$$d + 2^{\frac{t}{k^{d-2}}} < 2 \cdot 2^{\varepsilon k/5} < 2^{\varepsilon k/2},$$

we conclude that

$$\Pr\left[\sum_{i=1}^{t} \bigotimes_{j=1}^{d} x^{(i,j)} = 0\right] < 2^{-(1-\varepsilon/2)kt}.$$

This completes the proof. ◀

On the List Recoverability of Randomly Punctured Codes

Abstract

We show that a random puncturing of a code with good distance is list recoverable beyond the Johnson bound. In particular, this implies that there are Reed-Solomon codes that are list recoverable beyond the Johnson bound. It was previously known that there are Reed-Solomon codes that do not have this property. As an immediate corollary to our main theorem, we obtain better degree bounds on unbalanced expanders that come from Reed-Solomon codes.

1 Introduction

List recoverable codes were defined by Guruswami and Indyk [7] in their study of list decodable codes. Here, we study list recoverable codes in their own right, showing that random puncturings of codes over a sufficiently large alphabet are list recoverable. Our result is analogous to earlier work by Rudra and Wooters [10, 11] on the list decodability of randomly punctured codes.

We use q to denote the alphabet size, and n to denote the block length of an arbitrary code $\mathcal{C} \subset [q]^n$. Given two codewords $c_1, c_2 \in [q]^n$, denote the Hamming distance between c_1 and c_2 by $\Delta(c_1, c_2)$. Denote the minimum distance between a codeword $c \in [q]^n$ and a set $\mathcal{L} \subseteq [q]^n$ by $\Delta(c, \mathcal{L})$.

▶ **Definition 1** (List recoverability). *Let q, n, ℓ, L be positive integers, and let $0 \leq \rho < 1$ be a real number. A code $\mathcal{C} \subset [q]^n$ is (ρ, ℓ, L) list recoverable if, for every collection of sets $\{A_i \subseteq [q]\}_{i \in [n]}$ with $|A_i| \leq \ell$ for each i, we have*

$$|\{c \in \mathcal{C} \mid \Delta(c, A_1 \times \cdots \times A_n) \leq \rho n\}| \leq L.$$

In the above definition, ℓ is called the *input list size*, and L is called the *output list size* from which the code can be recovered. The case $\rho = 0$ is already interesting, and is called *zero-error* list recoverability. We say that a code $\mathcal{C}$ is (ℓ, L) zero-error list recoverable if it is $(0, \ell, L)$ list recoverable.

A *puncturing* of a code $\mathcal{C} \subset [q]^n$ to a set $S \subset [n]$ is the code $\mathcal{C}_S \subset [q]^S$ defined by $\mathcal{C}_S[i] = \mathcal{C}[i]$ for each $i \in S$. A punctured code will typically have higher rate, but lower distance, than the unpunctured version. Our main result is that every code over a large enough alphabet $[q]$ can be punctured to a code of rate $R > q^{-1/2}$ while being list recoverable with input and output list sizes roughly R^{-2}.

▶ **Theorem 2.** *For any real α with $0 < \alpha \leq 1$, every code with distance at least $n(1-q^{-1}-\epsilon^2)$ can be punctured to rate $\Omega\left(\frac{\epsilon}{\log q}\right)$ so that it is $(\rho, \ell, \ell(1+\alpha))$-list recoverable, provided that the following inequalities are satisfied:*

- *n and q are sufficiently large,*
- *$0 \leq \rho < 1 - (1+\alpha)^{-1/2}$,*
- *$q^{-1/2} < \epsilon < \min(c, 2^{-1}\gamma\sigma)$,*
- *$\ell \leq \epsilon^{-2}\sigma^2\gamma$,*

where $c > 0$ is a constant, $\gamma = (1+\alpha)(1-\rho)^2 - 1$, and $\sigma = (1-\rho)(2-\rho)^{-1}$.

In fact, we show a random puncturing is list recoverable with the same list size with high probability; see Theorem 10 for a precise statement.

It is helpful to consider the case $\rho = 0$ and $\alpha = 1$. Then we obtain a $(\ell, 2\ell)$ zero-error list-recoverable code. If we start with a code having distance nearly as large as possible (*i.e.* take $\epsilon = \Theta(q^{-1/2})$), then we obtain input and output list sizes of $\Omega(q)$ and rate $\Omega(q^{-1/2}\log^{-1} q)$. In this way, we obtain a punctured code of rate $\Omega(\ell^{-1/2}\log^{-1}\ell)$. The main point is that this is better than the codes guaranteed by the Johnson bound (discussed in more detail below), which gives a code of rate $\Omega(\ell^{-1})$. A completely random code, however, can be $(\ell, 2\ell)$ zero-error list-recoverable with rate $\Omega(1)$.

One nice feature Theorem 2 is that it can yield an input list size as large as $\Omega(q)$. A second nice feature is that the theorem yields a tight relationship between the input and output list sizes; many results on list recovery give an output list that is much larger than the input list. Finally we mention that the proof of Theorem 2 is relatively simple and elementary; we draw a slightly more explicit comparison to the earlier work of Rudra and Wooters [10, 11] below.

2 Background

In this section, we give a brief discussion about the current state of the literature. Theorem 2 is analogous to a theorem of Rudra and Wooters [10, 11] on the *list decodability* of punctured codes over large alphabets. A code $\mathcal{C} \subset [q]^n$ is (ρ, ℓ)-list decodable if for each $x \in [q]^n$, there are at most ℓ codewords of $\mathcal{C}$ that differ from x in fewer than ρn coordinates.

▶ **Theorem 3** ([11])**.** *Let $\epsilon > q^{-1/2}$ be a real number, and q, n be sufficiently large integers. Every code $\mathcal{C} \subset [q]^n$ with distance $n(1-q^{-1}-\epsilon^2)$ can be punctured to rate $\tilde{\Omega}\left(\frac{\epsilon}{\log q}\right)$ so that it is $(1-O(\epsilon), O(\epsilon^{-1}))$-list decodable.*

Theorems 2 and 3 are most interesting in the case of Reed-Solomon codes. The codewords of the degree-d Reed-Solomon code over $\mathbb{F}_q$ with evaluation set $S \in \binom{[q]}{n}$ are the evaluations of all univariate polynomials of degree at most d on elements of S. In other words, suppose $S = \{s_1, \ldots, s_n\}$. The degree-d Reed-Solomon code on S is the set

$$\{(p(s_1), \ldots, p(s_n)) \mid \deg(p) \leq d\}.$$

The block length of this code is $n \leq q$. Since two distinct polynomials of degree at most d can agree on at most d locations, the distance of any degree-d Reed-Solomon code is at least $n - d$.

A fundamental result, which gives a lower bound on the list decodability of a code with given distance, is the *Johnson bound* (see, for example Corollary 3.2 in [6]).

▶ **Theorem 4** (Johnson bound for list decoding). *Every code $\mathcal{C} \subset [q]^n$ of minimum distance at least $n(1 - q^{-1} - \epsilon^2)$ is $((1 - q^{-1} - \epsilon), O(\epsilon^{-1}))$- list decodable.*

One of the main points of Theorem 3 is that it shows that there are Reed-Solomon codes that are list decodable beyond the Johnson bound. This is a very interesting result because variations of Reed-Solomon codes have been shown to beat the Johnson bound. On the other hand, Reed-Solomon codes are quite natural and some applications in Complexity theory specifically needed Reed-Solomon codes (and not the aforementioned variants).

A similar result as Theorem 4, using a similar argument, also known as the Johnson bound, is known for list recoverability (see for example, Lemma 5.2 in [4]).

▶ **Theorem 5** (Johnson bound for list recovery). *Let $\mathcal{C} \subseteq [q]^n$ be a code of relative distance $1 - \epsilon$. Then $\mathcal{C}$ is (ρ, ℓ, L)-list recoverable for any $\ell \leq \epsilon^{-1}(1 - \rho)^2$ with $L = \frac{\ell}{(1-\rho)^2 - \epsilon\ell}$.*

For perspective, the goal here is to have the input list size ℓ as large as possible for a given ρ while ensuring that the output list size L is small, for example, $L = \text{poly}(\ell)$ is a reasonable regime of efficiency. Theorem 5 roughly says that every q-ary code of distance $1 - q^{-1} - \epsilon$ is $(\rho, \ell, O(\ell))$-list recoverable for $\ell = O(\epsilon^{-1})$ and $\rho \leq 1 - \sqrt{2\epsilon\ell}$. Thus, a question naturally arises:

▶ **Question.** *Are there q-ary Reed-Solomon codes of distance $1 - q^{-1} - \epsilon$ which are (ρ, ℓ, L)-list recoverable for some $\rho \in [0, 1)$ and $\ell = \omega(\epsilon^{-1})$ and $L = \text{poly}(\ell)$?*

We would like to remark again, that the case $\rho = 0$ is also interesting. A result of Guruswami and Rudra [8] shows that there are Reed-Solomon codes where one cannot hope to beat the Johnson bound in the case when $\rho = 0$.

▶ **Theorem 6** (Theorem 1 in [8]). *Let $q = p^m$ where p is a prime, and let $\mathcal{C}$ denote the degree-$\left(\frac{p^m - 1}{p - 1}\right)$ Reed-Solomon code over $\mathbb{F}_q$ with $\mathbb{F}_q$ as the evaluation set. Then there are lists $S_1, \ldots, S_q$ each of size p such that*

$$|\mathcal{C} \cap (S_1 \times \cdots \times S_q)| = q^{2^m}.$$

In the proof of the above theorem, each list A_i is given by $\mathbb{F}_p \subset \mathbb{F}_q$, and the set of codewords contained in these lists are codewords of the *BCH code*. This result exploits the specific subfield structure of the input lists. To understand this result quantitatively, recall that a degree-d Reed-Solomon code has relative distance $1 - \frac{1}{q} - \frac{d}{q}$. Setting $\ell = p - 1$ and $\rho = 0$ in the Johnson bound tells us that such a code is $(p - 1, O(q))$ zero-error list recoverable. Setting the list size as p in the bound gives us nothing, and Theorem 6 says that the number of codewords grows superpolynomially in q.

One thing to note in Theorem 6 is that the same lists of size p also support at least q^{2^m} codewords for any punctured code. Thus in some sense, the reason why Theorem 2 is true is that lists of size $p-1$ do not support many more codewords in an appropriately punctured code than in the un-punctured case. This is very similar to the intuition in the results of [10], [11] for list-decodability.

Theorem 2 immediately gives the following corollary.

▶ **Corollary 7.** *For a prime power q and small enough $\epsilon \geq q^{-1/2}$, there are Reed-Solomon codes of rate $\tilde{\Omega}\left(\frac{\epsilon}{\log q}\right)$ which are $(\epsilon^{-2}, O(\epsilon^{-2}))$ zero-error list recoverable.*

Thus, one is able to go beyond the $O(\epsilon^{-1})$ size input lists. Again, one can easily check that setting $\ell = \epsilon^{-2}$ in the Johnson bound gives nothing. A point worth noting is that there is no inherent upper bound on the input list size, and the input lists can be as large as $\Omega(q)$ when ϵ is around $q^{-1/2}$. In fact, $\ell = \Omega(q)$ and $L \leq 2\ell$ is the regime for the main application of Theorem 2 (see Section 2.2).

A natural attempt at Theorem 2 is to use the method from the aforementioned result of Rudra and Wootters. This method uses tools from high dimensional probability. At a *very* high level, the main intuition in their argument is the following: Suppose there is a set Λ of $L = \Omega(\epsilon^{-1})$ codewords which are at a distance at most $1 - O(\epsilon)$ from some point $x \in [q]^n$, then there is a subset $\Lambda' \subset \Lambda$ which is much smaller where the distribution of distances from x is similar to that of Λ. The existence of such a Λ is a bad event, which is witnessed by a smaller bad event (i.e., existence of Λ') of the *same type*. Thus, this requires one to union bound just over Λ''s which are much smaller in number. Attempting to use this idea in a straightforward way to list recovery seems to be very lossy. The proof of Theorem 2 builds on this idea, and uses the fact that bad events can be witnessed by smaller bad events of a *different* (although related) type (see Section 3.1 for a somewhat more detailed sketch of the proof). Surprisingly though, the execution of this idea in this case is far simpler than in the previous works, and is completely elementary.

2.1 A quantitative summary of rate bounds for list recovery

We summarize the above discussion into a perspective with which one may view Theorem 2. Fix a $\rho \in [0, 1)$ to be the fraction of errors from which we wish to list-recover q-ary codes where q is larger than the block length. Suppose one wanted to list recover from input lists of size ℓ where the output list is $\text{poly}(\ell)$[1], the Johnson bound (Theorem 5) guarantees that Reed-Solomon codes of rate $\Omega(1/\ell)$ achieve this. Theorem 6 says that in general, this dependence cannot be improved, i.e., there are Reed-Solomon codes of rate $O(1/\ell)$ where the output list is superpolynomial for infinitely many q and ℓ. However, Theorem 2 says that most Reed-Solomon codes of rate $\Omega(1/(\ell^{1/2} \log q))$ achieve this.

It should be worth noting that decoding from lists of size ℓ can be achieved by random codes of rate $\Omega(1)$, whereas random Reed-Solomon codes require that the rate is $O(1/\log \ell)$ (Theorem 11). In fact, nothing better is known even for random linear codes. In this sense random codes are much better at list recovery than random Reed-Solomon codes.

[1] The proof of Theorem 2 relies on a "birthday paradox" type argument that cannot exploit the additional structure when one allows L to grow as a larger function of ℓ.

2.2 Unbalanced expander graphs from codes

The zero-error case of Theorem 2 leads to some progress on a question of Guruswami regarding unbalanced expanders obtained from Reed-Solomon graphs. This was also the main motivation behind this theorem.

Informally, an expander graph is a graph where every small set of vertices has a relatively large neighborhood. In this case, we say that all small sets *expand*. One interesting type of expander graphs are *unbalanced expanders*. These are bipartite graphs where one side is much larger than the other side, and we want that all the small subsets of the *larger* side expand.

▶ **Definition 8** (Unbalanced expander). *A (k, d, ϵ)-regular unbalanced expander is a bipartite graph on vertex set $L \sqcup R$, $|L| \geq |R|$ where the degree of every vertex in L is d, and for every $S \subseteq L$ such that $|S| = k$, we have that $|N(S)| \geq d|S|(1-\epsilon)$.*

Note that in the above definition, $|N(S)| \leq d|S|$. We are typically interested in infinite families of unbalanced expanders for which $\epsilon = o(1)$, $d = o(|R|)$, and $k = \tilde{\Omega}(|R|/d)$.

Given a code $\mathcal{C} \subseteq [q]^n$, it is natural to look at the bipartite graph, which we will denote by $G(\mathcal{C})$ where the vertex sets are $\mathcal{C} \sqcup ([n] \times [q])$. For every $c = (c_1, \ldots, c_n) \in \mathcal{C}$ the set of neighbors is $\{(1, c_1), \ldots, (n, c_n)\}$. This graph is especially interesting when $\mathcal{C}$ is a low-degree Reed-Solomon code evaluated at an appropriate set.

The following is a open question in the study of pseudorandomness that is attributed to Guruswami [5], (also explicitly stated in [2]): Fix an integer d. For a subset $S \in \binom{[q]}{m}$, define $\mathcal{C}_S$ to be the degree-d Reed-Solomon code with S as the evaluation set, where d is a constant.

▶ **Question.** *What is the smallest m such that when S is chosen uniformly at random, $G(\mathcal{C}_S)$ is, with high probability, a $(\Omega(q), 1/2)$-unbalanced expander?*

There are examples of explicit constructions unbalanced expanders that come from other means [9]. In fact, [9] also contains a construction based on a variant of Reed-Solomon code known as *folded Reed-Solomon code*. However, the above question has a very natural geometric/combinatorial "core" which is interesting in its own right and so far, seems to evade known techniques.

It was probably well known that $m = \Omega(\log q)$, and we also give a proof of this (Theorem 11) since we could not find it in the literature. But for upper bounds, it seems nothing better than the almost trivial $m = O(q)$ was known [1]. Since the zero-error list recoverability of $\mathcal{C}$ is equivalent to the expansion of $G(\mathcal{C})$, an immediate Corollary to Theorem 10 gives an improved upper bound.

▶ **Corollary 9.** *Let q, n be sufficiently large integers and $\alpha \in (0, 1)$, $\epsilon > q^{-1/2}$ be real numbers. For every code $\mathcal{C} \subset [q]^n$ with relative distance $1 - q^{-1} - \epsilon^2$, there is a subset $S \subseteq [n]$ such that $|S| = O(\epsilon n \log q)$ such that $G(\mathcal{C}_S)$ is a $(\alpha\epsilon^{-2}, |S|, \alpha)$-unbalanced expander.*

Instantiating the above theorem for degree-d Reed-Solomon codes, we have $n = q$ and $\epsilon = (d/q)^{-\frac{1}{2}}$. This gives, $m = \tilde{O}(\sqrt{q})$.

3 Proof of Theorem 2

The bulk of this section is the statement and proof of Theorem 10. After the proof of Theorem 10, we show how to derive Theorem 2 from it.

3.1 A sketch of the proof

Here, we sketch the proof when $\rho = 0$, i.e., for *zero-error* list recovery. This contains most of the main ideas required for the general theorem. Let $S = \{s_1, \ldots, s_m\} \subseteq [n]$ be a randomly chosen evaluation set. The main observation is that if there are input lists $A_1, \ldots, A_m \subseteq [q]$, such that $(A_1 \times \cdots \times A_m)$ contains a large subset $\mathcal{D} \subseteq \mathcal{C}$ of codewords, then there is a small subset $\mathcal{C}' \subseteq \mathcal{D} \subseteq \mathcal{C}$ which agree on an unusually high number of coordinates. An appropriately sized random subset of $\mathcal{D}$ does this. Thus the event that a given puncturing is bad is contained witnessed by the event that there are few codewords that agree a lot on the coordinates chosen in S. The number of events of the latter kind are far fewer in number, leaving us with fewer bad events to overcome for the union bound.

3.2 Proof of Theorem 2

The calculations in the proof of Theorem 10 are all explicit, but we have not tried to optimize the constant terms.

▶ **Theorem 10.** *Let $0 < \alpha < 1$ and $0 \le \rho < 1 - (1+\alpha)^{-1/2}$ be real numbers. Let q, n, d, ℓ, and m be positive integers. Let $\mathcal{C} \subset [q]^n$ be a code of distance at least $n - nq^{-1} - d$. Denote $\gamma = (1+\alpha)(1-\rho)^2 - 1$ and $\sigma = (1-\rho)(2-\rho)^{-1}$. Suppose that the following inequalities are satisfied:*

$$\begin{aligned} d &\ge nq^{-1}, \\ 4\gamma^{-1} \le \ell &\le 800^{-1}\,\sigma\gamma n d^{-1}, \\ \sigma m &\ge 1280\sqrt{\ell\gamma^{-1}}\log|\mathcal{C}|, \\ m &< n. \end{aligned}$$

Then, for $S \in \binom{[n]}{m}$ chosen uniformly at random, the probability that $\mathcal{C}_S$ is $(\rho, \ell, \ell(1+\alpha))$-list recoverable is at least $1 - e^{-\sigma m/64}$.

Proof. For any $\mathcal{C}' \subseteq \mathcal{C}$, denote by $T(\mathcal{C}')$ the set of coordinates $i \in [n]$ such that there is a pair $c_1, c_2 \in \mathcal{C}'$ with $c_1[i] = c_2[i]$.

The basic outline of the proof is to first show that, for any S such that $\mathcal{C}_S$ is not $(\rho, \ell, \ell(1+\alpha))$-list recoverable, there is a pair $S', \mathcal{C}'$ such that S' is large and $|T(\mathcal{C}') \cap S'|$ is unusually large. Taking a union bound over all candidates for $\mathcal{C}'$ then shows that there cannot be too many pairs of this sort.

Let $S \in \binom{[n]}{m}$ so that $\mathcal{C}_S$ is not $(\rho, \ell, \ell(1+\alpha))$-list recoverable. We will show that there is a set $\mathcal{C}' \subset \mathcal{C}_S$ such that

$$|\mathcal{C}'| \le 10\sqrt{\ell/\gamma}, \text{ and} \tag{1}$$

$$|T(\mathcal{C}') \cap S| \ge \sigma m/4. \tag{2}$$

Since $\mathcal{C}_S$ is not $(\rho, \ell, \ell(1+\alpha))$-list recoverable, there are subsets $A_i \subseteq [q]$ for each $i \in S$ such that each $|A_i| \le \ell$ and $|\{c \in \mathcal{C}_S : \Delta(c, \prod_{i\in S} A_i) \le \rho n\}| > \ell(1+\alpha)$.

Let

$$\mathcal{D} = \{c \in \mathcal{C}_s : \Delta(c, \prod_{i\in S} A_i) \le \rho n\}.$$

For $i \in S$, let

$$\mathcal{D}_i = \{c \in \mathcal{D} : c[i] \in A_i\}.$$

Let

$$I = \{(c, i) \in \mathcal{D} \times S : c \in \mathcal{D}_i\}.$$

From the definition of $\mathcal{D}$, we have

$$|I| \geq |\mathcal{D}|(1-\rho)m. \tag{3}$$

Note that the average cardinality of the $\mathcal{D}_i$ is $(1-\rho)|\mathcal{D}|$. Let

$$S' = \{i \in S : |\mathcal{D}_i| \geq (1-\rho)^2|\mathcal{D}|\}.$$

If $\rho = 0$, then $\mathcal{D}_i = \mathcal{D}$ for each i, and hence $|S'| = m$. Next we show that, if $\rho > 0$, then $|S'| \geq (1-\rho)(2-\rho)^{-1}m = \sigma m$. Since $|\mathcal{D}_i \leq |\mathcal{D}|$ for each i, we have

$$|S'|\,|\mathcal{D}| \geq \sum_{i \in S'} |D_i| = |I| - \sum_{i \in S \setminus S'} \mathcal{D}_i. \tag{4}$$

Since $|D_i| < (1-\rho)^2|\mathcal{D}|$ for each $i \in S \setminus S'$, we have

$$\sum_{i \in S \setminus S'} \leq (m - |S'|)(1-\rho)^2|\mathcal{D}|. \tag{5}$$

A straightforward rearrangement of (3), (4), and (5) using the assumption that $\rho > 0$ leads to the claimed lower bound on $|S'|$:

$$|S'| \geq \sigma m. \tag{6}$$

Since $\sigma < 1$, the bound $|S'| \geq \sigma m$ holds for the case $\rho = 0$ as well.

For each $i \in S'$, choose a set $P_i \subset \binom{\mathcal{D}}{2}$ of $|P_i| \geq \gamma\ell/2$ disjoint pairs of codewords in $\mathcal{D}_i$ such that for each $\{c_1, c_2\} \in \mathcal{P}_i$, we have $c_1[i] = c_2[i]$. This is always possible since $|A_i| \leq \ell$ and $|\mathcal{D}_i| \geq (1+\rho)^2|\mathcal{D}| \geq (1+\gamma)\ell$. Now choose $\mathcal{C}'$ randomly by including each element of $\mathcal{D}$ with probability $p = (\gamma\ell/2)^{-1/2}\ell(1+\alpha)|\mathcal{D}|^{-1}$. Since $\ell \geq 4\gamma^{-1}$ by hypothesis and $|\mathcal{D}| \geq \ell(1+\alpha)$ by the assumption that $\mathcal{C}_S$ is not $(\rho, \ell, \ell(1+\alpha))$-list recoverable, we have $p < 1$. The expected size of $\mathcal{C}'$ is

$$\mathbf{E}[|\mathcal{C}'|] = p|\mathcal{D}| \leq (\gamma/(2\ell))^{-1/2}(1+\alpha) \leq (8\ell/\gamma)^{1/2}.$$

We remark that this is the only place where we use the assumption that $\alpha < 1$. For any fixed pair $c_1 \neq c_2$ of codewords in $\mathcal{D}$, the probability that both are included in $\mathcal{C}'$ is p^2. Since the pairs in P_i are disjoint, the events that two distinct pairs $\{c_1, c_2\}, \{c_3, c_4\} \in P_i$ are both included in $\mathcal{C}'$ are independent. Hence, the probability that no pair in P_i is included in $\mathcal{C}'$ is $(1-p^2)^{|P_i|} < e^{-p^2|P_i|} < 1/2$. Consequently, for each fixed $i \in S'$, the probability that $i \in T(\mathcal{C}')$ is greater than $1/2$. By linearity of expectation, $\mathbf{E}[|T(\mathcal{C}') \cap S'|] \geq |S'|/2 \geq \sigma m/2$.

Let

$$Y = |T(\mathcal{C}') \cap S'| - \frac{\sigma m}{4}\frac{|\mathcal{C}'|}{\mathbf{E}[|\mathcal{C}'|]}.$$

By linearity of expectation, $\mathbf{E}[Y] \geq \sigma m/4$, hence there is some specific choice of $\mathcal{C}'$ for which $Y \geq \sigma m/4$. This can hold only if $|T(\mathcal{C}') \cap S| \geq |T(\mathcal{C}') \cap S'| \geq m/4$ and $|\mathcal{C}'| \leq 3\mathbf{E}(|\mathcal{C}'|)$ simultaneously, which establishes (1) and (2).

Next we bound the probability that, for a fixed choice of $\mathcal{C}'$ and random S, we have have $|T(C') \cap S|$ large. Let $\mathcal{C}' \subset \mathcal{C}$ be an arbitrary set of $|\mathcal{C}'| \leq 10\ell^{1/2}\gamma^{-1/2}$ codewords. Since the distance of $\mathcal{C}'$ is at least $n - nq^{-1} - d$ and $d \geq nq^{-1}$, we have

$$|T(\mathcal{C}')| \leq (nq^{-1} + d)\binom{|\mathcal{C}'|}{2} < d|\mathcal{C}'|^2. \tag{7}$$

For $S \in \binom{[n]}{m}$ chosen uniformly at random, $|T(\mathcal{C}') \cap S|$ follows a hypergeometric distribution. Specifically, we are making m draws from a population size of n of which $|T(\mathcal{C}')| \leq d|\mathcal{C}'|^2$ contribute to $|T(\mathcal{C}') \cap S|$. Using the assumption that $\ell \leq \gamma\sigma n(800d)^{-1}$, the expected value of $|T(\mathcal{C}') \cap S|$ is

$$\mathbf{E}\left[|T(\mathcal{C}') \cap S|\right] \leq d|\mathcal{C}'|^2 n^{-1} m \leq 100\frac{d\ell}{\gamma n}m \leq \frac{\sigma m}{8}. \tag{8}$$

Next we use the following large deviation inequality for hypergeometric random variables (see [3]). Let X be a hypergeometric random variable with mean μ. Then for any $\alpha \geq 1$,

$$\mathbb{P}(X \geq (1+\alpha)\mu) \leq \exp(-\alpha\mu/4). \tag{9}$$

Together with (8), this gives

$$\mathbb{P}(|T(\mathcal{C}') \cap S| \geq \sigma m/4) \leq \exp\left(-\frac{\sigma m}{32}\right). \tag{10}$$

Finally, we take a union over all candidates for $\mathcal{C}'$. Let X be the event that $\mathcal{C}_S$ is not (ℓ, α, ρ) list recoverable, with $S \in \binom{[n]}{m}$ uniformly at random. Using the assumption that $\sigma m \geq 1280\sqrt{\ell/\gamma}\log|\mathcal{C}|$, we have

$$\begin{aligned}
\mathbb{P}(X) &\leq \sum_{\mathcal{C}' \subset \mathcal{C}_S : |\mathcal{C}'| \leq 10\sqrt{\ell/\gamma}} \mathbb{P}(|T(\mathcal{C}' \cap S)| \geq \sigma m/4) \\
&\leq \binom{|\mathcal{C}|}{\lceil 10\sqrt{\ell/\gamma}\rceil + 1} \exp\left(-\frac{m}{32}\right) \\
&< \exp\left(20\sqrt{\ell/\gamma}\log|\mathcal{C}| - \sigma m/32\right) \\
&\leq \exp(-\sigma m/64),
\end{aligned}$$

as claimed. ◀

We now show how to derive Theorem 2 from Theorem 10.

Proof of Theorem 2. Suppose we have α, ρ, n, q, and ϵ as in the hypotheses of Theorem 2. Let $\gamma = (1+\alpha)(1-\rho)^2 - 1$, $\sigma = (1-\rho)(2-\rho)^{-1}$ and $m = \lceil 1280\epsilon^{-1}\log|C|\rceil$. The singleton bound combined with the assumption that $\epsilon < c$ for a suitably chosen absolute constant c implies that $m < n$. Choose $S \in \binom{[n]}{m}$ uniformly at random. The rate of $\mathcal{C}_S$ is

$$R = \log|\mathcal{C}|(m\log q)^{-1} = \Omega(\epsilon(\log q)^{-1}).$$

It is straightforward to check that the hypotheses of Theorem 10 are satisfied if we take $\ell = \epsilon^{-2}\sigma^2\gamma$, and hence we have that $\mathcal{C}_S$ is $(\rho, \ell, \ell(1+\alpha))$-list recoverable with high probability. ◀

4 Upper bound

Here we show the aforementioned upper bound for the rate to which a degree-d Reed-Solomon code over $\mathbb{F}_q$ can be randomly punctured to be $(Omega(q), 1/2)$-zero-error list-recoverable.

First, we recall a bit of standard and relevant sumset notation. For a group G and subsets $A, B \subseteq G$, we denote the sumset $A + B = \{a + b \mid a \in A,\ b \in B\}$. Clearly, we have $|A + B| \leq |A| \cdot |B|$. If $G = \mathbb{Z}_p$, then for $n < p/2$, we have that $[n] + [n] = \{2, \ldots, 2n\}$. We are now ready to state and prove the upper bound.

▶ **Theorem 11.** *Let $m = o(\log q)$, and S be a uniformly random subset of $\mathbb{F}_q$ of size m where q is a large prime. Then for every $d \geq 1$, the degree-d Reed-Solomon code with the evaluation set at S is, with high probability, not $(\Omega(q), 1/2)$-zero-error list-recoverable.*

Proof. Let $S = \{s_0, \ldots, s_m\}$. Let t be a large number such that $t^m = o(\sqrt{q})$. We are using the fact that $m = o(\log q)$ for the existence of such a t. W.L.O.G assume $s_0 = 0$ and $s_1 = 1$ (if $0, 1 \notin S$, then adding them to S only makes the lower bound stronger). Consider the two sets

$$A_0 = \frac{1}{1 - s_2}[t] + \cdots \frac{1}{1 - s_{m-1}}[t]$$

and

$$A_1 = \frac{1}{s_2}[t] + \cdots \frac{1}{s_{m-1}}[t].$$

▷ Claim 12. With high probability over the choice of S, we have that $|A_0|, |A_1| = \Omega(\left(t^{m-2}\right))$.

Proof. We do the proof for A_0, the case for A_1 follows analogously. Let P be the set of "collisions" in A_0. Formally:

$$P := \left\{ (a_2, \ldots, a_{m-2}, b_2, \ldots, b_{m-2}) \mid \sum_{i=2}^{m-2} a_i s_i = \sum_{i=2}^{m-2} b_i s_i \right\}.$$

So the number of distinct elements in A_0 is at least $t^{m-2} - |P|$. We observe that

$$\begin{aligned} \mathbf{E}[|P|] &= \sum_{\substack{a_2,\ldots,a_{m-2} \in [t] \\ b_2,\ldots,b_{m-2} \in [t]}} \mathbb{P}\left(\sum_{i=2}^{m-2} a_i s_i = \sum_{i=2}^{m-2} b_i s_i \right) \\ &\leq \frac{1}{p} t^{2m-4} \\ &= o(t^{m-2}). \end{aligned}$$

So by Markov's Inequality, with high probability, $|A_0| \sim t^{m-2}$. ◀

Consider $\mathcal{D}$, the set of degree-1 Reed-Solomon codes given by the lines

$$\{Y = aX + b\}_{b \in A_0, a \in A_1}.$$

First, we note that $|Y| = \Omega(t^{2m-4})$. Geometrically, $\mathcal{D}$ is just the set of all lines passing through some point of $\{0\} \times A_0$ and $\{1\} \times A_1$. Clearly, $\{c[0] \mid c \in \mathcal{C}\} = A_0$ and $\{c[1] \mid c \in \mathcal{D}\} = A_1$. For $i \neq 0, 1$, let us similarly define $A_i := \{c[s_i] \mid c \in \mathcal{D}\}$.We have that

$$\begin{aligned}
A_i &= \{a(1-s_i) + bs_i\}_{b\in A_0, a\in A_1} \\
&= (1-s_i)\left(\frac{1}{1-s_2}[t] + \cdots \frac{1}{1-s_{m-1}}[t]\right) + s_i\left(\frac{1}{s_2}[t] + \cdots \frac{1}{s_{m-1}}[t]\right) \\
&= \left([t] + \sum_{2\le j\le m,\ j\neq i} \frac{1-s_i}{1-s_j}[t]\right) + \left([t] + \sum_{2\le j\le m,\ j\neq i} \frac{s_i}{s_j}[t]\right) \\
&= \{2, \ldots, 2t\} + \sum_{2\le j\le m,\ j\neq i} \frac{1-s_i}{1-s_j}[t] + \sum_{2\le j\le m,\ j\neq i} \frac{s_i}{s_j}[t].
\end{aligned}$$

Thus, $|A_i| \le (2t) \times t^{2m-6} \le 2t^{2m-5}$.

This shows that there are lists $A_0, A_1, \ldots, A_m$ each of size at most $\ell := 2t^{2m-5}$ such that there are at least $\Omega(t^{2m-4}) = \ell^{1+\frac{1}{2m}}$ codewords, namely $\mathcal{D}$, contained in $A_0 \times \cdots \times A_m$. ◀

For a fixed d, the above theorem rules out hope of randomly puncturing degree-d Reed-Solomon codes to rate $\omega\left(\frac{1}{\log q}\right)$ for the desired list recoverability. We believe that this is essentially the barrier. We state the concrete conjecture that we alluded to in Section 2.2.

▶ **Conjecture 13.** *The degree-d Reed-Solomon code with evaluation set $\mathbb{F}_q$ can be randomly punctured to rate $\Omega_d\left(\frac{1}{\log q}\right)$ so that is it $(\Omega(q), 1/2)$-list recoverable with high probability.*

5 Discussion and open problems

The main open problem that we would like to showcase is Conjecture 13. This was probably believed to be true but we could not find it written down explicitly in the literature. List recoverable codes have connections to various other combinatorial objects (see [12]) and if true, Conjecture 13 could lead to the construction of some other interesting combinatorial objects.

The second open problem is to derandomize Theorem 2, i.e., to find an *explicit* Reed-Solomon code which is list recoverable beyond the Johnson bound at least in the zero-error case. Understanding how these evaluation sets look like could lead to progress on Conjecture 13, or could be interesting in its own right.

Finally, the last open problem is that given a Reed-Solomon code $\mathcal{C} \subset [q]^m$ of rate R on a randomly chosen evaluation set S, find an efficient algorithm for list recovery, i.e., take input lists $A_1, \ldots, A_m$ of size $O(R^{-2}(\log q)^{-1})$, and output all the codewords contained in $A_1 \times \cdots \times A_m$ with high probability (over the choice of S and the randomness used by the algorithm). This would also likely require some understanding of the properties of the evaluation set.

On Perturbation Resilience of Non-Uniform k-Center

Sayan Bandyapadhyay

Abstract

The Non-Uniform k-center (NUkC) problem has recently been formulated by Chakrabarty, Goyal and Krishnaswamy [ICALP, 2016] as a generalization of the classical k-center clustering problem. In NUkC, given a set of n points P in a metric space and non-negative numbers $r_1, r_2, \ldots, r_k$, the goal is to find the minimum dilation α and to choose k balls centered at the points of P with radius $\alpha \cdot r_i$ for $1 \leq i \leq k$, such that all points of P are contained in the union of the chosen balls. They showed that the problem is NP-hard to approximate within any factor even in tree metrics. On the other hand, they designed a "bi-criteria" constant approximation algorithm that uses a constant times k balls. Surprisingly, no true approximation is known even in the special case when the r_i's belong to a fixed set of size 3. In this paper, we study the NUkC problem under perturbation resilience, which was introduced by Bilu and Linial [Combinatorics, Probability and Computing, 2012]. We show that the problem under 2-perturbation resilience is polynomial time solvable when the r_i's belong to a constant sized set. However, we show that perturbation resilience does not help in the general case. In particular, our findings imply that even with perturbation resilience one cannot hope to find any "good" approximation for the problem.

1 Introduction

Stability is a popular notion, which has been used in literature in the context of *beyond worst case analysis*. The general idea is to impose extra constraints on the inputs such that the (stable) instances that satisfy those constraints can capture the instances that appear in real life applications. In other words, we would like to exclude the "unrealistic" instances from consideration and obtain optimistic bounds for algorithms on the remaining inputs. For example, a major collection of work along this line have focused on designing polynomial time algorithms for NP-complete problems under different stability conditions. Bilu and Linial [10] introduced a notion of stability, which they termed as *ψ-perturbation resilience* for some $\psi > 1$. Informally, an instance is called ψ-perturbation-resilient if the optimal solution remains same even after the instance is perturbed by a factor of ψ.

Recently, researchers have shown sufficient interest in studying geometric clustering problems under perturbation resilience. An instance of a clustering problem is ψ-perturbation-resilient if the optimal clustering is unique and remains unchanged under ψ-factor perturbation of the input distances. Awasthi et al. [6] showed that the standard center based clustering problems (e.g. k-center, k-median) can be solved in polynomial time under ψ-perturbation-resilience for $\psi \geq 3$. In any such center based clustering problem, the clustering is obtained by assigning a point to its nearest center. In other words, the clustering is induced by the Voronoi partition of the points w.r.t. the chosen centers. Subsequently, Balcan and Liang [8] designed a polynomial time algorithm for these clustering problems under ψ-perturbation-resilience for $\psi \geq 1 + \sqrt{2}$, improving the bound of Awasthi et al. [6]. Later, Balcan et al. [7] improved the bound for k-center to 2. On the other hand, they showed that k-center under ψ-perturbation-resilience cannot be solved in polynomial time for $\psi < 2$, unless $\mathsf{NP} = \mathsf{RP}$. They also considered the more general asymmetric k-center problem, where the distances are not necessarily symmetric (but satisfy triangle inequality). The problem is known to not admit a constant approximation unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{\log \log n})$, where n is the input size [15]. Surprisingly, Balcan et al. [7] showed that asymmetric k-center under 2-perturbation-resilience can be solved in polynomial time. Angelidakis et al. [4] gave a generic polynomial time algorithm for clustering problems with center based objectives (e.g. k-center, k-median, k-means) under 2-perturbation-resilience. Recently, Cohen-Addad and Schwiegelshohn [16] proved that a simple local search scheme yields optimal solutions for problems like k-median and k-means, under ψ-perturbation-resilience for $\psi > 3$. Chekuri and Gupta [14] showed that an LP relaxation of k-center under 2-perturbation-resilience admits an integral solution. They also proved the same result for k-center with outliers. Balcan and Liang [8] introduced a weaker stability assumption called (ψ, ϵ)-perturbation-resilience, where the optimal solution under ψ-perturbation can differ in at most ϵ fraction of the points from the original optimal clustering (see Preliminaries for the formal definition). Assuming that each cluster contains more than $2\epsilon n$ points, Balcan et al. [7] showed that k-center under $(3, \epsilon)$-perturbation-resilience can be solved in polynomial time, where n is the number of input points.

The increasing interest in studying perturbation resilient clustering has given rise to several open directions. One such interesting direction is to study clustering problems, where the clustering is not necessarily induced by Voronoi partition. One such clustering problem is *Non-Uniform k-center* (NUkC). In NUkC, we are given a set of n points P in a metric space, non-negative integers $r_1, r_2, \ldots, r_k$, and the goal is to find the minimum dilation α and to choose k balls centered at the points of P with radius $\alpha \cdot r_i$ for $1 \leq i \leq k$, such that all points of P are contained in the union of the chosen balls. We refer to any feasible solution of this problem composed of the chosen balls as a *feasible placement*. From a feasible placement, a clustering is retrieved in the following way – each point is assigned to a fixed ball that contains the point, and then for each ball, the points that are assigned to that ball form a cluster. Figure 1 shows that, the optimal clustering for an instance of NUkC is not the same as the Voronoi partition w.r.t. the centers of the balls in the optimal placement. The NUkC problem was formulated by Chakrabarty et al. [13] as a generalization of the well-studied k-center clustering problem, where all r_i's are same. Apart from clustering, NUkC has several applications in vehicle routing, sensor placement, and so on. For example, in vehicle routing, we need to find k depot locations corresponding to k vehicles having different speeds, such that any customer can be served by some vehicle as quickly as possible.

As mentioned before, k-center is a special case of NUkC where all the input radii are equal. We call this version of the problem as NUkC with one radius class. In general, all the radii might not be equal. But, we can consider only distinct radii from the input and

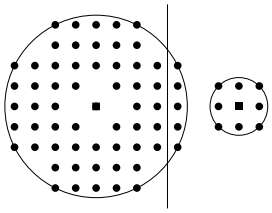

Figure 1 The optimal clusters are contained in the two disks in the Euclidean plane. The centers of balls are shown by boxes. The Voronoi partition w.r.t. the centers contains two subsets of points lying on the different sides of the vertical bisector line.

associate a multiplicity parameter k_i, with each such radius r_i, which denotes the number of balls of radius r_i that can be opened. Then the problem can be formulated equivalently in the following way.

▶ **Definition 1** (NUkC with t radii classes)**.** *Given a set of n points P in a metric space, $t \leq k$ distinct radii $r_1 > r_2 > \ldots > r_t$ and non-negative integers $k_1, \ldots, k_t$ such that $\sum_{i=1}^{t} k_i = k$, the goal is to find the minimum dilation α and to choose k_i balls centered at the points of P with radius $\alpha \cdot r_i$ for all $1 \leq i \leq t$, such that the union of the chosen balls contains all the input points.*

We note that k-center with outliers is a special case of NUkC with 2 radii classes where the radius $r_2 = 0$. Using a reduction from the Firefighters problem [1], Chakrabarty et al. (Theorem 2 in [13]) proved that NUkC is NP-hard to approximate within any constant factor even in tree metrics. In fact, their construction proves c-inapproximability of the problem for any c, not necessarily a constant. On the other hand, they designed a (c_1, c_2) bi-criteria approximation for the problem for large constants c_1 and c_2, i.e., if the algorithm is allowed to use $c_1 \cdot k_i$ balls of type i (thus $c_1 \cdot k$ in total), it can produce a solution with dilation at most c_2 times the optimal dilation. They also gave a $1 + \sqrt{5}$-approximation for NUkC with two radii classes. For k-center with outliers, they gave an improved 2-approximation. However, even when the number of distinct radii is 3, no true approximation is known.

The motivation behind the study of NUkC under perturbation resilience is that, in many applications, the distance function is heuristic. In fact, when the points represent structures like images, proteins, documents, etc., it is very hard to find the true distance function, and various standard distance/dissimilarity measures are used. If one solves a clustering problem with such a heuristic distance function and expects good results, then they implicitly assume that the optimal solution of the problem is not sensitive to small perturbations of the distance function. The perturbation resilience condition is a natural way to make this implicit assumption precise. And, the separation between the clusters forces an optimal clustering to be unique.

Our results. In this paper, we obtain the following results.

1. *Polynomial time exact algorithm for NUkC with a constant number of radii classes under "2-perturbation-resilience" and "$(3, \epsilon)$-perturbation-resilience when each cluster contains more than $\epsilon n + 1$ points".* Our algorithm reduces the NUkC problem to a version of Firefighters problem on trees (formally defined in Section 4). Under the stability assumptions, we can show that a feasible solution of NUkC maps to a feasible solution of Firefighters problem and vice versa. Here, in particular, we use the "well-separated" structure of the clusters in the optimal clustering that follows due to stability. The

reduction has the property that if NUkC has t distinct radii classes, then the height of the constructed tree instance is $t+1$. Then we show that using a dynamic programming based scheme the Firefighters problem can be solved in polynomial time for constant height tree instances. Thus we also obtain a polynomial time algorithm for NUkC under perturbation resilience with a constant number of radii classes. We note that the algorithms for center based clustering problems in [4, 8, 14] are also based on tree computation and dynamic programming. However, the structure of the tree we compute is very different. We also note that our result under 2-perturbation-resilience is tight, as even for k-center it is unlikely to obtain a polynomial time algorithm under ψ-perturbation-resilience for $\psi < 2$. To prove the result for $(3, \epsilon)$-perturbation-resilience, we assume that each cluster contains more than $\epsilon n + 1$ points. We note that such a lower bound is necessary, as in its absence even k-center is NP-hard [7] under (ψ, ϵ)-perturbation-resilience for all $\psi \geq 1$ and $\epsilon > 0$.

2. *γ-inapproximability for NUkC under ψ-perturbation-resilience for any $\gamma > 1$ and $\psi \leq \gamma$, unless* NP = RP. Our result implies that, for any $\psi, \gamma > 1$, even with ψ-perturbation-resilience one cannot hope to find a γ-approximation for the problem. Our result should be contrasted with the polynomial time algorithm for asymmetric k-center under 2-perturbation-resilience, as asymmetric k-center is another candidate problem which is hard to approximate within a constant factor. To prove the result, we use a chain of reductions starting from the satisfiability problem to the NUkC problem in tree metrics under perturbation resilience assumption. The last reduction in the chain is from a version of the Firefighters problem which shows that NUkC is hard to approximate within a factor of γ in tree metrics for any γ. Our reduction is similar to the reduction in [13]. Then, we argue that the constructed tree instances of NUkC are γ-perturbation-resilient, and hence the similar hardness follows even for NUkC under γ-perturbation-resilience. We also extend this hardness result to Euclidean metric of dimension d for $d \geq 1$ using a classical tree embedding result of Gupta [21].

The main contribution of this paper is twofold. The first one is to be able to establish an exact connection between NUkC under perturbation resilience and the Firefighters problem on trees. To establish this connection, we need to prove that perturbation resilience implies that the optimal clusters are "well-separated". Similar properties have been proved in the context of other problems (e.g., k-center). Our contribution is to be able to extend these proofs for NUkC as well. However, the extension is non-trivial, and one need sufficiently good amount of extra work, as here we need to deal with non-uniform radii. We note that Chakrabarty et al. [13] also showed a reduction from NUkC to Firefighters. However, their LP-aware reduction is very different. Our second contribution is the tight hardness result for the problem. This result along with the polynomial time algorithm gives the complete picture for NUkC under perturbation resilience. To prove this result we are faced with the following challenges. In any such hardness construction, one needs to show that the instances of NUkC to which we map are perturbation resilient. Thus, we need to show that these instances have unique optimal solution and the optimal solution does not change with some perturbation of the distances. Chakrabarty et al. [13] showed a reduction from Firefighers to NUkC. However, using their distance function it is not straightforward to show that the constructed instances are insensitive to the perturbation of distances. Nevertheless, we consider a similar distance function and show the reduction works out well with this modification. To prove the uniqueness of the optimal solutions, we reduce a "unique" version of 3SAT to a "unique" version of Firefighters using a chain of reductions.

Related work and Open questions. Other optimization problems have also been studied under stability assumptions [4, 17, 19, 25, 26]. Also different stability assumptions have been introduced and well-studied in the literature [5, 24, 27]. Most of the clustering problems mentioned here are NP-hard, but admit some constant approximations, e.g., see [3, 12, 20, 22] and the references therein. It would be interesting to see if one can obtain a constant approximation for NUkC with a constant number of radii classes without any perturbation resilience assumptions. Also, one can study similar hard clustering problems (e.g., k-clustering [9]) under perturbation resilience.

Organization. In Section 2, we define some notations that we use throughout the paper, and make a few observations that will be useful later. In Section 3, we list some properties implied due to perturbation resilience of the input instances. Then in Section 4, we discuss the algorithm for NUkC with any constant number of classes and prove its correctness by using the properties proved in the previous section. Lastly, in Section 5, we prove the hardness results for the general problem.

2 Preliminaries

We denote an instance of NUkC with t radii classes on metric d by (P, d, t). Note that the radii (r_i) and multiplicity (k_j) parameters remain implicit in this notation. But, references to these parameters will become clear from the context. A ball with center $p \in P$ and radius r, denoted by $B(p, r)$, is the set of points $\{q \in P \mid d(p, q) \leq r\}$. A set of balls *covers* a set of points if the union of the balls contains all the points. Recall that a feasible placement is a feasible solution of the problem composed of the chosen balls that cover all the input points. A feasible NUkC *clustering* $\mathcal{C}$ of the input set of points P is a partition $\{C_1, \ldots, C_k\}$, such that there is a feasible placement Π with the property that for all i, C_i is a subset of a ball in the placement. We say that the clustering $\mathcal{C}$ is *induced* by the placement Π. The radius of a cluster C w.r.t. any distance function d, denoted by c-radius(C, d), is $\min_{p \in P} \max_{q \in C} d(p, q)$. Note that no ball centered at a point $p \in P$ of radius smaller than c-radius(C, d) can cover all the points of C. For a placement with dilation α, a ball with radius αr_i (resp. $< \alpha r_i$ and $\geq \alpha r_i$) is called an r_i (resp. $< r_i$ and $\geq r_i$) -ball.

Consider a metric space P with metric $d : P \times P \to \mathbb{R}_{\geq 0}$. A metric d_1 is called a ψ-perturbation of d if for any $p, q \in P$, $d(p, q)/\psi \leq d_1(p, q) \leq d(p, q)$[1]. In this paper, all perturbations we consider satisfy the metric properties.

▶ **Definition 2.** *An instance $\mathcal{I} = (P, d, t)$ of NUkC is called ψ-perturbation-resilient (ψ-PR) if for any metric ψ-perturbation d_1 of d, the unique optimal NUkC clustering of $\mathcal{I}' = (P, d_1, t)$ is identical to the unique optimal clustering of $\mathcal{I}$.*

Note that in general, optimal clustering of NUkC might not be unique. We refer to the instance $\mathcal{I}'$ as a ψ-perturbed instance of $\mathcal{I}$. A few examples demonstrating the definition of perturbation resilience w.r.t. NUkC with t radii classes are shown in Appendix A. We also consider another notion of perturbation resilience introduced by Balcan and Liang [8], where the optimal clustering is allowed to be different by a few points when the distances are perturbed. Here we rewrite this notion in terms of NUkC. Two clusterings $\mathcal{C} = \{C_1, \ldots, C_k\}$ and $\mathcal{C}' = \{C'_1, \ldots, C'_k\}$ are called ϵ-close if at most ϵn points are clustered differently in the two clusterings, i.e., the minimum value of $\sum_{i=1}^{k} |C_i \setminus C'_{f(i)}|$ over all permutations f of $\{1, 2, \ldots, k\}$ is at most ϵn.

[1] One can also define ψ-perturbation by both increasing and decreasing the distances - the two definitions are equivalent modulo some factor, as one can always scale the input distances appropriately.

▶ **Definition 3.** *An instance $\mathcal{I} = (P, d, t)$ of NUkC is called (ψ, ϵ)-perturbation-resilient ((ψ, ϵ)-PR) if for any metric ψ-perturbation d_1 of d, any optimal NUkC clustering of $\mathcal{I}' = (P, d_1, t)$ is ϵ-close to any optimal clustering of $\mathcal{I}$.*

This is again a well-studied stability criterion [2]. Note that when $\epsilon = 0$, any optimal NUkC clustering of $\mathcal{I}'$ must be same as any optimal clustering of $\mathcal{I}$. This implies that optimal clustering of $\mathcal{I}$ and $\mathcal{I}'$ are unique and we obtain the definition of ψ-PR. Thus, if an instance of NUkC is ψ-PR, then it is also $(\psi, 0)$-PR, and hence any hardness result for NUkC under ψ-PR trivially follows for NUkC under (ψ, ϵ)-PR. Now, we have the following simple observation, which will be useful later in proving the properties of the PR instances.

▶ **Observation 4.** *Consider an NUkC instance $\mathcal{I} = (P, d, t)$ that admits a unique optimal clustering $\mathcal{O}$. Let C be any cluster in $\mathcal{O}$. Also, consider an optimal placement Π where C is covered by a ball B. Then, the following two properties hold.*

- *The center p of the ball B must belong to C.*
- *For any two points u, v that lie in two different clusters of $\mathcal{O}$, both of u, v cannot be contained in B.*

Proof.

- Suppose p belongs to the cluster C' such that $C \neq C'$. Construct another clustering $\mathcal{O}'$ by selecting all the clusters in $\mathcal{O}$ except C and C', and the clusters $C \cup \{p\}$ and $C' \setminus \{p\}$. It is not hard to see that $\mathcal{O}'$ is also a feasible clustering induced by Π. As Π is an optimal placement, $\mathcal{O}'$ is also an optimal clustering, which contradicts the uniqueness of the optimal clustering of $\mathcal{I}$. Hence, the statement follows.
- Suppose B contains both u and v. We construct a new clustering $\mathcal{O}'$, which is identical to $\mathcal{O}$ except, in $\mathcal{O}'$, we move the points u, v to the cluster C. Note that the clustering $\mathcal{O}'$ can be induced by the placement Π, as the ball B that covers $C \in \mathcal{O}$ also contains u, v. Hence, $\mathcal{O}'$ is an optimal clustering for $\mathcal{I}$ different than $\mathcal{O}$, which is a contradiction, and thus the statement follows. ◀

WLOG we can assume that the optimal dilation of a ψ-PR or a (ψ, ϵ)-PR instance of NUkC is 1. Like in the general case without perturbation resilience, in this case also the assumption can be introduced by scaling r_i values by a guessed value of the optimal dilation α.

▶ **Lemma 5.** *Suppose there is a polynomial time algorithm $\mathcal{A}$ for the NUkC problem with t radii classes under ψ-PR (resp. (ψ, ϵ)-PR) with the properties that (i) for an instance which admits a feasible placement of balls with dilation 1, $\mathcal{A}$ returns "yes" and a feasible clustering, and (ii) for an instance which does not admit a feasible placement of balls with dilation 1, $\mathcal{A}$ returns "no". Then, the NUkC problem with t radii classes under ψ-PR (resp. (ψ, ϵ)-PR) can be solved in polynomial time.*

Proof. Consider any instance $\mathcal{I} = (P, d, t)$ of the NUkC problem with t radii classes under ψ-PR (resp. (ψ, ϵ)-PR). Let α be the optimal dilation. Note that we do not know the value of α. However, as the input metric is finite, there are only polynomial number of guesses for α. We use the following procedure to obtain the optimal clustering for $\mathcal{I}$. In each step, we guess a value α' for the optimal dilation in the increasing order of the values. We construct a new instance $\mathcal{I}'$ from $\mathcal{I}$ by only changing the radius r_i to $\alpha' \cdot r_i$ for all i. Then, we apply the algorithm $\mathcal{A}$ on the constructed instance. If $\mathcal{A}$ returns "no", we repeat the process with a different guess. Otherwise, the procedure terminates. We return the same clustering returned by $\mathcal{A}$ as the solution for the instance $\mathcal{I}$.

Now, we argue about the correctness of the procedure. First, we claim that $\mathcal{I}'$ is a ψ-PR (resp. (ψ, ϵ)-PR) instance. Before proving this claim we discuss its consequences. Note that if there is no feasible solution for $\mathcal{I}$ with dilation α', then with k_i balls of radius $\alpha' \cdot r_i$ for all i it is not possible to cover the input points. Hence, in this case, for the constructed instance, there is no feasible solution with dilation 1. Thus, the algorithm correctly returns "no" assuming $\mathcal{I}'$ is a ψ-PR (resp. (ψ, ϵ)-PR) instance. If there is a feasible solution for $\mathcal{I}$ with dilation α', then with k_i balls of radius $\alpha' \cdot r_i$ for all i one can cover the input points. Thus, in that case, for the constructed instance, there is a feasible solution with dilation 1. Hence, $\mathcal{A}$ correctly returns "yes" assuming $\mathcal{I}'$ is ψ-PR (resp. (ψ, ϵ)-PR). Thus, when $\alpha' = \alpha$, $\mathcal{A}$ returns "yes" and the returned clustering is optimal for $\mathcal{I}$. Now, we prove the claim.

▷ Claim 6. $\mathcal{I}'$ is a ψ-PR (resp. (ψ, ϵ)-PR) instance.

Proof. First, we show that the optimal clustering of $\mathcal{I}'$ is unique. Note that the optimal dilation of $\mathcal{I}'$ is α/α'. Suppose optimal clustering of $\mathcal{I}'$ is not unique. Then, there are two different clusterings where the points can be covered using k_i balls of radius $(\alpha/\alpha') \cdot \alpha' \cdot r_i = \alpha \cdot r_i$ from each class i. It follows that there are two different optimal clusterings for $\mathcal{I}$. But, this is a contradiction, and thus the optimal clustering of $\mathcal{I}'$ is unique. Note that the optimal clusterings of $\mathcal{I}$ and $\mathcal{I}'$ are identical. Let $\mathcal{C}$ be that clustering. Now, consider any ψ-perturbation d_1 of the input metric d and the ψ perturbed instance $\mathcal{I}'_1$ of $\mathcal{I}'$. Let $\mathcal{I}_1 = (P, d_1, t)$ be the corresponding ψ perturbed instance of $\mathcal{I}$. Also, let $\mathcal{C}'_1$ be the optimal clustering of $\mathcal{I}'_1$ with dilation α'_1. For the sake of contradiction, suppose $\mathcal{C}'_1$ is not identical (resp. ϵ-close) to $\mathcal{C}$. We argue that $\mathcal{C}'_1$ is also an optimal clustering of $\mathcal{I}_1$. But, this is a contradiction, as $\mathcal{I}_1$ is a ψ perturbed instance of $\mathcal{I}$ and $\mathcal{I}$ is a ψ-PR (resp. (ψ, ϵ)-PR) instance. Now, note that a placement that induces the clustering $\mathcal{C}'_1$ of $\mathcal{I}'_1$ uses k_i balls of radius $\alpha'_1 \cdot \alpha' \cdot r_i$ from each class i. Thus, $\mathcal{C}'_1$ is a clustering for $\mathcal{I}_1$ with dilation $\alpha'_1 \cdot \alpha'$. It is sufficient to argue that this dilation is optimal for $\mathcal{I}_1$. Suppose the optimal dilation is $< \alpha'_1 \cdot \alpha'$. Then, using k_i balls of radius $< \alpha'_1 \cdot \alpha' \cdot r_i$ from each class i all the points can be covered. Hence, there is a clustering for $\mathcal{I}'_1$ with dilation $< \alpha'_1$, which is a contradiction, and hence the claim follows. ◁

Finally, as the number of guesses for α is a polynomial, the procedure terminates in polynomial time. ◀

3 Properties of Perturbation Resilience

In this section, we show that perturbation resilience imposes useful structure on the optimal solution. First, we consider the instances under (ψ, ϵ)-perturbation resilience with $\psi = 3$ and prove an interesting property of the optimal clustering.

▶ **Lemma 7.** *Consider any optimal placement* Π *for a* $(3, \epsilon)$*-PR NUkC instance* $\mathcal{I} = (P, d, t)$ *with optimal dilation 1 where the size of each optimal cluster is* $> \epsilon n + 1$*. Let* C_1 *and* C_2 *be two clusters induced by two balls of* Π *with radii* r_i *and* r_j*, respectively with* $r_i \geq r_j$*. Then, for any* $p \in C_1$ *and* $q \in C_2$*,* $d(p, q) > r_i$*.*

Proof. Let $\mathcal{O}$ be an optimal clustering of $\mathcal{I}$ that is induced by Π and contains C_1, C_2 as clusters. For the sake of contradiction, suppose there are two points $p \in C_1$ and $q \in C_2$ such that $d(p, q) \leq r_i$. Then, we show that there is a 3-perturbation d' of d such that an optimal clustering of $\mathcal{I}' = (P, d', t)$ is not ϵ-close to $\mathcal{O}$. But, this gives a contradiction to the assumption that $\mathcal{I}$ is a $(3, \epsilon)$-PR instance, and hence the lemma follows.

To construct the 3-perturbation d' of d, we at first construct another metric d_1. Later we will scale d_1 to construct d'. Let $B_1 = B(c_1, r_i)$ and $B_2 = B(c_2, r_j)$ be the balls in Π that induce C_1 and C_2, respectively. Then, for any $s \in C_2$, $d(p,s) \leq d(p,q) + d(q,s) \leq r_i + 2r_j \leq 3r_i$. Also, for any $w \in C_1$, $d(p,w) \leq 2r_i$. First, we construct a complete graph G with vertex set equal to P, and for any edge (u,v), its length is defined by the function l as follows.

$$l(u,v) = \begin{cases} 3r_i & \text{if } u = p, v \in (C_1 \cup C_2) \setminus \{c_1\} \text{ and } d(u,v) \geq r_i \\ 3 \cdot d(u,v) & \text{otherwise} \end{cases}$$

The distance d_1 is the shortest path metric on G. Note that, as mentioned before, for any $v \in (C_1 \cup C_2) \setminus \{c_1\}$, $d(p,v) \leq 3r_i$. Thus, it is not hard to see that, for any $u, v \in P$, $d(u,v) \leq d_1(u,v) \leq 3 \cdot d(u,v)$. Now, let us define the metric d'. For any two points u, v, $d'(u,v) = d_1(u,v)/3$. Hence, for any $u, v \in P$, $d(u,v)/3 \leq d'(u,v) \leq d(u,v)$. It follows that d' is a metric 3-perturbation of d, and thus the optimal clustering of $\mathcal{I}'$ is ϵ-close to $\mathcal{O}$.

Now, let $\mathcal{I}_1 = (P, d_1, t)$ and $\mathcal{O}_1$ be an optimal clustering of $\mathcal{I}_1$. As scaling does not change optimality of a clustering (for a formal proof see the proof of Lemma 5), $\mathcal{O}_1$ is also an optimal clustering of the instance $\mathcal{I}' = (P, d', t)$. Thus $\mathcal{O}_1$ is ϵ-close to $\mathcal{O}$. Next, we prove the following claim.

▷ Claim 8. The optimal dilation of $\mathcal{I}_1$ is 3.

Proof. As for any $u, v \in V$, $d_1(u,v) \leq 3 \cdot d(u,v)$, the optimal dilation of $\mathcal{I}_1$ is at most 3. We prove that this dilation is at least 3. Suppose the dilation is less than 3. Let Π' be any placement with dilation less than 3 that induces the optimal clustering $\mathcal{O}_1$ of $\mathcal{I}_1$. Then, we show that $\mathcal{O}_1$ is also a feasible clustering of $\mathcal{I}$ with dilation less than 1. But, this is a contradiction, and hence the claim follows. Next, given Π', we show the existence of a placement for $\mathcal{I}$ with dilation less than 1 that induces $\mathcal{O}_1$.

Consider any cluster $C' \in \mathcal{O}_1$, and suppose it gets covered by an r_l-ball $B = B(w, r)$ in Π'. Let x be any point in C'. Now, consider the distance d_1. Let π be any shortest path between w and x. We claim that π cannot contain the edge (p,v) for any $v \in (C_1 \cup C_2) \setminus \{c_1\}$ with $d(p,v) \geq r_i$. For the sake of contradiction, say π contains (p,v). Note that $d_1(p,v) = 3r_i$. As π contains (p,v), $d_1(w,p) \leq r - 3r_i$. Now, consider any point $u \in (C_1 \cup C_2) \setminus \{c_1\}$. If $d(p,u) \geq r_i$, $d_1(p,u) = 3r_i$. Otherwise, $d(p,u) < r_i$, and thus $d_1(p,u) = 3 \cdot d(p,u) < 3r_i$. Thus, $d_1(w,u) \leq d_1(w,p) + d_1(p,u) \leq r$. Hence, all the points of $(C_1 \cup C_2) \setminus \{c_1\}$ are in B. But, as C_1, C_2 contain more than $\epsilon n + 1$ points, it follows that there is an optimal clustering of $\mathcal{I}_1$ that is not ϵ-close to $\mathcal{O}$. Thus, we get a contradiction. Hence, π does not contain (p,v), and thus from the definition of the metric d_1, it follows that $d_1(w,x) = 3 \cdot d(w,x)$. Thus, a ball centered at w and having radius $r/3$ can cover the points of C' in $\mathcal{I}$. Now, note that $r < 3r_l$, and thus $r/3 < r_l$. Hence, it is sufficient to use an r_l-ball with less than 1 factor expansion to cover the points of C' in $\mathcal{I}$. In our new placement for $\mathcal{I}$, we use the r_l-ball $B(w, r/3)$ corresponding to each such cluster C'. Clearly, the dilation of the new placement is less than 1. ◁

Now, we show a clustering $\mathcal{O}_2$ of $\mathcal{I}_1$ that contains exactly k clusters, has dilation 3 and is not ϵ-close to $\mathcal{O}$. $\mathcal{O}_2$ contains all the clusters in $\mathcal{O}$ except C_1 and C_2, and the clusters $(C_1 \cup C_2) \setminus \{c_1\}, \{c_1\}$. Note that for any $s \in (C_1 \cup C_2) \setminus \{c_1\}$, $d(p,s) \leq 3r_i$. Thus, $(C_1 \cup C_2) \setminus \{c_1\}$ can be covered by a ball of radius $3r_i$. It follows that the dilation of $\mathcal{O}_2$ is at most 3 and hence it is an optimal clustering. Clearly, the two clusterings $\mathcal{O}$ and $\mathcal{O}_2$ differ in $> \epsilon n$ points, as $|C_1| > \epsilon n + 1$ and $|C_2| > \epsilon n + 1$. Now, for the same reason mentioned before, $\mathcal{O}_2$ is also an optimal clustering of the instance $\mathcal{I}' = (P, d', t)$. Hence, d' is the desired 3-perturbation. This completes the proof of the lemma. ◀

In the proof of the above lemma, one could have defined d' directly without going via d_1. However, for simplicity of exposition, we have followed this approach. Indeed, this approach shows that if one defines ψ-perturbation by increasing the (instead of decreasing) distances, the lemma still holds. A proof can directly use the 3-perturbation d_1 in that case.

Note that, as a 3-PR instance is also a $(3,0)$-PR instance, the above lemma trivially follows for 3-PR instances. In the following, we will show that the above mentioned property of the optimal clustering follows even for any 2-PR instance.

▶ **Lemma 9.** *Consider any optimal placement* Π *for a 2-PR NUkC instance* $\mathcal{I} = (P, d, t)$ *with optimal dilation 1. Let* C_1 *and* C_2 *be two clusters induced by two balls of* Π *with radius* r_i *and* r_j*, respectively, where* $r_i \geq r_j$*. Then, for any* $p \in C_1$ *and* $q \in C_2$*,* $d(p,q) > r_i$*.*

Proof. Let $\mathcal{O}$ be the optimal clustering induced by the placement Π. Also, let B_1 and B_2 be the balls that induce the clusters C_1 and C_2, respectively. For the sake of contradiction, suppose there exist two points $p \in C_1$, $q \in C_2$ such that $d(p,q) \leq r_i$. The idea is to show that there is a metric d_1 that is a 2-perturbation of d such that $\mathcal{I}' = (P, d_1, t)$ has different optimal clustering than $\mathcal{O}$. But, this is a contradiction, and thus the lemma follows.

Let c_t be the center of the ball B_t for $t \in \{1,2\}$. Then, $d(c_1,q) \leq d(c_1,p) + d(p,q) \leq 2r_i$. We define the distance function d_1 in the following way. First, we construct the complete graph with vertex set equal to P, and for any edge (u,v), its length is defined by the function l.

$$l(u,v) = \begin{cases} \min\{d(u,v), r_i\} & \text{if } u = c_1 \text{ and } v = q \\ d(u,v) & \text{otherwise} \end{cases}$$

We note that, for any u, v, $d(u,v)/2 \leq l(u,v) \leq d(u,v)$. The distance function d_1 is defined by the shortest path distance between any pair of vertices. It is not hard to verify the following observation.

▶ **Observation 10.** d_1 *is a metric* 2*-perturbation of* d*.*

Hence, the instance $\mathcal{I}' = (P, d_1, t)$ has the same optimal clustering $\mathcal{O}$. Next, we prove a claim that the optimal dilation of $\mathcal{I}'$ is also 1.

▷ Claim 11. The optimal dilation of $\mathcal{I}'$ is 1.

Proof. As for any $u, v \in V$, $d_1(u,v) \leq d(u,v)$, the optimal dilation of $\mathcal{I}'$ is at most 1. We prove that this dilation is at least 1. Suppose the dilation is less than 1. Let Π' be any placement with dilation less than 1 that induces the clustering $\mathcal{O}$ of $\mathcal{I}'$. Then, we show that there is a placement for $\mathcal{I}$ with dilation less than 1. But, this is a contradiction, and hence the claim follows. Consider any cluster $C \in \mathcal{O}$ that gets covered by an r_t-ball $B = B(w,r)$ in Π'. Let x be any point in C. Now, consider the distance d_1. Let π be any shortest path between w and x. We claim that π cannot contain the edge (c_1, q). For the sake of contradiction, say π contains (c_1, q). But, this implies $d_1(w,c_1) \leq d_1(w,x) \leq r$ and $d_1(w,q) \leq d_1(w,x) \leq r$. Thus, B contains both c_1 and q. Now, by the first property of Observation 4, c_1 belongs to C_1. Thus, by the second property of Observation 4, we obtain a contradiction, as $q \in C_2$. Hence, π does not contain (c_1, q). It follows that $d_1(w,x) \geq d(w,x)$. Thus, the radius of the ball needed to cover the points of C in $\mathcal{I}$ is at most r. Hence, it is sufficient to use an r_t-ball with at most $r/r_t < 1$ factor expansion to cover the points of C in $\mathcal{I}$. Now, we construct a placement for $\mathcal{I}$ by selecting the same balls to cover the clusters that are used in Π'. Clearly, the dilation of this placement is less than 1. ◁

Next, we show that there is a different clustering $\mathcal{O}'$ of $\mathcal{I}'$ with exactly k clusters that achieves the optimal dilation. This gives rise to a contradiction, and thus $d(p,q) > r_i$. Now, there are two cases. In the first case, q is the only point in C_2, and thus $C_2 \setminus \{q\}$ is empty. In this case, we pick a non-singleton cluster C from $\mathcal{O} \setminus \{C_1\}$ and choose a point $s \in C$. Such a cluster exists WLOG. Then, we define $\mathcal{O}'$ to be the set of clusters in $\mathcal{O}$ except C, C_1 and C_2, and the clusters $C_1 \cup \{q\}, \{s\}$ and $C \setminus \{s\}$. In the second case, q is not the only point in C_2, and thus $C_2 \setminus \{q\}$ is not empty. In this case, $\mathcal{O}'$ is defined to be the set of clusters in $\mathcal{O}$ except C_1 and C_2, and the clusters $C_1 \cup \{q\}, C_2 \setminus \{q\}$. It is not hard to see that $C_1 \cup \{q\}$ can be covered by the ball $B(c_1, r_i)$. Also, if $C_2 \setminus \{q\}$ is not empty, then $B(c_2, r_j)$ covers the points in $C_2 \setminus \{q\}$. Hence, in all the cases, it is trivial to verify that the dilation of the new clustering is 1. ◀

Note that, in the above proof, to show that $\mathcal{O}'$ has dilation 1, we argue that there is a placement with dilation 1. The balls in the placement might not be disjoint (both $B(c_1, r_i)$ and $B(c_2, r_j)$ cover q). But, for the sake of just showing the optimality of the clustering, it is sufficient to show the existence of such a placement.

4 NUkC with a Constant Number of Radii Classes

In this section, we show a polynomial time reduction from NUkC to the Constrained Resource Minimization for Fire Containment on Trees problem.

▶ **Definition 12** (Constrained Resource Minimization for Fire Containment on Trees (CRMFC-T))**.** *Given a rooted tree $T = (V, E)$ with height $t+1$, a set of forbidden nodes $F \subseteq V$, and integers $k_1, \ldots, k_t$, the goal is to decide if there is a collection of non-root nodes $U \subseteq (V \setminus F)$ such that (a) for every leaf-root path π, U contains at least one node from π, and (b) $|U \cap L_i| \leq k_i$ for $1 \leq i \leq t$, where L_i is the layer i nodes of T, i.e., the nodes at distance exactly i from the root.*

Given any instance $\mathcal{I} = (P, d, t)$ of NUkC under 2-PR or $(3, \epsilon)$-PR (the size of each optimal cluster is more than $\epsilon n + 1$), we will show how to construct an instance $\mathcal{I}'$ of CRMFC-T such that $\mathcal{I}$ has a feasible placement with dilation 1 iff $\mathcal{I}'$ has a feasible solution. Also, from a feasible solution for $\mathcal{I}'$, a feasible solution for $\mathcal{I}$ can be computed in polynomial time. In the constructed instance $\mathcal{I}'$, the height of the tree is one more than the number of radii classes in NUkC. We show that CRMFC-T can be solved in polynomial time if the height of the input tree is a constant. From Lemma 5, it follows that the perturbation resilient version of NUkC can be solved in polynomial time if the number of classes is a constant. Thus, we obtain the following theorem.

▶ **Theorem 13.** *NUkC under 2-PR (or $(3, \epsilon)$-PR, where the size of each optimal cluster is more than $\epsilon n + 1$) can be solved in polynomial time if the number of radii classes is a constant.*

4.1 Tree Construction

Let G be the complete graph that defines the distances between the input points. Note that we are also given the input radii $r_1 > r_2 > \ldots > r_t$. We construct the tree T in t rounds that contains t levels other than the root level. We denote the nodes at level i by L_i for $i \in \{0, \ldots, t\}$. L_0 contains a singleton node – the root of the tree. For $i \geq 1$, in i^{th} round,

we construct the nodes L_i and connect them with the nodes in L_{i-1}. Each node v in T corresponds to a connected subgraph G_v of G. The root corresponds to G itself. Also, each node is marked with either yes or no denoting if the node can be selected or it is in the forbidden set.

For each index $i \in \{1, \ldots, t\}$, in i^{th} round, we consider all the nodes $v \in L_{i-1}$ and the subgraph G_v corresponding to v. We remove all the edges with weight more than r_i from G_v. Let $G_v^1, \ldots, G_v^l$ be the connected components formed from G_v due to the removal of these edges. We add l children of v to L_i corresponding to these connected l subgraphs. For each such child u, if there is a node w in G_u, such that for all node x in G_u, $d(w, x) \leq r_i$, we label u with yes. Otherwise, we label u with no (forbidden). Lastly, for each level $i \geq 1$, the number of nodes that can be chosen from L_i in CRMFC-T is set to k_i. The following lemma establishes the connection between the two instances $\mathcal{I}$ and $\mathcal{I}'$.

▶ **Lemma 14.** *$\mathcal{I}$ has a feasible placement with dilation 1 iff $\mathcal{I}'$ has a feasible solution to CRMFC-T.*

Proof. First, suppose there is a feasible solution to $\mathcal{I}'$. For each chosen node v, v must be a yes node. Let i be the integer such that $v \in L_i$. Then, the points in G_v can be covered by an r_i ball centered at some point in G_v. We choose this ball in our placement. Note that we select at most k_i balls of radius r_i for all i. We prove that each point is covered in the constructed placement. Consider any point p. The way we construct the tree, each point can lie in the connected subgraph G_v of exactly one node v of L_j for all j. Let π be the root-leaf path in T, such that for any $v \in \pi$, p is in G_v. Now, there must be a node along π that is chosen in the solution of CRMFC-T. Let u be such a node. As we place a ball of radius r_i that covers all the points of G_u, p gets covered. Thus, $\mathcal{I}$ has a feasible placement with dilation 1.

Now, suppose $\mathcal{I}$ has a feasible placement with dilation 1. Let $\mathcal{O}$ be the clustering induced by the placement. Now, consider any cluster $C \in \mathcal{O}$, which is covered by a ball of radius r_j. Thus, c-radius$(C, d) \leq r_j$. The way the tree T is constructed it follows that all the points in C remain in the same connected subgraph G_v corresponding to a unique vertex $v \in L_i$ for each $i \leq j$. Let G_u be the subgraph corresponding to level $j-1$. As $\mathcal{I}$ is a 2-PR (resp. $(3, \epsilon)$-PR) instance, from Lemma 9 (resp. Lemma 7), we know that, for any $p \in C$ and $q \in P \setminus C$, $d(p, q) > r_j$. Thus, when the edges with weight more than r_j are removed from G_u, p and q cannot remain in the same component. But, as c-radius$(C, d) \leq r_j$ all the points of C remain in the same component. Also, by the first property of Observation 4, the center of the r_j-ball that covers C must lie in C. It follows that there is a yes node $C(v) \in L_j$ such that $G_{C(v)}$ contains only the points of C as vertices. For each cluster $C \in \mathcal{O}$, we select the yes node $C(v)$ in the solution to CRMFC-T. It is not hard to see that we choose at most k_j nodes from L_j. Now, consider any root-leaf path π in T corresponding to a leaf l. Let p be a point in G_l. Also, let p be a point in the cluster $C \in \mathcal{O}$. Then, there must be a yes node $C(v)$ in π such that $G_{C(v)}$ contains only the points of C. As we choose v in our solution, we have at least one node from the path π. Hence, the constructed solution is feasible. ◀

4.2 The Algorithm for CRMFC-T

In this section, we design a dynamic programming based algorithm that decides the feasibility of any instance of CRMFC-T. The algorithm runs in polynomial time when the height of the tree is a constant. Let T be the input tree having height t, i.e., T has $t+1$ levels $L_0, \ldots, L_t$.

L_0 contains only the root of T. Let $n_i = |L_i|$. We also assume that the nodes of L_i are ordered for all $i \geq 1$, i.e., $L_i = \{v_{i1}, \ldots, v_{in_i}\}$. For $j \leq l$, let $F(i,j,l)$ be the union of the induced subtrees of T rooted at the vertices $v_{ij}, \ldots, v_{il}$. We construct the tree $T(i,j,l)$ from $F(i,j,l)$ by connecting the roots of the subtrees to a common root.

Let feasible$(T(i,j,l), l_i, l_{i+1}, \ldots, l_t)$ be the function that decides if there is a feasible solution to CRMFC-T for the tree $T(i,j,l)$ by selecting at most l_m nodes from level m, where $i \leq m \leq t$. Note that computing the function feasible$(T = T(1,1,n_1), k_1, \ldots, k_t)$ solves the CRMFC-T problem. We consider the following recursive definition of feasible(). In the base case, if $i = t-1$, the function can be computed in polynomial time. Otherwise, if l_i is 0, let j' be the minimum index such that $v_{i+1,j'}$ is a child of v_{ij} and l' be the maximum index such that $v_{i+1,l'}$ is a child of v_{il}. In this case, feasible$(T(i,j,l), l_i, l_{i+1}, \ldots, l_t)$=feasible$(T(i+1, j', l'), l_{i+1}, \ldots, l_t)$. Otherwise, there must be a minimum index $j \leq j^1 \leq l$ such that a yes node v_{ij^1} is selected to be in the solution. For such a fixed $j < j^1 < l$, let j' be the minimum index such that $v_{i+1,j'}$ is a child of v_{ij} and l' be the maximum index such that $v_{i+1,l'}$ is a child of v_{i,j^1-1}. In this case, if there are values $l^1_{i+1}, \ldots, l^1_t, l^2_i, l^2_{i+1}, \ldots, l^2_t$ such that $l^2_i = l_i - 1$, $l_m = l^1_m + l^2_m$ for all $i+1 \leq m \leq t$, and both feasible$(T(i+1, j', l'), l^1_{i+1}, \ldots, l^1_t)$ and feasible$(T(i, j^1+1, l), l^2_i, l^2_{i+1}, \ldots, l^2_t)$ return yes, then feasible$(T(i,j,l), l_i, l_{i+1}, \ldots, l_t)$ also returns yes. Otherwise if for all j^1 there are no such values, feasible$(T(i,j,l), l_i, l_{i+1}, \ldots, l_t)$ returns no. The corner cases when $j^1 = j$ or $j^1 = l$ can be handled similarly.

It is not hard to verify that feasible$(T(i,j,l), l_i, l_{i+1}, \ldots, l_t)$ correctly decides whether there is a feasible solution or not for $T(i,j,l)$. To compute the feasible() function for all possible values one can use a simple dynamic programming based technique. In particular, one can store the values of the function for all possible parameters in a table. The table is filled up in a bottom-up manner, where the values corresponding to a level j subtree is computed before computations of the values corresponding to a level i subtree for $i < j$. It is not hard to see that the procedure would take polynomial time and space for a constant t.

5 Hardness of Approximation

In this section, we will prove the following theorem.

▶ **Theorem 15.** *For any constant c and any $\gamma \leq c^{n^c}$, NUkC under γ-PR is hard to approximate in polynomial time within a factor of γ, unless* NP = RP.

To prove this theorem, we use a chain of reductions that involves the following problems.

1-in-3SAT [28]

INSTANCE: An ordered pair (B, C) consisting of a set B of Boolean variables and a set C of clauses over B having three literals each in conjunctive normal form.

QUESTION: Is there a truth assignment for B such that every clause in C contains exactly one true literal?

RESOURCE MINIMIZATION FOR FIRE CONTAINMENT ON TREES (RMFC-T) [18, 23]

INSTANCE: A rooted tree T and an integer m.

QUESTION: Is there a set N of non-root nodes such that every root-leaf path contains a node from N and for any integer $j \geq 1$, $|N \cap L_j| \leq m$, where L_j is the set of nodes at distance exactly j from the root?

The chain of reductions that we use consists of the following reductions: (1) 3SAT to 1-in-3SAT, (2) 1-in-3SAT to RMFC-T, and (3) RMFC-T to NUkC. Note that NUkC under PR has a unique optimal solution. As we would like to show hardness for the PR version of

NUkC, we will consider "Unambiguous" version of all these problems. For "Unambiguous" version of 3SAT and 1-in-3SAT, if an instance has a feasible solution, the solution is unique. For "Unambiguous" version of RMFC-T, if an instance has a feasible solution, the solution has a specific structure that we will define shortly. For the reduction from 3SAT to 1-in-3SAT, we ensure that the reduction preserves the number of solutions. Such a reduction is called a parsimonious reduction. To refer to the Unambiguous version of a problem we add a prefix "U-" to the problem name. Next, we discuss the details of the reductions.

In a celebrated work, Valiant and Vazirani [29] showed that U-3SAT is hard, unless NP = RP. Schaefer [28] showed a reduction from 3SAT to 1-in-3SAT to prove the NP-hardness of the latter problem. As noted in [11] the reduction is parsimonious. We use the same reduction (now from U-3SAT to U-1-in-3SAT) to prove the hardness of U-1-in-3SAT, unless NP = RP.

Next, we discuss the reduction from 1-in-3SAT to RMFC-T. First, we define the Unambiguous version of RMFC-T. For a vertex v of a rooted tree T, let leaves(T_v) be the set of leaves at the subtree rooted at v. For any two feasible solutions S_1 and S_2 of RMFC-T, S_1 and S_2 are called equivalent, if the two sets $\cup_{v\in S_1}$ { leaves(T_v)} and $\cup_{v\in S_2}$ { leaves(T_v)} are identical. U-RMFC-T is same as RMFC-T except if the input instance has more than one feasible solutions, then all the feasible solutions are pairwise equivalent. The reduction from U-1-in-3SAT to U-RMFC-T appears in the appendix. The reduction is a non-trivial adaptation of the reduction due to Finbow et al. [18] from a version of 3SAT (RESTRICTED NAE 3-SAT) to the RMFC-T problem. We summarize our finding in the following lemma.

▶ **Lemma 16.** *Given a tree T, it is not possible to distinguish between the following two cases in polynomial time, unless* NP = RP.

- ***YES**: There is a solution to the* U-RMFC-T *instance with $m = 1$.*
- ***NO**: There is no solution to the* U-RMFC-T *instance with $m = 1$.*

To complete the chain of reductions, now we discuss the last reduction. In particular, we show a reduction from RMFC-T to NUkC that proves the following theorem.

▶ **Theorem 17.** *For any constant c and any $\gamma \leq c^{n^c}$, NUkC is* NP*-hard to approximate within a factor of γ in tree metrics.*

Note that this theorem has already been proved in [13]. However, it is not straightforward to show that the instances of NUkC they construct are perturbation resilient. Using a similar construction, we will argue that the instances of NUkC to which the instances of RMFC-T map are perturbation resilient. However, to ensure that the constructed instance of NUkC has a unique optimal solution, we will consider the Unambiguous version of RMFC-T.

5.1 Proof of Theorem 17

To prove the theorem we show a reduction from U-RMFC-T. As mentioned before, the reduction is similar to the reduction used by Chakrabarty et al. [13]. The construction is as follows. Let h be the height of the tree. We set P to be the leaves of the given tree T, i.e., $P = L_h$. For any edge (u, v) of T such that $u \in L_h$ and $v \in L_{h-1}$, assign a weight $(\gamma + 1)/2$ to (u, v). For any edge (u, v) of T such that $u \in L_i$ and $v \in L_{i-1}$ for $i \leq h - 1$, assign a weight $((\gamma + 1)^{h-i+1} - (\gamma + 1)^{h-i})/2$ to (u, v). Then the distance function d is the shortest-path metric on P induced by the weights of T. We set $t = h$, $r_t = 0$ and for any $1 \leq j < t$, $r_j = (\gamma + 1)^{t-j}$. Also $k_1 = \ldots = k_t = 1$. Now we have the following observation.

▶ **Observation 18.** *For any two leaves u, u' with a common ancestor $v \in L_j$, $d(u, u') \leq r_j$.*

Proof.

$$\begin{aligned} d(u,u') &\leq d(u,v) + d(v,u') \\ &= ((\gamma+1)/2 + ((\gamma+1)^2 - (\gamma+1))/2 + \ldots + ((\gamma+1)^{h-j} - (\gamma+1)^{h-j-1})/2) + \\ &\quad ((\gamma+1)/2 + ((\gamma+1)^2 - (\gamma+1))/2 + \ldots + ((\gamma+1)^{h-j} - (\gamma+1)^{h-j-1})/2) \\ &= r_j. \end{aligned}$$

◀

We note that the weight of any edge is bounded by $(\gamma+1)^{h-1} = c^{O(n^c h)}$ and thus can be represented using $O(n^c h)$ number of bits. It follows that the construction can be done in polynomial-time. We denote the constructed instance of NUkC by I. For simplicity, we use the terms point and leaf interchangeably. The following lemma completes the proof of Theorem 17 which follows from the construction and the fact that the feasible solutions for T are pairwise equivalent.

▶ **Lemma 19.** *If T is the "YES" case of Lemma 16, then the optimum dilation of I is 1. If T is the "NO" case of Lemma 16, then the optimum dilation of I is more than γ. Moreover, I has a unique optimal clustering.*

Proof. Let T be a "YES" instance and N be a solution for T. We construct a solution for I from N as follows. For any $v \in N$, let j be the integer such that $v \in L_j$. We select a leaf u from the subtree rooted at v and place a ball of radius r_j. We note that at most 1 ball of radius r_i is selected for all i, as $|N \cap L_i| \leq 1$. Now consider any point $w \in P$. Then there must be a node v in N along the path between w and the root. Let $v \in L_j$. Now the way we place the balls there must be a leaf u in the subtree rooted at v such that a ball of radius r_j is opened at u. As v is a common ancestor of u and w, from Observation 18, it follows that $d(u,w) \leq r_j$. Hence the ball $B(u, r_j)$ covers w.

Now let T be a "NO" instance and the optimum dilation of I be at most γ. Consider such a solution S corresponding to the instance I. We construct a solution N for U-RMFC-T on T using S as follows. For any $1 \leq j \leq t$, let u be the point where the ball (of radius at most γr_j) corresponding to r_j is placed. Let v be the ancestor of u that is in L_j. We add v to N. Note that, as S contains only one ball corresponding to the value r_i, $|N \cap L_i| \leq 1$ for all i. Now consider any leaf w. We show that N contains a node along the w-root path. Let B be a ball in S that covers w. Also let B be corresponding to the value r_j and is centered at the point u. Suppose v is the ancestor of u that is in L_j. As the radius of the ball at u is at most $\gamma r_j < r_{j-1}$, a point that is not contained in the subtree rooted at v cannot be covered by B. Hence w must be contained in the subtree rooted at v and thus w-root path contains $v \in N$. But this implies that N is a solution for T corresponding to the "YES" case and thus T must be a "YES" instance. But this is a contradiction and thus the optimum dilation of I must be more than γ.

As the feasible solutions for T are pairwise equivalent, it follows due to argument above that these feasible solutions get mapped to a unique optimal clustering of dilation 1. Similarly, the unique optimal clustering of dilation 1 gets mapped to a feasible solution of T. It follows that I has a unique optimal clustering. ◀

5.2 Hardness of Perturbation Resilient Version of NUkC

To show the hardness of the γ-perturbation-resilient version of NUkC, we prove that the constructed instances of U-NUkC in the reduction from U-RMFC-T to U-NUkC in tree metrics are γ-PR. First, we remind the reader of the tree metric d^* we used there. We are given a parameter γ and a tree T_γ with height h whose leaves are at the same distance from the root. The points in the metric space correspond to all the leaves of T_γ. Let n be the

number of leaves. Also, let L_i be the nodes of T_γ at level i for $1 \leq i \leq h$. For an edge (u, v) of T such that $u \in L_h$ and $v \in L_{h-1}$, we assign a weight $l(u, v) = (\gamma + 1)/2$ to (u, v). For each $u \in L_i$, $v \in L_{i-1}$ for $i \leq h - 1$ such that (u, v) is an edge in T_γ, we assign a weight $l(u, v) = ((\gamma + 1)^{h-i+1} - (\gamma + 1)^{h-i})/2$. For any two leaves w, w', $d^*(w, w')$ is the length of the shortest path between w and w', i.e., if the least common ancestor of w, w' is in L_j, then $d^*(w, w') = (\gamma + 1)^{h-j}$. We set $t = h$, $r_t = 0$ and for any $1 \leq j < t$, $r_j = (\gamma + 1)^{t-j}$. Also, $k_1 = \ldots = k_t = 1$. Let $L(\gamma)$ be the set of leaves of T_γ. As the distance between any two points and the r_j's are of the form $(\gamma + 1)^i$ for some i, we have the following observation.

▶ **Observation 20.** *The optimal dilation of the instance $\mathcal{I} = \{L(\gamma), d^*, t\}$ is $(\gamma + 1)^i$ for some integer $i \geq 0$.*

As we have shown before, for any constant c and any $\gamma \leq c^{n^c}$, U-NUkC is hard to approximate within a factor of γ for the metric space (T_γ, d^*), unless NP = RP. Next, we prove the following lemma.

▶ **Lemma 21.** *The instance $\mathcal{I} = \{L(\gamma), d^*, t\}$ is γ-PR.*

Proof. Let $\mathcal{O}$ be the optimal clustering of $\mathcal{I}$ and α be its dilation. Consider any γ-perturbation d' of d^*. We prove that the optimal clustering $\mathcal{O}'$ of the instance $\mathcal{I}' = \{L(\gamma), d', t\}$ is same as $\mathcal{O}$. Suppose for the sake of contradiction that $\mathcal{O}'$ is not same as $\mathcal{O}$. As d' is a γ-perturbation (the distances are non-increasing), the dilation of $\mathcal{O}'$ is at most α. We show that $\mathcal{O}'$ is also a feasible clustering for $\mathcal{I}$ with dilation at most α.

Consider any non-singleton cluster $C \in \mathcal{O}'$ with center c_1 that is covered by an r_j-ball for $j < t$. Then, for all pairs of points $p, q \in C$, $d'(p, q) \leq \alpha r_j$. This is true, as all the points are leaves of the tree. From Observation 20, it follows that $\alpha r_j = (\gamma + 1)^i$ for some i. As d' is a γ-perturbation of d^*, $d^*(p, q) \leq \gamma \cdot d'(p, q) < (\gamma + 1)^{i+1}$. Now, the way T_γ is constructed, there is no distance values strictly between $(\gamma + 1)^i$ and $(\gamma + 1)^{i+1}$. Hence, $d^*(p, q) \leq (\gamma + 1)^i = \alpha r_j$, and the ball $B(c_1, \alpha r_j)$ covers the points of the cluster C w.r.t. d^*. It follows that $\mathcal{O}'$ is also a feasible clustering for $\mathcal{I}$ with dilation at most α. But, as per our assumption $\mathcal{O}$ and $\mathcal{O}'$ are different, and thus the optimal clustering of $\mathcal{I}$ is not unique. This is a contradiction, and hence $\mathcal{O}$ and $\mathcal{O}'$ must be same. ◀

5.3 Hardness in Euclidean Metric

▶ **Theorem 22.** *For any constant κ and any $\beta \leq \kappa^{n^\kappa}$, NUkC under β-PR is hard to approximate within a factor of β in the Euclidean metric of dimension d for any $d \geq 1$, unless* NP = RP.

This result is in turn based on the following theorem due to Gupta [21].

▶ **Theorem 23** ([21])**.** *Any weighted tree T with L leaves can be embedded in polynomial-time into d-dimensional Euclidean space with $O(dL^{1/(d-1)} \min\{\log L, d\}^{1/2})$ distortion.*

The idea is to show that if there is a polynomial-time β-approximation for NUkC under β-PR in the Euclidean metric for any constant κ and any $\beta \leq \kappa^{n^\kappa}$, then there is also a polynomial-time γ-approximation for NUkC under γ-PR in tree metrics for any $\gamma \leq c^{n^c}$, where c is a constant. But, by Theorem 15 this is a contradiction, and hence the proof of the theorem follows. To obtain the γ-approximation in tree metrics we embed the tree metric into Euclidean metric of dimension d using the algorithm of Theorem 23. Then, we use the algorithm for Euclidean metric to obtain a solution for the embedded instance. Lastly, we map this solution back to the tree metric with sufficient expansion of the balls. For a suitable choice of β, one can show that the constructed solution is a γ-approximation. The details are given in the appendix.

A Examples demonstrating the definition of perturbation resilience

For more clarity, we describe the notion of ψ-perturbation-resilience in the context of NUkC using two examples in Figure 2 (top-left and bottom-left). In all our examples, the number of clusters $k = 2$ and the number of radii classes $t = 1$. For the instance shown at the top-left figure, let $r_1 = 10$. We claim that this instance is 2-perturbation-resilient. To see this note that here the optimal dilation is 1, and the optimal clusters are $\{a, c\}$ and $\{b, d\}$. Moreover, even if all the distances are perturbed by a factor of 2, the distance between a and c (resp. b and d) can be at most 10. Hence, the dilation of the previous clustering for the perturbed instance would be at most 1. But, as all the distances between a and b, a and d, c and b, and c and d are 50, in any 2-perturbation of the distances, the distance between the two points in any of these four pairs would be at least 25. Thus if both of the points in such a pair remain in same cluster, the dilation must be at least 2.5. As there is a clustering of dilation at most 1, in optimal clustering, both of these points cannot lie in the same cluster. Hence, the optimal clustering is unique and same as the one before. The top-right figure shows a 2-perturbed instance with the same optimal clustering. Now, consider the instance in the bottom-left figure. Let $r_1 = 15$. We claim that this instance is not 2-perturbation-resilient. To prove this we show a 2-perturbed instance where the optimal clustering is different. Note that in the original instance, the optimal dilation is 1, and the optimal clusters are $\{a, c\}$ and

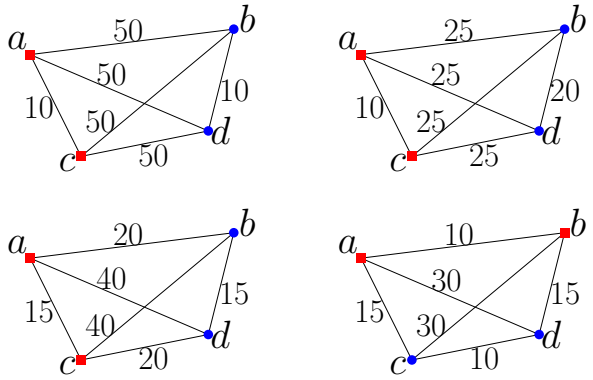

Figure 2 Examples demonstrating the definition of perturbation resilience. The top-right (resp. bottom-right) instance is a 2-perturbed instance of the top-left (resp. bottom-left) instance. The points in same optimal cluster are shown by same shape and color.

$\{b, d\}$. The 2-perturbed instance we consider is shown in the bottom-right figure. Note that in the perturbed instance the optimal clustering is $\{\{a, b\}, \{c, d\}\}$ with dilation 10/15=2/3. This is because any other clustering has a dilation at least 1.

B Reduction from 1-in-3SAT to RMFC-T

Finbow et al. [18] showed a reduction from Restricted NAE 3-SAT to RMFC-T. As per the definition of Restricted NAE 3-SAT, if the input instance has a feasible assignment, then it must at least have two. Thus, it cannot have a unique feasible solution. This is the reason behind our selection of the problem 1-in-3SAT, which can have a unique feasible solution. However, the reduction is motivated by the one in [18]. For consistency, we borrow some of their notations.

Given an instance I of 1-in-3SAT, we construct a rooted tree T with root r in multiple steps. Also, we choose the parameter $m = 1$. Before discussing the reduction, we have a few definitions to set up the stage. Throughout this discussion, we will use the operation *root* a copy of a rooted tree (T, r) at a vertex x of a graph G. This means we construct a new graph from the disjoint union of G and T by identifying x and r. A vertex v of a tree is said to be *defended* by a vertex u if the root to v path contains u. For any path, we assume that its root is one of the degree one vertices. Also, the length of a path is defined as the number of edges contained in it.

A *ladder tree* $\mathscr{L}^T(n)$ is a path having $2n + 1$ vertices such that the middle vertex of the path is identified as the root of the tree. See Figure 3(i). Thus, the root of $\mathscr{L}^T(n)$ has two branches each being a path of length n. A *bell tree* $\mathscr{B}^T(n, m)$ is formed by rooting a ladder tree $\mathscr{L}^T(n - m)$ at an endpoint of a path having m edges. The other endpoint of the path becomes the root of the bell tree. See Figure 3(ii). Thus, in the figure, the distance (in terms of edges) between a and b is m and the distance between a and a leaf is n. A *snake tree* $\mathscr{S}^T(n, m)$ is formed by rooting an $m - 1$ length path at the root of a bell tree $\mathscr{B}^T(n, m + 1)$. The root of the bell tree (or the path) becomes the root of the snake tree. Note that a snake tree has exactly one degree 3 vertex. See Figure 3(iii). Thus, in the figure, the distance between a and b is m, and the length of the path between a and a leaf such that the path contains b is n. A rooted tree T is called full if all leaves occur at the same level. A rooted tree T is called complete if every internal vertex has exactly two children. One simple observation is that a complete and full binary tree of height $h \geq 0$ has $2^{h+1} - 1$ vertices, and among those 2^h are leaves.

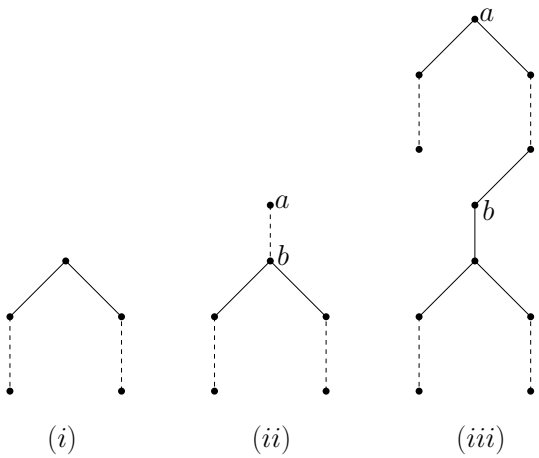

Figure 3 (i) A ladder tree. (ii) A bell tree. (iii) A snake tree. Dashed segments denote paths.

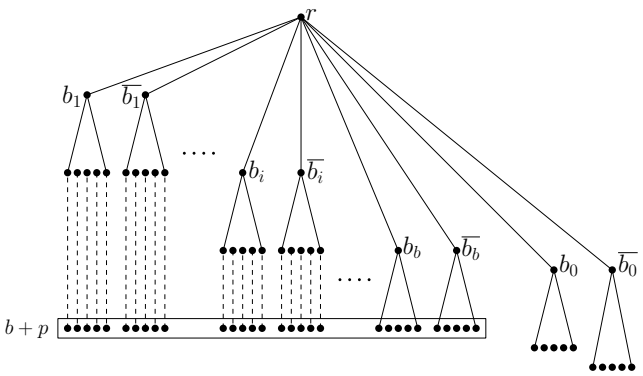

Figure 4 Figure showing the constructed tree after the first phase.

Now, we describe the construction. We are given the 1-in-3SAT instance $I=(B,C)$ with the set of variables $B = \{b_1, \ldots, b_b\}$ and the set of clauses $C = \{C_1, \ldots, C_n\}$. Let $p = \lceil \log n \rceil + 2$. Thus, $2^p \geq 4n$. We are going to construct a tree T which is initialized to the root vertex r. For each $1 \leq i \leq b$, root two paths of length i at the root r of T. Call the degree one vertices of these two paths b_i and $\overline{b_i}$. Root a complete and full binary tree of height p at b_i and $\overline{b_i}$ for each i. From each leaf of these trees root a path of length $b-i$. Call the leaves of these paths $t_{b_i,1}, \ldots, t_{b_i,2^p}$ and $t_{\overline{b_i},1}, \ldots, t_{\overline{b_i},2^p}$. Note that all the leaf nodes are now at a distance $b+p$ from r. Root two paths of length $b+1$ at r, and call the degree one vertices of these paths b_0 and $\overline{b_0}$. So far the construction is exactly the same as the one in [18]. In the following, we modify their construction to adapt it for our setting. From b_0 and $\overline{b_0}$ root a complete and full binary tree of height p and $p+1$, respectively, and call their leaves $t_{b_0,1}, \ldots, t_{b_0,2^p}$ and $t_{\overline{b_0},1}, \ldots, t_{\overline{b_0},2^{p+1}}$. This completes the first phase of the construction (see Figure 4).

In the second phase, we add clause gadgets by rooting special tree structures at the leaves of T constructed so far. For each $1 \leq j \leq n$, and for each literal l of C_j, root the snake tree $\mathscr{S}^T(4n+3, 4j-2)$ at $t_{\bar{l},j}$. For $1 \leq \tau \leq 3$, let q be the τ^{th} literal of C_j. Root $\mathscr{S}^T(4n+3, 4j-2+\tau)$ at $t_{q,j}$. Also, root the bell tree $\mathscr{B}^T(4n+3, 4j+1)$ at r for each $1 \leq j \leq n$. For $1 \leq i \leq 2^p$, add two children x_i and y_i of $t_{b_0,i}$. In each such added child,

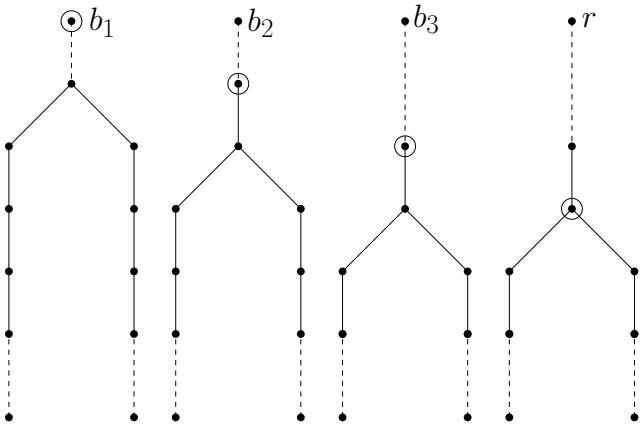

Figure 5 Figure showing parts of the three snake trees and the bell tree corresponding to the literals of C_j. The circled vertices are selected in the solution.

root the ladder tree $\mathscr{L}^T(4n+1)$. For $1 \leq i \leq 2^{p+1}$, add two children $\overline{x_i}$ and $\overline{y_i}$ of $t_{\overline{b_0},i}$. In each such added child, root the ladder $\mathscr{L}^T(4n)$. At each remaining leaf of T (as mentioned before) where no tree structure has been rooted so far, root $\mathscr{L}^T(4n+3)$. This completes the construction.

Now, let us give an intuitive description of the clause gadgets. Note that our main goal is to defend all the leaves. Consider the clause $C_j = (b_1 \vee b_2 \vee b_3)$. In a feasible solution, exactly one literal of C_j must be true, say b_1. Now suppose in the solution of U-RMFC-T we select the vertices corresponding to true literals, i.e., b_1, $\overline{b_2}$ and $\overline{b_3}$. Note that we have added one snake tree corresponding to each complemented literal of C_j. Thus, all the vertices in the snake trees corresponding to $\overline{b_2}$ and $\overline{b_3}$ are already defended. In this case, we can defend the degree three vertex (and all of its descendants) of the snake tree corresponding to $\overline{b_1}$ by choosing the degree three vertex itself. If more than one literal are true, then we need to defend vertices of at least two snake trees instead for which we would have to pick more than one vertices from a level. Now, we have also added three other snake trees one for each literal of C_j. As the snake tree corresponding to b_1 is already defended by b_1, we just need to defend the leaves of the remaining two. We can defend them by selecting the parent of the degree three vertex from the corresponding snake tree. In this way, we can also defend the last added bell tree by selecting its degree three vertex (see Figure 5). The alignments of these degree three vertices and their parents help us pick them in different levels. Note that if none of the literals are true, then we would need to defend the leaves of the three snake trees corresponding to the literals and in that case it is not possible to defend the leaves of the bell tree corresponding to C_j.

The argument behind the correctness of the reduction is similar to the one in [18]. The forward direction is simple. First, defend the vertices corresponding to true literals, i.e., if b_i (resp. $\overline{b_i}$) is true, defend b_i (resp. $\overline{b_i}$) at time i for $1 \leq i \leq b$. At time $b+1$, defend $\overline{b_0}$. From time $b+2$ to $b+p+1$, defend the unprotected descendant of b_0 which is not on the path from r to x_1. At time $b+p+2$, defend x_1. From time $b+p+3$ to $b+p+4n+3$, defend the tree greedily by picking a vertex at each level that contains the maximum number of nodes in the subtree rooted at it. The other direction is nontrivial, but similar counting arguments as in [18] should be used for the proof. It follows that the 1-in-3SAT formula is satisfiable if and only if all the leaves of T can be defended by selecting exactly one vertex from each level.

Finally, we show that all the feasible solutions are pairwise equivalent as claimed. This actually follows from the construction. Fix the unique feasible assignment to the 1-in-3SAT formula. Then, while finding a feasible solution for U-RMFC-T from the assignment in the above, in all the steps one need to select a unique vertex except when one needs to choose the parent of the degree three vertices of $\mathscr{S}^T(4n+3, 4j+1)$ and $\mathscr{B}^T(4n+3, 4j+1)$ both of which lie at the same level. However, irrespective of the selection, the set of leaves remains same. Thus, even though the solutions are different, the corresponding sets of leaves are same, and hence the solutions are pairwise equivalent.

C Hardness in Euclidean Metric

Let X and Y be two finite metric spaces with metrics d and d', respectively. Let $f : X \to Y$ be a map. Then, the *contraction* of f is defined as,

$$D_c(f) = \max_{x,y \in X} \frac{d(x,y)}{d'(f(x), f(y))}.$$

The *expansion* of f is similarly defined as,

$$D_e(f) = \max_{x,y \in X} \frac{d'(f(x), f(y))}{d(x,y)}.$$

The *distortion* of f, $D(f) = D_c(f) \cdot D_e(f)$. We need Theorem 23 due to Gupta [21] for proving the hardness result. Next, we prove Theorem 22.

Proof. Suppose there is a polynomial-time β-approximation for NUkC under β-PR in the Euclidean metric for any constant κ and any $\beta \leq \kappa^{n^\kappa}$. Then, we show that there is a polynomial-time γ-approximation for NUkC under γ-PR in tree metrics for any $\gamma \leq c^{n^c}$, where c is a constant. But, by Theorem 15 this is a contradiction, and hence the proof of the theorem follows.

Now, consider a constant c and any $\gamma \leq c^{n^c}$. Also, consider any instance of NUkC under γ-PR in the tree metric induced by the weighted tree T. We show how to get a γ-approximate solution for T using the approximation algorithm for the Euclidean metric. Let $\Delta = O(dn^{1/(d-1)} \log n)$. First, we embed the tree T into d-dimensional Euclidean space $\mathbb{R}^d$ using the algorithm of Theorem 23. Let $f : T \to \mathbb{R}^d$ be the embedding. Also, let d and d_f denote the tree and the Euclidean metric, respectively. We fix β such that $\beta \leq \gamma/\Delta$, and compute a β-approximate solution S of NUkC under β-PR for the Euclidean instance. Thereafter, we construct a solution S' for the problem on T from the solution S in the following way. For any node x of T, if S contains a ball centered at $f(x)$ with radius r, then we add the ball at x of radius $D_c(f) \cdot r$ to S', where $D_c(f)$ is the contraction of f. First, we show that the solution S' constructed in this way covers all the nodes of T. Consider any node x of T. Then, there is a ball in S centered at some point $f(y)$ that covers $f(x)$. Let r be the radius of this ball. It follows that S' contains the ball B centered at y having radius $D_c(f) \cdot r$. Now,

$$d(x,y) \leq D_c(f) \cdot d_f(f(x), f(y)) \leq D_c(f) \cdot r.$$

Hence, the ball B contains x, and thus S' is a feasible solution. Now, we show that the dilation $\alpha(S')$ of the balls in S' is at most γ times the optimum dilation. To this end, let OPT and OPT_f be the optimum dilation for the tree and the Euclidean instance, respectively.

Then, the dilation $\alpha(S')$ is at most $\beta \cdot OPT_f \cdot D_c(f)$. Now, as the distances between the points can get expanded by a factor of at most $D_e(f)$ due to the embedding, $OPT_f \leq D_e(f) \cdot OPT$. Here $D_e(f)$ is the expansion of f. Hence,

$$\alpha(S') \leq \beta \cdot D_e(f) \cdot OPT \cdot D_c(f) = \beta \cdot D(f) \cdot OPT \leq \beta \cdot \Delta \cdot OPT \leq \gamma \cdot OPT.$$

This completes the proof of the theorem. ◀

Low-Rank Binary Matrix Approximation in Column-Sum Norm

Abstract

We consider ℓ_1-Rank-r Approximation over GF(2), where for a binary $m \times n$ matrix $\mathbf{A}$ and a positive integer constant r, one seeks a binary matrix $\mathbf{B}$ of rank at most r, minimizing the column-sum norm $\|\mathbf{A}-\mathbf{B}\|_1$. We show that for every $\varepsilon \in (0,1)$, there is a randomized $(1+\varepsilon)$-approximation algorithm for ℓ_1-Rank-r Approximation over GF(2) of running time $m^{\mathcal{O}(1)}n^{\mathcal{O}(2^{4r}\cdot\varepsilon^{-4})}$. This is the first polynomial time approximation scheme (PTAS) for this problem.

1 Introduction

Low-rank matrix approximation is the method of compressing a matrix by reducing its dimension. It is the basic component of various methods in data analysis including Principal Component Analysis (PCA), one of the most popular and successful techniques used for dimension reduction in data analysis and machine learning [31, 15, 8]. In low-rank matrix approximation one seeks the best low-rank approximation of data matrix $\mathbf{A}$ with matrix $\mathbf{B}$ solving

$$\begin{aligned} &\text{minimize } \|\mathbf{A}-\mathbf{B}\|_\nu \\ &\text{subject to } \operatorname{rank}(\mathbf{B}) \leq r. \end{aligned} \tag{1}$$

Here $\|\cdot\|_\nu$ is some matrix norm. The most popular matrix norms studied in the literature are the *Frobenius* $||\mathbf{A}||_F^2 = \sum_{i,j} a_{ij}^2$ and the *spectral* $\|\mathbf{A}\|_2 = \sup_{x\neq 0} \frac{\|\mathbf{Ax}\|_2}{\|\mathbf{x}\|_2}$ norms. By the Eckart-Young-Mirsky theorem [8, 27], (1) is efficiently solvable via Singular Value Decomposition (SVD) for these two norms. The spectral norm is an "extremal" norm – it measures the worst-case stretch of the matrix. On the other hand, the Frobenius norm is "averaging". Spectral norm is usually applied in the situation when one is interested in actual columns for the subspaces they define and is of greater interest in scientific computing and numerical linear algebra. The Frobenius norm is widely used in statistics and machine learning, see the survey of Mahony [24] for further discussions.

Recently there has been considerable interest in developing algorithms for low-rank matrix approximation problems for binary (categorical) data. Such variants of dimension reduction for high-dimensional data sets with binary attributes arise naturally in applications involving binary data sets, like latent semantic analysis [4], pattern discovery for gene expression[32], or web search models [19], see [7, 17, 14, 20, 30, 37] for other applications. In many such applications it is much more desirable to approximate a binary matrix $\mathbf{A}$ with a binary matrix $\mathbf{B}$ of small (GF(2) or Boolean) rank because it could provide a deeper insight into the semantics associated with the original matrix. There is a big body of work done on binary and Boolean low-rank matrix approximation, see [2, 3, 7, 22, 25, 26, 28, 35, 34] for further discussions.

Unfortunately, SVD is not applicable for the binary case which makes such problems computationally much more challenging. For a binary matrix, its squared Frobenius norm is equal to the number of its 1-entries, that is $\|\mathbf{A}\|_F^2 = \sum_{j=1}^{n}\sum_{i=1}^{m} a_{ij}$. Thus, the value $\|\mathbf{A}-\mathbf{B}\|_F^2$ measures the total Hamming distance from points (columns) of $\mathbf{A}$ to the subspace spanned by the columns of $\mathbf{B}$. For this variant of the low-rank binary matrix approximation, a number of approximation algorithms were developed, resulting in efficient polynomial time approximation schemes (EPTASes) obtained in [1, 9]. However, the algorithmic complexity of the problem for any vector-induced norm, including the spectral norm, remained open.

For binary matrices, the natural "extremal" norm to consider is the $\|\cdot\|_1$ norm, also known as *column-sum norm*, operator 1-norm, or Hölder matrix 1-norm. That is, for a matrix $\mathbf{A}$,

$$\|\mathbf{A}\|_1 = \sup_{\|\mathbf{x}\|_1\neq 0} \frac{\|\mathbf{Ax}\|_1}{\|\mathbf{x}\|_1} = \max_{1\leq j\leq n} \sum_{i=1}^{m} |a_{ij}|.$$

In other words, the column-sum norm is the maximum number of 1-entries in a column in $\mathbf{A}$, whereas the Frobenius norm is the total number of 1-entries in $\mathbf{A}$. The column-sum norm is analogous to the spectral norm, only it is induced by the ℓ_1 vector norm, not the ℓ_2 vector norm.

We consider the problem, where for an $m\times n$ binary data matrix $\mathbf{A}$ and a positive integer constant r, one seeks a binary matrix $\mathbf{B}$ optimizing

$$\begin{aligned} &\text{minimize } \|\mathbf{A}-\mathbf{B}\|_1 \\ &\text{subject to } \operatorname{rank}(\mathbf{B}) \leq r. \end{aligned} \tag{2}$$

Here, by the rank of the binary matrix $\mathbf{B}$ we mean its GF(2)-rank. We refer to the problem defined by (2) as to ℓ_1-Rank-r Approximation over GF(2). The value $\|\mathbf{A}-\mathbf{B}\|_1$ is the maximum Hamming distance from each of the columns of $\mathbf{A}$ to the subspace spanned by columns of $\mathbf{B}$ and thus, compared to approximation with the Frobenius norm, it could provide a more accurate dimension reduction.

It is easy to see by the reduction from the Closest String problem, that already for $r = 1$, ℓ_1-Rank-r Approximation over GF(2) is NP-hard. The main result of this paper is that (2) admits a polynomial time approximation scheme (PTAS). More precisely, we prove the following theorem.

▶ **Theorem 1.** *For every $\varepsilon \in (0, 1)$, there is a randomized $(1 + \varepsilon)$-approximation algorithm for ℓ_1-Rank-r Approximation over GF(2) of running time $m^{\mathcal{O}(1)} n^{\mathcal{O}(2^{4r} \cdot \varepsilon^{-4})}$.*

In order to prove Theorem 1 we obtain a PTAS for a more general problem, namely Binary Constrained k-Center. This problem has a strong expressive power and can be used to obtain PTASes for a number of problems related to ℓ_1-Rank-r Approximation over GF(2). For example, for the variant, when the rank of the matrix $\mathbf{B}$ is not over GF(2) but is Boolean. Or a variant of clustering, where we want to partition binary vectors into groups, minimizing the maximum distance in each of the group to some subspace of small dimension. We provide discussions of other applications of our work in Section 4.

Related work. The variant of (1) with both matrices $\mathbf{A}$ and $\mathbf{B}$ binary, and $\|\cdot\|_\nu$ being the Frobenius norm, is known as Low GF(2)-Rank Approximation. Due to numerous applications, various heuristic algorithms for Low GF(2)-Rank Approximation could be found in the literature [16, 17, 11, 20, 32].

When it concerns rigorous algorithmic analysis of Low GF(2)-Rank Approximation, Gillis and Vavasis [13] and Dan et al. [7] have shown that Low GF(2)-Rank Approximation is NP-complete for every $r \geq 1$. A subset of the authors studied parameterized algorithms for Low GF(2)-Rank Approximation in [10]. The first approximation algorithm for Low GF(2)-Rank Approximation is due to Shen et al. [32], who gave a 2-approximation algorithm for the special case of $r = 1$. For rank $r > 1$, Dan et al. [7] have shown that a $(r/2 + 1 + \frac{r}{2(2^r-1)})$-approximate solution can be formed from r columns of the input matrix $\mathbf{A}$. Recently, these algorithms were significantly improved in [1, 9], where efficient polynomial time approximation schemes (EPTASes) were obtained.

Also note that for general (non-binary) matrices a significant amount of work is devoted to $L1$-PCA, where one seeks a low-rank matrix $\mathbf{B}$ approximating given matrix $\mathbf{A}$ in *entrywise* ℓ_1 norm, see e.g. [33].

While our main motivation stems from low-rank matrix approximation problems, ℓ_1-Rank-r Approximation over GF(2) extends Closest String, very well-studied problem about strings. Given a set of binary strings $S = \{s_1, s_2, \ldots, s_n\}$, each of length m, the Closest String problem is to find the smallest d and a string s of length m which is within Hamming distance d to each $s_i \in S$.

A long history of algorithmic improvements for Closest String was concluded by the PTAS of running time $n^{\mathcal{O}(\epsilon^{-5})}$ by Li, Ma, and Wang [21], which running time was later improved to $n^{\mathcal{O}(\epsilon^{-2})}$ [23]. Let us note that Closest String can be seen as a special case of ℓ_1-Rank-r Approximation over GF(2) for $r = 1$. Indeed, Closest String is exactly the variant of ℓ_1-Rank-r Approximation over GF(2), where columns of $\mathbf{A}$ are strings of S and approximating matrix $\mathbf{B}$ is required to have all columns equal. Note that in a binary matrix $\mathbf{B}$ of rank 1 all non-zero columns are equal. However, it is easy to construct an equivalent instance of Closest String by attaching to each string of S a string 1^{m+1}, such that the solution to ℓ_1-Rank-r Approximation over GF(2) for $r = 1$ does not have zero columns.

Cygan et al. [6] proved that the existence of an EPTAS for Closest String, that is $(1 + \varepsilon)$-approximation in time $n^{\mathcal{O}(1)} \cdot f(\varepsilon)$, for any computable function f, is unlikely, as it would imply that FPT=W[1], a highly unexpected collapse in the hierarchy of parameterized

complexity classes. They also showed that the existence of a PTAS for Closest String with running time $f(\varepsilon)n^{o(1/\varepsilon)}$, for any computable function f, would contradict the Exponential Time Hypothesis. The result of Cygan et al. implies that ℓ_1-Rank-r Approximation over GF(2) also does not admit EPTAS (unless FPT=W[1]) already for $r = 1$.

A generalization of Closest String, k-closest strings is also known to admit a PTAS [18, 12]. This problem corresponds to the variant of ℓ_1-Rank-r Approximation over GF(2), where approximating matrix $\mathbf{B}$ is required to have at most k different columns. However, it is not clear how solution to this special case can be adopted to solve ℓ_1-Rank-r Approximation over GF(2).

1.1 Our approach

The usual toolbox of techniques to handle NP-hard variants of low-rank matrix approximation problems like sketching [36], sampling, and dimension reduction [5] is based on randomized linear algebra. It is very unclear whether any of these techniques can be used to solve even the simplest case of ℓ_1-Rank-r Approximation over GF(2) with $r = 1$. For example for sampling, the presence of just one outlier outside of a sample, makes all information we can deduce from the sample about the column sum norm of the matrix, completely useless. This is exactly the reason why approximation algorithms for Closest String do not rely on such techniques. On the other hand, randomized dimension reduction appears to be very helpful as a "preprocessing" procedure whose application allows us to solve ℓ_1-Rank-r Approximation over GF(2) by applying linear programming techniques similar to the ones developed for the Closest String. From a very general perspective, our algorithm consists of three steps. While each of these steps is based on the previous works, the way to combine these steps, as well as the correctness proof, is a non-trivial task. We start with a high-level description of the steps and then provide more technical explanations.

Step 1. In order to solve ℓ_1-Rank-r Approximation over GF(2), we encode it as the Binary Constrained k-Center problem. This initial step is almost identical to the encoding used in [9] for Low GF(2)-Rank Approximation. Informally, Binary Constrained k-Center is defined as follows. For a given set of binary vectors X, a positive integer k, and a set of constraints, we want to find k binary vectors $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ satisfying the constraints and minimizing $\max_{\mathbf{x}\in X} d_H(\mathbf{x}, C)$, where $d_H(\mathbf{x}, C)$ is the Hamming distance between $\mathbf{x}$ and the closest vector from C. For example, when $k = 1$ and there are no constraints, then this is just the Closest String problem over binary alphabet.

In the technical description below we give a formal definition of this encoding and in Section 4 we prove that ℓ_1-Rank-r Approximation over GF(2) is a special case of Binary Constrained k-Center. Now on, we are working with Binary Constrained k-Center.

Step 2. We give an approximate Turing reduction which allows to find a partition of vector set X into clusters $X_1, \ldots, X_k$ such that if we find a tuple of vectors $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ satisfying the constraints and minimizing $\max_{1\leq i\leq k, \mathbf{x}\in X_i} d_H(\mathbf{x}, \{\mathbf{c}_i\})$, then the same tuple C will be a good approximation to Binary Constrained k-Center. In order to obtain such a partition, we use the dimension reduction technique of Ostrovsky and Rabani [29]. While this provides us with important structural information, we are not done yet. Even with a given partition, the task of finding the corresponding tuple of "closest strings" C satisfying the constraints, is non-trivial.

Step 3. In order to find the centers, we implement the approach used by Li, Ma, and Wang in [21] to solve Closest String. By brute-forcing, it is possible to reduce the solution of the problem to special instances, which loosely speaking, have a large optimum. Moreover, Binary Constrained k-Center has an Integer Programming (IP) formulation. Similar to [21], for the reduced instance of Binary Constrained k-Center (which has a "large optimum") it is possible to prove that the randomized rounding of the corresponding Linear Program (LP) relaxation of this IP, provides a good approximation.

Now we give a more technical description of the algorithm.

Step 1. Binary Constrained k-Center. Note that the Binary Constrained k-Center problem is nearly identical to Binary Constrained Clustering defined in [9], except for the cost function. Still, for completeness we define Binary Constrained k-Center formally next. First, we need to define some notations. A k-ary relation R is a set of binary k-tuples with elements from $\{0,1\}$. A k-tuple $t=(t_1,\ldots,t_k)$ *satisfies* R, we write $t\in R$, if t is equal to one of the k-tuples in R.

▶ **Definition 2** (Vectors satisfying $\mathcal{R}$). *Let $\mathcal{R}=(R_1,\ldots,R_m)$ be a tuple of k-ary relations. We say that a tuple $C=(\mathbf{c}_1,\mathbf{c}_2,\ldots,\mathbf{c}_k)$ of binary m-dimensional vectors* satisfies *$\mathcal{R}$ and write $<C,\mathcal{R}>$, if $(\mathbf{c}_1[i],\ldots,\mathbf{c}_k[i])\in R_i$ for all $i\in\{1,\ldots,m\}$.*

For example, for $m=2$, $k=3$, $R_1=\{(0,0,1),(1,0,0)\}$, and $R_2=\{(1,1,1),(1,0,1),(0,0,1)\}$, the tuple of vectors

$$\mathbf{c}_1=\begin{pmatrix}0\\1\end{pmatrix},\ \mathbf{c}_2=\begin{pmatrix}0\\0\end{pmatrix},\ \mathbf{c}_3=\begin{pmatrix}1\\1\end{pmatrix}$$

satisfies $\mathcal{R}=(R_1,R_2)$ because $(\mathbf{c}_1[1],\mathbf{c}_2[1],\mathbf{c}_3[1])=(0,0,1)\in R_1$ and $(\mathbf{c}_1[2],\mathbf{c}_2[2],\mathbf{c}_3[2])=(1,0,1)\in R_2$.

Let us recall that the *Hamming distance* between two vectors $\mathbf{x},\mathbf{y}\in\{0,1\}^m$, where $\mathbf{x}=(x_1,\ldots,x_m)^\intercal$ and $\mathbf{y}=(y_1,\ldots,y_m)^\intercal$, is $d_H(\mathbf{x},\mathbf{y})=\sum_{i=1}^m|x_i-y_i|$ or, in words, the number of positions $i\in\{1,\ldots,m\}$ where x_i and y_i differ. Recall that for a set of vectors $C\subseteq\{0,1\}^m$ and a vector $\mathbf{x}\in\{0,1\}^m$, $d_H(\mathbf{x},C)=\min_{\mathbf{c}\in C}d_H(\mathbf{x},\mathbf{c})$. For sets $X,C\subset\{0,1\}^m$, we define $\mathrm{cost}(X,C)=\max_{\mathbf{x}\in X}d_H(\mathbf{x},C)$.

Now we define Binary Constrained k-Center formally.

Binary Constrained k-Center
Input: A set $X\subseteq\{0,1\}^m$ of n vectors, a positive integer k, and a tuple of k-ary relations $\mathcal{R}=(R_1,\ldots,R_m)$.
Task: Among all tuples $C=(\mathbf{c}_1,\ldots,\mathbf{c}_k)$ of vectors from $\{0,1\}^m$ satisfying $\mathcal{R}$, find a tuple C minimizing $\mathrm{cost}(X,C)$.

As in the case of Low GF(2)-Rank Approximation in [9], we prove that ℓ_1-Rank-r Approximation over GF(2) is a special case of Binary Constrained k-Center, where $k=2^r$. For completeness, this proof and other applications of Binary Constrained k-Center are given in Section 4. Thus, to prove Theorem 1, it is enough to design a PTAS for Binary Constrained k-Center.

▶ **Theorem 3.** *There is an algorithm for Binary Constrained k-Center that given an instance $J=(X,k,\mathcal{R})$ and $0<\varepsilon<1$, runs in time $m^{\mathcal{O}(1)}n^{\mathcal{O}((k/\varepsilon)^4)}$, and outputs a $(1+\varepsilon)$-approximate solution with probability at least $1-2n^{-2}$.*

By the argument above, Theorem 1 is an immediate corollary of Theorem 3.

Step 2: Dimension reduction. Let $J = (X, k, \mathcal{R} = (R_1, \ldots, R_m))$ be an instance of Binary Constrained k-Center and $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ be a solution to J, that is, a tuple of vectors satisfying $\mathcal{R}$. Then, the cost of C is $\mathrm{cost}(X, C)$. Given the tuple C, there is a natural way we can partition the set of vectors X into k parts $X_1 \uplus \cdots \uplus X_k$ such that

$$\mathrm{cost}(X, C) = \max_{i \in \{1,\ldots,k\}, \mathbf{x} \in X_i} d_H(\mathbf{x}, \mathbf{c}_i).$$

Thus, for each vector $\mathbf{x}$ in X_i, the closest to $\mathbf{x}$ vector from C is $\mathbf{c}_i$. We call such a partition $X_1 \uplus \cdots \uplus X_k$ the *clustering of X induced by C* and refer to the sets $X_1, \ldots, X_k$ as the *clusters corresponding to C*. We use $\mathsf{OPT}(J)$ to denote the cost of an optimal solution to J. That is, $\mathsf{OPT}(J) = \min\{\mathrm{cost}(X, C) \mid < C, \mathcal{R} >\}$. In fact, even if we know the clustering of X induced by a hypothetical optimal solution, finding a good solution is not trivial as the case when $k = 1$ is the same as the Closest String problem.

As mentioned before, our approach is to reduce to a version of Binary Constrained k-Center, where we know the partition of X, and solve the corresponding problem. That is, we design an approximation scheme for the following partitioned version of the problem.

Binary Constrained Partition Center
Input: A positive integer k, a set $X \subseteq \{0,1\}^m$ of n vectors partitioned into $X_1 \uplus \ldots \uplus X_k$, and a tuple of k-ary relations $\mathcal{R} = (R_1, \ldots, R_m)$.
Task: Among all tuples $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ of vectors from $\{0,1\}^m$ satisfying $\mathcal{R}$, find a tuple C minimizing $\max_{i \in \{1,\ldots,k\}, \mathbf{x} \in X_i} d_H(\mathbf{x}, \mathbf{c}_i)$.

For an instance $J' = (k, X = X_1 \uplus \ldots \uplus X_k, \mathcal{R})$ of Binary Constrained Partition Center, we use $\mathsf{OPT}(J')$ to denote the cost of an optimal solution to J'. That is,

$$\mathsf{OPT}(J') = \min_{C=(\mathbf{c}_1,\ldots,\mathbf{c}_k) \text{ s.t. } <C,\mathcal{R}>} \left\{ \max_{i \in \{1,\ldots,k\}, \mathbf{x} \in X_i} d_H(\mathbf{x}, \mathbf{c}_i) \right\}.$$

Clearly, for an instance $J = (X, k, \mathcal{R})$ of Binary Constrained k-Center and a partition of X into $X_1 \uplus \ldots \uplus X_k$, any solution to the instance $J' = (k, X = X_1 \uplus \ldots X_k, \mathcal{R})$ of Binary Constrained Partition Center, of cost d, is also a solution to J with cost at most d. We prove that there is a randomized polynomial time algorithm that given an instance $J = (X, k, \mathcal{R})$ of Binary Constrained k-Center and $0 < \epsilon \leq \frac{1}{4}$, outputs a collection $\mathcal{I}$ of Binary Constrained Partition Center instances $J' = (k, X = X_1 \uplus \ldots \uplus X_k, \mathcal{R})$ such that the cost of at least one instance in $\mathcal{I}$ is at most $(1 + 4\epsilon)\mathsf{OPT}(J)$ with high probability.

▶ **Lemma 4.** *There is an algorithm that given an instance $J = (X, k, \mathcal{R})$ of Binary Constrained k-Center, $0 < \epsilon \leq \frac{1}{4}$, and $\gamma > 0$, runs in time $m^2 n^{\mathcal{O}(k/\epsilon^4)}$, and outputs a collection $\mathcal{I}$ of $m \cdot n^{\mathcal{O}(k/\epsilon^4)}$ instances of Binary Constrained Partition Center such that each instance in $\mathcal{I}$ is of the form $(k, X = X_1 \uplus \ldots \uplus X_k, \mathcal{R})$, and there exists $J' \in \mathcal{I}$ such that $\mathsf{OPT}(J') \leq (1 + 4\epsilon)\mathsf{OPT}(J)$ with probability at least $1 - n^{-\gamma}$.*

To prove Lemma 4, we use the dimension reduction technique of Ostrovsky and Rabani from [29]. Loosely speaking, this technique provides a linear map ψ with the following properties. For any $\mathbf{y} \in \{0,1\}^m$, $\psi(\mathbf{y})$ is a 0-1 vector of length $\mathcal{O}(\log n/\epsilon^4)$, and for any set Y of $n + k$ vectors, Hamming distances between any pair of vectors in $\psi(Y)$ are relatively preserved with high probability. So we assume that ψ is "a good map" for the set of vectors $X \cup C$, where $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ is a hypothetical optimal solution to J. Then, we guess the potential tuples of vectors $(\phi(\mathbf{c}_1), \ldots, \phi(\mathbf{c}_k))$ for the hypothetical optimal solution $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$, and use these choices for $(\phi(\mathbf{c}_1), \ldots, \phi(\mathbf{c}_k))$ to construct partitions of X, and thereby construct instances in $\mathcal{I}$. Lemma 4 is proved in Section 2.

Step 3: LP relaxation. Because of Lemma 4, to prove Theorem 3, it is enough to design a PTAS for Binary Constrained Partition Center which is more challenging part in our algorithm. So we prove the following lemma.

▶ **Lemma 5.** *There is an algorithm for Binary Constrained Partition Center that given an instance $J = (k, X = X_1^i \uplus \ldots \uplus X_k^i, \mathcal{R})$ and $0 < \epsilon < 1/2$, runs in time $m^{\mathcal{O}(1)} n^{\mathcal{O}((k/\epsilon)^4)}$, and outputs a solution of cost at most $(1+\epsilon)\mathsf{OPT}(J)$ with probability at least $1 - n^{-2}$.*

Towards the proof of Lemma 5, we encode Binary Constrained Partition Center using an Integer programming (IP) formulation (see (6) in Section 3). We show that the randomized rounding using the solution of the linear programming relaxation of this IP provides a good approximation if the optimum value is large. Here we follow the approach similar to the one used by Li, Ma, and Wang in [21] to solve Closest String. We prove that there exist $Y_1 \subseteq X_1, \ldots, Y_k \subseteq X_k$, each of size $r = 1 + \frac{4}{\epsilon}$, with the following property. Let Q be the set of positions in $\{1, \ldots, m\}$ such that for each $i \in \{1, \ldots, k\}$ and $j \in Q$, all the vectors in Y_i agree at the position j, and for each $j \in Q$, $(\mathbf{y}_1[j], \ldots, \mathbf{y}_k[j]) \in R_j$, where $\mathbf{y}_i \in Y_i$ for all $i \in \{1, \ldots, k\}$. Then, for any solution of J such that for each $j \in Q$ the entries at the position j coincide with $(\mathbf{y}_1[j], \ldots, \mathbf{y}_k[j])$, the cost of this solution restricted to Q deviates from the cost of an optimal solution restricted to Q by at most $\frac{1}{r-1}\mathsf{OPT}(J)$. Moreover, the subproblem of J restricted to $\{1, \ldots, m\} \setminus Q$ has large optimum value and we could use linear programming to solve the subproblem. Lemma 5 is proved in Section 3.

Putting together. Next we explain how to prove Theorem 3 using Lemmata 4 and 5. Let $J = (X, k, \mathcal{R})$ be the input instance of Binary Constrained k-Center and $0 < \varepsilon < 1$ be the given error parameter. Let $\beta = \frac{\varepsilon}{8}$. Since $\varepsilon < 1$, $\beta < \frac{1}{4}$. Now, we apply Lemma 4 on J, β, and $\gamma = 2$. As a result, we get a collection $\mathcal{I}$ of instances of Binary Constrained Partition Center such that each instance in $\mathcal{I}$ is of the form $(k, X = X_1 \uplus \ldots \uplus X_k, \mathcal{R})$, and there exists $J' \in \mathcal{I}$ such that $\mathsf{OPT}(J') \leq (1 + 4\beta)\mathsf{OPT}(J)$ with probability at least $1 - n^{-2}$. From now on, we assume that this event happened. Next, for each instance $\widehat{J} \in \mathcal{I}$, we apply Lemma 5 with the error parameter β, and output the best solution among the solutions produced. Let $J' \in \mathcal{I}$ be the instance such that $\mathsf{OPT}(J') \leq (1+4\beta)\mathsf{OPT}(J) \leq (1+\frac{\varepsilon}{2})\mathsf{OPT}(J)$. Any solution to $\widehat{J} \in \mathcal{I}$ of cost d, is also a solution to J of cost at most d. Therefore, because of Lemmas 4 and 5, our algorithm outputs a solution of J with cost at most $(1+\beta)\mathsf{OPT}(J') = (1+\frac{\varepsilon}{8})(1+\frac{\varepsilon}{2})\mathsf{OPT}(J) \leq (1+\varepsilon)\mathsf{OPT}(J)$ with probability at least $1 - 2n^{-2}$, since both Lemmas 4 and 5 have the success probability of at least $1 - n^{-2}$. The running time of the algorithm follows from Lemmata 4 and 5.

As Theorem 3 is already proved using Lemmas 4 and 5, the rest of the paper is devoted to the proofs of Lemmata 4 and 5, and to the examples of the expressive power of Binary Constrained k-Center, including ℓ_1-Rank-r Approximation over GF(2). In Sections 2 and 3, we prove Lemmata 4 and 5, respectively. In Section 4, we give applications of Theorem 3.

2 Proof of Lemma 4

In this section we prove Lemma 4. The main idea is to map the given instance to a low-dimensional space while approximately preserving distances, then try all possible tuples of centers in the low-dimensional space, and construct an instance of Binary Constrained Partition Center by taking the optimal partition of the images with respect to a fixed tuple of centers back to the original vectors.

To implement the mapping, we employ the notion of (δ, ℓ, h)-distorted maps, introduced by Ostrovsky and Rabani [29]. Intuitively, a (δ, ℓ, h)-distorted map approximately preserves distances between ℓ and h, does not shrink distances larger than h too much, and does not expand distances smaller than ℓ too much. In what follows we make the definitions formal.

A metric space is a pair (P, d) where P is a set (whose elements are called points), and d is a distance function $d : P \times P \to \mathbb{R}$ (called a metric), such that for every $p_1, p_2, p_3 \in P$ the following conditions hold: (i) $d(p_1, p_2) \geq 0$, (ii) $d(p_1, p_2) = d(p_2, p_1)$, (iii) $d(p_1, p_2) = 0$ if and only if $p_1 = p_2$, and (iv) $d(p_1, p_2) + d(p_2, p_3) \geq d(p_1, p_3)$. Condition (iv) is called the triangle inequality. The pair $(\{0,1\}^m, d_H)$, binary vectors of lentgh m and the Hamming distance, is a metric space.

▶ **Definition 6** ([29]). *Let (P, d) and (P', d') be two metric spaces. Let $X, Y \subseteq P$. Let δ, ℓ, h be such that $\delta > 0$ and $h > \ell \geq 0$. A mapping $\psi : P \to P'$ is (δ, ℓ, h)-distorted on (X, Y) if and only if there exists $\alpha > 0$ such that for every $x \in X$ and $y \in Y$, the following conditions hold.*

1. *If $d(x, y) < \ell$, then $d(\psi(x), \psi(y)) < (1 + \delta)\alpha\ell$.*
2. *If $d(x, y) > h$, then $d(\psi(x), \psi(y)) > (1 - \delta)\alpha h$.*
3. *If $\ell \leq d(x, y) \leq h$, then $(1 - \delta)\alpha d(x, y) \leq d(\psi(x), \psi(y)) \leq (1 + \delta)\alpha d(x, y)$.*

If $X = Y$, then we say that ψ is (δ, ℓ, h)-distorted on X.

For any $r, r' \in \mathbb{N}$ and $\varepsilon > 0$, $\mathcal{A}_{r,r'}(\varepsilon)$ denotes a distribution over $r' \times r$ binary matrices $M \in \{0,1\}^{r' \times r}$, where entries are independent, identically distributed, random 0/1 variables with $\Pr[1] = \varepsilon$.

▶ **Proposition 7** ([29]). *Let $m, \ell \in \mathbb{N}$, and let $X \subseteq \{0,1\}^m$ be a set of n vectors. For every $0 < \epsilon \leq 1/2$, there exists a mapping $\phi : X \to \{0,1\}^{m'}$, where $m' = \mathcal{O}(\log n/\epsilon^4)$, which is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on X (with respect to the Hamming distance in both spaces). More precisely, for every $\gamma > 0$ there exists $\lambda > 0$, such that, setting $m' = \lambda \log n/\epsilon^4$, the linear map $\mathbf{x} \mapsto A\mathbf{x}$, where A is a random matrix drawn from $\mathcal{A}_{m,m'}(\epsilon^2/\ell)$, is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on X with probability at least $1 - n^{-\gamma}$.*

Now we are ready to prove Lemma 4. We restate it for convenience.

▶ **Lemma 4.** *There is an algorithm that given an instance $J = (X, k, \mathcal{R})$ of Binary Constrained k-Center, $0 < \epsilon \leq \frac{1}{4}$, and $\gamma > 0$, runs in time $m^2 n^{\mathcal{O}(k/\epsilon^4)}$, and outputs a collection $\mathcal{I}$ of $m \cdot n^{\mathcal{O}(k/\epsilon^4)}$ instances of Binary Constrained Partition Center such that each instance in $\mathcal{I}$ is of the form $(k, X = X_1 \uplus \ldots \uplus X_k, \mathcal{R})$, and there exists $J' \in \mathcal{I}$ such that $\mathsf{OPT}(J') \leq (1 + 4\epsilon)\mathsf{OPT}(J)$ with probability at least $1 - n^{-\gamma}$.*

Proof. Without loss of generality, we may assume $\mathsf{OPT}(J) > 0$. If $\mathsf{OPT}(J) = 0$, there are at most k distinct vectors in X, and we trivially construct a single instance of Binary Constrained Partition Center by grouping equal vectors together.

Let $n = |X|$ and $n' = n + k$. Let $\lambda = \lambda(\gamma)$ be the constant mentioned in Proposition 7, and $m' = \lambda \log n'/\epsilon^4$. Then, for each $\ell \in [m]$[2], we construct the collection $\mathcal{I}_\ell$ of $n^{\mathcal{O}(k/\epsilon^4)}$ Binary Constrained Partition Center instances as follows.

- Start with $\mathcal{I}_\ell := \emptyset$.
- Randomly choose a matrix A^ℓ from the distribution $\mathcal{A}_{m,m'}(\epsilon^2/\ell)$.

[2] For an integer $n \in \mathbb{N}$, we use $[n]$ as a shorthand for $\{1, \ldots, n\}$.

- For each choice of k vectors $\mathbf{c}'_1, \ldots, \mathbf{c}'_k \in \{0,1\}^{m'}$, construct a partition $X_1 \uplus \ldots \uplus X_k$ of X such that for each $\mathbf{x} \in X_i$, $\mathbf{c}'_i$ is one of the closest vectors to $A^\ell \mathbf{x}$ among $C' = \{\mathbf{c}'_1, \ldots, \mathbf{c}'_k\}$. Then, add $(k, X = X^i_1 \uplus \ldots X^i_k, \mathcal{R})$ to $\mathcal{I}_\ell$.

Finally, our algorithm outputs $\mathcal{I} = \bigcup_{\ell \in [m]} \mathcal{I}_\ell$ as the required collection of Binary Constrained Partition Center instances. Notice that for any $\ell \in [m]$, $|\mathcal{I}_\ell| = 2^{m'k} = n^{\mathcal{O}(k/\epsilon^4)}$. This implies that the cardinality of $\mathcal{I}$ is upper bounded by $m \cdot n^{\mathcal{O}(k/\epsilon^4)}$, and the construction of $\mathcal{I}_\ell$ takes time $m \cdot n^{\mathcal{O}(k/\epsilon^4)}$. Thus, the total running time of the algorithm is $m^2 \cdot n^{\mathcal{O}(k/\epsilon^4)}$.

Next, we prove the correctness of the algorithm. Let $\ell = \mathsf{OPT}(J)$ and $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ be an optimum solution of J. Let $Y_1, \ldots, Y_k$ be the clusters corresponding to C. Consider the step in the algorithm where we constructed $\mathcal{I}_\ell$. By Proposition 7, the map $\psi \colon \mathbf{x} \mapsto A^\ell \mathbf{x}$ is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on $X \cup C$ with probability at least $1 - n^{-\gamma}$. In the rest of the proof, we assume that this event happened. Let $\mathbf{c}'_1 = A^\ell \mathbf{c}_1, \ldots, \mathbf{c}'_k = A^\ell \mathbf{c}_k$. Consider the Binary Constrained Partition Center instance constructed for the choice of vectors $\mathbf{c}'_1, \ldots, \mathbf{c}'_k$. That is, let $X_1, \ldots, X_k$ be the partition of X such that for each $\mathbf{x} \in X_i$, $\mathbf{c}'_i$ is one of the closest vector to $A^\ell \mathbf{x}$ from $C' = \{\mathbf{c}'_1, \ldots, \mathbf{c}'_k\}$. Let J' be the instance $(k, X = X^i_1 \uplus \ldots X^i_k, \mathcal{R})$ of Binary Constrained Partition Center.

Now, we claim that C is a solution to J' with cost at most $(1+4\epsilon)\ell = (1+4\epsilon)\mathsf{OPT}(J)$. Since C satisfies $\mathcal{R}$, C is a solution of J'. To prove $\mathsf{OPT}(J') \leq (1+4\epsilon)\ell$, it is enough to prove that for each $i \in [k]$ and $\mathbf{x} \in X_i$, $d_H(\mathbf{x}, \mathbf{c}_i) \leq (1+4\epsilon)\ell$. Fix an index $i \in [k]$ and $\mathbf{x} \in X_i$. Suppose $\mathbf{x} \in Y_i$. Since C is an optimum solution of J with corresponding clusters $Y_1, \ldots Y_k$, we have that $d_H(\mathbf{y}, \mathbf{c}_i) \leq \ell$ for all $\mathbf{y} \in Y_i \cap X_i$. Thus, $d_H(\mathbf{x}, \mathbf{c}_i) \leq \ell$. So, now consider the case $\mathbf{x} \in Y_j$ for some $j \neq i$. Notice that if $d_H(\mathbf{x}, \mathbf{c}_i) \leq \ell$, then we are done. We have the following two subcases.

Case 1: $d_H(\mathbf{x}, \mathbf{c}_i) \leq \frac{\ell}{2\epsilon}$. We know that the map $\psi \colon \mathbf{x} \mapsto A^\ell \mathbf{x}$ is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on $X \cup C$, and let $\alpha > 0$ be the number such that conditions of Definition 6 hold. Since $\mathbf{x} \in X_i$, we have that (a) $d_H(\psi(\mathbf{x}), \psi(\mathbf{c}_i)) \leq d_H(\psi(\mathbf{x}), \psi(\mathbf{c}_j))$. Since $d_H(\mathbf{x}, \mathbf{c}_j) \leq \ell$ (because $\mathbf{x} \in Y_j$) and ψ is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on $X \cup C$, we have that (b) $d_H(\psi(\mathbf{x}), \psi(\mathbf{c}_j)) \leq (1+\epsilon)\alpha\ell$. Since $\ell < d_H(\mathbf{x}, \mathbf{c}_i) \leq \frac{\ell}{2\epsilon}$, and ψ is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on $X \cup C$, we have that (c) $(1-\epsilon)\alpha d_H(\mathbf{x}, \mathbf{c}_i) \leq d_H(\psi(\mathbf{x}), \psi(\mathbf{c}_i))$. The statements (a), (b), and (c) imply that

$$d_H(\mathbf{x}, \mathbf{c}_i) \leq \frac{1+\epsilon}{1-\epsilon}\ell \leq (1+4\epsilon)\ell,$$

where the last inequality holds since $\epsilon \leq 1/4$.

Case 2: $d_H(\mathbf{x}, \mathbf{c}_i) > \frac{\ell}{2\epsilon}$. We prove that this case is impossible by showing a contradiction. Since $\epsilon \leq 1/4$, in this case, we have that $d_H(\mathbf{x}, \mathbf{c}_i) > 2\ell$. Since ψ is $(\epsilon, \ell/4, \ell/2\epsilon)$-distorted on $X \cup C$, $d_H(\mathbf{x}, \mathbf{c}_i) > 2\ell$, and $d_H(\mathbf{x}, \mathbf{c}_j) \leq \ell$, we have that

$(1-\epsilon)\alpha \cdot 2\ell \leq d_H(\psi(\mathbf{x}), \psi(\mathbf{c}_i)) \leq d_H(\psi(\mathbf{x}), \psi(\mathbf{c}_j)) \leq (1+\epsilon)\alpha \cdot \ell.$

Then $2(1-\epsilon) \leq (1+\epsilon)$ and thus $\epsilon \geq 1/3$, which contradicts the assumption that $\epsilon \leq 1/4$. This completes the proof of the lemma. ◀

3 Proof of Lemma 5

For a set of positions $P \subset [m]$, let us define the Hamming distance restricted to P by

$$d^P_H(\mathbf{x}, \mathbf{y}) = \sum_{i \in P} |x_i - y_i|.$$

We use the following lemma in our proof.

▶ **Lemma 8.** *Let $Y = \{\mathbf{y}_1, \cdots, \mathbf{y}_l\} \subset \{0,1\}^m$ be a set of vectors and $\mathbf{c}^* \in \{0,1\}^m$ be a vector. Let $d^* = \mathrm{cost}(Y, \{\mathbf{c}^*\}) = \max_{\mathbf{y}\in Y} d_H(\mathbf{y}, \mathbf{c}^*)$. For any $r \in \mathbb{N}$, $r \geq 2$, there exist indices $i_1, \ldots, i_r$ such that for any $\mathbf{x} \in Y$*

$$d_H^P(\mathbf{x}, \mathbf{y}_{i_1}) - d_H^P(\mathbf{x}, \mathbf{c}^*) \leq \frac{1}{r-1} d^*,$$

where P is any subset of $Q_{i_1,\ldots,i_r}$ and $Q_{i_1,\ldots,i_r}$ is the set of positions where all of $\mathbf{y}_{i_1}, \ldots, \mathbf{y}_{i_r}$ coincide (i.e., $Q_{i_1,\ldots,i_r} = \{j \in [m] \colon \mathbf{y}_{i_1}[j] = \mathbf{y}_{i_2}[j] = \ldots = \mathbf{y}_{i_r}[j]\}$).

Proof. For a vector $\mathbf{x} = \mathbf{y}_{\ell'} \in Y$ and $P \subseteq Q_{i_1,\ldots,i_r}$, let

$$\begin{aligned} J_P(\ell') &= \{j \in P \colon \mathbf{y}_{i_1}[j] \neq \mathbf{x}[j] \text{ and } \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}, \text{ and} \\ J(\ell') &= \{j \in Q_{i_1,\ldots,i_r} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{x}[j] \text{ and } \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}. \end{aligned}$$

To prove the lemma it is enough to prove that $|J_P(\ell')| \leq \frac{1}{r-1} d^*$. Also, since $J_P(\ell') \subseteq J(\ell')$, to prove the lemma, it is enough to prove that $|J(\ell')| \leq \frac{1}{r-1} d^*$. Recall that for any $s \in [\ell]$ and $1 \leq i_1, \ldots, i_s \leq \ell$, $Q_{i_1,\ldots,i_s}$ is the set of positions where all of $\mathbf{y}_{i_1}, \ldots, \mathbf{y}_{i_s}$ coincide. For any $2 \leq s \leq r+1$ and $1 \leq i_1, \ldots, i_s \leq \ell$, let $p_{i_1,\ldots,i_s}$ be the number of mismatches between $\mathbf{y}_{i_1}$ and $\mathbf{c}^*$ at the positions in $Q_{i_1,\ldots,i_s}$. Let

$$\rho_s = \min_{1 \leq i_1,\ldots,i_s \leq n} \frac{p_{i_1,\ldots,i_s}}{d^*}.$$

Notice that for any $2 \leq s \leq r+1$, $\rho_s \leq 1$.

▷ Claim 9 (Claim 2.2 [21]). [3] For any s such that $2 \leq s \leq r$, there are indices $1 \leq i_1, i_2, \ldots, i_r \leq \ell$ such that for any $\mathbf{x} = \mathbf{y}_{\ell'} \in Y$, $|J(\ell')| \leq (\rho_s - \rho_{s+1}) d^*$.

Proof. Consider indices $1 \leq i_1, \ldots, i_s \leq \ell$ such that $p_{i_1,\ldots,i_s} = \rho_s \cdot d^*$. Next arbitrarily pick $r - s$ indices $i_{s+1}, i_{s+2}, \ldots, i_r$ from $[\ell] \setminus \{i_1, \ldots, i_s\}$. Next we prove that $i_1, i_2, \ldots, i_r$ are the required set of indices. Towards that, fix $\mathbf{x} = \mathbf{y}_{\ell'} \in Y$,

$$\begin{aligned} J(\ell') &= |\{j \in Q_{i_1,\ldots,i_r} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{x}[j] \text{ and } \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}| \\ &\leq |\{j \in Q_{i_1,\ldots,i_s} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{x}[j] \text{ and } \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}| \\ &\qquad\qquad \text{(Because } Q_{i_1,\ldots,i_r} \subseteq Q_{i_1,\ldots,i_s}\text{)} \\ &= |\{j \in Q_{i_1,\ldots,i_s} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\} \setminus \{j \in Q_{i_1,\ldots,i_s} \colon \mathbf{y}_{i_1}[j] = \mathbf{x}[j] \wedge \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}| \\ &= |\{j \in Q_{i_1,\ldots,i_s} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\} \setminus \{j \in Q_{i_1,\ldots,i_s,\ell'} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}| \\ &\qquad\qquad \text{(Since } \mathbf{x} = \mathbf{y}_{\ell'}\text{)} \\ &= |\{j \in Q_{i_1,\ldots,i_s} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}| - |\{j \in Q_{i_1,\ldots,i_s,\ell'} \colon \mathbf{y}_{i_1}[j] \neq \mathbf{c}^*[j]\}| \qquad (3) \\ &= p_{i_1,\ldots,i_s} - p_{i_1,\ldots,i_s,\ell'} \qquad \text{(By definition)} \\ &\leq (\rho_s - \rho_{s+1}) d^* \qquad (4) \end{aligned}$$

The equality (3) holds since $Q_{i_1,\ldots,i_s} \supseteq Q_{i_1,\ldots,i_s,\ell'}$. The inequality (4) holds because $p_{i_1,\ldots,i_s} = \rho_s \cdot d^*$ by the choice of $i_1, \ldots, i_s$, and $\rho_{s+1} d^* \leq p_{i_1,\ldots,i_s,\ell'}$ by definition. ◁

Notice that $(\rho_2 - \rho_3) + (\rho_3 - \rho_4) + \ldots + (\rho_r - \rho_{r+1}) = (\rho_2 - \rho_{r+1}) \leq \rho_2 \leq 1$. Thus, one of $(\rho_2 - \rho_3), (\rho_3 - \rho_4), \ldots, (\rho_r - \rho_{r+1})$ is at most $1/(r-1)$. This completes the proof. ◀

[3] We remark that Claim 2.2 in [21] is stated for a vector $\mathbf{c}$ such that $d^* = \mathrm{cost}(Y, \{\mathbf{c}\}) = \min_{\mathbf{c}'} \mathrm{cost}(Y, \{\mathbf{c}'\})$. But the steps of the same proof work in our case as well.

Consider the instance $J = (k, X = X_1^i \uplus \dots X_k^i, \mathcal{R})$ of Binary Constrained Partition Center. Let $C^* = (\mathbf{c}_1^*, \cdots, \mathbf{c}_k^*) \subset \{0,1\}^m$ be an optimum solution to J. Let $d_{opt} = \mathsf{OPT}(J) = \max_{i\in[k],\mathbf{x}\in X_i} d_H(\mathbf{x}, \mathbf{c}_i^*)$. For each $i \in [k]$ and $r \geq 2$, by Lemma 8, there exist r elements $\mathbf{x}_i^{(1)}, \dots, \mathbf{x}_i^{(r)}$ of X_i such that for any $\mathbf{x} \in X_i$,

$$d_H^P(\mathbf{x}, \mathbf{x}_i^{(1)}) - d_H^P(\mathbf{x}, \mathbf{c}_i^*) \leq \frac{1}{r-1} d_{opt}, \tag{5}$$

where P is any subset of Q_i, and Q_i is the set of coordinates on which $\mathbf{x}_i^{(1)}, \dots, \mathbf{x}_i^{(r)}$ agree. Let us denote as Q the intersection of all Q_i from which the positions not satisfying $\mathcal{R}$ are removed. That is,

$$Q = \left\{ j \in \bigcap_{i\in[k]} Q_i \colon (\mathbf{x}_1^{(1)}[j], \mathbf{x}_2^{(1)}[j], \dots, \mathbf{x}_k^{(1)}[j]) \in R_j \right\}.$$

Because of (5), there is an approximate solution where the coordinates $j \in Q$ are identified using $\mathbf{x}_1^{(1)}, \dots, \mathbf{x}_k^{(1)}$. Let $\overline{Q} = [m] \setminus Q$. Now the idea is to solve the problem restricted to $\overline{Q}$ separately, and then complement the solution on Q by the values of $\mathbf{x}_i^{(1)}$. We prove that for the "subproblem" restricted on $\overline{Q}$, the optimum value is *large*. Towards that we first prove the following lemma.

▶ **Lemma 10 (⋆).** [4] *Let $J = (k, X = X_1^i \uplus \dots X_k^i, \mathcal{R})$ be an instance of Binary Constrained Partition Center. Let $(\mathbf{c}_1^*, \dots, \mathbf{c}_k^*)$ be an optimal solution for J, and $r \geq 2$ be an integer. Then, there exist $\{\mathbf{x}_1^{(1)}, \dots, \mathbf{x}_1^{(r)}\} \subset X_1, \dots, \{\mathbf{x}_k^{(1)}, \dots, \mathbf{x}_k^{(r)}\} \subset X_k$ with the following properties. For each $i \in [k]$, let Q_i be the set of coordinates on which $\mathbf{x}_i^{(1)}, \dots, \mathbf{x}_i^{(r)}$ agree, $Q = \left\{ j \in \bigcap_{i\in[k]} Q_i \colon (\mathbf{x}_1^{(1)}[j], \mathbf{x}_2^{(1)}[j], \dots, \mathbf{x}_k^{(1)}[j]) \in R_j \right\}$, and $\overline{Q} = [m] \setminus Q$.*

- *For any $i \in [k]$ and $\mathbf{x} \in X_i$, $d_H^Q(\mathbf{x}, \mathbf{x}_i^{(1)}) - d_H^Q(\mathbf{x}, \mathbf{c}_i^*) \leq \frac{1}{r-1}\mathsf{OPT}(J)$, and*
- *$|\overline{Q}| \leq rk \cdot \mathsf{OPT}(J)$.*

As mentioned earlier, we fix the entries of our solution in positions j of Q with values in $\mathbf{x}_1^{(1)}[j], \dots, \mathbf{x}_k^{(1)}[j]$. Towards finding the entries of our solution in positions of $\overline{Q}$, we define the following problem and solve it.

Binary Constrained Partition Center*
Input: A positive integer k, a set $X \subseteq \{0,1\}^m$ of n vectors partitioned into $X_1 \uplus \dots \uplus X_k$, a tuple of k-ary relations $\mathcal{R} = (R_1, \dots, R_m)$, and for all $\mathbf{x} \in X$, $d_{\mathbf{x}} \in \mathbb{N}$
Task: Among all tuples $C = (\mathbf{c}_1, \dots, \mathbf{c}_k)$ of vectors from $\{0,1\}^m$ satisfying $\mathcal{R}$, find a tuple C that minimizes the integer d such that for all $i \in [k]$ and $\mathbf{x} \in X_i$, $d_H(\mathbf{x}, \mathbf{c}_i) \leq d - d_{\mathbf{x}}$.

▶ **Lemma 11.** *Let $J' = (k, X = X_1 \uplus \dots X_k, \mathcal{R}, (d_{\mathbf{x}})_{\mathbf{x}\in X})$ be an instance of Binary Constrained Partition Center*, $\mathsf{OPT}(J') \geq \frac{m}{c}$ for some integer c, and $0 < \delta < 1/c$. Then, there is an algorithm which runs in time $m^{\mathcal{O}(1)} n^{\mathcal{O}(c^2 k/\delta^2)}$, and outputs a solution C of J', of cost at most $(1+\delta)\mathsf{OPT}(J')$ with probability at least $1 - n^{-2}$.*

Before proving Lemma 11, we explain how all these result put together to form a proof of Lemma 5. We restate Lemma 5 for the convenience of the reader.

[4] The proofs of results marked with ⋆ are deferred to the full version of the paper.

▶ **Lemma 5.** *There is an algorithm for* Binary Constrained Partition Center *that given an instance* $J = (k, X = X_1^i \uplus \ldots \uplus X_k^i, \mathcal{R})$ *and* $0 < \epsilon < 1/2$*, runs in time* $m^{\mathcal{O}(1)} n^{\mathcal{O}((k/\epsilon)^4)}$*, and outputs a solution of cost at most* $(1+\epsilon)\mathsf{OPT}(J)$ *with probability at least* $1 - n^{-2}$*.*

Proof. Let $J = (k, X = X_1^i \uplus \ldots X_k^i, \mathcal{R})$ be the input instance of Binary Constrained Partition Center, and $0 < \epsilon < \frac{1}{2}$ be the error parameter. Let $(\mathbf{c}_1^*, \ldots, \mathbf{c}_k^*)$ be an optimal solution for J. Let $r \geq 2$ be an integer which we fix later. First, for each $i \in [k]$ we obtain r vectors $\mathbf{x}_i^{(1)}, \ldots, \mathbf{x}_i^{(r)} \in X_i$ which satisfy the conditions of Lemma 10. Their existence is guaranteed by Lemma 10, and we guess them in time $n^{\mathcal{O}(rk)}$ over all $i \in [k]$. For each $i \in [k]$, let Q_i be the set of coordinates on which $\mathbf{x}_i^{(1)}, \ldots, \mathbf{x}_i^{(r)}$ agree, $Q = \left\{ j \in \bigcap_{i \in [k]} Q_i \colon (\mathbf{x}_1^{(1)}[j], \mathbf{x}_2^{(1)}[j], \ldots, \mathbf{x}_k^{(1)}[j]) \in R_j \right\}$, and $\overline{Q} = [m] \setminus Q$. Next, we construct a solution $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ as follows. For each $i \in [k]$ and $j \in Q$, we set $\mathbf{c}_i[j] = \mathbf{x}_i^{(1)}[j]$.

Towards finding the entries of vectors $\mathbf{c}_1, \ldots, \mathbf{c}_k$ at the coordinates in $\overline{Q}$, we use Lemma 11. Let J' be the instance of Binary Constrained Partition Center*, which is a natural restriction of J to $\overline{Q}$. That is, $J' = (k, X' = X_1' \uplus \ldots X_k', \mathcal{R}|_{\overline{Q}}, (d_{\mathbf{x}|_{\overline{Q}}})_{\mathbf{x} \in X'})$, where for each $i \in [k]$, $X_i' = \{\mathbf{x}|_{\overline{Q}} \colon \mathbf{x} \in X_i\}$ and for each $\mathbf{x} \in X_i$, $d_{\mathbf{x}|_{\overline{Q}}} = d_H^Q(\mathbf{x}, \mathbf{x}_i^{(1)})$. By the second condition in Lemma 10, we have that $|\overline{Q}| \leq rk \cdot \mathsf{OPT}(J)$.

▷ Claim 12. $\mathsf{OPT}(J) \leq \mathsf{OPT}(J') \leq \left(1 + \frac{1}{r-1}\right) \mathsf{OPT}(J)$.

Proof. First, we prove that $\mathsf{OPT}(J) \leq \mathsf{OPT}(J')$. Towards that we show that we can transform a solution $C' = (\mathbf{c}_1', \cdots, \mathbf{c}_k')$ of J' with the objective value d to a solution C of J with the same objective value. For each $i \in [k]$, consider $\widehat{\mathbf{c}}_i$ which is equal to $\mathbf{x}_i^{(1)}$ restricted to Q, and to $\mathbf{c}_i'$ restricted to $\overline{Q}$, and the solution $\widehat{C} = (\widehat{\mathbf{c}}_1, \cdots, \widehat{\mathbf{c}}_k)$. Clearly, $\widehat{C}$ satisfies $\mathcal{R}$ since on $\overline{Q}$ it is guaranteed by C' being a solution to J', and on Q by construction of Q. The objective value of C is

$$\begin{aligned}
\max_{i \in [k], \mathbf{x} \in X_i} d_H(\mathbf{x}, \mathbf{c}_i) &= \max_{i \in [k], \mathbf{x} \in X_i} \left(d_H^{\overline{Q}}(\mathbf{x}, \mathbf{c}_i) + d_H^Q(\mathbf{x}, \mathbf{c}_i) \right) \\
&= \max_{i \in [k], \mathbf{x} \in X_i} \left(d_H(\mathbf{x}|_{\overline{Q}}, \mathbf{c}_i') + d_H^Q(\mathbf{x}, \mathbf{x}_i^{(1)}) \right) \\
&= \max_{i \in [k], \mathbf{x} \in X_i} \left(d_H(\mathbf{x}|_{\overline{Q}}, \mathbf{c}_i') + d_{\mathbf{x}|_{\overline{Q}}} \right) = d.
\end{aligned}$$

Thus, $\mathsf{OPT}(J) \leq \mathsf{OPT}(J')$.

Next, we prove that $\mathsf{OPT}(J') \leq \left(1 + \frac{1}{r-1}\right) \mathsf{OPT}(J)$. Recall that $(\mathbf{c}_1^*, \ldots, \mathbf{c}_k^*)$ is an optimal solution for J. Then, $(\mathbf{e}_1^*, \ldots, \mathbf{e}_k^*)$, where each $\mathbf{e}_i^*$ is the restriction of $\mathbf{c}_i^*$ on $\overline{Q}$, is a solution for J'. For each $i \in [k]$ and $\mathbf{x} \in X_i$,

$$\begin{aligned}
d_H(\mathbf{x}|_{\overline{Q}}, \mathbf{e}_i^*) + d_{\mathbf{x}|_{\overline{Q}}} &= d_H^{\overline{Q}}(\mathbf{x}, \mathbf{c}_i^*) + d_H^Q(\mathbf{x}, \mathbf{x}_i^{(1)}) \\
&\leq d_H^{\overline{Q}}(\mathbf{x}, \mathbf{c}_i^*) + d_H^Q(\mathbf{x}, \mathbf{c}_i^*) + \frac{1}{r-1} \mathsf{OPT}(J) \qquad \text{(By Lemma 10)} \\
&\leq d_H(\mathbf{x}, \mathbf{c}_i^*) + \frac{1}{r-1} \mathsf{OPT}(J) \\
&\leq \left(1 + \frac{1}{r-1}\right) \mathsf{OPT}(J)
\end{aligned}$$

This completes the proof of the claim. ◁

Since $|\overline{Q}| \leq rk \cdot \mathsf{OPT}(J)$ and by Claim 12, we have that $\mathsf{OPT}(J') \geq \frac{|\overline{Q}|}{rk} = \frac{|\overline{Q}|}{c}$, where $c = rk$. Let $0 < \delta < \frac{1}{c}$ be a number which we fix later.

Now we apply Lemma 11 on the input J' and δ, and let $C' = (\mathbf{c}'_1, \ldots, \mathbf{c}'_k)$ be the solution for J' obtained. We know that the cost d' of $\mathbf{c}'$ is at most $(1+\delta)\mathsf{OPT}(J')$ with probability at least $1 - n^{-2}$. For the rest of the proof we assume that the cost $d' \leq (1+\delta)\mathsf{OPT}(J')$. Recall that we have partially computed the entries of the solution $\mathbf{c} = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ for the instance J. That is, for each $j \in Q$ and $i \in [k]$, we have already set the value of $\mathbf{c}_i[j]$. Notice that $C' \subseteq \{0,1\}^{|\overline{Q}|}$. Since J' is obtained from J by restricting to $\overline{Q}$, there is a natural bijection f from $\overline{Q}$ to $[|\overline{Q}|]$ such that for each $\mathbf{x} \in X$ and $j \in \overline{Q}$, $\mathbf{x}[j] = \mathbf{y}[f(j)]$, where $\mathbf{y} = \mathbf{x}|_{\overline{Q}}$. Now for each $i \in [k]$ and $j \in \overline{Q}$, we set $\mathbf{c}_i[j] = \mathbf{c}'_i[f(j)]$.

In Claim 12, we have proven that the solution C of J obtained in this way has cost at most d'. By Lemma 11, we know that $d' \leq (1+\delta)\mathsf{OPT}(J')$. By Claim 12, $\mathsf{OPT}(J') \leq (1 + \frac{1}{r-1})\mathsf{OPT}(J)$. Thus, we have that the cost of the solution C of J is at most $(1+\delta)(1 + \frac{1}{r-1})\mathsf{OPT}(J)$. Now we fix $r = (1 + \frac{4}{\epsilon})$ and $\delta = \frac{\epsilon}{(2\epsilon+8)k}$. Then the cost of C is at most $(1+\epsilon)\mathsf{OPT}(J)$.

Running time analysis. The number of choices for $\{\mathbf{x}_1^{(1)}, \ldots, \mathbf{x}_1^{(r)}\} \subset X_1, \ldots, \{\mathbf{x}_k^{(1)}, \ldots, \mathbf{x}_k^{(r)}\} \subset X_k$ is at most $n^{\mathcal{O}(rk)} = n^{\mathcal{O}(k/\epsilon)}$. For each such choice, we run the algorithm of Lemma 11 which takes time at most $m^{\mathcal{O}(1)} n^{\mathcal{O}(c^2 k/\delta^2)} = m^{\mathcal{O}(1)} n^{\mathcal{O}((k/\epsilon)^4)}$. Thus, the total running time is $m^{\mathcal{O}(1)} n^{\mathcal{O}((k/\epsilon)^4)}$. ◀

Now the only piece left is the proof of Lemma 11. We use the following tail inequality (a variation of Chernoff bound) in the proof of Lemma 11.

▶ **Proposition 13** (Lemma 1.2 [21]). *Let $X_1, \ldots, X_n$ be n independent 0-1 random variables, $X = \sum_{i=1}^{n} X_i$, and $0 < \epsilon \leq 1$. Then, $\Pr[X > E[X] + \epsilon n] \leq e^{-\frac{1}{3}n\epsilon^2}$.*

Finally, we prove Lemma 11.

Proof of Lemma 11. First, assume that $m < 9c^2 \log n/\delta^2$. If this is the case, we enumerate all possible solutions for J' and output the best solution. The number of solutions is at most $2^{k \cdot m} = n^{\mathcal{O}(c^2 k/\delta^2)}$. Thus, in this case the algorithm is exact and deterministic, and the running time bound holds. For the rest of the proof we assume that $m \geq 9c^2 \log n/\delta^2$.

Binary Constrained Partition Center* can be formulated as a 0-1 optimization problem as explained below. For each $j \in [m]$ and tuple $t \in R_j$, we use a 0-1 variable $y_{j,t}$ to indicate whether the j^{th} entries of a solution form a tuple $t \in R_j$ or not. For any $i \in [k]$, $\mathbf{x} \in X_i$, $j \in [m]$ and $t \in R_j$, denote $\chi_i(\mathbf{x}[j], t) = 0$ if $\mathbf{x}[j] = t[i]$ and $\chi_i(\mathbf{x}[j], t) = 1$ if $\mathbf{x}[j] \neq t[i]$. Now Binary Constrained Partition Center* can be defined as the following 0-1 optimization problem.

$$
\begin{aligned}
&\min d \\
&\text{subject to} \\
&\sum_{t \in R_j} y_{j,t} = 1, && \text{for all } j \in [m]; \qquad (6)\\
&\sum_{j \in [m]} \sum_{t \in R_j} \chi_i(\mathbf{x}[j], t) \cdot y_{j,t} \leq d - d_{\mathbf{x}}, && \text{for all } i \in [k] \text{ and } \mathbf{x} \in X_i \\
&y_{j,t} \in \{0,1\}, && \text{for all } j \in [m] \text{ and } t \in R_j.
\end{aligned}
$$

Any solution $y_{j,t}$ ($j \in [m]$ and $t \in R_j$) to (6) corresponds to the solution $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ where for all $j \in [m]$ and $t \in R_j$ such that $y_{j,t} = 1$, we have $(\mathbf{c}_1[j], \ldots, \mathbf{c}_k[j]) = t$.

Now, we solve the above optimization problem using linear programming relaxation and obtain a fractional solution $y^\star_{j,t}$ ($j \in [m]$ and $t \in R_j$) with cost d'. Clearly, $d' \leq d_{opt} = \mathsf{OPT}(J')$. Now, for each $j \in [m]$, independently with probability $y^\star_{j,t}$, we set $y'_{j,t} = 1$ and $y'_{j,t'} = 0$, for any $t' \in R_j \setminus \{t\}$. Then $y'_{j,t}$ ($j \in [m]$ and $t \in R_j$) form a solution to (6). Next we construct the solution $C = (\mathbf{c}_1, \ldots, \mathbf{c}_k)$ to Binary Constrained Partition Center*, corresponding to $y'_{j,t}$ ($j \in [m]$ and $t \in R_j$). That is, for all $j \in [m]$ and $t \in R_j$ such that $y_{j,t} = 1$, we have $(\mathbf{c}_1[j], \ldots, \mathbf{c}_k[j]) = t$.

For the running time analysis, notice that solving the linear program and performing the random rounding takes polynomial time in the size of the problem (6). And the size of (6) is polynomial in the size of J', so the running time bound is satisfied. It remains to show that the constructed solution has cost at most $(1+\delta)\mathsf{OPT}(J')$ with probability at least $1 - n^{-2}$.

For any $j \in [m]$, the above random rounding procedure ensures that there is exactly one tuple $t \in R_j$ such that $y'_{j,t} = 1$. This implies that for any $j \in [m]$, $i \in [k]$ and $\mathbf{x} \in X_i$, $\sum_{t \in R_j} \chi_i(\mathbf{x}[j], t) \cdot y'_{j,t}$ is a 0-1 random variable. Since for each $j \in [m]$ the rounding procedure is independent, we have that for any $i \in [k]$ and $\mathbf{x} \in X_i$ the random variables $(\sum_{t \in R_1} \chi_i(\mathbf{x}[1], t) \cdot y'_{1,t}), \ldots, (\sum_{t \in R_m} \chi_i(\mathbf{x}[m], t) \cdot y'_{j,t})$ are independent. Hence, for any $i \in [k]$ and $\mathbf{x} \in X_i$, the Hamming distance between $\mathbf{x}$ and $\mathbf{c}_i$, $d_H(\mathbf{x}, \mathbf{c}_i) = \sum_{j \in [m]} \sum_{t \in R_j} \chi_i(\mathbf{x}[j], t) \cdot y'_{j,t}$, is the sum of m independent 0-1 random variables. For each $i \in [k]$ and $\mathbf{x} \in X_i$, we upper bound the expected value of $d_H(\mathbf{x}, \mathbf{c}_i)$ as follows.

$$\begin{aligned}
E[d_H(\mathbf{x}, \mathbf{c}_i)] &= E\left[\sum_{j \in [m]} \sum_{t \in R_j} \chi_i(\mathbf{x}[j], t) \cdot y'_{j,t}\right] \\
&= \sum_{j \in [m]} \sum_{t \in R_j} \chi_i(\mathbf{x}[j], t) \cdot E[y'_{j,t}] \\
&= \sum_{j \in [m]} \sum_{t \in R_j} \chi_i(\mathbf{x}[j], t) \cdot y^\star_{j,t} \\
&\leq d' - d_{\mathbf{x}} \qquad \text{(By the constraints of (6))}
\end{aligned}$$

Fix $\epsilon = \frac{\delta}{c}$. Then, by Proposition 13, for all $i \in [k]$, and $\mathbf{x} \in X_i$,

$$\Pr[d_H(\mathbf{x}, \mathbf{c}_i) > d' - d_{\mathbf{x}} + \epsilon m] \leq e^{-\frac{1}{3} m \epsilon^2}.$$

Therefore, by the union bound,

$$\Pr[\text{There exist } i \in [k] \text{ and } \mathbf{x} \in X_i \text{ such that } d_H(\mathbf{x}, \mathbf{c}_i) > d' - d_{\mathbf{x}} + \epsilon m] \leq n \cdot e^{-\frac{1}{3} m \epsilon^2} \quad (7)$$

We remind that $m \geq 9c^2 \log n / \delta^2 = 9 \log n / \epsilon^2$ and so $n \cdot e^{-\frac{1}{3} m \epsilon^2} \leq n^{-2}$. Thus, by (7),

$$\Pr[\text{There exist } i \in [k] \text{ and } \mathbf{x} \in X_i \text{ such that } d_H(\mathbf{x}, \mathbf{c}_i) > d' - d_{\mathbf{x}} + \epsilon m] \leq n^{-2}. \quad (8)$$

Since $d' \leq \mathsf{OPT}(J')$ and $\mathsf{OPT}(J') \geq m/c$, $d' + \epsilon m \leq (1 + c\epsilon)\mathsf{OPT}(J')$. Then, the probability that there exist $i \in [k]$ and $\mathbf{x} \in X_i$ such that $d_H(\mathbf{x}, \mathbf{c}_i) > (1 + c\epsilon)\mathsf{OPT}(J') - d_{\mathbf{x}}$ is at most n^{-2} by (8). Since $c\epsilon = \delta$, the proof is complete. ◀

4 Applications

In this section we explain the impact of Theorem 3 about Binary Constrained k-Center to other problems around low-rank matrix approximation. We would like to mention that Binary Constrained k-Center is very similar to the Binary Constrained Clustering problem from [9]. In Binary Constrained k-Center we want to minimize the maximum

distance of a vector from the input set of vectors to the closest center, whereas in Binary Constrained Clustering the sum of distances is minimized. While these problems are different, the reduction we explain here, except a few details, are identical to the ones described in [9]. For reader's convenience, we give one reduction (Lemma 14) in full details and skip all other reductions, which are similar.

In the following lemma we show that ℓ_1-Rank-r Approximation over GF(2) is a special case of Binary Constrained k-Center.

▶ **Lemma 14** (⋆). *There is an algorithm that given an instance $(\mathbf{A}, r)$ of ℓ_1-Rank-r Approximation over GF(2), where $\mathbf{A}$ is an $m \times n$-matrix and r is an integer, runs in time $\mathcal{O}(m + n + 2^{2r})$, and outputs an instance $J = (X, k = 2^r, \mathcal{R})$ of Binary Constrained k-Center with the following property. Given any α-approximate solution C to J, an α-approximate solution $\mathbf{B}$ to $(\mathbf{A}, r)$ can be constructed in time $\mathcal{O}(rmn)$ and vice versa.*

Thus, Theorem 1 follows from Theorem 3 and Lemma 14.

Low Boolean-Rank Approximation. Let $\mathbf{A}$ be a binary $m \times n$ matrix. Now we consider the elements of $\mathbf{A}$ to be *Boolean* variables. The *Boolean rank* of $\mathbf{A}$ is the minimum r such that $\mathbf{A} = \mathbf{U} \wedge \mathbf{V}$ for a Boolean $m \times r$ matrix $\mathbf{U}$ and a Boolean $r \times n$ matrix $\mathbf{V}$, where the product is Boolean, that is, the logical $\wedge$ plays the role of multiplication and $\vee$ the role of sum. Here $0 \wedge 0 = 0$, $0 \wedge 1 = 0$, $1 \wedge 1 = 1$, $0 \vee 0 = 0$, $0 \vee 1 = 1$, and $1 \vee 1 = 1$. Thus the matrix product is over the Boolean semi-ring $(0, 1, \wedge, \vee)$. This can be equivalently expressed as the normal matrix product with addition defined as $1 + 1 = 1$. Binary matrices equipped with such algebra are called *Boolean matrices*.

In Boolean ℓ_1-Rank-r Approximation, we are given an $m \times n$ binary data matrix $\mathbf{A}$ and a positive integer r, and we seek a binary matrix $\mathbf{B}$ optimizing

$$\begin{aligned} &\text{minimize } \|\mathbf{A} - \mathbf{B}\|_1 \\ &\text{subject to } \operatorname{rank}(\mathbf{B}) \leq r. \end{aligned}$$

Here, by the rank of binary matrix $\mathbf{B}$ we mean its Boolean rank, and norm $\|\cdot\|_1$ is the *column sum norm*. Similar to Lemma 14, one can prove that Boolean ℓ_1-Rank-r Approximation is a special case of Binary Constrained k-Center, where $k = 2^r$. Thus, we get the following corollary from Theorem 3.

▶ **Corollary 15.** *There is an algorithm for Boolean ℓ_1-Rank-r Approximation that given an instance $I = (\mathbf{A}, r)$ and $0 < \varepsilon < 1$, runs in time $m^{\mathcal{O}(1)} n^{\mathcal{O}(2^{4r}/\varepsilon^4)}$, and outputs a $(1 + \varepsilon)$-approximate solution with probability at least $1 - 2n^{-2}$.*

Projective k-center. The Binary Projective k-Center problem is a variation of the Binary k-Center problem, where the centers of clusters are linear subspaces of bounded dimension r. (For $r = 1$ this is Binary k-Center and for $k = 1$ this is ℓ_1-Rank-r Approximation over GF(2).) Formally, in Binary Projective k-Center we are given a set $X \subseteq \{0, 1\}^m$ of n vectors and positive integers k and r. The objective is to find a family of r-dimensional linear subspaces $C = \{C_1, \ldots, C_k\}$ over GF(2) minimizing $\max_{\mathbf{x} \in X} d_H(\mathbf{x}, \bigcup_{i=1}^{k} C)$.

To see that Binary Projective k-Center is a special case of Binary Constrained k-Center, we observe that the condition that C_i is an r-dimensional subspace over GF(2) can be encoded (as in Lemma 14) by 2^r constraints. This observation leads to the following lemma.

▶ **Lemma 16.** *There is an algorithm that given an instance (X, r, k) of* Binary Projective k-Center*, runs in time $\mathcal{O}(m + n + 2^{\mathcal{O}(rk)})$, and outputs an instance $J = (X, k' = 2^{kr}, \mathcal{R})$ of* Binary Constrained k-Center *with the following property. Given any α-approximate solution C to J, an α-approximate solution C' to (X, r, k) can be constructed in time $\mathcal{O}(rkmn)$ and vice versa.*

Combining Theorem 3 and Lemma 16 together, we get the following corollary.

▶ **Corollary 17.** *There is an algorithm for* Binary Projective k-Center *that given an instance $I = (X, r, k)$ and $0 < \varepsilon < 1$, where $X \subseteq \{0,1\}^m$ is a set of n vectors and $r, k \in \mathbb{N}$, runs in time $m^{\mathcal{O}(1)} n^{\mathcal{O}(2^{4kr}/\varepsilon^4)}$, and outputs a $(1+\varepsilon)$-approximate solution with probability at least $1 - 2n^{-2}$.*

5 Conclusion

In this paper we gave a randomized PTAS for the Binary Constrained k-Center problem. This yields the first approximation scheme for ℓ_1-Rank-r Approximation over GF(2) and its Boolean variant. This paper leaves several interesting open problems. The running time of our $(1+\varepsilon)$-approximation algorithm is $m^{\mathcal{O}(1)} n^{\mathcal{O}(2^{4r} \cdot \varepsilon^{-4})}$. How far is this running time from being optimal? A simple adaptation of the result of Cygan et al. [6] for Closest String, yields that already for $r = 1$, an $(1+\varepsilon)$-approximation in time $n^{\mathcal{O}(1)} \cdot f(\varepsilon)$, for any computable function f, would imply that FPT=W[1]. Also the existence of a PTAS for $r = 1$ with running time $f(\varepsilon) n^{o(1/\varepsilon)}$, for any computable function f, would contradict the Exponential Time Hypothesis [6]. But these results do not exclude the opportunity of having an algorithm of running time $f(r, \varepsilon) \cdot (nm)^{poly(1/\varepsilon)}$ for some function f. Even the existence of an algorithm for ℓ_1-Rank-r Approximation over GF(2) of running time $m^{\mathcal{O}(1)} n^{poly(r,\varepsilon)}$ is an interesting open question.

Abstract

The dynamic optimality conjecture, postulating the existence of an $O(1)$-competitive online algorithm for binary search trees (BSTs), is among the most fundamental open problems in dynamic data structures. Despite extensive work and some notable progress, including, for example, the Tango Trees (Demaine et al., FOCS 2004), that give the best currently known $O(\log\log n)$-competitive algorithm, the conjecture remains widely open. One of the main hurdles towards settling the conjecture is that we currently do not have approximation algorithms achieving better than an $O(\log\log n)$-approximation, even in the offline setting. All known non-trivial algorithms for BST's so far rely on comparing the algorithm's cost with the so-called Wilber's first bound (WB-1). Therefore, establishing the worst-case relationship between this bound and the optimal solution cost appears crucial for further progress, and it is an interesting open question in its own right.

Our contribution is two-fold. First, we show that the gap between the WB-1 bound and the optimal solution value can be as large as $\Omega(\log\log n/\log\log\log n)$; in fact, we show that the gap holds even for several stronger variants of the bound. Second, we provide a simple algorithm, that, given an integer $D > 0$, obtains an $O(D)$-approximation in time $\exp\left(O\left(n^{1/2^{\Omega(D)}}\log n\right)\right)$. In particular, this yields a constant-factor approximation algorithm with sub-exponential running time. Moreover, we obtain a simpler and cleaner efficient $O(\log\log n)$-approximation algorithm that can be used in an online setting. Finally, we suggest a new bound, that we call the *Guillotine Bound*, that is stronger than WB-1, while maintaining its algorithm-friendly nature, that we hope will lead to better algorithms. All our results use the geometric interpretation of the problem, leading to cleaner and simpler analysis.

1 Introduction

Binary search trees (BST's) are a fundamental data structure that has been extensively studied for many decades. Informally, suppose we are given as input an **online** access sequence $X = \{x_1, \ldots, x_m\}$ of keys from $\{1, \ldots, n\}$, and our goal is to maintain a binary search tree T over the set $\{1, \ldots, n\}$ of keys. The algorithm is allowed to modify the tree T after each access; the tree obtained after the ith access is denoted by T_{i+1}. Each such modification involves a sequence of *rotation* operations that transform the current tree T_i into a new tree T_{i+1}. The cost of the transformation is the total number of rotations performed plus the depth of the key x_i in the tree T_i. The total cost of the algorithm is the total cost of all transformations performed as the sequence X is processed. We denote by $\mathsf{OPT}(X)$ the smallest cost of any algorithm for maintaining a BST for the access sequence X, when the whole sequence X is known to the algorithm in advance.

Several algorithms for BST's, whose costs are guaranteed to be $O(m \log n)$ for any access sequence, such as AVL-trees [1] and red-black trees [2], are known since the 60's. Moreover, it is well known that there are length-m access sequences X on n keys, for which $\mathsf{OPT}(X) = \Omega(m \log n)$. However, such optimal worst-case guarantees are often unsatisfactory from both practical and theoretical perspectives, as one can often obtain better results for "structured" inputs. Arguably, a better notion of the algorithm's performance to consider is *instance optimality*, where the algorithm's performance is compared to the optimal cost $\mathsf{OPT}(X)$ for the specific input access sequence X. This notion is naturally captured by the algorithm's *competitive ratio*: we say that an algorithm for BST's is α-*competitive*, if, for every online input access sequence X, the cost of the algorithm's execution on X is at most $\alpha \cdot \mathsf{OPT}(X)$. Since for every length-m access sequence X, $\mathsf{OPT}(X) \geq m$, the above-mentioned algorithms that provide worst-case $O(m \log n)$-cost guarantees are also $O(\log n)$-competitive. However, there are many known important special cases, in which the value of the optimal solution is $O(m)$, and for which the existence of an $O(1)$-competitive algorithm would lead to a much better performance, including some interesting applications, such as, for example, adaptive sorting [23, 6, 19, 22, 13, 20, 12, 8, 7, 3, 5, 4]. A striking conjecture of Sleator and Tarjan [21] from 1985, called the *dynamic optimality conjecture*, asserts that the *Splay Trees* provide an $O(1)$-competitive algorithm for BST's. This conjecture has sparked a long line of research, but despite the continuing effort, and the seeming simplicity of BST's, it remains widely open. In a breakthrough result, Demaine et al. [10] proposed the Tango Trees algorithm, that achieves an $O(\log \log n)$-competitive ratio, and has remained the best known algorithm for the problem, for over 15 years. A natural avenue for overcoming this barrier is to first consider the "easier" task of designing (offline) approximation algorithms, whose approximation factor is below $O(\log \log n)$. Designing better approximation algorithms is often a precursor to obtaining better online algorithms, and it is a natural stepping stone towards this goal.

The main obstacle towards designing better algorithms, both in the online and the offline settings, is obtaining tight lower bounds on the value $\mathsf{OPT}(X)$, that can be used in algorithm design. If the input access sequence X has length m, and it contains n keys, then it is easy to see that $\mathsf{OPT}(X) \geq \Omega(m)$, and, by using any balanced BST's, such as AVL-trees, one can show that $\mathsf{OPT}(X) = O(m \log n)$. This trivially implies an $O(\log n)$-approximation for both offline and online settings. However, in order to obtain better approximation, these simple bounds do not seem sufficient. Wilber [25] proposed two new bounds, that we refer to as the first Wilber Bound (WB-1) and the second Wilber Bound (WB-2). He proved that, for every input sequence X, the values of both these bounds on X are at most $\mathsf{OPT}(X)$.

The breakthrough result of Demaine et al. [10], that gives an $O(\log\log n)$-competitive online algorithm, relies on the WB-1 bound. In particular, they show that the cost of the solution produced by their algorithm is within an $O(\log\log n)$-factor from the WB-1 bound on the given input sequence X, and hence from $\mathsf{OPT}(X)$. This in turn implies that, for every input sequence X, the value of the WB-1 bound is within an $O(\log\log n)$ factor from $\mathsf{OPT}(X)$. Follow-up work [24, 14] improved several aspects of Tango Trees, but it did not improve the approximation factor. Additional lower bounds on OPT, that subsume both the WB-1 and the WB-2 bounds, were suggested in [9, 11, 15], but unfortunately it is not clear how to exploit them in algorithm design. To this day, the only method we have for designing non-trivial online or offline approximation algorithms for BST's is by relying on the WB-1 bound, and this seems to be the most promising approach for obtaining better algorithms. In order to make further progress on both online and offline approximation algorithms for BST's, it therefore appears crucial that we better understand the relationship between the WB-1 bound and the optimal solution cost.

Informally, the WB-1 bound relies on recursive partitioning of the input key sequence, that can be represented by a partitioning tree. The standard WB-1 bound (that we refer to as the *weak* WB-1 bound) only considers a single such partitioning tree. It is well-known (see e.g. [10, 24, 16]), that the gap between $\mathsf{OPT}(X)$ and the weak WB-1 bound for an access sequence X may be as large as $\Omega(\log\log n)$. However, the "bad" access sequence X used to obtain this gap is highly dependent on the fixed partitioning tree T. It is then natural to consider a stronger variant of WB-1, that we refer to as *strong* WB-1 bound and denote by $\mathsf{WB}(X)$, that maximizes the weak WB-1 bound over all such partitioning trees. As suggested by Iacono [16], and by Kozma [17], this gives a promising approach for improving the $O(\log\log n)$-approximation factor.

In this paper, we show that, even for this strong variant of Wilber Bound, the gap between $\mathsf{OPT}(X)$ and $\mathsf{WB}(X)$ may be as large as $\Omega(\log\log n/\log\log\log n)$. This negative result extends to an even stronger variant of the Wilber Bound that we discuss below.

Our second set of results is algorithmic. We show an (offline) algorithm that, given an input sequence X and a positive integer D, obtains an $O(D)$-approximation, in time $\mathrm{poly}(m)\cdot\exp\left(n^{1/2^{\Omega(D)}}\log n\right)$. When D is constant, the algorithm obtains an $O(1)$-approximation in sub-exponential time. When D is $\Theta(\log\log n)$, it matches the best current efficient $O(\log\log n)$-approximation algorithm. In the latter case, we can also adapt the algorithm to the online setting, obtaining an $O(\log\log n)$-competitive online algorithm.

All our results use the geometric interpretation of the problem, introduced by Demaine et al. [9], leading to clean divide-and-conquer-style arguments that avoid, for example, the notion of pointers and rotations. We feel that this approach, in addition to providing a cleaner and simpler view of the problem, is more natural to work with in the context of approximation algorithms, and should be more amenable to the powerful geometric techniques in the field.

Independent Work. Independently from our work, Lecomte and Weinstein [18] showed that second Wilber Bound (WB-2) dominates the WB-1 bound, and moreover, they show an access sequence X for which the two bounds have a gap of $\Omega(\log\log n)$. In particular, their result implies that the gap between $\mathsf{WB}(X)$ and $\mathsf{OPT}(X)$ is $\Omega(\log\log n)$ for that access sequence. We note that the access sequence X that is used in our negative results also provides a gap of $\Omega(\log\log n/\log\log\log n)$ between the WB-2 and the WB-1 bounds, although we only realized this after hearing the statement of the results of [18]. Additionally, Lecomte and Weinstein show that the WB-2 bound is invariant under rotations, and use this to show that, when the WB-2 bound is constant, then the Independent Rectangle bound of [9] is linear.

We now provide a more detailed description of our results.

Our Results and Techniques

We use the geometric interpretation of the problem, introduced by Demaine et al. [9], that we refer to as the Min-Sat problem. Let P be any set of points in the plane. We say that two points $p, q \in P$ are *collinear* iff either their x-coordinates are equal, or their y-coordinates are equal. If p and q are non-collinear, then we let $\square_{p,q}$ be the smallest closed rectangle containing both p and q; notice that p and q must be diagonally opposite corners of this rectangle. We say that the pair (p, q) of points is *satisfied* in P iff there is some additional point $r \neq p, q$ in P that lies in $\square_{p,q}$ (the point may lie on the boundary of the rectangle). Lastly, we say that the set P of points is satisfied iff for every pair $p, q \in P$ of distinct points, either p and q are collinear, or they are satisfied in P.

In the Min-Sat problem, the input is a set P of points in the plane with integral x- and y-coordinates; we assume that all x-coordinates are between 1 and n, and all y-coordinates are between 1 and m and distinct from each other, and that $|P| = m$. The goal is to find a minimum-cardinality set Y of points, such that the set $P \cup Y$ of points is satisfied.

An access sequence X over keys $\{1, \ldots, n\}$ can be represented by a set P of points in the plane as follows: if a key x is accessed at time y, then add the point (x, y) to P. Demaine et al. [9] showed that, for every access sequence X, if we denote by P the corresponding set of points in the plane, then the value of the optimal solution to the Min-Sat problem on P is $\Theta(\mathsf{OPT}(X))$. They also showed that, in order to obtain an $O(\alpha)$-approximation algorithm for BST's, it is sufficient to obtain an α-approximation algorithm for the Min-Sat problem. In the online version of the Min-Sat problem, at every time step t, we discover the unique input point whose y-coordinate is t, and we need to decide which points with y-coordinate t to add to the solution. Demaine et al. [9] also showed that an α-competitive online algorithm for Min-Sat implies an $O(\alpha)$-competitive online algorithm for BST's. For convenience, we do not distinguish between the input access sequence X and the corresponding set of points in the plane, that we also denote by X.

Negative Results for WB-1. We say that an input access sequence X is a *permutation* if each key in $\{1, \ldots, n\}$ is accessed exactly once. Equivalently, in the geometric view, every column with an integral x-coordinate contains exactly one input point.

Informally, the WB-1 bound for an input sequence X is defined as follows. Let B be the bounding box containing all points of X, and consider any vertical line L drawn across B, that partitions it into two vertical strips, separating the points of X into two subsets X_1 and X_2. Assume that the points of X are ordered by their y-coordinates from smallest to largest. We say that a pair $(x, x') \in X$ of points *cross* the line L, iff x and x' are consecutive points of X, and they lie on different sides of L. Let $C(L)$ be the number of all pairs of points in X that cross L. We then continue this process recursively with X_1 and X_2, with the final value of the WB-1 bound being the sum of the two resulting bounds obtained for X_1 and X_2, and $C(L)$. This recursive partitioning process can be represented by a binary tree T that we call a *partitioning tree* (we note that the partitioning tree is not related to the BST tree that the BST algorithm maintains). Every vertex v of the partitioning tree is associated with a vertical strip $S(v)$, where for the root vertex r, $S(r) = B$. If the partitioning algorithm uses a vertical line L to partition the strip $S(v)$ into two sub-strips S_1 and S_2, then vertex v has two children, whose corresponding strips are S_1 and S_2. Note that every sequence of vertical lines used in the recursive partitioning procedure corresponds to a unique partitioning tree and vice versa. Given a set X of points and a partitioning tree T, we denote by $\mathsf{WB}_T(X)$ the WB-1 bound obtained for X while following the partitioning scheme defined by T. Wilber [25] showed that, for every partitioning tree T, $\mathsf{OPT}(X) \geq \Omega(\mathsf{WB}_T(X))$ holds. Moreover, Demaine et al. [10]

showed that, if T is a balanced tree, then $\mathsf{OPT}(X) \leq O(\log\log n) \cdot \mathsf{WB}_T(X)$. These two bounds are used to obtain the $O(\log\log n)$-competitive algorithm of [10]. We call this variant of WB-1, that is defined with respect to a fixed tree T, the *weak* WB-1 bound.

Unfortunately, it is well-known (see e.g. [10, 24, 16]), that the gap between $\mathsf{OPT}(X)$ and the weak WB-1 bound on an input X may be as large as $\Omega(\log\log n)$. In other words, for any fixed partitioning tree T, there exists an input X (that depends on T), with $\mathsf{WB}_T(X) \leq O(\mathsf{OPT}(X)/\log\log n)$. However, the construction of this "bad" input X depends on the fixed partitioning tree T. We consider a stronger variant of WB-1, that we refer to as *strong* WB-1 bound and denote by $\mathsf{WB}(X)$, that maximizes the weak WB-1 bound over all such partitioning trees, that is, $\mathsf{WB}(X) = \max_T\{\mathsf{WB}_T(X)\}$. Using this stronger bound as an alternative to weak WB-1 in order to obtain better approximation algorithms was suggested by Iacono [16], and by Kozma [17].

Our first result rules out this approach: we show that, even for the strong WB-1 bound, the gap between $\mathsf{WB}(X)$ and $\mathsf{OPT}(X)$ may be as large as $\Omega(\log\log n/\log\log\log n)$, even if the input X is a permutation.

▶ **Theorem 1.** *For every integer n', there is an integer $n \geq n'$, and an access sequence X on n keys with $|X| = n$, such that X is a permutation, $\mathsf{OPT}(X) \geq \Omega(n\log\log n)$, but $\mathsf{WB}(X) \leq O(n\log\log\log n)$. In other words, for every partitioning tree T, $\frac{\mathsf{OPT}(X)}{\mathsf{WB}_T(X)} \geq \Omega\left(\frac{\log\log n}{\log\log\log n}\right)$.*

We note that it is well known (see e.g. [5]), that any c-approximation algorithm for permutation input can be turned into an $O(c)$-approximation algorithm for any input sequence. However, the known instances that achieve an $\Omega(\log\log n)$-gap between the weak WB-1 bound and OPT are not permutations. Therefore, our result is the first to provide a super-constant gap between WB-1 and OPT for permutations, even for the case of weak WB-1.

Extension of WB-1. We consider several generalizations of the WB-1 bound that allow partitioning the plane both horizontally and vertically. We call the new bounds the *consistent Guillotine Bound* and the *Guillotine Bound*. Our negative result extends to the consistent Guillotine Bound but *not* to the Guillotine Bound. The Guillotine Bound seems to maintain the algorithm-friendly nature of WB-1, and in particular it naturally fits into the algorithmic framework that we propose. We hope that this bound can lead to improved algorithms, both in the offline and the online settings

Separating the Two Wilber Bounds. The sequence X given by Theorem 1 not only provides a separation between WB-1 and OPT, but it also provides a separation between the WB-1 bound and the WB-2 bound (also called the *funnel* bound). The latter can be defined in the geometric view as follows. Recall that, for a pair of points $x, y \in X$, $\square_{x,y}$ is the smallest closed rectangle containing both x and y. For a point x in the access sequence X, the *funnel* of x is the set of all points $y \in X$, for which $\square_{x,y}$ does not contain any point of $X \setminus \{x, y\}$, and $\mathrm{alt}(x)$ is the number of alterations between the left of x and the right of x in the funnel of x. The second Wilber Bound for sequence X is then defined as: $\mathsf{WB}^{(2)}(X) = |X| + \sum_{x\in X}\mathrm{alt}(x)$. We show that, for the sequence X given by Theorem 1, $\mathsf{WB}^{(2)}(X) \geq \Omega(n\log\log n)$ holds, and therefore $\mathsf{WB}^{(2)}(X)/\mathsf{WB}(X) \geq \Omega(\log\log n/\log\log\log n)$ for that sequence, implying that the gap between $\mathsf{WB}(X)$ and $\mathsf{WB}^{(2)}(X)$ may be as large as $\Omega(\log\log n/\log\log\log n)$. We note that we only realized that our results provide this stronger separation between the two Wilber bounds after hearing the statements of the results from the independent work of Lecomte and Weinstein [18] mentioned above.

Algorithmic Results. We provide new simple approximation algorithms for the problem, that rely on its geometric interpretation, namely the Min-Sat problem.

▶ **Theorem 2.** *There is an offline algorithm for Min-Sat, that, given any integral parameter $D \geq 1$, and an access sequence X to n keys of length m, produces a solution of cost at most $O(D \cdot OPT(X))$ and has running time at most* $\text{poly}(m) \cdot \exp\left(O\left(n^{1/2^{\Theta(D)}} \log n\right)\right)$. *For $D = O(\log \log n)$, the algorithm's running time is polynomial in n and m, and it can be adapted to the online setting, achieving an $O(\log \log n)$-competitive ratio.*

Our results show that the problem of obtaining a constant-factor approximation for Min-Sat cannot be NP-hard, unless NP $\subseteq$ SUBEXP, where SUBEXP $= \bigcap_{\epsilon>0} \text{DTime}[2^{n^\epsilon}]$. This, in turn, provides a positive evidence towards the dynamic optimality conjecture, as one natural avenue to disproving it is to show that obtaining a constant-factor approximation for BST's is NP-hard. Our results rule out this possibility, unless NP $\subseteq$ SUBEXP. While the $O(\log \log n)$-approximation factor achieved by our algorithm in time $\text{poly}(mn)$ is similar to that achieved by other known algorithms [10, 14, 24], this is the first algorithm that relies solely on the geometric formulation of the problem, which is arguably cleaner, simpler, and better suited for exploiting the rich toolkit of algorithmic techniques developed in the areas of online and approximation algorithms.

Organization. We start with preliminaries in Section 2. In Section 3, we state decomposition theorems which are useful for both of our negative and positive results. In Section 4, we provide the proof of Theorem 1, our main negative result. We discuss extensions of the Wilber Bound in Section 5. Lastly, we show our main positive result – the proof of Theorem 2 – in Section 6. Due to lack of space, many of the proofs are deferred to the full version.

2 Preliminaries

All our results only use the geometric interpretation of the problem, that we refer to as the Min-Sat problem. We include the formal definition of algorithms for BST's and formally state their equivalence to Min-Sat in the full version.

2.1 The Min-Sat Problem

For a point $p \in \mathbb{R}^2$ in the plane, we denote by $p.x$ and $p.y$ its x- and y-coordinates, respectively. Given any pair p, p' of points, we say that they are *collinear* if $p.x = p'.x$ or $p.y = p'.y$. If p and p' are not collinear, then we let $\square_{p,p'}$ be the smallest closed rectangle containing both p and p'; note that p and p' must be diagonally opposite corners of the rectangle.

▶ **Definition 3.** *We say that a non-collinear pair p, p' of points is* satisfied by a point p'' *if p'' is distinct from p and p' and $p'' \in \square_{p,p'}$ (where p'' may lie on the boundary of the rectangle). We say that a set S of points is* satisfied *iff for every non-collinear pair $p, p' \in S$ of points, there is some point $p'' \in S$ that satisfies this pair.*

We refer to horizontal and vertical lines as *rows* and *columns* respectively. For a collection of points X, the *active rows* of X are the rows that contain at least one point in X. We define the notion of *active columns* analogously. We denote by $r(X)$ and $c(X)$ the number of active rows and active columns of the point set X, respectively. We say that a point set X is a *semi-permutation* if every active row contains exactly one point of X. Note that, if X is a semi-permutation, then $c(X) \leq r(X)$. We say that X is a *permutation* if it is a

semi-permutation, and additionally, every active column contains exactly one point of X. Clearly, if X is a permutation, then $c(X) = r(X) = |X|$. We denote by B the smallest closed rectangle containing all points of X, and call B the *bounding box*.

We are now ready to define the Min-Sat problem. The input to the problem is a set X of points that is a semi-permutation, and the goal is to compute a minimum-cardinality set Y of points, such that $X \cup Y$ is satisfied. We say that a set Y of points is a *feasible solution* for X if $X \cup Y$ is satisfied. We denote by $\mathsf{OPT}(X)$ the minimum value $|Y|$ of any feasible solution Y for X.[1] In the online version of the Min-Sat problem, at every time step t, we discover the unique input point from X whose y-coordinate is t, and we need to decide which points with y-coordinate t to add to the solution Y. The Min-Sat problem is equivalent to the BST problem, in the following sense:

▶ **Theorem 4** ([9]). *Any efficient α-approximation algorithm for Min-Sat can be transformed into an efficient $O(\alpha)$-approximation algorithm for BST's, and similarly any online α-competitive algorithm for Min-Sat can be transformed into an online $O(\alpha)$-competitive algorithm for BST's.*

2.2 Basic Geometric Properties

The following observation is well known (see, e.g. Observation 2.1 from [9]).

▶ **Observation 5.** *Let Z be any satisfied point set. Then for every pair $p, q \in Z$ of distinct points, there is a point $r \in \square_{p,q} \setminus \{p, q\}$ such that $r.x = p.x$ or $r.y = p.y$.*

Collapsing Sets of Columns or Rows. Assume that we are given any set X of points, and any collection $\mathcal{C}$ of consecutive active columns for X. In order to collapse the set $\mathcal{C}$ of columns, we replace $\mathcal{C}$ with a single representative column C (for concreteness, we use the column of $\mathcal{C}$ with minimum x-coordinate). For every point $p \in X$ that lies on a column of $\mathcal{C}$, we replace p with a new point, lying on the column C, whose y-coordinate remains the same. Formally, we replace point p with point $(x, p.y)$, where x is the x-coordinate of the column C. We denote by $X_{|\mathcal{C}}$ the resulting new set of points. We can similarly define collapsing set of rows. The following useful observation is easy to verify.

▶ **Observation 6.** *Let S be any set of points, and let $\mathcal{C}$ be any collection of consecutive active columns (or rows) with respect to S. If S is a satisfied set of points, then so is $S_{|\mathcal{C}}$.*

Canonical Solutions. We say that a solution Y for input X is *canonical* iff every point $p \in Y$ lies on an active row and an active column of X. It is easy to see that *any* solution can be transformed into a canonical solution, without increasing its cost (see the full version of the paper for the proof).

▶ **Observation 7.** *There is an efficient algorithm, that, given an instance X of Min-Sat and any feasible solution Y for X, computes a feasible canonical solution $\hat{Y}$ for X with $|\hat{Y}| \leq |Y|$.*

2.3 Partitioning Trees

We now turn to define partitioning trees, that are central to both defining the WB-1 bound and to describing our algorithm.

[1] We remark that in the original paper that introduced this problem [9], the value of the solution is defined as $|X \cup Y|$, while our solution value is $|Y|$. It is easy to see that for any semi-permutation X and solution Y for X, $|Y| \geq \Omega(|X|)$ must hold, so the two definitions are equivalent to within factor 2.

Let X be the a set of points that is a semi-permutation. We can assume without loss of generality that every column with an integral x-coordinate between 1 and $c(X)$ inclusive contains at least one point of X. Let B be the bounding box of X. Assume that the set of active columns is $\{C_1, \ldots, C_a\}$, where $a = c(X)$, and that for all $1 \leq i \leq a$, the x-coordinate of column C_i is i. Let $\mathcal{L}$ be the set of all vertical lines with half-integral x-coordinates between $1 + 1/2$ and $a - 1/2$ (inclusive). Throughout, we refer to the vertical lines in $\mathcal{L}$ as *auxiliary columns*. Let σ be an arbitrary ordering of the lines of $\mathcal{L}$ and denote $\sigma = (L_1, L_2, \ldots, L_{a-1})$. We define a hierarchical partition of the bounding box B into vertical strips using σ, as follows. We perform $a - 1$ iterations. In the first iteration, we partition the bounding box B, using the line L_1, into two vertical strips, S_L and S_B. For $1 < i \leq a - 1$, in iteration i we consider the line L_i, and we let S be the unique vertical strip in the current partition that contains the line L_i. We then partition S into two vertical sub-strips by the line L_i. When the partitioning algorithm terminates, every vertical strip contains exactly one active column.

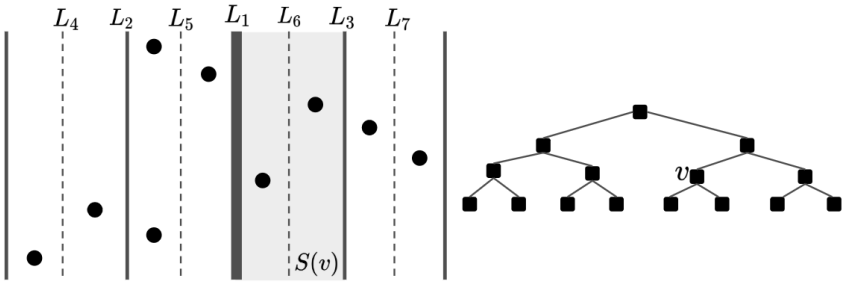

Figure 1 An Illustration of partitioning tree and the corresponding sequence $\sigma = (L_1, \ldots, L_7)$. Strip $S(v)$ corresponds to node v that owns line L_6.

This partitioning process can be naturally described by a binary tree $T = T(\sigma)$, that we call a *partitioning tree* associated with the ordering σ (see Figure 1). Each node $v \in V(T)$ is associated with a vertical strip $S(v)$ of the bounding box B. The strip $S(r)$ of the root vertex r of T is the bounding box B. For every inner vertex $v \in V(T)$, if $S = S(v)$ is the vertical strip associated with v, and if $L \in \mathcal{L}$ is the first line in σ that lies strictly in S, then line L partitions S into two sub-strips, that we denote by S_L and S_R. Vertex v then has two children, whose corresponding strips are S_L and S_R respectively. We say that v *owns* the line L, and we denote $L = L(v)$. For each leaf node v, the corresponding strip $S(v)$ contains exactly one active column of X, and v does not own any line of $\mathcal{L}$. For each vertex $v \in V(T)$, let $N(v) = |X \cap S(v)|$ be the number of points from X that lie in $S(v)$, and let width(v) be the width of the strip $S(v)$. Given a partition tree T for point set X, we refer to the vertical strips in $\{S(v)\}_{v \in T}$ as T-strips.

2.4 The WB-1 Bound

The WB-1 bound[2] is defined with respect to an ordering (or a permutation) σ of the auxiliary columns, or, equivalently, with respect to the partitioning tree $T(\sigma)$. It will be helpful to keep both these views in mind. In this paper, we will make a clear distinction between a weak variant of the WB-1 bound, as defined by Wilber himself in [25] and a strong variant, as mentioned in [16].

[2] Also called Interleaving bound [10], the first Wilber bound, "interleave lower bound" [25], or alternation bound [16]

Let X be a semi-permutation, and let $\mathcal{L}$ be the corresponding set of auxiliary columns. Consider an arbitrary fixed ordering σ of columns in $\mathcal{L}$ and its corresponding partition tree $T = T(\sigma)$. For each inner node $v \in V(T)$, consider the set $X' = X \cap S(v)$ of input points that lie in the strip $S(v)$, and let $L(v) \in \mathcal{L}$ be the line that v owns. We denote $X' = \{p_1, p_2, \ldots, p_k\}$, where the points are indexed in the increasing order of their y-coordinates; since X is a semi-permutation, no two points of X may have the same y-coordinate. For $1 \leq j < k$, we say that the ordered pair (p_j, p_{j+1}) of points form a *crossing* of $L(v)$ iff p_j, p_{j+1} lie on the opposite sides of the line $L(v)$. We let $\mathsf{cost}(v)$ be the total number of crossings of $L(v)$ by the points of $X \cap S(v)$. When $L = L(v)$, we also write $\mathsf{cost}(L)$ to denote $\mathsf{cost}(v)$. If v is a leaf vertex, then its cost is set to 0.

▶ **Definition 8** (WB-1 bound). *For any semi-permutation X, an ordering σ of the auxiliary columns in $\mathcal{L}$, and the corresponding partitioning tree $T = T_\sigma$, the (weak) WB-1 bound of X with respect to σ is: $\mathsf{WB}_\sigma(X) = \mathsf{WB}_T(X) = \sum_{v \in V(T)} \mathsf{cost}(v)$. The strong WB-1 bound of X is $\mathsf{WB}(X) = \max_\sigma \mathsf{WB}_\sigma(X)$, where the maximum is taken over all permutations σ of the lines in $\mathcal{L}$.*

It is well known that the WB-1 bound is a lower bound on the optimal solution cost:

▷ Claim 9. For any semi-permutation X, $\mathsf{WB}(X) \leq 2 \cdot \mathsf{OPT}(X)$.

The original proof of this fact is due to Wilber [25], which was later presented in the geometric view by Demaine et al. [9], via the notion of *independent rectangles*.

3 Geometric Decomposition Theorems

In this section, we develop several technical tools that will allow us to decompose a given instance into a number of sub-instances. We then analyze the optimal solution costs and the Wilber bound values for the resulting subinstances.

Split Instances. Consider a semi-permutation X and its partitioning tree T. Let $U \subseteq V(T)$ be a collection of vertices of the tree T, such that the strips $\{S(v)\}_{v \in U}$ partition the bounding box. In other words, every root-to-leaf path in T must contain exactly one vertex of U. We now define splitting an instance X via the set U of vertices of T.

▶ **Definition 10** (A Split). *A* split *of (X, T) at U is a collection of instances $\{X^c, \{X^s_v\}_{v \in U}\}$, defined as follows.*

- *For each vertex $v \in U$, instance X^s_v is called a* ***strip instance****, and it contains all points of X that lie in the interior of the strip $S(v)$.*
- *Instance X^c is called a* ***compressed instance****, and it is obtained from X by collapsing, for every vertex $v \in U$, all active columns in the strip $S(v)$ into a single column.*

We also partition the tree T into sub-trees that correspond to the new instances: for every vertex $v \in U$, we let T_v be the sub-tree of T rooted at v. Observe that T_v is a partitioning tree for instance X^s_v. The tree T^c is obtained from T by deleting from it, for all $v \in U$, all vertices of $V(T_v) \setminus \{v\}$. It is easy to verify that T^c is a valid partitioning tree for instance X^c. The following observation, whose proof appears in the full version of the paper, establishes several basic properties of a split. Recall that, given an instance X, $r(X)$ and $c(X)$ denote the number of active rows and active columns in X, respectively.

▶ **Observation 11.** *If X is a semi-permutation, then the following properties hold for any (X,T)-split at U:*

- $\sum_{v\in U} r(X^s_v) = r(X)$
- $\sum_{v\in U} c(X^s_v) = c(X)$
- $c(X^c) \leq |U|$
- $\sum_{v\in U} \mathsf{WB}_{T_v}(X^s_v) + \mathsf{WB}_{T^c}(X^c) = \mathsf{WB}_T(X)$.

The first property holds since X is a semi-permutation. In order to establish the last property, consider any vertex $x \in V(T)$, and let $T' \in \{T^c\} \cup \{T_v\}_{v\in U}$ be the new tree to which v belongs; if $x \in U$, then we set $T' = T_x$. It is easy to see that the cost of v in tree T' is the same as its cost in the tree T (recall that the cost of a leaf vertex is 0). The last property can be viewed as a "perfect decomposition" property of the weak WB-1 bound. We will show below an (approximate) decomposition property of strong WB-1 bound.

Splitting by Lines. We can also define the splitting with respect to any subset $\mathcal{L}' \subseteq \mathcal{L}$ of the auxiliary columns for X, analogously: Notice that the lines in $\mathcal{L}'$ partition the bounding box B into a collection of internally disjoint strips, that we denote by $\{S'_1, \ldots, S'_k\}$. We can then define the strip instances X^s_i as containing all vertices of $X \cap S_i$ for all $1 \leq i \leq k$, and the compressed instance X^c, that is obtained by collapsing, for each $1 \leq i \leq k$, all active columns that lie in strip S_i, into a single column. We also call these resulting instances *a split of X by $\mathcal{L}'$*.

We can also consider an arbitrary ordering σ of the lines in $\mathcal{L}$, such that the lines of $\mathcal{L}'$ appear at the beginning of σ, and let $U \subseteq V(T(\sigma))$ contain all vertices u for which the strip $S(u)$ is in $\{S_i\}_{1\leq i\leq k}$. If we perform a split of (X,T) at U, we obtain exactly the same strip instances $X^s_1, \ldots, X^s_k$, and the same compressed instance X^c.

Decomposition Theorem for OPT. The following theorem gives a crucial decomposition property of OPT. The theorem is used in our algorithm for Min-Sat, and its proof appears in the full version of the paper.

▶ **Theorem 12.** *Let X be a semi-permutation, let T be any partitioning tree for X, let $U \subseteq V(T)$ be a subset of vertices of T such that the strips in $\{S(v) \mid v \in U\}$ partition the bounding box, and let $\{X^c, \{X^s_v\}_{v\in U}\}$ be an (X,T)-split at U. Then:*

$$\sum_{v\in U} \mathit{OPT}(X^s_v) + \mathit{OPT}(X^c) \leq \mathit{OPT}(X).$$

Decomposition Theorem for the Strong WB-1 bound. We also prove, in the full version of the paper, the following theorem about the strong WB-1 bound, that we use several times in our negative result.

▶ **Theorem 13.** *Let X be a semi-permutation and let T be a partitioning tree for X. Let $U \subseteq V(T)$ be a set of vertices of T such that the strips in $\{S(v) \mid v \in U\}$ partition the bounding box. Let $\{X^c, \{X^s_v\}_{v\in U}\}$ be the split of (X,T) at U. Then:*

$$\mathsf{WB}(X) \leq 4\mathsf{WB}(X^c) + 8\sum_{v\in U} \mathsf{WB}(X^s_v) + O(|X|).$$

This result is somewhat surprising. One can think of the expression $\mathsf{WB}(X^c) + \sum_{v\in U} \mathsf{WB}(X^s_v)$ as a WB-1 bound obtained by first cutting along the lines that serve as boundaries of the strips $S(v)$ for $v \in U$, and then cutting the individual strips. However,

$\mathsf{WB}(X)$ is the maximum of $\mathsf{WB}_T(X)$ obtained over all trees T, including those that do not obey this partitioning order. The proofs of both Theorems 12 and 13 are given in the full version.

4 Separation of OPT and the Strong Wilber Bound

In this section we present our negative results, proving Theorem 1. We start by defining several basic tools used in our construction in Section 4.1. From Section 4.2 onward, we describe our construction and its analysis.

4.1 Basic Tools

Monotonically Increasing Sequence. We say that an input set X of points is *monotonically increasing* iff X is a permutation, and moreover for every pair $p, p' \in X$ of points, if $p.x < p'.x$, then $p.y < p'.y$ must hold. It is well known that the value of the optimal solution of monotonically increasing sequences is low, and we exploit this fact in our negative results.

▶ **Observation 14.** *If X is a monotonically increasing set of points, then $\mathsf{OPT}(X) \leq |X| - 1$.*

Bit Reversal Sequence (BRS). We use the geometric variant of BRS, which is more intuitive and easier to argue about. Let $\mathcal{R} \subseteq \mathbb{N}$ and $\mathcal{C} \subseteq \mathbb{N}$ be sets of integers (which are supposed to represent sets of active rows and columns.) The instance $\mathsf{BRS}(i, \mathcal{R}, \mathcal{C})$ is only defined when $|\mathcal{R}| = |\mathcal{C}| = 2^i$. It contains 2^i points, and it is a permutation, whose sets of active rows and columns are exactly $\mathcal{R}$ and $\mathcal{C}$ respectively; so $|\mathcal{R}| = |\mathcal{C}| = 2^i$. We define the instance recursively. The base of the recursion is instance $\mathsf{BRS}(0, \{C\}, \{R\})$, containing a single point at the intersection of row R and column C. Assume now that we have defined, for all $1 \leq i' \leq i$, and any sets $\mathcal{R}', \mathcal{C}'$ of $2^{i'}$ integers, the corresponding instance $\mathsf{BRS}(i, \mathcal{R}', \mathcal{C}')$. We define instance $\mathsf{BRS}(i+1, \mathcal{R}, \mathcal{C})$, where $|\mathcal{R}| = |\mathcal{C}| = 2^{i+1}$, as follows.

Consider the columns in $\mathcal{C}$ in their natural left-to-right order, and define $\mathcal{C}_{left}$ to be the first 2^i columns and $\mathcal{C}_{right} = \mathcal{C} \setminus \mathcal{C}_{left}$. Denote $\mathcal{R} = \{R_1, \ldots, R_{2^{i+1}}\}$, where the rows are indexed in their natural bottom to top order, and let $\mathcal{R}_{even} = \{R_2, R_4, \ldots, R_{2^{i+1}}\}$ and $\mathcal{R}_{odd} = \{R_1, R_3, \ldots, R_{2^{i+1}-1}\}$ be the sets of all even-indexed and all odd-indexed rows, respectively. Notice that $|\mathcal{C}_{left}| = |\mathcal{C}_{right}| = |\mathcal{R}_{even}| = |\mathcal{R}_{odd}| = 2^i$. The instance $\mathsf{BRS}(i+1, \mathcal{R}, \mathcal{C})$ is defined to be $\mathsf{BRS}(i, \mathcal{R}_{odd}, \mathcal{C}_{left}) \cup \mathsf{BRS}(i, \mathcal{R}_{even}, \mathcal{C}_{right})$.

For $n = 2^i$, we denote by $\mathsf{BRS}(n)$ the instance $\mathsf{BRS}(i, \mathcal{C}, \mathcal{R})$, where $\mathcal{C}$ contains all columns with integral x-coordinates from 1 to n, and $\mathcal{R}$ contains all rows with integral y-coordinates from 1 to n; see Figure 2 for an illustration.

It is well-known that, if X is a bit-reversal sequence on n points, then $\mathsf{OPT}(X) \geq \Omega(n \log n)$.

▷ Claim 15. Let $X = \mathsf{BRS}(i, \mathcal{C}, \mathcal{R})$, for any $i \geq 0$ and any sets $\mathcal{C}$ and $\mathcal{R}$ of columns and rows, respectively, with $|\mathcal{R}| = |\mathcal{C}| = 2^i$. Then $|X| = 2^i$, and $\mathsf{OPT}(X) \geq \frac{\mathsf{WB}(X)}{2} \geq \frac{|X|(\log |X|-2)+1}{2}$.

Next, we present two additional technical tools that we use in our construction.

Exponentially Spaced Columns. Recall that we defined the bit reversal instance $\mathsf{BRS}(\ell, \mathcal{R}, \mathcal{C})$, where $\mathcal{R}$ and $\mathcal{C}$ are sets of 2^ℓ rows and columns, respectively, that serve in the resulting instance as the sets of active rows and columns; the instance contains $n = 2^\ell$ points. In the Exponentially-Spaced BRS instance $\mathsf{ES\text{-}BRS}(\ell, \mathcal{R})$, we are still given a set $\mathcal{R}$ of 2^ℓ rows that will serve as active rows in the resulting instance, but we define the set

$\mathcal{C}$ of columns in a specific way. For an integer i, C_i be the column whose x-coordinate is i. We then let $\mathcal{C}$ contain, for each $0 \leq i < 2^\ell$, the column C_{2^i}. Denoting $N = 2^n = 2^{2^\ell}$, the x-coordinates of the columns in $\mathcal{C}$ are $\{1, 2, 4, 8, \ldots, N/2\}$. The instance is then defined to be $\mathsf{BRS}(\ell, \mathcal{R}, \mathcal{C})$ for this specific set $\mathcal{C}$ of columns. Notice that the instance contains $n = \log N = 2^\ell$ input points.

It is easy to see that any point set $X = \mathsf{ES\text{-}BRS}(\ell, \mathcal{R})$ satisfies $\mathsf{OPT}(X) = \Omega(n \log n)$. We remark that this idea of exponentially spaced columns is inspired by the instance used by Iacono [16] to prove a gap between the weak WB-1 bound and $\mathsf{OPT}(X)$. However, Iacono's instance is tailored to specific partitioning tree T, and it is clear that there is another partitioning tree T' with $\mathsf{OPT}(X) = \Theta(WB_{T'}(X))$. Therefore, this instance does not give a separation result for the strong WB-1 bound, and in fact it does not provide negative results for the weak WB-1 bound when the input point set is a permutation.

Cyclic Shift of Columns. Suppose we are given a point set X, and let $\mathcal{C}' = \{C_0, \ldots, C_{N-1}\}$ be any set of columns indexed in their natural left-to-right order, such that all points of X lie on columns of $\mathcal{C}$ (but some columns may contain no points of X). Let $0 \leq s < N$ be any integer. We denote by X^s a cyclic shift of X by s units, obtained as follows. For every point $p \in X$, we add a new point p^s to X^s, whose y-coordinate is the same as that of p, and whose x-coordinate is $p.x + s \mod N$. In other words, we shift the point p by s steps to the right in a circular manner. Equivalently, we move the last s columns of $\mathcal{C}'$ to the beginning of the instance. The following claim, whose proof appears in the full version of the paper, shows that the value of the optimal solution does not decrease significantly in the shifted instance.

▷ Claim 16. Let X be any point set that is a semi-permutation. Let $0 \leq s < N$ be a shift value, and let $X' = X^s$ be the instance obtained from X by a cyclic shift of its points by s units to the right. Then $\mathsf{OPT}(X') \geq \mathsf{OPT}(X) - |X|$.

4.2 Construction of the Bad Instance

We construct two instances: instance $\hat{X}$ on N^* points, that is a semi-permutation (but is somewhat easier to analyze), and instance X^* in N^* points, which is a permutation; the analysis of instance X^* heavily relies on the analysis of instance $\hat{X}$. We will show that the optimal solution value of both instances is $\Omega(N^* \log\log N^*)$, but the cost of the Wilber Bound is at most $O(N^* \log\log\log N^*)$. Our construction uses the following three parameters. We let $\ell \geq 1$ be an integer, and we set $n = 2^\ell$ and $N = 2^n$.

First Instance. We now construct our first final instance $\hat{X}$, which is a semi-permutation containing N columns. Intuitively, we create N instances $X^0, X^1, \ldots, X^{N-1}$, where instance X^s is an exponentially-spaced BRS instance that is shifted by s units. We then stack these instances on top of one another in this order.

Formally, for all $0 \leq j \leq N-1$, we define a set $\mathcal{R}_j$ of n consecutive rows with integral coordinates, such that the rows of $\mathcal{R}_0, \mathcal{R}_1, \ldots, \mathcal{R}_{N-1}$ appear in this bottom-to-top order. Specifically, set $\mathcal{R}_j$ contains all rows whose y-coordinates are in $\{jn+1, jn+2, \ldots, (j+1)n\}$.

For every integer $0 \leq s \leq N-1$, we define a set of points X^s, which is a cyclic shift of instance $\mathsf{ES\text{-}BRS}(\ell, \mathcal{R}_s)$ by s units. Recall that $|X^s| = 2^\ell = n$ and that the points in X^s appear on the rows in $\mathcal{R}_s$ and a set $\mathcal{C}_s$ of columns, whose x-coordinates are in $\{\left(2^j + s\right) \mod N : 0 \leq j < n\}$. We then let our final instance be $\hat{X} = \bigcup_{s=0}^{N-1} X^s$. From now on, we denote $N^* = |\hat{X}|$. Recall that $|N^*| = N \cdot n = N \log N$.

Observe that the number of active columns in $\hat{X}$ is N. Since the instance is symmetric and contains $N^* = N \log N$ points, every column contains exactly $\log N$ points. Each row contains exactly one point, so $\hat{X}$ is a semi-permutation. (See Figure 2 for an illustration).

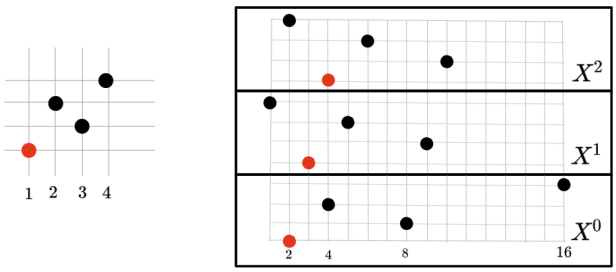

Figure 2 An illustration of our construction. The figure on the left shows the instance $\mathsf{BRS}(2, \{1,2,3,4\}, \{1,2,3,4\})$. The figure on the right combines three copies X^0, X^1, X^2 of the corresponding exponentially-spaced instance, with horizontal shifts of 0, 1, and 2, respectively. The red points show how copies of the same point in different sub-instances.

Lastly, we need the following bound on the value of the optimal solution of instance $\hat{X}$.

▶ **Observation 17.** $OPT(\hat{X}) = \Omega(N^* \log\log N^*)$

Proof. From Claims 15 and 16, for each $0 \leq s \leq N-1$, each sub-instance X^s has $\mathsf{OPT}(X^s) \geq \Omega(n \log n) = \Omega(\log N \log\log N)$. Therefore, $\mathsf{OPT}(\hat{X}) \geq \sum_{s=0}^{N-1} \mathsf{OPT}(X^s) = \Omega(N \log N \log\log N) = \Omega(N^* \log\log N^*)$ (we have used the fact that $N^* = N \log N$). ◀

Second Instance. We now construct our second and final instance, X^*, that is a permutation. In order to do so, we start with the instance $\hat{X}$, and, for every active column C of $\hat{X}$, we create $n = \log N$ new columns (that we view as copies of C), $C^1, \ldots, C^{\log N}$, which replace the column C. We denote this set of columns by $\mathcal{B}(C)$, and we refer it as the *block of columns representing* C. Recall that the original column C contains $\log N$ input points of $\hat{X}$. We place each such input point on a distinct column of $\mathcal{B}(C)$, so that the points form a monotonically increasing sequence (see the definition in Section 4.1). This completes the definition of the final instance X^*. We obtain the following immediate bound on the optimal solution cost of instance X^*.

▷ Claim 18. $\mathsf{OPT}(X^*) \geq \mathsf{OPT}(\hat{X}) = \Omega(N^* \log\log N^*)$.

4.3 Upper Bound for $\mathsf{WB}(\hat{X})$

In this section we prove the following theorem.

▶ **Theorem 19.** $\mathsf{WB}(\hat{X}) \leq O(N^* \log\log\log N^*)$.

In order to prove the theorem, consider again the instance $\hat{X}$. Recall that it consists of N instances $X^0, X^1, \ldots, X^{N-1}$ that are stacked on top of each other vertically in this order. We rename these instances as $X_1, X_2, \ldots, X_N$, so X_j is exactly $\mathsf{ES\text{-}BRS}(\log N)$, that is shifted by $(j-1)$ units to the right. Recall that $|\hat{X}| = N^* = N \log N$, and each instance X_s contains exactly $\log N$ points. We denote by $\mathcal{C}$ the set of N columns, whose x-coordinates are $1, 2, \ldots, N$. All points of $\hat{X}$ lie on the columns of $\mathcal{C}$. For convenience, for $1 \leq j \leq N$, we denote by C_j the column of $\mathcal{C}$ whose x-coordinate is j.

Let σ be any ordering of the auxiliary columns in $\mathcal{L}$, and let $T = T_\sigma$ be the corresponding partitioning tree. It is enough to show that, for any such ordering σ, the value of $\mathsf{WB}_\sigma(\hat{X})$ is bounded by $O(N^* \log\log\log N^*)$. Recall that $WB_\sigma(\hat{X})$ is the sum, over all vertices $v \in V(T)$, of $\mathsf{cost}(v)$. The value of $\mathsf{cost}(v)$ is defined as follows. If v is a leaf vertex, then $\mathsf{cost}(v) = 0$. Otherwise, let $L = L(v)$ be the line of $\mathcal{L}$ that v owns. Index the points in $X \cap S(v)$ by $q_1, \ldots, q_z$ in their bottom-to-top order. A consecutive pair (q_j, q_{j+1}) of points is a *crossing* iff they lie on different sides of $L(v)$. We distinguish between the two types of crossings that contribute towards $\mathsf{cost}(v)$. We say that the crossing (q_j, q_{j+1}) is of *type*-1 if both q_j and q_{j+1} belong to the same shifted instance X_s for some $0 \leq s \leq N-1$. Otherwise, they are of type-2. Note that, if (q_j, q_{j+1}) is a crossing of type 2, with $q_j \in X_s$ and $q_{j+1} \in X_{s'}$, then s, s' are not necessarily consecutive integers, as it is possible that for some indices s'', $X_{s''}$ has no points that lie in the strip $S(v)$. We now let $\mathsf{cost}_1(v)$ be the total number of type-1 crossings of $L(v)$, and $\mathsf{cost}_2(v)$ the total number of type-2 crossings. Note that $\mathsf{cost}(v) = \mathsf{cost}_1(v) + \mathsf{cost}_2(v)$. We also define $\mathsf{cost}_1(\sigma) = \sum_{v \in V(T)} \mathsf{cost}_1(v)$ and $\mathsf{cost}_2(\sigma) = \sum_{v \in V(T)} \mathsf{cost}_2(v)$. Clearly, $\mathsf{WB}_\sigma(\hat{X}) = \mathsf{cost}_1(\sigma) + \mathsf{cost}_2(\sigma)$. In the full version of the paper, we prove the following two theorems:

▶ **Theorem 20.** *For every ordering σ of the auxiliary columns in $\mathcal{L}$, $\mathsf{cost}_1(\sigma) \leq O(N^* \log\log\log N^*)$.*

▶ **Theorem 21.** *For every vertex $v \in V(T)$, $\mathsf{cost}_2(v) \leq O(\log N) + O(\mathsf{cost}_1(v))$.*

Notice that from the latter theorem, we get that $\mathsf{cost}_2(\sigma) \leq O(\mathsf{cost}_1(\sigma)) + O(|V(T)| \cdot \log N) = O(N^* \log\log\log N^*) + O(N \log N) = O(N^* \log\log\log N^*)$. Combining the two theorems together completes the proof of Theorem 19.

4.4 Upper Bound for $\mathsf{WB}(X^*)$

In this section we show that $\mathsf{WB}(X^*) = O(N^* \log\log\log N^*)$, completing the proof of Theorem 1. Recall that instance X^* is obtained from instance $\hat{X}$ by replacing every active column C of X^* with a block $\mathcal{B}(C)$ of columns, and then placing the points of C on the columns of $\mathcal{B}(C)$ so that they form a monotone increasing sequence, while preserving their y-coordinates. The resulting collection of all blocks $\mathcal{B}(C)$ partitions the set of all active columns of X^*. We denote this set of blocks by $\mathcal{B}_1, \ldots, \mathcal{B}_N$. The idea is to use Theorem 13 in order to bound $\mathsf{WB}(X^*)$.

Consider a set of lines $\mathcal{L}'$ (with half-integral x-coordinates) that partition the bounding box B into strips, where the ith strip contains the block $\mathcal{B}_i$ of columns, so $|\mathcal{L}'| = (N-1)$. We consider a split of instance X^* by $\mathcal{L}'$: This gives us a collection of strip instances $\{X_i^s\}_{1 \leq i \leq N}$ and the compressed instance X^c. Notice that the compressed instance is precisely $\hat{X}$, and each strip instance X_i^s is a monotone increasing point set.

Since each strip instance X_i^s is monotonously increasing, from Observation 14 and Claim 9, for all i, $\mathsf{WB}(X_i^s) \leq O(\mathsf{OPT}(X_i^s)) \leq O(|X_i^s|)$. From Theorem 13, we then get that: $\mathsf{WB}(X^*) \leq 4\mathsf{WB}(\hat{X}) + 8\sum_i \mathsf{WB}(X_i^s) + O(|X^*|) \leq 4\mathsf{WB}(\hat{X}) + O(|X^*|) \leq O(N^* \log\log\log N^*)$.

5 Guillotine Bounds

In this section we consider an extension of the Wilber bound which we call the Guillotine bound. The *Guillotine bound* $\mathsf{GB}(X)$ extends $\mathsf{WB}(X)$ by allowing both vertical and horizontal partitioning lines. Specifically, given the bounding box B, we let L be any vertical or horizontal line crossing B, that separates X into two subsets X_1 and X_2. We define the

number of crossings of L exactly as before, and then recurse on both sides of L as before. This partitioning scheme can be represented by a binary tree T, where every vertex of the tree is associated with a rectangular region of the plane. We denote the resulting bound obtained by using the partitioning tree T by $\mathsf{GB}_T(X)$, and we define $\mathsf{GB}(X) = \max_T \mathsf{GB}_T(X)$. We show that GB is a lower bound on the optimal solution cost in the following lemma, whose proof is deferred to the full version.

▶ **Lemma 22.** *For any point set X that is a permutation, $\mathsf{GB}(X) \leq 2\mathit{OPT}(X)$.*

The *Consistent Guillotine bound* restricts the Guillotine bound by maximizing only over partitioning schemes that are "consistent" in the following sense: suppose that the current partition of the bounding box B, that we have obtained using previous partitioning lines, is a collection $\{R_1, \ldots, R_k\}$ of rectangular regions. We need to choose a vertical or a horizontal line L that spans the whole bounding box B, that is, L intersects the boundary of B in two points. Once line L is chosen, for **every** rectangular region R_i that intersects L, we must partition R_i into two sub-regions using the line L, and then count the number of consecutive pairs of points in $X \cap R_i$ that cross the line L. In other words, we must partition all rectangles $R_1, \ldots, R_k$ consistently with respect to the line L. In contrast, in the Guillotine bound, we are allowed to partition each area R_i independently. From the definitions, the value of the Guillotine bound $\mathsf{GB}(X)$ is always at least as large as the value of the Consistent Guillotine bound, denoted by $\mathsf{cGB}(X)$, on any input sequence X, which is at least as large as $\mathsf{WB}(X)$. We generalize our negative result to the Consistent Guillotine bound in the following theorem, whose proof appears in the full version of the paper.

▶ **Theorem 23.** *For every integer n', there is an integer $n \geq n'$, and a set X of points that is a permutation with $|X| = n$, such that $\mathit{OPT}(X) \geq \Omega(n \log\log n)$ but $\mathsf{cGB}(X) \leq O(n \log\log\log n)$.*

Our negative results do not extend to the general GB bound, while our divide-and-conquer framework can naturally be adapted to work with GB. We leave open an interesting question of establishing the worst-case gap between the value of OPT and that of the Guillotine bound, and we hope that combining the Guillotine bound with our algorithmic framework will lead to better online and offline approximation algorithms.

6 The Algorithms

In this section we provide the high level intuition for the proof of Theorem 2. A more detailed description appears in the Appendix. Both the polynomial time and the sub-exponential time algorithms follow the same framework. We start with a high-level overview of this framework. For simplicity, assume that the number of active columns in the input instance X is an integral power of 2. The key idea is to decompose the input instance into smaller sub-instances, using the split instances defined in Section 3. We solve the resulting instances recursively and then combine the resulting solutions.

Suppose we are given an input point set X that is a semi-permutation, with $|X| = m$, such that the number of active columns is n. We consider a *balanced* partitioning tree T, where for every vertex $v \in V(T)$, the line $L(v)$ that v owns splits the strip $S(v)$ in the middle, with respect to the active columns that are contained in $S(v)$. Therefore, the height of the partitioning tree is $\log n$.

Consider now the set U of vertices of T that lie in the middle layer of T. We consider the split of (X, T) at U, obtaining a new collection of instances $(X^c, \{X^s_i\})_{i=1}^k$ where $k = \Theta(\sqrt{n})$. Note that each resulting strip instance X^s_i contains $\Theta(\sqrt{n})$ active columns, and so does the compressed instance X^c.

We recursively solve each such instance and then combine the resulting solutions. The key to the algorithm and its analysis is to show that there is a collection Z of $O(|X|)$ points, such that, if we are given any solution Y^c to instance X^c, and, for all $1 \leq i \leq k$, any solution Y_i to instance X_i^s, then $Z \cup Y^c \cup \left(\bigcup_{i=1}^{N} Y_i\right)$ is a feasible solution to instance X. We also show that the total number of input points that appear in all instances that participate in the same recursive level is bounded by $O(\mathsf{OPT}(X))$. This ensures that in every recursive level we add at most $O(\mathsf{OPT}(X))$ points to the solution, and the total solution cost is at most $O(\mathsf{OPT}(X))$ times the number of the recursive levels, which is bounded by $O(\log \log n)$.

In order to obtain the sub-exponential time algorithm, we restrict the recursion to D levels, and then solve each resulting instance directly in time $r(X)c(X)^{O(c(X))}$. This approach gives an $O(D)$-approximation algorithm with running time at most $\mathrm{poly}(m) \cdot \exp\left(n^{1/2^{\Omega(D)}} \log n\right)$ as desired. A more detailed description of the algorithm appears in the Appendix.

A A Detailed Description of the Algorithms

In this section we provide additional details for the proof of Theorem 2. Due to lack of space, some of the proofs are deferred to the full version.

A.1 Special Solutions

Our algorithm will produce feasible solutions of a special form, that we call *special solutions*. Recall that, given a semi-permutation point set X, the auxiliary columns for X are a set $\mathcal{L}$ of vertical lines with half-integral coordinates. We say that a solution Y for X is *special* iff every point of Y lies on an row that is active for X, and on a column of $\mathcal{L}$. In particular, special solutions are by definition non-canonical (see Figure 3 for an illustration). The main advantage of the special solutions is that they allow us to easily use the divide-and-conquer approach. We use the following observation, whose proof appears in the full version of the paper.

(a) Canonical Solution. **(b)** Special Solution.

Figure 3 Canonical and T-special solutions of X. The input points are shown as circles; the points that belong to the solution Y are shown as squares.

▶ **Observation 24.** *There is an algorithm, that, given a set X of points that is a semi-permutation, and a canonical solution Y for X, computes a special solution Y' for X, such that $|Y'| \leq 2|X| + 2|Y|$. The running time of the algorithm is $O(|X| + |Y|)$.*

If σ is any ordering of the auxiliary columns in $\mathcal{L}$, and $T = T_\sigma$ is the corresponding partitioning tree, then any point set Y that is a special solution for X is also called a *T-special solution* (although the notion of the solution Y being special does not depend on the tree T, this notion will be useful for us later; in particular, a convenient way of thinking of a T-special solution is that every point of Y must lie on an active row of X, and on a column that serves as a boundary for some strip $S(v)$, where $v \in V(T)$.)

A.2 Redundant Points and Reduced Point Sets

Consider a semi-permutation X, that we think of as a potential input to the Min-Sat problem. We denote $X = \{p_1, \ldots, p_m\}$, where the points are indexed in their natural bottom-to-top order, so $(p_1).y < (p_2).y < \ldots < (p_m).y$. A point p_i is said to be *redundant*, iff $(p_i).x = (p_{i+1}).x = (p_{i-1}).x$. We say that a semi-permutation X is in the *reduced form* if there are no redundant points in X; in other words, if p_{i-1}, p_i, p_{i+1} are three points lying on three consecutive active rows, then their x-coordinates are not all equal. We use the following observation and lemma, whose proofs appear in the full version of the paper.

▶ **Observation 25.** *Let X be a semi-permutation, and let $X' \subseteq X$ be any point set, that is obtained from X by repeatedly removing redundant points. Then $\mathsf{OPT}(X') \leq \mathsf{OPT}(X)$.*

▶ **Lemma 26.** *Let X be a semi-permutation, and let $X' \subseteq X$ be any point set, that is obtained from X by repeatedly removing redundant points. Let Y be any feasible solution for X' such that every point of Y lies on a row that is active for X'. Then Y is also a feasible solution for X.*

From Lemma 26, whenever we need to solve the Min-Sat problem on an instance X, it is sufficient to solve it on a sub-instance, obtained by iteratively removing redundant points from X. We obtain the following immediate corollary of Lemma 26.

▶ **Corollary 27.** *Let X be a semi-permutation, and let $X' \subseteq X$ be any point set, that is obtained from X by repeatedly removing redundant points. Let Y be any special feasible solution for X'. Then Y' is also a special feasible solution for X.*

Lastly, we need the following lemma, which is a simple application of the Wilber bound.

▶ **Lemma 28.** *Let X be a point set that is a semi-permutation in reduced form. Then $\mathsf{OPT}(X) \geq |X|/4 - 1$.*

A.3 The Algorithm Description

Suppose we are given an input set X of points that is a semi-permutation. Let T be any partitioning tree for X. We say that T is a *balanced* partitioning tree for X iff for every non-leaf vertex $v \in V(T)$ the following holds. Let v' and v'' be the children of v in the tree T. Let X' be the set of all input points lying in strip $S(v)$, and let X'', X''' be defined similarly for $S(v')$ and $S(v'')$. Let c be the number of active columns in instance X', and let c' and c'' be defined similarly for X'' and X'''. Then we require that $c', c'' \leq \lceil c/2 \rceil$.

Given a partitioning tree T, we denote by Λ_i the set of all vertices of T that lie in the ith *layer* of T – that is, the vertices whose distance from the root of T is i (so the root belongs to Λ_0). The *height* of the tree T, denoted by $\text{height}(T)$, is the largest index i such that $\Lambda_i \neq \emptyset$. If the height of the tree T is h, then we call the set $\Lambda_{\lceil h/2 \rceil}$ of vertices the *middle layer* of T. Notice that, if T is a balanced partitioning tree for input X, then its height is at most $2 \log c(X)$.

Our algorithm takes as input a set X of points that is a semi-permutation, a balanced partition tree T for X, and an integral parameter $\rho > 0$.

Intuitively, the algorithm uses the splitting operation to partition the instance X into subinstances that are then solved recursively, until it obtains a collection of instances whose corresponding partitioning trees have height at most ρ. We then either employ dynamic programming, or use a trivial $O(\log c(X))$-approximation algorithm. The algorithm returns a special feasible solution for the instance. Recall that the height of the tree T is bounded by $2 \log c(X) \leq 2 \log n$. The following two theorems will be used as the recursion basis.

▶ **Theorem 29.** *There is an algorithm called* LeafBST-1 *that, given a semi-permutation instance X of* Min-Sat *in reduced form, and a partitioning tree T for it, produces a feasible T-special solution for X of cost at most $2|X| + 2\mathsf{OPT}(X)$, in time $|X|^{O(1)} \cdot c(X)^{O(c(X))}$.*

▶ **Theorem 30.** *There is an algorithm called* LeafBST-2 *that, given a semi-permutation instance X of* Min-Sat *in reduced form, and a partitioning tree T for it, produces a feasible T-special solution of cost at most $2|X| \cdot \text{height}(T)$, in time $\text{poly}(|X|)$.*

The proofs of both theorems are deferred to the full version of the paper. We now provide a schematic description of our algorithm. Depending on the guarantees that we would like to achieve, whenever the algorithm calls procedure LeafBST, it will call either procedure LeafBST-1 or procedure LeafBST-2; we specify this later.

Algorithm 1 RecursiveBST(X, T, ρ).

1. Keep removing redundant points from X until X is in reduced form.
2. IF T has height at most ρ,
3. **return** LeafBST(X, T)
4. Let U be the set of vertices lying in the middle layer of T.
5. Compute the split $(X^c, \{X^s_v\}_{v \in U})$ of (X, T) at U.
6. Compute the corresponding sub-trees $(T^c, \{T^s_v\}_{v \in U})$ of T.
7. For each vertex $v \in U$, call to RecursiveBST with input (X^s_v, T^s_v, ρ), and let Y_v be the solution returned by it.
8. Call RecursiveBST with input (X^c, T^c, ρ), and let $\hat{Y}$ be the solution returned by it.
9. Let Z be a point set containing, for each vertex $v \in U$, for each point $p \in X^s_v$, two copies p' and p'' of p with $p'.y = p''.y = p.y$, where p' lies on the left boundary of $S(v)$, and p'' lies on the right boundary of $S(v)$.
10. **return** $Y^* = Z \cup \hat{Y} \cup (\bigcup_{v \in U} Y_v)$

A.4 Analysis

We start by showing that the solution that the algorithm returns is T-special in the following observation, whose proof appears in the full version of the paper.

▶ **Observation 31.** *Assuming that* LeafBST(X,T) *returns a* T*-special solution, the solution* Y^* *returned by Algorithm* RecursiveBST(X,T,ρ) *is a* T*-special solution.*

We next turn to prove that the solution Y^* computed by Algorithm RecursiveBST(X,T,ρ) is feasible. In order to do so, we will use the following immediate observation.

▶ **Observation 32.** *Let* Y^* *be the solution returned by Algorithm* RecursiveBST(X,T,ρ)*, and let* $u \in U$ *be any vertex. Then:*

- *Any point* $y \in Y^*$ *that lies in the interior of* $S(u)$ *must lie on an active row of instance* X^s_u*.*
- *Any point* $y \in Y^*$ *that lies on the boundary of* $S(u)$ *must belong to in* $\hat{Y} \cup Z$*. Moreover, the points of* $\hat{Y} \cup Z$ *may not lie in the interior of* $S(u)$*.*
- *If* R *is an active row for instance* X^s_u*, then set* Z *contains two points, lying on the intersection of* R *with the left and the right boundaries of* $S(u)$*, respectively.*

The following theorem, whose proof is deferred to the full version of the paper, shows that the algorithm returns a feasible solution.

▶ **Theorem 33.** *Assume that the recursive calls to Algorithm* RecursiveBST *return a feasible special solution* $\hat{Y}$ *for instance* X^c*, and for each* $v \in U$*, a feasible special solution* Y_v *for the strip instance* X^s_v*. Then the point set* $Y^* = Z \cup \hat{Y} \cup (\bigcup_{v \in U} Y_v)$ *is a feasible solution for instance* X*.*

In order to analyze the solution cost, consider the final solution Y^* to the input instance X. We distinguish between two types of pints in Y^*: a point $p \in Y^*$ is said to be of type 2 if it was added to the solution by Algorithm LeafBST, and otherwise we say that it is of type 1. We start by bounding the number of points of type 1 in Y^*.

▷ Claim 34. The number of points of type 1 in the solution Y^* to the original instance X is at most $O(\log(\text{height}(T)/\rho)) \cdot \mathsf{OPT}(X)$.

Proof. Observe that the number of recursive levels is bounded by $\lambda = O(\log(\text{height}(T)/\rho))$. This is since, in every recursive level, the heights of all trees decrease by a constant factor, and we terminate the algorithm once the tree heights are bounded by ρ. For each $1 \leq i \leq \lambda$, let $\mathcal{X}_i$ be the collection of all instances in the ith recursive level, where the instances are in the reduced form. Notice that the only points that are added to the solution by Algorithm RecursiveBST directly are the points in the sets Z. The number of such points added at recursive level i is bounded by $\sum_{X' \in \mathcal{X}_i} 2|X'|$. It is now sufficient to show that for all $1 \leq i \leq \lambda$, $\sum_{X' \in \mathcal{X}_i} |X'| \leq O(\mathsf{OPT}(X))$. We do so using the following observation.

▶ **Observation 35.** *For all* $1 \leq i \leq \lambda$, $\sum_{X' \in \mathcal{X}_i} \mathit{OPT}(X') \leq \mathit{OPT}(X)$.

Assume first that the observation is correct. For each instance $X' \in \mathcal{X}_i$, let T' be the partitioning tree associated with X'. From Lemma 28, $|X'| \leq O(\mathsf{OPT}(X'))$. Therefore, the number of type-1 points added to the solution at recursive level i is bounded by $O(\mathsf{OPT}(X))$. We now turn to prove Observation 35.

Proof of Observation 35. The proof is by induction on the recursive level i. It is easy to see that the claim holds for $i = 1$, since, from Observation 25, removing redundant points from X to turn it into reduced form cannot increase $\mathsf{OPT}(X)$.

Assume now that the claim holds for level i, and consider some level-i instance $X' \in \mathcal{X}_i$. Let $(X^c, \{X^s_u\}_{u \in U})$ be the split of (X', T') that we have computed. Then, from Theorem 12, $\sum_{v \in U} \mathsf{OPT}(X^s_v) + \mathsf{OPT}(X^c) \leq \mathsf{OPT}(X')$. Since, from Observation 25, removing redundant points from an instance does not increase its optimal solution cost, the observation follows. ◀

◁

In order to obtain an efficient $O(\log \log n)$-approximation algorithm, we set ρ to be a constant (it can even be set to 1), and we use algorithm LeafBST-2 whenever the algorithm calls to subroutine LeafBST. Observe that the depth of the recursion is now bounded by $O(\log \log n)$, and so the total number of type-1 points in the solution is bounded by $O(\log \log n) \cdot \mathsf{OPT}(X)$. Let $\mathcal{I}$ denote the set of all instances to which Algorithm LeafBST is applied. Using the same arguments as in Claim 34, $\sum_{X' \in \mathcal{I}} |X'| = O(\mathsf{OPT}(X))$. The number of type-2 points that Algorithm LeafBST adds to the solution for each instance $X' \in \mathcal{I}$ is bounded by $O(|X'| \cdot \rho) = O(|X'|)$. Therefore, the total number of type-2 points in the solution is bounded by $O(\mathsf{OPT}(X))$. Overall, we obtain a solution of cost at most $O(\log \log n) \cdot \mathsf{OPT}(X)$, and the running time of the algorithm is polynomial in $|X|$.

Finally, in order to obtain the sub-exponential time algorithm, we set the parameter ρ to be such that the recursion depth is bounded by D. Since the number of active columns in instance X is $c(X)$, and the height of the partitioning tree T is bounded by $2 \log c(X)$, while the depth of the recursion is at most $2 \log(\text{height}(T)/\rho)$, it is easy to verify that $\rho = O\left(\frac{\log c(X)}{2^{D/2}}\right) = \frac{\log c(X)}{2^{\Omega(D)}}$. We use algorithm LeafBST-1 whenever the algorithm calls to subroutine LeafBST. As before, let $\mathcal{I}$ be the set of all instances to which Algorithm LeafBST is applied. Using the same arguments as in Claim 34, $\sum_{X' \in \mathcal{I}} (|X'| + \mathsf{OPT}(X')) = O(\mathsf{OPT}(X))$. For each such instance X', Algorithm LeafBST-1 produces a solution of cost $O(|X'| + \mathsf{OPT}(X'))$. Therefore, the total number of type-2 points in the final solution is bounded by $O(\mathsf{OPT}(X))$. The total number of type-1 points in the solution is therefore bounded by $O(D) \cdot \mathsf{OPT}(X)$ as before. Therefore, the algorithm produces a factor-$O(D)$-approximate solution. Finally, in order to analyze the running time of the algorithm, we first bound the running time of all calls to procedure LeafBST-1. The number of such calls is bounded by $|X|$. Consider now some instance $X' \in \mathcal{I}$, and its corresponding partitioning tree T'. Since the height of T' is bounded by ρ, we get that $c(X') \leq 2^{\rho} \leq 2^{\log c(X)/2^{\Omega(D)}} \leq (c(X))^{1/2^{\Omega(D)}}$. Therefore, the running time of LeafBST-1 on instance X' is bounded by $|X'|^{O(1)} \cdot (c(X'))^{O(c(X'))} \leq |X'|^{O(1)} \cdot \exp\left(O(c(X') \log c(X')\right) \leq |X'|^{O(1)} \cdot \exp\left(c(X)^{1/2^{\Omega(D)}} \cdot \log c(X)\right)$.

The running time of the remainder of the algorithm, excluding the calls to LeafBST-1, is bounded by $\text{poly}(|X|)$. We conclude that the total running time of the algorithm is bounded by $|X|^{O(1)} \cdot \exp\left(c(X)^{1/2^{\Omega(D)}} \cdot \log c(X)\right) \leq \text{poly}(m) \cdot \exp\left(n^{1/2^{\Omega(D)}} \cdot \log n\right)$.

Revisiting Alphabet Reduction in Dinur's PCP

Abstract

Dinur's celebrated proof of the PCP theorem alternates two main steps in several iterations: gap amplification to increase the soundness gap by a large constant factor (at the expense of much larger alphabet size), and a composition step that brings back the alphabet size to an absolute constant (at the expense of a fixed constant factor loss in the soundness gap). We note that the gap amplification can produce a Label Cover CSP. This allows us to reduce the alphabet size via a direct long-code based reduction from Label Cover to a Boolean CSP. Our composition step thus bypasses the concept of Assignment Testers from Dinur's proof, and we believe it is more intuitive – *it is just a gadget reduction.* The analysis also uses only elementary facts (Parseval's identity) about Fourier Transforms over the hypercube.

1 Introduction

Constraint Satisfaction Problem (CSP) is a canonical NP-complete problem. Assuming P $\neq$ NP, no polynomial time algorithm can find a satisfying assignment to a satisfiable CSP instance. If we are happy with the easier goal of satisfying a $1 - o(1)$ fraction of constraints, does there exist an efficient algorithm to do so? Answering this in the negative, the fundamental PCP theorem [1, 2] implies that for some fixed integers $k, q \geq 2$ and $c < 1$, it is NP-hard to find an assignment satisfying a fraction c of constraints in a satisfiable CSP of arity k over alphabet $\{0, 1, \ldots, q-1\}$. Further this result holds for the combinations $(q, k) = (2, 3)$ and $(3, 2)$. The PCP theorem lies at the center of a rich body of work that has yielded numerous inapproximability results, including many optimal ones.

The PCP theorem was originally proved using algebraic techniques such as the low-degree test and the sum-check protocol. In a striking work, Dinur [7] gave an alternative combinatorial proof of the PCP theorem. Her proof works by amplifying the "Unsat value" of a CSP instance – the fraction of constraints any assignment should violate. The goal is to show that it is NP-hard to distinguish if the Unsat value of a CSP instance is equal to 0 or at least a constant $c > 0$. Starting with a NP-hard problem such as 3-coloring with m constraints, we can already deduce that it is NP-hard to identify if Unsat value is equal to 0 or at least $1/m$. The Unsat value is increased slowly and iteratively via two steps – *gap amplification* and *alphabet reduction*. In gap amplification, we incur a constant factor blow up in the size of the instance, and get a constant factor improvement in the Unsat value. However, this step also blows up the alphabet size. To alleviate this, alphabet reduction brings back the alphabet size to an absolute constant while losing a constant factor in the Unsat value (and blows up the instance size by a constant factor). Combining both the steps, we can increase the Unsat value by a constant factor (say 2) incurring a constant factor blow up in the size of the instance. Repeating this $\log m$ times proves the PCP theorem.

In this paper we revisit the alphabet reduction step. Dinur implemented this step by an "inner" PCP construction, which is in effect a gadget reducing a specific predicate ψ to be tested to a collection Ψ of constraints over a fixed (say Boolean) alphabet, such that if ψ is unsatisfiable, then a constant fraction of constraints of Ψ must be violated by any assignment.[1] This inner PCP is then applied to all constraints in the CSP instance (say $\mathcal{G}$) produced by the gap amplification step. The collection of inner PCPs as such only ensure that each constraint of $\mathcal{G}$ is individually satisfiable, which is not very meaningful. To ensure that the inner PCPs together ensure that the constraints of $\mathcal{G}$ are all satisfiable by a *single consistent* assignment, error-correcting codes are used to encode the purported assignments to the variables of $\mathcal{G}$. The inner PCP is also replaced by an *Assignment Tester* that ascertains whether the specific assignment given by these encodings satisfies the predicate ψ being checked.

The key observation driving this work is that instead of designing the inner PCP for *arbitrary* constraints (as in Dinur's paper), we can first reduce the CSP instance $\mathcal{G}$ produced by gap amplification to a *Label Cover* instance. Label Cover is a special kind of CSP which has arity 2, and whose underlying relations are functions (so the value of one of the variables in each constraint is determined by the value taken by the other variable in that constraint). Conveniently for us, we also observe that Dinur's gap amplification step in fact already produces a CSP with this Label Cover structure, allowing us to skip the reduction step.[2] We can thus focus on alphabet reduction when the CSP we are reducing from has the Label Cover structure, and is over a fixed, albeit large, alphabet. We then follow the influential Label Cover and Long Code framework, originally proposed in [5] and strengthened in [11] and since then applied in numerous works on inapproximability, to reduce the CSP obtained from gap amplification, now viewed as Label Cover, to a Boolean CSP. Finally, we reduce the Boolean CSP back to a Label Cover instance (see Section 4) that can be plugged in as input to the gap amplification step.

[1] While this might seem circular, as this is what the PCP reduction is trying to accomplish in the first place, the key is that this inner reduction can be highly inefficient (even triply exponential blow up is okay!), as it is applied to a constraint of constant size.

[2] Technically, the gap amplification step produces a version of Label Cover whose constraints are *rectangular* rather than functions, but this is a minor difference that can be easily accommodated in reductions from Label Cover.

Our main result is the following, which can be viewed as reproving a case of alphabet reduction from [8, 7].

▶ **Theorem 1.** *There is a polynomial time reduction from Label Cover with soundness* $1-\delta$ *to a fixed template CSP with soundness* $1-C\delta$ *for an absolute constant* $C>0$.

We analyze our reduction using Fourier analysis as pioneered by Håstad [11]. Usually, in this framework, we reduce from low soundness Label Cover to strong (and at times optimal) soundness of CSP. But here we start with a high soundness Label Cover, and we reduce to high soundness CSP.

We highlight a couple of differences from previous works that make our proof easier:

- We have the freedom to choose any CSP rather than trying to prove inapproximability of a CSP. We choose the following 4-ary predicate R in our reduction: $(u,v,w,x)\in R$ if and only if $u\neq v\vee w\neq x$. This predicate appears in [11] in the context of proving optimal hardness for NAE-4SAT.
- In [11] and [5], the objective is to prove optimal inapproximability, or at least to get good soundness. However, our present goal is to prove "just" a nontrivial soundness. (On the other hand, we also start with high soundness Label Cover.) This allows us to use a very convenient test distribution leading to a simple analysis.
- We remark that a similar statement as Theorem 1 can be also deduced using [5, Section 4.1.1]. We believe that the test presented in this paper is more direct since we benefit from ideas in [11].
- It is possible to perform alphabet reduction using the Hadamard code instead of the long code as described in [10, 12]; the latter [12], similarly to our proof, avoids explicit use of Assignment Testers.
- Long code tests correspond exactly to testing whether a function is a *polymorphism* of the corresponding CSP, and as such corresponds to gadget reductions in the algebraic approach to CSP (see e.g. [4]). The PCP theorem surpasses these algebraic (gadget) reductions; this is even more evident when extending the scope from CSPs to *promise constraint satisfaction problems* (PCSPs) as there are PCSPs that can be shown to be NP-hard by using PCP theorem via a natural reduction through Label Cover, but cannot be shown to be NP-hard using only algebraic reductions [3, 6]. In this sense, the present paper shows that this strength of the PCP theorem comes from the Gap Amplification step.

Alphabet Reduction is an essential step in both the original proof of the PCP theorem as well as Dinur's proof and deserves further attention. Our proof of alphabet reduction bypasses the concept of Assignment Testers and is more intuitive in our opinion as it is *nothing but a gadget reduction*. Our proof is elementary using only Parseval's identity from Fourier Analysis over the hypercube. Dinur's analysis used the Friedgut-Naor-Kalai theorem [9] about Boolean functions with most of the Fourier mass at level 1. We believe that this makes our proof more accessible to readers that are new to PCPs. We also hope that this material might be useful in teaching the proof of PCP theorem as it relies only on techniques that any such basic course would cover anyway.

Outline

We start by formally defining CSP, Label Cover, and other preliminaries in Section 2. Then, in Section 3, we prove the main reduction from Label Cover to CSP. In Section 4, we show how the reduction can be used in the alphabet reduction step of Dinur's proof.

2 Preliminaries

2.1 CSPs and Label Cover

Loosely speaking, a CSP over some domain Σ is a decision problem which gets as input a set of variables and a set of constraints on the values of these variables. The goal is to decide whether there is an assignment of values from Σ to the variables such that all the constraints are satisfied. Usually, the shape of the constraints is somehow restricted. We first give a formal definition of the general CSP, and then two restrictions that we will use further.

▶ **Definition 2** (CSP). *The constraint satisfaction problem over an alphabet Σ takes as input a set of variables $V = \{x_1, \ldots, x_n\}$ and a finite set of* constraints *where each constraint is a pair $((x_{i_1}, \ldots, x_{i_k}), R)$ where k is a number (the arity of the constraint), $i_1, \ldots, i_k \in \{1, \ldots, n\}$, and $R \subseteq \Sigma^k$. The goal is to decide whether there exists an assignment $s\colon V \to \Sigma$ such that for each constraint $((x_{i_1}, \ldots, x_{i_k}), R)$ we have $(s(x_{i_1}), \ldots, s(x_{i_k})) \in R$.*

A fixed template CSP is a restriction of the general CSP that requires that the constraints only involve relations from a fixed list of relations over the given alphabet (a template). In the case the domain is Boolean, often negation of variables is allowed. Below, we formally define a Boolean fixed template CSP with a template consisting of a single relation allowing for negation of variables.

▶ **Definition 3** (Boolean fixed template CSP). *Let $\Sigma = \{0, 1\}$ be a Boolean domain, and fix a relation $R \subseteq \Sigma^k$. The constraint satisfaction problem associated with R, denoted by $\mathrm{CSP}(R)$, takes input as a set of variables V and a set of constraints of the form $((x_{i_1}, \ldots, x_{i_k}), R)$ where each x_i is either a variable x, or a negation of a variable (i.e., an expression $\neg x$). An assignment $s\colon V \to \Sigma$ is said to satisfy the constraint $((x_{i_1}, \ldots, x_{i_k}), R)$ if $(s(x_{i_1}), \ldots, s(x_{i_k})) \in R$ where $s(\neg x)$ is defined as $\neg s(x)$ for each $x \in V$.*

The restriction of CSP to binary constraints is traditionally referred to as Label Cover.

▶ **Definition 4** (Label Cover). *In an instance of Label Cover problem, we are given a tuple $(G = (V, E), \Sigma, \Pi)$ where*

1. *G is a graph on vertex set V.*
2. *Each vertex in G has to be assigned a label from Σ.*
3. *For each edge $e = (u, v) \in E$, there is a relation $\Pi_e \subseteq \Sigma \times \Sigma$. This relation corresponds to a constraint between u and v.*

A labeling of graph is a function $s\colon V \to \Sigma$ that assigns a label to each vertex of G. Such labeling is said to satisfy a constraint e if and only if $(s(u), s(v)) \in \Pi_e$.

For a Label Cover instance or in general for a CSP instance I, we use $\mathrm{size}(I)$ to denote $m + n$, where m is the number of constraints and n is the number of variables. We remark that Label Cover usually refers to the case when G is bipartite, and the constraint relations are functions. However, in this work, we find it convenient to consider a (closely related) version which has *rectangular relations*.

▶ **Definition 5** (Rectangular relation). *A relation $R \subseteq A \times B$ is said to be rectangular if there is a set C and functions $\pi\colon A \to C$ and $\sigma\colon B \to C$ such that $(a, b) \in R$ if and only if $\pi(a) = \sigma(b)$. Equivalently, R is rectangular if for all $a, a' \in A$ and $b, b' \in B$ such that $(a, b) \in R$, $(a, b') \in R$, and $(a', b) \in R$, we have $(a', b') \in R$.*

2.2 The long code

Loosely speaking, the *long code* is the longest (error-correcting) code over the Boolean alphabet that does not repeat bits. It is constructed as follows: the long code is a Boolean code of length 2^n which encodes a value $i \in [n]$ into a tuple p_i whose k-th coordinate, $k < 2^n$, is the i-th least significant digit of k in binary.

The long code be also described in another way: we view a Boolean tuple of length 2^n as an n-ary function $p\colon \{0,1\}^n \to \{0,1\}$ (each coordinate of the tuple encodes one value of p). In this perspective, the code words of the long code are functions p_i defined as $p_i(x_1,\dots,x_n) = x_i$. These functions are often called *dictators*.

We also remark that in the conjunction with the long-code, a rectangular constraint can be expressed as an identity. More precisely, given a rectangular relation $R \subseteq [n] \times [m]$, say $R = \{(i,j) : \pi(i) = \sigma(j)\}$ for some $\pi\colon [n] \to [k]$ and $\sigma\colon [m] \to [k]$, then the long codes p_i and p_j of values i, j satisfy

$$p_i(x_{\pi(1)},\dots,x_{\pi(n)}) = p_j(x_{\sigma(1)},\dots,x_{\sigma(m)})$$

for all $x_1,\dots,x_k \in \{0,1\}$ if and only if $(i,j) \in R$. This is a key property of rectangular relations that is used implicitly in our proof.

2.3 Boolean Fourier analysis

As usual in Boolean Fourier analysis, we treat TRUE as -1 and FALSE as $+1$. In particular, in this notation, "negation" is expressed as $\neg x = -x$, "xor" $x \oplus y$ is expressed as $x \oplus y = xy$, and "or" is the expressed by the following function:

$$x \vee y = \begin{cases} -1 & \text{if } x = -1 \text{ or } y = -1, \text{ and} \\ 1 & \text{otherwise.} \end{cases}$$

Throughout the paper, we will use all the same symbols to denote the coordinatewise (or bitwise) application of these functions to tuples, e.g. $(x_1,x_2) \oplus (y_1,y_2) = (x_1y_1, x_2y_2)$.

We define an inner product space on functions from $\{-1,+1\}^n \to \mathbb{R}$ as $\langle f,g\rangle = \mathbb{E}_x[f(x)g(x)]$. For a set $\alpha \subseteq [n]$, let

$$\chi_\alpha(x_1,\dots,x_n) = \prod_{i\in\alpha} x_i.$$

The set of such functions form an orthonormal basis for all functions from $\{-1,+1\}^n$ to $\mathbb{R}$ in the above defined inner product space. Moreover, if $\alpha \neq \emptyset$, then $\mathbb{E}_x[\chi_\alpha(x)] = 0$.

▶ **Definition 6** (Fourier expansion). *Given a function $f\colon \{-1,+1\}^n \to \mathbb{R}$, we can thus write it uniquely as a linear combination of this basis –*

$$f = \sum_{\alpha\subseteq[n]} \hat{f}(\alpha)\chi_\alpha$$

The real quantities $\hat{f}(\alpha)$ are called the Fourier coefficients *of f. We abuse the notation $\hat{f}(i)$ to denote $\hat{f}(\{i\})$.*

The following simple but crucial identity follows from the definitions and is all that we will need in our analysis.

▶ **Theorem 7** (Parseval's Identity). *For each Boolean valued function f, i.e., $f\colon \{-1,+1\}^n \to \{-1,+1\}$,*

$$\sum_{\alpha\subseteq[n]} \hat{f}(\alpha)^2 = 1.$$

2.3.1 Connection to the long code

We remark, that the function $\chi_{\{i\}}$ corresponds to a valid long code: the function p_i encoding the value i. Also observe that there is a connection between the natural distance defined by the inner product $\langle f, g\rangle$ on Boolean functions and *relative Hamming distance* of f and g: This is thanks to the fact that if $x, y \in \{-1, 1\}$ then $x = y$ if and only if $xy = 1$, and consequently, the relative Hamming distance of f to the long code word $p_i = \chi_{\{i\}}$ can be expressed as $\big(1 - \hat{f}(i)\big)/2$. This means that the closest valid long code to a function f is the p_i for which $\hat{f}(i)$ is maximal.

These ideas are manifested in the common strategy in rounding a Boolean function f to a long code: First make sure that coefficients $\hat{f}(\alpha)$ for large sets α are small enough, then decode to a value i that belongs to a small-enough (ideally 1-element) set α with a large-enough $\hat{f}(\alpha)$.

3 Label Cover to CSP

This section describes our gadget reduction from Label Cover to CSP(R) where R is the 4-ary relation over Boolean domain defined as

$$R = \{(x, x', z, z') \mid x \neq x' \vee z \neq z'\}.$$

▶ **Theorem 8.** *There exists absolute constant C such that given a Label Cover instance (not necessarily bipartite) $G = (V, E, \Sigma, \Pi)$ with rectangular constraints, there is a reduction from G that outputs an instance I of* CSP(R) *such that* size(I) $= O($size($G)$) *and*

- *If G is satisfiable, then I is satisfiable as well.*
- *If no labeling can satisfy $1 - \delta$ fraction of constraints of G, then no assignment can satisfy $1 - C\delta$ fraction of constraints in I for all δ.*

Since the domain of CSP(R) is Boolean, the above reduces from an alphabet Σ of arbitrary size to the alphabet of size 2. We note that the constant in $O($size$(G))$ above hides exponential dependency on $|\Sigma|$.

We describe the reduction as a probabilistic checker of a solution to G encoded using a long code, i.e., the proof contains for each $u \in V$ a word $f_u \colon \{-1, 1\}^{|\Sigma|} \to \{-1, 1\}$. In other words, we design the test in such a way that if $s \colon V \to \Sigma$ is a solution to G, then the assignment $f_u \mapsto p_{s(u)}$ passes the test. This will then immediately give the completeness of the reduction. The test is as follows: Sample an edge $e = (u, v)$ from E uniformly at random, and then with equal probability do one of the following

1. run a long code test inside f_u;
2. run a long code test inside f_v;
3. run a constraint test between f_u and f_v.

We describe the long code test and the constraint test below. Both query the respective tables of f_u and f_v at some 4 bits that are generated by a certain randomized algorithm, and then check whether these 4 Boolean values satisfy the predicate R defined above.

This checker can be viewed as a gadget reduction in the following sense: We replace each vertex $u \in V$ with $2^{|\Sigma|}$ Boolean variables labeled by $f_u(x)$ for $x \in \{-1, 1\}^{|\Sigma|}$ (we see an assignment to such variables as a function $f_u \colon \{-1, 1\}^{|\Sigma|} \to \{-1, 1\}$), and each edge $e = (u, v)$ with a set of weighted 4-ary constraints on f_u and f_v, each involving the relation R and some 4 values of f_u and f_v (the result is therefore an instance of CSP(R)). These constraints depend only on the relation Π_e.

To simplify some notation, we assume $\Sigma = [n]$. We also assume that the tables for f_u's are *folded* so f_u is forced to satisfy $f(-x) = -f(x)$. This is a standard technique. Such a folding is ensured by including only one variable of each pair $x, -x$, and if the test queries f_u at the bit corresponding to some x that is not included, the bit $f(-x)$ is queried instead, and the value is negated. As a consequence of this folding, we have to allow for negation of variables in CSP(R). An important and useful consequence of this is that all "even" Fourier coefficients of f vanish, i.e., $\hat{f}(\beta) = 0$ for all β such that $|\beta|$ is even. We remark that folding can be avoided in the construction of the gadget. Nevertheless, it considerably simplifies the calculations below. Further, for calculations, it is useful to view R as a predicate $\rho\colon \{\pm 1\}^4 \to \{0,1\}$ defined as

$$\rho(x,x',z,z') = 1 - \frac{(xx'+1)(zz'+1)}{4}.$$

It is easy to check that $\rho(x,x',z,z') = 1$ if and only if $(x,x',z,z') \in R$.

Let us now describe the two probabilistic checkers.

3.1 Long code test

The long code test has on input a table of a function f ($= f_u$ or f_v), and it is supposed to check whether this function is a code word of the long code, i.e., there is i such that $f = p_i$. We design the test so that all these words pass with probability 1. Since we are only using the predicate R, this further limits possible checks. In fact, we include all checks of the form $f(x_1,x_2,x_3,x_4) \in R$ that are passed by all dictators.[3]

Long code test. Given $f\colon \{-1,1\}^n \to \{-1,1\}$ to test against being a long code word. Choose $x,y,z,\mu \in \{-1,1\}^n$ uniformly at random. Test whether

$$(f(x), f(x \oplus (\mu \vee y)), f(z), f(z \oplus (\mu \vee \neg y))) \in R. \tag{1}$$

Note that for all $x,y,z,\mu \in \{-1,1\}$, $(x, x \oplus (\mu \vee y), z, z \oplus (\mu \vee \neg y)) \in R$. This implies that any dictator function passes the test with probability 1, and therefore provides the completeness of the test. We also note that this test can give some false positives, e.g. the function $-p_i\colon x \mapsto -p_i(x)$ passes the test with probability 1, but is not a long code word. It is in fact a negation of the word p_i. It can be checked that all functions that pass are either long code words, or their negations. In the decoding, we simply decode the above function f to i.

The following lemma bounds the probability that the test accepts in the means of the Fourier coefficients. We remark, that since we want to ensure that f is as close to a valid long code as possible, the probability should decrease as the coefficients $\hat{f}(\alpha)$ for $\alpha \neq \{i\}$ increase. Indeed, the lemma states that this is the case.

▶ **Lemma 9.** *Assuming that f is folded, the probability the long code test accepts is at most*

$$1 - \frac{3}{16} \sum_{|\alpha|>1} \hat{f}(\alpha)^2.$$

[3] Any function that passes any such test with probability 1 is called a *polymorphism of R*, see also [4].

Proof. Assume $f(x) = \sum_\alpha \hat{f}(\alpha)\chi_\alpha(x)$. The probability that the test accepts is

$$\begin{aligned}
&\mathbb{E}_{x,y,z,\mu}\, \rho(f(x),f(x \oplus (\mu \vee y)), f(z), f(z \oplus (\mu \vee \neg y))) \qquad (2)\\
&\quad = \mathbb{E}_{x,y,z,\mu}\left[1 - \frac{\big(f(x)f(x \oplus (\mu \vee y) + 1\big)\big(f(z)f(z \oplus (\mu \vee \neg y)) + 1\big)}{4}\right]\\
&\quad = \frac{3}{4} - \frac{1}{4}\,\mathbb{E}_{x,y,\mu}\, f(x)f(x \oplus (\mu \vee y)) - \frac{1}{4}\,\mathbb{E}_{y,z,\mu}\, f(z)f(z \oplus (\mu \vee \neg y))\\
&\qquad - \frac{1}{4}\,\mathbb{E}_{x,y,z,\mu}\, f(x)f(x \oplus (\mu \vee y))f(z)f(z \oplus (\mu \vee \neg y))
\end{aligned}$$

We further simplify this expression one term at a time.

$$\begin{aligned}
\mathbb{E}_{x,y,\mu}\, f(x)f(x \oplus (\mu \vee y)) &= \mathbb{E}_{x,y,\mu} \sum_{\alpha,\beta} \hat{f}(\alpha)\hat{f}(\beta)\chi_\alpha(x)\chi_\beta(x \oplus (\mu \vee y)) \qquad (3)\\
&= \sum_{\alpha,\beta} \hat{f}(\alpha)\hat{f}(\beta)\,\mathbb{E}_x[\chi_\alpha(x)\chi_\beta(x)]\,\mathbb{E}_{y,\mu}[\chi_\beta(\mu \vee y)]\\
&= \sum_{\alpha} \hat{f}(\alpha)^2\,\mathbb{E}_{y,\mu}[\chi_\alpha(y \vee \mu)] = \sum_{\alpha} \hat{f}(\alpha)^2(-1/2)^{|\alpha|}.
\end{aligned}$$

The third equality follows since χ_α and χ_β are orthogonal if $\alpha \neq \beta$. The last equality follows from the fact that $\mathbb{E}_{y,\mu}[y \vee \mu] = (-1) \cdot 3/4 + 1 \cdot 1/4 = -1/2$ and coordinates are chosen independently. Similarly, we get that

$$\mathbb{E}_{y,z,\mu}\, f(z)f(z \oplus (\mu \vee \neg y)) = \sum_{\alpha} \hat{f}(\alpha)^2(-1/2)^{|\alpha|}. \qquad (4)$$

Moving to the next term, we get

$$\begin{aligned}
&\mathbb{E}_{x,y,z,\mu}\, f(x)f(x \oplus (\mu \vee y))f(z)f(z \oplus (\mu \vee \neg y))\\
&\quad = \sum_{\alpha,\beta} \hat{f}(\alpha)^2\hat{f}(\beta)^2\,\mathbb{E}_{y,\mu}\,\chi_\alpha(\mu \vee y)\chi_\beta(\mu \vee \neg y) = \sum_{\alpha \cap \beta = \emptyset} \hat{f}(\alpha)^2\hat{f}(\beta)^2(-1/2)^{|\alpha \cup \beta|}. \qquad (5)
\end{aligned}$$

The last equality follows since $\mathbb{E}_{y,\mu}[(\mu \vee y) \oplus (\mu \vee \neg y)] = \mathbb{E}_{y,\mu}[\neg\mu] = 0$ and $\mathbb{E}_{y,\mu}[\mu \vee y] = \mathbb{E}_{y,\mu}[\mu \vee \neg y] = -1/2$. The overall acceptance probability is then

$$\begin{aligned}
&\frac{3}{4} - \frac{1}{2}\sum_{\alpha} \hat{f}(\alpha)^2(-1/2)^{|\alpha|} - \frac{1}{4}\sum_{\alpha \cap \beta = \emptyset} \hat{f}(\alpha)^2\hat{f}(\beta)^2(-1/2)^{|\alpha \cup \beta|}\\
&\qquad = 1 - \frac{1}{2}\sum_{\alpha} \hat{f}(\alpha)^2\big((-1/2)^{|\alpha|} + 1/2\big) - \frac{1}{4}\sum_{\alpha \cap \beta = \emptyset} \hat{f}(\alpha)^2\hat{f}(\beta)^2(-1/2)^{|\alpha \cup \beta|} \qquad (6)
\end{aligned}$$

where for the last equality, we used Parseval's identity. Further, we assumed that f is folded, and therefore $\hat{f}(\alpha) = 0$ for all α such that $|\alpha|$ is even. Restricting the sums to α and β with odd cardinality, and using that for such disjoint α and β, $|\alpha \cup \beta|$ is even, the last expression of (6) can be bounded from above by

$$1 - \frac{1}{2}\sum_{|\alpha|>1} \hat{f}(\alpha)^2\,(3/8) - \frac{1}{4}\sum_{\alpha \cap \beta = \emptyset} \hat{f}(\alpha)^2\hat{f}(\beta)^2(1/2)^{|\alpha \cup \beta|} \leq 1 - \frac{3}{16}\sum_{|\alpha|>1} \hat{f}(\alpha)^2 \qquad (7)$$

which concludes the proof. ◀

3.2 Constraint test

The constraint test has on input tables for functions f and g corresponding to some u and v such that $(u, v) \in E$, and it is supposed to test (assuming f and g are correct long code words) whether the values these functions encode satisfy the constraint given by a rectangular relation Π_e. We construct the test in a similar way as the long code test: We test functions f and g in 4 bits in such a way that long code words encoding satisfying values pass. In contrast with the long code test, we do not include all such tests, but only a selection; in particular, we include only tests that query two values from each function.

