (1) $\ell_C^{G_U}(v) = \ell_P^{G_K}(u)$ (2) u is still unmapped (such node always exists). Since r knows G_K and $\ell_C^{G_U}(v)$ for every $v \in I$, it is able to compute $f(v)$ for every $v \in I$, as desired.

Notice that if we evaluated f in the same manner as described above for nodes, v, whose labels, ℓ, are such that $|S_C^{G_U}(\ell)| \neq |S_P^{G_K}(\ell)|$ then the selection of f would not be independent of I. For instance, if $|S_C^{G_U}(\ell)| > |S_P^{G_K}(\ell)|$ then the first queries of nodes in $S_C^{G_U}(\ell)$ will be mapped to $S_P^{G_K}(\ell)$ but then we will run out of nodes in $S_P^{G_K}(\ell)$, implying that the rest of the nodes in $S_C^{G_U}(\ell)$ will be mapped to nodes with a different label than ℓ. Hence, in this case the selection of f will not be oblivious to the order of queries we make to it (and in particular is not independent of I). In the next section we describe a bijection g which can be evaluated on all the nodes in G_U (with the same round complexity as the testing algorithm) and at the same time is close enough to f.

3 Computing an Approximate Isomorphism

In this section we prove the following theorem.

▶ **Theorem 13.** *Let G_U denote the input graph and let G_K be a graph which is isomorphic to G_U and is given as an input to all nodes in the network. There exists a randomized algorithm such that each node in G_U, v, outputs $g(v)$ where $g : V_U \to V_K$ is a bijection such that $g(G_U)$ is ϵ-close to G_K (i.e. g ϵ-approximates isomorphism). The round complexity of the algorithm is $O(D + (\epsilon^{-1} \log n)^2)$. The algorithm succeeds with high probability.*

Proof. The first step of the algorithm is to run Algorithm 1 with the only difference that in Step 6 the root also verifies that $|S_C^{G_U}(\ell)| = |S_P^{G_K}(\ell)|$ for $\ell = (0, \ldots, 0)$. Since G_K and G_U are isomorphic, by Lemma 11, w.h.p. the algorithm accepts and hence finds P and the corresponding f that pass Step 6. Recall that since f passes the test in Sub-step 6.4 then w.h.p. $f(G_U)$ is ϵ-close to G_K. If every node v could output $f(v)$ then we were done. However, we can not compute f for every node v because for a constant fraction of the nodes its computation might require global information on G_U. Instead, our goal is to output g which is $O(\epsilon)$-close to f and can be computed for every node without causing too much congestion. We next describe g and its computation.

We begin with some notation. Let $L_i \subseteq \{0,1\}^s$ denote the set of labels ℓ for which $\mathrm{msb}(\ell) = i$. Namely, L_i contains all the labels in $\{0,1\}^s$ that can be generated by the following regular expression $0^{i-1}1(0 \cup 1)^{s-i}$. Let Y denote the set of nodes in V_U whose C-label is $(0, \ldots, 0)$. Similarly, let Y' denote the set of nodes in V_K whose P-label is $(0, \ldots, 0)$. For a graph H and a sequence D let $J_D^H(i) \triangleq \cup_{\ell \in L_i} S_D^H(\ell)$, namely, this is the set of all nodes in H whose D-label belongs to L_i. We may refer to $J_D^H(i)$ as the i-th cluster of the graph H w.r.t. D. For $i \in [s]$, define $j_i \triangleq |J_C^{G_U}(i)| - |J_P^{G_K}(i)|$. Namely, j_i is the difference between the sizes of the i-th clusters in both graphs (w.r.t. C and P, respectively).

We next define the set of *reserved* nodes of V_K, denote by R. For each i such that $j_i < 0$, $|j_i|$ nodes from $J_P^{G_K}(i)$ belong to R. Specifically, these are the nodes whose order [9] is the least from the vertices in $J_P^{G_K}(i)$. We consider the order to be the same order as in V_K only that elements in P have the highest order (this is to ensure that none of the elements in P belong to R).

The function g is selected randomly. We next describe the selection of g the outcome of a global random process. Thereafter we describe how this random process can be implemented distributively.

[9] Recall that we assume that there is a total order on V_K which is known to all the nodes in G_U.

Description of g . We describe the selection of g by describing how the nodes in $J_C^{G_U}(i)$ are mapped to V_K, for every $i \in [s]$. We consider three cases, according to the value of j_i.

The first case is when $j_i = 0$. We have the following sub-cases.

1. For every $\ell' \in L_i$ such that $|S_C^{G_U}(\ell')| = |S_P^{G_K}(\ell')|$, g matches u.a.r. the elements in $S_C^{G_U}(\ell')$ to the elements in $S_P^{G_K}(\ell')$.
2. The rest of the elements in $J_C^{G_U}(i)$ are matched u.a.r. to the unmatched elements in $J_P^{G_K}(i)$.

Therefore, in this case the elements in $J_C^{G_U}(i)$ are matched only to the elements in $J_P^{G_K}(i)$ and vice versa.

The second case is when $j_i < 0$. We have the following sub-cases.

1. For every $\ell' \in L_i$ such that $|S_C^{G_U}(\ell')| = |S_P^{G_K}(\ell')|$ and $S_P^{G_K}(\ell') \cap R = \emptyset$, g matches the elements in $S_C^{G_U}(\ell')$ u.a.r. to the elements in $S_P^{G_K}(\ell')$.
2. For every $\ell' \in L_i$ such that $|S_C^{G_U}(\ell')| = |S_P^{G_K}(\ell')|$ and $S_P^{G_K}(\ell') \cap R \neq \emptyset$, g matches u.a.r. a random set of $|S_P^{G_K}(\ell') \setminus R|$ elements from $S_C^{G_U}(\ell')$ to $S_P^{G_K}(\ell') \setminus R$.
3. The rest of the un-matched elements in $J_C^{G_U}(i)$ are mapped u.a.r. to the un-matched elements in $J_P^{G_K}(i) \setminus R$.

Observe that all the elements in $J_C^{G_U}(i)$ are matched to elements in $J_P^{G_K}(i)$ and that the elements that belong to $J_P^{G_K}(i) \cap R$ are still un-matched.

The third case is when $j_i > 0$. We have the following sub-cases.

1. For every $\ell' \in L_i$ such that $|S_C^{G_U}(\ell')| = |S_P^{G_K}(\ell')|$, g matches the elements in $S_C^{G_U}(\ell')$ u.a.r. to the elements in $S_P^{G_K}(\ell')$.
2. The rest of the elements in $J_C^{G_U}(i)$ are matched u.a.r. to the unmatched elements in $J_P^{G_K}(i)$.
3. The remaining $|j_i|$ elements in $J_C^{G_U}(i)$ are matched to the nodes of order $(\sum_{a<i} j_a) + 1$ to $(\sum_{a<i} j_a) + j_i$ in R.

This concludes the description of g for nodes that do not belong to Y. It remains to describe g for nodes that belong to Y. We defer this description to Appendix C.5 as well as the description on how it is computed distributively.

We next describe how g can be computed distributively for nodes that have at least one neighbor in C (namely, nodes that do not belong to Y). Each node $c_i \in C$ is responsible to compute and to send to each node v whose C-label is in L_i the value $g(v)$ (note that c_i and v are necessarily neighbors). As a preliminary step, each node c_i computes $j_i = |J_C^{G_U}(i)| - |J_P^{G_K}(i)|$ and sends (i, j_i) up the BFS tree. Notice that $\sum_{i \in s} j_i = 0$ as $|S_C^{G_U}(\ell)| = |S_P^{G_K}(\ell)|$ for $\ell = (0, \ldots, 0)$ and $|V_U| = |V_K|$. The root sends the set $\{(i, j_i)\}_{i \in s}$ down the BFS tree. By knowing G_K and the set $\{(i, j_i)\}_{i \in s}$, every node c_i can easily compute R. It is not hard to see that this suffices in order to match the elements in $J_C^{G_U}(i)$ to V_K as described above.

By construction it follows that g is a bijection. The bound on the round complexity follows from the bound on the round complexity of Algorithm 1 and the fact that there are only $s = O(\epsilon^{-1} \log n)$ clusters. It remains to prove the following claim.

▷ Claim 14. With high probability $\Delta(g(G_U), G_K) < \epsilon n^2$.

Proof. We observe that both f and g are functions that are chosen randomly. To prove the claim about g we couple g to f and show that they agree on the mapping of most vertices from the set of vertices that have $\Omega(\epsilon n)$ neighbors. This will imply that $\Delta(f(G_U), g(G_U)) = O(\epsilon n^2)$. By Claim 10, since f passed the test in Step 4, w.h.p. $\Delta(f(G_U), G_K) < \epsilon n^2$. We denote this event by E_1. From the fact that w.h.p. E_1 occurs, with combination with the coupling it will follow that w.h.p. $\Delta(g(G_U), G_K) = O(\epsilon n^2)$. Therefore, by setting the proximity parameter to be $\Theta(\epsilon)$ the claim will follow.

Consider the following description of g in terms of f. Let $B = \{\ell \in \{0,1\}^s : |S_C^{G_U}(\ell)| \neq |S_P^{G_K}(\ell)|\}$. For every $v \in V_U$, $g(v) = f(v)$ unless $v \in Y \cup B$ or, $v \notin Y \cup B$ and $f(v) \in R$. In these cases we match v to a node in V_K as listed in the description of g. Observe that under this formulation the distribution of g remains the same. The only difference is that now, for the sake of the analysis, it is coupled to the distribution of f.

It follows that the number of nodes $v \in V_U$ for which $f(v) \neq g(v)$ is at most $|Y|+|R|+|B|$. By Step 2 of Algorithm 1, with high probability it holds that $\sum_{\ell \in B} |S_C^{G_U}(\ell)| \leq \epsilon n$. On the other hand, w.h.p., the number of neighbors of every node in Y is at most ϵn. This implies that the number of nodes in the neighborhood of Y' is at most $O(\epsilon n^2)$ (since otherwise would reject f w.h.p.). Therefore, w.h.p., the contribution of the nodes in Y and Y' to $\Delta(f(G_U), g(G_U))$ is at most $O(\epsilon n^2)$. Thus, w.h.p. $\Delta(f(G_U), g(G_U)) = O(\epsilon n^2)$, as desired. We denote this event by E_2.

Hence, we obtain by union bound over the probability that either $\overline{E_1}$ or $\overline{E_2}$ occur, that w.h.p. $\Delta(g(G_U), G_K) = O(\epsilon n^2)$. By setting the proximity parameter of the algorithm to be ϵ/c for some absolute constant $c > 1$ (which does not affect the asymptotic complexity of the algorithm), we obtain the desired result. ◁

This concludes the proof of the Theorem. ◀

4 Distributed Algorithm for Deciding Isomorphism

In this section we prove the following theorem.

▶ **Theorem 15.** *There exists a randomized distributed algorithm in the CONGEST model that decides if G_K and G_U are isomorphic with high probability. The round complexity of the algorithm is $O(n)$. The algorithm works even if G_K is given only to a single (arbitrary) node.*

Proof. The idea of the algorithm is to go over all possible one-to-one mappings between the nodes of G_K and the nodes of G_U and to test for equality of the corresponding adjacency matrices. The test for equality is performed with very high confidence level in order to ensure that the total error probability is bounded by a small constant. We note that a similar reduction for testing equality also appears in the algorithm of [2, Sec. 6.2] for the Identical Subgraph Detection problem (ISDP).

The first step of our algorithm is to construct a BFS tree and to assign to each node in the network a unique label in $[n]$ where $n \triangleq |V(G_K)|$. This step requires $\Omega(D)$ rounds where D denotes the diameter of G_U (see details on the implementation of this step in the proof of Theorem 13). Consider the adjacency matrix of G_U, M, in which the rows are sorted according to the labels assigned to the nodes. We consider the natural total order on the following set of pairs of nodes $P = \{(i,j) : i \in [n], j \in [n], i < j\}$ in which the pairs are sorted according to the first element and ties are broken according to the second element. Let $\ell(i,j)$ denote the order of the pair (i,j). Each pair $(i,j) \in P$ corresponds to the potential edge between the pair of nodes with labels i and j, respectively. The matrix M can be represented as an integer $s(M)$ where for each $(i,j) \in P$ the $\ell(i,j)$-th lsb (least significant bit) of the binary representation of $s(M)$ indicates whether (i,j) is an edge in the graph. Observe that we can calculate $s(M)$ in D rounds by starting the calculation at the lowest layer of the BFS tree and summing up the outcomes as we go up the tree, layer by layer. The calculation is performed such that each power of two, 2^ℓ, is added (once) if and only if the corresponding edge is present in the graph (i.e. $2^{\ell(i,j)}$ is added if and only if (i,j) is present in the graph).

Since the representation of $s(M)$ requires $O(n^2)$ bits, for our goal we calculate $s(M)$ mod p instead, where p is a prime number in $[n^2]$ chosen uniformly at random. To this end we proceed in the same manner as mentioned above only that before the nodes send up the

tree the outcome of the intermediate sums, they apply the $\mod p$ operation on the outcome. Let $\mathcal{P} = \{p_1, \ldots, p_k\}$ be a multiset of k prime numbers, where $k = \Theta(n)$, each chosen, by a single node v, independently and uniformly at random from the first n^2 primes. [10] The node v broadcasts $\mathcal{P}$ to all the nodes in network in $O(n)$ rounds. Let M' denote the adjacency matrix of G_K. If $M' \neq M$ then the probability that $s(M) \equiv s(M') \mod p$ for a random prime number in $[n^2]$ is at most $1/\Omega(n)$ [37]. Therefore the probability that $s(M) \equiv s(M') \mod p$ every $p \in \mathcal{P}$ is at most $1/\Omega(n^k) = 1/\Omega(n^n)$. Thus we can test with one-sided error if G_U and G_K are equal. The soundness of the equality test is $1 - 1/\Omega(n^n)$. We can apply the equality test for every mapping π between G_K and G_U and return yes if and only if there exists a mapping for which the test accepts. Namely, we go over all possible permutations over the nodes of G_K and for each permutation, π, we perform the equality test between $s(M)$ and $s(\pi(M'))$ where $\pi(M')$ denotes adjacency matrix of G_K after applying the permutation π on the nodes. By the soundness of the equality test and the union bound, the probability that this test returns no when G_K and G_U are not isomorphic is at least $2/3$ (for an appropriate adjustment of the parameters).

By standard pipelining, it is possible to calculate $s(M) \mod p$ for every $p \in \mathcal{P}$ in $O(D+k)$ rounds, therefore the round complexity of the above test is $O(n)$. To verify this observe that in order to execute the above test the only information we need is of G_K and the result of $s(M) \mod p$ for every $p \in \mathcal{P}$. This concludes the proof. ◀

We observe that the above-mentioned algorithm can be adapted to the semi-streaming in a straight-forward way as follows.

▶ **Theorem 16.** *There exists an algorithm in the semi-streaming model that receives a graph G_K over n nodes as an input, where the space for storing G_K is a read-only memory, and a stream of the edges of another graph G_U (according to any order) and decides, with one-sided error, whether G_K and G_U are isomorphic or not. The algorithm performs one-pass and uses $O(n \log n)$ bits of space.*

Proof. Assume w.l.o.g. that the labels of the nodes in G_U and G_K are taken from $[n]$. Otherwise we can re-name then by using a table of size $O(n \log n)$ bits. Let M denote the adjacency matrix of G_U. We first compute $s(M) \mod p$ for every $p \in \mathcal{P}$ as in the proof of Theorem 15, in one-pass, using $O(n \log n)$ bits of space. We then go over all permutations of the nodes of G_K and perform the same computation for the corresponding adjacency matrix. We accept if and only if there exists a permutation π for which $s(M) \equiv s(M') \mod p$ every $p \in \mathcal{P}$, where M' denotes the adjacency matrix of G_K after we permuted the nodes according to π. Observe that we can go over the permutations one by one according to the lexicographical order by using $O(n \log n)$ bits of space. Therefore, the total space the algorithm uses is $O(n \log n)$, as desired. ◀

A Lower Bounds

In this section we establish two lower bounds. The first is for the decision variant of GI, and the second is for the testing variant.

For the decision variant, we prove a near-quadratic lower bound for any deterministic distributed algorithm in the CONGEST model. The second lower bound states that any Isomorphism testing distributed algorithm requires diameter time. This lower bound holds also for randomized algorithms, and in fact holds in the LOCAL model, even if *all* vertices are given as an input the graph G_K.[11]

A.1 An $\Omega(n^2/\log n)$ Lower Bound for Deciding Isomorphism Deterministically

The decision variant of our Isomorphism testing problem is as follows: if G_K and G_U are isomorphic, then all nodes should output yes, while if the graphs are not isomorphic, at least one node should output no.

▶ **Theorem 17.** *Any distributed deterministic algorithm in the CONGEST model for deciding whether G_U is isomorphic to G_K requires $\Omega(n^2/\log n)$ rounds for the setting in which G_K is given as an input to a single node. Moreover, this bound holds even for graphs with constant diameter.*

Proof. We reduce the problem of Set-Equality to the problem of deciding Isomorphism. The reduction is as follows. Alice and Bob each receives as an input a subset of k^2 elements, $A \subseteq \{(x,y) \mid x \in \{a_1^0,\ldots,a_1^{k-1}\}, y \in \{a_2^0,\ldots,a_2^{k-1}\}\}$ and $B \subseteq \{(x,y) \mid x \in \{b_1^0,\ldots,b_1^{k-1}\}, y \in \{b_2^0,\ldots,b_2^{k-1}\}\}$, respectively. According to their inputs they construct a pair of graphs, G_U and G_K, such that $A = B$ if and only if G_U is isomorphic to G_K, as described momentarily.

[11] In the LOCAL model there is no limitation on message size per round per edge. Obviously, a lower bound in the LOCAL model also applies to the CONGEST model.

Since, Set-Equality has a deterministic communication complexity which is linear in size of the universe [37], which is $\Omega(k^2)$ in this case, it follows that any distributed deterministic algorithm in the CONGEST model for deciding whether G_U is isomorphic to G_K requires $\Omega(n^2/\log n)$ rounds.

We now describe the graph G_U which is constructed by Alice and Bob. The set of nodes in Alice's graph is composed of u, u', u'', the subsets $A_1 = \{a_1^0, \ldots, a_1^{k-1}\}$ and $A_2 = \{a_2^0, \ldots, a_2^{k-1}\}$, and the nodes $t_{A_1}, t_{A_2}, t_u^1, t_u^2$ (see Figure 2). The subgraph induced on the nodes in A_1 is the path $a_1^0, \ldots, a_1^{k-1}$. Similarly, the subgraph induced on the nodes in A_2 is the path $a_2^0, \ldots, a_2^{k-1}$. The nodes u and u'' are adjacent to all nodes in A_1 and A_2, respectively. Both nodes u and u'' are adjacent to the node u'. The node u is adjacent to t_u^1 and t_u^2. The nodes a_1^0 and a_2^0 are adjacent to the nodes t_{A_1} and t_{A_2}, respectively. Additionally, the edge (a_1^x, a_2^y) belongs to Alice's subgraph if and only if the corresponding (x, y) element is in A.

The subgraph of Bob is defined similarly only that the nodes $v, v', v'', t_{B_1}, t_{B_2}$ take the role of $u, u', u'', t_{A_1}, t_{A_2}$, respectively, and the subsets B_1 and B_2 take the role of A_1 and A_2, respectively. The edges between B_1 and B_2 are determined by Bob's input B. The other difference is that v is adjacent to three "tails" t_v^1, t_v^2, t_v^3 (whereas u is adjacent to only two, t_v^1, t_v^2).

The subgraphs of Alice and Bob are connected by a single edge (u, v).

The graph G_K is constructed by Alice exactly as the graph G_U, the only difference is that Alice does not know the subset B, instead of B Alice uses A to determine both the edges between A_1 and A_2 and the edges between B_1 and B_2.

Clearly, if A and B are such that $(a_1^i, a_2^j) \in A$ if and only if $(b_1^i, b_2^j) \in B$, then G_U and G_K are isomorphic. We next prove that if this is not the case then G_U and G_K are not isomorphic.

We assume towards contradiction that G_K and G_U are isomorphic and that there exists $(a_1^i, a_2^j) \in A$ such that $(b_1^i, b_2^j) \notin B$ or vice versa. We first observe that it is possible to identify u and v based on the structure of G_U (i.e. regardless to the labels of the nodes) because these are the only nodes that are neighbors to 2 and 3 nodes with degree exactly 1, respectively. Next, we identify u' and v' - these are the nodes that have degree exactly 2 and are adjacent to u and v, receptively. Once we identify u' and v' we can identify u'' and v'' and in turn identify A_2 and B_2. The nodes in A_1 and B_1 are the neighbors of u and v, excluding u' and v', receptively. Finally, we are able to identify a_1^0, a_2^0, b_1^0 and b_2^0 since these are the only nodes that are adjacent to a node of degree exactly one - $t_{A_1}, t_{A_2}, t_{B_1}$ and t_{B_2}, respectively. Once we identify a_1^0 and A_1 we can identify the path $a_1^0, \ldots, a_1^{k-1}$. Likewise for the paths induced on A_2, B_1 and B_2. This implies that there if there exists $(a_1^i, a_2^j) \in A$ such that $(b_1^i, b_2^j) \notin B$ or vice versa then it has to be that the graph G_U, which is constructed with correspondence to the to the pair (A, B), has to be not isomorphic to the graph G_K, which is constructed with correspondence to the to the pair (A, A). This concludes the proof. ◀

A.2 An $\Omega(D)$ lower bound for the Testing Isomorphism Problem

In this section we establish the following theorem.

▶ **Theorem 18.** *For any D there exists a family of graphs with diameter $\Theta(D)$ such that any distributed two-sided error property testing algorithm for testing isomorphism on this family of graphs requires $\Omega(D)$ rounds. This lower bound applies also in the LOCAL model and even if all nodes receive G_K as an input.*

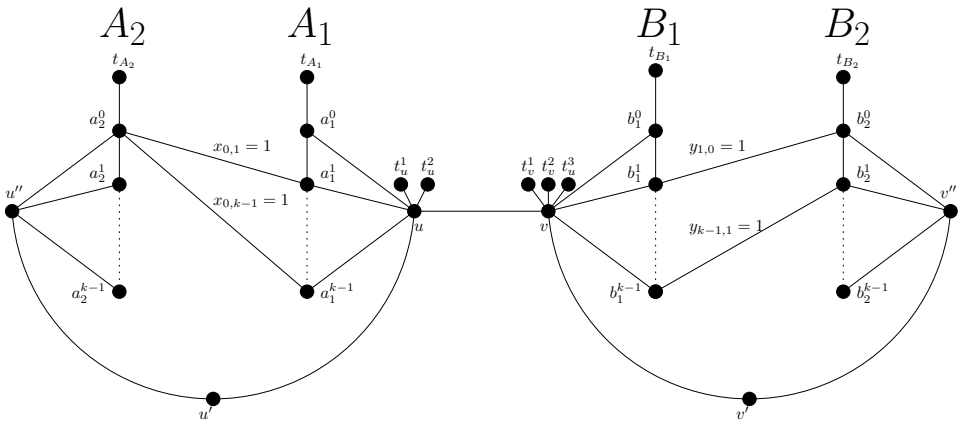

Figure 2 Deciding Isomorphism lower bound construction.

Proof. We define a family of graphs $\mathcal{H}$, where each $H \in \mathcal{H}$ takes the role of the unknown graph G_U. We fix $G_K \in \mathcal{H}$ and require from $\mathcal{H}$ that all graphs in $\mathcal{H} \setminus \{G_K\}$ are ϵ'-far from being isomorphic to G_K. Theorem 18 then follows by applying Yao's principle [47].

Construction of $\mathcal{H}$. We begin our construction with a pair of graphs on n nodes and diameter $\Theta(D)$, G_1 and G_2, such that $|E(G_1)| = (1+\epsilon)|E(G_2)|$. [12] Clearly, G_2 is ϵ-far from being isomorphic to G_1 (since G_1 has $\epsilon|E(G_2)|$ more edges than G_2). Let $\mathcal{H}$ denote a family of graphs where each graph in $\mathcal{H}$, denoted by $G_{i,j}$ for $i,j \in \{1,2\}$, is constructed by using two copies from $\{G_1, G_2\}$. The definition of $G_{i,j}$ is as follows:

1. Let $p \triangleq (p_1, \ldots, p_D)$ denote a path of D nodes.
2. Let v_i and v_j denote arbitrary nodes in G_i and G_j, respectively.
3. Identify, v_i with p_1 and v_j with p_D, to obtain $G_{i,j}$. Observe that $|V(G_{i,j})| = 2n + D - 2 = O(n)$, and that the diameter of $G_{i,j}$ is $\Theta(D)$.

Note that from the reasoning above, for every $G_{i,j}, G_{a,b} \in \mathcal{H}$, where $\{i,j\} \neq \{a,b\}$, $G_{i,j}$ is $\Omega(\epsilon)$-far from being isomorphic to $G_{a,b}$.

We assume towards a contradiction that there is a two-sided tester $\mathcal{A}$ that is correct with probability at least $2/3$ and runs for $D(G_U)/3$ rounds, where $D(G_U)$ denotes the diameter of the distributed network G_U. The lower bound then follows from Yao's principle [47]. We next specify the distribution over the inputs and explicitly apply Yao's principle.

We define a set of inputs to the distributed tester: (1) we fix the known graph G_K to be $G_{1,2}$, (2) the unknown graph G_U is chosen randomly from the distribution $\tilde{\mathcal{H}}$ which is defined as follows: the probability to obtain the graph $G_{1,2}$ is $1/2$ and each of the graphs $G_{1,1}$ and $G_{2,2}$ is obtained with probability $1/4$. Now we consider two cases. The first case is that $\mathcal{A}$ outputs (correctly) yes when G_U is $G_{1,2}$. By the definition of the problem this implies that all nodes output yes. Since the number of rounds of the tester is at most $D/3$, it follows that all nodes in both graphs $G_{1,1}$, and $G_{2,2}$, output yes. To verify this observe that for any node u in either $G_{1,1}$ or $G_{2,2}$ there exists a node in $G_{1,2}$, v, such that the $(D/3)$-hop

[12] Observe that such graphs exist for any D for G_1 and G_2 that are dense. On the other extreme, if we want G_1 and G_2 to be bounded degree trees then it is possible to obtain such graphs for any $D = \Omega(\log n)$.

neighborhoods of v and u are the same (up to labels and port numbers [13]). Thus, in this case, $\mathcal{A}$ errs on $G_{1,1}$ and $G_{2,2}$. In the second case $\mathcal{A}$ outputs no when G_U is $G_{1,2}$. Thus, in both cases $\mathcal{A}$ errs with probability at least $1/2$ when G_U is drawn according to $\tilde{\mathcal{H}}$.

By Yao's principle it is implied that any randomized tester must err with probability at least $1/2$ as well, in contradiction to our assumption that $\mathcal{A}$ is correct with probability of at least $2/3$. ◀

B Simulating Centralized Property Testing Algorithms

In this section we prove the following claim.

▷ Claim 19. Let $\mathcal{A}$ be a centralized property testing algorithm that is allowed to make adjacency queries, incidence queries and degree queries. There exists a distributed algorithm that can simulate $\mathcal{A}$ in $O(D \cdot q)$ rounds if $\mathcal{A}$ is adaptive and in $O(D + q)$ rounds if $\mathcal{A}$ is non-adaptive, where D denotes the diameter of the graph and q denotes the number of queries that $\mathcal{A}$ makes.

Proof. In order to simulate $\mathcal{A}$ on the distributed network we first pick a leader r and construct a BFS tree rooted at r in D rounds. We also assume w.l.o.g. that r knows the size of the network, n. If $\mathcal{A}$ is non-adaptive then r can determine the queries that $\mathcal{A}$ makes by using (only) the knowledge of n and random bits. The root r sends this information to the entire network in $D + q$ rounds and in additional $D + q$ rounds the answers are gathered by pipelining back at r. Once that all the answers are gathered, r can complete the simulation of $\mathcal{A}$. The outcome is then sent to all the nodes in the network. If $\mathcal{A}$ is adaptive then r simulates $\mathcal{A}$ step by step where each query is gathered in $2D$ rounds. This yields a round complexity of $O(D \cdot q)$, as desired. ◁

Application to minor-free graphs and Outerplanar graphs. For graphs which are minor-free with a bound $d = O(1)$ on the degree Newman and Sohler [42] argued the following in the centralized property testing model: (a) graph isomorphism is possible with constant number of queries, and (b) any property is testable with constant number of queries in the respective families of graphs. The latter means that there is an algorithm that performs a constant number of queries and succeeds with constant probability. Here, "constant" means independent of n.

For graphs which are forests and outerplanar (which include forests), Kusumoto and Yoshida [38] and Babu, Khoury, and Newman [3] argued, respectively, the following in the centralized property testing model: (a) graph isomorphism is possible with $\operatorname{poly}\log n$ number of queries, and (b) any property is testable with the same number of queries in the respective families of graphs. The latter means that there is an algorithm that performs $\operatorname{poly}\log n$ number of queries and succeeds with constant probability.

Their results are summarized in the following theorems.

▶ **Theorem 20** ([42, Thm. 3.2, 3.3]). *Given an oracle access to a minor-free graph with maximum degree $d = O(1)$, any graph property is testable with constant number of queries. This testing algorithm succeeds with constant probability. Specifically, testing isomorphism of two such graphs can be done in a constant number of queries and with constant probability.*

[13] We assume that the output of the algorithm is invariant to the labeling of the nodes and the port numbers of the edges. In the full version we remove this assumption and provide a general and more detailed proof.

▶ **Theorem 21** ([38, Thm. 1.3, 1.1], [3, Thm. 4.3, 4.2]). *Given an oracle access to a k-edge-outerplanar graph, any graph property is testable with* $\text{poly}\log n$ *queries.* [14] *This testing algorithm succeeds with constant probability. Specifically, testing isomorphism of two k-edge-outerplanar graph can be done in* $\text{poly}\log n$ *queries and with constant probability.*

Given the simulation argument above and Theorems 20, 21, we obtain the following corollaries.

▶ **Corollary 22.** *Any property is testable in the CONGEST model for minor-free graphs with maximum degree $d = O(1)$ within $O(D)$ rounds in the bounded-degree model. Specifically, this holds for the graph isomorphism problem.*

▶ **Corollary 23.** *Any property is testable in the CONGEST model for trees and k-edge-outerplanar graphs within $\tilde{O}(D)$ rounds in the general model. Specifically, this holds for the graph isomorphism problem.*

C Missing proofs and details

C.1 Proof of Claim 8

Proof. Let u and v be such that $|\triangle(N(u), N(v))| \geq \beta n$. The probability that C does not contain a node from $|\triangle(N(u), N(v))|$ is at most $(1-\beta)^s \leq \delta/n^2$, for an appropriate setting of s. Therefore, the claim follows by a union bound over all pairs u, v. ◀

C.2 Proof of Lemma 9

Proof. Let C be an ϵ-separating sequence of the nodes of G. Since π is an isomorphism between G are H, it follows that $\pi(C)$ is ϵ-separating in H (since for any u, v that have the same $\pi(C)$-label in H it must hold that $\pi^{-1}(u), \pi^{-1}(v)$ have the same C-label in G). Thus, by definition, for any pair of nodes v, u such that $\ell^H_{\pi(C)}(v) = \ell^H_{\pi(C)}(u)$ it holds that $|\triangle(N_H(u), N_H(v))| < \epsilon n$. Let f be $(C, \pi(C))$-label-consistent. By definition, $\ell^G_C(v) = \ell^H_{\pi(C)}(f(v))$, for every $v \in V(G)$. Therefore, there exists a bijection $g : V(H) \to V(H)$ such that $f = g \circ \pi$ and g only maps between nodes with the same $\pi(C)$-label. Thus, f can be obtained from π by making at most n swaps, one by one, between elements of $V(H)$ that have the same $\pi(C)$-label. Since each swap changes the adjacency matrix by at most ϵn, we obtain the desired result. ◀

C.3 Proof of Claim 10

Proof. Consider the outcome of querying the adjacency-matrices of G and H in $y \triangleq \Theta(\log(1/\delta)/\epsilon)$ random locations. Define the random variables $\{x_i\}_{i\in[y]}$ as follows: $x_i = 1$ if the values in the i-th location of both matrices are the same, and 0 otherwise. Let $p \triangleq \Delta(G, H)/n^2$ and define $\hat{p} = \sum_{i=1}^{y} x_i/|y|$. If $p = \epsilon/2$, then by the Multiplicative Chernoff's Bound, the probability that $\hat{p} > (3\epsilon)/2$ is at most δ (for the right setting of the parameter in the Θ-notation). Clearly, the same is true if $p < \epsilon/2$. On the other hand, if $p > \epsilon$ then by the Multiplicative Chernoff's Bound, the probability that $\hat{p} \leq (3\epsilon)/2$ is at most δ. Therefore, by accepting if and only if $\hat{p} \leq (3\epsilon)/2$ we can distinguish $\Delta(G, H) = p \cdot n^2 > \epsilon n^2$ from $\Delta(G, H) \leq \epsilon n^2/2$, as desired. ◀

[14] A graph G is 1-edge-outerplanar if it has a planar embedding in which all vertices of G are on the outer face. A graph G is k-edge-outerplanar if G has a planar embedding such that if all edges on the exterior face are deleted, the connected components of the remaining graph are all $(k-1)$-edge-outerplanar.

C.4 Selecting s Nodes u.a.r.

The procedure proceeds as follows. Each node selects a random number in $[n^{c+2}]$ where c is an absolute constant. For a fixed pair of nodes, the probability that both nodes pick the same number is at most $1/n^{c+2}$. Therefore, by union bound over all pairs, with probability at least $1 - 1/n^c$, all selected numbers are distinct. Conditioned on this event, the nodes with the s highest numbers are distributed uniformly at random. Each node sends its ID and its selected number up the BFS tree and the messages are forwarded up the tree in a manner that prioritizes messages whose number is higher. Therefore, the root receives the s highest numbers (along with the IDs of the corresponding nodes) in $D + s$ rounds. To see this observe that the message with the highest number is never delayed and in general the message with the i-highest number may be delayed for at most $i - 1$ rounds.

C.5 Matching of Y to Y'

We next describe the matching of Y to Y' according to g and explain how it is computed distributively. We aim to assign to each node in Y a label in $[|Y|]$ uniquely. This way each node in Y can match itself to a node in Y' (recall that all nodes know V_K and the total order on V_K). To this end, we use the BFS tree as follows. Each node in the BFS tree computes how many nodes in its subgraph are in Y. This can be done in $O(D)$ rounds as follows. We assume w.l.o.g. that each node knows its layer in the BFS tree. Let b denote the number of layers. We proceed in b rounds. In the first round, every node in Y which is in the b-th layer sends to its parent the message 1. In the next round, all the nodes in layer $b - 1$ sum up the messages they received and add 1 if they belong to Y. Then they send the result to their parents and so on until we end up at the root. Now the root partitions the interval $[1, \ldots, |Y|]$ into consecutive sub-intervals and assigns these sub-intervals to its children. Each child receives an interval whose size equals to the number of nodes in its subgraph that are in Y. In a similar manner, these sub-intervals are partitioned recursively down the tree until each node in Y is assigned with a unique number in $|Y|$, as desired.

Abstract

A community of n individuals splits into two camps, Red and Blue. The individuals are connected by a social network, which influences their colors. Everyday, each person changes his/her color according to the majority of his/her neighbors. Red (Blue) wins if everyone in the community becomes Red (Blue) at some point.

We study this process when the underlying network is the random Erdos-Renyi graph $G(n,p)$. With a balanced initial state ($n/2$ persons in each camp), it is clear that each color wins with the same probability.

Our study reveals that for any constants p and ε, there is a constant c such that if one camp has $\frac{n}{2}+c$ individuals at the initial state, then it wins with probability at least $1-\varepsilon$. The surprising fact here is that c *does not* depend on n, the population of the community. When $p=1/2$ and $\varepsilon=.1$, one can set $c=6$, meaning one camp has $\frac{n}{2}+6$ members initially. In other words, it takes only 6 extra people to win an election with overwhelming odds. We also generalize the result to $p=p_n=\mathrm{o}(1)$ in a separate paper.

1 Introduction

1.1 The opinion exchange dynamics

Building mathematical models to explain how collective opinions are formed is an important and interesting task (see [12] for a survey on the topic, with examples from various fields, economy, sociology, statistical physics, to mention a few).

Obviously, our opinions are influenced by people around us, and this motivates the study of the following natural and simple model. A community of n individuals splits into two camps, Red and Blue, representing two competing opinions, which can be on any topic such

© Linh Tran and Van Vu;
licensed under Creative Commons License CC-BY

as brand competition, politics, ethical issues, etc. The individuals are connected by a social network, which influences their opinion on a daily basis (by some specific rule). We say that Red (respectively Blue) *wins* if everyone in the community becomes Red (respectively Blue) at some point.

We study this process when the underlying network is random. In this paper, we focus on the Erdos-Renyi random graph $G(n,p)$, which is the most popular model of random graphs [4, 10]. We use the majority rule, which is a natural choice. When a new day comes, a vertex scans its neighbors' colors in the previous day and adopts the dominant one. If there is a tie, it keeps its color.

▶ **Definition 1.** *The random graph $G(n,p)$ on $n \in \mathbb{N}$ vertices and density $p \in (0,1)$ is obtained by putting an edge between any two vertices with probability p, independently.*

1.2 Results

With a balanced initial state ($n/2$ persons in each camp), by symmetry, each color wins with the same probability $q < 1/2$, regardless of p. (Notice that there are graphs, such as the empty and complete graphs, on which no one wins.)

Our study reveals that for any given p and ε, there is a constant c such that if one camp has $\frac{n}{2} + c$ individuals at the initial state, then it wins with probability at least $1 - \varepsilon$. The surprising fact here is that c does not depend on n, the population of the community. When $p = 1/2$ and $\varepsilon = .1$, one can set c as small as 6.

▶ **Theorem 2** (The power of few)**.** *Consider the (majority) process on $G(n, 1/2)$. Assume that the Red camp has at least $\frac{n}{2} + 6$ vertices at the initial state, where $n \geq 300$. Then Red wins after the fourth day with probability at least* 90%*.*

This result can be stated without the Erd˝os-Renyi model; one can state an equivalent theorem by choosing the network uniformly, from the set of all graphs on n vertices.

This result reveals an interesting phenomenon, which we call "the power of few". The collective outcome can be extremely sensitive, as a modification of the smallest scale in the initial setting leads to the opposite outcome.

Our result applies in the following equivalent settings.

Model 1. We fix the two camps of size $n/2+6$ and $n/2-6$, respectively, and draw a random graph on their union.

Models 2. Draw a random graph first, let Red be a random subset of $n/2+6$ vertices (chosen uniformly from all subsets of that size), and Blue be the rest.

Model 3. Split the society into two camps of size $n/2$ each. Draw the random graph on their union, then recolor 6 random selected Blue vertices to Red.

Model 4. Split the society into two camps (Red and Blue) of size $n/2 - 6$ each and a "swinging" group (with no color yet) of 12 individuals. Draw the random graph on their union. Now let the swinging group join the Red camp.

With Model 3, we can imagine a balanced election process at the beginning. Then 6 persons change camp. This tiny group already guarantees the final win with an overwhelming odds. Similarly, Model 4 asserts that a swinging group of size 12 decides the outcome.

Our result can also be used to model the phenomenon that outcomes in seemingly identical situations become opposite. Consider two communities, each has exactly n individuals, sharing the same social network. In the first community, Red camp has size $n/2 + c$, and Blue camp has $n/2 - c$. In the second community, Blue camp has $n/2 + c$ and Red camp has $n/2 - c$. If

n is large, there is no way to tell the difference between the two communities. Even if we record everyone's initial opinion, clerical errors will surely swallow the tiny difference of $2c$. However, at the end, the collective opinion will be opposite, with high probability.

Now we state the general result for arbitrary constant density p.

▶ **Theorem 3** (Asymptotic bound). *Let p be a constant in $(0,1)$ and c_n be a positive integer which may depend on n . Assume that Red has $n/2 + c_n$ individuals in day zero and the random graph is $G(n,p)$. Then Red wins after the fourth day with probability at least $1 - K(p)\max\{n^{-1}, c_n^{-2}\}$, where $K(p)$ depends only on p.*

Both results follow from Theorem 6, which, in a slightly technical form, describes how the process evolves day by day. Our results can be extended to cover the case when there are more than 2 opinions; details will appear in a later paper [14].

1.3 Related results

Our problem is related to a well studied class of *opinion exchange dynamics* problems. In the field of Computer Science, loosely-related processes are studied in *population protocols* [2, 1], where individuals/agents/nodes choose their next state based on that of their neighbors. The most separating difference is the network, as connections in these models often randomly change with time, while our study concerns a fixed network (randomly generated before the process begins).

The survey by Mossel and Tamuz [12] discussed severals models for these problems, including the *DeGroot model* [6], where an individual's next state is a weighted average of its neighbors' current states, the *voter model* [5], where individuals change states by emulating a random neighbor each day. The *majority dynamics* model is in fact the same as ours, and is also more popular than the other two, having been studied in [11, 8, 3]. The key difference, as compared to our study, is in the set-ups. In these earlier papers, each individual chooses his/her initial color uniformly at random. The central limit theorem thus guarantees that with high probability, the initial difference between the two camps is of order $\Theta(\sqrt{n})$. Therefore, these papers did not touch upon the "power of few" phenomenon, which is our key message. On the other hand, they considered sparse random graphs where the density $p = p_n$ goes to zero as $n \to +\infty$.

In [3], Benjamini, Chan, O'Donnell, Tamuz, and Tan considered random graphs with $p \geq \lambda n^{-1/2}$, where λ is a sufficiently large constant, and showed that the dominating color wins with probability at least .4 [3, Theorem 1.2], while conjecturing that this probability in fact tends to 1 as $n \to \infty$. This conjecture was proved by Fountoulakis, Kang, and Makai [8, Theorem 1.1].

▶ **Theorem 4.** *For any $0 < \varepsilon \leq 1$ there is $\lambda = \lambda(\varepsilon)$ such that the following holds for $p \geq \lambda n^{-1/2}$. With probability at least $1 - \varepsilon$, over the choice of the random graph $G(n,p)$ and the choice of the initial state, the dominating color wins after four days.*

For related results on random regular graphs, see [11, 12].

1.4 Extension for sparse random graphs

Note that the results presented in this paper only applies for a constant p, which, in the context of $G(n,p)$, produces *dense graphs*. For *sparse graphs*, i.e. when $p = p_n$ depends on n and tends to 0 as $n \to +\infty$, the main ideas in this paper can be used, but with slightly different algebraic techniques, to obtain a similar result.

▶ **Theorem 5.** *For any $0 < \varepsilon \leq 1$ there is $c = c(\varepsilon)$ such that the following holds for $p \geq (2 + o(1))(\log n)/n$. Assume that Red camp has size at least $n/2 + c/p$ initially, then it wins with probability at least $1 - \varepsilon$.*

The technical changes needed to prove this theorem require rewriting entire proofs with new computations, so we leave the proof to our future paper [14]. Additional information such as the length of the process and the explicit relation between the bound with p and c will also be discussed there. Notice that when p is a constant, this result covers the "Power of Few" phenomenon as a special case, albeit with c much larger than 6. Therefore, the techniques and results in this paper still have merit since they achieve a specific, surprisingly small constant. Theorem 5 no longer holds for $p < (\log n)/n$ as in this case there are, with high probability, isolated vertices. Any of these vertices keeps it original color forever. In this case, the number of Blue vertices converges with time, and we obtain a bound on the limit in [14].

One can use Theorem 5 to derive a "delayed" version (in which Red may need more than 4 days) of Theorem 4, by first proving that with high probability, one side gains an advantage of size at least $C\sqrt{n}$ after the first day, for some constant C. This "majority side" then wins with high probability given $p \geq \lambda n^{-1/2}$ (which satisfies the requirement $p \geq (2 + o(1))(\log n)/n$) with λ sufficiently large so that $\lambda C = pC\sqrt{n}$ is large. The detailed argument is in Appendix A.3.

1.5 Notation

- R_t, B_t: Respectively the sets of Red and Blue vertices after day t. (At this point each person has updated their color t times.)
- $\mathrm{I}_t(u) \stackrel{\text{def}}{=} \mathbf{1}_{\{u \in R_t\}}$: $\{0,1\}$-indicator of the event that u is Red after day t.
- $\mathrm{J}_t(u) \stackrel{\text{def}}{=} 2\mathrm{I}_t(u) - 1$: $\{-1,1\}$-indicator of the same event.
- $u \sim v \equiv (u,v) \in E$: Event that u and v are adjacent.
- $\Gamma(v) \stackrel{\text{def}}{=} \{u : u \sim v\}$: The neighborhood of v.
- $W_{uv} \stackrel{\text{def}}{=} \mathbf{1}_{\{u \sim v\}}$ - Indicator of the adjacency between u and v.
- $\mathcal{N}(\mu, \sigma^2)$: The Normal Distribution with mean μ and variance σ^2.
- $\Phi(a,b) \stackrel{\text{def}}{=} (2\pi)^{-1/2} \int_a^b e^{-\frac{x^2}{2}} dx$ and $\Phi(a) \stackrel{\text{def}}{=} \Phi(-\infty, a)$, $\Phi_0(a) \stackrel{\text{def}}{=} \Phi(0,a)$.

1.6 Main Theorem

The main theorem concerns dense graphs, where p is at least a constant. When given appropriate values for the parameters, it implies the "Power of Few" phenomenon in Theorem 2. Before stating the theorem, we define some expressions.

$$C_0 \stackrel{\text{def}}{=} 0.56, \quad C_1 \stackrel{\text{def}}{=} \sqrt{3\log 2}, \quad \sigma = \sigma(p) \stackrel{\text{def}}{=} \sqrt{p(1-p)},$$

$$P_1 = P_1(n,p,c,\varepsilon_2) \stackrel{\text{def}}{=} \frac{1/4 + 4C_0^2\left(1-2\sigma^2\right)^2 \cdot \frac{n-1}{n-2}}{\left(\sqrt{n-1}\Phi_0\left(\frac{2pc+\min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) - C_0\frac{1-2\sigma^2}{\sigma} - \frac{C_1+\varepsilon_2}{2p} - \frac{1}{2\sqrt{n}}\right)^2},$$

$$P_2 = P_2(n,\varepsilon_2,\varepsilon_1) \stackrel{\text{def}}{=} \frac{1}{n}\exp\left(-n\left[(1-2\varepsilon_1)\varepsilon_2 - \varepsilon_1\right]\right),$$

$$P_3 = P_3(n,p,\varepsilon_1) \stackrel{\text{def}}{=} \frac{1}{n}\exp\left(-\tfrac{1}{2}p^3(2\varepsilon_1 n - 1)^2 + 2n\log 2\right),$$

$$P_4 = P_4(n,p) \stackrel{\text{def}}{=} n\exp\left(-\tfrac{2}{9}p^2(n-1)\right).$$

▶ **Theorem 6.** *Let $p \in (0,1)$, $c \in \mathbb{N}$, $n \in \mathbb{N}$, and $\varepsilon_1, \varepsilon_2 > 0$. Define C_0, C_1, σ, P_1, P_2, P_3, P_4 as above. Assume that*

$$2\sqrt{n-1}\Phi_0\left(\frac{2pc + \min\{p, 1-p\}}{\sigma\sqrt{n-1}}\right) > \frac{C_1 + \varepsilon_2}{p} + \frac{1}{\sqrt{n}} \quad \text{and} \quad 2\varepsilon_1 n > 1. \tag{1}$$

With n^R, n^B being integers such that $n^R + n^B = n$ and $1 \le n^B \le \frac{n}{2} - c$, the election process on $G \sim G(n,p)$ with $|B_0| = n^B$ satisfies the following

1. *With $n_0^B = \frac{n}{2} - c$, $n_1^B = \frac{n-1}{2} - \left(\frac{C_1+\varepsilon_2}{2p}\right)\sqrt{n}$, $n_2^B = \left(\frac{1}{2} - \varepsilon_1\right)n$, $n_3^B = \frac{1}{3}p(n-1)$, $n_4^B = 0$, we have $\mathbf{P}\left(|B_t| \le n_t^B \mid |B_{t-1}| \le n_{t-1}^B\right) \ge 1 - P_t$ for each $t = 1, 2, 3, 4$.*
2. *$\mathbf{P}\left(R_4 = V(G) \mid |B_0| = n^B\right) \ge 1 - (P_1 + P_2 + P_3 + P_4)$.*

Intuitively, P_i is a upper bound on the probability of some abnormal event happening on Day i. If none of these "catastrophes" occur, the whole population becomes Red after Day Four. Note that if one let $n \to +\infty$ while fixing all other parameters, P_2, P_3 and P_4 all tend to 0, leaving P_1 as the main asymptotic component of the probability bound.

The proof for this theorem has two main parts corresponding to the next two sections. In Section 2, we apply a concentration bound to the number of Red vertices after Day 1 to show that with probability at least $1 - P_1$, this number is at least $n - n_1^B$. In Section 3, we show that with high probability, this $\Omega(n^{1/2})$ advantage leads Red to win, using a *shrinking argument* that bypasses the dependency of the coloring on the current day.

From Theorem 6, one can deduce Theorems 2 and 3 in a few steps. Detailed proofs appear in Appendix A.1.

1.7 Open questions

Let $\rho(k,n)$ be the probability that Red win if its camp has size $n/2 + k$ in the beginning, when $p = .5$. Theorem 2 shows that $\rho(6,n) \ge .9$ (given that n is sufficiently large). In other words, six defectors guarantee Red's victory with an overwhelming odd. In fact, we have $\rho(4,n) \ge .7$ by plugging in the same values for ε_1 and ε_2 with $c = 4$ in Theorem 2's proof. We conjecture that one defector already brings a non-trivial advantage.

▶ **Conjecture 7** (The power of one)**.** *There is a constant $\delta > 0$ such that $\rho(1,n) \ge 1/2 + \delta$ for all sufficiently large n.*

In the following numerical experiment, we run $T = 10000$ independent trials. In each trial, we fix a set of $N = 10000$ nodes with 5001 Red and 4999 Blue (meaning $c = 1$), generate a graph from $G(N, 1/2)$, and simulate the process on the resulting graph. We record the number of wins and the number of days to achieve the win in percentage in Table 1. Among others, we see that Red wins within 3 days with frequency more than .9. The source code for the simulation along with execution instructions can be found online at `https://github.com/thbl2012/majority-dynamics-simulation`.

Imagine that people defect from Blue camp to Red camp one by one. The *value* of the ith defector is defined as $v(i,n) = \rho(i,n) - \rho(i-1,n)$ (where we take $\rho(n,0) = 1/2$). It is intuitive to think that the values of the defectors decrease. (Clearly defector number $n/2$ adds no value.)

▶ **Conjecture 8** (Values of defectors)**.** *For any fixed i and sufficiently large n, we have $v(i,n) \ge v(i+1,n)$.*

It is clear that the Conjecture 8 implies Conjecture 7, with $\delta = \frac{4}{5} = .08$, although the simulation results above suggests that δ can be at least .43.

Table 1 Winners and winning days with their frequencies.

T	p	Red	Blue	Winner	Last day	Count	Frequency
10^4	1/2	5001	4999	Blue	3	496	4.96 %
10^4	1/2	5001	4999	Blue	4	77	0.77 %
10^4	1/2	5001	4999	Blue	5	3	0.03 %
10^4	1/2	5001	4999	Blue	7	1	0.01 %
10^4	1/2	5001	4999	Red	2	25	0.25 %
10^4	1/2	5001	4999	Red	3	9313	93.13 %
10^4	1/2	5001	4999	Red	4	85	0.85 %

2 Day One

At day one, the number of Red and Blue neighbors of each node v are both binomial random variables, with means roughly $n/2 + c$ and $n/2 - c$ respectively. The central limit theorem then implies that most of their masses are concentrated within an interval of length $\Theta(\sqrt{n})$ around their respective expectations. A subinterval of constant length in this interval will have $\Theta(n^{-1/2})$ mass. Therefore, one expects that the probability that the number of Red exceeds the number of Blues (in that particular neighborhood) is $1/2 + \Omega(n^{-1/2})$. Thus, the expectation of Red nodes after the first day is $n/2 + \Omega(n^{1/2})$. We consolidate this intuition in the main result of this section, Theorem 9.

Firstly, let us recall a few terms defined in Section 1.6.

$$\sigma \stackrel{\text{def}}{=} \sqrt{p(1-p)}, \quad \text{and } P_1 \stackrel{\text{def}}{=} \frac{\frac{1}{4} + 4C_0^2\left(1-2\sigma^2\right)^2 \cdot \frac{n-1}{n-2}}{\left(\sqrt{n-1}\Phi_0\left(\frac{2pc+\min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) - \frac{C_0(1-2\sigma^2)}{\sigma} - \frac{C_1+\varepsilon_2}{2p} - \frac{1}{2\sqrt{n}}\right)^2}.$$

Define a new term Q by

$$Q = Q(n,p,c,d) \stackrel{\text{def}}{=} \frac{\frac{1}{4} + 4C_0^2\left(1-2\sigma^2\right)^2 \cdot \frac{n-1}{n-2}}{\left(\sqrt{n-1}\Phi_0\left(\frac{2pc+\min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) - \frac{C_0(1-2\sigma^2)}{\sigma} - d - \frac{1}{2\sqrt{n}}\right)^2}.$$

Observe that $Q\left(n,p,c,\frac{C_1+\varepsilon_2}{2p}\right) = P_1(n,p,c,\varepsilon_2)$. The following result thus covers the first day in Theorem 6 by just plugging in $d = (C_1+\varepsilon_2)/(2p)$.

▶ **Theorem 9.** *Let $p \in (0,1)$ and c be constants and σ and Q be defined above. Then if $n, n^R, n^B \in \mathbb{N}$ such that $n^R + n^B = n$, $1 \le n^B \le \frac{n}{2} - c$. Then for all $d \in \mathbb{R}_{>0}$ and $n \in \mathbb{N}$ such that*

$$\sqrt{n-1}\Phi_0\left(\frac{2pc+\min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) - \frac{C_0(1-2\sigma^2)}{\sigma} > d + \frac{1}{2\sqrt{n}}, \tag{2}$$

we have

$$\mathbf{P}\left(|B_1| > \frac{n-1}{2} - d\sqrt{n} \;\middle|\; |B_0| = n^B\right) \le Q\left(n,p,c,d\right).$$

The crux of the proof relies on some preliminary results regarding the difference of two binomial random variables, which we discuss next.

2.1 Background on difference of Binomial Random Variables

The difference of two binomial random variables with the same probability p be written as a sum of independent random variables, each of which is either a $\mathrm{Bin}(1,p)$ variable or minus of one. A natural way to bound this sum is done via a Berry-Esseen normal approximation.

▶ **Theorem 10** (Berry-Esseen). *Let n be any positive integer. If $X_1, X_2, X_3, \dots, X_n$ are random variables with zero means, variances $\sigma_1^2, \sigma_2^2, \cdots, \sigma_n^2 > 0$, and absolute third moments $\mathbf{E}\left[|X_i|^3\right] = \rho_i < \infty$, we have:*

$$\sup_{x\in\mathbb{R}} \left| \mathbf{P}\left(\sum_{i=1}^{n} X_i \le x\right) - \Phi\left(\frac{x}{\sigma_X}\right)\right| \le C_0 \cdot \frac{\sum_{i=1}^n \rho_i}{\sigma_X^3},$$

where $\sigma_X = \left(\sum_{i=1}^n \sigma_i^2\right)^{1/2}$ and $C_0 = .56$ is a constant.

The original proof by Esseen [7] yielded $C_0 = 7.59$, and this constant has been improved a number of times. The latest work by Shevtsova [13] achieved $C_0 = .56$, which will be used for the rest of the paper. A direct application of this theorem gives the following lemma.

▶ **Lemma 11.** *For $p \in (0,1)$, $\sigma = \sqrt{p(1-p)}$ and $n_1, n_2 \in \mathbb{N}$ such that $n_1 > n_2$. let $Y_1 \sim Bin(n_1, p)$, $Y_2 \sim Bin(n_2, p)$ be independent random variables. Then for any $d \in \mathbb{R}$,*

$$\mathbf{P}\left(Y_1 > Y_2 + d\right) \ge \frac{1}{2} + \Phi_0\left(\frac{p(n_1-n_2)-d}{\sigma\sqrt{n_1+n_2}}\right) - \frac{C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n_1+n_2}}.$$

Proof. By definition, the difference $Y = Y_1 - Y_2$ can be expressed as

$$X = X_1 + X_2 + X_3 + \cdots + X_{n_1+n_2},$$

where all X_i's are independent and either $X_i \sim \mathrm{Bin}(1,p)$ or $-X_i \sim \mathrm{Bin}(1,p)$. Then $\mathbf{E}[X] = \sum_i \mathbf{E}[X_i] = p(n_1-n_2)$. For all i, $\mathbf{Var}[X_i] = \sigma^2$ and $\mathbf{E}\left[|X_i - \mathbf{E}[X_i]|^3\right] = p(1-p)^3 + (1-p)p^3 = \sigma^2(1-2\sigma^2)$ Applying Theorem 10, we have

$$\begin{aligned}
\mathbf{P}\left(Y_1 \le Y_2 + d\right) &= \mathbf{P}\left(X - \mathbf{E}[X] \le d - p(n_1-n_2)\right) \\
&\le \Phi\left(\frac{d-p(n_1-n_2)}{\sigma_X}\right) + C_0\frac{\sum_i \mathbf{E}\left[|X_i - \mathbf{E}[X_i]|^3\right]}{\sigma_X^3} \\
&= \Phi\left(\frac{d-p(n_1-n_2)}{\sigma\sqrt{n_1+n_2}}\right) + C_0\frac{\sigma^2(1-2\sigma^2)(n_1+n_2)}{\sigma^3(n_1+n_2)^{3/2}} \\
&= \frac{1}{2} - \Phi_0\left(\frac{p(n_1-n_2)-d}{\sigma\sqrt{n_1+n_2}}\right) + \frac{C_0(1-2\sigma^2)}{\sigma\sqrt{n_1+n_2}},
\end{aligned}$$

and the claim follows by taking the complement event. ◀

▶ **Lemma 12.** *Let $p \in (0,1)$ be a constant and $\sigma = \sqrt{p(1-p)}$, $X_1 \sim Bin(n_1,p)$ and $X_2 \sim Bin(n_2,p)$ be independent r.v.s. Then for any integer d,*

$$\mathbf{P}\left(X_1 = X_2 + d\right) \le \frac{2C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n_1+n_2}}.$$

Proof. Let $n = n_1 + n_2$ and $\mu = \mathbf{E}[X_1] - \mathbf{E}[X_2] = p(n_1-n_2)$. Fix $\varepsilon \in (0,1)$, by the same computations in Lemma 11, we have

$$\mathbf{P}\left(X_1 - X_2 \le d - \varepsilon\right) \ge \Phi\left(\frac{d-\mu-\varepsilon}{\sigma\sqrt{n}}\right) - \frac{C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n}},$$

$$\mathbf{P}\left(X_1 - X_2 < d + \varepsilon\right) \le \Phi\left(\frac{d-\mu+\varepsilon}{\sigma\sqrt{n}}\right) + \frac{C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n}}.$$

It follows that

$$\begin{aligned}\mathbf{P}(X_1 = X_2 + d) \;&\le\; \mathbf{P}(d-\varepsilon < X_1 - X_2 < d+\varepsilon)\\ &\le\; \Phi\left(\frac{d-\mu+\varepsilon}{\sigma\sqrt{n}}\right) - \Phi\left(\frac{d-\mu-\varepsilon}{\sigma\sqrt{n}}\right) + \frac{2C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n}}.\end{aligned}$$

Letting $\varepsilon \to 0$, we obtain the desired claim. ◀

Proof of Theorem 9

Recall that $\left|R_1\right| = n - \left|B_1\right|$. Our goal is to lower-bound the probability that $\left|R_1\right| < \frac{n+1}{2} + d\sqrt{n}$ for any given constant d. Recall the indicator $\mathrm{I}_1(v)$ which is 1 if v is Red after Day One and 0 otherwise. We have:

$$\left|R_1\right| = \sum_{v\in V} \mathrm{I}_1(v).$$

Since the indicators are not independent, a natural choice for bounding their sum is to use Chebysev's inequality. We proceed in two steps:

1. Lower-bound $\mathbf{E}\left[\left|R_1\right|\right]$ by lower-bounding each term $\mathbf{E}\left[\mathrm{I}_1(v)\right]$.
2. Upper-bound $\mathbf{Var}\left[\left|R_1\right|\right]$ by upper-bounding each $\mathbf{Var}\left[\mathrm{I}_1(v)\right]$ and $\mathbf{Cov}\left[\mathrm{I}_1(v), \mathrm{I}_1(v')\right]$.

▷ Claim 13. $\mathbf{E}\left[\left|R_1\right|\right] \;\ge\; \dfrac{n+1}{2} + \left(T(n,p,c,d) + d\right)\sqrt{n}$,

where $T(n,p,c) \stackrel{\text{def}}{=} \sqrt{n-1}\,\Phi_0\left(\dfrac{2pc + \min\{p, 1-p\}}{\sigma\sqrt{n-1}}\right) - \dfrac{C_0\left(1-2\sigma^2\right)}{\sigma}$.

Proof. For each vertex v, let $d_0^R(v)$ and $d_0^B(v)$ respectively be the numbers of its Red and Blue neighbors before the first day. By our rule, the event $\{v \in R_1\}$ is equivalent to $d_0^R(v) > d_0^B(v)$ if $v \in B_0$, i.e. $\mathrm{I}_0(v) = 0$, and to $d_0^R(v) \ge d_0^B(v)$ if $v \in R_0$, i.e. $\mathrm{I}_0(v) = 1$. This implies

$$\forall v \in V.\, \left[v \in R_1 \;\Leftrightarrow\; d_0^R(v) + \mathrm{I}_0(v) > d_0^B(v)\right]. \tag{3}$$

Note that $d_0^R(v) \sim \mathrm{Bin}\left(n^R - \mathrm{I}_0(v), p\right)$ and $d_0^B(v) \sim \mathrm{Bin}\left(n^B + \mathrm{I}_0(v) - 1, p\right)$. By Lemma 11, we have:

$$\begin{aligned}&\mathbf{E}\left[\mathrm{I}_1(v)\right] = \mathbf{P}\left(v \in R_1\right) = \mathbf{P}\left(d_0^R(v_i) + \mathrm{I}_0(v_1) > d_0^B(v_i)\right)\\ &\ge \frac{1}{2} + \Phi_0\left(\frac{p\left(n^R - n^B + 1 - 2\mathrm{I}_0(v)\right) + \mathrm{I}_0(v)}{\sigma\sqrt{n^R + n^B - 1}}\right) - \frac{C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n^R + n^B - 1}}\\ &= \frac{1}{2} + \Phi_0\left(\frac{2pc + p_v}{\sigma\sqrt{n-1}}\right) - \frac{C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n-1}},\end{aligned}$$

where $p_v \stackrel{\text{def}}{=} p\left(1 - \mathrm{I}_0(v)\right) + (1-p)\mathrm{I}_0(v) \ge \min\{p, 1-p\}$. Now

$$\begin{aligned}&\mathbf{E}\left[\left|R_1\right|\right] = \sum_{v\in V}\mathbf{E}\left[\mathrm{I}_1(v)\right] \ge \sum_{v\in V}\Phi_0\left(\frac{2pc + \min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) + n\left(\frac{1}{2} - \frac{C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n-1}}\right)\\ &\ge \frac{n}{2} + \left[\sqrt{n-1}\,\Phi_0\left(\frac{2pc + \min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) - \frac{C_0\left(1-2\sigma^2\right)}{\sigma}\right]\sqrt{n}\\ &= \frac{n}{2} + \left(T(n,p,c,d) + d + \frac{1}{2\sqrt{n}}\right)\sqrt{n} = \frac{n+1}{2} + \left(T(n,p,c,d) + d\right)\sqrt{n},\end{aligned}$$

The proof is complete. ◁

▷ Claim 14. $\mathbf{Var}\left[\left|R_1\right|\right] \leq \frac{n}{4} + 4C_0^2\left(1-2\sigma^2\right)^2 \cdot \frac{n(n-1)}{n-2}$.

Proof. We first have: $\mathbf{Var}\left[\left|R_1\right|\right] = \sum_{i=1}^{k} \mathbf{Var}\left[\mathrm{I}_1(v_1)\right] + 2\sum_{v_1 \neq v_2} \mathbf{Cov}\left[\mathrm{I}_1(v_1), \mathrm{I}_1(v_2)\right]$.
The variances $\mathbf{Var}\left[\mathrm{I}_1(v)\right]$ are easy due to $\mathrm{I}_1(v)$ being a Bernoulli r.v.:

$$\mathbf{Var}\left[\mathrm{I}_1(v)\right] = \mathbf{E}\left[\mathrm{I}_1(v)\right]\left(1-\mathbf{E}\left[\mathrm{I}_1(v)\right]\right) = \frac{1}{4} - \left(\mathbf{E}\left[\mathrm{I}_1(v)\right] - \frac{1}{2}\right)^2 \leq \frac{1}{4}. \tag{4}$$

Bounding the covariance $\mathbf{Cov}\left[\mathrm{I}_1(v_1), \mathrm{I}_1(v_2)\right]$ for two distinct vertices v_1, v_2 requires a bit more care, as the indicators are not independent. By definition

$$\mathbf{Cov}\left[\mathrm{I}_1(v_1), \mathrm{I}_1(v_2)\right] = \mathbf{P}\left(v_1, v_2 \in R_1\right) - \mathbf{P}\left(v_1 \in R_1\right)\mathbf{P}\left(v_2 \in R_1\right).$$

Consider the event $\{v_1, v_2 \in R_1\}$; $\mathbf{P}\left(v_1, v_2 \in R_1\right)$ can be written as

$$\mathbf{P}\left(v_1, v_2 \in R_1 | v_1 \sim v_2\right)\mathbf{P}(v_1 \sim v_2) + \mathbf{P}\left(v_1, v_2 \in R_1 | v_1 \not\sim v_2\right)\mathbf{P}(v_1 \not\sim v_2).$$

Notice that after we specify the adjacency between v_1 and v_2, the remaining vertices in the neighborhoods of v_1 and v_2 are independent. Letting $a_i = \mathbf{P}(v_i \in R_1 \mid v_1 \sim v_2)$, $b_i = \mathbf{P}(v_i \in R_1 \mid v_1 \not\sim v_2)$ and using shorthand $q \stackrel{\text{def}}{=} 1-p$, we have

$$\mathbf{P}\left(v_1, v_2 \in R_1\right) = pa_1a_2 + (1-p)b_1b_2.$$

Now consider $\mathbf{P}\left(v_1 \in R_1\right)\mathbf{P}\left(v_2 \in R_1\right)$. Splitting up the two events by $\{v_1 \sim v_2\}$ gives $\mathbf{P}\left(v_1 \in R_1\right) = pa_1 + qb_1$ and $\mathbf{P}\left(v_2 \in R_1\right) = pa_2 + qb_2$. Putting everything together, we have

$$\begin{aligned}\mathbf{Cov}\left[\mathrm{I}_1(v_1), \mathrm{I}_1(v_2)\right] &= pa_1a_2 + qb_2b_2 - \left(pa_1 + qb_1\right)\left(pa_2 + qb_2\right) \\ &= pq(a_1-b_1)(a_2-b_2) = \sigma^2(a_1-b_1)(a_2-b_2).\end{aligned} \tag{5}$$

We next analyze the relationship between a_1 and b_1. (The analysis for a_2 and b_2 is similar). Define

$$\begin{aligned}m^R &\stackrel{\text{def}}{=} \left|R_0 \setminus \{v_1, v_2\}\right| &&= n^R - \left(\mathrm{I}_0(v_1) + \mathrm{I}_0(v_2)\right), \\ m^B &\stackrel{\text{def}}{=} \left|B_0 \setminus \{v_1, v_2\}\right| &&= n^B + \left(\mathrm{I}_0(v_1) + \mathrm{I}_0(v_2)\right) - 2, \\ d^R &\stackrel{\text{def}}{=} \left|\left(\Gamma(v_1) \cap R_0\right) \setminus \{v_2\}\right| &&= d_0^R(v_1) - \mathrm{I}_0(v_2)W_{v_1v_2} \\ d^B &\stackrel{\text{def}}{=} \left|\left(\Gamma(v_1) \cap B_0\right) \setminus \{v_2\}\right| &&= d_0^B(v_1) + \left(\mathrm{I}_0(v_2) - 1\right)W_{v_1v_2}\end{aligned}$$

We have $m^R + m^B = n-2$, $d^R \sim \mathrm{Bin}(m^R, p)$, $d^B \sim \mathrm{Bin}(m^B, p)$ and $d_0^R(v_1) - d_0^B(v_1) = d^R - d^B + \mathrm{J}_0(v_2)W_{v_1v_2}$. Now we can rewrite a_1 and b_1 using (3) in terms of the above:

$$\begin{aligned}a_1 &= \mathbf{P}\left(d_0^R(v_1) + \mathrm{I}_0(v_1) > d_0^B(v_1) \;\middle|\; v_1 \sim v_2\right) = \mathbf{P}\left(d^R - d^B > -\mathrm{J}_0(v_2) - \mathrm{I}_0(v_1)\right), \\ b_1 &= \mathbf{P}\left(d_0^R(v_1) + \mathrm{I}_0(v_1) > d_0^B(v_1) \;\middle|\; v_1 \not\sim v_2\right) = \mathbf{P}\left(d^R - d^B > -\mathrm{I}_0(v_1)\right).\end{aligned}$$

Case analysis on $\mathrm{J}_0(v_2)$: $\begin{cases}\mathrm{J}_0(v_2) = -1 & \implies a_1 - b_1 = \mathbf{P}\left(d^R - d^B = -\mathrm{I}_0(v_1)\right) \\ \mathrm{J}_0(v_2) = 1 & \implies b_1 - a_1 = \mathbf{P}\left(d^R - d^B = -1 - \mathrm{I}_0(v_1)\right).\end{cases}$

In any case, by Lemma 12 we have $\left|a_1 - b_1\right| \leq \frac{2C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{m^R + m^B}} = \frac{2C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n-2}}$.
The same analysis for a_2 and b_2, and Equation (5) then imply

$$\mathbf{Cov}\left[\mathrm{I}_1(v_1), \mathrm{I}_1(v_2)\right] \leq \sigma^2 \cdot \frac{2C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n-2}} \cdot \frac{2C_0\left(1-2\sigma^2\right)}{\sigma\sqrt{n-2}} = \frac{4C_0^2\left(1-2\sigma^2\right)^2}{n-2}. \tag{6}$$

Equations (4) and (6) together yield

$$\mathbf{Var}\left[\left|R_1\right|\right] \le \frac{1}{4}\cdot n + 2\cdot\frac{4C_0^2\left(1-2\sigma^2\right)^2}{n-2}\cdot\binom{n}{2} = \frac{n}{4} + 4C_0^2\left(1-2\sigma^2\right)^2\cdot\frac{n(n-1)}{n-2}. \tag{7}$$

The proof is complete. ◁

From Claims 13 and 14, a standard Chebyshev's inequality gives

$$\begin{aligned}\mathbf{P}\Big(\left|B_1\right| > \tfrac{n-1}{2} - d\sqrt{n}\Big) &= \mathbf{P}\Big(\left|R_1\right| < \tfrac{n+1}{2} + d\sqrt{n}\Big) \le \frac{\mathbf{Var}\left[\left|R_1\right|\right]}{\left(\mathbf{E}\left[\left|R_1\right|\right] - \frac{n+1}{2} - d\sqrt{n}\right)^2} \\ &\le \frac{\frac{n}{4} + 4C_0^2\left(1-2\sigma^2\right)^2\cdot\frac{n(n-1)}{n-2}}{T(n,p,c,d)^2 n} = Q(n,p,c,d).\end{aligned}$$

The proof of Theorem 9 is complete. This theorem forms the first part of Theorem 6, which shrinks the Blue camp from size $\frac{n}{2}-c$ to $\frac{n}{2}-\Omega(\sqrt{n})$. We state explicitly the relevant result to wrap up this section.

▶ **Corollary 15.** *For any $p\in(0,1)$, $c>0$, $\varepsilon_2>0$ and $n\in\mathbb{N}$, if the Blue side starts with at most $\frac{n}{2}-c=n_0^B$ members, it shrinks to size at most $\frac{n-1}{2}-\left(\frac{C_1+\varepsilon_2}{2p}\right)\sqrt{n}=n_1^B$ with probability at least $1-P_1(n,p,c,\varepsilon_2)$.*

3 Day Two and after

Next, we analyze the situation after the first day. Clearly, if one fixes the coloring after Day 1 and examine the graph, its distribution is no longer $G(n,p)$. Therefore, we cannot apply the same method in proving Theorem 9 for later days. Instead, we use "shrinking arguments" to argue that it is likely for the Blue camp to monotonously shrink to empty, regardless of the choice of its members, due to G's structure.

The core of our shrinking argument is *Hoeffding's inequality*, a classical result that gives exponentially small probability tails for sums of independent random variables.

▶ **Theorem 16** (Hoeffding's inequality). *Let $\{X_i\}_{i=1}^n$ be independent random variables and $\{a_i\}_{i=1}^n$, $\{b_i\}_{i=1}^n$, such that for all $i=1,2,\cdots,n$, $a_i\le X_i\le b_i$ almost surely. Then for $X=X_1+X_2+\cdots+X_n$, we have*

$$\max\Big\{\mathbf{P}\left(X-\mathbf{E}\left[X\right]\ge t\right),\ \mathbf{P}\left(X-\mathbf{E}\left[X\right]\le -t\right)\Big\} \le \exp\left(-\frac{2t^2}{\sum_{i=1}^n(b_i-a_i)^2}\right).$$

The proof of Hoeffding's inequality is available in most graduate level probability textbooks, e.g. [15]. The original proof given by Hoeffding appeared in [9].

A simple yet useful shrinking argument is that, in the $G(n,p)$ model, it is with high probability that all vertices in G have many neighbors, so a small enough Blue camp will not be able to influence anyone by a majority, thus inevitably vanishes the next day.

▶ **Lemma 17.** *For $p\in(0,1)$ and $n\in\mathbb{N}_{>1}$, with probability at least*

$$1-n\exp\left(-\tfrac{2}{9}p^2(n-1)\right) = 1-P_4(n,p),$$

G is such that all vertices have more than $\frac{2}{3}p(n-1)$ neighbors, thus any choice of the Blue camp of at most $\frac{1}{3}p(n-1)=n_3^B$ members shrinks to $0=n_4^B$ the next day.

The proof is standard using the Hoeffding bound, so we refer to Appendix A.2 for details.

This simple lemma forms the first block of our shrinking argument. The overall aim is to argue that with high probability, G is such that a Blue camp of size $\frac{n}{2} - \mathrm{O}(\sqrt{n})$ in Day 1 will inevitably be reduced to size $\mathrm{O}(n)$ in Day 2, and then to size less than $\frac{1}{2}p(n-1)$ in Day 3, then vanishes in the fourth day by Lemma 17. The remaining blocks, which correspond to days before the fourth, will require a more complicated argument.

▶ **Lemma 18.** *Let $p \in (0,1)$, $n, n_0 \in \mathbb{N}$, $n_0 < \frac{n}{2}$. Then for all $m \in \mathbb{N}, m \leq n$, with probability at least*

$$1 - \frac{4^n}{n} \exp\left(-\frac{2p^2(n-2n_0-1)^2 m}{n+m-2}\right),$$

G is such that any choice of the Blue camp of at most n_0 members shrinks to below m in the next day.

Proof. Consider a subset S of V with m elements. We will first bound the probability that S entirely turn Blue the next day. Let (R, B) be the initial coloring with $\big|B\big| = n_0 < n - n_0 = \big|R\big|$. For each $v \in V$, let $\mathrm{dif}(v) \stackrel{\text{def}}{=} \big|\Gamma(v) \cap R\big| - \big|\Gamma(v) \cap B\big|$, and let $\mathrm{dif}(S) \stackrel{\text{def}}{=} \sum_{v \in S} \mathrm{dif}(v)$. We break down each $\mathrm{dif}(v)$ and $\mathrm{dif}(S)$ as follows:

$$\begin{aligned} \mathrm{dif}(v) &= \sum_{u \in R \cap S} W_{vu} + \sum_{u \in R \setminus S} W_{vu} - \sum_{u \in B \cap S} W_{vu} - \sum_{u \in B \setminus S} W_{vu} \\ \mathrm{dif}(S) &= \sum_{v \in S} \sum_{u \in R \cap S} W_{vu} + \sum_{v \in S} \sum_{u \in R \setminus S} W_{vu} - \sum_{v \in S} \sum_{u \in B \cap S} W_{vu} - \sum_{v \in S} \sum_{u \in B \setminus S} W_{vu}. \end{aligned} \tag{8}$$

We have

$$\sum_{v \in S} \sum_{u \in R \cap S} W_{vu} = \sum_{v \in R \cap S} \sum_{u \in R \cap S} W_{vu} + \sum_{v \in B \cap S} \sum_{u \in R \cap S} W_{vu} = \sum_{\{u,v\} \subset S \cap R} 2W_{uv} + \sum_{v \in B \cap S} \sum_{u \in R \cap S} W_{vu}.$$

Similarly, $\sum_{v \in S} \sum_{u \in B \cap S} W_{vu} = \sum_{\{u,v\} \subset S \cap B} 2W_{uv} + \sum_{v \in B \cap S} \sum_{u \in R \cap S} W_{vu}$.
Substituting back into Equation 8, we get

$$\mathrm{dif}(S) = \sum_{\{u,v\} \subset S \cap R} (2W_{uv}) - \sum_{\{u,v\} \subset S \cap B} (2W_{uv}) + \sum_{u \in S} \sum_{v \in R \setminus S} W_{uv} - \sum_{u \in S} \sum_{v \in R \setminus B} W_{uv}.$$

This is now a sum of independent variables, so we can apply Theorem 16. Firstly,

$$\mathbf{E}\left[\mathrm{dif}(S)\right] = p\big|S\big|(\big|R\big| - \big|B\big|) - p(|S \cap R| - |S \cap B|) \geq pm(n - 2n_0 - 1). \tag{9}$$

Moreover, each W_{uv} takes values in $[0,1]$ (a range of length 1) and $2W_{uv}$ takes values in $[0,2]$ (a range of length 2), so the sum of squares of these lengths are

$$\begin{aligned} F &= 4\binom{\big|S \cap R\big|}{2} + 4\binom{\big|S \cap B\big|}{2} + \big|S\big|\big|R \setminus S\big| + \big|S\big|\big|B \setminus S\big| \\ &= \big|S\big|(n - 2 + \big|S\big|) - 4\,|S \cap R|\,|S \cap B| \leq m(n - 2 + m). \end{aligned}$$

By Hoeffding's inequality:

$$\begin{aligned} \mathbf{P}\left(S \subseteq B_1 \mid R_0, B_0\right) &\leq \mathbf{P}\left(\mathrm{dif}(S) \leq 0\right) = \mathbf{P}\left(\mathrm{dif}(S) - \mathbf{E}\left[\mathrm{dif}(S)\right] \leq -\mathbf{E}\left[\mathrm{dif}(S)\right]\right) \\ &\leq \exp\left(-\frac{\mathbf{E}\left[\mathrm{dif}(S)\right]^2}{F}\right) \leq \exp\left(-\frac{2p^2(n-2n_0-1)^2 m}{n-2+m}\right). \end{aligned}$$

Applying a double union bound over choices of S and (R, B), noting that there are $\binom{n}{n_0}\binom{n}{m} \leq 4^n/n$ choices, we have

$$\mathbf{P}\left(\exists(R,B).\exists S.\ \left|B\right| = n_0, \left|S\right| = m, S \subset B_1\right) \ \leq\ \frac{4^n}{n}\exp\left(-\frac{2p^2(n-2n_0-1)^2 m}{n+m-2}\right).$$

Taking the complement event, we get the desired result. ◀

Lemma 18 turns out to be sufficient for the remaining blocks of our shrinking argument. The following lemmas are direct corollaries of Lemma 18.

▶ **Lemma 19.** *For $p \in (0,1)$, $\varepsilon_1 \in \left(0, \frac{1}{2}\right)$ and $n \in \mathbb{N}_{>1}$, with probability at least*

$$1 - \frac{1}{n}\exp\left(-\tfrac{1}{2}p^3(2\varepsilon_1 n - 1)^2 + 2n\log 2\right) = 1 - P_3(n,p,\varepsilon_1),$$

G is such that any choice of the Blue camp of at most $\left(\frac{1}{2} - \varepsilon_1\right)n = n_2^B$ members shrinks to size at most $\frac{1}{3}p(n-1) = n_3^B$ the next day.

▶ **Lemma 20.** *With $C_1 = (3\log 2)^{1/2}$ defined in Section 1.6, let $p \in (0,1)$, $n \in \mathbb{N}$ and $\varepsilon_1, \varepsilon_2 > 0$, then with probability at least*

$$1 - \exp\left(-n\left[(1-2\varepsilon_1)\varepsilon_2 - \varepsilon_1\right] - \log n\right) = 1 - P_2(n, \varepsilon_2, \varepsilon_1), \tag{10}$$

G is such that any choice of the Blue camp of at most $\frac{n-1}{2} - \left(\frac{C_1+\varepsilon_2}{2p}\right)\sqrt{n} = n_1^B$ members shrinks to size at most $\left(\frac{1}{2} - \varepsilon_1\right)n = n_2^B$ the next day.

A routine calculation shows that for appropriate choices of values for ε_1 and ε_2 such that $\varepsilon_1 < \varepsilon_2/(1+2\varepsilon_2)$, the bound in Equation (10) tends to 1 as $n \to +\infty$. Detailed proofs of Lemmas 19 and 20 are in Appendix A.2. These lemmas and Lemma 17, together with Corollary 15 form the complete "chain of shrinking" for the number of Blue vertices to reach 0 in four days, hence wrapping up the proof of Theorem 6.

4 Conclusion

The majority dynamics scheme on a network of n individuals is a process where each person is assigned an initial color, which changes daily to match the majority among their neighbors. The main results in this paper reveal a surprising facts. When the underlying network is a random $G(n,p)$ graph, for any given constants p and ε, there is a constant $c = c(p,\varepsilon)$ such that if one color has $\frac{n}{2} + c$ members in the initial state, then with probability at least $1-\varepsilon$, it covers the whole network in just four days, regardless of n.

Our main result, Theorem 6, yields an explicit lower-bound based on n, p and c for the probability that the side with the initial majority wins. It has two important implications. The first is the *Power of Few* phenomenon (Theorem 2), which shows that when $p = 1/2$ and $\varepsilon = .1$, c can be set to just 6, meaning six extra people is all it takes to win a large election with overwhelming odds. The second is an asymptotic dependency between the ε, n and c (Theorem 3), which shows that for any fixed p, there is a constant $K(p)$ such that choosing n and c both large enough so that $K(p)\max\{n^{-1}, c^{-2}\} < \varepsilon$ will ensure that the winning probability is at least $1-\varepsilon$.

The main idea behind Theorem 6 involves shrinking the set of Blue, the side with the initial minority, from $(n/2 - c)$ to 0 members in the course of four days. This chain of shrinking goes from $(n/2 - c)$ through $(n/2 - \Omega(\sqrt{n}))$, $(1/2 - \Omega(1))n$ and $(1/2 - \Omega(1))pn$, eventually reaching 0 after Day 4. There is a small probability that the shrinking fails to occur on each day, and their sum is the bound we obtained in the theorem's statement.

Although the results in this paper only applies for dense $G(n,p)$ graphs, we do cover sparse graphs in a separate in-progress paper [14], where we obtain the Power of Few phenomenon for $p = \Omega((\log n)/n)$, and discuss the end result (other than a win) for lower values of p. We nevertheless included one of the main proven results of the upcoming paper (Theorem 5), and used it to prove the main theorem in the paper [8] by Fountoulakis, Kang and Makai in Appendix A.3.

A Appendix

In this appendix we provided detailed proofs for claims and lemmas not proven in the main text. We begin with some useful general probabilistic lemmas that are used throughout these proofs.

A.1 Proofs of Theorems 2 and 3

Proof of Theorem 2. Assume Theorem 6. Observe that if the conditions in (1) hold for some value of n, then they hold for all larger values of n. Let $n = 300$, $\varepsilon_1 = .15$ and $\varepsilon_2 = .3$ (along with $p = 1/2$ and $c = 6$), we have the condition in Equation (1) satisfied. Furthermore, a routine calculation shows that

$$P_1 \leq .08454, \quad P_2 < .00001, \quad P_3 < .00001, \quad P_4 \leq .00001,$$

which implies that $\mathbf{P}(B_4 \neq \varnothing) < 0.1$ or equivalently that Red wins in the fourth day with probability at least .9 (conditioned on the event $|B_0| = n^B \leq \frac{n}{2} - c$). ◀

Proof of Theorem 3. In this proof, only n and $c = c_n$ can vary. We can assume, without loss of generality, that $c_n \leq n/2$. Assuming Theorem 6, we choose (constants) $\varepsilon_1, \varepsilon_2$ such that $\varepsilon_2(1 - 2\varepsilon_1) - \varepsilon_1 > 0$, then a routine calculation shows that $P_2, P_3, P_4 = \mathrm{o}(n^{-2})$ and $P_1 = \Omega(n^{-1})$, so $P_1 + P_2 + P_3 + P_4 = P_1 + \mathrm{o}(1)$. We have, for sufficiently large c_n and sufficiently large n,

$$\sqrt{n-1}\,\Phi_0\left(\tfrac{2pc_n + \min\{p,1-p\}}{\sigma\sqrt{n-1}}\right) - \tfrac{C_0(1-2\sigma^2)}{\sigma} - \tfrac{C_1+\varepsilon_2}{2p} - \tfrac{1}{2\sqrt{n}} \geq \tfrac{\sqrt{n}}{2}\,\Phi_0\left(\tfrac{2c_n\sqrt{p}}{\sqrt{n}}\right) = \tfrac{T(n)}{2},$$
$$1/4 + 4C_0^2(1-2\sigma^2)^2\tfrac{n-1}{n-2} \leq 1/4 + 4 \cdot 0.6^2 \cdot 1.5 < 3.$$

Thus, $P_1 \leq 12T(n)^{-2}$. It then suffices to show $T(n) \geq H(p)\min\{c_n^{-2}, n^{-1}\}$ for some term $H(p)$ depending solely on p. Consider 2 cases:

If $c_n \geq \sqrt{n}$, then: $T(n) \geq \sqrt{n} \cdot \Phi_0(2\sqrt{p}) \geq \sqrt{n} \cdot 2\sqrt{p} \cdot \dfrac{\Phi_0(2)}{2} = \sqrt{p}\,\Phi_0(2)\sqrt{n}$.

If $c_n < \sqrt{n}$, then: $T(n) \geq \sqrt{n} \cdot \dfrac{2c_n\sqrt{p}}{\sqrt{n}} \cdot \dfrac{\Phi_0(2)}{2} = \sqrt{p}\,\Phi_0(2)\,c_n$.

