We begin with a sketch of the proof of Lemma 6. As mentioned in the introduction, the proof follows in the footsteps of the analysis of the BLR linearity test. We define $\phi(x)$ to be $\text{plurality}_{y,\pi} f(x_\pi y) + f(y_\pi x) - f(y)$. Markov's inequality allows us to bound the distance between ϕ and f by $2\rho(f)$.

To show that Test 1 rejects ϕ with probability at most $\rho(f)/2$, we first show that for all but a $o(\rho(f))$-fraction of choices of x, $\phi(x)$ is defined by a strict majority that makes up at least 6/7-th of the plurality vote (See Claim 10). The fraction of x's that contribute to the plurality is at least the probability of a collision, i.e., $\Pr_{y,z,\sigma,\pi}[f(x_\pi y) + f(y_\pi x) - f(y) = f(x_\sigma z) + f(z_\sigma x) - f(z)]$. Using the algebraic identity in Claim 8, we can express this probability as

$$\Pr_{y,z,\pi,\sigma}[D_f(\pi; x_\pi z_{\overline{\pi}}, y) - D_f(\pi; y_\pi x_{\overline{\pi}}, z) + D_f(\pi \oplus \sigma; x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}) = 0].$$

The analysis of the BLR test also uses an analogous algebraic identity to bound the collision probability. The difference is that the resulting expression in the BLR analysis is made up of evaluations of the BLR test at points independent of x. This allows one to argue that the plurality vote is made up of a strict majority at all points x. In our setting, the arguments of D_f in the expression above are correlated with x. However, we can view these arguments as the result of passing x through a noisy binary erasure channel. This allows for the application of the hypercontractive inequality to bound the fraction of x for which the collision probability is less than 6/7.

We then show that for all but $o(\rho(f))$ choices of $x, y, \pi \in \{0,1\}^n$ there exist $z, w, \sigma \in \{0,1\}^n$ such that, (A) the value of $D_\phi(\pi; x, y) = \phi(x) - \phi(x_\pi y) - \phi(y_\pi x) + \phi(y)$ does not change after the following substitutions, and (B) the resulting expression post substitution evaluates to zero.

$$\begin{aligned}
\phi(x) &\leftarrow f(x_\sigma z) + f(z_\sigma x) - f(z) \\
\phi(x_\pi y) &\leftarrow f((x_\pi y)_\sigma (z_\pi w)) + f((z_\pi w)_\sigma (x_\pi y)) - f(z_\pi w) \\
\phi(y_\pi x) &\leftarrow f((y_\pi x)_\sigma (w_\pi z)) + f((w_\pi z)_\sigma (y_\pi x)) - f(w_\pi z) \\
\phi(y) &\leftarrow f(y_\sigma w) + f(w_\sigma y) - f(y).
\end{aligned} \tag{2}$$

It follows that the probability that ϕ is rejected by the test is $o(\rho(f))$.

By Claim 10, for all but $o(\rho(f))$ choices of x, y, π the substitutions do not change the value of $D_\phi(\pi; x, y)$ with probability at least 4/7. For (B), we use the algebraic identity in Claim 9 to rewrite the expression after substitution as

$$D_f(\pi \oplus \sigma; x_\sigma z, y_\sigma w) - D_f(\pi \oplus \overline{\sigma}; x_{\overline{\sigma}} z, y_{\overline{\sigma}} w) + D_f(\pi; z, w).$$

Again we show that the arguments of the D_f terms can be viewed as the result of passing x, y and π through independent binary erasure channels. Using the hypercontractive inequality, we conclude that for all but $o(\rho(f))$ choices of x, y and π the expression after substitution evaluates to zero for most choices of z, w and σ. By a union bound we can ensure that (A) and (B) hold simultaneously for the same z, w and σ.

The following technical lemma establishes the bounds we prove using the hypercontractivity of the binary erasure channel. The proof is presented in Section 3.1.