We assume that the constraint relation Π_e is given by $\pi, \sigma \colon [n] \to [m]$ such that $(i, j) \in \Pi_e$ if and only if $\pi(i) = \sigma(j)$, and we denote by y^π the vector in $\{-1, 1\}^n$ such that $y^\pi(i) = y(\pi(i))$.

Constraint test. Given $f, g \colon \{-1, 1\}^n \to \{-1, 1\}$ to test against satisfying a constraint Π_e given by $(i, j) \in \Pi_e$ if and only if $\pi(i) = \sigma(j)$ for fixed $\pi, \sigma \colon [n] \to [m]$. Choose $x, z \in \{-1, 1\}^n$ and $y \in \{-1, 1\}^m$ uniformly at random, and test whether

$$(f(x), f(x \oplus y^\pi), g(z), g(z \oplus (\neg y)^\sigma)) \in R. \tag{8}$$

Note that if both f and g are dictators, say $f = p_i$ and $g = p_j$, such that $\pi(i) = \sigma(j) = k$ then the above test accepts with probability 1. Indeed, the tuple gets evaluated to

$$(x(i), (x \oplus y^\pi)(i), z(j), (z \oplus (\neg y)^\sigma)(j)) = (x(i), x(i) \oplus y(k), z(j), z(j) \oplus \neg y(k))$$

which is in R for all x, y and z. This provides the completeness of the test.

In the analysis below, we will use the following notation.

▶ **Definition 10.** *Let $\alpha \subseteq [n]$ and $\pi \colon [n] \to [m]$, we denote by $\pi[\alpha]$ the subset of $[m]$ defined by $\pi[\alpha] = \{k : |\pi^{-1}(k) \cap \alpha| \text{ is odd}\}$.*

The goal of the constraint check is to ensure that functions f, g which are far from valid long codes that encode values satisfying the constraint pass with low probability. Unfortunately, the test gives a lot of false positives: it accepts any pair of functions χ_α and χ_β such that $\pi[\alpha] = \sigma[\beta]$ with probability 1.[4] This is nevertheless good-enough since the long code test provides that relevant α and β contain only one element, and $\pi[\{i\}] = \sigma[\{j\}]$ if and only if $\pi(i) = \sigma(j)$.

Naturally, the pairs of α and β with $\pi[\alpha] = \sigma[\beta]$ will appear in the analysis below. A useful fact that will simplify the computation below is that $\prod_{i \in \alpha} x_{\pi(i)} = \prod_{i \in \pi[\alpha]} x_i$, for all $x_1, \ldots, x_m \in \{-1, 1\}$, which implies that

$$\chi_\alpha(x^\pi) = \chi_{\pi[\alpha]}(x).$$

▶ **Lemma 11.** *Given that both f and g are folded, the probability that the consistency test accepts is at most*

$$1 - \frac{1}{4} \sum_{i,j : \pi(i) \neq \sigma(j)} \hat{f}(i)^2 \hat{g}(j)^2.$$

[4] We note that $\pi[\alpha] = \sigma[\beta]$ is equivalent to $\chi_\alpha(x_{\pi(1)}, \ldots, x_{\pi(n)}) = \chi_\beta(x_{\sigma(1)}, \ldots, x_{\sigma(n)})$ for all $x \in \{-1, 1\}^m$.

Proof. We can compute the acceptance probability in the same way as before, i.e., as

$$\frac{3}{4} - \frac{1}{4}\,\mathbb{E}_{x,y}[f(x)f(x \oplus y^\pi)] - \frac{1}{4}\,\mathbb{E}_{z,y}[g(z)g(z \oplus (\neg y)^\sigma)] \\ - \frac{1}{4}\,\mathbb{E}_{x,y,z}[f(x)f(x \oplus y^\pi)g(z)g(z \oplus (\neg y)^\sigma)] \quad (9)$$

We have

$$\mathbb{E}_{x,y}[f(x)f(x \oplus y^\pi)] = \sum_\alpha \hat{f}(\alpha)^2\,\mathbb{E}_y[\chi_\alpha(y^\pi)] = \sum_\alpha \hat{f}(\alpha)^2\,\mathbb{E}_y[\chi_{\pi[\alpha]}(y)] = 0 \quad (10)$$

where the last equality holds since $|\alpha|$ is odd, and consequently $\pi[\alpha] \neq \emptyset$. Similarly, $\mathbb{E}_{x,z}[g(z)g(z \oplus (\neg y)^\sigma)]$ vanishes. Thus the probability that the test accepts is

$$\begin{aligned} &\frac{3}{4} - \frac{1}{4}\,\mathbb{E}_{x,y,z}\, f(x)f(x \oplus y^\pi)g(z)g(z \oplus (\neg y)^\sigma) \quad (11)\\ &\qquad = \frac{3}{4} - \frac{1}{4}\sum_{\alpha,\beta} \hat{f}(\alpha)^2\hat{g}(\beta)^2\,\mathbb{E}_y[\chi_\alpha(y^\pi)\chi_\beta(-y^\sigma)] \\ &\qquad = \frac{3}{4} + \frac{1}{4}\sum_{\alpha,\beta} \hat{f}(\alpha)^2\hat{g}(\beta)^2\,\mathbb{E}_y[\chi_\alpha(y^\pi)\chi_\beta(y^\sigma)] \\ &\qquad = \frac{3}{4} + \frac{1}{4}\sum_{\alpha,\beta} \hat{f}(\alpha)^2\hat{g}(\beta)^2\,\mathbb{E}_y[\chi_{\pi[\alpha]}(y)\chi_{\sigma[\beta]}(y)] \\ &\qquad = \frac{3}{4} + \frac{1}{4}\sum_{\alpha,\beta:\pi[\alpha]=\sigma[\beta]} \hat{f}(\alpha)^2\hat{g}(\beta)^2 \\ &\qquad = 1 - \frac{1}{4}\sum_{\alpha,\beta:\pi[\alpha]\neq\sigma[\beta]} \hat{f}(\alpha)^2\hat{g}(\beta)^2 \end{aligned}$$

where the second equality follows from $|\beta|$ being odd, and the last equality follows from the Parseval's identity. Since $\pi(i) = \sigma(j)$ implies that $\pi[\{i\}] = \sigma[\{j\}]$, the claim follows. ◀

3.3 The full test

Putting the analysis of the two tests together we get the following.

▶ **Lemma 12.** *Given that both f and g are folded, the probability that the joint test accepts is at most*

$$1 - \frac{1}{16}\Big(\sum_{|\alpha|>1} f(\alpha)^2 + \sum_{|\beta|>1} g(\beta)^2 + \sum_{i,j:\pi(i)\neq\sigma(j)} \hat{f}(i)^2\hat{g}(j)^2\Big)$$

Proof. Follows directly from Lemmas 9 and 11. ◀

Finally, we are ready to prove the main theorem of this section.

Proof of Theorem 8. The completeness follows in a straightforward way from the two comments after the description of the tests. We prove the soundness. Suppose that the test passes with probability $1 - \delta$. We will show that this implies that there is an assignment to the Label Cover instance that satisfies $(1 - 16\delta)$-fraction of constraints.

Our decoding is as follows: for a node $v \in V$, decode v to $i \in \Sigma$ with probability proportional to $\hat{f}_v(i)^2$. Intuitively, we decode to the value i with higher probability if f is closer to the code word $p_i = \chi_{\{i\}}$ or its negative $-p_i$ (see also Section 2.3.1). We will show that in expectation, this decoding satisfies at least $1 - 16\delta$ fraction of constraints, which proves that there exists a labeling that satisfies at least $1 - 16\delta$ fraction of constraints.

Let $1-\delta_e$ denote the probability that the test passes when we pick edge e. As test passes with probability $1-\delta$, we know that $\mathbb{E}_e[\delta_e] = \delta$. Suppose that we pick $e = (u, v)$ with f and g being the functions corresponding to u and v respectively. From the above lemma, we have that

$$1 - \delta_e \leq 1 - \frac{1}{16}\Big(\sum_{|\alpha|>1} \hat{f}(\alpha)^2 + \sum_{|\beta|>1} \hat{g}(\beta)^2 + \sum_{i,j:\pi(i)\neq\sigma(j)} \hat{f}(i)^2\hat{g}(j)^2\Big), \tag{12}$$

and therefore,

$$16\delta_e \geq \sum_{|\alpha|>1} \hat{f}(\alpha)^2 + \sum_{|\beta|>1} \hat{g}(\beta)^2 + \sum_{i,j:\pi(i)\neq\sigma(j)} \hat{f}(i)^2\hat{g}(j)^2. \tag{13}$$

The probability that our decoding satisfies edge e of Label Cover is at least

$$\begin{aligned}
\sum_{i,j:\pi(i)=\sigma(j)} \hat{f}(i)^2\hat{g}(j)^2 &= 1 - \sum_{\substack{\alpha,\beta \\ |\alpha|>1, \text{ or } |\beta|>1, \text{ or } \alpha=\{i\} \text{ and } \beta=\{j\} \text{ and } \pi(i)\neq\sigma(j)}} \hat{f}(\alpha)^2\hat{g}(\beta)^2 \qquad (14)\\
&\geq 1 - \sum_{\substack{\alpha,\beta \\ |\alpha|>1}} \hat{f}(\alpha)^2\hat{g}(\beta)^2 - \sum_{\substack{\alpha,\beta \\ |\beta|>1}} \hat{f}(\alpha)^2\hat{g}(\beta)^2 - \sum_{\substack{i,j \\ \pi(i)\neq\sigma(j)}} \hat{f}(i)^2\hat{g}(j)^2\\
&= 1 - \sum_{|\alpha|>1} \hat{f}(\alpha)^2 - \sum_{|\alpha|>1} \hat{g}(\alpha)^2 - \sum_{i,j:\pi(i)\neq\sigma(j)} \hat{f}(i)^2\hat{g}(j)^2\\
&\geq 1 - 16\delta_\epsilon
\end{aligned}$$

where the first equality follows from Perseval's identity. Thus, the expected number of constraints satisfied by the labeling is at least $\mathbb{E}_e[1 - 16\delta_e] = 1 - 16\delta$ which proves the required claim with $C = 1/16$. ◀

Theorem 1 is stated without the assumption that the constraints are rectangular. This slightly more general version follows from Theorem 8 by a standard reduction which we describe below, in the proof of Theorem 13.

4 CSP to Label Cover

In this section, we recall the basic structure of Dinur's proof of PCP Theorem, and show how the previous reduction can be used in the alphabet reduction step of Dinur's proof. The resulting proof requires a gap amplification step for which we refer to Dinur's paper [7].

We first prove that the previous reduction can be combined with standard reductions to get back Label Cover from the CSP.

▶ **Theorem 13** (Alphabet reduction). *Given a Label Cover instance $G = (V, E, \Pi, \Sigma_0)$ with rectangular constraints, there is a polynomial time reduction that outputs another Label Cover instance with rectangular constraints $G' = (V', E', \Pi', \Sigma)$ with alphabet size Σ such that $|\Sigma|$ is an absolute constant, $size(G') = O(size(G))$ and*

- *If G is satisfiable, then G' is satisfiable as well.*
- *If every labeling violates δ fraction of constraints of G, then every labeling violates $C\delta$ fraction of constraints in G' for an absolute constant C.*

Proof. We first convert the Label Cover instance G to a CSP instance I as in Theorem 8. The CSP instance can be converted to bipartite Label Cover using standard clause-variable Label-coverization technique. We include the proof here for the sake of completeness. We

have n vertices $x_1, x_2, \ldots, x_n$ corresponding to the variables of I on the left L, and m vertices corresponding to constraints $C_1, C_2, \ldots, C_m$ of I on the right R. The label set is binary on the left, and satisfying assignments (at most 16) on the right corresponding to the possible assignments to four variables in the constraint. We add an edge between $u \in L$ and $v \in R$ if $x_u \in C_v$. The constraint on this edge enforces that the assignment to x_u is consistent with the assignment C_v assigns to x_u.

If there is a satisfying labeling to G, there is a satisfying assignment to I. Using this, we can assign the variables on the left the satisfying assignment, and the corresponding assignment to tuples for the vertices of constraints on the right, and thus get a satisfying assignment to G'. Suppose that every labeling violates at least δ fraction of constraints of G. From Theorem 8, every assignment violates at least $C\delta$ fraction of constraints in I. Suppose there is a labeling to G' that satisfies δ' fraction of constraints. Consider the assignment obtained by this labeling on the left. This assignment violates at least $C\delta m$ number of constraints in I. Note that this should violate at least $C\delta m$ constraints in G' and thus $\delta' \geq C'\delta$ for an absolute constant C'. The constraints are in fact projections, and thus are rectangular too. ◀

In order for us to use this as Composition step in the PCP of Dinur, we need the final observation that the output of Gap Amplification applied to a CSP with rectangular constraints results in a Label Cover with rectangular constraints. Dinur achieves gap amplification by "graph powering" which is described more formally below.

▶ **Definition 14** (Constraint Graph Powering). *Given a d-regular Label Cover (a.k.a. Constraint graph) $G = (V, E, \Sigma, \Pi)$, we obtain t-th power of it $G^t = (V, E', \Sigma', \Pi')$ as follows:*

- *Vertices. The vertices in G^t are the same as vertices in G.*
- *Edges. u and v are connected by k parallel edges in E' if there are exactly k paths of length t between u and v in G.*
- *Alphabet. The alphabet of G^t is $\Sigma^{d^{\lceil t/2 \rceil}}$. A value $a \in \Sigma^{d^{\lceil t/2 \rceil}}$ is interpreted as assigning values $a \colon \Gamma(u) \to \Sigma$ to $d^{\lceil t/2 \rceil}$ elements from Σ. This value is treated as u's opinion on $\Gamma(u)$, the set of all vertices within $\lceil t/2 \rceil$ distance from u.*
- *Constraints. An edge $(u, v) \in E'$ is satisfied by $a, b \in \Sigma^{d^{\lceil t/2 \rceil}}$ if and only if the following holds: there is an assignment $\sigma \colon \Gamma(u) \cup \Gamma(v) \to \Sigma$ that satisfies every constraint $c(e)$ where $e \in E \cap (\Gamma(u) \times \Gamma(v))$, and such that*

$$\forall u' \in \Gamma(u), \sigma(u) = a_{u'}; \forall v' \in \Gamma(v), \sigma(v) = b_{v'}$$

where $a_{u'}$ (and respectively $b_{v'}$) is the value a (and resp. b) assigned to u' (and resp. v').

The output G^t is also a binary CSP, and hence can be viewed as a Label Cover. We claim that if every constraint of G is rectangular, then every constraint of G^t is rectangular as well. Let $e = (u, v)$ be an edge in E' with constraint relation as R_e. Suppose $(a, b), (a', b), (a, b') \in R_e$. This implies that for all $(u', v') \in E \cap (\Gamma(u) \times \Gamma(v))$ with constraint relation c_e,

$$(a_{u'}, b_{v'}), (a'_{u'}, b_{v'}), (a_{u'}, b'_{v'}) \in R_{c_e}.$$

Since R_{c_e} is rectangular, $(a'_{u'}, b'_{v'}) \in R_{c_e}$ as well. As this holds for all such u' and v', $(a', b') \in R_e$, thus proving that R_e is a rectangular relation.

Combined with the preprocessing step, the gap amplification theorem of Dinur can be rewritten as follows.

▶ **Theorem 15** (Gap amplification). *Fix a parameter t. Given a Label Cover $G = (V, E, \Pi, \Sigma)$ where Σ is an absolute constant, there is a polynomial time reduction to output a rectangular Label Cover instance $G' = (V', E', \Pi', \Sigma')$ with the alphabet size $|\Sigma'| = c(|\Sigma|, t)$ such that*

- *If G is satisfiable, G' is satisfiable as well.*
- *If every labeling violates at least δ fraction of the constraints of G, then every labeling violates at least $\Omega(\delta\sqrt{t})$ fraction of the constraints of G'.*

Choosing t large enough constant and iterating Theorem 13 and Theorem 15 $\log(m)$ times proves the PCP theorem.

A Derandomization of the gadget decoding

In this appendix, we provide a derandomization of the decoding used in Theorem 8. This requires only a little additional argument. The idea is, instead of decoding to i with probability $\hat{f}(i)^2$, to decode to the i with the largest $\hat{f}(i)^2$. We set i_f to be such i. In this light, the reduction can be analyzed by analyzing completeness and soundness of the gadget separately without considering the rest of the instance. The following lemma then shows that the gadget has perfect completeness and soundness 99% not depending on the parameters n and m (the alphabet sizes), π and σ.

▶ **Lemma 16.** *There is a gadget with inputs n, m, k, $\pi\colon [n] \to [k]$, and $\sigma\colon [m] \to [k]$ that produces an instance of* $\mathrm{CSP}(R)$ *with variables $f(a_1, \ldots, a_n)$ and $g(a_1, \ldots, a_m)$ such that*
1. *if $\pi(i) = \sigma(j)$ then p_i and p_j satisfy all the constraints, and*
2. *if at least 99% of the constraints are satisfied, then $\pi(i_f) = \sigma(i_g)$.*

Proof. First, we bound the probability that the test accepts. For the long code test, starting with the first expression in (7), we obtain the following bound.

$$1 - \frac{1}{2}\sum_{|\alpha|>1} \hat{f}(\alpha)^2\,(3/8) - \frac{1}{4}\sum_{\alpha\cap\beta=\emptyset} \hat{f}(\alpha)^2\hat{f}(\beta)^2(1/2)^{|\alpha\cup\beta|} \le 1 - \frac{3}{16}\sum_{|\alpha|>1}\hat{f}(\alpha)^2 - \frac{1}{16}\sum_{i\neq j}\hat{f}(i)^2\hat{f}(j)^2$$

For the consistency test, we use the bound from Lemma 11. Thus the overall probability that the whole test accepts is at most

$$1 - \frac{1}{16}\sum_{|\alpha|>1}\hat{f}(\alpha)^2 - \frac{1}{48}\sum_{i\neq j}\hat{f}(i)^2\hat{f}(j)^2 - \frac{1}{16}\sum_{|\alpha|>1}\hat{g}(\alpha)^2 - \frac{1}{48}\sum_{i\neq j}\hat{g}(i)^2\hat{g}(j)^2 - \frac{1}{12}\sum_{i,j:\pi(i)\neq\sigma(j)}\hat{f}(i)^2\hat{g}(j)^2.$$

Given that the acceptance probability is at least $99\% > 1 - 1/96$, we get that

$$\sum_{|\alpha|>1}\hat{f}(\alpha)^2 \le 1/6 \tag{15}$$

$$\sum_{i\neq j}\hat{f}(i)^2\hat{f}(j)^2 \le 1/2 \tag{16}$$

$$\sum_{|\alpha|>1}\hat{g}(\alpha)^2 \le 1/6 \tag{17}$$

$$\sum_{i\neq j}\hat{g}(i)^2\hat{g}(j)^2 \le 1/2 \tag{18}$$

$$\sum_{i,j:\pi(i)\neq\sigma(j)}\hat{f}(i)^2\hat{g}(j)^2 \le 1/8 \tag{19}$$

From Parseval's identity and (15), we get that $1 \ge \sum_i \hat{f}(i)^2 \ge 5/6$. Recall that i_f is such i that $\hat{f}(i)^2$ is maximal. Then using the above and (16), we obtain that

$$\hat{f}(i_f)^2 \ge \hat{f}(i_f)^2\sum_i \hat{f}(i)^2 \ge \sum_i \hat{f}(i)^4 = \sum_{i,j}\hat{f}(i)^2\hat{f}(j)^2 - \sum_{i\neq j}\hat{f}(i)^2\hat{f}(j)^2 \ge (5/6)^2 - 1/2 = 4/9. \tag{20}$$

Similarly, from (17) and (18), we get $\hat{g}(i_g)^2 \ge 4/9$. Finally, since $\hat{f}(i_f)^2\hat{g}(i_g)^2 \ge (4/9)^2 > 1/8$, we have that $\pi(i_f) = \sigma(i_g)$ otherwise (19) cannot be true. ◀

Theorem 8 can be also directly obtained from this lemma albeit with a worse constant than in the above proof: Let $C = 1\%$ and assume that $\delta < 1$. Given that the resulting CSP instance has an assignment fails no more than $C\delta$-fraction of the constraints, we derive that in at least $(1-\delta)$-fraction of the gadgets, no more than C-fraction of constraints are unsatisfied. Lemma 16 then shows that the assignment $s\colon u \mapsto i_{f_u}$ is an assignment of the Label Cover instance that satisfies all the constraints corresponding to these gadgets. This completes the proof.

L_p Pattern Matching in a Stream

Abstract

We consider the problem of computing distance between a pattern of length n and all n-length subwords of a text in the streaming model.

In the streaming setting, only the Hamming distance (L_0) has been studied. It is known that computing the exact Hamming distance between a pattern and a streaming text requires $\Omega(n)$ space (folklore). Therefore, to develop sublinear-space solutions, one must relax their requirements. One possibility to do so is to compute only the distances bounded by a threshold k, see [SODA'19, Clifford, Kociumaka, Porat] and references therein. The motivation for this variant of this problem is that we are interested in subwords of the text that are similar to the pattern, i.e. in subwords such that the distance between them and the pattern is relatively small.

On the other hand, the main application of the streaming setting is processing large-scale data, such as biological data. Recent advances in hardware technology allow generating such data at a very high speed, but unfortunately, the produced data may contain about 10% of noise [Biol. Direct.'07, Klebanov and Yakovlev]. To analyse such data, it is not sufficient to consider small distances only. A possible workaround for this issue is the $(1 \pm \varepsilon)$-approximation. This line of research was initiated in [ICALP'16, Clifford and Starikovskaya] who gave a $(1 \pm \varepsilon)$-approximation algorithm with space $\widetilde{\mathcal{O}}(\varepsilon^{-5}\sqrt{n})$.

In this work, we show a suite of new streaming algorithms for computing the Hamming, L_1, L_2 and general L_p $(0 < p < 2)$ distances between the pattern and the text. Our results significantly extend over the previous result in this setting. In particular, for the Hamming distance and for the L_p distance when $0 < p \leq 1$ we show a streaming algorithm that uses $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n})$ space for polynomial-size alphabets.

1 Introduction

In the problem of pattern matching, we are given a pattern P of length n and a text T and must find all occurrences of P in T. A particularly relevant variant of this fundamental question is approximate pattern matching, where the goal is to find all subwords of the text that are similar to the pattern. This can be restated in the following way: given a

pattern P, a text T, and a distance function, compute the distance between P and every n-length subword of T. A very natural similarity measure for words is the Hamming distance. Furthermore, if both P and T are over an integer alphabet Σ, one can consider the Manhattan distance or the Euclidean distance.

▶ **Definition 1** (Hamming, Manhattan and Euclidean distances). *For a vector $U = u_1u_2 \dots u_n$, its Hamming norm is defined as $\|U\|_H = |\{i : u_i \neq 0\}|$, Manhattan norm is defined as $\|U\|_1 = \sum_i |u_i|$ and Euclidean norm is defined as $\|U\|_2 = \left(\sum_i u_i^2\right)^{1/2}$. For two words $V = v_1v_2 \dots v_n$ and $W = w_1w_2 \dots w_n$, their Hamming distance is defined as $\|V - W\|_H$, their Manhattan distance as $\|V - W\|_1$, and their Euclidean distance as $\|V - W\|_2$.*

Those distance functions naturally generalize to the so called L_p distances, where $p > 0$ is the exponent.

▶ **Definition 2** (p'th moment, p'th norm). *For a vector $U = u_1u_2 \dots u_n$ and $p \geq 0$, its p'th moment F_p is defined as $F_p(U) = \sum_i |u_i|^p$, and for $p > 0$ its L_p norm is defined as $\|U\|_p = F_p(U)^{1/p} = (\sum_i |u_i|^p)^{1/p}$. For two words $V = v_1v_2 \dots v_n$ and $W = w_1w_2 \dots w_n$ considered as vectors, the p'th moment of their difference is $F_p(V-W)$ and their L_p distance is defined as $\|V - W\|_p = F_p(V - W)^{1/p} = (\sum_i |v_i - w_i|^p)^{1/p}$.*

In other words, the Manhattan distance is the L_1 distance, the Euclidean distance is the L_2 distance, and the Hamming distance can be considered as the L_0 distance.

Below we assume that the length of the text is $2n$, as any algorithm on a text of larger length can be reduced to repeated application of an algorithm that runs on texts of length $2n$. This is done by splitting the text into blocks of length $2n$ which overlap by n characters.

Offline setting. For the Hamming distance, the problem has been extensively studied in the offline setting, where we assume random access to the input. The first algorithm, for a constant-size alphabet, was shown by Fischer and Paterson [21]. The algorithm uses $\mathcal{O}(n \log n)$ time and in substance computes the Boolean convolution of two vectors a constant number of times. This was later extended to polynomial-size alphabets in [1, 33]. With a somewhat similar approach, the same complexity can be achieved for the L_1 distance in [13]. Later, in [34, 35] the authors proved that these problems must have equal (up to polylogarithmic factors) complexities by showing reductions from the Hamming to the L_1 distance and back.

To improve the complexity for large alphabets, the natural next step was to study approximation algorithms. Until very recently, the fastest $(1 \pm \varepsilon)$-approximation algorithm for computing the Hamming distances was by Karloff [29]. The algorithm combines random projections from an arbitrary alphabet to the binary one and Boolean convolution to solve the problem in $\mathcal{O}(\varepsilon^{-2}n \log^3 n)$ time. In a breakthrough paper Kopelowitz and Porat [31] gave a new approximation algorithm improving the time complexity to $\mathcal{O}(\varepsilon^{-1}n \log^3 n \log \varepsilon^{-1})$, which was later significantly simplified [32]. Using a similar technique, Gawrychowski and Uznański [23] showed an approximation algorithm for computing the L_1 distance in $\mathcal{O}(\varepsilon^{-1}n \log^4 n)$ (randomized) time, later made deterministic in time $\mathcal{O}(\varepsilon^{-1}n \log^2 n)$ in [39]. Using similar techniques, the authors of [39] gave $\widetilde{\mathcal{O}}(\varepsilon^{-1}n)$-time $(1 + \varepsilon)$-approximation algorithm for L_p distances for any constant positive p.[1]

[1] Across the paper we use $\widetilde{\mathcal{O}}$ to indicate that we are suppressing poly-log(n) factors.

Streaming setting. In the streaming setting, we assume that the pattern and the text arrive as streams, one character at a time (the pattern arrives before the text). The main objective is to design algorithms that use as little space as possible, and we must account for all the space used by the algorithm, including the space required to store the input, in full or in part. It is also often the case that the text arrives at a very high speed and we must be able to process it faster than it arrives to fulfil the space guarantees, preferably, in real time. To this aim, the time complexity of streaming algorithms is defined as the worst-case amount of time spent on processing one character of the text, i.e. *per arrival*.

In the streaming setting, only the Hamming distance (L_0) has been studied. It is known that computing the Hamming distance between a pattern and a streaming text exactly requires $\Omega(n)$ space, even for the binary alphabet and with a small probability error allowed, which can be shown by a straightforward reduction to communication complexity (folklore).

Therefore, to develop sublinear-space solutions, one must relax their requirements. One possibility to do so is to compute only the distances bounded by a threshold k. This variant of the problem is often reffered to as *k-mismatch problem*. The k-mismatch problem has been extensively studied in the literature [15, 16, 25, 38], with this line of work reaching $\widetilde{\mathcal{O}}(k)$ memory complexity and $\widetilde{\mathcal{O}}(\sqrt{k})$ time per input character. The motivation for this variant of this problem is that we are interested in subwords of the text that are similar to the pattern, in other words, the distance between the pattern and the text should be relatively small. On the other hand, the main application of the streaming setting is processing large-scale data, such as biological data. To decrease the cost of generating such data, recently new hardware approaches have been developed. They have become widely used due to cost efficiency, but unfortunately, the produced data may contain about 10% of noise [30]. To analyse such data, it is not sufficient to consider small distances only, and a possible workaround for this issue is $(1 \pm \varepsilon)$-approximation. This line of research was initiated by Clifford and Starikovskaya [17] who gave a $(1 \pm \varepsilon)$-approximation algorithm with space $\widetilde{\mathcal{O}}(\varepsilon^{-5}\sqrt{n})$ that uses $\widetilde{\mathcal{O}}(\varepsilon^{-4})$ time per arriving character of the text.

Independently and in parallel with this work, authors of [12] showed a $(1\pm\varepsilon)$-approximation streaming algorithm for the k-mismatch problem that uses $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{k})$ space. For a special case of $k = n$, they show how to reduce the space further to $\widetilde{\mathcal{O}}(\varepsilon^{-1.5}\sqrt{n})$. Compared to our solution, their algorithm has worse time complexity of $\widetilde{\mathcal{O}}(\varepsilon^{-3})$ per arrival, and more importantly, it is not obvious whether it can be generalised to other L_p norms as it uses a very different set of techniques.

Sliding window. The problem of computing distance between P and every n-length subword of T in the streaming setting resembles the problem of maintaining the L_p norm of a n-length suffix of a streaming text, also referred to as *sliding window*. In fact, the latter is a simplification of the former, with setting $P = [0, 0, \ldots, 0]$. There is an extensive line of work on maintaining the L_p norm of a sliding window, refer to [4, 5, 6, 7, 8, 18] and references therein. The main message is that the norm of a sliding window can be maintained efficiently, e.g. for $1 \leq p \leq 2$ the L_p norms can be maintained $(1 \pm \varepsilon)$-approximately in space $\widetilde{\mathcal{O}}(\varepsilon^{-1})$. However, those results do not translate to our case: in the sliding window, one can easily isolate "heavy hitters", that is updates with a significant contribution to the output. In our case, the contribution of an update depends on its relative position to the pattern, and one can easily construct instances where a contribution of a position in the text changes drastically relative to its alignment with the pattern, which necessitates a significantly different approach.

1.1 Our results

In this work, we show a suite of new streaming algorithms for computing the Hamming, L_1, L_2 and general L_p ($0 < p \leq 2$) distances between the pattern and the text. Our results significantly improve and extend the results of [17].

▶ **Theorem 3.** *Given a pattern P of length n and a text T over an alphabet $\Sigma = [1, 2, \ldots, \sigma]$, where $\sigma = n^{\mathcal{O}(1)}$, there is a streaming algorithm that computes a $(1 \pm \varepsilon)$-approximation of the L_p distance between P and every n-length subword of T correctly w.h.p.*

1) *in $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n} + \log \sigma)$ space, and $\widetilde{\mathcal{O}}(\varepsilon^{-2})$ time per arrival when $p = 0$ (Hamming distance);*
2) *in $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n} + \log^2 \sigma)$ space and $\widetilde{\mathcal{O}}(\sqrt{n} \log \sigma)$ time per arrival when $p = 1$ (Manhattan distance);*
3) *in $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n} + \log^2 \sigma)$ space and $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n})$ time per arrival when $0 < p < 1/2$;*
4) *in $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n} + \log^2 \sigma)$ space and $\widetilde{\mathcal{O}}(\varepsilon^{-3}\sqrt{n})$ time per arrival when $p = 1/2$;*
5) *in $\widetilde{\mathcal{O}}(\varepsilon^{-2}\sqrt{n} + \log^2 \sigma)$ space and $\widetilde{\mathcal{O}}(\sigma^{\frac{2p-1}{1-p}}\sqrt{n}/\varepsilon^{2+3\cdot\frac{2p-1}{1-p}})$ time per arrival when $1/2 < p < 1$;*
6) *in $\widetilde{\mathcal{O}}(\varepsilon^{-2-p/2}\sqrt{n}\log^2 \sigma)$ space and $\mathcal{O}(\varepsilon^{-p/2}\sqrt{n} + \varepsilon^{-2}\log \sigma)$ time per arrival for $1 < p \leq 2$.*

We also improve and extend the space lower bound of [17], who showed that any streaming algorithm that computes a $(1 \pm \varepsilon)$-approximation of the Hamming distance between a pattern and a streaming text must use $\Omega(\varepsilon^{-2} \log^2 n)$ bits for all ε such that $1/\varepsilon < n^{1/2-\gamma}$ for some constant γ (condition inherited from [27]). We show the following result:

▶ **Lemma 4.** *Let $2 \leq 1/\varepsilon < n$ and $0 \leq p \leq 2$. Any $(1 \pm \varepsilon)$-approximation algorithm that computes the L_p distance between a pattern and a streaming text for each alignment, must use $\Omega(\min(1/\varepsilon^2, n))$ bits of space.*

1.2 Techniques

At a very high level, the structure of all algorithms presented in this paper is similar to that of [17]. We process the text by blocks of length $b \approx \sqrt{n}$. To compute an approximation of the distance / the p'th moment at a particular alignment, we divide the pattern into two parts: a prefix of length $\leq b$ aligned with a suffix of some block of the text, and the remaining suffix (see Fig. 1). We compute an approximation of the distance / the p'th moment for both of the parts and sum them up to obtain the final answer. Our main contribution is a set of new tools that allows computing the approximations efficiently.

To be able to compute the approximation of the distance / the p'th moment between the prefix and the corresponding block of the text, we compute, while reading each block of the text, its compact lossy description that we refer to as *prefix encoding*. The prefix encoding captures the relation between the read block and the prefix of the pattern of length b. To compute the distance / the p'th moment between the suffix and the text, we will use *suffix sketches*. For each position i of the text, the suffix sketch describes the subword $T[b \cdot k + 1, i]$ of the text where k is the smallest integer such that $i - b \cdot k \leq n$ (see Fig. 1).

For the Hamming distance, we define the prefix encodings in Section 2.1 and the suffix sketches in Section 3.1. Our Hamming prefix encoding introduces a novel use of a known technique called *subsampling*. The prefix encodings are used to approximate the distance between any suffix of one word and the prefix of another word of the same length. In brief, the idea is to replace each character of the two words by the don't care character "?", a special character that matches any other character of the alphabet. We repeat the process a logarithmic number of times to create a logarithmic number of pairs of "subsamples". For each pair, we find the longest suffix of one subsample that matches the prefix of the

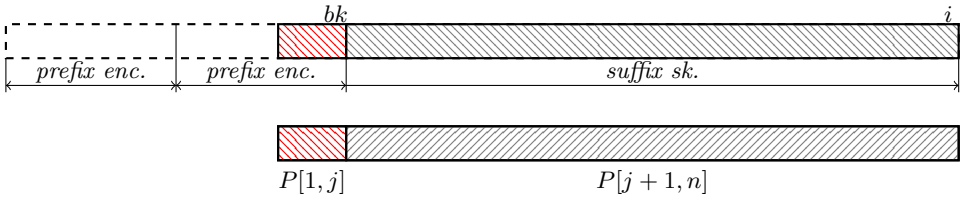

Figure 1 High level structure of the algorithms. To compute the distance between the prefix (red) of the pattern and the text, we use the prefix encoding, between the suffix (grey) and the text we use the suffix sketch.

second subsample up to at most $\Theta(1/\varepsilon^2)$ mismatches. We then show that this information can be used to approximate the Hamming distance between any suffix-prefix pair. Similar techniques were used in [3, 19, 22, 24, 28, 37] for estimating the Hamming norm in streams. The crucial difference with our approach is that we must be able to compute the Hamming norm of any suffix-prefix pair of the two words, and we must be able to do it efficiently. As for the suffix sketches, for the binary alphabet we use the sketches introduced in [17]. We then show a reduction from arbitrary alphabets to the binary alphabet, which improves the space consumption of Hamming suffix sketches by a factor of $1/\varepsilon^2$.

We can solve the problem of L_1 (Manhattan distance) pattern matching by replacing each character of the pattern and of the stream with its unary encoding and running the solution for the Hamming distance. However, this would introduce a multiplicative factor of σ (the size of the alphabet) to the time complexity. We show efficient randomised reductions from the Manhattan to Hamming distance that allow simulating the solution for the Hamming distance without a significant overhead. In particular, to design the prefix encodings we use random shifting and rounding, while for the suffix sketches we use range-summable hash functions [9]. We show the Manhattan prefix encodings in Section 2.2 and the Manhattan suffix sketches in Section 3.2.

For generic L_p distances, $0 < p \leq 2$, we discuss the prefix encodings in Section 2.4 and the suffix sketches in Section 3.3. Our approach to L_p prefix encodings is rather involved. In the case of $0 < p < 1$, we construct a novel embedding from L_p^p space into the Hamming space, which might be of independent interest. While the target dimension of the Hamming space is large, we construct the embedding in such a way that each value is mapped into a compressible sequence of form $c_1^{d_1} \dots c_t^{d_t}$ for some small value of t, and where values of $d_1, \dots, d_t$ are constant across all input values. Such compressed representation allows us to efficiently apply the subsampling framework and reduce the problem to the Hamming distance case. For $1 < p \leq 2$, we identify a logarithmic number of anchor suffixes, and partition each of them into ε^{-p} words of roughly even contribution to the distance. We then use the partition to decode prefix-suffix distance queries for arbitrary length queries. Such construction is a generalization and improvement of the approach presented in [17]. For suffix sketches, we simply use the p-stable distributions [26].

Finally, we combine the prefix encodings and the suffix sketches to prove Theorem 3 in Section 4. To simplify the notation, we use $x \overset{\varepsilon}{=} y$ to denote $(1-\varepsilon)y \leq x \leq (1+\varepsilon)y$ from now on. We will also use the fact that for $p > 0$ we can speak of approximating the p'th moment of differences between the pattern and the n-length substrings of the text and the L_p distances between the pattern and the n-length substrings of the text interchangeably, it changes the complexities up to a constant factor only:

▶ **Observation 5.** *For any constant $p > 0$ and $\varepsilon < 1/2$, there is a constant C_p such that finding a $(1 \pm C_p \cdot p\varepsilon)$ approximation of the p'th moment of a vector suffices for $(1 \pm \varepsilon)$-approximating its p'th norm, and finding a $(1 \pm C_p \cdot \varepsilon/p)$ approximation of its p'th norm suffices for $(1 \pm \varepsilon)$-approximating its p'th moment.*

2 Prefix encodings

In this section we present a solution to the following problem. Imagine we have a block of text $T'[1, b] = T[i + 1, i + b]$ and a prefix of the pattern $P' = P[1, b]$. We want to find a compressed representation (encoding) of T' so that the following is possible: given any $1 \le d \le b$, the compressed representation of T', and P' (explicitly), we can $1 \pm \varepsilon$ approximate $\|T'' - P''\|_p$, where $T'' = T'[b - d + 1, b]$ is a suffix of T' and $P'' = P'[1, d]$ is a prefix of P'.

We start by presenting a solution to the Hamming distance case, which is a basis to our solution for all other L_p norms for $0 < p \le 2$.

2.1 Hamming (L_0) distance

Recall that "?" is the don't care character, a special character that matches any other character of the alphabet.

▶ **Definition 6** (Hamming subsampling). *Consider a word U of length n. Let $q = \lceil 3 \log n \rceil$ and let $h(i) : [n] \to \{0, 1\}^q$ be a function drawn at random from a pairwise independent family. For $r = 0, \ldots, q$, we define the r-th level Hamming subsample of U, $\mathsf{hSub}_r(U)$, as follows:*

$$\mathsf{hSub}_r(U)[i] = \begin{cases} U[i], & \text{if the } r \text{ lowest bits of } h(i) \text{ are all } 0; \\ ?, & \text{otherwise.} \end{cases}.$$

In particular, $\mathsf{hSub}_0(U) = U$.

Fix an integer $k = \Theta(1/\varepsilon^2)$ large enough. For two words U, V, consider the following estimation procedure:

▶ **Algorithm 7.**

1. *Denote X_r to be the Hamming distance between $\mathsf{hSub}_r(U)$ and V and let $f = \min\{i : X_i \le k\}$.*[2]
2. *Output $Z_f = 2^f \cdot X_f$ as an estimate of $\|U - V\|_H$.*

The following lemma is a rephrasing of a known result regarding subsampling in estimation of the Hamming norm (cf. [3, Theorem 3], or [24, Theorem 2]).

▶ **Lemma 8.** *For Z_f as in Algorihtm 7 there is $Z_f \overset{\varepsilon}{=} \|U - V\|_H$ with probability at least $3/4$.*

Since the subsampling is performed independently for each position, one can use subsampling to approximate the Hamming distance between any suffix of B and any prefix of P of equal lengths in a similar fashion.

We are now ready to define the Hamming prefix encoding of a block. For brevity, let $B_r^j = \mathsf{hSub}_r(B)[b - j + 1, b]$ and $P_r^j = P[1, j]$ (the same for all r). Furthermore, given two words U, V of equal length, define the *mismatch information* $\mathsf{MI}(U, V) = \{(i, U[i], V[i]) : U[i] \text{ does not match } V[i]\}$.

[2] We emphasize that $\mathsf{hSub}_r(U)$ contains don't care characters, so the Hamming distance is defined as the number of pairs of characters of $\mathsf{hSub}_r(U)$ and V that do not match.

▶ **Definition 9.** *Consider a b-length block B of the text T. For each $0 \le r \le \lceil 3 \log n \rceil$, let $j^*(r)$ be the maximal integer such that the Hamming distance between $B_r^{j^*(r)}$ and $P_r^{j^*(r)}$ is at most $k = \Theta(\varepsilon^{-2})$. We define the Hamming prefix encoding of B to be a tuple of pairs $j^*(r), \mathsf{MI}(B_r^{j^*(r)}, P_r^{j^*(r)})$.*

Note that the prefix encoding of B uses $\mathcal{O}(k \log n) = \mathcal{O}(\varepsilon^{-2} \log n)$ space. We can compute it efficiently:

▶ **Lemma 10.** *Assume constant-time random access to $P[1, b]$. Given a b-length block B of the text T, its Hamming prefix encoding can be computed in $\widetilde{\mathcal{O}}(kb) = \widetilde{\mathcal{O}}(b\varepsilon^{-2})$ time.*

Proof. To compute the encoding, we use the algorithm of [14]. Formally, for each r we create a word T' by appending b don't care characters to the subsample hSub_r. The algorithm of [14] can be used to find all b-length subwords of T' that match $P[1, b]$ with up to k mismatches, moreover for each of these subwords the algorithm outputs the mismatch information. We take the leftmost subword only, which corresponds to $j^*(r)$ because of the don't care characters. In total, our algorithm uses $\widetilde{\mathcal{O}}(kb) = \widetilde{\mathcal{O}}(\varepsilon^{-2}b)$ time. ◀

We now show how to compute the Hamming distance between any j-length suffix of B and any j-length prefix of P given $P[1, b]$ and the Hamming prefix encoding of a block B.

▶ **Lemma 11.** *Given the prefix encoding of a b-length block B of the text T, there is an algorithm that computes, for any $j = 1, \ldots, b$, a $(1 + \varepsilon)$-approximation of the Hamming distance between the j-length suffix of B and the j-length prefix of P in $\widetilde{\mathcal{O}}(kb) = \widetilde{\mathcal{O}}(b\varepsilon^{-2})$ time.*

Proof. Denote X_r to be the Hamming distance between P_r^j and B_r^j. We compute the smallest f such that $X_f \le k$ in the following way. For each r, we use $\mathsf{MI}(B_r^{j^*(r)}, P_r^{j^*(r)})$ to restore $B_r^{j^*(r)}$. We then append $P_r^{j^*(r)}$ with b don't care characters and run the algorithm of [14] for the resulting text and the pattern. This allows to compute X_r for all $j \le j^*(r)$, and if $j > j^*(r)$, then $X_f > k$ by definition. In total, the algorithm takes $\widetilde{\mathcal{O}}(kb) = \widetilde{\mathcal{O}}(\varepsilon^{-2}b)$ time. ◀

2.2 Manhattan (L_1) distance

Recall a word morphism $\nu : \Sigma \to \{0,1\}^\sigma$, $\nu(a) = 1^a 0^{\sigma - a}$. Our goal in this section is to simulate implicitly procedures from Lemma 10 and Lemma 11 on words $\nu(B)$ and $\nu(T)$ without introducing any significant overhead.

▶ **Definition 12** (Manhattan scaling)**.** *Consider a word U of length n. Let $q = \lceil 3 \log n\sigma \rceil$ and let $h : [n] \to 2^q$ be a function drawn at random from a 4-wise independent family. For $r = 0, \ldots, q$, we define the r-th level Manhattan subsample of U, $\mathsf{mSub}_r(U)$, as a word of length n such that $\mathsf{mSub}_r(U)[i] = \left\lfloor \frac{U[i] + (h(i) \bmod 2^r)}{2^r} \right\rfloor$. In particular, $\mathsf{mSub}_0(U) = U$.*

Fix an integer $k = \Theta(1/\varepsilon^2)$ large enough. For words U, V, consider $\mathsf{mSub}_r(U), \mathsf{mSub}_r(V)$ for all $r = 0, \ldots, q$, and the following estimation procedure:

▶ **Algorithm 13.**
1. *Denote $X_r = \|\mathsf{mSub}_r(U) - \mathsf{mSub}_r(V)\|_1$ and let $f = \min\{i : X_i \le k\}$.*
2. *Output $Z_f = 2^f \cdot X_f$ as an estimate of $\|U - V\|_1$.*

▶ **Lemma 14.** *For Z_f as in Algorihtm 13 there is $Z_f \overset{\varepsilon}{=} \|U - V\|_1$ with probability $\ge 3/4$.*

To approximate the Manhattan distance between any suffix of B and any prefix of P of equal lengths, we define the encoding similar to the Hamming distance case. Specifically, we still use the *mismatch information*, building on the fact that for any two words $\|U - V\|_H \leq \|U - V\|_1$ and from the mismatch information the exact value of $\|U - V\|_1$ can be found. We define $B_r^j = \mathsf{mSub}_r(B)[b - j + 1, b]$ as before, but change the definition of P_r^j slightly. Intuitively, we define P_r^j to be the j-length prefix of P subsampled in a synchronized way with B_r^j. Formally, $P_r^j[i] = \left\lfloor \frac{P[i] + (h(b-j+i) \bmod 2^r)}{2^r} \right\rfloor$.

▶ **Definition 15.** *Consider a b-length block B of the text T. For each $0 \leq r \leq \lceil 3 \log n\sigma \rceil$, let $j^*(r)$ be the maximal integer such that the Manhattan distance between $B_r^{j^*(r)}$ and $P_r^{j^*(r)}$ is at most $k = \Theta(\varepsilon^{-2})$. We define the Manhattan prefix encoding of B to be a tuple of pairs $j^*(r), \mathsf{MI}(B_r^{j^*(r)}, P_r^{j^*(r)})$.*

Note that the prefix encoding of B uses $\mathcal{O}(k \log n\sigma) = \mathcal{O}(\varepsilon^{-2} \log n)$ space.

▶ **Lemma 16.** *Assume constant-time random access to $P[1, b]$. Given a b-length block B of the text T, its Manhattan prefix encoding can be computed in $\widetilde{\mathcal{O}}(b^2)$ time and $\widetilde{\mathcal{O}}(b)$ space.*

Proof. Let $q = \lceil 3 \log n\sigma \rceil$. For each $r = 0, \ldots, q$ and $j = 1, \ldots, b$ we compare B_r^j and P_r^j character by character in $\mathcal{O}(b)$ time to find $j^*(r)$ and the corresponding mismatch information. The claim follows. ◀

▶ **Lemma 17.** *Given the prefix encoding of a b-length block B of the text T, there is an algorithm that computes, for all $j = 1, \ldots, b$, a $(1 \pm \varepsilon)$-approximation of the Manhattan distance between the j-length suffix of B and the j-length prefix of P in $\widetilde{\mathcal{O}}(b^2)$ time.*

Proof. Denote $X_r = \|P_r^j - B_r^j\|_H$. We compute the smallest f such that $X_f \leq k$ in the following way. For each r, we use $\mathsf{MI}(B_r^{j^*(r)}, P_r^{j^*(r)})$ to restore $B_r^{j^*(r)}$. If $j > j^*(r)$, the Manhattan distance between P_r^j and B_r^j is at least k. Otherwise, we compare P_r^j and B_r^j character by character to compute the Manhattan distance in $\mathcal{O}(b)$ time. The claim follows. ◀

2.3 Generic (L_p) distance for $0 < p < 1$

Our goal is to construct a morphism (parametrised by p) acting as a randomized embedding of $(L_p)^p$ into the Hamming distance. The intuition behind our approach is as follows. Let $r_0, r_1, \ldots \in [0, 1]$ be a sequence of real numbers picked independently and u.a.r. Define a sequence of values

$$d_i = \begin{cases} \varepsilon^{-1} \cdot (1+\varepsilon)^{pi} & \text{when } i > 0 \\ \varepsilon^{-1} \cdot \frac{(1+\varepsilon)^p}{(1+\varepsilon)^p - 1} & \text{when } i = 0 \end{cases}$$

and for a character $c \in \Sigma$ consider sequence of characters $c_0, c_1, \ldots$ where $c_i = \lfloor \frac{c}{(1+\varepsilon)^i} + r_i \rfloor$ (similarly, a character c' defines a sequence $c'_0, c'_1, \ldots$). Now consider two characters $c, c' \in \Sigma$ such that $|c - c'| = (1+\varepsilon)^\ell$ for some integer ℓ and a random variable $x = \sum_{i=0}^{\infty} d_i \cdot \|c_i - c'_i\|_H$.

There is

$$\begin{aligned}\mathbb{E}[x] &= \sum_{i=0}^{\infty} d_i \cdot \Pr[c_i \neq c'_i] = \sum_{i=0}^{\ell} d_i \cdot 1 + \sum_{i=\ell+1}^{\infty} d_i \cdot \frac{|c-c'|}{(1+\varepsilon)^i} = \\ &= \varepsilon^{-1}\frac{(1+\varepsilon)^p}{(1+\varepsilon)^p-1} + \varepsilon^{-1}\sum_{i=1}^{\ell}\left((1+\varepsilon)^p\right)^i + \varepsilon^{-1}|c-c'|\sum_{i=\ell+1}^{\infty}\left((1+\varepsilon)^{p-1}\right)^i = \\ &= \varepsilon^{-1}\frac{((1+\varepsilon)^{\ell+1})^p}{(1+\varepsilon)^p-1} + |c-c'|\varepsilon^{-1}\frac{((1+\varepsilon)^{\ell+1})^{p-1}}{1-(1+\varepsilon)^{p-1}} = \\ &= |c-c'|^p\left(\frac{(1+\varepsilon)^p}{(1+\varepsilon)^p-1} + \frac{1}{(1+\varepsilon)^{1-p}-1}\right)\varepsilon^{-1} \approx \varepsilon^{-2}|c-c'|^p\frac{1}{p(1-p)}. \end{aligned} \tag{1}$$

We thus see that an idealized morphism of the form $\varphi : c \to c_0^{d_0}c_1^{d_1}\dots$ would have the property that $\|U-V\|_p^p \sim \|\varphi(U)-\varphi(V)\|_H$ on words of length n. But there are the following issues: (i) characters are mapped into infinite length words, (ii) number of repetitions of characters (d_i) is fractional, (iii) we cannot guarantee that character distance is always of form $(1+\varepsilon)^i$ and (iv) the distance is preserved only in expectation. We show how to overcome these issues to achieve the following result:

▶ **Theorem 18.** *Given $0 < p < 1$ and $\varepsilon > 0$ there is a word morphism $\varphi : c \in \Sigma \to c_0^{d_0}c_2^{d_2}\dots c_{t-1}^{d_{t-1}}$ such that:*

1) *$t = \widetilde{\mathcal{O}}(\varepsilon^{-2})$ when $0 < p < 1/2$, $t = \widetilde{\mathcal{O}}(\varepsilon^{-3})$ when $p = 1/2$ and $t = \widetilde{\mathcal{O}}(\sigma^{\frac{2p-1}{1-p}}/\varepsilon^{2+3\cdot\frac{2p-1}{1-p}})$ when $1/2 < p < 1$.*
2) *values of t and $d_0, \dots, d_{t-1}$ do not depend on c,*
3) *there exists a constant $\alpha = \alpha(p,\varepsilon)$ such that for any two words U, V of length at most n, we have $\|U-V\|_p^p \overset{\varepsilon}{=} \alpha \cdot \|\varphi(U)-\varphi(V)\|_H$ with probability at least $9/10$,*
4) *it is enough for the randomness to be realized by a hash function $r : [t] \to [D]$ from a 4-independent hash function family for some $D = \mathrm{poly}(n\sigma\varepsilon^{-1})$, which can be generated from a $\widetilde{\mathcal{O}}(\log\sigma)$ bits size seed.*

We now describe how to use the morphism φ to approximate the L_p distances in a small space. To design an efficient algorithm, we take advantage of the fact that $\varphi(U)$ has a compressed representation of size comparable with the length of U (at least when $p \le 1/2$).

▶ **Definition 19** (L_p scaling)**.** *Consider a word $S = s_1^{e_1}s_2^{e_2}\dots s_m^{e_m}$ of length $m' = \sum_i e_i$. Let $h : [m] \to 2^q$ be a function drawn at random from a 4-wise independent family, where $q = \lceil 3\log m'\rceil$. For $r = 0, \dots, q$, we define the r-th level subsample of S,*

$$\mathsf{Sub}_r(S) = (s_1)^{\left\lfloor \frac{e_1+(h(1) \bmod 2^r)}{2^r}\right\rfloor}(s_2)^{\left\lfloor \frac{e_2+(h(2) \bmod 2^r)}{2^r}\right\rfloor}\dots(s_m)^{\left\lfloor \frac{e_m+(h(m) \bmod 2^r)}{2^r}\right\rfloor}$$

In particular, $\mathsf{Sub}_0(U) = U$.

Consider two words S, Q of form $S = s_1^{e_1}\dots s_m^{e_m}$ and $Q = q_1^{e_1}\dots q_m^{e_n}$. Fix an integer $k = \Theta(1/\varepsilon^2)$ large enough and consider $\mathsf{Sub}_r(S), \mathsf{Sub}_r(Q)$ for all $r = 0, 1, \dots, \lceil 3\log m'\rceil$, where $m' = \sum_i e_i$.

▶ **Algorithm 20.**

1. *Denote $X_r = \|\mathsf{Sub}_r(S) - \mathsf{Sub}_r(Q)\|_H$ and let $f = \min\{i : X_i \le k\}$.*
2. *Output $Z_f = 2^f \cdot X_f$ as an estimate of $\|S-Q\|_H$.*

▶ **Lemma 21.** *For Z_f as in Algorihtm 20 there is $Z_f \overset{\varepsilon}{=} \|S-Q\|_H$ with probability $\ge 3/4$.*

We are now ready to define L_p prefix encodings. Consider a b-length block B of the text and define $B_r^j = \mathsf{Sub}_r(\varphi(B))[(b-j)t+1, bt]$ (t is defined as in Theorem 18). Also, define P_r^j to be the (tj)-length prefix of $\varphi(P)$ subsampled in a synchronized way with B_r^j.

▶ **Definition 22.** *Consider a b-length block B of the text T. For each $r = 0, \ldots, \lceil 3 \log n' \rceil$, where $n' = |\varphi(B)|$, let $j^*(r)$ be the maximal integer such that the Hamming distance between $B_r^{j^*(r)}$ and $P_r^{j^*(r)}$ is at most $k = \Theta(\varepsilon^{-2})$. We define the L_p prefix encoding of B to be a tuple of pairs $j^*(r), \mathsf{MI}(B_r^{j^*(r)}, P_r^{j^*(r)})$.*

The L_p prefix encoding of B uses $\mathcal{O}(k \log n') = \mathcal{O}(\varepsilon^{-2} \log(n\sigma\varepsilon^{-1}))$ space.

▶ **Lemma 23.** *Assume constant-time random access to $P[1, b]$. Given a b-length block B of the text T, its L_p prefix encoding can be computed in $\mathcal{O}(b^2 \cdot t \log n\sigma\varepsilon^{-1})$ time and $\mathcal{O}(b + \varepsilon^{-2} \log n\sigma\varepsilon^{-1})$ space.*

Proof. For each $r = 0, \ldots, \lceil 3 \log n' \rceil$ and $j = 1, \ldots, b$, we compute the Hamming distance between B_r^j and P_r^j in $\mathcal{O}(bt)$ time using the compressed representation to find $j^*(r)$ and the corresponding mismatch information. The claim follows. ◀

▶ **Lemma 24.** *Given the L_p prefix encoding of a b-length block B of the text T, there is an algorithm that computes, for all $j = 1, \ldots, b$, a $(1 \pm \varepsilon)$-approximation of the L_p distance between the j-length suffix of B and the j-length prefix of P in $\widetilde{\mathcal{O}}(b^2 \cdot t \log n\sigma\varepsilon^{-1})$ time and $\mathcal{O}(b + \varepsilon^{-2} \log n\sigma\varepsilon^{-1})$ space.*

Proof. Denote $X_r = \|P_r^j - B_r^j\|_H$. We compute the smallest f such that $X_f \le k$ in the following way. For each r, we use $\mathsf{MI}(B_r^{j^*(r)}, P_r^{j^*(r)})$ to restore $B_r^{j^*(r)}$. If $j > j^*(r)$, the Hamming distance between P_r^j and B_r^j is at least k. Otherwise, we compare P_r^j and B_r^j to compute the Hamming distance in $\mathcal{O}(bt)$ time. The claim follows. ◀

2.4 Generic (L_p) distance for $1 < p \le 2$

For $1 < p \le 2$, we use a scheme similar to the one developped in [17] for the Hamming distance, but adapt it to generic L_p distances. Particularly, we plug in a standard tool used in this situation, the p-stable distribution. We additionally have to adapt the scheme a bit, taking into account that L_p norm is sub-additive under concatenation when $p > 1$.

▶ **Definition 25** (p-stable distribution [40])**.** *For a parameter $p > 0$, we say that a distribution $\mathcal{D}$ is p-*stable *if for all $a, b \in \mathbb{R}$ and random variables X, Y drawn independently from $\mathcal{D}$, the variable $aX + bY$ is distributed as $(|a|^p + |b|^p)^{1/p} Z$, where Z is a random variable with distribution $\mathcal{D}$.*

Consider a word $X = x_1 x_2 \ldots x_n$, and let $\alpha_1, \alpha_2, \ldots, \alpha_n$ be independent random variables drawn from a p-stable distribution $\mathcal{D}$ with expected value $\mu_{\mathcal{D}}$. By Definition 25, we have $\mathbb{E}\left[\sum_i \alpha_i x_i\right] / \mu_{\mathcal{D}} = \|X\|_p$. The p-stable distributions exist for all $0 < p \le 2$, and a random variable X from a p-stable distribution can be generated using the formula $X = \frac{\sin(p\Theta)}{\cos^{1/p}(\Theta)} \left(\frac{\cos(\Theta(1-p))}{\ln(1/r)}\right)^{(1-p)/p}$ [11, 40], where Θ is uniform on $[-\pi/2, \pi/2]$ and r is uniform on $[0, 1]$.

However, to be able to design an efficient sketching scheme that allows to approximate the L_p norm with high probability, there are three technicalities to be overcome: First, one must show that $\sum_i \alpha_i x_i$ concentrates well, second, the formula above assumes infinite precision of computation, and finally, one cannot use fully independent random variables α_i as above

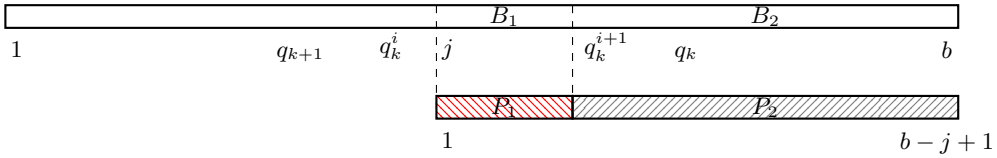

Figure 2 Using the prefix encoding of B to compute the L_p distance between a suffix of B and a prefix of the pattern. To compute the distance between B_1 and P_1, we replace B_1 with a subword of the pattern, and between B_2 and P_2 we use the sketches.

as this would require much space. To overcome these issues, Indyk [26] combined p-stable distributions and pseudorandom generators for bounded space computation [36]. We restate the final result of Indyk below, in the form that will be convenient for us later.

▶ **Theorem 26** (cf. Theorem 2, Theorem 4 [26]). *For any $0 < p \leq 2$, there is a non-uniform streaming algorithm that maintains a sketch $\mathsf{Sketch_p}(S)$ of a word S of length n over an alphabet of size σ such that:*

1) *when a new character of S arrives, the sketch can be updated in $\mathcal{O}(\varepsilon^{-2}\log(n/\varepsilon))$ time;*

2) *the algorithm and the sketch use $\mathcal{O}(\varepsilon^{-2}\log(\sigma n/\varepsilon)\log(n/\varepsilon))$ bits of space.*

Given the sketches $\mathsf{Sketch_p}(X), \mathsf{Sketch_p}(Y)$ of two words X, Y of length n, one can estimate $\|X-Y\|_p$ up to a factor $1\pm\varepsilon$ with probability at least $9/10$ in time $\widetilde{\mathcal{O}}(1/\varepsilon^2)$.

We now proceed to building the L_p prefix encoding by using $\mathsf{Sketch_p}$ and the landmarking technique.

▶ **Definition 27** (L_p prefix encoding). *Let $1 < p \leq 2$. Consider a word S of length b on the alphabet of size σ. Define $q_0 = b$. For $k = 0, \ldots, \lceil \log b\sigma^p \rceil$, let $q_k \leq q_{k-1}$ be the leftmost position such that the p'th moment of the difference between $S[q_k, b]$ and $P[1, b-q_k+1]$, i.e. $\|S[q_k,b] - P[1,b-q_k+1]\|_p^p$, is at most 2^k.*

Further, divide $S[q_k, b]$ into $\Theta(1/\varepsilon^p)$ blocks such that each block is either a single character, or the p'th moment of the difference between each block and the corresponding subword of $P[1, b-p_k+1]$ is at most $\varepsilon^p \cdot 2^k$. Let $q_k = q_k^0 \leq q_k^1 \leq \ldots q_k^{\ell_k} = b$ be the block borders. We choose $q_k^1, q_k^2, \ldots, q_k^{\ell_k}$ from left to right, and each position q_k^i is chosen to be the rightmost possible.

The L_p prefix encoding *of S is defined to contain sorted lists of the positions q_k and q_k^i, characters $S[q_k^i]$, and sketches for $(1 \pm C_p \cdot \varepsilon/p)$-approximating the p'th norm of $S[q_k^j, b]$, for all k, j and C_p as in Observation 5, see also Theorem 26.*

The encoding takes $\widetilde{\mathcal{O}}(\varepsilon^{-2-p}\log\sigma\log(\sigma n/\varepsilon)\log(n/\varepsilon))$ bits of space. We now show that given the L_p prefix encoding of a block B of the text of length b, one can compute a $(1\pm\varepsilon)$-approximation of the L_p distance between any prefix $P[1, b-j+1]$ of the pattern P and the corresponding suffix $B[j, b]$ of B.

▶ **Lemma 28.** *Let $1 < p \leq 2$. For any two vectors X, Y of equal length, $\left| \|X+Y\|_p^p - \|X\|_p^p \right| = \mathcal{O}(\|Y\|_p^p + \|Y\|_p \cdot \|X\|_p^{p-1})$.*

▶ **Lemma 29.** *Let $1 < p \leq 2$. Given the L_p prefix encoding of a block B of the text T of length b, one can find $(1\pm\varepsilon)$-approximation of the p'th moment of the difference between any prefix $P[1, b-j+1]$ of the pattern P and the corresponding suffix $B[j, b]$ of B in time $\widetilde{\mathcal{O}}(\varepsilon^{-2} + \log\sigma)$.*

Proof. Let q_k be the position that is closest to i from the left, and $q_k^i \le j < q_k^{i+1}$ (see Fig. 2). We can find q_k, q_k^i, q_k^{i+1} in time $\mathcal{O}(\log(b\sigma^p) + 1/\varepsilon^p)$ by iterating over the sorted lists.

The position q_k^{i+1} divides $P[1, b-j+1]$ into two parts, P_1 and P_2. Denote B_1 and B_2 the respective subwords of B they are aligned with (see Fig. 2). Let $m_1 = F_p(P_1 - B_1)$ and $m_2 = F_p(P_2 - B_2)$. Then $m = F_p(P[1, b-j+1] - B[j, b])$, being the value we need to approximate, is equal to $m_1 + m_2$.

We can find $m_2' \overset{\varepsilon}{=} m_2$ using the sketches for $B_2 = B[q_k^{i+1}, b]$ and P_2 in time $\widetilde{\mathcal{O}}(1/\varepsilon^2)$. Furthermore, if $q_k^i = q_k^{i+1} - 1$, then we can compute m_1 exactly as we store $B[q_k^i]$. Otherwise, we consider the subword $\tilde{P} = P[j - q_k + 1, q_k^{i+1} - q_k + 1]$ of the pattern P. Denote $m_1' = F_p(P_1 - \tilde{P})$ and use it as our estimation of m_1.

Since $1 \le p \le 2$, by definition, $F_p(B_1 - \tilde{P}) \le \varepsilon^p \cdot 2^{k-1}$, and $F_p(P_1 - B_1) \le 2^k$. By Lemma 28 with $X = P_1 - B_1$ and $Y = B_1 - \tilde{P}$,

$$|m_1' - m_1| = \mathcal{O}(\|B_1 - \tilde{P}\|_p^p + \|B_1 - \tilde{P}\|_p \|P_1 - B_1\|_p^{p-1}) = \mathcal{O}(\varepsilon^p 2^k + \varepsilon (2^k)^{\frac{1}{p}} (2^k)^{\frac{p-1}{p}}) = \mathcal{O}(\varepsilon 2^k)$$

and finally $|(m_1 + m_2) - (m_1' + m_2')| \le \mathcal{O}(\varepsilon m) + \varepsilon m_2 = \mathcal{O}(\varepsilon m)$. ◀

▶ **Lemma 30.** *Let $1 < p \le 2$. The L_p prefix encoding of a b-length block B of the text can be computed in time $\tilde{\mathcal{O}}(b^2 + \varepsilon^{-2} b \log \sigma)$ and space $\tilde{\mathcal{O}}(b + \varepsilon^{-2-p} \log^2 \sigma)$.*

Proof. For $j = 1, \ldots, b$, we naively compute the L_p distance between the suffix of B and the prefix of P in $\mathcal{O}(b)$ time. We then find the positions q_k. For each $k = 0, \ldots, \lceil \log b\sigma^p \rceil$, we can find the positions q_k^i in $\mathcal{O}(b)$ time and compute the sketches in $\tilde{\mathcal{O}}(\varepsilon^{-2} b)$ time by Theorem 26. ◀

3 Suffix sketches

In this section, we give the definitions and explain how we maintain the suffix sketches for each of the distances.

3.1 Hamming distance

We first recall Euclidean suffix sketches as presented in [17]. In fact, we will not use them for the Euclidean distance as for it we can use the generic solution of Section 3.3, but they will serve as a foundation of Hamming suffix sketches.

All sketches presented in this section are correct with constant probability, which can be amplified to $1 - \delta$ for arbitrarily small δ by a standard method of repeating sketching independently $\Theta(\log \delta^{-1})$ times and taking the median of the estimates.

▶ **Lemma 31** (Euclidean sketches [2])**.** *Let M be a random matrix of size $d \times n$ filled with 4-wise independent random ± 1 variables, for $d = \Theta(\varepsilon^{-2})$ chosen big enough. For a vector $X \in \mathbb{R}^n$ there is $\frac{1}{\sqrt{d}} \|MX\|_2 \overset{\varepsilon}{=} \|X\|_2$ with constant probability $9/10$, taken over all possible choices of M. We say that a vector MX of dimension d is a Euclidean sketch of X.*

▶ **Definition 32** (Euclidean suffix sketches [17])**.** *Consider a word X of length n. We define its Euclidean suffix sketch as follows.*

Let b be the block length*. Let $\mathcal{R}$ be a random matrix of size $d \times b$ filled with 4-wise independent random ± 1 variables and let $\alpha_1, \ldots, \alpha_{\lceil n/b \rceil}$ be 4-wise independent random coefficients with values ± 1 as well. We define a matrix M of size $d \times n$ such that $M_{i,jb+k} = \alpha_j \cdot \mathcal{R}_{i,k}$.*

Let X' be a word of length $\lceil n/b \rceil \cdot b$ obtained from X by appending an appropriate number of zeroes. The Euclidean suffix sketch *of X is defined as $\mathsf{eSketch}(X) = MX'$, where X' is considered as a vector.*

Observe that the matrix M does not need to be accessed explicitly. Indeed, from $MX' = \sum_i \alpha_i \cdot \mathcal{R} \cdot \left[X'[bi],\ \ldots,\ X'[bi+b-1]\right]^T$ it follows that the Euclidean suffix sketch can be computed by first sketching each block of X' using the matrix $\mathcal{R}$, and then taking a linear combination of the sketches of the blocks (using the random ± 1 coefficients α_i).

▶ **Lemma 33** ([17]). *Selecting $d = \Theta(\varepsilon^{-2})$ gives $\frac{1}{\sqrt{d}}\|\mathsf{eSketch}(X)\|_2 \overset{\varepsilon}{=} \|X\|_2$ with probability at least $9/10$ (taken over all possible choices of $\mathcal{R}, \alpha_i$).*

By linearity of sketches, we obtain $\|X - Y\|_2 \overset{\varepsilon}{=} \frac{1}{\sqrt{d}}\|\mathsf{eSketch}(X) - \mathsf{eSketch}(Y)\|_2$ with probability at least $9/10$ as well.

We now define Hamming suffix sketches. First note that for binary words X, Y there is $\mathsf{Ham}(X,Y) = \|X - Y\|_2$, and therefore in the case of the binary alphabet we can use the Euclidean suffix sketches. We will now show how to reduce the case of arbitrary polynomial-size alphabets to the case of the binary alphabet.

To this end, [17] used a random mapping of Karloff [29] as a black-box reduction, which led to sketches of size $\sim \varepsilon^{-4}$. We now show a more careful reduction to avoid this overhead and to achieve dependency ε^{-2} in total. Consider a word morphism defined on alphabet as $\mu : \Sigma \to \{0,1\}^\sigma$, $\mu(a) = 0^a 10^{\sigma-a-1}$ (and acting on words by concatenating the images of each character of the input word). Note that $\|\mu(X) - \mu(Y)\|_2^2 = 2 \cdot \|X - Y\|_H$, thus using the Euclidean suffix sketches on top of $\mu(X)$ and $\mu(Y)$ allows computation of the respective Hamming distance. Formally,

▶ **Definition 34** (Hamming suffix sketches [17]). *Consider a word X of length n on the alphabet of size σ. We define its Hamming suffix sketch as follows.*

Let b be the block length*, $\mathcal{R}$ be a random matrix of size $d \times \sigma b$ filled with 4-wise independent random ± 1 variables, and $\alpha_1, \ldots, \alpha_{\lceil n/b \rceil}$ be 4-wise independent random coefficients with values ± 1 as well. We define a matrix M of size $d \times \sigma n$ such that $M_{i,\sigma j b+k} = \alpha_j \cdot \mathcal{R}_{i,k}$.*

Let X' be a word of length $\lceil n/b \rceil \cdot b$ obtained from X by appending an appropriate number of zeroes. The Hamming suffix sketch *of X is defined as $\mathsf{hSketch}(X) = M\mu(X')$, where $\mu(X')$ is considered as a vector.*

▶ **Lemma 35.** *Selecting $d = \Theta(\varepsilon^{-2})$ gives $\frac{1}{2d}\|\mathsf{hSketch}(X)\|_2^2 \overset{\varepsilon}{=} \|X\|_H$ with probability at least $9/10$ (taken over all possible choices of $\mathcal{R}, \alpha_i$).*

Proof. Follows immediately as a corollary of Lemma 33 and the properties of the embedding μ. In more detail, the following holds with probability at least $9/10$:

$$\frac{1}{2d} \cdot \|\mathsf{hSketch}(X)\|_2^2 =$$
$$= \frac{1}{2d}\|M\mu(X')\|_2^2 = \frac{1}{2d}\|M\mu(X)\|_2^2 = \frac{1}{2d}\|\mathsf{eSketch}(\mu(X))\|_2^2 \overset{\varepsilon}{=} \frac{1}{2}\|\mu(X)\|_2^2 = \|X\|_H. \qquad \blacktriangleleft$$

As $\mu(X), \mu(Y)$ are sparse, there is an efficient streaming algorithm for maintaining the Hamming suffix sketches of a text:

▶ **Lemma 36.** *Given a text T, there is a streaming algorithm that for every position i outputs the Hamming suffix sketch of a word $T[b \cdot k + 1, i]$, where k is the largest integer such that $i - b \cdot k \le n$. The algorithm takes $\mathcal{O}(dn/b + \log d\sigma n)$ space and $\mathcal{O}(d(1 + n/b^2))$ time per character.*

3.2 Manhattan (L_1) distance

To show efficient suffix sketches for the Manhattan distance, we consider a word morphism $\nu : \Sigma \to \{0,1\}^\sigma$, $\nu(a) = 1^a 0^{\sigma-a}$. Note that $\|\nu(X) - \nu(Y)\|_2^2 = \|\nu(X) - \nu(Y)\|_H = \|X - Y\|_1$, thus using the Hamming suffix sketches on top of $\nu(X)$ and $\nu(Y)$ allows computation of the respective Manhattan distance.

However, if we apply the morphism straightforwardly, we will have to pay an extra σ factor per character to compute the Manhattan suffix sketches. To improve the running time, we will use range-summable hash functions. Range-summable hash functions were introduced by Feigenbaum et al. [20], and later their construction was improved by Calderbank et al. [9].

▶ **Definition 37** (cf. [9]). *A family $\mathcal{H}$ of hash functions $h(x;\xi) : [t] \times \{0,1\}^s \to \{-1,1\}$ (here x is the argument and ξ is the seed) is called k-independent, range-summable if it satisfies the following properties for any $h \in \mathcal{H}$:*

1. (k-independent) *for all distinct $0 \le x_1, \ldots, x_k < t$ and all $b_1, \ldots, b_k \in \{-1,+1\}$,*

$$\Pr_{\xi \in \{0,1\}^s}[h(x_1;\xi) = b_1 \wedge \cdots \wedge h(x_k;\xi) = b_k] = 2^{-k}$$

2. (range-summable) *there exists a function g such that given a pair of integers $0 \le \alpha, \beta \le \sigma$, and a seed ξ, the value $g(\alpha,\beta;\xi) = \sum_{\alpha \le x < \beta} h(x;\xi)$ can be computed in time polynomial in $\log t$.*[3]

▶ **Corollary 38** (cf. Theorem 3.1 [9]). *There is a 4-independent, range-summable family of hash functions $h(x;\xi) : [t] \times \{0,1\}^s \to \{-1,+1\}$ with a random seed ξ of length $s = \mathcal{O}(\log^2 t)$ such that any range-sum $g(\alpha,\beta;\xi)$ can be computed in $\mathcal{O}(\log^3 t)$ time.*

▶ **Observation 39.** *For a word $X = x_1 x_2 \ldots x_n$, let $Y = \nu(X) = y_1 y_2 \ldots y_{n\sigma}$. Let h, g be as in Corollary 38 with $t = n\sigma$. Then $\sum_{i=1}^{n} g(i\sigma, i\sigma + x_i; \xi) = \sum_{i=1}^{n\sigma} y_i h(i;\xi)$.*

Thus, we see that range-summable hash functions can be used to efficiently simulate ν.

▶ **Definition 40** (Manhattan suffix sketches). *Consider X be a word of length n. We define its Manhattan suffix sketch as follows.*

Let b be the block length. *Let h, g be as in Corollary 38 with $t = bd\sigma$. Let $\mathcal{R}$ be a random matrix of size $d \times \sigma b$ filled with 4-wise independent random ± 1 variables, such that $\mathcal{R}_{i,k} = h(ib\sigma + k;\xi)$ and let $\alpha_1, \ldots, \alpha_{\lceil n/b \rceil}$ be 4-wise independent random coefficients with values ± 1 as well. We define a matrix M of size $d \times \sigma n$ such that $M_{i,\sigma jb+k} = \alpha_j \cdot \mathcal{R}_{i,k} = \alpha_j \cdot h(dk+i;\xi)$.*

Let X' be a word of length $\lceil n/b \rceil \cdot b$ obtained from X by appending an appropriate number of zeroes. The Manhattan suffix sketch *of X is defined as $\mathsf{mSketch}(X) = M\nu(X')$, where $\nu(X')$ is considered as a vector.*

▶ **Lemma 41.** *Selecting $d = \Theta(1/\varepsilon^2)$ gives $\frac{1}{d}\|\mathsf{mSketch}(X)\|_2^2 \overset{\varepsilon}{=} \|X\|_1$ with probability at least $9/10$ (taken over all possible choices of α_i and ξ).*

Proof. Follows immediately as a corollary of Lemma 33 and the properties of the embedding ν. In more detail, the following holds with probability at least $9/10$:

$$\frac{1}{d} \cdot \|\mathsf{mSketch}(X)\|_2^2 =$$
$$= \frac{1}{d}\|M\nu(X')\|_2^2 = \frac{1}{d}\|M\nu(X)\|_2^2 = \frac{1}{d}\|\mathsf{eSketch}(\nu(X))\|_2^2 \overset{\varepsilon}{=} \|\nu(X)\|_2^2 = \|X\|_1. \qquad \blacktriangleleft$$

[3] In [9], the function h was defined to take values in $\{0,1\}$. We can change the range of values to $\{-1,+1\}$ by taking $h' = 1 - 2h$ while preserving the properties.

▶ **Lemma 42.** *Given a text T, there is a streaming algorithm that for every position i outputs the Manhattan suffix sketch of a word $T[b \cdot k + 1, i]$, where k is the smallest integer such that $i - b \cdot k \leq n$. The algorithm takes $\mathcal{O}(d \cdot (n/b) + \log^2 \sigma)$ space, and $\mathcal{O}(d(1 + n/b^2) \cdot \log^3(bd\sigma))$ time per character.*

3.3 Generic (L_p) distance for $0 < p \leq 2$

For generic L_p distances, we use the approach of [26] based on p-stable distributions.

▶ **Corollary 43.** *Given a text T, there is a streaming algorithm that for every position i outputs the L_p suffix sketch of a word $T[b \cdot k + 1, i]$, where k is the smallest integer such that $i - b \cdot k \leq n$. The algorithm takes $\mathcal{O}(\varepsilon^{-2}(n/b) \cdot \log(\sigma n/\varepsilon) \log(n/\varepsilon))$ bits of space and $\mathcal{O}(\varepsilon^{-2}(n/b) \log(n))$ time per character.*

Proof. We start a new instance of the sketching algorithm of Theorem 26 at every block border and continue running it for the next $\lceil n/b \rceil$ blocks. At each moment, there are $\mathcal{O}(n/b)$ active instances of the algorithm. The bounds follow. ◀

4 Proof of Theorem 3

Recall the structure of the algorithms. During the preprocessing, we compute the suffix sketches of suffixes $P[1, n], P[2, n], \ldots, P[b, n]$ of P. During the main stage, the text is processed by blocks of length b. To compute an approximation of the distance / the p'th moment at a particular alignment, we divide the pattern into two parts: a prefix of length at most b, and the remaining suffix. We compute an approximation of the distance / the p'th moment for both of the parts and sum them up to obtain the final answer. To compute an approximation of the distance / the p'th moment between the prefix and the corresponding block of the text, we compute, while reading each block of the text, its prefix encoding, and to compute an approximation of the distance / the p'th moment between the suffix and the text, we use the suffix sketches.

1) **Hamming (L_0) distance.** When we receive a new block of the text, we compute its Hamming prefix encoding using the algorithm of Lemma 10 in $\mathcal{O}(b)$ space. We de-amortize the computation over the subsequent block and spend $\widetilde{\mathcal{O}}(\varepsilon^{-2})$ time per character. We store the resulting encoding for the next $\mathcal{O}(n/b)$ blocks. In total, the encodings require $\widetilde{\mathcal{O}}(\varepsilon^{-2}n/b)$ space. The Hamming suffix sketches of $P[1, n], P[2, n], \ldots, P[b, n]$ occupy $\mathcal{O}(\varepsilon^{-2}b)$ space. The algorithm of Lemma 36 that computes the suffix sketches takes $\mathcal{O}(\varepsilon^{-2}n/b + \log(\varepsilon^{-2}\sigma n))$ space and $\mathcal{O}(\varepsilon^{-2}(1 + n/b^2))$ time per character. Consider a block starting with position p. To compute the Hamming distances between n-length subwords that end in this block and the pattern, we apply the following approach. First, while reading the block preceding the current one, we decode the Hamming prefix encoding of the block that starts at position $p - n$ using Lemma 11. We de-amortize the algorithm to spend $\widetilde{\mathcal{O}}(\varepsilon^{-2})$ time per character. Hence, at the position i, we know the $(1 \pm \varepsilon)$-approximation between the prefixes of the pattern and the corresponding subwords of the text. At each position, we can compute the Hamming distance between the corresponding suffix of the pattern and the text in $\widetilde{\mathcal{O}}(\varepsilon^{-2})$ time using the Hamming suffix sketch. By taking $b = \sqrt{n}$, we obtain the claim.
2) **Manhattan (L_1) distance.** We proceed analogously to the Hamming distance case. The Manhattan prefix encoding of each block is computed using Lemma 16, in $\widetilde{\mathcal{O}}(b)$ time per character. We store the resulting encoding for the next $\mathcal{O}(n/b)$ blocks, giving

in total $\widetilde{\mathcal{O}}(\varepsilon^{-2}n/b)$ space. The Manhattan suffix sketches of $P[1,n], P[2,n], \ldots, P[b,n]$ occupy $\mathcal{O}(\varepsilon^{-2}b)$ space. Algorithm of Lemma 42 takes $\widetilde{\mathcal{O}}(\varepsilon^{-2}(b+n/b)+\log^2\sigma)$ space and $\widetilde{\mathcal{O}}(\varepsilon^{-2}(1+n/b^2))$ time per character. For decoding the prefix encoding we use Lemma 17, spending $\widetilde{\mathcal{O}}(b)$ time per character. Once again we take $b=\sqrt{n}$, and assume w.l.o.g. $\varepsilon^{-1}\leq\sqrt{n}$ (as otherwise we can use a naive algorithm with $\mathcal{O}(n)$ space and $\mathcal{O}(n)$ time per character).

3) **Generic (L_p) distance for $0<p<1$.** The L_p prefix encodings of the blocks are computed using Lemma 23, using $\widetilde{\mathcal{O}}(t\cdot b)$ time per character. We store the resulting encodings for the next $\mathcal{O}(n/b)$ blocks, giving in total $\widetilde{\mathcal{O}}(\varepsilon^{-2}n/b)$ space. The L_p suffix sketches of $P[1,n], P[2,n], \ldots, P[b,n]$ occupy $\widetilde{\mathcal{O}}(\varepsilon^{-2}b\log\sigma)$ space. Algorithm of Corollary 43 computes the L_p suffix sketches for the text in $\widetilde{\mathcal{O}}(\varepsilon^{-2}(n/b)\log\sigma)$ space and $\widetilde{\mathcal{O}}(\varepsilon^{-2}n/b)$ time per character. For decoding the prefix encoding we use Lemma 24, spending $\widetilde{\mathcal{O}}(t\cdot b)$ time per character. We take $b=\sqrt{n}$, and substitute t accordingly to Theorem 18.
4) **Generic (L_p) distance for $1<p<2$.** Note that for $\varepsilon<1/n$ we can use a naive algorithm, that is to store S itself in $\mathcal{O}(n)$ space. The update takes constant time, and computing the L_p norm takes $\mathcal{O}(n)$ time which is better than the guarantees of the theorem for such values of ε. For $\varepsilon\geq 1/n$, the algorithm of Lemma 30 computes the L_p prefix encodings of the blocks in $\widetilde{\mathcal{O}}(b+\varepsilon^{-2-p}\log^2\sigma)$ space and $\widetilde{\mathcal{O}}(b+\varepsilon^{-2}\log\sigma)$ time per character. The encodings occupy $\widetilde{\mathcal{O}}(\varepsilon^{-2-p}(n/b)\log^2\sigma)$ space. The L_p suffix sketches of $P[1,n], P[2,n], \ldots, P[b,n]$ occupy $\widetilde{\mathcal{O}}(\varepsilon^{-2}b\log\sigma)$ space. Algorithm of Corollary 43 computes the L_p suffix sketches for the text in $\widetilde{\mathcal{O}}(\varepsilon^{-2}(n/b)\log\sigma)$ space and $\widetilde{\mathcal{O}}(\varepsilon^{-2}n/b)$ time per character. Taking $b=\varepsilon^{-p/2}\sqrt{n}$ and assuming w.l.o.g. $\varepsilon^{-1}<\sqrt{n}$, we obtain the claim.

5 Conclusion

We pose several open questions. First is whether the time-complexity for $1/2<p<1$ can be improved to not involve any dependency on σ. For this we need a better technique than bounding variance of the embedding into Hamming distance: in our technique, the tail gets "too heavy". Another pressing question is whether for all values of $p>0$ we could improve upon $\sqrt{n}$ time per character. We also remark that it seems unlikely that an embedding to Hamming space could be used to reduce space complexity for $p>1$: L_p^p does not admit the triangle inequality while the Hamming distance does, and the L_p distance is not additive with respect to concatenation, while the Hamming distance is.

6 Omitted proofs

▶ **Lemma 4.** *Let $2 \leq 1/\varepsilon < n$ and $0 \leq p \leq 2$. Any $(1 \pm \varepsilon)$-approximation algorithm that computes the L_p distance between a pattern and a streaming text for each alignment, must use $\Omega(\min(1/\varepsilon^2, n))$ bits of space.*

Proof. Let us first show the lower bound for $p = 0$, i.e., for Hamming distance. We show the lower bound by reduction to a two-party communication complexity problem called GAP-Hamming-distance. In this problem, the two parties, Alice and Bob are given two binary words of length n and a parameter $g = \varepsilon n$, $1 \leq g \leq n/2$. Alice sends Bob a message, and Bob's task is to output 1 if the Hamming distance between his and Alice's word is larger than $n/2 + g$, and zero if it is at most $n/2 - g$. Otherwise, he can output "don't know". By Proposition 4.4 [10], the communication complexity of this problem is $\Omega(\min\{1/\varepsilon^2, n\})$.

We can now show a space lower bound for any $(1\pm\varepsilon)$-approximate algorithm for computing the Hamming distance between the pattern and the text by a standard reduction. Suppose that $2 \leq 1/\varepsilon \leq n$ there is an algorithm that uses $o(\min\{1/\varepsilon^2, n\})$ bits of space. Let P be Alice's word, T Bob's word. After reading P, the algorithm stores all the information about it in $o(\min\{1/\varepsilon^2, n\})$ bits of space. We construct the communication protocol as follows: Alice sends the information about P to Bob. Using it, Bob can continue running the algorithm and compute the approximation of the Hamming distance between P and T. We have thus developed a communication protocol with complexity $o(\min\{1/\varepsilon^2, n\})$, a contradiction.

We can now show the lower bound for $0 < p \leq 2$. We immediately obtain a space lower bound for any $(1 \pm \varepsilon)$-approximate algorithm for computing the p'th moment between the pattern and the text at every alignment. Indeed, on binary words the p'th moment is equal to the Hamming distance for all $0 < p \leq 2$. The lower bound for the L_p distance follows by Observation 5. ◀

▶ **Lemma 8.** *For Z_f as in Algorihtm 7 there is $Z_f \overset{\varepsilon}{=} \|U-V\|_H$ with probability at least $3/4$.*

Proof. Denote $m = \|U-V\|_H$. Consider a fixed value r. Let $I_1, I_2, \ldots, I_n$ be binary variables indicating existence of a mismatch between $\mathsf{hSub}_r(U)$ and V at positions $1, \ldots, n$, so that $X_r = \sum_j I_j$. We observe that $\mathbb{E}[X_r] = m/2^r$ and therefore $\mathbb{E}[Z_r] = m$, because each of the m positions with mismatch between U and V generates a mismatch between $\mathsf{hSub}_r(U)$ and V with probability $1/2^r$.

Furthermore, as the function h in Definition 6 is drawn from a pairwise independent family, there is $\mathrm{Var}[X_r] = \sum_j \mathrm{Var}[I_j] \le \sum_j \mathbb{E}\left[(I_j)^2\right] = \sum_j \mathbb{E}[I_j] = \mathbb{E}[X_r] = m/2^r$. Let $c = \min\{i : \mathbb{E}[X_i] \le k\} = \lceil \log_2\left(\frac{m}{k}\right)\rceil$. By Chebyshev's inequality, we have

$$\Pr[|Z_r - m| \ge 4\sqrt{m2(c+1)}] = \Pr[|X_r - m/2^r| \ge 2^{2+(c+1-r)/2}\sqrt{m/2^r}] \le 1/2^{4+(c+1-r)} \quad (2)$$

We estimate $\Pr[f > c+1] = \Pr[X_{c+1} > k]$. Assume w.l.o.g. that $k \ge 32$. Observe that $m/2^c \le k$, which implies, for $k \ge 32$, $m/2^{c+1} + 4\sqrt{m/2^{c+1}} \le k/2 + 4\sqrt{k/2} \le k$. By Equation 2, there is

$$\Pr[X_{c+1} > k] \le \Pr[X_{c+1} \ge m/2^{c+1} + 4\sqrt{m/2^{c+1}}] \le 1/16.$$

It follows that $\Pr[f > c+1] = \Pr[X_{c+1} > k] \le 1/16$. Hence, we obtain

$$\begin{aligned}
\Pr[|Z_f - m| \ge 4\sqrt{2/k}\cdot m] &\le \Pr[|Z_f - m| \ge 4\sqrt{m2^{c+1}}] \le \\
&\le \Pr[f > c+1] + \sum_{r=0}^{c+1} \Pr[|Z_f - m| \ge 4\sqrt{m2^{c+1}} \text{ and } f = r] \le \\
&\le \Pr[f > c+1] + \sum_{r=0}^{c+1} \Pr[|Z_r - m| \ge 4\sqrt{m2^{c+1}}] \le \\
&\le 1/16 + \sum_{r=1}^{c+1} 1/2^{4+(c+1-r)} < 1/4.
\end{aligned}$$

It follows that we can choose $k = \Theta(1/\varepsilon^2)$ large enough so that $Z_f \overset{\varepsilon}{=} \|U-V\|_H$ with probability $\ge 3/4$. ◀

▶ **Lemma 14.** *For Z_f as in Algorihtm 13 there is $Z_f \overset{\varepsilon}{=} \|U-V\|_1$ with probability $\ge 3/4$.*

Proof. Take some position i and denote for short $a = \mathsf{mSub}_r(U)[i]$ and $b = \mathsf{mSub}_r(V)[i]$ and $c = \frac{U[i]-V[i]}{2^r}$. There is $|a-b| \in \left\{\lfloor|c|\rfloor, \lceil|c|\rceil\right\}$ and $\mathbb{E}[|a-b|] = |c|$. Since $|a-b| - \lfloor|c|\rfloor$ is a 0/1 variable, there is $\mathrm{Var}[|a-b|] = \mathrm{Var}\left[(|a-b| - \lfloor|c|\rfloor)\right] \le \mathbb{E}\left[(|a-b| - \lfloor|c|\rfloor)\right] \le \mathbb{E}[|a-b|]$. Summing for all values of i, we reach that

$$\mathrm{Var}[X_r] = \mathrm{Var}[\|\mathsf{mSub}_r(U) - \mathsf{mSub}_r(V)\|_1] \le \mathbb{E}[\|\mathsf{mSub}_r(U) - \mathsf{mSub}_r(V)\|_1] = \mathbb{E}[X_r].$$

Since we have reached an identical variance bound, the proof follows step-by-step the proof of Lemma 8. ◀

▶ **Theorem 18.** *Given $0 < p < 1$ and $\varepsilon > 0$ there is a word morphism $\varphi : c \in \Sigma \to c_0^{d_0} c_2^{d_2} \ldots c_{t-1}^{d_{t-1}}$ such that:*

1) *$t = \widetilde{\mathcal{O}}(\varepsilon^{-2})$ when $0 < p < 1/2$, $t = \widetilde{\mathcal{O}}(\varepsilon^{-3})$ when $p = 1/2$ and $t = \widetilde{\mathcal{O}}(\sigma^{\frac{2p-1}{1-p}}/\varepsilon^{2+3\cdot\frac{2p-1}{1-p}})$ when $1/2 < p < 1$.*
2) *values of t and $d_0, \ldots, d_{t-1}$ do not depend on c,*

3) *there exists a constant $\alpha = \alpha(p, \varepsilon)$ such that for any two words U, V of length at most n, we have $\|U - V\|_p^p \overset{\varepsilon}{=} \alpha \cdot \|\varphi(U) - \varphi(V)\|_H$ with probability at least $9/10$,*
4) *it is enough for the randomness to be realized by a hash function $r : [t] \to [D]$ from a 4-independent hash function family for some $D = poly(n\sigma\varepsilon^{-1})$, which can be generated from a $\widetilde{\mathcal{O}}(\log \sigma)$ bits size seed.*

Proof. We will consider three cases: $0 < p < 1/2$, $p = 1/2$, and $1/2 < p < 1$.

Case $0 < p < 1/2$. Our plan is to build upon the scheme highlighted earlier in this section. Specifically, we preserve the values of c_i.

Consider a pair of characters c, c'. First, note that $\mathbb{E}[x]$ is an increasing function of $|c - c'|$. From this and Equation 1 we obtain that $\mathbb{E}[x] \overset{\varepsilon}{=} |c - c'|^p \left(\frac{(1+\varepsilon)^p}{(1+\varepsilon)^p - 1} + \frac{1}{(1+\varepsilon)^{1-p} - 1} \right) \varepsilon^{-1}$ for all values of $|c - c'|$.

Second, fix $q = \lceil \frac{1}{1-p} \log_{1+\varepsilon}(\sigma\varepsilon^{-3}) \rceil$ and observe that truncating the sum after the $(q-1)$-th term introduces an additional factor $1 \pm \Theta(\varepsilon)$ to the approximation, since for $c \neq c'$ we have

$$\sum_{i \geq q} d_i \cdot \frac{|c - c'|}{(1+\varepsilon)^i} = \varepsilon^{-1}|c - c'| \frac{((1+\varepsilon)^q)^{p-1}}{1 - (1+\varepsilon)^{p-1}} \leq \frac{\varepsilon^{-1}\sigma}{(1 - (1+\varepsilon)^{p-1})\sigma\varepsilon^{-3}} = \Theta(\varepsilon).$$

We also round d_i down to the nearest integer, which introduces an additional $1 \pm \Theta(\varepsilon)$ relative error, since $\forall_i d_i \geq \varepsilon^{-1}$. Finally, we set $\varphi(c) = c_0^{d_0} \dots c_{q-1}^{d_{q-1}}$. We then have $\mathbb{E}[\|\varphi(c) - \varphi(c')\|_H] = \Theta(\varepsilon^{-2}|c - c'|^p \frac{1}{p(1-p)})$.

To guarantee that the equality holds with probability at least $9/10$ and not just in expectation, we repeat the scheme several times, with independent random seeds. That is, consider morphisms $\varphi_1(c), \varphi_2(c), \dots, \varphi_s(c)$ and define a morphism $\varphi(c) = \varphi_1(c)\varphi_2(c) \dots \varphi_s(c)$ with property:

$$\mathbb{E}[\|\varphi(c) - \varphi(c')\|_H] = s \cdot \mathbb{E}[\|\varphi_i(c) - \varphi_i(c')\|_H] = s \cdot \Theta(\varepsilon^{-2}|c - c'|^p \frac{1}{p(1-p)}).$$

Assume w.l.o.g. that $(1+\varepsilon)^{\ell-1} < |c - c'| \leq (1+\varepsilon)^\ell$. We proceed to bound

$$\begin{aligned}
\mathrm{Var}[\|\varphi(c) - \varphi(c')\|_H] &\leq s \cdot \sum_{i=\ell+1}^{q} (d_i)^2 \cdot \Pr[c_i \neq c_i'] \leq \\
&\leq s \cdot \sum_{i=\ell+1}^{q} \varepsilon^{-2}((1+\varepsilon)^{2p})^i \frac{|c - c'|}{(1+\varepsilon)^i} \leq \\
&\leq s \cdot \varepsilon^{-2}|c - c'| \sum_{i=\ell+1}^{\infty} ((1+\varepsilon)^{2p-1})^i \leq \\
&\leq s \cdot \varepsilon^{-2}|c - c'|^{2p} \frac{(1+\varepsilon)^{2p-1}}{1 - (1+\varepsilon)^{2p-1}} \leq \\
&= s \cdot \mathcal{O}(|c - c'|^{2p}\varepsilon^{-3} \frac{1}{1-2p}).
\end{aligned}$$

We set $s = \Theta(\frac{|c-c'|^{2p}\varepsilon^{-3}(p(p-1))^2}{\varepsilon^2(|c-c'|^p\varepsilon^{-2})^2(1-2p)}) = \mathcal{O}(\varepsilon^{-1}\frac{1}{1-2p})$ for the claim to hold via Chebyshev's inequality. The error probability coming from Chebyshev's inequality can be made arbitrarily small constant by fixing the constant factor in s to be large enough. We finally set $t = sq$.

Case $p = 1/2$. Note that for p, p' such that $|p - p'| \leq \log_\sigma(1+\varepsilon)$ we have $|x|^p \overset{\varepsilon}{=} |x|^{p'}$ for all $-\sigma \leq x \leq \sigma$. We can therefore reduce this case to $p = 1/2 - \log_\sigma(1+\varepsilon)$. However, we have to take into account that the asymptotic growth of t hides $1/(1-2p)$ dependency on p for $0 < p < 1/2$, hence $t = \widetilde{\mathcal{O}}(\varepsilon^{-3})$ for $p = 1/2$.

Case $1/2 < p < 1$. The proof follows the steps of the case $0 < p < 1/2$. We first bound the variance:

$$\begin{aligned}\operatorname{Var}\left[\|\varphi(c) - \varphi(c')\|_H\right] &\leq s \cdot \sum_{i=\ell+1}^{q} (d_i)^2 \cdot \Pr[c_i \neq c'_i] = \\ &= s \cdot \varepsilon^{-2}|c - c'| \sum_{i=\ell+1}^{q} ((1+\varepsilon)^{2p-1})^i = \\ &= s \cdot \mathcal{O}(\varepsilon^{-3}|c - c'|((1+\varepsilon)^q)^{2p-1}) = \\ &= s \cdot \mathcal{O}(\varepsilon^{-3}|c - c'|\sigma^{\frac{2p-1}{1-p}}/\varepsilon^{3\cdot\frac{2p-1}{1-p}}).\end{aligned}$$

We set $s = \Theta\left(\frac{\varepsilon^{-3}|c-c'|\sigma^{\frac{2p-1}{1-p}}/\varepsilon^{3\cdot\frac{2p-1}{1-p}}}{\varepsilon^{-2}|c-c'|^{2p}}\right) = \mathcal{O}(\sigma^{\frac{2p-1}{1-p}}/\varepsilon^{1+3\cdot\frac{2p-1}{1-p}})$, so that by Chebyshev's inequality, the probability of obtaining $\|U - V\|_p^p \overset{\varepsilon}{=} \alpha \cdot \|\varphi(U) - \varphi(V)\|_H$ is an arbitrarily small constant (by setting s to be large enough).

Randomness. The only source of randomness in the description are the values $r_i \in [0,1]$ picked u.a.r. and independently. We note that the values r_i can be picked instead as a finite precision floating-point numbers. Since all the values we are working with are bounded by $\operatorname{poly}(n\sigma\varepsilon^{-1})$, it is enough to set precision accordingly. We also observe that our concentration argument involves only Chebyshev's inequality and thus only the variance and the expected value, so it suffices to require that r_i are 4-wise independent. ◀

▶ **Lemma 21.** *For Z_f as in Algorihtm 20 there is $Z_f \overset{\varepsilon}{=} \|S - Q\|_H$ with probability $\geq 3/4$.*

Proof. Consider a fixed subsampling level r. For simplicity, let $\mathsf{Sub}_r(S) = s_1^{e'_1} s_2^{e'_2} \dots s_m^{e'_m}$ and $\mathsf{Sub}_r(Q) = q_1^{e'_1} q_2^{e'_2} \dots q_m^{e'_m}$. Define a random variable x_i to be the contribution of of $s_i^{e'_i}, q_i^{e'_i}$ to the Hamming distance X_r, i.e.

$$x_i = \|s_i^{e'_i} - q_i^{e'_i}\|_H = e'_i \cdot \|s_i - q_i\|_H.$$

Since $e'_i \in \{\lceil e_i/2^r \rceil, \lfloor e_i/2^r \rfloor\}$ and $\mathbb{E}[e'_i] = e_i/2^r$, we have $\mathbb{E}[x_i] = e_i \cdot \|s_i - q_i\|_H$ and

$$\operatorname{Var}[x_i] = \operatorname{Var}[x_i - \lfloor e_i/2^r \rfloor] \leq \mathbb{E}[x_i - \lfloor e_i/2^r \rfloor] \leq \mathbb{E}[x_i].$$

Summing over all values of i, we reach $\mathbb{E}[X_r] = \|S - Q\|_H$ and $\operatorname{Var}[X_r] \leq \mathbb{E}[X_r]$. These bounds are identical to that of Lemma 8 and we can proceed in a similar fashion to obtain the claim. ◀

▶ **Lemma 28.** *Let $1 < p \leq 2$. For any two vectors X, Y of equal length, $\left|\|X+Y\|_p^p - \|X\|_p^p\right| = \mathcal{O}(\|Y\|_p^p + \|Y\|_p \cdot \|X\|_p^{p-1})$.*

Proof. Consider $x, y \in \mathbb{R}$. If $|x| \geq |y|$, then by Taylor expansion, $|x+y|^p = |x|^p(1+y/|x|)^p = |x|^p(1 + \mathcal{O}(|y/x|)) = |x|^p \pm \mathcal{O}(|y||x|^{p-1})$. If $|x| < |y|$, then $|x+y|^p = \mathcal{O}(|y|^p)$. Thus for any real values, we have

$$|x+y|^p = |x|^p + \mathcal{O}(|y|^p + |y| \cdot |x|^{p-1}).$$

Denote $X = [x_1, x_2, \ldots, x_n]^T$ and $Y = [y_1, y_2, \ldots, y_n]^T$. There is

$$\|X+Y\|_p^p = \sum_i |x_i + y_i|^p = \sum_i |x_i|^p \pm \mathcal{O}\left(\sum_i |y_i|^p + \sum_i |y_i||x_i|^{p-1}\right).$$

Pick $q = p/(p-1)$ so that $1/p + 1/q = 1$. By Hölder's inequality:

$$\sum_i |y_i||x_i|^{p-1} \leq \left(\sum_i |y_i|^p\right)^{1/p} \left(\sum_i |x_i|^{(p-1)q}\right)^{1/q} = \|Y\|_p \|X\|_p^{p-1}. \quad \blacktriangleleft$$

▶ **Lemma 36.** *Given a text T, there is a streaming algorithm that for every position i outputs the Hamming suffix sketch of a word $T[b \cdot k + 1, i]$, where k is the largest integer such that $i - b \cdot k \leq n$. The algorithm takes $\mathcal{O}(dn/b + \log d\sigma n)$ space and $\mathcal{O}(d(1 + n/b^2))$ time per character.*

Proof. We fix the matrix $\mathcal{R}$ and the random coefficients $\alpha_1, \ldots, \alpha_{\lceil n/b \rceil}$ from Definition 34. We do not store $\mathcal{R}$ and α_i explicitly, but generate them using two hash functions drawn at random from a 4-wise independent family. For example, to generate $\mathcal{R}$ we can consider a family of polynomials $2((ax^3 + bx^2 + cx + d \bmod p) \bmod 2) - 1$, with parameters a, b, c, d chosen u.a.r. from the prime field $\mathbb{F}_p$ for $p \geq db$, and α_i can be generated in a similar fashion. This way, we need to store only $\mathcal{O}(\log(d\sigma b) + \log(n/b)) = \mathcal{O}(\log d\sigma n)$ random bits that define the coefficients of two polynomials to generate $\mathcal{R}$ and α_i.

We process the text T by blocks $B_1, B_2, \ldots$ of length b. For each block B_k we compute its sketch using the matrix $\mathcal{R}$. That is, at the beginning of each block we initialize its sketch as a zero vector of length d. When a new character $T[i]$ of a block B_k arrives, we compute and add $[M[1, i \cdot b\sigma + T[i]], M[2, i \cdot b\sigma + T[i]], \ldots, M[d, i \cdot b\sigma + T[i]]]^T$ to the sketch, which takes $\mathcal{O}(d)$ time. We store the sketch of B_k until the block $B_{k+\lceil n/b \rceil}$ and use it to compute the suffix sketches for the positions in this block.

Consider now a block $B_{k+\lceil n/b \rceil}$. We first compute the suffix sketch for the position $b \cdot (k + \lceil n/b \rceil)$, which is the position preceding the block $B_{k+\lceil n/b \rceil}$. The suffix sketch for it is simply a linear combination of the sketches of the blocks $B_{k+\lceil n/b \rceil - 1}, B_{k+\lceil n/b \rceil - 2}, \ldots, B_k$ with coefficients $\alpha_1, \ldots, \alpha_{\lceil n/b \rceil - 1}$. Since each sketch is a vector of length d, we can compute the linear combination in $\mathcal{O}(dn/b)$ time. To make this computation time-efficient, we start it b positions before position $b \cdot (k + \lceil n/b \rceil)$ arrives, and de-amortise the computation over these b positions. This way, we use only $\mathcal{O}(dn/b^2)$ time per character.

Now, using the suffix sketch for the position $b \cdot (k + \lceil n/b \rceil)$, we can compute the suffix sketches for all positions in the block $B_{k+\lceil n/b \rceil}$ one-by-one, using only $\mathcal{O}(d)$ time per character: When a new character $T[i]$ arrives, we add $[\alpha_{\lceil n/b \rceil} M[1, i \cdot b\sigma + T[i]], \alpha_{\lceil n/b \rceil} M[2, i \cdot b\sigma + T[i]], \ldots, \alpha_{\lceil n/b \rceil} M[d, i \cdot b\sigma + T[i]]]^T$ to the suffix sketch to update it.

Note that at any time we store $\mathcal{O}(n/b)$ sketches of the blocks, so the algorithm uses $\mathcal{O}(dn/b + \log d\sigma n)$ space in total. $\blacktriangleleft$

▶ **Lemma 42.** *Given a text T, there is a streaming algorithm that for every position i outputs the Manhattan suffix sketch of a word $T[b \cdot k + 1, i]$, where k is the smallest integer such that $i - b \cdot k \leq n$. The algorithm takes $\mathcal{O}(d \cdot (n/b) + \log^2 \sigma)$ space, and $\mathcal{O}(d(1 + n/b^2) \cdot \log^3(bd\sigma))$ time per character.*

Proof. The proof mirrors the proof of Lemma 36, and we describe the key elements. We fix the random coefficients $\alpha_1, \ldots, \alpha_{\lceil n/b \rceil}$ and the hash function h from Definition 40. As previously, we do not store the coefficients α_i explicitly, but generate them using a hash

function drawn at random from a 4-wise independent family. The matrix $\mathcal{R}$ is already defined by h, with the following parameters: it requires $\mathcal{O}(\log^2(bd\sigma))$ bits of seed, and range-sum queries are answered in time $\mathcal{O}(\log^3(bd\sigma))$.

In the sketching of blocks, we proceed in the same manner, except that when a new character $T[i]$ of a block B_k arrives, we compute and add $\sum_{0\leq j<T[i]}[M[1, i\cdot b\sigma+j], \ldots, M[d, i\cdot b\sigma + j]]^T = \alpha_i \cdot [g(b\sigma, b\sigma + T[i]; \xi), g(2b\sigma, 2b\sigma + T[i]; \xi), \ldots, g(d \cdot b\sigma, d \cdot b\sigma + T[i]; \xi)]^T$ to the sketch, which takes $\mathcal{O}(d \cdot \log^3(bd\sigma))$ time ($\log^3(bd\sigma)$ times slower as the corresponding step in Lemma 36).

Consider now a block $B_{k+\lceil n/b\rceil}$. When a new character $T[i]$ arrives, we update the suffix sketch by adding $\alpha_{\lceil n/b\rceil} \cdot [g(b\sigma, b\sigma + T[i]; \xi), g(2b\sigma, 2b\sigma + T[i]; \xi), \ldots, g(d \cdot b\sigma, d \cdot b\sigma + T[i]; \xi)]^T$ to it.

All of the operations are $\mathcal{O}(\log^3(bd\sigma))$ time slower than the corresponding steps in Lemma 36, and the memory complexity is increased by the seed size $\mathcal{O}(\log^2(bd\sigma))$ term ($\log^2 b$ and $\log^2 d$ terms get absorbed). ◀

Computing Bi-Lipschitz Outlier Embeddings into the Line

Abstract

The problem of computing a bi-Lipschitz embedding of a graphical metric into the line with minimum distortion has received a lot of attention. The best-known approximation algorithm computes an embedding with distortion $O(c^2)$, where c denotes the optimal distortion [Bădoiu et al. 2005]. We present a bi-criteria approximation algorithm that extends the above results to the setting of *outliers*.

Specifically, we say that a metric space (X, ρ) admits a (k, c)-embedding if there exists $K \subset X$, with $|K| = k$, such that $(X \setminus K, \rho)$ admits an embedding into the line with distortion at most c. Given $k \geq 0$, and a metric space that admits a (k, c)-embedding, for some $c \geq 1$, our algorithm computes a $(\mathsf{poly}(k, c, \log n), \mathsf{poly}(c))$-embedding in polynomial time. This is the first algorithmic result for outlier bi-Lipschitz embeddings. Prior to our work, comparable outlier embeddings where known only for the case of additive distortion.

1 Introduction

The theory of metric embeddings provides an extensive toolbox that has found applications in several geometric data-analytic tasks. At the high level, an embedding of a metric space $\mathcal{M} = (X, \rho)$ into some metric space $\mathcal{M}' = (X', \rho)$ is a mapping $f : X \to X'$ that preserves certain interesting geometric properties of $\mathcal{M}$. In most cases, it is desirable to obtain embeddings that minimize some notion of *distortion*.

Despite the success of metric embeddings methods in several application domains, one significant limitation of most existing methods is that they are not robust to noise in the form of outlier points in the input. This setting is of particular interest in the case where the data does not perfectly fit the underlying geometric model, or when some points are corrupted due to measurement errors. The outlier model also has connections to the setting of adversarial machine learning [13]. More specifically, in the setting of *poisoning attacks*, it is often assumed that a small subset of the training data set is corrupted adversarially. For example, in a classification application, some of the training samples can be modified arbitrarily. Therefore, it is important to design data-analytic primitives that are robust against this type of adversarial input perturbation.

Our aim is to bypass the limitations of current metric embedding methods by designing approximation algorithms that given some input space $\mathcal{M}$, they compute a small subset of points to delete, and an embedding of the residual space into some desired host space.

1.1 Our contribution

We now formally define outlier embeddings and state our main result. Let $\mathcal{M} = (X, \rho)$, $\mathcal{M}' = (X', \rho')$ be metric spaces. An injection $f : X \to X'$ is called an *embedding*. Given an embedding f, its *distortion* is defined as

$$\mathsf{distortion}(f) = \sup_{x \neq y \in X} \frac{\rho'(f(x), f(y))}{\rho(x, y)} \cdot \sup_{x' \neq y' \in X} \frac{\rho(x', y')}{\rho'(f(x'), f(y'))}.$$

We also refer to this notion of distortion as *multiplicative distortion*. An embedding is *bi-Lipschitz* if its distortion is bounded. When $\mathcal{M}' = (\mathbb{R}, \ell_2)$ then we say that $\mathcal{M}$ admits an embedding into the line. If $\mathsf{distortion}(f) \leq c$, then we say that f is a *c-embedding*. We use the following definition for outlier embeddings (see also [19]).

A metric space $\mathcal{M} = (X, \rho)$ *admits a* (k, c)*-embedding* into another metric space $\mathcal{M}' = (X', \rho')$ for some $c \geq 1$, $k \geq 0$ if there exists $K \subseteq X$, with $|K| \leq k$, and $f : X \setminus K \to X'$, with $\mathsf{distortion}(f) \leq c$. We say that such $K \subseteq X$ is an *outlier set* (w.r.t. f).

In the present work, we focus on the case where the input metric space is the shortest-path metric of an unweighted graph, and the host space is the real line. This setting, but without outliers, has been studied extensively in the literature (see Section 1.2 for a more detailed discussion). The shortest-path metrics of unweighted graphs arise naturally in applications, for example, when considering the k-NN graph of a point set; that is, by taking the set of vertices to be a set of samples from some unknown manifold, and the edge set to be all pairs $\{u, v\}$, where u is one of the k nearest neighbors of v. Moreover, the case of embedding into the real line is a prototypical mathematical model for the problem of discovering 1-dimensional structure in a metrical data set.

The following summarizes the main result of this paper.

▶ **Theorem 1.** *Let G be a graph, $k \geq 0$, $c \geq 1$. There exists a polynomial-time algorithm which given G, k, and c, terminates with exactly one of the following outcomes:*
(1) *Correctly decides that G does not admit a (k, c)-embedding into the line.*
(2) *Computes a $(O(c^6 k \log^{5/2} n), O(c^{13}))$-embedding of G into the line.*

1.2 Related work

Low-distortion metric embeddings have been studied extensively within mathematics and computer science. We refer the reader to [14] for a detailed exposition of the work that is of main interest for computer science. Here, we discuss some results relevant to our work.

Approximation algorithms. The problem of computing an embedding of some input metric space $\mathcal{M}$ into some host space $\mathcal{M}'$ with approximately minimum distortion has received a lot of attention. Most positive results are concerned with the case where $\mathcal{M}'$ is the line, or, more generally, some 1-dimensional space. Specifically, Bădoiu et al. [6] obtained an algorithm which given an unweighted graph that admits a c-embedding into the line, computes a $O(c^3)$-embedding into the line. Approximation algorithms have also been obtained by Bădoiu et al. [5] for the case where the input is a weighted tree, and by Nayyeri and Raichel [17] for the case where the input is a general metric space.

Approximation algorithms for embedding into more general 1-dimensional spaces have also been considered. Bădoiu et al. [3] consider the case where the host space is a tree, Chepoi et al. [8] consider the case where the host space is an outerplanar graph, and Nayyeri and Raichel [18] generalize this to the case where the host space is a graph of bounded treewidth. Carpenter et al. [7] obtain an approximation algorithm for embedding unweighted graphs into subdivisions of any fixed "pattern" graph H (embedding into the line corresponds to H being a single edge, while embedding into a cycle is the case where H is a triangle).

The case of higher-dimensional host spaces appears to be significantly more challenging. The only positive results are an approximation algorithm for embedding finite subsets of the 2-sphere into $\mathbb{R}^2$ [6], and approximation algorithms for embedding ultrametrics into $\mathbb{R}^d$ [4, 10]. On the negative side, it is shown that for any $d \geq 1$, the problem of embedding into d-dimensional Euclidean space with minimum distortion is hard to approximate within a factor of $n^{\alpha/d}$, for some constant $\alpha > 0$ (the case $d = 1$ is due to [5] and $d \geq 2$ is due to [16]).

FPT algorithms. The problem of computing an embedding into the line parameterized by the optimal distortion has also been considered. Fellows et al. [12] gave an FPT algorithm for embedding unweighted graphs into the line. A nearly-matching lower bound on the running time (assuming ETH) was obtained by Lokshtanov et al. [15]. FTP algorithms for embedding unweighted graphs into subdivisions of an arbitrary fixed pattern graph H have also been obtained by Carpenter et al. [7].

Outlier embeddings. The problem of computing outlier embeddings was introduced by Sidiropoulos et al. [19]. They considered the case of embedding into d-dimensional Euclidean space, and into trees. The main difference with our work is that [19] deals with the case of *additive* distortion, while we are concerned with multiplicative distortion. As a result, the results in [19] are incomparable to ours. We remark, however, that the case of mutliplicative distortion is known to be significantly more challenging. To the best of our knowledge, our result is the first non-trivial upper bound for computing outlier embeddings minimizing the multiplicative distortion.

1.3 High-level overview of the algorithm

We now give an informal description of our algorithm, highlighting the main technical challenges. The input consists of an undirected graph G and some $k \geq 0$, $c \geq 1$. The algorithm either correctly decides that there exists no (k, c)-embedding of G into the line, or outputs a (k', c')-embedding of G into the line, for some $k' = \mathsf{poly}(k, c, \log n)$, $c' = \mathsf{poly}(c)$.

The crux of the algorithm is to identify and remove three "obsrtuctions" for low-distortion embeddability into the line. These three obstructions are *regions of high density*, *large metrical cycles* and *large metrical tripods*. We next discuss the steps used to handle each one of these obstructions, and describe how all the steps are combined in the final algorithm.

Obstruction 1: Reducing the density. The *density* of a graph is defined to be

$$\Delta(G) = \max_{v \in V(G), R \in \mathbb{N}} \frac{|\mathsf{Ball}_G(v, R)| - 1}{2R}.$$

It is known that the density of any graph that admits a c-embedding into the line is $O(c)$ [6]. Therefore, if G admits a (k, c)-embedding, then there must exist some set of at most k vertices, whose deletion leaves a graph with density $O(c)$. We observe that the density of a graph is a hereditary property, meaning that for any $H \subseteq G$, we have $\Delta(H) \leq \Delta(G)$. This leads to a following recursive procedure: if the density is higher than $O(c)$, we compute a balanced vertex separator $X \subseteq V(G)$, and recurse on $G \setminus X$. We set

$$K_{\mathsf{density}} := \bigcup_{\text{all separators } X} X.$$

Let us also denote $G \setminus K_{\mathsf{density}}$ as G'. It is immediate that $\Delta(G') = O(c)$, and we show that $|K_{\mathsf{density}}| = \mathsf{poly}(k, c, \log n)$.

Obstruction 2: Eliminating large metrical cycles. It is known that any embedding of the n-cycle into the line must incur distortion $\Omega(n)$ [6]. More generally, it is possible to define an obstruction, which we refer to as a *metrical cycle*, and which contains cycles as a special case, but allows for more general shortest-path distances (see Figure 1). We show how to delete a small number of vertices so that the resulting graph does not contain any large metrical cycles, and then we find a low-distortion embedding into some forest.

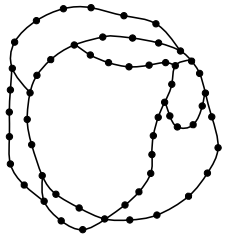

Figure 1 Example of a large metrical cycle.

We now briefly describe the procedure for eliminating large metrical cycles. We start by computing a $\mathsf{poly}(c)$-net N in G'. We then find a Voronoi partition $\mathcal{P}$ centered at N: for any vertex $v \in G'$, we assign v to a cluster centered at its nearest neighbour $y \in N$ (we break ties to ensure connectivity). Let H be the minor of G obtained by contracting each cluster to its center $y \in N$. We compute an approximate minimum feedback vertex set Y in H. We set

$$K_{\mathsf{forest}} := \bigcup_{x \in Y} \mathcal{P}(x),$$

and $G'' = G' \setminus K_{\mathsf{forest}}$. Note that the low density of G' ensures that $|K_{\mathsf{forest}}|$ is small. Furthermore, we show that G'' admits a low-distortion embedding into a forest.

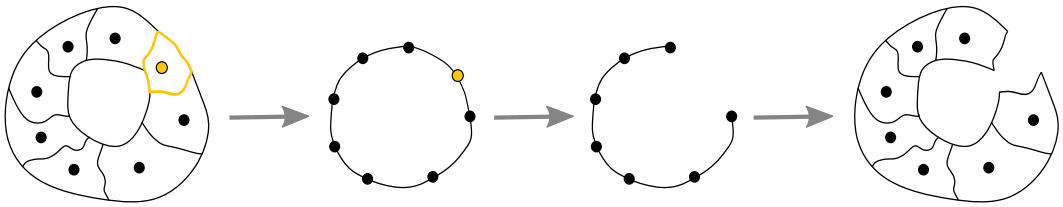

Figure 2 Elimination of large metrical cycles. From left to right: the graph G', the minor H, the forest $H \setminus Y$, and the graph G''.

Obstruction 3: Eliminating large metrical tripods. A *tripod* is a tree consisting of the union of three paths with a common endpoint; we say that a tripod is R-large if the length of each of the three paths is at least R. Any embedding of a R-large tripod into the line must incur distortion $\Omega(R)$. We show how to delete a small number of vertices so that the resulting graph does not have any subgraphs with a shortest-path metric that resembles that of a $\Omega(\mathsf{poly}(c))$-large tripod. More specifically, via a reduction to the Minimum Set Cover problem, we compute some $Z \subseteq V(H \setminus Y)$, so that the forest $H \setminus (Y \cup Z)$ does not contain any $\Omega(\mathsf{poly}(c))$-large tripods (see Figure 3). We set

$$K_{\mathsf{tripod}} := \bigcup_{w \in (H \setminus Y) \setminus Z} \mathcal{P}(w).$$

and $G'' = G' \setminus K_{\text{tripod}}$. Since the forest $H \setminus (Y \cup Z)$ does not contain any large tripods, we can show that it admits a low-distortion embedding into the line. Furthermore, we can use this embedding to also embed G'' into the line.

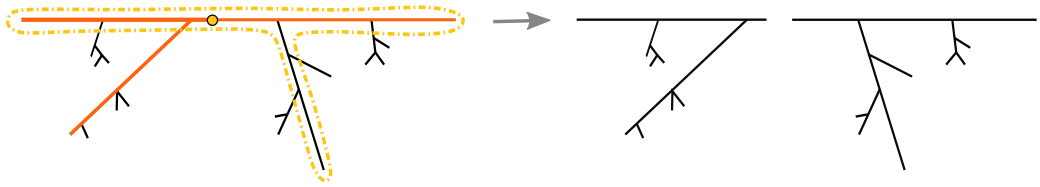

Figure 3 Elimination of a large tripod. A yellow vertex removes the red tripod and the yellow dotted tripod simultaneously.

Putting everything together. The final algorithm combines the above procedures for eliminating the three obstructions that we have identified. At each obstruction elimination step, we remove a small set of vertices. One additional complication is that, because c-embeddability into the line is not a hereditary property, this can produce a graph that does not admit a low-distortion embedding into the line. We show that this issue can be avoided by deleting a slightly larger superset of vertices, which eliminates the obstruction at hand, while maintaining the existence of a low-distortion embedding.

1.4 Organization

The rest of the paper is organized as follows. We introduce necessary notation and definitions in Section 2. In Section 3, we present our main algorithm and we state the main technical results needed. In Section 3.2 we prove a technical lemma which will be applied throughout the paper. Sections A, B, C, D elaborate on the subroutines executed by the main algorithm.

2 Preliminaries

2.1 Graphs

Given a graph G, we refer to its vertex set as $V(G)$ and to its edge set as $E(G)$. For any $C \subseteq V(G)$, we denote by $G[C]$ the subgraph of G induced on C. Let d_G denote the shortest-path distance of G; unless otherwise noted, we assume that all edges in G are undirected and have unit length.

▶ **Definition 2** (Local density). *For any $v \in V(G)$ and $R \in \mathbb{N}$, we define*

$$\Delta_G(v, R) = \frac{|\mathsf{Ball}_G(v, R)| - 1}{2R}$$

The local density *of the graph G is defined to be*

$$\Delta(G) = \max_{v \in V(G), R \in \mathbb{N}} \Delta_G(v, R).$$

▶ **Definition 3** (Tripod). *Let G be a graph, $R \geq 1$, $v, v_1, v_2, v_3 \in V(G)$, and let P_1, P_2, P_3 be paths in G, where for all $i \in [3]$, P_i is a path with endpoints v and v_i. Suppose that for all $i \neq j \in [3]$, and for all $u \in P_j$, we have $d_G(v_i, u) \geq R$. In other words, each endpoint v_i is at distance at least R from every vertex in the other two paths. Then we say that the tree $P_1 \cup P_2 \cup P_3$ is a* R-tripod *with* root v *(in G).*

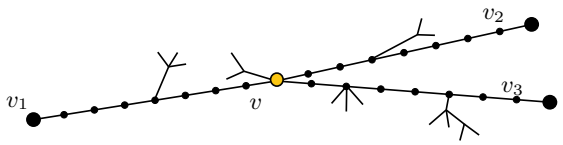

Figure 4 A tripod rooted at v with leaves v_1, v_2, v_3.

2.2 Some useful approximation results

For a graph G, a *feedback vertex set* is some $X \subseteq V(G)$, such that $G \setminus X$ is acyclic. In the Minimum Feedback Vertex Set problem we are given a graph G and the goal is to find a feedback vertex set in G of minimum cardinality. We recall the following result on approximating the Minimum Feedback Vertex Set problem.

▶ **Theorem 4** (Bafna et al. [1]). *There exists a polynomial-time 2-approximation algorithm for the Minimum Feedback Vertex Set problem.*

Given a graph G and some $\alpha \in [0, 1)$, we say that some $X \subseteq V(G)$ is a *α-balanced vertex separator* (of G) if every connected component of $G \setminus X$ has at most $\alpha \cdot |V(G)|$ vertices. We recall the following algorithmic result on computing balanced vertex separators.

▶ **Theorem 5** (Feige et al. [11]). *There exists a polynomial-time algorithm which given a graph that admits a $2/3$-balanced vertex separator of size s, outputs a $3/4$-balanced vertex separator of size at most $O(\sqrt{\log n} \cdot s)$.*

Recall that an instance to the Minimum Set Cover problem consists of some set U (the *universe*), and a set $\mathcal{C}$ of subsets of U. The goal is to find a subset of $\mathcal{C}$ of minimum cardinality that covers U.

▶ **Theorem 6** (Chvátal [9]). *There exists a polynomial-time $O(\log n)$-approximation algorithm for the Minimum Set Cover problem.*

2.3 Voronoi minors

For some metric space $\mathcal{M} = (X, \rho)$, and some $R > 0$, we say that some $N \subseteq X$ is a *R-net* of M if for any $p, q \in N$, $\rho(p, q) > R$, and $X \subseteq \bigcup_{p \in N} \mathsf{Ball}_{\mathcal{M}}(p, R)$. For a graph G, we say that some $N \subseteq V(G)$ is a R-net of G if N is a R-net of the shortest-path metric of G.

▶ **Definition 7** (Graphical Voronoi partition). *Let G be a graph, and let $Y \subseteq V(G)$. Let $\mathcal{P}$ be a partition of $V(G)$ satisfying the following conditions:*

(1) *Every cluster in $\mathcal{P}$ contains exactly one vertex in Y.*

(2) *For any $v \in V(G)$, the cluster containing v, $\mathcal{P}(v)$, also contains some nearest neighbor of v in Y.*

(3) *For any cluster $C \in \mathcal{P}$, we have that $G[C]$ is connected.*

We say that $\mathcal{P}$ is a Voronoi partition *of G* centered at *Y.*

We note the following easy fact.

▶ **Lemma 8.** *For any graph G, and $Y \subseteq V(G)$, there exists a Voronoi partition $\mathcal{P}$ of G centered at Y.*

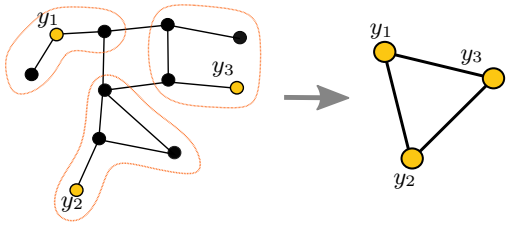

Figure 5 A Voronoi partition centred at 3-net $N = \{y_1, y_2, y_3\}$ and a corresponding 3-minor.

Proof. Construct $\mathcal{P}$ by assigning each $v \in V(G)$ to the cluster containing its nearest neighbor in Y. In order to ensure that each cluster C induces connected subgraph $G[C]$ it suffices to ensure that shortest-paths in G are unique. This can be achieved by breaking ties between different paths lexicographically (viewing paths as sequences of vertices with unique integer labels) (see also [6]). ◀

▶ **Definition 9** (R-Minor). *Let G be a graph, $R > 0$, and let N be a R-net of G. Let $\mathcal{P}$ be a Voronoi partition of G centered at N. Let H be the minor of G obtained by contracting each cluster in C in $\mathcal{P}$ into the unique net point in C. Then we say that $\mathcal{P}$ is a* R-partition *and H is a* R-minor *of G induced by $\mathcal{P}$ (see Figure 5 for an example).*

3 The Main Algorithm

In this section we present and analyze the main algorithm of the paper. For the clarity, we first state some key technical ingredients used by the algorithm. We then present the main algorithm and its analysis. The proofs of the technical ingredients appear in latter Sections.

3.1 Technical ingredients used by the main algorithm

Density reduction. The first technical ingredient used by the main algorithm is a procedure for reducing the local density of the input graph. This is summarized in Lemma 10. Its proof is given in Section A.

▶ **Lemma 10** (Density Reduction). *There exists a polynomial-time algorithm given given a graph G, $k \geq 0$, $c \geq 1$, terminates with exactly one of the following outcomes:*

(1) *Correctly decides that G does not admit a (k, c)-embedding into the line.*

(2) *Outputs some $Y \subseteq V(G)$ such that $\Delta(G \backslash Y) \leq c$, with $|Y| = O(ck \log^{3/2} n)$. In particular, if $\Delta(G) \leq c$, then the algorithm outputs $\emptyset$.*

Eliminating large metrical cycles. The next technical ingredient is a procedure for eliminating large metrical cycles. This is summarized in Lemma 11, whose proof is given in Section B.

▶ **Lemma 11** (Embedding into a forest). *There exists a polynomial-time algorithm which given a graph G, $c \geq 1$, and $k \geq 0$, terminates with exactly one of the following outcomes:*

(1) *Correctly decides that G does not admit a (k, c)-embedding into the line.*

(2) *Outputs a c-net N of G, a c-partition $\mathcal{P}$ centered at N, a c-minor H induced by $\mathcal{P}$, and some feedback vertex set X of H, with $|X| \leq 2k$.*

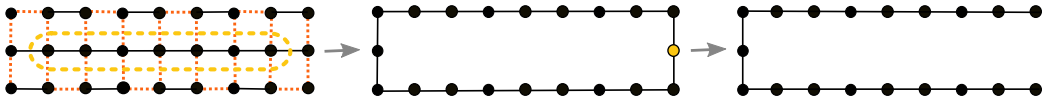

Figure 6 A $3 \times n$ grid G can be embedded into the line with distortion $O(1)$; one could follow the red dotted path on the grid an embed the vertices consequently. A yellow line depicts U. Now, if we delete a yellow vertex from $G \setminus U$, the resulting graph will be just a path.

Eliminating large metrical tripods. The next obstruction that the main algorithm needs to remove is large metrical tripods. This is done using Lemmas 12 and 13. Their proofs appear in Section C.

▶ **Lemma 12** (Tripods as obstructions to embeddability)**.** *Let G be a graph, $R \geq 1$, and let J be a R-tripod in G. Then for any c-embedding of G into the line we have $c \geq 2R$.*

▶ **Lemma 13** (Tripod elimination)**.** *There exists a polynomial-time algorithm which given a forest F, $R \geq 1$, $k \geq 0$, terminates with exactly one of the following outcomes:*

(1) *Correctly decides that there exists no $X' \subseteq V(F)$, with $|X'| \leq k$, such that $F \setminus X'$ does not contain any R-tripod as a subgraph.*

(2) *Outputs some $X' \subseteq V(F)$, with $|X'| = O(k \log n)$, such that $F \setminus X'$ does not contain any R-tripod as a subgraph.*

Embedding a tree with no large tripods into the line. Once all the obstructions have been removed, the problem is reduced to computing an embedding of a tree with no large tripods into the line. This is done using Lemma 14, whose proof appears in Section D.

▶ **Lemma 14.** *Let $R \geq 1$, and let T be a tree that does not contain any R-tripod as a subgraph. Then T admits a $O(\Delta(T) \cdot R)$-embedding into the line. Moreover, this embedding can be computed in polynomial time.*

3.2 The Repairing Lemma

The main algorithm proceeds in several steps. At each step, it uses some of the procedures described above to delete small subsets of vertices. However, because c-embeddability into the line is not a hereditary property, it is possible that the deletion of some small set of vertices destroys some candidate solution. As an illustrative example, let G be the $3 \times (n/3)$ grid. Note that G admits a $O(1)$-embedding into the line (i.e. without outliers). This embedding can be realized by consecutively traversing the columns of the grid. Let U be the set of vertices that do not lie on the outer boundary cycle of G. Then, $G \setminus U$ is the $(2n/3 + 2)$-cycle, and therefore any embedding of $G \setminus U$ into the line has distortion $\Omega(n)$. However, by removing one additional vertex from $G \setminus U$ we obtain a path, which admits a 1-embedding into the line (see Figure 6). We show that the above "repairing" process can be performed for arbitrary U. First, we prove two auxiliary statements.

▶ **Lemma 15.** *Let G be a graph, $k > 0$, $c > 1$. Assume that G admits a (k, c)-embedding into a line. Suppose G admits a (k, c)-embedding into the line realized by $f : G \setminus K \to \mathbb{R}$. Then, there exists a (k, c)-embedding f' of G into a line such that if $j > i$ then for any $v \in G_i, w \in G_j$ we have $f'(w) > f'(v)$.*

Proof. Let

$$v_1 = \arg\min_{v \in V(G) \setminus K} \{f(v)\}$$
$$v_2 = \arg\max_{v \in V(G) \setminus K} \{f(v)\}$$

and let $M = f(v_2) - f(v_1)$. Without loss of generality, we can assume that $f(v_1) = 0$ and $f(v_2) = M$ by setting $f(v) := f(v) - f(v_1)$. For each $v \in G_i$ we define $f'(v) = f(v) + 2i \cdot M$. We claim that f' and f have the same distortion. If $v, w \in G_i$ then we have

$$|f'(w) - f'(v)| = |(f(w) + 2i \cdot M) - (f(w) + 2i \cdot M)| = |f(w) - f(v)|.$$

If $v \in G_i$ and $w \in G_j$ for $i \neq j$ then the distance between them in the embedding does not contribute to the distortion.

It remains to show that $f'(w) > f'(v)$ for all $w \in G_j, v \in G_i$ with $j > i$. We have

$$f'(w) - f'(v) = f(w) - f(v) + 2(j - i)M > -M + 2M > 0$$

and the claim follows by induction. ◀

Let $G = (V(G), E(G))$ be a graph and let $f : G \to \mathbb{R}$. Consider $Z = \{v_1, \ldots, v_m\} \subseteq V(G)$ such that $f(v_1) < f(v_2) < \cdots < f(v_m)$. Then Z is *consecutive with respect to* f if for all $w \in V(G) \setminus U$ either $f(w) < f(v_1)$ or $f(v_m) < f(w)$.

▶ **Lemma 16.** *Let G be a graph, $c > 0$. Assume that G admits a $(0, c)$-embedding into the line realized by $f : G \to \mathbb{R}$. Let $Z = \{z_1, \ldots, z_m\} \subseteq V$ be consecutive with respect to f. Suppose that $f(v_m) - f(v_1) \geq c$; then Z is a vertex separator in G.*

Proof. We claim that

$$X = \{x \in V(G) \mid f(x) < f(v_1)\}$$
$$Y = \{y \in V(G) \mid f(v_k) < f(y)\}$$

are disconnected in $G \setminus Z$. Assume otherwise; then there exists $\{x, y\} \in E(G)$ with $x \in X, y \in Y$. Thus

$$|f(y) - f(x)| = f(y) - f(v_k) + f(v_k) - f(v_1) + f(v_1) - f(x) \geq c + 1 > c \cdot d_G(x, y)$$

which contradicts the distortion assumption. ◀

We can now prove the Repairing Lemma:

▶ **Lemma 17** (Repairing Lemma)**.** *Let G be a graph, $U \subset V(G)$, $k \geq 0$, $c \geq 1$. Suppose that G admits a (k, c)-embedding into a line. Then, $G \setminus U$ admits a $((2c+1)|U| + k, 4c^3 + c)$-embedding into a line.*

Proof. Let f be a (K, c)-embedding of G into the line, with $|K| = k$. Let $U' = U \cap K$, and $U'' = U \setminus K$. For any $v \in U \setminus K$, let

$$I_{\mathsf{inner}}(v) = \mathsf{Ball}_{\mathbb{R}}(f(v), c),$$
$$I_{\mathsf{outer}}(v) = \mathsf{Ball}_{\mathbb{R}}(f(v), 2c^2) \setminus I_{\mathsf{inner}}(v),$$
$$V_{\mathsf{inner}}(v) = \{u \in V(G) \setminus K : f(u) \in I_{\mathsf{inner}}(v)\}$$
$$V_{\mathsf{outer}}(v) = \{u \in V(G) \setminus K : f(u) \in I_{\mathsf{outer}}(v)\}$$

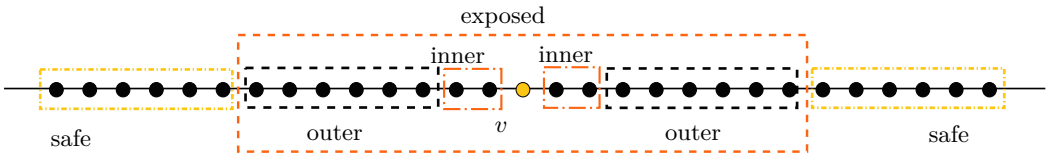

Figure 7 Inner, outer, safe and exposed vertices with respect to v for $c = 2$.

Let also

$$I_{\mathsf{inner}} = \bigcup_{v \in U \setminus K} I_{\mathsf{inner}}(v)$$

$$I_{\mathsf{outer}} = \left(\bigcup_{v \in U \setminus K} I_{\mathsf{outer}}(v) \right) \setminus I_{\mathsf{inner}}$$

$$V_{\mathsf{inner}} = \{u \in V(G) \setminus K : f(u) \in I_{\mathsf{inner}}\},$$

$$V_{\mathsf{outer}} = \{u \in V(G) \setminus K : f(u) \in I_{\mathsf{outer}}\},$$

$$V_{\mathsf{exposed}} = V_{\mathsf{inner}} \cup V_{\mathsf{outer}},$$

$$V_{\mathsf{safe}} = V(G) \setminus V_{\mathsf{exposed}}.$$

We can now define

$$K' = K \cup V_{\mathsf{inner}}.$$

Since the minimum distance in G is one, and f is non-contracting, it follows that

$$|K'| \leq |K| + (2c+1)|U|.$$

Let $c' = (4c^3 + c)$. It remains to construct any (K', c')-embedding f'. By lemma 15 it is enough to construct a c'-embedding for each connected component of $G \setminus K'$

We may thus focus on any connected component C of $G \setminus K'$. Let $f' = (4c^2+1) \cdot f|_C$ (that is, f' is the restriction of f on C scaled by a factor of $4c^2+1$). It suffices to show that f' is a $(4c^3 + c)$-embedding of C.

If there exist $v \in U \setminus K$, and $u \in C$ such that $f(v) < f(u)$, then we set

$$z_L = \operatorname*{arg\,max}_{v \in U \setminus K : \forall u \in C, f(z_L) < f(u)} \{f(v)\},$$

Similarly, if there exist $v \in U \setminus K$, and $u \in C$ such that $f(v) > f(u)$, then we set

$$z_R = \operatorname*{arg\,min}_{v \in U \setminus K : \forall u \in C, f(z_R) > f(u)} \{f(v)\}.$$

Let $u, v \in V(C)$. We first bound the expansion of f'. Since $K \subset K'$, it follows what $d_{G \setminus K}(u,v) \leq d_{G \setminus K'}(u,v)$, and thus

$$\begin{aligned} |f'(u) - f'(v)| = (4c^2+1) \cdot |f(u) - f(v)| &\leq (4c^3 + c) \cdot d_{G \setminus K}(u,v) \\ &\leq (4c^3 + c) \cdot d_{G \setminus K'}(u,v). \end{aligned} \tag{1}$$

It remains to show that f' is non-contractive. Let P be the shortest path between u and v in $G \setminus K$. Let us first assume that $u, v \in V_{\mathsf{safe}}$; we will consider the general case later. If z_L is defined and $P \cap V_{\mathsf{outer}}(z_L)$, we first construct a new path P' that avoids $V_{\mathsf{outer}}(z_L)$, as

follows. When traversing P starting from u, let u_1 be the last vertex before visiting $V_{\mathsf{outer}}(z_L)$ for the first time; let also u_2 be the first vertex visited immediately after leaving $V_{\mathsf{outer}}(z_L)$ for the last time.

Since the expansion of f is at most c, it follows that

$$f(u_1) \in (f(z_L) + 2c^2, f(z_L) + 2c^2 + c],$$
$$f(u_2) \in (f(z_L) + 2c^2, f(z_L) + 2c^2 + c],$$

and thus

$$d_{G\setminus K}(u_1, u_2) \leq |f(u_1) - f(u_2)| \leq c. \tag{2}$$

Let W be the shortest path between u_1 and u_2 in $G \setminus K$. Since every edge of W is stretched by at most a factor of c in f, it follows by (2) that W cannot enter $V_{\mathsf{inner}}(z_L)$, and thus $W \subseteq G \setminus K'$. Therefore $d_{G\setminus K'}(u_1, u_2) = d_{G\setminus K}(u_1, u_2) \leq c$. We can replace P be the path $P' := P[u, u_1] \circ W \circ P[u_2, v]$, which does not intersect $v_{\mathsf{outer}}(z_L)$. We obtain that $\mathsf{length}(P') = \mathsf{length}(P[u, u_1]) + \mathsf{length}(W) + \mathsf{length}(P[u_2, v]) \leq c + \mathsf{length}(P) \leq c + d_{G\setminus K}(u, v)$.

Next, if z_R exists and $P' \cap V_{\mathsf{outer}}(z_R) \neq \emptyset$, then via a symmetric process we can replace P' by a new path P'' between u and v in $G \setminus K$ avoids $V_{\mathsf{outer}}(z_R) \cup V_{\mathsf{outer}}(z_L)$, with

$$\mathsf{length}(P'') \leq \mathsf{length}(P') + c \leq \mathsf{length}(P) + 2c.$$

This implies that $P' \subseteq G \setminus K'$.

We therefore obtain

$$\begin{aligned} |f'(u) - f'(v)| &= (4c^2 + 1) \cdot |f(u) - f(v)| \geq (4c^2 + 1) \cdot d_{G\setminus K}(u, v) \\ &\geq (4c^2 + 1) \cdot (d_{G\setminus K'}(u, v) - 2c) > d_{G\setminus K'}(u, v). \end{aligned} \tag{3}$$

By (1) and (3) we obtain that f is a $(4c^3 + c)$-embedding of $G \setminus K'$, as required.

It remains to consider the case where either $u \in V_{\mathsf{exposed}}$, or $v \in V_{\mathsf{exposed}}$. Let Q be a shortest path between u and v in $G \setminus K'$. If $Q \cap V_{\mathsf{safe}} = \emptyset$, then $\mathsf{length}(Q) \leq 4c^2 - 2c$, thus

$$d_{G\setminus K'}(u, v) \leq (4c^2 - 2c) \leq (4c^2 - 2c) \cdot d_{G\setminus K'}(u, v),$$

which implies that f' is non-contractive, as required. We may therefore assume for the remainder of the proof that $Q \cap V_{\mathsf{safe}} \neq \emptyset$. If $u \in V_{\mathsf{exposed}}$, then we may assume w.l.o.g. that $u \in V_{\mathsf{outer}}(z_L)$. When traversing P starting from u, let u_1 be the first vertex visited immediately after leaving $V_{\mathsf{outer}}(z_L)$. When traversing Q starting from u, let u_2 be the first vertex visited in V_{safe}. By an argument identical to the one used in the previous case, we can obtain a new path between u and v, given by $Q[u, u_2] \circ W \circ P[u_1, v]$, where $\mathsf{length}(Q[u, u_2]) \leq 2c^2 - c$ (since all vertices in $Q[u, u_2]$ except the last one are contained in the rightmost segment of $V_{\mathsf{outer}}(z_L)$), $W \subseteq G \setminus K'$, and $\mathsf{length}(W) \leq c$ (as in the previous case). We thus obtain a path of length at most $d_{G\setminus K}(u, v) + 2c^2$. If $v \in V_{\mathsf{exposed}}$, we repeat the above process after exchanging u and v. We thus arrive at a path between u and v of length at most $d_{G\setminus K}(u, v) + 4c^2 \leq (4c^2 + 1) \cdot d_{G\setminus K}$, which does not intersect V_{inner}, and thus it is contained in $G \setminus K'$. It follows that f' is non-contractive, and thus a $(4c^3 + c)$-embedding, which concludes the proof. ◀

3.3 The algorithm

Given the technical ingredients presented above, we are now ready to describe our main algorithm. Recall that the input consists of a graph G, and $k \geq 0$, $c \geq 1$. The algorithm proceeds in the following steps.

Step 1: Density reduction. Using the algorithm from Lemma 10 we can either correctly decide that G does not admit a (k, c)-embedding into the line, in which case we terminate, or we compute some $X_{\mathsf{density}} \subseteq V(G)$, with $|X_{\mathsf{density}}| \leq O(ck \log^{3/2} n)$, such that $\Delta(G \setminus X_{\mathsf{density}}) \leq c$.

Step 2: Cycle elimination. Let $k' = (2c+1)|X_{\mathsf{density}}| + k$ and $c' = 4c^3 + c$. Using the algorithm from Lemma 11 we either correctly decide that G' does not admits a (k', c')-embedding into the line, or we compute a c'-net N of G', a c'-partition $\mathcal{P}$ centered at N, a c'-minor H induced by $\mathcal{P}$, and some feedback vertex set Y_{forest} of H, with $|Y_{\mathsf{forest}}| \leq 2k'$. If G' does not admit a (k', c')-embedding into the line, then we terminate by deciding that G does not admit a (k, c)-embedding into the line.

Step 3: Tripod elimination. Let $F = H \setminus Y_{\mathsf{forest}}$, and recall that Y_{forest} is a feedback vertex set for H, and thus F is a forest. Using the algorithm from Lemma 13, in polynomial time, we either decide that there exists no $Y_{\mathsf{tripod}} \subseteq V(F)$, with $|Y_{\mathsf{tripod}}| \leq k'$, such that $F \setminus T_{\mathsf{tripod}}$ does not contain any $(c'/2+1)$-tripod, in which case we terminate deciding that G does not admit a (k, c)-embedding into the line, or we compute some $Y_{\mathsf{tripod}} \subseteq V(F)$, with $|Y_{\mathsf{tripod}}| = O(k \log n)$, such that $F \setminus Y_{\mathsf{tripod}}$ does not contain any $(c'/2+1)$-tripods.

Step 4: Embedding into a forest. Let $F' = F \setminus Y_{\mathsf{tripod}}$. Let

$$X_{\mathsf{forest}} = \bigcup_{v \in Y_{\mathsf{forest}}} \mathcal{P}(v),$$

$$X_{\mathsf{tripod}} = \bigcup_{v \in Y_{\mathsf{tripod}}} \mathcal{P}(v),$$

and

$$K = X_{\mathsf{density}} \cup X_{\mathsf{forest}} \cup X_{\mathsf{tripod}}.$$

Let F'' be the forest obtained from F' as follows. Initially, we set $F'' := F'$. For each $v \in V(G) \setminus K$, let $u(v)$ be the unique vertex in $N \cap \mathcal{P}(v)$; we add v to F'' as a leaf attached to $u(v)$. This completes the construction of the forest F''.

Step 5: Embedding into the line. Finally, we compute an embedding f of F'' into the line using the algorithm from Theorem 14. We output the embedding $\varphi := 2c'c \cdot f$ (that is, f scalled by a factor of $2c'c$).

3.4 Analysis of the main algorithm

We now analyze the main algorithm presented above. First, we state some auxiliary properties of c-minors and c-partitions.

▶ **Lemma 18.** *Let G be a graph, $R \geq 1$. Let N be a R-net of G, $\mathcal{P}$ a corresponding R-partition and H a R-minor G induced by $\mathcal{P}$. Then for any $Y \subseteq V(H)$ all of the following hold:*

(1) *$N' := N \setminus Y$ is a R-net in $G' := G \setminus (\cup_{v \in Y} \mathcal{P}(v))$*

(2) *$\mathcal{P}' := \mathcal{P} \setminus (\cup_{v \in Y} \{\mathcal{P}(v)\})$ is the R-partition of G' centered at N'*

(3) *$H' := H \setminus Y$ is the R-minor of G' induced by $\mathcal{P}'$.*

Proof. We first show (1). Since by deleting vertices the shortest-path distances cannot increase, we have that for all $u, v \in N'$, $d_{G'}(u, v) \geq d_G(u, v) > R$. It thus remains to show that for any $x \in V(G')$ there exists $v \in N'$ such that $d_{G'}(x, v) \leq R$. Consider an arbitrary

$x \in V(G')$. Let $v \in N$ be such that $x \in \mathcal{P}(v)$. Since the shortest path between v and x in G is contained in $\mathcal{P}(v)$, it follows that

$$d_{G'}(x,v) \leq d_{G'[\mathcal{P}(v)]}(x,v) = d_{G[\mathcal{P}(v)]}(x,v) = d_G(x,v) \leq c,$$

which implies that N' is a c-net of G'.

Next, we show (2). Since for all $v \in N'$, we have $\mathcal{P}'(v) = \mathcal{P}(v)$, it follows that $\mathcal{P}'$ is a partition of $V(G')$. Since by (1) N' is a R-net of G', and for all $v \in N'$, and for all $x \in \mathcal{P}'(v)$ we have $d_{G'}(v,x) \leq R$, it follows that $\mathcal{P}'$ is a R-partition of G' centered at N'.

Finally, we show (3). Let $\widetilde{H}$ be the R-minor of G' induced by $\mathcal{P}'$. We prove that $V(H') = V(\widetilde{H})$ and $E(H') = E(\widetilde{H})$. For the first equality, observe that

$$V(H') = V(H \setminus Y) = N \setminus Y = N' = V(\widetilde{H}).$$

It remains to show that $E(H') = E(\widetilde{H})$. Consider an arbitrary $\{u,v\} \in E(H')$. Since $H' \subseteq H$ we have that $\{u,v\} \in E(H)$. Then there must exist a path $P \subseteq G$ between u, v with $P \subseteq \mathcal{P}(u) \cup \mathcal{P}(v)$. Since $u,v \in V(H \setminus Y) = N'$ we have that $\mathcal{P}(u) = \mathcal{P}'(u)$, $\mathcal{P}(v) = \mathcal{P}'(v)$. Thus, $P \subseteq \mathcal{P}'(u) \cup \mathcal{P}'(v)$ which yields $\{u,v\} \in E(\widetilde{H})$. Now consider an arbitrary $\{u,v\} \in E(\widetilde{H})$; it induces a path $Q \subseteq G'$ between u, v such that $Q \subseteq \mathcal{P}'(u) \cup \mathcal{P}'(v)$. Since $\mathcal{P}'(u) = \mathcal{P}(u)$, $\mathcal{P}'(v) = \mathcal{P}(v)$ we obtain $\{u,v\} \in E(H)$. Then from $u,v \in N' = N \setminus Y$ we have $\{u,v\} \in E(H \setminus Y) = E(H')$ which concludes the proof. ◀

▶ **Lemma 19.** *Let G be a graph and let $R > 0$. Let N be c-net of G, $\mathcal{P}$ a c-partition centered at N, and H a R-minor induced by $\mathcal{P}$. Then for any $u,v \in N$ we have $d_H(u,v) \leq d_G(u,v)$.*

Proof. Let $P \subseteq G$ be a shortest path between u,v and let $J := \{w \in N : P \cap \mathcal{P}(w) \neq \emptyset\}$. Let $Q \subseteq H$ be a shortest path between u,v. We claim that

$$\mathsf{length}(Q) \leq |J| - 1 \leq \mathsf{length}(P).$$

Assume for contradiction that $\mathsf{length}(Q) > |J| - 1$. Consider arbitrary $\{x_1,x_2\} \in E(P)$ such that $x_1 \in \mathcal{P}(w_1), x_2 \in \mathcal{P}(w_2)$ for $w_1 \neq w_2$; hence $\{w_1,w_2\} \in E(H)$. Therefore, P induces a walk $W \subseteq H$ such that $v,u \in V(W)$. Hence, there is a path $Q' \subseteq W$ such that $v,u \in V(Q')$; note that $\mathsf{length}(Q) \leq |V(W)| - 1 = |J| - 1$. Thus,

$$\mathsf{length}(Q') \leq |J| - 1 < \mathsf{length}(Q) = d_H(v,u).$$

which gives a contradiction, and concludes the proof. ◀

We now have all the necessary ingredients in place to prove Theorem 1, which is the main result of this paper.

Proof of Theorem 1. We analyze the algorithm presented above. By Lemma 10, if we terminate at Step 1, then we correctly decide that G does not admit a (k,c)-embedding. Otherwise, by Lemma 17, it follows that if G admits a (k,c)-embedding into the line, then $G' = G \setminus X_{\mathsf{density}}$ admits a (k',c')-embedding into the line, with $k' = (2c+1)|X_{\mathsf{density}}| + k = O(c^2 k \log^{3/2} n))$ and $c' = 4c^3 + c$.

By Lemma 11, if we decide that G' does not admit a (k',c')-embedding into the line, then, by the above discussion, this certifies that G does not admit a (k,c)-embedding into the line; we can thus correctly decide this fact in Step 2.

Suppose that G' admits a (k',c')-embedding into the line. Thus, there exists some $K' \subseteq V(G')$, with $|K'| \leq k'$, such that $G' \setminus K'$ admits a c'-embedding into the line. Let J be the set of all $v \in N$ such that the Voronoi cell of v intersects K', that is $J = \{v \in N : K' \cap \mathcal{P}(v) \neq \emptyset\}$.

We claim that $F \setminus J$ does not contain any $(3c'/2+1)$-tripod. For the sake of contradiction, suppose that $F \setminus J$ contains some $(3c'/2+1)$-tripod $T = P_1 \cup P_2 \cup P_3$, where P_1, P_2, P_3 are three paths sharing a root r. For any $i \in [3]$ let z_i be the endpoint of P_i other than r. Then for any $i \in [3]$ there exists a path Q_i in $G' \setminus K'$ between r and z_i. We claim that for all $i \neq j \in [3]$, for all $u \in V(Q_j)$, we have $d_{G \setminus K}(z_i, u) \geq c'/2 + 1$. By Lemma 18, $F \setminus J$ is a c'-minor of $G' \setminus K'$ with respect to the Voronoi partition $\mathcal{P}_J$ with $\mathcal{P}(w) = \mathcal{P}_J(w)$ for all $w \in V(F \setminus J)$. Let w' be such that $u \in \mathcal{P}_J(w')$. By Lemma 19 obtain

$$\begin{aligned}
d_{G' \setminus K'}(z_i, u) &\geq d_{G' \setminus K'}(z_i, w') - d_{G' \setminus K'}(w', u) && \text{(by the triangle inequality)} \\
&\geq d_{G' \setminus K'}(z_i, w') - c' && \text{(since } u \in \mathcal{P}_J(w')\text{)} \\
&\geq d_{F \setminus J}(z_i, w) - c' && \text{(by Lemma 19)} \\
&\geq 3c'/2 + 1 - c' && \text{(since } T \text{ is a } (3c'/2+1)\text{-tripod)} \\
&= c'/2 + 1.
\end{aligned}$$

Therefore, by Lemma 12 we conclude that $G' \setminus K'$ does not admit a c'-embedding into the line, which is a contradiction. Therefore, we have established that if G' admits a (k, c)-embedding into the line, then there exists some $J \setminus V(F)$, with $|J| \leq k'$, such that $F \setminus J$ does not contain any $(3c'/2+1)$-tripods.

Therefore, in Step 3, if we do not find a set Y_{tripod} of the desired size, then we correctly decide that G does not admit a (k, c)-embedding into the line.

Next consider the case where in Step 3 we compute a set Y_{tripod} of the desired size. Since F' does not contain any $(3c'/2+1)$-tripods, it follows by the construction of F'', that F'' does not contain any $(3c'/2+3)$-tripods (since every leaf in F becomes the center of a star in F'). Moreover, we have $\Delta(F'') \leq \Delta(F') \cdot O(c'\Delta(G'))$, since every vertex in F'' corresponds to a star that contains the vertices of a Voronoi cell in G', and every such cell has size at most $O(c'\Delta(G'))$. Thus, by Lemma 14 we compute a c''-embedding of F'' into the line, where $c'' = O(\Delta(F'')c') = O(\Delta(F')c^3\Delta(G')) = O(\Delta(F)c^3\Delta(G)) = O(\Delta(H)c^4)$, since $\Delta(\Gamma_1) \leq \Delta(\Gamma_2)$ for all $\Gamma_1 \subset \Gamma_2$. Moreover we have $\Delta(H) \leq \Delta(G') \cdot O(c' \cdot \Delta(G')) = O(c^5)$, since every vertex in H corresponds to a Voronoi cell consisting of at most $O(c' \cdot \Delta(G'))$ vertices. Therefore $c'' = O(c^9)$, and thus we have obtained a $O(c^9)$-embedding f of F'' into the line. Note that since $V(F'') = V(G \setminus K)$, it follows that f is also a (κ, σ)-embedding of G into the line, where $\kappa = |K|$, for some $\sigma \geq 1$.

It remains to bound κ and σ. We have

$$\kappa = |X_{\mathsf{density}}| + |X_{\mathsf{forest}}| + |X_{\mathsf{tripod}}|.$$

Since G admits a (k, c)-embedding into the line, it follows from Lemma 10 that

$$|X_{\mathsf{density}}| = O(ck \log^{3/2} n).$$

Moreover, $\Delta(G \setminus X_{\mathsf{density}}) \leq c$, thus for any $\widetilde{c}$-partition $\mathcal{P}$ induced by an arbitrary $\widetilde{c}$-net N of $G \setminus X_{\mathsf{density}}$, and any $v \in N$, we have

$$|\mathcal{P}(v)| = O(\widetilde{c} \cdot \Delta(G \setminus X_{\mathsf{density}})) = O(\widetilde{c} \cdot c).$$

Therefore, using Lemma 11 with $\widetilde{c} := c'$ in the Step 3 we obtain

$$|X_{\mathsf{forest}}| = O(c' \cdot c) \cdot 2k' = O((4c^3 + c) \cdot c \cdot (c^2 k \log^{3/2} n)) = O(c^6 k \log^{3/2} n).$$

Similarly, from Lemma 13, we have

$$|X_{\mathsf{tripod}}| = O(c' \cdot c)O(k' \log n) = O((4c^3 + c) \cdot c) \cdot O(c^2 k \log^{3/2} n) \log n) = O(c^6 k \log^{5/2} n),$$

which implies that

$$\kappa = O(ck \log^{3/2} n) + O(c^6 k \log^{3/2} n) + O(c^6 k \log^{5/2} n) = O(c^6 k \log^{5/2} n).$$

To find σ, we show that $G \setminus K$ admits a $O(c^4)$-embedding ι into F'' with $\iota(v) = v$ for all $v \in G \setminus K$. By Lemma 18 F' is a c'-minor of $G' \setminus (X_{\mathsf{forest}} \cup X_{\mathsf{tripod}}) = G \setminus K$ with respect to the partition $\mathcal{P}' := \mathcal{P} \setminus (\cup_{v \in Y_{\mathsf{forest}} \cup Y_{\mathsf{tripod}}} \mathcal{P}(v))$. Consider arbitrary $x_1, x_2 \in V(G \setminus K)$ and let $v_1, v_2 \in V(F')$ be such that $x_1 \in \mathcal{P}'(v_1)$, $x_2 \in \mathcal{P}'(v_2)$. Let Q be the unique v_1-v_2 path in F'. We use Q to construct a v_1-v_2 path P in $G \setminus K$, with

$$\mathsf{length}(Q) \leq \mathsf{length}(P) \leq 2c'c \cdot \mathsf{length}(Q).$$

Since F' is a c'-minor of $G \setminus K$, for any $\{w_1, w_2\} \in E(Q)$ there is $\{z_1, z_2\} \in E(G \setminus K)$ with $z_i \in \mathcal{P}'(w_i)$ for $i \in [2]$. Moreover, for any $w \in V(Q)$ the corresponding $\mathcal{P}'(w)$ is a connected subgraph such that $|V(\mathcal{P}'(w_i))| \leq 2c'\Delta(G \setminus K) + 1 = 2c'c + 1$. Thus, Q induces a walk $W \subseteq G \setminus K$ with $|V(W)| \leq 2c'c \cdot \mathsf{length}(Q)$ and $v_1, v_2 \in W$. It follows that there is a v_1-v_2 path P in W, such that

$$\mathsf{length}(P) \leq 2c'c \cdot \mathsf{length}(Q).$$

Note that since Q is the v_1-v_2 shortest path in F', we obtain

$$\mathsf{length}(P) \leq 2c'c \cdot d_{F'}(v_1, v_2) = 2c'c \cdot d_{F''}(v_1, v_2),$$

where the last equality follows from the construction of F''.

We claim that ι has contraction $O(c^4)$. By construction of F'' we have that $d_{F''}(x_i, v_i) = 1$ thus

$$d_{G \setminus K}(x_i, v_i) \leq c' \leq c' d_{F''}(x_i, v_i).$$

Therefore, we have that

$$\begin{aligned} d_{G \setminus K}(x_1, x_2) &\leq d_{G \setminus K}(x_1, v_1) + d_{G \setminus K}(v_1, v_2) + d_{G \setminus K}(v_2, x_2) \\ &\leq c' d_{F''}(x_1, v_1) + 2c'c \cdot \mathsf{length}(Q) + c' d_{F''}(v_2, x_2) \\ &\leq 2c'c \cdot d_{F''}(x_1, v_1) + 2c'c \cdot d_{F''}(v_1, v_2) + 2c'c \cdot d_{F''}(v_2, x_2). \end{aligned}$$

Since F'' is a tree, it follows that

$$2c'c \cdot d_{F''}(x_1, v_1) + 2c'c \cdot d_{F''}(v_1, v_2) + 2c'c \cdot d_{F''}(v_2, x_2) = 2c'c \cdot d_{F''}(x_1, x_2).$$

Since $c' = O(c^3)$, it follows that the contraction of ι is at most $O(c^4)$. Now we prove that the expansion of ι is $O(1)$. We claim that $d_{F''}(x_1, x_2) \leq d_{G \setminus K}(x_1, x_2) + 2$. By the construction of F'' we have

$$\begin{aligned} d_{F''}(x_1, x_2) &= d_{F''}(x_1, v_1) + d_{F''}(v_1, v_2) + d_{F''}(v_2, x_2) \\ &= d_{F''}(x_1, v_1) + d_{F'}(v_1, v_2) + d_{F''}(v_2, x_2) = d_{F'}(v_1, v_2) + 2. \end{aligned}$$

Since F' is a c'-minor of $G \setminus K$, by Lemma 19 we get

$$d_{F'}(v_1, v_2) + 2 \leq d_{G \setminus K}(v_1, v_2) + 2,$$

thus the expansion of ι is $O(1)$. Therefore, the distortion of ι is $O(c^4)$. Hence, we obtain that the map $\phi := f \circ \iota : G \setminus K \to \mathbb{R}^1$ has distortion $\sigma = O(c^9) \cdot O(c^4) = O(c^{13})$, which concludes the proof. ◀

A Density Reduction

A.1 The algorithm for density reduction

Let us describe the algorithm for reducing the density of a graph. The algorithm takes as input a graph G and some $k \geq 0$, $c \geq 1$, and outputs some $Y \subseteq V(G)$, such that $\Delta(G \setminus Y) \leq c$. This is summarized in Algorithm 1.

Algorithm 1 SPARSIFY.

```
procedure SPARSIFY(G, c)
    if Δ(G) ≤ c then
        return ∅
    else
        Let X be a 3/4-balanced vertex separator of G computed by Theorem 5.
        Let G_1, ..., G_t be the connected components of G \ X.
        return X ∪ ( ⋃_{i=1}^{t} SPARSIFY(G_i, c) )
```

A.2 Analysis of the algorithm for density reduction

We now analyze the algorithm described above. We first recall the following result from [6].

▶ **Lemma 20** (Bădoiu et al. [6]). *If G admits a c-embedding into the line then $\Delta(G) \leq c$.*

The following establishes the existence of small balanced separators.

▶ **Lemma 21.** *Let G be a graph such that G admits a (k, c)-embedding into the line. Let $Z \subseteq V(G)$ with $|Z| = k$ be such that $G \setminus Z$ is c-embeddable into the line. Then any $H \subseteq G$ contains a 2/3-balanced vertex separator of size at most $c + |Z \cap V(H)|$.*

Proof. Let $f : G \setminus Z \to \mathbb{R}$ be an embedding with distortion c. Let $V(H) = \{v_1, \ldots, v_h\}$, and assume w.l.o.g. that $f(v_1) < f(v_2) < \ldots < f(v_h)$. Let $X = \{v_{\lfloor h/3 \rfloor + 1}, v_{\max\{h, \lfloor h/3 \rfloor + c + 1\}}\}$. By lemma 16 we get that X is a balanced separator of $H \setminus Z = H \setminus (Z \cap V(H))$. Therefore, $W := X \cup (V(H) \cap Y)$ is a balanced separator for H, with $|W| = |X| + |Z \cap V(H)| \leq c + |Z \cap V(H)|$, as required. ◀

We are now ready to prove the main result of this Section.

Proof of Lemma 10. It is immediate that the output, Y, of the procedure SPARSIFY is such that $\Delta(G \setminus Y) \leq c$. Also, if $\Delta(G) \leq c$, the algorithm outputs $Y = \emptyset$.

It thus remains to bound $|Y|$. Fix some $K \subseteq V(G)$, with $|K| = k$, and some c-embedding f of $G \setminus K$ into the line. Consider some recursive call of procedure SPARSIFY(H, c), for some $H \subseteq G$. If $H \cap K = \emptyset$, then $H \subseteq G \setminus K$, and thus $\Delta(H) \leq \Delta(G \setminus K) \leq c$, where the last inequality follows by lemma 20. Therefore, procedure SPARSIFY computes a balanced separator, X_H, only if H intersects K. By lemma 21 and Theorem 5 it follows that

$$|X_H| \leq O\left(\sqrt{\log n} \cdot (c + |K \cap V(H)|)\right) \leq O\left(|K \cap V(H)| \cdot c \cdot \sqrt{\log n}\right).$$

We charge the vertices in X_H to the vertices in $K \cap H$; thus every vertex in $K \cap H$ receives at most $O\left(\sqrt{\log n}\right)$ units of charge. Since any two subgraphs on the same level of the recursion are disjoint, it follows that each vertex in K receives at most $O\left(c\sqrt{\log n}\right)$ units of charge per level of the recursion. Since each separator is 3/4-balanced, it follows that the depth of the recursion is at most $\log_{4/3} n$. Thus, every vertex in K receives at most $\log_{4/3} n \cdot O(c \log n) = \beta \cdot c \log^{3/2}_{4/3} n$ units of charge throughout the execution of the procedure SPARSIFY. The constant β comes from the bound on the size of the vertex separator computed by Theorem 5. Hence, if $Y > \beta \cdot kc \log^{3/2}_{4/3} n$, then we have certified that G does not admit a (k, c)-embedding into the line, which concludes the proof. ◀

B Eliminating large metrical cycles

B.1 The algorithm

The input consists of a graph G, some $c \geq 1$, and $k \geq 0$. The algorithm proceeds in steps, that are formally described below.

Algorithm for eliminating large metrical cycles:

Step 1. Compute a c-net N of G.

Step 2. Compute a Voronoi partition $\mathcal{P}$ of G centered at N, and the corresponding c-minor H of G.

Step 3. Using the algorithm from Theorem 4 compute a 2-approximate solution S to the Minimum Feedback Vertex Set problem on H. If $|S| > 2k$, then decide that G does not admit a (k, c)-embedding into the line.

B.2 Analysis

First, we prove the following statement about embeddability into a subgraph of a c-minor.

▶ **Lemma 22.** *Let G be a graph, $R > 0$, let N be a R-net in G, let $\mathcal{P}$ be a R-partition centered at N, and let H be the R-minor of G induced by $\mathcal{P}$. Let $X \subset N$, and let*

$$Y = \bigcup_{x \in X} \mathcal{P}(x).$$

Then the metric space $(N \setminus X, d_{G \setminus Y})$ admits a $(2R+1)$-embedding into $H \setminus X$. Moreover, this embedding can be computed in polynomial time.

Proof. Let $u, v \in N \setminus X$. Let Q be a u-v shortest path in $G \setminus Y$. When traversing Q starting from u let $C_1, \ldots, C_\ell$ be the sequence of clusters of $\mathcal{P}$ visited. For each $i \in [\ell]$ let q_i be the center of C_i; that is, $C_i = \mathcal{P}(q_i)$. Since for all $i \in [\ell - 1]$ there is an edge in $G \setminus Y$ between some vertex in C_i and some vertex in C_{i+1}, it follows that there also exists an edge in $H \setminus X$ between q_i and q_{i+1}. Therefore $Q' = q_1, \ldots, q_\ell$ is a path in $H \setminus X$. We thus obtain

$$d_{H\setminus X}(u,v) \leq \mathsf{length}(Q') \leq \mathsf{length}(Q) = d_{G\setminus Y}(u,v). \tag{4}$$

Let $W = w_1, \ldots, w_t$ be a u-v shortest path in $H \setminus X$. Since each cluster in $\mathcal{P}$ has radius at most R, it follows that for all $i \in [t-1]$ there exists a w_i-w_{i+1} path in $G \setminus Y$ of length at most $2R+1$. Concatenating all these paths we obtain a u-v path W' in $G \setminus Y$ of length at most $(t-1)\cdot(2R+1)$. Thus

$$d_{G\setminus Y}(u,v) \leq \mathsf{length}(W') \leq (2R+1)(t-1) = (2R+1)d_{H\setminus X}(u,v). \tag{5}$$

Combining (4) and (5) the assertion follows. ◀

We recall the Borsuk-Ulam Theorem [2].

▶ **Theorem 23** (Borsuk-Ulam Theorem [2]). *Let $d \geq 1$, and let $\mathbb{S}^d$ denote the d-dimensional sphere. Let $f : \mathbb{S}^d \to \mathbb{R}^d$ be a continuous map. Then there exists $x \in \mathbb{S}^d$, such that $f(x) = f(-x)$.*

The following is a simple consequence of Theorem 23. A similar argument is used in [6].

▶ **Lemma 24.** *Let C be a cycle and let $f : V(C) \to \mathbb{R}$ be an injective map. Then there exist $u, v, w \in V(C)$, such that $\{u,v\} \in E(C)$, and $f(u) < f(w) < f(v)$.*

Proof. Suppose that C is the n-cycle for some $n \in \mathbb{N}$. We identify the vertices in C with distinct points in $\mathbb{S}^1$, so that the points appear in the same order as in C along a clockwise traversal of $\mathbb{S}^1$. For each $\{x,y\} \in E(C)$ ther exists an arc $A_{x,y}$ in $\mathbb{S}^1$ that does not contain any other vertex in C; we extend f to $A_{x,z}$ affinely. After repeating for all edges in C, we obtain a continuous map $f : \mathbb{S}^1 \to \mathbb{R}^1$. By Theorem 23 we get that there exists $x \in \mathbb{S}^1$ with $f(x) = f(-x)$. This means that there exist two edges in C whose images in f span overlapping intervals in $\mathbb{R}^1$. Since f is injective on $V(C)$ this implies that one endpoint is contained inside the interval of the other edge, which concludes the proof. ◀

We next establish the existence of a small feedback vertex set in the minor computed by the algorithm.

▶ **Lemma 25.** *Let G be a graph, $c \geq 1$, $k \geq 0$, such that G admits a (k,c)-embedding into the line. Let H be a R-minor of G, for some $R \geq c$. Then there exists a feedback vertex set X in H with $|X| \leq k$.*

Proof. Let $\mathcal{P}$ be the R-partition of G such that H is the R-minor of G induced by $\mathcal{P}$. Since G admits a (k,c)-embedding into the line, it follows that there exists some $Y \subseteq V(G)$, with $|Y| \leq k$, such that $G \setminus Y$ admits a c-embedding f into the line.

Let X be the set of all $v \in V(H)$, such that Y intersects the cluster in $\mathcal{P}$ centered at v; that is $X = \{v \in V(H) : \mathcal{P}(v) \cap Y \neq \emptyset\}$. Since $\mathcal{P}$ is a partition, it is immediate that $|X| \leq |Y| \leq k$. It therefore remains to show that $H \setminus X$ is acyclic. Suppose, for the sake of contradiction, that $H \setminus X$ is not acyclic. Let C be a cycle in $H \setminus X$. By Lemma 24 there exist $u, v, w \in V(C)$, such that $\{u,v\} \in E(C)$, and $f(u) < f(w) < f(v)$.

Since $\{u,v\} \in E(C)$, and $C \subseteq H$, it follows that $\{u,v\} \in E(H)$. Since H is R-minor, it follows that there exists a path Q between u and v, with $Q \subseteq \mathcal{P}(u) \cup \mathcal{P}(v)$. When traversing Q starting from u let u' be the last vertex visited with $f(u') < f(w)$; let also v' be the vertex visited immediately after u'. We have $f(u') < f(w) < f(v')$.

Since H is a R-minor and $u' \notin \mathcal{P}(w)$, it follows that $d_G(w,u') \geq d_G(u,u')$. By the definition of a R-partition we have that $d_G(u,w) > c$, and therefore $d_G(u',w) > R/2$. Similarly, we obtain $d_G(v',w) > R/2$. Since f is non-contracting, we obtain $|f(u') - f(v')| = |f(u') - f(w)| + |f(w) - f(v')| \geq d(u,w) + d(w,v) > R/2 + R/2 = R \geq c$, which contradicts the fact that f has expansion at most c, and concludes the proof. ◀

We are now ready to prove the main result of this Section.

Proof of Lemma 11. By Lemma 25, either G does not admit a (k,c)-embedding into the line, or there exists $X \subseteq V(H)$, with $|X| \leq k$, such that $H \setminus X$ is acyclic. Using the algorithm from Theorem 4 we compute in Step 3 a 2-approximation $S \subseteq V(H)$ to the Minimum Feedback Vertex Set in H. Therefore, if $|S| > 2k$, then we can terminate with outcome (1), and otherwise terminate with outcome (2), which completes the proof. ◀

C Eliminating large metrical tripods

In this Section we present and analyze the procedure for eliminating large metrical tripods. We begin by showing that large tripods are an obstruction to embeddability into the line. This is summarized in Lemma 12.

Proof of Lemma 12. Let f be a non-contractive embedding of J into the line. Let v be the common endpoint of P_1, P_2, P_3. For each $i \in [3]$ let v_i be the other endpoints of P_i. We may assume w.l.o.g. (by change of indices) that $f(v_1) < f(v_2) < f(v_3)$. Let Q be the unique v_1-v_3 path in J. It follows that there exists $\{u,w\} \in E(Q)$, such that $f(u) < f(v_2) < f(w)$. This implies that $|f(u) - f(w)| = |f(u) - f(v_2)| + |f(v_2) - f(w)| \geq d_G(u,v_2) + d_G(v_2,w) \geq 2R = 2Rd_J(u,w)$. Therefore the distortion of f is at least $2R$, which concludes the proof. ◀

The above easily implies the following results, which asserts the existence of a small set of vertices whose removal eliminates all large tripods.

▶ **Lemma 26.** *Let F be a forest that admits a (k,c)-embedding into the line. Then there exists some $X \subseteq V(F)$, with $|X| \leq k$, such that $F \setminus X$ does not contain any $(c/2+1)$-tripod as a subgraph.*

Proof. Since F admits a (k,c)-embedding into the line, it follows that there exists some $X \subseteq V(F)$, with $|X| \leq k$, such that $F \setminus X$ admits a c-embedding into the line. It suffices to show that $F \setminus X$ does not contain any $(c/2+1)$-tripods. Suppose, for the sake of contradiction, that $F \setminus X$ contains some $(c/2+1)$-tripod J. Since $(V(J), d_J)$ is a submetric of $(V(F) \setminus X, d_{F \setminus X})$, it follows that J admits a c-embedding into the line, which contradicts Lemma 12, and concludes the proof. ◀

Now are now ready to prove the main result of this Section.

Proof of Lemma 13. Any tripod $T \subseteq F$ can be uniquely specified by selecting its root and its three leaves. Therefore, there are at most $O(|V(F)|^4)$ distinct tripods in F. Moreover, the set of all tripods, $\mathcal{T}$, can be enumerated in polynomial time. We form an instance of the Minimum Set Cover problem with universe $U = \mathcal{T}$. We also let

$$\mathcal{C} = \bigcup_{v \in V(F)} \{C_v\},$$

where $C_v = \{T \in \mathcal{T} : v \in V(T)\}$. It is immediate that for any $Y \subseteq V(F)$, $F \setminus Y$ contains no R-tripods iff $\bigcup_{v \in Y} C_v = U$. Therefore, computing a minimum-cardinality subset of vertices of F whose deletion removes all R-tripods, is equivalent to solving the Minimum Set Cover instance on $(U, \mathcal{C})$. The result now follows from Theorem 6. ◀

D Embedding Trees Without Large Tripods into the Line

This Section is devoted to proving Lemma 14, which asserts that any tree with no large tripods admits a low-distortion embedding into the line.

Proof of Lemma 14. Since T is a tree, we can compute in polynomial time a longest path Q in T. Let $Q = v_1, \ldots, v_t$. Let $\mathcal{P}$ be a Voronoi partition centered at $V(Q)$. Since T does not contain any R-tripod as a subgraph, it follows that for all $u \in V(T)$, there exists some $v \in V(Q)$, with $d_T(u, v) < R$. Therefore, for each $v_i \in V(Q)$, we have

$$|\mathcal{P}(v_i)| \leq |\mathsf{Ball}_T(v_i, R-1)| \leq \Delta(T) \cdot 2(R-1) + 1 \leq \Delta(T) \cdot 2R - 1.$$

By the definition of a graphical Voronoi partition we have that for all $i \in [t]$, the vertex-induced subgraph $T_i := T[\mathcal{P}(v_i)]$ is connected, and thus T_i is a subtree of T. Let W_i be a closed walk in T_i that visits all vertices in T_i, obtained by duplicating every edge (or, equivalently, the walk obtained by any traversal of T_i). Since every edge in T_i is traversed twice, we have $\mathsf{length}(T_i) = 2(|V(T_i)| - 1)$. Let $W_i = w_{i,1}, \ldots, w_{i,t_i}$.

We define the embedding $f_i : V(T_i) \to \mathbb{R}$ as follows. For each $v \in V(T_i)$, we define $f_i(v) = \min\{j \in [t_i] : v = w_{i,j}\}$.

We combine the mappings $f_1, \ldots, f_t$ into a mapping $f : V(G) \to \mathbb{R}$. Informally, this is done by translating each f_i so that for all $i \in [t-1]$, the image of f_i appears to the left of the image of f_{i+1}, and there is a gap of length $2R$ between these two images.

Formally, for each $u \in \mathcal{P}_{v_i}$, we set $f(u) = L_i + f_i(u)$, where

$$L_i = \begin{cases} 0 & \text{if } i = 0 \\ L_{i-1} + \max_{z \in \mathcal{P}(v_{i-1})}\{f_{i-1}(z)\} + 2R & \text{otherwise} \end{cases}$$

This completed the definition of the embedding f.

It remains to bound the distortion of f. For vertices that lie in the same cluster in $\mathcal{P}$, the map is non-contractive since the distance in the embedding is at least the distance in some walk W_i, which is at least the distance in T. Moreover, the expansion is upper bounded by the length of the walk, which is at most $\Delta(T) \cdot (2R-1)$.

Next, let us consider $p, q \in V(T)$ that fall in different clusters in $\mathcal{P}$. Suppose that $p \in \mathcal{P}(v_i)$, and $q \in \mathcal{P}(v_j)$, for some $i, j \in [t]$, with $i < j$. We have

$$\begin{aligned} |f(p) - f(q)| &\leq 2R(j-1) + \sum_{r=i}^{j} \mathsf{length}(W_i) \leq (j-1)2R + (j-i+1)\Delta(T) \cdot (2R-1) \\ &\leq (j-i) \cdot O(\Delta(T) \cdot R) = d_T(v_i, v_j) \cdot O(\Delta(T) \cdot R) \leq d_T(p, q) \cdot O(\Delta(T) \cdot R). \end{aligned}$$

Moreover $|f(p) - f(q)| \geq 2R(j-i) + 1 \geq 2R + (j-i) \geq d_T(p, v_i) + d_T(v_i, v_j) + d_T(v_j, q) = d_T(p, q)$.

Therefore, in all cases, f is non-contractive and has expansion at most $O(\Delta(T) \cdot R)$. ◀

Online Minimum Cost Matching with Recourse on the Line

Abstract

In online minimum cost matching on the line, n requests appear one by one and have to be matched immediately and irrevocably to a given set of servers, all on the real line. The goal is to minimize the sum of distances from the requests to their respective servers. Despite all research efforts, it remains an intriguing open question whether there exists an $O(1)$-competitive algorithm. The best known online algorithm by Raghvendra [29] achieves a competitive factor of $\Theta(\log n)$. This result matches a lower bound of $\Omega(\log n)$ [3] that holds for a quite large class of online algorithms, including all deterministic algorithms in the literature.

In this work, we approach the problem in a recourse model where we allow to revoke online decisions to some extent, i.e., we allow to reassign previously matched edges. We show an $O(1)$-competitive algorithm for online matching on the line with amortized recourse of $O(\log n)$. This is the first non-trivial result for min-cost bipartite matching with recourse. For so-called alternating instances, with no more than one request between two servers, we obtain a near-optimal result. We give a $(1+\varepsilon)$-competitive algorithm that reassigns any request at most $O(\varepsilon^{-1.001})$ times. This special case is interesting as the aforementioned quite general lower bound $\Omega(\log n)$ holds for such instances.

1 Introduction

Matching problems are among the most fundamental problems in combinatorial optimization with great importance in theory and applications. In the bipartite matching problem, we are given a complete bipartite graph $G = (R \cup S, E)$ with positive edge cost c_e for $e \in E$. Elements of R and S are called *requests* and *servers*, respectively, with $n := |R| \leq |S|$. A *matching* $M \subseteq E$ is a set of pairwise non-incident edges. A matching is called *complete* if every request in R is matched to a server in S, i.e. if it is incident to exactly one edge of M. The task is to compute a complete matching of minimum cost, where the *cost* of a matching M is $c(M) := \sum_{e \in M} c_e$. When all information is given in advance, the optimum can be computed efficiently, e.g., by using the Hungarian Method [22].

In the *online setting*, however, the set of requests is not known a priori. Requests arrive online, one by one, and have to be matched immediately and irrevocably to a unmatched server. As we cannot hope to find an optimal matching under these restrictions, we use standard

competitive analysis to evaluate the performance of algorithms. An online algorithm is α-*competitive* if it computes for any instance a matching M with $c(M) \leq \alpha \cdot \mathrm{OPT}$, where OPT is the cost of an optimal matching. For arbitrary edge costs, the competitive ratio of any online algorithm is unbounded [19,21]. For metric costs, there is a deterministic $(2n-1)$-competitive algorithm and this is optimal for deterministic online algorithms [19, 21]. A remarkable recent result by Nayyar and Raghvendra [27] is a fine-grained analysis of an online algorithm based on *t-net cost* [28] showing a competitive ratio of $O(\mu(G)\log^2 n)$, where $\mu(G)$ is the maximum ratio of minimum TSP tour and weighted diameter of a subset of G.

So far, the online matching problem has resisted all attempts for achieving an $O(1)$-competitive algorithm even for special metric spaces such as the line. In *online matching on the line* the edge costs are induced by a line metric; that is, we identify each vertex of G with a point on the real line and the cost of an edge between a request and a server equals their distance on the line. The competitive ratio of the aforementioned algorithm is then $O(\log^2 n)$, as $\mu(G) = 2$. This has been improved to $\Theta(\log n)$ [29], which is best possible for a large class of algorithms [2]. It remains a major open question whether there exists an $O(1)$-competitive online algorithm (deterministic or randomized) on the line.

In this paper, we consider online matching on the line with *recourse*. In the recourse model, we allow to change a small number of past decisions. Specifically, at any point, we may delete a set of edges $\{(r_i, s_i)\}_i$ of the current matching and rematch the requests r_i to different (free) servers. Online optimization with recourse is an alternative model to standard online optimization which has received increasing popularity recently; see, e.g., [1, 4, 6, 13, 18, 25]. Obviously, if the recourse is not limited then one can just simulate an optimal offline algorithm, and the online nature of the problem disappears. We say an algorithm requires *amortized recourse budget* β if it rematches requests at most βn times in total. The challenging question for online matching on the line is whether it is possible to maintain an $O(1)$-competitive solution with bounded recourse, i.e., with sublinear recourse budget.

Our results. We answer this question to the affirmative and give non-trivial results for the min-cost online matching problem with recourse. We show that with limited recourse, one can indeed maintain a constant competitive solution on the line.

▶ **Theorem 1.** *The online bipartite matching problem on the line admits an $O(1)$-competitive algorithm with amortized recourse budget $O(\log n)$.*

Our algorithm builds on the t-net-cost algorithm by Raghvendra [28, 29]; details follow later. It has the nice property that it interpolates between an $O(\log n)$-competitive online solution (without recourse) and an $O(1)$-approximate offline solution (with large recourse).

Furthermore, we investigate a special class of instances, called *alternating* instances, where between any two requests on the line there is at least one server. This class is interesting as the quite strong lower bound of $\Omega(\log n)$ for a large class of algorithms given in [3], that includes all deterministic online algorithms *without recourse* in literature, holds even on such instances. For alternating instances, we present a more direct and near-optimal algorithm with a scalable performance-recourse trade-off.

▶ **Theorem 2.** *For alternating instances of online matching on the line, there exists a $(1+\varepsilon)$-competitive algorithm that reassigns each request $O(\varepsilon^{-1.001})$ times.*

While the algorithm is quite simple, the proof requires a clever charging scheme that exploits the special structure of optimal solutions on alternating instances. We observe that a large number of recourse actions for a specific request involves large edges in the optimal solution elsewhere on the line.

As a byproduct we give a simple analysis of (a variant of) the algorithm in the traditional online setting without recourse. We show that it is $O(\log \Delta)$-competitive for alternating requests on the line, where Δ is the ratio between the largest and shortest request-server distance. This result compares to $\Theta(\log n)$ for the currently best known online algorithm [29].

▶ Remark. Simultaneously and independently of our work, Gupta, Krishnaswamy and Sandeep [17] obtained a similar result for online min-cost matching with recourse on the line. Their algorithm builds on the $O(n)$-competitive Permutation algorithm [19, 21] and adapts it for the recourse setting. On the line this is done by first matching edges according to Permutation and then asymmetrically applying recourse to arcs (r, s) of the current matching that overlap in a certain way. Both, their algorithm and analysis are completely different from ours. They further obtain a more general $O(\log n)$-competitive algorithm with amortized recourse $O(\log n)$ for arbitrary metrics.

Further related work. Extensive literature is devoted to online bipartite matching problems. The maximum matching variant is quite well understood. For the unweighted setting optimal deterministic and randomized algorithms with competitive ratio 2 and $e/(e-1)$ are known [20]. The weighted maximization setting does not admit bounded guarantees in general, but intensive research investigates models with additional assumptions; see, e.g., the survey [26]. The online min-cost matching problem is much less understood. It remains a wide open question whether a constant-competitive algorithm, deterministic or randomized, is possible for online min-cost matching on the line. In fact, the strongest known lower bound is $9+\varepsilon$ [10]. For a quite large class of algorithms, including all deterministic ones in the literature, there is lower bound of $\Omega(\log n)$ [3].

Randomization allows an improvement upon the best possible deterministic competitive ratio of $(2n-1)$ for metric online bipartite matching [19,21]; there is an $O(\log^2 n)$-competitive randomized algorithm [5]. On the line, no such improvement on the deterministic result by randomization is known; the competitive factor of $O(\log n)$ is the best known result for both, deterministic and randomized, algorithms [16, 29].

Interestingly, when assuming randomization in the order of request arrivals (instead of an adversarial arrival order), the natural Greedy algorithm is n-competitive [11] for general metric spaces. Furthermore, the online *t-net cost* algorithm is in this case $O(\log n)$-competitive [28] here. Very recently, Gupta et al. [14] gave an $O((\log\log\log n)^2)$-competitive algorithm in the model with online known i.i.d. arrivals.

Maintaining an online cardinality-maximal bipartite matching with recourse was studied extensively; see, e.g., [1, 6–8, 12, 30] and references therein. Bernstein et al. [6] showed recently that the 2-competitive greedy algorithm uses amortized $O(n \log^2 n)$ reassignments, leaving a small gap to the lower bound of $\Omega(n \log n)$. In contrast, for the min-cost variant, it remained a challenging question whether recourse can improve upon the competitive ratio. Even on the line, it remained open whether and how recourse can improve the bound of $O(\log n)$ [29].

The following two models address other types of matching with recourse. In a setting motivated by scheduling, several requests can be matched to the same server and the goal is to minimize the maximum number of requests assigned to a server. Gupta et al. [15] achieve an $O(1)$-competitive ratio with amortized $O(n)$ edge reassignments. A quite different two-stage robust model has been proposed recently by Matuschke et al. [24]. In a first stage one must compute a perfect matching on a given graph and in a second stage a batch of $2k$ new nodes appears which must be incorporated into the first-stage solution to maintain a low-cost matching by reassigning only few edges. For matching on the line, they give an algorithm that maintains a 10-approximate matching reassigning $2k$ edges.

Recourse in online optimization has been investigated also for other min-cost problems even though less than for maximization problems. Most notably seems the online minimum Steiner tree problem [13, 18, 23, 25]. Here, one edge reassignment per iteration suffices to maintain an $O(1)$-competitive algorithm [13], whereas the online setting without recourse admits a competitive ratio of $\Omega(\log n)$.

The recourse model has some relation to *dynamic algorithms*. Instead of minimizing the number of past decisions that are changed (recourse), the dynamic model focuses on the running time to implement this change (*update time*). A full body of research exists on maximum (weighted) bipartite matching; we refer to the nice survey in [9]. We are not aware of any results for min-cost matching.

2 Preliminaries

A path P is called *alternating* with respect to a matching M, if every other edge in P is contained in M. An alternating path is called *augmenting* with respect to M if it starts and ends at vertices are not covered by M. A common method for increasing the cardinality of an existing matching M is to augment along an augmenting path P. After augmentation, the resulting matching $\tilde{M}$ is given by the symmetric difference[1] $M \oplus P$. There may be a choice between different augmenting paths; typically, a path of minimum cost (w.r.t. some metric) is selected. Recently, Raghvendra [28] introduced the following metric. For $t > 1$, the *t-net-cost* of a path P w.r.t. a matching M is

$$\phi_t^M(P) \coloneqq t \cdot c(P \setminus M) - c(P \cap M) \;=\; t \cdot c(P \cap \tilde{M}) - c(P \cap M). \tag{1}$$

Our algorithm maintains three matchings: the *recourse matching* M, the actual output of the algorithm, and two auxiliary matchings based on (online and offline versions of) the t-net-cost algorithm [28], namely, the *offline matching* M^* and the *online matching* M'. While M^* is a near-optimal offline matching that possibly requires a large amount of recourse, M' is an online matching that is $O(\log n)$-competitive [29] but uses no recourse. We describe how M^* and M' are obtained based on the above cost function; see also [27–29]. By speaking of the matching M_i, M_i^* or M_i', we refer to the state of the respective matching after serving the i-th request including possible reassignments.

On arrival of the i-th request r_i, the offline t-net-cost algorithm constructs the offline matching M_i^* by augmenting M_{i-1}^* along an alternating path P_i of minimum t-net-cost w.r.t. M_{i-1}^*. That is, $M_i^* \coloneqq M_{i-1}^* \oplus P_i$. By definition, this path starts at r_i and ends at a free server, which we denote by s_i. While this procedure may require a large amount of recourse, the resulting matching has been shown to have bounded cost.

▶ **Lemma 3** (Raghvendra [28]). *For any i and $t > 1$, it holds that $c(M_i^*) \le t \cdot \mathrm{OPT}_i$, where $\mathrm{OPT}_i \coloneqq c(M_i^{\mathrm{OPT}})$ is denotes the cost of an optimal offline matching M_i^{OPT} of the first i requests.*

For constructing the online matching M_i', augmentation along a path is impossible since using recourse is not permitted. Instead, the online t-net-cost algorithm maintains M^* as an auxiliary matching and constructs M_i' by directly connecting the end points r_i and s_i of the augmenting path P_i. That is, $M_i' \coloneqq M_{i-1}' \cup \{(r_i, s_i)\}$. In particular, M_i' and M_i^* utilize the same sets of servers.

[1] For two sets X, Y, their symmetric difference is given by $X \oplus Y \coloneqq (X \cup Y) \setminus (X \cap Y)$. For matchings M_1, M_2, their symmetric difference $M_1 \oplus M_2$ consists of disjoint alternating paths and cycles.

Intuitively, in putting a higher weight on edges that would be added to M^* during augmentation, the parameter t in the t-net cost function discourages the offline t-net-cost algorithm from choosing long paths for augmentation (w.r.t. actual length). This allows for a trade-off between minimizing the cost of the underlying offline matching, and the connection costs in M' (with the latter in a greedy fashion). Looking at the extremal cases, this becomes even more clear. When $t = 1$, the offline t-net-cost algorithm is in fact equivalent to the Hungarian Method [22] which computes an optimal offline solution. The corresponding online matching, however, has a competitive ratio of $\Omega(n)$. In contrast, as t tends to infinity, the algorithm's behavior resembles that of the greedy online algorithm matching a request to the nearest free server. Its competitive ratio can be exponential [19]. Interestingly though, when $t = 3$, the t-net-cost algorithm has a competitive ratio of $O(\log n)$ [29].

3 A Constant-Competitive Algorithm

We start by giving an overview of our algorithm for the recourse model. It exploits the properties of the t-net-cost algorithm by carefully balancing between the offline matching M^* and the online matching M', simultaneously bounding competitive ratio and recourse budget. On a high level, this is done as follows. When a request arrives, we match it as in M' and locally group it with other recent requests into *blocks* that partition the line. Matching requests as in the online matching within a block somewhat increases total cost but requires zero recourse. A structural result, Lemma 8, allows us to bound this increase in cost up to a certain point at which the requests in the block are matched according to M^* causing a local update. During such an update, which we call a *recourse step*, the changes in M^* caused by the arrivals of the requests in the respective block are applied simultaneously, eliminating any redundant recourse actions. Intuitively, blocks can therefore be seen as input buffers for M^* that temporarily use edges from M'. The underlying structure of the blocks guarantees that recourse steps affect only the corresponding portion of the line. To prevent the recourse steps from causing too many reassignments, we additionally incorporate an edge freezing scheme that targets low-cost edges and at the same time keeps the overall cost low.

Given the precise value of OPT and n a priori, one could employ a very simple freezing scheme, which freezes all edges of M' with cost $\frac{\mathrm{OPT}}{n}$ or less. However, in the online model, we do not know OPT or n and, thus, need a dynamic freezing scheme. A typical guess-and-double approach may work concerning the costs. Yet, care has to be taken as $\frac{\mathrm{OPT}_i}{i}$ is not monotone. A major obstacle appears to be the bounding of the recourse budget. Details on our algorithm and dynamic freezing scheme are given in Section 3.

In Section 4, we consider alternating instances. Again, we simulate the offline matching M^* and employ a simple freezing scheme. After a request reaches a certain threshold of reassignments, we freeze this request and the currently associated matching edge. We charge detours that are taken due to frozen edges to large non-frozen edges of M^{OPT}.

3.1 Further Definitions and Notation

Our algorithm classifies requests according to the structure of intervals that describe where on the line the t-net-cost algorithm searches for a free server. Define the *search interval* of a request r_i as the open interval $\bar{\mathrm{I}}_i = (s_i^{\mathrm{L}}, s_i^{\mathrm{R}})$, where s_i^{L} and s_i^{R} are points on the line farthest to the left and right of r_i, respectively, reachable from r_i with t-net-cost $\phi_t^{M_{i-1}^*}(P_i)$. One of $s_i^{\mathrm{L}}, s_i^{\mathrm{R}}$ is the server s_i (which r_i is matched to in M'), see Lemma 6, while the other may not necessarily be a point of $R \cup S$. For the purposes of this definition, we think of it as a (virtual) server. That is, we ask the question "If point p was a server in S, would

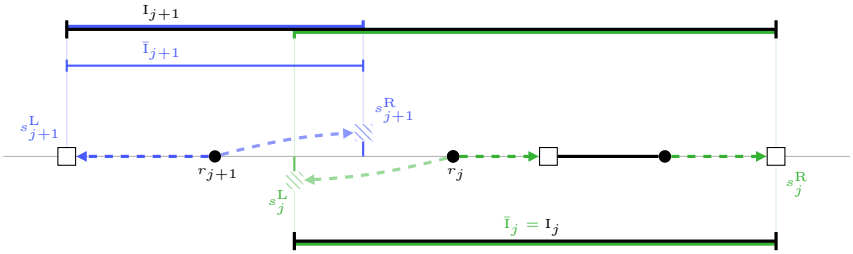

Figure 1 Construction of search intervals and aggregate search intervals of requests r_j and r_{j+1}. The points s^{L}_j and s^{R}_{j+1} (hatched) are points on the line that do not lie in S. We think of them as virtual servers for the purpose of defining $\bar{\mathrm{I}}_j$ and $\bar{\mathrm{I}}_{j+1}$ respectively.

we be able to reach it with t-net-cost $\phi_t^{M^*_{i-1}}(P_i)$?". In other words, $\bar{\mathrm{I}}_i$ is the convex hull of all points on the line, reachable from r_i via an augmenting path of t-net-cost (strictly) less than $\phi_t^{M^*_{i-1}}(P_i)$.

Define the *aggregate search interval* of r_i to be the maximal (open) interval I_i which contains r_i and is a subset of $\bigcup_{j\le i}\bar{\mathrm{I}}_j$. Intuitively, $\bigcup_{j\le i}\bar{\mathrm{I}}_j$ consists of the (disjoint) portions of the line, which the t-net-cost algorithm has considered, up to time i, in its search for free servers; the interval I_i is simply the portion containing r_i. See Figure 1 for an illustration. By definition, the portions of the line constituting $\bigcup_{j\le i}\bar{\mathrm{I}}_j$ grow monotonously (and possibly merge). Thus, the aggregate search intervals inhibit a laminar structure as detailed in the following observation.

▷ Observation 4. Whenever $i < j$, then either $\mathrm{I}_i \cap \mathrm{I}_j = \emptyset$ or $\mathrm{I}_i \subseteq \mathrm{I}_j$.

Another important observation is the fact, that the arrival of a request r_i only affects requests and servers in its search interval $\bar{\mathrm{I}}_i$. This is due to the fact that the augmenting path used by the t-net-cost algorithm is entirely contained in the search interval. Outside of $\bar{\mathrm{I}}_i$, the matchings M^* and M' remain unchanged motivating the following observation.

▷ Observation 5. Altering the arrival order of requests via a permutation π for which $\mathrm{I}_i \subseteq \mathrm{I}_j$ and $i < j$ imply $\pi(i) < \pi(j)$ does not alter the final matching.

We say an aggregate search interval I_i has *level* k, if $(1+\varepsilon)^{k-1} \le |\mathrm{I}_i| < (1+\varepsilon)^k$ and write $\ell(\mathrm{I}_i) = k$. Throughout, we set $t = 3$ and $\varepsilon = \frac{1}{32t}$. Further, two aggregate search intervals are said to belong to the same *block*, if they intersect with each other and are of same level. If the aggregate search intervals of a block do not intersect those of higher level, then this block is said to be a *top block*. With Observation 5 in mind, we note that the top blocks partition the line into portions that are compatible with the structure of M^*. A typical block-structure is depicted in Figure 2.

Our definition of search intervals was motivated by intuition and practicality (specifically for the proof of Lemma 12 later on). However, it describes intervals different from the search intervals defined in [29]. The following lemma shows that our definition of aggregate search intervals coincides with Raghvendra's definition of *intervals of a cumulative search region*. We may therefore use the corresponding results from [29].

▶ **Lemma 6.** *For a request r_i, the corresponding aggregate search interval I_i and interval of a cumulative search region C_i are equal. Further, for the search interval $\bar{\mathrm{I}}_i = (s^{\mathrm{L}}_i, s^{\mathrm{R}}_i)$, we have $s_i \in \{s^{\mathrm{L}}_i, s^{\mathrm{R}}_i\}$.*

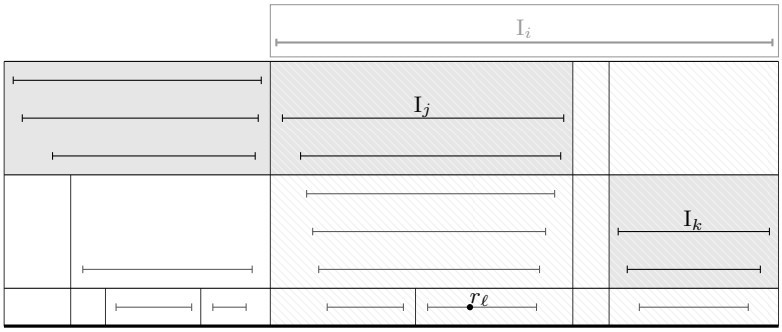

Figure 2 Illustration of a typical block structure. On arrival of r_i, its aggregate search interval I_i creates a top block (active) initiating a recourse step. Requests in the hatched area (now inactive) are reassigned w.r.t. $M^*_{i-1} \oplus M^{\mathrm{F}}_i$. On I_i, locally, $M^*_{i-1} = M^*_h$ for $j, k \leq h < i$.

Proof. To see that the first claim holds, note that the intervals C_i and I_i are constructed the same way. They are built by by taking the union of all known search intervals (for the respective definition) and choosing of the resulting new intervals that which contains the considered request. The definition of search intervals in [29], which, to avoid confusion, we call *dual intervals*, is as follows. The t-net-cost algorithm maintains dual values $y : S \cup R \to \mathbb{R}^+$ satisfying $y_s + y_r = c_{(s,r)}$ if $(s,r) \in M^*$ and $y_s + y_r \leq t \cdot c_{(s,r)}$ otherwise. Additionally, duals of free requests or servers are zero. When a request r_i arrives, a shortest t-net-cost path P_i is found and the duals of all vertices in the search tree (denoted by $A_i \subseteq S$ and $B_i \subseteq R$) are updated before augmentation so that the dual constraints on P_i are tight. This is true for both augmenting paths P^{L}_i and P^{R}_i that are used to reach s^{L}_i and s^{R}_i respectively. A dual interval of a request r_i is defined as $\mathit{interior}(\bigcup_{r \in B_i} \mathit{cspan}(r,i))$, where $\mathit{cspan}(r,i) = [r - \frac{y^i_{\max}(r)}{t}, r + \frac{y^i_{\max}(r)}{t}]$ and $y^i_{\max}(r)$ is the highest dual weight assigned to r until time i.

Raghvendra [28] shows, that the dual constraints on P^{L}_i and P^{R}_i are tight before augmentation. Therefore, we obtain our search intervals I_i by replacing $y^i_{\max}(r)$ with the dual weight of r before augmentation along P_i. Hence, a search interval is contained in the dual interval and therefore $\mathrm{I}_i \subseteq C_i$. At the same time, dual weights of requests are increased when the request is contained in some B_i as detailed above or reduced right after an augmentation. Thus, the maximal value $y^i_{\max}(r)$ is attained right before an augmentation, in which case the request is part of some P^{L}_h or P^{R}_h, implying $C_i \subseteq \mathrm{I}_i$. Therefore, the intervals I_i and C_i coincide and we may use the respective results from [29].

The second claim follows directly from Lemma 6 in [29], which states that there are no free servers in the dual interval. As seen above, search intervals are contained in dual intervals, so this statement is true for our definition as well. And lastly, since clearly $s_i \in [s^{\mathrm{L}}_i, s^{\mathrm{R}}_i]$, it follows that $s_i \in \{s^{\mathrm{L}}_i, s^{\mathrm{R}}_i\}$. ◀

3.2 The Algorithm

Our algorithm uses the above structures to partition the requests (dynamically) into three groups. For each group, we follow a different assignment procedure to construct our recourse matching M. We first give some intuition and then, further below, the precise description.

Group 1: The first group consists of all requests whose aggregate search intervals belong to a top block. We label requests in this group *active* and all other requests *inactive*. In M, we match an active request r_i exactly as in the online matching M'. That is, we have e_i

in M, where $e_i = (r_i, s_i) \in M'$ connects the endpoints of the minimum t-net-cost augmenting path P_i with respect to M^*_{i-1} (Algorithm 1, Step 1). In particular, any arriving request belongs immediately to a top block and is labeled active, by definition of aggregate search intervals. In the course of the algorithm's execution new blocks may appear (on top) rendering previously active requests inactive. We call this a *recourse step*.

Group 2: This group consists of inactive requests r_i, whose corresponding edge $e_i \in M'$ is of negligible size. The precise freezing scheme (Algorithm 1, Steps 2-4) is detailed below. Intuitively, it is not worth to spend recourse on them; it would ruin our recourse budget, see Figure 4. We call such a request or edge *frozen* and denote by $F_j \subseteq M'_j$ the set of frozen edges at time j. These requests, too, are to be matched in M according to the online matching M'. However, for technical reasons, the update on M for a newly frozen request is implemented with a subsequent recourse step. Denote by $M^{\mathrm{F}}_j \subseteq F_j$ the subset of frozen edges that is in $M_j \cap M'$. Their low costs ensures that frozen edges contribute in total at most OPT to the cost of M.

Group 3: The remaining requests (inactive and unfrozen) are in this group. Ideally, we would like to match these as in the offline matching M^*. This may not be possible, as M^* could assign a request r to a server s that is already covered by M^{F}. In such a case, we match r via a detour of low additional cost as follows; we call this *detour matching*.

Detour Matching. Consider an unfrozen request r and the symmetric difference $M^* \oplus M^{\mathrm{F}}$ consisting of alternating paths and cycles. There exists a (unique) alternating path P from r to some server s' not yet matched via M^{F}. To see this, note that the path starts with the edge $(r, s) \in M^*$ which cannot be contained in an alternating cycle as r is not frozen. Additionally, it cannot end at a request, since every request on P is reached via an edge of M^{F}. But since a request on P matched in M^{F} is certainly also matched (via a different edge) in M^*, it can be used to extend P. Thus, P ends at a server s' not matched in M^{F}. In M, we match r directly to this server s' (Alg. 1, Step 7). While the online matching M' does not change but only gets revealed over time, the offline matching M^* can change its structure drastically at any point. As this causes a lot of recourse, the first group is used as an input buffer and the detour matching is updated only periodically and locally, whenever a new top block appears. Specifically, at time i, an inactive request r_j is matched with respect to the detour matching $M^*_{h(i,j)} \oplus M^{\mathrm{F}}_i$, where $h(i,j) = \max\{k \leq i \mid r_j \in \mathrm{I}_k$ and I_k is not in a top block$\}$. That is, $h(i,j)$ is the last time before i when r_j participated in a recourse step. For an example, see Figure 2, where $h(i,\ell) = j$.

When considering active, inactive or frozen objects, or membership in a block, we identify a request r_i, the edge $e_i \in M'$ and the interval I_i. For instance, we say r_i is of level k and belongs to a certain block, when this holds for I_i, or, e_i is active when this is the case for r_i.

We describe Algorithm 1 in a step-by-step manner and detail the precise freezing scheme. On arrival of a request r_i, label it active and match it according to the online matching M'.

Freezing/unfreezing inactive requests. We update the set of frozen edges as follows. If the cost of an inactive edge $e_j \in M'$ falls below $\frac{\mathrm{OPT}_i}{i^2}$, then freeze it and add it to F_i. Note that while we use e_j to determine whether r_j is frozen, r_j may use another edge in M_i.

If for a previously frozen e_j, we have $c_{e_j} > \frac{\mathrm{OPT}_i}{i}$, unfreeze and delete it from F_i and M^{F}_i. Matching it according to M' is now too costly. Reassign it w.r.t. $M^*_{h(i,j)} \oplus M^{\mathrm{F}}_i$ as follows.

Consider an edge $e = (s, r)$ right before it is unfrozen. If e is already matched according to the offline matching, then there is nothing to do. Otherwise, it must be part of an alternating path or cycle in $M^* \oplus M^{\mathrm{F}}$. In the latter case, again, no recourse action needs to be taken as

Algorithm 1 for computing an online bipartite matching with recourse on the line.

On arrival of the i-th request r_i: ▷ r_i matched in M' via $e_i = (r_i, s_i)$
1: match r_i to s_i as in M' ▷ active
Freezing/Unfreezing
2: determine the set F_i of frozen edges
3: **for** inactive requests r_j that become unfrozen **do**
4: remove e_j from M_i^{F} and repair assignments on corresponding path of $M^*_{h(i,j)} \oplus M_i^{\mathrm{F}}$
Recourse step (new top block)
5: **if** there is no $j < i$ such that $\mathrm{I}_j \subseteq \mathrm{I}_i$ and $\ell(\mathrm{I}_j) = \ell(\mathrm{I}_i)$ **then**
6: **for** $r_j \in \mathrm{I}_i$ recently frozen **do** add $e_j = (r_j, s_j)$ to M_i^{F} and reassign r_j to s_j
7: **for** unfrozen $r_j \in \mathrm{I}_i \setminus \{r_i\}$ **do** reassign r_j according to $M^*_{i-1} \oplus M_i^{\mathrm{F}}$ ▷ now inactive

Figure 3 Illustration of Step 4 in Algorithm 1. Edges of M^* are snaked, edges of M^{F} solid and edges of $M \setminus M^{\mathrm{F}}$ dashed. After unfreezing r, the removal of (r, s) splits the path in $M^* \oplus M^{\mathrm{F}}$ in two parts.

the removal of e results in a path from r to s. In the detour matching, we want to connect the ends of this path, which is already accomplished by the edge $e = (s, r)$. Consider the case that $e \in P$ for some alternating path P in $M^* \oplus M^{\mathrm{F}}$ that starts in a request r' and ends in a server s'. Unfreezing e and matching according to $M^* \oplus M^{\mathrm{F}}$ decomposes P into the r'-s-path P_1 and the r-s'-path P_2. In Algorithm 1, we implement these changes via two recourse actions: we reassign r to s' and r' to s; see Figure 3.

Recourse step. If there is no $j < i$ such that $\mathrm{I}_j \subseteq \mathrm{I}_i$ and $\ell(\mathrm{I}_j) = \ell(\mathrm{I}_i)$, then the arrival of r_i produces a new top block and may render a number of previously active requests inactive. This triggers, what we call a *recourse step* involving a number of recourse actions to accommodate the newly inactive requests as follows.

First, assign requests in I_i that were recently frozen according to M' and add the corresponding edge to M_i^{F}. Next, reassign all other requests (non-frozen, inactive) that lie in I_i according to $M^*_{i-1} \oplus M_i^{\mathrm{F}}$. We described this as detour matching above; see Figure 2.

Delaying the reassignment of frozen requests according to the frozen edge until their next recourse step, prevents reassignments when a request repeatedly alternates between frozen and unfrozen. This "delayed reassignment" accounts for the difference between M_i^{F} and F_i.

To see that the freezing scheme is indeed necessary, consider the example in Figure 4 showing an alternating instance with exponentially increasing edge costs. Without freezing low-cost edges, at the arrival of any request r_i with $i > 2$, all requests r_j with $j < i$ are reassigned. Thus, the recourse budget is linear.

Bounding the competitive ratio. The work already put into structuring M enables us to bound its cost rather easily. Recall that $c(M^*) \leq t \cdot \mathrm{OPT}$ due to Lemma 3. Frozen edges satisfy $c(M^{\mathrm{F}}) \leq \mathrm{OPT}$ as, after arrival of the last request, there are at most n frozen edges of cost at most $\frac{\mathrm{OPT}}{n}$ each. By triangle inequality, the contribution of inactive non-frozen requests to the cost of M is at most $c(M^* \oplus M^{\mathrm{F}}) \leq (t+1) \cdot \mathrm{OPT}$.

▷ Observation 7. The cost of inactive edges is at most $(t+2) \cdot \mathrm{OPT}$.

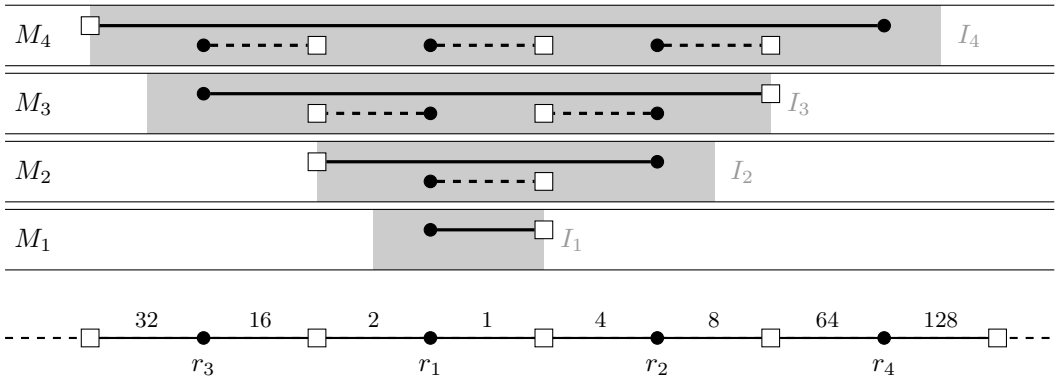

Figure 4 An alternating instance with exponentially increasing connection costs. Edge costs are indicated above the corresponding portion of the line (drawing not to scale). Note that the aggregate search intervals grow exponentially in size. Therefore, a (top) block consists of a single aggregate search interval only and every arrival of a request triggers a recourse step. Active edges are drawn solid, inactive edges dashed.

To bound the cost of active edges, we build on the analysis of Raghvendra [29]. We refine his technical propositions and perform a slightly more fine-grained analysis. Instead of simultaneously bounding the cost of all blocks of the same level, we argue more generally on the cost of any set of disjoint blocks at different levels. In particular, we are interested in bounding the cost contribution of the top blocks.

▶ **Lemma 8.** *For $t = 3$, the cost of all active edges of M is bounded by $O(\mathrm{OPT})$.*

To prove this lemma, we may closely follow the argumentation given in [29] for the online problem without recourse. In fact, there is given essentially the same statement for all edges of blocks of a particular level. We can adapt the approach, crucially using Observation 5, to make the arguments work for (disjoint) blocks of different levels. We leave the detailed proof for the full version.

▶ **Corollary 9.** *Algorithm 1 has a constant competitive ratio.*

Bounding the recourse. Due to delayed reassignments, freezing a request r does not cause any immediate recourse actions. Unfreezing r, on the other hand, may cause reassignments (Step 4), namely to r and possibly one additional request, see Figure 3. We charge these two recourse actions to r, in particular to the last recourse step it participated in. However, recourse due to unfreezing r happens at most once between two consecutive recourse steps of r. This implies, that a request is charged at most three times per recourse step it participates in, once for the recourse step itself and possible two times more for a subsequent unfreezing.

▷ Observation 10. A request is charged at most three times per recourse step it is involved in.

For a request getting frozen at time i and unfrozen at time $j > i$, we have $c_e \leq \frac{\mathrm{OPT}_i}{i^2}$ and $c_e > \frac{\mathrm{OPT}_j}{j}$ for the corresponding $e \in M'$. As $\mathrm{OPT}_i \leq \mathrm{OPT}_j$, this implies the following.

▷ Observation 11. A request frozen at time i stays frozen until time at least i^2.

On the other hand, the number of recourse steps in which a continuously non-frozen request takes part in can be bounded from above.

▶ **Lemma 12.** *If a request $r \in \mathrm{I}_i \subseteq \mathrm{I}_j$ is not frozen from time i to time j, then it holds that $\ell(\mathrm{I}_j) - \ell(\mathrm{I}_i) = O(\log j)$. In particular, between time i and j, there are $O(\log j)$ recourse steps in which r can participate.*

Proof. Consider the search interval $\bar{\mathrm{I}}_j = (s_j^{\mathrm{L}}, s_j^{\mathrm{R}})$. By definition of search intervals, there exist augmenting paths $P_j^{\mathrm{L}}, P_j^{\mathrm{R}}$ connecting r_j to s_j^{L} and s_j^{R} with the same t-net-cost as P_j, the path used by the t-net-cost algorithm. We bound the length of $P_j \in \{P_j^{\mathrm{L}}, P_j^{\mathrm{R}}\}$ by

$$c(P_j) = c(P_j \cap M_{j-1}^*) + c(P_j \cap M_j^*) \leq 2t \cdot \mathrm{OPT}_j. \tag{2}$$

Without loss of generality, assume $P_j = P_j^{\mathrm{L}}$. Interpreting the point s_j^{R} as a virtual server and assuming that it is a contained in S, we could augment M_{j-1}^* also along P_j^{R} yielding a different matching $\tilde{M}_j^*$. By definition of P_j^{R} and Equation (1), we have

$$t \cdot c(P_j \cap M_j^*) - c(P_j \cap M_{j-1}^*) = \phi_t^{M_{j-1}^*}(P_j) = \phi_t^{M_{j-1}^*}(P_j^{\mathrm{R}}) = t \cdot c(P_j^{\mathrm{R}} \cap \tilde{M}_j^*) - c(P_j^{\mathrm{R}} \cap M_{j-1}^*).$$

Thus,

$$\begin{aligned} c(P_j^{\mathrm{R}}) &= c(P_j^{\mathrm{R}} \cap M_{j-1}^*) + c(P_j^{\mathrm{R}} \cap \tilde{M}_j^*) \\ &\leq c(P_j^{\mathrm{R}} \cap M_{j-1}^*) + c(P_j \cap M_j^*) + \tfrac{1}{t} c(P_j^{\mathrm{R}} \cap M_{j-1}^*) \leq 3t \cdot \mathrm{OPT}_j. \end{aligned}$$

From Equation (2), we get $|\bar{\mathrm{I}}_j| \leq c(P_j^{\mathrm{L}}) + c(P_j^{\mathrm{R}}) \leq 5t \cdot \mathrm{OPT}_j$, which implies $|\mathrm{I}_j| \leq \sum_{k \leq j} |\bar{\mathrm{I}}_k| \leq 5t \cdot j \cdot \mathrm{OPT}_j$. On the other hand, the cost of $|\mathrm{I}_i|$ can be bounded from below by c_e, where e is the edge in M' incident to r, as both ends of e are contained in the interval. We then obtain

$$\frac{|\mathrm{I}_j|}{|\mathrm{I}_i|} \leq \frac{5t \cdot j \cdot \mathrm{OPT}_j}{c_e} < 5t \cdot j^3.$$

The last inequality follows from the assumption that r is not frozen at time j, implying that $c_e > \frac{\mathrm{OPT}_j}{j^2}$. Recall that $|\mathrm{I}_i| < (1+\varepsilon)^{\ell(\mathrm{I}_i)}$ and $(1+\varepsilon)^{\ell(\mathrm{I}_j)-1} \leq |\mathrm{I}_j|$. We conclude

$$\ell(\mathrm{I}_j) - \ell(\mathrm{I}_i) \leq 1 + \log_{(1+\varepsilon)}(5t \cdot j^3) = 1 + \log_{(1+\varepsilon)}(5t) + \frac{\log j}{\log(1+\varepsilon)} \leq \; c \cdot \log j\,, \tag{3}$$

for some constant c. Regarding the second claim, recall that r participates in a recourse step when an interval containing r opens a new top block (i.e. a new level) while r is not (freshly) frozen. Between time i and time j, this can only happen for intervals I_h of distinct levels for which $\mathrm{I}_i \subseteq \mathrm{I}_h \subseteq \mathrm{I}_j$. The claim follows. ◀

Lemma 12 and Observation 11 bound the total number of recourse actions taken by Algorithm 1.

▶ **Lemma 13.** *Algorithm 1 uses a recourse budget of at most $O(\log n)$.*

Proof. Consider a request r. By Observation 10, it suffices to bound the number of recourse steps that r is involved in. Let $[i_h^U, i_h^F]$, for $h = 0, 1, \ldots, k$, be maximal intervals of consecutive time points during which r is not frozen, i.e., r is not frozen at any time $i \in [i_h^U, i_h^F]$. We use induction on k to show that r participates in at most $2c \cdot \log(i_k^F)$ recourse steps, where c is the constant from Equation (3). The base case, $k = 0$, follows directly from Lemma 12. For $k \geq 1$, we have $(i_{k-1}^F)^2 \leq i_k^U \leq i_k^F$ due to Observation 11. By induction hypothesis, the number of reassignments that involve r in the first $k-1$ time intervals is at most

$$2c \cdot \log(i_{k-1}^F) \leq 2c \cdot \log\left(\sqrt{i_k^F}\right) = c \cdot \log(i_k^F).$$

For the last time interval, we have at most $c \cdot \log(i_k^F)$ many such recourse steps by Lemma 12. Since $i_k^F \leq n$, this concludes the proof. ◀

Corollary 9 and Lemma 13 together imply Theorem 1.

4 A Near-Optimal Algorithm on Alternating Instances

For alternating instances, we may assume that requests and servers alternate from $-\infty$ to ∞ on the line, with servers at $\pm\infty$. For such instances, an optimum matching matches all requests either to the server directly to their left or all requests to the server on their right. Denote these matchings by M^{L} and M^{R} respectively and call their edges *minimal*.

We describe a $(1+\varepsilon)$-competitive algorithm for alternating instances that reassigns each request at most a constant number of times. In addition to its output M, it maintain M^* and a set of frozen edges M^{F}. A request is frozen when it is reassigned the k-th time, for some k only depending on ε. The request remains matched to its current server perpetually and the corresponding edge is added to M^{F}. Non-frozen requests are matched according to the detour matching $M^* \oplus M^{\mathrm{F}}$ as described in Section 3. By design, the recourse budget per request is constant, only the competitive analysis remains.

Notation. We use a similar interval structure as before and keep the notation. Consider intervals $\mathrm{I}_i = [s_i^{\mathrm{L}}, s_i^{\mathrm{R}}]$, where $s_i^{\mathrm{L}}, s_i^{\mathrm{R}} \in S$ are the closest free servers on the line to the left and right of r_i respectively at the time of its arrival. Denote by $P_i^{\mathrm{L}}, P_i^{\mathrm{R}}$ the alternating paths connecting r to s_i^{L} and s_i^{R} respectively that have shortest t-net-cost.

Considered as line segments, the augmenting paths P_i have a laminar structure. We view them as nodes of a forest, where P_i is a child of the minimal augmenting path that properly contains it, or a root if no such path exists (see Figure 5). The *depth* of a path P_i denotes its distance to the root and determines the number of reassignments of the corresponding request r_i in M^*.

▶ **Lemma 14.**

(i) *The paths $P_i^{\mathrm{L}}, P_i^{\mathrm{R}}$ and the matching M_i^* only use minimal edges.*

(ii) *If $P_i = P_i^X$, for $X \in \{\mathrm{L}, \mathrm{R}\}$, then in the area of I_i, locally, we have that $M_i^* = M^{\mathrm{X}}$. Specifically, this implies $\phi_t^{M_{i-1}^*}(P_i) = \phi_t^{M^Y}(P_i)$ for $X \neq Y \in \{\mathrm{L}, \mathrm{R}\}$.*

(iii) *If P_j is a child of P_i, then $P_i = P_i^{\mathrm{L}}$ if and only if $P_j = P_j^{\mathrm{R}}$. In particular, we have $\mathrm{I}_j \subseteq P_i$ and $\mathrm{I}_j \cap M_j^* \cap M_i^* = \emptyset$.*

Proof. (i): We use induction on i. The base case, $i = 1$, is easy. Let $i \geq 2$. Without loss of generality $P_i = P_i^{\mathrm{R}}$. Assume P_i contains a non-minimal edge e. Let the notation (s, r) for an edge reflect that s is to the left of r on the line. Edges $(s, r) \in P_i$ are contained in M_{i-1}^* and by induction hypothesis minimal, so $e = (r, s) \in M_i^*$. Consider the server s' right of r. Since e is not minimal, $r < s' < r' < s$, with r' being the server right of s'. If s' was free, altering P_i to go from r directly to s' would yield a lower cost. This follows from the fact that the t-net-cost of a path from a request to a free server is always non-negative, see [28]. If s' is matched, it must be matched to r'. Therefore, replacing e by $(r, s'), (s', r'), (r', s)$ reduces the cost as well, contradicting the minimality of P_i.

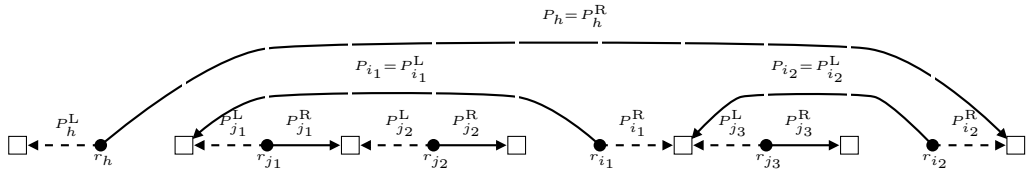

Figure 5 Illustration of a path tree in an alternating instance. Paths not chosen for augmentation are dashed. Servers are depicted as squares and requests as filled circles.

(ii): By statement (i), P_i^{L} and P_i^{R} only consist of minimal edges. Then $P_i^{\mathrm{L}} \cap M_{i-1}^* = M^{\mathrm{R}}$ and $M_{i-1}^* \cap P_i^{\mathrm{R}} = M^{\mathrm{L}}$. After augmenting M_{i-1}^* along P_i, the matching is flipped (locally).

(iii): By (ii), we know that $M_j^* \cap \mathrm{I}_j = M^{\mathrm{X}}$, say $X = R$, so edges are of the form (r, s). From part (i), only augmenting paths $P_h = P_h^{\mathrm{L}}$ can traverse them. If this happens, all of I_j is traversed as there is no free server in its interior. As parent of P_j, P_i is the first path to properly contain P_j and thus $P_i = P_i^{\mathrm{L}}$ and in particular $\mathrm{I}_j \subseteq P_i$. Therefore, the equation $\mathrm{I}_j \cap M_j^* \cap M_i^* = \emptyset$ follows directly from (ii). ◀

The above lemma can be used to show that the sum of lengths of augmenting paths of some depth grows exponentially towards the root. For a path P_h, denote by $|P_h|$ the length of the corresponding line segment. Further, let $\mathcal{H}_k$ be the set of indices of paths at depth k in the induced subtree of P_h with the root P_h at depth 0.

▶ **Lemma 15.** *Consider a path P_h and its grandchildren P_j, for $j \in \mathcal{H}_2$. Then*

$$|P_h| \geq \left(2 - \tfrac{1}{t}\right) \cdot \sum_{j \in \mathcal{H}_2} |P_j|.$$

Proof. Denote by P_i, $i \in \mathcal{I} = \mathcal{H}_1$, children of P_h in the path-forest and by $\mathcal{J}_i \subseteq \mathcal{J} = \mathcal{H}_2$ the sets of indices of their respective children. Without loss of generality, assume $P_h = P_h^{\mathrm{R}}$. Lemma 14, (iii), implies $P_i = P_i^{\mathrm{L}}$, and $P_j = P_j^{\mathrm{R}}$, for $i \in \mathcal{I}, j \in \mathcal{J}$; see Figure 5. With again Lemma 14, (iii), and $\phi_t^{M_{i-1}^*}(P_i^{\mathrm{R}}) \geq \phi_t^{M_{i-1}^*}(P_i^{\mathrm{L}})$, we get

$$\begin{aligned} t \cdot |P_h| &\geq t \cdot \sum_{i \in \mathcal{I}} |I_i| = t \cdot \sum_{i \in \mathcal{I}} \left(|P_i^{\mathrm{L}}| + |P_i^{\mathrm{R}}|\right) \geq \sum_{i \in \mathcal{I}} \left(t \cdot |P_i^{\mathrm{L}}| + \phi_t^{M_{i-1}^*}(P_i^{\mathrm{R}})\right) \\ &\geq t \cdot \sum_{j \in \mathcal{J}} |P_j^{\mathrm{R}}| + t \cdot \sum_{i \in \mathcal{I}} |P_i \setminus (\cup_{j \in \mathcal{J}_i} P_j^{\mathrm{R}})| + \sum_{i \in \mathcal{I}} \phi_t^{M_{i-1}^*}(P_i^{\mathrm{L}}). \end{aligned} \tag{4}$$

Using Lemma 14, we get

$$\begin{aligned} \phi_t^{M_{i-1}^*}(P_i^{\mathrm{L}}) = \phi_t^{M^{\mathrm{R}}}(P_i^{\mathrm{L}}) &= \sum_{j \in \mathcal{J}_i} \left(\phi_t^{M^{\mathrm{R}}}(P_j^{\mathrm{L}}) + \phi_t^{M^{\mathrm{R}}}(P_j^{\mathrm{R}})\right) + \phi_t^{M^{\mathrm{R}}}(P_i \setminus (\cup_{j \in \mathcal{J}_i} \mathrm{I}_j)) \\ &\geq \sum_{j \in \mathcal{J}_i} \left(\phi_t^{M_{j-1}^*}(P_j^{\mathrm{L}}) + \phi_t^{M^{\mathrm{R}}}(P_j^{\mathrm{R}})\right) - t \cdot |P_i \setminus (\cup_{j \in \mathcal{J}_i} \mathrm{I}_j)|. \end{aligned}$$

Since $\phi_t^{M_{j-1}^*}(P_j^{\mathrm{L}}) \geq \phi_t^{M_{j-1}^*}(P_j^{\mathrm{R}}) = \phi_t^{M^{\mathrm{L}}}(P_j^{\mathrm{L}})$, the above together with Equation (4) implies

$$t \cdot |P_h| \geq \sum_{j \in \mathcal{J}} \left(t \cdot |P_j^{\mathrm{R}}| + \phi_t^{M^{\mathrm{L}}}(P_j^{\mathrm{L}}) + \phi_t^{M^{\mathrm{R}}}(P_j^{\mathrm{R}})\right) \geq (2t - 1) \cdot \sum_{j \in \mathcal{J}} |P_j^{\mathrm{R}}|,$$

where last inequality follows from the observation that $\phi_t^{M^{\mathrm{L}}}(P) + \phi_t^{M^{\mathrm{R}}}(P) = (t-1) \cdot |P|$. ◀

Proof of Theorem 2. We in fact prove a stronger result than in the theorem statement and show that the algorithm described in the beginning of this section is $(1+\varepsilon)$-competitive while reassigning each request at most $O(\varepsilon^{-(1+\lambda)})$ times for fixed $\lambda > 0$. Consider a path P_h. The intervals I_j, $j \in \mathcal{H}_{2k+2}$, are contained in paths $P_{j'}$, $j' \in \mathcal{H}_{2k+1}$, by Lemma 14, (iii). Lemma 15 implies

$$\textstyle\sum_{j \in \mathcal{H}_{2k+2}} |I_j| \leq \sum_{j' \in \mathcal{H}_{2k+1}} |P_{j'}| \leq \left(2 - \frac{1}{t}\right)^{-k} \cdot \sum_{i \in \mathcal{H}_1} |P_i|. \tag{5}$$

Raghvendra [28] shows that the t-net-cost of augmenting paths is always non-negative. In particular, $\phi_t^{M_{h-1}^*}(P_h) = t \cdot c(P_h \cap M_h^*) - c(P_h \cap M_{h-1}^*) \geq 0$, and thus

$$|P_h| = c(P_h \cap M_h^*) + c(P_h \cap M_{h-1}^*) \leq (t+1) \cdot c(P_h \cap M_h^*). \tag{6}$$

Similarly, $\sum_{i\in\mathcal{H}_1}|P_i| \le (t+1)\cdot\sum_{i\in\mathcal{H}_1} c(P_i\cap M_i^*) \le (t+1)\cdot c(P_h\cap M_i^*)$. In an interval I_i, locally, $M_h^* = M^{\mathrm{L}}$ if and only if $M_i^* = M^{\mathrm{R}}$ by Lemma 14 (ii). With (5) and (6), this implies

$$\left[\tfrac{1}{t+1}\left(2-\tfrac{1}{t}\right)^k - 1\right]\cdot \sum_{j\in\mathcal{H}_{2k+2}} |\mathrm{I}_j| \le c\left(P_h \setminus (\cup_{j\in\mathcal{H}_{2k+2}}\mathrm{I}_j)\cap M^{\mathrm{X}}\right), \quad X\in\{\mathrm{L},\mathrm{R}\}. \tag{7}$$

Denote by $\alpha(k,t)$ the term in square brackets. When a (minimal) edge is frozen, the remaining instance is again alternating and at most one request will take a detour due to (r,s) being frozen. The additional cost is bounded by $|\mathrm{I}_r|$ and can, via Equation (7), be charged to non-frozen parts of M^{OPT}. A part $P_h\cap M^{\mathrm{OPT}}$ is charged this way at most $2k+2$ times before P_h itself is frozen which leads to a competitive factor of $(t+\frac{2k+2}{\alpha(k,t)})$. Substituting $\alpha(k,t)$ from Equation (7) and setting $t = 1+\frac{\varepsilon}{2}$ and $k = \frac{4c(\lambda)}{\varepsilon}\cdot\frac{\varepsilon^{-\lambda}}{\lambda}$, for a constant $c(\lambda)$, we can show that this term is at most $1+\varepsilon$, yielding a recourse of $O_\lambda(\varepsilon^{-(1+\lambda)})$. ◀

As a byproduct, we show, for this special class of instances, a result in the online setting without recourse. It relates the competitive ratio to the cost metric, i.e., the maximum difference in edge cost for connecting a request to a server. This result compares to the best known competitive ratio of $O(\log n)$ by Raghvendra [29].

▶ **Theorem 16.** *The online t-net-cost algorithm is $O(\log\Delta)$-competitive for online matching on an alternating line, where $\Delta = \max_{r,r'\in R,s,s'\in S}\frac{c(r,s)}{c(r',s')}$.*

Proof. Consider an edge e_i of M' and assume $P_i = P_i^{\mathrm{R}}$. By Lemma 14, (ii),

$$t\cdot c(P_i^{\mathrm{L}}\cap M^{\mathrm{L}}) - c(P_i^{\mathrm{L}}\cap M^{\mathrm{R}}) = \phi_t^{M_{i-1}^*}(P_i^{\mathrm{L}}) \ge \phi_t^{M_{i-1}^*}(P_i) = t\cdot c(P_i\cap M^{\mathrm{R}}) - c(P_i\cap M^{\mathrm{L}}).$$

Therefore,

$$|P_i| = c(P_i\cap M^{\mathrm{L}}) + c(P_i\cap M^{\mathrm{R}}) \le \left(1+\tfrac{1}{t}\right)\cdot c(P_i\cap M^{\mathrm{L}}) + c(P_i^{\mathrm{L}}\cap M^{\mathrm{L}}).$$

As in Equation (6), we obtain $|P_i| \le (t+1)\cdot c(P_i\cap M^{\mathrm{R}})$. Together with the above, this implies that $c_{e_i} = |P_i| \le c(\mathrm{I}_i\cap M^{\mathrm{OPT}})\cdot\max\{t+1, 1+\frac{1}{t}\}$. Since intervals corresponding to the same depth in the path-forest are disjoint, we can bound the lengths of paths which are of same depth by $\max\{t+1,1+\frac{1}{t}\}\cdot\mathrm{OPT}$. As there are at most $2\cdot\log_{(2-1/t)}\Delta$ levels in total, by Lemma 15, the theorem's statement follows. ◀

5 Conclusion

In this paper, we give non-trivial results for the min-cost online bipartite matching problem with recourse. The results were obtained simultaneously with and independently of Gupta et al. [17] who consider also more general metrics than the line. We confirm that an average recourse of $O(\log n)$ per request is sufficient to obtain an $O(1)$-competitive matching on the line. It remains open if such a result can be obtained in a non-amortized setting, where the recourse is available only per iteration. Our algorithm is clearly designed for the amortized setting as it buffers online matching decisions and repairs them in batches.

Further, it remains open whether constant recourse per request is sufficient for maintaining an $O(1)$-competitive matching on the line, as for the case of alternating requests. This may be very well possible as there is, currently, no lower bound that rules this out.

Finally, we remind of a major open question in this field: Does there exist an $O(1)$-competitive algorithm for online matching on the line without any recourse?

Abstract

The problem of finding longest common subsequence (LCS) is one of the fundamental problems in computer science, which finds application in fields such as computational biology, text processing, information retrieval, data compression etc. It is well known that (decision version of) the problem of finding the length of a LCS of an arbitrary number of input sequences (which we refer to as Multi-LCS problem) is NP-complete. Jiang and Li [SICOMP'95] showed that if Max-Clique is hard to approximate within a factor of s then Multi-LCS is also hard to approximate within a factor of $\Theta(s)$. By the NP-hardness of the problem of approximating Max-Clique by Zuckerman [ToC'07], for any constant $\delta > 0$, the length of a LCS of arbitrary number of input sequences of length n each, cannot be approximated within an $n^{1-\delta}$-factor in polynomial time unless P=NP. However, the reduction of Jiang and Li assumes the alphabet size to be $\Omega(n)$. So far no hardness result is known for the problem of approximating Multi-LCS over sub-linear sized alphabet. On the other hand, it is easy to get $1/|\Sigma|$-factor approximation for strings of alphabet Σ.

In this paper, we make a significant progress towards proving hardness of approximation over small alphabet by showing a polynomial-time reduction from the well-studied *densest k-subgraph* problem with *perfect completeness* to approximating Multi-LCS over alphabet of size $poly(n/k)$. As a consequence, from the known hardness result of densest k-subgraph problem (e.g. [Manurangsi, STOC'17]) we get that no polynomial-time algorithm can give an $n^{-o(1)}$-factor approximation of Multi-LCS over an alphabet of size $n^{o(1)}$, unless the Exponential Time Hypothesis is false.

1 Introduction

Finding *longest common subsequence* (LCS) of a given set of strings over some alphabet is one of the fundamental problems of computer science. The computational problem of finding (the length of a) LCS has been intensively studied for the last five decades (see [16] and the references therein). This problem finds many applications in the fields of computational biology, data compression, pattern recognition, text processing and others. LCS is often considered among two strings, and in that case it is considered to be one of the classic string similarity measures (see [5]). The general case, when the number of input strings is unrestricted, is also very interesting and well-studied. To avoid any confusion we refer to this general version of the LCS problem as *Multi-LCS* problem. One of the major applications of Multi-LCS is to find similar regions of a set of DNA sequences. Multi-LCS is also a special case of the multiple sequence alignment and consensus subsequence discovery problem (e.g. [27]). Interested readers may refer to the chapter entitled "Multi String Comparison-the Holy Grail" of the book [13] for a comprehensive study on this topic. Other applications of Multi-LCS include text processing, syntactic pattern recognition [22] etc.

Using a basic dynamic programming algorithm [30] we can find a LCS between two strings of length n in quadratic time. However the general version, i.e., the Multi-LCS problem is known to be NP-hard [23] even for the binary alphabet. This problem remains NP-hard even with certain restrictions on input strings (e.g. [7]). For m input strings a generalization of the basic dynamic programming algorithm finds LCS in time $O(mn^m)$. Recently, Abboud, Backurs and Williams [2] showed that an $O(n^{m-\varepsilon})$ time (for any $\varepsilon > 0$) algorithm for this problem would refute the Strong Exponential Time Hypothesis (SETH) even for alphabet of size $O(m)$.

Due to the computational hardness of exact computation of a LCS, an interesting problem is what is the best approximation factor that we can achieve within a reasonable time bound. A c-approximate solution (for some $0 < c \leq 1$) of a LCS is a common subsequence of length at least $c \cdot |LCS|$, where $|LCS|$ denotes the length of a LCS. For the Multi-LCS problem, Jiang and Li [18] showed that if Max-Clique is hard to approximate within a factor of s then Multi-LCS is also hard to approximate within a factor of $\Theta(s)$. By the NP-hardness of the problem of approximating Max-Clique by Zuckerman [31], for any constant $\delta > 0$, the length of a LCS of arbitrary number of input sequences of length n each, cannot be approximated within an $n^{1-\delta}$-factor in polynomial time unless P=NP. However, the result of Jiang and Li [18] is only true for alphabets of size $\Omega(n)$. For smaller alphabets (even for size sublinear in n) we do not know any such hardness result. Jiang and Li [18] conjectured that Multi-LCS for even binary alphabet is MAX-SNP-hard (see [26] for the definition of MAX-SNP-hardness). To the best of our knowledge no progress has been done so far on the direction of showing any conditional hardness for smaller alphabets. On the other hand, it is very easy to get a $1/|\Sigma|$-approximation algorithm for the Multi-LCS problem over any alphabet Σ. The algorithm just outputs the best subsequence among the subsequences of the same symbol.

In this paper, we make a significant progress towards showing hardness of approximation of Multi-LCS by refuting the existence of a polynomial time constant factor approximation algorithm under the Exponential Time Hypothesis (ETH).

▶ **Theorem 1.** *There exists a growing function $f(n) = n^{o(1)}$ such that assuming ETH, there is no polynomial time $\frac{1}{f(n)}$-factor approximation algorithm for the Multi-LCS problem over $n^{o(1)}$-sized alphabet.*

This rules out *any* efficient poly-logarithmic factor approximation algorithm for the Multi-LCS problem over any $n^{o(1)}$-sized alphabet. We show the above theorem by providing a polynomial time reduction from the well-studied *densest k-subgraph* problem with *perfect completeness* and its gap version γ-DkS (for the definition see Section 2).

▶ **Theorem 2.** *Let $\frac{k}{n} = \frac{\beta(n)}{\gamma(n)}$ for $\beta < \gamma \leq 1$. If there is no polynomial time algorithm that solves $(\gamma^2/4)$-DkS(k, n), then there is no polynomial time algorithm that solves 2γ-approximate Multi-LCS problem over some alphabet of size $O(\frac{1}{\beta^6})$.*

The above reduction together with the ETH-based hardness result for the densest k-subgraph problem given by Manurangsi [24] implies Theorem 1. We refer to Appendix 1.2 for the previous works related to the LCS problem and the densest k-subgraph problem.

1.1 Techniques

Our reduction starts with the reduction from the Max-Clique problem to Multi-LCS given by [18]. Given a graph G on n vertices the reduction outputs a Multi-LCS instance $\mathcal{I}$ over an alphabet $\{a_1, a_2, \ldots, a_n\}$ of size n with $2n$ strings. The reduction has a guarantee that the maximum LCS size of $\mathcal{I}$ is *equal* to the size of the maximum clique in G.

A natural way to reduce the alphabet size is to replace each symbol a_i in a string with a string $S_i \in \Sigma^m$ over a smaller alphabet Σ. Let us denote this new instance by $\mathcal{I}'$. The hope is that the only way to get a large LCS in $\mathcal{I}'$ is to match the corresponding strings whenever the respective symbols in $\mathcal{I}$ are matched. But this wishful thinking is not true when the alphabet size is much smaller than the original alphabet size as one might get a large common subsequence by matching parts of strings S_i, S_j corresponding to the different symbols a_i, a_j in the original strings.

We get away with this issue by using a special collection of strings $\{S_1, S_2, \ldots, S_n\}$ with the guarantee that for every pair $i \neq j$, $\mathrm{LCS}(S_i, S_j)$ is much smaller than m. We can construct such a set deterministically by using the known deterministic construction of the so called *long-distance synchronization strings* [14, 9]. There is also a much simpler randomized construction (see Theorem 11). It is easy to see that if the original strings have a LCS of size t, then the new Multi-LCS instance $\mathcal{I}'$ over alphabet Σ has an LCS of size at least tm.

The interesting direction is to prove the converse i.e., if the LCS of $\mathcal{I}'$ is large then the LCS of $\mathcal{I}$ is also large. We do not know if this is true in general. So we rely on the starting problem of Max-Clique from which the instance $\mathcal{I}$ (and hence $\mathcal{I}'$) was created. We show that if $\mathcal{I}'$ has large LCS, then we can find a large subgraph of G which has a non trivial density (instead of finding a large clique). Thus, the reduction relies on hardness of approximation of the DkS problem with *perfect completeness*. Then we use the result of Manurangsi [24] which shows that given a graph G with a guarantee that there is a clique of size k, there is no polynomial time algorithm which finds a subgraph of G of size k with density at least $\gamma(n)$ for some $\gamma(n) = o(n)$, assuming the ETH.

1.2 Related works

1.2.1 Results on LCS problem

Finding LCS between two strings is an important problem in computer science. Wagner and Fischer [30] gave a quadratic time algorithm, which is in fact prototypical to dynamic programming. The running time was later improved to (slightly) sub-quadratic, more specifically $O(\frac{n^2 \log\log n}{\log^2 n})$ [25, 12]. Abboud, Backurs and Williams [2] showed that a truly

sub-quadratic algorithm ($O(n^{2-\varepsilon})$ for some $\varepsilon > 0$) would imply a $2^{(1-\delta)n}$ time algorithm for CNF-satisfiability, contradicting the Strong Exponential Time Hypothesis (SETH). They in fact showed that for m input strings an algorithm with running time $O(n^{m-\varepsilon})$ would refute SETH. Abboud et al. [3] later further strengthened the barrier result by showing that even shaving an arbitrarily large polylog factor from n^2 would have the plausible, but hard-to-prove, consequence that NEXP does not have non-uniform NC^1 circuits. In case of approximation algorithm for LCS over arbitrarily large alphabets a simple sampling based technique achieves $O(n^{-x})$-approximation in $O(n^{2-2x})$ time. Very recently, an $O(n^{-0.497956})$ factor approximation (breaking $O(\sqrt{n})$ barrier) linear time algorithm is provided by Hajiaghayi et al. [15]. For binary alphabets another very recent result breaks 1/2-approximation factor barrier in subquadratic time [29]. (Note, $1/|\Sigma|$-approximation over any alphabet Σ is trivial.) The only hardness (or barrier) results for approximating LCS in subquadratic time are presented in [1, 4].

For the general case (which we also refer as Multi-LCS), when the number of input strings is unrestricted, the decision version of the problem is known to be NP-complete [23] even for the binary alphabet. The problem remains NP-complete even with further restriction like bounded *run-length* on input strings [7]. As cited earlier, Jiang and Li [18] (along with the result of Zuckerman [31]) showed that for every constant $\delta > 0$, there is no polynomial time algorithm that achieves $n^{1-\delta}$-approximation factor, unless P=NP. One interesting aspect of the reduction in [18] is that in any input string any particular symbol appears at most twice. It is worth mentioning that if we restrict ourselves to the input strings where a symbol appears exactly once, then we can find a LCS in polynomial time. The algorithm is just an extension of the dynamic programming algorithm that finds a longest increasing subsequence of an input sequence. It is also not difficult to show that the decision version of the Multi-LCS problem with the above restrictions on the input strings can be solved even in non-deterministic logarithmic space. To see this consider a LCS as a certificate. Then the verification algorithm makes single pass on the certificate, and check whether every two consecutive symbols in the certificate appears in the same order in all the input strings. Clearly, the above verification algorithm uses only logarithmic space. Since we know that each symbol appears exactly once in a string, the above verification algorithm correctly decides whether the given certificate is a valid LCS or not.

1.2.2 Hardness results related to densest k-subgraph problem

Our starting point of the reduction is the hardness of approximating the densest k-subgraph problem. In the densest k-subgraph problem (DkS), we are given a graph $G(V, E)$ and an integer $1 \leq k \leq |V|$. The task is to find a subgraph of G of size k with maximum density. Various approximation algorithms are known for DkS [21, 10], and the current best known is by [6] which gives $n^{1/4+\varepsilon}$-approximation algorithm for any constant $\varepsilon > 0$.

A special case of DkS is when it is guaranteed that G has a clique of size k and the task is to find a subgraph of size[1] k with density at least γ for $0 < \gamma \leq 1$. In this *perfect completeness* case, Feige and Seltser [11] gave an algorithm which finds a k sized subgraph with density $(1 - \varepsilon)$ in time $n^{O((1+\log \frac{n}{k})/\varepsilon)}$.

There are several inapproximability results known for DkS based on worst-case assumptions. Khot [19] ruled out a PTAS assuming NP $\not\subseteq$ BPTIME $(2^{n^{\varepsilon}})$ for some constant $\varepsilon > 0$. Raghavendra and Steurer [28] showed that DkS is hard to approximate to within any constant ratio assuming the Unique Games Conjecture where the constraint graph satisfies a small set expansion property.

[1] Note, here *size* of a subgraph refers to the number of vertices present in that subgraph.

Assuming the Exponential Time Hypothesis, Braverman et al. [8], showed that for some constant $\varepsilon > 0$, there is no polynomial time algorithm which when given a graph with a k-clique finds a k sized subgraph with density $(1-\varepsilon)$. This result is significantly improved by Manurangsi [24] in which he showed that assuming ETH, no polynomial time algorithm can distinguish between the cases when G has a clique of size k and when every k sized subgraph has density at most $n^{-1/(\log\log n)^c}$ for some constant $c > 0$.

2 Preliminaries

Notations

We use $[n]$ to denote the set $\{1, 2, \cdots, n\}$. For any string S we use $|S|$ to denote its length. By abuse of notation, for any set V we also use the notation $|V|$ to denote the size of V. For any string S of length n and two indices $i, j \in [n]$, $S[i, j]$ denotes the substring of S that starts at index i and ends at index j. We use $\alpha(n), \beta(n), \gamma(n)$ to denote that α, β, γ are allowed to depend on n.

2.1 Longest Common Subsequence

Given m sequences $S_1, \ldots, S_m$ of length n over an alphabet Σ, the longest common subsequence is the longest sequence S such that $\forall i \in [m], S$ is a subsequence of S_i.

We will refer to the computational problem of finding or deciding the length of LCS as a Multi-LCS problem. In this paper, we consider the decision variant of this problem: Given an integer $\ell \leq n$, we have to decide whether LCS has a length greater than equal to ℓ, or less than ℓ. For the approximation, we consider the following gap-version of this problem.

▶ **Problem 3.** For any $0 < \kappa < 1$, the κ-approximate Multi-LCS problem is defined as: Given sequences $S_1, \ldots, S_m$ of length n over an alphabet Σ and an integer ℓ, the goal is to distinguish between the following two cases

- YES instance: A LCS of $S_1, \ldots, S_m$ has length greater than or equal to ℓ.
- NO instance: A LCS of $S_1, \ldots, S_m$ has length less than $\kappa \cdot \ell$.

We use the following definition of alignment.

▶ **Definition 4** (Alignment). *Given two strings S_1 and S_2 of lengths n and m respectively, alignment σ is a function from $[n]$ to $[m] \cup \{*\}$ which satisfies $\forall i \in [n]$, if $\sigma(i) \neq *$ then $S_1[i] = S_2[\sigma(i)]$ and for any i and j if $\sigma(i) \neq *, \sigma(j) \neq *$ then for $i > j$, $\sigma(i) > \sigma(j)$.*

For an alignment σ between two strings S_1 and S_2 we say σ *aligns* some subsequence $T_1 = S_1[i_1]S_1[i_2]\cdots S_1[i_{\ell_1}]$ of S_1 with some subsequence $T_2 = S_2[j_1]S_2[j_2]\cdots S_2[j_{\ell_2}]$ of S_2 if and only if for all $p \in [\ell_1]$, $\sigma(i_p) \in \{j_1, j_2, \cdots, j_{\ell_2}\}$.

2.2 Exponential Time Hypothesis

The Exponential Time Hypothesis (ETH) was introduced by Impagliazzo and Paturi [17]. It refutes the possibility of getting much faster algorithm to decide satisfiability of a 3-CNF formula (also referred as 3-SAT problem) than that by the trivial brute force method.

▶ **Hypothesis 5** (ETH). *There is no $2^{o(n)}$ time algorithm for the 3-SAT problem over n variables.*

2.3 Densest k-Subgraph problem and related hardness results

For any graph, the density is defined as the ratio of the number of edges present in it and the number of edges in any complete graph of the same size. So given a graph $G = (V, E)$, the density of G is $\frac{2|E|}{|V|^2-|V|}$.

The Densest k-Subgraph (DkS) problem is the following: Given a graph G on n vertices and a positive integer $k \leq n$, the goal is to find a subgraph of G with k vertices which has maximum density.

In this paper we will consider the following gap-version of densest k-subgraph, which in the literature is sometimes referred as densest k-subgraph with *perfect completeness*.

▶ **Problem 6.** For any $\gamma \leq 1$, γ-DkS(k, n) is defined as: Given a graph G on n vertices and a positive integer $k \leq n$, the goal is to distinguish between the following two cases

- YES instance: There exists a clique of size k.
- NO instance: All subgraphs of size k have density at most γ.

We say that an algorithm solves γ-DkS(k, n) if given any input it can distinguish whether the input is a YES instance or a NO instance. If the algorithm is randomized then it should succeed with probability at least 2/3.

In this paper we use the following hardness result by Manurangsi [24].

▶ **Theorem 7** ([24])**.** *There exists a constant $c_0 > 0$ such that assuming the Exponential Time Hypothesis, for all constants $\varepsilon > 0$, there is no polynomial time algorithm for γ-DkS(k, n) where $\gamma = n^{-O\left(\frac{1}{(\log\log n)^{c_0}}\right)}$ and $\frac{k}{n} \in \left[n^{-\varepsilon}, n^{-\Omega\left(\frac{1}{\log\log n}\right)}\right]$.*

3 Reduction

In this section we provide a reduction from the densest k-subgraph problem to the problem of approximating Multi-LCS and prove Theorem 2. Note that, Theorem 2 and Theorem 7 together immediately imply Theorem 1 by plugging $\gamma(n) = n^{-O\left(\frac{1}{(\log\log n)^{c_0}}\right)}, \beta(n) = \gamma(n)^2$.

▶ Remark 8. If we want to get the hardness of Multi-LCS for a constant sized alphabet using Theorem 2 then k must be $\Omega(n)$. However, when $k = \Omega(n)$ Theorem 7 does not imply any hardness result. In fact, when $k = \Omega(n)$, there is a polynomial time algorithm for $(1 - \varepsilon)$-DkS(k, n) for any constant $\varepsilon > 0$ [11]. Therefore our reduction will not give any hardness for constant sized alphabet. However, if one can improve Theorem 7 for $k/n = 1/\text{poly}(\log n)$ and $\gamma(n) = 1/\text{poly}(\log n)$, then our main reduction in Theorem 2 will imply Multi-LCS hardness for $\text{poly}(\log n)$ sized alphabet!

Our reduction involves two steps: First, we use the reduction from the Max-Clique problem to the Multi-LCS problem over large alphabet given in [18]. Next we perform alphabet reduction by replacing each character by a "short" string over a small-sized alphabet.

Revisiting the reduction from Max-Clique to Multi-LCS

We first recall the reduction from [18]. We are given a graph $G = (V, E)$ on n vertices and an integer $k \leq n$. Fix an arbitrary labeling on the vertices of V as $v_1, \ldots, v_n$. For every vertex v_i, partition its neighbors into two subsets: $\mathcal{N}_<(v_i)$ contains all the neighboring vertices v_j with $j < i$; and $\mathcal{N}_>(v_i)$ contains all the neighboring vertices v_j with $j > i$.

Consider an alphabet Σ containing a separate symbol for each vertex. We use v_i to denote both the vertex and its corresponding symbol in Σ. Now for each vertex $v_i \in V$, construct the following two strings X_i and X'_i

$$X_i = v_1 \dots v_{i-1} v_{i+1} \dots v_n v_i v_{i_r} \dots v_{i_s} \text{ and } X'_i = v_{i_p} \dots v_{i_q} v_i v_1 \dots v_{i-1} v_{i+1} \dots v_n$$

where $\mathcal{N}_>(v_i) = \{v_{i_r}, \cdots, v_{i_s}\}$ with $i_r < \cdots < i_s$, and $\mathcal{N}_<(v_i) = \{v_{i_p}, \cdots, v_{i_q}\}$ with $i_p < \cdots < i_q$. The following proposition is immediate from the above construction.

▶ **Proposition 9** ([18]). *If there is a clique of size c in G, then there is a common subsequence of $X_1, \cdots, X_n, X'_1, \cdots, X'_n$ of length c.*

The converse has also been shown in [18].

▶ **Proposition 10** ([18]). *For any common subsequence S of $X_1, \cdots, X_n, X'_1, \cdots, X'_n$, all the v_i's present in S form a clique in G.*

The proofs of these propositions follow from the facts that any common subsequence is of the form $v_{i_1}, v_{i_2}, \dots, v_{i_t}$ where $i_1 < i_2 < \dots < i_t$ and that there must be an edge between v_{i_j} and $v_{i_{j'}}$ for $1 \le j < j' \le t$.

Reducing the size of the alphabet

For some parameter $\alpha(n) < 1$, let $\{S_1, \dots, S_n\}$ be a set of strings of length m over some alphabet Σ' such that: for all $i \neq j$ $|LCS(S_i, S_j)| \le \alpha m$. We will fix the value of m and $|\Sigma'|$ later. The following theorem (Theorem 1 of [20]) shows that if we pick strings from Σ'^m uniformly at random then for $|\Sigma'| = O(1/\alpha^2)$, with high probability the sampled strings will satisfy the above desired property.

▶ **Theorem 11** ([20]). *For every $\varepsilon > 0$ there exists $c > 0$ such that for large enough sized alphabet Σ' for any m if two strings S_1, S_2 are picked uniformly at random from Σ'^m then*

$$Pr\left[\left||LCS(S_1, S_2)| - \frac{2m}{\sqrt{|\Sigma'|}}\right| \ge \varepsilon \frac{2m}{\sqrt{|\Sigma'|}}\right] \le e^{-cm/\sqrt{|\Sigma'|}}.$$

Now by suitably choosing ε, m the following lemma directly follows from a union bound over every pair of n chosen strings.

▶ **Lemma 12.** *For any $\alpha \in (0,1)$, and $n \in \mathbb{N}$ there exists an alphabet Σ' of size $O(\alpha^{-2})$ such that for any $m \ge c\alpha^{-1} \log n$ (for some suitably chosen constant $c > 0$), if we choose a set of strings $S_1, \cdots, S_n$ uniformly at random from Σ'^m then with probability at least $1 - 1/n$ for each $i \neq j$, $|LCS(S_i, S_j)| \le \alpha m$.*

The above lemma gives us a randomized reduction. However we can deterministically find such a collection (with a slight loss in the parameters) using the known construction of *synchronization strings*. The proof of the following Lemma is deferred to Appendix A.

▶ **Lemma 13.** *For any $\alpha \in (0,1)$, and $n \in \mathbb{N}$ there exists an alphabet Σ' of size $O(\alpha^{-3})$ such that for any $m > 2\alpha^{-2} \log n$, there is a deterministic construction of a set of strings $S_1, \cdots, S_n \in \Sigma'^m$ such that for each $i \neq j$, $|LCS(S_i, S_j)| \le \alpha m$. Moreover, all the strings can be generated in time $O(\alpha^{-2} nm)$.*

▶ Remark 14. One advantage of using the randomized construction is the alphabet size (as well as the length of strings); randomized construction has only a quadratic loss whereas the deterministic construction has a cubic loss in the alphabet size. However this will not matter much for the parameters we need to prove our main theorem.

Now let us continue with the description of our reduction. We replace each $v_j \in \Sigma$ by the string S_j. After the replacement we get the following two strings Y_i and Y'_i respectively from X_i and X'_i.

$$Y_i = S_1 \dots S_{i-1} S_{i+1} \dots S_n S_i S_{i_r} \dots S_{i_s} \text{ and } Y'_i = S_{i_p} \dots S_{i_q} S_i S_1 \dots S_{i-1} S_{i+1} \dots S_n$$

Note, Y_i and Y'_i's are over the alphabet Σ'. For notational convenience we use $S_{\mathcal{N}_{>i}}$ to denote the substring $S_{i_r} \dots S_{i_s}$, and $S_{\mathcal{N}_{<i}}$ to denote the substring $S_{i_p} \dots S_{i_q}$. From now on, for simplicity, we will refer to these S_i's as *blocks*. Note, due to deterministic construction of strings S_i's by Lemma 13 our whole reduction is deterministic and polynomial time.

It follows directly from Proposition 9 that:

▶ **Lemma 15** (Completeness). *If graph G is a YES instance of $\frac{\gamma^2}{4}$-DkS (with clique of size k), then a LCS of $Y_1, \dots, Y_n, Y'_1, \dots, Y'_n$ is of length at least km.*

We devote the rest of this section to proving the soundness of our reduction.

▶ **Lemma 16** (Soundness). *Let $\alpha \in (0, 1/8)$ and $\beta = \sqrt{8\alpha}$. If graph G is a NO instance of $\frac{\gamma^2}{4}$-DkS (every subgraph of size k has density less than $\frac{\gamma^2}{4}$), then a LCS of $Y_1, \dots, Y_n, Y'_1, \dots, Y'_n$ has length at most $2\beta mn$.*

3.1 Proof of Soundness

Let L be an (arbitrary) LCS of $Y_1, \cdots, Y_n, Y'_1, \cdots, Y'_n$ of size greater than $2\beta mn$. By the construction $Y_n = S_1 \dots S_n$ (since $\mathcal{N}_>(v_n) = \emptyset$). So we can partition the subsequence L as $Z_1, \cdots, Z_n$ where $\forall i \in [n]$ Z_i is a subsequence of S_i. (Z_i can be an empty string). Now consider all the Z_i of length at least βm, and let $\mathcal{W}$ denote the set of all such Z_i's, i.e., $\mathcal{W} = \{Z_i \mid |Z_i| \geq \beta m\}$. Suppose L_1 is the string formed by removing all $Z_i \notin \mathcal{W}$ from L. Clearly, $|L_1| \geq |L| - \beta mn \geq \beta mn$.

For all $i, j \in [n]$ such that $i < j$, define $C[i, j]$ as: $C[i, j] := \{Z_t \in \mathcal{W} \mid i \leq t \leq j\}$. Note, $\mathcal{W} = C[1, n]$. Next we show that either the size of $C[1, n]$ is small or there exists a subgraph in G which has large density.

Let us consider the set of vertices $V_H := \{v_t | Z_t \in \mathcal{W}\}$. So $|V_H| = |\mathcal{W}| \geq \frac{|L|}{m} - \beta n \geq \beta n$. If we could show that the subgraph H of G induced by the set of vertices V_H has high density (ideally, a clique), then that will imply Lemma 16.

Now consider an (arbitrary) alignment between L_1 and $Y_1, \cdots, Y_n, Y'_1, \cdots, Y'_n$. Let us denote the alignment between L_1 and Y_i (Y'_i) by σ_i (σ'_i). From now on whenever we will talk about alignment we will refer to these particular alignments (σ_i or σ'_i depending on strings under consideration) without specifying them explicitly. Consider a $Z_t \in \mathcal{W}$. We say Z_t is ε-*aligned* (for some $\varepsilon \in [0, 1]$) with some substring S' of some Y_i (or Y'_i) if and only if either the first or the last ε fraction of symbols of Z_t is aligned by the alignment σ'_i (or σ'_i) with some subsequence of S'. Throughout this proof we will set $\varepsilon = 1/2$. Note that, if we partition Y_i into (any) two parts Y_i^l and Y_i^r then Z_i is 1/2-*aligned* to at least one of Y_i^l and Y_i^r, and this justifies our setting of parameter ε.

By following the argument of the proof of Proposition 10 given in [18], it is possible to show that if σ aligns all Z_t with some subsequence of S_t in all strings Y_i (and Y'_i), then the subgraph H induced by vertices in V_H has high density (actually forms a clique). Unfortunately we do not know whether all the Z_t's are aligned with their corresponding S_t's in all the Y_i's (and Y'_i's). Following are the different cases of mapping $Z_i \in \mathcal{W}$ with Y_i:

1. Z_i is 1/2-*aligned* with the substring $S_1 \dots S_{i-1}$ of Y_i.
2. Z_i is 1/2-aligned with $S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ of Y_i and there exists a $j > i$ such that a symbol of Z_j in L_1 is aligned with some symbol of S_j in the substring $S_{i+1} \dots S_n S_i$.
3. Z_i is 1/2-aligned with the substring $S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ in Y_i and there exists no $j > i$ such that a symbol of $Z_j \in \mathcal{W}$ is aligned with some symbol of S_j in the substring $S_{i+1} \dots S_n$.

Similarly, we will also consider the mapping with Y_i''s. We will categorize first and second case as *sparse case* and the third one as the *dense case*. Next we analyze these cases.

3.1.1 Sparse Case: Improper mapping leads to small LCS locally

Let us recall that $Y_i = S_1 \dots S_{i-1} S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ and $Y_i' = S_{\mathcal{N}_{<i}} S_i S_1 \dots S_{i-1} S_{i+1} \dots S_n$. The next two claims demonstrate that if Z_i is not mapped to S_i in Y_i (or Y_i') then there is a portion $C[j,i]$ (or $C[i,j]$) in L_1 such that $\frac{|C[j,i]|}{i-j}$ (or $\frac{|C[i,j]|}{j-i}$) is small, i.e., that portion of L_1 is "sparse" with respect to the number of Z_t blocks present in it.

▷ Claim 17. If $Z_i \in \mathcal{W}$ is 1/2-aligned with the substring $S_1 \dots S_{i-1}$ of Y_i (by the alignment σ_i), then there exists a $j < i$ such that $|C[j,i]| \leq \frac{2\alpha}{\beta}(i-j+1)$. Similarly, if $Z_i \in \mathcal{W}$ is 1/2-aligned with the substring $S_{i+1} \dots S_n$ of Y_i' (by the alignment σ_i'), then there exists a $j > i$ such that $|C[i,j]| \leq \frac{2\alpha}{\beta}(j-i+1)$.

Proof. Suppose Z_i is 1/2-aligned with $S_1 \dots S_{i-1}$ of Y_i. Let j be the largest index less than i such that a symbol in Z_j is aligned (by σ_i) with some symbol in S_j in Y_i (if there does not exist such a j then take $j = 0$). Note, by the definition of 1/2-alignment at least first $\beta m/2$ symbols of Z_i are mapped (by σ_i) in $S_1 \dots S_{i-1}$. Recall, the definition of 1/2-alignment ensures the mapping of the first or the last half fraction of symbols. However in this case if Z_i's last $\beta m/2$ symbols are mapped in $S_1 \dots S_{i-1}$ then the whole Z_i is actually mapped in $S_1 \dots S_{i-1}$, which is even stronger than what we state.

By the properties of strings S_k's specified in Lemma 13, the first $\beta m/2$ symbols of Z_i require at least $\frac{\beta}{2\alpha}$ blocks from $\{S_j, S_{j+1}, \dots, S_{i-1}\}$ to map completely (see Figure 1).

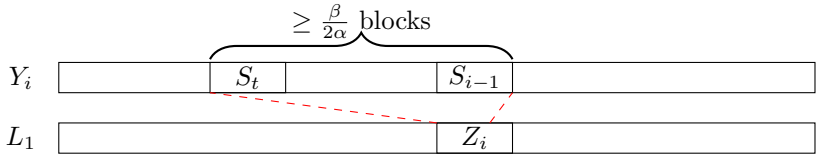

Figure 1 Z_i is 1/2-aligned with $S_1 \dots S_{i-1}$ where $t > j$.

Similarly each element of $C[j+1, i-1]$ also requires at least $\frac{\beta}{\alpha}$ blocks from $\{S_j, S_{j+1}, \dots, S_{i-1}\}$. However any two $Z_p, Z_{p+1} \in C[j+1, i]$ may share a block (more specifically, the last block used for Z_p and the first block used for Z_{p+1}) for mapping. So, we get

$$\frac{\beta}{2\alpha} + (\frac{\beta}{\alpha} - 1)|C[j+1, i-1]| \leq i - j \Rightarrow \frac{\beta}{2\alpha}|C[j+1, i]| \leq i - j.$$

Note, $\frac{\beta}{\alpha} - 1 \geq \frac{\beta}{2\alpha}$ as $\alpha \leq 1/8$ (recall, $\beta = \sqrt{8\alpha}$), and $C[j+1, i-1] \cup \{Z_i\} = C[j+1, i]$.

Similarly, suppose Z_i is 1/2-aligned with $S_{i+1} \dots S_n$ of Y_i'. Let j be the smallest index greater than i such that a symbol of Z_j is aligned (by σ_i') with some symbol of S_j in Y_i' (if there does not exist any j then take $j = n+1$). Using an argument similar to the above, we get

$$\frac{\beta}{2\alpha} + (\frac{\beta}{\alpha} - 1)|C[i+1, j-1]| \leq j - i \Rightarrow \frac{\beta}{2\alpha}|C[i, j-1]| \leq j - i. \quad \triangleleft$$

▷ Claim 18. Suppose (by the alignment σ_i) $Z_i \in \mathcal{W}$ is 1/2-aligned with $S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ of Y_i, and there exists a $j > i$ such that a symbol of Z_j in L_1 is aligned with some symbol of S_j in the substring $S_{i+1} \dots S_n S_i$. Then there exists r such that $i < r \leq j$ and $|C[i, r-1]| \leq \frac{2\alpha}{\beta}(r-i)$.

Similarly, suppose (by the alignment σ'_i) $Z_i \in \mathcal{W}$ is 1/2-aligned with $S_{\mathcal{N}_{<i}} S_i S_1 \dots S_{i-1}$ of Y'_i, and there exists a $j < i$ such that a symbol of Z_j in L_1 is aligned with some symbol of S_j in the substring $S_i S_1 \dots S_{i-1}$. Then there exists r such that $j \leq r < i$ and $|C[r+1, i]| \leq \frac{2\alpha}{\beta}(i-r)$.

Proof. Suppose Z_i is 1/2-aligned with $S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ of Y_i and there exists a $j > i$ such that a symbol of Z_j in L_1 is aligned (by σ_i) with some symbol of S_j in the substring $S_{i+1} \dots S_n S_i$. Let us choose r to be the smallest j with the above condition. By the argument used in the proof of Claim 17, Z_i requires at least $\frac{\beta}{2\alpha}$ blocks from $\{S_{i+1}, S_{i+2}, \cdots, S_r\}$, and every element in $C[i+1, r-1]$ requires at least $\frac{\beta}{\alpha}$ blocks from $\{S_{i+1}, S_{i+2}, \cdots, S_r\}$. Again, any two $Z_p, Z_{p+1} \in C[i, r-1]$ may share a block (more specifically, the last block used for Z_p and the first block used for Z_{p+1}) for mapping. So we get

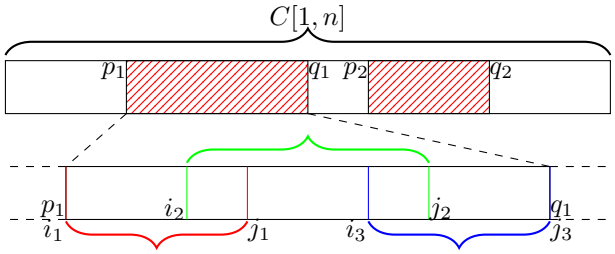
$$\frac{\beta}{2\alpha} + |C[i+1, r-1]|(\frac{\beta}{\alpha} - 1) \leq r - i \Rightarrow \frac{\beta}{2\alpha}|C[i, r-1]| \leq r - i.$$

Similarly, suppose Z_i is 1/2-aligned with $S_{\mathcal{N}_{<i}} S_i S_1 \dots S_{i-1}$ of Y'_i and there exists a $j < i$ such that a symbol of Z_j in L_1 is aligned (by σ'_i) with some symbol of S_j in the substring $S_i S_1 \dots S_{i-1}$. Let us choose r to be the largest j with the above condition. Then we get

$$\frac{\beta}{2\alpha} + |C[r+1, i-1]|(\frac{\beta}{\alpha} - 1) \leq i - r \Rightarrow \frac{\beta}{2\alpha}|C[r+1, i]| \leq i - r. \quad \triangleleft$$

3.1.2 Dense Case: Proper mapping implies large number of neighbors

Recall that $V_H = \{v_t \mid Z_t \in \mathcal{W}\}$. For each $v_i \in V_H$ further define $V_H^{>i} := \{v_t \in V_H \mid t > i\}$ and $V_H^{<i} := \{v_t \in V_H \mid t < i\}$. The next two claims show that if Z_i is aligned with S_i in Y_i and Y'_i then "most" of the vertices in V_H are connected to (i.e., neighbors of) the vertex v_i. This eventually helps us to show that density of H is high.



▷ Claim 19. Suppose (by the alignment σ_i) $Z_i \in \mathcal{W}$ is 1/2-aligned with $S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ in Y_i, and there exists no $j > i$ such that a symbol of $Z_j \in \mathcal{W}$ is aligned with some symbol of S_j in the substring $S_{i+1} \dots S_n$. Then

$$|V_H^{>i} \bigcap \mathcal{N}_>(v_i)| + \frac{\beta}{2\alpha}|V_H^{>i} \setminus \mathcal{N}_>(v_i)| \leq 2(n-i) + 1.$$

Proof. Z_i is 1/2-aligned with $S_{i+1} \dots S_n S_i S_{\mathcal{N}_{>i}}$ of Y_i. So to align all $Z_r \in C[i+1, n]$ (note, $|C[i+1, n]| = |V_H^{>i}|$) at most $2(n-i)+1$ blocks of S_p's are available. Since for no $j > i$ a symbol of $Z_j \in \mathcal{W}$ is aligned with some symbol of S_j in $S_{i+1} \dots S_n$, each Z_r such that $v_r \in V_H^{>i} \setminus \mathcal{N}_>(v_i)$ requires at least $\frac{\beta}{\alpha}$ blocks of S_p's to map. Any two Z_r, Z_{r+1} such that $v_r, v_{r+1} \in V_H^{>i} \setminus \mathcal{N}_>(v_i)$ may share a block (more specifically, the last block used for Z_p and the first block used for Z_{p+1}) for mapping. Recall for our choice of parameters α, β, $\frac{\beta}{\alpha} - 1 \geq \frac{\beta}{2\alpha}$. So we get

$$|V_H^{>i} \bigcap \mathcal{N}_>(v_i)| + \frac{\beta}{2\alpha}|V_H^{>i} \setminus \mathcal{N}_>(v_i)| \leq 2(n-i) + 1. \quad \triangleleft$$

Similarly, we consider the mapping of Z_i in the string Y'_i.

Shaded region is included in $\mathcal{T}$

Considering $s = 3$, (i_1, j_1),(i_2, j_2),(i_3, j_3) is a series of pairs to cover $C[p_1, q_1]$ where $i_1 = p_1$ and $j_3 = q_1$.

Figure 2 $\mathcal{T}$ as a union of disjoint subsets.

▷ Claim 20. Suppose (by the alignment σ'_i) $Z_i \in \mathcal{W}$ is 1/2-aligned with $S_{\mathcal{N}_<(i)} S_i S_1 \dots S_{i-1}$ in Y'_i, and there exists no $j < i$ such that a symbol of $Z_j \in \mathcal{W}$ is aligned with some symbol of S_j in the substring $S_1 \dots S_{i-1}$. Then

$$|V_H^{<i} \bigcap \mathcal{N}_<(v_i)| + \frac{\beta}{2\alpha} |V_H^{<i} \setminus \mathcal{N}_<(v_i)| \leq 2i - 1.$$

Proof. Z_i is 1/2-aligned with $S_{\mathcal{N}_<(i)} S_i S_1 \dots S_{i-1}$ of Y'_i. So to align all $Z_r \in C[1, i-1]$ (note, $|C[1, i-1]| = |V_H^{<i}|$), at most $2i-1$ blocks of S_p's are available. Since for no $j < i$ a symbol of $Z_j \in \mathcal{W}$ is aligned with some symbol of S_j in $S_1 \dots S_{i-1}$, each Z_r such that $v_r \in V_H^{<i} \setminus \mathcal{N}_<(v_i)$ requires at least $\frac{\beta}{\alpha}$ blocks of S_p's to map. Any two Z_r, Z_{r+1} such that $v_r, v_{r+1} \in V_H^{<i} \setminus \mathcal{N}_<(v_i)$ may share a block (more specifically, the last block used for Z_p and the first block used for Z_{p+1}) for mapping. Recall for our choice of parameters α, β, $\frac{\beta}{\alpha} - 1 \geq \frac{\beta}{2\alpha}$. So we get

$$|V_H^{<i} \bigcap \mathcal{N}_<(v_i)| + \frac{\beta}{2\alpha} |V_H^{<i} \setminus \mathcal{N}_<(v_i)| \leq 2i - 1.$$ ◁

3.1.3 Removing sparse blocks from LCS

Next we choose a subset of vertices from the set V_H so that the graph induced by that subset has high density. For that purpose we remove the "sparse" portions from the subsequence L_1 in the following way:

1. Initialize an empty set $\mathcal{T}$.
2. For each $Z_i \in \mathcal{W}$ identify the largest $j > i$ such that $\frac{|C[i,j]|}{j-i+1} \leq \frac{2\alpha}{\beta}$, and then add all $Z_k \in C[i, j]$ in the set $\mathcal{T}$. (If no such j exists then do not add anything to $\mathcal{T}$.)
3. Define a new set $\mathcal{W}' = \mathcal{W} \setminus \mathcal{T}$.

Let L_2 be the string formed by removing all $Z_i \notin \mathcal{W}'$ from L_1. Let us also define a set of vertices $V'_H = \{v_t | Z_t \in \mathcal{W}'\}$. (Note, $V'_H \subseteq V_H$.) Now we will argue that the set V_H has not shrunk by much after removing the sparse blocks and each vertex in V'_H has high degree in the subgraph H, which eventually implies that the subgraph H has high density.

▷ Claim 21. $|V'_H| \geq |V_H| - \frac{4\alpha}{\beta} n$.

Proof. Let us consider the set $\mathcal{T}$. We can write $\mathcal{T}$ as a union of disjoint subsets as $\mathcal{T} = C[p_1, q_1] \cup C[p_2, q_2] \cup \dots \cup C[p_r, q_r]$ for some integer $r \in [n]$, such that $\forall_{1 \leq \ell \leq r-1}\ C[q_\ell, p_{\ell+1}] \neq \emptyset$ (see Figure 2).

Now if we could show that for each $\ell \in [r]$, $|C[p_\ell, q_\ell]| \leq \frac{4\alpha}{\beta}(q_\ell - p_\ell)$, then

$$|\mathcal{T}| = \sum_{\ell=1}^{r} |C[p_\ell, q_\ell]| \leq \frac{4\alpha}{\beta} \sum_{\ell=1}^{r} (q_\ell - p_\ell) \leq \frac{4\alpha}{\beta} n$$

where the last inequality is true since $p_1 < q_1 < p_2 < q_2 < \dots < p_r < q_r$. So to conclude the proof of the claim next we show that for all $\ell \in [r]$ $|C[p_\ell, q_\ell]| \leq \frac{4\alpha}{\beta}(q_\ell - p_\ell)$.