In any case, $T(n) \geq H(p)\min\{c_n^{-2}, n^{-1}\}$, for $H(p) = \Phi_0(2)\sqrt{p}$, as desired. ◀

A.2 Proofs for lemmas in Day Two

We provide proofs for Lemmas 19 and 20 in Section 3.

Proof. In a $G(n,p)$ graph, $d(v)$ is a sum of $(n-1)$ $\mathrm{Bin}(1,p)$ random variables, so Theorem 16 implies that for any $u \in V$,

$$\mathbf{P}\left(d(u) \leq \tfrac{2}{3}p(n-1)\right) \leq \mathbf{P}\left(d(u) - \mathbf{E}\left[d(u)\right] \leq -\tfrac{1}{3}p(n-1)\right) \leq \exp\left(-\tfrac{2}{9}p^2(n-1)\right).$$

By a union bound, the probability that all vertices have more than $\frac{2}{3}p(n-1)$ neighbors is at least $1 - n\exp\left(-\frac{2}{9}p^2(n-1)\right) = 1 - P_4(n,p)$. Given this, a Blue camp of size $\frac{1}{3}p(n-1)$ surely vanishes the next day since it cannot form a majority in any vertex's neighborhood. The result then follows. ◀

Proof of Lemma 19. Let $n_2 \stackrel{\text{def}}{=} \left\lfloor\left(\frac{1}{2} - \varepsilon_1\right)n\right\rfloor$ and $m \stackrel{\text{def}}{=} \lceil\frac{1}{3}p(n-1)\rceil$. Lemma 18 implies that the G satisfies that every Blue set of at most n_2 vertices shrinks to size $m-1$ with probability at least

$$1 - \frac{4^n}{n}\exp\left(-\frac{2p^2(n-2n_2-1)^2m}{n+m-2}\right) = 1 - \frac{1}{n}\exp\left(-\frac{2p^2(n-2n_2-1)^2m}{n+m-2} + 2n\log 2\right).$$

Since $n_2 \le \left(\frac{1}{2} - \varepsilon_1\right) n$, $(n - 2n_2 - 1)^2 \ge (2\varepsilon_1 n - 1)^2$. Furthermore, $m \ge \frac{1}{3}p(n-1)$ so $\frac{m}{n+m-2} \ge \frac{p(n-1)/3}{n+p(n-1)/3-1} = \frac{p}{3+p} \ge \frac{p}{4}$. Therefore

$$\frac{1}{n}\exp\left(-\frac{2p^2(n-2n_2-1)^2 m}{n+m-2} + 2n\log 2\right) \le \frac{1}{n}\exp\left(-\frac{1}{2}p^3(2\varepsilon_1 n - 1)^2 + 2n\log 2\right).$$

The result then follows. ◀

Proof of Lemma 20. Let $n_2 \stackrel{\text{def}}{=} \left\lfloor \frac{n-1}{2} - \left(\frac{C_1+\varepsilon_2}{2p}\right)\sqrt{n} \right\rfloor$ and $m \stackrel{\text{def}}{=} \left\lceil \left(\frac{1}{2} - \varepsilon_1\right) n \right\rceil$. Lemma 18 implies that the G satisfies that every Blue set of at most n_2 vertices shrinks to size $m-1$ with probability at least

$$1 - \frac{4^n}{n}\exp\left(-\frac{2p^2(n-2n_2-1)^2 m}{n+m-2}\right) = 1 - \frac{1}{n}\exp\left[-\left(\frac{2p^2(n-2n_2-1)^2 m}{n+m-2} - 2n\log 2\right)\right].$$

Since $\frac{m}{n+m-2} \ge \frac{m}{n+m} \ge \frac{1-2\varepsilon_1}{3-2\varepsilon_1}$ and $n - 2n_2 - 1 \ge \left(\frac{C_1+\varepsilon_2}{p}\right)\sqrt{n}$, we can bound the exponent of the RHS of the above as follows

$$\begin{aligned}
&\frac{2p^2(n-2n_2-1)^2 m}{n+m-2} - 2n\log 2 \;\ge\; 2p^2\left(\frac{C_1+\varepsilon_2}{p}\right)^2 \frac{1-2\varepsilon_1}{3-2\varepsilon_1} n - \frac{2C_1^2}{3}n \\
&= \frac{2n}{3-2\varepsilon_1}\left[(C_1+\varepsilon_2)^2(1-2\varepsilon_1) - \frac{C_1^2}{3}(3-2\varepsilon_1)\right] \;\ge\; \frac{2n}{3}\left[\varepsilon_2(\varepsilon_2+2C_1)(1-2\varepsilon_1) - \frac{4}{3}\varepsilon_1 C_1^2\right] \\
&\ge \frac{2n}{3}\left[2.8\varepsilon_2(1-2\varepsilon_1) - 2.8\varepsilon_1\right] \;=\; \frac{5.6n}{3}\left[\varepsilon_2(1-2\varepsilon_1) - \varepsilon_1\right] \;\ge\; n\left[\varepsilon_2(1-2\varepsilon_1) - \varepsilon_1\right].
\end{aligned}$$

Note that we have used the facts that $C_1 > 1.4$ and $\log_2 < .7$. The proof is complete. ◀

A.3 Proof of Fountoulakis et al's Theorem from Theorem 5

We provide the proof of the main theorem in [8] (Theorem 4) with our Theorem 5.

Proof. Assume Theorem 5. Let R_0 and B_0 respectively be the initial Red and Blue camps. Fix a constant $0 < c' \le \varepsilon/6$. $\left|R_0\right| \sim \mathrm{Bin}(n, 1/2)$ since it is a sum of $\mathrm{Bin}(1, 1/2)$ variables. An application of the Berry-Esseen theorem (Theorem 10; with $C_0 = .56$) implies that

$$\mathbf{P}\left(\left|R_0\right| - \frac{n}{2} \le c'\sqrt{n}\right) \le \Phi(2c') + \frac{C_0}{\sqrt{n}} \;\text{ and }\; \mathbf{P}\left(\left|R_0\right| - \frac{n}{2} \le -c'\sqrt{n}\right) \ge \Phi(-2c') - \frac{C_0}{\sqrt{n}},$$

Thus

$$\begin{aligned}
\mathbf{P}\left(\left|\left|R_0\right| - \frac{n}{2}\right| \le c'\sqrt{n}\right) &\le \left(\Phi(2c') + \frac{C_0}{\sqrt{n}}\right) - \left(\Phi(-2c') - \frac{C_0}{\sqrt{n}}\right) \\
&\le \Phi(-2c', 2c') + \frac{2C_0}{\sqrt{n}} \;\le\; \frac{4c'}{\sqrt{2\pi}} + \frac{2C_0}{\sqrt{n}} \;\le\; \frac{\varepsilon}{3} + \frac{2C_0}{\sqrt{n}} \le \varepsilon/2,
\end{aligned}$$

for sufficiently large n.

On the other hand, if $\left|\left|R_0\right| - n/2\right| > c'\sqrt{n}$, then one of the sides has more than $n/2 + c'\sqrt{n}$ initial members, which we call the *majority side*. Now we apply Theorem 5 with ε replaced by $\varepsilon/2$. Notice that in the setting of Theorem 4 if we have $p = \lambda n^{-1/2}$ for λ sufficiently large, then $c'\sqrt{n} \ge c/p$, where c is the constant in Theorem 5. Thus, by this theorem, the probability for the majority side to win is at least $1 - \varepsilon/2$, and we are done by the union bound. ◀

Time-Space Tradeoffs for Distinguishing Distributions and Applications to Security of Goldreich's PRG

Abstract

In this work, we establish lower-bounds against memory bounded algorithms for distinguishing between natural pairs of related distributions from samples that arrive in a streaming setting.

Our first result applies to the problem of distinguishing the uniform distribution on $\{0,1\}^n$ from uniform distribution on some unknown linear subspace of $\{0,1\}^n$. As a specific corollary, we show that any algorithm that distinguishes between uniform distribution on $\{0,1\}^n$ and uniform distribution on an $n/2$-dimensional linear subspace of $\{0,1\}^n$ with non-negligible advantage needs $2^{\Omega(n)}$ samples or $\Omega(n^2)$ memory (tight up to constants in the exponent).

Our second result applies to distinguishing outputs of Goldreich's *local* pseudorandom generator from the uniform distribution on the output domain. Specifically, Goldreich's pseudorandom generator $\mathcal{G}$ fixes a predicate $P : \{0,1\}^k \to \{0,1\}$ and a collection of subsets $S_1, S_2, \ldots, S_m \subseteq [n]$ of size k. For any seed $x \in \{0,1\}^n$, it outputs $P(x_{S_1}), P(x_{S_2}), \ldots, P(x_{S_m})$ where x_{S_i} is the projection of x to the coordinates in S_i. We prove that whenever P is t-resilient (all non-zero Fourier coefficients of $(-1)^P$ are of degree t or higher), then no algorithm, with $< n^\epsilon$ memory, can distinguish the output of $\mathcal{G}$ from the uniform distribution on $\{0,1\}^m$ with a large inverse polynomial advantage, for stretch $m \leq \left(\frac{n}{t}\right)^{\frac{(1-\epsilon)}{36}\cdot t}$ (barring some restrictions on k). The lower bound holds in the streaming model where at each time step i, $S_i \subseteq [n]$ is a randomly chosen (ordered) subset of size k and the distinguisher sees either $P(x_{S_i})$ or a uniformly random bit along with S_i.

An important implication of our second result is the security of Goldreich's generator with super linear stretch (*in the streaming model*), against memory-bounded adversaries, whenever the predicate P satisfies the *necessary* condition of t-resiliency identified in various prior works.

Our proof builds on the recently developed machinery for proving time-space trade-offs (Raz 2016 and follow-ups). Our key technical contribution is to adapt this machinery to work for *distinguishing* problems in contrast to prior works on similar results for *search*/learning problems.

1 Introduction

This work is motivated by the following basic question: suppose an algorithm is provided with a stream of m i.i.d. samples from a random source. What's the minimum memory required to decide whether the source is "truly random" or "pseudorandom"?

Algorithmically distinguishing perfect randomness from pseudorandomness naturally arises in the context of learning theory (and can even be equivalent to learning in certain models [20, 24, 60, 36]), pseudorandomness and cryptography.

There has been a surge of progress in proving lower bounds for memory-bounded streaming algorithms beginning with Shamir [55] and Steinhardt-Valiant-Wager [57] who conjectured a $\Omega(n^2)$ memory lower bound for learning parity functions with $2^{o(n)}$ samples. This conjecture was proven in [53]. In a follow up work, this was generalized to learning sparse parities in [35] and more general learning problems in [54, 29, 45, 14, 18, 47, 46, 56, 30].

All of these lower bounds hold for learning (more generally, *search*) problems that ask to identify an unknown member of a target function class from samples. In this work, we build on the progress above and develop techniques to show lower bounds for apparently easier task of simply distinguishing uniformly distributed samples from pseudorandom ones. [25] studies the related problem of distribution testing under communication and memory constraints. [25] gave a one-pass streaming algorithm (and a matching lower bound for a broad range of parameters) for uniformity testing on $[N]$ that uses m memory and $O(N \log(N)/(m\epsilon^4))$ samples for distinguishing between uniform distribution on $[N]$ and any distribution that is ϵ-far from uniform.

As we next discuss, our results have consequences of interest in cryptography (ruling out memory-bounded attacks on Goldreich's pseudorandom generator [31] in the streaming model) and average-case complexity (unconditional lower bounds on the number of samples needed, for memory-bounded algorithms, to refute random constraint satisfaction problems, in the streaming model).

1.1 Our Results

We now describe our results in more detail. Our main results show memory-sample trade-offs for distinguishing between truly random and pseudorandom sources for the following two settings:

1. **Uniform vs k-Subspace Source**: The pseudorandom subspace source of dimension k chooses some arbitrary k-dimensional linear subspace $S \subseteq \{0,1\}^n$ and draws points uniformly from S. The truly random source draws points uniformly from $\{0,1\}^n$.
2. **Uniform vs Local Pseudorandom Source**: The pseudorandom source fixes a k-ary Boolean predicate $P : \{0,1\}^k \to \{0,1\}$. It chooses a uniformly random $x \in \{0,1\}^n$ and generates samples $(\alpha, b) \in [n]^{(k)} \times \{0,1\}$ where $[n]^{(k)}$ represents the set of all ordered k-tuples with exactly k elements from $[n]$ and α is chosen uniformly at random from $[n]^{(k)}$ and b is the evaluation of P at x^α - the k-bit string obtained by projecting x onto the coordinates indicated by α. The truly random source generates samples (α, b) where $\alpha \in [n]^{(k)}$ and $b \in \{0,1\}$ are chosen uniformly and independently.

We model our algorithm by a *read-once branching program* (ROBP) of width 2^b (or memory b) and length m. Such a model captures any algorithm that takes as input a stream of m samples and has a memory of at most b bits. Observe that there's no restriction on the computation done at any node of an ROBP.

Roughly speaking, this model gives the algorithm unbounded computational power and bounds only its memory-size and the number of samples used.

Our first main result shows a lower bound on memory-bounded ROBPs for distinguishing between uniform and k-subspace sources.

▶ **Theorem 1** (Uniform vs Subspace Sources). *Any algorithm that distinguishes between uniform and subspace source of dimension k (assuming $k > c \log n$ for some large enough constant c) with probability at least $1/2 + 2^{-o(k)}$ requires either a memory of $\Omega(k^2)$ or at least $2^{\Omega(k)}$ samples. In particular, distinguishing between the uniform distribution on $\{0,1\}^n$ and the uniform distribution on an unkown linear subspace of dimension $n/2$ in $\{0,1\}^n$ requires $\Omega(n^2)$ memory or $2^{\Omega(n)}$ samples.*

Crouch et. al. [16] recently proved that any algorithm that uses at most $n/16$ bits of space requires $\Omega(2^{n/16})$ samples to distinguish between uniform source and a subspace source of dimension $k = n/2$. They suggest the question of improving the space bound to $\Omega(n^2)$ while noting that their techniques do not suffice. For $k = \Theta(n)$, our lower bound shows that any algorithm with memory at most cn^2 for some absolute constant c requires $2^{\Omega(n)}$ samples. This resolves their question.

Upper bound. In Section 4, we exhibit a simple explicit branching program that uses $2^{O(k)}$ samples and $O(1)$ memory to succeed in solving the distinguishing problem with probability $3/4$. We also show a simple algorithm that uses $O(k^2)$ memory and $O(k)$ samples, and succeeds in solving the distinguishing problem with probability $3/4$. *Thus, in the branching program model, the lower bound is tight up to constants in the exponent.*

Our second main result gives a memory-sample trade-off for the uniform vs local pseudorandom source problem for all predicates that have a certain well-studied pseudorandom property studied in cryptography under the name of *resilience*.

A k-ary Boolean function P is said to be *t-resilient* if t is the maximum integer such that $(-1)^P$ (taking the range of the boolean function to be {-1,1}) has zero correlation with every parity function of at most $t-1$ out of k bits. In particular, the parity function on k bits is k-resilient.

▶ **Theorem 2** (Uniform vs Local Pseudorandom Sources). *Let $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$ and P be a t-resilient k-ary predicate for $k < n^{(1-\epsilon)/6}/3, n/c^2$. Then, any ROBP that succeeds with probability at least $1/2 + \Omega(\left(\frac{t}{n}\right)^{\Omega(t\cdot(1-\epsilon))})$ at distinguishing between uniform and local pseudorandom source for predicate P, requires $\left(\frac{n}{t}\right)^{\Omega(t\cdot(1-\epsilon))}$ samples or n^ϵ memory.*

Upper bound. In Subsection 5.3, we give an algorithm that takes $(n^\epsilon + k)k \log n$ memory and $(n^{(1-\epsilon)k})(n^\epsilon + k)$ samples, and distinguishes between uniform and local pseudorandom source for any predicate P, with probability $99/100$. Thus, the lower bounds are almost tight up to $\log n$ factors and constant factors in the exponent for certain predicates ($t = \Omega(k)$). The question of whether there exists a better algorithm that runs in $O(n^{(1-\epsilon)t})$ samples and $O(n^\epsilon)$ memory, and distinguishes between uniform and local pseudorandom source with high probability, for t-resilient predicates P, remains open.

[2] c is a large enough constant

This result has interesting implications for well-studied algorithmic questions in average-case complexity and cryptography such as refuting random constraint satisfaction [27, 2, 52, 37]) and existence of local pseudorandom generators [17, 49, 11, 43, 4, 5] with super linear stretch where a significant effort has focused on proving lower bounds on various restricted models such as propositional and algebraic proof systems, spectral methods, algebraic methods and semidefinite programming hierarchies. While bounded memory attacks are well-explored in cryptography [44, 15, 10, 9, 59, 26, 53, 61, 32, 58, 34, 19], to the best of our knowledge, memory has not been studied as explicit resource in this context. We discuss these applications further in the paper.

For the special case when $P(x) = \sum_i^k x^i \mod 2$, the parity function on k bits, we can prove stronger results for a wider range of parameters.

▶ **Theorem 3** (Uniform vs Local Pseudorandom Sources with Parity Predicate). *Let $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$ and P be the parity predicate on k bits for $0 < k < n/c$ (c is a large enough constant). Suppose there's a ROBP that distinguishes between uniform and local pseudorandom source for the parity predicate, with probability at least $1/2 + s$ and uses $< n^\epsilon$ memory. If $s > \Omega\left(\left(\frac{k}{n}\right)^{\Omega((1-\epsilon)\cdot k)}\right)$, then, the ROBP requires $\left(\frac{n}{k}\right)^{(\Omega((1-\epsilon)\cdot k)}$ samples.*

A recent concurrent work [19] builds symmetric encryption schemes which are secure against memory bounded adversaries, where each ciphertext makes at most k calls to a "random" function. Even though the applications and techniques are different, the setting of the analysis is almost identical and the paper obtains better bounds (in terms of constants in the exponent) for the (and only the) parity predicate on k bits.

The above results show lower bounds for *sublinear* memory algorithms. For a slight variant of the above uniform vs local pseudorandom source problem, we can in fact upgrade our results to obtain the following lower bounds against *super-linear* memory algorithms. See Section 4 for details.

▶ **Theorem 4.** *For large enough n and $k > c \log n$ (where c is a large enough constant) and $k \leq \frac{n}{4}$, any algorithm that can distinguish satisfiable sparse parities of sparsity k on n variables (of type $(a, b) = (a^1, a^2, ..., a^n, b) \in \{0,1\}^{n+1}$, where $\forall i \in [n]$, $a^i = 1$ with probability $\frac{k}{n}$ and $b = \langle a, x \rangle$) from random ones (of similar type (a, b) but b is now chosen uniformly at random from $\{0,1\}$), with success probability at least $\frac{1}{2} + 2^{-o(k)}$, requires either a memory of size $\Omega(nk)$ or $2^{\Omega(k)}$ samples.*

In Remark 15, we observe that the above theorem is almost tight. Specifically, we observe that there are ROBPs that use a constant memory and $O(n2^{O(k)})$ samples or $O(nklogn)$ memory and $O(n)$ samples to distinguish uniform sources from locally pseudorandom ones.

1.2 Applications to Security of Goldreich's Pseudorandom Generator

A fundamental goal in cryptography is to produce secure constructions of cryptographic primities that are highly efficient. In line with this goal, Goldreich [31] proposed a candidate one-way function given by the following pseudorandom mapping that takes n-bit input x and outputs m bits: fix a *predicate* $P : \{0,1\}^k \to \{0,1\}$, pick $a_1, a_2, \ldots, a_m$ uniformly at random[3] from $[n]^{(k)}$ and output $P(x^{a_1}), P(x^{a_2}), \ldots, P(x^{a_m})$. Here, $a_1, \ldots, a_m$ and P are public and the seed x is secret. Later works (starting with [48]) suggested using this candidate as pseudorandom generator.

[3] More generally, Goldreich proposed that $a_1, a_2, \ldots, a_m$ could be chosen in a pseudorandom way so as to ensure a certain "expansion" property. We omit a detailed discussion here.

The main question of interest is the precise trade-off between the *locality* k and the *stretch* m for a suitable choice of the predicate P. In several applications, we need that the generator has a super-linear stretch (i.e. $m = n^{1+\delta}$ for some $\delta > 0$) with constant locality (i.e. $k = O(1)$).

The simplicity and efficiency of such a candidate is of obvious appeal. This simplicity has been exploited to yield a host of applications including public-key cryptography from combinatorial assumptions [6], highly efficient secure multiparty computation [33] and most recently, basing *indistinguishability obfuscation* on milder assumptions [38, 3, 41, 39, 40].

Evidence for the security of Goldreich's candidate has been based on analyzing natural classes of attacks based on propositional proof systems [1], spectral methods and semidefinite programming hierarchies [51, 2, 12, 37, 42, 11] and algebraic methods [7, 8]. In particular, previous works [37, 8] identified t-resiliency of the predicate P as a necessary condition for the security of the candidate for $m = n^{\Omega(t)}$ stretch.

The *uniform vs local pseudorandom source* problem considered in this work is easily seen as the algorithmic question of distinguishing the output stream generated by Goldreich's candidate generator from a uniformly random sequence of bits. In particular, our results imply security of Goldreich's candidate against bounded memory algorithms for super-linear stretch when instantiated with any t-resilient predicate for large enough constant t (but in the streaming model). Goldreich's candidate generator would fix the sets $a_1, a_2, \ldots, a_m$ (which are public) and output $P(x^{a_1}), P(x^{a_2}), \ldots, P(x^{a_m})$ for n sized input x ($m > n$). We prove the security of Goldreich's generator in the model where $a_1, a_2, \ldots, a_m$, still public, are chosen uniformly at random from $[n]^{(k)}$ and streamed with the generated bits.

We note that our lower bounds continue to hold even when the locality k grows polynomially with the seed length n.

▶ **Corollary 5** (Corollary of Theorem 2). *Let $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$ and P be a t-resilient k-ary predicate for $k = O(n^{(1-\epsilon)/6})$. Then, Goldreich's PRG, when instantiated with any t-resilient k-ary predicate P such that $k \geq t > 36$ and stretch $m = (n/t)^{O(t)(1-\epsilon)}$, is secure against all read-once branching programs with memory-size bounded from above by n^{ϵ}, in the streaming model.*

1.3 Applications to Refuting Random CSPs

Theorems 2 and 3 can also be intepreted as lower bounds for the problem of refuting random constraint satisfaction problems.

A random CSP with predicate $P : \{0,1\}^k \to \{0,1\}$ is a constraint satisfaction problem on n variables $x \in \{0,1\}^n$. More relevant to us is the variant where the constraints are randomly generated as follows: choose an ordered k-tuple of variables a from $[n]$ at random, a bit $b \in \{0,1\}$ at random and impose a constraint $P(x^a) = b$. When the number of constraints $m \gg n$, the resulting instance is unsatisfiable with high probability for any non-constant predicate P. The natural algorithmic problem in this regime is that of *refutation* - efficiently finding a short witness that certifies that the given instance is far from satisfiable. It is then easy to note that the uniform vs local pseudorandom source problem is the task of distinguishing between constraints in a random CSP (with predicate P) and one with a satisfying assignment. Note that refutation is formally harder than the task of distinguishing between a random CSP and one that has a satisfying assignment.

Starting with investigating in proof complexity, random CSPs have been intensively studied in the past three decades. When P is t-resilient for $t \geq 3$, all known efficient algorithms [2] require $m \gg n^{1.5}$ samples for the refutation problem. This issue was brought

to the forefront in [27] where Feige made the famous "Feige's Hypothesis" conjecturing the impossibility of refuting random 3SAT in polynomial time with $\Theta(n)$ samples. Variants of Feige's hypothesis for other predicates have been used to derive hardness results in both supervised [21, 22, 23] and unsupervised machine learning [13].

In [51], t-resilience was noted as a necessary condition for the refutation problem to be hard. Our Theorems 2 and 3 confirm this as a sufficient condition for showing lower-bounds for the refutation (in fact, even for the easier "distinguishing" variant) of random CSPs, with t-resilient predicates, in the streaming model with bounded memory.

2 Preliminaries

Denote by log the logarithm to base 2. We use $Ber(p)$ to denote the Bernoulli distribution with parameter p (probability of being 1). We use $[n]$ to denote the set $\{1, 2, ..., n\}$.

For a random variable Z and an event E, we denote by $\mathbb{P}_Z$ the distribution of the random variables Z, and we denote by $\mathbb{P}_{Z|E}$ the distribution of the random variable Z conditioned on the event E.

Given an $n-$bit vector $y \in \{0,1\}^n$, we use y^i to denote the i^{th} coordinate of y, that is, $y = (y^1, y^2, ..., y^n)$. We use $y^{-i} \in \{0,1\}^{n-1}$ to denote y but with the ith coordinate deleted. Given two $n-$bit vectors y, y', we use $\langle y, y' \rangle$ to denote the inner product of y and y' modulo 2, that is, $\langle y, y' \rangle = \sum_{i=1}^{n} y^i y'^i \mod 2$. We use $|y|$ to denote the number of ones in the vector y.

Given a set S, we use $y \in_R S$ to denote the random process of picking y uniformly at random from the set S. Given a probability distribution D, we use $y \sim D$ to denote the random process of sampling y according to the distribution D.

Next, we restate (for convenience) the definitions and results from previous papers [53, 54, 35, 29] that we use.

Viewing a Learning Problem as a Matrix

Let X, A be two finite sets of size larger than 1.

Let $M : A \times X \to \{-1, 1\}$ be a matrix. The matrix M corresponds to the following learning problem: There is an unknown element $x \in X$ that was chosen uniformly at random. A learner tries to learn x from samples (a, b), where $a \in A$ is chosen uniformly at random and $b = M(a, x)$. That is, the learning algorithm is given a stream of samples, $(a_1, b_1), (a_2, b_2) \ldots$, where each a_t is uniformly distributed and for every t, $b_t = M(a_t, x)$.

These papers model the learner for the learning problem corresponding to the matrix M using a branching program:

▶ **Definition 6** (Branching Program for a Learning Problem). *A branching program of length m and width d, for learning, is a directed (multi) graph with vertices arranged in $m+1$ layers containing at most d vertices each. In the first layer, that we think of as layer 0, there is only one vertex, called the start vertex. A vertex of outdegree 0 is called a leaf. All vertices in the last layer are leaves (but there may be additional leaves). Every non-leaf vertex in the program has $2|A|$ outgoing edges, labeled by elements $(a, b) \in A \times \{-1, 1\}$, with exactly one edge labeled by each such (a, b), and all these edges going into vertices in the next layer. Each leaf v in the program is labeled by an element $\tilde{x}(v) \in X$, that we think of as the output of the program on that leaf.*

Computation-Path: *The samples $(a_1, b_1), \ldots, (a_m, b_m) \in A \times \{-1, 1\}$ that are given as input, define a computation-path in the branching program, by starting from the start vertex and following at step t the edge labeled by (a_t, b_t), until reaching a leaf. The program outputs the label $\tilde{x}(v)$ of the leaf v reached by the computation-path.*

Success Probability: *The success probability of the program is the probability that $\tilde{x} = x$, where $\tilde{x}$ is the element that the program outputs, and the probability is over $x, a_1, \ldots, a_m$ (where x is uniformly distributed over X and $a_1, \ldots, a_m$ are uniformly distributed over A, and for every t, $b_t = M(a_t, x)$).*

▶ **Theorem 7** ([53, 54, 29]). *Any branching program that learns $x \in \{0,1\}^n$, from random linear equations over $\mathbb{F}_2$ with success probability 2^{-cn} requires either a width of $2^{\Omega(n^2)}$ or a length of $2^{\Omega(n)}$ (where c is a small enough constant).*

▶ **Theorem 8** ([29]). *Any branching program that learns $x \in \{0,1\}^n$, from random sparse linear equations, of sparsity exactly ℓ, over $\mathbb{F}_2$ with success probability 2^{-cl} (where c is a small enough constant) requires:*

1. *Assuming $\ell \leq n/2$: either a width of size $2^{\Omega(n \cdot \ell)}$ or length of $2^{\Omega(\ell)}$.*
2. *Assuming $\ell \leq n^{0.9}$: either a width of size $\Omega(n \cdot \ell^{0.99})$ or length of $\ell^{\Omega(\ell)}$.*

Norms and Inner Products

Let $p \geq 1$. For a function $f : X \to \mathbb{R}$, denote by $\|f\|_p$ the ℓ_p norm of f, with respect to the uniform distribution over X, that is:

$$\|f\|_p = \left(\mathop{\mathbf{E}}_{x \in_R X} [|f(x)|^p] \right)^{1/p}.$$

For two functions $f, g : X \to \mathbb{R}$, define their inner product with respect to the uniform distribution over X as

$$\langle f, g \rangle = \mathop{\mathbf{E}}_{x \in_R X} [f(x) \cdot g(x)].$$

For a matrix $M : A \times X \to \mathbb{R}$ and a row $a \in A$, we denote by $M_a : X \to \mathbb{R}$ the function corresponding to the a-th row of M. Note that for a function $f : X \to \mathbb{R}$, we have $\langle M_a, f \rangle = \frac{(M \cdot f)_a}{|X|}$.

▶ **Definition 9** (L_2-Extractor, [29]). *Let X, A be two finite sets. A matrix $M : A \times X \to \{-1, 1\}$ is a (k', ℓ')-L_2-Extractor with error $2^{-r'}$, if for every non-negative $f : X \to \mathbb{R}$ with $\frac{\|f\|_2}{\|f\|_1} \leq 2^{\ell'}$ there are at most $2^{-k'} \cdot |A|$ rows a in A with*

$$\frac{|\langle M_a, f \rangle|}{\|f\|_1} \geq 2^{-r'}.$$

▶ **Lemma 10** ([35]). *Let T_l be the set of n-bit vectors with sparsity exactly-l for $l \in \mathbb{N}$, that is, $T_l = \{x \in \{0,1\}^n \mid \sum_{i=1}^n x^i = l\}$. Let $\delta \in (0, 1]$. Let $\mathcal{B}_{T_l}(\delta) = \{\alpha \in \{0,1\}^n \mid \left| \boldsymbol{E}_{x \in T_l} (-1)^{\langle \alpha, x \rangle} \right| > \delta\}$. Then, for $\delta \geq (\frac{8l}{n})^{\frac{l}{2}}$,*

$$|\mathcal{B}_{T_l}(\delta)| \leq 2e^{-\delta^{2/l} \cdot n/8} \cdot 2^n$$

Branching Program for a Distinguishing Problem

Let X, A be two finite sets of size larger than 1. Let D_0 be a distribution over the sample space $|A|$. Let $\{D_1(x)\}_{x \in X}$ be a set of distributions over the sample space $|A|$. Consider the following distinguishing problem: An unknown $\mathbf{b} \in \{0,1\}$ is chosen uniformly at random. If $\mathbf{b} = 0$, the distinguisher is given independent samples from D_0. If $\mathbf{b} = 1$, an unknown $x \in X$ is chosen uniformly at random, and the distinguisher is given independent samples from $D_1(x)$. The distinguisher tries to learn $\mathbf{b}$ from the samples drawn according to the respective distributions.

Formally, we model the distinguisher by a branching program as follows.

▶ **Definition 11** (Branching Program for a Distinguishing Problem). *A branching program of length m and width d, for distinguishing, is a directed (multi) graph with vertices arranged in $m+1$ layers containing at most d vertices each. In the first layer, that we think of as layer 0, there is only one vertex, called the start vertex. A vertex of outdegree 0 is called a leaf. All vertices in the last layer are leaves (but there may be additional leaves). Every non-leaf vertex in the program has $|A|$ outgoing edges, labeled by elements $a \in A$, with exactly one edge labeled by each such a, and all these edges going into vertices in the next layer. Each leaf v in the program is labeled by a $\tilde{\boldsymbol{b}}(v) \in \{0,1\}$, that we think of as the output of the program on that leaf.*

Computation-Path: *The samples $a_1, \ldots, a_m \in A$ that are given as input, define a computation-path in the branching program, by starting from the start vertex and following at step t the edge labeled by a_t, until reaching a leaf. The program outputs the label $\tilde{\boldsymbol{b}}(v)$ of the leaf v reached by the computation-path.*

Success Probability: *The success probability of the program is the probability that $\tilde{\boldsymbol{b}} = \boldsymbol{b}$, where $\tilde{\boldsymbol{b}}$ is the element that the program outputs, and the probability is over $\boldsymbol{b}, x, a_1, \ldots, a_m$ (where $\boldsymbol{b}$ is uniformly distributed over $\{0,1\}$, x is uniformly distributed over X and $a_1, \ldots, a_m$ are independently drawn from D_0 if $\boldsymbol{b} = 0$ and $D_1(x)$ if $\boldsymbol{b} = 1$).*

3 Overview of the Proofs

We prove our theorems using two different techniques. We prove Theorems 1 and 4 through reductions to the memory-sample lower bounds for the corresponding learning problems in Section 4. Informally, for Theorem 1, we construct a branching program that learns the unknown vector x from random linear equations in $\mathbb{F}_2$ by guessing each bit one by one sequentially and using the distinguisher, for distinguishing subspaces from uniform, to check if it guessed correctly. Then, we are able to lift the previously-known memory-sample lower bounds for the learning problem (Theorem 7) to the distinguishing problem. Similarly, we lift the memory-sample lower bounds for a variant of the learning problem in Theorem 8 to the get Theorem 4.

Theorems 2 and 3 are restated in Section 5. A brief overview of these theorems are as follows. Recall, a pseudorandom source fixes a k-ary Boolean predicate $P : \{0,1\}^k \to \{0,1\}$. It chooses a uniformly random $x \in \{0,1\}^n$ and generates samples $(\alpha, b) \in [n]^{(k)} \times \{0,1\}$ where α is a uniformly random (ordered) k-tuple of indices in $[n]$ and b is the evaluation of P at x^α - the k-bit string obtained by projecting x onto the coordinates indicated by α. The truly random source samples (α, b) where $\alpha \in [n]^{(k)}$ and $b \in \{0,1\}$ are chosen uniformly and independently. The problem for a distinguisher is to correctly guess whether the m samples are generated by a pseudorandom or a uniform source, when the samples arrive in a stream. We first show through a *hybrid argument* that a distinguisher A that distinguishes between the uniform and pseudorandom source, with an advantage of s over $1/2$, can also distinguish (with advantage of at least s/m) when only the jth (for some j) sample is drawn from the "unknown source", the first $j-1$ samples are drawn from the pseudorandom source and the last $m-j$ samples are drawn from the uniform source.

Let v be the memory state of A after seeing the first $j-1$ samples, which were generated from a pseudorandom source with a seed x picked uniformly at random from $\{0,1\}^n$. Let $\mathbb{P}_{x|v}$ be the probability distribution of the random variable x conditioned on reaching v. If the jth sample is generated using the same pseudorandom source, then $\forall \alpha \in [n]^{(k)}$, the bit b is 0 with probability $\sum_{x' : P(x'^\alpha)=0} \mathbb{P}_{x|v}(x')$ and 1 with probability $1 - \sum_{x' : P(x'^\alpha)=0} \mathbb{P}_{x|v}(x')$. If the jth sample is generated using the uniform source, then $\forall \alpha \in [n]^{(k)}$, the bit b is 0 with

probability 1/2 and 1 with probability 1/2. Thus, for any α, A can identify the "unknown source" with an at most $\left|\sum_{x':P(x'^{\alpha})=0} \mathbb{P}_{x|v}(x') - 1/2\right|$ advantage. We show that when A has low memory ($< n^{\epsilon}$ for some $0 < \epsilon < 1$), then with high probability, it reaches a state v such that $\mathbb{P}_{x|v}$ has high min-entropy (informally, it's hard to determine the seed for the pseudorandom source). The argument till now (last 2 paragraphs) is common and has been previously used to prove that a "source" fools bounded space, such as in [50].

Next, we use t-resiliency of P to show that when $\mathbb{P}_{x|v}$ has high min-entropy, then with high probability over $\alpha \in [n]^{(k)}$, b behaves almost like in a uniform source (Lemma 19), that is, $|\sum_{x':P(x'^{\alpha})=0} \mathbb{P}_{x|v}(x') - 1/2|$ is small. Hence, with high probability, it's hard for A to judge with 'good' advantage whether b was generated from a pseudorandom or a uniform source. Note that the last $m - j$ samples generated by a uniform source can't better this advantage.

4 Time-Space Tradeoff through Reduction to Learning

In this section, we will state time-space tradeoffs for the following distinguishing problems, which are proved using black-box reduction from the corresponding learning problems.

Distinguishing Subspaces from Uniform

Informally, we study the problem of distinguishing between the cases when the samples are drawn from a uniform distribution over $\{0,1\}^n$ and when the samples are drawn randomly from a subspace of rank k over $\mathbb{F}_2$. Let $L(k,n)$ be the set of all linear subspaces of dimension k ($\subseteq \{0,1\}^n$), that is, $L(k,n)$ contains all subspaces V such that $V = \{v \in \{0,1\}^n \mid \langle w_i, v\rangle = 0 \ \forall i \in [n-k]\}$ for some linearly independent vectors $w_1, w_2, ..., w_{n-k}$. Formally, we consider distinguishers for distinguishing between the following distributions:

1. D_0: Uniform distribution over $\{0,1\}^n$.
2. $D_1(S)$, $S \in L(k,n)$: Uniform distribution over S.

Note: If the subspace S is revealed, it's easy for a branching program of constant width to distinguish w.h.p. by checking the inner product of the samples with a vector in the orthogonal complement of S.

A distinguisher can distinguish subspaces if for an unknown random linear subspace $S \in L(k,n)$, it can distinguish between D_0 and $D_1(S)$. Formally, a distinguisher L, after seeing m samples, has a success probability of p if

$$\frac{\Pr_{u_1,...,u_m \sim D_0}[L(u_1,...,u_m)=0] + \Pr_{S \in_R L(k,n); u_1,...,u_m \sim D_1(S)}[L(u_1,...,u_m)=1]}{2} = p \quad (1)$$

▶ **Theorem 12.** *For $k > c_2 \log n$ (where c_2 is a large enough constant), any algorithm that can distinguish k-dimensional subspaces over $\mathbb{F}_2^n$ from $\mathbb{F}_2^n$ ($\{0,1\}^n$), when samples are drawn uniformly at random from the subspace or $\mathbb{F}_2^n$ respectively, with success probability at least $\frac{1}{2} + 2^{-o(k)}$ requires either a memory of size $\Omega(k^2)$ or $2^{\Omega(k)}$ samples.*

For the proof, refer to the full version of the paper [28]. Briefly, we prove that using a distinguisher for distinguishing subspaces, we can construct a branching program that learns an unknown bit vector x from random linear equations over $\mathbb{F}_2$. Then, we are able to lift the time-space tradeoffs of Theorem 7.

▶ Remark 13 (Tightness of the Lower Bound). We note two easy upper bounds that show that our results in Theorem 12 are tight (up to constants in the exponent). Firstly, we observe an algorithm B_1 that distinguishes subspaces of dimension k from uniform, using $O(k^2)$ memory and $O(k)$ samples, with probability at least 3/4 ($0 < k \leq n-1$). B_1 stores

the first $\min(8k, n)$ bits of the first $8k$ samples (in $O(k^2)$ memory); outputs 1 if the samples (projected onto the first $\min(8k, n)$ coordinates) belong to a $\leq k$-dimensional subspace (of $\{0,1\}^{\min(8k,n)}$), and 0 otherwise (can be checked using gaussian elimination). When the samples are drawn from $D_1(S)$ for some k-dimensional subspace S, then B_1 always outputs the correct answer. When the samples are drawn from a uniform distribution on $\{0,1\}^n$, the probability that $8k$ samples form a k-dimensional subspace is at most

$$\binom{8k}{k} \cdot \frac{1}{2^{7k}} \leq (8e)^k 2^{-7k} < 2^{-2k} \leq 1/4$$

(because, if the $8k$ samples form a k-dimensional subspace, then at least $7k$ of them are linearly dependent on the previously stored samples and that happens with at most $1/2$ probability for each sample). Hence, B_1 errs with at most $1/4$ probability.

Secondly, we observe that there exists a branching program that distinguishes subspaces of dimension k from uniform using constant width and $O(k \cdot 2^k)$ length with probability at least $3/4$. Before, we show a randomized algorithm P that distinguishes between D_0 and $D_1(S)$ for every $S \in L(k, n)$ with high probability. P is described as follows:

1. Repeat steps 2 to 3 sequentially for $t = 10 \cdot 2^k$ iterations.
2. Pick a non-zero vector v uniformly at random from $\{0,1\}^n$. For the next $2k$ samples (of the form $a \in \{0,1\}^n$), check if $\langle a, v \rangle = 0$.
3. If all the $2k$ samples are orthogonal to v, exit the loop and output 1.
4. Output 0 (None of the randomly chosen vectors were orthogonal to all the samples seen in its corresponding iteration).

The number of samples seen by P is $20k \cdot 2^k$. Now, we prove that for every subspace S of dimension k, that is, $S \in L(k, n)$, P distinguishes between D_0 and $D_1(S)$ with probability at least $1 - \frac{1}{2}(e^{-5} + \frac{10}{2^k}) \geq 3/4$[4].

When the samples are drawn from D_0, the probability that P outputs 1 is equal to the probability that in at least one of the t iterations, the randomly chosen non-zero vector v was orthogonal to the $2k$ samples drawn uniformly from $\{0,1\}^n$. Here, the probability is over v and the samples. By union bound, we can bound the probability of outputting 1 (error) by

$$10 \cdot 2^k \cdot \left(\frac{1}{2}\right)^{2k} = \frac{10}{2^k}.$$

For a fixed subspace $S \in L(k, n)$, the probability that we pick a non-zero vector $v \in \{0,1\}^n$ that is orthogonal to S is at least $\frac{2^{n-k}-1}{2^n-1} > 2^{-(k+1)}$. Therefore, when the samples are drawn from $D_1(S)$, the probability that P outputs 0 (error) is upper bounded by $\left(1 - \frac{1}{2^{k+1}}\right)^{10 \cdot 2^k} \leq e^{-5}$. Here, the probability is over the vectors v and the samples. Now to construct a constant width but $20k \cdot 2^k$ length branching program that distinguishes with probability at least $3/4$, we consider a bunch of branching programs each indexed by t vectors that are used in step 2 of the algorithm P. It's easy to see that for a fixed set of t vectors, P can be implemented by a constant width branching program. As, when the t vectors are uniformly distributed over $\{0,1\}^n$ (non-zero), P can distinguish with probability at least $3/4$ for every subspace $S \in L(k, n)$, there exists a fixing to the t vectors such that the corresponding branching program distinguishes between D_0 and $D_1(S)$ (when S is chosen uniformly at random from $L(k, n)$) with probability at least $3/4$.

[4] $k \geq 5$

Distinguishing Satisfiable Sparse Equations from Uniform

Informally, we study the problem of distinguishing between the cases when the samples are drawn from satisfiable sparse equations over $\mathbb{F}_2$ and when the samples are drawn from random sparse equations.

Formally, we consider the distinguishing problem between the following two distributions:

1. D_0: Distribution on $(n+1)$-length vectors $(v^1, v^2, ..., v^n, b) \in \{0,1\}^{n+1}$ where $\forall i \in [n]$, v^i is 1 with probability $\frac{k}{n}$ and 0 otherwise, and b is 1 with probability $\frac{1}{2}$ and 0 otherwise.
2. $D_1(x)$, $x \in \{0,1\}^n$: Distribution on $(n+1)$-length vectors $(v^1, v^2, ..., v^n, b) \in \{0,1\}^{n+1}$ where $\forall i \in [n]$, v^i is 1 with probability $\frac{k}{n}$ and 0 otherwise, and $b = \langle v, x \rangle$ where $v = (v^1, v^2, ..., v^n)$.

Here, k is the sparsity parameter.

We say that a distinguisher can distinguish satisfiable sparse equations of sparsity k from random ones if, when x is unknown and chosen uniformly at random from $\{0,1\}^n$, it can distinguish between D_0 and $D_1(x)$. Formally, a distinguisher L, after seeing m, has a success probability of p if

$$\frac{\Pr_{u_1,...,u_m \sim D_0}[L(u_1,...,u_m) = 0] + \Pr_{x \in_R \{0,1\}^n; u_1,...,u_m \sim D_1(x)}[L(u_1,...,u_m) = 1]}{2} \geq p \quad (2)$$

▶ **Theorem 14.** *For large enough n and $k > c_5 \log n$ (where c_5 is a large enough constant) and $k \leq \frac{n}{4}$, any algorithm that can distinguish random sparse parities of sparsity k on n variables from satisfiable ones, with success probability at least $\frac{1}{2} + 2^{-o(k)}$, requires either a memory of size $\Omega(nk)$ or $2^{\Omega(k)}$ samples.*

▶ Remark 15 (Tightness of our Lower Bound). We note two easy upper bounds that show that our results in Theorem 14 are almost tight. Firstly, we observe that there's an algorithm B_1 of memory $O(nk \log n)$ that uses $O(n)$ samples and can distinguish random sparse parities of sparsity k from satisfiable ones, with probability of at least $3/4$. B_1 just stores $O(n)$ samples (in $O(nk \log n)$ memory); if there exists x that satisfies all the samples, it outputs 1, otherwise it outputs 0. When the samples are satisfiable, that is, drawn from $D_1(x)$ (for some x), B_1 always outputs 1. When the samples are random, using the union bound, it's easy to see that the probability that there exists an x that satisfies all the $O(n)$ samples is exponentially small in n.

Second, there's an algorithm B_2 of constant memory that uses $O(n \cdot 2^{O(k)})$ samples and can distinguish random sparse parities of sparsity k from satisfiable ones, with probability of at least $3/4$. The probability that a learning algorithm sees sample (a, b), such that $a = (1, 0, ..., 0)$, is at least $\frac{ke^{-2k}}{n}$ for $k < n/2$; thus, one can just wait for say 5 such samples and see if the values of b are drawn randomly or are fixed, giving a constant memory and $O(ne^{2k})$ samples algorithm that distinguishes with high probability.

Refer to the full version of the paper [28] for the proof of Theorem 14. Briefly, we prove that using such a distinguisher, we can construct a branching program that learns an unknown bit vector x from sparse linear equations of sparsity k over $\mathbb{F}_2$. Unlike before, when we were able to lift, we are not able to directly lift the time-space tradeoffs of Theorem 8, because these lower bounds hold when the equations are of sparsity *exactly-k*. Following the proof of Theorem 8 in [29] very closely, we can prove the following lemma:

▶ **Lemma 16.** *Any branching program that learns $x \in \{0,1\}^n$ from random linear equations over $\mathbb{F}_2$ of type $(a, b) = (a^1, a^2, ..., a^n, b) \in \{0,1\}^{n+1}$, where $\forall i \in [n]$, $a^i = 1$ with probability $\frac{k}{n}$ and $b = \langle a, x \rangle$, with success probability 2^{-ck}, requires either width of size $2^{\Omega(n \cdot k)}$ or length of $2^{\Omega(k)}$ (where c is a small enough constant, $k \leq \frac{n}{4}$).*

The proof is given in full version [28]. Now through reduction, we are able to lift the time-space tradeoffs of Lemma 16 to get Theorem 14.

5 Sample-Memory Tradeoffs for Resilient Local PRGs

In this section, we prove our lower bound against memory bounded algorithms for distinguishing between streaming outputs of Goldreich's pseudorandom generator and perfectly random bits. Before stating our result in detail, we set up some notation and definitions that will be convenient for us in this section.

5.1 Formal Setup

A k-ary *predicate* P is a Boolean function $P : \{0,1\}^k \to \{0,1\}$. Let $\sum_{\alpha \subseteq [k]} \hat{P}(\alpha)\chi_\alpha$ be the Fourier polynomial for $(-1)^P$ ($(-1)^P(x) = (-1)^{P(x)}$). P is said to be *t-resilient* if t is the maximum positive integer such that $\hat{P}(\alpha) = 0$ whenever $|\alpha| < t$. In particular, the parity function $\langle \alpha, x \rangle$ is $|\alpha|$-resilient. Here, $\chi_\alpha : \{0,1\}^k \to \{-1,1\}$ is such that $\chi_\alpha(x) = (-1)^{\langle \alpha, x \rangle}$.

Let $[n]^{(k)}$ denote the set of all ordered k-tuples of exactly k elements of $[n]$. That is, no element of $[n]$ occurs more than once in any tuple of $[n]^{(k)}$. For any $a \in [n]^{(k)}$, let $a^i \in [n]$ denote the element of $[n]$ appearing in the ith position in a. Given $x \in \{0,1\}^n$ and $a \in [n]^{(k)}$, let $x^a \in \{0,1\}^k$ be defined so that $(x^a)^i = x^{a^i}$ for every $1 \le i \le k$.

For any k-ary predicate P, consider the problem of distinguishing between the following two distributions on $(a,b) \in [n]^{(k)} \times \{0,1\}$ where (a,b) are sampled as follows:

1. D_{null}: 1) Choose a uniformly at random from $[n]^{(k)}$, and 2) choose b uniformly at random and independently from $\{0,1\}$.
2. $D_{planted}(x)$, $x \in \{0,1\}^n$: 1) Choose a uniformly at random from $[n]^{(k)}$, and 2) set $b = P(x^a)$.

Note that a is chosen uniformly at random from $[n]^{(k)}$ in both distributions. However, while the bit b is independent of a in D_{null}, it may be correlated with a in $D_{planted}$.

A distinguisher for the above problem gets access to m i.i.d. samples $u_t = (a_t, b_t), t \in [m]$ from one of D_{null} and $D_{planted}(x)$ for a uniformly randomly chosen $x \in \{0,1\}^n$ and outputs either "planted" or "null". We say that the distinguisher succeeds with probability p if

$$\Pr_{u_1,\ldots,u_m \sim D_{null}}[L(u_1,\ldots,u_m) = \text{"null"}] + \Pr_{\substack{x \in_R \{0,1\}^n; \\ u_1,\ldots,u_m \sim D_{planted}(x)}}[L(u_1,\ldots,u_m) = \text{"planted"}]$$

is greater than $2p$. In the language used in the previous sections, think of "null" as being equivalent to 0 and "planted" being equivalent to 1, that is, $D_{null} \equiv D_0$ and $D_{planted}(x) \equiv D_1(x)$. Therefore, the success probability of the distinguisher L can be written as

$$\frac{\Pr_{u_1,\ldots,u_m \sim D_0}[L(u_1,\ldots,u_m) = 0] + \Pr_{x \in_R \{0,1\}^n; u_1,\ldots,u_m \sim D_1(x)}[L(u_1,\ldots,u_m) = 1]}{2} \ge p \quad (3)$$

In particular, if $x \in \{0,1\}^n$ is "revealed" to a distinguishing algorithm, then it is easy to use $\Theta(\log(1/\epsilon))$ samples and constant width branching program to distinguish correctly with probability at least $1 - \epsilon$ between D_{null} and $D_{planted}$.

5.2 Main Result

The main result of this section is the following sample-memory trade-off for any distinguisher.

▶ **Theorem 17.** *Let P be a t-resilient k-ary predicate. Let $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$ and $k < n/c$. Suppose there's an algorithm that distinguishes between D_{null} and $D_{planted}$ with probability at least $1/2 + s$ and uses $< n^\epsilon$ memory. Then, whenever $0 < t \le k < n^{\frac{(1-\epsilon)}{6}}/3$ and $s > c_1(\frac{n}{t})^{-(\frac{1-\epsilon}{36})t}$, the algorithm requires $(\frac{n}{t})^{(\frac{1-\epsilon}{36})t}$ samples. Here, c and c_1 are large enough constants.*

Note that when k is a constant, this theorem gives a sample-memory tradeoff even for $\Omega(n)$ memory.

Our argument yields a slightly better quantitative lower bound for the special case when P is the parity function, that is, $P(x) = (\sum_{i=1}^{k} x^i) \mod 2$. We will represent this function by Xor.

▶ **Theorem 18.** *Let $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$ and P be the parity predicate Xor on $k = t$ bits. Suppose there's an algorithm that distinguishes between D_{null} and $D_{planted}$ with probability at least $1/2 + s$ and uses $< n^{\epsilon}$ memory. Then for $k \leq n/c^5$, if $s > 3(\frac{n}{k})^{-(\frac{1-\epsilon}{18})k}$, the algorithm requires $(\frac{n}{k})^{(\frac{1-\epsilon}{18})k}$ samples.*

We prove both Theorem 17 and 18 via the same sequence of steps except for a certain quantitative bound presented in Lemma 19. In the next subsection, we give an algorithm that takes $\widetilde{O}(n^{\epsilon} + k)k$ memory and $\widetilde{O}(n^{(1-\epsilon)k})$ samples, and distinguishes between D_{null} and $D_{planted}$ for any predicate P, with probability 99/100. Thus, the lower bounds are almost tight up to constant factors in the exponent for the parity predicate. The question of whether there exists an algorithm that runs in $O(n^{(1-\epsilon)t})$ samples and $O(n^{\epsilon})$ memory, and distinguishes between D_{null} and $D_{planted}$ with high probability, for t-resilient predicates P, remains open.

5.3 Tightness of the Lower Bound

In this section, we observe that there exists an algorithm A that takes $O((n^{\epsilon} + k) \cdot k \log n)$ memory and $O(n^{(1-\epsilon)k} \cdot (n^{\epsilon} + k))$ samples, and distinguishes between D_{null} and $D_{planted}$ for any predicate P, with probability 99/100 (for $n^{\epsilon} > 10$).

A runs over $4n^{(1-\epsilon)k} \cdot (n^{\epsilon} + k)$ samples and stores the first $2(n^{\epsilon} + k)$ samples $(a, b) \in [n]^{(k)} \times \{0, 1\}$ such that $a^i \leq n^{\epsilon} + k, \forall i \in [k]$, that is, the bit b depends only on the first $n^{\epsilon} + k$ bits of x under the distribution $D_{planted}(x)$. If A encounters less than $2(n^{\epsilon} + k)$ samples of the above mentioned form, A outputs 1 ("planted"). Otherwise, A goes over all the possibilities of the first $n^{\epsilon} + k$ bits of x ($2^{n^{\epsilon}+k}$ possibilities in total) and checks if it could have generated the stored samples. If there exists a $y \in \{0, 1\}^{n^{\epsilon}+k}$ that generated the stored samples, A outputs 1 ("planted"), otherwise A outputs 0.

It's easy to see that A uses $m = 4n^{(1-\epsilon)k} \cdot (n^{\epsilon} + k)$ samples and at most $2(n^{\epsilon} + k) \cdot k \log n$ memory (as it takes only $k \log n$ memory to store a sample). Next, we calculate the probability of success. Let Z_j be a random variable as follows: $Z_j = 1$ if the j^{th} sample (a_j, b_j) is such that $a_j^i \leq n^{\epsilon} + k, \forall i \in [k]$ and 0 otherwise.

$$\Pr[Z_j = 1] = \frac{|[n^{\epsilon} + k]^{(k)}|}{|[n]^{(k)}|} \geq n^{-(1-\epsilon)k}$$

And $\mathbf{E}[\sum_{j=1}^{m} Z_j] = 4(n^{\epsilon} + k)$. By Chernoff bound, $\Pr[\sum_j Z_j < 2(n^{\epsilon} + k)] \leq e^{-\frac{4(n^{\epsilon}+k)}{8}} \leq \frac{1}{100}$. Therefore, the probability that A stores $2(n^{\epsilon} + k)$ samples is at least 99/100. It's easy to see that A always outputs 1 when the samples are generated from $D_{planted}(x)$ for any x.

The probability that A outputs 1, given that it stored $2(n^{\epsilon}+k)$ samples, when the samples are generate from D_{null} is equal to the probability that there exists a $y \in \{0, 1\}^{n^{\epsilon}+k}$ that could have generated the stored samples. Let $(a'_1, b'_1), ..., (a'_{2(n^{\epsilon}+k)}, b'_{2(n^{\epsilon}+k)})$ be the stored samples. There are at most $2^{n^{\epsilon}+k}$ sequences of $b'_1, ..., b'_{2(n^{\epsilon}+k)}$ generated by some y given

[5] c is a large enough constant

$\{a'_j\}_{j\in[2(n^\epsilon+k)]}$. As, under D_{null}, b is chosen uniformly at random from $\{0,1\}$, the probability that there exists $y \in \{0,1\}^{n^\epsilon+k}$ that could have generated the stored samples is at most $\frac{2^{n^\epsilon+k}}{2^{2(n^\epsilon+k)}} = 2^{-(n^\epsilon+k)} \leq 1/100$. Hence, the probability of success is at least 99/100.

5.4 Proof of Theorems 17 and 18

For the full proof, please refer to the full version of the paper [28]. In this section, we give a very brief outline of the proof and state a crucial lemma. Fix a t-resilient k-ary predicate P. Let B be a branching program with bounded width and length, that distinguishes between D_{null} and $D_{planted}(x)$ (x is uniformly distributed over $\{0,1\}^n$) for the predicate P, with non-negligible probability.

We first use hybrid argument to obtain that the branching program B must have a non-trivial probability of distinguishing with a single sample. Towards this, define $H_j(x)$ to be the distribution over m samples where the first j samples are drawn from $D_{planted}(x)$ and the remaining $m-j$ samples are from D_{null}. Using hybrid argument, there is a $j' \in \{1,...,m\}$ such that B distinguishes between the hybrids $H_{j'-1}(x)$ and $H_{j'}(x)$ with non-negligible probability. Then to contradict, we show that a bounded-width and bounded-length B cannot distinguish between the hybrids $H_{j'-1}(x)$ and $H_{j'}(x)$.

Let v_1 be a vertex of the branching program B after seeing the first $j'-1$ (generated from a pseudorandom source with a seed x picked uniformly at random from $\{0,1\}^n$). Let $\mathbb{P}_{x|v_1}$ be the probability distribution of the random variable x conditioned on reaching v_1. If the j'th sample is generated using the same pseudorandom source (as in $H_{j'}(x)$), then $\forall a \in [n]^{(k)}$, the bit b is 0 with probability $\sum_{x':P(x'^a)=0} \mathbb{P}_{x|v_1}(x')$ and 1 with probability $1 - \sum_{x':P(x'^a)=0} \mathbb{P}_{x|v_1}(x')$. If the j'th sample is generated using the uniform source (as in $H_{j'-1}(x)$), then $\forall a \in [n]^{(k)}$, the bit b is 0 with probability 1/2 and 1 with probability 1/2. Thus, for any a, B can distinguish with at most $\left|\sum_{x':P(x'^a)=0} \mathbb{P}_{x|v_1}(x') - 1/2\right|$ advantage. We show that when B has bounded width, then with high probability, it reaches a vertex v_1 such that $\mathbb{P}_{x|v_1}$ has high min-entropy. We then use t-resiliency of P to show that when $\mathbb{P}_{x|v_1}$ has high min-entropy, then with high probability over $a \in [n]^{(k)}$, the expression $\left|\frac{1}{2} - \sum_{x':P(x'^a)=0} \mathbb{P}_{x|v_1}(x')\right|$ is small (the following lemma). Hence, with high probability, it's hard for B to distinguish whether the j'th sample was generated from $H_{j'}(x)$ or $H_{j'-1}(x)$. Note that the last $m-j$ samples, generated by a uniform source, can't better this advantage.

Define $T_l = \{\bar{a} \in \{0,1\}^n : \sum_{i=1}^n \bar{a}^i = l\}$ for $l \in \mathbb{N}$. For $\epsilon > 0, k \geq t > 0$, let L be the set of vertices v such that $\mathbb{P}_{x|v}$ has min-entropy of at least $(n - n^\epsilon - t\log(n/t))$, that is, $\forall x' \in \{0,1\}^n$, $\mathbb{P}_{x|v}(x') \leq 2^{n^\epsilon - n} \cdot (n/t)^t$.

▶ **Lemma 19.** *For all $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$, $0 < t \leq k < \{\frac{n}{c}, n^{\frac{(1-\epsilon)}{6}}/3\}$, and $v_1 \in L$,*

$$\left|\sum_{x'} \mathbb{P}_{x|v_1}(x') \cdot (-1)^{P(x'^a)}\right| \leq c_2 n^{-(\frac{1-\epsilon}{18})t}$$

for all but at most $c_2 n^{-(\frac{1-\epsilon}{18})t}$ fraction of $a \in [n]^{(k)}$ (recall that P is a t-resilient k-ary predicate).

For all $v_1 \in L$, $0 < \epsilon < 1 - 3\frac{\log 24}{\log n}$, $0 < k < \frac{n}{c}$,

$$\left|\sum_{x'} \mathbb{P}_{x|v_1}(x') \cdot (-1)^{Xor(x'^a)}\right| \leq 2\left(\frac{n}{k}\right)^{-(\frac{1-\epsilon}{9})k}$$

for all but at most $2(\frac{n}{k})^{-(\frac{1-\epsilon}{9})k}$ fraction of $a \in [n]^{(k)}$.

Here, c and c_2 are large enough constants.

Please refer to the full version [28] for the proof of the above lemma.

Streaming Verification for Graph Problems: Optimal Tradeoffs and Nonlinear Sketches

Amit Chakrabarti
Dartmouth College, Hanover, NH, USA

Prantar Ghosh
Dartmouth College, Hanover, NH, USA

Justin Thaler
Georgetown University, Washington, DC, USA

Abstract

We study graph computations in an enhanced data streaming setting, where a space-bounded client reading the edge stream of a massive graph may delegate some of its work to a cloud service. We seek algorithms that allow the client to *verify* a purported *proof* sent by the cloud service that the work done in the cloud is correct. A line of work starting with Chakrabarti et al. (ICALP 2009) has provided such algorithms, which we call *schemes*, for several statistical and graph-theoretic problems, many of which exhibit a tradeoff between the length of the proof and the space used by the streaming verifier.

This work designs new schemes for a number of basic graph problems – including triangle counting, maximum matching, topological sorting, and single-source shortest paths – where past work had either failed to obtain smooth tradeoffs between these two key complexity measures or only obtained suboptimal tradeoffs. Our key innovation is having the verifier compute certain *nonlinear* sketches of the input stream, leading to either new or improved tradeoffs. In many cases, our schemes in fact provide optimal tradeoffs up to logarithmic factors.

Specifically, for most graph problems that we study, it is known that the product of the verifier's space cost v and the proof length h must be at least $\Omega(n^2)$ for n-vertex graphs. However, matching upper bounds are only known for a handful of settings of h and v on the curve $h \cdot v = \tilde{\Theta}(n^2)$. For example, for counting triangles and maximum matching, schemes with costs lying on this curve are only known for $(h = \tilde{O}(n^2), v = \tilde{O}(1))$, $(h = \tilde{O}(n), v = \tilde{O}(n))$, and the trivial $(h = \tilde{O}(1), v = \tilde{O}(n^2))$. A major message of this work is that by exploiting nonlinear sketches, a significant "portion" of costs on the tradeoff curve $h \cdot v = n^2$ can be achieved.

1 Introduction

It is far easier to verify a proof than to find one. This intuitively clear fact has been given precise meanings in several settings , leading to such landmark results as the IP = PSPACE [36] and PCP Theorems [3, 4]. There is a growing body of work on results of this flavor for space-efficient computations on large data streams [35]. In this setting, a space-bounded client (henceforth named Verifier) that can only process inputs in the restrictive *data streaming* setting has access to a computationally powerful entity (henceforth named Prover), such as cloud computing service, that has no such space limitations. As past work has shown, many fundamental problems that are intractable in the plain data-streaming model – in the sense that they cannot be solved using sublinear space – do admit nontrivial solutions in this Verifier/Prover model, *without* Verifier having to trust Prover blindly.

An algorithm in this model specifies a protocol to be followed by Verifier and Prover so that the former may compute some function $f(\sigma)$ of the input stream σ. Prover, by performing the specified actions honestly, convinces Verifier to output the correct value $f(\sigma)$. However, if Prover fails to follow the protocol, whether out of malice or error (modeling hardware, software, or network faults in the cloud service), then Verifier is highly likely to detect this and *reject*. Past work has considered a few different instances of this setup, such as (a) *annotated* data streaming algorithms [12, 30] – also called *online schemes* – where the parties read σ together and the protocol consists of Prover streaming a "help message" (a.k.a. proof) to Verifier either during stream processing and/or at the end; (b) *prescient schemes* [11], which are a variant of the above where Prover knows all of σ before Verifier sees it; (c) *streaming interactive proofs* (SIPs) [13, 19], where Verifier and Prover engage in multiple rounds of communication.

This work focuses on the first and arguably best-motivated of these models, namely, online schemes. We simply call them *schemes*. We give new and improved schemes for several graph-theoretic problems, including triangle counting, maximum matching, topological sorting, and shortest paths. In all cases, the input is a huge n-vertex graph G given as a stream σ of edge insertions and/or deletions. While most of our problems have been studied before, we give schemes that (a) have better complexity parameters, in some cases achieving optimality, and (b) use cleverer algebraic encodings of the relevant combinatorial problems, often exploiting the ability of a streaming algorithm to compute *nonlinear* sketches.

1.1 Setup, Terminology, and Motivation

We formalize the setup described above. A scheme for a function f specifies three things: (i) a space-bounded data streaming algorithm used by Verifier to process the input σ and compute a summary $\mathcal{V}_R(\sigma)$, using random coins R; (ii) a help function used by Prover to send a message $\mathcal{H}(\sigma)$ to Verifier as a "proof stream" after the input stream ends;[1] and (iii) an output algorithm $\text{out}_R(\mathcal{V}_R(\sigma), \mathcal{H}(\sigma))$ capturing Verifier's work during and after the proof stream, which produces values in $\text{range}(f) \cup \{\perp\}$, where an output of $\perp$ indicates "reject." If $\mathcal{V}_R$ and out_R run in $O(v)$ bits of space and $\mathcal{H}$ provides $O(h)$ bits of help, then this scheme is called an (h, v)-*scheme*. A scheme is interesting if we can use $h > 0$ to achieve a value of v asymptotically smaller than what is feasible or known for a basic streaming algorithm, where $h = 0$. A scheme is said to have

- completeness error ε_c if $\forall \sigma\, \exists \mathcal{H} : \Pr_R[\text{out}_R(\mathcal{V}_R(\sigma), \mathcal{H}(\sigma)) = f(\sigma)] \geqslant 1 - \varepsilon_c$;
- soundness error ε_s if $\forall \sigma, \mathcal{H}' : \Pr_R[\text{out}_R(\mathcal{V}_R(\sigma), \mathcal{H}'(\sigma)) \notin \{f(\sigma), \perp\}] \leqslant \varepsilon_s$.

[1] A more general (though seldom used) model allows Prover to send help messages after each data item in σ.

In designing schemes, we will aim for $\varepsilon_s \leqslant 1/3$, which can be reduced further via parallel repetition in standard ways. We will also achieve perfect completeness, i.e., $\varepsilon_c = 0$. For an (h, v)-scheme we refer to h as its hcost (short for "help cost") and v as its vcost ("verification cost"). We use the notation $[h, v]$-scheme as a shorthand for an $(\tilde{O}(h), \tilde{O}(v))$-scheme.[2]

It is intuitive that the parameters h and v are in tension, suggesting that they can be traded off against one another. Most of our algorithms do obtain such tradeoffs. We emphasize that actually obtaining a smooth tradeoff for large ranges of h and v values is not automatic: indeed, an important contribution of this work is to obtain such tradeoffs for problems where past work gave comparable results only for specific settings of h and v.

When studying the results discussed below, it is useful to keep a few cost regimes in mind. We focus on graph problems on n-vertex inputs. An (h, v)-scheme for such a problem is *sublinear* if $h = o(n^2)$ and $v = o(n^2)$; *frugal* if it is sublinear and achieves the stronger guarantee $v = o(n)$; and *laconic* if it is sublinear and achieves the stronger guarantee $h = o(n)$.

Many graph problems are *intractable* in the basic one-pass streaming model, meaning that they provably require $\Omega(n^2)$ space. Past work [12] implies that any (h, v)-scheme for such a problem must have $hv = \Omega(n^2)$. Thus, an $[h, v]$-scheme with $hv = O(n^2)$ for an intractable problem has achieved an optimal tradeoff, up to logarithmic factors. All of the problems we consider in this paper (except for counting connected components) are intractable for dense graphs (i.e., graphs with $\Omega(n^2)$ edges).

Frugal schemes are important when Verifier is so starved for space that it cannot afford to store even a constant fraction of the vertices. They are also very interesting from a theoretical standpoint, since even "easy" graph problems require at least $\Omega(n)$ space in the basic streaming model. On the other hand, laconic schemes are naturally motivated by settings where Verifier does not have streaming access to the proof and has to store it in full. Consider for example a retail client that uploads transactions to the cloud as they occur. It makes sense to have uploaded even terabytes of information *in total* over a long period of time: days, months, or years. However, it might not be reasonable for the cloud to transfer a proof consisting of, say, tens of gigabytes to the client. From a theoretical standpoint, in solving an intractable problem, if Verifier has to store the proof, there is no reason to ever try to reduce vcost to $o(n)$, since hcost will then blow up to $\omega(n)$.

1.2 Problems, Results, and Comparisons with Related Work

Throughout, the input graph G will be on the fixed vertex set $V = [n] := \{1, \ldots, n\}$ and will have m edges. Many results will be stated in terms of tunable parameters $t, s \in \mathbb{Z}^+$ that must satisfy $ts \geqslant n$. Since bounds are asymptotic, this condition can be read as $ts = n$.

Triangle Counting. Our starting point is the triangle counting problem (henceforth, TriangleCount), studied heavily in past work on graph streaming [7, 8, 10, 24, 25, 27, 34, 38]. Given a multigraph G as a dynamic stream (i.e., insertions and deletions), the goal is to compute T, the number of triangles in G. The exact counting version studied in this paper is an intractable problem in the sense of Section 1.1: it requires $\Omega(n^2)$ space in basic streaming.

As noted in Table 1, we give several new algorithms for TriangleCount. Our $[nt^2, s]$-scheme improves upon the best known frugal scheme for the problem: for a fixed hcost $\geqslant n$, it improves the vcost from $v^{4/3}$ to v, and for a fixed vcost $v \leqslant n$, it improves the hcost from $n^3/v^{3/2}$ to n^3/v^2. Our $[t, ns]$-scheme is not only the first laconic scheme for the problem but

[2] The notation $\tilde{O}(\cdot)$ hides factors polynomial in $\log n$.

Table 1 Summary of results on the problems considered in this paper. A scheme is deemed *optimal* if it has help cost at most h and space cost at most v for at least one pair h, v such that $h \cdot v \leqslant \tilde{O}(L)$, whereas it is known that *any* (h, v) scheme that applies to all graphs requires $h \cdot v \geqslant \Omega(L)$. A blank space in the *Tradeoff* column indicates that it remains open whether the scheme can be strictly improved. Here, α' is the size of a maximum matching in the input graph, K is the length of a shortest v_s–v_t path, D is the maximum distance from the source to the any other reachable vertex, and W is the maximum weight of an edge.

Problem	Scheme	Tradeoff	Reference
TriangleCount	$[h, v]$; $hv = n^3$	Suboptimal	[12]

also achieves smooth optimal tradeoff in its parameter range; thus, it settles the complexity of the problem in the laconic regime. The $[m+h, v]$-scheme whenever $hv = n^2$ generalizes the $[n^2, 1]$-scheme from prior work for any m-edge graph (for the setting $h = m$ and $v = n^2/m$) and is interesting in the frugal regime for sparse graphs.

The problem has also been studied in the adjacency-list model (call it TriangleCount-Adj) [10, 26, 31, 34], where the stream presents the full neighbor list for each vertex contiguously. We give an $[h, v]$-scheme for any $hv = n^2$ for TriangleCount-Adj (again, exact counting). In basic streaming, there is no nontrivial algorithm for computing T exactly, or even approximately when T is small; in fact, under a long-standing conjecture in communication complexity, these problems require $\Omega(m)$ space [26].

Maximum Matching. There is a recent and ongoing flurry of activity on streaming algorithms for MaxMatching, the problem of computing the cardinality $\alpha'(G)$ of a maximum-sized matching[3] in G [6, 16, 21, 22, 28, 33, 20, 29]. The exact version of the problem (which is what we study here) is intractable. For the special case of detecting whether a bipartite graph has a perfect matching, there is a frugal $[nt, s]$-scheme [12], which achieves optimal tradeoff. See Table 1 for previous results for the general problem.

In this work, we give (i) the first optimal frugal $[nt, s]$-scheme for the general MaxMatching problem, settling its complexity in the frugal regime, and (ii) an $[\alpha' + h, v]$-scheme whenever $hv = n^2$, which yields a laconic scheme provided $\alpha'(G) = o(n)$. Obtaining a fully general laconic scheme remains an interesting open problem and we suspect that it will require a breakthrough in exploiting the problem's combinatorial structure.

Further Graph Problems and a Common Framework. We obtain new schemes for the MIS problem, which asks for an inclusion-wise maximal independent set of vertices; the Acyclicity problem, which asks whether the input digraph is acyclic; and the TopoSort problem, which asks for a vertex ordering of the input DAG that orients all edges "forwards." In each case, we give an $[nt, s]$-scheme. Recent results show that MIS [5, 17] and TopoSort [15] are intractable in basic streaming, so our schemes are optimal in the frugal regime. Importantly, these schemes, the frugal MaxMatching scheme, and two of the TriangleCount schemes all fit a common framework: they boil the problem down to counting the number of edges in one or more induced subgraphs of the input graph. Our scheme for this InducedEdgeCount problem could be a useful technical result for future work.

Shortest Paths. The single-source shortest path (SSSP) problem is perhaps the most basic problem in classic graph algorithms. In the streaming setting, even the special case of undirected v_s–v_t connectivity in constant-diameter graphs is intractable [21]. As Table 1 shows, our $[Dnt, s]$-scheme for unweighted SSSP (where D is the maximum distance from the source vertex v_s to any vertex reachable from it) generalizes the result of Cormode et al. [18] from st-ShortestPath to SSSP. Again, as a corollary, we obtain a $[Knt, s]$-scheme for st-ShortestPath, where K is the length of a shortest v_s–v_t path. This result generalizes the $[Kn, n]$-scheme of Chakrabarti and Ghosh [14] and improves upon the $[Dnt, s]$-scheme of Cormode et al. [18], since K can be arbitrarily smaller than D. The schemes for the weighted version are interesting for small D and W, where W is the maximum weight of any edge.

1.3 Other Related Works

Abdullah et al. [1] studied the TriangleCount and MaxMatching problems in the stronger SIP model that allows rounds of interaction between Prover and Verifier. For TriangleCount, they gave a $(\log^2 n, \log^2 n)$-SIP using $\log n$ rounds of interaction. They also designed an $(n^{1/\gamma} \log n, \log n)$-SIP with $\gamma = O(1)$ rounds. For the weighted MaxMatching problem, they gave a $(\rho + n^{1/\gamma'} \log n, \log n)$-SIP using γ rounds of interaction, where γ' is a linear function of γ, and ρ is the weight of an optimal matching.

Early works on the concept of annotated streams include Tucker et al. [39] and Yi et al. [41], who studied *stream punctuations* and *stream outsourcing* respectively. Motivated by these works, Chakrabarti et al. [12] then formalised the model theoretically as the *annotated streaming model* and gave schemes for statistical streaming problems including

[3] The notation $\alpha'(G)$ is by analogy with $\alpha(G)$, which denotes the cardinality of a maximum independent set of *vertices*. It can be found, e.g., in the textbook by West [40].

frequency moments and heavy hitters, along with some basic results for graph problems. This non-interactive model was subsequently studied by multiple works including Klauck and Prakash [30], Cormode et al. [18], and Chakrabarti et al. [11]. Subsequent works considered generalized versions of the model, allowing rounds of interaction. These include *Arthur-Merlin streaming protocols* of Gur and Raz [23] and the *streaming interactive proofs* (SIP) of Cormode et al. [19]. Chakrabarti et al. [13] and Abdullah et al. [1] further studied this generalized setting. We refer to the expository article of Thaler [37] for a more detailed survey of this area.

1.4 Our Techniques

Sum-Check and Polynomial Encodings. As with much prior work in this area (and probabilistic proof systems more generally), our schemes are variants of the famous *sum-check protocol* of Lund et al. [32]. Specialized to our (non-interactive) schemes, this protocol allows Verifier to make Prover honestly compute $\sum_{x\in\mathcal{X}} g(x)$ for some low-degree polynomial $g(X)$ derived from the input data and some designated set $\mathcal{X}$. Verifier has no space to compute g explicitly, nor all values $\langle g(x) : x \in \mathcal{X}\rangle$, but he can afford to evaluate $g(r)$ at a *random* point r. The Prover steps in by explicitly providing $\hat{g}(X)$, a polynomial claimed to equal $g(X)$: this is cheap since g has low degree. Verifier can be convinced of this claim by checking that $\hat{g}(r) = g(r)$.

Hence, the main challenge in applying the sum-check technique is to find a way to encode the data stream problem's output as the sum of the evaluations of a low-degree polynomial g so that Verifier can, in small space, evaluate g at a random point r.

Sketches: Linearity and Beyond. A streaming Verifier evaluates $g(r)$ by suitably summarizing the input in a *sketch*. Viewing the input as updates to a data vector $\mathbf{f} = (f_1, \ldots, f_N)$, such a sketch $\mathbf{v}$ is *linear* if $\mathbf{v} = S\mathbf{f}$ for some matrix $S \in \mathbb{F}^{v\times N}$, for some field $\mathbb{F}$.[4] Typically, S is implicit in the sketching algorithm and enables stream processing in $\tilde{O}(v)$ space by translating a stream update $f_i \leftarrow f_i + \Delta$ into the sketch update $\mathbf{v} \leftarrow \mathbf{v} + \Delta S\mathbf{e}_i$, where $\mathbf{e}_i$ is the ith standard basis vector. In essentially all prior works on stream verification, the polynomial g was such that $g(r)$ could be derived from such a linear sketch $\mathbf{v}$.

There is one exception: Thaler [38] introduced an optimal $[n, n]$-scheme for Triangle-Count in which Verifier computes a *nonlinear* sketch.[5] Roughly speaking, the verifier in Thaler's protocol maintains two n-dimensional linear sketches $\mathbf{v}^{(1)}$ and $\mathbf{v}^{(2)}$, plus a value C that is *not* a linear function of the input stream but instead depends quadratically on $\mathbf{v}^{(1)}$ and $\mathbf{v}^{(2)}$. Moreover, the jth increment to C uses information that is available while processing the jth stream update, but not after the stream is gone. This is in contrast to linear sketches themselves, where the jth sketch update depends only on the jth stream update and no others.

The Shaping Technique. Another ubiquitous idea in streaming verification is the *shaping technique*, which transforms a data vector into a multidimensional array. This trick realizes $g(X)$ as a summation of an even simpler multivariate polynomial: the latter can be evaluated directly by Verifier at several points, which forms the basis for his sketching. When applied to graph problems, this technique was historically used to reshape the $\binom{n}{2}$-dimensional vector

[4] This field is finite in the streaming verification literature, whereas traditional data streaming uses $\mathbb{R}$.
[5] Simliar nonlinearity was used recently in the more powerful model of 2-*pass schemes* [14].

of edge multiplicities. Recently, Chakrabarti and Ghosh [14] introduced the idea of reshaping the graph's *vertex space*, rather than just the edge space, thereby transforming the adjacency matrix into a 4-dimensional array. This trick was crucial to obtaining the first frugal schemes for TriangleCount and MaxMatching.

Our Contributions. The new schemes in this work make the following contributions.

- We design new polynomial encodings for the graph-theoretic problems we study.
- We prominently employ nonlinear sketches, in the above sense, for almost all of our scheme designs.
- We use the shaping technique on the vertex space, often combining it with nonlinear sketching, thus expanding the applications of this very recent innovation.

Our solutions for TriangleCount are particularly good illustrations of all of these ideas. Where Thaler's nonlinear-sketch protocol treated each vertex as monolithic, our view of each vertex as an object in $[t] \times [s]$ (for some pair t, s with $t \cdot s = n$) let us do two things. In the laconic regime, we get to use Verifier's increased space allowance in a way that Thaler's protocol cannot, thereby extending his $[n, n]$-scheme to get an optimal tradeoff. In the frugal regime, it is significantly harder to exploit vertex-space shaping because Verifier cannot even afford to devote one entry per vertex in his linear sketches. We overcome this by finding a way for many vertices to "share" each entry of each linear sketch (see the string of equations culminating in Equation (7)), thus extending Thaler's protocol to smoothly trade off communication for space.

We also extend the applicability of nonlinear sketching by identifying many further graph problems for which it yields significant improvements. Specifically, in Section 3, we describe two technical problems called InducedEdgeCountand CrossEdgeCount, which are later used as primitives to optimally solve several important graph problems, including MaxMatching. We show how to apply sum-check with a nonlinear Verifier (see, e.g, Equation (11)) to optimally solve InducedEdgeCount and CrossEdgeCount.

Finally, our schemes for SSSP feature a different kind of innovation on top of vertex-space shaping and new, clever encodings of shortest-path problems in a manner amenable to sum-check. They overcome the frugal Verifier's space limitation by exploiting the Prover's room to generate a proof stream that mimics an iterative algorithm. For the Verifier to play along with such an iterative algorithm while lacking even one bit of space per vertex, a careful layering of fingerprint-based checks is needed on top of the sum-checks. We hope that our work here opens up possibilities for other instances of porting iterative algorithms to a streaming setting with the help of a prover.

1.5 Preliminaries

In this work, the input graph, multigraph, or digraph is denoted G and defined on a fixed vertex set $V = [n]$. In the *vanilla* streaming model, G is given as a stream of (u, v) tokens, where $u, v \in V$: the token is interpreted as an insertion of edge $\{u, v\}$ or directed edge (u, v). If G is edge-weighted, the tokens are of the form (u, v, w), where $w \in \mathbb{Z}^+$ is a weight. In the *turnstile* streaming model, tokens are of the form (u, v, Δ), denoting that the quantity $\Delta \in \mathbb{Z}$ (which can be negative) is added either to the multiplicity or the weight of the edge $\{u, v\}$.

An important primitive in all our schemes is sketching a data vector by evaluating its low-degree extension at a random point. Let us explain what this means. Suppose our data vector, which has dimensionality N, is shaped into a k-dimensional array f with

dimensions $(s_1, \ldots, s_k)$, where $s_1 s_2 \cdots s_k \geqslant N$. Equivalently, we have a function f on domain $[s_1] \times \cdots \times [s_k]$. We work over a suitable finite field[6] $\mathbb{F}$. By Lagrange interpolation, there is a unique polynomial $\tilde{f}(X_1, \ldots, X_k) \in \mathbb{F}[X_1, \ldots, X_k]$ such that

- for all $(x_1, \ldots, x_k) \in [s_1] \times \cdots [s_k]$, we have $\tilde{f}(x_1, \ldots, x_k) = f(x_1, \ldots, x_k)$, and
- for all $i \in [k]$, we have $\deg_{X_i} \tilde{f} \leqslant s_i - 1$.

We call $\tilde{f}$ the low-degree $\mathbb{F}$-*extension* of f. Since $f \mapsto \tilde{f}$ is a linear map, we can write $\tilde{f}$ as a linear combination of "unit impulse" functions (also known as Lagrange basis polynomials):

$$\delta_{u_1,\ldots,u_k}(X_1, \ldots, X_k) := \prod_{i=1}^{k} \prod_{x_i \in [s_i] \setminus \{u_i\}} (u_i - x_i)^{-1}(X_i - x_i)\,. \tag{1}$$

To be precise, $\tilde{f}(X_1, \ldots, X_k) = \sum_{(u_1,\ldots,u_k) \in [s_1] \times \cdots \times [s_k]} f(u_1, \ldots, u_k)\, \delta_{u_1,\ldots,u_k}(X_1, \ldots, X_k)$. In particular, if f is built up from a stream of pointwise updates, where the jth update adds Δ_j to entry $(u_1, \ldots, u_k)_j$ of the array, then

$$\tilde{f}(X_1, \ldots, X_k) = \sum_j \Delta_j\, \delta_{(u_1,\ldots,u_k)_j}(X_1, \ldots, X_k)\,. \tag{2}$$

▶ **Fact 1.** *Given $\mathbf{p} = (p_1, \ldots, p_k) \in \mathbb{F}^k$ and a stream of pointwise updates to an initially-zero array with dimensions $(s_1, \ldots, s_k)$, we can maintain the evaluation $\tilde{f}(\mathbf{p})$ using $O(\log |\mathbb{F}|)$ space, performing $O(k)$ field arithmetic operations per update. In applications, we usually take $\mathbf{p} \in_R \mathbb{F}^k$.*[7] *For details and implementation considerations, see Cormode et al. [19].* ◀

Another useful primitive is *fingerprinting*, used prominently in our SSSP scheme and subtly in subroutines within other schemes. Its goal is to check equality between two vectors $\mathbf{a} = (a_1, \ldots, a_N)$ and $\mathbf{b} = (b_1, \ldots, b_N)$ that are provided via turnstile streams in some possibly intermixed order. This is achieved by checking that $\varphi_{\mathbf{a}}(r) = \varphi_{\mathbf{b}}(r)$ for $r \in_R \mathbb{F}$, where $\varphi_{\mathbf{a}}(X) = \sum_{j=1}^{N} a_j X^j$ is the *fingerprint polynomial* of $\mathbf{a}$ and has degree at most N. Both fingerprinting and the eventual uses of Fact 1 in sum-check protocols depend upon the following basic but powerful result.

▶ **Fact 2** (Schwartz–Zippel Lemma)**.** *For a nonzero polynomial $P(X_1, \ldots, X_n) \in \mathbb{F}[X_1, \ldots, X_n]$ of total degree d, where $\mathbb{F}$ is a finite field, $\Pr_{(r_1,\ldots,r_n) \in_R \mathbb{F}^n}[P(r_1, \ldots, r_n) = 0] \leqslant d/|\mathbb{F}|$.* ◀

At various points, we shall use a couple of schemes from Chakrabarti et al. [11, 12].

▶ **Fact 3** (SUBSET and INTERSECTION schemes; Prop. 4.1 of [12] and Thm. 5.3 of [11])**.** *Given a stream of elements of sets $S, T \subseteq [N]$ interleaved arbitrarily, for any h, v with $hv \geqslant N$, there are $[h, v]$-schemes to compute $|S \cap T|$ and to determine whether $S \subseteq T$.* ◀

2 The Triangle Counting Problem

A triangle in a (multi)graph is a set of three edges of the form $\{\{u, v\}, \{v, w\}, \{u, w\}\}$. The TRIANGLECOUNT problem asks for the number of such triangles in the input graph. We solve this problem for multigraphs given by a turnstile stream, establishing the following two theorems. The first gives improved (but possibly still not tight) tradeoffs between hcost h and vcost v in the parameter regime where $h \geqslant n$ and $v \leqslant n$. The second gives *optimal*

[6] The characteristic of $\mathbb{F}$ must be large enough to avoid "wrap around" problems under arithmetic in $\mathbb{F}$.
[7] The notation $r \in_R A$ means that r is drawn uniformly at random from the finite set A.

tradeoffs (up to logarithmic factors) in the regime where $h \leqslant n$ and $v \geqslant n$, based on the known lower bound that hv must be $\Omega(n^2)$. Both results were previously only known when $h = \Theta(n)$.