Let $\text{QUERIES}(\pi; x, y)$ denote the vector in $(\{0,1\}^n)^4$ whose entries are the four queries that Algorithm 1 makes when π, x, y is sampled. That is, $\text{QUERIES}(\pi; x, y) = (x, x_\pi y, y_\pi x, y)$.

▶ **Lemma 7.** *Let* $B\textsc{ad} \subset (\{0,1\}^n)^4$ *be a set such that the probability that* $\textsc{queries}(\pi, x, y)$ *lands in* $B\textsc{ad}$*, when* π, x, y *are chosen independently and uniformly at random, is* ρ*.*

(i) $\mu_x(A_1) \le 21^2\rho^{4/3}$*, where*

$$A_1 = \{x \mid \Pr_{\pi,y,z}[\textsc{queries}(\pi; x_\pi z_{\overline{\pi}}, y) \in B\textsc{ad}] \ge 1/21\}.$$

(ii) $\mu_x(A_2) \le 21^2\rho^{4/3}$*, where*

$$A_2 = \{x \mid \Pr_{\pi,\sigma,z}[\textsc{queries}(\pi \oplus \sigma; x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}) \in B\textsc{ad}] \ge 1/21\}.$$

(iii) $\mu_{\pi,x,y}(A_3) \le 7^2\rho^{2/(1+\sqrt{2/3})} \le 7^2\rho^{1.1}$*, where*

$$A_3 = \{(\pi, x, y) \mid \Pr_{\sigma,z,w}[\textsc{queries}(\pi \oplus \sigma; x_\sigma z, y_\sigma w) \in B\textsc{ad}] \ge 1/7\}.$$

(iv) $\mu_\pi(A_4) \le 7^2\rho^{4/3}$*, where*

$$A_4 = \{\pi \mid \Pr_{z,w}[\textsc{queries}(\pi; z, w) \in B\textsc{ad}] \ge 1/7\}.$$

We will also need the following algebraic identities.

▷ Claim 8. The following identity holds:

$$D_f(\pi; x, y) - D_f(\sigma; x, z) = D_f(\pi; x_\pi z_{\overline{\pi}}, y) - D_f(\pi; y_\pi x_{\overline{\pi}}, z) + D_f(\pi \oplus \sigma; x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}).$$

Proof of Claim 8. The claim follows by adding the following two identities:

$$\begin{aligned} D_f(\pi; x, y) - D_f(\pi; x, z) &= -f(x_\pi y_{\overline{\pi}}) - f(y_\pi x_{\overline{\pi}}) + f(y) + f(x_\pi z_{\overline{\pi}}) + f(z_\pi x_{\overline{\pi}}) - f(z) \\ &= f(x_\pi z_{\overline{\pi}}) + f(y) - f(x_\pi y_{\overline{\pi}}) - f(y_\pi z_{\overline{\pi}}) \\ &\quad - f(y_\pi x_{\overline{\pi}}) - f(z) + f(y_\pi z_{\overline{\pi}}) + f(z_\pi x_{\overline{\pi}}) \\ &= D_f(\pi; x_\pi z_{\overline{\pi}}, y) - D_f(\pi; y_\pi x_{\overline{\pi}}, z) \end{aligned}$$

$$\begin{aligned} D_f(\pi; x, z) - D_f(\sigma; x, z) &= -f(x_{\pi\sigma} x_{\pi\overline{\sigma}} z_{\overline{\pi}\sigma} z_{\overline{\pi\sigma}}) - f(z_{\pi\sigma} z_{\pi\overline{\sigma}} x_{\overline{\pi}\sigma} x_{\overline{\pi\sigma}}) + f(x) + f(z) \\ &\quad + f(x_{\pi\sigma} z_{\pi\overline{\sigma}} x_{\overline{\pi}\sigma} z_{\overline{\pi\sigma}}) + f(z_{\pi\sigma} x_{\pi\overline{\sigma}} z_{\overline{\pi}\sigma} x_{\overline{\pi\sigma}}) - f(x) - f(z) \\ &= D_f(\pi \oplus \sigma; x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}) \end{aligned}$$

◀

To analyze the substitutions (2) we set $D_{\phi,f}(\pi; x, y) = \phi(x) - f(x_\pi y) - f(y_\pi x) + f(x)$. In particular, $D_{f,f} = D_f$.