It is immediate from the construction of the set $\mathcal{T}$ that there exists a sequence of pair of indices $(i_1, j_1), \cdots, (i_s, j_s)$ (for some positive integer s) where $i_1 = p_\ell$ and $j_s = q_\ell$, such that for all $t \in [s]$ while processing Z_{i_t} we add blocks of $C[i_t, j_t]$ in $\mathcal{T}$, and $C[p_\ell, q_\ell] = \bigcup_{t\in[s]} C[i_t, j_t]$. We can further assume that there exists no $t' \in [s]$ such that $C[i_{t'}, j_{t'}] \subseteq \bigcup_{t\in[s]\setminus\{t'\}} C[i_t, j_t]$. (In words it means that $C[i_1, j_1], \cdots, C[i_s, j_s]$ is a minimal sequence of subsets whose union is $C[i_1, j_s]$.) Due to this assumption we can write that $i_2 \le j_1 \le i_3 \le j_2 \le \cdots \le i_s \le j_{s-1}$ and $\forall t \in [s-2], i_{t+2} \ge j_t + 1$ (see Figure 2). So,

$$\begin{aligned}
|C[p_\ell, q_\ell]| \le \sum_{t=1}^{s} |C[i_t, j_t]| &\le \frac{2\alpha}{\beta} \sum_{t=1}^{s} (j_t - i_t + 1) \\
&= \frac{2\alpha}{\beta}\Big[s + (j_s - i_1) + \sum_{t=1}^{s-1}(j_t - i_{t+1})\Big] \\
&\le \frac{2\alpha}{\beta}\Big[s + (j_s - i_1) + (j_{s-1} - i_2 - (s-2))\Big] \\
&\le \frac{2\alpha}{\beta}\Big[2(j_s - i_1)\Big]
\end{aligned}$$

where second last inequality uses the fact that $\forall t \in [s-2], i_{t+2} \ge j_t + 1$ and last inequality uses the fact that $j_s \ge j_{s-1} + 1$ and $i_2 \ge i_1 + 1$. Hence we conclude that $|C[p_\ell, q_\ell]| \le \frac{4\alpha}{\beta}(q_\ell - p_\ell)$, and this completes the proof. ◁

▷ Claim 22. For each vertex $v_i \in V'_H$, $|V_H \bigcap \mathcal{N}(v_i)| \ge |V_H| - \frac{4\alpha}{\beta} n$.

Proof. By the construction of $\mathcal{W}'$, for each $Z_i \in \mathcal{W}'$ we know that there exists no $j > i$ (or $< i$) such that $\frac{|C[i,j]|}{j-i+1} \le \frac{2\alpha}{\beta}$ (or $\frac{|C[j,i]|}{i-j+1} \le \frac{2\alpha}{\beta}$). Then by Claim 17 and Claim 18 it follows that all $Z_i \in \mathcal{W}'$ satisfy preconditions of both Claim 19 and Claim 20. Otherwise by Claim 17 and Claim 18 we know that there exists a $j > i$ (or $< i$) such that $\frac{|C[i,j]|}{j-i+1} \le \frac{2\alpha}{\beta}$ (or $\frac{|C[j,i]|}{i-j+1} \le \frac{2\alpha}{\beta}$). For $j > i$ when we process Z_i to construct the set $\mathcal{T}$ we add all the blocks of $C[i, j]$, and for $j < i$ when we process Z_j we add all the blocks of $C[j, i]$. So it must be the case that the alignment σ_i between L_1 and Y_i, 1/2-aligns Z_i to the substring $S_{i+1} \dots S_n S_i S_{\mathcal{N}_>{}_i}$ and there exists no $j > i$ such that $Z_j \in \mathcal{W}$ aligns with S_j in the substring $S_{i+1} \dots S_n$. Also, σ'_i 1/2-aligns Z_i to the substring $S_{\mathcal{N}_<{}_i} S_i S_1 \dots S_{i-1}$ and there exists no $j < i$ such that $Z_j \in \mathcal{W}$ aligns with S_j in the substring $S_1 \dots S_{i-1}$. So by Claim 19

$$|V_H^{>i} \bigcap \mathcal{N}_>(v_i)| + \frac{\beta}{2\alpha}|V_H^{>i} \setminus \mathcal{N}_>(v_i)| \le 2(n-i) + 1,$$

and by Claim 20

$$|V_H^{<i} \bigcap \mathcal{N}_<(v_i)| + \frac{\beta}{2\alpha}|V_H^{<i} \setminus \mathcal{N}_<(v_i)| \le 2i - 1.$$

These two claims together imply

$$\begin{aligned}
&|V_H \bigcap \mathcal{N}(v_i)| + \frac{\beta}{2\alpha}|V_H \setminus \mathcal{N}(v_i)| \le 2n \\
\Rightarrow &|V_H \bigcap \mathcal{N}(v_i)| + \frac{\beta}{2\alpha}(|V_H| - |V_H \bigcap \mathcal{N}(v_i)|) \le 2n \\
\Rightarrow &(\frac{\beta}{2\alpha} - 1)|V_H \bigcap \mathcal{N}(v_i)| \ge \frac{\beta}{2\alpha}|V_H| - 2n \\
\Rightarrow &|V_H \bigcap \mathcal{N}(v_i)| \ge |V_H| - \frac{4\alpha}{\beta} n.
\end{aligned}$$

◁

Now we are ready to complete the proof of soundness (Lemma 16).

Proof of Lemma 16. For the sake of contradiction let us assume that the LCS is of size at least $2\beta mn$. Recall, we have already seen that $|V_H| \geq \beta n$. Now we consider the following two cases depending on the size of V_H.

Case 1: (When $|V_H| \leq \frac{\beta}{\gamma}n$). Suppose $|V_H| \leq \frac{\beta}{\gamma}n$ $(= k)$. Let $V' \supseteq V_H$ be an arbitrary set of size exactly $\frac{\beta}{\gamma}n$. Let H' be the subgraph induced by the vertices V'. Using Claim 21 and Claim 22, we can lower bound the density of the subgraph H' by:

$$\frac{\frac{1}{2}\sum_{v\in V'_H}\left(|V_H| - \frac{4\alpha}{\beta}n\right)}{\binom{|V'|}{2}} \geq \frac{\left(\beta - \frac{4\alpha}{\beta}\right)n \cdot \left(\beta - \frac{4\alpha}{\beta}\right)n}{\frac{\beta}{\gamma}n \cdot \frac{\beta}{\gamma}n} \geq \left(\gamma - \frac{4\alpha\gamma}{\beta^2}\right)^2.$$

As we set $\alpha = \beta^2/8$, we get that the density of the subgraph induced by V' is at least $(\gamma/2)^2$.

Case 2: (When $|V_H| > \frac{\beta}{\gamma}n$). If $|V_H| > \frac{\beta}{\gamma}n$, the density of the subgaph H induced by V_H is lower bounded by:

$$\begin{aligned}
\frac{\frac{1}{2}\sum_{v\in V'_H}\left(|V_H| - \frac{4\alpha}{\beta}n\right)}{\binom{|V_H|}{2}} &\geq \frac{|V'_H|\left(|V_H| - \frac{4\alpha}{\beta}n\right)}{|V_H|(|V_H|-1)} \\
&\geq \frac{\left(|V_H| - \frac{4\alpha}{\beta}n\right)^2}{|V_H|^2} \\
&= \left(1 - \frac{4\alpha n}{\beta|V_H|}\right)^2 \\
&\geq (1 - \frac{\gamma}{2})^2 && \text{(since } |V_H| > \frac{\beta}{\gamma}n \text{ and we set } \alpha = \beta^2/8) \\
&\geq (\gamma/2)^2 && \text{(since } \gamma \leq 1).
\end{aligned}$$

Now since density of the subgraph is at least $(\gamma/2)^2$, it follows from the following simple claim that there exists a subgraph of H of size $\frac{\beta}{\gamma}n$ which has density at least $(\gamma/2)^2$.

▷ Claim 23. Suppose a graph $G = (V, E)$ has edge density c, then for any $2 \leq k \leq |V|$, there exists a subgraph of size k with density at least c.

Proof. Let $n = |V|$. Pick a subset $H \subseteq V$ of size exactly k uniformly at random. For a fixed edge e in G, the probability that the edge e is present in the subgraph induced by H is exactly $\frac{\binom{n-2}{k-2}}{\binom{n}{k}}$. Since G has $c \cdot \binom{n}{2}$ edges, by linearity of expectation, the expected number of edges in the subgraph induced by H is equal to $c \cdot \binom{n}{2} \cdot \frac{\binom{n-2}{k-2}}{\binom{n}{k}} = c \cdot \binom{k}{2}$. Therefore, the expected density of the subgraph is exactly equal to c. Hence, by an averaging argument, there exists a subgraph of G of size k with density at least c. ◁

In both the cases, we have shown that there exists a subgraph of size $\frac{\beta}{\gamma}n(= k)$ with density at least $(\gamma/2)^2$, which is a contradiction to the fact that we started with a NO instance of $\frac{\gamma^2}{4}$-DkS$\left(\frac{\beta}{\gamma}n, n\right)$. Therefore in this case, the size of LCS must be at most $2\beta mn$. ◀

Proof of Theorem 2

If there is no polynomial time algorithm to distinguish between the YES and NO instances of $\frac{\gamma^2}{4}$-DkS$\left(\frac{\beta}{\gamma}n, n\right)$, then using Lemma 15 and Lemma 16, it follows that there is no polynomial time algorithm to distinguish between the cases when the LCS of $Y_1, \cdots, Y_n, Y'_1, \cdots, Y'_n$ is of size $\frac{\beta}{\gamma}mn$ vs. $2\beta mn$. Also note that if we use Lemma 13 to construct the strings S_i's then the alphabet size is $O(\alpha^{-3}) = O(\beta^{-6})$. This proves the main theorem.

4 Conclusion

In this paper we show hardness of constant factor approximation of Multi-LCS problem with input of length n over $n^{o(1)}$ sized alphabet assuming the Exponential Time Hypothesis (ETH). This is the first hardness result for approximating Multi-LCS problem for sublinear sized alphabet. To prove our result we provide a reduction from the densest k-subgraph problem with perfect completeness, and then use the known hardness results for the latter problem from [24]. One interesting fact is that if one could show hardness of the γ-DkS(k, n) problem for $k = \Theta(\frac{n}{poly \log n})$ and $\gamma = (\log n)^{-c}$ for some $c > 0$, then due to our reduction that will directly imply constant factor hardness for Multi-LCS over poly-logarithmic sized alphabet under ETH.

A Derandomized version of Lemma 12

To achieve deterministic reduction we need to construct the set of strings $S_1, \cdots, S_n$ deterministically in time $poly(n)$. For that purpose we use the notion of *synchronization strings* used in the literature of *insertion-deletion codes* [14, 9].

▶ **Definition 24** (c-long-distance ε-synchronization string). *A string $S \in \Sigma^n$ is called a c-long-distance ε-synchronization string for some parameter $\varepsilon \in (0,1)$, if for every $1 \leq i < j \leq i' < j' \leq n$ with $i' - j \leq n \cdot \mathbb{1}_{(j+j'-i-i')>c\log n}$, $|LCS(S[i,j], S[i',j'])| \leq \varepsilon(j + j' - i - i')$, where $\mathbb{1}_{(j+j'-i-i')>c\log n}$ is the indicator function for $(j + j' - i - i') > c \log n$.*

Note, in the definition of c-long-distance ε-synchronization string in [9] authors used the notion of *edit distance* instead of LCS. More specifically, they specified the edit distance between $S[i,j]$ and $S[i',j']$) is at least $(1-\varepsilon)(|S[i,j]| + |S[i',j']|)$. However both the notions can be used interchangeably since for any two strings S, S', $|LCS(S,S')| = |S| + |S'| - ED(S,S')$, where the edit distance $ED(S,S')$ is defined as the minimum number of insertion and deletion operations required to transform S to S'. One may note that, generally while defining the edit distance we also allow substitution operation. However here we are not allowing substitution operation, and that is why we are able to write the following equivalence between LCS and the edit distance of two strings S, S': $|LCS(S,S')| = |S| + |S'| - ED(S,S')$. We would like to mention that in [9] authors also used this particular version of the edit distance notion (i.e., without substitution operation).

Several constructions of such long-distance synchronization strings are given in [14, 9] with different parameters. However we restate one of the theorems from [9] that we find useful for our purpose.

▶ **Theorem 25** (Rephrasing of Theorem 5.4 of [9]). *For any $n \in \mathbb{N}$ and parameter $\varepsilon \in (0,1)$, there is a deterministic construction of an ε^{-2}-long-distance ε-synchronization string $S \in \Sigma^n$ for some alphabet Σ of size $O(\varepsilon^{-3})$. Moreover, for any $i \in [n]$ the substring $S[i, i + \log n]$ can be computed in time $O(\varepsilon^{-2} \log n)$.*

Now using the above we will provide deterministic construction of set of strings $S_1, \cdots, S_n$ with our desired property.

▶ **Lemma 13.** *For any $\alpha \in (0,1)$, and $n \in \mathbb{N}$ there exists an alphabet Σ' of size $O(\alpha^{-3})$ such that for any $m > 2\alpha^{-2} \log n$, there is a deterministic construction of a set of strings $S_1, \cdots, S_n \in \Sigma'^m$ such that for each $i \neq j$, $|LCS(S_i, S_j)| \leq \alpha m$. Moreover, all the strings can be generated in time $O(\alpha^{-2} nm)$.*

Proof. For a specified α and n, set $\varepsilon = \alpha/2$. Then use the construction from Theorem 25 to get an ε^{-2}-long-distance ε-synchronization string S of length $2nm$, for any $m > \frac{1}{2}\varepsilon^{-2} \log n$. The bound on m is required to satisfy the condition that $(j + j' - i - i') > c \log n$ of Definition 24. (Note, in our case $(j + j' - i - i') = 2m$ and $c = \varepsilon^{-2}$.) Then divide the string S into m length blocks. Finally choose alternate blocks as $S_1, \cdots, S_n$. More specifically, $S_1 = S[1,m], S_2 = S[2m+1, 3m], \cdots, S_n = S[(2n-2)m+1, (2n-1)m]$. Now the bound on $|LCS(S_i, S_j)|$ for any $i \neq j$, directly follows from Definition 24. ◀

Abstract

Directed Steiner Tree (DST) is a central problem in combinatorial optimization and theoretical computer science: Given a directed graph $G = (V, E)$ with edge costs $c \in \mathbb{R}^E_{\geq 0}$, a root $r \in V$ and k terminals $K \subseteq V$, we need to output a minimum-cost arborescence in G that contains an $r \to t$ path for every $t \in K$. Recently, Grandoni, Laekhanukit and Li, and independently Ghuge and Nagarajan, gave quasi-polynomial time $O(\log^2 k / \log\log k)$-approximation algorithms for the problem, which are tight under popular complexity assumptions.

In this paper, we consider the more general Degree-Bounded Directed Steiner Tree (DB-DST) problem, where we are additionally given a degree bound d_v on each vertex $v \in V$, and we require that every vertex v in the output tree has at most d_v children. We give a quasi-polynomial time $(O(\log n \log k), O(\log^2 n))$-bicriteria approximation: The algorithm produces a solution with cost at most $O(\log n \log k)$ times the cost of the optimum solution that violates the degree constraints by at most a factor of $O(\log^2 n)$. This is the first non-trivial result for the problem.

While our cost-guarantee is nearly optimal, the degree violation factor of $O(\log^2 n)$ is an $O(\log n)$-factor away from the approximation lower bound of $\Omega(\log n)$ from the Set Cover hardness. The hardness result holds even on the special case of the *Degree-Bounded Group Steiner Tree* problem on trees (DB-GST-T). With the hope of closing the gap, we study the question of whether the degree violation factor can be made tight for this special case. We answer the question in the affirmative by giving an $(O(\log n \log k), O(\log n))$-bicriteria approximation algorithm for DB-GST-T.

1 Introduction

Network design is a central problem in combinatorial optimization and computer science. To capture more practical situations, the more general model of network design with *degree-constraints* was suggested in the early 90's [22, 8] and has attracted researchers in both theory and practice for decades. One of the most famous examples is the *Degree-Bounded Minimum Spanning Tree* (DB-MST) problem, which models the problem of designing a multi-casting network in which each node only has enough power to broadcast to a bounded number of its neighbors. This problem has been studied in a sequence of works (see, e.g.,[16, 18, 11, 24]), leading to the breakthrough result of Goemans [11] followed by the work of Singh and Lau [24], which settled the problem by giving an algorithm that outputs a solution with optimum cost, while violating the degree bound by an additive factor of $+1$. Since the works on DB-MST, many efforts have been dedicated to the study the generalizations of the problem: the *Degree-Bounded Steiner Tree* problem, in which the goal is to find a minimum-cost subgraph that connects all the terminals, while meeting the given degree bounds, was studied in [17, 21]. The *Survivable Network Design* problem, where each pair of nodes v, w are required to have at least λ_{vw} edge-disjoint v-w paths, has also been studied in literature; see, e.g., [20, 21].

Recently, degree-bounded network design problems have been studied in the online setting [4, 3, 5]. Besides the standard (also called point-to-point) network design problems, Dehghani et al. [4] also studied the *Degree-Bounded Group Steiner Tree* problem (DB-GST). They gave a negative result, which shows that it is not possible to approximate both cost and weight of the Online DB-GST problem simultaneously, even when the input graph is a star. More specifically, there exists an input demand sequence that forces any algorithm to pay a factor of $\Omega(n)$ either in the cost or in the degree violation. To date, there was no non-trivial approximation algorithm for DB-GST, either in the online or offline setting, and even when all the edges have zero-cost. This was listed as an open problem by Hajiaghayi [14] at the 8th Flexible Network Design Workshop (FND 2016).

In this paper, we study a degree-bounded variant of the classic network design problem, the *Degree-Bounded Directed Steiner Tree* problem (DB-DST). Formally, in DB-DST, we are given an n-vertex directed graph $G = (V, E)$ with costs on edges, a root vertex r, a set of k terminals K, and degree bounds d_v for each vertex v. The goal is to find a minimum-cost rooted tree $T \subseteq G$ that contains a path from the root r to every terminal $t \in K$, while respecting the degree bound, i.e., the out-degree of each vertex v in T is at most d_v. Despite being a classic problem, there was no previous positive result on DB-DST as it is a generalization of DB-GST.

The barriers in obtaining any non-trivial approximation algorithm for DB-GST and DB-DST are similar. Most of the previous algorithms for these two problems either run on the metric closure of the input graph [9, 7, 23], require metric-tree embedding [9, 1, 6] or use height-reduction techniques [25, 2, 13, 10], all of which lose track of the degree of the solution subgraph.

We present a bi-criteria $(O(\log k \log n), O(\log^2 n))$-approximation algorithm for DB-DST that runs in quasi-polynomial-time (see Section 1.1 for the definition), thus solving the open problem of Hajiaghayi [14]. Our technique expands upon the recent result of Grandoni, Laekhanukit and Li [13] for the Directed Steiner Tree problem. We observe that the algorithm in [13] can be easily extended to the problem with degree bounds. Nevertheless, to amend the degree-constrained problem into their framework, we are required to prove a concentration bound for degrees, which is rather non-trivial. Notice that the $O(\log n \log k)$-approximation factor on the cost of the tree is almost tight due to the hardness of $\Omega(\log^{2-\epsilon} n)$ in [15] for Directed Steiner Tree and the slightly improved hardness of $\Omega(\log^2 n/\log\log n)$ in [13].

While our result for DB-DST is (almost) tight on the cost guarantee, the degree violation factor $O(\log^2 n)$ is an $O(\log n)$ factor away from the approximation lower bound of $\Omega(\log n)$ from the Set Cover hardness. To understand if the gap can be reduced, we study the special case of DB-DST obtained from the hardness construction in [15], namely the *Degree-Bounded Group Steiner Tree problem on trees* (DB-GST-T). In this problem, we are given an (undirected) tree $T^\circ = (V^\circ, E^\circ)$ with edge-costs, a root r, k subsets of vertices (called groups) $O_1, \ldots, O_k \subseteq V$ and a degree bound d_v for each vertex $v \in V^\circ$. The goal is to find a minimum-cost subtree $T \subseteq T^\circ$ that joins r to at least one vertex from each group O_t, for every $t \in [k]$, while respecting the degree bound, i.e., the number of children of each vertex v in T is at most d_v. We present an $(O(\log k \log n), O(\log n))$-bicriteria approximation algorithm for DB-GST-T. So, the degree violation of our algorithm is tight and the cost-guarantee is almost tight. This improves upon the $O(\log n \log k, \log n \log k)$-bicriteria approximation algorithm due to Kortsarz and Nutov [19] who observe that the randomized rounding algorithm in [9] also gives a guarantee on degree-violation.

1.1 Our Results

Our first result is an $(O(\log k \log n), O(\log^2 n))$-bicriteria approximation for DB-DST that runs in quasi-polynomial time: We say that a randomized algorithm is an (α, β)-bicriteria-approximation algorithm if it outputs a tree T containing an $r \to t$ path for every terminal $t \in K$ such that the number of children of every vertex v in T is at most $\beta \cdot d_v$, and the expected cost of the tree is at most α times the cost of the optimum tree that does not violate the degree constraints.

▶ **Theorem 1.** *There is a randomized $(O(\log n \log k), O(\log^2 n))$-bicriteria approximation algorithm for the degree-bounded directed Steiner tree problem in $n^{O(\log n)}$-time.*

To the best of our knowledge, our result for DB-DST is the first non-trivial bicriteria approximation for the problem. As we mentioned, the $O(\log n \log k)$-factor for the cost is almost tight due to the hardness results of [15] and [13] for DST. There is a hardness of $\Omega(\log n)$ for the degree violation factor from the Set Cover problem, even if we ignore the cost of the output tree.

▶ Remark. As in [13, 10], we could save a factor of $\log\log n$ in the approximation factor for the problem, with a slight increase in the running time. However, this complicates the algorithmic framework. To deliver the algorithmic idea in a cleaner way, we choose to present the results with $O(\log n \log k)$ approximation ratios.

Our second result is for the degree-bounded group Steiner tree problem on trees (DB-GST-T). We obtain an $\big(O(\log n \log k), O(\log n)\big)$-bicriteria approximation, which is (almost) tight on both factors:

▶ **Theorem 2.** *There is a randomized $\big(O(\log n \log k), O(\log n)\big)$-bicriteria approximation for the degree-bounded group Steiner tree problem on trees.*

1.2 Our Techniques

Our algorithm for DB-DST takes ingredients from both [13] and [10]. As in these papers, we consider an optimum solution, and recursively partition it into balanced sub-trees; we then assign a "state" to each of these sub-trees. The tree structure of this recursive partition, as well as all of the states, form what we call a *state tree*. We solve the problem indirectly, by finding a good state tree, which we can transform back into a corresponding good solution. The state of a sub-tree contains a set of special vertices in the sub-tree that we call *portals*; these were used in [10] to obtain their improved approximation algorithm for DST. We construct a super-tree $\mathbf{T}^\circ$ that contains all possible state trees as sub-trees and reduce the problem considered into that of finding a good sub-tree of small cost in $\mathbf{T}^\circ$. This can be done by formulating a linear program (LP) relaxation and rounding the LP solution using a recursive procedure. The construction of the super-tree and the LP rounding techniques are similar to those in [13]. To extend the algorithm to DB-DST, we need to store the degrees of all of the portals in the state.

This algorithmic framework outputs a so-called "multi-tree": This is a tree where a vertex or an edge can appear multiple times. Repeating the procedure for $Q = O(\log n \log k)$ times, we obtain a set of Q multi-trees. This process violates the degree requirements and thus we obtain bicriteria approximation results. The analysis of this process is non-trivial as we need to prove a concentration bound on the number of times a vertex appears in a multi-tree.

Our technique for DB-GST-T is in observing that the rounding algorithm for GST-T (no degree bounds) in [9] is indeed a generalization of random walk. As we slightly boost the branching probability by a constant factor, this (almost) does not affect the degree bound, but the probability of connecting the root vertex to each group is amplified dramatically. A drawback is that it also incurs a huge blow-up in the cost. To handle the blow-up, we stop amplifying the branching probability when the connecting probability is sufficiently large. The best (but inaccurate) way to illustrate our algorithm is by considering a random walk from the root vertex to a group O_t. We change the random process by branching into two directions simultaneously in each step, and then stop the extra branching when it generates $\Theta(\log n)$ simultaneous random walks. Since we have $O(\log n)$ simultaneous random walks, the cost incurred by the process is blown-up by a factor $O(\log n)$, but the degree-violation is blown-up by only a factor 2. At the same time, the probability of reaching the group O_t goes up by a factor $\Omega(\log n)$. Thus, if we need $O(\log k \log n)$ rounds to reach every group, then we now need only $O(\log k)$ rounds. There is no difference in the cost for running the algorithm for $O(\log k \log n)$ rounds or $O(\log k)$ rounds (with an extra $O(\log n)$ factor in the cost), but it saves a factor in the degree-violation of $O(\log n)$.

2 Preliminaries for Degree-Bounded Directed Steiner Tree

2.1 Notations and Assumptions

In our algorithm and analysis for the DB-DST problem, a tree is always an out-arborescence. Given a tree T, we use $\text{root}(T)$ to denote its root. Given T and a vertex v in T, we use $\Lambda_T(v)$ to denote the set of children of v, and $\Lambda^*_T(v)$ to denote the set of descendants of v

(including v itself) in the tree T. A sub-tree T' of T is a weakly-connected sub-graph of T; such a T' must be an out-arborescence. Sometimes, we shall use left and right children to refer to the two children of a vertex in a tree; in this case, the order of the two children is important and will be clearly specified. For an edge $e = (u, v)$, we use $\text{head}(e) = v$ to denote its head.[1] For a triple $\xi = (u, v, v')$ of three vertices, we use $\text{second}(\xi) = v$ and $\text{third}(\xi) = v'$ to denote the second and third parameter of ξ.

Our input digraph is G. Let $d_{\max} = \max_{v \in V} d_v$. We shall assume each terminal $t \in K$ has only one incoming edge and no outgoing edges in G. This can be assumed w.l.o.g using the following simple operation: For every terminal $t \in K$ that does not satisfy the condition, we add a new vertex t', an edge (t, t') with cost $c_{(t,t')} = 0$ and replace t with t' in K. We increase d_t by 1 and set $d_{t'} = 0$.

One more assumption we can make is that each non-terminal $u \in V \setminus K$ has at most 2 outgoing edges in G. To make sure that this holds, we focus on some non-terminal u with $b \geq 3$ outgoing edges. We replace the star centered at u with its b outgoing edges by a gadget which is a full binary-tree rooted at u with b leaves being the out-neighbors of u. For every newly added vertex u, we set $d_u = d_{\max}$. This way every vertex in G will have at most 2 outgoing edges. The cost of the edges in the gadget can be naturally defined: every leaf edge (of this gadget) ending at w has cost $c_{(u,w)}$, and all internal edges have zero cost. However, this operation changes the degree of vertices. To address this issue, we define a simple transformation function $\phi_v : \mathbb{Z} \to \mathbb{Z}$ for every $v \in V$ as follows: If v is a vertex in the original graph, then ϕ_v is identically 1. Otherwise, v is a non-root internal vertex of some gadget and we define ϕ_v to be the identity function. Then we can compute the *original degree* ρ_u of a vertex u in a tree T of G recursively as follows: $\rho_u = 0$ if u is a leaf, and $\rho_u = \sum_{v \in \Lambda_T(u)} \phi_v(\rho_v)$ otherwise. So, we require that for every v in the output tree T, the original degree ρ_v of v is at most d_v.

2.2 Balanced Tree Partition

We shall use the following basic tool as the starting point of our algorithm design. Its proof is elementary and deferred to Appendix B.

▶ **Lemma 3.** *Let $T = (V_T, E_T)$ be an n-vertex binary tree. Then there exists a vertex $v \in V_T$ with $n/3 < |\Lambda^*_T(v)| \leq 2n/3 + 1$.*

Given a tree $T = (V_T, E_T)$ as in the lemma, we can partition it into two trees $T_1 = (V_{T_1}, E_{T_1})$ and $T_2 = (V_{T_2}, E_{T_2})$, where T_2 contains vertices in $\Lambda^*_T(v)$ and T_1 contains vertices in $V_T \setminus (\Lambda^*_T(v) \setminus \{v\})$. First assume $n \geq 4$. Since $2n/3+1 < n$, we know that $v \neq \text{root}(T)$, thus implying $\text{root}(T_1) = \text{root}(T) \neq \text{root}(T_2) = v$, which is a leaf in T_1. Consequently, we have $E_{T_1} \uplus E_{T_2} = E_T$ and $V_{T_1} \cup V_{T_2} = V_T, V_{T_1} \cap V_{T_2} = \{\text{root}(T_2)\}$. Moreover, $|V_{T_1}|, |V_{T_2}| \leq 2n/3+1$, which is strictly less than n. Thus, T_1 and T_2 are sub-trees that form a balanced partition of (the edges of) T. We call this procedure the *balanced tree partitioning* on T.

When $n = 3$, there are 2 types of trees. If the root has two children, then we could not make both $|V_{T_1}|$ and $|V_{T_2}|$ to be smaller than 3. If the tree is a path of 2 edges, then we can choose v to be the middle vertex and the procedure partitions the tree into two edges. Later, we shall apply the balanced tree partitioning procedure recursively. We stop the recursion when the tree is either an edge, or only contains the root and its 2 children. In other words, the tree has only 1 level of edges.

[1] [12] mistakenly called u the head and v the tail. We follow the common convention to call v the head.

2.3 Multi-Tree

We define a *multi-tree* in G as an intermediate structure. It is simply a tree over *multi-sets* of vertices and edges in G:

▶ **Definition 4** (Multi-Tree). *Given the input digraph $G = (V, E)$, a* multi-tree *in G is a tree $T = (V_T, E_T)$ where every vertex $a \in V_T$ is associated with a label* $\text{label}(a) \in V$ *such that for every $(a, b) \in E_T$, we have* $(\text{label}(a), \text{label}(b)) \in E$.

We say that each vertex $a \in V_T$ is a copy of the vertex $\text{label}(a) \in V$ and each edge $(a, b) \in E_T$ is a copy of the edge $(\text{label}(a), \text{label}(b)) \in E$. So, we say that T is rooted at a copy of $v \in V$, if $\text{label}(\text{root}(T)) = v$, and T contains a copy of some $v \in V$ if there exists some $a \in V_T$ with $\text{label}(a) = v$. We extend the costs c_e, the functions ϕ_v and the degree bounds d_v to their copies in a multi-tree as follows: for a vertex a and an edge (a, b) in a multi-tree, $d_a = d_{\text{label}(a)}, \phi_a \equiv \phi_{\text{label}(a)}$ and $c_{(a,b)} = c_{(\text{label}(a),\text{label}(b))}$. The cost of a multi-tree $T = (V_T, E_T)$ is naturally defined as $\text{cost}(T) = \sum_{e \in E_T} c_e$. Given a multi-tree T, the "original degree" ρ_a of a vertex a can be computed in the same way as before.

▶ **Definition 5** (Good Multi-Trees). *Let $T = (V_T, E_T)$ be a multi-tree in G. We say that T is good if it is rooted at a copy of r, has leaves being copies of terminals, and the original degree of any vertex a in T is at most d_a.*

We can then state the main theorem for DB-DST, which we prove in Sections 3 to 5.

▶ **Theorem 6** (Main Theorem for DB-DST). *There is an $n^{O(\log n)}$-time randomized algorithm that outputs a good multi-tree $T = (V_T, E_T)$ such that*

(6a) $\mathbb{E}_T[\text{cost}(T)] \le \text{opt}$*, where* opt *is the cost of the optimum solution for the instance.*

(6b) *For every $t \in K$, we have* $\Pr_T[V_T \text{ contains a copy of } t] \ge \Omega(1/\log n)$.

(6c) *For some $s = \Omega\left(\frac{1}{\log n}\right)$, it holds, for every $v \in V$, that*

$$\mathbb{E}\left[\exp\left(s \cdot (\textit{number of copies of } v \textit{ in } T)\right)\right] \le 1 + O\left(\tfrac{1}{\log n}\right).$$

We show that this implies Theorem 1.

Proof of Theorem 1. We run the algorithm in Theorem 6 Q times to obtain Q good multi-trees $T_1, T_2, \ldots, T_Q$, for some large enough $Q = O(\log n \log k)$. Our output will contain all edges that appear in the Q multi-trees. Notice that the output may not be a tree, but we can remove edges so that it becomes a tree. Applying union bound, all terminals appear in the union of the Q trees with probability at least 0.9, when Q is big enough. By Property (6c) in the theorem statement, we have for every v,

$$\mathbb{E}\left[\exp\left(s \cdot (\#\text{ copies of } v \text{ in } T_1, \ldots, T_Q)\right)\right] \le \left(1 + O\left(\frac{1}{\log n}\right)\right)^Q = \exp(O(\log k)).$$

The above inequality holds since the Q trees are produced independently.

Thus, if $M = O(\log n)$ is big enough, by Markov's inequality we have

$$\Pr\left[\exp\left(s \cdot (\#\text{ copies of } v \text{ in } T_1, \ldots, T_Q)\right) \ge \exp(M)\right] \le \frac{1}{10n}.$$

The event on the left side is exactly that the number of copies of v in $T_1, \ldots, T_Q$ is at least M/s.

Thus, with probability at least 0.8, every terminal t appears in one of the Q trees and every vertex v appears at most $M/s = O(\log^2 n)$ times in the trees. Taking the union of all trees and reflecting the edges in the original graph G, we have a sub-graph G' of G containing a path

from r to every terminal $t \in K$. The total cost of edges in G' is at most $O(\log n \log k) \cdot \text{opt}$. For every vertex v, the out-degree of v in G' is at most $(M/s)d_v = O(\log^2 n)d_v$. We can take an arbitrary Steiner tree T in G' as the output of the algorithm. This gives us an $(O(\log n \log k), O(\log^2 n))$-bicriteria approximation algorithm for the degree-bounded directed Steiner tree problem. The running time of the algorithm is $n^{O(\log n)}$. ◀

Organization. The remaining part of the paper is organized as follows. In Section 3, we define states and good state trees. In Section 4, we argue that the problem of finding a small cost valid tree can be reduced to that of finding a small cost state-tree. In Section 5, we present our linear programming rounding algorithm that finishes the proof of Theorem 6. Section 6 is dedicated to the proof of Theorem 2 for the degree-bounded group Steiner tree problem on trees (DB-GST-T).

3 States and State-Trees

Given the optimum tree T^* (which is binary by our assumptions) for the DB-DST problem, we can apply the balanced tree partitioning recursively to obtain a *decomposition tree*: We start from T^* and partition it into two trees T_1 and T_2 using the balanced-tree-partitioning procedure, and then recursively partition T_1 and T_2 until we obtain sub-trees with 1 level of edges: Such a tree contains either a single edge, or two edges from the root. Then the decomposition tree is a full binary tree where each node corresponds to a sub-tree of T^*. Due to the balance condition, the height of the tree will be $O(\log n)$. Throughout the paper, we shall use $h = \Theta(\log n)$ to denote an upper bound on the height of this decomposition tree.

Thanks to its small depth, the decomposition tree becomes the object of interest. However, as each node in the tree corresponds to a sub-tree of the optimum solution T^*, it contains too much information for the algorithm to handle. Instead, we shall only extract a small piece of information from each node that we call the *state* of the node. On one hand, a state contains much less information than a sub-tree does, so we can afford to enumerate all possible states for a node. On the other hand, the states of nodes in the decomposition tree still contain enough information for us to check whether the correspondent multi-tree is good. We call the binary tree of states a *state tree*; we require in a *good state tree*, the states of nodes satisfy some consistency constraints. Then we can establish a two-direction connection between good multi-trees and good state trees.

Given a valid tree T in G and a sub-tree T' of T, we now start to make definitions related to the state of T' w.r.t T. It is convenient to think that T is the optimum tree T^* and T' is a sub-tree of $T = T^*$ obtained from the recursive balanced-partitioning procedure since this is how we use the definitions. However, the definitions are w.r.t. general T and T'; from now on till the end of Section 3, we fix any valid tree T and its sub-tree T'.

3.1 Portals

Other than root(T'), the state for T' w.r.t. T contains the set of *portals* of T':

▶ **Definition 7.** *A vertex v in T' is a* portal *in T' if v is* root(T') *or a non-terminal leaf of T'.*

In general, the set of portals of T' can be large, but if T' is obtained from the recursive balanced-tree-partitioning procedure for T, then the number of portals can be shown to be at most $h + 1$. As we shall often use the root and set of portals together, we make the following definition:

▶ **Definition 8** (Root-Portals-Pair). *A pair (r', S) is called a root-portals-pair for vertex r' and portals S if $r' \in S \subseteq V \setminus K$.*

It is easy to see that the root-portal-pairs for an internal node of the decomposition tree and its two children satisfy some properties stated in the following definition:

▶ **Definition 9** (Allowable Child-Pair). *Given three root-portals-pairs $(r', S), (r', S_1)$ and (r'', S_2), we say $((r', S_1), (r'', S_2))$ is an allowable child-pair of (r', S) if $r'' \notin S, S_1 \cup S_2 = S \cup \{r''\}$ and $S_1 \cap S_2 = \{r''\}$.*

The following claim motivates the definition of allowable child pairs:

▷ Claim 10. Assume $T' = (V', E')$ contains at least 2 levels of edges. Let $T'_1 = (V'_1, E'_1)$ and $T'_2 = (V'_2, E'_2)$ be the two sub-trees obtained by applying the balanced tree partitioning on T'. Let $r' = \text{root}(T') = \text{root}(T'_1)$, $r'' = \text{root}(T'_2) \neq r'$ and S, S_1, S_2 be the sets of portals in T', T'_1, T'_2 respectively. Then, $((r', S_1), (r'', S_2))$ is an allowable child-pair of (r', S).

Proof. First, r'' is not a portal of T' since it is a non-root internal vertex in of T'. Second, it is easy to see that $S_1 = (S \cup \{r''\}) \cap V'_1$ and $S_2 = (S \cup \{r''\}) \cap V'_2$. So, $S_1 \cup S_2 = S \cup \{r''\}$ and $S_1 \cap S_2 = \{r''\}$. ◁

3.2 Degree Vectors

The next piece of the information in a state is a *degree vector*:

▶ **Definition 11.** *A degree vector for a set $S \subseteq V \setminus K$ is a vector $\rho = (\rho_v)_{v \in S}$, where ρ_v is an integer in $[1, d_v]$ for every $v \in S$.*

As explained in section 2.1, ρ_v will be the original degree of v in the tree T.

▶ **Definition 12** (Consistency of degree vectors). *Given a root-portals-pair (r', S), an allowable child-pair $((r', S_1), (r'', S_2))$ of (r', S), three degree vectors ρ, ρ^1 and ρ^2 for S, S_1 and S_2 respectively, we say ρ^1 and ρ^2 are consistent with ρ, if*

- *for every $v \in S_1 \setminus \{r''\}$, we have $\rho_v = \rho^1_v$,*
- *for every $v \in S_2 \setminus \{r''\}$, we have $\rho_v = \rho^2_v$ and*
- *$\rho^1_{r''} = \rho^2_{r''}$.*

So, the degree vectors are consistent if there is no contradictory information among them.

▶ **Definition 13** (Edge/Triple Agreeing with Degree Vector). *Given a root-portals-pair (r', S) with $|S| \leq 2$, a degree vector ρ for S, and an edge $(r', v) \in E$ with $\{r', v\} \setminus K = S$, we say (r', v) agrees with ρ if $\rho_{r'} = (\phi_v(\rho_v)$ or $1)$, where $(\phi_v(\rho_v)$ or $1)$ denotes $\phi_v(\rho_v)$ if ρ_v is defined (i.e., if $v \in S$) and 1 otherwise.*

Similarly, given a root-portals-pair (r', S) with $|S| \leq 3$, a degree vector ρ for S, and two edges $(r', v), (r', v') \in E$ such that $\{r', v, v'\} \setminus K = S$, we say the triple (r', v, v') agrees with ρ if $\rho_{r'} = (\phi_v(\rho_v)$ or $1) + (\phi_{v'}(\rho_{v'})$ or $1)$.

Notice that, in the above definition, either $v \in S$ or $v \in K$. In the former case, ρ_v is defined; in the latter case ρ_v is not defined but we know ϕ_v is identically 1. The same argument holds for v'. The definition corresponds to the case when T' is a base case of the recursive balanced tree partitioning, i.e., T' contains only 1 level of edges. If T' contains an edge $e = (r', v)$, then the portal set of T' is $\{r', v\} \setminus K$. We shall have $\rho_{r'} = (\phi_v(\rho_v)$ or $1)$. Similarly, if T' contains 3 vertices (r', v, v') with r' being the root, then we must have $\rho_{r'} = (\phi_v(\rho_v)$ or $1) + (\phi_{v'}(\rho_{v'})$ or $1)$.

3.3 States and Good State-Trees

With degree vectors, we can define states and good state-trees:

▶ **Definition 14.** *A* state *is a tuple (r', S, ρ) where (r', S) is a root-portals-pair and ρ is a degree vector for S.*

The state of the tree T' w.r.t T is the tuple (r', S, ρ) with $r' = \mathrm{root}(T')$, S being the set of portals in T', and ρ being the vector of original degrees of vertices in S w.r.t. the tree T.

▶ **Definition 15** (Good State Trees)**.** A good state tree *is a full binary tree τ of depth at most h, where every node p is associated with a state (r'_p, S_p, ρ^p), and every leaf o is associated with either an edge $e_o \in E$ or a triple ξ_o such that the following conditions hold.*

(15a) $\left(r'_{\mathrm{root}(\tau)}, S_{\mathrm{root}(\tau)}\right) = (r, \{r\})$.

(15b) *For any leaf o of τ, either e_o or ξ_o agrees with ρ^o.*

(15c) *For an internal node p in τ, letting q and o be the left and right children of p, then the pair $((r'_q, S_q), (r'_o, S_o))$ is an allowable child-pair of (r'_p, S_p) (so, $r'_q = r'_p \neq r'_o$), and ρ^q and ρ^o are consistent with ρ^p.*

We say that a terminal $t \in K$ is involved *in a good state tree τ if there exists a leaf o of τ with $t = \mathrm{head}(e_o)$, or $t \in \{\mathrm{second}(\xi_o), \mathrm{third}(\xi_o)\}$.*

Given a good state tree τ, and a leaf o in τ, we define the cost $c(o)$ as follows. If e_o is defined, then we define $c(o) = c_{e_o}$; otherwise, define $c(o) = c_{(r'_o, \mathrm{second}(\xi_o))} + c_{(r'_o, \mathrm{third}(\xi_o))}$. The cost of a state-tree τ is defined as $\mathrm{cost}(\tau) := \sum_{o \text{ leaf of } \tau} c(o)$.

4 Reduction to Finding Good State-Trees

4.1 From a Valid Tree to a Good State-Tree Involving All Terminals

In this section, we show that the decomposition tree of the optimum tree T^* can be turned into a good state tree τ^* with desired properties. The procedure in the proof of the following lemma is only for the analysis purpose and is not a part of our algorithm.

▶ **Lemma 16.** *There is a good state-tree τ^* involving all terminals with $\mathrm{cost}(\tau^*) = \mathrm{cost}(T^*)$.*

Proof. As we alluded, the state tree τ^* is constructed by taking the state for each node in the decomposition tree for T^*. Formally, it is obtained by calling gen-state-tree(T^*) (defined in Algorithm 1). In the algorithm ρ^{T^*} is the vector of original degrees of all vertices in T^*.

Algorithm 1 gen-state-tree(T').

create a node p with $r'_p = \mathrm{root}(T'), S_p =$ portals of T' and ρ^p being ρ^{T^*} restricted to S_p
if T' has only 1 level of edges **then**
    if T' contains a single edge e **then** let $e_p = e$ and **return** the single node p
    otherwise, T' contains two edges (r', v) and (r', v'), let $\xi_p = (r', v, v')$ and **return** p
apply balanced tree partitioning to decompose T' into T'_1 and T'_2
$\tau_1 \leftarrow$ gen-state-tree(T'_1), $\tau_2 \leftarrow$ gen-state-tree(T'_2)
return the tree τ obtained by combining p, τ_1 and τ_2 with edges $(p, \mathrm{root}(\tau_1))$ and $(p, \mathrm{root}(\tau_2))$, with $\mathrm{root}(\tau_1)$ and $\mathrm{root}(\tau_2)$ being the left and right children of p respectively

We first show that τ^* is a good state tree, by showing that it satisfies all the properties in Definition 15. Property (15a) trivially holds by the way we define the parameters for the root recursion of gen-state-tree. Property (15b) holds by that each ρ^p is ρ^{T^*} restricted to S^p. Property (15c) follows from the same facts and Claim 10. $\text{cost}(\tau^*) = \sum_{e \in E_{T^*}} c_e = \text{cost}(T^*)$ since every edge in T^* is counted exactly once in τ^*. ◀

4.2 From a Good State Tree to a Good Multi-Tree

Now we focus on the other direction of the reduction and prove the following lemma:

▶ **Lemma 17.** *Given a good state tree τ, we can efficiently construct a good multi-tree T with $\text{cost}(T) = \text{cost}(\tau)$. Moreover, if a terminal $t \in K$ is involved in τ, then T contains a copy of t.*

Proof. The multi-tree T is constructed by joining the edges associated with all leaf nodes o in τ using a recursive procedure. For each node p in τ, we shall construct a multi-tree T_p for p, as well as a mapping π_p from S_p to vertices in T_p. The multi-tree T_p and the mapping π_p satisfy the following properties:

(P1) For every $v \in S_p$, we have $\text{label}(\pi_p(v)) = v$; that is, $\pi_p(v)$ is a copy of v.

(P2) $\pi_p(r'_p) = \text{root}(T_p)$.

In particular, the two properties imply that $\text{root}(T_p)$ is a copy of r'_p.

The trees and mappings are constructed from the bottom to the top of the tree τ. Focus on a leaf node p with $e_p = (r', v)$. If e_p is defined, then T_p only contains a copy of the edge (r', v). π_p maps r' to the copy of r', and if $v \notin K$ (thus, $v \in S_p$), v to the copy of v in T_p. Otherwise ξ_p is defined. Then T_p contains a tree with two edges: a copy of $(r'_p, \text{second}(\xi_p))$ and a copy of $(r'_p, \text{third}(\xi_p))$. π_p can also be defined naturally.

Now consider the case that p is an internal node and let q and o be its left and right children. Then, we have $r'_p = r'_q, r'_o \notin S_p, S_q \cup S_o = S_p \cup \{r'_o\}$ and $S_q \cap S_o = \{r'_o\}$ by Property (15c). Then we identify $\pi_q(r'_o)$ with $\pi_o(r'_o) = \text{root}(T_o)$, and then the multi-tree T_p is the new tree containing vertices in T_q and T_o. Notice that both $\pi_q(r'_o)$ and $\pi_o(r'_o)$ are copies of r'_o; thus, the obtained T_p can be well-defined. The mapping π_p is just the combination of π_q and π_o: For a vertex $v \in S_q$, let $\pi_p(v) = \pi_q(v)$; for a vertex $v \in S_o$, let $\pi_p(v) = \pi_o(v)$; since $S_q \cap S_o = \{r'_o\}$ and we identified $\pi_q(r'_o)$ with $\pi_o(r'_o)$, the mapping is well-defined. Also, it is easy to see that (P1) and (P2) holds for T_p and π_p.

Our final multi-tree for τ will be $T = T_{\text{root}(\tau)}$. It is straightforward to see that if $t \in K$ is involved in τ, then T contains a copy of t. Notice that all the ρ^p-vectors are consistent with each other, and for every leaf o, e_o or ϵ_o agrees with ρ^o. Thus, aggregating all the ρ^p vectors will recover the vector ρ^T of original degrees of vertices in ρ^T. So, the multi-tree T is good since every v in T has $\rho^T_v \in [1, d_v]$. The cost of T is $\sum_{e \in E_T} c_e = \sum_{o:\text{ leaves of } \tau} c(o) = \text{cost}(\tau)$. Finally, the running time of the algorithm is polynomial in the size of the state-tree τ. ◀

5 Finding a Good State Tree using LP Rounding

5.1 Extended State Trees and Construction of $\mathbf{T^0}$

With the relationship between good multi-trees and good state trees established, we can now focus on the problem of finding a good state-tree of small cost involving many terminals. We shall construct a quasi-polynomial sized tree $\mathbf{T}^\circ$ so that every good state-tree τ corresponds to a sub-tree $\mathbf{T}$ of $\mathbf{T}^\circ$ satisfying some property. Roughly speaking, $\mathbf{T}^\circ$ is the "super-set" of all potential good state-trees τ. However, since the consistency conditions are defined over three states for a parent and its two children, it is more convenient to insert a "virtual" node

between every internal node and its two children. Also, it is convenient to break a leaf state node o into two nodes, one containing the state information and the other containing e_o or ξ_o. Formally, for a good state-tree τ, we construct a correspondent tree $\mathbf{T}$ as follows.

1. Let $\mathbf{T}$ be a copy of τ. All nodes in $\mathbf{T}$ are called *state nodes*.
2. For every internal state node p in $\mathbf{T}$ with left and right children p_1 and p_2, we create a *virtual node* q and replace the two edges (p, p_1) and (p, p_2) with 3 edges $(p, q), (q, p_1)$ and (q, p_2); p_1 is still the left child and p_2 is the right child.
3. For every leaf state node p, we create a *base node* o and let o be the child of p. Then we move the e_p or ξ_p information from the node p to node o: If e_p is defined, then we let $e_o = e_p$ and undefine e_p; otherwise, let $\xi_o = \xi_p$ and undefine ξ_p.
4. We add a *super node* $\mathbf{r}$ and an edge from $\mathbf{r}$ to the root of $\mathbf{T}$. $\mathbf{r}$ will be the new root for $\mathbf{T}$.

We call this $\mathbf{T}$ the *extended state-tree* for τ; we say $\mathbf{T}$ is good if its correspondent τ is good. Clearly, there is a 1-to-1 correspondence between good state trees and good extended state trees.

Our $\mathbf{T}^\circ$ will be the "super-set" of all potential good extended state trees $\mathbf{T}$. Formally, we create a super node $\mathbf{r}$ to be the root of $\mathbf{T}^\circ$. Then, for every $\rho_r \in [1, d_r]$, we call cnstr-$\mathbf{T}^\circ(0, r, \{r\}, \rho = (\rho_r))$ to obtain a tree and let its root be a child of $\mathbf{r}$.

Algorithm 2 cnstr-$\mathbf{T}^\circ(h', r', S, \rho)$.

create a state node p with $(r'_p, S_p, \rho^p) = (r', S, \rho)$
for every $(r', v) \in E$ such that $\{r', v\} \setminus K = S$ and (r', v) agrees with ρ **do**
    create a "base node" o with $e_o = (r', v)$ and let o be a child of p
    let $c(o) = c_{(r',v)}$
for every $(r', v), (r', v') \in E$ such that $\{r', v, v'\} \setminus K = S$ and (r', v, v') agrees with ρ **do**
    create a "base node" o with $\xi_o = (r', v, v')$ and let o be a child of p
    let $c(o) = c_{(r',v)} + c_{(r',v')}$
if $h' < h$ **then**
    for every allowable child-pair $((r', S_1), (r'', S_2))$ of (r', S) **do**
        for every pair of degree vectors ρ^1 for S_1 and ρ^2 for S_2 such that ρ^1 and ρ^2 are consistent with ρ **do**
            create a "virtual node" q and let q be a child of p
            $\mathbf{T}_1 \leftarrow$ cnstr-$\mathbf{T}^\circ(h' + 1, r', S_1, \rho^1)$
            $\mathbf{T}_2 \leftarrow$ cnstr-$\mathbf{T}^\circ(h' + 1, r'', S_2, \rho^2)$
            let the left and right sub-trees of q be $\mathbf{T}_1$ and $\mathbf{T}_2$ respectively
return the tree $\mathbf{T}$ rooted at p

The following claim is immediate from the construction of $\mathbf{T}^\circ$.

▷ Claim 18. A subtree $\mathbf{T}$ of $\mathbf{T}^\circ$ with root($\mathbf{T}$) = root($\mathbf{T}^\circ$) is a good extended state tree if and only if the following happens:

- The super node in $\mathbf{T}$ has exactly one child (which is a state node).
- Each state node in $\mathbf{T}$ has exactly one child (which is a base node or a virtual node).
- For each virtual node q in $\mathbf{T}$, both q's children in $\mathbf{T}^\circ$ are in $\mathbf{T}$.

On the other hand, every good extended tree $\mathbf{T}$ of depth at most $h + 1$ is a sub-tree of $\mathbf{T}^\circ$ with root being root($\mathbf{T}^\circ$).

Also, we say that a vertex v is involved in $\mathbf{T}$ if there is a base node o in $\mathbf{T}$ with $v = \text{head}(e_o)$ or $v \in \{\text{second}(\xi_o), \text{third}(\xi_o)\}$. The cost of $\mathbf{T}$, denoted as cost($\mathbf{T}$), is defined as the sum of $c(o)$ over all base nodes in $\mathbf{T}$. So, the problem now becomes finding a small-cost good extended state tree in $\mathbf{T}^\circ$ that involves each terminal with large probability.

5.2 LP Formulation

We formulate an LP relaxation for our task. Let $\mathbf{V}^\circ$ be the set of nodes in $\mathbf{T}^\circ$, $\mathbf{r} = \text{root}(\mathbf{T}^\circ)$ and let $\mathbf{V}^\circ_{\text{state}}, \mathbf{V}^\circ_{\text{virt}}$ and $\mathbf{V}^\circ_{\text{base}}$ be the sets of state, virtual and base nodes in $\mathbf{T}^\circ$ respectively. Notice that there is only one super node, which is the root $\mathbf{r}$. For every $v \in V$, let $\mathbf{O}_v = \{v \in \mathbf{V}^\circ_{\text{base}} : v = \text{head}(e_o) \text{ or } v \in \{\text{second}(\xi_o), \text{third}(\xi_o)\}\}$ be the set of base nodes involving v. Let $\mathbf{T}^*$ be our target good extended state tree; this is the tree correspondent to the good state tree τ^*. Then, in our LP, we have a variable x_p for every $p \in \mathbf{V}^\circ$, that indicates whether p is in the $\mathbf{T}^*$ or not.

$$\min \quad \sum_{o \in \mathbf{V}^\circ_{\text{base}}} x_o c(o) \tag{1}$$

$$\sum_{q \in \Lambda_{\mathbf{T}^\circ}(p)} x_q = x_p, \quad \forall p \in \mathbf{V}^\circ_{\text{state}} \cup \{\mathbf{r}\} \tag{2}$$

$$x_p = x_q, \quad \forall q \in \mathbf{V}^\circ_{\text{virt}}, p \in \Lambda_{\mathbf{T}^\circ}(q) \tag{3}$$

$$x_p \in [0,1], \forall p \in \mathbf{V}^\circ \tag{4}$$

$$\sum_{o \in \Lambda^*_{\mathbf{T}^\circ}(p) \cap \mathbf{O}_t} x_o \le x_p, \quad \forall p \in \mathbf{V}^\circ, t \in K \tag{5}$$

$$\sum_{o \in \mathbf{O}_t} x_o = 1, \quad \forall t \in K \tag{6}$$

The objective function of LP (1) is to minimize the total cost of all leaves in $\mathbf{T}^*$. Constraint (2) requires that for every state or super node p in $\mathbf{T}^*$, exactly one child of p is in $\mathbf{T}^*$. Constraint (3) requires that a virtual node q in $\mathbf{T}^*$ has both its children in $\mathbf{T}^*$. Constraint (5) says for every node p in $\mathbf{T}^*$ and every terminal $t \in K$, there is a most one descendant base node o of p that is in $\mathbf{O}_t$. In the whole tree $\mathbf{T}^*$, exactly one leaf node o has $t = \text{head}(e_o)$ or $t \in \{\text{second}(\xi_o), \text{third}(\xi_o)\}$, for every $t \in K$ (Constraint (6)); in the LP, all the variables are between 0 and 1 (Constraint (4)).

Notice that (5) for $p = \mathbf{r}$ and any $t \in K$ and (6) for the same t imply that $x_{\mathbf{r}} = 1$. Constraint (2) and (3) imply that the x values over the nodes of a root-to-leaf path in $\mathbf{T}^\circ$ are non-increasing.

5.3 Rounding Algorithm

Given a valid solution x to LP (1), our rounding algorithm will round it to obtain the set $\mathbf{V} \subseteq \mathbf{V}^\circ$, which induces a good state tree. The algorithm is very similar to that of [9] with the only one difference: For every state node or super-node p that is added to $\mathbf{V}$, we add exactly one child q of p to $\mathbf{V}$, while the algorithm of [9] makes independent decisions for each child. The algorithm is formally described in Algorithm 3. In the main algorithm, we simply call round($\mathbf{r}$). It is straightforward to see that the tree induced by round($\mathbf{r}$) is a good extended state tree. The following claim also holds:

▷ Claim 19. Let $p \in \mathbf{V}^\circ$ and $q \in \Lambda^*_{\mathbf{T}^\circ}(p)$. Let $\mathbf{V}$ be the random set returned by round(p). Then we have $\Pr[q \in \mathbf{V}] = \frac{x_q}{x_p}$.

Applying the above claim for $p = \mathbf{r}$ and every $q \in \mathbf{V}^\circ_{\text{base}}$, we have that the expected cost of the tree induced by $\mathbf{V}$ is exactly $\text{cost}(x)$.

The main theorem we need about the rounding algorithm is as follows:

Algorithm 3 round(p).

1: **if** $p \in \mathbf{V}^{\circ}_{\text{state}} \cup \{\mathbf{r}\}$ **then**
2: randomly choose a child q of p according to probability vector $\left(\frac{x_q}{x_p}\right)_{q \in \Lambda_{\mathbf{T}^\circ}(p)}$
3: **return** $\{p\} \cup \text{round}(q)$
4: **else if** $p \in \mathbf{V}^{\circ}_{\text{virt}}$ **then**
5: **return** $\{p\} \cup \text{round}(\text{left child of } p) \cup \text{round}(\text{right child of } p)$
6: **else return** $\{p\}$

▶ **Theorem 20.** *Let* $\mathbf{V}$ *be the random set returned by* round($\mathbf{r}$). *Then, for any terminal* $t \in K$ *we have* $\Pr[\mathbf{V} \cap \mathbf{O}'_t \neq \emptyset] \geq \frac{1}{h+1}$.

Theorem 20 was proved [9] for the original rounding algorithm and was reproved in [23]. However, adapting the analysis to our slightly different rounding algorithm is straightforward and thus we omit the proof of the theorem here.

We now wrap up and finish the proof of the main theorem (Theorem 6) except for Property (6c), of which the proof is deferred to Appendix A due to the space constraint. We solve LP(1) to obtain a solution x. Notice that $\text{cost}(x) \leq \text{cost}(\mathbf{T}^*) = \text{cost}(\tau^*) = \text{cost}(T^*)$. Let $\mathbf{V} \leftarrow \text{round}(\mathbf{r})$. Then by Claim 18 and the rounding algorithm, the tree $\mathbf{T}$ induced by $\mathbf{V}$ is a good extended state tree. Let τ be the good state tree correspondent to $\mathbf{T}$, and let T be the good multi-tree in G constructed using the procedure in Section 4.2. The cost of the multi-tree T is at most $\text{cost}(x)$. By Theorem 20, for every $t \in K$, the probability that t is involved T is at least $1/(h+1) = \Omega(1/\log n)$.

Let us consider the running time of the algorithmic framework, which is polynomial on the size of the tree $\mathbf{T}^\circ$. First notice that if $((r', S_1), (r'', S_2))$ is an allowable child pair of (r', S), then we have $|S_1|, |S_2| \leq |S| + 1$ since $S_1 \cup S_2 = S \cup \{r''\}$. Thus, a state-node p at the h'-th level in $\mathbf{T}^\circ$ (the children of $\mathbf{r}$ have level 0 and for simplicity we do not consider super and virtual nodes when counting levels) has $|S_p| \leq h' + 1$. Thus, every state node p in $\mathbf{T}^\circ$ has $|S_p| \leq h + 1$.

Then we consider the degree of the tree $\mathbf{T}^\circ$, which is the maximum number of possible children of a state node p with $(r'_p, S_p, \rho^p) = (r', S, \rho)$. First, there are at most $n \times 2^{|S_p|} \leq n \cdot 2^{h+1}$ different allowable child pairs $((r', S_1), (r'', S_2))$ of the pair (r', S): there are at most n choices for r'' and 2^h ways to split S into S_1 and S_2. Then, for a fixed allowable child pair $((r', S_1), (r'', S_2))$, we consider the number of pairs of degree vectors $\left(\rho^1, \rho^2\right)$ such that ρ^1 and ρ^2 are consistent with ρ. This is determined by the value of $\rho^1_{r''} = \rho^2_{r''}$, which has at most $d_{\max}$ possibilities. So, the number of virtual children of a state node is at most $n \cdot 2^{h+1} \cdot d_{\max} = \text{poly}(n)$ since $h = O(\log n)$. The number of child base nodes of p is at most n^2. Since the height of the tree $\mathbf{T}^\circ$ is at most $O(\log n)$, its size is bounded by $(\text{poly}(n))^{O(\log n)} = n^{O(\log n)}$. So the running time of the LP rounding algorithm is $n^{O(\log n)}$. This finishes the proof of Theorems 6 except for Property (6c), whose is deferred to Appendix A.

6 Bicriteria-Approximation Algorithm for Degree-Bounded Group Steiner Tree on Trees

In this section, we prove Theorem 2, which is repeated here.

▶ **Theorem 2.** *There is a randomized* $\left(O(\log n \log k), O(\log n)\right)$*-bicriteria approximation for the degree-bounded group Steiner tree problem on trees.*

We first set up some notations for the theorem. Recall that T° is the input tree, V° denotes the set of vertices of T°, and r denotes the root of T°. For simplicity, we assume the costs are on the vertices instead of edges: Every vertex $u \in V^\circ$ has a cost $c_u \geq 0$. Notice that this does not change the problem. We have k groups indexed by $[k]$. For each group $t \in [k]$, we are given a set $O_t \subseteq V^\circ$ of leaves in T°. W.l.o.g, we assume all O_t's are disjoint. Every vertex $v \in V$ is given a degree bound D_v. The goal of the problem is then to output the smallest cost subtree T of T° that satisfies the degree constraints and contains the root r and one vertex from each O_t, $t \in [k]$. Since now we only have one tree T°, we use the following notations for children and descendants: For every vertex $u \in V^\circ$, let Λ_u denote the set of children of u in T°, and Λ_u^* to denote the set of descendants of u in T° (including u itself).

Now we describe the LP relaxation we use for our problem. For every vertex $u \in T^\circ$, we use x_u to indicate whether u is chosen or not (in the correspondent integer program). LP (7) is a valid LP relaxation for the DB-GST-T problem:

$$\min \quad \sum_{u \in V^\circ} c_u x_u \qquad \text{s.t.} \tag{7}$$

$$x_v \leq x_u \qquad \forall u \in V^\circ, v \in \Lambda_u \tag{8}$$

$$\sum_{o \in O_t} x_o = 1 \qquad \forall t \in [k] \tag{9}$$

$$\sum_{o \in O_t \cap \Lambda_u^*} x_o \leq x_u \qquad \forall t \in [k], \forall u \in V^\circ \tag{10}$$

$$\sum_{v \in \Lambda_u} x_v \leq d_u \cdot x_u \qquad \forall u \in V^\circ \tag{11}$$

$$x_u \in [0,1] \qquad \forall u \in V^\circ \tag{12}$$

In the correspondent integer program, the objective we try to minimize is $\sum_{u \in V^\circ} c_u x_u$, i.e, the total cost of all verticies we choose. Constraint (8) says that if we choose a vertex v, then we must choose its parent u. Constraint (9) requires for every group t, exactly one vertex in O_t is added to the tree. Constraint (10) holds since if u is chosen, at most one vertex in $\Lambda_u^* \cap O_t$ is chosen for every group t. Constraint (11) is the degree constraint. In the LP relaxation, we require each x_u to take value in $[0,1]$ (Constraint (12)). Notice that (9) and (10) for the root r imply that $x_r = 1$.

Modifying the LP solutions. Solving LP (7), we can obtain an optimum LP solution $(x_u)_{u \in V^\circ}$. In our rounding algorithm, it would be convenient if every x_u is a (non-positive) integer power of 2 that is not too small. So, we shall modify the LP solution using the following operations, which may violate many of the LP constraints slightly. For every $v \in V^\circ$ with $x_v < \frac{1}{2n}$, we change x_v to 0. This can only decrease the cost of the solution. It is easy to see that Constraints (8), (10) and (11) will not be violated. Constraint (9) may not hold any more, but we still have $\sum_{v \in O_t} x_v \geq 1 - n \times \frac{1}{2n} \geq \frac{1}{2}$ for every $t \in [k]$. We can remove all vertices v with $x_v = 0$ from the instance and thus assume $x_v \geq \frac{1}{2n}$ for every $v \in V^\circ$. Next, we increase each x_v to the smallest (non-positive) integer power of 2 that is greater than or equal to x_v. This will violate many constraints in the LP by a factor of 2. We list the properties that our new vector $(x_u)_{u \in V^\circ}$ has:

(P1) For every $u \in V^\circ$, x_u is an integer power of 2 between $\frac{1}{2n}$ and 1.
(P2) The x values along any root-to-leaf path in T° is non-increasing.
(P3) $\sum_{o \in O_t} x_o \in [\frac{1}{2}, 2]$ for every group $t \in [k]$.

(P4) $\sum_{o\in O_t\cap\Lambda_u^*} x_o \le 2x_u$ for every $t\in[k]$ and $u\in V^\circ$.
(P5) $\sum_{v\in\Lambda_u} x_v \le 2d_u x_u$ for every $u\in V^\circ$.
(P6) $\sum_{u\in V^\circ} c_u x_u \le 2\cdot\mathrm{opt}$, where opt is the cost of the optimum integer solution.

6.1 The rounding algorithm

We now describe our rounding algorithm. We define two important global parameters: $L := \lceil\log(2n)\rceil$ and $\gamma := \lfloor\log L\rfloor - 2$. We say an edge (u,v) with $v\in\Lambda_u$ has "hop value" 1 if $x_u < x_v$ and 0 if $x_u = x_v$. For every vertex $u\in V^\circ$, we define ℓ_u to be the sum of hop values over all edges in the path from the root to u in T°. Thus, for every $u\in V^\circ$ and $v\in\Lambda_u$, we have $\ell_v - \ell_u \in\{0,1\}$, and $\ell_v = \ell_u$ if and only if $x_v = x_u$. By Properties (P1) and (P2), we have that $\ell_v\in[0,L]$ for every $v\in V^\circ$.

Our rounding algorithm is applied on some scaled solution x', which is defined as follows:

$$x'_u = 2^{\min\{\ell_u,\gamma\}}x_u, \text{for every } u\in V^\circ.$$

As we mentioned in the introduction, this change will increase the probability of choosing v conditioned on choosing u by a factor of 2, for some $u\in V^\circ, v\in\Lambda_u$ with $\ell_u < \ell_v \le \gamma$.

We prove one important property for x', which is necessary for us to run the recursive rounding algorithm.

▷ Claim 21. For every $u\in V^\circ$ and $v\in\Lambda_u$, we have $x'_v \le x'_u$.

Proof. If $x_v = x_u$, then the edge (u,v) has hop value 0 and thus $\ell_v = \ell_u$. In this case we have $x'_v = x'_u$ as well. Otherwise, we have $x_v \le x_u/2$ and $h_v = h_u + 1$. So, $\min\{h_v,\gamma\} \le \min\{h_u,\gamma\}+1$ and therefore $x'_v \le x'_u$. ◁

Notice that $x'_r = 1$ and every x'_v is an integer power of 2 between 2^{-L} and 1. Our recursive rounding algorithm is run over x'. In the procedure recursive-rounding(u), we add u to our output tree and do the following: for every $v\in\Lambda_u$, with probability x'_v/x'_u independent of all other choices, we call recursive-rounding(v). In the root recursion, we shall call recursive-rounding(r).

Our final algorithm will repeat the recursive procedure M times independently, for a large enough $M = O(\log k)$. Let $T_1, T_2, \cdots, T_M$ be the M trees we obtained from the M repetitions. Our final tree T will be the union of the M trees.

We first analyze the expected cost of T. First focus on the tree T_1. It is easy to see that the probability u is chosen by T_1 is exactly $x'_u \le 2^\gamma x_u = O(L)x_u$. Therefore, the expected cost of T_1 is at most $O(L)\cdot\mathrm{opt}$ by Property (P6). Therefore, the expected cost of the tree T is at most $O(ML)\cdot\mathrm{opt} = O(L\log k)\cdot\mathrm{opt} = O(\log n\log k)\cdot\mathrm{opt}$.

We then analyze the degree constraints on T. Given that u is selected by T_1, the probability that we select a child of v of u is $\frac{x'_v}{x'_u} \le \frac{2x_v}{x_u}$. By Property (P5), we have $\sum_{v\in\Lambda_u}\frac{x'_v}{x'_u} \le \sum_{v\in\Lambda_u}\frac{2x_v}{x_u} \le 4d_u$. Consider all the M trees $T_1, T_2, \cdots, T_M$. Even if we condition on the event that u appears in all the M trees, the degree of u is the summation of many independent random $\{0,1\}$-variables. The expectation of the summation is at most $4Md_u = O(\log k)\cdot d_u$. Using Chernoff bound, one can show that the probability that the degree of u is more than $O(\log n)\cdot d_u$ is at most $\frac{1}{10n}$, for some large enough $O(\log n)$ factor. Therefore, with probability at least 0.9, every node u in T has degree at most $O(\log n)\cdot d_u$. Therefore, we proved that the degree violation factor of our algorithm is $O(\log n)$, as claimed in Theorem 2.

6.2 Analysis of connectivity probability

It remains to show that with high probability, the tree T contains a vertex from every group. This is the goal of this section. Till the end of the section, we focus on the tree T_1 and a fixed group t. For every vertex $u \in V^\circ$, we define $\mathbf{E}_u$ to be the event that u is chosen by T_1. Our goal is to give a lower bound on $\Pr[\bigvee_{o\in O_t} \mathbf{E}_o]$, i.e., the probability that some vertex in O_t is chosen by the tree T_1.

Notice that when two adjacent nodes in T° have the same x' value, then the child is chosen whenever the parent is. Thus, we can w.l.o.g contract any sub-tree of nodes in T° with the same x' value into one single super-vertex, without changing the rounding algorithm. Notice that if two adjacent vertices $u \in V^\circ, v \in \Lambda_u$ have $\ell_u = \ell_v$, then we have $x_u = x_v$ and thus $x'_u = x'_v$. So, we contract every maximal sub-tree of vertices in T° with the same ℓ value. After this operation, for every $u \in V^\circ$, ℓ_u is exactly the level of u in the tree T°. So, for every $u \in V^\circ$ and $v \in \Lambda_v$ we have $\ell_v = \ell_u + 1$. A super-vertex is in O_t if one of its vertices before contracting is in O_t. If an internal super-vertex is in O_t, we can remove all its descendants without changing the analysis in this section. So, again we have that O_t only contains leaves.

For every vertex u, we define $z_u := \sum_{o\in O_t\cap\Lambda^*_u} x_o$. Notice that $z_u \le 2x_u$ by Property (P4).

In the following, we shall bound $\Pr\left[\bigvee_{o\in O_t\cap\Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right]$ for every $u \in V^\circ$ from bottom to top. This is done in two stages due to the threshold γ we used when we define x' variables. First we consider the case when $\ell_u \ge \gamma$ and then we focus on the case when $\ell_u < \gamma$. The two stages are captured by Lemmas 22 and 23 respectively.

▶ **Lemma 22.** *For a vertex u with $\ell_u \ge \gamma$, we have* $\Pr\left[\bigvee_{o\in O_t\cap\Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right] \ge \frac{1}{2(L+1-\ell_u)} \frac{z_u}{x_u}$.

Similar lemmas have been proved multiple times in many previous results. Since our parameters are slightly different, we provide the complete proof in Appendix B. The lemma implies that for every u with $\ell_u \ge \gamma$, we have $\Pr\left[\bigvee_{o\in O_t\cap\Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right] \ge \frac{1}{2L} \cdot \frac{z_u}{x_u}$.

Now we analyze the probability for u with $\ell_u \le \gamma$. Recall that $\gamma = \lfloor \log L \rfloor - 2$ and thus we have $2^\gamma \in (L/8, L/4]$. Let $\alpha_\gamma = \frac{1}{2L}$ and for every $\ell \in [0, \gamma-1]$, define $\alpha_\ell = 2\alpha_{\ell+1} - 4\alpha^2_{\ell+1}$. It is easy to see that for every $\ell \in [0,\gamma]$, we have $\alpha_\ell \le \frac{2^{\gamma-\ell}}{2L}$. Then, we have for every $\ell \in [0, \gamma-1]$,

$$\begin{aligned}\alpha_\ell &= 2\alpha_{\ell+1} - 4\alpha^2_{\ell+1} = 2\alpha_{\ell+1}(1 - 2\alpha_{\ell+1})\\ &\ge 2\alpha_{\ell+1}\left(1 - 2\times\frac{2^{\gamma-\ell-1}}{2L}\right) = 2\alpha_{\ell+1}\left(1 - \frac{2^{\gamma-\ell-1}}{L}\right).\end{aligned}$$

Therefore, we have

$$\alpha_0 \ge 2^\gamma \prod_{\ell=1}^{\gamma}\left(1 - \frac{2^{\gamma-\ell-1}}{L}\right)\alpha_\gamma \ge \frac{2^\gamma}{2L}\prod_{\ell=1}^{\gamma} e^{-2^{\gamma-\ell}/L} \ge \frac{2^\gamma}{2L} e^{-2^\gamma/L} = \Omega(1).$$

The second inequality used that $1-\theta \ge e^{-2\theta}$ for every $\theta \in (0, 1/2)$. The last equality used that $\gamma = \lfloor \log L \rfloor - 2$ and thus $2^\gamma = \Theta(L)$.

With the α values defined, we also have the following lemma for the case when $\ell_u \le \gamma$:

▶ **Lemma 23.** *For every vertex $\ell_u = \ell \le \gamma$, we have* $\Pr\left[\bigvee_{o\in O_t\cap\Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right] \ge \alpha_\ell \frac{z_u}{x_u}$.

The proof of this lemma is deferred to Appendix B. Applying the lemma for the root r of T°, we have that $\Pr\left[\bigvee_{o\in O_t} \mathbf{E}_o\right] \ge \alpha_0 \cdot \frac{z_r}{x_r} \ge \alpha_0 \cdot \frac{1}{2} = \Omega(1)$.

Now we consider all the M trees $T_1, T_2, \cdots, T_M$ together. The probability that O_t is not chosen by any of the M trees is at most $(1 - \Omega(1))^M \leq \frac{1}{10k}$, if our $M = O(\log k)$ is big enough. Thus, the probability that T, the union of all trees $T_1, T_2, \cdots, T_M$, contains an r-to-O_t path for every t, is at least 0.9.

A Property (6c) of Theorem 6: Concentration Bound on Number of Copies of a Vertex Appearing in T

Finally, we prove Property (6c) in Theorem 6. To this end, we shall fix a vertex $v \in V$. For every vertex $p \in \mathbf{V}^\circ$, let $z_p = \sum_{o \in \Lambda^*_{\mathbf{T}^\circ}(p) \cap \mathbf{O}_v} x_o$. By Constraint (5), we have $z_p \leq x_p$. Let $m_p = |\Lambda^*_{\mathbf{T}^\circ}(p) \cap \mathbf{O}_v \cap \mathbf{V}|$ be the total number of nodes in $\Lambda^*_{\mathbf{T}^\circ}(p) \cap \mathbf{O}_v$ that are selected by the rounding algorithm.

As is typical, we shall introduce a parameter $s > 0$ and consider the expectation the random exponential variables $\mathbf{e}^{sm_p}$ (we use $\mathbf{e}$ for the natural constant). We shall bound $\mathbb{E}[\mathbf{e}^{sm_p} | p \in \mathbf{V}]$ from bottom to top by induction. So, in this proof, it is more convenient to for us to use a different definition of levels: the level of a node p in $\mathbf{T}^\circ$ is the maximum number of edges in a path in $\mathbf{T}^\circ$ starting from p. So, the leaves have level 0 and for an internal node p in $\mathbf{T}^\circ$, the level of p is 1 plus the maximum of the level of q over all children q of p. We define an α_i for every integer $i \geq 0$ as $\alpha_0 = \mathbf{e}^s$ and $\alpha^i = \mathbf{e}^{\alpha_{i-1}-1}, \forall i \geq 1$. Notice that $\alpha_0, \alpha_1, \ldots$ is an increasing sequence. Thus, we can induce the following lemma.

▶ **Lemma 24.** *For any node p in $\mathbf{T}^\circ$ of level at most i, $\mathbb{E}\left[\mathbf{e}^{sm_p} \middle| p \in \mathbf{V}\right] \leq \alpha_i^{z_p/x_p}$.*

Proof. We prove the lemma by induction on i. If $i = 0$, then p is a leaf, and thus, we have either $z_p = 0$ or $z_p = x_p$, depending on whether $p \in \mathbf{O}_v$ or not. If $z_p = 0$, then m_p is always 0, and thus, $\mathbb{E}\left[\mathbf{e}^{sm_p} | p \in \mathbf{V}\right] = 1 = \alpha_0^{z_p/x_p}$. If $z_p = x_p$, then m_p is always 1 (conditioned on $p \in \mathbf{V}$), and thus, $\mathbb{E}\left[\mathbf{e}^{sm_p} | p \in \mathbf{V}\right] = \mathbf{e}^s = \alpha_0^{z_p/x_p}$. So, the lemma holds if $i = 0$.

Now, let $i \geq 1$ be any integer and we assume the lemma holds for $i-1$. We shall prove that it also holds for i. Focus on a node p of level at most i. Then all children q of p have level at most $i-1$. If p is a virtual node, then $p \in \mathbf{V}$ implies that both children of p in $\mathbf{V}$. Since the two children are handled independently in the rounding algorithm, we have

$$\begin{aligned}\mathbb{E}\left[\mathbf{e}^{sm_p} | p \in \mathbf{V}\right] &= \prod_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \mathbb{E}\left[\mathbf{e}^{sm_q} | p \in \mathbf{V}\right] = \prod_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \left[\frac{x_q}{x_p} \cdot \mathbb{E}[\mathbf{e}^{sm_q} | q \in \mathbf{V}] + 1 - \frac{x_q}{x_p}\right] \\ &= \prod_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \left[1 + \frac{x_q}{x_p}\Big(\mathbb{E}[\mathbf{e}^{sm_q} | q \in \mathbf{V}] - 1\Big)\right].\end{aligned}$$

If p is the super node or a state node, then we have $\sum_{q \in \Lambda_{\mathbf{T}^\circ}(p)} x_q = x_p$. Conditioned on $p \in \mathbf{V}$, the rounding procedure adds exactly one child q of p to $\mathbf{V}$. Then, we have

$$\begin{aligned}\mathbb{E}\left[\mathbf{e}^{sm_p} | p \in \mathbf{V}\right] &= \sum_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \frac{x_q}{x_p} \mathbb{E}\left[\mathbf{e}^{sm_q} | q \in \mathbf{V}\right] = 1 + \sum_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \frac{x_q}{x_p}\Big(\mathbb{E}[\mathbf{e}^{sm_q} | q \in \mathbf{V}] - 1\Big) \\ &\leq \prod_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \left[1 + \frac{x_q}{x_p}\Big(\mathbb{E}[\mathbf{e}^{sm_q} | q \in \mathbf{V}] - 1\Big)\right].\end{aligned}$$

Thus, we always have

$$\begin{aligned}&\mathbb{E}\left[\mathbf{e}^{sm_p} | p \in \mathbf{V}\right] \\ &\leq \prod_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \left[1 + \frac{x_q}{x_p}\Big(\mathbb{E}[\mathbf{e}^{sm_q} | q \in \mathbf{V}] - 1\Big)\right] \\ &\leq \prod_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \left[1 + \frac{x_q}{x_p}\big(\alpha_{i-1}^{z_q/x_q} - 1\big)\right] && \text{by induction hypothesis} \\ &\leq \exp\left[\sum_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \frac{x_q}{x_p}\big(\alpha_{i-1}^{z_q/x_q} - 1\big)\right] \\ &\leq \exp\left[\frac{z_p}{x_p}(\alpha_{i-1} - 1)\right] = \alpha_i^{z_p/x_p}. && \text{since } 1 + \theta \leq e^\theta \text{ for every } \theta\end{aligned}$$

To see the second inequality in the last line, we notice the following three facts: (i) $\alpha_{i-1}^\theta - 1$ is a convex function of θ and when $\theta = 0$ its value is 0, (ii) $z_q/x_q \in [0,1]$ for every q in the summation, and (iii) $\sum_{q \in \Lambda_{\mathbf{T}^\circ}(p)} \frac{x_q}{x_p} \cdot \frac{z_q}{x_q} = \frac{z_p}{x_p}$. So, the quantity inside $\exp(\cdot)$ has maximum value $\frac{z_p}{x_p}(\alpha_{i-1}^1 - 1)$. The equality in the last line is by the definition of α_i. ◀

Let $h' = \Theta(h) = \Theta(\log n)$ be the level of the root. Now, we set $s = \ln(1 + \frac{1}{2h'})$. We prove inductively the following lemma:

▶ **Lemma 25.** *For every $i \in [0, h']$, we have $\alpha_i \leq 1 + \frac{1}{2h'-i}$.*

Proof. By definition, $\alpha_0 = \mathbf{e}^s = 1 + \frac{1}{2h'}$ and thus the statement holds for $i = 0$. Let $i \in [1, h']$ and assume the statement holds for $i-1$. Then, we have

$$\begin{aligned}\alpha_i = \mathbf{e}^{\alpha_{i-1}-1} &\le \mathbf{e}^{1+\frac{1}{2h'-i+1}} \le 1 + \frac{1}{2h'-i+1} + \left(\frac{1}{2h'-i+1}\right)^2 \\ &= 1 + \frac{2h'-i+2}{(2h'-i+1)^2} \le 1 + \frac{1}{2h'-i}.\end{aligned}$$

The first inequality used the induction hypothesis and the second one used that for every $\theta \in [0,1]$, we have $e^\theta \le 1 + \theta + \theta^2$. ◀

So, by Lemma 24 and 25, we have $\mathbb{E}[\mathbf{e}^{sm_{\mathbf{r}}}] \le \alpha^1_{h'} \le 1 + \frac{1}{h'} = 1 + O\left(\frac{1}{\log n}\right)$. This finishes the proof of Property (6c) in Theorem 6.

B Omitted Proofs

▶ **Lemma 3.** *Let $T = (V_T, E_T)$ be an n-vertex binary tree. Then there exists a vertex $v \in V_T$ with $n/3 < |\Lambda^*_T(v)| \le 2n/3 + 1$.*

Proof. We assume $n \ge 4$; otherwise, if $n = 3$, then we have $2n/3 + 1 = 3$, and $\mathrm{root}(T)$ satisfies the condition. Our goal is to find a vertex u with $n/3 < |\Lambda^*(u)| \le 2n/3 + 1$. Start from $u = \mathrm{root}(T)$ in the tree, and thus, we have $\Lambda^*(u) > 2n/3 + 1$. Let v be the child of u with the biggest $|\Lambda^*(v)|$. So, $|\Lambda^*(v)| \ge (|\Lambda^*(u)| - 1)/2 > n/3$. We then replace u with v. So $|\lambda^*(u)|$ has decreased but the condition $|\Lambda^*(u)| > n/3$ is maintained. Thus, if we repeat the process, we will eventually find a u with $n/3 < |\Lambda^*(u)| \le 2n/3 + 1$. ◀

▶ **Lemma 22.** *For a vertex u with $\ell_u \ge \gamma$, we have* $\Pr\left[\bigvee_{o \in O_t \cap \Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right] \ge \frac{1}{2(L+1-\ell_u)} \frac{z_u}{x_u}$.

Proof. There are two different approaches to prove the lemma, one based on bounding the conditional second moment of the random variable for the number of chosen vertices in $O_t \cap \Lambda^*_u$, and the other based on the mathematical induction on ℓ_u, which is the one we use here.

Suppose u is a leaf. Then $z_u/x_u = 1$ if $u \in O_t$ and $z_u/x_u = 0$ otherwise. So, we have $\Pr\left[\bigvee_{o \in O_t \cap \Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right] = \frac{z_u}{x_u}$ and the lemma clearly holds since we have $\ell_u \le L$.

Then, we prove the lemma by induction on ℓ_u. If $\ell_u = L$ then u must be a leaf and thus the lemma holds. We assume the lemma holds for every u with $\ell_u = \ell + 1$, for some $\ell \in [\gamma, L-1]$. Then we prove the lemma for u with $\ell_u = \ell$. If u is a leaf the lemma holds and thus we assume u is not a leaf.

$$\begin{aligned}&\Pr\left[\bigvee_{o \in O_t \cap \Lambda^*_u} \mathbf{E}_o \middle| \mathbf{E}_u\right] \\ &\ge 1 - \prod_{v \in \Lambda_u} \left(1 - \frac{x'_v}{x'_u} \cdot \frac{1}{2(L-\ell)} \frac{z_v}{x_v}\right) = 1 - \prod_{v \in \Lambda_u} \left(1 - \frac{x_v}{x_u} \cdot \frac{1}{2(L-\ell)} \cdot \frac{z_v}{x_v}\right) \\ &\ge 1 - \prod_{v \in \Lambda_u} \exp\left(-\frac{1}{2(L-\ell)} \cdot \frac{z_v}{x_u}\right) = 1 - \exp\left(-\frac{1}{2(L-\ell)} \cdot \frac{z_u}{x_u}\right) \\ &\ge \frac{1}{2(L-\ell)} \cdot \frac{z_u}{x_u} - \frac{1}{2}\left(\frac{1}{2(L-\ell)} \cdot \frac{z_u}{x_u}\right)^2 \ge \frac{1}{2(L-\ell)} \cdot \frac{z_u}{x_u} - \left(\frac{1}{2(L-\ell)}\right)^2 \frac{z_u}{x_u} \\ &= \left(\frac{2(L-\ell)-1}{(2(L-\ell))^2}\right) \frac{z_u}{x_u} \ge \frac{1}{2(L+1-\ell)} \cdot \frac{z_u}{x_u}.\end{aligned}$$

The inequality in the first line used the induction hypothesis: $\frac{x'_v}{x'_u}$ is the probability that we choose v in T_1 conditioned on that we choose u, and $\frac{1}{2(L-\ell)}\frac{z_v}{x_v}$ is the lower bound on the probability that we choose some vertex in $O_t \cap \Lambda_v^*$ conditioned on that v is chosen. The equality in the line used that $x'_u = 2^\gamma x_u$ and $x'_v = 2^\gamma x_v$. The inequality in the second line used that $1-\theta \le e^{-\theta}$ for every real number θ. The first inequality in the third line used that $e^{-\theta} \le 1-\theta+\frac{\theta^2}{2}$ for every $\theta \ge 0$. The second inequality in the line used Property 4, which says $\frac{z_u}{x_u} \le 2$. The last inequality used that $(2(L-\ell)-1)\cdot 2(L-\ell+1) \ge 4(L-\ell)^2$ since $L-\ell \ge 1$. ◀

▶ **Lemma 23.** *For every vertex $\ell_u = \ell \le \gamma$, we have* $\Pr\left[\bigvee_{o\in O_t\cap\Lambda_u^*} \mathbf{E}_o \middle| \mathbf{E}_u\right] \ge \alpha_\ell \frac{z_u}{x_u}$.

Proof. We prove this lemma via mathematical induction. The lemma holds if $\ell = \gamma$ as we mentioned. So, we assume $\ell < \gamma$ and the lemma holds with ℓ replaced by $\ell+1$. If u is a leaf, then we have $\Pr\left[\bigvee_{o\in O_t\cap\Lambda_u^*} \mathbf{E}_o \middle| \mathbf{E}_u\right] = \frac{z_u}{x_u}$ and the lemma holds. So, again we assume u is not a leaf. Then,

$$\begin{aligned}
\Pr\left[\bigvee_{o\in O_t\cap\Lambda_u^*} \mathbf{E}_o \middle| \mathbf{E}_u\right] &\ge 1 - \prod_{v\in\Lambda_u}\left(1-\frac{x'_v}{x'_u}\alpha_{\ell+1}\frac{z_v}{x_v}\right) = 1-\prod_{v\in\Lambda_u}\left(1-\frac{2x_v}{x_u}\alpha_{\ell+1}\frac{z_v}{x_v}\right)\\
&\ge 1-\prod_{v\in\Lambda_u}\exp\left(-2\alpha_{\ell+1}\frac{z_v}{x_u}\right) = 1-\exp\left(-2\alpha_{\ell+1}\frac{z_u}{x_u}\right)\\
&\ge 2\alpha_{\ell+1}\frac{z_u}{x_u} - \frac{1}{2}\left(2\alpha_{\ell+1}\frac{z_u}{x_u}\right)^2 \ge 2\alpha_{\ell+1}\frac{z_u}{x_u} - (2\alpha_{\ell+1})^2\frac{z_u}{x_u} = \alpha_\ell\frac{z_u}{x_u}.
\end{aligned}$$

To see the equality in the first line, we notice that $x'_u = 2^\ell x_u$ and $x'_v = 2^{\ell+1}x_v$ for every $v \in \Lambda_u$. Many other inequalities used the same arguments as in Lemma 22. ◀

Permutation Strikes Back: The Power of Recourse in Online Metric Matching

Abstract

In this paper, we study the online metric matching with recourse (OMM-Recourse) problem. Given a metric space with k servers, a sequence of clients is revealed online. A client must be matched to an available server on arrival. Unlike the classical online matching model where the match is irrevocable, the recourse model permits the algorithm to rematch existing clients upon the arrival of a new client. The goal is to maintain an online matching with a near-optimal total cost, while at the same time not rematching too many clients.

For the classical online metric matching problem without recourse, the optimal competitive ratio for deterministic algorithms is $2k-1$, and the best-known randomized algorithms have competitive ratio $O(\log^2 k)$. For the much-studied special case of line metric, the best-known algorithms have competitive ratios of $O(\log k)$. Improving these competitive ratios (or showing lower bounds) are important open problems in this line of work.

In this paper, we show that logarithmic recourse significantly improves the quality of matchings we can maintain online. For general metrics, we show a deterministic $O(\log k)$-competitive algorithm, with $O(\log k)$ recourse per client, an exponential improvement over the $2k-1$ lower bound without recourse. For line metrics we show a deterministic 3-competitive algorithm with $O(\log k)$ amortized recourse, again improving the best-known $O(\log k)$-competitive algorithms without recourse. The first result (general metrics) simulates a batched version of the classical algorithm for OMM called Permutation. The second result (line metric) also uses Permutation as the foundation but makes non-trivial changes to the matching to balance the competitive ratio and recourse.

Finally, we also consider the model when both clients and servers may arrive or depart dynamically, and exhibit a simple randomized $O(\log n)$-competitive algorithm with $O(\log \Delta)$ recourse, where n and Δ are the number of points and the aspect ratio of the underlying metric. We remark that no non-trivial bounds are possible in this fully-dynamic model when no recourse is allowed.

1 Introduction

The classical online metric matching (OMM) problem is defined on a metric space $(\mathcal{X}, d)$, where $\mathcal{X}$ denotes a set of n points where the servers and clients are located, and a distance function (metric) $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}_+$. A set $S \subseteq \mathcal{X}$ of servers, $|S| = k$, is given offline, and a

sequence of client requests $C = (c_1, \ldots, c_k)$ is revealed in an online manner. The algorithm is required to match each client request to an available (previously unmatched) server on arrival irrevocably. The objective is to minimize the total cost of the matching, which is the sum of distances between matched client-server pairs. The performance of an algorithm is measured using the notion of competitive ratio – the worst-case over all instances of the ratio of the cost of the online algorithm and the cost of an optimal offline matching.

This problem was first studied in two independent works [17, 18]. Both these works present a $(2k-1)$-competitive deterministic algorithm called PERMUTATION, and also show that *this bound is tight among deterministic algorithms.* Subsequently, the work of [22] shows that randomization can overcome this lower bound (for oblivious adversaries) by giving a $\mathcal{O}(\log^3 k)$-competitive[1] randomized algorithm, which was later improved in [4], where the authors show an $\mathcal{O}(\log^2 k)$-competitive algorithm. In contrast, the best known lower bound for randomized algorithms is a factor of $\Omega(\log k)$[22]. Resolving this gap has remained a challenging and long-standing open problem in this area.

The OMM problem has also elicited much interest in specialized metrics such as the line metric (OMM-LINE). It was long conjectured that OMM-LINE should admit a 9-competitive algorithm, by virtue of the connections between this problem and another classical problem in online algorithms known as the cow-path problem. However, [10] disproved this particular conjecture by presenting a lower bound of 9.001. In terms of upper bounds, no algorithms with better competitive ratios than those for general metrics were known until a recent line of work [15, 23, 25] gave improved algorithms for the line metric. The current best algorithm is a deterministic $\mathcal{O}(\log k)$-competitive algorithm [25]. It is still an open question whether constant-competitive algorithms exist for OMM-LINE. Intriguingly, there are $\Omega(\log k)$ lower bounds on natural families of algorithms [1, 19].

Given these barriers for OMM, we study whether we can obtain strictly better performance if we are *allowed to re-match a few clients* upon the arrival of a new client.

▶ **Problem 1** (OMM-RECOURSE)**.** *An instance consists of a metric space $(\mathcal{X}, d)$, and a set $S \subseteq X$ of servers with $|S| = k$. A sequence of client requests $C_k = (c_1, \ldots, c_k)$ is revealed in an online manner. At time t, after the algorithm observes c_t, it must maintain a matching $\mathcal{M}_t$ such that every client is matched to exactly one server, and each server is matched to at most one client. The algorithm can re-match some earlier clients, and the number of times clients are re-matched is called the recourse.*

▶ **Definition 2.** *We say that an online algorithm is α-competitive with β-amortized recourse for* OMM-RECOURSE *if for all $t \in [k]$, the cost of the algorithm's matching for $C_t := (c_1, \ldots, c_t)$ is at most α times the cost of the optimal matching for C_t, and the total number of recourse steps taken so far is at most βt. Additionally, the algorithm is said to have a per-client recourse of β if no client is rematched more than β times.*

While our main theoretical motivation is in understanding the power of recourse in the classical OMM problem, often it is also the case in practice that matching decisions *are not irrevocable*, and instead, there is simply a cost (or) penalty for re-assignments. For example, in a video streaming setting, users arrive online and want to stream a video. The ISP must choose a server to stream from, preferring a server closer to the user. Of course, this decision can be changed over the time horizon, but this will cause a temporary disruption that must be minimized. The recourse model then naturally captures the competing goals of minimizing cost and the number of re-assignments. Moreover, the stronger notion of *per-client* recourse guarantees a fairness property by bounding the inconvenience for each client.

[1] Throughout the paper, logarithms are with respect to base 2.

The main results of this paper affirmatively answer the question of whether limited recourse can help in the OMM problem.

▶ **Theorem 3.** *There is an efficient deterministic* $2 \log k$*-competitive algorithm with* $\log k$ *per-client recourse for* OMM-Recourse *on general metrics. (Section 3)*

Theorem 3 coupled with the $(2k - 1)$ lower bound for deterministic algorithms without recourse highlights the exponential improvement in competitive ratio possible with limited recourse. We complement the above result by noting that the guarantees given above are tight for our algorithm. We also show that *any deterministic algorithm* which has constant per-client recourse must have a logarithmic competitive ratio.

▶ **Theorem 4.** *No deterministic algorithm for* OMM-Recourse *with per-client recourse at most an absolute constant* C *can have a competitive ratio* $o(\log k)$*. (Appendix C)*

Our algorithm for Theorem 3 is an adaptation of the classical Permutation algorithm for OMM [17, 18] which recomputes the offline optimal matching on the arrival of a new client, and matches the arriving client to the server that is part of the new offline matching but as yet unmatched in the online matching. While Permutation is a very natural and elegant algorithm, it fares poorly in the standard model without recourse where it has a competitive ratio of $\Omega(k)$ *even on line metrics*! At a high level, the worst-case behavior for the classical Permutation algorithm for OMM occurs when clients arrive one-by-one, and the competitive ratio improves if the clients arrive in batches. Our algorithm then *uses recourse to mimic* the output of such a batched version of Permutation.

We next turn our attention to the special case of the line metric, where we present a special-purpose algorithm that significantly improves on Theorem 3:

▶ **Theorem 5.** *There is a deterministic* 3*-competitive algorithm with* $\mathcal{O}(\log k)$*-amortized recourse for* OMM-Line-Recourse*. (Section 4)*

Note that obtaining constant-competitive algorithms for the line metric has been a challenging open problem for OMM– our algorithm achieves such a guarantee when equipped with a small amount of recourse. This result is also the main technical contribution of our work. Once again, our algorithm builds on the classical Permutation algorithm for OMM. Exploiting the nature of the line metric, we view the online matching determined by Permutation as a collection of directed forward or backward arcs from the clients to servers. Noting that such a matching may be sub-optimal only if *overlapping* forward and backward arcs are present, our algorithm tries to re-match some clients to eliminate such overlaps. However, blindly re-matching to eliminate all overlapping arcs can lead to a large recourse. Instead, we propose a clever *asymmetric uncrossing method* to balance the competitive ratio and recourse. Our analysis is somewhat non-standard in that we first identify a *family of algorithms* for OMM-Line-Recourse, all of which share the same asymmetric uncrossing criterion, and incur the same cost. Of this family, we first choose one algorithm (whose cost analysis is most intuitive) to bound the competitive ratio of *all the algorithms* in the family. However, this algorithm can demonstrably incur large recourse. Hence, our actual algorithm is another one from this family which is designed for minimizing the recourse but whose cost analysis in a direct manner is not apparent to us.

Finally, we focus on another limitation of classical OMM– due to the irrevocable nature of assignments, the competitive ratio would be unbounded when both clients and/or servers can arrive or depart the system. Hence, the classical model only considers the setting when all servers are known ahead of time and clients arrive in an online manner. We show that by allowing recourse, we can, in fact, handle arrivals and departures of clients and servers:

▶ **Theorem 6.** *There is a randomized $\mathcal{O}(\log n)$-competitive algorithm with $\mathcal{O}(\log \Delta)$ amortized recourse for* OMM-Recourse *when clients and servers can arrive and depart, where Δ is the aspect ratio of the metric space.*

We defer the details of this dynamic model to [16].

Related Work. To the best of our knowledge, the only work which considers recourse for online min-cost matching is the recent work [20] where the authors consider a *two-stage* version of the uni-chromatic problem (where there is no distinction between servers and clients): In the first stage, a perfect matching between $2n$ given nodes must be selected; in the second stage $2k$ new nodes are introduced. The goal is to produce α-competitive matchings at the end of both stages, and such that the number of edges removed from the first stage matching is at most βk. The authors show that $\alpha = 3, \beta = 1$ and $\alpha = 10, \beta = 2$ are possible when k is known or unknown, respectively. Our results can be seen as a multi-stage generalization of this two-stage model, although the two models are slightly different in terms of the distinction between servers and clients.

A related model capturing a different kind of flexibility in online matching is that of *matching with delays* [8, 5]: here, the requests need not be matched at the time of arrival, but accrue a delay penalty until the algorithm matches them. The algorithm must minimize the total matching cost plus total delay penalty. The current best known randomized algorithms are $\mathcal{O}(\log n)$ competitive [2], which also proves a lower bound of $\Omega\left(\frac{\log n}{\log \log n}\right)$. The best known deterministic algorithms are $\mathcal{O}(k^{0.59})$-competitive [3]. Another class of beyond-worst case models are stochastic models, such as *i.i.d.* and *random order* settings. The majority of work in this vein has been done in the reward maximization objective (see e.g., [11, 7, 6] and references therein). For OMM, [24] gave a deterministic algorithm that is simultaneously $\mathcal{O}(\log k)$-competitive in the random order model and $(2k-1)$-competitive in worst case. Recently, [12] show $\mathcal{O}((\log \log \log k)^2)$-competitive algorithms in the known *i.i.d.* model.

Finally, online algorithms with recourse have also been studied in other settings such as scheduling and set cover (see, e.g., [14, 13, 9] and the references within.).

Recently, and independent of our work, [21] have obtained an $\mathcal{O}(1)$-competitive algorithm with $\mathcal{O}(\log k)$-amortized recourse for OMM-Line-Recourse with a very different approach of extending the t-net framework of [25].

2 Preliminaries

For most of the paper (except for the fully dynamic setting), we consider the setting where the servers $\mathcal{S}$ are known up front. The clients arrive online, and we denote by $C_t = (c_1, \ldots, c_t)$ the set of the first t clients. An optimal matching between C_t and $\mathcal{S}$ is denoted by $\mathcal{M}_t^*$, and similarly, the algorithm's matching between C_t and $\mathcal{S}$ will be denoted by $\mathcal{M}_t$. We denote by OPT_t, the cost of the optimal matching $\mathcal{M}_t^*$. For any matching $\mathcal{M}$, we use $\mathcal{M}(c)$ and $\mathcal{M}(C)$ to denote the server and the set of servers matched to the client c and the set of clients C, respectively. We define $\mathcal{M}(s)$ and $\mathcal{M}(S)$ similarly.

The Permutation algorithm. As mentioned in Section 1, [17] and [18] independently proposed a $(2k-1)$-competitive algorithm Permutation for OMM. Since our algorithms build extensively on this algorithm, we first summarize Permutation and its key properties. The algorithm maintains two matchings: the current online matching $\mathcal{M}_t$, and the optimal offline matching $\mathcal{M}_t^*$ of the clients C_t that have arrived so far. The main observation behind

Algorithm 1 PERMUTATION (metric $(\mathcal{X}, d)$, server-optimal matching $\mathcal{M}_{t-1}$ for C_{t-1}).

for new batch of clients $C_{\text{cur}} = C_{t+\ell} \setminus C_{t-1} = \{c_t, c_{t+1}, \ldots, c_{t+\ell}\}$ that arrives **do**
  let $\mathcal{M}^*_{t-1}$ and $\mathcal{M}^*_{t+\ell}$ be optimal matchings for C_{t-1} and $C_{t+\ell}$ from Lemma 7.
  let $S_{\text{cur}} = S^*_{t+\ell} \setminus S^*_{t-1}$ be the set of $\ell+1$ servers matched in $\mathcal{M}^*_{t+\ell}$ but not in $\mathcal{M}^*_{t-1}$
  let $\mathcal{M}_{\text{cur}}$ denote the minimum cost matching between C_{cur} and S_{cur}
  augment $\mathcal{M}_{t-1}$ using $\mathcal{M}_{\text{cur}}$ to obtain the new matching $\mathcal{M}_{t+\ell}$
end for

the algorithm is that, when a new client c_{t+1} arrives, there exists an optimal matching of C_{t+1} to $\mathcal{S}$ which uses *exactly the servers used in $\mathcal{M}^*_t$ plus one extra server*. PERMUTATION simply identifies the extra server s_{t+1} and matches c_{t+1} with s_{t+1}. This property can be formalized as follows.

▶ **Lemma 7** (Lemma 2.2 in [17]). *There exists a sequence of optimal matchings $\mathcal{M}^*_1, \ldots, \mathcal{M}^*_k$ matching client sets $C_1, \ldots, C_k$ to $\mathcal{S}$ such that the sets of servers used in these matchings, $S^*_i := \mathcal{M}^*_i(C_i)$ are nested, i.e., $S^*_1 \subseteq S^*_2 \subseteq \cdots \subseteq S^*_k$.*

▶ **Definition 8** (Server-optimal matching). *At time t, a matching $\mathcal{M}_t$ of client-set C_t is said to be* server-optimal *if it uses the same servers as $\mathcal{M}^*_t$, i.e., $\mathcal{M}^*_t(C_t) = \mathcal{M}_t(C_t)$.*

▶ **Proposition 9** ([17]). PERMUTATION *always maintains a server-optimal matching.*

The notion of server-optimality will be crucial throughout this paper. Intuitively, it says that the algorithm has identified the right set of servers from $\mathcal{S}$ to match to, and is only sub-optimal w.r.t to the actual matching maintained between C_t and $\mathcal{M}_t(C_t)$.

Algorithm 1 gives a more general version of PERMUTATION which we will use later, where clients arrive in *batches*, and we add a *minimum-cost matching* between the arriving clients in the batch and the additional servers an optimal solution uses (from Lemma 7).

▶ **Lemma 10** ([17]). *After the arrival of a batch of clients $C_{t+\ell} \setminus C_{t-1}$, the cost of the matching $\mathcal{M}_{\text{cur}}$ computed in Algorithm 1 is at most $2\mathit{OPT}_{t+\ell}$.*

▶ **Theorem 11** (Theorem 2.4 in [17]). *Algorithm 1 is $(2m-1)$-competitive for online weighted matching if the requests arrive in m batches.*

3 Online matching with recourse for general metrics

In this section, we prove Theorem 3 by showing that Algorithm 2 is a $(2\log k, \log k)$-competitive algorithm for OMM-RECOURSE in a general metric. To motivate the algorithm, note that Theorem 11 says that in order to minimize competitive ratio, it is best to feed the client sequence to PERMUTATION in as few batches as possible. However, we are also constrained in matching clients immediately on arrival. One way of balancing the two goals is to run PERMUTATION incrementally on each client arrival, and use recourse to periodically unmatch a suffix of client sequence and re-introduce these clients as *a single batch*. As an example, assume that we create B batches of k/B clients, with the jth batch consisting of clients $\text{Batch}_j = \{(j-1)k/B+1, \ldots, jk/B\}$. As clients in batch j arrive, we first match them via vanilla PERMUTATION. After the (jk/B)th client arrives, we unmatch all clients in Batch_j and re-introduce them as one single batch. The amortized recourse of this algorithm is 1. Moreover, the matching at any time t may be viewed as the output of running PERMUTATION with at most B batches of k/B clients each and k/B batches of 1 client each. Setting $B = \sqrt{k}$ then gives us an $O(\sqrt{k})$-competitive algorithm with a per-client recourse of 1!

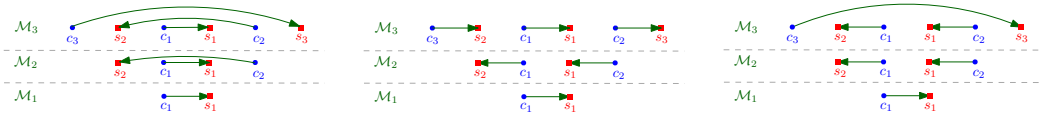
Algorithm 2 MultiScalePermutation (metric (X, d) and server set $\mathcal{S} \subseteq X$).

initialize matching $\mathcal{M}_0 = \emptyset$
for each new client c_t that arrives at time-step t **do**
  let $i(t) = \arg\max_i$ s.t t is divisible by 2^i
  unmatch the latest $2^{i(t)}$ clients $\{c_{t-2^{i(t)}+1}, \ldots, c_t\}$ and revert to matching $\mathcal{M}_{t-2^{i(t)}}$
  introduce a block of clients $\{c_{t-2^{i(t)}+1}, \ldots, c_t\}$ to Algorithm 1 with the current matching being $\mathcal{M}_{t-2^{i(t)}}$ and update $\mathcal{M}_t$ to be the resulting matching for the clients C_t
end for

To get a smaller competitive ratio at the expense of slightly higher recourse, we employ the following natural extension: imagine the first t clients as the leftmost t leaves of a balanced binary tree of depth $\lceil \log_2 k \rceil$. If an arriving client is the last leaf of some subtree, we unmatch all clients in the largest such subtree and re-introduce them as a single batch. The competitive ratio would then be bounded by $2 \log k$ since the matching at time t is simply the combination of at most $\log k$ batches (based on the binary decomposition of t) and by using Theorem 11. Further, any client is rematched at most $\log k$ times, since the size of the batch it is part of doubles on every rematch.

Proposition 12 generalizes the result in Theorem 3 to give a trade-off between the cost and recourse, and Proposition 13 proves that our analysis of Algorithm 2 is tight. The proofs of these propositions appear in Appendix B.

▶ **Proposition 12.** *Algorithm 2 with the constant 2 replaced by d, gives an $(d-1)\log_d k$-competitive algorithm with $\log_d k$-per client recourse. In particular, for any $d = \mathcal{O}(1)$ we get $\mathcal{O}(\log k)$-competitive algorithm with $\mathcal{O}(\log k)$-per client recourse, and for $d = k^\alpha$ ($\alpha \leq 1$), we get an $\tilde{\mathcal{O}}(k^\alpha)$-competitive algorithm with $1 + 1/\alpha$-per client recourse.*



▶ **Proposition 13.** *The cost-recourse tradeoff of Theorem 3/Proposition 12 is tight: for $d = 2$, there is a sequence of instances where Algorithm 2 is $\Omega(\log k)$-competitive and has $\Omega(\log k)$ per-client recourse. Further, there is an increasing sequence $\{d_i\}$, such that with $d = d_i$ there is a sequence of instances where Algorithm 2 is $\Omega(d \log_d k)$-competitive with $\Omega(\log_d k)$ per-client recourse.*

4 Online Matching on the Line Metric

In this section, we focus on the special case of a line metric, where, for all points $x \in \mathcal{X}$, we associate a location $\ell : \mathcal{X} \to \mathbb{R}$ such that $d(x, y) = |\ell(x) - \ell(y)|$. We also assume without loss of generality that all the clients and servers are in distinct locations on the line.

Our starting point is again the Permutation algorithm which, by itself can have $\Omega(k)$ competitive ratio even on line metrics: see Figure 1a, where the distance between any consecutive client and server is 1[2]. Permutation would first match c_1 to s_1, and then c_2 to s_2 (the set $\{s_1, s_2\}$ is server-optimal as it admits an optimal matching $(c_1, s_2), (c_2, s_1)$). Continuing in this manner, Permutation would incur a total cost of $\Omega(k^2)$, whereas the optimal matching would have a cost of k. A natural fix would seem to be to re-match the clients and servers in the existing matching to maintain an optimal matching at all times, but as illustrated in the example in Figure 1b, this can lead to $\Omega(k)$ amortized recourse.

[2] Even though in this example it seems that Permutation can perform well by breaking ties correctly, we can modify the edge lengths very slightly to force the matchings, thus proving that no clever tie-breaking can help the algorithm.

(a) PERMUTATION without re-match.

(b) PERMUTATION with full re-match.

(c) *Asymmetric* PERMUTATION with re-match.

Figure 1 Illustrative examples of OMM-LINE-RECOURSE.

One of our main observations is that we can view a matching on a line metric as composed of *forward* and *backward* arcs between the matched clients and servers based on their relative location (as in Figure 1a), and, as we formalize later, a matching between a given client and server set is sub-optimal *if and only if* it contains overlapping forward and backward arcs. Indeed, PERMUTATION does no recourse but has large overlaps, and always re-matching overlapping arcs output by PERMUTATION yields an optimal solution but with large recourse. Our idea is to balance the overlap and recourse by *re-matching overlapping pairs asymmetrically*. When a new client c_t arrives, let s_t be the new server that PERMUTATION brings in to the system. Then, if (c_t, s_t) is a forward arc i.e. if $\ell(c_t) \leq \ell(s_t)$, our algorithm simply adds it as is, even if it overlaps with existing backward arcs. On the other hand, when (c_t, s_t) is a backward arc, we use rematches to *maximally cancel* portions of this backward arc with overlapping portions of existing forward arcs. See Figure 1c for an example where $\mathcal{M}_2$ has undergone a re-matching, while $\mathcal{M}_3$ has not.

While this re-matching process is unambiguous for the example in Figure 1c, in general, there could be multiple ways of re-matching overlapping arcs in $\mathcal{M}_{t-1} \cup \{c_t, s_t\}$. We, therefore, begin by defining a *family of asymmetric maximally canceling algorithms* in Section 4.1 and prove that all algorithms in this family incur the same cost. In Section 4.2, we study one special algorithm, RECURSIVECANCEL in this family which is the most amenable for cost analysis and bound the competitive ratio of the entire family of algorithms by 3. However, RECURSIVECANCEL can incur a large $\Omega(k)$ recourse, and so our final algorithm MINIMUMCANCEL in Section 4.3 further identifies a way of re-matching backward arcs which *minimally changes the existing matching*. Using this property, we show that the MINIMUMCANCEL algorithm has $O(\log k)$ amortized recourse, thereby proving Theorem 5.

Before going into the details of the algorithms, we first introduce a property of the PERMUTATION algorithm on the line metric that is useful:

▶ **Lemma 14.** *If* PERMUTATION *maintains edges* $(c_1, s_1), (c_2, s_2), \ldots, (c_t, s_t)$ *at time* t*, then any server* $s_{t'}$ *added by the algorithm at time* $t' > t$ *will lie outside all these arcs.*

The proof follows from the server optimality of the PERMUTATION algorithm and is presented in Appendix B.

4.1 Preliminary Concepts and Notation

We begin by introducing a few concepts that are important for cost analysis of matching on the line metric: forward and backward arcs, atomic intervals, and discrepancy. We end the section by defining the family of asymmetric maximally canceling algorithms. Unless otherwise stated, $C_t = \{c_1, c_2, \ldots, c_t\}$ will denote the set of clients which have arrived by time t, and $S_t = \{s_1, s_2, \ldots, s_t\}$ will denote the set of servers chosen by PERMUTATION.

▶ **Definition 15** (Forward and Backward Arcs). *Let a client* c *be matched to server* s *in a given matching* $\mathcal{M}$*. We call the edge* (c, s) *a* forward arc $\overrightarrow{c, s}$ *if* $\ell(c) \leq \ell(s)$ *and a* backward arc $\overleftarrow{s, c}$ *otherwise.*

We now note that in an optimal matching, no pair of forward and backward arcs cross.

▶ **Proposition 16.** *Consider a set C of clients and a set S of servers with $|C| = |S|$. Then, a matching $\mathcal{M}$ between C and S is optimal for the client-server set (C, S) if and only if, for any forward arc $\overrightarrow{c_1, s_1} \in \mathcal{M}$ and backward arc $\overleftarrow{s_2, c_2} \in \mathcal{M}$, the intervals $[\ell(c_1), \ell(s_1)]$ and $[\ell(s_2), \ell(c_2)]$ are disjoint.*

Now, to compute the cost of any matching $\mathcal{M}_t$ between $C_t \cup S_t$, our approach will be to decompose the total cost into the contribution of what we call *atomic intervals* corresponding to $C_t \cup S_t$. Informally, the atomic intervals partition the line into open intervals between *two consecutive points* in $C_t \cup S_t$ in the metric space.

▶ **Definition 17** (Atomic intervals)**.** *For two nodes $p_1, p_2 \in C_t \cup S_t$ in the matching $\mathcal{M}_t$ at time t, we call the open interval $I = (\ell(p_1), \ell(p_2))$ an* atomic interval *if and only if for any other $p \in C_t \cup S_t$, it holds that $\ell(p) \notin (\ell(p_1), \ell(p_2))$. We denote the set of all atomic intervals at time t by $\mathcal{AI}_t$. We denote by $|I| = |\ell(p_1) - \ell(p_2)|$ the length of the interval I.*

Note that $\mathcal{AI}_t$ depends only on the set $C_t \cup S_t$, and grows in t as this set expands. We call $I' = (\ell(p_1'), \ell(p_2'))$ a subinterval of $I = (\ell(p_1), \ell(p_2))$, denoted $I' \subseteq I$ if $\ell(p_1) \leq \ell(p_1') \leq \ell(p_2') \leq \ell(p_2)$.

▶ **Definition 18** (Discrepancy)**.** *For any atomic interval $I \in \mathcal{AI}_t$ with its left end-point at location l, we define its* discrepancy *at time t to be the excess number of servers to the left of l in the currently used set of servers S_t:* $\mathrm{disc}_t(I) := |S_t \cap (-\infty, l]| - |C_t \cap (-\infty, l]|$.

The next lemma shows that the discrepancy of atomic intervals immediately gives the cost of the optimal matching.

▶ **Lemma 19.** *At any time t, and for any atomic interval $I \in \mathcal{AI}_t$, exactly $|\mathrm{disc}_t(I)|$ arcs cross I in an optimal matching between C_t and S_t. Further, if $\mathrm{disc}_t(I)$ is positive (respectively, negative), the direction of the crossing arcs is backward (resp., forward). Consequently, the cost of an optimal matching is $\mathsf{OPT}_t = \sum_{I \in \mathcal{AI}_t} |\mathrm{disc}_t(I)| \cdot |I|$.*

While $\mathrm{disc}_t(I)$ quantifies the minimum number of arcs that must cross I in any feasible matching, there could be many more arcs crossing I in the sub-optimal matching maintained by our algorithm. To this end, for a given matching $\mathcal{M}_t$ between $C_t \cup S_t$, and any subinterval $I' \subseteq I \in \mathcal{AI}_t$, let $n_t^f(I')$ and $n_t^b(I')$ denote the number of forward and backward arcs, respectively, crossing I' at time t. The following is then easy to see.

▷ Claim 20. For a matching $\mathcal{M}_t$, and any atomic interval $I \in \mathcal{AI}_t$, we have $n_t^b(I) - n_t^f(I) = \mathrm{disc}_t(I)$. Furthermore, the cost of $\mathcal{M}_t$ is $\mathsf{cost}(\mathcal{M}_t) = \sum_{I \in \mathcal{AI}_t} |n_t^f(I) + n_t^b(I)| \cdot |I|$.

We are now ready to define the family of asymmetric maximally canceling algorithms for OMM-Line-Recourse.

▶ **Definition 21** (Asymmetric maximally canceling algorithm)**.** *We call an algorithm an* asymmetric maximally canceling algorithm *if the sequence of matchings $\{\mathcal{M}_t\}$ produced by the algorithm satisfies:*

1. *The server sets $\{S_t\}$ are given by* Permutation *(with a deterministic tie breaking rule);*
2. *Denoting s_t as the new server added by* Permutation *at time t:*
   - *If (c_t, s_t) is a forward arc, then no rematches are made. In other words, for all atomic intervals $I \in \mathcal{AI}_t$ which overlap with $(\ell(c_t), \ell(s_t))$ we have: $n_t^f(I) = n_{t-1}^f(I) + 1$.*

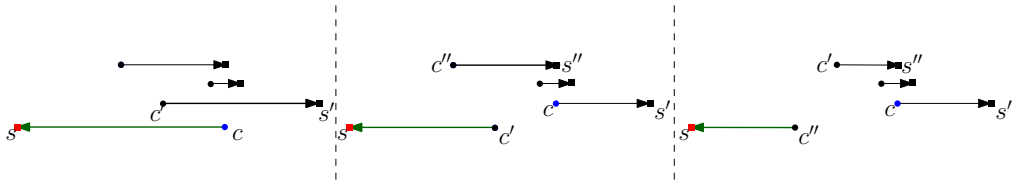


Figure 2 Illustration of RecursiveCancel: The leftmost figure shows the initial matching – (c, s) is the new backward arc and (c', s') is the forward arc chosen at step 9 of first iteration. The center figure shows the matching at step 11 after the rematching. The edge (c', s) becoems the new backward arc, and (c'', s'') is the forward edge picked in step 9 for the next iteration where (c', s) and (c'', s'') are replaced by (c'', s) and (c', s'') as in the rightmost figure.

- *If (c_t, s_t) is a backward arc, we use it to cancel existing forward arcs as much as possible. In other words, in the resulting matching $\mathcal{M}_t$ (after recourse), for all atomic intervals $I \in \mathcal{AI}_t$ which overlap with $(\ell(s_t), \ell(c_t))$ we have: $n^f_t(I) = \max\{n^f_{t-1}(I) - 1, 0\}$.*
- *$n^f_t(I)$ is unchanged for all atomic intervals that do not overlap with $(\ell(c_t), \ell(s_t))$.*

Note that it suffices to define just n^f_t as $n^b_t(I)$ can be derived from $n^f_t(I)$ for all I using Claim 20. Furthermore, the definition does not restrict how the rematches are performed, but only that all asymmetric maximally canceling algorithms have the same values of $n^f_t(I)$ and $n^b_t(I)$, for all the atomic intervals. Claim 20 immediately gives:

▷ Claim 22. All asymmetric maximally canceling algorithms incur the same matching cost.

The next section gives a bound on this cost by focusing on a specific member in this family by exploiting a useful invariant.

4.2 Algorithm RecursiveCancel for Bounding Cost

We now present our algorithm RecursiveCancel (Algorithm 3) and bound its cost. When a new backward arc overlapping with existing forward arcs is added, RecursiveCancel chooses the overlapping forward arc with the rightmost server and rematches the clients and servers of these two arcs to elimate overlap. This procedure results in at most one remnant backward arc (a strict suffix, i.e., server end, of the original backward arc) which can overlap with existing forward arcs. RecursiveCancel then recurses on this remnant until there is no overlap with a forward arc.

We begin with a couple of simple but useful observations about the behavior of rematches made by RecursiveCancel.

▶ **Lemma 23.** *Let (c, s) and (c', s') be two arcs defined in steps 8 and 9, respectively, of an iteration of* RecursiveCancel*. Then, (i) the new edge (c', s) added in step 11 is a backward arc, thereby proving that the while loop is well-defined; and (ii) the edge (c, s') added in step 10 is either a backward arc, or it is a suffix of the original forward arc (c', s').*

Proof. From Lemma 14, we know that there are no free servers inside an arc added by Permutation. Furthermore, since any arc in the current matching under RecursiveCancel is a sub-arc of some original arc added by Permutation, throughout the execution of RecursiveCancel algorithm there is never a free server inside an arc in the matching $\mathcal{M}_t$. Thus, c' is to the right of s, otherwise the server s which is free in $\mathcal{M}_{t-1}$, is inside the arc (c', s'). The second part of the lemma can be proved by noting that the forward arc (c', s') intersects the backward arc (c, s), and thus $\ell(c') < \ell(c)$. ◀

Algorithm 3 Algorithm RecursiveCancel.

1: set $\mathcal{M}_0 = \emptyset$
2: **for** each client c_t arriving at time $t \geq 1$ **do**
3: let s_t be the server Permutation matches c_t to, and let $a := (c_t, s_t)$
4: **if** a is a forward arc, i.e., $\ell(c_t) < \ell(s_t)$ **then**
5: $\mathcal{M}_t = \mathcal{M}_{t-1} \cup \{a\}$
6: **else** ▷ (c_t, s_t) is a backward arc
7: **while** there exists a forward arc in $\mathcal{M}_{t-1}$ which overlaps with a **do** ▷ a is the current backward arc
8: let $(c, s) := a$
9: let (c', s') be the forward arc overlapping with a with the *rightmost* server s'
10: $\mathcal{M}_{t-1} = \{\mathcal{M}_{t-1} \setminus \{(c', s')\}\} \cup \{(c, s')\}$
11: set $a := (c', s)$ ▷ From Lemma 23, a will be a backward arc for loop recursion
12: **end while**
13: $\mathcal{M}_t = \mathcal{M}_{t-1} \cup \{a\}$ ▷ a now has no overlapping forward arcs, and is added to $\mathcal{M}_t$
14: **end if**
15: **end for**

▶ **Lemma 24.** *Suppose that at some time t, the algorithm adds a backward arc (c, s) to the matching $\mathcal{M}_t$ (either by rematching an older edge in step 10 during the recursion, or as a new edge in step 13) at the end of the recursion. Then, this arc does not overlap with any existing forward arcs in $\mathcal{M}_t$.*

Proof. The proof follows directly from the fact that we use the forward arc with the rightmost server in the step 9 of the algorithm. ◀

We now try to quantify the excess cost of RecursiveCancel over the optimal solution using the above-defined quantities. Indeed, if RecursiveCancel adds an edge (c, s) which is a backward arc at some time step t, then from Lemma 24, we know that it does not have any existing forward arc overlapping with it, and hence would not contribute to any sub-optimality at this time. Hence, RecursiveCancel is sub-optimal only due to the addition of forward arcs which have overlaps with existing backward arcs. These could happen either in step 5 or in step 10. However, by Lemma 23, we also know that the forward arcs added in step 10 are only suffixes of the original forward arcs, and so the excess cost due to the rematched forward arc is only at most that of the original forward arc. Using this intuition, we label each atomic interval of each forward arc as either *redundant* (i.e., cost avoided by OPT_t) or *non-redundant* (cost incurred by OPT_t) as follows:

▶ **Definition 25** (Redundant/non-redundant forward arcs with respect to atomic intervals)**.** *Suppose at time t, client c_t is matched to server s_t with a forward arc $a := (c_t, s_t)$ in step 5 of Algorithm 3. Then, the forward arc a is said to be redundant with respect to $I \in [\ell(c_t), \ell(s_t)]$ if $n^b_{t-1}(I) > n^f_{t-1}(I)$, and* non-redundant *with respect to I otherwise. Alternatively, if a new forward arc (c, s') is added in step 10 of the recursion then it must be the suffix of some forward arc $(c', s') \in \mathcal{M}_{t-1}$ (Lemma 23), and for any atomic interval I (or its subinterval), the new arc simply inherits its status (redundant/non-redundant) from the status of (c', s') with respect to I.*

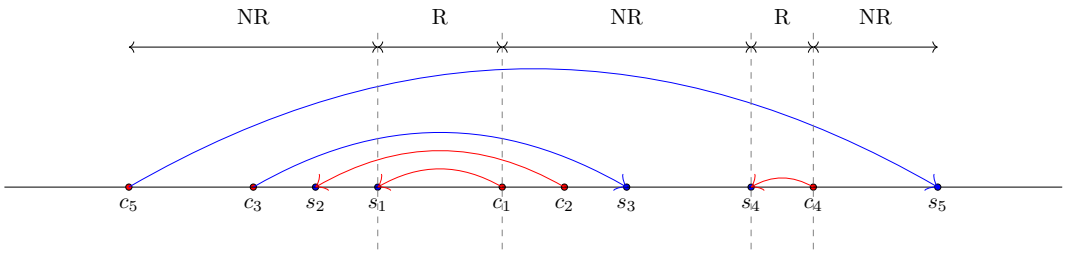

Figure 3 Illustration of Definition 25. In this example, when forward arc $a = (c_5, s_5)$ is added, a is redundant w.r.t. atomic intervals in $[\ell(s_1), \ell(c_1)]$ and $[\ell(s_4), \ell(c_4)]$ and *non-redundant* with respect to others.

We are now ready to bound the cost of RecursiveCancel. Indeed, we first show in Lemma 26 that the semantic meaning of redundant or non-redundant forward arcs with respect to atomic intervals is preserved throughout the algorithm. That is, for any atomic interval I, it will hold that there are exactly $\min(n_t^f(I), n_t^b(I))$ many forward arcs that are redundant with respect to I, since these can be avoided in an optimal matching.

▶ **Lemma 26.** *At any time t and for any atomic interval I, there are exactly* $\min(n_t^f(I), n_t^b(I))$ *forward arcs crossing I that are redundant w.r.t I.*

Proof. We prove the following two claims inductively on the number of client-server pairs added:

1. In any atomic interval $I \in \mathcal{AI}_t$, the number of forward arcs that are redundant with respect to I is equal to the minimum of the number of forward arcs and the number of backward arcs crossing I.
2. In any atomic interval I, if there exist two forward arcs $a_1 = (c_1, s_1)$ and $a_2 = (c_2, s_2)$ crossing the interval I such that a_1 is redundant w.r.t. I, and a_2 is non-redundant w.r.t. I, then $\ell(s_2) \geq \ell(s_1)$.

Let $a = (c, s)$ be the client-server pair given by Permutation. Consider the two cases, adding a forward arc and a backward arc:

1. Suppose that s is to the right of c i.e. the case when we add the forward arc directly. If in an atomic interval I between c and s, there are fewer forward arcs than backward arcs before adding c and s, then a is redundant w.r.t. I. Observe that this ensures that in such an interval I, the number of forward arcs that are redundant w.r.t. I increases, and is still equal to the minimum of the number of forward and the number of backward arcs crossing the interval. In intervals I where the number of forward arcs crossing I is at least the number of backward arcs crossing I before adding c and s, a is non-redundant w.r.t. I. In this case, the minimum of forward and backward arcs does not increase, and thus the claim continues to remain valid.
   For the second claim: If a is redundant w.r.t. an atomic interval I, then using claim 1 on the instance before adding a, we can infer that all the forward arcs crossing I are redundant w.r.t I. Thus, claim 2 is void in this case. If a is non-redundant w.r.t. an atomic interval I, we need to show that the new server is to the right of any server whose forward arc is redundant w.r.t. I. This follows directly from the fact that an unmatched server cannot be present in the middle of an arc (Lemma 14), and hence, s is to the right of the server of any forward arc that intersects I.
2. Suppose that s is to the left of c i.e. the case when we recursively add backward arc(s). In this case, in an atomic interval $I \in [\ell(s), \ell(c)]$, either a backward arc is added if there is no forward arc crossing I, or if there is at least one forward arc crossing I, the number of

forward arcs crossing I reduces by one. The intervals outside $[\ell(s), \ell(c)]$ are not affected. From Lemma 23, we know that the forward arcs corresponding to a server only shorten. Thus, the second claim trivially follows.

The algorithm deletes a forward arc from the atomic interval $I \in [\ell(s), \ell(c)]$ if there exists at least one forward arc crossing I before adding the new client c. If the number of forward arcs crossing I is at most the number of backward arcs crossing I, then all the forward arcs crossing I are marked redundant w.r.t. I, and we delete one such arc interval. The property of claim 1 still holds. Similarly, the property holds if there are no backward arcs are crossing I in which case, all the forward arcs crossing I are marked non-redundant. Thus, it remains to show that if there are both forward arcs that are labeled non-redundant and also ones that are marked redundant w.r.t. I cross I, our algorithm makes sure after the changes, one of the forward arc that is labeled non-redundant no longer crosses I. We use claim 2 here. If there are forward arcs a_1 and a_2 cross I and a_1 is redundant w.r.t I while a_1 is non-redundant w.r.t I, note that the server of a_2 is to the right of the server of a_1.

Recall that for any atomic interval I, there is at most one forward arc that crosses I is deleted. If a forward arc a that is redundant w.r.t. I is deleted, when the arc is selected in Line 9 of the algorithm, it has the farthest server among all arcs that intersect the backward arc. This combined with the above fact implies that if a forward arc that is redundant w.r.t. I is deleted, then there is no forward arc that is marked non-redundant crosses I. Thus, if there are forward arcs that are labeled non-redundant crossing I, our algorithm deletes one of them, which completes the proof of claim 1 in the case when we add a backward arc.

The both cases together complete the proof of the two claims, and in particular, of the original lemma. ◀

In order to analyze the cost of the algorithm, we define the *redundant cost* of a forward arc $a = (c, s)$ at time t as the sum of the lengths of all the atomic intervals $I \in \mathcal{AI}_t$ such that a is redundant w.r.t. I. Similarly, the *non-redundant cost* of a forward arc $a = (c, s)$ is the sum of the lengths of all the atomic intervals $I \in \mathcal{AI}_t$ such that a is non-redundant w.r.t. I. In Lemma 27, we bound the total redundant cost of all the forward arcs in terms of their non-redundant cost.

▶ **Lemma 27.** *At any time t, the redundant cost of any forward arc is at most the non-redundant cost of that forward arc.*

Proof. We will prove that for any forward arc a, at any time t, the redundant cost of a is at most the non-redundant cost of a at time t. Summing over all forward arcs will then complete the proof of Lemma 27.

To show this, we will in fact show the following: if RecursiveCancel adds a forward arc $a = (c_t, s_t)$ in step 5 at time t, then in *any suffix of* a, the redundant cost is at most the non-redundant cost. This suffices for us since we know from Lemma 23 that re-matched forward arcs are only suffixes of existing forward arcs, and their redundant/non-redundant labels remain the same from Definition 25.

Henceforth, we assume that at time t, the client c_t has arrived, and Permutation has chosen to match it using the server s_t by a forward arc, and RecursiveCancel has done the same. Let $A = C_{t-1} \cup S_{t-1}$ denote the set of clients and servers prior to adding c_t and s_t. Let $x \in [\ell(c_t), \ell(s_t)]$. Consider the suffix $[x, \ell(s_t)]$ of the arc (c_t, s_t), and introduce a *virtual client* c' at x. We claim that the optimal cost of matching clients and servers in $A \cup \{c', s_t\}$ is at least the optimal cost of matching clients and servers in A. Indeed, if this is

not the case, then we can produce a cheaper matching for the clients in C_{t-1} using a subset of servers in $S_{t-1} \cup \{s_t\}$ by ignoring the client c', which is a contradiction to Proposition 9 that Permutation maintains a solution that is server-optimal.

When we add $\{c', s_t\}$ to A, by Lemma 19, the increase in the cost of optimal matching occurs precisely at the intervals where the number of clients to the left is greater than the number of servers (after adding c' and s_t). And in other intervals in $[x, \ell(s_t)]$, the cost paid by the optimal matching decreases. However, this exactly corresponds to the redundancy and non-redundancy of the forward arc (c_t, s_t) with respect to the intervals inside $[x, \ell(s_t)]$. The intervals where the cost of optimal matching increases are the ones with respect to which the arc is non-redundant, and the intervals where the cost of optimal matching decreases are the ones with respect to which the arc is redundant. ◀

▶ **Theorem 28.** *At any point of time, the cost of the matching of Algorithm 3 (*RecursiveCancel*) is at most* 3 *times the cost of the optimal offline matching* OPT_t.

Proof. For the sake of analysis, for every atomic interval $I \in \mathcal{AI}_t$, let us label an arbitrary set of $\min(n_t^f(I), n_t^b(I))$ backward arcs as redundant with respect to I, and the rest as non-redundant with respect to I. Then, from Lemma 26, there will be an equal number of redundant backward arcs and redundant forward arcs with respect to any atomic interval $I \in \mathcal{AI}_t$. Using this, we conclude that, for any atomic interval $I \in \mathcal{AI}_t$, there are exactly $|\mathrm{disc}_t(I)|$ non-redundant arcs (including both forward and backward) w.r.t I. Indeed, if $n_t^f(I) \geq n_t^b(I)$, then there are $n_t^b(I)$ redundant forward (and redundant backward) arcs by Lemma 26, and the remaining $n_t^f(I) - n_t^b(I)$ forward arcs crossing I are non-redundant w.r.t I. But this is precisely the (absolute value of) the $\mathrm{disc}_t(I)$ by Claim 20. A similar argument holds when $n_t^b(I) > n_t^f(I)$.

For ease of notation, let us denote the total non-redundant cost of all the forward arcs (resp. backward) maintained by the algorithm at time t as $\mathsf{cost}(\mathcal{M}_t, NF)$ (resp. $\mathsf{cost}(\mathcal{M}_t, NB)$). Similarly, we denote the total redundant cost of all the forward arcs (resp. backward) as $\mathsf{cost}(\mathcal{M}_t, RF)$ (resp. $\mathsf{cost}(\mathcal{M}_t, RB)$). Now, from Lemma 19, and by noting that $|\mathrm{disc}_t(I)|$ is equal to the number of arcs crossing I which are non-redundant w.r.t. I, we have that

$$\mathsf{cost}(\mathcal{M}_t^*) = \sum_I |I||\mathrm{disc}_t(I)| = \mathsf{cost}(\mathcal{M}_t, NF) + \mathsf{cost}(\mathcal{M}_t, NB)\,.$$

On the other hand, the cost of $\mathcal{M}_t$ maintained by RecursiveCancel is at most

$$\begin{aligned}
\mathsf{cost}(\mathcal{M}_t) &= \mathsf{cost}(M_t, RF) + \mathsf{cost}(M_t, RB) + \mathsf{cost}(M_t, NF) + \mathsf{cost}(M_t, NB) \\
&= 2 \cdot \mathsf{cost}(M_t, RF) + \mathsf{cost}(M_t, NF) + \mathsf{cost}(M_t, NB) \\
&\leq 2 \cdot \mathsf{cost}(M_t, NF) + \mathsf{cost}(M_t, NF) + \mathsf{cost}(M_t, NB) \\
&\leq 3\,(\mathsf{cost}(\mathcal{M}_t, NF) + \mathsf{cost}(\mathcal{M}_t, NB)) \leq 3\mathsf{cost}(\mathcal{M}_t^*) = 3\mathsf{OPT}_t\,.
\end{aligned}$$

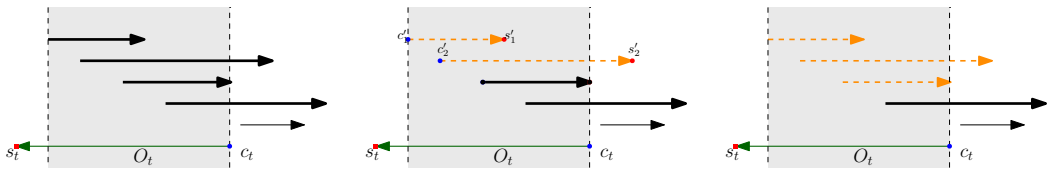
The first equality is from the definition of redundant backward arc w.r.t. atomic intervals and the first inequality is due to Lemma 27. ◀

4.3 Algorithm MinimumCancel

Even though the RecursiveCancel algorithm has a good competitive ratio, there are instances in which the algorithm performs $\Omega(k)$ rematches per client on average. We illustrate one such example in Appendix A. We, therefore, present another algorithm MinimumCancel which also satisfies Definition 21 and then bound its recourse.

Algorithm 4 Algorithm MinimumCancel.

1: **for** each client c_t arriving at time t **do**
2: let s_t be the server Permutation matches c_t to
3: **if** (c_t, s_t) is a forward arc **then**
4: $\mathcal{M}_t = \mathcal{M}_{t-1} \cup (c_t, s_t)$
5: **else**
6: let A_t denote all forward arcs $\overrightarrow{c,s} \in \mathcal{M}_{t-1}$ with $\ell(c) \in [\ell(s_t), \ell(c_t)]$
7: let $F_t = \cup_{\overrightarrow{c,s} \in A_t} [\ell(c), \ell(s)]$ denote the union of line segments contained within A_t, and let $O_t = F_t \cap [\ell(s_t), \ell(c_t)]$ denote the *overlapped* portion with $\overleftarrow{s_t, c_t}$
8: let A_t^* denote a *minimal subset* of A_t whose union covers the overlapped region O_t
9: order the edges in A_t^* as $(c'_1, s'_1), (c'_2, s'_2), \ldots, (c'_m, s'_m)$ such that $\ell(c'_1) \leq \ell(c'_2) \ldots \leq \ell(c'_m)$
10: let $\widetilde{A}_t = \{(c'_2, s'_1), (c'_3, s'_2), \ldots, (c'_m, s'_{m-1})\}$
11: update $\mathcal{M}_t = \{\mathcal{M}_{t-1} \setminus A_t^*\} \cup \widetilde{A}_t \cup \{(c_t, s'_m)\} \cup \{(c'_1, s_t)\}$
12: **end if**
13: **end for**



The crux of the algorithm is to cancel parts of forward arcs that overlap with the new backward arc in a manner that *minimally changes the existing solution*. We do this by identifying a minimal arc cover of the overlapping regions and perform the rematch only within the covering set of arcs. Figure 4a gives an illustration of the existing set of arcs when a new backward arc $\overleftarrow{s_t, c_t}$ is added. Figure 4b shows the minimal cover chosen in step 8 of the algorithm, and the final rematch will contain the arcs $\overleftarrow{s_t, c'_1}, \overrightarrow{c'_2, s'_1}$ and $\overrightarrow{c_t, s'_2}$. Figure 4c shows an example of a non-minimal cover where there are three overlapping forward arcs.

▶ **Lemma 29.** *When a new client c_t arrives, the re-matched set of forward arcs $\widetilde{A}_t$ computed in step 10 of Algorithm 4 are mutually disjoint.*

Proof. We first claim that in the minimum cover A_t^*, no three forward arcs intersect. Suppose for contradiction that there are forward arcs $a_1 = \overrightarrow{c_1, s_1}, a_2 = \overrightarrow{c_2, s_2}, a_3 = \overrightarrow{c_3, s_3}$ intersect at a point. Without loss of generality, let a_1 be the arc with left most client and a_3 be the arc with right most server. Then, the union of $[\ell(c_1, \ell(s_1))]$ and $[\ell(c_3), \ell(s_3)]$ fully contains $[\ell(c_2), \ell(s_2)]$, thus making the arc a_2 redundant in the cover, contradicting the minimality of the cover A_t^*. It is easy to conclude that the arcs $(c'_2, s'_1), (c'_3, s'_2), \ldots, (c'_m, s'_{m-1})$ are mutually disjoint. The minimal cover property is crucial as illutrated in Figure 4c; the disjointness property of residual forward arcs does not hold for the non-minimal cover. ◀

Using Lemma 29, we can bound the recourse of the MinimumCancel algorithm.

▶ **Theorem 30.** *After the arrival of k clients, the total recourse of* MinimumCancel *algorithm is at most $\mathcal{O}(k \log(k))$.*

(a) A backward arc and overlapping forward arcs.

(b) A minimal cover of O_t (in dashed orange).

(c) A non-minimal cover of O_t (in dashed orange).

Figure 4 Illustration for Algorithm 4. Forward arcs in A_t are shown with thick width.

Proof. Note that once a client is matched by a backward arc, it is not going to get re-matched later. We now bound the number forward-arc to forward-arc rematches.

For a vertex (either client or server) z, let us define a "length" $\text{len}(z)$ parameter which is equal to the number of vertices (all vertices which are part of the eventual matching after all the k clients have arrived) lying strictly inside the arc defined by z and its currently matched server/client. Therefore, before the start of the algorithm, the len value of every vertex is at most $2k$. We now define the level of vertex z as $\lfloor \log \text{len}(z) \rfloor$ so that the total initial level of all the vertices is at most $2k(1 + \log k)$. Suppose that a client c is currently matched to s by using a forward arc, and in an iteration gets re-matched to s' and s gets re-matched to c' both again using forward arcs. At least one of $\text{len}(c)$ or $\text{len}(s)$ should have decreased by at least a factor of 2 since these are now disjoint arcs from Lemma 29. And therefore the total level of c and s at least decreases by 1. In other words, on every re-match, the total level decreases by at least 1, which together with the bound on the total initial level gives the number of such re-matches to be at most $2k(1 + \log k)$. If at least one of c or s gets re-matched by a backward arc, its match does not change from then on. Thus, the number of these type of re-matches are at most $2k$. Thus, in total, the recourse of the algorithm is $\mathcal{O}(k \log k)$. ◀

5 Conclusion and Open Questions

The current work (together with the concurrent work [21]) represents the first attempt at exploring the trade-off between recourse and competitive ratio in online metric matching, and understanding the optimal trade-offs is an interesting direction to pursue. Concretely, can we get $o(\log k)$-competitive (even randomized) algorithms with $\text{polylog}(k)$-recourse for general metrics? This would be interesting given the $\Omega(\log k)$-lower bounds for algorithms without recourse. Similarly, obtaining or refuting $O(1)$-competitive algorithms with $O(1)$-recourse on line metrics is a very interesting question. Finally, extending our results to specialized inputs such as random order arrivals or unknown *i.i.d.* models would be interesting, as it better captures beyond-worst-case scenarios.

A Bad Example for Recourse of RecursiveCancel

We illustrate the fact that RecursiveCancel algorithm can have bad recourse in the following example:

In this instance, there are four clients c_1, c_2, c_3 and c_4, $\ell(c_1) < \ell(c_2) < \ell(c_3) < \ell(c_4)$ currently matched using forward arcs to s_1, s_2, s_3 and s_4 respectively such that $\ell(c_4) < \ell(s_1) < \ell(s_2) < \ell(s_3) < \ell(s_4)$. A new client c_5 arrives to the right of s_4 and Permutation outputs s_5 to the left of c_1 as the new server. Since the arc (c_5, s_5) is backward, the algorithms try to fix the matching. The RecursiveCancel i.e. Algorithm 3 changes the matching completely to obtain $(c_2, s_1), (c_3, s_2), (c_4, s_3)$ as the new forward arcs, where as Algorithm 4 changes only c_4's matching and keeps c_2 and c_3 intact. If there are k such forward arcs, and if k backward arcs arrive, Algorithm 3 has a recourse of $\Omega(k^2)$ where as Algorithm 4 has only $O(k)$ recourse.

B Missing Proofs

Proof of Proposition 12. For the sake of simplicity, we stick with $d = 2$, and the same proof holds for larger d as well. At any time t, we view our algorithm as simulating the Permutation algorithm for a certain batch sequence. Indeed, note, the solution maintained in $\mathcal{M}_t$ is exactly what Permutation maintains when fed $O(\log t)$ batches of consecutive clients corresponding to the different powers-of-two 2^{i-1} (in decreasing order) such that the

i^{th} bit from right in the binary representation of t is 1. Theorem 11 then bounds the cost. The recourse is bounded since any client is involved in a re-matching of size 2^i at most once for all i. ◀

Proof of Proposition 13. For simplicity, we prove the proposition for the case $d = 2$. An alternate view of Algorithm MultiScalePermutation is the following: Let the leaves of a complete balanced tree of degree d denote the k client arrivals. Whenever the arrival of a client completes a subtree (that is, it is the rightmost leaf in some subtree), the matching for the clients and their currently matched serves is re-solved optimally.

Our lower bound instance will be on the line metric and consist of two parts: a *core* instance and a *auxiliary* instance. The subsequent client arrival will be chosen as the next arrival from either the core or the auxiliary instance so as to obtain a large recourse cost as we describe soon. The servers for the core instance will at locations $\pm 1, \pm 2, \pm 3, \ldots, \pm k/2$, and the servers for the auxiliary instance will be k servers at location $10k$. The client arrival sequence in the core instance will be $\epsilon, -1-\epsilon, 1+\epsilon, -2-\epsilon, 2+\epsilon, -3-\epsilon, 3+\epsilon, \ldots$; the client arrival sequence for the auxiliary instance is $10k, 10k, 10k, \ldots$.

Note that the above instance have been set up so that on the arrival of a client from the core instance, the server added by Permutation to the matching is also from the core instance, and similarly for a client from the auxiliary instance a server from the auxiliary instance is added. Further, the same is done by OPTso that it suffices to study the cost and recourse for the arrivals in the core instance.

To decide whether the next client arrival happens from the core or the auxiliary sequence, we first check whether the arrival completes any subtree. If it does, denote the largest subtree it completes by T, and by $T_1, \ldots, T_d$ the d subtrees of the root of T (so that the new arrival is the rightmost leaf of T_d). If the number of core arrivals so far in T_d is even, then the new arrival is also chosen from the core sequence. Otherwise the new arrival is chosen from the auxiliary chosen.

We first prove the recourse bound. The sequence in which Permutation adds servers when the clients arrive from the core sequence is $1, -1, 2, -2, \ldots$. In particular, the new client and server are added on the opposite sides of a central matching that is built online. The construction of the client arrival sequence ensures that when MultiScalePermutation resolves the optimal matching for subtree $T = (T_1, T_2)$ the number of client arrivals in T_2 is odd, and hence batch resolving ends up rematching all clients in $T_1 \cup T_2$ (except at most one). (In the general d case we have to assume d is odd, in which case it is easy to show that all the subtrees $T_1, T_2, \ldots, T_d$ have odd number of core clients, and thus a $\frac{d-1}{d}$ fraction of clients are rematched in the subtree T.)

To study cost, consider the matching immediately after the arrival of the ith client, and let $i = \sum_{j=0}^{\ell} d^j k_j$ $(0 \le k_j \le d-1)$ denote the base d representation of i. In particular, consider the case $k_j = 1$ for $1 \le j \le \ell$. The matching consists of one batch of d^ℓ clients each, followed by 1 batch of $d^{\ell-1}$ clients and so forth. The cost of OPTis at most i. However, the cost of MultiScalePermutation is $\Omega(i \cdot \ell) = \Omega(i \log_d i)$. ◀

Proof of Lemma 14. Recall that Permutation maintains an offline optimal matching $\mathcal{M}_t^*$ at time t, and when a client c_t arrives, we pair it with the server that is present in $\mathcal{M}_t^* \setminus \mathcal{M}_{t-1}^*$. In fact, the symmetric difference of $\mathcal{M}_t^*$ and $\mathcal{M}_{t-1}^*$ is an augmenting path starting at c_t and ending at s_t. Let it be denoted by $P = c_t, s_{p_1}, c_{p_1}, \ldots, s_{p_m} = s_t$. The edges $(c_t, s_{p_1}), (c_{p_1}, s_{p_2}), \ldots, (c_{p_{m-1}}, s_{p_m})$ are the new edges, and the rest $(s_{p_1}, c_{p_1}), (s_{p_2}, c_{p_2}), \ldots,$ $(s_{p_{m-1}}, c_{p_{m-1}})$ are the old edges. Recall that the cost of $\mathcal{M}_t^*$ is at least that of $\mathcal{M}_{t-1}^*$, and thus, in the augmenting path, the cost of new edges is at least that of the old edges.

We claim a stronger property that in any suffix of the augmenting path, the cost of the new edges is at least that of old edges. Consider a suffix $s_{p_i}, c_{p_i}, \ldots, s_{p_m}$. If the cost of new edges is less than the old edges, we can change the old matching from $(s_{p_i}, c_{p_i}), \ldots, (s_{p_{m-1}}, c_{p_{m-1}})$ to $(c_{p_i}, s_{p_{i+1}}), \ldots, (c_{p_{m-1}}, s_{p_m})$ while keeping the rest of the edges intact to get a matching with cost less than $\mathcal{M}^*_{t-1}$, contradicting the fact that $\mathcal{M}^*_{t-1}$ is an optimal matching for the first $t-1$ clients. Now, suppose that there is a free server s' in between c_t and s_t. Consider the prefix of the augmenting path P starting at c_t and ending at s'. Let this prefix be denoted by P'. Let $\mathcal{M}'_t$ be the matching obtained from $\mathcal{M}^*_{t-1}$ by augmenting with the new augmenting path P'. Since the cost of new edges is at least that of old edges in any suffix of the original augmenting path, the difference between new edges and old edges in P' is at most that of the original augmenting path P. Thus, the cost of the matching $\mathcal{M}'_t$ is at most that of $\mathcal{M}^*_t$. Furthermore, as we have assumed that the location of all the clients and servers are distinct, the cost of $\mathcal{M}'_t$ is strictly smaller than $\mathcal{M}^*_t$, contradicting the fact that $\mathcal{M}^*_t$ is an optimal matching of first t clients. This proves the claim that when we execute Permutation on the line metric, there are no free servers inside any arc. ◀

C Lower bounds

In this section, we present our lower bound for OMM on general metrics.

▶ **Theorem 31.** *Suppose that there exists an algorithm for* OMM *such that for every client c, the number of servers s such that c is matched to s at some point of execution of the algorithm is at most C, for an absolute constant C. Then, the competitive ratio of the algorithm is at least $\Omega(\log(n))$.*

Proof. We first describe the hard instance for OMM that we use to prove the lower bound. The underlying metric space is the star metric i.e. there exists a node v_0 that is at the center of the star, and a set of nodes $v_1, v_2, \ldots, v_n$ such that $d(v_0, v_i) = 1$ for all $i \in [n]$, and $d(v_i, v_j) = 2$ for all $i, j \in [n], i \neq j$. For every $i \in [n]$, there is a server s_i at v_i. For each time $t = 0, 1, \ldots, n-1$ a single client c_t arrives at a point in the metric space. First, at $t = 0$, the client c_0 arrives at v_0. The next clients arrive at the location of the server just used by the algorithm. Suppose that the algorithm matches c_0 to s_i. Then, c_1 arrives at v_i. After t clients have arrived and have been matched by the algorithm, consider the server matched to c_0- let it be s_{i_1}. Let s_{i_2} be the server matched by the algorithm to the client at v_{i_1}, and so on till there is no client yet arrived at v_{i_k}. Then, in our instance, at time t, a new client arrives at v_{i_k}.

Note that all the clients arrive at different locations in the metric space. This implies that at any point of time t, the offline optimal algorithm cost is equal to 1. We can simply match each client c_i other than c_0 to the server s_i, and match c_0 to an arbitrary unused server.

Suppose that for each client c, the number of servers s such that (c, s) is part of the matching of the algorithm at some point, is at most C. Then, we claim that there is a time t such that the online algorithm has cost at least $\Omega(\log(n))$ at time t. Let M_t, $t = 0, 1, \ldots, n-1$ denote the matching maintained by the algorithm after time t. We consider a new algorithm that maintains a set of matchings M'_t, $t = 0, 1, \ldots, n-1$ after time t. For every time t, we obtain M'_t from M_t as follows: Let $M = M_t$. While there exists a client c located at v_i matched in M to a server s at $v_j \neq v_i$, but the server s_i is not used in M, we rematch c to s_i in M. Note that this process terminates in at most n steps. When this process can no longer proceed, we output $M'_t = M$. The cost of the matching M'_t is at most the cost of M_t, as every iteration of the above procedure only decreases the cost of the matching. For every

client c, the number of servers s such that c is matched to s in some M'_t, is at most $C+1$. Finally, the new algorithm that maintains the matchings M'_t has a key property that at any time t: the matching M'_t can be described as a path: $(c_0, s_{i_1}), (c_1, s_{i_2}), \ldots, (c_t, s_{i_{t+1}})$ such that c_j and s_{i_j} are at the same location.

We now claim that there exist some time t such that the size of M'_t is at least $\Omega(\log(n))$, which proves the required lower bound. We define a directed graph $G = (V, E)$. The vertex set of the graph V is equal to $\{0, 1, \ldots, n\}$. There is an edge from i to j if for some time t, the client c_i is matched to the server s_j in M'_t. The out-degree of every node is at most $C+1$ in G. We also define the graphs $G_0, G_1, \ldots, G_{n-1}$ as follows: The vertex set of G_k is the same as G for every k. There is an edge from i to j in G_k if client c_i is matched to s_j in M'_k. It follows from the definitions that for every $k \in \{0, 1, \ldots, n-1\}$, G_i is a subgraph of G.

Note that for each k, the graph G_k is a path that starts at 0 and ends at the index of the location of the client c_k. Thus, all the graphs $G_0, G_1, \ldots, G_{n-1}$ are different path subgraphs of G all of which start at vertex 0 and end at a different vertex in G. As the out-degree of every vertex is at most $C+1$ in G, the number of distinct paths of length at most l in G starting at 0 is at most $(C+1)^l$. Thus, there should exist at least one path whose length is $\frac{\log(n)}{\log(C+1)} = \Omega(\log(n))$. As the length of the subgraph G_i denotes the cost of the matching M'_i, we get the required lower bound on the competitive ratio. ◀

How to Cut a Ball Without Separating: Improved Approximations for Length Bounded Cut

Abstract

The Minimum Length Bounded Cut problem is a natural variant of Minimum Cut: given a graph, terminal nodes s, t and a parameter L, find a minimum cardinality set of nodes (other than s, t) whose removal ensures that the distance from s to t is greater than L. We focus on the approximability of the problem for bounded values of the parameter L.

The problem is solvable in polynomial time for $L \leq 4$ and NP-hard for $L \geq 5$. The best known algorithms have approximation factor $\lceil (L-1)/2 \rceil$. It is NP-hard to approximate the problem within a factor of 1.17175 and Unique Games hard to approximate it within $\Omega(L)$, for any $L \geq 5$. Moreover, for $L = 5$ the problem is $4/3 - \varepsilon$ Unique Games hard for any $\varepsilon > 0$.

Our first result matches the hardness for $L = 5$ with a 4/3-approximation algorithm for this case, improving over the previous 2-approximation. For 6-bounded cuts we give a 7/4-approximation, improving over the previous best 3-approximation. More generally, we achieve approximation ratios that always outperform the previous $\lceil (L-1)/2 \rceil$ guarantee for any (fixed) value of L, while for large values of L, we achieve a significantly better $((11/25)L + O(1))$-approximation.

All our algorithms apply in the weighted setting, in both directed and undirected graphs, as well as for edge-cuts, which easily reduce to the node-cut variant. Moreover, by rounding the natural linear programming relaxation, our algorithms also bound the corresponding bounded-length flow-cut gaps.

1 Introduction

In the Minimum Length Bounded Cut problem, we are given a directed (undirected) graph $G = (V, E)$, two distinguished vertices $s, t \in V$, called the source and the sink, and an integer parameter $L > 0$, and wish to find a minimum cardinality *L-bounded node cut* (edge cut, resp.): a subset $F \subseteq V \setminus \{s, t\}$ of vertices (a subset $F \subseteq E$ of edges, resp.) such that the every path between the source s and the sink t in $G \setminus F$ has length strictly greater than L; the path length is the number of edges in it.

Various aspects of the problem have been studied for almost half a century: its relationship to the maximum L-bounded flow [1, 2, 3, 17] and to the maximum number of disjoint L-bounded $s - t$ paths [1, 7, 16], its complexity [5, 3, 15] and approximability [3, 14], fixed-parameter tractability [6, 9, 10, 11], and polynomial time solvability for various graph classes [4, 9, 18, 14]. In this paper we focus on the approximability of the problem.

There are four basic versions of the L-Bounded Cut problem, depending on whether the graph G is directed or undirected, and whether we cut nodes or edges. As observed by Golovach and Thilikos [11], an α-approximation algorithm for Directed L-Bounded Node Cut yields an α-approximation algorithm for Undirected L-Bounded Node Cut, Undirected $(L-1)$-Bounded Edge cut, and Directed $(L-1)$-Bounded Edge Cut. Thus, we describe all our algorithms just for the directed node version, and in the rest of the paper we focus exclusively on this setting.

On the complexity and approximability side, the node (edge, resp.) version of Minimum L-Bounded Cut is solvable in polynomial time for $L \leq 4$ [16] (for $L \leq 3$ [17], resp.) and is NP-hard for $L \geq 5$ (for $L \geq 4$, resp.) [3]. With respect to the length parameter L, there are several simple $O(L)$-approximation algorithms [3, 17], and the best known algorithm has approximation ratio $\lceil (L-1)/2 \rceil$ [3].

For $L \geq 4$, L-Bounded Edge Cut is known to be NP-hard to approximate within a factor of 1.1377 [3]. In fact, we observe that the reduction in that paper also implies the NP-hardness of approximating the problem to within a factor of 1.1715, and Unique Games hardness of approximating it to within $4/3 - \varepsilon$ for any $\varepsilon > 0$ – see Appendix A for details. Note that these results imply the same hardness for L-Bounded Node Cut for $L \geq 5$. Recently, Lee [15] showed that for bounded values of L it is Unique Games hard to approximate the undirected edge variant within $\Omega(\sqrt{L})$, and the other three variants within $\Omega(L)$. Thus, assuming the Unique Games Conjecture, the best possible approximation for all but the undirected edge variant is $\Theta(L)$. However, the exact best possible approximation as a function of L is not known.

If the length bound is not a fixed constant but a part of the input, the gap between the known hardness results and approximations is even bigger: there are no stronger hardness results and the best known algorithms [3] have approximation ratio $O(\min\{L, n/L\}) \subseteq O(\sqrt{n})$ in the node case and $O(\min\{L, n^2/L^2, \sqrt{m}\}) \subseteq O(n^{2/3})$ in the edge case where m denotes the number of edges.

1.1 Our results

Our first result is an algorithmic upper bound matching the Unique Games hardness of 4-Bounded Edge Cut and 5-Bounded Node Cut; note that these two problems are the *first* hard instances of L-Bounded Cut – for L the corresponding problems are in P. For reasons explained earlier we state all our results for the node case only.

▶ **Theorem 1.** *There is a $\frac{4}{3}$-approximation algorithm for Minimum 5-Bounded Node Cut.*

Similarly, for $L = 6$ we also describe a new algorithm with an improved approximation ratio.

▶ **Theorem 2.** *There is a $\frac{7}{4}$-approximation algorithm for Minimum 6-Bounded Node Cut.*

This algorithm is based on the same, yet more involved, techniques as the algorithm for $L = 5$. More generally, we have an approximation algorithm that works for any value of L.

▶ **Theorem 3.** *For any fixed length bound $L \geq 6$, there exists an $\left(\frac{L-1}{2} - \frac{3}{L-2}\right)$-approximation algorithm for Minimum L-Bounded Node Cut.*

This algorithm is based on our algorithm for $L = 6$ and a general observation that an α-approximation algorithm for L-Bounded Cut with certain properties can be used to design an approximation algorithm for $(L+1)$-Bounded Cut, with a slightly weaker approximation ratio (see Theorem 10). This is always better than the previous best known $\lceil (L-1)/2 \rceil$-approximation, but for large values of L it is not significantly better. Though various algorithmic techniques, including the above theorem, all point to $L/2 - o(L)$ being the best possible approximation (cf. [3]), we are able to improve over this bound.

▶ **Theorem 4.** *For any fixed length bound $L > 5$, there exists an $((11/25)L + O(1))$-approximation algorithm for* Minimum L-Bounded Node Cut.

A succinct summary of the old and the new results on approximability of Minimum L-Bounded Cut is provided in Table 1. It is worth mentioning that all our algorithms work also in the more general setting where every node (edge) has a non-negative weight and the objective is to find an L-bounded cut of minimum total weight, simply by including these weights in the objective function of the linear program.

Table 1 Known and **new** (bold type) results for bounded values of L. All results hold for both directed and undirected cases, unless stated otherwise. We note that a hardness result for some value of L implies the same hardness result for larger values as well, thus we only state hardness results here for the smallest L for which they hold. NP stands for NP hardness of approximation, UG for Unique Games hardness of approximation.

Approximate duality of L-bounded flows and cuts

As we have already mentioned earlier, researchers investigated the relation between the minimum L-bounded cut and the maximum L-bounded flow (where an L-bounded flow is a flow that can be decomposed into flows along paths of length at most L) (e.g., [2, 3, 17]); in fact, this was one of the first questions Adámek and Koubek [1] asked back in 1971.

All our algorithms are based on rounding the linear program (1) (given in the next subsection) which is the dual of the exact linear programming formulation of the maximum L-bounded flow. Thus, as a corollary of our algorithmic results, we obtain improved approximate duality relations between L-bounded cuts and flows that are tighter than those previously known. For the sake of brevity we state the result just for 4-bounded edge cuts and flows.

▶ **Corollary 5.** *Given a graph $G = (V, E)$ and nodes $s, t \in V$, let $\mathcal{F}$ denote a maximum 4-bounded flow, and $\mathcal{C}$ a minimum 4-bounded edge cut. Then*

$$|\mathcal{F}| \leq |\mathcal{C}| \leq \frac{4}{3}|\mathcal{F}|,$$

and these bounds are tight.

1.2 Overview of our approach

All our algorithms are based on a rounding of a natural linear programming relaxation of the problem. This relaxation was studied in earlier works on L-Bounded Cut (e.g., [3, 17]) but for the sake of completeness we provide it here again. In the following linear program (solvable via a simple separation oracle), $\mathcal{P}_{s,t}(L)$ denotes the set of all paths between s and t of length at most L.

$$\min \sum_{v \in V \setminus \{s,t\}} x_v \tag{1}$$

$$\sum_{v \in p \setminus \{s,t\}} x_v \geq 1 \quad \forall p \in \mathcal{P}_{s,t}(L) \tag{2}$$

$$x_v \geq 0 \quad \forall v \in V$$

The previous approximation algorithms were based on cutting only shortest paths, which can be done optimally by taking a minimum cut in the layered graph of shortest paths from s to t. By iteratively cutting all shortest $s-t$ paths until the distance between s and t becomes larger then L, we get an L-approximation.

This approach can also be framed as a rounding of the above linear programming relaxation, via the following classical rounding which cuts in every iteration all shortest paths while paying at most the LP value:

Exact-Round$(G, (x_v)_{v \in V})$

- For every $v \in V \setminus \{s,t\}$, let $y_v := \min\{x(p) \mid p : s \rightsquigarrow v,\ |p| = d(s,v)\}$ and $I_v := [y_v, y_v + x_v]$, where $s \rightsquigarrow v$ stands for an $s-v$ path, d is the hop-distance in G and $x(p)$ is defined to be the total LP value of vertices in p excluding its endpoints.
- Sample $r \in [0,1]$ uniformly at random.
- Return the cut $\{v \mid r \in I(v)\}$.

In words, every vertex $v \in V \setminus \{s,t\}$ is mapped to an interval I_v of length x_v in such a way that for every $s-t$ path p of interest (i.e., path of length $d(s,v)$), we have $[0,1] \subseteq \bigcup_{v \in p} I_v$. The algorithm then cuts all vertices whose corresponding intervals lie on the boundary of a ball of uniformly random radius; by cutting these vertices the algorithm separates s from t in the layered subgraph of shortest $s-t$ paths, and, thus, increases the distance between s and t on the whole graph by one at least. The property that is important in the analysis, and that will be important later in our new algorithms, is the following:

▶ **Observation 6.** *Given a solution $(x_v)_{v \in V}$ of the LP (1), for every $v \in V$, **Exact-Round** cuts v with probability at most x_v.*

The difficulty with the outlined iterative approach to construct an L-bounded cut is that it uses up to L iterations (or up to $\lceil (L-1)/2 \rceil$, if we first cut all vertices with $x_v \geq 1/\lceil (L-1)/2 \rceil$), where each iteration may yield a cut as large as the LP value. See Figure 1 for an instance where more than one iteration is performed. Our idea is to circumvent the need for multiple iterations by mapping every vertex v to *multiple* intervals, each interval representing a possible position of the vertex in an L-bounded path. Thus, our algorithms are similar to classical ball cutting algorithms, yet they differ in that they do not (necessarily) separate s from t.

However, this is only a framework for our improvements. A naïve random ball growing algorithm would not yield a better approximation ratio when applied to these intervals. To fully take advantage of this framework, we introduce additional ideas such as cutting only a carefully chosen subset of the boundaries of more than one ball, and/or modifying the LP values in order to take better advantage of the structure of our mappings.

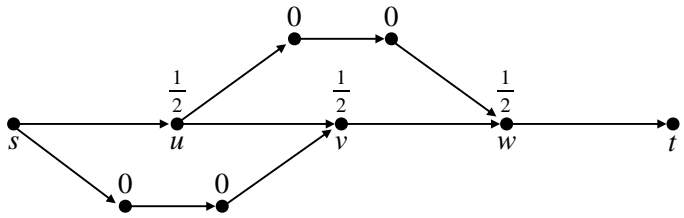

Figure 1 In this instance, $L = 5$, and the LP values appear above the vertices. In the first iteration of **Exact-Round**, we have $I_u = [0, 1/2]$, $I_v = [1/2, 1]$, and $I_w = [1, 3/2]$. Intervals for other vertices will have length 0. Thus, in this iteration either u or v will be cut (no other vertex is assigned an interval with a positive length intersection with $[0, 1]$), and we will need a second iteration to cut some remaining path of length 5.

2 A 4/3-approximation for $L = 5$

Here we prove Theorem 1. Specifically, we give a rounding of the natural LP relaxation for 5-Bounded Node Cut which cuts every vertex $v \in V$ with probability at most $(4/3) \cdot x_v$.

Before describing our rounding, we describe here a certain mapping of the vertices $V \setminus \{s, t\}$ to intervals. For a graph $G = (V, E)$ and an LP solution $(x_v)_{v \in V}$, we map every vertex v at distance most 2 from s or to t to two intervals, $I^+_G(v), I^-_G(v)$. For any vertices u, v such that $(s, u), (v, t) \in E$, we define

$$I^-_G(u) = I^+_G(u) = [0, x_u] \qquad I^-_G(v) = I^+_G(v) = [1 - x_v, 1].$$

Next, for any vertex u (for which $(u, t) \notin E$) at distance 2 from s, define

$$y^+_G(u) = \min_{u':(s,u'),(u',u) \in E} x_{u'} \qquad I^+_G(u) = [y^+_G(u), y^+_G(u) + x_u].$$

If $d_G(u, t) > 2$, define $I^-_G(u) = I^+_G(u)$; note that in such a case, within any 5-bounded $s - t$ path containing it, u will be at distance 2 from s and 3 from t. Finally, for any vertex v (for which $(s, v) \notin E$) at distance 2 to t, define

$$y^-_G(v) = \min_{u:(v,v'),(v',t) \in E} x_{v'} \qquad I^-_G(v) = [1 - y^-_G(v) - x_v, 1 - y^-_G(v)].$$

If $d_G(s, v) > 2$, define $I^+_G(v) = I^-_G(v)$.

We will drop the subscript G from the above definitions when it is clear from the context. Note that $I^+(v), I^-(v)$ have length x_v for every v, and $I^-(v) = I^+(v)$ for all vertices v except those which are both at distance 2 from s and at distance 2 to t. For v such that $I^-(v) \neq I^+(v)$, there exists a path $\langle s, u', v, v', t \rangle$ such that $y^+(v) = x_{u'}$ and $y^-(v) = x_{v'}$. Thus, the intervals have the same length, and $I^-(v)$ starts to the left of $I^+(v)$ (when plotted on the real number line). Indeed, the left endpoint of $I^+(v)$ will be $x_{u'}$, while the left endpoint of $I^-(v)$ will be $1 - (x_{v'} + x_v)$, which is at most $x_{u'}$ by Constraint (2).

We are now ready to define our rounding:

Algorithm 5-Round

- Let $C_0 = \{v \in V \mid x_v \geq 3/4\}$. Let G' be the remaining graph after deleting all vertices in C_0.
- Sample $r \in [0, 1]$ uniformly at random.

- Sample $r_1 \in [0, 1/2]$ uniformly at random, and let $r_2 = r_1 + 1/2$.
- Let C_1 be the set of all vertices v such that $r \in I^-_{G'}(v) \cup I^+_{G'}(v)$.
- Let C_2 be the set of all vertices v for which at least one of the following conditions holds:
  1. $r_1 \in I^-_{G'}(v) \cap I^+_{G'}(v)$ or $r_2 \in I^-_{G'}(v) \cap I^+_{G'}(v)$, or
  2. $r_1, r_2 \in I^-_{G'}(v)$ or $r_1, r_2 \in I^+_{G'}(v)$.
- With probability 2/3, return $C_0 \cup C_1$. Otherwise (with probability 1/3), return $C_0 \cup C_2$.

▶ Remark 7. This algorithm can be easily derandomized by trying $O(|V|)$ possible radii r, r_1 and choosing the better of the two cuts $C_0 \cup C_1$, $C_0 \cup C_2$.

First let us see why this is a valid 5-bounded cut.

▶ **Lemma 8.** *Algorithm **5-Round** cuts all paths of length at most 5 from s to t.*

Proof. Since vertices in C_0 are always cut, we focus on paths not cut by C_0. That is, on paths in G'.

First, let us see that C_1 cuts all 5-bounded $s-t$ paths in G' (the proof for paths of length < 5 is similar or simpler). Let $p = \langle s, u', u, v, v', t\rangle$ be such a path and assume that $(s,u), (v,t) \notin E$; otherwise cutting a vertex in a shorter path (i.e., $\langle s, u, v, v', t\rangle$ or $\langle s, u', u, v, t\rangle$) cuts p as well. Let u'', v'' be vertices such that $y^+(u) = x_{u''}$ and $y^-(v) = x_{v''}$. Since $\langle s, u'', u, v, v'', t\rangle$ is also a path in G', it follows from the definition of the intervals and Constraint (2) that $[0,1] \subseteq I^+(u'') \cup I^+(u) \cup I^-(v) \cup I^-(v'')$. Moreover, we clearly have $I^+(u'') \subseteq I^+(u')$ and $I^+(v'') \subseteq I^+(v')$, so r must be contained in one of of the intervals $I^+(u'), I^+(u), I^-(v), I^-(v')$, and so p will be cut by C_1.

Now we consider the cut C_2. First consider a path $p = \langle s, u', v, v', t\rangle$ of length 4. Note that $I^+(u') = I^-(u')$ and $I^+(v') = I^-(v')$, and by similar reasoning to the above, we have $[0,1] \subseteq I^+(u') \cup (I^+(v) \cap I^-(v)) \cup I^-(v')$, and so at least one of r_1 or r_2 must be in $I^-(u) \cap I^+(u)$ for some $u \in \{u', v, v'\}$, and this vertex will be cut by C_2.

Finally, let $p = \langle s, u', u, v, v', t\rangle$ be a 5-path in G', and let us see that p is cut by C_2. Since $I^+(u') = I^-(u')$ and $I^+(v') = I^-(v')$, we may assume that $r_1 > x_{u'}$ and $r_2 < 1 - x_{v'}$ (otherwise, u' or v', respectively, will be cut). Thus, $r_1, r_2 \in I^+(u) \cup I^-(v)$. In particular, $r_1 \in I^+(u)$ or $r_2 \in I^-(v)$; otherwise, we would have $r_2 \in I^+(u)$ and r_1 to the left of $I^+(u)$, that is $r_1 < y^+(u) \le x_{u'}$, contradicting our current assumption.

If both radii were in $I^+(u)$ or both in $I^-(v)$, then again the corresponding vertex would be cut by C_2, so assume $r_1 \in I^+(u)$ and $r_2 \in I^-(v)$. We claim that in this case we must have $r_1 \in I^-(u) \cap I^+(u)$ or $r_2 \in I^-(v) \cap I^+(v)$, and then the corresponding vertex will be cut in C_2. For the sake of contradiction, assume $r_1 \in I^+(u) \setminus I^-(u)$ and $r_2 \in I^-(v) \setminus I^+(v)$. The fact that both of these vertices are mapped to two distinct intervals means that there exist vertices u'', v'' in G' such that $\langle s, v'', v\rangle$ and $\langle u, u'', t\rangle$ are paths in G' and $y^-(u) = x_{u''}$ and $y^+(v) = x_{v''}$. As r_1 is to the right of $I^-(u)$ and r_2 is to the left of $I^+(v)$, we have $r_1 > 1 - x_{u''}$ and $r_1 + 1/2 = r_2 < x_{v''}$. Thus, we get $x_{u''} + x_{v''} > 3/2$, contradicting the fact that the LP value of every vertex in G' is at most 3/4. ◀

Next we bound the expected value of the cut.

▶ **Lemma 9.** *Every vertex $v \in V$ is cut by Algorithm 5-Round with probability at most $(4/3) \cdot x_v$.*

Proof. If $x_v \ge 3/4$, this is trivial. Thus, let us look at vertices in $V \setminus C_0$.

First, consider a vertex v such that $x_v < 1/2$. Note that v is cut by C_1 with probability at most $|I^-(v) \cup I^+(v)|$ (it is exactly this probability if both intervals are contained in $[0,1]$, but this is not necessarily the case). Now consider the definition of C_2. As $x_v < 1/2$, Condition 2

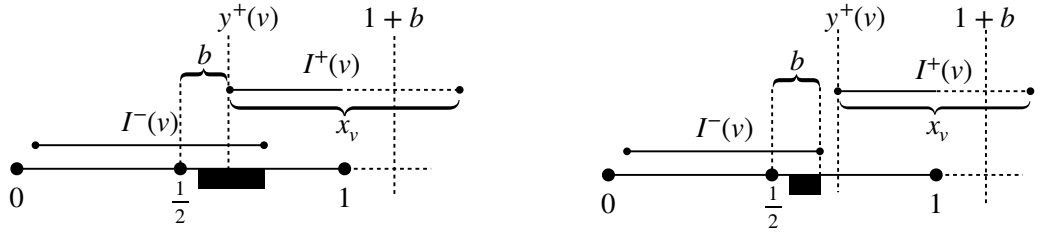

Figure 2 Two examples of the final case in the proof of Lemma 9. The black rectangles denote the range of r_2 for which $v \in C_2$. This range has length at most $|I^-(v) \cap I^+(v)| + b$, while the range of r for which $v \in C_1$ has length at most $|I^-(v) \cup I^+(v)| - b$.

in the algorithm can never occur. Thus the probability that v is cut by C_2 is the probability that it will be cut because of Condition 1, which is exactly $2 \cdot |I^-(v) \cap I^+(v) \cap [0, 1/2]| + 2 \cdot |I^-(v) \cap I^+(v) \cap [1/2, 1]| = 2 \cdot |I^-(v) \cap I^+(v)|$. Thus the overall probability that v is cut is at most

$$\tfrac{2}{3} \cdot |I^-(v) \cup I^+(v)| + \tfrac{1}{3} \cdot 2 \cdot |I^-(v) \cap I^+(v)| = \tfrac{2}{3} \cdot (|I^-(v)| + |I^+(v)|) = \tfrac{4}{3} \cdot x_v.$$

Now consider a vertex $v \in V$ such that $x_v \geq 1/2$ (but less than $3/4$). If Condition 2 never occurs, or only occurs when Condition 1 also occurs (for example, if $I^-(v) = I^+(v)$), then we are done by the same calculation as above. Otherwise, there exist values of r_1 for which Condition 2 occurs but not Condition 1. That is, either

- Case (i): There exists r_1 such that $r_1, r_2 \in I^-(v)$ and r_2 is to the left of $I^+(v)$, or
- Case (ii): There exists r_1 such that $r_1, r_2 \in I^+(v)$ and r_1 is to the right of $I^-(v)$.

Note that at most one of these cases is possible for a given vertex v, since Case (i) implies that $I^-(v)$ intersects the interval $[1/2, 1]$, whereas Case (ii) implies that $I^-(v)$ is strictly to the left of $1/2$. Without loss of generality, assume (only) Case (i) holds. Let $b = \min\{1/2 - y^-(v), y^+(v) - 1/2\}$, that is, the maximum value such that $1/2 + b \in I^-(v)$ and $1/2 + b \leq \min I^+(v)$ (see Figure 2). By our assumption, $b \geq 0$. Thus, $v \in C_2$ *only* if (not iff) $r_2 \in I^-(v) \cap I^+(v)$ or $r_2 \in [1/2, 1/2 + b]$. This happens with probability at most $2|I^-(v) \cap I^+(v)| + 2b$. As we've noted, v is cut by C_1 with probability at most $|I^-(v) \cup I^+(v)|$. However a tighter upper bound on this probability is $|(I^-(v) \cup I^+(v)) \cap [0, 1]|$. Since $x_v \geq 1/2$, $b \leq y^+(v) - 1/2$, and $I^+(v) = [y^+(v), y^+(v) + x_v]$, we have that $|I^+(v) \setminus [0, 1]| \geq b$, and so the total probability that v will be cut is upper bounded by

$$\begin{aligned}
\tfrac{2}{3}|(I^-(v) \cup I^+(v)) \cap [0, 1]| + \tfrac{1}{3} \cdot \big(2|I^-(v) \cap I^+(v)| + 2b\big) \\
&= \tfrac{2}{3}\big(|I^-(v) \cup I^+(v)| - |I^+(v) \setminus [0, 1]| + |I^-(v) \cap I^+(v)| + b\big) \\
&= \tfrac{2}{3}\big(|I^-(v)| + |I^+(v)| - |I^+(v) \setminus [0, 1]| + b\big) \\
&\leq \tfrac{2}{3}\big(|I^-(v)| + |I^+(v)|\big) = \tfrac{4}{3}x_v.
\end{aligned}$$

Figure 2 illustrates this final case. ◀

3 Improved approximations for other small values of L

In this section, we prove Theorem 3. Our approximation is based on an algorithm which takes as a black box a rounding for $(L-1)$-Bounded Cut and converts it into a rounding for L-Bounded Cut. In particular, we show the following result:

▶ **Theorem 10.** *Given a rounding algorithm for $(L-1)$-Bounded Cut which cuts every vertex v with probability at most $\alpha \cdot x_v$, there is a rounding for L-Bounded Cut which cuts every vertex v with probability at most $(1 + \alpha \cdot (1 - 1/(L-2))) \cdot x_v$.*

Theorem 3 now follows easily.

Proof of Theorem 3. Follows immediately by induction, where the base case is Theorem 2 for $L = 6$ (or technically, the more specific Lemma 19), and Theorem 10 gives the inductive step. ◀

We now describe our technique for converting a rounding for $(L-1)$-Bounded Cut to a rounding for L-Bounded Cut. The following algorithm takes as a black box a rounding algorithm A_{L-1} for $(L-1)$-Bounded Cut:

L-Recurse$(G, (x_v)_{v\in V}, A_{L-1})$

- Cut every vertex $v \in V$ such that $x_v \geq 1$, and let V' be the remaining vertices.
- Define $(z_v)_{v\in V'}$ as follows:

$$z_v = \left(1 - \tfrac{1}{L-2}\right) \cdot \tfrac{x_v}{1-x_v}.$$

- Run algorithm A_{L-1} on graph $G|_{V'}$ and LP solution $(z_v)_{v\in V'}$. Let V'' be the remaining vertices (not cut in this step).
- Run **Exact-Round**$(G|_{V''}, (x_v)_{v\in V''})$.

To understand this algorithm, first let us see the feasibility of the solution $(z_v)_{v\in V'}$ defined in the second step.

▶ **Lemma 11.** *If $(x_v)_{v\in V'}$ is a feasible solution for the natural LP relaxation for $(L-1)$-Bounded Cut on a graph with vertex set V', such that $x_v < 1$ for all $v \in V'$, then the solution $(z_v)_{v\in V'}$ defined above is also a feasible LP solution for the same LP relaxation.*

Proof. By our assumption that $x_v < 1$ for all $v \in V'$, we have $z_v \geq 0$ for all vertices. Now let $\langle s, v_1, \ldots, v_{L-2}, t\rangle$ be a path of length $L-1$. By the feasibility of $(x_v)_{v\in V'}$ we know that $\sum_{i=1}^{L-2} x_{v_i} \geq 1$. Therefore, by the convexity of the function $f(x) = x/(1-x)$ for all $x < 1$ (and Jensen's inequality), we have

$$\begin{aligned}\sum_{i=1}^{L-2} z_v &= (L-3) \cdot \tfrac{1}{L-2} \textstyle\sum_{i=1}^{L-2} x_{v_i}/(1-x_{v_i}) \\ &\geq (L-3) \cdot \tfrac{1}{L-2} \textstyle\sum_{i=1}^{L-2} x_{v_i} / \left(1 - \tfrac{1}{L-2} \sum_{i=1}^{L-2} x_{v_i}\right) \\ &\geq (L-3) \cdot \tfrac{1}{L-2} / (1 - \tfrac{1}{L-2}) = 1.\end{aligned}$$

Thus, Constraint (2) is satisfied for this path. For paths of length $L' < L-1$, the argument follows from the above calculation by taking the LP values along the path and appending additional values $x_{L'-1} = \ldots = x_{L-2} = 0$ which are mapped to $z_{L'-1} = \ldots z_{L-2} = 0$. ◀

We can now show our main guarantee for this section.

Proof of Theorem 10. Let us see that Algorithm L-Recurse satisfies the requirements. First note that the algorithm returns a feasible L-bounded cut. Indeed, by Lemma 11, $(z_v)_{v\in V'}$ is a feasible solution for the relaxation for $(L-1)$-Bounded Cut, and so the application of algorithm A_{L-1} will cut all paths of length at most $L-1$ not already cut in the first step. In the remaining graph we have $d(s,t) \geq L$, and so all remaining paths (if any) of length L will be cut in the last step.

As for the approximation guarantee, if $x_v \geq 1$, then the theorem follows trivially. For $v \in V'$, we know that algorithm A_{L-1} will cut v with probability $\alpha'_v \cdot z_v$, for some $\alpha'_v \leq \alpha$. Conditioned on surviving this phase, by Observation 6, v will be cut in the last step with probability at most x_v. Thus the overall probability that v is cut will be at most

$$\begin{aligned}\alpha'_v \cdot z_v + (1 - \alpha'_v \cdot z_v)x_v &= x_v + (1 - x_v)\alpha'_v \cdot z_v \\ &= x_v + \alpha'_v \cdot (1 - 1/(L-2)) \cdot x_v \\ &\leq (1 + \alpha \cdot (1 - 1/(L-2))) \cdot x_v.\end{aligned}$$

◀

4 An $((11/25) \cdot L + O(1))$-approximation

Here we prove Theorem 4, showing that $L(1/2 - o(1))$ is not the best possible approximation for general (bounded) L. Similarly to our algorithm for $L = 5$, we will map every vertex to different intervals corresponding to different positions the vertex can have in an L-bounded path from s to t, and then cut all intervals containing a random radius in $[0, 1]$. Our improvement follows from showing that these intervals will be mapped close together. However, for vertices with small LP value, this will not be sufficient, since the intervals can still be disjoint. See Appendix B for an example. To avoid this problem, we will define a new LP solution which will greatly decrease the LP value of vertices which already have a small LP value, giving us an advantage over previous algorithms for these vertices as well.

Distort-Round

- Cut all vertices $v \in V$ with $x_v \geq 25/(11(L-1))$. Let G' be the graph on remaining vertices.
- For every remaining vertex v, let $i_{\min}(v) = d(s, v)$ and $i_{\max}(v) = L - d(v, t)$ (the first and last possible positions of v in an L-bounded path), where d is the hop-distance in G'. Let $V' = \{v \in G \mid i_{\min}(v) \leq i_{\max}(v)\}$, and on these vertices define $(x'_v)_{v \in V'}$ as follows:

  $$x'_v = \max\{0, (23/20) \cdot x_v - 3/(20(L-1))\}.$$

- For all $v \in V'$ and $i \in \{i_{\min}(v), \ldots, i_{\max}(v)\}$ define the following intervals, where paths are in G' and as before $x'(p)$ is the total x' value of all vertices in p excluding the endpoints:

  $$y_i(v) := \min_{\substack{p: s \rightsquigarrow v \\ |p| \leq i}} x'(p) \qquad \text{and} \qquad I_i(v) = [y_i(v), y_i(v) + x'_v].$$

- Sample $r \in [0, 1]$ uniformly at random.
- Return the cut $\{v \in V' \mid r \in I_i(v) \text{ for some } i\}$.

Let us first see the correctness of the algorithm:

▶ **Lemma 12.** *Algorithm Distort-Round returns a valid L-bounded vertex cut.*

Proof. Since the first step cuts all paths not entirely in G', let us focus on paths in G'. It is straightforward to see that in this graph, the interior vertices of every L-bounded $s - t$ path are all in V', since if v is ith vertex in such a path, then $i_{\min}(v) \leq i \leq i_{\max}(v)$. For any such path we have $\sum_{v \in p \setminus \{s,t\}} x'_v \geq \sum_{v \in p \setminus \{s,t\}} (23/20) \cdot x_v - ((|p| - 1)/(L-1))\, 3/20 \geq 1$.

Let us see that such a path will necessarily be cut. Denote $p = \langle s, v_1, \ldots, v_{L'}, t \rangle$ for some $L' \leq L - 1$. By the definition of our intervals, it can be shown by induction that for every $i \in [L']$ we have $[0, y_i(v_i) + x'_{v_i}] \subseteq \bigcup_{j=1}^{i} I_j(v_j)$. Thus, to see that the path is cut in the last

step, it suffices to show that $y_{L'}(v_{L'}) + x'_{v_{L'}} \geq 1$. But since $(v_{L'}, t) \in E$, by the definition of y, this is the total x' value of some $s-t$ path of length at most $L'+1$, and so it must be at least 1. ◀

To bound the approximation guarantee, we need to bound the probability that any vertex $v \in V'$ is cut. Let $D(v) := i_{\max}(v) + 1 - i_{\min}(v)$ denote the number of intervals defined for v. Then one trivial bound is the following:

▶ **Observation 13.** *Every vertex $v \in V'$ is cut with probability at most $D(v) \cdot x'_v$.*

However, this bound may be too conservative. In fact, if v participates in a large number of intervals, we can show that these intervals cannot be too spread out.

▶ **Lemma 14.** *For any given vertex $v \in V'$, all the intervals $I_i(v)$ are contained in a single interval of length at most $161/110 - D(v) \cdot 271/(110(L-1)) + O(x_v)$.*

Proof. Let p be a shortest path from s to v in G'. By the definition of G', all vertices $u \in p$ have $x_u < 25/(11(L-1))$, and so $x'_u < 271/(110(L-1))$. By definition of $y_i(v)$, this means that for all $i \geq i_{\min}(v)$ we have

$$y_i(v) \leq x'(p) \leq (d(s,v)-1)271/(110(L-1)) = (i_{\min}(v)-1)271/(110(L-1)),$$

and in particular,

$$y_i(v) + x'_v \leq (i_{\min}(v)-1)271/(110(L-1)) + x'_v \tag{3}$$

Similarly, for any $i \in \{i_{\min}(v), \ldots, i_{\max}(v)\}$, let p_i be an $s-v$ path of length $\leq i$ such that $y_i(v) = x'(p_i)$, and let p' be a shortest path from v to t. Then $p_i \circ p'$ is an L-bounded $s-t$ path with x' value

$$\begin{aligned} x'(p_i) + x'_v + x'(p') &\leq y_i(v) + x'_v + (|p'|-1)271/(110(L-1)) \\ &= y_i(v) + x'_v + (L - i_{\max}(v) - 1)271/(110(L-1)) \\ &= y_i(v) + x'_v - i_{\max}(v)271/(110(L-1)) + 271/110. \end{aligned}$$

However, its x' value must also be at least 1, and so we get

$$y_i(v) \geq i_{\max}(v)271/(110(L-1)) - 161/110 - x'_v. \tag{4}$$

Since $I_i(v) = [y_i(v), y_i(v) + x'_v]$, equations (3) and (4) imply that all these intervals are contained in a single interval of length at most

$$\begin{aligned} (i_{\min}(v)-1)271/(110(L-1)) + x'_v - (i_{\max}(v)271/(110(L-1)) - 161/110 - x'_v) \\ = 161/110 - D(v) \cdot 271/(110(L-1)) + O(x_v). \end{aligned}$$ ◀

We can now prove our final guarantee for general (bounded) L:

▶ **Lemma 15.** *Every vertex $v \in V$ is cut by Algorithm Distort-Round with probability at most $((11/25)(L-1) + O(1))x_v$.*

Proof. For vertices $v \notin V'$, this is trivial, so assume $v \in V'$. Also, let us assume $x'_v > 0$, since otherwise v would not be cut. First, from Observation 13 and Lemma 14, we have that the probability that v is cut is at most

$$\min\{D(v) \cdot x'_v,\ 161/110 - D(v) \cdot 271/(110(L-1))\} + O(x_v) \leq \frac{161 x'_v}{110 x'_v + 271/(L-1)} + O(x_v),$$

where the inequality is obtained by maximizing over all possible values of $D(v)$. Let us scale up x_v and denote $c_v = (L-1)x_v$, which (by our assumption that $x'_v \neq 0$) implies that $x'_v = ((23 - 3/c_v)/20)x_v$. Thus, we can rewrite the above upper bound on the probability as

$$\left(\frac{23 - 3/c_v}{20} \cdot \frac{161(L-1)}{11(23c_v - 3)/2 + 271} + O(1)\right) x_v$$

Ignoring the $O(1)$ term, the expression in parentheses is maximized for $c_v = (3+\sqrt{1626/11})/23$, and so is at most $0.43954(L-1) < (11/25) \cdot (L-1)$. ◀

5 A 7/4-approximation for $L = 6$

We now prove Theorem 2. We note first that the techniques we have seen already give an improvement over the previous 3-approximation for Minimum 6-Bounded Node Cut. Indeed, Lemma 9 and Theorem 10 together give a 2-approximation.

As a warm-up to our final algorithm, let us first see an alternative 2-approximation which does not use Theorem 10 or our algorithm for $L = 5$. We introduce some notation which we will use both for our warm-up algorithm for $L = 6$ as well as our main algorithm.

Similarly to our algorithm for $L = 5$, we will map every vertex to a small number of possible intervals, corresponding to its possible positions in a 6-bounded path, relative to s and t. For all $i \in [3]$, and all vertices $u, v \in V \setminus \{s, t\}$ such that $d_G(s, u) \leq i$ and $d_G(v, t) \leq i$, define

$$y_i^G(u) := \min_{\substack{p: s \rightsquigarrow u \\ |p| \leq i}} x(p) \qquad \text{and} \qquad y_{-i}^G(v) := 1 - \min_{\substack{p: v \rightsquigarrow t \\ |p| \leq i}} x(p).$$

As before, if $(s, u), (v, t) \in E$, for such neighbors of s, t we define

$$I_1^G(u) = [0, x_u] \qquad I_{-1}^G(v) = [1 - x_v, 1].$$

For other vertices v, wherever the relevant $y_i^G(v)$ values are defined, we also define intervals

$$I_2^G(v) = \left[y_2^G(v), y_2^G(v) + x_v\right] \qquad I_3^G(v) = \left[y_3^G(v), y_{-3}^G(v)\right] \qquad I_{-2}(v) = \left[y_{-2}^G(v) - x_v, y_{-2}^G(v)\right].$$

We will drop the superscript G from the above definitions when it is clear from the context. If $I_1(v)$ (resp. $I_{-1}(v)$) is defined, we do not define any other interval for v, as such an interval would be contained in $I_1(v)$ (resp. $I_{-1}(v)$). Note that every interval associated with a vertex v has length at most x_v (in fact, exactly x_v except for $I_3(v)$). As before, it is not hard to see that the left (resp. right) endpoints of the intervals $I_2(v), I_3(v), I_{-2}(v)$ (or whichever subsequence of intervals is defined for this vertex) form a monotone non-increasing sequence.

Consider the following rounding algorithm.

Algorithm Simple-6-Round

- Cut all vertices v with $x_v \geq 1/2$, and let $G^{1/2}$ be the remaining graph after deleting these vertices.
- Sample $r \in [0, 1]$ uniformly at random.
- Cut all vertices v such that $r \in I_i^{G^{1/2}}(v)$ for some $i \in \{1, 2, 3, -2, -1\}$.

One can check easily that this algorithm will cut all 6-bounded $s-t$ paths (the proof is nearly identical to the first part of the proof of Lemma 8). To see that it gives a 2-approximation, first note that trivially every vertex v with $x_v \geq 1/2$ or for which at most two of the intervals $I_2^{G^{1/2}}(v), I_3^{G^{1/2}}(v), I_{-2}^{G^{1/2}}(v)$ are defined, will be cut with probability at most $2x_v$. Thus we only need to concern ourselves with vertices for which all three intervals are defined. Since we removed vertices with LP value at least $1/2$, this means that in the remaining graph we have $y_2^{G^{1/2}}(v) < 1/2$ and $y_{-2}^{G^{1/2}}(v) > 1/2$, and so by monotonicity, $I_2^{G^{1/2}}(v)$ and $I_{-2}^{G^{1/2}}(v)$ must intersect, and $I_3^{G^{1/2}}(v)$ must be contained in their union. Thus, the union of the three intervals has length at most $2x_v$, which bounds the probability of cutting v.

To improve over this algorithm, we must make a number of changes. First of all, we cannot cut all vertices with $x_v \geq 1/2$. We must allow some (at least slightly) costlier vertices to remain. This means that we will not have the nice overlap property described above. We can overcome this by avoiding a small subinterval in the middle of $[0,1]$ in our radius sampling. However, this does not resolve the issue that some vertices will still be mapped to two possibly disjoint intervals, and in fact will exacerbate the problem by increasing the probability of hitting any given interval (since we are restricting our radius to a smaller sample space). We are able to overcome all these pitfalls by choosing at random either a single radius or a two-radius cut as we did in Algorithm 5-Round, and defining our two-radius cut carefully.

Algorithm 6-Round

- Let $C_0 = \{v \in V \mid x_v \geq 4/7\}$. Let G' be the remaining graph after deleting all vertices in C_0.
- Sample $r \in [0, 3/7] \cup [4/7, 1]$ uniformly at random.
- Sample $r_1 \in [0, 3/7]$ uniformly at random, and let $r_2 = r_1 + 4/7$.
- Let C_1 be the set of all vertices v such that $r \in I_i^{G'}(v)$ for some $i \in \{1, 2, 3, -2, -1\}$.
- Let C_2 be the set of all vertices v satisfying at least one of the following conditions:
  1. $r_1 \in I_1^{G'}(v)$ or $r_2 \in I_{-1}^{G'}(v)$.
  2. $r_1 \in I_2^{G'}(v)$.
  3. $r_1 \in I_3^{G'}(v)$ and $\frac{3}{7} \in I_3^{G'}(v)$.
  4. $r_2 \in I_{-2}^{G'}(v)$ and $\frac{3}{7} \in I_{-2}^{G'}(v)$.
- Let C_3 be the set of all vertices v satisfying at least one of the following conditions:
  1. $r_1 \in I_1^{G'}(v)$ or $r_2 \in I_{-1}^{G'}(v)$.
  2. $r_2 \in I_{-2}^{G'}(v)$.
  3. $r_2 \in I_3^{G'}(v)$ and $\frac{4}{7} \in I_3^{G'}(v)$.
  4. $r_1 \in I_2^{G'}(v)$ and $\frac{4}{7} \in I_2^{G'}(v)$.
- Return a random cut according to the following distribution: $C_0 \cup C_1$ with probability $1/2$, $C_0 \cup C_2$ with probability $1/4$, and $C_0 \cup C_3$ with probability $1/4$.

First let us see why this is a valid 5-bounded cut.

▶ **Lemma 16.** *Algorithm 6-Round cuts all paths of length at most* 6 *from s to t.*

Proof. As we did for $L = 5$, we focus on paths in G'. Also, the proof of the correctness of $C_0 \cup C_1$ is essentially the same as the proof of correctness of the corresponding cut in Lemma 8.

Since C_2 and C_3 are symmetrically defined, let us focus on C_2. Let $\langle s, u, u', w, v', v, t\rangle$ be a 5-path from s to t in G'. The proof for paths of length < 5 is similar or simpler. As before, it can easily be seen that $[0,1] \subseteq I_1(u) \cup I_2(u') \cup I_3(w) \cup I_{-2}(v') \cup I_{-1}(v)$. If the first condition

in the definition of C_2 does not hold w.r.t. $I_1(u)$ or $I_{-1}(v)$, then r_1 and r_2 must both intersect the intervals $I_2(u') \cup I_3(w) \cup I_{-2}(v')$. If in addition, the second condition does not hold w.r.t. u, then both these radii (in fact all points in $[r_1, r_2]$) intersect the intervals $I_3(w) \cup I_{-2}(v')$. Since $r_2 - r_1 = 4/7$ and all intervals corresponding to vertices in G' have length less than $4/7$, this necessarily means that $r_1 \in I_3(w)$ and $r_2 \in I_{-2}(v')$. Since $\frac{3}{7} \in [r_1, r_2]$, either $\frac{3}{7} \in I_3(w)$ or $\frac{3}{7} \in I_{-2}(v')$. In the first case, $w \in C_2$ by Condition 3, and in the second, $\frac{3}{7} \in I_{-2}(v')$ and so $v' \in C_2$ by Condition 4. ◀

Before bounding the expected value of the cut, we note that, as before (in Algorithm **Simple-6-Round**), Algorithm **6-Round** also has the property that for every $v \notin C_0$, at most two intervals are responsible for v being in the single radius cut.

▶ **Lemma 17.** *For $v \notin C_0$, If $I_{-2}^{G'}(v)$ and $I_2^{G'}(v)$ are both defined, then the random radius r is in C_1 iff it is in $I_{-2}^{G'}(v) \cup I_2^{G'}(v)$.*

Proof. Note that in this case, $I_3^{G'}(v)$ is also defined. Since all three intervals are defined for v (and $I_1^{G'}(v), I_{-1}^{G'}(v)$ are not defined – so $d(s,v), d(v,t) > 1$), there must exist paths $\langle s, u, v\rangle$ and $\langle v, v', t\rangle$ in G', and by the bound on LP values of vertices in G', we have $y_2(v) \le x_u < 4/7$ and $y_{-2}(v) \ge 1 - x_{v'} > 3/7$. Thus, by the monotonicity of the interval sequence, $I_3(v) \setminus (3/7, 4/7)$ is contained in $(I_{-2}(v) \cup I_2(v)) \setminus (3/7, 4/7)$, and the lemma follows. ◀

Since this is the only case in which v will be mapped to more than two intervals, this immediately bounds the probability that such a vertex participates in C_1:

▶ **Corollary 18.** *For every $v \notin C_0$, the probability that $v \in C_1$ is at most $\frac{7}{6} \cdot 2x_v$.*

Now let us bound the expected value of the cut in our final algorithm.

▶ **Lemma 19.** *Every vertex $v \in V$ is cut by Algorithm 6-**Round** with probability at most $(7/4) \cdot x_v$.*

Proof. If $x_v \ge 4/7$, this is trivial. Thus, let us look at vertices cut by C_1, C_2, or C_3.

For convenience, define a random set

$$C' = \begin{cases} C_2, & \text{with probability } 1/2 \\ C_3, & \text{otherwise.} \end{cases}$$

Thus the final step in the algorithm can be equivalently stated as returning $C_0 \cup C_1$ w.p. $1/2$ and $C_0 \cup C'$ w.p. $1/2$.

To analyze the probability that a vertex v in G' will be cut overall, we will consider a number of different of cases for this vertex.

Case 1: v is mapped to only one interval. Suppose $I_1(v)$ or $I_{-1}(v)$ are defined. Then $v \in C'$ with probability at most $\frac{7}{3} \cdot x_v$ (by Condition 1 in both C_2 and C_3). In total, it will be cut with probability at most $\left(\frac{1}{2} \cdot \frac{7}{6} + \frac{1}{2} \cdot \frac{7}{3}\right) x_v = \frac{7}{4} \cdot x_v$. This holds similarly for any vertex v which is not necessarily a neighbor of s or t but which is mapped to only one interval.

Case 2: v is mapped to at least two intervals, and both $I_{-2}(v)$ and $I_2(v)$ are defined for v. Again, note that this implies that $I_3(v)$ is also defined and $I_1(v), I_{-1}(v)$ are not defined. Recall that $I_3(v) = [y_3(v), y_{-3}(v)]$ and as noted above, in this case we must have $y_{-3}(v) \ge y_{-2}(v) \ge \frac{3}{7}$ and $y_3(v) \le y_2(v) \le \frac{4}{7}$. Thus, $I_3(v)$ cannot be entirely to the left of $3/7$ or entirely to the right of $4/7$. This together with monotonicity of intervals gives us

the following implications: Conditions 2 and 3 of C_2 each imply $r_1 \in I_3(v) \cap \left[0, \frac{3}{7}\right)$ and Conditions 2 and 3 of C_3 each imply $r_2 \in I_3(v) \cap \left[\frac{4}{7}, 1\right)$, giving two possible ways v may be in C':

- $r_1 \in I_3(v) \cap \left[0, \frac{3}{7}\right)$ and $C' = C_2$, or
- $r_2 \in I_3(v) \cap \left[\frac{4}{7}, 1\right)$ and $C' = C_3$.

Note that the probability that at least one of these events occurs is at most $\frac{7}{6} \cdot |I_3(v)|$.

The final reason we may have $v \in C'$ is due to Condition 4 in either C_2 or C_3. That is, if one of the following occurs:

(a) $r_1 \in I_2(v) \cap \left[0, \frac{3}{7}\right)$ and $C' = C_3$, or

(b) $r_2 \in I_{-2}(v) \cap \left[\frac{4}{7}, 1\right)$ and $C' = C_2$.

Note that each of these two events implies that the given radius (r_1 in (a) and r_2 in (b)) is in fact in $I_2(v) \cap I_{-2}(v)$. Indeed, take event (b) for example. As we've noted, $y_2(v)$ (the left endpoint of $I_2(v)$) is at most $\frac{4}{7}$, so r_2 cannot be to the left of $I_2(v)$. On the other hand, by monotonicity of intervals, since $r \in I_{-2}(v)$, it also cannot be to the right of $I_2(v)$. Thus, $r_2 \in I_2(v) \cap I_{-2}(v)$. Thus, the probability that (a) or (b) occurs is at most $\frac{7}{6} \cdot |I_{-2}(v) \cap I_2(v)|$.

Combining these bounds with Lemma 17 for C_1, we can bound the total probability that v will be cut by

$$\frac{1}{2} \cdot \frac{7}{6} \cdot |I_2(v) \cup I_{-2}(v)| + \frac{1}{2} \cdot \left(\frac{7}{6} \cdot |I_3(v)| + \frac{7}{6} \cdot |I_2(v) \cap I_{-2}(v)| \right)$$
$$= \frac{1}{2} \cdot \frac{7}{6} \cdot (|I_3(v)| + |I_2(v)| + |I_{-2}(v)|) \leq \frac{7}{4} \cdot x_v.$$

Case 3: v is mapped to at two distinct intervals, $I_3(v)$ is defined, but only one of $I_{-2}(v)$, $I_2(v)$ is defined. As before, because v is mapped to two distinct intervals, Condition 1 for both C_2 and C_3 is irrelevant. Without loss of generality, assume only $I_2(v)$ and $I_3(v)$ are defined for v, and note that Condition 4 for C_2 and Condition 2 for C_3 are now also irrelevant. Thus, v can be in C' only if Conditions 2 or 3 for C_2 or Conditions 3 or 4 for C_3 occur. We further divide this case (under this assumption) into several subcases.

Subcase 3a: $\frac{4}{7} \notin I_2(v)$. As we've noted, $I_2(v)$ cannot lie entirely to the right of $\frac{4}{7}$, so in this subcase it must lie entirely to the left of $\frac{4}{7}$, and by monotonicity, so must $I_3(v)$. Thus, in fact v can only be in C' when $C' = C_2$. For C_2 consider two possibilities. If $\frac{3}{7} \notin I_3(v)$, then only Condition 2 can apply. Otherwise, we have $\frac{3}{7} \in I_3(v)$ and so by monotonicity Condition 2 would imply Condition 3, and so we need only consider Condition 3. Either way, only one interval is responsible for v being in C', and the probability that this occurs is at most $\frac{7}{6} \cdot x_v$. This together with Corollary 18 gives the desired bound on the probability that v is cut.

Subcase 3b: $\frac{4}{7} \in I_2(v)$ and $\frac{3}{7} \in I_3(v)$. In this subcase, we need to be slightly more precise for C_1, and note that the probability that $v \in C_1$ is at most $\frac{7}{6}|I_2(v) \cup I_3(v)|$. As above, because $\frac{3}{7} \in I_3(v)$, Condition 2 for C_2 implies Condition 3 for C_2, so the relevant conditions are Condition 3 in both C_2 and C_3, and Condition 4 in C_3. The probability that $v \in C'$ because of Condition 3 in either set is clearly at most $\frac{7}{6} \cdot x_v$. Similarly, Condition 4 for C_3 also implies that $r_1 \in I_3(v)$, so the probability that $C' = C_3$ and Condition 4 occurs is at most $\frac{7}{6} \cdot |I_2(v) \cap I_3(v)|$. Putting these three bounds together, the probability that v is cut is at most

$$\tfrac{1}{2} \cdot \tfrac{7}{6} \cdot |I_2(v) \cup I_3(v)| + \tfrac{1}{2} \cdot \left(\tfrac{7}{6} \cdot x_v + \tfrac{7}{6} \cdot |I_2(v) \cap I_3(v)| \right) = \tfrac{1}{2} \cdot \tfrac{7}{6} \cdot (x_v + |I_2(v)| + |I_3(v)|) \leq \tfrac{7}{4} \cdot x_v.$$

Subcase 3c: $\frac{4}{7} \in I_2(v)$ and $I_3(v)$ lies to the right of $\frac{3}{7}$. In this subcase, only Condition 3 for C_3 is relevant, and so $v \in C'$ with probability at most $\frac{7}{6} \cdot x_v$, which as we've noted (see Case 3a) is enough.

Subcase 3d: $\frac{4}{7} \in I_2(v)$ and $I_3(v)$ lies to the left of $\frac{3}{7}$. Note that in this case we will have $v \in C'$ precisely when $r_1 \in I_2(v) \cap [0, \frac{3}{7}]$ (regardless of whether $C' = C_2$ or $C' = C_3$), which occurs with probability $\frac{7}{3} \cdot |I_2(v) \cap [0, \frac{3}{7}]|$. Thus, we may also assume $\frac{3}{7} \in I_2(v)$, since otherwise we will never have $v \in C'$, and the probability that v is cut will be much better than we require. However, this means that $[\frac{3}{7}, \frac{4}{7}] \subseteq I_2(v)$, so we can improve our probability bounds by not charging for this omitted interval. That is, the probability that $v \in C_1$ is at most $\frac{7}{6} \cdot \left(|(I_2(v) \cup I_3(v)) \cap [0,1]| - \frac{1}{7}\right)$, and the probability that $v \in C'$ is $\frac{7}{3} \cdot (|I_2(v) \cap [0, \frac{4}{7}]| - \frac{1}{7})$.

Now, suppose first that $x_v \leq \frac{3}{7}$. Then by the above bounds, the probability that v is cut is at most

$$\begin{aligned} \frac{1}{2} \cdot \frac{7}{6} \cdot \left(|I_2(v)| + |I_3(v)| - \frac{1}{7}\right) + \frac{1}{2} \cdot \frac{7}{3} \cdot \left(|I_2(v)| - \frac{1}{7}\right) &\leq \frac{7}{3} \cdot x_v - \frac{1}{4} \\ &\leq \frac{7}{4} \cdot x_v. \qquad \text{since } x_v \leq \frac{3}{7} \end{aligned}$$

Otherwise, we have $x_v \geq \frac{3}{7}$ (and, since $v \notin C_0$, $x_v < \frac{4}{7}$), and so the proof will follow if we can show that v is cut with probability at most $\frac{3}{4}$. To see that this holds, recall that $I_2(v) = [y_2(v), y_2(v) + x_v]$. There are three ways that v might be cut:

- In C_1:
  - If $r \in [0, \frac{3}{7}]$ (where possibly $r \in I_2(v) \cup I_3(v)$) – with probability $\frac{1}{2}$.
  - If $r \in [\frac{4}{7}, y_2(v) + x_v]$ (where $r \in I_2(v)$) – with probability $\frac{7}{6} \cdot \left(y_2(v) + x_v - \frac{4}{7}\right) < \frac{7}{6} \cdot y_2(v)$.
- In C':
  - If $r_1 \in [y_2(v), \frac{3}{7}]$ (where $r_1 \in I_2(v)$) – with probability $\frac{7}{3} \cdot (\frac{3}{7} - y_2(v)) = 1 - \frac{7}{3} \cdot y_2(v)$.

And indeed, as required, the probability that at least one of these events happens is at most

$$\frac{1}{2} \cdot \left(\frac{1}{2} + \frac{7}{6} \cdot y_2(v)\right) + \frac{1}{2} \cdot \left(1 - \frac{7}{3} \cdot y_2(v)\right) = \frac{3}{4} - \frac{7}{6} \cdot y_2(v) \leq \frac{3}{4}. \qquad \blacktriangleleft$$

A Hardness of L-Bounded Cut for $L \geq 5$

The 1.1377-hardness of approximation result of Baier et al. [3] is based on a reduction from Vertex Cover. Given an instance $G = (V, E)$ of Vertex Cover, they construct an instance (G', s, t) of L-Bounded Cut such that, given a vertex cover of size x in G, one can efficiently construct an L-bounded cut of size $|V| + x$ in G', and vice versa. This yields the following general hardness:

▶ **Theorem 20** (Implicit in [3]). *For any $0 \leq c \leq s \leq 1$, approximating L-Bounded Edge Cut for $L \geq 4$ or L-Bounded Node Cut for $L \geq 5$ to within $(1+s)/(1+c)$ is at least as hard as Gap Vertex Cover(c, s).*

The 1.1377-hardness of approximation of L-Bounded Cut is in fact the hardness one gets from the above theorem by plugging in the NP-hardness of Gap Vertex Cover for $c = (\sqrt{5}-1)/2 + \varepsilon$ and $s = (71 - 31\sqrt{5})/2 - \varepsilon$, implied by the work of Dinur and Safra [8].

However, we can also plug in newer or different hardness results for Vertex Cover in the above theorem. For instance, the NP-hardness of Gap Vertex Cover has since been improved to include the case of $c = 1/\sqrt{2} + \varepsilon$, $s = 1 - \varepsilon$ [12], which improves the hardness of approximation of L-Bounded Cut to $2/(1 + 1/\sqrt{2}) - \varepsilon < 1.1715$. Also, plugging in the Unique Games hardness of Gap Vertex Cover$(1/2 + \varepsilon, 1 - \varepsilon)$ [13] gives a $(4/3 - \varepsilon)$ Unique Games hardness of approximation for L-Bounded Cut, which is now matched by our algorithm for 4-Bounded Edge Cut and 5-Bounded Node Cut.

B Short intervals may be disjoint

We motivate the distorted LP values x'_v in algorithm **Distort-Round** by giving an example in which, if the original LP values x_v are used instead of x'_v, some vertices may be cut with probability at least $L/2 - O(1)$ times their LP value.

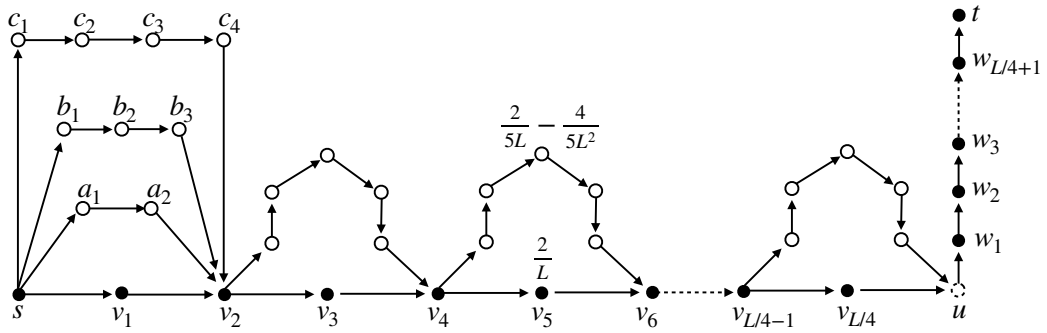

Figure 3 Motivating example for Algorithm Distort-Round.

Consider the graph in Figure 3, and suppose we are given the following LP values: $x_{v_i} = 2/L$ for all $i \in [L/4]$, $x_{w_i} = 2/L$ for all $i \in [L/4+1]$, $x_{a_1} = x_{a_2} = 1/L - 1/(2L^2)$, $x_{b_1} = x_{b_2} = x_{b_3} = 2/(3L) - 2/(3L^2)$, $x_{c_i} = 1/(2L) - 3/(4L^2)$ for all $i \in [4]$, all other white vertices have LP value $2/(5L) - 4/(5L^2)$, and finally $x_u = 1/(2L^2)$.

The following is easy to check:

1. These values are a feasible LP solution.
2. The vertex u may have all possible positions in an L-bounded path from $i_{\min}(u) = L/4+1$ up to $i_{\max}(u) = 3L/4 - 2$.
3. Defining $y_i(u)$ analogously to algorithm **Distort-Round** with values x_v instead of x'_v, for all $k \in [L/2 - 3]$ we have $y_{L/4+k} = 1/2 - (k-1)/L^2$, and $I_{L/4+k} = [y_{L/4+k}, y_{L/4+k} + 1/(2L^2)]$.

Thus, u is indeed mapped to $L/2 - 3$ disjoint intervals, and the probability that it would be cut by a uniformly chosen radius as in algorithm **Distort-Round** is $(L/2 - 3)x_u$.

On the Facility Location Problem in Online and Dynamic Models

Abstract

In this paper we study the facility location problem in the online with recourse and dynamic algorithm models. In the online with recourse model, clients arrive one by one and our algorithm needs to maintain good solutions at all time steps with only a few changes to the previously made decisions (called recourse). We show that the classic local search technique can lead to a $(1+\sqrt{2}+\epsilon)$-competitive online algorithm for facility location with only $O\left(\frac{\log n}{\epsilon}\log\frac{1}{\epsilon}\right)$ amortized facility and client recourse, where n is the total number of clients arrived during the process.

We then turn to the dynamic algorithm model for the problem, where the main goal is to design fast algorithms that maintain good solutions at all time steps. We show that the result for online facility location, combined with the randomized local search technique of Charikar and Guha [8], leads to a $(1+\sqrt{2}+\epsilon)$-approximation dynamic algorithm with total update time of $\tilde{O}(n^2)$ in the incremental setting against adaptive adversaries. The approximation factor of our algorithm matches the best offline analysis of the classic local search algorithm.

Finally, we study the fully dynamic model for facility location, where clients can both arrive and depart. Our main result is an $O(1)$-approximation algorithm in this model with $O(|F|)$ preprocessing time and $O(n\log^3 D)$ total update time for the HST metric spaces, where $|F|$ is the number of potential facility locations. Using the seminal results of Bartal [3] and Fakcharoenphol, Rao and Talwar [12], which show that any arbitrary N-point metric space can be embedded into a distribution over HSTs such that the expected distortion is at most $O(\log N)$, we obtain an $O(\log|F|)$ approximation with preprocessing time of $O(|F|^2\log|F|)$ and $O(n\log^3 D)$ total update time. The approximation guarantee holds in expectation for every time step of the algorithm, and the result holds in the oblivious adversary model.

1 Introduction

In the *(uncapacitated) facility location problem*, we are given a metric space $(F \cup C, d)$, where F is the set of facility locations, C is the set of clients, and $d : (F \cup C) \times (F \cup C) \to \mathbb{R}_{\geq 0}$ is a distance function, which is non-negative, symmetric and satisfies triangle inequalities. For each location $i \in F$, there is a facility opening cost $f_i \geq 0$. The goal is open a subset $S \subseteq F$ of facilities so as to minimize cost of opening the facilities and the connection cost. The cost of connecting a client j to an open facility i is equal to $d(j, i)$. Hence, the objective function can be expressed concisely as $\min_{S \subseteq F} \left(f(S) + \sum_{j \in C} d(j, S) \right)$, where for a set $S \subseteq F$, $f(S) := \sum_{i \in S} f_i$ is the total facility cost of S and $d(j, S) := \min_{i \in S} d(j, i)$ denotes the distance of j to the nearest location in S. The facility location problem arises in countless applications: in the placement of servers in data centers, network design, wireless networking, data clustering, location analysis for placement of fire stations, medical centers, and so on. Hence, the problem has been studied extensively in many different communities: approximation algorithms, operations research, and computational geometry. In the approximation algorithms literature in particular, the problem occupies a prominent position as the development of every major technique in the field is tied to its application on the facility location problem. See the text book by Williamson and Shmoys [27] for more details. The problem is hard to approximate to a factor better than 1.463 [20]. The current best-known polynomial-time algorithm is given by the third author, and achieves 1.488-approximation [23].

Motivated by its applications in network design and data clustering, Meyerson [24] initiated the study of facility location problem in the online setting. Here, clients arrive online one-by-one, the algorithm has to assign the newly arriving client to an already opened facility or needs to open a new facility to serve the request. The decisions made by the algorithm are *irrevocable*, in the sense that a facility that is opened cannot be closed and the clients cannot be reassigned. In the online setting, Meyerson [24] designed a very elegant randomized algorithm that achieves an $O(\log n)$ competitive ratio, and also showed that no online algorithm can obtain $O(1)$ competitive ratio. This result was later extended by Fotakis [15] to obtain an *asymptotically optimal* $O(\log n / \log \log n)$-competitive algorithm. Both the algorithms and analysis techniques in [15, 24] were influential, and found many applications in other models such as streaming [17]. The lowerbound in Fotakis [15] holds even in very special metric spaces such as HSTs or the real line. Since then, several online algorithms have been designed achieving the same competitive ratio with more desirable properties such as deterministic [1], primal-dual [14], or having a small memory footprint [16]. We refer to a beautifully written survey by Fotakis [17] for more details.

The main reason to assume that decisions made by an algorithm are irrevocable is because the cost of changing the solution is expensive in some applications. However, if one examines these above applications closely, say for example connecting clients to servers in data centers, it is more natural to assume that decisions need not be irrevocable but the algorithm *should not change the solution too much*. This is even more true in modern data centers where topologies can be reconfigured; see [18] for more details. There are two standard ways of enforcing that an algorithm does not make too many changes to the solution:

- **Recourse.** The recourse per step of an online algorithm is the *number of changes* it makes to the solution. Recourse captures the *minimal* amount of changes an online algorithm *has to make* to maintain a desired competitive ratio due to the *information theoretic* limits. For the facility location problem, depending on the application, the recourse can correspond to: 1) the number of changes made to the opened facilities (called *facility*

recourse) 2) the number of reconnections made to the clients (called *client recourse*). Notice that we can assume for every facility we open/close, we have to connect/disconnect at least one client. Thus the client recourse is at least the facility recourse.

- **Update time.** While having a small recourse is enough in some applications, it is not enough in some others. Take wireless networks as a concrete example. Here, the set of clients (mobile devices) keeps changing over time, and it is necessary to *update* the assignment of clients to facilities as *quickly* as possible so to minimize the service disruption. This motivates the *dynamic facility location problem*, which is similar to the one in online setting except that at each time step either *a new client arrives or an existing client departs*. The goal is to always maintain a solution that is a constant factor approximation to the optimal solution, while minimizing *the total time spent in updating the solution.* We emphasize that we require our dynamic algorithms to maintain *an actual assignment of clients to facilities*, not just the set of open facilities and an estimate of connection cost. This is important for applications mentioned above.

Recently, these applications have motivated the study of the facility location problem, and its closely related k-clustering problems, in the framework of recourse and dynamic algorithms [13, 10, 19, 9, 22, 21, 7]. The models for facility location problem considered in [13, 10] are different from what we study here, so we discuss them in Section 1.3; we also defer the discussion of k-clustering results [22, 21, 7] to Section 1.3. Goranci *et al* [19] showed that for metric spaces with *doubling dimension* κ, there is a deterministic *fully* dynamic algorithm with $\tilde{O}(2^{\kappa^2})$ update time, which maintains a constant approximation. Unfortunately, this result does not imply any non-trivial bound for the general metric spaces. More recently, Cohen-Addad *et al* [9] studied the facility location problem in general metric spaces but when the cost of opening facilities are same; that is, when $f_i = f, \forall i \in F$. They showed that there exists a *fully* dynamic algorithm that computes a $O(1)$ approximation with update time of $O(n \log n)$ and facility recourse of $O(1)$ per step. They also showed matching lowerbounds for both these results. However, their positive results do not imply any non-trivial bounds to the case when the cost of opening facilities are *non-uniform*. This is an important consideration in network design problems, and is also the form studied in Goranci *et al* [19] and in classic offline literature [27]. Further, to our understanding, none of the existing results bound the *client recourse*, which is an important consideration in real-world problems. As a concrete example, consider the problem of connecting clients to servers in datacenters, which was the original motivation for Meyerson [24] to initiate the study of online facility location problem. Here, it is important that one does not reconnect clients to servers too many times, as such changes can incur significant costs both in terms of disruption of service and the labor cost. Hence a natural question that arises is:

Are there online and dynamic algorithms for facility location problem in arbitrary metric spaces when the facility opening costs are not uniform, which achieve small client recourse and update times?

1.1 Our Contributions

In the following theorems, we use n to denote the total number of facility locations and all clients that ever arrived, $|F|$ the number of facilities, and D to denote the diameter of the metric d (assuming all distances are integers).

Our first result concerns online algorithms with small recourse in the incremental setting; that is, when clients only arrive and not depart.

▶ **Theorem 1.** *There is a deterministic online algorithm for the facility location problem that achieves a competitive ratio of* $(1+\sqrt{2}+\epsilon)$ *with* $O\left(\frac{\log n}{\epsilon}\log\frac{1}{\epsilon}\right)$ *amortized facility and client recourse against an adaptive adversary.*

Our next result is in the online dynamic model with the goal to achieve small update time. First we consider incremental setting.

▶ **Theorem 2.** *In the incremental setting against an adaptive adversary, there is a randomized dynamic algorithm for the facility location problem that, with probability at least* $1-1/n^2$*, maintains an approximation factor of* $(1+\sqrt{2}+\epsilon)$ *with amortized update time of* $O(\frac{n}{\epsilon^2}\log^3 n\log\frac{1}{\epsilon})$*. Further, there exists an* $O(1)$*-approximate dynamic algorithm with* $O(\frac{|F|}{\epsilon^2}\log^3 n\log\frac{1}{\epsilon})$*-amortized update time.*

Note that it takes $\Theta(n|F|)$ space to specify the input in our model (see Section 2.1). Our algorithm for the above theorem also simultaneously achieves an amortized *logarithmic* client recourse per step; see the remark at the end of Section 5.

Our algorithms to show the above two theorems differ from the previous approaches used in the context of online variants of facility location problem, and is based on *local search*. The local search algorithm is one of the most widely used algorithms for the facility location problem in practice, and is known to achieve an approximation factor of $(1+\sqrt{2})$ in the offline setting. See the influential paper by Arya *et al* [2] and a survey by Munagala [25]. Thus our result matches the best known approximation ratio for offline facility location using local search. Further, our result shows that the local search algorithm augmented with some small modifications is *inherently stable* as it does not make too many changes to the solutions even if clients are added in an online fashion. This gives further justification for its popularity among practitioners.

Finally, we study the fully dynamic setting, where the clients arrive and depart. Here, we first consider an important class of metric spaces called hierarchically well separated tree (HST) metrics [3]; see Definition 13 for the formal definition, and Section 2.1 for more details about how the input sequence is given. For HST metric spaces, we show the following result.

▶ **Theorem 3.** *In the fully dynamic setting against adaptive adversaries, there is a deterministic algorithm for the facility location problem that achieves an* $O(1)$ *approximation factor with* $O(|F|)$ *preprocessing time and* $O(\log^3 D)$ *amortized update time for the HST metric spaces.*

A seminal result by Bartal [3], which was later tightened by Fakcharoenphol, Rao and Talwar [12], shows that any arbitrary N-point metric space can be embedded into a distribution over HSTs such that the expected distortion is at most $O(\log N)$, which is also tight. Moreover, such a probabilistic embedding can also be computed in $O(N^2\log N)$ time; see recent results by Blelloch, Gu and Sun for details [5]. These results immediately imply the following theorem, provided the input is specified as in Section 2.1.

▶ **Theorem 4.** *In the fully dynamic setting against oblivious adversary, there is a randomized algorithm for the facility location problem that maintains an approximation factor of* $O(\log|F|)$ *with preprocessing time of* $O(|F|^2\log|F|)$ *and* $O(\log^3 D)$ *amortized update time. The approximation guarantee holds only in expectation for every time step of the algorithm.*

Observe that unlike the incremental setting, the above theorem holds only in the oblivious adversary model, as probabilistic embedding techniques preserve distances only in expectation as can be seen by taking a cycle on n points. Our result also shows that probabilistic tree embeddings using HSTs can be a very useful technique in the design of dynamic algorithms, similar to its role in online algorithms [3, 4, 26, 6].

Our algorithms in Theorems 3 and 4 in the fully dynamic setting also have the property that amortized client and facility *recourse* is $O(\log^3 D)$ (in fact, we can achieve a slight better bound of $O(\log^2 D)$ as can be seen from the analysis). This holds as our dynamic algorithms maintain the entire assignment of clients to facilities *explicitly* in memory at every time step. Thus, the amortized client reconnections is at most the amortized update time.

1.2 Our Techniques

Our main algorithmic technique for proving Theorems 1 and 2 is local search, which is one of the powerful algorithm design paradigms. Indeed, for both results, the competitive (approximation) ratio we achieve is $1 + \sqrt{2} + \epsilon$, which matches the best approximation ratio for offline facility location obtained using local search [2]. Both of our results are based on the following key lemma. Suppose we maintain local optimum solutions at every time step in our algorithm. When a new client j_t comes at time t, we add it to our solution using a simple operation, and let Δ_t be the increase of our cost due to the arrival of j_t. The key lemma states that the sum of Δ_t values in the first T' time steps can be bounded in terms the optimum cost at time T'. With a simple modification to the local search algorithm, in which we require each local operation decreases enough cost for every client it reconnects, one can bound the total client recourse.

The straightforward way to implement the local search algorithm takes time $\Omega(n^3)$. To derive a better running time, we leverage the randomized local search idea of Charikar and Guha [8]. At every iteration, we randomly choose a facility i or a closing operation, and then perform the best operation that opens or swaps in i, or closes a facility if that is what we choose. By restricting the facility i and with the help of the heap data structure, an iteration of the algorithm can be implemented in time $O(|C| \log |F|)$. As in [8] we can also show that each iteration can make a reasonable progress in expectation, leading to a bound of $\tilde{O}(|F|)$ on the number of iterations for the success of the algorithm with high probability. We remark that the algorithm in [8] used a different local search framework. Therefore, our result shows that the classic algorithm of [2] can also be made fast.

However, directly replacing the randomized local search procedure with a deterministic one does not work: The solution at the end of each time might not be a local optimum as we did not enumerate all possible local operations. Thus the key lemma does not hold any more. Nevertheless we show that applying a few local operations around j_t upon its arrival can address the issue. With the key lemma, one can bound the number of times we perform the iterative randomized local search procedure, and thus the overall running time.

Our proof for Theorem 3 is based on a generalization of the greedy algorithm for facility location on HST metrics, which was developed in [11] in the context of *differential privacy* but only for the case of *uniform* facility cost. The intuition of the algorithm is as follows: If for some vertex v of the HST T, the number of clients in the tree T_v (the sub-tree of T rooted at v) times the length of parent edge of v is big compared to the cost of the cheapest facility in T_v, then we should open that facility. Otherwise, we should not open it and let the clients in T_v be connected to outside T_v through the parent edge. This intuition can be made formal: We mark v in the former case; then simply opening the cheapest facility in T_v for all *lowest marked* vertices v leads to a constant approximation for facility location.

The above offline algorithm leads to a *dynamic data structure* that maintains $O(1)$-approximate solutions, supports insertion and deletion of clients, and reports the connecting facility of a client in $O(\log D)$ time. This is the case since each time a client arrives or departs, only its ancestors will be affected. However, in a dynamic algorithm setting, we need to maintain the assignment vector in memory, so that when the connecting facility of a

client changes, it needs to be notified. This requires that the number of reconnections made by our algorithm to be small. To achieve the goal, we impose two constants for each v when deciding whether v should be marked and the cheapest facility in T_v should be open. When a vertex v changes its marking/opening status, we update the constants in such a way that it becomes hard for the status to be changed back.

1.3 More Related Work

Lattanzi and Vassilvitskii [22] first studied the role of recourse (which they call "consistency") in online k-clustering problem when clients only arrive – a setting similar to our Theorem 1. Lattanzi and Vassilvitskii gave a constant approximation algorithm with $O(k^2 \log^4 n)$ total recourse (reclusterings). They also showed an $\Omega(k \log n)$ recourse lowerbound. There are some subsequent works studying the k-clustering problems in the context of recourse and dynamic algorithms; we refer the readers to [22, 21, 7, 9] for more details.

A fully dynamic online model of facility location problem, where clients arrive and depart was recently studied by Cygan *et al.* [10], but with different assumption on recourse. In this model, the set of facility locations is the same as the set of clients and thus they are also changing dynamically. When a client arrives, the algorithm has to assign it to an open facility immediately; while upon departure of a client, if a facility was opened at the same location, then the clients that were assigned to that location should be reassigned immediately and irrevocably. They showed that a delicate extension of Meyerson's [24] algorithm obtains asymptotically tight competitive ratio of $O(\log n / \log \log n)$. However, the result holds only for the *uniform facility costs* and Cygan *et al* [10] even showed an *unbounded* lower bound for the non-uniform facility cost case in their model. Moreover, in their model reconnections of clients are assumed to be "automatic" and do not count towards the client recourse; it is not clear how many client reconnections their algorithm will make. Hence, our result in Theorem 4 also implies that one can circumvent the unbounded lowerbound for the general problem with small recourse.

As we noted earlier, a strictly online algorithm for facility location problem cannot achieve a competitive ratio better than $O(\log n / \log \log n)$. To overcome this, the problem has been studied in the so-called *incremental model*, which allows two open facilities to be merged at any given time. In this model [13, 17] showed that one can obtain $O(1)$ approximation for case when facility opening costs are uniform. However, the recourse of such an algorithm may be arbitrary.

2 Preliminaries

Throughout the paper, we use F to denote the set of potential facilities for all the problems and models; we assume F is given upfront. C is the dynamic set of clients we need to connect by our algorithm. This is not necessarily the set of clients that are present: In the algorithms for online facility location with recourse and dynamic facility location in the incremental setting, we fix the connections of some clients as the algorithms proceed. These clients are said to be "frozen" and excluded from C. We shall always use d to denote the hosting metric containing F and all potential clients. For any point j and subset V of points in the metric, we define $d(j, V) = \min_{v \in V} d(j, v)$ to be the minimum distance from j to a point in V. We assume all distances are integers, the minimum non-zero distance between two points is 1. We define D, the diameter or the aspect ratio of a metric space, as the largest distance between two points in it. Let n be $|F|$ plus the total number of clients arrived during the whole process. The algorithms do not need to know the exact value of

n in advance, except that in the dynamic algorithm for facility location in the incremental setting (the problem in Theorem 2), to achieve the $1 - 1/n^2$ success probability, a sufficiently large $\Gamma = \text{poly}(n, \log D, \frac{1}{\epsilon})$ needs to be given.[1]

In all the algorithms, we maintain a set S of open facilities, and a connection $\sigma \in S^C$ of clients in C to facilities in S. We do not require that σ connects clients to their respective nearest open facilities. For any solution $(S' \subseteq F, \sigma' \in S'^C)$, we use $\mathsf{cc}(\sigma') = \sum_{j \in C} d(j, \sigma_j)$ to denote the connection cost of the solution. For facility location, we use $\mathsf{cost}(S', \sigma') = f(S') + \mathsf{cc}(\sigma')$ to denote the total cost of the solution (S', σ'), where $f(S') := \sum_{i \in S'} f_i$. Notice that σ and the definitions of cc and cost functions depend on the dynamic set C.

Throughout the paper, we distinguish between a "moment", a "time" and a "step". A moment refers to a specific time point during the execution of our algorithm. A time corresponds to an arrival or a departure event: At each time, exactly one client arrives or departs, and time t refers to the period from the moment the t-th event happens until the moment the $(t+1)$-th event happens (or the end of the algorithm). One step refers to one statement in our pseudo-codes indexed by a number.

2.1 Specifying Input Sequence

In this section we specify how the input sequence is given. For the online and dynamic facility location problem, we assume the facility locations F, their costs $(f_i)_{i \in F}$, and the metric d restricted to F are given upfront, and they take $O(|F|^2)$ space. Whenever a client $j \in C$ arrives, it specifies its distance to every facility $i \in F$ (notice that the connection cost of an assignment $\sigma \in S^C$ does not depend on distances between two clients and thus they do not need to be given). Thus the whole input contains $O(n|F|)$ words.

For Theorems 3 and 4, as we do not try to optimize the constants, we *do not* need that a client specifies its distance to every facility. By losing a multiplicative factor of 2 and an additive factor of 1 in the approximation ratio, we can assume that every client j is collocated with its nearest facility in F Thus, we only require that when a client j comes, it reports the position of its nearest facility. For Theorem 3, the HST T over F is given at the beginning using $O(|F|)$ words. For Theorem 4, the metric d over F is given at the beginning using $O(|F|^2)$ words. Then, we use an efficient algorithm [5] to sample a HST T.

2.2 Local Search for facility location

The local-search technique has been used to obtain the classic $(1+\sqrt{2})$-approximation offline algorithm for facility location [2]. We now give an overview of the algorithm, which will be the baseline of our online and dynamic algorithms for facility location. One can obtain a (tight) 3-approximation for facility location without scaling facility costs. Scaling the facility costs by a factor of $\lambda := \sqrt{2}$ when deciding whether an operation can decrease the cost, we can achieve a better approximation ratio of $\alpha_{\mathsf{FL}} := 1 + \sqrt{2}$. Throughout, we fix the constants $\lambda = \sqrt{2}$ and $\alpha_{\mathsf{FL}} = 1 + \sqrt{2}$. For a solution (S', σ') to a facility location instance, we use $\mathsf{cost}_\lambda(S', \sigma') = \lambda f(S') + \mathsf{cc}(\sigma')$ to denote the cost of the solution (S', σ') with facility costs scaled by $\lambda = \sqrt{2}$. We call $\mathsf{cost}_\lambda(S', \sigma')$ the *scaled cost* of (S', σ').

Given the current solution (S, σ) for a facility location instance defined by F, C, d and $(f_i)_{i \in F}$, we can apply a *local operation* that changes the solution (S, σ). A valid local operation is one of the following.

[1] For an algorithm that might fail, we need to have some information about n to obtain a failure probability that depends on n.

- An open operation, in which we open some facility $i \in F$ and reconnect a subset $C' \subseteq C$ of clients to i. We allow i to be already in S, in which case we simply reconnect C' to i. This needs to be allowed since our σ does not connect clients to their nearest open facilities.
- A close operation, we close some facility $i' \in S$ and reconnect the clients in $\sigma^{-1}(i')$ to facilities in $S \setminus \{i'\}$.
- In a swap operation, we open some facility $i \notin S$ and close some facility $i' \in S$, reconnect the clients in $\sigma^{-1}(i')$ to facilities in $S \setminus \{i'\} \cup \{i\}$, and possibly some other clients to i. We say i is *swapped in* and i' is *swapped out* by the operation.

Thus, in any valid operation, we can open and/or close at most one facility. A client can be reconnected if it is currently connected to the facility that will be closed, or it will be connected to the new open facility. After we apply a local operation, S and σ will be updated accordingly so that (S, σ) is always the current solution.

For the online algorithm with recourse model, since we need to bound the number of reconnections, we apply a local operation only if the *scaled* cost it decreases is large compared to the number of reconnections it makes. This motivates the following definition:

▶ **Definition 5** (Efficient operations for facility location)**.** *Given a $\phi \geq 0$, we say a local operation on a solution (S, σ) for a facility location instance is ϕ-efficient, if it decreases $\mathsf{cost}_\lambda(S, \sigma)$ by more than ϕ times the number of clients it reconnects.*

The following theorem can be derived from the analysis for the local search algorithms for facility location.

▶ **Theorem 6.** *Consider a facility location instance with cost of the optimum solution being* opt *(using the original cost function). Let (S, σ) be the current solution in our algorithm and $\phi \geq 0$ be a real number. If there are no ϕ-efficient local operations on (S, σ), then we have*

$$\mathsf{cost}(S, \sigma) \leq \alpha_{\mathsf{FL}}\big(\mathsf{opt} + |C|\phi\big).$$

In particular, if we apply the theorem with $\phi = 0$, then we obtain that (S, σ) is an $(\alpha_{\mathsf{FL}} = 1 + \sqrt{2})$-approximation for the instance.

2.3 A Useful Lemma

The following lemma will be used repeatedly in our analysis. It's not hard to prove, but due to space constraints, we only include the proof in the full version of this paper.

▶ **Lemma 7.** *Let $b \in \mathbb{R}^T_{\geq 0}$ for some integer $T \geq 1$. Let $B_{T'} = \sum_{t=1}^{T'} b_t$ for every $T' = 0, 1, \cdots, T$. Let $0 < a_1 \leq a_2 \leq \cdots \leq a_T$ be a sequence of real numbers and $\alpha > 0$ such that $B_t \leq \alpha a_t$ for every $t \in [T]$. Then we have*

$$\sum_{t=1}^{T} \frac{b_t}{a_t} \leq \alpha \left(\ln \frac{a_T}{a_1} + 1 \right).$$

Organization. The rest of the paper is organized as follows. In Section 3, we prove Theorem 1 by giving our online algorithm for facility location with recourse. Section 4 gives the randomized local search procedure, that will be used in the proof of Theorem 2 in Section 5. We give some open problems and future directions in Section 6. Finally, the proof of Theorem 4 is deferred to Appendix A, where we give the fully dynamic algorithm for facility location in HST metrics. Due to space constraint, some proofs are not included in this paper, and we refer interested readers to the full version.

3 $(1+\sqrt{2}+\epsilon)$-Competitive Online Algorithm with Recourse

In this section, we prove Theorem 1 by giving the algorithm for online facility location with recourse.

3.1 The Algorithm

For any $\epsilon > 0$, let $\epsilon' = \Theta(\epsilon)$ be a parameter that is sufficiently small so that the approximation ratio $\alpha_{\mathsf{FL}} + O(\epsilon') = 1 + \sqrt{2} + O(\epsilon')$ achieved by our algorithm is at most $\alpha_{\mathsf{FL}} + \epsilon$. Our algorithm for online facility location is easy to describe. Whenever the client j_t comes at time t, we use a simple rule to connect j_t, as defined in the procedure initial-connect in Algorithm 1: either connecting j_t to the nearest facility in S, or opening and connecting j_t to its nearest facility in $F \setminus S$, whichever incurs the smaller cost. Then we repeatedly perform ϕ-efficient operations (Definition 5), until no such operations can be found, for $\phi = \frac{\epsilon' \cdot \mathsf{cost}(S,\sigma)}{\alpha_{\mathsf{FL}}|C|}$. [2]

Algorithm 1 initial-connect(j).

1: **if** $\min_{i \in F \setminus S}(f_i + d(i,j)) < d(j,S)$ **then**
2: let $i^* = \arg\min_{i \in F \setminus S}(f_i + d(i,j))$, $S \leftarrow S \cup \{i^*\}, \sigma_j \leftarrow i^*$
3: **else** $\sigma_j \leftarrow \arg\min_{i \in S} d(j,i)$

We can show that the algorithm gives an $(\alpha_{\mathsf{FL}} + \epsilon)$-approximation with amortized recourse $O(\log D \log n)$; recall that D is the aspect ratio of the metric. To remove the dependence on D, we divide the algorithm into stages, and *freeze* the connections of clients that arrived in early stages. The final algorithm is described in Algorithm 3, and Algorithm 2 gives one stage of the algorithm.

Algorithm 2 One Stage of Online Algorithm for Facility Location.

Input:
- C: initial set of clients
- (S,σ): a solution for C which is $O(1)$-approximate
- Clients $j_1, j_2, \cdots$ arrive from time to time

Output: Guaranteeing that (S,σ) at the end of each time t is $\frac{\alpha_{\mathsf{FL}}}{1-\epsilon'}$-approximate

1: init $\leftarrow \mathsf{cost}(S,\sigma)$
2: **for** $t \leftarrow 1, 2, \cdots$, terminating if no more clients will arrive **do**
3: $C \leftarrow C \cup \{j_t\}$, and call initial-connect(j_t)
4: **while** there exists an $\frac{\epsilon' \cdot \mathsf{cost}(S,\sigma)}{\alpha_{\mathsf{FL}}|C|}$-efficient local operation **do** perform the operation
5: **if** $\mathsf{cost}(S,\sigma) > \mathsf{init}/\epsilon'$ **then** terminate the stage

In Algorithm 2, we do as described above, with two modifications. First, we are given an initial set C of clients and a solution (S,σ) for C which is $O(1)$-approximate. Second, the stage will terminate if the cost of our solution increases by a factor of more than $1/\epsilon'$. The main algorithm (Algorithm 3) is broken into many stages. Since we shall focus on one stage of the algorithm for most part of our analysis, we simply redefine the time so that every stage starts with time 1. The improved recourse comes from the *freezing* operation: at the

[2] There are exponential number of possible operations, but we can check if there is a ϕ-efficient one efficiently. close operations can be handled easily. To check if we can open a facility i, it suffices to check if $\sum_{j \in C: d(j,i)+\phi < d(j,\sigma_j)} (d(j,\sigma_j) - d(j,i) - \phi) > \lambda f_i \cdot 1_{i \notin S}$. swap operations are more complicated but can be handled similarly.

Algorithm 3 Online Algorithm for Facility Location.

1: $C \leftarrow \emptyset, S \leftarrow \emptyset, \sigma = ()$
2: **repeat**
3: $C^\circ \leftarrow C, (S^\circ, \sigma^\circ) \leftarrow (S, \sigma)$
4: redefine the next time to be time 1 and run one stage as defined in Algorithm 2
5: permanently open one copy of each facility in S°, and permanently connect clients in C° according to σ° (we call the operation *freezing* S° and C°)
6: $C \leftarrow C \setminus C^\circ$, restrict the domain of σ to be the new C
7: **until** no clients come

end of each stage, we permanently open one copy of each facility in S°, and permanently connect clients in C° to copies of S° according to σ°, where C° and (S°, σ°) are the client set and solution at the beginning of the stage. Notice that we assume the original facilities in S° will still participate in the algorithm in the future; that is, they are subject to opening and closing. Thus each facility may be opened multiple times during the algorithm and we take the facility costs of all copies into consideration. This assumption is only for the sake of analysis; the actual algorithm only needs to open one copy and the costs can only be smaller compared to the described algorithm.

From now on, we focus on one stage of the algorithm and assume that the solution given at the beginning of each stage is $O(1)$-approximate. In the end we shall account for the loss due to the freezing of clients and facilities. Within a stage, the approximation ratio follows directly from Theorem 6: Focus on the moment after the while loop at time step t in Algorithm 2. Since there are no $\frac{\epsilon' \cdot \mathsf{cost}(S,\sigma)}{\alpha_{\mathsf{FL}}|C|}$-efficient local operations on (S, σ), we have by the theorem that $\mathsf{cost}(S,\sigma) \le \alpha_{\mathsf{FL}} \left(\mathsf{opt} + |C| \cdot \frac{\epsilon' \cdot \mathsf{cost}(S,\sigma)}{\alpha_{\mathsf{FL}}|C|} \right) = \alpha_{\mathsf{FL}}\mathsf{opt} + \epsilon' \cdot \mathsf{cost}(S,\sigma)$, where opt is the cost of the optimum solution for C. Thus, at the end of each time, we have $\mathsf{cost}(S,\sigma) \le \frac{\alpha_{\mathsf{FL}}}{1-\epsilon'} \cdot \mathsf{opt}$.

3.2 Bounding Amortized Recourse in One Stage

We then bound the amortized recourse in a stage; we assume that $\mathsf{cost}(S,\sigma) > 0$ at the beginning of the stage since otherwise there will be no recourse involved in the stage (since we terminate the stage when the cost becomes non-zero). We use T to denote the last time of the stage. For every time t, let C_t be the set C at the end of time t, and opt_t to be the cost of the optimum solution for the set C_t. For every $t \in [T]$, we define Δ_t to be the value of $\mathsf{cost}(S,\sigma)$ after Step 3 at time step t in Algorithm 2, minus that before Step 3. We can think of this as the cost increase due to the arrival of j_t.

The key lemma we can prove is the following:

▶ **Lemma 8.** *For every $T' \in [T]$, we have*

$$\sum_{t=1}^{T'} \Delta_t \le O(\log T')\mathsf{opt}_{T'}.$$

With Lemma 8, we can now bound the amortized recourse of one stage. In time t, $\mathsf{cost}(S,\delta)$ first increases by Δ_t in Step 3. Then after that, it decreases by at least $\frac{\epsilon'\mathsf{cost}(S,\sigma)}{\alpha_{\mathsf{FL}}|C|} \ge \frac{\epsilon'\mathsf{opt}_t}{\alpha_{\mathsf{FL}}|C|} \ge \frac{\epsilon'\mathsf{opt}_t}{\alpha_{\mathsf{FL}}|C_T|}$ for every reconnection we made. Let $\Phi_{T'} = \sum_{t=1}^{T'} \Delta_t$; Lemma 8 says $\Phi_t \le \alpha\mathsf{opt}_t$ for some $\alpha = O(\log T)$ and every $t \in [T]$. Noticing that $(\mathsf{opt}_t)_{t\in T}$ is a non-decreasing sequence, the total number of reconnections is at most

$$\frac{\mathsf{init}}{\epsilon' \cdot \mathsf{opt}_1/(\alpha_{\mathsf{FL}}|C_T|)} + \sum_{t=1}^{T} \frac{\Delta_t}{\epsilon' \cdot \mathsf{opt}_t/(\alpha_{\mathsf{FL}}|C_T|)} = \frac{\alpha_{\mathsf{FL}}|C_T|}{\epsilon'} \left(\frac{\mathsf{init}}{\mathsf{opt}_1} + \sum_{t=1}^{T-1} \frac{\Delta_t}{\mathsf{opt}_t} + \frac{\Delta_T}{\mathsf{opt}_T} \right).$$

Notice that $\mathsf{init} \le O(1)\mathsf{opt}_0 \le O(1)\mathsf{opt}_1$. Applying Lemma 7 with T replaced by $T-1$, $b_t = \Delta_t, B_t = \Phi_t$ and $a_t = \mathsf{opt}_t$ for every t, we have that $\sum_{t=1}^{T-1} \frac{\Delta_t}{\mathsf{opt}_t} \le \alpha \left(\ln \frac{\mathsf{opt}_{T-1}}{\mathsf{opt}_1} + 1 \right) = O\left(\log T \log \frac{1}{\epsilon'} \right)$, since we have $\mathsf{opt}_{T-1} \le O(1/\epsilon') \cdot \mathsf{opt}_1$. Notice that $\Delta_T \le \mathsf{opt}_T$ since $\mathsf{opt}_T \ge \min_{i \in F}(f_i + d(i, j_T)) \ge \Delta_T$. So, the total number of reconnections is at most $O\left(\frac{\log T}{\epsilon'} \log \frac{1}{\epsilon'} \right) \cdot |C_T|$. The amortized recourse per client is $O\left(\frac{\log T}{\epsilon'} \log \frac{1}{\epsilon'} \right) \le O\left(\frac{\log n}{\epsilon'} \log \frac{1}{\epsilon'} \right)$, where in the amortization, we only considered clients involved in the stage. Recall that n is the total number of clients arrived.

As each client appears in at most 2 stages, the overall amortized recourse is $O\left(\frac{\log n}{\epsilon'} \log \frac{1}{\epsilon'} \right)$. Finally we consider the loss in the approximation ratio due to freezing of clients. Suppose we are in the p-th stage. Then the clients arrived at and before $(p-2)$-th stage has been frozen and removed. Let $\overline{\mathsf{opt}}$ be the cost of the optimum solution for all clients arrived at or before $(p-1)$-th stage. Then the frozen facilities and clients have cost at most $\overline{\mathsf{opt}} \cdot O\left(\epsilon' + \epsilon'^2 + \epsilon'^2 + \cdots \right) = O(\epsilon')\overline{\mathsf{opt}}$. In any time in the p-th stage, the optimum solution taking all arrived clients into consideration has cost $\overline{\mathsf{opt}}' \ge \overline{\mathsf{opt}}$, and our solution has cost at most $(\alpha_{\mathsf{FL}} + O(\epsilon'))\overline{\mathsf{opt}}'$ without considering the frozen clients and facilities. Thus, our solution still has approximation ratio $\frac{(\alpha_{\mathsf{FL}} + O(\epsilon'))\overline{\mathsf{opt}}' + O(\epsilon')\overline{\mathsf{opt}}}{\overline{\mathsf{opt}}'} = \alpha_{\mathsf{FL}} + O(\epsilon')$ when taking the frozen clients into consideration.

4 Fast Local Search via Randomized Sampling

From now on, we will be concerned with dynamic algorithms. Towards proving Theorem 2 for the incremental setting, we first develop a randomized procedure that allows us to perform local search operations fast. In the next section, we use this procedure and ideas from the previous section to develop the dynamic algorithm with the fast update time.

The high level idea is as follows: We partition the set of local operations into many "categories" depending on which facility it tries to open or swap in. In each iteration of the procedure, we sample the category according to some distribution and find the best local operation in this category. By only focusing on one category, one iteration of the procedure can run in time $O(|C| \log |F|)$. On the other hand, the categories and the distribution over them are designed in such a way that in each iteration, the cost of our solution will be decreased by a multiplicative factor of $1 - \Omega\left(\frac{1}{|F|}\right)$. This idea has been used in [8] to obtain their $\tilde{O}(n^2)$ algorithm for approximating facility location. However, their algorithm was based on a different local search algorithm and analysis; for consistency and convenience of description, we stick to original local search algorithm of [2] that leads to $(1+\sqrt{2})$-approximation for the problem. Our algorithm needs to use the heap data structure.

4.1 Maintaining Heaps for Clients

Unlike the online algorithm for facility location in Section 3, in the dynamic algorithm, we guarantee that the clients are connected to their nearest open facilities. That is, we always have $\sigma_j = \arg\min_{i \in S} d(j, i)$; we still keep σ for convenience of description. We maintain $|C|$ min-heaps, one for each client $j \in C$: The min-heap for j will contain the facilities in

Algorithm 4 Δ-open(i).

1: **return** $\lambda f_i - \sum_{j \in C} \max\{0, d(j,\sigma_j) - d(j,i)\}$

Algorithm 5 try-open(i).

1: **if** Δ-open$(i) < 0$ **then** open i by updating S, σ and heaps accordingly

Algorithm 6 Δ-swap-in(i).

1: $C' \leftarrow \{j \in C : d(j,i) < d(j,\sigma_j)\}$ and $\Psi \leftarrow \lambda f_i - \sum_{j \in C'} \big(d(j,\sigma_j) - d(j,i)\big)$
2: $\Delta \leftarrow \min_{i' \in S} \left\{ \sum_{j \in \sigma^{-1}(i') \setminus C'} \left[\min\{d(j,i), d(j,\text{heap-top}(j))\} - d(j,i') \right] - \lambda f_{i'} \right\} + \Psi$
3: **return** $(\Delta,$ the i' above achieving the value of $\Delta)$

Algorithm 7 Δ-close.

1: $\Delta \leftarrow \min_{i' \in S} \left\{ \sum_{j \in \sigma^{-1}(i')} \left[d(j,\text{heap-top}(j)) - d(j,i') \right] - \lambda f_{i'} \right\}$
2: **return** $(\Delta,$ the i' above achieving the value of $\Delta)$

$S \setminus \{\sigma_j\}$, with priority value of i being $d(j,i)$. This allows us to efficiently retrieve the second nearest open facility to each j: This is the facility at the top of the heap for j and we use the procedure heap-top(j) to return it.

We define four simple procedures Δ-open, try-open, Δ-swap-in and Δ-close that are described in Algorithms 4, 5, 6 and 7 respectively. Recall that we use the *scaled cost* for the local search algorithm; so we are working on the scaled cost function in all these procedures. Δ-open(i) for any $i \notin S$ returns Δ, the increment of the scaled cost that will be incurred by opening i. (For it to be useful, Δ should be negative, in which case $|\Delta|$ indicates the cost decrement of opening i). This is just one line procedure as in Algorithm 4; try-open will open i if it can reduce the scaled cost. Δ-swap-in(i) for some $i \notin S$ returns a pair (Δ, i'), where Δ is the smallest scaled cost increment we can achieve by opening i and closing some facility $i' \in S$, and i' gives the facility achieving the smallest value. (Again, for Δ to be useful, it should be negative, in which case i' is the facility that gives the maximum scaled cost decrement $|\Delta|$.) Similarly, Δ-close returns a pair (Δ, i'), which tells us the maximum scaled cost decrement we can achieve by closing one facility and which facility can achieve the decrement. Notice that in all the procedures, the facility we shall open or swap in is given as a parameter, while the facility we shall close is chosen and returned by the procedures.

With the heaps, the procedures Δ-open, Δ-swap-in and Δ-close can run in $O(|C|)$ time. We only analyze Δ-swap-in(i) as the other two are easier. First, we define C' to be the set of clients j with $d(j,i) < d(j,\sigma_j)$; these are the clients that will surely be reconnected to i once i is swapped in. Let $\Psi = \lambda f_i - \sum_{j \in C'} (d(j,\sigma_j) - d(j,i))$ be the net scaled cost increase by opening i and connecting C' to i. The computation of C' and Ψ in Step 1 takes $O(|C|)$ time. If additionally we close some $i' \in S$, we need to reconnect each client in $\sigma^{-1}(i') \setminus C'$ to either i, or the top element in the heap for j, whichever is closer to j. Steps 2 and 3 compute and return the best scaled cost increment and the best i'. Since $\sum_{i' \in S} |\sigma^{-1}(i')| = |C|$, the running time of the step can be bounded by $O(|C|)$.

The running time for try-open, swapping two facilities and closing a facility (which are not defined explicitly as procedures, but used in Algorithms 8) can be bounded by $O(|C| \log |F|)$. The running times come from updating the heap structures: For each of the $|C|$ heaps, we need to delete and/or add at most 2 elements; each operation takes time $O(\log |F|)$.

Algorithm 8 sampled-local-search.

```
1: if rand(0,1) < 1/3 then        ▷ rand(0,1) returns a uniformly random number in [0,1]
2:     (Δ, i') ← Δ-close
3:     if Δ < 0 then close i' by updating S, δ and heaps accordingly
4: else
5:     i ← random facility in F \ S
6:     Δ ← Δ-open(i), (Δ', i') ← Δ-swap-in(i)
7:     if Δ ≤ Δ' and Δ < 0 then open i by updating S, δ and heaps accordingly
8:     else if Δ' < 0 then open i and close i' by updating S, δ and heaps accordingly
```

Algorithm 9 FL-iterate(M).

```
1: (S^best, σ^best) ← (S, σ)
2: for ℓ ← 1 to M do
3:     call sampled-local-search
4:     if cost(S, σ) < cost(S^best, σ^best) then (S^best, σ^best) ← (S, σ)
5: return (S^best, σ^best)
```

4.2 Random Sampling of Local Operations

With the support of the heaps, we can design a fast algorithm to implement randomized local search. sampled-local-search in Algorithm 8 gives one iteration of the local search. We first decide which operation we shall perform randomly. With probability $1/3$, we perform the close operation that will reduce the scaled cost the most (if it exists). With the remaining probability $2/3$, we perform either an open or a swap operation. To reduce the running time, we randomly choose a facility $i \in F \setminus S$ and find the best operation that opens or swaps in i, and perform the operation if it reduces the cost. One iteration of sampled-local-search calls the procedures in Algorithms 4 to 7 at most once and performs at most one operation, and thus has running time $O(|C| \log |F|)$.

In the procedure FL-iterate(M) described in Algorithm 9, we run the sampled-local-search M times. It returns the best solution obtained in these iterations, according to the *original (non-scaled) cost*, which is not necessarily the solution given in the last iteration. So we have

▶ **Observation 9.** *The running time of* FL-iterate(M) *is* $O(M|C| \log |F|)$*, where* C *is the set of clients when we run the procedure.*

Throughout this section, we fix a facility location instance. Let (S^*, σ^*) be the optimum solution (w.r.t the original cost) and $\mathsf{opt} = \mathsf{cost}(S^*, \sigma^*)$ be the optimum cost. Fixing one execution of sampled-local-search, we use (S^0, σ^0) to denote the solution before the execution. Then, we have

▶ **Lemma 10.** *Let* (S°, σ°) *be the* (S, σ) *at the beginning of an execution of* FL-iterate(M)*, and assume it is an* $O(1)$*-approximation to the instance. Let* $\Gamma \geq 2$ *and* $M = O\left(\frac{|F|}{\epsilon'} \log \Gamma\right)$ *is big enough. Then with probability at least* $1 - \frac{1}{\Gamma}$*, the solution returned by the procedure is* $(\alpha_{\mathsf{FL}} + \epsilon')$*-approximate.*

5 $(1+\sqrt{2}+\epsilon)$-Approximate Dynamic Algorithm for Facility Location in Incremental Setting

In this section, we prove Theorem 2 by combining the ideas from Sections 3 and 4 to derive a dynamic algorithm for facility location in the incremental setting. As for the online algorithm in Section 3, we divide our algorithm into stages. Whenever a client comes, we use a simple rule to accommodate it. Now we can not afford to consider all possible local operations as in Section 3. Instead we use the randomized local search idea from the algorithm in Section 4 by calling the procedure FL-iterate. We call the procedure only if the cost of our solution has increased by a factor of $1+\epsilon'$ (where $\epsilon'=\Theta(\epsilon)$ is small enough). In our analysis, we show a lemma similar to Lemma 8: The total increase of costs due to arrival of clients is small, compared to the optimum cost for these clients. Then, we can bound the number of times we call FL-iterate. Recall that we are given an integer $\Gamma=\text{poly}\left(n,\log D,\frac{1}{\epsilon}\right)$ that is big enough: We are aiming at a success probability of $1-1/\Gamma$ for each call of FL-iterate. Our final running time will only depend on $O(\log\Gamma)$.

The main algorithm will be the same as Algorithm 3, except that we use Algorithm 10 as the algorithm for one stage. As before, we only need to design one stage of the algorithm. Recall that in a stage we are given an initial set C of clients, an $O(1)$-approximate solution (S,σ) for C. Clients come one by one and our goal is to maintain an $(\alpha_{\mathsf{FL}}+O(\epsilon'))$-approximate solution at any time. The stage terminates if no client comes or our solution has cost more than $1/\epsilon'$ times the cost of the initial solution.

Algorithm 10 One Stage of Dynamic Algorithm for Facility Location.

Input: C: the initial set of clients
(S,σ): initial solution for C, which is $O(1)$-approximate

1: let $M=O\left(\frac{|F|}{\epsilon'}\log\Gamma\right)$ be large enough
2: $(S,\sigma)\leftarrow$ FL-iterate (M), init $\leftarrow$ cost(S,σ), last $\leftarrow$ init
3: **for** $t\leftarrow 1,2,3,\cdots$, terminating if no more clients arrive **do**
4: **for** $q=\left\lceil\log\frac{\text{last}}{|F|}\right\rceil$ to $\left\lceil\log\frac{\text{last}}{\epsilon'}\right\rceil$ **do**
5: **if** $i\leftarrow\arg\min_{i\in F\setminus S,f_i\le 2^q}d(j_t,i)$ exists, **then** call try-open$'(i)$ ▷ try-open$'$ is the same as try-open except we consider the cost instead of scaled cost.
6: $C\leftarrow C\cup\{j_t\}$ and call try-open$'\left(\arg\min_{i\in F\setminus S}(d(j_t,i)+f_i)\right)$
7: **if** cost$(S,\sigma)>(1+\epsilon')\cdot$ last **then**
8: $(S,\sigma)\leftarrow$ FL-iterate (M)
9: **if** cost$(S,\sigma)>$ last **then** last $\leftarrow$ cost(S,σ)
10: **if** last $>$ init$/\epsilon'$ **then** terminate the stage

Notice that in a stage, we are considering the original costs of solutions (instead of scaled costs as inside FL-iterate). During a stage we maintain a value last which gives an estimation on the cost of the current solution (S,σ). Whenever a client j_t comes, we apply some rules to open some facilities and connect j_t (Steps 4 to 6). These operations are needed to make the cost increase due to the arrival of j_t (defined as Δ_t later) small. In the algorithm try-open$'$ is the same as try-open, except that we use the original cost instead of the scaled cost (this is not important but only for the sake of convenience). If cost(S,σ) becomes too large, i.e, cost$(S,\sigma)>(1+\epsilon')$last, then we call $(S,\sigma)\leftarrow$ FL-iterate(M) for the M defined in Step 1 (Step 8), and update last to cost(S,σ) if we have cost$(S,\sigma)>$ last (Step 9). We terminate the algorithm when last $\ge$ init$/\epsilon$, where init is cost(S,σ) at the beginning of the stage (Step 10).

We say an execution of FL-iterate(M) is successful if the event in Lemma 10 happens. Then we have

▶ **Lemma 11.** *If all executions of* FL-iterate *are successful, the solution* (S, σ) *at the end of each time is* $(1+\epsilon')(\alpha_{\mathsf{FL}}+\epsilon')$*-approximate.*

Now we argue each execution of FL-iterate(M) is successful with probability at least $1 - 1/\Gamma$. This will happen if (S, σ) is $O(1)$-approximate before the call. By Lemma 10, we only need to make sure that the (S, σ) before the execution is $O(1)$-approximate. This is easy to see: Before Step 6 in time t, we have $\mathsf{cost}(S, \sigma) \le O(1)\mathsf{opt}$; the increase of $\mathsf{cost}(S, \sigma)$ in the step is at most the value of opt after the step (i.e, we consider the client j_t when defining opt). Thus, we have $\mathsf{cost}(S, \sigma) \le O(1)\mathsf{opt}$ after the step.

5.1 Bounding Number of Times of Calling FL-iterate

It remains to bound the number of times we call FL-iterate. Again, we use T to denote the last time step of Algorithm 10 (i.e, one stage of the dynamic algorithm) and Δ_t to denote the cost increase due to the arrival of j_t: it is the value of $\mathsf{cost}(S, \sigma)$ before Step 6 minus that after Step 6 in time t. For every time $t \in [T]$, let C_t be the set C at the end of time t, and let opt_t be the cost of the optimum solution for C_t. Let last_t be the value of last at the *beginning* of time t.

Like in the online setting, we can bound the total cost increase in a similar manner as Lemma 8:

▶ **Lemma 12.** *For every* $T' \in [T-1]$*, we have*

$$\sum_{t=1}^{T'} \Delta_t \le O(\log T') \cdot \mathsf{opt}_{T'}$$

Then we can wrap up the proof of Theorem 2. Between two consecutive calls of FL-iterate in Step 8 at time t_1 and $t_2 > t_1$, $\mathsf{cost}(S, \sigma)$ should have increased by at least $\epsilon'\mathsf{last}_{t_2}$: At the end of time t_1, we have $\mathsf{cost}(S, \sigma) \le \mathsf{last}_{t_1+1} = \mathsf{last}_{t_2}$ since otherwise last should have been updated in time t_1. We need to have $\mathsf{cost}(S, \sigma) > (1+\epsilon')\mathsf{last}_{t_2}$ after Step 6 at time t_2 in order to call FL-iterate. Thus, the increase of the cost during this period is at least $\epsilon'\mathsf{last}_{t_2}$. Thus, we have $\sum_{t=t_1+1}^{t_2} \frac{\Delta_t}{\epsilon' \cdot \mathsf{last}_t} \ge 1$ since $\mathsf{last}_t = \mathsf{last}_{t_2}$ for every $t \in (t_1, t_2]$. The argument also holds when $t_1 = 0$ and $t_2 > t_1$ is the first time in which we call FL-iterate. Counting the call of FL-iterate in Step 2, we can bound the total number of times we call the procedure by $1 + \frac{1}{\epsilon'} \sum_{t=1}^{T} \frac{\Delta_t}{\mathsf{last}_t}$.

Again let $\Phi_{T'} = \sum_{t=1}^{T'} \Delta_t$ for every $T' \in [0, T]$. Lemma 12 says $\Phi_t \le O(\log t)\mathsf{opt}_t$ for every $t \in [0, T-1]$. For every $t \in [T]$, since $\Delta_t \le \mathsf{opt}_t$, thus we have $\Phi_t = \Phi_{t-1} + \Delta_t \le O(\log t)\mathsf{opt}_{t-1} \le O(\log T)\mathsf{last}_t$ since last_t will be at least the cost of some solution for C_{t-1}. Applying Lemma 7 with $a_t = \mathsf{last}_t, b_t = \Delta_t$ and $B_t = \Phi_t$ for every t, the number of times we call FL-iterate can be bounded by

$$1 + \frac{1}{\epsilon'} \sum_{t=1}^{T} \frac{\Delta_t}{\mathsf{last}_t} \le \frac{1}{\epsilon'} O(\log T) \left(\ln \frac{\mathsf{last}_T}{\mathsf{last}_1} + 1 \right) = O\left(\frac{\log T}{\epsilon} \log \frac{1}{\epsilon} \right).$$

We can then analyze the running time and the success probability of our algorithm. Focus on each stage of the algorithm. By Observation 9, each call to FL-iterate(M) takes time $O(M|C| \log |F|) = O\left(\frac{|F|}{\epsilon'} (\log \Gamma) |C| \log n \right) = O\left(\frac{n \cdot |C_T|}{\epsilon} \log^2 n \right)$, where C is the set of clients

in the algorithm at the time we call the procedure, $C_T \supseteq C$ is the number set of clients at the end of time T, and $M = O\left(\frac{|F|}{\epsilon'} \log \Gamma\right)$ is as defined in Step 1. The total number of times we call the procedure is at most $O\left(\frac{\log T}{\epsilon} \log \frac{1}{\epsilon}\right) \leq O\left(\frac{\log n}{\epsilon} \log \frac{1}{\epsilon}\right)$. Thus, the running time we spent on FL-iterate is $O\left(\frac{n \cdot |C_T|}{\epsilon^2} \log^3 n \log \frac{1}{\epsilon}\right)$. The running time for Steps 4 to 6 is at most $T \cdot O\big(\log \frac{|F|}{\epsilon'}\big) \cdot O\big(|C_T| \log |F|\big) = O(|C_T| T \log^2 \frac{|F|}{\epsilon}) \leq O(n|C_T| \log^2 \frac{n}{\epsilon})$. Thus, the total running time of a stage is at most $O\left(\frac{n \cdot |C_T|}{\epsilon^2} \log^3 n \log \frac{1}{\epsilon}\right)$. Now consider all the stages together. The sum of $|C_T|$ values over all stages is at most $2n$ since every client appears in at most 2 stages. So, the total running time of our algorithm is $O\left(\frac{n^2}{\epsilon^2} \log^3 n \log \frac{1}{\epsilon}\right)$.

For the success probability, we call FL-iterate(M) at most $O\left(\log_{1/\epsilon}(nD) \frac{\log n}{\epsilon} \log \frac{1}{\epsilon}\right)$ $= \text{poly}(\log n, \log D, \frac{1}{\epsilon})$ times. If we have Γ be at least n^2 times this number, which is still $\text{poly}(n, \log D, \frac{1}{\epsilon})$, then the success probability of our algorithm is at least $1 - 1/n^2$.

Finally, we remark that the success of the algorithm only depends on the success of all executions of FL-iterate. Each execution has success probability $1 - 1/\Gamma$ even if the adversary is adaptive. This finishes the proof of Theorem 2.

▶ Remark. We can indeed obtain an algorithm that has both $O(\log T)$ amortized client recourse and $\tilde{O}(n^2)$ running time, by defining $\phi = \frac{\text{cost}(S,\sigma)}{\alpha_{\text{FL}} \epsilon'}$ and only performing ϕ-efficient local operations. However, this will require us to put ϕ everywhere in our analysis and deteriorate the cleanness of the analysis. Thus, we choose to separate the two features in two algorithms: small recourse and $\tilde{O}(n^2)$ total running time.

We also remark that the total running time for all calls of FL-iterate is only $\tilde{O}(n|F|)$, and the $\tilde{O}(n^2)$ time comes from Steps 4 to 6. By losing a multiplicative factor of 2 and additive factor of 1 in the approximation ratio, we can assume every client is collocated with its nearest facility. Then at any time we only have $O(|F|)$ different positions for clients, and the running time of the algorithm can be improved to $O(\frac{n|F|}{\epsilon^2} \log^3 n \log \frac{1}{\epsilon})$.

6 Open Problems and Discussions

We initiated the study of facility location problem in general metric spaces in recourse and dynamic models. Several interesting problems remain open: The most obvious one is can we get $O(1)$-competitive online/dynamic algorithms with polylog amortized recourse or fast update times in the fully dynamic setting. Another interesting direction is can we extend our results to the capacitated facility location and capacitated k-median, where there is an upper bound on the number of clients that can be assigned to a single open facility. From technical point of view, it would be interesting to find more applications of local search and probabilistic tree embedding techniques in the dynamic algorithms model. Finally, as alluded in the introduction, an exciting research direction is to understand the power of recourse in the online model.

A Fully Dynamic Algorithm for Facility Location on Hierarchically Well Separated Tree Metrics

In this section, we give our fully dynamic algorithm for facility location on hierarchically-well-separated-tree (HST) metrics. Our algorithm achieves $O(1)$-approximation and $O(\log^2 D)$ amortized update time.

A.1 Hierarchically Well Separated Trees

▶ **Definition 13.** *A hierarchically-well-separated tree (or HST for short) is an edge-weighted rooted tree with the following properties:*

- *all the root-to-leaf paths have the same number of edges,*
- *if we define the level of vertex v, $\mathsf{level}(v)$, to be the number of edges in a path from v to any of its leaf descendant, then for an non-root vertex v, the weight of the edge between v and its parent is exactly $2^{\mathsf{level}(v)}$.*

Given a HST T with the set of leaves being X, we use d_T to denote the shortest path metric of the tree T (with respect to the edge weights) restricted to X.

The classic results by Bartal [3] and Fakcharoenphol, Rao and Talwar [12] state that we can embed any N-point metric (X, d) (with minimum non-zero distance being 1) to a distribution π of *expanding*[3] HST metrics (X, d_T) with distortion $O(\log N)$: For every $u, v \in X$, we have $d_T(u, v) \geq d(u, v)$ and $\mathbb{E}_{u,v}[d_T(u, v)] \leq O(\log N)d(u, v)$. Moreover, there is an efficient randomized algorithm [5] that outputs a sample of the tree T from π. Thus applying standard arguments, Theorem 3 implies Theorem 4.

Notations. As we mentioned early, we assume each client is collocated with a facility. From now on, we fix the HST T and assume the leaves of T is $X = F$; let V be the set of all nodes in T. Let d_T be the metric induced by T over the set V of vertices. Recall that $\mathsf{level}(v)$ is the level of v in T. For every vertex $v \in V$, define Λ_v to be the set of children of v, X_v to be the set of leaf descendants of v, and T_v be the maximal sub-tree of T rooted at v. We extend the facility cost from X to all vertices in V: for every $v \in V \setminus X$, we define $f_v = \min_{i \in X_v} f_i$. We can assume that each internal vertex v is a facility; by opening v we mean opening a copy of the $i \in X_v$ with $f_i = f_v$. This assumption only loses a factor of 2 in the competitive ratio: On one hand, having more facilities can only make our problem easier; on the other hand, the cost of connecting a client to any $i \in X_v$ is at most twice that of connecting it to v. By the definition, the facility costs along a root-to-leaf path are non-decreasing.

A.2 Offline Algorithm for Facility Location on HST Metrics

In this section, we first give an offline $O(1)$-approximation algorithm for facility location on the HST metric d_T as a baseline. Notice that facility location on trees can be solved exactly using dynamic programming. However the algorithm is hard to analyze in the dynamic algorithm model since the solution is sensitive to client arrivals and departures. Our algorithm generalizes the algorithm in [11] for facility location with uniform facility cost, that was used to achieve the differential privacy requirement.

For every vertex $v \in V$, we let N_v be the number of clients at locations in X_v. Although according to the definition N_v's are integers, in most part of the analysis we assume there are non-negative *real numbers*. This will be useful when we design the dynamic algorithm. Let $\alpha \in \{1, 2\}^V$ and $\beta \in \{1, 2\}^{V \setminus X}$ be vectors given to our algorithm. They are introduced solely for the purpose of extending the algorithm to the dynamic setting; for the offline algorithm we can set α and β to be all-1 vectors.

Marked and Open Facilities. For every vertex $v \in V$, we say v is *marked* w.r.t the vectors N and α if

$$N_v \cdot 2^{\mathsf{level}(v)} > f_v/\alpha_v$$

and *unmarked* otherwise. The following observation can be made:

▶ **Observation 14.** *Let u be the parent of v. If v is marked w.r.t N and α, so is u.*

Proof. v is marked w.r.t N and α implies $N_v 2^{\mathsf{level}(v)} > f_v/\alpha_v$. Notice that $N_u \geq N_v, \mathsf{level}(u) = \mathsf{level}(v) + 1, \alpha_v \leq 2\alpha_u$ and $f_u \leq f_v$. So, $N_u 2^{\mathsf{level}(u)} \geq 2N_v 2^{\mathsf{level}(v)} > 2f_v/\alpha_v \geq f_u/\alpha_u$. ◀

Thus there is a monotonicity property on the marking status of vertices in T. We say a vertex v is highest unmarked (w.r.t N and α) if it is unmarked and its parent is marked; we say a vertex v is lowest marked if it is marked but all its children are unmarked. However,

[3] A metric (X, d_T) is expanding w.r.t (X, d) if for every $u, v \in X$, we have $d_T(u, v) \geq d(u, v)$.

sometimes we say a vertex u is the lowest marked ancestor of a leaf $v \in X$ if either $u = v$ is marked, or $u \neq v$ is marked and the child of u in the u-v path is unmarked; notice that in this case, u might not be a lowest marked vertex since it may have some other marked children. If we need to distinguish between the two cases, we shall use that u is lowest marked *globally* to mean u is a lowest marked vertex.

If a leaf vertex $v \in X$ is marked, then we open v. For every marked vertex $v \in V \setminus X$, we open v if and only if

$$\left(\sum_{u \in \Lambda_v : u \text{ unmarked}} N_u \right) 2^{\mathsf{level}(v)} > f_v/(\alpha_v \beta_v).$$

Notice that all unmarked vertices are closed.

▶ **Observation 15.** *If v is lowest marked, then v is open.*

Proof. We can assume $v \notin X$ since otherwise v is open. So, $N_v 2^{\mathsf{level}(v)} > f_v/\alpha_v$ and all children of v are unmarked. Thus, $\sum_{u \in \Lambda_v : u \text{ unmarked}} N_u = \sum_{u \in \Lambda_v} N_u = N_v$. Therefore, $\left(\sum_{u \in \Lambda_v : u \text{ unmarked}} N_u\right) 2^{\mathsf{level}(v)} = N_v 2^{\mathsf{level}(v)} > f_v/\alpha_v \geq f_v/(\alpha_v \beta_v)$. Thus v will be open. ◀

With the set of open facilities defined, every client is connected to its nearest open facility according to d_T, using a consistent tie-breaking rule (e.g, the nearest open facility with the smallest index). We assume the root r of T has $\frac{f_v}{2^{\mathsf{level}(v)}} \leq 1$ by increasing the number of levels. So r will be marked whenever $N_r \geq 1$. This finishes the description of the offline algorithm.

Analysis of $O(1)$-Approximation Ratio. We show the algorithm achieves an $O(1)$-approximation. First we give a lower bound on the optimum cost. For every $v \in V$, let

$$\mathsf{LB}(v) = \min \left\{ N_v 2^{\mathsf{level}(v)}, f_v \right\}.$$

Then we have

▶ **Lemma 16.** *Let U be a set of vertices in T without an ancestor-descendant pair; i.e, for every two distinct vertex u and v in U, u is not an ancestor of v. Then the cost of the optimum solution is at least $\sum_{v \in U} \mathsf{LB}(v)$.*

Then let U be the set of highest unmarked vertices and marked leaves; clearly U does not have an ancestor-descendant pair. By Lemma 16, the optimum cost is at least $\sum_{v \in U} \mathsf{LB}(v)$. We prove the following lemma.

▶ **Lemma 17.** *The solution produced by our algorithm has cost at most $O(1) \sum_{u \in U} \mathsf{LB}(u)$.*

Combining Lemmas 16 and 17 gives that our algorithm is an $O(1)$-approximation. One lemma that will be useful in the analysis of dynamic algorithm is the following:

▶ **Lemma 18.** *For any open facility v in our solution, the number of clients connected to v that are outside T_v is at most $O(\log D) \frac{f_v}{2^{\mathsf{level}(v)}}$.*

▶ Remark. The algorithm so far gives a *data structure* that supports the following operations in $O(\log D)$ time: i) updating N_v for some $v \in X$ and ii) returning the nearest open facility of a leaf $v \in X$. Indeed the algorithm can be made simpler: We set α to be the all-1 vector, and we open the set of lowest marked facilities (so both α and β are not needed). For every vertex $u \in V$, we maintain the nearest open facility ψ_u to u in T_u. Whenever a client at v arrives or departs, we only need change N_u, ψ_u, marking and opening status of u for

ancestors u of v. To return the closest open facility to a leaf $v \in X$, we travel up the tree from v until we find an ancestor u with ψ_u defined, and return ψ_u. Both operations take $O(\log D)$ time. However, our goal is to maintain the solution (S, σ) *explicitly* in memory. Thus we also have to bound the the number of reconnections during the algorithm, since that will be a lower bound on the total running time.

A.3 Dynamic Algorithm for Facility Location on HST Metrics

In this section, we extend the offline algorithm to a dynamic algorithm with $O(\log^3 D)$-amortized update time; recall that D is the aspect ratio of the metric. We maintain α, β and N-vectors, and at any moment of the algorithm, the marking and opening status of vertices are exactly the same as that obtained from the offline algorithm for α, β and N.

Initially, let α and β be all-1 vectors, and N be the all-0 vector. So all the vertices are unmarked. Whenever a client at some $v \in X$ arrives or departs, the α, β values, the marking and opening status of ancestors of v may change and we show how to handle the changes. The vertices that are not ancestors of v are not affected during the process.

When a client at v arrives or departs, we increase or decrease the N_u values for all ancestors u of v by 1 *continuously* at the same rate (we can think of that the number of clients at v increases or decreases by 1 continuously). During the process, the marking and opening status of these vertices may change. If such an event happens, we change α and/or β values of the vertex so that it becomes harder for the status to change back in the future. Specifically, we use the following rules:

- If a vertex u changes to marked (from being unmarked), then we change α_u to 2 (notice that u remains marked w.r.t the new α), and β_u to 1. In this case, we do not consider the opening status change of u as an event.
- If a vertex u changes to unmarked (from being marked), we change α_u to 1 (notice that u remains unmarked w.r.t the new α). The β_u value becomes useless. In this case, we also do not consider the opening status change of u as an event.
- If a marked vertex u becomes open (from being closed), then we change β_u to 2 (notice that u remains open w.r.t the new β).
- If a marked vertex u becomes closed (from being open), then we change β_u to 1 (notice that u remains closed w.r.t the new β).

We call the 4 types of events above as marking, unmarking, opening and closing events.

Now we talk about the order the events happen. When we increase N_u values of ancestors of v continuously, one of the following two events may happen:

- The highest unmarked ancestor u of v may become globally lowest marked, and this may *induce* a closing event for the parent w of u.
- The lowest marked ancestor u of v may become open.

Similarly, when we decrease N_u values of ancestors of v continuously, one of the following two events may happen:

- The lowest marked ancestor u of v may become unmarked (we must that u was lowest marked globally), and this may *induce* an opening event for the parent w of u.
- The lowest marked ancestor u of v may become closed.

Above, if two events happen at the same time, we handle an arbitrary event. Notice that after we handle the event, the conditions for the other event might not hold any more, in which case we do not handle it.

Once we have finished the process of increasing or decreasing N_u values by 1, the clients will be connected to their respective nearest open facilities, breaking ties using the consistent rule. A reconnection happens if a client is connected to a different facility.

Bounding Number of Reconnections. Now we analyze the reconnections made in the algorithm. When a client at $v \in X$ arrives or departs, at most $O(\log D)$ vertices u will have their N_u values changed by 1. We distribute 4 tokens to each ancestor u of v, that are of type-A, type-B, type-C and type-D respectively.[4] We are going to use these tokens to charge the events happened.