We remind the reader that parameters $t, s \in \mathbb{Z}^+$ are tunable, subject to $ts = n$.

▶ **Theorem 4** (Improved frugal schemes). *There is an $[nt^2, s]$-scheme for* TriangleCount.

▶ **Theorem 5** (Optimal tradeoff for laconic schemes). *There is a $[t, ns]$-scheme for* TriangleCount. *This is optimal up to logarithmic factors.*

Overview of Our Methods. Consider an adjacency matrix A of a graph on vertex set V. The addition of a new edge $\{u, v\}$ creates $\sum_{z \in V} A(u, z)A(v, z)$ new triangles.

Suppose that the input stream consists of L edge updates, the jth being $(v_{1j}, v_{2j}, \Delta_j)$; recall that its effect is to add Δ_j to the multiplicity of edge $\{v_{1j}, v_{2j}\}$. Suppose that the cumulative effect of the first j updates is to produce a multigraph G_j whose adjacency matrix is A_j and which has T_j triangles (counting multiplicity). As in Thaler's protocol [38], we can then account for the number of triangles added by the jth update:

$$T_j - T_{j-1} = \sum_{v_3 \in V} \Delta_j \, A_{j-1}(v_{1j}, v_3) \, A_{j-1}(v_{2j}, v_3) \, .$$

As a result, the number of triangles T in the final graph $G = G_L$ is

$$T = \sum_{j \in [L]} \sum_{v_3 \in V} \Delta_j \, A_{j-1}(v_{1j}, v_3) \, A_{j-1}(v_{2j}, v_3) \, . \tag{3}$$

Our two new families of schemes for TriangleCount apply the shaping technique to the above equation in two distinct ways, resulting in markedly different complexity behaviors.

The Laconic Schemes Regime (Proof of Theorem 5). Let $t, s \in \mathbb{N}$ be parameters with $ts = n$. We first consider rewriting the variable v_3 in Equation (3) as a pair of integers $(x_3, y_3) \in [t] \times [s]$ using some canonical bijection. This shapes each matrix A_{j-1} into a 3-dimensional array a_{j-1}, i.e., a function with domain $[n] \times [t] \times [s]$. Let $\tilde{a}$ be the $\mathbb{F}$-extension of a for a sufficiently large finite field $\mathbb{F}$ to be chosen later. Then Equation (3) becomes

$$T = \sum_{j \in [L]} \sum_{x_3 \in [t]} \sum_{y_3 \in [s]} \Delta_j \, \tilde{a}_{j-1}(v_{1j}, x_3, y_3) \, \tilde{a}_{j-1}(v_{2j}, x_3, y_3) = \sum_{x_3 \in [t]} p(x_3) \, , \quad \text{where} \tag{4}$$

$$p(X_3) = \sum_{j \in [L]} \sum_{y_3 \in [s]} \Delta_j \, \tilde{a}_{j-1}(v_{1j}, X_3, y_3) \, \tilde{a}_{j-1}(v_{2j}, X_3, y_3) \, . \tag{5}$$

By the properties of $\mathbb{F}$-extensions observed above, we have the bound $\deg p \leqslant 2(t-1)$. We now design our scheme as follows.

Stream processing. Verifier starts by picking $r_3 \in_R \mathbb{F}$. As the stream arrives, he maintains a 2-dimensional array of values $\tilde{a}_{j-1}(v, r_3, y)$, for all $(v, y) \in [n] \times [s]$, using Fact 1. He also maintains an accumulator that starts at zero and, after the jth update, is incremented by $\Delta_j \sum_{y_3 \in [s]} \tilde{a}_{j-1}(v_{1j}, r_3, y_3) \, \tilde{a}_{j-1}(v_{2j}, r_3, y_3)$. By Equation (5), the final value of this accumulator is $p(r_3)$.

Help message. Prover sends Verifier a polynomial $\hat{p}(X_3)$ of degree $\leqslant 2(t-1)$ that she claims equals $p(X_3)$.

Verification and output. Using Prover's message, Verifier computes the check value $C := \hat{p}(r_3)$ and the result value $\hat{T} := \sum_{x_3 \in [t]} \hat{p}(x_3)$. If he finds that $C \neq p(r_3)$, he outputs $\perp$. Otherwise, he believes that $\hat{p} \equiv p$ and accordingly, based on Equation (4), outputs $\hat{T}$ as the answer.

The analysis of this scheme proceeds along standard lines long established in the literature.

Error probability. An honest Prover ($\hat{p} \equiv p$) clearly ensures perfect completeness. The soundness error is the probability that Verifier's check passes despite $\hat{p} \not\equiv p$, i.e., that the random point $r_3 \in \mathbb{F}$ is a root of the nonzero degree-$(2t-2)$ polynomial $\hat{p} - p$. By the Schwartz–Zippel Lemma (Fact 2), this probability is at most $(2t-2)/|\mathbb{F}| < 1/n$, by choosing $|\mathbb{F}|$ large enough.

Help and Verification costs. Prover describes $\hat{p}$ by listing its $O(t)$ many coefficients, spending $O(t \log n)$ bits, since each is an element of $\mathbb{F}$ and $|\mathbb{F}| = n^{O(1)}$ suffices above. Verifier maintains an $n \times s$ array whose entries are in $\mathbb{F}$, for a vcost of $O(ns \log n)$. Overall, we get a $[t, ns]$-scheme, as required.

The Frugal Schemes Regime (Proof of Theorem 4). Designing frugal schemes on the basis of Equation (3) is more intricate. This time we rewrite the variables v_{1j} and v_{2j} as pairs (x_{1j}, y_{1j}) and (x_{2j}, y_{2j}), each in $[t] \times [s]$ for parameters t, s with $ts = n$. The matrices A_{j-1} are now shaped into 3-dimensional arrays b_{j-1} that can be seen as functions on the domain $[t] \times [s] \times [n]$. As before, let $\tilde{b}$ be an appropriate $\mathbb{F}$-extension. Working from Equation (3) and cleverly using the "unit impulse" function δ seen in Equation (1),

$$\begin{aligned} T &= \sum_{v_3 \in V} \sum_{j \in [L]} \Delta_j \, \tilde{b}_{j-1}(x_{1j}, y_{1j}, v_3) \, \tilde{b}_{j-1}(x_{2j}, y_{2j}, v_3) \\ &= \sum_{v_3 \in V} \sum_{w_1, w_2 \in [t]} \sum_{j \in [L]} \Delta_j \, \tilde{b}_{j-1}(w_1, y_{1j}, v_3) \, \tilde{b}_{j-1}(w_2, y_{2j}, v_3) \, \delta_{x_{1j}}(w_1) \, \delta_{x_{2j}}(w_2) \\ &= \sum_{v_3 \in V} \sum_{w_1, w_2 \in [t]} q(w_1, w_2, v_3) \,, \quad \text{where} \end{aligned} \tag{6}$$

$$q(W_1, W_2, V_3) = \sum_{j \in [L]} \Delta_j \, \tilde{b}_{j-1}(W_1, y_{1j}, V_3) \, \tilde{b}_{j-1}(W_2, y_{2j}, V_3) \, \delta_{x_{1j}}(W_1) \, \delta_{x_{2j}}(W_2) \,. \tag{7}$$

In contrast to the laconic case, we have a *multivariate* polynomial $q(W_1, W_2, V_3)$. We have the bounds $\deg_{W_1} q \leqslant 2(t-1)$, $\deg_{W_2} q \leqslant 2(t-1)$, and $\deg_{V_3} q \leqslant 2(n-1)$, for a total degree of $O(t+n) = O(n)$. Importantly, the number of monomials in q is at most $(2t-1)^2(2n-1) = O(nt^2)$. We now present the corresponding scheme and its analysis.

Stream processing. Verifier picks $r_1, r_2, r_3 \in_R \mathbb{F}$. As the stream arrives, he maintains two 1-dimensional arrays: $\tilde{b}_{j-1}(r_1, y, r_3)$ and $\tilde{b}_{j-1}(r_2, y, r_3)$, for all $y \in [s]$ (using Fact 1). He also maintains an accumulator that starts at zero and, after the jth update $(x_{1j}, y_{1j}, x_{2j}, y_{2j})$, is incremented by $\Delta_j \tilde{b}_{j-1}(r_1, y_{1j}, r_3) \tilde{b}_{j-1}(r_2, y_{2j}, r_3) \delta_{x_{1j}}(r_1) \delta_{x_{2j}}(r_2)$. By Equation (7), the final value of this accumulator is $q(r_1, r_2, r_3)$.

Notice that the accumulator is a nonlinear sketch of the input.

Help message. Prover sends Verifier a polynomial $\hat{q}(W_1, W_2, V_3)$ that she claims equals $q(W_1, W_2, V_3)$. It should satisfy the degree bounds noted above. He lacks the space to store $\hat{q}$, so she streams the coefficients of $\hat{q}$ in some canonical order.

Verification and output. As $\hat{q}$ is streamed in, Verifier computes the check value $C := \hat{q}(r_1, r_2, r_3)$ and the result value $\hat{T} := \sum_{v_3 \in [n]} \sum_{w_1, w_2 \in [t]} \hat{q}(w_1, w_2, v_3)$. If he finds that $C \neq q(r_1, r_2, r_3)$, he outputs $\perp$. Otherwise, he believes that $\hat{q} \equiv q$ and accordingly, based on Equation (6), outputs $\hat{T}$ as the answer.

Error probability. As before, we have perfect completeness and by the Schwartz–Zippel Lemma (Fact 2, this time using its full multivariate strength), this soundness error is at most $\deg q / |\mathbb{F}| = O(n)/|\mathbb{F}| < 1/n$, by choosing $|\mathbb{F}|$ large enough.

Help and Verification costs. Prover can describe $\hat{q}$ by listing its $O(nt^2)$ coefficients. Verifier maintains two s-length arrays. Overall, we get an $[nt^2, s]$-scheme, as required.

3 A Technical Result: Counting Edges in Induced Subgraphs

We introduce two somewhat technical, though still natural, graph problems: InducedEdgeCount and CrossEdgeCount. We design schemes for these problems giving optimal tradeoffs (as usual, up to logarithmic factors). These schemes are key subroutines in our schemes for more standard, well-studied graph problems – such as MaxMatching– considered in Section 4.

The InducedEdgeCount problem is defined as follows. The input is a stream of edges of a graph $G = (V, E)$ followed by a stream of vertex subsets $\langle U_1, \ldots U_\ell \rangle$ for some $\ell \in \mathbb{N}$, where $U_i \subseteq V$ for $i \in [\ell]$. To be precise, the latter portion of the stream consists of the vertices of U_1 in arbitrary order, followed by a delimiter, followed by the vertices of U_2 in arbitrary order, and so on. The desired output is $\sum_{i=1}^{\ell} |E(G[U_i])|$, the sum of the numbers of edges in the induced subgraphs $G[U_1], \ldots, G[U_\ell]$. Note that $U_1, \ldots, U_\ell$ need not be pairwise disjoint, so the sum may count some edges more than once.

The CrossEdgeCount problem is an analog of the above for induced bipartite subgraphs. The input is a stream of edges followed by ℓ *pairs* of vertex subsets $\langle (U_1, W_1), \ldots, (U_\ell, W_\ell) \rangle$, where $U_i \cap W_i = \varnothing$ for $i \in [\ell]$. The desired output is $\sum_{i=1}^{\ell} |E(G[U_i, W_i])|$, the sum of the number of cross-edges in the induced bipartite subgraphs $G[U_1, W_1], \ldots, G[U_\ell, W_\ell]$. Note that the U_is (or W_is) need not be disjoint among themselves.

Importantly, in both of these problems, the edges *precede* the vertex subsets in the stream. This makes the problems intractable in the basic data streaming model. We shall prove the following results.

▶ **Lemma 6.** *For any h, v with $hv = n^2$, there is an $[h, v]$-protocol for InducedEdgeCount.*

▶ **Lemma 7.** *For any h, v with $hv = n^2$, there is an $[h, v]$-protocol for CrossEdgeCount.*

Scheme for InducedEdgeCount (Proof of Lemma 6). For the given instance, let M denote the desired output and let A be the adjacency matrix of G. For each $i \in \ell$, let $B_i \in \{0,1\}^V$ be the indicator vector of the set U_i, i.e., $B_i(v) = 1 \iff v \in U_i$. Then,

$$M = \frac{1}{2} \sum_{i=1}^{\ell} \sum_{v_1, v_2 \in V} B_i(v_1)\, B_i(v_2)\, A(v_1, v_2)\,. \tag{8}$$

Let t, s be integer parameters such that $ts = n$. We apply the shaping technique to Equation (8) by rewriting the variables v_j as pairs of integers $(x_j, y_j) \in [t] \times [s]$, for $j \in \{1, 2\}$. This transforms the matrix A into a 4-dimensional array a and each B_i into a 2-dimensional array b_i. Let $\tilde{a}$ and $\tilde{b}_i$ be the respective $\mathbb{F}$-extensions. Equation (8) now gives

$$2M = \sum_{i=1}^{\ell} \sum_{x_1, x_2 \in [t]} \sum_{y_1, y_2 \in [s]} \tilde{b}_i(x_1, y_1)\, \tilde{b}_i(x_2, y_2)\, \tilde{a}(x_1, y_1, x_2, y_2) = \sum_{x_1, x_2 \in [t]} p(x_1, x_2)\,, \tag{9}$$

$$\text{where } \; p(X_1, X_2) = \sum_{i=1}^{\ell} \sum_{y_1, y_2 \in [s]} \tilde{b}_i(X_1, y_1)\, \tilde{b}_i(X_2, y_2)\, \tilde{a}(X_1, y_1, X_2, y_2)\,. \tag{10}$$

Our scheme exploits this expression in the same general manner as the analogous expressions for the TriangleCount schemes from Section 2 (e.g., Equation (4)). Prover sends a bivariate polynomial $\hat{p}(X_1, X_2)$, which is claimed to be p, by streaming its coefficients. Since $\deg_{X_j} p \leqslant 2(t-1)$ for $j \in \{1, 2\}$, Prover need only send $O(t^2)$ coefficients, for a help cost of $\tilde{O}(t^2)$. Verifier computes his output using Equation (9), giving perfect completeness. On

the soundness side, Verifier checks the condition $\hat{p}(r_1, r_2) = p(r_1, r_2)$ for randomly chosen $r_1, r_2 \in_R \mathbb{F}$. By the Schwartz-Zippel Lemma (Fact 2), the probability that he is fooled is at most $\deg p/|\mathbb{F}| = O(t)/|\mathbb{F}| < 1/n$, for the right choice of $\mathbb{F}$. It remains to describe how exactly Verifier evaluates $p(r_1, r_2)$, which we now address.

Processing the stream of edges. This is straightforward: Verifier maintains the 2-dimensional array of values $\tilde{a}(r_1, w, r_2, z)$, for all $w, z \in [s]$, using Fact 1.

Processing the stream of vertex subsets. Verifier initializes an accumulator to zero and allocates workspace for two arrays of length s with entries in $\mathbb{F}$. For each $i \in [\ell]$, as the vertices of U_i arrive, he maintains $\tilde{b}_i(r_1, z)$ and $\tilde{b}_i(r_2, z)$ for each $z \in [s]$, using that workspace. Upon seeing the delimiter marking the end of U_i, he computes

$$\sum_{y_1, y_2 \in [s]} \tilde{b}_i(r_1, y_1)\, \tilde{b}_i(r_2, y_2)\, \tilde{a}(r_1, y_1, r_2, y_2) \tag{11}$$

and adds this quantity to the accumulator. Note that the workspace is reused when the stream moves on from U_i to U_{i+1}. By Equation (10), after the last set U_ℓ is streamed, the accumulator holds $p(r_1, r_2)$.

Help and verification costs. We argued above that the hcost is $\tilde{O}(t^2)$. Meanwhile, Verifier's storage is dominated by the $s \times s$ array he maintains, leading to a vcost of $\tilde{O}(s^2)$.

Therefore, we obtain a $[t^2, s^2]$-scheme for any parameters t, s with $ts = n$. In other words, we get an $[h, v]$-scheme for any h, v with $hv = n^2$.

Scheme for CrossEdgeCount (Proof of Lemma 7). Our solution for InducedEdgeCount can easily be modified to obtain a protocol for CrossEdgeCount with the same costs. If B_i and C_i are the indicator vectors of the sets U_i and W_i, respectively, then the desired output is

$$M = \sum_{i=1}^{\ell} \sum_{v_1, v_2 \in V} B_i(v_1)\, C_i(v_2)\, A(v_1, v_2)\,, \tag{12}$$

where we used the fact that each $U_i \cap W_i = \varnothing$. Since Equation (12) has essentially the same form as Equation (8), a scheme very similar to the previous one solves CrossEdgeCount: Verifier simply keeps track of arrays corresponding to C_i alongside ones corresponding to B_i.

4 Maximum Matching and Other Applications of Edge Counting

In this section, we show how InducedEdgeCount and CrossEdgeCount can be used as subroutines to solve multiple problems that have been widely studied in the basic and annotated data streaming models. These problems include Maximum Matching, Triangle-Counting, Maximal Independent Set, Acyclicity Testing, Topological Sorting, and Graph Connectivity. For the frugal regime where vcost $= o(n)$, our schemes are often optimal. We specifically discuss the application to MaxMatching in Section 4.1, state the results on the other applications in Section 4.2, and give a detailed account on them in Appendix B.

4.1 The Maximum Matching Problem

We give the first optimal frugal scheme for computing the cardinality $\alpha'(G)$ of a maximum matching. As noted in prior works [14, 38], checking whether $\alpha'(G) \geqslant k$ for some k is not hard, given $\tilde{\Omega}(k)$ bits of help: Prover can simply send a matching of size k and prove its validity. The interesting part is to verify that $\alpha'(G) \leqslant k$. For this, as in prior works, we exploit the Tutte–Berge formula [9]:

$$\alpha'(G) = \frac{1}{2} \min_{U \subseteq V} \Big(|U| + |V| - \mathrm{odd}(G \setminus U) \Big), \tag{13}$$

where $\mathrm{odd}(G \setminus U)$ denotes the number of connected components in $G \setminus U$ with an odd number of vertices. Thus, to show that $\alpha'(G) \leqslant k$, Prover needs to exhibit $U^* \subseteq V$ such that $k = \frac{1}{2}(|U^*| + |V| - \mathrm{odd}(G \setminus U^*))$. Set $H := G \setminus U^*$. To verify the value of $\mathrm{odd}(H)$, the most important sub-check that Verifier must do is to check that all purported connected components of H (sent by Prover) are actually disconnected from each other. Thaler [38] gave an $[n, n]$-scheme for this subproblem (thus obtaining the first $[n, n]$-scheme for MaxMatching), while Chakrabarti and Ghosh [14] gave a $[t^3, s^2]$-scheme for any $ts = n$ (thus designing the first frugal scheme for MaxMatching, though suboptimal). The latter work notes that all other sub-checks for MaxMatching can be done by *optimal* frugal schemes (see [14], Section 4).

Optimal Frugal Scheme. To optimally check that the purported connected components of H are indeed disconnected from each other, we use the InducedEdgeCount scheme as a subroutine. Prover streams the vertices in H by listing its connected components in some order $\langle U_1, \ldots, U_\ell \rangle$. Verifier uses Lemma 6 to count $m_1 := |E(H)|$ (invoking that lemma with a single subset $V(H)$). In parallel, using the same scheme, Verifier computes the sum $m_2 = \sum_{i=1}^{\ell} |E(G[U_i])|$. The subsets U_i are pairwise disconnected iff $m_2 = m_1$, which Verifier checks. The sub-checks of whether U_is are indeed pairwise disjoint (as sets) and whether $U^* \sqcup V(H) = V(G)$ can be done via fingerprinting (as in Section 1.5).

Help and verification costs. Prover streams U^* and the vertices in H in a certain order, which adds $O(n \log n)$ bits to the hcost of the InducedEdgeCount protocol. The vcost stays the same, asymptotically, giving us an $[n + h, v]$-scheme for MaxMatching for any h, v with $hv = n^2$. Overall, we have established the following theorem.

▶ **Theorem 8.** *There is an $[nt, s]$-scheme for MaxMatching. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$ [12].*

Protocol for Space Larger Than n. There is no laconic scheme known for the general MaxMatching problem. The barrier seems to be that a natural witness for the problem is an actual maximum matching of the graph, which can be of size $\Theta(n)$. We show that large maximum matching size $\alpha'(G)$ is indeed the sole barrier to obtaining a laconic scheme. In particular, for any graph G, we give a scheme for MaxMatching with hcost $\alpha'(G)$. This yields a laconic scheme for the case when $\alpha'(G) = o(n)$. We defer the proof to Appendix A.

▶ **Theorem 9.** *For any h, v with $hv \geqslant n^2$ and $v \geqslant n$, there is an $[\alpha' + h, v]$-scheme for MaxMatching, where α' is the size of the maximum matching of the input graph. In particular, there is an $[\alpha', n^2/\alpha']$-scheme.*

4.2 Applications to Other Graph Problems

Here, we state the results we obtain for several graph problems by applying InducedEdgeCount and CrossEdgeCount. The details and proofs appear in Appendix B.

We apply the edge-counting protocols to solve the triangle-counting problem in both the standard edge arrival and the vertex arrival (adjacently list) streaming models and obtain the following theorems.

▶ **Theorem 10.** *For any h, v with $hv \geqslant n^2$, there is an $[m + h, v]$-scheme for TriangleCount. In particular, there is an $[m, n^2/m]$-scheme.*

▶ **Theorem 11.** *For any h, v with $hv \geqslant n^2$, there is an $[h, v]$-scheme for TriangleCountAdj.*

We obtain optimal frugal schemes for the fundamental graph problems of maximal independent set (MIS) and for topological sorting and acyclicity testing in directed graph streams.

▶ **Theorem 12.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for MIS. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$.*

▶ **Theorem 13.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for TopoSort. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$.*

▶ **Corollary 14.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for Acyclicity. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$.*

Finally, we show that we can apply edge-counting schemes to count the number of connected components of a graph.

▶ **Theorem 15.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for counting the number of connected components of an input graph.*

5 The Single-Source Shortest Path Problem

In the single-source shortest path (SSSP) problem, the goal is to find the distances from a source vertex v_s to every other vertex reachable from it. In Section 5.1, we give a $[Dnt, s]$-scheme for the unweighted version, whenever $ts = n$. If $s = o(n)$, Verifier does not have enough space to store the output; therefore, we aim for a protocol where Prover streams the output, and Verifier checks that it is correct using $o(n)$ space, thus achieving a frugal scheme.

In Section 5.2, we state our results for weighted SSSP for the two different weight update models (vanilla and turnstile) described in Section 1.5. The proofs follow in Appendix C.

5.1 Unweighted SSSP

We shall design a scheme that works even if the same edge appears multiple times in the stream (unlike prior work [18] that assumes that an edge appears at most once).

Prover sends distance labels $\widehat{\text{dist}}[v]$ for all $v \in V$, claiming that $\widehat{\text{dist}}[v] = \text{dist}(v_s, v)$, the actual distance from the source vertex v_s to v. Let the radius-d ball around v_s be $B_d := \{v \in V : \text{dist}(v_s, v) \leqslant d\}$ and let $\mathcal{B} := \{B_d : d \in [D]\}$ be the family of such balls. Let $\widehat{B}_d$ be the corresponding balls implied by Prover's $\widehat{\text{dist}}$ labels, and $\widehat{\mathcal{B}} := \{\widehat{B}_d : d \in [D]\}$.

To check correctness, Verifier uses fingerprinting (Section 1.5) modified as follows. Letting $B, \widehat{B}$ also denote the respective characteristic vectors, define fingerprint polynomials

$$\varphi_{\mathcal{B}}(X,Y) := \sum_{i\in[n]}\sum_{d\in[D]} B_d(i)X^iY^d\,, \quad \varphi_{\widehat{\mathcal{B}}}(X,Y) := \sum_{i\in[n]}\sum_{d\in[D]} \widehat{B}_d(i)X^iY^d\,,$$

As the $\widehat{\text{dist}}$ labels are streamed, Verifier constructs the fingerprint $\varphi_{\widehat{\mathcal{B}}}(\beta_1,\beta_2)$ for some $\beta_1,\beta_2 \in_R \mathbb{F}$.

Over the course of the protocol, using further help from Prover, Verifier will construct the sets B_d inductively and, in turn, the "actual" fingerprint $\varphi_{\mathcal{B}}(\beta_1,\beta_2)$. The next claim shows that comparing this with $\varphi_{\widehat{\mathcal{B}}}(\beta_1,\beta_2)$ validates Prover's $\widehat{\text{dist}}$ labels.

▷ Claim 16. If $\widehat{B}_d = B_d$ for all d, then $\widehat{\text{dist}}[v] = \text{dist}(v_s, v)$ for all vertices v.

Proof. Suppose not. Let d^* be the smallest d such that $\exists\, u \in B_{d^*}$ with $\widehat{\text{dist}}[u] \neq \text{dist}(v_s,u)$. Therefore, $\text{dist}(v_s,u) = d^*$. Now, d^* cannot be 0 since v_s is the only vertex in B_0 and Verifier would reject immediately if $\widehat{\text{dist}}(v_s) \neq 0$. Since $B_{d^*} = \widehat{B}_{d^*}$, we have $u \in \widehat{B}_{d^*}$. This means $\widehat{\text{dist}}(u) \leqslant d^*$. Since $\widehat{\text{dist}}(u) \neq d^*$, we have $\widehat{\text{dist}}(u) \leqslant d^* - 1$. Thus, $u \in \widehat{B}_{d^*-1}$, i.e., $u \in B_{d^*-1}$, which is a contradiction to the minimality of d^*. ◁

As before, A denotes the adjacency matrix of the graph. Putting

$$q_d(u) := \sum_{v\in V} B_d(v)\,A(v,u)\,, \text{ for each } u \in V\,, \tag{14}$$

$$\text{we have } \; B_{d+1} = \{u \in V : q_d(u) \neq 0\}\,. \tag{15}$$

To apply the shaping technique to (14), rewrite v as $(x,y) \in [t]\times[s]$. This reshapes A into a $t \times s \times n$ array $a(x,y,u)$ and B_d into a $t \times s$ array $b_d(x,y)$. As usual, let $\tilde{a}$ and $\tilde{b}_d$ be the respective $\mathbb{F}$-extensions for a suitable finite field $\mathbb{F}$. Then, Equation (14) gives

$$q_d(u) = \sum_{x\in[t]} p_d(x,u)\,, \quad \text{where} \tag{16}$$

$$p_d(X,U) := \sum_{y\in[s]} \tilde{b}_d(X,y)\,\tilde{a}(X,y,U)\,. \tag{17}$$

Stream processing. Verifier picks $r_1, r_2 \in_R \mathbb{F}$ and maintains $\tilde{a}(r_1,y,r_2)$. When he sees vertices in B_1, i.e., v_s and its neighbors, he maintains $b_1(r_1,y)$ for all $y \in [s]$ and also updates the fingerprint $\varphi_{\mathcal{B}}(\beta_1,\beta_2)$ accordingly.

Verifier wants to construct the values $b_d(r_1,y)$ inductively for $d \in [D]$. For constructing b_{d+1} values for some d, he wants all u such that $q_d(u) \neq 0$ (Equation (15)) in streaming order since he doesn't have enough space to either store the entire polynomial of degree $n-1$ that agrees with q_d (so as to go over all evaluations), or to parallelly evaluate it at n values while its coefficients are streamed. Hence, he asks for the following help message.

Help message processing. Prover continues her proof stream by sending $\langle \hat{p}_1, Q_1, \ldots, \hat{p}_D, Q_D\rangle$, where $Q_d := \langle \hat{q}_d(u) : u \in V\rangle$, claiming that $\hat{p}_d \equiv p_d$ and $\hat{q}_d(u) = q_d(u)$ for each $d \in [D]$ and $u \in [n]$.

While $\hat{p}_d$ is streamed, Verifier computes the following in parallel:

- $\hat{p}_d(r_1,r_2)$;
- $p_d(r_1,r_2)$, using Equation (17);
- the fingerprint $g_d := \sum_{u\in[n]}\sum_{x\in[t]} \hat{p}_d(x,u)\beta^u$ (for some $\beta \in_R \mathbb{F}$).

After reading $\hat{p}_d$, he checks whether $\hat{p}_d(r_1, r_2) = p_d(r_1, r_2)$. If so, he believes that $\hat{p}_d \equiv p_d$ and, in turn, that $g_d = \sum_{u\in[n]} q_d(u)\beta^u$ (by Equation (16)). Next, as Q_d is streamed,

- Verifier computes the fingerprint $g'_d := \sum_{u\in[n]} \hat{q}_d(u)\beta^u$.
- For each u with $\hat{q}_d(u) \neq 0$, due to Equation (15) (and assuming for now that the $\hat{q}_d$ values are correct), he treats u as a stream update for B_{d+1}, and (i) maintains $b_{d+1}(r_1, y)$ for all $y \in [s]$, and (ii) accordingly updates the fingerprint $\varphi_{\mathcal{B}}(\beta_1, \beta_2)$.

After reading Q_d, he checks if the fingerprints g_d and g'_d match. If they do, he believes that all $\hat{q}_d$ values in Q_d were correct and hence, the b_{d+1} values he constructed are correct as well. He moves on to the next iteration, i.e., starts reading $\hat{p}_{d+1}$.

Final Verification. After the Dth iteration, Verifier checks if the two fingerprints $\varphi_{\mathcal{B}}(\beta_1, \beta_2)$ and $\varphi_{\widehat{\mathcal{B}}}(\beta_1, \beta_2)$ match. If the check passes, then he believes that the $\widehat{\text{dist}}$ labels were correct, at least upto distance D (by Claim 16). Finally, he checks if fingerprints for B_D and B_{D+1} match to verify that vertices in $V \setminus B_D$ are indeed unreachable.

Error probability. Verifier does $O(D)$ fingerprint-checks and $O(D)$ sum-checks, using degree-$O(n)$ polynomials. Using $|\mathbb{F}| > n^3$ (and a union bound), the soundness error is $< 1/n$.

Help and verification costs. The set of $\widehat{\text{dist}}$ labels sent by the Prover has size $\tilde{O}(n)$. Each polynomial $\hat{p}_d$ has nt monomials and each Q_d has $O(n)$ field elements, and hence, size $\tilde{O}(n)$. Therefore, the total hcost is $\tilde{O}(Dnt)$. Initially, the $\tilde{A}$ and $\tilde{b}_1$ values are stored using $\tilde{O}(s)$ space. Next, the $\tilde{b}_d$ and g_d values are maintained reusing space of b_{d-1} and g_{d-1} values respectively. We also use $O(1)$ many other fingerprints that take $O(\log n)$ space each. Hence, the total vcost is $\tilde{O}(s)$.

▶ **Theorem 17.** *There is a $[Dnt, s]$-scheme for unweighted SSSP, where $D = \max_{v\in V} \text{dist}(v_s, v)$.*

▶ **Corollary 18.** *There is a $[Knt, s]$-scheme for st-ShortestPath, where $K = \text{dist}(v_s, v_t)$.*

Proof. The protocol for SSSP incurs a factor of D in the hcost since it constructs B_d for each $d \in [D]$. For the simpler st-ShortestPath problem, we can inductively construct balls and stop as soon as we find the destination vertex v_t in some B_d (i.e., get $\hat{q}_{d-1}(v_t) \neq 0$). We must find it in B_K where K is the length of a shortest v_s–v_t path. Thus, we will only incur a factor of K in the hcost, which implies a $[Knt, s]$-scheme for st-ShortestPath. ◀

Thus, we generalize the $[Dnt, s]$-scheme of Cormode et al. [18] from st-ShortestPath to SSSP. Our result for st-ShortestPath generalizes the $[Kn, n]$-scheme of Chakrabarti and Ghosh [14] by giving a smooth tradeoff and also improves upon the $[Dnt, s]$-scheme of Cormode et al. [18], since K can be arbitrarily smaller than D.

5.2 Weighted SSSP

We consider the more general weighted version of SSSP in the turnstile and the vanilla weight update models (see Section 1.5 for the definitions) and obtain the following results. The details of the schemes along with the proofs of correctness appear in Appendix C.

▶ **Theorem 19.** *There is a $[DWn, n]$-scheme for weighted SSSP in the turnstile weight update model.*

▶ **Theorem 20.** *There is a $[Dn, Wn]$-scheme for weighted SSSP in the vanilla streaming model.*

A Maximum Matching Redux (Proof of Theorem 9)

In Section 4.1, we gave a frugal scheme for MaxMatching, i.e., one that has hcost $\geqslant n$ and vcost $\leqslant n$. Here, we show that we can get a laconic scheme, i.e., one with hcost $= o(n)$ and vcost $= \omega(n)$ as long as the maximum matching size is $o(n)$.

Let $H = G \setminus U^*$, where U^* is as in the MaxMatching protocol in Section 4.1, and let $U_1, \ldots, U_\ell$ be the connected components of H. By the Tutte-Berge formula (Equation (13)), we have $2k = |U^*| + (n - \text{odd}(H))$. This leads to the following observations.

▶ **Observation 21.** $|U^*| = O(k)$.

▶ **Observation 22.** *The number of edges in a spanning forest of H is $|V(H)| - \ell \leqslant n - \text{odd}(H) = O(k)$.*

We now describe our protocol, which is along the lines of the protocol in Section 4.1, but this time we crucially use the fact that we are allowing Verifier a space usage of $v \geqslant n$.

To show that $\alpha'(G) \geqslant k$, Prover sends a matching M of size k. Verifier stores M explicitly and checks that it is indeed a matching. Then, he verifies that $M \subseteq E$ using the Subset Scheme (Fact 3). Therefore, this part of the scheme uses hcost $\tilde{O}(k+h)$ and vcost $\tilde{O}(v)$ for any h, v with $hv = n^2$ and $v \geqslant n$.

Recall from Section 4.1 that to show that $\alpha'(G) \leqslant k$, it suffices to compute $\text{odd}(H)$. Prover sends the set U^*. By Observation 21, this takes $\tilde{O}(k)$ hcost. Verifier has $\Omega(n)$ space, and hence, he can store $V \setminus U^* = V(H)$. Next, Prover sends a spanning forest F of H. By Observation 22, this again incurs hcost $\tilde{O}(k)$. Verifier stores F and verifies that $F \subseteq E$ using the Subset Scheme (Fact 3). From F, Verifier explicitly knows the purported connected components $U_1, \ldots, U_\ell$ of H. He finally verifies that U_i's are disconnected from each other by checking that all edges in H are contained in these components. He can do this by checking whether $|E \cap (V(H) \times V(H))| = |E \cap (\cup_{i=1}^{\ell} U_i \times U_i)|$ using the Intersection Scheme (Fact 3). If the check passes he goes over the U_is to compute $\text{odd}(H)$ and thus, this part can also be solved using a $[k+h, v]$ scheme for any h, v with $hv = n^2$ and $v \geqslant n$. Hence, we obtain the following theorem.

▶ **Theorem 9.** *For any h, v with $hv \geqslant n^2$ and $v \geqslant n$, there is an $[\alpha' + h, v]$-scheme for MaxMatching, where α' is the size of the maximum matching of the input graph. In particular, there is an $[\alpha', n^2/\alpha']$-scheme.*

B Applications of Edge-Counting to Other Graph Problems

In Section 4.1, we used a scheme for InducedEdgeCount to obtain an optimal frugal scheme for MaxMatching. Below, we give applications of edge-counting schemes to several other well-studied graph problems.

Triangle-Counting. A scheme for TriangleCount follows immediately from InducedEdgeCount. For $v \in [n]$, set the subsets $U_v = N(v)$, the neighborhood of vertex v. Then, observe that InducedEdgeCount returns three times the total number of triangles in the graph. The sets U_v, however, need to be sent in some order by Prover, and so the additional hcost to InducedEdgeCount is $\tilde{O}\left(\sum_v |N(v)|\right) = \tilde{O}(m)$. As Prover basically repeats the edge stream in a different order, we can check if it's consistent with the input stream by fingerprinting (see Section 1.5). Hence, we get an $[m + h, v]$-scheme for any h, v with $hv = n^2$.

▶ **Theorem 10.** *For any h, v with $hv \geqslant n^2$, there is an $[m + h, v]$-scheme for TriangleCount. In particular, there is an $[m, n^2/m]$-scheme.*

The only other scheme for TriangleCount achieving $hv = n^2$ tradeoff with vcost $= o(n)$ was an $[n^2, 1]$-scheme by Chakrabarti et al. [12]. Our result generalizes it for any graph with m edges, thus achieving a better hcost and a smooth tradeoff for sparse graphs.

We note that in the above scheme, Prover needs to send the sets $U_v = N(v)$ because the InducedEdgeCount protocol needs the neighborhood of each vertex to arrive contiguously in the stream. This is essentially the input stream order in the *adjacency-list* or the *vertex-arrival* streaming model. Thus, for the problem TriangleCount-Adj, Verifier gets the U_vs in the desired order as part of the input; so Prover need not repeat them, saving the huge $\tilde{O}(m)$ hcost. However, there is another issue in directly applying the InducedEdgeCount subroutine in this case. In the definition of InducedEdgeCount, we assume that all the edges in the graph arrive before the vertex subsets U_i. Here, the U_vs and the edges arrive in interleaved manner (although each U_v arrives contiguously). But we show that we can still apply the scheme for InducedEdgeCount to get the desired output. Let the order in which the U_vs appear be $\langle U_1, \ldots U_n \rangle$, and let G_v denote the graph consisting of edges seen till the arrival of $U_v = N(v)$. Then, applying InducedEdgeCount, what we count is

$$\sum_{v \in [n]} |E(G_v[N(v)])| = \sum_{v \in [n]} \#\{\text{triangles incident on } v \text{ in } G_v\} = 2T\,.$$

The last equality follows since every triangle whose vertices appear in the order $\langle v_1, v_2, v_3 \rangle$ will be counted twice: once when v_2 arrives and once when v_3 arrives. We therefore obtain the following theorem.

▶ **Theorem 11.** *For any h, v with $hv \geqslant n^2$, there is an $[h, v]$-scheme for TriangleCount-Adj.*

Maximal Independent Set (MIS). Recent works [5, 17] have studied the problem of finding a maximal independent set in the basic data streaming model. They show a lower bound of $\Omega(n^2)$ for a one-pass streaming algorithm. This implies a lower bound of $hv \geqslant n^2$ for any $[h, v]$-scheme for MIS. Hence, we aim for $hv = n^2$ and describe a frugal scheme using InducedEdgeCount. Since the output size of the problem can be $\Theta(n)$, it would only make sense in the frugal regime if the Prover sends the output as a stream and the Verifier checks that it is valid using $o(n)$ space.

Let U be an MIS in the graph G. Prover sends U and Verifier uses InducedEdgeCount to count the number of edges in $G[U]$ and verifies that it equals 0. If the check passes, U is indeed an independent set. It remains to check the maximality of U. If U is maximal, then, for each vertex v in $G \setminus U$, there must be a vertex u in U, such that (v, u) is an edge. Prover points out such a vertex $u \in U$ for each $v \in G \setminus U$. Let F denote this set of $|G \setminus U|$

purported edges. Now, we use Subset Scheme (Fact 3) to verify that $F \subseteq E$, i.e., all these edges are actually present in G. We can use fingerprinting (as in Section 1.5) to check that F contains an edge for each vertex in $G \setminus U$ and the Intersection Scheme to verify that the set of their partners is disjoint from $G \setminus U$, i.e., belong to U. Thus, the additional hcost to InducedEdgeCount, Subset, and Intersection Schemes is $\tilde{O}(n)$, the number of bits required to send U and F. Therefore, by Lemma 6, we get an $[n+h, v]$-scheme for MIS for any h, v with $hv = n^2$. Thus, our scheme is optimal for the frugal regime.

▶ **Theorem 12.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for MIS. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$.*

Acyclicity Testing and Topological Sorting. We now turn to the Acyclicity problem in directed graphs. It is easy to prove that a graph is *not* acyclic by showing the existence of a cycle C. Verifier checks that $C \subseteq E$ using Subset Scheme (Fact 3). Hence, this can be done using an $[h, v]$-scheme for any $h \geqslant |C|$.

The more interesting case is when the graph is indeed acyclic. Note that a directed graph is acyclic if and only if it has a topological ordering. Thus, it suffices to show a valid topological ordering of the vertices. TopoSort is a fundamental graph algorithmic problem of independent interest. Acyclicity has a one-pass lower bound of $\Omega(n^2)$ in the basic data streaming model. Recently, Chakrabarti et al. [15] showed that TopoSort also requires $\Omega(n^2)$ space in one pass. These translate to a lower bound of $hv \geqslant n^2$ for any $[h, v]$-scheme for these problems. Hence, we aim for a scheme with $hv = n^2$ and design a protocol for TopoSort in the frugal regime. Since this problem has output size $\tilde{\Theta}(n)$, we aim for a protocol where Prover sends a topological ordering of the graph and Verifier checks its validity using $o(n)$ space. Moreover, this protocol can be used for the YES case of Acyclicity.

Verifier uses CrossEdgeCount to solve this. As Prover sends the topological order $\langle v_1, \ldots, v_n \rangle$, for each $i \in [n-1]$, Verifier sets $U_i = \{v_1, \ldots, v_i\}$ and $W_i = \{v_{i+1}\}$ for CrossEdgeCount. Thus, the protocol counts precisely the number of forward edges induced by the ordering. If it equals m, then the ordering is indeed a valid topological order. Note that since $U_{i+1} = U_i \cup \{v_{i+1}\}$, Prover doesn't need to send U_{i+1} afresh; just v_{i+1} is enough for Verifier to update his sketch. Verifier can use fingerprinting (see Section 1.5) to make sure that precisely the set V was sent in some order. Hence, the additional hcost to CrossEdgeCount is the number of bits required to express the topological order, i.e., $\tilde{O}(n)$. Therefore, by Lemma 7, we get a $[n+h, v]$-scheme for any $hv = n^2$.

▶ **Theorem 13.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for TopoSort. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$.*

▶ **Corollary 14.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for Acyclicity. This is optimal up to logarithmic factors, since any (h, v)-scheme is known to require $hv = \Omega(n^2)$.*

For dense graphs, our result generalizes the $[m, 1]$-scheme of Cormode et al. [18] for Acyclicity by achieving a smooth tradeoff.

Graph Connectivity. The graph connectivity problem has garnered considerable attention in the basic and annotated streaming settings [2, 12, 38]. For any t, s with $ts = n$, Chakrabarti et al. [12] gave an $[nt, s]$-scheme that determines whether an input graph is connected or not. Their scheme cannot, however, solve the more general problem of returning the number of connected components. The $[t^3, s^2]$-scheme (for any $ts = n$) of Chakrabarti and Ghosh [14] does solve this problem, but has a worse tradeoff. As noted in Section 4.1, we can

use InducedEdgeCount to check that all purported connected components are indeed disconnected from each other. On the other hand, the scheme of Chakrabarti et al. [12] can check whether each component is actually connected. Hence, we can verify the number of connected components claimed by Prover by running these schemes parallelly. Thus, we generalize the result of Chakrabarti et al. [12] by obtaining an $[nt, s]$-scheme for counting the number of connected components of a graph.

▶ **Theorem 15.** *For any t, s with $ts = n$, there is an $[nt, s]$-scheme for counting the number of connected components of an input graph.*

C Details of Weighted SSSP Schemes

Here, we give full details of the schemes for weighted SSSP in our two streaming models, thereby proving Theorems 19 and 20.

Turnstile weight update (Proof of Theorem 19). Assume that the edge weights are positive integers. Each stream update increments/decrements the weight of an edge. The *distance* from vertex u to vertex v refers to the weight of the shortest path from u to v. Let D be the longest distance from the source s to any other vertex reachable from it, and W be the maximum weight of an edge.

Define

$$\delta_w(X) := \prod_{\substack{w' \in [W] \\ w' \neq w}} (X - w') \Big/ \prod_{\substack{w' \in [W] \\ w' \neq w}} (w - w') .$$

Let A denote the adjacency matrix of the weighted graph G, i.e., $A(u, v)$ is the weight of the edge (u, v). Let B_d (resp. N_d) denote the set of vertices at a distance of at most (resp. exactly) d from the source vertex v_s. Then,

$$N_{d+1} = \{u \in V \setminus B_d : p_d(u) \neq 0\} , \tag{18}$$

$$\text{where } \; p_d(U) = \sum_{v \in B_d} \delta_{w(v)}(\tilde{A}(v, U)) \;\text{ and }\; w(v) = d + 1 - \text{dist}[v] . \tag{19}$$

Stream processing. Verifier chooses $r \in_R \mathbb{F}$ and maintains $\tilde{A}(v, r)$ for all v. He stores B_1 with dist$[v]$ labelled as 1 for each $v \in B_1$.

Help message processing and verification. Prover sends polynomials $\hat{p}_d$ and claims that $\hat{p}_d \equiv p_d$ for each $d \in [D]$. Verifier computes B_d inductively for $d \in [D]$ as follows.

Assume that, for some $d \in [D - 1]$, he has the set B_d with dist$[v]$ labeled on each vertex $v \in B_d$; this holds initially as he has stored B_1. He computes $p_d(r)$ using Equation (19) and checks whether $\hat{p}_d(r) = p_d(r)$. If the check passes, he believes that $\hat{p}_d \equiv p_d$ and evaluates $\hat{p}_d(u)$ for each $u \in V \setminus B_d$ and constructs N_{d+1} using Equation (18). Then, B_{d+1} is given by $N_{d+1} \uplus B_d$.

After B_D is obtained, we get all vertices reachable from s along with their distances from s. Finally, Verifier checks if the other vertices are indeed unreachable from s by verifying that there is no cross-edge between B_D and $V \setminus B_D$, i.e., if $E \cap (B_D \times (V \setminus B_D)) = \varnothing$. (Intersection scheme, see Fact 3)

Error probability. Verifier uses the same element r for $O(D)$ invocations of the sum-check protocol, where each application of the sum-check protocol is to a univariate polynomial of degree $O(Wn)$. Choosing $|\mathbb{F}| > DWn^2$, the soundness error for each invocation of the sum-check protocol is at most $1/(Dn)$. Taking a union bound over all $O(D)$ invocations, we get that the total error probability of the protocol is at most $O(1/n)$.

Help and verification costs We have $\deg p_d = O(Wn)$ for each $d \in [D]$ and hence, hcost is $\tilde{O}(DWn)$. Verifier needs to store all vertices and $\tilde{A}(v, r)$ for each $v \in [n]$, and hence, vcost is $\tilde{O}(n)$. The final disjointness can be checked by an $[n, n]$ intersection scheme.

▶ **Theorem 19.** *There is a $[DWn, n]$-scheme for weighted SSSP in the turnstile weight update model.*

Vanilla Stream (Proof of Theorem 20). We now describe a protocol for SSSP in the model where the edges arrive with their weights, without any further update on them. This is the "vanilla" streaming model.

At the end of the stream, Prover sends the distances dist$[v]$ and prev$[v]$ – the parent of v in the shortest path tree rooted at s – for all $v \in V$. Verifier checks whether the edges and their weights implied by this proof are correct, using a $[Wn, n]$ subset scheme. Thus, if Prover is honest, we get the distance as well as shortest path from s to each vertex. But we also need to check that there is no path to any vertex shorter than the ones claimed by Prover. We describe a protocol for this.

For $u, v \in V$ and $w \in [W]$, define the indicator function f as $f(u, v, w) = 1$ iff $A(u, v) = w$. Let $\tilde{f}$ be the $\mathbb{F}$-extension of f, for some large finite field $\mathbb{F}$.

Retain the definitions of B_d and N_d from last section with the definition of the polynomial p_d changed to

$$p_d(U) = \sum_{v \in B_d} \tilde{f}(v, U, d + 1 - \text{dist}_s[v]) \tag{20}$$

Hence, it still holds that

$$N_{d+1} = \{u \in V \setminus B_d : p_d(u) \neq 0\} \ . \tag{21}$$

Stream processing. The stream updates are of the form (u, v, w) denoting that $A(u, v) = w$. Verifier picks $r \in_R \mathbb{F}$ and maintains $\tilde{f}(v, r, w)$ for each $v \in V$ and $w \in [W]$. He also stores the set B_1 with dist$_s$ labels set to 1 for each vertex in the set.

Help message processing and verification. This part is similar to the turnstile weight update protocol. Of course, this time, the Verifier computes $p_d(r)$ using Equation (20).

Error probability. Each polynomial p_d has degree $O(n)$. Verifier does sum-checks for $O(D)$ such polynomials. Choosing $|\mathbb{F}| \gg Dn$, we can make the error probability small by union bound.

Help and Verification costs. Since the degree of each p_d is at most n, the total hcost is $\tilde{O}(Dn)$. Verifier stores $\tilde{f}(v, r, w)$ for each $v \in V$ and $w \in [W]$, which requires $\tilde{O}(Wn)$ space. We also need to store all vertices as we go on assigning the distance labels. Hence, the total vcost of this protocol is $\tilde{O}(Wn)$.

▶ **Theorem 20.** *There is a $[Dn, Wn]$-scheme for weighted SSSP in the vanilla streaming model.*

Disjointness Through the Lens of Vapnik–Chervonenkis Dimension: Sparsity and Beyond

Abstract

The disjointness problem – where Alice and Bob are given two subsets of $\{1, \ldots, n\}$ and they have to check if their sets intersect – is a central problem in the world of communication complexity. While both deterministic and randomized communication complexities for this problem are known to be $\Theta(n)$, it is also known that if the sets are assumed to be drawn from some restricted set systems then the communication complexity can be much lower. In this work, we explore how communication complexity measures change with respect to the complexity of the underlying set system. The complexity measure for the set system that we use in this work is the Vapnik–Chervonenkis (VC) dimension. More precisely, on any set system with VC dimension bounded by d, we analyze how large can the deterministic and randomized communication complexities be, as a function of d and n. The d-sparse set disjointness problem, where the sets have size at most d, is one such set system with VC dimension d. The deterministic and the randomized communication complexities of the d-sparse set disjointness problem have been well studied and is known to be $\Theta\left(d \log\left(n/d\right)\right)$ and $\Theta(d)$, respectively, in the multi-round communication setting. In this paper, we address the question of whether the randomized communication complexity is always upper bounded by a function of the VC dimension of the set system, and does there always exist a gap between the deterministic and randomized communication complexity for set systems with small VC dimension.

In this paper, we construct two natural set systems of VC dimension d, motivated from geometry. Using these set systems we show that the deterministic and randomized communication complexity can be $\widetilde{\Theta}\left(d \log\left(n/d\right)\right)$ for set systems of VC dimension d and this matches the deterministic upper bound for all set systems of VC dimension d. We also study the deterministic and randomized communication complexities of the set intersection problem when sets belong to a set system of bounded VC dimension. We show that there exists set systems of VC dimension d such that both deterministic and randomized (one-way and multi-round) complexities for the set intersection problem can be as high as $\Theta\left(d \log\left(n/d\right)\right)$, and this is tight among all set systems of VC dimension d.

1 Introduction

Since its introduction by Yao [22], communication complexity occupies a central position in theoretical computer science. A striking feature of communication complexity is its interplay with other diverse areas like analysis, combinatorics, and geometry [9, 17]. Vapnik and Chervonenkis [21] introduced the measure *Vapnik-Chervonenkis dimension* or *VC dimension* for set systems in the context of statistical learning theory. As was the case with communication complexity, VC dimension has found numerous connections and applications in many different areas like approximation algorithms, discrete and combinatorial geometry, computational geometry, discrepancy theory and many other areas [10, 3, 14, 11]. In this work we study both of them under the same lens: of restricted systems and, for the first time, prove that geometric simplicity does not necessarily imply efficient communication complexity.

Lets start with recollecting some definitions from Vapnik–Chervonenkis theory. Let $\mathcal{S}$ be a collection of subsets of a *universe* $\mathcal{U}$. For a subset y of $\mathcal{U}$, we define

$$\mathcal{S}|_y := \{y \cap x \,:\, x \in \mathcal{S}\}\,.$$

We say a subset y of $\mathcal{U}$ is *shattered* by $\mathcal{S}$ if $\mathcal{S}|_y = 2^y$, where 2^y denotes the power set of y. *Vapnik–Chervonenkis (VC) dimension* of $\mathcal{S}$, denoted as VC-dim($\mathcal{S}$), is the size of the largest subset y of $\mathcal{U}$ shattered by $\mathcal{S}$. VC dimension has been one of the fundamental measures for quantifying complexity of a collection of subsets.

Now let us revisit the world of communication complexity. Let $f : \Omega_1 \times \Omega_2 \to \Omega$. In *communication complexity*, two players Alice and Bob get as inputs $x \in \Omega_1$ and $y \in \Omega_2$ respectively, and the goal for the players is to device a protocol to compute $f(x, y)$ by exchanging as few bits of information between themselves as possible.

The *deterministic communication complexity* $D(f)$ of a function f is the minimum number of bits Alice and Bob will exchange in the worst case to deterministically compute the function f. In the randomized setting, both Alice and Bob share an infinite random source[1] and the goal is to give the correct answer with probability at least 2/3. The randomized communication complexity $R(f)$ of f denotes the minimum number of bits exchanged by the players in the worst case input by the best randomized protocol computing f. In both deterministic and randomized settings, Alice and Bob are allowed to make multiple rounds of interaction. Communication complexity when the number of rounds of interaction is bounded is also often studied. An important special case is when only one round of communication is allowed, that is, only Alice is allowed to send messages to Bob and Bob computes the output. We will denote by $D^{\rightarrow}(f)$ and $R^{\rightarrow}(f)$ the *one way deterministic communication complexity* and *one way randomized communication complexity* respectively, of f.

[1] This is the communication complexity setting with shared random coins. If no random string is shared, it is called the private random coins setting. By [13] we know that the communication complexity in both the setting differs by at most a logarithmic additive factor.

One of the most well studied functions in communication complexity is the disjointness function. Given a universe $\mathcal{U}$ known to both Alice and Bob, the *disjointness function*, $\textsc{Disj}_{\mathcal{U}} : 2^{\mathcal{U}} \times 2^{\mathcal{U}} \to \{0, 1\}$, where $2^{\mathcal{U}}$ denotes the power set of $\mathcal{U}$, is defined as follows:

$$\textsc{Disj}_{\mathcal{U}}(x, y) = \begin{cases} 1, & \text{if } x \cap y = \emptyset \\ 0, & \text{o/w} \end{cases} \tag{1}$$

We also define the *intersection function*. Given a universe $\mathcal{U}$ known to both Alice and Bob, the *intersection function*, $\textsc{Int}_{\mathcal{U}} : 2^{\mathcal{U}} \times 2^{\mathcal{U}} \to 2^{\mathcal{U}}$, where $2^{\mathcal{U}}$ denotes the power set of $\mathcal{U}$, is defined as $\textsc{Int}_{\mathcal{U}}(x, y) = x \cap y$. It is easy to see that $\textsc{Int}_{\mathcal{U}}$ is harder function to compute than $\textsc{Disj}_{\mathcal{U}}$. The $\textsc{Disj}_{\mathcal{U}}$ function and its different variants, like $\textsc{Int}_{\mathcal{U}}$, have been one of the most important problems in communication complexity and have found numerous applications in areas like streaming algorithms for proving lower bounds [17, 15]. By abuse of the notation, when $\mathcal{U} = [n]$, where $[n]$ denotes the set $\{1, \ldots, n\}$, we will denote the functions $\textsc{Disj}_{[n]}$ and $\textsc{Int}_{[n]}$ by $\textsc{Disj}_n$ and $\textsc{Int}_n$ respectively.

Using the standard *rank argument* [9, 15] one can show that $D(\textsc{Disj}_n) = \Theta(n)$. In a breakthrough paper, Kalyanasundaram and Schnitger [8] proved that $R(\textsc{Disj}_n) = \Omega(n)$. Razborov [16] and Bar-Yossef et al. [1] gave alternate proofs for the above result. From the above cited results we can also see the $D(\textsc{Int}_n) = R(\textsc{Int}_n) = \Theta(n)$.

Naturally, one would also like to ask what happens to the deterministic and randomized communication complexity (one way or multiple round) of $\textsc{Disj}_n$, when both Alice and Bob know that their inputs have more structure. In particular what can we say if the inputs are guaranteed to be from a subset of $\mathcal{S} \subseteq 2^{\mathcal{U}}$, where $\mathcal{S}$ is known to both players. Let $\textsc{Disj}_{\mathcal{U}}$ functions *restricted* to $\mathcal{S} \times \mathcal{S}$ be denoted by $\textsc{Disj}_{\mathcal{U}}|_{\mathcal{S}\times\mathcal{S}}$. This problem has also been studied extensively, mostly for certain special classes of subsets $\mathcal{S} \subseteq 2^{\mathcal{U}}$. For example, the *sparse set disjointness* function, where the set $\mathcal{S}$ contains all the subsets of $\mathcal{U}$ of size at most d, is an important special case of these works.

We will denote by d-$\textsc{SparseDisj}_n$ and d-$\textsc{SparseInt}_n$, the functions $\textsc{Disj}_n|_{S\times\mathcal{S}}$ and $\textsc{Int}_n|_{S\times S}$ respectively, where S is the collections of all subsets of $[n]$ of size at most d. Using the *rank argument* [9, 15], one can again show that, for all $d \leq n$, the deterministic communication complexity of d-$\textsc{SparseDisj}_n$ is $\Omega\left(d \log \frac{n}{d}\right)$. Håstad and Wigderson [6], and Dasgupta et al. [4] showed that the randomized communication complexity and one round randomized communication complexity of d-$\textsc{SparseDisj}_n$ is $R(d\text{-}\textsc{SparseDisj}_n) = \Theta(d)$ and $R^{\rightarrow}(d\text{-}\textsc{SparseDisj}_n) = \Theta(d \log d)$ respectively. In a follow up work, Saglam and Tardos [18] proved that with $O(\log^* d)$ rounds of communication and $O(d)$ bits of communication it is possible to compute d-$\textsc{SparseDisj}_n$. More recently, Brody et al. [2] proved that $R^{\rightarrow}(d\text{-}\textsc{SparseInt}_n) = \Theta(d \log d)$ and $R(d\text{-}\textsc{SparseInt}_n) = \Theta(d)$. These results show that in the d-sparse setting, there is a separation between randomized and deterministic communication complexity of $\textsc{Disj}_n$ and $\textsc{Int}_n$ functions.

One would like to ask what happens to the communication complexity for other restrictions to the disjointness (and intersection) problem. The following are two natural problems, with a geometric flavor, for which one would like to study the communication complexity.

▶ **Problem 1** (Discrete Line Disj). Let $G \subset \mathbb{Z}^2$ be a set of n points in $\mathbb{Z}^2$ and L be the set of all lines in $\mathbb{R}^2$. Also, let $\mathcal{L} = L^d$ denote the collection of all d-size subsets of L. The Discrete Line Disj on G and $\mathcal{L}$ is a function, $\textsc{Disj}_G|_{\mathcal{L}\times\mathcal{L}}$: $\mathcal{L} \times \mathcal{L} \to \{0, 1\}$ defined as $\textsc{Disj}_G|_{\mathcal{L}\times\mathcal{L}}(\{\ell_1, \ldots, \ell_d\}, \{\ell'_1, \ldots, \ell'_d\})$ is 1 if and only if there exists a line in Alice's set[2]

[2] We assume that Alice has the set $\{\ell_1, \ldots, \ell_d\}$ and Bob has the set $\{\ell'_1, \ldots, \ell'_d\}$.

that intersects some line in Bob's set at some point in G. Formally,

$$\textsc{Disj}_G\,|_{\mathcal{L}\times\mathcal{L}}\,(\{\ell_1,\ldots,\ell_d\},\{\ell'_1,\ldots,\ell'_d\}) = \begin{cases} 1, & \text{if } \exists i,j\in[d] \text{ s.t. } \ell_i\cap\ell'_j\cap G=\emptyset \\ 0, & \text{o/w} \end{cases} \tag{2}$$

▶ **Problem 2** (Discrete Interval Disj)**.** Let $X\subset\mathbb{Z}$ be a set of n points in $\mathbb{Z}$ and Int be the set of all possible intervals. Also, let $\mathcal{I}=Int^d$ denote the collection of all d-size subsets of Int. The Discrete Interval Disj on X and $\mathcal{I}$ is a function, $\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}\colon \mathcal{I}\times\mathcal{I}\to\{0,1\}$ defined as $\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}\,(\{I_1,\ldots,I_d\},\{I'_1,\ldots,I'_d\})$ is 1 if and only if there exists an interval in Alice's set[3] that intersects some interval in Bob's set at some point in X.

$$\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}\,(\{I_1,\ldots,I_d\},\{I'_1,\ldots,I'_d\}) = \begin{cases} 1, & \text{if } \exists i,j\in[d] \text{ s.t. } I_i\cap I'_j\cap X=\emptyset \\ 0, & \text{o/w} \end{cases} \tag{3}$$

Note that both the Discrete Line Disj and Discrete Interval Disj functions are generalizations of sparse set disjointness function.[4] Although it may not be obvious at first look, but both the Discrete Line Disj function and the Discrete Interval Disj functions are disjointness functions restricted to a suitable subset. In fact, the connection between the *Sparse set disjointness* function (d-SparseDisj$_n$), the Discrete Line Disj function and the Discrete Interval Disj function run deep - all the three subsets of the domain which help to define the functions as restriction of the disjointness function have VC dimension $\Theta(d)$, see Appendix A. Naturally one would like to know, if the fact that the collection of subsets $\mathcal{S}$ has VC dimension d has any implication on the communication complexity of $\textsc{Disj}_{\mathcal{U}}\,|_{\mathcal{S}\times\mathcal{S}}$. For example, is the randomized communication complexity of Discrete Line Disj function and the Discrete Interval Disj function upper bounded by a function of d (independent of n)? And, do the Discrete Line Disj function and the Discrete Interval Disj function also have a separation between their randomized and deterministic communication complexities similar to that of the *Sparse set disjointness* function (d-SparseDisj$_n$)? We show that these are not necessarily the cases.

▶ **Theorem 3.** *For Discrete Interval Disj: there exists a $X\subset\mathbb{Z}$ with n points such that*

$$D(\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}) = D^{\to}(\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}) = R^{\to}(\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}) = \Theta\left(d\log\frac{n}{d}\right).$$

▶ **Theorem 4.** *For Discrete Line Disj: there exists a $G\subset\mathbb{Z}^2$ with n points such that $D(\textsc{Disj}_G\,|_{\mathcal{L}\times\mathcal{L}}) = D^{\to}(\textsc{Disj}_G\,|_{\mathcal{L}\times\mathcal{L}}) = \Theta\left(d\log\frac{n}{d}\right)$ and, for the randomized setting,*

$$R(\textsc{Disj}_G\,|_{\mathcal{L}\times\mathcal{L}}) = \Omega\left(d\frac{\log(n/d)}{\log\log(n/d)}\right)$$

Discrete Line Int , that is, the intersection finding version of Discrete Line Disj is defined as follows : the objective is to compute a function $\textsc{Int}_G\,|_{\mathcal{L}\times\mathcal{L}}\colon \mathcal{L}\times\mathcal{L}\to G$ that is defined as

$$\textsc{Int}_G\,|_{\mathcal{L}\times\mathcal{L}}\,(\{\ell_1,\ldots,\ell_d\},\{\ell'_1,\ldots,\ell'_d\}) = \bigcup_{i,j\in[d]}\left(\ell_i\cap\ell'_j\cap G\right).$$[5]

[3] We assume that Alice has the set $\{I_1,\ldots,I_d\}$ and Bob has the set $\{I'_1,\ldots,I'_d\}$.

[4] Take n integer points on the x-axis. For Discrete Line Disj setting, restrict only to lines orthogonal to x-axis. For Discrete Interval Disj setting, take n integer points on $\mathbb{Z}$ and only restrict to intervals containing one integer point. Both of these restriction will give the disjointness problem in the d-sparse setting.

As we have already mentioned, Brody et al. [2] proved that $R(d\text{-SparseInt}_n) = \Theta(d)$, whereas $D(d\text{-SparseInt}_n) = \Theta\left(d \log \frac{n}{d}\right)$. We show that Discrete Line Int does not demonstrate such a separation between the deterministic and randomized communication complexity.

▶ **Theorem 5.** *For Discrete Line Int : there exists a $G \subset \mathbb{Z}^2$ with n points such that*

$$D(\text{Int}_G|_{\mathcal{L}\times\mathcal{L}}) = D^{\rightarrow}(\text{Int}_G|_{\mathcal{L}\times\mathcal{L}}) = R^{\rightarrow}(\text{Int}_G|_{\mathcal{L}\times\mathcal{L}}) = R(\text{Int}_G|_{\mathcal{L}\times\mathcal{L}}) = \Theta\left(d \log \frac{n}{d}\right).$$

The upper bound for all the above three theorems can be obtained from the fact that the corresponding sets have VC dimension $\Theta(d)$, see Appendix A. *Sauer-Shelah Lemma* [19, 20, 21] states that if $\mathcal{S} \subseteq 2^{[n]}$ and VC-dim$(\mathcal{S}) \leq d$ then $|\mathcal{S}| \leq \left(\frac{en}{d}\right)^d$. Thus if VC-dim$(\mathcal{S}) \leq d$, then the Sauer-Shelah Lemma implies that $D^{\rightarrow}(\text{Int}_n|_{\mathcal{S}\times\mathcal{S}}) = O\left(d \log \frac{n}{d}\right)$. So, $O\left(d \log \frac{n}{d}\right)$ is a upper bound to the above questions, both for randomized and deterministic and also for the one-way communication. But can the randomized communication complexity of $\text{Disj}_{\mathcal{U}}|_{\mathcal{S}\times\mathcal{S}}$ and $\text{Int}_{\mathcal{U}}|_{\mathcal{S}\times\mathcal{S}}$ be even lower when S has VC dimension d? The following result, which is a direct consequence of Theorems 3, 4 and 5, enables us to we answer the question in the negative:

▶ **Theorem 6.** *Let $1 \leq d \leq n$.*

1. *There exists $\mathcal{S} \subseteq 2^{[n]}$ with VC-dim$(\mathcal{S}) \leq d$ and $R^{\rightarrow}(\text{Disj}_n|_{\mathcal{S}\times\mathcal{S}}) = \Omega\left(d \log \frac{n}{d}\right)$.*
2. *There exists $\mathcal{S} \subseteq 2^{[n]}$ with VC-dim$(\mathcal{S}) \leq d$ and $R(\text{Disj}_n|_{\mathcal{S}\times\mathcal{S}}) = \Omega\left(d \frac{\log(n/d)}{\log\log(n/d)}\right)$.*
3. *There exists $\mathcal{S} \subseteq 2^{[n]}$ with VC-dim$(\mathcal{S}) \leq d$ and $R(\text{Int}_n|_{\mathcal{S}\times\mathcal{S}}) = \Omega\left(d \log \frac{n}{d}\right)$.*

The following table compares our result with the previous best known lower bound for $\text{Disj}_{\mathcal{U}}|_{\mathcal{S}\times\mathcal{S}}$ and $\text{Int}_{\mathcal{U}}|_{\mathcal{S}\times\mathcal{S}}$ among all sets $S \subset 2^{\mathcal{U}}$ of VC dimension d.

Table 1 The largest communication complexity, for the functions $\text{Disj}_n|_{\mathcal{S}\times\mathcal{S}}$ and $\text{Int}_n|_{\mathcal{S}\times\mathcal{S}}$, among all $S \subseteq 2^{[n]}$ of VC dimension d, that was previously known and what we prove in this paper. Tight bounds of $\Omega\left(d \log \frac{n}{d}\right)$ for the largest $D(\text{Disj}_n|_{\mathcal{S}\times\mathcal{S}})$, $D^{\rightarrow}(\text{Disj}_n|_{\mathcal{S}\times\mathcal{S}})$, $D(\text{Int}_n|_{\mathcal{S}\times\mathcal{S}})$ and $D^{\rightarrow}(\text{Int}_n|_{\mathcal{S}\times\mathcal{S}})$, among all $S \subset 2^{[n]}$ of VC dimension d, follows directly from the fact that if $\mathcal{S}$ is a collection of all subsets of $[n]$ of size at most d then $D(\text{Disj}_n|_{\mathcal{S}\times\mathcal{S}}) = D(\text{Int}_n|_{\mathcal{S}\times\mathcal{S}}) = \Omega\left(d \log\left(\frac{n}{d}\right)\right)$, see [9, 15].

Notations

We denote the set $\{1, \ldots, n\}$ by $[n]$. For a binary number $\mathbf{x}$, *decimal*$(\mathbf{x})$ denotes the decimal value of $\mathbf{x}$. For two vectors $\mathbf{x}$ and $\mathbf{y}$ in $\{0,1\}^n$, $\mathbf{x} \cap \mathbf{y} = \{i \in [n] : \mathbf{x}_i = \mathbf{y}_i = 1\}$, and $\mathbf{x} \subseteq \mathbf{y}$ when $\mathbf{x}_i \leq \mathbf{y}_i$ for each $i \in [n]$. For a finite set X, 2^X denotes the power set of X. For $x, y \in \mathbb{R}$ with $x < y$, $[x, y]$ denotes the closed interval is the set of all real numbers that lies between x and y.

2 One way communication complexity (Theorems 3 and 6 (1))

In this section we will prove the following result.

▶ **Theorem 7.** *For all $n \geq d$, there exists $X \subset \mathbb{Z}$ with $|X| = n$ and $\mathcal{R} \subseteq 2^X$ with VC-dim$(\mathcal{R}) = 2d$, such that*

$$\mathcal{R} \subseteq \left\{ X \cap \left(\bigcup_{1 \leq j \leq d} I_j \right) \mid \{I_1, \ldots, I_d\} \in \mathcal{I} \right\} \text{ and } R^{\rightarrow}(\textsc{Disj}_X \mid_{\mathcal{R} \times \mathcal{R}}) = \Omega\left(d \log \frac{n}{d}\right).$$

Note that the set $\mathcal{I}$ is defined in Problem 2.

▶ Remark 8. The above result takes care of the proofs of Theorem 3 and Theorem 6 (1).

The *hard* instance, for the proof of the above theorem, is inspired by the *interval* set systems in combinatorial geometry and is constructed in Section 2.1. In Section 2.2, we proof Theorem 7 by using a reduction from Augmented Indexing, which we denote by AugIndex$_\ell$. Formally the problem AugIndex$_\ell$ is defined as follows: Alice gets a string $\mathbf{x} \in \{0,1\}^\ell$ and Bob gets an index $j \in [\ell]$ and all $x_{j'}$ for $j' < j$. Bob reports x_j as the output.

▶ **Proposition 9.** (Miltersen et al. [12]) $R^{\rightarrow}(\textsc{AugIndex}_\ell) = \Omega(\ell)$.

2.1 Construction of a hard instance

We construct a set $X \subset \mathbb{Z}$ with $|X| = n$ and $\mathcal{R} \subseteq 2^X$ with VC-dim$(\mathcal{R}) = 2d$. Informally, X is the union of the set of points present in the union of d pairwise disjoint intervals, in $\mathbb{Z}$, each containing $\frac{n}{d}$ points. Each set in $\mathcal{R}$ is the union of the set of points in the subintervals anchored either at the left or the right end point of each of the above d intervals. Formally, the description of X and $\mathcal{R}$ are given below along with some of its properties that are desired to show Theorem 7.

The ground set X

Let $m = \frac{n}{d} - 2$. Without loss of generality we can assume that $m = 2^k$, where $k \in \mathbb{N}$. Let $J_0 = \{0, \ldots, m+1\}$ be the set of $m+2$ consecutive integers that starts from the origin and ends at $m+1$. Similarly, let J_p be the set of $m+1$ consecutive integers that starts at $p \in \mathbb{Z}$ and ends at $p+m+1$. Let $p_1, \ldots, p_d$ be d points in $\mathbb{Z}$ such that the sets $J_{p_1}, \ldots, J_{p_d}$ are pairwise disjoint. Let the *ground* set X be $\bigcup_{i=1}^{d} J_{p_i}$. Note that $X \subset \mathbb{Z}$ and $|X| = (m+2)d = n$.

The subsets of X in $\mathcal{R}$

$\mathcal{R} \subseteq 2^X$ contains two types of sets $\mathcal{R}_0$ and $\mathcal{R}_{m+1}$, where

- Take any d intervals $R_1, \ldots, R_d$ of integer lengths such that, for all $i \in [d]$, length of R_i is at most $m+1$, $R_i \subseteq [p_i, p_i + m + 1]$, and R_i starts at p_i. Note that R_i does not intersect with any $X \setminus J_{p_i}$. The set $A = \bigcup_{i=1}^{d} (R_i \cap X)$ is an element in $\mathcal{R}_0$. We say that A is *generated* by $R_1, \ldots, R_d$.
- Take any d intervals $R'_1, \ldots, R'_d$ of integer lengths such that, for all $i \in [d]$, length of R'_i is at most $m+1$, $R'_i \subseteq [p_i, p_i + m + 1]$ and R'_i ends at $p_i + m + 1$. Note that R'_i does not intersect with any $X \setminus J_{p_i}$. The set $B = \bigcup_{i=1}^{d} (R'_i \cap X)$ is an element in $\mathcal{R}_{m+1}$. We say that B is *generated* by $R'_1, \ldots, R'_d$.

The following claim bounds the VC dimension of $\mathcal{R}$, constructed as above.

▷ Claim 10. For $X \subset \mathbb{Z}$ with $|X| = n$ and $\mathcal{R} \subset 2^X$ as described above, VC-dim$(\mathcal{R}) = 2d$,

Proof. The proof follows from the fact that any subset of of X containing $2d+1$ points will contain at least three points from some J_{p_i}, where $i \in [d]$. These points in J_{p_i} can not be shattered by the sets in $\mathcal{R}$. Also, observe that there exists $2d$ points, with two from each J_{p_j}, that can be shattered by the sets in $\mathcal{R}$. ◁

Now, we give a claim about X and $\mathcal{R}$ constructed above that will be required for our proof of Theorem 7.

▷ Claim 11. Let $A \in \mathcal{R}_0$ and $B \in \mathcal{R}_{m+1}$ be such that A is generated by $R_1, \ldots, R_d$ and B is generated by $R'_1, \ldots, R'_d$. Then A and B intersects if and only if there exists an $i \in [d]$ such that R_i intersects R'_i at a point in J_{p_i}.

The proof of Claim 11 follows directly from our construction of $X \subset \mathbb{Z}$ and $\mathcal{R} \subseteq 2^X$, as $J_{p_1}, \ldots, J_{p_d}$ are pairwise disjoint.

2.2 Reduction from AugIndex$_{d \log m}$ to Disj$_X$ $|_{\mathcal{R}\times\mathcal{R}}$

Before presenting the reduction we recall the definitions of AugIndex$_{d\log m}$ and Disj$_X|_{\mathcal{R}\times\mathcal{R}}$. In AugIndex$_{d\log m}$, Alice gets $\mathbf{x} \in \{0,1\}^{d\log m}$ and Bob gets an index j and $x_{j'}$ for each $j' < j$. The objective of Bob is to report x_j as the output. In Disj$_X|_{\mathcal{R}\times\mathcal{R}}$, Alice gets $A \in \mathcal{R}_0$ and Bob gets $B \in \mathcal{R}_{m+1}$. The objective of Bob is to determine whether $A \cap B = \emptyset$. Note that $X, \mathcal{R}, \mathcal{R}_0$ and $\mathcal{R}_{m+1}$ are as discussed in the Section 2.1.

Let $\mathcal{P}$ be an one-way protocol that solves Disj$_X|_{\mathcal{R}\times\mathcal{R}}$ with $o\left(d \log \frac{n}{d}\right) = o(d \log m)$ bits of communication. Now, we consider the following protocol $\mathcal{P}'$ for AugIndex$_{d\log m}$ that has the same one way communication cost as that of Disj$_X|_{\mathcal{R}\times\mathcal{R}}$. Then we will be done with the proof of Theorem 7.

Protocol $\mathcal{P}'$ for AugIndex$_{d\log m}$ problem

Step-1 Let $\mathbf{x} \in \{0,1\}^{d\log m}$ be the input of Alice. Bob gets an index $j \in [d \log m]$ and bits $x_{j'}$ for each $j' < j$.

Step-2 Alice will form d strings $\mathbf{a}_1, \ldots, \mathbf{a}_d \in \{0,1\}^{\log m}$ by partitioning the string $\mathbf{x}$ into d parts such that $\mathbf{a}_i = x_{(i-1)\log m+1} \ldots x_{i \log m}$, where $i \in [d]$. Bob first forms a string $\mathbf{y} \in \{0,1\}^{d\log m}$, where $y_{j'} = x_{j'}$ for each $j' < j$, $y_j = 1$, and $y_{j'} = 0$ for each $j' > j$. Then Bob finds $\mathbf{b}_1, \ldots, \mathbf{b}_d \in \{0,1\}^{\log m}$ by partitioning the string $\mathbf{y}$ in to d parts such that $\mathbf{b}_i = y_{(i-1)\log m+1} \ldots y_{i \log m}$, where $i \in [d]$.

Step-3 For each $i \in [d]$, let R_i and R'_i be the intervals that starts at p_i and ends at $p_i + m + 1$, respectively, where $R_i = [p_i, m + p_i - \mathit{decimal}(\mathbf{a}_i)]$ and $R'_i = [p_i + m + 1 - \mathit{decimal}(\mathbf{b}_i), p_i + m + 1]$. Alice finds the set $A \in \mathcal{R}_0$ generated by $R_1, \ldots, R_d$ and Bob finds the set $B \in \mathcal{R}_{m+1}$ generated by $R'_1, \ldots, R'_d$, i.e., $A = \bigcup_{i\in[d]} (R_i \cap X)$ and $B = \bigcup_{i\in[d]} (R'_i \cap X)$.

Step-4 Alice and Bob solves Disj$_X|_{\mathcal{R}\times\mathcal{R}}$ on inputs A and B, and report $x_j = 0$ if and only if Disj$_X|_{\mathcal{R}\times\mathcal{R}}(A, B) = 0$. Note that x_j is the output of AugIndex$_{d\log m}$ problem.

The following observation follows from the description of the protocol $\mathcal{P}'$ and from the construction of $X \subset \mathbb{Z}$ and $\mathcal{R} \subseteq 2^X$.

▶ **Observation 12.** Let $i^* \in [d]$ such that $j \in \{(i^*-1)\log m + 1, i^* \log m\}$. Then
(i) $R_i \cap R'_i = \emptyset$ for all $i \neq i^*$.
(ii) $R_{i^*} \cap R'_{i^*} = \emptyset$ if and only if $\mathit{decimal}(\mathbf{b}_{i^*}) \leq \mathit{decimal}(\mathbf{a}_{i^*})$.
(iii) $\mathit{decimal}(\mathbf{b}_{i^*}) \leq \mathit{decimal}(\mathbf{a}_{i^*})$ if and only if $x_j = 0$.
We will use the above observation to show the correctness of the protocol $\mathcal{P}'$.

First consider the case $\textsc{Disj}_X\ |_{\mathcal{R}\times\mathcal{R}}\ (A, B) = 0$. Then, by Claim 11, there exists an $i \in [d]$ such that R_i and R'_i intersects at a point in J_{p_i}. From Observation 12 (i), we can say $R_{i*} \cap R'_{i*} \neq \emptyset$. Combining $R_{i*} \cap R'_{i*} \neq \emptyset$ with Observations 12 (ii) and (iii), we have $x_j = 0$. Hence, $\textsc{Disj}_X\ |_{\mathcal{R}\times\mathcal{R}}\ (A, B) = 0$ implies $x_j = 0$. The converse part, i.e., $x_j = 0$ implies $\textsc{Disj}_X\ |_{\mathcal{R}\times\mathcal{R}}\ (A, B) = 0$, can be shown in the similar fashion.

The one-way communication complexity of protocol $\mathcal{P}'$ for $\textsc{AugIndex}_{d\log m}$ is the same as that of $\mathcal{P}$ for $\textsc{Disj}_X|_{\mathcal{R}\times\mathcal{R}}$, that is, $o(d\log m)$. However, this is impossible as the one-way communication complexity of Augmented Indexing, over $d\log m$ bits, is $\Omega(d\log m) = \Omega\left(d\log\frac{n}{d}\right)$ bits. This completes the proof of Theorem 7.

3 Two way communication complexity (Theorems 4, 5, 6 (2) and 6 (3))

In this section, we prove the following theorems.

▶ **Theorem 13.** *For all $n \geq d$, there exists a $G \subset \mathbb{Z}^2$ with $|G| = n$ and $\mathcal{T} \subseteq 2^G$ with VC-dim$(\mathcal{T}) = 2d$, such that*

$$\mathcal{T} \subseteq \left\{ G \cap \left(\bigcup_{1\leq j\leq d} \ell_j \right) \mid \{\ell_1, \ldots, \ell_d\} \in \mathcal{L} \right\} \text{ and } R(\textsc{Disj}_G\ |_{\mathcal{T}\times\mathcal{T}}) = \Omega\left(d\frac{\log(n/d)}{\log\log(n/d)} \right).$$

The set $\mathcal{L}$ is as defined in Problem 1.

▶ **Theorem 14.** *For all $n \geq d$, there exists a $G \subset \mathbb{Z}^2$ with $|G| = n$ and $\mathcal{T} \subseteq 2^G$ with VC-dim$(\mathcal{T}) = 2d$, such that*

$$\mathcal{T} \subseteq \left\{ G \cap \left(\bigcup_{1\leq j\leq d} \ell_j \right) \mid \{\ell_1, \ldots, \ell_d\} \in \mathcal{L} \right\} \text{ and } R(\textsc{Int}_G\ |_{\mathcal{T}\times\mathcal{T}}) = \Omega\left(d\log\frac{n}{d} \right).$$

The set $\mathcal{L}$ is as defined in problem 1.

▶ Remark 15. Theorem 13 takes care of Theorem 4 and 6(2). Theorem 14 takes care of Theorem 5 and 6(3).

Note that the same set system will be used for the proofs of the above theorems. The *hard* instance, for the proof of the above theorems, is inspired by *point line incidence* set systems in computational geometry and is constructed in Section 3.1. We prove Theorems 13 and 14 in Sections 3.2 and 3.3, respectively, using reductions.

3.1 The hard instance for the proofs of Theorems 13 and 14

In this subsection, we give the description of $G \subset \mathbb{Z}^2$ with $|G| = n$ and $\mathcal{T} \subseteq 2^G$, with VC-Dim$(\mathcal{T}) = 2d$. The same G and $\mathcal{T}$ will be our *hard* instance for the proofs of Theorems 13 and 14. In this subsection, without loss of generality, we can assume that d divides n and n/d is a perfect square.

Informally, G is the set of points present in the union of d many pairwise disjoint square grids each containing $\frac{n}{d}$ points and the grids are taken in such a way that any straight line of non-negative can intersects with at most one grid. Also, each set in $\mathcal{T}$ is the union of the set of points present in d many lines of non-negative slope such that one line intersects with exactly one grid. Moreover, all of the d lines have slopes either zero or positive. Formally, the description of G and $\mathcal{T}$ are given below along with some of its properties that are desired to show Theorems 13 and 14.

The ground set G

Let $m = \sqrt{\frac{n}{d}}$, and $G_{(0,0)} = \{(x, y) \in \mathbb{Z}^2 : 0 \leq x, y \leq m-1\}$ be the grid of size $m \times m$ anchored at the origin $(0, 0)$. For any $p, q \in \mathbb{Z}$, the $m \times m$ grid anchored at (p, q) will be denoted by $G_{(p,q)}$, i.e., $G_{(p,q)} = \{(i+p, j+q) : (i, j) \in G_{(0,0)}\}$. For $d \in \mathbb{N}$, consider $G_{(p_1,q_1)}, \ldots, G_{(p_d,q_d)}$ satisfying the following property:

PROPERTY *For any $i, j \in [d]$, with $i \neq j$, let L_1 and L_2 be lines of non-negative slopes that pass through at least two points of $G_{(p_i,q_i)}$ and $G_{(p_j,q_j)}$, respectively. Then L_1 and L_2 does not intersect at any point* inside $\bigcup_{\ell=1}^{d} G_{(p_\ell,q_\ell)}$.

Observe that there exists $G_{(p_1,q_1)}, \ldots, G_{(p_d,q_d)}$ satisfying PROPERTY. We will take $G = \bigcup_{\ell=1}^{d} G_{(p_\ell,q_\ell)}$ as the ground set. Without loss of generality, we can assume that $(p_1, q_1) = (0, 0)$. Note that $G \subset \mathbb{Z}^2$ and $|G| = dm^2 = n$.

The subsets of G in $\mathcal{T}$

$\mathcal{T}$ contains two types of subsets $\mathcal{T}_1$ and $\mathcal{T}_2$ of G, and they are generated by the following ways:

- Take any d lines $L_1, \ldots, L_d$ of non negative slope such that, $\forall i \in [d]$, L_i passes through $(p_i, q_i) \in G_{(p_i,q_i)}$ and (at least) another point in $G_{(p_i,q_i)}$. Note that L_i does not contain any point from $G \setminus G_{(p_i,q_i)}$. The set $A = \bigcup_{i=1}^{d} \left(L_i \cap G_{(p_i,q_i)}\right)$ is in $\mathcal{T}_1$, and we say A is *generated* by the lines $L_1, \ldots, L_d$.
- Take any d vertical lines $L'_1, \ldots, L'_d$ such that, $\forall i \in [d]$, L'_i contains at least one point from $G_{(p_i,q_i)}$. Note that L'_i does not contain any point from $G \setminus G_{(p_i,q_i)}$. The set $B = \bigcup_{i=1}^{d} (L'_i \cap G_{(p_i,q_i)})$ is in $\mathcal{T}_2$, and we say B is generated by the lines $L'_1, \ldots, L'_d$.

The following claim bounds the VC dimension of $\mathcal{T}$, which as described above.

▷ Claim 16. For $G \subset \mathbb{Z}^2$ and $\mathcal{T} \subseteq 2^G$ as described above, VC-dim$(\mathcal{T}) = 2d$.

Proof. The proof follows from the fact that any subset of X containing $2d + 1$ points will contain at least three points from some $G_{(p_j,q_j)}, j \in [d]$. These points in $G_{(p_j,q_j)}$ can not be shattered by the sets in $\mathcal{T}$. Also, observe that there exists $2d$ points two from each $G_{(p_j,q_j)}$ that can be shattered by the sets in $\mathcal{T}$. ◁

Now, we give two claims about G and $\mathcal{T}$, constructed above, that follow directly from our construction of $G \subset \mathbb{Z}^2$ and $\mathcal{T} \subseteq 2^G$.

▷ Claim 17. Let $A \in \mathcal{T}_1$ and $B \in \mathcal{T}_2$ such that A is generated by lines $L_1, \ldots, L_d$ and A is generated by lines $L'_1, \ldots, L'_d$. Then A and B intersect if and only if there exists $i \in [d]$ such that L_i and L'_i intersect at a point in $G_{(p_i,q_i)}$.