▷ Claim 9 (16-point identity). The following identity holds:

$$\begin{aligned} &D_{\phi,f}(\sigma; x, z) - D_{\phi,f}(\sigma; x_\pi y, w_\pi z) - D_{\phi,f}(\sigma; y_\pi x, z_\pi w) + D_{\phi,f}(\sigma; y, w) \\ &\qquad = D_\phi(\pi; x, y) - D_f(\pi \oplus \sigma; x_\sigma z, y_\sigma w) - D_f(\pi \oplus \overline{\sigma}; x_{\overline{\sigma}} z, y_{\overline{\sigma}} w) + D_f(\pi; z, w). \end{aligned}$$

Proof of Claim 9. We write $xyzw$ to denote the string $x_{\pi\sigma} y_{\pi\overline{\sigma}} z_{\overline{\pi}\sigma} w_{\overline{\pi\sigma}}$. With this notation,

$$\begin{array}{lllll} +D_{\phi,f}(\sigma; x, z) & = +\phi(xxxx) & -f(xzxz) & -f(zxzx) & +f(zzzz) \\ -D_{\phi,f}(\sigma; x_\pi y, w_\pi z) & = -\phi(xxyy) & +f(xwyz) & +f(wxzy) & -f(wwzz) \\ -D_{\phi,f}(\sigma; y_\pi x, z_\pi w) & = -\phi(yyxx) & +f(yzxw) & +f(zywx) & -f(zzww) \\ +D_{\phi,f}(\sigma; y, w) & = +\phi(yyyy) & -f(ywyw) & -f(wywy) & +f(wwww) \\ & \quad \| & \| & \| & \| \\ & +D_\phi(\pi; x, y) & -D_f(\pi \oplus \sigma; x_\sigma z, y_\sigma w) & -D_f(\pi \oplus \overline{\sigma}; x_{\overline{\sigma}} z, y_{\overline{\sigma}} w) & +D_f(\pi; z, w) \end{array}$$

The identity states that the column sums and the row sums add up. ◁

Proof of Lemma 6. Let ϕ be a function defined as $\phi(x) = \text{plurality}_{y,\pi}\, f(x_\pi y) + f(y_\pi x) - f(y)$. That is, $\phi(x)$ is the most frequent value of $f(x_\pi y) + f(y_\pi x) - f(y)$, where $y, \pi \in \{0,1\}^n$. Ties are broken arbitrarily. We show that ϕ satisfies the hypothesis of the lemma.

(i) ϕ is $2\rho(f)$-close to f: For $x \in \{0,1\}^n$, let $\rho_x \doteq \Pr_{y,\pi}[f(x) \neq f(x_\pi y) + f(y_\pi x) - f(y)]$. Note that $\mathbb{E}_x[\rho_x] = \rho(f)$, and that if $\rho_x < 1/2$ then $f(x) = \phi(x)$. Thus, by Markov's inequality,

$$\Pr_x[f(x) \neq \phi(x)] \leq \Pr_x[\rho_x \geq 1/2] \leq 2\rho(f).$$

(ii) $\rho(\phi) \leq \rho(f)/2$: We begin by showing that with probability $\rho(f)/12$ over the choice of x, the plurality that defines $\phi(x)$ is a majority made up of 6/7-th of the votes. Then $\Pr_{\pi,y}[D_{\phi,f}(\pi; x, y) = 0]$ is the fraction of votes that constitute the plurality defining $\phi(x)$. Let

$$\textsc{Weak-Maj} = \left\{x \;\middle|\; \Pr_{y,\pi}[D_{\phi,f}(\pi; x, y) \neq 0] \geq 1/7\right\}.$$

▷ Claim 10 (Strong Majority). $\mu_x(\textsc{Weak-Maj}) \leq \rho(f)/12$.