First focus on the sequence of marking/unmarking events happened at a vertex u. Right before u becomes unmarked we have $N_u \leq f_u/(2 \times 2^{\mathsf{level}(u)})$ since at the moment we have $\alpha_u = 2$. Immediate after that α_u is changed to 1. For u to become marked again, we need $N_u \leq f_u/2^{\mathsf{level}(u)}$. So during the period N_u must have been increased by at least $f_u/(2 \times 2^{\mathsf{level}(u)})$. Similarly, right before u becomes marked we have $N_u \geq f_u/2^{\mathsf{level}(u)}$ since at the moment we have $\alpha_u = 1$. Then we change α_u to 2 immediately. For u to become unmarked again, N_u should be decreased by at least $f_u/(2 \times 2^{\mathsf{level}(u)})$. So, when a marking/unmarking event happens at u, we can spend $\Omega(f_u/2^{\mathsf{level}(u)})$ type-A tokens owned by u.

Then we focus on the sequence $\mathcal{S}$ of opening/closing events at u between two adjacent marking/unmarking events at u. At these moments, u is marked and $\alpha_u = 2$. For the first event in $\mathcal{S}$, we can spend $\Omega(f_u/2^{\mathsf{level}(u)})$ type-B tokens owned by u. If some opening/closing event e in $\mathcal{S}$ is induced by an unmarking/marking event of some child u' of u, then we can spend $\Omega(f_{u'}/2^{\mathsf{level}(u')}) \geq \Omega(f_u/2^{\mathsf{level}(u)})$ type-C tokens owned by u' for e, and the event e' after e in $\mathcal{S}$ if it exists. Notice that we already argued that u' has collected enough number of type-C tokens.

Then we focus on an event e' in $\mathcal{S}$ such that both e and the event e before e' in $\mathcal{S}$ are not induced. First, assume e is an opening event and e' is a closing event. Then, after e we have $\sum_{u' \in \Lambda_u : u' \text{ unmarked}} N_{u'} = f_u/(2 \times 2^{\mathsf{level}(u)})$ and before e' we have $\sum_{u' \in \Lambda_u : u' \text{ unmarked}} N_{u'} = f_u/(4 \times 2^{\mathsf{level}(u)})$. Notice that the set of unmarked children of u may change, and let U' and U'' be the sets of unmarked children of u at the moments after e and before e' respectively. Again if there is some $u' \in (U' \setminus U'') \cup (U'' \setminus U')$, we spend $\Omega(\frac{f_{u'}}{2^{\mathsf{level}(u')}}) \geq \Omega(\frac{f_u}{2^{\mathsf{level}(u)}})$ type-C tokens owned by u'. Otherwise, $U = U'$ and $f_u/(4 \times 2^{(\mathsf{level}(u))})$ clients in T_u must have departed between e and e' and we can then spend $\Omega(f_u/2^{\mathsf{level}(u)})$ type-D tokens for e'. The case when e is an closing event and e' is an opening event can be argued in the same way.

Thus, whenever an event happens at u, we can spend $\Omega(f_u/2^{\mathsf{level}(u)})$ tokens; moreover if an opening/closing event at u was induced by an unmarking/marking event at some child u' of u, then we can spend $\Omega(f_{u'}/2^{\mathsf{level}(u')})$ tokens for the event at u. A facility u changes its opening status when an event happens at u. Notice that, we reconnect a client only if it was connected to a ready-to-close facility, or it needs to be connected to newly open facility. By Lemma 18, at any moment the number of clients connected to u from outside T_u is at most $O(\log D) \cdot \frac{f_u}{2^{\mathsf{level}(u)}}$. At the moment u changes its opening status because of an non-induced event, then before and after the event the number of clients connected to u from T_u is of order $O\left(\frac{f_u}{2^{\mathsf{level}(u)}}\right)$. u changes its opening status due to a marking/unmarking event happened at some child u' of u, then before and after the event the number of clients connected to u from T_u is of order $\Theta\left(\frac{f_{u'}}{2^{\mathsf{level}(u')}}\right)$. Thus, on average, for each token we spent we connect at most $O(\log D)$ clients. Since each client arrival or departure distributes at most $O(\log D)$ tokens, we have that the amortized number of reconnections (per client arrival/departure) is at most $O(\log^2 D)$.

Analyzing Update Time. Then with the bound on the number of reconnections (recourse), we can bound the update time easily. Indeed, we can maintain a ψ_u for every $u \in V$, which indicates the nearest open facility to u in $T_u \setminus u$ (ψ_u could be undefined). We also maintain

[4] The types are only defined for convenience.

a value N'_u for marked vertices u where $N'_u = \sum_{v \in \Lambda_v, v \text{ unmarked}} N_v$. Whenever a client at v arrives or departs, we need to change $\alpha_u, \beta_u, N_u, N'_u, \psi_u$, marking and opening status of u only for ancestors u of v. The update can be made in $O(\log D)$ time for every client arrival or departure using the information on the vertices. The bottleneck of the algorithm comes from reconnecting clients. We already argued that the amortized number of reconnections per client arrival/departure is $O(\log^2 D)$ and thus it suffices to give an algorithm that can find the clients to be connected efficiently.

For every vertex u, we maintain a double-linked-list of unmarked children u' of u with $N_{u'} \geq 1$. With this structure it is easy to see that for every client that needs to be reconnected, we need $O(\log D)$ time to locate it. If u becomes open, we need to consider each unmarked children u' of u and reconnect clients in $T_{u'}$ to u. The time needed to locate these clients can be made $O(\log D)$ times the number of clients. For every strict ancestor w of u for which there are no open facilities in between we can use the ψ_w information to see if we need to reconnect clients in T_w. If yes, then for every unmarked child w' of w with $N_{w'} \geq 1$ that is not an ancestor of u, we need to connect the clients in $T_{w'}$ to u. Again enumerating these clients takes time $O(\log D)$ times the number of clients. Similarly, if u becomes closed, we then need to connect all clients connected to u to the nearest open facility to u, which can be computed using ψ values of u and its ancestors. Enumerating the clients takes time $O(\log D)$ times the number of clients. Overall, the amortized running time per client arrival/departure is $O(\log^3 D)$.

Nearly Optimal Embeddings of Flat Tori

Abstract

We show that for any n-dimensional lattice $\mathcal{L} \subseteq \mathbb{R}^n$, the torus $\mathbb{R}^n/\mathcal{L}$ can be embedded into Hilbert space with $O(\sqrt{n \log n})$ distortion. This improves the previously best known upper bound of $O(n\sqrt{\log n})$ shown by Haviv and Regev (APPROX 2010, J. Topol. Anal. 2013) and approaches the lower bound of $\Omega(\sqrt{n})$ due to Khot and Naor (FOCS 2005, Math. Ann. 2006).

1 Introduction

Low distortion embeddings play an important role in many approximation algorithms, allowing one to map points in a "difficult" metric space into another simpler metric space (such as Hilbert space), in a way that approximately preserves distances. See the survey by Indyk [2] for many examples of algorithmic applications. One interesting family of difficult metric spaces is given by *flat tori*. These are defined as quotients of Euclidean space by a lattice, and play an important role in lattice problems and algorithms.

In more detail, an n-dimensional lattice $\mathcal{L} \subseteq \mathbb{R}^n$ is defined as the set of all integer linear combinations of some n linearly independent vectors in $\mathbb{R}^n$. The torus $\mathbb{R}^n/\mathcal{L}$ is the quotient space obtained by identifying points in $\mathbb{R}^n$ with each other if their difference is a lattice vector. The torus has a natural metric associated to it; namely, the distance between any two elements of the torus is defined as the minimum distance between any representative of these elements. So for instance, in the one-dimensional case $\mathbb{R}/\mathbb{Z}$, the distance between 0.1 and 0.9 is 0.2.

Khot and Naor [3] considered the question of how well one can embed flat tori $\mathbb{R}^n/\mathcal{L}$ into Hilbert space. They proved that for any $\mathcal{L}$ and any embedding of $\mathbb{R}^n/\mathcal{L}$ into Hilbert space, the distortion must be at least $\Omega(\frac{\lambda_1(\mathcal{L}^*)}{\mu(\mathcal{L}^*)}\sqrt{n})$. Here, $\mathcal{L}^*$ is the dual lattice of $\mathcal{L}$ and $\lambda_1(\mathcal{L})$ and $\mu(\mathcal{L})$ represent the length of the shortest nonzero vector and the covering radius of $\mathcal{L}$ respectively. It is known by a result of Conway and Thompson (see [4, Page 46]) that, for large enough n, there exist lattices $\mathcal{L}$ where $\lambda_1(\mathcal{L}) = \mu(\mathcal{L})$. Thus the lower bound of Khot and Naor shows that there are n-dimensional lattices whose torus requires distortion

$\Omega(\sqrt{n})$ in any embedding into Hilbert space. In the same paper, they also present an embedding that achieves a distortion of $O(n^{3n/2})$ for any lattice $\mathcal{L}$. While the distortion of their embedding might be better than this upper bound, it is known that for some lattices it is super-polynomial [1, Section 7].

In [1] an $O(n\sqrt{\log n})$ distortion metric embedding is constructed, significantly reducing the gap between the upper and lower bounds. They also provide an alternative upper bound of $O(\sqrt{n \log(\mu(\mathcal{L})/\lambda_1(\mathcal{L}))})$. For lattices with good geometric structure (specifically, where the ratio $\mu(\mathcal{L})/\lambda_1(\mathcal{L})$ is only polynomial) this gives an $O(\sqrt{n \log n})$ upper bound. However, in general, the ratio $\mu(\mathcal{L})/\lambda_1(\mathcal{L})$ can be arbitrarily big, in which case this alternative bound is not useful.

Our result is a nearly tight embedding of flat tori, essentially resolving the question of Khot and Naor up to a $\sqrt{\log n}$ factor.

▶ **Theorem 1.1.** *For any lattice $\mathcal{L} \subseteq \mathbb{R}^n$ there exists a metric embedding of $\mathbb{R}^n/\mathcal{L}$ into Hilbert space with distortion $O(\sqrt{n \log n})$.*

1.1 Proof Overview

Our starting point is the embedding by Haviv and Regev [1], which is based on Gaussian measures. Their embedding achieves a distortion of $O(\sqrt{n \log n})$ assuming that the lattice $\mathcal{L}$ has poly(n) "aspect ratio," i.e., the ratio between $\mu(\mathcal{L})$ (the diameter of the torus, or equivalently, the covering radius of the lattice) and $\lambda_1(\mathcal{L})$ (the length of the shortest nonzero vector in the lattice) is polynomial in the dimension n. Their embedding can also be applied to arbitrary lattices; the only issue is that it "saturates" at distance poly$(n)\lambda_1(\mathcal{L})$ – points at greater distance will be contracted by the embedding. See Section 3 for the details.

A natural way to address this issue is to first partition the lattice into scales, and to then embed each scale separately. Specifically, one can define a filtration of sublattices $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$ with each $\mathcal{L}_j$ capturing a different scale of the lattice. Then, for each $j = 1, \ldots, m$, we project the torus on the space orthogonal to $\mathcal{L}_{j-1}$, and embed each projection in Hilbert space separately. Our embedding is then the direct sum of the m individual embeddings.

This approach does work, and is used as part of the construction in [1]. The difficulty is that it introduces an additional $\sqrt{m}$ loss in the distortion, which at worst can be $O(\sqrt{n})$ and is the reason they only achieved an overall distortion of $O(n\sqrt{\log n})$. To see where this loss comes from, consider a short vector inside the span of $\mathcal{L}_1$; this vector only contributes to the first embedding (because it becomes zero in the other $m-1$ projections). On the other hand, a short vector orthogonal to $\mathcal{L}_{m-1}$ gets accounted for in all m projections, leading to an expansion of $\sqrt{m}$ (the square root due to the L_2 norm in the target Hilbert space).

In order to avoid this loss and achieve a $O(\sqrt{n \log n})$ distortion, it is tempting to decompose space into *orthogonal* subspaces (and not nested subspaces as in the above). So instead of projecting on the subspace orthogonal to $\mathcal{L}_{j-1}$, we would like to only project on the subspace of $\mathcal{L}_j$ that is orthogonal to $\mathcal{L}_{j-1}$ (i.e., on the span of $\mathcal{L}_j/\mathcal{L}_{j-1}$). This, however, is impossible; projecting a lattice in such a way in general gives a dense set, and not a lattice.[1]

Our novel contribution is to replace this "harsh" two-sided projection (which is in general impossible) by a more gentle "compressed projection." Namely, we first project orthogonally to $\mathcal{L}_{j-1}$, and then *scale down* the subspace orthogonal to $\mathcal{L}_j$. Returning to the example above,

[1] To see why, consider the two-dimensional lattice generated by $(1, 0)$ and $(\pi, 1)$; its projection on the first coordinate is a dense set.

a short vector orthogonal to $\mathcal{L}_{m-1}$ is still accounted for in all m "compressed projections," but the scaling factors are such that its contributions form a geometric series, so the overall expansion is only a constant instead of $\sqrt{m}$. The technical effort is in showing that these compressions do not distort the geometry by too much; see Section 4 for details. We remark that this "compressed projection" idea might find applications in other cases where decomposing a lattice into scales is desirable.

2 Preliminaries

2.1 Embeddings and Distortion

A metric space is a tuple $(\mathcal{M}, \mathrm{dist}_{\mathcal{M}})$ where $\mathcal{M}$ is a set and $\mathrm{dist}_{\mathcal{M}} : \mathcal{M} \times \mathcal{M} \to \mathbb{R}$ is a function such that the following hold for all $x, y, z \in \mathcal{M}$:

- $\mathrm{dist}_{\mathcal{M}}(x, y) \geq 0$, and the equality holds if and only if $x = y$,
- $\mathrm{dist}_{\mathcal{M}}(x, y) = \mathrm{dist}_{\mathcal{M}}(y, x)$,
- $\mathrm{dist}_{\mathcal{M}}(x, y) + \mathrm{dist}_{\mathcal{M}}(y, z) \geq \mathrm{dist}_{\mathcal{M}}(x, z)$.

For simplicity, we often write metric space $\mathcal{M}$ for $(\mathcal{M}, \mathrm{dist}_{\mathcal{M}})$. We also use dist without the subscript to represent the standard Euclidean metric over $\mathbb{R}^n$ (for some n that is clear from the context). A (metric) embedding is a mapping from one metric space to another.

▶ **Definition 2.1.** *Suppose $F : \mathcal{M}_1 \to \mathcal{M}_2$ is an embedding of metric space $\mathcal{M}_1$ into $\mathcal{M}_2$. The distortion of F is defined by*

$$\inf\left\{ \frac{c_u}{c_l} : \forall x, y \in \mathcal{M}_1,\ c_l \cdot \mathrm{dist}_{\mathcal{M}_1}(x, y) \leq \mathrm{dist}_{\mathcal{M}_2}(F(x), F(y)) \leq c_u \cdot \mathrm{dist}_{\mathcal{M}_1}(x, y) \right\} .$$

2.2 Lattices

We now recall some standard definitions and notations regarding lattices. A (full-rank) *lattice* $\mathcal{L} \subseteq \mathbb{R}^n$ is the set of all integer linear combinations of n linearly independent vectors. This set of vectors is called a *basis* of the lattice. Equivalently, a lattice is a discrete subgroup of the additive group $\mathbb{R}^n$. The *dual lattice* $\mathcal{L}^*$ of $\mathcal{L}$ is defined as the set of all vectors $y \in \mathrm{span}(\mathcal{L})$ such that $\langle x, y \rangle$ is an integer for all vectors $x \in \mathcal{L}$. A *sublattice* $\mathcal{L}' \subseteq \mathcal{L}$ is an additive subgroup of $\mathcal{L}$. We say that a sublattice $\mathcal{L}' \subseteq \mathcal{L}$ is *primitive* if $\mathcal{L}' = \mathcal{L} \cap \mathrm{span}(\mathcal{L}')$. All sublattices in this paper will be primitive. For a lattice $\mathcal{L}$ and a primitive sublattice $\mathcal{L}' \subseteq \mathcal{L}$, the *quotient lattice* $\mathcal{L}/\mathcal{L}'$ is defined as the projection of $\mathcal{L}$ onto the subspace orthogonal to $\mathrm{span}(\mathcal{L}')$. Sublattices and quotient lattices can be thought of as full rank while sitting inside some lower-dimensional space. For lattice $\mathcal{L} \subseteq \mathbb{R}^n$, the *torus* $\mathbb{R}^n/\mathcal{L}$ is naturally associated with the quotient metric, defined as

$$\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x}, \mathbf{y}) = \mathrm{dist}(\mathbf{x} - \mathbf{y}, \mathcal{L}) = \min_{\mathbf{v} \in \mathcal{L}} \mathrm{dist}(\mathbf{x} - \mathbf{y}, \mathbf{v}) .$$

The *length of the shortest vector* of a lattice $\mathcal{L}$, denoted by $\lambda_1(\mathcal{L})$, is defined as the minimum length of a non-zero vector in $\mathcal{L}$. Note that here and elsewhere, length refers to the Euclidean norm. The *covering radius* of a lattice $\mathcal{L}$, denoted by $\mu(\mathcal{L})$, is defined as the maximum (Euclidean) distance from any vector in $\mathrm{span}(\mathcal{L})$ to $\mathcal{L}$. Equivalently, as its name suggests, it is the minimum radius such that balls of that radius centered at all lattice points cover the entire $\mathrm{span}(\mathcal{L})$.

We end with two simple technical lemmas, where we denote by π_V the orthogonal projection onto subspace V.

▶ **Lemma 2.2.** *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, vectors $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{v} \in \mathcal{L}$ such that $\|\mathbf{x}-\mathbf{v}\| = \operatorname{dist}(\mathbf{x},\mathcal{L})$, and sublattice $\mathcal{L}' \subseteq \mathcal{L}$,*

$$\|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})\| \leq \mu(\mathcal{L}') \ .$$

Proof. Suppose towards contradiction that $\|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})\| > \mu(\mathcal{L}')$. Then consider the lattice point $\mathbf{u} \in \mathcal{L}'$ that is a closest lattice point to $\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})$ in $\mathcal{L}'$. By definition $\|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})-\mathbf{u}\| \leq \mu(\mathcal{L}')$. Observe that

$$\begin{aligned}\|\mathbf{x}-(\mathbf{v}+\mathbf{u})\|^2 &= \|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v}-\mathbf{u})\|^2 + \|\pi_{\operatorname{span}(\mathcal{L}/\mathcal{L}')}(\mathbf{x}-\mathbf{v}-\mathbf{u})\|^2 \\ &= \|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})-\mathbf{u}\|^2 + \|\pi_{\operatorname{span}(\mathcal{L}/\mathcal{L}')}(\mathbf{x}-\mathbf{v})\|^2 \\ &< \|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})\|^2 + \|\pi_{\operatorname{span}(\mathcal{L}/\mathcal{L}')}(\mathbf{x}-\mathbf{v})\|^2 \\ &= \|\mathbf{x}-\mathbf{v}\|^2 \ ,\end{aligned}$$

which contradicts with the fact that $\|\mathbf{x}-\mathbf{v}\| = \operatorname{dist}(\mathbf{x},\mathcal{L}) = \min_{\mathbf{v}'\in\mathcal{L}} \|\mathbf{x}-\mathbf{v}'\|$. ◀

▶ **Lemma 2.3.** *For any lattice $\mathcal{L}$ and sublattice $\mathcal{L}' \subseteq \mathcal{L}$,*

$$\mu(\mathcal{L})^2 \leq \mu(\mathcal{L}')^2 + \mu(\mathcal{L}/\mathcal{L}')^2 \ .$$

Proof. For any $\mathbf{x} \in \operatorname{span}(\mathcal{L})$, let $\mathbf{v} \in \mathcal{L}$ be a lattice point such that

$$\|\pi_{\operatorname{span}(\mathcal{L}/\mathcal{L}')}(\mathbf{x}-\mathbf{v})\| = \operatorname{dist}(\pi_{\operatorname{span}(\mathcal{L}/\mathcal{L}')}(\mathbf{x}),\mathcal{L}/\mathcal{L}') \ .$$

Without loss of generality it can be assumed that $\|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})\| \leq \mu(\mathcal{L}')$ (since otherwise, we can use $\mathbf{v}+\mathbf{u}$ instead of $\mathbf{v}$, where $\mathbf{u}$ is a closest lattice point to $\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})$ in $\mathcal{L}'$). Then

$$\begin{aligned}\operatorname{dist}(\mathbf{x},\mathcal{L})^2 &\leq \|\mathbf{x}-\mathbf{v}\|^2 \\ &= \|\pi_{\operatorname{span}(\mathcal{L}')}(\mathbf{x}-\mathbf{v})\|^2 + \|\pi_{\operatorname{span}(\mathcal{L}/\mathcal{L}')}(\mathbf{x}-\mathbf{v})\|^2 \\ &\leq \mu(\mathcal{L}')^2 + \mu(\mathcal{L}/\mathcal{L}')^2 \ .\end{aligned}$$

The bound holds for any vector $\mathbf{x}$. Hence $\mu(\mathcal{L})^2 \leq \mu(\mathcal{L}')^2 + \mu(\mathcal{L}/\mathcal{L}')^2$, as desired. ◀

3 Embedding Tori into Hilbert Space

The goal of this section is to prove Lemma 3.6, which summarizes the properties of the Gaussian embedding from [1], including a modified contraction property which we make explicit (see left-hand side of (1)). The proof closely follows that of [1, Theorem 1.4]. We start with some preliminary definitions and results from [1].

For $s > 0$ and $\mathbf{x} \in \mathbb{R}^n$ we define $\rho_s(\mathbf{x}) = \exp(-\pi\|\mathbf{x}/s\|^2)$. For any discrete set A, its Gaussian mass $\rho_s(A)$ is defined as $\sum_{\mathbf{x}\in A} \rho_s(\mathbf{x})$. The *smoothing parameter* of a lattice $\mathcal{L}$ is defined with respect to an $\varepsilon > 0$ and is given by

$$\eta_\varepsilon(\mathcal{L}) = \min\{s : \rho_{1/s}(\mathcal{L}^*) \leq 1+\varepsilon\} \ .$$

▶ **Lemma 3.1** ([1, Lemma 2.5])**.** *For any $n \geq 1$ and lattice $\mathcal{L} \subseteq \mathbb{R}^n$, $\eta_\varepsilon(\mathcal{L}^*) \leq \frac{2\sqrt{n}}{\lambda_1(\mathcal{L})}$ where $\varepsilon = 2^{-10n}$.*

Consider the function

$$h_{\mathcal{L},s}(\mathbf{x}) = 1 - \frac{\rho_s(\mathcal{L}-\mathbf{x})}{\rho_s(\mathcal{L})} \ .$$

Below we list some basic properties of this function, which ideally we would like to be proportional to the squared distance from the lattice. This is indeed the case, assuming the distance is not too large compared to s, and that s itself is small compared to the geometry of the lattice. The upper bound is shown in Item 1, and the lower bound is established in Items 2 and 3 (which give very similar bounds). When the distance is sufficiently larger than s, the function reaches saturation, as shown in Item 4.

▶ **Lemma 3.2** ([1, Lemmas 3.1 and 3.2]). *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, $s > 0$, and vector $\mathbf{x} \in \mathbb{R}^n$,*

1. $s^2 \cdot h_{\mathcal{L},s}(\mathbf{x}) \leq \pi \cdot \mathrm{dist}(\mathbf{x}, \mathcal{L})^2$,
2. $s^2 \cdot h_{\mathcal{L},s}(\mathbf{x}) \geq c \cdot \mathrm{dist}(\mathbf{x}, \mathcal{L})^2$ *if* $s \leq \frac{1}{2\,\eta_\varepsilon(\mathcal{L}^*)}$ *for some* $0 < \varepsilon \leq \frac{1}{1000}$ *and* $\mathrm{dist}(\mathbf{x}, \mathcal{L}) \leq \frac{s}{\sqrt{2}}$, *where c is an absolute constant,*
3. $h_{\mathcal{L},s}(\mathbf{x}) \geq 1 - e^{-\pi\,\mathrm{dist}(\mathbf{x},\mathcal{L})^2/s^2} - 2^{-11n}$ *if* $\lambda_1(\mathcal{L}) \geq 4\sqrt{n} \cdot s$,
4. $h_{\mathcal{L},s}(\mathbf{x}) \geq 1 - 2^{-11n}$ *if* $\mathrm{dist}(\mathbf{x}, \mathcal{L}) > 2\sqrt{n} \cdot s$.

▶ **Definition 3.3** ([1, Section 5]). *For lattice $\mathcal{L} \subseteq \mathbb{R}^n$ and $s > 0$, the embedding $H_{\mathcal{L},s} : \mathbb{R}^n/\mathcal{L} \to L_2(\mathbb{R}^n/\mathcal{L})$ maps vector $\mathbf{x} \in \mathbb{R}^n$ to the function $H_{\mathcal{L},s}(\mathbf{x}) \in L_2(\mathbb{R}^n/\mathcal{L})$ given by*

$$H_{\mathcal{L},s}(\mathbf{x})(\mathbf{y}) = \frac{s}{\sqrt{2\rho_s(\mathcal{L})}} \left(\frac{2}{s}\right)^{n/2} \rho_{\frac{s}{\sqrt{2}}}(\mathcal{L} + \mathbf{y} - \mathbf{x}) \ .$$

▶ **Lemma 3.4** ([1, Proposition 5.1]). *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, $s > 0$, and vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, $\mathrm{dist}_{L_2(\mathbb{R}^n/\mathcal{L})}(H_{\mathcal{L},s}(\mathbf{x}), H_{\mathcal{L},s}(\mathbf{y}))^2 = s^2 \cdot h_{\mathcal{L},s}(\mathbf{x} - \mathbf{y})$.*

▶ **Definition 3.5** ([1, Section 5.1]). *For lattice $\mathcal{L} \subseteq \mathbb{R}^n$, $s > 0$, and $k \geq 1$, the embedding $H^{(k)}_{\mathcal{L},s}$ is defined by $H^{(k)}_{\mathcal{L},s} = (H_{\mathcal{L},s_1}, \ldots, H_{\mathcal{L},s_k})$ where $s_i = 2^{i-1}s$. We often take $s = \lambda_1(\mathcal{L})/(4\sqrt{n})$, in which case we omit the subscript s and simply write $H^{(k)}_{\mathcal{L}}$.*

▶ **Lemma 3.6.** *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, $k \geq 1$, and vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$,*

$$\begin{aligned} \frac{c_H}{n} \cdot \min(\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x}, \mathbf{y}), 2^{k-1}\,\lambda_1(\mathcal{L}))^2 &\leq \mathrm{dist}_{L_2(\mathbb{R}^n/\mathcal{L})^k}(H^{(k)}_{\mathcal{L}}(\mathbf{x}), H^{(k)}_{\mathcal{L}}(\mathbf{y}))^2 \\ &\leq \pi k \cdot \mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x}, \mathbf{y})^2 \ , \end{aligned} \tag{1}$$

where $c_H > 0$ is an absolute constant.

Proof. By Lemma 3.4, and recalling the notation $s_i = 2^{i-1}s$ where $s = \frac{\lambda_1(\mathcal{L})}{4\sqrt{n}}$,

$$\begin{aligned} \mathrm{dist}_{L_2(\mathbb{R}^n/\mathcal{L})^k}(H^{(k)}_{\mathcal{L}}(\mathbf{x}), H^{(k)}_{\mathcal{L}}(\mathbf{y}))^2 &= \sum_{i=1}^{k} \mathrm{dist}_{L_2(\mathbb{R}^n/\mathcal{L})}(H_{\mathcal{L},s_i}(\mathbf{x}), H_{\mathcal{L},s_i}(\mathbf{y}))^2 \\ &= \sum_{i=1}^{k} s_i^2 \cdot h_{\mathcal{L},s_i}(\mathbf{x} - \mathbf{y}) \ . \end{aligned}$$

Noting that $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x}, \mathbf{y}) = \mathrm{dist}(\mathbf{x} - \mathbf{y}, \mathcal{L})$, the upper bound in (1) follows from Item 1 in Lemma 3.2:

$$\sum_{i=1}^{k} s_i^2 \cdot h_{\mathcal{L},s_i}(\mathbf{x} - \mathbf{y}) \leq \sum_{i=1}^{k} \pi \cdot \mathrm{dist}(\mathbf{x} - \mathbf{y}, \mathcal{L})^2 = \pi k \cdot \mathrm{dist}(\mathbf{x} - \mathbf{y}, \mathcal{L})^2 \ .$$

For the lower bound in (1), we will show that for any $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, there exists $i \in \{1, \ldots, k\}$ such that

$$s_i^2 \cdot h_{\mathcal{L},s_i}(\mathbf{x} - \mathbf{y}) \geq \frac{c_H}{n} \cdot \min(\mathrm{dist}(\mathbf{x} - \mathbf{y}, \mathcal{L}), 2^{k-1}\,\lambda_1(\mathcal{L}))^2 \ . \tag{2}$$

We consider three cases.

1. $\operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L}) \le \frac{\lambda_1(\mathcal{L})}{4\sqrt{2n}} = \frac{s}{\sqrt{2}}$. Note that according to Lemma 3.1, $s \le \frac{1}{2\,\eta_\varepsilon(\mathcal{L}^*)}$ for some $0 < \varepsilon \le \frac{1}{1000}$. Then by Item 2 of Lemma 3.2,

$$s^2 \cdot h_{\mathcal{L},s}(\mathbf{x}-\mathbf{y}) \ge c \cdot \operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L})^2 \ge \frac{c}{n} \cdot \operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L})^2 ,$$

   which proves (2) with $i = 1$.
2. $\frac{s}{\sqrt{2}} < \operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L}) \le \lambda_1(\mathcal{L}) = 4\sqrt{n} \cdot s$. By Item 3 of Lemma 3.2,

$$\begin{aligned} s^2 \cdot h_{\mathcal{L},s}(\mathbf{x}-\mathbf{y}) &\ge s^2 \cdot (1 - e^{-\pi/2} - 2^{-11n}) \\ &= \frac{1 - e^{-\pi/2} - 2^{-11n}}{16n} \cdot \lambda_1(\mathcal{L})^2 \\ &\ge \frac{1 - e^{-\pi/2} - 2^{-11n}}{16n} \cdot \operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L})^2 , \end{aligned}$$

   which again proves (2) with $i = 1$.
3. $\operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L}) > 4\sqrt{n} \cdot s$. Let $j \in \{2,\dots,k\}$ be the largest index such that $2\sqrt{n} \cdot s_j < \operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L})$. Notice that if $j < k$ then $4\sqrt{n} \cdot s_j = 2\sqrt{n} \cdot s_{j+1} \ge \operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L})$, and that if $j = k$, then $4\sqrt{n} \cdot s_j = 2^{k-1}\,\lambda_1(\mathcal{L})$. Then by Item 4 of Lemma 3.2,

$$\begin{aligned} s_j^2 \cdot h_{\mathcal{L},s_j}(\mathbf{x}-\mathbf{y}) &\ge s_j^2 \cdot (1 - 2^{-11n}) \\ &= \frac{1 - 2^{-11n}}{16n} \cdot (4\sqrt{n} \cdot s_j)^2 \\ &\ge \frac{1 - 2^{-11n}}{16n} \cdot \min(\operatorname{dist}(\mathbf{x}-\mathbf{y},\mathcal{L}), 2^{k-1}\,\lambda_1(\mathcal{L}))^2 , \end{aligned}$$

   which proves (2) with $i = j$. ◀

4 Embedding into Tori

The goal of this section is to prove Lemma 4.13, which shows that there exists an embedding from an arbitrary torus into a tuple of tori with good geometry. The embedding is constructed based on "good filtrations," which we define and instantiate in Section 4.1. The definition of the embedding is given in Section 4.2, and its expansion and contraction properties are shown in Section 4.3 and Section 4.4 respectively. The contraction property matches the modified notion of contraction used in Lemma 3.6.

4.1 Good Filtrations

In this section we define the notion of a (q,γ)-*filtration* (Definition 4.1) and show how to construct a good one for every lattice (Lemma 4.3). We also include a small technical lemma that will be useful later (Lemma 4.4).

A *filtration* of a lattice $\mathcal{L}$ is a chain of sublattices $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$. We call m the *size* of the filtration.

▶ **Definition 4.1.** *For $q \ge 1$, $\gamma > 1$, we say that a filtration $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$ is a* (q,γ)-filtration *if it satisfies both*

1. $\mu(\mathcal{L}_j/\mathcal{L}_{j-1}) \le q\,\lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})/2$ *for all* $1 \le j \le m$, *and*
2. $\lambda_1(\mathcal{L}_{j+1}/\mathcal{L}_j) \ge \gamma\,\lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})$ *for all* $1 \le j < m$.

Our construction of good filtrations is based on Korkine-Zolotarev bases, defined next. Recall first that for a sequence of vectors $(\mathbf{b}_1, \ldots, \mathbf{b}_n)$, its *Gram-Schmidt orthogonalization* $(\mathbf{b}'_1, \ldots, \mathbf{b}'_n)$ is defined by

$$\mathbf{b}'_i = \mathbf{b}_i - \sum_{j=1}^{i-1} \mu_{i,j} \mathbf{b}'_j \ , \quad \text{where } \mu_{i,j} = \frac{\langle \mathbf{b}_i, \mathbf{b}'_j \rangle}{\langle \mathbf{b}'_j, \mathbf{b}'_j \rangle} \ ,$$

i.e., $\mathbf{b}'_i$ is the projection of $\mathbf{b}_i$ on the space orthogonal to $\text{span}(\mathbf{b}_1, \ldots, \mathbf{b}_{i-1})$.

▶ **Definition 4.2.** *A basis $(\mathbf{b}_1, \ldots, \mathbf{b}_n)$ for a lattice $\mathcal{L} \subseteq \mathbb{R}^n$ is called a* Korkine-Zolotarev basis *if*

- *$\mathbf{b}'_i$ is a shortest vector of $\mathcal{L}/\mathcal{L}_{i-1}$ for all $1 \le i \le n$, and*
- *$|\mu_{i,j}| \le 1/2$ for all $1 \le j < i \le n$,*

where $(\mathbf{b}'_1, \ldots, \mathbf{b}'_n)$ is the Gram-Schmidt orthogonalization of $(\mathbf{b}_1, \ldots, \mathbf{b}_n)$, $\mu_{i,j}$ are the corresponding coefficients, and $\mathcal{L}_i$ is the lattice generated by $(\mathbf{b}_1, \ldots, \mathbf{b}_i)$ (with $\mathcal{L}_0 = \{\mathbf{0}\}$).

It is easy to prove that a Korkine-Zolotarev basis exists for any lattice. We remark that the second property above will not be used in this paper.

▶ **Lemma 4.3.** *For any $n \ge 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, and $\gamma > 1$, there exists a $(\gamma\sqrt{n}, \gamma)$-filtration of $\mathcal{L}$.*

Proof. Let $(\mathbf{b}_1, \ldots, \mathbf{b}_n)$ be a Korkine-Zolotarev basis of $\mathcal{L}$. Let $(\mathbf{b}'_1, \ldots, \mathbf{b}'_n)$ be its Gram-Schmidt orthogonalization, and consider the filtration $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_n = \mathcal{L}$ where $\mathcal{L}_i$ is the lattice generated by $(\mathbf{b}_1, \ldots, \mathbf{b}_i)$. From Definition 4.2 we know that $\lambda_1(\mathcal{L}/\mathcal{L}_{i-1}) = \|\mathbf{b}'_i\| = \lambda_1(\mathcal{L}_k/\mathcal{L}_{i-1})$, for all $1 \le i \le k \le n$. Construct a coarsening of this filtration, $\{\mathbf{0}\} = \mathcal{L}_{i_0} \subset \mathcal{L}_{i_1} \subset \cdots \subset \mathcal{L}_{i_m} = \mathcal{L}$, as follows. Let $i_0 = 0$ and for $j \ge 1$, $i_j \in \{i_{j-1}+1, \ldots, n\}$ be the largest index such that $\|\mathbf{b}'_k\| \le \gamma \|\mathbf{b}'_{i_{j-1}+1}\|$ for all $k \in \{i_{j-1}+1, \ldots, i_j\}$. Finally, stop when $i_m = n$. We are going to show that this coarser filtration is a $(\gamma\sqrt{n}, \gamma)$-filtration.

We observe that for all $1 \le j \le m$,

$$\lambda_1(\mathcal{L}_{i_j}/\mathcal{L}_{i_{j-1}}) = \|\mathbf{b}'_{i_{j-1}+1}\| \ .$$

Then, by construction of the coarsening, for all $1 \le j < m$,

$$\lambda_1(\mathcal{L}_{i_{j+1}}/\mathcal{L}_{i_j}) = \|\mathbf{b}'_{i_j+1}\| > \gamma \|\mathbf{b}'_{i_{j-1}+1}\| = \gamma \, \lambda_1(\mathcal{L}_{i_j}/\mathcal{L}_{i_{j-1}}) \ .$$

This proves the second property of a $(\gamma\sqrt{n}, \gamma)$-filtration. Moreover,

$$\begin{aligned}
\mu(\mathcal{L}_{i_j}/\mathcal{L}_{i_{j-1}})^2 &\le \sum_{k=i_{j-1}+1}^{i_j} \mu(\mathcal{L}_k/\mathcal{L}_{k-1})^2 \\
&= \sum_{k=i_{j-1}+1}^{i_j} \|\mathbf{b}'_k\|^2/4 \\
&\le \sum_{k=i_{j-1}+1}^{i_j} \gamma^2 \|\mathbf{b}'_{i_{j-1}+1}\|^2/4 \\
&\le \gamma^2 n \cdot \lambda_1(\mathcal{L}_{i_j}/\mathcal{L}_{i_{j-1}})^2/4 \ ,
\end{aligned}$$

where the first inequality is by Lemma 2.3 and the second inequality is by construction of the coarsening. This proves the first property of a $(\gamma\sqrt{n}, \gamma)$-filtration. ◀

We end by proving a small property of (q, γ)-filtrations.

▶ **Lemma 4.4.** *For any (q,γ)-filtration $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$ and $1 \le j \le m$,*

$$\mu(\mathcal{L}_j) \le \frac{q}{\sqrt{1-1/\gamma^2}} \cdot \lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})/2 \ .$$

Consequently, if $\gamma \ge 2$, then $\mu(\mathcal{L}_j) \le q\,\lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})$.

Proof. The inequality can be proved as follows:

$$\begin{aligned}
\mu^2(\mathcal{L}_j) &\le \sum_{i=1}^{j} \mu^2(\mathcal{L}_i/\mathcal{L}_{i-1}) \\
&\le \sum_{i=1}^{j} q^2\,\lambda_1^2(\mathcal{L}_i/\mathcal{L}_{i-1})/4 \\
&\le \sum_{i=1}^{j} \frac{q^2}{\gamma^{2(j-i)}} \cdot \lambda_1^2(\mathcal{L}_j/\mathcal{L}_{j-1})/4 \\
&\le \frac{q^2}{1-1/\gamma^2} \cdot \lambda_1^2(\mathcal{L}_j/\mathcal{L}_{j-1})/4 \ ,
\end{aligned}$$

where the first inequality uses Lemma 2.3, the second inequality uses the first property in Definition 4.1, and the third inequality uses the second property in Definition 4.1. ◀

4.2 The Embedding

Let $\mathcal{F}$ be a filtration $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$ of a lattice $\mathcal{L} \subseteq \mathbb{R}^n$. The filtration naturally induces an orthogonal decomposition of $\mathbb{R}^n$ into m subspaces, namely, $\mathrm{span}(\mathcal{L}_j/\mathcal{L}_{j-1})$ for $j = 1, \ldots, m$. We use $\pi_{\mathcal{F},j}$ to denote $\pi_{\mathrm{span}(\mathcal{L}_j/\mathcal{L}_{j-1})}$, the projection on the j-th subspace. We will similarly use $\pi^{\ge}_{\mathcal{F},j}$, $\pi^{<}_{\mathcal{F},j}$, $\pi^{>}_{\mathcal{F},j}$, and $\pi^{\le}_{\mathcal{F},j}$ to denote projections on the span of prefixes and suffixes of this decomposition. Specifically, for $1 \le j \le m$ we have $\pi^{\ge}_{\mathcal{F},j} = \pi_{\mathrm{span}(\mathcal{L}/\mathcal{L}_{j-1})}$, $\pi^{<}_{\mathcal{F},j} = \pi_{\mathrm{span}(\mathcal{L}_{j-1})}$, $\pi^{>}_{\mathcal{F},j} = \pi_{\mathrm{span}(\mathcal{L}/\mathcal{L}_j)}$, and $\pi^{\le}_{\mathcal{F},j} = \pi_{\mathrm{span}(\mathcal{L}_j)}$.

▶ **Definition 4.5.** *For filtration $\mathcal{F}$ of size m, $0 < \alpha < 1$, and $1 \le j \le m$, the embedding $E_{\mathcal{F},\alpha,j}$ is defined by*

$$E_{\mathcal{F},\alpha,j}(\mathbf{x}) = \sum_{i=j}^{m} \alpha^{i-j} \pi_{\mathcal{F},i}(\mathbf{x}) \ .$$

Note that since $E_{\mathcal{F},\alpha,j}$ is linear, for any lattice $\mathcal{L} \subseteq \mathbb{R}^n$ and vector $\mathbf{x} \in \mathbb{R}^n$, $E_{\mathcal{F},\alpha,j}(\mathbf{x}+\mathcal{L}) = E_{\mathcal{F},\alpha,j}(\mathbf{x}) + E_{\mathcal{F},\alpha,j}(\mathcal{L})$, and thus $E_{\mathcal{F},\alpha,j}$ is a well-defined embedding from the torus $\mathbb{R}^n/\mathcal{L}$ to the torus $E_{\mathcal{F},\alpha,j}(\mathbb{R}^n/\mathcal{L})$.

▶ **Definition 4.6.** *For a filtration $\mathcal{F}$ of size m and $0 < \alpha < 1$, the embedding $E_{\mathcal{F},\alpha}$ is defined by $E_{\mathcal{F},\alpha} = (E_{\mathcal{F},\alpha,1}, \ldots, E_{\mathcal{F},\alpha,m})$ with the metric being ℓ_2 of the tori metrics.*

4.3 Expansion of the Embedding

▶ **Definition 4.7** (Realization of distance in torus)**.** *For any $n \ge 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, and vector $\mathbf{x} \in \mathbb{R}^n$, since $\mathrm{dist}(\mathbf{x},\mathcal{L}) = \min_{\mathbf{v}\in\mathcal{L}} \|\mathbf{x}-\mathbf{v}\|$, there always exists $\mathbf{v} \in \mathcal{L}$ such that $\mathrm{dist}(\mathbf{x},\mathcal{L}) = \|\mathbf{x}-\mathbf{v}\|$. We say such minimizer $\mathbf{v}$* realizes *the distance $\mathrm{dist}(\mathbf{x},\mathcal{L})$. Similarly, for vectors $\mathbf{x},\mathbf{y} \in \mathbb{R}^n$, we say $\mathbf{v}$* realizes *the distance $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})$ if $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y}) = \|\mathbf{x}-\mathbf{y}-\mathbf{v}\|$.*

▶ **Lemma 4.8** (Expansion of the embedding). *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$ with filtration $\mathcal{F}$, $0 < \alpha < 1$, and vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$,*

$$\begin{aligned}\mathrm{dist}_{E_{\mathcal{F},\alpha}(\mathbb{R}^n/\mathcal{L})}(E_{\mathcal{F},\alpha}(\mathbf{x}), E_{\mathcal{F},\alpha}(\mathbf{y}))^2 &:= \sum_{j=1}^{m} \mathrm{dist}_{E_{\mathcal{F},\alpha,j}(\mathbb{R}^n/\mathcal{L})}(E_{\mathcal{F},\alpha,j}(\mathbf{x}), E_{\mathcal{F},\alpha,j}(\mathbf{y}))^2 \\ &\leq \frac{1}{1-\alpha^2} \cdot \mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})^2 \ .\end{aligned}$$

Proof. Let m be the size of $\mathcal{F}$. For all $\mathbf{v} \in \mathcal{L}$, the embedded distance can be bounded from above by

$$\begin{aligned}\sum_{j=1}^{m} \mathrm{dist}_{E_{\mathcal{F},\alpha,j}(\mathbb{R}^n/\mathcal{L})}(E_{\mathcal{F},\alpha,j}(\mathbf{x}), E_{\mathcal{F},\alpha,j}(\mathbf{y}))^2 &\leq \sum_{j=1}^{m} \|E_{\mathcal{F},\alpha,j}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 \\ &= \sum_{j=1}^{m}\sum_{i=j}^{m} \alpha^{2(i-j)} \|\pi_{\mathcal{F},i}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 \\ &\leq \frac{1}{1-\alpha^2} \cdot \sum_{i=1}^{m} \|\pi_{\mathcal{F},i}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 \\ &= \frac{1}{1-\alpha^2} \cdot \|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2 \ ,\end{aligned}$$

which, for $\mathbf{v}$ realizing $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})$, gives $\frac{1}{1-\alpha^2} \cdot \mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})^2$ as desired. ◀

4.4 Contraction of the Embedding

▶ **Lemma 4.9.** *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$, lattice point $\mathbf{v}' \in \mathcal{L}$ realizing $\mathrm{dist}(\mathbf{x},\mathcal{L})$, and lattice point $\mathbf{v} \in \mathcal{L}$,*

$$\|\mathbf{x}-\mathbf{v}\| \geq \frac{1}{2}\|\mathbf{v}-\mathbf{v}'\| \ .$$

Consequently, if $\mathbf{v}$ does not realize $\mathrm{dist}(\mathbf{x},\mathcal{L})$, then $\mathbf{v} \neq \mathbf{v}'$ and

$$\|\mathbf{x}-\mathbf{v}\| \geq \frac{1}{2}\,\lambda_1(\mathcal{L}) \ .$$

Proof. By definition, $\|\mathbf{x}-\mathbf{v}'\| \leq \|\mathbf{x}-\mathbf{v}\|$. Then by the triangle inequality, $\|\mathbf{v}-\mathbf{v}'\| \leq \|\mathbf{x}-\mathbf{v}\| + \|\mathbf{x}-\mathbf{v}'\| \leq 2\|\mathbf{x}-\mathbf{v}\|$, as desired. ◀

▶ **Lemma 4.10.** *For any (q,γ)-filtration $\mathcal{F}$ given by $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$, $1/\gamma \leq \alpha < 1$, and $1 \leq j \leq m$, $\lambda_1(E_{\mathcal{F},\alpha,j}(\mathcal{L})) = \lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})$.*

Proof. We prove the claim by induction on j. When $j = m$, $E_{\mathcal{F},\alpha,m}(\mathcal{L}) = \mathcal{L}_m/\mathcal{L}_{m-1}$, and thus the claim holds trivially.

Suppose the claim holds for $j+1$. Then for j, note that $\mathcal{L}_j/\mathcal{L}_{j-1} \subseteq E_{\mathcal{F},\alpha,j}(\mathcal{L})$. Therefore $\lambda_1(E_{\mathcal{F},\alpha,j}(\mathcal{L}))$ is the minimum of $\lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})$ and the minimum length of vectors in the set $E_{\mathcal{F},\alpha,j}(\mathcal{L}) \setminus (\mathcal{L}_j/\mathcal{L}_{j-1})$. Since $E_{\mathcal{F},\alpha,j} = \pi_{\mathcal{F},j} + \alpha E_{\mathcal{F},\alpha,j+1}$, the length of any vector in $E_{\mathcal{F},\alpha,j}(\mathcal{L}) \setminus (\mathcal{L}_j/\mathcal{L}_{j-1})$ is bounded from below by

$$\begin{aligned}\alpha\,\lambda_1(E_{\mathcal{F},\alpha,j+1}(\mathcal{L})) &= \alpha\,\lambda_1(\mathcal{L}_{j+1}/\mathcal{L}_j) \\ &\geq \alpha\gamma\,\lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1}) \\ &\geq \lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1}) \ ,\end{aligned}$$

where the equality is the induction assumption and the first inequality uses the second property in Definition 4.1. Hence $\lambda_1(E_{\mathcal{F},\alpha,j}(\mathcal{L})) = \lambda_1(\mathcal{L}_j/\mathcal{L}_{j-1})$, as desired. ◀

Combining Lemma 4.10 with Lemma 4.4 as well as Definition 4.1, we immediately get the following corollary.

▶ **Corollary 4.11.** *For any (q,γ)-filtration $\mathcal{F}$ given by $\{\mathbf{0}\} = \mathcal{L}_0 \subset \mathcal{L}_1 \subset \cdots \subset \mathcal{L}_m = \mathcal{L}$ with $\gamma \geq 2$ and $1/\gamma \leq \alpha < 1$,*
1. *$\mu(\mathcal{L}_j) \leq q\,\lambda_1(E_{\mathcal{F},\alpha,j}(\mathcal{L}))$ for all $1 \leq j \leq m$, and*
2. *$\lambda_1(E_{\mathcal{F},\alpha,j+1}(\mathcal{L})) \geq \gamma\,\lambda_1(E_{\mathcal{F},\alpha,j}(\mathcal{L}))$ for all $1 \leq j < m$.*

▶ **Lemma 4.12** (Contraction of the embedding)**.** *For any $n \geq 1$, lattice $\mathcal{L} \subseteq \mathbb{R}^n$ with (q,γ)-filtration $\mathcal{F}$ of size m satisfying $\gamma \geq 2$ and $q \leq \gamma^2/32$, $\frac{1}{2} \leq \alpha < 1$, and vectors $\mathbf{x},\mathbf{y} \in \mathbb{R}^n$,*

$$\sum_{j=1}^{m} \min\Big(\mathrm{dist}_{E_{\mathcal{F},\alpha,j}(\mathbb{R}^n/\mathcal{L})}(E_{\mathcal{F},\alpha,j}(\mathbf{x}), E_{\mathcal{F},\alpha,j}(\mathbf{y})), q^2\,\lambda_1(E_{\mathcal{F},\alpha,j}(\mathcal{L}))\Big)^2 \geq c_E \cdot \mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})^2\,, \quad (3)$$

where $c_E > 0$ is an absolute constant.

Proof. For simplicity, we omit the subscript $\mathcal{F}$ in the notations $\pi_{\mathcal{F},j}$, $\pi^{\geqslant}_{\mathcal{F},j}$, $\pi^{<}_{\mathcal{F},j}$, $\pi^{>}_{\mathcal{F},j}$, $\pi^{\leqslant}_{\mathcal{F},j}$, $E_{\mathcal{F},\alpha,j}$ and $E_{\mathcal{F},\alpha}$ in this proof.

Let $\mathbf{v} \in \mathcal{L}$ be a lattice point that realizes $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})$. Then $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y}) = \|\mathbf{x}-\mathbf{y}-\mathbf{v}\|$. Hence our goal is equivalently to show that the left-hand side of (3) satisfies

$$\sum_{j=1}^{m} \min\Big(\mathrm{dist}_{E_{\alpha,j}(\mathbb{R}^n/\mathcal{L})}(E_{\alpha,j}(\mathbf{x}), E_{\alpha,j}(\mathbf{y})), q^2\,\lambda_1(E_{\alpha,j}(\mathcal{L}))\Big)^2 \geq c_E \cdot \|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2\,. \quad (4)$$

Let $j_1 \in \{0,1,\ldots,m\}$ be the smallest index satisfying that for all $j \in \{j_1+1,\ldots,m\}$, $E_{\alpha,j}(\mathbf{v})$ realizes $\mathrm{dist}_{E_{\alpha,j}(\mathbb{R}^n/\mathcal{L})}(E_{\alpha,j}(\mathbf{x}), E_{\alpha,j}(\mathbf{y}))$. Then for all $j \in \{j_1+1,\ldots,m\}$,

$$\begin{aligned}\mathrm{dist}_{E_{\alpha,j}(\mathbb{R}^n/\mathcal{L})}(E_{\alpha,j}(\mathbf{x}), E_{\alpha,j}(\mathbf{y})) &= \|E_{\alpha,j}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \\ &\geq \|\pi_j(\mathbf{x}-\mathbf{y}-\mathbf{v})\|\,.\end{aligned} \quad (5)$$

Moreover, according to Lemma 2.2 and Corollary 4.11,

$$\|\pi_j(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \leq \|\pi^{\leqslant}_j(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \leq \mu(\mathcal{L}_j) \leq q\,\lambda_1(E_{\alpha,j}(\mathcal{L})) \leq q^2\,\lambda_1(E_{\alpha,j}(\mathcal{L}))\,. \quad (6)$$

Combining (5) and (6), the left-hand side of (4) is bounded from below by

$$\sum_{j=j_1+1}^{m} \|\pi_j(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 = \|\pi^{>}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2\,. \quad (7)$$

If it is the case that

$$\|\pi^{>}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 \geq \frac{1}{2}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2\,,$$

then (7) clearly suffices to prove (4). So from now on we assume that

$$\begin{aligned}&\|\pi^{>}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 < \frac{1}{2}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2\,,\\ \text{i.e., }&\|\pi^{\leqslant}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 > \frac{1}{2}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2\,.\end{aligned} \quad (8)$$

In particular, this implies $j_1 > 0$. Then, by definition of j_1, $E_{\alpha,j_1}(\mathbf{v})$ does not realize $\mathrm{dist}_{E_{\alpha,j_1}(\mathbb{R}^n/\mathcal{L})}(E_{\alpha,j_1}(\mathbf{x}), E_{\alpha,j_1}(\mathbf{y}))$, which, by using Lemma 4.9 with lattice $E_{\alpha,j_1}(\mathcal{L})$, implies

$$\|E_{\alpha,j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \geq \frac{1}{2}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L}))\,. \quad (9)$$

Under assumption (8), it suffices to prove that there exists an index $j_0 \in \{1, \ldots, m\}$ such that

$$\min\left(\mathrm{dist}_{E_{\alpha,j_0}(\mathbb{R}^n/\mathcal{L})}(E_{\alpha,j_0}(\mathbf{x}), E_{\alpha,j_0}(\mathbf{y})), q^2\,\lambda_1(E_{\alpha,j_0}(\mathcal{L}))\right)^2 \geq c \cdot \|\pi^{\leq}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 ,$$

or equivalently,

$$\|E_{\alpha,j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|^2 \geq c \cdot \|\pi^{\leq}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 \text{ , and} \tag{10}$$

$$q^4\,\lambda_1^2(E_{\alpha,j_0}(\mathcal{L})) \geq c \cdot \|\pi^{\leq}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 , \tag{11}$$

where $\mathbf{v}' \in \mathcal{L}$ is a lattice point such that $E_{\alpha,j_0}(\mathbf{v}')$ realizes $\mathrm{dist}_{E_{\alpha,j_0}(\mathbb{R}^n/\mathcal{L})}(E_{\alpha,j_0}(\mathbf{x}), E_{\alpha,j_0}(\mathbf{y}))$, and c is some absolute constant. Note that, without loss of generality, it can be assumed that

$$\|\pi^{<}_{j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v}')\| \leq \mu(\mathcal{L}_{j_0-1}) \tag{12}$$

(since otherwise, we can use $\mathbf{v}'+\mathbf{u}$ instead of $\mathbf{v}'$, where $\mathbf{u} \in \mathcal{L}_{j_0-1}$ realizes $\mathrm{dist}(\pi^{<}_{j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v}'), \mathcal{L}_{j_0-1})$).

We choose $j_0 = j_1$ if

$$\mu(\mathcal{L}_{j_1-1}) \leq \frac{1}{4}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L})) ,$$

and otherwise $j_0 = j_1 - 1$. By Corollary 4.11 and the condition $q \leq \gamma^2/32$, we know that

$$\mu(\mathcal{L}_{j_1-2}) \leq \frac{q}{\gamma^2} \cdot \lambda_1(E_{\alpha,j_1}(\mathcal{L})) \leq \frac{1}{32}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L})) .$$

Moreover, as $\mathcal{L}_{j_1}/\mathcal{L}_{j_1-1}$ is both a quotient of $\mathcal{L}_{j_1}$ and a sublattice of $E_{\alpha,j_1}(\mathcal{L})$,

$$\mu(\mathcal{L}_{j_1}) \geq \mu(\mathcal{L}_{j_1}/\mathcal{L}_{j_1-1}) \geq \frac{1}{2}\,\lambda_1(\mathcal{L}_{j_1}/\mathcal{L}_{j_1-1}) \geq \frac{1}{2}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L}))$$

(and the last inequality is actually an equality due to Lemma 4.10). Therefore j_0 satisfies

$$\mu(\mathcal{L}_{j_0-1}) \leq \frac{1}{4}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L})) \text{ , and} \tag{13}$$

$$\mu(\mathcal{L}_{j_0}) > \frac{1}{4}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L})) . \tag{14}$$

We first prove (11) for this choice of j_0:

$$\begin{aligned} q^2\,\lambda_1(E_{\alpha,j_0}(\mathcal{L})) &\geq q\,\mu(\mathcal{L}_{j_0}) \\ &> \frac{q}{4} \cdot \lambda_1(E_{\alpha,j_1}(\mathcal{L})) \\ &\geq \frac{1}{4}\,\mu(\mathcal{L}_{j_1}) \\ &\geq \frac{1}{4}\|\pi^{\leq}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| , \end{aligned}$$

where the first and third inequalities use Corollary 4.11, the second inequality follows from (14), and the last inequality uses Lemma 2.2.

We next prove (10) for this choice of j_0. We begin with showing that

$$\pi^{\geq}_{j_2}(\mathbf{v}') = \pi^{\geq}_{j_2}(\mathbf{v}) , \tag{15}$$

where $j_2 = \min(j_1+1, m)$. Suppose towards contradiction that $\pi^{>}_{j_2}(\mathbf{v}') \neq \pi^{>}_{j_2}(\mathbf{v})$ (implying $j_2 < m$, and thus $j_2 = j_1+1$). Then, by definition, $\|E_{\alpha,j_1+2}(\mathbf{v}-\mathbf{v}')\| \geq \lambda_1(E_{\alpha,j_1+2}(\mathcal{L}))$. Hence

$$\begin{aligned}
\|\pi^{\leq}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| &> \frac{1}{2}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\| \\
&\geq \frac{1}{2}\|E_{\alpha,j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \\
&\geq \frac{1}{4}\|E_{\alpha,j_0}(\mathbf{v}-\mathbf{v}')\| \\
&\geq \frac{1}{4}\|\pi^{\geq}_{j_1+2}(E_{\alpha,j_0}(\mathbf{v}-\mathbf{v}'))\| \\
&= \frac{\alpha^{j_1-j_0+2}}{4}\|E_{\alpha,j_1+2}(\mathbf{v}-\mathbf{v}')\| \\
&\geq \frac{\alpha^{j_1-j_0+2}}{4}\,\lambda_1(E_{\alpha,j_1+2}(\mathcal{L}))\,,
\end{aligned}$$

where the first inequality follows from (8) and the third inequality uses Lemma 4.9 with lattice $E_{\alpha,j_0}(\mathcal{L})$. On the other hand, we know that $\|\pi^{\leq}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \leq \mu(\mathcal{L}_{j_1})$ according to Lemma 2.2. Then we have

$$\frac{\alpha^{j_1-j_0+2}}{4}\,\lambda_1(E_{\alpha,j_1+2}(\mathcal{L})) < \mu(\mathcal{L}_{j_1}) \leq \frac{q}{\gamma^2}\,\lambda_1(E_{\alpha,j_1+2}(\mathcal{L}))\,, \tag{16}$$

where the last inequality uses Corollary 4.11. Since $\alpha^{j_1-j_0+2} \geq \alpha^3 \geq 1/8$, (16) contradicts the condition $q \leq \gamma^2/32$.

Based on (15), we continue to prove (10) with the following observation:

$$\begin{aligned}
\|E_{\alpha,j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|^2 &= \sum_{i=j_0}^{m} \alpha^{2(i-j_0)}\|\pi_i(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|^2 \\
&\geq \alpha^{2(j_2-j_0)} \sum_{i=j_0}^{j_2} \|\pi_i(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|^2 \\
&= \alpha^{2(j_2-j_0)}(\|\mathbf{x}-\mathbf{y}-\mathbf{v}'\|^2 - \|\pi^{<}_{j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|^2 - \|\pi^{>}_{j_2}(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|^2) \\
&\geq \alpha^{2(j_2-j_0)}(\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2 - \mu^2(\mathcal{L}_{j_0-1}) - \|\pi^{>}_{j_2}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2)\,,
\end{aligned} \tag{17}$$

where the last inequality uses the following three facts: (i) as $\mathbf{v}$ realizes $\mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})$, $\|\mathbf{x}-\mathbf{y}-\mathbf{v}'\| \geq \|\mathbf{x}-\mathbf{y}-\mathbf{v}\|$; (ii) the term $\|\pi^{<}_{j_0}(\mathbf{x}-\mathbf{y}-\mathbf{v}')\|$ is bounded from above by (12); and (iii) $\pi^{>}_{j_2}(\mathbf{x}-\mathbf{y}-\mathbf{v}') = \pi^{>}_{j_2}(\mathbf{x}-\mathbf{y}-\mathbf{v})$ due to (15). Moreover, according to (13) and (9),

$$\begin{aligned}
\mu(\mathcal{L}_{j_0-1}) &\leq \frac{1}{4}\,\lambda_1(E_{\alpha,j_1}(\mathcal{L})) \\
&\leq \frac{1}{2}\|E_{\alpha,j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\| \\
&\leq \frac{1}{2}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|\,,
\end{aligned}$$

and according to (8),

$$\begin{aligned}
\|\pi^{>}_{j_2}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 &\leq \|\pi^{>}_{j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 \\
&< \frac{1}{2}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2\,.
\end{aligned}$$

Hence (17) is further bounded from below by

$$\alpha^{2(j_2-j_0)}\Big(1-\frac{1}{4}-\frac{1}{2}\Big)\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2 \geq \frac{\alpha^4}{4}\|\mathbf{x}-\mathbf{y}-\mathbf{v}\|^2 \geq \frac{\alpha^4}{4}\|\pi_{\overline{\leq} j_1}(\mathbf{x}-\mathbf{y}-\mathbf{v})\|^2 .$$

This completes the proof of (10), and the proof of the lemma. ◀

4.5 Summary of Embedding into Tori

By Lemma 4.3, for any lattice $\mathcal{L}$, there exists an $(n\sqrt{n}, n)$-filtration[2] $\mathcal{F}$ of $\mathcal{L}$. Applying Lemmas 4.8 and 4.12 to the embedding $E_{\mathcal{F},\alpha}$ with $\alpha = 1/2$, we have the following.

▶ **Lemma 4.13.** *For any sufficiently large $n \geq 1$ and lattice $\mathcal{L} \subseteq \mathbb{R}^n$, there exists $m \geq 1$ and embedding $F_{\mathcal{L}} = (F_{\mathcal{L},1}, \ldots, F_{\mathcal{L},m})$ such that each $F_{\mathcal{L},j}$ maps the torus $\mathbb{R}^n/\mathcal{L}$ to some other torus, and $F_{\mathcal{L}}$ satisfies*

$$\sum_{j=1}^{m} \mathrm{dist}_{F_{\mathcal{L},j}(\mathbb{R}^n/\mathcal{L})}(F_{\mathcal{L},j}(\mathbf{x}), F_{\mathcal{L},j}(\mathbf{y}))^2 \leq c_{E,u} \cdot \mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})^2 \text{ , and}$$

$$\sum_{j=1}^{m} \min\big(\mathrm{dist}_{F_{\mathcal{L},j}(\mathbb{R}^n/\mathcal{L})}(F_{\mathcal{L},j}(\mathbf{x}), F_{\mathcal{L},j}(\mathbf{y})), p(n)\,\lambda_1(F_{\mathcal{L},j}(\mathcal{L}))\big)^2 \geq c_{E,l} \cdot \mathrm{dist}_{\mathbb{R}^n/\mathcal{L}}(\mathbf{x},\mathbf{y})^2 ,$$

where $c_{E,u}$ and $c_{E,l}$ are positive absolute constants and $p(n)$ is a fixed polynomial.

5 Putting it All Together

▶ **Theorem 1.1.** *For any lattice $\mathcal{L} \subseteq \mathbb{R}^n$ there exists a metric embedding of $\mathbb{R}^n/\mathcal{L}$ into Hilbert space with distortion $O(\sqrt{n \log n})$.*

Proof. It suffices to show the embedding for sufficiently large n (by, say, using the embedding from [3] for small n). Consider the composition

$$\Big(H^{(k)}_{F_{\mathcal{L},1}(\mathcal{L})} \circ F_{\mathcal{L},1}, \ldots, H^{(k)}_{F_{\mathcal{L},m}(\mathcal{L})} \circ F_{\mathcal{L},m}\Big) ,$$

where $(F_{\mathcal{L},1}, \ldots, F_{\mathcal{L},m})$ is the embedding provided by Lemma 4.13. Let $k = \lceil \log_2 p(n) \rceil + 1$ (where $p(n)$ is the fixed polynomial in Lemma 4.13). By Lemma 3.6 and Lemma 4.13, noting that the modified contraction properties in both match, it follows immediately that the composed embedding has distortion at most

$$\sqrt{\frac{\pi k n \cdot c_{E,u}}{c_H \cdot c_{E,l}}} ,$$

where c_H, $c_{E,u}$ and $c_{E,l}$ are all absolute constants. Note that $k = \Theta(\log n)$. Hence the distortion of the composed embedding is $O(\sqrt{n \log n})$. ◀

[2] This choice of filtration actually only shows the Lemma 4.13 for sufficiently large n. Choosing a $(32n\sqrt{n}, 32n)$-filtration gives us the lemma for all $n \geq 1$.

Abstract

In the *Strip Packing* problem, we are given a vertical half-strip $[0, W] \times [0, +\infty)$ and a collection of open rectangles of width at most W. Our goal is to find an axis-aligned (non-overlapping) packing of such rectangles into the strip such that the maximum height OPT spanned by the packing is as small as possible. Strip Packing generalizes classical well-studied problems such as *Makespan Minimization* on identical machines (when rectangle widths are identical) and *Bin Packing* (when rectangle heights are identical). It has applications in manufacturing, scheduling and energy consumption in smart grids among others. It is NP-hard to approximate this problem within a factor $(3/2 - \varepsilon)$ for any constant $\varepsilon > 0$ by a simple reduction from the *Partition* problem. The current best approximation factor for Strip Packing is $(5/3+\varepsilon)$ by Harren et al. [Computational Geometry '14], and it is achieved with a fairly complex algorithm and analysis.

It seems plausible that Strip Packing admits a $(3/2 + \varepsilon)$-approximation. We make progress in that direction by achieving such tight approximation guarantees for a special family of instances, which we call *skewed instances*. As standard in the area, for a given constant parameter $\delta > 0$, we call *large* the rectangles with width at least δW and height at least δOPT, and *skewed* the remaining rectangles. If all the rectangles in the input are large, then one can easily compute the optimal packing in polynomial time (since the input can contain only a constant number of rectangles). We consider the complementary case where all the rectangles are skewed. This second case retains a large part of the complexity of the original problem; in particular, it is NP-hard to approximate within a factor $(3/2 - \varepsilon)$ and we provide an (almost) tight $(3/2 + \varepsilon)$-approximation algorithm.

1 Introduction

In this paper, we consider the *Strip Packing* problem, a well-studied classical rectangle packing problem (see Section 2 for a formal definition). Here, we are given a vertical half-strip of (integral) width W, plus a collection $\mathcal{R}$ of rectangles of width at most W. Our objective is to find an axis-aligned packing of $\mathcal{R}$ (where rectangles do not overlap) such that the maximum height spanned by the packing is as small as possible.

Strip Packing generalizes famous problems. For example, it generalizes Makespan Minimization (on identical machines) [11] when all the rectangle widths are 1 (here W would be the number of processors), and also generalizes Bin Packing [12] when all the rectangle heights are 1 (here the height OPT of the optimal solution would be the optimal number of bins). Strip Packing has several natural applications. For example, there are many manufacturing settings where rectangular pieces have to be cut out of some roll of raw material while using a rectangular piece of that roll of minimum length. Another application is the minimization of the peak energy consumption in smart-grids [28, 37]: here heights and widths model the energy consumption and duration, respectively, of a given set of jobs. For analogous reasons, it captures scenarios where a given set of jobs needs to be allocated a *consecutive* amount of a given resource (memory locations, frequencies, etc.) for a given amount of time.

Strip Packing is strongly NP-hard [17], and hence it is reasonable to consider approximation algorithms for it. A simple reduction from the *Partition* problem shows that it is not possible to obtain a $(\frac{3}{2} - \varepsilon)$-approximation algorithm (with polynomial running time) for any $\varepsilon > 0$ unless P=NP (more details on this reduction are given later). The first non-trivial approximation algorithm for Strip Packing, with approximation ratio 3, was given by Baker, Coffman, and Rivest [4]. The First-Fit-Decreasing-Height algorithm (FFDH) by Coffman et al. [27] gives a 2.7-approximation. Sleator [35] gave an algorithm that generates a packing of height $2OPT + \frac{h_{max}}{2}$, where h_{max} is the maximum height of a rectangle in the instance, hence achieving a 2.5-approximation. Afterwards, Steinberg [36] and Schiermeyer [34] independently improved the approximation ratio to 2. Harren and van Stee [19] first broke the barrier of 2 with their 1.9396-approximation. The present best $(\frac{5}{3} + \varepsilon)$-approximation is due to Harren et al. [18].

The Strip Packing problem has also been studied in the pseudopolynomial setting, i.e., when $N = n^{O(1)}$. After a series of recent improvements [33, 1, 16, 20, 23], Jansen and Rau [22] have given a pseudopolynomial time algorithm with an almost tight $(\frac{5}{4} + \varepsilon)$-approximation ratio.

In terms of asymptotic approximations, the barrier of $\frac{3}{2}$ can also be beaten. The best results in these terms are an AFPTAS presented by Kenyon and Rémila [29] which produces a solution of height $(1 + \varepsilon)OPT + O\left(\frac{h_{max}}{\varepsilon^2}\right)$, and an APTAS which generates a solution of height $(1 + \varepsilon)OPT + h_{max}$ by Jansen and Solis-Oba [24]. For the variant of Strip Packing *with Rotations*, where the rectangles are allowed to be rotated by 90 degrees, Jansen and van Stee [25] gave an APTAS (see also [13, 32] for related results).

1.1 Related Work

Strip Packing has rich connections with many other important geometric packing problems such as Two-dimensional Bin Packing (2BP) and Two-dimensional Geometric Knapsack (2GK). In 2BP, we are given a set of rectangles and unit square bins, and the goal is to pack

all the rectangles into minimum number of bins. The problem is known to be APX-hard [6] and the present best approximation ratio is 1.405 [7]. In 2GK, we are given a set of rectangles (with associated profit) and unit square knapsack, and the goal is to pack a subset of rectangles into the knapsack maximizing the total profit. This problem is strongly NP-hard even when all items are squares with unit profit [31]. The present-best approximation ratio is 1.89 due to Gálvez et al. [14] (see also [3, 26]).

Strip Packing has also been well studied for higher dimensions. The present best asymptotic approximation for 3-D Strip Packing is due to Jansen and Prädel [21] who presented a 1.5-approximation extending techniques from 2-D Bin Packing.

Another related problem is the *Independent Set of Rectangles* problem: here we are given a collection of axis-parallel rectangles embedded in the plane, and we need to find a maximum cardinality/weight subset of non-overlapping rectangles [2, 8, 9].

We refer the readers to [10, 30] for surveys on geometric packing problems.

1.2 Our Contribution

In this paper, we study a special case of Strip Packing, where all rectangles are *skewed*. In more detail, we say that a rectangle R is δ-*large* if, for some fixed constant $\delta > 0$, its width is at least a δ fraction of the width W of the strip and its height is at least a δ fraction of the height OPT of the optimal packing; otherwise, the rectangle is δ-*skewed*. We just say that a rectangle is large or skewed when δ is clear from the context. An instance of Strip Packing is δ-skewed if all the rectangles in the input are such.

This special case is non-trivial: in particular, the mentioned $3/2 - \varepsilon$ hardness of approximation holds also for this special case with minor adaptations (see Section 5). We also believe that this special case is practically relevant: e.g., it captures scenarios where no job can consume a significant amount of the global resource (energy, memory space, etc.) for a significant amount of time. Our main result is as follows (see Sections 3-4).

▶ **Theorem 1.** *For a given constant $\varepsilon' > 0$ and a small enough positive constant $\delta \leq (\varepsilon')^{(1/\varepsilon')^{O(1)}}$, there exists a polynomial-time $\left(\frac{3}{2} + \varepsilon'\right)$-approximation algorithm for δ-skewed Strip Packing.*

We remark that our algorithm does not need to recognize first if the instance is δ-skewed: It always returns a feasible solution, but only if the instance satisfies the requirements, its approximation ratio is guaranteed.

Our result suggests that, in order to obtain a better (possibly $3/2 + \varepsilon$) approximation for the general case of Strip Packing, one of the main obstacles is the interaction between large and skewed rectangles.

1.2.1 Organization

In Section 2, we introduce some useful notation and preliminary results. In Section 3, we prove the existence of a good enough packing with certain structural properties. The mentioned structure is exploited to derive an algorithm with the claimed approximation guarantee in Section 4. Section 5 contains our hardness of approximation result.

2 Preliminaries

A Strip Packing instance consists of a vertical strip of integral width W in the two-dimensional plane, i.e. $[0, W] \times \mathbb{R}_{\geq 0}$, and a set of open rectangles $\mathcal{R}$, where each rectangle $R \in \mathcal{R}$ is characterized by its integral height $h(R)$ and integral width $w(R)$. An embedding of $\mathcal{R}$ is

given by specifying a bottom-left position $(x(R), y(R))$ for each $R \in \mathcal{R}$. The interpretation is that R is embedded in the plane in the region $\big(x(R), x(R)+w(R)\big) \times \big(y(R), y(R)+h(R)\big)$. An embedding is a feasible packing into the strip if the following two conditions hold: (1) each $R \in \mathcal{R}$ is embedded inside the strip, namely $0 \leq x(R) \leq W - w(R)$ and $y(R) \geq 0$ and (2) rectangles do not overlap, namely, for any two $R, S \in \mathcal{R}$, $\Big(\big(x(R), x(R)+w(R)\big) \times \big(y(R), y(R)+h(R)\big)\Big) \cap \Big(\big(x(S), x(S)+w(S)\big) \times \big(y(S), y(S)+h(S)\big)\Big) = \emptyset$. The height of a feasible packing is the maximum height spanned by any embedded rectangle, namely the maximum value of $y(R)+h(R)$. The goal of Strip Packing is to compute a feasible packing of minimum height OPT. W.l.o.g. we can restrict our attention to packings where the coordinates $(x(R), y(R))$ are integral as any feasible packing can be transformed into a feasible packing satisfying this property (intuitively, by pushing rectangles to the bottom-left as much as possible while keeping feasibility).

Given a subset of rectangles $\mathcal{S} \subseteq \mathcal{R}$, we denote by $w(\mathcal{S}) := \sum_{R \in \mathcal{S}} w(R)$, $h(\mathcal{S}) := \sum_{R \in \mathcal{S}} h(R)$, and $a(\mathcal{S}) := \sum_{R \in \mathcal{S}} h(R)w(R)$ the total width, height, and area of $\mathcal{S}$, respectively. The operation of changing the bottom-left corner of a rectangle R in a given packing from $(x(R), y(R))$ to $(x(R), y(R)+a)$ will be denoted by *shifting R vertically by a*. Analogously, changing the bottom-left coordinate from $(x(R), y(R))$ to $(x(R)+a, y(R))$ will be denoted by *shifting R horizontally by a*. These operations are only allowed if the resulting packing is feasible.

A *box* of size $w \times h$ denotes a rectangular region of width w and height h. We sometimes embed boxes into the strip similarly to rectangles. A monotone polygonal chain is a curve specified by a sequence of points $(A_1, A_2, \ldots, A_n)$ called its vertices. The curve itself consists of the line segments connecting the consecutive vertices, and we require that the x-coordinates of points A_i are non-decreasing and the segments are horizontal or vertical. We say that a rectangle R in the packing *lies above (resp. below)* one such P if for any $x_1 \in (x(R), x(R)+w(R))$ we have that $y(R)$ (resp. $y(R)+h(R)$) is not smaller (resp. not larger) than the largest (resp., smallest) y-coordinate of P at x-coordinate x_1.

We can assume w.l.o.g. that W is lower bounded by a sufficiently large constant, in particular $W \geq 1/\varepsilon$. Otherwise one easily obtains a PTAS for δ-skewed instances[1].

2.1 Next Fit Decreasing Height

One of the most recurring tools used as a subroutine in countless results on geometric packing problems is the Next Fit Decreasing Height (NFDH) algorithm, which was originally analyzed in [27]. We will use a variant of this algorithm to pack rectangles inside a rectangular box and analyze its properties. We provide a full proof for the sake of completeness.

Suppose we are given a box C of size $w \times h$, and a set of rectangles $\mathcal{R}'$ each one fitting in the box. NFDH computes in polynomial time a packing of $\mathcal{R}'' \subseteq \mathcal{R}'$ as follows. It sorts the rectangles $R \in \mathcal{R}'$ in non-increasing order of height $h(R)$, and considers rectangles in that order $R_1, \ldots, R_n$. Then the algorithm works in rounds $j \geq 1$. At the beginning of round j it is given an index $n(j)$ and a horizontal segment $L(j)$ going from the left to the right side of C. Initially $n(1) = 1$ and $L(1)$ is the bottom side of C. In round j the algorithm packs a maximal set of rectangles $R_{n(j)}, \ldots, R_{n(j+1)-1}$, with bottom side touching $L(j)$ one next to the other from left to right (a *shelf*). The segment $L(j+1)$ is the horizontal segment

[1] Choosing δ such that $\delta W < 1$ enforces each rectangle to have height at most δOPT (otherwise it would be large). A PTAS follows, e.g., from [24].

containing the top side of $R_{n(j)}$ and ranging from the left to the right side of C. The process halts at round r when either all rectangles have being packed or $R_{n(r+1)}$ does not fit above $R_{n(r)}$.

We prove the following standard result.

▶ **Lemma 2** ([27]). *Let C be a given box of size $w \times h$ and $\mathcal{R}' \subseteq \mathcal{R}$. Assume that, for some given parameter $\varepsilon' \in (0,1)$, for each $R \in \mathcal{R}'$ one has $w(R) \leq \varepsilon' w$ and $h(R) \leq \varepsilon' h$. Then NFDH is able to pack in C a subset $\mathcal{R}'' \subseteq \mathcal{R}'$ of area at least $a(\mathcal{R}'') \geq \min\{a(\mathcal{R}'), (1-2\varepsilon')w \cdot h\}$. In particular, if $a(\mathcal{R}') \leq (1-2\varepsilon')w \cdot h$, all rectangles in $\mathcal{R}'$ are packed.*

Proof. The claim trivially holds if all rectangles are packed. Thus suppose that this is not the case. Observe that $\sum_{j=1}^{r+1} h(R_{n(j)}) > h$, otherwise rectangle $R_{n(r+1)}$ would fit in the next shelf above $R_{n(r)}$; hence $\sum_{j=2}^{r+1} h(R_{n(j)}) > h - h(R_{n(1)}) \geq (1-\varepsilon')h$. Observe also that the total width of rectangles packed in each round j is at least $w - \varepsilon' w = (1-\varepsilon')w$, since $R_{n(j+1)}$, of width at most $\varepsilon' w$, does not fit to the right of $R_{n(j+1)-1}$. It follows that the total area of the rectangles packed in round j is at least $(w-\varepsilon' w)h(R_{n(j+1)-1})$, and thus

$$a(\mathcal{R}'') \geq \sum_{j=1}^{r} (1-\varepsilon')w \cdot h(R_{n(j+1)-1}) \geq (1-\varepsilon')w \sum_{j=2}^{r+1} h(R_{n(j)}) \geq (1-\varepsilon')^2 w \cdot h \geq (1-2\varepsilon')w \cdot h. \quad \blacktriangleleft$$

2.2 Container Packings

Similar to recent work on related problems (e.g., [14, 5]), we will exploit a *container-based* packing approach. The idea is to partition the solution into a constant number of axis-aligned rectangular regions (*containers*). The sizes (and therefore positions) of these containers can be *guessed* in polynomial time, and subsequently, rectangles are packed inside the containers in a simple way: either one next to the other from left to right (*vertical container*), or one on top of the other from bottom to top (*horizontal container*), or by means of NFDH (*area container*). We further require that the rectangles R packed into an area container of size $w \times h$ satisfy $w(R) \leq \varepsilon' w$ and $h(R) \leq \varepsilon' h$ for a constant $\varepsilon' > 0$ to be fixed later. We call this an ε'-area container.

We will make use of the following standard PTAS to pack rectangles into a constant number of containers. The basic idea is to reduce the problem to an instance of the Maximum Generalized Assignment Problem (GAP) with one bin per container, and then use a PTAS for the latter problem plus NFDH to repack rectangles in area containers. We recall that in GAP, we are given a collection of n items and a set of k (one-dimensional) bins, each one characterized by a positive size. Each item has a profit[2] and a positive size per bin (possibly different for different bins). Our goal is to compute a maximum profit subset of items and an assignment of them into the bins so that the total size of items packed in each bin is at most the size of the bin. GAP admits a PTAS for constant k (see e.g. Section E.2 in [15]) and the following lemma shows how to use it to pack the rectangles into a given set of containers.

▶ **Lemma 3.** *For any constant $\varepsilon' > 0$, given a set of rectangles $\mathcal{R}$ that can be packed into a given set of k containers (each container being either vertical, horizontal or ε'-area), k constant, there is an algorithm to pack $\mathcal{R}' \subseteq \mathcal{R}$ with $a(\mathcal{R}') \geq (1-3\varepsilon')a(\mathcal{R})$ into the mentioned containers.*

[2] The same item might have different profit on different knapsacks; however, we do not need this extension here.

Proof. We let $w(C_j) \times h(C_j)$ be the size of the j-th container C_j. We build an instance of GAP as follows. There is one item R per rectangle $R \in \mathcal{R}$, with profit $a(R)$. For each horizontal container C_j, we create a knapsack j of size $S_j := h(C_j)$. Furthermore, we define the size $s(R,j)$ of rectangle R w.r.t. knapsack j as $h(R)$ if $h(R) \leq h(C_j)$ and $w(R) \leq w(C_j)$. Otherwise $s(R,j) = +\infty$ (meaning that R does not fit in C_j). The construction for vertical containers is symmetric. For each area container C_j we create a knapsack j of size $S_j = a(C_j)$ and define the size $s(R,j)$ of rectangle R w.r.t. knapsack j as $a(R)$ if $h(R) \leq \varepsilon' h(C_j)$ and $w(R) \leq \varepsilon' w(C_j)$, setting $b(R,j) = +\infty$ otherwise (meaning that the rectangle is not small enough with respect to the dimensions of the container).

We next apply the mentioned PTAS for GAP to this instance, so as to obtain a solution $\mathcal{R}''$ to GAP of profit at least $a(\mathcal{R}'') \geq (1-\varepsilon')a(\mathcal{R})$. We build a feasible packing of $\mathcal{R}' \subseteq \mathcal{R}''$ into the containers as follows. Let $\mathcal{R}_j$ be the items packed into knapsack j. If C_j is vertical, we pack rectangles $\mathcal{R}_j$ into this container bottom-most and from left to right one next to the other in any order. By definition all rectangles $\mathcal{R}_j$ will fit. A symmetric construction works if C_j is horizontal. If C_j is area, we pack a subset $\mathcal{R}'_j$ of $\mathcal{R}_j$ into it using NFDH. By Lemma 2, we either have $\mathcal{R}'_j = \mathcal{R}_j$, or it must be the case that $a(\mathcal{R}'_j) \geq (1-2\varepsilon')w(C_j)h(C_j) = (1-2\varepsilon')a(C_j)$. Consider the second case. Let $\mathcal{R}''_j = \mathcal{R}_j \setminus \mathcal{R}'_j$ be the rectangles which are not packed. Observe that $a(\mathcal{R}_j) \leq a(C_j)$ by the feasibility of the GAP solution, hence

$$\frac{a(\mathcal{R}''_j)}{a(\mathcal{R}_j)} = 1 - \frac{a(\mathcal{R}'_j)}{a(\mathcal{R}_j)} \leq 1 - \frac{(1-2\varepsilon')a(C_j)}{a(\mathcal{R}_j)} \leq 2\varepsilon'.$$

Thus altogether $a(\mathcal{R}') \geq a(\mathcal{R}'')(1-2\varepsilon') \geq a(\mathcal{R})(1-2\varepsilon')(1-\varepsilon') \geq a(\mathcal{R})(1-3\varepsilon')$. ◀

Notice that the containers may have considerable free space inside, but the lemma just claims that the total area of the rectangles that the algorithm is not packing is negligible. Whenever this lemma is applied, we will pack the remaining rectangles into an extra rectangular box of small area and carefully argue where to place it.

2.3 Classification of Rectangles

From now on, we will assume that instance $(\mathcal{R}, W)$ is δ-skewed for some $\delta > 0$ to be fixed later. By OPT, we denote both the optimal height and an optimal packing: the meaning will be clear from the context. We can assume that OPT is even (otherwise, multiply heights by a factor 2).

We will assume that our algorithm is given in the input a value OPT' such that $OPT \leq OPT' \leq (1+\varepsilon)OPT$. This assumption can be removed as follows. We compute, say, a 2-approximation APX by Steinberg's algorithm for Strip Packing and then run our algorithm for all the (constantly many) values $OPT' = (1+\varepsilon)^j \frac{APX}{2(1+\varepsilon)}$ which fit in the range $[\frac{APX}{2(1+\varepsilon)}, APX(1+\varepsilon)]$. One of these values will satisfy the claim. In order to keep the notation light, we simply use OPT to denote this value OPT'. Therefore, all the approximation factors should be scaled by a factor $(1+\varepsilon)$ in order to consider the true value of OPT.

Let $\varepsilon > 0$ and assume for simplicity that $\frac{1}{\varepsilon} \in \mathbb{N}$. We will classify the rectangles according to their heights as follows:

- The set of *tall* rectangles $\mathcal{T} = \{R \in \mathcal{R} : h(R) > \frac{1}{2}OPT\}$;
- The set of *vertical* rectangles $\mathcal{V} = \{R \in \mathcal{R} : h(R) \in (\delta OPT, \frac{1}{2}OPT]\}$;
- The set of *short* rectangles $\mathcal{S} = \{R \in \mathcal{R} : h(R) \leq \delta OPT\}$;

2.4 Linear Grouping

We need the following lemma whose proof (given in the appendix) is based on *linear grouping*, a standard technique in the area of rectangle packing. Given a subset $\mathcal{S}$ of rectangles, let $\mathcal{S}_{hslice}$ be the set of rectangles obtained by taking each $R \in \mathcal{S}$ and replacing it with $h(R)$ rectangles of height 1 and width $w(R)$ (*horizontal slices*). We define symmetrically the set $\mathcal{S}_{vslice}$ of *vertical slices*. Notice that any embedding of $\mathcal{S}$ naturally induces an embedding of $\mathcal{S}_{hslice}$ and $\mathcal{S}_{vslice}$.

▶ **Lemma 4.** *Let $\varepsilon' > 0$ be a given constant, $\mathcal{P}$ be a rectangular region of size $W \times H$ and $\mathcal{H}$ be a subset or rectangles of height at most $\delta \cdot H$ each for some constant $\delta \in [1, 0)$. Suppose that $\mathcal{H}_{hslice}$ can be packed into a set $\mathcal{B}$ of $K = O_{\varepsilon'}(1)$ boxes contained in $\mathcal{P}$. Then, for $\delta \leq (\varepsilon'/K)^{(K/\varepsilon')^{O(1)}}$, there exists a partition of $\mathcal{H}$ into two sets $\mathcal{H}^{cont}$ and $\mathcal{H}^{disc}$ such that:*

1. *$\mathcal{H}^{cont}$ can be packed into a set of at most $K' = O_{\varepsilon'}(1)$ horizontal and ε'-area containers, where each container is fully contained in some box in $\mathcal{B}$.*
2. *$\mathcal{H}^{disc}$ can be packed in one horizontal container of size $\max_{R \in \mathcal{H}}\{w(R)\} \times (\varepsilon')^2 H$ and one ε'-area container of size $\varepsilon' W \times \varepsilon' H$.*
3. *The sizes of the above containers belongs to a set that can be computed in polynomial time.*

A symmetric claim holds for a subset of rectangles $\mathcal{V}'$ of width at most $\delta \cdot W$ such that $\mathcal{V}'_{vslice}$ can be packed into the corresponding boxes.

3 Existence of a Structured Solution

In this section, we will prove our main structural result.

▶ **Theorem 5.** *For any given constant $\varepsilon > 0$ and any given instance of δ-skewed Strip Packing $(\mathcal{R}, W)$ with $\delta = \Omega_\varepsilon(1)$ small enough, there exists a feasible container packing such that the following holds:*

1. *The total height of the packing is $\left(\frac{3}{2} + O(\varepsilon)\right) OPT$.*
2. *The number of containers is $O_\varepsilon(1)$ and their possible sizes belong to a set that can be computed in polynomial time.*
3. *Given any fixed ordering of $\mathcal{T}$ in non-increasing order of height, $\mathcal{T}$ can be partitioned into subsequences each one fitting in precisely one vertical container.*
4. *The packing leaves a free rectangular region (**free box**) of size $\varepsilon^2 W \times \frac{1}{2} OPT$.*

To achieve the above result, we proceed in three steps:

1. We describe a packing of $\mathcal{T} \cup \mathcal{S}_{hslice}$ with height at most $(3/2 + O(\varepsilon))OPT$ (see Section 3.1) into $O_\varepsilon(1)$ boxes. This packing leaves a free space of at least $(1/2 + \Omega(\varepsilon))OPT + a(\mathcal{V})$.
2. We describe (see Section 3.2) how to pack $\mathcal{V}_{vslice}$ within the free space of the previous packing using $O_\varepsilon(1)$ extra boxes. Furthermore, we guarantee that there is a free box (not containing any rectangle) of size at least $\Omega(\varepsilon)W \times \frac{1}{2}OPT$. Guaranteeing the latter property is critical, and it is the main technical novelty in our approach.
3. Finally (see Section 3.3), we convert the above packing into a feasible container packing (via Lemma 4) inside the above boxes. The residual containers that do not fit into the boxes can be placed inside the free box (still leaving enough space) plus a new box of size $W \times O(\varepsilon^2)OPT$ that can be placed on top of the previous packing.

The reason for leaving a free box will be clearer in Section 4, where we will describe our final algorithm.

3.1 Packing of $\mathcal{T} \cup \mathcal{S}_{hslice}$

In this section, we describe a packing of $\mathcal{T} \cup \mathcal{S}_{hslice}$. The proof of the following Lemma is illustrated in Figure 1.

▶ **Lemma 6.** *For any given constant $\varepsilon \in (0, 1/4]$ with $1/\varepsilon$ integral and $\delta = \Omega_\varepsilon(1)$ sufficiently small, it is possible to pack $\mathcal{T} \cup \mathcal{S}_{hslice}$ into the region $\mathcal{P} = [0, W] \times [0, (\frac{3}{2} + 15\varepsilon)OPT]$ in such a way that:*

1. *Rectangles in $\mathcal{T}$ are packed into at most $1/\varepsilon$* vertical boxes*, slices in $\mathcal{S}_{hslice}$ are packed into at most $1/\varepsilon + 1$* horizontal boxes*, and the remaining area is partitioned into at most $2/\varepsilon$* free boxes*. Furthermore, given any fixed ordering of $\mathcal{T}$ in non-increasing order of height, it is possible to partition $\mathcal{T}$ into subsequences such that each subsequence fits into precisely one vertical box.*
2. *The sizes of the boxes belong to a set that can be computed in polynomial time.*
3. *The total area of the free boxes is at least $(\frac{1}{2} + 9\varepsilon)OPT \cdot W + a(\mathcal{V})$.*

Proof. Consider the embedding of $\mathcal{T} \cup \mathcal{S}_{hslice}$ induced by the optimum solution. Let us draw the horizontal line $y = \frac{1}{2}OPT$ and partition $\mathcal{S}_{hslice}$ into two sets $\mathcal{S}^{top}_{hslice}$ and $\mathcal{S}^{bottom}_{hslice}$ corresponding to the rectangles in $\mathcal{S}_{hslice}$ which are packed above and below the line $y = \frac{1}{2}OPT$ respectively (notice that this line does not intersect any rectangle in S_{hslice} as OPT is even by assumption). If we shift up rectangles in $\mathcal{S}^{bottom}_{hslice}$ by OPT, we obtain a feasible packing (since the region $[0, W] \times [OPT, \frac{3}{2}OPT]$ was empty) with final height at most $\frac{3}{2}OPT$. Notice that every rectangle in $\mathcal{T}$ intersects the horizontal segment $[0, W] \times \left\{\frac{1}{2}\right\}$.

Now, let us shift down each rectangle R in $\mathcal{T}$ so that its bottom coordinate becomes zero (again, the packing remains feasible). Next, we shift rectangles so that the ones in $\mathcal{T}$ appear one next to the other in the bottom left part of the packing, in non-increasing order of height. To this aim, we proceed recursively as follows. Let $T_1, \ldots, T_q$ be the considered ordering of $\mathcal{T}$ in non-increasing order of height. At the beginning of iteration $i \geq 1$, we are given a feasible packing where $T_1, \ldots, T_{i-1}$ are packed from left to right one next to the other as left as possible (and with bottom coordinate 0). We consider the region $A_i := [w_{i-1}, W] \times [0, h(T_i)]$, where $w_{i-1} = \sum_{j \leq i-1} w(T_j)$. Let L_i be the portion of A_i to the left of (the current embedding of) T_i. Note that every rectangle is either completely contained in or disjoint from L_i since T_i is the tallest rectangle contained in A_i and T_{i-1} is taller than T_i. We move T_i so that its left coordinate is w_{i-1}, and shift L_i to the right by $w(T_i)$, moving consistently all rectangles in L_i. Obviously the new packing satisfies the invariant for the next iteration. At the end of iteration q the packing satisfies the claim.

In the next step, we partition the area not occupied by $\mathcal{T}$ into unit-height stripes. Notice that each rectangle in $\mathcal{S}_{hslice}$ is fully contained in some stripe. We need (for a reason that will be clearer later) to temporarily discard, meaning that we remove them from the packing, some slices as follows. Let us say that a slice is *wide* if its width is at least εW, and *narrow* otherwise. Consider the slices $\mathcal{S}'_{hslice}$ in a given horizontal stripe. This set contains at most $1/\varepsilon$ wide slices. Let w' be the total width of the remaining narrow slices and let $w'' \leq w'$ be the largest multiple of εW. We discard a minimal subset of narrow slices so that the remaining ones have width at most w''. We let $\mathcal{S}^{disc}_{hslice}$ be the set of discarded slices, and $\mathcal{S}^{sel}_{hslice}$ be the remaining (selected) slices.

Next, we push slices $\mathcal{S}^{sel}_{hslice}$ as right as possible. Afterward, we permute the y-coordinates of slices in pairs of stripes so that stripes are sorted from top to bottom in non-increasing order of the total width of the slices contained in them. Observe that this cannot create any conflict with $\mathcal{T}$ (hence the packing remains feasible).

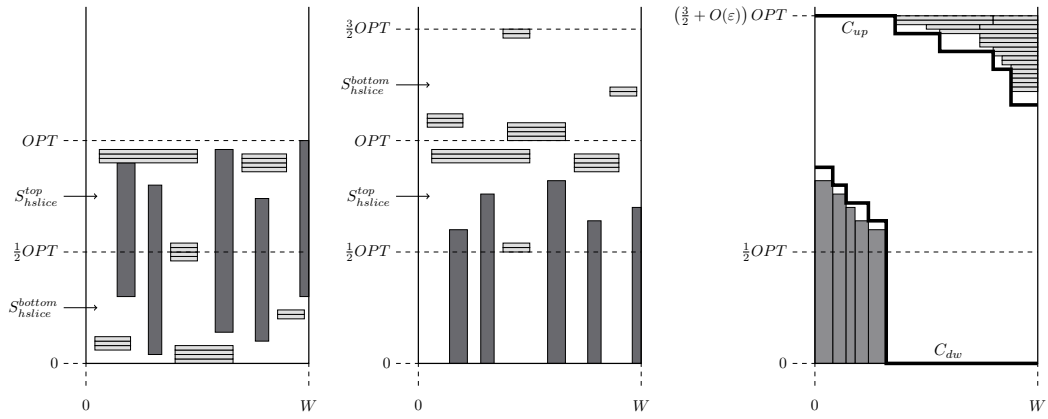

Figure 1 Depiction of the proof of Lemma 6. **Left:** Packing of $\mathcal{T} \cup \mathcal{S}_{hslice}$ in the optimal solution. Light gray rectangles correspond to $\mathcal{S}_{hslice}$, dark gray rectangles correspond to $\mathcal{T}$. **Center:** By shifting $\mathcal{S}^{bottom}_{hslice}$ to the top we can shift down the rectangles in $\mathcal{T}$. **Right:** We can shift now horizontally rectangles in $\mathcal{T}$ and sort stripes. Finally one obtains C_{up} and C_{dw}.

We proceed as follows. We shift up $\mathcal{S}^{sel}_{hslice}$ by $11\varepsilon \cdot OPT$ and construct a polygonal chain C_{up} with the following procedure. The chain starts at coordinate $p^{up}_0 = (0, (\frac{3}{2} + 11\varepsilon)OPT)$. We extend the chain to the right (possibly by a zero amount) until the chain hits some rectangle in $\mathcal{S}^{sel}_{hslice}$. We denote this point by $(x_1, (\frac{3}{2} + 11\varepsilon)OPT)$ and extend the chain down by εOPT, hence reaching some point $p^{up}_1 = (x_1, (\frac{3}{2} + 10\varepsilon)OPT)$. We continue from p^{up}_1 in the same fashion. The procedure ends when the chain reaches the x-coordinate W. Observe that, by construction, every rectangle in $\mathcal{S}^{sel}_{hslice}$ lies above C_{up}. Furthermore, C_{up} is defined by axis parallel segments only and at most $1/\varepsilon$ of them.

Afterward, we build symmetrically a polygonal chain C_{dw} as follows. We start from $p^{dw}_0 = (W, 0)$ and extend the chain to the left (possibly by a zero amount) until we hit some rectangle R in $\mathcal{T}$. Then, we extend the chain up by εOPT, hence reaching a point $p^{dw}_1 = (x_1, \varepsilon OPT)$. We continue from p^{dw}_1 in the same fashion until we reach the x-coordinate 0. Notice that each rectangle from $\mathcal{T}$ lies below C_{dw}. Notice also that C_{dw} is defined by axis parallel segments only and at most $1/\varepsilon$ of them. Furthermore, it is fully below C_{up}. To see the latter, take any coordinate $x \in (0, W)$ (which, for simplicity, is not the position of a vertex of any one of the two chains). Let y_{up} and y_{dw} be the corresponding y-coordinates in C_{up} and C_{dw}, resp. Suppose by contradiction that $y_{dw} > y_{up}$. Observe that by construction the segment $x \times (y_{up}, y_{up} + \varepsilon OPT)$ must hit some rectangle R_{up} in $\mathcal{S}^{sel}_{hslice}$. Symmetrically, the segment $x \times (y_{dw} - \varepsilon OPT, y_{dw})$ must hit some rectangle R_{dw} in $\mathcal{T}$. This however implies that R_{up} and R_{dw} overlapped before the shifting up of $\mathcal{S}^{sel}_{hslice}$ by $11\varepsilon OPT$, a contradiction[3].

We claim that points p^{up}_i and p^{dw}_i have coordinates that belong to a set that can be computed in polynomial time. Recall that OPT is known to the algorithm. Notice that the y coordinates of the points p^{up}_i and p^{dw}_i are multiples of εOPT, hence they satisfy the requirement. Since we know the precise packing of $\mathcal{T}$, we can compute the x-coordinates of points p^{dw}_i explicitly. The x-coordinates of points p^{up}_i have value W minus the sum w'' of the widths of the slices in a given strip. By the previous discarding procedure, w'' is the sum of up to $1/\varepsilon$ widths of input rectangles, plus a multiple of εW. Hence we can compute the set of the possible coordinates in polynomial time.

[3] A shifting up by $2\varepsilon OPT$ would be sufficient to achieve a contradiction here. The extra shift by $9\varepsilon OPT$ is used to create some more free space that is needed in the following arguments.

Let us subdivide the area in the strip between C_{up} and $[0,W]\times(\frac{3}{2}+11\varepsilon)OPT$ by extending to the right the horizontal segments in C_{up}. This gives up to $1/\varepsilon$ boxes $\mathcal{B}_{up}$ that fully contain $\mathcal{S}^{sel}_{hslice}$. Symmetrically, we can subdivide the area in the strip between C_{dw} and $[0,W]$ by extending down the vertical segments in C_{dw}. This provides up to $1/\varepsilon$ boxes $\mathcal{B}_{dw}$ that fully contain $\mathcal{T}$. Next, consider the free area between $\mathcal{B}_{up}$ and $\mathcal{B}_{dw}$. By extending down the vertical sides of the boxes in $\mathcal{B}_{up}$ until reaching $\mathcal{B}_{dw}$ and symmetrically extending up the vertical sides of the boxes in $\mathcal{B}_{dw}$ until reaching $\mathcal{B}_{up}$, we obtain a partition of the free area into up to $2/\varepsilon$ free boxes $\mathcal{B}_{free}$. By the previous discussion, the possible sizes of all the mentioned boxes can be computed in polynomial time.

It remains to pack $\mathcal{S}^{disc}_{hslice}$. To that aim, we create a new box $\mathcal{B}_{disc}$ of width W and height $4\varepsilon OPT$ that we place on top of the current packing, hence increasing the total height to $(\frac{3}{2}+15\varepsilon)OPT$. Notice that each $R\in\mathcal{S}^{disc}_{hslice}$ satisfies $w(R)\le\varepsilon W$ and $h(R)=1\le\delta OPT$. Hence assuming $\varepsilon\le 1/4$ and $\delta\le 4\varepsilon^2$, Lemma 2 with $\varepsilon'=1/4$ guarantees that $\mathcal{S}^{disc}_{hslice}$ can be fully packed in $\mathcal{B}_{disc}$ via NFDH.

Properties (1) and (2) follow by contruction. It remains to prove (3). Notice that by construction the area inside $\mathcal{B}_{up}$ not occupied by $\mathcal{S}^{sel}_{hslice}$ is at most $\varepsilon OPT\cdot W$. Indeed, as observed earlier, if we take any point (x,y) along C_{up}, where x does not correspond to a step of C_{up}, the segment $x\times[y,y+\varepsilon OPT]$ hits some rectangle in $\mathcal{S}^{sel}_{hslice}$. Thus $a(\mathcal{B}_{up})\le a(\mathcal{S}^{sel}_{hslice})+\varepsilon OPT\cdot W$. A symmetric argument shows that $a(\mathcal{B}_{dw})\le a(\mathcal{T})+\varepsilon OPT\cdot W$. We can therefore conclude that

$$\begin{aligned}
a(\mathcal{B}_{free}) &\ge W\cdot\left(\frac{3}{2}+11\varepsilon\right)OPT - a(\mathcal{S}^{sel}_{hslice}) - a(\mathcal{T}) - 2\varepsilon OPT\cdot W\\
&\ge W\cdot\left(\frac{3}{2}+9\varepsilon\right)OPT - a(\mathcal{S}\cup\mathcal{T})\\
&\ge W\cdot\left(\frac{3}{2}+9\varepsilon\right)OPT - OPT\cdot W + a(\mathcal{V}) = W\cdot\left(\frac{1}{2}+9\varepsilon\right)OPT + a(\mathcal{V}).
\end{aligned}$$

◀

3.2 Including $\mathcal{V}_{vslice}$

In this section, we show how to incorporate $\mathcal{V}_{vslice}$ in the packing from the previous subsection. Critically, we need to leave a free box of sufficiently large size.

▶ **Lemma 7.** *Consider the packing from Lemma 6 and assume ε is small enough. It is possible to pack $\mathcal{V}_{vslice}$ inside the free boxes and furthermore define an empty rectangular region of size $2\varepsilon^2 W\times\frac{1}{2}OPT$.*

Proof. Consider the set of (at most) $2/\varepsilon$ free boxes $\mathcal{B}_1,\dots,\mathcal{B}_q$ sorted non-decreasingly by height. We partition them into unit-width vertical stripes $\mathcal{S}'=\{S_1,\dots,S_k\}$ sorted in the same order, and breaking ties so that stripes of the same box appear consecutively. Recall that $a(\mathcal{S}')\ge\left(\frac{1}{2}+9\varepsilon\right)OPT\cdot W+a(\mathcal{V})$.

We next place slices of $\mathcal{V}_{vslice}$ in these stripes from bottom to top in a greedy manner. In particular, we consider rectangles R in $\mathcal{V}_{vslice}$ in any order, and place R in the left-most stripe where it fits, as low as possible. Assume that the non-empty stripes are $\mathcal{S}'_{used}$. Notice that the unused space in these stripes is at most $(w(\mathcal{S}'_{used})-1)(\frac{OPT}{2}-1)+OPT\le\left(\frac{w(\mathcal{S}'_{used})+1}{2}\right)OPT$, hence

$$a(\mathcal{S}'_{used})\le a(\mathcal{V})+\frac{w(\mathcal{S}'_{used})+1}{2}OPT.$$

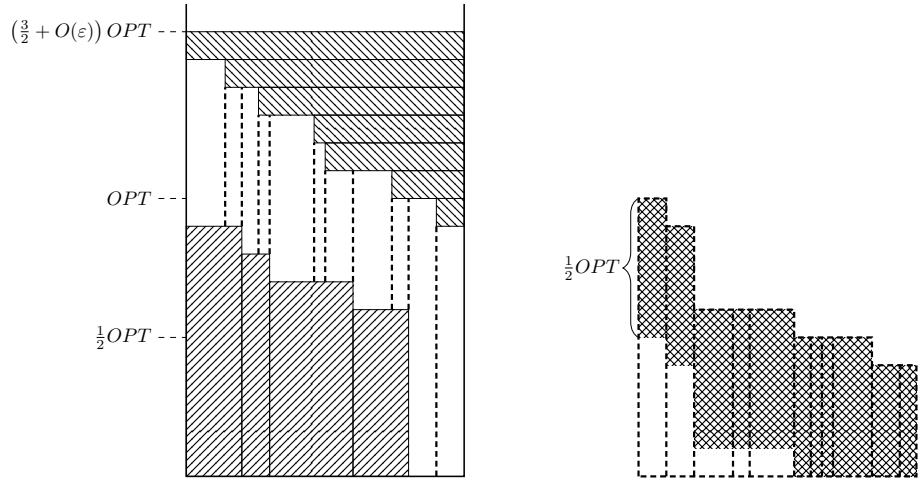

Figure 2 Description of the packing of $\mathcal{V}_{vslice}$. **Left:** Packing of $\mathcal{T} \cup \mathcal{S}_{hslice}$ as described in Lemma 6 and the $O_\varepsilon(1)$ boxes for the free area defined by the dashed lines. **Right:** Boxes in the free area sorted by height. Even if we ignore $\frac{1}{2}OPT$ height from each box we have enough space for $\mathcal{V}_{vslice}$ and even to reserve space for future discarded vertical rectangles.

Let us distinguish the unused stripes $\mathcal{S}'_{unused}$ into the ones $\mathcal{S}'^{tall}_{unused}$ of height at least $OPT/2$, and the remaining ones $\mathcal{S}'^{short}_{unused}$. One has that

$$\begin{aligned} a(\mathcal{S}'^{tall}_{unused}) &\geq \Big(\frac{1}{2}+9\varepsilon\Big)OPT\cdot W + a(\mathcal{V}) - a(\mathcal{S}'_{used}) - a(\mathcal{S}'^{short}_{unused}) \\ &\geq \Big(\frac{1}{2}+9\varepsilon\Big)OPT\cdot W + a(\mathcal{V}) - \Big(a(\mathcal{V}) + \frac{\big(w(\mathcal{S}'_{used})+1\big)}{2}OPT\Big) \\ &\quad - \frac{OPT}{2}w(\mathcal{S}'^{short}_{unused}) \\ &= \Big(\frac{1}{2}+9\varepsilon\Big)OPT\cdot W - \frac{\big(w(\mathcal{S}'_{used})+w(\mathcal{S}'^{short}_{unused})\big)}{2}OPT - \frac{OPT}{2} \\ &\geq 9\varepsilon OPT\cdot W - \frac{OPT}{2} \geq 8\varepsilon OPT\cdot W, \end{aligned}$$

The second last inequality follows from the fact that $\big(w(\mathcal{S}'_{used}) + w(\mathcal{S}'^{short}_{unused})\big) \leq W$. In the last inequality, we used the assumption $W \geq 1/\varepsilon$.

Since $a(\mathcal{S}'^{tall}_{unused}) \leq (\frac{3OPT}{2} + 11\varepsilon OPT)w(\mathcal{S}'^{tall}_{unused})$, it follows that, for $\varepsilon \leq 1/22$,

$$w(\mathcal{S}'^{tall}_{unused}) \geq \frac{8\varepsilon\cdot W}{\frac{3}{2}+11\varepsilon} \geq 4\varepsilon\cdot W.$$

Next, consider the set of boxes spanned by $\mathcal{S}'^{tall}_{unused}$. All these boxes contain a free rectangular region of height $\frac{1}{2}OPT$ induced by the bottom part of $\mathcal{S}'^{tall}_{unused}$: let us call these regions $F_1,\ldots,F_k$. Since the number of these regions is at most $\frac{2}{\varepsilon}$ (i.e. the total number of boxes) and their total width is at least $4\varepsilon\cdot W$, by an averaging argument there exists one such F_i of width at least $2\varepsilon^2 W$. ◀

3.3 Rounding

In this section, we show how to round the packing from Lemma 7 by means of Lemma 4, hence concluding the proof of Theorem 5.

Proof of Theorem 5. We start with the packing of $\mathcal{T} \cup \mathcal{S}_{hslice} \cup \mathcal{V}_{vslice}$ obtained from Lemma 7. Recall that $\mathcal{S}_{hslice}$ is packed into $1/\varepsilon + 1$ boxes $\mathcal{B}_S$ and $\mathcal{V}_{vslice}$ into $2/\varepsilon$ boxes $\mathcal{B}_V$. The total height of this packing is $(\frac{3}{2} + 15\varepsilon)OPT$, and this packing leaves a free region F of size $2\varepsilon^2 W \times \frac{1}{2}OPT$. Provided that δ is small enough, we can apply Lemma 4 to $(\mathcal{S}_{hslice}, \mathcal{B}_S)$ and obtain a packing of $\mathcal{S}$ into a set of containers fully contained in $\mathcal{B}_S$, plus two containers of size at most $W \times \frac{\varepsilon^2}{2}OPT$ each. We place the latter two containers on top of the packing, hence increasing the total height by $\varepsilon^2 OPT$. By applying the same Lemma to $(\mathcal{V}_{vslice}, \mathcal{B}_V)$, we obtain a packing of $\mathcal{V}$ into a set of containers fully contained in $\mathcal{B}_V$ plus two containers of size at most $\frac{\varepsilon^2}{2}W \times \frac{1}{2}OPT$ each. The latter two containers can be placed inside F without further increasing the height of the packing, still leaving a free region of size $\varepsilon^2 W \times \frac{1}{2}OPT$.

By construction, the number of used containers is $O_\varepsilon(1)$ and their sizes belong to a set that can be computed in polynomial time. ◀

4 Algorithm

In this section, we describe an algorithm based on Theorem 5 to compute our final solution.

Consider the set of containers guaranteed by Theorem 5. In polynomial time we can guess such containers by trying all possibilities. By brute force we can also compute (in polynomial time) a packing of these containers plus the free box in the strip of total height at most $(\frac{3}{2} + O(\varepsilon))OPT$. We guess which ones among the vertical containers contain $\mathcal{T}$, and pack the whole set $\mathcal{T}$ there greedily in non-increasing order of height.

We next apply Lemma 3 with parameter $\varepsilon' = \varepsilon^3$ to the remaining containers and to the remaining rectangles $\mathcal{V} \cup \mathcal{S}$. This way we can pack a set $\mathcal{R}' \subseteq \mathcal{V} \cup \mathcal{S}$ of area at least $a(\mathcal{V} \cup \mathcal{S})(1 - \varepsilon^3)$. It remains to pack $\mathcal{R}'' := (\mathcal{V} \cup \mathcal{S}) \setminus \mathcal{R}'$, $a(\mathcal{R}'') \leq \varepsilon^3 a(\mathcal{V} \cup \mathcal{S}) \leq \varepsilon^3(\frac{3}{2} + O(\varepsilon))OPT \cdot W \leq 2\varepsilon^3 OPT \cdot W$. We partition $\mathcal{R}''$ into 3 subsets and pack them as follows:

1. The rectangles $\mathcal{V}'' \subseteq \mathcal{R}''$ of height at least $2\varepsilon OPT$ (notice that they have height at most $OPT/2$). By an area argument their total width is at most $\frac{2\varepsilon^3 OPT \cdot W}{2\varepsilon OPT} = \varepsilon^2 W$. Hence they fit in a vertical container of size $\varepsilon^2 W \times \frac{1}{2}OPT$ that can be placed in the area occupied by the free box (without increasing the height of the packing).
2. The rectangles $\mathcal{H}'' \subseteq \mathcal{R}''$ of width at least $\varepsilon^2 W$. By a similar area argument their total height is at most $\frac{2\varepsilon^3 OPT \cdot W}{\varepsilon^2 W} = 2\varepsilon OPT$. Hence they can be placed into a horizontal container of size $W \times 2\varepsilon OPT$ that can be placed on top of the current packing.
3. The remaining rectangles $\mathcal{S}'' \subseteq \mathcal{R}''$ with height at most $2\varepsilon OPT$ and width at most $\varepsilon^2 W$. By Lemma 2 with parameter $\varepsilon' = \sqrt{\varepsilon}$ and for small enough ε, we can pack $\mathcal{S}''$ by means of NFDH into an area container of size $\varepsilon\sqrt{\varepsilon}W \times 2\sqrt{\varepsilon}OPT$ to be placed on top of the current packing.

We now have all the ingredients to prove our main theorem.

Proof of Theorem 1. Consider the above algorithm. Clearly it runs in polynomial time for any fixed parameter $\varepsilon > 0$. Furthermore, for δ small enough, it generates a feasible packing of all rectangles of total height at most $\left(\frac{3}{2} + O(\sqrt{\varepsilon})\right) OPT$. Considering the initial rounding of OPT by a factor $(1+\varepsilon)$, this gives a $\frac{3}{2} + O(\sqrt{\varepsilon})$ approximation. The claim then follows by choosing ε appropriately. ◀

5 Hardness of Approximation

In this section, we prove that the lower bound of $\frac{3}{2}$ on the approximability of Strip Packing still holds in the case of δ-skewed instances.

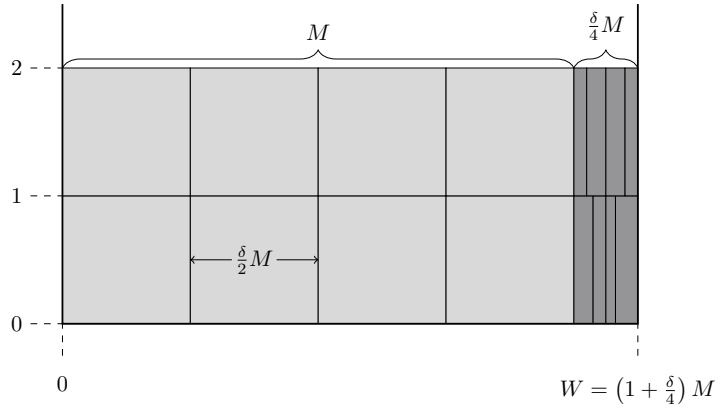

Figure 3 Construction from Lemma 8. Light gray rectangles represent dummy rectangles and dark gray rectangles represent partition rectangles.

▶ **Lemma 8.** *Given $\delta > 0$ and $\varepsilon > 0$, there is no polynomial-time $\left(\frac{3}{2} - \varepsilon\right)$-approximation for δ-skewed Strip Packing unless P=NP.*

Proof. We will prove this result via a reduction from the NP-complete *Partition* problem. Recall that in Partition we are given a set of integers $\mathcal{I} = \{x_1, \ldots, x_n\}$ whose sum is p. Our goal is to determine whether $\mathcal{I}$ can be partitioned into two sets $\mathcal{I}_1$ and $\mathcal{I}_2$ such that $\sum_{x_i \in \mathcal{I}_1} x_i = \frac{p}{2}$. We define our Strip Packing instance as follows: The width of the strip will be $W = (1 + \delta/4)M$ where $M = \frac{2p}{\delta}$. Also, we will have $n + \frac{4}{\delta}$ rectangles in the instance, from which $\frac{4}{\delta}$ will have height 1 and width $\frac{\delta}{2}M$ (*dummy rectangles*) and the remaining n rectangles will have, for each $i = 1, \ldots, n$, height 1 and width x_i (*partition rectangles*). Notice that the instance is indeed δ-skewed as the width of the rectangles is either $\frac{\delta}{2}M \leq \frac{\delta}{2}W$ or at most $p = \frac{\delta}{2}M \leq \frac{\delta}{2}W$. Notice also that $OPT \geq 2$ since the area of the rectangles is $2W$.

We will now prove that the Partition instance is a YES instance if and only if $OPT = 2$. Since all the heights in the instance are 1, as a consequence a NO instance has height at least 3, hence concluding the proof of the claim. Notice that if the Partition instance is a YES instance then we can pack one next to the other $\frac{2}{\delta}$ dummy rectangles plus one side of the partition since their total width would be $M + \frac{p}{2} = \left(1 + \frac{\delta}{4}\right) M$. We then analogously pack the rest of the rectangles on top, obtaining a packing of height 2 which is optimal as the total area of the rectangles is $2W$ (see Figure 3). On the other hand, if the optimal height of the Strip Packing instance is 2, the subregion $[0, W] \times [0, 2]$ in the strip must be fully occupied by rectangles. This actually implies that the horizontal segment $[0, W] \times \{1\}$ does not intersect the interior of any rectangle in the packing: indeed otherwise the space below that rectangle could not be occupied by any other rectangle (as heights are all 1). This divides the solution into two rows of height 1 and width W which are completely filled with rectangles. The only way to divide dummy rectangles into the two rows is to have exactly $\frac{2}{\delta}$ in each row (as the largest total width below W that they can sum up to is M and their total width is $2M$), hence the remaining partition rectangles in each row have total width exactly $\frac{p}{2}$, forming then a feasible solution to the Partition instance. ◀

A Omitted Proofs

Proof of Lemma 4. We prove the claim for $\mathcal{H}$, the case of $\mathcal{V}'$ being symmetric. For a proper parameter $\alpha > 0$ to be fixed later, we define a rectangle R (and its horizontal slices) to be *narrow* if $w(R) \leq \alpha^2 W$ and *wide* otherwise. We temporarily remove narrow rectangles, and pack the wide ones.

The first step in our construction is to round up the widths of the wide slices, while discarding a small-area subset of them. Let $\beta > 0$ be a parameter to be fixed later. Let us sort the wide slices $\mathcal{H}^{wide}_{hslice}$ in non-increasing order of width, and let us partition the obtained sequence into subsequences $\mathcal{H}_1, \ldots, \mathcal{H}_{1/\beta}$ of total height $\beta h(\mathcal{H}^{wide}_{hslice})$ each (excluding possibly the last group that can have smaller height). For a group i, we define w_i^{min} as the minimum width in $\mathcal{H}_i$. For each $i = 1, \ldots, 1/\beta - 1$, we define an injection between $\mathcal{H}_{i+1}$ and $\mathcal{H}_i$. Next, we delete slices $\mathcal{H}_1$. Let $\mathcal{H}_{wdisc1}$ denote the rectangles of which we removed at least one slice. Notice that all rectangles having some slice in $\mathcal{H}_1$ have all their slices in $\mathcal{H}_1$ excluding possibly one rectangle (which has part of its slices in $\mathcal{H}_1$). Observe that $h(\mathcal{H}^{wide}_{hslice}) \leq \frac{H}{\alpha}$ since otherwise $a(\mathcal{H}^{wide}_{hslice}) \geq \alpha W \cdot h(\mathcal{H})$ would be too large to fit into the region of size $W \times H$. Hence $h(\mathcal{H}_1) = \beta h(\mathcal{H}) \leq \frac{\beta}{\alpha} H$. It follows that $h(\mathcal{H}_{wdisc1}) \leq (\frac{\beta}{\alpha} + \delta)H$. For any fixed α, this quantity is at most $\frac{(\varepsilon')^2}{2} H$ if $\beta \leq \alpha(\varepsilon')^2/4$ and $\delta \leq (\varepsilon')^2/4$.

For $i = 1, \ldots, 1/\beta - 1$, we temporarily increase the width of each $H \in \mathcal{H}_{i+1}$ to w_i^{min}, hence getting an enlarged slice $\overline{H}$. Then, we move each such $\overline{H}$ into the region that was occupied by the slice $H' \in \mathcal{H}_i$ associated with H according to the above injection. Notice that this is possible since we removed $\mathcal{H}_1$ and since $w(\overline{H}) = w_i^{min} \leq w(H')$. Let $\overline{\mathcal{H}}$ be the final set of enlarged slices. Observe that the number of possible distinct widths in $\overline{\mathcal{H}}$ is $1/\beta - 1$.

Let us focus on a specific box $B \in \mathcal{B}$ of size $w(B) \times h(B)$, and let $\mathcal{H}'_{hslice}$ be the slices contained in B. Next, we partition B into unit height stripes. We shift slices in each stripe as left as possible, and permute them so that slices in $\overline{\mathcal{H}}$ appear to the left of each stripe. We call a *configuration* C of a stripe the sequence of (enlarged) widths $(w_1, \ldots, w_q)$ of its slices in $\overline{\mathcal{H}}$ from left to right. Notice that there are $1/\beta - 1$ possible enlarged widths, and each stripe can contain at most $1/\alpha^2$ wide slices. Hence the number of possible configurations is at most $n_{conf} = \sum_{i=0}^{1/\alpha^2} (1/\beta - 1)^i \leq 2(1/\beta - 1)^{1/\alpha^2} \leq (1/\beta)^{1/\alpha^2}$.

We reorder the stripes in $\mathcal{H}'_{hslice}$ vertically so that equal configurations appear consecutively from top to bottom, and stripes without narrow rectangles appear at the bottom. Suppose that the number of stripes in B with a given configuration $C = (w_1, \ldots, w_q)$ is $h(C)$, and $A(C)$ is the corresponding region. We initially cover $A(C)$ by creating q consecutive horizontal containers of height $h(C)$ and width $w_1, \ldots, w_q$ respectively. These containers altogether cover all the wide slices in B. The width of each container belongs to a set that can be computed in polynomial time (it is the width of some input rectangle). In order to enforce the same property for their heights, we round down the height of each such container to the largest multiple $h'(C)$ of $\frac{\delta}{\gamma}H$ not larger than $h(C)$, for some parameter $\gamma > 0$ to be fixed later. The number of these containers is $n_{wcont} \leq K n_{conf}$.

We next use the obtained horizontal containers to place most of the wide rectangles. We consider the containers in non-increasing order of width and the slices of wide rectangles in the same order, breaking ties so that slices of the same rectangle appear consecutively. We also create a dummy final container of sufficient width and of height large enough to accommodate the total height of the wide slices minus the total height of the containers. Now, we place back the slices into the containers following the previous order. Notice that all slices will fit. We discard each wide rectangle whose slices are contained in 2 containers (3 is not possible) and all the wide rectangles whose slices are contained in the dummy final container. Let $\mathcal{H}_{wdisc2}$ be the set of discarded rectangles. Their total height is

$$h(\mathcal{H}_{wdisc2}) \leq n_{wcont}\delta H + n_{wcont}\frac{\delta}{\gamma}H.$$

The above quantity is at most $\frac{(\varepsilon')^2}{2}H$ for any choice of ε', α, β, and γ, provided that $\delta \leq \frac{(\varepsilon')^2\gamma}{4n_{wcont}} \leq \frac{(\varepsilon')^2\gamma}{4K(1/\beta)^{(1/\alpha^2)}}$.

So we packed all the wide rectangles into horizontal containers except for the set $\mathcal{H}_{wdisc} = \mathcal{H}_{wdisc1} \cup \mathcal{H}_{wdisc2}$. The latter set has, by the above discussion, height at most $(\varepsilon')^2 H$, hence we can pack it into a container of size $\max_{R \in \mathcal{H}^{wide}}\{w(R)\} \times (\varepsilon')^2 H$.

It remains to pack the narrow rectangles. Consider again a given box B. For each configuration C, there is some free region $F(C)$ to the right of the containers built for C whose height is $h'(C)$ (in particular, a multiple of $\frac{\delta}{\gamma}H$) and of some width $w(F(C))$. We build an area container of the same height and with width equal to the largest multiple $w'(F(C))$ of $\frac{\alpha}{\gamma}W$ not larger than $w(F(C))$. We apply a similar construction to the free rectangular region F in B below all the previous containers, if any: in particular we create an area container whose width is the largest multiple of $\frac{\alpha}{\gamma}W$ not larger than $w(F) = w$ and whose height is the largest multiple of $\frac{\delta}{\gamma}H$ not larger than $h(F)$. The total number of constructed area containers is $n_{ncont} \leq K \cdot n_{conf}$.

Next, we start packing the narrow rectangles in non-increasing order of height in the area containers using NFDH. Observe that these rectangles satisfy the claim of Lemma 2 with parameter γ. If all narrow rectangles are packed this way, we are done. Otherwise, let $\mathcal{H}_{ncont}$ and $\mathcal{H}_{ndisc}$ be the subset of narrow rectangles that are packed and not packed in the area containers, resp. By Lemma 2, $a(\mathcal{H}_{ncont}) \geq (1 - 2\gamma)A_{acont}$, where A_{acont} is the

total area of the area containers. Let a_{free} be the total area in the boxes not occupied by horizontal containers. Clearly $a_{free} \geq a(\mathcal{H}^{narrow})$ since all narrow slices did fit in a region of area not smaller than a_{free}. Due to the rounding involved in the construction, in each box there is some area which is not used by area containers nor by horizontal ones. The latter area is at most $W \cdot \frac{\delta}{\gamma}H + H \cdot \frac{\alpha}{\gamma}W$ per container, hence at most $\Delta \leq K \cdot (\frac{\delta+\alpha}{\gamma})WH$ in total. We can conclude that

$$a(\mathcal{H}_{ncont}) \geq (1-2\gamma)A_{acont} = (1-2\gamma)(a_{free}-\Delta) \geq (1-2\gamma)(a(\mathcal{H}^{narrow})-K\cdot(\frac{\delta+\alpha}{\gamma})WH).$$

Thus

$$a(\mathcal{H}_{ndisc}) \leq 2\gamma \cdot a(\mathcal{H}^{narrow}) + K \cdot (\frac{\delta+\alpha}{\gamma})WH) \leq (2\gamma + K \cdot (\frac{\delta+\alpha}{\gamma}))WH.$$

If we choose $\gamma \leq (\varepsilon')^2/6$, $\delta \leq \frac{(\varepsilon')^2\gamma}{6K}$ and $\alpha \leq \frac{(\varepsilon')^2\gamma}{6K}$, then the latter quantity is at most $\frac{(\varepsilon')^2}{2}WH$. Next, we create a new area container C_{darea} of size $\varepsilon' W \times \varepsilon' H$, and use NFDH to pack $\mathcal{H}_{ndisc}$ in it. It is not difficult to verify that, for such values of δ and α, rectangles in $\mathcal{H}_{ndisc}$ satisfy the conditions of Lemma 2 with parameter ε'. Thus we have

$$a(\mathcal{H}_{ndisc}) \leq \frac{1}{2}(\varepsilon')^2 WH = \frac{1}{2}a(C_{darea}) \leq (1-2\varepsilon')a(C_{darea}).$$

Thus all rectangles in $\mathcal{H}_{ndisc}$ are packed into C_{darea}.

It is possible to choose constant parameters α, β and γ such that the above conditions are all satisfied (for δ small enough) and the total number of containers is $O_{\varepsilon'}(1)$. More precisely, this is true if $\gamma = (\varepsilon')^2/6$, $\alpha = (\varepsilon')^4/(36 \cdot K)$, $\beta = (\varepsilon')^6/(144 \cdot K)$ and $\delta = \frac{(\varepsilon')^2\gamma}{4K(1/\beta)^{(1/\alpha^2)}} \in \delta \leq (\varepsilon'/K)^{(K/\varepsilon')^{O(1)}}$, leading to at most $(K/\varepsilon')^{(K/\varepsilon')^{O(1)}}$ containers. By the above construction, the sizes of the containers belong to a set that can be computed in polynomial time. ◀

Abstract

We study the problem of finding a mapping f from a set of points into the real line, under ordinal triple constraints. An ordinal constraint for a triple of points (u, v, w) asserts that $|f(u) - f(v)| < |f(u) - f(w)|$. We present an approximation algorithm for the dense case of this problem. Given an instance that admits a solution that satisfies $(1-\varepsilon)$-fraction of all constraints, our algorithm computes a solution that satisfies $(1 - O(\varepsilon^{1/8}))$-fraction of all constraints, in time $O(n^7) + (1/\varepsilon)^{O(1/\varepsilon^{1/8})}n$.

1 Introduction

Geometric methods provide several tools for the analysis of complicated data sets, such as nearest-neighbor search, clustering, and dimensionality reduction. The key abstraction is to encode a set of objects by mapping each object to a point in some metric space, such that the distance between points quantifies the pairwise dissimilarity between the corresponding

© Bohan Fan, Diego Ihara, Neshat Mohammadi, Francesco Sgherzi, Anastasios Sidiropoulos, and Mina Valizadeh;

objects. The success of this paradigm crucially depends on the metrical representation used to encode the data. Motivated by this fact, metric learning aims at developing methods for discovering an underlying metric space from proximity information (we refer the reader to [23, 17] for a detailed exposition). There are several different formulations of the metric learning problem that have been considered in the literature. Here, we focus on the popular case of *ordinal* constraints. In this case, the input consists of a set of points $X = [n]$, together with a set $\mathcal{T}$ of ordered triples (u, v, w) of points, representing the fact that u is *more similar* to v than to w. The goal is to find a mapping $f : X \to Y$, for some host metric space (Y, ρ), such that for all $(u, v, w) \in \mathcal{T}$, we have

$$\rho(f(u), f(v)) < \rho(f(u), f(w)). \tag{1}$$

In general, there might be no mapping f that satisfies all constraints of the form (1), so we are interested in the algorithmic problem of computing a mapping that minimizes the fraction of violated constraints. We focus on the case where the host space is the real line, so the objective can be formulated as computing a mapping $f : [n] \to \mathbb{R}$, where for each $(u, v, w) \in \mathcal{T}$ we have the constraint

$$|f(u) - f(v)| < |f(u) - f(w)|. \tag{2}$$

We refer to this problem as Line Learning with Ordinal Constraints (LLOC).

1.1 Our contribution

We present an approximation algorithm for learning a line metric space under ordinal constraints, for the case of dense instances. Here, the density condition means that all ordinal information is given, i.e. for any distinct $u, v, w \in [n]$, we have either $(u, v, w) \in \mathcal{T}$, or $(u, w, v) \in \mathcal{T}$. Our main result is summarized in the following.

▶ **Theorem 1.1.** *There exists an algorithm that given an instance of LLOC that admits a solution satisfying $(1 - \varepsilon)$-fraction of all constraints, outputs a solution that satisfies $(1 - O(\varepsilon^{1/8}))$-fraction of all constraints, in time $O(n^7) + (1/\varepsilon)^{O(1/\varepsilon^{1/8})} n$.*

Brief overview of our approach

The main idea used to obtain Theorem 1.1 is to first compute an ordering that is close to the ordering of the points in the optimal solution. This is done by "guessing" a point p^* that lies within the few left-most points in an optimal solution, and such that p^* is not involved in many violated constraints. We show that the ordinal constraints involving p^* can be used to order the points by first solving an instance of the Minimum Feedback Arc Set problem on a tournament, and then computing a topological ordering of the remaining acyclic graph. We use this ordering to partition the points into "buckets", and we show that for almost all buckets, almost all their points must be mapped inside an interval that does not contain many other points. This property allows us to define a smaller instance of the problem by contracting each bucket into a single point. This new smaller instance can be solved exactly, and its solution can be pulled back to the original problem.

1.2 Related work

Metric learning

Another popular formulation of the metric learning problem uses *contrastive* constraints. In this case, the input consists of a set of points $X = [n]$, together with sets $\mathcal{S}, \mathcal{D} \subseteq \binom{X}{2}$, where $\mathcal{S}$ contains pairs labeled as *similar*, and $\mathcal{D}$ contains pairs labeled as *dissimilar*. The goal is to find a mapping $f : X \to Y$, for some host metric space (Y, ρ), such that for all $\{u, v\} \in \mathcal{S}$,

$$\rho(f(u), f(v)) \leq \ell,$$

and for all $\{u, v\} \in \mathcal{D}$,

$$\rho(f(u), f(v)) \geq h,$$

for some given threshold values $\ell, h > 0$. This problem is easily seen to be a generalization of Correlation Clustering. It has been studied for the case dense instances, when the host metric space is either Euclidean or a tree [13]. The main result of [13] is a FPTAS for the case where there exists a mapping that satisfies all constraints, that is allowed to violate the constraints by a small multiplicative factor which is referred to as *contrastive distortion*. In contrast, in the present work, we do not introduce any distortion, and we do not need to assume that there exists a mapping satisfying all the constraints.

We also note that the case of arbitrary instances (i.e., not necessarily dense) under contrastive constraints has been studied for the setting of learning Mahalanobis metric spaces (i.e., when X is a set of points in d-dimensional Euclidean space, and f is required to be linear) [12]. This version of the problem is related to the theory of LP-type problems.

Embedding into the line

The problem of computing a geometric representation of a data set into the real line has been studied extensively in various forms. This is arguably the simplest instance of dimensionality reduction, which is also a prototypical unsupervised metric learning task. Various objectives have been studied, including multiplicative [19, 20, 6, 5, 7, 11], additive [3], and average [10, 22] distortion. We refer the read to [14] for a detailed exposition. A related notion is ordinal embeddings, where one seeks to obtain mappings that approximately preserve the relative ordering of pairwise distances [2, 4]. We remark that a key difference between these works and our result is that they seek to minimize the *ordinal distortion*, which is a multiplicative factor of violation of the ordinal constraints, while we are interested in minimizing the number of violated ordinal constraints (without introducing ordinal distortion).

Betweenness

In the Betweenness problem we are given some set $X = [n]$ and a set $\mathcal{T}$ of ordered triples $(a, b, c) \in [n]^3$. The goal is to find a bijection $g : [n] \to [n]$ such that for any $(a, b, c) \in \mathcal{T}$, $g(b)$ appears between $g(a)$ and $g(c)$. This problem has been studied extensively in the literature. It is known to be MAXSNP-hard [9] (see also [21]), and remains hard to approximate even on dense instances [1]. The case of tournaments has been shown to admit a PTAS [15], while the best approximation algorithm for general instances is the 1/3-approximation obtained by taking a uniformly random ordering, assuming the Unique Games conjecture [8] (see also [18]).

The Betweenness problem is conceptually similar to the Line Learning with Ordinal Constraints problem studied here. However, as we now explain, the two problems have some important differences. A first difference is that the ordinal constraint (2) does not imply any

ordering constraint[1]. A second difference is that the solution space to the Line Learning with Ordinal Constraints problem that we study is larger. In other words, the ordering of the points is not always enough to recover a nearly-optimal constraint. For example, consider the instance on $X = \{0, 2, 4, \ldots, 2k, 2k+1, \ldots, 3k\}$, with all constraints $(u, v, w) \in X^3$, such that $|u - v| < |u - w|$. Clearly, setting f to be the identity results in a solution that satisfies all constraints. However, just the ordering of the points in f is not enough to obtain a good solution: setting $g(u_i) = i$, where $g(u_1) < g(u_2) < \ldots < g(u_n)$ results in a solution g that violates a constant fraction of all constraints.

1.3 Organization

The rest of the paper is organized as follows. Section 2 presents, as a warm up, an exact polynomial-time algorithm for the case where there exists a solution that satisfies all constraints. Section 3 presents the algorithm for the general case. Section 4 presents the analysis. Section 5 gives the proof of a technical Lemma which is used in the proof of the main result.

2 Warm up: An exact algorithm with no violations

We now describe an exact polynomial-time algorithm for the case where there exists an optimal solution that satisfies all constraints. This algorithm is significantly simpler than the one used to prove our main result. However, it illustrates the main idea of using the constraints involving some point p to deduce an ordering of all points, and then using this ordering to obtain an embedding into the line. The algorithm is summarized in the following.

▶ **Theorem 2.1.** *Let ε^* be the fraction of violated constraints, then there exists a polynomial-time algorithm which given an instance $([n], \mathcal{T})$ of the LLOC problem, either computes a mapping $f : [n] \to \mathbb{R}$ that satisfies all the constraints, or correctly decides that no such mapping exists.*

Proof. Fix some optimal mapping $f^* : [n] \to \mathbb{R}$, that satisfies all constraints in $\mathcal{T}$. We guess $p = \arg\min_{x \in [n]} f^*(x)$. For all $i, j \in [n]$, let $d_{i,j} = |f^*(x_j) - f^*(x_i)|$. We first determine the ordering of all the points on the real line, and then we compute the mapping using their distance constraints and solving some LP.

Suppose that $[n] = \{x_1, \ldots, x_n\}$, such that

$$f^*(p) = f^*(x_1) < f^*(x_2) < \ldots < f^*(x_n).$$

Since $\varepsilon^* = 0$, it follows that for all $i < j \in [n]$, we have $d_{1,i} < d_{1,j}$, and $(1, i, j) \in \mathcal{T}$. Therefore, for any $q, q' \in [n]$, we can decide whether $f^*(q) < f^*(q')$ or $f^*(q') < f^*(q)$ based on whether $(p, q, q') \in \mathcal{T}$ or $(p, q', q) \in \mathcal{T}$. Therefore, we can compute the ordering $x_1, \ldots, x_n$ of $[n]$ by running a sorting algorithm using pairwise comparisons.

We now compute a mapping using an LP. For any $i < j \in \{1, \ldots, n\}$, we have $|f^*(x_i) - f^*(x_j)| = \sum_{t=i}^{j-1} d_{t,t+1}$. Therefore for each $(x_i, x_j, x_k) \in \mathcal{T}$, the constraint $|f^*(x_i) - f^*(x_j)| < |f^*(x_i) - f^*(x_k)|$ can be written as $\sum_{t=i}^{j-1} d_{t,t+1} < \sum_{t=i}^{k-1} d_{t,t+1}$. Thus computing the desired mapping f can be done by computing a feasible solution to the following LP:

[1] For example, the constraint (u, v, w) is satisfied by both solutions $f(u) = 1, f(v) = 2, f(w) = 3$, and $f(u) = 2, f(v) = 1, f(w) = 4$, however the former solution implies the ordering $f(u) < f(v) < f(w)$, while the latter implies $f(v) < f(u) < f(w)$

$$d_{i,j} \geq 0 \text{ for all } i < j \in [n]$$
$$\sum_{t=i}^{j-1} d_{t,t+1} < \sum_{t=i}^{k-1} d_{t,t+1} \text{ for all } (x_i, x_j, x_k) \in \mathcal{T}$$

This concludes the proof. ◀

3 The algorithm for the general case

In this Section we present the algorithm for the general case of the problem. The algorithm uses as a subroutine an exact algorithm for a generalized weighted version of the problem. This exact algorithm is used on small instances that are constructed via a process which we refer to as a *retraction*.

3.1 Retractions

We now define a weighted version of the metric learning problem, where each constraint is associated with some weight, and the goal is to maximize the total weight of all satisfied constraints. Formally, an input to the Weighted Line Learning with Ordinal Constraints (WLLOC) problem is defined by a tuple $([b], \mathcal{T}, w)$, where $b \in \mathbb{N}$, and $\mathcal{T}$ are as before, and $w : \mathcal{T} \to \mathbb{R}$ is a weight function. The goal is to find a solution $f : [b] \to [0, 1]$ that minimizes the total weight of violated constraints.

▶ **Theorem 3.1.** *There exists an exact algorithm for the WLLOC problem with running time* $O(n^{3n})$.

Proof. We identify the space of possible solutions with $[0, 1]^n$, by mapping each solution $f : [b] \to [0, 1]$ to the vector $x_f = (f(1), \ldots, f(n)) \in [0, 1]^n$. For any $(i, j, k) \in \mathcal{T}$, we have the constraint

$$|f(i) - f(j)| < |f(i) - f(k)|.$$

The feasible region for this constraint is thus defined as a union of certain cells in an arrangement $A_{(i,j,k)}$ of a constant number of open halfspaces in $\mathbb{R}^n$. Let A be the arrangement obtained as the union of all halfspaces for all $(i, j, k) \in \mathcal{T}$. It is known that any arrangement of a halfspaces in $\mathbb{R}^b$ has complexity $O(a^b)$ (see [24] and references therein), and thus A has complexity $O(|\mathcal{T}|^n) = O(n^{3n})$. By enumerating all the cells in this arrangement, we find a solution that satisfies a set of constraints of maximum total weight, which results in an algorithm with running time $O(n^{3n})$. ◀

As mentioned earlier, the exact algorithm from Theorem 3.1 will be used as a subroutine on smaller instances. The following Definition describes a process for mapping large unweighted instances to smaller weighted ones.

▶ **Definition 3.2** (Retraction). *Given an instance* $\phi = ([n], \mathcal{T})$ *of the LLOC problem, and some partition* $\mathcal{B} = \{B_1, \ldots, B_b\}$ *of* $[n]$*, we define the* $\mathcal{B}$*-retraction of* ϕ *to be the instance* $\phi' = ([b], \mathcal{T}', w)$ *of the WLLOC problem where for any* $(i, j, k) \in \mathcal{T}'$*, we have*

$$w((i, j, k)) = |\mathcal{T} \cap (B_i \times B_k \times B_j)|.$$

3.2 The algorithm

The last ingredient we need is an approximation algorithm for the Minimum Feedback Arc Set problem on tournaments, which is summarized in the following.

▶ **Theorem 3.3** (Kenyon-Mathieu & Schudy [16]). *There exists a randomized algorithm for the Minimum Feedback Arc Set problem on weighted tournaments. Given $\epsilon > 0$, it outputs a solution with expected cost at most $(1+\epsilon)\mathsf{OPT}$. The expected running time is $O(1/\varepsilon)n^6 + 2^{\tilde{O}(1/\varepsilon)}n^2 + 2^{2^{\tilde{O}(1/\varepsilon)}}n$.*

We are now ready to describe the general algorithm. Let $\mathcal{T}_n$ denote the set of all ordered triples of distinct elements in $[n]$. Recall that the input consists of a set $\mathcal{T} \subseteq \mathcal{T}_n$, such that for any set of distinct $i, j, k \in [n]$, we have that exactly one of the triples (i, j, k) and (i, k, j) is contained in $\mathcal{T}$.

The algorithm proceeds in the following steps:

Step 1: Exhaustively computing a left-most point. Iterate Steps 2–5 for all values $p \in [n]$.

Step 2: Cycle removal. Construct a tournament $G^{(p)} = ([n], A^{(p)})$, where

$$A^{(p)} = \{(i, j) : (p, i, j) \in \mathcal{T}\}.$$

Compute an $O(1)$-approximate minimum feedback arc set, $F^{(p)} \subset A^{(p)}$, in $G^{(p)}$, using the algorithm in Theorem 3.3.

Step 3: Ordering. Compute a topological ordering $z_1^{(p)}, \ldots, z_n^{(p)}$ of $G^{(p)} \setminus F^{(p)}$.

Step 4: Retraction. Let $b = O(\varepsilon^{-1/8})$. For any $i \in [b]$, let

$$\mathcal{B}_i^{(p)} = \bigcup_{j=(i-1)n/b+1}^{in/b} \{z_j^{(p)}\}.$$

Let $\psi^{(p)}$ be the $\mathcal{B}^{(p)}$-retraction of $\phi^{(p)}$.

Step 5: Extension. Using the algorithm from Theorem 3.1, we compute an optimal solution $g^{(p)} : [b] \to [0, 1]$ for the instance $\psi^{(p)}$ of WLLOC. We define $f^{(p)} : [n] \to [0, 1]$ by setting for any $i \in [n]$, $f^{(p)}(i) = g^{(p)}(j)$, where $j \in [b]$ such that $i \in B_j^{(p)}$. The algorithm outputs the solution $f^{(p)}$.

Step 6: Return the best solution found among $f^{(1)}, \ldots, f^{(n)}$.

This completes the description of the algorithm.

4 Analysis of the algorithm

This Section presents the analysis of the algorithm, which is the proof of Theorem 1.1.

For the remainder of the analysis, let us fix some optimal solution $f_{\mathsf{OPT}} : [n] \to [0, 1]$ for the instance $([n], \mathcal{T})$ of the LLOC problem. Fix a numbering $\{x_1, \ldots, x_n\} = [n]$, such that

$$f_{\mathsf{OPT}}(x_1) \leq f_{\mathsf{OPT}}(x_2) \leq \ldots \leq f_{\mathsf{OPT}}(x_n).$$

For any $f : [n] \to [0, 1]$, for any $i \in [n]$, and for any $\alpha \in [0, 1]$, we say that i is *α-good in f*, if at least α-fraction of the constraints of the form $(i, j, k) \in \mathcal{T}$ are satisfied; i.e.:

$$|\{(i, j, k) \in \mathcal{T} : |f(i) - f(j)| < |f(i) - f(k)|\}| \geq \alpha \binom{n-1}{2}.$$

We first argue that there exists a $(1 - \varepsilon^{1/2})$-good point that is close to the left-most point in the optimal solution:

▶ **Lemma 4.1.** *There exists $i^* \in [2\varepsilon^{1/2}n]$, such that x_{i^*} is $(1-\varepsilon^{1/2})$-good in f_{OPT}.*

Proof. Let ξ be the total number of constraints violated by f_{OPT}. We have $\xi \leq \varepsilon \cdot |\mathcal{T}| = \varepsilon n\binom{n-1}{2}$. Suppose that there exists no $i \in [2\varepsilon^{1/2}n]$ such that x_i is $(1-\varepsilon^{1/2})$-good. Therefore every $i \in [2\varepsilon^{1/2}n]$ participates in at least $\varepsilon^{1/2}\binom{n-1}{2}$ violated constraints of the form (i,j,k), for some $j,k \in [n]$. Thus the total number of violated constraints is at least $\xi \geq 2n\varepsilon\binom{n-1}{2}$, which is a contradiction, concluding the proof. ◀

For the remainder of this section, fix some $i^* \in [2\varepsilon^{1/2}n]$, such that x_{i^*} is $(1-\varepsilon^{1/2})$-good, as in Lemma 4.1. Let f' be the embedding obtained from f_{OPT} by exchanging the images of x_1 and x_{i^*}, that is for all $i \in [n]$,

$$f'(x_i) = \begin{cases} f_{\mathsf{OPT}}(x_{i^*}) & \text{if } i = 1 \\ f_{\mathsf{OPT}}(x_1) & \text{if } i = i^* \\ f_{\mathsf{OPT}}(x_i) & \text{otherwise} \end{cases}$$

We next show that f' is near-optimal.

▶ **Lemma 4.2.** *The total number of violated constraints in f' is at most $(\varepsilon + O(1/n))n\binom{n-1}{2}$.*

Proof. Let $\mathcal{T}_1 \subseteq \mathcal{T}$ be the set of constraints that are violated in f' and in f_{OPT}. Let $\mathcal{T}_2 \subseteq \mathcal{T}$ be the set of constraints that are violated in f' but not in f_{OPT}. We have $|\mathcal{T}_1| \leq \varepsilon n\binom{n-1}{2}$. Since f_{OPT} and f' differ only on x_1 and x_{i^*}, it follows that every constraint $(i,j,k) \in \mathcal{T}_2$ must contain at least one of 1 and i^*. There are at most $6n^2$ such constraints. Thus $|\mathcal{T}_2| \leq 6n^2$. We conclude that the total number of constraints violated in f' is at most $|\mathcal{T}_1| + |\mathcal{T}_2| \leq (\varepsilon + O(1/n))n\binom{n-1}{2}$, which concludes the proof. ◀

The next Lemma shows that x_{i^*} remains $(1-O(\varepsilon^{1/2}))$-good in f'.

▶ **Lemma 4.3.** *We have that x_{i^*} is $(1-O(\varepsilon^{1/2}))$-good in f'.*

Proof. Let $\gamma = (x_{i^*}, j, k) \in \mathcal{T}$, and suppose that γ is satisfied in f_{OPT}. If

$$f_{\mathsf{OPT}}(x_{i^*}) \leq f_{\mathsf{OPT}}(j) \leq f_{\mathsf{OPT}}(k),$$

then, since $f'(j) = f_{\mathsf{OPT}}(j)$, and $f'(k) = f_{\mathsf{OPT}}(k)$, it follows that

$$f'(x_{i^*}) \leq f'(j) \leq f'(k),$$

and thus γ is also satisfied in f'.

Thus, the only possible constraints of the form $(x_{i^*}, j, k) \in \mathcal{T}$, that are not violated in f_{OPT}, but are violated in f', must satisfy either $f_{\mathsf{OPT}}(j) < f_{\mathsf{OPT}}(x_{i^*})$, or $f_{\mathsf{OPT}}(k) < f_{\mathsf{OPT}}(x_{i^*})$. In other words, we must have $\{j,k\} \cap \{x_1, \ldots, x_{i^*-1}\} \neq \emptyset$. Therefore, there are at most $2\varepsilon^{1/2}n^2$ such constraints. Since x_{i^*} is $(1-\varepsilon^{1/2})$-good in f_{OPT}, it follows that x_{i^*} is $(1-O(\varepsilon^{1/2}))$-good in f', which concludes the proof. ◀

Let $F' = \{(j,k) \in A^{(i^*)} : (x_{i^*}, j, k) \in \mathcal{T}$ and f' violates $(x_{i^*}, j, k)\}$. The next Lemma shows F' is a valid feedback arc set for $G^{(i^*)}$.

▶ **Lemma 4.4.** *F' is a feedback arc set for $G^{(i^*)}$, with $|F'| \leq (O(\varepsilon^{1/2}))\binom{n-1}{2}$.*

Proof. By Lemma 4.3, x_{i^*} is $(1 - O(\varepsilon^{1/2}))$-good, and thus $|F'| \leq (O(\varepsilon^{1/2}))\binom{n-1}{2}$. Thus, it suffices to show that F' is a feedback vertex set. For any $(j,k) \in A^{(i^*)} \setminus F'$, we have that (x_{i^*}, j, k) is satisfied in f'. Since x_{i^*} is mapped to the left-most point in f', it follows that $f'(j) < f'(k)$. Thus,

$$x_{i^*}, x_2, x_3, \ldots, x_{i^*-1}, x_1, x_{i^*+1}, x_{i^*+2}, \ldots, x_n$$

is a topological ordering of $G^{(i^*)} \setminus F'$, and thus F' is a feedback arc set, which concludes the proof. ◀

If the instance admits a solution with no violations, then it can be shown that the bucketing $\mathcal{B}^{(i^*)}$ computed by the algorithm agrees with a partition of the optimal solution to contiguous disjoint intervals. In the following, we show that, in the general case, the bucketing is "close" to such a partition. First, we introduce a notion of "stability" which formalizes what it means for a bucket to be close to an optimal interval.

▶ **Definition 4.5** (Stability). *Let $i \in [b]$. We say that i is* stable *if there exists some interval $I \subset \mathbb{R}$, such that*

$$\left| I \cap f'\left(B_i^{(i^*)}\right)\right| \geq (1 - \varepsilon^{1/8}) \cdot n/b,$$

and

$$\left| I \cap f'\left([n] \setminus B_i^{(i^*)}\right)\right| \leq \varepsilon^{1/8} \cdot n/b,$$

We also say that i is I-stable. We say that i is unstable *(I-unstable) if it is not stable (I-stable).*

The following Lemma gives a characterization of unstable buckets.

▶ **Lemma 4.6.** *Suppose that $i \in [b]$ is unstable. Then there exist pairwise disjoint intervals $I_1, I_2, I_3 \subset \mathbb{R}$, that appear in this order from left to right in the line, such that*

$$\left| I_1 \cap f'\left(B_i^{(i^*)}\right)\right| \geq n\varepsilon^{1/8}/(2b),$$

$$\left| I_3 \cap f'\left(B_i^{(i^*)}\right)\right| \geq n\varepsilon^{1/8}/(2b),$$

and

$$\left| I_2 \cap f'\left([n] \setminus B_i^{(i^*)}\right)\right| > \varepsilon^{1/8} \cdot n/b,$$

Proof. Let $I_1 \subset \mathbb{R}$ be the minimal interval that contains the $n\varepsilon^{1/8}/(2b)$ left-most points in $f'(B_i^{(i^*)})$, and let $I_3 \subset \mathbb{R}$ be the minimal interval that contains the $n\varepsilon^{1/8}/(2b)$ right-most points in $f'(B_i^{(i^*)})$. Let $I_2 \subset \mathbb{R}$ be the maximal interval that is contained between I_1 and I_3. Since $\varepsilon^{1/8} < 1$, we have that $I_1 \cap I_3 = \emptyset$, and therefore, all intervals I_1, I_2, I_3 are well-defined and pairwise disjoint. By construction, I_1 and I_3 each contains exactly $n\varepsilon^{1/8}/(2b)$ points in $f'(B_i^{(i^*)})$. Therefore, it remains to show that I_2 contains more than $\varepsilon^{1/8}n/b$ points in $f'([n] \setminus B_i^{(i^*)})$. Suppose, for the sake of contradiction, that I_2 contains at most $\varepsilon^{1/8}n/b$ in $f'([n] \setminus B_i^{(i^*)})$. Then, I_2 contains exactly $(1 - \varepsilon^{1/8})n/b$ points in $f'(B_i^{(i^*)})$, and at most $\varepsilon^{1/8}n/b$ points in $f'([n] \setminus B_i^{(i^*)})$, implying that B_i is stable, which is a contradiction. This concludes the proof. ◀

We next show that for each unstable bucket, the feedback arc set must contain many edges incident to vertices in the bucket.

▶ **Lemma 4.7.** *Let $i \in [b]$ be unstable. Then, $F^{(i^*)} \cup F'$ contains at least $\varepsilon^{1/4}n^2/(2b^2)$ arcs having exactly one endpoint in $B_i^{(i^*)}$.*

Proof. Let $I_1, I_2, I_3 \subset \mathbb{R}$ be the intervals given by Lemma 4.6. Let $v \in [n] \setminus B_i^{(i^*)}$, such that $f'(v) \in I_2$. Pick $j \in [b]$, such that $v \in B_j^{(i^*)}$. We consider two cases:

Case 1: Suppose that $j < i$. Let $u \in B_i^{(i^*)}$, such that $f'(u) \in I_1$. If $(v,u) \in A^{(i^*)}$, then it follows that f' violates (x_{i^*}, v, u), and thus $(v,u) \in F'$. Otherwise, we have $(u,v) \in A^{(i^*)}$. Since u appears after v in the topological sort of $G^{(i^*)} \setminus F^{(i^*)}$, it follows that $(u,v) \in F^{(i^*)}$. Thus, in either case, $F^{(i^*)} \cup F'$ contains either (u,v) or (v,u). Therefore, $F^{(i^*)} \cup F'$ contains at least $n\varepsilon^{1/8}/(2b)$ arcs having u as an endpoint.

Case 2: Suppose that $j > i$. This case is similar to Case 1, and is included for completeness. Let $u \in B_i^{(i^*)}$, such that $f'(u) \in I_3$. If $(u,v) \in A^{(i^*)}$, then it follows that f' violates (x_{i^*}, u, v), and thus $(u,v) \in F'$. Otherwise, we have $(v,u) \in A^{(i^*)}$. Since u appears before v in the topological sort of $G^{(i^*)} \setminus F^{(i^*)}$, it follows that $(v,u) \in F^{(i^*)}$. Thus, in either case, $F^{(i^*)} \cup F'$ contains either (u,v) or (v,u). Therefore, $F^{(i^*)} \cup F'$ contains at least $n\varepsilon^{1/8}/(2b)$ arcs having u as an endpoint.

We conclude that, in either case, for any $u \in B_i^{(i^*)}$, $F^{(i^*)} \cup F'$ contains at least $n\varepsilon^{1/8}/(2b)$ arcs having u as an endpoint. Summing over all $u \in B_i^{(i^*)}$, we obtain that $F^{(i^*)} \cup F'$ contains at least $\varepsilon^{1/4}n^2/(2b^2)$ arcs having an endpoint in $B_i^{(i^*)}$. This concludes the proof. ◀

Next, we bound the number of unstable buckets.

▶ **Lemma 4.8.** *Let $J = \{i \in [b] : i \text{ is unstable}\}$, we have $|J| \leq O(\varepsilon^{1/4})2b^2$.*

Proof. By Lemma 4.3 we have that x_{i^*} is $(1 - O(\varepsilon^{1/2}))$-good in f', and by Lemma 4.4 we have that $G^{(i^*)}$ admits a feedback arc set of size at most $(O(\varepsilon^{1/2}))\binom{n-1}{2}$. Thus, by Theorem 3.3, the algorithm computes some feedback arc set $F^{(i^*)} \subset A^{(i^*)}$, with $|F^{(i^*)}| = O(\varepsilon^{1/2}n^2)$. We note that here we only use Theorem 3.3 to obtain a $O(1)$-approximation. By Lemma 4.7,

$$\begin{aligned} |J| &\leq |F^{(i^*)} \cup F'|/(\varepsilon^{1/4}n^2/(2b^2)) \\ &\leq O(\varepsilon^{1/4})2b^2, \end{aligned}$$

which concludes the proof. ◀

For any stable $i \in [b]$, let $\mathcal{I}_i \subset \mathbb{R}$ be the interval that contains at least $(1 - \varepsilon^{1/8})n/b$ points in $f'(B_i^{(i^*)})$, and at most $\varepsilon^{1/8}n/b$ other points. Let also $\mathcal{J}_i \subset \mathcal{I}_i$ be an open interval that contains all but the $\varepsilon^{1/8}n/b$ leftmost points in $f'(B_i^{(i^*)}) \cap \mathcal{I}_i$, and the $\varepsilon^{1/8}n/b$ rightmost points in $f'(B_i^{(i^*)}) \cap \mathcal{I}_i$. Thus, $|\mathcal{J}_i \cap f'(B_i^{(i^*)})| \geq (1 - 3\varepsilon^{1/8})n/b$. It follows that for any $i \neq j \in [b]$, such that both i and j are stable, we have $\mathcal{J}_i \cap \mathcal{J}_j = \emptyset$.

Intuitively, we intend to find a solution that satisfies a nearly-optimal fraction of constraints, while ignoring all constraints that involve points that are mapped outside the intervals $\mathcal{J}_i$, where $i \in [b]$ is stable. To that end, we define a small set of points that the analysis can safely "ignore":

$$X_{\mathsf{Noise}} = \bigcup_{i \in [b] : i \text{ stable}} \left\{ v \in B_i^{(i^*)} : f'(v) \notin \mathcal{J}_i \right\}.$$

Since $|\mathcal{J}_i \cap f'(B_i^{(i^*)})| \geq (1 - 3\varepsilon^{1/8})n/b$, it follows that

$$|X_{\mathsf{Noise}}| \leq 3\varepsilon^{1/8} n \tag{3}$$

Let also, for any $i \in [b]$,

$$\bar{B}_i^{(i^*)} = B_i^{(i^*)} \setminus X_{\mathsf{Noise}}.$$

We identify a set of triples $(i, j, k) \in [b]^3$ for which, intuitively, it is difficult to satisfy at least some significant fraction of all constraints with one point from each of the clusters $B_i^{(i^*)}$, $B_j^{(i^*)}$, and $B_k^{(i^*)}$. Formally, we say that some $(i, j, k) \in [b]^3$ is *brittle* if there exist $u, u' \in \mathcal{J}_i$, $v, v' \in \mathcal{J}_j$, and $w, w' \in \mathcal{J}_k$, such that

$$|u - v| < |u - w|,$$

and

$$|u' - v'| > |u' - w'|.$$

Intuitively, the above property implies that if for all $t \in [b]$, all points in $\bar{B}_t^{(i^*)}$ get mapped to the same point $p_t \in \mathcal{J}_t$, then there exist choices for the points $\{p_t\}_t$, such that some constraint in $\bar{B}_i^{(i^*)} \times \bar{B}_j^{(i^*)} \times \bar{B}_k^{(i^*)}$ is violated; in other words, if a triple (i, j, k) is not brittle, then the choice of the points p_t does not affect the satisfiability of the constraints in $\bar{B}_i^{(i^*)} \times \bar{B}_j^{(i^*)} \times \bar{B}_k^{(i^*)}$.

We are now ready to show that the retraction computed by the algorithm admits a solution of low total cost.

▶ **Lemma 4.9.** *The instance $\psi^{(i^*)}$ of WLLOC constructed in Step 4 admits a solution that satisfies constraints of total weight at least $|\mathcal{T}| \cdot (1 - O(\varepsilon^{1/8}))$.*

Proof. We define a mapping $g : [b] \to [0, 1]$, and $g' : [b] \to [0, 1]$, as follows. For each $i \in [b]$, pick $v_i \in \mathcal{B}_i^{(i^*)}$, arbitrarily, and set

$$g'(i) = f'(v_i).$$

For any $j \in [b]$, we set

$$g(j) = g'(i),$$

where $i \in [b]$ is the unique integer such that $i \in B_i^{(i^*)}$. By the definition of the WLLOC instance $\psi^{(i^*)}$, the total weight of the constraints violated by g' equals the total number of constraints violated by g. It therefore suffices to upper bound the number of constraints in $\mathcal{T}$ that are violated by g.

We define a partition $\mathcal{T} = \mathcal{T}_0 \cup \mathcal{T}_1 \cup \mathcal{T}_2 \cup \mathcal{T}_3 \cup \mathcal{T}_4 \cup \mathcal{T}_5$, where

$$\mathcal{T}_0 = \{(u, v, w) \in \mathcal{T} : f' \text{ violates } (u, v, w)\},$$
$$\mathcal{T}_1 = \{(u, v, w) \in \mathcal{T} : \text{ at least two of } u, v, w \text{ are in the same cluster in } \mathcal{B}^{(i^*)}\},$$
$$\mathcal{T}_2 = \{(u, v, w) \in \mathcal{T} : u \in B_i^{(i^*)}, v \in B_j^{(i^*)}, w \in B_k^{(i^*)}, \text{ at least one of } i, j, k \text{ is unstable}\},$$
$$\mathcal{T}_3 = \{(u, v, w) \in \mathcal{T} : u \in B_i^{(i^*)}, v \in B_j^{(i^*)}, w \in B_k^{(i^*)}, \text{ and } (i, j, k) \text{ is brittle}\},$$
$$\mathcal{T}_4 = \{(u, v, w) \in \mathcal{T} : \{u, v, w\} \cap X_{\mathsf{Noise}} \neq \emptyset\},$$
$$\mathcal{T}_5 = \mathcal{T} \setminus (\mathcal{T}_0 \cup \mathcal{T}_1 \cup \mathcal{T}_2 \cup \mathcal{T}_3 \cup \mathcal{T}_4).$$

By Lemma 4.2 we have

$$|\mathcal{T}_1| \leq (\varepsilon + O(1/n))n\binom{n-1}{2}.$$

Since every cluster in $\mathcal{B}^{(i^*)}$ has n/b points, we have

$$|\mathcal{T}_1| \leq 3n^3/b^2. \tag{4}$$

In order to bound $|\mathcal{T}_3|$ we need a bound on the number of brittle triples. This is done in Lemma 4.8, which appears in Section 5. We thus have

$$|\mathcal{T}_2| \leq O(\varepsilon^{1/4})2n^3 b. \tag{5}$$

By Lemma 5.5 we have

$$|\mathcal{T}_3| \leq n^3/b. \tag{6}$$

By (3) we have

$$|\mathcal{T}_4| \leq O(\varepsilon^{1/8})n^3 \tag{7}$$

Let $(u, v, w) \in \mathcal{T}_5$. By the definition of $\mathcal{T}_5$, we have that $u \in \bar{B}_i^{(i^*)}$, $v \in \bar{B}_j^{(i^*)}$, and $w \in \bar{B}_k^{(i^*)}$, for some distinct $i, j, k \in [b]$, such that (i, j, k) is not brittle, and f' satisfies (u, v, w), that is

$$|f'(u) - f'(v)| < |f'(u) - f'(w)|.$$

By the definition of a brittle triple we get

$$|g(u) - g(v)| < |g(u) - g(w)|,$$

and thus g satisfies (u, v, w). We obtain that g satisfies all constraints in $\mathcal{T}_5$. Thus, by (4)–(7), the number of constraints violated by g is at most $|\mathcal{T}_0| + \ldots + |\mathcal{T}_4| \leq n^3 O(\varepsilon^{1/8})$, which concludes the proof. ◀

We are now ready to prove our main result.

Proof of Theorem 1.1. By Lemma 4.9 we have that WLLOC instance $\psi^{(i^*)} = ([b], \mathcal{T}', w)$ constructed at Step 4 of the algorithm, admits a mapping $g' : [b] \to \mathbb{R}$, such that the total weight of the constraints in $\mathcal{T}'$ violated by g' is at most $O(\varepsilon^{1/8}n^3)$. Therefore, in Step 5, using the exact algorithm from Theorem 3.1, we compute a mapping $g : [b] \to \mathbb{R}$, violating the same total weight as g'. By the definition of retraction, it follows that the mapping $f^{(i^*)}$ computed in Step 5 violates at most $O(\varepsilon^{1/8}n^3)$ constraints in $\mathcal{T}$, as required.

It remains to bound the running time. Step 2 uses the algorithm from Theorem 3.3 to obtain a $O(1)$-approximate minimum feedback arc set, and thus takes time $O(n^6)$. Step 3 takes time $O(n)$ and Step 4 takes time $O(n^2)$. Step 5 runs the algorithm from Theorem 3.1 on an input of size b, and thus takes time $O(b^{3b}) + O(n)$. Step 6 requires computing the number of violated constraints in each of the n solutions, and thus takes total time $O(n^4)$. Due to Step 1, the Steps 2–5 are repeated n times, and thus the total running time is at most $O(n^7 + b^{3b}n) = O(n^7) + (1/\varepsilon)^{O(1/\varepsilon^{1/8})}n$, which concludes the proof. ◀

5 Bounding the number of brittle triples

This Section is devoted to proving an upper bound on the number of brittle triples. We begin by deriving a simple condition that is a consequence of brittleness.

▶ **Lemma 5.1.** *Let $j < i < k \in [b]$. We have that if (i, j, k) is brittle, then there exist $p_i \in \mathcal{J}_i$, $p_j \in \mathcal{J}_j$, $p_k \in \mathcal{J}_k$, such that*

$$p_i - p_j = p_k - p_i.$$

Proof. If (i, j, k) is brittle, it is easy to see that $\mathcal{J}_i$ must be located between $\mathcal{J}_j$ and $\mathcal{J}_k$; otherwise, any representative point chosen in $\mathcal{J}_i$ must be closer to all the points in $\mathcal{J}_j$ than those in $\mathcal{J}_k$, or vice versa. By definition, there exist $p_i \in \mathcal{J}_i$, $p'_j \in \mathcal{J}_j$, $p'_k \in \mathcal{J}_k$, such that

$$p_i - p'_j \geq p'_k - p_i,$$

and $p''_j \in \mathcal{J}_j$, $p''_k \in \mathcal{J}_k$, such that

$$p_i - p''_j < p''_k - p_i.$$

Without loss of generality, assume $p'_j < p''_j$ and $p'_k < p''_k$, and define $\delta \in [0, 1]$. Comparing $d_{ij}(\delta) = p_i - (p'_j + \delta(p''_j - p'_j))$ and $d_{ik}(\delta) = (p'_k + \delta(p''_k - p'_k)) - p_i$, we have $d_{ij}(0) - d_{ik}(0) \geq 0$ and $d_{ij}(1) - d_{ik}(1) < 0$. There exist $\delta' \in [0, 1]$, s.t. $d_{ij}(\delta') - d_{ik}(\delta') = 0$.

Define $p_j = (p'_j + \delta'(p''_j - p'_j)) \in \mathcal{J}_i$ and $p_k = (p'_k + \delta'(p''_k - p'_k)) \in \mathcal{J}_j$, we have

$$p_i - p_j = p_k - p_i,$$

which concludes the proof. ◀

▶ **Lemma 5.2.** *Let $i_1, i_2, i_3, j_1, j_2, j_3, k_1, k_2, k_3 \in \mathbb{R}$, with $i_1 < i_2 < i_3$, $j_1 < j_2 < j_3$, $k_1 < k_2 < k_3$. For any $\alpha, \beta, \gamma \in \{1, 2\}$, let $H_{\alpha,\beta,\gamma}$ be the axis-parallel parallelepiped defined by*

$$H_{\alpha,\beta,\gamma} := \mathcal{CH}(\{(i_{\alpha+\alpha'}, j_{\beta+\beta'}, k_{\gamma+\gamma'}) : \alpha', \beta', \gamma' \in \{0, 1\}\}).$$

Let h be any plane in $\mathbb{R}^3$. Then, there exist $\alpha^*, \beta^*, \gamma^* \in \{0, 1\}$, such that h does not intersect the interior of $H_{\alpha^*,\beta^*,\gamma^*}$.

Proof. For any $d \geq 2$, any d-dimensional halfspace containing the origin must also contain at least one d-orthant. The assertion follows immediately from the case $d = 3$. ◀

▶ **Lemma 5.3.** *Let $i, j, k \in [b]$, with $j+1 < i$, and $i+1 < k$. Then, there exist $i', j', k' \in \{0, 1\}$ such that $(i + i', j + j', k + k')$ is not brittle.*

Proof. Define the plane

$$h = \{(x_I, x_J, x_K) \in \mathbb{R}^3 : x_I - x_J = x_K - x_I\}.$$

By Lemma 5.1, we have that if $(i + i', j + j', k + k')$ is brittle, then h must intersect the hyperrectangle $\mathcal{J}_{i+i'} \times \mathcal{J}_{j+j'} \times \mathcal{J}_{k+k'}$. However, by Lemma 5.2, it follows that there exist $i', j', k' \in \{0, 1\}$, such that h does not intersect $\mathcal{J}_{i+i'} \times \mathcal{J}_{j+j'} \times \mathcal{J}_{k+k'}$, and thus $(i + i', j + j', k + k')$ is not brittle, which concludes the proof. ◀

▶ **Lemma 5.4** (Brittle convexity)**.** *Let $\{e_1, e_2, e_3\}$ be the standard orthonormal basis in $\mathbb{R}^3$. Let $v \in [b-2]^3$, and let $w \in \{e_1, e_2, e_3\}$, such that v and $v + 2w$ are both brittle. Then, $v + w$ is also brittle.*

Proof. By Lemma 5.1, there exist $p_i \in \mathcal{J}_i$, $p_j \in \mathcal{J}_j$, $p_k \in \mathcal{J}_k$, such that

$$p_i - p_j = p_k - p_i. \tag{8}$$

Let $w = (i', j', k')$. Similarly, there exist $q_i \in \mathcal{J}_{i+2i'}$, $q_j \in \mathcal{J}_{j+2j'}$, $q_k \in \mathcal{J}_{k+2k'}$, such that

$$q_i - q_j = q_k - q_i. \tag{9}$$

For any $\alpha \in [0,1]$, let

$$z_i^{(\alpha)} = (1-\alpha)p_i + \alpha q_i,$$

$$z_j^{(\alpha)} = (1-\alpha)p_j + \alpha q_j,$$

$$z_k^{(\alpha)} = (1-\alpha)p_k + \alpha q_k.$$

Let us assume that $w = e_1$. The cases $w = e_2$ and $w = e_3$ can be handled in a similar manner. We have that for all $\alpha \in [0,1]$, $z_j^{(\alpha)} \in \mathcal{J}_j$, and $z_k^{(\alpha)} \in \mathcal{J}_k$. Moreover, $z_i^{(0)} \in \mathcal{J}_i$, and $z_i^{(1)} \in \mathcal{J}_{i+2}$, which implies that there exists some $\alpha^* \in [0,1]$, such that $z_i^{(\alpha^*)} \in \mathcal{J}_{i+1}$. We have

$$\begin{aligned} z_i^{(\alpha^*)} - z_j^{(\alpha^*)} &= (1-\alpha^*)p_i + \alpha^* q_i - (1-\alpha^*)p_j - \alpha^* q_j \\ &= (1-\alpha^*)(p_i - p_j) + \alpha^*(q_i - q_j) \\ &= (1-\alpha^*)(p_k - p_i) + \alpha^*(q_k - q_i) \\ &= (1-\alpha^*)p_k + \alpha^* q_k - (1-\alpha^*)p_i - \alpha^* q_i \\ &= z_k^{(\alpha^*)} - z_i^{(\alpha^*)}, \end{aligned}$$

which by Lemma 5.1 implies that $v + w$ is brittle, and concludes the proof. ◀

We are now ready to bound the number of brittle triples, which is the main result of this Section.

▶ **Lemma 5.5.** *The number of brittle triples is at most $O(b^2)$.*

Proof. Let $B \subseteq [b]^3$ be the set of all brittle triples, and let $B' = [b]^3 \setminus B$. For any $s \in \{0,1\}^3$, let

$$U_s = s \cdot b/2 + [b/2]^3,$$

and $B_s = B \cap U_s$. Since $B = \bigcup_s B_s$, and there are only 8 different values for s, it suffices to show that for any $s \in \{0,1\}^3$, $|B_s| = O(b^2)$. We shall prove this for the case $s = (0,0,0)$. All remaining cases can be handled in a similar manner.

For the remainder for the proof, let $s = (0,0,0)$. By Lemma 5.3, it follows that for any $v \in B_s^3$, there exists $v' \in B'$, with $v' - v \in \{0,1\}^3$. This implies that there exists $u \in B$, and $u' \in B'$, with $u - v \in \{0,1\}^3$, $u' - v \in \{0,1\}^3$, and $u' - u \in \{e_1, e_2, e_3\}$, where $\{e_1, e_2, e_3\}$ is the standard orthonormal basis in $\mathbb{R}^3$. Let $t = u' - u$. By Lemma 5.4, it follows by induction that for any $i \in \{1, \ldots, b/2\}$, the triple $u + i \cdot t$ is brittle. Let

$$R_v = \bigcup_{i=1}^{b/2} \{u + c \cdot i\}.$$

Thus $R_v \subseteq B'$. Note that, since $s = (0,0,0)$, we have

$$|R_v| \geq b/2. \tag{10}$$

For any $j \in \{1,2,3\}$, we say that v is *type-j*, if $t = e_j$.

Let

$$B_{s,j} = \{v \in B_s : v \text{ is type-}j\}.$$

Let $j^* \in \{1,2,3\}$, such that $|B_{s,j^*}| \geq |B_s|/3$.

By the above construction, it follows that for any $v, w \in B_{s,j^*}$, with $\|v - w\|_\infty \geq 2$, we have $R_v \cap R_w = \emptyset$. We greedily construct some $C \subseteq B_{s,j^*}$ as follows. We start with $C := \emptyset$, and $D := B_{s,j^*}$. While $D \neq \emptyset$, we pick any $v \in D$, and we set $C := C \cup \{v\}$, and $D := D \setminus \mathsf{Ball}_\infty(v,1)$, where $\mathsf{Ball}_\infty(v,r)$ denotes the ℓ_∞-ball of radius r centered at v. For every v added to C, we delete at most 9 elements from D, and thus

$$|C| \geq |B_{s,j^*}|/9 \geq |B_s|/27.$$

Since for any $v, w \in C$, we have $\|v - w\|_\infty$, it follows that $R_v \cap R_w = \emptyset$. Combining with (10), we get

$$b^3 \geq |B'| \geq \left| \bigcup_{v \in C} R_v \right| = \sum_{v \in C} |R_v| \geq |C| \cdot b/2 \geq |B_s| \cdot b/54,$$

and thus $|B_s| \leq 54b^2$, which concludes the proof. ◀

Abstract

The shift distance $\mathsf{sh}(S_1, S_2)$ between two strings S_1 and S_2 of the same length is defined as the minimum Hamming distance between S_1 and any rotation (cyclic shift) of S_2. We study the problem of sketching the shift distance, which is the following communication complexity problem: Strings S_1 and S_2 of length n are given to two identical players (encoders), who independently compute sketches (summaries) $\mathtt{sk}(S_1)$ and $\mathtt{sk}(S_2)$, respectively, so that upon receiving the two sketches, a third player (decoder) is able to compute (or approximate) $\mathsf{sh}(S_1, S_2)$ with high probability.

This paper primarily focuses on the more general k-mismatch version of the problem, where the decoder is allowed to declare a failure if $\mathsf{sh}(S_1, S_2) > k$, where k is a parameter known to all parties. Andoni et al. (STOC'13) introduced exact circular k-mismatch sketches of size $\tilde{O}(k + D(n))$, where $D(n)$ is the number of divisors of n. Andoni et al. also showed that their sketch size is optimal in the class of linear homomorphic sketches.

We circumvent this lower bound by designing a (non-linear) exact circular k-mismatch sketch of size $\tilde{O}(k)$; this size matches communication-complexity lower bounds. We also design $(1 \pm \varepsilon)$-approximate circular k-mismatch sketch of size $\tilde{O}(\min(\varepsilon^{-2}\sqrt{k}, \varepsilon^{-1.5}\sqrt{n}))$, which improves upon an $\tilde{O}(\varepsilon^{-2}\sqrt{n})$-size sketch of Crouch and McGregor (APPROX'11).

1 Introduction

The *Hamming distance* [25] is a fundamental metric for strings, and computing the Hamming distances in various settings is a central task in text processing. The Hamming distance of two length-n strings S_1 and S_2 is defined as the number of aligned mismatches between S_1 and S_2. In the k-mismatch variant [1, 4, 14, 22, 32], the problem is parameterized by an integer $1 \leq k \leq n$, and the task is relaxed so that if $\mathsf{Ham}(S_1, S_2) > k$, then instead of computing $\mathsf{Ham}(S_1, S_2)$, the algorithm is only required to report that this is the case, without computing the distance. Since computing the exact Hamming distance, both in the classic version and the k-mismatch version, is challenging under some efficiency constraints, a large body of research [14, 27, 30, 31] focused on the approximation version of both problems. Formally, in the $(1 \pm \varepsilon)$-approximation variant of either problem, the problem is parameterized by $\varepsilon > 0$, and whenever the algorithm should report $\mathsf{Ham}(S_1, S_2)$ in the original problem, in the approximation variant, the algorithm may report a $(1 \pm \varepsilon)$-approximation of $\mathsf{Ham}(S_1, S_2)$.

Sketching. Sketching is one of the settings of sublinear algorithms designed for space-efficient and time-efficient processing of big data, with applications in streaming algorithms, signal processing, network traffic monitoring, and other areas [18, 17, 34]. The task of sketching the Hamming distance boils down to constructing two (randomized) functions $\mathtt{sk} : \Sigma^n \to \{0,1\}^*$ and $\mathtt{dec} : \{0,1\}^* \times \{0,1\}^* \to \mathbb{N}$ such that $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) = \mathsf{Ham}(S_1, S_2)$ holds with high probability[1]. The communication-complexity interpretation of this problem involves three players sharing public randomness: two identical encoders and a decoder. The first encoder receives a string S_1, while the second encoder receives a string S_2. Each of the encoders needs to independently summarize its string. The summaries (sketches) are then sent to the decoder, whose task is to retrieve $\mathsf{Ham}(S_1, S_2)$ based on the summaries alone, without access to S_1 or S_2. The sketching complexity of Hamming distance, which is the size of the sketch, is well understood: the optimal sketch size is $\tilde{\Theta}(n)$ for the base variant [37, 40], $\tilde{\Theta}(k)$ for the k-mismatch variant [26, 37], and $\tilde{\Theta}(\varepsilon^{-2})$ for the $(1 \pm \varepsilon)$-approximate variants [2, 33, 40].[2] Much less is known about the sketching complexity of edit distance: it is $\tilde{\Theta}(n)$ for the base variant and $\tilde{O}(k^8)$ for the k-error variant [9]. Approximate edit distance sketches with super-constant approximation ratios are also known; see e.g. [11, 35].

The shift distance. We consider the *shift distance* [5, 6, 19], which is a cyclic variant of Hamming distance. For two strings $S_1, S_2 \in \Sigma^n$, the shift distance is defined as the minimum Hamming distance between S_1 and any cyclic shift (rotation) of S_2. Formally, if cyc is a function cyclically shifting a given string (by one position to the left), then $\mathsf{sh}(S_1, S_2) = \min\{\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \mid m \in \mathbb{Z}\}$ is the shift distance between S_1 and S_2. The research on shift distance for sublinear algorithms is mostly motivated by the observation that the shift distance shares many similarities with the fundamental Hamming distance. At the same time, shift distance inherits some of the challenges exhibited in the edit distance, e.g., in the context of low-dimensional embeddings to ℓ_1 [29] and asymmetric query complexity [7].

The first sketching scheme for shift distance, by Andoni et al. [6], allows for $O(\log^2 n)$-approximation using sketches of size $\tilde{O}(1)$. Crouch and McGregor [19] showed $(1 \pm \varepsilon)$-approximate sketches for shift distance that use $\tilde{O}(\varepsilon^{-2}\sqrt{n})$ space. Andoni et al. [5] designed

[1] An event $\mathcal{E}$ is said to happen with high probability if $\Pr[\mathcal{E}] \geq 1 - n^{-\Omega(1)}$.

[2] Throughout this paper, the $\tilde{\Theta}(\cdot), \tilde{\Omega}(\cdot)$, and $\tilde{O}(\cdot)$ notations suppress $\log^{O(1)} n$ factors.

exact k-mismatch circular sketches that use $\tilde{O}(D(n)+k)$ space, where $D(n)$ is the number of divisors of n, which is $n^{\Theta(1/\log\log n)}$ in the worst case. In [5], it is proven that $\tilde{\Omega}(D(n))$ is a lower bound for any linear homomorphic sketch for the shift distance k-mismatch problem.[3]

Our results. We consider a (slight) generalization of the problem of sketching the shift distance, where the decoder needs to retrieve $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ for every $m \in \mathbb{Z}$. We consider the problem both in the exact setting and in the $(1 \pm \varepsilon)$-approximation version.

▶ **Problem 1.1.** An *exact circular k-mismatch sketch* (k-ECS) for $\Pi \subseteq \Sigma^n$ is a pair of randomized functions[4] $\mathtt{sk} : \Pi \to \{0,1\}^*$ and $\mathtt{dec} : \{0,1\}^* \times \{0,1\}^* \times \mathbb{Z} \to \mathbb{N}$ such that, for every $S_1, S_2 \in \Pi$ and $m \in \mathbb{Z}$, the following holds with high probability:
- if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \le k$, then $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$,
- otherwise, $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) > k$.

▶ **Problem 1.2.** A *$(1 \pm \varepsilon)$-approximate circular k-mismatch sketch* ((ε, k)-ACS) for $\Pi \subseteq \Sigma^n$ is a pair of randomized functions $\mathtt{sk} : \Pi \to \{0,1\}^*$ and $\mathtt{dec} : \{0,1\}^* \times \{0,1\}^* \times \mathbb{Z} \to \mathbb{R}$ such that, for every $S_1, S_2 \in \Pi$ and $m \in \mathbb{Z}$, the following holds with high probability:
- if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \le k$, then $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) \in (1 \pm \varepsilon)\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$,
- otherwise, $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) > (1-\varepsilon)k$.

In this paper, a sketch for $\Pi \subseteq \Sigma^n$ is of size s if for every $S \in \Pi$, we have $|\mathtt{sk}(S)| \le s$ with high probability. Our results are stated in the following theorems.

▶ **Theorem 1.3.** *There exists a k-ECS sketch for Σ^n of size $\tilde{O}(k)$.*

▶ **Theorem 1.4.** *There exists an (ε, k)-ACS sketch for Σ^n of size $\tilde{O}(\min(\varepsilon^{-2}\sqrt{k}, \varepsilon^{-1.5}\sqrt{n}))$.*

Notice that Theorem 1.3 circumvents the lower bound of Andoni et al. [5] by using non-linear sketches (however, the sketches are still homomorphic). Moreover, Theorem 1.4 improves upon the $\tilde{O}(\varepsilon^{-2}\sqrt{n})$ size sketches of Crouch and McGregor [19], and also addresses the more general k-mismatch variant of the problem.

Decoding efficiency. We also discuss the efficiency of evaluating $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m)$ for a given $m \in \mathbb{Z}$ and the efficiency of evaluating or approximating $\mathsf{sh}(S_1, S_2)$ based on our sketches. We show that the naive solution of minimizing $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m)$ across all $m \in [n]$ can be sped up significantly. Formally, this yields solutions to the following problems.

▶ **Problem 1.5.** An *exact k-mismatch shift distance sketch* (k-ESDS) for $\Pi \subseteq \Sigma^n$ is a pair of randomized functions $\mathtt{sk} : \Pi \to \{0,1\}^*$ and $\mathtt{dec}^{\mathsf{sh}} : \{0,1\}^* \times \{0,1\}^* \to \mathbb{N}$ such that, for every $S_1, S_2 \in \Pi$, the following holds with high probability:
- if $\mathsf{sh}(S_1, S_2) \le k$, then $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) = \mathsf{sh}(S_1, S_2)$,
- otherwise, $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) > k$.

▶ **Problem 1.6.** A *$(1 \pm \varepsilon)$-approximate k-mismatch shift distance sketch* ((ε, k)-ASDS) for $\Pi \subseteq \Sigma^n$ is a pair of randomized functions $\mathtt{sk} : \Pi \to \{0,1\}^*$ and $\mathtt{dec}^{\mathsf{sh}} : \{0,1\}^* \times \{0,1\}^* \to \mathbb{R}$ such that, for every $S_1, S_2 \in \Pi$, the following holds with high probability:
- if $\mathsf{sh}(S_1, S_2) \le k$, then $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) \in (1 \pm \varepsilon)\mathsf{sh}(S_1, S_2)$,
- otherwise, $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) > (1-\varepsilon)k$.

The task of designing efficient algorithms for computing our sketches is left open.

[3] A sketch is *homomorphic* if $\mathtt{sk}(\mathsf{cyc}(S))$ can be retrieved from $\mathtt{sk}(S)$ and *linear* if $\mathtt{sk}$ is a linear mapping.
[4] A randomized function $f : X \to Y$ is a random variable whose values are functions from X to Y.

Related work. A problem closely related to the *circular Hamming distances* problem, asking to determine $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ for all $0 \leq m < n$, is the *text-to-pattern Hamming distances* problem, where the input consists of a pattern P (of length m) and a text T (of length n), and the task is to compute the Hamming distances between P and every length-m substring of T. A straightforward reduction from the circular Hamming distances problem to the text-to-pattern Hamming distances problem is given by $P = S_1$ and $T = S_2 \cdot S_2$.

In the offline setting, including the exact and approximate k-mismatch variants, we are not aware of any separation between the two problems. The state-of-the-art exact solution combines an $\tilde{O}(n\sigma)$-time solution for small alphabets (of size σ) [21] with an $\tilde{O}(n + \frac{nk}{\sqrt{m}})$-time algorithm [22], which culminates a long line of research [1, 4, 14, 32]. The approximate variant can be solved in $\tilde{O}(\varepsilon^{-1}n)$ time [30, 31]; these results improve upon [27]. On the other hand, sketches for text-to-pattern Hamming distances need to be much larger than circular sketches: already recovering exact occurrences requires $\Omega(n - m)$ space [8].

Interestingly, both in the exact and in the approximate setting, the sizes of our circular k-mismatch sketches coincide with the current upper bounds for space usage in the *streaming* k-mismatch problem. In that model, the text arrives in a stream, one character at a time, and the goal is to compute, or estimate, after the arrival of each text character, the Hamming distance between P and the current suffix of T. The state-of-the-art exact algorithm [15] uses $\tilde{O}(k)$ space and costs $\tilde{O}(\sqrt{k})$ time per character, which improves upon [14, 23, 36, 38]. A recent approximate streaming algorithm [12] uses $\tilde{O}(\min(\varepsilon^{-2}\sqrt{k}, \varepsilon^{-1.5}\sqrt{n}))$ space and costs $\tilde{O}(\varepsilon^{-3})$ time per character, which improves upon [16, 39].

2 Algorithmic Overview and Organization

The central technical contribution of our work is a randomized scheme of selecting positions in a given string $S \in \Sigma^n$ so that if $f(S) \subseteq \{1, \ldots, n\}$ is the set of selected positions, then the following properties hold: $|f(S)| = \tilde{O}(k)$ with high probability, the selection is preserved by rotations (the selected positions are shifted along with the underlying characters), and $|f(S) \cap f(T)| \geq k$ with high probability for every $T \in \Sigma^n$ such that $\mathsf{Ham}(S, T) \leq k$.

Unfortunately, for integer exponents $\alpha \gg k$, such a selection of positions is infeasible for strings of the form $S = Q^\alpha$ (that we call *high powers*), which are fixed points of $\mathsf{cyc}^{n/\alpha}$. Moreover, the selection of positions is also infeasible for strings with a relatively small Hamming distance to some high power. Hence, we define the problematic strings to be *pseudo-periodic*, exclude them from the selection scheme, and deal with them separately.

Sketches for non-pseudo-periodic strings. In Section 4, we construct sketches for non-pseudo-periodic strings using a selection function f satisfying the aforementioned properties.

Our (ε, k)-ACS sketch stores (non-circular) approximate Hamming distance sketches of $\mathsf{cyc}^i(S)$ for a random sample of $\tilde{O}(\sqrt{k})$ positions $i \in f(S)$. Given the (ε, k)-ACS sketches of two strings S_1, S_2 and a shift value m such that $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, with high probability, there is a shift i such that the non-circular sketches of both $\mathsf{cyc}^i(S_1)$ and $\mathsf{cyc}^{i+m}(S_2)$ are available. The decoder uses these approximate Hamming distance sketches to approximate $\mathsf{Ham}(\mathsf{cyc}^i(S_1), \mathsf{cyc}^{i+m}(S_2)) = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$; see Section 4.1 for details.

Our k-ECS sketch, for each position $i \in f(S)$, stores a (non-circular) sketch of $\mathsf{cyc}^i(S)$ capable of retrieving each mismatch with probability $\Theta(\frac{\log n}{k})$, but no more than $O(\log n)$ mismatches in total. Given circular sketches of two strings S_1, S_2 and a shift value m such that $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, with high probability, there are at least k shifts i such that the non-circular sketches of both $\mathsf{cyc}^i(S_1)$ and $\mathsf{cyc}^{i+m}(S_2)$ are available. Each of these k pairs of

non-circular sketches yields random mismatches between S_1 and $\mathsf{cyc}^m(S_2)$. Consequently, with high probability, each mismatch between S_1 and $\mathsf{cyc}^m(S_2)$ is reported at least once, which allows for the exact computation of $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$; see Section 4.2 for details.

Selection function. The selection function f for non-pseudo-periodic strings is constructed in Section 5. Our baseline solution is to sample strings of length $\frac{n}{\gamma k}$ (for a constant γ fixed in Section 4) with rate $\tilde{O}(\frac{k}{n})$ and, for each sampled string u, to add to $f(S)$ the positions where u occurs in S. Unfortunately, since substrings could have much more than γk occurrences, the variance of $|f(S)|$ could be rather large, and thus substrings with a large number of occurrences need to be excluded from the sample. This workaround is feasible unless highly periodic regions cover most positions of S; see Section 5.1, where the properties of f are proved using concentration arguments (the Chernoff–Hoeffding bound).

In the complementary case of strings mostly covered by highly periodic regions, we utilize the structure of these regions to deterministically select positions. If there are many disjoint regions, it suffices to select the boundaries of the regions. However, in general we follow a more involved approach inspired by [10, 13]: periodic regions are extended as long as the number of mismatches between the extended region and the period of the region is relatively small compared to the length of the extended region. The positions of these mismatches are also added to $f(S)$. Selection of f in this case is the most technically challenging component of our construction; see Section 5.2 for details.

Sketches for pseudo-periodic strings. Each pseudo-periodic string can be assigned to the nearest high power (the *base*) so that two pseudo-periodic strings S_1, S_2 satisfy $\mathsf{Ham}(S_1, S_2) \leq k$ only if they share the same base. Thus, we first design a 0-mismatch circular sketch (of size $\tilde{O}(1)$) to be used for comparing the bases both in the exact and approximate variants.

Our exact k-mismatch circular sketch stores the mismatches between the string and its base. Once the decoder verifies that S_1 and $\mathsf{cyc}^m(S_2)$ share the same base, the mismatches between S_1 and $\mathsf{cyc}^m(S_2)$ are reconstructed from the mismatches between each of the strings $S_1, \mathsf{cyc}^m(S_2)$ and their common base. The (ε, k)-ACS sketch stores only the mismatches between the string and its base at $\tilde{O}(\frac{n}{\varepsilon\sqrt{k}})$ sampled positions (so that $\tilde{O}(\varepsilon^{-1}\sqrt{k})$ mismatches are stored with high probability). Once the decoder verifies that S_1 and $\mathsf{cyc}^m(S_2)$ share the same base, the mismatches between S_1 and $\mathsf{cyc}^m(S_2)$ at $\tilde{O}(\frac{n}{\varepsilon^2 k})$ jointly sampled positions are retrieved to estimate $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$; see Section 6.

Organization. In Sections 4 and 5, we describe the main novel ideas and techniques of this paper, which are used in sketches for strings that are not pseudo-periodic. In Section 6, we provide sketches for pseudo-periodic strings, and in Section 7 we combine the sketches of Section 4 with the sketches of Section 6 in order to prove the main theorems. Notice that these two cases require a slight overlap so that whenever $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, one of the cases accommodates *both* S_1 and S_2. In Section 7, we also develop another (ε, k)-ACS sketch, tailored to approximating large distances. This simple construction improves the size of (ε, k)-ACS sketches (for $k \geq \varepsilon n$) from $\tilde{O}(\varepsilon^{-2}\sqrt{k})$ to $\tilde{O}(\varepsilon^{-1.5}\sqrt{n})$. Finally, in Appendix A, we describe efficient decoding algorithms for retrieving the shift distance from the encodings developed for the circular k-mismatch sketches. A few simple or folklore proofs are deferred from Sections 3–7 to Appendix B.

3 Preliminaries

For integers $\ell \leq r$, we denote $[\ell\,..\,r] = \{\ell, \ell+1, \ldots, r\}$. Moreover, $[n] = [1\,..\,n]$.

A string S of length $|S| = n$ is a sequence of characters $S[1]S[2]\cdots S[n]$ over an alphabet Σ; in this work, we assume that $\Sigma = [\sigma]$. The set of all length-n strings over Σ is denoted by Σ^n. A string T is a *substring* of a string $S \in \Sigma^n$ if $T = S[i]S[i+1]\cdots S[j]$ for $1 \leq i \leq j \leq n$. In this case, we denote the occurrence of T at position i by $S[i\,..\,j]$. Such an occurrence is a *fragment* of S. A fragment $S[i\,..\,j]$ is a *prefix* of S if $i = 1$ and a *suffix* of S if $j = n$.

Hamming distance. The *Hamming distance* $\mathsf{Ham}(S,T)$ of two strings $S, T \in \Sigma^n$ is defined as the number of positions $i \in [n]$ such that $S[i] \neq T[i]$. We denote $\mathsf{MP}(S,T) = \{i \in [n] \mid S[i] \neq T[i]\}$ to be the set of *mismatch positions* and $\mathsf{MI}(S,T) = \{(i, S[i], T[i]) \mid i \in [n], S[i] \neq T[i]\}$ to be the underlying *mismatch information*. Note that $\mathsf{Ham}(S,T) = |\mathsf{MP}(S,T)| = |\mathsf{MI}(S,T)|$.

For a subset $A \subseteq [n]$, we denote $\mathsf{MI}_A(S,T) = \{(i,a,b) \in \mathsf{MI}(S,T) \mid i \in A\}$ and $\mathsf{Ham}_A(S,T) = |\mathsf{MI}_A(S,T)|$. The following result, based on the Chernoff bound and proved in Appendix B, shows that $\mathsf{Ham}_A(S,T)$ for random A yields an approximation of $\mathsf{Ham}(S,T)$.

▶ **Lemma 3.1.** *Let A be a random subset of $[n]$ with elements chosen independently at rate p. For $0 < \varepsilon < 1$, we have* $\Pr[\mathsf{Ham}_A(S,T) \in (1 \pm \varepsilon)p\mathsf{Ham}(S,T)] \geq 1 - 2\exp\left(-\frac{p\mathsf{Ham}(S,T)\varepsilon^2}{3}\right)$.

The triangle inequality yields $\mathsf{Ham}(S,U) \leq \mathsf{Ham}(S,T) + \mathsf{Ham}(T,U)$ for $S,T,U \in \Sigma^n$. The underlying phenomenon also allows retrieving $\mathsf{MI}(S,U)$ from $\mathsf{MI}(S,T)$ and $\mathsf{MI}(T,U)$. The following fact is proved in Appendix B.

▶ **Fact 3.2.** *For every $S,T,U \in \Sigma^n$ and every $A \subseteq [n]$, the mismatch information $\mathsf{MI}_A(S,U)$ can be retrieved from $\mathsf{MI}_A(S,T)$ and $\mathsf{MI}_A(T,U)$ in time $\tilde{O}(\mathsf{Ham}_A(S,T) + \mathsf{Ham}_A(T,U))$.*

Periods. An integer p is a *period* of $S \in \Sigma^*$ if and only if $S[i] = S[i+p]$ for all $1 \leq i \leq |S| - p$. The shortest period of S is denoted $\mathsf{per}(S)$. If $\mathsf{per}(S) \leq \frac{1}{2}|S|$, we say that S is *periodic*.

Rotations. For a string $S = S[1]S[2]\cdots S[n]$, let $\mathsf{cyc}(S) = S[2]\cdots S[n]S[1]$. For $i \in \mathbb{Z}$, we denote $i \circlearrowright n = ((i-1) \bmod n) + 1$ so that, for $i \in [n]$, the value $(i-1) \circlearrowright n$ is the position of $S[i]$ in $\mathsf{cyc}(S)$.[5] Moreover, for $M \subseteq \mathbb{Z}$, we denote $M \circlearrowright n = \{i \circlearrowright n \mid i \in M\}$. For $P \subseteq [n]$, let $\mathsf{rot}_n(P) = \{(i-1) \circlearrowright n \mid i \in P\}$ be the rotated set P.

The *primitive root* of a string S is the shortest string Q such that $S = Q^\alpha$ for an integer $\alpha \geq 1$. The length of the primitive root is denoted by $\mathsf{root}(S)$. Notice that $\mathsf{per}(S) \leq \mathsf{root}(S)$. Moreover, for every $m, m' \in \mathbb{Z}$, we have that $\mathsf{root}(\mathsf{cyc}^m(S)) = \mathsf{root}(S)$, and $\mathsf{cyc}^m(S) = \mathsf{cyc}^{m'}(S)$ if and only if $\mathsf{root}(S) \mid (m - m')$.

4 Sketches for Non-pseudo-periodic Strings

We say that a string $S \in \Sigma^n$ is (α,β)-*pseudo-periodic* if there exists a string $S' \in \Sigma^n$, called an (α,β)-*base* of S, such that $\mathsf{root}(S') \leq \frac{n}{\alpha}$ and $\mathsf{Ham}(S,S') \leq \beta$.

▶ **Observation 4.1.** *If S is (α,β)-pseudo-periodic with an (α,β)-base S', then every rotation $\mathsf{cyc}^m(S)$ with $m \in \mathbb{Z}$ is also (α,β)-pseudo-periodic and $\mathsf{cyc}^m(S')$ is an (α,β)-base of $\mathsf{cyc}^m(S)$.*

[5] We introduce the $\circlearrowright$ operator because positions in strings are indexed from 1 rather than from 0.

Let $\mathcal{H}_{n,k}$ be the set of strings in Σ^n that are $(3\gamma k, \gamma k)$-pseudo-periodic, where γ is the smallest constant such that $\gamma \geq 14$ and $\frac{n}{3\gamma k}$ is an integer. In this section, we present two circular sketches for strings in $\Sigma^n \setminus \mathcal{H}_{n,k}$: an (ε, k)-ACS sketch and a k-ECS sketch. Both sketches rely on the following result, proved in Section 5.

▶ **Theorem 4.2.** *For every two integers $1 \leq k \leq n$, there exists a randomized function $f : \Sigma^n \setminus \mathcal{H}_{n,k} \to 2^{[n]}$ such that the following holds for every $S_1, S_2 \in \Sigma^n \setminus \mathcal{H}_{n,k}$:*
1. *$|f(S_1)| = \tilde{O}(k)$ with high probability,*
2. *$f(\mathsf{cyc}(S_1)) = \mathsf{rot}_n(f(S_1))$,*
3. *if $\mathsf{Ham}(S_1, S_2) \leq k$, then $|f(S_1) \cap f(S_2)| \geq k$ with high probability.*

4.1 An (ε, k)-ACS Sketch

We start with briefly presenting a useful technical tool, that is, the non-circular version of the approximate sketch. We remark that many variants of this sketch exist, with equivalent space complexity. A short proof is given in Appendix B for the sake of completeness.

▶ **Theorem 4.3** ($(1 \pm \varepsilon)$-approximate sketches, folklore)**.** *There exists a $(1 \pm \varepsilon)$-approximate sketch $\mathtt{sk}_\varepsilon$ such that, given $\mathtt{sk}_\varepsilon(S_1)$ and $\mathtt{sk}_\varepsilon(S_2)$ for two strings $S_1, S_2 \in \Sigma^n$, one can decode $\mathsf{Ham}(S_1, S_2)$ with a $(1 \pm \varepsilon)$-multiplicative error. The sketches use $\tilde{O}(\varepsilon^{-2})$ space, the decoding algorithm is correct with high probability and costs $\tilde{O}(\varepsilon^{-2})$ time.*

Next, we describe our sketching scheme and prove that, together with an appropriate decoding algorithm, it forms an (ε, k)-ACS sketch for $\Sigma^n \setminus \mathcal{H}_{n,k}$.

▶ **Construction 4.4.** The encoding function $\mathtt{circ}_{\varepsilon,k} : \Sigma^n \setminus \mathcal{H}_{n,k} \to \{0,1\}^*$ is defined as follows:
1. Let $f : \Sigma^n \setminus \mathcal{H}_{n,k} \to 2^{[n]}$ be the selection function of Theorem 4.2.
2. Let $\mathtt{sk}_\varepsilon : \Sigma^n \to \{0,1\}^*$ be the sketch of Theorem 4.3.
3. Let $A, B \subseteq [n]$ be two subsets[6] with elements sampled independently with rate $p = 2\sqrt{\frac{\ln n}{k}}$.
4. For $S \in \Sigma^n \setminus \mathcal{H}_{n,k}$, the encoding $\mathtt{circ}_{\varepsilon,k}(S)$ stores $(i, \mathtt{sk}_\varepsilon(\mathsf{cyc}^i(S)))$ for $i \in f(S) \cap (A \cup B)$.

▶ **Proposition 4.5.** *There exists a decoding function which, together with the encoding $\mathtt{circ}_{\varepsilon,k}$ of Construction 4.4, forms an (ε, k)-ACS sketch of $\Sigma^n \setminus \mathcal{H}_{n,k}$. The size of this sketch is $\tilde{O}(\varepsilon^{-2}\sqrt{k})$, and the decoding algorithm costs $\tilde{O}(\sqrt{k} + \varepsilon^{-2})$ time with high probability.*

Proof. Our decoding procedure iterates over $i \in f(S_1) \cap A$. If $i' := (i + m) \circlearrowright n \in f(S_2) \cap B$, the procedure retrieves the sketches $\mathtt{sk}_\varepsilon(\mathsf{cyc}^i(S_1))$ and $\mathtt{sk}_\varepsilon(\mathsf{cyc}^{i'}(S_2))$ and recovers a $(1+\varepsilon)$-approximation of $\mathsf{Ham}(\mathsf{cyc}^i(S_1), \mathsf{cyc}^{i'}(S_2)) = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$. Otherwise, ∞ is returned.

We now reason that if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, then, with high probability, $i' \in f(S_2) \cap B$ for some $i \in f(S_1) \cap A$. By Theorem 4.2, $|f(S_1) \cap f(\mathsf{cyc}^m(S_2))| \geq k$. Thus, for any $i \in f(S_1) \cap f(\mathsf{cyc}^m(S_2))$, we have that $i \in f(S_1) \cap A$ with probability p. Similarly, $i' \in f(S_2) \cap B$ with probability p. Since A and B are independent, we have a success probability p^2 for each i independently. The probability of at least one success is at least $1 - (1-p^2)^k \geq 1 - n^{-4}$.

The decoding time is given by the time needed to compute the intersection of $f(S_1) \cap A$ and $\mathsf{rot}_n^m(f(S_2) \cap B)$, which is $\tilde{O}(\sqrt{k})$ with high probability, and $\tilde{O}(\varepsilon^{-2})$ time to decode the distance from a single pair of indices i, i', provided that the intersection is not empty. ◀

[6] The sketch would remain valid with one subset only. However, introducing the second subset simplifies the arguments and makes the construction more similar to the counterpart for pseudo-periodic strings.

4.2 An k-ECS Sketch

We begin with the following corollary of [37, Theorem 5.1]. The original statement in [37] is given for $A = [n]$ only, but it can be generalized in a straightforward manner, e.g., by replacing all characters at positions in $[n] \setminus A$ with a fixed character.

▶ **Theorem 4.6** (based on [37, Theorem 5.1]). *For every $k \leq n$ and $A \subseteq [n]$, there is a sketch $\mathtt{sk}_{k,A}$ of size $\tilde{O}(k)$ such that, given $\mathtt{sk}_{k,A}(S_1)$ and $\mathtt{sk}_{k,A}(S_2)$ for two strings $S_1, S_2 \in \Sigma^n$:*

- *if $\mathsf{Ham}_A(S_1, S_2) \leq k$, then the decoding function returns $\mathsf{MI}_A(S_1, S_2)$;*
- *otherwise, if $\mathsf{Ham}_A(S_1, S_2) > k$, the decoding function reports that this is the case.*

The decoding algorithm is correct with high probability and costs $\tilde{O}(k)$ time.

▶ **Construction 4.7.** The encoding function $\mathtt{circ}_k : \Sigma^n \setminus \mathcal{H}_{n,k} \to \{0,1\}^*$ is defined as follows:

1. Let $f : \Sigma^n \setminus \mathcal{H}_{n,k} \to 2^{[n]}$ be the selection function of Theorem 4.2.
2. Let $A \subseteq [n]$ be a subset with elements sampled independently with rate $p := \frac{9 \ln n}{k}$.
3. Denote $t = \lceil 18 \ln n \rceil$, and let $\mathtt{sk}_{t,A} : \Sigma^n \to \{0,1\}^*$ be the sketch of Theorem 4.6.
4. For $S \in \Sigma^n \setminus \mathcal{H}_{n,k}$, the encoding $\mathtt{circ}_k(S)$ stores the pairs $(i, \mathtt{sk}_{t,A}(\mathsf{cyc}^i(S)))$ for $i \in f(S)$.

▶ **Proposition 4.8.** *There exists a decoding function which, together with the encoding $\mathtt{circ}_k$ of Construction 4.7, forms a k-ECS sketch of $\Sigma^n \setminus \mathcal{H}_{n,k}$. The size of this sketch is $\tilde{O}(k)$, and the decoding algorithm costs $\tilde{O}(k)$ time with high probability.*

Proof. The decoding procedure iterates over $i \in f(S_1) \cap \mathsf{rot}_n^m(f(S_2))$, If the number of such positions is less than k, then ∞ is returned. Otherwise, for each $i \in f(S_1) \cap \mathsf{rot}_n^m(f(S_2))$, we have $i' := (i + m) \circlearrowright n \in f(S_2)$, and the algorithm runs a decoding procedure for $\mathtt{sk}_{t,A}(\mathsf{cyc}^i(S_1))$ and $\mathtt{sk}_{t,A}(\mathsf{cyc}^{i'}(S_2))$. If any such decoding fails, then ∞ is returned. Otherwise, for each mismatch position j found, say with $\mathsf{cyc}^i(S_1)[j] \neq \mathsf{cyc}^{i'}(S_2)[j]$, the algorithm adds $(i + j) \circlearrowright n$ to a set M, initialized as the empty set. Finally, the size $|M|$ is returned.

The decoding procedure costs $\tilde{O}(k)$ time, which is needed both to find all the aligned pairs $i \in f(S), i' \in f(S_2)$ by computing the intersection $f(S_1) \cap \mathsf{rot}_n^m(f(S_2))$ and to retrieve and gather the mismatches obtained from the aligned pairs (in $\tilde{O}(t) = \tilde{O}(1)$ time per pair).

Correctness. Recall that $\mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$ is the set of mismatch positions between S_1 and $\mathsf{cyc}^m(S_2)$. First, notice that each $j \in M$ is a mismatch position between S_1 and $\mathsf{cyc}^m(S_2)$, since $\mathsf{cyc}^i(S_1)[j] \neq \mathsf{cyc}^{i'}(S_2)[j]$ is equivalent to $S_1[(i + j) \circlearrowright n] \neq S_2[(i + j + m) \circlearrowright n]$. Hence, $M \subseteq \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$ and $|M| \leq \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$

Now, we prove that, with high probability, if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, then the algorithm reports $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$, and if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) > k$, then the algorithm reports a value larger than k. In the case where $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, we have that $|f(S_1) \cap \mathsf{rot}_n^m(f(S_2))| \geq k$ with high probability due to Theorem 4.2. Moreover, for every $i \in f(S_1) \cap \mathsf{rot}_n^m(f(S_2))$, the expected number of positions in $A \cap \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$ is $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \cdot p \leq k \cdot \frac{9 \ln n}{k} = 9 \ln n$. Hence, by a Chernoff bound $\Pr[|A \cap \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))| > 18 \ln n] \leq \exp(-\frac{9 \ln n}{3}) = n^{-3}$. Thus, when $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, decoding $\mathtt{sk}_{t,A}(\mathsf{cyc}^i(S_1))$ and $\mathtt{sk}_{t,A}(\mathsf{cyc}^{i'}(S_2))$ succeeds for all $i \in f(S_1) \cap \mathsf{rot}_n^m(f(S_2))$ with high probability.

Conditioned on the event that $|f(S_1) \cap \mathsf{rot}_n^m(f(S_2))| \geq k$ and the decoding algorithm of $\mathtt{sk}_{t,A}$ is successful, we now prove that $|M| = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$. For each mismatch $j \in \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$, there is an independent trial associated with each $i \in f(S_1) \cap \mathsf{rot}_n^m(f(S_2))$, which is whether $((j - i) \circlearrowright n) \in A$ or not. The trial is successful with probability p. The probability that at least one of those trials succeeds is at least $1 - (1-p)^k \geq 1 - n^{-9}$. Applying the union bound over all $j \in \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$, we conclude that $M = \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$ and $|M| = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ with high probability.

If $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) > k$, then the decoding algorithm may return ∞ because of $|f(S_1) \cap \mathsf{rot}_n^m(f(S_2))| < k$ or due to a decoding failure. If neither of these events happen, the algorithm returns $|M|$, which is equal to $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ with high probability (as proved above). Thus, in both cases, a value larger than k is reported. ◀

5 Construction of the Selection Function

For $S \in \Sigma^n$, let $S^* = S \cdot S \cdot S \cdots$ be the infinite string which is the infinite concatenation of S to itself (for any $i \in \mathbb{N}$, we have $S^*[i] = S[i \circlearrowright n]$). Let $\ell = \frac{n}{3\gamma k}$ (recall it is an integer). A position $i \in [n]$ is called *cubic* if $u_i = S^*[i \,..\, i+3\ell-1]$ has $\mathsf{per}(u_i) \le \frac{|u_i|}{3} = \ell$, i.e., if the cyclic fragment of length 3ℓ starting at position i consists of at least three repetitions of the same factor. Otherwise, position i is called *non-cubic*. We denote the set of cubic positions in a string S as $\mathsf{C}(S)$, and the set of non-cubic positions as $\mathsf{N}(S)$. Notice that $\mathsf{C}(S) \cup \mathsf{N}(S) = [n]$ and $\mathsf{C}(S) \cap \mathsf{N}(S) = \emptyset$.

We present two selection techniques, resulting in functions f_{n} and f_{c}, designed for strings with many non-cubic positions and for strings with many cubic positions, respectively. Both functions satisfy the first two properties of Theorem 4.2 for any string $S_1 \in \Sigma^n \setminus \mathcal{H}_{n,k}$. The functions f_{n} and f_{c} have the third property of Theorem 4.2 if $|\mathsf{N}(S_1)| \ge \frac{n}{2}$ and if $|\mathsf{C}(S_1)| \ge \frac{n}{2}$, respectively. Thus, the function f defined through $f(S) = f_{\mathsf{n}}(S) \cup f_{\mathsf{c}}(S)$ satisfies Theorem 4.2.

5.1 Selecting Positions for Strings with Many Non-cubic Positions

Throughout this subsection, let $h : \Sigma^{3\ell} \to \{0,1\}$ be a hash function assigning values independently to each $u \in \Sigma^{3\ell}$ such that $\Pr[h(u) = 1] = \frac{4k \ln n}{n}$. For clarity, we omit the explicit dependence on h in our notation. For $S \in \Sigma^n$, define $f_{\mathsf{n}}(S) = \{i \in \mathsf{N}(S) \mid h(u_i) = 1\}$.

Our proofs rely on the following multiplicative Chernoff–Hoeffding bound:

▶ **Proposition 5.1** (Corollary of [20, Theorems 1.10.1 and 1.10.5]). *Let $X_1, \ldots, X_n$ be independent random variables taking values in $[0, M]$, let $X = \sum_{i=1}^n X_i$, and let $\mu \ge 0$.*

(a) *If $\mu \ge \mathbb{E}[X]$, then, for every $\delta > 0$, we have $\Pr[X \ge (1+\delta)\mu] \le \exp(-\frac{\min(\delta,\delta^2)\mu}{3M})$.*

(b) *If $\mu \le \mathbb{E}[X]$, then, for every $0 < \delta < 1$, we have $\Pr[X \le (1-\delta)\mu] \le \exp(-\frac{\delta^2\mu}{2M})$.*

We first prove that f_{n} satisfies the first property of Theorem 4.2.

▶ **Lemma 5.2.** *For every $S \in \Sigma^n$, we have $\Pr\left[|f_{\mathsf{n}}(S)| < 8k \ln n\right] \ge 1 - n^{-\Omega(1)}$.*

Proof. For each $u \in \Sigma^{3\ell}$, we introduce a random variable $X_u = |\{i \in f_{\mathsf{n}}(S) \mid u_i = u\}|$; notice that X_u depends only on $h(u)$, so the variables X_u are independent. In order to apply Proposition 5.1 for $|f_{\mathsf{n}}(S)| = \sum_{u \in \Sigma^{3\ell}} X_u$, we prove that each X_u is bounded.

First, note that if $\mathsf{per}(u) \le \ell$ or $h(u) = 0$, then $X_u = 0$. Otherwise, as $u_i = u = u_{i'}$ for $i < i' \le i + 3\ell$ implies $i' - i \ge \mathsf{per}(u) > \ell$, we conclude that $X_u = |\{i \in [n] \mid u_i = u\}| \le \frac{n}{\ell} = 3\gamma k$. Now, $\mathbb{E}[|f_{\mathsf{n}}(S)|] = \sum_{i \in \mathsf{N}(S)} \Pr[h(u_i) = 1] = |\mathsf{N}(S)| \cdot \frac{4k \ln n}{n} \le 4k \ln n$, so, by Proposition 5.1(a) with $\delta = 1$, we have $\Pr[|f_{\mathsf{n}}(S)| \ge 8k \ln n] \le \exp(-\frac{4k \ln n}{3 \cdot 3\gamma k}) = n^{-4/(9\gamma)} = n^{-\Omega(1)}$. ◀

The following lemma states that f_{n} satisfies Property 2 of Theorem 4.2.

▶ **Lemma 5.3.** *For every $S \in \Sigma^n$, we have $f_{\mathsf{n}}(\mathsf{cyc}(S)) = \mathsf{rot}_n(f_{\mathsf{n}}(S))$.*

Proof. Let $i \in f_{\mathsf{n}}(\mathsf{cyc}(S))$ and let $u = (\mathsf{cyc}(S))^*[i \,..\, i + \ell - 1] = S^*[i+1 \,..\, i+\ell]$. Since $i \in f_{\mathsf{n}}(\mathsf{cyc}(S))$, we have that $\mathsf{per}(u) > \frac{\ell}{3}$ and $h(u) = 1$. Therefore, $(i+1) \circlearrowright n \in f_{\mathsf{n}}(S)$, which means that $i \circlearrowright n = i \in \mathsf{rot}_n(f_{\mathsf{n}}(S))$. Hence, $f_{\mathsf{n}}(\mathsf{cyc}(S)) \subseteq \mathsf{rot}_n(f_{\mathsf{n}}(S))$. Symmetrically, $\mathsf{rot}_n(f_{\mathsf{n}}(S)) \subseteq f_{\mathsf{n}}(\mathsf{cyc}(S))$. Thus, $f_{\mathsf{n}}(\mathsf{cyc}(S)) = \mathsf{rot}_n(f_{\mathsf{n}}(S))$. ◀

Finally, the following lemma states that f_{n} satisfies Property 3 of Theorem 4.2.

▶ **Lemma 5.4.** *Suppose that* $S_1, S_2 \in \Sigma^n$ *satisfy* $\mathsf{Ham}(S_1, S_2) \leq k$. *If* $|\mathsf{N}(S_1)| \geq \frac{1}{2}n$, *then* $\Pr[|f_{\mathsf{n}}(S_1) \cap f_{\mathsf{n}}(S_2)| \geq k] \geq 1 - n^{-\Omega(1)}$.

Proof. For each $i \in [n]$, let $u_i = S_1^*[i\,..\,i+3\ell-1]$ and $v_i = S_2^*[i\,..\,i+3\ell-1]$, and let $\Lambda = \{i \in \mathsf{N}(S_i) \mid u_i = v_i\}$. Notice that, for $i \in [n]$, we have $u_i \neq v_i$ if and only if $\mathsf{MP}(S_1, S_2) \cap ([i\,..\,i+3\ell-1] \circlearrowleft n) \neq \emptyset$. Hence, the number of indices $i \in [n]$ with $u_i \neq v_i$ is at most $|\mathsf{MP}(S_1, S_2)| \cdot 3\ell \leq k \cdot \frac{n}{\gamma k} \leq \frac{n}{\gamma}$. Since $|\mathsf{N}(S_1)| \geq \frac{1}{2}n$, then $|\Lambda| \geq \frac{1}{2}n - \frac{1}{\gamma}n > \frac{1}{3}n$ due to $\gamma \geq 6$. Thus, $\mathbb{E}[|f_{\mathsf{n}}(S_1) \cap f_{\mathsf{n}}(S_2)|] \geq |\Lambda| \cdot \frac{4k \ln n}{n} \geq \frac{4}{3}k \ln n$. The rest of the proof follows from Proposition 5.1(b) similarly as Proposition 5.1(a) is applied in the proof of Lemma 5.2. ◀

5.2 Selecting Positions for Strings with Many Cubic Positions

Recall that our goal is to design a rotation-invariant mechanism for selecting $\tilde{O}(k)$ indices so that, given two fairly similar strings, at least k common indices are selected in both strings. In the selection procedure described in Section 5.1, the decision whether or not to include position i was based on whether or not $S^*[i\,..\,i+3\ell-1] \in \Pi$ for a certain family $\Pi \subseteq \Sigma^{3\ell}$. Then, we argued that $S_1^*[i\,..\,i+3\ell-1] = S_2^*[i\,..\,i+3\ell-1] \in \Pi$ for at least k positions $i \in [n]$.

Unfortunately, this strategy might be infeasible if $\mathsf{C}(S)$ is large, that is, when there is a large number of cubic positions in S. For example, it could be the case that $S_1^*[i\,..\,i+3\ell-1] \neq S_2^*[i\,..\,i+3\ell-1]$ holds for $3\ell k = \frac{n}{\gamma}$ positions $i \in [n]$, and $S_1^*[i\,..\,i+3\ell-1] = S_2^*[i\,..\,i+3\ell-1] = \mathsf{a}^{3\ell}$ for the remaining $n - \frac{n}{\gamma}$ positions $i \in [n]$. This may happen even if $\mathsf{Ham}(S_1, \mathsf{a}^n) = \Omega(\frac{n}{\gamma})$, i.e., for strings far from being $(3\gamma k, \gamma k)$-pseudo-periodic.

We begin with some intuition for the construction of the function f_{c}. First, suppose that, for each position $i \in \mathsf{C}(S)$, we include in $f_{\mathsf{c}}(S)$ the smallest $j > i$ such that $\mathsf{per}(S^*[i\,..\,j]) > \mathsf{per}(S^*[i\,..\,i+3\ell-1])$. In other words, $f_{\mathsf{c}}(S)$ contains the positions following each maximal cyclic fragment of length at least 3ℓ and period at most ℓ. Notice that this construction satisfies Property 2 of Theorem 4.2. Moreover, since each position may belong to at most two such maximal repetitions, the number of positions selected is at most $\frac{2n}{3\ell} = 2\gamma k$ (so that Property 1 of Theorem 4.2 is satisfied), and a substitution of a single character in S may remove at most two positions from $f_{\mathsf{c}}(S)$. However, if the cubic positions are clustered in few blocks, then this mechanism is not enough to guarantee that Property 3 of Theorem 4.2 is satisfied, i.e., that $|f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)| \geq k$ when $\mathsf{Ham}(S_1, S_2) \leq k$. Hence, instead of selecting just one position j for each $i \in \mathsf{C}(S)$, several positions are selected using a process inspired by [10] with subsequent improvements in [13]: The fragment $S^*[i\,..\,i+3\ell-1]$ is maximally extended to $S^*[i\,..\,i+\tau_i-1]$ so that the period of $S^*[i\,..\,i+\tau_i-1]$ drops to $\mathsf{per}(S^*[i\,..\,i+3\ell-1])$ after $\Theta(\frac{k}{n}\tau_i)$ substitutions, and the underlying mismatching positions are added to $f_{\mathsf{c}}(S)$.

5.2.1 Definition of f_{c}

For any $i \in \mathsf{C}(S^*)$, let $u_i = S^*[i\,..\,i+3\ell-1]$, let $\rho_i = \mathsf{per}(u_i)$, and let $\mu_{S,i} = S^*[i\,..\,i+\rho_i-1]$, which is the string period of u_i. To avoid clutter in the presentation, we use $\mu_i = \mu_{S,i}$ when S is clear from context. Notice that, for $\tau \geq 2\rho_i$, the string $\mu_i^*[1\,..\,\tau]$ is the (unique) string of length τ with string period μ_i.

We are now ready to formally define the concept of extending (to the right) a cubic fragment starting at position i for as long as the ratio between the length of the extended fragment and the Hamming distance between the extended fragment and the appropriate prefix of μ_i^* is large enough. The length of such a (maximal) extended fragment is defined as

$$\tau_{S,i} = \min\left\{\tau \mid \tau < \tfrac{n}{\gamma k}\mathsf{Ham}\left(S^*[i\,..\,i+\tau-1], \mu_i^*[1\,..\,\tau]\right)\right\}.$$

The following lemma shows that $\tau_{S,i}$ is well-defined, i.e., that the minimum in the definition of $\tau_{S,i}$ is taken over a non-empty set. The bound $\tau_{S,i} \le 2n$ is also useful later on.

▶ **Lemma 5.5.** *For every $S \in \Sigma^n \setminus \mathcal{H}_{n,k}$ and $i \in \mathsf{C}(S)$, we have $\tau_{S,i} \le 2n$.*

Proof. Let $i \in \mathsf{C}(S)$ and assume by contradiction that $\tau_{S,i} > 2n$. This yields

$$2n \ge \tfrac{n}{\gamma k}\mathsf{Ham}\left(S^*[i\,..\,i+2n-1], \mu_i^*[1\,..\,2n]\right).$$

Moreover, $S^*[i\,..\,i+n-1] = S^*[i+n\,..\,i+2n-1]$, and so, by the triangle inequality,

$$\begin{aligned}
2\gamma k &\ge \mathsf{Ham}\left(S^*[i\,..\,i+2n-1], \mu_i^*[1\,..\,2n]\right)\\
&= \mathsf{Ham}\left(S^*[i\,..\,i+n-1], \mu_i^*[1\,..\,n]\right) + \mathsf{Ham}\left(S^*[i+n\,..\,i+2n-1], \mu_i^*[n+1\,..\,2n]\right)\\
&= \mathsf{Ham}\left(S^*[i\,..\,i+n-1], \mu_i^*[1\,..\,n]\right) + \mathsf{Ham}\left(S^*[i\,..\,i+n-1], \mu_i^*[n+1\,..\,2n]\right)\\
&\ge \mathsf{Ham}\left(\mu_i^*[1\,..\,n], \mu_i^*[n+1\,..\,2n]\right).
\end{aligned}$$

Notice that for any strings x, y, z (with $|x| = |y|$) and any integer m, we have $\mathsf{Ham}(x,y) = \frac{1}{m}\mathsf{Ham}(x^m, y^m)$ and $\mathsf{Ham}(x,y) \le \mathsf{Ham}(xz, yz)$. Thus, due to $|\mu_i| = \rho_i \le \ell \le \frac{n}{3\gamma k}$, we have

$$\begin{aligned}
\mathsf{Ham}\left(\mu_i, \mu_i^*[n+1\,..\,n+\rho_i]\right) &= \tfrac{1}{3\gamma k}\mathsf{Ham}\left(\mu_i^*[1\,..\,3\gamma k\rho_i], \mu_i^*[n+1\,..\,n+3\gamma k\rho_i]\right)\\
&\le \tfrac{1}{3\gamma k}\mathsf{Ham}\left(\mu_i^*[1\,..\,n], \mu_i^*[n+1\,..\,2n]\right) \le \tfrac{2\gamma k}{3\gamma k} < 1.
\end{aligned}$$

Consequently, $\mu_i = \mu_i^*[n+1\,..\,n+\rho_i] = \mathsf{cyc}^n(\mu_i)$, which implies $\rho_i \mid n$ by primitivity of μ_i (recall that $\mu_i = \mathsf{cyc}^m(\mu_i)$ only for $\rho_i \mid m$). Since $\tau_{S,i} > n$, we have $n \ge \frac{n}{\gamma k}\mathsf{Ham}(S^*[i\,..\,i+n-1], \mu_i^*[1\,..\,n])$, that is $\gamma k \ge \mathsf{Ham}\big(S^*[i\,..\,i+n-1], \mu_i^*[1\,..\,n]\big) = \mathsf{Ham}\big(S^*[i\,..\,i+n-1], \mu_i^{n/\rho_i}\big)$. Hence, $S^*[i\,..\,i+n-1] \in \mathcal{H}_{n,k}$ so, by Observation 4.1, $S \in \mathcal{H}_{n,k}$. ◀

Let $R_{S,i} = [i\,..\,i+\tau_i-1]$ be the positions in the extended fragment, and let $M_{S,i} = \{j \in R_{S,i} \mid S[j] \ne \mu_i^*[j-i+1]\}$ be the set of positions in $R_{S,i}$ corresponding to mismatches between $S^*[i\,..\,i+\tau_i-1]$ and $\mu_i^*[1\,..\,\tau_i]$. To avoid clutter in the presentation, we use $\tau_i = \tau_{S,i}$, $R_i = R_{S,i}$, and $M_i = M_{S,i}$ when S is clear from context. Define

$$f_{\mathsf{c}}(S) = \bigcup_{i \in \mathsf{C}(S)} (M_i \circlearrowleft n) = \{p \circlearrowleft n \mid p \in M_i, i \in \mathsf{C}(S)\}.$$

5.2.2 Properties of f_{c}

Property 1 of Theorem 4.2. Our strategy for proving an upper bound on the size of $f_{\mathsf{c}}(S)$ is to associate each $i \in \mathsf{C}(S)$ with a carefully defined set $A_i \subseteq R_i$. We then select a subset $\Gamma \subseteq \mathsf{C}(S)$ so that the sets A_i for $i \in \Gamma$ are disjoint subsets of $[1\,..\,3n]$ and $\bigcup_{i\in\Gamma} M_i = \bigcup_{i\in\mathsf{C}(S)} M_i$. Finally, we show that $|M_i| = O(\frac{\gamma k}{n}|A_i|)$ for each $i \in \mathsf{C}(S)$, and so $|\bigcup_{i\in\mathsf{C}(S)} M_i| = |\bigcup_{i\in\Gamma} M_i| = O(\sum_{i\in\Gamma}\frac{\gamma k}{n}|A_i|) = O(\gamma k)$.

For each R_i, consider the set of indices $j \in R_i$ such that $[j, j+2\ell) \cap M_i = \emptyset$. Formally, let $A_i = \{j \in R_i \mid [j, j+2\ell) \subseteq R_i \setminus M_i\}$. The following lemma lets us define $f_{\mathsf{c}}(S)$ as the union of $M_i \circlearrowleft n$ for a restricted set of values of i, with the property of having disjoint sets A_i.

▶ **Lemma 5.6.** *Let $i, i' \in \mathsf{C}(S)$. If $i < i'$ and $A_i \cap A_{i'} \ne \emptyset$, then $M_{i'} \subseteq M_i$.*

The following fact is useful in the proof of Lemma 5.6.

▶ **Fact 5.7** ([24, Lemma 6])**.** *Let S be a periodic string. If T is a substring of S of length at least $2\mathsf{per}(S)$, then $\mathsf{per}(S) = \mathsf{per}(T)$.*

Proof of Lemma 5.6. Let $j \in A_i \cap A_{i'}$. By definition, $[j\,..\,j+2\ell) \subseteq (R_i \setminus M_i) \cap (R_{i'} \setminus M_{i'})$. Thus, $\mu_i^*[1{+}j{-}i\,..\,2\ell{+}j{-}i] = S^*[j\,..\,j{+}2\ell{-}1] = \mu_{i'}^*[1{+}j{-}i'\,..\,2\ell{+}j{-}i']$. Since $\rho_i = \mathsf{per}(\mu_i^*) \leq \ell$ and $\rho_{i'} = \mathsf{per}(\mu_{i'}^*) \leq \ell$, by Fact 5.7, we have $\rho_i = \mathsf{per}(\mu_i^*) = \mathsf{per}(\mu_i^*[1+j-i\,..\,2\ell+j-i]) = \mathsf{per}(\mu_{i'}^*[1+j-i'\,..\,2\ell+j-i']) = \rho_{i'}$. Therefore, $\mu_{i'}^*[1\,..\,\tau_{i'}] = \mu_i^*[i'-i+1\,..\,i'-i+\tau_{i'}]$ (since the two fragments are extensions of the same periodic string with the same period). Hence, for any $\tau \leq \tau_{i'}$, we have $\mathsf{Ham}(S^*[i'\,..\,i'+\tau-1], \mu_{i'}^*[1\,..\,\tau]) = \mathsf{Ham}(S^*[i'\,..\,i'+\tau-1], \mu_i^*[i'-i+1\,..\,i'-i+\tau])$.

Since $\min(A_i \cap A_{i'}) \geq i'$ and $A_i \subseteq R_i$, we have that $\tau_i > i'-i$. Therefore, for $\tau = i'-i$, we have $i'-i \geq \frac{n}{\gamma k}\mathsf{Ham}(S^*[i\,..\,i+i'-i-1], \mu_i^*[1\,..\,i'-i]) = \frac{n}{\gamma k}\mathsf{Ham}(S^*[i\,..\,i'-1], \mu_i^*[1\,..\,i'-i])$.

Thus, for any $\tau < i'-i+\tau_{i'}$, we have

$$\begin{aligned}
&\tfrac{n}{\gamma k}\mathsf{Ham}\left(S^*[i\,..\,i+\tau-1], \mu_i^*[1\,..\,\tau]\right)\\
&\quad= \tfrac{n}{\gamma k}\mathsf{Ham}\left(S^*[i\,..\,i'-1], \mu_i^*[1\,..\,i'-i]\right) + \tfrac{n}{\gamma k}\mathsf{Ham}\left(S^*[i'\,..\,i+\tau-1], \mu_i^*[i'-i+1\,..\,\tau]\right)\\
&\quad\leq i'-i+\tfrac{n}{\gamma k}\mathsf{Ham}\left(S^*[i'\,..\,i'-(i'-i)+\tau-1], \mu_{i'}^*[1\,..\,\tau-(i'-i)]\right)\\
&\quad\leq i'-i+\tau-(i'-i) = \tau.
\end{aligned}$$

Consequently, $\tau_i \geq i'-i+\tau_{i'}$, which means that $R_{i'} \subseteq R_i$. For a proof that $M_{i'} \subseteq M_i$, let us choose $j' \in M_{i'}$. By definition, $S[j'] \neq \mu_{i'}^*[j'-i'+1] = \mu_i^*[j'-i'+1+(i'-i)] = \mu_i^*[j'-i+1]$. Hence, $j' \in M_i$. ◀

Lemma 5.6 implies that for any two indices $i < i'$, if $A_i \cap A_{i'} \neq \emptyset$, then $M_{i'} \subseteq M_i$, and thus it is enough to consider only the index i when defining $f_{\mathsf{c}}(S)$. Therefore, we define $\Gamma = \{i' \in \mathsf{C}(S) \mid \forall i < i' : A_i \cap A_{i'} = \emptyset\}$. Notice that, among $i \in \Gamma$, all the sets A_i are disjoint. Moreover, since for any $i \in \mathsf{C}(S)$ we have $A_i \subseteq R_i \subseteq [1\,..\,3n]$ by Lemma 5.5, we have $\sum_{i\in\Gamma}|A_i| = \left|\bigcup_{i\in\Gamma} A_i\right| \leq |[1\,..\,3n]| = 3n$.

For every $i \in \mathsf{C}(S)$, we have $|A_i| \geq |R_i| - 2\ell|M_i| = |R_i| - \frac{2n}{3\gamma k}|M_i|$. Furthermore, $|R_i|-1 \geq \frac{n}{\gamma k}(|M_i|-1)$ by definition of $\tau_i = |R_i|$. Thus, $|A_i| > \frac{n}{\gamma k}|M_i| - \frac{n}{\gamma k} - \frac{2n}{3\gamma k}|M_i| = \frac{n}{3\gamma k}(|M_i|-3)$. Due to $[i\,..\,i+\ell) \subseteq A_i$, we have $|A_i| \geq \ell = \frac{n}{3\gamma k}$, and therefore $|M_i| < \frac{3\gamma k}{n}|A_i| + 3 \leq \frac{3\gamma k}{n}|A_i| + \frac{9\gamma k}{n}|A_i| = \frac{12\gamma k}{n}|A_i|$. Hence, $|f_{\mathsf{c}}(S)| \leq \left|\bigcup_{i\in\mathsf{C}(S)} M_i\right| = \left|\bigcup_{i\in\Gamma} M_i\right| \leq \sum_{i\in\Gamma}|M_i| \leq \sum_{i\in\Gamma}\frac{12\gamma k}{n}|A_i| = \frac{12\gamma k}{n}\sum_{i\in\Gamma}|A_i| \leq 36\gamma k$.

Property 2 of Theorem 4.2. The following lemma states that f_{c} satisfies Property 2.

▶ **Lemma 5.8.** *For every $S \in \Sigma^n$, we have $f_{\mathsf{c}}(\mathsf{cyc}(S)) = \mathsf{rot}_n(f_{\mathsf{c}}(S))$.*

Proof. Let $j \in f_{\mathsf{c}}(\mathsf{cyc}(S))$. There exists $i \in \mathsf{C}(\mathsf{cyc}(S))$ such that $j \in M_{\mathsf{cyc}(S),i} \circlearrowright n$. Let $j' \in M_{\mathsf{cyc}(S),i}$ such that $j = j' \circlearrowright n$. We distinguish between two cases: if $i \in [1\,..\,n-1]$, then, since $i \in \mathsf{C}(\mathsf{cyc}(S))$, we have $i+1 \in \mathsf{C}(S)$ and $\tau_{S,i+1} = \tau_{\mathsf{cyc}(S),i}$. Therefore, $j'+1 \in M_{S,i+1}$ and $(j'+1) \circlearrowright n \in f_{\mathsf{c}}(S)$. Thus, $j = (j'+1-1) \circlearrowright n \in \mathsf{rot}_n(f_{\mathsf{c}}(S))$. If $i = n$, then it must be that $1 \in \mathsf{C}(S)$ and $\tau_{S,1} = \tau_{\mathsf{cyc}(S),n}$. Therefore, $j'-n+1 \in M_{S,1}$ and $(j'-n+1) \circlearrowright n \in f_{\mathsf{c}}(S)$. Thus, $j = (j'-n+1-1) \circlearrowright n \in \mathsf{rot}_n(f_{\mathsf{c}}(S))$. The converse inclusion holds symmetrically. ◀

Property 3 of Theorem 4.2. We first give a lower bound on $|f_{\mathsf{c}}(S)|$ in terms of $|\mathsf{C}(S)|$.

▶ **Lemma 5.9.** *For every string $S \in \Sigma^n \setminus \mathcal{H}_{n,k}$, we have $|f_{\mathsf{c}}(S)| \geq \frac{\gamma k}{3n}|\mathsf{C}(S)|$.*

Proof. First, we shall construct a set $\Delta \subseteq \mathsf{C}(S)$ such that $\sum_{i\in\Delta}|R_i| \geq |\mathsf{C}(S)|$ and, for any two distinct indices $i, i' \in \Delta$, we have $R_i \cap R_{i'} = \emptyset$. We build Δ iteratively. We start with $\Delta = \emptyset$ and, as long as $\mathsf{C}(S) \not\subseteq \bigcup_{i\in\Delta} R_i$, we add $\min\left(\mathsf{C}(S) \setminus \bigcup_{i\in\Delta} R_i\right)$ to Δ. Let $i < i'$ be

two indices in Δ. When i' was added to Δ, we already had $i \in \Delta$. Thus, R_i ends to the left of i', which is the starting point of $R_{i'}$. Hence, $R_i \cap R_{i'} = \emptyset$. The algorithm terminates when $\mathsf{C}(S) \subseteq \bigcup_{i\in\Delta} R_i$, so $|\mathsf{C}(S)| \le |\bigcup_{i\in\Delta} R_i| = \sum_{i\in\Delta} |R_i|$.

For any $i \in \mathsf{C}(S)$, we have $|R_i| = \tau_i < \frac{n}{\gamma k}\mathsf{Ham}\,(S^*[i\,..\,i+\tau_i-1], \mu_i^*[1\,..\,\tau_i])$, i.e., $|R_i| < \frac{n}{\gamma k}|M_i|$. Since $M_i \subseteq R_i$ for every i, the sets M_i for $i \in \Delta$ are disjoint. Consequently, $|\bigcup_{i\in\Delta} M_i| = \sum_{i\in\Delta} |M_i| > \frac{\gamma k}{n}\sum_{i\in\Delta} |R_i| \ge \frac{\gamma k}{n}|\mathsf{C}(S)|$.

By Lemma 5.5, for any $i \in \mathsf{C}(S)$, we have $\tau_i \le 2n$. Therefore, $\bigcup_{i\in\Delta} M_i \subseteq [1\,..\,3n]$ and each position in $j \in \bigcup_{i\in\Delta}(M_i \circlearrowleft n)$ may be introduced by at most 3 positions $j, j+n, j+2n \in \bigcup_{i\in\Delta} M_i$. Thus, $|f_{\mathsf{c}}(S)| = \left|\bigcup_{i\in\Delta}(M_i \circlearrowleft n)\right| \ge \frac{1}{3}\left|\bigcup_{i\in\Delta} M_i\right| \ge \frac{\gamma k}{3n}|\mathsf{C}(S)|$. ◀

Using Lemma 5.9, we prove the third property of Theorem 4.2, assuming $|\mathsf{C}(S_1)| \ge \frac{1}{2}n$.

▶ **Lemma 5.10.** *Suppose that $S_1, S_2 \in \Sigma^n \setminus \mathcal{H}_{n,k}$ satisfy $\mathsf{Ham}(S_1, S_2) \le k$. If $|\mathsf{C}(S_1)| \ge \frac{1}{2}n$, then $|f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)| \ge k$.*

Proof. Let S' be a string of length n, where, for any i with $S_1[i] = S_2[i]$, we have $S'[i] = S_1[i]$ and, for any other i (i.e., for $i \in \mathsf{MP}(S_1, S_2)$), we have $S'[i] = \$_i$, where $\$_i \notin \Sigma$ differs from any other character $\$_{i'}$ for $i' \ne i$.

▷ Claim 5.11. $f_{\mathsf{c}}(S') \subseteq (f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)) \cup \mathsf{MP}(S_1, S_2)$.

Proof. Let $j \in f_{\mathsf{c}}(S')$. If $j \in \mathsf{MP}(S_1, S_2)$, the claim follows; thus, assume $j \notin \mathsf{MP}(S_1, S_2)$. By the definition of $f_{\mathsf{c}}(S')$, there is an index $i \in \mathsf{C}(S')$ such that $j \in M_{S',i} \circlearrowleft n$; let $j' \in M_{S',i}$ be an integer such that $j = j' \circlearrowleft n$. Notice that $\mu_{S_1,i} = \mu_{S',i}$ since if $\mu_{S',i}$ contains some $\$_k$ character, then i cannot be cubic and so $i \notin \mathsf{C}(S')$. Therefore, $\mu_{S_1,i} = \mu_{S',i}$, and let $\mu_i = \mu_{S_1,i}$. For any integer τ, we have $\mathsf{Ham}(S_1^*[i\,..\,i+\tau-1], \mu_i^*[1\,..\,\tau]) \le \mathsf{Ham}((S')^*[i\,..\,i+\tau-1], \mu_i^*[1\,..\,\tau])$ because the new $\$_k$ characters in S' just form new mismatches. In particular, for $\tau_{S_1,i}$ we have $\frac{n}{\gamma k}\mathsf{Ham}((S')^*[i\,..\,i+\tau_{S_1,i}-1], \mu_i^*[1\,..\,\tau_{S_1,i}]) \ge \frac{n}{\gamma k}\mathsf{Ham}(S_1^*[i\,..\,i+\tau_{S_1,i}-1], \mu_i^*[1\,..\,\tau_{S_1,i}]) > \tau_{S_1,i}$. Hence, $\tau_{S',i} \le \tau_{S_1,i}$ and $R_{S',i} \subseteq R_{S_1,i}$. Since $j' \in M_{S',i}$ and $j \notin \mathsf{MP}(S_1, S_2)$, it must be that $j' \in M_{S_1,i}$. Similarly, $j' \in M_{S_2,i}$. Thus, $j = j' \circlearrowleft n \in (f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)) \cup \mathsf{MP}(S_1, S_2)$. ◁

▷ Claim 5.12. $|\mathsf{C}(S')| \ge \frac{\gamma-2}{2\gamma}n$.

Proof. Recall that $|\mathsf{C}(S_1)| \ge \frac{1}{2}n$. If $\mu_{S_1,i} = \mu_{S',i}$ and $i \in \mathsf{C}(S_1)$, then $i \in \mathsf{C}(S')$. The only indices $i \in \mathsf{C}(S_1) \cap \mathsf{N}(S')$ are indices such that $\mu_{S_1,i} \ne \mu_{S',i}$, which means that $\mathsf{MP}(S_1, S_2) \cap ([i\,..\,i+3\ell-1] \circlearrowleft n) \ne \emptyset$. Hence, each $m \in \mathsf{MP}(S_1, S_2)$ will remove at most 3ℓ positions from $\mathsf{C}(S_1)$. Thus, $|\mathsf{C}(S')| \ge \frac{1}{2}n - |\mathsf{MP}(S_1, S_2)|3\ell \ge \frac{1}{2}n - k\frac{n}{\gamma k} = \frac{\gamma-2}{2\gamma}n$. ◁

Due to Claim 5.12, we have $|\mathsf{C}(S')| \ge \frac{\gamma-2}{2\gamma}n$, and therefore $|f_{\mathsf{c}}(S')| > \frac{\gamma k}{3n}\frac{\gamma-2}{2\gamma}n = \frac{(\gamma-2)k}{6}$ by Lemma 5.9. Due to Claim 5.11, $f_{\mathsf{c}}(S') \subseteq (f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)) \cup \mathsf{MP}(S_1, S_2)$, and therefore $|f_{\mathsf{c}}(S')| \le |\,(f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)) \cup \mathsf{MP}(S_1, S_2)| \le |f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)| + |\mathsf{MP}(S_1, S_2)| \le |f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)| + k$. Consequently, since $\gamma \ge 14$, we have $|f_{\mathsf{c}}(S_1) \cap f_{\mathsf{c}}(S_2)| \ge \frac{\gamma-8}{6}k \ge \frac{14-8}{6}k = k$. ◀

6 Sketches for Pseudo-periodic Strings

Let $\mathcal{H}'_{n,k} \subseteq \Sigma^n$ be the family of $(3\gamma k, (\gamma+1)k)$-pseudo-periodic strings in Σ^n. In this section, we develop circular sketches for $\mathcal{H}'_{n,k}$. We start with a few properties of pseudo-periodic strings. Recall that a string $S \in \Sigma^n$ is called (α, β)-*pseudo-periodic* if it has an (α, β)-base $S' \in \Sigma^n$ with $\mathsf{root}(S') \le \frac{n}{\alpha}$ and $\mathsf{Ham}(S, S') \le \beta$. If $\lfloor\alpha\rfloor > 2\beta$, then the (α, β)-base is unique.

▶ **Lemma 6.1.** *If $S \in \Sigma^n$ is an (α, β)-pseudo-periodic string for some parameters $\lfloor \alpha \rfloor > 2\beta$, then S' has a unique (α, β)-base.*

Proof. Suppose that S has two bases S', S''. Alzamel et al. [3] show that if $|X| = |Y| \geq \mathsf{per}(X) + \mathsf{per}(Y)$ and $X \neq Y$, then $\mathsf{Ham}(X, Y) \geq \left\lfloor \frac{2n}{\mathsf{per}(X)+\mathsf{per}(Y)} \right\rfloor$. Setting $X = S'$ and $Y = S''$, we get a contradiction: $\mathsf{Ham}(S', S'') \geq \left\lfloor \frac{2n}{\mathsf{per}(S')+\mathsf{per}(S'')} \right\rfloor \geq \left\lfloor \frac{2n}{\mathsf{root}(S')+\mathsf{root}(S'')} \right\rfloor \geq \left\lfloor \frac{2n}{n/\alpha+n/\alpha} \right\rfloor = \lfloor \alpha \rfloor > 2\beta \geq \mathsf{Ham}(S, S') + \mathsf{Ham}(S, S'') \geq \mathsf{Ham}(S', S'')$. ◀

Moreover, the triangle inequality immediately yields the following observation.

▶ **Observation 6.2.** *Let $S \in \Sigma^n$ be an (α, β)-pseudo-periodic string and let $T \in \Sigma^n$ be a string such that $\mathsf{Ham}(S, T) \leq k$. Then, T is $(\alpha, \beta + k)$-pseudo-periodic, and every (α, β)-base of S is an $(\alpha, \beta + k)$-base of T.*

Combining Lemma 6.1 with Observations 4.1 and 6.2, we obtain the following corollary.

▶ **Corollary 6.3.** *Let $S_1, S_2 \in \mathcal{H}'_{n,k}$ with $(3\gamma k, (\gamma+1)k)$-bases S'_1 and S'_2, respectively. If, for some $m \in \mathbb{Z}$, we have $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$, then $S'_1 = \mathsf{cyc}^m(S'_2)$.*

Proof. By Observation 6.2, S'_1 is a $(3\gamma k, (\gamma+2)k)$-base of $\mathsf{cyc}^m(S_2)$. Moreover, by Observation 4.1, $\mathsf{cyc}^m(S'_2)$ is a $(3\gamma k, (\gamma+1)k)$-base of $\mathsf{cyc}^m(S_2)$, and thus also a $(3\gamma k, (\gamma+2)k)$-base of $\mathsf{cyc}^m(S_2)$. Since $\lfloor 3\gamma k \rfloor > 2(\gamma+2)k$ due to $\gamma \geq 5$, Lemma 6.1 implies that $S'_1 = \mathsf{cyc}^m(S'_2)$. ◀

6.1 A 0-mismatch Circular Sketch

Both the exact and the $(1 \pm \varepsilon)$-approximation sketches of strings in $\mathcal{H}'_{n,k}$ rely on 0-mismatch circular sketches, which we implement using Karp–Rabin fingerprints.

▶ **Fact 6.4** (Karp–Rabin fingerprints [28])**.** *For every positive integer n, there exists a randomized function $\Phi : \Sigma^n \to \{0,1\}^{O(\log n)}$ such that, for every $S_1, S_2 \in \Sigma^n$, the following holds with high probability: if $S_1 \neq S_2$, then $\Phi(S_1) \neq \Phi(S_2)$.*

Proof. The function Φ is based on a fixed prime number $p \geq \max(\sigma, n^2)$ and a uniformly random $x \in [0\,..\,p-1]$. The function Φ maps a string S to $(\sum_{i=1}^{|S|} x^{i-1} \cdot S[i]) \bmod p$. This way, for every two strings $S_1 \neq S_2$ in Σ^n, we have $\Pr[\Phi(S_1) = \Phi(S_2)] \leq \frac{n}{p} \leq \frac{n}{n^2} = n^{-1}$. ◀

▶ **Lemma 6.5.** *There exists a 0-ECS sketch $(\mathtt{sk}_0, \mathtt{dec}_0)$ for Σ^n of size $O(\log n)$ bits with constant decoding time.*

Proof. The construction relies on a Karp–Rabin fingerprint function Φ. The sketch $\mathtt{sk}_0(S)$ for a string $S \in \Sigma^n$ is defined based on the minimum cyclic rotation of S, denoted $\mathsf{minrot}(S)$, and consists of the following components:

- the fingerprint $\Phi(\mathsf{minrot}(S))$ of the minimum cyclic rotation of S,
- the length $\mathsf{root}(S)$ of the primitive root of S,
- the smallest integer $r \geq 0$ such that $S = \mathsf{cyc}^r(\mathsf{minrot}(S))$.

The decoding function $\mathtt{dec}_0$ is given two sketches $\mathtt{sk}_0(S_1) = (\Phi(\mathsf{minrot}(S_1)), \mathsf{root}(S_1), r_1)$, $\mathtt{sk}_0(S_2) = (\Phi(\mathsf{minrot}(S_2)), \mathsf{root}(S_2), r_2)$, and a shift m. If $\Phi(\mathsf{minrot}(S_1)) \neq \Phi(\mathsf{minrot}(S_2))$, then $S_1 \neq \mathsf{cyc}^m(S_2)$, and thus the function returns ∞. Otherwise, $\mathsf{minrot}(S_1) = \mathsf{minrot}(S_2)$ with high probability, and the implementation proceeds assuming that $\mathsf{minrot}(S_1) = T = \mathsf{minrot}(S_2)$ for a string $T \in \Sigma^n$. In particular, this implies $\mathsf{root}(S_1) = \mathsf{root}(T) = \mathsf{root}(S_2)$. Finally, since $S_1 = \mathsf{cyc}^{r_1}(T)$ equals $\mathsf{cyc}^m(S_2) = \mathsf{cyc}^{m+r_2}(T)$ if and only if $\mathsf{root}(T) \mid (m + r_2 - r_1)$, the function returns 0 or ∞ depending on whether $\mathsf{root}(S_1) \mid (m + r_2 - r_1)$ or not. ◀

6.2 A k-ECS Sketch

▶ **Construction 6.6.** The encoding function $\mathtt{circ}_k : \mathcal{H}'_{n,k} \to \{0,1\}^*$ is defined as follows:

1. Let $\mathtt{sk}_0$ be the 0-mismatch sketch of Lemma 6.5.
2. For $S \in \mathcal{H}'_{n,k}$, the encoding $\mathtt{circ}_k(S)$ stores the sketch $\mathtt{sk}_0(S')$ of the $(3\gamma k, (\gamma+1)k)$-base S' of S and the mismatch information $\mathsf{MI}(S, S')$.

▶ **Proposition 6.7.** *There exists a decoding function which, together with the encoding* $\mathtt{circ}_k$ *of Construction 6.6, forms a k-ECS sketch of $\mathcal{H}'_{n,k}$. The size of the sketch is $\tilde{O}(k)$, and the decoding time is $\tilde{O}(k)$ with high probability.*

Proof. The decoding function is given two sketches $\mathtt{circ}_k(S_1) = (\mathtt{sk}_0(S'_1), \mathsf{MI}(S_1, S'_1))$, $\mathtt{circ}_k(S_2) = (\mathtt{sk}_0(S'_2), \mathsf{MI}(S_2, S'_2))$, and a shift m. By Corollary 6.3, if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \le k$, then $S'_1 = \mathsf{cyc}^m(S'_2)$, and this condition is checked by applying $\mathtt{dec}_0(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2), m)$. If the call returns a non-zero result, then ∞ is returned. Otherwise, $S'_1 = \mathsf{cyc}^m(S'_2)$ holds with high probability. The analysis below is conditioned on this event.

First, $\mathsf{MI}(\mathsf{cyc}^m(S_2), \mathsf{cyc}^m(S'_2))$ is retrieved from $\mathsf{MI}(S_2, S'_2)$ by shifting all the the mismatches. Next, the decoding function retrieves $\mathsf{MI}(S_1, \mathsf{cyc}^m(S_2))$ from $\mathsf{MI}(S_1, S'_1)$ and $\mathsf{MI}(\mathsf{cyc}^m(S_2), \mathsf{cyc}^m(S'_2))$ (using Fact 3.2 and assuming that $S'_1 = \mathsf{cyc}^m(S'_2)$) and returns $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = |\mathsf{MI}(S_1, \mathsf{cyc}^m(S_2))|$. ◀

6.3 An (ε, k)-ACS Sketch

For the pseudo-periodic (ε, k)-ACS sketches, we relax the problem statement; we overcome this relaxation in Section 7. In the *relaxed* (ε, k)-ACS sketch, the distances smaller than $\frac{k}{2}$ do not need to be approximated. More precisely, we require the following:

- if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) < \frac{1}{2}k$, then $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) < \frac{1+\varepsilon}{2}k$,
- if $\frac{1}{2}k \le \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \le k$, then $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) \in (1 \pm \varepsilon)\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$,
- otherwise, $\mathtt{dec}(\mathtt{sk}(S_1), \mathtt{sk}(S_2), m) > (1-\varepsilon)k$.

▶ **Construction 6.8.** The encoding function $\mathtt{circ}_{\varepsilon,k} : \mathcal{H}'_{n,k} \to \{0,1\}^*$ is defined as follows:

1. Let $\mathtt{sk}_0$ be the 0-mismatch sketch of Lemma 6.5.
2. Let $A, B \subseteq [n]$ be two subsets with elements sampled independently with rate $p := \sqrt{\frac{\log n}{\varepsilon^2 k}}$.
3. For $S \in \mathcal{H}'_{n,k}$, the encoding $\mathtt{circ}_{\varepsilon,k}(S)$ stores the sketch $\mathtt{sk}_0(S')$ of the $(3\gamma k, (\gamma+1)k)$-base S' of S and the mismatch information $\mathsf{MI}_{A\cup B}(S, S')$.

▶ **Proposition 6.9.** *There exists a decoding function which, together with the encoding* $\mathtt{circ}_{\varepsilon,k}$ *of Construction 6.8, forms a relaxed (ε, k)-ACS sketch of $\mathcal{H}'_{n,k}$. The size of the sketch is $\tilde{O}(\varepsilon^{-1}\sqrt{k})$, and the decoding time is $\tilde{O}(\varepsilon^{-1}\sqrt{k})$ with high probability.*

Proof. The decoding function is given two sketches $\mathtt{circ}_{\varepsilon,k}(S_1) = (\mathtt{sk}_0(S'_1), \mathsf{MI}_{A\cup B}(S_1, S'_1))$ and $\mathtt{circ}_{\varepsilon,k}(S_2) = (\mathtt{sk}_0(S'_2), \mathsf{MI}_{A\cup B}(S_2, S'_2))$, and a shift m. According to Corollary 6.3, if $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \le k$, then $S'_1 = \mathsf{cyc}^m(S'_2)$, and this condition is checked by applying $\mathtt{dec}_0(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2), m)$. If the call returns a non-zero result, then ∞ is returned. Otherwise, $S'_1 = \mathsf{cyc}^m(S'_2)$ holds with high probability. The analysis below is conditioned on this event.

First, $\mathsf{MI}_{A\cap\mathsf{rot}_n^m(B)}(\mathsf{cyc}^m(S_2), \mathsf{cyc}^m(S'_2))$ is retrieved by filtering and shifting $\mathsf{MI}_{A\cup B}(S_2, S'_2)$. Secondly, $\mathsf{MI}_{A\cap\mathsf{rot}_n^m(B)}(S_1, S'_1)$ is retrieved by filtering $\mathsf{MI}_{A\cup B}(S_1, S'_1)$. Then, the algorithm retrieves $\mathsf{MI}_{A\cap\mathsf{rot}_n^m(B)}(S_1, \mathsf{cyc}^m(S_2))$ combining $\mathsf{MI}_{A\cap\mathsf{rot}_n^m(B)}(S_1, S'_1)$ and $\mathsf{MI}_{A\cap\mathsf{rot}_n^m(B)}(\mathsf{cyc}^m(S_2), \mathsf{cyc}^m(S'_2))$ (using Fact 3.2 and assuming that $S'_1 = \mathsf{cyc}^m(S'_2)$). Since $A \cap \mathsf{rot}_n^m(B)$ is a random subset of $[n]$ with elements sampled independently with rate $\frac{\log n}{\varepsilon^2 k}$, the quantity $\frac{\varepsilon^2 k}{\log n}\mathsf{Ham}_{A\cap\mathsf{rot}_n^m(B)}(S_1, \mathsf{cyc}^m(S_2))$ is a $(1 \pm \varepsilon)$-approximation of $\mathsf{Ham}(S_1, S_2)$ with high probability provided that $\mathsf{Ham}(S_1, S_2) = \Omega(k)$; see Lemma 3.1. ◀

7 Proofs of Main Theorems

In this section, we complete our construction of circular k-mismatch sketches for Σ^n.

▶ **Theorem 1.3.** *There exists a k-ECS sketch for Σ^n of size $\tilde{O}(k)$.*

Proof. Our construction combines the k-ECS sketches of Propositions 6.7 and 4.8. For each string $S \in \Sigma$, if $S \in \mathcal{H}'_{n,k}$, then the sketch contains the sketch of Proposition 6.7, and if $S \in \Sigma^n \setminus \mathcal{H}_{n,k}$, then the sketch contains the sketch of Proposition 4.8. Notice that the sketch contains both components if $S \in \mathcal{H}'_{n,k} \setminus \mathcal{H}_{n,k}$.

For two strings $S_1, S_2 \in \Sigma^n$, given the sketches of S_1 and S_2, the decoder works as follows. If the two sketches contain compatible components (of Proposition 4.8 or of Proposition 6.7), then the decoder uses the decoder corresponding to these components. Otherwise, without loss of generality, it must be that $S_1 \in \mathcal{H}_{n,k}$ and $S_2 \notin \mathcal{H}'_{n,k}$. Thus, by Observation 6.2, $\mathsf{Ham}(S_1, S_2) > k$, and therefore the decoder outputs ∞. The decoding time is $\tilde{O}(k)$. ◀

Similarly, combining the results of Sections 4 and 6 gives $(1+\varepsilon)$-approximate sketches. The proof of the following result mimics the proof of Theorem 1.3 and is given in Appendix B for completeness.

▶ **Proposition 7.1.** *There exists a relaxed (ε, k)-ACS sketch for Σ^n of size $\tilde{O}(\varepsilon^{-2}\sqrt{k})$. Its decoding time is $\tilde{O}(\varepsilon^{-1}\sqrt{k} + \varepsilon^{-2})$ with high probability.*

A simple alternative approach yields smaller sketches when k is large compared to n.

▶ **Construction 7.2.** The encoding function $\mathtt{circ}_{\varepsilon,k} : \Sigma^n \to \{0,1\}^*$ is defined as follows:

1. Let $A, B \subseteq [n]$ be two subsets with elements sampled independently with rate $p := \sqrt{\frac{\log n}{\varepsilon^2 k}}$.
2. For $S \in \Sigma^n$, the encoding $\mathtt{circ}_{\varepsilon,k}(S)$ consists of pairs $(i, S[i])$ for $i \in A \cup B$.

▶ **Proposition 7.3.** *There exists a decoding function which, together with the encoding $\mathtt{circ}_{\varepsilon,k}$ of Construction 7.2, forms a relaxed (ε, k)-ACS sketch of Σ^n. The size of the sketch is $\tilde{O}(\frac{n}{\varepsilon\sqrt{k}})$, and the decoding time is $\tilde{O}(\frac{n}{\varepsilon\sqrt{k}})$ with high probability.*

Proof. The decoder, given the sketches of $S_1, S_2 \in \Sigma^n$ and a shift m, uses Lemma 3.1 to estimate $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ based on $\mathsf{Ham}_{A \cap \mathsf{rot}_n^m(B)}(S_1, \mathsf{cyc}^m(S_2))$. For each $i \in A \cap \mathsf{rot}_n^m(B)$, the decoder retrieves $S_1[i]$ from the sketch of S_1 and $\mathsf{cyc}^m(S_2)[i] = S_2[(i-m) \circlearrowleft n]$ from the sketch of S_2. Since $A \cap \mathsf{rot}_n^m(B)$ is a random subset of $[n]$ with elements sampled independently with rate $\frac{\log n}{\varepsilon^2 k}$, the quantity $\frac{\varepsilon^2 k}{\log n}\mathsf{Ham}_{A \cap \mathsf{rot}_n^m(B)}(S_1, \mathsf{cyc}^m(S_2))$ is a $(1 \pm \varepsilon)$-approximation of $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ with high probability provided that $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = \Omega(k)$; see Lemma 3.1. ◀

▶ **Theorem 1.4.** *There exists an (ε, k)-ACS sketch for Σ^n of size $\tilde{O}(\min(\varepsilon^{-2}\sqrt{k}, \varepsilon^{-1.5}\sqrt{n}))$.*

Proof. An (ε, k)-ACS sketch is obtained by combining $O(\log k)$ relaxed (ε, k')-ACS sketches, where k' ranges over powers of two between 1 and $2k$. Depending on whether $k' \le \varepsilon n$ or not, Proposition 7.1 or Proposition 7.3 is used to implement k'-mismatch sketches. ◀

▶ Remark 7.4. Applying Proposition 7.3 instead of Proposition 7.1 improves the sketch size (for $k \ge \varepsilon n$) but degrades the decoding time. We get two alternatives: $\tilde{O}(\varepsilon^{-2}\sqrt{k})$-size sketches with decoding time $\tilde{O}(\varepsilon^{-1}\sqrt{k} + \varepsilon^{-2})$, and $\tilde{O}(\varepsilon^{-1.5}\sqrt{n})$-size sketches with decoding time $\tilde{O}(\varepsilon^{-1.5}\sqrt{n})$.

A Efficient Shift Distance Decoders

In this section, we develop exact and approximate k-mismatch shift distance sketches with efficient decoding procedures. These sketches use the same encoding functions as the corresponding k-mismatch circular sketches, so we only need to develop the decoding procedures.

Our decoding procedures for shift distance heavily rely on their counterparts for decoding the Hamming distance between S_1 and a fixed rotation of S_2. Hence, each of the following four propositions refers to its counterpart in Section 4 or Section 6.

A.1 Shift Distance Sketches for Non-Pseudo-Periodic Strings

▶ **Proposition A.1** (see Proposition 4.5). *There exists a decoding function which, together with the encoding* $\mathtt{circ}_{\varepsilon,k}$ *of Construction 4.4, forms an* (ε, k)*-ASDS sketch of* $\Sigma^n \setminus \mathcal{H}_{n,k}$*. The decoding algorithm costs* $\tilde{O}(\varepsilon^{-2}k)$ *time with high probability.*

Proof. Our decoding procedure iterates over $i \in f(S_1) \cap A$ and $i' \in f(S_2) \cap B$. For each such pair (i, i'), the procedure retrieves the sketches $\mathtt{sk}_\varepsilon(\mathsf{cyc}^i(S_1))$ and $\mathtt{sk}_\varepsilon(\mathsf{cyc}^{i'}(S_2))$ and recovers a $(1+\varepsilon)$-approximation of $\mathsf{Ham}(\mathsf{cyc}^i(S_1), \mathsf{cyc}^{i'}(S_2))$. The algorithm returns the smallest among the values obtained across all the iterations.

Since $\mathsf{Ham}(\mathsf{cyc}^i(S_1), \mathsf{cyc}^{i'}(S_2)) \geq \mathsf{sh}(S_1, S_2)$, the returned value is at least $(1-\varepsilon)\mathsf{sh}(S_1, S_2)$ with high probability (unless the sketches $\mathtt{sk}_\varepsilon$ fail). Moreover, if $\mathsf{sh}(S_1, S_2) \leq k$ with $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = \mathsf{sh}(S_1, S_2)$ for some integer m, then, as in the proof of Proposition 4.5, with high probability, there is a pair of indices $i \in f(S_1) \cap A$ and $i' \in f(S_2) \cap B$ with $i' = (i+m) \circlearrowright n$. Hence, the returned value is at most $(1+\varepsilon)\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = (1+\varepsilon)\mathsf{sh}(S_1, S_2)$ with high probability. ◀

▶ **Proposition A.2** (see Proposition 4.8)**.** *There exists a decoding function which, together with the encoding* $\mathtt{circ}_k$ *of Construction 4.7, forms a k-ESDS sketch of $\Sigma^n \setminus \mathcal{H}_{n,k}$. The decoding algorithm costs $\tilde{O}(k^2)$ time with high probability.*

Proof. The decoding algorithm first computes the sizes $s_m := |f(S_1) \cap \mathsf{rot}_n^m(f(S_2))|$ for all shifts $m \in [n]$. For this, the algorithm iterates over $i \in f(S_1)$ and $i' \in f(S_2)$ incrementing $s_{(i'-i)\circlearrowright n}$. Next, for each shift $m \in [n]$ with $c_m \geq k$, the algorithm uses the decoding function of Proposition 4.8 to retrieve $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$ (or learn that $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) > k$). Finally, the algorithm returns the smallest among the reported values. (If $c_m < k$ for each $m \in [n]$, then the algorithm returns ∞.)

As for correctness, first note that $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \geq \mathsf{sh}(S_1, S_2)$ holds for each $m \in [n]$, so the returned value is at least $\min(k+1, \mathsf{sh}(S_1, S_2))$ with high probability (unless the decoding procedure of Proposition 4.8 fails). Next, suppose that $\mathsf{sh}(S_1, S_2) = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$. As argued in the proof of Proposition 4.8, $s_m = |f(S_1) \cap f(\mathsf{cyc}^m(S_1))| \geq k$ holds with high probability. Consequently, the decoding procedure of Proposition 4.8 was called for S_1, S_2, and m, resulting in $\mathsf{sh}(S_1, S_2)$ with high probability. Hence, the returned value is at most $\mathsf{sh}(S_1, S_2)$ with high probability.

The decoder iterates over $f(S_1) \times f(S_2)$, which is of size $\tilde{O}(k^2)$ with high probability due to Theorem 4.2. Hence, by the pigeonhole principle there are at most $\tilde{O}(\frac{k^2}{k}) = \tilde{O}(k)$ positions $m \in [n]$ such that $c_m \geq k$. For each such position, the decoding time of Proposition 4.8 is $\tilde{O}(k)$. Thus, the total decoding time is $\tilde{O}(k^2)$. ◀

A.2 Shift Distance Sketches for Pseudo-Periodic Strings

▶ **Lemma A.3** (see Lemma 6.5)**.** *There exists a decoding function* $\mathtt{dec}_0^{\mathsf{sh}}$ *which, together with the encoding* $\mathtt{sk}_0$ *of Lemma 6.5, forms an exact 0-ESDS sketch with constant decoding time.*

Proof. The decoding function, given the sketches $\mathtt{sk}_0(S_1) = (\Phi(\mathsf{minrot}(S_1)), \mathsf{root}(S_1), r_1)$ and $\mathtt{sk}_0(S_2) = (\Phi(\mathsf{minrot}(S_2)), \mathsf{root}(S_2), r_2)$, returns 0 or ∞ based on whether $\Phi(\mathsf{minrot}(S_1)) = \Phi(\mathsf{minrot}(S_2))$ or not. ◀

▶ **Proposition A.4** (see Proposition 6.7)**.** *There exists a decoding function which, together with the encoding* $\mathtt{circ}_k$ *of Construction 6.6, forms a k-ESDS sketch of $\mathcal{H}'_{n,k}$. The decoding algorithm costs $\tilde{O}(k^2)$ time with high probability.*

Proof. The decoding algorithm is given the sketches $\mathtt{circ}_k(S_1) = (\mathtt{sk}_0(S'_1), \mathsf{MI}(S_1, S'_1))$ and $\mathtt{circ}_k(S_2) = (\mathtt{sk}_0(S'_2), \mathsf{MI}(S_2, S'_2))$. First, the algorithm applies $\mathtt{dec}_0^{\mathsf{sh}}(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2))$ of Lemma A.3. If this call returns a non-zero result, then ∞ is returned. Otherwise, for each $m \in [n]$, the algorithm constructs the following sets:

$$\mathsf{P}_m := \mathsf{MP}(S_1, S'_1) \cap \mathsf{MP}(\mathsf{cyc}^m(S_2), \mathsf{cyc}^m(S'_2))$$
$$\mathsf{P}'_m := \mathsf{P}_m \setminus \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$$

For this, the algorithm iterates over $(i, a, b) \in \mathsf{MI}(S_1, S'_1)$ and $(i', c, d) \in \mathsf{MP}(S_2, S'_2)$, adding i to $\mathsf{P}_{(i'-i)\circlearrowright n}$ and, provided that $a = c$, also to $\mathsf{P}'_{(i'-i)\circlearrowright n}$.

For each shift m with $\mathsf{P}_m \neq \emptyset$, the algorithm uses $\mathtt{dec}_0(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2), m)$ of Lemma 6.5. If this call returns a non-zero result, then m is ignored. Otherwise, $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = \mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2) - |\mathsf{P}_m| - |\mathsf{P}'_m|$ is computed. Finally, the algorithm returns the minimum of $\mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2)$ and the smallest among the computed values $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$.

Correctness. By Corollary 6.3, $\mathsf{sh}(S_1, S_2) \leq k$ guarantees $\mathsf{sh}(S'_1, S'_2) = 0$, so the algorithm correctly returns ∞ if $\mathtt{dec}_0^{\mathsf{sh}}(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2))$ yields a non-zero result. Moreover, $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$ guarantees $S'_1 = \mathsf{cyc}^m(S'_2)$, so the algorithm correctly ignores $m \in [n]$ if $\mathtt{dec}_0(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2), m)$ yields a non-zero result. In the following, we assume $\mathsf{sh}(S'_1, S'_2) = 0$ with $S'_1 = \mathsf{cyc}^m(S'_2)$ for all the shifts considered. The latter assumption implies $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = \mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2) - |\mathsf{P}_m| - |\mathsf{P}'_m|$ (compare the proof of Fact 3.2). Moreover, $\mathsf{sh}(S_1, S_2) \leq \mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2)$ holds by the triangle inequality, Hence, the returned value is at least $\mathsf{sh}(S_1, S_2)$ with high probability.

On the other hand, if $\mathsf{sh}(S_1, S_2) = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$ for some shift $m \in [n]$, then $S'_1 = \mathsf{cyc}^m(S'_2)$ and $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = \mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2) - |\mathsf{P}_m| - |\mathsf{P}'_m|$. This either yields $\mathsf{sh}(S_1, S_2) = \mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2)$ (in case of $\mathsf{P}_m = \emptyset$, which yields $|\mathsf{P}_m| = |\mathsf{P}'_m| = 0$) or that m was among the shifts considered (otherwise). In both cases, we conclude that the returned value is at most $\mathsf{sh}(S_1, S_2)$ with high probability. ◀

A relaxed (ε, k)-ASDS sketch is defined analogously to a relaxed (ε, k)-ACS sketch:

- if $\mathsf{sh}(S_1, S_2) < \frac{1}{2}k$, then $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) < \frac{1+\varepsilon}{2}k$,
- if $\frac{1}{2}k \leq \mathsf{sh}(S_1, S_2) \leq k$, then $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) \in (1 \pm \varepsilon)\mathsf{sh}(S_1, S_2)$,
- otherwise, $\mathtt{dec}^{\mathsf{sh}}(\mathtt{sk}(S_1), \mathtt{sk}(S_2)) > (1 - \varepsilon)k$.

▶ **Proposition A.5** (see Proposition 6.9). *There exists a decoding function which, together with the encoding $\mathtt{circ}_{\varepsilon,k}$ of Construction 6.8, forms a relaxed (ε, k)-ASDS sketch of $\mathcal{H}'_{n,k}$. The decoding algorithm costs $\tilde{O}(\varepsilon^{-2}k)$ time with high probability.*

Proof. The decoding algorithm is given sketches $\mathtt{circ}_{\varepsilon,k}(S_1) = (\mathtt{sk}_0(S'_1), \mathsf{MI}_{A\cup B}(S_1, S'_1))$ and $\mathtt{circ}_{\varepsilon,k}(S_2) = (\mathtt{sk}_0(S'_2), \mathsf{MI}_{A\cup B}(S_2, S'_2))$. First, the algorithm applies $\mathtt{dec}_0^{\mathsf{sh}}(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2))$ of Lemma A.3. If this call returns a non-zero result, then ∞ is returned. Otherwise, for each $m \in [n]$, the algorithm constructs the sets $\mathsf{P}_m \cap A \cap \mathsf{rot}_n^m(B)$ and $\mathsf{P}'_m \cap A \cap \mathsf{rot}_n^m(B)$, where

$$\mathsf{P}_m := \mathsf{MP}(S_1, S'_1) \cap \mathsf{MP}(\mathsf{cyc}^m(S_2), \mathsf{cyc}^m(S'_2))$$
$$\mathsf{P}'_m := \mathsf{P}_m \setminus \mathsf{MP}(S_1, \mathsf{cyc}^m(S_2))$$

are defined as in the proof of Proposition A.4. For this, the algorithm iterates over $(i, a, b) \in \mathsf{MI}_A(S_1, S'_1)$ and $(i', c, d) \in \mathsf{MI}_B(S_2, S'_2)$, adding i to $\mathsf{P}_{(i'-i)\circlearrowright n} \cap A \cap \mathsf{rot}_n^{(i'-i)\circlearrowright n}(B)$ and, provided that $a = c$, also to $\mathsf{P}'_{(i'-i)\circlearrowright n} \cap A \cap \mathsf{rot}_n^{(i'-i)\circlearrowright n}(B)$.

For each shift m with $\mathsf{P}_m \cap A \cap \mathsf{rot}_n^m(B) \neq \emptyset$, the algorithm uses $\mathtt{dec}_0(\mathtt{sk}_0(S'_1), \mathtt{sk}_0(S'_2), m)$ of Lemma 6.5. If this call returns a non-zero result, then m is ignored. Otherwise, the algorithm computes

$$d_m := \mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2) - \tfrac{\varepsilon^2 k}{\log n}(|\mathsf{P}_m \cap A \cap \mathsf{rot}_n^m(B)| + |\mathsf{P}'_m \cap A \cap \mathsf{rot}_n^m(B)|).$$

Finally, the algorithm returns the minimum of $\mathsf{Ham}(S_1, S'_1) + \mathsf{Ham}(S_2, S'_2)$ and the smallest among the computed values d_m.

Correctness. By Corollary 6.3, $\mathsf{sh}(S_1, S_2) \leq k$ guarantees $\mathsf{sh}(S_1', S_2') = 0$, so the algorithm correctly returns ∞ if $\mathtt{dec}_0^{\mathsf{sh}}(\mathtt{sk}_0(S_1'), \mathtt{sk}_0(S_2'))$ yields a non-zero result. Moreover, $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$ guarantees $S_1' = \mathsf{cyc}^m(S_2')$, so the algorithm correctly ignores $m \in [n]$ if $\mathtt{dec}_0(\mathtt{sk}_0(S_1'), \mathtt{sk}_0(S_2'), m)$ yields a non-zero result. In the following, we assume $\mathsf{sh}(S_1', S_2') = 0$ with $S_1' = \mathsf{cyc}^m(S_2')$ for all the shifts considered.

Recall that $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) = \mathsf{Ham}(S_1, S_1') + \mathsf{Ham}(S_2, S_2') - |\mathsf{P}_m| - |\mathsf{P}'_m|$ holds provided that $S_1' = \mathsf{cyc}^m(S_2')$. Since $A \cap \mathsf{rot}_n^m(B)$ is a random subset of $[n]$ with elements sampled independently with rate $\frac{\log n}{\varepsilon^2 k}$, the quantity $\frac{\varepsilon^2 k}{\log n}(|\mathsf{P}_m \cap A \cap \mathsf{rot}_n^m(B)| + |\mathsf{P}'_m \cap A \cap \mathsf{rot}_n^m(B)|)$ is with high probability a $\pm\frac{\varepsilon k}{2}$-additive approximation of $|\mathsf{P}_m| + |\mathsf{P}'_m|$ (which can be argued as in the proof of Lemma 3.1). Consequently, the computed value d_m is with high probability a $\pm\frac{\varepsilon k}{2}$-additive approximation of $\mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2))$. As $\mathsf{sh}(S_1, S_2) \leq \mathsf{Ham}(S_1, S_1') + \mathsf{Ham}(S_2, S_2')$ holds by the triangle inequality, this means that the returned value is at least $(1-\varepsilon)\mathsf{sh}(S_1, S_2)$ with high probability provided that $\mathsf{sh}(S_1, S_2) \geq \frac{1}{2}k$.

On the other hand, if $\mathsf{sh}(S_1, S_2) = \mathsf{Ham}(S_1, \mathsf{cyc}^m(S_2)) \leq k$ for some shift $m \in [n]$, then $S_1' = \mathsf{cyc}^m(S_2')$ and d_m is a $\pm\frac{\varepsilon k}{2}$-additive approximation of $\mathsf{sh}(S_2, S_2')$. This either yields $\mathsf{Ham}(S_1, S_1') + \mathsf{Ham}(S_2, S_2') \leq (1+\varepsilon)\mathsf{sh}(S_1, S_2)$ (if $\mathsf{P}_m \cap A \cap \mathsf{rot}_n^m(B) = \emptyset$, which yields $|\mathsf{P}_m \cap A \cap \mathsf{rot}_n^m(B)| = |\mathsf{P}'_m \cap A \cap \mathsf{rot}_n^m(B)| = 0$) or that m was among the shifts considered (otherwise). In both cases, we conclude that the returned value is at most $(1+\varepsilon)\mathsf{sh}(S_1, S_2)$ with high probability. ◀

A.3 Shift Distance Sketches for Σ^n

After handling non-pseudo-periodic and pseudo-periodic strings separately, we derive sketches for the whole Σ^n. The following results provide efficient shift distance decoding procedures for the circular k-mismatch sketches described in Section 7.

For the exact case, using Propositions A.2 and A.4, the same construction as in the proof of Theorem 1.3 yields the following corollary.

▶ **Corollary A.6** (see Theorem 1.3). *There exists a k-ESDS sketch of size $\tilde{O}(k)$ with decoding time $\tilde{O}(k^2)$.*

For the approximate case, using Propositions A.1 and A.5, the same construction as in Proposition 7.1 yields a relaxed (ε, k)-ASDS sketch of size $\tilde{O}(\varepsilon^{-2}\sqrt{k})$ with decoding time $\tilde{O}(\varepsilon^{-2}k)$.

▶ **Proposition A.7** (see Proposition 7.1). *There exists a relaxed (ε, k)-ASDS sketch of size $\tilde{O}(\varepsilon^{-2}\sqrt{k})$ and decoding time of $\tilde{O}(\varepsilon^{-2}k)$.*

The following provides an alternative method for constructing (ε, k)-ASDS sketches which improves the sketch size (for $k \geq \varepsilon n$) but degrades the decoding time.

▶ **Proposition A.8** (see Proposition 7.3). *There exists a decoding function which, together with the encoding $\mathtt{circ}_{\varepsilon,k}$ of Construction 7.2, forms a relaxed (ε, k)-ASDS sketch of Σ^n. The decoding time is $\tilde{O}(\frac{n^2}{\varepsilon^2 k})$ with high probability.*

Proof. The decoding function, given the sketches of $S_1, S_2 \in \Sigma^n$, computes a value $d_m := \mathsf{Ham}_{A \cap \mathsf{rot}_n^m(B)}(S_1, \mathsf{cyc}^m(S_2))$ for each $m \in [n]$. For this, the algorithm iterates over $(i, S_1[i])$ with $i \in A$ (retrieved from the sketch of S_1) and $(i', S_2[i'])$ with $i' \in B$ (retrieved from the sketch of S_2), and increments $d_{(i'-i)\circlearrowright n}$ if $S_1[i] \neq S_2[i']$.