▷ Claim 18. Let $A \in \mathcal{T}_1$ and $B \in \mathcal{T}_2$ such that A is generated by lines $L_1, \ldots, L_d$ and B is generated by lines $L'_1, \ldots, L'_d$. Also let $|A \cap B| = d$. Then for each $i \in [d]$, L_i and L'_i intersect at a point in $G_{(p_i,q_i)}$. Moreover, A (B) can be determined if we know B (A) and $A \cap B$.

The above claims will be used in the proofs of Theorems 13 and 14.

3.2 Proof of Theorem 13

Let us consider a problem in communication complexity denoted by Or-Disj$^t_{\{0,1\}^\ell}$ that will be used in our proof. In Or-Disj$^t_{\{0,1\}^\ell}$, Alice gets t strings $\mathbf{x}_1, \ldots, \mathbf{x}_t \in \{0,1\}^\ell$ and Bob also gets t strings $\mathbf{y}_1, \ldots, \mathbf{y}_t \in \{0,1\}^\ell$. The objective is to compute $\bigvee_{i=1}^{t} \textsc{Disj}_{\{0,1\}^\ell}(\mathbf{x}_i, \mathbf{y}_i)$. Note that $\textsc{Disj}_{\{0,1\}^\ell}(\mathbf{x}_i, \mathbf{y}_i)$ is a binary variable that takes value 1 if and only if $\mathbf{x}_i \cap \mathbf{y}_i = \emptyset$.

▶ **Proposition 19** (Jayram et al. [7]). $R\left(\textsc{Or-Disj}^t_{\{0,1\}^\ell}\right) = \Omega(\ell t)$.

Note that Proposition 19 directly implies the following result.

▶ **Proposition 20.** $R\left(\textsc{Or-Disj}^t_{\{0,1\}^\ell} \mid_{S_\ell \times S_\ell}\right) = \Omega(\ell t)$, *where* $S_\ell = \{0,1\}^\ell \setminus \{0^\ell\}$.

Let $k \in \mathbb{N}$ be the largest integer such that first k consecutive primes $p_1, \ldots, p_k$ satisfy the following inequalty:

$$\Pi_{i=1}^{k} p_i \leq \sqrt{\frac{n}{d}}. \tag{4}$$

Using the fact that $\Pi_{i=1}^{k} p_i = e^{(1+o(1))k \log k}$, we get $k = \Theta\left(\frac{\log(n/d)}{\log\log(n/d)}\right)$.

We prove the theorem by a reduction from Or-Disj$^d_{\{0,1\}^k} \mid_{S_k \times S_k}$ to $\textsc{Disj}_G \mid_{\mathcal{T}\times\mathcal{T}}$, where $S_k := \{0,1\}^k \setminus \{0^k\}$.

Note that $G \subset \mathbb{Z}^2$ with $|G| = n$, and $\mathcal{T} \subseteq 2^G$, with VC-dim$(\mathcal{T}) = 2d$, are the same as that we constructed in Section 3.1. To reach a contradiction, assume that there exists a two way protocol $\mathcal{P}$ that solves $\textsc{Disj}_G \mid_{\mathcal{T}\times\mathcal{T}}$ with communication cost of $o\left(d\frac{\log m}{\log\log m}\right) = o\left(d\frac{\log(n/d)}{\log\log(n/d)}\right)$ bits. Now, we give protocol $\mathcal{P}'$ that solves Or-Disj$^d_{\{0,1\}^k} \mid_{S_k \times S_k}$, as described below.

Protocol $\mathcal{P}'$ for Or-Disj$^d_{\{0,1\}^k} \mid_{S_k \times S_k}$

Step-1 Let $A = (\mathbf{x}_1, \ldots, \mathbf{x}_d) \in [S_k]^d$ [6] and $B = (\mathbf{y}_1, \ldots, \mathbf{y}_d) \in [S_k]^d$ be the inputs of Alice and Bob for Or-Disj$^d_{\{0,1\}^k} \mid_{S_k \times S_k}$. Recall that $S_k = \{0,1\}^k \setminus \{0^k\}$. Bob finds $\bar{B} = (\bar{\mathbf{y}}_1, \ldots, \bar{\mathbf{y}}_d) \in \left[\{0,1\}^k\right]^d$, where $\bar{\mathbf{y}}_i$ is obtained by complementing each bit of $\mathbf{y}_i$.

Step-2 Both Alice and Bob privately determine first k prime numbers $p_1, \ldots, p_k$ without any communication.

Step-3 Let $\Phi : \{0,1\}^k \to \{0,1\}^{\lceil \log(\sqrt{\frac{n}{d}}) \rceil}$ be the function such that $\phi(\mathbf{x})$ is the bit representation of the number $\prod_{i=1}^{k} p_i^{x_i}$, where $\mathbf{x} = (x_1, \ldots, x_k) \in \{0,1\}^k$. Alice finds $A' = (\mathbf{a}_1, \ldots, \mathbf{a}_d) \in \left[\{0,1\}^{\lceil \log(\sqrt{\frac{n}{d}}) \rceil}\right]^d$ and Bob finds $B' = (\mathbf{b_1}, \ldots, \mathbf{b_1} \in \left[\{0,1\}^{\lceil \log(\sqrt{\frac{n}{d}}) \rceil}\right]^d$ privately without any communication, where $\mathbf{a_i} = \phi(\mathbf{x_i})$ and $\mathbf{b_i} = \phi(\bar{\mathbf{y}}_i)$ for each $i \in [d]$.

[6] For a set W, $[W]^d = W \times \ldots \times W$ (d times).

Step-4 For each $i \in [d]$, let L_i and L'_i be the lines having equation $y - q_i = \frac{decimal(\mathbf{a}_i)-1}{decimal(\mathbf{a}_i)}(x - p_i)$ and $x - p_i = decimal(\mathbf{b}_i)$ respectively. Alice finds $A'' \in \mathcal{T}$ that is generated by the lines $L_1, \ldots, L_d$, and Bob finds $B'' \in \mathcal{T}$ which is generated by the lines $L'_1, \ldots, L'_d$, i.e., $A'' = \bigcup_{i\in[d]} (L_i \cap G_{(p_i,q_i)})$ and $B'' = \bigcup_{i\in[d]} (L'_i \cap G_{(p_i,q_i)})$.

Step-5 Then Alice and Bob solve $\textsc{Disj}_G\,|_{\mathcal{T}\times\mathcal{T}}\,(A'', B'')$, and report $\bigvee_{i=1}^{d} \textsc{Disj}_{\{0,1\}^k}(\mathbf{x}_i, \mathbf{y}_i) = 1$ if and only if $\textsc{Disj}_G\,|_{\mathcal{T}\times\mathcal{T}}\,(A'', B'') = 0$.

Now we argue for the correctness of the protocol $\mathcal{P}'$. Let $\textsc{Disj}_G\,|_{\mathcal{T}\times\mathcal{T}}\,(A'', B'') = 0$, that is, $A'' \cap B'' \neq \emptyset$. By Claim 17 and from the description of $\mathcal{P}'$, there exists $i \in [d]$ such that the lines $L_i : y - q_i = \frac{decimal(\mathbf{a}_i)-1}{decimal(\mathbf{a}_i)}(x - p_i)$ and $L'_i : x - p_i = decimal(\mathbf{b_i})$ intersect at a point in $G_{(p_i,q_i)}$, that is, the lines $y = \frac{decimal(\mathbf{a}_i)-1}{decimal(\mathbf{a}_i)}x$ and $x = decimal(\mathbf{b}_i)$ intersect at a point in $G_{(0,0)}$. Now, we can say that, there exists $i \in [d]$ such that $decimal(\mathbf{a}_i)$ divides $decimal(\mathbf{b_i})$, equivalently, $\phi(\mathbf{x}_i)$ divides $\phi(\bar{\mathbf{y}}_i)$. This implies $\mathbf{x}_i$ is a subset of $\bar{\mathbf{y}}_i$ (or $\mathbf{x}_i \cap \mathbf{y_i} = \emptyset$) for some $i \in [d]$. Hence, $\bigvee_{i=1}^{d} \textsc{Disj}_{\{0,1\}^k}(\mathbf{x}_i, \mathbf{y}_i) = 1$. The converse part, that is, $\bigvee_{i=1}^{d} \textsc{Disj}_{\{0,1\}^k}(\mathbf{x}_i, \mathbf{y}_i) = 1$ implies $\textsc{Disj}_G\,|_{\mathcal{T}\times\mathcal{T}}\,(A'', B'') = 0$ can be shown in the similar fashion.

Observe that the communication cost of protocol $\mathcal{P}'$ for $\textsc{Or-Disj}^d_{\{0,1\}^k}\,|_{S\times S}$ is same as that of protocol $\mathcal{P}$ for $\textsc{Disj}_G\,|_{\mathcal{T}\times\mathcal{T}}$, which is $o\left(d\frac{\log m}{\log\log m}\right) = o\left(d\frac{\log(n/d)}{\log\log(n/d)}\right) = o(dk)$ as $m = \sqrt{\frac{n}{d}}$ and $k = \Theta\left(\frac{\log(n/d)}{\log\log(n/d)}\right)$. This contradicts Proposition 20 which says that $R\left(\textsc{Or-Disj}^d_{\{0,1\}^k}\,|_{S\times S}\right) = \Omega(dk)$.

3.3 Proof of Theorem 14

With out loss of generality, we also assume that d divides n and, more over, n/d is a perfect square.

First, consider the problem $\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}$, where the objective of Alice and Bob is to learn each other's set. Note that $G \subset \mathbb{Z}^2$ with $|G| = n$ and $\mathcal{T} \subseteq 2^G$ with VC-Dim$(\mathcal{T}) = 2d$ are same as that constructed in Section 3.1. In $\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}$, Alice and Bob get two sets A and B, respectively, from $\mathcal{T}$ with a promise $|A \cap B| = d$. The objective of Alice (Bob) is to learn B (A). Observe that $R(\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}) = \Omega(d\log n)$ as there are $\Omega(m^d) = \Omega\left(\left(\sqrt{\frac{n}{d}}\right)^d\right)$ many candidate sets for the inputs of Alice and Bob. We prove the theorem by a reduction from $\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}$ to $\textsc{Int}_G\,|_{\mathcal{T}\times\mathcal{T}}$.

Let by contradiction consider a protocol $\mathcal{P}$ that solves $\textsc{Int}_G\,|_{\mathcal{T}\times\mathcal{T}}$ by using $o(d\log n)$ bits of communication. To solve $\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}$, Alice and Bob first run a protocol $\mathcal{P}$ and finds $A \cap B$. Now by Claim 17, it is possible for Alice (Bob) to determine B (A) by combining A (B) along with $A \cap B$, with out any communication with Bob (Alice). Now, we have a protocol $\mathcal{P}'$ that solves $\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}$ with $o(d\log n)$ bits of communication. However, this is impossible as $R(\textsc{Learn}_G\,|_{\mathcal{T}\times\mathcal{T}}) = \Omega(d\log n)$. Hence, we are done with the proof of Theorem 14.

4 Conclusion and Discussion

In this paper, we studied $\textsc{Disj}_n\,|_{\mathcal{S}\times\mathcal{S}}$ and $\textsc{Int}_n\,|_{\mathcal{S}\times\mathcal{S}}$ when $\mathcal{S}$ is a subset of $2^{[n]}$ and VC-dim$(\mathcal{S}) \leq d$. One of the main contributions of our work is the result (Theorem 6) showing that unlike in the case of d-$\textsc{SparseDisj}_n$ and d-$\textsc{SparseDisj}_n$ functions, there is no separation between randomized and deterministic communication complexity of $\textsc{Disj}_n\,|_{\mathcal{S}\times\mathcal{S}}$ and

$\textsc{Int}_n|_{\mathcal{S}\times\mathcal{S}}$ functions when VC-dim$(S) \leq d$. Note that we have settled both the one-way and two-way (randomized) communication complexities of $\textsc{Int}_n|_{\mathcal{S}\times\mathcal{S}}$ when VC-dim$(\mathcal{S}) \leq d$ (Theorem 6 (1) and (3)). In the context of $\textsc{Disj}_n|_{\mathcal{S}\times\mathcal{S}}$, we have settled the one-way (randomized) communication complexity. The two-way communication complexity for $\textsc{Disj}_n|_{\mathcal{S}\times\mathcal{S}}$ is tight up to factor $\log\log\frac{n}{d}$ (See Theorem 6 (2)). However, we believe that the factor of $\log\log\frac{n}{d}$ should not be present in the statement of Theorem 6 (2).

▶ **Conjecture 21.** *There exists $\mathcal{S} \subseteq 2^{[n]}$ with VC-dim$(\mathcal{S}) \leq d$ and $R(\textsc{Disj}_n|_{\mathcal{S}\times\mathcal{S}}) = \Omega\left(d\log\frac{n}{d}\right)$.*

Recall $G \subset \mathbb{Z}^2$ with $|G| = n$ and $\mathcal{T} \subseteq 2^G$ with VC-Dim$(\mathcal{T}) = 2d$ construction from Section 3.1, that served as the hard instance for the proof of Theorem 13 and Theorem 14. The same G and $\mathcal{T}$ can not be the hard instance for the proof of Conjecture 21 because of the following result.

▶ **Theorem 22.** *Let us consider $G \subset \mathbb{Z}^2$ with $|G| = n$ and $\mathcal{T} \subseteq 2^G$ with VC-Dim$(\mathcal{T}) = 2d$ as defined in Section 3.1. Also, recall the definition of $\mathcal{T}_1$ and $\mathcal{T}_2$. There exists a randomized communication protocol that can, $\forall A \in \mathcal{T}_1$ and $\forall B \in \mathcal{T}_2$, can compute $\textsc{Disj}_G|_{\mathcal{T}\times\mathcal{T}}(A,B)$, with probability at least $2/3$, and uses $O\left(\frac{d\log d\log\frac{n}{d}}{\log\log\frac{n}{d}}\cdot\log\log\log\frac{n}{d}\right)$ bits of communication.*

We use the following observation to prove the above theorem.

▶ **Observation 23.** Let us consider the communication problem $\textsc{Gcd}_k(a,b)$, where Alice and Bob get a and b respectively from $\{1,\ldots,k\}$, and the objective is for both the players to compute $\gcd(a,d)$. Then there exists a randomized protocol, with success probability at least $1-\delta$, for $\textsc{Gcd}_k$ that uses $O\left(\frac{\log k}{\log\log k}\cdot\log\log\log k\cdot\log\frac{1}{\delta}\right)$ bits of communication.

Proof. We will give a protocol P for the case when $\delta = 1/3$ that uses $O\left(\frac{\log k}{\log\log k}\cdot\log\log\log k\right)$ bits of communication. By repeating $O\left(\log\frac{1}{\delta}\right)$ times protocol $\mathcal{P}$ and reporting the majority of the outcomes as the output, we will get the correct answer with probability at least $1-\delta$. Both Alice and Bob generate all the prime numbers $p_1, \ldots, p_t$ between 1 and k. From the Prime Number Theorem, we known that $t = \Theta\left(\frac{k}{\log k}\right)$. Alice and Bob separately, construct the sets S_a and S_b that contain the prime numbers that divides a and b respectively. Note that $|S_a|$ and $|S_b|$ is bounded by $O\left(\frac{\log k}{\log\log k}\right)$.[7] Alice and Bob compute $S_a \cap S_b$ by solving *Sparse Set Intersection* problem on input S_a and S_b using $O\left(\frac{\log k}{\log\log k}\right)$ bits of communication [2]. For $p \in S_a \cap S_b$, let $\alpha_{p,a}$ and $\alpha_{p,b}$ denote the exponent of p in a and b, respectively. Observe that

$$\gcd(a,b) = \prod_{p\in S_a\cap S_b} p^{\min\{\alpha_{p,a},\alpha_{p,b}\}}.$$

For each $p \in S_a$, Alice sends $\alpha_{p,a}$ to Bob. Number of bits of communication required to send the exponents of all the primes in $S_a \cap S_b$, is

[7] The product of first t prime numbers is $e^{(1+o(1))t\log t}$.

$$|S_a \cap S_b| + \sum_{p \in S_a \cap S_b} \log(\alpha_{p,a}) \leq O\left(\frac{\log k}{\log\log k}\right) + |S_a \cap S_b| \log\left(\frac{\sum_{p \in S_a \cap S_b} \alpha_{p,a}}{|S_a \cap S_b|}\right)$$
$$\leq O\left(\frac{\log k}{\log\log k}\right) + |S_a \cap S_b| \log\left(\frac{\log k}{|S_a \cap S_b|}\right)$$
$$\leq O\left(\frac{\log k}{\log\log k} \cdot \log\log\log k\right)$$

In the above inequalities, we used the facts that $|S_a \cap S_b| = O\left(\frac{\log k}{\log\log k}\right)$, $\sum_{p \in S_a \cap S_b} \alpha_{p,a} \leq \log k$ and $\log x$ is a concave function. After getting the exponents $\alpha_{p,a}$ of the primes $p \in S_a \cap S_b$ from Alice, Bob also sends the exponents $\alpha_{p,b}$ of the primes $p \in S_a \cap S_b$ to Alice using $O\left(\frac{\log k}{\log\log k} \log\log\log k\right)$ bits of communication to Alice. Since both Alice and Bob now know the set $S_a \cap S_b$, and the exponents $\alpha_{p,a}$ and $\alpha_{p,b}$ for all $p \in S_a \cap S_b$, both of them can compute $\gcd(a, b)$. Total number of bits communicated in this protocol is $O\left(\frac{\log k}{\log\log k} \log\log\log k\right)$. ◀

We will now give the proof of Theorem 22.

Proof of Theorem 22. Consider the case when $d = 1$. From the description of G and $\mathcal{T}$ in Section 3.1, we can say that $G = G_{(0,0)}$, where $G_{(0,0)} = \{(x, y) \in \mathbb{Z}^2 : 0 \leq x, y \leq \sqrt{n}\}$ [8]. Moreover, each set in $\mathcal{T}_1$ is a set of points present in a straight line of non-negative slope that passes through two points of $G_{(0,0)}$ with one point being $(0, 0)$ and each set in $\mathcal{T}_2$ is a set of points present in a vertical straight line that passes through exactly $\sqrt{n}$ many grid points. Keeping Claims 17 and 18 in mind, we will be done if we can show the existence of a randomized communication protocol for computing the function $\textsc{Disj}_G\ |_{\mathcal{T} \times \mathcal{T}}$, with probability of success at least $1 - \delta$ and number of bits communicated by the protocol being bounded by $O\left(\frac{\log n}{\log\log n} \cdot \log\log\log n \cdot \log\frac{1}{\delta}\right)$, for the special case when $d = 1$. This is because for general d, we will be solving d instances of the above problem, with the number of points in each grid being $\frac{n}{d}$ [9] and setting $\delta = \frac{1}{3d}$ for each of the d instances.

Protocol for $d = 1$

Alice and Bob get A and B from $\mathcal{T}_1$ and $\mathcal{T}_2$, respectively. Let A is generated by the straight line L_A and B is generated by L_B, where L_A is a straight line with non-negative slope and L_B is a vertical line. If L_A is a horizontal one : Alice just sends this information to Bob and then both report that $A \cap B \neq \emptyset$. If L_A is a vertical line : Alice sends this information to Bob and he reports $A \cap B \neq \emptyset$ if and only if L_B passes through origin. Now assume that L_A is neither a horizontal nor a vertical line. Let the equation of L_A be $y = \frac{p}{q}x$, where $1 \leq p, q \leq \sqrt{n}$, and p and q are relatively prime to each other. Also, let equation of Bob's line L_B be $x = r$, where $0 \leq r \leq \sqrt{n}$. Observe that $A \cap B \neq \emptyset$ if and only if L_A and L_B intersects at a point of $G_{(0,0)}$. Moreover, L_A and L_B intersects at a grid point if and only if q divides r and $1 \leq \frac{pr}{q} \leq \sqrt{n}$. So, Alice and Bob run the communication protocol for $\textsc{Gcd}_{\sqrt{n}}(q, r)$ to decide whether $q = \gcd(q, r)$. If $q = \gcd(q, r)$ and $1 \leq \frac{pr}{q} \leq \sqrt{n}$ (again Alice and Bob can decide this using $O(1)$ bits of communications) then $A \cap B \neq \emptyset$, otherwise $A \cap B = \emptyset$. Alice and Bob can decide if $q = \gcd(q, r)$ and $1 \leq \frac{pr}{q} \leq \sqrt{n}$ using $O(1)$ bits of communication.

[8] With out loss of generality assume that $\sqrt{n}$ is an integer

[9] Recall that we have assumed, without loss of generality, that d divides n.

The communication cost of our protocol is dominated by the communication complexity of $\textsc{Gcd}_{\sqrt{n}}(q, r)$, which is equal to $O\left(\frac{\log n}{\log\log n} \log\log\log n \log\frac{1}{\delta}\right)$ by Observation 23. ◀

A VC dimension, and Problems 1 and 2

VC dimension, and collection of d lines

Let $G \subset \mathbb{Z}^2$ be a set of n points in $\mathbb{Z}^2$. Observe, that the communication functions $\textsc{Disj}_G\,|_{\mathcal{L}\times\mathcal{L}}$ (defined in Problem 1) and $\textsc{Disj}_G\,|_{\mathcal{G}\times\mathcal{G}}$, where

$$\mathcal{G} = \left\{ G \cap \left(\bigcup_{1\le j\le d} \ell_j \right) \mid \{\ell_1, \ldots, \ell_d\} \in \mathcal{L} \right\},$$

are equivalent problems. Note that the set $\mathcal{L}$ is defined in Problem 1. Using standard geometric arguments, see [11, Chap. 10] and [5, Chap. 5], we can show that VC-dim$(\mathcal{G}) = 2d$.

VC dimension, and collection of d intervals

Let $X \subset \mathbb{Z}$ be a set of n points in $\mathbb{Z}$. Observe, that the communication functions $\textsc{Disj}_X\,|_{\mathcal{I}\times\mathcal{I}}$ (defined in Problem 2) and $\textsc{Disj}_X\,|_{\mathcal{F}\times\mathcal{F}}$, where

$$\mathcal{F} = \left\{ X \cap \left(\bigcup_{1\le j\le d} I_j \right) \mid \{I_1, \ldots, I_d\} \in \mathcal{I} \right\},$$

are equivalent problems. Note that the set $\mathcal{I}$ is defined in Problem 2. Using standard geometric arguments, as in the above case, we can show that VC-dim$(\mathcal{F}) = 2d$.

Testing Data Binnings

Abstract

Motivated by the question of data quantization and "binning," we revisit the problem of identity testing of discrete probability distributions. Identity testing (a.k.a. one-sample testing), a fundamental and by now well-understood problem in distribution testing, asks, given a reference distribution (model) $\mathbf{q}$ and samples from an unknown distribution $\mathbf{p}$, both over $[n] = \{1, 2, \ldots, n\}$, whether $\mathbf{p}$ equals $\mathbf{q}$, or is significantly different from it.

In this paper, we introduce the related question of *identity up to binning*, where the reference distribution $\mathbf{q}$ is over $k \ll n$ elements: the question is then whether there exists a suitable binning of the domain $[n]$ into k intervals such that, once "binned," $\mathbf{p}$ is equal to $\mathbf{q}$. We provide nearly tight upper and lower bounds on the sample complexity of this new question, showing both a quantitative and qualitative difference with the vanilla identity testing one, and answering an open question of Canonne [6]. Finally, we discuss several extensions and related research directions.

1 Introduction

Distribution testing [3], an area at the intersection of computer science, data science, and statistics which emerged as an offspring of the field of property testing [19, 15], concerns itself with the following type of questions: "upon observing independent data points originating from some unknown process or probability distribution $\mathbf{p}$, can we quickly and efficiently decide whether $\mathbf{p}$ satisfies some desirable property, or significantly violates this property?" One of the prototypical instances of this is the question of *identity testing* (also commonly known as one-sample testing, or goodness-of-fit), where one is given a reference distribution $\mathbf{q}$ and aims to test whether the unknown $\mathbf{p}$ is equal to this purported model $\mathbf{q}$, or far from it in statistical distance.

The sample and time complexity of identity testing have been thoroughly studied, and this question is now well-understood with regard to all parameters at play (see [16, 2, 18, 13, 11, 14, 10, 21, 4], or the surveys [5, 1]). However, at the very heart of the question's formulation lies a significant assumption: namely, that the *domain* of the distributions, generally taken to be the set $[n] \coloneqq \{1, 2, \ldots, n\}$, is the "right" representation of the data. In many situations, this is not the case: the observations are made with a given (often arbitrary) level of granularity, e.g., imposed by the accuracy of the measuring equipment; this may lead to falsely (over)accurate measurements, with non-significant precision in the observations. In such cases, the domain $[n]$ of both the model $\mathbf{q}$ and the distribution of the measurements $\mathbf{p}$

are somewhat of a red herring, and relying on it to perform identity testing may lead to a wrong answer, by introducing discrepancies where there is none. Instead, a more robust approach is to decide if $\mathbf{p}$ conforms to $\mathbf{q}$ on some suitable quantization of the data: which leads to the question, first suggested as an open question in [6] and introduced in this work, of *testing identity up to binning*.

In more detail, the question we consider is the following:

> **Identity-Up-To-Binning**$(n, \mathbf{q}, k, \varepsilon)$: Given a target number of bins k and a reference distribution $\mathbf{q}$ over $[k]$, a distance parameter ε, and i.i.d. samples from an unknown distribution $\mathbf{p}$ over $[n]$, is there a partition[1] of the domain in k intervals $I_1, \ldots, I_k$ such that $\mathbf{p}(I_j) = \mathbf{q}(j)$ for all $1 \leq j \leq k$, or is $\mathbf{p}$ at total variation distance at least ε from all distributions for which such a binning exists?

Before proceeding further, let us discuss some aspects of this formulation (which is illustrated in Figure 1). First of all, this formulation is intrinsically tied to discrete distributions (which aligns with the motivations laid out earlier, relating to discretization of observations): indeed, if $\mathbf{p}$ is continuous, then for all choices of $\mathbf{q}$ there always exists a suitable partition of the domain; so that $\mathbf{p}$ trivially satisfies the property. This formulation also allows us to test for some underlying structure, without caring about other irrelevant details of the distribution. For instance, setting $\mathbf{q} = (1/3, 1/3, 1/3)$ captures all distributions $\mathbf{p}$ with three disjoint groups of elements, separated by an arbitrary number of zero-probability elements, each with total probability mass $1/3$.

In terms of the range of parameters, we encourage the reader to keep in mind the setting where $k \ll n$ (or even where k is a relatively small constant), which captures fitting an over-accurate set of measurements to a simple model. Yet, we emphasize that even the case $k = n$ is of interest and does not collapse to identity testing. Indeed, due to our allowing empty intervals, the problem is both qualitatively and quantitatively different from identity testing, and can be interpreted as identity testing up to merging some clusters of adjacent domain elements and having zero-probability elements in the reference distributions for data points considered irrelevant (see Figure 2 for a simple illustration).

(a) Distribution $\mathbf{p}$ on $[n]$. **(b)** Distribution $\mathbf{q}$ on $[k]$.

Figure 1 An example, for $n = 20$ and $k = 4$. Here, $\mathbf{q} = (3/10, 0, 1/2, 1/5)$, and $\mathbf{p} = \frac{1}{50}(1, 2, 3, 0, 3, 3, 2, 1, 4, 3, 5, 4, 2, 0, 0, 3, 4, 2, 4, 4)$. A possible partitioning is $I_1 = \{1, 2, \ldots, 8\}$, $I_2 = \emptyset$, $I_3 = \{9, \ldots, 17\}$, and $I_4 = \{18, 19, 20\}$.

[1] Throughout this paper, by *partitions* we refer to ordered partitions with possibly empty subsets: i.e., a partition of $[n]$ in k sets is a sequence of pairwise disjoint sets $(I_1, \ldots, I_k)$ such that $\cup_{j=1}^{k} I_j = [n]$, with $|I_j| \geq 0$ for all j.

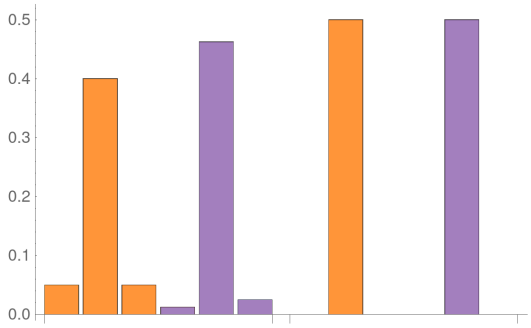

Figure 2 An example for $n = k = 6$. Here, $\mathbf{q} = (0, 1/2, 0, 0, 1/2, 0)$ (on the right), and $\mathbf{p} = (1/20, 2/5, 1/20, 1/80, 37/80, 1/40)$ (on the left). The reference distribution $\mathbf{q}$ focuses on the two modes of the distribution (writing off the other elements as "noise" or spurious), while the sampled distribution $\mathbf{p}$ also features those elements.

We further note that one could consider variants of this problem, each with a slightly different focus. The first variant, *simultaneous binning*, would feature a reference distribution $\mathbf{q}$ over $[n]$ (instead of a set of bin probabilities $\mathbf{q}$ on $[k]$), and ask about the existence of an interval partition $I_1, \ldots, I_k$ such that $\mathbf{p}(I_j) = \mathbf{q}(I_j)$ for all j. One interesting aspect of this variant is that it generalizes non-trivially to continuous distributions (or mixtures of continuous and discrete). However, even insisting for non-empty intervals I_j's, this formulation is only interesting for distributions putting significant probability mass on the first $k-1$ elements.[2] For $k = o(n)$, and in particular constant n, this is a significant restriction. A second variant, which suffers the same drawback but allows more flexibility, also provides a reference distribution $\mathbf{q}$ over $[n]$, but only asks about the existence of *independent binnings*: two interval partitions $I_1, \ldots, I_k$ and $I'_1, \ldots, I'_k$ such that $\mathbf{p}(I_j) = \mathbf{q}(I'_j)$ for all j.

We note that our upper bound (Theorem 1) easily extends to these two different variants as well; and our lower bound (Theorem 2) applies to the last independent binnings variant as well.

1.1 Our results and techniques

In this paper, we establish nearly matching upper and lower bounds on the **Identity-Up-To-Binning** problem. Our first result is an efficient algorithm for testing the property:

▶ **Theorem 1.** *For every domain size n, number of bins $1 \leq k \leq n$, and fixed reference distribution $\mathbf{q}$ over $[k]$, there exists a (computationally efficient) algorithm for testing identity-up-to-binning to $\mathbf{q}$ with sample complexity $O\big(k/\varepsilon^2\big)$, where $\varepsilon \in (0, 1]$ is the distance parameter.*

Crucially, this upper bound is *independent* of the underlying domain size n of the unknown distribution, and only depends, linearly, on the target number of bins k. This is to be compared to the "standard" identity testing problem, which is known to have sample complexity $\Theta(\sqrt{n})$. One may wonder if the dependence on the number of bins in the above theorem is necessary, or if one could hope to achieve a *sublinear* dependence on k. Our next (and main) result shows that a near-linear dependence is unavoidable, ruling out any strongly sublinear dependence on k:

[2] Indeed, unless both the reference $\mathbf{q}$ and the unknown $\mathbf{p}$ put $\Omega(\varepsilon)$ mass on $\{1, 2, \ldots, k-1\}$, a trivial partitioning with $I_j = \{j\}$ for $1 \leq j \leq k-1$ and $I_k = \{k, \ldots, n\}$ provides an immediate answer to the problem.

▶ **Theorem 2** (Informal version of Theorem 6). *For every $k \geq 1$, there exists $n = n(k)$ and an absolute constant $\varepsilon_0 > 0$ such that the following holds. There exists a reference distribution $\mathbf{q}$ over $[k]$ such that any algorithm for testing identity-up-to-binning to $\mathbf{q}$ to distance ε_0 must have sample complexity $\Omega\big(k^{1-o(1)}\big)$.*

Note that by standard techniques, this readily implies a lower bound of $\Omega\big(k^{1-o(1)}/\varepsilon\big)$, for all $\varepsilon \in (0, \varepsilon_0]$. We further conjecture the tight bound to be $\Omega\big(k/\varepsilon^2\big)$ (i.e., matching our upper bound). It is worth noting that the obvious and natural approach, a reduction from (standard) identity testing, would fall short of this goal, as it would only lead to a much weaker $\Omega(\sqrt{k}/\varepsilon^2)$ lower bound.

Our techniques

Our upper bound proceeds via the "testing-by-learning" paradigm. Specifically, given a reference distribution $\mathbf{q}$ over $[k]$, and sample access to an unknown distribution $\mathbf{p}$ over $[n]$, we learn a hypothesis distribution $\hat{\mathbf{p}}$ such that, informally, for every binning of $[n]$ into k intervals, the distributions $\mathbf{p}$ and $\hat{\mathbf{p}}$ are close. (More formally, the distribution $\hat{\mathbf{p}}$ is close to $\mathbf{p}$ in $\mathcal{A}_k$-distance, which we define later.) Since we have exact access to $\hat{\mathbf{p}}$, we can enumeratively test every potential binning. Although this does not save on the query complexity, we are able to use dynamic programming to find the best binning in time polynomial in n and k.

The proof of our lower bound is significantly more involved and proceeds in three stages, which we outline here. We first show that, if n is sufficiently large as a function of k, then we may assume that the algorithm only looks at the ordering of the samples received from $[n]$, instead of at their actual "names" (we refer to the ordering as the *ordered fingerprint* of the sample). Our bound uses a Ramsey theory argument very similar to that of [12].

We then show, for every integer m, the existence of two different distributions $\mathbf{p}'$ and $\mathbf{q}'$ over $[\mathrm{poly}(m) \cdot 2^m]$ such that (i) $\mathbf{p}'$ and $\mathbf{q}'$ are far in total variation distance, and (ii) given the ordered fingerprint of m samples generated by one of $\mathbf{p}'$ and $\mathbf{q}'$, it is information-theoretically impossible to determine which of $\mathbf{p}'$ and $\mathbf{q}'$ generated the ordered fingerprint. There are 2^m such ordered fingerprints, one for every composition of m, so it is unclear if the support size of the distributions in this claim can be significantly reduced. While this is an independently interesting problem, any progress on this problem would only directly result in a decrease of the $o(1)$ exponent in our main theorem.

Finally, using the above pair of distributions as "buckets" of two distributions $\mathbf{p}$ and $\mathbf{q}$, respectively, we show that any algorithm distinguishes $\mathbf{p}$ and $\mathbf{q}$ and only considers ordered fingerprints must have access to at least $m + 1$ samples from at least one of the (assuming m is independent of k) $\Omega(k)$ buckets. By collision bounds for the generalized birthday problem (see also [20] for more formal statements), with high probability we need a sample size of $\Omega(k^{1-1/(m+1)})$ to ensure that the algorithm succeeds.

1.2 Future directions

We conclude with a few research directions we deem particularly promising. A first natural question is to understand the analogue of the **Identity-Up-To-Binning** problem for *closeness* testing, that is, when both $\mathbf{p}$ (over $[n]$) and $\mathbf{q}$ (over $[k]$) are unknown and available only through i.i.d. samples. This would in particular capture situations where data is collected from two different sources (or sensors), each using a different discretization scheme or with different precision, and one aims at deciding whether the underlying distributon is the same.

Another avenue is to consider the *tolerant* testing version of the problem, that is, to decide whether $\mathbf{p}$ is *close* to a binning of $\mathbf{q}$ (versus far from any such binning). It is known that tolerant identity testing has significantly larger (namely, nearly linear in the domain size) sample complexity than identity testing; whether this is still the case for their identity-up-to-binning analogues is an intriguing question.

Lastly, it would be interesting to generalize the question to other partially-ordered domains (e.g., the hypergrid $[n]^d$, or the Boolean hypercube $\{0,1\}^n$), for the suitable notion of "interval" in these posets.

2 Preliminaries

All throughout the paper, we write log for the binary logarithm. Given integers n and k, we write $\mathcal{J}_{n,k}$ for the set of all $\binom{n+k-1}{n}$ partitions of $[n]$ in k consecutive (and possibly empty) pairwise disjoint intervals. Recall that the total variation distance between two distributions $\mathbf{p}, \mathbf{p}'$ over $[n]$ is $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}_1, \mathbf{p}_2) = \sup_{S \subseteq [n]} (\mathbf{p}(S) - \mathbf{p}'(S))$, and is equal to $\frac{1}{2}\sum_{i=1}^{n} |\mathbf{p}(i) - \mathbf{p}'(i)|$, half the ℓ_1 distance between their probability mass functions.

The **Identity-Up-To-Binning**$(n, \mathbf{q}, k, \varepsilon)$ problem we consider in this paper is then formally defined as follows. Given a reference distribution $\mathbf{q}$ on $[k]$, we consider the property

$$\mathcal{P}_{\mathbf{q}} \coloneqq \left\{ \mathbf{p}' \text{ distribution on } [n] \,:\, \exists (I_1, \dots, I_k) \in \mathcal{J}_{n,k}\,,\ \max_{j \in [k]} |\mathbf{p}'(I_j) - \mathbf{q}(j)| = 0 \right\} \tag{1}$$

The question is then, given a distance parameter $\varepsilon \in (0,1]$, to distinguish (i) $\mathbf{p} \in \mathcal{P}_{\mathbf{q}}$ from (ii) $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}}) > \varepsilon$, where $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}}) = \min_{\mathbf{p}' \in \mathcal{P}_{\mathbf{q}}} \mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathbf{p}')$. We will rely extensively, for our lower bounds, on the below fact, which allows us to lower bound $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}})$ by a more actionable quantity.

▷ Claim 3. For any distributions $\mathbf{p}$ and $\mathbf{q}$ (over $[n]$ and $[k]$, respectively) we have

$$\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}}) \geq \frac{1}{2}\,\mathrm{dist}(\mathbf{p}, \mathbf{q}) \coloneqq \min_{f} \sum_{j=1}^{k} \Big| \mathbf{q}(j) - \sum_{t : f(t) = j} \mathbf{p}(t) \Big|,$$

where the minimum is taken over all nondecreasing functions $f \colon [n] \to [k]$.

Proof. Fix $\mathbf{p}, \mathbf{q}$ as in the statement. One can think of such a nondecreasing f as defining a decomposition of $[n]$ into k disjoint (and possible empty) intervals $I_1, \dots, I_k$, where $I_j = f^{-1}(j)$. In particular, let $\mathbf{p}^* \in \mathcal{P}_{\mathbf{q}}$ such that $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathbf{p}^*) = \mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}})$, and $I_1^*, \dots, I_k^*$ the corresponding partition for $\mathbf{p}^*$. Define $f^* \colon [n] \to [k]$ from this partition by setting $f(t) \coloneqq \sum_{j=1}^{k} j \mathbb{1}_{I_j^*}(t)$: f^* is then non-decreasing, and

$$\sum_{j=1}^{k} \Big| \mathbf{q}(j) - \sum_{t : f^*(t) = j} \mathbf{p}(t) \Big| = \sum_{j=1}^{k} \big| \mathbf{q}(j) - \mathbf{p}(I_j^*) \big| = \sum_{j=1}^{k} \big| \mathbf{p}^*(I_j^*) - \mathbf{p}(I_j^*) \big| \leq \sum_{i=1}^{n} \big| \mathbf{p}^*(i) - \mathbf{p}(i) \big|$$

where the last equality is due to the fact that $\mathbf{p}^*(I_j^*) = \mathbf{q}(j)$ for all $j \in [k]$ (since $\mathbf{p}^* \in \mathcal{P}_{\mathbf{q}}$), and last inequality is the triangle inequality. Since the RHS equals $2\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathbf{p}^*)$, we get $\min_f \sum_{j=1}^{k} |\mathbf{q}(j) - \sum_{t : f(t) = j} \mathbf{p}(t)| \leq 2\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}})$. ◁

3 Algorithms

In this section, we prove Theorem 1, restated below:

▶ **Theorem 4.** *For any fixed reference distribution* $\mathbf{q}$ *over* $[k]$ *and number of bins* $1 \leq k \leq n$*, there exists a (computationally efficient) algorithm for* **Identity-Up-To-Binning**$(n, \mathbf{q}, k, \varepsilon)$ *with sample complexity* $O\big(k/\varepsilon^2\big)$*.*

Proof. We will use the following notion of $\mathcal{A}_\ell$*-distance*, which interpolates between Kolmogorov distance ($\ell = 2$) and (twice the) total variation ($\ell = n$) [9, 7, 13, 12]: for any two distributions $\mathbf{p}', \mathbf{q}'$ over $[n]$,

$$\|\mathbf{p}' - \mathbf{q}'\|_{\mathcal{A}_\ell} \coloneqq \max_{(I_1,\dots,I_\ell)\in\mathcal{J}_{n,\ell}} \sum_{j=1}^{\ell} |\mathbf{p}'(I_j) - \mathbf{q}'(I_j)| \tag{2}$$

One can check that this defines a *bona fide* norm. Further, it is known, from the VC inequality, that $O\big(\ell/\varepsilon^2\big)$ samples are sufficient to learn any distribution in $\mathcal{A}_\ell$-distance ε (and with failure probability 1/6) [9, 7], and, further, that the empirical estimator achieves this bound. Using this, the algorithm is as follows:

1. Learn the unknown $\mathbf{p}$ to $\mathcal{A}_k$-distance ε, with failure probability 1/6. Call the result (the empirical estimator, which is a distribution over $[n]$) $\hat{\mathbf{p}}$.
2. Compute the minimum $\Delta_{\mathbf{q}}(\mathcal{I}, \hat{\mathbf{p}}) \coloneqq \sum_{j=1}^{k} |\hat{\mathbf{p}}(I_j) - \mathbf{q}(j)|$ over all partitions $(I_1, \dots, I_k) \in \mathcal{J}_{n,k}$ in intervals such that $|I_j| > 0$ whenever $\mathbf{q}(j) > 0$.
3. If there exists $\mathcal{I}$ such that $\Delta_{\mathbf{q}}(\mathcal{I}, \hat{\mathbf{p}}) \leq \varepsilon$, return accept; otherwise, return reject.

Note that only the first step requires samples from $\mathbf{p}$, so that the sample complexity is indeed $O\big(k/\varepsilon^2\big)$. The second step is purely computational, and can be implemented in time $\mathrm{poly}(n, k)$ via a simple dynamic programming approach.

We now argue correctness. With probability at least 5/6, the first step produced a correct $\hat{\mathbf{p}}$, i.e., one that is ε-close to $\mathbf{p}$ in $\mathcal{A}_k$-distance; we hereafter assume this holds.

Completeness. Suppose $\mathbf{p} \in \mathcal{P}_{\mathbf{q}}$, and let $\mathcal{I}^* = (I_1^*, \dots, I_k^*) \in \mathcal{J}_{n,k}$ be any partition witnessing it. Note that this partition then satisfies $|I_j^*| > 0$ for all j such that $\mathbf{q}(j) > 0$, as otherwise the distance after binning is positive. Then,

$$\Delta_{\mathbf{q}}(\mathcal{I}^*, \hat{\mathbf{p}}) = \sum_{j=1}^{k} \big|\hat{\mathbf{p}}(I_j^*) - \mathbf{q}(j)\big| \leq \sum_{j=1}^{k} \big|\hat{\mathbf{p}}(I_j^*) - \mathbf{p}(I_j^*)\big| + \sum_{j=1}^{k} \big|\mathbf{p}(I_j^*) - \mathbf{q}(j)\big| \leq \|\hat{\mathbf{p}} - \mathbf{p}\|_{\mathcal{A}_k} \leq \varepsilon$$

the second-to-last inequality by definition of $\mathcal{A}_k$-distance and the fact that $\sum_{j=1}^{k} |\mathbf{p}(I_j^*) - \mathbf{q}(j)| = 0$. Therefore, the algorithm will find a good partition and output accept.

Soundness. Suppose now by contrapositive that the algorithm outputs accept. This means it found, in step 2, some partition $\mathcal{I}^* = (I_1^*, \dots, I_k^*) \in \mathcal{J}_{n,k}$ such that $\Delta_{\mathbf{q}}(\mathcal{I}^*, \hat{\mathbf{p}}) \leq \varepsilon/4$. But then,

$$\sum_{j=1}^{k} \big|\mathbf{p}(I_j^*) - \mathbf{q}(j)\big| \leq \sum_{j=1}^{k} \big|\mathbf{p}(I_j^*) - \hat{\mathbf{p}}(I_j^*)\big| + \sum_{j=1}^{k} \big|\hat{\mathbf{p}}(I_j^*) - \mathbf{q}(j)\big| \leq \|\hat{\mathbf{p}} - \mathbf{p}\|_{\mathcal{A}_k} + \Delta_{\mathbf{q}}(\mathcal{I}^*, \hat{\mathbf{p}}) \leq 2\varepsilon$$

the second-to-last inequality again by definition of $\mathcal{A}_k$-distance. We claim that this implies that $\mathbf{p}$ is ε-close (in total variation distance) to some $\mathbf{p}^* \in \mathcal{P}_{\mathbf{q}}$. Indeed, we can build $\mathbf{p}^*$ in a greedy fashion from $\mathbf{p}$: as long as there exist $I_{j_1}^*$, $I_{j_2}^*$ such that $\mathbf{p}(I_{j_1}^*) > \mathbf{q}(j_1)$ but $\mathbf{p}(I_{j_2}^*) < \mathbf{q}(j_2)$, we move $\delta \coloneqq \min(|\mathbf{p}(I_{j_1}^*) - \mathbf{q}(j_1)|, |\mathbf{p}(I_{j_2}^*) - \mathbf{q}(j_2)|)$ probability mass from

(arbitrary) elements of $I^*_{j_1}$ to an arbitrary element of $I^*_{j_2}$. Here, we used our condition on the partition found in step 2, which ensures $I^*_{j_2}$ is non-empty. This incurs total variation δ (from $\mathbf{p}$), and reduces $\sum_{j=1}^{k} |\mathbf{p}(I^*_j) - \mathbf{q}(j)|$ by 2δ. Repeating until it is no longer possible, we obtain the claimed $\mathbf{p}^*$, and therefore that $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}}) \leq \varepsilon$. ◀

▶ Remark 5. As mentioned in the introduction, it is straightforward to adapt the algorithm and argument to either the "simultaneous binning" and "independent binnings" variants of the problem, leading to the same sample complexity upper bound (and time complexity) for these related questions.

4 Lower Bounds

In this section, we prove our main theorem (Theorem 2), restated below:

▶ **Theorem 6.** *For every $k \geq 1$, there exists $n = n(k)$ such that the following holds. There exists a reference distribution $\mathbf{q}$ over $[k]$ such that any algorithm for* **Identity-Up-To-Binning**$(n, \mathbf{q}, k, \varepsilon)$ *must have sample complexity $\frac{k}{2^{O(\sqrt{\log k})}}$.*

At a high level, the proof of Theorem 6 consists of three parts:

(1) First, we show that, for every n, there is an $N(n)$ such that, if there is a algorithm that succeeds in the data binning problem over $[N(n)]$ with s samples, then there is an algorithm that succeeds in the data binning problem over $[n]$ with s samples, such that this latter algorithm only considers the "ordered fingerprint" of the sample. This approach, analogous to that of [12], uses Ramsey theory, and enables us to restrict ourselves to (simpler to analyze) order-based algorithms. (Proposition 9)

(2) Second, we show for every constant m, there exist $b(m)$ and two distributions $\mathbf{p}'$ and $\mathbf{q}'$ on $[b(m)]$ that (i) are "far from being cyclic shifts" of one another (which will allow us to argue about distance to being a binning on k intervals later), and (ii) cannot be distinguished from ordered fingerprints from s samples. The function $b(m)$ is exponential in m. (Lemma 12)

(3) Third, we consider the distributions $\mathbf{p}$ and $\mathbf{q}$ on $[k]$ constructed such that the distribution restricted to each block of $b(m)$ elements is $\mathbf{p}'$ and $\mathbf{q}'$, respectively, in the natural way. We show that (i) $\mathbf{p}$ is "far" from any binning of $\mathbf{q}$, and (ii) distinguishing these two distributions with ordered fingerprints requires seeing $m+1$ samples from one particular block. By folklore collision bounds, this implies a $\Omega(k^{1-1/(m+1)})$ sample lower bound for distinguishing $\mathbf{p}$ and $\mathbf{q}$ from ordered fingerprints. (Corollary 16)

Combining the three (applying 1 with n set to k, and m in 3 set to $\sqrt{\log k}$) then yields the theorem.

4.1 From samples to ordered fingerprints

The first step of our reduction will consist in "hiding" information from the algorithms. Roughly speaking, for the sake of our lower bound analysis we would like to argue that, without loss of generality, any testing algorithm can be assumed to only be given the *order relations* between the samples from the unknown distribution, instead of the samples themselves. For instance, instead of seeing four samples $12, 7, 98, 7$, we wish to restrict our analysis to algorithms which only see that $x_{(1)} = x_{(2)} < x_{(3)} < x_{(4)}$. Since we are drawing i.i.d. samples from the distribution, the order that the samples come in does not matter.

However, this simplifying assumption is not actually without loss of generality, and does not quite hold as stated: an algorithm *can* sometimes infer more information from the values of the samples from $\mathbf{p}$ than from their ordered relations alone. We will prove a weaker statement, sufficient for our purposes; in order to do so, we start by introducing some notions formalizing the aforementioned "order relations."

▶ **Definition 7** (Ordered fingerprints). *The* ordered fingerprint *of a sequence of s values in $[n]$ is an ordered frequency vector of the elements occurring in the sequence, with labels removed. Formally, for each element $i \in [n]$, let $\boldsymbol{F}_i$ be the number of times element i appears, and let $j_1 < j_2 < \ldots < j_t$ be the indices such that $\boldsymbol{F}_{j_i}$ is positive (so that t is the number of distinct elements in the sequence). The ordered fingerprint is then the ordered collection of positive integers $(\boldsymbol{F}_{j_1}, \boldsymbol{F}_{j_2}, \ldots, \boldsymbol{F}_{j_t})$ such that $\sum_{i=1}^{t} \boldsymbol{F}_{j_i} = s$.*

To later argue about indistinguishability of our instances, we will also rely on the below notion of s-way moments (induced by an ordered fingerprint):

▶ **Definition 8** (s-way moments). *Given a distribution $\mathbf{p}$ over $[n]$ and an ordered tuple of positive integers $F = (F_1, F_2, \ldots, F_t)$ such that $\sum_{i=1}^{t} F_i = s$, the probability that the ordered fingerprint on s samples is $(F_1, F_2, \ldots, F_t)$ is given by*

$$\mathbf{p}^F \coloneqq \binom{s}{F_1, F_2, \ldots, F_t} \sum_{1 \le i_1 < i_2 < \cdots < i_t \le n} \prod_{j=1}^{t} \mathbf{p}(i_j)^{F_j} \tag{3}$$

We call such an expression an s-way moment of $\mathbf{p}$. *Note that the s-way moments of $\mathbf{p}$ completely determine the distribution of the ordered fingerprint of s random samples drawn from $\mathbf{p}$. Thus, for two distributions $\mathbf{p}$ and $\mathbf{q}$, if $\mathbf{p}^F = \mathbf{q}^F$ for all F such that $|F| = s$, then $\mathbf{p}$ and $\mathbf{q}$ cannot be distinguished from ordered fingerprints on s samples.*[3]

We now state and prove the following lemma, which captures the intuition discussed above and will be the first component of our lower bound:

▶ **Proposition 9.** *For every $n \ge 1$ and $s \ge 1$, there exists $N \ge 1$ such that the following holds for every $k \ge 1$, reference distribution $\mathbf{q}$ over $[k]$, and $\varepsilon \in (0, 1]$. If there exists an algorithm $\mathcal{A}_N$ that, for every distribution $\mathbf{p}'$ over $[N]$, solves the problem* **Identity-Up-To-Binning**$(N, \mathbf{q}, k, \varepsilon)$ *with s samples from $\mathbf{p}'$, then there exists an algorithm $\mathcal{A}_n$ that, for every distribution $\mathbf{p}$ over $[n]$, solves the problem* **Identity-Up-To-Binning**$(n, \mathbf{q}, k, \varepsilon)$ *with s samples from $\mathbf{p}$. Moreover, $\mathcal{A}_n$ only considers the ordered fingerprint of the s samples.*

Proof. The argument is similar to that of Diakonikolas, Kane, and Nikishkin [12], and relies on a result of Conlon, Fox, and Sudakov:

▶ **Lemma 10** ([8]). *Given a set S and an integer t, let $\binom{S}{t}$ denote the set of subsets of cardinality t. For all positive integers, a, b, and c, there exists a positive integer N so that for any function $\chi\colon \binom{[N]}{a} \to [b]$, there exists $S \subseteq [N]$ with $|S| = c$ such that χ is constant on $\binom{S}{a}$.*

As in the proof of [12, Theorem 13], given n, s, we will invoke Lemma 10 to obtain a new domain size N, in a way detailed below: loosely speaking, a corresponds to the number of samples s, b to the number of possible decision (binary) functions from a given set of s

[3] Indeed, for every s, the $(s-1)$-way moments are linear combinations of s-way moments; we omit the details.

samples which only depend on the ordered fingerprint of those samples, and c to the target domain size s. We will use this to, given $\mathcal{A}_N$ (which induces a mapping χ from sets of s samples to such order-based decision functions), find a set $S \subseteq [N]$ of size n, and a monotone function $f\colon [n] \to [N]$ such that $f([n]) = S$. The algorithm $\mathcal{A}_s$ then runs the promised algorithm $\mathcal{A}_N$ on the distribution $f(\mathbf{p})$ obtained by applying f to the s samples. Since f is order-preserving, the distances will not change. Since we can assume that $\mathcal{A}_N$ is deterministic once we know which distinct samples we get from $[n]$, the fact that the induced χ is constant on $\binom{f([n])}{s}$ guarantees the output will be a function of the ordered fingerprint only.

However, we have an issue that [12] does not. When we draw a total of s samples, we likely will not get s distinct samples. [12] gets around this issue by "dividing" all elements of $[n]$ into sub-elements, and upon seeing an element in the sample, assign it to a uniformly random one of its sub-elements. However, our main parameter of interest k differs from theirs: if we applied this procedure to our problem, the bounds obtained would deteriorate. That is, while the $\mathcal{A}_k$-distance (the focus of [12]) would not change, the coarsening distance we consider here would.

We handle this issue as follows. Given an integer s, we will color all nonempty subsets of $[N]$ with *at most* s elements. This color associates to a set of s samples the function that $\mathcal{A}_N$ uses to accept or reject given the ordered fingerprint that accompanies these samples. Now, we apply Lemma 10 repeatedly. In our first application, we find a subset $S_s \subseteq [N]$ such that, conditioning on distinct samples, $\mathcal{A}_N$ has consistent behavior.[4] Now we remove all subsets that contain elements outside of S_s, and we apply Lemma 10 again to find a set $S_{s-1} \subseteq S_s$ such that $\mathcal{A}_N$'s behavior only depends on the ordered fingerprint given that in the s samples, there are at least $s-1$ distinct values seen. Continuing in this fashion, after applying Lemma 10 a total of s times, we arrive at a set S_1 (with $S_1 \subseteq S_2 \subseteq \cdots \subseteq S_s$) such that, conditioned on samples coming only from S_1, $\mathcal{A}_N$ depends only on the ordered fingerprint of the samples seen. In every application of the lemma, we have $a \leq s$, and since there are 2^s possible ordered fingerprints given s samples, we have $b \leq 2^{2^s}$. We set $c = n$ in our final application. ◀

4.2 Sequences far from being shifts of each other

As a building block from our lower bound construction, we will require the existence of (non-negative) sequences which are "far" from each other, in that any circular shift of the first remains far, in Hamming distance, from the second.

▶ **Definition 11** (Partial shifts). *Given an alphabet Σ and two strings x and y in Σ^n, we say that y is an r-*partial cyclic shift *of x if there exist an integer ℓ and a nondecreasing function $f\colon [n] \to [n]$ such that, for at least r indices i of $[n]$, $x_i = y_{(f(i)+\ell) \bmod n}$. That is, thinking of the symbols of y placed in a circle, y contains a substring of length r of x (without wrapping around more than once).*

For two distributions $\mathbf{p}$ and $\mathbf{q}$ over $[n]$, we then say that $\mathbf{q}$ is an *r-partial cyclic shift of $\mathbf{p}$ if the string $\mathbf{q}(1)\mathbf{q}(2)\cdots\mathbf{q}(n)$ is an r-partial cyclic shift of $\mathbf{p}(1)\mathbf{p}(2)\cdots\mathbf{p}(n)$.*

We observe that finding a witness to x and y being r-partial cyclic shifts of each other is equivalent to finding the *cyclic longest common subsequence* between x and y, which is a problem with applications in DNA sequencing [17]. With these notions in hand, we are ready to prove the key technical lemma underlying part 2 of our argument:

[4] In this case, the ordered fingerprint is the all ones vector of length s, so the functions are not very interesting.

▶ **Lemma 12.** *Let $m > 4$ be a positive integer, and $b = 5m^2 2^m$. Then there exist two distributions $\mathbf{p}'$ and $\mathbf{q}'$ over $[b]$ such that (i) $\mathbf{p}'$ and $\mathbf{q}'$ are not $(99b/100)$-partial cyclic shifts of each other, and (ii) $\mathbf{p}'$ and $\mathbf{q}'$ agree on all m-way moments.*

Proof. Let $\mathbf{p}$ be a probability distribution over $[b]$ such that its probability mass function takes the values $2/(\frac{5}{2}b)$ and $3/(\frac{5}{2}b)$ each on $b/2$ of the elements of $[b]$. Each m-way moment $\mathbf{p}^F$ can be expressed as a homogeneous polynomial in the b values $\mathbf{p}(i)$ of total degree m, such that each coefficient is 0 or $K_F := \binom{s}{F_1, F_2, \ldots, F_t}$; note that K_F is independent of $\mathbf{p}$. The number of terms of such a polynomial is at most $\binom{b+m-1}{m} \leq (b+m-1)^m \leq (2b)^m$. Thus, every m-way moment of $\mathbf{p}$ evaluates to an expression of the form $qK_F/(\frac{5}{2}b)^m$, where q is a integer such that $0 \leq q \leq (6b)^m$. Since there are 2^m m-way moments of $\mathbf{p}$, there are at most $(6b)^{m2^m}$ possible values of the m-way moments of $\mathbf{p}$.

For the claim about cyclic shifts, we use a counting argument. We will show that for any string $x \in \{2,3\}^b$, there are at most $2^{b/5}$ other strings that are $(99b/100)$-partial cyclic shifts of x. Indeed, any $(99b/100)$-partial cyclic shift y of x can be constructed by the following process: first, select $99b/100$ positions of x that will be present in y–these positions will form a witness. Next, select $99b/100$ positions of y that these bits of x will appear in, and a cyclic shift for these bits. Finally, select any values in $\{2,3\}$ for the remaining $b/100$ positions of y. Thus, the number of possible y's is at most

$$\binom{b}{b/100}^2 (99b/100) 2^{b/100} \leq 2^{2h(1/100)} 2^{b/50} \leq 2^{b/5}$$

where we have used the bound $\binom{n}{\alpha n} \leq 2^{nh(\alpha)}$, where $h(\alpha) = \alpha \log \alpha + (1-\alpha)\log(1-\alpha)$ is the binary entropy. Since there are a total of $\binom{b}{b/2} \geq 2^b/b$ strings of length b with an equal number of 2's and 3's, then for every b, we can find a set S of $2^{4b/5}/b$ strings of length b such that no two of them are $(99b/100)$-partial cyclic shifts of each other. We map strings over $\{2,3\}^b$ to distributions over $[b]$ in a natural way: given $x \in S$, we define the corresponding distribution $\mathbf{p}$ such that $\mathbf{p}(i) = x_i/(\frac{5}{2}b)$. Thus, we have $2^{4b/5}/b$ distributions over $[b]$, no two of which are $(99b/100)$-partial cyclic shifts of each other. Setting $b = 5m^2 2^m$, we then have

$$\frac{1}{b} 2^{4b/5} = \frac{2^{4m^2 2^m}}{5m^2 2^m} \geq 2^{3m^2 2^m} = (2^{3m})^{m2^m} > (30m^2 2^m)^{m2^m} = (6b)^{m2^m}.$$

Thus, by the pigeonhole principle there exist two distributions $\mathbf{p}'$ and $\mathbf{q}'$ over $[b]$ that are not $(99b/100)$-partial cyclic shifts of each other, yet such that $\mathbf{p}'$ and $\mathbf{q}'$ agree on all m-way moments. ◀

4.3 Constructing the hard-to-distinguish instances over $[n]$

For a fixed integer $m > 1$ (to be determined later) and sufficiently large k, let $\mathbf{p}'$ and $\mathbf{q}'$ be the two distributions over $[b]$ promised by Lemma 12, where $b = 5m^2 2^m$; and let $k' := k/b$. We will define $\mathbf{p}$ and $\mathbf{q}$ to be distributions over $[bk']$ in the following way: We partition $[bk']$ into blocks $B_1, B_2, \ldots, B_{k'}$, where $B_j = \{b(j-1)+1, b(j-1)+2, \ldots, bj\}$. Now $\mathbf{p}$ (resp. $\mathbf{q}$) is the distribution resulting from the following process:

- Pick a uniformly random element $i \in [k']$ and a random sample j from $\mathbf{p}'$ (resp. $\mathbf{q}'$).
- Output, as resulting sample from $\mathbf{p}$ (resp. $\mathbf{q}$), the element $(i-1)k' + j$.

Since $\mathbf{p}'(i)$ and $\mathbf{q}'(i)$ are in $\{4/(5b), 6/(5b)\}$ for $i \in [b]$, we have that $\mathbf{p}(i)$ and $\mathbf{q}(i)$ are always in $\{4/(5bk'), 6/(5bk')\}$ for all $i \in [bk']$.

We will prove that $\mathrm{d_{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}})$ is large. To facilitate this, recalling Claim 3 we will lower bound the distance of $\mathbf{p}$ to a binning of $\mathbf{q}$ in the following way:

$$\mathrm{d_{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}}) \geq \frac{1}{2}\,\mathrm{dist}(\mathbf{p}, \mathbf{q}) = \frac{1}{2}\min_{f} \sum_{i=1}^{bk'} \Big|\mathbf{q}(i) - \sum_{t:f(t)=i} \mathbf{p}(t)\Big|, \tag{4}$$

where the minimum is taken over all nondecreasing functions $f\colon [bk'] \to [bk']$. To use the language of a partition[5], the interval I_i is simply $f^{-1}(i)$. We show the following:

▷ Claim 13. There exists $\varepsilon_0 > 0$ such that, for $\mathbf{p}$ and $\mathbf{q}$ as described above, $\mathrm{d_{TV}}(\mathbf{p}, \mathcal{P}_{\mathbf{q}}) \geq \varepsilon_0$. (Moreover, one can take $\varepsilon_0 = 10^{-7}$.)

Proof. We will show that $\mathrm{dist}(\mathbf{p}, \mathbf{q}) \geq 1/(5 \cdot 10^6)$. We first rewrite the distance as $\mathrm{dist}(\mathbf{p}, \mathbf{q}) = \min_f \sum_{j=1}^{k'} d(B_j)$, where, using the same blocks as described earlier, we define

$$d(B_j) \coloneqq \sum_{i \in B_j} \Big|\mathbf{q}(i) - \sum_{t:f(t)=i} \mathbf{p}(t)\Big|$$

(suppressing its dependence on $\mathbf{p}, \mathbf{q}$, and f). We will call a block B_j *good* if $d(B_j) \leq 1/(2500k')$. Note that f need not be a function that maps elements of B_j to other elements of B_j. Since $\mathbf{p}(i)$ and $\mathbf{q}(i)$ are always in $\left\{\frac{4}{5bk'}, \frac{6}{5bk'}\right\}$, any element $i \in B_j$ such that $|f^{-1}(i)| \neq 1$ will contribute at least $\frac{2}{5bk'}$ to $d(B_j)$. Thus, we call an element i *good* if there is a unique t such that $f(t) = i$ and $\mathbf{q}(i) = \mathbf{p}(t)$. Since each element that is not good contributes $\frac{2}{5bk'}$ to $d(B_j)$, it follows that, in a good block, at most $1/(2500k')/(\frac{2}{5bk'}) = b/1000$ elements are not good, and therefore a good block must contain at least $999b/1000$ good elements.

Let B_j be a good block: it must be the case that for at least $999b/1000$ values of $g \in B_j$, there exists a unique t such that $f(t) = g$. Let $g_1 < g_2 < \ldots < g_v$ be the good elements in B_j (where $v \geq 999b/1000$), and let $t_1, t_2, \ldots, t_v$ be such that $f(t_i) = g_i$ for $i = 1, 2, \ldots, v$. By assumption, the distributions $\mathbf{p}$ and $\mathbf{q}$ are not $(99b/100)$-partial cyclic shifts of each other. Thus, for every i' and i'' where $i' < i''$, if $t_{i''} - t_{i'} < b$, then $i'' - i' \leq 99b/100$, or else the good elements of B_j and their preimages under f would be a witness to $\mathbf{p}'$ and $\mathbf{q}'$ being $(99b/100)$-partial cyclic shifts of one another. It follows that

$$t_v - t_1 \geq b + (999b/1000 - 99b/100) \geq (1 + 1/1000)b.$$

That is, every good block "uses up" a bit more than b elements of the domain of f. Since $f\colon [bk'] \to [bk']$ must be a nondecreasing function, we can have at most $\dfrac{bk'}{(1+1/1000)b} \leq (1 - 1/2000)k'$ good blocks. Thus, at least $k'/2000$ of the blocks are not good. It follows that

$$\mathrm{dist}(\mathbf{p}, \mathbf{q}) = \min_f \sum_{j=1}^{k'} d(B_j) \geq (k'/2000)(1/2500k') = 1/(5 \cdot 10^6),$$

as claimed. ◁

We are now in position to conclude the step 3 of our overall proof, establishing the following lower bound:

[5] Recall that the sets in the partition are allowed to be empty.

▶ **Theorem 14.** *There exists an absolute constant $\varepsilon_0 > 0$ such that, for every sufficiently large integers $k, m \geq 1$, there exists $\mathbf{q}$ over $[k$ for which testing* **Identity-Up-To-Binning**$(k, \mathbf{q}, k, \varepsilon_0)$ *from ordered fingerprints only requires $\Omega\big((k/m^2 2^m)^{1-1/m}\big)$ samples. (Moreover, one can take $\varepsilon_0 = 10^{-7}$.)*

Proof. Let $\mathbf{p}$ and $\mathbf{q}$ be the distributions described above, with $k = bk'$ and $\varepsilon_0 \coloneqq 10^{-7}$ as in Claim 13. We consider the problem **Identity-Up-To-Binning**$(k, \mathbf{q}, k, \varepsilon_0)$. We will show that any algorithm that takes too few samples, and only considers their ordered fingerprint, can distinguish between $\mathbf{p}$ and $\mathbf{q}$ with probability at most 1/3. Since $\mathrm{d}_{\mathrm{TV}}(\mathbf{p}, \mathbf{q}) > \varepsilon_0 \coloneqq 10^{-7}$ (and, of course, $\mathrm{d}_{\mathrm{TV}}(\mathbf{q}, \mathbf{q}) = 0$), this will establish our lower bound.

By Lemma 12, an ordered fingerprint from m samples from one of the k' blocks of size b gives no information in distinguishing $\mathbf{p}$ and $\mathbf{q}$. Further, it is immediate to see, from the definition of ordered fingerprints, that the following holds as well:

▷ Claim 15. Let $\mathbf{p}_1$ and $\mathbf{p}_2$ be two distributions over $[n]$, such that the distribution of fingerprints for $\mathbf{p}_b$ is given by $\{\boldsymbol{F}^b_j\}_{j\in[n]}$. Suppose there exists a partition of $[n]$ into $(I_1, I_2, \ldots, I_m)$ such that the sequences $\{\boldsymbol{F}^1_j\}_{j\in I_i}$ and $\{\boldsymbol{F}^2_j\}_{j\in I_i}$ are identically distributed for all i in $[m]$. Then $\mathbf{p}_1$ and $\mathbf{p}_2$ cannot be distinguished by ordered fingerprints.

This implies that if an algorithm sees at most m samples from every block, then it cannot distinguish between $\mathbf{p}$ and $\mathbf{q}$ with ordered fingerprints from this sample. It follows that any algorithm that distinguishes between $\mathbf{p}$ and $\mathbf{q}$ using ordered fingerprints must receive at least $m + 1$ samples from at least one of the k' many blocks.

To conclude, note that the distribution over the blocks is uniform; thus, by folklore collision estimates (see also Suzuki et al. [20]), the probability that one of the k' blocks contains $m+1$ samples is at most 1/3, given $O(k'^{1-1/(m+1)})$ samples. Since $k' = k/b = k/(5m^2 2^m)$, we get the claimed lower bound. ◀

Setting $m = \sqrt{\log k}$ in Theorem 14, we get:

▶ **Corollary 16.** *There exists an absolute constant $\varepsilon_0 > 0$ such that, for every sufficiently large integers $k \geq 1$, there exists $\mathbf{q}$ over $[k$ for which testing* **Identity-Up-To-Binning**$(k, \mathbf{q}, k, \varepsilon_0)$ *from ordered fingerprints only requires $\frac{k}{2^{O(\sqrt{\log k})}}$ samples.*

Abstract

We generalize the expander Chernoff bound to high-dimensional expanders. The expander Chernoff bound is an essential property of expanders, first proved by Gillman [9]. Given a graph G and a function f on the vertices, it states that the probability of f's mean sampled via a random walk on G to deviate from its actual mean, has a bound that depends on the spectral gap of the walk and decreases exponentially as the walk's length increases.

We are interested in obtaining an analog Chernoff bound for high order walks on high-dimensional expanders. A naive generalization of the expander Chernoff bound from expander graphs to high-dimensional expanders gives a very poor bound due to obstructions that occur in high-dimensional expanders and are not present in (one-dimensional) expander graphs. Because of these obstructions, the spectral gap of high-order random walks is inherently small.

A natural question that arises is how to get a meaningful Chernoff bound for high-dimensional expanders. In this paper, we manage to get a strong Chernoff bound for high-dimensional expanders by looking beyond the spectral gap.

First, we prove an expander Chernoff bound that depends on a notion that we call the "shrinkage of a function" instead of the spectral gap. In one-dimensional expanders, the shrinkage of any function with zero-mean is bounded by $\lambda(M)$. Therefore, the spectral gap is just the one-dimensional manifestation of the shrinkage.

Next, we show that in good high-dimensional expanders, the shrinkage of functions that "do not come from below" is good. A function does not come from below if from any local point of view (called "link") its mean is zero.

Finally, we prove a high-dimensional Chernoff bound that captures the expansion of the complex. When the function on the faces has a small variance and does not "come from below", our bound is better than the naive high-dimensional expander Chernoff bound.

1 Introduction

Expander graphs have been studied extensively for several decades. Essentially, these are graphs that are sparse yet highly connected. They have countless applications in computer science, mathematics and physics (see e.g. the surveys of [13] and [19]).

Since expanders are such a marvelous tool, it is believed that their generalization to higher dimensions is promising. Expanders consist of edges, which are sets of two vertices. In contrast, high-dimensional (abbreviated as HD) expanders consist of faces, which are sets of any amount of vertices, like edges, triangles, pyramids, and more. Since HD expanders expand at *all dimensions*, they are much stronger objects than expander graphs, which only expand at one dimension.

Recently, HD expanders have attracted a lot of attention. A notable example is the paper of [1] which solves a major open problem on counting the bases of matroids. The algorithms and proofs in their paper build on recent results about *random walks on HD expanders* (e.g. [16] and [15]).

In this paper, we study further aspects of random walks on HD expanders. In particular, we generalize the expander Chernoff bound to HD expanders. Generally speaking, this bound states that a random walk on an expander acts "as expected".

Let us present the (one-dimensional) expander Chernoff bound in a more precise way. There are many forms for this bound (see e.g. [10, 14, 18, 21, 12, 20, 5]), the form we present appears in [10] and is considered standard.

Let G be an undirected connected graph on vertices $V \coloneqq \{1, \ldots, n\}$ with positive weights on its edges. The graph is equivalent to a connected random walk with transition matrix M. Let π be the stationary distribution of M and let $\{w_i\}_{i=1}^{t}$ be a random walk according to M with initial distribution π. Let $f : V \to [0, 1]$ be a function on the vertices.

The general form of the graph generalization of Chernoff bound is as follows: for all $0 \leq \epsilon \leq 1$,

$$\mathbb{P}\Big[\big|\frac{1}{t}\sum_{i=1}^{t} f(w_i) - \mathbb{E}_{\pi}[f]\big| \geq \epsilon\Big] \leq 4 \cdot \exp\big(-\Omega(\epsilon^2 st)\big). \tag{1}$$

Note that for a better bound, we want s to be bigger.

The expander Chernoff bound states that inequality (1) holds for $s = 1 - \lambda_2(M)$, where $\lambda_2(M)$ is the second largest eigenvalue of M. This bound works best for graphs with λ_2 as close to 0 as possible. By Definition 7, these are exactly (one-sided) expander graphs.

As thoroughly explained in [21], this bound is a very useful tool in theoretical computer science. It has applications in a variety of areas like construction of efficient error-correcting codes, hardness of approximation, deterministic amplification, security amplification in cryptography, extractor construction, and more.

Since high-dimensional expanders are very promising, and the Chernoff bound for expander graphs is fundamental and extremely useful, we see great potential in further generalizing it to higher dimensions.

Such a generalization should provide a Chernoff bound for random walks on high-dimensional faces, that is similar to the bound we have for walks on vertices. Since high-dimensional expanders are better than one-dimensional, one could expect to obtain a generalization simply by applying the existing expander Chernoff bound to high-order walks.

However, this method results in a surprisingly poor bound, due to natural obstructions that occur even in the best high-dimensional expanders, and do not happen for one-dimensional expanders. Because of these obstructions, the spectral gap $1 - \lambda(M)$ of high-order random walks is inherently small.

In this paper, we manage to overcome this problem by looking beyond the spectral gap. First, we prove an expander Chernoff bound that depends on the "shrinkage of the function" f (see Definition 3) instead of the spectral gap. In one-dimensional expanders, the shrinkage of any function with zero-mean is bounded by $\lambda(M)$. Therefore, the spectral gap is just the one-dimensional manifestation of the shrinkage.

Next, we show that in good high-dimensional expanders, the shrinkage of functions that "do not come from below" (see Definition 1) is good. A function does not come from below if its mean is zero from any local point of view (called "link", see Definition 11). This criterion naturally generalizes zero-mean functions since there is only one local point of view on vertices and it includes all of them.

Thus, we obtain a high-dimensional expander Chernoff bound that works well for functions that have a small variance and do not come from below.

1.1 Background

Let us provide a simplified version of the definitions we need in order to present our results. The detailed definitions are deferred to Section 2.

Given a weighted undirected connected graph G, its normalized second largest eigenvalue in absolute value is denoted $\lambda(G)$. We say that G is a (two-sided) λ-*spectral expander* if $\lambda(G) < \lambda$.

We study a generalization of the above definition to higher dimensions, based on *simplicial complexes*. A pure d-dimensional simplicial complex X consists of sets of size $d+1$ and all of their subsets. These sets are called faces, and $X(i)$ denotes the set of faces of size $i+1$. Our complexes are equipped with a probability distribution π_d over the d-faces, which induces probability distributions π_k over k-faces. In addition, each π_k induces an inner-product on the subspace of k-cochains (functions from $X(k)$ to $\mathbb{R}$) denoted $C^k(X)$.

There are several different ways to define high-dimensional expanders. We use a notion called (two-sided) local-spectral expander, defined in [7], since it is the generalization of spectral-expanders to higher dimensions. Given a face $\tau \in X(i)$, the *link* of τ, denoted X_τ, is its local point of view. Formally, it is a simplicial complex obtained by taking the faces of X that contain τ and removing τ from them. A pure complex is a γ-*local-spectral expander* if for any link, the underlying graph is a γ-spectral expander (see Definition 13).

The high-order random walk we study is called the lazy upper random walk on k-faces, defined in [15] and denoted M_k^+. This walk naturally generalizes the standard lazy walk on graphs. It can move between two k-faces if they are both contained in the same $(k+1)$-face.

Given a function $f : X(k) \to \mathbb{R}$ and a face $\tau \in X(j)$, the localization of f on X_τ is the function $f_\tau : X_\tau(k-j-1) \to \mathbb{R}$ defined by $f_\tau(\sigma) = f(\tau \cup \sigma)$.

▶ **Definition 1.** *We say that a function $f : X(k) \to \mathbb{R}$ is* from level $j+1$ *if its expectation on the links of j-faces is zero. Formally, f is from level $j+1$ if $\mathbb{E}_{\pi_\tau}[f_\tau] = 0$ for all $\tau \in X(j)$.*

Informally, we say that f *does not come from below* if it is from a high level (e.g. from level k). Our high-dimensional Chernoff bound works best for functions f that do not come from below and have a small variance.

1.2 Our Contribution: Approach and Considerations

A bound for high-order random walks. Observe that the graph Chernoff bound is actually a bound for *random walks* on graphs. Hence, what we are looking for is a bound for *random walks* on high-dimensional expanders. Specifically, we study the lazy upper random walk, since it is highly related to the structure of the HD expander (see Definition 17).

Capturing the expansion. Given a HD γ-local-spectral expander X (see Definition 13), we want a bound that captures the expansion of X. We can apply the graph Chernoff bound (1) to the random walk M_k^+ and get a bound where $s = 1 - \lambda(M_k^+)$ (see Definitions 7). Unfortunately, this value of s is bounded away from 1 (in fact, it behaves like $1/k$, so it approaches 0 as k increases) and hence does not capture the expansion of X well.

According to [17], $\lambda(M_k^+)$ is large due to natural obstructions that occur in HD expanders and not in one-dimensional expander graphs. To bypass the obstructions, our Chernoff bound takes into account the entire spectrum of M_k^+.

Generalizing a one-dimensional Chernoff bound. We prove our high-dimensional Chernoff bound by generalizing a one-dimensional Chernoff bound. Given an expander graph G and a function f on the vertices (as in (1)), our key idea is to only look at eigenvalues λ_i that correspond to eigenvectors that are part of the orthogonal decomposition of f into eigenspaces. We prove a Chernoff bound that depends on the shrinkage of f, denoted $\lambda(f) = \max_i|\lambda_i|$ (see Definition 3), instead of $\lambda(G)$. When f is "good" (not an obstruction), $\lambda(f)$ is a small eigenvalue of G. By applying our one-dimensional Chernoff bound to M_k^+, we obtain a high-dimensional Chernoff bound that can see beyond $\lambda(M_k^+)$ and therefore capture the expansion of X well.

A bound for functions that do not come from below. The standard one-dimensional expander Chernoff bound depends on $\lambda(G)$, which is the largest eigenvalue in absolute value except for 1. Namely, the bound only considers eigenspaces orthogonal to $\text{span}\{\mathbf{1}\}$. Equivalently, it considers eigenspaces of zero-mean functions. These are exactly functions that their expectation on the links of (-1)-faces is zero (since the only (-1)-face is the empty face and its link is the entire set of vertices), which we call functions from level 0. Therefore, the existing bound is in fact an expander Chernoff bound for functions from level 0. Similarly, our HD expander Chernoff bound applies to functions from level j.

Moreover, as we will prove in Corollary 37, given a good enough γ-local-spectral expander, a function is from level $j+1$ if and only if its orthogonal decomposition into eigenspaces of M_k^+ only includes eigenvectors matching eigenvalues smaller than $\frac{k-j}{k+2} + o_\gamma(1)$. Namely, a function does not come from below if and only if its shrinkage is small. Hence, considering functions that do not come from below is highly natural.

Irregularity matters. Some expander Chernoff bounds apply only to regular graphs (see e.g. [12, 8]). In the case of HD expanders, even when the weights of the largest faces are uniform, the weights of other k-dimensional faces are usually not uniform, and hence M_k^+ is usually irregular. Therefore, it is important that our bound applies to irregular graphs too.

1.3 Results and Technique

Our main result is a Chernoff bound for HD expanders. When the function on the k-faces has a small variance and does not "come from below", our bound captures the expansion of the complex well. Namely, we present a Chernoff bound for M_k^+ in the form of (1), where s approaches 1 as k increases, as opposed to the naive bound where s approaches 0.

▶ **Theorem 2** (Main theorem, HD expander Chernoff bound, informal, for formal see Theorem 48)**.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \le k < d$, and assume that γ is small enough. Let $\pi = \pi_k$ be the probability distribution over $X(k)$ and denote $\pi_* := \min \pi_i$. Let $w_1, \ldots, w_t$ be a random walk according to M_k^+ with initial distribution π. Let $f : X(k) \to \mathbb{R}$ such that f is from level $j+1$ for some $-1 \le j < k$, and assume $\|f\|_\infty = 1$. Then the following hold:*

1. *If $\text{Var}_\pi(f) \le \pi_* \epsilon^2 c$ for a constant $c \in \mathbb{R}$ then inequality (1) holds for $s = \left(1 - \frac{k-j}{k+2} + o_\gamma(1)\right)^2$. In particular, for $j = k-1$, inequality (1) holds for $s = \left(1 - \frac{1}{k+2} + o_\gamma(1)\right)^2$.*
2. *If $\text{Var}_\pi(f) \le \pi_* \epsilon^2 c$ such that $4c \le \left(\frac{k+2}{k-j+o_\gamma(1)}\right)^2$, then inequality (1) holds for $s = 1$.*

   In particular, for $j = k-1$, if $c \le \frac{(k+2)^2}{4+o_\gamma(1)}$ then inequality (1) holds for $s = 1$.

Note that $o_\gamma(1)$ refers to a value that approaches 0 as γ goes to 0.

Extensions of the theorem. In the detailed version of this theorem, stated in Theorem 48, we also provide a bound for larger $\mathrm{Var}_\pi(f)$. Additionally, in Remark 49 we provide a bound for cases where f does come from below, but its mass on the lower eigenspaces is small.[1]

Comparison with the naive bound. One could try to achieve a similar bound by applying to M_k^+ a standard expander Chernoff bound like [10]. However, this standard bound depends on the spectral gap, which is low even in the best HD expanders. This method would give $s \approx 1/(k+2)$, which approaches 0 as k increases. We successfully overcome this problem by considering the shrinkage of f in functions that do not come from below, instead of the spectral gap. Indeed, we achieve a value of s that is either 1 or it approaches 1 as k grows.

Proof overview. To prove this theorem, we first define the *shrinkage* of a vector by an operator (Definition 3). The shrinkage is key to overcoming the obstructions which make $\lambda(M_k^+)$ large. We then prove a (one-dimensional) expander Chernoff bound that depends on the shrinkage of the function on the vertices, instead of on the graph's expansion (Theorem 4). Next, we apply to M_k^+ our expander Chernoff bound for shrinking functions. Finally, we bound the shrinkage of k-cochains (Proposition 5) to prove the HD expander Chernoff bound.

1.3.1 Defining the Shrinkage of a Vector

Let W be a finite-dimensional vector-space with inner-product $\langle \cdot, \cdot \rangle$. Let $M : W \to W$ be a self-adjoint operator. By the spectral theorem, $W = \bigoplus_i E_{\lambda_i}$ where E_{λ_i} is the eigenspace of M associated with the eigenvalue $\lambda_i \in \mathbb{R}$. Moreover, there exists an orthonormal basis of W that consists of eigenvectors of M.

▶ **Definition 3.** *Let $w \in W$. The* shrinkage *of w is $\lambda_M(w) \coloneqq \max_i\{|\lambda_i| \mid w \not\perp E_{\lambda_i}\}$. Equivalently, $\lambda_M(w)$ is the largest eigenvalue of M (in absolute value) that matches an eigenvector that spans w. Formally, let B be any orthonormal basis of W consisting of eigenvectors ϕ_i corresponding to eigenvalues λ_i respectively. Then $\lambda_M(w) \coloneqq \max_i\{|\lambda_i| \mid w \not\perp \phi_i\}$. For ease of notation, when M is clear from context, we simply write $\lambda(w)$.*

1.3.2 Expander Chernoff Bound for Shrinking Functions

We prove an expander Chernoff bound that depends on the shrinkage of the function on the vertices, $\lambda(f)$, instead of on the graph's expansion, $\lambda(G)$. As far as we are aware, this is the first bound of this kind. The bound is a generalization of a similar bound from [8].

▶ **Theorem 4** (Expander Chernoff bound that depends on $\lambda(f)$ instead of $\lambda(G)$, informal, for formal see Theorem 29)**.** *In the setting of inequality (1), assume the function $f : V \to \mathbb{R}$ satisfies $\mathbb{E}_\pi[f] = 0$ and $\|f\|_\infty = 1$, and denote $\pi_* \coloneqq \min \pi_i$. Then the following hold:*

1. *If $\mathrm{Var}_\pi(f) \le \pi_* \epsilon^2 c$ for some constant $c \in \mathbb{R}$ then inequality (1) holds for $s = (1 - \lambda(f))^2$.*
2. *Moreover, if $\mathrm{Var}_\pi(f) \le \pi_* \epsilon^2 c$ such that $c \le \dfrac{1}{4\lambda(f)^2}$ then inequality (1) holds for $s = 1$.*

In the detailed version of this theorem, stated in Theorem 29, we also provide a bound for when $\mathrm{Var}_\pi(f)$ is larger.

[1] Namely, denote $P_{k,j} \coloneqq P_{(\mathrm{Im}\, d_{j \nearrow k})^\perp}$ the orthogonal projection on the upper subspaces and $\ell \coloneqq \|f - P_{k,j} f\|_\pi$. Then the bound above holds if $\ell < \epsilon\sqrt{\pi_*}/2$ and $\mathrm{Var}_\pi(f) \le (\epsilon\sqrt{\pi_*} - 2\ell)^2 c$.

The proof is by showing a generic reduction from the problem of concentration for random walks to the well-studied problem of concentration for martingales (see e.g. [4]). This reduction is a generalization of [8, Theorem 1.6] and it may be of independent interest. As in [8], we then use Azuma's inequality to finish the proof.

1.3.3 Bounding the Shrinkage of k-cochains

The following proposition shows that functions that do not "come from below" shrink well, thereby relating the structure of a complex and its spectral properties.

▶ **Proposition 5** (Shrinkage of k-cochains, informal, for formal see Proposition 41)**.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \leq k < d$, and assume γ is small enough. Let $f : X(k) \to \mathbb{R}$ such that f is from level $j+1$ for some $-1 \leq j < k$. Then*

$$\lambda_{M_k^+}(f) \leq \frac{k-j}{k+2} + o_\gamma(1).$$

We prove the proposition by showing that the spectral decomposition (see Definition 24) and the combinatorial decomposition (see Definition 23) of $C^k(X)$, both originally defined in [17], are identical (see Theorem 36).

Furthermore, we calculate the number of functions that do not come from below and hence shrink well (see Corollary 45), to show that they are very common.