Proof. The fraction of votes that contribute to the plurality $\Pr_{y,\pi}[D_{\phi,f}(\pi; x, y) = 0]$ is an upper bound on the collision probability $\Pr_{y,\pi,z,\sigma\in\{0,1\}^n}[D_{\phi,f}(\pi; x, y) = D_{\phi,f}(\sigma; x, z)]$. This is because

$$\begin{aligned}\Pr_{y,\pi,z,\sigma}[D_{\phi,f}(\pi; x, y) = D_{\phi,f}(\sigma; x, z)] &= \sum_{\gamma\in\mathcal{G}} \Pr_{y,\pi}[D_{\phi,f}(\pi; x, y) = \gamma]^2 \\ &\leq \max_{\gamma\in\mathcal{G}} \Pr_{y,\pi}[D_{\phi,f}(\pi; x, y) = \gamma] \\ &= \Pr_{y,\pi}[D_{\phi,f}(\pi; x, y) = 0].\end{aligned}$$

The final equality holds because $\phi(x) = \arg\max_{\beta\in\mathcal{G}} \Pr_{y,\pi}[\beta - f(x_\pi y) - f(y_\pi x) + f(y) = 0]$. We showed that

$$\mu_x(\textsc{Weak-Maj}) \leq \mu_x\{x \mid \Pr_{y,\pi,z,\sigma}[D_{\phi,f}(\pi; x, y) \neq D_{\phi,f}(\sigma; x, z)] \geq 1/7\}.$$

We now use Lemma 7 to bound the right hand side. Let $\textsc{Bad}_f \subset (\{0,1\}^n)^4$ be the set of queries on which D_f fails, namely

$$\textsc{Bad}_f = \{\textsc{queries}(\pi; x, y) \mid D_f(\pi; x, y) \neq 0\}.$$

This is a set of measure $\mu_{\pi,x,y}(\textsc{Bad}) = \rho(f)$. Since $D_{\phi,f}(\pi; x, y) - D_{\phi,f}(\sigma; x, z) = D_f(\pi; x, y) - D_f(\sigma; x, z)$, by the algebraic identity in Claim 8 and a union bound, we have

$$\begin{aligned}\mu_x(\textsc{Weak-Maj}) &\leq \mu_x\{x \mid \Pr_{\pi,\sigma,y,z}[D_{\phi,f}(\pi; x, y) - D_{\phi,f}(\sigma; x, z) \neq 0] \geq 1/7\} \\ &\leq \mu_x\{x \mid \Pr_{\pi,y,z}[D_f(\pi; x_\pi z_{\overline{\pi}}, y) \neq 0] \geq 1/21\} \\ &\quad + \mu_x\{x \mid \Pr_{\pi,y,z}[D_f(\pi; y_\pi x_{\overline{\pi}}, z) \neq 0] \geq 1/21\} \\ &\quad + \mu_x\{x \mid \Pr_{\pi,\sigma,z}[D_f(\pi \oplus \sigma; x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}) \neq 0] \geq 1/21\} \\ &= \mu_x(A_1) + \mu_x(A_1) + \mu_x(A_2),\end{aligned}$$

where A_1 and A_2 are the sets

$$A_1 = \{x \mid \Pr_{\pi,y,z}[\textsc{queries}(\pi; x_\pi z_{\overline{\pi}}, y) \in \textsc{Bad}_f] \geq 1/21\},$$

$$A_2 = \{x \mid \Pr_{\pi,\sigma,z}[\textsc{queries}(\pi \oplus \sigma; x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}) \in \textsc{Bad}_f] \geq 1/21\}.$$

By Lemma 7 we get that $\mu_x(\textsc{Weak-Maj}) \leq \rho(f)/12$, for small enough η. ◁

We are now ready to prove that $\rho(\phi) = \Pr_{\pi,x,y}[D_\phi(\pi;x,y) \neq 0] \leq \rho(f)/2$. In order to do so we define a set $\textsc{Bad}_\phi$ of triples (π,x,y) such that $\mu_{\pi,x,y}(\textsc{Bad}_\phi) \leq \rho(f)/2$, and if $(\pi,x,y) \notin \textsc{Bad}_\phi$ then $D_\phi(\pi,x,y) = 0$.