As in the proof of Proposition 7.3, $\frac{\varepsilon^2 k}{\log n}\mathsf{Ham}_{A\cap\mathsf{rot}_n^m(B)}(S_1,\mathsf{cyc}^m(S_2))$ is a $(1\pm\varepsilon)$-approximation of $\mathsf{Ham}(S_1,\mathsf{cyc}^m(S_2))$ with high probability provided that $\mathsf{Ham}(S_1,\mathsf{cyc}^m(S_2))=\Omega(k)$ (and $\frac{\varepsilon^2 k}{\log n}\mathsf{Ham}_{A\cap\mathsf{rot}_n^m(B)}(S_1,\mathsf{cyc}^m(S_2))=o(k)$ otherwise). Hence, the algorithm returns as an approximation of $\mathsf{sh}(S_1,S_2)$ the smallest value $\frac{\varepsilon^2 k}{\log n}\mathsf{Ham}_{A\cap\mathsf{rot}_n^m(B)}(S_1,\mathsf{cyc}^m(S_2))$ among $m\in[n]$. ◀

▶ **Corollary A.9** (see Theorem 1.4). *There exists an (ε,k)-ASDS sketch of size $\tilde{O}(\varepsilon^{-2}\sqrt{k})$ with decoding time $\tilde{O}(\varepsilon^{-2}k)$, and an (ε,k)-ASDS sketch of size $\tilde{O}(\varepsilon^{-1.5}\sqrt{n})$ with decoding time $\tilde{O}(\varepsilon^{-3}n)$.*

B Missing Proofs

▶ **Lemma 3.1.** *Let A be a random subset of $[n]$ with elements chosen independently at rate p. For $0<\varepsilon<1$, we have $\Pr[\mathsf{Ham}_A(S,T)\in(1\pm\varepsilon)p\mathsf{Ham}(S,T)]\geq 1-2\exp\left(-\frac{p\mathsf{Ham}(S,T)\varepsilon^2}{3}\right)$.*

Proof. For each index $i\in[n]$, let x_i be an indicator variable such that $x_i=1$ if $i\in\mathsf{MI}_A(S,T)$ and $x_i=0$ otherwise. Note that $\mathsf{Ham}_A(S,T)=|\mathsf{MI}_A(S,T)|=\sum_{i=1}^n x_i$ and that x_i are independent variables. For every $i\in\mathsf{MI}(S,T)$, we have $\Pr[x_i=1]=p$ and, for every $i\notin\mathsf{MI}(S,T)$, we have $\Pr[x_i=1]=0$. Thus, $\mathbb{E}[\sum_{i=1}^n x_i]=\mathbb{E}[\sum_{i\in\mathsf{MI}_A(S,T)}x_i]=p\mathsf{Ham}_A(S,T)$. Hence, by the Chernoff bound (see, e.g., [20])

$$\Pr\left[\left|\sum_{i=1}^n x_i - p\mathsf{Ham}_A(S,T)\right|>\varepsilon p\mathsf{Ham}_A(S,T)\right]\leq 2\exp\left(-\frac{p\mathsf{Ham}_A(S,T)\varepsilon^2}{3}\right).$$

Thus, $\Pr[\mathsf{Ham}_A(S,T)\in(1\pm\varepsilon)p\mathsf{Ham}(S,T)]\geq 1-2\exp(-\frac{p\mathsf{Ham}(S,T)\varepsilon^2}{3})$. ◀

▶ **Fact 3.2.** *For every $S,T,U\in\Sigma^n$ and every $A\subseteq[n]$, the mismatch information $\mathsf{MI}_A(S,U)$ can be retrieved from $\mathsf{MI}_A(S,T)$ and $\mathsf{MI}_A(T,U)$ in time $\tilde{O}(\mathsf{Ham}_A(S,T)+\mathsf{Ham}_A(T,U))$.*

Proof. For each $i\in A$, we have one of the following four cases:
- if $i\notin\mathsf{MP}(S,T)$ and $i\notin\mathsf{MP}(T,U)$, then $S[i]=T[i]=U[i]$, so $i\notin\mathsf{MP}(S,U)$,
- if $(i,a,b)\in\mathsf{MI}(S,T)$ and $i\notin\mathsf{MP}(T,U)$, then $S[i]=a\neq b=T[i]=U[i]$, so $(i,a,b)\in\mathsf{MI}(S,U)$,
- if $i\notin\mathsf{MP}(S,T)$ and $(i,b,c)\in\mathsf{MP}(T,U)$, then $S[i]=T[i]=b\neq c=U[i]$, so $(i,b,c)\in\mathsf{MI}(S,U)$,
- if $(i,a,b)\in\mathsf{MI}(S,T)$ and $(i,b,c)\in\mathsf{MP}(T,U)$, then $S[i]=a\neq b=T[i]=b\neq c=U[i]$, so $(i,a,c)\in\mathsf{MI}(S,U)$ (if $a\neq c$) or $i\notin\mathsf{MP}(S,U)$ (if $a=c$). ◀

▶ **Theorem 4.3** ($(1\pm\varepsilon)$-approximate sketches, folklore). *There exists a $(1\pm\varepsilon)$-approximate sketch $\mathtt{sk}_\varepsilon$ such that, given $\mathtt{sk}_\varepsilon(S_1)$ and $\mathtt{sk}_\varepsilon(S_2)$ for two strings $S_1,S_2\in\Sigma^n$, one can decode $\mathsf{Ham}(S_1,S_2)$ with a $(1\pm\varepsilon)$-multiplicative error. The sketches use $\tilde{O}(\varepsilon^{-2})$ space, the decoding algorithm is correct with high probability and costs $\tilde{O}(\varepsilon^{-2})$ time.*

Proof. Consider $\mu:\Sigma\to\{0,1\}^\sigma$ defined as $\mu(c)=0^{c-1}10^{\sigma-c}$. For every words u,v, we have $\mathsf{Ham}(\mu(u),\mu(v))=2\cdot\mathsf{Ham}(u,v)$. We then use AMS sketches [2] on $\mu(u)$ and $\mu(v)$ which allow for decoding of ℓ_2 distance $\|\mu(u)-\mu(v)\|_2$. This is enough since, for binary words, the ℓ_2^2 distance coincides with the Hamming distance. We then note that the AMS sketches of $\mu(u)$ and $\mu(v)$ can be computed without explicitly constructing $\mu(u)$ or $\mu(v)$. ◀

▶ **Proposition 7.1.** *There exists a relaxed (ε,k)-ACS sketch for Σ^n of size $\tilde{O}(\varepsilon^{-2}\sqrt{k})$. Its decoding time is $\tilde{O}(\varepsilon^{-1}\sqrt{k}+\varepsilon^{-2})$ with high probability.*

Proof. Our construction combines the (ε, k)-ACS sketch of Proposition 4.5 and the relaxed (ε, k)-ACS sketch of Proposition 6.9. For each strings S, if $S \in \mathcal{H}'_{n,k}$, then the sketch contains the sketch of S by Proposition 6.9 and, if $S \in \Sigma^n \setminus \mathcal{H}_{n,k}$, then the sketch contains the sketch of S by Proposition 4.5. Notice that, for $S \in \mathcal{H}'_{n,k} \setminus \mathcal{H}_{n,k}$ the sketch contains both components.

For any two strings $S_1, S_2 \in \Sigma^n$, given the sketches of S_1 and S_2, the decoder works as follows. If the two sketches contains compatible components (of Proposition 4.5 or of Proposition 6.9), then the decoder uses the decoder corresponding to these components. Otherwise, without loss of generality, it must be that $S_1 \in \mathcal{H}_{n,k}$ and $S_2 \notin \mathcal{H}'_{n,k}$. Thus, by Observation 6.2, $\mathsf{Ham}(S_1, S_2) > k$, and therefore the decoder outputs ∞. ◀

On Guillotine Separability of Squares and Rectangles

Abstract

Guillotine separability of rectangles has recently gained prominence in combinatorial optimization, computational geometry, and combinatorics. Consider a given large stock unit (say glass or wood) and we need to cut out a set of required rectangles from it. Many cutting technologies allow only end-to-end cuts called *guillotine cuts*. Guillotine cuts occur in *stages*. Each stage consists of either only vertical cuts or only horizontal cuts. In k-stage packing, the number of cuts to obtain each rectangle from the initial packing is at most k (plus an additional trimming step to separate the rectangle itself from a waste area). Pach and Tardos [20] studied the following question: Given a set of n axis-parallel rectangles (in the weighted case, each rectangle has an associated weight), cut out as many rectangles (resp. weight) as possible using a sequence of guillotine cuts. They provide a guillotine cutting sequence that recovers $1/(2\log n)$-fraction of rectangles (resp. weights). Abed et al. [1] claimed that a guillotine cutting sequence can recover a constant fraction for axis-parallel squares. They also conjectured that for any set of rectangles, there exists a sequence of axis-parallel guillotine cuts that recovers a constant fraction of rectangles. This conjecture, if true, would yield a combinatorial $O(1)$-approximation for *Maximum Independent Set of Rectangles (MISR)*, a long-standing open problem. We show the conjecture is not true, if we only allow $o(\log\log n)$ stages (resp. $o(\log n/\log\log n)$-stages for the weighted case). On the positive side, we show a simple $O(n\log n)$-time 2-stage cut sequence that recovers $1/(1+\log n)$-fraction of rectangles. We improve the extraction of squares by showing that 1/40-fraction (resp. 1/160 in the weighted case) of squares can be recovered using guillotine cuts. We also show $O(1)$-fraction of rectangles, even in the weighted case, can be recovered for many special cases of rectangles, e.g. fat (bounded width/height), δ-large (large in one of the dimensions), etc. We show that this implies $O(1)$-factor approximation for Maximum Weighted Independent Set of Rectangles, the weighted version of MISR, for these classes of rectangles.

1 Introduction

Cutting stock problem is a well-studied problem in combinatorial optimization, starting from the seminal work of Gilmore and Gomory [13]. Specially, the 2-D variant has received a lot of attention due to its application in practice [14, 27]. In these problems, we need to cut out some required geometric objects under some constraints, from a large source material such as glass, rubber, metal, wood or cloth. One special constraint, guillotine cut (end-to-end cut) emerges naturally from the design of cutting machines. Starting from the initial source material (*piece*), in each step such a cutting sequence takes one of the available pieces and finds an end-to-end cut along a straight line to divide it into two smaller pieces. Ultimately, each of the required objects corresponds to one of the final pieces. These cuts are simple to program due to column generation techniques [10, 26]. Due to lower cost and simple usability, we find many real-world applications of guillotine cuts, such as in crepe-rubber mill [23], glass industry [22], and paper cutting [19].

The problem has also been studied extensively from theoretical viewpoint. Urrutia [25] asked the following question: Given a family of pairwise disjoint compact convex sets on a sheet of glass, is it true that one can always separate out a constant fraction of them using a guillotine cutting sequence? Pach and Tardos [20] answered the question in negative for line segments. They provided a family of n straight line segments where at most $O(n^{\log_3 2})$ line segments can be separated using guillotine cuts. However, they showed that one can always cut out a constant fraction of the input objects, if all objects have roughly the same size (contains a circle of radius r_1 and contained within a circle of radius r_2, for $r_2 \geq r_1 > 0$). For any family of n pairwise disjoint compact convex sets (resp. line segments) in the plane, one can always separate $\Omega(n^{1/3})$ (resp. $\Omega(n^{1/2})$) of members using guillotine cuts. For any family of n pairwise disjoint compact convex sets (resp. line segments) in the plane, one can always separate $\Omega(n^{1/3})$ (resp. $\Omega(n^{1/2})$) of members.

In this paper, we focus on guillotine separability of rectangles and squares. Given a set of n pairwise disjoint axis-parallel open rectangles $\mathcal{R} := \{R_1, R_2, \ldots, R_n\}$ embedded on a square $[0, N] \times [0, N]$, our goal is to separate as many rectangles as possible by a sequence of axis-parallel guillotine cuts. Pach and Tardos [20] showed that $\Omega(n/\log n)$ rectangles can be separated using guillotine cuts. Abed et al. [1] studied the problem for squares. They claimed a guillotine cutting sequence that recovers 1/81-fraction of any set of axis-parallel squares and made the following conjecture:

▶ **Conjecture 1** ([1]). *For any set of n non-overlapping axis-parallel rectangles there is a guillotine cutting sequence with only axis-parallel cuts separating $\Omega(n)$ of them.*

Furthermore, they extend the problem to the weighted case in which each rectangle R_i has an associated weight $p_i \in \mathbb{Q}$ and the goal is to separate a subset of rectangles using guillotine cuts such that the total profit of separated rectangles is maximized. For this weighted version for squares, they claimed recovery of 4/729-fraction of squares, and a $1/2^{O(d)}$-fraction in the weighted case in d-dimensions (where objects are hypercubes). They also showed that a proof of Conjecture 1 will imply an $O(1)$-approximation for maximum independent set of rectangles (MISR), a notoriously difficult NP-hard problem [2, 8]. In maximum weighted independent set of rectangles (MWISR), we are given a set of possibly overlapping axis-parallel rectangles (with associated profit) and the goal to compute a non-overlapping subset of maximum profit. MISR is the cardinality variant, i.e., when all rectangles have equal profit. This connection between MISR and guillotine separability has made the guillotine separability to rise into prominence in recent years [18].

Guillotine cutting for rectangles can also be viewed as a packing problem where all rectangles are packed in such a way that all of them can be cut out using a guillotine cutting sequence. Gilmore and Gomory [13] initiated systematic study of guillotine packing by *k-stage packing*, where each stage consists of either horizontal or vertical guillotine cuts (but not both). Geometric packing problems are a classical well-studied area in approximation algorithms [9, 15]. In 2-D geometric knapsack problem (2GK) [16], we are given a set of rectangular items (with associated profit) and unit square knapsack, and the goal is to pack a subset of items into the knapsack maximizing the total profit. This problem is strongly NP-hard [17], even for squares with unit profit. The present-best approximation ratio is 1.89 [12]. In 2-D strip packing problem (2SP) [11], we are given a set of rectangular items and fixed-width unbounded-height strip, and the goal is to pack all the items into the strip such that the height of the strip is minimized. Kenyon and Rémila gave an APTAS for the problem [14] using a 3-stage packing. In 2-D bin packing problem (2BP), we are given a set of rectangular items and unit square bins, and the goal is to pack all the items into minimum number of bins. The problem is APX-hard [3] and the present best approximation ratio is 1.405 [4].

All these problems have been studied under k-stage packing [21]. Abed et al. [1] have studied 2GK under guillotine cuts and have given a QPTAS for the cardinality case with quasi-polynomially bounded input. Caprara [6] obtained a 2-stage $T_\infty(\approx 1.691)$-approximation for 2BP, and conjectured that the worst-case asymptotic ratio between the optimal 2-stage 2BP and optimal general 2BP is 3/2. Later, Caprara et al. [7] gave an APTAS for 2-stage 2BP and 2-stage 2SP. Afterwards, Bansal et al. [5] showed an APTAS for guillotine 2BP. Seiden and Woeginger [24] gave an APTAS for guillotine 2SP. Both the APTAS for guillotine 2BP and guillotine 2SP are based on the fact that general guillotine 2BP or guillotine 2SP can be approximated arbitrary well by $O(1)$-stage packing, and such $O(1)$-stage packing can be found efficiently. Bansal et al. [4] conjectured the worst-case asymptotic ratio between the best guillotine 2BP and the best general 2BP is 4/3. This conjecture, if true, along with APTAS for guillotine packing [5], will imply a $(4/3 + \varepsilon)$-approximation for 2BP.

1.1 Our contributions

We obtain improved guillotine separability for many classes of rectangles. We show a simple $O(n \log n)$-time algorithm that recovers $1/(\log n + 1)$-fraction of rectangles. The recursive algorithm of [20] can recover $1/(2 \log n)$-fraction of rectangles, but can also take $\Omega(\log n)$-stages in the worst case, whereas our algorithm takes only 2-stages. We define multi-level lines called poles to partition the rectangles into guillotine separable classes and used this technique to recover a constant fraction of rectangles for many classes (see Section 5). Using ternary partitions we show a slightly improved bound of $n/\log_3(n+2)$. We then show that unlike other packing problems (such as 2BP or 2SP), in our problem any guillotine packing can not be approximated arbitrary well by $O(1)$-stages. In particular, we show:

▶ **Theorem 2.** *Any guillotine cutting algorithm with a constant number of stages can recover at most $O(\frac{\log\log n}{\log n})$ fraction of total weight. In order to recover a constant fraction of weight we require $\Omega(\frac{\log n}{\log\log n})$ stages.*

▶ **Theorem 3.** *Any guillotine cutting algorithm with a constant number of stages can extract at most $O(\frac{1}{\log\log n})$ fraction of total rectangles. In order to extract a constant fraction of rectangles, we require $\Omega(\log\log n)$ number of stages.*

For the case of squares, we found bugs in [1]. We could fix them by loosing additional multiplicative factor. Then using a more involved sampling and exploiting structural properties of guillotine cuts, we obtain further improvement. These structural properties might find usage in related guillotine packing problems.

▶ **Theorem 4.** *For axis-parallel squares, always there exists a guillotine cutting sequence that recovers* $1/40$ *(resp.* $1/160$ *in the weighted case)-fraction.*

We also show that $O(1)$-fraction of rectangles can be recovered for many special classes of rectangles, such as (a) *Fat*: when for each rectangle the ratio of width and height is in $[1/\beta, \beta]$, for some constant β. Fat objects generalize squares and are well-studied [20], (b) *δ-large*: when each rectangle has either width $\geq \delta N$ or height $\geq \delta N$. These rectangles are well-studied in the context of MISR [2], (c) *part-similar*, (d) *anti-laminar* (see Section 5). We also show that if $1/c$-fraction of weight can be recovered for a class of rectangles, then we obtain an $O(n^5)$-time c-approximation for MWISR. Thus obtaining $O(1)$-approximation for MWISR for the above classes of rectangles.

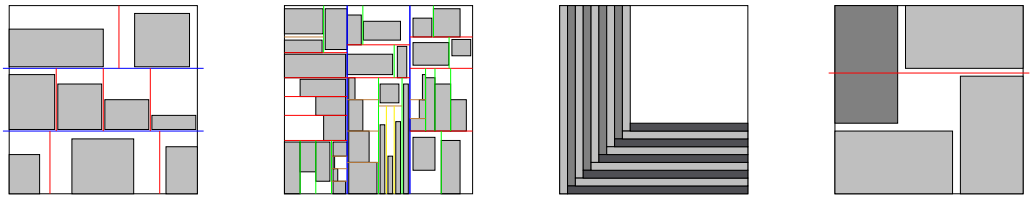
1.2 Organization of the paper

Section 2 describes some building blocks and known results used in this article. Section 3 gives improved guillotine separability of squares. Section 4 describes algorithms and hardness for rectangles. Section 5 studies several special classes of rectangles and obtains constant factor extraction for them. Due to space constraints, some proofs are deferred to the full version .

2 Preliminaries

Let $\mathbb{Z}^+$ (resp. $\mathbb{Z}^{\geq 0}$) be the set of positive (resp. nonnegative) integers. Let us define $[n] := \{1, 2, \ldots, n\}$ and $[n \cup 0] := \{0, 1, 2, \ldots, n\}$, for $n \in \mathbb{Z}^+$. We are given a set of axis-parallel nonoverlapping rectangles $\mathcal{R} := \{R_1, R_2, \ldots, R_n\}$ embedded in a box $K := [0, N] \times [0, N]$. Each rectangle $R_i \in \mathcal{R}$ has width w_i, height h_i, and bottom-left corner at (x_i, y_i). Thus rectangle R_i is defined by the region $R(i) := [x_i, x_i + w_i] \times [y_i, y_i + h_i]$, where $x_i \geq 0, y_i \geq 0, x_i + w_i \leq N, y_i + h_i \leq N$. For any two input rectangles $R_i, R_j (j \neq i)$, we have $R(i) \cap R(j) = \emptyset$. Rectangle R_i has an associated weight p_i. In the unweighted case, all rectangles have the same (unit) weight.

2.1 Guillotine separability



▶ **Definition 5** (Piece)**.** *A* piece *is an axis-aligned rectangular region with axis-parallel rectangles $\mathcal{R}$ embedded on it.*

▶ **Definition 6** (Guillotine cut)**.** *A* guillotine cut *for a piece P is an end-to-end axis-parallel cut along a straight line ℓ dividing the piece into two (rectangular) subpieces P_1 and P_2.*

We define a *stage* of guillotine cuts as a set of end to end, equal, axis-parallel cuts separating piece P into further sub-pieces. Cuts in alternate stages alternate between vertical (parallel to y-axis) and horizontal (parallel to x-axis) cuts.

A guillotine cutting strategy is represented by two types of trees.

▶ **Definition 7** (Guillotine binary tree)**.** A guillotine binary tree *for a set of rectangles $\mathcal{R}$ is a binary tree $\mathcal{T}_B$ where each non-leaf node $v \in V(\mathcal{T}_B)$ is equipped with a piece P_v and the straight line ℓ_v corresponding to the cut such that cutting P_v along the straight line ℓ_v gives us*

(a) 2-stage. **(b)** 5-stage. **(c)** many stage. **(d)** non-guillotine.

Figure 1 Different types of packing: (a), (b), (c) are guillotine packing, while (d) is not.

subpieces P_{v_1} and P_{v_2}, where v_1, v_2 are the children of v. Thus the piece P_r corresponding to the root node r contains $\mathcal{R}$ and for each leaf node v, the piece P_v contains only one rectangle. For each non-leaf node v, let $cutrec(v)$ (resp. $cutwt(v)$) denote the number (resp. total weight) of rectangles cut by line ℓ_v.

▶ **Definition 8** (Guillotine stage tree). *A guillotine stage cutting strategy for a set of rectangles $\mathcal{R}$ is represented by a* guillotine stage tree *$\mathcal{T}_S$ where each non-leaf node $v \in V(\mathcal{T}_S)$ is equipped with a piece P_v and the set of straight lines $\mathcal{L}_v$ corresponding to the stage of the cut such that cutting P_v along the straight lines in $\mathcal{L}_v$ gives us subpieces $P_{v_1}, P_{v_2}, \ldots, P_{v_{|\mathcal{L}_v|}}$, where $v_1, v_2, \ldots, v_{|\mathcal{L}_v|}$ are the children of v. For each non-leaf node $v \in V(\mathcal{T}_S)$, let $cutrec(v)$ (resp. $cutwt(v)$) denote the number (resp. weights) of rectangles cut by lines in $\mathcal{L}_v$. A guillotine cutting strategy has k-stages if the tree $\mathcal{T}_S$ has height k.*

We say that $\mathcal{T}_B$ (resp. $\mathcal{T}_S$) separates a set of rectangles $\mathcal{R}$ if $cutrec(v) = 0$ for all $v \in V(\mathcal{T}_B)$ (resp. $\mathcal{T}_S$).

▶ **Definition 9** (k-good cut). *A cut ℓ_v cutting P_v is a k-good cut, if it intersects at most k rectangles and each side contains at least one rectangle completely.*

▶ **Definition 10** ((k, c)-good cut). *For any piece P having at least $2c$ rectangles, a (k, c)-good cut is a cut which cuts at most k rectangle and also has at least c rectangles on both sides.*

▶ **Definition 11** (Extraction factor). *A guillotine cutting strategy is said to have an extraction factor f if it separates f-fraction of rectangles (resp. weight).*

2.2 Grid sampling for squares

Here we briefly discuss grid sampling from [1] (but modify slightly to fix the bugs) when all input rectangles in $\mathcal{R}$ are squares. Let $len(i)$ be the side length of square R_i. Abed et al. [1] introduced a collection of (multi-level) grid lines to do a four step sampling to show that a constant fraction of squares are guillotine separable. First, we define these gridlines and related notions as they constitute an important component in our proofs too. A square $R_i \in \mathcal{R}$ is said to be at level-i if $len(i) \in \left(\frac{N}{2^{i+1}}, \frac{N}{2^i}\right]$. We independently pick random numbers $\tilde{x}, \tilde{y} \in [0, N)$ to define a random shift for drawing the grid. The vertical grid lines at level-i are drawn at $\tilde{x}, \tilde{x} + \frac{N}{2^i}, \tilde{x} + \frac{2N}{2^i}, \cdots$. Similarly, the horizontal grid lines at level-i are drawn at $\tilde{y}, \tilde{y} + \frac{N}{2^i}, \tilde{y} + \frac{2N}{2^i}, \cdots$ (Note that the coordinates mentioned for the vertical and horizontal grid lines are taken *modulo* N). Grid cells circumscribed by successive grid lines at level-$(i-1)$ are said to be at level-i. Thus the level-i grid cells are square regions of size $\frac{2N}{2^i} \times \frac{2N}{2^i}$. Hence, if a level-$j$ square is completely contained within a level-i grid cell, then $i \leq j + 1$. Note that higher the level, more fine grained the grid is, and smaller the grid cells and squares are.

In the *first* step of sampling, we pick squares from either even levels or odd levels, randomly. Let $\mathcal{R}_0$ be the set of squares remaining afterwards. Then $\mathbb{P}[R \in \mathcal{R}_0] = 1/2$.

In the *second* step of sampling, a square $R \in \mathcal{R}_0$ is removed if it intersects with grid lines in the level below it, i.e., any level-i ($i \geq 1$) square R is removed if it intersects a gridline of level $0, \ldots, i-1$. Let $\mathcal{R}_1$ be the set of squares that remained after this step.

▶ **Lemma 12** ([1]). *A level-i square $R \in \mathcal{R}_0$ of side length $len(R) \in \left(\frac{N}{2^{i+1}}, \frac{N}{2^i}\right]$ remains in $\mathcal{R}_1$ with probability $(1-\mu_R)^2 \geq 1/4$, where $\mu_R = len(R) \cdot \frac{2^{i-1}}{N}$*

In the *third* sampling step, the squares in $\mathcal{R}_1$ are sampled to obtain $\mathcal{R}_2$ so that each level-i grid cell contains at most one square of level-i. Let $\mathcal{R}_1^C$ denote the subset of level-i squares contained within a grid cell C at level-i. We sample each $R \in \mathcal{R}_1^C$ with probability $\{(1-\mu_R)^2 \cdot M_C)^{-1}$ for $M_C = \sum_{S \in \mathcal{R}_1^C} (1-\mu_S)^{-2}$. Let $\mathcal{R}_2$ be the set of squares remaining after this process. Then the probability that a level-i square R remains in $\mathcal{R}_2$ is: $\mathbb{P}[R \in \mathcal{R}_0] \cdot \mathbb{P}[R \in \mathcal{R}_1 | R \in \mathcal{R}_0] \cdot \mathbb{P}[R \in \mathcal{R}_2 | R \in \mathcal{R}_1] = \frac{1}{2} \cdot (1-\mu_R)^2 \cdot \left(\frac{1}{(1-\mu_R)^2 \cdot M_C}\right) = 1/(2 \cdot M_C)$

In the *fourth* step, squares in $\mathcal{R}_2$ are sampled further to obtain a guillotine separable set.

▶ **Definition 13** (ε-guillotine sampling). *An* ε-guillotine sampling *for objects $\mathcal{O}$ is a distribution $\mathcal{D} : 2^{\mathcal{O}} \to [0,1]$ such that any object $r \in \mathcal{O}$ is sampled by $\mathcal{D}$ with probability at least ε and each subset in the support of $\mathcal{D}$ is guillotine separable.*

▶ **Lemma 14** ([1]). *For any set of objects $\mathcal{O}$, the following two statements are equivalent:*

- **(i)** *there is an ε-guillotine sampling for $\mathcal{O}$,*
- **(ii)** *for any $w : \mathcal{O} \to \mathbb{Z}_{\geq 0}$, there is a guillotine seperable subset $\mathcal{O}' \subseteq \mathcal{O}$ with $w(\mathcal{O}') \geq \varepsilon \cdot w(\mathcal{O})$.*

Let $level(R)$ be the level of square R. For a level-i square R, let $cell(R)$ be the level-i gridcell containing R. We say that two squares R and S are *conflicting* if either R overlaps the boundary of $cell(S)$ or S overlaps the boundary of $cell(R)$. Note that if R overlaps the boundary of $cell(S)$, then $level(R) < level(S)$. A conflict graph H encodes the conflict structures between squares, where the vertex set $V(H)$ corresponds to the squares in $\mathcal{R}$, and there is an edge between squares R and S if and only if R and S are conflicting.

▶ **Lemma 15** ([1]). *For an independent set $I \subseteq V(H)$, $\{R\}_{R \in I}$ are guillotine separable.*

Let H be the conflict graph defined by the squares in $\mathcal{R}_2$. If H is χ-colorable, then we obtain a guillotine separable set of size at least $|\mathcal{R}_2|/\chi$. Abed et al. [1] showed that H is 9-colorable and showed $M_C \leq 81/4$. This shows $\frac{1}{9 \cdot (2M_C)} \geq \frac{2}{729}$-fraction of squares are guillotine separable. For the unweighted case, they claimed an improved bound of $1/81$, by exploiting the structure of the tree representing the binary cutting strategy. However, there are bugs in both the proofs of weighted and unweighted cases.

3 Improved guillotine separability of squares

In this subsection, we prove extraction for unweighted and weighted squares to be $\frac{1}{40}$ and $\frac{1}{160}$, respectively. First we prove the following structural property to showing 5-colorability of conflict graph H. We say that a set of squares cover the edges of a level-l grid cell if the level-l cell has atleast one level-l square inside it and every square in the set intersects atleast one of the edges of the grid cell.

▶ **Lemma 16.** *The edges of any level-l grid cell can be covered by at most 4 squares after the second sampling.*

Proof. Other than squares covering the corners, there can not be any squares on the edges because any square on the edge has to be of level $\leq l-1$ because it intersects a level $l-1$ grid line. But since by first sampling we picked either odd or even parity levels the square on the edge has to be of level $\leq l-2$ which implies that the side of this square exceeds the side length of the level-l grid cell. ◀

▶ **Lemma 17.** *The conflict graph H is 5-colorable.*

Proof. Using similar proof as in [1], we prove this by induction on the number of vertices (squares). The base case (when there is only one square) is obvious. When there are at least two squares, consider the smallest square and the squares adjacent to it in the graph H. By Lemma 16, the vertex corresponding to smallest square has degree at most 4. Now assuming the graph without this vertex is 5-colorable, we can add this vertex and color it with one of the available 5-colors because the degree of this vertex is at most four. So inductively it is proven that the graph H is 5-colorable. ◀

From Lemma 15, the squares representing any independent set of graph H are guillotine separable. The first three (modified) steps of sampling selects every square with probability at least $\varepsilon = 2/81$. Now by sampling the five independent sets from H, uniformly at random, we obtain a set of squares which is ε-guillotine samplable for $\varepsilon = \frac{2}{81} \cdot \frac{1}{5} = 2/405$. From Lemma 14, we obtain extraction factor of $2/405$.

3.1 Further improvement in the unweighted case

We can see that the initial set of squares were sampled thrice after picking a parity of levels and drawing a random grid so that no square of level-l was intersected by a grid line of level less than l and every level-l grid cell has at most one square of level-l inside it. We shall do the third sampling a bit differently. After we draw random grid lines and remove all the squares intersected by grid lines of level lower than that of the square, we now allow up to 6 squares inside a grid cell. Let the set of squares that remained after the first sampling be $\mathcal{R}_1$. If the length of a square $R \in \mathcal{R}$ be $len(R) \in (N/2^{i+1}, N/2^i]$, then the probability that this square stays in $\mathcal{R}_1$ is $(1-\mu_R)^2$ where $\mu_R = len(R) \cdot 2^{i-1}/N$. Let $|C|$ denote the number of squares in cell C. Now for the third sampling let us sample each square from a cell C with a probability $\frac{\min(6,|C|)}{(1-\mu_R)^2 \cdot M_C}$, for $M_C = \sum_{S \in C} \frac{1}{(1-\mu_S)^2}$. Let the set of squares that remained after this third sampling be $\mathcal{R}'_2$. Now the probability that a square remains in $\mathcal{R}'_2$ after the third sampling can be written as: $\mathbb{P}[R \in \mathcal{R}_0] \cdot \mathbb{P}[R \in \mathcal{R}_1 | R \in \mathcal{R}_0] \cdot \mathbb{P}[R \in \mathcal{R}_2 | R \in \mathcal{R}_1]$ $= \frac{1}{2} \cdot (1-\mu_R)^2 \cdot \left(\frac{\min(6,|C|)}{(1-\mu_R)^2 \cdot M_C} \right) = \frac{1}{2} \cdot \frac{\min(6,|C|)}{M_C}$.

▷ Claim 18. $M_C / \min(6, |C|) \leq 4$

Proof. Let us find the maximum possible value of $\sum_{r \in C} \frac{1}{(1-\mu_R)^2 \cdot \min(6,|C|)}$ with $\mu_R \in (1/4, 1/2]$.

As $len(R) > len(C)/4$, we have $|C| \leq 9$. As the sum of the areas of squares in C is less than that of the area of C, we have $\sum_{R \in C} {\mu_R}^2 \leq 1$. For the case when $|C| \leq 6$, we have the sum to be at most $\frac{|C|}{(1-1/2)^2 \cdot \min(6,|C|)} = 4$. For $|C| \geq 7$, we use the fact from [1] that the function above is maximized for a given $|C|$ when all μ_R are equal. Thus a simple calculation gives that the maximum occurs when $|C| = 9$ and the value of the summation is equal to $81/24 < 4$. ◁

Therefore, at the end of this sampling, each square is left with probability at least $1/8$. Now we consider further properties of guillotine cuts to obtain a better guillotine separable set.

▶ **Definition 19** (T-cut). *A T-cut is constituted by two axis-parallel line segments ℓ_A and ℓ_B such that one of the end points of ℓ_B lies on ℓ_A and $\ell_A \perp \ell_B$.*

A set of rectangles is said to be intersected by a T-cut if each rectangle in the set has a non-empty intersection with the T-cut. The following observations will be helpful in proving the existence of good cuts.

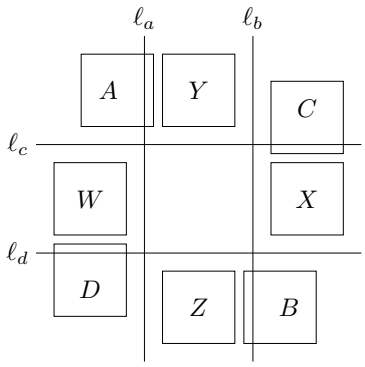
▶ **Observation 20.** *Any set of rectangles intersected by a T-cut is guillotine separable.*

Proof. W.l.o.g. assume in the T-cut ℓ_B is vertical and the bottom endpoint is lying on horizontal line segment ℓ_A. Consider the cut along the bottom edge of the topmost rectangle that is intersected by ℓ_B. If this line is a guillotine cut then we are done, otherwise consider the line aligned with the edge of the rectangle that got intersected first by this line. This has to be a guillotine cut otherwise will contradict our assumption about the top most rectangle. ◀

▶ **Observation 21.** *If there are at most 3 rectangles in a piece, they are guillotine separable.*

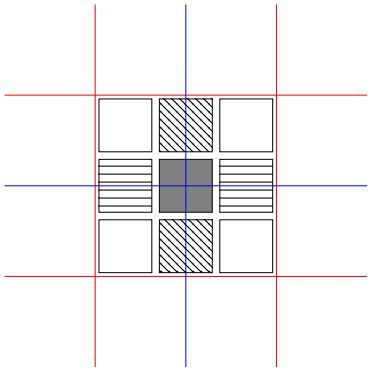
Proof. If there are no axis-parallel line intersecting at least two rectangles, the rectangles are guillotine separable by guillotine cuts along the edges of rectangles. Otherwise, if there exists such a line ℓ, we can extend a perpendicular line segment to ℓ that intersects the third remaining rectangle. This will form a T-cut and the proof follows from Observation 21. ◀

▶ **Observation 22.** *If there are at most n (≤ 6) rectangles in a piece, then we can separate at least $(n-1)$ squares by a sequence of guillotine cuts.*



Proof. W.l.o.g. assume that there is no 0-good cut in the piece.
Case 1: There is a 1-good cut ℓ. Let R be the square intersected by ℓ. If there are at most three rectangles on both sides of this cut then we can extract all rectangles, except the one cut by ℓ, due to Observation 21. The other case is when there is one rectangle on one side and four on the other side. If those four rectangles are guillotine separable then we are done. Otherwise, w.l.o.g. assume ℓ is vertical and these four rectangles are on the right side of ℓ and a single rectangles R' is on the left side of ℓ. Let ℓ_1 be the line aligned with the right edge of R'. Then ℓ_1 should intersect R as there are no 0-good cuts. W.l.o.g. assume R lies above R'. Let ℓ_2 be the line aligned with the bottom edge of R and ℓ_3 be the line aligned with the left most edge of the first rectangle (from the left) that ℓ_2 intersects. We can see that ℓ_3 is again a 1-good cut and cut along ℓ_2 after cutting along ℓ_3 is a 0-good cut. These two cuts seperated the piece into three parts with atmost three rectangles in each sub-piece by cutting atmost one rectangle. By Observation 21 we are done.
Case 2: There is no 1-good cut in the piece. Let ℓ_1 be the line aligned with the left most right edge of the rectangles. This line has at least two rectangles on it as there is no 1-good cut. If we have at least four rectangles intersected by ℓ_1 then we are done because we can form a T-cut with all rectangles except possibly one rectangles and by Observation 20 we can extract all of them. Now consider if we have exactly three rectangles on ℓ_1. Then consider the line ℓ_2 that is aligned with the bottom edge of the top most rectangle on ℓ_1. This line should have at least two rectangles on it by our assumption which will again lead to a T containing five rectangles and we are done. Now suppose ℓ_1 has exactly two rectangles on it and ℓ_2 also has exactly two rectangles on it. Let ℓ_3 be the line aligned with the left edge of the first rectangle intersected by ℓ_2. For ℓ_3 to also intersect two rectangles, one of the rectangles have to be the lower rectangle that ℓ_1 intersects. However this implies that the cut along the top edge of the bottom rectangle on ℓ_1 is a 1-good cut which is a contradiction. ◀

▶ **Observation 23.** *If there are at most* 10 *rectangles, then there exists a* $(4,1)$*-good cut.*



Proof. Consider the median cut that has almost equal number of rectangles on each side and let the line corresponding to the cut be ℓ_1. Suppose if the cut has at least six rectangles on it then any cut separating these rectangles cuts at most four rectangles and hence is a $(4,1)$ good cut. If ℓ_1 cuts at most four then it itself is a $(4,1)$ good cut. The only case is when it has exactly five rectangles on it. Consider every cut separating these five rectangles. If none of these cuts are $(4,1)$-good cuts then every cut has to intersect all other remaining rectangles. This implies that there is one guillotine stage cut separating all the five rectangles on ℓ_1 from the rest. ◀

▶ **Observation 24.** *If there are at most* 12 *squares with level less than* l *in a piece* P *and at least* 7 *squares lie on a grid line of level-*$(l-1)$ *then there exists a* $(6,2)$*-good cut in* P*.*

Proof. W.l.o.g. assume that the level-$(l-1)$ gridline ℓ_h that is intersecting at least 7 squares, is horizontal. Consider the leftmost level-$(l-1)$ vertical line ℓ_v with at least 2 squares on its left. We now prove that ℓ_v is a $(6,2)$-good cut. Note that this vertical line can cut at most 6 squares because there are a total of at most 12 squares. Let ℓ'_v be the vertical line of level-$(l-1)$ that is immediately to the left of ℓ_v. Then ℓ'_v can have at most 1 square to the left of it by definition of line ℓ_v. We know that there can be at most 1 square of level $< l$ in the space between ℓ_v and ℓ'_v. Thus there are at most 3 squares to the left of line ℓ_v. Therefore, we obtain ℓ_v to be a $(6,2)$-good cut. ◀

(a) Different classes of squares after sampling in the unweighted case.

(b) Different third sampling for weighted case (squares with diagonal, horizontal, full, and no shading belong to classes X, Y, Z, W, respectively).

Figure 2

▶ **Lemma 25.** *Using the new sampling scheme, every sampled instance in the piece (and the following subpieces) admits either a* $(4,1)$*-good cut or a* $(6,2)$*-good cut.*

Proof. For contradiction, assume that there are no $(4,1)$ and $(6,2)$-good cuts. Let P' be the considered piece. Now there are two cases:
Case 1: P' *has at least* 13 *squares.* Label the largest 13 squares as $R_1, R_2, \ldots, R_{12}, R_{13}$ in non-increasing order of size. Consider the grid cell C_{13} of square R_{13} (say, of level l). Let the left, right, top and bottom grid lines forming the edges of C_{13} be $\ell_a, \ell_b, \ell_c, \ell_d$, respectively (see Figure 2a). Let us also label the set of squares that are intersected by $\ell_a, \ell_b, \ell_c, \ell_d$ as A, B, C, D, respectively. Also let us label the set of squares lying completely to the left

of line ℓ_a as W, right of line ℓ_b as X, above line ℓ_c as Y, and below line ℓ_d as Z. We observe that at least one of the sets W, X, Y, Z are non empty because there can be at most six squares inside C_{13} after the sampling, and at most four squares are in the set $(A \cup B \cup C \cup D) \setminus (W \cup X \cup Y \cup Z)$ (squares intersecting the edges of the cell). W.l.o.g. let the largest non-empty set be W.
First, we consider the case when $|W| = 1$. As we don't have $(4, 1)$-good cuts, ℓ_a intersects at least 5 squares. So, $|Y \cup Z| \geq 2$. However, $|Y|, |Z| \leq |W|$. Hence, $|Y| = 1$ and $|Z| = 1$. Then both the lines ℓ_c and ℓ_d should intersect 5 squares each. Which implies $|X| \geq 2$ which is a contradiction to our assumption that $|W| = 1$ is the largest among $|W|, |X|, |Y|, |Z|$. Now we consider the case when $|W| \geq 2$. If there is any square on the right of ℓ_a other than R_{13} then consider ℓ_a can not intersect ≤ 6 squares, as then we obtain a $(6, 2)$-good cut. On the other hand if it intersects at least 7 squares, then from Observation 24 we have a $(6, 2)$ good cut which is a contradiction. So let us consider the case when there are no squares on the right of ℓ_a except R_{13}. As there are no $(4, 1)$-good cuts, ℓ_a should intersect at least 5 squares. Since we have at least 5 squares on ℓ_a, $|Y \cup Z| \geq 2$. W.l.o.g let us assume $|Y| \geq 1$. Then it implies again that there have to be at least 5 squares on line ℓ_c and all these squares are on or to the left of line ℓ_a. Using similar arguments as in proof of Observation 24, let ℓ_p be the left most level-$(l-1)$ vertical grid line that has at least two squares on its left. Note that $\ell_p \neq \ell_a$ and thus has at least two squares on its right. Then ℓ_p must intersect ≥ 7 squares as there are no $(6, 2)$-good cuts. However, then by observation 24, we will again have a $(6, 2)$-good cut, giving a contradiction.
Case 2: P' has at most 12 *squares.* Consider any two squares and draw a line ℓ_1 that separates both these squares. The number of squares lying on this line have to be at least 5 by our assumption that there is no $(4, 1)$-good cut. Now draw a line ℓ_2 perpendicular to ℓ_1 which has at least two squares on both its sides out of the 5 squares that were lying on ℓ_1. The line ℓ_2 should have at least 7 squares on it to avoid being the $(6, 2)$-good cut. Now consider the line ℓ_3 perpendicular to ℓ_2 that has at least 2 squares on each side of ℓ_3 out of the 7 squares lying on l_2. Line ℓ_3 also should have at least 7 squares lying on it by the previous argument. Two perpendicular lines each having 7 squares lying on them guarantee a total of at least 13 squares in total. This is a contradiction. ◀

Using these observations and several other properties of guillotine cuts, we show existence of good cuts in the sample instance.

▶ **Theorem 26.** *Given a set of n squares obtained after the sampling, we can find a subset of at least $n/40$ squares that are guillotine separable.*

Proof. Using Lemma 25, we define a guillotine cutting sequence on a piece using only $(4, 1)$ and $(6, 2)$-good cuts until each subpiece has 6 or fewer rectangles. Then if the subpiece has $4, 5$ or 6 rectangles and is not guillotine separable, we use Observation 22 to separate them, cutting at most one rectangle. This whole cutting strategy can be represented by a binary tree with internal nodes storing the number of squares that were killed by the cut. Each leaf node contains guillotine separable squares. Let f_1, f_2 be the number of leaf nodes containing one square and greater than one square, respectively. By the property of binary tree we know that the number of internal nodes is $f_1 + f_2 - 1$. Let v_i be a leaf node and v_j be its parent node. Now if v_i has one square in it and v_j corresponds to a $(4, 1)$-good cut, then v_j has at most 4 squares in it. If v_i was obtained using Observation 22 then its parent node v_j again has only one square in it. Now assume that there is an internal node v_a which has two leaf children v_b, v_c, and both v_b and v_c have exactly one square in each of them. Then as v_a can have at most four squares, the three nodes v_a, v_b, v_c have at most six squares in

total. By our assumption then we would have used the strategy as defined in Observation 22. This gives a contradiction. Thus every internal node can have at most one leaf child which has 1 square in it. This observation tells us that there are at least f_1 internal nodes each of which correspond to at most 4 squares. The maximum number of rectangles killed is at most $4f_1 + 6(f_2 - 1)$ and at least $f_1 + 2f_2$ squares are extracted. So the fraction of squares that are saved is at least $\frac{f_1+2f_2}{5f_1+8f_2-6} \geq 1/5$. This implies an overall extraction factor of $\frac{1}{8} \cdot \frac{1}{5} = \frac{1}{40}$. ◀

3.2 Further improvement in the weighted case

From Claim 18, The probability for a square to survive after the second sampling is at least 1/8. Now we will divide these squares into four groups and select a group uniformly at random. Every level-l grid cell contains at most six squares of level-l due to the property of second sampling. Now, consider a particular cell C, then assume ℓ_v, ℓ_h be the vertical line and the horizontal line, respectively, that bisect the cell (see Figure 2b). Note that ℓ_v (resp. ℓ_h) belongs to the vertical (resp. horizontal) gridlines of level-(l). Now we define four sets. Let W_C be the set of squares in C that does not intersect either of ℓ_v, ℓ_h; X_C be the set of squares in C that intersects only ℓ_v, but not ℓ_h; Y_C be the set of squares in C that intersects only ℓ_h, but not ℓ_v; and Z_C be the set of squares in C that intersects both ℓ_h and ℓ_v. Let W (resp. X, Y, Z) be the set of all squares of type W_C for all cells C in the grid decomposition. We select one of these sets W, X, Y, Z uniformly at random. Let $\mathcal{R}_3$ be the squares that survive. Then each square will survive with probability $\geq \frac{1}{8} \times \frac{1}{4} = \frac{1}{32}$.

Now we will look at the conflict graph H of $\mathcal{R}_3$ and prove that the independent sets of H are actually guillotine separable.

▶ **Lemma 27.** *The independent set of squares obtained from the conflict graph H as defined above, is guillotine separable*

Proof. Let P be a piece obtained from such sampling as defined above. We will show the existence of a guillotine cut that does not cut any of the squares in P. Iteratively, this will show guillotine separability of all rectangles embedded on P. If we only have one square in our piece, then we are done. So let us assume that we have at least two squares. Now consider the two squares with the lowest levels. Let the squares be R_1 and R_2 and the levels to which they belong are l_1 and l_2, respectively. There are two cases:

Case 1: $l_1 = l_2$. Then we have two subcases.

In *subcase (a)*, they belong to *different* grid cells. Then we can separate them by cutting along one of the grid lines coinciding with one of the edges of grid cells containing one of the two considered squares. This line does not cut any of the other squares because the level of this line is lesser than every square in the piece (by definition of R_1 and R_2). Now let us apply this cutting procedure as long as we have a set of squares having the lowest level and are in different grid cells. At the end, we should obtain a piece in which the lowest level squares are either of different levels or they belong to the same level and same cell.

In *subcase (b)*, they belong to the *same* grid cell. As sampling S gives at most one square per grid cell, R_1, R_2 belong to one of the groups among W, X or Y. But we can then separate any two squares from the same group along one of the level-l grid lines. This level-l line does not intersect any of the squares in this piece as we do not have any level-l squares outside this cell. By the first sampling, this line can not intersect any higher level squares.

Case 2: $l_1 \neq l_2$. Then we can cut along the grid line coinciding with the edges of grid cell of the second largest square. This does not cut any of the smaller squares by definition of the first sampling. Also this line does not intersect the largest square by the definition of independent set in conflict graph. ◀

Now we are ready to prove the final theorem of this section.

▶ **Theorem 28.** *Given a set of axis-parallel weighted squares embedded in a plane, there is always a guillotine cutting sequence that recovers* $\frac{1}{160}$*-fraction of weights.*

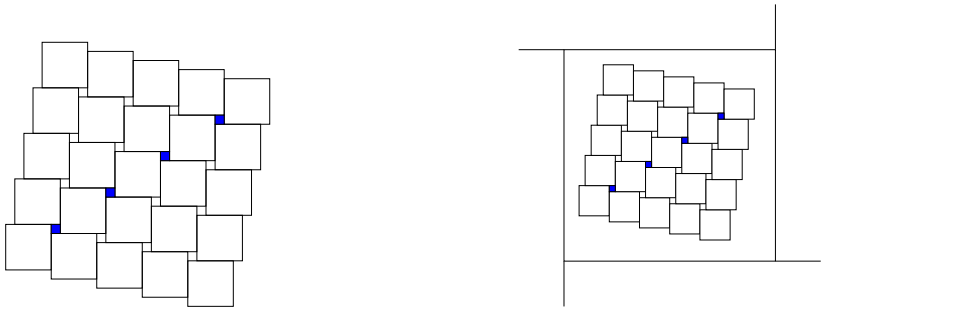
Proof. As the smallest square can have at most four neighbors after the first sampling step, inductively we can show the conflict graph to be 5-colorable. Hence, from Lemma 27 we can conclude that any set of weighted squares is ε-guillotine sampleable for $\varepsilon = 1/32 \times 1/5$. ◀

4 Extraction of rectangles

Using standard techniques from [1], we can assume that all rectangles are embedded in a $2n \times 2n$ rectangular box with all corners of rectangles having integral coordinates in $[2n \cup 0] \times [2n \cup 0]$. When we refer to the width or height of these rectangles we refer to the width or height of those rectangles in this embedding. W.l.o.g. assume that $\log n \in \mathbb{Z}$. Let us define some horizontal lines called *poles* and give an attribute to each rectangle called *level*. A set of *poles at level-i* is defined as equally spaced horizontal lines with y-coordinates $\{\frac{(2k+1)\times n}{2^{i-1}} \mid k \in [(2^{i-1}-1) \cup 0]\}$. A level-0 line has y-coordinate either 0 or $2n$. The *level of a rectangle* is defined as the smallest level i such that some pole at level i intersects the rectangle. The union of all poles from levels 1 to i divides the plane into 2^i equal partitions which we will call as the *grid-partition of level* i. Let $\mathcal{R}_i$ be the set of rectangles present in i'th level for $i \in [\log n \cup 0]$. Further, assume that $\alpha_i = |\mathcal{R}_i|$.

Now we will use poles to show that we can partition all the input rectangles into $\log n + 1$ groups such that the embedding of rectangles in each group is guillotine separable.

▶ **Theorem 29.** *Given a set of rectangles (possibly weighted)* $\mathcal{R}$ *embedded in a square,* $\frac{1}{\log n+1}$ *fraction of total rectangles (resp., weight) can be extracted using 2-stage cuts.*



Proof. Rectangles in $\mathcal{R}_i$ are 2-stage separable, for any $i \in [\log n + 1]$. The first stage consists of cuts along the poles of level $\leq i-1$. These cuts divide the plain into 2^i equal partitions without cutting rectangles in $\mathcal{R}_i$. In each of the partitions, all rectangles are intersected by a pole of level-i and thus no vertical line within a partition can intersect two rectangles. Hence, the second stage can separate all rectangles by vertical cuts. As $\mathcal{R}_i$'s partition $\mathcal{R}$, taking $\mathcal{R}_i$ with the maximum cardinality (resp. weight) gives extraction factor of $\frac{1}{\log n+1}$. ◀

Using a k-ary partition, we can gain even further.

▶ **Lemma 30.** *We can extract* $n/\log_3(n+2)$ *rectangles by a series of guillotine cuts.*

Proof. We prove this by induction on n. The base case is trivial. Consider a T-cut partitioning the plane into three parts with almost equal number of rectangles on each part. Suppose the number of rectangles on the T is greater than $\frac{n}{\log_3(n+2)}$ then we can just extract all of it using Observation 20. Otherwise, by induction on each of the small parts we can extract $\frac{n-\frac{n}{\log_3(n+2)}}{\log_3(n+2-\frac{n}{\log_3(n+2)})-1} \geq \frac{n-\frac{n}{\log_3(n+2)}}{\log_3(n+2)-1} = n/\log_3(n+2)$. ◀

For general rectangles, we will show that we can not obtain much better extraction factor using $O(1)$-stage cuts. However, in Section 5, we use poling arguments to obtain $O(1)$-extraction factor for many special cases of rectangles.

(a) External square skew-grid. **(b)** Level-$(\alpha-1)$ instance in the hole of Level-α instance.

Figure 3 Level-α square skew-grid.

4.1 Hardness for k-stage algorithms in weighted case

In this section, we will prove Theorem 2.

▶ **Definition 31** ([1]). *A $k \times k$ unit square skew-grid is defined as a set of k^2 unit squares arraged in k rows and k columns numbered from bottom to top and left to right, respectively. With the bottom left coordinates of the square belonging to i^{th} row and j^{th} column as $(j + i \cdot \varepsilon, i - j \cdot \varepsilon)$ for $i, j \in [(k-1) \cup 0], \varepsilon \leq \frac{1}{k}$. A square in i^{th} row and j^{th} column is said to have* location *(i,j). The gaps formed by four adjacent squares are called holes. Those holes that are formed by the four squares with location $(i,i), (i+1, i+1), (i+1, i), (i, i+1)$ for $i \in [0 \leq [(k-2) \cup 0]$ are called diagonal holes and they are indexed by i.*

▶ **Observation 32.** *Let $\mathcal{S}$ be a $k \times k$ square skew-grid. Consider a set of $p \in [(k-1) \cup 0]$ vertical lines passing through different diagonal holes of $\mathcal{S}$ partitioning the plane into $p+1$ sub-pieces and in each of these pieces consider some horizontal lines through different diagonal holes (each hole has at most one line passing through it) with total number of horizontal lines $q \in [(k-1) \cup 0]$. This set of $p+q$ lines intersect a total of at least $k \cdot p + q$ squares.*

Proof. We can see that every vertical line through j^{th} diagonal hole intersects all squares with location $(i+1, j)$, $j \leq i$ and $(i, j+1)$, $i \leq j$. So all the p vertical lines intersect a total of $p \cdot k$ squares and none of these squares have location (i, i). Every horizontal line through j^{th} diagonal hole intersects the square with location (j, j), which gives a total of atleast q diagonal squares that get intersected by the horizontal lines. ◀

▶ **Definition 33.** *A level-α $k \times k$ square skew-grid (see Figure 3) is defined as a $k \times k$ square skew-grid with each of the $k-1$ diagonal holes having a level-$(\alpha-1)$ $k \times k$ skew-grid in it scaled appropriately to fit inside it. A level-0 square skew-grid is defined to be empty. We also say that a square belongs to level-i if it is among the largest squares in the level-i $k \times k$ square skew-grid that it is contained in.*

Now we show that for level-α $k \times k$ square skew-grid extraction factor is bounded based on the number of stages used. We assign weights uniformly to squares of same level so that the total weight of each level is 1. This implies the overall weight of this instance is α.

▶ **Theorem 34.** *Let $f_c(\alpha)$ be the best extraction factor for any c-stage extraction algorithm for level-α $k \times k$ square skew-grid instance. Then, $f_c(\alpha) \leq \frac{\alpha}{k} + c - 1$.*

Proof. We prove it by induction on $c+\alpha$. As we can extract at most one square out of k in each column by slicing vertically, we have $f_1(\alpha) \leq \alpha/k$ and $f_c(1) \leq 1$. Thus for $c=1$ and ($c \geq 2$ and $\alpha = 1$), the claim is true. This proves the base case: $c+\alpha = 2$. Let us prove the inductive step from $c+\alpha$ to $c+\alpha+1$. Let us assume that for every c, α with $c+\alpha \leq s$, the bound on $f_c(\alpha)$ is true. Now we will prove this for every $(c, \alpha+1)$ with $c+\alpha = s$.

Consider the best c-stage maximum weight extraction cutting sequence for a level-$(\alpha+1)$ instance. On every diagonal hole of it, a cutting sequence of stage $\leq c$ is induced. So considering an $(\alpha+1)$-stage configuration, suppose that the number of holes on which an i-stage cutting ($i \leq c$)) is induced is h_i. One observation is that the function $f_c(\alpha)$ is monotonic for a fixed α (extraction factor should be non decreasing by increasing stages). Thus using Observation 32,

$$f_c(\alpha+1) \leq \frac{k^2 - k \times h_c - h_{c-1}}{k^2} + \sum_{i=1}^{c} \frac{h_i}{k-1} \times f_i(\alpha) \tag{1}$$

$$\leq \frac{k^2 - k \times h_c - h_{c-1}}{k^2} + \sum_{i=1}^{c} \frac{h_i}{k-1} \times \left(\frac{\alpha}{k} + i - 1\right) \tag{2}$$

$$\leq 1 + h_c \times \left(\frac{\frac{\alpha}{k} + c - 1}{k-1} - \frac{1}{k}\right) + \sum_{i=1}^{c-1} h_i \times \left(\frac{\frac{\alpha}{k} + c - 2}{k-1} - \frac{1}{k^2}\right) \tag{3}$$

$$\leq 1 + h_c \times \left(\frac{\frac{\alpha}{k} + c - 1}{k-1} - \frac{1}{k}\right) + (k - 1 - h_c) \times \left(\frac{\frac{\alpha}{k} + c - 2}{k-1} - \frac{1}{k^2}\right) \tag{4}$$

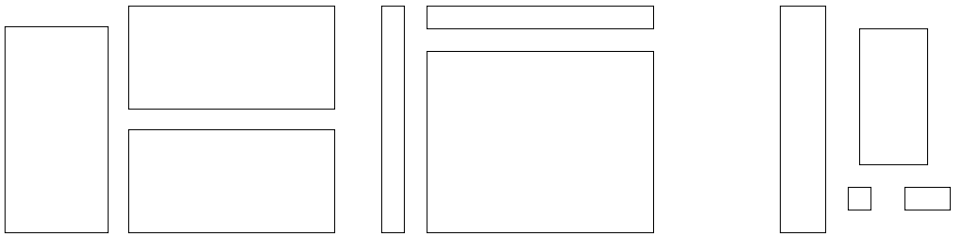
$$\leq 1 + h_c \times \left(\frac{1}{k(k-1)} + \frac{1}{k^2}\right) + \frac{\alpha}{k} + c - 2 - \frac{k-1}{k^2} \tag{5}$$

$$\leq \frac{\alpha+1}{k} + c - 1 \tag{6}$$

The first term in RHS of (1) is the maximum total weight of level-α squares that can be extracted, following from Observation 32. The second summation term in (1) is the total weight extracted through the i^{th} stage cutting sequence induced on the diagonal holes over all $i \in [c]$. In (2) we can substitute $\frac{\alpha}{k} + i - 1$ in place of $f_i(\alpha)$ by inductive assumption. We get (3) from (2) by rearranging terms and replacing i for all $i \in [c-1]$ by $c-1$. Since $\sum_{i=1}^{c} h_i \leq k-1$ and also $\left(\frac{\frac{\alpha}{k}+c-2}{k-1} - \frac{1}{k^2}\right) \geq 0$, we can replace $\sum_{i=1}^{c-1} h_i$ by $k - 1 - h_c$ in (3). ◀

▶ **Observation 35.** *The total number of squares n in a level-α $k \times k$ square skew-grid is $k^2 \cdot \sum_{i=0}^{\alpha-1} (k-1)^i$. It follows that $(k-1)^{\alpha+1} \leq n \leq k^{\alpha+1}$.*

So it follows from the result that the maximum extraction fraction using any c-stage algorithm is $f_c(\alpha)/\alpha \leq 1/k + (c-1)/\alpha$ which can be bounded by $n^{-\frac{1}{\alpha+1}} + \frac{c-1}{\alpha}$, using Observation 35. Taking $\alpha = \frac{\log n}{\log\log n} - 1$, we get the total extraction factor as $\frac{1}{\log n} + \frac{(c-1)\cdot\log\log n}{\log n - \log\log n}$.



This concludes the proof of Theorem 2. Note that this does not disprove Conjecture 1 for $\Omega(n)$ stages as this instance already admits $O(1)$-extraction factor for $\Omega(n)$ stages.

For the unweighted case (Theorem 3), a more involved analysis shows that any guillotine cutting algorithm with a constant number of stages can extract at most $O(\frac{1}{\log\log n})$ fraction of total rectangles. See Section A.1 for the proof of Theorem 3.

We also consider guillotine separability of d-dimensional axis parallel disjoint hyper cubes. The proof of the following theorem is deferred to the full version.

▶ **Theorem 36.** *There exist a family of d-dimensional axis parallel disjoint hyper cubes for which the guillotine extraction factor is asymptotically upper bounded by $\frac{1}{2\cdot(d-1)}$.*

5 Constant extraction-factor for special classes

(a) fat rectangles ($\beta = 2$). **(b)** δ-large rectangles. **(c)** part-simillar instance ($\gamma = 2$).

Figure 4 special cases.

First, let us show a connection between the weighted case of guillotine separability of rectangles and MWISR (see Section B.1 for details).

▶ **Theorem 37.** *If there is a guillotine extraction algorithm which guarantees at least* $1/\alpha$ *fraction of the total weight, then we have a* $O(\alpha)$ *approximation algorithm for the MWISR problem that runs with running time* $O(n^5)$.

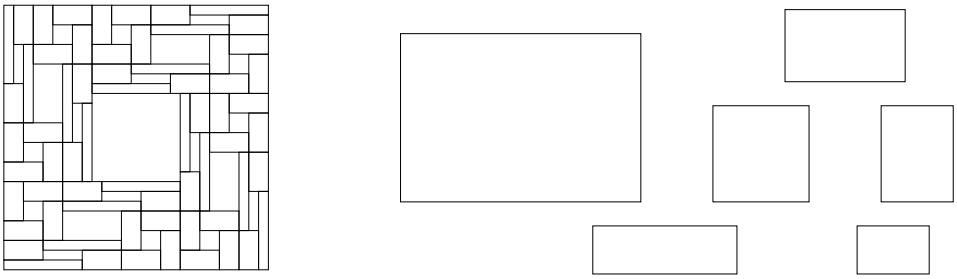
Now we show $\Omega(1)$-extraction factor for special classes of rectangles. Using Theorem 37, we obtain $O(1)$-approximation for MISR (also MWISR, except for the balanced instance) for these classes. For omitted proofs of this section, see Appendix B.

5.1 Fat rectangles

A rectangle i is fat if $\max_i(\frac{w_i}{h_i}, \frac{h_i}{w_i}) \leq \beta$, where β is a constant (see Figure 4a). We divide the rectangles into two sets: (i) $w \geq h$ and (ii) $w \leq h$, and pick the one with maximum weight. W.l.o.g assume this to be the former set. We generalize the grid sampling techniques for squares and randomly pick a size class modulo $(\log \beta + 2)$ among widths and modulo 2 among heights. Then we exploit properties of this sampling to extract a constant fraction.

▶ **Lemma 38.** *If a piece has* n *rectangles with* $\max_i(\frac{w_i}{h_i}, \frac{h_i}{w_i}) \leq \beta, \beta \geq 1$, *then there is a guillotine cutting strategy with extraction factor* $\frac{1}{1584 \cdot (\log \beta + 2)}$.

5.2 δ-large rectangles



A rectangle i is δ-large if either $w_i \geq \delta N$ or $h_i \geq \delta N$, where $0 < \delta < 1$ (see Figure 4b). By using the poles that we have defined in Section 4, we obtain $O(1)$ extraction factor.

▶ **Lemma 39.** *Given an embedding of a set of* δ*-large rectangles in an* $N \times N$ *square, we can extract* $1/(\log(1/\delta) + 1)$ *fraction of rectangles (resp. weights) using 2-stage cuts.*

5.3 Part-similar instance

An instance is *part-similar* if $\min(\frac{\max_i h_i}{\min_i h_i}, \frac{\max_i w_i}{\min_i w_i}) = \gamma$, where γ is a constant, i.e., rectangles have either similar width or similar height (see Figure 4c). Using random position for poles, we find an interesting relation between the level of pole a rectangle belongs to and the size class of rectangle along the dimension perpendicular to the pole. This bounds the range of poles that any rectangle can belong to and we extract from one of the levels in that range.

▶ **Lemma 40.** *Given a set of rectangles with* $\min(\frac{\max_i h_i}{\min_i h_i}, \frac{\max_i w_i}{\min_i w_i}) = \gamma$, *there exists a 2-stage guillotine cutting sequence with extraction factor* $\frac{1}{2 \times (\lfloor \log \gamma \rfloor + 3)}$.

(a) balanced instance (every sub piece has a balanced $\sqrt{k}$ cut).

(b) anti-laminar instance (no rectangles is x-contained in another).

Figure 5 special cases.

5.4 Balanced instance

Balanced instances are instances where in any sub-piece with k rectangles, there exists a cut that cuts $c(k)$ rectangles ($c(k)$ should be either $\Omega(k)$ or $O(k^{1-\varepsilon})$, where $0 < \varepsilon < 1$), dividing the remaining rectangles in a balanced way such that the ratio of number of rectangles on both sides is at most a constant $r \geq 1$. We show a constant factor $O(1)$-extraction factor for these instances. This instance includes many probable candidates for worst-case examples, including the skew-grid (see Figure 5a).

▶ **Lemma 41.** *For a fixed $\alpha = 1 + \frac{1}{r}, r \geq 1, 0 \leq \varepsilon < 1, 0 < f$, if a configuration has the property that for every large sub-piece of k rectangles, there is a cut that cuts either at least $k \cdot f_1$ rectangles or at most $k^{1-\varepsilon} \cdot f$ rectangles and also divide rectangles into two sets such that the ratio of number of rectangles on the two sides is at most r, then we can extract $n \cdot f_1$ fraction of rectangles for $f_1 = e^{-\frac{f \cdot \alpha^{-\varepsilon}}{(1-f \cdot \alpha^{-\varepsilon})(1-\alpha^{-\varepsilon})}}, f \leq \alpha^{\varepsilon}$.*

5.5 Anti-laminar instance

A rectangle i is said to be x-contained (resp. y-contained) in another rectangle j if $x_j < x_i < x_i + w_i < x_j + w_j$ (resp. $y_j < y_i < y_i + h_i < y_j + h_j$). A set of rectangles is said to be x-containment free (resp. y-containment free) if no rectangle is x-contained (resp. y-contained) in other. A set of rectangles is *anti-laminar* if it is either x-containment free or y-containment free (see Figure 5b).

▶ **Lemma 42.** *For an anti-laminar instance, we always have an extraction factor $1/2$.*

6 Conclusion

We have made progress towards understanding guillotine separability of rectangles. We showed that Pach-Tardos conjecture is not true, even for squares, if we use $o(\log \log n)$-stages. However, if we allow $\Omega(n)$ stages, even with general rectangles we were unable to find any instance where we can not recover more than $n/2$ rectangles. The balanced instance (see Figure 5a) or its variants are probable candidates for such hard instances. However, we showed that we can still separate a constant fraction of rectangles from these instances. It is interesting to obtain guillotine separability of even $(\log \log n / \log n)$-fraction of rectangles. This will give an $O(n^5)$-time algorithms for MWISR, matching the present best approximation guarantee. Apart from the existential questions, an interesting problem is to find a polynomial-time $O(1)$-approximation algorithm to recover rectangles through a sequence of guillotine cuts.

A Omitted proofs from Section 4

A.1 Hardness for small stage algorithms in unweighted case

Here we prove Theorem 3.

▶ **Lemma 43** (Restatement of lemma 18 from [1]). *The number of squares of a $n \times n$ square skew-grid that can be seperated by a guillotine cutting strategy is at most $\lceil \frac{n^2+2n-2}{2} \rceil \leq \frac{n^2}{2} + n$*

In this subsection we show another example which is constructed almost similarly as in the weighted case such that the extraction factor is bounded based on the number of stages used. In the construction so that the number of squares in all levels is almost same.

▶ **Definition 44.** *For $k \geq 2$, A k-modified level-α square skew-grid is defined as a $\left(2^{2^{\alpha+k-1}}+1\right) \times \left(2^{2^{\alpha+k-1}}+1\right)$ square skew-grid with each of the $2^{2^{\alpha+k-1}}$ diagonal holes having a k-modified level-$(\alpha-1)$ square skew-grid in it scaled appropriately to fit inside it. A k-modified level-0 square skew-grid is defined to be empty. We also say that a square belongs to level-i if it is among the largest squares in the k-modified level-i square skew-grid that it is contained in.*

▶ **Lemma 45.** *Let $E_c(\alpha)$ be the maximum total number of squares that can be extracted using a c-stage cutting sequence on a level α configuration. Let $f_c(\alpha) = E_c(\alpha) \cdot 2^{-2^{k+\alpha}}$. Then $f_c(\alpha) \leq c - 1 + \sum_{i=1}^{\alpha}(2^{-2^{\alpha+k-i}} + 2^{-2^{\alpha+k+1-i}})$.*

Proof. We prove it by induction on $c+\alpha$. Let us prove some boundary cases first and use inductive step to cover all the cases. For the case when $c = 1$, it is clear that

$$E_1(\alpha) = (2^{2^{\alpha+k-1}}+1) + 2^{2^{\alpha+k-1}} \times (2^{2^{\alpha+k-2}}+1) + 2^{2^{\alpha+k-1}} \times 2^{2^{\alpha+k-2}} \times (2^{2^{\alpha+k-3}}+1) \ldots (7)$$

which gives $f_1(\alpha) = \sum_{i=1}^{\alpha}(2^{-2^{\alpha+k-i}} + 2^{-2^{\alpha+k+1-i}})$ which satisfies the bound we assumed. Now for the case when $c \geq 2$,$\alpha = 1$ we have

$$f_c(1) = E_c(1) \times 2^{-2^{1+k}} \leq 2^{-2^{1+k}} \times \left(\frac{(2^{2^k}+1)^2}{2} + 2^{2^k} + 1\right) \leq 1 \quad (8)$$

By using the upper bound given in Lemma 43 and the fact that $k \geq 2$, we get the above bound which also satisfies the bound for $f_c(\alpha)$ we assumed. We have proved the base case when $c + \alpha = 2$. Let us assume for every c, α with $c + \alpha \leq s$ the bound on $f_c(\alpha)$ is true. Let us prove that for every $(c, \alpha+1)$ with $c + \alpha = s$ the bound on $f_c(\alpha+1)$ is true (h_i is defined similarly as in the weighted case).

$$E_c(\alpha+1) \leq \left((2^{2^{\alpha+k}}+1)^2 - h_c \times (2^{2^{\alpha+k}}+1) - h_{c-1}\right) + \sum_{i=1}^{c} h_i \times E_i(\alpha) \quad (9)$$

$$\Rightarrow f_c(\alpha+1) \leq c - 1 + \sum_{i=1}^{\alpha+1}(2^{-2^{\alpha+k-i}} + 2^{-2^{\alpha+k+1-i}}) \quad (10)$$

The inequality (9) is obtained similarly as in the weighted case. We obtain (10) by using the inductive assumptions and some simple algebraic manipulations. ◀

Now we also have that the total number of squares $n = 2^{2^{\alpha+k}} \times \sum_{i=1}^{\alpha}(1+2^{-2^{k+i-1}})^2$. This gives the extraction fraction $E_c(\alpha)/n = f_c(\alpha)/\sum_{i=1}^{\alpha}(1+2^{-2^{k+i-1}})^2 \leq c-1+\sum_{i=1}^{\alpha}(2^{-2^{\alpha+k-i}}+2^{-2^{\alpha+k+1-i}})/\sum_{i=1}^{\alpha}(1+2^{-2^{k+i-1}})^2 \leq c/\alpha$ (because the numerator is $< c$ and denominator $> \alpha$). Now in order to get a good upper bound we need to minimize c/α for fixed n, c which means we need to maximize α for fixed n. which happens when $k = 2$. So $n \approx \alpha \cdot 2^{2^{\alpha}}$. Thus α is in the order of $\log\log n$ and the upper bound c/α in the order of $c/\log\log n$. Which says we need at least order $\log\log n$ number of stages for any algorithm to guarantee a constant extraction factor even for squares case. Strangely the results we got say that using constant stages we cannot guarantee better than $\frac{\log n}{\log\log n}$ and $\log\log n$ factors for the weighted and unweighted cases, respectively, which matches the best-known approximation ratios for MISR.

B Omitted proofs from Section 5

B.1 Connection between MWISR and weighted guillotine problem

In this subsection we prove Theorem 37. Note that Abed et al. [1] already showed a similar connection between MISR and the unweighted guillotine problem. We build on their approach to build a dynamic program to handle the weighted case.

We are given a set of n axis-parallel rectangles. We can assume that the corners of rectangles have integer coordinates in the range $\{0, \ldots, 2n\}$ and w.l.o.g no two rectangles are exactly coinciding (if such a case exists just consider the rectangle with the largest weight). Consider a piece P out of $O(n^4)$ such pieces possible in integer plane $[0, 2n] \times [0, 2n]$.
If P has no rectangle completely lying inside, we take the solution to be an empty set.
If $P = R$ (plane exactly coincides rectangle R), we take the maximum of the below two cases:
Case 1: Consider solution for P to be only R and discard all other rectangles inside R.
Case 2: Discard R and consider all rectangles inside R. Try all possibilities of dividing P into two smaller pieces using a horizontal or vertical guillotine cut such that the horizontal/vertical coordinates of this cut is an integer. Consider one such cut and let $P_1 \neq \emptyset \neq P_2$ denote the resulting pieces. The DP looks up the solutions for the cells representing P_1 and P_2 and combines them to a solution for P. It selects the cut yielding the optimal total profit from the resulting two subproblems. Let us define two tables $DPG[i][j][k][l]$ and $RECT[k_1][l_1][k_2][l_2]$. Where $DPG[i][j][k][l]$ stores the maximum weight guillotine separable independent set of rectangles in the piece having bottom left coordinates(k, l) and top right coordinates $(k+i, l+j)$ and $RECT[k_1][l_1][k_2][l_2]$ stores the weight of the rectangle in the input having bottom left and top right coordinates (k_1, l_1) and (k_2, l_2) respectively if such a rectangle is present else it stores zero otherwise.

$$DPG[i][j][k][l] = \max\Big(\max_{1\leq s\leq j-1}(DPG[i][s][k][l] + DPG[i][j-s][k+s][l]),$$
$$\max_{1\leq s\leq i-1}\big(DPG[s][j][k][l] + DPG[i-s][j][k+s][l]\big), RECT[k][l][k+i][l+j]\Big).$$

With constraints $1 \leq i \leq 2n$, $1 \leq j \leq 2n$, $0 \leq k \leq 2n-i$, $0 \leq l \leq 2n-j$.
This DP gives an $O(n^5)$ time algorithm and returns the maximum weight guillotine separable independent set of rectangles.

B.2 Fat rectangles

We give proof of Lemma 38. Let us consider objects that have bounded $\frac{w}{h} \leq \beta$, $\frac{h}{w} \leq \beta$, $\beta \geq 1$ for any rectangle in $\mathcal{R}$. Previously, a square of side length $\ell \in (\frac{N}{2^{i+1}}, \frac{N}{2^i}]$ is said to belong to level i. Now similarly, for a rectangle with width w and height h, we say that its width

w belongs to level i if $w \in (\frac{N}{2^{i+1}}, \frac{N}{2^i}]$ and height h belongs to level j if $h \in (\frac{N}{2^{j+1}}, \frac{N}{2^j}]$. Let us only consider that class of rectangles for which $h \geq w$ and we can assume w.l.o.g. that they are at least half in weight (resp. number). Now it follows that for every rectangle $j \leq i$, since $\beta \geq \frac{h}{w} > \frac{\frac{N}{2^{j+1}}}{\frac{N}{2^i}} = 2^{i-j-1}$, we have $j \leq i < j + 1 + \log\beta$. Now consider all the width classes and select all the classes that are congruent to some random $r \in [0, \log\beta + 1]$ modulo $(2 + \log\beta)$. Also randomly select either even or odd classes from the height class. The expected number(or weight) of rectangles that remain until now are $\frac{1}{4\cdot(2+\log\beta)}$. To this set of rectangles let us apply the sampling procedures that we applied for squares. In the first sampling, we remove all those rectangles that are intersected by vertical lines of level less than that of its width or horizontal lines of level less than that of its height. Which guarantees an expected number of $\frac{1}{4}$ number of rectangles that remained after our first two sampling procedures. In the next sampling procedure, we define a cell for a rectangle of level (i, j) (let us say for now informally that the level of a rectangle is (width class, height class) as the rectangle formed by the two pair of vertical and horizontal level $i-1$ and level $j-1$ lines that contain this rectangle. We want every cell of a rectangle to have at most one rectangle with level (i, j). It is an important observation that any rectangle with $i' < i$ or $j' < j$ cannot stay inside a level (i, j) cell, because $i' < i$ implies $i' \leq i - (2 + \log\beta) \leq i - 2$, which implies the width of this rectangle exceeds that of the cell. And $j' < j$ implies that $j' \leq j - 2$, which exceeds the height of the cell. A bug arises in the second sampling mentioned in [1] because a cell of level-i can have a level $i-1$ square inside it which causes problems in all the results that follow. Since there can be at most 9 rectangles of level (i, j) inside a level (i, j) cell. We select a square randomly. The total expected weight (resp. number) of squares that remain after the previous sampling is $\frac{1}{9}$. After these samplings we have an important property that we can use.

▶ **Observation 46.** *If a rectangle of level-(i', j') intersects one of the grid lines of a level (i, j) rectangle then $i' + j' < i + j$.*

Proof. Suppose the rectangle intersects the horizontal level $j-1$ line then we have $j' \leq j - 1 \leq i - 1$ and $i' < j' + \log\beta + 1 \leq i + \log\beta$, which implies $i' \leq i$, which then implies $i' + j' < i + j$. Suppose the rectangles intersects the vertical $i-1$ level lines then we have $i' \leq i - 1$, which implies $i' \leq i - 2 - \log\beta < j - 1$ and $j' \leq i' \leq i - 2 - \log\beta < j - 1$, which then implies $i' + j' < i + j$. We can also see that the total number of rectangles that can intersect the boundary of this cell can be at most 10 (4 in corners, 0 on vertical edges because $j' < j - 1$, 3 each on horizontal edges). ◀

We can define the conflict graph H same as defined for squares and it is easy to see that H is 11 colorable. And also if we think $i + j$ as the level of a rectangle now it also follows similarly that independent set of H is guillotine separable. So combining all of this gives a $\frac{1}{1584\cdot(\log\beta+2)}$ extraction algorithm. Even when we have bounded $\frac{w_{max}}{w_{min}}$ or $\frac{h_{max}}{h_{min}}$ we can extract $O(\frac{1}{\log\beta})$ where β is the bound using the same grid sampling techniques. However, we will solve that problem with a different technique in the later subsection.

B.3 δ-large rectangles

Now we prove Lemma 39.

Proof. All rectangles will be intersected by some poles of level $\leq \lceil\log(1/\delta)\rceil$. Similar to proof of Theorem 29, we can select the level with the maximum number of rectangles (resp. weights) to extract $n/(\log(1/\delta) + 1)$ rectangles (resp. weights) using 2-stages of cuts. ◀

B.4 Part-similar instance

Here we prove Lemma 40.

Proof. Let us define the size classes for a rectangles based on their height. A rectangle belongs to size class i if its height is in the range $(\frac{2n}{2^{i+1}}, \frac{2n}{2^i}]$ for $i \in [\log 2n \cup 0]$.

Now let us choose a random $y \in [2n \cup 0]$ uniformly and shift all the horizontal poles by y wrapping up appropriately. Let us delete all those rectangles that are intersected by a pole of level less than its size class. The probability that a rectangle stays after this sampling is at least $1/2$. Which implies that there exists a y such that more than half of the rectangles are not intersected by a line with level lesser than their size classes. Now if an object has height $> \frac{N}{2^{i+1}}$ then it has to belong to level $\leq i+1$. This implies that after the random sampling, every rectangle from size class i belongs to level i or $i+1$. Suppose we have a set of rectangles with $\frac{h_{max}}{h_{min}} = \gamma$. Let all the rectangles after the sampling be distributed over levels $[\alpha, \alpha + c - 1]$. The minimum size difference between any two rectangles in levels α and $\alpha + c - 1$ is $> 2^{c-3}$. So $\gamma > 2^{c-3}$ gives $c \leq \lfloor \log \gamma \rfloor + 3$. This guarantees a level with at least $\frac{n}{2\times(\lfloor \log \gamma \rfloor + 3)}$ rectangles. ◀

B.5 Balanced instance

▶ **Lemma 47.** *For an instance of n rectangles, if in any sub-piece with k rectangles we have a cut that cuts at most $c(k)$ rectangles dividing the remaining rectangles in a balanced way such that the number of rectangles on both sides has ratio at most $r \geq 1$, then we have an extraction factor $f(n) \geq n \cdot e^{-\frac{\alpha}{\alpha - c(\alpha)} \cdot \sum_{i=1}^{\log_\alpha n} \frac{c(\alpha^i)}{\alpha^i}}$, where $\alpha = 1 + \frac{1}{r}$ (note that in this result $c(k)$ can be any function).*

Let us start with a simpler case where any sub-configuration obtained after few cuts has a $O(\sqrt{p})$ cut that divides the number of rectangles on each side almost equally, where p is the number of rectangles in that sub-configuration. Let $f(n) = n/g(n)$ be the number of rectangles that can be extracted by simply cutting using the available $O(\sqrt{n})$ cut. We have $f(n) \geq 2 \cdot f((n - \sqrt{n})/2)$. This implies $g(n) \leq (\frac{n}{n-\sqrt{n}}) \cdot g(\frac{n-\sqrt{n}}{2}) \leq (\frac{n}{n-\sqrt{n}}) \cdot g(\frac{n}{2})$ (since $g(n)$ is a non decreasing function). We have base cases $g(p) = 1, p \leq 3$. Using the above inequality recursively, we obtain the upper bound for $g(2^k)$ as $\prod_{i=1}^{k} (1 - 2^{-i/2})^{-1} = e^{-\sum_{i=1}^{k} \log(1-2^{-i/2})}$. Using $1 - 1/x \leq \log(x)$ for $x \geq 0$, we obtain $g(2^k) \leq e^{\sum_{i=1}^{k} \frac{2^{-i/2}}{1-2^{-i/2}}} \leq e^{\sum_{i=1}^{k} \frac{2^{-i/2}}{1-2^{-1/2}}} \leq e^{3\sqrt{2}+4}$. So $f(n) \geq n/e^{3\sqrt{2}+4}$.

Now we state the proof of Lemma 47, a more general case.

Proof. In balanced instance, in any sub-configuration with k rectangles we always have a cut which cuts at most $c(k)$ and divides the remaining rectangles in a balanced way such the number of rectangles on both sides are in some $r : 1$ ratio with $r \geq 1$. Then we have $f(n) \geq f(\frac{r}{r+1} \cdot (n - c(n))) + f(\frac{1}{r+1} \cdot (c - c(n)))$. This after replacing $f(n)$ with $n/g(n)$ gives $\frac{n}{g(n)} \geq \frac{(\frac{r}{r+1}) \cdot (n - c(n))}{g(\frac{r}{r+1} \cdot (n - c(n)))} + \frac{\frac{1}{r+1} \cdot (n - c(n))}{g(\frac{1}{r+1} \cdot (n - c(n)))}$. Now using the fact that the function $g(n)$ is non decreasing, we obtain $g(n) \leq (1 - \frac{c(n)}{n})^{-1} \cdot g(\frac{n}{1+\frac{1}{r}})$. Taking $\alpha = 1 + 1/r$ and applying the inequality recursively, we get that $g(n) \leq e^{-\frac{\alpha}{\alpha - c(\alpha)} \cdot \sum_{i=1}^{\log_\alpha n} \frac{c(\alpha^i)}{\alpha^i}}$. Whenever $c(n) = O(n^{1-\varepsilon})$ and $\alpha = 1 + \frac{1}{r}$ is constant, the value of $g(n)$ is bounded by a constant. For $c(n) = n^{1-\varepsilon}$ we get $f(n) \geq n \cdot e^{-\frac{\alpha^\varepsilon}{(\alpha^\varepsilon - 1)^2}}$. This implies we can always extract a constant fraction of the number of rectangles. ◀

The proof of Lemma 41 follows from the proof of Lemma 47. Using Lemma 47, we can extract a constant fraction of items if $c(k)$ is either $\Omega(k)$ or $O(k^{1-\varepsilon})$. The idea is that if $c(k)$ is $\Omega(k)$ then we can extract all the rectangles that are cut and this is already a constant fraction. If $c(k)$ is $O(k^{1-\varepsilon})$ then we can cut and recurse into the subpieces.

B.6 Anti-laminar instance

Intuitively, a set of rectangles is *anti-laminar*, if along one of the axes, the intervals formed by projecting the rectangles on that axis have the property that no interval is completely inside another. First we show the proof of Lemma 48.

▶ **Lemma 48.** *Let I be a set of n intervals on the x-axis such that no two intervals are completely contained inside each other. Let $\{p_1, \cdots, p_{2n}\}$ be the endpoints of intervals in I. Then we can distribute weight n to the intervals (p_i, p_{i+1}) for $i \in [2n-1]$ such that each interval in I gets weight 1.*

Proof. Let us prove this by induction on the number of intervals. This is obviously true when there is only one interval. Let us sort the intervals by increasing value of the left end point and label them $1, \ldots, k+1$. Suppose the claim is true until $n = k$. Then for $n = k+1$ we can assume that the first interval intersects the second interval w.l.o.g (otherwise we can assign weights for intervals other than the first interval and assign unit weight to the first interval which completes the inductive step) and consider the left end point of second interval. Consider the k intervals to the right of this point and assign weights so that all this k intervals have the same weights. Now since the second interval is not contained in the first interval, the right end point of the second interval is to the right of the right end point of the first interval. We can just assign the weight contained in the region from the right end point of first interval to the right end point of the second interval in the region from the left end point of the first interval to the left endpoint of the second interval. Which makes the weight of first interval equal to that of the second and hence this gives equal weight to all the intervals. We can also observe that this is impossible when an interval is contained in another interval. ◀

▶ **Lemma 49** (Restatement of Lemma 13 in [1])**.** *For a set of rectangles with equal width (or height) there exists a guillotine cutting strategy that separates at least $1/2$ of the weight.*

Now we are ready to prove of Lemma 42.

Proof. Without loss of generality let us suppose that the projection of rectangles on x-axis satisfies the no containment property. By Lemma 48, we can assign weights to intervals on x-axis such that the total weight inside each interval is same. Now if we scale each strip associated with the intervals with a scaling factor equal to its weight then we get another set of rectangles where each rectangle has the same width. Now by lemma 49 we can separate $1/2$ the total weight of the given set of rectangles. ◀

Maximizing Throughput in Flow Shop Real-Time Scheduling

Abstract

We consider scheduling real-time jobs in the classic flow shop model. The input is a set of n jobs, each consisting of m segments to be processed on m machines in the specified order, such that segment I_i of a job can start processing on machine M_i only after segment I_{i-1} of the same job completed processing on machine M_{i-1}, for $2 \leq i \leq m$. Each job also has a release time, a due date, and a weight. The objective is to maximize the throughput (or, profit) of the n jobs, i.e., to find a subset of the jobs that have the maximum total weight and can complete processing on the m machines within their time windows. This problem has numerous real-life applications ranging from manufacturing to cloud and embedded computing platforms, already in the special case where $m = 2$. Previous work in the flow shop model has focused on makespan, flow time, or tardiness objectives. However, little is known for the flow shop model in the real-time setting. In this work, we give the first nontrivial results for this problem and present a pseudo-polynomial time $(2m + 1)$-approximation algorithm for the problem on $m \geq 2$ machines, where m is a constant. This ratio is essentially tight due to a hardness result of $\Omega(\frac{m}{\log m})$ for the approximation ratio. We further give a polynomial-time algorithm for the two-machine case, with an approximation ratio of $(9 + \varepsilon)$ where $\varepsilon = O(1/n)$. We obtain better bounds for some restricted subclasses of inputs with two machines. To the best of our knowledge, this fundamental problem of throughput maximization in the flow shop scheduling model is studied here for the first time.

1 Introduction

Flow shop is a fundamental scheduling model where a set of jobs needs to be processed in multiple stages in a specified order that is the same for all jobs. There are many real-world applications of flow shop scheduling, ranging from production planning and computing platforms to satellite systems and service centers. For instance, an autonomous car runs applications, such as obstacle detection and route planning, applying deep neural networks on an embedded computing platform, which are composed of a CPU host and a GPU accelerator connected via a non-preemptive bidirectional bus. Each execution instance (i.e., job) of the applications is first initiated in the CPU to preprocess the input data, then transfers the data from CPU to GPU via the bus, executes the computation on the GPU, and finally transfers the results back via the bidirectional bus. There are multiple such jobs running in real-time with different release times and deadlines, e.g., multiple images to be processed by the object detection application in a time window. Hence, the computing platform needs to schedule the execution on the CPU and GPU, as well as the data transfers on the bus, to meet preset deadlines, e.g., to maximize the number of images processed in a time window.

The flow shop model has been widely studied for minimizing the latest completion time of any job (or, *makespan*) since the 1950s, starting with the seminal work of Johnson [16], which showed that makespan minimization in two-machine flow shop can be solved in polynomial time. However, most extensions of the problem are strongly NP-hard [7]. For example, makespan minimization for flow shop with three machines is already NP-complete, even if the input length is measured by the sum of the job lengths [12]. Hence, later works studied approximation algorithms for the problem (see, e.g., [13, 18, 20, 22, 24]).

In this paper, we are interested in flow shop scheduling for jobs with different release times, due dates, and weights, and the scheduling objective is to maximize the throughput – the total weight of the jobs that are completed by their due dates. Surprisingly, in contrast to the extensive results on minimizing the makespan, flow time, and tardiness in the flow shop model, there is little work on maximizing the throughput of jobs with due dates. On the other hand, the problem of maximizing the throughput of jobs with release times, due dates, and weights, also known in the literature as (aperiodic) *real-time scheduling*, has been widely studied. In this classic model, each job can be processed to completion on a *single* machine or any of the *parallel* machines (see, e.g., [1–4, 9, 15, 17, 19, 25]).

We now formalize our problem. In the m-machine flow shop model, there is a set of n jobs, $\mathcal{J} = \{J_1, \ldots, J_n\}$, and m machines, $M_1, \ldots, M_m$. Each job J_j, $1 \leq j \leq n$, has a release time, a due date, and a weight, given by $r_j \geq 0$, $d_j \geq 0$, and $w_j > 0$, respectively. A job can only start executing on machine M_i, $2 \leq i \leq m$, after it has finished its execution on the previous machine M_{i-1}. In addition, at any time $t \geq 0$, each of the machines can process at most one job. For a job J_j, we denote the processing time of its i-th segment to be executed on machine M_i by $p_{j,i}$. We assume that $p_{j,i}, r_j$ and d_j are rational numbers. We further assume that all job segments are non-preemptive. In other words, once a job J_j has started its execution on a machine, this machine cannot stop or switch to another job until J_j has finished its execution on this machine. We seek a subset of jobs $\mathcal{J}' \subseteq \mathcal{J}$ that can be *feasibly* scheduled (i.e., each job J_j can complete processing on all machines in a flow shop manner in its time window $(r_j, d_j]$) and has a maximum total weight. We denote this *maximum throughput* objective by MaxT. We obtain results for MaxT in the m-machine flow shop model, with a focus on the special case of two-machine flow shop.

1.1 Applications

In the following, we motivate MaxT in the flow shop model with some real-life applications.

Scheduling in Cloud Data Centers. A *cloud-data-center (CDC)* consists of a set of server clusters connected with clients through a network. Since all the resources are stored on the servers, clients generate resource requests from the CDC. A data request consists of two steps: task *execution*, in which data is obtained from a disk or distributed storage systems and stored in memory, and then *transmission* from memory to the client over the network (see, e.g., [26]). When data requests have release times and due dates, a natural goal is to maximize the total number of requests that can be processed by the CDC in a given time interval. This yields an instance of MaxT in the flow shop model.

Earth Observation Satellites. An earth observation satellite (EOS) is equipped with high-resolution cameras for observing target objects across the surface of Earth. There are available time windows for multiple EOSs to observe a given object and to download the acquired image/video data to ground receiver stations. The problem of observation scheduling (at stage 1) and data downlink scheduling (at stage 2) with the objective of maximizing the number of satellites that can complete processing in their time windows yields an instance of MaxT in the two-machine flow shop model (see, e.g., [26]).

Autonomous Vehicle Navigation. An object detection application running in autonomous cars takes images from a front-facing camera as input and produces car steering angles as output (see, e.g., [6]). Since the algorithm uses deep neural networks (DNN), each image is handled in stages (preprocessing data in CPU, data transfers between CPU and GPU, and DNN computation in GPU), the process of handling the images in real-time so as to maximize the number of images processed in a given time window can be viewed as a MaxT instance in the flow shop model.

1.2 Contributions and Techniques

We say that $\mathcal{A}$ is a ρ-approximation algorithm for a maximization problem Π, for $\rho \geq 1$, if for any instance I of Π, $\mathcal{A}(I) \geq \frac{OPT(I)}{\rho}$, where $OPT(I)$ is the value of an optimal solution for I.

In this paper, we study the fundamental problem of throughput maximization in the flow shop scheduling model. Our main result is a polynomial-time $(9+\varepsilon)$-approximation algorithm for MaxT in the two-machine flow shop, where $\varepsilon = O(1/n)$ for an input of size n (i.e., $n = |\mathcal{J}|$). We derive the algorithm by first obtaining a pseudo-polynomial time $(2m+1)$-approximation algorithm for MaxT on m machines, where $m \geq 2$ is a constant. We note that the ratio of $(2m+1)$ is essentially tight for any $m \geq 3$, due to a known hardness of approximation result for a ratio $\Omega(\frac{m}{\log m})$ [14].

We show that MaxT admits better approximations on some restricted instances of the two-machine model. In particular, we present a 4-approximation algorithm for instances where all jobs have the same release time, i.e., $r_j = 0$ for all $J_j \in \mathcal{J}$, and uniform weights. For the special case where all jobs have the same time window and arbitrary weights, we give a $(3+\varepsilon)$-approximation algorithm, for any fixed $\varepsilon > 0$.

Techniques. In Section 2, we give an approximation algorithm for instances of MaxT on m machines, where m is some constant. As our algorithm requires solving a Configuration Linear Program (LP), this implies a pseudo-polynomial running time. Showing that this

algorithm can be implemented in polynomial time, with only a slight degradation in the approximation ratio, is a major challenge even in the two machine case. We use the following key observation. Any instance $\mathcal{J}$ can be modified to an instance $\mathcal{J}_{new}$ (by replacing some jobs with *new* jobs) in which for every job $J_j \in \mathcal{J}_{new}$ either *both* $p_{j,1}$ and $p_{j,2}$ are *large* relative to $d_j - r_j$, or *both* $p_{j,1}$ and $p_{j,2}$ are *small* relative to $d_j - r_j$. Then, by an intricate analysis, we show how to reduce the number of variables associated with the jobs in $\mathcal{J}_{new}$ to be of size polynomial in $|\mathcal{J}_{new}|$ (and consequently also in $|\mathcal{J}|$, since we add only a polynomial number of new jobs) with only a minor degradation in the quality of the solution. The resulting polynomial-size linear program can then be solved and rounded in polynomial time to obtain an approximate solution (details are in Section 3). In one of the special cases, we establish a precise relation between the approximability of classic real-time scheduling on a single machine and MaxT in the two-machine flow shop (details are in Section 4.1). This allows the use of approximation algorithms for the single machine case for solving our problem.

1.3 Prior Work

The problem of real-time scheduling with the objective of throughput maximization is discussed widely in the literature. A general instance of the problem consists of a set of n jobs and k machines, for some $k \geq 1$, where each job j has a weight $w_j > 0$, a release time r_j, a due date d_j and a processing time p_{ji} on machine i, for $1 \leq i \leq k$ and $1 \leq j \leq n$. The goal is to find a non-preemptive schedule that maximizes the weight of jobs that meet their respective due dates. Note that all the related works in this domain do not consider the flow shop model. Instead, the k machines form a single stage, where each job needs to be processed on *any one* of the machines.

The problem is known to be NP-complete already in the single machine case (i.e., $k = 1$), where all jobs have the same (unit) weight [11]. Some special cases of the problem are known to be solvable in polynomial time. Moore [19] showed for the single machine case and uniform job weights that, if $r_j = 0\ \forall j$ the problem can be solved in time $O(n^2)$. Sahni presented in [21] a *fully polynomial time approximation scheme (FPTAS)*, whose running time is $O(\frac{n^3}{\varepsilon})$, for the more general case where jobs have the same release time and arbitrary weights.

Bar-Noy et al. [3, 4] considered the real-time scheduling problem for general instances with k machines, for some $k \geq 1$, where jobs may have arbitrary weights and arbitrary release times and due dates. They presented in [3] a $(2+\varepsilon)$-approximation algorithm, using the local ratio technique. A quasi-polynomial time dynamic programming framework was proposed in [15], which gives a $(1+\varepsilon)$-speed $(1+\varepsilon)$-approximation algorithm for the weighted throughput problem on k machines. The best known result without speed augmentation is an $\frac{e}{e-1} < 1.582$ approximation algorithm [9], for a single machine and uniform job weights.

We note that a variant of MaxT, where for every job $J_j \in \mathcal{J}$, the start-times of all segments of J_j are given explicitly, yields an instance of *maximum weight independent set* in m-union graphs. Recall that an m-union graph can be modeled as the intersection graph of m-segments, i.e., each vertex in the graph can be represented by at most m segments on the real line. Two vertices are adjacent if their ith segments intersect. For this problem, the paper [5] presented a $2m$-approximation algorithm that was shown to be close to the best possible, due to a hardness of approximation result for a ratio of $\Omega(\frac{m}{\log m})$ [14]. The hardness result carries over to MaxT in the flow shop model and m machines, for any $m \geq 3$. Our approximation algorithm for a constant number of machines builds on an algorithm presented in [5]. However, further steps are required to obtain polynomial running time, which is the main contribution of this paper.

Another line of work that relates to MaxT deals with maximizing the total weight of *just-in-time (JIT)* jobs, i.e., the weighted number of jobs that are completed *exactly* on their due dates. All previous studies assume that $r_j = 0\ \forall j$. Choi and Yoon [8] show that JIT two-machine flow shop with arbitrary job weights is NP-complete. The special case of uniform job weights is solvable in polynomial time on two machines and is strongly NP-hard for instances with three machines. The best known result is an FPTAS in [10] (see also [23]).

We are not aware of earlier studies of throughput maximization in the flow shop model.

2 Approximation Algorithm for Fixed Number of Machines

In this section, we present a pseudo-polynomial time algorithm for MaxT on flow shop instances with $m \geq 2$ machines, where m is some constant. Given the set of jobs $\mathcal{J}$, each job J_j, $1 \leq j \leq n$, is associated with m segments and a weight $w_j \geq 0$. Also, J_j has a release time and a due date, $r_j \geq 0$ and $d_j \geq 0$, respectively. We seek a subset of the jobs that can be feasibly scheduled on the machines in a flow shop manner, such that the total weight of scheduled jobs is maximized.

As the processing time $p_{j,i}$ on machine M_i, release time r_j, and deadline d_j of job J_j are all rational numbers, we can obtain integer values for these parameters by appropriate scaling. Since all these values are integral, it is easy to see that any feasible solution can be "tweaked" so that the start times of all segments of all jobs begin at an integral time point. Thus, from now on we assume that this is the case. This allows us to discretize the input and consider all the possible occurrences of a job J_j in its time window $(r_j, d_j]$. An occurrence of J_j specifies the start times of all segments of J_j on the m machines in $(r_j, d_j]$. Note that the number of such possible occurrences of job J_j is upper bounded by $(d_j - r_j)^m$.

We give some notations towards solving MaxT on m machines using a linear program. Let $\mathcal{L}_j$ denote the set of occurrences of job J_j, so the number of the occurrences of J_j is $|\mathcal{L}_j|$. Let $\mathcal{L} = \bigcup_{j=1}^{n} \mathcal{L}_j$. Clearly, $|\mathcal{L}| = \sum_{j=1}^{n} |\mathcal{L}_j|$. Let $x^\ell(j) \in \{0, 1\}$ be an indicator variable for the selection of the ℓ-th occurrence J_j^ℓ of J_j in the solution, where $1 \leq \ell \leq |\mathcal{L}_j|$. We note that the number of variables and the number constraints in the linear program is $O(\sum_{j=1}^{n}(d_j - r_j)^m)$, and is thus pseudo-polynomial in the input size. Let $\mathbf{w} \in \mathbb{R}^n$, $\mathbf{x} \in \mathbb{R}^{|\mathcal{L}|}$ be a weight vector and a relaxed indicator vector, respectively. Then, $\mathbf{w} \cdot \mathbf{x} = \sum_{j=1}^{n} \sum_{\ell=1}^{|\mathcal{L}_j|} w_j x^\ell(j)$.

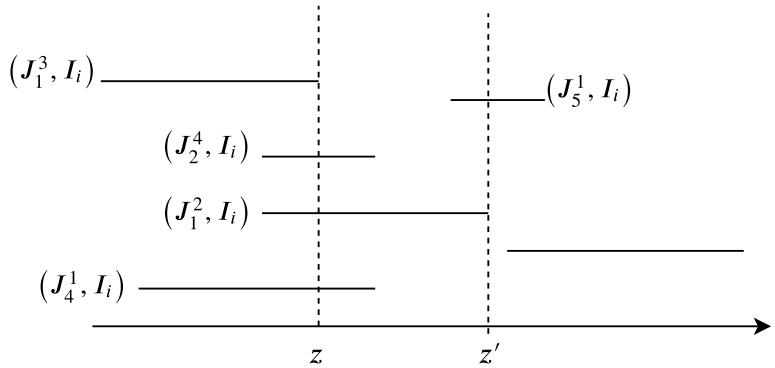

Figure 1 The job clique $(J_1^3, J_2^4, J_1^2, J_4^1)$ is defined by z, the right endpoint of the ith segment of J_1^3. The clique contains two occurrences of J_1: J_1^3 and J_1^2. The next clique, (J_1^2, J_5^1), is defined by the segment having its right endpoint at z'.

We now define *job cliques* on each of the m machines as follows. For machine $1 \leq i \leq m$, we examine the time axis from left to right and find among the segments that need to be processed on machine i a segment whose right endpoint is earliest. Let z be the time point

where this segment ends. We now define a clique $\mathcal{C}$ consisting of all job occurrences whose ith segment intersects the time point z. The next clique is defined by the earliest endpoint z' of an ith segment of a job, for which the following holds: there exists a job occurrence J_k^r, such that the ith segment of J_k^r intersects z', but $J_k^r \notin \mathcal{C}$, as shown in Figure 1. Intuitively, the endpoints z and z' in the definition of job cliques capture the maximum intersecting job occurrences in the time window $[z, z']$. Hence, a feasible schedule can only select one job occurrence in each clique.

We formulate the linear programming relaxation for MaxT as follows.

$$
\begin{array}{llll}
\text{(P)} \quad \text{maximize} \quad \mathbf{w} \cdot \mathbf{x} \quad \textit{subject to}: & & & \\
\displaystyle\sum_{J_j^\ell \in \mathcal{C}} x^\ell(j) & \leq & 1 & \text{for each clique } \mathcal{C} \\
\displaystyle\sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(j) & \leq & 1 & \forall 1 \leq j \leq n \\
x^\ell(j) & \geq & 0 & \forall 1 \leq j \leq n,\ 1 \leq \ell \leq |\mathcal{L}_j|
\end{array}
$$

The first constraint ensures that at most one job occurrence is selected from each clique. The second constraint guarantees that at most one occurrence of a job J_j is selected for the solution, $\forall J_j \in \mathcal{J}$. We note that (P) can be viewed as a Configuration LP, where each occurrence, J_j^ℓ, defines a *configuration*, $\forall J_j \in \mathcal{J}$.

Considering the neighbors of a job occurrence J_j^ℓ, we define two subsets of job occurrences.

1. Let $\tilde{N}_1(J_j^\ell)$ be the set of all job occurrences J_k^r where $k \neq j$, such that a segment of J_k^r intersects a segment of J_j^ℓ (recall that two segments can intersect only if both need to be processed on the *same* machine).
2. Let $\tilde{N}_2(J_j^\ell)$ be the set of all job occurrences J_j^r where $r \neq \ell$, i.e., other occurrences of J_j.

The *neighborhood* of a job occurrence J_j^ℓ is defined as $\tilde{N}(J_j^\ell) = \tilde{N}_1(J_j^\ell) \bigcup \tilde{N}_2(J_j^\ell)$.

▶ **Lemma 1.** *Let* $\mathbf{x}$ *be a feasible solution to* (P). *There exists a job occurrence* J_j^ℓ *satisfying:*

$$x^\ell(j) + \sum_{J_k^r \in \tilde{N}(J_j^\ell)} x^r(k) \leq 2m + 1.$$

Proof. We first show that there exists a job occurrence J_j^ℓ for which the following holds:

$$x^\ell(j) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} x^r(k) \leq 2m. \tag{1}$$

For two "neighboring" job occurrences J_j^ℓ and J_k^r (i.e., $J_k^r \in \tilde{N}_1(J_j^\ell)$ and $J_j^\ell \in \tilde{N}_1(J_k^r)$), define $z(J_j^\ell, J_k^r) = x^\ell(j) \cdot x^r(k)$. We also define $z(J_j^\ell, J_j^\ell) = (x^\ell(j))^2$. We prove (1) using a weighted averaging argument, where the weights are the values $z(J_j^\ell, J_k^r)$ for all pairs of job occurrences which have intersecting segments. The full proof is given in Appendix A. ◀

2.1 The Algorithm

We now show how to use Lamma 1 to get a $(2m+1)$-approximation for MaxT on m machines for some constant $m \geq 2$. Let $\mathcal{I}$ be the set of all half open subintervals of the interval $(0, 2m+1]$. Given an optimal solution $\mathbf{x}$ for the linear program (P), we construct a mapping $\psi : \mathcal{L} \to 2^{\mathcal{I}}$ such that for each job occurrence J_j^ℓ the following properties are satisfied:

1. All the subintervals in $\psi(J_j^\ell)$ are disjoint.
2. The total size of the subintervals in $\psi(J_j^\ell)$ is $x^\ell(j)$.
3. None of the subintervals in $\psi(J_j^\ell)$ intersects any of the subintervals in $\bigcup_{J_k^r \in \tilde{N}[J_j^\ell]} \psi(J_k^r)$.

The mapping is constructed for one job occurrence at a time according to a *hierarchical* order induced by Lemma 1. We first define this hierarchical order. The *last* job occurrence in the order is the occurrence J_j^ℓ that satisfies the inequality of Lemma 1. We then remove this job occurrence from the feasible solution to (P). We still remain with a feasible solution to (P) and we can apply Lemma 1 again and find yet another job occurrence that satisfies the inequality of the lemma. We append this job occurrence to the order. We continue in the same manner until we order all the job occurrences.

We compute $\psi(J_j^\ell)$ for one job occurrence at a time from the first to the last in the hierarchical order defined above. When $\psi(J_j^\ell)$ is computed, we remove from the interval $(0, 2m+1]$ all the subintervals in $\bigcup_{J_k^r \in \bar{N}} \psi(J_k^r)$, where $\bar{N} \subset \tilde{N}[J_j^\ell]$ is the set of all job occurrences in $\tilde{N}[J_j^\ell]$ that precede J_j^ℓ in the hierarchical order. By Lemma 1 the total size of these subintervals is no more than $2m + 1 - x^\ell(j)$. Thus, the remainder contains a set of disjoint subintervals of a total size at least $x^\ell(j)$. If we assign $\psi(J_j^\ell)$ greedily, that is, we assign the leftmost collection of such disjoint subintervals, then it can be shown that $|\psi(J_j^\ell)|$ is bounded by $|\mathcal{L}|$. This is because each job occurrence may increase the number of subintervals by at most one.

For a point $y \in (0, 2m+1]$, let $\phi(y) \subseteq \mathcal{L}$ be the subset of $\mathcal{L}$ consisting of all job occurrences J_j^ℓ for which one of the subintervals in $\psi(J_j^\ell)$ contains the point y. From the definition of the mapping ψ, it is evident that the subset $\phi(y)$ does not contain two job occurrences that intersect and also does not contain two job occurrences of the same job. Thus, the job occurrences in $\phi(y)$ can be scheduled feasibly to yield a weight of $w(y) = \sum_{J_j^\ell \in \phi(y)} w_j$. Let $y^* = \arg\max_{y \in (0,2m+1]}\{w(y)\}$. Note that if the mapping is computed greedily there are at most $|\mathcal{L}|^2$ possible values of $w(y^*)$. These values are determined by the right endpoints of all subintervals. The pseudocode of the algorithm, Flowshop_Time_Windows, is in Algorithm 1.

Algorithm 1 Flowshop_Time_Windows.

Find an optimal solution $\mathbf{x}$ for the linear program (P).
Order the job occurrences according to the hierarchical order.
for each job occurrence J_j^ℓ in order **do**
    Remove from the interval $(0, 2m+1]$ all subintervals assigned to "neighbors" of J_j^ℓ that precede it in the hierarchical order.
    Assign to J_j^ℓ the leftmost collection of subintervals of total size $x^\ell(j)$.
end for
Let $maxwy = 0$.
for a point y that is a right endpoint of a subinterval **do**
    Let $\phi(y) \subseteq \mathcal{L}$ be the subset of all job occurrences J_j^ℓ for which one of the subintervals in $\psi(J_j^\ell)$ contains the point y.
    Let $w(y) = \sum_{J_j^\ell \in \phi(y)} w_j$.
    if $w(y) > maxwy$ **then**
        Let $maxwy = w(y)$ and $y^* = y$.
    end if
end for
Return $\phi(y^*)$.

▶ **Theorem 2.** Flowshop_Time_Windows *yields a* $(2m+1)$*-approximation for* MaxT *on* m *machines.*

Proof. Consider $\int_0^{2m+1} w(y)dy$. By our definitions,

$$\int_0^{2m+1} w(y)dy = \sum_{j=1}^{n}\sum_{\ell=1}^{|\mathcal{L}_j|}\int_{\psi(J_j^\ell)} w_j dz_j = \sum_{j=1}^{n}\sum_{\ell=1}^{|\mathcal{L}_j|} w_j x^\ell(j) = \mathbf{w}\cdot\mathbf{x}$$

The first equality is derived by a variable substitution and the second equality follows from the second property of the mapping. Since $\int_0^{2m+1} w(y)dy = \mathbf{w}\cdot\mathbf{x}$ it follows that $(2m+1)w(y^*) \geq \mathbf{w}\cdot\mathbf{x}$. ◀

▶ **Corollary 3.** *There is a pseudo-polynomial time* $(2m+1)$*-approximation algorithm for* MaxT *on* m *machines, where* $m \geq 2$ *is some constant.*

3 Approximating MaxT on Two Machines

We now show that, with a slight degradation of the approximation ratio, we can use the algorithm presented in Section 2 to obtain a polynomial-time algorithm for $m = 2$.

We start with some notations. Consider two machines, M_1 and M_2, and each job consists of two non-preemptive segments. For notation simplicity, in the following sections, we denote the processing times of J_j on M_1 and M_2 as a_j and b_j, respectively. Recall that a job $J_j \in \mathcal{J}$ has a release time $r_j \geq 0$, a due date $d_j \geq 0$, and a weight $w_j \geq 0$. Thus, in any feasible schedule of $\mathcal{J}' \subseteq \mathcal{J}$ in the flow shop model, $J_j \in \mathcal{J}'$ is processed first for a_j time units on M_1 after its release time r_j, then processed for b_j time units on M_2 and finished no later than its due date d_j.

We distinguish between three types of jobs based on their *slackness*:

- **(i)** Small jobs $\mathcal{J}_\mathcal{S}$: Job J_j is a Small job, if it has a large slack in its time window $[r_j, d_j]$, satisfying $a_j + b_j < \frac{d_j - r_j - a_j - b_j}{n^2-1}$. Note that this implies $a_j + b_j < \frac{d_j - r_j}{n^2}$.
- **(ii)** Large jobs $\mathcal{J}_\mathcal{L}$: Job J_j is a Large job, if $a_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$ and $b_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$.
- **(iii)** Almost-Large jobs $\mathcal{J}_{\mathcal{AL}}$: Job J_j is a Almost-Large job, if it satisfies $a_j + b_j \geq \frac{d_j - r_j - a_j - b_j}{n^2-1}$ (and hence $a_j + b_j \geq \frac{d_j - r_j}{n^2}$), and also one of the following:
  - **(a)** $a_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$ and $b_j < \frac{d_j - r_j - a_j - b_j}{2n^2-2}$.
  - **(b)** $a_j < \frac{d_j - r_j - a_j - b_j}{2n^2-2}$ and $b_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$.

We modify the linear program (P) in Section 2 to solve it in polynomial time in the following steps. First, we eliminate Almost-Large jobs and replace each Almost-Large job by two Large jobs and one Small job. Then, we define the modified linear program (P_{new}) of polynomial size by identifying only a polynomial number of job occurrences for each job included in this formulation. We call these job occurrences the *selected* job occurrences. All the unselected job instances will not be scheduled (fractionally). We show that any feasible solution of (P) induces a feasible solution of (P_{new}) with a slight degradation in the value of the objective function. Finally, we show how a feasible solution of (P_{new}) can be "rounded" to a schedule whose weight is $\frac{1}{9}$ of the objective value of this feasible solution of (P_{new}). This schedule is a $(9+\epsilon)$-approximation of the optimal solution.

3.1 Eliminating the Almost-Large Jobs

We first partition the set $\mathcal{J}_{\mathcal{AL}}$ of Almost-Large jobs into two subsets $\mathcal{J}^1_{\mathcal{AL}}$ and $\mathcal{J}^2_{\mathcal{AL}}$.

- **(1)** The subset $\mathcal{J}^2_{\mathcal{AL}}$ of jobs J_j satisfying $a_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$ and $b_j < \frac{d_j - r_j - a_j - b_j}{2n^2-2}$.
- **(2)** The subset $\mathcal{J}^2_{\mathcal{AL}}$ of jobs J_j satisfying $a_j < \frac{d_j - r_j - a_j - b_j}{2n^2-2}$ and $b_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$.

Consider a job $J_j \in \mathcal{J}^1_{\mathcal{AL}}$. Let time point $t_j = d_j - a_j - (2n^2-1)b_j$, so $b_j = \frac{d_j - t_j - a_j - b_j}{2n^2-2}$. Partition the occurrences of J_j into two subsets. The first subset consists of all occurrences J^ℓ_j in which the first segment of J^ℓ_j starts (on M_1) at or after t_j, and the complement subset consists of all occurrences J^ℓ_j in which the first segment of J^ℓ_j starts processing before time t_j. We replace job J_j with three new jobs as follows.

Note that the job occurrences in the first subset are essentially the job occurrences of a new job consisting of two segments of lengths a_j, b_j with new release time t_j and due date d_j. We add such a job J_{n+j} to the input. This job is Large, since $a_j \geq \frac{d_j - t_j - a_j - b_j}{2n^2-2}$ and $b_j = \frac{d_j - t_j - a_j - b_j}{2n^2-2}$.

For the second subset of job occurrences, we ignore (for now) all the occurrences where the second segment starts before $t_j + a_j$. Note that the rest of the job occurrences in the second subset are essentially the job occurrences of two new jobs: one job consisting of a single segment of length a_j (to be processed on M_1) with release time r_j and new due date $t_j + a_j$, and a second job consisting of a single segment of length b_j (to be processed on M_2) with new release time $t_j + a_j$ and due date d_j. We add these two jobs J_{2n+j} and J_{3n+j} to the input. Since $d_j - b_j = t_j + a_j + (2n^2-2)b_j \geq t_j + a_j$ and $a_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$, we have $a_j \geq \frac{t_j + a_j - r_j - a_j}{2n^2-2}$. Thus, the job J_{2n+j} is Large. The job J_{3n+j} is Small, since $b_j = \frac{d_j - t_j - a_j - b_j}{2n^2-2} < \frac{d_j - t_j - a_j - b_j}{n^2-1}$. We make sure that J_{2n+j} and J_{3n+j} are scheduled together by modifying the linear program.

Jobs $J_j \in \mathcal{J}^2_{\mathcal{AL}}$ are handled symmetrically. Let t_j be the time point satisfying $a_j = \frac{t_j - r_j - a_j - b_j}{2n^2-2}$. Partition the occurrences of J_j into two subsets. The first subset consists of all occurrences where the second segment ends at or before t_j, and the complement subset consists of all occurrences where the second segment ends processing (on M_2) after time t_j. The job occurrences in the first subset are the same as the new job occurrences of a job with two segments of lengths a_j, b_j, release time r_j and new due date t_j. We add such a job J_{n+j} to the input. This job is Large since $a_j = \frac{t_j - r_j - a_j - b_j}{2n^2-2}$ and $b_j \geq \frac{t_j - r_j - a_j - b_j}{2n^2-2}$. For the second subset, we again ignore (for now) all the occurrences where the first segment finishes after $t_j - b_j$. Then the rest job occurrences in the second subset are the same as the job occurrences of two new jobs: one job with a single segment of length b_j (to be processed on M_2) with new release time $t_j - b_j$ and due date d_j, and a second job consisting of a single segment of length a_j (to be processed on M_1) with release time r_j and new due date $t_j - b_j$. We add these jobs J_{2n+j} and J_{3n+j} to the input. Since $t_j - b_j = r_j + a_j + (2n^2-2)a_j \geq r_j + a_j$ and $b_j \geq \frac{d_j - r_j - a_j - b_j}{2n^2-2}$, we have $b_j \geq \frac{d_j - (t_j - b_j) - b_j}{2n^2-2}$. Thus, the job J_{2n+j} is Large. Since $a_j = \frac{t_j - r_j - a_j - b_j}{2n^2-2} < \frac{(t_j - b_j) - r_j - a_j}{n^2-1}$, the job J_{3n+j} is Small.

3.2 The Selected Occurrences of Small and Large Jobs

After eliminating Almost-Large jobs, the set of Small jobs in the modified LP becomes

$$\mathcal{J}_{\mathcal{S}}{}^{new} = \mathcal{J}_{\mathcal{S}} \bigcup \{J_{3n+j} |\ J_j \in \mathcal{J}_{\mathcal{AL}}\} \text{ and } |\mathcal{J}_{\mathcal{S}}{}^{new}| = |\mathcal{J}_{\mathcal{S}}| + |\mathcal{J}_{\mathcal{AL}}|.$$

For each Small job $J_j \in \mathcal{J}_{\mathcal{S}}{}^{new}$, find n^2 non-overlapping occurrences of J_j: $J^1_j, \ldots, J^{n^2}_j$, such that in each such occurrence, the two segments of J_j are scheduled with no wait, i.e., the second segment is scheduled on M_2 immediately after completing the first segment on M_1. We can find n^2 such job occurrences since $a_j + b_j < \frac{d_j - r_j}{n^2}$. These non-overlapping occurrences are the selected occurrences of job J_j.

After eliminating Almost-Large jobs, the set of Large jobs in the modified LP is

$$\mathcal{J}_{\mathcal{L}}{}^{new} = \mathcal{J}_{\mathcal{L}} \bigcup \{J_{n+j}, J_{2n+j} |\ J_j \in \mathcal{J}_{\mathcal{AL}}\} \text{ and } |\mathcal{J}_{\mathcal{L}}{}^{new}| = |\mathcal{J}_{\mathcal{L}}| + 2|\mathcal{J}_{\mathcal{AL}}|.$$

For every $J_j \in {\mathcal{J}_{\mathcal{L}}}^{new}$, define $2n^2+1$ dividers on the time axis for machine M_1, at the time points $r_j + h \cdot \frac{(d_j - b_j - r_j)}{2n^2}$, for $h = 0, \ldots, 2n^2$, and $2n^2+1$ dividers on the time axis for machine M_2, at the time points $r_j + a_j + h \cdot \frac{(d_j - r_j - a_j)}{2n^2}$, for $h = 0, \ldots, 2n^2$. The $|{\mathcal{J}_{\mathcal{L}}}^{new}|(4n^2+2)$ dividers define half open time slots for M_1 and M_2, where each time slot is between adjacent dividers. We note that for any $J_j \in {\mathcal{J}_{\mathcal{L}}}^{new}$, no segment of J_j is completely contained in a time slot, i.e., it lies between two adjacent dividers.

Consider a LARGE job $J_j \in {\mathcal{J}_{\mathcal{L}}}^{new}$. For each time slot s for M_1 and time slot t for M_2, consider the set of all job occurrences of J_j where the right endpoint of its first segment is in time slot s and the right endpoint of its second segment is in t. Select one arbitrary job occurrence from this set. Let J_j^ℓ, for $1 \leq \ell \leq (2n^2+1)^2$, be all the selected job occurrences.

3.3 The Modified Linear Program

The set of jobs in the modified LP is $\mathcal{J}_{new} = {\mathcal{J}_{\mathcal{S}}}^{new} \bigcup {\mathcal{J}_{\mathcal{L}}}^{new}$. Thus, $|\mathcal{J}_{new}| = |\mathcal{J}_{\mathcal{S}}| + |\mathcal{J}_{\mathcal{L}}| + 3|\mathcal{J}_{\mathcal{AL}}| \leq 3n$. All the jobs in $\mathcal{J}_{new}$ are either SMALL or LARGE. We only consider variables that correspond to the selected job occurrences. We define job cliques as before but only with respect to the selected job occurrences. The modified linear program is as follows.

$$
\begin{array}{lllll}
(\mathrm{P}_{new}) \quad \text{maximize} \quad \mathbf{w} \cdot \mathbf{x} \quad \textit{subject to}: & & & & \\
\displaystyle\sum_{J_j^\ell \in \mathcal{C}} x^\ell(j) & & \leq & 2 & \text{for each clique } \mathcal{C} \\
\displaystyle\sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(j) & & \leq & 1 & \forall J_j \in \mathcal{J}_{new} \\
\displaystyle\sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(n+j) + \sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(2n+j) & & \leq & 1 & \forall J_j \in J_{\mathcal{AL}} \\
\displaystyle\sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(2n+j) - \sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(3n+j) & & = & 0 & \forall J_j \in J_{\mathcal{AL}} \\
x^\ell(j) & & \geq & 0 & \forall J_j \in \mathcal{J}_{new},\ 1 \leq \ell \leq (2n^2+1)^2
\end{array}
$$

The first constraint is a relaxation of the original clique constraint and ensures that the total value of the variables associated with the selected job occurrences in each clique is at most *two*. The second constraint guarantees that at most one occurrence of a job J_j is selected for the solution, $\forall J_j \in \mathcal{J}_{new}$. The third and fourth constraints deal with the jobs that replace the ALMOST-LARGE jobs. Recall that in Section 3.1 the occurrences of any $J_j \in \mathcal{J}_{\mathcal{AL}}$ were partitioned into two subsets. The third constraint ensures that the total value of the variables associated with the two LARGE jobs that replace a single ALMOST-LARGE job (one LARGE job for each subset of job occurrences of the ALMOST-LARGE job) is at most one. The fourth constraint ensures that for each pair of LARGE job and SMALL job that replace the second subset of job occurrences of a single ALMOST-LARGE job, the total value of the variables associated with the replacement LARGE job is the same as the total value of the variables associated with the replacement SMALL job.

3.4 The Induced Solution of the Modified Linear Program

Consider a solution of the linear program (P) for an instance with two machines. Denote this solution $y^\ell(j)$, for $1 \le j \le n$, $1 \le \ell \le \mathcal{L}_j$. We show how it induces a solution to the modified linear program (P_{new}) as follows. If $J_j \in \mathcal{J}_\mathcal{S}$, then for $\ell = 1, \ldots, n^2$, $x^\ell(j) = \frac{1}{n^2} \sum_{r=1}^{\mathcal{L}_j} y^r(j)$.

If $J_j \in \mathcal{J}_\mathcal{L}$, then for each selected job occurrence J_j^ℓ, the variable $x^\ell(j)$ is the sum of all variables $y^\ell(r)$, over all job occurrences J_j^r such that the right endpoint of the first segment of J_j^r is in the same time slot as the right endpoint of the first segment of J_j^ℓ and the right endpoint of the second segment of J_j^r is in the same time slot as the right endpoint of the second segment of J_j^ℓ.

Suppose $J_j \in \mathcal{J}^1_{\mathcal{AL}}$. Recall that in Section 3.1 the occurrences of J_j were partitioned into two subsets, denoted as S_1 and S_2. (The subset S_2 includes the job occurrences we ignored in Section 3.1.) For each selected job occurrence J_{n+j}^ℓ, the variable $x^\ell(n+j)$ is the sum of all variables $y^\ell(r)$, over all job occurrences $J_j^r \in S_1$ such that the right endpoint of the first (second) segment of J_j^r is in the same time slot as the right endpoint of the first (second) segment of J_j^ℓ. Similarly, for each selected job occurrence J_{n+2j}^ℓ, the variable $x^\ell(n+2j)$ is the sum of all variables $y^\ell(r)$, over all $J_j^r \in S_2$ such that the right endpoint of the first segment of J_j^r is in the same time slot as the right endpoint of the first segment of J_j^ℓ.

Symmetrically, suppose $J_j \in \mathcal{J}^2_{\mathcal{AL}}$. For each selected job occurrence J_{n+j}^ℓ, the variable $x^\ell(n+j)$ is defined as above. For each selected job occurrence J_{n+2j}^ℓ, the variable $x^\ell(n+2j)$ is the sum of all variables $y^\ell(r)$, over all $J_j^r \in S_2$ such that the right endpoint of the second segment of J_j^r is in the same time slot as the right endpoint of the second segment of J_j^ℓ.

Finally, suppose $J_j \in \mathcal{J}_\mathcal{AL}$ for $\ell = 1, \ldots, n^2$, we have $x^\ell(n+3j) = \frac{1}{n^2} \sum_{J_j^r \in S_2} y^r(j)$.

It is straightforward to verify that the induced solution of the modified linear program (P_{new}) satisfies all constraints but the relaxed clique constraint. We show that the relaxed clique constraint is satisfied as well. First, we show that it is satisfied when we ignore the variables associated with Small jobs.

Consider a time slot s for M_1, and assume that at least one selected job occurrence J_j^ℓ has the right endpoint of its first segment is time slot s. Let $\mathcal{C}$ be the clique defined by this endpoint. Let S be the set of all job occurrences J_k^r whose first segment intersects time slot s. Clearly, $\sum_{J_k^r \in \mathcal{C}} x^r(k) \le \sum_{J_k^r \in S} y^r(r)$. Since all jobs are Large, the first segment of any $J_k^r \in S$ intersects at least one of the dividers that define time slot s. It follows $\sum_{J_k^r \in \mathcal{C}} x^r(k) \le 2$. The same argument holds for any time slot t for M_2.

Next, we show how the relaxed clique constraint is satisfied when we add the variables associated with Small jobs. Note that for each variable associated with a Small job J_j, $x^\ell(j) \le \frac{1}{n^2}$, for $1 \le \ell \le n^2$. Still, adding these variables may render the solution infeasible. Since for each Small job J_j, the job occurrences J_j^ℓ, $1 \le \ell \le n^2$ are nonoverlapping, any job clique $\mathcal{C}$ contains at most one segment out of all segments of the job occurrences J_j^ℓ, $1 \le \ell \le n^2$. Thus, the total sum of fractions assigned to Small jobs in any job clique $\mathcal{C}$ is at most $\frac{1}{n^2} \cdot n = \frac{1}{n}$. It follows that scaling the fractions assigned to Large jobs by a factor of $(1 - \frac{1}{n})$ will make the solution feasible. This scaling degrades the value of the objective function of the fractional solution by a factor of $(1 - \frac{1}{n})$.

3.5 Rounding the Solution of the Modified Linear Program

Since the clique constraint is relaxed, we need to reformulate Lemma 1.

▶ **Lemma 4.** *Let* $\mathbf{x}$ *be a feasible solution to* (P_{new}). *Then, there exists a job occurrence* J_j^ℓ *satisfying* $x^\ell(j) + \sum_{J_k^r \in \tilde{N}(J_j^\ell)} x^r(k) \le 9$.

Proof. The proof is similar to the proof of Lemma 1. We first show that there exists a selected job occurrence J_j^ℓ for which

$$x^\ell(j) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} x^r(k) \leq 8. \tag{2}$$

As before, we define $z(J_j^\ell, J_k^r) = x^\ell(j) \cdot x^r(k)$. The analysis is slightly different from the one in the proof of Lemma 1 since the first constraint in (P_{new}) is now relaxed. We omit the details. ◀

We apply Lemma 4 to obtain a mapping (as defined in Section 2.1). This can be done in polynomial time since we are guaranteed to have a polynomial number of nonzero variables that correspond to job occurrences. The mapping yields a schedule of a subset of jobs in $\mathcal{J}_{new}$ as defined in Section 2.1 with total weight $\frac{1}{9}$ of the objective value of the feasible solution of (P_{new}). Recall that this value is the objective value of the feasible solution of (P) scaled down by a factor of $(1 - \frac{1}{n})$. We summarize in the next theorem.

▶ **Theorem 5.** *There is a polynomial time $(9+\epsilon)$-approximation algorithm for MaxT on two machines.*

4 Better Approximations for Special Cases on Two Machines

4.1 A 4-approximation Algorithm for Unit Weight Jobs with the Same Release Time

Consider instances of flow shop with two machines, in which all jobs have the same release time, i.e., $r_j = 0\ \forall J_j \in \mathcal{J}$, arbitrary due dates, and unit weight. Below, we show that for such instances a simple algorithm yields an improved approximation ratio of 4 for MaxT. We note that the problem of maximizing throughput on a *single* machine with the same release times and unit job weights is solvable in polynomial time using Moore's algorithm [19]. We call this problem below MaxT$_S$. Moore's algorithm can thus be used as a subroutine in our algorithm for MaxT, Split_the_Schedule. We give the pseudocode in Algorithm 2.

Algorithm 2 Split_the_Schedule.

1: For any job $J_j \in \mathcal{J}$ let $p_j = a_j + b_j$.
2: Solve optimally MaxT$_S$, where each job J_j has a processing time p_j, a release time $r_j = 0$, and a due date d_j. Let SOL be the set of jobs in the solution.
3: Define the following flow shop schedule of SOL on M_1 and M_2: for any $J_j \in SOL$ that is processed on the single machine in $(s_j, t_j]$, process J_j on M_1 in $(s_j, s_j + a_j]$ and on M_2 in $(s_j + a_j, t_j]$.
4: Return the schedule of SOL on M_1 and M_2.

▶ **Theorem 6.** *Let OPT be the set of jobs in an optimal solution for MaxT. Then $|SOL| \geq \frac{|OPT|}{4}$.*

We use the following two lemmas to prove our main result in Theorem 6.

▶ **Lemma 7.** *For any instance of MaxT where $r_j = 0\ \forall J_j \in \mathcal{J}$, there exists an optimal* permutation schedule, *i.e., a schedule where jobs are scheduled in the same order on both machines.*

Proof. Consider an optimal schedule that is not a permutation schedule, then we show that by swapping jobs we can obtain a feasible permutation schedule. Formally, given a schedule of the jobs on the two machines, we scan the schedule on M_2, starting from time $t = 0$. For any two consecutive jobs on M_2, J_k, J_j, if J_k precedes J_j on M_2, but J_j precedes J_k on M_1, we modify the schedule on M_1 as follows. Let s_j^1, s_k^1 the start-times of J_j, J_k on M_1, and t_k^1 the completion time of J_k on M_1 (see Figure 2). Then we schedule J_k on M_1 at time $t_k^1 - a_k - a_j$ and J_j at time $t_k^1 - a_j$. For M_1 we have:

- J_k completes processing earlier.
- J_j has a later completion time on M_1, but it still completes processing on M_2 by its due date. Indeed, as before, J_j starts processing on M_2 at time $s_j^2 \geq t_k^1$ and completes by d_j.
- For any other job J_r, $r \neq j, k$, the above swap can only result in an earlier completion time of J_r on M_1.

In addition, since we made no change on M_2, the schedule is still feasible. ◀

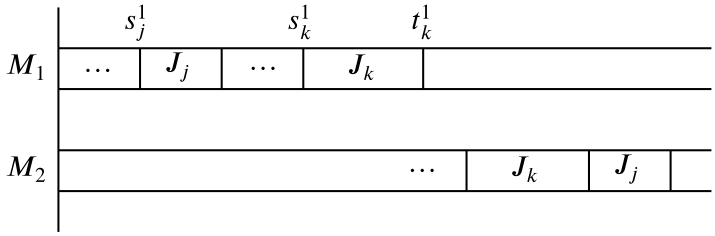

Figure 2 A non permutation schedule. J_j and J_k can be swapped on M_1 and scheduled consecutively, so that J_j completes processing on M_1 at time t_k^1.

▶ **Lemma 8.** *Let OPT be an optimal solution for a MaxT instance $\mathcal{J}$ for which there is a permutation schedule. Then there exists a subset of jobs $OPT_{single} \subseteq OPT$ satisfying:*

(i) *The jobs in OPT_{single} can be feasibly scheduled on a single machine, taking the processing time of each $J_j \in OPT_{single}$ to be $p_j = a_j + b_j$.*

(ii) $|OPT_{single}| \geq \frac{|OPT|}{4}$.

Proof. Consider an optimal subset of jobs, OPT, which has a permutation schedule. Assume w.l.o.g. that this permutation is the identity permutation. We now show how to move from a two machine schedule to a schedule of a subset of jobs in OPT, such that each job is completely processed either on M_1 or on M_2. We note that if $|OPT|$ is odd then we can always process the two segments of the last job on M_1. Hence, we assume from now on that $|OPT| = 2k$ for some integer $k \geq 1$. We now partition OPT to k pairs of jobs: $(J_1, J_2), \ldots, (J_{2i-1}, J_{2i}), \ldots$. Consider the jobs J_{2i-1}, J_{2i} with the processing times (a_{2i-1}, b_{2i-1}) and (a_{2i}, b_{2i}), respectively. We distinguish between two cases:

(i) If $a_{2i} > b_{2i-1}$ then we schedule J_{2i-1} on M_1 with processing time $p_{2i-1} = a_{2i-1} + b_{2i-1}$.

(ii) If $a_{2i} \leq b_{2i-1}$ then we schedule J_{2i} on M_2 with processing time $p_{2i} = a_{2i} + b_{2i}$.

We note that the schedules obtained on M_1 and M_2 are feasible. In addition, from each pair of jobs in OPT, one job is scheduled (either on M_1 or on M_2). Therefore, $|OPT|/2$ jobs are scheduled. Now, we choose the machine with a maximum number of jobs. This yields a solution consisting of at least $|OPT|/4$ jobs. ◀

Proof of Theorem 6. Recall that for an instance in which $r_j = 0$ $\forall J_j \in \mathcal{J}$ we can use Moore's algorithm to solve MaxTs optimally. By Lemma 8, there exists a subset of $|OPT|/4$ jobs that can be scheduled feasibly on a single machine, where OPT is an optimal solution for MaxT on two machines. Since Moore's algorithm outputs an optimal solution on a single machine, we have the statement of the theorem. ◀

4.2 A $(3+\varepsilon)$-approximation Algorithm for Jobs with the Same Release Time and Due Date

Consider instances of flow shop with two machines, in which all jobs have the same release time and the same due date. We assume below that for all $1 \leq j \leq n$, $r_j = 0$ and $d_j = T$, for some $T > 0$. We note that MaxT on such instances is NP-hard, as Knapsack is the special case where $b_j = 0$ for all $1 \leq j \leq n$.

Algorithm 3 below is a $(3+\varepsilon)$-approximation algorithm for such instances. The algorithm partitions the jobs into two groups: *large* and *small* jobs. For the large jobs the algorithm finds an optimal solution by applying an algorithm for makespan minimization in two-machine flow shop due to Johnson [16]. For the small jobs it finds a $(2+\varepsilon)$-approximation by applying a greedy algorithm for the *knapsack* problem. The algorithm then outputs the better of the two solutions, to yield a $(3+\varepsilon)$-approximation.

Let $\Delta_j = \max\{a_j, b_j\}$ for each job J_j, $1 \leq j \leq n$. Also, let $\Delta_0 = 0$. For a set of jobs $\mathcal{J}$, define the weight of $\mathcal{J}$ to be $w(\mathcal{J}) = \sum_{J_j \in \mathcal{J}} w_j$.

Algorithm 3 Pack_and_Schedule.

Fix $0 < \varepsilon < 1$.
Let $\mathcal{L} = \{J_j \in \mathcal{J} \mid \Delta_j \geq \frac{\varepsilon T}{6}\}$ and $\mathcal{S} = \mathcal{J} \setminus \mathcal{L}$.
Let $M_L = 0$
for all $R \subseteq \mathcal{L}$ such that $|R| \leq \frac{12}{\varepsilon}$ jobs **do**
  if R can be scheduled with makespan at most T **then**

▶ **Theorem 9.** *For any fixed $0 < \varepsilon < 1$, Algorithm 3 runs in polynomial time and yields a $(3+\varepsilon)$-approximation for MaxT on instances where $r_j = 0$ and $d_j = T$, $\forall j$.*

To prove Theorem 9 we need an observation and a few lemmas.

▶ **Observation 10.** Any feasible solution R of MaxT on instances where $r_j = 0$ and $d_j = T$ $\forall j$ satisfies $\sum_{J_j \in R} \Delta_j \leq 2T$.

Proof. We note that $\sum_{J_j \in R} \Delta_j = \sum_{J_j \in R} \max\{a_j, b_j\} \leq \sum_{J_j \in R} (a_j + b_j) \leq 2T$. The last inequality follows from the fact that R can be scheduled feasibly. ◀

▶ **Lemma 11.** *The set SOL_L is an optimal solution for input $\mathcal{L}$.*

Proof. Since for every job $J_j \in \mathcal{L}$ we have $\Delta_j \geq \frac{\varepsilon T}{6}$, it follows from Observation 10 that any feasible solution for $\mathcal{L}$ cannot include more than $\frac{12}{\varepsilon}$ jobs. Since we enumerate over all feasible schedules with up to this number we are guaranteed to find the optimum. ◀

▶ **Lemma 12.** *The jobs in $SOL_S = \{J_1, \ldots, J_k\}$ can be scheduled feasibly.*

Proof. Sort the jobs $J_1, \ldots, J_k$ in non-ascending order of Δ_j. Let π be the resulting permutation; that is, $\Delta_{\pi(1)} \geq \Delta_{\pi(2)} \geq \ldots \geq \Delta_{\pi(k)}$. Let $\pi(0) = 0$.

Schedule job $J_{\pi(j)}$ at time $t_1^j = \sum_{i=0}^{j-1} \Delta_{\pi(i)}$ on M_1 and at time $t_2^j = t_1^j + \Delta_{\pi(1)}$ on M_2. The schedule is feasible since (i) no two jobs overlap in any of the machines (recall that $\Delta_j = \max\{a_j, b_j\}$), (ii) the makespan of the schedule is $\Delta_{\pi(1)} + \sum_{j=1}^{k} \Delta_{\pi(j)} \leq T$ since $\Delta_{\pi(1)} < \frac{\varepsilon T}{6}$, and (iii) for any job J_j, its segment on M_2 is executed after the completion of its segment on M_1, since the schedule on M_2 is shifted by $\Delta_{\pi(1)} = \max_{j \in [1..k]} \Delta_j$. ◀

▶ **Lemma 13.** *The set SOL_S is a $(2+\varepsilon)$-approximation of the optimal solution for input $\mathcal{S}$.*

Proof. First, consider a knapsack problem with set of items corresponding to the jobs in $\mathcal{S}$, where the size of item j is Δ_j and its weight is w_j. Assume that the knapsack capacity is T. We claim that the weight of the optimal solution to this knapsack problem has weight that is at least $\frac{1}{2}$ of the weight of optimal solution for input $\mathcal{S}$. To see this consider an optimal solution for input $\mathcal{S}$ and partition the set of jobs in this solution into two disjoint sets: the first set O_1 consists of all jobs J_j in the solution for which $\Delta_j = a_j$, and the second set O_2 consists of all jobs J_j in the solution for which $\Delta_j > a_j$ (and $\Delta_j = b_j$). Let i be the index of the set whose total weight is larger; that is $w(O_i) \geq w(O_{3-i})$. Clearly $w(O_i)$ is at least half the optimum. Since we start from a feasible solution, the total size of the items corresponding to the jobs in O_i is bounded by T. Thus, there is a feasible solution to the knapsack problem with weight that is at least $\frac{1}{2}$ of the weight of optimal solution for input $\mathcal{S}$. Note that we may not be able to feasibly schedule the set of jobs corresponding to the items in an optimal solution of this knapsack problem.

From the way we chose k and since for all $J_j \in \mathcal{S}$, $\Delta_j < \frac{\varepsilon T}{6}$, it follows that $\sum_{j=1}^{k} \Delta_j > T(1 - \frac{\varepsilon}{3})$. Since the jobs are sorted in non-ascending order of the ratio $\frac{w_j}{\Delta_j}$, we are guaranteed that $w(SOL_S)$ is at least $(1 - \frac{\varepsilon}{3})$ of the weight of the optimal solution to the knapsack problem and thus it is at least $\frac{1}{2}(1 - \frac{\varepsilon}{3})$ of the weight of the optimal solution for input $\mathcal{S}$. Since $(2+\varepsilon) \cdot \frac{1}{2}(1 - \frac{\varepsilon}{3}) = 1 + \frac{1}{6}(\varepsilon - \varepsilon^2) \geq 1$, for $0 < \varepsilon < 1$, it follows that SOL_S is a $(2+\varepsilon)$-approximation of the optimal solution for input $\mathcal{S}$. ◀

▶ **Lemma 14.** *The time complexity of Algorithm 3 is $O(n^{\frac{12}{\varepsilon}})$.*

Proof of Theorem 9. Consider an optimal solution O for input $\mathcal{J}$, and partition the jobs in this solution into two disjoint sets $O_L = O \cap \mathcal{L}$ and $O_S = O \cap \mathcal{S}$. By Lemmas 11 and 13, we have that $w(O_L) \leq w(\mathsf{SOL})$ and $w(O_S) \leq (2+\varepsilon) \cdot w(\mathsf{SOL})$. It follows that $w(O) \leq (3+\varepsilon) \cdot w(\mathsf{SOL})$.

By the algorithm and Lemma 12 the jobs in SOL can be scheduled feasibly, and by Lemma 14 the running time is polynomial in n. The theorem follows. ◀

▶ **Corollary 15.** *If $a_j \leq b_j$, for all $J_j \in \mathcal{J}$, or $a_j \geq b_j$, for all $J_j \in \mathcal{J}$, then, for any fixed $0 < \varepsilon < 1$, Algorithm 3 is a $(2+\varepsilon)$-approximation algorithm for MaxT on instances where $r_j = 0$ and $d_j = T$, $\forall j$.*

Proof. It is easy to see that if any of the conditions in the corollary hold then the weight of an optimal solution to the knapsack problem defined in Lemma 13 is at least the weight of the optimal solution for input $\mathcal{S}$, and thus the set SOL_S is a $(1+\varepsilon)$-approximation of the optimal solution for input $\mathcal{S}$. ◀

A Some Proofs

Proof of Lemma 1. We first show that there exists a job occurrence J_j^ℓ for which the following holds:

$$x^\ell(j) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} x^r(k) \leq 2m. \tag{3}$$

For two "neighboring" job occurrences J_j^ℓ and J_k^r (i.e., $J_k^r \in \tilde{N}_1(J_j^\ell)$ and $J_j^\ell \in \tilde{N}_1(J_k^r)$), define $z(J_j^\ell, J_k^r) = x^\ell(j) \cdot x^r(k)$. We also define $z(J_j^\ell, J_j^\ell) = (x^\ell(j))^2$. We prove (3) using a weighted averaging argument, where the weights are the values $z(J_j^\ell, J_k^r)$ for all pairs of job occurrences which have intersecting segments.

Consider the sum $\sum_{j=1}^{n} \sum_{\ell=1}^{\mathcal{L}_j} \left(z(J_j^\ell, J_j^\ell) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} z(J_j^\ell, J_k^r) \right)$. We upper bound this sum as follows. Let $\mathcal{I}(J_j^\ell)$ denote the set of segments of a job occurrence J_j^ℓ. For each job occurrence J_j^ℓ, we consider all of its segments $I \in \mathcal{I}(J_j^\ell)$. For each such segment I, we sum up $z(J_j^\ell, J_k^r)$ for all job occurrences J_k^r having at least one segment that intersects with I (including J_j^ℓ itself). Let $R(J_j^\ell, I)$ be the set of job occurrences that have a segment intersecting the right endpoint of I (including J_j^ℓ itself). We note that it suffices to sum up $z(J_j^\ell, J_k^r)$ only for job occurrences $J_k^r \in R(J_j^\ell, I)$ and then multiply the total sum by 2. This is because, for the intersecting segment I of J_j^ℓ and segment I' of J_k^r, if the right endpoint of I precedes the right endpoint of I', then $J_k^r \in R(J_j^\ell, I)$; otherwise, $J_j^\ell \in R(J_k^r, I')$. Since $z(J_j^\ell, J_k^r) = z(J_k^r, J_j^\ell)$, each of them contributes the same value to the other. Therefore, it follows that

$$\sum_{j=1}^{n} \sum_{\ell=1}^{|\mathcal{L}_j|} \left(z(J_j^\ell, J_j^\ell) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} z(J_j^\ell, J_k^r) \right) \leq 2 \sum_{j=1}^{n} \sum_{\ell=1}^{|\mathcal{L}_j|} \sum_{I \in \mathcal{I}(J_j^\ell)} \sum_{J_k^r \in R(J_j^\ell, I)} z(J_j^\ell, J_k^r). \tag{4}$$

By the first constraint in (P), the definition of job cliques and the definition of $z(J_j^\ell, J_k^r)$, we have

$$\sum_{J_k^r \in R(J_j^\ell, I)} z(J_j^\ell, J_k^r) \leq \; x^\ell(j) \cdot \sum_{J_k^r \in R(J_j^\ell, I)} x^r(k) \leq x^\ell(j). \tag{5}$$

Using (4), (5), and the fact that $|\mathcal{I}(J_j^\ell)| \leq m$, we get that

$$\sum_{j=1}^{n} \sum_{\ell=1}^{|\mathcal{L}_j|} \left(z(J_j^\ell, J_j^\ell) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} z(J_j^\ell, J_k^r) \right) \leq 2 \sum_{j=1}^{n} \sum_{\ell=1}^{|\mathcal{L}_j|} \sum_{I \in \mathcal{I}(J_j^\ell)} x^\ell(j) \leq 2m \sum_{j=1}^{n} \sum_{\ell=1}^{|\mathcal{L}_j|} x^\ell(j).$$

Hence, there exists a job occurrence J_j^ℓ satisfying

$$z(J_j^\ell, J_j^\ell) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} z(J_j^\ell, J_k^r) = (x^\ell(j))^2 + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} x^r(k)x^\ell(j) \leq 2m \cdot x^\ell(j).$$

By factoring out $x^\ell(j)$ from both sides we get inequality (3).

To complete the proof of the lemma, we note that for a job J_j^ℓ satisfying (3) it also holds that

$$x^\ell(j) + \sum_{J_k^r \in \tilde{N}(J_j^\ell)} x^r(k) = x^\ell(j) + \sum_{J_k^r \in \tilde{N}_1(J_j^\ell)} x^r(k) + \sum_{J_k^r \in \tilde{N}_2(J_j^\ell)} x^r(k) \leq 2m + \sum_{r=1}^{|\mathcal{L}_j|} x^r(j) \leq 2m+1.$$

The last inequality follows from the second constraint in (P). ◀

Proof of Lemma 14. It is easy to see that the most time consuming part is the loop defined in Step 4 where we enumerate over all subsets of $\mathcal{L}$ of size at most $\frac{12}{\varepsilon}$ and thus the time complexity. ◀

Maximizing the Correlation: Extending Grothendieck's Inequality to Large Domains

Abstract

Correlation Clustering is an elegant model where given a graph with edges labeled + or −, the goal is to produce a clustering that agrees the most with the labels: + edges should reside within clusters and − edges should cross between clusters. In this work we study the MaxCorr objective, aiming to find a clustering that maximizes the difference between edges classified correctly and incorrectly. We focus on the case of bipartite graphs and present an improved approximation of 0.254, improving upon the known approximation of 0.219 given by Charikar and Wirth [FOCS'2004] and going beyond the 0.2296 barrier imposed by their technique. Our algorithm is inspired by Krivine's method for bounding Grothendieck's constant, and we extend this method to allow for more than two clusters in the output. Moreover, our algorithm leads to two additional results: (1) the first known approximation guarantees for MaxCorr where the output is constrained to have a bounded number of clusters; and (2) a natural extension of Grothendieck's inequality to large domains.

1 Introduction

Correlation Clustering is a classic model, where given objects and possibly inconsistent pairwise similarity (or dissimilarity) information regarding the objects, the goal is to cluster the objects in a way that agrees the most with the given information. Since its introduction by Bansal et al. [7] close to two decades ago, Correlation Clustering has found numerous practical applications in a wide range of settings: image segmentation [35], cross-lingual link detection [33], clustering gene expression patterns [5, 8], coreference resolution [14, 15, 28] and aggregating inconsistent clusterings [18], to name a few (refer to the survey [35] and the references therein for additional details). Moreover, from a theoretical perspective it can be shown that Correlation Clustering captures classic graph cuts problems, including Min $s-t$ Cut, Multiway Cut and Multicut.

Formally, in Correlation Clustering we are given an undirected graph $G = (V, E)$ equipped with non-negative edge weights $w : E \to \mathbb{R}_+$. Additionally, each edge is labeled either with a + or a −, where + indicates similarity and − indicates dissimilarity. We consider E to be the disjoint union of E^+ (all edges labeled +) and E^- (all edges labeled −). Intuitively, two nodes connected by a + edge (− edge) are said to be similar (dissimilar) and the weight of the edge quantifies the strength of the similarity (dissimilarity) between the

two nodes. A *clustering* of the graph is a partition $\mathcal{C} = \{S_1, \ldots, S_\ell\}$ of V, for some ℓ, where each S_i is called a cluster. Two nodes u and v are in *agreement* with respect to a clustering $\mathcal{C}$ if $(u,v) \in E^+$ (or $(u,v) \in E^-$) and u and v belong to the same cluster (different clusters), and are in *disagreement* otherwise.

The above leads to three natural objectives, which were introduced in the original paper of Bansal *et. al.* [7], measuring the compliance of a clustering $\mathcal{C}$ with the input: MaxAgree, MinDisagree and MaxCorr. Given a clustering $\mathcal{C}$, the first objective aims to maximize the total weight of edges that are in agreement, the second objective aims to minimize the total weight of edges that are in disagreement, and the third objective combines the previous two objectives and aims to maximize the difference between the total weight of edges in agreement and disagreement. Formally, given a clustering $\mathcal{C}$ the MaxCorr objective value of $\mathcal{C}$ is denoted by $\text{Corr}(\mathcal{C})$ and is defined as follows: $\text{Corr}(\mathcal{C}) \triangleq \text{Agree}(\mathcal{C}) - \text{DisAgree}(\mathcal{C})$, where:

$$\text{Agree}(\mathcal{C}) = \sum_{(u,v)\in E^+:\mathcal{C}(u)=\mathcal{C}(v)} w_{u,v} + \sum_{(u,v)\in E^-:\mathcal{C}(u)\neq\mathcal{C}(v)} w_{u,v}$$

$$\text{DisAgree}(\mathcal{C}) = \sum_{(u,v)\in E^+:\mathcal{C}(u)\neq\mathcal{C}(v)} w_{u,v} + \sum_{(u,v)\in E^-:\mathcal{C}(u)=\mathcal{C}(v)} w_{u,v}.$$

In the above $\mathcal{C}(u)$ denotes the cluster in $\mathcal{C}$ that u belongs to. The goal is to find a clustering $\mathcal{C}$ that maximizes $\text{Corr}(\mathcal{C})$.[1] A generalization of MaxCorr, denoted by Max-k-Corr, is where we are also given as input a parameter k that upper bounds the possible number of clusters in $\mathcal{C}$.

All the above objectives have been extensively studied for almost two decades for important special cases, such as bipartite graphs [1, 5, 6, 12], complete unweighted graphs [7, 10] and weights satisfying specific constraints [2, 12], as well as general graphs [10, 11, 17, 32]. The more general problem where the number of clusters is bounded has also been studied, e.g., [7, 16, 20, 24, 6]. From a practical perspective, the study of clustering of bipartite graphs was motivated by numerous applications, such as gene expression and biological data analysis [13, 27], and data mining applications [36].

The only known algorithm for MaxCorr is given by Charikar and Wirth [11] who elegantly reduced the problem to maximizing a quadratic form. We denote the latter by Max Quad: given a matrix $B \in \mathbb{R}^{n\times n}$ find $\mathbf{x} \in \{\pm 1\}^n$ maximizing $\mathbf{x}^T B \mathbf{x}$.[2] The algorithm of [11] works as follows (for simplicity of presentation we assume that $V = \{1, \ldots, n\}$): First, set $B_{i,j}$ to be $w_{i,j}$ if $(i,j) \in E^+$, $-w_{i,j}$ if $(i,j) \in E^-$ (and 0 otherwise) and approximately solve $\max_{\mathbf{x}\in\{\pm1\}^n}\{\mathbf{x}^T B\mathbf{x}\}$. Second, consider the clustering $\mathcal{C}_1 = \{S_1, S_2\}$ defined by $\mathbf{x}$: $S_1 = \{i : x_i = 1\}$ and $S_2 = \{i : x_i = -1\}$. Third, consider the clustering $\mathcal{C}_2 = \{S_1, \ldots, S_n\}$ of V into singletons, where $S_i = \{i\}$. Finally, return the best from $\mathcal{C}_1$ and $\mathcal{C}_2$, i.e., $\max\{\text{Corr}(\mathcal{C}_1), \text{Corr}(\mathcal{C}_2)\}$. [11] proved that if there exists an α approximation algorithm for Max Quad, the above reduction provides an approximation of $\alpha/(2+\alpha)$ for MaxCorr. Since Max Quad is known to have a logarithmic approximation [11, 31], i.e., $\alpha = \Omega(1/\log n)$, this results in an approximation of $\Omega(1/\log n)$ for MaxCorr on general graphs.

We note that using the above exact same reduction, one can implicitly deduce an improved approximation algorithm for MaxCorr for bipartite graphs by simply substituting the approximation algorithm for Max Quad with one for maximizing a bipartite quadratic form.

---

[1] Equivalently one can formulate MaxCorr without the edge labels by negating the weight of $-$ edges and then maximizing the total weight of edges inside clusters minus the total weight of edges that cross between clusters.

[2] It is assumed that the diagonal of B is all zeros, i.e., $B_{i,i} = 0$ for every $i = 1, \ldots, n$.

We denote the latter by Max BiQuad: given $A \in \mathbb{R}^{n\times m}$ find $\mathbf{x} \in \{\pm 1\}^n$ and $\mathbf{y} \in \{\pm 1\}^m$ maximizing $\mathbf{x}^T A\mathbf{y}$.[3] Specifically, assuming G is a bipartite graph containing n vertices on one side and m vertices on the other, instead of the previously defined B consider a matrix $A \in \mathbb{R}^{n\times m}$ as follows: $A_{i,j}$ is set to $w_{i,j}$ if $(i,j) \in E^+$, $-w_{i,j}$ if $(i,j) \in E^-$ and 0 otherwise. Given A, approximately solve the instance of Max BiQuad defined by A, i.e., $\max_{\mathbf{x}\in\{\pm1\}^n,\mathbf{y}\in\{\pm1\}^m}\{\mathbf{x}^T Ay\}$. The rest of [11]'s reduction remains unchanged. One can easily verify that the overall approximation guarantee of the reduction remains as before. Max BiQuad is known to have an approximation of ≈ 0.5611 [4, 26] that follows from Grothendieck's inequality, resulting in an improved approximation of $0.5611/(2+0.5611) = 0.219$ for MaxCorr when G is a bipartite graph.[4]

To the best of our knowledge, no other approximation algorithm for MaxCorr besides Charikar and Wirth [11] is known, both for general and bipartite graphs. It is important to note that when restricting attention to bipartite graphs, the algorithm of [11] imposes an intrinsic barrier of 0.2296 that follows from lower bounds on Grothendieck's constant K_G (see Section 1.2 for more details). Thus, it seems there is no much room to improve the current 0.219 approximation using [11]'s approach. Moreover, no approximation is known for Max-k-Corr, even when considering bipartite graphs. The reason for the latter is that the algorithm of [11] might output n singleton clusters, thus violating the bound k on the number of clusters. The only exception is Max-2-Corr, which coincides with Max Quad and Max BiQuad for general and bipartite graphs, respectively.

Grothendieck's Inequality with Large Domains

Our work closely relates to Grothendieck's inequality. This classic inequality, first presented in [21], states that there is a universal constant K_G such that for every matrix $A \in \mathbb{R}^{n\times m}$ (recall that S^d denotes the Euclidean unit sphere in $\mathbb{R}^{d+1}$):

$$\max_{\{\mathbf{u}_i\}_{i=1}^n \cup \{\mathbf{v}_j\}_{j=1}^m \subseteq S^{n+m-1}} \left\{ \sum_{i=1}^n \sum_{j=1}^m A_{i,j} \langle \mathbf{u}_i, \mathbf{v}_j \rangle \right\} \leq K_G \cdot \max_{\mathbf{x}\in\{\pm1\}^n,\mathbf{y}\in\{\pm1\}^m} \left\{ \sum_{i=1}^n \sum_{j=1}^m A_{i,j} x_i y_j \right\}.$$

The problem of bounding K_G, both upper and lower bounds, has been studied for more than half a century [9, 21, 26, 29, 30]. Specifically, upper bounding K_G is typically achieved by providing an approximation algorithm for Max BiQuad that rounds a fractional solution to the natural semi-definite relaxation: each x_i and y_j is assigned a unit vector $\mathbf{u}_i$ and $\mathbf{v}_j$ respectively and $x_i y_j$ is replaced with $\langle \mathbf{u}_i, \mathbf{v}_j \rangle$. Intuitively, K_G^{-1} can be viewed as the integrality gap of this relaxation.

One can easily note that the existence of a $1/\beta_k$ approximation for Max-k-Corr for bipartite graphs, that is based on rounding the natural semi-definite relaxation (see Section 2), implies a generalization of Grothendieck's inequality to larger domains. This generalization states that there exists an α_k, where $\alpha_k \leq \beta_k$, such that for every matrix $A \in \mathbb{R}^{n\times m}$,

$$\max_{\{\mathbf{u}_i\}_{i=1}^n \cup \{\mathbf{v}_j\}_{j=1}^m \in \mathcal{P}_k} \left\{ \sum_{i=1}^n \sum_{j=1}^m A_{i,j} \frac{(2(k-1)\langle \mathbf{u}_i, \mathbf{v}_j \rangle - (k-2))}{k} \right\} \leq$$
$$\alpha_k \cdot \max_{\mathbf{x}\in[k]^n,\mathbf{y}\in[k]^m} \left\{ \sum_{i=1}^n \sum_{j=1}^m A_{i,j} s(x_i, y_j) \right\}.$$

[3] Both problems, Max BiQuad and Max Quad, are known to be NP-hard [4, 11].

[4] Braverman et al. [9] showed an improvement over 0.5611 by a very small absolute constant, thus one can in fact obtain an approximation for MaxCorr in bipartite graphs that is slightly better than 0.219.

In the above $\mathcal{P}_k$ is defined as follows: $\mathcal{P}_k \triangleq \{\mathcal{U} \subseteq S^{n+m-1} : \langle \mathbf{u}, \mathbf{v} \rangle \geq -1/(k-1)\ \forall \mathbf{u}, \mathbf{v} \in \mathcal{U}\}$, s is the signed indicator function, i.e., $s(x_i, y_j) = 1$ if $x_i = y_j$ and $s(x_i, y_j) = -1$ if $x_i \neq y_j$, and $[k] = \{0, \ldots, k-1\}$. It is important to note that when $k = 2$ the above inequality reduces to the classic Grothendieck's inequality since $\mathcal{P}_2$ only enforces that all vectors $\{\mathbf{u}_i\}_{i=1}^n$ and $\{\mathbf{v}_j\}_{j=1}^m$ are unit vectors. Thus, Grothendieck's original inequality corresponds to the case where the size of the domain is 2. Hence, for larger values of k the above inequality can be viewed as an extension of Grothendieck's original inequality to larger domains. To the best of our knowledge, such an extension was not considered in the past. A special case of particular interest of the above extended inequality, in addition to the case $k = 2$, is when $k \to \infty$. In this case the above extended inequality reduces to:

$$\max_{\{\mathbf{u}_i\}_{i=1}^n \cup \{\mathbf{v}_j\}_{j=1}^m \in \mathcal{P}_\infty} \left\{ \sum_{i=1}^n \sum_{j=1}^m A_{i,j} \left(2 \langle \mathbf{u}_i, \mathbf{v}_j \rangle - 1\right) \right\} \leq \alpha_\infty \cdot \max_{\mathbf{x} \in [n+m]^n, \mathbf{y} \in [n+m]^m} \left\{ \sum_{i=1}^n \sum_{j=1}^m A_{i,j} s(x_i, y_j) \right\},$$

where $\mathcal{P}_\infty$ only enforces that all vectors are unit and in the positive orthant. This case is interesting since one can easily observe that if MaxCorr admits an approximation of $1/\beta$ for bipartite graphs, that is based on rounding the natural semi-definite relaxation (see Section 2), then $\alpha_\infty \leq \beta$.

CSP Over Large Domains

We note that MaxCorr and Max-k-Corr can be equivalently cast as a constraint satisfaction problem over a large domain with negative payoffs. Specifically, when considering bipartite graphs, we are given variables $x_1, \ldots, x_n, y_1, \ldots, y_m$, and weighted equality/inequality constraints containing exactly two variables per constraint (one from each type), i.e., $x_i = y_j$ or $x_i \neq y_j$. Given an assignment of values from the domain $[k]$ to each of the variables, the value of a constraint is its weight if it is satisfied and the negation of its weight if it is unsatisfied. The goal is to find an assignment maximizing the sum of values of the constraints. The above equivalence obviously applies to general graphs as well. CSP over large (non-binary) domains was studied, for example, by Guruswami and Raghavendra [22] (see the references therein for additional related work). Moreover, the classic problem of Max k-Cut, studied by Frieze and Jerum [19], is also a CSP (or equivalently a clustering problem) over a domain of size k.

1.1 Our Results

In this work we focus on MaxCorr and Max-k-Corr in bipartite graphs. We obtain the following main result for MaxCorr.

▶ **Theorem 1.** *There exists a polynomial-time* 0.254*-approximation algorithm for the problem of* MaxCorr *on bipartite graphs.*

There are three important things to note regarding Theorem 1. First, it improves upon the previously known approximation of 0.219 of Charikar and Wirth [11]. Second, it goes beyond the 0.2296 barrier which is intrinsic to the algorithm of [11] and follows from lower bounds on Grothendieck's constant K_G (see Section 1.2 for more details). Third, our algorithm that proves Theorem 1 produces at most three clusters, whereas the optimal solution might have any number of clusters.

We show how our main algorithm can be adapted to handle any bound k on the number of clusters. This results in an approximation factor that for $k = 2$ equals Krivine's [4, 26] guarantee of 0.5611, gracefully degrades as k increases, and reaches the guarantee of 0.254 of Theorem 1 for unbounded k (see Table 1 for approximation guarantees for some values of k). To the best of our knowledge, no previous approximation for Max-k-Corr for bipartite graphs is known. Similarly to Theorem 1, the number of clusters produced by our algorithm for Max-k-Corr in bipartite graphs does not exceed four, regardless of how many clusters are in the optimal solution. Moreover, allowing our algorithms to produce more clusters than four is not beneficial.

Table 1 Approximation for Max-k-Corr.

k	2	3	4	5	6	10
approximation	0.561	0.397	0.348	0.32	0.309	0.285

The above approximation guarantees of MaxCorr and Max-k-Corr for bipartite graphs lead to the following results regarding α_∞ and α_k for the extension of Grothendieck's inequality to large domains.

▶ **Theorem 2.** *α_k is a universal constant for every $k \geq 2$. Moreover, α_∞ is also a universal constant.*

The specific values of the bounds on α_∞ and α_k can be derived directly from our approximation factors and integrality gaps.

1.2 Our Techniques

The existing approach for approximating MaxCorr in bipartite graphs, i.e., the reduction of Charikar and Wirth [11], poses two difficulties. The first main difficulty is that this approach most likely cannot provide a much better approximation than its promised 0.219 guarantee. Recall that its approximation equals $\alpha/(2+\alpha)$, where α is the known approximation for Max BiQuad. It can be shown that the dependence on α in the approximation is tight, i.e., [11]'s algorithm cannot provide an approximation better than $\alpha/(2+\alpha)$. Thus, improving this algorithm requires improving α, a task that most likely will improve Grothendieck's constant K_G as well. Moreover, the known lower bound of $\beta = 1.6769$ on K_G [29] yields that [11]'s approach cannot provide an approximation better than $(1/\beta)/(2+1/\beta) \approx 0.2296$ for MaxCorr on bipartite graphs. The latter is true since the only known method for approximating Max BiQuad uses the standard semi-definite relaxation whose integrality gap is exactly K_G^{-1}. We note that our guarantee of 0.254 in Theorem 1 goes beyond this 0.2296 barrier that is inherent to the approach of [11]. The second main difficulty is that the approach of Charikar and Wirth [11] results in an algorithm that might produce up to n clusters. Therefore, it cannot be applied to Max-k-Corr as it violates the constraint on the number of clusters k in the output.

To eschew the above difficulties, we adopt an approach that is inspired by Krivine's result for bounding K_G [26]. This approach is based on transforming two collections of disjoint vectors in such a way that allows random hyperplane rounding to be successful even when negative values are present in the objective function. We first show that a straightforward adaptation of this method yields an approximation of 0.198 for MaxCorr on bipartite graphs. To obtain our main result for MaxCorr we show that it suffices to extend Krivine's method to only three clusters and present suitable transformations to this end. Focusing on Max-k-Corr we require more subtlety, as we build upon and adapt our two algorithms for

MaxCorr which are based on Krivine's method (the straightforward adaptation as well as the three cluster extension). We note that allowing our algorithms to produce more than four clusters is not beneficial.

1.3 Related Work

Many variants of Correlation Clustering were presented and studied throughout the years, both from theoretical and practical perspectives. We present here only some of the more relevant previous work. For general graphs, [7, 32] presented a 0.766-approximation for MaxAgree, [10, 17] presented an $O(\log n)$ approximation for MinDisagree, [11] presented an $\Omega(1/\log n)$ approximation for MaxCorr (while [3] presented a more refined guarantee of $\Omega(1/\log(\vartheta(\bar{G})))$).

For complete unweighted graphs, Bansal *et al.* [7] presented a PTAS for MaxAgree, a constant factor approximation for MinDisagree, and a simple 3-approximation for MinDisagree restricted to two clusters. The approximation factor for MinDisagree was continually improved by Charikar et al. [10] to 4, Ailon et al. [2] to 2.5 and by Chawla et al. [12] to $2.06 - \varepsilon$. Moreover, Giotis et al. [20] presented a PTAS for MaxAgree and MinDisagree when the number of clusters is restricted to a constant k.

Focusing on bipartite graphs, Asteris et al. [6] presented a PTAS for MaxAgree on complete bipartite graphs, even when the number of clusters is restricted. Amit [5] presented a 11-approximation algorithm for MinDisagree on complete bipartite graphs. The latter was subsequently improved by [1] to a factor of 4 and by [12] to a factor of 3.

In the context of Grothendieck's Inequality, numerous studies were conducted. For bounding K_G, Grothendieck [21] showed that $\frac{\pi}{2} \leq K_G \leq \sinh(\frac{\pi}{2})$. Later on, Reeds [29] presented a lower bound of 1.6769. The upper bound was also improved by Rietz [30] to 2.261 and by Krivine [26] to 1.78821 who conjectured that this is the correct number. Many years later, Braverman et al. [9] showed that Krivine's bound is not the correct answer for K_G, by slightly improving the upper bound. These days, the value of K_G is still unknown. Many extensions of Grothendieck's Inequality were presented and studied, e.g., [3, 25]. In addition, Nesterov [34] presented a $(2/\pi)$-approximation for Max Quad for the special case the matrix A is positive semi-definite.

2 Semi-Definite Relaxations for MaxCorr and Max-k-Corr

In this section we present natural semi-definite programming relaxations for both MaxCorr and Max-k-Corr. These relaxation apply to both general and bipartite graphs. Focusing first on MaxCorr, we consider the following natural semi-definite programming formulation, denoted by SDP, which assigns to each vertex u a unit vector y_u.

$$\begin{aligned} \max \quad & \sum_{(u,v)\in E^+} w_{u,v} \cdot (2y_u \cdot y_v - 1) + \sum_{(u,v)\in E^-} w_{u,v} \cdot (1 - 2y_u \cdot y_v) && (1)\\ \text{s.t.} \quad & y_v \cdot y_v = 1 && \forall v \in V \\ & y_u \cdot y_v \geq 0 && \forall u, v \in V \end{aligned}$$

In the following lemma, we prove that (1) is a relaxation[5] for the MaxCorr problem.

▶ **Lemma 3.** *Let* $\mathrm{OPT}_{\mathrm{SDP}}$ *be the optimum value of* (1)*, and* OPT *be the value of the optimal clustering. Then it holds that* $\mathrm{OPT}_{\mathrm{SDP}} \geq \mathrm{OPT}$.

[5] The integrality gap of this relaxation is discussed in Appendix C.

Proof. Given an optimal solution $\mathcal{C}_{\text{OPT}}$, we can assign each y_v to be a standard unit vector in $\mathbb{R}^n$, while a pair of vectors y_u, y_v will be the same unit vector if and only if u and v are in the same cluster in $\mathcal{C}_{\text{OPT}}$. This way, all the constrains are satisfied: for each $v \in V$ we have that $y_v \cdot y_v = 1$, and for each $u, v \in V$ it holds that $y_u \cdot y_v \in \{0, 1\}$. Moreover, the value of this solution for the SDP formulation is the same as $\text{Corr}(\mathcal{C}_{\text{OPT}})$: for a plus edge (u, v), if u and v are in the same cluster in $\mathcal{C}_{\text{OPT}}$, then $y_u \cdot y_v = 1$ and so it contributes $w_{u,v}$. If they are in different cluster, then $y_u \cdot y_v = 0$ and the edge contributes $-w_{u,v}$ to the objective function. Similar argument can be placed for the minus edges. Therefore, it holds that $\text{OPT}_{\text{SDP}} \geq \text{OPT}$. ◀

Recall that in Max-k-Corr the output can contain at most k clusters. Therefore, focusing on Max-k-Corr we consider the following natural semi-definite formulation, inspired by the work of Karger *et. al.* on 3-Coloring [23], which we denote by SDP_k:

$$\begin{aligned} \max \quad & \sum_{(u,v)\in E^+} w_{u,v}\left(\frac{2(k-1)}{k} y_u \cdot y_v - \frac{k-2}{k}\right) + \sum_{(u,v)\in E^-} w_{u,v}\left(\frac{k-2}{k} - \frac{2(k-1)}{k} y_u \cdot y_v\right) \\ \text{s.t.} \quad & y_v \cdot y_v = 1 && \forall v \in V \\ & y_u \cdot y_v \geq -1/(k-1) && \forall u, v \in V \end{aligned} \tag{2}$$

One may observe, that if we are limited to two clusters only, i.e., $k = 2$, then SDP_2 is exactly the standard semi-definite relaxation for both Max Quad and Max BiQuad (as in Grothendieck's inequality). Moreover, when $k \to \infty$, namely k is large enough such that Max-k-Corr becomes MaxCorr, SDP_∞ becomes the relaxation for MaxCorr. Similarly to MaxCorr, we prove the following lemma which shows that (2) is indeed a relaxation for the problem of Max-k-Corr.

▶ **Lemma 4.** *Let* $\text{OPT}_{\text{SDP}_k}$ *be the optimum value of* (2)*, and* OPT_k *be the value of the optimal clustering with at most* k *clusters. Then it holds that* $\text{OPT}_{\text{SDP}_k} \geq \text{OPT}_k$.

Proof. Given an optimal solution with at most k clusters, $\mathcal{C}_{\text{OPT}}$, we construct the following fractional solution. Let $v_1, \ldots, v_k$ be the vectors that form the $k-1$-regular simplex centered at the origin. We know that $v_1 + \cdots + v_k = 0$, and therefore

$$0 = \|v_1 + \cdots + v_k\|^2 = \sum_{i=1}^{k} v_i \cdot v_i + \sum_{i \neq j} v_i \cdot v_j = k + \sum_{i \neq j} v_i \cdot v_j.$$

Since the vertices of the regular simplex are in equal distance from each other, it must be the case that $v_i \cdot v_j = -1/(k-1)$ for all $i \neq j$. One can show that this is the most efficient solution, in terms of maximizing the minimum distance between k points on the Euclidean unit sphere.

Let us assign the vectors $\{y_v\}_{v\in V}$ to the vectors $v_1, \ldots, v_k$ where $y_u = y_v$ iff u and v are in the same cluster in $\mathcal{C}_{\text{OPT}}$. One can see that if $y_u \cdot y_v = 1$, it holds that

$$\frac{2(k-1)}{k} y_u \cdot y_v - \frac{k-2}{k} = \frac{2k-2-k+2}{k} = 1,$$

and if $y_u \cdot y_v = -1/(k-1)$, then it holds that

$$\frac{2(k-1)}{k} y_u \cdot y_v - \frac{k-2}{k} = \frac{-2-k+2}{k} = -1.$$

Hence, the value of the objective of (2) with this fractional solution equals the value of the integral solution. Thus, $\text{OPT}_{\text{SDP}_k} \geq \text{OPT}_k$. ◀

3 Approximation Algorithms for MaxCorr

In this section we present our approximation algorithms for MaxCorr on bipartite graphs, thus proving Theorem 1. First, for simplicity of presentation, we show that a straightforward adaptation of Krivine's method to SDP yields an approximation of 0.198. Second, we present an improved algorithm that achieves the guarantee of Theorem 1 by extending Krivine's method to more than two clusters.

3.1 Case Study: A Simple Two Clusters Algorithm

In this section we present a straightforward adaptation of Krivine's method to round SDP that produces at most two clusters. Denote by $V = V_1 \cup V_2$ the two sides of the graph and by n the total number of vertices in V. Let $A \in \mathbb{R}^{n \times n}$ be the matrix of the solution of (1). That is, $A_{i,j} = y_i \cdot y_j$ for all $i, j \in V$. Given a solution A, we can construct the corresponding vectors $\{y_v\}_{v \in V}$ in polynomial time. Additionally, we note that (1) can be solved, in polynomial time, and the value of the solution will be far from the optimum up to some additive error which is arbitrarily small.

Algorithm 1 Two Clusters Algorithm.

Input: $G = (V_1, V_2, E)$ and $w : E \to \mathbb{R}$
Output: clustering $\mathcal{C}$

1 Solve (1) for G and w to obtain a positive semi-definite matrix $A \in \mathbb{R}^{n \times n}$.
2 Define $\tilde{A} \in \mathbb{R}^{n \times n}$ as follows: $\tilde{A}_{i,j} \leftarrow \begin{cases} f(A_{i,j}) & \text{if } i \text{ and } j \text{ in different sides of } V \\ g(A_{i,j}) & \text{otherwise} \end{cases}$
3 Find vectors $\{\tilde{y}_i\}_{i \in V}$ s.t.: $\tilde{y}_i \cdot \tilde{y}_j = \tilde{A}_{i,j}$ $\forall i, j \in V$ (via Cholesky decomposition of $\tilde{A}$).
4 Choose z uniformly at random from S^{n-1}.
5 Set $C_1 \leftarrow \{i \in V : \tilde{y}_i \cdot z \geq 0\}$ and $C_2 \leftarrow \{i \in V : \tilde{y}_i \cdot z < 0\}$.
6 Return $\mathcal{C} = \{C_1, C_2\}$.

Next, we show how to choose the transformation functions f and g, and prove that the algorithm achieves the desired approximation factor. Specifically, we prove that it suffices to choose:

$$f(x) \triangleq \sin(c\pi x)\cos(\frac{c\pi}{2}) - \cos(c\pi x)\sin(\frac{c\pi}{2})$$
$$g(x) \triangleq \sinh(c\pi x)\cos(\frac{c\pi}{2}) + \cosh(c\pi x)\sin(\frac{c\pi}{2}),$$

where c is the solution to the equation $\sinh(c\pi)\cos(\frac{c\pi}{2}) + \cosh(c\pi)\sin(\frac{c\pi}{2}) = 1$. The reader is referred to Appendix A for the complete analysis.

3.2 Producing More Clusters – Better Approximation

Algorithm 1 always clusters the graph into at most two clusters while ignoring the fact that the optimal solution might contain a larger number of clusters. Building upon Algorithm 1, we present an algorithm that clusters the graph into at most three clusters. Though this seems like only a minor change, it enables us to improve the approximation factor to 0.254, well beyond the 0.2296 barrier of the approach of Charikar and Wirth [11].

We note that Algorithm 2 differs from Algorithm 1 since it uniformly at random picks one of the two initial clusters and splits it again using another independent random hyperplane. This subtle change incurs a significant change in the choice of f and g, as will be evident

Algorithm 2 Three Clusters Algorithm.

Input: $G = (V_1, V_2, E)$ and $w : E \to \mathbb{R}$
Output: clustering $\mathcal{C}$

Solve (1) for G and w to obtain a positive semi-definite matrix $A \in \mathbb{R}^{n \times n}$.
Define $\tilde{A} \in \mathbb{R}^{n \times n}$ as follows: $\tilde{A}_{i,j} \leftarrow \begin{cases} f(A_{i,j}) & \text{if } i \text{ and } j \text{ in different sides of } V \\ g(A_{i,j}) & \text{otherwise} \end{cases}$
Find vectors $\{\tilde{y}_i\}_{i \in V}$ s.t.: $\tilde{y}_i \cdot \tilde{y}_j = \tilde{A}_{i,j}\ \forall i, j \in V$ (via Cholesky decomposition of $\tilde{A}$).
Choose z and z' independently and uniformly from S^{n-1}.
Set $C' \leftarrow \{i \in V : \tilde{y}_i \cdot z \geq 0\}$ and $C'' \leftarrow \{i \in V : \tilde{y}_i \cdot z < 0\}$.
Let C_1 be a uniform random cluster from C' and C'', and C the remaining cluster.
Set $C_2 \leftarrow \{i \in C : \tilde{y}_i \cdot z' \geq 0\}$ and $C_3 \leftarrow \{i \in C : \tilde{y}_i \cdot z' < 0\}$.
Return $\mathcal{C} = \{C_1, C_2, C_3\}$.

from the analysis. Furthermore, this subtle change also makes the analysis more challenging, compared to Krivine's original method. The reason is that the separation probability of two vectors is quadractically dependent on the angle between them, as opposed to linear dependency in Krivine's original method. In order to analyze this algorithm, we first calculate the probability that two vertices will be in the same cluster.

▶ **Lemma 5.** *Let $u, v \in V$ whose corresponding vectors are $\tilde{y}_u, \tilde{y}_v$ respectively. Then,*

$$\Pr[u, v \text{ are in the same cluster}] = \frac{1}{2}\left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right) + \frac{1}{2}\left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right)^2.$$

Proof. If u and v are in different clusters after splitting V into C' and C'', then u and v will remain apart. Otherwise, with probability $1/2$ we will choose to split their cluster, and then the chance of separating u and v is the same as before. That is,

$$\Pr[u, v \text{ are in the same cluster}] = \left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right) \cdot \left(\frac{1}{2} + \frac{1}{2}\left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right)\right).$$

This concludes the proof. ◀

Similarly to Lemma 11 we have the following lemma. In what follows, $X_{u,v}$ is the random variable denoting the contribution of the edge (u, v) to the value of the output of Algorithm 2.

▶ **Lemma 6.** *For every edge $(u, v) \in E$:*

$$\mathbb{E}[X_{u,v}] = \begin{cases} w_{u,v} \cdot \left(1 - 3 \cdot \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} + \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)^2}{\pi^2}\right) & (u, v) \in E^+ \\ w_{u,v} \cdot \left(3 \cdot \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)^2}{\pi^2} - 1\right) & (u, v) \in E^-. \end{cases}$$

Proof. For every edge $(u, v) \in E^+$:

$$\begin{aligned} \mathbb{E}[X_{u,v}] &= w_{u,v} \cdot \Pr[u, v \text{ are in the same cluster}] - w_{u,v} \cdot (1 - \Pr[u, v \text{ are in the same cluster}]) \\ &= w_{u,v} \cdot \left(2\left(\frac{1}{2}\left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right) + \frac{1}{2}\left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right)^2\right) - 1\right) \\ &= w_{u,v} \cdot \left(1 - 3 \cdot \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} + \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)^2}{\pi^2}\right). \end{aligned}$$

For a minus edge, we can simply multiply the above by -1. ◀

The following lemma lies at the heart of the argument as it provides the existence of suitable transformations f and g.

▶ **Lemma 7.** *There exist functions $f, g : \mathbb{R} \to \mathbb{R}$ and a constant $c \in (0,1)$ such that the matrix $\tilde{A}$ obtained in Algorithm 2 can be decomposed into unit vectors $\{\tilde{y}_v\}_{v\in V}$ in $\mathbb{R}^n$, and these vectors satisfy that for all $(u,v) \in E$:*

$$\begin{cases} \left(1 - 3 \cdot \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} + \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)^2}{\pi^2}\right) = c \cdot (2y_u \cdot y_v - 1) & \text{if } (u,v) \in E^+ \\ \left(3 \cdot \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)^2}{\pi^2} - 1\right) = c \cdot (1 - 2y_u \cdot y_v) & \text{if } (u,v) \in E^-. \end{cases}$$

Proof. We wish to find the appropriate functions f, g and the constant c, that will satisfy the above conditions. That is, we need to solve the equation:

$$\left(1 - 3 \cdot \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} + \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)^2}{\pi^2}\right) = c \cdot (2y_u \cdot y_v - 1)\,.$$

It has two solutions: $\arccos(\tilde{y}_u \cdot \tilde{y}_v) = \frac{1}{2}(3\pi \pm \pi\sqrt{5 - 4c + 8c(y_u \cdot y_v)})$. Therefore, we have two candidates for f: $\cos(\frac{1}{2}(3\pi - \pi\sqrt{5 - 4c + 8cx}))$ and $\cos(\frac{1}{2}(3\pi + \pi\sqrt{5 - 4c + 8cx}))$. We know that $\arccos(x)$ is bounded between 0 and π, and expect that f will satisfy $f(1) > f(0)$, so we dismiss the latter candidate solution and remain with:

$$f(x) = \cos(\frac{1}{2}(3\pi - \pi\sqrt{5 - 4c + 8cx})).$$

Moreover, since $y_u \cdot y_v \geq 0$ and $0 \leq c \leq 1$, it holds that $5 - 4c + 8c(y_u \cdot y_v) \geq 0$ for all u, v and so f is well defined for our case. In fact, we can see that f is well defined for all $x \geq {}^{(4c-5)}/_{(8c)}$. Hence, we consider the Taylor expansion of f at $x = 0$, defined by $p(x) = \sum_{k=0}^{\infty}(k!)^{-1} f^{(k)}(0)x^k$. Let f_k be the coefficient of x^k in $p(x)$. We note that the coefficients depend on the value of c. Thus, $p(x)$ has the following two properties, described in two technical lemmas that are given without a proof.

▶ **Lemma 8** (The convergence radius of p)**.** *The function $f(x)$ is equal to its Taylor series, $p(x)$, for all $x \in (\frac{4c-5}{8c}, -\frac{4c-5}{8c})$, and in particular, $p(x) = f(x)$ for all $x \in [-1,1]$ if $c < 5/12$.*

▶ **Lemma 9** (The signs of the coefficients of p)**.** *For all $c \in (0.25, 0.4)$, it holds that $f_0 < 0$, $f_1 > 0$, $f_2 < 0$ and for all $k \geq 2$, $f_{2k} > 0$ and $f_{2k-1} < 0$.*

Thus, from now on we assume that c is in the range $(0.25, 0.4)$, and can consider the function $f(-x)$. It holds that for all $x \in [-1,1]$,

$$f(-x) = p(-x) = \sum_{k=0}^{\infty} f_{2k}x^{2k} - \sum_{k=0}^{\infty} f_{2k+1}x^{2k+1} = f_0 - f_1 x + f_2 x^2 + \sum_{k=3}^{\infty} |f_k| x^k.$$

Therefore, we conclude that $\sum_{k=0}^{\infty} |f_k| x^k = f(-x) - 2f_0 + 2f_1 x - 2f_2 x^2$. Hence, let us define $g(x) = f(-x) - 2f_0 + 2f_1 x - 2f_2 x^2$. We can prove that $\tilde{A}$ is positive semi-definite, and can be decomposed to the above vectors $\{\tilde{y}_v\}_{v\in V}$ in a similar way to Lemma 13. Next, we wish to find the value of c for which the new vectors $\{\tilde{y}_v\}_{v\in V}$ will be unit vectors. Plugging $x = 1$ in the equation $g(x) = 1$ and then solving for c in the required range, will yield the solution $c \approx 0.254013$. This completes the proof of Lemma 7. ◀

Proof of Theorem 1. According to Lemma 6 and Lemma 7, it follows that Algorithm 2 achieves an approximation of 0.254 for the problem of MaxCorr on bipartite graphs. ◀

As a result from Theorem 1, we obtain an upper bound on α_∞, proving the second part of Theorem 2. Additionally, we note that Algorithm 2 can be slightly improved. If we consider the probability that two vertices will be in the same cluster, we can notice that it is the same as if we split the hyper-sphere with one hyper-plane with probability 1/2, or with two hyper-planes with probability 1/2. Hence, we can find the value of p for which the algorithm that splits the hyper-sphere with one hyper-plane with probability p or with two hyper-planes with probability $1-p$, achieves the best approximation factor (with the above analysis). It turns out that the best p is very close to 1/2, i.e., if we set $p = 0.49$ the approximation factor will be $c \approx 0.2551$. As previously mentioned, allowing the algorithm to produce more than four clusters is not beneficial (refer to Appendix B for additional details).

4 Restricting the Number of Clusters – Approximating Max-k-Corr

In this section we focus on Max-k-Corr, where the solution is constrained to contain at most k clusters. We build upon Algorithms 1 and 2 to obtain our results.

4.1 Two Clusters – Adapting Algorithm 1

We start with adapting Algorithm 1 to Max-k-Corr. It is obvious that this algorithm produces a feasible solution, no matter which transformations f and g we employ, since $k \geq 2$ and it produces at most two clusters. However, since SDP_k changes with k, the original transformations f and g, that were chosen when considering MaxCorr and SDP (equivalently SDP_∞), do not yield a meaningful approximation anymore. Thus, all that remains is to choose these transformations, given k. This is done by requiring that the transformed vectors satisfy the following for every edge $(u,v) \in E$:

$$1 - 2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} = c\left(\frac{2(k-1)}{k} y_u \cdot y_v - \frac{k-2}{k}\right).$$

To satisfy the above we choose f as follows:

$$\begin{aligned} f(x) &= \cos\left(\frac{\pi}{2k}(k + c(k-2) - 2cx(k-1))\right) \\ &= \sin\left(c\pi x\frac{k-1}{k}\right)\cos\left(\frac{c\pi}{2}\frac{k-2}{k}\right) - \cos\left(c\pi x\frac{k-1}{k}\right)\sin\left(\frac{c\pi}{2}\frac{k-2}{k}\right). \end{aligned}$$

Hence, the function g will be:

$$g(x) = \sinh\left(c\pi x\frac{k-1}{k}\right)\cos\left(\frac{c\pi}{2}\frac{k-2}{k}\right) + \cosh\left(c\pi x\frac{k-1}{k}\right)\sin\left(\frac{c\pi}{2}\frac{k-2}{k}\right).$$

The analysis continues the same as in Algorithm 1, and we require for the transformed vectors to be unit vectors, i.e., that $g(1) = 1$. Solving this equation for each value of k, yields the desired approximation factor c. These appear in Table 2 for some values of k.

Table 2 Approximation factors obtained by adapting Algorithm 1 for Max-k-Corr.

k	2	3	4	5	10	50	1000
c	0.5611	0.3441	0.2901	0.2654	0.2269	0.2034	0.1985

We can see that when $k = 2$, we have exactly the constant obtained by Krivine. As k increases the approximation factor gracefully degrades, and when $k \to \infty$ it approaches 0.1985 (the approximation we obtained for MaxCorr with Algorithm 1). Additionally, we note that this result proves the first part of Theorem 2 as it provides upper bounds on α_k for $k \geq 2$.

4.2 More Than Two Clusters – Adapting Algorithm 2

The success of Algorithm 2 implies that allowing more than two clusters in the output might be beneficial. However, adapting this approach, and specifically Algorithm 2, to Max-k-Corr requires much care as the value of k will have a considerable influence on the resulting algorithm and its transformations.

Specifically, given k, we need to choose from the following clustering techniques: (1) two clusters produced by a random hyperplane (similarly to Algorithm 1); (2) three clusters produced by a random hyperplane and then further partioning of one of the clusters by an additional random hyperplane (similarly to Algorithm 2); and (3) four clusters produced by choosing two random hyperplanes. The exact convex combination of these techniques will uniquely dictate the transformations f and g that will ensure the success of the algorithm. We refer the reader to Appendix B for a more detailed discussion of the above, the approximation guarantees obtained for specific values of k, and additional details, e.g., why not use a larger number of hyperplanes to construct a clustering.

A Analysis of Algorithm 1

Lemma 10 is widely known and is given without proof (see, e.g., [3]).

▶ **Lemma 10.** *Let y_u, y_v be two unit vectors in $\mathbb{R}^n$ and z be a random unit vector chosen uniformly from S^{n-1}. Then,*

$$\Pr[\text{sign}(y_u \cdot z) = \text{sign}(y_v \cdot z)] = 1 - \frac{\arccos(y_u \cdot y_v)}{\pi}.$$

▶ **Lemma 11.** *Let $\tilde{y}_u, \tilde{y}_v$ be the vectors representing u and v respectively. Additionally, denote by $X_{u,v} = w_{u,v} \cdot \text{sign}(\tilde{y}_u \cdot z)\text{sign}(\tilde{y}_v \cdot z)$ the random variable that represents the contribution of the edge (u, v) to the value of the solution. Therefore,*

$$\mathbb{E}[X_{u,v}] = \begin{cases} w_{u,v}\left(1 - 2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right) & (u,v) \in E^+ \\ w_{u,v}\left(2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} - 1\right) & (u,v) \in E^-. \end{cases}$$

Proof. From Algorithm 1, we can see that that two vertices u, v will be in the same cluster if and only if $\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)$. Therefore, for every plus edge $(u, v) \in E^+$,

$$\begin{aligned} \mathbb{E}[X_{u,v}] &= w_{u,v} \Pr[\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)] + (-1)w_{u,v}(1 - \Pr[\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)]) \\ &= w_{u,v}(2 \Pr[\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)] - 1). \end{aligned}$$

Additionally, for every minus edge $(u, v) \in E^-$,

$$\begin{aligned} \mathbb{E}[X_{u,v}] &= w_{u,v}(1 - \Pr[\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)]) + (-1)w_{u,v} \Pr[\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)] \\ &= w_{u,v}(1 - 2 \Pr[\text{sign}(\tilde{y}_u \cdot z) = \text{sign}(\tilde{y}_v \cdot z)]) \end{aligned}$$

Consequently, we can use Lemma 10 to complete this proof. ◀

The following corollary is immediate from linearity of expectation.

▶ **Corollary 12.** *Let X_{ALG} be the value of the output of Algorithm 1 . Then*

$$\mathbb{E}[X_{ALG}] = \sum_{(u,v)\in E^+} w_{u,v}\left(1 - 2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right) + \sum_{(u,v)\in E^-} w_{u,v}\left(2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} - 1\right).$$

Proof. Follows directly from Lemma 11 and the linearity of expectation. ◀

The following lemma lies at the heart of the argument as it proves the existence of suitable transformations f and g.

▶ **Lemma 13.** *There exist functions $f, g : \mathbb{R} \to \mathbb{R}$ and a constant $c \in (0,1)$ such that the matrix $\tilde{A}$ obtained in Algorithm 1 can be decomposed into unit vectors $\{\tilde{y}_v\}_{v \in V}$ in $\mathbb{R}^n$, and these vectors satisfy that for all $(u,v) \in E^+$,*

$$1 - 2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} = c(2y_u \cdot y_v - 1)$$

and for all $(u,v) \in E^-$,

$$2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} - 1 = c(1 - 2y_u \cdot y_v).$$

Proof. First, we want to choose a function f such that

$$1 - 2\frac{\arccos(f(y_u \cdot y_v))}{\pi} = c(2y_u \cdot y_v - 1)$$

for all $(u,v) \in E$. This will satisfy the condition on plus edges and minus edges as well. The constant c will be determined later. We choose the function f in the following way:

$$f(x) \triangleq \cos\left(\frac{\pi}{2}(1 - c(2x-1))\right) = \sin\left(c\pi x - \frac{c\pi}{2}\right) = \sin(c\pi x)\cos(\frac{c\pi}{2}) - \cos(c\pi x)\sin(\frac{c\pi}{2}),$$

where the last equality follows from the identity: $\sin(a-b) = \sin(a)\cos(b) - \cos(a)\sin(b)$ for all $a, b \in \mathbb{R}$. In addition, using the Taylor series expansion of $\sin(x)$ and $\cos(x)$, f can be written as follows:

$$f(x) = \cos(\frac{c\pi}{2}) \sum_{k=0}^{\infty} \frac{(-1)^k (c\pi x)^{2k+1}}{(2k+1)!} - \sin(\frac{c\pi}{2}) \sum_{k=0}^{\infty} \frac{(-1)^k (c\pi x)^{2k}}{(2k)!}.$$

Let f_k be the coefficient of x^k in the Taylor expansion of f. We define the following functions:

$$g(x) = \sum_{k=0}^{\infty} |f_k| x^k, \qquad a(x) = \sum_{k=0}^{\infty} \sqrt{|f_k|} x^k, \qquad b(x) = \sum_{k=0}^{\infty} \text{sign}(f_k)\sqrt{|f_k|} x^k.$$

Let a_k and b_k be the coefficients of x^k in the above series expansions of a and b. Recall that our goal is to show that there exist vectors $\{\tilde{y}_v\}_{v \in V}$ such that $\tilde{y}_u \cdot \tilde{y}_v = \tilde{A}_{u,v}$ for all $u, v \in V$. Given the set of vectors $\{y_v\}_{v \in V}$, we define the following vectors: if $u \in V_1$ then

$$y'_u = (a_0, a_1 y_u, a_2(y_u \otimes y_u), a_3(y_u \otimes y_u \otimes y_u), \dots)$$

and if $u \in V_2$ then

$$y'_u = (b_0, b_1 y_u, b_2(y_u \otimes y_u), b_3(y_u \otimes y_u \otimes y_u), \dots).$$

We note that the k-times tensor product $y_u \otimes y_u \otimes \cdots \otimes y_u$ are in fact n^k coordinates in the vector y'_u, as n is the dimension of the vector y_u. For every vector v and integer k, we denote by $v^{\otimes k}$ the k-times tensor product of v with itself. It is a known fact, that for every two vectors u, v and integer k, it holds that $u^{\otimes k} \cdot v^{\otimes k} = (u \cdot v)^k$.

Thus, we can see that if u, v are not both in V_1 or V_2, that is, not in the same side of the bipartite graph, then

$$y'_u \cdot y'_v = \sum_{k=0}^{\infty} a_k b_k (y_u^{\otimes k} \cdot y_v^{\otimes k}) = \sum_{k=0}^{\infty} a_k b_k (y_u \cdot y_v)^k = \sum_{k=0}^{\infty} f_k (y_u \cdot y_v)^k = f(y_u \cdot y_v).$$

Otherwise, if u and v are in the same side of the graph, without loss of generality, let it be V_1, then:

$$y'_u \cdot y'_v = \sum_{k=0}^{\infty} a_k^2 (y_u^{\otimes k} \cdot y_v^{\otimes k}) = \sum_{k=0}^{\infty} |f_k| (y_u \cdot y_v)^k = g(y_u \cdot y_v).$$

That is, it holds that $\tilde{A}_{i,j} = y'_i \cdot y'_j$ for all $i, j \in V$. Consequently, the matrix $\tilde{A}_{i,j} \in \mathbb{R}^{n \times n}$ is the symmetric Gramian matrix of the vectors $\{y'_v\}_{v \in V}$, and can be decomposed in polynomial time with Cholesky decomposition into $\tilde{A} = \tilde{Y}\tilde{Y}^T$. The rows of $\tilde{Y}$ will be the desired vectors $\{\tilde{y}_v\}_{v \in V}$.

To complete the proof we need to show that these vectors are unit vectors. That is, we want to show that $y'_u \cdot y'_u = 1$ for all $u \in V$. Since y_u is a unit vector, we have that

$$y'_u \cdot y'_u = \sum_{k=0}^{\infty} |f_k| (y_u \cdot y_v)^k = g(1).$$

Since $c \in (0, 1)$, we have that $\cos(\frac{c\pi}{2}) \geq 0$ and $\sin(\frac{c\pi}{2}) \geq 0$. Therefore, we can write g in the form:

$$g(x) = \sum_{k=0}^{\infty} |a_k| x^k = \sinh(c\pi x) \cos(\frac{c\pi}{2}) + \cosh(c\pi x) \sin(\frac{c\pi}{2}).$$

Hence, we can choose c to be the solution of the equation

$$\sum_{k=0}^{\infty} |f_k| = \sinh(c\pi) \cos(\frac{c\pi}{2}) + \cosh(c\pi) \sin(\frac{c\pi}{2}) = 1$$

in the range $(0, 1)$, and the vectors $\{\tilde{y}_v\}_{v \in V}$ will be unit vectors. The constant c turns out to be at least 0.19829. ◀

Finally, we are ready to complete the analysis of Algorithm 1, which is given in the following theorem.

▶ **Theorem 14.** *There exists a polynomial-time* 0.198*-approximation algorithm for the problem of* MaxCorr *on bipartite graphs that clusters the graph to at most 2 clusters.*

Proof of Theorem 14. From Corollary 12, Lemma 13 and Lemma 3, it follows that:

$$\begin{aligned}
\mathbb{E}[X_{ALG}] &= \sum_{(u,v) \in E^+} w_{u,v} \left(1 - 2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right) + \sum_{(u,v) \in E^-} w_{u,v} \left(2\frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi} - 1\right) \\
&= \sum_{(u,v) \in E^+} w_{u,v} c(2y_u \cdot y_v - 1) + \sum_{(u,v) \in E^-} w_{u,v} c(1 - 2y_u \cdot y_v) \\
&= c \cdot \mathrm{OPT}_{\mathrm{SDP}} \geq c \cdot \mathrm{OPT},
\end{aligned}$$

where c is at least 0.19828. ◀

B Max-k-Corr: Adapting Algorithm 2

As previously mentioned, given k, we need to present the combination of clustering techniques that will be used to approximate Max-k-Corr. Let us start by doing exactly this. In what follows, it is important to note that given k: (1) the mixing probability p appearing below depends on k; and (2) the transformations f and g also depend on k.

First, when $k = 3$, with a probability of p we produce two clusters by a single random hyperplane and with the remaining probability of $1-p$ we produce three clusters as described in Algorithm 2 (use one random hyperplane to produce two clusters, choose uniformly at random one of the two clusters, and further partition it using the second random hyperplane). Second, when $k \geq 4$, with a probability of p we produce two clusters by a single random hyperplane and with the remaining probability of $1-p$ we produce four clusters by using two random hyperplanes.

Let focus now on the analysis, specifically, how the transformations f and g are chosen. First, when $k = 3$, the probability that two vertices u and v are in the same cluster equals:

$$p\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)+(1-p)\left(\frac{1}{2}\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)+\frac{1}{2}\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)^2\right)$$
$$=\frac{1}{2}(1+p)\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)+\frac{1}{2}(1-p)\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)^2.$$

Thus, we wish to find the optimal parameters p and c that will satisfy that:

$$2\Pr[u,v \text{ are in the same cluster}]-1=c\left(\frac{4}{3}y_u\cdot y_v-\frac{1}{3}\right)$$

and the transformed vectors remain unit vectors. Hence, the function f is chosen to be:

$$f(x)=\cos\left(\frac{\pi\left(\sqrt{9\left(p^2-2p+5\right)-12c(p-1)(4x-1)}+3p-9\right)}{6(p-1)}\right),$$

and g is chosen accordingly. Performing the computation of the parameters, similarly to the previous sections of the paper, we obtain that $p\approx 0.47$ and $c\approx 0.397$.

Second, when $k \geq 4$, the probability that two vertices u and v are in the same cluster equals:

$$p\cdot\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)+(1-p)\cdot\left(1-\frac{\arccos(\tilde{y}_u\cdot\tilde{y}_v)}{\pi}\right)^2.$$

Thus, following the same footsteps as before we can conclude that f is chosen to be:

$$f(x)=\cos\left(\frac{\pi\left(\sqrt{-\frac{2c(p-1)(2kx-k-2x+2)}{k}+p^2-2p+2}+p-2\right)}{2(p-1)}\right),$$

and g is chosen accordingly. For every $k \geq 4$ we can repeat the process and find the best parameters p and c. Summarizing, we present these parameters (optimized numerically) for several values of k (refer to Table 3).

Table 3 Approximation factors obtained by adapting Algorithm 1 and Algorithm 2 for Max-k-Corr.

k	3	4	5	6	10
p	0.47	0.655	0.648	0.595	0.541
approximation	0.397	0.348	0.32	0.309	0.285

We note that when k is large it is not clear why one should not use more than two hyperplanes and obtain a clustering that might contain a large number of clusters. An interesting phenomenon arises when we want to split the hypersphere to m slices. If $m \in (2^t, 2^{t+1})$ for some integer t, then we can sample t random hyperplanes and split the hypersphere into 2^t slices. Then, we randomly choose $m - 2^t$ of the slices, and split each one of them with a random hyperplane. The result is m slices, and the probability that two vertices will be in the same cluster equals:

$$\frac{2^{t+1} - m}{2^t} \cdot \left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right)^t + \frac{m - 2^t}{2^t} \cdot \left(1 - \frac{\arccos(\tilde{y}_u \cdot \tilde{y}_v)}{\pi}\right)^{t+1}.$$

That is, this probability is a convex combination of the probabilities that two vertices will be in the same cluster when we randomly chose t or $t+1$ hyperplanes. Since the analysis of the algorithm is edge-wise, we can simply consider a distribution $\{p_t\}_{t>0}, \sum_{t=1}^{\infty} p_t = 1$, where p_t is the probability that we split the hypersphere into 2^t slices using t random independent hyperplanes. However, numeric calculations of splitting into more than four clusters did not yield better approximation factors. Thus, for a fixed k, the behavior of the value of c is unimodal, and reaches a peak when $p_1 + p_2 = 1$. Therefore, we focus on on algorithms that pick one hyperplane with a probability of p and two hyperplanes with the remaining probability of $1 - p$.

C The Integrality Gap of (1)

In this section, we wish to discuss the integrality gap of the relaxation presented in (1). We consider the following simple example: a 4-cycle graph that has 3 plus edges and 1 minus edge. We denote it by $V = \{1, 2, 3, 4\}$ and $E^+ = \{(1, 2), (2, 3), (3, 4)\}, E^- = \{(1, 4)\}$. Clearly, this graph is bipartite and the value of the optimal solution is 2. However, the optimum of (1) is obtained when the vectors y_1, y_4 are orthogonal, and $y_1 \cdot y_2 = y_2 \cdot y_3 = y_3 \cdot y_4 = \sqrt{3}/2$. One possible solution will be $y_1 = (1, 0), y_2 = (\sqrt{3}/2, 1/2), y_3 = (1/2, \sqrt{3}/2), y_4 = (0, 1)$, and the value of this solution is $3\sqrt{3} - 2$. Therefore, (1) admits an integrality gap of at most $\frac{2}{3\sqrt{3}-2} \approx 0.62575$.

In addition, we can give better bound on the integrality gap for general graphs. We consider the simple 3-cycle graph, that has two plus edges, $(1, 2), (2, 3)$, and one minus edge, $(1, 3)$. One can see that the value of the optimal integral solution is 1, whereas the fractional optimum is obtained when $y_1 \cdot y_3 = 0$ and $y_1 \cdot y_2 = y_2 \cdot y_3 = \sqrt{2}/2$. Therefore, the integrality gap on general graphs is at most $\frac{1}{2\sqrt{2}-1} \approx 0.54691$.

Streaming Complexity of SVMs

Abstract

We study the space complexity of solving the bias-regularized SVM problem in the streaming model. In particular, given a data set $(x_i, y_i) \in \mathbb{R}^d \times \{-1, +1\}$, the objective function is $F_\lambda(\theta, b) = \frac{\lambda}{2}\|(\theta, b)\|_2^2 + \frac{1}{n}\sum_{i=1}^n \max\{0, 1 - y_i(\theta^T x_i + b)\}$ and the goal is to find the parameters that (approximately) minimize this objective. This is a classic supervised learning problem that has drawn lots of attention, including for developing fast algorithms for solving the problem approximately: i.e., for finding (θ, b) such that $F_\lambda(\theta, b) \leq \min_{(\theta', b')} F_\lambda(\theta', b') + \varepsilon$.

One of the most widely used algorithms for approximately optimizing the SVM objective is Stochastic Gradient Descent (SGD), which requires only $O(\frac{1}{\lambda\varepsilon})$ random samples, and which immediately yields a streaming algorithm that uses $O(\frac{d}{\lambda\varepsilon})$ space. For related problems, better streaming algorithms are only known for *smooth* functions, unlike the SVM objective that we focus on in this work.

We initiate an investigation of the space complexity for both finding an approximate optimum of this objective, and for the related "point estimation" problem of sketching the data set to evaluate the function value F_λ on any query (θ, b). We show that, for both problems, for dimensions $d = 1, 2$, one can obtain streaming algorithms with space polynomially smaller than $\frac{1}{\lambda\varepsilon}$, which is the complexity of SGD for strongly convex functions like the bias-regularized SVM [12], and which is known to be tight in general, even for $d = 1$ [1]. We also prove polynomial lower bounds for both point estimation and optimization. In particular, for point estimation we obtain a tight bound of $\Theta(1/\sqrt{\varepsilon})$ for $d = 1$ and a nearly tight lower bound of $\widetilde{\Omega}(d/\varepsilon^2)$ for $d = \Omega(\log(1/\epsilon))$. Finally, for optimization, we prove a $\Omega(1/\sqrt{\epsilon})$ lower bound for $d = \Omega(\log(1/\epsilon))$, and show similar bounds when d is constant.

1 Introduction

The Support Vector Machine (SVM) optimization problem is a classic supervised learning problem with a rich and extensive literature. In this work, we consider the SVM problem in the *space-constrained* setting. Specifically, we focus on the bias-regularized SVM[1]. For n labelled data points $(x_i, y_i) \in \mathbb{R}^d \times \{-1, +1\}$, with $\|x_i\| \leq 1$, and $(\theta, b) \in \mathbb{R}^d \times \mathbb{R}$ the unknown model parameters, the SVM objective function is defined as:

$$F_\lambda(\theta, b) := \frac{\lambda}{2}\|(\theta, b)\|_2^2 + \frac{1}{n}\sum_{i=1}^{n} \max\{0, 1 - y_i(\theta^T x_i + b)\}, \tag{1}$$

where λ is the regularization parameter. The SVM optimization problem is then to minimize the objective:

$$(\theta^*, b^*) := \arg\min_{\theta, b} F_\lambda(\theta, b). \tag{2}$$

This problem is of both theoretical and practical interest, and has received lots of attention in the machine learning community. One of the main lines of work on SVMs has focused on trying to find approximately optimal solutions quickly (see, e.g., [12], [3], [11], and the references therein). Most notably, using a variant of stochastic gradient descent (SGD), one can compute a solution $(\hat{\theta}, \hat{b})$ which is at most ε away from the optimal $F_\lambda(\theta^*, b^*)$ in $O(\frac{1}{\lambda\varepsilon})$ SGD steps, each using a single randomly sampled data point (x_i, y_i) [12].

However, in many applications of SVMs, the number of data points is sufficiently large that even storing all of the data may be prohibitively expensive. In this case, it may be desirable to store a smaller summary of the data that is alone sufficient for optimizing the SVM objective within a desired error tolerance.

This goal has been studied for related smooth objective functions, but not for non-smooth objectives like SVMs. For example, [5] focuses on this problem for the more general setting of Generalized Linear Models (GLMs), where F is defined as $F = \frac{1}{n}\sum_{i=1}^{n} \phi(y_i, \theta^T x_i)$ for an arbitrary function ϕ. This includes the SVM objective. The authors of [5] show that if ϕ is well-approximable by a low-degree polynomial, then one can stream through the data points while keeping a small sketch of the data that is sufficient for minimizing the objective. However, the space complexity depends exponentially on the degree of the approximating polynomial, so it is only feasible for relatively smooth functions ϕ.

In this work we study SVMs, the most common non-smooth GLM, and focus on space complexity in the streaming setting. In addition to optimization, we also focus on the problem of *point estimation*: sketching the data points so that, given (θ, b), we can output a value within ε of $F_\lambda(\theta, b)$. While we use this as an intermediate step for achieving improved optimization upper bounds in the low-dimensional setting, this problem is also of independent interest. It occurs, for example, in estimating the GLM posterior distribution: the distribution of the parameters (θ, b) given the observed data and some prior distribution over (θ, b) [5].

[1] In the standard SVM formulation, the bias is not regularized, but the bias-regularized version is common both in theoretical work and in practice. See, for example, [12].

1.1 Our Results

Our results are for the two considered problems, and include both upper and lower bounds. We present the results for the point estimation problem independently. Then we present our results for optimization, the upper bounds for which rely on our point estimation results.

Point estimation. First, we show that one can obtain a *multiplicative* $(1+\varepsilon)$-factor approximation for $d = 1$ that uses $\tilde{O}(1/\varepsilon^2)$ space. However, we then show that it is not possible to get a multiplicative approximation algorithm for dimension $d > 1$ that uses space sub-linear in n. Given this, we otherwise focus on the space complexity of *additive* $\pm\varepsilon$ approximation streaming algorithms. For $d = 1$, we obtain space $O(1/\sqrt{\varepsilon})$, and for $d = 2$, we obtain space $O(\varepsilon^{-4/5})$. We complement our algorithms with a lower bound of $\Omega(\varepsilon^{-(d+1)/(d+3)})$ for dimension d, for any sketching algorithm, which goes up to ε^{-1} as we increase d. Note that, for $d = 1$, our bounds are tight. For $d = 2$, our lower bound translates to $\Omega(\varepsilon^{-3/5})$.

We also prove a lower bound of $\Omega(d/(\varepsilon^2 \operatorname{polylog}(1/\varepsilon)))$ for $d = \Omega(\log(1/\varepsilon))$, which is tight up to $\operatorname{polylog}(1/\varepsilon)$ factors. Together with the $O(1/\lambda\varepsilon)$ upper bound achieved from SGD, this shows that there is a *strict gap* between point estimation and optimization. This is also the case for linear regression in the streaming model: while getting a multiplicative $1 \pm \varepsilon$ point estimation approximation for linear regression requires space $\tilde{\Theta}(\varepsilon^{-2})$ [6], the (multiplicative) optimization problem requires only $\tilde{\Theta}(\varepsilon^{-1})$ space [4].

Optimization. First, using standard net arguments, we show how to use our point estimation results to approximately minimize the SVM objective.

▶ **Theorem 1.** *Suppose there is a streaming algorithm that, after seeing data* $\{(x_i, y_i)\}_{i=1}^n$, *where* $\|x_i\| \le 1$, *can produce a sketch of size* s *that, given any* (θ, b) *such that* $\|(\theta, b)\| \le \sqrt{2/\lambda}$, *is able to output* $\hat{F}(\theta, b)$ *such that* $|\hat{F}(\theta, b) - F(\theta, b)| \le \varepsilon$ *with probability at least* 0.9. *Then there is also a streaming algorithm that, under the same input, will output* $(\hat{\theta}, \hat{b})$ *with* $|F_\lambda(\hat{\theta}, \hat{b}) - F_\lambda(\theta^*_\lambda, b^*_\lambda)| \le \varepsilon$ *with probability at least* 0.9, *while using space* $O(s \cdot d \log d/(\lambda\varepsilon))$.

Together with our point estimation results, we immediately obtain streaming algorithms that, for dimensions one and two, obtain space polynomially smaller than $\frac{1}{\lambda\varepsilon}$, which is the complexity of SGD for strongly convex functions like the bias-regularized SVM [12], and which is tight in general [1].

We also prove space lower bounds for optimization. First, we consider the high-dimensional case when $\lambda = 10^{-4}$ is a constant:

▶ **Theorem 2.** *Let* $\lambda = 10^{-4}$ *and* $d = O(\log n)$ *for* $n = \Theta(\varepsilon^{-1/2})$. *Suppose there exists a sketch such that, given a stream of inputs* $\{(x_i, y_i)\}_{i=1}^n$, *outputs some* $(\hat{\theta}, \hat{b})$ *with probability at least* 0.9 *such that* $F_\lambda(\hat{\theta}, \hat{b}) \le F_\lambda(\theta^*, b^*) + \varepsilon$. *Then such a sketch requires* $\Omega(\varepsilon^{-1/2})$ *space.*

We can adapt the lower bound to the low dimensional setting if we let $\lambda = \operatorname{poly}(1/n)$. Specifically, we show a somewhat weaker lower bound of $\Omega(\varepsilon^{-1/4})$ for $d = 2$ as long as $\lambda = \Theta(1/n^2)$. Moreover, we are able to show the same $\Omega(\varepsilon^{-1/2})$ bound for any $d \ge 3$ as long as $\lambda = \Theta(1/n)$. Note that $\lambda = 1/n$ is a reasonable setting that is often used in practice.

1.2 Related Work

Stochastic optimization methods. SGD for strongly convex functions, which includes the bias-regularized SVM, has a sample complexity $O(\frac{1}{\lambda\varepsilon})$. Consequently, in the streaming setting we can simply maintain $O(\frac{1}{\lambda\varepsilon})$ random elements from the stream, then at the end

run SGD, yielding a space complexity of $O(\frac{d}{\lambda\varepsilon})$. Moreover, this is tight for general Lipschitz, strongly convex functions; there is an $\Omega(\frac{1}{\varepsilon})$ SGD sample complexity lower bound for this function class [1].

Some stochastic optimization methods like Stochastic Average Gradient (SAG) [10] achieve *linear* convergence, meaning that after T iterations $F_\lambda(\theta_T) - F_\lambda(\theta^*) \leq O(\rho^T)$ for some $\rho < 1$. However, in this case, $\rho \approx 1 - 1/n$, so we would need $T > n$ iterations, which is worse than $\frac{1}{\lambda\varepsilon}$ when n is sufficiently large.

Similarly, some stochastic optimization methods like Katyusha [2] achieve a sample complexity that has a dependence on ε like $1/\sqrt{\varepsilon}$. However, the sample complexity for such methods also has a sample complexity that scales linearly with n, again making them worse than $\frac{1}{\lambda\varepsilon}$ for the regime we care about.

Finally, note that if the elements of the stream are drawn IID from some distribution, and the size of the stream, n, is sufficiently large, then we can simply run online gradient descent (OGD) and use $O(d)$ space. However, we focus on the general setting where we cannot make any distributional assumptions.

Core-set and streaming algorithms for SVMs. Tsang et al. focuses on trying to speed up SVM optimization via *core-sets* [13]: a subset of training points that are sufficient for approximately optimizing the objective corresponding to the full training set. They approximately solve a Minimum Enclosing Ball (MEB) problem that they show is equivalent to the SVM. In the language of our paper, it shows an algorithm for achieving a $\pm\varepsilon$ additive approximation for the SVM objective in the batch setting using space $O(\varepsilon^{-2})$. [9] adapts these ideas to the streaming setting by showing a simple one-pass approximate MEB algorithm. However, they only achieve a *constant* approximation, rather than one with a target error ε. To the best of our knowledge, we are the first to analyze streaming SVM algorithms with sub-constant approximation guarantees.

1.3 Techniques

Multiplicative approximation algorithm. First note that by considering the points labeled $+1$ and -1 separately, the point estimation problem that we consider reduces to the following: given a set of n points, the goal is to sketch them such that later, given a query hyperplane denoted by $H = (\theta, b)$, one can estimate the sum of distances of the points on one side of H to H. In one dimension, the points are positioned on the real line and the query is also a value b on the real line and the goal is to compute $\sum_i \max\{0, b - x_i\}$.

The idea behind the streaming algorithm is the following: we uniformly sample a $1/2^i$ fraction of the input points, for $i = 1, 2, \ldots, O(\log n)$, and for each of the $O(\log n)$ sampling rates, we store the smallest $\tilde{O}(\epsilon^{-2})$ points that we have seen. Now given a query point q, we want to estimate the sum of distances of points $p < q$ to q. If there are fewer than $\tilde{O}(\epsilon^{-2})$ input points p less than q, then we have stored all of them and can compute this sum exactly. Otherwise we can think of partitioning the input points p into geometric scales, in powers of 2, based on their distance to q. The main insight is if one of these scales contributes to the overall sum, it must have a number n' of points in it of roughly the same order as the total number of points p' even further away from q. This is because each such point p' contributes even more than any point p in this scale to the sum. Consequently, if we choose i for which $1/2^i \approx 1/(n'\epsilon^2)$, then there will be about $\tilde{\Theta}(1/\epsilon^2)$ survivors in the sampling that are at this distance scale, and we will have stored all of them. By separately estimating the contribution of each scale and adding them together, we obtain our overall estimate. We note that to achieve our overall $\tilde{O}(\epsilon^{-2})$ space bound we need to obtain as crude of an additive error as

possible for scales that do not contribute as much as other scales to the overall objective. We do this by separately first estimating the contribution of each scale up to a constant factor, and then refining it appropriately.

Additive approximation algorithms. We also show *additive* approximation algorithms in the low dimensional regimes. As our lower bound depends on the diameter of the points, we assume without loss of generality that our point set has diameter 1. For $d = 1$, the sketching algorithm groups the points into $2/\sqrt{\varepsilon}$ groups in a way that i) each group has diameter at most $\sqrt{\varepsilon}$, and ii) each group has at most $n\sqrt{\varepsilon}$ points in it. It is easy to verify that such a grouping results in an additive approximation of ε. To make the algorithm work in the streaming setting, we must maintain the groups as the points arrive. Note that the partitioning based on the diameter can be done in advance. However in order to also partition based on the number of points (and make sure each group gets at most $n\sqrt{\varepsilon}$ points in it), we create a binary tree for each original group (that has diameter $\sqrt{\varepsilon}$). Whenever a group reaches its maximum size of $n\sqrt{\varepsilon}$, we create two children corresponding to that group and further points arriving in the group will be assigned to one of the children. Note that it is important that we cannot partition the previous points into the two children as we already discarded them in the stream.

For $d = 2$, we maintain a quad tree on the points in $[-1, 1] \times [-1, 1]$. Whenever a cell gets too many points we further partition it into four until its side length becomes too small. We process every cell of the quad tree so that if the query (which is a line now) does not collide with the cell, we can exactly compute the sum of distances of the points in the cell to the line (using [5]). Ignoring the points in the cells that the line crosses, will result in an algorithm with space usage of $O(\varepsilon^{-1})$. To push it down to $O(\varepsilon^{-4/5})$, we randomly sample a point from each cell and for the crossing cells, we will use the single sampled point to estimate the average distances of the points in the cell to the query line.

Finally, for the lower bounds in low dimensions, we develop reductions from the INDEXING problem. We show how to consider $k = \Omega(\varepsilon^{-\frac{d+1}{d+3}})$ positions inside a d-dimensional sphere, where they correspond to a bit-string of length k by Alice. If her i-th bit in the string is 1, then she will put n/k actual points in the corresponding positions, otherwise she does not put any point there. We show that Bob can recover Alice's input using hyper-plane queries.

Lower bound in high dimensions. We let $b = 0$ so that $F(\theta, 0) = \frac{1}{n}\sum_i \max\{0, \theta \cdot x_i\}$. This is similar to the subspace sketch problem studied in [7], which considers approximating $\sum_i \phi(\theta \cdot x_i)$ for $\phi(t) = |t|$ up to a multiplicative factor of $(1+\varepsilon)$. Here we have $\phi(t) = \max\{0, t\}$ instead (by flipping θ) and an additive error εn. The proof in [7] turns the multiplicative error into an additive error and so we can adapt the same approach in our current case. Following the same approach, we can show an $\Omega(d/(\varepsilon^2 \operatorname{polylog}(1/\varepsilon)))$ lower bound when $d = \Omega(\log(1/\varepsilon))$ for the point estimation problem. Below we sketch the main idea for the proof, which is similar to that in [7].

We show an $\tilde{\Omega}(1/\varepsilon^2)$ lower bound for $d = \Theta(\log(1/\varepsilon))$. The lower bound for general d follows from the concatenation of $\Theta(d/\log(1/\varepsilon))$ independent smaller hard instances.

In the remainder of this subsection let $d = \Theta(\log(1/\varepsilon))$ be such that $n = 2^d = \tilde{\Theta}(1/\varepsilon)$. Consider all the $\{-1, 1\}^d$ vectors and let x_i be the i-th $\{-1, 1\}$-vector scaled by some scalar r_i. Define a matrix $M \in \mathbb{R}^{n \times n}$, indexed by $\{-1, 1\}$-vectors, as $M_{ij} = \phi(\langle i, j\rangle)$. Then we have for $\theta \in \{-1, 1\}^d$ that $\sum_i \phi(-\langle \theta, x_i\rangle) = \sum_i \phi(\langle \theta, x_i\rangle) = \sum_i \phi(r_i\langle \theta, i\rangle) = \sum_i r_i\phi(\langle \theta, i\rangle) = \sum_i M_{\theta,i}r_i = \langle M_\theta, r\rangle$ if all $r_i \geq 0$, where M_θ denotes the θ-th row of M. Our goal is to encode random bits s_i in the scalars r_i, such that obtaining $\langle M, \theta\rangle$ within additive εn allows us to recover as many bits s_i as possible.

First we allow r_i to be negative and consider $(Mr)_\theta$. Let $r = \sum_i s_i \cdot \frac{M_i}{\|M_i\|_2}$, where $s_1, \ldots, s_n$ are i.i.d. Rademacher random variables. It follows from a standard concentration inequality that $\|r\|_\infty \leq \text{poly}(d)$. If M had orthogonal rows, then $\langle M_\theta, r\rangle = s_\theta \|M_\theta\|_2$, in which case we can recover the bit s_θ from the sign of $\langle M_\theta, r\rangle$, provided that $\|M_\theta\|_2$ is larger than the additive error εn.

However, M does not have orthogonal rows. The argument above still goes through so long as we can identify a subset $\mathcal{R} \subseteq [n] = [2^d]$ of size $|\mathcal{R}| = \Omega(2^d/\text{poly}(d))$ such that the rows $\{M_i\}_{i\in\mathcal{R}}$ are nearly orthogonal, meaning that the ℓ_2 norm of the orthogonal projection of M_i onto the subspace spanned by other rows $\{M_j\}_{j\in\mathcal{R}\setminus\{i\}}$ is much smaller than $\|M_i\|_2$. To this end, we study the spectrum of M using Fourier analysis on the hypercube, which shows that the eigenvectors of M are the rows of the normalized Hadamard matrix, while the eigenvalues of M are the Fourier coefficients associated with the function $g(s) = \phi(d - 2w_H(s))$, where $w_H(s)$ is the Hamming weight of a vector $s \in \{0,1\}^d$. It can be shown that M has at least $\Omega(2^d/\text{poly}(d))$ eigenvalues of magnitude $\Omega(2^{d/2}/\text{poly}(d))$. For the θ's which correspond to those eigenvalues, we have $\|M_\theta\|_2 = \Omega(2^{d/2}/\text{poly}(d))$ so that $\|M_\theta\|_2 = \Omega(\varepsilon n)$ for our choice of n and d, as required by the argument.

Recall that we require $r_i \geq 0$. Since $\|r\|_\infty \leq \text{poly}(d)$ with high probability, we can just shift each coordinate of r by a fixed amount of $\text{poly}(d)$ to ensure that all entries of r are positive. We can still obtain $\langle M_\theta, r\rangle$ with an additive error $O(\varepsilon 2^d \text{poly}(d))$, since the amount of the shift is fixed and bounded by $\text{poly}(d)$.

Last, rescaling θ and x_i's to unit vectors loses $\text{poly}(d) = \text{poly}(\log(1/\varepsilon))$ factors in the lower bound and we continue to have an $\Omega(1/(\varepsilon^2 \,\text{polylog}(1/\varepsilon)))$ lower bound.

Optimization lower bound. We prove optimization lower bounds by reducing from the INDEXING problem: Alice encodes points at specific locations on the unit sphere, then Bob uses the optimization sketch to decode whether a point was added at some particular location. The challenge is that Bob must be able to reason about a *single* data point when given access to an approximate optimum corresponding to an *entire* dataset. The key idea in getting this to work is for Bob to add some additional points with the following property: if the location being queried does not contain a point, then the added points are the *only* support vectors, i.e. (θ^*, b^*) is entirely determined by the added points, whereas if the the location being queried does contain a point, then (θ^*, b^*) is entirely determined by the added points and the point at that location. Hence, (θ^*, b^*) can take on exactly two possible values, and does not depend on any of the remaining points in the dataset. Moreover, the strong convexity of F_λ allows us to upper bound $\|(\theta^*, b^*) - (\hat{\theta}, \hat{b})\|$ in terms of ε. We make this precise in the following lemma, which we will refer to multiple times later on:

▶ **Lemma 3.** *If $F_\lambda(\hat{\theta}, \hat{b}) \leq F_\lambda(\theta^*, b^*) + \varepsilon$, then $\|(\hat{\theta}, \hat{b}) - (\theta^*, b^*)\|_2 \leq \sqrt{2\varepsilon/\lambda}$.*

By exactly characterizing what (θ^*, b^*) is in these two possible cases, and showing that the gap is more than $2\sqrt{2\varepsilon/\lambda}$, we show that Bob can distinguish these two situations and decode the bit. The analysis is delicate, requiring a carefully chosen construction for the proof to go through.

Open Problems. For the case of $d = 1$, we have matching upper and lower bounds for (additive) point estimation of $\Theta(\varepsilon^{-1/2})$. This also translates into an *optimization* upper bound of $O(\varepsilon^{-1/2})$, the best upper bound we know of for this setting. However, we have no optimization lower bound for $d = 1$. Instead, we have an optimization lower bound of $\Omega(\varepsilon^{-1/4})$ for $d = 2$ and $\Omega(\varepsilon^{-1/2})$ for $d \geq 3$. Moreover, for optimization in high dimensions, there remains a gap between the $\Omega(\varepsilon^{-1/2})$ lower bound and $O(1/\varepsilon)$ upper bound. It remains to close all of these gaps.

Also, while in this work we focus on linear SVMs, often times non-linear kernels are preferred in practice. This raises the question of whether we can extend our results to this setting. One approach is to use random feature maps that allow one to convert a kernel SVM problem into a linear SVM problem [8]. However, this increases the dimension significantly, so that sampling and running SGD is more efficient than optimization via point estimation.[2]

2 Point Estimation

In this section, we study the streaming complexity of the point estimation problem. Specifically, the algorithm sees the data points (x_i, y_i), for $1 \le i \le n$, one by one. The goal is to keep a sketch of the data such that later, given the query parameters (θ, b), it can output an estimate of the SVM objective function $F(\theta, b)$.

Setup for point estimation. We can simplify the presentation by focusing on a slight simplification of the SVM objective (without loss of generality). First, we note that, since $y_i \in \{+1, -1\}$, we can estimate the contribution from x_i's with $y_i = +1$ and $y_i = -1$ separately. Hence, for point estimation it is enough to assume that $y_i = +1$, as well as that $\lambda = 0$ (since the regularization can be computed independently of the data). Furthermore, we can just work with the following related objective:

$$F(\theta, b) := \frac{1}{n} \sum_{i=1}^{n} \max\{0, b - \theta \cdot x_i\}, \tag{3}$$

by adjusting b accordingly. Hence we focus on estimating the function from Eqn. (3) for the rest of this section.

Note that when $d = 1$, it is enough to consider the case of $\theta = +1$. First, because for $\theta \in (0, 1)$, we can rescale the output of a sketch (that uses $\theta = +1$ and accordingly rescaled b). Second, because the case of $\theta \in [-1, 0)$ is precisely symmetric, so one can just keep two sketches, one for each of $\theta \in \{-1, +1\}$. Note that the objective simplifies to $F = \frac{1}{n} \sum_{i=1}^{n} \max\{0, q - x_i\}$ where $q = b$. We will call the value q the query.

2.1 Multiplicative $(1 + \varepsilon)$ approximation algorithm for $d = 1$

Here we consider the case of $d = 1$: We are given a set of n points $x_i \in \mathbb{R}$, and given any query $q \in \mathbb{R}$, the goal is to approximate $\sum_{i: x_i \le q} (q - x_i)$ up to a multiplicative $1 + \varepsilon$ factor. To analyze the bit complexity of the problem, we assume the points are integers between 1 and W. A simple sketching algorithm is given in the full version. Here we present a streaming algorithm for the problem.

Streaming. Here we assume that the values $x_1, \ldots, x_n$ are given in a stream in this order, and we are allowed to make a single pass over it, and the query q is given at the end of the stream. Note that x_i's are not necessarily sorted, and for simplicity, we assume all x_i's are distinct. The algorithm maintains the following sketch throughout the stream.

[2] As described in [12], one can use adapt SGD to work for kernelized SVMs. This involves tracking dual variables α_i, which we can do with the same space complexity of $O(\frac{d}{\lambda \varepsilon})$ as before.

Sketch. The sketch consists of two collections of sets of samples as described below. The first collection is used to get a crude (constant factor) approximation of the contribution of each contributing interval as defined later, and the second collection is used for a more precise approximation.

- For each $0 \leq i \leq \log n$, sample every point with probability $1/2^i$, and preserve the $m_1 = C_1\varepsilon^{-1}\log^2 W$ points with the smallest x value in the set E_i, where C_1 is a constant to be specified later.
- For each $0 \leq i \leq \log n$, sample every point with probability $1/2^i$, and preserve the $m_2 = C_2\varepsilon^{-2}\log W$ points with the smallest x value in the set S_i, where C_2 is a constant to be specified later.

▶ **Observation 4** (Space). *The sets E_i and S_i can be maintained in a stream. Let $M = \max\{m_1, m_2\}$, then the space usage of the algorithm is $O(\log n \cdot M \cdot \log W) = O(\frac{\log n \cdot \log^2 W}{\varepsilon}(\frac{1}{\varepsilon} + \log W))$ bits.*

Next we describe the query processing algorithm. The analysis is deferred to Appendix A.

Query algorithm. Let p be the largest value in $S_0 \cup E_0$. Given the query point $q \in \mathbb{R}$, we proceed as follows.

- If $q \leq p$, then we can report an exact solution using the corresponding sample set: e.g. if $p \in S_0$, then we output $\sum_{x \in S_0, x \leq q}(q - x)$.
- Otherwise, we group the points based on their distance to q and estimate the contribution of each group separately. More precisely, let $D = q - p$, which is a positive number, and for each $1 \leq j \leq \log D$, define the interval $R_j = (q - \frac{D}{2^{j-1}}, q - \frac{D}{2^j}]$. For notational convenience, let R_0 be the interval covering $S_0 \cap E_0$ which ends at the point p. Finally for each $0 \leq j \leq \log D$, let $t_j = |P \cap R_j|$ be the number of points in the interval R_j, and $T_j = |P \cap (\bigcup_{k<j} R_k)|$ be the number of points to the left of interval R_j.
- Let $i'(j)$ be the largest i such that E_i contains at least $\log D$ points from R_j. If no such i' exists, let $i'(j) = -1$. The value $i'(j)$ shows which sampled set ($E_{i'(j)}$) we should use for our crude approximation. As we show in Lemma 17, if $i'(j) = -1$, the contribution of the points in R_j can be ignored).
- Let $\phi_j = \min\{1, \frac{|E_{i'(j)} \cap R_j|}{|E_{i'(j)} \cap (\cup_{k<j} R_k)|}\}$. This value is used to approximate the ratio of the points in R_j to the points that are to the left of R_j, i.e., $\phi_j \approx \frac{t_j}{T_j}$. This is verified in Lemma 18.
- We set the value of $i(j)$ as follows.
  - If $i'(j) = -1$ or $\phi_j \leq \frac{\varepsilon}{\log W}$, then set $i(j) = -1$. In this case, the contribution of R_j can be ignored.
  - Otherwise, if $\phi_j \geq \frac{1}{\log W}$, then set $i(j)$ to be the largest i such that S_i contains at least $1/\varepsilon^2$ points from R_j. If no such i exists let $i(j) = -1$. This case in analyzed in Lemma 19 and Lemma 20.
  - Finally, if $\frac{\varepsilon}{\log W} \leq \phi_j \leq \frac{1}{\log W}$, then set $i(j)$ to be the largest i such that S_i contains at least $(\phi_j \log W/\varepsilon)^2$ points from R_j. This case in analyzed in Lemma 21 and Lemma 22.
- Report $\sum_{j \leq \log D, i(j) \neq -1} \sum_{x \in S_{i(j)} \cap R_j} 2^i(q - x)$. That is for all sets whose contribution is significant (equivalently $i(j) \neq -1$) we estimate their contribution using sample set $S_{i(j)}$.

We then have the following results.

▶ **Lemma 5** (main lemma). *This algorithm returns a $(1 + O(\varepsilon))$ multiplicative approximation.*

▶ **Corollary 6.** *There exists a one pass streaming algorithm that computes a $(1+\varepsilon)$ multiplicative approximation for point estimation variant of the problem in one dimensional case. Moreover, if the points come from $[W]$, the space usage of the algorithm is $O(\frac{\log^2 n \cdot \log W}{\varepsilon}(\log n + 1/\varepsilon))$ bits.*

2.2 Lower Bounds

We now show that one cannot hope to get a sketch with multiplicative approximation in higher dimensions than one with a bound independent of n. In fact we show the following additive approximation lower bound for any sketching algorithm (and hence streaming algorithm as well).

▶ **Theorem 7.** *For any $d \geq 1$, $\varepsilon \in (0,1)$, and $n \geq 1/\varepsilon$, there exists an instance of the problem, where the point set has diameter $O(1)$, such that getting an algorithm with additive approximation factor ε, requires space of $\Omega(\varepsilon^{-(d+1)/(d+3)})$ bits.*

Moreover, getting a $(1+\varepsilon)$-multiplicative approximation for $d \geq 2$ requires $\Omega(n)$ space.

The proof is given in Appendix B. We note that while this theorem formally applies to the simplified objective, it immediately translates to the SVM objective as well as we only use points with one label (when the problems are exactly equivalent).

The preceding theorem gives at most an $\Omega(1/\varepsilon)$ lower bound, leaving a quadratic gap from the simple random sampling algorithm of $\tilde{O}(d/\varepsilon^2)$ bits. In fact, for high dimensions $d = \Omega(\log(1/\varepsilon))$, we can prove a lower bound of $\tilde{\Omega}(d/(\varepsilon^2 \operatorname{polylog}(1/\varepsilon))$ bits, tight up to logarithmic factors. We state the theorem below and give the proof in the full version.

▶ **Theorem 8** (high-dimensional)**.** *There exist constants $C \in (0,1]$ and $\varepsilon_0 > 0$ such that the following holds. Let $d_0 = 2\log_2(C/(\varepsilon \operatorname{polylog}(1/\varepsilon))$. For any $\varepsilon \in (0, \varepsilon_0)$, $d \geq d_0$, $n \geq (d/d_0)2^{d_0}$, any algorithm that gives an additive ε-approximation for the point estimation problem with probability at least $2/3$ requires $\Omega\left(d/(\varepsilon^2 \operatorname{polylog}(1/\varepsilon))\right)$ bits.*

2.3 Additive approximation algorithms

We now design streaming algorithms that achieve an additive ε-approximation to the objective Eqn. (3). We also generalize these results to a slightly modified objective in the full version. We start with dimension $d = 1$.

▶ **Theorem 9.** *There exists a one pass streaming algorithm for the point estimation variant of the problem in the one dimensional regime, that achieves an additive error of ε, space of $O(\varepsilon^{-1/2}\sqrt{\log(1/\varepsilon)})$ words, and that succeeds with constant probability per query.*

Recall that for $d = 1$, the objective simplifies to $F(q) = \frac{1}{n}\sum_{i=1}^{n} \max\{0, q - x_i\}$. We describe a *sketching* algorithm that produces a sketch of size $O(1/\sqrt{\varepsilon})$ that is able to answer point estimation queries to this F. Later, we show how to adapt this algorithm to the streaming setting.

Let $m = (1/\sqrt{\varepsilon})$ and consider two sets of m points. First consider $Y_1, \ldots, Y_m$ such that Y_i is at position i/m. Moreover consider m points $X_1, \ldots, X_m$ such that X_i is at position $x_{(i \cdot n)/m}$, where we assume that x_i's are in a sorted order, i.e., $x_1 \leq \cdots \leq x_n$. Now sort these $2m$ points and name them $Z_1, \ldots, Z_{2m}$. For each $i \leq 2m$ we store three numbers: i) Z_i itself, ii) s_i, the sum of the distances of the points to the left of Z_i to the point Z_i, and iii) c_i, the number of points x_i to the left of Z_i.

Given a query $q \in [0,1]$, we will find i such that $Z_i \leq q < Z_{i+1}$. We will return $s_i + c_i \cdot (q - Z_i)$. Clearly for the the points that are to the left of Z_i this distance is computed correctly. The only points that are not computed in the sum are part of the points in the

interval $[Z_i, Z_{i+1}]$, but we know that there are at most $n\sqrt{\varepsilon}$ of them (by our choice of the X_i's) and their distance to q is at most $(Z_{i+1} - Z_i) \leq \sqrt{\varepsilon}$ (by our choice of Y_i's). Therefore they introduce an average error of at most ε as we require.

Streaming. We adapt the above algorithm to the streaming setting as follows. We keep a binary tree, where each node corresponds to an interval in $[-1, 1]$ (the domain of x_i). The root corresponds to the entire interval $[-1, 1]$, and the two children of a node/inverval are the 2 half correspondingly (applied recursively). Initially, we start with a tree of height $\log_2 1/\sqrt{\varepsilon}$, where the leaves correspond to intervals of length precisely $\sqrt{\varepsilon}$ (assuming it's a power of two, w.l.o.g.).

As we stream through the points x_i, we add the information about the point x_i to the leaf corresponding to the interval containing x_i. In particular, each node v, with associated interval I_v, keeps a count of points c_v, as well as s_v which is the sum, over of the points accounted in c_v, of their distance to the right border of the interval.

We may also expand this leaf v to add its two children (v ceases to be a leaf). The leaf is split when c_v reaches value $\sqrt{\varepsilon}n$. The new children start with their counters equal to 0. One exception is that if the depth of the node is more than $3\log(1/\varepsilon)$ (the interval's diameter is $< \varepsilon$), in which case we don't do the expansion.

To answer a query $q \in [-1, 1]$, we sum up, over all nodes v (internal nodes and leaves) whose interval I_v is entirely to the left of q, the quantity $s_v + c_v \cdot (q - I_v)$, where $q - I_v$ is the distance from q to (the rightmost endpoint of) I_v. The analysis is given in Appendix C.1.

Now we study dimension $d = 2$. We now develop a streaming algorithm for sketching a set of points in the 2D plane such that given any query (affine) line in the plane, one can approximate the cost. To simplify the ensuing notation, we denote the set of points by $p_1 = (x_1, y_1), \ldots, p_n = (x_n, y_n) \in [0, 1] \times [0, 1]$, and the query by a line $\{x : \theta^T x = b\}$, which we denote by $L = (\theta, b)$. Recall the assumption that $\|\theta\| \leq 1$, we may assume that $\|\theta\| = 1$. Our goal is equivalent to reporting the sum of distances of the points on one side of L to L. Henceforth we denote the distance from point p to line L as $D(p, L)$.

▶ **Theorem 10.** *There is a streaming algorithm for the point estimation problem in two dimensions, that with constant probability, achieves additive error ε, with sketch size $O(\varepsilon^{-4/5})$ words.*

The following shows how to get an $O(1/\varepsilon)$-size sketch with an additive error of $O(\varepsilon^{5/4})$, and at the end we just replace $\varepsilon' = \Theta(\varepsilon^{4/5})$ to prove the above theorem.

We use a quad-tree over the unit square $[0, 1] \times [0, 1]$, where each node is associated with a number of points (each point is associated with exactly one node of the quad-tree). Thus each node v contains a counter c_v for the number of associated points, a randomly chosen associated points (chosen using reservoir sampling), as well as a sketch S_v to be described later. Initially, the quad-tree is of depth $\log(1/\sqrt{\varepsilon})$ and all counters/sketches are initialized to zero. When we stream over a point p_i, we associate it with the corresponding leaf of the quad-tree (process defined later), unless the counter c_v is already $\varepsilon \cdot n$ and the depth is at least $2\log(1/\varepsilon)$ (i.e., the side length is at least ε^2). In that case the leaf v is expanded by adding its 4 children, which become new leaves (with counters initialized to 0).

When we associate a point with a node v, we increment c_v and update the sketch S_v on the associated points. The sketch S_v for the associated points, say termed P_v, allows us to compute, for any query line $L = (\theta, b)$, the sum $\sum_{p \in P_v} (b - \theta^T p)$. The sum $\sum_{p \in P_v} \theta^T p$ can be computed in a streaming fashion using the sketch from [5]. In particular, the sketch actually consists of two counters: X_v, the sum of the x coordinates, and Y_v, the sum of the y coordinates.

Query algorithm. Given a query line L, we distinguish contribution from points in two types of quad-tree nodes: nodes that do not intersect the line and those that do. For the first kind, we can just use the sketch S_v to estimate the distance to the line, without incurring any error. More precisely we have that $\sum_{p\in P_v} D(p,L) = \sum_{p\in P_v}(b - \langle p,\theta\rangle) = c_v b - \langle (X_v, Y_v),\theta\rangle$. Note that this is included in the final sum iff the entire node lies in the halfplane $\langle x,\theta\rangle \le b$.

For the second kind of nodes, we estimate their contribution as follows. For each non-empty node v, with the random sample r_v, we add to the final sum the quantity $(1/n)\cdot c_v \cdot \max\{0, b - \theta^T r_v\}$.

The analysis is deferred to Appendix C.2.

3 Optimization

In this section we consider the problem of finding the (approximate) optima for the SVM objective in the streaming setting. First, we show that a streaming solution for the point estimation problem immediately leads to a solution for the optimization problem, with only a $O(d\log 1/\varepsilon)$ loss in space complexity. Second, we give lower bounds for the optimization problem, showing a (different) polynomial dependence on $1/\varepsilon$ is still required for dimension $d > 1$.

As before, we consider the SVM optimization problem in which the bias is regularized: $\min_{\theta,b} F_\lambda(\theta, b)$, where F_λ is as defined in (1). Without loss of generality, we assume that the inputs are contained in a ball of radius 1, i.e., $\|x_i\| \le 1$, and that $y_i \in \{-1, +1\}$.

Recall that [12] show that $O(1/(\lambda\varepsilon))$ random samples (x_i, y_i) are enough for computing an ε-approximate optimum (by running SGD). This can be seen as a streaming algorithm with space complexity $O(d/(\lambda\varepsilon))$. We show that, given an efficient streaming algorithm for point estimation, we can solve the optimization problem with only a minor blowup.

▶ **Theorem 11.** *Suppose there is a streaming algorithm that, after seeing data $\{(x_i, y_i)\}_{i=1}^n$, where $\|x_i\| \le 1$, can produce a sketch of size s that, given any (θ, b) such that $\|(\theta, b)\| \le \sqrt{2/\lambda}$, is able to output $\hat{F}(\theta, b)$ such that $|\hat{F}(\theta, b) - F(\theta, b)| \le \varepsilon$ with probability at least 0.9. Then there is also a streaming algorithm that, under the same input, will output $(\hat{\theta}, \hat{b})$ with $|F_\lambda(\hat{\theta}, \hat{b}) - F_\lambda(\theta^*_\lambda, b^*_\lambda)| \le \varepsilon$ with probability at least 0.9, while using space $O(s \cdot d\log d/(\lambda\varepsilon))$.*

The proof of this theorem is a standard net argument and is given in the full version.

Recall that our point estimation results assume $\|(\theta, b)\| \le 1$, which can be adapted to $\|(\theta, b)\| \le R$ by replacing ϵ with ϵ/R. Letting $R = \sqrt{2/\lambda}$, the above theorem implies that we get an optimization algorithm for $d = 1$ that uses $\tilde{O}(\varepsilon^{-1/2}\lambda^{-1/4})$ space, and an optimization algorithm for $d = 2$ that uses $\tilde{O}(\varepsilon^{-4/5}\lambda^{-2/5})$ space. Note that this has a polynomially better dependence on both ε and λ relative to the $O(1/\lambda\varepsilon)$ bound that we get from SGD.

Lower bounds. We start with the high-dimensional case. Suppose there exists a sketch such that, given a stream of inputs $\{(x_i, y_i)\}_{i=1}^n$, $\|x_i\|_2 \le 1$, with probability at least 0.9 outputs some $(\hat{\theta}, \hat{b})$ such that $F_\lambda(\hat{\theta}, \hat{b}) \le F_\lambda(\theta^*, b^*) + \varepsilon$, where $F_\lambda(\theta, b) := \frac{\lambda}{2}(\|\theta\|^2 + b^2) + \frac{1}{n}\sum_{i=1}^n \max\{0, 1 - y_i(\theta^T x_i + b)\}$. For now, suppose $\lambda = 10^{-4}$ and $d = O(\log n)$. Later, we show a similar lower bound for low dimensions when $\lambda = \Theta(1/n)$.

▶ **Theorem 12.** *Such a sketch requires $\Omega(\varepsilon^{-1/2})$ words of space.*

Proof idea: We will reduce from the INDEXING problem in the one-way communication model. At a high level, we will argue that we can query whether a point exists at a given location on the unit sphere by adding additional points with the property that the optimal

parameters are determined entirely by the added points and the point being queried (if it exists). This yields a separation in the optimal parameters in these two cases, which we will argue (via strong convexity) is distinguishable using such a sketch.

Specifically, suppose Alice is given a bit string $b \in \{0,1\}^{n/2}$ which she wants to encode. Let $T = \{v_1, \ldots, v_n\}$ be a subset of the unit sphere in d dimensions satisfying $\forall v_1 \neq v_2 \in T$, $v_i^T v_j < 1 - 10\delta$, where δ will be specified later, with $|T| = n$. For $\delta = \frac{1}{100}$, such a set exists for $d = \text{poly}(\log n)$. If $b_i = 0$, Alice adds $(v_i, -1)$ to the sketch S; otherwise, if $b_i = 1$, Alice adds $(v_{n/2+i}, -1)$ to S. Alice then sends the sketch to Bob, who decodes b_q for $q \in [\frac{n}{2}]$ by querying whether a point exists at location x_q. In particular, Bob adds $\frac{n}{4}$ copies of $(x_\alpha, -1)$, and $\frac{n}{4}$ copies of $(x_\beta, +1)$, where $x_\alpha := (1-\delta)x_q$ and $x_\beta := (1+\delta)x_q$. Let $(\hat{\theta}, \hat{b})$ be the output of the sketch after doing so. Define $\theta_0 := \frac{2\lambda(1+\delta)+\delta}{2\lambda(1+(1+\delta)^2)}$ and $\theta_1 := \frac{2\lambda(1+\delta)+\delta(1+\frac{1}{n})}{2\lambda(1+(1+\delta)^2)}$. If $\|\hat{\theta} - \theta_0\| < \|\hat{\theta} - \theta_1\|$ then Bob outputs "$b_i = 0$"; otherwise, Bob outputs "$b_i = 1$".

3.1 Preliminaries for the lower bound

We introduce some standard facts about the SVM objective. We can rewrite the SVM objective as a constrained optimization problem:

$$\min_{\theta,b} \frac{\lambda}{2}\|(\theta,b)\|_2^2 + \frac{1}{n}\sum_{i=1}^{n}\gamma_i \tag{4}$$

subject to $\gamma_i \geq 0$ and $\gamma_i \geq 1 - y_i(\theta^T x_i + b)$.

The corresponding Lagrangian is then:

$$\min_{\theta,b,\gamma,\eta,\alpha} \mathcal{L} := \frac{\lambda}{2}\|(\theta,b)\|_2^2 + \frac{1}{n}\sum_{i=1}^{n}\gamma_i - \sum_{i=1}^{n}\gamma_i\eta_i + \sum_{i=1}^{n}\nu_i[1 - \gamma_i - y_i(\theta^T x_i + b)] \tag{5}$$

subject to: $\gamma_i \geq 0$, $\gamma_i \geq 1 - y_i(\theta^T x_i + b)$, $\eta_i \geq 0$, and $\nu_i \geq 0$.

The KKT conditions are:

$$\eta_i\gamma_i = 0 \tag{6}$$
$$\nu_i(1 - \gamma_i - y_i(\theta^T x_i + b)) = 0 \tag{7}$$
$$\theta^* = \frac{1}{\lambda}\sum_{i=1}^{n}\nu_i y_i x_i \tag{8}$$
$$b^* = \frac{1}{\lambda}\sum_{i=1}^{n}\nu_i y_i \tag{9}$$
$$\eta_i = \frac{1}{n} - \nu_i \tag{10}$$
$$\gamma_i = \max\{0, 1 - y_i(\theta^T x_i + b)\} \tag{11}$$
$$\eta_i \geq 0, \nu_i \geq 0 \tag{12}$$

3.1.1 Notation

We will characterize the optimal solutions for the two scenarios (there exists a point at x_q or there does not) for the case that the dimension is $d = 1$. We will later show how this provides results for $d > 1$. We will specify δ later, but will always maintain the relation $\lambda = \delta^2$.

Let $n = \frac{1}{20\sqrt{\varepsilon}}$, and define a set S_0 of n points as follows:

- $\frac{n}{4}$ points are $x_\alpha := 1 - \delta$ with $y_\alpha := -1$.
- $\frac{n}{4}$ points are $x_\beta := 1 + \delta$ with $y_\beta := +1$.
- The remaining $\frac{n}{2}$ points are not support vectors and are otherwise arbitrary; i.e. are such that $1 - y((\theta_0^*)^T x + b_0^*) < 0$, where

$$(\theta_0^*, b_0^*) = \arg\min_{(\theta,b)} F_\lambda^{(0)}(\theta, b) := \frac{\lambda}{2}(\|\theta\|^2 + b^2) + \frac{1}{n}\sum_{(x,y)\in S_0} \max\{0, 1 - y(\theta^T x + b)\} \quad (13)$$

Observe that such points exist as long as $\theta_0^* \neq 0$, which is easy to show.

Define $\gamma_\alpha^{(0)} := \max\{0, 1 - y_\alpha((\theta_0^*)^T x_\alpha + b_0^*)\} = \max\{0, 1 + \theta_0^*(1-\delta) + b_0^*\}$ and $\gamma_\beta^{(0)} := \max\{0, 1 - y_\beta((\theta_0^*)^T x_\beta + b_0^*)\} = \max\{0, 1 - \theta_0^*(1+\delta) - b_0^*\}$.

Similarly, define S_1 to be the set of n points that is exactly the same as S_0, except that instead of $\frac{n}{2}$ points that are not support vectors, there are $\frac{n}{2} - 1$ points that are not support vectors and one additional point at $x_q := 1$ with $y_q := -1$. Similarly define $F_\lambda^{(1)}$, (θ_1^*, b_1^*), $\gamma_\alpha^{(1)}$, and $\gamma_\beta^{(1)}$ to be the analogous quantities where S_0 is replaced with S_1, and let $\gamma_q^{(1)} := \max\{0, 1 - y_\beta((\theta_1^*)^T x_q + b_1^*)\} = \max\{0, 1 + \theta_1^* + b_1^*\}$. We will also sometimes use the notation $\gamma_\alpha(\theta, b) := \max\{0, 1 - y_\alpha(\theta^T x_\alpha + b)\}$, and similarly for $\gamma_\beta(\theta, b)$.

3.1.2 Lemmas

Next, we show some properties of the optimal solutions in each of the two cases.

▶ **Lemma 13.** *Suppose $\delta < \frac{1}{100}$ and $n \geq \frac{1}{\delta^2}$. Then we have that $\gamma_\alpha^{(i)} > 0$ and $\gamma_\beta^{(i)} = 0$ for $i \in \{0, 1\}$.*

Proof. To see that $\gamma_\alpha^{(i)} > 0$ and $\gamma_\beta^{(i)} = 0$ for $i \in \{0, 1\}$, we will rule out the other possibilities.

▷ Claim. Suppose $\delta < \frac{1}{7}$ and $n \geq \frac{1}{\delta^2}$. Then we cannot have $\gamma_\beta^{(i)} > 0$.

Suppose, for the sake of contradiction, that $\gamma_\beta^{(i)} > 0$, and let (θ_i^*, b_i^*) be the corresponding optimal parameters. First consider $i = 0$. Then since $\gamma_\beta^{(0)} > 0$, by the KKT conditions we have that the dual variables corresponding to each of the $\frac{n}{4}$ copies of x_β, call them ν_β, satisfy $\nu_\beta = \frac{1}{n}$. Moreover, note that this is the maximal value possible for the dual variables. Additionally, for points that are not support vectors, the dual variables are $\nu_i = 0$. The KKT conditions then imply:

$$\theta_0^* = \frac{1}{\lambda}\sum_{i=1}^n \nu_i x_i y_i \geq \frac{1}{\lambda}\left(\frac{n}{4}\frac{1}{n}(1+\delta) - \frac{n}{4}\frac{1}{n}(1-\delta)\right) = \frac{\delta}{2\lambda} = \frac{1}{2\delta} \quad (14)$$

and $b_0^* = \frac{1}{\lambda}\sum_{i=1}^n \nu_i y_i \geq 0$. But this implies that $1 - \theta_0^*(1+\delta) - b_0^* \leq 1 - \frac{1}{2\delta}(1+\delta) = \frac{1}{2}(1 - \frac{1}{\delta}) < 0$ (since $\delta < 1$), which contradicts that $\gamma_\beta^{(0)} > 0$.

Next, consider when $i = 1$. This time, we also have x_q as a support vector. Again using the fact that the corresponding dual variable is at most $\nu_q \leq \frac{1}{n}$, we have:

$$\theta_1^* = \frac{1}{\lambda}\sum_{i=1}^n \nu_i x_i y_i \geq \frac{1}{\lambda}\left(\frac{\delta}{2} - \frac{1}{n}\right) \geq \frac{1}{\lambda}\left(\frac{\delta}{2} - \delta^2\right) \geq \frac{1}{\lambda}\left(\frac{\delta}{2} - \frac{\delta}{4}\right) = \frac{1}{4\delta} \quad (15)$$

and $b_1^* = \frac{1}{\lambda}\sum_{i=1}^n \nu_i y_i \geq -\frac{1}{\lambda n}$. But this implies that $1 - \theta_1^*(1+\delta) - b_1^* \leq 1 - \frac{1}{4\delta}(1+\delta) + \frac{1}{\delta^2 n} \leq \frac{1}{4}(3 - \frac{1}{\delta}) + 1 < 0$, contradicting that $\gamma_\alpha^{(1)} > 0$ and proving the claim.

▷ Claim. It cannot hold that $\gamma_\alpha^{(i)} = \gamma_\beta^{(i)} = 0$ for either $i \in \{0, 1\}$.

First consider $i = 0$. We will show that in this case $\theta_0^* = \frac{1}{\delta}$ and $b_0^* = -\frac{1}{\delta}$. By assumption, we know that $1 + \theta^* + b^* - \theta^*\delta \leq 0$ and $1 - (\theta^* + b^*) - \theta^*\delta \leq 0$. Summing these implies that

$$1 - \theta_0^*\delta \leq 0 \Rightarrow \theta_0^* \geq \frac{1}{\delta} \tag{16}$$

Combining this last result with $\gamma_\alpha^{(0)} = 0$:

$$0 \geq 1 + \theta_0^*(1 - \delta) + b_0^* \geq 1 + \frac{1}{\delta}(1 - \delta) + b_0^* = \frac{1}{\delta} + b_0^* \Rightarrow b_0^* \leq -\frac{1}{\delta} \tag{17}$$

We have that $\theta = \frac{1}{\delta}$ and $b = -\frac{1}{\delta}$ satisfy $\gamma_\alpha(\theta, b) = \gamma_\beta(\theta, b) = 0$. By these last two equations, they are also clearly the *smallest norm* values satisfying these; hence they indeed minimize the overall optimization problem. But then $F_0(\theta, b) = \frac{\lambda}{2}(\frac{2}{\delta^2}) = 1$. But since we also have that $F_0(0, 0) = 1$, this cannot be the optimal solution, so we indeed cannot have $\gamma_\alpha^{(0)} = \gamma_\beta^{(0)} = 0$.

Now consider when $i = 1$. By the same argument as before, we must again have that if $\gamma_\alpha^{(1)} = \gamma_\beta^{(1)} = 0$ then $\theta_1^* \geq \frac{1}{\delta}$ and $b_1^* \leq -\frac{1}{\delta}$. Observe also that $F_1(\theta, b) = F_0(\theta, b) + \frac{1}{n}\gamma_q(\theta, b) \geq F_0(\theta, b)$. Hence:

$$F_1(\theta_1^*, b_1^*) \geq F_0(\theta_1^*, b_1^*) = \frac{\lambda}{2}(2\frac{1}{\delta^2}) = 1 \tag{18}$$

which again contradicts the optimality of (θ_1^*, b_1^*) since $F_1(0, 0) = 1$. The proof of the claim is complete.

Since under the assumption of the lemma we cannot have $\gamma_\alpha^{(i)} = \gamma_\beta^{(i)} = 0$, and we cannot have that $\gamma_\beta^{(i)} > 0$, we must have that $\gamma_\alpha^{(i)} > 0$ and $\gamma_\beta^{(i)} = 0$, concluding the proof. ◀

Next, we show what the optimal parameters are in this case.

▶ **Lemma 14.** *Suppose that $\gamma_\alpha^{(0)} > 0$ and $\gamma_\beta^{(0)} = 0$. Then we have:*

$$\theta_0^* = \frac{2\lambda(1 + \delta) + \delta}{2\lambda(1 + (1 + \delta)^2)} \tag{19}$$

and $b_0^* = 1 - (1 + \delta)\theta_0^*$.

Similarly, if $\gamma_\alpha^{(1)} > 0$ and $\gamma_\beta^{(1)} = 0$. Then we have:

$$\theta_1^* = \frac{2\lambda(1 + \delta) + \delta(1 + \frac{1}{n})}{2\lambda(1 + (1 + \delta)^2)} \tag{20}$$

and $b_1^* = 1 - (1 + \delta)\theta_1^*$.

Proof. First, observe that for $i \in \{0, 1\}$ we not only have $\gamma_\beta^{(i)} = \max\{0, 1 - (\theta_i^* + b_i^*) - \theta_i^*\delta\} = 0$, but also have that

$$1 - (\theta_i^* + b_i^*) - \theta_i^*\delta = 0 \tag{21}$$

To see this, suppose otherwise, that $1 - (\theta_i^* + b_i^*) - \theta_i^*\delta < 0$. Then there exists some $0 < \theta' < \theta_i^*$ such that we still have $1 - (\theta' + b_i^*) - \theta'\delta = 1 - \theta'(1 + \delta) - b_i^* < 0$. Moreover, this can only decrease the regularization term, $\frac{\lambda}{2}\theta^2$, and can only decrease the $\gamma_\alpha^{(i)} = \max\{0, 1 + \theta(1 - \delta) + b\}$ term. In the case that $i = 1$, this can also only decrease the $\gamma_q^{(1)} = \max\{0, 1 + \theta + b\}$ term. Either way, this contradicts the optimality of θ_i^*. Hence, $b_i^* = 1 - \theta_i^*(1 + \delta)$.

For $i = 0$, plugging this in and simplifying, we can rewrite the optimization problem as:

$$\min_{\theta} \frac{\lambda}{2}(\theta^2 + (1 - \theta(1+\delta))^2) + \frac{1}{2}(1 - \theta\delta) \tag{22}$$

Differentiating with respect to θ and setting the expression equal to zero,

$$\begin{aligned} 0 &= \frac{\partial}{\partial\theta}\left[\frac{\lambda}{2}(\theta^2 + (1-\theta(1+\delta))^2) + \frac{1}{2}(1-\theta\delta)\right]\Big|_{\theta=\theta_0^*} \\ &= \frac{\lambda}{2}(2\theta_0^* - 2(1-\theta_0^*(1+\delta))(1+\delta)) - \frac{\delta}{2} \\ &= \lambda\theta_0^*(1 + (1+\delta)^2) - \lambda(1+\delta) - \frac{\delta}{2} \end{aligned}$$

from which we can solve for θ_0^* and obtain that

$$\theta_0^* = \frac{2\lambda(1+\delta)+\delta}{2\lambda(1+(1+\delta)^2)}.$$

Similarly, for $i = 1$, we can rewrite the optimization problem as:

$$\min_{\theta} \frac{\lambda}{2}(\theta^2 + (1 - \theta(1+\delta))^2) + \frac{1}{4}(1 + \theta + 1 - \theta(1+\delta) - \theta\delta) + \frac{1}{n}(1 + \theta + 1 - \theta\delta) \tag{23}$$

We can again differentiate with respect to θ and set the expression equal to zero, then solve for θ_1^*, yielding the desired expression. ◀

We now adapt these results to the case that we care about: when $d > 1$ and there are points other than just x_α, x_β, and x_q.

First, note that when $d > 1$ and the only possible support vectors are x_α, x_β, and x_q, $\theta_i^* \in \mathbb{R}^d$ is parallel to x_q. Hence, θ_i^* reduces to the one-dimensional case, and is simply projected onto x_q. For d dimensions, we can thus replace what was previously $\theta_i^* \in \mathbb{R}$ with $(\theta_i^*)^T x_q \in \mathbb{R}$, where $\theta_i^*, x_q \in \mathbb{R}^d$.

Recall that up to this point we have been assuming that the remaining $\frac{n}{2}$ or $\frac{n}{2} - 1$ points that were added by Alice are *not* support vectors. We will now show that this is the case.

Redefine S_0 to be the set of points including $\frac{n}{4}$ copies of $(x_\alpha, -1)$, $\frac{n}{4}$ copies of $(x_\beta, +1)$, and $\frac{n}{2}$ arbitrary points $\{v_i\}_{i=1}^{n/2}$, but this time with the requirement that $v_i^T x_q < 1 - 10\delta$, $\forall i \in [\frac{n}{2}]$. Similarly, let S_1 be the set of points including $\frac{n}{4}$ copies of $(x_\alpha, -1)$, $\frac{n}{4}$ copies of $(x_\beta, +1)$, one copy of $(x_q, -1)$ and $\frac{n}{2} - 1$ arbitrary points $\{v_i\}_{i=1}^{n/2-1}$, all satisfying $v_i^T x_q < 1 - 10\delta$.

Define

$$F_\lambda^{(0)}(\theta, b; \lambda) := \frac{\lambda}{2}(\|\theta\|^2 + b^2) + \frac{1}{n}\sum_{(x,y)\in S_0} \max\{0, 1 - y(\theta^T x + b)\} \tag{24}$$

and

$$F_\lambda^{(1)}(\theta, b; \lambda) := \frac{\lambda}{2}(\|\theta\|^2 + b^2) + \frac{1}{n}\sum_{(x,y)\in S_1} \max\{0, 1 - y(\theta^T x + b)\} \tag{25}$$

Finally, let $(\theta_i^*, b_i^*) = \arg\min_{\theta,b} F_\lambda^{(i)}(\theta, b)$ for $i \in \{0, 1\}$.

▶ **Lemma 15.** *Suppose $\lambda = \delta^2$, $\delta < \frac{1}{7}$ and $n \geq \frac{1}{\delta^2} = \frac{1}{\lambda}$. Then for both S_0 and S_1, none of the points v satisfying $v^T x_q < 1 - 10\delta$ are support vectors. Moreover, we have*

$$\theta_0^* = \left(\frac{2\lambda(1+\delta)+\delta}{2\lambda(1+(1+\delta)^2)}\right) x_q \tag{26}$$

$$\theta_1^* = \left(\frac{2\lambda(1+\delta)+\delta(1+\frac{1}{n})}{2\lambda(1+(1+\delta)^2)}\right) x_q \tag{27}$$

and $b_i^* = 1 - \|\theta_i^*\|(1+\delta)$ *for both* $i \in \{0,1\}$.

Proof. By the preceding discussion and lemmas, it suffices to show that for $(v,-1) \in S_i$ such that $v^T x_q < 1 - 10\delta$, $(v,-1)$ is not a support vector. This implies that (θ_i^*, b_i^*) does not depend on such v, so that the equations for the optimal parameters from before (adapted slightly for $d > 1$) indeed hold. For this, it suffices to show that for the (θ_i^*, b_i^*) described above, we have $1 + ((\theta_i^*)^T v + b_i^*) < 0$ when $v^T x_q < 1 - 10\delta$.

For the given δ, λ, and n, one can easily verify that for both $i = 0$ and $i = 1$ we have $\|\theta_i^*\| \geq \frac{\delta}{5\lambda}$. Moreover, since $b_i^* = 1 - (1+\delta)\|\theta_i^*\|$ and $(\theta_i^*)^T x_q = \|\theta_i^*\|$, we have:

$$1+(\theta_i^*)^T v+b_i^* \leq 1+(1-10\delta)\|\theta_i^*\|+1-(1+\delta)\|\theta_i^*\| = 2-11\delta\|\theta_i^*\| \leq 2-11\delta\frac{\delta}{5\lambda} = 2-\frac{11}{5} < 0$$

proving the claim. ◀

3.2 Proofs of Main Results

We now use the preceding lemmas to complete the proof of Theorem 12.

Proof. Let $n = \frac{1}{20\sqrt{\varepsilon}}$, and let x_q be the point being queried by Bob. If x_q was added to the set by Alice, then $i := b_q = 0$; otherwise, $i := b_q = 1$. Let $(\hat{\theta}, \hat{b})$ be the output of the sketch. Then using the guarantee of the sketch and of strong convexity, we have that $\|(\hat{\theta}, \hat{b}) - (\theta_i^*, b_i^*)\| \leq \sqrt{\frac{2\varepsilon}{\lambda}}$. Hence, to distinguish these two scenarios, it suffices to show that $\|(\theta_0^*, b_0^*) - (\theta_1^*, b_1^*)\| > 2\sqrt{\frac{2\varepsilon}{\lambda}}$. Indeed,

$$\|(\theta_0^*, b_0^*) - (\theta_1^*, b_1^*)\| \geq \|\theta_0^* - \theta_1^*\| = \frac{1}{n}\frac{\delta}{2\lambda(1+(1+\delta)^2)} \geq \frac{\delta}{5\lambda n} = \frac{20\delta\sqrt{\varepsilon}}{5\lambda} = 4\sqrt{\frac{\varepsilon}{\lambda}} > 2\sqrt{\frac{2\varepsilon}{\lambda}},$$

proving the claim. ◀

Now we extend this result to the low-dimensional case. When d is a constant, the above lower bound cannot be directly applied because there does not exist a set T of size $|T| = n$ such that $\forall v \neq v' \in T$, $v^T v' < 1 - 10\delta$ when δ is a constant. However, we can adapt the lower bound to the low dimensional setting if we let δ be sub-constant. Since we always maintain the relationship that $\lambda = \delta^2$, this means that λ also scales with $\frac{1}{n}$. Note that $\lambda = \Theta(\frac{1}{n})$ is often used in practice.

▶ **Theorem 16.** *For* $d = 2$ *and* $\lambda = \Theta(\frac{1}{n^2})$*, a sketch as defined above requires space* $\Omega(\varepsilon^{-1/4})$*. For* $d \geq 3$ *and* $\lambda = \Theta(\frac{1}{n})$*, such a sketch requires space* $\Omega(\varepsilon^{-1/2})$*.*

Proof. First, note that if $n = O(\delta^{-(d-1)})$ for $d > 1$, then there exists a subset T of the unit sphere in $\mathbb{R}^d$ satisfying $\forall v \neq v' \in T$, $v^T v' \leq 1 - 10\delta$. Alice will use such a set to encode bits.

In the high dimensional lower bound construction, the constraints we had on the points were $\delta < \frac{1}{7}$ and $n \geq \frac{1}{\delta^2} = \frac{1}{\lambda}$. Moreover, for the final step of the analysis, we needed that $\frac{\delta}{5\lambda n} = \frac{1}{5\delta n} > 2\sqrt{\frac{2\varepsilon}{\lambda}} = 2\sqrt{2\varepsilon}\frac{1}{\delta}$, which is always satisfied for $n \leq \frac{1}{20\sqrt{\varepsilon}}$ (regardless of λ and δ, as long as $\lambda = \delta^2$). Additionally, for the construction we must also have $n \leq \Theta(\delta^{-(d-1)})$. Hence, for $d = 3$, by letting $\lambda = \frac{1}{n} = \Theta(\varepsilon^{1/2})$, all of these constraints are satisfied, so that we again get a $\frac{1}{\sqrt{\varepsilon}}$ lower bound. For $d = 2$ and $\lambda = \Theta(\varepsilon^{1/2})$, this also implies that we can encode $\Theta(\delta^{-(d-1)}) = \Theta(\varepsilon^{-1/4})$ bits. ◀

A Analysis of the streaming algorithm for $(1+\varepsilon)$-multiplicative approximation in the case of $d = 1$

First, it is clear from the algorithm description that in the case of $q \le p$, the algorithm produces an exact solution. To show the correctness in the otherwise case, as stated in the description let t_j be the number of points in P that fall in the interval R_j, and let T_j be the number of points that fall to the left of R_j, i.e., $T_j = |\{x \in P\colon x \le q - (D/2^{j-1})\}| = |\bigcup_{k<j} R_k|$ and note that $T_j \ge \max\{|S_0|, |E_0|\} \ge \frac{2\log W}{\varepsilon}\max\{\log W + 1/\varepsilon\}$. Moreover, let $V = \sum_{x\in P, x\le q}(q-x)$ be the value of the solution and $V_j = \sum_{x\in P\cap R_j}(q-x)$ be the contribution of the points in R_j to the solution.

▶ **Lemma 17** (If Not Enough Samples, Set Doesn't Contribute). *If $t_j < \log D$, then $i'(j) = -1$. Moreover, if $i'(j) = -1$, then with high probability $\frac{t_j}{T_j} \le \frac{2\varepsilon}{\log W}$.*

Proof. For the first claim, note that for such j, even if we sample the points with probability 1, we don't get $\log D$ points in E_i, and thus $i'(j) = -1$.

Now suppose $i'(j) = -1$. If $t_j \le 2\log D$, then since $T_j \ge \log^2 W/\varepsilon$, we have that $\frac{t_j}{T_j} \le \frac{2\varepsilon}{\log W}$. Otherwise, let i' be such that $2^{-(i'+1)} \le \frac{2\log D}{t_j} \le 2^{-i'}$. Now, if we sample every point in R_j with probability $2^{-i'}$, in expectation, we sample $t_j 2^{-i'}$ points which is between $2\log D$ and $4\log D$. Moreover, since $t_j \ge 2\log D$, we can use Chernoff bound, proving that

with high probability the number of samples is between $\log D$ and $8 \log D$. Therefore, since the final sample $E_{i'}$ does not contain $\log D$ points from R_j, it means that it contains at least $m_1 - 8 \log D \geq m_1/2 = \frac{C_1 \log^2 W}{2\varepsilon}$ points from $\cup_{k<j} R_k$ (for sufficiently large constant C_1).

On the other hand, the expected number of sampled points from $\bigcup_{k<j} R_k$ is $T_j 2^{-i'}$ which with high probability (using Chernoff again) should be at least $m_1/4 \geq \frac{C_1 \log^2 W}{4\varepsilon}$. Therefore, we get that

$$T_j \geq 2^{i'} \frac{C_1 \log^2 W}{4\varepsilon} \geq \frac{t_j}{4 \log D} \cdot \frac{C_1 \log^2 W}{4\varepsilon} \geq \frac{C_1 t_j \log W}{16\varepsilon}$$

Thus for $C_1 \geq 8$, we get that $\frac{t_j}{T_j} \leq \frac{2\varepsilon}{\log W}$ ◀

▶ **Lemma 18** (If Enough Samples, Get Initial Constant Factor Approximation). *If $i'(j) \neq -1$, then ϕ_j approximates $\min\{1, \frac{t_j}{T_j}\}$ by a constant factor.*

Proof. By Lemma 17, we know that $t_j \geq \log D$.

- First note that if $T_j \leq t_j$, with high probability the number of sampled points from $\cup_{k<j} R_k$ is less than 2 times the number of sampled points from R_j, and therefore, $\phi_j \geq 1/2$, and the lemma is proved.
- Second, note that if $\frac{t_j}{T_j} \leq \frac{\varepsilon}{2C_1 \log W} \cdot \frac{\log D}{\log W}$, then the number of sampled points from $\cup_{k<j} R_k$ with high probability (using Chernoff) is at least $\frac{1}{2} \cdot \frac{T_j}{t_j} \cdot \log D \geq \frac{\log D}{2} \cdot \frac{2C_1 \log^2 W}{\log D \varepsilon} \geq \frac{C_1 \log^2 W}{\varepsilon} = m_1$ which is a contradiction, because then we would not have picked $\log D$ points in $E_{i'(j)}$ from R_j.
- In the otherwise case, we show that the sample $E_{i'(j)}$ suffices to get a constant factor approximation to both values t_j and T_j (and hence, t_j/T_j). First, to see the latter, note that $T_j \geq t_j$ and therefore with high probability (using Chernoff) we get at least $\frac{\log D}{2}$ samples from $\cup_{k<j} R_k$ in the set $E_{i'(j)}$ which are chosen uniformly at random. This is enough for computing a constant factor approximation of T_j with high probability.
  Second, if $E_{i'(j)}$ only contains samples from the first $t_j/8$ fraction of the points in R_j, then with high probability, there would still be $\log D$ samples from R_j in $E_{i'(j)+1}$ (this is because with high probability, we only get less points from $\bigcup_{k<j} R_k$ in $E_{i'(j)+1}$ and still at least $\log D$ points from R_j in it). However, this contradicts the choice of $i'(j)$. Therefore, we get a uniform sample of size $\Omega(\log D)$, from a constant fraction of the points in R_j, meaning that we can approximate t_j up to a constant factor with high probability. Therefore, ϕ_j will be a constant approximation to the value of $\min\{1, \frac{t_j}{T_j}\}$. ◀

The following two lemmas analyze the case of $\phi_j \geq \frac{1}{\log W}$.

▶ **Lemma 19** (Enough Samples are Found From Large Contributing Sets). *If $i'(j) \neq -1$ and $\phi_j \geq \frac{1}{\log W}$, then we have $i(j) \neq -1$.*

Proof. Note that by Lemma 18, ϕ_j is a constant factor approximation for $\min\{1, t_j/T_j\}$ which means that either $t_j \geq \Omega(T_j)$ or $t_j \geq \Omega(T_j/\log W)$ as $\phi_j \geq 1/\log W$. Let C_3 be the constant in this inequality, i.e., $t_j \geq T_j/(C_3 \log W)$. Moreover, as $T_j \geq |S_0| = \frac{C_2 \log W}{\varepsilon^2}$, we get that $t_j \geq \frac{C_2}{C_3 \varepsilon^2} \geq 2/\varepsilon^2$ for $C_2 \geq 2C_3$.

Now let i be such that $2^{-(i+1)} \leq 2/(\varepsilon^2 t_j) \leq 2^{-i}$. This means that by sampling the points with rate 2^{-i}, in expectation, we sample $2^{-i} t_j \geq 2/\varepsilon^2$ points from R_j and moreover, with high probability we will sample at least $1/\varepsilon^2$ points from R_j (here we used the fact that since $i'(j) \neq -1$, we have $t_j \geq \log D$ and thus we can apply Chernoff bound). Furthermore,

in expectation, we will sample $2^{-i}T_j \leq 4T_j/(t_j\varepsilon^2) \leq 4C_3 \cdot \log W/\varepsilon^2$ points from intervals $R_0, \ldots, R_{j-1}$. Therefore, since we keep $m_2 = C_2 \log W/\varepsilon^2$ smallest sampled points in S_i, by choosing C_2 large enough, i.e., $C_2 \geq (4C_3 + 2)$, we will store all sampled points of R_j in S_i as well. Therefore, $i(j) \neq -1$. ◀

▶ **Lemma 20** (Large Contributing Sets have Small Relative Error). *If $i'(j) \neq -1$ and $\phi_j \geq \frac{1}{\log W}$, then we have that $\sum_{x \in S_{i(j)} \cap R_j} 2^i(q-x)$ is a $(1+2\varepsilon)$ approximation of V_j.*

Proof. As in the previous lemma, let i be such that $2^{-(i+1)} \leq 2/(\varepsilon^2 t_j) \leq 2^{-i}$. Therefore, by similar arguments to the above lemma, we know that $i(j) \geq i$, which further means that all sampled points from R_j are kept in $S_{i(j)}$. We thus get a uniform sample of size at least $1/\varepsilon^2$ from the interval R_j, which is enough for an additive $\varepsilon t_j(D/2^{j-1})$ approximation as every point in the interval is contributing at least $D/2^{j-1}$. On the other hand, we have that $V_j \geq t_j D/2^j$. Thus this additive approximation translates to a $(1+2\varepsilon)$ multiplicative approximation. ◀

The following two lemmas analyze the case of $\frac{\varepsilon}{\log W} \leq \phi_j \leq \frac{1}{\log W}$.

▶ **Lemma 21** (Enough Samples are Found from Small Contributing Sets). *If $i'(j) \neq -1$ and $\frac{\varepsilon}{\log W} \leq \phi_j \leq \frac{1}{\log W}$, then if $V_j \geq V(\varepsilon/\log W)$, we have $i(j) \neq -1$.*

Proof. Note that $V_j \geq V(\varepsilon/\log W)$ means that $t_j \geq T_j(\varepsilon/\log W)$, as otherwise if $t_j < T_j(\varepsilon/\log W)$, we have that the total contribution of R_j is at most $V_j \leq t_j D/2^{j-1}$, while we have that $V \geq T_j D/2^{j-1}$; which means that $V_j \leq T_j(\varepsilon/\log W)D/2^{j-1} \leq (\varepsilon/\log W)V$, which is a contradiction.