1.4 Related Work and Comparison

First of all, let us compare our expander Chernoff bound, stated in Theorem 29, to other related results. Compared to the bound from [8, Theorem 1.6], our bound improves and generalizes their proof in a few ways. First, our proof applies to any stationary distribution, not necessarily a uniform one. Secondly, our bound depends on $\lambda(f)$ (see Definition 3) instead of $\lambda(G)$. Thirdly, we provide a better bound for the case where $\mathrm{Var}_\pi(f)$ is small enough. Lastly, we maintain the dependence of the bound on $\mathrm{Var}_\pi(f)/\pi_*$ instead of bounding it by n. Note that the proof of [8] applies to vector-valued functions $f : V \to \mathbb{R}^N$, but we only prove the case of $N = 1$ for simplicity.

Compared to other similar bounds, the first advantage of our bound is that it depends on $\lambda(f)$ instead of $\lambda(G)$. Secondly, our proof has the advantage of being elementary and not use perturbation theory. Lastly, our bound includes a special case concerning $\mathrm{Var}_\pi(f) \leq \pi_* \epsilon^2 / 4\lambda(f)^2$, in which the bound does not depend on the spectral gap at all and therefore it is better than any other bound that we know of.

Since our bound depends on $\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*)$, it is a better fit for cases where $\mathrm{Var}_\pi(f)$ is small enough compared to ϵ (or, equivalently, ϵ is large enough), and where the stationary distribution is close to being uniform.

For example, compared to [10] (see (1)), the main advantage of our bound is that it depends on $(1-\lambda(f))^2$, which can sometimes be much larger than $1-\lambda_2(G)$. Moreover, our proof is elementary whereas their proof is based on perturbation theory. However, their bound does not depend on $\mathrm{Var}_\pi(f)$ at all, so it is better when $\mathrm{Var}_\pi(f)/\pi_*$ is large compared to ϵ.

Compared to [18, Theorem 1.1], both bounds are influenced by the variance of f, but our bound depends on $\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*)$ whereas their bound depends on $\|f\|_2^2$. So for most values of $\|f\|_2$, π_* and ϵ, e.g. when $\|f\|_2 > 8$, $\pi_* = 1/|V|$ and $\epsilon > 0.01$, our bound is better. Other than that, as with [10], their bound has $1-\lambda_2(G)$ while our bound has $(1-\lambda(f))^2$, and their proof is based on the non-elementary perturbation theory while our method has the advantage of being elementary.

Compared to [18, Section 4], their bound depends on $\|f\|_2^2$, whereas our bound depends on $\ln(4\operatorname{Var}_\pi(f)/\epsilon^2\pi_*)$, which is mostly better when ϵ is not too small. Moreover, their bound is only applicable for $\epsilon \le \|f\|_2^2$. Lastly, as before, their bound depends on $1-\lambda(G)$, and our bound depends on $(1-\lambda(f))^2$ which can be significantly smaller.

Secondly, let us compare our Chernoff bound for high-dimensional expanders, stated in Theorem 48, to related results. As far as we know, there are no existing high-dimensional Chernoff bounds. However, we can still compare our bound to the bounds we get by applying the existing (one-dimensional) graph Chernoff bounds to M_k^+. This comparison is covered in depth by the above paragraphs. In short, if f has a small enough variance and does not "come from below", our bound is better since it depends on $\lambda(f)$ instead of $\lambda(M_k^+)$ or $\lambda_2(M_k^+)$. Note that since all of the eigenvalues of M_k^+ are non-negative, $\lambda(f) \le \lambda(M_k^+) = \lambda_2(M_k^+)$.

Finally, our work in Section 5 improves some results from [17]. Corollary 39 improves [17, Theorem 5.9] (stated here as Proposition 19). It shows that the set containing the spectrum of M_k^+ is even smaller than what was known before. As a consequence, corollary 40, which gives an upper bound on $\|(M_k^+)^i\phi\|$, improves [17, Corollary 5.11].

1.5 Organization

This paper is organized as follows. Section 2 provides the relevant background in detail. In Section 3 we study the shrinkage of a vector denoted $\lambda(w)$. In Section 4 we provide a Chernoff bound for expander graphs which depends on the shrinkage of the function on the vertices. In Section 5 we study the shrinkage of vectors by high-order random walks and also improve some existing results. In Section 6 we prove our main result regarding Chernoff bound for high-dimensional expanders. In Appendix A we prove the the bound from Section 4. Due to space restrictions, some of the proofs are omitted and can be found in the full version of the paper.

2 Preliminaries

In this section, we present the relevant background about expander graphs, high-dimensional expanders, random walks, and decompositions of the subspace of k-cochains. We provide more details in the full version of this paper.

2.1 Expander Graphs and Random Walks

In this subsection, we define walk operators and the inner product-space they act on. Then, we define λ-spectral expander graphs.

In this paper, we will consider only finite state-spaces and only *time-homogeneous* Markov chains. A *random walk* M is a finite reversible Markov chain. A sequence of random variables according to M is also called random walk. Throughout this paper, for ease of presentation and connection with graphs, we say that a random walk is *connected* instead of irreducible. By the book of [11], a connected random walk has a positive and unique stationary distribution.

▶ **Definition 6** (Walk operator, $l_2(\pi)$)**.** *Let M be a connected random walk over state-space V and let π be its stationary distribution. We denote by $l_2(\pi)$ the vector-space of functions $f : V \to \mathbb{R}$ with inner product $\langle f,g\rangle_\pi = \sum_{i\in V}\pi(i)f(i)g(i)$. It is indeed an inner product since π is positive. The* walk operator *$M : l_2(\pi) \to l_2(\pi)$ is defined by $(Mf)(i) \coloneqq \sum_{j\in V} M(i,j)f(j)$.*

It is easy to see that a connected random walk operator M is self-adjoint. Therefore, by the spectral theorem, there is an orthonormal basis of $l_2(\pi)$ consisting of eigenvectors of M, and each eigenvalue of M is real. We are now ready to define expanders:

▶ **Definition 7** (λ-spectral expander graph). *Let G be an undirected connected graph with n vertices and let $\lambda_1 \geq \cdots \geq \lambda_n$ be its (real) eigenvalues. G is a* λ-spectral expander *if $\lambda(G) \leq \lambda$ where $\lambda(G) \coloneqq \max\{|\lambda_2|, |\lambda_n|\}$. Alternatively, G is a* one-sided λ-spectral expander *if $\lambda_2 \leq \lambda$.*

A small value of λ means that the graph is a better expander. λ also controls how well M shrinks functions, since $\|Mf\|_\pi \leq \lambda\|f\|_\pi$ for any f such that $\mathbb{E}_\pi[f] = 0$ (again by the spectral theorem). Therefore good expanders *shrink functions* well. The following proposition is well-known:

▶ **Proposition 8.** *Let G be an undirected connected graph. G is non-bipartite if and only if $\lambda(G) < 1$.*

2.2 High-Dimensional Expanders

High-dimensional expanders are a special type of abstract simplicial complexes. They are similar to graphs, but they consist of faces instead of just edges. Faces can be edges, but they can also be vertices, triangles, pyramids, etc. Let us provide the formal definitions.

A *face* τ is a set of vertices. The *dimension* of τ is defined by $\dim(\tau) \coloneqq |\tau| - 1$. Let X be a set of faces. X is an *abstract simplicial complex* if for every face $\tau \in X$, if $\sigma \subset \tau$ then $\sigma \in X$. We denote by $X(k)$ the set of faces of dimension $k \geq -1$. The *dimension* of X is $\max\{\dim(\tau) \mid \tau \in X\}$.

▶ **Definition 9** (Pure simplicial complex). *Let X be a d-dimensional abstract simplicial complex. X is called* pure *if for every $\sigma \in X$, there is a d-dimensional face τ such that $\sigma \subset \tau$.*

As a generalization of weighted graphs, we have weighted simplicial complexes. The weight of smaller faces is induced by the weight of larger faces to comply with the high-dimensional structure.

▶ **Definition 10** (Weighted simplicial complex). *Let X be a pure d-dimensional simplicial complex. Let π_d be a positive probability distribution over its d-dimensional faces. For each $-1 \leq k \leq d$, the induced probability distribution over the k-faces is denoted π_k, where $\pi_k(\sigma)$ is the probability to choose a d-face τ according to π_d and then get σ when uniformly choosing a k-face contained by τ. A pure simplicial complex equipped with a distribution is called a* weighted simplicial complex.

There are a few related but not equivalent definitions of HD expanders. Each one of them generalizes a different aspect of expander graphs. We stick to the definition that is related to random walks, called *local-spectral expander*. Basically, it says that from any local point of view (or *link*), the complex should be expanding.

▶ **Definition 11** (Link). *Let X be a pure d-dimensional simplicial complex. Let $\tau \in X(k)$ be a k-dimensional face. The* link *of τ, denoted X_τ, is a pure $(d-k-1)$-dimensional simplicial complex obtained by taking every face that contains τ and removing τ's vertices from it. Formally speaking, $X_\tau \coloneqq \{\sigma \setminus \tau \mid \tau \subseteq \sigma \in X\}$.*

If X is weighted, we give each top face in X_τ a probability proportional to its probability in X, normalized so that the sum of the probabilities is 1. The probability is well-defined since every face in X_τ is also a face in X.

▶ **Definition 12** (Skeleton). *Let X be an abstract simplicial complex. The* skeleton *of X, also called the* underlying graph*, is an undirected graph with $X(0)$ as its vertices and $X(1)$ as its edges. If X is weighted, the skeleton inherits its weights.*

▶ **Definition 13** (High-dimensional expander). *Let X be a pure complex. If the skeleton of every one of its links is a γ-spectral expander then X is a* γ-local-spectral expander*.*

▶ **Definition 14** (Degree). *Let X be an abstract simplicial complex and let $v \in X(0)$ be a vertex in X. The* degree *of v is the number of faces that contain it, namely, $|X_v|$. The* degree *of X is* $\max_{v \in X(0)} |X_v|$.

As with expander graphs, we are interested in infinite families of d-dimensional bounded degree γ-local-spectral expanders. Explicit constructions of such families exist, see [7, Lemma 1.5] for example. Moreover, we know that explicit constructions with a D-flat top distribution exist:

▶ **Definition 15** (D-flat). *Let π be a probability distribution over V and let $D \in \mathbb{N}$. We say that π is D-flat if there exists some $R \in \mathbb{R}$ such that $\pi_v \in \{\frac{1}{R}, \frac{2}{R}, \ldots, \frac{D}{R}\}$ for all $v \in V$.*

▶ **Proposition 16** ([6, Claim 6.2]). *For every $\gamma > 0$ and $d \in \mathbb{N}$ there exists an explicit infinite family of bounded degree d-dimensional complexes which are γ-local-spectral expanders. They have top distribution π_d that is D-flat, for $D \leq (1/\gamma)^{O(d^2/\gamma^2)}$.*

2.2.1 Random Walks on High-Dimensional Expanders

One can define many different random walks on a given HD expander. We are specifically interested in a walk that captures the expanding structure of the complex. Such walks were defined for the first time by [15].

▶ **Definition 17** (Lazy upper random walk). *Let X be a weighted pure d-dimensional simplicial complex. Let $0 \leq k < d$. Define M_k^+ to be the* lazy upper random walk *on the k-dimensional faces: For each $\sigma, \tau \in X(k)$, $M_k^+(\sigma, \tau)$ is the probability to choose a $(k+1)$-face $\eta \supset \sigma$ according to π_{k+1} and then get τ when uniformly choosing a k-face contained by η. Equivalently, $M_k^+ : X(k) \times X(k) \to \mathbb{R}$ is:*

$$M_k^+(\sigma,\tau) := \begin{cases} \frac{1}{k+2} & \sigma = \tau \\ \frac{\pi_{k+1}(\sigma \cup \tau)}{(k+2)\pi_k(\sigma)} & \sigma \cup \tau \in X(k+1) \\ 0 & \text{otherwise} \end{cases}$$

This walk is called lazy *since $M(\sigma, \sigma) > 0$ so it considers standing-still a possible move.*

Let us provide the following definition from [17, Theorem 5.6]:

▶ **Definition 18.** *Let X be a weighted pure d-dimensional γ-local-spectral expander. Define $\epsilon_0 = \gamma$ and $\epsilon_k = 2k(1 + 2k\sqrt{k})\epsilon_{k-1} + (k+1)\gamma$ for all $0 < k < d$. We say that γ is* small enough with respect to d *if $\epsilon_{k-1} \leq \frac{1}{2(1+2k\sqrt{k})}$ for all $0 < k < d$, and $\epsilon_{d-1} < \frac{1}{2\sqrt{d}}$.*

Note that $\lim_{\gamma \to 0} \epsilon_k = 0$. Therefore, we can construct a γ-local-spectral expander with a small enough γ by using the explicit construction from Proposition 16 with a sufficiently small γ.

The following proposition shows that even though the second largest eigenvalue of M_k^+ goes to 1 as k increases, we can go beyond that eigenvalue to achieve much better results. For example, when γ is small enough, the smallest eigenvalue of M_k^+ goes to 0 as k increases.

▶ **Proposition 19** ([17, Theorem 5.9]). *Let X be a weighted d-dimensional γ-local-spectral expander. If γ is small enough with respect to d then for every $0 \le k < d$:*

$$\mathrm{Spec}(M_k^+) \subseteq \{1\} \cup \bigcup_{j=0}^{k} \left[\frac{k+1-j}{k+2} - \frac{\sqrt{k+1}}{k+2}\epsilon_k, \frac{k+1-j}{k+2} + \frac{\sqrt{k+1}}{k+2}\epsilon_k \right]$$

where $\mathrm{Spec}(M_k^+)$ *is the set of eigenvalues of* M_k^+.

2.2.2 Decompositions of the Subspace of k-Cochains

Let X be an d-dimensional γ-local-spectral expander. For all $-1 \le k \le d$, define $C^k(X)$ to be the subspace of k-cochains, i.e., functions $\phi : X(k) \to \mathbb{R}$. Let $\pi = \pi_k$ be the probability distribution over $X(k)$. Let the inner-product of $C^k(X)$ be $\langle \phi, \psi \rangle \coloneqq \sum_{i \in X(k)} \pi(i)\phi(i)\psi(i)$ and let $\|\cdot\|$ be the induced norm. Note that as a walk operator, $M_k^+ : C^k(X) \to C^k(X)$.

For all $-1 \le k \le d$, define $C_0^k(X) \coloneqq \{\phi \in C^k(X) \mid \phi \perp \mathbf{1}\}$ where $\mathbf{1}$ is the constant 1 function. For all $-1 \le j \le k \le d$, the operator $d_{j \nearrow k} : C^j(X) \to C^k(X)$ is defined by:

$$d_{j \nearrow k}\phi(\sigma) \coloneqq \sum_{\substack{\tau \in X(j) \\ \tau \subseteq \sigma}} \phi(\tau)$$

for all $\phi \in C^j(X)$ and $\sigma \in C^k(X)$. Note that $d_{k \nearrow k}$ is the identity function. In addition, for $k < d$, we denote $d_k \coloneqq d_{k \nearrow k+1}$.

▶ **Lemma 20** ([17, Section 5.3]). *Let $0 \le j \le k$. Then $d_{j-1 \nearrow k}(C_0^{j-1}(X)) \subseteq d_{j \nearrow k}(C_0^j(X))$.*

This operator is highly related to the lazy upper random walk:

▶ **Lemma 21** ([17, Corollary 3.7]). *$d_k^* d_k = (k+2)M_k^+$ for all $-1 \le k < d$.*

In addition, $d_{j \nearrow k}$ and d_j are related in the following way:

▶ **Lemma 22** ([17, Proposition 5.5]). *$d_{j \nearrow k} = \frac{1}{(k-j)!} d_{k-1} \dots d_j$ for all $-1 \le j < k \le d$.*

The following definition implies a combinatorial orthogonal decomposition of $C^k(X)$.

▶ **Definition 23.** *For all $0 \le j \le k \le d$, let U_k^j be a subspaces of C_0^k that contains k-cochains that come from j-cochains but not from $(j-1)$-cochains. Formally,*

$$U_k^j \coloneqq d_{j \nearrow k}(C_0^j(X)) \cap (d_{j-1 \nearrow k}(C_0^{j-1}(X)))^\perp$$

By [17, Section 5.3], the following is an orthogonal decomposition:

$$C^k(X) = \mathrm{span}\{\mathbf{1}\} \oplus U_k^k \oplus U_k^{k-1} \oplus \cdots \oplus U_k^0.$$

This decomposition is *combinatorial* in the sense that each subspace U_k^j is related to the structure of X. Let us provide the definition of another orthogonal decomposition of $C^k(X)$, which is a *spectral* decomposition, relying on Proposition 19.

▶ **Definition 24.** *For all $0 \le j \le k < d$, we define the* neighborhoods *of M_k^+ to be:*

$$W_k^j \coloneqq \mathrm{span}\left\{ \phi \;\middle|\; M_k^+\phi = \mu\phi, \mu \in \left[\frac{k+1-j}{k+2} - \frac{\sqrt{k+1}}{k+2}\epsilon_k, \frac{k+1-j}{k+2} + \frac{\sqrt{k+1}}{k+2}\epsilon_k \right] \right\}$$

If γ is small enough then these subspaces intersect trivially and hence:

$$C^k(X) = \mathrm{span}\{\mathbf{1}\} \oplus W_k^k \oplus W_k^{k-1} \oplus \cdots \oplus W_k^0.$$

3 The Shrinkage of a Vector

Let W be a finite-dimensional vector-space with inner-product $\langle \cdot, \cdot \rangle$ and induced norm $\|\cdot\|$.

Given $u, w \in W$, we say that u is perpendicular to w and denote by $u \perp w$, if $\langle u, w \rangle = 0$. Similarly, $u \not\perp w$ if $\langle u, w \rangle \neq 0$. Moreover, given a subspace U, we denote $w \perp U$ if $w \perp u$ for all $u \in U$. We denote $w \not\perp U$ if there exists a vector $u \in U$ such that $w \not\perp u$.

Let $M : W \to W$ be a self-adjoint operator. By the spectral theorem, there exists an orthonormal basis of W that consists of eigenvectors of M.

▶ **Lemma 25.** *Let $w \in W$ and $k \geq 0$. Then $\lambda(M^k w) = \lambda(w)$.*

Proof. Let $k \geq 0$. By the definition of $\lambda(w)$ it is enough to show that $w \perp \phi \iff (M^k w) \perp \phi$ where ϕ is an eigenvector of M with eigenvalue $\lambda \neq 0$. This is true because $\langle M^k w, \phi \rangle = \langle w, M^k \phi \rangle = \langle w, \lambda^k \phi \rangle = \lambda^k \langle w, \phi \rangle$ since M^k is self-adjoint. ◀

The following lemmas explains why the shrinkage of a vector is called this way. They show that $\lambda(w)$ is an upper bound for how much M shrinks w.

▶ **Lemma 26.** *Let $w \in W$. Then $\|Mw\| \leq \lambda(w)\|w\|$.*

▶ **Lemma 27.** *Let $w \in W$ and $k \geq 0$. Then $\|M^k w\| \leq \lambda(w)^k \|w\|$.*

Proof. The proof is by induction on k together with Lemma 25 and Lemma 26. ◀

▶ **Lemma 28.** *Let $w \in W$ and let $B = \{\phi_i\}$ be an orthogonal basis of eigenvectors of M matching eigenvalues λ_i respectively. Let $C \subseteq B$ such that $w \in \text{span}(C)$. Then $\lambda(w) \leq \max_{\phi_i \in C} |\lambda_i|$.*

Proof. By definition $\lambda(w) = |\lambda_j|$ for some index j such that $w \not\perp \phi_j$. This implies that $\phi_j \in C$ since $w \in \text{span}(C)$. Therefore $\lambda(w) = |\lambda_j| \leq \max_{\phi_i \in C} |\lambda_i|$. ◀

4 Expander Chernoff Bound for Shrinking Functions

In the following section, we show an expander Chernoff bound that depends on the shrinkage of the function on the vertices $\lambda(f)$, instead of the graph's expansion. It allows us to see beyond the spectral gap and instead consider the entire spectrum of the expander. As far as we are concerned, it is the only bound of this kind. The proof is deferred to the Appendix.

▶ **Theorem 29** (Expander Chernoff bound that depends on $\lambda(f)$ instead of $\lambda(M)$)**.** *Let $M : l_2(\pi) \to l_2(\pi)$ be a connected non-bipartite random walk operator over state-space $V = \{1, \ldots, n\}$ with a stationary distribution π. Let $w_1, \ldots, w_t$ be a random walk according to M with initial distribution π and denote $\pi_* := \min_i \pi_i$. Let $f \in l_2(\pi)$ be a function satisfying $\mathbb{E}_\pi[f] = 0$. Then for every $\epsilon > 0$:*

$$\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \leq \begin{cases} 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2}\right) & \text{Var}_\pi(f) \leq \frac{\epsilon^2 \pi_*}{4\lambda(f)^2} \\ 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2 \mathcal{L}^2}\right) & \textit{otherwise} \end{cases}$$

where $\mathcal{L} := \left\lceil \frac{\ln(4\,\text{Var}_\pi(f)/\epsilon^2 \pi_*)}{1-\lambda(f)} \right\rceil$.

▶ Remark 30. We can prove a more general version of Theorem 29, appropriate for functions that have a small mass on eigenspaces associated with a large eigenvalue. The proof is the same, except we use the generalized version of Proposition 52 which appears in Remark 62. Define P as the orthogonal projection on eigenspaces associated with small eigenvalues, and denote $\ell := \|f - Pf\|_\pi$. If $\ell < \epsilon\sqrt{\pi_*}/2$, then we get the following expander Chernoff bound. For all $\epsilon > 0$:

$$\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \leq \begin{cases} 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2}\right) & \mathrm{Var}_\pi(f) \leq \left(\frac{\epsilon\sqrt{\pi_*} - 2\ell}{2\lambda(Pf)}\right)^2 \\ 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2\mathcal{L}^2}\right) & \text{otherwise} \end{cases}$$

where $\mathcal{L} := \left\lceil \frac{\ln(4\,\mathrm{Var}_\pi(f)/(\epsilon\sqrt{\pi_*} - 2\ell)^2)}{1 - \lambda(Pf)} \right\rceil$.

5 Shrinking Functions Do Not Come From Below

In this section, we discuss which functions M_k^+ shrinks well. We prove that these are exactly functions that do not come from below. In addition, we find what it means to "come from below" and how rare it is, by studying the two decompositions of $C_0^k(X)$ and the spectrum of M_k^+.

First, we provide an equivalent definition for functions from level $j+1$ (and for functions that do not come from below). The following lemmas relate functions that do not come from below to the subspace $(\mathrm{Im}\, d_{j\nearrow k})^\perp$.

▶ **Lemma 31.** *Let X be a d-dimensional γ-local-spectral expander. Let $-1 \leq j \leq k \leq d$ and $f \in C^k(X)$. Then $d^*_{j\nearrow k} f(\tau) = \mathbb{E}_{\pi_\tau}[f_\tau]$ for all $\tau \in X(j)$.*

Proof. We prove by induction on j. For $j = k$, we have that $d^*_{k\nearrow k} f(\tau) = f(\tau)$. On the other hand, $X_\tau = \varnothing$ and $\pi_\tau(\varnothing) = 1$. Therefore, $\mathbb{E}_{\pi_\tau}[f_\tau] = f_\tau(\varnothing) = f(\tau \cup \varnothing) = f(\tau) = d^*_{k\nearrow k} f(\tau)$ as needed. Next, we assume that the lemma holds for all $j < m \leq k$ and prove for j. Note that

$$\mathbb{E}_{\pi_\tau}[f_\tau] = \sum_{\sigma \in X_\tau(k-j-1)} \pi_\tau(\sigma) f_\tau(\sigma) = \sum_{\nu \in X(k), \tau \subseteq \nu} \frac{\pi(\nu)}{\pi(\tau)} f(\nu)$$

And by the induction assumption,

$$\begin{aligned} d^*_{j\nearrow k} f(\tau) &= \frac{1}{k-j} \cdot d^*_j d^*_{j+1\nearrow k} f(\tau) = \frac{1}{k-j} \cdot \sum_{\eta \in X(j+1), \tau \subseteq \eta} \frac{\pi(\eta)}{\pi(\tau)} d^*_{j+1\nearrow k} f(\eta) \\ &= \frac{1}{k-j} \cdot \sum_{\eta \in X(j+1), \tau \subseteq \eta} \frac{\pi(\eta)}{\pi(\tau)} \mathbb{E}_{\pi_\eta}[f_\eta] \\ &= \frac{1}{k-j} \cdot \sum_{\eta \in X(j+1), \tau \subseteq \eta} \frac{\pi(\eta)}{\pi(\tau)} \sum_{\nu \in X(k), \eta \subseteq \nu} \frac{\pi(\nu)}{\pi(\eta)} f(\nu) \\ &= \sum_{\nu \in X(k), \tau \subseteq \nu} \frac{\pi(\nu)}{\pi(\tau)} f(\nu) = \mathbb{E}_{\pi_\tau}[f_\tau]. \end{aligned}$$

◀

▶ **Lemma 32.** *Let X be a d-dimensional γ-local-spectral expander. Let $-1 \leq j \leq k \leq d$ and $f \in C^k(X)$. Then $f \in (\mathrm{Im}\, d_{j\nearrow k})^\perp$ if and only if f is from level $j+1$.*

Proof. First note that $f \in (\operatorname{Im} d_{j\nearrow k})^{\perp}$ if and only if $f \in \ker d^*_{j\nearrow k}$, if and only if $d^*_{j\nearrow k} f = 0$. Therefore, by Lemma 31, $\mathbb{E}_{\pi_\tau}[f_\tau] = 0$ for all $\tau \in X(j)$, which means f is from level $j+1$. ◀

Next, we provide a lemma that formulates the relation between functions that do not "come from below" and the subspaces U^j_k. But first, we need the following lemma.

▶ **Lemma 33.** *Let X be a d-dimensional γ-local-spectral expander. For all $-1 \le j \le k \le d$:*

$$C^k_0(X) \cap (d_{j\nearrow k} C^j_0(X))^{\perp} = (\operatorname{Im} d_{j\nearrow k})^{\perp}$$

Note that $\operatorname{Im} d_{j\nearrow k} := d_{j\nearrow k}(C^j(X)) = \{d_{j\nearrow k}(\psi) \mid \psi \in C^j(X)\}$ is the subspace of all k-cochains that come from j-cochain.

Proof. Since $(C^k_0(X) \cap (d_{j\nearrow k} C^j_0(X))^{\perp})^{\perp} = \operatorname{span}\{\mathbf{1}_k\} + d_{j\nearrow k} C^j_0(X)$, the lemma follows from the following equality: $d_{j\nearrow k}\mathbf{1}_j = \binom{k+1}{j+1}\mathbf{1}_k$. ◀

The following lemma shows that functions belong to $\bigoplus_{j<m\le k} U^m_k$ if and only if they are from level $j+1$.

▶ **Lemma 34.** *Let X be a d-dimensional γ-local-spectral expander. For all $-1 \le j \le k \le d$:*

$$\bigoplus_{j<m\le k} U^m_k = (\operatorname{Im} d_{j\nearrow k})^{\perp}$$

(we define the left-hand side to be the zero subspace when $j = k$).

Proof. The Lemma follows from Lemma 20, the definition of U^j_k, and Lemma 33. ◀

Now, let us study how well M^+_k shrinks functions that do not come from below. By the above lemmas, we already know that if a function does not come from below, it does not belong to U^j_k where j is low. Additionally, by the definition of W^j_k, we know that M^+_k shrinks $f \in W^j_k$ well when j is high. Therefore, our next step is to show how the two decompositions of $C^k_0(X)$: the spectral decomposition denoted W^j_k, and the combinatorial decomposition denoted U^j_k, are related.

From the work of [17] we already know that the projection of ϕ on W^j_k can be approximated by its projection on U^j_k:

▶ **Proposition 35** ([17, Theorem 5.10, simplified])**.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \le k < d$, and assume γ is small enough. For all $0 \le j \le k$ and $\phi \in C^k_0(X)$:*

$$(1 - b(k)\gamma)\|P_{U^j_k}\phi\| \le \|P_{W^j_k}\phi\| \le (1 + b(k)\gamma)\|P_{U^j_k}\phi\|$$

where $b(k)$ is an explicit positive constant such that $b(k)\gamma < 1$, and P is the orthogonal projection.

Let us prove that the two decompositions are actually identical:

▶ **Theorem 36** (Spectral decomposition and combinatorial decomposition are identical)**.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \le k < d$, and assume γ is small enough. Then $W^j_k = U^j_k$ for all $0 \le j \le k$.*

Proof. Let $0 \le j \le k$. We will prove that $U^j_k = W^j_k$ by showing that $(U^j_k)^{\perp} = (W^j_k)^{\perp}$. Let $\phi \in (U^j_k)^{\perp}$. Then $P_{U^j_k}\phi = 0$ and by Proposition 35 we get that $P_{W^j_k}\phi = 0$, and hence $\phi \in (W^j_k)^{\perp}$. Conversely, assume that $\phi \in (W^j_k)^{\perp}$, so $P_{W^j_k}\phi = 0$. By Proposition 35:

$$\frac{1}{1 + b(k)\gamma}\|P_{W^j_k}\phi\| \le \|P_{U^j_k}\phi\| \le \frac{1}{1 - b(k)\gamma}\|P_{W^j_k}\phi\|.$$

Hence $\|P_{U^j_k}\phi\| = 0$, and therefore $\phi \in (U^j_k)^{\perp}$. ◀

▶ **Corollary 37.** *Let X be a d-dimensional γ-local-spectral expander and assume γ is small enough. Let $-1 \leq j < k \leq d$ and $f \in C^k(X)$. Then f is from level $j+1$ if and only if $f \in W_k^{j+1} \oplus \cdots \oplus W_k^k$.*

Proof. The Corollary follows from Lemma 34, Lemma 32, and Theorem 36. ◀

Therefore, functions from "good neighborhoods" do not "come from below". By good neighborhoods we mean the subspaces W_k^j related to small eigenvalues of M_k^+.

We will now use Theorem 36 to improve some existing results. First, the following result improves the spectral decomposition of $C^k(X)$ for the case where X is a good enough expander. It easily follows from [17, Corollary 5.8]

▶ **Proposition 38.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \leq k < d$, and assume γ is small enough. Then for all $0 \leq j \leq k$:*

$$W_k^j = \operatorname{span}\left\{\phi \;\middle|\; M_k^+\phi = \mu\phi, \mu \in \left[\frac{k+1-j}{k+2} - \frac{\epsilon_k}{k+2}, \frac{k+1-j}{k+2} + \frac{\epsilon_k}{k+2}.\right]\right\}$$

Next, the following corollary improves [17, Theorem 5.9].

▶ **Corollary 39.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \leq k < d$, and assume γ is small enough. Then*

$$\operatorname{Spec}(M_k^+) \subseteq \{1\} \cup \bigcup_{j=0}^{k}\left[\frac{k+1-j}{k+2} - \frac{\epsilon_k}{k+2}, \frac{k+1-j}{k+2} + \frac{\epsilon_k}{k+2}\right].$$

Finally, the following corollary of Proposition 38 and Theorem 36 improves [17, Corollary 5.11].

▶ **Corollary 40.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \leq k < d$, and assume that γ is small enough. Then for all $i \in \mathbb{N}$ and $\phi \in C_0^k(X)$:*

$$\sum_{j=0}^{k}\left(\frac{k+1-j}{k+2} - \frac{\epsilon_k}{k+2}\right)^{2i}\left\|P_{U_k^j}\phi\right\|^2 \leq \|(M_k^+)^i\phi\|^2 \leq \sum_{j=0}^{k}\left(\frac{k+1-j}{k+2} + \frac{\epsilon_k}{k+2}\right)^{2i}\left\|P_{U_k^j}\phi\right\|^2$$

where P is the orthogonal projection.

Therefore if ϕ does not come from below then M_k^+ will shrink it better. For example, the best shrinking functions are from U_k^k.

Now, let us bound the shrinkage of f in a way that depends on its neighborhood.

▶ **Proposition 41.** *Let X be a d-dimensional γ-local-spectral expander, let $0 \leq k < d$, and assume γ is small enough. Let $f \in (\operatorname{Im} d_{j\nearrow k})^\perp$ for some $-1 \leq j < k$. Then*

$$\lambda_{M_k^+}(f) \leq \frac{k-j}{k+2} + \frac{\epsilon_k}{k+2}.$$

Proof. By Lemma 34, Theorem 36 and Proposition 38:

$$\begin{aligned} f \in (\operatorname{Im} d_{j\nearrow k})^\perp &= \bigoplus_{j<m\leq k} U_k^m = \bigoplus_{j<m\leq k} W_k^m \\ &= \operatorname{span}\left\{\phi \;\middle|\; M_k^+\phi = \mu\phi, \mu \in \left[\frac{1}{k+2} - \frac{\epsilon_k}{k+2}, \frac{k-j}{k+2} + \frac{\epsilon_k}{k+2}\right]\right\}. \end{aligned}$$

Lemma 28 finishes the proof. ◀

Next, our goal is to prove that there are many functions that shrink well. Therefore, we want to calculate the dimension of each W_k^j. First, let us prove the following lemmas.

▶ **Lemma 42.** *Let X be a d-dimensional γ-local-spectral expander and let $-1 \leq k < d$. If γ is small enough then d_k is one-to-one.*

Proof. Let μ be the smallest eigenvalue of M_k^+. By Corollary 39, $\mu \geq \frac{1-\epsilon_k}{k+2}$. Since γ is small enough, by Definition 18, $\epsilon_k < 1$ and therefore $\mu > 0$. Hence, M_k^+ is invertible. By Lemma 21, $d_k^* d_k = (k+2)M_k^+$ and therefore d_k is one-to-one. ◀

▶ **Lemma 43.** *Let X be a d-dimensional γ-local-spectral expander and let $-1 \leq j \leq k \leq d$. If γ is small enough then $\dim \operatorname{Im} d_{j\nearrow k} = \dim C^j(X)$ and $\dim(\operatorname{Im} d_{j\nearrow k})^\perp = \dim C^k(X) - \dim C^j(X)$.*

Proof. By Lemma 22, $d_{j\nearrow k} = \frac{1}{(k-j)!} d_{k-1} \dots d_j$. Therefore, since γ is small enough, by Lemma 42, $d_{j\nearrow k}$ is one-to-one. Hence, $\dim \ker d_{j\nearrow k} = 0$. By the rank-nullity theorem, $\dim \operatorname{Im} d_{j\nearrow k} + \dim \ker d_{j\nearrow k} = \dim C^j(X)$ and therefore $\dim \operatorname{Im} d_{j\nearrow k} = \dim C^j(X)$. Next, $(\operatorname{Im} d_{j\nearrow k})^\perp \oplus \operatorname{Im} d_{j\nearrow k} = C^k(X)$ implies that $\dim(\operatorname{Im} d_{j\nearrow k})^\perp = \dim C^k(X) - \dim \operatorname{Im} d_{j\nearrow k}$. Therefore, $\dim(\operatorname{Im} d_{j\nearrow k})^\perp = \dim C^k(X) - C^j(X)$. ◀

Since the combinatorial and spectral decompositions are equal, we can calculate the dimension of U_k^j instead of finding the dimension of W_k^j.

▶ **Proposition 44.** *Let X be a d-dimensional γ-local-spectral expander and let $0 \leq j \leq k \leq d$. If γ is small enough then $\dim U_k^j = |X(j)| - |X(j-1)|$.*

Proof. By [2, Proposition 2.43], $\dim(U_k^j \oplus \dots \oplus U_k^k) = \dim U_k^j + \dim(U_k^{j+1} \oplus \dots \oplus U_k^k)$. Applying Lemma 34, we get: $\dim(\operatorname{Im} d_{(j-1)\nearrow k})^\perp = \dim U_k^j + \dim(\operatorname{Im} d_{j\nearrow k})^\perp$. And by Lemma 43: $\dim C^k(X) - \dim C^{j-1}(X) = \dim U_k^j + \dim C^k(X) - \dim C^j(X)$. Therefore, $\dim U_k^j = \dim C^j(X) - \dim C^{j-1}(X) = |X(j)| - |X(j-1)|$. ◀

▶ **Corollary 45.** *Let X be a d-dimensional γ-local-spectral expander and let $0 \leq j \leq k < d$. If γ is small enough then $\dim W_k^j = |X(j)| - |X(j-1)|$.*

The above corollary shows that the amount of eigenvalues of M_k^+ in each neighborhood is not affected by the dimension k. We conclude that as j increases, W_k^j becomes much bigger, and hence most of the functions do not come from below.

Finally, we show how neighborhoods of different dimensions are connected.

▶ **Proposition 46.** *Let X be a d-dimensional γ-local-spectral expander and let $0 \leq j \leq k < d$. If γ is small enough then $d_k U_k^j = U_{k+1}^j$ and $d_k^* U_{k+1}^j = U_k^j$.*

The following corollary unravels what it means to "come from below" and provides a simpler decomposition of $C^k(X)$.

▶ **Corollary 47.** *Let X be a d-dimensional γ-local-spectral expander and let $0 \leq j \leq m \leq k < d$. If γ is small enough then:*

$$d_{m\nearrow k} W_m^j = d_{m\nearrow k} U_m^j = U_k^j = W_k^j \qquad \text{and} \qquad d^*_{m\nearrow k} W_k^j = d^*_{m\nearrow k} U_k^j = U_m^j = W_m^j.$$

In particular, for $m = j$, $W_k^j = d_{j\nearrow k} \ker d^*_{j-1}$ and therefore

$$C^k(X) = \operatorname{span}\{\mathbf{1}\} \oplus d_{0\nearrow k} \ker d^*_{-1} \oplus d_{1\nearrow k} \ker d_0^* \oplus \dots \oplus d_{k-1\nearrow k} \ker d^*_{k-2} \oplus \ker d^*_{k-1}.$$

6 Chernoff Bound for High-Dimensional Expanders

In this section, we apply our findings regarding high-order random walks and the Chernoff bound, to get a Chernoff bound for high-dimensional expander graphs. For functions that do not "come from below" and have a small variance, our bound is better than the naive HD Chernoff bound.

▶ **Theorem 48** (HD expander Chernoff bound). *Let X be a weighted d-dimensional γ-local-spectral expander, let $0 \le k < d$, and assume that γ is small enough. Let $\pi = \pi_k$ be the probability distribution over $X(k)$ and denote $\pi_* := \min_i \pi_i$. Let $w_1, \ldots, w_t$ be a random walk according to M_k^+ with initial distribution π. Let $f : X(k) \to \mathbb{R}$ such that f is from level $j+1$ (see Definition 1) for some $-1 \le j < k$. Then for all $\epsilon > 0$:*

$$\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \le \begin{cases} 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2}\right) & \mathrm{Var}_\pi(f) \le \frac{\epsilon^2\pi_*}{4h_k(j)^2} \\ 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2 \mathcal{L}^2}\right) & \textit{otherwise} \end{cases}$$

where $\mathcal{L} := \left\lceil \frac{\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*)}{1-h_k(j)} \right\rceil$, *and* $h_k(j) := \frac{k-j}{k+2} + \frac{\epsilon_k}{k+2}$ *where* $\lim_{\gamma\to 0}\epsilon_k = 0$ *(see Definition 18).*

Proof. First note that by Lemma 32, $f \in (\mathrm{Im}\, d_{j\nearrow k})^\perp$. By Lemma 34, $f \in C_0^k(X)$. By definition of $C_0^k(X)$, we know that $\mathbb{E}_\pi[f] = 0$. Hence, by Theorem 29, for every $\epsilon > 0$:

$$\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \le \begin{cases} 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2}\right) & \mathrm{Var}_\pi(f) \le \frac{\epsilon^2\pi_*}{4\lambda(f)^2} \\ 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2 \mathcal{Q}^2}\right) & \text{otherwise} \end{cases}$$

where $\mathcal{Q} := \left\lceil \frac{\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*)}{1-\lambda(f)} \right\rceil$. Now, by Proposition 41: $\lambda(f) \le \frac{k-j}{k+2} + \frac{\epsilon_k}{k+2} = h_k(j)$. Therefore $\mathcal{Q} \le \mathcal{L}$ and the theorem follows. ◀

▶ Remark 49. We can prove a more general version of this theorem, which applies to cases where f does come from below, but its mass on the lower subspaces is small. Denote $P_{k,j} := P_{(\mathrm{Im}\, d_{j\nearrow k})^\perp}$ the orthogonal projection on the upper subspaces. Denote $\ell := \|f - P_{k,j}f\|_\pi$ and assume $\ell < \epsilon\sqrt{\pi_*}/2$. Then for all $\epsilon > 0$:

$$\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \le \begin{cases} 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2}\right) & \mathrm{Var}_\pi(f) \le \left(\frac{\epsilon\sqrt{\pi_*} - 2\ell}{2h_k(j)}\right)^2 \\ 2\exp\left(-\frac{t\epsilon^2}{32\|f\|_\infty^2 \mathcal{L}^2}\right) & \text{otherwise} \end{cases}$$

where $\mathcal{L} := \left\lceil \frac{\ln(4\,\mathrm{Var}_\pi(f)/(\epsilon\sqrt{\pi_*} - 2\ell)^2)}{1-h_k(j)} \right\rceil$.

A Proving the Expander Chernoff Bound

Our proof is a generalization of [8]. As in [8], the proof is by reduction to the well-studied subject of martingales. First, let us provide the relevant definitions.

A.1 Preliminaries

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability-space: Ω is the sample space which is the set of possible outcomes of an experiment; $\mathcal{F}$ is a σ-algebra that is a set of events, where each event is a set of outcomes; and $\mathbb{P}$ is a probability measure function that assigns a probability to each event.

For example, in our case, the experiment is a random walk of length t on a graph $G = (V, E)$. A single outcome is a sequence of t vertices. The sample space is the set of possible sequences. The σ-algebra of our probability-space is the power set of the sample space. A set in this power set is an event (a set of walks), and the probability of an event is the probability that one of the walks in that event has occurred.

A probability-space can be equipped with a *filtration*, which is a monotone sequence of sub-σ-algebras $\mathcal{F}_0 \subseteq \mathcal{F}_1 \subseteq \cdots \subseteq \mathcal{F}$. Intuitively, each sub-$\sigma$-algebra $\mathcal{F}_i$ is the information known at time i (which includes what was known before that).

In our case, we are interested in the filtration generated by a random walk on the graph. Let $w_1, \ldots, w_t$ denote a random walk. Each w_i is a random variable from our sample space Ω to $V = \{1, \ldots, n\}$. The value of w_i given a sequence from Ω, is the i-th vertex in that sequence. The σ-algebra generated by $w_1, \ldots, w_i$ represents the information known after i steps and is denoted by $\sigma(w_1, \ldots, w_i)$. This σ-algebra is generated by the events $E_{v_1,\ldots,v_i}$ for all possible walks $(v_1, \ldots, v_i) \in V^i$, where $E_{v_1,\ldots,v_i}$ denotes the event of all possible outcomes that start with $v_1, \ldots, v_i$.

A sequence $\{X_n\}$ of random variables is said to be *adapted* to a filtration $\{\mathcal{F}_n\}$ if X_n is $\mathcal{F}_n$-measurable for all n. Informally, X_n is $\mathcal{F}_n$-*measurable* if X_n is known at time n. A random variable w_i is $\mathcal{F}_j$-measurable if $w_i^{-1}(v) \in \mathcal{F}_j$ for all $v \in V$, which means that w_i is known after j steps. Note that w_i is $\mathcal{F}_j$-measurable for $i \leq j$, and therefore $w_1, \ldots, w_t$ is adapted to the filtration $\{\sigma(w_1, \ldots, w_i)\}_{i=1}^t$.

We can now provide the definition of martingales and martingale difference sequences.

▶ **Definition 50** (Martingale, MDS). *Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability-space and let $\{\mathcal{F}_n\}$ be a filtration. Let $\{X_n\}$ be a sequence of random variables such that $\{X_n\}$ is adapted to $\{\mathcal{F}_n\}$ and $\mathbb{E}[|X_n|] < \infty$ for all n.*

1. *If $\mathbb{E}[X_{n+1} \mid \mathcal{F}_n] = X_n$ for all n then $\{X_n\}$ is a* martingale *with respect to $\{\mathcal{F}_n\}$.*
2. *If $\mathbb{E}[X_{n+1} \mid \mathcal{F}_n] = 0$ for all n then $\{X_n\}$ is an* MDS *(martingale difference sequence) with respect to the filtration $\{\mathcal{F}_n\}$.*

The following inequality is a generalization of the Chernoff bound to martingales.

▶ **Proposition 51** (Azuma's inequality [3]). *Let $X_0, \ldots, X_t$ be a martingale and suppose there is $c > 0$ such that $|X_i - X_{i-1}| \leq c$ for all $1 \leq i \leq t$ a.s. Then for all $\epsilon > 0$:*

$$\mathbb{P}(|X_t - X_0| \geq \epsilon) \leq 2 \exp\left(\frac{-\epsilon^2}{2tc^2}\right).$$

A.2 Reduction to Martingales

In this subsection we prove the following reduction from the problem of concentration for random walks to the problem of concentration for martingales. The proof is a generalization of the proof from [8, Theorem 1.6].

▶ **Proposition 52** (Reduction to martingales). *Let $M : l_2(\pi) \to l_2(\pi)$ be a connected non-bipartite random walk operator over state-space $V = \{1, \ldots, n\}$ with a stationary distribution π. Let $w_1, \ldots, w_t$ be a random walk according to M with initial distribution π and denote $\pi_* \coloneqq \min_i \pi_i$. Let $f \in l_2(\pi)$ be a function satisfying $\mathbb{E}_\pi[f] = 0$. Then for every $\epsilon > 0$, there is a martingale difference sequence $Z_1, \ldots, Z_t$ (see Definition 50) with respect to the filtration $\{\sigma(w_1, \ldots, w_i)\}_{i=1}^t$ such that $\frac{1}{t}\sum_{i=1}^t f(w_i) = W + \frac{1}{t}\sum_{i=1}^t Z_i$, where $|W| \leq \epsilon$ and each term Z_i satisfies $|Z_i| \leq 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(\|f\|_\pi / \epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}, 1 \right\} \right\rceil$.*

In order to prove this proposition, we first need to prove several lemmas. Let $K \in \mathbb{N}$. We will set it to its optimal value later in the subsection.

Our goal is to show that the sum $\sum_{i=1}^t f(w_i)$ is a martingale difference sequence with respect to the filtration $\{\sigma(w_1, \ldots, w_i)\}_{i=1}^t$, with a small error W. Ideally, we would have wanted $\mathbb{E}[f(w_{i+1}) \mid w_i]$ to be equal to 0. But in fact, the following holds:

▶ **Lemma 53.** *Let $1 \leq k \leq K$ and $1 \leq i \leq t-k$. Then $(M^k f)(w_i) = \mathbb{E}\left[(M^{k-1}f)(w_{i+1}) \;\middle|\; w_i\right]$.*

Proof. By definition of conditional expectation with respect to an event, we get that: $\mathbb{E}\left[(M^{k-1}f)(w_{i+1}) \;\middle|\; w_i\right] = \sum_{j=1}^n \mathbb{P}[w_{i+1} = j \mid w_i](M^{k-1}f)(j) = \sum_{j=1}^n M(w_i, j)(M^{k-1}f)(j)$ $= \big(M(M^{k-1}f)\big)(w_i) = (M^k f)(w_i)$. ◀

Therefore, to create an MDS out of $\sum_{i=1}^t f(w_i)$ we define the following random variables: $Y_1^{(k)} \coloneqq (M^{k-1}f)(w_1)$ for all $1 \leq k \leq K$, and $Y_i^{(k)} \coloneqq (M^{k-1}f)(w_i) - (M^k f)(w_{i-1})$ for all $1 < i \leq t - k + 1$.

▶ **Lemma 54.** *The following holds: $\sum_{i=1}^t f(w_i) = \sum_{k=1}^K \sum_{i=1}^{t-k+1} Y_i^{(k)} + \sum_{i=1}^{t-K} (M^K f)(w_i)$.*

Proof. Let $1 \leq m \leq t$ and $1 \leq k \leq K$. Then $\sum_{i=1}^m (M^{k-1}f)(w_i) = \sum_{i=1}^m Y_i^{(k)} + \sum_{i=1}^{m-1} (M^k f)(w_i)$, and the lemma is easy to prove by induction on K. ◀

The following corollary separates $\sum_{i=1}^t f(w_i)$ to an MDS part and an error part W. Later in this subsection, we will show that $\{Z_i\}$ is indeed an MDS and that W is small.

▶ **Corollary 55.** *Denote $W \coloneqq \frac{1}{t}\sum_{i=1}^{t-K} (M^K f)(w_i)$, and $Z_i \coloneqq \sum_{k=1}^{\min\{t-i+1, K\}} Y_i^{(k)}$ for all $1 \leq i \leq t$. Then $\frac{1}{t}\sum_{i=1}^t f(w_i) = W + \frac{1}{t}\sum_{i=1}^t Z_i$.*

Proof. By interchanging the order of summation,

$$\sum_{k=1}^K \sum_{i=1}^{t-k+1} Y_i^{(k)} = \sum_{i=1}^t \sum_{k=1}^{\min\{t-i+1, K\}} Y_i^{(k)} = \sum_{i=1}^t Z_i.$$

Lemma 54 finishes the proof. ◀

Our next step is to show that $\{Z_i\}$ is a martingale difference sequence with respect to the filtration $\{\sigma(w_1, \ldots, w_i)\}_{i=1}^t$. We prove it by showing that $\{Y_i\}$ is an MDS.

▶ **Lemma 56.** *For all* $1 \le k \le K$, $Y_1^{(k)}, \dots, Y_{t-k+1}^{(k)}$ *is an MDS with respect to the filtration* $\{\sigma(w_1, \dots, w_i)\}_{i=1}^{t-k+1}$.

Proof. First note that for all $0 \le k \le K$ and $1 \le i \le t-k$:

1. $(M^k f)(w_i)$ is $\sigma(w_1, \dots, w_i)$-measurable.
2. By the Markov property, $\mathbb{E}\big[(M^k f)(w_{i+1}) \bigm| w_1, \dots, w_i\big] = \mathbb{E}\big[(M^k f)(w_{i+1}) \bigm| w_i\big]$.

Let $1 \le k \le K$. By 1, $Y_i^{(k)}$ is $\sigma(w_1, \dots, w_i)$-measurable.

Secondly, we should prove that $Y_1^{(k)}, \dots, Y_{t-k+1}^{(k)}$ has the MDS property. Let $1 \le i \le t-k$. By 1, $(M^k f)(w_i)$ is $\sigma(w_1, \dots, w_i)$-measurable, hence by the stability property of conditional expectation:

$$\mathbb{E}\big[(M^k f)(w_i) \bigm| w_1, \dots, w_i\big] = (M^k f)(w_i). \tag{2}$$

Therefore, we have $\mathbb{E}\big[Y_{i+1}^{(k)} \bigm| w_1, \dots, w_i\big] = \mathbb{E}\big[(M^{k-1} f)(w_{i+1}) - (M^k f)(w_i) \bigm| w_1, \dots, w_i\big] = \mathbb{E}\big[(M^{k-1} f)(w_{i+1}) \bigm| w_i\big] - \mathbb{E}\big[(M^k f)(w_i) \bigm| w_1, \dots, w_i\big] = (M^k f)(w_i) - (M^k f)(w_i) = 0$ where the second equality is by 2 and the third equality is by Lemma 53 and (2). ◀

▶ **Corollary 57.** $Z_1, \dots, Z_t$ *is an MDS with respect to* $\{\sigma(w_1, \dots, w_i)\}_{i=1}^{t}$.

Now, let us bound the size of each Z_i. We need the following lemma:

▶ **Lemma 58.** *Let* M *be a connected random walk and let* $f \in l_2(\pi)$. *Then* $\|Mf\|_\infty \le \|f\|_\infty$.

Proof. Let $1 \le i \le n$. Then we have $|(Mf)(i)| \le \sum_j |M(i,j) f(j)| = \sum_j M(i,j)|f(j)| \le \sum_j M(i,j)\|f\|_\infty = \|f\|_\infty$, and therefore $\|Mf\|_\infty \le \|f\|_\infty$. ◀

▶ **Corollary 59.** *Let* $1 \le i \le t$. *Then* $|Z_i| \le 2K\|f\|_\infty$.

Proof. Since $|Z_i| = |\sum_{k=1}^{\min\{t-i+1,K\}} Y_i^{(k)}| \le \sum_{k=1}^{\min\{t-i+1,K\}} |Y_i^{(k)}| \le \sum_{k=1}^{K} |Y_i^{(k)}|$, we have

$$\begin{aligned} |Z_i| &\le \sum_{k=1}^{K} |(M^{k-1} f)(w_i) - (M^k f)(w_{i-1})| \le \sum_{k=1}^{K} \big(|(M^{k-1} f)(w_i)| + |(M^k f)(w_{i-1})|\big) \\ &\le \sum_{k=1}^{K} (\|M^{k-1} f\|_\infty + \|M^k f\|_\infty) \le \sum_{k=1}^{K} (\|f\|_\infty + \|f\|_\infty) = 2K\|f\|_\infty \end{aligned}$$

where the last inequality is by Lemma 58. ◀

Our last step before proving Proposition 52 is to bound the error $|W|$. First note that

▶ **Lemma 60.** *Let* $1 \le i \le n$. *Then* $\sqrt{\pi_i}|(M^K f)(i)| \le \lambda(f)^K \|f\|_\pi$.

Proof. By Lemma 27, we have that $\pi_i (M^K f)(i)^2 \le \sum_{j=1}^{n} \pi_j (M^K f)(j)^2 = \|M^K f\|_\pi^2 \le (\lambda(f)^K \|f\|_\pi)^2$ as needed. ◀

Let us now bound the error W.

▶ **Proposition 61.** $|W| \le \dfrac{\lambda(f)^K \|f\|_\pi}{\sqrt{\pi_*}}$.

Proof. From Lemma 60 we have:

$$|W| \leq \frac{1}{t}\sum_{i=1}^{t-K}|(M^K f)(w_i)| \leq \frac{1}{t}\sum_{i=1}^{t-K}\frac{1}{\sqrt{\pi_{w_i}}}\sqrt{\pi_{w_i}}|(M^K f)(w_i)|$$
$$\leq \frac{1}{t}\sum_{i=1}^{t-K}\frac{1}{\sqrt{\pi_{w_i}}}\cdot\lambda(f)^K\|f\|_\pi \leq \frac{t-K}{t}\lambda(f)^K\|f\|_\pi \max_i\frac{1}{\sqrt{\pi_i}} \leq \frac{\lambda(f)^K\|f\|_\pi}{\sqrt{\pi_*}}$$

where the last inequality is by definition of π_*. ◀

We can now prove Proposition 52.

Proof of Proposition 52. By Corollary 55: $\frac{1}{t}\sum_{i=1}^{t} f(w_i) = W + \frac{1}{t}\sum_{i=1}^{t} Z_i$ where

1. $W \coloneqq \frac{1}{t}\sum_{i=1}^{t-K}(M^K f)(w_i)$.
2. $Z_i \coloneqq \sum_{k=1}^{\min\{t-i+1,K\}} Y_i^{(k)}$ for all $1 \leq i \leq t$.

By Proposition 61, $|W| \leq \frac{\lambda(f)^K\|f\|_\pi}{\sqrt{\pi_*}}$. In order for $|W| \leq \epsilon$ to apply, we should choose K such that $\frac{\lambda(f)^K\|f\|_\pi}{\sqrt{\pi_*}} \leq \epsilon$. Note that by Proposition 8, $\lambda(f) < 1$. Therefore

$$K \geq \frac{\ln(\|f\|_\pi/\epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}. \tag{3}$$

By Corollary 57, $Z_1,\ldots,Z_t$ is an MDS with respect to $\{\sigma(w_1,\ldots,w_i)\}_{i=1}^t$. Moreover, by Corollary 59, $|Z_i| \leq 2K\|f\|_\infty$ for all $1 \leq i \leq t$. So to get the best bound on $|Z_i|$ we should choose the smallest K possible. Therefore, to comply with (3): $K \coloneqq \left\lceil \max\left\{\frac{\ln(\|f\|_\pi/\epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}, 1\right\}\right\rceil$ which yields the advertised bound on $|Z_i|$. ◀

▶ Remark 62. We can prove a more general version of this bound that applies to functions that most of their mass is on eigenspaces of small eigenvalues, and a small portion of their mass is on eigenspaces associated with large eigenvalues.

Let P be an orthogonal projection to a direct sum of some of the eigenspaces, such that $\lambda(Pf)$ is small and $\ell \coloneqq \|f - Pf\|_\pi$ is small too. Then $\|M^K f\|_\pi \leq \|M^K Pf\| + \|M^K(I-P)f\|_\pi \leq \lambda(Pf)^K\|Pf\|_\pi + \|(I-P)f\|_\pi \leq \lambda(Pf)^K\|f\|_\pi + \ell$. Therefore, in Lemma 60 we would get $\sqrt{\pi_i}|(M^K f)(i)| \leq \|M^K f\|_\pi \leq \lambda(Pf)^K\|f\|_\pi + \ell$. This means we would get that $|W| \leq \frac{\lambda(Pf)^K\|f\|_\pi + \ell}{\sqrt{\pi_*}}$ and therefore, for $\ell < \epsilon\sqrt{\pi_*}$ we get $|Z_i| \leq 2\|f\|_\infty\left\lceil \max\left\{\frac{\ln(\|f\|_\pi/(\epsilon\sqrt{\pi_*}-\ell))}{-\ln(\lambda(f))}, 1\right\}\right\rceil$.

A.3 Proof of Theorem 29

Proof. We prove an Expander Chernoff bound that depends on $\lambda(f)$. Let $\epsilon > 0$. Applying Proposition 52 with $\epsilon/2$ we get that there is an MDS $Z_1,\ldots,Z_t$ with respect to the filtration $\{\sigma(w_1,\ldots,w_i)\}_{i=1}^t$ such that $\frac{1}{t}\sum_{i=1}^t f(w_i) = W + \frac{1}{t}\sum_{i=1}^t Z_i$, where $|W| \leq \epsilon/2$ and each term

Z_i satisfies $|Z_i| \le 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(2\|f\|_\pi/\epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}, 1 \right\} \right\rceil$. In order to use Azuma's inequality, we first need to define a martingale out of our MDS $\{Z_i\}$. Let $X_0 = 0$ and $X_i \coloneqq X_{i-1} + Z_i$ for all $i \ge 1$. Then

$$|X_i - X_{i-1}| = |Z_i| \le 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(2\|f\|_\pi/\epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}, 1 \right\} \right\rceil, \tag{4}$$

$$\sum_{j=1}^{i} Z_j = \sum_{j=1}^{i} (X_j - X_{j-1}) = \sum_{j=1}^{i} X_j - \sum_{j=0}^{i-1} X_j = X_i - X_0. \tag{5}$$

▶ **Lemma 63.** *$X_1, \dots, X_t$ is a martingale with respect to $\{\sigma(w_1, \dots, w_i)\}_{i=1}^t$.*

Proof. First we'll prove that $X_1, \dots, X_t$ is adapted to the filtration, so we should prove that for all $i \ge 1$, X_i is $\sigma(w_1, \dots, w_i)$-measurable. Since $X_i = \sum_{j=1}^{i} Z_j$, it's enough to show that each Z_j is $\sigma(w_1, \dots, w_i)$-measurable when $j \le i$. From 57 we know that $Z_1, \dots, Z_t$ is an MDS with respect to our filtration, hence each Z_j is $\sigma(w_1, \dots, w_j)$-measurable. In addition, $\sigma(w_1, \dots, w_j) \subseteq \sigma(w_1, \dots, w_i)$ so each Z_j is also $\sigma(w_1, \dots, w_i)$-measurable. Therefore $X_1, \dots, X_t$ is adapted to the filtration.

Next we will prove that $X_1, \dots, X_t$ has the martingale property. Let $i \ge 1$. Since X_i is $\sigma(w_1, \dots, w_i)$-measurable, $\mathbb{E}[X_i \mid w_1, \dots, w_i] = X_i$ by the stability property of conditional expectation. In addition, since by Corollary 57 $Z_1, \dots, Z_t$ is an MDS, $\mathbb{E}[Z_{i+1} \mid w_1, \dots, w_i] = 0$. Therefore, $\mathbb{E}[X_{i+1} \mid w_1, \dots, w_i] = \mathbb{E}[X_i + Z_{i+1} \mid w_1, \dots, w_i] = \mathbb{E}[X_i \mid w_1, \dots, w_i] + \mathbb{E}[Z_{i+1} \mid w_1, \dots, w_i] = X_i$. ◀

Continuing with the proof of Theorem 29, by equation (5) we have that

$$\mathbb{P}\Big[\Big|\frac{1}{t}\sum_{i=1}^{t} f(w_i)\Big| > \epsilon\Big] = \mathbb{P}\Big[\Big|W + \frac{1}{t}\sum_{i=1}^{t} Z_i\Big| > \epsilon\Big] \le \mathbb{P}\Big[|W| + \Big|\frac{1}{t}\sum_{i=1}^{t} Z_i\Big| > \epsilon\Big]$$
$$\le \mathbb{P}\Big[\Big|\frac{1}{t}\sum_{i=1}^{t} Z_i\Big| > \frac{\epsilon}{2}\Big] = \mathbb{P}\Big[|\sum_{i=1}^{t} Z_i| > \frac{t\epsilon}{2}\Big] = \mathbb{P}\Big[|X_t - X_0| > \frac{t\epsilon}{2}\Big],$$

Let $c \coloneqq 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(2\|f\|_\pi/\epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}, 1 \right\} \right\rceil$. By (4) we know that $|X_i - X_{i-1}| \le c$. Furthermore, by Lemma 63, X_t is a martingale. Therefore we can apply Azuma's inequality to get: $\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \le 2\exp\left(\frac{-(\frac{t\epsilon}{2})^2}{2tc^2}\right) = 2\exp\left(-\frac{t^2\epsilon^2}{8tc^2}\right) = 2\exp\left(-\frac{t\epsilon^2}{8c^2}\right)$.

Since $\mathbb{E}_\pi[f] = 0$, we get $\mathrm{Var}_\pi(f) \coloneqq \sum_i \pi_i (f(i) - \mathbb{E}_\pi[f])^2 = \sum_i \pi_i f(i)^2 = \|f\|_\pi^2$, so

$$c = 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(2\sqrt{\mathrm{Var}_\pi(f)}/\epsilon\sqrt{\pi_*})}{-\ln(\lambda(f))}, 1 \right\} \right\rceil = 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*)}{-2\ln(\lambda(f))}, 1 \right\} \right\rceil.$$

Note that $c = 2\|f\|_\infty$ if $\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*) \le -2\ln(\lambda(f))$, or $\mathrm{Var}_\pi(f) \le \epsilon^2\pi_*/4\lambda(f)^2$. Moreover, $c \le 2\|f\|_\infty \left\lceil \max\left\{ \frac{\ln(4\,\mathrm{Var}_\pi(f)/\epsilon^2\pi_*)}{1-\lambda(f)}, 1 \right\} \right\rceil$ since $2\ln(r) \le r - 1$ for all $0 < r \le 1$. Hence,

$$\mathbb{P}[|\frac{1}{t}\sum_{i=1}^{t} f(w_i)| > \epsilon] \le \begin{cases} 2\exp\Big(-\frac{t\epsilon^2}{32\|f\|_\infty^2}\Big) & \mathrm{Var}_\pi(f) \le \frac{\epsilon^2\pi_*}{4\lambda(f)^2} \\ 2\exp\Big(-\frac{t\epsilon^2}{32\|f\|_\infty^2\mathcal{L}^2}\Big) & \text{otherwise.} \end{cases}$$ ◀

Vector-Matrix-Vector Queries for Solving Linear Algebra, Statistics, and Graph Problems

Abstract

We consider the general problem of learning about a matrix through vector-matrix-vector queries. These queries provide the value of $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}$ over a fixed field $\mathbb{F}$ for a specified pair of vectors $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{F}^n$. To motivate these queries, we observe that they generalize many previously studied models, such as independent set queries, cut queries, and standard graph queries. They also specialize the recently studied matrix-vector query model. Our work is exploratory and broad, and we provide new upper and lower bounds for a wide variety of problems, spanning linear algebra, statistics, and graphs. Many of our results are nearly tight, and we use diverse techniques from linear algebra, randomized algorithms, and communication complexity.

1 Introduction

In the past few decades, there has been a significant amount of research on query-based algorithms, motivated by compressed sensing, streaming, sketching, distributed methods, graph parameter estimation, and property testing [14, 23, 26, 43, 45]. Most of this work focuses on local queries that only access a small portion of the unknown data at a time. For example, prior work on graph parameter estimation has considered *degree* queries (which output the degree of a vertex v), *edge existence* queries (which answer whether a pair $\{u, v\}$ forms an edge), and *neighbor* queries (which provide the i^{th} neighbor of a vertex v). Not surprisingly, such queries have limited utility for certain problems. Even estimating the number of edges in a graph is known to require a polynomial number of edge existence, degree, and neighbor queries [24, 25].

This has led researchers to consider queries that still reveal a small amount of information, while being more global in nature. For example, *bipartite independent set* queries (which indicate whether or not there is at least one edge between two disjoint sets of vertices) can be used to estimate the number of edges with only polylog(n) queries [9, 19]. Similarly, *cut* queries (which provide the number of edges crossing a graph cut) can be used to find the

exact minimum cut in a graph [39, 35]. Augmenting edge existence, degree, and neighbor queries with access to an edge sampling oracle (which provides a uniformly random edge) leads to elegant algorithms for estimating the number of certain subgraphs (e.g., triangles or cliques) [5], which was a major open problem (without edge sampling) until recently [21, 40].

As the diversity of queries increases (along with the range of applicable problems), it is natural to wonder whether there is a more general framework for understanding the power and limitations of query-based algorithms. In this work, we initiate the study of querying a matrix through bilinear forms, which generalizes the above mentioned queries and several more (sometimes with an $O(\log n)$ factor overhead). Formally, let $\boldsymbol{M}$ be an $n \times n$ matrix over a field $\mathbb{F}$. We consider vector-matrix-vector queries, which we call $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries for short. Given a pair of vectors $\boldsymbol{u}, \boldsymbol{v} \in \mathbb{F}^n$, these queries return the value of $\boldsymbol{u}^\mathsf{T}\boldsymbol{M}\boldsymbol{v}$ over $\mathbb{F}$. For graph applications, we often let the matrix $\boldsymbol{M}$ be the adjacency matrix of a graph. We later explain how to simulate standard graph queries with $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries. Allowing $\boldsymbol{M}$ to take values in other fields enables us to consider a greater variety of linear algebra, statistics, and data analytic problems. The underlying field $\mathbb{F}$ will play an important role in our results, where working over $\mathbb{F}_2$ or $\mathbb{R}$ will change the query complexity of certain problems. We assume that the entries have $O(\log n)$ bit-complexity, and therefore, the output of one $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ query provides only $O(\log n)$ bits of information. We strive for algorithms using a subquadratic number of queries, which allows us to solve the problem without trivially learning the whole matrix. Unless we specify otherwise, we allow the queries to be randomized and adaptive.

From a practical point of view, algorithms based on $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries would most likely be useful in the context of specialized hardware or distributed environments. Computing a query only requires a weighted sum of entries of $\boldsymbol{M}$, and hence, it would be easy to execute in a massively parallel fashion. For example, if each processor handled a single row, then the local memory would be bounded by $O(n \log n)$ for storing $\boldsymbol{u}$ and $\boldsymbol{v}$. In a shared-nothing system, the number of communication rounds would be proportional to the number of queries. Similarly, in a streaming environment where single entries of $\boldsymbol{M}$ are changed at each step, the memory would be $O(\log n)$ times the number of queries. Working over a finite field $\mathbb{F}$ would reduce the memory overhead to $O(\log |\mathbb{F}|)$.

That being said, our focus is on the theoretical aspects of the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ query model. We consider many problems, spanning linear algebra, statistics, and graph properties. Part of our motivation comes from finding algorithms that are query-efficient in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model, while surpassing lower bounds for more restricted models. For example, we consider properties that depend on the whole matrix (e.g., having low rank, being unitary or doubly stochastic) or the entire graph (e.g., being a perfect matching or a star). As these are global properties, it is intuitively challenging to verify them using local queries without simply learning the whole matrix or graph. Overall, the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ query model opens up many theoretical directions, and it facilitates new connections between linear algebra, randomized algorithms, and communication complexity.

1.1 Related work and other queries

The $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model provides a unifying lens and generalizes many previously studied queries. We give a brief overview of how to simulate other models and mention other related work.

- **Standard Graph Queries.** To gain intuition about $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries, we note that if $\boldsymbol{M}$ is the adjacency matrix of a graph, then a single query over a large field (e.g., $\mathbb{Q}$ or $\mathbb{R}$) provides the exact edge count. It is also easy to show that $O(\log n)$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries suffice to simulate degree, edge existence, neighbor, or edge sampling queries

(see Section A.1 for details). Therefore, $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries achieve a variety of previous results with only an $O(\log n)$ factor overhead, such as estimating the number of cliques of different sizes [2, 5, 21, 22, 40], the number of stars [27], and the minimum vertex cover [37].

- **Independent Set Queries.** Another line of work considers *independent set* oracles for graphs (which return whether a given set of vertices induces an independent set or contains at least one edge), mostly in the context of estimating the number of edges in a graph [9, 17, 18, 19]. Interestingly, bipartite independent set queries are known to be much stronger than independent set queries [9, 17]. A special case of bipartite independent set query (where one of the bipartition sets is a singleton) has been used for testing k-colorability of graphs [10], and high degree vertex discovery [44]. While these algorithms are randomized and approximate, prior work also studies exact graph learning problems [1, 3, 4]. When $\boldsymbol{M}$ is a binary matrix over a large enough field (e.g., $\mathbb{Q}$ or $\mathbb{R}$), then $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries generalize both independent and bipartite independent set queries by taking $\boldsymbol{u}$ and $\boldsymbol{v}$ to be indicator vectors for the sets. In particular, the power of the bipartite version motivates allowing $\boldsymbol{u}$ and $\boldsymbol{v}$ to differ in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model.
- **Fine-Grained Complexity.** Independent set queries are partially motivated by studying the complexity of decision vs. counting problems [18, 19]. While we do not know of a (natural) use of $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries in this area, future work could consider using our algorithms for a similar complexity-theoretic reduction. Our model could also be extended to tensors, where queries are k-linear forms, analogous the generalization to k-partite independent set queries for counting k-cliques, which has applications to k-SUM and related problems [19].
- **Cut Queries.** Another global graph query model considers *cut* queries (which provide the number of edges in a graph $G = (V, E)$ crossing a cut $(S, V \setminus S)$). It is known that $\widetilde{O}(n)$ cut queries suffice to exactly compute a minimum cut in a graph, and $\widetilde{O}(n^{5/3})$ suffice to compute an s-t cut [39]. This has also been extended to multigraphs [35]. We can directly simulate cut queries via indicator vectors $\boldsymbol{u} = \mathbf{1}_S$ and $\boldsymbol{v} = \mathbf{1}_{\{V\setminus S\}}$, when $\boldsymbol{M}$ is the adjacency matrix of the graph. As the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model is more general than cut queries, it an interesting open question whether a sublinear number of queries suffice for these problems.
- **Matrix-Vector Queries.** A similar but more powerful query model considered by previous work involves matrix-vector queries [42]. In this case, the queries return a vector of n values $\boldsymbol{v}^\mathrm{T}\boldsymbol{M}$ or $\boldsymbol{M}\boldsymbol{v}$ when given a vector $\boldsymbol{v} \in \mathbb{F}^n$. We study many of the same problems as this prior work. In some cases, we show that certain problems (such as determining if a matrix is symmetric or diagonal) have constant query complexity in both models, even though $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries reveal much less information than matrix-vector queries. Previous work also considers lower bounds for the operator norm in the matrix-vector model [13]. There is also work on the query complexity of computing PCA in this model [41]. Finally, we provide examples where matrix-vector queries are more powerful because there are lower bounds for $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries (see, e.g., Section 3.1).
- $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ **Data Structures.** A complementary line of work considers the data structure complexity of $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries [15, 16, 20, 30, 36]. More precisely, the goal is to preprocess $\boldsymbol{M}$ using a small amount space so that the value of $\boldsymbol{u}^\mathrm{T}\boldsymbol{M}\boldsymbol{v}$ can be obtained with a small query time (e.g., in the cell-probe model or natural restrictions of that model). Since there are connections between such data structures and challenging complexity theoretic problems (e.g., matrix rigidity, see [20, 36]), it is an outstanding question to further explore whether our results have implications for $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ data structures or vice versa.

Table 1 Our upper and lower bounds on the query complexity in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model for $n \times n$ matrices and constant success probability. Results hold over any field unless stated otherwise.

Linear Algebra Problems

Triangle detection	$\Omega(n^2/\log n)$	Theorem 20
Star graph	$O(1)$ over $\mathbb{R}$	Theorem 21
Local graph queries	$O(\log n)$	Lemma 22

1.2 Our Results

We provide new upper and lower bounds on the query complexity of various problems in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model. Table 1 summarizes our results. Many of the bounds are nearly tight: for some problems $O(1)$ queries suffice, and for others, either $\widetilde{\Theta}(n)$ or $\widetilde{\Theta}(n^2)$ are necessary and sufficient. For brevity, we defer formal definitions to the relevant subsections. Here we highlight some interesting results.

Linear Algebra Problems. Section 3.1 provides lower bounds for approximately computing many matrix norms, such as the trace norm, Frobenius norm, and operator norm (in general, we study Schatten p-norms; see Section 3.1 for the definition). To prove this result, we develop a general simulation result that allows us to establish lower bounds for adaptive $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries by reducing them to lower bounds for non-adaptive *entry-wise* queries. The key idea is that such a simulation result holds whenever the input matrix distribution is rotationally invariant (under row permutations). Then, we utilize known sketching lower bounds for matrix norms that identify a hard distribution that is rotationally invariant [31].

We give constant-query algorithms for testing if a matrix is diagonal (Section 3.4) or symmetric (Section 3.5). While these algorithms are fairly straightforward, they exhibit the power of $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries to efficiently test for global properties of the matrix. We prove nearly-matching bounds for testing if a matrix is orthonormal (over $\mathbb{R}$) or unitary (over $\mathbb{C}$). The lower bound uses an encoding of information via the Hadamard matrix.

Statistics Problems. Turning to other matrix problems, we consider properties of one or more columns (our results also hold for rows, by symmetry of the query model). For example, Section 4.1 and Section 4.2 provide nearly matching upper and lower bounds for testing if there is an all ones column or two identical columns. Many of our lower bounds follow from communication complexity via Disjointness. While this may be technically simple, we note that our reductions require certain gadgets that seem to be new in the context of query complexity; for example, see our lower bounds for permutation matrices (Theorem 17). This also led us to study negative entry detection in its own right, because a lower bound of $\Omega(n^2/\log n)$ from Theorem 19 essentially provides the reason why certain results for binary matrices (e.g., graphs) cannot be generalized.

Graph Problems. Our upper bound on permutation matrices (Theorem 16) gives a constant-query algorithm for detecting whether a graph is a perfect matching. We also provide a constant-query upper bound for testing whether a graph is a star on n vertices (Theorem 21). Both of these are global properties that would be difficult to verify using standard graph queries. They also complement previous results for learning hidden matchings or other structures using independent set queries [3, 4]. As mentioned previously, being able to simulate local graph queries with $O(\log n)$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries gives rise to a number of results on graph parameter estimation in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model (see, e.g., [2, 5, 21, 22, 27, 40, 37]).

Organization. We start with preliminaries in Section 2. We provide results for linear algebra problems in Section 3, for statistics problems in Section 4, and for graph problems in Section 5. We conclude in Section 6.

2 Preliminaries

We use capital bold letters $(\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{M}, \ldots)$ to represent matrices, lower-case bold letters $(\boldsymbol{u}, \boldsymbol{v}, \boldsymbol{x}, \boldsymbol{y}, \ldots)$ to represent column vectors. We use non-bold lower-case letters $(x, y, \ldots)$ to represent strings. For a matrix $\boldsymbol{M}$, we let M_{ij} denote the entry in i^{th} row and j^{th} column. For a vector $\boldsymbol{v}$, we use v_i to denote the i^{th} entry. For a string x, we use x_i to denote the i^{th} entry. We use $\mathbb{F}$ to represent arbitrary fields, and use $\mathbb{F}_p$ to represent the finite field with p elements where p is prime, and $\mathbb{R}$ to denote the reals. We use $G = (V, E)$ to represent a simple graph, where V denotes the set of vertices and E denotes the set of edges. We query the adjacency matrix. Some of our lower bounds use the communication complexity of Disjointness, where Alice has $x \in \{0,1\}^n$, Bob has $y \in \{0,1\}^n$, and they decide if there exists an index i with $x_i = y_i = 1$. The randomized communication complexity is $\Omega(n)$ [29, 38]. We also use the following result: if x and y contain exactly $n/4$ ones, then the randomized complexity is still $\Omega(n)$ [7, 28].

3 Linear Algebra Problems

3.1 Lower Bounds for Approximating Matrix Norms

Say that a distribution over matrices $\boldsymbol{X} \in \mathbb{R}^{n \times n}$ is *orthonormal and rotationally invariant* if all rows of each $\boldsymbol{X}$ in the support are orthonormal and the distribution remains the same under any permutation of the rows of $\boldsymbol{X}$. We will consider distributions over matrices $\boldsymbol{M}$ formed by fixing a diagonal matrix $\boldsymbol{\Sigma}$, sampling two matrices $\boldsymbol{X}$ and $\boldsymbol{Y}$ from orthonormal and rotationally invariant distributions, and letting $\boldsymbol{M} = \boldsymbol{X}\boldsymbol{\Sigma}\boldsymbol{Y}^{\mathrm{T}}$. At a high level, are interested in algorithms for computing functions of the singular values $\boldsymbol{\Sigma}$, which remain invariant over matrices in such distributions.

Our first goal is to prove a structural result relating $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries to entry-wise queries of $\boldsymbol{M}$. Then, we use this reduction to prove new lower bounds. To do so, we utilize known streaming lower bounds, and we take advantage of the fact that these lower bounds are based on hard distributions that are orthonormal and rotationally invariant. Recall that $[s] = \{1, 2, \ldots, s\}$ and that $\boldsymbol{e}_i \in \{0,1\}^n$ denotes the i^{th} standard basis vector.

▶ **Lemma 1.** *Let $\boldsymbol{M} = \boldsymbol{X}\boldsymbol{\Sigma}\boldsymbol{Y}^\mathrm{T}$ be a random $n \times n$ real-valued matrix, where $\boldsymbol{\Sigma}$ is diagonal, and $\boldsymbol{X}$ and $\boldsymbol{Y}$ are sampled from orthonormal and rotationally invariant distributions. Any $s \leq n$ deterministic, adaptive queries in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model can be simulated by s^2 non-adaptive entry-wise queries to the values of $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_j$ for $i, j \in [s]$.*

Proof. We proceed by induction on the number of queries $s \geq 1$. For the base case, consider a query $\boldsymbol{u}_1\boldsymbol{M}\boldsymbol{v}_1$, where $\boldsymbol{u}_1, \boldsymbol{v}_1$ are arbitrary unit vectors. Observe that $\boldsymbol{u}_1^\mathrm{T}\boldsymbol{X}$ and $\boldsymbol{Y}^\mathrm{T}\boldsymbol{v}_1$ are random unit vectors, and moreover, they follow the same distribution as $\boldsymbol{e}_1^\mathrm{T}\boldsymbol{X}$ and $\boldsymbol{Y}^\mathrm{T}\boldsymbol{e}_1$, respectively. Since $\boldsymbol{M} = \boldsymbol{X}\boldsymbol{\Sigma}\boldsymbol{Y}^\mathrm{T}$, we see that the values of $\boldsymbol{u}_1^\mathrm{T}\boldsymbol{M}\boldsymbol{v}_1$ and $\boldsymbol{e}_1^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_1$ are identically distributed as well.

Suppose the lemma holds for any $s-1$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries. Consider a sequence of s queries

$$\boldsymbol{u}_1^\mathrm{T}\boldsymbol{M}\boldsymbol{v}_1,\ \boldsymbol{u}_2^\mathrm{T}\boldsymbol{M}\boldsymbol{v}_2,\ \ldots\ ,\ \boldsymbol{u}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{v}_s, \tag{1}$$

for unit vectors $\boldsymbol{u}_i, \boldsymbol{v}_i$ for $i \in [s]$ that may depend adaptively on the previous queries. Assume without loss of generality that $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_s$ and $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_s$ are respectively linearly independent. For the final query vectors $\boldsymbol{u}_s$ and $\boldsymbol{v}_s$, decompose them as

$$\boldsymbol{u}_s = \boldsymbol{a}_s + \boldsymbol{b}_s \qquad \text{and} \qquad \boldsymbol{v}_s = \boldsymbol{c}_s + \boldsymbol{d}_s,$$

where

$$\boldsymbol{a}_s \in \mathsf{span}\{\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_{s-1}\} \qquad \text{and} \qquad \boldsymbol{c}_s \in \mathsf{span}\{\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_{s-1}\},$$

and where $\boldsymbol{a}_s$ is orthogonal to $\boldsymbol{b}_s$, and $\boldsymbol{c}_s$ is orthogonal to $\boldsymbol{d}_s$.

Invoking the inductive hypothesis, this decomposition implies that $\boldsymbol{a}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{c}_s$ can be simulated using $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_j$ for $i, j \in [s-1]$. Furthermore, by the orthogonality assumptions, we have that $\boldsymbol{b}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{d}_s$ follows the same distribution as $\boldsymbol{e}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_s$, even conditioned on the previous queries.

It remains to argue about $\boldsymbol{a}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{d}_s$ and $\boldsymbol{b}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{c}_s$. We begin with the former, noting that the latter follows by a symmetric argument. Let $\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_{s-1}$ denote an orthonormal basis for $\mathsf{span}\{\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_{s-1}\}$. Considering the expansion of $\boldsymbol{a}_s$ in this basis, we observe that, by linearity, it suffices to simulate

$$\boldsymbol{w}_1^\mathrm{T}\boldsymbol{M}\boldsymbol{d}_s,\ \boldsymbol{w}_2^\mathrm{T}\boldsymbol{M}\boldsymbol{d}_s,\ \ldots\ ,\ \boldsymbol{w}_{s-1}^\mathrm{T}\boldsymbol{M}\boldsymbol{d}_s \tag{2}$$

using only the information from $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_s$ for $i \in [s-1]$. To establish this, consider any vector $\boldsymbol{w}_i$ for $i \in [s-1]$. By assumption, $\boldsymbol{X}$ and $\boldsymbol{Y}$ are drawn from orthonormal and rotationally invariant distributions. Since $\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_s$ form an orthonormal basis, we have that $\boldsymbol{w}_i^\mathrm{T}\boldsymbol{X}$ is a random unit vector following the same distribution as $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{X}$. Moreover, by orthogonality, for any $i \geq 2$, the distribution of $\boldsymbol{w}_i^\mathrm{T}\boldsymbol{X}$ remains the same as $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{X}$ even conditioned on

$$\boldsymbol{w}_1^\mathrm{T}\boldsymbol{X},\ \boldsymbol{w}_2^\mathrm{T}\boldsymbol{X},\ \ldots\ ,\ \boldsymbol{w}_{i-1}^\mathrm{T}\boldsymbol{X}.$$

an analogous argument implies that $\boldsymbol{Y}^\mathrm{T}\boldsymbol{d}_s$ follows the same distribution as $\boldsymbol{Y}^\mathrm{T}\boldsymbol{e}_s$, even conditioned on the previous queries. Therefore, we have that $\boldsymbol{w}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{d}_s$ is identically distributed as $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_s$. As this holds for all $i \in [s-1]$, the queries in Eq. (2) can be simulated by $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_s$ for $i \in [s-1]$. By symmetry, a similar result holds for simulating $\boldsymbol{b}_s^\mathrm{T}\boldsymbol{M}\boldsymbol{c}_s$. Therefore, we have shown that all s deterministic queries in Eq. (1) can be simulated by the s^2 entry-wise non-adaptive queries to $\boldsymbol{e}_i^\mathrm{T}\boldsymbol{M}\boldsymbol{e}_j$ for $i, j \in [s]$, as desired. ◀

We use this structural result to prove lower bounds for computing certain matrix norms by applying sketching lower bounds due to Li, Nguyen, and Woodruff [31]. For $p \in (0, \infty)$, the *Schatten p-norm* of a real matrix $\boldsymbol{M} \in \mathbb{R}^{n \times n}$ with singular values $\sigma_1, \ldots, \sigma_n$ is defined as

$$\|\boldsymbol{M}\|_p = \left(\sum_{i=1}^{n} \sigma_i^p \right)^{1/p}.$$

By convention, the Schatten 0-norm is the rank of the matrix, and the Schatten ∞-norm equals the largest singular value (a.k.a., operator norm). We have the following result for the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model.

▶ **Theorem 2.** *Let $\boldsymbol{M} \in \mathbb{R}^{n \times n}$ be a matrix. For any value $p \in [0, 4)$, computing a constant-factor approximation to the Schatten p-norm of $\boldsymbol{M}$ requires $\Omega(\sqrt{n})$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries. For $p \geq 4$, computing a constant-factor approximation to the Schatten p-norm of $\boldsymbol{M}$ requires $\Omega(n^{1-2/p})$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries. Both results hold for randomized, adaptive queries with constant success probability.*

We sketch the proof of this theorem, which now follows directly from previous results. Before applying Lemma 1, we use Yao's principle [46] to show that it suffices to consider deterministic query algorithms for distributions over input matrices. Also, the query vectors can be taken to be unit vectors without loss of generality, as the algorithm can rescale the results. Then, we note that the previous lower bounds use hard distributions that are orthonormal and rotationally invariant [31]. As a result, the distribution of matrices $\boldsymbol{M}$ satisfies the conditions of Lemma 1.

The previous results hold over the *bilinear sketching model*, where the sketches correspond to an $r \times n$ matrix $\boldsymbol{U}$ and an $s \times n$ matrix $\boldsymbol{V}$, and the goal is to approximate $\|\boldsymbol{M}\|_p$ up to a constant factor using $\boldsymbol{U}\boldsymbol{M}\boldsymbol{V}^\mathrm{T}$. Applying Lemma 1, we see that any algorithm making s queries in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model corresponds to a bilinear sketch with both matrices being $s \times n$. Moreover, as the conclusion of the lemma only uses entry-wise queries, the corresponding matrices consist of the $s \times s$ identity matrix in the upper left-hand corner, while the rest of the matrix is all zeroes. The lower bound on bilinear sketches implies

- $s^2 = \Omega(n)$ for approximating the Schatten p-norm with $p \in [0, 4)$
- $s^2 = \Omega(n^{2-4/p})$ for approximating the Schatten p-norm with $p \geq 4$.

Taking a square root leads to the bounds in Theorem 2.