Let A_3 and A_4 denote the sets

$$A_3 = \{(\pi,x,y) \mid \Pr_{\sigma,z,w}[\textsc{queries}(\pi \oplus \sigma; x_\sigma z, y_\sigma w) \in \textsc{Bad}_f] \geq 1/7\},$$

$$A_4 = \{\pi \mid \Pr_{z,w}[\textsc{queries}(\pi; z, w) \in \textsc{Bad}_f] \geq 1/7\}.$$

Let $\textsc{Bad}_\phi$ be the set

$$\{(\pi,x,y) \mid (\text{One of } x, y, x_\pi y, y_\pi x \text{ lies in } \textsc{Weak-Maj}) \text{ or } ((\pi,x,y) \in A_3) \text{ or } (\pi \in A_4)\}.$$

By Lemma 7, $\mu_{\pi,x,y}(A_3) \leq \rho(f)/12$, and $\mu_\pi(A_4) \leq \rho(f)/12$, for small enough η. As $x, y, x_\pi y, y_\pi x$ are all random, by a union bound we have

$$\mu_{\pi,x,y}(\textsc{Bad}_\phi) \leq 4\mu_x(\textsc{Weak-Maj}) + \mu_{\pi,x,y}(A_3) + \mu_\pi(A_4) \leq \rho(f)/2.$$

All that remains to show is that if $(\pi,x,y) \notin \textsc{Bad}_\phi$, $D_\phi(\pi;x,y) = 0$. On rearranging the terms in the algebraic identity of Claim 9, we get

$$\begin{aligned} D_\phi(\pi;x,y) = \; & D_{\phi,f}(\sigma;x,z) - D_{\phi,f}(\sigma;x_\pi y, w_\pi z) - D_{\phi,f}(\sigma;y_\pi x; z_\pi w) + D_{\phi,f}(\sigma;y,w) \\ & + D_f(\pi \oplus \sigma; x_\sigma z, y_\sigma w) + D_f(\pi \oplus \overline{\sigma}; x_{\overline{\sigma}} z, y_{\overline{\sigma}} w) - D_f(\pi;z,w). \end{aligned} \tag{3}$$

Fix a triple $(\pi,x,y) \notin \textsc{Bad}_\phi$. We show that $D_\phi(\pi,x,y) = 0$, by showing that there exists a choice of σ, z and w for which the right hand side of Equation (3) evaluates to zero. By Equation (3) and a union bound,

$$\begin{aligned} \Pr_{\sigma,z,w}[D_\phi(\pi;x,y) \neq 0] &= \Pr_{\sigma,z,w}\begin{bmatrix} D_{\phi,f}(\sigma;x,z) \neq 0 \\ \text{or } D_{\phi,f}(\sigma;x_\pi y, w_\pi z) \neq 0 \\ \text{or } D_{\phi,f}(\sigma;y_\pi x; z_\pi w) \neq 0 \\ \text{or } D_{\phi,f}(\sigma;y,w) \neq 0 \\ \text{or } D_f(\pi \oplus \sigma; x_\sigma z, y_\sigma w) \neq 0 \\ \text{or } D_f(\pi \oplus \overline{\sigma}; x_{\overline{\sigma}} z, y_{\overline{\sigma}} w) \neq 0 \\ \text{or } D_f(\pi;z,w) \neq 0 \end{bmatrix} \\ &< 4/7 + \Pr_{\sigma,z,w}\begin{bmatrix} \textsc{queries}(\pi \oplus \sigma; x_\sigma z, y_\sigma w) \in \textsc{Bad}_f \\ \text{or } \textsc{queries}(\pi \oplus \overline{\sigma}; x_{\overline{\sigma}} z, y_{\overline{\sigma}} w) \in \textsc{Bad}_f \\ \text{or } \textsc{queries}(\pi;z,w) \in \textsc{Bad}_f \end{bmatrix} \\ &< 4/7 + 3/7 = 1. \end{aligned}$$