Now let i be such that $2^{-(i+1)} \leq 2(\phi_j \log W)^2/(\varepsilon^2 t_j) \leq 2^{-i}$ [3]. This means that in expectation, we sample $2^{-i}t_j \geq 2(\phi_j \log W/\varepsilon)^2$ points from R_j and moreover, with high probability we will sample at least $(\phi_j \log W/\varepsilon)^2$ points from R_j. Furthermore, in expectation, we will sample $2^{-i}T_j \leq 4T_j(\phi_j \log W)^2/(t_j\varepsilon^2) \leq 4\phi \log^2 W/\varepsilon^2 \leq 2\log W/\varepsilon^2$ points from intervals $R_0, \ldots, R_{j-1}$, where in the last inequality we used the fact that $\phi_j \leq 1/\log W$. Therefore, since we keep $m_2 \geq 6\log W/\varepsilon^2$ smallest points in S_i, we will store all sampled points of R_j in S_i. Therefore, $i(j) \neq -1$. ◀

▶ **Lemma 22** (Small Contributing Sets have Small Additive Error). *If $i'(j) \neq -1$ and $\frac{\varepsilon}{\log W} \leq \phi_j \leq \frac{1}{\log W}$, then if $V_j \geq V(\varepsilon/\log W)$, we have that $\sum_{x \in S_{i(j)} \cap R_j} 2^i(q-x)$ is a $\frac{\varepsilon}{\log W}$ additive approximation of V.*

Proof. As in the previous lemma, let i be such that $2^{-(i+1)} \leq 2(\phi_j \log W)^2/(\varepsilon^2 t_j) \leq 2^{-i}$. Therefore, by similar arguments to the above lemma, we know that $i(j) \geq i$, which further means that all sampled points from R_j are kept in $S_{i(j)}$. We thus get a uniform sample of size at least $(\phi_j \log W/\varepsilon)^2$ from the interval R_j, which is enough for an additive $\frac{\varepsilon}{\phi_j \log W} t_j(D/2^{j-1})$ approximation as every point in the interval is contributing at least $D/2^{j-1}$. However, as $V \geq T_j D/2^{j-1}$, this translates to a $\frac{\varepsilon}{\phi_j \log W}\frac{t_j}{T_j}V = \frac{\varepsilon}{\log W}V$ additive approximation. ◀

We now restate and prove Lemma 5 and Corollary 6.

▶ **Lemma 23** (Lemma 5). *The algorithm returns a $(1+O(\varepsilon))$ multiplicative approximation.*

[3] Note that again by the conditions of the lemma on ϕ_j, the fact that ϕ_j approximates t_j/T_j, and the fact that $T_j \geq C_2 \log W/\varepsilon^2$, this value is always at most 1 and therefore such i exists.

Proof. Let us consider the following cases separately.

- For $j = 0$, we get the exact contribution of the points in R_0.
- For j where $i'(j) = -1$, we know by lemma 17 that $\frac{t_j}{T_j} \leq 2\varepsilon/\log W$. Therefore the total contribution of all V_j for such j is at most $2\varepsilon V$.
- Moreover, whenever $i(j) = -1$, using Lemmas 19 and 21, we know that $V_j \leq V(\varepsilon/\log W)$. Summing over all such j, we get a total additive error of εV.
- Now consider all $j \geq 1$ such that $\phi_j \geq \frac{1}{\log W}$. By Lemma 19 and Lemma 20, we get a $(1 + 2\varepsilon)$ multiplicative approximation of their contribution.
- Finally consider all $j \geq 1$ such that $\frac{\varepsilon}{\log W} \leq \phi_j \leq \frac{1}{\log W}$. If $V_j \geq V(\varepsilon/\log W)$, by lemma 22, we get an additive $\frac{\varepsilon}{\log W} V$ approximation of their contribution. Summing over all such j, this will give a $(1 + \varepsilon)$ multiplicative approximation.
  However if $V_j < V(\varepsilon/\log W)$ and $i(j) \neq -1$ for such j, it means that we have sampled points in R_j with probability $2^{-i(j)}$ and potentially kept only some of them in $S_{i(j)}$ this only causes an under estimation of the contribution of R_j. However, the samples that the algorithm has chosen to keep in S_i might be biased towards the smaller end of the interval, i.e., $D/2^{j-1}$, however this can only cause an over estimation by a factor of 2. Therefore, for such a j, we have $0 \leq \sum_{x \in S_{i(j)} \cap R_j} 2^i(q - x) \leq 2(1 + \varepsilon)V_j$. Again because $V_j \leq V\varepsilon/\log W$, the total error of such j will be at most a multiplicative $(1 + \varepsilon)$ factor. ◀

▶ **Corollary 24** (Corollary 6). *There exists a one pass streaming algorithm that computes a $(1 + \varepsilon)$ multiplicative approximation for point estimation variant of the problem in one dimensional case. Moreover, if the points come from $[W]$, the space usage of the algorithm is $O(\frac{\log^2 n \cdot \log W}{\varepsilon}(\log n + 1/\varepsilon))$ bits.*

Proof. Note that in the above algorithm we do not need to consider R_j for which $j \geq \log n^2 = 2 \log n$, as the overall contribution of such points to the solution is as most D/n whereas the value of the solution is at least D. Thus we can bound one of the $\log W$ in the bound of Observation 4 by $\log n$. ◀

B Multiplicative point estimation lower bound

Proof. We prove this theorem by a reduction from the standard Augmented Indexing problem. In this problem, Alice is given a bit string s of length m and Bob has an index $i \in [m]$ as well as bits $s_1, \ldots, s_{i-1}$. The goal is for Alice to send a message to Bob so that he can recover s_i, the ith bit in Alice's string. It is a standard fact that this requires $\Omega(m)$ bits.

Case of $d = 1$. First consider the one dimensional case and let $r = 1/\sqrt{\varepsilon}$. Suppose that Alice holds a string of length r, termed $s_1 \ldots s_r$. From that, she will construct an instance of our point estimation sketching problem. For each $0 \leq i < r$, if her ith bit is one, she will put $n/r = n\sqrt{\varepsilon}$ points in position $3i/r = 3i\sqrt{\varepsilon}$. Otherwise if the bit is 0, she will not put any point there. Thus all points will be positioned in $[0, 1)$ with the diameter less than 1.

To learn the ith bit, Bob will query the presumed sketch with $b = 3(i + 1)\sqrt{\varepsilon}$, obtaining a value v. Bob will subtract the contribution from the points associated with the first $i - 1$ bits. Note that the resulting value is $\frac{1}{n} \cdot s_i \cdot n\sqrt{\varepsilon} \cdot 3\sqrt{\varepsilon}$, up to an additive error ε. Therefore it is possible to recover the value of the encoded bit. Hence the one-dimensional point estimation problem cannot be solved in space less than $\Omega(r) = \Omega(1/\sqrt{\varepsilon})$.

Case of $d = 2$. Next, consider the two dimensional case, and for parameters s and r (to be specified later), consider the $s \times r$ potential positions inside a circle of unit radius. More specifically, for $1 \le i \le s, 1 \le j \le r$, the (i, j)-th position is the point at angle $2\pi i/s$ and at radius $1 - \frac{j-1}{2r}$. These positions correspond to the sr bits in the index problem held by Alice. For the $((j-1)s+i)$-th bit in her bit-string, Alice will put $n/(sr)$ actual points at the (i, j)-th position described above iff the corresponding bit is equal to 1. She will then send her point set to Bob.

Bob can recover any bit of Alice using hyperplane queries. Specifically, in order to figure out the $((j-1)s+i)$-th bit of Alice, Bob can ask the hyper-plane corresponding to $\theta = 2\pi i/s$ and $b = 1 - j/(2r)$; and subtract the contribution of points corresponding to bits up to $((j-1)s+i)$. Note that, if there is no point at that location, the result should be 0, otherwise it should be $(n/(sr)) \cdot (1/(2r))$. Thus, if the algorithm has an additive approximation less than $\frac{1}{3}(n/(sr)) \cdot (1/(2r))$, it can correctly recover the respective bit in Alice's input.

Also, note that the above means that no multiplicative approximation is possible unless Alice sends s bits. But setting $s = n$ and $r = 1$, this will require Alice to send all her input to Bob.

Note that for the hyperplane to include only the ith point from the tier j circle, we need to set r so that $1/(2r) \approx (1 - \cos(2\pi/s)) \approx 2\pi^2/s^2$. Thus we need additive approximation $\Theta(n/s^5)$. We set $s = \varepsilon^{-1/5}$, and get that the total size of the sketch is at least $\Omega(sr) = \Omega(\varepsilon^{-3/5})$.

Case of $d > 2$. To generalize the result to higher dimensions, we put s points uniformly on the $d-1$ dimensional unit sphere and repeat this for r different radii as before. More precisely, using we put an ℓ-net on the surface of the unit sphere. It is a standard fact that we can have $s = \Theta(1/\ell)^{d-1}$ points on the surface so that their pairwise distance is at least ℓ. Similar to the two-dimensional case, we have that $(1/2r) \approx (1 - \cos(O(\pi/\ell))) \approx O(1/\ell^2)$. Therefore, the additive approximation the algorithm can tolerate is $\frac{n}{sr} \cdot \frac{1}{2r}$ which should be at most $n\varepsilon$ and therefore, we get that $\varepsilon = 1/(sr^2)$. Inserting the values of s and r using the value of ℓ, we get that $\varepsilon = \ell^{d+3}$. As the space lower bound for the index problem is $\Omega(sr)$, we get that the space requirement for our problem is $sr = 1/(\varepsilon r) = \ell^2/\varepsilon = \varepsilon^{2/(d+3)}/\varepsilon = \varepsilon^{-\frac{d+1}{d+3}}$. ◀

C Additive point estimation upper bounds

C.1 $d = 1$

Proof. We now argue the correctness and space complexity of the algorithm given in Theorem 9. For correctness, the output of a query q accounts for all the data points entirely to the left of the interval $I_{v(q)}$, where $v(q)$ is the unique leaf $v(q)$ with $q \in I_{v(q)}$. Hence the error comes entirely from the unaccounted points in $v(q)$ as well as the predecessors of $v(q)$. By construction any (non-empty) predecessor has diameter $\sqrt{\varepsilon}$ and contains less than $\sqrt{\varepsilon}n$ points, or, alternatively, has diameter less than ε (for expansion exception). Hence the error is $\le \varepsilon$ for each predecessor, and $O(\varepsilon \log 1/\varepsilon)$ overall. As usual, we can rescale ε to obtain error ε and correspondingly larger space.

For space complexity, note that the space is proportional to the size of the tree. The tree has size at most $O(1/\sqrt{\varepsilon})$ since each leaf is either one of the original $2/\sqrt{\varepsilon}$ one or has a parent node with $\sqrt{\varepsilon}n$ points. ◀

C.2 $d = 2$

Proof. We now analyze the procedure described in Theorem 10. It is clear that the total space usage of the algorithm is at most order of the size of the quad-tree. The size of the tree is bounded by $O(1/\varepsilon)$ as follows. First, there at most $O(1/\varepsilon)$ of the original nodes. Second, each new children created has the property that its parent got associated with εn points, hence at most $4/\varepsilon$ such children can be ever created.

We now analyze the error of the sketching algorithm. For the nodes that do not cross the line L, the distances of their points are computed exactly. So we only need to argue about the crossing nodes. First of all, note that we can ignore all leaves with more than εn points at them as their diameter is less than $2\varepsilon^2$.

Let $\mathcal{C}$ be the set of leaves that cross the query line and have diameter at least $2\varepsilon^2$ (and hence less than εn associated points). It is immediate to check that, in expectation, our estimator outputs the correct value; in particular for P_v the set of points associated to a node v:

$$\mathbb{E}\left[\sum_{v\in\mathcal{C}} c_v \cdot \max\{0, D(r_v, L)\}\right] = \sum_{v\in\mathcal{C}}\sum_{p\in P_v} \frac{1}{c_v} c_v \cdot \max\{0, D(p, L)\} = \sum_{v\in\mathcal{C}}\sum_{p\in P_v} \max\{0, D(p, L)\}.$$

Thus we only need to argue that it concentrates closely around its expectations, with constant probability. Let us compute the variance. The point in each (non-empty) node is chosen independently at random. Thus we can sum up the variances of each node. Consider a node v with side length $\ell \geq \varepsilon^2$. Then we have that

$$\mathrm{Var}\left[c_v \cdot \max\{0, D(r_v, L)\}\right] \leq \sum_{i=1}^{c_v} \frac{1}{c_v} \cdot (c_v \cdot \ell)^2 \leq c_v^2 \ell^2 \leq (n\varepsilon)^2 \ell^2.$$

Now note that any line can intersect only $(1/\ell)$ nodes with side length ℓ, and thus the total variance of all nodes with side length ℓ is at most $(n\varepsilon)^2\ell$. Hence, the total variance over all nodes (over all levels) is at most $O(n^2\varepsilon^2\sqrt{\varepsilon})$. Overall, the standard deviation is at most $O(n\varepsilon^{5/4})$. By Chebyshev's bound, the reported answer has an additive error of $O(n\varepsilon^{5/4})$ with constant probability.

As stated before, replacing $\varepsilon' = \Theta(\varepsilon^{4/5})$ we get that the algorithm is providing an additive ε' approximation using space $\tilde{O}((\varepsilon')^{-4/5})$, completing the proof of the result. ◀

On the Parameterized Approximability of Contraction to Classes of Chordal Graphs

Abstract

A graph operation that *contracts edges* is one of the fundamental operations in the theory of graph minors. Parameterized Complexity of editing to a family of graphs by contracting k edges has recently gained substantial scientific attention, and several new results have been obtained. Some important families of graphs, namely the subfamilies of chordal graphs, in the context of edge contractions, have proven to be significantly difficult than one might expect. In this paper, we study the $\mathcal{F}$-Contraction problem, where $\mathcal{F}$ is a subfamily of chordal graphs, in the realm of parameterized approximation. Formally, given a graph G and an integer k, $\mathcal{F}$-Contraction asks whether there exists $X \subseteq E(G)$ such that $G/X \in \mathcal{F}$ and $|X| \leq k$. Here, G/X is the graph obtained from G by contracting edges in X. We obtain the following results for the $\mathcal{F}$-Contraction problem.

- Clique Contraction is known to be FPT. However, unless NP $\subseteq$ coNP/poly, it does not admit a polynomial kernel. We show that it admits a polynomial-size approximate kernelization scheme (PSAKS). That is, it admits a $(1+\epsilon)$-approximate kernel with $\mathcal{O}(k^{f(\epsilon)})$ vertices for every $\epsilon > 0$.
- Split Contraction is known to be W[1]-Hard. We deconstruct this intractability result in two ways. Firstly, we give a $(2+\epsilon)$-approximate polynomial kernel for Split Contraction (which also implies a factor $(2+\epsilon)$-FPT-approximation algorithm for Split Contraction). Furthermore, we show that, assuming Gap-ETH, there is no $\left(\frac{5}{4}-\delta\right)$-FPT-approximation algorithm for Split Contraction. Here, $\epsilon, \delta > 0$ are fixed constants.
- Chordal Contraction is known to be W[2]-Hard. We complement this result by observing that the existing W[2]-hardness reduction can be adapted to show that, assuming FPT$\neq$ W[1], there is no $F(k)$-FPT-approximation algorithm for Chordal Contraction. Here, $F(k)$ is an arbitrary function depending on k alone.

We say that an algorithm is an $h(k)$-FPT-approximation algorithm for the $\mathcal{F}$-Contraction problem, if it runs in FPT time, and on any input (G,k) such that there exists $X \subseteq E(G)$ satisfying $G/X \in \mathcal{F}$ and $|X| \leq k$, it outputs an edge set Y of size at most $h(k) \cdot k$ for which G/Y is in $\mathcal{F}$. We find it extremely interesting that three closely related problems have different behavior with respect to FPT-approximation.

1 Introduction

Graph modification problems have been extensively studied since the inception of Parameterized Complexity in the early '90s. The input of a typical graph modification problem consists of a graph G and a positive integer k, and the objective is to edit k vertices (or edges) so that the resulting graph belongs to some particular family, $\mathcal{F}$, of graphs. These problems are not only mathematically and structurally challenging, but have also led to the discovery of several important techniques in the field of Parameterized Complexity. It would be completely appropriate to say that solutions to these problems played a central role in the growth of the field. In fact, just in the last few years, parameterized algorithms have been developed for several graph editing problems [12, 10, 11, 9, 5, 6, 26, 24, 17, 18, 19, 27]. The focus of all of these papers and the vast majority of papers on parameterized graph editing problems has so far been limited to edit operations that delete vertices, delete edges or add edges.

In recent years, a different edit operation has begun to attract significant scientific attention. This operation, which is arguably the most natural edit operation apart from deletions/insertions of vertices/edges, is the one that contracts an edge. Here, given an edge uv that exists in the input graph, we remove the edge from the graph and merge its two endpoints. Edge contraction is a fundamental operation in the theory of graph minors. For some particular family of graphs, $\mathcal{F}$, we say that a graph G belongs to $\mathcal{F} + kv$, $\mathcal{F} + ke$ or $\mathcal{F} - ke$ if some graph in $\mathcal{F}$ can be obtained by deleting at most k vertices from G, deleting at most k edges from G or adding at most k edges to G, respectively. Using this terminology, we say that a graph G belongs to $\mathcal{F}|ke$ if some graph in $\mathcal{F}$ can be obtained by contracting at most k edges in G. In this paper, we study the following problem.

$\mathcal{F}$-Contraction **Parameter:** k
Input: A graph G and an integer k
Question: Does G belong to $\mathcal{F}|ke$?

For several families of graphs $\mathcal{F}$, early papers by Watanabe et al. [46, 47], and Asano and Hirata [3] showed that $\mathcal{F}$-Edge Contraction is NP-complete.

In the framework of Parameterized Complexity, these problems exhibit properties that are quite different from those problems where we only delete or add vertices and edges. Indeed, a well-known result by Cai [7] states that in case $\mathcal{F}$ is a hereditary family of graphs

with a finite set of forbidden induced subgraphs, then the graph modification problems, $\mathcal{F}+kv$, $\mathcal{F}+ke$ or $\mathcal{F}-ke$, defined by $\mathcal{F}$ admits a simple FPT algorithm (an algorithm with running time $f(k)n^{\mathcal{O}(1)}$). However, for $\mathcal{F}$-Contraction, the result by Cai [7] does not hold. In particular, Lokshtanov et al. [38] and Cai and Guo [8] independently showed that if $\mathcal{F}$ is either the family of P_ℓ-free graphs for some $\ell \geq 5$ or the family of C_ℓ-free graphs for some $\ell \geq 4$, then $\mathcal{F}$-Contraction is W[2]-Hard (W[i]-hardness, for $i \geq 1$, is an analogue to NP-hardness in Parameterized Complexity, and is used to rule out FPT-algorithm for the problem) when parameterized by k (the number of edges to be contracted). These results immediately imply that Chordal Contraction is W[2]-Hard when parameterized by k. The parameterized hardness result for Chordal Contraction led to finding subfamilies of chordal graphs, where the problem could be shown to be FPT. Two subfamilies that have been considered in the literature are families of *split graphs* and *cliques*. Cai and Guo [8] showed that Clique Contraction is FPT, however, it does not admit a polynomial kernel. Later, Cai and Guo [32] also claimed to design an algorithm that solves Split Contraction in time $2^{\mathcal{O}(k^2)} \cdot n^{\mathcal{O}(1)}$, which proves that the problem is FPT. However, Agrawal et al. [2] found an error with the proof and showed that Split Contraction is W[1]-Hard.

Inspired by the intractable results that Chordal Contraction, Split Contraction and Clique Contraction are W[2]-Hard, W[1]-Hard, and does not admit polynomial kernel, respectively, we study them from the viewpoint of parameterized approximation.

Our Results and Methods. We start by defining a few basic definitions in parameterized approximation. To formally define these, we need a notion of parameterized optimization problems. We defer formal definitions to Section 2 and give intuitive definitions here. We say that an algorithm is an $h(k)$-FPT-approximation algorithm for the $\mathcal{F}$-Contraction problem, if it runs in FPT time, and on any input (G,k) if there exists $X \subseteq E(G)$ such that $G/X \in \mathcal{F}$ and $|X| \leq k$, it outputs an edge set Y of size at most $h(k) \cdot k$ and $G/Y \in \mathcal{F}$. Let $\alpha \geq 1$ be a real number. We now give an informal definition of α-approximate kernels. The kernelization algorithm takes an instance I with parameter k, runs in polynomial time, and produces a new instance I' with parameter k'. Both k' and the size of I' should be bounded in terms of just the parameter k. That is, there exists a function $g(k)$ such that $|I'| \leq g(k)$ and $k' \leq g(k)$. This function $g(k)$ is called the *size* of the kernel. For minimization problems, we also require the following from α-approximate kernels: For every $c \geq 1$, a c-approximate solution S' to I' can be transformed in polynomial time into a $(c \cdot \alpha)$-approximate solution S to I. However, if the quality of S' is "worse than" k', or $(c \cdot \alpha) \cdot OPT(I) > k$, the algorithm that transforms S' into S is allowed to fail. Here, $OPT(I)$ is the value of the optimum solution of the instance I.

Our first result is about Clique Contraction. It is known to be FPT. However, unless NP $\subseteq$ coNP/poly, it does not admit a polynomial kernel [8]. We show that it admits a PSAKS. That is, it admits a $(1+\epsilon)$-approximate polynomial kernel with $\mathcal{O}(k^{f(\epsilon)})$ vertices for every $\epsilon > 0$. In particular, we obtain the following result.

▶ **Theorem 1.** *For any $\epsilon > 0$, Clique Contraction parameterized by the size of solution k, admits a time efficient $(1+\epsilon)$-approximate polynomial kernel with $\mathcal{O}(k^{d+1})$ vertices, where $d = \lceil \frac{1}{\epsilon} \rceil$.*

Overview of the proof of Theorem 1. Let us fix an input (G, k) and a constant $\epsilon > 0$. Given a graph G, contracting edges of G to get into a graph class $\mathcal{F}$ is same as partitioning the vertex set $V(G)$ into connected sets, $W_1, W_2, \ldots, W_\ell$, and then contracting each connected set to a vertex. These connected sets are called *witness sets*. A witness set W_i is called *non-trivial*, if $|W_i| \geq 2$, and *trivial* otherwise.

Observe that if a graph G can be transformed into a clique by contracting edges in F, then G can also be converted into a clique by deleting all the endpoints of edges in F. This observation implies that if G is *k-contractible* to a clique, then there exists an induced clique of size at least $|V(G)| - 2k$. Let I be a set of vertices in G, which induces this large clique and let $C = V(G) \setminus I$. Observe that C forms a vertex cover in the graph $\overline{G}$ (graph with vertex set $V(G)$ and those edges that are not present in $E(G)$). Using a factor 2-approximation algorithm, we find a vertex cover X of $\overline{G}$. Let $Y = V(\overline{G}) - X$ be an independent set in $\overline{G}$. If $|X| > 4k$, we immediately say No. Now, suppose that we have some solution and let $W_1, W_2, \ldots, W_\ell$ be those witness sets that are either non-trivial or contained in X. Now, let us say that a set W_i is *nice* if it has at least one vertex outside X, and *small* if it contains less than $\mathcal{O}(1/\epsilon)$ vertices. A set that is not *small* is *large*. Observe that there exists a $(1+\epsilon)$-approximate solution where *the only sets* that are not nice are small. Also, observe that all nice sets are adjacent. Now, we classify all subsets of X of size at most $\mathcal{O}(1/\epsilon)$ as *possible* and *impossible* small witness sets. Notice that if a set $A \subseteq X$ has more than $2k$ non-neighbors, then it can not possibly be a witness set, as one of these non-neighbors will be a trivial witness set. Now for every set, $A \subseteq X$ of size at most $\mathcal{O}(1/\epsilon)$ mark all of its non-neighbors, but if there are more than $2k$, then mark $2k+1$ of them. Now, look at an unmarked vertex in Y, the only reason it could still be relevant if it is part of some W_i. So its job is (a) connecting the vertices in W_i, or (b) potentially being the vertex in Y that is making some W_i nice, or (c) it is a neighbor to *all* the small (not nice) subsets of X in the solution. Now notice that any vertex in Y that is unmarked does jobs (b) and (c) equally well. So we only need to care about connectivity. Look at some nice and small set W_i; we only need to preserve the neighborhoods of the vertices of Y into W_i. For every subset of size $\mathcal{O}(1/\epsilon)$, we keep one vertex in Y that has that set in its neighborhood. Notice that we do not care that different W_i's use different marked vertices for connectivity because merging two W_i's is more profitable for us. Finally, we delete all unmarked vertices and obtain an $(1+\epsilon)$-approximate kernel of size roughly $k^{\mathcal{O}(1/\epsilon)}$. We argue that this kernelization algorithm is time efficient i.e. the running time is polynomial in the size of an input and the constant in the exponent is independent of ϵ. This completes the overview of the proof for Theorem 1. Next, we move to Split Contraction.

Split Contraction is known to be W[1]-Hard [2]. We ask ourselves whether Split Contraction is *completely* FPT-*inapproximable* or admits an α-FPT-approximation algorithm, for some fixed constant $\alpha > 0$. We obtain two results towards our goal.

▶ **Theorem 2.** *For every $\epsilon > 0$, Split Contraction admits a factor $(2+\epsilon)$-FPT-approximation algorithm. In fact, for any $\epsilon > 0$, Split Contraction admits a $(2+\epsilon)$-approximate kernel with $\mathcal{O}(k^{f(\epsilon)})$ vertices.*

Given, Theorem 2, it is natural to ask whether Split Contraction admits a factor $(1+\epsilon)$-FPT-approximation algorithm, for every $\epsilon > 0$. We show that this is not true and obtain the following hardness result.

▶ **Theorem 3.** *Assuming Gap-ETH, no FPT time algorithm can approximate Split Contraction within a factor of $\left(\frac{5}{4} - \delta\right)$, for any fixed constant $\delta > 0$.*

Overview of the proofs of Theorems 2 and 3. Our proof for Theorem 2 uses ideas for $(1+\epsilon)$-approximate kernel for Clique Contraction (Theorem 1) and thus we omit its overview. Towards the proof of Theorem 3, we give a gap preserving reduction from a variant of the Densest-k-Subgraph problem (given a graph G and an integer k, find a subset $S \subseteq V(G)$ of k vertices that induces maximum number of edges). Chalermsook et al. [13] showed that, assuming Gap-ETH[1], for any $g = o(1)$, there is no FPT-time algorithm that, given an integer k and any graph G on n vertices that contains at least one k-clique, always output $S \subseteq V(G)$, of size k, such that $\mathsf{Den}(S) \geq k^{-g(k)}$. Here, $\mathsf{Den}(S) = |E(G[S])|/\binom{|S|}{2}$. We need a strengthening of this result that says that assuming Gap-ETH, for any $g = o(1)$ and for any constant $\alpha > 1$, there is no FPT-time algorithm that, given an integer k and any graph G on n vertices that contains at least one k-clique, always outputs $S \subseteq V(G)$, of size αk, such that $\mathsf{Den}(S) \geq k^{-g(k)}$. Starting from this result, we give a gap-preserving reduction to Split Contraction that takes FPT time and obtain Theorem 3. Given an instance (G, k) of Densest-k-Subgraph, we first use color coding to partition the edges into $t = \binom{k}{2}$ color classes such that every color class contains exactly one edge of a "densest subgraph" (or a clique). For each color class we make one *edge selection gadget*. Each edge selection gadget corresponding to the color class j consists of an independent set $\mathtt{ES}_j$ that contains a vertex corresponding to each edge in the color class$j$, and a *cap vertex* g_j that is adjacent to every vertex in $\mathtt{ES}_j$. Next, we add a sufficiently large clique Z of size $\rho \cdot |V(G)|$, where for every vertex $v \in V(G)$, we have ρ vertices. Every vertex in an edge selection gadget is adjacent to every vertex of Z, except those corresponding to the endpoints of the edge the vertex represents. Finally, we add a clique $\mathtt{SV}$ of size t that has one vertex s_j for each edge selection gadget. Make the vertex s_j adjacent to every vertex in $\mathtt{ES}_j$. We also add sufficient guards on vertices everywhere, so that "unwanted" contractions do not happen. The idea of the reduction is to contract edges in a way that the vertices in $\mathtt{SV}$, Z, and g_j, $j \in \{1, \ldots, t\}$, become a giant clique and other vertices become part of an independent set, resulting in a split graph. Towards this we first use $2t$ contractions so that g_j, s_j, and a vertex $a_j \in \mathtt{ES}_j$ are contracted into one. One way to ensure that they form a clique along with Z is to contract each of them to a vertex in Z. However, this will again require t edge contractions. We set our budget in a way that this is not possible. Thus, what we need is to destroy the non-neighbors of a_j. One way to do this again will be to match the vertices obtained after the first round of $2t$ contractions in a way that there are no non-adjacencies left. However, this will also cost $t/2$, and our budget does not allow this. The other option (which we take) is to take the union of all non-neighbors of a_j, say N, and contract each of them to one of the vertex in $Z \setminus N$. Observe that to minimize the contractions to get rid of non-neighbors of a_j, we would like to minimize $|N|$. This will happen when N spans a large number of edges. Thus, it precisely captures the Densest-k-Subgraph problem. The budget is chosen in a way that we get the desired gap-preserving reduction, which enables us to prove Theorem 3.

Our final result concerns Chordal Contraction. Lokshtanov et al. [38] showed that Chordal Contraction is W[2]-Hard. We observe that the existing W[2]-hardness reduction can be adapted to show the following theorem.

▶ **Theorem 4.** *Assuming* FPT$\neq$ *W[1], no* FPT *time algorithm can approximate* Chordal Contraction *within a factor of $F(k)$. Here, $F(k)$ is a function depending on k alone.*

[1] We refer the readers to [13] for the definition of Gap-ETH and related terms.

Overview of the proof of Theorem 4. Towards proving Theorem 4, we give a 1-approximate polynomial parameter transformation (1-appt) from Set Cover (given a universe U, a family of subsets $\mathcal{S}$, and an integer k, we shall decide the existence of a subfamily of size k that contains all the elements of U) to Chordal Contraction. That is, given any solution of size at most ℓ for Chordal Contraction, we can transform this into a solution for Set Cover of size at most ℓ. Karthik et al. [35] showed that assuming FPT$\neq$ W[1], no FPT time algorithm can approximate Set Cover within a factor of $F(k)$. Pipelining this result with our reduction we get Theorem 4.

Related Work. To the best of our knowledge, Heggernes et al. [33] was the first to explicitly study $\mathcal{F}$-Contraction from the viewpoint of Parameterized Complexity. They showed that in case $\mathcal{F}$ is the family of trees, $\mathcal{F}$-Contraction is FPT but does not admit a polynomial kernel, while in case $\mathcal{F}$ is the family of paths, the corresponding problem admits a faster algorithm and an $\mathcal{O}(k)$-vertex kernel. Golovach et al. [28] proved that if $\mathcal{F}$ is the family of planar graphs, then $\mathcal{F}$-Contraction is again FPT. Moreover, Cai and Guo [8] showed that in case $\mathcal{F}$ is the family of cliques, $\mathcal{F}$-Contraction is solvable in time $2^{\mathcal{O}(k \log k)} \cdot n^{\mathcal{O}(1)}$, while in case $\mathcal{F}$ is the family of chordal graphs, the problem is W[2]-Hard. Heggernes et al. [34] developed an FPT algorithm for the case where $\mathcal{F}$ is the family of bipartite graphs. Later, a faster algorithm was proposed by Guillemot and Marx [30].

Pioneering work of Lokshtanov et al. [40] on the approximate kernel is being followed by a series of papers generalizing/improving results mentioned in this work and establishing lossy kernels for various other problems. Lossy kernels for some variations of Connected Vertex Cover [21, 36], Connected Feedback Vertex Set [43], Steiner Tree [20] and Dominating Set [22, 44] have been established (also see [41, 45]). Krithika et al. [37] were first to study graph contraction problems from the lenses of lossy kernelization. They proved that for any $\alpha > 1$, Tree Contraction admits an α-lossy kernel with $\mathcal{O}(k^d)$ vertices, where $d = \lceil \alpha/(\alpha - 1) \rceil$. Agarwal et al. [1] proved similar result for $\mathcal{F}$-Contraction problems where graph class $\mathcal{F}$ is defined in parametric way from set of trees. Eiben et al. [21] obtained similar result for Connected $\mathcal{H}$-Hitting Set problem.

Organization. Due to space constraints, we omit some of the results from this extended abstract. We present the notations and preliminaries in Section 2 and in Section 3 we give the $(1 + \epsilon)$–approximate polynomial kernel for Clique Contraction.

2 Preliminaries

In this section, we give notations and definitions that we use throughout the paper. Unless specified, we will be using all general graph terminologies from the book of Diestel [15].

2.1 Graph Theoretic Definitions and Notations

For an undirected graph G, sets $V(G)$ and $E(G)$ denote the set of vertices and edges, respectively. Two vertices u, v in $V(G)$ are said to be *adjacent* if there is an edge uv in $E(G)$. The neighborhood of a vertex v, denoted by $N_G(v)$, is the set of vertices adjacent to v in G. For subset S of vertices, we define $N(S) = \bigcup_{v \in S} N(v)) \setminus S$. The subscript in the notation for the neighborhood is omitted if the graph under consideration is clear. For a set of edges F, set $V(F)$ denotes the endpoints of edges in F. For a subset S of $V(G)$, we denote the graph obtained by deleting S from G by $G - S$ and the subgraph of G induced on set S by $G[S]$. For two subsets S_1, S_2 of $V(G)$, we say S_1, S_2 *are adjacent if there exists an edge* with one endpoint in S_1 and other in S_2.

An edge e in G is a *chord* of a cycle C (resp. path P) if (i) both the endpoints of e are in C (resp. in P), and (ii) edge e is not in C (resp. not in P). An *induced cycle* (resp. *path*) is a cycle (resp. path) which has no chord. We denote induced cycle and path on ℓ vertices by C_ℓ and P_ℓ, respectively. A *complete graph* G is an undirected graph in which for every pair of vertices $u, v \in V(G)$, there is an edge uv in $E(G)$. As an immediate consequence of definition we get the following.

▶ **Lemma 5.** *A connected graph G is complete if and only if G does not contain an induced P_3.*

A *clique* is a subset of vertices in the graph that induces a complete graph. A set $I \subseteq V(G)$ of pairwise non-adjacent vertices is called an *independent set*. A graph G is a *split graph* if $V(G)$ can be partitioned into a clique and an independent set. For split graph G, partition (X, Y) is *split partition* if X is a clique and Y is an independent set. In this article, whenever we mention a split partition, we first mention the clique followed by the independent set. We will also use the following well-known characterization of split graphs. Let, $2K_2$ be a graph induced on four vertices, which contains exactly two edges and no isolated vertices.

▶ **Lemma 6** ([29])**.** *A graph G is a split graph if and only if it does not contain C_4, C_5 or $2K_2$ as an induced subgraph.*

A graph G is *chordal* if every induced cycle in G is a triangle; equivalently, if every cycle of length at least four has a chord. A vertex subset $S \subseteq V(G)$ is said to *cover* an edge $uv \in E(G)$ if $S \cap \{u, v\} \neq \emptyset$. A vertex subset $S \subseteq V(G)$ is called a *vertex cover* in G if it covers all the edges in G.

We start with the following observation, which is useful to find a large induced clique in the input graph. The *complement* of G, denoted by $\overline{G}$, is a graph whose vertex set is $V(G)$ and edge set is precisely those edges which are not present in $E(G)$. Note that given a graph G, if S is a set of vertices such that $G - S$ is a clique, then S is a vertex cover in the complement graphs of G, denoted by $\overline{G}$, as $\overline{G} - S$ is edgeless. Using the well-known factor 2-approximation algorithm for Vertex Cover [4], we have following.

▶ **Observation 2.1** ([4])**.** *There is a factor 2-approximation algorithm to compute a set of vertices whose deletion results in a complete graph.*

Using, Lemma 6 one can obtain a simple factor 5-approximation algorithm for deleting vertices to get a split graph.

▶ **Observation 2.2.** *There is a factor 5-approximation algorithm to compute a set of vertices whose deletion results in a split graph.*

Recently, for every $\epsilon > 0$, a factor $(2+\epsilon)$-approximation algorithm for deleting vertices to get a split graph has been obtained [39]. However, for our purposes Observation 2.2 will suffice.

2.2 Graph Contraction

The *contraction* of edge $e = uv$ in G deletes vertices u and v from G, and adds a new vertex, which is made adjacent to vertices that were adjacent to either u or v. Any parallel edges added in the process are deleted so that the graph remains simple. The resulting graph is denoted by G/e. Formally, for a given graph G and edge $e = uv$, we define G/e in the following way: $V(G/e) = (V(G) \cup \{w\}) \setminus \{u, v\}$ and $E(G/e) = \{xy \mid x, y \in V(G) \setminus \{u, v\}, xy \in E(G)\} \cup \{wx \mid x \in N_G(u) \cup N_G(v)\}$. For a subset of edges F in G, graph G/F denotes the graph obtained from G by repeatedly contracting edges in F until no such edge remains. We say that a graph G is *contractible* to a graph H if there exists an onto function $\psi : V(G) \to V(H)$ such that the following properties hold.

- For any vertex h in $V(H)$, graph $G[W(h)]$ is connected, where set $W(h) := \{v \in V(G) \mid \psi(v) = h\}$.
- For any two vertices h, h' in $V(H)$, edge hh' is present in H if and only if there exists an edge in G with one endpoint in $W(h)$ and another in $W(h')$.

For a vertex h in H, set $W(h)$ is called a *witness set* associated with h. We define *H-witness structure* of G, denoted by $\mathcal{W}$, as collection of all witness sets. Formally, $\mathcal{W} = \{W(h) \mid h \in V(H)\}$. Witness structure $\mathcal{W}$ is a partition of vertices in G, where each witness forms a connected set in G. Recall that if a *witness set* contains more than one vertex, then we call it *non-trivial* witness set, otherwise a *trivial* witness set.

If graph G has a H-witness structure, then graph H can be obtained from G by a series of edge contractions. For a fixed H-witness structure, let F be the union of spanning trees of all witness sets. By convention, the spanning tree of a singleton set is an empty set. Thus, to obtain H from G, it is *sufficient* to contract edges in F. If such witness structure exists, then we say that graph G is contractible to H. We say that graph G is *k-contractible* to H if cardinality of F is at most k. In other words, H can be obtained from G by at most k edge contractions. Following observation is an immediate consequence of definitions.

▶ **Observation 2.3.** *If graph G is k-contractible to graph H, then the following statements are true.*

- *For any witness set W in a H-witness structure of G, the cardinality of W is at most $k + 1$.*
- *For a fixed H-witness structure, the number of vertices in G, which are contained in non-trivial witness sets is at most $2k$.*

In the following two observations, we state that if a graph can be transformed into a clique or a split graph by contracting few edges, then it can also be converted into a clique or split graph by deleting few vertices.

▶ **Observation 2.4.** *If a graph G is k-contractible to a clique, then G can be converted into a clique by deleting at most $2k$ vertices.*

Proof. Let F be a set of edges of size at most k such that G/F is a clique. Let $\mathcal{W}$ be a G/F-witness structure of G. Let X be a set of all vertices which are contained in the non-trivial witness sets in $\mathcal{W}$. By Observation 2.3, size of X is at most $2k$. Any two vertices in $V(G) \setminus X$ are adjacent to each other as these vertices form singleton sets, which are adjacent in G/F. Hence, G can be converted into a clique by deleting vertices in X. ◀

▶ **Observation 2.5.** *If a graph G is k-contractible to a split graph then G can be converted into a split graph by deleting at most $2k$ vertices.*

Proof. For graph G, let F be the set of edges such that G/F is a split graph and $|F| \leq k$. Let $V(F)$ be the collection of all endpoints of edges in F. Since cardinality of F is at most k, $|V(F)|$ is at most $2k$. We argue that $G - V(F)$ is a split graph. For the sake of contradiction, assume that $G - V(F)$ is not a split graph. We know that a graph is split if and only if it does not contain induced C_4, C_5 or $2K_2$. This implies that there exists a set of vertices V' in $V(G) \setminus V(F)$ such that $G[V']$ is either C_4, C_5 or $2K_2$. Since no edge in F is incident on any vertices in V', $G/F[V']$ is isomorphic to $G[V']$. Hence, there exists a C_4, C_5 or $2K_2$ in G/F contradicting the fact that G/F is a split graph. Hence, our assumption is wrong and $G - V(F)$ is a split graph. ◀

Consider a connected graph G which is k-contractible to the clique K_ℓ. Let $\mathcal{W}$ be a K_ℓ-witness structure of G. The following observation gives a sufficient condition for obtaining a witness structure of an induced subgraph of G from $\mathcal{W}$.

▶ **Observation 2.6.** *Let $\mathcal{W}$ be a clique witness structure of G. If there exists two different witness sets $W(t_1), W(t_2)$ in $\mathcal{W}$ and a vertex v in $W(t_1)$ such that the set $W(t) = (W(t_1) \cup W(t_2)) \setminus \{v\}$ is a connected set in $G - \{v\}$, then $\mathcal{W}'$ is a clique witness structure of $G - \{v\}$, where $\mathcal{W}'$ is obtained from $\mathcal{W}$ by removing $W(t_1), W(t_2)$ and adding $W(t)$.*

Proof. Let $G' = G - \{v\}$. Note that $\mathcal{W}'$ is a partition of vertices in G'. Any set in $\mathcal{W}' \setminus \{W(t)\}$ is a witness set in $\mathcal{W}$ and does not contain v. Hence, these sets are connected in G'. Since $G'[W(t)]$ is also connected, all the witness sets in $\mathcal{W}'$ are connected in G'.

Consider any two witness sets $W(t'), W(t'')$ in $\mathcal{W}'$. If none of these two is equal to $W(t)$ then both of these sets are present in $\mathcal{W}$. Since none of these witness sets contains vertex v, they are adjacent to each other in G'. Now, consider a case when one of them, say $W(t'')$, is equal to $W(t)$. As witness sets $W(t')$ and $W(t_2)$ are present in $\mathcal{W}$, there exists an edge with one endpoint in $W(t')$ and another in $W(t_2)$. The same edge is present in graph G' as it is not incident on v. Since $W(t_2)$ is subset of $W(t)$, sets $W(t')$ and $W(t)$ are adjacent in G'. Hence any two witness sets in $\mathcal{W}'$ are adjacent to each other. This implies that $\mathcal{W}'$ is a clique witness structure of graph $G - \{v\}$. ◀

In the case of Split Contraction, the following observation guarantees the existence of witness structure with a particular property.

▶ **Observation 2.7.** *For a connected graph G, let F be a set of edges such that G/F is a split graph. Then, there exists a set of edges F' which satisfy the following properties: (i) G/F' is a split graph. (ii) The number of edges in F' is at most $|F|$. (iii) There exists a split partition of G/F' such that all vertices in G/F' which correspond to a non-trivial witness set in G/F'-witness structure of G are in clique side.*

Proof. Let (C, I) be a split partition of vertices of G/F such that C is a clique and I is an independent set. If all the vertices corresponding to non-trivial witness sets are in C, then the observation is true. Consider a vertex a in I which corresponds to a non-trivial witness set W_a. Since G is connected, G/F is a connected split graph. This implies that there exists a vertex, say b, in C which is adjacent to a in G/F. We denote witness set corresponding to b by W_b. We construct a new witness structure by shifting all but one vertices in W_a to W_b. Since ab is an edge in G/F, there exists an edge in G with one endpoint in W_a and another in W_b. Let that edge be $u_a u_b$ with vertices u_a and u_b contained in sets W_a and W_b, respectively. Consider a spanning tree T of graph $G[W_a]$ which is rooted at u_a. We can replace edges in F whose both endpoints are in $V(W_a)$ with $E(T)$ to obtain another set of edges F^* such that G/F^* is a split graph. Formally, $F^* = (F \cup E(T)) \setminus (E(G[W_a]) \cap F)$. Note that the number of edges in F^* and F are same. Let v_1 be a leaf vertex in T and v_2 be its unique neighbor. Consider $F' = (F^* \cup \{u_a u_b\}) \setminus \{v_1 v_2\}$. Since edge $v_1 v_2$ is in F^* and $u_a u_b$ is not in F^*, $|F'| = |F^*|$. We now argue that G/F' is also a split graph. Let $\mathcal{W}'$ be the G/F'-witness structure of G. Note that $\mathcal{W}'$ can be obtained from G/F^*-witness structure $\mathcal{W}^*$ of G by replacing W_a by $\{v_1\}$ and W_b by $W_b \cup (W_a \setminus \{v_1\})$. Since all other witness set remains unchanged any witness set which was adjacent to W_b is also adjacent to $W_b \cup (W_a \setminus \{v_1\})$. Similarly, any witness set which was not adjacent to W_a is not adjacent to $\{v_2\}$. In other words, this operation of shifting edges did not remove any vertex from the neighborhood of b (which is in C) nor it added any vertex in the neighborhood of a (which is in I). Hence, G/F' is also a split graph with (C, I) as one of its split partition. Note that there exists a split partition of G/F' such that the number of vertices in the independent side corresponding to non-trivial witness set is one less than the number of vertices in I which corresponds to non-trivial witness sets. Hence, by repeating this process at most $|V(G)|$ times, we get a set of edges that satisfy three properties mentioned in the observation. ◀

2.3 Parameterized Complexity and Lossy Kernelization

An important notion in parameterized complexity is *kernelization*, which captures the efficiency of data reduction techniques. A parameterized problem Π admits a kernel of size $g(k)$ (or $g(k)$-kernel) if there is a polynomial time algorithm (called *kernelization algorithm*) which takes as input (I, k), and returns an instance (I', k') of Π such that: (i) (I, k) is a yes-instance if and only if (I', k') is a yes-instance; and (ii) $|I'| + k' \leq g(k)$, where $g(\cdot)$ is a computable function whose value depends only on k. Depending on whether the function $g(\cdot)$ is *linear, polynomial* or *exponential*, the problem is said to admit a *linear, polynomial* or *exponential kernel*, respectively. We refer to the corresponding chapters in the books [25, 14, 16, 23, 42] for a detailed introduction to the field of kernelization.

In lossy kernelization, we work with the optimization analog of parameterized problem. Along with an instance and a parameter, an optimization analog of the problem also has a string called *solution*. We start with the definition of a *parameterized optimization problem*. It is the parameterized analog of an optimization problem used in the theory of approximation algorithms.

▶ **Definition 7** (Parameterized Optimization Problem)**.** *A parameterized optimization problem is a computable function* $\Pi : \Sigma^* \times \mathbb{N} \times \Sigma^* \mapsto \mathbb{R} \cup \{\pm\infty\}$*. The instances of* Π *are pairs* $(I, k) \in \Sigma^* \times \mathbb{N}$ *and a solution to* (I, k) *which is simply a string* $S \in \Sigma^*$ *such that* $|S| \leq |I| + k$*.*

The *value* of a solution S is $\Pi(I, k, S)$. In this paper, all optimization problems are minimization problems. Therefore, we present the rest of the section only with respect to parameterized *minimization* problem. The *optimum value* of (I, k) is defined as:

$$\mathrm{OPT}_\Pi(I, k) = \min_{S \in \Sigma^*,\, |S| \leq |I|+k} \Pi(I, k, S),$$

and an *optimum solution* for (I, k) is a solution S such that $\Pi(I, k, S) = \mathrm{OPT}_\Pi(I, k)$. For a constant $c > 1$, S is *c-factor approximate* solution for (I, k) if $\frac{\Pi(I,k,S)}{OPT_\Pi(I,k)} \leq c$. We omit the subscript Π in the notation for optimum value if the problem under consideration is clear from the context.

For some parameterized optimization problems we are unable to obtain FPT algorithms, and we are also unable to find satisfactory polynomial time approximation algorithms. In this case one might aim for FPTapproximation algorithms, algorithms that run in time $f(k)n^c$ and provide good approximate solutions to the instance.

▶ **Definition 8.** *Let* $\alpha \geq 1$ *be constant. A fixed parameter tractable* α*-approximation algorithm for a parameterized optimization problem* Π *is an algorithm that takes as input an instance* (I, k)*, runs in time* $f(k)|I|^{\mathcal{O}(1)}$*, and outputs a solution* S *such that* $\Pi(I, k, S) \leq \alpha \cdot OPT(I, k)$ *if* Π *is a minimization problem, and* $\alpha \cdot \Pi(I, k, S) \geq OPT(I, k)$ *if* Π *is a maximization problem.*

Note that Definition 8 only defines constant factor FPT-approximation algorithms. The definition can in a natural way be extended to approximation algorithms whose approximation ratio depends on the parameter k, on the instance I, or on both. Next, we define an α-*approximate polynomial-time preprocessing algorithm* for a parameterized minimization problem Π as follows.

▶ **Definition 9** (α-Approximate Polynomial-time Preprocessing Algorithm)**.** *Let* $\alpha \geq 1$ *be a real number and* Π *be a parameterized minimization problem. An* α*-approximate polynomial-time preprocessing algorithm is defined as a pair of polynomial-time algorithms, called the* reduction algorithm *and the* solution lifting algorithm*, that satisfy the following properties.*

- *Given an instance* (I, k) *of* Π*, the reduction algorithm computes an instance* (I', k') *of* Π.
- *Given instances* (I, k) *and* (I', k') *of* Π*, and a solution* S' *to* (I', k')*, the solution lifting algorithm computes a solution* S *to* (I, k) *such that* $\frac{\Pi(I,k,S)}{OPT(I,k)} \leq \alpha \cdot \frac{\Pi(I',k',S')}{OPT(I',k')}$.

We sometimes refer α-approximate polynomial-time preprocessing algorithm kernel as *α-lossy rule* or *α-reduction rule*.

3 Lossy Kernel for Clique Contraction

In this section, we present a lossy kernel for Clique Contraction. We first define a natural optimization version of the problem.

$$\textsc{Clc}(G, k, F) = \begin{cases} \min\{|F|, k+1\} & \text{if } G/F \text{ is a clique} \\ \infty & \text{otherwise} \end{cases}$$

If the number of vertices in the input graph is at most $k+3$, then we can return the same instance as a kernel for the given problem. Further, we assume that the input graph is connected; otherwise, it can not be edited into a clique by edge contraction only. Thus, we only consider *connected graphs with at least* $k+3$ *vertices*. By the definition of optimization problem, for any set of edges F, if G/F is a clique, then the maximum value of $\textsc{Clc}(G, k, F)$ is $k+1$. Hence, any spanning tree of G is a solution of cost $k+1$. We call it a *trivial solution* for the given instance. Consider an instance $(P_4, 1)$, where P_4 is a path on four vertices. One needs to contract at least two edges to convert P_4 into a clique. We call $(P_4, 1)$ a *trivial No-instance* for this problem. Finally, we assume that we are given an $\epsilon > 0$.

We start with a reduction rule, which says that if the minimum number of vertices that need to be deleted from an input graph to obtain a clique is large, then we can return a trivial instance as a lossy kernel.

▶ **Reduction Rule 3.1.** *For a given instance* (G, k)*, apply the algorithm mentioned in Observation 2.1 to find a set* X *such that* $G - X$ *is a clique. If the size of* X *is greater than* $4k$*, then return* $(P_4, 1)$.

▶ **Lemma 10.** *Reduction Rule 3.1 is a* 1*-reduction rule.*

Proof. Let (G, k) be an instance of Clique Contraction such that the Reduction Rule 3.1 returns $(P_4, 1)$ when applied on it. The solution lifting algorithm returns a spanning tree F of G. Note that for a set of edges F', if P_4/F' is a clique then F' contains at least two edges. This implies $\textsc{Clc}(P_4, 1, F') = 2$ and $\text{OPT}(P_4, 1) = 2$.

Since a factor 2-approximation algorithm returned a set of size strictly more than $4k$, for any set X' of size at most $2k$, $G - X'$ is not a clique. But by Observation 2.4, if G is k-contractible to a clique then G can be edited into a clique by deleting at most $2k$ vertices. Hence, for any set of edges F^* if G/F^* is a clique, then the size of F^* is at least $k+1$. This implies that $\text{OPT}(G, k) = k+1$, and for a spanning tree F of G, $\textsc{Clc}(G, k, F) = k+1$.

Combining these values, we get $\frac{\textsc{Clc}(G,k,F)}{\text{OPT}(G,k)} = \frac{k+1}{k+1} = \frac{2}{2} = \frac{\textsc{Clc}(P_4,1,F')}{\text{OPT}(P_4,1)}$. This implies that if F' is factor c-approximate solution for $(P_4, 1)$, then F is factor c-approximate solution for (G, k). This concludes the proof. ◀

We now consider an instance (G, k) for which Reduction Rule 3.1 does not return a trivial instance. This implies that for a given graph G, in polynomial time, one can find a partition (X, Y) of $V(G)$ such that $G - X = G[Y]$ is a clique and $|X|$ is at most $4k$. For $\epsilon > 0$, find a smallest integer d, such that $\frac{d+1}{d} \leq 1 + \epsilon$. In other words, fix $d = \lceil \frac{1}{\epsilon} \rceil$. We note that if the

number of vertices in the graph is at most $\mathcal{O}(k^{d+1})$, then the algorithm returns this graph as a lossy kernel of the desired size. Hence, without loss of generality, we assume that the number of vertices in the graph is larger than $\mathcal{O}(k^{d+1})$.

Given an instance (G, k), a partition (X, Y) of $V(G)$ with $G[Y]$ being a clique, and an integer d, consider the following two marking schemes.

▶ **Marking Scheme 3.1.** *For a subset A of X, let $M_1(A)$ be the set of vertices in Y whose neighborhood contains A. For every subset A of X which is of size at most d, mark a vertex in $M_1(A)$.*

Formally, $M_1(A) = \{y \in Y | A \subseteq N(y)\}$. If $M_1(A)$ is an empty set, then the marking scheme does not mark any vertex. If it is non-empty, then the marking scheme arbitrarily chooses a vertex and marks it.

▶ **Marking Scheme 3.2.** *For a subset A of X, let $M_2(A)$ be the set of vertices in Y whose neighborhood does not intersect A. For every subset A of X which is of size at most d, mark $2k + 1$ vertices in $M_2(A)$.*

Formally, $M_2(A) = \{y \in Y | N(y) \cap A = \emptyset\}$. If the number of vertices in $M_2(A)$ is at most $2k + 1$, then the marking scheme marks all vertices in $M_2(A)$. If it is larger than $2k + 1$, then it arbitrarily chooses $2k + 1$ vertices and marks them.

▶ **Reduction Rule 3.2.** *For a given instance (G, k), partition (X, Y) of $V(G)$ with $G[Y]$ being a clique, and an integer d, apply the Marking Schemes 3.1 and 3.2. Let G' be the graph obtained from G by deleting all the unmarked vertices in Y. Return the instance (G', k).*

Above reduction rule can be applied in time $|X|^d \cdot |V(G)|^{\mathcal{O}(1)} = \mathcal{O}(k^{\mathcal{O}(d)}|V(G)|^{\mathcal{O}(1)})$ as $|X|$ is at most $4k$. Note that G' is an induced subgraph of G. We first show that since G is a connected graph, G' is also connected. In the following lemma, we prove a stronger statement.

▶ **Lemma 11.** *Consider instance (G, k) of Clique Contraction. Let Y' be the set of vertices marked by Marking Scheme 3.1 or 3.2 for some positive integer d. For any subset Y'' of $Y \setminus Y'$, let G'' be the graph obtained from G by deleting Y''. Then, G'' is connected.*

Proof. Recall that, by our assumption, G is connected and Y is a clique in G. Hence, for every vertex in X, there exists a path from it to some vertex in Y. By the construction of G'', $(X, Y \setminus Y'')$ forms a partition of $V(G'')$ and $Y \setminus Y''$ is a clique in G''. To prove that G'' is connected, it is sufficient to prove that for every vertex in X, there exists a path from it to a vertex in $Y \setminus Y''$ in G.

Fix an arbitrary vertex, say x, in X. Consider a path P from x to y in G, where y is some vertex in Y. Without loss of generality, we can assume that y is the only vertex in $V(P) \cap Y$. We argue that there exists another path, say P_1, from x to a vertex in $Y \setminus Y''$. If y is in $Y \setminus Y''$ then $P_1 = P$ is a desired path. Consider the case when y is in Y''. Let x_0 be the vertex in $V(P)$ which is adjacent with y. Note that x_0 may be same as x. As Marking Scheme 3.1 considers all subsets of size at most d, it considered singleton set $\{x_0\}$. As x_0 is adjacent with y, we have $\{x_0\} \subseteq N(y)$. Since y is in Y'', and hence unmarked, there exists a vertex, say y_1, in Y which has been marked by Marking Scheme 3.1. Consider a path P_1 obtained from P by deleting vertex y (and hence edge x_0y) and adding vertex y_1 with edge x_0y_1. This is a desired path from x to a vertex in $Y \setminus Y''$. As x is an arbitrary vertex in X, this statement is true for any vertex in X and hence G'' is connected. ◀

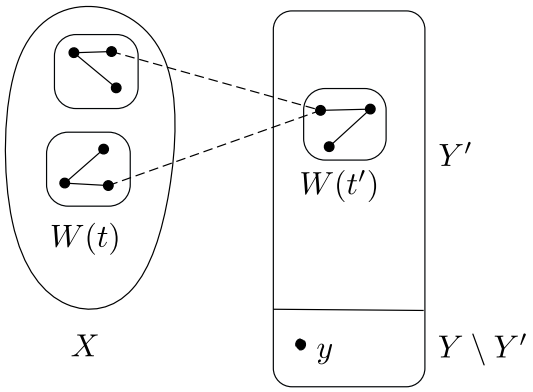

Figure 1 Straight lines (e.g within $W(t)$) represent edges in original solution F. Dashed lines (e.g. across $W(t)$ and $W(t')$) represents extra edges added to solution F. Please refer to the proof of Lemma 12.

Thus, because of Lemma 11, from now onwards, we assume that G' is connected. In fact, in our one of the proof, we will iteratively remove vertices from $Y \setminus Y'$, and Lemma 11 ensures that the graph at each step remains connected. In the following lemma, we argue that given a solution for (G', k), we can construct a solution of almost the same size for (G, k).

▶ **Lemma 12.** *Let (G', k) be the instance returned by Reduction Rule 3.2 when applied on an instance (G, k). If there exists a set of edges of size at most k, say F', such that G'/F' is a clique, then there exists a set of edges F such that G/F is a clique and cardinality of F is at most $(1 + \epsilon) \cdot |F'|$.*

Proof. If no vertex in Y is deleted, then G' and G are identical graphs, and the statement is true. We assume that at least one vertex in Y is deleted. Let Y' be the set of vertices in Y, which are marked. Note that the sets X, Y' forms a partition of $V(G')$ such that Y' is a clique and a proper subset of Y. Let $\mathcal{W}'$ be a G'/F'-witness structure of G'. We construct a clique witness structure $\mathcal{W}$ of G from $\mathcal{W}'$ by adding singleton witness sets $\{y\}$ for every vertex y in $Y \setminus Y'$. Since $G[Y \setminus Y']$ is a clique in G, any two newly added witness sets are adjacent to each other. Moreover, any witness set in $\mathcal{W}'$, which intersects Y' is also adjacent to the newly added witness sets. We now consider witness sets in $\mathcal{W}'$, which do not intersect Y'.

Let $\mathcal{W}^\star$ be a collection of witness sets $W(t)$ in $\mathcal{W}'$ such that $W(t)$ is contained in X and there exists a vertex y in $Y \setminus Y'$ whose neighborhood does not intersect with $W(t)$. See Figure 1. We argue that every witness set in $\mathcal{W}^\star$ has at least $d + 1$ vertices. For the sake of contradiction, assume that there exists a witness set $W(t)$ in $\mathcal{W}^\star$ which contains at most d vertices. Since Marking Scheme 3.2 iterated over all the subsets of X of size at most d, it also considered $W(t)$ while marking. Note that the vertex y belongs to the set $M_2(W(t))$. Since y is unmarked, there are $2k + 1$ vertices in $M_2(W(t))$ which have been marked. All these marked vertices are in G'. Since the cardinality of F' is at most k, the number of vertices in $V(F')$ is at most $2k$. Hence, at least one marked vertex in $M_2(W(t))$ is a singleton witness set in $\mathcal{W}'$. However, there is no edge between this singleton witness set and $W(t)$. This non-existence of an edge contradicts the fact that any two witness sets in $\mathcal{W}'$ are adjacent to each other in G'. Hence, our assumption is wrong, and $W(t)$ has at least $d + 1$ vertices.

Next, we show that there exists a witness set in $\mathcal{W}'$ that intersects Y'. This is ensured by the fact that G' is connected, and we are in the case where at least one vertex in Y is deleted. The last assertion implies that Y' is non-empty, and hence there must be a witness set in $\mathcal{W}'$ that intersects Y'. Let $W(t')$ be a witness set in $\mathcal{W}'$ that intersects Y'. Note that $W(t')$ is adjacent to every vertex in $Y \setminus Y'$. Let $W(t)$ be a witness set in $\mathcal{W}^\star$. Since $W(t')$ and $W(t)$ are two witness sets in the G'/F'-witness structure, there exists an edge with one endpoint in $W(t')$ and another in $W(t)$. Therefore, the set $W(t') \cup W(t)$ is adjacent to every other witness set in $\mathcal{W}$.

We now describe how to obtain F from F'. We initialize $F = F'$. For every witness set $W(t)$ in $\mathcal{W}^\star$ add an edge between $W(t)$ and $W(t')$ to the set F'. Equivalently, we construct a new witness set by taking the union of $W(t')$ and all witness sets $W(t)$ in $\mathcal{W}^\star$. This witness set is adjacent to every vertex in $Y \setminus Y'$, and hence G/F is a clique. We now argue the size bound on F. Note that we have added one extra edge for every witness set $W(t)$ in $\mathcal{W}^\star$. We also know that every such witness set has at least $d+1$ vertices. Hence, we have added one extra edge for at least d edges in the solution F'. Moreover, since witness sets in $\mathcal{W}^\star$ are vertex disjoint, no edge in F can be part of two witness sets. This implies that the number of edges in F' is at most $({}^{d+1}/_{d})|F| \leq (1+\epsilon) \cdot |F|$. ◀

In the following lemma, we argue that the value of the optimum solution for the reduced instance can be upper bounded by the value of an optimum solution for the original instance.

▶ **Lemma 13.** *Let (G', k) be the instance returned by Reduction Rule 3.2 when applied on an instance (G, k). If $OPT(G, k) \leq k$, then $OPT(G', k) \leq OPT(G, k)$.*

Proof. Let F be a set of at most k edges in G such that $\mathrm{OPT}(G, k) = \textsc{Clc}(G, k, F)$ and $\mathcal{W}$ be a G/F-witness structure of G. Since we are working with a minimization problem, to prove this lemma it is sufficient to find a solution for G' which is of size $|F|$. Recall that (X, Y) is a partition of $V(G)$ such that $G - X = G[Y]$ is a clique. Let Y' be the set of vertices that were marked by either of the marking schemes. In other words, (X, Y') is a partition of G' such that $G' - X = G'[Y]$ is a clique. We proceed as follows. At each step, we construct graph $G^\star$ from G by deleting one or more vertices of $Y \setminus Y'$. Simultaneously, we also construct a set of edges $F^\star$ from F by either replacing the existing edges by new ones or by simply adding extra edges to F. At any intermediate state, we ensure that $G^\star/F^\star$ is a clique, and the number of edges in $F^\star$ is at most $|F|$. Let $F^\circ = F$ be an optimum solution for the input instance (G, k). *For notational convenience, we rename $G^\star$ to G and $F^\star$ to F at regular intervals but do not change F°.*

To obtain $G^\star$ and $F^\star$, we delete witness sets which are subsets of $Y \setminus Y'$ (Condition 3.1) and modify the ones which intersect with $Y \setminus Y'$. Every witness set of latter type intersects with Y' or X or both. We partition these non-trivial witness sets in $\mathcal{W}$ into two groups depending on whether the intersection with X is empty (Condition 3.2) or not (Condition 3.3). We first modify the witness sets that satisfy the least indexed condition. If there does not exist a witness set which satisfies either of these three conditions, then $Y \setminus Y'$ is an empty set, and the lemma is vacuously true.

▶ **Condition 3.1.** *There exists a witness set $W(t)$ in $\mathcal{W}$ which is a subset of $Y \setminus Y'$.*

Construct $G^\star$ from G by deleting the witness sets $W(t)$ in $\mathcal{W}$. Let $F^\star$ be obtained from F by deleting those edges whose both the endpoints are in $W(t)$. Since the class of cliques is closed under vertex deletion, $G^\star/F^\star$ is a clique, and as we only deleted edges from F, we have $|F^*| \leq |F|$. We repeat this process until there exists a witness set that satisfies Condition 3.1.

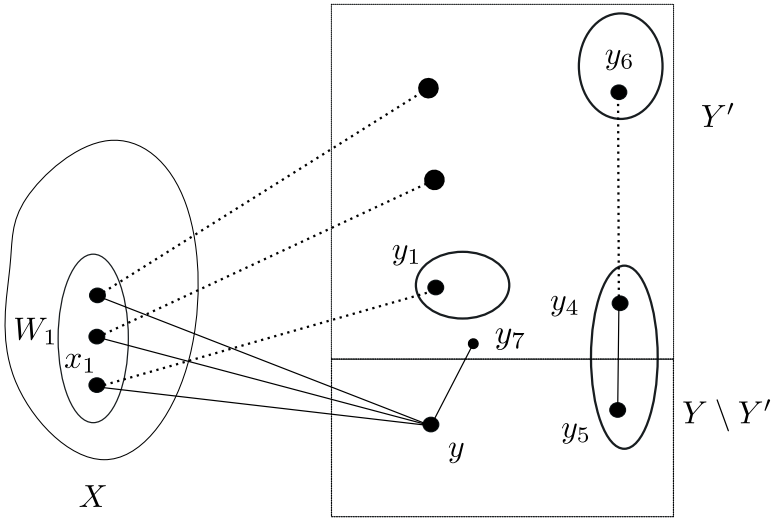

Figure 2 Straight lines (e.g. y_4y_5) represent edges in original solution F. Dotted lines (e.g. y_4y_6) represents edges which are replaced for some edges in F. Please refer to the proof of Lemma 13.

At this stage we rename $G^\star$ to G and $F^\star$ to F.

▶ **Condition 3.2.** *There exists a witness set $W(t)$ in $\mathcal{W}$ which contains vertices from $Y \setminus Y'$ but does not intersect X.*

Since $W(t)$ is not contained in $Y \setminus Y'$ and $W(t) \cap X$ is empty it must intersect with Y'. See Figure 2. Let y_4 and y_5 be vertices in $W(t) \cap Y'$ and $W(t) \cap (Y \setminus Y')$, respectively. Let $W(t_1)$, different from $W(t)$, be a witness set which intersects Y'. Since Y' is large and non-empty, such a witness set exists. Let y_6 be a vertex in the set $W(t_1) \cap Y'$. Consider the witness sets $W(t), W(t_1)$ and vertex y_5 in $W(t)$ in graph G. Lemma 11 implies that these witness sets satisfy the premise of Observation 2.6. This implies $\mathcal{W}^\star$ is a clique witness structure of $G - \{y_5\}$, where $\mathcal{W}^\star$ is obtained from $\mathcal{W}$ by removing $W(t), W(t_1)$ and adding $(W(t) \cup W(t_1)) \setminus \{y_5\}$. This corresponds to replacing an edge in F which was incident to y_5 with the one across $W(t)$ and $W(t_1)$. For example, in Figure 2, we replace edge y_4y_5 in the set F with an edge y_4y_6 to obtain a solution for $G - \{y_5\}$. An edge in F has been replaced with another edge and one vertex in $Y \setminus Y'$ is deleted. The size of $F^\star$ is same as that of F and $G^\star/F^\star$ is a clique. We repeat this process until there exist a witness set which satisfies Condition 3.2.

At this stage we rename $G^\star$ to G and $F^\star$ to F.

▶ **Condition 3.3.** *There exists a witness set $W(t)$ in $\mathcal{W}$ which contains vertices from $Y \setminus Y'$ and intersects X.*

Let y be a vertex in $W(t) \cap (Y \setminus Y')$, X_t be the set of vertices in $W(t) \cap X$ which are adjacent to y via edges in F, and Q_t be the set of vertices in $W(t) \cap Y$ which are adjacent to y via edges in F. We find a *substitute* for y in Y'. If the set X_t is empty then the vertex y is adjacent only with the vertices of Y, in this case the edges incident to y can be replaced as

mentioned in the Condition 3.2. Assume that X_t is non-empty. For every vertex x in X_t the set $\{x\}$ is considered by Marking Scheme 3.1. Since y is adjacent to every vertex x in X_t, the set $M_1(\{x\})$ is non-empty. As y is in $Y \setminus Y'$, and hence unmarked, for every x in X_t, there is a vertex in $M_1(\{x\})$, say y_x, different from y which has been marked. We construct $F^\star$ from F by the following operation: For every vertex x in X_t, replace the edge xy in F by xy_x. Fix a vertex x_o in X_t, and for every vertex u in Q_t, replace the edge uy in F with uy_{x_o}. Since we are replacing a set of edges in F with another set of edges of same size we have $|F^\star| \leq |F|$. (For example, in Figure 2, $X_t = W_1$ and $Q_t = \{y_7\}$. Edges yx_1, yy_7 are replaced by x_1y_1, y_1y_7 resp.) We argue that if $G^\star$ is obtained from G by removing y, then $G^\star/F^\star$ is a clique.

We argue that contracting edges in $F^\star$ partitions $W(t)$ into $|X_t| + |Q_t|$ many parts and merges each part with some witness set in $\mathcal{W} \setminus \{W(t)\}$. Recall that F contains a spanning tree of graph $G[W(t)]$. Let T be a spanning tree of $G[W(t)]$ such that $E(T) \subseteq F$ and T contains all edges in F that are incident on y. It is easy to see that such a spanning tree exists. Let y be the root of tree T. For every z in $X_t \cup Q_t$, let $W'(z)$ be the set of vertices in the subtree of T rooted at z. As $V(T) = W(t)$, set $\{W'(z) |\ z \in X_t \cup Q_t\}$ is a partition of $W(t) \setminus \{y\}$. For every x in X_t, let $W(y_x)$ be the witness set in $\mathcal{W}$ containing the vertex y_x. For every x in $X_t \setminus \{x_o\}$, let $W^\star(y_x)$ be the set $W(y_x) \cup W'(x)$. Let $W^\star(y_{x_o})$ be the set $W(y_{x_o}) \cup W'(x_o) \cup \bigcup_{y'} W'(y')$ for all y' in Q_t. We obtain $\mathcal{W}^\star$ from $\mathcal{W}$ by removing $W(t)$ and $W(y_x)$ for every x in X_t, and adding the sets $W^\star(y_x)$ for every x in X_t. Since $W^\star(y_x)$ contains the set $W(y_x)$ which was adjacent to every witness set in $\mathcal{W}$, $W^\star(y_x)$ will be adjacent with every witness set in $\mathcal{W}^\star$. We repeat this process until there exists a witness set that satisfies this condition.

Any vertex in $Y \setminus Y'$ must be a part of some witness set in $\mathcal{W}$, and any witness set in $\mathcal{W}$ satisfies at least one of the above conditions. If there are no witness sets that satisfy these conditions, then $Y \setminus Y'$ is empty. This implies $G^\star = G'$ and there exists a solution $F^\star$ of size at most $|F^\circ|$. This concludes the proof of the lemma. ◀

We are now in a position to prove the following lemma.

▶ **Lemma 14.** *Reduction Rule 3.2, along with a solution lifting algorithm, is an* $(1+\epsilon)$*-reduction rule.*

Proof. Let (G', k) be the instance returned by Reduction Rule 3.2 when applied on an instance (G, k). We present a solution lifting algorithm as follows. For a solution F' for (G, k) if $\textsc{Clc}(G', k, F') = k+1$, then the solution lifting algorithm returns a spanning tree F of G (a trivial solution) as solution for (G, k). In this case, $\textsc{Clc}(G, k, F) = \textsc{Clc}(G', k, F')$. If $\textsc{Clc}(G', k, F') \leq k$, then size of F' is at most k and G'/F' is a clique. Solution lifting algorithm uses Lemma 12 to construct a solution F for (G, k) such that cardinality of F is at most $(1+\epsilon) \cdot |F'|$. In this case, $\textsc{Clc}(G, k, F) \leq (1+\epsilon) \cdot \textsc{Clc}(G', k, F')$. Hence, there exists a solution lifting algorithm which given a solution F' for (G', k') returns a solution F for (G, k) such that $\textsc{Clc}(G, k, F) \leq (1+\epsilon) \cdot \textsc{Clc}(G', k, F')$.

If $\mathrm{OPT}(G, k) \leq k$, then by Lemma 13, $\mathrm{OPT}(G', k) \leq \mathrm{OPT}(G, k)$. If $\mathrm{OPT}(G, k) = k+1$ then $\mathrm{OPT}(G', k) \leq k+1 = \mathrm{OPT}(G, k)$. Hence in either case, $\mathrm{OPT}(G', k) \leq \mathrm{OPT}(G, k)$.

Combining the two inequalities, we get $\frac{\textsc{Clc}(G,k,F)}{\mathrm{OPT}(G,k)} \leq \frac{(1+\epsilon)\cdot\textsc{Clc}(G',k,F')}{\mathrm{OPT}(G',k)}$. This implies that if F' is a factor c-approximate solution for (G', k) then F is a factor $(c \cdot (1+\epsilon))$-approximate solution for (G, k). This concludes the proof. ◀

We are now in a position to present the main result of this section.

Proof. (of Theorem 1) For a given instance (G, k) with $|V(G)| \geq k + 3$, a kernelization algorithm applies the Reduction Rule 3.1. If it returns a trivial instance, then the statement is vacuously true. If it does not return a trivial instance, then the algorithm partitions $V(G)$ into two sets (X, Y) such that $G - X = G[Y]$ is a clique and size of X is at most $4k$. Then the algorithm applies the Reduction Rule 3.2 on the instance (G, k) with the partition (X, Y) and the integer $d = \lceil \frac{1}{\epsilon} \rceil$. The algorithm returns the reduced instance as $(1 + \epsilon)$-lossy kernel for (G, k).

The correctness of the algorithm follows from Lemma 10 and Lemma 14 combined with the fact that Reduction Rule 3.2 is applied at most once. By Observation 2.1, Reduction Rule 3.1 can be applied in polynomial time. The size of the instance returned by Reduction Rule 3.2 is at most $\mathcal{O}((4k)^d \cdot (2k + 1) + 4k) = \mathcal{O}(k^{d+1})$. Reduction Rule 3.2 can be applied in time $n^{\mathcal{O}(1)}$ if the number of vertices in (G, k) is more than $\mathcal{O}(k^{d+1})$. ◀

Abstract

We study the online graph coloring problem restricted to the intersection graphs of intervals with lengths in $[1, \sigma]$. For $\sigma = 1$ it is the class of unit interval graphs, and for $\sigma = \infty$ the class of all interval graphs. Our focus is on intermediary classes. We present a $(1 + \sigma)$-competitive algorithm, which beats the state of the art for $1 < \sigma < 2$, and proves that the problem we study can be strictly easier than online coloring of general interval graphs. On the lower bound side, we prove that no algorithm is better than 5/3-competitive for any $\sigma > 1$, nor better than 7/4-competitive for any $\sigma > 2$, and that no algorithm beats the 5/2 asymptotic competitive ratio for all, arbitrarily large, values of σ. That last result shows that the problem we study can be strictly harder than unit interval coloring. Our main technical contribution is a recursive composition of strategies, which seems essential to prove any lower bound higher than 2.

1 Introduction

In the *online graph coloring* problem the input graph is presented to the algorithm vertex by vertex, along with all the edges adjacent to the already presented vertices. Each vertex must be assigned a color, different than any of its neighbors, immediately and irrevocably at the moment it is presented, without any knowledge of the remaining part of the graph. The objective is to minimize the number of used colors. The problem and its variants attract much attention, both for theoretical properties and practical applications in network multiplexing, resource allocation, and job scheduling.

The standard performance measure, used to analyze online algorithms, is the *competitive ratio*, i.e., the worst-case guarantee on the ratio of the solution given by an online algorithm to the optimal offline solution (see Section 1.1 for a formal definition).

In the general case, of online coloring of arbitrary graphs, there is no hope for any algorithm with a constant competitive ratio. The best known algorithm [7] uses $O(\chi \cdot n/\log n)$ colors for n-vertex χ-colorable graphs, i.e. it is $O(n/\log n)$-competitive, and there is a lower bound [8] showing that no online graph coloring algorithm can be $o\big(n/\log^2 n\big)$-competitive. It is thus common to study the problem restricted to particular graph classes.

Having in mind the applications in scheduling, one of the important special cases is the class of *interval graphs*, i.e. intersection graphs of intervals on the real line. The classic result is by Kierstead and Trotter [11], who designed a 3-competitive algorithm and proved a matching lower bound. However, in the special case of *unit interval graphs*, i.e. intersection graphs of intervals of a fixed length, already the simple greedy FirstFit algorithm is 2-competitive [4].

Coloring unit interval graphs can model only a restricted scheduling setting, with all jobs having the same processing time. On the other hand, allowing arbitrary processing times, modeled by (general) interval graphs, might be a too permissive setting, precluding efficient online algorithms. Thus, we ask what happens in between the interval and unit interval graph classes. In particular, we are interested in the optimal competitive ratio of online coloring algorithms for intersection graphs of intervals of length restricted to a fixed range. Formally, let us introduce the σ-interval coloring problem.

▶ **Definition 1.** *For $\sigma \geqslant 1$, the* σ-interval coloring *problem asks: Given a sequence of closed intervals $[l_1, r_1], [l_2, r_2], \ldots, [l_n, r_n]$, such that $1 \leqslant (r_i - l_i) \leqslant \sigma$ for every $i \in [n]$, find a sequence of* colors*, $c_1, c_2, \ldots, c_n$, such that*

$$\forall_{i \neq j} \ \big([l_i, r_i] \cap [l_j, r_j] \neq \emptyset\big) \implies (c_i \neq c_j),$$

minimizing the number of distinct colors $\big|\{c_1, c_2, \ldots, c_n\}\big|$.

We study the problem in the online setting, i.e., intervals are presented one by one, in an arbitrary order, and each interval has to be colored immediately and irrevocably after it is presented.

Note that we choose to include the interval representation in the input, instead of presenting the mere graph. It seems a plausible modeling choice given the scheduling applications. Moreover, it lets algorithms exploit geometric properties of the input, and not only structural graph properties. Naturally, any lower bound obtained for this variant of the problem transfers to the harder variant with no interval representation in the input.

Among others, we look to answer the following two apparent questions.

▶ **Question 1.** *Is σ-interval coloring strictly easier than interval coloring?*

▶ **Question 2.** *Is σ-interval coloring strictly harder than unit interval coloring?*

Naturally, we ask these questions in the online setting, where easier (harder) mean smaller (greater) best possible competitive ratio.

1.1 Our Results

Before we state our results, let us give a formal definition of the competitive ratio. In this paper we focus on the *asymptotic* competitive ratio.

▶ **Definition 2.** *Let A be an online graph coloring algorithm, and let $A(\chi)$ denote the maximum number of colors A uses to color any graph which can be colored offline using χ-colors (i.e. its chromatic number is at most χ). We say that A has the asymptotic competitive ratio α (or that A is α-competitive, for short), if* $\limsup_{\chi\to\infty} \frac{A(\chi)}{\chi} \leqslant \alpha$.

Another popular performance measure for online algorithms is the *absolute* competitive ratio, which requires that $\frac{A(\chi)}{\chi} \leqslant \alpha$ holds for *all* χ (and not only in the limit). The choice of the asymptotic, instead of absolute, competitive ratio for our analysis makes things easier for the algorithm and harder for the lower bounds. In our algorithm, sadly, we do not know how to get rid of a constant additive overhead, which vanishes only with growing χ. This is in contrast to the FirstFit and Kierstead-Trotter algorithms, whose claimed competitive ratios are not only asymptotic but also absolute. The good side is, our lower bounds for the asymptotic competitive ratio imply the identical lower bounds for the absolute competitive ratio.

Algorithm. Our positive result is the existence of a $(1+\sigma)$-competitive algorithm.

▶ **Theorem 3.** *For every $\sigma \in \mathbb{Q}$, $\sigma \geqslant 1$, there is an algorithm for online σ-interval coloring with $1+\sigma$ asymptotic competitive ratio.*

Note that for $\sigma' > \sigma$ every σ'-interval coloring algorithm is also a correct σ-interval coloring algorithm, with the same upper bound on its competitive ratio. Therefore, for $\sigma \in \mathbb{R} \setminus \mathbb{Q}$ Theorem 3 yields an online σ-interval coloring algorithm with a competitive ratio arbitrarily close to $1+\sigma$. This distinction between rational and irrational values of σ becomes somewhat less peculiar in the light of the results of Fishburn and Graham [5], who proved, among other things, that the classes $C(\sigma)$'s of graphs with interval representation with lengths in $[1,\sigma]$ are *right-continuous*, i.e. $C(\sigma) = \bigcap_{\tau>\sigma} C(\tau)$, exactly at irrational σ's.

Until now, the state-of-the art was the 2-competitive FirstFit algorithm [4] for $\sigma = 1$, and the 3-competitive Kierstead-Trotter algorithm [11] for $\sigma > 1$. Our algorithm matches the performance of FirstFit for $\sigma = 1$, and beats the Kierstead-Trotter algorithm for $\sigma < 2$.

The algorithm is inspired by the recent result for online coloring of unit disk intersection graphs [9]. We cover the real line with overlapping blocks, grouped into a constant number of classes, with each class constituting a partition of the real line. We assign to each class a private set of available colors. When an interval is presented, the algorithm chooses, in a round-robin fashion, a block containing the interval's left end, and greedily picks a color from the block's class.

While not being overly complicated, the algorithm already answers positively our Question 1. Indeed, since there cannot exist a less-than-3-competitive algorithm for (general) interval coloring [11], σ-interval coloring is strictly easier, for $\sigma < 2$.

Lower Bounds. Our negative results include a series of constructions with the following consequences.

▶ **Theorem 4.** *For every $\sigma > 1$ there is no online algorithm for σ-interval coloring with the asymptotic competitive ratio less than $5/3$.*

▶ **Theorem 5.** *For every $\sigma > 2$ there is no online algorithm for σ-interval coloring with the asymptotic competitive ratio less than $7/4$.*

▶ **Theorem 6.** *For every $\varepsilon > 0$ there is $\sigma \geqslant 1$ such that there is no online algorithm for σ-interval coloring with the asymptotic competitive ratio $5/2 - \varepsilon$.*

The following, more illustrative, statement is a direct corollary of Theorem 6.

▶ **Corollary 7.** *There is no online algorithm that works for all $\sigma \geqslant 1$ and uses at most $2.499 \cdot \omega + f(\sigma)$ colors for ω-colorable graphs (for any function f).*

Theorem 6 gives a positive answer to our Question 2. Indeed, while FirstFit is 2-competitive for unit interval coloring, there is no 2-competitive algorithm for σ-interval coloring (for large enough σ), therefore the latter problem is strictly harder. Working out the exact number from our proof, this starts to be the case for $\sigma > 2^{78}$, however we did not attempt to optimize the constant.

Our proofs of Theorems 4 and 5 can be considered as generalizations of the $3/2$ lower bound for online coloring of unit interval graphs by Epstein and Levy [4]. In particular, we heavily use their *separation strategy*, which also appears in [1].

Our main technical contribution is a recursive composition of strategies, which seems essential to prove any lower bound higher than 2. Our $5/2$ lower bound (Theorem 6) borrows also from the work of Kierstead and Trotter [11]. However, in order to control the length of intervals independently of the number of colors, we cannot simply use the pigeonhole principle, as they did. Instead, we develop Lemmas 19 and 20, which let us overcome this issue, at a cost of a worse bound for the competitive ratio, i.e. $5/2$ instead of 3.

1.2 Related Work

Interval graphs have been intensively studied since the sixties [2, 12], and, in particular, they are known to be *perfect*, i.e. the chromatic number χ of an interval graph always equals the size of the largest clique ω (see, e.g., [6]). To construct an optimal coloring offline it is sufficient to color the graph greedily in a nondecreasing order of the left ends of the intervals.

For the most basic approach for online coloring, that is the FirstFit algorithm, the competitive ratio for interval graphs is still not known exactly. After a series of papers, the most recent results state that FirstFit is at least 5- and at most 8-competitive [10, 13]. Kierstead and Trotter [11] designed a more involved online coloring algorithm, which uses at most $3\omega - 2$ colors for ω-colorable interval graphs, and proved that there exists a strategy that forces any online coloring algorithm to use exactly that number of colors. The same lower and upper bounds were obtained independently by Chrobak and Ślusarek [3, 14]. For intersection graphs of intervals of unit length any online coloring algorithm uses at least $\frac{3}{2}\omega$ colors, and FirstFit uses at most $2\omega - 1$ colors [4].

It seems a natural question to ask if it is possible to improve the bound of $3\omega - 2$ by assuming that interval lengths belong to a fixed range. The study of interval graphs with bounded length representations was initiated by Fishburn and Graham [5]. However, it focused mainly on the combinatorial structure, and not its algorithmic applications.

Kierstead and Trotter [11] give, for every $\omega \in \mathbb{N}_+$, a strategy for Presenter to construct an ω-colorable set of intervals while forcing Algorithm to use at least $3\omega - 2$ colors. However, the lengths of presented intervals increase with the increasing ω. For this reason, with the

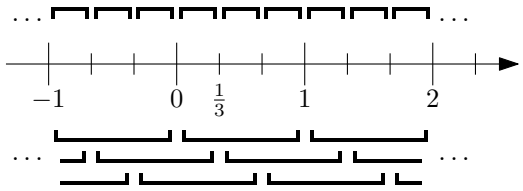

Figure 1 Small blocks (above), and large blocks (below), for $b = 3$.

interval length restricted to $[1, \sigma]$, their lower bound is only for the absolute competitive ratio and does not exclude, say, an algorithm that always uses at most $2\omega + \sigma^{10}$ colors. On the contrary, in Theorem 6 we rule out the existence of such an algorithm.

2 Algorithm

▶ **Theorem 3.** *For every $\sigma \in \mathbb{Q}$, $\sigma \geqslant 1$, there is an algorithm for online σ-interval coloring with $1 + \sigma$ asymptotic competitive ratio.*

Proof. Let us present an algorithm which, in principle, works for any real σ, however only for a rational σ it achieves the declared competitive ratio. The algorithm has a positive integer parameter b. Increasing the parameter brings the asymptotic competitive ratio closer to $1 + \sigma$ at the cost of increasing the additive constant. More precisely, given an ω-colorable set of intervals our algorithm colors it using at most $\lceil b \cdot (1 + \sigma) \rceil \cdot \left(\frac{\omega}{b} + b - 1\right)$ colors, and thus its competitive ratio is $\frac{\lceil b \cdot (1+\sigma) \rceil}{b} + O(1/\omega)$. For a rational σ, in order to obtain exactly the declared $1 + \sigma$ asymptotic competitive ratio it is sufficient to set b to the smallest possible denominator of a simple fraction representation of σ. Let $\varphi = \lceil b \cdot (1 + \sigma) \rceil$. The algorithm will use colors from the set $\{0, 1, \ldots, \varphi - 1\} \times \mathbb{N}$.

Now, let us consider the partition of the real line into *small blocks*. For $i \in \mathbb{Z}$, the i-th small block occupies the interval $[i \cdot \frac{1}{b}, (i + 1) \cdot \frac{1}{b})$. Moreover, we define *large blocks*. The i-th large block occupies the interval $[i \cdot \frac{1}{b}, i \cdot \frac{1}{b} + 1)$. See Figure 1.

Let us point out certain properties of the blocks, which will be useful in the further analysis. Each large block is the union of b consecutive small blocks, and each small block is a subset of b consecutive large blocks. Further, the length of a large block is 1, and for any two intervals of length in $[1, \sigma]$ that both have the left endpoint in the same large block, the two intervals intersect. Thus, the intervals whose left endpoints belong to a fixed large block form a clique. Finally, if the indices of two large blocks differ by at least φ, then any two intervals – one with the left endpoint in one block, the other with the left endpoint in the other – do not intersect.

With each small block the algorithm associates a *small counter*, and with each large block the algorithm associates a *large counter*. Let S_i denote the small counter of the i-th small block, and L_j denote the large counter of the j-th large block. Initially, all the small and large counters are set to zero.

The small counter S_i tracks how many intervals with left endpoint in the i-th small block appeared so far. Based on the small counter the algorithm assigns, in a round-robin fashion, the processed interval to one of the b large blocks containing its left endpoint. The large counter L_j tracks how many intervals were assigned to the j-th large block so far. The color of the processed interval will depend on the large counter.

To assign a color to an interval, the algorithm proceeds as follows:

1. Let i be the index of the small block containing the left endpoint of the interval.
2. Let j be the index of the large block containing the left endpoint of the interval such that $j \equiv S_i \pmod{b}$. Note that there is exactly one such j.

3. Assign to the interval the color $(j \bmod \varphi, L_j)$.
4. Increase the small counter S_i by one.
5. Increase the large counter L_j by one.

First let us argue that the algorithm outputs a proper coloring. Consider any two intervals which were assigned the same color. Let j_1 and j_2 denote the indices of the large blocks selected for these intervals by the algorithm. Since the colors of the two intervals have the same first coordinates, we have that $j_1 \equiv j_2 \pmod{\varphi}$. However, since the second coordinates, which are determined by large counters, are also the same, j_1 and j_2 must be different, and thus they differ by at least φ. Hence the left endpoints of the large blocks j_1 and j_2 are at least $1 + \sigma$ apart, and the two considered intervals do not intersect, thus the coloring is proper.

It remains to bound the number of colors in terms of the clique number ω. Let j be the index of the maximum large counter L_j at the end of the algorithm. Clearly, the algorithm used at most $\varphi \cdot L_j$ colors in total. Let C denote the set of intervals with the left endpoints in the j-th large block and colored with a color in $\{j \bmod \varphi\} \times \mathbb{N}$. Observe that $|C| = L_j$. Let x_k denote the number of intervals in C which have the left endpoint in the k-th small block. Recall that the j-th large block is the union of b small blocks – indexed $j, j+1, \ldots, j+b-1$ – and thus $L_j = x_j + x_{j+1} + \cdots + x_{j+b-1}$. Because of the the formula $j \equiv S_i \pmod{b}$ in the step (2) of the algorithm, the large counter L_j is incremented by one out of every b intervals with the left endpoints in any given small block. Hence either $x_k = \lfloor \frac{S_k}{b} \rfloor$ or $x_k = \lfloor \frac{S_k}{b} \rfloor + 1$. In particular

$$S_k \geqslant b \cdot (x_k - 1) + 1.$$

Let D denote the set of all intervals with the left endpoints in the j-th large block. We can bound the number of intervals in D

$$|D| \;=\; \sum_{k=j}^{j+b-1} S_k \;\geqslant\; \sum_{k=j}^{j+b-1} \left(b \cdot (x_k - 1) + 1\right) \;=\; b \cdot (L_j - b) + b.$$

Recall that D is a clique and thus the clique number ω of the input graph is at least the size of D. Therefore $L_j \leqslant \frac{\omega + b \cdot (b-1)}{b}$, and the algorithm used at most

$$\lceil b \cdot (1 + \sigma) \rceil \cdot \left(\frac{\omega}{b} + b - 1 \right)$$

colors. ◀

3 Lower Bounds

3.1 Technical Overview

Algorithm-vs-Presenter game. In order to prove lower bounds for online problems, it is often convenient to look at the problem as a combinatorial game between two players, Algorithm and Presenter. In our case, in each round Presenter reveals an interval, and Algorithm immediately and irrevocably assigns a color to it. Algorithm tries to minimize the number of different colors it assigns. Contrarily, the Presenter's goal is to force Algorithm to use as many colors as possible, while guaranteeing that the introduced set of intervals is colorable with a smaller number of colors, and contains only short intervals. A strategy for Presenter implies a lower bound on the competitive ratio of any algorithm solving the problem.

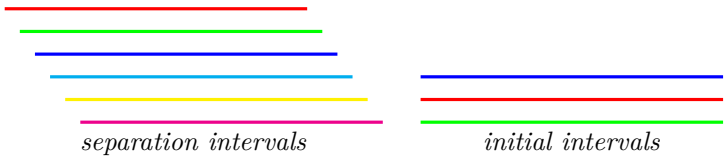

Figure 2 Separation strategy.

Separation Strategy. Epstein and Levy [4] prove their $\frac{3}{2}$ lower bound for online coloring of unit intervals by giving the following strategy for Presenter. The strategy has three phases.

1. Presenter introduces a clique of $\frac{\omega}{2}$ equal (i.e. located at the same place) *initial intervals*. Algorithm has to use $\frac{\omega}{2}$ different colors. Let $\mathcal{X}$ denote the set of these colors.
2. Just to the left of the initial intervals, Presenter introduces a clique of ω *separation intervals*. These intervals are not equal, they all have slightly different endpoints, and in total they occupy a place of length $1+\varepsilon$. None of them intersect the initial intervals. The specific way the separation intervals are presented ensures that all separation intervals with colors in $\mathcal{X}$ have their left (resp. right) endpoints to the left of all left (resp. right) endpoints of separation intervals with colors not in $\mathcal{X}$ (see Figure 2). In particular, each of $\frac{\omega}{2}$ right-most separation intervals has a color not in $\mathcal{X}$.
3. Presenter introduces a clique of equal $\frac{\omega}{2}$ *final intervals* that intersect all the initial intervals, and $\frac{\omega}{2}$ right-most separation intervals.

Algorithm has to use at least $\frac{3}{2}\omega$ different colors, but the largest clique size (i.e. the offline optimum) is only ω.

The second phase of the above strategy is an example of the *separation strategy*. The formal details are included in the proof of Lemma 14.

Recursive Composition of Strategies. Let us generalize the above strategy. Observe, that instead of presenting a clique in the first phase, Presenter can use an arbitrary strategy, presenting a set of intervals with the clique number equal to $\frac{\omega}{2}$ but possibly enforcing more than $\frac{\omega}{2}$ colors. Moreover, Presenter might be able to achieve a better trade-off by allowing a clique of size $\beta\omega$ (for some $0 < \beta < 1$) in the first phase, and introducing a clique of size $(1-\beta)\omega$ in the third phase. Actually, it turns out that if the strategy used in the first phase enforces a competitive ratio α (e.g. presenting a clique has $\alpha = 1$), then it is optimal to set $\beta = \frac{1}{1+\alpha}$.

Assume we have a strategy that enforces a competitive ratio α, uses intervals of length at most σ, and needs a place of length M on the real axis (e.g. presenting a clique gives $\alpha = \sigma = M = 1$). Consider the following strategy.

1. Presenter plays the assumed strategy to obtain a set of initial intervals with the clique number $\frac{\omega}{1+\alpha}$. Algorithm has to use $\alpha\frac{\omega}{1+\alpha}$ different colors, denoted by $\mathcal{X}$.
2. Presenter introduces a clique of ω separation intervals (of unit length), and at least the right-most $\omega - |\mathcal{X}| \geqslant \frac{\omega}{1+\alpha}$ of them get new colors, not in $\mathcal{X}$.
3. Presenter introduces a clique of $\alpha\frac{\omega}{1+\alpha}$ final intervals of length $M+\varepsilon$ that intersect all the initial intervals, and the $\frac{\omega}{1+\alpha}$ right-most separation intervals.

In total, the intervals can be colored with ω colors, but the algorithm uses at least

$$\alpha\frac{\omega}{1+\alpha} + \frac{\omega}{1+\alpha} + \alpha\frac{\omega}{1+\alpha} = \frac{(2\alpha+1)\omega}{1+\alpha}$$

colors, i.e. it is at most $(2 - \frac{1}{\alpha+1})$-competitive

Let S_0 be a trivial strategy that presents a clique of equal unit intervals. Now, let S_{i+1} be a strategy obtained as above by playing S_i in the first phase. It enforces a competitive ratio α_{i+1}, uses intervals of length at most σ_{i+1}, and needs a place of length M_{i+1}, where $\alpha_0 = \sigma_0 = M_0 = 1$, and each $\alpha_{i+1} = 2 - \frac{1}{\alpha_i+1}$, $\sigma_{i+1} = M_i + \varepsilon$, $M_{i+1} = M_i + 1 + \varepsilon$. By solving the recurrence equations we get the following corollary.

▶ **Corollary 8.** *For every $n \in \mathbb{N}_+$ and every $\varepsilon > 0$, there is no online algorithm for $(n+\varepsilon)$-interval coloring with the asymptotic competitive ratio less than $\frac{F_{2n+1}}{F_{2n}}$, where F_n is the n-th Fibonacci number ($F_0 = F_1 = 1$, $F_{n+2} = F_{n+1} + F_n$).*

Note that this method cannot give a lower bound higher than $\lim_{n\to\infty} \frac{F_{2n+1}}{F_{2n}} = \frac{1+\sqrt{5}}{2} \approx 1.61803$. However, we can get arbitrarily close to this bound. That is, for every $\varepsilon > 0$ there is a σ and ω_0 such that for each $\omega \geqslant \omega_0$ there is a strategy for Presenter to present intervals of length at most σ and force Algorithm to use $\left(\frac{1+\sqrt{5}}{2} - \varepsilon\right) \cdot \omega$ colors on an ω-colorable set of intervals.

▶ **Observation 9.** *There is no online algorithm that works for all $\sigma \geqslant 1$ and uses at most $1.618 \cdot \omega + f(\sigma)$ colors for ω-colorable graphs (for any function f).*

Overview of the 5/2 Lower Bound. Our $5/2$ lower bound also works by recursively combining strategies, however the three phases are substantially different than above. In particular, in the first phase, instead of playing the simpler strategy only once, Presenter plays many instances of it, independently, side by side. Intuitively, either Algorithm uses mostly different colors for different instances, and it already uses too many colors, or there must be many colors shared by many instances.

So far the argument resembles the lower bound for interval graphs by Kierstead and Trotter [11]. They use pigeonhole principle to argue that if the total number of colors is bounded, then after playing exponentially many instances, there must be four instances that use exactly the same subset of colors. Thus, the number of instances – and consequently the length of intervals in the subsequent phases – required in their approach grows with the number of colors, which makes it infeasible in our setting.

To overcome the above difficulty we show (see Lemmas 19 and 20) that, if the total number of colors is small, there must be four groups of consecutive instances, which do not necessarily use exactly the same colors, but at least have large intersection.

3.2 Preliminaries

To properly capture asymptotic properties of the introduced strategies we give the following formal definitions.

▶ **Definition 10.** *For $\omega, C \in \mathbb{N}_+$ and $\sigma, M \in \mathbb{R}_+$, an* $\langle \omega, C, \sigma, M\rangle$-strategy *is a strategy for Presenter that forces Algorithm to use at least C colors subject to the following constraints:*

1. *the set of introduced intervals is ω-colorable,*
2. *every introduced interval has length at least 1 and at most σ,*
3. *every introduced interval is contained in the interval $[0, M]$.*

We are interested in providing strategies that achieve the biggest possible ratio $\frac{C}{\omega}$ for large ω. This motivates the following definition.

▶ **Definition 11.** *An* $\langle \alpha, \sigma, M\rangle$-schema *is a set of $\langle \omega, C_\omega, \sigma, M\rangle$-strategies for all $\omega \in \mathbb{N}_+$ such that $C_\omega = \alpha\omega - o(\omega)$.*

The $o(\omega)$ term in the above definition accounts for the fact that sometimes in a proof we would like to introduce, say, $\frac{\omega}{2}$-clique. Then, for odd ω's a rounding is required, which results in small inaccuracies we need to control.

▶ Remark 12. Note that the existence of an $\langle \alpha, \sigma, M \rangle$-*schema* implies a lower bound of α for the asymptotic competitive ratio of any online algorithm solving the σ-interval coloring problem.

To put the above definitions in context, note that Kierstead and Trotter [11] give, for all $\omega \in \mathbb{N}_+$, an $\langle \omega, 3\omega - 2, f(\omega), f(\omega) \rangle$-strategy. However, their family of strategies does not yield an $\langle \alpha, \sigma, M \rangle$-schema, because the length of the presented intervals grows with ω.

▶ **Example 13** ($\langle 1, 1, 1 \rangle$-schema)**.** For any $\omega \in \mathbb{N}_+$, a strategy that introduces the interval $[0, 1]$ in every round $1, \ldots, \omega$ is an $\langle \omega, \omega, 1, 1 \rangle$-strategy. The set of these strategies is a $\langle 1, 1, 1 \rangle$-schema.

In this section we show a series of constructions that use an existing schema to create another schema with different parameters. The $\langle 1, 1, 1 \rangle$-schema given above is the initial step for those constructions.

Let S be an $\langle \omega, C, \sigma, M \rangle$-strategy. We will say that *Presenter uses strategy S in the interval* $[x, x + M]$ to denote that Presenter plays according to S, presenting intervals shifted by x, until Algorithm uses C colors.

3.3 Warm-up

Our first construction is a natural generalization of the strategy for unit intervals given by Epstein and Levy [4], already described in Section 3.1 in an informal way. The construction is surpassed by more involved strategies coming later, but it serves as a gentle introduction to our formal framework.

▶ **Lemma 14.** *If there is an $\langle \alpha, \sigma, M \rangle$-schema, then there is a $\left\langle 2 - \frac{1}{\alpha+1}, M + \varepsilon, M + 1 + \varepsilon \right\rangle$-schema for every $\varepsilon > 0$.*

Proof. To prove the lemma we need to provide an $\left\langle \omega, (2 - \frac{1}{\alpha+1})\omega - o(\omega), M + \varepsilon, M + 1 + \varepsilon \right\rangle$-strategy for every $\omega \in \mathbb{N}_+$. Let us fix an $\omega \in \mathbb{N}_+$, and let $\omega' = \left\lfloor \frac{\omega}{\alpha+1} \right\rfloor$. The $\langle \alpha, \sigma, M \rangle$-schema contains an $\langle \omega', \alpha\omega' - \delta, \sigma, M \rangle$-strategy S for some $\delta = o(\omega')$. The strategy for Presenter consists of three phases (see Figure 3). In the first phase, called the *initial phase*, Presenter uses strategy S inside the interval $[1 + \varepsilon, M + 1 + \varepsilon]$. Let $C = \alpha\omega' - \delta$ and let $\mathcal{X}$ denote the set of C colors used by Algorithm in the initial phase.

The second phase, borrowed from [4, 1], is called the *separation phase*. In this phase, Presenter plays the following separation strategy for ω rounds. Let $l_1 = 0$ and $r_1 = \frac{\varepsilon}{2}$. In the i-th round of the separation phase Presenter introduces the interval $[\frac{l_i + r_i}{2}, \frac{l_i + r_i}{2} + 1]$. If Algorithm colors the interval with one of the colors in $\mathcal{X}$, let $l_{i+1} = \frac{l_i + r_i}{2}$ and $r_{i+1} = r_i$, which means that the next interval will be shifted slightly to the right. Otherwise, let $l_{i+1} = l_i$ and $r_{i+1} = \frac{l_i + r_i}{2}$, which means that the next interval will be shifted slightly to the left.

The above procedure guarantees the following invariant. At the beginning of round i all the previously introduced intervals with a color in $\mathcal{X}$ have their left endpoints to the left of l_i, and, conversely, all the previously introduced intervals with a color not in $\mathcal{X}$ have their left endpoints to the right of r_i. Moreover, all the intervals yet to be introduced will have their left endpoints strictly between l_i and r_i.

Observe that all intervals introduced in the separation phase have length 1 and $\forall_i \frac{l_i + r_i}{2} < \frac{\varepsilon}{2}$. Thus, every interval introduced in the separation phase is contained in $\left[0, 1 + \frac{\varepsilon}{2}\right]$ and any two of those intervals intersect. Furthermore, the above invariant guarantees that for any two

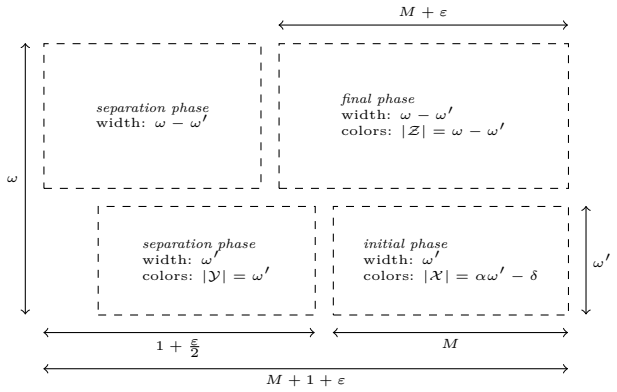

Figure 3 Strategy construction in Lemma 14.

intervals x, y introduced in the separation phase, x colored with a color in $\mathcal{X}$, and y colored with a color not in $\mathcal{X}$, we have that the left endpoint of x is to the left of the left endpoint of y. Let Y be the set of $\omega' \leqslant \omega - |\mathcal{X}|$ right-most intervals introduced in the separation phase, and let $\mathcal{Y}$ be the set of colors used by Algorithm on the intervals in Y. Note that $\mathcal{X}$ and $\mathcal{Y}$ are disjoint.

For the last phase, called the *final phase*, let r be the left-most right endpoint of an interval in Y. In the final phase Presenter introduces $\omega - \omega'$ times the same interval $[r, M+1+\varepsilon]$. This interval intersects all intervals introduced in the initial phase, all intervals in Y, and no other interval introduced in the separation phase. Thus, Algorithm must use $\omega - \omega'$ colors in the final phase that are different from the colors in both $\mathcal{X}$ and $\mathcal{Y}$. Let $\mathcal{Z}$ denote the set of colors used by Algorithm in the final phase.

The presented set of intervals is clearly ω-colorable and Algorithm used at least $|\mathcal{X}| + |\mathcal{Y}| + |\mathcal{Z}| = \alpha\omega' - \delta + \omega' + \omega - \omega' = \left(2 - \frac{1}{\alpha+1}\right)\omega - o(\omega)$ many colors. The longest interval presented has length $M+\varepsilon$, and all intervals are contained in $[0, M+1+\varepsilon]$. Thus, we have constructed a $\left\langle 2 - \frac{1}{\alpha+1}, M+\varepsilon, M+1+\varepsilon \right\rangle$-schema. ◀

3.4 The 5/3 Lower Bound

▶ **Lemma 15.** *If there is an $\langle \alpha, \sigma, M\rangle$-schema, then there is a $\left\langle 2 - \frac{1}{\alpha+2}, M+\varepsilon, M+2+\varepsilon \right\rangle$-schema for every $\varepsilon > 0$.*

Proof. The proof of this lemma is very similar to the proof of Lemma 14, but now we have two separation phases instead of just one, see Figure 4. Let us fix an $\omega \in \mathbb{N}_+$, and let $\omega' = \left\lfloor \frac{\omega}{\alpha+2} \right\rfloor$. Let S be an $\langle \omega', \alpha\omega' - \delta, \sigma, M\rangle$-strategy for some $\delta = o(\omega')$.

In the initial phase, Presenter uses S inside interval $\left[1+\frac{\varepsilon}{2}, M+1+\frac{\varepsilon}{2}\right]$, and forces Algorithm to use $C = \alpha\omega' - \delta$ colors. Let $\mathcal{X}$ denote the set of those colors.

In the separation phase, Presenter plays the separation strategy two times. First, Presenter plays the separation strategy for ω rounds in the region $\left[0, 1+\frac{\varepsilon}{4}\right]$ pushing to the right colors not in $\mathcal{X}$. Let Y_1 be the set of ω' right-most intervals from this first separation. Let $\mathcal{Y}_1$ denote the set of colors used by Algorithm to color Y_1. Then, Presenter plays the separation strategy for ω rounds in the region $\left[M+1+\frac{3\varepsilon}{4}, M+2+\varepsilon\right]$ pushing to the left colors not in $\mathcal{X} \cup \mathcal{Y}_1$. Let Y_2 be the set of ω' left-most intervals from this second separation. Let $\mathcal{Y}_2$ denote the set of colors used by Algorithm to color Y_2.

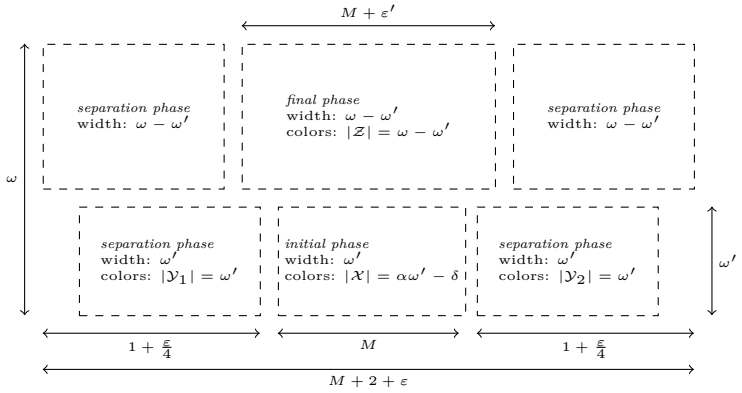

Figure 4 Strategy construction in Lemma 15.

Let r be the left-most right endpoint of an interval in Y_1. Let l be the right-most left endpoint of an interval in Y_2. In the final phase Presenter introduces $\omega - \omega'$ times the same interval $[r, l]$.

The presented set of intervals is clearly ω-colorable and Algorithm used at least $|\mathcal{X}| + |\mathcal{Y}_1| + |\mathcal{Y}_2| + |\mathcal{Z}| = \alpha\omega' - \delta + \omega' + \omega' + \omega - \omega' = \left(2 - \frac{1}{\alpha+2}\right)\omega - o(\omega)$ many colors. The longest interval presented has length at most $M + \varepsilon$, and all intervals are contained in $[0, M + 2 + \varepsilon]$. Thus, we have constructed a $\left\langle 2 - \frac{1}{\alpha+2}, M + \varepsilon, M + 2 + \varepsilon \right\rangle$-schema. ◀

▶ **Corollary 16.** *There is an $\langle \alpha_n, 2n - 1 + \varepsilon, 2n + 1 + \varepsilon \rangle$-schema, for every $n \in \mathbb{N}_+$ and every $\varepsilon > 0$, where*

$$\alpha_n = \frac{\left(\sqrt{3} - 3\right)\left(\sqrt{3} - 2\right)^n + \left(\sqrt{3} + 3\right)\left(-\sqrt{3} - 2\right)^n}{\left(\sqrt{3} - 1\right)\left(\sqrt{3} - 2\right)^n + \left(\sqrt{3} + 1\right)\left(-\sqrt{3} - 2\right)^n}.$$

Proof. Starting with a $\langle 1, 1, 1 \rangle$-schema and repeatedly applying Lemma 15 one can generate[1] a family of $\langle \alpha_n, \sigma_n + \varepsilon_n, M_n + \varepsilon_n \rangle$-schemas, such that $\alpha_{n+1} = 2 - \frac{1}{\alpha_n + 2}$, $\sigma_{n+1} = M_n$, $M_{n+1} = M_n + 2$, and $\alpha_0 = \sigma_0 = M_0 = 1$. Solving the recurrence equations we get $\alpha_n = \frac{F_{2n+1}}{F_{2n}}$, $\sigma_n = 2n - 1$, and $M_n = 2n + 1$. ◀

Note that, similarly to Observation 9, one could already use Corollary 16 to get a lower bound arbitrarily close to $\lim_{n\to\infty} \alpha_n = \sqrt{3} \approx 1.73205$ for the asymptotic competitive ratio of any online algorithm that work for all $\sigma \geqslant 1$. Nonetheless in Section 3.6 we prove a stronger $5/2$ lower bound.

▶ **Theorem 4.** *For every $\sigma > 1$ there is no online algorithm for σ-interval coloring with the asymptotic competitive ratio less than $5/3$.*

Proof. Assume for contradiction that for some $\sigma > 1$ there exists an online algorithm for σ-interval coloring with the asymptotic competitive ratio $\frac{5}{3} - \varepsilon$, for some $\varepsilon > 0$. By the definition of the asymptotic competitive ratio, there is an ω_A such that for every $\omega \geqslant \omega_A$ the algorithm colors every ω-colorable set of intervals using at most $\left(\frac{5}{3} - \varepsilon + \frac{\varepsilon}{3}\right)\omega = \left(\frac{5}{3} - \frac{2\varepsilon}{3}\right)\omega$ colors.

[1] Knowing the desired target values of n and ϵ, one needs to properly adjust the ϵ value for each application of Lemma 15, e.g., it is sufficient to set it to ϵ/n.

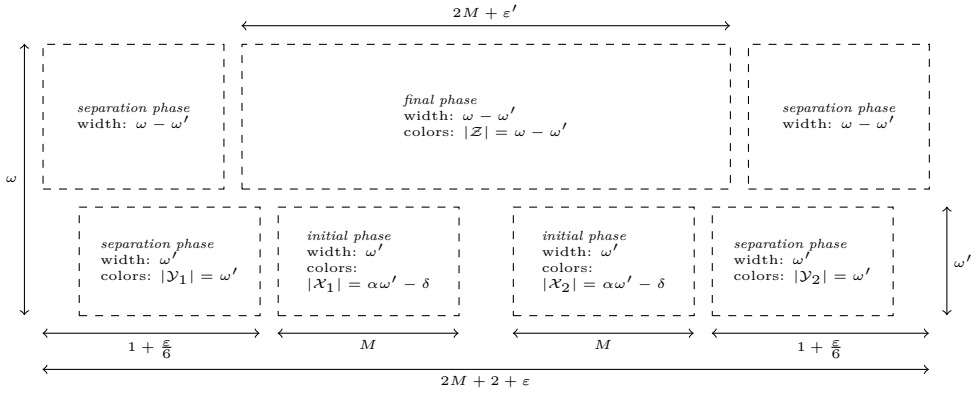

Figure 5 Lemma 17, Case 1: $|\mathcal{C}_2 \setminus \mathcal{C}_1| \geqslant \frac{\omega}{2\alpha+2}$.

Observe that, for $n = 1$, Corollary 16 gives a $\left\langle \frac{5}{3}, 1 + (\sigma - 1), 3 + (\sigma - 1) \right\rangle$-schema. By the definition of schema, there is an ω_P such that for every $\omega \geqslant \omega_P$ there is a strategy for Presenter to present an ω-colorable set of intervals, of length in $[1, \sigma]$, and force Algorithm to use $\left(\frac{5}{3} - \frac{\varepsilon}{3}\right)\omega$ colors. For $\omega = \max(\omega_A, \omega_P)$ we reach a contradiction. ◀

3.5 The 7/4 Lower Bound

▶ **Lemma 17.** *If there is an $\langle \alpha, \sigma, M \rangle$-schema, then there is a $\left\langle \frac{2\alpha+1}{2\alpha+2}, 2M + \varepsilon, 2M + 2 + \varepsilon \right\rangle$-schema for every $\varepsilon > 0$.*

Proof. The proof of this lemma is a bit more complicated than the previous ones, as we now have two initial phases, two separation phases and a strategy branching, see Figure 5 and Figure 6. Let us fix an $\omega \in \mathbb{N}_+$, and let $\omega' = \left\lfloor \frac{\omega}{\alpha+1} \right\rfloor$. Let S be an $\langle \omega', \alpha\omega' - \delta, \sigma, M \rangle$-strategy for some $\delta = o(\omega')$.

In the initial phase, Presenter uses strategy S twice: (1) inside interval $\left[1 + \frac{\varepsilon}{3}, M + 1 + \frac{\varepsilon}{3}\right]$, and (2) inside interval $\left[M + 1 + \frac{2\varepsilon}{3}, 2M + 1 + \frac{2\varepsilon}{3}\right]$. Algorithm uses $C = \alpha\omega' - \delta$ colors in each of these intervals. We get a set of colors $\mathcal{X}_1$ used by Algorithm in the first interval, and a set of colors $\mathcal{X}_2$ used by Algorithm in the second interval. Note that $\mathcal{X}_1 \cap \mathcal{X}_2$ might be non-empty.

In the separation phase, Presenter plays the separation strategy two times. First, Presenter plays the separation strategy for ω rounds in the region $\left[0, 1 + \frac{\varepsilon}{6}\right]$ pushing to the right colors not in $\mathcal{X}_1$. Let Y_1 be the set of ω' right-most intervals from the first separation phase. Let $\mathcal{Y}_1$ denote the set of colors used by Algorithm to color Y_1. Then, Presenter plays the separation strategy for ω rounds in the region $\left[2M + 1 + \frac{5\varepsilon}{6}, 2M + 2 + \varepsilon\right]$ pushing to the left colors not in $\mathcal{X}_2$. Let Y_2 be the set of ω' left-most intervals from the second separation phase. Let $\mathcal{Y}_2$ denote the set of colors used by Algorithm to color Y_2. Let r be the left-most right endpoint of an interval in Y_1. Let l be the right-most left endpoint of an interval in Y_2.

There are two cases in the final phase. Let $\mathcal{C}_1 := \mathcal{X}_1 \cup \mathcal{Y}_1$, and analogously $\mathcal{C}_2 := \mathcal{X}_2 \cup \mathcal{Y}_2$. We have that $|\mathcal{C}_1| = |\mathcal{C}_2| = (\alpha + 1)\omega' - \delta = \omega - o(\omega)$.

Case 1. If $|\mathcal{C}_2 \setminus \mathcal{C}_1| \geqslant \frac{\omega}{2\alpha+2}$, then Presenter introduces $\omega - \omega'$ times the same interval $[r, l]$. Each interval introduced in the final phase intersects with all intervals from both initial phases and all intervals in $Y_1 \cup Y_2$. Thus, Algorithm is forced to use $|\mathcal{C}_1 \cup \mathcal{C}_2| + \omega - \omega' = |\mathcal{C}_1| + |\mathcal{C}_2 \setminus \mathcal{C}_1| + \omega - \omega' \geqslant \omega - o(\omega) + \frac{\alpha + \frac{1}{2}}{\alpha+1}\omega = \left(2 - \frac{1}{2\alpha+2}\right)\omega - o(\omega)$ colors in total.

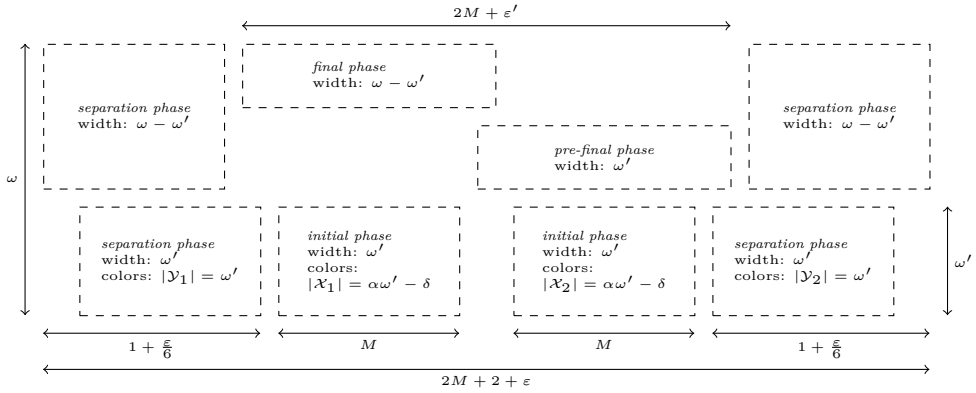

Figure 6 Lemma 17, Case 2: $|\mathcal{C}_2 \setminus \mathcal{C}_1| < \frac{\omega}{2\alpha+2}$.

Case 2. If $|\mathcal{C}_2 \setminus \mathcal{C}_1| < \frac{\omega}{2\alpha+2}$, then Presenter introduces ω' intervals, all of them having endpoints $[M + 1 + 5\varepsilon/12, l]$. Let Q be the set of colors used by Algorithm in this *pre-final phase*. We have $\mathcal{C}_2 \cap Q = \emptyset$, and we assumed that $|\mathcal{C}_2 \setminus \mathcal{C}_1| \leqslant \frac{\omega}{2\alpha+2}$, thus we have $|Q \setminus \mathcal{C}_1| \geqslant \frac{\omega}{2\alpha+2}$, and now we are in a situation analogous to Case 1, with Q playing the role of $\mathcal{C}_2$, see Figure 6.

The longest interval introduced by Presenter in both cases has length strictly less than $2M + \varepsilon$, and the whole game is played in the region $[0, 2M + 2 + \varepsilon]$. ◀

▶ **Corollary 18.** *There is an $\langle \alpha_n, 3 \cdot 2^n - 4 + \varepsilon, 3 \cdot 2^n - 2 + \varepsilon \rangle$-schema, for every $n \in \mathbb{N}_+$ and every $\varepsilon > 0$, where*

$$\alpha_n = \frac{(\sqrt{7}-4)(\sqrt{7}-3)^n + (\sqrt{7}+4)(-\sqrt{7}-3)^n}{(\sqrt{7}-1)(\sqrt{7}-3)^n + (\sqrt{7}+1)(-\sqrt{7}-3)^n}.$$

Proof. The argument is similar to Corollary 16, but now we solve the recurrence equations $\alpha_0 = 1$, $\alpha_{n+1} = 2 - \frac{1}{2\alpha_n+2}$, and $M_0 = 1$, $M_{n+1} = 2M_n + 2$, $\sigma_0 = 1, \sigma_{n+1} = 2M_n$. ◀

Note that, similarly to Observation 9, one could already use Corollary 18 to get a lower bound arbitrarily close to $\lim_{n\to\infty} \alpha_n = \frac{1+\sqrt{7}}{2} \approx 1.82287$ for the asymptotic competitive ratio of any online algorithm that work for all $\sigma \geqslant 1$. Nonetheless in Section 3.6 we prove a stronger $5/2$ lower bound.

▶ **Theorem 5.** *For every $\sigma > 2$ there is no online algorithm for σ-interval coloring with the asymptotic competitive ratio less than $7/4$.*

Proof. Observe that, for $\sigma > 2$ and $n = 1$, Corollary 18 gives a $\langle \frac{7}{4}, 2 + (\sigma - 2), 4 + (\sigma - 2) \rangle$-schema. Then proceed analogously to the proof of Theorem 4. ◀

3.6 The $5/2$ Lower Bound

To prove our main negative result we need two simple combinatorial lemmas.

▶ **Lemma 19.** *Let $\gamma \in [0, 1]$. For every four sets $X_1, \ldots, X_4$, each of size k, if their intersection is small: $\left|\bigcap_{i=1}^4 X_i\right| \leqslant (1 - \gamma) \cdot k$, their union is large: $\left|\bigcup_{i=1}^4 X_i\right| \geqslant \frac{3+\gamma}{3} \cdot k$.*

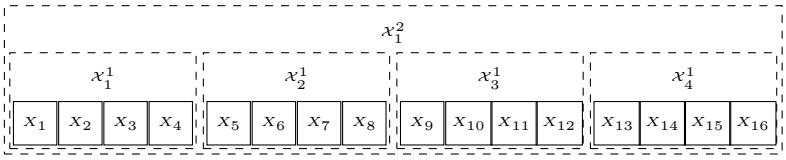

Figure 7 $\mathcal{X}_i^j$ sets in Lemma 20.

Proof. Each element which belongs to the union but does not belong to the intersection can belong to at most three sets. Thus, we have

$$3 \cdot \left(\left| \bigcup_{i=1}^{4} X_i \right| - \left| \bigcap_{i=1}^{4} X_i \right| \right) \geqslant 4 \cdot \left(k - \left| \bigcap_{i=1}^{4} X_i \right| \right),$$

and so

$$3 \cdot \left| \bigcup_{i=1}^{4} X_i \right| \geqslant 4k - \left| \bigcap_{i=1}^{4} X_i \right| \geqslant (3+\gamma) \cdot k. \qquad \blacktriangleleft$$

▶ **Lemma 20.** *Let $\gamma \in [0,1]$, and $X_1, \ldots, X_{4^n}$ be a family of 4^n sets, each of size k. Then, either*

$$\left| \bigcup_{i=1}^{4^n} X_i \right| \geqslant \left(\frac{3+\gamma}{3} \right)^n k,$$

or the sequence $1, 2, \ldots, 4^n$ can be covered with four disjoint intervals $[l_1, r_1], \ldots, [l_4, r_4]$, $l_1 = 1$, $l_{i+1} = r_i + 1$, $r_4 = 4^n$, such that for $Y_i = \bigcup_{j=l_i}^{r_i} X_j$ the intersection of Y_i's is large:

$$|Y_1 \cap Y_2 \cap Y_3 \cap Y_4| \geqslant (1-\gamma) \cdot k.$$

Proof. Consider $n+1$ families of sets defined as follows: $\mathcal{X}_i^0 := X_i$ for every $i \in [4^n]$, and $\mathcal{X}_i^j := \bigcup_{l=4i-3}^{4i} \mathcal{X}_l^{j-1}$ for every $j \in [n]$ and $i \in [4^{n-j}]$. See Figure 7.

If for some i, j we have $|\bigcap_{l=4i-3}^{4i} \mathcal{X}_l^j| \geqslant (1-\gamma) \cdot k$, then we are done. Thus, we assume that $\forall_{i,j}\ |\bigcap_{l=4i-3}^{4i} \mathcal{X}_l^j| < (1-\gamma) \cdot k$. Let $\varrho := \frac{3+\gamma}{3} \in \left[1, \frac{4}{3}\right]$. We prove that $\forall_{i,j}\ |\mathcal{X}_i^j| \geqslant \varrho^j k$, by induction on j. For $j = 0$ the statement is obvious because $\forall_i\ |\mathcal{X}_i^0| = |X_i| = k = \varrho^0 k$. For $j+1$ and arbitrary i, let $k' = \varrho^j k$. By the induction hypothesis $|\mathcal{X}_{4i-3}^j|, \ldots, |\mathcal{X}_{4i}^j| \geqslant \varrho^j k = k'$. We may ignore some elements of those sets and assume that $|\mathcal{X}_{4i-3}^j| = \ldots = |\mathcal{X}_{4i}^j| = k'$, moreover we assumed that $|\mathcal{X}_{4i-3}^j \cap \ldots \cap \mathcal{X}_{4i}^j| < (1-\gamma)k = \frac{1-\gamma}{\varrho^j} \varrho^j k = (1-\gamma')k'$, where $\gamma' \in [0,1]$ and $\gamma' > \gamma$. We apply Lemma 19 and get $|\mathcal{X}_{4i-3}^j \cup \ldots \cup \mathcal{X}_{4i}^j| \geqslant \frac{3+\gamma'}{3} k'$. Thus, $|\mathcal{X}_i^{j+1}| \geqslant \frac{3+\gamma'}{3} k' > \frac{3+\gamma}{3} k' = \varrho k' = \varrho^{j+1} k$. $\blacktriangleleft$

▶ **Lemma 21.** *If there is an $\langle \alpha, \sigma, M \rangle$-schema, then for every $\varepsilon > 0$ and for every $\gamma \in (0,1)$, there is a $\left\langle \frac{5}{4} + \frac{1}{2}(1-\gamma)\alpha, 4^n M + \varepsilon, 4^n M + \varepsilon \right\rangle$-schema, for some $n := n(\gamma)$.*

Proof. Let us fix an $\omega \in \mathbb{N}_+$, and let $\omega' = \left\lfloor \frac{\omega}{2} \right\rfloor$. Let S be an $\langle \omega', \alpha\omega' - \delta, \sigma, M \rangle$-strategy for some $\delta = o(\omega')$. Presenter repeats strategy S in the initial phase 4^n times. For each $i \in [4^n]$ the i-th game is played inside interval $\left[(i-1)(M + \frac{\varepsilon}{4^n}), (i-1)(M + \frac{\varepsilon}{4^n}) + M\right]$. See Figure 8. Algorithm uses $C = \alpha\omega' - \delta$ colors in each of these games. Let $\mathcal{X}_i$ denote the set of C colors used by Algorithm in the i-th game. Let $\mathcal{X}$ denote the set of all colors used in the initial phase, i.e., $\mathcal{X} = \bigcup_{i \in [4^n]} \mathcal{X}_i$.

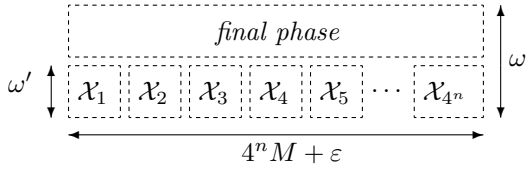

Figure 8 Case 1: $|\mathcal{X}|$ is large.

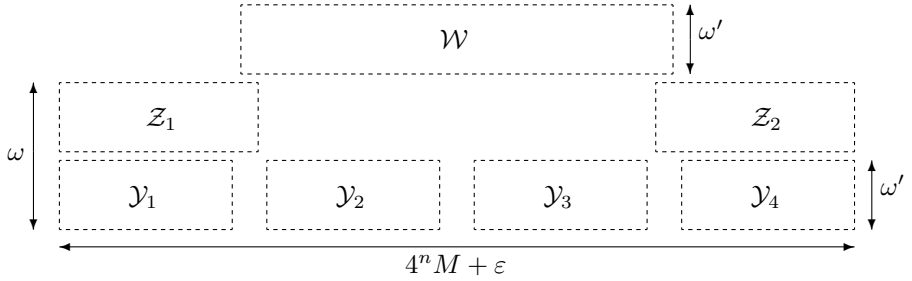

Figure 9 Case 2.1: $|\mathcal{Y}|$ is large and $|\mathcal{Z}_2 \setminus \mathcal{Z}_1| \geqslant \frac{1}{4}\omega$.

We apply Lemma 20 to the family $\mathcal{X}_1, \ldots, \mathcal{X}_{4^n}$ and get that either the union of these sets has at least $\left(\frac{3+\gamma}{3}\right)^n C$ elements, or we get four disjoint consecutive subfamilies $\mathcal{Y}_1, \ldots, \mathcal{Y}_4$ ($\mathcal{Y}_i = \bigcup_{j=l_i}^{r_i} \mathcal{X}_j$) such that the size of the intersection $\mathcal{Y}_1 \cap \mathcal{Y}_2 \cap \mathcal{Y}_3 \cap \mathcal{Y}_4$ has at least $(1-\gamma) \cdot C$ elements.

Case 1. If the size of the union $|\mathcal{X}|$ is at least $\left(1 + \frac{\gamma}{3}\right)^n \cdot C$, then Presenter introduces ω' intervals, all of them having endpoints $[0, 4^n M + \varepsilon]$. See Figure 8. Each interval introduced in the final phase intersects with all intervals introduced in the initial phase. Thus, Algorithm is forced to use at least $|\mathcal{X}| + \omega' \geqslant \frac{1}{2}\left(\left(1 + \frac{\gamma}{3}\right)^n \alpha + 1\right)\omega - o(\omega)$ colors in total. Easy calculation shows that for $\gamma \in (0,1)$, $\alpha \in [1,3]$ and for any $n \geqslant \log_{1+\frac{\gamma}{3}}(5/2 - \gamma)$, we have $\frac{1}{2} + \frac{1}{2}\left(1 + \frac{\gamma}{3}\right)^n \alpha \geqslant \frac{5}{4} + \frac{1}{2}(1-\gamma)\alpha$.

Case 2. The size of the intersection $|\mathcal{Y}_1 \cap \ldots \cap \mathcal{Y}_4|$ is at least $(1-\gamma) \cdot C$. Let $\mathcal{Y} = \mathcal{Y}_1 \cap \mathcal{Y}_2 \cap \mathcal{Y}_3 \cap \mathcal{Y}_4$ denote the colors that appear in all four parts of the initial phase. Presenter introduces a set Z_1 of ω' identical intervals covering all intervals contributing to $\mathcal{Y}_1$ and disjoint with intervals contributing to $\mathcal{Y}_2$. See Figure 9. Let $\mathcal{Z}_1$ be the set of colors used by Algorithm to color Z_1.

Then Presenter introduces a set Z_2 of ω' identical intervals covering all intervals contributing to $\mathcal{Y}_4$ and disjoint with intervals contributing to $\mathcal{Y}_3$. Let $\mathcal{Z}_2$ be the set of colors used by Algorithm to color Z_2.

Clearly, $|\mathcal{Z}_1| = |\mathcal{Z}_2| = \omega'$, and $\mathcal{Z}_1 \cap \mathcal{Y} = \mathcal{Z}_2 \cap \mathcal{Y} = \emptyset$. Now we distinguish two subcases depending on the size of the set $\mathcal{Z}_2 \setminus \mathcal{Z}_1$.

Case 2.1. If $|\mathcal{Z}_2 \setminus \mathcal{Z}_1| \geqslant \frac{1}{4}\omega$, then Presenter introduces a set W of ω' identical intervals intersecting all the intervals in Z_1 and Z_2, and covering all the intervals contributing to $\mathcal{Y}_2$ and $\mathcal{Y}_3$. Let $\mathcal{W}$ be the set of colors used by Algorithm to color W. By the definition, we have $\mathcal{W} \cap \mathcal{Y} = \mathcal{W} \cap \mathcal{Z}_1 = \mathcal{W} \cap \mathcal{Z}_2 = \emptyset$. Algorithm was forced to use $|\mathcal{W}| + |\mathcal{Z}_1| + |\mathcal{Z}_2 \setminus \mathcal{Z}_1| + |\mathcal{Y}| \geqslant \left(\frac{1}{2} + \frac{1}{2} + \frac{1}{4}\right)\omega + \frac{1}{2}(1-\gamma)\alpha\omega - o(\omega) = \left(\frac{5}{4} + \frac{1}{2}(1-\gamma)\alpha\right)\omega - o(\omega)$ colors in total. See Figure 9.

Case 2.2. If $|\mathcal{Z}_2 \setminus \mathcal{Z}_1| < \frac{1}{4}\omega$, then let $\mathcal{Z} = \mathcal{Z}_1 \cap \mathcal{Z}_2$ and observe that $|\mathcal{Z}| \geqslant \left\lfloor \frac{\omega}{4} \right\rfloor$. Presenter introduces a set W_1 of ω' identical intervals intersecting all the intervals in Z_1, and covering all the intervals contributing to $\mathcal{Y}_2$. Then, presenter introduces a set W_2 of

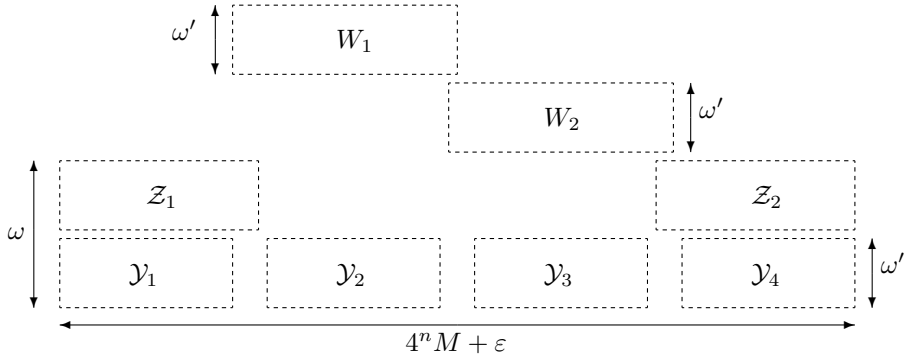

Figure 10 Case 2.2: $|\mathcal{Y}|$ is large and $|\mathcal{Z}_2 \setminus \mathcal{Z}_1| < \frac{1}{4}\omega$.

ω' identical intervals, intersecting all the intervals in W_1 and Z_2, and covering all the intervals contributing to $\mathcal{Y}_3$. Let $\mathcal{W}$ be the set of colors used by Algorithm to color intervals in $W_1 \cup W_2$. We have that $|\mathcal{W}| = 2\omega'$, and $\mathcal{W} \cap \mathcal{Y} = \mathcal{W} \cap \mathcal{Z} = \emptyset$. Algorithm was forced to use $|\mathcal{W}|+|\mathcal{Z}|+|\mathcal{Y}| \geqslant \left(1 + \frac{1}{4}\right)\omega + \frac{1}{2}(1-\gamma)\alpha\omega - o(\omega) = \left(\frac{5}{4} + \frac{1}{2}(1-\gamma)\alpha\right)\omega - o(\omega)$ colors in total. See Figure 10. ◀

▶ **Corollary 22.** *There is an an $\langle \alpha_n, 4^{nf(\gamma)} + \varepsilon, 4^{nf(\gamma)} + \varepsilon \rangle$-schema, for every $n \in \mathbb{N}_+$, every $\varepsilon > 0$, and every $\gamma \in (0,1)$, where*

$$\alpha_n = \frac{5}{2} \cdot \frac{1}{1+\gamma} - \frac{(3-2\gamma)}{2(1+\gamma)} \cdot \left(\frac{1-\gamma}{2}\right)^n, \quad f(\gamma) = \left\lceil \frac{\log\left(\frac{5}{2} - \gamma\right)}{\log\left(1 + \frac{\gamma}{3}\right)} \right\rceil.$$

Proof. The argument is similar to Corollaries 16, and 18, but now we solve the recurrence equations $\alpha_0 = 1$, $\alpha_{n+1} = \frac{5}{4} + \frac{1}{2}(1-\gamma)\alpha_n$ for competitive ratio, and $M_0 = 1$, $M_{n+1} = 4^{f(\gamma)} M_n$, $\sigma_n = M_n$ for region and interval lengths. ◀

▶ **Theorem 6.** *For every $\varepsilon > 0$ there is $\sigma \geqslant 1$ such that there is no online algorithm for σ-interval coloring with the asymptotic competitive ratio $5/2 - \varepsilon$.*

Proof. Assume for contradiction that, for some $\varepsilon > 0$, there are $(5/2 - \varepsilon)$-competitive algorithms for every $\sigma \geqslant 1$. Setting γ small enough and n large enough, Corollary 22 gives us a $\left\langle \frac{5}{2} - \frac{\varepsilon}{4}, \sigma, \sigma \right\rangle$-schema, for some value of σ. This means, there is ω_P such that for every $\omega \geqslant \omega_P$ there exists an $\left\langle \omega, (\frac{5}{2} - \frac{2\varepsilon}{4})\omega, \sigma, \sigma \right\rangle$-strategy. On the other hand, for the assumed σ-interval coloring algorithm, there exists ω_A such that for every $\omega \geqslant \omega_A$ the algorithm uses at most $\left(\frac{5}{2} - \frac{3\varepsilon}{4}\right)\omega$ colors for every ω-colorable set of intervals. For $\omega = \max(\omega_A, \omega_P)$ we reach a contradiction. ◀

A Open Problems

Throughout the paper we presented several constructions which can be combined recursively to obtain strategies proving higher and higher lower bounds for larger and larger interval lengths σ. Table 1 summarizes a selection of these strategies.

Table 1 Summary of selected strategies for Presenter.

ratio	interval length	strategy
1.5	1	Epstein and Levy [4]
1.6	$2+\varepsilon$	Corollary 8, $n=2$ iterations
1.66	$1+\varepsilon$	Corollary 16, $n=1$ iteration
1.72	$3+\varepsilon$	Corollary 16, $n=2$ iterations
1.75	$2+\varepsilon$	Corollary 18, $n=1$ iteration
1.81	$8+\varepsilon$	Corollary 18, $n=2$ iterations
2	$4^{39}+\varepsilon$	Corollary 22, $n=3$ iterations, $\gamma=0.21030395$
2.4	$4^{486}+\varepsilon$	Corollary 22, $n=6$ iterations, $\gamma=0.0339$
2.49	$4^{7970}+\varepsilon$	Corollary 22, $n=10$ iterations, $\gamma=0.003449$

There are still large gaps between the best known lower and upper bounds for the optimal competitive ratios for online σ-interval coloring problems (see Figure 11). It would be interesting to close the gap, even for a single specific σ. For example, for $\sigma = 3/2$ the optimal online algorithm has the competitive ratio somewhere between $5/3$ and $5/2$.

Finally, let us conjecture that the lower bound of Theorem 6 is tight.

▶ **Conjecture 23.** *There is a $5/2$-competitive online algorithm for σ-interval coloring, for every $\sigma \geqslant 1$.*

Abstract

We consider the Requirement Cut problem, where given an undirected graph $G = (V, E)$ equipped with non-negative edge weights $c : E \to \mathbb{R}_+$, and g groups of vertices $X_1, \ldots, X_g \subseteq V$ each equipped with a requirement r_i, the goal is to find a collection of edges $F \subseteq E$, with total minimum weight, such that once F is removed from G in the resulting graph every X_i is broken into at least r_i connected components. Requirement Cut captures multiple classic cut problems in graphs, e.g., Multicut, Multiway Cut, Min k-Cut, Steiner k-Cut, Steiner Multicut, and Multi-Multiway Cut. Nagarajan and Ravi [Algoritmica'10] presented an approximation of $O(\log n \log R)$ for the problem, which was subsequently improved to $O(\log g \log k)$ by Gupta, Nagarajan and Ravi [Operations Research Letters'10] (here $R = \sum_{i=1}^{g} r_i$ and $k = |\cup_{i=1}^{g} X_i|$). We present an approximation of $O(X \log R \sqrt{\log k} \log \log k)$ for Requirement Cut (here $X = \max_{i=1,\ldots,g}\{|X_i|\}$). Our approximation in general is incomparable to the above mentioned previous results, however when all groups are not too large, i.e., $X = o\left((\sqrt{\log k} \log g)/(\log R \log \log k)\right)$, it is better. Our algorithm is based on a new configuration linear programming relaxation for the problem, which is accompanied by a remarkably simple randomized rounding procedure.

1 Introduction

We consider the Requirement Cut problem (RC), where we are given an undirected graph $G = (V, E)$ equipped with non-negative edge weights $c : E \to \mathbb{R}_+$ and g groups of vertices $X_1, \ldots, X_g \subseteq V$. Every group X_i is associated with a requirement r_i, where $2 \leq r_i \leq |X_i|$. The goal is to find a collection of edges $F \subseteq E$, with total minimum weight, such that once F is removed from G in the resulting graph $G_F = (V, E \backslash F)$ every X_i is broken into at least r_i connected components. To simplify presentation we use the notation $\text{Cut}(G, X_i)$ to denote the number of connected components of G that contain at least one vertex of X. The above requirement implies that $\text{Cut}(G_F, X_i) \geq r_i$, $\forall i = 1, \ldots, g$.

Requirement Cut captures multiple classic cut problems in graphs, e.g., Multicut [11, 15], Multiway Cut [4, 5, 6, 9, 13, 22], Min k-Cut [19, 20, 21], Steiner k-Cut [8], Steiner Multicut [14], and Multi-Multiway Cut [3]. To simplify presentation of known results for (RC), we denote by R the sum of requirements, i.e., $R = \sum_{i=1}^{g} r_i$, by X the largest group, i.e., $X = \max_{i=1,\ldots,g}\{|X_i|\}$, and by k the number of vertices in groups, i.e., $k = |\cup_{i=1}^{g} X_i|$. Nagarajan and Ravi [18] were the first to consider (RC), presenting

approximations of $O(\log n \log R)$ and $O(\log R)$ for general graphs and trees, respectively.[1] They also proved that there is a hardness of approximation of $\Omega(\log g)$ when the graph is a tree. Subsequently, Gupta et al. [12] presented improved approximations of $O(\log k \log g)$ and $O(\log g)$ for general graphs and trees, respectively. Thus, providing a tight approximation when the graph is a tree. In both these works, the main approach to solving (RC) in general graphs is first to formulate a linear programming relaxation which finds a suitable spreading metric over the vertices of V, then transform the metric into a tree metric, and finally round the solution on the tree. In [18], an additional greedy combinatorial approach is presented. In this approach the algorithm repeatedly finds cuts that (approximately) minimize the ratio between their cost and the number of groups they separate. This algorithm also yields an approximation of $O(\log n \log R)$ for (RC).

1.1 Our Result

The following theorem summarizes our main result for the (RC) problem.

▶ **Theorem 1.** *There is a randomized polynomial time algorithm for* Requirement Cut *that achieves an approximation of* $O\left(X \log R \sqrt{\log k} \log\log k\right)$.

We note that our approximation is incomparable to the current state of the art [12]. However, when all groups are not too large, i.e., $X = o\left((\sqrt{\log k} \log g)/(\log R \log\log k)\right)$, our approximation is better. Our algorithm in fact provides an approximation guarantee of $O\left(DX \log R\right)$, where D is the distortion of embedding a metric of negative type into ℓ_1 (refer to Section 2 for an exact definition). The guarantee of Theorem 1 follows by employing the embedding of Arora et al. [2].

1.2 Our Techniques

Our approach for obtaining the result is based on three ingredients, on which we currently elaborate.

The first is a new configuration linear programming relaxation of exponential size, in which each cut S is associated with a variable λ_S. In this relaxation the goal is to assign a fractional value λ_S to each cut S while satisfying two requirements: (1) for each group X_i the total fractional value of cuts that separate it is high enough, i.e., X_i is broken into enough pieces; and (2) for each vertex u the total fractional value of cuts containing u is at most one, i.e., the connected components in the output are disjoint. This configuration LP differs from the relaxation used in [12, 18], which imposes a metric over the vertices of the graph while ensuring that for every X_i the total length of every tree spanning X_i is high enough.

The second ingredient is a remarkably simple randomized rounding procedure of the configuration LP. When considering classic randomized rounding applied to our setting, each cut S, independently of other cuts, chooses all edges that cross it with a probability of λ_S. This straightforward use of randomized rounding is problematic, as it might separate a group into very few pieces, even though the total fraction of cuts that separate the group is quite high. To intuitively exemplify this, it is enough to note that choosing ℓ cuts that separate some group X_i might result in breaking X_i into only $O(\log \ell)$ pieces due to non-trivial

[1] In [18], in contrast to what is cited above, the claimed approximation does not depend on R but rather on the maximum requirement multiplied by g. However, the algorithms of [18] provide the above claimed approximation guarantee.

overlaps between the cuts. To overcome this difficulty, we note that cuts S with a high fractional value λ_S are disjoint. Hence, for these cuts the above difficulty does not occur. Unfortunately, cuts S with a high fractional value λ_S might be few and we are not guaranteed that choosing all of them breaks each X_i into enough pieces. To remedy this, we introduce a remarkably simple analysis for the classic randomized rounding procedure that assumes all cuts S have a small fractional value λ_S. In our analysis we show that for each cut S, if all other cuts have a small fractional value, then with a high enough probability S is able to break at least one additional piece from X_i on its own. This enables us to lower bound the number of pieces each X_i is broken into.

The third and last ingredient relates to solving the configuration LP. Since the configuration LP has an exponential number of variables, we need to present an (approximate) dual separation oracle for it. It turns out that the dual separation oracle for the configuration LP is a node weighted variant of Sparsest Cut with general demands where demands are given over groups, as opposed to pairs. Our approximation algorithm for the dual separation oracle, similarly to classic algorithms for Sparsest Cut, finds a suitable metric of negative type, embeds it into ℓ_1, and chooses the best cut S among all cuts in the decomposition of the ℓ_1 metric into a non-negative combination of cut metrics. The only caveat in this approach is that, unlike Sparsest Cut, our problem is not symmetric, i.e., S and $\overline{S}$ have different objective value. To overcome this, we break symmetry and introduce an artificial point to the metric space, while ensuring that all cuts in the decomposition of the ℓ_1 metric do not contain this artificial point.

We note that our dual separation oracle captures the Steiner Ratio problem (SR) [14], used in the greedy step of the combinatorial approach of [18] for (RC). Thus, it can be proved that our approximation guarantee of $O(X\sqrt{\log k}\log\log k)$ for the dual separation oracle (Theorem 8) also extends to (SR). Incorporating this into the analysis of [18] yields an overall approximation of $O\left(X\log R\sqrt{\log k}\log\log k\right)$, matching the result of Theorem 1 in yet another way.

1.3 Related Work

The literature on approximating cut problems and metric embedding is vast, we mention here only some of the most relevant work. Let us start by surveying problems captured by (RC). Multicut, a special case of (RC) where each group X_i is of size two and its requirement r_i also equals two, admits an approximation of $O(\log C\log^2 k)$ (where C is the total weight of edges in the graph) [15] and $O(\log k)$ [11]. Multiway Cut, another special case of (RC) where there is a single group X of size k and its requirement also equals k, exhibits a long sequence of works [4, 5, 6, 9, 13, 22] which culminates in an approximation of 1.2965 [22]. Min k-Cut, a special case of (RC) where there is a single group X that spans all of V and its requirement equals k, admits a simple combinatorial approximation of $2(1-1/k)$ [19, 20, 21]. Steiner k-Cut is similar to Min k-Cut, with the difference that X does not necessarily equal all of V, also admits a similar approximation of $2(1-1/k)$ [8]. Steiner Multicut is similar to Multicut, with the difference that each group X_i might be larger than two, though its requirement r_i still remains two. This problem admits an approximation of $O(\log^3(gX))$ [14], which was subsequently improved to $O(\log g\log n)$ [18] and to $O(\log g\log k)$ [12]. Multi-Multiway Cut is similar to Multiway Cut, with the difference that there are multiple groups (though the requirement of each group equals its size). This problem admits an approximation of $O(\log g)$ [3].

Metric embedding also play a central role in our work, specifically embedding metrics of negative type into ℓ_1. Chawla et al. [7] presented an embedding with a distortion of $O(\log^{3/4} n)$, which was later improved to $O(\sqrt{\log n}\log\log n)$ by Arora et al. [1, 2]. The above

works are based on the seminal result of Arora et al. for Sparsest Cut, which obtained an approximation of $O(\sqrt{\log n})$, improving upon the $O(\log n)$ guarantee of Leighton and Rao [16].

Paper Organization

Section 2 contains needed preliminaries regarding metric spaces. Section 3 presents our new configuration LP for (RC). The rounding algorithm appears in Section 4, and Section 5 is dedicated to approximately solving the configuration LP. All missing proofs appear in the appendix.

2 Preliminaries

A metric space (V, d) embeds into ℓ_1 with distortion D if there exists an embedding f satisfying: $d(a,b) \leq ||f(a) - f(b)||_1 \leq D \cdot d(a,b)$, $\forall a, b \in V$. Moreover, a metric space (V, d) is of negative-type if $(V, \sqrt{d})$ is isometric to a subset of Euclidean space. Arora et al. [1, 2] proved that $D = O(\sqrt{\log n} \log\log n)$ for metrics of negative type, when $|V| = n$. We can exploit a slightly improved guarantee (see Corollary 5.1 in [2]), which we rephrase here for simplicity of presentation.[2]

▶ **Theorem 2** (Corollary 5.1 in [2]). *Given a metric space (V, d) of negative type and $U \subseteq V$ of size k, there exists an embedding f into ℓ_1 that satisfies: (1) $||f(a) - f(b)||_1 \leq D \cdot d(a,b)$, $\forall a, b \in V$; and (2) $||f(a) - f(b)||_1 \geq d(a,b)$, $\forall a, b \in U$. In the above $D = O(\sqrt{\log k} \log\log k)$. Furthermore, f can be computed in polynomial time.*

We note that in the above theorem, expansion is upper bounded for all pairs of points in the metric space, whereas contraction is lower bounded only for pairs of points in the given subset. This enables the improvement in the value of D from $O(\sqrt{\log n} \log\log n)$ to $O(\sqrt{\log k} \log\log k)$.

3 Configuration LP

We consider the following new linear relaxation for the (RC) problem. In this relaxation each possible cut $S \subseteq V$ is associated with a variable λ_S. We denote by $\delta_G(S)$ the total weight of edges crossing the cut S defines in the graph G, and let $\mathcal{C}(T) = \{S : 0 < |S \cap T| < |T|\}$ be the collection of cuts S that separate T, i.e., S contains at least one vertex of T but does not contain T as a whole.

$$
\begin{aligned}
\text{(LP)} \quad \min \quad & \sum_{S \in V} \frac{1}{2} \delta_G(S) \cdot \lambda_S & & \\
\text{s.t.} \quad & \sum_{S \in \mathcal{C}(X_i)} \lambda_S \geq r_i & \forall i = 1, \ldots g & \quad (1) \\
& \sum_{S : u \in S} \lambda_S \leq 1 & \forall u \in V & \quad (2) \\
& \lambda_S \geq 0 & \forall S \subseteq V &
\end{aligned}
$$

In the above relaxation, Constraint (1) ensures that X_i is broken into at least r_i pieces, and Constraint (2) ensures that each vertex belongs to at most a single cut.

[2] The cited theorem of [2] is originally given for ℓ_2 and not ℓ_1. However, standard arguments imply it also applies to ℓ_1, see, e.g., [2], for further details.

For our rounding algorithm to work we actually need to iteratively resolve (LP) for subgraphs of G. To this end, let us formally define the relaxation when considering $G_F = (V, E \setminus F)$, for some $F \subseteq E$, which we denote by (LP$_F$). Moreover, we denote by $Y_{i,1}, \ldots, Y_{i,\ell_i}$ the ℓ_i pieces X_i is broken into in G_F. Formally, if G_F is broken into ℓ connected components $C_1, \ldots, C_\ell$, which form a partition of V, then every $Y_{i,j}$ is obtained by $X_i \cap C_j$ and discarding the result if X_i and C_j are disjoint (hence $\ell_i \leq \ell$). Additionally, let us denote by r'_i the residual requirement of X_i in G_F, i.e., $r'_i = \max\{0, r_i - \ell_i\}$ (we can assume that groups X_i for which the residual requirement reached zero are removed from the instance).

$$
\begin{aligned}
(\mathrm{LP}_F) \quad \min \quad & \sum_{S \in V} \frac{1}{2} \delta_{G_F}(S) \cdot \lambda_S & & \\
\text{s.t.} \quad & \sum_{j=1}^{\ell_i} \sum_{S \in C(Y_{i,j})} \lambda_S \geq r'_i & \forall i = 1, \ldots g & \quad (3) \\
& \sum_{S : u \in S} \lambda_S \leq 1 & \forall u \in V & \quad (4) \\
& \lambda_S \geq 0 & \forall S \subseteq V &
\end{aligned}
$$

Similarly to (LP), Constraint (3) ensures that X_i is broken to at least r'_i pieces, and Constraint (4) ensures that each vertex belongs to at most a single cut.

The following lemma proves that (LP$_F$), for every $F \subseteq E$, is a relaxation when considering G_F. We denote by $\mathrm{OPT}_{\mathrm{LP}_F}$ the value of an optimal solution to (LP$_F$) and by OPT the value of an optimal solution to the original instance.

▶ **Lemma 3.** *$OPT_{LP_F} \leq OPT$, for every $F \subseteq E$.*

Proof. Let F^* be an optimal solution to the problem with respect to the original instance, and denote by $\tilde{F} = F^* \setminus F$ the edges of F^* still remaining in G_F. Thus, $G_{\tilde{F} \cup F} = (V, E \setminus (\tilde{F} \cup F))$ denotes the graph resulting in the removal of F^* from G_F. Let $S^*_1, \ldots, S^*_\ell$ be the connected components in $G_{\tilde{F} \cup F}$. Define the following solution to (LP$_F$): $\lambda_{S^*_i} = 1$ for every $i = 1, \ldots, \ell$ (and $\lambda_S = 0$ for all other cuts S). We notice that $S^*_1, \ldots, S^*_\ell$ are disjoint cuts, hence Constraint (4) is satisfied for every $u \in V$. Since F^* is a feasible solution with respect to the original instance, i.e., X_i is broken to at least r_i pieces in G_{F^*} (or equivalently $\mathrm{Cut}(G_{F^*}, X_i) \geq r_i$), we can conclude that removing $\tilde{F}$ from G_F breaks X_i to at least the same number of pieces. Thus, since X_i is already broken into ℓ_i pieces in G_F: $Y_{i,1}, \ldots, Y_{i,\ell_i}$, we can conclude that $\sum_{j=1}^{\ell_i} \mathrm{Cut}(G_{\tilde{F} \cup F}, Y_{i,j}) \geq r'_i$. Therefore, Constraint (3) is also satisfied and the defined solution is feasible for (LP$_F$). Since $\delta_{G_F}(S) \leq \delta_G(S)$, for every $S \subseteq V$, we can conclude that the value of the solution is at most OPT. This finishes the proof. ◀

A main challenge is solving (LP$_F$) since it has an exponential number of variables. The following theorem summarizes our guarantee for solving (LP$_F$), and Section 5 is dedicated to its proof. The solution found is bicriteria as it violates the constraints and incurs some loss in the objective.

▶ **Theorem 4.** *For every $F \subseteq E$, there exists an efficient algorithm that finds a bicriteria solution $\{\lambda_S\}_{S \subseteq V} \subseteq \mathbb{R}_+$ to (LP$_F$) satisfying:*

1. $\sum_{S : u \in S} \lambda_S \leq \alpha$, $\forall u \in V$.
2. $\sum_{j=1}^{\ell_i} \sum_{S \in C(Y_{i,j})} \lambda_S \geq \beta \cdot r'_i$, $\forall i = 1, \ldots, g$.
3. $\sum_{S \subseteq V} \frac{1}{2} \delta_{G_F}(S) \lambda_S \leq \gamma \cdot OPT$.

In the above $\alpha = \gamma = O(XD)$ (where D is as in Theorem 2 when considering $U = \cup_{i=1}^{g} X_i \subseteq V$) and $\beta = 1$.

4 Rounding the Configuration LP

In this section we present our rounding algorithm and prove the main result, Theorem 1, given Theorem 4. Our rounding algorithm progresses in iterations, similar in spirit to the classic randomized rounding for the Set Cover problem (a similar method was employed in the context of (RC) by [18]). However, unlike the latter rounding method, we require a different handling of cuts S with a large λ_S fraction and cuts S with a small λ_S fraction.

We start by focusing on the algorithm for a single iteration, which given G_F, for some $F \subseteq E$, outputs a random collection $L \subseteq E \setminus F$ of edges such that: (1) if L is removed from G_F then the number of pieces every X_i is broken into increases additively in expectation, up to some scaling, by X_i's residual requirement r'_i; and (2) the expected cost of edges in L is not too large. We denote by $\{\tilde{\lambda}_S\}_{S\subseteq V}$ the solution $\{\lambda_S\}_{S\subseteq V}$ scaled by a factor of $1/\alpha$, where α is as in guarantee (1) of Theorem 4, *i.e.*, $\tilde{\lambda}_S = \lambda_S/\alpha$. The single iteration algorithm removes all edges crossing a collection of cuts chosen according to two different criterions to ensure that the number of pieces X_i is broken into increases as required. The first criterion consists of all cuts whose $\tilde{\lambda}_S$ value is sufficiently large. The second criterion consists of executing randomized rounding on all cuts whose $\tilde{\lambda}_S$ is sufficiently small. Algorithm 1 summarizes the single iteration rounding procedure (in the algorithm's description we denote by $\Gamma_G(S)$ the collection of edges in the graph G crossing the cut S), and Lemma 5 summarizes the guarantee of Algorithm 1.

Algorithm 1 Single Iteration.

Input: $G_F = (V, E\setminus F), \{\tilde{\lambda}_S\}_{S\subseteq V}$
Output: $L \subseteq E\setminus F$
$F_1 \leftarrow \{e \in E \setminus F : \exists S, \tilde{\lambda}_S \geq 2/3 \wedge e \in \Gamma_{G_F}(S)\}$
let $\{I_S\}_{S\subseteq V:\tilde{\lambda}_S<2/3}$ be independent random indicators where $\Pr[I_S = 1] = \tilde{\lambda}_S$
$F_2 \leftarrow \{e \in E \setminus F : \exists S \text{ s.t. } \tilde{\lambda}_S < 2/3 \wedge I_S = 1 \wedge e \in \Gamma_{G_F}(S)\}$
$L \leftarrow F_1 \cup F_2$
output L

▶ **Lemma 5.** *For every $F \subseteq E$ and $\{\lambda_S\}_{S\subseteq V}$ guaranteed in Theorem 4, executing Algorithm 1 on G_F with $\{\tilde{\lambda}_S\}_{S\subseteq V}$ results in $L \subseteq E \setminus F$ satisfying:*
1. $\mathbb{E}\left[Cut(G_{F\cup L}, X_i)\right] \geq Cut(G_F, X_i) + \Omega\left(\beta/\alpha\right) \cdot r'_i$, $\forall i = 1, ...g$.
2. $\mathbb{E}\left[\sum_{e\in L} c_e\right] \leq O\left(\gamma/\alpha\right) \cdot OPT$.

Proof. Let us start with requirement (1) above. Note that for every vertex $u \in V$, since $\{\lambda_S\}_{S\subseteq V}$ satisfies guarantee (1) of Theorem 4, we can conclude that: $\sum_{S:u\in S} \tilde{\lambda}_S \leq 1$. Thus, we can conclude that all cuts S whose $\tilde{\lambda}_S$ is large, i.e., $\tilde{\lambda}_S \geq 2/3$, are disjoint. Therefore, removing F_1 from G_F additively increases the number of pieces every X_i is broken into by:

$$\sum_{j=1}^{\ell_i} \left|\left\{S : S \in C(Y_{i,j}) \wedge \tilde{\lambda}_s \geq 2/3\right\}\right| \geq \sum_{j=1}^{\ell_i} \sum_{S:S\in C(Y_{i,j})\wedge\tilde{\lambda}_S\geq 2/3} \tilde{\lambda}_S,$$

where the above inequality follows from the fact that $\tilde{\lambda}_S \leq 1, \forall S \subseteq V$.

Let us now consider cuts $S \subseteq V$ whose $\tilde{\lambda}_S$ is small, i.e., $\tilde{\lambda}_S < 2/3$. We analyze the expected additive increase in the number of pieces X_i is broken into when removing F_2 from G_F. A cut S satisfying: $\tilde{\lambda}_S < 2/3$ and $S \in C(Y_{i,j})$, increases the number of pieces $Y_{i,j}$ is broken into by one if there exists a vertex $u \in Y_{i,j} \cap S$ such that S is the only cut having $I_S = 1$, among all cuts T with $\tilde{\lambda}_T < 2/3$ containing u. Let us denote this event by $A_{Y_{i,j},S,u}$. Thus,

$$\Pr\left[A_{Y_{i,j},S,u}\right] = \tilde{\lambda}_S \cdot \prod_{T:\tilde{\lambda}_T<2/3\wedge u\in T} \left(1 - \tilde{\lambda}_T\right).$$

We note that since $\sum_{T:u\in T}\tilde{\lambda}_T \leq 1$ (as previously mentioned in the proof), and the fact that we consider only cuts T satisfying $\tilde{\lambda}_T < 2/3$, the following holds: $\prod_{T:\tilde{\lambda}_T<2/3\wedge u\in T}(1-\tilde{\lambda}_T) = \Omega(1)$. Hence, $\Pr[A_{Y_{i,j},S,u}] \geq \Omega(\tilde{\lambda}_S)$. Therefore, removing F_2 from G_F additively increases the expected number of pieces every X_i is broken into by at least:

$$\sum_{j=1}^{\ell_i}\sum_{S:S\in C(Y_{i,j})\wedge\tilde{\lambda}_S<2/3}\Pr\left[\exists u\in Y_{i,j}\cap S \text{ s.t. } A_{Y_{i,j},S,u}\right] \geq \sum_{j=1}^{\ell_i}\sum_{S:S\in C(Y_{i,j})\wedge\tilde{\lambda}_S<2/3}\Omega(\tilde{\lambda}_S).$$

The above inequality follows since for every $Y_{i,j}$ and every $S\in C(Y_{i,j})$, satisfying $\tilde{\lambda}_S < 2/3$, one can choose an arbitrary vertex $u\in Y_{i,j}\cap S$ and apply the lower bound on the probability of the event $A_{Y_{i,j},S,u}$.

Recall that $\{\lambda_S\}_{S\subseteq V}$ satisfies guarantee (2) of Theorem 4, therefore we can conclude that $\forall i = 1,\ldots,g$:

$$\sum_{j=1}^{\ell_i}\sum_{S:S\in C(Y_{i,j})\wedge\tilde{\lambda}_S<2/3}\tilde{\lambda}_S \geq \frac{\beta}{2\alpha}r'_i \qquad \text{or} \qquad \sum_{j=1}^{\ell_i}\sum_{S:S\in C(Y_{i,j})\wedge\tilde{\lambda}_S\geq 2/3}\tilde{\lambda}_S \geq \frac{\beta}{2\alpha}r'_i.$$

Thus, removing all edges in $F_1\cup F_2$ from G_F additively increases the number of pieces every X_i is broken into, in expectation, by at least $\Omega\left(\beta/\alpha\right)r'_i$. This concludes the proof of requirement (1).

Let us focus on requirement (2). It is easy to note that the definition of F_1 implies that $\sum_{e\in F_1}c_e \leq 3/2\sum_{S:\tilde{\lambda}_S\geq 2/3}\delta_{G_F}(S)\tilde{\lambda}_S$. Additionally, it is easy to note from the definition of F_2 that $\mathbb{E}[\sum_{e\in F_2}c_e] \leq \sum_{S:\tilde{\lambda}_S<2/3}\delta_{G_F}(S)\tilde{\lambda}_S$. Summing the former and the latter and recalling that $\tilde{\lambda}_S = \lambda_S/\alpha\ \forall S\subseteq V$, along with the fact that $\{\lambda_S\}_{S\subseteq V}$ satisfies guarantee (3) of Theorem 4, we can conclude that: $\mathbb{E}[\sum_{e\in L}c_e] \leq O(\gamma/\alpha)\mathrm{OPT}$. This concludes the proof of requirement (2). ◀

We are now ready to describe our rounding algorithm, which is depicted in Algorithm 2. The algorithm is straightforward, as it iteratively applies the single iteration algorithm, Algorithm 1, as long as there is a group X_i that is not broken to its required r_i number of pieces. We note that unlike previous algorithms for the (RC) problem, e.g., [18], we need to resolve (LP_F) in each iteration as it is not clear whether the original fractional solution remains feasible for G_F.

Algorithm 2 Rounding.

Input: $G(V,E), \{X_i\}_{i=1}^g, \{r_i\}_{i=1}^g, c: E\to\mathbb{R}_+$
Output: $F\subseteq E$

```
F ← ∅
while ∃i = 1,...,g s.t. X_i is not broken into at least r_i pieces in G_F do
    solve (LP_F) to obtain {λ_S}_{S⊆V} using Theorem 4
    λ̃_S ← λ_S/α, ∀S ⊆ V
    execute Algorithm 1 with G_F and {λ̃_S}_{S⊆V} to obtain L
    F ← F ∪ L
output F
```

The following lemma bounds the number of iterations Algorithm 2 performs, and its proof follows similar lines to the proof of [18]. We present it here for completeness.

▶ **Lemma 6.** *With a probability of at least* $1/2$ *Algorithm 2 performs at most* $O(\alpha/\beta \cdot \log R)$ *iterations.*

Proof. Let R_i^s be the random variable that equals the residual requirement of X_i at the beginning of iteration s of Algorithm 2, and let $R^s = \sum_{i=1}^{g} R_i^s$ be the random variable that equals the total residual requirement at the beginning of iteration s. Requirement (1) of Lemma 5 implies that there exists an absolute constant c such that for every iteration s: $\mathbb{E}[R_i^s | R_i^{s-1}] \leq (1 - c \cdot \beta/\alpha) R_i^{s-1}$, where $(1 - c \cdot \beta/\alpha) < 1$. From linearity of expectation we get that for every iteration s: $\mathbb{E}[R^s] \leq (1 - c \cdot \beta/\alpha)^s R$. Recall that R denotes the total initial requirement, i.e., $R = R^0 = \sum_{i=1}^{g} r_i$. Thus, if we choose $s^* = \log(4R) / \log((1 - c \cdot \beta/\alpha)^{-1})$ then $\mathbb{E}[R^{s^*}] \leq 1/4$. Using Markov's Inequality we get that $\Pr[R^{s^*} < 1/2] \geq 1/2$. However, since R^{s^*} is integral we can conclude that with a probability of at least $1/2$ Algorithm 2 terminates after s^* iterations because all requirements are satisfied, i.e., R^{s^*} reached a value of 0. Noting that $s^* = O(\alpha/\beta \cdot \log R)$ concludes the proof. ◀

Proof of Theorem 1. Lemma 6 proves that with a probability of at least $1/2$ Algorithm 2 performs $O(\alpha/\beta \cdot \log R)$ iterations. Requirement (2) of Lemma 5 implies that the expected cost of every iteration is at most $O(\gamma/\alpha) \cdot \mathrm{OPT}$. Hence, the expected value of the output of the algorithm is $O(\gamma/\beta \cdot \log R) \cdot \mathrm{OPT}$. Plugging the values of γ and β as guaranteed in Theorem 4 concludes the proof. ◀

5 Solving the Configuration LP

In this section we address the problem of solving the relaxation (LP_F). This task requires us to provide an (approximate) separation oracle for the dual of (LP_F), thus proving Theorem 4. Intuitively, the dual separation oracle is a node weighted variant of sparsest cut where demands are given over subsets, as opposed to pairs, of vertices. We denote this problem by Sparsest Requirement Cut (SRC). There are multiple methods of proving that an approximate dual separation oracle provides a bicriteria solution to the primal formulation, e.g., via the Ellipsoid algorithm. In this version of the paper we use Young's iterative method [23]. To simplify presentation, let us denote by $\mathrm{Cross}(S, i) = |\{Y_{i,j} : S \in C(Y_{i,j})\}|$ the number of sets among $Y_{i,1}, \ldots, Y_{i,\ell_i}$ that S separates.

5.1 The Sparsest Requirement Cut Problem

Let us start by formally introducing the (SRC) problem, which is essential to proving Theorem 4.

▶ **Definition 7.** *An instance of the Sparsest Requirement Cut problem consists of the following tuple* $(G, F, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c, y, z)$*, where:* $G = (V, E)$ *is an undirected graph,* $F \subseteq E$ *is a collection of edges removed from* G*, for every* $i = 1, \ldots, g$*:* $\{Y_{i,j}\}_{j=1}^{\ell_i}$ *is the partition of* X_i *according to the connected components of* G_F*, non-negative edge weights* $c : E \to \mathbb{R}_+$*, non-negative group weights* $z : \{1, \ldots, g\} \to \mathbb{R}_+$*, and non-negative vertex weights* $y : V \to \mathbb{R}_+$*. The goal is to find a cut* $S \subseteq V$ *minimizing:*

$$\frac{\delta_{G_F}(S) + \sum_{u \in S} y_u}{\sum_{i=1}^{g} \mathit{Cross}(S, i) z_i}.$$

The following theorem summarizes our algorithm for (approximately) solving (SRC), and it has a key role in proving Theorem 4. Its proof follows the lines of the classic algorithm for Sparsest Cut (SC) with general demands (see, e.g., [17]): first a metric is found that forms a lower bound on the value of an optimal solution, then it is rounded by embedding it

into ℓ_1. Unfortunately, (SRC) is inherently different from (SC) since it is not symmetric, i.e., S and $\overline{S}$ have (possibly) different objective values. To overcome this we introduce a new artificial point o to the metric space which represents $\overline{S}$. Furthermore, when embedding the metric into ℓ_1 we make sure to consider only cuts that do not contain o.

▶ **Theorem 8.** *Given an instance $(G, F, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c, y, z)$ of the Sparsest Requirement Cut problem, there exists a polynomial time algorithm that returns a cut S satisfying:*

$$\frac{\delta_{G_F}(S) + \sum_{u\in S} y_u}{\sum_{i=1}^{g} Cross(S,i)z_i} \leq (X-1)\cdot D \cdot OPT_{SRC},$$

where OPT_{SRC} is the value of an optimal solution to the given instance, and D is as in Theorem 2 when considering $U = \cup_{i=1}^{g} X_i \subseteq V$.

Proof. Our proof is comprised of two steps: (1) introducing a semi-definite relaxation and proving it lower bounds $\mathrm{OPT}_{\mathrm{SRC}}$; and (2) rounding the fractional solution and proving it yields the desired approximation factor.

Step 1. We start by presenting a semi-definite relaxation for (SRC) which we denote by (SDP). In (SDP), a squared Euclidean metric space is imposed over $V \cup \{o\}$, where o denotes a special artificial point which is the origin. Thus, every vertex $a \in V \cup \{o\}$ is associated with a vector $\mathbf{v}_a$ and $\mathbf{v}_o$ is constrained to be the origin, i.e., the zero vector. Moreover, we denote by $\mathcal{T}_{i,j}$ the collection of all spanning trees over the complete graph whose vertices are $Y_{i,j}$.

$$\begin{aligned}
\min \quad & \sum_{e=(a,b)\in E\setminus F} c_e ||\mathbf{v}_a - \mathbf{v}_b||_2^2 + \sum_{a\in V} y_a ||\mathbf{v}_a||_2^2 & & \\
\text{s.t.} \quad & ||\mathbf{v}_a - \mathbf{v}_b||_2^2 + ||\mathbf{v}_b - \mathbf{v}_c||_2^2 \geq ||\mathbf{v}_a - \mathbf{v}_c||_2^2 & \forall a,b,c \in V\cup\{o\} & \quad (5)\\
& ||\mathbf{v}_o||_2^2 = 0 & & \quad (6)\\
& \sum_{(a,b)\in T} ||\mathbf{v}_a - \mathbf{v}_b||_2^2 \geq s_{i,j} & \forall i = 1,\ldots,g, \forall j = 1,\ldots,\ell_i, \forall T \in \mathcal{T}_{i,j} & \quad (7)\\
& \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} s_{i,j} \geq 1 & & \quad (8)
\end{aligned}$$

Constraint (5) is the triangle inequality, whereas Constraint (6) enforces that $\mathbf{v}_o$ is the origin. Constraint (7) states that each $s_{i,j}$ is upper bounded by the length of the minimum spanning tree in $\mathcal{T}_{i,j}$. Constraint (8) is a scaling constraint, similar to the standard relaxation for (SC). Clearly, (SDP) is solvable in polynomial time since the separation oracle is just the computation of a minimum spanning tree.

Let us now prove that the optimal value of (SDP) lower bounds $\mathrm{OPT}_{\mathrm{SRC}}$. Let S^* be an optimal solution to the problem, let us define the following solution to (SDP):

$$\mathbf{v}_a = \begin{cases} 0 & a \notin S^* \\ \frac{1}{\sqrt{\sum_{i=1}^{g} \mathrm{Cross}(S^*,i)z_i}}\mathbf{e} & a \in S^* \end{cases} \quad \text{and} \quad s_{i,j} = \begin{cases} \frac{1}{\sum_{i=1}^{g} \mathrm{Cross}(S^*,i)z_i} & S^* \in C(Y_{i,j}) \\ 0 & S^* \notin C(Y_{i,j}) \end{cases},$$

where $\mathbf{e}$ is an arbitrary unit vector. Additionally, we set $\mathbf{v}_0 = \mathbf{0}$. The crucial observation is that $||\mathbf{v}_a - \mathbf{v}_b||_2^2 = (\sum_{i=1}^{g} \mathrm{Cross}(S^*,i)z_i)^{-1}$ if a and b are on different sides of S^* and 0 otherwise. Clearly, the above solution satisfies Constraints (5) and (6). Focusing on Constraint (7), if $s_{i,j} \neq 0$ then $S^* \in C(Y_{i,j})$ and the minimum spanning tree of $Y_{i,j}$ crosses S^* exactly once and its length equals $(\sum_{i=1}^{g} \mathrm{Cross}(S^*,i)z_i)^{-1}\mathbf{e}\cdot\mathbf{e} = s_{i,j}$. Considering Constraint (8), we note that:

$$\sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} s_{i,j} = \sum_{i=1}^{g} z_i \frac{\mathrm{Cross}(S^*,i)}{\sum_{i=1}^{g} \mathrm{Cross}(S^*,i)z_i} = 1.$$

Hence, we can conclude that the above solution is feasible. Moreover, we note that the objective value of the above defined solution equals:

$$\sum_{e=(a,b)\in E\setminus F} c_e||\mathbf{v}_a-\mathbf{v}_b||_2^2+\sum_{a\in V} y_a||\mathbf{v}_a||_2^2=\frac{\delta_{G_F}(S^*)+\sum_{u\in S^*}y_u}{\sum_{i=1}^{g}\text{Cross}(S^*,i)z_i}.$$

Therefore, the value of an optimal solution to (SDP) lower bounds OPT_{SRC}.

Step 2. We start by presenting the rounding algorithm, Algorithm 3. As previously mentioned, Algorithm 3 follows the lines of classis algorithms for (SC) with non-uniform demands [17]. The main difference is that we make sure to consider only cuts that do not contain o when decomposing the ℓ_1 metric into a non-negative combination of cut metrics (such a decomposition can be easily found, see, e.g., [10, 17]). In what follows we use the notation δ_S to denote the cut metric S defines, i.e., $\delta_S(a,b)=1$ if a and b are on different sides of S and 0 otherwise.

Algorithm 3 Rounding (SDP).

Input: $\{\mathbf{v}_a\}_{a\in V\cup\{o\}}$
Output: $S\subseteq V$
let f be the embedding into ℓ_1 of Theorem 2 when considering $U=\cup_{i=1}^{g}X_i\subseteq V\cup\{o\}$
find $\{\mu_r\}_{r=1}^{L}\subseteq\mathbb{R}_+$ and $\{S_r\}_{r=1}^{L}\subseteq 2^V$ s.t. $||f(a)-f(b)||_1=\sum_{r=1}^{L}\mu_r\delta_{S_r}(a,b)$, $\forall a,b\in V\cup\{o\}$
for $r=1$ *to* L **do**
    if $o\in S_r$ **then**
        swap S_r with $V\cup\{o\}\setminus S_r$
output $\text{argmin}_{r=1,\ldots,L}\{(\delta_{G_F}(S_r)+\sum_{a\in S_r}y_a)/(\sum_{i=1}^{g}\text{Cross}(S_r,i)z_i)\}$

Let us now analyze Algorithm 3. Note that:

$$\min_{r=1,\ldots,L}\left\{\frac{\delta_{G_F}(S_r)+\sum_{a\in S_r}y_a}{\sum_{i=1}^{g}\text{Cross}(S_r,i)z_i}\right\}\leq\frac{\sum_{r=1}^{L}\mu_r\left(\sum_{e=(a,b)\in\Gamma(S_r)}c_e\delta_{S_r}(a,b)+\sum_{a\in S_r}y_a\right)}{\sum_{r=1}^{L}\mu_r\sum_{i=1}^{g}\text{Cross}(S_r,i)z_i}.$$

Focusing on the numerator we get that:

$$\begin{aligned}
&\sum_{r=1}^{L}\mu_r\left(\sum_{e=(a,b)\in\Gamma(S_r)}c_e\delta_{S_r}(a,b)+\sum_{a\in S_r}y_a\right)\\
&=\sum_{e=(a,b)\in E\setminus F}c_e\sum_{r=1}^{L}\mu_r\delta_{S_r}(a,b)+\sum_{a\in V}y_a\sum_{r=1}^{L}\mu_r\delta_{S_r}(o,a)\\
&=\sum_{e=(a,b)\in E\setminus F}c_e||f(a)-f(b)||_1+\sum_{a\in V}y_a||f(a)-f(o)||_1\\
&\leq D\left(\sum_{e=(a,b)\in E\setminus F}c_e||\mathbf{v}_a-\mathbf{v}_b||_2^2+\sum_{a\in V}y_a||\mathbf{v}_a||_2^2\right).
\end{aligned}$$

The first equality follows from changing the order of summation and the fact that $o\notin S_r$, $\forall r=1,\ldots,L$, i.e., $\mathbf{1}_{\{a\in S_r\}}=\delta_{S_r}(o,a)$. The inequality follows from Theorem 2 and Constraint (6).

Focusing on the denominator and choosing an arbitrary spanning tree $T_{i,j} \in \mathcal{T}_{i,j}$, we get that:

$$\begin{aligned}
\sum_{r=1}^{L} \mu_r \sum_{i=1}^{g} \text{Cross}(S_r, i) z_i &= \sum_{r=1}^{L} \mu_r \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} \mathbf{1}_{\{S_r \in C(Y_{i,j})\}} \\
&\geq \sum_{r=1}^{L} \mu_r \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} \frac{1}{|Y_{i,j}| - 1} \sum_{(a,b) \in T_{i,j}} \delta_{S_r}(a,b) \\
&\geq \frac{1}{X-1} \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} \sum_{(a,b) \in T_{i,j}} \sum_{r=1}^{L} \mu_r \delta_{S_r}(a,b) \\
&= \frac{1}{X-1} \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} \sum_{(a,b) \in T_{i,j}} ||f(a) - f(b)||_1 \\
&\geq \frac{1}{X-1} \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} \sum_{(a,b) \in T_{i,j}} ||\mathbf{v}_a - \mathbf{v}_b||_2^2 \\
&\geq \frac{1}{X-1} \sum_{i=1}^{g} z_i \sum_{j=1}^{\ell_i} s_{i,j} \geq \frac{1}{X-1}.
\end{aligned}$$

The first equality follows from the definition of $\text{Cross}(S_r, i)$. The first inequality follows from the fact that any spanning tree in $\mathcal{T}_{i,j}$ can cross the cut $S_r \in C(Y_{i,j})$ at most $|Y_{i,j}|-1$ times. The second inequality follows from changing the order of summation and from $|Y_{i,j}| \leq X$. The third inequality follows from Theorem 2 and the fact that if $(a,b) \in T_{i,j}$ then $a, b \in Y_{ß,j} \subseteq U$. The before last inequality follows from Constraint (7), whereas the last inequality follows from Constraint (8). The second step of the proof is concluded by combining the upper bound on the nominator with the lower bound on the denominator, along with the first step of the proof. ◀

5.2 Proving Theorem 4

As previously mentioned we follow the footsteps of Young's iterative method [23]. Please refer to Appendix A for the details.

A Proving Theorem 4

For simplicity of presentation, for the remainder of this section, we assume that $F \subseteq E$ is given and fixed. Let M be a guess of the value of OPT, and given M define the following polytope capturing (LP_F):

$$\mathcal{Q}(M) = \Big\{\lambda \in \mathbb{R}^{2^V} : \frac{1}{M}\sum_{S\subseteq V}\frac{1}{2}\delta_{G_F}(S)\lambda_S \leq 1 \qquad , \tag{9}$$

$$\sum_{S:u\in S}\lambda_S \leq 1 \qquad \forall u \in V, \tag{10}$$

$$\frac{1}{r'_i}\sum_{j=1}^{\ell_i}\sum_{S\in C(Y_{i,j})}\lambda_S \geq 1 \qquad \forall i = 1,\ldots,g, \tag{11}$$

$$\lambda_S \geq 0 \qquad \forall S \subseteq V\Big\}.$$

We refer to Constraints (9) and (10) as the packing constraints, and Constraint (11) as the covering constraint. For a sufficiently large parameter N, to be determined later, we use the smoothed definitions of the max and min functions for the packing and covering constraints of $\mathcal{Q}(M)$, respectively:

$$\ell max(\lambda) \triangleq \frac{1}{N}\ln\left(R(\lambda) + \sum_{u\in V} y(\lambda,u)\right) \quad \text{and} \quad \ell min(\lambda) \triangleq -\frac{1}{N}\ln\left(\sum_{i=1}^{g} z(\lambda,i)\right),$$

where:

$$R(\lambda) \triangleq \exp\left(\frac{N}{M}\sum_{S\subseteq V}\frac{1}{2}\delta_{G_F}(S)\lambda_S\right)$$

$$y(\lambda,u) \triangleq \exp\left(N\sum_{S:u\in S}\lambda_S\right)$$

$$z(\lambda,i) \triangleq \exp\left(-\frac{N}{r'_i}\sum_{j=1}^{\ell_i}\sum_{S\in C(Y_{i,j})}\lambda_S\right).$$

To simplify presentation, we denote the following value of a cut $S \subseteq V$ by $\phi_\lambda(S)$:

$$\phi_\lambda(S) \triangleq \frac{\sum_{i=1}^{g} z(\lambda,i)}{R(\lambda)+\sum_{u\in V} y(\lambda,u)} \cdot \frac{\frac{1}{M}\frac{1}{2}\delta_{G_F}(S)R(\lambda) + \sum_{u\in S} y(\lambda,u)}{\sum_{i=1}^{g}\frac{1}{r'_i}\mathrm{Cross}(S,i)z(\lambda,i)}.$$

There are two important things to note regarding ϕ_λ. First, for every $S \subseteq V$:

$$\phi_\lambda(S) = \frac{\frac{\partial \ell max(\lambda)}{\partial \lambda_S}}{\frac{\partial \ell min(\lambda)}{\partial \lambda_S}}. \tag{12}$$

Observation (12) plays a crucial role when analyzing Young's iterative method applied to our setting. Second, $\phi_\lambda(S)$ equals the value of S when considering the following instance $(G, F, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c_\lambda, y_\lambda, z_\lambda)$ of (SRC):

$$c_\lambda(e) = \frac{\frac{1}{2M}R(\lambda)c_e}{R(\lambda)+\sum_{u\in V} y(\lambda,u)} \qquad \forall e \in E\setminus F$$

$$y_\lambda(u) = \frac{y(\lambda,u)}{R(\lambda)+\sum_{u\in V} y(\lambda,u)} \qquad \forall u \in V$$

$$z_\lambda(i) = \frac{\frac{1}{r'_i}z(\lambda,i)}{\sum_{i=1}^{g} z(\lambda,i)} \qquad \forall i = 1,\ldots,g.$$

The following lemma proves that there exists a solution to the above instance of (SRC) whose value is at most 1, assuming our guess for M is not smaller than OPT.

▶ **Lemma 9.** *For every $\lambda \in \mathbb{R}^{2^V}$, if $M \geq OPT$ then there exists a cut $S \subseteq V$ such that $\phi_\lambda(S) \leq 1$.*

Proof. We define two vectors $\mathbf{a}, \mathbf{b} \in \mathbb{R}^{2^V}$, indexed by S, as follows:

$$a_S \triangleq \frac{\frac{1}{M}\frac{1}{2}\delta_{G_F}(S)R(\lambda) + \sum_{u\in S} y(\lambda,u)}{R(\lambda) + \sum_{u\in V} y(\lambda,u)} \quad \text{and} \quad b_S \triangleq \frac{\sum_{i=1}^{g} \frac{1}{r'_i}\text{Cross}(S,i)z(\lambda,i)}{\sum_{i=1}^{g} z(\lambda,i)},$$

and prove that $\langle \mathbf{a}, \lambda^* \rangle \leq 1$ and $\langle \mathbf{b}, \lambda^* \rangle \geq 1$, for some non-negative vector $\lambda^* \in \mathbb{R}_+^{2^V}$. Since $\mathbf{a}$, $\mathbf{b}$, and λ^* are all non-negative, we can conclude that there exists $S \subseteq V$ such that $a_S \leq b_S$. This will conclude the proof.

We note that since $M \geq \text{OPT}$, $\mathcal{Q}(M)$ is non-empty. The reason for the latter is that $\lambda^* \in \mathcal{Q}(M)$, where λ^* is an optimal solution to the (RC) problem applied to G_F (as defined in the proof of Lemma 3). Hence, we know that:

$$\sum_{S\subseteq V} \frac{1}{2}\delta_{G_F}(S)\lambda^*_S \leq \text{OPT} \tag{13}$$

$$\sum_{S:u\in S} \lambda^*_S \leq 1 \qquad \forall u \in V \tag{14}$$

$$\sum_{j=1}^{\ell_i} \sum_{S\in C(Y_{i,j})} \lambda^*_S \geq r'_i \qquad \forall i = 1,\ldots,g. \tag{15}$$

We note that (13) above follows from Lemma 3. First, let us prove that $\langle \mathbf{a}, \lambda^* \rangle \leq 1$:

$$\begin{aligned}
\langle \mathbf{a}, \lambda^* \rangle &= \sum_{S\subseteq V} \frac{\frac{1}{M}\frac{1}{2}\delta_{G_F}(S)R(\lambda) + \sum_{u\in S} y(\lambda,u)}{R(\lambda) + \sum_{u\in V} y(\lambda,u)}\lambda^*_S \\
&= \frac{\frac{R(\lambda)}{M}\sum_{S\subseteq V}\frac{1}{2}\delta_{G_F}(S)\lambda^*_S + \sum_{u\in V} y(\lambda,u)\sum_{S:u\in S}\lambda^*_S}{R(\lambda) + \sum_{u\in V} y(\lambda,u)} \\
&\leq \frac{\frac{R(\lambda)}{M}\text{OPT} + \sum_{u\in V} y(\lambda,u)}{R(\lambda) + \sum_{u\in V} y(\lambda,u)} \leq 1.
\end{aligned}$$

The second equality follows from changing the order of summation. The first inequality follows from (13) and (14), whereas the last inequality follows since $M \geq \text{OPT}$. Second, let us prove that $\langle \mathbf{b}, \lambda^* \rangle \geq 1$:

$$\begin{aligned}
\langle \mathbf{b}, \lambda^* \rangle &= \sum_{S\subseteq V} \frac{\sum_{i=1}^{g}\frac{1}{r'_i}\text{Cross}(S,i)z(\lambda,i)}{\sum_{i=1}^{g} z(\lambda,i)}\lambda^*_S \\
&= \frac{\sum_{i=1}^{g}\frac{1}{r'_i} z(\lambda,i)\sum_{j=1}^{\ell_i}\sum_{S\in C(Y_{i,j})}\lambda^*_S}{\sum_{i=1}^{g} z(\lambda,i)} \geq 1.
\end{aligned}$$

The second equality follows from changing the order of summation, whereas the inequality follows from (15). ◀

The following lemma establishes the connection between the above and our algorithm for (approximately) solving (SRC), i.e., Theorem 8.

▶ **Lemma 10.** *Given $\lambda \in \mathbb{R}^{2^V}$, if $M \geq OPT$ then executing the algorithm of Theorem 8 on the instance $(G, F, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c_\lambda, y_\lambda, z_\lambda)$ of (SRC) yields a cut $\tilde{S} \subseteq V$ satisfying: $\phi_\lambda(\tilde{S}) \leq (X-1)D$.*

Proof. Let S^* be an optimal solution to the instance $(G, F, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c_\lambda, y_\lambda, z_\lambda)$ of (SRC), or equivalently, a cut that minimizes $\phi_\lambda(S^*)$. Since $M \geq \mathrm{OPT}$, we can apply Lemma 9 and obtain that $\mathrm{OPT}_{\mathrm{SRC}} \leq 1$ for the given instance. Theorem 8 concludes the proof. ◀

We are now ready to present Young's iterative approach adapted to (LP_F), Algorithm 4. The parameter $\zeta > 0$ in the input determines the step size of the algorithm and will be determined later.

Algorithm 4 Solving (LP_F).

Input: $G = (V, E), F \subseteq E, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c : E \to \mathbb{R}_+, \zeta > 0$
Output: $\lambda \in \mathbb{R}_+^{2^V}$
$\lambda \leftarrow \mathbf{0}$
while $\exists i = 1, \ldots, g$ *s.t.* $\frac{1}{r'_i} \sum_{j=1}^{\ell_i} \sum_{S \in C(Y_{i,j})} \lambda_S < 1$ **do**
  apply Theorem 8 on instance $(G, F, \{\{Y_{i,j}\}_{j=1}^{\ell_i}\}_{i=1}^{g}, c_\lambda, y_\lambda, z_\lambda)$ of (SRC) to obtain $\tilde{S}$
  $\lambda_{\tilde{S}} \leftarrow \lambda_{\tilde{S}} + \zeta$
output λ

The following lemma is used to upper bound the step size ζ in Algorithm 4 and it follows directly by adapting Lemma 1 of [23] to our setting.

▶ **Lemma 11.** *For every $0 < \varepsilon \leq 1$ and $\zeta > 0$ such that $\zeta \leq \varepsilon \min\{1, 1/X, (2M)/(\sum_{e \in E \setminus F} c_e)\}$, the following two hold for every $S \subseteq V$:*

$$\frac{\ell max(\lambda + \zeta \mathbf{1}_S) - \ell max(\lambda)}{\zeta(1+\varepsilon)} \leq \frac{\partial \ell max(\lambda)}{\partial \lambda_S} = \frac{\frac{1}{M} \cdot \frac{1}{2}\delta_{G_F}(S) \cdot R(\lambda) + \sum_{u \in S} y(\lambda, u)}{R(\lambda) + \sum_{u \in V} y(\lambda, u)} \tag{16}$$

$$\frac{\ell min(\lambda + \zeta \mathbf{1}_S) - \ell min(\lambda)}{\zeta(1-\varepsilon/2)} \geq \frac{\partial \ell min(\lambda)}{\partial \lambda_S} = \frac{\sum_{i=1}^{g} \frac{1}{r'_i} \cdot Cross(S, i) z(\lambda, i)}{\sum_{i=1}^{g} z(\lambda, i)}. \tag{17}$$

The following lemma states that when Algorithm 4 terminates, assuming $M \geq \mathrm{OPT}$, it produces an approximate solution to $\mathcal{Q}(M)$.

▶ **Lemma 12.** *For every $0 < \varepsilon \leq 1$, $\zeta > 0$ satisfying the conditions of Lemma 11, and $N = \varepsilon^{-1} \ln(g(n+1))$, when Algorithm 4 terminates, assuming $M \geq OPT$, it outputs $\lambda \in \mathbb{R}_+^{2^V}$ satisfying:*

$$\sum_{S: u \in S} \lambda_S \leq \alpha \qquad \forall u \in V \tag{18}$$

$$\frac{1}{r'_i} \sum_{j=1}^{\ell_i} \sum_{S \in C(Y_{i,j})} \lambda_S \geq \beta \qquad \forall i = 1, \ldots, g \tag{19}$$

$$\frac{1}{M} \sum_{S \subseteq V} \frac{1}{2} \delta_{G_F}(S) \lambda_S \leq \gamma. \tag{20}$$

In the above $\alpha = \gamma = \varepsilon + \frac{(1+\varepsilon)(1+2\varepsilon)}{1-\varepsilon/2}(X-1)D$ and $\beta = 1$.

Proof. From the stopping condition of Algorithm 4, it is clear that (19) holds with $\beta = 1$, i.e., the covering constraints are satisfied. Let us now focus on the remaining two covering constraints. Denote the sequence of cuts Algorithm 4 increased by: $S_1, \ldots, S_L$ (note that some cuts might appear several times in the sequence), and by λ the output, i.e., $\lambda = \zeta \sum_{r=1}^{L} \mathbf{1}_{S_r}$. For simplicity of presentation, we denote by λ^r the solution Algorithm 4 maintains after the r^{th} iteration, i.e., $\lambda^r = \zeta \sum_{s=1}^{r} \mathbf{1}_{S_s}$. Note that $\lambda^0 = \mathbf{0}$ and $\lambda^L = \lambda$. Let us now upper bound the worst packing constraint upon termination of the algorithm:

$$\begin{aligned}
&\max\left\{\frac{1}{M}\sum_{S\subseteq V}\frac{1}{2}\delta_{G_F}(S)\lambda_S, \max_{u\in V}\left\{\sum_{S:u\in S}\lambda_S\right\}\right\} \leq \ell max(\lambda)\\
&= \frac{\ln(n+1)}{N} + \sum_{r=1}^{L}\left(\ell max\left(\lambda^r\right) - \ell max\left(\lambda^{r-1}\right)\right)\\
&\leq \frac{\ln(n+1)}{N} + \frac{1+\varepsilon}{1-\varepsilon/2}\sum_{r=1}^{L}\phi_{\lambda^{r-1}}(S_r)\left(\ell min\left(\lambda^r\right) - \ell min\left(\lambda^{r-1}\right)\right)\\
&\leq \frac{\ln(n+1)}{N} + \frac{1+\varepsilon}{1-\varepsilon/2}(X-1)D\sum_{r=1}^{L}\left(\ell min\left(\lambda^r\right) - \ell min\left(\lambda^{r-1}\right)\right)\\
&= \frac{\ln(n+1)}{N} + \frac{1+\varepsilon}{1-\varepsilon/2}(X-1)D\frac{\ln g}{N} + \frac{1+\varepsilon}{1-\varepsilon/2}(X-1)D\ell min(\lambda)\\
&\leq \varepsilon + \frac{\varepsilon(1+\varepsilon)}{1-\varepsilon/2}(X-1)D + \frac{1+\varepsilon}{1-\varepsilon/2}(X-1)D\min_{i=1,\ldots,g}\left\{\frac{1}{r'_i}\sum_{j=1}^{\ell_i}\sum_{S\in C(Y_{i,j})}\lambda_S\right\}\\
&\leq \varepsilon + \frac{\varepsilon(1+\varepsilon)}{1-\varepsilon/2}(X-1)D + \frac{1+\varepsilon}{1-\varepsilon/2}(X-1)D\cdot(1+\zeta X)\\
&\leq \varepsilon + \frac{\varepsilon(1+\varepsilon)}{1-\varepsilon/2}(X-1)D + \frac{1+\varepsilon}{1-\varepsilon/2}(X-1)D\cdot(1+\varepsilon)\\
&= \varepsilon + \frac{(1+\varepsilon)(1+2\varepsilon)}{1-\varepsilon/2}(X-1)D.
\end{aligned}$$

The first inequality follows from the definition of ℓmax. Since $\ell max(\lambda^0) = \ell max(\mathbf{0}) = \ln(n+1)/N$, the first equality follows. The second inequality follows from Lemma 11 and the definition of ϕ. We note that the third inequality follows from Lemma 10 and how S_r is chosen by Algorithm 4. Since $\ell min(\lambda^0) = \ell min(\mathbf{0}) = -\ln g/N$, the second equality follows. The fourth inequality follows from the choice of N and the definition of ℓmin. Note that the fifth inequality follows from the stopping condition of Algorithm 4, i.e., the algorithm stops once all coverings constraints are satisfied. The last inequality follows from the restrictions on ζ. ◀

Proof of Theorem 4. All that remains is to choose ζ, such that for every guess of M Algorithm 4 performs a polynomial number of iterations. We do this by tracking the following potential: $\Phi(\lambda) \triangleq \sum_{u\in V}\sum_{S:u\in S}\lambda_S$. Note that initially $\Phi(\lambda) = \Phi(\mathbf{0}) = 0$. From guarantee (18) of Lemma 12, we know that once Algorithm 4 terminates the value of $\Phi(\lambda)$ cannot exceed $n(\varepsilon + (1+\varepsilon)(1+2\varepsilon)/(1-\varepsilon/2)\cdot(X-1)D)$. Setting the step size $\zeta = \varepsilon\min\{1, 1/X, (2M)/(\sum_{e\in E\setminus F} c_e)\}$ and choosing $\varepsilon = 1$ implies that Algorithm 4 performs at most $O(nXD/\zeta)$ iterations. Applying standard weight rescaling techniques, we can assume without loss of generality, that $1 \leq c_e \leq \text{poly(n)}$, $\forall e \in E$. Thus, given a guess M, Algorithm 4 performs at most a polynomial number of iterations (recall that $M \geq 1$ due to the rescaling). Since all edge weights are rescaled as above, one can find in polynomial time a value M such that $\text{OPT} \leq M \leq 2\text{OPT}$. This concludes the proof. ◀

Parametrized Metrical Task Systems

Abstract

We consider parametrized versions of metrical task systems and metrical service systems, two fundamental models of online computing, where the constrained parameter is the number of possible distinct requests m. Such parametrization occurs naturally in a wide range of applications. Striking examples are certain power management problems, which are modeled as metrical task systems with $m = 2$. We characterize the competitive ratio in terms of the parameter m for both deterministic and randomized algorithms on hierarchically separated trees. Our findings uncover a rich and unexpected picture that differs substantially from what is known or conjectured about the unparametrized versions of these problems. For metrical task systems, we show that deterministic algorithms do not exhibit any asymptotic gain beyond one-level trees (namely, uniform metric spaces), whereas randomized algorithms do not exhibit any asymptotic gain even for one-level trees. In contrast, the special case of metrical service systems (subset chasing) behaves very differently. Both deterministic and randomized algorithms exhibit gain, for m sufficiently small compared to n, for any number of levels. Most significantly, they exhibit a large gain for uniform metric spaces and a smaller gain for two-level trees. Moreover, it turns out that in these cases (as well as in the case of metrical task systems for uniform metric spaces with m being an absolute constant), deterministic algorithms are essentially as powerful as randomized algorithms. This is surprising and runs counter to the ubiquitous intuition/conjecture that, for most problems that can be modeled as metrical task systems, the randomized competitive ratio is polylogarithmic in the deterministic competitive ratio.

1 Introduction

1.1 Motivation

Metrical task systems are a general framework proposed in the early days of online computing to model a wide range of problems. In this model, an algorithm controls its state among n possible states. It is presented with a sequence of requests. Each request indicates the cost of serving it in each of the n states. The algorithm must choose a state to serve the request, then pay both the transition cost and the service cost. It competes against the optimal offline solution, and is c-competitive iff for any request sequence it pays at most c times this yardstick (plus an allowed additive term independent of the request sequence). The transition costs are assumed to be distances in a finite metric space whose points are the states. The seminal paper [12] introduces this model and also solves completely a fundamental

problem regarding the proposed model. It gives a tight $2n-1$ upper and lower bound on the competitive ratio of any deterministic algorithm. The paper also raises the same question regarding randomized algorithms. For a uniform metric space, it gives a lower bound of $\mathcal{H}_n$ and a nearly tight upper bound of $2\mathcal{H}_n$, where $\mathcal{H}_n = 1 + \frac{1}{2} + \cdots + \frac{1}{n}$ is the n-th harmonic number. In light of this result, a natural folklore conjecture asserts that in any metric space the randomized competitive ratio is $\Theta(\log n)$. This conjecture turned out to be far more elusive than the deterministic case. Currently, the best universal bounds are a lower bound of $\Omega(\log n/\log\log n)$ [7, 9] and a very recent upper bound of $O(\log^2 n)$ [13].

Many online problems can be modeled as special cases of metrical task systems. For instance, paging [31] and more generally the k-server problem [27] are task systems on the state space of k-tuples of points in an underlying metric space. But the best bounds that are known for these problems are much lower than the general bounds that apply to any metrical task system. Clearly, there are constraints on the allowed requests. For instance, in the k-server problem in an n-point metric space, the state space has size $\binom{n}{k}$, but the number of possible requests is just n, and they have only 0 or ∞ values. Such constraints often characterize concrete applications of metrical task systems (e.g., various problems in networks, see [8] and the references therein). A striking example of the gain from instances with a restricted set of requests is the power management problem [25]. It allows only two possible requests, and admits an $O(1)$-competitive algorithm [2]. In view of these examples, it is natural to seek a meaningful measure of instance complexity that will provide at least partial prediction of the better bounds in special cases, a prediction that may be applied to new problems. An obvious choice is the cardinality m of the set of possible requests. (Clearly, this question is interesting only for $m \ll n$, otherwise the known general lower bounds kick in.) Examining request sequences drawn from a given set is proposed explicitly in [15]. They give a deterministic algorithm that in uniform metric spaces achieves a competitive ratio of $O(\log n)$ times the (unknown) best possible bound.

Motivated by the k-server example, the restriction of the requests to have costs in $\{0, \infty\}$ is a natural and attractive problem of chasing subsets of points in a finite metric space. Indeed, this problem setting was proposed in [17], dubbed metrical service systems. We note that this is part of a broader theme of online chasing and searching, and other seminal papers in this theme include [28, 3, 23]. The focus of the metrical service systems literature (e.g. [17, 20, 29, 14, 19, 16]) is the *width* of the requests, which is the maximum size of a requested set. In view of the above discussion, it is equally natural to ask about chasing sets drawn from a small-sized pool of possible requests and deriving bounds that are independent of the width.

1.2 Our results

Our main contribution is an explicit analysis of the competitive ratio of metrical task systems and metrical service systems with m possible requests, $m \ll n$. Perhaps surprisingly, we show that unlike the general case, the answer here depends on the metric space. In particular, for metrical task systems we show that in uniform metric spaces, restricting thus the request sequence improves dramatically the deterministic competitive ratio, which we characterize tightly, up to constant factors. In contrast, there exist other metric spaces, namely two-level HSTs (uniform metrics are one-level HSTs), that exhibit no deterministic asymptotic improvement, even if $m = 2$. Perhaps even more surprisingly, in uniform metric spaces the randomized competitive ratio does not improve asymptotically even if $m = 2$, and in this case the deterministic competitive ratio is asymptotically the same as the randomized competitive ratio.

We also analyze unrestricted width metrical service systems with m possible requests in uniform metric spaces versus two-level HSTs. This case, too, exhibits complex and fascinating behavior, and furthermore it is not identical to the general case. In sufficiently large uniform metric spaces the restriction to m requests improves both the deterministic and the randomized competitive ratio. However the two ratios are asymptotically the same, linear in m and independent of the size of the metric. The two-level HSTs case also deviates from the general case. As with uniform metric spaces, both the deterministic and the randomized competitive ratios improve and are independent of the size of the metric space. However, both the deterministic and the randomized competitive ratios are now exponential in m (the base of the exponent may be different in the two cases). We discuss the surprising aspects of these results and their features that persist beyond two levels in the following sections.

We note that our results, most strikingly the bounds for $m = 2$ metrical task systems in uniform metric spaces, refute a folklore conjecture that for most problems that can be cast as metrical task systems, the randomized competitive ratio is polylogarithmic in the deterministic competitive ratio.

Finally, we relate some of our results to the question of quantifying the amount of information an adversary needs in order to force an online algorithm to perform poorly.

2 Definitions and Results

A *metrical task system* instance consists of a finite metric space $\mathcal{M} = (X, d)$, an initial state $s_0 \in X$, and a sequence of requests $\rho_1, \rho_2, \ldots, \rho_L$, where for every $t \in \{1, 2, \ldots, L\}$, the request ρ_t is a cost function that maps X to $\mathbb{R}_+ \cup \{+\infty\}$. We will denote $n \triangleq |X|$. A solution consists of a choice of states $s_1, s_2, \ldots, s_L \in X$, which incurs a total cost of

$$\sum_{t=1}^{L} \left(d(s_{t-1}, s_t) + \rho_t(s_t) \right).$$

A deterministic online algorithm chooses, for every $t = 1, 2, \ldots, L$, the next state s_t based only on $\mathcal{M}$ and $\rho_1, \rho_2, \ldots, \rho_t$, without knowing the suffix of the requests sequence or even its length L. A randomized online algorithm is a probability distribution over deterministic online algorithms, and its cost is defined to be the expectation of the cost of the deterministic algorithms in the support of the distribution.

We use the following notation. For a sequence of requests ρ, let $z^*(\rho)$ denote the optimal cost of serving ρ. Define $c_{\mathcal{M}}^{\det}$ to be the infimum over c such that there exists a constant a and a deterministic online algorithm A such that for every sequence of requests ρ, the cost of A of serving ρ is at most $c \cdot z^*(\rho) + a$. Define similarly $c_{\mathcal{M}}^{\mathrm{rand}}$ for randomized algorithms. The following theorem is well-known:

▶ **Theorem 1** (Borodin et al. [12]). *For every finite metric space $\mathcal{M}$,*

$$c_{\mathcal{M}}^{\det} = 2n - 1.$$

It is also conjectured that $c_{\mathcal{M}}^{\mathrm{rand}} = \Theta(\log n)$. The conjecture has been established in special cases. For instance tight bounds are known in uniform metric spaces. The currently best known bounds (following substantial previous work [26, 11, 15, 10, 6, 24, 30, 22, 4, 1]) that hold for every metric space are (see below for the definition of an HST):

▶ **Theorem 2** (Bartal et al. [7, 9]). *For every finite metric space $\mathcal{M}$,*

$$c_{\mathcal{M}}^{\mathrm{rand}} = \Omega\left(\frac{\log n}{\log \log n} \right).$$

▶ **Theorem 3** (Bubeck et al. [13]). *For every HST $\mathcal{M}$,*

$$c_{\mathcal{M}}^{\mathrm{rand}} = O(\log n),$$

and therefore, for every finite metric space $\mathcal{M}$,

$$c_{\mathcal{M}}^{\mathrm{rand}} = O(\log^2 n).$$

We are interested in analyzing metrical task systems with constrained requests. The primary constraint that we investigate in this paper is the following: there exists a finite set $\mathcal{R} \subsetneq (\mathbb{R}_+ \cup \{+\infty\})^X$ such that all the requests lie in $\mathcal{R}$. We will denote $m \triangleq |\mathcal{R}|$. Let $c_{\mathcal{M},\mathcal{R}}^{\mathrm{det}}$ ($c_{\mathcal{M},\mathcal{R}}^{\mathrm{rand}}$, respectively) denote the deterministic (randomized, respectively) competitive ratio when requests are restricted to the set $\mathcal{R}$. Also let $c_{\mathcal{M},m}^{\mathrm{det}}$ ($c_{\mathcal{M},m}^{\mathrm{rand}}$, respectively) denote the supremum of $c_{\mathcal{M},\mathcal{R}}^{\mathrm{det}}$ ($c_{\mathcal{M},\mathcal{R}}^{\mathrm{rand}}$, respectively) over $|\mathcal{R}| = m$. We find that unlike the general case, the competitive ratio that can be guaranteed for constrained metrical task systems depends crucially on the underlying metric space $\mathcal{M}$. In particular, we study a class of ultrametrics called hierarchically separated trees (HSTs), invented in [5]. HSTs play a critical role in both the best known upper bounds and the best known lower bounds for metrical task systems, as well as other problems involving metric spaces. For metrical task systems, the best known upper bounds rely on an asymptotically optimal approximation of any metric space by a convex combination of HSTs, discovered in [18]. The best known lower bounds rely on a lower bound on HSTs and the fact that any metric space contains a large approximate HST subspace [7, 9]. More concretely, an L-level HST is a metric space defined on the leaves of a leveled rooted node-weighed tree with $L+1$ levels. The leaves are at level 0, the root is the unique node at level L, each node other than the root has a parent at one level above its own, all the nodes at level i have the same weight, and this weight increases rapidly with the level number. The distance between two leaves is the weight of their least common ancestor. (We note that HSTs are often defined alternatively without the uniformity constraint on levels.) This defines an ultrametric (which is in particular a metric) on the leaves.

We exhibit on the one hand that for uniform metric spaces (which are in the above terms one-level HSTs), restricting m helps immensely deterministic algorithms, but not randomized algorithms:

▶ **Theorem 4.** *If $\mathcal{M}$ is a uniform metric space, then for every $m \leq n$,*

$$c_{\mathcal{M},m}^{\mathrm{det}} = \Theta(m \log(en/m)),$$

and

$$c_{\mathcal{M},2}^{\mathrm{rand}} = \Theta(c_{\mathcal{M}}^{\mathrm{rand}}) = \Theta(\log n).$$

On the other hand, we study what is in some sense just a slightly more sophisticated family of metric spaces. We consider the following family of two-level HSTs, which we call *paired-uniform*. Let n be an even number of points. Partition the points into pairs $\{i, i'\}$. (So, according to this notation $i'' = i$.) Let $C \gg 1$ be a large constant to be determined later. Set $d(i, i') = 1$ for all pairs, and set $d(i, j) = C$ for every two points $i \neq j \neq i'$. It turns out that here restricting m helps neither the asymptotic performance of deterministic algorithms, nor that of randomized algorithms:

▶ **Theorem 5.** *If $\mathcal{M}$ is a paired-uniform metric space, then*

$$c_{\mathcal{M},2}^{\mathrm{det}} = \Theta(n),$$

whereas

$$c_{\mathcal{M},2}^{\mathrm{rand}} = \Theta(\log n).$$

Notice that by prior results, the upper bounds hold even for arbitrary requests in arbitrary HSTs.

The lower bound constructions in the proofs of Theorems 4 and 5 use sets of requests that assign many widely varying cost values. Thus, it makes sense to consider requests using costs from a small set of scales, and in particular to consider metrical service systems that use just two scales, 0 or ∞ (a.k.a. set chasing). Let $\hat{c}^{\det}_{\mathcal{M},m}$, ($\hat{c}^{\rm rand}_{\mathcal{M},m}$, respectively) denote the best deterministic (randomized, respectively) competitive ratio that can be achieved for chasing sets drawn from a collection $\mathcal{R}$ of m subsets of points in $\mathcal{M}$. In this case we show that for uniform spaces, restricting m helps *both* deterministic and randomized algorithms. Moreover, if $m = O(\log n)$, the deterministic and the randomized competitive ratios are asymptotically identical. More precisely we have:

▶ **Theorem 6.** *If $\mathcal{M}$ is a uniform metric space, then for every $m \in \mathbb{N}$,*

$$\min\{m, n\} - 1 \leq \hat{c}^{\det}_{\mathcal{M},m} \leq \min\{m, n\},$$

and,

$$\hat{c}^{\rm rand}_{\mathcal{M},m} = \Theta\left(\min\{m, \log n\}\right).$$

Unlike the more general case of Theorem 5, in the case of metrical service systems on two-level HSTs, restricting the number of possible requests helps, but not as much as in uniform metric spaces. In order to state the results, we introduce a bit more notation. Let $\hat{c}^{\det}_{L,m}$ ($\hat{c}^{\rm rand}_{L,m}$, respectively) denote the supremum of $\hat{c}^{\det}_{\mathcal{M},m}$ ($\hat{c}^{\rm rand}_{\mathcal{M},m}$, respectively) over all L-level HSTs $\mathcal{M}$. We prove:

▶ **Theorem 7.** *For every $m \in \mathbb{N}$,*

$$2^{\lfloor m/2 \rfloor - 1} \leq \hat{c}^{\rm rand}_{2,m} \leq \hat{c}^{\det}_{2,m} \leq m2^m.$$

We note that we actually prove a somewhat tighter lower bound of $\binom{m}{\lfloor m/2 \rfloor}$ on $\hat{c}^{\det}_{2,m}$, see Lemma 16. We also note that it is not surprising that for sufficiently large HSTs, the competitive ratio (deterministic or randomized) depends solely on m and the number of levels. This is because one can trim isomorphic nodes from the tree. (Note however that for deterministic algorithms the trivial bound obtained this way is exponentially worse than the ones proposed above.) The surprising aspects of these theorems are (a) that the deterministic competitive ratio nearly matches the randomized competitive ratio, and (b) that for two-level HSTs, a collection of $O(\log \log n)$ set chasing requests is sufficient to generate a randomized lower bound of $\Omega(\log n)$ (while the classical lower bound requires $\Omega(n)$ such requests). In fact, this latter aspect extends to and is amplified in HSTs with any number of levels. So, using just 6 set chasing requests, we can get a lower bound of $\Omega(\log n)$ for infinitely many n, on HSTs with more and more levels. The argument is outlined in Section 4.

Our main results are summarized in Table 1.

Table 1 Summary of our results, for any $n \gg m$.

one-level HSTs (uniform metrics)

	deterministic	randomized
MTS	$\Theta(m \log n)$	$\Theta(\log n)$
MSS	$\Theta(m)$	$\Theta(m)$

two-level HSTs

	deterministic	randomized
MTS	$\Theta(n)$	$\Theta(\log n)$
MSS	$2^{\Theta(m)}$	$2^{\Theta(m)}$

3 Proofs

▶ **Lemma 8.** *Let $\mathcal{M} = (X, d)$ be an n-point uniform metric space. Consider any set of requests $\mathcal{R}$ of cardinality $|\mathcal{R}| = m$ and any set $S \subseteq X$ of cardinality $|S| > m \log(n/m)$. Then, there exists a state $s \in S$ such that for every $r \in \mathcal{R}$,*

$$|\{s' \in S : \ r_{s'} \geq r_s\}| \geq \frac{1}{m} \cdot |S|. \tag{1}$$

Proof. The proof is a simple application of the probabilistic method. Choose $s \in S$ uniformly at random. We have that for every $r \in \mathcal{R}$,

$$\Pr\left[|\{s' \in S : \ r_{s'} \geq r_s\}| < \frac{1}{m} \cdot |S|\right] < \frac{1}{m}.$$

Therefore, applying the union bound,

$$\Pr\left[\exists r \in \mathcal{R} : \ |\{s' \in S : \ r_{s'} \geq r_s\}| < \frac{1}{m} \cdot |S|\right] < 1,$$

so there is a choice of $s \in S$ that satisfies Equation (1). ◀

▶ **Lemma 9.** *Let $\mathcal{M}$ be an n-point uniform metric space. Then, $c^{\det}_{\mathcal{M},m} = O(m \log(en/m))$.*

Proof. Consider the following algorithm. The algorithm works in phases, and these are further partitioned into rounds. In a phase, we will denote by S_r the set S at the end of round r. We define the cost that a state s acrues during some interval I as $\Sigma(I; s) = \sum_{t \in I} \rho_t(s)$. In the beginning of a phase, set $S_0 = X$ and move to a state s that satisfies Equation (1). As soon as at least $|S_{r-1}|/2m$ states in S_{r-1} acrue a cost of at least 1 in the current phase (including the new request), round r ends. When this happens, remove from S_{r-1} the $\lceil |S_{r-1}|/2m \rceil$ states that acrued the highest cost. Set S_r to be the remaining states in S_{r-1}. If $|S_r| \geq m \log(en/m)$, repeat the above process with a new $s \in S_r$. Otherwise, this is the last round. In this last round, use a $(2|S_r| - 1)$-competitive algorithm, restricted to S_r. Execute this algorithm until the optimal cost of serving this round reaches at least 1. Notice that this implies that by the end of the phase, all states in X acrued a cost of at least 1 during the phase. Therefore, the adversary's cost for the entire phase must be at least 1, because it either stayed at one state and paid a service cost of 1, or moved at least once and paid a movement cost of 1.

In order to analyze this algorithm, fix a phase and denote by a_r the total cost that the algorithm acrues in round r of this phase. Also denote by o_r the average over $s \in S_r$ of the minimum between 1 and the cost acrued by s in this phase by the end of round r. (Set $o_0 = 0$.) Notice that $|S_r| \leq \left(1 - \frac{1}{2m}\right) \cdot |S_{r-1}|$. This implies that the number of rounds (including the special last round) is at most $2m \log(n/m) + 1$. Also notice that throughout round r, at each request at least $|S_{r-1}|/m$ states in S_{r-1} pay at least the cost that the algorithm pays, but less than $|S_{r-1}|/2m$ states in S_{r-1} acrued a total cost of at least 1. Thus, the average over S_{r-1} increases by at least $a_r/2m$. Each state in $S_{r-1} \setminus S_r$ contributes $\frac{1}{|S_{r-1}|}$ to this average, and there are $|S_{r-1}|/2m$ such states, so removing them reduces the average by at most $\frac{1}{2m}$. Thus,

$$o_r \geq o_{r-1} + \frac{a_r}{2m} - \frac{1}{2m}.$$

Let $\bar{r}$ be the penultimate round. Notice that for all r, $o_r \leq 1$. Then

$$2m \geq 2m \cdot o_{\bar{r}} \geq \sum_{r=1}^{\bar{r}} a_r - \bar{r} \geq \sum_{r=1}^{\bar{r}} a_r - 2m \log(n/m).$$

Thus, $\sum_{r=1}^{\bar{r}} a_r = O(m \log(en/m))$. The last phase also costs the algorithm $O(m \log(en/m))$. This is because $|S_{\bar{r}}| < m \log(en/m)$, we use a $(2|S_{\bar{r}}| - 1)$-competitive algorithm, and an adversary with the same initial state in this round as the algorithm pays at most 2 – one for moving to the best initial state, and one for serving the request sequence in the round. ◀

▶ **Lemma 10.** *Let $\mathcal{M}$ be an n-point uniform metric space. Then, $c^{\mathrm{rand}}_{\mathcal{M},2} = \Omega(\log n)$.*

Proof. Assume without loss of generality that $n = 2^q$ is a power of 2 (otherwise we can restrict the instance to the power of 2 closest to n; the redundant states can be blocked by assigning to them a cost of ∞ in both elements of $\mathcal{R}$). Let $\{0, 1, \ldots, n-1\}$ be an arbitrary enumeration of the points of $\mathcal{M}$. Let $C = C(n)$ be a large constant. Set $\mathcal{R} = \{r^0, r^1\}$, where $r^0_i = C^{i-n}$, and let $r^1_i = C^{-i-1}$. We use the minimax principle and generate a random request sequence that "beats" every deterministic algorithm. The request sequence is generated in phases. In each phase we choose uniformly at random one state $h \in \{0, 1, \ldots, n-1\}$ where the adversary "hides." Let $h_0 h_1 \cdots h_{q-1}$ be the binary representation of h. This defines a natural sequence of nested intervals in the dyadic partition of the set of states. The interval J_i consists of all the states whose binary representation has the prefix $h_0 \cdots h_i$. For notational convenience, let $J_{-1} = \{0, 1, \ldots, n-1\}$. The phase consists of q rounds numbered $0, 1, \ldots, q-1$. Then, in round i, we request repeatedly r^{h_i} until the state adjacent to J_i on the right, if $h_i = 0$, or on the left, if $h_i = 1$, acrues a cost of at least 1 in this round. Notice that the algorithm knows the entire round once its first request is given.

The analysis is completed as follows. Define

$$\bar{J}_i = \begin{cases} \{j : j \le \max s \in J_i\} & h_i = 0, \\ \{j : j \ge \min s \in J_i\} & h_i = 1. \end{cases}$$

When round i starts, with probability at least $\frac{1}{2}$, the algorithm occupies a state $s \notin \bar{J}_i$. In this case the algorithm pays at least 1 in this round. This is clear if it moves. Otherwise, every state not in $\bar{J}_i$ pays at least as much as the state in this set that is adjacent to J_i. Thus, the expected cost of the algorithm for the entire phase is at least $q/2 = \log(n-1)$. On the other hand, the adversary pays at most 1 to move to h. Notice that the state adjacent to J_i that determines the stopping condition pays less than 2 in round i (in fact it pays close to 1). Thus, all the states in J_i pay at most $\frac{2}{C}$. If the adversary stays at h for the duration of the phase, it pays a service cost of at most $\frac{2q}{C}$, which can be made arbitrarily close to 0 by choosing $C \gg q$. ◀

▶ **Lemma 11.** *Let $\mathcal{M}$ be an n-point uniform metric space. Then, $c^{\mathrm{det}}_{\mathcal{M},m} = \Omega(m \log(en/m))$.*

Proof Sketch. Without loss of generality, we may assume that m is an even number which is at most $n/2$, that $2n$ is divisible by m and that $2n/m$ is a power of 2. (Otherwise, eliminate some states by having their cost always ∞ and use fewer requests. A constant fraction of both states and requests remains.) So, partition the states into $m/2$ disjoint subsets of size $2n/m$ each. For each subset, define two new requests as per the proof of Lemma 10, and outside the subset have both requests cost 0. In each subset, use the adversary's strategy from the proof of Lemma 10. The requests according to this strategy will be used in the steps when the algorithm occupies a state in the subset. Clearly, while the algorithm hasn't paid at least $\Omega(\log(n/m))$ in all subsets, there's at least one state that hasn't paid 1. Thus, the adversary can choose the last such surviving state and cause the algorithm to pay $\Omega(m \log(n/m))$ before no state survives. When no state survives, a phase that cost the adversary less than 2 and the algorithm $\Omega(m \log(n/m))$ ends, and we can repeat the process in a new phase. ◀

Proof of Theorem 4. The theorem is a corollary of Lemmas 9, 10, and 11. ◀

Proof of Theorem 5. The upper bound on $c^{\text{rand}}_{\mathcal{M},2}$ follows from the general upper bound on trees of Bubeck et al. [13], and the lower bound follows from Theorem 4. The lower bound on $c^{\text{det}}_{\mathcal{M},2}$ goes as follows. Denote the pairs of leaves by i, i' for $i = 0, 1, \ldots, n/2 - 1$. Let $h_0, h_1, \ldots, h_{n/2-1}$ be the sequence defined by $h_i = (Cn)^{i-n}$. We use two requests: r is defined by $r_i = h_i$ and $r_{i'} = 0$, for all i, and r' is defined by $r'_i = 0$ and $r'_{i'} = h_{n-i-1}$, for all i. The request sequence is simple: if the algorithm occupies a state i, use r, otherwise the algorithm occupies a state i', so use r'.

For analyzing the competitive ratio, partition the request sequence into rounds. A round ends whenever the algorithm either moves from one pair to another pair or pays C while staying in one pair $\{i, i'\}$. Notice that either way, the algorithm's cost is at least C per round. Further partition the rounds into phases. Each phase contains exactly $n/2 - 1$ rounds. Thus, the cost of the algorithm per phase is at least $C(n/2 - 1)$. We show that the adversary can pay less than $C + n/2$ per round. Choosing $C = \Omega(n)$ completes the proof. To show that the adversary's cost per phase is less than $C + n/2$, notice that in a phase, the algorithm cannot visit all the pairs. Let $\{i, i'\}$ be a pair that is not visited by the algorithm during the phase. The adversary will "hide" in such a pair. Moving to this pair in the beginning of the round costs at most C. For each round in the phase, the adversary stays either at i or at i', so moving between i and i' costs at most $n/2 - 1$.

To complete the analysis, we have to explain how the adversary chooses between i and i', and we have to analyze the cost of staying at the chosen state. Notice that in a round, by definition the algorithm stays in one pair $\{j, j'\}$, where $i \neq j$. If $i < j$, the adversary stays at i, otherwise the adversary stays at i'. Consider the first case (the other case is analogous). By the definition of a round, j acrues a cost of at most C during the round, because it is hit by a positive cost only when the algorithm occupies j, and the algorithm pays at least this cost (it might decide to move to j' and pay 1). Therefore, i acrues a cost of at most $C \cdot (Cn)^{i-j} \leq \frac{1}{n}$. This is the service cost that the adversary pays during the round. Thus, since there are $n/2 - 1$ rounds in a phase, the total service cost of the adversary during a phase is less than 1. ◀

▶ **Lemma 12.** *Let $\mathcal{M}$ be an n-point uniform metric space. Then,* $\min\{m, n\} - 1 \leq \hat{c}^{\text{det}}_{\mathcal{M},m} \leq \min\{m, n\}$

Proof. The lower bound follows from restricting the number of states that can get a request with a 0 value to $k + 1 = \min\{m, n\}$ and then applying the deterministic k-server lower bound to this subspace. Notice that this lower bound uses $k + 1$ different requests.

The upper bound is achieved with a variant of the marking algorithm, as follows. Each request r can be associated with a subset $S_r = \{i \in X : \ r_i = 0\}$. If there exists a state i that is in the intersection of all m subsets S_r, the algorithm can pay at most 1 to move to this state, and then pay 0 for the rest of the sequence. Otherwise, the algorithm partitions the sequence into phases. In each phase, if the current location of the algorithm is hit by an ∞ value, it moves to a state in the intersection of all the sets seen so far in the phase. The phase ends, and a new phase begins, when this intersection is empty. Notice that to move, the algorithm needs to get a request not seen so far in the phase, so the algorithm moves at most m times per phase. At the end of the phase, all states were hit by an ∞ value at least once, so any algorithm would have to move at least once per phase. ◀

▶ **Lemma 13.** *Let $\mathcal{M}$ be an n-point uniform metric space. Then,* $\hat{c}^{\text{rand}}_{\mathcal{M},m} = O\left(\min\{m, \log n\}\right)$.

Proof. Theorem 3 implies in particular an upper bound of $O(\log n)$. Lemma 12 gives an upper bound of m (because the randomized competitive ratio is upper bounded by the deterministic competitive ratio). ◀

▶ **Lemma 14.** *Let $\mathcal{M}$ be an n-point uniform metric space. Then, $\hat{c}^{\mathrm{rand}}_{\mathcal{M},m} = \Omega\left(\min\{m, \log n\}\right)$.*

Proof. If $m \geq n$, then we get a lower bound of $\mathcal{H}_{n-1}$ from the paging problem [21], which requires n possible requests. Otherwise, let $k = \lfloor \min\{m/2, \log_2 n\} \rfloor$. We restrict our attention to a set of size 2^k states. (If there are more, all the others have cost ∞ in all the requests.) We label the states in this set with the nodes of the binary cube $\{0,1\}^k$. We use $2k$ possible requests that are constructed as follows. There are two requests $r_{i,0}$ and $r_{i,1}$ corresponding to each coordinate $i = 1, 2, \ldots, k$ of the binary cube. The request $r_{i,b}$ has a cost of ∞ at points with the i-th coordinate of their label being b, and 0 at states with the complement i-th coordinate. We use the minimax principle and construct a probabilistic request sequence that beats every deterministic algorithm. The request sequence consists of phases. In each phase the adversary draws independently a point $b_1 b_2 \cdots b_k$ in the binary cube uniformly at random, and then requests the sequence r_{i,b_i}, $i = 1, 2, \ldots, k$, in that order. Against any deterministic algorithm, the expected cost of each request in the phase is $\frac{1}{2}$, so the total expected cost of $\frac{k}{2}$. The adversary needs to move at most once per phase, to the point labeled with the bitwise complement of $b_1 b_2 \cdots b_k$. ◀

Proof of Theorem 6. The theorem is an immediate corollary of Lemmas 12, 13, and 14. ◀

▶ **Lemma 15.** *For every two-level HST $\mathcal{M}$, $\hat{c}^{\mathrm{det}}_{\mathcal{M},m} \leq m2^m$.*

Proof. Let $C > 1$ denote the aspect ratio of $\mathcal{M}$. Let T be any level-1 subtree of $\mathcal{M}$ (so in particular T indicates a uniform subspace of $\mathcal{M}$). We say that T is hit by a subset S of requests iff for every state $s \in T$ there is a request $r \in S$ such that $r_s = \infty$. The algorithm works in periods. In the beginning of a period all level-1 subtrees are unmarked, and a period ends when they are all marked. Each period is divided into epochs. In an epoch, the algorithm chooses an unmarked subtree T and stays in it for the entire epoch. While in a subtree T, the algorithm runs the uniform metric procedure from the proof of Lemma 12, ignoring the states outside T. Notice that this divides the epoch into phases, where during a phase the algorithm encounters one subset S of requests that hits T, for which the algorithm pays $|S| \leq m$ and any algorithm staying in T pays at least 1. The epoch ends as soon as the algorithm executes C phases in T. When the epoch ends, the algorithm marks T and any other subtree that was hit at least C times so far in the period. The cost of the algorithm in a period is upper bounded as follows. In each phase the algorithm encounters a hitting set S. If the same set is encountered C times, all the subtrees that it hits get marked. Therefore, since the empty set is not a hitting set, the total number of phases is at most $C(2^m - 1)$. The number of epochs in a period is therefore $2^m - 1$, and thus the total cost of transition between subtrees is $C(2^m - 2)$ (because no transition is required at the end of the last epoch in the period). Since the algorithm encounters each non-empty set S at most C times, the total "internal" cost of the phases is at most $C \cdot \sum_S |S| = Cm2^{m-1}$. Therefore, the total cost of the algorithm per period is $C(m2^{m-1} + 2^m - 2) < Cm2^m$, for all $m \in \mathbb{N}$. Any algorithm must pay at least C per period. If it stays in one subtree, then every subtree is hit at least C times. If it moves between subtrees, this incurs a cost of at least C. ◀

▶ **Lemma 16.** *For all $m \in \mathbb{N}$, $\hat{c}^{\mathrm{det}}_{2,m} \geq \binom{m}{\lfloor m/2 \rfloor}$.*

Proof. We construct the following two-level HST with aspect ratio C and request set $\mathcal{R}$. There are $\binom{m}{\lfloor m/2 \rfloor}$ subtrees, each labeled by a different subset of the requests of cardinality $\lfloor m/2 \rfloor$. Each subtree has $\lfloor m/2 \rfloor$ states labeled by the elements of the subtree's label. A request has cost ∞ at all the states that are labeled by it, and 0 otherwise. The adversary's strategy is simple: if the algorithm is currently at a subtree labeled S, apend to the sequence all the requests in S (the order doesn't matter), then repeat after updating the location that the algorithms reaches after the apended requests. In order to analyze the competitive ratio, partition the request sequence into periods, where in each period the algorithm leaves all the subtrees. Fix a period, and let k denote the number of times the algorithm changes a subtree in this period, including the departure that ends the period. Clearly, $k \geq \binom{m}{\lfloor m/2 \rfloor}$. The algorithm pays at least Ck in this period. The adversary can hide at the last tree that is visited. At each step, no matter which subtree the algorithm occupies, there is at least one state in the last tree that won't be hit by the apended requests. Each time the algorithm switches trees, the adversary must move to a new state in this last subtree. At the end of the period, the adversary may have to move to a new subtree. So, the total cost of the adversary per period is at most $k + C$. If we choose $C = \binom{m}{\lfloor m/2 \rfloor}$, this gives a lower bound of $\frac{1}{2} \cdot \binom{m}{\lfloor m/2 \rfloor}$. However, we can get a lower bound arbitrarily close to $\binom{m}{\lfloor m/2 \rfloor}$ by choosing a larger C. ◀

▶ **Lemma 17.** *For all $m \in \mathbb{N}$, $\hat{c}^{rand}_{2,m} \geq 2^{\lfloor m/2 \rfloor - 1}$.*

Proof. The argument is basically a "lifting" of the construction in the proof of Lemma 14. As in that proof, we associate the requests with the coordinates of the binary cube $\{0,1\}^{m/2}$ (we assume without loss of generality that m is even, otherwise, discard one request). Each state is labeled by a node of the cube, and request $r_{i,b}$ has cost ∞ for all states with a label that has value b in its i-th coordinate, and cost 0 otherwise. The requests are paired into pairs $r_{i,0}, r_{i,1}$. Notice that each request hits half of the possible state labels, and the sets of labels that two paired requests hit are complements. Now, consider a sequence of requests generated by choosing one request from each pair. We can label this sequence with a point b in the binary cube, where the sequence requests r_{i,b_i} for $i = 1, 2, \ldots, m/2$. Thus, there are $2^{m/2}$ possible such sequences. If such a sequence is requested, it hits all the labels, except for one – the bitwise complement of b. Thus, we can pair such sequences into pairs that have complement labels, and the two sequences in a pair miss complement labels of states. There are $2^{m/2-1}$ pairs of sequences. We can create a meta-sequence of requests by choosing one sequence in each pair and concatenating all the chosen sequences. This gives $2^{2^{m/2-1}}$ possible meta-sequences. This structure is used to generate the adversary's strategy.

But, before we state the adversary's strategy, we construct the metric space and set the labels of the states (which imply the structure of the individual requests). The two-level HST that we use has $2^{2^{m/2-1}}$ subtrees. A subtree is labeled by a subset of the binary cube $\{0,1\}^{m/2}$ of cardinality $2^{m/2-1}$ (half the cube) that contains exactly one node of each antipodal (i.e., complementary) pair of nodes. There are $2^{2^{m/2-1}}$ possible choices, hence the number of subtrees. Such a subtree has $2^{m/2-1}$ states, each labeled with a distinct node in the label of the subtree. Aside from the aspect ratio C, to be defined later, this specifies completely $\mathcal{M}$ and $\mathcal{R}$.

We are now ready to define the adversary's strategy. As usual, we rely on the minimax principle and define a randomized strategy that beats any deterministic algorithm. The adversary repeats the following process. Choose one meta-sequence uniformly at random, then loop through its list of sequences and repeat each sequence C times. Notice that regardless of the state of the algorithm at the beginning of any sequence of the meta-sequence, it pays at least C for this sequence with probability at least $\frac{1}{2}$. This is because each sequence

hits half the subtrees, and the two possible choices for the sequence hit complement sets of subtrees: a sequence labeled b hits all subtrees that contain b, a sequence labeled $\bar{b}$ hits all subtrees that contain $\bar{b}$, and every subtree contains either b or $\bar{b}$, regardless of b. If the sequence hits the subtree where the algorithm is located, it either stays there and pays at least 1 for each time the sequence is requested (because it hits all the states in that subtree), or it moves to a different tree and pays C for the transition. On the other hand, after requesting the entire meta-sequence, there exists one subtree that was not hit even once. This is the subtree that is labeled with the set of complements of all the labels of the sequences in the meta-sequence. The adversary can hide in that subtree. It pays C to move there at the start of the current meta-sequence, and at most 1 to move to a safe state at the start of each sequence in the meta-sequence. So, the expected cost of the algorithm per meta-sequence is $C2^{m/2-1}$, and the total cost of the adversary per meta-sequence is $C + 2^{m/2-1}$. As C grows, the ratio approaches $2^{m/2-1}$. ◀

Proof of Theorem 7. The theorem is a corollary of Lemmas 15 and 17. ◀

4 Discussion

4.1 Open problems

Our work initiates the study of metrical task systems (MTS) and metrical service systems (MSS) parametrized by the number of distinct requests. Roughly speaking (and somewhat surprisingly) we find that this restriction has little effect in general for MTS, in the sense that beyond uniform metric spaces, the achievable competitive ratio with $m = 2$ is already asymptotically as bad as for $m = \infty$ (Theorem 5). In fact, as far as randomized algorithms are concerned this is already true for uniform metric spaces (Theorem 4). On the other hand, the situation for MSS is very different. A number of questions remain open regarding MSS. A particularly interesting qualitative open problem would be to characterize the class of infinite size metric spaces for which there exist online MSS algorithms with finite competitiveness for fixed m, say even for $m = 3$. For example, is it possible to obtain a finite competitive ratio for chasing 3 arbitrary sets on the real line? Another intriguing quantitative open problem is to determine if the deterministic competitive ratio on a weighted star metric is linear or exponential in m. (A simple argument bounds the deterministic competitive ratio by $O(2^m)$ and the randomized competitive ratio by $O(m)$. A lower bound of $\Omega(m)$ in both cases clearly follows from Theorem 6.)

4.2 Deeper trees

Consider MSS on an HST. Label each leaf by a binary vector of dimension m indicating which requests hit it. Clearly, if there are two identically labeled leaves that share a parent, we can eliminate one from consideration. Similarly, label each internal node by the set of labels of its children. If there are two identically labeled internal nodes with the same label and the same parent, we can eliminate one. Thus, effectively, the maximum number T_L of distinct L-level HSTs satisfies: $T_0 < 2^m$ and $T_L < 2^{T_{L-1}}$ (the reason for the strict inequality is that we can eliminate the empty tree and also every leaf labeled by the all-ones vector). The maximum number of leaves N_L of an L-level HST therefore satisfies $N_L \le \prod_{i=0}^{L-1} T_i$ (in fact, this estimate is far from tight for large L). Notice that $\log_2 N_L = \sum_{i=0}^{L-1} \log_2 T_i = O(\log_2 T_{L-1})$. Theorem 7 can be generalized to any number of levels $L \ge 2$. Let $c_1 = \lfloor m/2 \rfloor$ and for $L \ge 2$ let $c_L = 2^{c_{L-1}-1}$. Then, for $L \ge 1$,

$$\Omega(c_L) \le \hat{c}^{\mathrm{rand}}_{L,m} \le O(\log N_L).$$

The upper bound follows from the above observations and previous work (Theorem 3). As for the lower bound, in the proof of Lemma 17 we constructed $2^{2^{m/2-1}}$ one-level subtrees, each labeled with a subset of the binary cube $\{0,1\}^{m/2}$ of cardinality $2^{m/2-1}$, and also $2^{2^{m/2-1}}$ meta-sequences. Each meta-sequence misses one subtree. The subtrees can be paired into complement halves of the binary cube, and the meta-sequences can be paired into complement choices of the sequences that compose them. Complement meta-sequences miss complement subtrees. Thus, we can "lift" this construction just as we "lifted" the uniform metric construction to get a $2^{2^{m/2-1}-1}$ randomized lower bound for three-level HSTs, and this "lifting" can be iterated ad infinitum.

For three or more levels, we do not know reasonably tight upper and lower bounds on the deterministic competitive ratio. We leave this as an open problem. For two levels, the upper and lower bounds of Theorem 7 are similar but not tight asymptotically in m. Thus, deriving asymptotically tight bounds, and moreover determining if the deterministic and randomized competitive ratios are asymptotically (in m) equal (as is the case for uniform metric spaces), are interesting open problems.

4.3 Leaky randomization

Generally our results show that the characteristics of the metric spaces have a strong influence on the type of guarantees one can hope for, in stark contrast with the well-known results and conjectures for non-parametrized sequences (e.g., randomized MTS, or the k-server problem). Moreover our lower bounds constructions also shed a new light on randomization, in the following sense. In online computing randomness may help because it hides the state of the algorithm. An adversary generating the worst-case sequence for a given algorithm knows the probability distribution but not the outcome of the algorithm's coin flips. A natural question in this context is to quantify this phenomenon. In particular, consider an adversary that is given at each step t a signal σ_t indicating some information on the algorithm's state s_t (which is a random variable). Suppose that there exists b such that for all t, the mutual information is $I(\sigma_t; s_t) = b$. If the adversary is allowed to choose the signals subject to this constraint, what can we say about the competitive ratio? Before we proceed, two comments are in place. Firstly, by "algorithm's state" we could mean simply the position reached by the algorithm in the state space, or we could mean more broadly also the internal state of the algorithm. The distinction is immaterial for our results. Secondly, notice that such an adversary is restricted even from having perfect recall, because past requests may reveal more than b bits of information regarding the algorithm's current state. So, we denote the best competitive ratio against the above adversary by $c^b_{\mathcal{M}}$. In every metric space $\mathcal{M}$, the deterministic lower bound in Theorem 1 implies that $c^{\lceil \log n \rceil}_{\mathcal{M}} = 2n - 1$. Notice that $c^{\det}_{\mathcal{M},2^b}$ reveals something about $c^b_{\mathcal{M}}$. In particular, in paired-uniform metric spaces, revealing a single bit is sufficient to force the algorithm to pay asymptotically as much as a deterministic algorithm.

▶ **Corollary 18.** *If $\mathcal{M}$ is a paired-uniform metric space, then*

$$c^1_{\mathcal{M}} = \Omega(n).$$

Proof of Corollary 18. If $c^{\det}_{\mathcal{M},m} = \Omega(n)$, then in order to force an algorithm to a competitive ratio of $\Omega(n)$, all that the adversary needs to know is which of the m requests to use at each step. For this $\log_2 m$ bits of information are sufficient, and this is clearly an upper bound on the mutual information. Thus, the corollary follows from Theorem 5. ◀

Abstract

Given a graph $G = (V, E)$ with non-negative real edge lengths and an integer parameter k, the (uncapacitated) Min-Max Tree Cover problem seeks to find a set of at most k trees which together span V and each tree is a subgraph of G. The objective is to minimize the maximum length among all the trees. In this paper, we consider a capacitated generalization of the above and give the first constant factor approximation algorithm. In the capacitated version, there is a hard uniform capacity (λ) on the number of vertices a tree can cover. Our result extends to the rooted version of the problem, where we are given a set of k root vertices, R and each of the covering trees is required to include a distinct vertex in R as the root. Prior to our work, the only result known was a $(2k-1)$-approximation algorithm for the special case when the total number of vertices in the graph is $k\lambda$ [Guttmann-Beck and Hassin, *J. of Algorithms, 1997*]. Our technique circumvents the difficulty of using the minimum spanning tree of the graph as a lower bound, which is standard for the uncapacitated version of the problem [Even et al.,*OR Letters 2004*] [Khani et al.,*Algorithmica 2010*]. Instead, we use *Steiner trees* that cover λ vertices along with an iterative refinement procedure that ensures that the output trees have low cost and the vertices are well distributed among the trees.

1 Introduction

Covering vertices of a given graph using simpler structures, for example, paths, trees, stars and so on, have long attracted the attention of the Computer Science and Operations Research communities. This can be attributed to a variety of applications in vehicle routing, network design and related problems. One classical example is the so-called "Nurse Location Problem" [10]. The goal is to place a group of nurses at different locations and finding a tour for each of them so that every patient is visited by a nurse. A similar setting arises in vehicle routing. Suppose we are given a set of vehicles, initially located at a given set of depots. The goal is to find a tour for each of these vehicles, each starting and ending at the respective depots so as to cover client demands at various locations. One of the most popular objectives is to minimize the maximum distance travelled by any vehicle, also known as the

makespan of the solution. A standard reduction shows that this problem is equivalent, within an approximation factor of 2, to finding trees in a graph such that all vertices in the graph are covered by the union of these trees. In this paper, we consider a natural generalization of the above setting. As before, we are given a set of vehicles, initially located at a given set of depots and a set of clients. Additionally one package is to be delivered to each of the clients and each vehicle can carry at most a fixed number of packages (all packages are identical). We have to find a set of tour such that each client receives a package and the objective, as before is to minimize the maximum distance travelled by any vehicle. This can be seen as a capacitated version of the Nurse Location Problem, where each nurse can visit at most a given number of patients. Within a factor of two, this problem is equivalent to the following generalization of the TSP problem : given a metric and two constants k, λ, find k tours, each tour on no more than λ vertices, such that the maximum cost over all the tours is minimized. We formally define the problem now, which will be useful in further discussions.

1.1 Notations and Preliminaries

We set up some preliminaries, notations and definitions from literature that will be useful in the exposition of our contributions. The set of positive integers $\{1, 2, , \ldots, n\}$ is denoted by $[n]$. Given a graph $G = (V, E)$, $H = (V_H, E_H)$ is a subgraph of G if $V_H \subseteq V$ and $E_H \subseteq E$. We use $\ell(H)$ to denote the total length of edges in the subgraph H. For any two vertices u, v, $d(u, v)$ denotes the shortest path distance between u, v. We extend the definition to subsets of vertices U, V - define $d(U, V)$ to be $\min_{u \in U, v \in V} d(u, v)$. The set of vertices in any graph H is denoted by $V(H)$.

▶ **Definition 1** (Min-Max Tree Cover Problem (MMTC)). *Given a graph $G(V, E)$, edge length $\ell : E \to \mathbb{R}_{\geq 0}$ and a parameter k, one is required to output a set of k trees T_i for $i \in [k]$, such that each T_i is a subgraph of G and $\cup_{i=1}^{k} V(T_i) = V$. The objective is to minimize $max_{i=1}^{k} \ell(T_i)$.*

Note that two trees in a feasible solution can share vertices as well as edges. In the capacitated version of the problem, we are also given an additional parameter λ. A feasible solution to the Capacitated Min-Max k-Tree Cover consists of a set of trees (not necessarily disjoint) $\mathcal{T} = \{T_1, T_2, \ldots, T_k\}$ along with an assignment of each vertex $v \in V$ to one of the trees containing it, such that no more than λ vertices are assigned to any $T \in \mathcal{T}$. The goal, as in the case of uncapacitated case, is to minimize the maximum length of any tree in $\mathcal{T}$. Let $\text{cov}(T)$ denote the set of vertices assigned to T. We think of the vertices in $\text{cov}(T)$ as being covered by T. Hence, in any feasible assignment $\cup_{T \in \mathcal{T}} \text{cov}(T) = V$ and $|\text{cov}(T)| \leq \lambda$ for all $T \in \mathcal{T}$. Note that a vertex may be a part of multiple trees, but it is covered by exactly one of them. Whenever the notation $\text{cov}(T)$ is used, there is an (implicit) underlying assignment of vertices to the trees. We do not explicitly mention the assignment if it is clear from the context.

▶ **Definition 2** (Capacitated Min-Max Tree Cover (CapMMTC)). *Given a graph $G(V, E)$, edge length $\ell : E \to \mathbb{R}_{\geq 0}$, and two integer parameters k, λ, one is required to output a set of k trees T_i for $i \in [k]$ along with an assignment of every vertex in G to a tree containing it, such that each T_i is a subgraph of G, $\cup_{i=1}^{k} \text{cov}(T_i) = V$ and $|\text{cov}(T_i)| \leq \lambda$ for $i \in [k]$. The objective is to minimize $max_{i=1}^{k} \ell(T_i)$.*

In rooted version of MMTC and CapMMTC, we are given a set of k roots as well. The only additional constraint being that each tree in the output should contain a distinct root. We will refer to these problems as Rooted Min-Max Tree Cover Problem(RMMTC) and Capacitated Rooted Min-Max Tree Cover (CapRMMTC).

1.2 Our Contribution

We give the first polynomial time constant factor approximation algorithm for CapMMTC and CapRMMTC.

▶ **Theorem 3.** *There is a polynomial time $\mathcal{O}(1)$-approximation algorithm for* CapMMTC.

▶ **Theorem 4.** *There is a polynomial time $\mathcal{O}(1)$-approximation algorithm for* CapRMMTC.

Our algorithms are much more intricate and involved than those which give an $\mathcal{O}(1)$ approximation for the uncapacitated case, as is generally the case with capaciated versions of many problems in combinatorial optimization, for instance k-median and facility location problems. These are the first approximation algorithms for both the problems, to the best of our knowledge. The only known result is a $(2k-1)$-approximation for the special case when the total number of vertices in the graph is $k\lambda$ and hence every tree must contain exactly λ vertices [12]. All our algorithms are combinatorial. We first show the result for the unrooted case, ie. CapMMTC and then extend the ideas to prove the result for the rooted problem CapRMMTC. We show that value of the constant in Theorem 3 and 4 is ≤ 300. For simplicity of exposition, we have not tried to optimize the constant. We believe that it should be possible to do so with some more effort and leave it as an open problem. We prove Theorem 3 in Section 2 and defer the proof of Theorem 4 to the Appendix, Section 3.

1.3 Related Work

Even et al. [10] and Arkin et al. [3] gave 4-approximation algorithms for both rooted and unrooted (uncapacitated) MMTC. Khani et al. improved the unrooted version to a 3-approximation [16], whereas Nagamochi and Okada [17] gave a $3-2/(k+1)$-approximation for the special case of the rooted version where all roots are co-located. On the other hand, the MMTC problem has been shown to be hard to approximate to a factor better than $3/2$, assuming $P \neq NP$ [20]. The problem has been considered when the underlying graph has special structure. The rooted version of the MMTC problem on a tree admits a PTAS, as shown recently by Becker and Paul [5], while the unrooted version has a $(2+\epsilon)$-approximation, given by Nagamochi and Okada [17]. Further, Chen and Marx gave fixed parameter tractable algorithms for the problem on a tree [8]. MMTC on a star is equivalent to the classical makespan minimization problem on identical machine, for which elegant EPTAS-es are well known [1]. In stark contrast, no approximation algorithms have been reported so far for the capacitated versions of these problems, to the best of our knowledge. Guttmann-Beck and Hassin gave an $(2k-1)$-approximation for the special case where the number of vertices in each the tree is exactly λ [12]. On the other special case of a star metric, an EPTAS result follows from the work on identical machine scheduling with capacity constraints [7]. Interestingly, the problem becomes inapproximable if one disallows sharing of vertices and edges between the trees in the solution [12], even when $k = 2$. A related but quite different setting is that of bounded capacity vehicle routing with the objective of minimizing the total length of all the tours. Here, a vehicle is allowed to make multiple tours to cover all the points, however, each tour can serve at the most λ clients. This problem has been well studied, a $2.5 - \lambda^{-1}$-approximation is known for general graphs [13], while Becker et al. have reported a PTAS on planar graphs recently [4]. Capacitated versions of other classical combinatorial optimization problems are very well studied and we give a highly non-exhaustive list here. Capacitated unweighted vertex cover admits a 2-approximation [14, 19]. Capacitated versions of clustering problems like k-center [2], k-median [6] and scheduling problems [18] have also been widely popular.

1.4 High Level Ideas and Techniques

Most algorithms for either MMTC or rooted MMTC build upon the following idea. Assume that we know the optimal tree cost - say $T^\star$. Further, for ease of exposition, let us assume that the graph is connected and does not contain any edge of length more than $T^\star$. Now consider the k trees in the optimal solution, each of total length at most $T^\star$. Adding at most $k-1$ edges to the union of these trees forms a spanning tree of the entire graph. Hence, the minimum spanning tree (MST) cost is upper bounded by $(2k-1)T^\star$. This leads to the natural idea of starting with the MST of the graph. At a high-level, we can root the tree at an arbitrary vertex, traverse it bottom-up and chop it off as soon as the total cost of the traversed sub-tree is between $[2T^\star, 4T^\star]$. This needs to be done carefully and we would refer the reader to [10] for details. Now, this can create at most k partitions of the MST, each of cost at most $4T^\star$. The rooted version uses a similar idea, but requires more care. Let us try to apply this idea to the capacitated case. A potential problem is that, we have no control over the structure of the MST. In particular, some part of the MST might be dense - it might contain a connected subtree that has small length but covers a large number of vertices, while some other parts might be sparse. Hence, cutting off the MST on the basis of length as above might end up producing infeasible trees, although the cost might be bounded. One possible idea to fix this could be to further cut off the dense subtrees and try and re-combine them with the sparse subtrees. However, it is not clear how to avoid either combining more than a constant number of subtrees or subtrees that are more than $\mathcal{O}(T^\star)$ distance away from each other and hence cannot lead to a constant factor approximation.

Our Approach: Using λ-Steiner Trees. In order to develop the intuition for our core ideas, we focus on the special case where each tree in the optimal solution *covers* exactly λ vertices (note that each tree may span more than λ vertices). We take a different approach to the problem by utilizing the concept of λ-Steiner Trees. Given a graph G and a subset of vertices R called *terminals*, a λ-Steiner tree on R is a minimum length subtree of G that contains exactly λ vertices from R. We begin with the observation that each tree in the optimal solution covers λ vertices and hence OPT can be thought of as an union of k λ-Steiner trees in G, although not necessarily of the minimum possible cost. A natural algorithm is to pick an arbitrary root vertex and construct a λ-Steiner tree. Computing the λ-MST and hence λ-Steiner trees is NP-Hard and hence we resort to the 4-approximation algorithm that essentially follows from Garg's algorithm [11]. If we are lucky, we might end up capturing an optimal tree and continue. However, in the unlucky case, the λ-Steiner tree might cover vertices from several of the optimal trees. Now if we disregard these vertices in further iterations and try to build another λ-Steiner Tree on the uncovered vertices, we might be stuck since such vertices in the union of the optimal trees might be far away from each other. Hence we cannot guarantee that a low cost λ-Steiner tree exists on these vertices.

We fix this problem by being less aggressive in the first step. We try to build as many $\lceil \lambda/2 \rceil$-Steiner trees as possible that have cost at the most $\mathcal{O}(T^\star)$ using Garg's algorithm - call such trees *good*. At some point, we might be left with vertices such that there does not exist any $\lceil \lambda/2 \rceil$-Steiner trees of low cost that can cover them - let us call them *bad vertices*. In order to cover the bad vertices, we deploy an iterative clustering procedure. We begin by applying the algorithm of Khani and Salavatipour [16] for MMTC, henceforth termed as the KS-algorithm, on the bad vertices. Note that this will return at most k trees each of cost $\mathcal{O}(T^\star)$, although we still cannot prove any lower bound on the number of vertices covered by each tree. Next we set up a bipartite matching instance with these newly formed trees on the left hand side and the good trees on the right hand side. We introduce an edge

between two trees if and only if they are separated by a distance of at the most $T^\star$. The crucial claim now is - if there exists a Hall Set in this matching instance, say S, then the number of trees in S is strictly greater than the number of trees that the optimal solution forms with the vertices covered by S. Hence, applying the KS-algorithm on the vertices in S reduces the number of trees in S without increasing the cost of each tree. This idea forms the heart of our algorithm. We apply the KS-algorithm iteratively until there is no Hall Set, at which point we can compute a perfect matching of the bad trees. Each bad tree can now be combined with a good tree to produce a tree that has cost $\mathcal{O}(T^\star)$ and contains at least $\lambda/2$ vertices each. In a nutshell, the above procedure circumvents the problem of creating too many sparse trees. It ensures that every tree is sufficiently dense - covers at least $\lceil \lambda/2 \rceil$ vertices and are of low cost. Consider a modified graph $\tilde{G}$ created by contracting the edges of the dense trees. Since the original graph is connected and each edge has length at the most $T^\star$, $\tilde{G}$ is also connected and any edge in $\tilde{G}$ has length at the most $T^\star$. We utilize these properties to distribute the vertices and ensure that the final set of trees have exactly λ vertices each and cost at the most $\mathcal{O}(T^\star)$. We note that under the assumption that every optimal solution tree has exactly λ vertices as well, the above algorithm will produce exactly k trees.

Our algorithm for the capacitated problem builds upon the above ideas. However, one major bottleneck is that we can no longer assume that each tree in the optimal solution contains exactly λ vertices. In fact, there could be trees which have a small number of vertices, say less than $\lambda/2$ - call them *light* trees and the rest *heavy*. Handling this situation requires more subtle ideas. We again start by creating $\lceil \lambda/4 \rceil$-Steiner trees of low cost as long as possible which we call good trees and as before, we shall be left with some bad trees that contain less than $\lambda/4$ vertices each, but have bounded cost. Unfortunately, the iterative refinement procedure is no longer guaranteed to produce a perfect matching, as before. However, we are able to show the following. Existence of a Hall Set even after applying the said refinement is a certificate of the fact that optimal solution contains a significant number of light trees - suppose this number is k_ℓ. Then, we add $k_\ell \cdot \lceil \lambda/2 \rceil$ dummy vertices co-located with suitably chosen bad vertices. The upshot is that, this addition ensures that each bad tree now becomes a good tree, together with the dummy vertices. Further, the total number of vertices including the dummy vertices is still bounded above by $k\lambda$. Together, this gives us that, creating trees of size exactly λ cannot result in more than k trees in the solution.

2 Capacitated Min-Max Tree Cover

In this section, we shall describe our algorithm for the CapMMTC problem and prove Theorem 3. The first step in our algorithm is to guess the value of the optimal solution - call it $T^\star$. We remove all edges from G that are of length bigger than $T^\star$ since the optimal solution can never use any such edge. The resulting graph $\hat{G}$ has, say, p connected components - call them $G_1, G_2, \cdots G_p, p \leq k$. Suppose, in the optimal solution, there are k_i trees that cover all vertices in $G_i, i = 1, 2 \cdots p$. Then, $\Sigma_{i=1}^{p} k_i = k$. For each connected component i, we run our algorithm to get at most k_i trees with cost $\mathcal{O}(T^*)$. Due to the above argument, in subsequent exposition, we shall assume that we have a connected graph $G(V, E)$ with edge lengths $\ell(e) \leq T^\star, \forall e \in E$ and there are k trees in the optimal solution that cover V such that every tree has cost at most $T^\star$ and covers at most λ vertices. There could be multiple optimal solutions. For the purpose of our discussion we pick one arbitrarily and whenever we refer to an optimal solution, we mean this particular solution. We shall divide the trees in the optimal solution into two classes for the purpose of analysis. Define a tree T in the optimal solution to be *light* if $|\text{cov}(T)| \leq \lfloor \lambda/2 \rfloor$ and *heavy* otherwise. Define k_{heavy} and k_{light} to be the number of heavy and light trees respectively. We shall prove the following theorem.

▶ **Theorem 5.** *Given a connected graph $G(V, E)$ with the edge lengths $\ell : E \to \mathbb{R}_{\geq 0}$, $\ell(e) \leq T^\star, \forall e \in E$ and non-negative integers k, λ, suppose there exists k trees $T_1, T_2, \ldots, T_k$ along with an assignment of vertices to the trees, such that T_i is a subgraph of G, $|\text{cov}(T_i)| \leq \lambda$ and $\ell(T_i) \leq T^\star$ for $i \in [k]$. Then there exists a polynomial time algorithm that finds a set of trees $T'_1, T'_2, \cdots T'_{k'}$ along with an assignment of vertices to the trees such that $k' \leq k$, for each T'_j, $\ell(T'_j) = \mathcal{O}(T^\star)$ and $|\text{cov}(T'_j)| \leq \lambda$.*

Before proceeding to the proof of the Theorem above, we show how it implies a proof for Theorem 3.

Proof of Theorem 3. We can use Theorem 5 to carry out a binary search for the correct value of $T^\star$ - the optimal solution - in the range $[0, \Sigma_{e \in E} \ell(e)]$. For a particular choice of $T^\star$, we remove all edges that are of length more than $T^\star$ and apply Theorem 5 to each of the connected components. If the total number of trees formed by our algorithm over all components is at most k, then we iterate with a guess $T^\star/2$, otherwise with $2T^\star$. The correctness follows from Theorem 5, since our algorithm will create at most k' trees for connected component V', provided optimal solution makes k' trees as well and the guessed value $T^\star$ is correct. ◀

▶ **Definition 6.** *Given an integer $\lambda > 0$, a tree T is called λ-good if $|\text{cov}(T)| \geq \lambda/4$.*

▶ **Definition 7** (λ-Steiner Trees)**.** *Given a graph $G(V, E)$ and a subset of vertices R called terminals, λ-Steiner tree is a tree which is a subgraph of G that spans exactly λ terminals. The special case of $R = V$ is called λ-MST.*

We shall be using the 2-approximation algorithm for minimum cost λ-MST from [11] as a black-box, which implies a 4-approximation for the minimum cost λ-Steiner tree problem. Our algorithm has three phases $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$, each making progress towards the proof of Theorem 5.

2.1 Algorithm $\mathcal{A}$: Constructing λ-good trees

Recall that the input is a graph $G = (V, E)$, with edge lengths $l_e \leq T^\star, e \in E$. Further, we assume that there exists a partition of V into k trees such that the cost of each tree is at most $T^\star$ and each tree covers at most λ vertices (with respect to some assignment). We maintain a set of covered vertices V_c throughout our algorithm. Initially $V_c = \phi$. The following is done iteratively. Pick an arbitrary vertex $v \in V \setminus V_c$ which has not been considered in any previous iteration. Construct a 4-approximate minimum cost $\lceil \lambda/4 \rceil$-Steiner Tree in G, rooted at v with the terminal set being $V \setminus V_c$. If the cost of this tree is at most $4T^\star$, then add this tree to the set λ_{good}, add all terminals spanned by this tree to V_c. At the termination of this loop, set $V_{bad} = V \setminus V_c$.

▶ **Lemma 8.** *At termination of Algorithm $\mathcal{A}$,*
1. *$V = \text{cov}(\lambda_{good}) \cup V_{bad}$, where $\text{cov}(\lambda_{good}) = \bigcup_{T \in \lambda_{good}} \text{cov}(T)$*
2. *For any tree $T \in \lambda_{good}$, $|\text{cov}(T)| = \lceil \lambda/4 \rceil$ and $\ell(T) \leq 4T^\star$*

▶ **Lemma 9.** *For any heavy tree in* OPT*, say T, at least half of the vertices covered by T in* OPT*, ie.* $\text{cov}(T)$ *are covered by the union of trees in λ_{good}*

Proof. Assume otherwise. This implies that at least $\lambda/4$ vertices covered by T are added to V_{bad} - let us call this set V'. Now, $\ell(T) \leq T^\star$ and there must exist a connected sub-tree of T that covers exactly $\lceil \lambda/4 \rceil$ vertices from V'. Hence, some iteration of Algorithm $\mathcal{A}$ must have returned a tree of cost at most $4T^\star$ covering $\lceil \lambda/4 \rceil$ vertices from V' and this tree was added to λ_{good}. Consequently, V' cannot be a subset of V_{bad} leading to a contradiction. ◀

Algorithm 1 Algorithm $\mathcal{A}$.

Input: Graph $G = (V, E), \lambda$
Output: Set of trees λ_{good} and set of vertices V_{bad}
$V_c \leftarrow \phi$, $\lambda_{good} \leftarrow \phi$, $V_{temp} \leftarrow V$
While $V_{temp} \neq \phi$
Pick $v \in V_{temp}$ arbitrarily
$T \leftarrow \lceil * \rceil \lambda/4$-Steiner tree rooted at v with terminal set defined as $V \setminus V_c$
$\text{cov}(T) \leftarrow$ terminals in $V \setminus V_c$ covered by T
If $\ell(T) \leq 4T^\star$ **Then**
Add T to λ_{good}
Update $V_{temp} \leftarrow V_{temp} \setminus \text{cov}(T), V_c \leftarrow V_c \cup \text{cov}(T)$
Else
Update $V_{temp} \leftarrow V_{temp} \setminus \{v\}$
$V_{bad} \leftarrow V \setminus V_c$
Return λ_{good} and V_{bad}

2.2 Algorithm $\mathcal{B}$: Covering V-bad vertices with λ-good trees

Recall that in the previous section, we gave algorithm to construct a set of trees λ_{good} such that for any tree $T \in \lambda_{good}$, $\ell(T) \leq 4T^\star$ and $|\text{cov}(T)| = \lceil \lambda/4 \rceil$. Further, we extracted a subset of vertices V_{bad} such that no $\lceil \lambda/4 \rceil$-Steiner tree of cost at the most $4T^\star$ exists covering these vertices. In this section, we shall give a procedure to cover the vertices in V_{bad}, either by constructing new trees that have large size but low cost, or by merging them in to the existing λ-good trees. In the following procedure, we shall be making use of the 3-approximation algorithm by Khani and Salavatipour [16] for the MMTC problem. Recall the main theorem from above paper, re-phrased to suit our notations.

▶ **Theorem 10** ([16]). *Given an undirected graph $G(V, E)$, an integer k and edge lengths ℓ, if there exists a set of k trees (subgraphs of G) $T_1, T_2, \cdots T_k$, along with an assignment of vertices to the trees, such that $\max_{i \in [k]} \ell(T_i) \leq T^\star$ and $\cup_{i=1}^{k} \text{cov}(T_i) = V$, then there exists a polynomial time algorithm that outputs trees (subgraphs of G) $T'_1, T'_2, \cdots T'_{k'}$, along with an assignment of vertices to the trees such that $\max_{j \in [k']} \ell(T'_j) \leq 3T^\star$, $\cup_{j=1}^{k'} \text{cov}(T'_j) = V$ and $k' \leq k$.*

We refer to the algorithm referred to in the above theorem as the KS-Algorithm in subsequent sections. As mentioned earlier, although the trees T'_j might share vertices and edges, the set of vertices that such trees *cover* forms a partition of V. Note that KS algorithm takes an edge weighted graph and number of trees as input.

A Bipartite Matching Instance. Our algorithm first constructs a maximum matching instance on a suitably defined bipartite graph $H = (B, Q, F)$. In the course of algorithm, Q remains fixed. However, the other partitite set B and consequently the edge set F is refined iteratively, each time giving rise to a new maximum matching instance. Our invariants will ensure that, either we end up with a perfect matching of B or conclude that there are significantly many light trees in the optimal solution, which need to be handled separately. For clarity of notation, we parameterize set B by iteration index t - define B_t to be the partite set B at iteration t. A vertex in the set B_t represents a subtree $T_{j,t}, j = 1, 2, \cdots |B_t|$ such that $\cup_{j=1}^{|B_t|} \text{cov}(T_{j,t}) = V_{bad}$. The set Q contains a vertex corresponding to each tree in $T \in \lambda_{good}$. Next, we define the edges in F_t at any iteration t. There exists an edge

$e = (T_{j,t}, T) \in F_t, T \in Q$ if and only if $d(V(T_{j,t}), V(T)) \leq T^\star$. For a fixed t, define $\mathcal{M}_t$ to be a maximum matching instance on the graph (B_t, Q, F_t). For any subset $B' \subseteq B_t$, let $\mathcal{N}(B')$ be the neighborhood set of B' in Q.

Algorithm IterRefine. We initialize by setting $B_0 = V_{bad}$ - each vertex in B_0 is a trivial tree containing a single vertex. Now we have the required setup to describe the iterative refinement procedure. At any iteration t, we solve the maximum matching instance $\mathcal{M}_t$. If $\mathcal{M}_t$ admits a perfect matching of B_t, then we terminate. Otherwise we consider the Hall Set $S \subseteq B_t$ with maximum deficiency, that is $\text{argmax}_{S \subseteq B_t}(|S| - |\mathcal{N}(S)|)$. Let set S contains the subtrees $T_{1,t}, T_{2,t}, \cdots T_{s,t}, s = |S|$. Let $G_t = (V_t, E_t)$ be defined as: $V_t = \cup_{j=1}^{s} \text{cov}(T_{j,t}), E_t = \{(u,v) | u, v \in V_t\}$ and $\ell(u,v)$ is the length of shortest path between u and v in G. We run the KS algorithm on G_t with $k = s - 1$. Suppose it returns trees $T'_{1,t}, T'_{2,t}, \cdots T'_{s',t}$, $s' \leq s - 1$. If cost of each such tree is at most $6T^*$, we define $B_{t+1} = (B_t \setminus S) \bigcup_{j=1}^{s'} \{T'_{j,t}\}$, the edge set F_{t+1} accordingly and proceed to the next iteration, else we terminate.

Algorithm 2 Algorithm IterRefine.

Input : λ_{good}, V_{bad}
Output: A maximum matching in H_t and Unmatched Set $\overline{B_m}$
Initialize the bipartite graph $H_0 = (B_0, Q, F_0), t \leftarrow 0$
While there exists a Hall Set in B_t
Pick the Hall Set $S = \text{argmax}_{S \subseteq B_t}(|S| - |\mathcal{N}(S)|)$
Apply KS-algorithm on G_t with $k = s - 1$. Let $T'_{1,t} \cdots T'_{s',t}$ be the output of the algorithm with $s' \leq s - 1$.
If $\max_{i=1}^{s'} \ell(T'_{i,t}) > 6T^*$ **Then** STOP
Else { $B_{t+1} \leftarrow (B_t \setminus S) \bigcup_{j=1}^{s'} \{T'_{j,t}\}$ and $t \leftarrow t + 1$ }
Return Maximum Matching $\mathcal{M}_t$ and unmatched subset $\overline{B_m} \subseteq B_t$

The following lemmas are crucial to prove the correctness of our algorithm. Lemma 11 is a well known result, but we give the proof for completion. We define the projection of the optimal solution on S as follows:

$$\text{OPT}\big|_S = \{T' \in \text{OPT} : \exists T_{i,t} \in S, \text{cov}(T') \cap \text{cov}(T_{i,t}) \neq \phi\}$$

▶ **Lemma 11.** *At any iteration t, let the number of trees in $\text{OPT}\big|_S$ be m. Then there exist m trees $T_i, i \in [m]$ such that $\cup_{i=1}^{m} V(T_i) = V_t, \ell(T_i) \leq 2T^*$ and T_i is a subtree of G_t for $i \in [m]$.*

Proof. Let $T'_i, i \in [m]$ be the trees in $\text{OPT}\big|_S$. Fix a tree, say T'_i. Consider the graph with each edge of T'_i doubled. It is connected and all degrees are even, hence there exists an eulerian walk, say $v_1, v_2, \ldots, v_l$. Note that vertices in this walk may be repeated. Identify a unique vertex for each $v \in V(T'_i) \cap V_t$ in this sequence. This defines a subsequence of the walk, say $v_{i_1}, v_{i_2}, \ldots, v_{i_l}$ with every vertex in $V_t \cap V(T'_i)$ occurring exactly once. This sequence defines a path in G_t since G_t is a complete graph. The total length of path is at most $2T^*$, as length of any edge in G_t is the shortest path distance between the end points in G and total length of the walk is at most $2T^*$. Repeating this argument for all trees in $\text{OPT}\big|_S$, we get that vertices in V_t can be covered by m trees of length at most $2T^*$ each. ◀

▶ **Lemma 12.** *Suppose S is the maximum deficiency Hall Set, if any, at termination of Algorithm IterRefine. Further, let k_ℓ be the number of light trees in $\text{OPT}\big|_S$. Then $|S| - |N(S)| \leq k_\ell$.*

Proof. Let k_h be the number of heavy trees in $\text{OPT}\big|_S$. We first claim that $|S| \leq k_h + k_\ell$. Assume otherwise. But then, by Lemma 11, there exists a partition of S into exactly $k_h + k_\ell$ trees in G_t with cost at most $2T^*$, by Theorem 10, the KS-algorithm applied on the Hall Set S with $k = |S| - 1$ must have produced trees with cost at most $6T^*$ and the algorithm would not have terminated.

Now, we prove that $|N(S)| \geq k_h$. Consider any heavy tree in $\text{OPT}\big|_S$, say $\widehat{T}$. By Lemma 9, at least half of the vertices in $\widehat{T}$ are covered by λ-good trees. By construction of the bipartite graph (B_t, Q), all such λ-good trees belong to the set $N(S)$, since any two vertices in the same tree of the optimal solution can be at the most $T^\star$ distance away from each other. Thus, adding up over all heavy trees in $\text{OPT}\big|_S$, the total number of vertices covered by the λ-good trees in $N(S)$ is at least $k_h \cdot \lceil \lambda/4 \rceil$. But, each λ-good tree in $N(S)$ covers exactly $\lceil \lambda/4 \rceil$ vertices. Hence, by pigeon-hole principle, $|N(S)| \geq k_h$. Combining the above two facts, we have $|S| - |N(S)| \leq k_\ell$. ◀

▶ **Corollary 13.** *Let t' be the final iteration of the Algorithm IterRefine. Then, the total number of unmatched trees in $B_{t'}$ is at most k_{light}.*

Proof. We use the fact that the size of the maximum matching in $B_{t'}$ is exactly equal to $|B_{t'}| - (|S| - |N(S)|)$, where S is the maximum deficiency Hall Set [9]. Hence, the total number of unmatched trees in $B_{t'}$ is at exactly $|S| - |N(S)| \leq k_\ell \leq k_{light}$, by Lemma 12. ◀

We proceed to the final phase of our algorithm, equipped with the above Lemmas. Recall that, there are two types of partitions in $B_{t'}$ - either matched or unmatched by $\mathcal{M}_{t'}$. First, let us consider the matched partitions - call this set B_m. For each tree T in B_m, we take its union with the λ-good tree in Q, say $\widehat{T}$ that it is matched to in $\mathcal{M}_{t'}$. More formally, we build a tree T' by connecting $T, \widehat{T}$ using the shortest path between the closest pair of vertices in T and $\widehat{T}$. We set $\text{cov}(T') = \text{cov}(T) \cup \text{cov}(\widehat{T})$. We remove $\widehat{T}$ and add the newly constructed tree T' to the set λ-good.

Finally, we consider the set of unmatched trees $\overline{B_m}$. For each such tree, we add $\lceil \lambda/2 \rceil$ dummy vertices co-located with any arbitrary vertex in the tree. We add this tree to λ_{good}. This completes the description of the algorithm.

▶ **Lemma 14.** *At termination, Algorithm $\mathcal{B}$ returns a set of trees λ_{good} that*

1. *covers all vertices in the set $V \cup V_{dummy}$.*
2. *The cost of any tree in λ_{good} is at most $11T^\star$.*
3. *$|V \cup V_{dummy}| \leq k\lambda$*

Proof. First we show that all trees in λ_{good} are indeed λ-good, that is, they cover at least $\lambda/4$ vertices. Recall that, after algorithm $\mathcal{A}$, the set Q contains only λ-good trees, by Lemma 8. At termination of algorithm $\mathcal{B}$, each tree is either formed by joining of a tree in the set Q with some tree in B_m. Hence, the tree continues to be λ-good. The only other type of tree in λ_{good} are formed by adding $\lceil \lambda/2 \rceil$ dummy vertices to an unmatched tree in $\overline{B_m}$. Hence, they are λ-good by construction. Property 1 follows from Lemma 8 and the fact that cover of trees in $B_{t'}$ is a partition of the vertices in V_{bad}. Next we prove Property 2. There are two types of trees in λ_{good}. Let us consider any tree that is formed by the union of some matched tree in B_m, say $\mathcal{T}$ and some already existing λ-good tree in Q, say $\widehat{T}$. By Lemma 8, $\ell(\widehat{T}) \leq 4T^\star$. By Lemma 11, $\ell(\mathcal{T}) \leq 6T^\star$. A tree is formed by joining these two trees by a path of cost at the most $T^\star$. So, the resultant tree has cost at the most $(4+6+1)T^\star = 11T^\star$. The second kind of tree corresponds to the unmatched vertices in $B_{t'}$ and hence their cost is bounded above by $3T^\star$, by Lemma 11. Addition of dummy vertices does not affect the cost at all.

Property 3 can be proved as follows. Recall that $|V| \leq k_{heavy}\lambda + k_{light}\lambda/2$. Now, we add $\lambda/2$ dummy vertices to each unmatched partition in $B_{t'}$, which, by Corollary 13, can be at the most $k_{light}\lambda/2$. Hence, $|V \cup V_{dummy}| \leq k_{heavy} \cdot \lambda + 2 \cdot k_{light} \cdot \lambda/2 \leq k\lambda$ ◀

The above lemma guarantees that the total number of vertices in the graph is at the most $k\lambda$. For technical reasons that would be clear in Section 2.3, we add some more dummy vertices co-located with an arbitrarily selected $v \in V$, such that the total number of vertices is an integer multiple of λ. We note at this point that we do not make any claim about the number of trees in the set λ_{good}. In fact, the number can be larger that k, the original budget. However, in the next Section, we show how to refine the trees such that number of trees is at most k, without increasing the cost by more than a constant factor and maintaining the capacity constraints. Also note that all our procedures are polynomial time.

2.3 Algorithm $\mathcal{C}$: Converting λ-good trees to feasible trees

In the previous section, we gave algorithms that ensure the property that each tree covers at least $\lambda/4$ vertices and the cost of each tree is bounded by $\mathcal{O}(T^\star)$. In this section, we prove that it is possible to construct a solution that creates at most k admissible trees given the previous solution, where k is the number of trees that the optimal solution uses to cover the vertices in the connected component $G = (V, E)$. We prove the following theorem in this section.

▶ **Theorem 15.** *Let $T_1, T_2, \ldots, T_m$ be trees returned by the Algorithms $\mathcal{A}$ and $\mathcal{B}$ such that $|\text{cov}(T_i)| \geq \lambda/c$, where $c \geq 1$, $\ell(T_i) \leq \alpha T^*$ for $1 \leq i \leq m$. If λ divides $|\cup_{i=1}^{m} \text{cov}(T_i)|$, then there exist trees $T'_1, T'_2, \ldots, T'_l$ spanning V such that $|\text{cov}(T'_i)| = \lambda, \ell(T'_i) \leq (6c+6c\alpha-2\alpha-6)T^*$ for $1 \leq i \leq l$. Further, such trees can be found in polynomial time.*

Define G_P be to be an unweighted graph with $T_1, T_2, \ldots, T_m$ as vertices. There is an edge (T_i, T_j) if $d(T_i, T_j) = d(V(T_i), V(T_j)) \leq T^*$.

▷ Claim 16. *G_P is connected. Further, the implicit cost of each unweighted edge in G_p is at most $T^\star$.*

Proof. The claim follows from the fact that we run Algorithms $\mathcal{A}$ and $\mathcal{B}$ only on connected components of $\hat{G}$ formed after removing all edges that are of length more than $T^\star$ from G. ◁

We will need the following theorem by Karaganis [15] to prove our result:

▶ **Theorem 17** ([15])**.** *Let $G = (V, E)$ be a connected simple unweighted graph. Define G^3 to be the graph on the same set of vertices and set of edges*

$$E^3 = \{(u, v) | \textit{shortest path distance between } u \textit{ and } v \textit{ in } G \textit{ is at the most } 3\}$$

Then, G^3 has a Hamiltonian path.

By the above theorem, there exists a Hamiltonian path in G_P^3. After renaming, let $T_1, T_2, \ldots, T_m$ be the order in which the vertices of G appear on that path. Then $d(T_i, T_{i+1}) \leq 3T^* + 2(\text{max diameter of any } T_i) \leq (2\alpha + 3)T^*$ for $1 \leq i \leq m-1$. We are now ready to prove the main results of this section.

▶ **Lemma 18.** *Let $T_1, T_2, \ldots, T_m$ be trees such that $|\text{cov}(T_i)| \geq \lambda/c$ for some $c > 1$, $\ell(T_i) \leq \alpha T^*$ for $1 \leq i \leq m$ and $d(T_i, T_{i+1}) \leq D$ for $1 \leq i \leq m-1$. There exist trees $T'_1, T'_2, \ldots, T'_l$ such that $d(T'_i, T'_{i+1}) \leq D$, $|\text{cov}(T'_i)| \geq \lambda$ for $1 \leq i \leq l-1$ and $\ell((T'_i) \leq (c-1)D + c\alpha T^*$ for $1 \leq i \leq l$. Further, such trees can be computed in polynomial time.*

Proof. We make $l = \lceil m/c \rceil$ trees. Let $P(T_p, T_q)$ denote the shortest path connecting trees T_p and T_q. $T'_i = \bigcup_{j=(i-1)c+1}^{min(ic,m)} (T_j \cup P(T_j, T_{j+1}))$ for $1 \leq i \leq l$. Since $T'_1, T'_2, \ldots, T'_{l-1}$ are formed by combining c trees, each covering at least λ/c vertices, $|\text{cov}(T'_i)| \geq \lambda$ vertices. Since any V' is formed by combining at most c trees, $\ell(T') \leq (c-1)D + c\alpha T^*$. Also, by construction $d(T'_i, T'_{i+1}) \leq D$ for $1 \leq i \leq l-1$ ◀

▶ **Lemma 19.** *Let $T_1, T_2, \ldots, T_m$ be trees such that $|\text{cov}(T_i)| \geq \lambda$ for $2 \leq i \leq m$, $\ell(T_i) \leq \alpha T^*$ for $1 \leq i \leq m$ and $d(T_i, T_{i+1}) \leq D$ for $1 \leq i \leq m-1$. If λ divides $|\cup_{i=1}^{m} \text{cov}(T_i)|$, then there exist trees $T'_1, T'_2, \ldots, T'_l$ such that $|\text{cov}(T'_i)| = \lambda, \ell(T'_i) \leq D + 2\alpha T^*$ for $1 \leq i \leq l$. Further, such trees can be found in polynomial time.*

Proof. We will prove this by induction on m. If $m = 1$, then λ divides $|\text{cov}(T_1)|$. We partition $\text{cov}(T_1)$ into sets of size λ arbitrarily. Cost of a tree covering each of these partitions will be at most αT^* (T_1 is one such tree). Let $m > 1$ and $|\text{cov}(T_1)| = c\lambda + p$, where $c \geq 0, 1 \leq p \leq \lambda - 1$. We first make c partitions of size λ each out of $\text{cov}(T_1)$. Cost of spanning tree covering each of these partitions is at most αT^*. We create a new tree, say T_p, by taking p remaining points of $\text{cov}(T_1)$ and any $\lambda - p$ points of $\text{cov}(T_2)$. $|\text{cov}(T_p)| = \lambda$ and $\ell(T_p) \leq \ell(T_1) + D + \ell(T_2) \leq D + 2\alpha T^*$. The remaining points form a smaller instance and by induction can be covered by trees with desired properties. This completes the induction step and proof of the theorem. ◀

Proof of Theorem 15. From the discussion above and applying Lemma 18, we get trees covering at least λ vertices and cost at most $C = (c-1)D + c\alpha T^*$. Using Lemma 19 on these trees, we get trees covering exactly λ vertices and cost at most $D + 2C$. Plugging in $D = (2\alpha + 3)T^*$ gives the desired result. ◀

Proof of Theorem 5. Plugging in $c = 4$ and $\alpha = 11$ from Lemma 14 gives a 260-factor approximation algorithm for the capacitated min max tree cover problem. ◀

3 Extension to Capacitated Rooted Tree Cover

In this section, we show how to extend Theorem 5 to the rooted setting. Recall that in CapRMMTC, in addition to the settings of CapMMTC, we given a set of root vertices, $R = \{r_1, r_2, \cdots r_k\}$. The k output trees need to be rooted at each of these root vertices. We prove the following theorem.