The above provides separations between the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ and matrix-vector models [42]. Indeed, it is known that there exist non-trivial bilinear sketching matrices for approximating the Schatten p-norm whenever p is an even integer. Denoting such sketching matrices as $\boldsymbol{U}$ and $\boldsymbol{V}$, it suffices for $\boldsymbol{U}$ and $\boldsymbol{V}^\mathrm{T}$ to each have $O(n^{1-2/p})$ rows [31] to approximate the Schatten p-norm up to a constant factor. Observe that the Schatten p-norm of a matrix $\boldsymbol{M}$ is the same as the Schatten $p/2$-norm of the matrix $\boldsymbol{M}\boldsymbol{M}^\mathrm{T}$. Thus, if p is an integer multiple of 4, then in the matrix-vector model one can first compute $\boldsymbol{U}\boldsymbol{M}$ and then compute $\boldsymbol{M}^\mathrm{T}\boldsymbol{V}$, and then multiply these together to obtain $\boldsymbol{U}\boldsymbol{M}\boldsymbol{M}^\mathrm{T}\boldsymbol{V}$, where $\boldsymbol{U}$ and $\boldsymbol{V}$ are the corresponding sketching matrices for the Schatten $p/2$-norm. The total cost is $O(n^{1-4/p})$ queries in the matrix-vector model.

On the other hand, Theorem 2 implies that $\Omega(n^{1-2/p})$ queries are necessary in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model, thus providing a separation for integers $p \geq 4$ which are multiples of 4. We also directly get an $\Omega(n)$ lower bound for approximating the operator norm up to a constant factor, using the $\Omega(n^2)$ lower bound bound for general sketches in [33]. For recent work on actually finding the top eigenvector and solving a linear system in the matrix-vector model in the high accuracy regime, see [13].

3.2 Rank Testing

Given a matrix $\boldsymbol{M} \in \mathbb{F}^{n\times n}$, a natural problem is to determine the rank of $\boldsymbol{M}$. We first consider matrices over a finite field $\mathbb{F}_p$ for a prime p.

▶ **Theorem 3.** *Given a matrix $\boldsymbol{M} \in \mathbb{F}_p^{n\times n}$ and an integer k, at least $\Omega(k^2)$ adaptive queries are necessary to decide the rank whether the rank of $\boldsymbol{M}$ is k or $k+1$ with constant probability.*

Proof. We reduce this problem to a communication complexity problem. Alice holds a matrix $\boldsymbol{A} \in \mathbb{F}_p^{n\times n}$ and Bob holds a matrix $\boldsymbol{B} \in \mathbb{F}_p^{n\times n}$, where $\boldsymbol{M} = \boldsymbol{A}+\boldsymbol{B}$ and $\mathsf{rank}(\boldsymbol{M}) \in \{k, k+1\}$. Corollary 23 in [32] implies that the randomized communication complexity is $\Omega(k^2 \log p)$ to determine whether the rank of $\boldsymbol{M}$ is k or $k+1$. Alice and Bob can simulate the query algorithm using $O(\log p)$ bits of communication per query. Let $q(n,k)$ be the query complexity of this problem in the $\mathsf{u^TMv}$ model. Then $q(n,k)\log p = \Omega(k^2 \log p)$, and we conclude that $q(n,k) = \Omega(k^2)$. ◀

Now consider the real-valued version of rank testing with $\boldsymbol{M} \in \mathbb{R}^{n\times n}$. It is known that if we want to compute the rank of $\boldsymbol{M}$ up to a factor of $(1\pm\epsilon)$, then this requires $\Omega(n^{2-O(\varepsilon)})$ space in the streaming model [6]. Assadi et. al. [6] has shown that even for some special matrices of which the entries are only in $\{-1,0,1\}$, there exists an $\Omega(n^{2-O(\varepsilon)})$ space lower bound for $(1+\varepsilon)$-approximation of the rank. Notice that for $\mathsf{u^TMv}$ queries, if we choose $\boldsymbol{u} = (1,3,3^2,\ldots,3^{m-1})^{\mathrm{T}}$ and $\boldsymbol{v} = (1,3^m,3^{2m},\ldots,3^{m(m-1)})^{\mathrm{T}}$, then we can exactly reconstruct $\boldsymbol{M}$ using the value of $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}$. Therefore, we assume that the matrix and the query vectors have integral values bounded by a polynomial in n. Under this assumption, we prove the following theorem:

▶ **Theorem 4.** *Given a matrix $\boldsymbol{M} \in \mathbb{R}^{n\times n}$, if we restrict that the entry of query vectors can be chosen only from $\{0,1,2,\ldots,n^c\}$ for some constant c, then $\Omega(n^{2-O(\varepsilon)})$ non-adaptive queries are necessary to obtain a $(1+\varepsilon)$-estimation of $\mathsf{rank}(\boldsymbol{M})$.*

Proof. Let $q(n)$ be the number of $\mathsf{u^TMv}$ queries sufficient to estimate the rank up to a factor of $(1\pm\epsilon)$. Consider a streaming model with updates of the form $\boldsymbol{u}_1^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}_1$, $\boldsymbol{u}_2^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}_2$, …, $\boldsymbol{u}_{q(n)}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}_{q(n)}$, where $\boldsymbol{u}_i$ and $\boldsymbol{v}_i$ are the i^{th} queries made in the $\mathsf{u^TMv}$ model for $i = 1,2,\ldots,q(n)$. We can store these queries using $O(q(n)\cdot\log n)$ bits of space (as the matrix and vector entries are polynomially bounded). Using the previous results of [6], we see that $\Omega(n^{2-O(\varepsilon)})$ bits of space are necessary. This implies that $q(n)O(\log n) = \Omega(n^{2-O(\varepsilon)})$, and hence, $q(n) = \Omega(n^{2-O(\varepsilon)}/\log n) = \Omega(n^{2-O(\varepsilon)})$. ◀

3.3 Trace Estimation

Estimating the trace of a matrix presents a simple problem where $\mathsf{u^TMv}$ queries are just as powerful as matrix-vector queries, even though the latter obtains much more information per query. Sun et. al. [42] proves an $\Omega(n/\log n)$ lower bound for trace estimation of symmetric matrix, of which the entries are in $\{0,1,2,\ldots,n^3\}$, using matrix-vector queries. Since $\boldsymbol{M}\boldsymbol{v}$ contains all information of $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}$, it is also a lower bound for the $\mathsf{u^TMv}$ model. Of course, n queries suffice to obtain all the diagonal elements of matrix $\boldsymbol{M}$, i.e., $\mathrm{tr}(\boldsymbol{M}) = \sum_{i=1}^n M_{ii} = \sum_{i=1}^n \boldsymbol{e}_i^{\mathrm{T}}\boldsymbol{M}\boldsymbol{e}_i$, where $\boldsymbol{e}_i$ is the i^{th} standard basis vector. Thus, for trace estimation, we obtain an $\Omega(n/\log n)$ lower bound and an $O(n)$ upper bound. We formalize this as the following theorem.

▶ **Theorem 5.** *Let $\boldsymbol{M}$ be an $n\times n$ matrix over $\mathbb{R}$ with entries in $\{0,1,2,\ldots,n^3\}$. Assume the query vectors have entries in $\{0,1,2,\ldots,n^c\}$ for a constant $c>0$. Computing a constant factor approximation to the trace $tr(\boldsymbol{M})$ has query complexity between $\Omega(n/\log n)$ and $O(n)$.*

3.4 Deciding if a Matrix is Diagonal

In this section, we show that over any field $\mathbb{F}$, $O(\log(\frac{1}{\varepsilon}))$ queries suffice to test whether a matrix is a diagonal matrix with error probability at most $\varepsilon \in (0,1)$. Actually, it is equivalent that 1 $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ query can test with constant error probability.

For each test, we randomly and uniformly choose a subset S of $[n] = \{1, 2, 3, \ldots, n\}$ with size $|S| = \frac{n}{2}$. We select a subset G of size $|G| = 2$ from $\mathbb{F}$. Construct the query vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ as follows. For each $i \in [n]$, if $i \in S$, then let u_i be randomly and uniformly sampled from G, and $v_i = 0$; otherwise let v_i be randomly and uniformly sampled from G and $u_i = 0$. If $\boldsymbol{u}^\mathrm{T}\boldsymbol{M}\boldsymbol{v} = 0$, then output 'Success', otherwise output 'Fail'. The whole algorithm outputs 'Success' iff every test outputs 'Success'. The proof of Theorem 6 is presented in Appendix A.

▶ **Theorem 6.** *Let $\boldsymbol{M}$ be an $n \times n$ matrix over any field $\mathbb{F}$. Then with $O(\log(\frac{1}{\varepsilon}))$ queries, one can test whether $\boldsymbol{M}$ is a diagonal matrix with probability at least $1 - \varepsilon$.*

3.5 Deciding if a Matrix is Symmetric

Sun et. al. [42] has shown an $O(\log(\frac{1}{\varepsilon}))$ query upper bound in the matrix-vector model to test whether an $n \times n$ matrix $\boldsymbol{M}$ is symmetric with probability $1 - \epsilon$. We can simulate their method in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model. To do so, repeat the following process $O(\log(\frac{1}{\varepsilon}))$ times: choose two random vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ and test whether $\boldsymbol{u}^\mathrm{T}\boldsymbol{M}\boldsymbol{v} = \boldsymbol{v}^\mathrm{T}\boldsymbol{M}\boldsymbol{u}$. Using the previous results [42], we see that the error probability is at most ε. We formalize this as follows:

▶ **Theorem 7.** *Let $\boldsymbol{M}$ be an $n \times n$ matrix over any field $\mathbb{F}$. Then with $O(\log(\frac{1}{\varepsilon}))$ queries, one can test whether $\boldsymbol{M}$ is a symmetric matrix with probability at least $1 - \varepsilon$.*

3.6 Deciding if a Matrix is Unitary

The results on query complexity in this subsection also apply for testing if a matrix is orthonormal over $\mathbb{R}$, since orthonormal is a special case of unitary.

3.6.1 Randomized Queries

Given an $n \times n$ complex matrix $\boldsymbol{M}$, a single matrix-vector query can determine whether $\boldsymbol{M}$ is unitary with probability one [42]. Hence in the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model, n randomized queries suffice, by obtaining the entries of the vector $\boldsymbol{M}\boldsymbol{v}$ using $\boldsymbol{u} = \boldsymbol{e}_i$ for $1 \le i \le n$.

Now we show that the $O(n)$ algorithm is nearly optimal by proving a lower bound $\Omega(n/\log n)$ in random case.

▶ **Theorem 8.** *Let $\boldsymbol{M}$ be an $n \times n$ matrix over $\mathbb{C}$. Then to determine whether $\boldsymbol{M}$ is a unitary matrix with a constant probability, the lower bound of query complexity is $\Omega(n/\log n)$ and the upper bound is $O(n)$.*

Proof. WLOG, let $n = 2^k$, and then this problem can be reduced to Disjointness. Suppose Alice has a string $x \in \{0,1\}^n$, and Bob has a string $y \in \{0,1\}^n$. Moreover, $\boldsymbol{x}$ and $\boldsymbol{y}$ both contain exactly $\frac{n}{4}$ ones, i.e. $|\{i \in [n] \mid x_i = 1\}| = \frac{n}{4}$ and $|\{i \in [n] \mid y_i = 1\}| = \frac{n}{4}$. Now Alice and Bob want to find whether there exists an index i such that $x_i = y_i = 1$. The communication complexity of this problem is $\Omega(n)$ [7, 28]. Now we show a protocol of the communication. First, let's recall one construction of a Hadamard matrix.

▶ **Definition 9.** *Let $\boldsymbol{H}_1 = \begin{bmatrix} 1 \end{bmatrix}$, and $\boldsymbol{H}_{2^k} = \begin{bmatrix} \boldsymbol{H}_{2^{k-1}} & \boldsymbol{H}_{2^{k-1}} \\ \boldsymbol{H}_{2^{k-1}} & -\boldsymbol{H}_{2^{k-1}} \end{bmatrix}$ be a Hadamard matrix, then we define $\boldsymbol{G}_{2^k} = \frac{1}{\sqrt{2^k}}\boldsymbol{H}_{2^k}$ for any $k \ge 1$.*

By the definition, $\boldsymbol{G}_{n/4}^{*}\boldsymbol{G}_{n/4} = \boldsymbol{I}_{n/4}$, which means $\boldsymbol{G}_{n/4}$ is a unitary matrix. Also, we denote the element of row i and column j of matrix $\boldsymbol{G}_{n/4}$ by $g_{i,j}$. Then Alice constructs an $n \times n$ matrix $\boldsymbol{X}$ with the following method. Let a_i denote the i^{th} smallest position of string x of which the value is 1. For example, if $x = 00100010$, then $a_1 = 3, a_2 = 7$. Then Alice fills exactly $(n/4) \times (n/4)$ elements of matrix $\boldsymbol{X}$, i.e.

$$\boldsymbol{X}_{a_i,a_j} = \begin{cases} g_{i,j} & ,i \neq j \\ g_{i,j} - 1 & ,i = j, \end{cases} \quad \text{where } 1 \leq i,j \leq n/4.$$

Other elements of $\boldsymbol{X}$ are all 0s. Alice then constructs another matrix $\boldsymbol{X}'$, which is the same as $\boldsymbol{X}$ except that

$$\boldsymbol{X}'_{a_i,a_j} = \begin{cases} -g_{i,j} & ,i \neq j \\ -g_{i,j} - 1 & ,i = j, \end{cases} \quad \text{where } 1 \leq i,j \leq n/4.$$

Let $\boldsymbol{X}_1 = \boldsymbol{X}$ and $\boldsymbol{X}_2 = \boldsymbol{X}'$. Bob uses the similar method to construct matrices $\boldsymbol{Y}_1$ and $\boldsymbol{Y}_2$ using his string y. If x and y are not intersected, i.e. there does not exist an index k, such that $x_k = y_k = 1$, then the four matrices $\boldsymbol{M}_{ij} = \boldsymbol{X}_i + \boldsymbol{Y}_j + \boldsymbol{I}$ are all unitary for $1 \leq i,j \leq 2$, where $\boldsymbol{I}$ is the identity matrix. However, if x and y intersects, then there exists an index k such that $x_k = y_k = 1$, so there exists $i,j \in \{1,2\}$, such that the element of k^{th} row and k^{th} column of matrix $\boldsymbol{M}_{ij}$ equals

$$(-\frac{1}{\sqrt{n/4}} - 1) + (-\frac{1}{\sqrt{n/4}} - 1) + 1 = -1 - \frac{2}{\sqrt{n/4}} < -1,$$

so $\boldsymbol{M}_{ij}$ is not unitary.

Therefore, Alice and Bob can compute $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}_{ij}\boldsymbol{v}$ by sending $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{X}_i\boldsymbol{v}$ and $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{Y}_j\boldsymbol{v}$, which take $O(\log n)$ bits by one communication. Assume that $q(n)$ queries can determine whether an $n \times n$ matrix is unitary, since Disjointness requires $\Omega(n)$ bits, $q(n)O(\log n) = \Omega(n)$, which demonstrates that $q(n) = \Omega(n/\log n)$. We summarize the above results and obtain the following theorem. ◀

3.6.2 Deterministic Queries

For deterministic case, a trivial upper bound is $O(n^2)$ by retrieving all the entries of matrix $\boldsymbol{M}$ one by one. Now we show a strong lower bound $\Omega(n^2/\log n)$, which demonstrates that the trivial algorithm can nearly perform the best.

▶ **Theorem 10.** *Let $\boldsymbol{M}$ be an $n \times n$ matrix over $\mathbb{C}$. Then to determine whether $\boldsymbol{M}$ is a unitary matrix in deterministic case, the lower bound of query complexity is $\Omega(n^2/\log n)$.*

Proof. We reduce the problem to Disjointness. Without loss of generality, let $n = 2^k$. One can calculate easily that there are $n^- = \frac{n(n-1)}{2}$ (-1)s in matrix $\boldsymbol{H}_n$, and $n^+ = \frac{n(n+1)}{2}$ 1s. We denote the element of row i and column j of matrix $\boldsymbol{H}_n$ by $h_{i,j}$. Then, let $\boldsymbol{Z}$ be the matrix of $n \times n$, which satisfies that

$$Z_{i,j} = \begin{cases} -1, & h_{i,j} = -1 \\ 0, & h_{i,j} = 1. \end{cases}$$

Denote the positions in which elements are 1s in $\boldsymbol{H}_n$ by 1, 2, 3, ..., n^+ respectively. Now Alice holds a string x and Bob holds a string y, where $x,y \in \{0,1\}^{n^+}$. Each of them has exactly $\frac{n^+}{2}$ 1s. In the deterministic case, it requires $\Omega(n^+) = \Omega(n^2)$ bits of communication to decide whether the two strings intersect. Alice then constructs a matrix $\boldsymbol{X}$ of $n \times n$, and initially, all the entries of $\boldsymbol{X}$ are zero. Next, for each i, where $1 \leq i \leq n^+$, if $x_i = 1$, then Alice fills in 1 at position i in $\boldsymbol{X}$. Bob constructs a matrix $\boldsymbol{Y}$ with the same method. Let $\boldsymbol{M} = \frac{1}{\sqrt{n}}(\boldsymbol{X} + \boldsymbol{Y} + \boldsymbol{Z})$. Then x and y do not intersect if and only if $\boldsymbol{M}$ is unitary. To exchange $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{X}\boldsymbol{v}$ or $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{Y}\boldsymbol{v}$ needs only $O(\log n)$ bits, so the lower bound is $\Omega(n^2/\log n)$. ◀

4 Statistics Problems

4.1 All Ones Column

Let $\boldsymbol{M} \in \{0,1\}^{n\times n}$ be a binary matrix. Sun et. al. [42] show a lower bound of $\Omega(n/\log n)$ for matrix-vector queries over $\mathbb{R}$ when restricting the entries in the query vector to $[n^c] = \{1, 2, \ldots, n^c\}$ for some constant c. This lower bound can be applied directly to the $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ model. The following theorem shows that this is tight (up to logarithmic factors) and the proof is presented in Appendix A.

▶ **Theorem 11.** *Given a matrix $\boldsymbol{M} \in \{0,1\}^{n\times n}$ over $\mathbb{R}$, then $O(n)$ queries suffice to test whether there exists an all ones column in $\boldsymbol{M}$ with probability one.*

4.2 Identical Columns

Let $\boldsymbol{M} \in \{0,1\}^{n\times n}$. Rearrange $\boldsymbol{M}$ in the following way: $\boldsymbol{M} = \begin{bmatrix} \boldsymbol{c}_1 & \boldsymbol{c}_2 & \cdots & \boldsymbol{c}_n \end{bmatrix}$. Our task is to determine whether there exists i, j, such that $1 \le i < j \le n$ and $\boldsymbol{c}_i = \boldsymbol{c}_j$.

We consider the lower bound of query complexity over $\mathbb{F}_2$ first.

▶ **Theorem 12.** *Let $\boldsymbol{M} \in \{0,1\}^{n\times n}$ be a binary matrix over $\mathbb{F}_2$. Let ε be a real number such that $0 < \varepsilon < 1$ and $n \ge 2(1 + \log \frac{n^2}{\varepsilon})$, then $\Omega(n)$ queries are necessary to detect whether there exist two identical columns in $\boldsymbol{M}$ with probability at least $1 - \varepsilon$.*

Proof. We reduce this problem to Disjointness. Assume Alice has a string $x \in \{0,1\}^{n-1}$, and Bob has a string $y \in \{0,1\}^{n-1}$. Now Alice could construct a matrix $\boldsymbol{X} \in \{0,1\}^{\frac{n}{2}\times n}$, where

$$\boldsymbol{X} = \begin{bmatrix} \boldsymbol{x} & \boldsymbol{a}_1 & \boldsymbol{a}_2 & \cdots & \boldsymbol{a}_{\frac{n}{2}-1} \\ 1 & 1 & 1 & \cdots & 1 \end{bmatrix}^{\mathrm{T}}.$$

We denote the $j^{\,\mathrm{th}}$ element of vector $\boldsymbol{a}_i$ as a_{ij}. For each a_{ij}, when $x_j = 1$, we let $a_{ij} = 1$; and when $x_j = 0$, we let a_{ij} be a random variable drawn from a uniform distribution in $\{0,1\}$. Bob constructs $\boldsymbol{Y}$ by the same method. Then let

$$\boldsymbol{M} = \begin{bmatrix} \boldsymbol{X} \\ \boldsymbol{Y} \end{bmatrix}$$

be an $n \times n$ matrix. If x and y intersect, then the corresponding column of $\boldsymbol{M}$ is all ones. Since the last column of $\boldsymbol{M}$ is also all ones, $\boldsymbol{M}$ contains two identical columns. If x and y do not intersect, then for every two columns, the probability that they are identical is at most $\frac{1}{2^{\frac{n}{2}-1}}$. By a union bound, the probability that there exist two identical columns is less than $\binom{n}{2} \times \frac{1}{2^{\frac{n}{2}-1}} \le \frac{n^2}{2^{\frac{n}{2}-1}} \le \varepsilon$, since $n \ge 2(1 + \log \frac{n^2}{\varepsilon})$. Alice and Bob must communicate $\Omega(n)$ bits, and sending $\boldsymbol{u}^\mathrm{T}\boldsymbol{X}\boldsymbol{v}$ and $\boldsymbol{u}^\mathrm{T}\boldsymbol{Y}\boldsymbol{v}$ each need only one bit over $\mathbb{F}_2$, so $\Omega(n)$ queries are necessary to detect two identical columns. ◀

For the upper bounds over $\mathbb{F}_2$ and $\mathbb{R}$ we have the following theorem.

▶ **Theorem 13.** *Let $\boldsymbol{M} \in \{0,1\}^{n\times n}$ be a binary matrix.*

- *$O(n \log(n/\varepsilon))$ queries over $\mathbb{F}_2$ suffice to detect two identical columns with probability $1-\varepsilon$.*
- *$O(n)$ queries over $\mathbb{R}$ suffice to detect two identical columns with probability one.*

Proof. We choose a random n-dimensional vector $\boldsymbol{u}$, where each u_i is independent. Over $\mathbb{R}$, let u_i be chosen from a standard normal distribution $N(0,1)$; and over $\mathbb{F}_2$, let u_i be chosen uniformly from $\{0,1\}$. Notice that n queries suffice to obtain $\langle \boldsymbol{u}, \boldsymbol{c}_i \rangle$ for $1 \le i \le n$, where $\boldsymbol{c}_i$ is the i^{th} column of $\boldsymbol{M}$. If there are two identical columns $\boldsymbol{c}_i$ and $\boldsymbol{c}_j$, then $\langle \boldsymbol{u}, \boldsymbol{c}_i \rangle = \langle \boldsymbol{u}, \boldsymbol{c}_j \rangle$ always holds.

Now we analyze the probability that $\langle \boldsymbol{u}, \boldsymbol{c}_i \rangle = \langle \boldsymbol{u}, \boldsymbol{c}_j \rangle$ holds for two columns that are not equal. For convenience, let $\boldsymbol{v} = \boldsymbol{c}_i - \boldsymbol{c}_j$. Since $\boldsymbol{c}_i \neq \boldsymbol{c}_j$, we know that $\boldsymbol{v} \neq \boldsymbol{0}$. Assume $v_k \neq 0$ for some index k such that $1 \le k \le n$. When querying over $\mathbb{R}$, we have that

$$\langle \boldsymbol{u}, \boldsymbol{c}_i \rangle - \langle \boldsymbol{u}, \boldsymbol{c}_j \rangle = \langle \boldsymbol{u}, \boldsymbol{c}_i - \boldsymbol{c}_j \rangle = \langle \boldsymbol{u}, \boldsymbol{v} \rangle = \sum_{i=1}^{n} u_i v_i = u_k v_k + \sum_{i \neq k} u_i v_i.$$

Since $u_k \sim N(0,1)$ and $v_k \neq 0$, we have that $u_k v_k + \sum_{i \neq k} u_i v_i = 0$ with probability 0, which means that $\langle \boldsymbol{u}, \boldsymbol{c}_i \rangle \neq \langle \boldsymbol{u}, \boldsymbol{c}_j \rangle$ with probability one. Therefore, $O(n)$ queries suffice over $\mathbb{R}$ to detect identical columns with probability one.

Working over the field $\mathbb{F}_2$, we see that $u_k v_k + \sum_{i \neq k} u_i v_i = 0$ with probability $\frac{1}{2}$. This means that $\langle \boldsymbol{u}, \boldsymbol{c}_i \rangle = \langle \boldsymbol{u}, \boldsymbol{c}_j \rangle$ with probability $\frac{1}{2}$. If we choose $\log(n^2/\varepsilon) = O(\log(n/\varepsilon))$ independent vectors $\boldsymbol{u}$, then this equality holds for every $\boldsymbol{u}$ with probability $\frac{\varepsilon}{n^2}$. Since there are $\binom{n}{2} \le n^2$ pairs (i,j), the overall error probability is less than $\frac{\varepsilon}{n^2} \cdot n^2 = \varepsilon$ by a union bound. Therefore, the query complexity in the $\mathsf{u^T Mv}$ model over $\mathbb{F}_2$ is $O(n \log(n/\varepsilon))$. ◀

4.3 Majority

Given an $n \times n$ matrix $\boldsymbol{M}$ over $\mathbb{F}_2$, we consider computing the *column-wise majority* of $\boldsymbol{M}$. That is, for each column, we compute whether it contains at least $n/2$ ones or not. We prove that $\Theta(n^2)$ queries are necessary and sufficient, even for randomized algorithms.

▶ **Theorem 14.** *Let $\boldsymbol{M} \in \mathbb{F}_2^{n \times n}$ be a binary matrix. Computing the column-wise majority of $\boldsymbol{M}$ requires $\Omega(n^2)$ queries, even for constant success probability.*

Proof. We reduce this problem to Disjointness. Assume Alice has n binary strings of length n, i.e. $x_1, x_2, \ldots, x_n$, each of which contains exactly $\frac{n}{4}$ 1s. Bob has n binary strings of length n, i.e. $y_1, y_2, \ldots, y_n$, each of which contains exactly $\frac{n}{4}$ 1s as well. We define $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ as follows:

$$f(x,y) = \begin{cases} 0, & x \text{ and } y \text{ have non-empty intersection,} \\ 1, & \text{otherwise.} \end{cases}$$

By a direct sum theorem in communication complexity, $\Omega(n^2)$ bits of communication are required to decide $(f(x_1,y_1), f(x_2,y_2), \ldots, f(x_n,y_n))$ simultaneously [34]. Let $\boldsymbol{x}_i$ be the corresponding n-dimensional column vector of string x_i. Also, let $\boldsymbol{y}_i$ be the corresponding column vector of string y_i. Alice and Bob construct matrices $\boldsymbol{X}$ and $\boldsymbol{Y}$, where

$$\boldsymbol{X} = \begin{bmatrix} \boldsymbol{x}_1 & \boldsymbol{x}_2 & \cdots & \boldsymbol{x}_n \end{bmatrix} \qquad \text{and} \qquad \boldsymbol{Y} = \begin{bmatrix} \boldsymbol{y}_1 & \boldsymbol{y}_2 & \cdots & \boldsymbol{y}_n \end{bmatrix}.$$

Let $\boldsymbol{M} = \boldsymbol{X} + \boldsymbol{Y}$. Then x_i and y_i intersect if and only if the majority of i^{th} column of $\boldsymbol{M}$ is 0 since the elements are over $\mathbb{F}_2$. Furthermore, $\boldsymbol{u}^{\mathrm{T}} \boldsymbol{M} \boldsymbol{v}$ can be computed by the communication of $\boldsymbol{u}^{\mathrm{T}} \boldsymbol{X} \boldsymbol{v}$ and $\boldsymbol{u}^{\mathrm{T}} \boldsymbol{Y} \boldsymbol{v}$, each communication requiring one bit. Thus, the number of queries needed to decide the majority of every column is $q(n) = \Omega(n^2)$. ◀

▶ **Corollary 15.** *Given a matrix $\boldsymbol{M} \in \{0,1\}^{n \times n}$ over $\mathbb{F}_2$, then the query complexity of computing the column-wise majority is $\Theta(n^2)$, for both deterministic and randomized queries.*

4.4 Permutation Matrix

A matrix $\boldsymbol{M} \in \{0,1\}^{n\times n}$ is a *permutation matrix* if each column and each row contains exactly one entry equal to 1. We consider the query complexity over both $\mathbb{R}$ and $\mathbb{F}_2$, which are very different.

We observe checking if a graph G is a perfect matching is equivalent to checking if the adjacency matrix is a permutation matrix. This also holds for the bipartite version: for a graph on $2n$ vertices, let $M_{ij} = 1$ when the i^{th} vertex on the left is connected to the j^{th} vertex on the right. The following theorem states that $O(1)$ queries suffice over the reals to check whether $\boldsymbol{M}$ is a permutation matrix with constant probability.

▶ **Theorem 16.** *Let $\boldsymbol{M} \in \{0,1\}^{n\times n}$ be a binary matrix over $\mathbb{R}$. Then, $O(1)$ queries suffice to check whether $\boldsymbol{M}$ is a permutation matrix with constant probability.*

Proof. Using a single query $\boldsymbol{u} = \boldsymbol{v} = (1,1,\ldots,1)^{\mathrm{T}}$, we first verify that $\boldsymbol{M}$ contains exactly n ones. Assume this holds. Also, assume without loss of generality that n is even.

We first describe an algorithm to test with constant probability whether each column contains a single one. Reversing the roles of columns and rows will establish the same for rows. The algorithm repeats the following process a constant number of times. Randomly select a subset $A \subseteq [n]$ of exactly $n/2$ columns. Let $\boldsymbol{u}$ be the all ones vector, and let $\boldsymbol{v} = \mathbf{1}_A$ and $\boldsymbol{v}' = \mathbf{1}_{A\setminus[n]}$ be the indicator vectors for A and its complement. Reject if either $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} \neq n/2$ or $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}' \neq n/2$.

If $\boldsymbol{M}$ is a permutation matrix, then $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = \boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}' = n/2$ holds. If $\boldsymbol{M}$ is not a permutation matrix, there must be a pair of columns (or rows), one with all zeros, and one with at least two ones. Suppose column c contains all zeros, and column c' contains at least two ones. With constant probability in choosing A, we have $c \in A$ and $c' \notin A$ or vice versa. Conditioned on this, we claim that either $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} \neq n/2$ or $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}' \neq n/2$ with constant probability as well.

To see this, consider randomly partitioning the $n-2$ columns (excluding c and c') into two groups of size $\frac{n}{2}-1$. Let s_1 and s_2 be the number of ones in Groups 1 and 2, respectively. Without loss of generality, assume $s_1 \leq s_2$. Now, consider adding c and c' to the two groups, conditioned on them being separated. If c' is in Group 2, then Group 2 will have more ones than Group 1. Thus, one of the groups must not have $n/2$ ones, and our algorithm rejects with constant probability. ◀

Interestingly, the query complexity depends on the field. If $\boldsymbol{M} \in \{0,1\}^{n\times n}$ is over $\mathbb{F}_2$, then $O(1)$ queries are far from enough.

▶ **Theorem 17.** *Let $\boldsymbol{M} \in \mathbb{F}_2^{n\times n}$ be a matrix. Then, $\Omega(n)$ queries are necessary to determine whether $\boldsymbol{M}$ is a permutation matrix with constant probability.*

Proof. We reduce this problem to Disjointness. Alice holds a string $x \in \{0,1\}^n$ and Bob holds a string $y \in \{0,1\}^n$. Now Alice constructs a $3n \times 3n$ matrix

$$\boldsymbol{A} = \begin{bmatrix} \boldsymbol{A}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \boldsymbol{A}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \boldsymbol{A}_n \end{bmatrix} \quad \text{where} \quad \boldsymbol{A}_i = \begin{cases} \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} & \text{if } x_i = 0 \\ \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} & \text{if } x_i = 1. \end{cases}$$

Bob constructs a $3n \times 3n$ matrix

$$\boldsymbol{B} = \begin{bmatrix} \boldsymbol{B}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \boldsymbol{B}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \boldsymbol{B}_n \end{bmatrix} \quad \text{where} \quad \boldsymbol{B}_i = \begin{cases} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} & \text{if } y_i = 0 \\ \begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{bmatrix} & \text{if } y_i = 1. \end{cases}$$

Let $\boldsymbol{M} = \boldsymbol{A} + \boldsymbol{B}$, with addition over $\mathbb{F}_2$. Then $\boldsymbol{M}$ is a permutation matrix if and only if x and y are disjoint. Thus, the query complexity is $\Omega(n)$ since $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{A}\boldsymbol{v}$ and $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{B}\boldsymbol{v}$ are both a single bit. ◀

4.5 Doubly Stochastic Matrix

A non-negative real-valued matrix is *doubly stochastic* if all rows and columns sum to one.

▶ **Theorem 18.** *Let $\boldsymbol{M} \in (\mathbb{R}^+ \cup \{0\})^{n \times n}$ be a non-negative real matrix. Then $O(1)$ queries suffices to check whether $\boldsymbol{M}$ is doubly stochastic with constant probability.*

Proof. First, check whether the sum of all entries is n by choosing $\boldsymbol{u} = \boldsymbol{v} = (1, 1, \ldots, 1)^{\mathrm{T}}$ and checking whether $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = n$. Assume equality holds. If $\boldsymbol{M}$ is not doubly stochastic, then some column c (or row r) has sum > 1 and another column c' (or row r' respectively) has sum < 1. Partition the columns (rows) into two groups of size $\frac{n}{2}$. By the argument in the proof of Theorem 16, two groups sum to different values with constant probability. ◀

4.6 Matrix with Negative Entries

In our previous result for doubly stochastic matrices, we assumed that all the entries are non-negative. This assumption is necessary. If we allow negative entries in a matrix, then even checking whether or not there exists a negative entry requires $\Omega(n^2/\log n)$ queries.

▶ **Theorem 19.** *Let $\boldsymbol{M} \in \mathbb{R}^{n \times n}$ be a matrix. Then $\Omega(n^2/\log n)$ queries are necessary to test if $\boldsymbol{M}$ contains a negative entry using query vectors with entries in $\{0, \pm 1, \pm 2, \ldots, \pm n^c\}$ for a constant c.*

Proof. We reduce this problem to Disjointness. Alice holds a bit-string x with size n^2, and Bob holds a bit-string y with the same size. Alice and Bob construct $n \times n$ matrices $\boldsymbol{A}$ and $\boldsymbol{B}$, where

$$A_{ij} = \begin{cases} 1, & x_{(i-1)n+j} = 0 \\ 0, & x_{(i-1)n+j} = 1 \end{cases} \quad \text{and} \quad B_{ij} = \begin{cases} 0, & y_{(i-1)n+j} = 0 \\ -1, & y_{(i-1)n+j} = 1 \end{cases}$$

Let $\boldsymbol{M} = \boldsymbol{A} + \boldsymbol{B}$, and notice that $\boldsymbol{M}$ contains negative entries if and only if x and y intersect. If the query complexity is $q(n)$, then by the Disjointness lower bound, $q(n) \log n = \Omega(n^2)$. ◀

5 Graph Problems

5.1 Triangle Detection

Triangle detection task means that a simple graph G is given in the form of adjacency matrix $\boldsymbol{M} \in \{0, 1\}^{n \times n}$, where n is the number of vertices in G, and we want to decide whether there exists a triangle, i.e. there exists $1 \le i < j < k \le n$, such that $M_{ij} = M_{jk} = M_{ki} = 1$. The following theorem shows a lower bound on the number of $\mathsf{u}^{\mathsf{T}}\mathsf{M}\mathsf{v}$ queries to detect a triangle.

▶ **Theorem 20.** *Given a simple graph G consisting of n vertices in the form of its adjacency matrix $\boldsymbol{M} \in \{0,1\}^{n\times n}$, then even with a constant probability, $\Omega(n^2/\log n)$ queries are necessary to determine whether there exists a triangle in G.*

Proof. We reduce this problem to a communication complexity problem, that is [8], given a graph G with n vertices, where Alice holds some edges of G, and Bob holds the remaining edges of G, then $\Omega(n^2)$ bits of communication is required to determine whether there exists a triangle in G, even in the random case with a constant probability.

Now suppose the graph is G, and its adjacency matrix is $\boldsymbol{M} \in \{0,1\}^{n\times n}$. Alice holds some edges represented by the matrix $\boldsymbol{X}$, and Bob holds the remaining edges represented by the matrix $\boldsymbol{Y}$. Obviously $\boldsymbol{M} = \boldsymbol{X} + \boldsymbol{Y}$. Then Alice and Bob can communicate by sending $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{X}\boldsymbol{v}$ and $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{Y}\boldsymbol{v}$, and $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}$ can be obtained immediately since $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = \boldsymbol{u}^{\mathrm{T}}\boldsymbol{X}\boldsymbol{v}+\boldsymbol{u}^{\mathrm{T}}\boldsymbol{Y}\boldsymbol{v}$. Assume $q(n)$ queries can determine whether there exists a triangle, then $q(n)\log n = \Omega(n^2)$. Thus $q(n) = \Omega(n^2/\log n)$. ◀

5.2 Deciding if a Graph is a Star

Star is a special kind of tree where there exists one vertex adjacent to all the other vertices.

▶ **Theorem 21.** *$\boldsymbol{M} \in \{0,1\}^{n\times n}$ is the adjacency matrix of a simple graph G. Then $O(1)$ queries suffice to determine whether G is a star with constant probability.*

The proof of Theorem 21 is shown in Appendix A.

6 Conclusion

In this paper, we undertook an exploratory study of a new query model that considers querying a matrix through vector-matrix-vector queries. We provided new algorithms and lower bounds for problems spanning three domains: linear algebra, statistics, and graphs. For many of our results, we showed nearly matching bounds on the query complexity, sometimes up to logarithmic factors. We also demonstrated that many previously studied queries can be viewed as special cases or variants of the $\mathsf{u}^{\mathsf{T}}\mathsf{M}\mathsf{v}$ model, and therefore, $\mathsf{u}^{\mathsf{T}}\mathsf{M}\mathsf{v}$ queries provide a unified way to study the query complexity of various graph and matrix problems.

In terms of open questions, an interesting direction would be to identify cases where $\mathsf{u}^{\mathsf{T}}\mathsf{M}\mathsf{v}$ queries are much more efficient than previously studied models. Some options include: determining the minimum cut more efficiently than cut queries [39, 35] or estimating subgraph counts (e.g., triangles) more efficiently than local graph queries [6, 21, 40]. It could also be interesting to study the generalization of our model to k-linear forms (i.e., querying a k-tensor by specifying k vectors), comparing against k-partite independent set queries for counting k-cliques [12, 11, 19].

A Remaining Proofs

Proof of Theorem 6. We show that for each query, if $\boldsymbol{M}$ is a diagonal matrix, then the test will always succeed; if not, then the test will fail with constant probability. Then by error reduction, $O(\log(\frac{1}{\varepsilon}))$ queries suffice to achieve error probability at most ε.

For each query, we choose $\boldsymbol{u}$, $\boldsymbol{v}$ as the above algorithm describes. Therefore,

$$\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = \sum_{i\in S, j\in[n]-S} u_i v_j M_{ij}.$$

If $\boldsymbol{M}$ is diagonal, then $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = 0$ always holds. If $\boldsymbol{M}$ is not diagonal, then we claim that $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}$ is non-zero with constant probability. In this case, there exists an off-diagonal element $M_{k\ell} \neq 0$ with $k \neq \ell$. With probability at least $\frac{1}{4}$, $k \in S$ and $\ell \in [n] \setminus S$ simultaneously. Conditioning on this event, let $t_i = \sum_{j\in[n]-S} v_j M_{ij}$, and rewrite $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v}$ as

$$\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = \sum_{i\in S} u_i \sum_{j\in[n]-S} v_j M_{ij} = \sum_{i\in S} u_i t_i.$$

Since

$$t_p = \sum_{j\in[n]\setminus S} v_j M_{kj} = v_\ell M_{k\ell} + \sum_{j\in[n]\setminus S\setminus\{\ell\}} v_j M_{kj} \triangleq v_\ell M_{k\ell} + T,$$

and $M_{k\ell} \neq 0$, $v_\ell M_{k\ell}$ has two different possible values. Moreover, at most one choice satisfies $v_\ell M_{k\ell} + T = 0$. So $t_k \neq 0$ with probability at least $\frac{1}{2}$. Now under the condition that $t_k \neq 0$,

$$\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} = \sum_{i\in S} u_i t_i = u_k t_k + \sum_{i\in S\setminus\{k\}} u_i t_i \triangleq u_k t_k + R.$$

Since $t_k \neq 0$, by the same argument, $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{v} \neq 0$ with probability at least $\frac{1}{2}$. Combining all of these events, the test fails with probability at least $\frac{1}{16}$, which completes the proof. ◀

Proof of Theorem 11. We construct a random vector $\boldsymbol{u} \in \mathbb{R}^n$, where each entry u_i is independent and follows the standard Gaussian distribution. Let $\boldsymbol{e}_i$ denote the n dimensional vector with i^{th} entry 1 and all other entries 0s, and let $\boldsymbol{e} = \sum_{i=1}^n \boldsymbol{e}_i$ be the all ones n-dimensional vector. Also, let $\boldsymbol{c}_i$ denote the i^{th} column of matrix $\boldsymbol{M}$. Since we have

$$\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{e}_i = \boldsymbol{u}^{\mathrm{T}} \begin{bmatrix} \boldsymbol{c}_1 & \boldsymbol{c}_2 & \cdots & \boldsymbol{c}_n \end{bmatrix} \boldsymbol{e}_i = \boldsymbol{u}^{\mathrm{T}}\boldsymbol{c}_i = \sum_{j=1}^n u_j c_{ij},$$

if we compute the sum of all entries of $\boldsymbol{u}$, i.e., $s = \sum_{i=1}^n u_i$, then when $\boldsymbol{c}_i$ is an all ones column, all $c_{ij} = 1$, so $s = \boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{e}_i$. Otherwise,

$$s - \boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{e}_i = \sum_{1\le j\le n, c_{ij}=0} u_j.$$

The above quantity equals to 0 with probability 0, which means $s \neq \boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{e}_i$ with probability one. By querying $\boldsymbol{u}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{e}_i$ for $1 \le i \le n$, and comparing the result to s, we can detect whether there is an all ones column with probability one using $O(n)$ queries. ◀

Proof of Theorem 21. First, check whether $\boldsymbol{M}$ contains exact $2(n-1)$ ones. If not, $\boldsymbol{M}$ is obviously not a star. Now we assume that $\boldsymbol{M}$ contains exact $2(n-1)$ ones, which means G contains $(n-1)$ edges. Then equally divide the vertices into 2 groups of size $\frac{n}{2}$ randomly and uniformly. We only need to check whether the sum of degrees in one group is $\frac{n}{2}$, and another $\frac{3n}{2}-2$. If this is true, the algorithm should report that $\boldsymbol{G}$ is a star. Otherwise, the algorithm reports that $\boldsymbol{G}$ is not a star. We prove this algorithm has a constant error probability.

If G is a star, then the sum of degrees in one group is $\frac{n}{2}$, and another $\frac{3n}{2}-2$.

If G is not a star, we claim that there exists two vertices v_1 and v_2 with different degrees, which satisfies $|\deg(v_1) - \deg(v_2)| < n-2$.

Since G is not a star, then the degree of any vertex can be at most $n-2$.

- If there exists a vertex v_1 with degree $n-2$, then when n is large (e.g. $n > 10$), there must exists another vertex v_2 with degree 1. Therefore,

  $$|\deg(v_1) - \deg(v_2)| = (n-2) - 1 = n-3 < n-2.$$

- If there does not exists a vertex with degree $n-2$, then the degree of all vertices are in $\{0, 1, 2, \ldots, n-3\}$. When n is large enough (e.g. $n > 10$), there must exist two vertices v_1 and v_2 with different degrees, and

  $$|\deg(v_1) - \deg(v_2)| \le (n-3) - 0 = n-3 < n-2.$$

Now with probability at least $\frac{1}{2}$, v_1 and v_2 are in the different groups. Without loss of generality, assume $\deg(v_1) > \deg(v_2)$. Conditioned on this, we can decompose the random partition procedure into 2 steps. First, we randomly and uniformly partition the other $n-2$ vertices except v_1 and v_2 into 2 groups with size $\frac{n}{2}-1$. Assume in Group 1 the sum of degrees in these vertices is s_1 and in Group 2 the sum is s_2. Without loss of generality, assume $s_1 \le s_2$. The second step is to place v_1 in Group 1, v_2 in Group 2, or v_2 in Group 2, v_1 in Group 1 both with probability $\frac{1}{2}$.

If we have that

$$\begin{aligned} s_1 + \deg(v_1) &= \tfrac{3n}{2} - 2, & s_2 + \deg(v_2) &= \tfrac{n}{2}, \\ s_1 + \deg(v_2) &= \tfrac{n}{2}, & s_2 + \deg(v_1) &= \tfrac{3n}{2} - 2 \end{aligned}$$

hold simultaneously, then $\deg(v_1) - \deg(v_2) = n-2$, a contradiction.

If

$$\begin{aligned} s_1 + \deg(v_1) &= \tfrac{n}{2}, & s_2 + \deg(v_2) &= \tfrac{3n}{2} - 2, \\ s_1 + \deg(v_2) &= \tfrac{n}{2}, & s_2 + \deg(v_1) &= \tfrac{3n}{2} - 2, \end{aligned}$$

then $\deg(v_1) = \deg(v_2)$, a contradiction.

Also, since $s_1 \le s_2, \deg(v_1) > \deg(v_2)$ and $\frac{3n}{2} - 2 \ge \frac{n}{2}$, it is impossible that $s_1 + \deg(v_2) = \frac{3n}{2} - 2$ and $s_2 + \deg(v_1) = \frac{n}{2}$ both holds.

So with probability at least $\frac{1}{2}$, the sums of the two groups will not be $\frac{3n}{2} - 2$ and $\frac{n}{2}$.

Overall, with probability at least $\frac{1}{4}$, the sums of the two groups will not be $\frac{3n}{2} - 2$ and $\frac{n}{2}$. ◀

A.1 Local Graph Queries and Estimating Subgraph Counts

The following four local graph queries can be implemented by $O(\log n)$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries.

▶ **Lemma 22.** *Given the adjacency matrix $\boldsymbol{M} \in \{0,1\}^{n\times n}$ of a simple graph $G = (V, E)$, then the following four queries:*

- ***Degree query*** *i: the degree of vertex i.*
- ***Neighbor query*** *(i, j): the j^{th} neighbor of vertex i.*
- ***Pair query*** *(i, j): whether the edge (i, j) exists.*
- ***Edge-sample query****: sample an edge e uniformly at random from E.*

can be implemented by $O(\log n)$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries.

As one application, we mention the problem of counting subgraphs. Given the adjacency matrix $\boldsymbol{M} \in \{0,1\}^{n\times n}$ of a simple graph G, we want to estimate the number of occurrences of H in G, where H is a given subgraph (such as a triangle). Assadi et. al. [5] shows that with

$$\widetilde{O}\left(\min\left\{m, \frac{m^{\rho(H)}}{\#H}\right\}\right)$$

of the above four standard graph queries, we can obtain a $(1\pm\varepsilon)$-approximation to the number of occurrences of H in G with high probability. Here, $\#H$ is the number of occurrences of H in G, m is the number of edges, and $\rho(H)$ is the fractional edge-cover of H. Also, the $\widetilde{O}(\cdot)$ notation ignores ε and $\log n$ terms, as well as the size of graph H. By Lemma 22, the four standard graph queries can be implemented by $O(\log n)$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries. Therefore, we derive the following result.

▶ **Proposition 23.** *Given the adjacency matrix $\boldsymbol{M} \in \{0,1\}^{n\times n}$ of a simple graph G and an arbitrary small target graph H, $\widetilde{O}\left(min\left\{m, \frac{m^{\rho(H)}}{\#H}\right\}\right)$ $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries suffice to obtain a $(1 \pm \varepsilon)$-approximation to the number of occurrences of H in G with high probability.*

We briefly compare this to work on independent set queries [12, 11, 19]. Proposition 23 achieves a general result for $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries, whereas estimating triangles or other subgraphs with bipartite independent set queries is an open question. Moreover, estimating larger subgraphs seems to require higher-order queries (e.g., tripartite independent set queries). This suggests that, as expected, $\mathsf{u}^\mathsf{T}\mathsf{M}\mathsf{v}$ queries may be more powerful for a variety of problems.

Almost Optimal Distribution-Free Sample-Based Testing of k-Modality

Abstract

For an integer $k \geq 0$, a sequence $\sigma = \sigma_1, \ldots, \sigma_n$ over a fully ordered set is k-modal, if there exist indices $1 = a_0 < a_1 < \cdots < a_{k+1} = n$ such that for each i, the subsequence $\sigma_{a_i}, \ldots, \sigma_{a_{i+1}}$ is either monotonically non-decreasing or monotonically non-increasing. The property of k-modality is a natural extension of monotonicity, which has been studied extensively in the area of property testing. We study one-sided error property testing of k-modality in the distribution-free sample-based model. We prove an upper bound of[1] $O\left(\frac{\sqrt{kn}\log k}{\epsilon}\right)$ on the sample complexity, and an almost matching lower bound of $\Omega\left(\frac{\sqrt{kn}}{\epsilon}\right)$. When the underlying distribution is uniform, we obtain a completely tight bound of $\Theta\left(\sqrt{\frac{kn}{\epsilon}}\right)$, which generalizes what is known for sample-based testing of monotonicity under the uniform distribution.

1 Introduction

Monotonicity of functions has been studied extensively in the area of property testing [30, 35, 29, 46, 33, 32, 6, 45, 1, 37, 38, 31, 12, 16, 19, 20, 15, 24, 23, 41, 7, 21, 36, 18, 4, 26, 27, 13, 40, 42, 22, 25, 14, 43]. The different works vary in the domains and ranges they consider, as well as in the precise task studied (e.g., standard testing vs. tolerant testing and distance approximation). However, what is common to almost all of these results, is that they allow query access to the tested function, and the underlying distribution is uniform.

[1] Since our results hold for any $k \geq 0$, we should actually replace the term $\sqrt{kn}$ by $\sqrt{(k+1)n}$ and $\log k$ by $\log(k+2)$, but for the sake of readability, we refrain from doing so.

In this work, we consider a natural extension of monotonicity: *k-modality*. Since the domain we study is $[n] = \{1, \ldots, n\}$, it is convenient to think of the tested object as being a sequence $\sigma = \sigma_1, \ldots, \sigma_n$, whose elements belong to a fully ordered set. A sequence σ is said to be *k-modal* if there exist indices $1 = a_0 < a_1 < \cdots < a_{k+1} = n$, such that for each i, the subsequence $\sigma_{a_i}, \ldots, \sigma_{a_{i+1}}$ is either monotonically non-decreasing or monotonically non-increasing. In other words, a sequence is k-modal if there are at most k "peaks" and "valleys" (excluding the endpoints). For example, the sequence $3, 2, 2, 1, 2, 3, 4, 2$ is 2-modal, but not 1-modal (see Figure 1). We shall assume for simplicity that σ is over $\mathbb{R}$, and use $\mathcal{M}_k$ to denote the set of all k-modal sequences over $\mathbb{R}$. Observe that a sequence is unate (i.e., either monotonically non-decreasing or monotonically non-increasing) if and only if it is 0-modal.

We study distribution-free sample-based testing of k-modality with one-sided error. Namely, the testing algorithm is given as input $k \geq 0$ and $\epsilon > 0$. For an arbitrary unknown distribution $p : [n] \to [0, 1]$, it is provided with a sample of pairs (i, σ_i), where i is selected i.i.d according to p. If σ is k-modal, then the algorithm should accept with probability 1, while if σ is ϵ-far from k-modality with respect to p, then the algorithm should reject with probability at least $2/3$. A sequence σ is ϵ-far from k-modality with respect to p, if $\sum_{i:\tau_i \neq \sigma_i} p(i) > \epsilon$ for every k-modal sequence $\tau = \tau_1, \ldots, \tau_n$.

Thus, the algorithm cannot select the symbols of σ that it observes (as in the case when queries are allowed), and it must work for every underlying distribution p. Since we require that the testing algorithm have one-sided error, it may reject σ only if the sample contains evidence that σ is not k-modal. Therefore, the question we address is:

> What is the minimum sample size $s = s(n, k, \epsilon)$ such that for every sequence σ (of length n) and underlying distribution p, if σ is ϵ-far from being k-modal with respect to p, then the sample contains evidence that σ is not k-modal?

It is known that for monotonicity and unateness (i.e., the special case of $k = 0$), when the underlying distribution p is uniform, then a sample of size $\Theta(\sqrt{n/\epsilon})$ is both necessary and sufficient.[2] The question is how does the sample complexity increase as k increases, and what is the effect of having a general underlying distribution p.[3]

1.1 Our results

Our first result is the following upper bound for distribution-free testing.[4]

▶ **Theorem 1.1.** *The sample complexity of distribution-free one-sided error sample-based testing of k-modality is $O\left(\frac{\sqrt{kn}\log k}{\epsilon}\right)$.*

We show that the upper bound in Theorem 1.1 is almost tight (up to a factor of $\log k$), by establishing the next lower bound.

▶ **Theorem 1.2.** *The sample complexity of distribution-free one-sided error sample-based testing of k-modality is $\Omega\left(\frac{\sqrt{kn}}{\epsilon}\right)$. This lower bound holds for any $\epsilon < 1/4$ and $k \leq n/4 - 1$.*

---

[2] The lower bound for monotonicity can be found for example in [36, Claim 7.5.1] (where it actually holds for two-sided error), and this extends to unateness. The upper bound is folklore, where a more general statement, regarding any poset, follows from [33, Theorems 6&14].

[3] The problem of distribution-free sample-based testing of monotonicity is also considered in [36, Claim 7.5.2]. The upper bound they claim is correct in terms of the dependence on n (which is $\sqrt{n}$), but not in terms of the dependence on $1/\epsilon$. In our analysis, we fix the flaw in their argument.

[4] See footnote 1.

When the underlying distribution is uniform, we obtain a completely tight result, which generalizes the known result for testing monotonicity. Here, rather than having a linear dependence on $1/\epsilon$, the complexity grows like $1/\sqrt{\epsilon}$.

▶ **Theorem 1.3.** *The sample complexity of one-sided error sample-based testing of k-modality under the uniform distribution is $\Theta\left(\sqrt{\frac{kn}{\epsilon}}\right)$. The lower bounds holds for any $\epsilon < 1/4$ and $k \leq \epsilon n$.*

Note that the requirement that $k \leq \epsilon n$ is not really a constraint as we are only interested in the sublinear regime.

1.2 Techniques

The lower bounds. We start by shortly discussing our lower bounds (Theorem 1.2 for the distribution-free case, and the lower bound in Theorem 1.3, for the uniform case). They are both variants of the known lower bound for testing monotonicity with one-sided error under the uniform distribution. In both lower bounds, the sequence σ is of the form $2, 1, 4, 3, \ldots, 2m, 2m-1, 3m, \ldots, 3m$ (where the value $3m$ appears $n-2m$ times), for an appropriate choice of m. When the underlying distribution is uniform, m is set to be $2\epsilon n$ (assuming, for simplicity, that $2\epsilon n$ is an integer). In the distribution-free case, m is set to be $n/2-1$, and the underlying distribution p assigns weight $\frac{2\epsilon}{m} = \frac{4\epsilon}{n-2}$ to each of the first $2m = n-2$ symbols, and weight $\frac{1-4\epsilon}{2}$ to each of the remaining two symbols. In both cases it is not hard to verify that σ is ϵ-far from being k-modal (with respect to the corresponding distribution). What is also common to both cases is that in order to obtain evidence that σ is not k-modal, it is necessary that the sample "hit" at least $k/2$ pairs of indices $(2i-1, 2i)$ for $i \in [m]$. By a birthday-paradox-type argument, the sample must be of size $\Omega\left(\sqrt{km}/\epsilon\right)$. The lower bounds now diverge due to the difference in the setting of m, where the flexibility of the distribution-free case allows us to set m to be $\Theta(n)$ and obtain a higher lower bound.

The upper bound for the distribution-free case. We first observe that in order to test k-modality, it suffices to test two closely related properties. For the sake of simplicity, here we describe and discuss one of them, which we denote by $\mathcal{F}_t^{\Uparrow}$ where $t = k+3$. A sequence $\sigma = \sigma_1, \ldots, \sigma_n$ belongs to $\mathcal{F}_t^{\Uparrow}$ if and only if there is no subsequence of indices $x_1, \ldots, x_t$ such that $1 \leq x_1 < \cdots < x_t \leq n$ and such that $\sigma_{x_i} < \sigma_{x_{i+1}}$ for every odd i and $\sigma_{x_i} > \sigma_{x_{i+1}}$ for every even i. We show that for any distribution p, if σ is ϵ-far with respect to p from $\mathcal{F}_t^{\Uparrow}$, then a sample of size $O(\sqrt{tn}\log t/\epsilon)$ will contain such a subsequence of indices.

A central ingredient in the proof of this sample-complexity upper bound is a structural claim. It states that if a sequence σ is ϵ-far from $\mathcal{F}_t^{\Uparrow}$, then there exist t indices $1 = a_1 < a_2 < \cdots < a_t = n$ for which the following holds. For each subsequence $\sigma_{a_i}, \ldots, \sigma_{a_{i+1}}$, if i is odd, then the subsequence is at least (ϵ/t)-far (with respect to p) from being monotonically non-decreasing, and if i is even, then it is at least (ϵ/t)-far from being monotonically non-increasing. Observe that the i^{th} subsequence and the $(i+1)^{\text{th}}$ subsequence share a common symbol. This is of importance when the common symbol has relatively large weight according to p.

The next ingredient is a claim regarding the probability of obtaining evidence, for each such subsequence, concerning its non-monotonicity (in the appropriate direction). In a certain sense we are reducing the problem of testing k-modality to testing monotonicity, where there are several subtleties to address. First, when considering the task of testing monotonicity for each of these subsequences, the fact that the underlying distribution is arbitrary, means

that we need to deal both with very large probabilities and with very small probabilities, which makes the analysis more complex than in the uniform case. Second, recall that each subsequence is (ϵ/t)-far from being monotone. The "stand-alone" problem of distribution-free testing of monotonicity has sample complexity that grows linearly with the inverse of the distance to monotonicity. This seems to suggest that we get a linear dependence on t (recall that $t = k + 3$), while we claim that the dependence is $\tilde{O}(\sqrt{k})$. Therefore, the reduction to the $t - 1$ instances of testing monotonicity, should be done with care. Finally, assume that we obtain evidence of non-monotonicity (in the appropriate direction) for each subsequence (where there may be overlap between neighboring subsequences due to the common symbol). We observe that we can combine these "small pieces of evidence" to infer that σ does not belong to $\mathcal{F}_t^{\Uparrow}$.

The upper bound for the uniform case. The improvement in the sample complexity for the uniform case (as compared to the distribution-free case) has two sources. The first is that the basic task of testing monotonicity requires a smaller sample when the underlying distribution is uniform. The second is that we do not apply the structural claim described above to "break" σ into predetermined subsequences and then consider the task of testing monotonicity for each of them. Instead, the subsequences are essentially determined as part of the probabilistic analysis, together with the evidence against their monotonicity. Thus, rather than taking a union bound over events of violating monotonicity in predetermined subsequences, we lower bound the probability of sampling a sufficient number of violations by analysing an appropriate sum of geometric random variables.

Specifically, we apply the Poissonization technique (see, e.g., [48, Chapter 10]), which allows us to analyze the sample as if each pair (i, σ_i) is selected independently. We then define a process that can be viewed as traversing the sequence σ while selecting the sample "on the fly", and gathering evidence against monotonicity of subsequences. We lower bound the probability (over the selection of the sample) that the process gathers sufficient pieces of evidence before σ is fully traversed.

1.3 Related results

As noted at the start of this section, there is a plethora of works on testing monotonicity and unateness. Here we focus only on those results in which the domain is the same as ours, namely $[n]$. Unless stated explicitly otherwise, the results are for testing with queries and under the uniform distribution.

Monotonicity testing over $[n]$ was first studied by Ergun et al. [30]. They gave an algorithm whose query complexity is $O(\log n/\epsilon)$. They also showed that $\Omega(\log n)$ queries are necessary for any non-adaptive comparison-based algorithm and constant ϵ. Fischer [32] proved that this lower bound actually holds for adaptive algorithms as well.

For the special case of binary sequences, k-modality is essentially the same as k-monotonicity, which was studied in [17]. To be precise, k-monotonicity of binary sequences is equivalent to $\mathcal{F}_{k+2}^{\Uparrow}$ (where $\mathcal{F}_{k+2}^{\Uparrow}$ is as defined in Section 1.2). They show that it is possible to test k-monotonicity by performing $O(k/\epsilon)$ (non-adaptive) queries. Furthermore, they prove that any one-sided error (possibly adaptive) tester for k-monotonicity over $[n]$ must have query complexity $\Omega(k/\epsilon)$. If two-sided error is allowed, then no dependence on k is necessary, and the query complexity is $\mathrm{poly}(1/\epsilon)$ [17, 14].

The related property of k-interval functions over $[0, 1]$ was studied in [39, 3]. Each such function is defined by a partition of $[0, 1]$ into (at most) k intervals, where on each interval the value of the function is constant (either 0 or 1). Observe that if we consider a discretized

version of this property where the domain is $[n]$, then it is the same as $(k-2)$-modality. Balcan et al. [3] (strengthening the result of [39]) give an upper bound of $\sqrt{k} \cdot \text{poly}(1/\epsilon)$ on the sample complexity of testing this property under the uniform distribution with two-sided error. We note that if queries are allowed, then the dependence on k can be removed [39, 3]. In addition, the result can be generalized to the distribution-free case in the active testing model [3].[5]

Other related works on testing (with queries) that generalize testing monotonicity include [8] for testing local properties of d-dimensional arrays and [44, 9, 10] for testing forbidden order patterns.

Distribution-free testing of monotonicity (with queries) was studied in [37], approximating the distance of a sequence to monotonicity was studied in [45, 2], and the problem of testing monotonicity of distributions (over totally ordered domains) was addressed in [5].

1.4 Organization

We start with some general preliminaries in Section 2. In Section 3 we present several definitions and observations relating to k-modality, which are later applied in our analysis. The upper bound for distribution-free testing is provided in Section 4, and the one for the uniform distribution in Section 5. Both lower bounds are given in Appendix C.

2 Preliminaries: sequences, distances and property testing

For an integer n, let $[n] = \{1, \ldots, n\}$, and for two integers $i \leq j$, let $[i, j] = \{i, \ldots, j\}$. For a sequence $\sigma = \sigma_1 \ldots \sigma_n$ and a subset of indices $Q \subseteq [n]$, we use $\sigma_{|Q}$ to denote the subsequence of σ corresponding to the indices in Q. A *property* of sequences $\mathcal{P}$ is simply a set of sequences. We say that σ *has property* $\mathcal{P}$, or that σ *satisfies* $\mathcal{P}$, if $\sigma \in \mathcal{P}$.

In what follows, we present several notions and notations that are defined based on a probability distribution $p : [n] \to [0, 1]$. For a set $S \subseteq [n]$, let $p(S) = \sum_{i \in S} p(S)$. Whenever p is clear from the context, we refer to $p(S)$ as the *probability weight* of S, or simply the *weight* of S.

The *distance* between σ and τ *with respect to* p, denoted $\text{dist}(\sigma, \tau, p)$, is $\sum_{i:\sigma_i \neq \tau_i} p(i)$ (or ∞ if they are not of the same length). For a property $\mathcal{P}$, the distance of σ from $\mathcal{P}$ with respect to p, denoted $\text{dist}(\sigma, \mathcal{P}, p)$, is $\min_{\tau \in \mathcal{P}}\{\text{dist}(\sigma, \tau, p)\}$. We say that σ is ϵ-far from $\mathcal{P}$ with respect to p, or (more concisely) that (σ, p) is ϵ-far from $\mathcal{P}$, if $\text{dist}(\sigma, \mathcal{P}, p) > \epsilon$. Otherwise it is ϵ-close.

▶ **Definition 2.1.** *A distribution-free sample-based testing algorithm for a property $\mathcal{P}$ of sequences is given parameters n and ϵ as well as access to samples from an unknown sequence σ of length n, generated according to an unknown distribution $p : [n] \to [0, 1]$. Namely, it receives pairs (i, σ_i) where i is distributed i.i.d. according to p. The algorithm should satisfy the following:*

[5] The notion of *active testing* is an adaptation of the notion of *active learning* to the context of property testing. The algorithm is given an unlabeled sample distributed according to the underlying distribution p and it may query the labels of part of the sample points. The two complexity measures of interest are hence the (unlabeled) sample complexity, and the query complexity (number of queries performed on the sample points). When the latter equals the former, this coincides with sample-based (distribution-free) testing (referred to as *passive testing* in [3]). However, one may aim at performing fewer queries at the cost of a larger number of unlabeled samples.

- *If $\sigma \in \mathcal{P}$, then the algorithm should accept with probability at least $2/3$.*
- *If $\mathrm{dist}(\sigma, \mathcal{P}, p) > \epsilon$, then the algorithm should reject with probability at least $2/3$.*

If p is known to be the uniform distribution over $[n]$, then we simply say that the algorithm is a sample-based testing algorithm.

If the algorithm always accepts sequences that have property $\mathcal{P}$, then we say that it has one-sided error. otherwise it has two-sided error. The sample-complexity of the algorithm is the number of samples it views (as a function of ϵ and n) when performing the aforementioned task.

In the context of testing k-modality (which is a special case of testing properties that are determined by some parameter), the algorithm is also provided with the parameter k, and its sample complexity may depend on k.

▶ **Definition 2.2.** *For positive integers n and s, and a distribution $p : [n] \to [0, 1]$, we let $I_n(s, p)$ denote the random variable corresponding to a set [6] consisting of s indices from $[n]$ that are selected i.i.d. according to p.*

Note that in order to obtain an upper bound s on the sample complexity of distribution-free sample-based one-sided error testing for a hereditary property $\mathcal{P}$ of sequences,[7] it suffices to show that $\Pr[\sigma_{|I_n(s,p)} \notin \mathcal{P}] \geq 2/3$, for every distribution $p : [n] \to [0, 1]$ and for every sequence σ of length n that is ϵ-far from $\mathcal{P}$ with respect to p.

It will also be useful to define an additional distance measure, which we refer to as the *deletion distance*. Let σ be a sequence of length n and $p : [n] \to [0, 1]$ a weight function (so that $\sum_{i=1}^{n} p(i)$ is not necessarily 1). For a property of sequences $\mathcal{P}$ and a subset $R \subseteq [n]$, let $\mathrm{del}(\sigma, \mathcal{P}, p, R)$ denote the minimum, taken over subsets $D \subseteq R$ such that $\sigma_{|R \setminus D} \in \mathcal{P}$, of $p(D)$ (if there is no such D, then $\mathrm{del}(\sigma, \mathcal{P}, p, R) = \infty$). If $R = [n]$, then we use the shorthand $\mathrm{del}(\sigma, \mathcal{P}, p)$ for $\mathrm{del}(\sigma, \mathcal{P}, p, [n])$.

3 Definitions and observations for k-modality

In this subsection we introduce several notions that will be used in our analysis.

For a pair of indices $x, y \in [n]$ such that $x < y$, we say that (x, y) is an *ascent* (*descent*) with respect to a sequence $\sigma = \sigma_1, \ldots, \sigma_n$, if $\sigma_x < \sigma_y$ ($\sigma_x > \sigma_y$). A pair (x, y) is an *up-pair*, denoted $\Uparrow$-pair (*down-pair*, denoted $\Downarrow$-pair) if it is an ascent (descent). We say that (x, y) and (x', y') are disjoint if $\{x, y\} \cap \{x', y'\} = \emptyset$. For $\Updownarrow \in \{\Uparrow, \Downarrow\}$, we denote $\mathrm{inv}(\Uparrow) = \Downarrow$ and $\mathrm{inv}(\Downarrow) = \Uparrow$.

The next notion will aid us in characterizing k-model sequences by being "free" of certain patterns.

▶ **Definition 3.1.** *Let σ be a sequence of length n, let t be an integer, and let $1 \leq x_1 < \cdots < x_t \leq n$. We say that $(x_1, \ldots, x_t)$ is a t-upward (t-downward) subsequence with respect to σ if for every odd $i \in [t-1]$, (x_i, x_{i+1}) is an ascent (descent), and for every even $i \in [t-1]$, (x_i, x_{i+1}) is a descent (ascent).*
We shall use the symbolic shorthand t-$\Uparrow$ for t-upward sequences and t-$\Downarrow$ for t-downward sequences.

[6] Note that while the sampled indices i (as defined in Definition 2.1) are i.i.d. and hence may appear with repetitions, $I_n(s)$ is a set and hence does not include repetitions

[7] A property of sequences is hereditary if it is preserved under restrictions to subsequences.

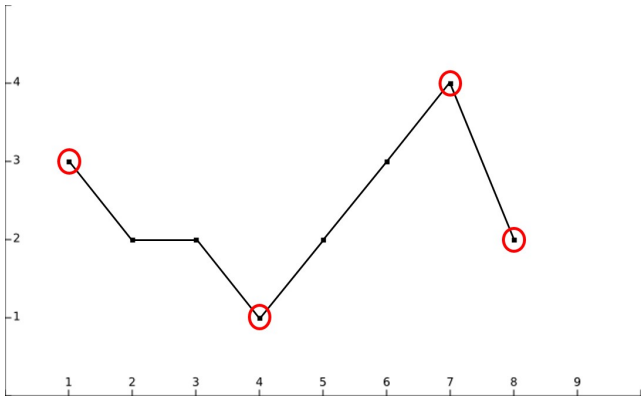

Figure 1 An illustration of the sequence $\sigma = 3,2,2,1,2,3,4,2$. Notice that the marked subsequence $(1,4,7,8)$ is a 4-downward (4-$\Downarrow$) subsequence with respect to σ, and that $\sigma \in \mathcal{F}_5^{\Downarrow}$.

▶ **Definition 3.2.** *For $\Updownarrow \in \{\Uparrow, \Downarrow\}$, we denote by $\mathcal{F}_t^{\Updownarrow}$ the set of all sequences σ such that there is no t-$\Updownarrow$ subsequence with respect to σ (so that $\mathcal{F}$ stands for "free").*
For the special case of $t = 2$, we say that a sequence is $\Updownarrow$-monotone if it belongs to $\mathcal{F}_2^{\mathrm{inv}(\Updownarrow)}$.

For example, if $\sigma = 3,2,2,1,2,3,4,2$, then $(1,4,7,8)$ is a 4-downward (4-$\Downarrow$) subsequence with respect to σ, and $\sigma \in \mathcal{F}_5^{\Downarrow}$. For an Illustration, see Figure 1.

Observe that a sequence σ is k-modal if and only if there is no $(k+3)$-$\Uparrow$ subsequence nor any $(k+3)$-$\Downarrow$ subsequence with respect to σ:

▶ **Observation 3.3.** *For any non-negative integer k we have that $\mathcal{M}_k = \mathcal{F}_{k+3}^{\Uparrow} \bigcap \mathcal{F}_{k+3}^{\Downarrow}$.*

The next notion and observation will be useful when analyzing the evidence found in a sample, that a sequence is not k-modal.

▶ **Definition 3.4.** *Let σ be a sequence of length n, let t be a positive integer, and let $1 \leq x_1 < y_1 \leq x_2 < y_2 \leq \cdots \leq x_t < y_t$. We say that $((x_1,y_1),\ldots,(x_t,y_t))$ is a t-upward-pair (t-downward-pair) sequence with respect to σ, if for every odd $i \in [t]$, (x_i,y_i) is an ascent (descent), and for every even $i \in [t]$, (x_i,y_i) is a descent (ascent). Here too we use the symbolic shorthands t-$\Uparrow$-pair (for t-upward-pair sequences) and t-$\Downarrow$-pair (for t-downward-pair sequences).*

▶ **Observation 3.5.** *For any sequence σ, integer $t \geq 2$, and $\Updownarrow \in \{\Uparrow, \Downarrow\}$, if there is a $(t-1)$-$\Updownarrow$-pair sequence with respect to σ, then there is a t-$\Updownarrow$ subsequence with respect to σ.*

To verify the validity of the last observation, consider for simplicity the case that $\Updownarrow = \Uparrow$. Given a $(t-1)$-$\Uparrow$-pair sequence $((x_1,y_1),\ldots,(x_{t-1},y_{t-1}))$ we define a t-$\Uparrow$ subsequence $(x'_1,\ldots,x'_t)$ as follows: $x'_1 = x_1$, $x'_t = y_{t-1}$, $x'_i = \max(y_{i-1},x_i)$ for each even $i \in [2,t-1]$, and $x'_i = \min(y_{i-1},x_i)$ for each odd $i \in [2,t-1]$.

We shall also make use of the following observation, which will allow us to work with the deletion distance. Its simple proof is given in Appendix B.

▶ **Observation 3.6.** *Let σ be a sequence of length n, $p : [n] \to [0,1]$ a probability distribution, and k a non-negative integer. Then $\mathrm{dist}(\sigma, \mathcal{M}_k, p) = \mathrm{del}(\sigma, \mathcal{M}_k, p)$.*

The last observation in this section will allow us to reduce the problem of testing $\mathcal{M}_k$ to testing $\mathcal{F}_{k+3}^{\Uparrow}$ and $\mathcal{F}_{k+3}^{\Downarrow}$.

▶ **Observation 3.7.** *Let σ be a sequence of length n, $p : [n] \to [0,1]$ a probability distribution, and k a non-negative integer. Then* $\mathrm{dist}(\sigma, \mathcal{M}_k, p) \leq \mathrm{del}(\sigma, \mathcal{F}^{\Uparrow}_{k+3}, p) + \mathrm{del}(\sigma, \mathcal{F}^{\Downarrow}_{k+3}, p)$.

To verify Observation 3.7, let $t = k+3$ and for each $\Updownarrow \in \{\Uparrow, \Downarrow\}$ let $D^{\Updownarrow} \subseteq [n]$ be a subset satisfying $\sigma_{|[n]\setminus D^{\Updownarrow}} \in \mathcal{F}^{\Updownarrow}_t$ and $p(D^{\Updownarrow}) = \mathrm{del}(\sigma, \mathcal{F}^{\Updownarrow}_t, p)$. Since $\mathcal{F}^{\Uparrow}_t$ and $\mathcal{F}^{\Downarrow}_t$ are hereditary properties, for $D = D^{\Uparrow} \cup D^{\Downarrow}$, we have that $\sigma_{|[n]\setminus D} \in \mathcal{F}^{\Uparrow}_t \cap \mathcal{F}^{\Downarrow}_t$. By Observation 3.3, this means that $\sigma_{|[n]\setminus D} \in \mathcal{M}_k$, so that $\mathrm{del}(\sigma, \mathcal{M}_k, p) \leq p(D^{\Updownarrow}) \leq p(D^{\Uparrow}) + p(D^{\Downarrow}) = \mathrm{del}(\sigma, \mathcal{F}^{\Uparrow}_t, p) + \mathrm{del}(\sigma, \mathcal{F}^{\Downarrow}_t, p)$. By Observation 3.6, $\mathrm{dist}(\sigma, \mathcal{M}_k, p) = \mathrm{del}(\sigma, \mathcal{M}_k, p)$ and Observation 3.7 is verified.

4 The upper bound for distribution-free testing

In this section we prove Theorem 1.1, which is restated next.

▶ **Theorem 1.1.** *The sample complexity of distribution-free one-sided error sample-based testing of k-modality is $O\left(\frac{\sqrt{kn}\log k}{\epsilon}\right)$.*

4.1 Structural claims

We start with two structural claims, where the second builds on the first (and where the first will also serve us for the upper bound under the uniform distribution).

▷ Claim 4.1. Let $\sigma = \sigma_1, \ldots, \sigma_n$ be a sequence of length n and $p : [n] \to [0,1]$ a weight function. Then for any $m \in [n]$, $t > 2$ and $\Updownarrow \in \{\Uparrow, \Downarrow\}$,

$$\mathrm{del}(\sigma, \mathcal{F}^{\Updownarrow}_t, p) \leq \mathrm{del}(\sigma, \mathcal{F}^{\Updownarrow}_2, p, [m]) + \mathrm{del}(\sigma, \mathcal{F}^{\mathrm{inv}(\Updownarrow)}_{t-1}, p, [m+1, n]) \ .$$

In order to prove this claim, we essentially show that if it is possible to partition a sequence into two parts, such that the first is free of upward pairs, and the second is free of $(t-1)$-downward sequences, then the entire sequence is free of t-upward sequences.

Proof. By the definition of the deletion distance, there exists a set $I_1 \subseteq [m]$ of weight $\mathrm{del}(\sigma, \mathcal{F}^{\Updownarrow}_2, p, [m])$, such that $\sigma_{|[m]\setminus I_1} \in \mathcal{F}^{\Updownarrow}_2$. Similarly, there exists a set $I_2 \subseteq [m+1, n]$ of weight $\mathrm{del}(\sigma, \mathcal{F}^{\mathrm{inv}(\Updownarrow)}_{t-1}, p, [m+1, n])$, such that $\sigma_{|[m+1,n]\setminus I_2} \in \mathcal{F}^{\mathrm{inv}(\Updownarrow)}_{t-1}$.

Let $\tilde{\sigma}$ denote the sequence that is obtained from σ by deleting all the indices in $I_1 \cup I_2$. Namely, $\tilde{\sigma} = \sigma_{[n]\setminus I_1 \cup I_2}$. We next show that $\tilde{\sigma} \in \mathcal{F}^{\Updownarrow}_t$. We represent $\tilde{\sigma}$ as a concatenation of two sequences, τ_1 and τ_2, where $\tau_1 = \sigma_{|[m]\setminus I_1}$ and $\tau_2 = \sigma_{|[m+1,n]\setminus I_2}$. Assume, contrary to the claim, that there exists a t-$\Updownarrow$ subsequence $(x_1, x_2 \ldots, x_t)$ with respect to $\tilde{\sigma}$. Since (x_1, x_2) is a $\Updownarrow$-pair (by the definition of a t-$\Updownarrow$ subsequence) while $\tau_1 \in \mathcal{F}^{\Updownarrow}_2$, necessarily $x_2 > |\tau_1|$. But then $(x_2, \ldots, x_t)$ is a $(t-1)$-inv($\Updownarrow$) subsequence with respect to τ_2 (more precisely, $(x_2 - |\tau_1|, \ldots, x_t - |\tau_1|)$ is such a subsequence), in contradiction to $\tau_2 \in \mathcal{F}^{\Updownarrow}_{t-1}$.

We conclude that

$$\mathrm{del}(\sigma, \mathcal{F}^{\Updownarrow}_t, p) \leq p(I_1 \cup I_2) = \mathrm{del}(\sigma, \mathcal{F}^{\Updownarrow}_2, p, [m]) + \mathrm{del}(\sigma, \mathcal{F}^{\mathrm{inv}(\Updownarrow)}_{t-1}, p, [m+1, n]) \ ,$$

as claimed. ◁

We next recursively apply Claim 4.1 to show that if σ is far from $\mathcal{F}^{\Updownarrow}_t$, then we can define $t-1$ (almost disjoint) consecutive subsequences, such that each is relatively far from either $\mathcal{F}^{\Updownarrow}_2$ or $\mathcal{F}^{\mathrm{inv}(\Updownarrow)}_2$.

▷ Claim 4.2. Let σ be a sequence of length n, $p : [n] \to [0,1]$ a weight function, $t \geq 2$, and $\Updownarrow \in \{\Uparrow, \Downarrow\}$. Denote $\Delta = \mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p)$ and suppose that $\Delta > 0$. Then there exist indices $1 = a_1 < \cdots < a_t = n$ such that $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, [a_i, a_{i+1}]) \geq \Delta/(t-1)$ for every odd $i \in [t-1]$, and $\mathrm{del}(\sigma, \mathcal{F}_2^{\mathrm{inv}(\Updownarrow)}, p, [a_i, a_{i+1}]) \geq \Delta/(t-1)$ for every even $i \in [t-1]$.

Note that partitioning the domain into disjoint intervals that obey the condition stated in Claim 4.2 may not be possible, due to the existence of indices with a large weight according to p. To address this issue we allow each pair of consecutive intervals ($[a_i, a_{i+1}]$ and $[a_i, a_{i+1}]$) to share a common index. This suffices for our purposes as we shall see in Section 4.3

Proof. We prove the claim by induction on t. For the base case, $t = 2$, the claim is trivial. Turning to the induction step, we assume that the claim holds for $t-1$ (where $t > 2$), and prove it for t.

Define a_2 to be the smallest index in $[n]$ satisfying the required condition $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, [a_2]) \geq \Delta/(t-1)$ (recall that Δ denotes $\mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p)$). Note that: (1) such an index exists, as $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, [n]) \geq \mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p, [n]) = \Delta \geq \Delta/(t-1)$, and (2) $a_2 > 1$, as $\sigma_1 \in \mathcal{F}_2^{\Updownarrow}$ so that $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, \{1\}) = 0$.

Thus, we can apply Claim 4.1 with $m = a_2 - 1$ to obtain that $\mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p) \leq \mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, [a_2 - 1]) + \mathrm{del}(\sigma, \mathcal{F}_{t-1}^{\mathrm{inv}(\Updownarrow)}, p, [a_2, n])$. By the definition of a_2, we have that $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, [a_2 - 1]) < \Delta/(t-1)$. We infer that $\mathrm{del}(\sigma, \mathcal{F}_{t-1}^{\mathrm{inv}(\Updownarrow)}, p, [a_2, n]) > \Delta - \Delta/(t-1) = (t-2)\Delta/(t-1)$.

The claim is established because the existence of $a_3, \ldots, a_t$ (recall that $t > 2$) satisfying the required conditions is implied by the induction hypothesis, using $\tilde{t} = t - 1$, $\tilde{\Updownarrow} = \mathrm{inv}(\Updownarrow)$, $\widetilde{\sigma} = \sigma_{a_2} \ldots \sigma_n$ and $\widetilde{\Delta} = (t-2)\Delta/(t-1)$. Notice that the conditions are satisfied, as $\widetilde{\Delta}/(t-2) = \Delta/(t-1)$. ◁

4.2 Probabilistic claims – obtaining evidence of non-monotonicity

In the following claim we give conditions under which a sample contains evidence that a subsequence is not in $\mathcal{F}_2^{\Updownarrow}$ (with probability at least 2/3). We later apply this claim to the subsequences defined in Claim 4.2.

▷ Claim 4.3. Let σ be a sequence of length n, $p : [n] \to [0,1]$ a probability distribution, and R a subset of $[n]$. Suppose that for $\Updownarrow \in \{\Uparrow, \Downarrow\}$ and for positive β and δ, we have that $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, R) \geq \beta$, and that $p(i) \geq \delta$ for each $i \in R$. Then for $s = \Theta(1/\sqrt{\delta \cdot \beta})$, the probability over the choice of $Q = I_n(s, p)$ that $\sigma_{|R \cap Q} \notin \mathcal{F}_2^{\Updownarrow}$, is at least 2/3.

In order to prove Claim 4.3, we lower bound the probability weight of a sample that falls into a prespecified subset of the domain $[n]$.

▷ Claim 4.4. Let $p : [n] \to [0,1]$ be a probability distribution, and C a subset of $[n]$. Suppose that for positive β and $\delta \leq \beta/c$, where c is a sufficiently large constant, $p(C) \geq \beta$ and $p(x) \geq \delta$ for each $x \in C$. Then for $s = 1/\sqrt{\delta \cdot \beta}$, letting $Q = I_s(n, p)$,

$$\Pr_Q \left[p(C \cap Q) \geq \frac{\delta \beta s}{4} \right] \geq \frac{9}{10} .$$

Note that if Q and $C \cap Q$ were defined as multisets rather than sets, i.e., if we were to take repetitions into account, then Claim 4.4 would have followed from a standard tail bound (Fact A.3). However, since in our case $C \cap Q$ is a set, we need to analyse the effect of collisions in the sample. As the distribution p may contain large probabilities, the collisions can have a significant impact. In order to overcome this difficulty, we use a "flattening technique" that is similar to the one introduced in [28] (see also [34]).

Proof. We prove the claim in two stages. In the first stage we define a "flattened" probability distribution $\hat{p}$ over $[\hat{n}]$ for $\hat{n} \geq n$ together with a subset $\widehat{C} \subseteq [\hat{n}]$, for which we show the following: for any positive integer s, letting $\widehat{Q} = I_s(\hat{n}, \hat{p})$, we have that

$$\text{for any } \tau \geq 0, \quad \Pr_Q[p(C \cap Q) \geq \tau] \geq \Pr_{\widehat{Q}}[\hat{p}(\widehat{C} \cap \widehat{Q}) \geq \tau] \,. \tag{1}$$

In the second stage we show, using certain properties of $\hat{p}$ and $\widehat{C}$, that for s as in the premise of the claim,

$$\Pr_{\widehat{Q}}\left[\hat{p}(\widehat{C} \cap \widehat{Q}) \geq \frac{\delta\beta s}{4}\right] \geq \frac{9}{10} \,. \tag{2}$$

Stage I. If $p(x) \in [\delta, 2\delta]$ for each $x \in C$, then we simply let $\hat{n} = n$, $\hat{p} = p$, and $\widehat{C} = C$, so that Equation (1) holds trivially. Otherwise, the high level idea is that we "split" each $x \in C$ into a subset of indices, each with probability weight in $[\delta, 2\delta]$ (according to $\hat{p}$), as explained precisely next. Assume, without loss of generality, that $C = \{m+1, \ldots, n\}$ for some $m < n-1$. For each $x \in C$ let $\alpha(x) = \lceil \frac{p(x)}{2\delta} \rceil$. Set $\hat{n} = m + \sum_{x=m+1}^{n} \alpha(x)$ and $\widehat{C} = \{m+1, \ldots, \hat{n}\}$. It remains to define $\hat{p}$. With each $x \in C$ we associate a (disjoint) subset, denoted $J(x)$, of $\alpha(x)$ indices in $\{m+1, \ldots, \hat{n}\}$. In particular, we can let $J(x) = \{m+1+\sum_{x'=m+1}^{x-1} \alpha(x'), \ldots, m+\sum_{x'=m+1}^{x} \alpha(x')\}$ for each $x \in \{m+1, \ldots, n\}$. It will be useful to define a mapping $\phi : [\hat{n}] \to [n]$, where for each $y \in \widehat{C}$, $\phi(y) = x$ where x satisfies $y \in J(x)$. For $y \notin \widehat{C}$, we let $\phi(y) = y$. For each $y \notin C$ we set $\hat{p}(y) = p(y)$, and for each $y \in \widehat{C} = \{m+1, \ldots, \hat{n}\}$ we set $\hat{p}(y) = p(\phi(y))/\alpha(\phi(y))$. Note that by the definition of $\alpha(\cdot)$, this ensures that $\hat{p}(y) \in [\delta, 2\delta]$ and that $p(x) = \hat{p}(J(x))$ for each $x \in C$.