The first inequality holds because $x, x_\pi y, y_\pi x, y \notin \textsc{Weak-Maj}$, and the second inequality holds because $(\pi,x,y) \notin A_3$ and $\pi \notin A_4$. Since the probability $\Pr_{\sigma,z,w}[D_\phi(\pi;x,y) \neq 0]$ is either 0 or 1, it must be that $D_\phi(\pi;x,y) = 0$. Therefore,

$$\rho(\phi) = \Pr_{\pi,x,y}[D_\phi(\pi;x,y) \neq 0] \leq \mu_{\pi,x,y}(\textsc{Bad}_\phi) \leq \rho(f)/2. \qquad \blacktriangleleft$$

3.1 Proof of Lemma 7

We begin with some preliminaries on discrete channels and hypercontractivity. For a motivating discussion on hypercontractivity and a proof of Fact 14 below see Chapter 9 of [12].

▶ **Definition 11** (Discrete channels). *A* discrete channel *is a triple* $(\mathcal{U}, P, \mathcal{V})$*, where* $\mathcal{U}$ *and* $\mathcal{V}$ *are finite sets representing the* input alphabet *and* output alphabet*, and* P *is a* $\mathcal{U} \times \mathcal{V}$ *probability* transition matrix *that describes the distribution of the output conditioned on the input. The* composition *of two channels* $(\mathcal{U}, P_1, \mathcal{V})$ *and* $(\mathcal{V}, P_2, \mathcal{W})$ *is the channel* $(\mathcal{U}, P_1 \cdot P_2, \mathcal{W})$*, where* $\cdot$ *is matrix multiplication.*

The binary erasure channel will play an important role in the proof of Lemma 7.

▶ **Definition 12** (Binary Erasure Channel). *The* binary erasure channel $BEC(e)$ *with erasure probability* e *has input alphabet* $\{0,1\}$ *and output alphabet* $\{0,1,\perp\}$*, and probability transition matrix* $P(x|x) = 1-e, P(\perp|x) = e$*.*

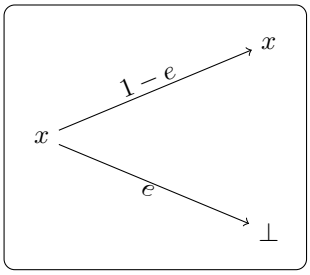

Figure 1 The binary erasure channel $BEC(e)$.

For a real valued random variable U and $p \geq 1$, we denote the p-norm of U by $\|U\|_p \doteq \mathbb{E}_U[|U|^p]^{1/p}$.

▶ **Definition 13** (Hypercontractivity). *For* $1 \leq q \leq p$*, A pair of random variables* (U, V) *is* (p,q)*-hypercontractive if for every pair of real valued functions* f, g*,*

$$\mathbb{E}[f(U)g(V)] \leq \|f(U)\|_{p'} \|\|g(V)\|_q,$$

where $p' = p/(p-1)$ *is the Hölder conjugate of* p*.*

▶ **Fact 14** (Tensorisation [7]). *If* (U_1, V_1) *and* (U_2, V_2) *are independent random variables that are* (p,q)*-hypercontractive, then* $((U_1, U_2), (V_1, V_2))$ *is* (p,q) *hypercontractive.*

▶ **Theorem 15** (Hypercontractivity of $BEC(e)$ [11]). *Let* U *be distributed uniformly over* $\{0,1\}$ *and let* $V \in \{0,1,\perp\}$ *denote the output of* $BEC(e)$ *on input* U*. Then* (U, V) *is* (p,q)*-hypercontractive for all* $1 \leq q \leq p$ *such that*

$$\frac{q-1}{p-1} \geq 1 - e.$$

▶ **Fact 16** (Composition). *Let* $(\mathcal{U}, P_1, \mathcal{V})$ *and* $(\mathcal{V}, P_2, \mathcal{W})$ *be two channels. Let* U *be a random variable over* $\mathcal{U}$*. Let* V *be the random variable that represents the output of the first channel on input* U*, and* W *the random variable that represents the output of the second channel on input* V*. If* (U, V) *is* (p,q)*-hypercontractive then so is* (U, W)*.*