▶ **Theorem 20.** *Given a graph $G = (V, E)$ with the edge lengths $\ell : E \to \mathbb{R}_{\geq 0}$, a set of roots $R \subseteq V, |R| = k$ and a parameter λ, suppose there exist subtrees of G, $T_1, T_2, \cdots, T_{k'}$, where $\cup_{i=1}^{k} \text{cov}(T_i) = V$, $\max_{i \in [k']} |\text{cov}(T_i)| \leq \lambda, V(T_i) \cap R \neq \phi$ and $\ell(T_i) \leq T^\star, \forall i = 1, 2, \cdots k$. Then there exists a polynomial time algorithm that finds subtrees of G, $T'_1, T'_2, \cdots T'_{k'}, k' \leq k$ such that $\cup_{i=1}^{k'} \text{cov}(T'_i) = V$, $\max_{i \in [k']} |\text{cov}(T'_i)| \leq \lambda$, $V(T'_i) \cap R \neq \phi$ and $\ell(T'_i) \leq \beta T^\star$, where $\beta = \mathcal{O}(1)$.*

Proof. Similar to Section 2, we focus on one of the connected components, say G' obtained after deleting all edges of length larger than $T^\star$. Let $R' = \{r_1, r_2, \cdots, r_{k'}\}$ be the subset of roots belonging to this component. There exists a partition of $V' - R'$ into k' trees, each covering at most $\lambda - 1$ vertices and cost no more than $T^\star$. Using Theorem 5, we first compute subtrees of G' , $T_1, \ldots, T_{k'}$, such that $|\text{cov}(T'_i)| \leq \lambda - 1$ and cost is $\mathcal{O}(T^\star)$. We construct a bipartite graph $H' = (\mathcal{T} \cup R', E')$, where $\mathcal{T}$ contains a vertex corresponding to each tree $T'_j, j = 1, 2, \cdots, k'$. We shall abuse notations slightly and interchangeably use T'_j to denote the vertex in $\mathcal{T}$ corresponding to the tree T'_j and the actual tree itself, noting the difference

wherever necessary. $(r_i, T'_j) \in E'$ if and only if $d(r_i, T'_j) \leq T^\star$. If there exists a matching in H' such that all vertices of $\mathcal{T}$ are matched, we add the matching root vertex to T'_j. This increases the cost of a component by at most $T^\star$. Now each component contains at least one root vertex, covers at most λ vertices and costs $\mathcal{O}(T^\star)$. If all the vertices of $\mathcal{T}$ cannot be matched, there exists a set $S \subseteq T$ such that $|N(S)| < |S|$. Let $V(S) = \cup_{T'_j \in S} V(T'_j)$. In optimal solution, every vertex of $V(S)$ is contained in a tree with one of the vertices in $N(S)$ as its root. Hence, there exists $|N(S)|$ trees such that each tree covers at most $\lambda - 1$ points of $V(S)$, costs no more than $4T^\star$ and union of all the trees cover $V(S)$. We use the result of Theorem 5 to get at most $|N(S)|$ trees covering $V(S)$, such that each tree covers at most $\lambda - 1$ vertices and costs $\mathcal{O}(T^\star)$. Note that this procedure is similar to **IterRefine** defined earlier. We now have a new set of trees. We modify our bipartite graph H' by removing vertices corresponding to trees in S and replacing them by vertices corresponding to newly formed trees. We modify E' suitably. If there exists a matching in the new graph, we are done, otherwise we repeat the above procedure till we find a perfect matching. Note that the size (in terms of number of vertices) of H' decreases by at least $|S| - |N(S)| \geq 1$ after every step and hence will halt in at most k' steps. ◀

4 Conclusion

In this paper, we give the first constant factor approximation algorithms for the hard uniform capacitated versions of unrooted and rooted Min Max Tree Cover problem on a weighted graph. Our main technical contribution lies is devising an iterative refinement procedure that distributes vertices as evenly as possible among the different trees in the cover, without incurring too much cost.

Our current approximation factor is large (> 250) and although we did not attempt to optimize, it is unlikely that our approach can reduce the factor to a very small constant. Such a result requires new ideas. Perhaps somewhat surprisingly, no LPs with constant integrality gap is known, even for the uncapacitated problem. We leave open the question of finding such an LP, in particular, configuration-style LPs, which can possibly lead to a small approximation ratio. On the other hand, the only known hardness result, to the best of our knowledge, follows from the hardness of the uncapacitated version [20]. It would be interesting to prove a better lower bound for the capacitated case, if possible.

As mentioned in Section 1, there is a PTAS known for the uncapacitated rooted MMTC problem on a tree metric. We conclude with our second open question of proving a PTAS for the hard capacitated version of the same.

Abstract

Given a matrix A and $k \geq 0$, we study the problem of finding the $k \times k$ submatrix of A with the maximum determinant in absolute value. This problem is motivated by the question of computing the determinant-based lower bound of Lovász et al. [11] on hereditary discrepancy, which was later shown to be an approximate upper bound as well [14]. The special case where k coincides with one of the dimensions of A has been extensively studied. Nikolov [17] gave a $2^{O(k)}$-approximation algorithm for this special case, matching known lower bounds; he also raised as an open problem the question of designing approximation algorithms for the general case.

We make progress towards answering this question by giving the first efficient approximation algorithm for general $k \times k$ subdeterminant maximization with an approximation ratio that depends only on k. Our algorithm finds a $k^{O(k)}$-approximate solution by performing a simple local search. Our main technical contribution, enabling the analysis of the approximation ratio, is an extension of Plücker relations for the Grassmannian, which may be of independent interest; Plücker relations are quadratic polynomial equations involving the set of $k \times k$ subdeterminants of a $k \times n$ matrix. We find an extension of these relations to $k \times k$ subdeterminants of general $m \times n$ matrices.

Acknowledgements We would like to thank Aleksandar Nikolov for initial discussions about general subdeterminant maximization.

1 Introduction

We consider the problem of finding the $k \times k$ submatrix of a given $m \times n$ matrix A that has the largest determinant in absolute value:

$$\operatorname{maxdet}_k(A) := \max\left\{ |\det(A_{I,J})| \;\middle|\; I \in \binom{[m]}{k}, J \in \binom{[n]}{k} \right\}.$$

A well-studied special case of this problem asks to find the maximum absolute determinant of a *maximal* submatrix. In other words, k is set to $\min\{m, n\}$. This special case is known in the literature as the largest volume simplex problem or simply (sub)determinant maximization [10, 4, 17], and it was originally framed as the problem of finding a largest simplex in

a convex body, a simplex-based analog of the John ellipsoid. The best approximation algorithm for when $k = \min\{m, n\}$ was obtained by Nikolov [17] who gave an efficient $2^{O(k)}$-approximation algorithm, improving upon $\log(k)^{O(k)}$-approximation of [4], and the earlier $k^{O(k)}$-approximation of [10], and also matching known lower bounds [4].

More recently, a line of work has studied various generalizations of the largest volume simplex problem, where the returned indices of the submatrix are required to satisfy a matroid constraint [18, 2, 22, 6, 3, 12]. This line of work led to fruitful applications in several problems in combinatorial optimization: experimental design, network design, fair allocation, column subset selection, and more (see [12] for the history and applications).

Despite the extensive study of variants of the special case $k = \min\{m, n\}$, little has been done for the general case where $k < \min\{m, n\}$. A key motivation behind studying the general case comes from discrepancy theory, namely the problem of computing the determinant lower bound on hereditary discrepancy, due to Lovász et al. [11]. This quantity is defined formally as

$$\operatorname{detlb}(A) := \max\left\{ \sqrt[k]{\operatorname{maxdet}_k(A)} \;\middle|\; k \geq 0 \right\}.$$

Matoušek [14] showed, by completing earlier results of Lovász et al. [11], that $\operatorname{detlb}(A)$ is a polylogarithmic approximation to the hereditary discrepancy of A. This raised the question of efficiently approximating $\operatorname{detlb}(A)$. Nikolov and Talwar [19] showed how to approximately compute the hereditary discrepancy by bypassing $\operatorname{detlb}(A)$ and instead computing a quantity known as $\gamma_2(A)$; they showed that $\gamma_2(A)$ is a logarithmic approximation of $\operatorname{detlb}(A)$ [15] and a polylogarithmic approximation of hereditary discrepancy. But efficient $O(1)$-approximation of detlb remains open. Nikolov [17] who obtained the best approximation algorithm for the largest volume simplex problem, posed this as an open problem. Such a result has the potential to improve the approximation factor for hereditary discrepancy, as the worst known gap between detlb and hereditary discrepancy is only logarithmic [21, 14].

As a step towards answering this question, we show how to approximate $\operatorname{maxdet}_k(A)$ efficiently, with an approximation factor that depends only on k.

▶ **Theorem 1.** *There is a polynomial time algorithm that on input $A \in \mathbb{R}^{m \times n}$, outputs sets of indices $I \in \binom{[m]}{k}$ and $J \in \binom{[n]}{k}$ guaranteeing*

$$k^{O(k)} \cdot |\det(A_{I,J})| \geq \operatorname{maxdet}_k(A).$$

To the best of our knowledge, this is the first nontrivial approximation algorithm for maxdet_k. Our algorithm is based on a simple local search procedure, where in each iteration indices of *up to two* rows and/or columns are replaced by new ones, until an approximate local maximum is found.

Local search and greedy algorithms have been studied for the related problems of largest volume simplex, D-optimal design, and maximum a posteriori inference in (constrained) determinantal point processes [7, 9, 13, 8]. A key difference in our work, compared to prior works, is that we need to allow *two changes* per iteration. It is easy to construct examples where replacing only one row or one column at a time can get us stuck in an arbitrarily bad local optimum. For example, consider a diagonal matrix:

$$A := \begin{bmatrix} d_1 & 0 & \dots & 0 \\ 0 & d_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & d_n \end{bmatrix}$$

Any principal $k \times k$ submatrix is a local optimum. Changing any row or column results in a 0 determinant. But obviously, d_is can be planted in a way that some of the local optima become arbitrarily bad. On the other hand, allowing simultaneous change of a row and a column lets us move between various subsets of d_is, and escape the bad local optima.

1.1 Techniques

Despite the simplicity of applying local search to combinatorial optimization problems, it is often difficult to prove approximation guarantees for its performance. We take a page from the study of matroids and discrete convexity [16], and prove a quantitative exchange inequality for subdeterminants. We will formally show that if (I, J) and (I^*, J^*) are two sets of indices determining $k \times k$ submatrices, one can swap at most two elements in total between I and I^*, and J and J^*, and obtain

$$|\det(A_{I,J})| \cdot |\det(A_{I^*,J^*})| \leq k^{O(1)} \cdot |\det(A_{I\Delta dI, J\Delta dJ})| \cdot |\det(A_{I^*\Delta dI, J\Delta dJ})| \tag{1}$$

for $dI \subseteq I\Delta I^*, dJ \subseteq J\Delta J^*$ of total size $|dI| + |dJ| \in \{2, 4\}$. This can be viewed as a form of discrete log-concavity for the determinant function on submatrices, and allows us to bound the approximation ratio of a local maximum.

Exchange properties have a long history in the theory of matroids, valuated matroids, and M-concavity [16]. Besides their use in proving the performance of greedy and local search algorithms for optimization problems, they have also recently found applications in sampling problems [1].

In order to prove the exchange inequality, we find an extension of Plücker relations to $k \times k$ subdeterminants of $m \times n$ matrices. The relations are in the form of an identity expressing the l.h.s. of Equation (1) as a linear combination of the possible values, for different choices of dI, dJ on the r.h.s. Classical Plücker relations establish exactly this form of identity in the case of $k = \min\{m, n\}$, and have been known to be connected to variants of matroids and exchange properties [5], although not quantitative exchanges of the approximate multiplicative type. Our key technical contribution is the establishment of a variant of these identities when $k < \min\{m, n\}$.

Several variants of Plücker relations have been studied in the literature. For example Dress and Wenzel [5] extended the Plücker relations to Pfaffians of skew-symmetric matrices. Their extension involves submatrices of varying sizes, and does not immediately yield a relationship involving just $k \times k$ submatrices. Both our approximate exchange inequality, and our extension of Plücker relations appear to be novel and might be of independent interest.

2 Preliminaries

We use the notation $[n] = \{1, \ldots, n\}$ for integers n. We denote the family of subsets of size k from $[n]$ by $\binom{[n]}{k}$. We use $S\Delta T = (S \setminus T) \cup (T \setminus S)$ to denote the symmetric set difference between S and T. When m, n, k are clear from context, we denote by $\mathcal{I}$ the family of valid submatrix index pairs for $k \times k$ submatrices

$$\mathcal{I} := \binom{[m]}{k} \times \binom{[n]}{k}.$$

For a pair $S = (S_{\text{row}}, S_{\text{col}}) \in \mathcal{I}$, and a matrix $A \in \mathbb{R}^{m \times n}$, we denote by $A_S = A_{S_{\text{row}}, S_{\text{col}}}$ the submatrix of A with rows and columns indexed by $S_{\text{row}}, S_{\text{col}}$ respectively. We extend set operations, such as Δ to pairs of sets denoting row and column indices in the natural way.

For example for $S = (S_{\text{row}}, S_{\text{col}})$ and $U = (U_{\text{row}}, U_{\text{col}})$ we let $S\Delta U = (S_{\text{row}}\Delta U_{\text{row}}, S_{\text{col}}\Delta U_{\text{col}})$. Similarly we let $|S| = |S_{\text{row}}| + |S_{\text{col}}|$. The reader might wish to think of pairs of row and column index sets as one single set, with the caveat that row indices are distinguished from column indices.

Throughout the paper, we keep the input matrix $A \in \mathbb{R}^{m\times n}$ for subdeterminant maximization fixed. We also assume, w.l.o.g. that $m \leq n$. For $S = (S_{\text{row}}, S_{\text{col}}) \in \mathcal{I}$, we use $[S] = [S_{\text{row}}, S_{\text{col}}]$ and $[A_S] = [A_{S_{\text{row}},S_{\text{col}}}]$, interchangeably as a shorthand for $\det(A_S) = \det(A_{S_{\text{row}},S_{\text{col}}})$.

In Section 6, we use the following famous formula for determinants of rectangular matrix products.

▶ **Fact 2** (Cauchy-Binet Formula). *Let $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{n\times m}$. Then*

$$\det(AB) = \sum_{S\in\binom{[n]}{m}} \det(A_{[m],S}) \det(B_{S,[m]}).$$

For indices $S = (S_{\text{row}}, S_{\text{col}}), T = (T_{\text{row}}, T_{\text{col}}) \in \mathcal{I}$, let

$$d(S,T) := |S\Delta T|/2 = |S_{\text{row}}\Delta T_{\text{row}}|/2 + |S_{\text{col}}\Delta T_{\text{col}}|/2$$

be the *distance* between S and T.

Armed with this distance, we can define the neighborhoods of a submatrix indexed by $S \in \mathcal{I}$:

▶ **Definition 3.** *For $r \geq 0$ let the r-neighborhood of $S \in \mathcal{I}$ be*

$$\mathcal{N}_r(S) := \{T \in \mathcal{I} \mid d(S,T) \leq r\}.$$

3 Subdeterminant Maximization via Local Search

In this section we prove our main result, Theorem 1. Our strategy is to use a simple local search that starts with a submatrix indexed by $S \in \mathcal{I}$, and myopically finds better and better solutions by searching 2-neighborhoods until no more improvement can be found.

To make sure that our algorithm terminates within polynomial time, we will only take improvements that increase the magnitude of the determinant by at least a lower multiplicative threshold; for our purposes, even a factor 2 improvement works. We will then show how to find a good *start*, needed to bound the number of local search steps, by bootstrapping with the help of a crude approximation algorithm.

We will find a locally approximately maximum solution as defined below.

▶ **Definition 4.** *For $\alpha > 0$, we say $S \in \mathcal{I}$ is an (r,α)-local maximum if*

$$|\det(A_S)| \geq \alpha|\det(A_T)|$$

for all $T \in \mathcal{N}_r(S)$.

Algorithm 1 finds this locally approximate maximum. It starts with some arbitrary solution $S_0 \in \mathcal{I}$, and iteratively finds α-factor improvements within the 2-neighborhood, until no more improvement can be found.

It is immediate to see that when Algorithm 1 terminates, the output is a (r,α)-local maximum.

▶ **Proposition 5.** *The output of Algorithm 1 is a $(2,\alpha)$-local maximum.*

Algorithm 1 α-Local Search.

Let $S \leftarrow S_0$
while *there is* $T \in \mathcal{N}_2(S)$ *such that* $\alpha|\det(A_T)| > |\det(A_S)|$ **do**
  Let $S \leftarrow T$
end
Output $S = (S_{\text{row}}, S_{\text{col}})$

The most challenging part of local search algorithms is proving that local (approximate) optimality implies global (approximate) optimality. We appeal to approximate exchange properties that we prove for $k \times k$ subdeterminants, and show the following statement in Section 4.

▶ **Lemma 6.** *Suppose that $S \in \mathcal{I}$ is a $(2, \alpha)$-local maximum. Then S is a $(k/\alpha)^{O(k)}$-approximate global optimum:*

$$(k/\alpha)^{O(k)} \cdot |\det(A_S)| \geq \text{maxdet}_k(A).$$

We prove the remaining part of Theorem 1, that with a suitable choice for S_0, Algorithm 1 runs in polynomial time.

▶ **Proposition 7.** *The number of steps taken by Algorithm 1 starting from S_0 is at most*

$$\log_{1/\alpha}\left(\frac{\text{maxdet}_k(A)}{|\det(A_{S_0})|}\right).$$

Proof. Each iteration improves $|\det(A_S)|$ by a factor of $1/\alpha$. On the other hand, this value can never exceed $\text{maxdet}_k(A)$, and it starts as $|\det(A_{S_0})|$. ◀

In Section 6, we show how to obtain a good S_0 by a crude algorithm, that appeals to known results for the case of $k = \min\{m, n\}$. We will formally show the following.

▶ **Lemma 8.** *There is a polynomial time algorithm that returns S_0 with*

$$(n+m)^{O(k)} \cdot |\det(A_{S_0})| \geq \text{maxdet}_k(A).$$

Having all the ingredients for Theorem 1, we finish its proof.

Proof of Theorem 1. We set α to be some constant below 1, say $1/2$. We first apply Lemma 8 to obtain a good starting point S_0. If $\det(A_{S_0}) = 0$, then $\text{maxdet}_k(A) = 0$, and there is nothing to be done. Otherwise, we run Algorithm 1 with $\alpha = 1/2$. The output of the algorithm, S, is a $(2, 1/2)$-local maximum, which by Lemma 6, is a $(2k)^{O(k)} = k^{O(k)}$-approximate solution.

Each iteration of Algorithm 1 clearly runs in polynomial time, since $\mathcal{N}_2(S)$ has at most $O(k^2(m+n)^2)$ elements. So we just need to bound the number of iterations. But by Lemma 8 and Proposition 7, the number of steps is at most

$$\log\Big((n+m)^{O(k)}\Big) = O(k \log(m+n)).$$ ◀

▶ Remark 9. The approximation factor of $k^{O(k)}$ is the best possible for local search, even when we consider (c, α)-local maxima for any constant number of row/column swaps $c \in \mathbb{Z}_{>0}$. This is true even for the special case of $k = \min\{m, n\}$. To see why, consider the $\text{maxdet}_k(A)$ problem on input $A \in \mathbb{R}^{k \times 2k}$ defined by the block form

$$A = \begin{bmatrix} I_k & c^{-\frac{1}{2}} H_k \end{bmatrix}$$

where $H_k \in \mathbb{R}^{k\times k}$ is the Hadamard matrix, a matrix with ± 1 entries whose columns are orthogonal to each other. Observe that $A_{[k],[k]} = I_k$ is a $(c,1)$-local maximum, since for any $(I,J) \in \mathcal{N}_c([k],[k])$, after rearranging rows and columns, we can write

$$|\det(A_{I,J})| = \left|\det \begin{bmatrix} I_{k-c} & \star \\ 0 & c^{-\frac{1}{2}}D \end{bmatrix}\right| = |\det(c^{-\frac{1}{2}}D)| \le 1,$$

where $D \in \{\pm 1\}^{c\times c}$, and $|\det(D)| \le c^{\frac{c}{2}}$ by the Hadamard inequality. However the global optimum is achieved by the Hadamard matrix part of A. Letting $J^* = \{k+1, \cdots, 2k\}$,

$$\left|\det(A_{[n],J^*})\right| = \left|\det(c^{-\frac{1}{2}}H_k)\right| = \left(\frac{k}{c}\right)^{\frac{k}{2}} \left|\det(A_{[k],[k]})\right|.$$

In other words, the local optimum is worse than the global optimum by a factor of $(k/c)^{k/2}$.

4 Approximate Exchange and Local to Global Optimality

Here we prove Lemma 6. Our main tool will be an exchange property, that we state below. First we define the notion of an r-exchange.

▶ **Definition 10.** *Let $S,T \in \mathcal{I}$ denote two submatrices. We call $U = (U_{\text{row}}, U_{\text{col}})$ an r-exchange between S and T, if $S\Delta U$ and $T\Delta U$ are still indices of $k\times k$ submatrices, $U \subseteq S\Delta T$, and $|U| = 2r$. Note that U simply represents the exchange of r pairs of rows and/or columns between S and T. We denote by $\mathcal{E}(S,T)$, the set of all 1-exchanges and 2-exchanges between S and T.*

Now we are ready to state the key ingredient for proving local to global optimality.

▶ **Theorem 11** (Exchange Property)**.** *Let $S,T \in \mathcal{I}$ be indices of two $k\times k$ submatrices, and assume that $S \neq T$. Then*

$$|\det(A_S)| \cdot |\det(A_T)| \le O(k^2) \max\{|\det(A_{S\Delta U})| \cdot |\det(A_{T\Delta U})| \mid U \in \mathcal{E}(S,T)\}.$$

Note that Theorem 11 can be thought of a form of discrete log-concavity for subdeterminants. Starting from submatrices S,T, we move to two "nearby" submatrices $S\Delta U$ and $T\Delta U$ that are closer to T and S respectively, and then we get that up to some error terms, the average log of the determinant goes up.

We will prove Theorem 11 in Section 5 by appealing to a new extension of Plücker relations, which is an identity between subdeterminants. Here we show how to leverage Theorem 11 to show global approximate optimality from local approximate optimality. Our strategy is to start from S being the locally optimal solution and T being the globally optimal solution, and to gradually move from T to S, accumulating at most a $(k/\alpha)^{O(k)}$ loss.

Proof of Lemma 6 using Theorem 11. Let $S \in \mathcal{I}$ be a $(2,\alpha)$-local maximum and let $L \in \mathcal{I}$ be the indices of a submatrix that has the highest subdeterminant in magnitude. We first prove the following claim.

▷ Claim 12. For any $T \in \mathcal{I}$, there exists $W \in \mathcal{I}$ such that $d(S,W) \le \max(0, d(S,T)-1)$ and

$$|\det(A_T)| \le O(k^2/\alpha) \cdot |\det(A_W)|.$$

Proof of Claim 12. If $T = S$ then the claim is trivially true, since we can take $W = S$. Assume $T \neq S$. By Theorem 11, there exists $U \in \mathcal{E}(S,T)$ such that

$$\begin{aligned}|\det(A_S)| \cdot |\det(A_T)| &\leq O(k^2) \cdot |\det(A_{S\Delta U})| \cdot |\det(A_{T\Delta U})| \\ &\leq O(k^2) \cdot \frac{|\det(A_S)|}{\alpha} \cdot |\det(A_{T\Delta U})|\end{aligned}$$

where the last inequality follows from the definition of $(2,\alpha)$-local maximum.

Setting $W = T\Delta U$ and dividing both sides by $|\det(A_S)|$ gives the desired inequality. ◁

Note that initially $d(S,L) \leq 2k$. We can iteratively apply Claim 12 for up to $2k$ times, and obtain $W \in \mathcal{I}$ such that $|\det(A_L)| \leq O(k^2/\alpha)^{2k}|\det(A_W)|$ and

$$d(S,W) \leq \max(0, d(S,L) - 2k) = 0.$$

The latter condition implies $S = W$, and we are done. ◀

5 An Extension of Plücker Relations

In this section, we prove Theorem 11 by proving an extension of the Plücker relations. These are identities relating the $k \times k$ subdeterminants of a matrix. Theorem 11 will be derived from applying the triangle inequality to these identities.

To give some intuition, let us demonstrate why the regular Plücker relations, imply an exchange property when $k = \min\{m,n\}$;

5.1 Regular Plücker Relations and Exchange

W.l.o.g., let us take $k = m$ and assume $n \geq m$. Given any subsets $S,T \in \binom{[n]}{m}$, the classical Plücker relation (see, e.g., [5]) states that, for any fixed $j \in T \setminus S$

$$\det(A_{[m],S}) \det(A_{[m],T}) = \sum_{i \in S \setminus T} \delta^i_j \det(A_{[m],S\Delta\{i,j\}}) \cdot \det(A_{[m],T\Delta\{i,j\}}),$$

where $\delta^i_j \in \{\pm 1\}$ is a sign determined by the indices i and j. The triangle inequality then implies the following exchange property

$$\begin{aligned}&|\det(A_{[m],S})| \cdot |\det(A_{[m],T})| \leq \\ &\qquad k \cdot \max\big\{|\det(A_{[m],S\Delta\{i,j\}})| \cdot |\det(A_{[m],T\Delta\{i,j\}})| \;\big|\; i \in S \setminus T, j \in T \setminus S\big\}.\end{aligned}$$

This is an analog of Theorem 11, but with just one exchange between S and T. As we saw before, we cannot hope for just *one exchange* in the general case of $k < \min\{m,n\}$. But we manage to prove an extended form of Plücker relations and, by appealing to the triangle inequality, prove Theorem 11.

5.2 Extended Plücker Relations

In this subsection, we state and prove a "two-dimensional" extension of Plücker relations. In trying to find this relationship, we did a bit of guesswork; we knew we were looking for an identity involving only neighbors of the submatrices S and T, to make sure we can extract an exchange inequality. By running computer algebra systems on small values of k, we discovered the correct form of the identity, and then proceeded to prove it.

Consider $S = (S_{\text{row}}, S_{\text{col}}), T = (T_{\text{row}}, T_{\text{col}}) \in \mathcal{I}$. Note that only the entries in $A_{S\cup T}$ matter and that permuting the rows and/or columns in $S \cup T$ will preserve determinants of $k \times k$ minors up to sign.

We first show a Plücker relation for the case when S and T are disjoint, i.e., $S_{\text{row}} \cap T_{\text{row}} = S_{\text{col}} \cap T_{\text{col}} = \emptyset$. W.l.o.g., we can assume that

$$S_{\text{row}} = S_{\text{col}} = \{1, \ldots, k\} \quad \text{and} \quad T_{\text{row}} = T_{\text{col}} = \{k+1, \cdots, 2k\}, \tag{2}$$

and that A has the following block form:

$$A = \left[\begin{array}{c|c} C & V \\ \hline U & D \end{array}\right].$$

Note that $A_S = C$ and $A_T = D$.

We adopt a few notations for this section.

- We use $[U_{\text{row}}, U_{\text{col}}]$ to denote $\det(A_{U_{\text{row}}, U_{\text{col}}})$.
- Matrix entries are denoted by lowercase letter. Submatrices are denoted by uppercase letter. For example, we denote entries of submatrix C by $c_{i,j}$ for $i \in S_{\text{row}}, j \in S_{\text{col}}$.
- For a set L and $i \in L$ we use $L - i$ and L^{-i} as short hand for $L \setminus \{i\}$. Let $r_L(i)$ denote the rank of i in L, i.e., the number of $i' \in L$ that are smaller than i.
- For $U_{\text{row}} \subseteq S_{\text{row}} \Delta T_{\text{row}}, U_{\text{col}} \subseteq S_{\text{col}} \Delta T_{\text{col}}$, let $\delta^U = (-1)^{\sum_{i\in U_{\text{row}}} r_*(i) + \sum_{j \in U_{\text{col}}} r_*(j)}$, where, with some abuse of notation we use r_* for both row indices and column indices, and let

$$r_*(i) = \begin{cases} r_{S_{\text{row}}}(i) \text{ if } i \in S_{\text{row}} \\ r_{T_{\text{row}}}(i) \text{ if } i \in T_{\text{row}} \end{cases}, \quad r_*(j) = \begin{cases} r_{S_{\text{col}}}(j) \text{ if } j \in S_{\text{col}} \\ r_{T_{\text{col}}}(j) \text{ if } j \in T_{\text{col}} \end{cases}.$$

▶ **Lemma 13** (Extended Plücker Relation in the Disjoint Case). *Consider $S = (S_{\text{row}}, S_{\text{col}}), T = (T_{\text{row}}, T_{\text{col}})$ as in Equation (2).*

Let $\Omega := (S, T)$. Define

$$\begin{aligned} s_1(\Omega) &= \sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} [S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}\Delta\{j,j'\}] \times [T_{\text{row}}\Delta\{i,i'\}, T_{\text{col}}\Delta\{j,j'\}] \\ s_2(\Omega) &= (-1)^k \sum_{i,i'} \delta^{\{i,i'\},\emptyset} [S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}] \times [T_{\text{row}}\Delta\{i,i'\}, T_{\text{col}}] \\ s_3(\Omega) &= \sum_{i<h,i'<h'} \delta^{\{i,i',h,h'\},\emptyset} [S_{\text{row}}\Delta\{i,h,i',h'\}, S_{\text{col}}] \times [T_{\text{row}}\Delta\{i,h,i',h'\}, T_{\text{col}}], \end{aligned} \tag{3}$$

where in above summations, $i, h \in S_{\text{row}}, i', h' \in T_{\text{row}}, j \in S_{\text{col}}, j' \in T_{\text{col}}$.

Let $s_i := s_i(\Omega)$. Then, we have the following relation

$$s_1 - 2(k-1)s_2 - 4s_3 - k^2[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] = 0 \tag{4}$$

The proof is elementary; we only use well-known identities about the determinant and perform some algebraic manipulation.

Proof of Lemma 13. Expanding $[S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}\Delta\{j,j'\}]$ along row i', we get:

$$\begin{aligned} &[S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}\Delta\{j,j'\}] = \\ &\qquad d_{i',j'}[S_{\text{row}} - i, S_{\text{col}} - j] + \sum_{\ell \in S_{\text{col}} \setminus \{j\}} (-1)^{k + r_{S_{\text{col}}^{-j}}(\ell)} u_{i',\ell}[S_{\text{row}} - i, S_{\text{col}} - j - \ell + j']. \end{aligned}$$

Expanding $[S_{\text{row}} - i, S_{\text{col}} - j - \ell + j']$ along column j', we get:

$$[S_{\text{row}} - i, S_{\text{col}} - j - \ell + j'] = \sum_{h \in S_{\text{row}} \setminus \{i\}} (-1)^{k-1+r_{S_{\text{row}}^{-i}}(h)} v_{k,j'}[S_{\text{row}} - i - h, S_{\text{col}} - j - \ell].$$

Thus

$$[S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}\Delta\{j,j'\}] =$$
$$d_{i',j'}[S_{\text{row}} - i, S_{\text{col}} - j] - \sum_{h,\ell} (-1)^{r_{S_{\text{row}}^{-i}}(h) + r_{S_{\text{col}}^{-j}}(\ell)} u_{i',\ell} v_{k,j'}[S_{\text{row}} - i - h, S_{\text{col}} - j - \ell].$$

Similarly,

$$[T_{\text{row}}\Delta\{i,i'\}, T_{\text{col}}\Delta\{j,j'\}] =$$
$$c_{i,j}[T_{\text{row}} - i', T_{\text{col}} - j'] - \sum_{h',\ell'} (-1)^{r_{T_{\text{row}}^{-i'}}(h') + r_{T_{\text{col}}^{-j'}}(\ell')} v_{i,\ell'} u_{h',j}[T_{\text{row}} - i' - h', T_{\text{col}} - j' - \ell']$$

Now, consider $[S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}\Delta\{j,j'\}] \times [T_{\text{row}}\Delta\{i,i'\}, T_{\text{col}}\Delta\{j,j'\}]$ as a multivariate polynomial p in variables $\vec{u} = \{u_{\cdot,\cdot}\}, \vec{v} = \{v_{\cdot,\cdot}\}$. For $s \in \{0,1,2\}$ let $p_s^{i,i',j,j'}$ denote the sum over monomials of p which have degree s in $\vec{u}$ and in $\vec{v}$. We will omit the superscript when appropriate.

We further decompose p_1 into $p_1 = -(p_{1A} + p_{1B})$, where

$$p_{1A} = \sum_{h,\ell} (-1)^{r_{S_{\text{row}}^{-i}}(h) + r_{S_{\text{col}}^{-j}}(\ell)} c_{i,j}[T_{\text{row}} - i', T_{\text{col}} - j'] u_{i',\ell} v_{h,j'}[S_{\text{row}} - i - h, S_{\text{col}} - j - \ell],$$

and

$$p_{1B} = \sum_{h',\ell'} (-1)^{r_{T_{\text{row}}^{-i'}}(h') + r_{T_{\text{col}}^{-j'}}(\ell')} d_{i',j'}[S_{\text{row}} - i, S_{\text{col}} - j] v_{i,\ell'} u_{h',j}[T_{\text{row}} - i' - h', T_{\text{col}} - j' - \ell'].$$

▷ Claim 14. We have

$$\sum \delta^{\{i,i'\},\{j,j'\}} p_1^{i,i',j,j'} = 2(k-1)(-1)^k \sum_{h,i'} (-1)^{h+i'} [S_{\text{row}} - h + i', S_{\text{col}}] \cdot [T_{\text{row}} - i' + h, T_{\text{col}}] \quad (5)$$

Proof. In $\sum_{i,j} \delta^{\{i,i'\},\{j,j'\}} p_{1A}^{i,i',j,j'}$ we consider the sum of all terms with the same i', j', h, l. Note that $r_{S_{\text{col}}^{-j}}(\ell) + r_{S_{\text{col}}}(j) = r_{S_{\text{col}}}(\ell) + r_{S_{\text{col}}^{-\ell}}(j) + 1 \mod 2$. This is because,

$$r_{S_{\text{col}}^{-j}}(\ell) = \begin{cases} r_{S_{\text{col}}}(\ell) \text{ if } \ell < j \\ r_{S_{\text{col}}}(\ell) - 1 \text{ if } \ell > j \end{cases} \quad \text{and } r_{S_{\text{col}}^{-\ell}}(j) = \begin{cases} r_{S_{\text{col}}}(j) - 1 \text{ if } \ell < j \\ r_{S_{\text{col}}}(j) \text{ if } \ell > j \end{cases}.$$

Similarly, $r_{S_{\text{row}}^{-i}}(h) + r_{S_{\text{row}}}(i) = r_{S_{\text{row}}}(h) + r_{S_{\text{row}}^{-h}}(i) + 1 \mod 2$. Thus, this sum is exactly,

$$\delta^{\{i',h\},\{j',\ell\}} u_{i',\ell} v_{h,j'}[T_{\text{row}} - i', T_{\text{col}} - j'] \times$$
$$\sum_{i \neq h, j \neq \ell} (-1)^{r_{S_{\text{col}}^{-\ell}}(j) + r_{S_{\text{row}}^{-h}}(i)} c_{i,j}[S_{\text{row}} - i - h, S_{\text{col}} - j - \ell] =$$
$$(k-1)\delta^{\{i',h\},\{j',\ell\}} u_{i',\ell} v_{h,j'}[T_{\text{row}} - i', T_{\text{col}} - j'][S_{\text{row}} - h, S_{\text{col}} - \ell],$$

Indeed, for each $i \in S_{\text{row}} - h$, expanding $[S_{\text{row}} - h, S_{\text{col}} - \ell]$ along row i gives

$$\sum_{j \neq \ell} (-1)^{r_{S_{\text{col}}^{-\ell}}(j) + r_{S_{\text{row}}^{-h}}(i)} c_{i,j}[S_{\text{row}} - i - h, S_{\text{col}} - j - \ell].$$

Taking sum over $i \in S_{\text{row}} - h$ gives the above equality.

Thus

$$\begin{aligned}
&\sum \delta^{\{i,i'\},\{j,j'\}} p_{1A}^{i,i',j,j'} \\
&= (k-1) \sum_{i',j',h,\ell} \delta^{\{i',h\},\{j',\ell\}} u_{i',\ell} v_{h,j'} [T_{\text{row}} - i', T_{\text{col}} - j'][S_{\text{row}} - h, S_{\text{col}} - \ell] \\
&= -(k-1)(-1)^k \sum_{h,i'} \delta^{\{i',h\},\emptyset} \Big((\sum_{\ell} (-1)^{h + r_{S_{\text{col}}}(\ell)} u_{i',\ell} [S_{\text{row}} - h, S_{\text{col}} - \ell]) \times \\
&\quad (\sum_{j'} (-1)^{1 + r_{T_{\text{col}}}(j')} v_{h,j'} [T_{\text{row}} - i', T_{\text{col}} - j']) \Big) \\
&= -(k-1)(-1)^k \sum_{h,i'} \delta^{\{i',h\},\emptyset} [S_{\text{row}} - h + i', S_{\text{col}}][T_{\text{row}} - i' + h, T_{\text{col}}]
\end{aligned}$$

Similarly,

$$\sum p_{1B} = -(k-1)(-1)^k \sum_{i,h'} \delta^{\{i',h\}} [S_{\text{row}} - i + h', S_{\text{col}}][T_{\text{row}} - h' + i, T_{\text{col}}] \qquad \lhd$$

Next, we show

▷ Claim 15.

$$\sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} p_2^{i,i',j,j'} = 4 \sum_{i<h,i'<h'} [S_{\text{row}} - i - h + i' + h', S_{\text{col}}][T_{\text{row}} - i' - h' + i + h, T_{\text{col}}] \quad (6)$$

Proof. Recall that $p_2^{i,i',j,j'}$ equals

$$\sum_{h,\ell,h',\ell'} (-1)^{\omega(h,h',\ell,\ell')} u_{i',\ell} v_{i,\ell'} v_{h,j'} u_{h',j} [S_{\text{row}} \setminus \{i,h\}, S_{\text{col}} \setminus \{j,\ell\}][T_{\text{row}} \setminus \{i',h'\}, T_{\text{col}} \setminus \{j',\ell'\}],$$

where $\omega(h,h',\ell,\ell') = r_{S_{\text{row}}^{-i}}(h) + r_{S_{\text{col}}^{-j}}(\ell) + r_{T_{\text{row}}^{-i'}}(h') + r_{T_{\text{col}}^{-j'}}(\ell')$. Taking sum and rearranging terms, we have

$$\sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} p_2^{i,i',j,j'} = \sum_{i,i',h,h'} (-1)^{r_{S_{\text{row}}}(i) + r_{T_{\text{row}}}(i') + r_{S_{\text{row}}^{-i}}(h) + r_{T_{\text{row}}^{-i'}}(h')} X_{i,i',h,h'} \times Y_{i,i',h,h'}$$

where

$$\begin{aligned}
X_{i,i',h,h'} &= \sum_{j,\ell} (-1)^{r_{S_{\text{col}}^{-j}}(\ell) + r_{S_{\text{col}}}(j)} u_{i',\ell} u_{h',j} [S_{\text{row}} - i - h, S_{\text{col}} - j - \ell] \\
Y_{i,i',h,h'} &= \sum_{j',\ell'} (-1)^{r_{T_{\text{col}}^{-j'}}(\ell') + r_{T_{\text{col}}}(j')} v_{i,\ell'} v_{h,j'} [T_{\text{row}} - i' - h', T_{\text{col}} - j' - \ell']
\end{aligned}$$

Expanding $[S_{\text{row}} - i - h + i' + h', S_{\text{col}}]$ along row h' then i', we get that $[S_{\text{row}} \Delta \{i, i', h, h'\}, S_{\text{col}}]$

$$\begin{aligned}
&= \sum_{j} (-1)^{r_{S_{\text{col}}}(j) + k + \mathbb{1}\{i' > h'\}} u_{h',j} [S_{\text{row}} - i - h + i', S_{\text{col}} - j] \\
&= \sum_{j,\ell} (-1)^{r_{S_{\text{col}}}(j) + k + \mathbb{1}\{i' > h'\}} (-1)^{r_{S_{\text{col}}^{-j}}(\ell) + k - 1} u_{i',\ell} u_{h',j} [S_{\text{row}} - i - h, S_{\text{col}} - j - \ell] \\
&= (-1)^{\mathbb{1}\{i' < h'\}} X_{i,i',h,h'}
\end{aligned}$$

Similarly, $Y_{i,i',h,h'} = (-1)^{\mathbb{1}\{i<h\}}[T_{\text{row}}\Delta\{i,i',h,h'\},T_{\text{col}}]$. Note that $\mathbb{1}\{i<h\} + r_{S_{\text{row}}}(i) + r_{S_{\text{row}}^{-i}}(h) \equiv 0 \pmod 2$. A similar equation holds for i',h'. Substituting back in we get the desired equation

$$\sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} p_2^{i,i',j,j'} = 4 \sum_{i<h,i'<h'} [S_{\text{row}}\Delta\{i,i',h,h'\},S_{\text{col}}][T_{\text{row}}\Delta\{i,i',h,h'\},T_{\text{col}}] \quad \lhd$$

Lastly, we compute $\sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} p_0^{i,j,i',j'}$. By rearranging terms and using the determinant expansion for $[S_{\text{row}},S_{\text{col}}]$ and $[T_{\text{row}},T_{\text{col}}]$, we get:

$$\begin{aligned}
&\sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} p_0^{i,j,i',j'} \\
&= \sum \delta^{\{i,i'\},\{j,j'\}} (d_{i',j'}[S_{\text{row}}-i,S_{\text{col}}-j]c_{i,j}[T_{\text{row}}-i',T_{\text{col}}-j']) \\
&= \left(\sum_{i,j} (-1)^{r_{S_{\text{row}}}(i)+r_{S_{\text{col}}}(j)} c_{i,j}[S_{\text{row}}-i,S_{\text{col}}-j]\right) \times \\
&\quad \left(\sum_{i',j'} (-1)^{r_{T_{\text{row}}}(i')+r_{T_{\text{col}}}(j')} d_{i',j'}[T_{\text{row}}-i',T_{\text{col}}-j']\right) \\
&= (t[S_{\text{row}},S_{\text{col}}])(t[T_{\text{row}},T_{\text{col}}]) \qquad (7)
\end{aligned}$$

Substituting equations Equations (5) to (7) back into s_1 we get Equation (4). ◀

Now consider the general case when $S_{\text{row}},T_{\text{row}}$ and $S_{\text{col}},T_{\text{col}}$ are not necessarily disjoint. We will create a new larger matrix A with a new set of row and column indices. In particular we create new disjoint subsets $S^*_{\text{row}},T^*_{\text{row}}$ and $S^*_{\text{col}},T^*_{\text{col}}$ with copied versions of common rows and columns. We use Lemma 13 for $S^*_{\text{row}},T^*_{\text{row}},S^*_{\text{col}},T^*_{\text{col}}$, then argue that any nonzero terms in Equation (4) must be equal to $[S_{\text{row}}\Delta U_{\text{row}},S_{\text{col}}\Delta U_{\text{col}}][T_{\text{row}}\Delta U_{\text{row}},T_{\text{col}}\Delta U_{\text{col}}]$ for some $U \subseteq S_{\text{row}}\Delta T_{\text{row}}, U_{\text{col}} \subseteq S_{\text{col}}\Delta T_{\text{col}}$.

Let $r := |S_{\text{row}} \cap T_{\text{row}}|, c := |S_{\text{col}} \cap T_{\text{col}}|$. W.l.o.g., we can assume

$$\begin{aligned}
&S_{\text{row}} = \{1,\cdots,r,r+1,\cdots,k\}, T_{\text{row}} = \{1,\cdots,r,k+(r+1),\cdots,2k\}, \\
&S_{\text{col}} = \{1,\cdots,c,c+1,\cdots,k\}, T_{\text{col}} = \{1,\cdots,c,k+(c+1),\cdots,2k\}. \qquad (8)
\end{aligned}$$

For $i \in [r]$, set row $k+i$ to be identical to row i. For $j \in [c]$, set column $k+j$ to be identical to row j.

Let $S^*_{\text{row}} := S_{\text{row}}, S^*_{\text{col}} := S_{\text{col}}, T^*_{\text{row}} = \{k+1,\cdots,2k\}, T^*_{\text{col}} = \{k+1,\cdots,2k\}$. Clearly, $S^*_{\text{row}} \cap T^*_{\text{row}} = S^*_{\text{col}} \cap T^*_{\text{col}} = \emptyset$.

Let $\Omega^* = (S^*,T^*)$ and $s^*_i := s_i(\Omega^*)$ as in Equation (3). We first prove the following claims on the structure of nonzero terms in s^*_1, s^*_2, s^*_3.

▷ Claim 16. Consider $U_{\text{row}} \subseteq S^*_{\text{row}}, U'_{\text{row}} \subseteq T^*_{\text{row}}$ of the same cardinality. Let $\overline{U}_{\text{row}} = U_{\text{row}} \cup U'_{\text{row}}$. Consider sets V,W of the same cardinality t that partition $S^*_{\text{col}} \cup T^*_{\text{col}}$.

1. If there exists $i \in U_{\text{row}} \cap [r]$ such that $k+i \notin U'_{\text{row}}$ then

$$[S^*_{\text{row}}\Delta\overline{U}_{\text{row}},V][T^*_{\text{row}}\Delta\overline{U}_{\text{row}},W] = 0.$$

2. If there exists $k+i \in U'_{\text{row}} \cap \{k+1,\cdots,k+r\}$ such that $i \notin U_{\text{row}}$ then

$$[S^*_{\text{row}}\Delta\overline{U}_{\text{row}},V][T^*_{\text{row}}\Delta\overline{U}_{\text{row}},W] = 0.$$

▷ Claim 17. Consider $U_{\text{col}} \subseteq S^*_{\text{col}}, U'_{\text{col}} \subseteq T^*_{\text{col}}$ of the same cardinality. Let $\overline{U}_{\text{col}} = U_{\text{col}} \cup U'_{\text{col}}$. Consider sets V, W of the same cardinality t that partition $S^*_{\text{row}} \cup T^*_{\text{row}}$.

1. If there exists $i \in U_{\text{col}} \cap [c]$ such that $k + i \notin U'_{\text{col}}$ then

$$[V, S^*_{\text{col}} \Delta \overline{U}_{\text{col}}][W, T^*_{\text{col}} \Delta \overline{U}_{\text{col}}] = 0.$$

2. If there exists $k + i \in U'_{\text{col}} \cap \{k+1, \cdots, k+c\}$ such that $i \notin U_{\text{col}}$ then

$$[V, S^*_{\text{col}} \Delta \overline{U}_{\text{col}}][W, T^*_{\text{col}} \Delta \overline{U}_{\text{col}}] = 0.$$

We prove Claim 16. The argument for Claim 17 is similar.

Proof of Claim 16. We prove the first statement. The second one follows by a similar argument, since the role of $U_{\text{row}}, U'_{\text{row}}$ are symmetric.

Suppose there exists $i \in U_{\text{row}} \cap [c]$ such that $k + i \notin U'_{\text{row}}$. Then $T^*_{\text{row}} \Delta \overline{U}_{\text{row}}$ contains both rows i and $k + i$, which are identical by our construction, thus $[T^*_{\text{row}} \Delta \overline{U}_{\text{row}}, W] = 0$. ◁

▶ **Lemma 18.** *Consider $S = (S_{\text{row}}, S_{\text{col}}), T = (T_{\text{row}}, T_{\text{col}})$ as in Equation (8).*
Let $\Omega := (S, T), r := |S_{\text{row}} \cap T_{\text{row}}|, c := |S_{\text{col}} \cap T_{\text{col}}|$.
Define

$$\begin{aligned}
s_1(\Omega) &= (-1)^{r+c} \sum_{i,j,i',j'} \delta^{\{i,i'\},\{j,j'\}} [S_{\text{row}} \Delta \{i,i'\}, S_{\text{col}} \Delta \{j,j'\}] \times [T_{\text{row}} \Delta \{i,i'\}, T_{\text{col}} \Delta \{j,j'\}] \\
s_2(\Omega) &= (-1)^{k-r} \sum_{i,i'} \delta^{\{i,i'\},\emptyset} [S_{\text{row}} \Delta \{i,i'\}, S_{\text{col}}][T_{\text{row}} \Delta \{i,i'\}, T_{\text{col}}] \\
\hat{s}_2(\Omega) &= (-1)^{k-c} \sum_{j,j'} \delta^{\emptyset,\{j,j'\}} [S_{\text{row}}, S_{\text{col}} \Delta \{j,j'\}][T_{\text{row}}, T_{\text{col}} \Delta \{j,j'\}] \\
s_3(\Omega) &= \sum_{i<h,i'<h'} \delta^{\{i,h,i',h'\},\emptyset} [S_{\text{row}} \Delta \{i,h,i',h'\}, S_{\text{col}}][T_{\text{row}} \Delta \{i,h,i',h'\}, T_{\text{col}}] \\
\hat{s}_3(\Omega) &= \sum_{j<\ell,j'<\ell'} \delta^{\emptyset,\{j,\ell,j',\ell'\}} [S_{\text{row}}, S_{\text{col}} \Delta \{j,\ell,j',\ell'\}][T_{\text{row}}, T_{\text{col}} \Delta \{j,\ell,j',\ell'\}],
\end{aligned} \tag{9}$$

where in above summations, $j, \ell \in S_{\text{col}} \setminus T_{\text{col}}; j', \ell' \in T_{\text{col}} \setminus S_{\text{col}}; i, h \in S_{\text{row}} \setminus T_{\text{row}}; i', h' \in T_{\text{row}} \setminus S_{\text{row}}$.

Let $s_i := s_i(\Omega)$. we have the following relations.

$$\begin{aligned}
(k^2 - 2(k-1)r + 4\binom{r}{2} - rc)[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] &= s_1 - r\hat{s}_2 - (2(k-1) + c - 4r)s_2 - 4s_3 \\
(k^2 - 2(k-1)c + 4\binom{c}{2} - rc)[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] &= s_1 - cs_2 - (2(k-1) + r - 4c)\hat{s}_2 - 4\hat{s}_3
\end{aligned} \tag{10}$$

Summing the two equations above, we get:

$$\begin{aligned}
((k-r)^2 + (k-c)^2 + (r-c)^2)[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] = \\
2s_1 - 2(k-1+r-2c)\hat{s}_2 - 2(k-1+c-2r)s_2 - 4(s_3 + \hat{s}_3)
\end{aligned} \tag{11}$$

Proof. We prove the first statement. The second one can be obtained by switching the role of columns and rows. Consider s^*_1, and let

$$X_{i,i',j,j'} := \delta^{\{i,i'\},\{j,j'\}} [S^*_{\text{row}} \Delta \{i,i'\}, S^*_{\text{col}} \Delta \{j,j'\}][T^*_{\text{row}} \Delta \{i,i'\}, T^*_{\text{col}} \Delta \{j,j'\}].$$

By Claim 16 and Claim 17, any nonzero term $X_{i,i',j,j'}$ in s_1^* must belong to one of the following cases:

1. $i \in [r], i' = k+i, j \notin [c], j' \notin \{k+1, \cdots, k+c\}$: Note that $j \in S_{\text{col}} \setminus T_{\text{col}}, j' \in T_{\text{col}} \setminus S_{\text{col}}$. Obviously $\delta^{\{i,i'\},\{j,j'\}} = \delta^{\emptyset,\{j,j'\}}$.
   Since rows $k+i$ and i are identical,

$$[S^*_{\text{row}}\Delta\{i,i'\}, S^*_{\text{col}}\Delta\{j,j'\}] = (-1)^{k+i}[S^*_{\text{row}}, S^*_{\text{col}}\Delta\{j,j'\}] = (-1)^{k+i}[S_{\text{row}}, S_{\text{col}}\Delta\{j,j'\}],$$

   and

$$[T^*_{\text{row}}\Delta\{i,i'\}, T^*_{\text{col}}\Delta\{j,j'\}] = (-1)^{1+i}[T^*_{\text{row}}, T^*_{\text{col}}\Delta\{j,j'\}] = (-1)^{1+i+c}[T_{\text{row}}, T_{\text{col}}\Delta\{j,j'\}].$$

   Therefore,

$$X_{i,i',j,j'} = (-1)^{k-c+1}\delta^{\emptyset,\{j,j'\}}[S_{\text{row}}, S_{\text{col}}\Delta\{j,j'\}][T_{\text{row}}, T_{\text{col}}\{j,j'\}].$$

2. $j \in [c], j' = k+j, i \notin [r], i' \notin \{k+1, \cdots, k+r\}$: similarly,

$$X_{i,i',j,j'} = (-1)^{k-r+1}\delta^{\{i,i'\},\emptyset}[S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}][T_{\text{row}}\Delta\{i,i'\}, T_{\text{col}}].$$

3. $i \in [r], j \in [c], i' = k+i, j' = k+j$: $X_{i,i',j,j'} = [S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}]$.
4. $i \in S_{\text{row}} \setminus T_{\text{row}}, i' \in T_{\text{row}} \setminus S_{\text{row}}, j \in j \in S_{\text{col}} \setminus T_{\text{col}}, j' \in T_{\text{col}} \setminus S_{\text{col}}$, then

$$\begin{aligned} X_{i,i',j,j'} &= \delta^{\{i,i'\},\{j,j'\}}[S^*_{\text{row}}\Delta\{i,i'\}, S^*_{\text{col}}\Delta\{j,j'\}][T^*_{\text{row}}\Delta\{i,i'\}, T^*_{\text{col}}\Delta\{j,j'\}] \\ &= (-1)^{r+c}\delta^{\{i,i'\},\{j,j'\}}[S_{\text{row}}\Delta\{i,i'\}, S_{\text{col}}\Delta\{j,j'\}][T_{\text{row}}\Delta\{i,i'\}, T_{\text{col}}\Delta\{j,j'\}] \end{aligned}$$

We can rewrite

$$s_1^* = s_1 + rc[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] - (r\,\hat{s}_2 + c\,s_2)$$

By a similar argument

$$s_2^* = s_2 - r[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}]$$
$$s_3^* = s_3 + \binom{r}{2}[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] - rs_2$$

Substitute into Equation (4) we get:

$$(k^2 - 2(k-1)r + 4\binom{r}{2} - rc)[S_{\text{row}}, S_{\text{col}}][T_{\text{row}}, T_{\text{col}}] = s_1 - r\hat{s}_2 - (2(k-1) + c - 4r)s_2 - 4s_3$$ ◀

5.3 From the Extended Plücker Relations to Exchange

Armed with the extended Plücker relations, we are now ready to prove Theorem 11.

Proof of Theorem 11. We can permute the rows and columns of A so that S_{row}, S_{col}, T_{row}, and T_{col} are as in Equation (8), while preserving the absolute value of determinant of minors. W.l.o.g., we can assume the permutation has already been applied; thus Equation (11) holds.

Let $r = |S_{\text{row}} \cap T_{\text{row}}|, c = |S_{\text{col}} \cap T_{\text{col}}|$.

With $\Omega = (S, T)$, we define

$$\begin{aligned}
\mathcal{E}_1^\Omega &:= \{(\{i, i'\}, \{j, j'\}) \mid i \in S_{\text{row}} \setminus T_{\text{row}}, i' \in T_{\text{row}} \setminus S_{\text{row}}, j \in S_{\text{col}} \setminus T_{\text{col}}, j' \in T_{\text{col}} \setminus S_{\text{col}}\} \\
\mathcal{E}_2^\Omega &:= \{(\{i, i'\}, \emptyset) \mid i \in S_{\text{row}} \setminus T_{\text{row}}, i' \in T_{\text{row}} \setminus S_{\text{row}}\} \\
\hat{\mathcal{E}}_2^\Omega &:= \{(\emptyset, \{j, j'\}) \mid j \in S_{\text{col}} \setminus T_{\text{col}}, j' \in T_{\text{col}} \setminus S_{\text{col}}\} \\
\mathcal{E}_3^\Omega &:= \{(\{i, h, i', h'\}, \emptyset) \mid i, h \in S_{\text{row}} \setminus T_{\text{row}}; i', h' \in T_{\text{row}} \setminus S_{\text{row}}\} \\
\hat{\mathcal{E}}_3^\Omega &:= \{(\emptyset, \{j, \ell, j', \ell'\}) \mid j, \ell \in S_{\text{col}} \setminus T_{\text{col}}; j', \ell' \in T_{\text{col}} \setminus S_{\text{col}}\}
\end{aligned} \tag{12}$$

then $\mathcal{E}(S, T) = \mathcal{E}_1^\Omega \cup \mathcal{E}_2^\Omega \cup \hat{\mathcal{E}}_2^\Omega \cup \mathcal{E}_3^\Omega \cup \hat{\mathcal{E}}_3^\Omega$, where $\mathcal{E}(\Omega)$ is as defined in Definition 10.

Note that

$$|\mathcal{E}_1| = (k-r)^2(k-c)^2, |\mathcal{E}_2| = (k-r)^2, |\hat{\mathcal{E}}_2| = (k-c)^2, |\mathcal{E}_3| = \binom{k-r}{2}^2, |\hat{\mathcal{E}}_3| = \binom{k-c}{2}^2.$$

Let $\gamma := \max\{|\det(A_{S\Delta U})| \cdot |\det(A_{T\Delta U})| \mid U \in \mathcal{E}(S, T)\}$. By the triangle inequality,

$$|s_1| \leq |\mathcal{E}_1|\gamma.$$

A similar inequality holds for $s_2, \hat{s}_2, s_3, \hat{s}_3$.

Consider Equation (11). Let $M := (k-r)^2 + (k-c)^2 + (r-c)^2$. By the triangle inequality and the above observation,

$$\begin{aligned}
&M \cdot [S_{\text{row}}, S_{\text{col}}] \cdot [T_{\text{row}}, T_{\text{col}}] \\
&\leq \gamma(2|\mathcal{E}_1| + |k-1+c-2r| \cdot |\mathcal{E}_2| + |k-1+r-2c| \cdot |\hat{\mathcal{E}}_2| + 4(|\mathcal{E}_3| + |\hat{\mathcal{E}}_3|)) \\
&\leq \gamma\left(((k-r)^2 + (k-c)^2)^2 + 8k((k-r)^2 + (k-c)^2)\right) \\
&\leq M(2k^2 + 8k).
\end{aligned}$$

Since $S \neq T$ so $M > 0$. Dividing both sides by M gives the desired inequality. ◀

6 A Crude Approximation Algorithm

In this section we describe a crude approximation algorithm that can be used to provide the starting point for Algorithm 1. We will formally prove Lemma 8. Our strategy is to appeal to prior results on simpler variants of determinant maximization. Specifically we use the following result of Nikolov [17]:[1]

▶ **Theorem 19** ([17]). *There is a polynomial time algorithm that given a positive semidefinite matrix $B \in \mathbb{R}^{n \times n}$ and $k \geq 0$, outputs a set $S \in \binom{[n]}{k}$ that approximately maximizes $\det(B_{S,S})$. The approximation factor of this algorithm is guaranteed to be $2^{O(k)}$.*

Using Theorem 19, we will provide an algorithm that constructs S_0, a $(n+m)^{O(k)}$-approximation to $\text{maxdet}_k(A)$ in the general case where $k < \min\{m, n\}$.

Proof of Lemma 8. Consider the following procedure that outputs $S = (S_{\text{row}}, S_{\text{col}}) \in \mathcal{I}$:

1. Let $B := AA^\intercal \in \mathbb{R}^{m \times m}$. Note that B is positive semidefinite. Use Theorem 19 to pick $S_{\text{row}} \in \binom{[m]}{k}$ that approximately maximizes $|\det(B_{S_{\text{row}}, S_{\text{row}}})|$.

[1] We remark that the approximation factor of $2^{O(k)}$ is not very important, and one can use simpler and cruder algorithms, such as [20], instead of [17].

2. Let $C := A_{S_{\text{row}},[n]} \in \mathbb{R}^{k\times n}, D := C^\intercal C \in \mathbb{R}^{n\times n}$. Use Theorem 19 to pick $S_{\text{col}} \in \binom{[n]}{k}$ that approximately maximizes $|\det(D_{S_{\text{col}},S_{\text{col}}})|$.

   We claim that for $S = (S_{\text{row}}, S_{\text{col}})$:

   $(n+m)^{O(k)} \cdot |\det(A_S)| \geq \max\{|\det(A_T)| \mid T \in \mathcal{I}\}$.

Let $T \in \mathcal{I}$ denote the indices of the submatrix with the maximum $k \times k$ subdeterminant. Note that $B_{S_{\text{row}},S_{\text{row}}} = CC^\intercal$. Thus, by the Cauchy-Binet formula,

$$\begin{aligned}\det(B_{S_{\text{row}},S_{\text{row}}}) &= \sum_{W_{\text{col}}\in\binom{[n]}{k}} \det(C_{[k],W_{\text{col}}}) \det(C^\intercal_{W_{\text{col}},[k]}) = \sum_{W_{\text{col}}\in\binom{[n]}{k}} \det(C_{[k],W_{\text{col}}})^2 \\ &= \sum_{W_{\text{col}}\in\binom{[n]}{k}} \det(A_{S_{\text{row}},W_{\text{col}}})^2 \leq \sum_{W_{\text{col}}\in\binom{[n]}{k}} 2^{O(k)} \cdot \det(A_{S_{\text{row}},S_{\text{col}}})^2 \\ &= n^{O(k)} \cdot \det(A_{S_{\text{row}},S_{\text{col}}})^2. \end{aligned} \tag{13}$$

Similarly, the Cauchy-Binet formula applied to $B_{T_{\text{row}},T_{\text{row}}} = A_{T_{\text{row}},[n]}(A_{T_{\text{row}},[n]})^\intercal$ gives

$$\det(B_{T_{\text{row}},T_{\text{row}}}) = \sum_{W_{\text{col}}\in\binom{[n]}{k}} \det(A_{T_{\text{row}},W_{\text{col}}})^2 \geq \det(A_{T_{\text{row}},T_{\text{col}}})^2 \tag{14}$$

Thus,

$$n^{O(k)} \det(A_{S_{\text{row}},S_{\text{col}}})^2 \geq 2^{O(k)} \det(B_{S_{\text{row}},S_{\text{row}}}) \geq \det(B_{T_{\text{row}},T_{\text{row}}}) \geq \det(A_{T_{\text{row}},T_{\text{col}}})^2,$$

where the first inequality follows from (13) and the second from definition of S_{row}. ◀

Approximating Star Cover Problems

Abstract

Given a metric space $(F \cup C, d)$, we consider star covers of C with balanced loads. A star is a pair (i, C_i) where $i \in F$ and $C_i \subseteq C$, and the load of a star is $\sum_{j \in C_i} d(i, j)$. In minimum load k-star cover problem (MLkSC), one tries to cover the set of clients C using k stars that minimize the maximum load of a star, and in minimum size star cover (MSSC) one aims to find the minimum number of stars of load at most T needed to cover C, where T is a given parameter.

We obtain new bicriteria approximations for the two problems using novel rounding algorithms for their standard LP relaxations. For MLkSC, we find a star cover with $(1 + O(\varepsilon))k$ stars and $O(1/\varepsilon^2)\mathrm{OPT}_{\mathrm{MLk}}$ load where $\mathrm{OPT}_{\mathrm{MLk}}$ is the optimum load. For MSSC, we find a star cover with $O(1/\varepsilon^2)\mathrm{OPT}_{\mathrm{MS}}$ stars of load at most $(2 + O(\varepsilon))T$ where $\mathrm{OPT}_{\mathrm{MS}}$ is the optimal number of stars for the problem. Previously, non-trivial bicriteria approximations were known only when $F = C$.

1 Introduction

Facility location (FL) is a family of problems in computer science where the general goal is to assign a set of clients to a set of facilities under various constraints and optimization criteria. FL family encompasses many natural clustering problems like k-median and k-means, most of which are well studied. In this work, we study two relatively less studied FL problems which we call minimum load k-star cover (MLkSC) and minimum size star cover (MSSC). The goal of MLkSC is to assign clients to at most k facilities, minimizing the maximum assignment cost of a facility, while that of MSSC is to find a client-facility assignment with the minimum number of facilities such that the total assignment cost of each facility is upper bounded by a given threshold T.

We begin by formally defining the two problems. Let C be a finite set of clients and F be a finite set of facilities. Let $(F \cup C, d)$ be a finite metric space where $d : (F \cup C) \times (F \cup C) \to \mathbb{R}_0^+$ is a distance metric. By a *star* in (F, C), we mean any tuple (i, C_i), where $i \in F$ and $C_i \subseteq C$. We say two stars (i, C_i) and (h, C_h) are *disjoint* if $i \neq h$ and $C_i \cap C_h = \varnothing$. A *star cover* of (F, C) is a finite collection $S = \{(i_1, C_{i_1}), \ldots, (i_{|S|}, C_{i_{|S|}})\}$ of disjoint stars such that $C = C_{i_1} \cup \cdots \cup C_{i_{|S|}}$. The size of a star cover S is the number of stars $|S|$ in the cover. Given a star cover S, a star $(i, C_i) \in S$, and a client $j \in C_i$, we say that client j is *assigned* to facility i under S and the facility i is *serving* client j under S. For a star (i, C_i), the *load* of facility i

© Buddhima Gamlath and Vadim Grinberg;

is the sum of pair-wise distances $\sum_{j \in C_i} d(i,j)$ between itself and its clients. The *load* $L(S)$ of a star cover S is the load of its maximum load star. I.e., $L(S) \coloneqq \max_{(i,C_i) \in S} \sum_{j \in C_i} d(i,j)$. For notational convenience, we denote the collection of all star covers of (F,C) by $\mathcal{S}$. Using the introduced notation, we now define MLkSC and MSSC.

▶ **Definition 1** (Minimum Load k-Star Cover). *Given a finite metric space $(F \cup C, d)$ and number $k \in \mathbb{N}$, the task of minimum load k-star cover problem is to find a star cover of size at most k that minimizes the load; I.e., find $S^* \coloneqq \operatorname{argmin}_{S \in \mathcal{S}: |S| \leq k} L(S)$. We denote the optimal load $L(S^*)$ by $\mathrm{OPT}_{\mathrm{MLk}}$.*

▶ **Definition 2** (Minimum Size Star Cover). *Given a finite metric space $(F \cup C, d)$ and a number $T \in \mathbb{R}_+$, the task of minimum size star cover problem is to find a star cover of load at most T that minimizes the size; I.e., find a star cover $S^\star \coloneqq \operatorname{argmin}_{S \in \mathcal{S}: L(S) \leq T} |S|$. We denote the optimal size $|S^\star|$ by $\mathrm{OPT}_{\mathrm{MS}}$.*

Even et al. [5] showed that both MLkSC and MSSC are NP-hard for general metrics even when $F = C$. Both Even et al. [5] and Arkin et al. [3] studied the problem in $F = C$ setting and gave constant factor bicriteria approximation algorithms for MLkSC. The latter work also gave a constant factor approximation algorithm for MSSC in the same setting.

Arkin et al. [3] use k-median clustering and then split the individual clusters that are too large into several smaller clusters to obtain their approximation guarantees. However, the splitting of clusters rely on that the clients and facilities are indistinguishable, which allows one to conveniently choose a new facility for each new partition created in the splitting process. Meanwhile, the technique of Even et al. [5] is to formulate the problem as an integer program, round its LP relaxation using minimum make-span rounding techniques, and use a clustering approach that also relies on F being equal to C to obtain the final bicriteria approximation guarantees. Both the techniques do not generalize to the case where $F \neq C$ unless it is allowed to open the same facility multiple times.

Recently, Ahmadian et al. [1] showed that MLkSC is NP-hard even if we restrict the metric space to be a line metric. They further gave a PTAS for MLkSC in line metrics and a quasi-PTAS for the same in tree metrics. However, their techniques are specific to line and tree metrics, and it is not known whether they can be extended to general metrics.

The main goal of this work is to extend the approach of Even et al. [5] to $F \neq C$ setting where any given facility can be opened at most once. To do so, we introduce a novel clustering technique and an accompanied new algorithm to modify the LP solution before applying the minimum makespan rounding at the end. This yields the following theorem:

▶ **Theorem 3.** *There exists a polynomial time algorithm that, given an instance $(F \cup C, d)$ of* MLkSC *problem and any $\varepsilon \in (0,1)$, finds a star cover of (F,C) of size at most $(1+O(\varepsilon))k$ and load at most $O(\mathrm{OPT}_{\mathrm{MLk}}/\varepsilon^2)$.*

As a complementary result, we also show that the standard LP relaxation has some inherent limitations. That is, we construct a family of MLkSC instances where the load of any integral $(1+\varepsilon)k$-star cover is at least $\Omega(1/\varepsilon)$ times the optimal value of the standard LP.

With slight modifications to our clustering and rounding techniques, we further obtain the following theorem on MSSC:

▶ **Theorem 4.** *There exists a polynomial time algorithm that, given an instance of* MSSC *problem with load parameter T and any $\varepsilon \in (0,1)$, finds a star cover of load at most $(2+O(\varepsilon))T$ and size at most $O(\mathrm{OPT}_{\mathrm{MS}}/\varepsilon^2)$.*

As with MLkSC, we show that the standard LP-relaxation for MSSC also suffers from inherent limitations; I.e., for any $\varepsilon > 0$, we give an instance of MSSC for which there is a *fractional* star cover of load at most T but any integral star cover of that instance has load at least $(2-\varepsilon)T$ even with all facilities opened.

We end the introduction with a brief section on other related work. In Section 2, we introduce the LP relaxations of the two problems and provide a more elaborate description of our techniques. Later in Section 3 and Section 4 we describe the proofs of Theorem 3 and Theorem 4 in detail. We present the explicit constructions of families of MLkSC and MSSC that show inherent limitations of the respective standard LP relaxations in Appendix B.

Other Related Work

To the best of our knowledge, Even et al. [5] and Arkin et al. [3] were among the first to explicitly address close relatives of MLkSC and MSSC problems. Both of their works considered the problem where one has to cover nodes (or edges) of a graph using a collection of *objects* (I.e.,trees or stars). Even et al. considered the problem of minimizing the maximum cost of an object when the number of objects is fixed, for which they gave a 4-approximation algorithm. Arkin et al. also studied the same problem and additionally considered paths and walks as covering objects. They further discussed the MSSC version of the problems where the goal is to minimize the number of covering objects such that the cost of each object is at most a given threshold. For min-max tree cover with k trees, Khani and Salavatipour [6] later improved the approximation guarantee to a factor of three.

In general, many well-known facility location problems have constant factor approximation guarantees. For example, for uncapacitated facility location, the known best algorithm (Li et al. [8]) gives an approximation ratio of 1.488. For k-median in general metric spaces, the current best is 2.675 due to Byrka et al. [4], and for k-means in general metric spaces, it is $(9+\varepsilon)$ due to Ahmadian et al. [2]. Remarkably, all these results follows from LP based approaches. A common theme of all these problems is that their objectives are to minimize a summation of costs. I.e., we minimize the sum of distances from clients to their respective closest opened facilities, where in uncapacitated facility location problem, we additionally have the sum of opening costs of the opened facilities. This *min-sum* style objective is in contrast with the min-max style objective of minimum star cover problem which makes it immune to algorithmic approaches that are applicable to other common facility location counterparts.

As discussed, minimum star cover problems are closely related to minimum makespan scheduling and the generalized assignment problem. Two most influential literature in this regard include Lenstra et al. [7] and Shmoys et al. [10].

2 Our Results and Techniques

We start with the LP relaxations of the standard integer program formulations for MLkSC and MSSC. To make the presentation easier, we first define a polytope SC-LP(T,k) such that the *integral* points of SC-LP(T,k) are feasible star covers of load at most T and size at most k.

For $i \in F$, let variable $y_i \in \{0,1\}$ denote whether i'th facility is *opened* (I.e., $y_i = 1$ if and only if there is a star (i,C_i) in the target star cover), and for $(i,j) \in F \times C$, let variable $x_{ij} \in \{0,1\}$ denote whether j'th client is *assigned* to facility i (I.e., $x_{ij} = 1$ if and only if $j \in C_i$ where (i,C_i) is a star in the target star cover). Then the following set of constraints define

SC-LP(T,k):

$$\begin{aligned}
&\sum_{j\in C} d(i,j)\cdot x_{ij} \le T\cdot y_i && \forall i\in F, && (1)\\
&\sum_{i\in F} y_i \le k, && && (2)\\
&\sum_{i\in F} x_{ij} = 1 && \forall j\in C, && (3)\\
&x_{ij}\le y_i && \forall i\in F,\forall j\in C, && (4)\\
&y_i\in[0,1] && \forall i\in F, && (5)\\
&x_{ij}\in[0,1] && \forall i\in F,\forall j\in C && (6)\\
&x_{ij}=0 && \forall i\in F,\forall j\in C : d(i,j)>T. && (7)
\end{aligned} \qquad \text{(SC-LP}(T,k)\text{)}$$

Here, Constraint (1) ensures that the load of an opened facility $i \in F$ is at most T, while Constraint (2) limits the maximum number of opened facilities to k. Constraint (3) and Constraint (4) ensure that each client is fully assigned and they are only assigned to opened facilities. Finally Constraint (5) and Constraint (6) ensures that the only integral values of x_{ij}'s and y_i's are 0 or 1, while Constraint (7) essentially removes any (i,j) pair from consideration if the distance between them is larger than T.

Note that we can now define the LP for MLkSC as

$$\text{Minimize } T \text{ such that SC-LP}(T,k) \text{ is feasible,} \qquad \text{(MLkSC-LP)}$$

where one can find the minimum such T using the standard binary search technique. Similarly, the LP for MSSC can be stated as

$$\text{Minimize } k \text{ such that SC-LP}(T,k) \text{ is feasible.} \qquad \text{(MSSC-LP)}$$

Recall that k is part of the MLkSC input and T is a part of the MSSC input.

For an arbitrary (not necessarily feasible) solution (x,y) to SC-LP(T,k), for $i \in F$ let $L(i,x)$ denote the *fractional load* of facility i with respect to the assignment x, I.e., $L(i,x) \coloneqq \sum_{j\in C} d(i,j)x_{ij}$. A solution (x,y) to SC-LP(T,k) is called (α,β)-*approximate*, if for every $i \in F$, $L(i,x) \le \alpha T y_i$, and $\sum_{i\in F} y_i \le \beta k$. The proofs of Theorem 3 and Theorem 4 immediately follow from the two theorems on rounding feasible solutions of SC-LP presented below:

▶ **Theorem 5.** *There exists a polynomial time rounding algorithm that, given a feasible solution (x^*,y^*) to* SC-LP(T,k) *and any $\varepsilon \in (0,1)$, outputs an integral $(O(1/\varepsilon^2), 1+O(\varepsilon))$-approximate solution to* SC-LP(T,k).

Proof of Theorem 3. Let $\varepsilon \in (0,1)$ be given. Using standard binary search approach, we can guess the value T^*, such that $\mathrm{OPT}_{\mathrm{MLk}} \le T^* \le 2\mathrm{OPT}_{\mathrm{MLk}}$, by solving MLkSC-LP multiple times for different values of T^* and either finding a feasible fractional solution of load at most T^*, or determining that no such solution exists. Let (x^*,y^*) be the corresponding fractional solution to MLkSC-LP. Observe that (x^*,y^*) is a feasible solution to SC-LP(T^*,k). By Theorem 5, we can round (x^*,y^*) to an integral solution $(\dot{x},\dot{y})$, which opens at most $(1+O(\varepsilon))k$ facilities and achieves maximum load at most $O(1/\varepsilon^2)T^*$, and it will take polynomial time. Therefore, $(\dot{x},\dot{y})$ will be an integral solution to MLkSC-LP with opening at most $(1+O(\varepsilon))k$ and maximum load at most $O(1/\varepsilon^2)\mathrm{OPT}_{\mathrm{MLk}}$. ◀

▶ **Theorem 6.** *There exists a polynomial time rounding algorithm that, given a feasible solution* (x^*, y^*) *to* SC-LP(T, k) *and any* $\varepsilon \in (0, 1)$*, outputs an integral* $(2 + O(\varepsilon), O(1/\varepsilon^2))$*-approximate solution to* SC-LP(T, k).

The proof of Theorem 4 using Theorem 6 is just the same as the proof of Theorem 3 using Theorem 5, omitting the binary search part (as we optimize over k instead of T).

Note that MLkSC-LP closely resembles the LP used in minimum make-span rounding by Lenstra et al. [7]. In fact, for the case where we do not have a restriction on number of opened facilities, we can assume $y_i = 1$ for all $i \in F$, and the LP reduces to the minimum make-span problem, yielding a 2-approximation algorithm. The main difficulty here is to figure out which facilities to open. Once we have an integral opening of facilities, we can still use minimum make-span rounding at a loss of only a factor 2 in the guarantee for minimum load. Thus, our algorithm for MLkSC essentially transforms the initial solution for MLkSC-LP via a series of steps to a solution with integral openings, I.e., $y_i \in \{0, 1\}$ for all $i \in F$, and fractional assignments, without violating Constraint 1 by too much.

When we fully open (I.e., set $y_i = 1$) some facilities in the solution, inevitably, we have to close down (set $y_i = 0$) some other partially opened facilities, which requires redistributing their assigned clients' demand to the opened ones. This process is called *rerouting* and is a well-known technique in rounding facility-location-like problems. However, instead of bounding the total load of all facilities, our problem requires bounding each $L(i, x)$ for $i \in F$ separately, and consequently, many facility-location rounding algorithms which use rerouting fail to produce a good solution.

Let x° be the solution we obtain from x after rerouting facility i to facility h. Using triangle inequality $d(h, j) \le d(h, i) + d(i, j)$ for $j \in C$, we bound $L(h, x^\circ)$, the new load of h:

$$L(h, x^\circ) \le L(h, x) + L(i, x) + d(h, i) \sum_{j \in C} x_{ij}.$$

If both $L(h, x)$ and $L(i, x)$ were initially $O(T)$, the new load of h will also be $O(T)$ if and only if the value $d(h, i) \sum_{j \in C} x_{ij} \le d(h, i)|N(i)|$ is also at most $O(T)$ (here $N(i)$ is the set of all clients partially served by i). However, if $d(h, i)|N(i)|$ is large for all other facilities h, a good alternative to rerouting is to open i integrally and assign every client in $N(i)$ to i. We call such facilities *heavy* facilities. There is still an issue if the integral load $\sum_{j \in N(i)} d(i, j)$ is too large compared to T, but we show that we can prevent having too large integral loads in heavy facilities by preceding the rerouting step with additional filtering and preprocessing steps. The filtering step blows-up the load constraint by a $(1 + \varepsilon)$ factor while ensuring that no client is fractionally assigned to far away facilities. The preprocessing step uses techniques similar to those of minimum make-span rounding by Lenstra et al. [7] to ensure that any non-zero fractional assignment x_{ij} to a facility i is at least a constant factor times its opening y_i, while slightly relaxing other constraints.

Once we identify the heavy facilities, we cluster the remaining, non-heavy facilities, and choose which ones should be opened based on the clustering. Then we redistribute the assignments of the remaining facilities to those that were opened. Using the properties of the preprocessed solution and the clustering, and using the fact that none of the non-opened facilities are heavy, we show that the resulting fractional assignment satisfies the constraints up to an $O(1/\varepsilon^2)$ factor violation of load constraints. Hence, the algorithmic result of Theorem 5 follows from the minimum make-span rounding of Lenstra et al. [7], which gives us an integral assignment with maximum load increased at most by another factor of 2

The algorithm for MSSC problem, on a high level, resembles that for MLkSC: We first alter the solution of MSSC-LP to have integral y_i's and fractional x_{ij}'s, allowing the total opening $\sum_{i \in F} y_i$ to be at most $O(1/\varepsilon^2)$ factor larger than the value of MSSC-LP, and then

use minimum make-span rounding of Lenstra et al. [7] to obtain the final solution. However, since make-span rounding guarantees only a factor 2 violation in the load constraint, we need to make sure that our modified solution with integral openings and fractional assignments introduces only small error in load constraints. Namely, to ensure that the final solution satisfies $(2+O(\varepsilon))T$ maximum load, before applying the minimum make-span rounding, all the loads must be at most $(1+O(\varepsilon))T$. We ensure this by re-arranging the steps of the algorithm for MLkSC and carefully choosing parameters.

3 $(O(1/\varepsilon^2), 1+O(\varepsilon))$-approximation to SC$(T,k)$

In this section, we show how to convert a (feasible) fractional solution (x,y) of SC-LP in to a $(O(1/\varepsilon^2), 1+O(\varepsilon))$-approximate solution with integral y values. This together with minimum make-span rounding scheme by Lenstra et al. [7] proves Theorem 5.

3.1 Preprocessing and filtering

Suppose that for each $(i,j) \in F \times C$ we either have $x_{ij} = 0$ or $x_{ij} \geq \gamma y_i$ for constant $\gamma \in (0,1)$. Then, if $L(i,x) = \sum_{j \in C} d(i,j)x_{ij} \leq \nu T y_i$ for some constant $\nu \geq 1$, we have $\sum_{j \in N(i)} d(i,j) \leq \frac{\nu}{\gamma} T$. Therefore, if we open i integrally and assign all $N(i)$ to i, the resulting load of i will be $O(T)$. Even though we cannot guarantee the property above for every solution (x,y) to SC-LP(T,k), we can modify (x,y) so that all non-zero assignments x_{ij} satisfy $x_{ij} \geq \gamma y_i$ for some constant $\gamma \in (0,1)$ at the expense of slightly relaxing other constraints of SC-LP. This is exactly the statement of the preprocessing theorem.

▶ **Theorem 7** (Preprocessing). *Let (x,y) be such that, for all $i \in F$, $L(i,x) \leq \mu T y_i$ for some constant $\mu \geq 1$ and all other constraints of* SC-LP(T,k) *on variables x are satisfied. There exists a polynomial time algorithm that, given such solution (x,y) and a constant $\gamma \in (0,1)$, finds a solution (x',y') such that*

1. *$y' = y$, and if $x_{ij} = 0$, then $x'_{ij} = 0$;*
2. *for every $(i,j) \in F \times C$, $y'_i \geq x'_{ij}$, and if $x'_{ij} > 0$, then $x'_{ij} \geq \gamma y'_i$;*
3. *for every $j \in C$, $1 \geq \sum_{i \in F} x'_{ij} \geq 1-\gamma$;*
4. *for every $i \in F$, $L(i,x') \leq (\mu + 2 - \gamma) T y'_i$.*

That is to say, we can guarantee the property $\{x_{ij} > 0 \iff x_{ij} \geq \gamma y_i\}$ by loosing at most γ portion of each client's demand and slightly increasing each facility's load. Loosing a factor of γ demand is affordable for our purposes, as one can meet the demand constraint by scaling each x_{ij} by a factor of at most $1/(1-\gamma)$. Since γ is a constant, this would blow up the load constraint only by an additional constant factor. The proof of Theorem 7 is rather technical and is given in Appendix A.

We now present our rounding algorithm step by step. Let (x,y) be a feasible fractional solution to SC-LP(T,k) and let $\varepsilon \in (0,1)$. By $(\dot{x},\dot{y})$ we denote the final rounded solution with integral $\dot{y}$ and fractional $\dot{x}$.

▶ **Definition 8.** *For $j \in C$, let $D(j) := \sum_{i \in F} d(i,j)x_{ij}$, the average facility distance to j.*

Let $\rho := \frac{1+\varepsilon}{\varepsilon}$. By applying the well-known filtering technique of Lin and Vitter [9] to (x,y), we construct a new solution $(\hat{x},\hat{y})$, such that $\sum_{i \in F} \hat{y}_i \leq (1+\varepsilon)k$, $L(i,\hat{x}) \leq (1+\varepsilon)T\hat{y}_i$ for all $i \in F$, and for every i,j, $\hat{x}_{ij} \leq \hat{y}_i$ and if $\hat{x}_{ij} > 0$, then $d(i,j) \leq \rho D(j)$. Applying Theorem 7 to $(\hat{x},\hat{y})$, we obtain solution (x',y') such that

1. $\sum_{i \in F} y'_i \leq (1+\varepsilon)k$,
2. for all (i,j), $y'_i \geq x'_{ij}$, and if $x'_{ij} > 0$, then $x'_{ij} \geq \gamma y'_i$ and $d(i,j) \leq \rho D(j)$,

3. for every $j \in C$, $1 \geq \sum_{i \in F} x'_{ij} \geq 1 - \gamma$, and
4. for every $i \in F$, $L(i, x') \leq (\mu + 2 - \gamma) T y'_i = \nu T y'_i$.

Here $\nu := (\mu + 2 - \gamma)$ is a new load bound. We choose $\mu := 1 + \varepsilon$ and $\gamma := \varepsilon/(1+\varepsilon)$, but will keep the parameters unsubstituted, for convenience. It is easy to see from the bounds above that for every $j \in C$, $\sum_{i \in F : x'_{ij} > 0} y'_i \geq 1/(1+\varepsilon)$.

3.2 Opening heavy facilities

We now give an algorithm to choose heavy facilities based on (x', y').

▶ **Definition 9.** *For subsets $F' \subseteq F$, $C' \subseteq C$, for $i \in F'$ denote $N'(i) := \{j \in C' : x'_{ij} > 0\}$, and for $j \in C'$ denote $N'(j) := \{i \in F' : x'_{ij} > 0\}$.*

The algorithm internally maintains two subsets $F' \subseteq F$ and $C' \subseteq C$. Notice that N' changes as the algorithm modifies F' and C'.

▶ **Definition 10.** *A facility $i \in F'$ is* λ-heavy *for $\lambda > 0$, if $\sum_{j \in N'(i)} D(j) > \lambda T$.*

Algorithm 1 opens all λ-heavy facilities for the given value of λ. It starts with $F' = F$ and $C' = C$ and scans F' for λ-heavy facilities. It fully opens every λ-heavy facility $i \in F'$ and assigns all $N'(i)$ integrally to i. Then, it discards i from F' and $N'(i)$ from C', and continues until all facilities are processed.

Algorithm 1 Opening Heavy Facilities.

Input: A solution (x', y'), $\lambda > 0$.
Output: Partial solution $(\dot{x}, \dot{y})$, sets F', C', such that $\sum_{j \in N'(i)} D(j) \leq \lambda T$, $\forall i \in F'$.

```
Initialize F' ← F, C' ← C
for i ∈ F' do
    if Σ_{j∈N'(i)} D(j) > λT then
        Initialize C(i) ← N'(i)
        F' ← F' ∖ {i}, ẏ_i ← 1
        for j ∈ C(i) do
            C' ← C' ∖ {j}, ẋ_ij ← 1
            for h ∈ F ∖ {i} do ẋ_hj ← 0
return (ẋ, ẏ), F', C'.
```

Since for each $h \in F'$ we may discard some clients from $N'(h)$ after every step, facilities that were λ-heavy might become non-λ-heavy under updated F' and C'. Lemma 11 shows that this procedure does not open too many facilities and that the load of opened facilities does not exceed T by too much.

▶ **Lemma 11.** *Let F', C' be the sets returned by Algorithm 1. Then $|F \setminus F'| \leq k/\lambda$, and for each facility $i \in F \setminus F'$, $L(i, \dot{x}) \leq \frac{\nu}{\gamma} T$.*

Proof. The set $F \setminus F'$ is exactly the set of facilities integrally opened during Algorithm 1. For $i \in F \setminus F'$, set $C(i)$ in Algorithm 1 is exactly the set of clients, integrally assigned to i by the algorithm. Observe that for every $i, h \in F \setminus F'$, $i \neq h$, the sets $C(i)$ and $C(h)$ are *disjoint*. Hence, by feasibility of (x, y),

$$|F \setminus F'| \cdot \lambda T < \sum_{i \in F \setminus F'} \sum_{j \in C(i)} D(j) \leq \sum_{j \in C} D(j) = \sum_{j \in C} \sum_{i \in F} d(i,j) x_{ij} \leq \sum_{i \in F} T y_i \leq Tk$$

and $|F \setminus F'| < \frac{Tk}{\lambda T} = \frac{k}{\lambda}$. Next, by the properties of solution (x', y'), $\nu T y'_i \geq \sum_{j \in C(i)} d(i,j) x'_{ij} \geq \gamma y'_i \sum_{j \in C(i)} d(i,j)$, implying $L(i, \dot{x}) = \sum_{j \in C(i)} d(i,j) \leq \frac{\nu}{\gamma} T$. ◀

We apply Algorithm 1 with $\lambda := 1/\varepsilon$, and by Lemma 11 this opens at most εk additional facilities. The load of each opened facility is at most $\frac{\nu}{\gamma}T = \frac{(1+\varepsilon)(\mu+2-\gamma)}{\varepsilon}T = O(T/\varepsilon)$. For the returned sets F' and C', $\sum_{j\in N'(i)} D(j) \le T/\varepsilon$ for all $i \in F'$. Moreover, since $j \in C'$ if and only if j was not served by any λ-heavy facility (which got opened), for all $j \in C'$ we have $\sum_{i\in N'(j)} y'_i = \sum_{i\in F: x'_{ij}>0} y'_i \ge 1/(1+\varepsilon)$. Facilities in $F \setminus F'$ are all integral, and it remains to find the integral opening among facilities in F'.

As discussed earlier, if we reroute $i \in F'$ to $h \in F'$, to guarantee a good approximation we have to bound the term $d(h,i)|N'(i)|$. Observe that $\sum_{j\in N'(i)} D(j)$ is an upper bound for $|N'(i)| \min_{j\in N'(i)} D(j)$. Therefore, to get a good bound, we need to choose h for i so that $d(h,i)$ is at most some constant times $\min_{j\in N'(i)} D(j)$. This requires some sophisticated clustering technique and a wise choice of facility h for every such i.

3.3 Clustering

To create an integral opening over F', we partition F' into disjoint clusters, open some facilities in every cluster and reroute the closed ones into opened ones within the same cluster. Our goal is to cluster F' so that, if i and h belong to the same cluster and we reroute h to i, $d(h,i) \le O(\min_{j\in N'(i)} D(j))$. Classic clustering approaches for facility-location-like problems do not work, and to achieve this bound we are required to design a novel approach.

Let $\mathcal{C} \subseteq C'$ be the set of cluster centers. For every $j \in \mathcal{C}$, let $F'(j) \subseteq F'$ be the set of facilities belonging to the cluster centered at j, for $i \in F'$ let $\mathcal{C}(i)$ be the center of the cluster i belongs to (I.e., $i \in F'(j) \iff \mathcal{C}(i) = j$). Figure 1 visualizes the clustering procedure and Algorithm 2 gives its pseudocode. Below we explain each step of the algorithm in detail.

Algorithm 2 Clustering.

Input: Solution (x', y'), sets F' and C'.
Output: Centers $\mathcal{C} \subseteq C'$ and disjoint clusters $F'(s)$ for every $s \in \mathcal{C}$, $\cup_{s\in\mathcal{C}} F'(s) = F'$.

Initialize $\mathcal{C} \leftarrow \varnothing$, sort $j \in C'$ by the values of $D(j)$ in ascending order
for $j \in C'$ **do**
  if $\forall s \in \mathcal{C} : d(s,j) > 2\rho D(j)$ **then**
    $\mathcal{C} \leftarrow \mathcal{C} \cup \{j\}$
For all $s \in \mathcal{C}$, initialize $F'(s) \leftarrow \varnothing$
for $i \in F'$ **do**
  if $\exists s \in \mathcal{C} : i \in N'(s)$ **then**
    $\mathcal{C}(i) \leftarrow s$, $F'(s) \leftarrow F'(s) \cup \{i\}$
  else
    Let $j := \operatorname{argmin}_{r\in N'(i)} D(r)$
    Take $s \in \mathcal{C}$, such that $D(s) \le D(j)$, $d(s,j) \le 2\rho D(j)$
    $\mathcal{C}(i) \leftarrow s$, $F'(s) \leftarrow F'(s) \cup \{i\}$
return $\mathcal{C}$, $F'(s)$ for $s \in \mathcal{C}$.

The clustering procedure works as follows. First, we form cluster centers $\mathcal{C}$ by scanning $j \in C'$ in ascending order of $D(j)$ and adding j to $\mathcal{C}$ only if there are no other centers in $\mathcal{C}$ within the distance $2\rho D(j)$ from j. Having determined $\mathcal{C}$, we add facilities from F' to different clusters. Most classical clustering approaches would put i into $F'(s)$, if s is closest to i among $\mathcal{C}$. Our approach is different: if $i \in F'$ is serving some $s \in \mathcal{C}$, we add $i \in F'(s)$ regardless the distance $d(i,s)$. Otherwise, we consider $j \in N'(i)$ with *minimum* $D(j)$ (j is not a cluster center), take $s \in \mathcal{C}$ that prevented j from becoming a center, and add i to $F'(s)$. One can easily check that, after Algorithm 2 finishes, for any $s, v \in \mathcal{C}$,

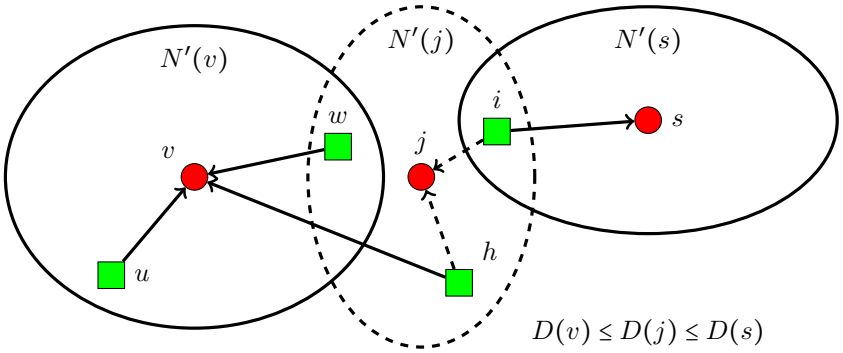

Figure 1 Here, $v, j, s \in C'$, $v, s \in \mathcal{C}$, $j \notin \mathcal{C}$, $u, w, h, i \in F'$. The bold arrow $\rightarrow$ shows that a facility belongs to the cluster centered at that client, the dashed arrow $\dashrightarrow$ shows that a particular client has minimum average distance among all clients served by a facility.

$s \neq v$, $d(s,v) > 2\rho \max\big(D(s), D(v)\big)$, and as a result $N'(s)$ and $N'(v)$, as well as $F'(s)$ and $F'(v)$ are disjoint. Also, for every $j \notin \mathcal{C}$ there exists $s \in \mathcal{C}$ such that $D(s) \le D(j)$ and $d(s,j) \le 2\rho D(j)$, simply by construction of the algorithm. Algorithm 2 allows us to obtain an upper bound on the distance between a facility an its cluster center, represented in terms of minimum average distance of the client served by this facility.

▶ **Lemma 12.** *Let $i \in F'$, let $j = \operatorname{argmin}_{r \in N'(i)} D(r)$. Then $d(i, \mathcal{C}(i)) \le 3\rho D(j)$.*

Proof. Let $\mathcal{C}(i) = s$. There are two cases to distinguish.

- $i \notin N'(s)$ (this case is shown by clients j, v and facility h in Figure 1). By construction of Algorithm 2, client s is exactly the one that prevented j from becoming a cluster center, therefore $D(s) \le D(j)$ and $d(j,s) \le 2\rho D(j)$. Thus, by triangle inequality $d(i,s) \le d(i,j) + d(j,s) \le \rho D(j) + 2\rho D(j) = 3\rho D(j)$.
- $i \in N'(s)$. Then $D(j) = \min_{r \in N'(i)} D(r) \le D(s)$. If $s = j$ or $D(s) = D(j)$, then $d(i,s) \le \rho D(j)$ automatically. Suppose that $s \neq j$, and $D(j) < D(s)$, then $j \notin \mathcal{C}$, as $s \in \mathcal{C}$ and $i \in N'(j) \cap N'(s)$ (this case is shown by clients j, s and facility i in Figure 1). Hence, there exists some $s' \in \mathcal{C}$ that prevented j from becoming a cluster center, so $D(s') \le D(j)$ and $d(s', j) \le 2\rho D(j)$. It is easy to see that $D(j)$ must be strictly greater than zero, and since both s and s' are cluster centers, $d(s', s) > 2\rho D(s)$. So, by triangle inequality,

$$2\rho D(s) < d(s', s) \le d(s', j) + d(i, j) + d(i, s) \le 2\rho D(j) + \rho D(j) + \rho D(s),$$

  implying $2\rho D(s) \le 3\rho D(j) + \rho D(s)$ and $D(s) \le 3D(j)$. Since $i \in N'(s)$, it immediately follows that $d(i,s) \le \rho D(s) \le 3\rho D(j)$. ◀

By applying the triangle inequality once more, we get the desired upper bound on the distances between any two facilities within the same cluster.

▶ **Corollary 13.** *Let $i, h \in F'$, such that $\mathcal{C}(i) = \mathcal{C}(h)$. Let $j = \operatorname{argmin}_{r \in N'(i)} D(r)$ and $v = \operatorname{argmin}_{l \in N'(h)} D(l)$. Then $d(i,h) \le 6\rho \max\big(D(j), D(v)\big)$.*

Another useful observation is that $\sum_{i \in F'(s)} y'_i \ge 1/(1+\varepsilon)$ for every cluster center $s \in \mathcal{C}$. It follows from $N'(s) \subseteq F'(s)$ and $\sum_{i \in N'(s)} y'_i \ge 1/(1+\varepsilon)$.

3.4 Rerouting

The last part of our rounding algorithm is opening some facilities in every cluster and rerouting the closed ones. For $s \in \mathcal{C}$ we open $\lfloor (1+\varepsilon) \sum_{u \in F'(s)} y'_u \rfloor$ facilities in cluster $F'(s)$, prioritizing facilities i with minimum values of $\min_{r \in N'(i)} D(r)$. Since $\sum_{u \in F'(s)} y'_u \ge 1/(1+\varepsilon)$,

we will open at least one facility in every cluster $F'(s)$ for $s \in \mathcal{C}$. Then, the demand of each closed facility in $F'(s)$ is redistributed at an equal fraction between all the opened ones in $F'(s)$, I.e. we reroute it to all opened facilities in $F'(s)$. This gives us an integral opening $\dot{y}$ over facilities in F' and a fractional assignment $\dot{x}$ over clients in C'.

Lemma 14 shows that by opening $|K_s| = \lfloor (1+\varepsilon) \sum_{u \in F'(s)} y'_u \rfloor$ facilities in cluster $F'(s)$ and rerouting all closed facilities in $F'(s)$, we open at most $(1+3\varepsilon)k$ facilities in total, and the load of every opened facility in F' exceeds T at most by a constant factor.

Algorithm 3 Rerouting.

Input: Solution (x', y'), cluster centers $\mathcal{C}$ and clusters $F'(s)$ for $s \in \mathcal{C}$.
Output: Solution $(\dot{x}, \dot{y})$, sets of opened facilities K_s for $s \in \mathcal{C}$.

for $s \in \mathcal{C}$ **do**
  Initialize $K_s \leftarrow \varnothing$
  Sort $i \in F'(s)$ in ascending order of $\min_{r \in N'(i)} D(r)$
  for $i \in F'(s)$ **do**
    if $y'_i = 0$ **then**
      $\dot{y}_i \leftarrow 0$
    else if $|K_s| + 1 \le \lfloor (1+\varepsilon) \sum_{u \in F'(s)} y'_u \rfloor$ **then**
      $K_s \leftarrow K_s \cup \{i\}$, $\dot{y}_i \leftarrow 1$
      for $j \in N'(i)$ **do** $\dot{x}_{ij} \leftarrow x'_{ij}$
    else
      $\dot{y}_i \leftarrow 0$
      for $r \in N'(i)$ **do**
        $\dot{x}_{ir} \leftarrow 0$
        for $h \in K_s$ **do**
          $\dot{x}_{hr} \leftarrow \dot{x}_{hr} + x'_{ir}/|K_s|$
return $(\dot{x}, \dot{y})$, K_s for $s \in \mathcal{C}$.

▶ **Lemma 14.** *After Algorithm 3, for every facility $h \in F'$, $\dot{y}_h = 1$: $L(h, \dot{x}) \le 3(\nu + 4\rho\lambda)T$. Moreover, $\sum_{h \in F'} \dot{y}_h \le (1+3\varepsilon)k$.*

Proof. Since for every $s \in \mathcal{C}$ we have $\sum_{u \in F'(s)} y'_u \ge 1/(1+\varepsilon)$, $\lfloor (1+\varepsilon) \sum_{u \in F'(s)} y'_u \rfloor \ge 1$ and $|K_s| \ge 1$. After filtering and preprocessing steps, $\sum_{u \in F'} y'_u \le (1+\varepsilon)k$, so

$$\sum_{h \in F'} \dot{y}_h = \sum_{s \in \mathcal{C}} \sum_{h \in K_s} \dot{y}_h \le (1+\varepsilon) \sum_{s \in \mathcal{C}} \sum_{u \in F'(s)} y'_u = (1+\varepsilon) \sum_{u \in F'} y'_u \le (1+\varepsilon)^2 k \le (1+3\varepsilon)k.$$

Next, let $h \in F'$, $\dot{y}_h = 1$, and let $\mathcal{C}(h) = s$. Take $i \in F'(s)$ that was closed by Algorithm 3. The demand of every $r \in N'(i)$ served by i gets split between all opened facilities from K_s at an equal fraction. So, after we reroute i into h, the *additional* load of h is

$$\sum_{r \in N'(i)} d(h,r) \frac{x'_{ir}}{|K_s|} \le \frac{1}{|K_s|} \sum_{r \in N'(i)} d(i,r) x'_{ir} + \frac{d(h,i)}{|K_s|} \sum_{r \in N'(i)} x'_{ir}.$$

Recall that $\sum_{r \in N'(i)} d(i,r) x'_{ir} = L(i, x') \le \nu T y'_i$. Let $v = \operatorname{argmin}_{l \in N'(h)} D(l)$ and $j = \operatorname{argmin}_{r \in N'(i)} D(r)$. Since h was opened, and i was closed, $D(v) \le D(j)$, and by Corollary 13 $d(h,i) \le 6\rho D(j)$. Hence, the *additional* load of h is at most

$$\frac{1}{|K_s|}\sum_{r\in N'(i)} d(i,r)x'_{ir} + \frac{d(h,i)}{|K_s|}\sum_{r\in N'(i)} x'_{ir} \le \frac{\nu T y'_i}{|K_s|} + \frac{6\rho D(j)}{|K_s|}\sum_{r\in N'(i)} x'_{ir} \le$$
$$\le \frac{\nu T y'_i}{|K_s|} + \frac{6\rho D(j)}{|K_s|}\sum_{r\in N'(i)} y'_i = \frac{y'_i}{|K_s|}\left(\nu T + 6\rho\cdot|N'(i)|D(j)\right) \le$$
$$\le \frac{y'_i}{|K_s|}\left(\nu T + 6\rho\cdot\lambda T\right) = \frac{y'_i}{|K_s|}(\nu + 6\rho\lambda)T.$$

We used the bound $|N'(i)|\min_{r\in N'(i)} D(r) \le \sum_{r\in N'(i)} D(r) \le \lambda T$ for non-λ-heavy facilities. Hence, the *total additional* load of h, gained after rerouting all closed facilities $i \in F'(s)\setminus K_s$ in its cluster, is at most

$$\sum_{i\in F'(s)\setminus K_s}\sum_{r\in N'(i)} d(h,r)\frac{x'_{ir}}{|K_s|} \le \sum_{i\in F'(s)\setminus K_s}\frac{y'_i}{|K_s|}(\nu+6\rho\lambda)T =$$
$$= (\nu+6\rho\lambda)T\cdot\frac{\sum_{i\in F'(s)\setminus K_s} y'_i}{\lfloor(1+\varepsilon)\sum_{u\in F'(s)} y'_u\rfloor} \le (\nu+6\rho\lambda)T\cdot\frac{(1+\varepsilon)\sum_{i\in F'(s)} y'_i}{\lfloor(1+\varepsilon)\sum_{u\in F'(s)} y'_u\rfloor} \le$$
$$\le (2\nu+12\rho\lambda)T.$$

The load of h before rerouting was $L(h,x') \le \nu T y'_h \le \nu T$, so after Algorithm 3 the total load of facility h is $L(h,\dot{x}) \le 3(\nu+4\rho\lambda)T$. This holds for every $h \in K_s$ and every center $s \in \mathcal{C}$. ◀

Now we are ready to complete the analysis of the rounding algorithm.

Proof of Theorem 5. We claim that, having completed all the intermediate steps from filtering and up to Algorithm 3 included, with parameter values $\rho = \frac{1+\varepsilon}{\varepsilon}$, $\gamma = \varepsilon/(1+\varepsilon)$ and $\lambda = 1/\varepsilon$, for the resulting solution $(\dot{x},\dot{y})$ it holds:

1. $\dot{y}$ is integral, and $\sum_{i\in F}\dot{y}_i \le (1+4\varepsilon)k$;
2. for every $j \in C$, $1 \ge \sum_{i\in F}\dot{x}_{ij} \ge 1/(1+\varepsilon)$, and if $j \in C\setminus C'$, $\sum_{i\in F}\dot{x}_{ij} = 1$;
3. for every $i \in F$, $L(i,\dot{x}) \le 12\left(1+\frac{1+\varepsilon}{\varepsilon^2}\right)T\dot{y}_i$.

By Lemma 11, Algorithm 1 could open additional εk facilities, so $\sum_{i\in F\setminus F'}\dot{y}_i \le \varepsilon k$. By Lemma 14, $\sum_{h\in F'}\dot{y}_h \le (1+3\varepsilon)k$. This gives us total opening $\sum_{i\in F}\dot{y}_i \le (1+4\varepsilon)k$.

Next, take $j \in C$. If j was serving some λ-heavy facility i, then $j \in C\setminus C'$, and Algorithm 1 sets $\dot{x}_{ij} = 1$ and $\dot{x}_{hj} = 0$ for all other facilities $h \ne i$. If j did not serve any λ-heavy facility, then $j \in C'$, and we get $1 \ge \sum_{i\in F}\dot{x}_{ij} = \sum_{i\in F} x'_{ij} \ge 1/(1+\varepsilon)$ after rerouting.

Finally, if $i \in F$ was λ-heavy, by Lemma 11 $L(i,\dot{x}) \le \frac{\nu}{\gamma}T \le \frac{4}{\varepsilon}T\dot{y}_i$. Let i be non-λ-heavy, I.e. $i \in F'$. If $\dot{y}_i = 0$, I.e. i is closed, then Algorithm 3 assures that $L(i,\dot{x}) = 0$. If $\dot{y}_i = 1$, then by Lemma 14 we have $L(i,\dot{x}) \le 3(\nu+4\rho\lambda)T \le 3\left(4+4\frac{1+\varepsilon}{\varepsilon^2}\right)T\dot{y}_i = 12\left(1+\frac{1+\varepsilon}{\varepsilon^2}\right)T\dot{y}_i$.

For every $(i,j) \in F'\times C'$, we multiply the assignment variables $\dot{x}_{ij}$ by $1/\left(\sum_{i\in F}\dot{x}_{ij}\right)$. Since $\sum_{i\in F}\dot{x}_{ij} \ge 1/(1+\varepsilon)$, the load of every opened facility in F' gets increased at most by a factor of $1+\varepsilon \le 2$. After this change, $\sum_{i\in F}\dot{x}_{ij} = 1$ and $L(i,\dot{x}) \le 24\left(1+\frac{1+\varepsilon}{\varepsilon^2}\right)T$ for all $j \in C$, $i \in F$.

The solution $(\dot{x},\dot{y})$ has integral opening $\dot{y}$, and every client $j \in C$ is served fully (I.e. $\sum_{i\in F}\dot{x}_{ij} = 1$). By applying minimum makespan rounding algorithm [7], we get an integral assignment with respect to facilities opened in $\dot{y}$, sacrificing another factor of 2 in approximation. We obtain a $\left(48\left(1+\frac{1+\varepsilon}{\varepsilon^2}\right), 1+4\varepsilon\right)$-approximate solution to SC(T,k) problem, and the whole algorithm clearly runs in polynomial-time. ◀

4 $(2+O(\varepsilon), O(1/\varepsilon^2))$-approximation to $\mathrm{SC}(T,k)$

Similar to the $(O(1/\varepsilon^2), 1+O(\varepsilon))$-approximation to $\mathrm{SC}(T,k)$, our goal is, given some solution (x,y) to SC-LP(T,k), find an integral opening $\dot{y}$ and fractional assignment $\dot{x}$, and then apply minimum makespan rounding [7], which will prove Theorem 6. However, this time we need to assure that $L(i,\dot{x}) \le (1+O(\varepsilon))T$ for every $i \in F$. To achieve this, we use the same steps, applied in different order and with different values of parameters.

4.1 Preprocessing and opening heavy facilities

Let (x,y) be a feasible fractional solution to SC-LP(T,k), and let $\varepsilon \in (0,1)$. Straightahead, we apply preprocessing algorithm from Theorem 7 to (x,y) with parameters $\mu = 1$ and $\gamma = \frac{1}{1+\varepsilon}$. This will give us a solution (x',y') such that

1. $y' = y$, and $\sum_{i\in F} y'_i \le k$,
2. for all $(i,j) \in F \times C$, $y'_i \ge x'_{ij}$ and if $x'_{ij} > 0$ then $x'_{ij} \ge \gamma y'_i = y'_i/(1+\varepsilon)$,
3. for every $j \in C$, $1 \ge \sum_{i\in F} x'_{ij} \ge 1-\gamma = \varepsilon/(1+\varepsilon)$, and
4. for every $i \in F$, $L(i,x') \le (\mu+2-\gamma)Ty'_i = (2+\frac{\varepsilon}{1+\varepsilon})Ty'_i = \nu T y'_i$.

In this algorithm, we overuse the notation and define $D(j)$ with respect to assignment x'.

▶ **Definition 15.** *For $j \in C$, let $D(j) := \sum_{i\in F} d(i,j)x'_{ij}$, the average facility distance to j.*

The definitions of $N'(i)$, $N'(j)$ for $i \in F'$, $j \in C'$, given $F' \subseteq F$ and $C' \subseteq C$, are the same.

▶ **Definition 16.** *For $F' \subseteq F$, $C' \subseteq C$, let $N'(i) := \{j \in C' : x'_{ij} > 0\}$, $N'(j) := \{i \in F' : x'_{ij} > 0\}$.*

▶ **Definition 17.** *A facility $i \in F'$ is λ-heavy for $\lambda > 0$, if $\sum_{j\in N'(i)} D(j) > \lambda T$.*

We apply Algorithm 1 to solution (x',y') with $\lambda := \varepsilon^2/15$. Observe that $\sum_{j\in C} D(j) = \sum_{i\in F}\sum_{j\in C} d(i,j)x'_{ij} \le \sum_{i\in F} \nu T y'_i \le \nu T k$. Hence, using a similar analysis as in Lemma 11, we open at most $\frac{\nu}{\lambda}k = O(k/\varepsilon^2)$ additional facilities, and the load of every opened facility is at most $\frac{\nu}{\gamma}T = (1+\varepsilon)\left(2+\frac{\varepsilon}{1+\varepsilon}\right)T = (2+3\varepsilon)T$.

For the returned sets F' and C', $\sum_{j\in N'(i)} D(j) \le \lambda T = \varepsilon^2 T/15$, for every $i \in F'$. As before, it remains to find the integral opening among facilities in F'. However, there may be clients $j \in C'$, for which preprocessing step might have dropped a very huge portion of their demand, as the best bound we have is $\sum_{i\in F'} x'_{ij} \ge \varepsilon/(1+\varepsilon)$. Just for the same reason, the opening $\sum_{i\in N'(j)} y'_i$ may be too small for some clients $j \in C'$, so we cannot apply the clustering and rerouting steps to solution (x',y'), as we did in Section 3, without loosing a lot in both approximation factors, we even do not have any distance upper bounds. We are going to handle these issues by applying a specific filtering step to (x',y'), bounding distances between facilities and clients they serve, as well retrieving the lost demand of every client in C'.

4.2 Filtering

We apply filtering to the restriction of (x',y') on $F' \times C'$, however, the filtering process will be quite different from [9] (the analysis though is similar). We will rely a lot on the fact that we now operate with non-λ-heavy facilities only.

▶ **Definition 18.** *Let $\rho := \frac{(1+\varepsilon)^2}{\varepsilon^2}$. For every $j \in C$ define $F'_j := \{i \in F' : d(i,j) \le \rho D(j)\}$.*

▶ **Lemma 19.** *For every $j \in C'$, $\sum_{i\in F'_j} x'_{ij} \ge 1/(\rho\varepsilon) = \varepsilon/(1+\varepsilon)^2$.*

Proof. Every $j \in C'$ was served by F' only, therefore $D(j) = \sum_{i \in F'} d(i,j)x'_{ij}$. Observe that at most a portion of $1/\rho$ demand of j can be served by facilities not in F'_j. Otherwise,

$$D(j) = \sum_{i \in F'} d(i,j)x'_{ij} \geq \sum_{i \in F' \setminus F'_j} d(i,j)x'_{ij} \geq \rho D(j) \sum_{i \in F' \setminus F'_j} x'_{ij} > \rho D(j) \cdot \frac{1}{\rho} = D(j),$$

a contradiction. Hence, $\sum_{i \in F' \setminus F'_j} x'_{ij} \leq 1/\rho$. Since $\sum_{i \in F'} x'_{ij} \geq \varepsilon/(1+\varepsilon)$ for all $j \in C'$, we have

$$\sum_{i \in F'_j} x'_{ij} = \sum_{i \in F'} x'_{ij} - \sum_{i \in F' \setminus F'_j} x'_{ij} \geq \frac{\varepsilon}{1+\varepsilon} - \frac{\varepsilon^2}{(1+\varepsilon)^2} = \frac{\varepsilon}{(1+\varepsilon)^2} = \frac{1}{\rho\varepsilon}.$$ ◀

We construct a new solution $(\hat{x}, \hat{y})$ as follows:

$$\text{for all } (i,j) \in F' \times C', \qquad \hat{x}_{ij} = \begin{cases} 0, & i \notin F'_j; \\ \frac{x'_{ij}}{\sum_{i \in F'_j} x'_{ij}}, & i \in F'_j; \end{cases} \qquad \hat{y}_i = \min\left(1, \rho\varepsilon y'_i\right).$$

Clearly, $\sum_{i \in F'} \hat{y}_i \leq \rho\varepsilon \sum_{i \in F'} y'_i \leq \rho\varepsilon k = O(k/\varepsilon)$. Also, by Lemma 19, $\hat{x}_{ij} \leq \min(1, \rho\varepsilon x'_{ij}) \leq \hat{y}_i$ for every $(i,j) \in F' \times C'$. To bound $L(i,\hat{x})$ for $i \in F'$, recall that i is non-λ-heavy, therefore $\sum_{j \in N'(i)} D(j) \leq \lambda T = \varepsilon^2 T/15$. Since $\hat{x}_{ij} > 0$ if and only if $x'_{ij} > 0$ and $d(i,j) \leq \rho D(j)$,

$$\lambda T \hat{y}_i \geq \sum_{j \in N'(i)} D(j)\hat{y}_i \geq \sum_{\substack{j \in N'(i) \\ s.t.\ \hat{x}_{ij} > 0}} D(j)\hat{y}_i \geq \frac{1}{\rho} \sum_{\substack{j \in N'(i) \\ s.t.\ \hat{x}_{ij} > 0}} d(i,j)\hat{y}_i \geq \frac{1}{\rho} \sum_{\substack{j \in N'(i) \\ s.t.\ \hat{x}_{ij} > 0}} d(i,j)\hat{x}_{ij},$$

implying

$$L(i,\hat{x}) = \sum_{\substack{j \in N'(i) \\ s.t.\ \hat{x}_{ij} > 0}} d(i,j)\hat{x}_{ij} \leq \rho\lambda T\hat{y}_i = \frac{\rho\varepsilon^2}{15} T\hat{y}_i = \frac{(1+\varepsilon)^2}{15} T\hat{y}_i.$$

Also, for every $j \in C'$ we now have $\sum_{i \in F'} \hat{x}_{ij} = 1$ and $\sum_{i : \hat{x}_{ij} > 0} \hat{y}_i \geq 1$.

Since $\{i \in F' : \hat{x}_{ij} > 0\} \subseteq N'(j)$ and $\{j \in C' : \hat{x}_{ij} > 0\} \subseteq N'(i)$, we will abuse the notation and redefine $N'(i)$ and $N'(j)$ in terms of assignment $\hat{x}$. Let $\hat{\nu} := \frac{(1+\varepsilon)^2}{15}$. It holds for $(\hat{x}, \hat{y})$:

1. $\sum_{i \in F'} \hat{y}_i \leq \rho\varepsilon k = O(k/\varepsilon)$,
2. for all $(i,j) \in F' \times C'$, $\hat{y}_i \geq \hat{x}_{ij}$ and if $\hat{x}_{ij} > 0$ then $d(i,j) \leq \rho D(j)$,
3. for every $j \in C'$, $\sum_{i \in F'} \hat{x}_{ij} = 1$ and $\sum_{i \in N'(j)} \hat{y}_i \geq 1$,
4. for every $i \in F'$, $L(i,\hat{x}) \leq \hat{\nu} T \hat{y}_i$.

4.3 Finishing the algorithm

Now we can correctly use our clustering and rerouting algorithms with $(\hat{x}, \hat{y})$. We subsequently apply Algorithm 2 and Algorithm 3 to $(\hat{x}, \hat{y})$ with newly defined sets N' for F' and C', with corresponding values of of parameters λ, ρ and $\nu \equiv \hat{\nu}$, obtaining the integral opening $\dot{y}$ and possibly fractional assignment $\dot{x}$ over (F', C'). By Lemma 14, for $h \in F'$ with $\dot{y}_h = 1$,

$$L(h,\dot{x}) \leq 3(\hat{\nu} + 4\rho\lambda)T = 3\left(\frac{(1+\varepsilon)^2}{15} + 4\frac{(1+\varepsilon)^2}{\varepsilon^2} \cdot \frac{\varepsilon^2}{15}\right) = (1+\varepsilon)^2 T \leq (1+3\varepsilon)T,$$

and we open at most $(1+\varepsilon)\sum_{i \in F'} \hat{y}_i = O(k/\varepsilon)$ facilities.

Since for every $j \in C$ we have $\sum_{i \in F} \dot{x}_{ij} = 1$, there is no need to modify fractional variables $\dot{x}$ to regain lost demand (as we loose nothing). Observe that all $i \in F \setminus F'$ serve $j \in C \setminus C'$ only, these j are assigned to $i \in F \setminus F'$ integrally, and for all $i \in F \setminus F'$ we have $L(i,\dot{x}) \leq (2+3\varepsilon)T$. Therefore, it remains to obtain integral assignment over (F', C'), where for every $i \in F'$

we have $L(i,\dot{x}) \le (1+3\varepsilon)T$. By applying minimum makespan rounding algorithm [7] to the restriction of $(\dot{x},\dot{y})$ on (F',C'), we get integral assignment, sacrificing a factor of 2 in load approximation for $i \in F'$, resulting in maximum load of the final solution at most $(2+6\varepsilon)T$. Algorithm 1 might have opened at most $O(k/\varepsilon^2)$ additional facilities, so we obtain a $\left(2+6\varepsilon, O(1/\varepsilon^2)\right)$-approximate solution to $\mathrm{SC}(T,k)$ problem, and the whole algorithm clearly runs in polynomial-time, proving Theorem 6.

A Preprocessing

▶ **Theorem 20** (Theorem 7 restated). *Let (x,y) be such that, for all $i \in F$, $L(i,x) \le \mu T y_i$ for some constant $\mu \ge 1$ and all other constraints of* SC-LP(T,k) *on variables x are satisfied. There exists a polynomial time algorithm that, given such solution (x,y) and a constant $\gamma \in (0,1)$, finds a solution (x',y') such that*

1. *$y' = y$, and if $x_{ij} = 0$, then $x'_{ij} = 0$;*
2. *for every $(i,j) \in F \times C$, $y'_i \ge x'_{ij}$, and if $x'_{ij} > 0$, then $x'_{ij} \ge \gamma y'_i$;*
3. *for every $j \in C$, $1 \ge \sum_{i \in F} x'_{ij} \ge 1-\gamma$;*
4. *for every $i \in F$, $L(i,x') \le (\mu + 2 - \gamma) T y'_i$.*

The algorithm we use in Theorem 7 is heavily inspired by the minimum makespan rounding algorithm, introduced by Lenstra et. al in [7]. In a sense, their algorithm achieves the desired property: in minimum makespan problem we have $y_i = 1$ for all $i \in F$, so for $j \in C$ we wish to have either $x'_{ij} = 0$ or $x'_{ij} = 1 = y'_i$. The key difference is that in our case y is *not* integral, which requires several modifications of the original algorithm.

Let (x, y) and $\gamma \in (0, 1)$ be given. Let $\tilde{F} \subseteq F$, $\tilde{C} \subseteq C$, let $E \subseteq \tilde{F} \times \tilde{C}$. Consider a bipartite graph $G = (\tilde{F} \cup \tilde{C}, E)$, let $\delta_E(v)$ be the neighbors of $v \in \tilde{F} \cup \tilde{C}$ in G, I.e., for $i \in \tilde{F}$, $\delta_E(i) = \{j \in \tilde{C} : (i, j) \in E\}$, and for $j \in \tilde{C}$, $\delta_E(j) = \{i \in \tilde{F} : (i, j) \in E\}$. For $(i, j) \in \tilde{F} \times \tilde{C}$ we introduce a variable w_{ij}, and numbers $d_j \leq 1$ and $L_i \leq \mu T y_i$, which can be thought of as the remaining demand of client $j \in \tilde{C}$ and the remaining load of facility $i \in \tilde{F}$ respectively. Given sets $\tilde{F}, \tilde{C}, E$ and numbers d, L, we define the polytope $P(\tilde{F}, \tilde{C}, E, d, L)$ as the solution set of the following feasibility linear program:

$$\begin{aligned}
&\sum_{i \in \delta_E(j)} w_{ij} = d_j, && \forall j \in \tilde{C}, \\
&\sum_{j \in \delta_E(i)} d(i,j) w_{ij} \leq L_i, && \forall i \in \tilde{F}, \\
&w_{ij} \leq \min(y_i, d_j), && \forall (i,j) \in E, \\
&w_{ij} \geq 0, && \forall (i,j) \in E.
\end{aligned} \tag{$P(\tilde{F}, \tilde{C}, E, d, L)$}$$

Note that all values y_i for $i \in F$ are fixed, so for every number d_j, $j \in C$, we have either constraint $\{w_{ij} \leq y_i\}$ or constraint $\{w_{ij} \leq d_j\}$. The extreme points of $P(\tilde{F}, \tilde{C}, E, d, L)$ possess some very important properties, which resemble the properties of the extreme point solutions to the auxiliary program for the minimum makespan rounding algorithm of [7].

▶ **Lemma 21.** *Let w be an extreme point of $P(\tilde{F}, \tilde{C}, E, d, L)$, where $d_j \geq \gamma$ for all $j \in \tilde{C}$. One of the following must hold:*

(a) *there exists $(i, j) \in E$ such that $w_{ij} = 0$,*
(b) *there exists $(i, j) \in E$ such that $w_{ij} = y_i$,*
(c) *there exists $(i, j) \in E$ such that $w_{ij} = d_j$,*
(d) *there eixsts $i \in \tilde{F}$ such that $|\delta_E(i)| \leq 1$,*
(e) *there exists $i \in \tilde{F}$ such that $|\delta_E(i)| = 2$ and $\sum_{j \in \delta_E(i)} w_{ij} \geq \gamma y_i$.*

Proof. Suppose that none of (a), (b), (c), or (d) hold. We will show that (e) must hold then.

For all $(i, j) \in E$ we have $0 < w_{ij} < \min(y_i, d_j)$, and for every $i \in \tilde{F}$ we have $|\delta_E(i)| \geq 2$. Since $\sum_{i \in \delta_E(j)} w_{ij} = d_j$ for all $j \in \tilde{C}$, we must also have $|\delta_E(j)| \geq 2$. As w is an extreme point of $P(\tilde{F}, \tilde{C}, E, d, L)$, there exist $\tilde{F}_* \subseteq \tilde{F}$ and $\tilde{C}_* \subseteq \tilde{C}$ such that $\sum_{i \in \delta_E(j)} w_{ij} = d_j$ for all $j \in \tilde{C}_*$, $\sum_{j \in \delta_E(i)} d(i, j) w_{ij} = L_i$ for all $i \in \tilde{F}_*$, $|\tilde{F}_*| + |\tilde{C}_*| = |E|$, and constraints corresponding to $\tilde{F}_*, \tilde{C}_*$ are linearly independent. Since $2|E| = 2|\tilde{F}_*| + 2|\tilde{C}_*| \leq \sum_{i \in \tilde{F}_*} |\delta_E(i)| + \sum_{j \in \tilde{C}_*} |\delta_E(j)| \leq 2|E|$, for all $i \in \tilde{F}_*$ we must have $|\delta_E(i)| = 2$, as well as $|\delta_E(j)| = 2$ for all $j \in \tilde{C}_*$. Therefore, the subgraph $G[\tilde{F}_* \cup \tilde{C}_*]$ of G induced on $\tilde{F}_* \cup \tilde{C}_*$ is a bipartite union of disjoint cycles.

Let H be a cycle of $G[\tilde{F}_* \cup \tilde{C}_*]$, let $H_{\tilde{F}_*} := H \cap \tilde{F}_*$, $H_{\tilde{C}_*} := H \cap \tilde{C}_*$. Since for all $i \in H_{\tilde{F}_*}$ we have $|\delta_E(i)| = 2$, $\delta_E(i) \subseteq H \cap E$, and similarly, as $|\delta_E(j)| = 2$ for all $j \in H_{\tilde{C}_*}$, $\delta_E(j) \subseteq H \cap E$. Suppose that (e) does not hold, then for all $i \in H_{\tilde{F}_*}$ we have $\sum_{j \in \delta_E(i)} w_{ij} < \gamma y_i$. Consequently,

$$\sum_{i \in H_{\tilde{F}_*}} y_i > \frac{1}{\gamma} \sum_{i \in H_{\tilde{F}_*}} \sum_{j \in \delta_E(i)} w_{ij} = \frac{1}{\gamma} \sum_{(i,j) \in H \cap E} w_{ij} = \frac{1}{\gamma} \sum_{j \in H_{\tilde{C}_*}} \sum_{i \in \delta_E(j)} w_{ij} = \frac{1}{\gamma} \sum_{j \in H_{\tilde{C}_*}} d_j.$$

The last equality follows from $\sum_{i \in \delta_E(j)} w_{ij} = d_j$ for every $j \in \tilde{C}_*$. Since $d_j \geq \gamma$ for all $j \in \tilde{C}$, $d_j \geq \gamma y_i$ for all $(i, j) \in E$. Since H is a cycle in bipartite graph, it has even length, its vertices alternate between $\tilde{F}_*$ and $\tilde{C}_*$, and $|H_{\tilde{F}_*}| = |H_{\tilde{C}_*}|$. Then, we can split vertices of H into disjoint

consecutive pairs (i,j), so that $i \in H_{\tilde{F}_*}$, $j \in H_{\tilde{C}_*}$, $(i,j) \in H \cap E$, and apply $d_j \geq \gamma y_i$ for every pair. Therefore, $\sum_{j \in H_{\tilde{C}_*}} d_j \geq \gamma \sum_{i \in H_{\tilde{F}_*}} y_i$, which combined with inequalities above leads to a contradiction. So, there must exist $i \in H_{\tilde{F}_*}$ such that $\sum_{j \in \delta_E(i)} w_{ij} \geq \gamma y_i$, implying (e). ◀

We transform (x,y) into (x',y') using a similar approach as in [7]. On every step $t \geq 1$ of the algorithm, we provide values of parameters $\tilde{F}^t, \tilde{C}^t, E^t, d^t, L^t$ so that polytope $P^t := P(\tilde{F}^t, \tilde{C}^t, E^t, d^t, L^t)$ is nonempty and $d^t_j \geq \gamma$ for $j \in \tilde{C}^t$, and find its extreme point w^t. By Lemma 21, either (a), (b), (c), (d) or (e) cases may occur for w^t. If (a), we set $x'_{ij} \leftarrow 0$, $E^{t+1} \leftarrow E^t \setminus \{(i,j)\}$. If (b), we set $x'_{ij} \leftarrow y_i$, $d^{t+1}_j \leftarrow d^t_j - y_i$, $L^{t+1}_i \leftarrow L^t_i - d(i,j)w^t_{ij}$, $E^{t+1} \leftarrow E^t \setminus \{(i,j)\}$. If (c), we set $x'_{ij} \leftarrow d^t_j$, $d^{t+1}_j \leftarrow 0$, $L^{t+1}_i \leftarrow L^t_i - d(i,j)w^t_{ij}$, $E^{t+1} \leftarrow E^t \setminus \{(i,j)\}$. If (d) or (e), we set $\tilde{F}^{t+1} \leftarrow \tilde{F}^t \setminus \{i\}$. After processing exactly one case (a), (b), (c), (d) or (e), we scan $j \in \tilde{C}^{t+1}$, and if $d^{t+1}_j < \gamma$ for some j, set $\tilde{C}^{t+1} \leftarrow \tilde{C}^{t+1} \setminus \{j\}$, $x'_{ij} \leftarrow 0$ for all (i,j) such that $i \in \delta_{E^{t+1}}(j)$, and then $E^{t+1} \leftarrow E^{t+1} \setminus \{(i,j) : i \in \delta_{E^{t+1}}(j)\}$. If the change of $\tilde{F}^{t+1}, \tilde{C}^{t+1}, E^{t+1}, d^{t+1}$ or L^{t+1} is not mentioned for current case, the values are as in step t, so even though we drop facility i from $\tilde{F}^t$ in case (d) or (e), the edges (i,j) for $j \in \delta_{E^t}(i)$ are still kept in E^{t+1}. Having processed $\tilde{C}^{t+1}$, if $E^{t+1} \neq \varnothing$, we move to step $t+1$ and consider P^{t+1}. Algorithm 4 gives the full pseudocode, summarizing all the steps.

Algorithm 4 Preprocessing.

Input: Initial values of $\tilde{F}$, $\tilde{C}$, E, d, L, parameter $\gamma \in (0,1)$.
Output: An assignment x'.

while $E \neq \varnothing$ **do**
  Find an extreme point w of $P(\tilde{F}, \tilde{C}, E, d, L)$
  if $\exists (i,j) \in E : w_{ij} = 0$ **then** $x'_{ij} \leftarrow 0$, $E \leftarrow E \setminus \{(i,j)\}$
  else if $\exists (i,j) \in E : w_{ij} = y_i$ **then**
    $x'_{ij} \leftarrow y_i$, $d_j \leftarrow d_j - y_i$, $L_i \leftarrow L_i - d(i,j)w_{ij}$, $E \leftarrow E \setminus \{(i,j)\}$
  else if $\exists (i,j) \in E : w_{ij} = d_j$ **then**
    $x'_{ij} \leftarrow d_j$, $d_j \leftarrow 0$, $L_i \leftarrow L_i - d(i,j)w_{ij}$, $E \leftarrow E \setminus \{(i,j)\}$
  else if $\exists i \in \tilde{F} : |\delta_E(i)| \leq 1$ **then** $\tilde{F} \leftarrow \tilde{F} \setminus \{i\}$
  else if $\exists i \in \tilde{F} : |\delta_E(i)| = 2$ **and** $\sum_{j \in \delta_E(i)} w_{ij} \geq \gamma y_i$ **then** $\tilde{F} \leftarrow \tilde{F} \setminus \{i\}$

    if $d_j < \gamma$ **then**
      $\tilde{C} \leftarrow \tilde{C} \setminus \{j\}$, **for** $\boldsymbol{i \in \delta_E(j)}$ **do** $x'_{ij} \leftarrow 0$, $E \leftarrow E \setminus \{(i,j)\}$
return x', extended to $F \times C$ by adding zero entries

It is easy to see that if P^t is nonempty and $d^t_j \geq \gamma$ for $j \in \tilde{C}^t$, the very same holds for P^{t+1} in the next step, unless $E^{t+1} = \varnothing$. Indeed, we manually assure that for all j kept in $\tilde{C}^{t+1}$ the condition $d^{t+1}_j \geq \gamma$ must hold, and the restriction of w^t to the set $E^{t+1} \subseteq E^t$ is a feasible solution to P^{t+1}, by construction of the algorithm. Moreover, if we take $\tilde{F}^1 = F$, $\tilde{C}^1 = C$, $E^1 = \{(i,j) \in F \times C : x_{ij} > 0\}$, $d^1_j = 1$ for $j \in C$ and $L^1_i = \mu T y_i$ for $i \in F$, $d^1_j \geq \gamma$ and P^1 is nonempty, since there is a feasible solution $w_{ij} := x_{ij}$ for $(i,j) \in E^1$. We run Algorithm 4 with these initial values of $\tilde{F}$, $\tilde{C}$, E, d and L given as input, obtaining an assignment x'. By setting $y' := y$, we obtain a solution (x',y').

We claim that Algorithm 4 runs in polynomial-time, and solution (x',y') satisfies all requirements of Theorem 7. By Lemma 21, on every step $t \geq 1$ either (a), (b), (c), (d) or (e) must occur for w^t, the extreme point of P^t. Then, either $|E^t|$, $|\tilde{F}^t|$ or $|\tilde{C}^t|$ is reduced at least by 1 after step t. So, since $|E^1| \leq |F||C|$, after at most $2|F||C|$ steps we will have $E^{t+1} = \varnothing$ for some $1 \leq t \leq 2|F||C|$. Each step t takes only polynomial time to perform, thus the total running time is also polynomial.

Since $E^1 = \{(i,j) \in F \times C : x_{ij} > 0\}$, the only positive coordinates of x' can be (i,j) such that $x_{ij} > 0$, as if $x_{ij} = 0 \iff (i,j) \notin E^1$, Algorithm 4 sets $x'_{ij} = 0$ in the very end. The constraint $\{w_{ij} \le \min(y_i, d_j)\}$ of $P(\tilde{F}, \tilde{C}, E, d, L)$ assures that $x'_{ij} \le y'_i$, for all $(i,j) \in F \times C$. If $x'_{ij} > 0$, then either $x'_{ij} = y'_i$ (case (b)) or $x'_{ij} = d^t_j$ for some step $t \ge 1$ (case (c)). Since $y'_i \le 1$ and for all steps $t \ge 1$ we maintain $d^t_j \ge \gamma$ for all $j \in \tilde{C}$, in both cases we have $x'_{ij} \ge \gamma y'_i$.

Next, if after processing cases for w^t during some step $t \ge 1$ we end up with $d^{t+1} < \gamma$, client j gets discarded from $\tilde{C}^{t+1}$. Since $d^1_j = 1$ initially, by the end of step t we must have assigned at least $1-\gamma$ portion of j's demand before discarding j having $d^{t+1}_j < \gamma$. Then, after Algorithm 4 finishes, for all $j \in C$ we have $1 \ge \sum_{i \in F} x'_{ij} \ge 1 - \gamma$.

Finally, fix $i \in F$. Observe that if $i \in \tilde{F}^t$ in the beginning of step $t \ge 1$, then

$$\sum_{j \in \delta_{E^t}(i)} d(i,j) w^t_{ij} \le L^t_i = L^1_i - \sum_{C \setminus \tilde{C}^t} d(i,j) x'_{ij} \implies \sum_{C \setminus \tilde{C}^t} d(i,j) x'_{ij} + \sum_{j \in \delta_{E^t}(i)} d(i,j) w^t_{ij} \le \mu T y_i,$$

by feasibility of w^t for polytope P^t. Suppose that after step t facility i gets removed from $\tilde{F}^t$, so $i \notin \tilde{F}^{t+1}$. If case (d) occurred and $|\delta_{E^t}(i)| \le 1$, let $j \in \delta_{E^t}(i)$ be a single client served by facility i. After removing i from $\tilde{F}^t$, the constraint $\{\sum_{j \in \delta_E(i)} d(i,j) w_{ij} \le L_i\}$ is not present in P^{t+1} and all future-step polytopes. So, for any step $r \ge t+1$, the load we may get after obtaining w^r and determining the value of x'_{ij} is at most $d(i,j) w^r \le d(i,j) y_i \le T y_i$ (as $d(i,j) \le T$ for all $x_{ij} > 0$). The total load of facility i becomes $L(i,x') \le (\mu+1) T y_i$.

If case (e) occurred for this facility i, $|\delta_{E^t}(i)| = 2$ and $\sum_{j \in \delta_{E^t}(i)} w^t_{ij} \ge \gamma y_i$. Let j' and j'' be the two clients belonging to $\delta_{E^t}(i)$. Their contribution to facility i's load on step t is exactly $d(i,j') w^t_{ij'} + d(i,j'') w^t_{ij''}$, which is at most L^t_i. After removing i from $\tilde{F}^t$, the constraint $\{\sum_{j \in \delta_E(i)} d(i,j) w_{ij} \le L_i\}$ is not present in P^{t+1} and all future-step polytopes. So, for any step $r \ge t+1$, the load we may get after obtaining w^r and determining the values of both $x'_{ij'}$ and $x'_{ij''}$ is at most $d(i,j') w^r_{ij'} + d(i,j'') w^r_{ij''} \le d(i,j') y_i + d(i,j'') y_i$. Hence, the *additional* load facility i gained since the end of step t is at most

$$\begin{aligned}
&(d(i,j')y_i + d(i,j'')y_i) - (d(i,j')w^t_{ij'} + d(i,j'')w^t_{ij''}) = \\
&= d(i,j')(y_i - w^t_{ij'}) + d(i,j'')(y_i - w^t_{ij''}) \le T(2y_i - (w^t_{ij'} + w^t_{ij''})) \le \\
&\qquad \le T(2y_i - \gamma y_i) = (2-\gamma) T y_i.
\end{aligned}$$

Therefore, the total load of facility i becomes $L(i,x') \le (\mu + 2 - \gamma) T y_i$.

As a result, solution (x', y') and the preprocessing algorithm (Algorithm 4) indeed satisfy all the claimed properties of Theorem 7, thus finishing the proof.

B Hard instances

We first present a hard instance for MLkSC problem. Let R, M be integers, $R \ll M$. Let $k = 2R - 1$, $|F| = 2R$, $|C| = (M+R)R$. F and C are partitioned into R disjoint groups, each has exactly 2 facilities and exactly $M + R$ clients. For $i, h \in F$, $d(i,h) = 1$ if i, h are in the same group, otherwise $d(i,h) = R$. In every group, one facility has M collocated clients (call it M-facility), the other has R collocated clients (R-facility). The instance is illustrated in Figure 2.

There is a feasible fractional solution to MLkSC-LP for this instance with $T = 1$. Open every M-facility fully, and there assign all its collocated clients. Next, open every R-facility to $1 - 1/R$, and let it serve $(1 - 1/R)$-fraction of its collocated clients' demand. The remaining $1/R$ fraction of these clients' demand will be served by M-facility of the same group. It is easy to see that the load of every R-facility is 0, the load of every M-facility is $R \cdot 1/R \cdot 1 = 1$, and the opening is exactly $R \cdot (1 + 1 - 1/R) = 2R - 1 = k$.

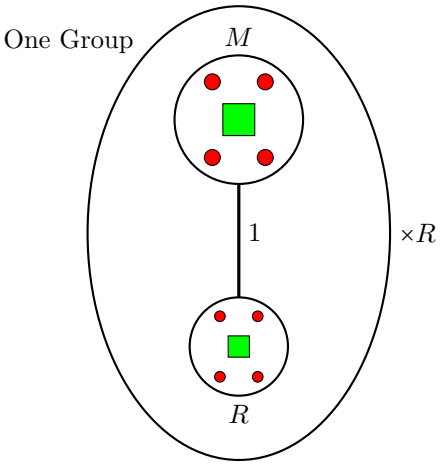

Figure 2 Hard instance for MLkSC-LP.

Consider any integral solution to this instance of MLkSC. If it assigns some client to a facility from different group, maximal load will be at least R. Suppose that all clients are assigned to facilities only from the same group. Since $k = 2R - 1$, there will be at least one group with at most one facility opened, take this group. If M-facility is opened, both its clients and clients of R-facility must be assigned to M-facility fully, resulting in its load $R \cdot 1 \cdot 1 = R$. Similarly, if R-facility is opened, maximum load will be at least $M \gg R$. Hence, the load of any integral star cover of size k is at least R. Furthermore, even if we allow opening $(1+\varepsilon)k$ facilities for $\varepsilon = 1/(2R)$, since

$$(1+\varepsilon)k = \left(1 + \frac{1}{2R}\right)(2R-1) = 2R - \frac{1}{2R} < 2R,$$

there will still be a group with at most one facility opened, resulting in maximum load at least $R = T/(2\varepsilon)$, where $T = 1$ is maximal fractional load. It follows that if T^* is an optimal load to MLkSC-LP, any integral $(1+\varepsilon)k$ star cover of (F, C) has load is at least $\Omega(1/\varepsilon)T^*$.

Now, we move to a hard instance for MSSC. For integer N, let $|F| = N$ and $|C| = N + 1$, the load bound $T \geq 1$ is arbitrary. Both $F = \{i_1, \ldots, i_N\}$ and $C = \{J, j_1, \ldots, j_N\}$ are vertices of a bipartite graph, and the metric d is a shortest-path metric. For every $1 \leq r \leq N$ we have an edge (i_r, j_r) or length $d(i_r, j_r) = (1 - 1/N)T$. Also, every facility i_r for $1 \leq r \leq N$ is connected to a "central" client J by an edge of length $d(i_r, J) = T$. The instance is illustrated in Figure 3.

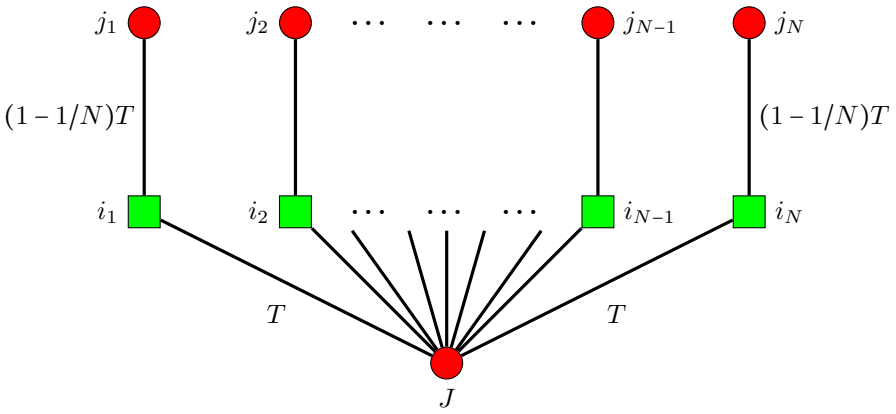

Figure 3 Hard instance for MSSC-LP.

It is easy to see that in any integral solution to MSSC-LP every client j_r for $1 \leq r \leq N$ can be served only by facility i_r. Furthermore, client J should also be served fully, so it should be assigned to one of $i \in F$. Therefore, even if we open all facilities in F fully, for some facility $i \in F$ which gets J assigned to it, the load will be at least $(2 - 1/N)T$. This means that there is no feasible integral solution to MSSC-LP, and any integral solution violates the maximum load constraint at least by a factor of $(2 - 1/N)$.

On the other hand, there exists a feasible *fractional* solution to MLkSC-LP for this instance. We open all i_r for $1 \leq r \leq N$ and assign j_r fully to it. Also, client J gets served by all $i \in F$ at an equal fraction of $1/N$. In this solution, the load of every facility $i \in F$ is exactly T.

On the Approximability of Presidential Type Predicates

Abstract

Given a predicate $P : \{-1,1\}^k \to \{-1,1\}$, let CSP($P$) be the set of constraint satisfaction problems whose constraints are of the form P. We say that P is approximable if given a nearly satisfiable instance of CSP(P), there exists a probabilistic polynomial time algorithm that does better than a random assignment. Otherwise, we say that P is approximation resistant.

In this paper, we analyze presidential type predicates, which are balanced linear threshold functions where all of the variables except the first variable (the president) have the same weight. We show that almost all presidential type predicates P are approximable. More precisely, we prove the following result: for any $\delta_0 > 0$, there exists a k_0 such that if $k \geq k_0$, $\delta \in (\delta_0, 1 - 2/k]$, and $\delta k + k - 1$ is an odd integer then the presidential type predicate $P(x) = \text{sign}(\delta k x_1 + \sum_{i=2}^{k} x_i)$ is approximable. To prove this, we construct a rounding scheme that makes use of biases and pairwise biases. We also give evidence that using pairwise biases is necessary for such rounding schemes.

1 Introduction

In constraint satisfaction problems (CSPs), we have a set of constraints and we want to satisfy as many of them as possible. Many fundamental problems in computer science are CSPs, including 3-SAT, MAX CUT, k-colorability, and unique games.

One fundamental question about CSPs is as follows. For a given type of CSP, is there a randomized polynomial time algorithm which is significantly better than randomly guessing an assignment? More precisely, letting r be the expected proportion of constraints satisfied by a random assignment, is there an $\epsilon > 0$ and a randomized polynomial time algorithm A such that given a CSP instance where at least $(1 - \epsilon)$ of the constraints can be satisfied, A returns an x which satisfies at least $(r + \epsilon)$ of the constraints in expectation? If so, we say that this type of CSP is approximable. If not, then we say that this type of CSP is approximation resistant.

For example, Håstad's 3-bit PCP theorem [10] proves that 3-XOR instances (where every constraint is a linear equation modulo 2 over 3 variables) are NP-hard to approximate. A direct corollary of Håstad's 3-bit PCP theorem is that 3-SAT is also NP-hard to approximate and this theorem has served as the basis for numerous other inapproximability results. On

the other hand, Goemans and Williamson's [7] breakthrough algorithm for MAX CUT, which gives an approximation ratio of .878 for MAX CUT, shows that MAX CUT is approximable as a random cut would only cut half of the edges in expectation.

However, while the approximability or approximation resistance of CSPs has been extensively investigated, there is still much that is unknown. In this paper, we investigate CSPs where every constraint has the form of some fixed presidential type predicate P. We show that for almost all presidential type predicates P, this type of CSP is approximable.

1.1 Definitions

In order to better describe our results and their relationship to prior work, we need a few definitions.

▶ **Definition 1.** *A* Boolean predicate P *of arity* k *is a function* $P : \{-1,1\}^k \to \{-1,1\}$.

We remark that in general a predicate can be non-Boolean.

▶ **Definition 2.** *A* presidential type predicate *is a Boolean predicate of the form*

$$P(x_1, \ldots, x_k) = \text{sign}(a \cdot x_1 + x_2 + \cdots + x_k),$$

where a *is an integer and* $a + k - 1$ *is odd.*

▶ Remark 3. In the definition above we require that a is an integer. This is not a serious restriction because if a is not an integer, then we can shift a up or down slightly to find another predicate with integer coefficient a' which is equivalent to the original predicate. We require $a + k - 1$ to be odd in order to prevent a tie.

We can think of the predicate as a vote where the vote of x_1, the "president", has weight a, while the votes of the remaining voters, the "citizens", have the same weight 1.

▶ Remark 4. Note that presidential type predicates are balanced linear threshold functions, i.e. functions of the form $sign(\sum_{i=1}^k c_i x_i)$ where $\forall i, c_i \in \mathbb{R}$ and $\forall x \in \{-1,1\}^k, \sum_{i=1}^k c_i x_i \neq 0$ (so that the function is well-defined). Note that if a predicate P is a balanced linear threshold function, $P(-x) = -P(x)$ so exactly half of the assignments satisfy the predicate and thus a uniformly random assignment has expected value 0.

▶ **Definition 5.** *Given a Boolean predicate* $P : \{-1,1\}^k \to \{-1,1\}$*, an instance* Φ *of* $\text{CSP}(P)$ *consists of a set of* n *variables* $x_1, \ldots, x_n$ *and* m *constraints* $C_1, \ldots, C_m$ *where each* C_i *has the form*

$$C_i(x_{i_1}, \ldots, x_{i_k}) = P(z_{i,1}x_{i_1}, \ldots, z_{i,k}x_{i_k})$$

for some distinct $i_1, \ldots, i_k \in [n]$ *and* $z_{i,1} \ldots z_{i,k} \in \{-1,1\}$.

▶ **Definition 6.** *A Boolean predicate* P *is* approximable *if there exists a constant* $\epsilon > 0$ *and a polynomial time algorithm, possibly randomized, that on input* $\Phi \in \text{CSP}(P)$ *such that* $\text{OPT}(\Phi) \geq 1 - \epsilon$*, produces an assignment to* Φ*'s variables that in expectation satisfies* $r_P + \epsilon$ *fraction of the constraints in* Φ*, where* $r_P = \mathbb{E}_{x \in \{-1,1\}^k}[(1 + P(x))/2]$ *is the probability that a constraint in* Φ *is satisfied by a random assignment. Otherwise, we say* P *is* approximation resistant.

We say that a Boolean predicate P *is* weakly approximable *if there exists a constant* $\epsilon > 0$ *and a polynomial time algorithm, possibly randomized, that on input* $\Phi \in \text{CSP}(P)$ *such that* $\text{OPT}(\Phi) \geq 1 - \epsilon$*, produces an assignment to* Φ*'s variables that in expectation either satisfies at least* $r_P + \epsilon$ *fraction of the constraints in* Φ *or satisfies at most* $r_P - \epsilon$ *fraction of the constraints in* Φ*. Otherwise, we say that* P *is* strongly approximation resistant.

▶ Remark 7. For presidential type predicates, and in fact any odd predicate P (i.e. a predicate P where $P(-x) = -P(x)$), the notions of being approximable and being weakly approximable are equivalent.

1.2 Our Results

In this paper, we prove the following result.

▶ **Theorem 8.** *For any $\delta_0 > 0$, there exists a $k_0 \in \mathbb{N}$ such that if $k \geq k_0$, $\delta \in (\delta_0, 1 - 2/k]$, and $\delta k + k - 1$ is an odd integer then the presidential type predicate*

$$P(x) = \text{sign}\left(\delta k x_1 + \sum_{i=2}^{k} x_i\right)$$

is approximable.

▶ Remark 9. Informally, this theorem says that if the weight of x_1 (the "president") is at least a constant times k, then the predicate is approximable for sufficiently large k. We have the condition $\delta \leq 1 - 2/k$ because if $\delta > 1 - 2/k$ and $\delta k + k - 1$ is an odd integer, then $\delta k \geq k$, which means the predicate is a dictator predicate which is trivially approximable.

We will prove this theorem by constructing a *rounding scheme* that makes use of *biases* and *pairwise biases*, which are given by a standard semi-definite program (see Section 2.2). Complementarily, we also give evidence that using pairwise biases is necessary for such rounding schemes. In particular, we show that for any fixed $\delta > 0$ and degree m, for sufficiently large k there is no rounding scheme for the predicate $P(x) = \text{sign}\left(\delta k x_1 + \sum_{i=2}^{k} x_i\right)$ which has degree at most m and does not use pairwise biases (see Theorem 40).

1.3 Relationship to Prior Work

We now describe known criteria for determining whether a predicate P is approximable or approximation resistant and how our techniques compare to these criteria.

In 2008, Raghavendra [14] gave a characterization of which predicates are approximable and which predicates are approximation resistant. Raghavendra showed that either a standard semi-definite program (SDP) together with an appropriate rounding scheme gives a better approximation ratio than a random assignment or it is unique games hard to do so. However, this characterization leaves much to be desired because for a given predicate, it can be extremely hard to tell which case holds. In fact, it is not even known to be decidable!

Khot, Tulsiani, and Worah [12] gave a characterization of which predicates are weakly approximable which is based on whether there exist certain vanishing measures over a polytope which we call the KTW polytope (though similar polytopes were analyzed in some earlier papers, see e.g. [2, 3, 4, 11]). Unfortunately, it is also unknown whether this characterization is decidable.

Thus, if we want to determine if a given predicate P is approximable or approximation resistant, it is often better to use more direct criteria. For showing that predicates are hard to approximate, the following criterion, proved by Austrin and Mossel [5], is extremely useful.

▶ **Definition 10.** *We say that a Boolean predicate P has a balanced pairwise independent distribution of solutions if there exists a distribution D on $\{-1,1\}^k$ such that*

1. *D is supported on $\{x \in \{-1,1\}^k : P(x) = 1\}$ (D is a distribution of solutions to P)*
2. *For all $i \in [k]$, $\mathbb{E}_{x \in D}[x_i] = 0$ and for all $i < j \in [k]$, $\mathbb{E}_{x \in D}[x_i x_j] = 0$*

▶ **Theorem 11.** *If P has a balanced pairwise independent distribution of solutions then P is unique games hard to approximate.*

This criterion captures most but not all predicates which are known to be unique games hard to approximate. One example of a predicate which is not captured by this criterion is the predicate which was recently constructed by Potechin [13] which is unique games hard to approximate and is a balanced linear threshold function. [1]

For approximation resistance which does not rely on the hardness of unique games, Chan [6] gave the following stricter criterion which implies NP-hardness of approximation.

▶ **Theorem 12.** *If a predicate P has a balanced pairwise independent subgroup of solutions then P is NP-hard to approximate.*

For showing that predicates are approximable, the general technique is as follows:

1. Run Raghavendra's SDP to obtain biases $\{b_i : i \in [n]\}$ and pairwise biases $\{b_{ij} : i < j \in [n]\}$ for the variables.
2. Construct a rounding scheme which takes these biases and pairwise biases and gives us a solution x such that if the SDP "thinks" that almost all of the constraints are satisfiable then x satisfies significantly more constraints than a random assignment in expectation.

Based on rounding schemes which are essentially linear in the biases and pairwise biases, Hast [9] obtained the following criterion for when predicates are approximable:

▶ **Theorem 13** (Hast's criterion)**.** *Given a predicate $P : \{-1,+1\}^k \to \{-1,+1\}$,*

1. *Define $P_1 : \{-1,+1\}^k \to \mathbb{R}$ to be $P_1(x) = \sum_{i=1}^{k} \hat{P}_{\{i\}} x_i$*
2. *Define $P_2 : \{-1,+1\}^k \to \mathbb{R}$ to be $P_2(x) = \sum_{i=1}^{k-1} \sum_{j=i+1}^{k} \hat{P}_{\{i,j\}} x_i x_j$.*

If there are constants c_1, c_2 such that $c_2 \geq 0$ and $c_1 P_1(x) + c_2 P_2(x) > 0$ for all x such that $P(x) = 1$ then P is approximable.

Aside from Hast's criterion, most of the known approximability results are ad-hoc. Some such results are as follows.

1. Austrin, Benabbas, and Magen [1] showed that the monarchy predicate $P(x_1, \cdots, x_k) = \text{sign}((k-2)x_1 + \sum_{i=2}^{k} x_i)$ is approximable and that any predicate P which is a balanced symmetric quadratic threshold function is approximable.
2. Potechin [13] showed that the almost monarchy predicate $P(x_1, \cdots, x_k) = \text{sign}((k-4)x_1 + \sum_{i=2}^{k} x_i)$ is approximable for sufficiently large k.

In this paper, we prove that almost all presidential type predicates are approximable by generalizing the ideas Potechin [13] used to prove that the almost monarchy predicate is approximable for sufficiently large k and making these ideas more systematic. Our work compares to previous criteria as follows.

1. Raghavendra's criterion and the KTW criterion give a space of rounding schemes which should be considered but don't provide an efficient way to search for the best rounding scheme in this space. For our techniques, we take full advantage of this space of rounding schemes while also providing a way to systematically construct the rounding scheme which we need.

[1] There were previously known predicates, such as the GLST predicate [8] $P(x_1, x_2, x_3, x_4) = \frac{1+x_1}{2} x_2 x_3 + \frac{1-x_1}{2} x_2 x_4$, which are unique games hard (in fact NP-hard) to approximate yet do not have a balanced pairwise independent distribution of solutions. However, the hardness of these predicates can be reduced to the hardness of predicates which do have a balanced pairwise independent distribution of solutions, so Austrin and Mossel's criterion can still be used for these predicates.

2. Like Hast's criterion, we need to check that a certain expression is positive for all x such that $P(x) = 1$. However, there are two key differences between our techniques and Hast's criterion. First, as noted above, we use a larger space of rounding schemes. In particular, we use rounding schemes which are very much non-linear in the biases and pairwise biases. Second, because these rounding schemes are nonlinear in the biases and pairwise biases, it is not sufficient to check all x such that $P(x) = 1$. Instead, we need to check over the entire KTW polytope.

2 Techniques for Analyzing Boolean Predicates

In this section, we recall techniques for analyzing the approximability of boolean predicates.

2.1 Fourier Analysis

In this paper, we will make extensive use of the Fourier expansion of boolean predicates. The Fourier expansion of a k-ary boolean predicate P is of the form $P(x) = \sum_{I \subset [k]} \hat{P}_I x_I$, where $x_I = \prod_{i \in I} x_i$ and $\{\hat{P}_I : I \subseteq [k]\}$ are the Fourier coefficients $\hat{P}_I = \mathbb{E}_{x \in \{-1,1\}^k}[P(x)x_I]$ of P. We have the following lemma for the Fourier coefficients of presidential type predicates, the proof of which can be found in the full version.

▶ **Lemma 14** (Fourier coefficients of presidential type predicates). *Let $P(x_1, \ldots, x_k) = \mathrm{sign}(a \cdot x_1 + x_2 + \cdots + x_k)$ be a presidential type predicate where $a \leq k-2$ and $a + k - 1$ is an odd integer. Let $\hat{P}_{tC}$ denote the Fourier coefficient of a set of t citizens (indices from 2 to k) and $\hat{P}_{P+tC}$ denote the Fourier coefficient of a set of t citizens together with the president (index 1). Let $\tau = \lfloor (k-a-1)/2 \rfloor$. We have*

(1) $\hat{P}_P = 1 - \frac{1}{2^{k-2}} \sum_{l=0}^{\tau} \binom{k-1}{l}$,

(2) $\hat{P}_{tC} = \frac{1}{2^{k-2}} \sum_{i=0}^{\tau} \sum_{j=0}^{\tau-i} (-1)^j \binom{k-t-1}{i} \binom{t}{j}$, $\quad \forall t (1 \leq t \leq k-1 \wedge t \text{ is odd})$,

(3) $\hat{P}_{P+tC} = -\frac{1}{2^{k-2}} \sum_{i=0}^{\tau} \sum_{j=0}^{\tau-i} (-1)^j \binom{k-t-1}{i} \binom{t}{j}$, $\quad \forall t (2 \leq t \leq k-1 \wedge t \text{ is even})$.

2.2 Choosing Rounding Schemes

Our approximation algorithms for presidential type predicates work as follows. We first run the standard SDP given by Raghavendra [14]. This standard SDP gives us biases $\{b_i : i \in [n]\}$ and pairwise biases $\{b_{ij} : i < j \in [n]\}$ such that for each constraint, these biases and pariwise biases give us a point in the KTW polytope for that constraint, which is defined below and which plays a crucial role in Khot, Tulsiani and Worah's [12] characterization of which predicates are weakly approximable. For a more detailed discussion of this standard SDP and the KTW polytope, see the full version of this paper.

▶ **Definition 15.** *Given $x \in \{-1,1\}^k$, let $p(x) \in \{-1,1\}^{k+\binom{k}{2}}$ be the vector obtained by concatenating x and $(x_1x_2, x_1x_3, \ldots, x_{k-1}x_k)$. Define*

$$KTW_P = \mathrm{Conv}(\{p(x) \mid x \in \{-1,1\}^k, P(x) = 1\}),$$

where $P : \{-1,1\}^k \to \{-1,1\}$ is a boolean predicate and $\mathrm{Conv}(S)$ is the convex hull of S.

Once we have these biases $\{b_i : i \in [n]\}$ and pairwise biases $\{b_{ij} : i < j \in [n]\}$, we use a probabilistic rounding scheme to obtain an actual $x \in \{-1,1\}^n$. To choose this rounding scheme, we choose $\mathbb{E}[x_I]$ for each monomial $x_I = \prod_{i \in I} x_i$. However, we do not have complete freedom for these choices. Intuitively, $\mathbb{E}[x_I]$ should obey the following constraints:

1. $\mathbb{E}[x_I]$ is a function of $\{b_i \mid i \in I\}$ and $\{b_{ij} \mid i, j \in I\}$.
2. $\mathbb{E}[x_I]$ is invariant under permutations of the indices in I.
3. If we flip the sign of any variable x_i where $i \in I$ (by flipping the signs of b_i and $\{b_{ij} : j \in I, j \neq i\}$), then the sign of $\mathbb{E}[x_I]$ should be flipped as well.

It turns out that for determining whether a predicate P is *weakly approximable* (which is the same as approximable for presidential type predicates), these are the only constraints on $\mathbb{E}[x_I]$. More precisely, we have the following theorem from [13], which is also implicit in [12]:

▶ **Theorem 16** (Theorem 5.1 in [13]). *Let $\{b_i \mid i \in [k]\}$ and $\{b_{ij} \mid i, j \in [k], i < j\}$ be biases and pairwise biases produced by the standard SDP. For every $a \in [k]$, let $f_a : [-1,1]^{a+\binom{a}{2}} \to [-1,1]$ be a continuous function satisfying the following symmetric requirements.*

1. *For all permutations $\sigma \in S_a$,*

$$f_a(b_{i_{\sigma(1)}}, \ldots, b_{i_{\sigma(a)}}, b_{i_{\sigma(1)}i_{\sigma(2)}}, \ldots, b_{i_{\sigma(a-1)}i_{\sigma(a)}}) = f_a(b_{i_1}, \ldots, b_{i_a}, b_{i_1 i_2}, \ldots, b_{i_{a-1}i_a})$$

2. *For all signs $s_{i_1}, \ldots, s_{i_a} \in \{-1, 1\}^a$,*

$$f_a(s_{i_1}b_{i_1}, \ldots, s_{i_a}b_{i_a}, s_{i_1}s_{i_2}b_{i_1 i_2}, \ldots, s_{i_{a-1}}s_{i_a}b_{i_{a-1}i_a}) = f_a(b_{i_1}, \ldots, b_{i_a}, b_{i_1 i_2}, \ldots, b_{i_{a-1}i_a}) \cdot \prod_{j=1}^{a} s_{i_j}$$

Then there exists a sequence of rounding schemes $\{R_q\}$ and coefficients $\{c_q\}$ such that for all subsets $I = \{i_1, \ldots, i_a\}$ of size at most k,

$$\sum_q c_q \mathbb{E}_{R_q}[x_I] = f_a(b_{i_1}, \ldots, b_{i_a}, b_{i_1 i_2}, \ldots, b_{i_{a-1}i_a}),$$

where $\mathbb{E}_{R_q}[x_I]$ is the expected value of x_I given by rounding scheme R_q. Moreover, this sum can be taken to be globally convergent.

▶ Remark 17. This theorem gives us a linear combination of rounding schemes. The coefficients c_q can be thought of as a probability distribution of rounding schemes, but there are two problems:

1. $\sum_q |c_q|$ may not be 1. One fix to this issue is to scale f by an appropriate constant ϵ.
2. c_q may be negative. In general, this can be a real issue but here the predicates we consider are odd, which means if c_q is negative we can simply flip the rounding scheme R_q and take it with probability $-c_q$.

▶ **Example 18.** This theorem says the following about $\mathbb{E}[x_i]$ and $\mathbb{E}[x_i x_j]$.

1. We can take $\mathbb{E}[x_i] \sim f_1(b_i)$ for any continuous function f_1 such that $f_1(b_i) = -f_1(-b_i)$ (i.e. f_1 is odd).
2. We can take $\mathbb{E}[x_i x_j] \sim f_2(b_i, b_j, b_{ij})$ for any continuous function f_2 such that $f_2(b_i, b_j, b_{ij}) = f_2(b_j, b_i, b_{ij}) = -f_2(-b_i, b_j, -b_{ij})$. The first equality corresponds to exchanging i and j while the second equality corresponds to flipping x_i.

▶ **Example 19.** Some examples of possible functions f_3 are as follows:

1. We can take $\mathbb{E}[x_i x_j x_k] \sim x_i x_j x_k$
2. As discussed in the following subsections, we will take $\mathbb{E}[x_i x_j x_k] \sim (b_i b_{jk} + b_j b_{ik} + b_k b_{ij})$
3. Potechin [13] found a simpler rounding scheme for the monarchy predicate where $\mathbb{E}[x_i x_j x_k] \sim sign(x_i x_j x_k) \max\{|x_i|, |x_j|, |x_k|\}$

In choosing the rounding scheme, our goal is as follows. For each constraint, the standard SDP could give us any point in the KTW polytope. We need to show that no matter which point in the KTW polytope we are given, the probability that the rounding scheme satisfies the constraint is better than a random guess. Equivalently, we need to show that for all points in the KTW polytope, $\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I] > 0$.

▶ **Example 20.** Consider the majority predicate $P(x_1,\ldots,x_k) = \text{sign}(x_1+\ldots+x_k)$. If we take $E[x_i] = f_1(b_i) = \epsilon b_i$ and take $f_a = 0$ whenever $a > 1$ then

$$\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I] = \epsilon\hat{P}_{\{1\}}\sum_{i=1}^{k}b_i$$

Since $\sum_{i=1}^{k}x_i \geq 1$ for every satisfying assignment, for any point in the KTW polytope, $\sum_{i=1}^{k}b_i \geq 1$ and thus $\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I] \geq \epsilon\hat{P}_{\{1\}} > 0$.

3 Techniques for Approximating Presidential Type Predicates

In this section, we describe our techniques for approximating presidential type predicates. These techniques are a generalization of the techniques used in [13] to show that the almost monarchy predicate is approximable for sufficiently large k.

3.1 High Level Overview

To approximate the presidential type predicate $P(x) = \text{sign}\left(\delta k x_1 + \sum_{i=2}^{k}x_i\right)$, we use the following type of rounding scheme.

1. $f_1(b_i) = c_1 b_i$.
2. $f_{2l+1}(b_{i_1},\ldots,b_{i_{2l+1}},b_{i_1i_2},\ldots,b_{i_{2l}i_{2l+1}}) = c_{2l+1}\left(b_{i_1}b_{i_2i_3}\cdots b_{i_{2l}i_{2l+1}} + \text{symmetric terms}\right)$

where we need to carefully choose the coefficients $c_1, c_3, \ldots$ so that for all points in the KTW polytope,

$$\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I] > 0.$$

Because of the symmetry of presidential type predicates P, we can analyze $\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I]$ in terms of a few key functions of the biases and pairwise biases.

▶ **Definition 21.** *Given biases $\{b_i : i\in[k]\}$ and pairwise biases $\{b_{ij} : i<j\in[k]\}$, we make the following definitions:*

1. *We define $\alpha = b_1$*
2. *We define $\beta = \sum_{i=2}^{k}b_i$*
3. *We define $S_{\{\{i_1,i_2\}\}} = \sum_{1<i<j\in[k]}b_{ij}$. We then write $S_{\{\{i_1,i_2\}\}} = E(1+\Delta)$ where $E = \frac{\delta^2k^2}{2} - \frac{k}{2} + 1$ is the value we expect for $S_{\{\{i_1,i_2\}\}}$ and Δ measures how far $S_{\{\{i_1,i_2\}\}}$ is from this expected value.*

With these definitions, we can approximate $\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I]$ in terms of α, β, and Δ. Our strategy is now as follows:

1. We choose a polynomial $h(x) = \sum_{l=1}^{m}a_l x^l$ so that $h(1+\Delta)\approx 1$ except near $\Delta = -1$ as we must have that $h(0) = 0$. More precisely, we choose h to satisfy certain properties (see Lemma 36).

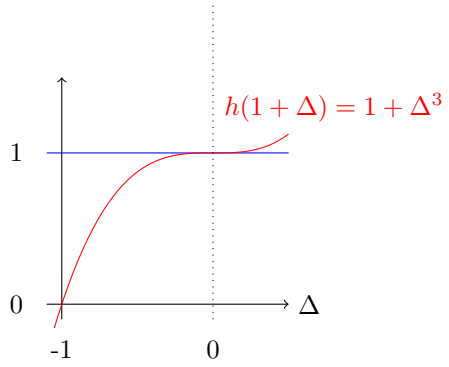

Figure 1 Plot of $h(1+\Delta) = 1+\Delta^3$.

▶ Remark 22. A reasonably good choice for h is $h(1+\Delta) = 1+\Delta^3$, which was used to give an approximation algorithm for the almost monarchy predicate for sufficiently large k [13]. In fact, while we don't prove it here, for quasi-monarchy predicates of the form $P(x_1,\ldots,x_k) = sign\left((k-2c)x_1 + \sum_{i=2}^{k} x_i\right)$ for a fixed constant c, $h(1+\Delta) = 1+\Delta^3$ is sufficient to give an approximation algorithm for sufficiently large k. However, this h is not sufficient to give an approximation algorithm for more general presidential type predicates because $h(1+\Delta) = 1+\Delta^3$ is far from 1 if Δ is much larger than 0.

2. We choose the coefficients $\{c_1\} \cup \{c_{2l+1} : l \in [m]\}$ so that

$$\begin{aligned}\sum_{I\subseteq[k]:I\neq\emptyset} \hat{P}_I \mathbb{E}[x_I] &= \left(\delta k^2 + \frac{k}{\delta}\right)\alpha + k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) + O(k)\cdot\Delta + O(1)\\ &= k(\delta k\alpha + \beta) + k\left(\beta - \frac{\alpha}{\delta}\right)(h(1+\Delta) - 1) + O(k)\cdot\Delta + O(1)\end{aligned}$$

3. Since for every satisfying assignment, $\delta k x_1 + \sum_{i=2}^{k} x_i \geq 1$, for every point in the KTW polytope,

$$\delta k b_1 + \sum_{i=2}^{k} b_i = \delta k\alpha + \beta \geq 1$$

and thus $k(\delta k\alpha + \beta) \geq k$. If we could show that the remaining terms $k\left(\beta - \frac{\alpha}{\delta}\right)(h(1+\Delta) - 1) + O(k)\cdot\Delta + O(1)$ are $o(k)$, then we would be done. Unfortunately, this may not be true when $|\Delta|$ is large.

4. To handle this, we show that if $|\Delta|$ is large then we can obtain a considerably better bound on $\delta k\alpha + \beta$ More precisely, we proceed as follows:
   a. When $\Delta \geq -0.55$, we show that $\delta k\alpha + \beta \geq \frac{(\delta^2 k-1)|\Delta|}{4} + \frac{1}{2}$ (see Lemma 37). As long as $h(1+\Delta)$ is sufficiently close to 1, this allows us to show that $k(\delta k\alpha + \beta) + k\left(\beta - \frac{\alpha}{\delta}\right)(h(1+\Delta) - 1) + O(k)\cdot\Delta + O(1)$ is positive.
   b. When $\Delta < -0.55$, we show that we must have $\alpha > 0$. In this case, we rewrite $\sum_{I\subseteq[k]:I\neq\emptyset} \hat{P}_I \mathbb{E}[x_I] = \left(\delta k^2 + \frac{k}{\delta}\right)\alpha + k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) + O(k)\cdot\Delta + O(1)$ as

$$k(\delta k\alpha + \beta)h(1+\Delta) + \left(\delta k^2 + \frac{k}{\delta}\right)\alpha(1 - h(1+\Delta)) + O(k)\cdot\Delta + O(1).$$

   and show that the sum of the first two terms is positive and $\Omega(k^2)$.

3.2 Sums of Products of Biases and Pairwise Biases

In order to implement this strategy, we need some notations related to biases and pairwise biases. Note that similar definitions were also used in [13].

▶ **Definition 23.** *For $E_1 \subseteq [k]$ and $E_2 \subseteq \binom{[k]}{2}$, define*

$$B_{E_1,E_2} = \prod_{i \in E_1} b_i \prod_{\substack{\{i,j\} \in E_2 \\ i<j}} b_{ij}.$$

▶ **Definition 24.** *Let $V = \{\alpha, i_1, i_2, \ldots, i_{k-1}\}$. Let $H = H_1 \cup H_2$ where $H_1 \subseteq V$ and $H_2 \subseteq \binom{V}{2}$. Define*

$$S_H = \sum_{\substack{E_1,E_2:\exists \sigma: V \to [k] \text{ bijective} \\ \sigma(\alpha)=1, \sigma(H_1)=E_1, \sigma(H_2)=E_2}} B_{E_1,E_2},$$

where $\sigma(H_1) = \{\sigma(i) \mid i \in H_1\}$, $\sigma(H_2) = \{\{\sigma(i), \sigma(j)\} \mid \{i,j\} \in H_2\}$.

Intuitively, S_H is the sum of products B_{E_1,E_2} where $E_1 \cup E_2$ has the form H. One particularly important such sum in our algorithms is $S_{\{\{i_1,i_2\}\}}$, which is the sum of pairwise biases with indices in $[2,k]$.

▶ **Definition 25.** *We define the following shorthand notations for some important sums.*

$$S_{1,l} = S_{\{i_1,\{i_2,i_3\},\{i_4,i_5\},\ldots,\{i_{2l},i_{2l+1}\}\}},$$
$$S_{2,l} = S_{\{\alpha,\{i_1,i_2\},\{i_3,i_4\},\ldots,\{i_{2l-1},i_{2l}\}\}},$$
$$S_{3,l} = S_{\{i_1,\{\alpha,i_2\},\{i_3,i_4\},\ldots,\{i_{2l-1},i_{2l}\}\}}.$$

▶ **Example 26.** In the case where $k = 4, l = 1$, we have

$$S_{1,l} = b_2b_{34} + b_3b_{24} + b_4b_{23},$$
$$S_{2,l} = b_1b_{23} + b_1b_{24} + b_1b_{34},$$
$$S_{3,l} = b_2b_{13} + b_2b_{14} + b_3b_{12} + b_3b_{14} + b_4b_{12} + b_4b_{13}.$$

The reason that these sums are important is because they are the main terms which appear when we evaluate $\sum_{I \subseteq [k]: I \neq \emptyset} \hat{P}_I \mathbb{E}[x_I]$.

▶ **Proposition 27.** *If we take*

$$f_{2l+1}(b_{i_1}, \ldots, b_{i_{2l+1}}, b_{i_1i_2}, \ldots, b_{i_{2l}i_{2l+1}}) = c_{2l+1}\left(b_{i_1}b_{i_2i_3}\cdots b_{i_{2l}i_{2l+1}} + \textit{symmetric terms}\right)$$

then

$$\sum_{|I|=2l+1} \hat{P}_I \mathbb{E}[X_I] = c_{2l+1}\left(\hat{P}_{(2l+1)^C} S_{1,l} + \hat{P}_{P+(2l)^C}(S_{2,l} + S_{3,l})\right).$$

To approximate these sums, we use the following proposition (recall that we set $S_{\{\{i_1,i_2\}\}} = E(1+\Delta)$). The proof of this proposition can be found in the appendix.

▶ **Proposition 28.** *For every $l \geq 1$,*

$$\frac{l!}{E^l} S_{1,l} = \beta(1+\Delta)^l - \frac{S_{\{i_1,\{i_1,i_2\}\}}}{E} l(1+\Delta)^{l-1} - \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2} l(l-1)(1+\Delta)^{l-2} + O\left(\frac{1}{k}\right),$$

$$\frac{l!}{E^l} S_{2,l} = \alpha(1+\Delta)^l + O\left(\frac{1}{k}\right),$$

$$\frac{l!}{E^l} S_{3,l} = \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E} l(1+\Delta)^{l-1} + O\left(\frac{1}{k}\right),$$

where the hidden constants in big-O may depend on l.

4 Proof of Theorem 8

In this section, we prove Theorem 8.

▶ **Theorem 8.** *For any $\delta_0 > 0$, there exists a $k_0 \in \mathbb{N}$ such that if $k \geq k_0$, $\delta \in (\delta_0, 1 - 2/k]$, and $\delta k + k - 1$ is an odd integer then the presidential type predicate*

$$P(x) = \operatorname{sign}\left(\delta k x_1 + \sum_{i=2}^{k} x_i\right)$$

is approximable.

In particular, we prove that for sufficiently large k and a carefully chosen polynomial h, the following rounding scheme approximates the presidential type predicate $P(x) = \operatorname{sign}\left(\delta k x_1 + \sum_{i=2}^{k} x_i\right)$.

▶ **Definition 29.** *Given a polynomial $h(x) = \sum_{l=1}^{m} a_l x^l$, we define $R_{k,\delta,h}$ to be the rounding scheme such that setting $u = \frac{1+\delta}{2}k$, $v = \frac{1-\delta}{2}k$, and $E = \frac{\delta^2 k^2}{2} - \frac{k}{2} + 1$,*

1. *$f_1(b_i) = \left(\delta k^2 + \frac{k}{\delta}\right) b_i$*
2. *For all $l \in [m]$,*

$$f_{2l+1}(b_{i_1}, \ldots, b_{i_{2l+1}}, b_{i_1 i_2}, \ldots, b_{i_{2l} i_{2l+1}}) = c_{2l+1}\left(b_{i_1} b_{i_2 i_3} \cdots b_{i_{2l} i_{2l+1}} + \textit{symmetric terms}\right)$$

where $c_{2l+1} = a_l \cdot \frac{2^{k-2}(u-1)!(v-1)!}{(k-2l-2)!\delta^{2l} k^{2l-1} E^l}$, .

▶ **Theorem 30.** *For all $\delta_0 > 0$, if $h = \sum_{l=1}^{m} a_l x^l$ is a polynomial such that*

1. *$h'(1) = h''(1) = 0$,*
2. *For all $\Delta \in [-0.55, \frac{1}{\delta_0^2}]$, $|h(1+\Delta) - 1| \leq \frac{\delta_0^2 |\Delta|}{5}$,*
3. *For all $\Delta \in [-1, -0.55]$, $0 \leq h(1+\Delta) \leq 1$,*

then there exists a $k_0 \in \mathbb{N}$ such that for all $\delta \geq \delta_0$ and $k \geq k_0$ where $\delta k + k - 1$ is an odd integer, $R_{k,\delta,h}$ approximates the presidential type predicate $P(x) = \operatorname{sign}\left(\delta k x_1 + \sum_{i=2}^{k} x_i\right)$.

▶ Remark 31. As described in Section 3.1, our proof contains a case analysis of Δ. The value -0.55 is chosen because when $\Delta < -0.55$, the bias α of the president is always positive.

This section is organized as follows. We first compute the expected value of the rounding scheme in terms of h. Then, we show that if h has the required properties, then the expected value is positive over the entire polytope, which implies that our predicate is approximable. Finally, we find such a polynomial with the desired properties.

4.1 Evaluating the Rounding Scheme

In this subsection, we analyze $\sum_{I\subseteq[k]:I\neq\emptyset}\hat{P}_I\mathbb{E}[x_I]$ in terms of h. We have the following lemma for the Fourier coefficients, the proof of which can be found in the full version.

▶ **Lemma 32.** *Let $\delta_0 > 0$ be a constant. Let $P(x_1,\dots,x_k) = \text{sign}(\delta\cdot kx_1 + x_2 + \cdots + x_k)$ where $\delta\in[\delta_0,1)$ such that $\delta k + k - 1$ is an odd integer. Let $u = \frac{1+\delta}{2}k$ and $v = \frac{1-\delta}{2}k$. Let $\hat{P}_{tC}$ denote the Fourier coefficient of a set of t citizens and $\hat{P}_{P+tC}$ denote the Fourier coefficient of a set of t citizens together with the president. We have the following:*

1. $\hat{P}_P = 1 - \frac{1}{2^{k-2}}\sum_{l=0}^{v-1}\binom{k-1}{l}$.
2. *If t is an odd integer, then*

$$\hat{P}_{tC} = \frac{1}{2^{k-2}}\cdot\frac{(k-t-1)!}{(u-1)!(v-1)!}\left(\delta^{t-1}k^{t-1} - \frac{(t-1)(t-2)}{2}\delta^{t-3}k^{t-2} + O(k^{t-3})\right).$$

3. *If t is an even integer, then*

$$\hat{P}_{P+tC} = -\frac{1}{2^{k-2}}\cdot\frac{(k-t-1)!}{(u-1)!(v-1)!}\left(\delta^{t-1}k^{t-1} - \frac{(t-1)(t-2)}{2}\delta^{t-3}k^{t-2} + O(k^{t-3})\right).$$

Here, the constants inside the big Os grows with t but not with δ.

▶ Remark 33. The lemma allows δ to depend on k as long as $\delta = \Omega(1)$. In particular, we can take $\delta = 1 - \frac{2c}{k}$ for any constant $c \geq 1$. Also, when δ is at least a constant we have that $\hat{P}_P$ is exponentially larger than $\hat{P}_C$.

Recall that we set $S_{\{\{i_1,i_2\}\}} = E(1+\Delta)$ where $E = \frac{\delta^2k^2}{2} - \frac{k}{2} + 1$ (see Definition 21). The reason for this choice for E is as follows. We expect that the cases which are most difficult to round are the two cases where $\delta k\alpha + b = 1$:

1. The president and $\frac{1-\delta}{2}k$ citizens vote 1, others vote -1. In this case,

$$\sum_{i<j\in[2,k]} x_ix_j = \binom{k-1}{2} - 2\frac{(1-\delta)k}{2}\left(\frac{(1+\delta)k}{2} - 1\right)$$

2. The president and $\frac{1+\delta}{2}k$ citizens vote -1, others vote 1. In this case,

$$\sum_{i<j\in[2,k]} x_ix_j = \binom{k-1}{2} - 2\frac{(1+\delta)k}{2}\left(\frac{(1-\delta)k}{2} - 1\right)$$

For both of these cases, $\sum_{i<j\in[2,k]} x_ix_j$ is approximately $\frac{\delta^2k^2}{2}$. Taking the average of these two cases we have $E = \frac{\delta^2k^2}{2} - \frac{k}{2} + 1$. Note that since $\delta > \delta_0$ is at least a constant, we have $E = \Omega(k^2)$.

The following lemma analyzes $\sum_{I\subseteq[k]:|I|\geq 3}\hat{P}_I\mathbb{E}[x_I]$ in terms of h. Its proof can be found in the appendix.

▶ **Lemma 34.** *Assume that we have $h(x) = \sum_{l=1}^{m} a_lx^l$ and coefficients*

$$c_{2l+1} = a_l\cdot\frac{2^{k-2}(u-1)!(v-1)!}{(k-2l-2)!\delta^{2l}k^{2l-1}E^l}$$

where $u = \frac{1+\delta}{2}k$, $v = \frac{1-\delta}{2}k$, and $E = \frac{\delta^2k^2}{2} - \frac{k}{2} + 1$. The contribution of degree ≥ 3 terms is

$$k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) - \frac{2(1+\Delta)^2\beta h''(1+\Delta)}{\delta^2} + \frac{(1+\Delta)\beta h'(1+\Delta)}{\delta^2}$$
$$- k\left(\frac{S_{\{i_1,\{i_1,i_2\}\}}}{E}h'(1+\Delta) + \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2}h''(1+\Delta) + \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E\delta}h'(1+\Delta)\right) + O(1)$$

▶ **Corollary 35.** *If we have* $h(x) = \sum_{l=1}^{m} a_l x^l$ *such that* $h'(1) = h''(1) = 0$ *and choose coefficients*

$$c_{2l+1} = a_l \cdot \frac{2^{k-2}(u-1)!(v-1)!}{(k-2l-2)!\delta^{2l}k^{2l-1}E^l}$$

then the contribution of degree ≥ 3 *terms is*

$$k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) + O(k)\cdot\Delta + O(1).$$

Proof. This follows from the fact that $E = \Omega(k^2), \beta = O(k), S_{\{i_1,\{i_1,i_2\}\}} = O(k^2)$, $S_{\{\{i_1,i_2\},\{i_1,i_3\}\}} = O(k^3)$ and $S_{\{\{\alpha,i_1\}\}} = O(k)$. ◀

4.2 Conditions on the Rounding Polynomial

▶ **Lemma 36.** *For all* $\delta_0 > 0$*, if* $h = \sum_{l=1}^{m} a_l x^l$ *is a polynomial such that*

1. $h'(1) = h''(1) = 0$
2. *For all* $\Delta \in [-0.55, \frac{1}{\delta_0^2}]$, $|h(1+\Delta) - 1| \leq \frac{\delta_0^2|\Delta|}{5}$
3. *For all* $\Delta \in [-1, -0.55]$, $0 \leq h(1+\Delta) \leq 1$

then there exists $k_0 \in \mathbb{N}$ *such that for all* $k \geq k_0$ *and all* $\delta \geq \delta_0$*, the rounding scheme* $R_{k,\delta,h}$ *has positive expected value over the entire KTW polytope.*

To prove this, we need the following lemma about points in the KTW polytope for P:

▶ **Lemma 37.** *For sufficiently large* k *we have*

$$\delta k\alpha + \beta \geq \frac{(\delta^2 k - 1)|\Delta|}{4} + \frac{1}{2}.$$

The proof of Lemma 37 can be found in the appendix.

Proof of Lemma 36. Since $h'(1) = h''(1) = 0$, by Corollary 35 the contribution of degree ≥ 3 terms becomes

$$k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) + O(k)\cdot\Delta + O(1).$$

Now we add in the contribution of degree 1 terms. Since $\hat{P}_P$ is extremely close to 1 and $\hat{P}_C$ is exponentially small, the contribution of degree 1 terms is extremely close to $c_1\alpha = (\delta k^2 + k/\delta)\alpha$. Adding this to the contribution from the higher degree terms, we get that

$$\sum_{I\subseteq[k]:I\neq\emptyset} \hat{P}_I \mathbb{E}[x_I] = k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) + \left(\delta k^2 + \frac{k}{\delta}\right)\alpha + O(k)\cdot\Delta + O(1). \qquad (*)$$

To establish the theorem, we need to show that $(*)$ is positive over the entire KTW polytope. We proceed with a case analysis on Δ. Note that the range of Δ is approximately $(-1 - O(1/k), 1/\delta^2)$. We have the following cases.

1. $\Delta \geq -0.55$. In this case we have

$$\begin{aligned}(*) &= k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) + \left(\delta k^2 + \frac{k}{\delta}\right)\alpha + O(k)\cdot\Delta + O(1)\\ &= k(\delta k\alpha + \beta) + k\left(\beta - \frac{\alpha}{\delta}\right)(h(1+\Delta) - 1) + O(k)\cdot\Delta + O(1)\\ &\geq k\left(\frac{(\delta^2 k - 1)|\Delta|}{4} + \frac{1}{2}\right) + k\left(\beta - \frac{\alpha}{\delta}\right)(h(1+\Delta) - 1) + O(k)\cdot\Delta + O(1)\end{aligned}$$

The last inequality is due to Lemma 37. Here the two terms which are quadratic in k are $\delta^2 k^2|\Delta|/4$ (note that $\delta > \delta_0$ is at least a constant) and $k\beta(h(1+\Delta)-1)$. Since $|\beta| < k$ and $|h(1+\Delta)-1| \leq \frac{\delta_0^2|\Delta|}{5}$, the above quantity is positive when k is sufficiently large.

2. $\Delta < -0.55$. Note that if $x_1 = -1$ then the minimum value of Δ is about 0. If $x_1 = 1$, then the minimum value of Δ is about -1. This means that when $\Delta < -0.55$, with probability > 0.5 we have $x_1 = 1$, which implies $\alpha > 0$ and is $\Omega(1)$. We can write $(*)$ as

$$(*) = k(\delta k\alpha + \beta)h(1+\Delta) + \left(\delta k^2 + \frac{k}{\delta}\right)\alpha(1 - h(1+\Delta)) + O(k)\cdot\Delta + O(1).$$

If $\Delta \geq -1$, then $h(1+\Delta) \in [0,1]$ and both the first two terms are positive and at least one of the two terms is $\Omega(k^2)$. If $\Delta \leq -1$ then since $\Delta \geq -1 - O(1/k)$ we know that the first term is $O(k)$ and the second term is $\Omega(k^2)$ and positive. Either way, we get a positive value when k is sufficiently large. ◀

4.3 Choosing the Rounding Polynomial

To finish the proof of our main theorem, we need to construct a polynomial that satisfies the conditions in Lemma 36. We claim that $h(x) = 1 - (1-x)^3\exp(-Bx)$ works for some constant B except that it's not a polynomial. However, by truncating the Taylor expansion of this function, we can get a polynomial which also works. See full version for the proof of these claims.

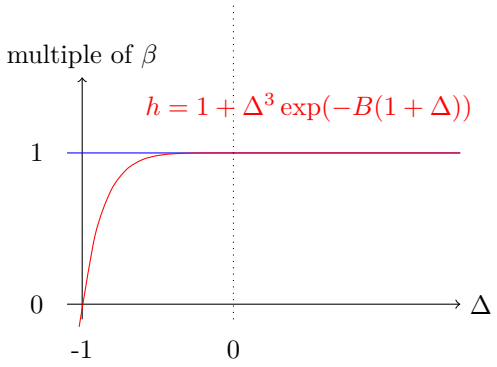

Figure 2 Plot of $h = 1 + \Delta^3\exp(-B(1+\Delta))$.

5 Evidence for the Necessity of Pairwise Biases

We have now given rounding schemes for almost all presidential predicates. These rounding schemes crucially use the pairwise biases $\{b_{ij} : i < j \in [k]\}$. A natural question is whether this is necessary or it is possible to only use the biases $\{b_i : i \in [k]\}$. If there is a rounding scheme which only uses the biases, then instead of using a semidefinite program, it is sufficient to use a linear program, which is much faster. Indeed, such rounding schemes exist for predicates which are close to the majority function [9] and for the monarchy predicate [5, 13].

In this section, we give evidence that this is not possible for more general presidential type predicates and it is necessary to use the pairwise biases. In particular, we prove the following theorem.

Recall that we choose a rounding scheme by specifying $f_a(b_{i_1}, \ldots, b_{i_a}, b_{i_1 i_2}, \ldots, b_{i_{a-1} i_a})$ for each $a \in [k]$.

▶ **Definition 38.** *We say that a rounding scheme has degree m if $f_m \neq 0$ and $f_a = 0$ for all $a > m$.*

▶ **Definition 39.** *We say that a rounding scheme does not use pairwise biases if for all $a \in [k]$, $f_a(b_{i_1}, \ldots, b_{i_a}, b_{i_1 i_2}, \ldots, b_{i_{a-1} i_a})$ only depends on $\{b_{i_1}, \ldots, b_{i_a}\}$.*

▶ **Theorem 40.** *For all $\delta_0 > 0$ and all $m \in \mathbb{N}$, there exists a k_0 such that for all $k \geq k_0$ and $\delta \in (\delta_0, 1 - 4/k]$ where $\delta k + k - 1$ is an odd integer, the presidential type predicate $P(x) = \operatorname{sign}\left(\delta k x_1 + \sum_{i=2}^{k} x_i\right)$ cannot be approximated by any rounding scheme of degree at most m which does not use pairwise biases.*

Proof. Let us consider a two-player zero-sum game where Alice chooses a point $b \in [-1, 1]^k$ in the KTW polytope[2] of P and Bob chooses a rounding scheme R of degree at most m. The objective of Alice is to minimize $R(b) = \sum_{I \subseteq [k]: I \neq \emptyset} \hat{P}_I \mathbb{E}[x_I]$, the expected value of $P(x)$ if we are given the point b in the KTW polytope and apply the rounding scheme R.

The lemma will follow if we can show a mixed strategy for Alice, which is a distribution μ over points in KTW polytope, such that for any rounding scheme R, $\mathbb{E}_{b \sim \mu}[R(b)] = 0$. Recalling that for each $a \in [m]$ and monomial $x_{i_1} x_{i_2} \ldots x_{i_a}$ of degree a, $\mathbb{E}[x_{i_1} x_{i_2} \ldots x_{i_a}] = f_a(b_{i_1}, \ldots, b_{i_a})$, it suffices to have the sum of degree a terms be zero for every $a \in [m]$, i.e.,

$$\mathbb{E}_{b \sim \mu} \left[\sum_{\substack{I \subset [k], |I| = a \\ I = \{i_1, \ldots, i_a\}}} \hat{P}_I f_a(b_{i_1}, \ldots, b_{i_a}) \right] = 0, \quad \forall a \in [m].$$

Now let us construct such a distribution μ. By Lemma 14, $\hat{P}_P$, the Fourier coefficient of the president x_1, is exponentially larger than $\hat{P}_C$, and $\lim_{k \to \infty} \hat{P}_{P+(t-1)C} / \hat{P}_{tC} = -1$ for every odd integer $t \leq m$. For concreteness, let us assume that $m = 5$. Then we will have the following distribution for μ:

Probability	x_1	x_2	x_3	x_4	x_5	x_6	x_7	$\cdots$	x_k
p_1	0	1	0	0	0	0	0	$\cdots$	0
p_2	0	1	1	-1	0	0	0	$\cdots$	0
p_3	0	1	1	1	0	0	0	$\cdots$	0
p_4	0	1	1	1	1	-1	0	$\cdots$	0
p_5	-1	1	1	1	1	1	1	$\cdots$	1

First of all, it is easy to check that all these points are inside the KTW polytope for $P(x)$. The following is a table of contribution of each degree from each of these points.

Degrees \ Points	1st type	2nd type	3rd type	4th type	5th type
$f_1(1)$	$p_1 \hat{P}_C$	$p_2 \hat{P}_C$	$3p_3 \hat{P}_C$	$3p_4 \hat{P}_C$	$p_5(-\hat{P}_P + (k-1)\hat{P}_C)$
$f_3(1,1,1)$	0	$-p_2 \hat{P}_{3C}$	$p_3 \hat{P}_{3C}$	$-2p_4 \hat{P}_{3C}$	$p_5(\binom{k-1}{2} \hat{P}_{P+2C} + \binom{k-1}{3} \hat{P}_{3C})$
$f_5(1,1,1,1,1)$	0	0	0	$-p_4 \hat{P}_{5C}$	$p_5(\binom{k-1}{4} \hat{P}_{P+4C} + \binom{k-1}{5} \hat{P}_{5C})$

To balance degree 1 terms, we need

$$p_1 \cdot \hat{P}_C + p_2 \cdot \hat{P}_C + p_3 \cdot 3\hat{P}_C + p_4 \cdot 3\hat{P}_C + p_5 \cdot (-\hat{P}_P + (k-1)\hat{P}_C) = 0.$$

[2] The KTW polytope of P actually has dimension $k + \binom{k}{2}$, but since pairwise biases play no role here, we omit those coordinates for simplicity.

Notice that every point in this distribution has a positive contribution from citizens (i.e., variables $x_2, \ldots, x_k$), so we need a negative contribution from x_1. Since $\hat{P}_P$ is exponentially larger than $\hat{P}_C$, we can achieve the balance by having p_5 be exponentially small in k. Then we balance degree 5 terms, for which we need

$$-p_4 \cdot \hat{P}_{5C} + p_5 \cdot \left(\binom{k-1}{4} \hat{P}_{P+4C} + \binom{k-1}{5} \hat{P}_{5C} \right) = 0.$$

Recall that $\lim_{k\to\infty} \hat{P}_{P+4C}/\hat{P}_{5C} = -1$, so we can achieve the balance by having $p_4 = poly(k) \cdot p_5$, where $poly(k)$ is a polynomial in k. For degree 3 terms, we need

$$-p_2 \cdot \hat{P}_{3C} + p_3 \cdot \hat{P}_{3C} - 2p_4 \cdot \hat{P}_{3C} + p_5 \cdot \left(\binom{k-1}{2} \hat{P}_{P+2C} + \binom{k-1}{3} \hat{P}_{3C} \right) = 0.$$

We can then use either the second type or the third type to balance degree 3 terms. Again we will only use $poly(k) \cdot p_5$ amount of probability. When k is sufficiently large, $p_2 + p_3 + p_4 + p_5 \leq 1$ and we let the first type of points take up the remaining probability. This method can be easily extended to handle the case where m is any fixed positive integer. ◀

▶ Remark 41. For the monarchy predicate $P(x) = sign\left((k-2)x_1 + \sum_{i=2}^{k} x_i\right)$, this argument fails for the following reason. The only satisfying assignment to the monarchy predicate where $x_1 = -1$ is when all of the other x_i are 1. This implies that for all $i \in [2, k]$, $b_i \geq -b_1$, which means that the point $b = (0, 1, 1, -1, 0, \ldots, 0)$ and similar points are not in the KTW polytope.

▶ Remark 42. This theorem rules out any fixed degree rounding schemes that use only biases, but it does not rule out the possibility that a rounding scheme might be able to succeed with just biases if its degree grows with k.

6 Conclusions

In this paper, we showed that almost all presidential type predicates are approximable. To do this, we carefully constructed rounding schemes which have positive expected value over the entire KTW polytope. These rounding schemes use both the biases $\{b_i : i \in [k]\}$ and the pairwise biases $\{b_{ij} : i < j \in [k]\}$ and have relatively high (but still constant) degree.

This work raises a number of open questions, including the following:

1. Which other types of predicates can this technique be applied to? For example, can we show that almost all oligarchy-type predicates are approximable, where oligarchy-type predicates are balanced LTFs where all but a few of the inputs have the same weight? As another example, can we extend the result of Austrin, Bennabas, and Magen that all symmetric quadratic threshold functions with no constant term are approximable to show that almost all quadratic threshold functions with no constant term which are symmetric with respect to all but one variable are approximable or at least weakly approximable?
2. Can we show that for almost all presidential type predicates, there is no rounding scheme which only uses the biases $\{b_i : i \in [k]\}$? Note that by Theorem 40, such rounding schemes would have to have degree which increases with k.
3. Our results only hold if k is sufficiently large. Is it true that all presidential type predicates are approximable? Less ambitiously, can we either extend our techniques or develop new techniques to handle presidential type predicates where k is relatively small?

A Proof of Proposition 28

▶ **Proposition 28.** *For every $l \geq 1$,*

$$\frac{l!}{E^l} S_{1,l} = \beta(1+\Delta)^l - \frac{S_{\{i_1,\{i_1,i_2\}\}}}{E} l(1+\Delta)^{l-1} - \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2} l(l-1)(1+\Delta)^{l-2} + O\left(\frac{1}{k}\right),$$

$$\frac{l!}{E^l} S_{2,l} = \alpha(1+\Delta)^l + O\left(\frac{1}{k}\right),$$

$$\frac{l!}{E^l} S_{3,l} = \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E} l(1+\Delta)^{l-1} + O\left(\frac{1}{k}\right),$$

where the hidden constants in big-O may depend on l.

Proof. Here we only prove the first equality since the other two can be proved similarly. Recall that $S_{\{\{i_1,i_2\}\}} = E(1+\Delta)$ and $E = \Theta(k^2)$. The first equality is equivalent to

$$\begin{aligned} l!S_{1,l} =& \beta(S_{\{\{i_1,i_2\}\}})^l - S_{\{i_1,\{i_1,i_2\}\}} l (S_{\{\{i_1,i_2\}\}})^{l-1} - \beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}} l(l-1)(S_{\{\{i_1,i_2\}\}})^{l-2} \\ &+ O\left(k^{2l-1}\right). \end{aligned}$$

Let's analyze the term $\beta(S_{\{\{i_1,i_2\}\}})^l$, by definition, it's equal to

$$\left(\sum_{i\geq 2} b_i\right)\left(\sum_{2\leq i<j} b_{ij}\right)^l = \sum_{\substack{j_1,j_2,\ldots,j_{2l+1}\in\{2,3,\ldots,k\} \\ j_2<j_3, j_4<j_5,\cdots,j_{2l}<j_{2l+1}}} b_{j_1}b_{j_2j_3}b_{j_4j_5}\cdots b_{j_{2l}j_{2l+1}}.$$

Let's call the sum on the right hand side T. We classify the terms in T according to number of repetitions in indices. If there is no repetition, then the term $b_{j_1}b_{j_2j_3}b_{j_4j_5}\cdots b_{j_{2l}j_{2l+1}}$ is also in $S_{1,l}$. Note that in $S_{1,l}$ the order of the l pairwise biases can be arbitrary, so the sum of terms with no repeated indices is equal to $l!S_{1,l}$. If there are two or more repetitions, then the number of distinct indices is at most $2l-1$, and the contribution of such terms is $O(k^{2l-1})$. If there is exact one repetition, then there are two cases.

1. j_1 is equal to some j_t for $t \geq 2$. Without loss of generality consider the terms where the only repetition is $j_1 = j_2$ or $j_1 = j_3$ (note that $j_2 < j_3$). The contribution of these terms are

$$\begin{aligned} &\sum_{\substack{j_1,j_2,\ldots,j_{2l+1}\in\{2,3,\ldots,k\} \\ j_2<j_3, j_4<j_5,\cdots,j_{2l}<j_{2l+1} \\ j_1=j_2 \text{ or } j_1=j_3 \\ j_2,j_3,\ldots,j_{2l+1} \text{ distinct}}} b_{j_1}b_{j_2j_3}b_{j_4j_5}\cdots b_{j_{2l}j_{2l+1}} \\ =& \sum_{\substack{j_1,j_2,\ldots,j_{2l+1}\in\{2,3,\ldots,k\} \\ j_2<j_3, j_4<j_5,\cdots,j_{2l}<j_{2l+1} \\ j_1=j_2 \text{ or } j_1=j_3}} b_{j_1}b_{j_2j_3}b_{j_4j_5}\cdots b_{j_{2l}j_{2l+1}} + O(k^{2l-1}) \\ =& S_{\{i_1,\{i_1,i_2\}\}}(S_{\{\{i_1,i_2\}\}})^{l-1} + O(k^{2l-1}). \end{aligned}$$

   This is because the terms where $j_2, j_3, \ldots, j_{2l+1}$ are not distinct have at most $2l-1$ distinct indices and contribute $O(k^{2l-1})$. So the contribution of this case is

$$lS_{\{i_1,\{i_1,i_2\}\}}(S_{\{\{i_1,i_2\}\}})^{l-1} + O(k^{2l-1}).$$

2. $j_s = j_t$ for some $s,t \geq 2$. Note that in this case s and t cannot appear in the same pairwise bias. Without loss of generality assume $s \in \{2,3\}$ and $t \in \{4,5\}$. We have

$$\begin{aligned} &\sum_{\substack{j_1,j_2,\ldots,j_{2l+1}\in\{2,3,\ldots,k\} \\ j_2<j_3, j_4<j_5,\cdots,j_{2l}<j_{2l+1} \\ \text{one repetition in } j_2,j_3,j_4,j_5 \\ \text{other indices distinct}}} b_{j_1}b_{j_2j_3}b_{j_4j_5}\cdots b_{j_{2l}j_{2l+1}} \\ =& \sum_{\substack{j_1,j_2,\ldots,j_{2l+1}\in\{2,3,\ldots,k\} \\ j_2<j_3, j_4<j_5,\cdots,j_{2l}<j_{2l+1} \\ \text{one repetition in } j_2,j_3,j_4,j_5}} b_{j_1}b_{j_2j_3}b_{j_4j_5}\cdots b_{j_{2l}j_{2l+1}} + O(k^{2l-1}) \\ =& \quad 2\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}(S_{\{\{i_1,i_2\}\}})^{l-2} + O(k^{2l-1}). \end{aligned}$$

   So the contribution of this case is

$$\begin{aligned} &\binom{l}{2}\cdot\left(2\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}(S_{\{\{i_1,i_2\}\}})^{l-2} + O(k^{2l-1})\right) \\ =& \beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}} l(l-1)(S_{\{\{i_1,i_2\}\}})^{l-2} + O\left(k^{2l-1}\right). \end{aligned}$$

We conclude that

$$\beta(S_{\{\{i_1,i_2\}\}})^l = l!S_{1,l} + lS_{\{i_1,\{i_1,i_2\}\}}(S_{\{\{i_1,i_2\}\}})^{l-1} + \beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}} l(l-1)(S_{\{\{i_1,i_2\}\}})^{l-2} + O\left(k^{2l-1}\right).$$

We get the desired equality by shifting the terms. ◀

B Proof of Lemma 34

▶ **Lemma 34.** *Assume that we have* $h(x) = \sum_{l=1}^{m} a_l x^l$ *and coefficients*

$$c_{2l+1} = a_l \cdot \frac{2^{k-2}(u-1)!(v-1)!}{(k-2l-2)!\delta^{2l}k^{2l-1}E^l}$$

where $u = \frac{1+\delta}{2}k$, $v = \frac{1-\delta}{2}k$, *and* $E = \frac{\delta^2k^2}{2} - \frac{k}{2} + 1$. *The contribution of degree* ≥ 3 *terms is*

$$k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) - \frac{2(1+\Delta)^2\beta h''(1+\Delta)}{\delta^2} + \frac{(1+\Delta)\beta h'(1+\Delta)}{\delta^2}$$
$$- k\left(\frac{S_{\{i_1,\{i_1,i_2\}\}}}{E}h'(1+\Delta) + \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2}h''(1+\Delta) + \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E\delta}h'(1+\Delta)\right) + O(1)$$

Proof. We have the following computation:

$$\sum_{l=1}^{m}\sum_{|I|=2l+1}\hat{P}_I\mathbb{E}[X_I]$$
$$= \sum_{l=1}^{m} c_{2l+1}\left(\hat{P}_{(2l+1)C}S_{1,l} + \hat{P}_{P+(2l)C}(S_{2,l}+S_{3,l})\right)$$
$$= \sum_{l=1}^{m} a_l\Bigg(\left(k - l(2l-1)\delta^{-2} + O\left(\frac{1}{k}\right)\right)\cdot$$
$$\left(\beta(1+\Delta)^l - \frac{S_{\{i_1,\{i_1,i_2\}\}}}{E}l(1+\Delta)^{l-1} - \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2}l(l-1)(1+\Delta)^{l-2} + O\left(\frac{1}{k}\right)\right) -$$
$$\left(1 - \frac{2l+1}{k}\right)\cdot\left(\frac{k}{\delta} - \frac{(l-1)(2l-1)}{\delta^3} + O\left(\frac{1}{k}\right)\right)\cdot$$
$$\left(\alpha(1+\Delta)^l + \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E}l(1+\Delta)^{l-1} + O\left(\frac{1}{k}\right)\right)\Bigg)$$
$$= \sum_{l=1}^{m} a_l\Bigg(k\left(\beta - \frac{\alpha}{\delta}\right)(1+\Delta)^l - \frac{l(2l-1)\beta(1+\Delta)^l}{\delta^2}$$
$$- kl(1+\Delta)^{l-1}\left(\frac{S_{\{i_1,\{i_1,i_2\}\}}}{E} + \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2(1+\Delta)}(l-1) + \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E\delta}\right) + O(1)\Bigg)$$
$$= k\left(\beta - \frac{\alpha}{\delta}\right)h(1+\Delta) - \frac{2(1+\Delta)^2\beta h''(1+\Delta)}{\delta^2} + \frac{(1+\Delta)\beta h'(1+\Delta)}{\delta^2}$$
$$- k\left(\frac{S_{\{i_1,\{i_1,i_2\}\}}}{E}h'(1+\Delta) + \frac{\beta S_{\{\{i_1,i_2\},\{i_1,i_3\}\}}}{E^2}h''(1+\Delta) + \frac{\beta S_{\{\{\alpha,i_1\}\}}}{E\delta}h'(1+\Delta)\right) + O(1).$$ ◀

C Proof of Lemma 37

▶ **Lemma 37.** *For sufficiently large* k *we have*

$$\delta k\alpha + \beta \geq \frac{(\delta^2k-1)|\Delta|}{4} + \frac{1}{2}.$$

Proof. Since $|\Delta|$ is a convex function on the KTW polytope, it suffices to check that for each satisfying assignment, $\delta k\alpha + \beta \geq \frac{\delta k|\Delta|}{4} + \frac{1}{2}$. Letting t be the number of ones in $x_2, \ldots, x_k$, we have that $\beta = t - (k-1-t) = 2t - k + 1$ and

$$\sum_{2 \leq i < j} x_i x_j = \binom{t}{2} + \binom{k-1-t}{2} - t(k-1-t) = 2t^2 - 2(k-1)t + \binom{k-1}{2},$$

Recalling that $E = \frac{\delta^2 k^2}{2} - \frac{k}{2} + 1$, this implies that

$$\begin{aligned}\Delta = \frac{\sum_{2 \leq i < j} x_i x_j - E}{E} &= \frac{1}{E}\left(2t^2 - 2(k-1)t + \binom{k-1}{2} - \frac{\delta^2 k^2}{2} + \frac{k}{2} - 1\right) \\ &= \frac{1}{E}\left(2t^2 - 2(k-1)t + \frac{(1-\delta^2)k^2}{2} - k\right)\end{aligned}$$

Since $E > \frac{\delta^2 k^2}{2} - \frac{k}{2}$, we have

$$\begin{aligned}\frac{\delta^2 k - 1}{4}|\Delta| &= \frac{\delta^2 k - 1}{4E}\left|2t^2 - 2(k-1)t + \frac{(1-\delta^2)k^2}{2} - k\right| \\ &< \frac{1}{2k}\left|2t^2 - 2(k-1)t + \frac{(1-\delta^2)k^2}{2} - k\right| \\ &= \left|\frac{t^2}{k} - \frac{(k-1)t}{k} + \frac{(1-\delta^2)k}{4} - \frac{1}{2}\right|\end{aligned}$$

We will show that $\delta k\alpha + \beta \geq \left|\frac{t^2}{k} - \frac{(k-1)t}{k} + \frac{(1-\delta^2)k}{4} - \frac{1}{2}\right| + \frac{1}{2}$, from which our lemma will follow. To this end, we show that $\delta k\alpha + \beta \geq \left(\frac{t^2}{k} - \frac{(k-1)t}{k} + \frac{(1-\delta^2)k}{4} - \frac{1}{2}\right) + \frac{1}{2}$ and $\delta k\alpha + \beta \geq -\left(\frac{t^2}{k} - \frac{(k-1)t}{k} + \frac{(1-\delta^2)k}{4} - \frac{1}{2}\right) + \frac{1}{2}$.

1. $\delta k\alpha + \beta \geq \left(\frac{t^2}{k} - \frac{(k-1)t}{k} + \frac{(1-\delta^2)k}{4} - \frac{1}{2}\right) + \frac{1}{2}$.
   We have two cases, $\alpha = 1$ or $\alpha = -1$. If $\alpha = 1$, then $\delta k\alpha + \beta = \delta k + 2t - k + 1$ and since it's a satisfying assignment we have $t \geq \frac{1-\delta}{2}k$. The inequality becomes

   $$\frac{t^2}{k} - \frac{(k-1)t}{k} - 2t + \frac{(1-\delta^2)k}{4} - \delta k + k - 1 \leq 0.$$

   The left hand side is a quadratic function on t with positive leading coefficient, and to check it's non-positive we simply need to check its values on $t = \frac{1-\delta}{2}k$ and $t = k - 1$, the boundary points of t's domain. When $t = \frac{1-\delta}{2}k$,

   $$\begin{aligned}&\frac{t^2}{k} - \frac{(k-1)t}{k} - 2t + \frac{(1-\delta^2)k}{4} - \delta k + k - 1 = \\ &\left(\frac{t^2}{k} - t + \frac{(1-\delta^2)k}{4}\right) + (-2t - \delta k + k) + \left(\frac{t}{k} - 1\right) = \\ &\left(\frac{(1-\delta)^2 k}{4} - \frac{(1-\delta)k}{2} + \frac{(1-\delta^2)k}{4}\right) + 0 + \left(\frac{1-\delta}{2} - 1\right) = \\ &\frac{1-\delta}{2} - 1 < 0\end{aligned}$$

When $t = k - 1$,

$$\frac{t^2}{k} - \frac{(k-1)t}{k} - 2t + \frac{(1-\delta^2)k}{4} - \delta k + k - 1 =$$
$$\left(\frac{t^2}{k} - \frac{(k-1)t}{k}\right) + (-t + k - 1) + \left(-t - \delta k + \frac{(1-\delta^2)k}{4}\right) =$$
$$-\frac{3 - 4\delta + \delta^2}{4}k + 1$$

which is negative when k is sufficiently large (note that $\delta \leq 1 - \frac{3}{k}$).
If $\alpha = -1$, then $\delta k\alpha + \beta = -\delta k + 2t - k + 1$ and we have that $t \geq \frac{1+\delta}{2}k$. The inequality becomes

$$\frac{t^2}{k} - \frac{(k-1)t}{k} - 2t + \frac{(1-\delta^2)k}{4} + \delta k + k - 1 \leq 0.$$

We check the value of LHS on $t = \frac{1+\delta}{k}$ and $t = k-1$. Following exactly the same argument we used for $\alpha = 1$ except that δ is replaced by $-\delta$, when $t = \frac{1+\delta}{2}k$,

$$\frac{t^2}{k} - \frac{(k-1)t}{k} - 2t + \frac{(1-\delta^2)k}{4} + \delta k + k - 1 = \frac{1+\delta}{2} - 1 < 0$$

and when $t = k - 1$,

$$\frac{t^2}{k} - \frac{(k-1)t}{k} - 2t + \frac{(1-\delta^2)k}{4} + \delta k + k - 1 = -\frac{3 - 4\delta + \delta^2}{4}k + 1 < 0$$

2. $\delta k\alpha + \beta \geq -\left(\frac{t^2}{k} - \frac{(k-1)t}{k} + \frac{(1-\delta^2)k}{4} - \frac{1}{2}\right) + \frac{1}{2}$.
We again have two cases, $\alpha = 1$ or $\alpha = -1$. If $\alpha = 1$, we have $\delta k\alpha + \beta = \delta k + 2t - k + 1$ and the inequality becomes

$$\frac{t^2}{k} + \left(2 - \frac{k-1}{k}\right)t + \frac{(1-\delta^2)k}{4} + \delta k - k \geq 0.$$

The left hand side is a quadratic function that achieves minimum when t is negative, so we simply need the inequality to hold when $t = \frac{1-\delta}{2}k$, at which point the value of LHS is $\frac{1-\delta}{2} \geq 0$.
If $\alpha = -1$, the inequality becomes

$$\frac{t^2}{k} + \left(2 - \frac{k-1}{k}\right)t + \frac{(1-\delta^2)k}{4} - \delta k - k \geq 0.$$

Again, we simply need it to hold when $t = \frac{1+\delta}{2}k$, at which point the value of LHS is $\frac{1+\delta}{2} \geq 0$.
This completes our proof. ◀

An Approximation Algorithm for the MAX-2-Local Hamiltonian Problem

Abstract

We present a classical approximation algorithm for the MAX-2-Local Hamiltonian problem. This is a maximization version of the QMA-complete 2-Local Hamiltonian problem in quantum computing, with the additional assumption that each local term is positive semidefinite. The MAX-2-Local Hamiltonian problem generalizes NP-hard constraint satisfaction problems, and our results may be viewed as generalizations of approximation approaches for the MAX-2-CSP problem. We work in the product state space and extend the framework of Goemans and Williamson for approximating MAX-2-CSPs. The key difference is that in the product state setting, a solution consists of a set of normalized 3-dimensional vectors rather than boolean numbers, and we leverage approximation results for rank-constrained Grothendieck inequalities. For MAX-2-Local Hamiltonian we achieve an approximation ratio of 0.328. This is the first example of an approximation algorithm beating the random quantum assignment ratio of 0.25 by a constant factor.

1 Introduction

The k-Local Hamiltonian problem is the most studied QMA-complete problem in quantum computing [19] and generalizes classical constraint satisfaction problems (CSPs). It is physically motivated, asking about the ground state energy of a system specified by its Hamiltonian, or equivalently the minimum eigenvalue of an exponentially large Hermitian

matrix. Even though the matrix is exponentially large in the number of qubits, it can be succinctly described as a sum of matrices that are each a tensor product of a $2^k \times 2^k$ Hermitian matrix and the $2^{n-k} \times 2^{n-k}$ identity matrix, where n is the size of the whole matrix, and k is some constant given by a problem instance (called locality). Note that one only needs to describe the $2^k \times 2^k$ matrices to describe the whole problem. A precise definition will be given later. There are many variations depending on the locality, the number of levels each particle has (instead of 2 for the qubit case above), and other assumptions that can be made on the Hamiltonian. The class QMA has also been well-studied, and a large set of problems has been shown to be QMA-complete [6].

There has been much less progress in finding approximation algorithms for these problems. One difference arising in the quantum case is that classical algorithms cannot efficiently represent arbitrary solutions, which in general are entangled quantum states and thus reside in an exponentially large space (2^n dimensional). One approach to circumvent this problem is to only consider product state solutions, which are a subset of quantum states that exhibit no entanglement and admit efficient classical descriptions. Bansal, Bravyi, and Terhal [5] proved that a polynomial time approximation scheme (PTAS) (a polynomial-time algorithm that offers an arbitrarily good approximation at the expense of increase in run time) exists for Quantum Ising Spin Glass when assuming the underlying graph describing the interaction of the qubits is planar with bounded degree. Brandão and Harrow [7] analyze the D-regular case and give an additive approximation algorithm.

Another issue in the design of approximation algorithms is ensuring that problems have well-defined approximations. For general Hamiltonians, which are Hermitian, the spectrum can include positive and negative numbers, so it is difficult to define a meaningful approximation ratio. Gharibian and Kempe [12] defined the MAX-k-Local Hamiltonian problem and analyze the dense case. Their definition requires the k-local terms of the Hamiltonian to be positive semidefinite, so that meaningful approximations exist. This case is still QMA-hard and includes the classical constraint satisfaction problem, MAX-k-CSP as a special case.

The Max-2-Local Hamiltonian problem

In this paper we give a randomized classical approximation algorithm for the MAX-2-Local Hamiltonian (MAX-2-LH) problem on qubits. MAX-2-LH is QMA-hard, so approximation algorithms are a natural solution strategy. The problem is NP-hard because it includes MAX-2-CSP as a special case. To see that it is QMA-hard requires relating it to the decision (promise) k-Local Hamiltonian problem, defined on n qubits. In this problem, $2^k \times 2^k$ Hermitian matrices H_S are given for each subset $S \subseteq [n]$ of size k, together with real numbers a and b with $b - a \geq 1/poly(n)$. The H_S are called k-local terms and may be viewed as quantum generalizations of classical boolean constraints on k variables. The promise on the input is that either some eigenvalue of the Hamiltonian $H := \sum_S H_S \otimes I_{[n]\setminus S}$ is less than a, or all eigenvalues are greater than b (the notation $H_S \otimes I_{[n]\setminus S}$ signifies that H_S acts on the k qubits of S and is tensored with identity on the other $n - k$ qubits). The QMA witness for the yes case is a quantum state that is an eigenstate with eigenvalue less that a, and a quantum algorithm can verify in polynomial time whether its eigenvalue is less than a or larger by $1/poly(n)$. The QMA-hard 2-Local Hamiltonian problem may be reduced to the optimization problem, MAX-2-LH by negating H (since MAX-2-LH is a maximization problem) and adding identity terms, if necessary, to ensure that each 2-local term is positive semidefinite. MAX-2-LH also generalizes the NP-hard MAX-2-CSP problem, which is illustrated in Section 2.2.

For MAX-2-LH, we assume an edge set E over the vertex set $[n]$ and a set of 4×4 positive semidefinite Hermitian matrices $\{H_{pq}\}_{(p,q)\in E}$ are given. The goal is to compute the maximum eigenvector of $H := \sum_{(p,q)\in E} H_{pq} \otimes I_{[n]\setminus\{p,q\}}$. The Hermitian matrix H acts on n qubits, and each term H_{pq} acts on the two qubits p, q and as the identity on the remaining $n-2$ qubits. More precisely, $H_{pq} : \mathcal{H}_p \otimes \mathcal{H}_q \to \mathcal{H}_p \otimes \mathcal{H}_q$, where for all $p \in [n]$, $\mathcal{H}_p$ is the 2 dimensional complex Hilbert space, representing the qubit p, and $I_{[n]\setminus\{p,q\}}$ is the identity matrix on $\bigotimes_{i\in[n]\setminus\{p,q\}} \mathcal{H}_i$. The input matrices $\{H_{pq}\}_{(p,q)\in E}$ therefore implicitly describe the $2^n \times 2^n$ Hermitian matrix H, whose maximum eigenvector we wish to compute.

Related work

Other generalizations of classical problems to physically motivated Local Hamiltonian problems have been studied, but the exact relationship to well-studied classical problems such as MAX-2-SAT, MAX-CUT, and MAX-2-AND depends on which variant of the Local Hamiltonian problem is being considered. Gharibian and Parekh [14] study a maximization problem on 2-Local Hamiltonians for the Heisenberg model, which is a physically motivated generalization of MAX-CUT. These have the form $H = \sum_{(p,q)\in E} w_{pq} H_{pq}$ for $w_{pq} \geq 0$, where $H_{pq} = I - \alpha X_p X_q - \beta Y_p Y_q - \gamma Z_p Z_q$, for $\alpha, \beta, \gamma \in \{0, 1\}$, where X_p, Y_p, Z_p are the Pauli matrices on qubit p (e.g., X_p is a $2^n \times 2^n$ matrix formed by taking the 2×2 Pauli X matrix on qubit p tensored with identity on all the other $n-1$ qubits). They get approximation ratios 0.498 (when $\alpha+\beta+\gamma = 3$), 0.649 (when $\alpha+\beta+\gamma = 2$), or 0.878 (when $\alpha+\beta+\gamma = 1$). Furthermore, they show that their ratios are almost tight in the product state space. In particular they give a simple instance on which a product state cannot provide an approximation ratio better than 0.5, for the $\alpha+\beta+\gamma = 3$ case. This case of their problem is a special case of MAX-2-LH, hence 0.5 is also an upper bound on the best attainable approximation ratio for MAX-2-LH using product states. Anshu, Gosset, and Morenz [2] have very recently demonstrated that it is possible for a classical algorithm to provide an approximation ratio better than 0.5 for this problem, by outputting descriptions of relatively simple entangled states.

Bravyi, Gosset, König, and Temme [8] consider traceless 2-local Hamiltonians. This generalizes the Maximum Quadratic Programming problem (MAX-QP) where the diagonal entries are zero [10, 3]. In addition to generalizing MAX-QP, it also captures a variety of physical quantum models. They give a randomized classical algorithm that outputs a product state with expected energy $\mathrm{OPT}/O(\log n)$, where OPT is the maximum eigenvalue of the input Hamiltonian.

Our results

In this paper we achieve an approximation ratio of 0.328 for MAX-2-LH. The approximation algorithm for MAX-2-LH that picks a random assignment (i.e., the fully mixed quantum state) achieves ratio 0.25. Ours is the first example of an approximation algorithm for this problem that beats the trivial bound by a constant. It is also possible to achieve a ratio of $0.25 + 1/O(\log(n))$ by taking the input instance, shifting each term H_i so that it is traceless, and using the result in [8]. In MAX-2-LH each local term, acting on 2 qubits, is a rank 1 projector. In the special case when each local term is a rank 1 projector that is a product of two rank 1 projectors, one on each qubit, we get a better ratio of 0.40. This special case is detailed in Section 4. It is QMA-hard to find the maximum eigenvalue of this special type of Hamiltonian by Theorem 7 in [11].

In terms of techniques, we follow the framework that was first introduced by Goemans and Williamson. We first formulate a semidefinite program (SDP) whose optimal objective value provides an upper bound on the maximum energy of a given 2-local Hamiltonian. We can solve the SDP to arbitrary precision in polynomial time. Then we randomly round the solution, which resides in a larger space, down to the original solution space. Analyzing the randomized rounding is considerably more complicated than in the classical setting, because we need to round the solutions to a continuous 3-dimensional space, whereas the solution space is the boolean space for classical cases. We build upon a rounding procedure analyzed for generalizing the positive-semidefinite Grothendieck problem to a rank-constrained setting, by Briët, de Oliveira Filho, and Vallentin [9].

Even with this rounding procedure, obtaining a multiplicative bound that outperforms a random assignment for MAX-2-LH is a nontrivial task. In particular, our analysis takes the 1-local part of the input Hamiltonian explicitly into account. Ours is the first work of its kind to do so. Bravyi, Gosset, König, and Temme [8] showed that in the context of their problem, 1-local terms could be ignored without loss of generality, while Gharibian and Parekh [14] considered a problem without 1-local terms.

It is natural to consider SDP relaxations for our problem, because most approximation algorithms for classical MAX-2-CSP employ SDP rounding [15, 23, 22, 20]. Our SDP formulation is similar to that of [14, 8]; however, we must use additional constraints to handle the 1-local part. We also consider a different SDP formulation in order to get an improved approximation ratio in the special case where each local term is a product projector. The alternative formulation is described in Section 4. An advantage of the first SDP formulation is that the optimal value of the program provides an upper bound on OPT itself (the maximum eigenvalue of the Hamiltonian), whereas the optimal value of the alternative program gives an upper bound on $\mathrm{OPT}_{\mathrm{prod}}$, the objective value achieved by the best product state.

Open questions

There are several open questions. Is it possible to close the gap between 0.328 that we achieve and the 0.5 upper bound for product states? Is it possible to beat the uniformly random assignment when each term is a rank 3 projector, which is a quantum generalization of the classical Max 2-SAT problem? Is it possible to use more general states than product states, for example, as in the recent developments of Anshu, Gosset, and Morenz [2]? Does the approximation algorithm shed any light on the quantum PCP theorem?

2 Background

2.1 Approximating quantum problems

We first define the MAX-2-Local Hamiltonian problem.

▶ **Definition 1** (MAX-2LH). *An instance is given as a set of Hamiltonians* $\{H_{pq} : (p,q) \in E\}$, *for some edge set* $E \subseteq [n] \times [n]$, *where* $H_{pq} \otimes I_{[n]\setminus\{p,q\}}$ *is positive semidefinite and operates non-trivially on qubits* p *and* q. *Given such a list of Hamiltonians on 2 qubits, the goal of the problem is to find the largest eigenvalue of* $H = \sum_{(p,q)\in E} H_{pq} \otimes I_{[n]\setminus\{p,q\}}$, *which we denote as* OPT.

To simplify notation we will write $H = \sum_{pq} H_{pq}$, *where terms* H_{pq} *for* $(p,q) \notin E$ *are the zero matrix (so have rank 0). Also, let* $\mathrm{OPT}_{\mathrm{prod}}$ *denote the maximum energy achievable over the set of product states, i.e.,* $\mathrm{OPT}_{\mathrm{prod}} = \max_{|\phi_1\rangle\cdots|\phi_n\rangle} \langle\phi_1| \cdots \langle\phi_n| H |\phi_1\rangle \cdots |\phi_n\rangle$.

Since the 2-Local Hamiltonian problem can be reduced to the MAX-2-Local Hamiltonian problem, this problem is QMA-hard. So instead, we turn to approximating OPT with a multiplicative error. The goal of this paper is to beat the trivial approximation for the maximum eigenvalue of 2-local Hamiltonians presented in the following theorem.

▶ **Theorem 2.** *Given a 2-local Hamiltonian* $H = \sum_{pq} H_{pq} \otimes I_{[n]\setminus\{p,q\}}$ *with local terms that are rank* r *projectors,* H_{pq} *(*$r \in \{1,2,3\}$*), if the maximum eigenvalue (energy) of* H *is* OPT*, then the uniformly random product state achieves energy at least* $r/4 \cdot \mathrm{OPT}$*.*

Proof. Consider the contribution of the local term H_{pq} to the energy. Since we are assigning the uniformly random product state, the qubit p, q is assigned

$$\rho_{pq} := \begin{pmatrix} 1/2 & 0 \\ 0 & 1/2 \end{pmatrix} \otimes \begin{pmatrix} 1/2 & 0 \\ 0 & 1/2 \end{pmatrix} = I/4$$

jointly. The energy contribution of H_{pq} is then $\mathrm{Tr}(H_{pq}\rho_{pq}) = \mathrm{Tr}(H_{pq})/4 = r/4$, because H_{pq} is a rank r projector. Therefore if ρ_n is the uniformly random product state on n qubits, the total energy is $\mathrm{Tr}(H\rho_n) = rm/4$ where m is the number of local terms. We know that $m \geq \mathrm{OPT}$. So $\mathrm{Tr}(H\rho_n) \geq r/4 \cdot \mathrm{OPT}$. ◀

Harrow and Montanaro [16] consider approximation of the minimum and maximum eigenvalue of local Hamiltonians where each qubit can appear in at most D local terms. They give an algorithm with approximation ratio $c + \Omega(1/\sqrt{D})$, where c is the ratio achieved by uniformly random assignment. More related to the problem we consider, Gharibian and Kempe [12] consider approximating the maximum eigenvalue of a k-local Hamiltonian with positive semidefinite local terms.

▶ **Theorem 3** ([12])**.** *For a* k*-local Hamiltonian* H *on* n*,* d*-dimensional qudits with positive semidefinite local terms and maximum eigenvalue (energy)* OPT*, there exists a product state assignment with energy of* OPT/d^{k-1}*.*

We are interested in the case of $(d, k) = (2, 2)$ in this paper. In this case, the above theorem implies there exists a product state with energy $\mathrm{OPT}/2$ and this means $\mathrm{OPT}_{\mathrm{prod}} \geq \mathrm{OPT}/2$; however, finding such a product state is NP-hard in general. They also give an approximation algorithm achieving a constant approximation ratio for dense instances.

▶ **Theorem 4** ([12])**.** *For any* k*-local Hamiltonian* H *on* n *qubits, there exists a deterministic poly-time algorithm outputting a product state achieving* $\langle\psi|H|\psi\rangle > \mathrm{OPT}_{\mathrm{prod}} - \epsilon n^k$*.* $\mathrm{OPT}_{\mathrm{prod}}$ *is the highest energy that can be achieved by a product state.*

In the case of $k = 2$, this implies a product state with energy $\mathrm{OPT}_{\mathrm{prod}} - \epsilon n^2$ can be efficiently found. If the constraint graph is dense, combining the two gives a $(1/2 - \epsilon')$-approximation algorithm. With a dense constraint graph, we know that $\mathrm{OPT}_{\mathrm{prod}} = \Theta(n^2)$ (by assigning a random product state). So $\mathrm{OPT}_{\mathrm{prod}} - \epsilon n^2 = \mathrm{OPT}_{\mathrm{prod}} - c\epsilon\,\mathrm{OPT}_{\mathrm{prod}} = (1 - c\epsilon)\,\mathrm{OPT}_{\mathrm{prod}}$, for some constant c. By Theorem 3, we know that this value is at least $(1/2 - c\epsilon/2)\,\mathrm{OPT}$.

Brandão and Harrow's result [7] also says that product states do better on regular constraint graphs as the degree increases.

▶ **Theorem 5** ([7])**.** *Suppose a 2-local Hamiltonian* H *on qudits has non-trivial terms on a* D*-regular graph. For all edges* (p, q) *on the graph, suppose the local term* H_{pq} *satisfies* $\|H_{pq}\| \leq 1$*. Then there exists a product state* $|\psi\rangle$ *such that* $\langle\psi|H|\psi\rangle \geq \mathrm{OPT} - 12\frac{nD}{2}(\frac{d^2 \ln d}{D})^{1/3}$*, where* OPT *is the largest eigenvalue of* H*.*

The above theorems imply that there exists a product state that achieves approximation ratio of $1 - 12(\frac{d^2 \ln d}{D})^{1/3}$ when the constraint graph is D-regular.

More recent and closely related work is that of Gharibian and Parekh [14] and Bravyi, Gosset, König, and Temme [8]. These works and our work all aim to optimize 2-local Hamiltonians in the product state space, and they all use SDP to do so. The work [14] considers a specialization of Max-2-LH; however, a key difference is that their main target Hamiltonian is more restricted and physically motivated, a maximization version of the quantum Heisenberg model. The special case they consider is qualitatively simpler in some sense, as their Hamiltonian does not have any 1-local terms, which present an additional complication in our work. They also consider additional Hamiltonians that do not have PSD local terms, which are not special cases of MAX-2-LH. Another difference is in the SDP relaxations employed. We must use additional constraints yielding a strengthened SDP relaxation to obtain our results. They get the following results.

▶ **Theorem 6** ([14]). *Consider a local Hamiltonian $H = \sum_{(p,q)\in E} w_{pq} H_{pq}$ for $w_{pq} \geq 0$, where $H_{pq} = I - \alpha X_p X_q - \beta Y_p Y_q - \gamma Z_p Z_q$, for $\alpha, \beta, \gamma \in \{0, 1\}$. There exists a randomized classical approximation algorithm with approximation ratio 0.498 (when $\alpha + \beta + \gamma = 3$), 0.649 (when $\alpha + \beta + \gamma = 2$), or 0.878 (when $\alpha + \beta + \gamma = 1$).*

The $\alpha + \beta + \gamma = 3$ case of the above problem is when H_{pq} is a rank 1 projector onto the Bell state $|\Psi^-\rangle = |01\rangle - |10\rangle$, on qubits p and q. Thus this case is an instance of MAX-2-LH.

The work [8] uses similar techniques for a slightly different problem. They consider the problem of approximating the maximum eigenvalue of traceless 2-local Hamiltonians on n qubits. They give a randomized classical approximation algorithm that outputs a product state with expected energy $\mathrm{OPT}/O(\log n)$ where OPT is the maximum eigenvalue of the input Hamiltonian. They use the same SDP relaxation as [14] for the maximum eigenvalue, but they use a different rounding technique from [14] or this work; as with [14], being able to ignore 1-local terms simplifies their algorithm and analysis relative to this work.

Another related work is by Bansal, Bravyi, and Terhal, where they prove that a PTAS (an algorithm that runs in polynomial time in problem size and $1/\epsilon$ where ϵ is an arbitrarily small approximation ratio) exists [5] for Quantum Ising Spin Glass defined over a planar interaction graph with bounded degree, where the goal is to find the minimum eigenvalue of Hamiltonians of form $H = \sum_{(u,v)\in E} c_{uv} L_{uv} + \sum_u L_u$, where L_{uv} is quadratic in Pauli matrices and L_u is linear.

There are limited results on the hardness of approximation of quantum problems. Gharibian and Kempe introduce a quantum version of Σ_2^p called cq-Σ_2 [13]. They prove that QSSC and QIRR, defined in the paper, are cq-Σ_2-hard to approximate to certain ratios. Moreover, they also show that it is QCMA-hard to approximate Quantum Monotone Minimum Satisfying Assignment, defined in their paper, to approximation ratio $N^{1-\epsilon}$ for all $\epsilon > 0$, where N is the size of instance.

2.2 Reducing Max-2-CSP to Max-2-LH

MAX-2-CSP is reduced to MAX-2-Local Hamiltonian as follows. Suppose we are given a MAX-2-CSP instance on n boolean variables $x_1, x_2, \ldots, x_n \in \{0, 1\}$, a set of edges E between the x_i's, and functions $f_{ij} : \{0, 1\}^2 \to \{0, 1\}$ on (x_i, x_j) for $(i, j) \in E$. The question is to compute the quantity $\mathrm{OPT}_{\mathrm{CSP}} = \max_{x_1,\ldots,x_n} \sum_{(i,j)\in E} f_{ij}(x_i, x_j)$. We can reduce this instance to a MAX-2-LH instance on n qubits $q_1, q_2, \ldots, q_n$ with projectors $P_{ij} := \sum_{(x_i,x_j)\in \mathrm{Supp}(f_{ij})} |x_i x_j\rangle\langle x_i x_j|$ on qubit i, j for $(i, j) \in E$, where $\mathrm{Supp}(f_{ij}) = \{(x_i, x_j) \mid f_{ij}(x_i, x_j) = 1\}$. To see that this is a correct reduction, consider an optimizer $|\phi\rangle = \sum_{x\in\{0,1\}^n} c_x |x\rangle$ to the MAX-2-LH instance. The energy of $|\phi\rangle$ is $\langle\phi| \sum_{(i,j)\in E} P_{ij} |\phi\rangle = \sum_{x\in\{0,1\}^n} |c_x|^2 \langle x| \sum_{(i,j)\in E} P_{ij} |x\rangle$. Measuring $|\phi\rangle$ in the computational basis and using it as

an assignment for the original instance, we satisfy $\sum_{x\in\{0,1\}^n} |c_x|^2 \sum_{(i,j)\in E} f_{ij}(x_i, x_j)$ constraints in expectation, which coincides with the energy of $|\phi\rangle$. So MAX-2-Local Hamiltonian on qubits is NP-hard. Then MAX-k-Local Hamiltonian with $k > 2$ on qudits is also NP-hard because MAX-2-LH on qubits is a special case of MAX-k-LH on qudits, when each projector acts non-trivially on 2 locations within an embedded 2 dimensional space.

2.3 Approximating 2-CSPs using SDP

SDP has been a major tool for approximating 2-CSP problems since Goemans and Williamson used semidefinite programming to obtain a 0.878-approximation for MAX-CUT and MAX-2-SAT, as well as a 0.796-approximation for a MAX-DICUT [15].

There had been gradual improvements in the approximation ratio [23, 22], and finally [20] obtained the best approximation ratios to date, 0.94016 for MAX-2-SAT and 0.87401 for MAX-DICUT. All of the papers mentioned above employ SDP rounding techniques.

On the other hand, [17] showed that the approximation ratio 0.878 for MAX-CUT is tight and the approximation ratio for MAX-DICUT is upper bounded by 0.878, assuming that the Unique Game Conjecture (UGC) is true. Austrin proved that the approximation ratio 0.94016 is tight for MAX-2-SAT and the approximation ratio for MAX-2-AND is upper bounded by 0.87435, assuming the UGC [4]. More details about CSP approximation can be found in a recent survey by Makarychev and Makarychev [21].

2.4 Lemmas on randomized rounding

We use the following lemmas without proof. The inequalities are special cases of more general "Grothendieck inequalities." Grothendieck inequalities have begun playing an important role in theoretical computer science with a variety of applications. For more details see a survey by Khot and Naor [18].

The first two lemmas below are given by Goemans and Williamson with which they prove approximation ratios for their MAX-CUT and MAX-2SAT algorithms respectively, namely, Theorem 3.3 and Lemma 7.3.2 in [15].

▶ **Lemma 7** ([15]). *Let $u, v \in S^N$ be unit vectors in $\mathbb{R}^{N+1}$ for $N \geq 2$, and let $x = \operatorname{sgn}(u \cdot r), y = \operatorname{sgn}(v \cdot r)$ for a uniformly random vector $r \in S^N$. Then*

$$\mathbb{E}_r[1 \pm xy] \geq \alpha_1(1 \pm u \cdot v),$$

where $\alpha_1 = \frac{2}{\pi} \min_{0<\theta<\pi} \frac{\theta}{1-\cos\theta} = 0.878\ldots$.

▶ **Lemma 8** ([15]). *Let $u, v, w \in S^N$ be unit vectors in $\mathbb{R}^{N+1}$ for $N \geq 2$, and let $x = \operatorname{sgn}(u \cdot r), y = \operatorname{sgn}(v \cdot r), z = \operatorname{sgn}(w \cdot r)$, for a uniformly random vector $r \in S^N$. Then*

$$\mathbb{E}_r[1 \pm xy \pm xz + yz] \geq \alpha_2(1 \pm u \cdot v \pm u \cdot w + v \cdot w),$$

where $\alpha_2 = \min_{0<\theta<\arccos(-1/3)} \frac{2}{\pi} \frac{2\pi-3\theta}{1+3\cos\theta} = 0.796\ldots$.

We will also use the following lemma, obtained by Briët, de Oliveira Filho, and Vallentin [9] in considering a rank-constrained version of the Grothendieck problem, to bound randomized rounding for positive semidefinite matrices.

▶ **Lemma 9** ([9]). *Let A be a $m \times m$ real-valued positive semidefinite matrix and $u_1, \ldots, u_m$ be unit vectors in S^N for an integer $N \geq m$. For all $1 \leq i \leq m$, let $x_i = \operatorname{sgn}(r \cdot u_i)$ for a uniformly random vector $r \in S^N$. Then*

$$\mathbb{E}\left[\sum_{1\leq i,j\leq m} A_{ij}x_ix_j\right] \geq \frac{m}{\pi}\left(\frac{\Gamma(m/2)}{\Gamma((m+1)/2)}\right)^2 \sum_{1\leq i,j\leq m} A_{ij}u_i \cdot u_j.$$

The coefficient $\frac{m}{\pi}\left(\frac{\Gamma(m/2)}{\Gamma((m+1)/2)}\right)^2$ is asymptotically $2/\pi + \Theta(1/m)$. We will use the lemma for $m = 6$, which has associated constant $\alpha_7 := \frac{6}{\pi}\left(\frac{\Gamma(3)}{\Gamma(3.5)}\right)^2 = \frac{6}{\pi}\left(\frac{2}{15\sqrt{\pi}/8}\right)^2 = 0.691\cdots$.

Since Lemma 9 is not explicitly stated in the form of a theorem in [9], we give a brief description about how to piece the statements in [9] together. This lemma follows from the analysis in [9], where they give an approximation algorithm for the Grothendieck problem. In particular, Lemma 1 and the argument surrounding Equation (3) are used as follows. Using their notation, let $E_1(t) = \frac{2}{\pi}\arcsin t$ and let $\widetilde{E}_1(t) = \frac{2}{\pi}\arcsin t - \frac{2}{\pi}\frac{t}{\gamma(m)}$. It turns out that the functions only depend on the inner product between two vectors, so $E_1(u_i, u_j)$ means $E_1(t)$, where $t = u_i \cdot u_j$. Lemma 1 states that $\widetilde{E}_1(t)$ is of positive type for S^{m-1}. This means that for any vectors $u_1, \ldots, u_m \in S^{m-1}$, the matrix $\left(\widetilde{E}_1(u_i, u_j)\right)_{1\leq i,j\leq m}$ is positive semidefinite. Since A is also positive semidefinite, it holds that $\sum_{i,j=1}^m A_{ij}\left(\frac{2}{\pi}\arcsin u_i \cdot u_j - \frac{2}{\pi}\frac{u_i\cdot u_j}{\gamma(m)}\right) = \sum_{i,j=1}^m A_{ij}\widetilde{E}_1(u_i, u_j) \geq 0$. Therefore $\sum_{ij} A_{ij}\frac{2}{\pi}\arcsin u_i \cdot u_j \geq \sum_{ij} A_{ij}\frac{2}{\pi}\frac{u_i\cdot u_j}{\gamma(m)}$. Finally, use the fact that $\mathbb{E}\left[\operatorname{sgn}(r \cdot u_i)\operatorname{sgn}(r \cdot u_j)\right] = \frac{2}{\pi}\arcsin u_i \cdot u_j$, and the fact that $\frac{2}{\pi}\frac{1}{\gamma(m)}$ is equal to the factor given in the lemma above, as in Theorem 2 in [9].

2.5 Notation

▶ **Definition 10** (Pauli matrices). *We denote the Pauli matrices on a qubit as $W_0 := I = \begin{pmatrix}1 & 0\\ 0 & 1\end{pmatrix}$, $W_1 := X = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}$, $W_2 := Y = \begin{pmatrix}0 & -i\\ i & 0\end{pmatrix}$, and $W_3 := Z = \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}$. On n qubits, we write $W_{pi} := W_i \otimes I_{[n]\setminus\{p\}}$, where W_i is on the qubit p, and $I_{[n]\setminus\{p\}}$ is the identity on the rest of the qubits.*

3 The algorithm and analysis

The setup

A 2-local Hamiltonian is given as a set of Hamiltonians $\{H_{pq} : (p, q) \in E\}$, for some edge set $E \subseteq [n] \times [n]$, where H_{pq} operates on qubits p and q. This means H_{pq} is a 4×4 matrix on the Hilbert space $\mathcal{H}_p \otimes \mathcal{H}_q$ that represents the joint space of qubits p, q. Given such a list of Hamiltonians on 2 qubits, the goal is to approximate the maximum eigenvalue of $H := \sum_{(p,q)\in E} H_{pq} \otimes I_{[n]\setminus\{p,q\}}$. In this paper we assume each term H_{pq} is a PSD matrix. We will decompose H_{pq} using its eigenvectors $H_{pq} = \sum_{t=1}^4 w_{pq,t}|\gamma_{pq,t}\rangle\langle\gamma_{pq,t}|$, where $w_{pq,i} \geq 0$ for all p, q, t.

Let OPT denote the maximum eigenvalue of H over quantum states. Stated in terms of energy, $\mathrm{OPT} = \max_{|\phi\rangle}\langle\phi|H|\phi\rangle$. We seek to produce an approximately optimal state; however, since our approximation algorithms are classical polynomial-time algorithms, we output an efficient representation of such a state. Our approach is to formulate an SDP that upper-bounds the maximum energy of the given Hamiltonian. We then randomly round the solution vectors of the SDP to real numbers to get a product quantum state, admitting a polynomial-size representation, with a relatively high energy.

A semidefinite program relaxation

We start with an SDP relaxation that gives an upper bound on the optimal energy. By "relaxation", we mean an SDP for which each quantum state generates a feasible solution, with objective function value matching its energy. This way, we know that the value of the SDP is at least the highest energy possible by a physical state.

For each pair of qubits $(p,q) \in E$ (E consists of ordered pairs pq with $p<q$), we have a local Hamiltonian $H_{pq} = \sum_{t=1}^{4} w_{pq,t}|\gamma_{pq,t}\rangle\langle\gamma_{pq,t}|$. We denote the Pauli decomposition of the local terms $C_{pqij} = \mathrm{Tr}(H_{pq}(W_i \otimes W_j))/4$. Note that the matrix $C_{pq} = (C_{pqij})_{ij}$ is real for all $(p,q) \in E$, since tensor products of Pauli matrices form a real-coefficient basis for the Hermitian matrices. Consider the SDP:

$$\text{Maximize} \quad \sum_{(p,q)\in E} \sum_{i,j=0}^{3} C_{pqij} v_{pi} \cdot v_{qj} \tag{S1}$$

subject to:

$$\begin{aligned}
&||v_0|| = 1 \\
&||v_{pi}|| = 1, \ \forall p, i \\
&v_0 \cdot v_{p0} = 1, \ \forall p \\
&v_{pi} \cdot v_{pj} = 0, \ \forall p, \ i,j > 0 : i \neq j \\
&v_0, v_{pi} \in \mathbb{R}^N, \ \forall p, i \\
&\sum_{i,j=0}^{3} C_{pqij} v_{pi} \cdot v_{qj} \leq \sum_{t=1}^{4} w_{pq,t}, \ \forall (p,q) \in E.
\end{aligned}$$

and N can be taken to be the total number of vectors, v_0 and the v_{pi} in the program, which is $4n+1$. The motivation for this relaxation is that, for any quantum state $|\phi\rangle$, we may construct additional complex unit vectors by applying tensor products of Pauli matrices to $|\phi\rangle$. In particular, setting $v_0 := |\phi\rangle$, and $v_{pi} := W_{pi}|\phi\rangle$, for all p and i, yields a solution that is "almost" feasible for the above SDP. The first three constraints are satisfied, noting that $W_{p0} = W_0 = I$ for all p. For the fourth constraint, we have that $v_{pi} \cdot v_{pj} = \langle\phi|W_{pi}W_{pj}|\phi\rangle = -\langle\phi|W_{pj}W_{pi}|\phi\rangle$, since distinct nontrivial Pauli matrices anticommute. This implies that $\mathrm{Re}(v_{pi} \cdot v_{pj}) = 0$. Indeed, we obtain a true solution to the SDP by modifying the vectors so that the imaginary part of their inner products is discarded. This is formalized in the claim below.

▶ Remark 11. The complex vectors v_{pi}, as constructed above from $|\phi\rangle$, suggest a complex SDP relaxation; however, the real version, ($S1$) is simpler and equivalent in terms of optimal objective value. The relationship $v_{pi} \cdot v_{qj} = \langle\phi|W_{pi}W_{qj}|\phi\rangle$ connects 2-moments of the state $|\phi\rangle$ to SDP relaxations. Considering higher-order moments leads to larger but stronger SDP relaxations, and considering n-moments leads to an exact SDP formulation of exponential size. Restricting the moments considered to products over only $W_{p3} = Z_p$ for different p yields an SDP hierarchy equivalent to the celebrated classical Lasserre hierarchy.

▷ Claim 12. This SDP is a relaxation, i.e., there is a mapping from pure quantum states to vectors such that objective value is the energy of the state.

Proof. Let $|\phi\rangle$ be a quantum state, and let $v_0 := (\mathrm{Re}(|\phi\rangle), \mathrm{Im}(|\phi\rangle))$, and $v_{pi} := (\mathrm{Re}(W_{pi}|\phi\rangle), \mathrm{Im}(W_{pi}|\phi\rangle))$, for $p \in [n], i \in \{0,1,2,3\}$. Here $\mathrm{Re}(u) := (\mathrm{Re}(u_i))_{i\in[d]}$, $\mathrm{Im}(u) := (\mathrm{Im}(u_i))_{i\in[d]}$ for a d-dimensional complex vector u.

To check the SDP constraints, first note the v_0 has norm 1, and $v_0 = v_{p0}$ for all p. Next, each vector v_{pi} has norm 1, and two different vectors on qubit p are orthogonal:

$$\begin{aligned} v_{pi} \cdot v_{pj} &= (\mathrm{Re}(W_{pi}|\phi\rangle), \mathrm{Im}(W_{pi}|\phi\rangle)) \cdot (\mathrm{Re}(W_{pj}|\phi\rangle), \mathrm{Im}(W_{pj}|\phi\rangle)) \\ &= \mathrm{Re}(\langle\phi|W_{pi}W_{pj}|\phi\rangle) = \delta_{ij}, \end{aligned}$$

for all $i, j \in \{1, 2, 3\}$, $p \in [n]$. This follows from the Pauli matrices anticommutation relations $W_iW_j + W_jW_i = 2\delta_{ij}I$.

Next, we consider two vectors on different qubits. Let $\rho := |\phi\rangle\langle\phi|$. Then

$$\begin{aligned} v_{pi} \cdot v_{qj} &= (\mathrm{Re}(W_{pi}|\phi\rangle), \mathrm{Im}(W_{pi}|\phi\rangle)) \cdot (\mathrm{Re}(W_{qj}|\phi\rangle), \mathrm{Im}(W_{qj}|\phi\rangle)) \\ &= \mathrm{Re}(\langle\phi|W_{pi}W_{qj}|\phi\rangle) = \mathrm{Re}(\mathrm{Tr}(W_{pi}W_{qj}\rho)), \end{aligned}$$

for all $p \neq q$, and $i, j \in \{0, 1, 2, 3\}$. This follows from the fact that two Pauli matrices commute when they act on different qubits.

The SDP objective is therefore equal to the enegy of the state:

$$\begin{aligned} \sum_{(p,q)\in E} \sum_{i,j=0}^{3} C_{pqij} v_{pi} \cdot v_{qj} &= \sum_{(p,q)\in E} \sum_{i,j=0}^{3} \frac{1}{4} \mathrm{Tr}(H_{pq}(W_i \otimes W_j)) \mathrm{Re}(\mathrm{Tr}(W_{pi}W_{qj}\rho)) \\ &= \mathrm{Re}\left(\sum_{(p,q)\in E} \sum_{i,j=0}^{3} \frac{1}{4} \mathrm{Tr}(H_{pq}(W_i \otimes W_j)) \mathrm{Tr}((W_i \otimes W_j)\rho_{pq}) \right) \\ &= \sum_{(p,q)\in E} \mathrm{Tr}(H_{pq}\rho_{pq}) = \mathrm{Tr}(H\rho), \end{aligned}$$

where ρ_{pq} is the reduced density matrix of ρ onto qubits $\{p, q\}$. The second last equality is because the Pauli matrices form an orthogonal basis. The last constraint of $(S1)$ asserts that the energy contribution from the site (p, q) should not exceed the sum of the eigenvalues of (p, q). The seemingly unnecessary last constraint will be useful in the analysis. ◁

We can solve the SDP to arbitrary multiplicative quality $1 - \epsilon$ using existing SDP solvers (for example, [1]), in time polynomial to the size of the program and $\log(1/\epsilon)$. This gives us a solution of quality $\mathrm{OPT}_{\mathrm{SDP}}(1 - \epsilon)$, where $\mathrm{OPT}_{\mathrm{SDP}}$ is the optimal value of the SDP. We will ignore $(1 - \epsilon)$ factor because it can be absorbed into our approximation ratio.

The algorithm and analysis

Algorithm 1 MAX-2-Local Hamiltonian with PSD local terms.

1: Input: $\{H_{pq} : (p, q) \in E\}, E \subseteq [n] \times [n]$.
2: Calculate $(C_{pqij} := \mathrm{Tr}(H_{pq}(W_i \otimes W_j))/4)_{pqij}$.
3: Solve the SDP $(S1)$, and get $(v_0, (v_{pi})_{pi})$.
4: Pick a uniformly random unit vector $r \in \mathbb{R}^N$ (use $N := 4n + 1$).
5: Set $(x_0, (x_{pi})_{pi}) := (\mathrm{sgn}(v_0 \cdot r), (\mathrm{sgn}(v_{pi} \cdot r))_{pi})$.
6: If $\sum_{(p,q)\in E} \left(\sum_{i=1}^{3} C_{pqi0} x_{pi} x_0 + \sum_{j=1}^{3} C_{pq0j} x_0 x_{qj} \right) < 0$, set $\widetilde{x}_{pi} := -x_{pi}x_0$ for all p and $1 \leq i \leq 3$. Otherwise set $\widetilde{x}_{pi} := x_{pi}x_0$ for all p, $1 \leq i \leq 3$.
7: Output state $\rho := \bigotimes_{p=1}^{n} \rho_p$, where $\rho_p := \frac{1}{2}I + \frac{1}{2} \sum_{i=1}^{3} \frac{1}{\sqrt{3}} \widetilde{x}_{pi} W_i$

Algorithm 1 describes our rounding procedure. Let $C_{pq} \in \mathbb{R}^{4\times 4}$ refer to the matrix $(C_{pqij})_{ij}$, let $c_{pq} := C_{pq00} = \frac{1}{4}\sum_{t=1}^{4} w_{pq,t}$, let $a_{pq} \in \mathbb{R}^3$ refer to the vector $(C_{pqi0})_{i:i>0}$, and $b_{pq} := (C_{pq0j})_{j:j>0}$ is defined analogously. Finally $\bar{C}_{pq} \in \mathbb{R}^{3\times 3}$ is $(C_{pqij})_{ij:i,j>0}$. So we have

$$C_{pq} = \begin{bmatrix} c_{pq} & b_{pq}^T \\ a_{pq} & \bar{C}_{pq} \end{bmatrix}.$$

To apply the bound from [9], we need a symmetrized and PSD version of C_{pq}, so define

$$C_{pq}^{+} = \begin{bmatrix} c_{pq} & a_{pq}^T & b_{pq}^T \\ a_{pq} & c_{pq} I & \bar{C}_{pq} \\ b_{pq} & \bar{C}_{pq}^T & c_{pq} I W_{pqi} \end{bmatrix} \in \mathbb{R}^{7\times 7}.$$

The matrix C_{pq}^{+} is clearly symmetic. To see that $C_{pq}^{+} \succeq 0$, use the fact that $H_{pq} = \sum_{t=1}^{4} w_{pq,t}|\gamma_{pq,t}\rangle\langle\gamma_{pq,t}|$ for non-negative $w_{pq,t}$'s, and get

$$\begin{aligned} 4W_{pqj}C_{pqij}^{+} &= \sum_{t=1}^{4} w_{pq,t}\mathrm{Re}\left(\mathrm{Tr}\left[|\gamma_{pq,t}\rangle\langle\gamma_{pq,t}|W_{pqi}W_{pqj}\right]\right) \\ &= \sum_{t=1}^{4} w_{pq,t}(\mathrm{Re}(W_{pqi}|\gamma_{pq,t}\rangle), \mathrm{Im}(W_{pqi}|\gamma_{pq,t}\rangle)) \cdot (\mathrm{Re}(W_{pqj}|\gamma_{pq,t}\rangle), \mathrm{Im}(W_{pqj}|\gamma_{pq,t}\rangle)), \end{aligned}$$

where $(W_{pqi})_{0\le i\le 6} := (I, W_1\otimes I, W_2\otimes I, W_3\otimes I, I\otimes W_1, I\otimes W_2, I\otimes W_3)$. Since C_{pq}^{+} is therefore a non-negative-weighted sum of Gram matrices, it is PSD. Now we state the main theorem.

▶ **Theorem 13.** *Algorithm 1 runs in polynomial time and outputs a product state with expected energy at least* $0.328\,\mathrm{OPT}$*, where* OPT *is the maximum energy of the 2-local Hamiltonian* $H = \sum_{(p,q)\in E} H_{pq}\otimes I_{[n]\setminus\{p,q\}}$ *where* H_{pq} *is PSD for all* $(p,q)\in E$*.*

Proof. Algorithm 1 outputs a product state, whose reduced part on p and q is

$$\rho_p\otimes\rho_q = \frac{1}{4}\left(I + \frac{\widetilde{x}_{p1}}{\sqrt{3}}W_1 + \frac{\widetilde{x}_{p2}}{\sqrt{3}}W_2 + \frac{\widetilde{x}_{p3}}{\sqrt{3}}W_3\right)\otimes\left(I + \frac{\widetilde{x}_{q1}}{\sqrt{3}}W_1 + \frac{\widetilde{x}_{q2}}{\sqrt{3}}W_2 + \frac{\widetilde{x}_{q3}}{\sqrt{3}}W_3\right).$$

Thus the total energy of the approximate solution is $\mathbb{E}_r\left[\sum_{(p,q)\in E}\mathrm{Tr}(H_{pq}(\rho_p\otimes\rho_q))\right]$, which is equal to

$$\mathbb{E}_r \sum_{(p,q)\in E}\left[c_{pq} + \frac{\sum_{i=1}^{3} a_{pqi}\widetilde{x}_{pi} + \sum_{j=1}^{3} b_{pqj}\widetilde{x}_{qj}}{\sqrt{3}} + \frac{\sum_{i,j=1}^{3}\bar{C}_{pqij}\widetilde{x}_{pi}\widetilde{x}_{qj}}{3}\right]. \tag{1}$$

Meanwhile, the SDP objective value is

$$\sum_{(p,q)\in E}\left[c_{pq} + \sum_{i=1}^{3} a_{pqi}v_{pi}\cdot v_0 + \sum_{j=1}^{3} b_{pqj}v_0\cdot v_{qj} + \sum_{i,j=0}^{3}\bar{C}_{pqij}v_{pi}\cdot v_{qj}\right]. \tag{2}$$

Fix an edge $(p,q) \in E$, and let $v_{pq} := (v_0, v_{p1}, v_{p2}, v_{p3}, v_{q1}, v_{q2}, v_{q3})$. By applying Lemma 9 to C^+_{pq} and v_{pq}, we get

$$\mathbb{E}_r \left[7c_{pq} + 2\sum_{i=1}^{3} a_{pqi} x_{pi} x_0 + 2\sum_{j=1}^{3} b_{pqj} x_0 x_{qj} + 2\sum_{i,j=1}^{3} \bar{C}_{pqij} x_{pi} x_{qj} \right] \geq$$
$$\alpha_7 \left(7c_{pq} + 2\sum_{i=1}^{3} a_{pqi} v_{pi} \cdot v_0 + 2\sum_{j=1}^{3} b_{pqj} v_0 \cdot v_{qj} + 2\sum_{i,j=1}^{3} \bar{C}_{pqij} v_{pi} \cdot v_{qj} \right). \tag{3}$$

The coefficients 7 and 2 above come from how many times each parts are in C^+_{pq}. We would like to compare the energy of our solution (1) against the SDP objective (2) using the inequality (3). For the series of inequalities that will appear below, we define some short-hand:

$$L_x := \sum_{(p,q)\in E} \left[\sum_{i=1}^{3} a_{pqi} x_{pi} x_0 + \sum_{j=1}^{3} b_{pqj} x_0 x_{qj} \right],$$
$$Q_x := \sum_{(p,q)\in E} \left[\sum_{i,j=1}^{3} \bar{C}_{pqij} x_{pi} x_{qj} \right],$$
$$L_v := \sum_{(p,q)\in E} \left[\sum_{i=1}^{3} a_{pqi} v_{pi} \cdot v_0 + \sum_{j=1}^{3} b_{pqj} v_0 \cdot v_{qj} \right],$$
$$Q_v := \sum_{(p,q)\in E} \left[\sum_{i,j=1}^{3} \bar{C}_{pqij} v_{pi} \cdot v_{qj} \right],$$
$$\widetilde{L}_x := \sum_{(p,q)\in E} \left[\sum_{i=1}^{3} a_{pqi} \widetilde{x}_{pi} + \sum_{j=1}^{3} b_{pqj} \widetilde{x}_{qj} \right],$$
$$\widetilde{Q}_x := \sum_{(p,q)\in E} \left[\sum_{i,j=1}^{3} \bar{C}_{pqij} \widetilde{x}_{pi} \widetilde{x}_{qj} \right],$$
$$c := \sum_{(p,q)\in E} c_{pq}.$$

After summing the inequality (3) over the edges and moving the terms, we get

$$\mathbb{E}_r \left[c + \frac{L_x + Q_x}{3} \right] \geq \frac{\alpha_7(\frac{7}{2}c + L_v + Q_v) - \frac{1}{2}c}{3}. \tag{4}$$

Because $\widetilde{L}_x \geq 0$ (Step 6 of Algorithm 1), and $\widetilde{L}_x + \widetilde{Q}_x \geq L_x + Q_x$ for every r, we can bound the energy of the approximate solution:

$$\mathbb{E}_r \left[c + \frac{\widetilde{L}_x}{\sqrt{3}} + \frac{\widetilde{Q}_x}{3} \right] \geq \mathbb{E}_r \left[c + \frac{\widetilde{L}_x + \widetilde{Q}_x}{3} \right] \geq \mathbb{E}_r \left[c + \frac{L_x + Q_x}{3} \right] \geq \frac{\alpha_7(\frac{7}{2}c + L_v + Q_v) - \frac{1}{2}c}{3},$$

where the last inequality follows from (4). We can now bound the approximation factor,

$$\frac{\mathbb{E}_r \left[c + \frac{\widetilde{L}_x}{\sqrt{3}} + \frac{\widetilde{Q}_x}{3} \right]}{c + L_v + Q_v} \geq \frac{\alpha_7(\frac{7}{2}c + L_v + Q_v) - \frac{1}{2}c}{3(c + L_v + Q_v)} = \frac{\alpha_7(\frac{7}{2}c + S) - \frac{1}{2}c}{3(c + S)},$$

letting $S := L_v + Q_v$ for convenience. The value of the SDP $(S1)$ is $c + S$ and the energy of the maximally mixed state is $c = \sum_{(p,q)\in E} c_{pq}$. The SDP value $c + S$ should at least be the energy of the maximally mixed state, so $c + S \geq c$. This implies that $S \geq 0$. By summing the last constraint of $(S1)$ over the edges, we get $c + S \leq \sum_{(p,q)\in E, 1\leq t\leq 4} w_{pq,t} = 4c$. Therefore, the approximation ratio is at least

$$\min_{S\in[0,3c]} \frac{\alpha_7(\frac{7}{2}c + S) - \frac{1}{2}c}{3(c + S)} \geq \frac{\alpha_7(\frac{13}{8}) - \frac{1}{8}}{3} = 0.328\ldots.$$

The min occurs at $S = 3c$ since $\frac{\alpha_7(\frac{7}{2}c+S)-\frac{1}{2}c}{3(c+S)} = \frac{\alpha_7(c+S)+\alpha_7\frac{5}{2}c-\frac{1}{2}c}{3(c+S)} = \frac{\alpha_7}{3} + \frac{5\alpha_7-1}{6(c+S)}c$ is decreasing for $c + S \geq 0$. ◀

4 Improved approximation in for tensor product projectors using a different SDP and rounding

In this section we show that a better approximation factor is possible when each local term is a rank 1 projector that is a product of 2 rank 1 projectors on a qubit. Namely, $H_{pq} = H_{pq,p} \otimes H_{pq,q}$, and $H_{pq,p}, H_{pq,q}$ are rank 1 projectors on qubit p, q respectively for all $(p, q) \in E$. The algorithm is similar to the previous one in that Goemans-Williamson approach is used. This time, however, we formulate the SDP and round the vector solution in a different way: we first formulate a quadratic programming (QP) in the real space that has the highest energy by a product state as the objective value, and relax the QP to an SDP. The previous rounding reduced the norms of the solution vectors by $1/\sqrt{3}$, but here we will keep the norms. The first observation we make is that the value of the following quadratic program (Q) is the maximum energy achieved by a product state.

Quadratic program for MAX-2-Local Hamiltonian over product states:

$$\text{Maximize } 4\sum_{pq}\sum_{i,j=0}^{3} C_{pqij}x_{pi}x_{qj} \tag{Q}$$

subject to:

$$x_{p0} = \frac{1}{2},\ \forall p$$

$$\sum_{i=0}^{3} x_{pi}^2 = \frac{1}{2},\ \forall p$$

$$x_{pi} \in \mathbb{R},\ \forall p, i.$$

The Pauli coefficients C_{pqij} are the same as defined previously. The constraints will restrict us to the set of quantum states that are product states. We use the Pauli basis so that all numbers we solve for are real valued. Representing qubits as density matrices, let $\Phi_p := |\phi_p\rangle\langle\phi_p|$ for all p.

For any density matrix, there exists a unique decomposition into Pauli matrices. So we can write $\Phi_p = \sum_{i=0}^{3} x_{pi}W_i$, and $H_{pq} = \sum_{i,j=0}^{3} C_{pqij}W_i \otimes W_j$. Moreover, we know that $\mathrm{Tr}[\Phi_p] = 1$ because the state $|\phi_p\rangle$ is norm 1, and also $\mathrm{Tr}[\Phi_p^2] = 1$ if we assume, without loss of generality, that the state $|\phi_p\rangle$ is pure. This implies that (i) $x_{p0} = \frac{1}{2}$ for all p, (ii) $\sum_i x_{pi}^2 = \frac{1}{2}$ for all p, (iii) $C_{pq00} = \frac{1}{4}$ for all p, q, and (iv) $\sum_{ij} C_{pqij}^2 = \frac{1}{4}$ for all p, q.

The reverse process also works: Given real numbers $(x_{p0}, x_{p1}, x_{p2}, x_{p3})$ as a part of a feasible solution to (Q), one can construct a state $|\phi_p\rangle$ such that $|\phi_p\rangle\langle\phi_p| = \sum_{i=0}^{3} x_{pi}W_i$.

This is because of the properties of the Pauli basis:

$$\begin{aligned}\Phi_p^2 &= \sum_{i,j=0}^{3} x_{pi}x_{pj}W_iW_j = x_{p0}^2W_0^2 + 2\sum_{i=0}^{3} x_{pi}x_{p0}W_i + \sum_{i,j=1}^{3} x_{pi}x_{pj}W_iW_j \\ &= \frac{1}{4}W_0 + \sum_{i=0}^{3} x_{pi}W_i + \sum_{i=1}^{3} x_{pi}^2W_i^2 + \sum_{1\le i,j\le 3, i\neq j}^{3} x_{pi}x_{pj}W_iW_j \\ &= \frac{1}{4}W_0 + \sum_{i=0}^{3} x_{pi}W_i + \sum_{i=1}^{3} x_{pi}^2W_0 + \sum_{1\le i<j\le 3}^{3} x_{pi}x_{pj}(W_iW_j + W_jW_i) \\ &= \frac{1}{4}W_0 + \sum_{i=0}^{3} x_{pi}W_i + \frac{1}{4}W_0 + 0 = \Phi_p.\end{aligned}$$

The fact that $\Phi_p^2 = \Phi_p$ implies that Φ_p is a projector, and $\operatorname{Tr}\Phi_p = 1$ implies that it is a rank 1 projector. So there exists a vector $|\phi_p\rangle$ such that $|\phi_p\rangle\langle\phi_p| = \Phi_p = \sum_{i=0}^{3} x_{pi}W_i$.

Exactly solving this program is NP-hard, because as noted in Section 2.2, MAX-2-CSP can be cast as an instance of MAX-2-LH. Additionally, an optimum solution to such a MAX-2-LH instance is always, without loss of generality, a product state. We can, however, solve this approximately by first relaxing the program to an SDP, solving the SDP in polynomial time, and performing randomized rounding to the SDP solution we get to obtain a valid solution to the original program. Below is the SDP to which we relax. The coefficients C_{pqij}'s are given as constants.

SDP relaxation for MAX-2-Local Hamiltonian over product states:

$$\text{Maximize } 4\sum_{pq}\sum_{i,j=0}^{3} C_{pqij}v_{pi}\cdot v_{qj} \tag{S2}$$

subject to:

$$\begin{aligned}&\|v_0\| = \frac{1}{2} \\ &\|v_{p0}\| = \frac{1}{2},\ \forall p \\ &v_0\cdot v_{p0} = \frac{1}{4},\ \forall p \\ &\sum_{i=0}^{3}\|v_{pi}\|^2 = \frac{1}{2},\ \forall p \\ &v_0 \in \mathbb{R}^N \\ &v_{pi} \in \mathbb{R}^N,\ \forall p, i.\end{aligned}$$

The first three conditions simply force that for all p, $v_{p0} = v_0$. The SDP is in fact a relaxation of the quadratic program in the sense that given a solution x_{pi}, for all p, i, to the first program, the vector solution $v_0 := (1, 0, \ldots, 0), v_{pi} := x_{pi}v_0$, for all p, i, is a feasible solution to the SDP that achieves the same objective value. Therefore the value of the SDP is at least the value of the first program. Algorithm 2 details our approach.

▶ **Theorem 14.** *Given a local Hamiltonian on n qubits $H = \sum_{pq} P_{pq}$, where P_{pq} is a product of a rank 1 projector on qubit p and a rank 1 projector on qubit q, Algorithm 2 outputs a product state that has an expected energy of at least $\alpha_2 \cdot \mathrm{OPT}_{\mathrm{prod}}$, where $\alpha_2 = 0.796\ldots$, and $\mathrm{OPT}_{\mathrm{prod}} = \max_{|\phi_1\rangle,\ldots,|\phi_n\rangle}\langle\phi_1|\ldots\langle\phi_n|H|\phi_1\rangle\ldots|\phi_n\rangle$.*

Algorithm 2 MAX-2-local Hamiltonian with PSD local terms.

1: Input: $\{H_{pq} : (p,q) \in E\}, E \subseteq [n] \times [n]$.
2: Calculate $(C_{pqij} := \mathrm{Tr}(H_{pq}(W_i \otimes W_j))/4)_{pqij}$.
3: Solve the SDP $(S2)$, and get $(v_0, (v_{pi}))$.
4: Pick a random unit vector $r \in \mathbb{R}^N$ (use $N := 4n+1$).
5: For all $p \in [n]$ and $i \in \{0,1,2,3\}$, assign $x_{pi} := \|v_{pi}\| \operatorname{sgn}(v_0 \cdot r) \operatorname{sgn}(v_{pi} \cdot r)$.
6: Output $\Phi_p := \bigotimes_{p=1}^n \sum_{i=0}^3 x_{pi} W_i$ as the resulting product state assignment.

Proof. We express the rank 1 projector H_{pq} as $|\gamma_{pq}\rangle\langle\gamma_{pq}|$ for some state $|\gamma_{pq}\rangle$. $\mathrm{OPT}_{\mathrm{prod}}$ is the value of the program (Q). We relax the program (Q) to the SDP $(S2)$ and get v_{pi} for all p, i as a solution to the SDP. To get real-valued x_{pi}, we perform randomized rounding reminiscent of the Goemans-Williamson algorithm: $x_{pi} = \|v_{pi}\| \operatorname{sgn}(v_0 \cdot r) \operatorname{sgn}(v_{pi} \cdot r)$. The x_{pi} are used in Step 6 of the algorithm to produce a product state; these variables constitute a feasible solution to (Q) because $x_{p0} = \|v_{p0}\| \operatorname{sgn}(v_0 \cdot r) \operatorname{sgn}(v_{p0} \cdot r) = \frac{1}{2} \operatorname{sgn}(v_0 \cdot r)^2 = \frac{1}{2}$, and

$$\sum_{i=0}^3 x_{pi}^2 = \sum_{i=0}^3 \|v_{pi}\|^2 \operatorname{sgn}(v_0 \cdot r)^2 \operatorname{sgn}(v_{pi} \cdot r)^2 = \sum_{i=0}^3 \|v_{pi}\|^2 = \frac{1}{2}.$$

We apply Lemma 16 below to analyze the performance of the rounding term by term to yield:

$$\mathbb{E}\left[4 \sum_{pq} \sum_{i,j=0}^3 C_{pqij} x_{pi} x_{qj}\right] \geq \alpha_2 4 \sum_{pq} \sum_{i,j=0}^3 C_{pqij} v_{pi} \cdot v_{qj} = \alpha_2 \,\mathrm{OPT}_{\mathrm{SDP}} \geq \alpha_2 \,\mathrm{OPT}_{\mathrm{prod}}\,. \blacktriangleleft$$

▶ **Corollary 15.** *Algorithm 2 outputs a product state achieving* $0.40 \cdot \mathrm{OPT}$.

Proof. By Theorem 14 the algorithm outputs a state achieving $0.796 \cdot \mathrm{OPT}_{\mathrm{prod}}$, which is at least $0.40 \cdot \mathrm{OPT}\,/2$ by Theorem 3. ◀

Note that we have not yet used the assumption that H_{pq} is a tensor product of rank 1 projectors. In this case we have that $|\gamma_{pq}\rangle\langle\gamma_{pq}| = H_{pq} = H_{pq,p} \otimes H_{pq,q} = |\gamma_p\rangle\langle\gamma_p| \otimes |\gamma_q\rangle\langle\gamma_q| = (|\gamma_p\rangle \otimes |\gamma_q\rangle)(\langle\gamma_p| \otimes \langle\gamma_q|)$, for some states $|\gamma_p\rangle$ and $|\gamma_q\rangle$. Consequently $|\gamma_{pq}\rangle = |\gamma_p\rangle \otimes |\gamma_q\rangle$ is a product state, and the Pauli coefficients are $C_{pqij} = \mathrm{Tr}(|\gamma_{pq}\rangle\langle\gamma_{pq}|W_i \otimes W_j)/4 = \mathrm{Tr}((|\gamma_p\rangle\langle\gamma_p| \otimes |\gamma_q\rangle\langle\gamma_q|)(W_i \otimes W_j))/4 = \mathrm{Tr}(|\gamma_p\rangle\langle\gamma_p|W_i)\,\mathrm{Tr}(|\gamma_p\rangle\langle\gamma_p|W_i)/4 = C_{pi}C_{qj}$. So for all i, j, $C_{pqij} = C_{pi}C_{qj}$. Note that since $|\gamma_p\rangle$ is a 1 qubit state, $C_{p0}^2 = (\frac{1}{2})^2 = \sum_{i=1}^3 C_{pi}^2$. To conclude our analysis, we leverage this structure in the lemma below.

▶ **Lemma 16.** *Let* $u_0, \ldots, u_3, v_0, \ldots, v_3 \in \mathbb{R}^N$ *be vectors such that* $u_0 = v_0$, $\|u_0\| = \|v_0\| = 1/2$, *and* $\sum_{i=0}^3 \|u_i\|^2 = \sum_{i=0}^3 \|v_i\|^2 = 1/2$. *Let* $x_i = \|u_i\| \operatorname{sgn}(u_0 \cdot r) \operatorname{sgn}(u_i \cdot r)$, $y_j = \|v_j\| \operatorname{sgn}(v_0 \cdot r) \operatorname{sgn}(v_j \cdot r)$ *be the rounding of the vectors with respect to a uniformly random vector* $r \in S^{N-1}$. *Let* $C_{ij} = C_i D_j$ *where* $C_i, D_j \in \mathbb{R}$ *such that* $C_0^2 = \sum_{i=1}^3 C_i^2 = D_0^2 = \sum_{i=1}^3 D_i^2$. *Then*

$$\alpha_2 \sum_{i,j=0}^3 C_{ij} u_i \cdot v_j \leq \mathbb{E}\left[\sum_{i,j=0}^3 C_{ij} x_i y_j\right], \text{ where } \alpha_2 = \min_{0<\theta<\arccos -1/3} \frac{2}{\pi} \frac{2\pi - 3\theta}{1 + 3\cos\theta} = 0.796\ldots.$$

Proof. The proof is by applying Lemma 7, Lemma 8, and the Cauchy-Schwarz inequality. Let $U_i = \operatorname{sgn}(u_i \cdot r)$ and $V_i = \operatorname{sgn}(v_i \cdot r)$ and note that $U_0 = V_0$. Also for convenience, set

$$A_0 := C_0\|u_0\| - \sum_{i=1}^{3} |C_i|\|u_i\|, \quad A_1 := \sum_{i=1}^{3} |C_i|\|u_i\|(1 + \operatorname{sgn}(C_i)U_0U_i),$$
$$B_0 := D_0\|v_0\| - \sum_{j=1}^{3} |D_j|\|v_j\|, \quad B_1 := \sum_{i=1}^{3} |C_i|\|u_i\|(1 + \operatorname{sgn}(C_i)U_0U_i)$$

$$\begin{aligned}
\mathbb{E}\left[\sum_{i,j=0}^{3} C_{ij}x_iy_j\right] &= \mathbb{E}\left[\sum_{i,j=0}^{3} C_iD_j\|u_i\|U_0U_i\|v_j\|V_0V_j\right] \\
&= \mathbb{E}\left[\sum_{i=0}^{3} C_i\|u_i\|U_0U_i \sum_{j=0}^{3} D_j\|v_j\|V_0V_j\right] \\
&= \mathbb{E}\left[\left(C_0\|u_0\| + \sum_{i=1}^{3} C_i\|u_i\|U_0U_i\right)\left(D_0\|v_0\| + \sum_{j=1}^{3} D_j\|v_j\|V_0V_j\right)\right] \\
&= \mathbb{E}\left[(A_0 + A_1)(B_0 + B_1)\right] \\
&= A_0B_0 + \mathbb{E}\left[A_1B_0\right] + \mathbb{E}\left[A_0B_1\right] + \mathbb{E}\left[A_1B_1\right].
\end{aligned}$$

For convenience, set

$$A_0' := A_0, \quad A_1' := \sum_{i=1}^{3} |C_i|\|u_i\|(1 + \operatorname{sgn}(C_i)\frac{u_0 \cdot u_i}{\|u_0\|\|u_i\|}),$$
$$B_0' := B_0, \quad B_1' := \sum_{i=1}^{3} |D_i|\|v_i\|(1 + \operatorname{sgn}(D_i)\frac{u_0 \cdot v_i}{\|u_0\|\|v_i\|}).$$

From Lemma 7,

$$\mathbb{E}\left[1 + \operatorname{sgn}(C_i)\operatorname{sgn}(u_0 \cdot r)\operatorname{sgn}(u_i \cdot r)\right] \geq \alpha_1\left(1 + \operatorname{sgn}(C_i)\frac{u_0 \cdot u_i}{\|u_0\|\|u_i\|}\right)$$

for all i. Therefore $\mathbb{E}\left[A_1\right] \geq \alpha_1 A_1'$ and $\mathbb{E}\left[B_1\right] \geq \alpha_1 B_1'$.

Using the fact that either exactly one of $\operatorname{sgn}(C_i)$, $\operatorname{sgn}(D_j)$, or $\operatorname{sgn}(C_i)\operatorname{sgn}(D_j)$ is positive, or all three are, Lemma 8 implies

$$\begin{aligned}
&\mathbb{E}\left[(1 + \operatorname{sgn}(C_i)\operatorname{sgn}(u_0 \cdot r)\operatorname{sgn}(u_i \cdot r))(1 + \operatorname{sgn}(D_j)\operatorname{sgn}(v_0 \cdot r)\operatorname{sgn}(v_j \cdot r))\right] \geq \\
&\alpha_2\left(1 + \operatorname{sgn}(C_i)\frac{u_0 \cdot u_i}{\|u_0\|\|u_i\|} + \operatorname{sgn}(D_j)\frac{v_0 \cdot v_j}{\|v_0\|\|v_j\|} + \operatorname{sgn}(C_iD_j)\frac{u_i \cdot v_j}{\|u_i\|\|v_j\|}\right)
\end{aligned}$$

for all i, j. Therefore $\mathbb{E}\left[A_1B_1\right] \geq \alpha_2 A_1'B_1'$.