In order to establish Equation (1), we apply a coupling argument. Specifically, we define a random variable $\widetilde{Q} \subseteq [n]$ based on $\widehat{Q} \subseteq [\hat{n}]$ as follows: $\widetilde{Q} = \{\phi(y) : y \in \widehat{Q}\}$. Since for each $x \in [n]$ we have that $p(x) = \sum_{y:\phi(y)=x} \hat{p}(y)$, by its definition, $\widetilde{Q}$ is identically distributed to Q. Next observe that for each $x \in C$, if $x \notin \widetilde{Q}$, then necessarily $J(x) \cap \widehat{Q} = \emptyset$, while if $x \in \widetilde{Q}$, then $p(x) \geq \hat{p}(J(x) \cap \widehat{Q})$. Therefore, $p(C \cap \widetilde{Q}) \geq \hat{p}(\widehat{C} \cap \widehat{Q})$, and Equation (1) follows.

Stage II. Since $\hat{p}(\widehat{C}) = p(C)$, and $p(C) \geq \beta$, we have that $\hat{p}(\widehat{C}) \geq \beta$. For $s = 1/\sqrt{\delta\beta}$, let $Y_1, \ldots, Y_s$ be independent random variables such that for each $y \in [\hat{n}]$, $\Pr[Y_r = y] = \hat{p}(y)$. Let $\hat{s} = |\{r : Y_r \in \widehat{C} \setminus \{Y_1, \ldots, Y_{r-1}\}\}|$, and observe that $\hat{p}(\widehat{C} \cap \widehat{Q}) \geq \hat{s} \cdot \delta$ (since $\hat{p}(y) \geq \delta$ for each $y \in \widehat{C}$). Hence, in order to establish Equation (2), it suffices to upper bound the probability that $\hat{s} < \beta s/4$.

To this end we also define $s' = |\{r : Y_r \in \widehat{C}\}|$, so $\mathbb{E}[s'] = \hat{p}(\widehat{C}) \cdot s$. We may think of $\hat{s}$ as being determined by first determining s', and then taking s' samples from $\widehat{C}$, where each $y \in \widehat{C}$ is selected independently with probability $\hat{p}(y)/\hat{p}(\widehat{C})$. Since $s' \sim \mathrm{Bin}(s, \hat{p}(\widehat{C}))$, we have (by Fact A.3) that $\Pr[s' < \mathbb{E}[s']/2] \leq e^{-\hat{p}(\widehat{C})s/8}$. By our setting of s and since $\delta \leq \beta/c$, this probability is at most $1/20$ for a sufficiently large constant c. We henceforth condition on the event that $s' \geq \mathbb{E}[s']/2 \geq \beta s/2$. If all Y_r that belong to C were distinct, then we would have that $\hat{s} = s'$, and we would be done. Since this is not necessarily the case, it remains to show that $\hat{s}$ is not much smaller than s'. To be precise, since our goal is to lower bound the probability that $\hat{s} < \beta s/4$, we condition on the event that $s' = \beta s/2$ (as the probability that $\hat{s} < \beta s/4$ can only decrease as s' increases).

Let $q = |\{r : Y_r \in \widehat{C} \cap \{Y_1, \ldots, Y_{r-1}\}\}|$, so that $\hat{s} = s' - q$. Observe that $\mathbb{E}[q] \leq \binom{s'}{2} \cdot \frac{2\delta}{\hat{p}(\widehat{C})} \leq s' \cdot \frac{\delta s'}{\hat{p}(\widehat{C})}$, which by our condition on s' and since $\hat{p}(\widehat{C}) \geq \beta$ is at most $\frac{\beta s}{2} \cdot \frac{\delta s}{2}$. Once again by our setting of s and since $\delta \leq \beta/c$, this is at most $\frac{\beta s}{80}$ for a sufficiently large constant c. By Markov's inequality, $\Pr\left[q > \frac{\beta s}{4}\right] \leq 1/20$. We can conclude that with probability at least $1 - 2/20 = 9/10$, $\hat{s} \geq \beta s/4$, and the claim follows. ◁

We are now ready to prove Claim 4.3, which applies Claim 4.4 to a vertex cover C in the "violation graph", as defined next.

Proof of Claim 4.3. For indices $x, y \in R$, we say that (x, y) is a "violating pair" if $x < y$ and $\sigma_x \sigma_y \notin \mathcal{F}_2^{\Updownarrow}$. Consider the "violation graph" $G_R = ([n], E_R)$, where E_R is the set of all violating pairs, and recall that a *vertex cover* of a graph is a subset C of vertices such that each edge of the graph contains at least one vertex in C. For a subset of vertices S, let $\Gamma_R(S)$ denote the set of neighbors of vertices belonging to S in the graph G_R.

Let C be a minimum-weight vertex cover of G_R with respect to p. Note that $\sigma_{|R\setminus C} \in \mathcal{F}_2^{\Updownarrow}$, so that $p(C) = \mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, R) \geq \beta$. Let $s = 16/\sqrt{\delta \cdot \beta}$. First, consider a sample, denoted Q_1, of $s/16$ vertices (indices in $[n]$) drawn independently according to p. By Claim 4.4, the probability that $p(C \cap Q_1) \geq \beta\delta s/64$ is at least $9/10$. Conditioned on this event occurring, we consider a second sample, denoted Q_2, of $15s/16$ vertices drawn independently according to p. As observed in [36], $p(\Gamma_R(C \cap Q_1)) \geq p(C \cap Q_1)$ (since otherwise, $C' = (C \setminus Q_1) \cup \Gamma_R(C \cap Q_1)$ is a vertex cover with smaller weight than C). Hence, each of these $15s/16$ sampled vertices belongs to $\Gamma_R(C \cap Q_1)$ with probability at least $p(C \cap Q_1)$. Therefore, the probability that $Q_1 \times Q_2$ contains no violating pair is upper bounded by

$$(1 - p(C \cap Q_1))^{15s/16} \leq \left(1 - \frac{\beta\delta s}{64}\right)^{15s/16} \leq e^{-15\beta\delta s^2/1024} \leq e^{-3.75} \leq 1/10 \,.$$

We conclude that the sample Q contains a violating pair, and hence $\sigma_{|R\cap Q} \notin \mathcal{F}_2^{\Updownarrow}$, with probability at least $1 - 1/10 - 1/10 > 2/3$, as claimed. ◁

4.3 Wrapping things up

By combining Claims 4.2 and Claim 4.3, we can establish the next lemma, which gives an upper bound on the sample complexity of one-sided error distribution-free testing of $\mathcal{F}_t^{\Updownarrow}$.

▶ **Lemma 4.5.** *Let σ be a sequence of length n, $p : [n] \to [0, 1]$ a probability distribution, $t \geq 2$, $\epsilon > 0$ and $\Updownarrow \in \{\Uparrow, \Downarrow\}$. If $\mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p) > \epsilon$, then for $s = \Theta(\sqrt{tn} \log t/\epsilon)$ and $Q = I_n(s, p)$ we have that $\Pr\left[\sigma_{|R\cap Q} \notin \mathcal{F}_t^{\Updownarrow}\right] \geq \frac{2}{3}$.*

Proof. Let $\delta = \frac{\epsilon}{2n}$ and let $B = \{x \in [n] : p(x) \geq \delta\}$. Since $p([n] \setminus B) < n \cdot \delta = \epsilon/2$, we have that $\mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p, B) > \epsilon/2$. We would like to apply Claim 4.2 to $\sigma_{|B}$, and hence we need to first define a corresponding weight function (over $[|B|]$), which we denote by $p_{|B}$. Specifically, denoting the elements in B by $\{b_1, \ldots, b_{|B|}\}$ where $b_1 < \cdots < b_{|B|}$, we let $p_{|B}(j) = p(b_j)$. Observe that $\mathrm{del}(\sigma_{|B}, \mathcal{F}_t^{\Updownarrow}, p_{|B}) = \mathrm{del}(\sigma, \mathcal{F}_t^{\Updownarrow}, p, B)$.

We can now apply Claim 4.2 to $\sigma_{|B}$ and $p_{|B}$ (as well as t and $\Updownarrow$), and obtain $1 \leq a_1 < \cdots < a_t \leq |B|$ as stated in the claim. For each $i \in [t-1]$, let $R_i = B \cap [b_{a_i}, b_{a_{i+1}}]$. Therefore, $\mathrm{del}(\sigma, \mathcal{F}_2^{\Updownarrow}, p, R_i) > \epsilon/(2(t-1))$ for each odd $i \in [t-1]$, and $\mathrm{del}(\sigma, \mathcal{F}_2^{\mathrm{inv}(\Updownarrow)}, p, R_i) > \epsilon/(2(t-1))$ for each even $i \in [t-1]$.

Consider any fixed choice of $i \in [t-1]$. In particular, assume first that i is odd. Suppose we apply Claim 4.3 with $R = R_i$, $\beta = \epsilon/(2(t-1))$, $\delta = \epsilon/(2n)$ (and $\Updownarrow$). Observe that $1/\sqrt{\delta\beta} = \Theta(\sqrt{tn}/\epsilon)$. Since in the current lemma $s = \Theta(\sqrt{tn} \log t/\epsilon)$, we get that for $Q = I_n(s, p)$ (i.e., a sample of size $c \log t$ times larger than the sample in the statement of Claim 4.3), $\Pr_Q[\sigma_{|R_i\cap Q} \in \mathcal{F}_2^{\Updownarrow}] \leq (1/3)^{c \log t} < 1/(3t)$ (for an appropriate constant c). That is, $\sigma_{|R_i\cap Q}$ does not contain an $\mathrm{inv}(\Updownarrow)$-pair with probability at most $1/(3t)$. An analogous statement holds for each even $i \in [t-1]$ (with respect to $\mathcal{F}_2^{\mathrm{inv}(\Updownarrow)}$).

By applying a union bound over all $i \in [t-1]$, we get that with probability at least $2/3$, there are $(t-1)$ pairs $(x_1, y_1), \ldots, (x_{t-1}, y_{t-1})$ such that $x_i, y_i \in R_i \cap Q$, for which the following holds: For every odd $i \in [t-1]$, the pair (x_i, y_i) is a $\Updownarrow$-pair, and for every even $i \in [t-1]$, the pair (x_i, y_i) is an inv($\Updownarrow$)-pair. Notice that for each $i \in [t-1]$, $y_i \in R_i$ and $x_{i+1} \in R_{i+1}$, so we have that $y_i \leq x_{i+1}$. Therefore (recalling Definition 3.5), with probability at least $2/3$, the sample Q contains a $(t-1)$-$\Updownarrow$-pair sequence with respect to σ. By Observation 3.5, this implies that the sample contains a t-$\Updownarrow$ subsequence with respect to σ, that is, $\sigma_{|Q} \notin \mathcal{F}_t^{\Updownarrow}$. ◀

We are now ready to prove Theorem 1.1.

Proof of Theorem 1.1. If $\mathrm{dist}(\sigma, \mathcal{M}_k, p) > \epsilon$, then, by Observation 3.7, for some $\Updownarrow \in \{\Uparrow, \Downarrow\}$, $\mathrm{del}(\sigma, \mathcal{F}_{k+3}^{\Updownarrow}, p) > \epsilon/2$ (otherwise, $\mathrm{del}(\sigma, \mathcal{F}_{k+3}^{\Uparrow}, p) + \mathrm{del}(\sigma, \mathcal{F}_{k+3}^{\Downarrow}, p) \leq \epsilon$, so that by Observation 3.7, $\mathrm{dist}(\sigma, \mathcal{M}_k, p) \leq \epsilon$, and we obtain a contradiction). The theorem follows by applying Lemma 4.5 and Observation 3.3. ◀

5 The upper bound for testing under the uniform distribution

In this section we prove the upper bound of Theorem 1.3, which is restated next.

▶ **Theorem 1.3** *The sample complexity of one-sided error sample-based testing of k-modality under the uniform distribution is $\Theta\left(\sqrt{\frac{kn}{\epsilon}}\right)$. The lower bounds holds for any $\epsilon < 1/4$ and $k \leq \epsilon n$.*

Referring to the notations introduced in Section 2, when p is the uniform distribution over $[n]$, we shall use the shorthand $\mathrm{dist}(\sigma, \mathcal{P})$ for $\mathrm{dist}(\sigma, \mathcal{P}, p)$, $I_n(s)$ for $I_n(s, p)$, and $\mathrm{del}(\sigma, \mathcal{P})$ for $\mathrm{del}(\sigma, \mathcal{P}, p)$. Actually, rather than working with the weighted/normalized deletion distance $\mathrm{del}(\sigma, \mathcal{P})$, it will be convenient to work with the absolute deletion distance $\mathrm{Del}(\sigma, \mathcal{P}) = \mathrm{del}(\sigma, \mathcal{P}) \cdot n$. Namely, $\mathrm{Del}(\sigma, \mathcal{P})$ is the minimum *size* of a subset $D \subseteq [n]$ such that $\sigma_{|[n]\setminus D} \in \mathcal{P}$ (where for hereditary properties, such a subset always exists).

For the sake of the analysis, it will be useful to analyze the sample complexity of testing k-modality (with one-sided error and under the uniform distribution) when the sample is selected according to the Poisson distribution. Recall that the Poisson distribution $\mathrm{Poi}(\lambda)$ takes value $x \in \mathbb{N}$ with probability $e^{-\lambda}\lambda^x/x!$. The next definition is analogous to Definition 2.2.

▶ **Definition 5.1.** *For positive integers n and s, we use $I_n^{\mathrm{Poi}}(s)$ to denote the random variable consisting of a subset of $[n]$ such that for each $i \in [n]$ we have $\Pr[i \in I_n^{\mathrm{Poi}}(s)] = \Pr[\mathrm{Poi}(s/n) \neq 0] = 1 - e^{-s/n}$.*

The following lemma is directly implied by [11, Lemma 2.2] (which in turn refers to [47]).

▶ **Lemma 5.2.** *For any property $\mathcal{P}$, positive integers n and s, and sequence σ of length n,*

$$\Pr[\sigma_{|I_n(s)} \notin \mathcal{P}] \geq \Pr[\sigma_{|I_n^{\mathrm{Poi}}(s/2)} \notin \mathcal{P}] - \frac{4}{s}\,.$$

We next introduce a definition and a simple claim.

▶ **Definition 5.3.** *An ascent/descent (x, y) is said to* start *at x and* end *at y.*
We define the first *ascent (descent) in a sequence σ to be the ascent (descent) that ends first. In case that there are multiple such ascents (descents), choose the one that starts first.*
For an integer $r > 1$, we recursively define the r^{th} ascent (descent) in σ to be the first ascent (descent) in the subsequence obtained from σ by deleting the first $r-1$ ascents (descents).

Recall that we use the notations $\Uparrow$-pair for an ascent and $\Downarrow$-pair for a descent.

▷ Claim 5.4. Let σ be a sequence of length n, $t \geq 2$ an integer, and $\Updownarrow \in \{\Uparrow, \Downarrow\}$. Then σ contains at least $\frac{1}{2}\mathrm{Del}(\sigma, \mathcal{F}_t^{\Updownarrow})$ disjoint $\Updownarrow$-pairs.

Proof. We prove that at least $\frac{1}{2}\mathrm{Del}(\sigma, \mathcal{F}_t^{\Updownarrow})$ disjoint $\Updownarrow$-pairs exist. Delete the first $\Updownarrow$-pair (as defined in Definition 5.3), if it exists. Continue to delete the second $\Updownarrow$-pair, third $\Updownarrow$-pair, etc. as long as possible. Assume that after deleting the y^{th} $\Updownarrow$-pair, no $\Updownarrow$-pair remains. Therefore, by deleting $2y$ symbols from σ we turned it into a sequence in $\mathcal{F}_2^{\Uparrow}$, and hence also in $\mathcal{F}_t^{\Uparrow}$ (for any $t \geq 2$). Thus $y \geq \frac{1}{2}\mathrm{Del}(\sigma, \mathcal{F}_t^{\Uparrow})$, so at least $\frac{1}{2}\mathrm{Del}(\sigma, \mathcal{F}_t^{\Uparrow})$ disjoint $\Updownarrow$-pairs exist. ◁

The next structural claim is a corollary of Claim 4.1.

▷ Claim 5.5. Let σ be a sequence of length n, $t \geq 2$ an integer, $\Updownarrow \in \{\Uparrow, \Downarrow\}$, and y an integer smaller than $\frac{1}{2}\mathrm{Del}(\sigma, \mathcal{F}_t^{\Updownarrow})$. Let $m \in [n]$ be the index such that the y^{th} $\Updownarrow$-pair in σ ends at m. Then $\mathrm{Del}(\sigma, \mathcal{F}_t^{\Updownarrow}) \leq 2y + \mathrm{Del}(\sigma_{m+1}, \ldots, \sigma_n, \mathcal{F}_{t-1}^{\mathrm{inv}(\Updownarrow)})$.

We are now ready to state and prove the lemma that is the heart of our upper bound argument. As opposed to the upper-bound argument for the distribution-free case (Lemma 4.5), In the proof of Lemma 5.6 we do not apply the structural claim described above to "break" σ into predetermined subsequences and then consider the task of testing monotonicity for each of them. Instead, the subsequences are determined by a process that traverses the sequence while selecting the sample "on the fly", and gathering evidence against monotonicity of subsequences.

▶ **Lemma 5.6.** *Let $\epsilon > 0$, $t \geq 2$ an integer, and $\Updownarrow \in \{\Uparrow, \Downarrow\}$. If $\mathrm{Del}(\sigma, \mathcal{F}_t^{\Updownarrow}) > \epsilon n$, then for $s = \Theta(\sqrt{\frac{tn}{\epsilon}})$ and $Q = I_n^{\mathrm{Poi}}(s)$ we have that*

$$\Pr\left[\sigma_{|Q} \notin \mathcal{F}_t^{\Updownarrow}\right] \geq \frac{5}{6}\,.$$

Proof. Denote $\Delta = \mathrm{Del}(\sigma, \mathcal{F}_t^{\Updownarrow})$, so that $\Delta > \epsilon n$. Let $s = 20\sqrt{\frac{tn}{\epsilon}}$ and consider the random variable $Q = I_n^{\mathrm{Poi}}(s)$. We shall prove that $\Pr[\sigma_{|Q} \notin \mathcal{F}_t^{\Updownarrow}] \geq 5/6$.

Let $r = t - 1$. For $2 \leq u \leq t$, we define $\hat{\mathcal{F}}_u$ as follows.

$$\hat{\mathcal{F}}_u = \begin{cases} \mathcal{F}_u^{\Updownarrow} & t-u \text{ is even} \\ \mathcal{F}_u^{inv(\Updownarrow)} & t-u \text{ is odd} \end{cases}$$

We define a process that given a sample Q, tries to find evidence that $\sigma_{|Q}$ does not belong to $\mathcal{F}_t^{\Updownarrow}$. Following this, we analyze the probability that Q is such that the process succeeds.

To be precise, our process aims to find indices $a_0 < b_0 < a_1 < b_1 < \cdots < a_r < b_r$ and numbers $y_0, \ldots, y_r$, such that the following holds for every $0 \leq i \leq r$:

- **Property 1:** If i is odd, then (a_i, b_i) is a $\Updownarrow$-pair, and if i is even and $i > 0$, then (a_i, b_i) is an $\mathrm{inv}(\Updownarrow)$-pair.
- **Property 2:** $\mathrm{Del}(\sigma_{b_i+1} \ldots \sigma_n, \hat{\mathcal{F}}_{t-i}) \geq \Delta - 2\sum_{j=0}^{i} y_j$.

Notice that if the process succeeds, then in particular $((a_1, b_1), \ldots, (a_r, b_r))$ is an r-$\Updownarrow$-pair sequence, which implies by Observation 3.5 that $\sigma_{|Q} \notin \mathcal{F}_t^{\Updownarrow}$.

The process initializes $a_0 = -1$, $b_0 = 0$ and $y_0 = 0$, so that for $i = 0$ Property 1 holds trivially and Property 2 holds by Δ's definition.

For each $\ell \in [r]$, we henceforth condition on the process having succeeded in finding indices $a_0 < b_0 < \cdots < a_{\ell-1} < b_{\ell-1}$ and $y_0, \ldots, y_{\ell-1}$ such that Property 1 and Property 2 both hold for every $i \leq \ell - 1$. We now try to find a_ℓ, b_ℓ and y_ℓ such that $b_{\ell-1} < a_\ell < b_\ell$, and

both properties hold for $i = \ell$ as well. We refer to this attempt as the ℓ^{th} step of the process. For convenience, we assume that ℓ is odd (the other case is analogous). According to our assumption, since Property 2 holds for $i = \ell - 1$, we have that

$$\mathrm{Del}(\sigma_{b_{\ell-1}+1} \dots \sigma_n, \mathcal{F}^{\Updownarrow}_{t-\ell+1}) \geq \Delta - 2\sum_{j=0}^{\ell-1} y_j \ . \tag{3}$$

By Claim 5.4, there exist at least $\frac{1}{2}\mathrm{Del}(\sigma_{b_{\ell-1}+1} \dots \sigma_n, \mathcal{F}^{\Updownarrow}_{t-\ell+1})$ disjoint $\Updownarrow$-pairs in $\sigma_{b_{\ell-1}+1} \dots \sigma_n$, which by Equation (3) is at least $\frac{1}{2}\Delta - \sum_{j=0}^{\ell-1} y_j$. Consider the first $\Updownarrow$-pair, second $\Updownarrow$-pair, etc. in $\sigma_{b_{\ell-1}+1}, \dots, \sigma_n$, as defined in Definition 5.3. Assume that the first $\Updownarrow$-pair among them that belongs to Q is the q^{th} $\Updownarrow$-pair. Then we set $y_\ell = q$, a_ℓ to be the first index of this pair, and b_ℓ to be the last index of this pair (if no such pair belongs to Q, set $y_j = a_j = b_j = \infty$ for every $\ell \leq j \leq r$). If $y_\ell < \frac{1}{2}\Delta - \sum_{j=0}^{\ell-1} y_j$, then by using Claim 5.5 with $y = y_\ell$ and $m = b_\ell$, we infer that $\mathrm{Del}(\sigma_{b_\ell+1} \dots \sigma_n, \mathcal{F}^{\mathrm{inv}(\Updownarrow)}_{r-\ell}) \geq \Delta - 2\sum_{j=0}^{\ell} y_j$ (notice that the last sum now includes y_ℓ).

We conclude that if

$$y_\ell < \frac{1}{2}\Delta - \sum_{j=0}^{\ell-1} y_j \text{ for every } \ell \in [r] \ , \tag{4}$$

then the process succeeds and thus $\sigma_{|Q} \notin \mathcal{F}^{\Updownarrow}_t$. As $y_\ell \geq 0$ for every $\ell \in [r]$ and as $y_0 = 0$, the condition in Equation (4) is equivalent to

$$\sum_{j=1}^{r} y_j < \frac{1}{2}\Delta \ . \tag{5}$$

We now turn to analyze the probability that the condition in Equation (5) holds. Notice that by the definition of $Q = I_n^{\mathrm{Poi}}(s)$, each one of the pairs that were considered during the ℓ^{th} step of the process was sampled with probability ρ^2 for $\rho = 1 - e^{-\frac{s}{n}}$, independent of the others. Observe that from its construction, y_ℓ (for every $\ell \in [r]$) is distributed very similarly to a geometric random variable with parameter ρ^2. To be precise, for every $\ell \in [r]$ let z_ℓ be an i.i.d. geometric random variable with parameter ρ^2, and define $h_\ell = z_\ell$ if z_ℓ is no bigger than the number of pairs that were considered during the ℓ^{th} step, and $h_\ell = \infty$ otherwise. Then h_ℓ and y_ℓ have the same probability distribution. Therefore,

$$\begin{aligned}
\mathrm{Pr}_Q[\sigma_{|Q} \notin \mathcal{F}^{\Updownarrow}_t] \ &\geq \ \mathrm{Pr}_Q\left[\sum_{j=1}^{r} y_j < \frac{1}{2}\Delta\right] \ = \ \mathrm{Pr}_{Q,\{z_\ell\}_{\ell\in[r]}}\left[\sum_{j=1}^{r} h_j \ < \ \frac{1}{2}\Delta\right] \\
&\geq \ \mathrm{Pr}_{\{z_\ell\}_{\ell\in[r]}}\left[\sum_{j=1}^{r} z_j < \frac{1}{2}\Delta\right] \ \geq \ 1 - \mathrm{Pr}_{\{z_\ell\}_{\ell\in[r]}}\left[\sum_{j=1}^{r} z_j > \frac{1}{2}\epsilon n\right] \ .
\end{aligned}$$

Since $z_\ell \sim G(\rho^2)$ for every $\ell \in [r]$ and they are mutually independent, we know by Fact A.4 that their sum distributes as a negative binomial random variable, and that $\mathrm{Pr}_{\{z_\ell\}_{\ell\in[r]}}[\sum_{j=1}^{r} z_j > \frac{1}{2}\epsilon n] = \Pr[\mathrm{Bin}(\frac{1}{2}\epsilon n, \rho^2) < r]$. Let $\mu = \mathbb{E}[\mathrm{Bin}(\frac{1}{2}\epsilon n, \rho^2)] = \frac{1}{2}\epsilon n \rho^2$, and recall that $\rho = 1 - e^{-\frac{s}{n}}$. Applying Fact A.1 we get $\rho \geq \frac{s}{2n}$, so $\mu \geq \frac{\epsilon s^2}{8n}$. For $s = 20\sqrt{\frac{tn}{\epsilon}}$, the expected value of μ is at least $50t$, which is at least $10r$. Using a tail bound for the binomial distribution (Fact A.3) we conclude that

$$\Pr\left[\frac{1}{2}\mathrm{Bin}(\epsilon n, \rho) < r\right] \leq \Pr\left[\frac{1}{2}\mathrm{Bin}(\epsilon n, \rho) < \frac{1}{10}\mu\right] \leq e^{-\frac{(\frac{9}{10})^2\mu}{2}} \leq e^{-\frac{2}{5}\mu} \leq e^{-\frac{2}{5}\cdot 50t} \leq e^{-20} < \frac{1}{6} \ ,$$

which means that $\mathrm{Pr}_Q\left[\sigma_{|Q} \notin \mathcal{F}^{\Updownarrow}_t\right] \geq 5/6$, as claimed. ◀

The upper bound in Theorem 1.3 follows by combining Observation 3.7 with Lemma 5.6 and Observation 3.3 (in an analogous fashion to what was shown in the proof of Theorem 1.1).

$$\Pr[W(n,p) \leq m] = \Pr[\mathrm{Bin}(m,p) \geq k] \ .$$

B Proof of Observation 3.6

Since $\mathcal{M}_k$ is a hereditary property, $\mathrm{del}(\sigma, \mathcal{M}_k, p) \leq \mathrm{dist}(\sigma, \mathcal{M}_k, p)$. We next show that $\mathrm{dist}(\sigma, \mathcal{M}_k, p) \leq \mathrm{del}(\sigma, \mathcal{M}_k, p)$. By the definition of $\mathrm{del}(\sigma, \mathcal{M}_k, p)$, there exists a subset $D \subseteq [n]$ such that $\sigma_{[n]\setminus D} \in \mathcal{M}_k$ and $p(D) = \mathrm{del}(\sigma, \mathcal{M}_k, p)$. If there is more than one such subset, we select one with minimal size, so that $D \neq [n]$. We next define a sequence τ such that $\tau \in \mathcal{M}_k$, and such that $\tau_i = \sigma_i$ for every $i \in [n] \setminus D$, implying that $\mathrm{dist}(\sigma, \mathcal{M}_k, p) \leq \mathrm{dist}(\sigma, \tau, p) = p(D) \leq \mathrm{del}(\sigma, \mathcal{M}_k, p)$, as desired. We define τ as follows: For each $i \in [n]$, if $i \notin D$, then $\tau_i = \sigma_i$, and if $i \in D$, then $\tau_i = \sigma_j$ for $j \notin D$ such that $|j - i|$ is minimized (breaking ties arbitrarily). To verify that $\tau \in \mathcal{M}_k$, assume, contrary to the claim, that $\tau \notin \mathcal{M}_k$. By Observation 3.3, this means that for $\Updownarrow \in \{\Uparrow, \Downarrow\}$ and $t = k + 3$, there is a t-$\Updownarrow$ subsequence $(x_1, \ldots, x_t)$ with respect to τ. But by the definition of τ, this implies that there exists a t-$\Updownarrow$ subsequence $(x'_1, \ldots, x'_t)$ with respect to $\sigma_{[n]\setminus D}$, and we have reached a contradiction.

C The lower bounds

In this section we prove Theorem 1.3 and the lower bound of Theorem 1.2. Given n, k and ϵ, we construct a sequence and a corresponding probability distribution that are determined by a parameter m. The two lower bounds differ in the setting of this parameter.

Let ϵ, k satisfy $\epsilon < 1/4$ and $k < n/4 - 1$, and let m be an integer satisfying $2k \leq m < n/2$. Consider the sequence $\sigma = 2, 1, 4, 3, \ldots, 2m, 2m-1, 3m, 3m, \ldots, 3m$ (where the value $3m$ appears $n - 2m$ times and was chosen as an arbitrary value greater than $2m$). Define $p : [n] \to [0, 1]$ by $p(i) = \rho = \frac{2\epsilon}{m}$ for $i \leq 2m$ and $p(i) = \frac{1-2m\rho}{n-2m} = \frac{1-4\epsilon}{n-2m}$ for $i > 2m$, so that $\sum_{i\in[n]} p(i) = 1$. We shall show that σ is ϵ-far from being k-modal with respect to p, but the probability that a sample of size $s = \frac{1}{5}\frac{\sqrt{km}}{\epsilon}$, selected according to p, contains a subsequence that is not k-modal, is a small constant.

First, note that σ has exactly m descents: $(1, 2), \ldots, (2m-1, 2m)$, that is: $(2i-1, 2i)$ for every $i \in [m]$. Next, observe that any subsequence of σ with k descents is not k-modal (in fact, $\frac{k}{2} + 2$ descents are sufficient). Thus, by deleting at most $m - k$ indices, it is possible to eliminate at most $m - k$ descents, so that the resulting sequence is not k-modal. Since $p(i) = \rho$ for every $i \in [2m]$, we get that $\mathrm{del}(\sigma, \mathcal{F}_k, p) > (m - k)\rho \geq (m/2)\rho = \epsilon$, where the last inequality follows from the condition $m \geq 2k$. By Observation 3.6, $\mathrm{dist}(\sigma, \mathcal{F}_k, p) > \epsilon$, as claimed.

We now turn to show that the probability of sampling a subsequence of σ that is not k-modal is very low using $s = \frac{1}{5}\frac{\sqrt{km}}{\epsilon}$ samples. We do so by bounding the number of descents in the sampled subsequence, and the proof is a variant of a birthday-paradox argument. Let $q_1, \ldots, q_s$ denote our s samples. For every two different indices $\alpha, \beta \in [s]$, we define the event $E_{\alpha,\beta} = \{(q_\alpha, q_\beta) \text{ is a descent}\}$. Since there are exactly m descents and they are all disjoint, there are m options (each of weight ρ) for a first index in a descent, and given such an index there is exactly one option for the second index. As any two samples are independent, this means that $\Pr[E_{\alpha,\beta}] = m\rho \cdot \rho = m\rho^2$ for every $\alpha, \beta \in [s]$ such that $\alpha \neq \beta$. For every $\alpha, \beta \in [s]$ such that $\alpha \neq \beta$, let $\chi_{\alpha,\beta} = \mathbb{1}_{E_{\alpha,\beta}}$ denote the indicator function of the event $E_{\alpha,\beta}$. Then $X = \sum_{\alpha\neq\beta} \chi_{\alpha,\beta}$ is the number of descents in our sample. Using linearity of expectation, we can calculate its expected value:

$$\mathbb{E}[X] = \sum_{\alpha\neq\beta} \mathbb{E}[\chi_{\alpha,\beta}] = \sum_{\alpha\neq\beta} \Pr[E_{\alpha,\beta}] = s(s-1) \cdot m\rho^2 < \frac{km}{25\epsilon^2} \cdot m \cdot \left(\frac{2\epsilon}{m}\right)^2 < \frac{1}{6}k \,.$$

By Markov's inequality (Fact A.2),

$$\Pr\left[X \geq \frac{1}{2}k\right] \leq \Pr\left[X \geq 3\mathbb{E}[x]\right] \leq \frac{1}{3}\,.$$

Therefore with probability at least 2/3 the sampled subsequence contains less than $k/2$ descents and thus must be k-modal. Hence the tester rejects with a small constant probability.

We next choose appropriate values of m and infer Theorem 1.3 and the lower bound of Theorem 1.2.

Proof of Theorem 1.2. Set $m = \lfloor (n-1)/2 \rfloor$, and note that m fulfills its requirements as $k \leq n/4 - 1$ by the premise of the theorem. We conclude that $\Omega(\frac{\sqrt{km}}{\epsilon}) = \Omega(\frac{\sqrt{kn}}{\epsilon})$ samples are necessary for distribution-free one-sided error sample-based testing of k-modality. ◀

Proof of Theorem 1.3, lower bound. We shall assume that $2\epsilon n$ is an integer (otherwise, the analysis is similar but more cumbersome). Set $m = 2\epsilon n$, and note that m fulfills its requirements by the premise of the theorem that $k \leq \epsilon n$ and $\epsilon < 1/4$. We get that both $\rho = 2\epsilon/m = 1/n$ and $\frac{1-4\epsilon}{n-2m} = 1/n$, hence p is the uniform distribution over n. We conclude that $\Omega(\frac{\sqrt{km}}{\epsilon}) = \Omega(\sqrt{\frac{kn}{\epsilon}})$ samples are necessary for one-sided error sample-based testing of k-modality under the uniform distribution. ◀

When Is Amplification Necessary for Composition in Randomized Query Complexity?

Abstract

Suppose we have randomized decision trees for an outer function f and an inner function g. The natural approach for obtaining a randomized decision tree for the composed function $(f \circ g^n)(x^1, \ldots, x^n) = f(g(x^1), \ldots, g(x^n))$ involves amplifying the success probability of the decision tree for g, so that a union bound can be used to bound the error probability over all the coordinates. The amplification introduces a logarithmic factor cost overhead. We study the question: When is this log factor necessary? We show that when the outer function is parity or majority, the log factor can be necessary, even for models that are more powerful than plain randomized decision trees. Our results are related to, but qualitatively strengthen in various ways, known results about decision trees with noisy inputs.

1 Introduction

A deterministic decision tree for computing a partial function $f\colon \{0,1\}^n \to Z$ is a binary tree where each internal node is labeled with an index from $[n]$ and each leaf is labeled with an output value from Z. On input $x \in \{0,1\}^n$, the computation follows a root-to-leaf path where at a node labeled with index i, the value of x_i is queried and the path goes to the left child if $x_i = 0$ and to the right child if $x_i = 1$. The leaf reached on input x must be labeled with the value $f(x)$ (if the latter is defined). The cost of the decision tree is its depth, i.e., the maximum number of queries it makes over all inputs. The deterministic query complexity of f is the minimum cost of any deterministic decision tree that computes f. We will consider several more general models of decision trees (randomized, etc.), so we repurpose traditional complexity class notation to refer to the various associated query complexity measures. Since

P is the traditional complexity class corresponding to deterministic computation, we let $\mathsf{P}(f)$ denote the deterministic query complexity of f. (Some of the recent literature uses the notation $\mathsf{P}^{\mathsf{dt}}(f)$, but this paper deals exclusively with decision trees, so we drop the dt superscript.)

A randomized decision tree is a probability distribution over deterministic decision trees. Computing f with error ε means that for every input x (for which $f(x)$ is defined), the probability that the output is not $f(x)$ is at most ε. The cost of a randomized decision tree is the maximum depth of all the deterministic trees in its support. The randomized query complexity $\mathsf{BPP}_\varepsilon(f)$ is the minimum cost of any randomized decision tree that computes f with error ε. When we write $\mathsf{BPP}(f)$ with no ε specified, we mean $\varepsilon = 1/3$. A basic fact about randomized computation is that the success probability can be amplified, with a multiplicative overhead in cost, by running several independent trials and taking the majority vote of the outputs: $\mathsf{BPP}_\varepsilon(f) \leq O(\mathsf{BPP}(f) \cdot \log(1/\varepsilon))$. See [9] for a survey of classic results on query complexity.

If $f\colon \{0,1\}^n \to Z$ and $g\colon \{0,1\}^m \to \{0,1\}$ are two partial functions, their composition is $f \circ g^n\colon (\{0,1\}^m)^n \to Z$ where $(f \circ g^n)(x^1, \ldots, x^n) \coloneqq f(g(x^1), \ldots, g(x^n))$ (which is defined iff $g(x^i)$ is defined for all i and $f(g(x^1), \ldots, g(x^n))$ is defined). How does the randomized query complexity of $f \circ g^n$ depend on the randomized query complexities of f and g? A simple observation is that to design a randomized decision tree for $f \circ g^n$, we can take a 1/6-error randomized decision tree for f and replace each query – say to the i^{th} input bit of f – with a $1/6n$-error randomized decision tree for evaluating $g(x^i)$. By a union bound, with probability at least 5/6 all of the (at most n) evaluations of g return the correct answer, and so with probability at least 2/3 the final evaluation of f is also correct. Since $\mathsf{BPP}_{1/6n}(g) \leq O(\mathsf{BPP}_{1/n}(g))$, we can write this upper bound as

$$\mathsf{BPP}(f \circ g^n) \;\leq\; O(\mathsf{BPP}(f) \cdot \mathsf{BPP}_{1/n}(g)) \;\leq\; O(\mathsf{BPP}(f) \cdot \mathsf{BPP}(g) \cdot \log n). \tag{1}$$

When is this tight? It will take some effort to suitably formulate this question. We begin by reviewing known related results.

1.1 When is amplification necessary?

As for general lower bounds (that hold for all f and g), much work has gone into proving lower bounds on $\mathsf{BPP}(f \circ g^n)$ in terms of complexity measures of f and g that are defined using models more powerful than plain randomized query complexity [16, 3, 6, 4, 5]. In terms of just $\mathsf{BPP}(f)$ and $\mathsf{BPP}(g)$, the state-of-the-art is that $\mathsf{BPP}(f \circ g^n) \geq \Omega(\mathsf{BPP}(f) \cdot \sqrt{\mathsf{BPP}(g)})$ for all f and g [14]. Furthermore, it is known that the latter bound is sometimes tight: There exist partial boolean functions f and g such that $\mathsf{BPP}(f \circ g^n) \leq \widetilde{O}(\mathsf{BPP}(f) \cdot \sqrt{\mathsf{BPP}(g)})$ and $\mathsf{BPP}(f), \mathsf{BPP}(g) \geq \omega(1)$ [14, 5]. Thus (1) is far from being *always* tight, even without worrying about the need for amplification. However, it remains plausible that $\mathsf{BPP}(f \circ g^n) \geq \Omega(\mathsf{BPP}(f) \cdot \mathsf{BPP}(g))$ holds for all *total* f and all partial g. We take this as a working conjecture in this paper. This conjecture has been confirmed for some specific outer functions f, such as the identity function $\textsc{Id}\colon \{0,1\}^n \to \{0,1\}^n$ [21] (this is called a "direct sum" result) and the boolean functions $\textsc{Or}$, $\textsc{Xor}$ (parity), and $\textsc{Maj}$ (majority) [17]. These results, however, do not address the need for amplification in the upper bound (1). To formulate our question of whether (1) is tight, a first draft could be:

Question A, with respect to a particular f: Is (1) tight for *all* partial functions g?

This is not quite a fair question, for at least two reasons:

- Regarding the first inequality in (1): The simple upper bound actually shows $\mathsf{BPP}(f \circ g^n) \leq O(\mathsf{BPP}(f) \cdot \mathsf{BPP}_{1/\mathsf{BPP}(f)}(g))$ (the union bound is only over queries that take place, not over all possible queries). So for simplicity, let us restrict our attention to f satisfying $\mathsf{BPP}(f) \geq \Omega(n)$, which is the case for Id, Or, Xor, and Maj.
- Regarding the second inequality in (1): Some functions g satisfy $\mathsf{BPP}_{1/n}(g) \leq o(\mathsf{BPP}(g) \cdot \log n)$ (e.g., if $\mathsf{P}(g) \leq O(\mathsf{BPP}(g))$). So for simplicity, let us restrict our attention to g satisfying $\mathsf{BPP}_{1/n}(g) \geq \Omega(\mathsf{BPP}(g) \cdot \log n)$, which (as we show later) is the case for two partial functions GapOr and GapMaj defined as follows ($|x|$ denotes the Hamming weight of $x \in \{0,1\}^m$):

$$\textsc{GapOr}(x) \coloneqq \begin{cases} 0 & \text{if } |x| = 0 \\ 1 & \text{if } |x| = m/2 \end{cases} \quad \text{and} \quad \textsc{GapMaj}(x) \coloneqq \begin{cases} 0 & \text{if } |x| = m/3 \\ 1 & \text{if } |x| = 2m/3 \end{cases}.$$

Thus, a better formulation of Question A would be: Assuming $\mathsf{BPP}(f) \geq \Omega(n)$, is (1) tight for all partial g satisfying $\mathsf{BPP}_{1/n}(g) \geq \Omega(\mathsf{BPP}(g) \cdot \log n)$? Even with these caveats, the answer is always "no." It will be instructive to examine a counterexample. Let $\textsc{Which}\colon \{0,1\}^2 \to \{0,1\}$ be the partial function such that $\textsc{Which}(y)$ indicates the location of the unique 1 in y, under the promise that $|y| = 1$. Then $g = \textsc{Which} \circ \textsc{GapOr}^2$ takes an input of length $2m$ with the promise that there are exactly $m/2$ many 1s, either all in the left half or all in the right half, and outputs which half has the 1s. It turns out $\mathsf{BPP}(g) \leq O(1)$ and $\mathsf{BPP}_{1/n}(g) \geq \Omega(\log n)$ provided $m \geq \log n$ (for similar reasons as GapOr itself) and yet $\mathsf{BPP}(f \circ g^n) \leq O(\mathsf{BPP}(f))$ for all f: To compute $f \circ g^n$, we can run an optimal randomized decision tree for f and whenever it queries $g(x^i)$, we repeatedly query uniformly random bit positions of x^i until we find a 1 (so the value of $g(x^i)$ is determined by which half we found a 1 in). This has the same error probability as the randomized decision tree for f, and the total number of queries to the bits of $(x^1, \ldots, x^n)$ is $O(\mathsf{BPP}(f))$ in expectation, because for each i it takes $O(1)$ queries in expectation to locate a 1 in x^i. By Markov's inequality, with high constant probability this halts after only $O(\mathsf{BPP}(f))$ total queries. Thus by aborting the computation if it attempts to make too many queries, we obtain a randomized decision tree for $f \circ g^n$ that always makes $O(\mathsf{BPP}(f))$ queries, with only a small hit in the error probability.

Blais and Brody [7] adjust the statement of Question A so the answer becomes "yes" in the case $f = \textsc{Id}$. Specifically, they weaken the right-hand side in such a way that the above counterexample is ruled out. Defining[1] $\overline{\mathsf{BPP}}_\varepsilon(g)$ similarly to $\mathsf{BPP}_\varepsilon(g)$ but where the cost of a randomized decision tree is the maximum over all inputs (on which g is defined) of the expected number of queries, we now have $\overline{\mathsf{BPP}}_{1/n}(g) \leq \overline{\mathsf{BPP}}_0(g) \leq O(1)$ for the g from the counterexample. The theorem from [7] is $\mathsf{BPP}(f \circ g^n) \geq \Omega(\mathsf{BPP}(f) \cdot \overline{\mathsf{BPP}}_{1/n}(g))$ when $f = \textsc{Id}$, in other words, $\mathsf{BPP}(g^n) = \Omega(n \cdot \overline{\mathsf{BPP}}_{1/n}(g))$ (a "strong direct sum" result). [7] also explicitly asked whether similar results hold for other functions f. The corresponding conjecture for $f = \textsc{Or}$ is false (as we note below) while for $f = \textsc{Xor}$ and $f = \textsc{Maj}$ it remains open.

To make progress, we step back and ask a seemingly more innocuous version of the question:

Question B, with respect to a particular f: Is (1) tight for *some* partial function g?

It turns out the answer is "no" for $f = \textsc{Or}$ and is "yes" for both $f = \textsc{Xor}$ and $f = \textsc{Maj}$.

[1] [7] used the notation $\overline{\mathsf{R}}$ instead of $\overline{\mathsf{BPP}}$.

1.2 Decision trees with noisy inputs

Question B is related to "query complexity with noisy inputs" (introduced in [13]), so let us review the latter model: When input bit y_i is queried, the wrong bit value is returned to the decision tree with some probability $\leq 1/3$ (and the correct value of y_i is returned with the remaining probability). The "noise events" are independent across all queries, including multiple queries to the same input bit. Now the adversary gets to pick not only the input, but also the "noise probabilities." [13] distinguishes between two extreme possibilites: A static adversary has a single common noise probability for all queries, while a dynamic adversary can choose a different noise probability for each node in the decision tree. In this paper we make a reasonable compromise: The adversary gets to choose a tuple of noise probabilities $(\nu_1, \dots, \nu_n)$, and each query to y_i returns $1 - y_i$ with probability exactly ν_i. When a randomized decision tree computes f with error probability ε, that means for every input $y \in \{0,1\}^n$ and every noise probability tuple $(\nu_1, \dots, \nu_n)$ (with $\nu_i \leq 1/3$ for each i), the output is $f(y)$ with probability $\geq 1 - \varepsilon$ over the random noise and randomness of the decision tree. We invent the notation $\mathsf{BPP}^*(f)$ for the minimum cost of any randomized decision tree that computes f on noisy inputs, with error probability $1/3$. We have $\mathsf{BPP}^*(f) \leq O(\mathsf{BPP}(f) \cdot \log n) \leq O(n \log n)$ by repeating each query $O(\log n)$ times and taking the majority vote (to drive the noise probabilities down to $o(1/n)$), and using a union bound to absorb the noise probabilities into the error probability. The connection with composition is that $\mathsf{BPP}(f \circ g^n) \leq \mathsf{BPP}^*(f) \cdot \mathsf{BPP}(g)$, because to design a randomized decision tree for $f \circ g^n$, we can take a $1/3$-error randomized decision tree for f with noisy inputs, and replace each query – say to y_i – with a $1/3$-error randomized decision tree for evaluating $g(x^i)$.

There is a similar connection for 1-sided error and 1-sided noise. When a randomized decision tree has 1-sided error ε, that means on 0-inputs the output is wrong with probability 0, and on 1-inputs the output is wrong with probability at most ε. We let $\mathsf{RP}(g)$ denote the minimum cost of any randomized decision tree that computes g with 1-sided error $1/2$. Similarly, 1-sided noise means that when input bit y_i is queried, if the actual value is $y_i = 0$ then 1 is returned with probability 0, and if the actual value is $y_i = 1$ then 0 is returned with probability $\nu_i \leq 1/2$. We invent the notation $\mathsf{BPP}^\dagger(f)$ for the minimum cost of any randomized decision tree that computes f on 1-sided noisy inputs, with 2-sided error probability $1/3$. We have $\mathsf{BPP}(f) \leq \mathsf{BPP}^\dagger(f) \leq \mathsf{BPP}^*(f)$. The connection $\mathsf{BPP}(f \circ g^n) \leq \mathsf{BPP}^\dagger(f) \cdot \mathsf{RP}(g)$ holds like in the 2-sided noise setting. We officially record these observations:

▶ **Observation 1.** *For all f and g,*

$$\mathsf{BPP}(f \circ g^n) \;\leq\; \mathsf{BPP}^*(f) \cdot \mathsf{BPP}(g) \quad \textit{and} \quad \mathsf{BPP}(f \circ g^n) \;\leq\; \mathsf{BPP}^\dagger(f) \cdot \mathsf{RP}(g).$$

The upshot is that noisy upper bounds imply composition upper bounds, and composition lower bounds imply noisy lower bounds. There are many proofs of the result $\mathsf{BPP}^*(\textsc{Or}) \leq O(n)$ [13, 23, 25, 20]:

▶ **Theorem 2** ($\textsc{Or}$ never necessitates amplification)**.** $\mathsf{BPP}^*(O_R) \leq O(n)$ *and thus for every partial function g,*

$$\mathsf{BPP}(O_R \circ g^n) \;\leq\; O(n \cdot \mathsf{BPP}(g)).$$

Theorem 2 is not new, but in Appendix A we provide a particularly clean and elementary proof (related to, but more streamlined than, the proof in [23]). We mention that the proof straightforwardly generalizes to some other functions f, such as "odd-max-bit": $\textsc{Omb}(y) = 1$ iff the highest index of any 1 in y is odd.

We turn our attention to lower bounds. Various special-purpose techniques have been developed for proving query complexity lower bounds in the noisy setting [13, 12, 11, 20]. However, a conceptual consequence of Observation 1 is that special-purpose techniques are not generally necessary: We can just use techniques for lower bounding plain (non-noisy) randomized query complexity, applied to composed functions.

1.3 Lower bound for parity

[13] proved that $\mathsf{BPP}^*(\textsc{Xor})$ and $\mathsf{BPP}^*(\textsc{Maj})$ are $\Omega(n \log n)$. Although apparently not recorded in the literature, it is possible to generalize this result to show $\mathsf{BPP}^\dagger(\textsc{Xor})$ and $\mathsf{BPP}^\dagger(\textsc{Maj})$ are $\Omega(n \log n)$. However, we prove results even stronger than that, using the composition paradigm. Our results involve query complexity models that are more powerful than BPP, and even more powerful than the $\overline{\mathsf{BPP}}$ model from [7]. This follows a theme from a lot of prior work: Since BPP query complexity is rather subtle, we can make progress by studying related models that are somewhat more "well-behaved."

- As observed in [7], the $\overline{\mathsf{BPP}}$ model is equivalent to one where the cost is the worst-case (rather than expected) number of queries, and a randomized decision tree is allowed to abort (i.e., output a special symbol $\perp$) with at most a small constant probability, and the output should be correct with high probability conditioned on not aborting.
- If we strengthen the above model by allowing the non-abort probability to be arbitrarily close to 0 (rather than close to 1), but require that the non-abort probabilities are approximately the same for all inputs (within some factor close to 1), the resulting model has been called $\mathsf{2WAPP}$ ("2-sided weak almost-wide PP") [18, 17]. The "1-sided" version WAPP, defined later, will be relevant to us.
- If we further strengthen the model by allowing the non-abort probabilities to be completely unrelated for different inputs (and still arbitrarily close to 0), the resulting model has been called $\mathsf{PostBPP}$ ("BPP with post-selection") [18, 10].

We first consider the last of these models. $\mathsf{PostBPP}_\varepsilon(f)$ is the minimum cost of any randomized decision tree such that on every input x (for which $f(x)$ is defined), the probability of outputting $\perp$ is < 1, and the probability of outputting $f(x)$ is $\geq 1 - \varepsilon$ conditioned on not outputting $\perp$. Trivially, $\mathsf{PostBPP}(f) \leq \mathsf{BPP}(f)$. In fact, the $\mathsf{PostBPP}$ model is much more powerful than plain randomized query complexity; for example (noted in [18]) it can efficiently compute the aforementioned odd-max-bit function: $\mathsf{PostBPP}(\textsc{Omb}) \leq 1$.

For the noisy input setting, $\mathsf{PostBPP}^*$ and $\mathsf{PostBPP}^\dagger$ are defined in the natural way, and $\mathsf{PostBPP}(f \circ g^n) \leq \mathsf{PostBPP}^*(f) \cdot \mathsf{BPP}(g)$ and $\mathsf{PostBPP}(f \circ g^n) \leq \mathsf{PostBPP}^\dagger(f) \cdot \mathsf{RP}(g)$ hold like in Observation 1.

In Section 2 we prove something qualitatively much stronger than $\mathsf{BPP}^*(\textsc{Xor}) \geq \Omega(n \log n)$:

▶ **Theorem 3** ($\textsc{Xor}$ sometimes necessitates amplification). *For some partial function g, namely $g = \textsc{GapMaj}$ with $m \geq \log n$,*

$$\mathsf{PostBPP}(\textsc{Xor} \circ g^n) \;\geq\; \Omega(n \cdot \mathsf{BPP}_{1/n}(g)) \;\geq\; \Omega(n \log n \cdot \mathsf{BPP}(g)).$$

In particular, $\mathsf{PostBPP}^*(\textsc{Xor}) \geq \Omega(n \log n)$.

Let us compare Theorem 3 to two previous results.

- [12] proved that $\overline{\mathsf{BPP}}^*(\textsc{Xor}) \geq \Omega(n \log n)$ and that this lower bound holds even in the average-case setting (i.e., $\Omega(n \log n)$ queries are needed in expectation to succeed with high probability over a uniformly random input, random noise, and randomness of the decision tree). Our proof of Theorem 3 is simpler than the proof in [12] (though both proofs have a Fourier flavor), it also works in the average-case setting, and it yields a stronger result since the model is $\mathsf{PostBPP}$ instead of just $\overline{\mathsf{BPP}}$ (and the lower bound holds for composition rather than just noisy inputs). [11] presented a different simplified proof of the result from [12], but that proof does not generalize to $\mathsf{PostBPP}^*$.
- Our proof of Theorem 3 shows something analogous, but incomparable, to the strong direct sum from [7]. As we explain in Section 2, our proof shows that $\mathsf{PostBPP}(\textsc{Xor} \circ g^n) \geq \Omega(n \cdot \mathsf{PostBPP}_{1/n}(g))$ holds for *all* g (thus addressing a version of our Question A). Compared to the [7] result that $\overline{\mathsf{BPP}}(\textsc{Id} \circ g^n) \geq \Omega(n \cdot \overline{\mathsf{BPP}}_{1/n}(g))$ for all g, our result has the advantages of working for $f = \textsc{Xor}$ rather than $f = \textsc{Id}$ and yielding a qualitatively stronger lower bound ($\mathsf{PostBPP}$ rather than $\overline{\mathsf{BPP}}$ on the left side), but the disadvantage of also requiring the qualitatively stronger type of lower bound on g. Our result shows that if amplifying g requires a log factor in a very strong sense (even $\mathsf{PostBPP}$-type decision trees cannot avoid the log factor), then that log factor will be necessary when composing $\textsc{Xor}$ with g.

1.4 Lower bound for majority

Our main result strengthens the bound $\mathsf{BPP}^*(\textsc{Maj}) \geq \Omega(n \log n)$ from [13], mainly by holding for the stronger model WAPP (rather than just BPP), but also by directly handling 1-sided noise and by holding for composition rather than just noisy inputs.

$\mathsf{WAPP}_\varepsilon(f)$ is the minimum cost of any randomized decision tree such that for some $t > 0$, on input x the probability of outputting 1 is in the range $[(1-\varepsilon)t, t]$ if $f(x) = 1$, and in the range $[0, \varepsilon t]$ if $f(x) = 0$. The ε subscript should always be specified, because unlike BPP and $\mathsf{PostBPP}$, WAPP is not amenable to efficient amplification of the error parameter ε [18]. For every constant $0 < \varepsilon < 1/2$, we have $\mathsf{PostBPP}(f) \leq O(\mathsf{WAPP}_\varepsilon(f)) \leq O(\mathsf{BPP}(f))$.

WAPP-type query complexity has several aliases, such as "approximate conical junta degree" and "approximate query complexity in expectation," and it has recently played a central role in various randomized query (and communication) complexity lower bounds [22, 18, 16, 17]. One can think of WAPP as a nonnegative version of approximate polynomial degree (which corresponds to the class AWPP); in other words, it is a classical analogue of the polynomial method used to lower bound quantum algorithms.

For the noisy input setting, WAPP^* and $\mathsf{WAPP}^\dagger$ are defined in the natural way, and $\mathsf{WAPP}_\varepsilon(f \circ g^n) \leq \mathsf{WAPP}^*_\varepsilon(f) \cdot \mathsf{BPP}(g)$ and $\mathsf{WAPP}_\varepsilon(f \circ g^n) \leq \mathsf{WAPP}^\dagger_\varepsilon(f) \cdot \mathsf{RP}(g)$ hold like in Observation 1. We prove the following theorem, which shows that WAPP sometimes requires amplification, even in the one-sided noise setting.

▶ **Theorem 4** ($\textsc{Maj}$ sometimes necessitates amplification)**.** *For some partial function g, namely $g = \textsc{GapOr}$ with $m \geq \log n$, and some constant $\varepsilon > 0$,*

$$\mathsf{WAPP}_\varepsilon(\textit{Maj} \circ g^n) \;\geq\; \Omega(n \cdot \mathsf{BPP}_{1/n}(g)) \;\geq\; \Omega(n \log n \cdot \mathsf{RP}(g)).$$

In particular, $\mathsf{WAPP}^\dagger_\varepsilon(\textit{Maj}) \geq \Omega(n \log n)$.

This theorem should be contrasted with the work of Sherstov about making polynomials robust to noise [27]. In that work, Sherstov showed that approximate polynomial degree never requires a log factor in the noisy input setting, nor in composition. That is to say, he

improved the simple bound $\mathsf{AWPP}^*(f) \le O(\mathsf{AWPP}(f) \cdot \log n)$ to $\mathsf{AWPP}^*(f) \le O(\mathsf{AWPP}(f))$ for all Boolean functions f, and showed $\mathsf{AWPP}(f \circ g^n) \le O(\mathsf{AWPP}(f) \cdot \mathsf{AWPP}(g))$. In contrast, for conical juntas (nonnegative linear combinations of conjunctions), Theorem 4 shows that in a strong sense, the simple bound $\mathsf{WAPP}^*_\epsilon(f) \le O(\mathsf{WAPP}_\delta(f) \cdot \log n)$ (for all constants $0 < \delta < \varepsilon < 1/2$ and total Boolean functions f) cannot be improved: $\mathsf{WAPP}^\dagger_\varepsilon(f) \ge \Omega(\mathsf{WAPP}_0(f) \cdot \log n)$ for some constant ε and some total f, namely $f = \textsc{Maj}$. Thus unlike polynomials, conical juntas cannot be made robust to noise.

Our proof of Theorem 4 (in Section 3) introduces some technical ideas that may be useful for other randomized query complexity lower bounds.

By a simple reduction, Theorem 4 for $g = \textsc{GapOr}$ implies the same for $g = \textsc{GapMaj}$ (with $\mathsf{BPP}(g) = 1$ instead of $\mathsf{RP}(g) = 1$ at the end of the statement), but we do not know of a simpler direct proof for the latter result. Theorem 4 cannot be strengthened to have $\mathsf{PostBPP}$ in place of WAPP, because $\mathsf{PostBPP}(\textsc{Maj} \circ \textsc{GapMaj}^n) \le O(n)$. However, Theorem 4 does hold with $\textsc{Xor}$ in place of $\textsc{Maj}$, by the same proof.

2 Proof of Theorem 3: Xor sometimes necessitates amplification

We first discuss a standard technique for proving randomized query complexity lower bounds, which will be useful in the proof of Theorem 3. For any conjunction $C\colon \{0,1\}^k \to \{0,1\}$ and distribution $\mathcal{D}$ over $\{0,1\}^k$, we write $C(\mathcal{D}) \coloneqq \mathbb{E}_{x\sim\mathcal{D}}[C(x)] = \mathbb{P}_{x\sim\mathcal{D}}[C(x) = 1]$. The number of literals in a conjunction is called its width.

▶ **Fact 5.** *Let $h\colon \{0,1\}^k \to \{0,1\}$ be a partial function, and for each $z \in \{0,1\}$ let $\mathcal{D}_z$ be a distribution over $h^{-1}(z)$. Then for every ε there exist a conjunction C of width $\mathsf{PostBPP}_\varepsilon(h)$ and a $z \in \{0,1\}$ such that $\varepsilon \cdot C(\mathcal{D}_z) \ge (1-\varepsilon) \cdot C(\mathcal{D}_{1-z})$ and $C(\mathcal{D}_z) > 0$.*

Proof. Abbreviate $\mathsf{PostBPP}_\varepsilon(h)$ as r. Fix a randomized decision tree of cost r computing h with error ε conditioned on not aborting, and assume w.l.o.g. that for each outcome of the randomness, the corresponding deterministic tree is a perfect tree with 2^r leaves, all at depth r. Consider the probability space where we sample input x from the mixture $\frac{1}{2}\mathcal{D}_0 + \frac{1}{2}\mathcal{D}_1$, sample a deterministic decision tree T as an outcome of the randomized decision tree, and sample a uniformly random leaf ℓ of T. Let A be the indicator random variable for the event that ℓ is the leaf reached by $T(x)$ and its label is $h(x)$. Let B be the indicator random variable for the event that ℓ is the leaf reached by $T(x)$ and its label is $1 - h(x)$. Conditioned on any particular x and T, the probability that ℓ is the leaf reached by $T(x)$ is 2^{-r}. Thus conditioned on any particular x, if the non-abort probability is $t_x > 0$ then $\mathbb{E}[A \,|\, x] \ge 2^{-r} t_x (1-\varepsilon)$ and $\mathbb{E}[B \,|\, x] \le 2^{-r} t_x \varepsilon$ and thus $\varepsilon \cdot \mathbb{E}[A \,|\, x] - (1-\varepsilon) \cdot \mathbb{E}[B \,|\, x] \ge 0$. Over the whole probability space, we have $\varepsilon \cdot \mathbb{E}[A] - (1-\varepsilon) \cdot \mathbb{E}[B] \ge 0$, so by linearity the same must hold conditioned on some particular T and ℓ with $\mathbb{E}[A \,|\, T, \ell] > 0$. Let C be the conjunction of width r such that $C(x) = 1$ iff $T(x)$ reaches ℓ, and let z be the label of ℓ. Then we have $C(\mathcal{D}_z) = \mathbb{E}[A \,|\, T, \ell \text{ and } h(x) = z] = 2 \cdot \mathbb{E}[A \,|\, T, \ell] > 0$ and similarly $C(\mathcal{D}_{1-z}) = 2 \cdot \mathbb{E}[B \,|\, T, \ell]$. Thus

$$\varepsilon \cdot C(\mathcal{D}_z) - (1-\varepsilon) \cdot C(\mathcal{D}_{1-z}) \;=\; 2 \cdot \big(\varepsilon \cdot \mathbb{E}[A \,|\, T, \ell] + (1-\varepsilon) \cdot \mathbb{E}[B \,|\, T, \ell]\big) \;\ge\; 0. \qquad \blacktriangleleft$$

Now we work toward proving Theorem 3. Throughout, n is the input length of $\textsc{Xor}$, and m is the input length of $\textsc{GapMaj}$. We have $\mathsf{BPP}(\textsc{GapMaj}) \le 1$ by outputting the bit at a uniformly random position from the input. We describe one way of seeing that $\mathsf{BPP}_{1/n}(\textsc{GapMaj}) \ge \mathsf{PostBPP}_{1/n}(\textsc{GapMaj}) \ge \Omega(\log n)$ provided $m \ge \log n$. For $z \in \{0,1\}$, define $\mathcal{G}_z$ as the uniform distribution over $\textsc{GapMaj}^{-1}(z)$.

▶ **Fact 6.** *For every conjunction* $C\colon \{0,1\}^m \to \{0,1\}$ *of width* $w \le m/7$ *and for each* $z \in \{0,1\}$*,*

$$C(\mathcal{G}_z) \;\le\; 3^w \cdot C(\mathcal{G}_{1-z}).$$

Proof. By symmetry we just consider $z = 0$. Suppose C has u positive literals and v negative literals ($u + v = w$). Then

$$C(\mathcal{G}_0) \;=\; \tbinom{m-w}{m/3-u}/\tbinom{m}{m/3} \;\le\; \tbinom{m-w}{m/3}/\tbinom{m}{m/3} \;=\; \tfrac{(2m/3)\cdot(2m/3-1)\cdots(2m/3-w+1)}{m\cdot(m-1)\cdots(m-w+1)} \;\le\; (2/3)^w,$$

$$\begin{aligned} C(\mathcal{G}_1) \;=\; \tbinom{m-w}{m/3-v}/\tbinom{m}{m/3} \;\ge\; \tbinom{m-w}{m/3-w}/\tbinom{m}{m/3} \;&=\; \tfrac{(m/3)\cdot(m/3-1)\cdots(m/3-w+1)}{m\cdot(m-1)\cdots(m-w+1)} \\ &\ge\; \left(\tfrac{m/3-w}{m-w}\right)^w \;\ge\; \left(\tfrac{m/3-m/7}{m-m/7}\right)^w \;=\; (2/9)^w. \end{aligned}$$

Thus $C(\mathcal{G}_0)/C(\mathcal{G}_1) \le \left(\frac{2/3}{2/9}\right)^w = 3^w$. ◀

Combining Fact 5 and Fact 6 (using $h = \textsc{GapMaj}$, $k = m$, $\mathcal{D}_z = \mathcal{G}_z$, $\varepsilon = 1/n$, and $w = \mathsf{PostBPP}_\varepsilon(h)$) implies that $(1-\varepsilon)/\varepsilon \le 3^w$, in other words we have $\mathsf{PostBPP}_{1/n}(\textsc{GapMaj}) \ge \log_3(n(1-1/n)) \ge \Omega(\log n)$, provided $w \le m/7$. If $w > m/7$ then $\mathsf{PostBPP}_{1/n}(\textsc{GapMaj}) \ge \Omega(\log n)$ holds anyway provided $m \ge \log n$.

Hence, our result can be restated as follows.

▶ **Theorem 3 (Restated).** $\mathsf{PostBPP}(\textsc{Xor} \circ \textsc{GapMaj}^n) \ge \Omega(n \log n)$ *provided* $m \ge \log n$.

Proof. We show $\mathsf{PostBPP}(\textsc{Xor} \circ \textsc{GapMaj}^n) > \frac{1}{14} n \log n$. By Fact 5 (using $h = \textsc{Xor} \circ \textsc{GapMaj}^n$, $k = nm$, and $\varepsilon = 1/3$) it suffices to exhibit for each $z \in \{0,1\}$ a distribution $\mathcal{D}_z$ over $(\textsc{Xor} \circ \textsc{GapMaj}^n)^{-1}(z)$, such that for every conjunction C of width $\le \frac{1}{14} n \log n$ and for each $z \in \{0,1\}$, either $C(\mathcal{D}_z) < 2C(\mathcal{D}_{1-z})$ or $C(\mathcal{D}_z) = 0$. Letting $\mathcal{F}_z$ be the uniform distribution over $\textsc{Xor}^{-1}(z)$, define $\mathcal{D}_z$ as the mixture over $y \sim \mathcal{F}_z$ of $\mathcal{G}_y \coloneqq \mathcal{G}_{y_1} \times \cdots \times \mathcal{G}_{y_n}$ (i.e., $(x^1, \ldots, x^n) \sim \mathcal{G}_y$ is sampled by independently sampling $x^i \sim \mathcal{G}_{y_i}$ for all i). Put succinctly, $\mathcal{D}_z \coloneqq \mathbb{E}_{y \sim \mathcal{F}_z}[\mathcal{G}_y]$. Letting $\mathcal{G} \coloneqq \frac{1}{2}\mathcal{G}_0 + \frac{1}{2}\mathcal{G}_1$ and $\mathcal{F} \coloneqq \frac{1}{2}\mathcal{F}_0 + \frac{1}{2}\mathcal{F}_1$ and $\mathcal{D} \coloneqq \frac{1}{2}\mathcal{D}_0 + \frac{1}{2}\mathcal{D}_1$, we have $\mathcal{D} = \mathcal{G}^n$ since $\mathcal{F}$ is uniform over $\{0,1\}^n$. Since $C(\mathcal{D}) = \frac{1}{2}C(\mathcal{D}_0) + \frac{1}{2}C(\mathcal{D}_1)$, our goal of showing "$\frac{1}{2}C(\mathcal{D}_0) < C(\mathcal{D}_1) < 2C(\mathcal{D}_0)$ or $C(\mathcal{D}_0) = C(\mathcal{D}_1) = 0$" is equivalent to showing "$\frac{2}{3}C(\mathcal{D}) < C(\mathcal{D}_1) < \frac{4}{3}C(\mathcal{D})$ or $C(\mathcal{D}) = 0$."

Now consider any conjunction C of width $w \le \frac{1}{14} n \log n$ such that $C(\mathcal{D}) > 0$, and write $C(x^1, \ldots, x^n) = \prod_i C_i(x^i)$ where C_i is a conjunction. Since $C_i(\mathcal{G}) = \frac{1}{2}C_i(\mathcal{G}_0) + \frac{1}{2}C_i(\mathcal{G}_1)$, for each $y_i \in \{0,1\}$ we can write $C_i(\mathcal{G}_{y_i}) = (1 + a_i(-1)^{y_i})C_i(\mathcal{G})$ for some number a_i with $|a_i| \le 1$ (so $a_i \ge 0$ iff $C_i(\mathcal{G}_0) \ge C_i(\mathcal{G}_1)$). Let w_i be the width of C_i, so $\sum_i w_i = w \le \frac{1}{14} n \log n$. Then $w_i \le \frac{1}{7}\log n \le m/7$ for at least $n/2$ many values of i, and for such i note that by Fact 6, $C_i(\mathcal{G}_{y_i}) \le 3^{(\log n)/7} \cdot C_i(\mathcal{G}_{1-y_i}) \le n^{1/4} \cdot C_i(\mathcal{G}_{1-y_i})$ for each $y_i \in \{0,1\}$. The latter implies that $|a_i| \le 1 - 2/(n^{1/4}+1) \le 1 - n^{-1/4}$. Thus

$$\left|\textstyle\prod_i a_i\right| \;=\; \textstyle\prod_i |a_i| \;\le\; (1 - n^{-1/4})^{n/2} \;\le\; e^{-n^{3/4}/2} \;\le\; 1/4.$$

For $S \subseteq [n]$, let $\chi_S\colon \{0,1\}^n \to \{1,-1\}$ be the character $\chi_S(y) \coloneqq \prod_{i \in S}(-1)^{y_i} = (-1)^{\sum_{i \in S} y_i}$. Note that $\mathbb{E}_{y \sim \mathcal{F}_1}[\chi_S]$ is 1 if $S = \emptyset$, is -1 if $S = [n]$, and is 0 otherwise. Putting everything together,

$$\begin{aligned} C(\mathcal{D}_1) \;&=\; \mathbb{E}_{y \sim \mathcal{F}_1}[C(\mathcal{G}_y)] \;=\; \mathbb{E}_{y \sim \mathcal{F}_1}\left[\textstyle\prod_i C_i(\mathcal{G}_{y_i})\right] \;=\; \mathbb{E}_{y \sim \mathcal{F}_1}\left[\textstyle\prod_i (1 + a_i(-1)^{y_i})C_i(\mathcal{G})\right] \\ &=\; \left(\textstyle\prod_i C_i(\mathcal{G})\right) \cdot \mathbb{E}_{y \sim \mathcal{F}_1}\left[\textstyle\sum_{S \subseteq [n]} \prod_{i \in S} a_i(-1)^{y_i}\right] \\ &=\; C(\mathcal{D}) \cdot \textstyle\sum_{S \subseteq [n]} \left(\prod_{i \in S} a_i\right) \cdot \mathbb{E}_{y \sim \mathcal{F}_1}[\chi_S(y)] \\ &=\; C(\mathcal{D}) \cdot \left(1 - \textstyle\prod_{i \in [n]} a_i\right) \;\in\; C(\mathcal{D}) \cdot (1 \pm 1/4) \end{aligned}$$

which implies $\frac{2}{3}C(\mathcal{D}) < C(\mathcal{D}_1) < \frac{4}{3}C(\mathcal{D})$ since we are assuming $C(\mathcal{D}) > 0$. This concludes the proof of Theorem 3. ◀

Using strong LP duality (as in [15]), it can be seen that Fact 5 is a tight lower bound method up to constant factors: $\mathsf{PostBPP}_\varepsilon(h) \geq \Omega(c)$ iff it is possible to prove this via Fact 5 by exhibiting "hard input distributions" $\mathcal{D}_0$ and $\mathcal{D}_1$ (as we did for GapMaj in Fact 6). Since this was the only property of g used in the proof of Theorem 3, this implies that $\mathsf{BPP}(\textsc{Xor}\circ g^n) \geq \mathsf{PostBPP}(\textsc{Xor}\circ g^n) \geq \Omega(n\cdot\mathsf{PostBPP}_{1/n}(g))$ holds for all g, as we mentioned in Subsection 1.3.

3 Proof of Theorem 4: Maj sometimes necessitates amplification

We first discuss a standard technique for proving randomized query complexity lower bounds, which will be useful in the proof of Theorem 4. For any conjunction $C\colon \{0,1\}^k \to \{0,1\}$ and distribution $\mathcal{D}$ over $\{0,1\}^k$, we write $C(\mathcal{D}) \coloneqq \mathbb{E}_{x\sim\mathcal{D}}[C(x)] = \mathbb{P}_{x\sim\mathcal{D}}[C(x)=1]$. The number of literals in a conjunction is called its width.

▶ **Fact 7.** *Let $h\colon \{0,1\}^k \to \{0,1\}$ be a partial function, and let $\mathcal{D}_0$, $\mathcal{D}_1$, $\mathcal{D}_2$ be three distributions, over $h^{-1}(0)$, $h^{-1}(1)$, and $h^{-1}(0)\cup h^{-1}(1)$ respectively. Then for every $0 < \varepsilon \leq 1/10$ there exists a conjunction C of width $\mathsf{WAPP}_\varepsilon(h)$ such that $C(\mathcal{D}_0) \leq \delta\cdot C(\mathcal{D}_1)$ and $C(\mathcal{D}_2) \leq (1+\delta)\cdot C(\mathcal{D}_1)$ and $C(\mathcal{D}_1) > 0$, where $\delta \coloneqq 2\sqrt{\varepsilon}$.*

The key calculation underlying the proof of Fact 7 is encapsulated in the following:

▶ **Fact 8.** *Let P_0, P_1, P_2 be three jointly distributed nonnegative random variables with $\mathbb{E}[P_1] > 0$. For any $0 < \varepsilon \leq 1/10$, if $\mathbb{E}[P_0] \leq \varepsilon$ and $\mathbb{E}[P_1] \geq 1-\varepsilon$ and $\mathbb{E}[P_2] \leq 1$, then there exists an outcome o such that $P_0(o) \leq \delta\cdot P_1(o)$ and $P_2(o) \leq (1+\delta)\cdot P_1(o)$ and $P_1(o) > 0$, where $\delta \coloneqq 2\sqrt{\varepsilon}$.*

Proof of Fact 8. Let $W \coloneqq \{o : P_1(o) > 0\} \neq \emptyset$. Suppose for contradiction that for every outcome $o \in W$, either $P_0(o) > \delta\cdot P_1(o)$ or $P_2(o) > (1+\delta)\cdot P_1(o)$. Then W can be partitioned into events U and V such that $P_0(o) > \delta\cdot P_1(o)$ for every $o \in U$ and $P_2(o) > (1+\delta)\cdot P_1(o)$ for every $o \in V$. Letting I_U and I_V be the indicator random variables for these events, we have $\mathbb{E}[P_1\cdot I_U] + \mathbb{E}[P_1\cdot I_V] = \mathbb{E}[P_1]$ and thus either:

- $\mathbb{E}[P_1\cdot I_U] \geq \sqrt{\varepsilon}\cdot\mathbb{E}[P_1]$, in which case

$$\mathbb{E}[P_0] \;\geq\; \mathbb{E}[P_0\cdot I_U] \;>\; \delta\cdot\mathbb{E}[P_1\cdot I_U] \;\geq\; \delta\cdot\sqrt{\varepsilon}\cdot(1-\varepsilon) \;=\; 2\varepsilon(1-\varepsilon) \;>\; \varepsilon, \quad \text{or}$$

- $\mathbb{E}[P_1\cdot I_V] \geq (1-\sqrt{\varepsilon})\cdot\mathbb{E}[P_1]$, in which case

$$\mathbb{E}[P_2] \;\geq\; \mathbb{E}[P_2\cdot I_V] \;>\; (1+\delta)\cdot\mathbb{E}[P_1\cdot I_V] \;\geq\; (1+\delta)\cdot(1-\sqrt{\varepsilon})\cdot(1-\varepsilon) \;>\; 1$$

where the last inequality can be verified by a little calculus for $0 < \varepsilon \leq 1/10$.
Both cases yield a contradiction. ◀

Proof of Fact 7. Abbreviate $\mathsf{WAPP}_\varepsilon(h)$ as r. Fix a randomized decision tree of cost r computing h with error parameter ε and threshold $t > 0$ (from the definition of WAPP), and assume w.l.o.g. that for each outcome of the randomness, the corresponding deterministic tree is a perfect tree with 2^r leaves, all at depth r. Consider the probability space where we sample a deterministic decision tree T as an outcome of the randomized decision tree, and sample a uniformly random leaf ℓ of T. For any outcome T, ℓ, let $C_{T,\ell}$ be the conjunction of width r such that $C_{T,\ell}(x) = 1$ iff $T(x)$ reaches ℓ. Define three joint random variables P_0, P_1, P_2 as

$$P_j(T,\ell) \;\coloneqq\; \begin{cases} C_{T,\ell}(\mathcal{D}_j) & \text{if the label of } \ell \text{ is } 1 \\ 0 & \text{if the label of } \ell \text{ is } 0 \end{cases}.$$

Conditioned on any particular x and T, the probability that ℓ is the leaf reached by $T(x)$ is 2^{-r}. Thus

$$\begin{aligned}\mathbb{E}[P_j] &= \mathbb{P}_{T,\ell,\,x\sim\mathcal{D}_j}[\ell \text{ is the leaf reached by } T(x) \text{ and its label is } 1] \\ &= \mathbb{E}_{x\sim\mathcal{D}_j}\left[2^{-r}\cdot\mathbb{P}_T[T(x) \text{ outputs } 1]\right]\end{aligned}$$

which implies $\mathbb{E}[P_0] \le 2^{-r}t\varepsilon$ and $\mathbb{E}[P_1] \ge 2^{-r}t(1-\varepsilon)$ and $\mathbb{E}[P_2] \le 2^{-r}t$. Applying Fact 8 to the scaled random variables $(2^r/t)P_0$, $(2^r/t)P_1$, $(2^r/t)P_2$ yields an outcome T, ℓ such that

$$P_0(T,\ell) \le \delta\cdot P_1(T,\ell) \quad\text{and}\quad P_2(T,\ell) \le (1+\delta)\cdot P_1(T,\ell) \quad\text{and}\quad P_1(T,\ell) > 0.$$

Since $P_1(T,\ell) > 0$, the label of ℓ must be 1, so we get

$$C_{T,\ell}(\mathcal{D}_0) \le \delta\cdot C_{T,\ell}(\mathcal{D}_1) \quad\text{and}\quad C_{T,\ell}(\mathcal{D}_2) \le (1+\delta)\cdot C_{T,\ell}(\mathcal{D}_1) \quad\text{and}\quad C_{T,\ell}(\mathcal{D}_1) > 0.$$

◀

Now we work toward proving Theorem 4. Throughout, n is the input length of Maj, and m is the input length of GapOr. We have $\mathsf{RP}(\text{GapOr}) \le 1$ by outputting the bit at a uniformly random position from the input. We describe one way of seeing that $\mathsf{BPP}_{1/n}(\text{GapOr}) \ge \mathsf{WAPP}_{1/n}(\overline{\text{GapOr}}) \ge \Omega(\log n)$ provided $m \ge \log n$ (this cannot be shown via Fact 5). For $z \in \{0,1\}$, define $\mathcal{G}_z$ as the uniform distribution over $\text{GapOr}^{-1}(z)$.

▶ **Fact 9.** *For every conjunction $C\colon \{0,1\}^m \to \{0,1\}$:*
(i) *$C(\mathcal{G}_0) \in \{0,1\}$.*
(ii) *If $C(\mathcal{G}_0) = 1$ and C has width $w \le m/4$ then $C(\mathcal{G}_1) \ge 3^{-w}$.*

Proof. *(i)*: Note that $\mathcal{G}_0$ is supported entirely on the input 0^m. If C has a positive literal then $C(\mathcal{G}_0) = 0$. If C has only negative literals then $C(\mathcal{G}_0) = 1$.

(ii): Suppose C has w negative literals and no positive literals. Then

$$C(\mathcal{G}_1) = \tbinom{m-w}{m/2}/\tbinom{m}{m/2} = \tfrac{(m/2)\cdot(m/2-1)\cdots(m/2-w+1)}{m\cdot(m-1)\cdots(m-w+1)} \ge \left(\tfrac{m/2-w}{m-w}\right)^w \ge \left(\tfrac{m/2-m/4}{m-m/4}\right)^w = 3^{-w}.$$

◀

Combining Fact 7 and Fact 9 (using $h = \overline{\text{GapOr}}$, $k = m$, $\mathcal{D}_0 = \mathcal{G}_1$, $\mathcal{D}_1 = \mathcal{G}_0$, $\mathcal{D}_2$ is not needed, $\varepsilon = 1/n$, and $w = \mathsf{WAPP}_\varepsilon(h)$) implies that $3^{-w} \le \delta$, in other words $\mathsf{WAPP}_{1/n}(\overline{\text{GapOr}}) \ge \log_3(1/(2\sqrt{1/n})) \ge \Omega(\log n)$, provided $w \le m/4$. If $w > m/4$ then $\mathsf{WAPP}_{1/n}(\overline{\text{GapOr}}) \ge \Omega(\log n)$ holds anyway provided $m \ge \log n$.

Hence, our result can be restated as follows.[2]

▶ **Theorem 4 (Restated).** $\mathsf{WAPP}_\varepsilon(\text{Maj}\circ\text{GapOr}^n) \ge \Omega(n\log n)$ *for some constant $\varepsilon > 0$ provided $m \ge \log n$.*

We show $\mathsf{WAPP}_{1/36}(\text{Maj}\circ\text{GapOr}^n) > \frac{1}{16}n\log n$. By Fact 7 (using $h = \text{Maj}\circ\text{GapOr}^n$, $k = nm$, $\varepsilon = 1/36$, and $\delta = 1/3$) it suffices to exhibit distributions $\mathcal{D}_0$, $\mathcal{D}_1$, $\mathcal{D}_2$ over $h^{-1}(0)$, $h^{-1}(1)$, and $h^{-1}(0)\cup h^{-1}(1)$ respectively, such that for every conjunction C of width $\le \frac{1}{16}n\log n$, either $C(\mathcal{D}_0) > \frac{1}{3}C(\mathcal{D}_1)$ or $C(\mathcal{D}_2) > \frac{4}{3}C(\mathcal{D}_1)$ or $C(\mathcal{D}_1) = 0$. Assume n is

[2] Properties *(i)* and *(ii)* from Fact 9 are somewhat stronger than necessary for the proof of Theorem 4 to go through. The proof works, with virtually no modification, for any g satisfying the following for some distributions $\mathcal{G}_z$ over $g^{-1}(z)$ ($z \in \{0,1\}$): For every conjunction $C\colon \{0,1\}^m \to \{0,1\}$ such that $C(\mathcal{G}_0) > 0$, we have $C(\mathcal{G}_1) \le C(\mathcal{G}_0)$ and if furthermore C has width $w \le m/4$ then $C(\mathcal{G}_1) \ge 2^{-O(w)}\cdot C(\mathcal{G}_0)$.

even and for the tiebreaker, $\textsc{Maj}(y) = 1$ if $|y| = n/2$. For $\zeta \in \{0,1,2\}$ letting $\mathcal{F}_\zeta$ be the uniform distribution over all $y \in \{0,1\}^n$ with $|y| = n/2 - 1 + \zeta$ (so $\mathcal{F}_0$, $\mathcal{F}_1$, $\mathcal{F}_2$ are over $\textsc{Maj}^{-1}(0)$, $\textsc{Maj}^{-1}(1)$, $\textsc{Maj}^{-1}(1)$ respectively), define $\mathcal{D}_\zeta$ as the mixture over $y \sim \mathcal{F}_\zeta$ of $\mathcal{G}_y \coloneqq \mathcal{G}_{y_1} \times \cdots \times \mathcal{G}_{y_n}$ (i.e., $(x^1, \ldots, x^n) \sim \mathcal{G}_y$ is sampled by independently sampling $x^i \sim \mathcal{G}_{y_i}$ for all i). Put succinctly, $\mathcal{D}_\zeta \coloneqq \mathbb{E}_{y \sim \mathcal{F}_\zeta}[\mathcal{G}_y]$.

Now consider any conjunction C of width $w \le \frac{1}{16} n \log n$, and write $C(x^1, \ldots, x^n) = \prod_i C_i(x^i)$ where C_i is a conjunction. By Fact 9.*(i)*, $[n]$ can be partitioned into $A \cup B$ such that $C_i(\mathcal{G}_0) = 1$ for all $i \in A$, and $C_i(\mathcal{G}_0) = 0$ for all $i \in B$. Abbreviate $C_i(\mathcal{G}_1)$ as c_i, and for $S \subseteq [n]$ write $c_S \coloneqq \prod_{i \in S} c_i$. Identify $y \in \{0,1\}^n$ with $Y \coloneqq \{i : y_i = 1\}$, so $|y| = |Y|$. Let the uniform distribution over all size-s subsets of S be denoted by $\binom{S}{s}$, so $y \sim \mathcal{F}_\zeta$ corresponds to $Y \sim \binom{[n]}{n/2-1+\zeta}$. Let $I_{Y \supseteq B} \coloneqq \prod_{i \notin Y} C_i(\mathcal{G}_0)$ be the indicator random variable for the event $Y \supseteq B$. Now for $\zeta \in \{0,1,2\}$,

$$C(\mathcal{D}_\zeta) \;=\; \mathbb{E}_{y \sim \mathcal{F}_\zeta}[C(\mathcal{G}_y)] \;=\; \mathbb{E}_{y \sim \mathcal{F}_\zeta}\big[\textstyle\prod_i C_i(\mathcal{G}_{y_i})\big] \;=\; \mathbb{E}_{Y \sim \binom{[n]}{n/2-1+\zeta}}\big[c_Y \cdot I_{Y \supseteq B}\big]$$

$$= \underbrace{\mathbb{P}_{Y \sim \binom{[n]}{n/2-1+\zeta}}[Y \supseteq B]}_{p_\zeta} \cdot c_B \cdot \underbrace{\mathbb{E}_{S \sim \binom{A}{n/2-1+\zeta-|B|}}[c_S]}_{q_\zeta}.$$

If $c_B = 0$ then $C(\mathcal{D}_1) = 0$, so assume $c_B > 0$. Factoring out c_B and defining p_ζ and q_ζ as above (but q_ζ is undefined if $p_\zeta = 0$), our goal is to show that either $p_0 q_0 > \frac{1}{3} p_1 q_1$ or $p_2 q_2 > \frac{4}{3} p_1 q_1$ or $p_1 q_1 = 0$. There are three cases depending on whether $|B|$ is greater than, equal to, or less than $n/2$. First we collect some generally useful properties:

▷ Claim 10.

(i) $p_0 = \frac{n/2-|B|}{n/2} \cdot p_1$ and $p_1 = \frac{n/2+1-|B|}{n/2+1} \cdot p_2$.

(ii) $0 < q_1 \le \sqrt{n} \cdot q_2$ if q_1 is defined.