From Cauchy-Schwarz we have $A_0, B_0 \geq 0$, and using this inequality we can bound

$$\begin{aligned}
&\mathbb{E}\left[\sum_{i,j=0}^{3} C_{ij} x_i y_j\right] \\
&= A_0 B_0 + \mathbb{E}\left[A_1 B_0\right] + \mathbb{E}\left[A_0 B_1\right] + \mathbb{E}\left[A_1 B_1\right]. \\
&\geq A_0 B_0 + \alpha_1 A_1' B_0' + \alpha_1 A_0' B_1' + \alpha_2 A_1' B_1' \\
&\geq \alpha_2 A_0 B_0 + \alpha_2 A_1' B_0' + \alpha_2 A_0' B_1' + \alpha_2 A_1' B_1' \\
&= \alpha_2 (A_0' + A_1')(B_0' + B_1') \\
&= \alpha_2 \sum_{i,j=0}^{3} C_i D_j u_i \cdot v_j = \alpha_2 \sum_{i,j=0}^{3} C_{ij} u_i \cdot v_j.
\end{aligned}$$

Better and Simpler Learning-Augmented Online Caching

Alexander Wei
Harvard University, Cambridge, MA, USA

weia@college.harvard.edu

Abstract

Lykouris and Vassilvitskii (ICML 2018) introduce a model of online caching with machine-learned advice that marries the predictive power of machine learning with the robustness guarantees of competitive analysis. In this model, each page request is augmented with a prediction for when that page will next be requested. The goal is to design algorithms that (1) perform well when the predictions are accurate and (2) are robust in the sense of worst-case competitive analysis.

We continue the study of algorithms for online caching with machine-learned advice, following the work of Lykouris and Vassilvitskii as well as Rohatgi (SODA 2020). Our main contribution is a substantially simpler algorithm that outperforms all existing approaches. This algorithm is a black-box combination of an algorithm that just naïvely follows the predictions with an optimal competitive algorithm for online caching. We further show that combining the naïve algorithm with LRU in a black-box manner is optimal among deterministic algorithms for this problem.

1 Introduction

The study of online algorithms traditionally focuses on *worst-case* robustness, where algorithms provide the same competitive guarantee against the offline optimal over all possible inputs. In recent years, however, there has been a surge of interest in online algorithms for structured inputs [20, 18, 24, 11, 15, 16, 25, 17, 23]. A principal motivation for these works is the philosophy of "beyond worst-case analysis" [13, 26]: Many practical settings have inputs that follow restricted patterns, making worst-case competitive analysis too pessimistic to inform practice. Algorithms designed with the worst case in mind can be hamstrung by these considerations, sacrificing performance on "easy" inputs in order to eke out a better worst-case guarantee.

Learning-augmented online algorithms, introduced by Lykouris and Vassilvitskii [18] and Purohit et al. [24], is a "beyond worst-case" framework motivated by the powerful predictive abilities of modern machine learning. In this framework, the classical online algorithm model is augmented with a machine-learned oracle that predicts future inputs. A concern with simply relying on the oracle is that machine learning models typically have few worst-case guarantees. Thus, with learning-augmented online algorithms, we seek to obtain the best of both worlds. Given a predictor, our objective is to design algorithms that:

© Alexander Wei;

1. Perform well in the optimistic scenario, where the predictor has low error;
2. Remain robust in the classical worst-case sense, when the predictor can be arbitrarily bad.

In other words, we want our algorithm to be $c(\eta)$-competitive against the offline optimal on all inputs, for c a function of the predictor's total error η, such that $\sup_\eta c(\eta) \leq \gamma$ for some constant $\gamma \geq 1$. This γ is the classical worst-case competitive ratio and is a measure of the robustness of our algorithm.

This paper focuses on learning-augmented *online caching* [18, 25]. In the online caching (a.k.a. online paging) problem, one maintains a cache of size k online while serving requests for pages that may or may not be in the cache. For simplicity, assume that pages must always be served from the cache and that bringing a page into the cache has unit cost. (In particular, if the cache is full, bringing a page into the cache requires also *evicting* a page already in the cache.) Thus, one wishes to minimize the number of *cache misses*, i.e., requests for which the page is not already in the cache. This is a classical online problem that has been the subject of extensive study over the past several decades (see [6] for an overview). From the worst-case perspective, this problem is well-understood for not only the version stated above [27, 10, 1], but also for weighted generalizations [3, 4].

Online caching in the learning-augmented context was first considered by Lykouris and Vassilvitskii [18]. They introduce a model of prediction where the predictor, upon the arrival of each page, predicts the next time that this page will be requested. They show that the BlindOracle algorithm, which follows the predictor naïvely and evicts the page with the latest predicted arrival time, can have unbounded competitive ratio (i.e., is *non-robust*). They then give a different algorithm, PredictiveMarker, based on the Marker algorithm of Fiat et al. [10], that achieves a competitive ratio of

$$2 + O\left(\min\left(\sqrt{\frac{\eta}{\mathsf{OPT}}}, \log k\right)\right),$$

where η is the ℓ_1 error of the predictor and OPT is the cost of the offline optimal. (For precise definitions, refer to Section 2.1.) Notably, this competitive ratio approaches 2 as the error η goes to 0 and is bounded by $O(\log k)$ regardless of how large η gets.

In recent work, Rohatgi [25] introduces the LNonMarker algorithm, which is also based on randomized marking, and shows that LNonMarker achieves a competitive ratio of

$$O\left(1 + \min\left(\frac{\log k}{k}\frac{\eta}{\mathsf{OPT}}, \log k\right)\right).$$

This bound is obtained by constructing a non-robust algorithm and then using the black-box combination technique discussed in [18] to combine this non-robust algorithm with the Marker algorithm. Rohatgi also shows a lower bound of

$$1 + \Omega\left(\min\left(\log\left(\frac{1}{k \log k}\frac{\eta}{\mathsf{OPT}}\right), \log k\right)\right)$$

for the competitive ratio of any learning-augmented online algorithm for caching in terms of k, OPT, and η. The main difference between two bounds is that the former has a linear dependence on η/OPT, whereas the latter has only a logarithmic dependence on the same. We will make some progress in closing this gap and also show that deterministic algorithms fundamentally cannot approach Rohatgi's lower bound.

1.1 Our Contribution

We show that the strikingly simple approach of combining BlindOracle with an $O(\log k)$-competitive online caching algorithm (e.g., Marker) in a black-box fashion achieves state-of-the-art performance, improving over LNonMarker with a competitive ratio bound of

$$O\left(1+\min\left(\frac{1}{k}\frac{\eta}{\mathsf{OPT}}, \log k\right)\right).$$

Thus, although BlindOracle was previously shown to be non-robust [18], our result demonstrates that using BlindOracle appropriately can actually lead to very effective algorithms for learning-augmented online caching.

In addition to achieving better theoretical bounds, our approach to learning-augmented online caching is substantially simpler than previous work. The algorithms of Lykouris and Vassilvitskii [18] and Rohatgi [25] rely on intricate constructions based on randomized marking, whereas our main ingredient is a careful analysis of perhaps the simplest algorithm possible. We thus believe that our approach may yield better practical performance and may generalize more readily to other learning-augmented settings. We note that our optimal deterministic algorithm is especially simple: For each eviction, "follow" whichever of BlindOracle and LRU has performed better so far.

The crux of our result is a tight analysis of BlindOracle's performance as a function of η. We prove that BlindOracle has excellent performance when η/OPT is small, improving over $O(\log k)$-competitive online caching algorithms for η up to $O(k \log k) \cdot \mathsf{OPT}$. This is in contrast to the lower bound on BlindOracle given by Lykouris and Vassilvitskii [18], who rule out BlindOracle due to its poor performance when $k = 2$. In particular, our bound has a $1/k$ dependence on k, meaning BlindOracle obtains drastically better bounds for larger k. Stated formally, our main theorem is the following:

▶ **Theorem 1.1.** *For learning-augmented online caching, BlindOracle obtains a competitive ratio of*

$$\min\left(1+2\frac{\eta}{\mathsf{OPT}}, 4+\frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}\right),$$

where η is the ℓ_1 loss incurred by the predictor and OPT is the optimal offline cost. (For precise definitions, see Section 2.1.)

We then obtain robust deterministic and randomized algorithms for learning-augmented online caching as corollaries, by combining BlindOracle with LRU and Equitable [1]. We apply the algorithms of Fiat et al. [10] and Blum and Burch [5] for combining online algorithms in a black-box manner online. These algorithms achieve better constants in the competitive ratio than the approach discussed by Lykouris and Vassilvitskii [18] and applied by Rohatgi [25]. By composing our analysis of BlindOracle with these "combiners," we obtain constants in the competitive ratio that are significantly lower than those of previous works. Indeed, we have the following corollaries for deterministic and randomized algorithms for learning-augmented online caching:

▶ **Corollary 1.2.** *There exists a deterministic algorithm for learning-augmented online caching that achieves a competitive ratio of*

$$2\min\left(\min\left(1+2\frac{\eta}{\mathsf{OPT}}, 4+\frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}\right), k\right).$$

▶ **Corollary 1.3.** *There exists a randomized algorithm for learning-augmented online caching that achieves a competitive ratio of*

$$(1+\gamma)\min\left(\min\left(1+2\frac{\eta}{\mathsf{OPT}}, 4+\frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}\right), H_k\right)$$

for any $\gamma \in (0, 1/4)$.[1] *(Here,* $H_k = 1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{k} = \ln(k) + O(1)$ *is the* k*-th harmonic number.)*

Finally, we show that combining BlindOracle with a k-competitive deterministic algorithm (e.g., LRU [27]) is the best one could hope to do among deterministic algorithms for learning-augmented online caching. In particular, we show that a linear dependence on $\eta/(k \cdot \mathsf{OPT})$ in the competitive ratio is necessary. Therefore, if a logarithmic dependence on $\eta/(k \cdot \mathsf{OPT})$ is to be achieved, as in Rohatgi's lower bound, then randomization is needed, (perhaps surprisingly) even in the regime where $\eta/(k \cdot \mathsf{OPT})$ is bounded.

▶ **Theorem 1.4.** *The competitive ratio bound for any deterministic learning-augmented online caching algorithm must be at least*

$$1 + \Omega\left(\min\left(\frac{1}{k}\frac{\eta}{\mathsf{OPT}}, k\right)\right)$$

in terms of k *and* η/OPT.

1.2 Related Work

In addition to the predecessor works by Lykouris and Vassilvitskii [18] and Rohatgi [25] on learning-augmented online caching, there have been several other recent papers in the space of learning-augmented online algorithms: Medina and Vassilvitskii [20] study repeated posted-price auctions, Purohit et al. [24] and Gollapudi and Panigrahi [11] study the ski rental problem, and Purohit et al. [24], Lattanzi et al. [17], and Mitzenmacher [23] study online scheduling. Of these, the scheduling algorithm of Purohit et al. [24] is the most similar in spirit to this present work: Both algorithms are based on combining a naïve and optimistic algorithm with a robust algorithm.

Other threads of research falling under beyond worst-case online algorithms include work on combining multiple algorithms with different performance characteristics [10, 5, 19, 11], designing online algorithms with distributional assumptions (e.g., stochasticity) on the input [13, 8, 21], and semi-online algorithms, where the input is assumed to have a predictable offline component and an adversarial online component [15, 16].

The idea of learning-augmentation has also been explored in many other algorithmic and data structural settings in recent years. These include learned indices [14], bloom filters [22], frequency estimation in streams [12], and nearest neighbor search [9], among others.

Finally, advice for online algorithms has also been considered with a more complexity theoretic spirit through the study of advice complexity of online algorithms; see the survey of Boyar et al. [7] for an overview.

1.3 Recent Developments

Recently, in work done independently of and concurrently with this paper, Antoniadis et al. [2] also study a BlindOracle-like algorithm, which they term FollowThePrediction, in the more general setting of learning-augmented metrical task systems; they also use the "combiner"

[1] The trade-off in γ and the cost is additive; thus, it does not factor into the competitive ratio.

of Blum and Burch [5] to make this algorithm robust. However, their prediction model, when specialized to online caching, is incomparable to that of Lykouris and Vassilvitskii [18] (which we follow).[2] Thus, the theoretical results proved in these two models do not imply each other.

1.4 Outline

The remainder of this paper is organized as follows: In Section 2, we formally describe our model of learning-augmented online caching and BlindOracle; we also introduce background results that will later be used in our proofs. In Section 3, we prove our upper bounds (i.e., Theorem 1.1 and Corollaries 1.2 and 1.3). In Section 4, we prove our lower bound (Theorem 1.4) for deterministic algorithms. Section 5 concludes.

2 Preliminaries

2.1 Setup and Notation

In the online caching problem, we receive a sequence $\sigma = (\sigma_1, \ldots, \sigma_n)$ of page requests online, and our goal is to serve these requests using a cache of size k while minimizing cost. In this problem, pages must be served from the cache and can be served at no cost; however, evicting a page from the cache has unit cost.[3]

We will establish competitive bounds comparing the performance of two caching algorithms $\mathcal{A}$ and $\mathcal{B}$. More precisely, we will show bounds of the form

$$\mathsf{ALG}_{\mathcal{B}}(\sigma) \leq \gamma \cdot \mathsf{ALG}_{\mathcal{A}}(\sigma) + O(1),$$

where $\mathsf{ALG}_{\mathcal{A}}(\sigma)$ and $\mathsf{ALG}_{\mathcal{B}}(\sigma)$ are the costs of $\mathcal{A}$ and $\mathcal{B}$, respectively, as measured in number of evictions made while serving a sequence σ of page requests. Ultimately, $\mathcal{A}$ will be the optimal offline algorithm and $\mathcal{B}$ will be BlindOracle. We will also use $\mathsf{OPT}(\sigma)$ to denote the optimal offline cost; that is, $\mathsf{OPT}(\sigma)$ is the minimum possible cost of serving the request sequence σ. We will omit the argument σ when the context is clear (i.e., just writing $\mathsf{ALG}_{\mathcal{A}}$ to represent $\mathsf{ALG}_{\mathcal{A}}(\sigma)$).

In our analysis, we use A_t and B_t to denote the cache states of $\mathcal{A}$ and $\mathcal{B}$, respectively, just before the t-th request. Formally, A_t and B_t are subsets of $\{1, \ldots, t-1\}$ of size at most k, containing for each cached page the index at which it was last served. That is, when serving the t-th request, we remove some old request index t' from the cache and insert t. Thus, if t' is such that $\sigma_t = \sigma_{t'}$, this operation is free; otherwise, it has unit cost. In the sequel, we will also refer to these indices t as *page requests*.

In the learning-augmented online caching problem, the t-th page request comes with a prediction h_t for the next time page σ_t is requested. That is, at the time of the t-th request, our algorithm receives the pair (σ_t, h_t). Let $h = (h_1, \ldots, h_n)$ be the tuple of all n predictions. To define a notion of loss, let y_t denote for each t the next time page t is actually requested, with $y_t = n + 1$ if page σ_t is never requested again. The ℓ_1 loss is then defined to be

$$\eta(\sigma, h) = \sum_t |h_t - y_t|.$$

[2] Namely, their algorithms expect predictions to be in a different form: They expect predictions to be cache states (i.e., the set of pages in the cache at time t) rather than next arrival times of pages. Moreover, there exist sequences of "corresponding" inputs for each of these two models such that the predictor error approaches infinity in one model while remaining constant in the other.

[3] Observe that this formulation is equivalent to the "standard" formulation of online caching, where each cache miss has unit cost, up to an additive constant of k.

We will omit arguments to η if the context is clear. Note that if $\eta(\sigma, h) = 0$, then the offline optimal can be obtained, as the optimal algorithm always evicts the page that is next requested furthest into the future.

In stating our bounds, the essential quantity is often η/OPT. To make this clear, we will take $\varepsilon = \eta/\mathsf{OPT}$ and state our bounds in terms of ε in the sequel.

2.1.1 Inversions

Call a pair (i, j) of page requests an *inversion* if $y_i < y_j$ but $h_i \geq h_j$. Let $M(\sigma, h)$ denote the total number of inversions between the pair of sequences σ and h. We will omit arguments to M when the context is clear.

2.1.2 BlindOracle

We formally define the BlindOracle algorithm as follows: For each page request, if the requested page is already in the cache, do nothing. Otherwise, evict the page request p whose predicted next arrival time h_p is furthest into the future, with ties broken consistently (e.g., by always evicting the least recently used page among those with maximal h_p).

2.2 Combining Online Algorithms Competitively

To define our algorithms, we will need two classical results on competitively combining online algorithms online, due to Fiat et al. [10] and Blum and Burch [5], respectively. This type of "black-box" combination was also considered by Lykouris and Vassilvitskii [18], but their approach has a worse constant than that of Fiat et al. [10]. We also note that results of a similar flavor are proven by Purohit et al. [24] and Mahdian et al. [19], but for other online problems.

The question of combining multiple online algorithms while remaining competitive against each was first considered in the seminal paper of Fiat et al. [10]. They consider combining n online algorithms $\mathcal{B}_1, \ldots, \mathcal{B}_n$ for the online caching problem into a single algorithm $\mathcal{B}$ such that $\mathcal{B}$ is C_i-competitive against $\mathcal{B}_i$ for each i. They show such an $\mathcal{B}$ is achievable if and only if

$$\sum_{i=1}^{n} \frac{1}{C_i} \leq 1.$$

We will need only the special case of $n = 2$ and $C_1 = C_2 = 2$, which we state below:

▶ **Theorem 2.1** ([10], special case)**.** *Given two algorithms $\mathcal{B}_1$ and $\mathcal{B}_2$ for the online caching problem, there exists an algorithm $\mathcal{B}$ such that*

$$\mathsf{ALG}_{\mathcal{B}}(\sigma) \leq 2\min(\mathsf{ALG}_{\mathcal{B}_1}(\sigma), \mathsf{ALG}_{\mathcal{B}_2}(\sigma)) + O(1).$$

Moreover, if $\mathcal{B}_1$ and $\mathcal{B}_2$ are deterministic, then so is $\mathcal{B}$.

We note that this can be done deterministically with a "follow-the-leader" approach, where we simulate both algorithms and at each step evict any page that is not in the cache of the better performing algorithm (as measured by total number of evictions after serving the current request).

Blum and Burch [5] show that one can obtain a better approximation factor using a *randomized* scheme, namely multiplicative weights.[4] That is, at each point in time, the probability that the combined algorithm is following one of the n algorithms is given by a probability distribution over the n algorithms governed by the multiplicative weights update rule. For $n = 2$, their result can be stated as follows:

▶ **Theorem 2.2** ([5], special case). *Given two algorithms $\mathcal{B}_1$ and $\mathcal{B}_2$ for the online caching problem and any γ such that $0 < \gamma < 1/4$, there exists an algorithm $\mathcal{B}$ such that*

$$\mathsf{ALG}_{\mathcal{B}}(\sigma) \leq (1+\gamma)\min(\mathsf{ALG}_{\mathcal{B}_1}(\sigma), \mathsf{ALG}_{\mathcal{B}_2}(\sigma)) + O(\gamma^{-1}k).$$

▶ Remark. Although we do not state the versions of these results for combining several algorithms, one can imagine that they could be useful if one wishes to ensemble multiple machine-learned predictors.

2.3 From ℓ_1 Loss to Inversions

We now state a lemma of Rohatgi [25] that relates ℓ_1 loss to the number of inversions, letting us lower bound the ℓ_1 loss $\eta(\sigma, h)$ by lower bounding the number of inversions $M(\sigma, h)$. Thus, instead of reasoning in terms of ℓ_1 loss, we will reason in terms of inversions.

▶ **Lemma 2.3** ([25, Lemma 11]). *For any σ and h, $\eta(\sigma, h) \geq \frac{1}{2}M(\sigma, h)$.*

With this lemma, it suffices (up to a factor of 2) to give our competitive ratio upper bounds in terms of the number of inversions M.

3 Upper Bounds

3.1 A First Analysis of BlindOracle

In this section, we give a first analysis of BlindOracle, showing that it gets very good performance when the ratio $\varepsilon = \eta/\mathsf{OPT}$ is very small. In particular, our analysis shows that as $\varepsilon \to 0$, the competitive ratio achieved approaches 1.

Let $\mathcal{A}$ be the offline optimal algorithm (i.e., such that $\mathsf{ALG}_{\mathcal{A}} = \mathsf{OPT}$). Let $\mathcal{B}$ be BlindOracle. Note that we can think of each of $\mathsf{ALG}_{\mathcal{A}}$, $\mathsf{ALG}_{\mathcal{B}}$, and M as functions of the time t, i.e., they are the cost of $\mathcal{A}$, the cost of $\mathcal{B}$, and the number of inversions, respectively, on the prefix consisting of the first $t-1$ requests.[5] We use the Δ operator to denote the change (in a function of t) from time t to time $t+1$. For example, $\Delta\mathsf{ALG}_{\mathcal{A}} = 1$ if $\mathsf{ALG}_{\mathcal{A}}$ evicts an element upon the t-th request.

In our analysis, we maintain a matching X_t between A_t and B_t at all times t. Call a matching *valid* if it consists only of pairs $(a, b) \in A_t \times B_t$ such that the next arrival of b is no later than the next arrival of a. Our matching $X_t \subseteq A_t \times B_t$ will be valid throughout the execution of the algorithm.

We now proceed with a potential function analysis, taking our potential Φ (as a function of A_t, B_t, and X_t) to be the number of unmatched pages in B_t. For notational simplicity, we denote $\Phi(A_t, B_t, X_t)$ by $\Phi(t)$. Given this setup, we show:

[4] The result of Blum and Burch [5] in fact holds more generally for all metrical task systems.
[5] This indexing is to be consistent with the definitions of A_t and B_t.

▶ **Proposition 3.1.** *There exists a valid matching X_n such that*

$$\mathsf{ALG}_{\mathcal{B}} + \Phi(n) \leq \mathsf{OPT} + M.$$

Proof. We induct on the length n of the input and perform a case analysis to show that we can maintain a valid matching X_t such that at each time step, the right-hand side increases at least as much as the left-hand side, i.e., $\Delta\mathsf{ALG}_{\mathcal{B}} + \Delta\Phi \leq \Delta\mathsf{OPT} + \Delta M$.

For our base case, note that $A_1 = B_1$, so we may take X_1 to be the identity matching.

Now, upon a request at time t, we update X_t according to the following cases (and with the consequences listed for each case):

1. The requested page p is in both A_t and B_t.
   a. The cached pages are matched to each other.
      - Do nothing.
   b. Otherwise:
      i. Both cached pages are matched.
         - Remove the pairs (c, p) and (p, d) from X_t.
         - Add the pairs (p, p) and (c, d) to X_t.
         - As a result:
            - Nothing changes. (For conciseness, we omit obviously unchanged quantities here and for the remainder of this proof.)
      ii. Otherwise:
         - Remove any pairs involving p from X_t. (There is at most one such pair.)
         - Add the pair (p, p) to X_t.
         - As a result:
            - $\Delta\Phi \leq 0$.
2. The requested page p is in B_t only.
   - Remove any pairs involving the evicted page a from X_t. (There is at most one such pair.)
   - Remove any pairs involving the requested page p from X_t. (There is at most one such pair.)
   - Add the pair (p, p) to X_t.
   - As a result:
      - $\Delta\mathsf{OPT} = 1$.
      - $\Delta\Phi \leq 1$.
3. The requested page p is in A_t only.
   a. The evicted page $b \in B_t$ is unmatched.
      - Add the pair (p, p) to X_t. (The arriving page $p \in A_t$ cannot be in any valid matching.)
      - As a result:
         - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
         - $\Delta\Phi = -1$.
   b. The evicted page $b \in B_t$ is matched.
      i. b arrives later than all unmatched pages in B_t.
         - Remove the pair (c, b) involving the evicted page b from X_t.
         - Add the pair (c, b') to X_t, where $b' \in B_t$ is any unmatched page.
         - Add the pair (p, p) to X_t. (The arriving page $p \in A_t$ cannot be in any valid matching.)
         - As a result:
            - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
            - $\Delta\Phi = -1$.

   - **ii.** There is an unmatched page $b' \in B_t$ arriving later than b.
     - Remove the pair (c, b) involving the evicted page b from X_t.
     - Add the pair (p, p) to X_t. (The arriving page $p \in A_t$ cannot be in any valid matching.)
     - As a result:
       - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
       - $\Delta\Phi = 0$.
       - $\Delta M = 1$, as there is an inversion between b and b'. (Note that we do not count this inversion ever again, as b gets evicted.)

4. The requested page p is in neither A_t nor B_t.
   - **a.** $\mathcal{A}$ evicts an unmatched page $a \in A_t$.
     - **i.** $\mathcal{B}$ evicts an unmatched page $b \in B_t$.
       - Add the pair (p, p) to X_t.
       - As a result:
         - $\Delta\mathsf{OPT} = 1$.
         - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
         - $\Delta\Phi = 1$.
     - **ii.** $\mathcal{B}$ evicts a matched page $b \in B_t$.
       - Remove the pair (c, b) involving b from X_t.
       - Add the pair (p, p) to X_t.
       - As a result:
         - $\Delta\mathsf{OPT} = 1$.
         - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
   - **b.** $\mathcal{A}$ evicts a matched page $a \in A_t$.
     - **i.** $\mathcal{B}$ evicts an unmatched page $b \in B_t$.
       - Remove the pair (a, d) involving a from X_t.
       - Add the pair (p, p) to X_t.
       - As a result:
         - $\Delta\mathsf{OPT} = 1$.
         - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
     - **ii.** $\mathcal{B}$ evicts a matched page $b \in B_t$.
       - Remove the pair (a, d) involving a from X_t.
       - Remove the pair (c, b) involving b from X_t.
       - Add the pair (p, p) to X_t.
       - As a result:
         - $\Delta\mathsf{OPT} = 1$.
         - $\Delta\mathsf{ALG}_{\mathcal{B}} = 1$.
         - Note that either b arrives after d, in which case we can add (c, d) to X_t and $\Delta\Phi = 0$, or the pair (b, d) forms an inversion, in which case $\Delta\Phi = 1$ and $\Delta M = 1$. (As before, since b is getting evicted, we will not count this pair twice.)

It is not hard to verify that the change in the left-hand side of the bound is no more than the change in the right-hand side in each of the cases listed above, from which the proposition follows. ◀

▶ **Proposition 3.2.** *The competitive ratio of algorithm $\mathcal{B}$ is at most $1 + 2\varepsilon$.*

Proof. Note that 2η is bounded below by the number of inversions M of (σ, h) by Lemma 2.3. By Proposition 3.1, $\mathsf{ALG}_{\mathcal{A}} \leq \mathsf{OPT} + M$, so $\mathsf{ALG}_{\mathcal{A}}/\mathsf{OPT} \leq 1 + M/\mathsf{OPT} \leq 1 + 2\varepsilon$. ◀

3.2 A More Careful Analysis

We now give an asymptotically better (in k) bound for the performance of BlindOracle. A more careful analysis is needed to show an upper bound with a $1/k$ coefficient on the ratio $\varepsilon = \eta/\mathsf{OPT}$. We use the same high-level approach for the proof as before, but with a more complicated potential function. Again, $\mathcal{A}$ is the offline optimal algorithm and $\mathcal{B}$ is the BlindOracle algorithm, and also as before, we use Δ to denote change (in functions of t) from request t to request $t+1$.

We maintain in this proof a matching X_t over pairs of page requests $(a, b) \in A_t \times B_t$ such that $h_a \geq h_b$ for each time step t. (Recall that h_a is the prediction for the next time that page σ_a is requested.) We also require that X_t restricts to the identity matching on $A_t \cap B_t$. That is, if a page p is in both caches at time t, then it is matched to itself in X_t. If X_t satisfies both of these properties, we say that it is *allowable*. Our potential function Φ – which will really be a sum of three separate potential functions – will be a function of A_t, B_t, and an allowable matching X_t. For notational simplicity, we denote $\Phi(A_t, B_t, X_t)$ by $\Phi(t)$.

Given A_t, B_t, and X_t at time t, define $\Phi_0(t)$ to be the number of $b \in B_t$ that are unmatched. Define $\Phi_1(t)$ to be the number of $b \in B_t$ such that $(b, b) \notin X_t$. In other words, Φ_1 counts how many page requests in B_t are not matched to the *same* page request in A_t. For a page request p, let $z_p(t)$ be the number of pages in B_t predicted to appear before h_p (with pages predicted to appear at the same time tie-broken in a consistent manner, e.g., by the last time each page was requested[6]). Next, define

$$\Phi_2(t) = \sum_{(a,b)\in X_t} \big(z_b(t) - z_a(t)\big).$$

With these "sub"-potential functions defined, we take

$$\Phi(t) = (k-1)\Phi_0(t) + (k-1)\Phi_1(t) + \Phi_2(t)$$

as our overall potential function. This completes our setup for the analysis. But before we give the details of the proof, we make a few observations about these definitions and discuss some intuition.

First, observe that for any p, we have $0 \leq z_p(t) \leq k$. And if $p \in B_t$, then $z_p(t) \leq k-1$ because there are only $k-1$ other pages that could be predicted to appear before. Next, if $(a, b) \in X_t$, then $z_a(t) \geq z_b(t)$ as $h_a \geq h_b$. Hence $\Phi_2(t) \leq 0$ always. As a result, Φ may sometimes be negative, but it satisfies $|\Phi(t)| \leq 3k^2$ for all t. Finally, we note that Φ_2 is equivalently a sum over the $(a, b) \in X_t$ such that $a \neq b$.

In terms of intuition for these definitions, the main substance perhaps lies in Φ_2: Suppose $(a, b) \in X_t$ and $a \neq b$; in particular, $a \notin B_t$. The quantity $z_a(t) - z_b(t)$ is the future number of inversions that we are "guaranteed" from this pair (a, b). If we request σ_p for any p such that $h_b < h_p < h_a$, then we have an inversion (p, b). On the other hand, if σ_p is not requested before the next time σ_a is requested, then the request for σ_a forms an inversion (a, p). Thus, the quantity $M - \Phi_2$ accounts not only for the inversions already encountered, but also for future inversions. The matching of a and b also serves another purpose: We couple the decrease of z_a to the decrease of z_b whenever z_a decreases without generating an inversion. Therefore, if z_a is small when σ_a is next requested, then $z_b \leq z_a$ is also small. It follows that if we form a new pair (a', b), then $z_{a'} - z_b$ will be comparatively large, i.e., we get many future inversions.

[6] Alternatively, one can simply perturb all predictions by infinitesimal amounts so that there are no ties.

We execute on this intuition to prove the following proposition:

▶ **Proposition 3.3.** *For any input (σ, h), there exists a matching $X_n \subseteq A_n \times B_n$ consisting only of pairs (a, b) satisfying $h_a \geq h_b$ such that*

$$(k-1)\mathsf{ALG}_{\mathcal{B}} + \Phi(n) \leq 2k \cdot \mathsf{OPT} + 2M.$$

Proof. Like in the proof of Proposition 3.1, we induct on the length of the input and perform a case analysis to show that we can maintain a allowable matching X_t such that the right-hand side increases at least as much as the left-hand side for each page request.

We split the serving of each page request into two phases:

1. **Matching.** Update X_t so that the page requests in A_t and B_t that are to be removed are unmatched. (Note that page requests are removed either because the corresponding page was requested again or because the corresponding page was evicted.)
2. **Updating.** Replace a page request from each of A_t and B_t with the new request and add the new page request pair (t, t) into X_t.

In doing so, we ensure that the pages to be removed are unmatched by the time updating occurs, so they do not contribute to Φ_2.

We first analyze how updating affects the overall potential Φ. This operation decreases each of Φ_0 and Φ_1 by 1, since we remove an unmatched pair and replace it with the matched pair (t, t). For Φ_2, observe that for a matched pair (a, b), the difference $z_b - z_a$ increases on the t-th request only if a page predicted to arrive between b and p is removed. This occurs if and only if there is a $p \in B_t$ such that $\sigma_p = \sigma_t$ and $h_b < h_p < h_a$. In this case, the pair (p, b) forms an inversion, i.e., it increases M by 1. Any inversion (p, b) is counted at most once this way because p is getting removed from B_t. Thus $\Delta\Phi_2 \leq \Delta M$. In summary, updating leaves us with an extra $2(k-1)$ in potential due to the changes in Φ_0 and Φ_1; the change in potential of Φ_2 is offset by the change in one of the two M terms on the right-hand side.

We now specify the matching phase in greater detail and analyze it using a case analysis. We will show

$$(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} + \Delta\Phi \leq 2k \cdot \Delta\mathsf{OPT} + \Delta M + 2(k-1),$$

with the extra $2(k-1)$ being covered by the updating step. The analysis proceeds as follows:

1. The requested page is in both A_t and B_t.
   - The previous page requests for σ_t in A_t and B_t are matched to each other by assumption, so we can just unmatch them.
   - As a result:
     - $(k-1)\Delta\Phi_0 = k-1$.
     - $(k-1)\Delta\Phi_1 = k-1$.
2. The requested page is in A_t only.
   a. The previous request $p \in A_t$ for the requested page is matched as (p, d) and the page request $b \in B_t$ evicted by $\mathcal{B}$ is matched as (c, b).
      - Unmatch (p, d) and (c, b) and match (c, d). The latter is allowable because $h_c \geq h_b \geq h_d$.
      - As a result:
        - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.
        - $(k-1)\Delta\Phi_0 = k-1$.
        - $(k-1)\Delta\Phi_1 \leq k-1$, since $p \neq d$.
        - $\Delta\Phi_2 = z_p - (k-1)$, since $z_b = k-1$.
        - $\Delta M \geq z_p$, since the arrival of σ_p generates z_p inversions of the form (p, b') for all $b' \in B_t$ such that $h_p > h_{b'}$.

b. The previous request $p \in A_t$ for the requested page is matched as (p, d) and the page request $b \in B_t$ evicted by $\mathcal{B}$ is unmatched.
- Unmatch (p, d).
- As a result:
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.
  - $(k-1)\Delta\Phi_0 = k-1$.
  - $(k-1)\Delta\Phi_1 = 0$, since $p \neq d$.
  - $\Delta\Phi_2 = z_p - z_b \leq z_p$.
  - $\Delta M \geq z_p$, since the arrival of σ_p generates z_p inversions of the form (p, b') for all $b' \in B_t$ such that $h_p \geq h_{b'}$.

c. The previous request $p \in A_t$ for the requested page is unmatched and the page request $b \in B_t$ evicted by $\mathcal{B}$ is matched as (c, b).
- Unmatch (c, b) and match (c, d) for an arbitrary unmatched $d \in B_t \setminus \{b\}$. This is allowable because $h_c \geq h_b \geq h_d$.
- As a result:
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.
  - $(k-1)\Delta\Phi_0 = 0$.
  - $(k-1)\Delta\Phi_1 \leq k-1$.
  - $\Delta\Phi_2 = z_d - (k-1) \leq 0$, since $z_b = k-1$.

d. The previous request $p \in A_t$ for the requested page is unmatched and the page request $b \in B_t$ evicted by $\mathcal{B}$ is unmatched.
- Do nothing.
- As a result:
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.

3. The requested page is in B_t only.

a. The previous request $p \in B_t$ for the requested page is matched as (c, p) and the page request $a \in A_t$ evicted by $\mathcal{A}$ is matched as (a, d).
- Unmatch (c, p) and (a, d).
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\Phi_0 = 2(k-1)$.
  - If $a = d$:
    - $(k-1)\Delta\Phi_1 = k-1$, since $c \neq p$.
    - $\Delta\Phi_2 = z_c - z_p \leq k$, since $z_c \leq k$.
  - Otherwise, if $a \neq d$:
    - $(k-1)\Delta\Phi_1 = 0$, since $c \neq p$.
    - $\Delta\Phi_2 = (z_c - z_p) + (z_a - z_d) \leq 2k$, since $z_c, z_a \leq k$.

b. The previous request $p \in B_t$ for the requested page is matched as (c, p) and the page request $a \in A_t$ evicted by $\mathcal{A}$ is unmatched.
- Unmatch (c, p).
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\Phi_0 = k-1$.
  - $(k-1)\Delta\Phi_1 = 0$, since $c \neq p$.
  - $\Delta\Phi_2 \leq z_c - z_p \leq k$, since $z_c \leq k$.

c. The previous request $p \in B_t$ for the requested page is unmatched and the page request $a \in A_t$ evicted by $\mathcal{A}$ is matched as (a, d).
- Unmatch (a, d).

- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\Phi_0 = k-1$.
  - $(k-1)\Delta\Phi_1 \leq k-1$.
  - $\Delta\Phi_2 \leq z_a - z_d \leq k$, since $z_a \leq k$.

d. The previous request $p \in B_t$ for the requested page is unmatched and the page request $a \in A_t$ evicted by $\mathcal{A}$ is unmatched.

- Do nothing.
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.

4. The requested page is in neither A_t nor B_t.

a. The previous request $a \in A_t$ evicted by $\mathcal{A}$ is matched as (a, d) and the page request $b \in B_t$ evicted by $\mathcal{B}$ is matched as (c, b).

- If $(a, d) = (c, b)$, simply unmatch (a, d) (and thus (c, b)). Otherwise, unmatch (a, d) and (c, b) and match (c, d). The latter is allowable because $h_c \geq h_b \geq h_d$.
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.
  - $(k-1)\Delta\Phi_0 = k-1$.
  - $(k-1)\Delta\Phi_1 \leq 2(k-1)$.
  - $\Delta\Phi_2 = z_a - (k-1) \leq 0$, since $z_b = k-1$.

b. The previous request $a \in A_t$ evicted by $\mathcal{A}$ is matched as (a, d) and the page request $b \in B_t$ evicted by $\mathcal{B}$ is unmatched.

- Unmatch (a, d).
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.
  - $(k-1)\Delta\Phi_0 = k-1$.
  - $(k-1)\Delta\Phi_1 \leq k-1$.
  - $\Delta\Phi_2 = z_a - z_d \leq k$, since $z_a \leq k$.

c. The previous request $a \in A_t$ evicted by $\mathcal{A}$ is unmatched and the page request $b \in B_t$ evicted by $\mathcal{B}$ is matched as (c, b).

- Unmatch (c, b) and match (c, d) for an arbitrary unmatched $d \in B_t \setminus \{b\}$. This is allowable because $h_c \geq h_b \geq h_d$.
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.
  - $(k-1)\Delta\Phi_0 = 0$.
  - $(k-1)\Delta\Phi_1 \leq k-1$.
  - $\Delta\Phi_2 = z_d - (k-1) \leq 0$, since $z_b = k-1$.

d. The previous request $a \in A_t$ evicted by $\mathcal{A}$ is unmatched and the page request $b \in B_t$ evicted by $\mathcal{B}$ is unmatched.

- Do nothing.
- As a result:
  - $2k \cdot \Delta\mathsf{OPT} = 2k$.
  - $(k-1)\Delta\mathsf{ALG}_{\mathcal{B}} = k-1$.

Recall that we have an extra $2(k-1)$ in potential from the updating phase that we can use to defray the costs of the matching phase. One can verify that this is sufficient for all of the cases described above – the "tight" cases are 1, 2(a), 2(b), 2(c), 3(a), and 4(a). The proposition now follows. ◀

▶ **Proposition 3.4.** *The competitive ratio of algorithm $\mathcal{B}$ is at most $2+2/(k-1)+4\varepsilon/(k-1)$.*

Proof. Compose Proposition 3.3 with Lemma 2.3. In particular, we have

$$\frac{\mathsf{ALG}_{\mathcal{B}}}{\mathsf{OPT}} + \frac{O(k)}{\mathsf{OPT}} \leq \frac{2k}{k-1} + \frac{2M}{(k-1)\mathsf{OPT}} \leq 2 + \frac{2}{k-1} + \frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}.$$ ◀

3.3 Finishing Up

The results stated in Section 1 now follow easily from what we have already shown:

▶ **Theorem 1.1.** *For learning-augmented online caching, BlindOracle obtains a competitive ratio of*

$$\min\left(1 + 2\frac{\eta}{\mathsf{OPT}}, 4 + \frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}\right),$$

where η is the ℓ_1 loss incurred by the predictor and OPT is the optimal offline cost. (For precise definitions, see Section 2.1.)

Proof. From the analysis of the previous two sections, the desired bound immediately follows from taking the minimum of the bounds in Propositions 3.2 and 3.4, noting that $2/(k-1) \leq 2$ when $k \geq 2$. ◀

▶ **Corollary 1.2.** *There exists a deterministic algorithm for learning-augmented online caching that achieves a competitive ratio of*

$$2\min\left(\min\left(1 + 2\frac{\eta}{\mathsf{OPT}}, 4 + \frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}\right), k\right).$$

Proof. Combine BlindOracle with LRU using the "combiner" from Theorem 2.1, with the performance of BlindOracle being bounded by Theorem 1.1. ◀

▶ **Corollary 1.3.** *There exists a randomized algorithm for learning-augmented online caching that achieves a competitive ratio of*

$$(1+\gamma)\min\left(\min\left(1 + 2\frac{\eta}{\mathsf{OPT}}, 4 + \frac{4}{k-1}\frac{\eta}{\mathsf{OPT}}\right), H_k\right)$$

for any $\gamma \in (0, 1/4)$.[7] *(Here, $H_k = 1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{k} = \ln(k) + O(1)$ is the k-th harmonic number.)*

Proof. Like in the proof above, combine BlindOracle with algorithm Equitable of Achlioptas et al. [1][8], this time using the "combiner" from Theorem 2.2. ◀

[7] The trade-off in γ and the cost is additive; thus, it does not factor into the competitive ratio.

[8] We use Equitable because it achieves the optimal worst-case competitive ratio of H_k for online caching; Marker has a competitive ratio of $2H_k - 1$ [1].

4 Lower Bound for Deterministic Algorithms

We now show that combining BlindOracle with LRU achieves an optimal competitive ratio bound (in terms of k and $\varepsilon = \eta/\mathsf{OPT}$) among all deterministic algorithms for learning-augmented online caching by proving Theorem 1.4:

▶ **Theorem 1.4.** *The competitive ratio bound for any deterministic learning-augmented online caching algorithm must be at least*

$$1 + \Omega\left(\min\left(\frac{1}{k}\frac{\eta}{\mathsf{OPT}}, k\right)\right)$$

in terms of k and η/OPT.

Proof. Fix a $k > 2$, and let $\mathcal{A}$ be any deterministic algorithm for learning-augmented online caching. We show that for any even integer $2j$ such that $1 < 2j < k$, there exists a sequence of inputs with $\mathsf{OPT}(\sigma)$ growing arbitrarily large that satisfies $\varepsilon/k = 2j$ and

$$\frac{\mathsf{ALG}_{\mathcal{A}}(\sigma, h)}{\mathsf{OPT}(\sigma)} \geq 1 + \frac{\varepsilon}{4k}$$

for all (σ, h) in the sequence. As $2j$ nears k, this lower bound on competitive ratio approaches $1 + k/4$, so this lower bound binds up to a competitive ratio of $\Omega(k)$, thus yielding the stated result.

We spend the remainder of this proof constructing such inputs (σ, h). Let $P_1, \ldots, P_k, Q$ be $k + 1$ distinct pages. We make the following sequence of requests, which we call a *phase*:

1. For $i = 1, \ldots, k - 1$:
   a. Request pages $P_1, \ldots, P_k$ in order, predicting each page to next appear k requests from now.
2. Request pages $P_1, \ldots, P_k$ in order, predicting each page to next appear $k + j + 2$ requests from now.
3. Request page Q and predict that it will next appear $j + 1$ requests from now.
4. For $i = 1, \ldots, j$:
   a. Request the page evicted by $\mathcal{A}$ during the previous request if it exists. Otherwise, request an arbitrary page. For each page, provide the same prediction as the last time this page was requested.
5. Request page Q and predict that it will next appear $k^2 + 1 + z$ requests from now, for some $z \geq 0$ that we will specify below.

As an outer loop, we can repeat the above "phase" as many times as needed.

In a single phase, observe that OPT makes at most two evictions: One to evict Q if it is in the cache at the beginning of the phase and one upon the arrival of Q in step (3). For the latter, it suffices to evict a page that does not appear among the at most $j + 1 \leq k$ pages requested in steps (4) and (5). Note also that OPT makes at least one eviction in any phase, since each phase involves serving $k + 1$ distinct pages.

On the other hand, I claim $\mathcal{A}$ makes at least $j + 1$ evictions. First, if the cache of $\mathcal{A}$ at the end of step (2) does not consist of pages $P_1, \ldots, P_k$, then $\mathcal{A}$ must have incurred cost at least $k \geq j + 1$ during steps (1) and (2). Thus, we may assume that $\mathcal{A}$'s cache consists exactly of pages $P_1, \ldots, P_k$ at the end of step (2). If so, $\mathcal{A}$ has to evict a page for each of the $j + 1$ requests made in steps (3) and (4).

Finally, observe that all the predictions are accurate except those made for the pages that arrive in step (4) and the prediction in step (5). I claim that each prediction for a page arriving in step (4) is off by at most $k + j < 2k$. Indeed, a request to Q will be off by

at most j, as Q is requested again in step (5). And a request to P_ℓ will be off by at most $k + j$, as either page P_ℓ appears in step (1) of the next phase or the sequence of requests terminates. To bound the error for the former, note that P_ℓ will appear at most k requests into step (1) of the next phase, which starts j requests after the first request of step (4). For the prediction made in step (5), note that it is off from the ground truth by exactly z.

Putting everything together, we have that $1 \leq \mathsf{OPT} \leq 2$ and $\eta \leq j \cdot 2k + z$. In fact, we can set z so that $\eta = 2jk \cdot \mathsf{OPT}$ exactly. In this case,

$$\mathsf{ALG}_{\mathcal{A}} \geq j + 1 = 2 + \frac{1}{2}\left(1 - \frac{1}{j}\right) \cdot 2j \geq \mathsf{OPT} + \frac{1}{4}\frac{\eta}{k},$$

with $\varepsilon/k = 2j$. To finish, notice that we can make OPT arbitrarily large by repeating the "phase" defined above multiple times in sequence; the same analysis holds. ◀

5 Conclusion

In this paper, we show that the simple approach of combining BlindOracle with competitive algorithms for online caching surprisingly achieves state-of-the-art performance for learning-augmented online caching. We additionally show that combining BlindOracle with LRU is optimal among deterministic algorithms for learning-augmented online caching. An open question is whether the bounds we achieve can be improved using randomization to match the lower bound of Rohatgi [25].

Abstract

Given a connected undirected graph $\overline{G}$ on n vertices, and non-negative edge costs c, the 2ECM problem is that of finding a 2-edge connected spanning multisubgraph of $\overline{G}$ of minimum cost. The natural linear program (LP) for 2ECM, which coincides with the subtour LP for the Traveling Salesman Problem on the metric closure of $\overline{G}$, gives a lower bound on the optimal cost. For instances where this LP is optimized by a half-integral solution x, Carr and Ravi (1998) showed that the integrality gap is at most $\frac{4}{3}$: they show that the vector $\frac{4}{3}x$ dominates a convex combination of incidence vectors of 2-edge connected spanning multisubgraphs of $\overline{G}$.

We present a simpler proof of the result due to Carr and Ravi by applying an extension of Lovász's splitting-off theorem. Our proof naturally leads to a $\frac{4}{3}$-approximation algorithm for half-integral instances. Given a half-integral solution x to the LP for 2ECM, we give an $O(n^2)$-time algorithm to obtain a 2-edge connected spanning multisubgraph of $\overline{G}$ whose cost is at most $\frac{4}{3}c^T x$.

1 Introduction

The 2-edge connected multisubgraph (2ECM) problem is a fundamental problem in survivable network design where one wants to be resilient against a single edge failure. In this problem, we are given an undirected graph $\overline{G} = (\overline{V}, \overline{E})$ with non-negative edge costs c and we want to find a 2-edge connected spanning multisubgraph of $\overline{G}$ of minimum cost. Below we give an integer linear program for 2ECM. The variable x_e denotes the number of copies of edge e that are used in a feasible solution. For any $S \subset V$, $\delta(S) := \{e = uv \in \overline{E} : u \in S, v \notin S\}$ denotes the cut induced by S. For any $F \subseteq E$ and vector $x \in \mathbb{R}^E$, we use $x(F)$ as a shorthand for $\sum_{e \in F} x_e$. Also, for any graph H with edge costs c, we sometimes use $c(H)$ as a shorthand for $c(E(H))$.

$$\text{(2ECM-IP)} \qquad \begin{aligned} \min \quad & \sum_{e \in \overline{E}} c_e x_e && && (1)\\ \text{subject to} \quad & x(\delta(S)) \geq 2 && \forall \emptyset \subsetneq S \subsetneq \overline{V}, && (2)\\ & x_e \geq 0 && \forall e \in \overline{E}, && (3)\\ & x_e \text{ integral} && \forall e \in \overline{E}. && (4) \end{aligned}$$

It is easy to see that an optimal solution for 2ECM never has to use more than two copies of an edge. As is discussed in [6], since we are allowed to use more than one copy of an edge, without loss of generality, we may assume that $\overline{G}$ is complete by performing the metric completion: for each $u, v \in \overline{V}$ we set the new cost of the edge uv to be the shortest path distance between u and v in $\overline{G}$. In the sequel, we assume that $\overline{G}$ is a complete graph and that the cost function c is metric i.e., $c \geq 0$ and for every $u, v, w \in \overline{V}$, we have $c_{uw} \leq c_{uv} + c_{vw}$.

The linear relaxation (2ECM-LP) for 2ECM is obtained by dropping the integrality constraints given by (4). By a result due to Goemans and Bertsimas [8] called the *parsimonious property*, adding the constraint $x(\delta(v)) = 2$ for each $v \in \overline{V}$ to (2ECM-LP) does not increase the optimal solution value; here, we require the assumption that the costs form a metric. So, the optimal value of (2ECM-LP) is the same as the optimal value for the well-known subtour elimination LP (Subtour-LP) for the Traveling Salesman Problem (TSP) defined below. Due to this connection, we often refer to an optimal solution for (2ECM-LP) as an optimal solution to (Subtour-LP), and vice versa. Another consequence of the parsimonious property is that for graphs with at least 3 vertices, the constraint $x_e \leq 1$ is implied by (Subtour-LP): for any $e = uv$, we have $2x_e = x(\delta(u)) + x(\delta(v)) - x(\delta(\{u, v\})) \leq 2$.

$$\text{(Subtour-LP)} \qquad \begin{aligned} \min \quad & \sum_{e \in \overline{E}} c_e x_e && && (5)\\ \text{subject to} \quad & x(\delta(S)) \geq 2 && \forall \emptyset \subsetneq S \subsetneq \overline{V}, && (6)\\ & x(\delta(v)) = 2 && \forall v \in \overline{V}, && (7)\\ & x_e \geq 0 && \forall e \in \overline{E}. && (8) \end{aligned}$$

A long-standing open problem called the "four-thirds conjecture" states that the integrality gap of (Subtour-LP) is $\frac{4}{3}$. Besides the importance of 2ECM in the field of survivable network design, the connection between (2ECM-LP) and (Subtour-LP) has spurred interest in determining the integrality gap for (2ECM-LP) as a means to gaining useful lower bounds on the integrality gap for (Subtour-LP). The general version of metric TSP has resisted all attempts at proving an upper bound better than $\frac{3}{2}$ on the integrality gap, so a great deal of research has focused on obtaining improvements for important special cases. In [13], the authors conjecture that the integrality gap for (Subtour-LP) is achieved on instances where

an optimal (fractional) solution to (Subtour-LP) is half integral i.e., $2x_e \in \mathbb{Z}_{\geq 0}$ for all e. We refer to such instances as *half integral instances*. More than two decades ago, Carr and Ravi [6] proved that the integrality gap of (2ECM-LP) is at most $\frac{4}{3}$ in the half-integral case. They show that $\frac{4}{3}x$ dominates a convex combination of 2-edge connected spanning multisubgraphs of $\overline{G}$. This supports the four-thirds conjecture for TSP since the (integer) optimal value for 2ECM lower bounds the (integer) optimal value for TSP. However, the proof of Carr and Ravi does not give a polynomial-time algorithm for 2ECM. Very recently, in [12], Karlin, Klein, and Oveis Gharan gave a randomized approximation algorithm for half-integral instances of TSP whose (expected) approximation factor is $\frac{3}{2} - 0.00007$. This immediately implies a better than $\frac{3}{2}$-approximation algorithm, albeit randomized, for 2ECM as well.

We note that the result of Carr and Ravi mentioned above does not apply to the strict variant of 2ECM (henceforth denoted by 2ECS) where we are allowed to pick at most one copy of an edge in $\overline{G}$, i.e. where we are considering subgraphs of $\overline{G}$ rather than multisubgraphs; similarly, our main result does not apply to 2ECS.

1.1 Our Work

Our main contribution is a deterministic approximation algorithm for 2ECM on half-integral instances that matches the existence result in [6].

▶ **Theorem 1.** *Let x denote an optimal half-integral solution to an instance $(\overline{G}, c)$ of* (Subtour-LP) *(and* (2ECM-LP)*). There is an $O(|V(\overline{G})|^2)$-time algorithm for computing a 2-edge connected spanning multisubgraph of $\overline{G}$ with cost at most $\frac{4}{3}c^T x$.*

Given a half-integral solution x to (Subtour-LP) for $\overline{G}$, let $G = (V, E)$ denote the multigraph induced by $2x$. Formally, the vertex-set $V := \overline{V}$, and for each edge $e \in \overline{E}$, the edge-set E has $2x_e$ copies of the edge e. Note that if $|\overline{V}| \geq 3$, then $2x_e \in \{0, 1, 2\}$ for all $e \in \overline{E}$, and if $|\overline{V}| = 2$, then $2x_e = 4$ for the unique edge $e \in \overline{E}$. With a slight abuse of notation, we use the same cost function c to denote the edge costs in G i.e., $c_f := c_e$ where $e \in \overline{E}$ gave rise to the edge $f \in E$. By (7) and (6), G is a 4-regular 4-edge connected multigraph. Theorem 1 follows from the following result applied to the graph G induced by $2x$.

▶ **Theorem 2.** *Let $G = (V, E)$ be a 4-regular 4-edge connected multigraph on n vertices. Let $c : E \to \mathbb{R}$ be an arbitrary cost function on the edges of G (negative costs on the edges are allowed), and let e be an arbitrary edge in G. Then, in $O(n^2)$ time, we can find a 2-edge connected spanning subgraph H of $G - e$ satisfying:*

- **(i)** *$c(H) \leq \frac{2}{3}c(G - e)$; and*
- **(ii)** *each multiedge of G appears at most once in H (multiedges may arise in H due to multiedges in G).*

For any $F \subseteq E$, let $\chi^F \in \{0, 1\}^E$ denote the characteristic vector of F: $\chi^F_e = 1$ if and only if $e \in F$. Note that distinct multiedges in E correspond to distinct coordinates in χ^F. As mentioned before, Carr and Ravi prove the existence of such a subgraph H by showing that for any 4-regular 4-edge connected multigraph G, there exists a finite collection $H_1, \ldots, H_k$ of 2-edge connected spanning subgraphs of G such that $\frac{2}{3}\chi^{E(G)\setminus\{e\}}$ lies in the convex hull of $\{\chi^{H_i}\}_i$. At a high level, their proof is inductive and splits into two cases based on whether G has a certain kind of a tight set (a cut of size 4). In the first case they construct two smaller instances of the problem by contracting each of the shores of the tight set, and in the second case they perform two distinct splitting-off operations at a designated vertex to obtain two smaller instances of the problem. In either case, the convex combinations from the

two subinstances are merged to obtain a convex combination for G. The first case requires gluing since the subgraphs obtained from the two subinstances need to agree on a (tight) cut. Merging the convex combinations arising from the second case is rather straightforward as the two subinstances are more or less independent.

Our first insight in this work is that the case from Carr and Ravi's proof that requires the gluing step can be completely avoided, thereby unifying the analysis. This is discussed in Section 2. Our proof relies on an extension of Lovász's splitting-off theorem that is due to Bang-Jensen et al., [2]. For further discussion on splitting-off theorems, see [7, Chapter 8]. The challenge in efficiently finding a cheap subgraph H from the above convex combination construction is that each inductive step requires solving two subinstances of the problem, each with one fewer vertex, leading to an exponential-time algorithm. Having said that, an (expected) polynomial-time Las Vegas randomized algorithm can be easily designed that randomly recurses on one of the two subinstances and produces a 2-edge connected spanning subgraph whose expected cost is at most $\frac{2}{3}c(G-e)$. Our second insight, which is used in derandomizing the above procedure, is that it is easy to recognize which of the two subinstances leads to a "cheaper" solution, so we recurse only on the cheaper subinstance. Complementing this step, we lift the solution back to the original instance. This operation can lead to two different outcomes so the cost analysis must account for the worst outcome. There is a choice of defining the costs in the subinstance such that the cost of the lifted subgraph is the same irrespective of the outcome. Such a choice can lead to negative costs, but this is not a hindrance for our inductive step because Theorem 2 allows arbitrary real-valued edge costs. This generality of cost functions is crucial to our algorithm.

In Section 4 we consider a well-studied special case of the 2ECM problem. We present a simple $O(n^3)$-time algorithm that given a 3-regular 3-edge connected graph G, finds a 2-edge connected spanning multisubgraph of cost at most $\frac{7}{8}c(G)$ (see Theorem 10). The proof is inspired by that of Haddadan, Newman, and Ravi in [11] where they give a polynomial-time algorithm for this problem with a factor $\frac{15}{17}(> \frac{7}{8})$. In [10, Theorem 1.1], Haddadan and Newman improve this result to a factor $\frac{7}{8}$, and very recently, in [9, Theorem 1.20], Haddadan claims a stronger result with a factor of $\frac{41}{47} = \frac{7}{8} - \frac{1}{376}$. We remark that these proofs are longer and/or more complicated than that of Theorem 10. Another motivation for Section 4 is to illustrate the potential of Theorem 2 in giving simpler proofs for results that may not have any explicit half-integrality restrictions.

1.2 Related Work

The 2ECM problem has been intensively studied in network design and several works have tried to bound the integrality gap α2ECM of (2ECM-LP). For the general case with metric costs, we have $\frac{6}{5} \leq \alpha\text{2ECM} \leq \frac{3}{2}$, where the lower bound is from [1] and the upper bound follows from the polyhedral analysis of Wolsey [16] and Shmoys and Williamson [15] (this analysis also gives a $\frac{3}{2}$-approximation algorithm). It is generally conjectured that $\alpha\text{2ECM} = \frac{4}{3}$, however in [1], Alexander et al., study α2ECM and conjecture that $\alpha\text{2ECM} = \frac{6}{5}$ based on their findings. As mentioned before, Carr and Ravi [6] show that the integrality gap of (2ECM-LP) is at most $\frac{4}{3}$ in the half-integral case. In [5] Boyd and Legault consider a more restrictive collection of instances called half-triangle instances where the optimal LP solution is half-integral and the graph induced by the half-edges is a collection of disjoint triangles. They prove that $\alpha\text{2ECM} = \frac{6}{5}$ in this setting. Half-triangle solutions are of interest as there is evidence that the integrality gap of (2ECM-LP) is attained at such solutions (see [1]). When the costs come from a graphic metric (i.e., we want to find a minimum-size 2-edge connected spanning multisubgraph of a given unweighted graph), we have $\frac{8}{7} \leq \alpha\text{2ECM} \leq \frac{4}{3}$ (see [3, 14]).

2 A Simpler Proof of a Result of Carr and Ravi

In this section, we give a simplified proof of the following result from [6]. As mentioned before, avoiding the case involving the gluing operation is useful for our algorithm in Section 3. For notational convenience, for any subgraph K of some graph, we use χ^K to denote $\chi^{E(K)}$ whenever the underlying graph is clear from the context.

▶ **Theorem 3** (Statement 1 from [6]). *Let $G = (V, E)$ be a 4-regular 4-edge connected multigraph and $e = uv$ be an arbitrary edge in this graph. There exists a finite collection $\{H_1, \ldots, H_k\}$ of 2-edge connected spanning subgraphs of $G - e$ such that for some nonnegative $\mu_1, \ldots, \mu_k$ with $\sum_i \mu_i = 1$, we have $\frac{2}{3}\chi^{E\setminus\{e\}} = \sum_{i=1}^{k} \mu_i \chi^{H_i}$. Moreover, we may assume that none of the H_i's use more than one copy of an edge in E; H_i may have multiedges as long as they come from distinct edges in G.*

2.1 Operations involving splitting-off at a vertex

The following tools on the splitting-off operation will be useful. In keeping with standard terminology, we designate a vertex v (one of the endpoints of e in the theorem statement) at which the splitting-off operation is applied. For a multigraph $H = (V, E)$ and $x, y \in V$, let $\lambda_H(x, y)$ denote the size of a minimum (x, y)-cut in H, and let $\deg_H(x)$ denote the degree of x in H. Note that each multiedge is counted separately towards the degree of a vertex and the size of a cut.

▶ **Definition 4.** *Given a multigraph G and two edges sv and vt that share an endpoint v, the graph $G_{s,t}$ obtained by* splitting off *the pair (sv, vt) at v is given by $G + st - sv - vt$.*

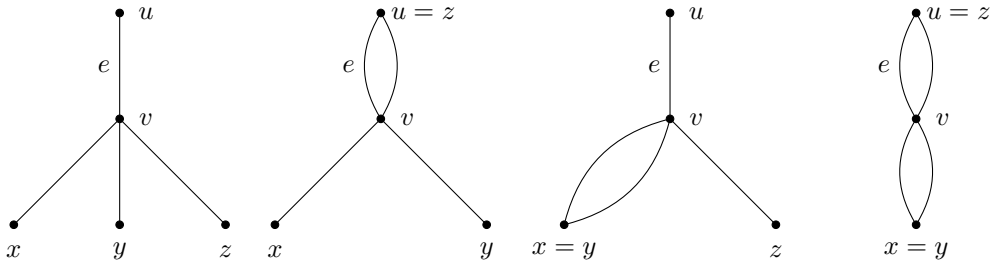
▶ **Definition 5.** *Given a multigraph G and a vertex v of G of even degree, a* complete splitting at *v is a sequence of $\frac{1}{2}deg_G(v)$ splitting off operations that result in vertex v having degree zero in the resulting graph.*

▶ **Definition 6.** *Let $k \geq 2$ be an integer and let G be a multigraph such that for all $x, y \in V \setminus \{v\}$, $\lambda_G(x, y) \geq k$. Let $e = sv$ and vt be two edges incident to v. We say that the pair (sv, vt) is* admissible *if for all $x, y \in V \setminus \{v\}$, $\lambda_{G_{s,t}}(x, y) \geq k$, and for a particular edge $e \in \delta(v)$, we let A_e denote the set of edges $f \in \delta(v) \setminus \{e\}$ such that (e, f) is an admissible pair.*

The following result due to Bang-Jensen et al., [2] shows that in our setting with a 4-regular 4-edge connected multigraph at least two distinct edges incident to v form an admissible pair with $e = uv$. Using this we can perform a complete splitting at v in two distinct ways.

▶ **Lemma 7** (Theorem 2.12 from [2]). *Let $k \geq 2$ be an even integer. Let G be a multigraph such that for all $x, y \in V \setminus \{v\}$, $\lambda_G(x, y) \geq k$. Let $\deg_G(v)$ be even (each multiedge is counted separately towards the degree). Then, $|A_{uv}| \geq \frac{1}{2}\deg_G(v)$.*

▶ **Lemma 8.** *Let G be a 4-regular 4-edge connected multigraph and $e = vx$ be an edge incident to v. Then, (i) $|A_e| \geq 2$; and (ii) if (e, f) is an admissible pair for some $f = vy \in \delta(v) \setminus \{e\}$, then the remaining two edges in $\delta(v) \setminus \{e, f\}$ form an admissible pair in $G_{x,y}$.*



Proof. Conclusion (i) follows from Lemma 7 since G is 4-regular and 4-edge connected. For conclusion (ii), let $f \in \delta(v) \setminus \{e\}$ be such that (e, f) forms an admissible pair in G. Let $G_{x,y}$ denote the graph obtained by splitting off the pair $(e = vx, f = vy)$ i.e.,

$G_{x,y} = G - vx - vy + xy$. Observe that the hypothesis of Lemma 7 still holds for $G_{x,y}$ with $k = 4$ because (a) we performed a splitting off operation using an admissible pair of edges; and (b) $\deg_{G_{x,y}}(v) = 2$ is even. Let g denote one of the two remaining edges in $\delta(v) \setminus \{e, f\}$. By Lemma 7, the other unique edge $h \in \delta(v) \setminus \{e, f, g\}$ forms an admissible pair with g in $G_{x,y}$. ◀

Equipped with the above tools, we give a proof of Theorem 3.

Proof of Theorem 3. Let $G = (V, E)$ be a 4-regular 4-edge connected multigraph and let $e = uv$ be an arbitrary edge in G. We prove this theorem via induction on $n := |V(G)|$. The base case $n = 2$ corresponds to a pair of vertices having four parallel edges, call them e, f, g, h. Observe that $\frac{2}{3}\chi^{E\setminus\{e\}} = \frac{1}{3}\big(\chi^{\{f,g\}} + \chi^{\{f,h\}} + \chi^{\{g,h\}}\big)$, so the induction hypothesis is true for the base case.

For the induction step, suppose that $n \geq 3$ and the hypothesis holds for all 4-regular 4-edge connected multigraphs with at most $n - 1$ vertices and for all choices of $e \in E$. Consider a 4-regular 4-edge connected multigraph G on n vertices and an arbitrary edge $e = uv \in E(G)$. Besides e, let vx, vy, vz be the other three edges incident to v. With a relabeling of vertices, by Lemma 8, we may assume that (uv, vx) and (uv, vy) form an admissible pair in G (see Figure 1).

(a) v has four distinct neighbors $|\mathsf{A_e}| \in \{2, 3\}$.

(b) v has two parallel edges with u $\mathsf{A_e} = \{vx, vy\}$.

(c) v has two parallel edges with $x, x \neq u$ $\mathsf{A_e} = \{vx, vy\}$.

(d) v has two parallel edges to each of $\{u, x\}$ $\mathsf{A_e} = \{vx, vy\}$.

Figure 1 Four configurations of edges in $\delta(v) = \{uv, vx, vy, vz\}$ that can arise in our proof.

By the second conclusion of Lemma 8, (vy, vz) is an admissible pair in $G_{u,x}$, and (vx, vz) is an admissible pair in $G_{u,y}$. Consider the graph G_1 obtained by splitting off the pair (vy, vz) in $G_{u,x}$ i.e., $G_1 = G - v + \{ux, yz\}$; it is customary to drop the vertex v after all its edges have been split off. Similarly, let G_2 be the graph obtained by splitting off the pair (vx, vz) in $G_{u,y}$ i.e., $G_2 = G - v + \{uy, xz\}$.

Since we only split off admissible pairs, both G_1 and G_2 are 4-regular 4-edge connected multigraphs on $n - 1$ vertices. Recall that for any subgraph K of some graph, χ^K is a shorthand for $\chi^{E(K)}$ whenever the underlying graph is clear from the context. Applying the induction hypothesis to G_1 with the designated edge $e_1 = ux$ gives:

$$\frac{2}{3} \cdot \chi^{E(G_1)\setminus\{e_1\}} = \frac{2}{3} \cdot \chi^{(E\setminus\delta(v))\cup\{yz\}} = \sum_{i=1}^{k_1} \mu_i^1 \chi^{H_i^1} \,, \qquad \text{(ConvexComb-}G_1\text{)}$$

where $\{\mu_i^1\}_i$ denote the coefficients in a convex combination, and $\{H_i^1\}_i$ are 2-edge connected spanning subgraphs of G_1 such that none of them use more than one copy of an edge in G_1.

Repeating the same argument for G_2 with the designated edge $e_2 = uy$ gives:

$$\frac{2}{3} \cdot \chi^{E(G_2)\setminus\{e_2\}} = \frac{2}{3} \cdot \chi^{(E\setminus\delta(v))\cup\{xz\}} = \sum_{i=1}^{k_2} \mu_i^2 \chi^{H_i^2} \ , \tag{ConvexComb-G_2}$$

where $\{\mu_i^2\}_i$ denote the coefficients in the other convex combination arising from $\{H_i^2\}_i$. It remains to combine (ConvexComb-G_1) and (ConvexComb-G_2) to obtain such a representation for G with the designated edge e. We mimic the strategy from [6].

For each $i \in \{1, \ldots, k_1\}$, we lift H_i^1 to a spanning subgraph $\hat{H}_i^1$ of $G - e$. Define $\hat{H}_i^1$ as follows:

$$\hat{H}_i^1 := \begin{cases} H_i^1 - yz + vy + vz & \text{if } yz \in E(H_i^1), \\ H_i^1 + vy + vx & \text{if } yz \notin E(H_i^1). \end{cases} \tag{Lift-G_1}$$

Similarly, for each $i \in \{1, \ldots, k_2\}$, we define $\hat{H}_i^2$ as the following spanning subgraph of $G - e$:

$$\hat{H}_i^2 := \begin{cases} H_i^2 - xz + vx + vz & \text{if } xz \in E(H_i^2), \\ H_i^2 + vx + vy & \text{if } xz \notin E(H_i^2). \end{cases} \tag{Lift-G_2}$$

We finish the proof of Theorem 3 by arguing that the following convex combination meets all the requirements:

$$q := \frac{1}{2} \sum_{i=1}^{k_1} \mu_i^1 \chi^{\hat{H}_i^1} + \frac{1}{2} \sum_{i=1}^{k_2} \mu_i^2 \chi^{\hat{H}_i^2} \ . \tag{ConvexComb-G}$$

Many of our arguments are the same for G_1 and G_2 so we just mention them in the context of G_1. First of all, by the induction hypothesis and (Lift-G_1) it is clear that $e(= uv), yz, ux \notin E(\hat{H}_i^1)$, where yz and ux refer to the edges that originated from the splitting off operations applied at v. Next, we argue that $\hat{H}_i^1$ is a spanning subgraph of G that uses no more than one copy of any edge in G. By the induction hypothesis, none of the subgraphs H_i^1 use more than one copy of an edge in G_1, and H_i^1 spans $V \setminus \{v\}$. By the way we lift H_i^1 to $\hat{H}_i^1$, it is clear that $\hat{H}_i^1$ uses no more than one copy of any multiedge in G, and that it is spanning. To see that $\hat{H}_i^1$ is 2-edge connected, observe that the two cases of lifting may be viewed as either (i) subdividing the edge yz by a node v when $yz \in E(H_i^1)$, or (ii) adding an edge yx and subdividing it by a node v when $yz \notin E(H_i^1)$. Clearly, these operations preserve 2-edge connectivity, hence, $\hat{H}_i^1$ is 2-edge connected.

It remains to argue that the vector q in the expression (ConvexComb-G) matches the vector $\frac{2}{3}\chi^{E(G)\setminus\{e\}}$. Since $\{\mu_i^1\}_i$ and $\{\mu_i^2\}_i$ denote coefficients in a convex combination, taking an unweighted average of these two combinations gives us another convex combination. Since none of the edges in $E(G) \setminus \delta(v)$ are modified in the lifting step, $q_f = 2/3$ for any such edge f. Next, consider the edge vy. Observe that $\hat{H}_i^1$ always contains the edge vy, whereas $\hat{H}_i^2$ contains vy only when $xz \notin E(H_i^2)$ (this happens with weight $1/3$). Therefore, $q_{vy} = \frac{1}{2} \cdot 1 + \frac{1}{2} \cdot \frac{1}{3} = \frac{2}{3}$. The analysis for vx is symmetric. Lastly, consider the edge vz. It appears in $\hat{H}_i^1$ ($\hat{H}_i^2$) if and only if $yz \in E(H_i^1)$ (respectively, $xz \in E(H_i^2)$). Therefore, $q_{vz} = \frac{1}{2} \cdot \frac{2}{3} + \frac{1}{2} \cdot \frac{2}{3} = \frac{2}{3}$. This completes the proof of Theorem 3. ◀

3 Our Algorithm and the Proof of Theorem 2

In this section we give a proof of Theorem 2 which we use to obtain a $\frac{4}{3}$-approximation algorithm for 2ECM on half-integral instances (Theorem 1). We apply the same splitting-off theorem of [2] together with an induction scheme that is captured in Theorem 2. A key feature of this theorem is that we allow edges of negative cost, although the edge costs in any instance of 2ECM are non-negative.

Consider a 4-regular 4-edge connected multigraph $G = (V, E)$ on n vertices, and let $e = uv$ be an edge in G. Let $c : E \to \mathbb{R}$ be an arbitrary real-valued cost function. Our goal is to obtain a 2-edge connected spanning subgraph H of G whose cost is at most $\frac{2}{3}c(G - e)$ while ensuring that H uses no more than one copy of any multiedge in G. Observe that if we had access to the collection $\{H_1, \ldots, H_k\}$ of 2-edge connected spanning subgraphs from Theorem 3 for some k that is polynomial in $|V(G)|$, then we would be done: for any cost function c, the cheapest subgraph in this collection (w.r.t. cost c) is one such desired subgraph. It is not clear how to efficiently obtain such a collection; a naive algorithm that follows the proof of Theorem 3 does not run in polynomial time.

As alluded to before, for the purposes of obtaining a cheap 2-edge connected subgraph, it suffices to only recurse on one of two subinstances that arise in the proof of Theorem 3. This insight comes from working backwards from (ConvexComb-G). Since this convex combination for G is a simple average of convex combinations from two subinstances (see (ConvexComb-G_1) and (ConvexComb-G_2)), it is judicious to only recurse on the "cheaper" subinstance. Combining (ConvexComb-G_1) and (Lift-G_1), we get that the first subinstance gives rise to a convex combination for $\frac{2}{3}\chi^{E(G)\setminus\{e\}} + \frac{1}{3}(\chi^{\{vy\}} - \chi^{\{vx\}})$. On the other hand, the second subinstance gives rise to a convex combination for $\frac{2}{3}\chi^{E(G)\setminus\{e\}} + \frac{1}{3}(\chi^{\{vx\}} - \chi^{\{vy\}})$. Thus, we should recurse on G_1 if $c_{vx} \geq c_{vy}$, and G_2 otherwise. For the sake of argument, suppose that we are recursing on G_1. So far, we have ignored an important detail in the recursion: the splitting-off operation creates a new edge yz that was not originally present in G, so we need to assign it some cost to apply the algorithm recursively. Depending on how we choose the cost of yz, it might either be included or excluded from the subgraph obtained for the smaller instance, so to bound the cost of the lifted solution we must have a handle on both outcomes of the lift operation. Setting $c_{yz} := c_{vz} - c_{vx}$ balances the cost of both outcomes. Note that c_{yz} could possibly be negative, but this is permissible since the statement of Theorem 2 allows for arbitrary edge costs. We formalize the above ideas.

In the recursive step, we pick one end vertex v of e and apply a complete splitting off operation at v to obtain a 4-regular 4-edge connected graph on $n - 1$ vertices; this can be implemented in $O(n)$ time. The running time of the algorithm is $O(n^2)$, since we apply the induction step $O(n)$ times.

Let $T = \{v, x, y, z\}$ be the four neighbors of v and let $e = uv$. Recall that A_e denotes the set of edges $f \in \delta(v) \setminus \{e\}$ such that (e, f) is an admissible pair (see Definition 6).

▶ **Lemma 9.** *For $vx \in \delta(v) \setminus \{e\}$, we can check whether $vx \in \mathsf{A_e}$ in $O(n)$ time.*

Proof. We may suppose that the elements of the set T of neighbors of v are all distinct. Otherwise, by Lemma 8, we know exactly which pairs are admissible, see Figure 1. Consider the graph $\hat{G} = (G_{u,x})_{y,z}$ obtained by splitting off the pairs (uv, vx) and (yv, vz) at v. Let G^* be the graph obtained from $\hat{G}$ by contracting ux to a single vertex s and contracting yz to a single vertex t. Then we apply a max $s - t$ flow computation to check whether G^* has ≥ 4 edge-disjoint $s - t$ paths; otherwise, G^* has an (s, t)-cut $\delta(S)$ of size ≤ 3. In the latter case, it is clear that our trial splitting is not admissible.

In the former case, we claim that our trial splitting is admissible. Suppose that $\hat{G}$ is not 4-edge connected. Then there exists a non-empty, proper vertex set S in $\hat{G}$ such that $|T \cap S| \leq |T \setminus S|$ and $|\delta_{\hat{G}}(S)| < 4$. Clearly, $|S \cap T| \leq 2$, and if $|S \cap T| = 2$, then we have $|S \cap \{u, x\}| = 1$ and $|S \cap \{y, z\}| = 1$ (otherwise, S would give an (s,t)-cut of G^* of size ≤ 3). Since the size of the cut of S is the same in G and in $\hat{G}$, we have, by 4-edge connectivity of G, $4 > |\delta_{\hat{G}}(S)| = |\delta_G(S)| \geq 4$, a contradiction.

To see that the running time is linear, observe that G^* has $\leq 2n$ edges, an $s-t$ flow of value ≥ 4 can be computed by finding 4 augmenting paths, and each augmenting path can be found in linear time. ◀

Proof of Theorem 2. First, consider the base case in the recursion when $n = 2$. The only such 4-regular 4-edge connected multigraph is given by four parallel edges between u and v, of which e is one. Picking the two cheapest edges from the remaining three edges gives the desired subgraph.

For the induction step, suppose that $n \geq 3$ and the induction hypothesis holds for all 4-regular 4-edge connected multigraphs with at most $n-1$ vertices and for all choices of edge e. Consider a 4-regular 4-edge connected multigraph G on n vertices and an edge $e = uv$ in G.

Our algorithm proceeds as follows. By Lemmas 8 and 9, we can find in $O(n)$-time two neighbors of v, say x and y, such that $vx, vy \in A_e$ and $c_{vx} \geq c_{vy}$. Next, we construct the graph $\hat{G} := (G_{u,x})_{y,z} = G - v + \{ux, yz\}$ and extend the cost function c to the new edge yz as $c_{yz} := c_{vz} - c_{vx}$ (note that the cost of ux is inconsequential and that c_{yz} may be negative or non-negative). We recursively find a 2-edge connected spanning subgraph $\hat{H}$ of $\hat{G}$ with cost at most $\frac{2}{3}c(\hat{G} - ux)$. Then, we lift $\hat{H}$ to obtain a spanning subgraph H of G:

$$H := \begin{cases} \hat{H} - yz + vy + vz & \text{if } yz \in E(\hat{H}), \\ \hat{H} + vy + vx & \text{if } yz \notin E(\hat{H}). \end{cases}$$

We analyze the cost of this subgraph. Regardless of the cases above, our choice of c_{yz} implies that $c(H) = c(\hat{H}) + c_{vy} + c_{vx}$. Therefore,

$$\begin{aligned} c(H) \leq \frac{2}{3}c(\hat{G} - ux) + c_{vy} + c_{vx} &= \frac{2}{3}\{c(G-e) - c_{vx} - c_{vy} - c_{vz} + (c_{vz} - c_{vx})\} + c_{vy} + c_{vx} \\ &= \frac{2}{3}c(G-e) + \frac{1}{3}(c_{vy} - c_{vx}) \leq \frac{2}{3}c(G-e)\ , \end{aligned}$$

where the last inequality follows from our choice of vx, vy to satisfy $c_{vx} \geq c_{vy}$.

It remains to argue that H is a 2-edge connected spanning subgraph of $G - e$ that uses no more than one copy of any multiedge in G. It is clear that the following hold: (a) $e \notin E(H)$; (b) H is a spanning subgraph of G; and (c) each multiedge of G appears at most once in H. Since $\hat{H}$ is 2-edge connected and adding and/or subdividing an edge preserves 2-edge connectivity, H is 2-edge connected. Overall, in $O(n^2)$-time we have constructed a 2-edge connected spanning subgraph H of $G - e$ whose cost is at most $\frac{2}{3}c(G-e)$, thereby proving Theorem 2. ◀

Using Theorem 2, we give a deterministic $\frac{4}{3}$-approximation algorithm for 2ECM on half-integral instances.

Proof of Theorem 1. Let x be an optimal half-integral solution to (Subtour-LP) (and (2ECM-LP)) for an instance given by an n-vertex graph $\overline{G} = (\overline{V}, \overline{E})$ and a metric cost function c. Let $G = (V, E)$ denote the graph induced by $2x$ where for each $e \in E$ we include

$2x_e$ copies of the edge e in G. Since x has (fractional) degree 2 at each vertex and it is fractionally 2-edge connected, G is a 4-regular 4-edge connected multigraph. With a slight abuse of notation, we use the same cost function for the edges of E: for any $e \in E$, $c_e := c_f$, where f denotes the edge in $\overline{E}$ that gave rise to e. We invoke Theorem 2 on G and some edge $e \in E$. This gives us a 2-edge connected spanning subgraph H of $G - e$ satisfying $c(H) \leq \frac{2}{3}c(G-e)$. Lifting the subgraph H to $\overline{G}$ gives a 2-edge connected spanning multisubgraph $\overline{H}$ (of $\overline{G}$); note that $\overline{H}$ uses at most two copies of any edge in $\overline{G}$. By the first conclusion of Theorem 2 and the non-negativity of c, $c(\overline{H}) = c(H) \leq \frac{2}{3}c(G-e) \leq \frac{2}{3}c(G) = \frac{4}{3}c^T x$, where the last equality follows by recalling that G is induced by $2x$. Besides invoking Theorem 2 we only perform trivial graph operations so the running time is $O(n^2)$. ◀

4 2ECM for 3-Regular 3-Edge Connected Graphs

Let $G = (V, E)$ be a 3-regular 3-edge connected graph with non-negative edge costs $c \in \mathbb{R}^E_{\geq 0}$. In this section we consider an analogous problem to that of Theorem 2, namely the problem of finding a polynomial-time algorithm which gives a 2-edge connected spanning multisubgraph of G of cost at most $\beta c(G)$ for some $\beta \geq 0$. Note that the everywhere $\frac{2}{3}$ vector for G is feasible for (Subtour-LP). For any costs c for which the everywhere $\frac{2}{3}$ vector is also optimal for (Subtour-LP) (such as for the graphic metric), such an algorithm would provide a $\frac{3\beta}{2}$-approximation for 2ECM. The conjecture that α2ECM $= \frac{4}{3}$ would then imply $\beta = \frac{4}{3} \cdot \frac{2}{3} = \frac{8}{9}$ should be possible, and the $\frac{6}{5}$ conjecture for α2ECM would imply $\beta = \frac{6}{5} \cdot \frac{2}{3} = \frac{4}{5}$ should be possible. In [5] a constructive algorithm for $\beta = \frac{4}{5}$ is given, however it does not run in polynomial time.

In [11, Theorem 2], Haddadan, Newman, and Ravi show that it is possible to do better than $\frac{8}{9}$ for this problem, and provide an efficient algorithm for $\beta = \frac{15}{17}$. In fact, they show that the everywhere $\frac{15}{17}$ vector can be expressed as a convex combination of 2-edge connected spanning multisubgraphs of G and this convex combination can be found in polynomial time. They remark that combining their ideas with an efficient algorithm for Theorem 3 would imply the result for $\beta = \frac{7}{8} (< \frac{15}{17})$. Although a polynomial-time algorithm for Theorem 3 is not currently known, it is possible to use our result in Theorem 2 to obtain $\beta = \frac{7}{8}$, as follows.

▶ **Theorem 10.** *Let $G = (V, E)$ be a 3-regular 3-edge connected graph on n vertices with non-negative edge costs $c \in \mathbb{R}^E_{\geq 0}$. Then in $O(n^3)$-time we can find a 2-edge connected spanning multisubgraph H of G such that $c(H) \leq \frac{7}{8}c(G)$.*

Proof. Let F be a 2-factor of G that intersects all of the 3-edge cuts and 4-edge cuts of G. Such a 2-factor can be found in $O(n^3)$-time (see [4, Theorem 5.4]). Let G' be the graph obtained by contracting the cycles of F and removing any resulting loops, and let $M := E(G')$. Clearly G' is 5-edge connected (by choice of F), and thus the vector $y \in \mathbb{R}^M_{\geq 0}$ defined by $y_e := \frac{2}{5}$ for all $e \in M$ is feasible for (2ECM-LP) for G'. It then follows from the polyhedral analysis of Wolsey [16] and Shmoys and Williamson [15] of the (Subtour-LP) that we can find a 2-edge connected spanning multisubgraph of G' with edge set R satisfying $c(R) \leq \frac{3}{2}c^T y = \frac{3}{5}c(M)$. Then the graph H_1 induced by $F \cup R$ is a 2-edge connected spanning multisubgraph of G such that

$$c(H_1) \leq c(F) + \frac{3}{5}c(M) \leq c(F) + \frac{3}{5}c(E \setminus F) \ . \tag{9}$$

Now consider the vector $z \in \mathbb{R}^E_{\geq 0}$ where $z_e := 1/2$ for all $e \in F$, and $z_e := 1$ otherwise. Vector z is a feasible half-integer solution for (Subtour-LP), and thus by Theorem 2 and the ideas used in the proof of Theorem 1, in $O(n^2)$-time we can find a 2-edge connected spanning multisubgraph H_2 of G such that

$$c(H_2) \leq \frac{2}{3}c(F) + \frac{4}{3}c(E \setminus F). \tag{10}$$

We complete the proof by showing that either H_1 or H_2 has cost at most $\frac{7}{8}c(G)$. Using (9) and (10) we have:

$$\min(c(H_1), c(H_2)) \leq \frac{5}{8}c(H_1) + \frac{3}{8}c(H_2) \leq \frac{5}{8}\big(c(F) + \frac{3}{5}c(E \setminus F)\big) + \frac{3}{8}\big(\frac{2}{3}c(F) + \frac{4}{3}c(E \setminus F)\big) = \frac{7}{8}c(G).$$

Abstract

We give improved multi-pass streaming algorithms for the problem of maximizing a monotone or arbitrary non-negative submodular function subject to a general p-matchoid constraint in the model in which elements of the ground set arrive one at a time in a stream. The family of constraints we consider generalizes both the intersection of p arbitrary matroid constraints and p-uniform hypergraph matching. For monotone submodular functions, our algorithm attains a guarantee of $p + 1 + \varepsilon$ using $O(p/\varepsilon)$-passes and requires storing only $O(k)$ elements, where k is the maximum size of feasible solution. This immediately gives an $O(1/\varepsilon)$-pass $(2 + \varepsilon)$-approximation for monotone submodular maximization in a matroid and $(3 + \varepsilon)$-approximation for monotone submodular matching. Our algorithm is oblivious to the choice ε and can be stopped after any number of passes, delivering the appropriate guarantee. We extend our techniques to obtain the first multi-pass streaming algorithms for general, non-negative submodular functions subject to a p-matchoid constraint. We show that a randomized $O(p/\varepsilon)$-pass algorithm storing $O(p^3 k \log(k)/\varepsilon^3)$ elements gives a $(p + 1 + \bar{\gamma}_{\text{off}} + O(\varepsilon))$-approximation, where $\bar{\gamma}_{\text{off}}$ is the guarantee of the best-known offline algorithm for the same problem.

1 Introduction

Many discrete optimization problems in theoretical computer science, operations research, and machine learning can be cast as special cases of maximizing a *submodular* function f subject to some constraint. Formally, a function $f : 2^X \to \mathbb{R}_{\geq 0}$ is submodular if and only if $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ for all $A, B \subseteq X$. One reason for the ubiquity of submodularity in optimization settings is that it also captures a natural "diminishing returns" property. Let $f(e \mid A) \triangleq f(A + e) - f(A)$ be the *marginal increase* obtained in f when adding an element e to a set A (where here and throughout we use the shorthands $A + e$

© Chien-Chung Huang, Theophile Thiery, and Justin Ward;

and $A - e$ for $A \cup \{e\}$ and $A \backslash \{e\}$, respectively). Then it is well-known that f is submodular if and only if $f(e \mid B) \leq f(e \mid A)$ for any $A \subseteq B$ and any $e \notin B$. If additionally we have $f(e \mid A) \geq 0$ for all A and $e \notin A$ we say that f is *monotone*.

Here, we consider the problem of maximizing both monotone and arbitrary submodular functions subject to an arbitrary *p-matchoid constraint* on the set of elements that can be selected. Formally, a p-matchoid $\mathcal{M}^p = (\mathcal{I}^p, X)$ on X is given by a collection of matroids $\{\mathcal{M}_i = (X_i, \mathcal{I}_i)\}$ each defined on some subset of X, where each $e \in X$ is present in at most p of these subsets. A set $S \subseteq X$ is then independent if and only if $S \cap X_i \in \mathcal{I}_i$ for each matroid $\mathcal{M}_i$. One can intuitively think of a p-matchoid as a collection of matroids in which each element "participates" in at most p of the matroid constraints. The resulting family of constraints is quite general and captures both intersections of p matroid constraints (by letting $X_i = X$ for all $\mathcal{M}_i$) and matchings in p-uniform hypergraphs (by considering X as a collection of hyperedges and defining a uniform matroid constraint for each vertex, ensuring that at most one hyperedge containing this vertex is selected).

In many applications of submodular optimization, such as summarization [19, 1, 21, 23] we must process datasets so large that they cannot be stored in memory. Thus, there has been recent interest in *streaming* algorithms for submodular optimization problems. In this context, we suppose the ground set X is initially unknown and elements arrive one-by-one in a stream. We suppose that the algorithm has an efficient oracle for evaluating the submodular function f on any given subset of X, but has only enough memory to store a small number of elements from the stream. Variants of standard greedy and local search algorithms have been developed that obtain a constant-factor approximation in this setting, but their approximation guarantees are considerably worse than that of their simple, offline counterparts.

Here, we consider the *multi-pass* setting in which the algorithm is allowed to perform several passes over a stream – in each pass all of X arrives in some order, and the algorithm is still only allowed to store a small number of elements. In the *offline* setting, simple variants of greedy [15] or local search [18, 13] algorithms in fact give the best-known approximation guarantees for maximizing submodular functions subject to the p matroid constraints or a general p-matchoid constraint. However, these algorithms potentially require considering all elements in X *each time a choice is made*. It is natural to ask whether this is truly necessary, or whether we could instead recover an approximation ratio nearly equal to these offline algorithms by using only a constant number of passes through the data stream.

1.1 Our Results

Here we show that for monotone submodular functions, $O(1/\varepsilon)$-passes suffice to obtain guarantees only $(1 + \varepsilon)$ times worse than those guaranteed by the offline local search algorithm. We give an $O(p/\varepsilon)$-pass streaming algorithm that gives a $p + 1 + \varepsilon$ approximation for maximizing a monotone submodular function subject to an arbitrary p-matchoid constraint. This immediately gives us an $O(1/\varepsilon)$ pass streaming algorithm attaining a $2+\varepsilon$ approximation for matroid constraints and a $3 + \varepsilon$ approximation for matching constraints in graphs. Each pass of our algorithm is equivalent to a single pass of the streaming local search algorithm described by Chakrabarti and Kale [6] and Chekuri, Gupta, and Quanrud [7]. However, obtaining a rapid convergence to a $p + 1 + \varepsilon$ approximation requires some new insights. We show that if a pass makes either large or small progress in the value of f, then the guarantee obtained at the end of this pass can be improved. Balancing these two effects then leads a carefully chosen sequence of parameters for each pass. Our general approach is similar to that of Chakrabarti and Kale [6], but our algorithm is *oblivious* to the choice of ε. This

Table 1 Summary of known approximation ratios for maximizing monotone and non-monotone submodular functions. M means that f is monotone, and NN means that f is non-negative. In stating results parameterized by p, we let $o(1)$ denote a term that approaches zero as p increases.

Constraint	Offline	
	M	NN
matroid	$e/(e-1)$ [5]	2.598 [3]
rank p hypergraph b-matching	$p+\varepsilon$ [13]	$\frac{p^2+\varepsilon}{p-1}$ [13]
p matroid intersection	$p+\varepsilon$ [18]	$\frac{p^2+(p-1)\varepsilon}{p-1}$ [18]
p-matchoid	$p+1$ [15]	$\frac{ep}{(1-\varepsilon)(2-o(1))}$ [12, 8]

Constraint	Streaming		Multipass		
	M	NN	M	NN	#-passes
matroid	4 [6, 7, 11]	5.8284 [11]	$2+\varepsilon$ [6]		$O\left(\varepsilon^{-1}\right)$
rank p hypergraph b-matching	$4p$ [7, 11]	$4p+2-o(1)$ [11]	$p+1+\varepsilon$ [6]		$O\left(\frac{p^4\log(p)}{\varepsilon^3}\right)$
p matroid intersection	$4p$ [6, 7, 11]	$4p+2-o(1)$ [11]	$p+1+\varepsilon$ [6]		$O\left(\frac{p^4\log(p)}{\varepsilon^3}\right)$
p-matchoid	$4p$ [7, 11]	$4p+2-o(1)$ [11]			

allows us to give a uniform bound on the convergence of the approximation factor obtained after some number d of passes. This bound is actually available to the algorithm, and so we can certify the quality of the current solution after each pass. In practice, this allows for terminating the algorithm early if a sufficient guarantee has already been obtained. Even in the worst case, however, we improve on the number of passes required by similar previous results by a factor of $O(\varepsilon^{-2})$. Our algorithm only requires storing $O(k)$ elements, where k is the *rank* of the given p-matchoid, defined as the size of the largest independent set of elements.

Building on these ideas, we also give a randomized, multi-pass algorithm that uses $O(p/\varepsilon)$-passes and attains a $p+1+\bar{\gamma}_{\text{off}}+O(\varepsilon)$ approximation for maximizing an arbitrary submodular function subject to a p-matchoid constraint, where $\bar{\gamma}_{\text{off}}$ is the approximation ratio attained by best-known offline algorithm for the same problem. To the best of our knowledge, ours is the first multipass algorithm when the function is non-monotone. In this case, our algorithm requires storing $O(\frac{p^3 k\log k}{\varepsilon^3})$ elements. We remark that to facilitate comparison with existing work, we have stated all approximation guarantees as factors $\gamma\geq 1$. However, we note that if one states ratios of the form $1/\gamma$ less than 1, then our results lead to $1/\gamma-\varepsilon$ approximations in which all dependence on p can be eliminated (by setting simply selecting some $\varepsilon'=p\varepsilon$).

1.2 Related Work

There is a vast literature on submodular maximization with various constraints and different models of computation. In the offline model, the work on maximizing a monotone submodular function goes back to Nemhauser, Wolsey and Fischer [24]. Monotone submodular functions are well studied and many new and powerful results have been obtained since then. The best approximation algorithm under a matroid constraint is due to Calinescu et al. [5] which is the best that can be done using a polynomial number of queries [24] (if f is given as a value oracle) or assuming $P\neq NP$ [9] (if f is given explicitly). For more general constraints, Lee, Sviridenko and Vondrák obtained a $p+\varepsilon$ approximation algorithm under p matroid

Table 2 Summary of our results maximizing monotone and non-monotone submodular functions.

Constraint	Our results		
	monotone	non-negative	#-passes
matroid	$2+\varepsilon$	$4.598+\varepsilon$	$O\left(\frac{1}{\varepsilon}\right)$
rank p hypergraph b-matching	$p+1+\varepsilon$	$p+1+\frac{p^2}{p-1}+O(\varepsilon)$	$O\left(\frac{p}{\varepsilon}\right)$
p matroid intersection	$p+1+\varepsilon$	$p+1+\frac{p^2}{p-1}+O(\varepsilon)$	$O\left(\frac{p}{\varepsilon}\right)$
p-matchoid	$p+1+\varepsilon$	$p+1+\frac{ep}{(1-\varepsilon)(2-o(1))}+O(\varepsilon)$	$O\left(\frac{p}{\varepsilon}\right)$

constraints [18]. Feldman et al. [13] obtained the same approximation ratio for the general class of p-exchange systems. For general p-matchoid constraints, the best approximation ratio is $p+1$, which is attained by the standard greedy algorithm [15].

Non-monotone objectives are less understood even under the simplest assumptions. The current best-known result for maximizing a submodular function under a matroid constraint is 2.598 [3], which is far from the 2.093 hardness result [16]. Table 1 gives the best known bounds for the constraints that we consider in the paper.

Due to the large volume of data in modern applications, there has also been a line of research focused on developing *fast* algorithms for submodular maximization [2, 22]. However, all results we have discussed so far assume that the entire instance is available at any time, which may not be feasible for massive datasets. This has motivated the study of streaming submodular maximization algorithms with low memory requirements. Badaniyuru et al. [1] achieved a $2+\varepsilon$-approximation algorithm for maximizing a monotone submodular function under a cardinality constraint in the streaming setting. This was recently shown to be the best possible bound attainable in one pass with memory sublinear in the size of the instance [14]. Chakrabarti and Kale [6] gave a $4p$-approximation for the intersection of p matroid constraints or p-uniform hypergraph matching. Later, Chekuri et al. [7] generalized their argument to arbitrary p-matchoid constraints, and also gave a modified algorithm for handling non-monotone submodular objectives. A fast, randomized variant of the algorithm of [6] was studied by Feldman, Karbasi and Kazemi [11], who showed that it has the same approximation guarantee when f is monotone and achieves a $2p+2\sqrt{p(p+1)}+1=4p+2-o(1)$-approximation for general submodular function.

When multiple passes through the stream are allowed, less is known and the tradeoff between the approximation guarantee and the number of passes requires more attention. Assuming cardinality constraints, one can obtain a $\frac{e}{e-1}+\varepsilon$-multipass streaming algorithm in $O\left(\varepsilon^{-1}\right)$ passes (see [2, 17, 20, 21, 25]). Huang et al. [17] achieved a $2+\varepsilon$-approximation under a knapsack constraint in $O\left(\varepsilon^{-1}\right)$ passes. For the intersection of p partition matroids or rank p hypergraph matching, the number of passes becomes dependent on p. Chakrabarti and Kale [6][1] showed that if one allows $O\left(\frac{p^4\log(p)}{\varepsilon^3}\right)$-passes, a $p+1+\varepsilon$ approximation is possible. Here we show how to obtain the same guarantee for an arbitrary p-matchoid constraint, while reducing the number of passes to $O(p/\varepsilon)$.

[1] In [6] a bound of $O(\log p/\varepsilon^3)$ is stated. We note that there appears to be a small oversight in their analysis, arising from the fact that their convergence parameter κ in this case is $O(\varepsilon^3/p^4)$. In any case, it seems reasonable to assume that p is a small constant in most cases.

  return C_x;

2 The main multi-pass streaming algorithm

Our main multi-pass algorithm is given by the procedure MultipassLocalSearch in Algorithm 1. We suppose that we are given a submodular function $f : 2^X \to \mathbb{R}_{\geq 0}$ and a p-matchoid constraint $\mathcal{M}^p = (\mathcal{I}^p, X)$ on X given as a collection of matroids $\{\mathcal{M}_i = (X_i, \mathcal{I}_i)\}$. Our procedure runs for d passes, each of which uses a modification of the algorithm of Chekuri, Gupta, and Quanrud [7], given as the procedure StreamingLocalSearch. In each pass, procedure StreamingLocalSearch maintains a current solution S, which is initially set to some S_{init}. Whenever an element $x \in S_{\text{init}}$ arrives again in the subsequent stream, the procedure simply discards x. For all other elements x, the procedure invokes a helper procedure Exchange, given formally in Algorithm 2, to find an appropriate set $C_x \subseteq S$ of up to p elements so that $S \backslash C_x + x \in \mathcal{I}$. It then exchanges x with C_x if this gives a significantly improved solution. This improvement is measured with respect to a set of auxiliary weights $\nu(x, S)$ maintained by the algorithm. For $u, v \in X$, let $u \prec v$ denote that "element u arrives before v" in the stream. Then, we define the *incremental value* of an element e with respect to a set T as

$$\nu(e, T) = f(e \mid \{t' \in T : t' \prec e\}) .$$

There is a slight difficulty here in that we must also define incremental values for the elements of S_{init}. To handle this difficulty, we in fact define $\prec$ with respect to a *pretend* stream ordering. Note that in all invocations of the procedure StreamingLocalSearch made by MultipassLocalSearch, the set S_{init} is either $\emptyset$ or the result of a previous application of StreamingLocalSearch. In our pretend ordering ($\prec$) all of S_{init} first arrives in the same relative pretend ordering as the previous pass, followed by all of $X \backslash S_{\text{init}}$ in the same order given by the stream X. We then define our incremental values with respect to this pretend stream ordering.

Using these incremental values, StreamingLocalSearch proceeds as follows. When an element $x \notin S_{\text{init}}$ arrives, StreamingLocalSearch computes a set of elements $C_x \subseteq S$ that can be exchanged for x. StreamingLocalSearch replaces C_x with x if and only if the marginal value $f(x \mid S)$ with respect to S is at least $(1+\beta)$ times larger than the sum of the current incremental values $\nu(c, S)$ of all elements $c \in C_x$ plus some threshold α, where $\alpha, \beta > 0$ are given as parameters. In this case, we say that the element x is *accepted*. Otherwise, we say that x is *rejected*. An element $x \in S$ that has been accepted may later be removed from S if $x \in C_y$ for some later element y that arrives in the stream. In this case we say that x is *evicted*.

The approximation ratio obtained by one pass of StreamingLocalSearch depends on the parameter β in two ways, which can be intuitively understood in terms of the standard analysis of the offline local search algorithm for the problem. Intuitively, if β is chosen to be too large, more valuable elements will be rejected upon arrival and so, in the offline setting, our solution would be only approximately locally optimal, leading to a deterioration of the guarantee by a factor of $(1+\beta)$. However, in the streaming setting, the algorithm only attempts to exchange an element upon its arrival, and so the final solution will not necessarily be even $(1+\beta)$-approximately locally optimal – an element x may be rejected because $f(x \mid S)$ is small when it arrives, but the processing of later elements in the stream can evict some elements of S. After these evictions, we could have $f(x \mid S)$ larger. The key observation in the analyses of [6, 7] is that the total value of these evicted elements – and so also the total increase in the marginal value of all rejected elements – can be bounded by $O(\frac{1}{\beta})$ times the final value of $f(S)$ at the end of the algorithm. Intuitively, if β is chosen to be too small, the algorithm will make more exchanges, evicting more elements, which may result in rejected elements being much more valuable with respect to the final solution. Selecting the optimal value of β thus requires balancing these two effects.

Here, we observe that this second effect depends only on the total value of those elements that were accepted *after* an element arrives. To use this observation, we measure the ratio $\delta = f(S_{\text{init}})/f(\tilde{S})$ between the value of the initial solution S_{init} of some pass of StreamingLocalSearch and the final solution $\tilde{S}$ produced by this pass. If δ is relatively small – and so one pass makes a lot of progress – then this pass gives us an improvement of δ^{-1} over the ratio already guaranteed by the previous pass since $f(\tilde{S}) = \delta^{-1} f(S_{\text{init}})$. On the other hand, if δ is relatively large – and so one pass does not make much progress – then the total increase in the value of our rejected elements can be bounded by $\frac{1-\delta}{\beta} f(\tilde{S})$, and so the potential loss due to only testing these elements at arrival is relatively small. Balancing these two effects allows us to set β smaller in each subsequent passes and obtain an improved guarantee.

We now turn to the analysis of our algorithm. Here we focus on a single pass of StreamingLocalSearch. For $T, U \subseteq X$ we let $f(T \mid U) \triangleq f(T \cup U) - f(U)$. Throughout, we use S to denote the current solution maintained by this pass (initially, $S = S_{\text{init}}$). The following key properties of incremental values will be useful in our analysis. We defer the proof to the Appendix.

▶ **Lemma 1.** *For any $T \subseteq U \subseteq X$,*
1. $\sum_{e \in T} \nu(e, T) = f(T) - f(\emptyset)$
2. $\nu(e, U) \leq \nu(e, T)$ *for all* $e \in T$.
3. $f(T \mid U \backslash T) \leq \sum_{t \in T} \nu(t, U)$
4. *At all times during the execution of* StreamingLocalSearch, $\nu(e, S) \geq \alpha$ *for all* $e \in S$.

Let A denote the set of elements *accepted* during the present pass. These are the elements which were present in the solution S at some previous time during the execution of this pass. Initially we have $A = S = S_{\text{init}}$ and whenever an element is added to S, during this pass we also add this element to A. Let $\tilde{A}$ and $\tilde{S}$ denote the sets of elements A and S at the end of this pass. Note that we regard all elements of S_{init} as having been accepted at the start of the pass. The following lemma follows from the analysis of Chekuri, Gupta, and Quanrud [7] in the single-pass setting. We give a complete, self-contained proof in Appendix A. Each element $e \in \tilde{A} \backslash \tilde{S}$ was accepted but later *evicted* by the algorithm. For any such evicted element, we let $\chi(e)$ denote the value of $\nu(e, S)$ at the moment that e was removed from S.

▶ **Lemma 2.** *Let $f : 2^X \to \mathbb{R}_{\geq 0}$ be a submodular function. Suppose $\tilde{S}$ is the solution produced at the end of one pass of* StreamingLocalSearch *and $\tilde{A}$ be the set of all elements accepted during this pass. Then,*

$$f(OPT \cup \tilde{A}) \leq (p + \beta p - \beta) \sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e) + (p + \beta p + 1) f(\tilde{S}) + k\alpha \,.$$

We now derive a bound for the summation $\sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e)$ (representing the value of *evicted* elements) in terms of the total gain $f(\tilde{S}) - f(S_{\text{init}})$ made by the pass, and also bound the total number of accepted elements in terms of $f(OPT)$.

▶ **Lemma 3.** *Let $f : 2^X \to \mathbb{R}_{\geq 0}$ be a submodular function. Suppose that $\tilde{S}$ is the solution produced at the end of one pass of* StreamingLocalSearch *and $\tilde{A}$ is the set of all elements accepted during this pass. Then, $|\tilde{A}| \leq f(OPT)/\alpha$ and*

$$\sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e) \leq \frac{1}{\beta} \left(f(\tilde{S}) - f(S_{\text{init}}) \right) .$$

Proof. We consider the quantity $\Phi(A) \triangleq \sum_{e \in A \backslash S} \chi(e)$. Suppose some element a with $C_a \neq \emptyset$ is added to S by the algorithm, evicting the elements of C_a. Then (as each element can be evicted only once) $\Phi(A)$ increases by precisely $\Delta \triangleq \sum_{e \in C_a} \chi(e)$. Let S_a^-, S_a^+ and A_a^-, A_a^+ be the sets S and A, respectively, immediately before and after a is accepted. Since a is accepted, we must have $f(a \mid S_a^-) \geq \alpha + (1 + \beta) \sum_{e \in C_a} \nu(e, S_a^-)$. Then,

$$\begin{aligned}
f(S_a^+) - f(S_a^-) &= f(S_a^- \backslash C_a + a) - f(S_a^-) \\
&= f(a \mid S_a^- \backslash C_a) - f(C_a \mid S_a^- \backslash C_a) \\
&\geq f(a \mid S_a^-) - f(C_a \mid S_a^- \backslash C_a) && \text{(by submodularity)} \\
&\geq f(a \mid S_a^-) - \sum_{e \in C_a} \nu(e, S_a^-) && \text{(by Lemma 1 (3))} \\
&\geq \alpha + (1 + \beta) \sum_{e \in C_a} \nu(e, S_a^-) - \sum_{e \in C_a} \nu(e, S_a^-) && \text{(since } a \text{ is accepted)} \\
&= \alpha + \beta \sum_{e \in C_a} \chi(e) \,. && \text{(by definition of } \chi(e)) \\
&= \alpha + \beta \Delta
\end{aligned}$$

It follows that whenever $\Phi(A)$ increases by Δ, $f(S)$ must increase by at least $\beta\Delta$. Initially, $\Phi(A) = 0$ and $f(S) = f(S_{\text{init}})$ and at the end of the algorithm, $\Phi(A) = \sum_{e\in\tilde{A}\setminus\tilde{S}} \chi(e)$ and $f(S) = f(\tilde{S})$. Thus, $\beta \sum_{e\in\tilde{A}\setminus\tilde{S}} \chi(e) \leq [f(\tilde{S}) - f(S_{\text{init}})]$.

It remains to show that $|\tilde{A}| \leq f(OPT)/\alpha$. For this, we note that the above chain of inequalities also implies that every time an element is accepted (and so $|A|$ increases by one), $f(S)$ also increases by at least α. Thus, we have $f(OPT) \geq f(\tilde{S}) \geq \alpha|\tilde{A}|$. ◀

Using Lemma 3 to bound the sum of exit values in Lemma 2 then immediately gives us the following guarantee for each pass performed in MultipassLocalSearch. In the i^{th} such pass, we will have $S_{\text{init}} = S_{i-1}$, $\tilde{S} = S_i$, and $\beta = \beta_i$. We let A_i denote the set of $\tilde{A}$ of all elements accepted during this particular pass.

▶ **Lemma 4.** *Let $f : 2^X \to \mathbb{R}_{\geq 0}$ be a submodular function. Consider the i^{th} pass of StreamingLocalSearch performed by MultipassLocalSearch, and let A_i be the set of all elements accepted during this pass. Then, $|A_i| \leq f(OPT)/\alpha$ and*

$$f(OPT \cup A_i) \leq (p/\beta_i + p - 1)\,[f(S_i) - f(S_{i-1})] + (p + p\beta_i + 1)f(S_i) + k\alpha\,.$$

3 Analysis of the multipass algorithm for monotone functions

We now show how to use Lemma 4 together with a careful selection of parameters α and $\beta_1, \ldots, \beta_d$ to derive guarantees for the solution $f(S_i)$ produced after the i^{th} pass made in MultipassLocalSearch. Here, we consider the case that f is a *monotone* function. In this case, we have $f(OPT) \geq f(OPT \cup A_i)$ for all i. We set $\alpha = 0$ in each pass. In the first pass, we will set $\beta_1 = 1$. Then, since $S_0 = \emptyset$ Lemma 4 immediately gives:

$$f(OPT) \leq f(OPT \cup A_1) \leq (2p - 1)\,[f(S_1) - f(\emptyset)] + (2p + 1)f(S_1) = 4pf(S_1)\,. \tag{1}$$

For passes $i > 1$, we use the following, which relates the approximation guarantee obtained in this pass to that from the previous pass.

▶ **Theorem 5.** *For $i > 1$, suppose that $f(OPT) \leq \gamma_{i-1} \cdot f(S_{i-1})$ and define $\delta_i = \frac{f(S_{i-1})}{f(S_i)}$. Then,*

$$f(OPT) \leq \min\left\{\gamma_{i-1}\delta_i, (\tfrac{p}{\beta_i} + p - 1)(1 - \delta_i) + p + \beta_i p + 1\right\} \cdot f(S_i) + k\alpha\,.$$

Proof. From the definition of γ_{i-1} and δ_i, we have:

$$f(OPT) \leq \gamma_{i-1} f(S_{i-1}) = \gamma_{i-1}\delta_i f(S_i)\,.$$

On the other hand, $f(S_i) - f(S_{i-1}) = (1 - \delta_i)f(S_i)$. Thus, Lemma 4 gives:

$$f(OPT) \leq [(p/\beta_i + p - 1)\,(1 - \delta_i) + p + \beta_i p + 1]\,f(S_i) + k\alpha\,.$$ ◀

Now, we observe that for any fixed guarantee γ_{i-1} from the previous pass, $\gamma_{i-1}\delta_i$ is an increasing function of δ_i and $((p/\beta_i + p - 1)(1 - \delta_i) + p + \beta_i p + 1)$ is an decreasing function of δ_i. Thus, the guarantee we obtain in Theorem 5 is always at least as good as that obtained when these two values are equal. Setting:

$$\gamma_{i-1}\delta_i = (\tfrac{p}{\beta_i} + p - 1)(1 - \delta_i) + p + \beta_i p + 1,$$

and solving for δ_i gives us:

$$\delta_i = \frac{p(1 + \beta_i)^2}{p + \beta_i(\gamma_{i-1} - 1 + p)}\,. \tag{2}$$

In the following analysis, we consider this value of δ_i since the guarantee given by Theorem 5 will always be no worse than that given by this value. The analysis for a single matroid constraint follows from our results for p-matchoids, but the analysis and parameter values obtained are much simpler, so we present it separately, first.

▶ **Theorem 6.** *Suppose we run Algorithm 1 for an arbitrary matroid constraint and monotone submodular function f, with $\beta_i = \frac{1}{i}$. Then $2(1+\frac{1}{i})f(S_i) \geq f(OPT)$ for all $i > 0$. In particular, after $i = \frac{2}{\varepsilon}$ passes, $(2+\varepsilon)f(S_i) \geq f(OPT)$.*

Proof. Let γ_i be the guarantee for our algorithm after i passes. We show, by induction on i, that $\gamma_i \leq \frac{2(i+1)}{i}$. For $i = 1$, we have $\beta_1 = 1$ and so from (1) we have $\gamma_1 = 4$, as required. For $i > 1$, suppose that $\gamma_{i-1} \leq \frac{2i}{i-1}$. Since $p = 1$ and $\beta_i = 1/i$ (2) gives:

$$\delta_i \leq \frac{(1+\frac{1}{i})^2}{1+\frac{1}{i}(\frac{2i}{i-1})} = \frac{\frac{(i+1)^2}{i^2}}{\frac{(i-1)+2}{i-1}} = \frac{(i-1)(i+1)}{i^2}\,.$$

Thus, by Theorem 5, the i^{th} pass of our algorithm has guarantee γ_i satisfying:

$$\gamma_i \leq \gamma_{i-1}\delta_i \leq \frac{2i}{i-1}\frac{(i-1)(i+1)}{i^2} = \frac{2(i+1)}{i}\,,$$

as required. ◀

▶ **Theorem 7.** *Suppose we run Algorithm 1 for an arbitrary p-matchoid constraint and monotone submodular function f, β_1 and*

$$\beta_i = \frac{\gamma_{i-1}-1-p}{\gamma_{i-1}-1+p}$$

for $i > 1$, where γ_i is given by the recurrence $\gamma_1 = 4p$ and

$$\gamma_i = 4p\frac{\gamma_{i-1}(\gamma_{i-1}-1)}{(\gamma_{i-1}-1+p)^2}$$

for $i > 1$. Then $\left(p+1+\frac{4p}{i}\right)f(S_i) \geq f(OPT)$ for all $i > 0$. In particular, after $i = \frac{4p}{\varepsilon}$ passes, $(p+1+\varepsilon)f(S_i) \geq f(OPT)$.

Proof. We first show that approximation guarantee of our algorithm after i passes is given by γ_i. Setting $\beta_1 = 1$, we obtain $\gamma_1 = 4p$ from (1), agreeing with our definition. For passes $i > 1$, let $\beta_i = \frac{\gamma_{i-1}-1-p}{\gamma_{i-1}-1+p}$. As in the case of matroid constraint, Theorem 5 implies that the guarantee for pass i will be at most $\delta_i\gamma_{i-1}$, where δ_i is chosen to satisfy (2). Specifically, if we set

$$\delta_i = \frac{p\left(1+\frac{\gamma_{i-1}-1-p}{\gamma_{i-1}-1+p}\right)^2}{p+\frac{\gamma_{i-1}-1-p}{\gamma_{i-1}-1+p}(\gamma_{i-1}-1+p)} = \frac{p\left(\frac{2(\gamma_{i-1}-1)}{\gamma_{i-1}-1+p}\right)^2}{\gamma_{i-1}-1} = \frac{4p(\gamma_{i-1}-1)}{(\gamma_{i-1}-1+p)^2}\,,$$

then we have $\delta_i\gamma_{i-1} = \gamma_i$.

We now show by induction on i that $\gamma_i \leq p+1+\frac{4p}{i}$. In the case $i = 1$, we have $\gamma_1 = 4p$ and the claim follows immediately from $p \geq 1$. In the general case $i > 0$, and we may assume without loss of generality that $\gamma_{i-1} \geq 1$. Otherwise the theorem holds immediately, as each subsequent pass can only increase the value of the solution. Then, we note (as shown in Appendix B) that for $p \geq 1$ and $\gamma_{i-1} \geq 1$, γ_i is an increasing function of γ_{i-1}. By the induction hypothesis, $\gamma_{i-1} \leq p+1+\frac{4p}{i-1}$. Therefore:

$$\gamma_i \leq \frac{4p\left(p+1+\frac{4p}{i-1}\right)\left(p+\frac{4p}{i-1}\right)}{\left(2p+\frac{4p}{i-1}\right)^2} \leq p+1+\frac{4p}{i}\,,$$

as required. The last inequality above follows from straightforward but tedious algebraic manipulations, which can be found in Appendix B. ◀

Algorithm 3 The randomized multi-pass streaming algorithm.

procedure MultipassRandomizedLocalSearch($\alpha, \beta_1, \ldots, \beta_d, m$)
  $S_0 \leftarrow \emptyset, S'_0 \leftarrow \emptyset$;
  for $i = 1$ **to** d **do**
    Let $(\tilde{S}, S')$ be the output of RandomizedLocalSearch($S_{i-1}, \alpha, \beta_i, m$);
    $S_i \leftarrow \tilde{S}$, $S'_i \leftarrow \arg\max\{f(S'_{i-1}), f(S')\}$;
  return $\bar{S} = \arg\max\{f(S_d), f(S'_d)\}$;

procedure RandomizedLocalSearch($S_{\text{init}}, \alpha, \beta, m$)
  $S \leftarrow S_{\text{init}}$; $B \leftarrow \emptyset$;

      $B \leftarrow B - x$; $S \leftarrow S + x - C_x$;
      foreach x' in B **do**
        $C_{x'} \leftarrow$ Exchange(x', S);
        if $f(x' \mid S) < \alpha + (1+\beta)\sum_{e \in C_{x'}} \nu(e, S)$ **then**
          $B \leftarrow B - x'$;
  $S' \leftarrow$ Offline(B);
  return (S, S');

4 A multi-pass algorithm for general submodular functions

In this section, we show that the guarantees for monotone submdodular maximization can be extended to non-monotone submodular maximization even when dealing with multiple passes. Our main algorithm is given by procedure MultipassRandomizedLocalSearch in Algorithm 3. In each pass, it calls a procedure RandomizedLocalSearch, which is an adaptation of StreamingLocalSearch, to process the stream. Note that each such pass produces a pair of feasible solutions S and S', which we now maintain throughout MultipassRandomizedLocalSearch. The set S is maintained similarly as before and gradually improves by exchanging "good" elements into a solution throughout the pass. The set S' will be maintained by considering the best output of an offline algorithm that we run after each pass as described in more detail below.

To deal with non-monotone submodular functions, we will limit the probability of elements being added to S. Instead of exchanging good elements on arrival, we store them in a buffer B of size m. When the buffer becomes full, an element is chosen uniformly at random and added to S. Adding a new element to the current solution may affect the quality of the remaining elements in the buffer and thus we need to re-evaluate them and remove the elements that are no longer good. As before, we let A denote the set of elements that were previously added to S during the current pass of the algorithm. Note that we do not consider an element to be accepted until it has actually been added to S from the buffer. For any fixed set of random choices, the execution of RandomizedLocalSearch can be considered

as the execution of StreamingLocalSearch on the following stream: we suppose that an element x arrives whenever it is selected from the buffer and accepted into S. All elements that are discarded from the buffer after accepting x then arrive, and will also be rejected by StreamingLocalSearch. Any elements remaining in the buffer after the execution of the algorithm do not arrive in the stream. Applying Lemma 4 with respect to this pretend stream ordering allows us to bound $f(\tilde{S})$ with respect to $f(OPT \setminus B)$ (that is, the value of the part of OPT that does not remain in the buffer B) after a single pass of RandomizedLocalSearch. Formally, let $\tilde{B}_i$ be the value of the buffer after the i^{th} pass of our algorithm. Then, applying Lemma 4 to the set $OPT \setminus \tilde{B}_i$, and taking expectation, gives:

$$\mathbb{E}[f(A_i \cup (OPT \setminus \tilde{B}_i))] \leq (p/\beta + p - 1)\,(\mathbb{E}[f(S_i)] - \mathbb{E}[f(S_{i-1})]) + (p + \beta p + 1)\,\mathbb{E}[f(S_i)] + \alpha k\,. \quad (3)$$

In order to bound the value of the elements in $\tilde{B}_i$, we apply any offline $\bar{\gamma}_{\text{off}}$-approximation algorithm Offline to the buffer at the end of the pass to obtain a solution S'. In MultipassRandomizedLocalSearch, we then remember the best such offline solution S'_i computed across the first i passes. Then, in the i^{th} pass, we have

$$\mathbb{E}[f(OPT \cap \tilde{B}_i)] \leq \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S')] \leq \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)]\,. \quad (4)$$

From submodularity of f and $A_i \cap \tilde{B}_i = \emptyset$ we have $f(A_i \cup OPT) \leq f(A_i \cup (OPT \setminus \tilde{B}_i)) + f(OPT \cap \tilde{B}_i)$. Thus, combining (3) and (4) we have:

$$\mathbb{E}[f(A_i \cup OPT)] \leq (p/\beta + p - 1)\,(\mathbb{E}[f(S_i)] - \mathbb{E}[f(S_{i-1})]) + (p + \beta p + 1)\,\mathbb{E}[f(S_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)] + \alpha k\,. \quad (5)$$

To relate the right-hand side to $f(OPT)$ we use the following result from Buchbinder et al. [4]:

▶ **Lemma 8** (Lemma 2.2 in [4]). *Let $f\colon 2^X \to \mathbb{R}_{\geq 0}$ be a non-negative submodular function. Suppose that A is a random set where no element $e \in X$ appears in A with probability more than p. Then, $\mathbb{E}[f(A)] \geq (1-p)\,f(\emptyset)$. Moreover, for any set $Y \subseteq X$, it follows that $\mathbb{E}[f(Y \cup A)\,] \geq (1-p) f(Y)$.*

We remark that a similar theorem also appeared earlier in Feige, Mirrokni, and Vondrák [10] for a random set that contains each element *independently* with probability *exactly* p. Here, the probability that an element occurs in A_i is delicate to handle because such an element may either originate from the starting solution S_{i-1} or be added during the pass. Thus, we use a rougher estimate. By definition $A_i \subseteq A_i \cup A_{i-1} \cup \ldots \cup A_1$. Thus, $\Pr[e \in A_i] \leq \Pr[e \in A_i \cup \ldots \cup A_1]$. The number of selections during the j^{th} pass is at most $|A_j|$ and by Lemma 4 (applied to the set $OPT \setminus \tilde{B}_j$ due to our pretend stream ordering in each pass j), $|A_j| \leq f(OPT \setminus \tilde{B}_j)/\alpha \leq f(OPT)/\alpha$ in any pass. Here, the second inequality follows from the optimality of OPT, and the fact that any subset of the feasible solution OPT is also feasible for our p-matchoid constraint. Thus, the total number of selections in the first i passes at most $\sum_{j=1}^{i} |A_j| \leq i \cdot f(OPT)/\alpha$. We select an element only when the buffer is full, and each selection is made independently and uniformly at random from the buffer. Thus, the probability that any given element is selected when the algorithm makes a selection is at most $1/m$ and by a union bound, $\Pr[e \in A_i \cup \ldots \cup A_1] \leq i \cdot f(OPT)/(m\alpha)$. Let d be the number of passes that the algorithm makes and suppose we set $\alpha = \varepsilon f(OPT)/2k$ (in Appendix C we show that this can be accomplished approximately by guessing $f(OPT)$, which can be done at the expense of an extra factor $O(\log k)$ space). Finally, let $m = 4dk/\varepsilon^2$. Then, applying Lemma 8, after $i \leq d$ passes we have:

$$\mathbb{E}[f(A_i \cup OPT)] \geq (1 - d \cdot f(OPT)/(m\alpha))\,f(OPT) \geq (1 - \varepsilon/2)\,f(OPT)\,. \quad (6)$$

Our definition of α also implies that $\alpha k \leq (1-\varepsilon/2)f(OPT)$. Using this and (6) in (5), we obtain:

$$(1-\varepsilon)f(OPT) \leq (p/\beta + p - 1)(\mathbb{E}[f(S_i)] - \mathbb{E}[f(S_{i-1})]) + (p + \beta p + 1)\,\mathbb{E}[f(S_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)]\,. \quad (7)$$

As we show in Appendix C, the rest of the analysis then follows similarly to that in Section 3, using the fact that $f(\bar{S}) = \max\{f(S_d), f(S'_d)\}$.

▶ **Theorem 9.** *Let $\mathcal{M}^p = (X, \mathcal{I})$ be a p-matchoid of rank k and let $f\colon 2^X \to \mathbb{R}_{\geq 0}$ be a non-negative submodular function. Suppose there exists an algorithm for the offline instance of the problem with approximation factor $\bar{\gamma}_{\text{off}}$. For any $\varepsilon > 0$, the randomized streaming local-search algorithm returns a solution $\bar{S} \in \mathcal{I}$ such that*

$$f(OPT) \leq (p + 1 + \bar{\gamma}_{\text{off}} + O(\varepsilon))\,\mathbb{E}[f(\bar{S})]$$

using a total space of $O\Big(\frac{p^3 k \log_2 k}{\varepsilon^3}\Big)$ and $O\big(\frac{p}{\varepsilon}\big)$-passes.

A Proof of Lemma 2

Here, we give a self-contained analysis of the single-pass algorithm of Chekuri, Gupta, and Quanrud [7], corresponding to Algorithm 1 initialized with $S_{\text{init}} = \emptyset$. First, we prove Lemma 1, which concerns properties of the incremental values maintained by Algorithm 1.

▶ **Lemma 1.** *For any $T \subseteq U \subseteq X$,*

1. $\sum_{e \in T} \nu(e, T) = f(T) - f(\emptyset)$
2. $\nu(e, U) \leq \nu(e, T)$ *for all* $e \in T$.
3. $f(T \mid U \backslash T) \leq \sum_{t \in T} \nu(t, U)$
4. *At all times during the execution of* StreamingLocalSearch, $\nu(e, S) \geq \alpha$ *for all* $e \in S$.

Proof. Property (1) follows directly from the telescoping summation

$$\sum_{e\in T}\nu(e,T)=\sum_{e\in T}[f(e\cup\{t'\in T:t'\prec e\})-f(\{t'\in T:t'\prec e\}]=f(T)-f(\emptyset).$$

Property (2) follows from submodularity since $T\subseteq U$ implies that $\{t'\in T:t'\prec e\}\subseteq\{t'\in U:t'\prec e\}$.

For property (3), we note that:

$$f(T\mid U\backslash T)=\sum_{t\in T}f(t\mid U\backslash T\cup\{t'\in T:t'\prec t\})\leq\sum_{t\in T}f(t\mid\{u'\in U:u'\prec t\})=\sum_{t\in T}\nu(t,U)\,,$$

where the first equation follows from a telescoping summation, and the inequality follows from submodularity, since $\{u'\in U:u'\prec t\}\subseteq U\setminus T\cup\{t'\in T:t'\prec t\}$.

We prove property (4) by induction on the stream of elements arriving. Initially $S=\emptyset$. Thus, the first time that any element x is accepted, we must have $C_x=\emptyset$ and so $f(x\mid S)\geq\alpha$. After this element is accepted, we have $\nu(x,S)=\nu(x,\{x\})=f(x\mid\emptyset)=\alpha$. Proceeding inductively, then, let S_x^- and S_x^+ be the set of elements in S before and after some new element x arrives and is processed by Algorithm 1, and suppose that $\nu(s,S_x^-)\geq\alpha$ for all $s\in S_x^-$. Then, if x is rejected, we have $S_x^+=S_x^-$ and so $\nu(s,S_x^+)=\nu(s,S_x^-)\geq\alpha$ for all $s\in S_x^+$. If x is accepted, then $S_x^+=S\backslash C_x+x$ and $f(x\mid S_x^-)\geq\alpha+(1+\beta)\sum_{e\in C_x}\nu(e,S_x^-)$. Thus,

$$\nu(x,S_x^+)\geq f(x\mid S_x^+-x)\geq f(x\mid S_x^-)\geq\alpha+(1+\beta)|C_x|\alpha\geq\alpha\,,$$

where the first inequality follows from property (2) of the lemma, the second from submodularity, and the third from the induction hypothesis and the assumption that x is accepted. For any other $s\in S_x^+$, we have $\{t'\in S\backslash C_x:t'\prec s\}\subseteq\{t'\in S:t'\prec s\}$ and so by property (3) of the lemma, $\nu(s,S_x^+)\geq\nu(s,S_x^-)\geq\alpha$, as required. ◀

In our analysis we will use the following structural lemma from Chekuri et al. [7] (here, restated in our notation). This lemma applies to the execution of our algorithm StreamingLocalSearch when $S_{\text{init}}=\emptyset$, and so no element is discarded upon arrival due to $x\in S_{\text{init}}$. However, we note that the execution of our algorithm is in fact exactly the same as this algorithm executed on the pretend stream ordering introduced in Section 2 to define the incremental values ν. Specifically, in each pass of our algorithm, the set S_{init} is a feasible solution produced by the preceding pass and in the pretend stream ordering, all elements of S_{init} arrive in our pretend ordering in the same relative (pretend) order as this preceding pass. It follows that whenever $x\in S_{\text{init}}$ arrives in our pretend ordering for the present pass, we have $C_x=\emptyset$ and $\nu(x,S)=\nu(x,S_{\text{init}})\geq\alpha$ by Lemma 1 (4), since x was present in the feasible solution $S=S_{\text{init}}$ at the end of the preceding pass. Thus, each $x\in S_{\text{init}}$ will first be accepted in our pretend stream ordering, and then the rest of $X\backslash S_{\text{init}}$ is processed, exactly as in StreamingLocalSearch.

Recall that we let $\tilde{A}$ be the set of all elements that were accepted by this pass of StreamingLocalSearch (and so at some point appeared in S). For each element $x\in X$, we let S_x^- be the current set S at the moment that x arrives and S_x^+ the set after x is processed. For an element e that is accepted but later *evicted* from S, let $\chi(e)$ be the incremental value $\nu(e,S)$ of e at the moment that e was evicted.

▶ **Lemma 10** (Lemma 9 of [7]). *Let $T\in\mathcal{I}$ be a feasible solution disjoint from $\tilde{A}$, and $\tilde{S}$ be the output of the streaming algorithm. There exists a mapping $\varphi:T\to 2^{\tilde{A}}$ such that:*

1. *Every $s \in \tilde{S}$ appears in the set $\varphi(t)$ for at most p choices of $t \in T$.*
2. *Every $e \in \tilde{A} \backslash \tilde{S}$ appears in the set $\varphi(t)$ for at most $p-1$ choices of $t \in T$.*
3. *For each $t \in T$:*

$$\sum_{c \in C_t} \nu(c, S_t^-) \leq \sum_{e \in \varphi(t) \backslash \tilde{S}} \chi(e) + \sum_{s \in \varphi(t) \cap \tilde{S}} \nu(s, \tilde{S}) \,.$$

Using this charging argument, we can now prove Lemma 2 directly.

▶ **Lemma 2.** *Let $f : 2^X \to \mathbb{R}_{\geq 0}$ be a submodular function. Suppose $\tilde{S}$ is the solution produced at the end of one pass of* StreamingLocalSearch *and $\tilde{A}$ be the set of all elements accepted during this pass. Then,*

$$f(OPT \cup \tilde{A}) \leq (p + \beta p - \beta) \sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e) + (p + \beta p + 1) f(\tilde{S}) + k\alpha \,.$$

Proof. Let $R = OPT \backslash \tilde{A}$. Since $S_r^- \subseteq \tilde{A}$ for all r, submodularity of f implies that

$$\sum_{r \in R} f(r \mid S_r^-) \geq \sum_{r \in R} f(r \mid \tilde{A}) \geq f(R \cup \tilde{A}) - f(\tilde{A}) = f(OPT \cup \tilde{A}) - f(\tilde{A}) \,. \tag{8}$$

For any $r \in R$, since r was rejected upon arrival,

$$f(r \mid S_r^-) \leq (1 + \beta) \sum_{c \in C_r} \nu(c, S_r^-) + \alpha \,. \tag{9}$$

Thus, applying Lemma 10 we obtain:

$$\begin{aligned}
\sum_{r \in R} f(r \mid S_r^-) &\leq (1+\beta) \sum_{r \in R} \sum_{c \in C_r} \nu(c, S_r^-) + k\alpha && \text{(by (9) and } |R| \leq k) \\
&\leq \sum_{r \in R} (1+\beta) \left[\sum_{e \in \varphi(r) \backslash \tilde{S}} \chi(e) + \sum_{s \in \varphi(r) \cap \tilde{S}} \nu(s, \tilde{S}) \right] + k\alpha && \text{(by Lemma 10 (3))} \\
&\leq (1+\beta) \left[(p-1) \sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e) + p \sum_{s \in \tilde{S}} \nu(s, \tilde{S}) \right] + k\alpha && \text{(by Lemma 10 (1) and (2))}
\end{aligned}$$

where in the last inequality we have also used Lemma 1 (4), which implies that each $\chi(e)$ and $\nu(s, \tilde{S})$ is non-negative. Combining the above inequality with (8), we obtain

$$f(OPT \cup \tilde{A}) \leq (1+\beta) \left[(p-1) \sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e) + p \sum_{s \in \tilde{S}} \nu(s, \tilde{S}) \right] + f(\tilde{A}) + k\alpha \,. \tag{10}$$

We now bound $f(\tilde{A})$ in terms of the values $\nu(s, \tilde{S})$ and $\chi(e)$. Since $S \subseteq \tilde{A}$ at all times during the algorithm, and $\chi(e) = \nu(e, S)$ at the moment e was evicted, we have $\chi(e) \geq \nu(e, \tilde{A})$ by Lemma 1 (2). Thus,

$$f(\tilde{A}) - f(\emptyset) = \sum_{a \in \tilde{A}} \nu(a, \tilde{A}) = \sum_{s \in \tilde{S}} \nu(s, \tilde{A}) + \sum_{e \in \tilde{A} \backslash \tilde{S}} \nu(e, \tilde{A}) \leq \sum_{s \in \tilde{S}} \nu(s, \tilde{S}) + \sum_{e \in \tilde{A} \backslash \tilde{S}} \chi(e) \,, \tag{11}$$

where the first equation follows from Lemma 1 (1), and the last inequality follows from Lemma 1 (2).

Combining (10) and (11) we have:

$$f(OPT \cup \tilde{A}) \leq ((1+\beta)(p-1)+1) \sum_{e \in \tilde{A} \setminus \tilde{S}} \chi(e) + ((1+\beta)p+1) \sum_{e \in \tilde{S}} \nu(s, \tilde{S}) + f(\emptyset) + k\alpha$$
$$= (p + p\beta - \beta) \sum_{e \in \tilde{A} \setminus \tilde{S}} \chi(e) + (p + \beta p + 1) \sum_{s \in \tilde{S}} \nu(s, \tilde{S}) + f(\emptyset) + k\alpha \,. \tag{12}$$

By Lemma 1 (1), we have the following bound for the second summation in (12):

$$(p + \beta p + 1) \sum_{e \in \tilde{S}} \nu(e, \tilde{S}) + f(\emptyset) = (p + \beta p + 1)[f(\tilde{S}) - f(\emptyset)] + f(\emptyset) \leq (p + \beta p + 1) f(\tilde{S}) \,.$$

Combining this and (12) we obtain:

$$f(OPT \cup \tilde{A}) \leq (p + p\beta - \beta) \sum_{e \in \tilde{A} \setminus \tilde{S}} \chi(e) + (p + \beta p + 1) f(\tilde{S}) + k\alpha$$ ◀

B Calculations for the proof of Theorem 7

We recall that

$$\gamma_i = \gamma_{i-1}\delta_i = \frac{4p\gamma_{i-1}(\gamma_{i-1}-1)}{(\gamma_{i-1}-1+p)^2} \,.$$

Then, to see that γ_i is an increasing function of γ_{i-1} for $p \geq 1$ and $\gamma_{i-1} \geq 1$, we note that:

$$\frac{d}{d\gamma_{i-1}}\gamma_i = \frac{4p(\gamma_{i-1}-1) + 4p\gamma_{i-1}}{(\gamma_{i-1}-1+p)^2} - \frac{8p\gamma_i(\gamma_{i-1}-1)}{(\gamma_{i-1}-1+p)^3}$$

$$= \frac{4p(\gamma_{i-1}-1)(\gamma_{i-1}-1+p) + 4p\gamma_i(\gamma_{i-1}-1+p) - 8p\gamma_{i-1}(\gamma_{i-1}-1)}{(\gamma_{i-1}-1+p)^3} \geq 0$$

Where the final inequality follows from $\gamma_{i-1} \geq 1$ and $p \geq 1$.

We now verify the following inequality used at the end of Theorem 7:

$$\frac{4p\left(p+1+\frac{4p}{i-1}\right)\left(p+\frac{4p}{i-1}\right)}{\left(2p+\frac{4p}{i-1}\right)^2} \leq p+1+\frac{4p}{i} \,.$$

Rearranging both sides and placing over a common denominator gives:

$$\frac{4p\left(p+1+\frac{4p}{i-1}\right)\left(p+\frac{4p}{i-1}\right)}{\left(2p+\frac{4p}{i-1}\right)^2} = \frac{4p\left((p+1)(i-1)+4p\right)\left(p(i-1)+4p\right)}{\left(2p(i-1)+4p\right)^2}$$
$$= \frac{4p\left((p+1)(i-1)+4p\right)\left(p(i-1)+4p\right)}{\left(2p(i+1)\right)^2}$$
$$= \frac{\left((i-1)(p+1)+4p\right)(i+3)}{(i+1)^2}$$
$$= \frac{(i-1)(i+3)i(p+1)+i(i+3)4p}{i(i+1)^2}$$
$$= \frac{\left(i^2+2i-3\right)i(p+1)+(i^2+3i)4p}{i(i+1)^2}$$

and

$$\begin{aligned} p+1+\tfrac{4p}{i} &= \frac{(p+1)i+4p}{i} \\ &= \frac{i(i+1)^2(p+1)+(i+1)^2 4p}{i(i+1)^2} \\ &= \frac{\left(i^2+2i+1\right)i(p+1)+\left(i^2+2i+1\right)4p}{i(i+1)^2}. \end{aligned}$$

Then, since $p \geq 1$ and $i \geq 1$,

$$\left(p+1+\tfrac{4p}{i}\right) - \frac{4p\left(p+1+\frac{4p}{i-1}\right)\left(p+\frac{4p}{i-1}\right)}{\left(2p+\frac{4p}{i-1}\right)^2} = \frac{4i(p+1)-4(i-1)p}{i(i+1)^2} \geq 0.$$

C Additional Details for the Non-Monotone Case

C.1 Guessing the value of $f(OPT)$

Guessing the value of $f(OPT)$ is a common technique in streaming submodular function maximization. Badanidiyuru et al. [1] showed how to approximate $f(OPT)$ within a constant factor using $O(\log(k))$ space in a single pass. To avoid extra complications, we show how to guess $f(OPT)$ in two passes and refer the reader to [1] for an approximation of $f(OPT)$ on the fly. Let $\tau = \max_{e \in X} f(e)$. Using submodularity, it is easy to see that $\tau \leq f(OPT) \leq k\tau$. Consider the set

$$\Lambda = \left\{2^i \mid i \in \mathbb{Z},\ \tau \leq 2^i \leq k \cdot \tau\right\}.$$

Then there exists a value $\lambda \in \Lambda$ such that $\frac{f(OPT)}{2} \leq \lambda \leq f(OPT)$. Setting the parameter $\alpha = \varepsilon\lambda/(2k)$, we get that $\alpha \in [\varepsilon f(OPT)/4k; \varepsilon f(OPT)/2k]$. The defined range of α is sufficient for the analysis[2]. Unfortunately, it is still not possible to know which $\lambda \in \Lambda$ satisfies the property. However, it suffices to run the randomized local-search algorithm for every $\lambda \in \Lambda$ in parallel and output the best solution of all the copies. This operation increases the space complexity by a multiplicative $O(\log_2 k)$ factor, and adds one additional pass to find τ.

C.2 Proof of Theorem 12

Here we give a full proof of the following theorem from Section 4:

▶ **Theorem 9.** *Let $\mathcal{M}^p = (X, \mathcal{I})$ be a p-matchoid of rank k and let $f\colon 2^X \to \mathbb{R}_{\geq 0}$ be a non-negative submodular function. Suppose there exists an algorithm for the offline instance of the problem with approximation factor $\bar{\gamma}_{\text{off}}$. For any $\varepsilon > 0$, the randomized streaming local-search algorithm returns a solution $\bar{S} \in \mathcal{I}$ such that*

$$f(OPT) \leq (p+1+\bar{\gamma}_{\text{off}}+O(\varepsilon))\,\mathbb{E}[f(\bar{S})]$$

using a total space of $O\left(\frac{p^3 k \log_2 k}{\varepsilon^3}\right)$ and $O\left(\frac{p}{\varepsilon}\right)$-passes.

[2] Equation (6) and the bound $\alpha k \leq \varepsilon f(OPT)$ are where we need the exact value of α, using upper and lower bounds for α yield the same result up to the hidden constant in the term $O(\epsilon)$.

In the same spirit as in Section 3, we show that we can derive a guarantee with respect to the solution $\mathbb{E}[f(S_i)]$ produced after the i^{th} pass even when the function is non-monotone. In fact, we show that the analysis of the non-monotone case reduces to the monotone case as shown in the following theorem.

▶ **Theorem 11.** *Let f be a non-negative submodular function. Assume $\alpha = \varepsilon f(OPT)/2k$ and let $d \geq i > 1$. Suppose that at the start of the i^{th} iteration of the randomized local-search algorithm with a buffer of size $m = 4dk/\varepsilon^2$ we have $(1-\varepsilon)f(OPT) \leq \gamma_{i-1}\,\mathbb{E}[f(S_{i-1})] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_{i-1})]$. Then,*

$$(1-\varepsilon)f(OPT) \leq \min\left\{\gamma_{i-1}\delta_i, \left(\frac{p}{\beta_i} + p - 1\right)(1-\delta_i) + p + \beta_i p + 1\right\} \cdot \mathbb{E}[f(S_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)],$$

where $\delta_i = \frac{\mathbb{E}[f(S_{i-1})]}{\mathbb{E}[f(S_i)]}$.

Proof. From the definition of γ_{i-1} and δ_i, it follows that,

$$(1-\varepsilon)f(OPT) \leq \gamma_{i-1}\,\mathbb{E}[f(S_{i-1})] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_{i-1})] \leq \gamma_{i-1}\delta_i\,\mathbb{E}[f(S_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)]\,. \quad (13)$$

where in the last inequality we have used the definition of δ_i and the fact that $f(S'_i) \geq f(S'_{i-1})$, which follows from the way S'_i is defined in Algorithm 3.

On the other hand, $\mathbb{E}[f(S_i)] - \mathbb{E}[f(S_{i-1})] = (1-\delta_i)\,\mathbb{E}[f(S_i)]$. Thus, by (7) we also have:

$$\begin{aligned}
&(1-\varepsilon)f(OPT)\\
&\quad\leq \left(\tfrac{p}{\beta_i} + p - 1\right)(\mathbb{E}[f(S_i)] - \mathbb{E}[f(S_{i-1})]) + (p + \beta p + 1)\,\mathbb{E}[f(S_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)]\\
&\quad= \left(\left(\tfrac{p}{\beta_i} + p - 1\right)(1-\delta_i) + p + \beta_i p + 1\right)\mathbb{E}[f(S_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)]\,. \qquad (14)
\end{aligned}$$

Since the right-hand side of equation 13 is an increasing function of δ_i and the right-hand side of equation 14 is a decreasing function of δ_i, the guarantee we obtain is always at least as good as that obtained when these two values are equal. ◀

As in the monotone case, the lemma enables us to derive values of β so as to minimize the value of the approximation ratio. The following follows directly from the same calculations as in Section 3 and Appendix B.

▶ **Theorem 12.** *Suppose we run Algorithm 3 with a buffer of size $m = 4dk/\varepsilon^2$ on a arbitrary p-matchoid constraint and a submodular function, with $\alpha = \varepsilon f(OPT)/2k$, $\beta_1 = 1$ and $\beta_i = \frac{\gamma_{i-1}-1-p}{\gamma_{i-1}-1+p}$ where γ_i is given by the recurrence, $\gamma_1 = 4p$ and $\gamma_i = \frac{4p\gamma_{i-1}(\gamma_{i-1}-1)}{(\gamma_{i-1}-1+p)^2}$. Then,*

$$(1-\varepsilon)f(OPT) \leq \left(p + 1 + \frac{4p}{i}\right)\mathbb{E}[f(\tilde{S}_i)] + \bar{\gamma}_{\text{off}}\,\mathbb{E}[f(S'_i)].$$

In particular after $d = \frac{4p}{\varepsilon}$ passes,

$$(1-\varepsilon)f(OPT) \leq (p + 1 + \bar{\gamma}_{\text{off}} + \varepsilon)\,\mathbb{E}[f(\bar{S}_d)]\,.$$

Under a matroid constraint, Algorithm 3 with $\alpha = \varepsilon f(OPT)/2k$, $\beta_i = 1/i$ and $d = 2\varepsilon^{-1}$ passes outputs a solution $\bar{S}$ such that,

$$(1-\varepsilon)f(OPT) \leq (2 + \bar{\gamma}_{\text{off}} + \varepsilon)\,\mathbb{E}[f(\bar{S})]\,,$$

where $\bar{\gamma}_{\text{off}}$ is the approximation ration of the best offline algorithm for maximizing f under a matroid constraint.

We are now ready to complete the proof of Theorem 9. We assume that we know the value of $f(OPT)$ before hand, which can be accomplished approximately as in Section C.1. Let $\varepsilon' = \varepsilon/p$ with $1/2 \geq \varepsilon' > 0$ and let $\alpha = \varepsilon' f(OPT)/2k$. We want to obtain an additive error term instead of a multiplicative error term as stated in Theorem 12. By Theorem 12,

$$(1-\varepsilon')f(OPT) \leq \left(p+1+\bar{\gamma}_{\text{off}}+\frac{4p}{d}\right)\mathbb{E}[f(\bar{S}_d)] = (p+1+\bar{\gamma}_{\text{off}})\left(1+O\left(d^{-1}\right)\right)\mathbb{E}[f(\bar{S}_d)]\,.$$

Using the fact that $(1-\varepsilon')^{-1} \leq 1+2\varepsilon'$ for $\varepsilon' \in (0, 1/2]$, we get that,

$$f(OPT) \leq (p+1+\bar{\gamma}_{\text{off}})\left(1+O\left(d^{-1}\right)\right)(1+2\varepsilon')\,\mathbb{E}[f(\bar{S}_d)]\,. \tag{15}$$

Since $\varepsilon' = \varepsilon/p$, setting $d = O(p/\varepsilon)$ we finally obtain the desired result:

$$f(OPT) \leq (p+1+\bar{\gamma}_{\text{off}})(1+O(\varepsilon/p))(1+2\varepsilon/p)\,\mathbb{E}[f(\bar{S}_d)] \leq (p+1+\bar{\gamma}_{\text{off}}+O(\varepsilon))\,\mathbb{E}[f(\bar{S}_d)].$$

For the space complexity, we note that the randomized local-search algorithm stores the buffer B and maintains two past solutions $S_i, S_i' \in \mathcal{I}$, together with the current solution $S \in \mathcal{I}$. Hence, the total space needed is equal to $O(|B| + |S_i'| + |S_i| + |S|) = O(m+3k) = O\left(p^3 k \varepsilon^{-3}\right)$, times an additional factor of $O(\log k)$ for guessing $f(OPT)$. The number of passes is $d = O(p/\varepsilon)$.

Polylogarithmic Approximation Algorithm for k-Connected Directed Steiner Tree on Quasi-Bipartite Graphs

Abstract

In the k-Connected Directed Steiner Tree problem (k-DST), we are given a directed graph $G = (V, E)$ with edge (or vertex) costs, a root vertex r, a set of q terminals T, and a connectivity requirement $k > 0$; the goal is to find a minimum-cost subgraph H of G such that H has k edge-disjoint paths from the root r to each terminal in T. The k-DST problem is a natural generalization of the classical Directed Steiner Tree problem (DST) in the fault-tolerant setting in which the solution subgraph is required to have an r, t-path, for every terminal t, even after removing $k - 1$ vertices or edges. Despite being a classical problem, there are not many positive results on the problem, especially for the case $k \geq 3$. In this paper, we present an $O(\log k \log q)$-approximation algorithm for k-DST when an input graph is quasi-bipartite, i.e., when there is no edge joining two non-terminal vertices. To the best of our knowledge, our algorithm is the only known non-trivial approximation algorithm for k-DST, for $k \geq 3$, that runs in polynomial-time Our algorithm is tight for every constant k, due to the hardness result inherited from the Set Cover problem.

1 Introduction

Designing a network that can operate under failure conditions is an important task for Computer Networking in both theory and practice. Many models have been proposed to capture this problem, giving rise to the area of survivable and fault-tolerant network design. In the past few decades, there have been intensive studies on the survivable network design problems; see, e.g., [55, 30, 35, 20, 14, 46, 32]. The case of link-failure is modeled by the *Edge-Connectivity Survivable Network Design* problem (EC-SNDP), which is shown to admit a 2-approximation algorithm by Jain [35]. The case of node-failure is modeled by the *Vertex-Connectivity Survivable Network Design* problem (VC-SNDP), which is shown to admit a polylogarithmic approximation algorithm by Chuzhoy and Khanna [14]. Nevertheless, most of the known algorithmic results pertain to only undirected graphs, where each link has no prespecified direction. In the directed case, only a few results are known as the general case of Survivable Network Design is at least as hard as the *Label-Cover* problem [16], which is believed to admit no sub-polynomial approximation algorithm [44, 2].

This paper studies the special case of the Survivable Network Design problem on directed graphs, namely the *k-Connected Directed Steiner Tree* problem (k-DST), which is also known as the *Directed Root k-Connectivity*. In this problem, we are given an n-vertex directed graph $G = (V, E)$ with edge-costs $c : E \to \mathbb{R}_0^+$, a root vertex r, a set of q terminals $T \subseteq V - \{r\}$ and a connectivity requirement $k \in \mathbb{Z}^+$; the goal is to find a minimum-cost subgraph $H \subseteq G$ that has k edge-disjoint[1] r, t-paths for every terminal $t \in T$. This problem was mentioned in [19] and have been subsequently studied in [12, 41, 8, 43, 32]. The only known non-trivial approximation algorithms for k-DST is for the case $k = 2$ due to the work of Grandoni and Laekhanukit [32], and for the case of γ-shallow instances due to the work of Laekhanukit [43]. To the best of our knowledge, for $k \geq 3$, there were only a couple of positive results on k-DST: (1) Laekhanukit [43] devised an approximation algorithm whose running time and approximation ratios depend on the diameter of the optimal solution, and (2) Chalermsook, Grandoni and Laekhanukit [8] devised a bi-criteria approximation algorithm for a special case of k-DST, namely the *k-Edge-Connected Group Steiner Tree* (k-GST), where the solution subgraph is guaranteed to be an $O(\log^2 n \log k)$-approximate solution, whereas the connectivity is only guaranteed to be at least $\Omega(k/\log n)$. We focus on the case of k-DST where an input graph is *quasi-bipartite*, i.e., there is no edge joining any pair of non-terminal (Steiner) vertices, which generalizes the works of Hibi and Fujito [34], and Friggstad, Könemann and Shadravan [26] for the classical *directed Steiner tree* problem (the case $k = 1$).

The main contribution of this paper is an $O(\log q \log k)$-approximation algorithm for k-DST on quasi-bipartite graphs, which runs in polynomial-time regardless of the structure of the optimal solution. Our result can be considered the first true polylogarithmic approximation algorithm whose running time is independent of the structure (i.e., diameter) of the optimal solution, albeit the algorithm is restricted to the class of quasi-bipartite graphs. Our technique is different from all the previous works on k-DST [32, 43, 8]; all these results rely on the tree-rounding algorithm for the *Group Steiner Tree* problem by Garg, Konjevod and Ravi [27], and thus require either an LP whose support is a tree or a tree-embedding technique (e.g., Räcke's decomposition [50] as used in [8]). Our algorithm, on the other hand, employs the *Halo-Set decomposition* devised by Kortsarz and Nutov [39] and further developed in a series

[1] While we define the problem here as an edge-connectivity problem, our algorithm itself works for both edge and vertex connectivity variants, and can handle both edge and vertex costs.

of works [17, 11, 46, 48, 42, 47]. It is worth noting that the families of subsets decomposed from our algorithm are not uncrossable. We circumvent this difficulty by reducing it to the *Set Cover* problem. Our algorithm can be seen as a variant of the *spider decomposition* method developed by Klein and Ravi [36], and Nutov [45].

Lastly, we remark that it was discussed in [32] that the tree-embedding approach reaches the barrier as soon as $k > 2$, and this holds even for quasi-bipartite graphs. Please see Appendix B for discussions. While our algorithm exploits the structure of quasi-bipartite graphs, we hope that our technique using the Halo-Set decomposition would be an alternative method that sheds some light on developing approximation algorithms for the general case of k-DST for $k > 2$.

1.1 Related Works

Directed Steiner tree has been a central problem in combinatorial optimization. There have been a series of work studying this problem; see, e.g., [56, 9, 54, 25, 33, 29]. The best approximation ratio of $O(q^\epsilon)$, for any $\epsilon < 0$, in the regime of polynomial-time algorithms, is known in the early work of Charikar et al. [9][2], which leads to an $O(\log^3 q)$-approximation algorithm that runs in quasi-polynomial-time. Very recently, Grandoni, Laekhanukit and Li [33] developed a framework that gives a quasi-polynomial-time $O(\log^2 q/\log\log q)$-approximation algorithm for the Directed Steiner Tree problem, and this approximation ratio is the best possible for quasi-polynomial-time algorithms, assuming the *Projection Games Conjecture* and $\text{NP} \subseteq \bigcup_{\delta>0} \text{ZPTIME}(2^{n^\delta})$. The same approximation ratio was obtained in an independent work of Ghuge and Nagarajan [29].

The study of Steiner tree problems on quasi-bipartite graphs was initiated by Rajagopalan and Vazirani [51] in order to understand the bidirected-cut relaxation of the (undirected) *Steiner tree* problem. Since then the special case of quasi-bipartite graphs has played a central role in studying the Steiner tree problem; see, e.g., [52, 6, 53, 37, 5, 31]. For the case of directed graphs, Hibi and Fujito [34], Friggstad, Könemann and Shadravan [26] independently discovered $O(\log n)$-approximation algorithms for the directed Steiner tree problem on quasi-bipartite graphs. Assuming $\text{P} \neq \text{NP}$, this matches to the lower bound of $(1-\epsilon)\ln n$, for any $\epsilon > 0$, inherited from the Set Cover problem [18, 15].

The generalization of the Steiner tree problem is known as the Survivable Network Design problem, which has been studied in both edge-connectivity [55, 30, 35], vertex-connectivity [14] and element-connectivity [20] settings. The edge and element connectivity Survivable Network Design problems admit factor 2 approximation algorithms via the iterative rounding method, while the vertex-connectivity variant admits no polylogarithmic approximation algorithm [38, 7, 41] unless $\text{NP} \subseteq \text{DTIME}(n^{\text{polylog}(n)})$. To date, the best approximation ratio known for the Vertex-Connectivity Survivable Network problem is $O(k^3 \log n)$ due to the work of Chuzhoy and Khanna [14]. The single-source k-vertex-connectivity variant, which is closely related to the problem considered in this paper, has been studied in [7, 13, 10, 46, 49], culminating in the best approximation ratio of $O(k \log k)$ due to Nutov [46].

In vertex-connectivity network design, one of the most common techniques is the Halo-Set decomposition method, which has been developed in a series of works [39, 17, 11, 48]. The main idea is to use the number of minimal deficient sets as a notion of progress. Here a deficient set is a subset of vertices that needs at least one incoming edge to satisfy the connectivity requirement. The minimal deficient sets in [39, 17, 11, 48], called cores, are

[2] The same result can be obtained by applying the algorithm by Kortsarz and Peleg in [40]

independent and have only polynomial number, while the total number of deficient sets is exponential on the number of vertices. The families of deficient sets defined by these cores allow us to keep track of how many deficient sets remain in a solution subgraph. The early version of this method can be traced back to the seminal result of Frank [22] and that of Frank and Jordan [23]; please see [24] for reference therein.

The spider decomposition method was introduced by Klein and Ravi [36] to handle the *Vertex-Weighted Steiner Tree* problem. This technique gives a tight approximation result (up to constant factor) to the problem. Later, Nutov generalized the technique to deal with the *Minimum Power-Cover* problems [45] and subsequently for the *Vertex-Weighted Element-Connectivity Survivable Network Design* problem [46].

1.2 Our Result

The main result in our paper is an $O(\log q \log k)$-approximation algorithm for k-DST on quasi-bipartite graphs. To keep the flow, our algorithm is presented as a randomized algorithm. The derandomization is provided in Appendix A. Since our algorithm is LP-based, it also gives an upper bound on the integrality gap of the standard LP-relaxation.

▶ **Theorem 1.** *Consider the k-Connected Directed Steiner Tree problem where an input graph consists of an n-vertex quasi-bipartite graph and a set of q terminals. There exists a polynomial-time $O(\log q \log k)$-approximation algorithm. Moreover, the algorithm gives an upper bound on the integrality gap of $O(\log q \log k)$ for the standard cut-based LP-relaxation of the problem.*

2 Preliminaries

We use standard graph terminologies. Given a graph G, we denote by $V(G)$ and $E(G)$ the vertex set and edge set of G, respectively. For any subset of vertices $U \subseteq V(G)$, we denote by $\delta^{in}_G(U)$ the set of edges in G entering the set U and denote by $\deg^{in}_G(U)$ its cardinality. We denote by $E_G(U)$ the set of edges that have both head and tail in U. That is,

$$\delta^{in}_G(U) = \{wv \in E(G) : v \in U, w \notin U\}, \quad \deg^{in}_G(U) = |\delta^{in}_G(U)|, \quad \text{and}$$
$$E_G(U) = \{vw \in E(G) : v, w \in U\}.$$

We will omit the subscript G if the graph G is known in the context, and we may replace E_G with another edge-set, e.g., E_+. Then, for any subset of edges E', we denote the total cost of edges in E' by $\mathsf{cost}(E') = \sum_{e \in E'} c_e$.

2.1 Problem Definitions

k-Edge-Connected Directed Steiner Tree (k-DST)

In the *k-Edge-Connected Directed Steiner Tree* problem (k-DST), we are given a graph G with non-negative edge-costs $c : E \longrightarrow \mathbb{R}^+_0$, a root vertex r and a set of q terminals $T \subseteq (V(G) - \{r\})$, and the goal is to find a minimum-cost subgraph $H \subseteq G$ such that H has k edge-disjoint $r \to t$-paths for every terminal $t \in T$.

Rooted Connectivity Augmentation (Rooted-Aug)

In Rooted-Aug, we are given a graph G with the edge-set $E(G) = E_0 \cup E_+$, where E_0 is the set of zero-cost edges and E_+ is the set of positive-cost edges, a root vertex r and a set of terminals $T \subseteq V(G) - r$ such that E_0 induces a subgraph $G_0 \subseteq G$ that has ℓ edge-disjoint

$r \to t$-paths for every terminal $t \in T$. The goal in this problem is to find a minimum-cost subset of edges $E' \subseteq E_+$ such that $E_0 \cup E'$ induces a subgraph $H \subseteq G$ that has $\ell + 1$ edge-disjoint $r \to t$-paths for every terminal $t \in T$.

We may phrase Rooted-Aug as a problem of covering deficient sets as follows. We say that a subset of vertices $U \subseteq V(G)$ is a *deficient set* if U separates the root vertex r and some terminal $t \in T$, but U has less than $\ell + 1$ incoming edges (which means that U has exactly ℓ incoming edges); that is, U is a deficient set if $r \notin U$, $U \cap T \neq \emptyset$ and $\deg^{in}_{G_0}(U) = \ell$. These subsets of vertices need at least one incoming edge to satisfy the connectivity requirement. We say that an edge $e \in E_+$ *covers* a deficient set U if $\deg^{in}_{E_0 \cup \{e\}}(U) \geq \ell$, which means that adding e to G_0 satisfies the connectivity requirement on U.

Let $\mathcal{F}$ denote the set of all deficient sets in the graph G_0. Then Rooted-Aug may be phrased as the problem of finding a minimum-cost subset of edges $E' \subseteq E_+$ that covers all the deficient sets, which can be described by the following optimization problem:

$$\min\{E' \subseteq E_+ : \deg^{in}_{E'}(U) \geq 1 \ \forall U \in \mathcal{F}\}.$$

Set Cover

Given a universe $\mathcal{U}$ of n elements and a collection of m subsets $S_1, \ldots, S_m \subseteq \mathcal{U}$, each associated with weight w_j, for $j = 1, \ldots, m$, the goal in the Set Cover problem is to find a collection $\mathcal{S}^*$ of subsets with minimum total weights so that the union of all subsets in $\mathcal{S}^*$ is equal to $\mathcal{U}$.

2.2 Deficient Sets, Cores and Halo-families

This section discusses subsets of vertices called deficient sets that certify that the current solution subgraph in Rooted-Aug (and also in k-DST) does not meet the connectivity requirement. To be formal, a subset of vertices $U \subseteq V(G)$ is called a *deficient set* in the graph G if $T \cap U \neq \emptyset$, $r \notin U$ and $\deg^{in}_G(U) < k$; that is, $(V(G) - U, U)$ induces an edge-cut of size $< k$ that separates some terminal $t \in U \cap T$ from the root vertex r. We say that an edge $vw \notin E(G)$ *covers* a deficient set U if $\deg^{in}_{G+vw}(U) \geq k$, i.e., the set U is not a deficient set after adding the edge vw. Similarly, we say that a subset of edges E' covers a deficient set or a collection of deficient sets $\mathcal{F}$ if $\deg^{in}_{G+E'}(U) \geq k$, for every deficient set $U \in \mathcal{F}$.

Let $\mathcal{F}$ be a family of deficient sets. A *core* $C \in \mathcal{F}$ is a deficient set such that there is no deficient set in $\mathcal{F}$ properly contained in C. The *Halo-family* $\mathsf{Halo}(C)$ of a core C is the collection of all deficient sets in $\mathcal{F}$ that contain C but no other core $C' \neq C$. The *Halo-set* $H(C)$ of C is the union of all the deficient sets in $\mathsf{Halo}(C)$, i.e., $H(C) = \bigcup_{U \in \mathsf{Halo}(C)} U$.

2.3 LP-relaxations

Throughout this paper, we will use the following standard (cut-based) LP-relaxation for k-DST and Rooted-Aug. Our LP-relaxations will be written in terms of deficient sets. We denote by $\mathsf{Val}(z)$ the cost of the optimal solution to an LP z.

LP for k-DST

Here we present the standard cut-based LP-relaxation for k-DST, denoted by $\mathsf{LP}(k)$. The collection of deficient sets in this LP is defined by $\mathcal{F}(k) = \{U \subseteq V - \{r\} : U \cap T \neq \emptyset\}$.

$$\mathsf{LP}(k) = \begin{cases} \min & \sum_{e \in E} c_e x_e & \\ \text{s.t.} & & \\ & \sum_{e \in \delta^{in}_G(U)} x_e \geq k & \forall U \in \mathcal{F}(k) \\ & 0 \leq x_e \leq 1 & \forall e \in E(G) \end{cases}$$

LP for Rooted-Connectivity Augmentation

Here we assume that the initial graph G_0 is already ℓ-rooted-connected, and the goal is to add edges to increase the connectivity of the solution subgraph by one. Thus, the collection of deficient sets in this problem is defined by $\mathcal{F}(\ell) = \{U \subseteq V : U \cap T \neq \emptyset, \deg^{in}_{G_0}(U)| = \ell\}$. Below is the standard cut-based LP-relaxation for the problem of increasing the rooted-connectivity of a graph by one.

$$\mathsf{LP}^{aug}(\ell) = \begin{cases} \min & \sum_{E(G)-E(G_0)} c_e x_e \\ \text{s.t.} & \\ & \sum_{e \in \delta^{in}_{E(G)-E(G_0)}(U)} x_e \geq 1 \quad \forall U \in \mathcal{F}(\ell) \\ & 0 \leq x_e \leq 1 \qquad\qquad\quad \forall e \in E(G) - E(G_0) \end{cases}$$

3 Properties of Deficient Sets in Rooted Connectivity Augmentation

This section presents the basic properties of deficient sets, cores and Halo-families in a Rooted-Aug instance, which will be used in the analysis of our algorithm. Readers who are familiar with these properties may skip this section. Similar lemmas and proofs can be seen, e.g., in [11]. Our proofs are rather standard. The readers who are familiar with these properties may skip to the next section.

The first property is the uncrossing lemma for deficient sets of Rooted-Aug.

▶ **Lemma 2** (Uncrossing Properties). *Consider an instance of Rooted-Aug. Let G_0 be a rooted ℓ-connected graph, and let A, B be deficient sets in G_0 that have a common terminal, i.e., $A \cap B \cap T \neq \emptyset$. Then both $A \cup B$ and $A \cap B$ are deficient sets.*

Proof. We prove the lemma by using Menger's theorem and the submodularity of the indegree function $\deg^{in}$. First, since G_0 is rooted ℓ-connected, we know from Menger's Theorem that $\deg^{in}(A)$ and $\deg^{in}(B) = \ell$. We also know that $\deg^{in}(A \cup B) \geq \ell$ and $\deg^{in}(A \cap B) \geq \ell$ because the root r is not contained in either A or B and that $A \cap B \cap T \neq \emptyset$. By the submodularity of $\deg^{in}$, it holds that

$$2\ell = \deg^{in}(A) + \deg^{in}(B) \geq \deg^{in}(A \cup B) + \deg^{in}(A \cap B) \geq 2\ell.$$

Therefore, $\deg^{in}(A \cup B) = \deg^{in}(A \cap B) = \ell$, implying that both $A \cup B$ and $A \cap B$ are deficient sets in the Rooted-Aug instance. ◀

The next lemma gives an important property of the cores arose from deficient sets in directed graphs; that is, two cores may have non-empty intersection on Steiner vertices, but they are disjoint on terminal vertices.

▶ **Lemma 3** (Members of Two Halo-families are Terminal Disjoint). *Let C and C' be two distinct cores. Then, for any deficient sets $U \in \mathsf{Halo}(C)$ and $U' \in \mathsf{Halo}(C)$, it holds that $U \cap U' \cap T = \emptyset$, i.e., any members of two distinct Halo-families have no common terminals.*

Proof. We prove the lemma by contradiction. Let U and U' be deficient sets $U \in \mathsf{Halo}(C)$ and $U' \in \mathsf{Halo}(C)$ such that U and U' share a terminal $t \in U \cap U' \cap T$. We may assume that U and U' are minimal such sets, i.e., there are no deficient sets $W \in \mathsf{Halo}(C)$ and $W' \in \mathsf{Halo}(C)$ such that (1) W is properly contained in U, (2) W' is properly contained in U' and (3) $t \in W \cap W'$. By Lemma 2, $U \cap U'$ must be a deficient set properly contained in both U and U' (because $C \neq C'$). This contradicts the minimality of U and U'. ◀

Then we combine Lemma 3 and that there is no edge joining any pair of Steiner vertices in quasi-bipartite graphs, we have the Internally Edge-Disjoint Lemma.

▶ **Lemma 4** (Internally Edge-Disjoint). *Consider a quasi-bipartite graph G. For any edge $e \in E(G)$, there is at most one core $C \in \mathcal{C}$ such that $e \in E(H(C))$.*

Proof. Consider any edge $uv \in E(G)$. Since G is a quasi-bipartite graph, one of u and v must be a terminal. By Lemma 3, we know that there can be at most one Halo-family $\mathsf{Halo}(C)$, for some $C \in \mathcal{C}$, whose member contains both u and v. Hence, the lemma follows. ◀

The next lemma shows that both the union and the intersection of any two deficient sets in a Halo-family $\mathsf{Halo}(C)$ are also deficient sets in $\mathsf{Halo}(C)$. This is a crucial property for computing the halo-set $H(C)$ as we are unable to list all the deficient sets in a Halo-family.

▶ **Lemma 5** (Union and Intersection of Halo-Family Members). *Let $\mathcal{F}$ be a family of all deficient sets in G_0, and let C be any core w.r.t. $\mathcal{F}$. Then, for any two deficient sets $A, B \in \mathsf{Halo}(C)$, both $A \cap B$ and $A \cup B$ are also deficient sets in $\mathsf{Halo}(C)$.*

Proof. Consider any deficient sets $A, B \in \mathsf{Halo}(C)$. Since both A and B contain C, they share at least one terminal. Thus, Lemma 2 implies that both $A \cup B$ and $A \cap B$ are deficient sets. Clearly, $A \cap B$ contains C and no other core $C' \neq C$. Thus, $A \cap B$ is a member of $\mathsf{Halo}(C)$.

Next consider $A \cup B$. Assume for a contradiction that $A \cup B$ is not a member of $\mathsf{Halo}(C)$. Then $A \cup B$ must contain a core $C' \neq C$. This means that at least one of the sets, say A, contains some terminal $t \in C'$. By Lemma 2, since A and C' have a common terminal, it holds that $A \cap C'$ is a deficient set. Since $C' \subsetneq A$ (because A is a member of $\mathsf{Halo}(C)$), we have that $A \cap C'$ is a deficient set that is strictly contained in C', a contradiction. ◀

It follows as a corollary that $H(C) = \bigcup_{U \in \mathsf{Halo}(C)} U$ is a also deficient set in $\mathsf{Halo}(C)$.

▶ **Corollary 6** (Halo-set is deficient). *Let $\mathcal{F}$ be a family of all deficient sets in G_0, and let C be any core w.r.t. $\mathcal{F}$. Then the Halo-set $H(C) = \bigcup_{U \in \mathsf{Halo}(C)} U$ is also a deficient set in $\mathsf{Halo}(C)$.*

Corollary 6 implies that $H(C)$ can be computed in polynomial-time using an efficient maximum-flow algorithm. Such an algorithm can be seen in [11].

▶ **Corollary 7.** *For any core C, its Halo-set $H(C) = \bigcup_{U \in \mathsf{Halo}(\mathcal{C})} U$ can be computed in polynomial-time.*

4 Our Algorithm and Its Overview

This section provides the overview of our algorithm, which is based on the *connectivity augmentation* framework plus the Halo-set decomposition method. To be specific, our algorithm starts with an empty graph called $H_0 = (V, \emptyset)$. Then we add edges from G to the graph H_0 to form a graph H_1 that has at least one path from the root vertex r to each terminal $t \in T$. We keep repeating the process, which produces graphs $H_2, \ldots, H_k$ such that each graph H_ℓ, for $\ell \in [k]$, has ℓ edge-disjoint r,t-paths for every terminal $t \in S$. In each iteration $\ell \in [k]$, we increase the rooted-connectivity of a graph by one using the Halo-set decomposition method.

We discuss the connectivity augmentation framework in Section 4.1 and discuss the algorithm based on the Halo-set decomposition method for Rooted-Aug in Section 4.2. We devote Section 5 to present a key subroutine for solving the the problem of *covering Halo-families* via a reduction to the Set Cover problem.

4.1 Connectivity Augmentation Framework

A straightforward analysis of the connectivity augmentation framework incurs a factor k in the approximation ratio. Nevertheless, provided that the approximation algorithm for Rooted-Aug is based on the standard LP for k-DST, the cost incurred by this framework is only $\sum_{\ell=1}^{k} 1/(k-\ell+1) = O(\log k)$. This is known as the *LP-scaling technique*, which has been used many times in literature; see, e.g., [30, 39, 12].

▶ **Lemma 8** (LP-Scaling). *Consider an instance of the k-DST problem, and its corresponding LP, namely $\mathsf{LP}(k)$. Suppose there exists an algorithm that produces an integer solution to $\mathsf{LP}^{aug}(\ell)$ with costs at most $\alpha_\ell \cdot \mathsf{Val}(\mathsf{LP}^{aug}(\ell))$. Then there exists an $\sum_{\ell=1}^{k} \alpha_\ell/(k-\ell+1) = O(\alpha \log k)$ approximation algorithm for k-DST, where $\alpha = \max_{\ell=1}^{k} \alpha_\ell$.*

Proof. Let G be the input graph in the k-DST instance. Let H^* be an optimal integral solution to k-DST (and thus $\mathsf{LP}(k)$), and let $G_0 \subseteq G$ be the initial solution subgraph of Rooted-Aug where we wish to increase the connectivity of G_0 from ℓ to $\ell+1$ by adding edges from $E(G) - E(G_0)$. Then we can define the following LP solution $\{x_e\}_{e \in E(G)}$ to $\mathsf{LP}^{aug}(\ell)$:

$$x_e = \begin{cases} \frac{1}{k-\ell} & \text{if } e \in E(H^*) - E(G_0) \\ 0 & \text{otherwise.} \end{cases}$$

Let $\mathcal{F}$ be the family of deficient sets in the Rooted-Aug instance. Then we know by Menger's theorem that any deficient set $U \in \mathcal{F}$ has at least k incoming edges in H^*, and at most ℓ of them are in G_0 (because $\deg^{in}_{G_0}(U) = \ell$ by the definition of the deficient set). Consequently, we have

$$\sum_{e \in \delta^{in}_{E(G)-E(G_0)}(U)} x_e \geq (k-\ell) \cdot \frac{1}{k-\ell} = 1.$$

This means that $\{x_e\}_{e \in E(G)-E(G_0)}$ is a feasible solution to $\mathsf{LP}^{aug}(\ell)$ whose cost is at most $(1/(k-\ell))\mathsf{Val}(\mathsf{LP}(k))$. The lemma then follows by taking the summation over all $\ell = 0, 1, \ldots, k-1$. ◀

4.2 Algorithm for Rooted-Aug via Halo-set Decomposition

The algorithm for rooted-connectivity augmentation is built on the Halo-set Decomposition framework. In detail, we decompose vertices in the graph G_0 into a collection of subsets of vertices, each is defined by a Halo-family $\mathsf{Halo}(C)$, which is in turn defined by its core C. Then we add edges to cover all the deficients that are contained in any of these families. However, the collection of Halo-families does not include all the deficient sets in the graph because a deficient set that contain two distinct cores are not recorgnized by any Halo-families. Thus, after we cover all these Halo-families (i.e., we add edges covering all its members), we need to recompute the deficient sets remaining in the graph and form the system of Halo-families again.

Following the above method, our algorithm runs in multiple iterations. In each iteration, we first compute all the cores and their corresponding Halo-set in the current solution subgraph, which can be done in polynomial time. (We recall that it is not possible to compute a Halo-family explicitly because it may contain exponential number of deficient sets.) These cores define a collection of Halo-families. Our goal is then to find a subset of edges E' that covers Halo-families in this collection. To be formal, by *covering a Halo-family*, we mean that we find a subset of edges that covers every deficient set in its family. Here

our algorithm departs from the previous application of the Halo-set decomposition as we are not aiming to cover all the Halo-families. We cover only a constant fraction of Halo-families from the collection, which is sufficient for our purposes. Once we found the subset of edges E', we add it to the solution subgraph and recompute the cores and their Halo-sets.

To find a set of edges E', we need to compute an optimal solution to the LP for augmenting the connectivity of a graph from ℓ to $\ell+1$ (i.e., $\mathsf{LP}^{aug}(\ell)$), denoted by $\{x_e\}_{e\in E_+}$, where E_+ is the set of edges not in the initial solution subgraph H_ℓ, which is ℓ-rooted-connected. Using this LP-solution, we can find a set of edges E' that covers at least $1/9$ fraction of the collection of Halo-families whose cost is at most $4\sum_{e\in E_+} c_e x_e$ via a reduction to the Set Cover problem. This subroutine is presented in Section 5. Note that the mentioned subroutine is a randomized algorithm that has a constant success probability; thus, we may need to run the algorithm for $O(\log n)$ times to guarantee that it successes with high probability. The derandomization of our subroutine is presented in Appendix A. Our algorithm for the rooted-connectivity augmentation is presented in Algorithm 1.

Algorithm 1 Rooted-Connectivity Augmentation.

Require: : An input graph G and an ℓ-rooted-connected graph H_ℓ
Ensure: : An $(\ell+1)$-rooted-connected graph $H_{\ell+1}$
1: Initialize $H_{\ell+1} := H_\ell$.
2: **repeat**
3: Find an optimal solution $\mathbf{x}$ to $\mathsf{LP}^{aug}(\ell)$.
4: Compute cores and their corresponding Halo-sets in $H_{\ell+1}$.
5: Find a subset of edges E' that covers at least $1/9$ fraction of the Halo-families whose cost is at most $4\sum_{e\in E_+} c_e x_e$.
6: Update $H_{\ell+1} := H_{\ell+1} + E'$.
7: **until** The graph $H_{\ell+1}$ has no deficient set (and thus has no core).
8: **return** $H_{\ell+1}$

One may observe that the covering problem in our setting is different from that in the usual Set Cover problem as after we add edges to cover γ fraction of the Halo-families, it is not guaranteed that the number of Halo-families will be decreased by a factor γ. This is because some of the deficient sets in the previous iterations may become new cores in the solution subgraph. Fortunately, we have a key property that any new core that was not contained in any Halo-families must contain at least two old cores. As a result, we can promise a factor $(1-\gamma/2)$ decrease. Please see Figure 1 for illustration. The subsets C_1 and C_2 are two cores covered by e_1 and e_2, respectively. After adding two edges, C_1 and C_2 are no longer a deficient set. Now the deficient set $C_3 \supseteq C_1 \bigcup C_2$ becomes a new core, which contains two old cores.

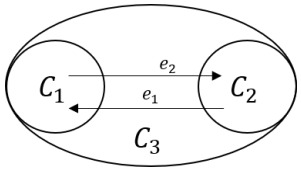

Figure 1 After adding edges e_1 and e_2 to cover C_1, C_2, a new core C_3 appear. The new core C_3 must contain at least two old cores.

▶ **Lemma 9** (The number of cores decreases by a constant factor). *Let H be the current solution subgraph whose number of cores is ν, and let E' be a set of edges that covers at least γ fraction of the Halo-families in H. Then the number of cores in $H \cup E'$ is at most $(1-\gamma/2)\nu$. In particular, the number of cores in the graph $H \cup E'$ decreases by a constant factor, provided that γ is a constant.*

Proof. Let us count the number of cores in the graph $H \cup E'$. Consider any core C in $H \cup E'$. If C is a member of some Halo-families $\mathsf{Halo}(C')$ in H, then we know that $\mathsf{Halo}(C')$ is not covered by E'. Thus, there can be at most $(1-\gamma)\nu$ cores of this type.

Next assume, otherwise, that C is not a member of any Halo-family in H. Then, by definition, C must contain at least two cores in H. Notice that, for every core C' in H that is contained in C, all of the deficients in $\mathsf{Halo}(C')$ must be covered by E'. Suppose not. Then there exists a deficient set U in $\mathsf{Halo}(C')$ that is not covered by E'. Since U interesects C on the terminal set, Lemma 2 implies that $U \cap C$ is also a deficient set. By Lemma 3, any two cores are disjoint on the terminal set, which means that $U \cap C$ is strictly contained in C (because C contains another core C'' distinct from C'). The existence of $U \cap C$ contradicts the fact that C is a core in $H \cup E'$. Thus, we conclude that $H \cup E'$ has at most $(\gamma/2)\nu$ cores of this type.

Summing it up, the total number of cores in $H \cup E'$ is at most $(1-\gamma/2)\nu$ as claimed. ◀

It follows as a corollary that our algorithm terminates within $O(\log q)$ iterations.

▶ **Corollary 10.** *The number of iterations of our algorithm is at most $O(\log q)$, where q is the number of terminals.*

By Corollary 10, our algorithm for rooted-connectivity augmentation terminates with in $O(\log q)$, and each round, we buy a set of edges whose cost is at most $4\sum_{e\in E_+} c_e x_e$; see Section 5. Therefore, the total cost incurred by our algorithm is at most $O(\log q)$ times the optimal LP solution, implying an LP-based $O(\log q)$-approximation algorithm as required by Lemma 8. The following lemma then follows immediately.

▶ **Lemma 11.** *Consider the problem of augmenting the rooted-connectivity of a directed graph from ℓ to $\ell+1$ when an input graph is quasi-bipartite. There exists a polynomial-time algorithm that gives a feasible solution whose cost at most $O(\log q)$ that of the optimal solution to the standard LP-relaxation. In particular, there exists a polynomial-time LP-based $O(\log q)$-approximation algorithm for the problem.*

▶ Remark. Lastly, we remark that one may simply cover all the Halo-families in each iteration. However, the number of rounds the randomized algorithm required will be at least $O(\log q)$, meaning that the total number of iterations is $O(\log^2 q)$. Consequently, this implies that the algorithm has to pay a factor $O(\log^2 q)$ in the approximation ratio. We avoid the extra $O(\log q)$ factor by covering only a constant fraction of the Halo-families.

4.3 Correctness and Overall Analysis

First, to prove the feasibility of the solution subgraph, it suffices to show that the rooted-connectivity of the solution subgraph increasess by at least one in each connectivity augmentation step. This simply follows by the stopping condition of the Halo-set decomposition method runs until there exists no core in the graph (and thus no deficient sets). It then follows by Menger's theorem that the number of edge-disjoint paths from the root vertex r to each terminal $t \in T$ must be increased by at least one.

Next we analyze the cost. By Lemma 11, the approximation factor incurred by Algorithm 1 is $O(\log q)$, and it also bounds the integrality gap of $\mathsf{LP}^{aug}(\ell)$. Consequently, letting OPT_k denote the cost of an optimal solution to k-DST, by Lemma 8, the total expected cost incurred by the algorithm is then

$$\sum_{\ell=1}^{k} O(\log q) \cdot \mathsf{Val}(\mathsf{LP}^{aug}(\ell)) = O(\log q) \cdot \left(\sum_{\ell=1}^{k} \frac{1}{k-\ell+1} \right) \cdot \mathsf{Val}(\mathsf{LP}(k))$$
$$= O(\log q \log k) \cdot \mathsf{OPT}_k.$$

This completes the proof of Theorem 1.

5 Covering Halo-Families via Set Cover

In this section, we present our subroutine for covering the Halo-families that arose from the Rooted-Aug problem. As mentioned in the introduction, the key ingredient in our algorithm is the reduction from the problem of covering Halo-families to the Set Cover problem. However, our instance of the Set Cover problem has an exponential number of subsets, which more resemblances to an instance of the *Facility Location* problem. To prove our result, one route would be using *Facility Location* as an intermediate problem in the presentation. However, we prefer to directly apply a reduction to the Set Cover problem to avoid confusing the readers.

5.1 The Reduction to Set Cover and Algorithm

As an overview, our reduction follows from simple observations.

- (P1) For any minimal subset of edges that covers a Halo-family $\mathsf{Halo}(C)$, there is only one edge e that has head in $\mathsf{Halo}(C)$ and tail outside. Let us say e is outer-cover $\mathsf{Halo}(C)$ since it is coming from the outside of the family.
- (P2) Any edge can be contained in at most one $\mathsf{Halo}(C)$. i.e., there is at most one halo-family $\mathsf{Halo}(C)$ such that both head and tail of e are contained in $H(C)$. (From Lemma 4.)
- (P3) An LP for covering a single Halo-family is integral.

We remark that while Properties (P1) and (P3) hold in general instances of k-DST, Property (P2) holds only in quasi-bipartite graphs.

Now an instance of the Set Cover problem can be easily deduced. We define each Halo-family $\mathsf{Halo}(C)$ as an element, and we define each edge e as a subset. However, we may have multiple subsets corresponding to the same edge e as it may serve as an "outer-cover" for many Halo-families. Thus, we need to enumerate all the possible collections of Halo-families that are outer-covered by e. We avoid getting exponential number of subsets by using the solution from an LP (for the connectivity augmentation problem) as a guideline.

Before proceeding, we need to formally define some terminologies. Let $\hat{G}$ be the current solution subgraph. We say that an edge e *outer-covers* a Halo-family $\mathsf{Halo}(C)$ if the head of e is in $H(C)$ and the tail is not in $H(C)$ and that there exists a subset of edges $E' \subseteq E_+ - E(\hat{G})$ such that (1) both endpoints of every edge in E' are contained in $H(C)$ and (2) the set of edges $E' \cup \{e\}$ covers $\mathsf{Halo}(C)$.

For each Halo-family $\mathsf{Halo}(C)$, we define the set of edges I_C^e to be the minimum-cost subset of edges $E' \subseteq E_+ - E(\hat{G})$ whose both endpoints are in $H(C)$ and that $E' \cup \{e\}$ covers $\mathsf{Halo}(C)$, and we denote the cost of I_C^e by σ_C^e. We may think that σ_C^e is the cost for covering

$\mathsf{Halo}(C)$ given that e has been taken for free. We use the notation $E[C]$ to mean the set of edges whose both endpoints are contained in the Halo-set $H(C)$. We denote the cost of the fractional solution restricted to $E[C]$ by $\mathsf{cost}_x(E(C)) = \sum_{e \in E[C]} c_e x_e$.

Our reduction is as follows. Let H be the current solution subgraph. For each core C in H, we define an element C. For each edge $e \in E_+ - E(H)$, we define a subset S_e by adding to S_e an element C if $\sigma_C^e \leq \mathsf{cost}_x(E[C])$. This completes a reduction. Notice that the resulting instance of the Set Cover problem has polynomial size. To show that our reduction runs in polynomial-time, we need to give a polynomial-time algorithm for computing σ_C^e, which we defer to Section 5.4. Here we leave a forward reference to Lemma 15. Our algorithm covers a constant fraction of the collection of Halo-families by simply picking each edge e with probability x_e and add all the edges I_C^e, for all cores $C \in S_e$, to the solution subgraph; if a core C is outer-covered by two picked edges, then we add only one edge-set I_C^e. We claim that the set of edges chosen by our algorithm covers at least $1/9$ fraction of the Halo-families, while paying a cost of at most four times the optimum (with a constant probability). In particular, we prove the following lemma.

▶ **Lemma 12.** *With constant probability, the above algorithm covers at least* $1/9$ *fraction of the collection of Halo-families, and the cost of the of the edges chosen by the algorithm has cost at most* $4\sum_{e \in E_+} c_e x_e$*. In particular, the algorithm partially covers the collection of the Halo-families, while paying the cost of at most constant times the optimum.*

To prove Lemma 12, we need to show that the fractional solution defined by $\{x_e\}_{e \in E+}$ is (almost) feasible to the Set Cover instance, which then implies that the set of edges we bought covers a constant fraction of the Halo-families with probability at least $2/3$. Then we will show that the cost of the fractional solution to the Set Cover instance is at most twice that of the optimal solution to $\mathsf{LP}^{aug}(\ell)$, thus implying that we pay at most six times the optimum with probability $2/3$.

To be more precise, we show in Section 5.2 that our algorithm covers at least $1/3$ fraction of the Halo-families in expectation, meaning that we cover less than $1/9$ fraction with probability at most $1/3$. Then we show in Section 5.3 that the expected cost incurred by our algorithm is $2\sum_{e \in E_+} c_e x_e$, thus implying that we pay more than six times that of the LP with probability at most $1/3$. Applying the union bound, we conclude that our algorithm covers at least $1/9$ fraction of the Halo-families, while paying the cost of at most six times the optimal LP solution with probability at least $1/3$. (Note that in Section 5.3, we show a slightly stronger statement that the cost incurred by our algorithm is $4\sum_{e \in E_+} c_e x_e$ with probability at least $2/3$.) To finish our proof, we proceed to prove the above two claims and then prove the structural properties used in the forward references.

5.2 Partial Covering

We show in this section that our algorithm covers at least $1/9$ fraction of the Halo-families with probability at least $1/3$

First, we show that the LP variable defined by x_e is almost feasible to the LP-relaxation of the Set Cover problem. We note that our proof will need a forward reference to Lemma 14.

▶ **Lemma 13.** *The LP variable* $\{y_e\}_{e \in E_+}$*, where* $y_e = \min\{1, 2x_e\}$ *for all edges* $e \in E_+$ *is feasible to the Set Cover instance. That is, for any core* C *in the graph,*

$$\sum_{e \in E_+ : C \in S_e} x_e \geq 1/2.$$

Proof. Consider a core C, which corresponds to an element in the Set Cover instance. We take the set of edges incident to its Halo-set $H(C)$, and find a minimal vectors $\{x'_e\}_{e\in E_+}$ such that $\{x'_e\}_{e\in E_+}$ fractionally covers the Halo-family $\mathsf{Halo}(C)$ and $x'_e \le x_e$ for all edges $e \in E_+$. (Note that by minimality we mean that, for any edge e and any $\epsilon > 0$, decreasing the value of x'_e by ϵ results in an infeasible solution.) By Lemma 14, we have $\sum_{e\in\delta^{in}(H(C))} x'_e = 1$, i.e., the total weight of the LP value of edges incoming to $H(C)$ is exactly one.

Next consider the following LP.

$$\mathsf{LP}^{halo} = \begin{cases} \min & \sum_{e'\in E_+(H(C))} c_{e'}x_{e'} & \\ \text{s.t} & \sum_{e'\in\delta^{in}_{E_+}(U)} x_{e'} \ge 1 & \forall U \in \mathsf{Halo}(C) \\ & 0 \le x_{e'} \le 1 & \forall e \in E_+(H(C)) \end{cases}$$

By Lemma 2, we know that both the intersection and union of any two deficient sets in $\mathsf{Halo}(C)$ are also deficient sets in $\mathsf{Halo}(C)$. This means that the Halo-family $\mathsf{Halo}(C)$ is an intersecting family. It then follows from the result of Frank [21] that the above LP is *Totally Dual Integral*, which means that any convex point of its polytope is an integral solution (including the optimal one). Since $\{x'_e\}_{e\in E'}$ is a feasible solution to LP^{halo}, it can be written as a convex combination of integral vectors in the polytope, i.e.,

$$\mathbf{x} = \sum_{i=1}^{w} \lambda_i \mathbf{z}^i, \text{ where } \sum_{i=1}^{w} \lambda_i = 1.$$

Let F_i be the set of edges induced by each integral vector $\mathbf{z}^i$ (i.e., F_i is the support of $\mathbf{z}^i$). Since the LP requires $H(C)$ to have at least one incoming edge, we deduce that, for each F_i, there exists one edge $e_i \in F_i$ entering $H(C)$.

Now we compare the cost of $\sigma_C^{e_i}$ to the cost of $F_i - \{e_i\}$. By minimality of $\sigma_C^{e_i}$, we know that $\sigma_C^{e_i} \le \mathsf{cost}(F_i - \{e_i\})$ for all $i = 1, \ldots, w$. We recall that we add a core C to the set S_{e_i} only if $\sigma_C^{e_i} \le \mathsf{cost}_x(E[C])$. Since $\mathsf{cost}_{x'}(E[C])$ is the convex combination of $\mathbf{Z}^i$, at least half of the F_i (w.r.t. to the weight λ_i) must have $\sigma_C^{e_i} \le \mathsf{cost}(F_i - \{e_i\}) \le \mathsf{cost}_x(E[C])$; that is, $\sum_{i:\sigma_C^e \le \mathsf{cost}(F_i-\{e_i\})} \lambda_i \ge 1/2$. Therefore, we conclude that the sum of y_{e_i} over all e_i such that $\sigma_C^{e_i} \le \mathsf{cost}_x(E[C])$ is at least one, thus proving the lemma. ◀

We remark that we may define the Set Cover instance so that $\{x_e\}_{e\in E_+}$ is exactly a feasible solution to the LP for the Set Cover problem by using the integer decomposition as in the proof of Lemma 13. However, we choose to present it this way to keep the reduction simple.

Now we finish the proof of our claim. Consider a core C. Note that by construction, every time we pick an edge e, we also add the set of edges I_C^e, for each $C \in S_e$ (recall that $I_C^e \cup \{e\}$ covers $\mathsf{Halo}(C)$). Thus, the probability that the algorithm picks no edges e such that $C \in S_e$ is

$$\Pi_{e\in E_+:C\in S_e}(1 - x_e) \le \exp\left(-\sum_{e\in E_+} x_e\right) \le \exp(-1/2) \le \frac{2}{3}.$$

The first inequality follows because $1 - x \le \exp(-x)$, for $0 < x \le 1$. That is, the probability that the algorithm does not cover a core C is at most $2/3$, which means that the expected fraction of Halo-families covered by our algorithm is at least $1/3$. Applying Markov's inequality, we conclude that with probability at least $2/3$ our algorithms covers at least $1/9$ fraction of the Halo-families. Our algorithm can be derandomized using the method of conditional expectation. Please see Appendix A for details.

5.3 Cost Analysis

Now we analyze the expected cost of the edges we add to the solution subgraph. We classify the cost incurred by our algorithm into two categories. The first case is the set of edges e that we pick with probability x_e. The expected cost of this case is $\sum_{e \in E_+} c_e x_e$. Applying Markov's inequality, we have that with probability at least $2/3$ the cost incurred by the edges of this case is at most $3 \sum_{e \in E_+} c_e x_e$.

The second case is the set of edges corresponding to each subset S_e whose edge e is added to the solution. By construction, a core C is added to S_e only if $\mathsf{cost}_x(E[C])$ is greater than σ^e_C (i.e., the cost of the set of edges I^e_C). We recall that we also add one set of edges I^e_C to the solution if there are more than one edges e such that $C \in S_e$ are chosen. As the set of edges $E[C]$ and $E[C']$ are disjoint for any two cores $C \neq C'$ (please see the forward reference to Lemma 4), we conclude that the cost incurred by the edges of this case is at most $\sum_{e \in E_+} c_e x_e$ (regardless of the choices of the edges randomly picked in the previous step). Therefore, with probability at least $2/3$ the cost of edges chosen by our algorithm is at most $4 \sum_{e \in E_+} c_e x_e$.

5.4 Structural Properties of the LP solution

We devote this last subsection to prove properties (P1) to (P3) and all the forward references as discussed earlier. Property (P3) simply follows from the fact that the intersection and union of any two members of a Halo-family $\mathsf{Halo}(C)$ are also members of $\mathsf{Halo}(C)$, which means that the polytope of the problem of covering $\mathsf{Halo}(C)$ is integral due to the result of Frank [21]. Thus, we are left to prove the property (P1) and (P2) and to present a polynomial-time algorithm for computing σ^e_C, which thus complete the proof that our reduction can be done in polynomial time.

First, we prove Property (P1), which allows us to reduce the instance of the problem of covering Halo-families to a Set Cover instance.

▶ **Lemma 14** (Unique Entering Edge in Minimal Cover)**.** *Consider a minimal fractional cover x of a Halo-family $\mathsf{Halo}(C)$. That is, x is a feasible solution to LP^{halo} whose collection of deficient sets is defined by $\mathsf{Halo}(C)$, and decreasing the value x_e of any edge $e \in E_+$ results in an infeasible solution. It holds that $\sum_{e \in \delta^{in}_{E_+}(H(C))} x_e = 1$. Thus, for an integral solution E', there is exactly one edge $e \in E'$ entering the Halo-set $H(C)$.*

Proof. Assume for a contradiction that $\sum_{e \in \delta^{in}_{E_+}(H(C))} x_e > 1$. By the minimality of x, for any edge $e \in \delta^{in}_{E_+}(H(C))$, there exists a deficient set $W_e \in \mathsf{Halo}(C)$ such that $\sum_{e \in \delta^{in}_{E_+}(W_e)} x_e = 1$. We choose W_e to be the maximum inclusionwise such set and call it the witness set of e.

Now we take two distinct witness sets W_e and $W_{e'}$, for $e \neq e'$. By Lemma 5, both $W_e \cap W_{e'}$ and $W_e \cup W_{e'}$ are deficient sets in $\mathsf{Halo}(C)$. Let us abuse the notation of x. For any subset of vertices $S \subseteq V(G)$, let $x(S) = \sum_{e \in \delta^{in}_{E_+}(S)} x_e$. The function $x(S)$ is known to be submodular [24], meaning that

$$2 = x(W_e) + x(W_{e'}) \geq x(W_e \cap W_{e'}) + x(W_e \cup W_{e'}) \geq 2.$$

The last inequality follows because $\{x\}_{e \in E_+}$ fractionally covers $\mathsf{Halo}(C)$, which then implies that $x(W_e \cap W_{e'}) = x(W_e \cup W_{e'}) = 1$. But, this contradicts the choice of W_e (and also $W_{e'}$) because $W_e \cup W_{e'}$ is a deficient set in $\mathsf{Halo}(C)$ strictly containing W_e in which the conditions $x(W_e \cup W_{e'}) = 1$ and $e \in \delta^{in}_{E_+}(W_e \cup W_{e'})$ hold. ◀

Next we prove Property (P2), which allows us to upper bound the cost incurred by the main algorithm.

Finally, we show that σ^e_C can be computed in polynomial time.

▶ **Lemma 15.** *For any core $C \in \mathcal{C}$ and an edge $e \in E(G)$, the set of edges I^e_C and, thus, its cost σ^e_C can be computed in polynomial time. Moreover, the value of σ^e_C is equal to the optimal value of the corresponding covering LP given below.*

$$\mathsf{LP}^{cover} = \begin{cases} \min & \sum_{e' \in E_+(H(C))} c_{e'} x_{e'} & \\ s.t & \sum_{e' \in \delta^{in}_{E_+}(U)} x_{e'} \geq 1 & \forall U \in \mathsf{Halo}(C) \\ & 0 \leq x_{e'} \leq 1 & \forall e \in E_+(H(C)) \\ & x_e = 1 & \end{cases}$$

Proof. Consider the Halo-family $\mathsf{Halo}(C)$. By Lemma 5, the union and intersection of any deficient sets $U, W \in \mathsf{Halo}(C)$ are also deficient sets in $\mathsf{Halo}(C)$. This means that $\mathsf{Halo}(C)$ is an *intersecting family*. It is known that the standard LP for covering an intersecting family is integral (see, e.g., [21]), which implies that we can compute σ^e_C and its corresponding set of edges I^e_C in polynomial time by solving LP^{cover}.

Alternatively, we may compute σ^e_C combinatorially using an efficient minimum-cost $(\ell+1)$-flow algorithm. In particular, we construct an s^*, t^*-flow network by setting the costs of edges in $\delta^{in}_{H_{\ell+1}}(H(C)) \cup \{e\}$ to zero, adding a source s^* connecting to $\ell+1$ edges entering $\mathsf{Halo}(C)$ (which consists of ℓ edges from $\delta^{in}_{H_{\ell+1}}(H(C))$ plus the edge e) and then picking an arbitrary terminal $t^* \in C$ as a sink. All the edges not in $E(H(C))$ except $\delta^{in}_{H_{\ell+1}}(H(C)) \cup \{e\}$ are removed. Applying Manger's theorem, it can be seen that every $(\ell+1)$-flow in this s^*, t^*-flow network corresponds to a feasible solution to the covering problem with the same cost. This gives a polynomial-time algorithm for computing σ^e_C and I^e_C as desired. ◀

6 Conclusion and Open Problems

We have presented our $O(\log q \log k)$-approximation algorithm for k-DST when an input graph is quasi-bipartite. This is the first polylogarithmic approximation algorithm for k-DST for arbitrary k that does not require an additional assumption on the structure of the optimal solution. In addition, our result implies that k-DST in quasi-bipartite graphs is equivalent to the Set Cover problem when $k = O(1)$.

Lastly, we conclude our paper with some open problems. A straightforward question is whether there exists a non-trivial approximation algorithm for k-DST for $k \geq 3$ in general case or for a larger class of graphs (perhaps, in quasi-polynomial-time). Another interesting question is whether our randomized rounding technique, which consists of dependent rounds of a randomized rounding algorithm for the Set Cover problem, can be applied without connectivity augmentation. If this is possible, it will give $O(\log k)$ improvements upon the approximation ratios for approximating many problems whose the best known algorithms are based on the Halo-Set decomposition technique.

A Derandomization

In this section, we present a derandomization of our algorithm in Section 5 using the method of conditional expectation [1]. We will mostly follow the proof presented in the work of Bertsimas and Vohra [4] who gave a derandomized technique for the randomized scheme for the Set Cover problem.

In more detail, first observe that the cost incurred by our algorithm comes from two parts. The firt part is the cost of edges e that we pick with probabilty x_e, and the second part is the cost of edges I_e^C in which the edge e is chosen. For the second part, our algorithm guarantees that, for each core C, only one set of edges I_e^C will be added to the solution. Thus, by the construction of S_e and Lemma 4, the cost incurred by this part is $\sum_{e\in E_+} c_e x_e$ regardless of the choices of the edges e added to the solution from the first part.

Hence, it suffices to show that there exists a deterministic algorithm that pick a set of edges E' that outter-covers at least $1/3$ fraction of the Halo-families, while paying the cost at most $\sum_{e\in E_+} c_e x_e$.

Let $\mathcal{C}$ be the collection of all the cores in the current solution subgraph. For a given set of edges $E' \subseteq E_+$, we define a function $\tau_C \in \{0,1\}$ for each Halo-family $\mathsf{Halo}(C)$ to indicate whether $\mathsf{Halo}(C)$ is covered by some edge in E', and we define a function $\mathbb{I}(\vec{\tau})$ to indicate whether E' outer-covers at least $1/9$ fraction of the Halo-families. The formal definition of these two functions are given below.

$$\tau_C(E') = \begin{cases} 1 & \text{if } E' \text{ outer-covers } \mathsf{Halo}(C) \\ 0 & \text{Otherwise} \end{cases}$$

$$\mathbb{I}(E') = \begin{cases} 1 & \sum_{C\in\mathcal{C}} \tau_C(E') < \frac{|\mathcal{C}|}{9} \\ 0 & \text{Otherwise} \end{cases}$$

Next we define the potential function:

$$\Phi(E') = \sum_{e\in E'} c_e + M \cdot \mathbb{I}(E'), \text{ where } M = 3 \sum_{e\in E_+} c_e x_e.$$

Observe that $\Phi(E') \leq M$ if E' outer-covers at least $1/9$ fraction of the Halo-families, while having the cost at most three times that of the LP solution; otherwise, $\Phi(X) > M$. Notice that, by Lemma 12, if we add each edge $e \in E_+$ to E' with probability x_e, then $\mathbb{E}[\Phi(E')] \leq M$. Thus, there exists an event that $\Phi(X) \leq M$, which will give us the desired integer solution. We then follow the method of conditional expectation (see, e.g., [1]). That is, we order edges in E_+ in an arbitrary order, say $e_1, e_2, \ldots, e_{|E_+|}$. Let E'' be the set of edges that we try to simulate the set of randomly chosen edges E'. Initially, $E_{det} = \emptyset$. Then we decide to add each edge e_i, for $i = 1, 2, \ldots, |E_+|$ to E' if $\mathbb{E}[\Phi(E')|E_{det} \cup \{e_i\} \subseteq E'] \leq \mathbb{E}[\Phi(E')|E_{det} \subseteq E']$. This way the resulting set of edges E_{det} outer-covers at least $1/9$ fraction of the Halo-families, while having the cost of at most $3\sum_{e\in E_+} c_e x_e$. Therefore, after adding the set of edges I_e^C for each core outer-covered by some edge $e \in E_{det}$, we have a set of edges that covers at least $1/9$ fraction of the Halo-families with cost at most $4\sum_{e\in E_+} c_e x_e$, i.e., with the same guarantee as desired in Lemma 12.

B Bad Example for Grandoni-Laekhanukit Tree-Embedding Approach

In [32], Grandoni and Laekhanukit proposed an approximation scheme for k-DST based on the decomposition of an optimal solution into k divergent arborescences [28, 3]. Their approach results in the first non-trivial approximation algorithm for 2-DST, and the algorithm achieves polylogarithmic approximation ratio in quasi-polynomial-time. Nevertheless, this technique meets a barrier as soon as $k \geq 3$ as it was shown in [3] that the decomposition of an optimal solution into k divergent arborescences does not exist for general graphs when $k \geq 3$. One would hope that the decomposition is still possible for some classes of graphs, e.g., quasi-bipartite graphs. We show that, unfortunately, even for the class of quasi-bipartite graphs the divergent arborescences decomposition does not exist for $k \geq 3$. The counter example of a 3-rooted-connected graph that has no 3 divergent arborescences is shown in Figure 2.

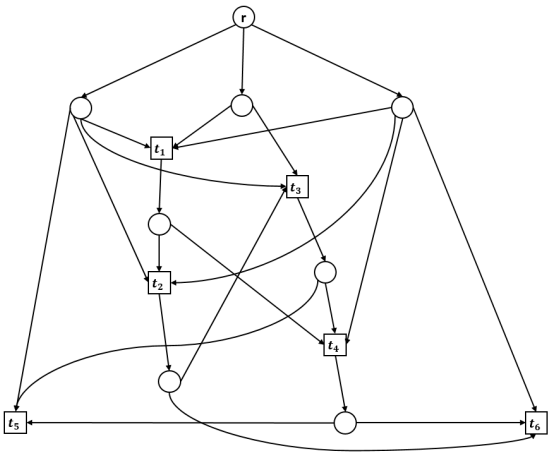

Figure 2 This figure shows an example 3-rooted-connected quasi-bipartite graph that cannot be decomposed into 3 divergent arborescences.

Weighted Maximum Independent Set of Geometric Objects in Turnstile Streams

Abstract

We study the Maximum Independent Set problem for geometric objects given in the data stream model. A set of geometric objects is said to be independent if the objects are pairwise disjoint. We consider geometric objects in one and two dimensions, i.e., intervals and disks. Let α be the cardinality of the largest independent set. Our goal is to estimate α in a small amount of space, given that the input is received as a one-pass stream. We also consider a generalization of this problem by assigning weights to each object and estimating β, the largest value of a weighted independent set. We initialize the study of this problem in the turnstile streaming model (insertions and deletions) and provide the first algorithms for estimating α and β.

For unit-length intervals, we obtain a $(2+\epsilon)$-approximation to α and β in $\text{poly}(\frac{\log(n)}{\epsilon})$ space. We also show a matching lower bound. Combined with the 3/2-approximation for insertion-only streams by Cabello and Perez-Lanterno [11], our result implies a separation between the insertion-only and turnstile model. For unit-radius disks, we obtain a $\left(\frac{8\sqrt{3}}{\pi}\right)$-approximation to α and β in $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ space, which is closely related to the hexagonal circle packing constant.

Finally, we provide algorithms for estimating α for arbitrary-length intervals under a bounded intersection assumption and study the parameterized space complexity of estimating α and β, where the parameter is the ratio of maximum to minimum interval length.

1 Introduction

Maximum Independent Set (MIS) is a fundamental combinatorial problem and in general, is NP-Hard to approximate within a $n^{1-\epsilon}$ factor, for any constant $\epsilon > 0$ [34]. We focus on the MIS problem for geometric objects: we are given as input n intervals on the real line or disks in the plane and our goal is to output the largest set of non-overlapping intervals

© Ainesh Bakshi, Nadiia Chepurko, and David P. Woodruff;

or disks. Computing the Maximum Independent Set of intervals and disks has numerous applications in scheduling, resource allocation, cellular networks, map labellings, clustering, wireless ad-hoc networks and coding theory, where it has been extensively studied [31] [4], [50], [12], [6], [5], [1], [33], [45].

In the one dimensional setting, the MIS problem, also known as the Interval Scheduling[1] problem, has a simple greedy algorithm that picks intervals in increasing order of their right endpoint to obtain an optimal solution. The variant with weighted intervals can also be solved in polynomial time using dynamic programming, which is shown in a number of modern algorithms textbooks [21], [41]. These algorithms have considerable applications in resource allocation and scheduling, where offline and online variants have been extensively studied and we refer the reader to [42] for a survey.

In the two dimensional setting, MIS of geometric objects, such as line segments [35], rectangles [30], [37] and disks [19], is *NP-Hard*. However, in the offline setting (polynomial space), a PTAS is known for fat objects (squares, disks) and pseudo-disks [15] (who also provide a recent survey). The MIS problem for arbitrary rectangles has also received considerable attention: [13] show a $\log\log(n)$ approximation in polynomial time and [18] obtain a $(1+\epsilon)$-approximation in $n^{\text{poly}(\log(n))\epsilon^{-1}}$ time for axis-aligned rectangles.

Streaming Model. The increase in modern computational power has led to massive amounts of available data. Therefore, it is unrealistic to assume that our data fits in RAM. Instead, working with the assumption that data can be efficiently accessed in a sequential manner has led to streaming algorithms for a number of problems. Several classical problems such as heavy-hitters and l_p sampling [38], l_p estimation [39], entropy estimation [44], [20], maximum matching [43] etc. have been studied in the turnstile model and recent work has led to interesting connections with linear sketches [2].

In this paper, we study the streaming complexity of the geometric MIS problem, where the input is a sequence of n updates, either inserting a new object or deleting a previously inserted object. We assume that the algorithm has poly-logarithmic bounded memory and at the end of the stream, the algorithm should output an estimate of the (weighted) cardinality of the MIS. Since most real world scheduling applications are dynamic, and scheduling constraints expire, it is crucial to allow for both insertions and deletions, while operating in the low-space setting. Consider the following concrete application: automatic point-label conflict resolution on interactive maps [48]. In this problem, the goal is to label features (geometric objects such as points, lines and polygons) on a map such that no two features with the same label overlap. Labelling maps in visual analytic software requires such labelling to be fast and dynamic, since features can be added and removed.

1.1 Our Contributions

We provide the first algorithmic and hardness results for the Weighted Maximum Independent Set (WMIS) problem for geometric objects in *turnstile streams* (where previously inserted objects may also be deleted). The aim of our work is to understand the MIS and WMIS problems in this common data stream model and we summarize the state of the art in Table 1. Our contributions are as follows:

1. **Unit-length Intervals.** Our main algorithmic contribution is a turnstile streaming algorithm achieving a $(2+\epsilon)$-approximation to α and β in $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ space. We also show a matching lower bound, i.e., any (possibly randomized) algorithm approximating

[1] See `https://en.wikipedia.org/wiki/Interval_scheduling`.

Table 1 The best known upper and lower bounds for estimating α and β in insertion-only and turnstile streams (defined below). Note, the weight and length above are still polynomially bounded in n. The folklore result follows from partitioning the input into $O(\log(n))$ weight classes, estimating α on each one in parallel and taking the maximum estimate.

Problem	Insertion-Only Streams		Turnstile Streams	
	upper bound	lower bound	upper bound	lower bound
Unit Intervals Unit Weight	$3/2+\epsilon$ [10]	$3/2-\epsilon$ [10]	$2+\epsilon$ Thm 8	$2-\epsilon$ Thm 16
Unit Intervals Arbitrary Weight	$3/2+\epsilon$ Thm 22	$3/2-\epsilon$ [10]	$2+\epsilon$ Thm 8	$2-\epsilon$ Thm 16
Unit Disks Arbitrary Weight	$\frac{8\sqrt{3}}{\pi}+\epsilon$ Thm 21	$2-\epsilon$ Thm 25	$\frac{8\sqrt{3}}{\pi}+\epsilon$ Thm 21	$2-\epsilon$ Thm 16

α up to a $(2-\epsilon)$ factor requires $\Omega(n)$ space. Interestingly, this shows a strict separation between insertion-only and turnstile models since [10] show that a $3/2$ approximation is tight in the insertion-only model.

An unintuitive yet crucial message here is that attaching polynomially bounded weights to intervals does not affect the approximation factor. Along the way, we also obtain new algorithms for estimating β in insertion-only streams which are presented in Section C.

2. **Arbitrary Length Intervals.** For arbitrary length intervals, we give a one-pass turnstile streaming algorithm that achieves a $(1+\epsilon)$-approximation to α under the assumption that the degree of the interval intersection graph is bounded by $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$. Our algorithm achieves $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ space. We also study the problem for arbitrary lengths by parameterizing the ratio of the longest to the shortest interval. We give a one-pass turnstile streaming algorithm that achieves a $(2+\epsilon)$-approximation to α, where the space complexity is parameterized by W_{max}, which is an upper bound on the length of an interval assuming the minimum interval length is 1. Here, the space complexity of our algorithm is $\text{poly}\left(W_{max}\frac{\log(n)}{\epsilon}\right)$ and this algorithm gives sublinear space whenever W_{max} is sublinear.
3. **Unit-radius Disks.** We show that we can extend the ideas developed for unit-length intervals in turnstile streams to unit disks in the 2-d plane. We describe an algorithm achieving an $\left(\frac{8\sqrt{3}}{\pi}+\epsilon\right)$-approximation to α and β in $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ space. One key idea in the algorithm is to use the hexagonal circle packing for the plane, where the fraction of area covered is $\frac{\pi}{\sqrt{12}}$ and our approximation constant turns out to be $4\cdot\frac{\sqrt{12}}{\pi}$.
We also show a lower bound that any (possibly randomized) algorithm approximating α or β for disks in insertion-only streams, up to a $(2-\epsilon)$ factor requires $\Omega(n)$ space. This shows a strict separation between estimating intervals and disks in insertion-only streams.

2 Related Work

There has been considerable work on streaming algorithms for graph problems. Well-studied problems include finding sparsifiers, identifying connectivity structure, building spanning trees, and matchings; see the survey by McGregor [46]. Recently, Cormode et. al. [22] provide guarantees for estimating the cardinality of a maximum independent set of general graphs via the Caro-Wei bound. Emek, Halldorsson and Rosen [24] studied estimating the cardinality of the maximum independent set for interval intersection graphs in insertion-only

streams. They output an independent set that is a $\frac{3}{2}$-approximation to the optimal (OPT) for unit-length intervals and a 2-approximation for arbitrary-length intervals in $O(|\mathsf{OPT}|)$ space. Note that $|\mathsf{OPT}|$ could be $\Theta(n)$ which is a prohibitive amount of space.

Subsequently, Cabello and Perez-Lantero [10] studied the problem of estimating the *cardinality* of OPT, which we denote by α, for unit-length and arbitrary length intervals in one-pass insertion-only streams. For unit-length intervals in insertion-only streams, Cabello and Perez-Lantero [10] give a $(\frac{3}{2}+\epsilon)$ approximation to α in $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ space. Additionally, they show that this approximation factor is tight, since any algorithm achieving a $(\frac{3}{2}-\epsilon)$-approximation to α requires $\Omega(n)$ space. For arbitrary-length intervals they give a $(2+\epsilon)$-approximation to α in $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ space. Additionally, they show that the approximation factor is tight, since any algorithm achieving a $(2-\epsilon)$-approximation to α requires $\Omega(n)$ space. Recently, [23] studied MIS of intersection graphs in insertion-only streams. They show achieving a $(5/2-\epsilon)$-approximation to MIS of squares requires $\Omega(n)$ space.

To the best of our knowledge there is no prior work on the problem of Maximum Independent Set of unit disks in turnstile streams. In the offline setting, the first PTAS for MIS of disks was developed by [26] and later improved in running time by Chan [14], while [36] shows a PTAS for MIS of $k \times k$ squares. We note that these algorithms require space linear in the number of disks and use a dynamic programming approach that is not suitable for streaming scenarios.

We note that MIS can also be viewed as a natural generalization of the distinct elements problem that has received considerable attention in the streaming model. This problem was first studied in the seminal work of [29] and a long sequence of work has addressed its space complexity in both insertion-only and turnstile streams [3], [7], [32], [27], [28], [40], [9] and [23].

3 Notation and Problem Definitions

We let $D(d_j, r_j, w_j)$ be a disk in $\mathbb{R}^d$, where $d \in \{1, 2\}$, such that it is centered at a point $d_j \in \mathbb{R}^d$ with radius $r_j \in \mathbb{N}$ and weight w_j. We represent $D(d_j, r_j, w_j)$ using the short form D_j when d_j, r_j and w_j are clear from context. Note, we use the same notation to denote intervals in $d = 1$. For a set $\mathcal{P} \subseteq \mathbb{R}^d$ of n disks (unweighted or weighted), let G be the induced graph formed by assigning a vertex to each disk and adding an edge between two vertices if the corresponding disks intersect. We call G an intersection graph. The Maximum Independent Set (MIS) and Weighted Maximum Independent Set (WMIS) problems in the context of intersection graphs are defined as follows:

▶ **Definition 1** (Maximum Independent Set). *Let $\mathcal{P} = \{D_1, D_2 \ldots, D_n\} \subseteq \mathbb{R}$ be a set of n disks such that each weight $w_j = 1$ for $j \in [n]$. The MIS problem is to find the largest disjoint subset $\mathcal{S}$ of $\mathcal{P}$ (i.e., no two objects in $\mathcal{S}$ intersect). We denote the cardinality of this set by α.*

▶ **Definition 2** (Weighted Maximum Independent Set). *Let $\mathcal{P} = \{D_1, D_2 \ldots, D_n\} \subseteq \mathbb{R}^d$ be a set of n weighted disks. We let the weight $w_{\mathcal{S}}$ of a subset $\mathcal{S} \subseteq \mathcal{P}$ be $w_{\mathcal{S}} = \sum_{D_j \in \mathcal{S}} w_j$. The WMIS Problem is to find a disjoint (i.e., non overlapping) subset $\mathcal{S}$ of $\mathcal{P}$ whose weight $w_{\mathcal{S}}$ is maximum. We denote the weight of the WMIS by β.*

For a set $\mathcal{P}$ of disks, let $\mathsf{OPT}_{\mathcal{P}}$ denote MIS or WMIS of $\mathcal{P}$. We use $|\mathsf{OPT}_{\mathcal{P}}|$ to denote the cardinality of MIS as well as the weight of WMIS for $\mathcal{P}$. When the set $\mathcal{P}$ is clear from context, we omit it. Next, we define the two streaming models we consider. In our context,

an *insertion-only* stream provides sequential access to the input, which is an ordered set of objects such that at any given time step a new interval arrives. *Turnstile streams* are an extension of this model such that at any time step, previously inserted objects can be deleted. An algorithm in the streaming model has access to space sublinear in the size of the input and is restricted to making one pass over the input.

For proving our lower bounds, we work in the two player one-way randomized communication complexity model, where the players are denoted by Alice and Bob, who have private randomness. The input of Alice is denoted by X and the input for Bob is denoted by Y. The objective is for Alice to communicate a message to Bob and compute a function $f : X \times Y \to \{0, 1\}$ on the joint inputs of the players. The communication is one-way and w.l.o.g. Alice sends one message to Bob and Bob outputs a bit denoting the answer to the communication problem. Let $\Pi(X, Y)$ be the random variable that denotes the transcript between sent from Alice to Bob when they execute a protocol Π.

A protocol Π is called a δ-error protocol for function f if there exists a function Π_{out} such that for every input $Pr[\Pi_{out}(\Pi(X, Y)) = f(X, Y)] \geq 1 - \delta$. The communication cost of a protocol, denoted by $|\Pi|$, is the maximum length of $\Pi(X, Y)$ over all possible inputs and random coin flips of the two players. The randomized communication complexity of a function f, $R_\delta(f)$, is the communication cost of the best δ-error protocol for computing f.

4 Technical Overview

In this section, we summarize our results and briefly describe the main technical ideas in our algorithms and lower bounds. We note that our results hold in the recently introduced Sketching Model [49]. This model captures applications of sketches in turnstile streams, distributed computing, communication complexity and property testing. While Sun et. al. study graph problems such as dynamic connectivity and triangle detection, we initiate the study of dynamic Maximum Independent Set in this model. While we state our results in for turnstile streams, they immediately extend to the sketching model.

4.1 Unit-length Intervals

Our main algorithmic contribution is to provide an estimate that obtains a $(2+\epsilon)$-approximation to WMIS of unit-length intervals in turnstile streams :

▶ **Theorem 3** (Theorem 8, informal)**.** *For any $\epsilon > 0$, there exists a turnstile streaming algorithm that outputs an estimate such that with probability at least $99/100$, it is a $(2+\epsilon)$-approximation to WMIS of unit intervals (polynomially bounded weights) and the algorithm requires $poly\left(\frac{\log(n)}{\epsilon}\right)$ space.*

A naïve approximation. We start by describing a simple approach (Algorithm 1) to obtain a 9-approximation. The algorithm proceeds by imposing a grid of side length 1 and shifts it by a random integer. This is a standard technique used in geometric algorithms. We then snap each interval to the cell containing the center of the interval and partition the real line into odd and even cells. This partitions the input space such that intervals landing in distinct odd (even) cells are pairwise independent. Let $\mathcal{C}_e$ be the set of all even cells and $\mathcal{C}_o$ be the set of all odd cells.

By averaging, either $|\mathsf{OPT}_{\mathcal{C}_e}|$ or $|\mathsf{OPT}_{\mathcal{C}_o}|$ is at least $\frac{\mathsf{OPT}}{2}$, where $|\mathsf{OPT}|$ is the max weight independent set of intervals. We develop an estimator that gives a $(1+\epsilon)$-approximation to $|\mathsf{OPT}_{\mathcal{C}_e}|$ as well as $|\mathsf{OPT}_{\mathcal{C}_o}|$. Therefore, taking the max of the two estimators, we obtain a $(2+\epsilon)$-approximation to $|\mathsf{OPT}|$.

Having reduced the problem to estimating $|\mathsf{OPT}_{\mathcal{C}_e}|$, we observe that for each even cell only the max weight interval landing in the cell contributes to $\mathsf{OPT}_{\mathcal{C}_e}$. Then, partitioning the cells in $\mathcal{C}_e$ into poly(log(n)) geometrically increasing weight classes based on the max weight interval in each cell and approximately counting the number of cells in each weight class suffices to estimate $|\mathsf{OPT}_{\mathcal{C}_e}|$ up to a $(1+\epsilon)$-factor.

Algorithm 1 Naïve Approximation.

Input: Given a turnstile stream $\mathcal{P}$ with weighted unit intervals, where the weights are polynomially bounded, ϵ and $\delta > 0$, Naïve Approximation outputs a $(9+\epsilon)$-approximation to β with probability $1-\delta$.

1. Randomly shift a grid Δ of side length 1. Partition the cells into even and odd, denoted by $\mathcal{C}_e$ and $\mathcal{C}_o$.
2. Consider a partition of cells in $\mathcal{C}_e$ into $b = \text{poly}(\log(n))$ weight classes $\mathcal{W}_i = \{c \in \mathcal{C}_e | (1+1/2)^i \leq m(c) < (1+1/2)^{i+1}\}$, where $m(c)$ is the maximum weight of an interval in c (this is not an algorithmic step since we do not know this partition a priori). Create a substream for each weight class $\mathcal{W}_i$ denoted by $\mathcal{W}'_i$.
3. For each new interval $D(d_j, 1, w_j)$, feed it to substream $\mathcal{W}'_i$ if $w_j \in [(1+1/2)^i, (1+1/2)^{i+1})$. For each substream $\mathcal{W}'_i$, maintain a $(1 \pm \epsilon)$-approximate ℓ_0-estimator (described below).
4. Let t_i be the ℓ_0 estimate corresponding to $\mathcal{W}'_i$. Let $X_e = \frac{2}{9(1+\epsilon)} \sum_{i \in [b]} (1+1/2)^{i+1} t_i$.
5. Repeat Steps 2-6 for the odd cells $\mathcal{C}_o$ to obtain the corresponding estimator X_o.

Output: $\max(X_e, X_o)$

Given such a partition, we can approximate the number of cells in each weight class by running an ℓ_0 norm estimator. Estimating the ℓ_0 norm of a vector in *turnstile streams* is a well studied problem and a result of Kane, Nelson and Woodruff [40] obtains a $(1 \pm \epsilon)$-approximation in poly$(\frac{\log(n)}{\epsilon})$ space. However, we do not know the partition of the cells into the weight classes a priori and this partition can vary drastically over the course of a stream given that intervals can be deleted. Therefore, the main technical challenge is to simulate this partition in *turnstile streams*.

As a first attempt, consider a partition of cells in $\mathcal{C}_e$ into $b = \text{poly}(\log(n))$ weight classes $\mathcal{W}_i = \{c \in \mathcal{C}_e | (1+1/2)^i \leq m(c) < (1+1/2)^{i+1}\}$, where $m(c)$ is the maximum weight of an interval in c. Create a substream for each weight class $\mathcal{W}_i$ and feed an input interval into this substream if its weight lies in the range $[(1+1/2)^i, (1+1/2)^{i+1})$. Let t_i be the corresponding ℓ_0 estimate for this substream. Approximate the contribution of $\mathcal{W}_i$ by $(1+1/2)^{i+1} \cdot t_i$. Sum up the estimates for all $i \in [b]$ to obtain an estimate for $|\mathsf{OPT}_{\mathcal{C}_e}|$.

We note that there are two issues with our algorithm. First, we overestimate the weight of intervals in class $\mathcal{W}_i$ by a factor of 3/2 and second, for a given cell we sum up the weights of all intervals landing in it, instead of taking the maximum weight for the cell. In the worst case, we approximate the true weight of a contributing interval, $(3/2)^{i+1}$, with $\sum_{i'=1}^{i} (3/2)^{i'+1} \leq 3((3/2)^{i+1} - 1)$. Note, we again overestimate the weight, this time by a factor of 3. Combined with the approximation for the ℓ_0 norm, we obtain a weaker $(\frac{9}{2} + \epsilon)$-approximation to $|\mathsf{OPT}_{\mathcal{C}_e}|$ in the desired space. From our discussion above, this implies a $(9+\epsilon)$-approximation to $|\mathsf{OPT}|$. We also note that this attempt is not futile as we use the above algorithm as a subroutine subsequently.

A refined attempt. Next, we describe an algorithm that estimates $|\mathsf{OPT}_{\mathcal{C}_e}|$ up to a $(1+\epsilon)$-factor. Here, we use more sophisticated techniques to simulate a finer partition of the cells in $\mathcal{C}_e$ into geometrically increasing weight classes in turnstile streams. One key algorithmic tool

we use here is a streaming algorithm for k-Sparse Recovery: given an input vector x such that x receives coordinate-wise updates in the turnstile streaming model and has at most k non-zero entries at the end of the stream of updates, there exist data structures that exactly recover x at the end of the stream. As mentioned in Berinde et al. [8], the k-tail guarantee is a sufficient condition for k-Sparse Recovery, since in a k-sparse vector, the elements of the tail are 0. We note that the Count-Sketch Algorithm [17] has a k-tail guarantee in *turnstile streams*.

This time around, we consider partitioning cells in $\mathcal{C}_e$ into poly $\left(\epsilon^{-1}\log(n)\right)$ weight classes, creating a substream for each one and computing the corresponding ℓ_0 norm. We also assume we know $|\mathsf{OPT}_{\mathcal{C}_e}|$ up to a constant (this can be simulated in *turnstile streams*). Formally, given $b = \text{poly}\left(\log(n), \epsilon^{-1}\right)$ weight classes, for all $i \in [b]$, let $\mathcal{W}_i$ denote the set of even cells with maximum weight sandwiched in the range $[(1+\epsilon)^i, (1+\epsilon)^{i+1})$. We then simulate sampling from the partition by subsampling cells in each $\mathcal{W}_i$ at the start of the stream, agnostic to the input. We do this at different sampling rates , i.e. for all $i \in [b]$, we subsample the cells in $\mathcal{W}_i$ with probability roughty $(1+\epsilon)^i/|\mathsf{OPT}_{\mathcal{C}_e}|$.

This presents several issues, as we cannot subsample non-empty cells in turnstile streams a priori. Further, if a weight class has a small number of non-empty cells, we cannot recover accurate estimates for the contribution of this weight class to $|\mathsf{OPT}_{\mathcal{C}_e}|$ at any level of the subsampling. To address the first issue, we agnostically sample cells from $\mathcal{C}_e$ according to a carefully chosen range of sampling rates and create a substream for each one. We then run a sparse recovery algorithm on the resulting substreams. At the right subsampling rate, we note that the resulting substream is sparse since we can filter out cells that belong to smaller weight classes. Further, we can ensure that the number of cells that survive from the relevant weight class (and larger classes) is small. Therefore, we recover all such cells using the sparse recovery algorithm.

To address the second issue, we threshold the weight classes that we consider in the algorithm based on the relative fraction of non-empty cells in them. This threshold can be computed in the streaming algorithm using the ℓ_0-norm estimates for each weight class. All the weight classes below the threshold together contribute at most an ϵ-fraction of $|\mathsf{OPT}_{\mathcal{C}_e}|$ and though we cannot achieve concentration for such weight classes, we show that we do not overestimate their contribution. Further, for all the weight classes above the threshold, we can show that sampling at the right rate can recover enough cells to achieve concentration.

We complement the above algorithmic result with a matching lower bound, i.e., a $(2-\epsilon)$-approximation to MIS, for any $\epsilon > 0$, requires $\Omega(n)$ space. This follows from an easy application of the Augmented Indexing problem. We note that our result combined with the 3/2-approximation by [11] implies an unexpected separation between insertion-only and turnstile streams.

4.2 Parametrized Algorithms for Arbitrary Length Intervals

In light of the lower bound discussed above, we identify two sources contributing to the streaming hardness of MIS for arbitrary length intervals : the number of pair-wise intersections (max-degree) and the ratio of the longest to shortest interval (scale). We show that when either of these quantities is poly-logarithmically bounded, we can approximate MIS for arbitrary length intervals.

Instead of assuming the max-degree or scale is bounded, we instead provide algorithms paramterized by these quantities. First, let the number of pair-wise intersections be bounded by $\kappa_{\max}$. Then,

▶ **Theorem 4** (Theorem 17, informal). *For $\epsilon > 0$, there exists a turnstile streaming algorithm that takes as input a set of unit-weight arbitrary-length intervals, with at most $\kappa_{\max}$ pairwise intersections and with probability $99/100$, outputs a $(1+\epsilon)$-approximation to MIS in poly$(\log(n), \epsilon^{-1}, \kappa_{\max})$ space.*

This result requires several new algorithmic ideas. Observe, placing a unit grid no longer suffices since the intervals now span different lengths. Therefore, we impose a nested grid on our input, where the grid size is geometrically increasing, and randomly shift it. Further, observe that the natural strategy that partitions the interval into geometrically increasing *length classes* and estimates each partition up to $1+\epsilon$ does not work since the intervals overlap.

We therefore define the following object that uniquely determines intervals of a particular *length class* contributing to the MIS :

▶ **Definition 5** (r_i-Structure). *We define an r_i-Structure to be a subset of the Nested Grid, such that there exists an interval at the i^{th} grid level, there exist no intervals in the grid at any level $i' > i$ and all the intervals in the grid at levels $i' < i$ intersect the interval at the i^{th} level.*

It is easy to see any interval that contributes to MIS corresponds to an r_i-Structure for some i. Therefore, it suffices to estimate the number of r_i-Structures for all i. Following our approach for unit intervals, we again use k-Sparse Recovery as our main tool. At a high level, we sub-sample poly$(\log(n), \epsilon^{-1})$ r_i-Structures from the set of all such structures at level i, and create a new substream for each i. We then run a $\kappa_{\max}$-Sparse Recovery Algorithm on each substream. We show that at the end of the stream, we obtain an estimate of the number of r_i-Structures at level i that concentrates. Since the structures form a partition, our overall estimate is simply the sum of the estimates obtained for each i.

The main algorithmic challenge here is to show that we can indeed detect and subsample the r_i-structures. These structures are defined in a way that takes into account how many intervals appear in the nested grid both above and below a given interval. Therefore, it is unclear how to track such updates as they constantly change over the stream. However, observe that since our space is parameterized by the max-degree, we can afford to store an r_i-Structure completely in memory.

Given a randomly sampled cell from the i-th level of the nested grid, we assume this cell contributes an r_i-structure. We then run $\kappa_{\max}$-Sparse Recovery on this cell. Our main insight is that at the end of the stream we can verify whether this cell indeed contributed an r_i-structure since we recover the nested intervals *exactly*. The final remaining challenge is to ensure that our sub-sample contains a sufficient number of non-empty structures for each level and the resulting estimate concentrates. We describe these details in Section A.1.

Finally, we show that similar algorithmic ideas also result in a turnstile streaming algorithm, if parametrize the input by the $W_{\max}$, the ratio of the largest to smallest interval :

▶ **Theorem 6** (Theorem 20, informal). *For $\epsilon > 0$, there exists a turnstile streaming algorithm that takes as input a set of unit-weight arbitrary-length intervals, with $W_{\max}$ being an upper bound on the ratio of the largest to smallest interval, and with probability $99/100$, outputs a $(2+\epsilon)$-approximation to MIS in poly$(\log(n), \epsilon^{-1}, W_{\max})$ space.*

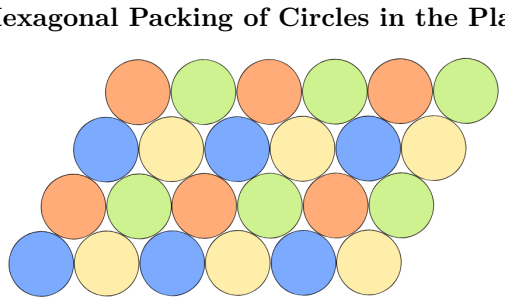

Figure 4.1 We illustrate the hexagonal circle packing in the Euclidean Plane. Each color represents an equivalence class. Observe that input disks that are centered in distinct circles of the same equivalence class are independent, since the circles are at least 2 units apart.

4.3 Unit-Radius Disks

We generalize the WMIS turnstile streaming algorithm for unit length intervals to unit radius disks in $\mathbb{R}^2$. The approximation ratio for disks is closely related to the optimal circle packing constant. We leverage the hexagonal packing of circles in the 2-D plane to obtain the following result:

▶ **Theorem 7** (Theorem 21, informal). *There exists a turnstile streaming algorithm achieving a* $\left(\frac{8\sqrt{3}}{\pi}+\epsilon\right)$*-approximation to estimate WMIS of unit disks with constant probability and in* $poly\left(\frac{\log(n)}{\epsilon}\right)$ *space.*

We note that a greedy algorithm for unweighted disks obtains a 5-approximation to α [25] and the space required is $O(\alpha)$. The greedy algorithm can be extended to obtain a $(5+\epsilon)$-approximation in $\text{poly}\left(\frac{\log n}{\epsilon}\right)$ space using the sampling approach we presented in Section 5. However, beating the approximation ratio achieved by the greedy algorithm requires geometric insight. Critically, we use the hexagonal packing of unit circles in a plane introduced by Lagrange , which was shown to be optimal by Toth [16].

The hexagonal packing covers a $\frac{\pi}{\sqrt{12}}$ fraction of the area in two dimensions. We then partition the unit circles in the hexagonal packing into equivalence classes such that two circles in the same equivalence class are at least a unit distance apart. Formally, let c_1, c_2 be two unit circles in the hexagonal packing of the plane lying in the same equivalence class. Then, for all points $p_1 \in c_1$, $p_i \in c_2$, $\|p_1 - p_2\|_2 \geq 1$. Therefore, if two input disks of unit radius have centers lying in distinct circles belong to the same equivalence class, the disks must be independent, as long as the disk are not centered on the boundary of the circles.

Randomly shifting the underlying hexagonal packing ensures this happens with probability 1. We then show that we can partition the hexagonal packing into four equivalence classes such that their union covers all the circles in the packing and disks lying in distinct circles of the same equivalence class are independent.

Algorithmically, we first impose a grid Δ of the hexagonal packing of circles with radius 1 and shift it by a random integer. We discard all disks that do not have centers lying inside the grid Δ. Given that a hexagonal packing covers a $\pi/\sqrt{12}$ fraction of the area, in expectation, we discard a $(1-\pi/\sqrt{12})$ fraction of $|\mathsf{OPT}|$. We note that if we could accurately estimate the remaining WMIS, and scale the estimator by $\sqrt{12}/\pi$, we would obtain a $(\sqrt{12}/\pi)$-approximation to $|\mathsf{OPT}|$. Let $||\mathsf{OPT}|_{\text{hp}}|$ denote the remaining WMIS. By Theorem 16 such an approximation requires $\Omega(n)$ space.

We then observe that the hexagonal circle packing grid can be partitioned into four equivalence classes. We use $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3$ and $\mathcal{C}_4$ to denote these equivalence classes. Since the equivalence classes form a partition of the hexagonal packing, at least one of them must contain a 1/4-fraction of the remaining maximum independent set. W.l.o.g, let $\mathcal{C}_1$ be the partition that contributes the most to $|\mathsf{OPT}|$. Then, $|\mathsf{OPT}_{\mathcal{C}_1}| \geq \frac{1}{4}|\mathsf{OPT}_{\text{hp}}|$. Therefore, we focus on designing an estimator for $\mathcal{C}_1$. We show a $(1+\epsilon)$-approximation to $\mathcal{C}_1$ in poly $\left(\log(n), \epsilon^{-1}\right)$ space generalizing the algorithmic ideas we introduced for Theorem 8. This implies an overall $\left(\frac{4\sqrt{12}}{\pi} + \epsilon\right) = \left(\frac{8\sqrt{3}}{\pi} + \epsilon\right)$ approximation for $|\mathsf{OPT}|$.

5 Weighted Interval Selection for Unit Intervals

In this section, we present an algorithm to approximate the weight of the maximum independent set, β, for unit-length intervals in turnstile streams. Interestingly, we note that estimating β has the same complexity as approximating α for unit-length intervals. That is, we obtain a $(2+\epsilon)$-approximation to β in the turnstile model, which immediately implies $(2+\epsilon)$-approximation for α, where the weights are identical. We complement this result with a lower bound that shows any $(2-\epsilon)$-approximation to α requires $\Omega(n)$ space. The main algorithmic guarantee we achieve is as follows:

▶ **Theorem 8.** *Let $\mathcal{P}$ be a turnstile stream of weighted unit intervals such that the weights are polynomially bounded in n and let $\epsilon \in (0, 1/2)$. There exists an algorithm that outputs an estimator Y such that with probability at least $9/10$ the following guarantees hold:*

1. $\frac{\beta}{2(1+\epsilon)} \leq Y \leq \beta$.
2. *The total space used is poly* $\left(\frac{\log(n)}{\epsilon}\right)$.

We first impose a grid Δ of side length 1 and shift it by a random integer. We then snap each interval to the cell containing the center of the interval and partition the real line into odd and even cells. Let $\mathcal{C}_e$ be the set of all even cells and $\mathcal{C}_o$ be the set of all odd cells. By averaging, either $|\mathtt{OPT}_{\mathcal{C}_e}|$ or $|\mathtt{OPT}_{\mathcal{C}_o}|$ is at least $\frac{\beta}{2}$. We describe an estimator that gives a $(1+\epsilon)$-approximation to $|\mathtt{OPT}_{\mathcal{C}_e}|$ and $|\mathtt{OPT}_{\mathcal{C}_o}|$. W.l.o.g let $|\mathtt{OPT}_{\mathcal{C}_e}| \geq |\mathtt{OPT}_{\mathcal{C}_o}|$. Therefore, taking the max of the two estimators, we obtain a $(2+\epsilon)$-approximation to β.

Having reduced the problem to estimating $|\mathtt{OPT}_{\mathcal{C}_e}|$, we observe that each even cell has at most 1 interval, namely the max weight interval landing in the cell, contributing to $\mathtt{OPT}_{\mathcal{C}_e}$. Then, partitioning the cells in $\mathcal{C}_e$ into poly$(\log(n))$ weight classes based on the max weight interval in each cell and approximately counting the number of cells in each weight class suffices to estimate $|\mathtt{OPT}_{\mathcal{C}_e}|$ up to a $(1+\epsilon)$-factor. Given such a partition, we can create a substream for each weight class in the partition and compute the ℓ_0 norm of each substream. However, we do not know the partition of the cells into the weight classes a priori and this partition can vary drastically over the course of stream given that intervals can be deleted. The main technical challenge is to simulate this partition. A key tool we use is to estimate the ℓ_0 norm of a vector in turnstile streams. Kane, Nelson and Woodruff [40] showed how to obtain a $(1 \pm \epsilon)$-approximation to the ℓ_0-norm of a vector in poly$(\frac{\log(n)}{\epsilon})$ space.

▶ **Theorem 9** (ℓ_0-Norm Estimation [40])**.** *In the turnstile model, there is an algorithm for $(1 \pm \epsilon)$-approximating the ℓ_0-norm (number of non-zero coordinates) of a vector using space poly* $\left(\frac{\log(n)}{\epsilon}\right)$ *with success probability $2/3$.*

We begin by describing a simple algorithm which obtains a weaker $(9/2+\epsilon)$-approximation to $|\mathtt{OPT}_{\mathcal{C}_e}|$ and in turn a $(9+\epsilon)$-approximation to β. Formally, consider a partition of cells in $\mathcal{C}_e$ into $b = \text{poly}(\log(n))$ weight classes $\mathcal{W}_i = \{c \in \mathcal{C}_e | (1+1/2)^i \leq m(c) < (1+1/2)^{i+1}\}$,

where $m(c)$ is the maximum weight of an interval in c. Create a substream for each weight class $\mathcal{W}_i$, denoted by $\mathcal{W}'_i$, and feed an input interval into this substream if its weight lies in the range $[(1+1/2)^i, (1+1/2)^{i+1})$. Let t_i be the corresponding ℓ_0 estimate for substream $\mathcal{W}'_i$. Then, we can approximate the contribution of $\mathcal{W}_i$ by $(1+1/2)^{i+1} \cdot t_i$. Summing over the b weight classes gives an estimate for $|\texttt{OPT}_{\mathcal{C}_e}|$.

Given access to an algorithm for estimating the ℓ_0-norm, the Naïve Approximation Algorithm (1) satisfies the following guarantee:

▶ **Lemma 10.** *The Naïve Approximation Algorithm (1) outputs an estimate X such that with probability $99/100$, $\frac{\beta}{9(1+\epsilon)} \leq X \leq \beta$ and runs in space poly$\left(\frac{\log(n}{\epsilon}\right)$.*

Proof. We observe that for each non-empty cell $c \in \mathcal{C}_e$, there is exactly 1 interval that can contribute to $|\texttt{OPT}_{\mathcal{C}_e}|$ since each cell of the grid has side length 1 and all intervals falling in a given cell pairwise intersect. This contributing interval lies in some weight class $\mathcal{W}_i$ and our estimator approximates its weight as $(1+1/2)^{i+1}$. Here, the weights of the intervals are sandwiched between $(1+1/2)^i$ and $(1+1/2)^{i+1}$. Therefore, we overestimate the weight by a factor of at most $3/2$.

Further, instead of taking the maximum over each cell c, we may have inserted intervals that lie in c into all substreams $\mathcal{W}'_i$. Therefore, we take the sum of our geometrically increasing weight classes over that cell. In the worst case, we approximate the true weight of a contributing interval, $(3/2)^{i+1}$, with $\sum_{i'=1}^{i}(3/2)^{i'+1} = 3((3/2)^{i+1} - 1)$. Note, we again overestimate the weight, this time by a factor of 3.

Finally, Theorem 9 overestimates the ℓ_0-norm of $\mathcal{W}_i$ by at most $1+\epsilon$ with probability at least $2/3$. We boost this probability by running $O(\log(n))$ estimators and taking the median. Union bounding over all $i \in [b]$, we simultaneously overestimate the ℓ_0-norm of all $\mathcal{W}_i$ by at most $1+\epsilon$ with probability at least $99/100$. Therefore, the overall estimator is a $(9/2+\epsilon)$-approximation to $|\texttt{OPT}_{\mathcal{C}_e}|$. Rescaling our estimator by the above constant underestimates $|\texttt{OPT}_{\mathcal{C}_e}|$. Finally, $|\texttt{OPT}_{\mathcal{C}_e}| \geq \beta/2$ and $\frac{\beta}{(9+\epsilon)} \leq X \leq \beta$.

Since our weights are polynomially bounded, we create poly$\left(\log_{1+\epsilon}(n)\right)$ substreams and run an ℓ_0 estimator from Theorem 9 on each substream. Therefore, the total space used by Algorithm 1 is poly$\left(\frac{\log(n}{\epsilon}\right)$. ◀

We can thus assume we know β and $|\texttt{OPT}_{\mathcal{C}_e}|$ up to a constant by initially making $O(\log(n))$ guesses and running the Naïve Approximation Algorithm for each guess in parallel. At the end of the stream, we know the correct guess up to a constant factor, and thus can output the estimator corresponding to that branch of computation. A key tool we use in this algorithm is k-`Sparse Recovery`. As mentioned in Berinde et al. [8], the k-tail guarantee is a sufficient condition for k-`Sparse Recovery`, since in a k-sparse vector, the elements of the tail are 0. We note that the `Count-Sketch` Algorithm [17] has a k-tail guarantee in turnstile streams.

▶ **Definition 11** (k-`Sparse Recovery`)**.** *Let x be the input vector such that x is updated coordinate-wise in the turnstile streaming model. Then, x is k-sparse if x has at most k non-zero entries at the end of the stream of updates. Given that x is k-sparse, a data structure that exactly recovers x at the end of the stream is referred to as a k-`Sparse Recovery` data structure.*

Intuitively, we again simulate partitioning cells in $\mathcal{C}_e$ into poly $\left(\frac{\log(n)}{\epsilon}\right)$ weight classes according to the maximum weight occurring in each cell. Since we do not know this partition a priori, we initially create $b = O\left(\frac{\log(n)}{\epsilon}\right)$ substreams, one for each weight class and run the

ℓ_0-estimator on each one. We then make $O\left(\frac{\log(n)}{\epsilon}\right)$ guesses for $|\texttt{OPT}_{\mathcal{C}_e}|$ and run the rest of the algorithm for each branch in parallel. Additionally, we run the Naïve Approximation Algorithm to compute the right value of $|\texttt{OPT}_{\mathcal{C}_e}|$ up to a constant factor, which runs in space poly $\left(\frac{\log(n)}{\epsilon}\right)$. Then, we create $b = \text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ substreams by agnostically sampling cells with probability $p_i = \Theta\left(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 X}\right)$, where X is the right guess for $|\texttt{OPT}_{\mathcal{C}_e}|$. Sampling at this rate preserves a sufficient number of cells from weight class $\mathcal{W}_i$. We then run a sparse recovery algorithm on the resulting substreams.

We note that the resulting substreams are sparse. To see this, note we can filter out cells that belong weight classes $\mathcal{W}_{i'}$ for $i' < i$ by simply checking if the maximum interval seen so far lies in weight classes $\mathcal{W}_i$ and higher. Further, sampling with probability proportional to $\Theta\left(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 |\texttt{OPT}_{\mathcal{C}_e}|}\right)$ ensures that the number of cells that survive from weight classes $\mathcal{W}_i$ and above are small. Therefore, we recover all such cells using the sparse recovery algorithm. Note, we limit the algorithm to considering weight classes that have a non-trivial contribution to $\texttt{OPT}_{\mathcal{C}_e}$.

Using the ℓ_0 norm estimates computed above, we can determine the number of non-empty cells in each of the weight classes. Thus, we create a threshold for weight classes that contribute, such that all the weight classes below the threshold together contribute at most an ϵ-fraction of $|\texttt{OPT}_{\mathcal{C}_e}|$ and we can set their corresponding estimators to 0. Further, for all the weight classes above the threshold, we can show that sampling at the right rate leads to recovering enough cells to achieve concentration in estimating their contribution.

Next, we show that the total space used by Algorithm 2 is poly $\left(\frac{\log(n)}{\epsilon}\right)$. We initially create $b = O\left(\frac{\log(n)}{\epsilon}\right)$ substreams, one for each weight class and run an ℓ_0-estimator on each one. Recall, this requires poly $\left(\frac{\log(n)}{\epsilon}\right)$. We then make $O\left(\frac{\log(n)}{\epsilon}\right)$ guesses for $|\texttt{OPT}_{\mathcal{C}_e}|$ and run the rest of the algorithm for each branch in parallel. Additionally, we run Algorithm 1 to compute the right value of $|\texttt{OPT}_{\mathcal{C}_e}|$ up to a constant factor, which runs in space poly $\left(\frac{\log(n)}{\epsilon}\right)$. Then, we create b substreams by sampling cells with probability $p_i = \Theta\left(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 X}\right)$, for $i \in [b]$. Subsequently, we run a poly $\left(\frac{\log(n)}{\epsilon}\right)$-sparse recovery algorithm on each one. Note, if each sample is not too large, this can be done in poly $\left(\frac{\log(n)}{\epsilon}\right)$ space. Therefore, it remains to show that each sample $\mathcal{S}_i$ is small.

▶ **Lemma 12.** *Given a turnstile stream $\mathcal{P}$, with probability at least 99/100, the Weighted Unit Interval Turnstile Sampling procedure (Algorithm 2) samples poly $\left(\frac{\log(n)}{\epsilon}\right)$ cells from the grid Δ.*

Proof. For $i \in [b]$, let $\mathcal{S}_i$ be a substream of cells in $\mathcal{C}_e$, sampled with probability p_i and having an interval with weight at least $(1+\epsilon)^i$ since we filter out all cells with smaller weight. Then, by an averaging argument, the total number of cells with an interval of weight at least $(1+\epsilon)^i$ is at most $\frac{\beta}{(1+\epsilon)^i}$. Sampling with probability $p_i = \Theta\left(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 X}\right)$, the expected number of cells from $\mathcal{W}_i$ that survive in $\mathcal{S}_i$ is at most $p_i \frac{\beta}{(1+\epsilon)^i} = \text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ in expectation. Next, we show that they are never much larger than their expectation. Let X_c be the indicator random variable for cell $c \in \mathcal{W}_i$ to be sampled in $\mathcal{S}_i$ and let μ be the expected number of cells in $\mathcal{S}_i$. By Chernoff bounds,

$$\Pr\left[\sum_c X_c \geq (1+\epsilon)\mu\right] \leq \exp\left(-\frac{2\epsilon^2 \text{poly}(\log(n))}{\text{poly}(\epsilon)}\right) \leq 1/n^k$$

for some large constant k. A similar argument holds for the number of cells from weight class $\mathcal{W}_{i'}$, for $i' > i$, surviving in substream $\mathcal{S}_i$. Note, for all $i' < i$, we never include such a cell from weight class $\mathcal{W}_{i'}$ in our sample $\mathcal{S}_i$, since the filtering step rejects all cells that do not contain an interval of weight at least $(1+\epsilon)^i$. Union bounding over the events that cells $c \in \mathcal{W}_{i'}$ get sampled in $\mathcal{S}_i$, for $i' \geq i$, the cardinality of $\mathcal{S}_i$ is at most poly $\left(\frac{\log(n)}{\epsilon}\right)$ with probability at least $1 - 1/n^{k'}$ for an appropriate constant k'. Since we create b such substreams for $\mathcal{C}_e$, we can union bound over such events in each of them and thus $\bigcup_{i\in[b]} |\mathcal{S}_i|$ is at most poly $\left(\frac{\log(n)}{\epsilon}\right)$ with probability at least 99/100. Since $|\mathcal{C}_e|$ is $|\Delta|/2$, the same result holds for the total cells sampled from Δ. Therefore, the overall space used by Algorithm 2 is poly $\left(\frac{\log(n)}{\epsilon}\right)$. ◀

Algorithm 2 Weighted Unit Interval Turnstile Sampling.

Input: Given a turnstile stream $\mathcal{P}$ with weighted unit intervals, where the weights are polynomially bounded, ϵ and $\delta > 0$, the sampling procedure outputs a $(2+\epsilon)$-approximation to β.

1. Randomly shift a grid Δ of side length 1. Partition the cells into $\mathcal{C}_e$ and $\mathcal{C}_o$.
2. For cells in $\mathcal{C}_e$, snap each interval in the input to a cell c that contains its center. Consider a partitioning of the cells in $\mathcal{C}_e$ into $b =$ poly $\left(\frac{\log(n)}{\epsilon}\right)$ weight classes $\mathcal{W}_i = \{c \in \mathcal{C}_e | (1+\epsilon)^i \leq m(c) \leq (1+\epsilon)^{i+1}\}$, where $m(c)$ is the maximum weight of an interval in c (we do not know this partition a priori.) Create a substream for each weight class $\mathcal{W}_i$ denoted by $\mathcal{W}'_i$.
3. Feed interval $D(d_j, 1, w_j)$ along substream $\mathcal{W}'_i$ such that $w_j \in [(1+\epsilon)^i, (1+\epsilon)^{i+1})$. Maintain a $(1 \pm \epsilon)$-approximate ℓ_0-estimator for each substream. Let $|\mathcal{W}'_i|$ denote the number of non-empty cells in substream $\mathcal{W}'_i$ and $X_{\mathcal{W}'_i}$ be the corresponding estimate returned by the ℓ_0-estimator.
4. Create $O(\log(n))$ substreams, one for each guess of $|\texttt{OPT}_{\mathcal{C}_e}|$. Let X be the guess for the current branch of the computation. In parallel, run Algorithm 1 estimates $|\texttt{OPT}_{\mathcal{C}_e}|$ up to a constant factor. Therefore, at the end of the stream, we know a constant factor approximation to the correct value of $|\texttt{OPT}_{\mathcal{C}_e}|$ and use the estimator from the corresponding branch of the computation.
5. In parallel, for $i \in [b]$, create substream $\mathcal{S}_i$ by subsampling cells in $\mathcal{C}_e$ with probability $p_i = \Theta\left(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 X}\right)$. Note, this sampling is done agnostically at the start of the stream.
6. Run a poly$\left(\frac{\log(n)}{\epsilon}\right)$-sparse recovery algorithm on each substream $\mathcal{S}_i$. For substream $\mathcal{S}_i$, filter out cells c such that $m(c) < (1+\epsilon)^i$. Let $\mathcal{S}'_i$ be the set of cells recovered by the sparse recovery algorithm. Let $\mathcal{S}'_{i|\mathcal{W}_i}$ be the cells in $\mathcal{S}'_i$ that belong to weight class $\mathcal{W}_i$.
7. Let $X_{\mathcal{W}'} = \sum_{i\in[b]} X_{\mathcal{W}'_i}$. Let Z_c be a random variable such that $Z_c = \frac{(1+\epsilon)^{i+1}}{p_i}$ if $c \in \mathcal{S}'_{i|\mathcal{W}_i}$ and 0 otherwise. If $X_{\mathcal{W}'_i} \geq \frac{\epsilon X_{\mathcal{W}'}}{(1+\epsilon)^{i+1}b}$, set the estimator for the i^{th} subsample, $Y_i = \sum_{c\in\mathcal{S}'_{i|\mathcal{W}_i}} X_{\mathcal{W}'_i} Z_c / \mathcal{S}'_{i|\mathcal{W}_i}$. Otherwise, set $Y_i = 0$. Let $Y_e = \sum_i Y_i$.
8. Repeat Steps 2-7 for the set $\mathcal{C}_o$ and let Y_o be the corresponding estimator.

Output: $Y = \max(Y_e, Y_o)$.

Next, we show that the estimate returned by our sampling procedure is indeed a $(2+\epsilon)$-approximation. We observe that the union of the $\mathcal{W}_i$'s form a partition of $\mathcal{C}_e$. Therefore, it suffices to show that we obtain a $(1+\epsilon)$-approximation to the WIS for each $\mathcal{W}_i$ with

good probability. Let c denote a cell in $\mathcal{W}_i$ and $\texttt{OPT}_c$ denote the $\texttt{WIS}$ in cell c. We create a substream for each weight class $\mathcal{W}_i$ denoted by $\mathcal{W}'_i$ and let $X_{\mathcal{W}'_i}$ be the corresponding estimate returned by the ℓ_0 norm of $\mathcal{W}'_i$. Let $X_{\mathcal{W}'} = \sum_{i\in[b]} X_{\mathcal{W}'_i}$ denote the sum of the estimates across the b substreams.

We say that weight class $\mathcal{W}_i$ contributes if $X_{\mathcal{W}'_i} \geq \frac{\epsilon X_{\mathcal{W}'}}{(1+\epsilon)^{i+1}b}$. Note, if we discard all the weight classes that do not contribute we lose at most an ϵ-fraction of β (as shown below). Therefore, setting the estimators corresponding to classes that do not contribute to 0 suffices. The main technical hurdle remaining is to show that if a weight class contributes we can accurately estimate $|\texttt{OPT}_{\mathcal{W}_i}|$.

▶ **Lemma 13.** *Let $Y_e = \sum_i Y_i$ be the estimator returned by Algorithm 2 for the set $\mathcal{C}_e$. Then, $Y_e = (1 \pm \epsilon)|\mathit{OPT}_{\mathcal{C}_e}|$ with probability at least 99/100.*

Proof. We first consider the case when $\mathcal{W}_i$ contributes, i.e., $X_{\mathcal{W}'_i} \geq \frac{\epsilon X_{\mathcal{W}'}}{(1+\epsilon)^{i+1}b}$. Note, $X_{\mathcal{W}'} = \sum_{i\in[b]} X_{\mathcal{W}'_i}$ is a $(1\pm\epsilon)$-approximation to the number of non-empty cells in $\mathcal{W}$ with probability at least $1-n^{-k}$, where $\mathcal{W} = \bigcup_{i\in[b]} \mathcal{W}_i$, since the ℓ_0-estimator is a $(1\pm\epsilon)$-approximation to the number of non-empty cells in $\mathcal{W}_i$ simultaneously for all i with high probability and the $\mathcal{W}_i$'s are disjoint. Recall, X is the correct guess for $|\texttt{OPT}_{\mathcal{C}_e}|$. Therefore, $(1+\epsilon)^i X_{\mathcal{W}'_i} = \Omega\left(\frac{\epsilon X}{(1+\epsilon)b}\right)$. Then, sampling at a rate $p_i = \Theta(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 X})$ implies at least $\Omega\left(\frac{\epsilon X}{(1+\epsilon)^{i+1}b}\right) \cdot \Theta(\frac{b(1+\epsilon)^i \log(n)}{\epsilon^3 X}) = \Omega\left(\frac{\log(n)}{(1+\epsilon)\epsilon^2}\right)$ cells from $\mathcal{W}_i$ survive in expectation. Let X_c denote an indicator random variable for cell $c \in \mathcal{W}_i$ being in substream $\mathcal{S}_i$. Then, by a Chernoff bound,

$$\Pr\left[\sum_{c\in\mathcal{W}_i} X_c \leq (1-\epsilon)\left(\frac{\log(n^{-c})}{2\epsilon^2}\right)\right] \leq \exp\left(\frac{-2\epsilon^2 \log(n^{-c})}{2\epsilon^2}\right) \leq n^{-c}$$

for some constant c. Union bounding over all the random events similar to the one above for $i \in [b]$, simultaneously for all i, the number of cells from $\mathcal{W}_i$ in $\mathcal{S}_i$ is at least $\Omega\left(\frac{\log(n)}{\epsilon^2}\right)$ with probability at least $1 - 1/n^k$ for some constant k. Note, for $i' < i$, no cell $c \in \mathcal{W}_{i'}$ exists in $\mathcal{S}_i$ since the filter step removes all cells c such that $m(c) < (1+\epsilon)^i$.

Next, consider a weight class $\mathcal{W}_{i'}$ for $i' > i$ such that it contributes. We upper bound the number of cells from $\mathcal{W}_{i'}$ that survive in substream $\mathcal{S}_i$. Note, weight class $\mathcal{W}_{i'}$ contains at most $\frac{\beta}{(1+\epsilon)^{i+1}}$ non empty cells for $i' > i$. In expectation, at most $\frac{\beta}{(1+\epsilon)^{i+1}} \cdot p_i = O\left(b\frac{\log(n)}{(1+\epsilon)\epsilon^3}\right)$ cells from $\mathcal{W}_{i'}$ survive in sample $\mathcal{S}_i$, for $i' > i$. By a Chernoff bound, similar to the one above, simultaneously for all $i' > i$, at most $O\left(b\frac{\log(n)}{(1+\epsilon)\epsilon^3}\right)$ cells from $\mathcal{W}_{i'}$ survive, with probability at least $1 - 1/n^{k'}$.

Now, we observe that the total number of cells that survive the sampling process in substream $\mathcal{S}_i$ is poly $\left(\frac{\log(n)}{\epsilon}\right)$ and therefore, they can be recovered exactly by the poly $\left(\frac{\log(n)}{\epsilon}\right)$-sparse recovery algorithm. Let the resulting set be denoted by $\mathcal{S}'_i$. We can also compute the number of cells that belong to weight class $\mathcal{W}_i$ that are recovered in the set $\mathcal{S}'_i$ and we denote this by $|\mathcal{S}'_{i|\mathcal{W}_i}|$. Recall, the corresponding estimator is $Y_i = \sum_{c\in\mathcal{S}'_{i|\mathcal{W}_i}} \frac{X_{\mathcal{W}'_i} Z_c}{|\mathcal{S}'_{i|\mathcal{W}_i}|}$, where $Z_c = \frac{(1+\epsilon)^{i+1}}{p_i}$ if $c \in \mathcal{S}'_{i|\mathcal{W}_i}$ and 0 otherwise. We first show we obtain a good estimator for $|\texttt{OPT}_{\mathcal{W}_i}|$ in expectation: $\mathbf{E}[Y_i] = \mathbf{E}\sum_{c\in\mathcal{S}'_{i|\mathcal{W}_i}} X_{\mathcal{W}'_i} Z_c / \mathcal{S}'_{i|\mathcal{W}_i} = (1 \pm 4\epsilon)|\texttt{OPT}_{\mathcal{W}_i}|$.

Since we know that $|\mathcal{S}'_{i|\mathcal{W}_i}| = \Omega(\frac{\log(n)}{(1+\epsilon)\epsilon^2})$, we show that our estimator concentrates. Note, $\mathbf{E}[Y_i] = (1+\epsilon)^{i+1} X_{\mathcal{W}'_i} = \Omega(\frac{\epsilon X}{\log(n)})$. Further, $0 \leq Z_c \leq \frac{(1+\epsilon)^{i+1}}{p_i} = O\left(\frac{(1+\epsilon)^{i+1}\epsilon^3 X}{b(1+\epsilon)^i \log(n)}\right)$. By a Hoeffding bound, $\Pr\left[|Y_i - E[Y_i]| \geq \epsilon E[Y_i]\right] \leq 2\exp\left(\frac{\Omega(\log(n))}{1+\epsilon}\right) \leq 1/n^k$ for some constant

k. Therefore, union bounding over all i, Y_i is a $(1 \pm \epsilon)^2$-approximation to $|\texttt{OPT}_{\mathcal{W}_i}|$ with probability at least $1 - 1/n$. Therefore, if $\mathcal{W}_i$ contributes we obtain a $(1 \pm \epsilon)$-approximation to $|\texttt{OPT}_{\mathcal{W}_i}|$.

In the case where $\mathcal{W}_i$ does not contribute, we set the corresponding estimator to 0. Note, $X_{\mathcal{W}_i'} < \frac{\epsilon X_{\mathcal{W}'}}{(1+\epsilon)^{i+1}b} = \frac{\epsilon(1\pm\epsilon)|\texttt{OPT}_{\mathcal{W}}|}{b} = O(\frac{\epsilon\beta}{b})$. Note, since there are at most b weight classes, discarding all weight classes that do not contribute discards at most $O(\epsilon\beta)$. We therefore lose at most an ϵ-fraction of β by setting the Y_i corresponding to non-contributing weight classes to 0. ◀

Combining Lemmas 10 and 13 finishes the proof for Theorem 8.

5.1 Lower bound for Unit Intervals

Here, we describe a communication complexity lower bound for estimating α for unit-length interval in turnstile streams and thus show the optimality of Theorem 8. Our starting point is the `Augmented Index` problem and its communication complexity is well understood in the two-player one-way communication model. In this model, we have two players Alice and Bob who are required to compute a function based on their joint input and Alice is allowed to send messages to Bob that are a function of her input and finally Bob announces the answer. Note, Bob isn't allowed to send messages to Alice.

▶ **Definition 14** (`Augmented Indexing`). *Let $\texttt{AI}_{n,j}$ denote the communication problem where Alice receives as input $x \in \{0,1\}^n$ and Bob receives an index $j \in [n]$, along with the $x_{j'}$ for $j' > j$. The objective is for Bob to output x_j in the one-way communication model.*

▶ **Theorem 15** (Communication Complexity of $\texttt{AI}_{n,j}$, [47]). *The randomized one-way communication complexity of $\texttt{AI}_{n,j}$ with error probability at most $1/3$ is $\Omega(n)$.*

Let `Alg` be a one-pass turnstile streaming algorithm that estimates α. We show that `Alg` can be used as a subroutine to solve $\texttt{AI}_{n,j}$, in turn implying a lower bound on the space complexity of `Alg`. We formalize this idea in the following theorem:

▶ **Theorem 16.** *Any randomized one-pass turnstile streaming algorithm `Alg` which approximates α to within a $(2-\epsilon)$-factor, for any $\epsilon > 0$, for unit intervals, with at least constant probability, requires $\Omega(n)$ space.*

Proof. Given her input x, Alice constructs a stream of unit-length intervals and runs `Alg` on the stream. For $i \in [n]$, Alice inserts the interval $\left[\frac{2i-x_i}{n^2}, (\frac{2i-x_i}{n^2}) + 1\right]$. She then communicates the state of `Alg` to Bob. Bob uses the message received from Alice as the initial state of the algorithm and continues the stream. Since Bob's input includes an index j and x_i for all $i > j$, Bob deletes all intervals corresponding to such i. Bob then inserts $\left[(\frac{2j-0.5}{n^2}) - 1, \frac{2j-0.5}{n^2}\right]$.

Let us consider the case where $x_j = 1$. We first note that Bob's interval is the leftmost interval in the remaining set. The right endpoint of this interval is $\frac{2j-0.5}{n^2}$. Next, the rightmost interval corresponds to the j^{th} interval inserted by Alice. The left endpoint of this interval is $\frac{2j-1}{n^2}$. Clearly, these intervals intersect each other and intersect all the intervals between them. Therefore, $\alpha = 1$.

Let us now consider the case where $x_j = 0$. Again, Bob's interval is the leftmost with its right endpoint at $\frac{2j-0.5}{n^2}$. However, the left endpoint of Alice's rightmost interval is $\frac{2j}{n^2}$ and thus these two intervals are independent. Therefore, $\alpha \geq 2$. Observe, any $(2-\epsilon)$-approximate algorithm can distinguish between these two cases and solve $\texttt{AI}_{n,j}$. By Theorem 15, any such algorithm requires $\Omega(n)$ communication and in turn $\Omega(n)$ space. ◀

A Arbitrary Length Intervals in Turnstile Streams

We now focus on estimating α and β for arbitrary-length intervals in turnstile streams. While we cannot obtain streaming algorithms in general, we show it is possible to estimate α and β when the maximum degree of the interval intersection graph or the maximum length of an interval arre bounded. In particular, we show an algorithm that achieves a $(1+\epsilon)$-approximation to α given that the maximum degree is upper bounded by $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$. We also parameterize the problem with respect to the maximum length of an interval, W_{max} (assuming the minimum length is 1), and give an algorithm using $\text{poly}\left(W_{max}\frac{\log(n)}{\epsilon}\right)$ space.

A.1 Algorithms under Bounded Degree Assumptions

In light of the lower bound, we study the problem of estimating α for arbitrary-length intervals assuming the number of pair-wise intersections are bounded by $\kappa_{\max} = \text{poly}\left(\frac{\log(n)}{\epsilon}\right)$. In this section we show the following theorem:

▶ **Theorem 17.** *Let $\mathcal{P}$ be an turnstile stream of unit-weight arbitrary-length intervals with lengths polynomially bounded in n and let $\epsilon \in (0, 1/2)$. Let $\kappa_{\max} = poly\left(\frac{\log(n)}{\epsilon}\right)$ be the maximum number of pairwise intersections in $\mathcal{P}$. Then, there exists an algorithm that outputs an estimator Y such that the following guarantees hold:*

1. *$\frac{\alpha}{(1+\epsilon)} \leq Y \leq \alpha$ with probability at least $2/3$.*
2. *The total space used is $poly\left(\frac{\log(n)}{\epsilon}\right)$.*

Algorithm 3 Level Estimator.

Input: Given a turnstile stream $\mathcal{P}$ with unit weight arbitrary length intervals, where the length is polynomially bounded, $\epsilon > 0$ and $\delta > 0$, the algorithm outputs a $(1+\epsilon)$-approximation to α, assuming that $\kappa_{\max} = \text{poly}\left(\frac{log(n)}{\epsilon}\right)$.

1. Let $t = O\left(\frac{\log(n)}{\epsilon}\right)$ be the number of level-classes. Let $\Delta = \bigcup_{i\in[t]} \Delta_i$ be a randomly shifted Nested Grid, where Δ_i is a grid of side length $\frac{(1+\epsilon)^{i+1}}{\epsilon}$.
2. For $i \in [t]$, let $\mathcal{R}_i$ be the set of all r_i-Structures at level i, where a r_i-Structure is a subset of the Nested Grid, Δ, such that there exists an interval at the i^{th} level of the structure, there exist no intervals in the structure at any level $i' > i$ and all the intervals in the structure at levels $i' < i$ intersect the interval at the i^{th} level.
3. For all $i \in [t]$, using Algorithm 4, sample $\text{poly}\left(\frac{\log(n)}{\epsilon}\right)$ r_i-Structures from the set $\mathcal{R}_i$ to create a substream R_i^s. Note, this sampling is carried out with probability p_i defined below.
4. At the end of the stream, we recover R_i^s, for all $i \in [t]$. Let $Y_i = \frac{|\texttt{OPT}_{R_i^s}|}{p_i}$ (where p_i is the sampling probability for the i^{th} level), where $|\texttt{OPT}_{R_i^s}|$ can be computed using an offline algorithm.

Output: $Y = \sum_{i\in[t]} Y_i$.

Let W be the maximum length of the intervals in our input. We split our input into $t = O\left(\frac{\log(n)}{\epsilon}\right)$ length classes $\mathcal{W}_i$ such that for all $i \in [t]$, $\mathcal{W}_i = \{D_j \in \mathcal{P} | (1+\epsilon)^i \leq r_j \leq (1+\epsilon)^{i+1}\}$. Let $\mathcal{W}$ denote $\bigcup_{i\in[t]} \mathcal{W}_i$. We note that the partition here is over the input to the problem.

We can estimate the number of non-empty cells in each weight class up to a $(1 \pm \epsilon)$-factor by creating a substream for each one and running an ℓ_0 estimator on them. At the end of the stream, we can discard classes that are not within $\log(W)$ non-empty cells of each other. Therefore, we can assume the remaining classes have the same number of non-empty cells up to a $\log(W)$ factor.

We then make $O(\log(n))$ guesses for the number of non-empty cells for any fixed level and run our algorithm in parallel for each guess. Since there are t levels, this gives rise to an $O(t \log(n))$ factor blowup in space. At the end of the stream we know the correct value for each level via the ℓ_0 estimates. Let the number of non-empty cells at every level be denoted by X_i.

In contrast with our previous algorithm, we note that placing a grid on the input with side length 1 no longer suffices since our intervals may now lie in multiple cells. Therefore, we impose a nested grid over the input space:

▶ **Definition 18** (Nested Grid). *Given a partition $\mathcal{W}$, let grid Δ_i, corresponding to $\mathcal{W}_i \in \mathcal{W}$, be a set of cells over the input space with length $\frac{(1+\epsilon)^{i+1}}{\epsilon}$. Then a Nested Grid, denoted by Δ, is defined to be $\bigcup_{i\in[t]} \Delta_i$.*

We then randomly shift the nested grid such that at most an ϵ-fraction of intervals in the i^{th} length class lie within a distance $(1+\epsilon)^{i+1}$ of the i^{th} grid. Since this holds for all $\mathcal{W}_i$, and $\mathcal{W}_i$ are a partition of our input, we lose at most an ϵ-fraction of α. We then define the following object that enables us to obtain accurate estimates for each length class.

▶ **Definition 19** (r_i-Structure). *We define an r_i-Structure to be a subset of the Nested Grid, Δ, such that there exists an interval at the i^{th} level of the structure, there exist no intervals in the structure at any level $i' > i$ and all the intervals in the structure at levels $i' < i$ intersect the interval at the i^{th} level.*

Algorithm 4 Sampling r_i-Structures from $\mathcal{R}_i$.

Input: Given a turnstile stream $\mathcal{P}$ with unit weight arbitrary length intervals, with the length being polynomially bounded, $\epsilon > 0$ and $\delta > 0$, the sampling procedure creates a poly $\left(\frac{\log(n)}{\epsilon}\right)$ size sample of the set $\mathcal{R}_i$.

1. Let Δ_i be the i^{th} level of a randomly shifted *Nested Grid* Δ. Let $\mathcal{R}_i$ be the set of r_i-Structures where the topmost cells lie in Δ_i. Let X_i be the correct guess for the number of non-empty cells in Δ_i up to a constant.
2. Agnostically sample cells from Δ_i with probability $p_i = \max\left(\text{poly}\left(\frac{\log(n)}{\epsilon}\right)\frac{1}{X_i}, 1\right)$. Let S_i be the corresponding substream created.
3. For each cell $c \in \mathcal{S}_i$, let r_i^c be a structure (as defined in 5) with c at the topmost level. Run κ_{max}-*Sparse Recovery* on substream $\mathcal{S}_i$.
4. At the end of the stream, verify that r_i^c is a valid r_i-Structure. Let R_i^s be the set of all such structures.
5. If $X_i > \frac{\epsilon \sum_{i\in[t]} X_i}{t}$, keep R_i^s, else discard it.

Output: $\bigcup_{i\in[t]} R_i^s$.

Let $\mathcal{R}_i$ denote the set of all r_i-Structures at level i. Observe that, taking the union over $i \in [t]$ of $\mathcal{R}_i$ gives a partition of the input. Therefore, estimating $|\texttt{OPT}_{\mathcal{R}_i}|$ separately and summing up the estimates is a good estimator for α.

Similar to the algorithm in Section 5 a key tool we use is k-Sparse Recovery. Intuitively, we subsample poly$\left(\frac{\log(n)}{\epsilon}\right)$ r_i-Structures from the set $\mathcal{R}_i$ to create a substream $\mathcal{R}_i^s$ and run a $\kappa_{\max}$-Sparse Recovery Algorithm on each substream. At the end of the stream, we get an estimate of $|\texttt{OPT}_{\mathcal{R}_i}|$ that concentrates. We then add up the estimates across all the levels to form our overall estimate. We formally describe the Level Estimator Algorithm in Algorithm 3, assuming we are given access to a black-box sampling algorithm for sampling an r_i-Structure. We describe how to sample r_i-Structures in *turnstile streams* in Algorithm 4.

Next, we consider the problem of estimating α for arbitrary-length intervals assuming that the space available is at most poly$\left(\frac{W_{max}\log(n)}{\epsilon}\right)$, where W_{max} is an upper bound on the ratio of the max to the min length of an interval. We note that this regime is interesting when W_{max} is sublinear in n. We obtain the following result:

▶ **Theorem 20.** *Let $\mathcal{P}$ be an turnstile stream of unit-weight arbitrary-length intervals s.t. the length is polynomially bounded in n and let $\epsilon \in (0, 1/2)$. Let $\mathcal{W}_{max}$ be an upper bound on the ratio of the max to the min length of intervals in $\mathcal{P}$. Then, there exists an algorithm that outputs an estimator Y s.t. the following guarantees hold:*

1. $\frac{\alpha}{(2+\epsilon)} \leq Y \leq \alpha$ *with probability at least* $2/3$.
2. *The total space used is poly* $\left(\frac{\mathcal{W}_{max}\log(n)}{\epsilon}\right)$.

B Unit Radius Disks in Turnstile Streams

In this section, we state our main result for approximating α and β for unit-radius disks in $\mathbb{R}^2$ that are received in a turnstile stream. Given space constraints, we defer the exposition to the full version.

The main algorithmic result we prove is the following:

▶ **Theorem 21.** *Let $\mathcal{P}$ be a sequence of unit-radius disks that are received as a turnstile stream and let $\epsilon \in (0, 1/2)$. Then, there exists an algorithm that outputs an estimator Y such that with probability at least $9/10$, $\left(\frac{\pi}{8\sqrt{3}} + \epsilon\right)\beta \leq Y \leq \beta$ where α is the cardinality of the largest independent set in $\mathcal{P}$. Further, the total space used is $O\left(\text{poly}\left(\frac{\log n}{\epsilon}\right)\right)$.*

C Insertion-Only Streams

In this section, we state our results for estimating the maximum weighted independent set of intervals in insertion-only streams. Recall, [10] show that $\left(\frac{3}{2} + \epsilon\right)$ is tight for the unweighted case in insertion-only streams. We also show a lower bound for estimating the maximum independent set of disks in insertion-only streams. The lower bound for intervals in [10] shows that $\left(\frac{3}{2} - \epsilon\right)$-approximation requires $\Omega(n)$ space and this naturally extends to disks. We improve this to $2 - \epsilon$, implying a strict separation between intervals and disks for insertion-only streams. Note, this is not yet known to be the case for turnstile streams.

Our theorem for weighted MIS of unit interval in insertion-only streams is as follows:

▶ **Theorem 22.** *Let P be an insertion-only stream of weighted unit intervals s.t. the weights are polynomially bounded in n and let $\epsilon \in (0, 1/2)$. Then, there exists an algorithm that outputs an estimator Y s.t. with probability at least $9/10$ the following guarantees hold:*

1. $\frac{2\beta}{3+\epsilon} \leq Y \leq \beta$.
2. *The total space used is poly $\left(\frac{\log(n)}{\epsilon}\right)$ bits.*

Next, we describe a lower bound for estimating α for unit disks in insertion-only streams via a reduction from the communication complexity of the `Indexing` problem, which we use as the starting point. We consider the one-way communication model between two players Alice and Bob and each player has access to private randomness. The randomized communication complexity of `Indexing` is well understood in the two-player one-way communication model.

▶ **Definition 23** (`Indexing`). *Let $\mathtt{I}_{n,j}$ denote the communication problem where Alice receives as input a bit vector $x \in \{0,1\}^n$ and Bob receives an index $j \in [n]$. The objective is for Bob to output x_j under the one-round one-way communication model with error probability at most $1/3$.*

▶ **Theorem 24** (Communication Complexity of $\mathtt{I}_{n,j}$). *The randomized one-round one-way communication complexity of $\mathtt{I}_{n,j}$ with error probability at most $1/3$ is $\Omega(n)$.*

We begin with considering the stream of disks $\mathcal{P}$. Let `Alg` be a one-pass insertion-only streaming algorithm that estimates the cardinality of the maximum independent set denoted by α. We then show that `Alg` can be used as a subroutine to solve the communication problem $\mathtt{I}_{n,j}$. Therefore, a lower bound on the communication complexity in turn implies a lower bound on the space complexity of `Alg`. Formally,

▶ **Theorem 25.** *Given a stream of disks $\mathcal{P}$, any randomized one-pass insertion-only streaming algorithm* `Alg` *which approximates α to within a $(2-\epsilon)$-factor, for any $\epsilon > 0$, with error at most $1/3$, requires $\Omega(n)$ space.*

Proof. We show that any such insertion-only streaming algorithm `Alg` can be used to construct a randomized protocol Π to solve the communication problem. Given her input x, Alice constructs a stream of unit disks and runs `Alg` on the stream. Consider the unit circle around the origin. Divide the half-circle above the x-axis into n equally spaced points, denoted by vectors $p_1, p_2, \ldots, p_n$. For $i \in [n]$, if $x_i = 0$, Alice streams a unit disk centered at p_i. If $x_i = 1$, Alice streams a unit disk centered at $-p_i$. After streaming n disks, Alice communicates the memory state of `Alg` to Bob. Bob uses the message received from Alice as the initial state of the algorithm and continues the stream. Recall, Bob's input only consists of a single index j. Therefore, Bob inserts a unit disk centered at $(1 + 1/n^2)p_j$.

We first observe that all disks inserted by Alice pairwise intersect. Since all her unit radius disks are centered on the unit circle around the origin, the distance between their center and the origin is 1. Since all the disks contain the origin, they pairwise intersect. Now, let us consider the case where $x_j = 0$. Recall, in this case, Alice inserts the disk centered p_j and Bob inserts the disk centered at $(1 + 1/n^2)p_j$. The distance between their centers is $1/n^2$ and they clearly intersect. Let us now consider the other disks inserted by Alice, centered at points p_i for $i \neq j$. The distance between their centers is

$$\begin{aligned} ||p_i - (1+1/n^2)p_j||_2^2 &= ||p_i||_2^2 + (1+1/n^2)^2||p_j||_2^2 \pm 2(1+1/n^2)\langle p_i, p_j\rangle \\ &\leq 1 + (1+3/n^2) \pm 2(1+1/n^2)\langle p_i, p_j\rangle \end{aligned} \tag{C.1}$$

where the last inequality follows from $(1+1/n^2)^2 = 1+1/n^4+2/n^2 \leq 1+3/n^2$ for sufficiently large n. Since $i \neq j$, $\langle p_i, p_j\rangle \leq 1 - \Theta(1/n)$. Note, $(1+1/n^2)(1-\Theta(1/n)) \leq 1 - \Theta(n)$ for sufficiently large n. Substituting this above, we get

$$\begin{aligned} ||p_i - (1+1/n^2)p_j||_2^2 &\leq 1 + (1+3/n^2) \pm 2(1+1/n^2)(1-\Theta(1/n)) \\ &\leq 2 + 3/n^2 \pm 2(1-\Theta(1/n)) \\ &\leq 4 - \Theta(1/n) \end{aligned} \tag{C.2}$$

where the last inequality follows from $\Theta(1/n) \geq 3/n^2$ for sufficiently large n. Therefore, the squared distance between the centers is strictly less 4 and the disks do intersect. As a consequence, all disks pairwise intersect and $\alpha = 1$.

Let us now consider the case where $x_j = 1$. Recall Alice inserts a disk centered at $-p_j$ and Bob inserts a disk centered at $(1 + 1/n^2)p_j$. The distance between the centers is $(2 + 1/n^2)$, therefore the two disks do not intersect. Then, α is at least 2. We observe that any $(2-\epsilon)$-approximate algorithm `Alg` can distinguish between these two cases because in the first case `Alg` outputs *at most* 1 and in the second case `Alg` outputs *at least* $1 + \epsilon$. Therefore it is a valid protocol for solving $\mathtt{I}_{n,j}$. If `Alg` has error at most $1/3$, the protocol has error at most $1/3$. By Theorem 24, any such protocol requires $\Omega(n)$ communication and in turn `Alg` requires $\Omega(n)$ space. ◀