Proof. *(i)*: We just consider p_0 vs. p_1 since p_1 vs. p_2 is similar. Imagine sampling $Y_1 \sim \binom{[n]}{n/2}$ and then obtaining the set Y_0 by removing a uniformly random $i \in Y_1$. If $Y_1 \supseteq B$, then $Y_0 \supseteq B$ when $i \in Y_1 \setminus B$, which happens with probability $\frac{n/2-|B|}{n/2}$ (assuming $|B| \le n/2$; if $|B| > n/2$ then $p_0 = p_1 = 0$). Thus

$$p_0 \;=\; \mathbb{P}[Y_0 \supseteq B] \;=\; \mathbb{P}[Y_0 \supseteq B \,|\, Y_1 \supseteq B] \cdot \mathbb{P}[Y_1 \supseteq B] \;=\; \tfrac{n/2-|B|}{n/2} \cdot p_1.$$

(ii): Let w_i be the width of C_i, so $\sum_i w_i = w \le \frac{1}{16} n \log n$. Then $w_i \le \frac{1}{4} \log n \le m/4$ for at least $3n/4$ many values of i, and for such i note that by Fact 9.*(ii)*, $c_i \ge 3^{-(\log n)/4} \ge n^{-2/5}$ if $i \in A$. This implies that if we sample a uniformly random i from any $A' \subseteq A$ with $|A'| = n/2$ (note that $|A| \ge n/2$ if q_1 is defined) then $\mathbb{E}_{i \in A'}[c_i] \ge \frac{1}{2} \cdot n^{-2/5} + \frac{1}{2} \cdot 0 \ge 1/\sqrt{n}$. Now to relate q_2 and q_1,

$$q_2 \;=\; \mathbb{E}_{S \sim \binom{A}{n/2-|B|}}\big[c_S \cdot \mathbb{E}_{i \in A \setminus S}[c_i]\big] \;\ge\; \mathbb{E}_{S \sim \binom{A}{n/2-|B|}}\big[c_S/\sqrt{n}\big] \;=\; q_1/\sqrt{n}$$

where the inequality uses $|A \setminus S| = (n - |B|) - (n/2 - |B|) = n/2$. Furthermore, $q_1 > 0$ if q_1 is defined, because $n/2 - |B| \le |A| - n/4$ and thus there exists an $S \subseteq A$ with $|S| = n/2 - |B|$ and $c_i \ge n^{-2/5} > 0$ for all $i \in S$, hence $c_S > 0$. (A similar argument shows $0 < q_0 \le \sqrt{n} \cdot q_1$ if q_0 is defined, but we will not need that.) ◁

Case $|B| > n/2$. In this case, $p_1 = 0$ so we are done.

Case $|B| = n/2$. By Claim 10, $p_2 = p_1 \cdot (n/2 + 1)$ and $q_2 \ge q_1/\sqrt{n} > 0$ and thus

$$p_2 q_2 \;\ge\; p_1 q_1 \cdot (n/2+1)/\sqrt{n} \;>\; \tfrac{4}{3} p_1 q_1.$$

Case $|B| < n/2$. We will show that $\frac{p_0}{p_1} \geq \frac{1}{2} \cdot \frac{p_1}{p_2}$ and $\frac{q_2}{q_1} \geq \frac{9}{10} \cdot \frac{q_1}{q_0}$, which yields the punchline:

If $p_0 q_0 \leq \frac{1}{3} p_1 q_1$ then $\frac{q_2}{q_1} \geq \frac{9}{10} \cdot \frac{q_1}{q_0} \geq \frac{9}{10} \cdot 3 \cdot \frac{p_0}{p_1} \geq \frac{9}{10} \cdot 3 \cdot \frac{1}{2} \cdot \frac{p_1}{p_2} > \frac{4}{3} \cdot \frac{p_1}{p_2}$ and thus $p_2 q_2 > \frac{4}{3} p_1 q_1$.

First, $\frac{p_0}{p_1} \geq \frac{1}{2} \cdot \frac{p_1}{p_2}$ follows from Claim 10.*(i)* using $|B| \leq n/2 - 1$:

$$\frac{p_0}{p_1} \;=\; \frac{n/2+1}{n/2} \cdot \frac{n/2-|B|}{n/2+1-|B|} \cdot \frac{p_1}{p_2} \;\geq\; 1 \cdot \frac{n/2-(n/2-1)}{n/2+1-(n/2-1)} \cdot \frac{p_1}{p_2} \;=\; \frac{1}{2} \cdot \frac{p_1}{p_2}.$$

It just remains to show $\frac{q_2}{q_1} \geq \frac{9}{10} \cdot \frac{q_1}{q_0}$. Henceforth let $s \coloneqq n/2 - 1 - |B| \geq 0$. The experiment $S \sim \binom{A}{s+2}$ in the definition of q_2 can alternatively be viewed as:

- Sample $S_0 \sim \binom{A}{s}$.
- Sample $i \in A \setminus S_0$ u.a.r. and let $S_1 \coloneqq S_0 \cup \{i\}$.
- Sample $j \in A \setminus S_1$ u.a.r. and let $S = S_2 \coloneqq S_1 \cup \{j\}$.

That is, i and j are sampled without replacement. We consider an "ideal" (easier to analyze) version of this experiment that samples i and j with replacement, in other words, the third step becomes:

- Sample $j \in A \setminus S_0$ u.a.r. and let $S_2^* \coloneqq S_1 \cup \{j\}$.

Now S_2^* is a *multiset*, which may have two copies of i, in which case the product $c_{S_2^*}$ has two factors of c_i. Just as $q_2 \coloneqq \mathbb{E}[c_{S_2}]$, we let $q_2^* \coloneqq \mathbb{E}[c_{S_2^*}]$, and we next show how to derive $\frac{q_2^*}{q_1} \geq \frac{q_1}{q_0}$ from the following claim:

▷ Claim 11. For all nonnegative numbers $\alpha_1, \ldots, \alpha_N$ and $\beta_1, \ldots, \beta_N$ such that $\alpha_k \beta_k > 0$ for some k,

$$\frac{\sum_k \alpha_k \beta_k^2}{\sum_k \alpha_k \beta_k} \;\geq\; \frac{\sum_k \alpha_k \beta_k}{\sum_k \alpha_k}.$$

Proof. By clearing denominators, this inequality is equivalent to

$$\big(\textstyle\sum_k \alpha_k\big)\big(\sum_k \alpha_k \beta_k^2\big) \;\geq\; \big(\sum_k \alpha_k \beta_k\big)^2$$

which can be rewritten as

$$\textstyle\sum_{k,\ell} \alpha_k \alpha_\ell \beta_\ell^2 \;\geq\; \sum_{k,\ell} \alpha_k \beta_k \alpha_\ell \beta_\ell.$$

Subtracting $\sum_k \alpha_k^2 \beta_k^2$ from both sides, this is equivalent to

$$\textstyle\sum_{k<\ell} \big(\alpha_k \alpha_\ell \beta_\ell^2 + \alpha_\ell \alpha_k \beta_k^2\big) \;\geq\; \sum_{k<\ell} 2 \alpha_k \beta_k \alpha_\ell \beta_\ell.$$

We show that this inequality holds for each summand separately. Factoring out $\alpha_k \alpha_\ell$, this reduces to showing $\beta_\ell^2 + \beta_k^2 \geq 2 \beta_k \beta_\ell$, which holds since

$$\beta_\ell^2 + \beta_k^2 - 2 \beta_k \beta_\ell \;=\; (\beta_\ell - \beta_k)^2 \;\geq\; 0. \qquad \triangleleft$$

In the statement of Claim 11, let the index k correspond to S_0, let $N \coloneqq \binom{|A|}{s}$, let $\alpha_k \coloneqq c_{S_0}/N$, and let $\beta_k \coloneqq \mathbb{E}_{i \in A \setminus S_0}[c_i]$. Then

$$q_0 = \textstyle\sum_k \alpha_k \quad \text{and} \quad q_1 = \sum_k \alpha_k \beta_k \quad \text{and} \quad q_2^* = \sum_k \alpha_k \beta_k^2$$

and $q_0 \geq q_1 > 0$ by Claim 10.*(ii)* (i.e., $\alpha_k \beta_k > 0$ for some k) so by Claim 11 we indeed have $\frac{q_2^*}{q_1} \geq \frac{q_1}{q_0}$. To conclude that $\frac{q_2}{q_1} \geq \frac{9}{10} \cdot \frac{q_1}{q_0}$, we just need to show $q_2 \geq \frac{9}{10} q_2^*$.

The third step of the S_2 experiment is just the third step of the S_2^* experiment conditioned on $j \neq i$, which happens with probability $1 - \frac{1}{|A|-s}$. With probability $\frac{1}{|A|-s}$, we get $j = i$ in

the S_2^* experiment. If we condition on the latter event, it yields another experiment, whose result we call S_2^{err}, which is a multiset definitely containing two copies of i. Correspondingly we define $q_2^{\mathrm{err}} \coloneqq \mathbb{E}[c_{S_2^{\mathrm{err}}}]$ (with two factors of c_i). Now we have

$$q_2^* \;=\; \mathbb{P}[j \neq i]\cdot\mathbb{E}\big[c_{S_2^*} \,\big|\, j \neq i\big] + \mathbb{P}[j = i]\cdot\mathbb{E}\big[c_{S_2^*} \,\big|\, j = i\big] \;=\; \big(1 - \tfrac{1}{|A|-s}\big)\cdot q_2 + \tfrac{1}{|A|-s}\cdot q_2^{\mathrm{err}} \;\leq\; q_2 + \tfrac{2}{n}\cdot q_2^{\mathrm{err}}$$

since $|A| - s = (n - |B|) - (n/2 - 1 - |B|) = n/2 + 1 \geq n/2$.

The S_2^{err} experiment can alternatively be viewed as:

- Sample $S_1 \sim \binom{A}{s+1}$.
- Sample $i \in S_1$ u.a.r. and let $S_2^{\mathrm{err}} \coloneqq S_1 \cup \{i\}$.

This implies that $q_2^{\mathrm{err}} \leq q_1$ because the extra factor of $c_i \leq 1$ cannot increase the expectation. By Claim 10.*(ii)* we get $q_2^{\mathrm{err}} \leq q_1 \leq \sqrt{n}\cdot q_2$. Combining, we have

$$q_2^* \;\leq\; q_2 + \tfrac{2}{n}\cdot\sqrt{n}\cdot q_2 \;=\; \big(1 + \tfrac{2}{\sqrt{n}}\big)q_2 \;\leq\; \tfrac{10}{9}q_2$$

and thus $q_2 \geq \frac{9}{10}q_2^*$ as desired. This concludes the proof of Theorem 4.

4 Open questions

▶ **Open Question 12.** *Is there a total function* $g\colon \{0,1\}^m \to \{0,1\}$ *such that* $\mathsf{BPP}(\textsc{Xor}\circ g^n) \geq \Omega(n\log n\cdot\mathsf{BPP}(g))$ *or* $\mathsf{BPP}(\textsc{Maj}\circ g^n) \geq \Omega(n\log n\cdot\mathsf{BPP}(g))$*?*

Since Fact 9 captures the only properties of $g = \textsc{GapOr}$ used in our proof of Theorem 4, this provides a possible roadmap for confirming Open Question 12: Just find a total function g satisfying properties similar to Fact 9, enabling our proof of Theorem 4 to go through. However, such a g would need to have certificate complexity $\omega(\mathsf{BPP}(g))$, and it remains a significant open problem to find any such total function g (the "pointer function" [19, 2] and "cheat sheet" [1] methods do not seem to work).

Another approach for confirming Open Question 12 would be to generalize the strong direct sum theorem from [7] to show that $\mathsf{BPP}(\textsc{Xor}\circ g^n) \geq \Omega(n\cdot\overline{\mathsf{BPP}}_{1/n}(g))$ or $\mathsf{BPP}(\textsc{Maj}\circ g^n) \geq \Omega(n\cdot\overline{\mathsf{BPP}}_{1/n}(g))$ holds for all g. This would answer Open Question 12 in the affirmative, since [7] designed a total function g satisfying $\overline{\mathsf{BPP}}_{1/n}(g) \geq \Omega(\mathsf{RP}(g)\cdot\log n)$ using the "pointer function" method. Compared to our approach from the previous paragraph, this approach involves less stringent requirements on g, which makes it easier to design g but harder to prove the composition lower bound.

▶ **Open Question 13.** *Is there a total function* $f\colon \{0,1\}^n \to \{0,1\}$ *such that* $\mathsf{BPP}^*(f) \geq \omega(\mathsf{BPP}^\dagger(f))$ *(or similarly,* $\mathsf{BPP}(f\circ\textsc{GapMaj}^n) \geq \omega(\mathsf{BPP}(f\circ\textsc{GapOr}^n))$*)?*

It is not difficult to find such a *partial* function f. Namely, take any function $f'\colon \{0,1\}^n \to \{0,1\}$ such that $\mathsf{BPP}^*(f') \geq \Omega(n\log n)$, such as $f' = \textsc{Xor}$ or $f' = \textsc{Maj}$. Then take $f = f'\circ\textsc{Which}^n$, which has input length $2n$ (recall from Subsection 1.1 that given $y \in \{0,1\}^2$ with the promise that y has Hamming weight 1, $\textsc{Which}(y)$ indicates the location of the unique 1 in y). A simple reduction shows $\mathsf{BPP}^*(f) \geq \mathsf{BPP}^*(f')$. However, $\mathsf{BPP}^\dagger(f) \leq O(n)$: For each block of 2 bits, we can repeatedly query both until one of them returns 1 (which takes $O(1)$ queries in expectation). After doing this for all n blocks (which takes $O(n)$ queries in expectation), we know for sure what the entire actual input is. By Markov's inequality, we can abort the execution after $O(n)$ queries while introducing only a small constant error probability. (Intuitively, composition with $\textsc{Which}$ preserves hardness for 2-sided noise but converts 1-sided noise to "0-sided noise", and no partial function needs $\omega(n)$ queries in the setting of 0-sided noise.)

In communication (rather than query) complexity, somewhat analogous questions have been studied in specific contexts [24, 8, 26]. The proof of Theorem 2 also works for communication complexity. It would be interesting to develop analogues of Theorem 3 and Theorem 4 for communication complexity.

A Proof of Theorem 2: Or never necessitates amplification

For completeness, we provide a self-contained proof that $\mathsf{BPP}^*(\textsc{Or}) \leq O(n)$, using the following standard fact about random walks ("the drunkard at the cliff").

▶ **Lemma 14.** *Consider a random walk on the integers that begins at* 0 *and in each step moves right* $(+1)$ *with probability* p *and moves left* (-1) *with probability* $1-p$.

(i) *If* $p < 1/2$ *then the expected time at which the walk first visits* -1 *is* $1/(1-2p)$.

(ii) *If* $p > 1/2$ *then the probability that the walk ever visits* -1 *is* $(1-p)/p$.

Proof of Lemma 14. *(i)*: If random variable X represents the time at which the walk first visits -1, then its expectation satisfies $\mathbb{E}[X] = 1 + p \cdot 2\mathbb{E}[X]$ since after the first step, it either is already at -1, or is at $+1$ in which case to reach -1 it must first get back to 0 ($\mathbb{E}[X]$ expected time) then from there get to -1 (another $\mathbb{E}[X]$ expected time). This equation has a unique solution $\mathbb{E}[X] = 1/(1-2p) < \infty$.

(ii): If event E represents the walk ever visiting -1, then its probability satisfies $\mathbb{P}[E] = (1-p) \cdot 1 + p \cdot \mathbb{P}[E]^2$ since after the first step, it either is already at -1, or is at $+1$ in which case to reach -1 it must first get back to 0 (probability $\mathbb{P}[E]$) then from there get to -1 (again probability $\mathbb{P}[E]$). This equation has two solutions $\mathbb{P}[E] \in \{(1-p)/p, 1\}$. To rule out

$\mathbb{P}[E] = 1$, we define q_k as the probability that the walk visits -1 within the first k steps, and we show by induction on k that $q_k \leq (1-p)/p$. The base case is trivial since $q_0 = 0$. Assuming $q_k \leq (1-p)/p$ we show $q_{k+1} \leq (1-p)/p$. After the first step, with probability $1-p$ it is already at -1, and with probability p it is at $+1$. In the latter case, to get to -1 within a total of $k+1$ steps (including the first step), it must get from $+1$ to 0 and then from there it must get to -1, all within k more steps; in particular, the walk must get from $+1$ to 0 within k steps (probability $\leq q_k$) and then from 0 to -1 within k steps (probability $\leq q_k$). Overall we can bound $q_{k+1} \leq (1-p) \cdot 1 + p \cdot q_k^2 \leq (1-p) + p \cdot (1-p)^2/p^2 = (1-p)/p$. ◀

Proof of Theorem 2. We may assume the noise probabilities are $\leq 1/4$ (rather than just $\leq 1/3$), because whenever an input bit is queried, we can instead query it five times and pretend that the majority vote was the result of the single query. This would only affect the cost by a constant factor. With this assumption, here is our decision tree, on input $y \in \{0,1\}^n$:

For $i = 1, 2, \ldots, n$:
  Repeat:
    Query y_i.
    If the queries to y_i have resulted in more 0s than 1s so far,
      then break out of the inner loop.
    If a total of $6n$ queries have been made (across all input bits), then halt and output 1.
Halt and output 0.

This decision tree's cost is $\leq 6n$. To see the correctness, consider any input $y \in \{0,1\}^n$ and any tuple of noise probabilities $(\nu_1, \ldots, \nu_n)$ where each $\nu_i \leq 1/4$. For each i, the random variable

"number of 1s minus number of 0s, among the queries to y_i so far"

is a random walk with move-right probability $p_i = \nu_i \leq 1/4$ if $y_i = 0$ and $p_i = 1 - \nu_i \geq 3/4$ if $y_i = 1$, and which stops when it visits -1.

First assume $\textsc{Or}(y) = 0$. Then for each i, $y_i = 0$ and so by Lemma 14.*(i)*, the expected number of queries until the inner loop is broken is $1/(1-2p_i) \leq 2$. By linearity, the expected total number of queries until all n inner loops have been broken is $\leq 2n$, so by Markov's inequality this number of queries is $< 6n$ with probability $\geq 2/3$. Thus the decision tree outputs 0 with probability $\geq 2/3$.

Now assume $\textsc{Or}(y) = 1$. Then for some i, $y_i = 1$ and so by Lemma 14.*(ii)*, with probability $1 - (1-p_i)/p_i = 2 - 1/p_i \geq 2/3$ there would never be more 0s than 1s from the queries to y_i. In that case, the decision tree would never break out of the i^{th} inner loop, even if it were allowed to run forever. Thus the decision tree outputs 1 with probability $\geq 2/3$. ◀

On Multilinear Forms: Bias, Correlation, and Tensor Rank

Abstract

In this work, we prove new relations between the bias of multilinear forms, the correlation between multilinear forms and lower degree polynomials, and the rank[5] of tensors over $\mathbb{F}_2$. We show the following results for multilinear forms and tensors.

Correlation bounds. We show that a random d-linear form has exponentially low correlation with low-degree polynomials. More precisely, for $d = 2^{o(k)}$, we show that a random d-linear form $f(X_1, X_2, \ldots, X_d) : \left(\mathbb{F}_2^k\right)^d \to \mathbb{F}_2$ has correlation $2^{-k(1-o(1))}$ with any polynomial of degree at most $d/2$ with high probability.
This result is proved by giving near-optimal bounds on the bias of a random d-linear form, which is in turn proved by giving near-optimal bounds on the probability that a sum of t random d-dimensional rank-1 tensors is identically zero.

Tensor rank vs Bias. We show that if a 3-dimensional tensor has small rank then its bias, when viewed as a 3-linear form, is large. More precisely, given any 3-dimensional tensor

$$T : [k]^3 \to \mathbb{F}_2$$

of rank at most t, the bias of the 3-linear form

$$f_T(X_1, X_2, X_3) := \sum_{(i_1,i_2,i_3)\in[k]^3} T(i_1, i_2, i_3) \cdot X_{1,i_1} \cdot X_{2,i_2} \cdot X_{3,i_3}$$

is at least $(3/4)^t$.

This bias vs tensor-rank connection suggests a natural approach to proving nontrivial tensor-rank lower bounds. In particular, we use this approach to give a new proof that the finite field multiplication tensor has tensor rank at least $3.52k$, which is the best known rank lower bound for any explicit tensor in three dimensions over $\mathbb{F}_2$. Moreover, this relation between bias and tensor rank holds for d-dimensional tensors for any fixed d.

1 Introduction

This work is motivated by two fundamental questions regarding "explicit constructions" in complexity theory: finding functions uncorrelated with low degree polynomials, and finding tensors with high tensor rank.

Functions uncorrelated with low degree polynomials

The first question is that of finding an explicit function uncorrelated with low degree polynomials. More concretely, we seek functions $f : \mathbb{F}_2^n \to \mathbb{F}_2$ such that for every polynomial $P(X_1, \ldots, X_n) \in \mathbb{F}_2[X_1, \ldots, X_n]$ of degree at most ℓ (assume $\ell \approx n^{0.1}$ say),

$$\Pr_{x \in \mathbb{F}_2^n}[f(x) = P(x)] = \frac{1}{2} + \varepsilon_n \,,$$

where ε_n is exponentially small in n. It is well known that a random function f has this property with ε_n superpolynomially small (and even exponentially small); the challenge is to find an explicit function f.

A solution to this problem will have immediate applications in Boolean circuit complexity. It will give hard-on-average problems for $\mathrm{AC}^0(\oplus)$, and via the Nisan-Wigderson hardness vs. randomness technique [15], it will give pseudorandom generators against $\mathrm{AC}^0(\oplus)$ (improving upon analogous results for AC^0 from the late 1980s). The original motivation for an explicit function with small ε_n came from the seminal work of Razborov [17] and Smolensky [20] who used such functions to prove lower bounds against sub-exponential sized $\mathrm{AC}^0(\oplus)$ circuits. In particular, they showed that for the MOD_3 function $\varepsilon_n \leq \frac{1}{3} + O(1/\sqrt{n})$ and for the MAJORITY function $\varepsilon_n = O(\ell/\sqrt{n})$.[6]

[6] In a recent work [23], Viola showed that there exist degree ℓ polynomials which have correlation $\Omega(\ell/\sqrt{n})$ with the MAJORITY function, thereby showing that the aforementioned upper bound in [17, 20] are essentially tight.

The current best known constructions of explicit functions [17, 20, 3, 24] that cannot be approximated by low-degree polynomials come in two flavors, (a) polynomially small ε_n (in fact, $O(1/\sqrt{n})$) for large degree bounds (ℓ as large as $n^{0.1}$) or (b) exponentially small ε_n for small degree bounds ($\ell = o(\log n)$). However, we do not know of any explicit function f that exhibits exponentially small ε_n against low-degree polynomials of polynomially large (or even super-logarithmically large) degree polynomials. For a nice survey on correlation with low degree polynomials, see [22].

Tensors with high rank

The second question is that of finding an explicit tensor of high tensor rank. Tensors are a high-dimensional generalization of (2-dimensional) matrices. Just as a matrix of size k over a field $\mathbb{F}$ is given by a map $M : [k]^2 \to \mathbb{F}$, a tensor T of dimension d and size k is given by a map $T : [k]^d \to \mathbb{F}$. A tensor T is said to be of rank one if there exist vectors $u_1, u_2, \ldots, u_d \in \mathbb{F}_2^k$ such that $T = u_1 \otimes u_2 \otimes \cdots \otimes u_d$ or equivalently, for all $(i_1, \ldots, i_d) \in [k]^d$, we have $T(i_1, \ldots, i_d) = u_{1,i_1} \cdot u_{2,i_2} \cdots u_{d,i_d}$. A tensor T is said to be of tensor-rank at most t if it can be written as the sum of t rank one tensors. We seek tensors with tensor-rank as high as possible.

It is well known (and easy to prove) that a random tensor T has tensor rank t as large as $\Omega(k^{d-1}/d)$. The challenge is to find an explicit such T with tensor rank larger than $k^{\lfloor \frac{d}{2} \rfloor}$. A substantial improvement on this lower bound for any explicit tensor will have immediate applications in arithmetic circuit complexity; for $d = 3$, it will give improved arithmetic circuit lower bounds [21], and for large d it will give superpolynomial arithmetic formula lower bounds [16, 6]. For general *odd* d, a lower bound of $2k^{\lfloor d/2 \rfloor} + k - O(d \log k)$ was shown for an explicit tensor by Alexeev et al. [1], while for *even* d, no lower bounds better than the trivial bound $k^{\lfloor \frac{d}{2} \rfloor}$ are known for any explicit tensor.

Unlike matrix rank, we do not have a good understanding of tensor-rank even for 3-dimensional tensors. For instance, it is known that for a given 3-dimensional tensor T over the rationals, the problem of deciding if the rank of T is at most k is NP-hard [10]. In the case of dimension three, the tensor-rank of very specific tensors like the matrix multiplication tensor [4, 19], the finite field multiplication tensor [7, 18] and the polynomial multiplication tensor [5, 11] has been studied in prior works. For this case, the current best lower bound known for any explicit tensor over $\mathbb{F}_2$ is a lower bound of $3.52k$ for the finite field multiplication tensor due to Chudnovsky and Chudnovsky [7, 18], which builds on the lower bound result of Brown and Dobkin [5] for the polynomial multiplication tensor. For general fields, the best known lower bound for any explicit tensor is $2.5k - o(k)$ for the matrix multiplication tensor due to Bläser [4].

Also relevant to this discussion is a recent result of Effremenko et al. [8], who showed that a fairly general class of lower bound techniques called *rank methods* are not strong enough to give lower bounds on tensor rank stronger than $2^d \cdot k^{\lfloor d/2 \rfloor}$. In a nutshell, not only can we not prove good tensor rank lower bounds, we do not even have techniques, which "in principle" could be useful for such lower bounds!

1.1 Our results

We make contributions to both the above questions by studying *multilinear forms* and their *bias*. A d-linear form is a map $f : (\mathbb{F}_2^k)^d \to \mathbb{F}_2$ which is linear in each of its d arguments. The *bias* of a d-linear form is defined as follows.

$$\mathrm{bias}(f) := \left| \mathbb{E}_{x_1, \ldots, x_d \in \mathbb{F}_2^k} [(-1)^{f(x_1, \ldots, x_d)}] \right| .$$

This measures the difference between the probability of output 1 and output 0. Similarly, the correlation of a d-linear form f with another function g is defined as $\mathrm{corr}(f,g) := \mathrm{bias}(f-g)$, which measures the difference between the probabilities (on a random input) that f and g agree and disagree.

A d-linear form f can naturally be viewed as a polynomial of degree d in $n = kd$ variables. We can then ask, for some $\ell \ll d$, is there a d-linear form f such that the correlation of f with every degree ℓ polynomial in $\mathbb{F}_2[X_1, \ldots, X_n]$ is small? Knowing the existence of a d-linear f that achieves this small correlation property gives a significantly reduced search space for finding an explicit f with small correlation with lower degree polynomials. Our first result gives a positive answer to this question for a large range of ℓ and d.

▶ **Theorem** (A). *Let $d = o(n/\log n)$ and let $k = \frac{n}{d}$. Let $\ell < d/2$. Then with high probability, for a uniformly random d-linear form $f : (\mathbb{F}_2^k)^d \to \mathbb{F}_2$, we have that for all polynomial $P(X_1, \ldots, X_n) \in \mathbb{F}_2[X_1, \ldots, X_n]$ of degree at most ℓ:*

$$\mathrm{corr}(f, P) \leq 2^{-k(1-o(1))} = 2^{-\frac{n}{d}(1-o(1))}.$$

Moreover, for every d-linear form f, there is a degree 0 polynomial P (namely the constant 0 polynomial) such that $\mathrm{corr}(f, P) \geq \Omega(2^{-k})$.

For d small enough ($\tilde{O}(\log n)$), the above theorem actually holds with $\ell = d - 1$.

An important step towards proving Theorem A is a precise understanding of the distribution of the *bias* of a random d-linear form. Along the way, we give tight upper bounds on the probability that the sum of t random *rank-1* d-dimensional tensors equals 0.

Previously, a beautiful result of Ben-Eliezer, Lovett and Hod [2] showed that for all $d < \alpha n$, there are polynomials $f(X_1, \ldots, X_n)$ of degree d whose correlation with polynomials of degree $\ell = d-1$ is $2^{-\Omega(n/d)}$. The results are incomparable; the f in [2] need not come from a d-linear form, and for this more general setting the bound $2^{-\Omega(n/d)}$ might not be tight, but on the positive side [2] can handle larger d while proving correlation bounds against polynomials with degree as large as $d - 1$.

A d-linear form f can also be naturally represented as a d-dimensional tensor. Indeed, f can be completely specified by the tensor T of values $f(e_{i_1}, e_{i_2}, \ldots, e_{i_d})$, as the i_j vary in $[k]$. We can then ask, are there natural properties of the d-linear form f which would imply that the tensor rank of T is high? In our next main result, we prove a lower bound on the rank of a three dimensional tensor by studying the bias of the corresponding trilinear form. As far as we know, this is the first *analytic* property of low rank tensors which appears to be useful for lower bounds on tensor rank. Prior to this work, all the tensor rank lower bound proofs appear to be *algebraic*.

▶ **Theorem** (B). [7] *Let $f : (\mathbb{F}_2^k)^3 \to \mathbb{F}_2$ be a 3-linear form. Let T be the natural representation of f as a tensor (see above), and let t be the rank[8] of T. Then*

$$\mathrm{bias}(f) \geq \left(\frac{3}{4}\right)^t.$$

In particular, if $\mathrm{bias}(f) = 2^{-(1-o(1))k}$, then $t \geq k \cdot \log_{\frac{4}{3}} 2$. Moreover, for every t there is a tensor T with tensor rank t such that the following is true.

$$\mathrm{bias}(f) \leq \left(\frac{3}{4}\right)^t + \frac{3}{2^k}.$$

[7] For brevity, we state this theorem here for $d = 3$, but it holds more generally for higher dimensional tensors as well. See Section 3 for details.

[8] Here, "rank" refers to the standard notion of the rank of a tensor.

This gives a natural and clean route to proving nontrivial tensor rank lower bounds for explicit 3 dimensional tensors. In particular, trilinear forms with nearly minimal bias of of $2^{-(1-o(1))k}$ must have tensor rank at least $2.409k$ (which happens to be tight). A finer analysis of our arguments shows that trilinear forms with *exactly* minimal bias of $\approx 2 \cdot 2^{-k}$, such as the finite field multiplication tensor, have tensor rank $\geq 3.52k$, thus matching the best known explicit tensor rank lower bound for 3-dimensional tensors [5, 7, 18] for *any* explicit tensor. It also immediately implies that the matrix multiplication tensor has tensor rank $\geq 1.8k$, which is nontrivial (but still far from the best known bound of $3k$ [19, 4]). We remark that since every a 3-linear form $f : (\mathbb{F}_2^k)^d \to \mathbb{F}_2$ has bias at least $\exp(-\Omega(k))$, we cannot hope to prove super linear lower bounds on tensor rank via a direct use of this connection between bias and tensor rank. We also note while that an analogous connection between bias and tensor rank also holds in 4 and higher dimensions (see Theorem 8), the quantitative bounds are not strong enough to give a non-trivial lower bound on tensor rank for d dimensional tensors for $d \geq 4$. Here, by *non-trivial* tensor rank lower bounds, we mean bounds are better than the bound of $k^{\lfloor d/2 \rfloor}$ that can be obtained by just flattening the tensor into a matrix and using the rank of the matrix as a lower bound on tensor rank.

We remark this method of studying the bias of a three dimensional tensor as a tool for proving tensor rank lower bounds appears to be new. Informally it shows a non-trivial connection between one of the weakest measures of computational pseudorandomness of a function, namely bias, and one of the strongest measures of computational pseudorandomness, namely tensor rank. While such a connection is well known for matrices, to the best of our knowledge, this connection between bias and rank is new for tensors of dimension 3 and larger. In addition to the intrinsic appeal, this connection lets us recover the lower bound of $3.52k$ for an explicit three dimensional tensor over $\mathbb{F}_2$. To recover this lower bound, we end up using the proof of Theorem B in a non-blackbox manner.

The results of Theorem B can also be phrased in terms of the notion of *analytic rank* introduced in the work of Gowers and Wolf [9]. The analytic rank of a multilinear form f over a finite field $\mathbb{F}$ is defined by:

$$\operatorname{arank}(f) := -\log_{|\mathbb{F}|}(\operatorname{bias}(f)) \ .$$

Stated in this language[9], our result says that if $f : (\mathbb{F}_2^k)^3 \to \mathbb{F}_2$ is a 3-linear form of tensor rank t then

$$t \geq \frac{1}{\log_2(8/7)} \cdot \operatorname{arank}(f) \ .$$

This is essentially the best lower bound one can hope to prove on the tensor rank in terms of the analytic rank.
In their work, Gowers and Wolf prove that analytic rank is approximately subadditive. In particular, they show that

$$\operatorname{arank}(f+g) \leq 2^d \left(\operatorname{arank}(f) + \operatorname{arank}(g)\right) \ .$$

This implies only a quantitatively much weaker version of Theorem B which does not give any nontrivial tensor rank lower bounds even for $d = 3$. Shortly after we posted our paper online, Lovett [13] showed that analytic rank is *fully* subadditive (improving upon the above

[9] Similar to Theorem B, this also holds for general d dimensional tensors. We focus on the $d = 3$ case here.

result of Gowers and Wolf by getting rid of the multiplicative factor of 2^d). The proof is extremely elegant and clever. This result of Lovett implies and greatly elucidates the real reason underlying Theorem B, although we do not know if a tensor rank lower bound of anything close to $3.52k$ can be recovered directly from it.

1.2 Organization

Section 2 contains the preliminaries. Section 3 discusses the connection between bias and tensor rank (Theorem B above) and proves rank lower bounds for explicit tensors. Section 4 proves correlation bounds for random d-linear forms (Theorem A above) and other related results.

2 Preliminaries

Unless otherwise stated, we always work over the field $\mathbb{F}_2$. We use capital X, Y, Z etc. to denote formal variables or sets of formal variables, and small letters x, y, z to denote instantiations of these formal variables.

For integers $n, d \geq 0$, denote by $\mathrm{Poly}(n, d)$ the set of all degree $\leq d$ multilinear polynomials in $\mathbb{F}_2[X]$, where $X = \{X_1, ..., X_n\}$ is a variable set. Note that every $f \in \mathrm{Poly}(n, d)$ naturally corresponds to a unique map $f : \mathbb{F}_2^n \to \mathbb{F}_2$.

2.1 Bias and Correlation

Two fundamental notions used in this paper are those of bias and correlation, which we now define.

▶ **Definition 1** (Bias). *Bias of a function $f : \mathbb{F}_2^n \to \{0, 1\}$ is defined as*

$$\mathrm{bias}(f) := \left| \mathbb{E}_{x \in \mathbb{F}_2^n} (-1)^{f(x)} \right| .$$

The bias of an $\mathbb{F}_2$-valued function $f : \mathbb{F}_2^n \to \mathbb{F}_2$ is defined as $\mathrm{bias}(f) := \mathrm{bias}(\iota(f))$, where ι is the standard map from $\mathbb{F}_2$ to $\{0, 1\}$.

▶ **Definition 2** (Correlation). *We define the correlation between two functions $f, g : \mathbb{F}_2^n \to \mathbb{F}_2$, by*

$$\mathrm{corr}(f, g) := \mathrm{bias}(f - g) .$$

Given a function $f : \mathbb{F}_2^n \to \mathbb{F}_2$, we will be interested in its maximum correlation with low degree polynomials. Towards this we define

$$\mathrm{corr}(f, d) := \max_{g \in \mathrm{Poly}(n,d)} \mathrm{corr}(f, g) .$$

More generally, given a class $\mathcal{C}$ of functions, we define

$$\mathrm{corr}(f, \mathcal{C}) := \max_{g \in \mathcal{C}} \mathrm{corr}(f, g) .$$

2.2 Tensors and d-linear forms

Tensors are generalizations of matrices to higher dimensions.

▶ **Definition 3** (Tensors and Tensor rank). *Let k and d be natural numbers. A d dimensional tensor T of size k over a field $\mathbb{F}$ is a map $T : [k]^d \to \mathbb{F}$. T is said to be of rank one if there exist d vectors $u_1, u_2, \ldots, u_d : [k] \to \mathbb{F}$ such that for every $(i_1, i_2, \ldots, i_d) \in [k]^d$, $T(i_1, i_2, \ldots, i_d) = \prod_{j=1}^{d} u_j(i_j)$. The rank of T is the minimum t such that T can be written as a sum of t rank one tensors.*

Every matrix can be naturally associated with a bilinear polynomial, and in some cases, one can study the properties of this bilinear polynomial as a proxy of studying various properties of the matrix itself. This paradigm also generalizes to tensors, as the following definition indicates.

▶ **Definition 4** (Tensors as Multilinear Forms). *Let $T : [k]^d \to \mathbb{F}$ be a d dimensional tensor. Then, the* set-multilinear *polynomial associated with T is the polynomial f_T in variables $\{X_{i,j} : i \in [d], j \in [k]\}$ over $\mathbb{F}$ defined as follows.*

$$f_T(X_{1,1}, X_{1,2}, \ldots, X_{d,k}) = \sum_{(i_1, i_2, \ldots, i_d) \in [k]^d} T(i_1, i_2, \ldots, i_d) \cdot \prod_{j=1}^{d} X_{j,i_j}.$$

Given the above association between d-dimensional tensors and d-linear forms, we will use the terms tensor and d-linear form interchangeably.

2.3 Some explicit tensors

We now define some explicit tensors which we shall use in the next section.

2.3.1 Trace tensor

▶ **Definition 5.** $\mathrm{Trace} : \mathbb{F}_{2^k} \to \mathbb{F}_2$ *is the $\mathbb{F}_2$-linear map defined as follows.*

$$\mathrm{Trace}(\alpha) = \alpha + \alpha^2 + \ldots + \alpha^{2^{k-1}}.$$

The Trace map will be useful for us as we define the candidate hard tensor for our lower bounds.

▶ **Definition 6.** *Let $Tr : \mathbb{F}_2^{k \times k \times k} \to \mathbb{F}_2$ be the function defined as follows.*

$$Tr(X, Y, Z) := \mathrm{Trace}(XYZ),$$

where XYZ denotes multiplication over the larger field $\mathbb{F}_{2^k}$ when $X = (X_1, X_2, \ldots, X_k), Y = (Y_1, Y_2, \ldots, Y_k), Z = (Z_1, Z_2, \ldots Z_k)$ are viewed as encodings of elements in $\mathbb{F}_{2^k}$.

Since Trace is an $\mathbb{F}_2$-linear map, the function $Tr(X, Y, Z)$ can be viewed as a 3-linear polynomial in the variables $X = (X_1, X_2, \ldots, X_k), Y = (Y_1, Y_2, \ldots, Y_k), Z = (Z_1, Z_2, \ldots Z_k)$. For the rest of this paper, when we say $Tr(X, Y, Z)$, we refer to this natural 3-linear polynomial and the three dimensional tensor associated with it. Up to a change of basis, this is the finite field multiplication tensor, which was analyzed by Chudnovsky-Chudnovsky [7] and Shparlinksi-Tsfasman-Vladut [18]. It is also worth noting that these papers also proved a surprising and beautiful $O(k)$ *upper bound* on the tensor rank of this tensor.

2.3.2 Matrix multiplication tensor

▶ **Definition 7.** *The tensor corresponding to the product of two $n \times n$ matrices is defined as*

$$M_n(X, Y, Z) = \sum_{i=1}^{n} \sum_{j=1}^{n} \sum_{k=1}^{n} X_{i,j} Y_{j,k} Z_{i,k} \,.$$

Here, $X = \{X_{i,j} : i, j \in [n]\}, Y = \{Y_{i,j} : i, j \in [n]\}, Z = \{Z_{i,j} : i, j \in [n]\}$.

Note that $M_n(X, Y, Z)$ is the trace of the matrix product $X \cdot Y \cdot Z^T$. In other words, $M_n(X, Y, Z^T) = \text{Trace}(X \cdot Y \cdot Z)$. Note this is the matrix trace and is different from the trace function considered in the previous section where we viewed X, Y, Z as elements of the large field.

3 High-rank tensors from unbiased polynomials

It is well-known that the bias of a bilinear form corresponding to a matrix $M \in \mathbb{F}_2^{k \times k}$ is tightly related to its rank $\text{rank}(M)$ (more precisely, $\text{bias}(M) = 2^{-\text{rank}(M)}$). In this section, we explore a similar connection for higher dimensional tensors. We then use this to (re)prove some existing tensor rank lower bounds (e.g., for the trace tensor and the matrix multiplication tensor). We note that while in the introduction we stated this connection between bias and tensor rank specifically for three dimensional tensors, we prove a general statement which holds even for higher dimensional tensors.

3.1 Small Bias implies large tensor rank

We begin with the main theorem of this section which shows tensors with small bias have large rank.

▶ **Theorem 8** (Small bias implies large rank)**.** *Let $P \in \mathbb{F}_2^{k \times k \cdots \times k}$ be any d-dimensional tensor of rank $\leq t$. Then*

$$\text{bias}(P) \geq \left(1 - \frac{2}{2^d}\right)^t \,.$$

An important ingredient of our proof will be the following lemma.

▶ **Lemma 9.** *Let d be a natural number. Let $M_1, M_2, \ldots, M_t \in \mathbb{F}_2^{k \times k \cdots \times k}$ be d-dimensional tensors of rank at most 1. Then,*

$$\Pr_{x_1, x_2, \ldots, x_d \in \mathbb{F}_2^k} [\forall i \in [t], M_i(x_1, x_2, \ldots, x_d) = 0] \geq \left(1 - \frac{1}{2^d}\right)^t \,. \tag{1}$$

Proof. Our proof is by induction on d.

Base Case. The base case when $d = 1$ trivially follows since if there are t linear forms $u_1, u_2, \ldots, u_t$ over $\mathbb{F}_2$, then the maximum number r of independent linear forms among them is at most t. We hence have,

$$\Pr_{x \in \mathbb{F}_2^k} [\forall i \in [t], u_i(x) = 0] = (1/2)^r \geq (1/2)^t \,. \tag{2}$$

Induction Step. For the inductive step, we assume that the lemma is true up to dimension $d-1$, and prove it for d dimensions. For every $i \in [t]$, we denote by u_i the linear form in $\mathbb{F}_2^k$ and by M_i' the $d-1$ dimensional tensor of rank 1 in $\mathbb{F}_2^{k \times k \times k \cdots \times k}$ such that

$$M_i(X_1, X_2, \ldots, X_d) = u_i(X_1) \cdot M_i'(X_2, X_3, \ldots, X_d)\,.$$

For every $S \subseteq [t]$, M_S denotes the tensor $\sum_{j \in S} M_j$, which has rank at most $|S|$. We now proceed via a sequence of inequalities.

$$\begin{aligned}
&\Pr_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} [\forall i \in [t], M_i(x_1, x_2, \ldots, x_d) = 0] \\
&= \mathbb{E}_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} \left[\prod_{i=1}^{t} \left(\frac{1 + (-1)^{M_i(x_1,x_2,\ldots,x_d)}}{2} \right) \right] \\
&= \mathbb{E}_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} \left[\frac{1}{2^t} \cdot \sum_{S \subseteq [t]} (-1)^{M_S(x_1,x_2,\ldots,x_d)} \right] \\
&= \mathbb{E}_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} \left[\mathbb{E}_{S \subseteq [t]} \left[(-1)^{M_S(x_1,x_2,\ldots,x_d)} \right] \right] \\
&= \mathbb{E}_{S \subseteq [t]} \left[\mathbb{E}_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} \left[(-1)^{M_S(x_1,x_2,\ldots,x_d)} \right] \right] .
\end{aligned}$$

Now, observe that for every $S \subseteq [t]$,

$$\mathbb{E}_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} \left[(-1)^{M_S(x_1,x_2,\ldots,x_d)} \right] \geq \Pr_{x_2,x_3,\ldots,x_d} \left[\forall j \in S, M_j'(x_2, x_3, \ldots, x_d) = 0 \right] .$$

Moreover, from the induction hypothesis, we get that for all $S \subseteq [t]$,

$$\Pr_{x_2,x_3,\ldots,x_d} \left[\forall j \in S, M_j'(x_2, x_3, \ldots, x_d) = 0 \right] \geq \left(1 - \frac{1}{2^{d-1}} \right)^{|S|} .$$

Plugging this back in the calculations, we get

$$\begin{aligned}
\Pr_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} [\forall i \in [t], M_i(x_1, x_2, \ldots, x_d) = 0] &\geq \mathbb{E}_{S \subseteq [t]} \left[\left(1 - \frac{1}{2^{d-1}} \right)^{|S|} \right] \\
&\geq \frac{1}{2^t} \cdot \left(1 + 1 - \frac{1}{2^{d-1}} \right)^t = \left(1 - \frac{1}{2^d} \right)^t . \quad \blacktriangleleft
\end{aligned}$$

We now complete the proof of Theorem 8.

Proof of Theorem 8. Since P has rank $\leq t$, then there is a collection of linear forms $u_1, u_2, \ldots, u_t$ and tensors $M_1, M_2, \ldots, M_t$ of rank at most 1 in $d-1$ dimensions such that

$$P(X_1, X_2, \ldots, X_d) = \sum_{i=1}^{t} u_i(X_1) \cdot M_i(X_2, X_3, \ldots, X_d)\,.$$

Now, observe that

$$\begin{aligned}
\mathrm{bias}(P) &= \left| \mathbb{E}_{x_1,x_2,\ldots,x_d \in \mathbb{F}_2^k} \left[(-1)^{P(x_1,x_2,\ldots,x_d)} \right] \right| \\
&= \Pr_{x_2,x_3,\ldots,x_d \in \mathbb{F}_2^k} [P(X_1, x_2, x_3, \ldots, x_d) \equiv 0] \\
&\geq \Pr_{x_2,x_3,\ldots,x_d \in \mathbb{F}_2^k} [\forall i \in [t],\ M_i(x_2, x_3, \ldots, x_d) = 0] \\
&\geq \left(1 - \frac{1}{2^{d-1}} \right)^t \qquad [\text{By Lemma 9}]\,. \quad \blacktriangleleft
\end{aligned}$$

We can complement the above theorem with an almost matching upper bound on the bias of random high rank tensors. It is known that a random high rank tensor has low bias. The following lemma gives a precise quantitative version of this observation (the idea for the proof was suggested to us by Shubhangi Saraf).

▶ **Lemma 10.** *For $i \in [t]$ and $j \in [d]$, let $u_{i,j} \in \mathbb{F}_2^k$ be a uniformly random vector. Consider the random rank-t d-linear form $p : (\mathbb{F}_2^k)^d \to \mathbb{F}_2$ given by*

$$p(x_1, x_2, \ldots, x_d) = \sum_{i=1}^{t} \prod_{j=1}^{d} \langle x_j, u_{i,j} \rangle \ .$$

Then

$$\mathbb{E}[\mathrm{bias}(p)] \leq d \cdot 2^{-k} + \left(1 - \frac{2}{2^d}\right)^t \ .$$

We refer the reader to the full version of our paper for the proof.

The following special cases of Theorem 8, for $d = 2$ and $d = 3$ will be useful for us, on our way to proving lower bounds on the rank of three dimensional tensors.

▶ **Corollary 11.** *Let $P \in \mathbb{F}_2^{k \times k}$ be a matrix of rank $\leq t \leq k$. Then,* $\mathrm{bias}(P) \geq 2^{-t}$.

▶ **Corollary 12.** *Let $P \in \mathbb{F}_2^{k \times k \times k}$ be a 3-dimensional tensor of rank $\leq t$. Then,* $\mathrm{bias}(P) \geq \left(\frac{3}{4}\right)^t$.

In the subsequent two sections, we will observe that some well-known explicit tensors in three dimensions have very low bias, and then use the above corollaries to conclude that these tensors have large rank.

3.2 A 3.52k Tensor Rank Lower Bound for $\mathrm{Trace}(XYZ)$

In this section, we use the bias-vs-tensor-rank connection explored in the previous section to construct explicit 3-dimensional tensors with large tensor rank.

It can be observed that $\mathrm{Trace}(XYZ)$ is a function with bias exactly $2/2^k - 1/2^{2k}$ (We omit the proof in interest of space).

▶ **Lemma 13.** $\mathrm{bias}(Tr(X, Y, Z)) = 2 \cdot 2^{-k} - 2^{-2k}$.

This lemma coupled with Corollary 12 immediately gives the following lower bound on tensor rank of $Tr(X, Y, Z)$.

▶ **Corollary 14.** $\mathrm{rank}(Tr(X, Y, Z)) \geq (\log_{4/3} 2) \cdot k \geq 2.409k$.

We remark that a much stronger rank lower-bound of $3.52k$ is known due to Chudnovsky and Chudnovsky [7, 18] and indeed we do a more careful analysis of our ideas to get a new proof of the $3.52k$ lower bound. We will need the following well-known rate-distance MRRW tradeoff for linear codes.

▶ **Theorem 15** ([14])**.** *Let S be a subspace of dimension at least k of $\mathbb{F}_2^t$, such that every non-zero vector in S has weight at least k. Then, $t \geq 3.52k$.*[10]

[10] The MRRW bound for binary codes states that any family of codes with fractional distance δ satisfies $R(\delta) \leq h_2\left(\frac{1}{2} - \sqrt{\delta(1-\delta)}\right)$ where $h_2(x) = x \log_2(1/x) + (1-x)\log_2(1/1-x)$ is the binary entropy function. The above mentioned bound can be obtained from this (see [5] for details).

▶ **Theorem 16.** *The rank of the tensor $Tr(X,Y,Z)$ is at least $3.52k$.*

Proof. Let the tensor rank of $Tr(X,Y,Z)$ be t. Then there exists t vectors $a_1, a_2, \ldots, a_t \in \mathbb{F}_2^k$ and t rank-1 matrices $M_1, M_2, \ldots, M_t$ such that

$$Tr(X,Y,Z) = \sum_{i=1}^{t} \langle a_i, X\rangle \cdot \langle Y, M_i Z\rangle \ . \tag{3}$$

Let A be the $k \times t$ matrix such that for every $i \in [t]$, the i^{th} column of A equals a_i. Let K be the kernel of A. Clearly, $\dim(K) \geq t-k$. In fact, $\dim(K) = t-k$. To see this, observe that if $\dim(K) \geq t-k+1$, then by the rank-nullity theorem, $\mathrm{rank}(A) \leq k-1$. Thus, there is a non-zero $x \in F_2^k$ denoted by x_0 such that for every $i \in [t]$, $\langle a_i, x_0\rangle = 0$. Thus, $Tr(x_0, Y, Z) \equiv 0$ for a non-zero x_0, which is a contradiction.

From the proof of Theorem 8 for $d = 3$, we know that

$$\mathrm{bias}(Tr(X,Y,Z)) = \Pr_{y,z\in\mathbb{F}_2^k}[Tr(X,y,z) = 0]\,.$$

So far we were proving a lower bound on $\Pr_{y,z\in\mathbb{F}_2^k}[Tr(X,y,z)=0]$ by proving a lower bound on $\Pr_{y,z\in\mathbb{F}_2^k}[\forall i \in [t], \langle y, M_i z\rangle = 0]$. Clearly, this seems to be somewhat lossy since even for a choice of y and z in $\mathbb{F}_2^k$ such that $\langle y, M_i z\rangle \neq 0$ for some $i \in [t]$, it is conceivable that $Tr(X,y,z)$ is identically zero. For this proof, we try to be a bit more careful about this. Note that for every $u \in K \subset \mathbb{F}_2^t$,

$$\sum_{i=1}^{t} u_i \cdot \langle a_i, X\rangle \equiv 0\,.$$

Thus, we have,

$$\begin{aligned}
\Pr_{y,z\in\mathbb{F}_2^k}[Tr(X,y,z)=0] &= \sum_{u\in K} \Pr_{y,z\in\mathbb{F}_2^k}[\forall i\in[t], \langle y, M_i z\rangle = u_i] \\
&= \sum_{u\in K} \mathbb{E}_{y,z}\left[\prod_{i\in[t]}\left(\frac{1+(-1)^{\langle y,M_i z\rangle + u_i}}{2}\right)\right] \\
&= \sum_{u\in K} \mathbb{E}_{y,z}\left[\mathbb{E}_{S\subseteq[t]}(-1)^{\langle y, M_S z\rangle}\cdot(-1)^{\langle u, 1_S\rangle}\right]\,.
\end{aligned}$$

Here, for every $S \subseteq [t]$, 1_S is the characteristic vector of S in t dimensions, and $M_S = \sum_{i\in S} M_i$. Simplifying further, we get,

$$\Pr_{y,z\in\mathbb{F}_2^k}[Tr(X,y,z)=0] = \mathbb{E}_{S\subseteq[t]}\left[\left(\mathbb{E}_{y,z}(-1)^{\langle y,M_S z\rangle}\right)\cdot\left(\sum_{u\in K}(-1)^{\langle u,1_S\rangle}\right)\right]\,.$$

Now, we observe that the term $\left(\sum_{u\in K}(-1)^{\langle u,1_S\rangle}\right) = |K|$ if and only if $1_S \in K^\perp$, otherwise it equals zero. Also, from Corollary 11, we know that $\left(\mathbb{E}_{y,z}(-1)^{\langle y,M_S z\rangle}\right) = 2^{-\mathrm{rank} M_S}$ is at at least $\max\{2^{-k}, 2^{-|S|}\}$. Plugging these into the inequality above, we have the following inequality (Below, $|v|$ denotes the Hamming weight of v).

$$\begin{aligned}
\Pr_{y,z\in\mathbb{F}_2^k}[Tr(X,y,z)=0] &\geq \frac{|K|}{2^t}\cdot\sum_{v\in K^\perp}\max\{2^{-k}, 2^{-|v|}\} \\
&\geq \mathbb{E}_{v\in K^\perp}\max\{2^{-k}, 2^{-|v|}\} \qquad [\text{ Since } |K|\cdot|K^\perp| = 2^t]
\end{aligned}$$

Recall that the dimension of $K^\perp$ equals k. Now,

$$\mathbb{E}_{v\in K^\perp} \max\{2^{-k}, 2^{-|v|}\} = 2^{-k} + \mathbb{E}_{v\in K^\perp\setminus\{0^k\}} \max\{2^{-k}, 2^{-|v|}\}\,.$$

From Lemma 13, we know that the bias of $Tr(X,Y,Z)$ is $2\cdot 2^{-k} - 2^{-2k}$. Thus, it must be the case that $\mathbb{E}_{v\in K^\perp\setminus\{0^k\}} \max\{2^{-k}, 2^{-|v|}\} \le (1-2^{-k})\cdot 2^{-k}$. But this is possible only if all the vectors in $K^\perp \setminus \{0^k\}$ have weight at least k. In this case, the space $K^\perp$ is a linear subspace of $\mathbb{F}_2^t$ of dimension k such that every non-zero vector in it has Hamming weight at least k. From Theorem 15, we get that $t \ge 3.52k$. This completes the proof. ◀

3.3 Lower Bound on the Rank of Matrix Multiplication Tensor

In this section, we obtain a lower bound on the rank of the matrix multiplication tensor by proving an upper bound on its bias. Even though better bounds are known for this tensor, our proof is a fairly straightforward application of our techniques, and we believe this is instructive.

Our main technical observation in this section is the following lemma which gives an upper bound on the bias of $M_n(\overline{X},\overline{Y},\overline{Z})$ as each of the variables take values in $\mathbb{F}_2$.

▶ **Lemma 17.** *The bias of $M_n(\overline{X},\overline{Y},\overline{Z})$ is at most $n\cdot 2^{-\frac{3n^2}{4}}$.*

Before proving Lemma 17, we note that Lemma 17 and Corollary 12 immediately imply a non-trivial lower bound on the tensor rank of M_n. .

▶ **Theorem 18.** *The tensor rank of M_n is at least $\frac{3n^2}{4\log_2(4/3)} \ge 1.8n^2$.*

Proof of Lemma 17. We observe that for any two fixed matrices x, y, the 3-linear form M_n reduces to a linear form in z which is non-zero iff the product of the two matrices x and y is non-zero. Furthermore, given a matrix y, the probability (over x) that the product matrix $x\cdot y$ is zero is exactly $2^{-n\cdot\mathrm{rank}(y)}$. Combining these observations, we have

$$\begin{aligned}\mathrm{bias}(M_n) &= \Pr_{x,y}[x\cdot y = 0_{n\times n}]\\ &= \mathbb{E}_y\left[2^{-n\cdot\mathrm{rank}(y)}\right]\\ &= \sum_{r=0}^{n}\Pr_y[\mathrm{rank}(y)=r]\cdot 2^{-nr}\,.\end{aligned}$$

To complete the proof, we rely on the following claim, whose proof we defer to the end of this section.

▷ Claim 19. For every $r\in\{0,1,\ldots,n\}$, the following inequality is true.

$$\Pr_y[\mathrm{rank}(y)=r] \le 2^{-(n-r)^2}\,.$$

From the claim above, we get

$$\begin{aligned}\mathrm{bias}(M_n) &\le \sum_{r=0}^{n} 2^{-(n-r)^2-nr} \\ &\le \sum_{r=0}^{n} 2^{-n^2-r^2+nr} \\ &\le 2^{-n^2}\sum_{r=0}^{n} 2^{r(n-r)} \\ &\le 2^{-n^2} n \cdot 2^{n^2/4} \\ &\le n \cdot 2^{-3n^2/4} .\end{aligned}$$

◀

For completeness, we now provide a proof of Claim 19. We remark that the following tighter bound is known (see [12, Theorem 3.2.1]).

$$\begin{aligned}\Pr_y[\mathrm{rank}(y) = r] &= 2^{-(n-r)^2} \cdot \prod_{i=n-r+1}^{n}\left(1-\frac{1}{2^i}\right) \cdot \left(\sum_{0\le i_1\le \ldots i_{n-r}\le r} \frac{1}{2^{i_1+\ldots+i_{n-r}}}\right) \\ &\le 2^{-(n-r)^2} \cdot \prod_{i=n-r+1}^{n}\left(1-\frac{1}{2^i}\right) \cdot \prod_{i=1}^{n-r}\left(1-\frac{1}{2^i}\right)^{-1} .\end{aligned}$$

However, the weaker bound given in the claim suffices for our purposes.

Proof of Claim 19. The goal is to upper bound the probability that a uniformly random $n \times n$ matrix y over $\mathbb{F}_2$ has rank equal to r. This probability is upper bounded by the probability that the rows of y are contained within a subspace of dimension r of $\mathbb{F}_2^n$. For any fixed subspace S of dimension equal to r, this event happens with a probability equal to $2^{-n(n-r)}$. The number of subspaces of $\mathbb{F}_2^n$ of dimension equal to r is given by the Gaussian binomial coefficient $\begin{bmatrix} n \\ r \end{bmatrix}_2 = \prod_{i=0}^{r-1} \frac{(2^n-2^i)}{(2^r-2^i)} \le \frac{2^{nr}}{2^{r^2}}$. Thus, by a union bound, we get the following.

$$\Pr_y[\mathrm{rank}(y) = r] \le \frac{2^{nr}}{2^{r^2}} \cdot 2^{-n(n-r)} = 2^{-(n-r)^2} .$$

◁

4 Correlation of random d-linear forms

In this section, we study the correlation of random d-linear forms with lower degree polynomials.

Our main result in this section is the following theorem, which states that a random d-linear form is uncorrelated with degree-ℓ polynomials under certain conditions.

▶ **Theorem 20.** *Let ℓ, d, n be integers such that d divides n, $d = o\left(\frac{n}{\log n}\right)$ and $\ell < d/2$. Set $k = n/d$. Pick a uniformly random d-linear form $f : (\mathbb{F}_2^k)^d \to \mathbb{F}_2$. Then, with probability $1 - o(1)$, f has the following property. For all polynomials $P(X_1, \ldots, X_n) \in \mathbb{F}_2[X_1, \ldots, X_n]$ with degree at most ℓ, we have,*

$$\mathrm{corr}(f, P) < 2^{-(1-o(1))n/d} .$$

Along the way, we develop several tools to understand the bias of random d-linear forms. For example, we show that a random d-linear form is unbiased with extremely high probability.

▶ **Theorem 21.** *Let $\varepsilon > 0$ be fixed. Let d, k be integers with $d < 2^{\varepsilon k/5}$, and consider a uniformly random d-linear form $f : (\mathbb{F}_2^k)^d \to \mathbb{F}_2$. Then,*

$$\Pr\left[\text{bias}(f) \geq 2^{-(1-\varepsilon)k}\right] \leq 2^{-\Omega(\varepsilon^2 k^d)} .$$

▶ Remark 22. Note that any d-linear form $f(X_1, \ldots, X_d)$ vanishes if any one of the block of variables $X_1, \ldots, X_d$ is zero. Hence, the bias of any d-linear form (or equivalently its correlation with the constant 0 polynomial) is at least $2^{-k} = 2^{-n/d}$. Theorem 21 states that it is extremely unlikely for a random d-linear form to have even slightly more bias while Theorem 20 states that it is extremely unlikely for a random d-linear form to have slightly better correlation with any degree ℓ polynomial.

The key ingredient in the proofs of the above theorems is the following theorem on the distribution of the sum of random rank-1 tensors.

▶ **Theorem 23.** *Let $\varepsilon > 0$ be a constant. Let d, k, t be integers with $d < 2^{\varepsilon k/5}$, and $t < \frac{\varepsilon}{5} k^{d-1}$. Let $\{x^{(i,j)}\}_{i\in[t], j\in[d]}$ be picked independently and uniformly distributed in $\mathbb{F}_2^k$. Then,*

$$\Pr\left[\sum_{i=1}^{t} \bigotimes_{j=1}^{d} x^{(i,j)} = 0\right] \leq 2^{-(1-\varepsilon/2)\cdot kt} .$$

▶ Remark 24. If any block of vectors (say wlog. $\{x^{(i,1)}\}_{i\in[t]}$, the first block of vectors) are all 0 (this happens with probability 2^{-kt}), then the d-dimensional linear form $\sum_{i=1}^{t} \bigotimes_{j=1}^{d} x^{(i,j)} = 0$. The above theorem states that the probability of the d-linear form vanishing is not significantly larger.

In turn, the proof of the above theorem is based on the following lemma, which gives an upper bound on the probability that a random rank-1 tensor lies in a fixed low dimensional subspace.

▶ **Lemma 25.** *Let k, d be integers and U be a subspace of $(\mathbb{F}_2^k)^{\otimes d}$ of dimension u. Let $x_1, \ldots, x_d \in \mathbb{F}_2^k$ be picked independently and uniformly at random, and let $T = \otimes_{i=1}^{d} x_i$. Then,*

$$\Pr[T \in U] \leq \frac{d}{2^k} + \frac{2^{u/k^{d-1}}}{2^k} .$$

▶ Remark 26. Let $U = V \otimes (\mathbb{F}_2^k)^{\otimes(d-1)}$ where V is a u/k^{d-1}-dimensional subspace of $\mathbb{F}_2^k$. Note, $\dim(U) = u$. Clearly, $\Pr[\otimes_{i=1}^{d} x_i \in U] = \Pr[x_1 \in V] = 2^{u/k^{d-1}}/2^k$. The above lemma states that the probability is not significantly larger than this for any other U.

In the next subsection, we show how Theorem 20 and Theorem 21 follow from Theorem 23. We defer the proof of Lemma 25 and Theorem 23 to Appendix A.

4.1 Proofs of Theorem 20 and Theorem 21

We first prove Theorem 21.

Proof of Theorem 21. We want to bound $\Pr_f[\text{bias}(f) \geq 2^{-(1-\varepsilon)k}]$. We shall do so by bounding the t^{th} moment of $\text{bias}(f)$ for a suitable choice of t and applying Markov's inequality.

Let $T : [k]^d \to \mathbb{F}_2$ denote the tensor associated with f. Thus $T(i_1, \ldots, i_d)$ are all independent and uniformly distributed in $\mathbb{F}_2$.

We now compute the t^{th} moment of f.

$$\begin{aligned}
&\mathbb{E}_f[(\mathrm{bias}(f))^t] \\
&= \mathbb{E}_f\left[\left(\mathbb{E}_{x^{(1)},\ldots,x^{(d)}\sim\mathbb{F}_2^k}\left[(-1)^{f\left(x^{(1)},\ldots,x^{(d)}\right)}\right]\right)^t\right] \\
&= \mathbb{E}_f\left[\prod_{i\in[t]}\left(\mathbb{E}_{x^{(i,1)},\ldots,x^{(i,d)}\sim\mathbb{F}_2^k}\left[(-1)^{f\left(x^{(i,1)},\ldots,x^{(i,d)}\right)}\right]\right)\right] \\
&= \mathbb{E}_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\mathbb{E}_f\left[(-1)^{\sum_{i=1}^t f\left(x^{(i,1)},\ldots,x^{(i,d)}\right)}\right]\right] \\
&= \mathbb{E}_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\prod_{(\ell_1,\ldots,\ell_d)\in[k]^d}\left(\mathbb{E}_{T(\ell_1,\ldots,\ell_d)\sim\mathbb{F}_2}\left[(-1)^{T(\ell_1,\ldots,\ell_d)\cdot\left(\sum_{i=1}^t\prod_{j=1}^d x_{\ell_j}^{(i,j)}\right)}\right]\right)\right] \\
&= \mathbb{E}_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\prod_{(\ell_1,\ldots,\ell_d)\in[k]^d}\mathbb{1}_{\sum_{i=1}^t\prod_{j=1}^d x_{\ell_j}^{(i,j)}=0}\right] \\
&= \mathbb{E}_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\mathbb{1}_{\forall(\ell_1,\ldots,\ell_d)\in[k]^d,\ \sum_{i=1}^t\prod_{j=1}^d x_{\ell_j}^{(i,j)}=0}\right] \\
&= \Pr_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\forall(\ell_1,\ldots,\ell_d)\in[k]^d,\ \sum_{i=1}^t\prod_{j=1}^d x_{\ell_j}^{(i,j)}=0\right] \\
&= \Pr_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\sum_{i=1}^t\bigotimes_{j=1}^d x^{(i,j)}=0\right].
\end{aligned}$$

Setting $t=\frac{\varepsilon}{10}k^{d-1}$, Theorem 23 tells us that

$$\mathbb{E}_f[(\mathrm{bias}(f))^t]=2^{-(1-\varepsilon/2)kt}.$$

Using Markov's inequality,

$$\Pr_f\left[\mathrm{bias}(f)\geq 2^{-(1-\varepsilon)k}\right]\leq\frac{2^{-(1-\varepsilon/2))kt}}{2^{-(1-\varepsilon)kt}}\leq 2^{-\varepsilon kt/2}\leq 2^{-\Omega(\varepsilon^2k^d)}$$

as claimed. ◀

We now use a similar argument to prove Theorem 20.

Proof of Theorem 20. Fix an arbitrary $\varepsilon>0$. Let $\mathcal{C}$ denote the space of degree $\leq\ell$ polynomials in $\mathbb{F}_2[X_1,\ldots,X_n]$. We want to show that with high probability over the choice of f, we have that for every $P\in\mathcal{C}$, $\mathrm{corr}(f,P)\leq 2^{-(1-\varepsilon)k}$.

Fix $P\in\mathcal{C}$ and consider the t^{th} moment of $\mathrm{bias}(f-P)$. Imitating the proof of Theorem 21, we get

$$\begin{aligned}
&\mathbb{E}_f[(\mathrm{bias}(f-P))^t] \\
&= \mathbb{E}_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[(-1)^{\sum_{i=1}^t P\left(x^{(i,1)},\ldots,x^{(i,d)}\right)}\cdot\mathbb{1}_{\forall(\ell_1,\ldots,\ell_d)\in[k]^d,\ \sum_{i=1}^t\prod_{j=1}^d x_{\ell_j}^{(i,j)}=0}\right] \\
&\leq \mathbb{E}_{\{x^{(i,j)}\}_{i\in[t],j\in[d]}}\left[\mathbb{1}_{\forall(\ell_1,\ldots,\ell_d)\in[k]^d,\ \sum_{i=1}^t\prod_{j=1}^d x_{\ell_j}^{(i,j)}=0}\right] \\
&= \Pr\left[\sum_{i=1}^t\bigotimes_{j=1}^d x^{(i,j)}=0\right].
\end{aligned}$$

Now we will apply Theorem 23. Observe that since $d = o(n/\log n)$, we have,

$$d < 2^{\varepsilon k/5}\,.$$

As in the proof of Theorem 21, we set $t = \frac{\varepsilon}{10}k^{d-1}$, invoke Theorem 23 and apply Markov's inequality to get,

$$\Pr_f\left[\text{bias}(f-P) \geq 2^{-(1-\varepsilon)k}\right] \leq 2^{-\varepsilon^2 k^d/20}\,.$$

Now $\text{bias}(f-P) = \text{corr}(f,P)$. Thus, by a union bound over all $P \in \mathcal{C}$, we have the following.

$$\Pr_f\left[\text{corr}(f,\mathcal{C}) \geq 2^{-(1-\varepsilon)k}\right] \leq |\mathcal{C}| \cdot 2^{-\varepsilon^2 k^d/20}. \tag{4}$$

It remains to estimate $|\mathcal{C}|$. We show below that $|\mathcal{C}| = 2^{o(k^d)}$. The proof of this lemma works for any other C as long as C satisfies $|\mathcal{C}| = 2^{o(k^d)}$. Note that $|\mathcal{C}| = 2^{\binom{n}{\leq \ell}}$. Let δ denote d/n.

$$\begin{aligned}\binom{n}{\leq \ell} \leq \binom{n}{\leq d/2} &\leq \left(\frac{2en}{d}\right)^{d/2} \leq \left(\frac{2e}{\delta}\right)^{\delta n/2} \\ &= o\left(\left(\frac{1}{\delta}\right)^{\delta n}\right) \qquad [\text{Since } \delta = o(1)] \\ &= o(k^d)\,.\end{aligned}$$

Combining this with Equation (4), we get,

$$\Pr_f\left[\text{corr}(f,\mathcal{C}) \geq 2^{-(1-\varepsilon)k}\right] \leq 2^{o(k^d)} \cdot 2^{-\varepsilon^2 k^d/20}\,.$$

Since this holds for every $\varepsilon > 0$, we get the desired result. ◀

A Random rank-1 tensors

In this subsection, we first prove Lemma 25 on the probability that a random rank-1 tensor lies in a fixed low-dimensional subspace. We then give a corollary of this lemma which bounds the probability that a collection of random rank-1 tensors spans a very low dimensional subspace. This corollary will be used in the proof of Theorem 23.

Proof of Lemma 25. Define

$$f_{d,k}(u) = \left(1 - \left(1 - \frac{1}{2^k}\right)^{d-1}\right) + \left(1 - \frac{1}{2^k}\right)^{d-1} \cdot \frac{2^{u/k^{d-1}}}{2^k}\,.$$

We will prove, by induction on d, the following stronger bound.

$$\Pr[T \in U] \leq f_{d,k}(u)\,.$$

The fact that this implies the lemma, follows from the observations that $1 - \frac{d-1}{2^k} \leq \left(1 - \frac{1}{2^k}\right)^{d-1}$ and that $\left(1 - \frac{1}{2^k}\right)^{d-1} \leq 1$.

Base case. The $d = 1$ case is trivial (using the observation that $f_{1,k}(u) = \frac{2^u}{2^k}$). We now show the statement holds for larger d.

Induction step. Let $k' = k^{d-1}$. We will view $(\mathbb{F}_2^k)^{\otimes d}$ as $\mathbb{F}_2^k \otimes \mathbb{F}_2^{k'}$. Every element v of $(\mathbb{F}_2^k)^{\otimes d}$ can thus be written as a tuple $(v_1, \ldots, v_k)$, where each v_i is an element of $\mathbb{F}_2^{k'}$ (thus the k^d coordinates are partitioned into k blocks of coordinates, with each block having k' coordinates). We let $\pi_i : (\mathbb{F}_2^k)^{\otimes d} \to \mathbb{F}_2^{k'}$ be the ith projection map, mapping v to v_i.

With this convention, we take a basis for U in *row echelon form*. Concretely, this gives us a basis $\mathcal{B}$ for U, such that $\mathcal{B}$ is a disjoint union of $\mathcal{B}_1, \ldots, \mathcal{B}_k$ ($\mathcal{B}_j$ is the set of basis vectors pivoted in the j'th block of coordinates), such that,

- for all $v \in \mathcal{B}_j$ and $i < j$, $\pi_i(v) = 0$,
- the vectors $\pi_j(v) \in \mathbb{F}_2^{k'}$, as v varies in $\mathcal{B}_j$, are linearly independent.

Define $U_j = \mathrm{span}\{\pi_j(v) \mid v \in \mathcal{B}_j)\}$. Thus we have $\dim(U_j) = |\mathcal{B}_j|$ and

$$\sum_{j=1}^{k} \dim(U_j) = \dim(U)\,.$$

For $i > j$, we define a linear map $\psi_{ij} : U_j \to \mathbb{F}_2^{k'}$ by defining ψ_{ij} on a basis for U_j:

$$\psi_{ij}(\pi_j(v)) = \pi_i(v),\ \forall v \in B_j\,.$$

Then we have the following basic claim (which follows immediately from the above echelon form representation of U).

▷ Claim 27. Let $v \in (\mathbb{F}_2^k)^{\otimes d}$. Then $v \in U$ only if there exists $(u_1, \ldots, u_k) \in \prod_{i=1}^{k} U_i$ such that for each $i \in [k]$ we have

$$\pi_i(v) = u_i + \sum_{j<i} \psi_{ij}(u_j)\,.$$

To simplify notation, we will denote x_1 by y and $\otimes_{i=2}^{d} x_i$ by z. We want to find an upper bound on $\Pr[y \otimes z \in U]$.

▷ Claim 28. Let $\tilde{z} \in (\mathbb{F}_2^k)^{\otimes(d-1)}$ and $S = \{i \mid \tilde{z} \in U_i\}$, then, $\Pr_{y \in \mathbb{F}_2^k}[y \otimes \tilde{z} \in U] \leq \frac{2^{|S|}}{2^k}$.

Proof. For fixed $\tilde{z}$, given the random variable $v = y \otimes \tilde{z}$, we define random variables $u_1, u_2, ..., u_k$ by: $u_i := \pi_i(v) - \sum_{j<i} \psi_{ij}(u_j)$. Note that $\pi_i(v) = \pi_i(y \otimes \tilde{z}) = y_i \tilde{z}$. Also note that u_i is only a function of $y_1, \ldots, y_i$. By Claim 27, $v \in U$ only if for all i, $u_i \in U_i$.

$$
\begin{aligned}
&\Pr_{y \in \mathbb{F}_2^k}[y \otimes \tilde{z} \in U] \\
&\leq \Pr_{y}[\forall i \leq k,\ u_i \in U_i] \\
&= \prod_{i=1}^{k} \Pr[u_i \in U_i \mid u_1 \in U_1, \ldots, u_{i-1} \in U_{i-1}] \\
&= \prod_{i=1}^{k} \mathbb{E}_{u_1 \in U_1, \ldots, u_{i-1} \in U_{i-1}} \left[\Pr_{u_i}[u_i \in U_i \mid u_1, \ldots, u_{i-1}] \right] \\
&= \prod_{i=1}^{k} \mathbb{E}_{u_1 \in U_1, \ldots, u_{i-1} \in U_{i-1}} \left[Pr_{u_i} \left[\pi_i(v) - \sum_{j<i} \psi_{ij}(u_j) \in U_i \,\middle|\, u_1, \ldots, u_{i-1} \right] \right] \\
&= \prod_{i=1}^{k} \mathbb{E}_{u_1 \in U_1, \ldots, u_{i-1} \in U_{i-1}} \left[Pr_{y_i} \left[y_i \tilde{z} - \sum_{j<i} \psi_{ij}(u_j) \in U_i \,\middle|\, u_1, \ldots, u_{i-1} \right] \right] \\
&\leq \prod_{i \notin S} \left(\frac{1}{2} \right) = \left(\frac{1}{2} \right)^{k-|S|},
\end{aligned}
$$

where the last inequality follows since for every $i \notin S$ and every vector w, at most one of w and $w + \tilde{z}$ can lie in U_i (as $\tilde{z} \notin U_i$). ◁

For $S \subseteq [k]$, let $U_S = \bigcap_{i \in S} U_i$. Then,

$$
\begin{aligned}
\Pr_{y,z}[y \otimes z \in U] &\leq \mathbb{E}_z \left[\frac{2^{\sum_{i=1}^{k} 1_{U_i}(z)}}{2^k} \right] \qquad \text{[Follows from the above claim]} \\
&= \frac{1}{2^k} \mathbb{E}_z \left[\prod_{i=1}^{k} 2^{1_{U_i}(z)} \right] \\
&= \frac{1}{2^k} \mathbb{E}_z \left[\prod_{i=1}^{k} (1 + 1_{U_i}(z)) \right] \\
&= \frac{1}{2^k} \mathbb{E}_z \left[\sum_{S \subseteq [k]} 1_{U_S}(z) \right] \\
&= \frac{1}{2^k} \sum_{S \subseteq [k]} \Pr_z[z \in U_S] \,.
\end{aligned}
$$

Now, observe that for each $i \in S$, we have $\Pr[z \in U_S] \leq \Pr[z \in U_i]$. Thus if we sort the U_i so that $\dim(U_1) \geq \dim(U_2) \geq \ldots \geq \dim(U_k)$, then we have the following sequence of inequalities.

$$\begin{aligned}\Pr_{y,z}[y \otimes z \in U] &\leq \frac{1}{2^k}\left(1 + \sum_{i\in[k]} \sum_{S\subseteq[i], i\in S} \Pr_z[z \in U_S]\right) \\ &\leq \frac{1}{2^k}\left(1 + \sum_{i\in[k]} 2^{i-1} \Pr_z[z \in U_i]\right) \\ &\leq \frac{1}{2^k}\left(1 + \sum_{i\in[k]} 2^{i-1} f_{d-1,k}(\dim(U_i))\right),\end{aligned}$$

where the last step follows from the induction hypothesis. To find an upper bound for this last expression, we let $a_i = \dim(U_i)$. We have the constraints

$$\sum_i a_i = u\,,$$

$$k' \geq a_1 \geq a_2 \geq \ldots \geq a_k \geq 0\,,$$

where $k' = k^{d-1}$, and we want to maximize an expression of the form

$$\sum_{i=1}^{k} 2^{i-1}(\alpha + \beta 2^{a_i/k^{d-2}}) = \alpha \cdot (2^k - 1) + \beta \cdot \left(\sum_{i=1}^{k} 2^{i-1+a_i/k^{d-2}}\right).$$

where $\alpha, \beta > 0$.

It is worth noting what happens in the two examples $U = V \otimes \mathbb{F}_2^{k'}$ and $U = \mathbb{F}_2^k \otimes W$, where $V \subseteq \mathbb{F}_2^k$ and $W \subseteq \mathbb{F}_2^{k'}$ are subspaces of the appropriate dimension. In the first case, $a_1 = a_2 = \ldots = a_{u/k'} = k'$ and the remaining a_i are 0. In the second case, all the $a_i = u/k$. Both are global maxima of the expression we want to maximize! The existence of these very different maxima makes this maximization problem somewhat tricky.

In Theorem 29 we prove a tight upper bound for this function. For every $i \in [k]$, let $b_i = a_i/k^{d-2}$, and let $\tilde{u} = u/k^{d-2}$. Then, $b_1, b_2, \ldots, b_k$ and $\tilde{u}$ satisfy the constraints in the hypothesis of Theorem 29, and Theorem 29 tells us that a global maxima is achieved when all the a_i are equal to $\dim(U)/k$. Thus,

$$\begin{aligned}\Pr_{y,z}[y \otimes z \in U] &\leq \frac{1}{2^k}\left(1 + \sum_{i\in[k]} 2^{i-1} f_{d-1,k}(u/k)\right) \\ &= \frac{1}{2^k}\left(1 + (2^k - 1) f_{d-1,k}(u/k)\right) \\ &= \left(\frac{1}{2^k} + (1 - \frac{1}{2^k}) f_{d-1,k}(u/k)\right) \\ &= f_{d,k}(u)\,.\end{aligned}$$

This completes the induction step. ◀

▶ **Theorem 29.** *Let k be a positive integer, and let $\tilde{u} \in [0, k^2]$ be a real number. Suppose $b_1, b_2, \ldots, b_k$ are real numbers satisfying the following constraints.*

$$k \geq b_1 \geq b_2 \ldots \geq b_k \geq 0\,, \tag{5}$$

$$\sum_{i=1}^{k} b_i = \tilde{u}\,. \tag{6}$$

Then,

$$\sum_{i=1}^{k} 2^{i-1} 2^{b_i} \leq \sum_{i=1}^{k} 2^{i-1} 2^{\tilde{u}/k} = (2^k - 1) 2^{\tilde{u}/k} .$$

We refer the reader to the full version of our paper for a proof of Theorem 29.

We now use the previous lemma to prove a corollary about the dimension of the span of several random rank 1 tensors.

▶ **Corollary 30.** *Let d, k, t be integers. For each $i \in [t]$ and $j \in [d]$, pick $x^{(i,j)} \in \mathbb{F}_2^k$ uniformly at random. For $i \in [t]$, let T_i be the rank-1 tensor $\otimes_{j=1}^{d} x^{(i,j)}$. Then, for every $0 \leq r \leq t$,*

$$\Pr[\dim(\mathrm{span}(\{T_1, \ldots, T_t\})) = r] \leq \binom{t}{r} \left(\frac{d + 2^{t/k^{d-1}}}{2^k} \right)^{t-r} .$$

Proof. Let us reveal $T_1, \ldots, T_t$ one at a time. For $0 \leq i \leq t$, let $V_i = \mathrm{span}(\{T_1, \ldots, T_{i-1}, T_i\})$. Thus we have $0 = \dim(V_0) \leq \dim(V_1) \leq \ldots \dim(V_t)$. We want to estimate the probability that $\dim(V_t) = r$. Let E_i denote the event that $T_i \in V_{i-1}$. For $I \subseteq [t]$, let E_I denote the event $\bigcap_{i \in I} E_i$. In terms of these events, we can bound $\Pr[\dim(V_t) = r]$ as follows.

$$\begin{aligned} \Pr[\dim(V_t) = r] &\leq \Pr[\exists I \subseteq [t], |I| = t - r \text{ such that } E_I \text{ occurs}] \\ &\leq \sum_{I \subseteq [t], |I| = t-r} \Pr[E_I] . \end{aligned}$$

We conclude the proof by bounding $\Pr[E_I]$. Fix $I \subseteq [t]$ with $|I| = t - r$. Let $I = \{i_1, \ldots, i_{t-r}\}$ with $i_1 < i_2 < \ldots < i_{t-r}$.

$$\Pr[E_I] = \prod_{j=1}^{t-r} \Pr[E_{i_j} | \bigcap_{\ell < j} E_{i_\ell}] .$$

Lemma 25 implies the following.

$$\Pr[E_i | T_1, \ldots, T_{i-1}] \leq \frac{d + 2^{\dim(V_{i-1})/k^{d-1}}}{2^k} .$$

For any given $j \in [t - r]$, the events $E_{i_1}, \ldots, E_{i_{j-1}}$ are all determined by $T_1, \ldots, T_{i_j - 1}$ (since E_{i_ℓ} depends on $T_1, \ldots, T_{i_\ell}$, and $i_{j-1} \leq i_j - 1$). Thus, for each $j \in [t - r]$, we have,

$$\Pr[E_{i_j} | \bigcap_{\ell < j} E_{i_\ell}] \leq \frac{d + 2^{t/k^{d-1}}}{2^k} .$$

Here we used the fact that $\dim(V_{i_j - 1}) \leq t$. Using this in our previous bound, we conclude that

$$\Pr[E_I] \leq \left(\frac{d + 2^{t/k^{d-1}}}{2^k} \right)^{t-r} ,$$

and thus,

$$\Pr[\dim(V_t) = r] \leq \binom{t}{r} \cdot \left(\frac{d + 2^{t/k^{d-1}}}{2^k} \right)^{t-r} . \qquad \blacktriangleleft$$

A.1 Proof of Theorem 23

We now use Corollary 30 to prove Theorem 23.

Proof of Theorem 23. The equation

$$\sum_{i=1}^{t} \bigotimes_{j=1}^{d} x^{(i,j)} = 0 \tag{7}$$

implies that

$$\forall \ell \in [k],\ \sum_{i=1}^{t} x_{\ell}^{(i,1)} \cdot \bigotimes_{j=2}^{d} x^{(i,j)} = 0\,. \tag{8}$$

Let T_i denote $\bigotimes_{j=2}^{d} x^{(i,j)}$ for $i \in [t]$ and $\mathcal{T} = \mathrm{span}(\{T_1, \ldots, T_t\})$. Then we have,

$$\begin{aligned}
&\Pr[\{x^{(i,j)}\}_{i\in[t],j\in[d]} \text{ satisfy (7)}] \qquad (9)\\
&\leq \Pr[\{x^{(i,j)}\}_{i\in[t],j\in[d]} \text{ satisfy (8)}]\\
&= \sum_{r=0}^{t} \Pr\left[\{x^{(i,j)}\}_{i\in[t],j\in[d]} \text{ satisfy (8)} \middle| \dim(\mathcal{T}) = r\right] \Pr\left[\dim(\mathcal{T}) = r\right]\\
&= \sum_{r=0}^{t} \left(\prod_{\ell\in[k]} \Pr\left[\sum_{i=1}^{t} x_{\ell}^{(i,1)} \cdot T_i = 0 \middle| \dim(\mathcal{T}) = r \right] \right) \cdot \Pr\left[\dim(\mathcal{T}) = r\right]\\
&\leq \sum_{r=0}^{t} \left(\frac{1}{2^r}\right)^k \cdot \Pr\left[\dim(\mathcal{T}) = r\right]. \qquad (10)
\end{aligned}$$

Here, the equality in the third step follows from the fact that $\{x_{\ell}^{(i,1)}\}_{i\in[t],\ell\in[k]}$ are independently and uniformly distributed in $\mathbb{F}_2$.
By the given distribution of $T_1, \ldots, T_t$ in $(\mathbb{F}_2^k)^{\otimes(d-1)}$, Corollary 30 says that

$$\Pr\left[\dim(\mathcal{T}) = r\right] \leq \binom{t}{r} \left(\frac{d - 1 + 2^{\frac{t}{k^{d-2}}}}{2^k}\right)^{t-r}.$$

Plugging this bound back into (9) gives

$$\begin{aligned}
\Pr[\{x^{(i,j)}\}_{i\in[t],j\in[d]} \text{ satisfy (7)}] &\leq \sum_{r=0}^{t} \binom{t}{r} \frac{1}{2^{rk}} \left(\frac{d - 1 + 2^{\frac{t}{k^{d-2}}}}{2^k}\right)^{t-r}\\
&\leq \sum_{r=0}^{t} \binom{t}{r} \left(\frac{1}{2^k}\right)^r \left(\frac{d - 1 + 2^{\frac{t}{k^{d-2}}}}{2^k}\right)^{t-r}\\
&= \left(\frac{1}{2^k} + \frac{d - 1 + 2^{\frac{t}{k^{d-2}}}}{2^k}\right)^t\\
&\leq \left(\frac{d + 2^{\frac{t}{k^{d-2}}}}{2^k}\right)^t.
\end{aligned}$$

Now, since $d < 2^{\varepsilon k/5}$ and $t < \varepsilon k^{d-1}/5$, we have