Proof of Fact 16. Let $f : \mathcal{U} \to \mathbb{R}$ and $g : \mathcal{W} \to \mathbb{R}$ be arbitrary functions. Since $U \to V \to W$ is a markov chain, we have

$$\mathbb{E}_{U,W}[f(U)g(W)] = \mathbb{E}_{U,V}[f(U)E_W[g(W) \mid V]] \leq \|f(U)\|_{p'} \|\mathbb{E}_W[g(W) \mid V]\|_q,$$

where the inequality holds because (U, V) is (p,q) hypercontractive.

Now, by Jensen's inequality,

$$\mathbb{E}_V[\mathbb{E}_W[g(W) \mid V]^q]^{1/q} \leq \mathbb{E}_V[\mathbb{E}_W[g(W)^q \mid V]]^{1/q} = \mathbb{E}_W[g(W)^q]^{1/q} = \|g(W)\|_q$$

Therefore, (U, W) is (p, q) hypercontractive. ◀

The following claim captures the small-set expansion interpretation of hypercontractivity [1] in the form used in the proof of Lemma 7.

▷ Claim 17. Let U, V be random variables that take values in $\mathcal{U}$ and $\mathcal{V}$ respectively. Let $B \subset \mathcal{V}$ be a set such that $\Pr[V \in B] = \rho$. Let $A \subset \mathcal{U}$ denote the set $\{u \mid \Pr[V \in B \mid U = u] \geq \theta\}$. If (U, V) is (p, q) hypercontractive, then $\Pr[U \in A] \leq \rho^{p/q}/\theta^p$.

Proof. Let 1_A and 1_B denote the indicator functions of the sets A and B. Since (U, V) are (p, q) hypercontractive,

$$\theta \cdot \Pr[U \in A] \leq \Pr[V \in B \mid U \in A] \Pr[U \in A] = \mathbb{E}[1_A(U)1_B(V)] \leq \|1_A(U)\|_{p'} \|1_B(V)\|_q,$$

where $p' = p/(p-1)$. Note that $\|1_B(V)\| = \rho^{1/q}$, and $\|1_A(U)\|_{p'} = \Pr[U \in A]^{1/p'}$. Therefore, $\Pr[U \in A]^{1/p} \leq \rho^{1/q}/\theta$, that is, $\Pr[U \in A] \leq \rho^{p/q}/\theta^p$. ◁

Proof of Lemma 7. We need to bound the probabilities of four sets of the form

$$\{u \in \Sigma^n \mid \Pr[\textsc{queries}(\psi(u)) \in \textsc{bad} | U = u]\} \geq \theta,$$

where ψ is some (randomized) function. All bounds of the form $\theta^{-2}\rho^{2/q}$ will follow from Claim 17 by showing that the channel $U \to \textsc{queries}(\psi(u))$ is $(2, q)$-hypercontractive for a suitable choice of q ($q = 3/2$ for parts (i), (ii), (iv) and $q = 1 + \sqrt{2/3}$ for part (iii)).

The *channel* $(\Sigma^n, P_n, \{0,1\}^{n\times 4})$ that maps $u \in \Sigma^n$ to $\textsc{queries}(\psi(u)) \in \{0,1\}^{n\times 4}$ acts independently on the symbols $u_1, \ldots, u_n$. In all cases, the i-th bits of the four queries (q_1, q_2, q_3, q_4) are obtained by applying the one-dimensional channel P_1 to u_i. Therefore, P_n tensorizes as $P_n = P_1^{\otimes n}$. By Fact 14, it is sufficient to show that the channel P_1 is hypercontractive. We may and will therefore assume, without loss of generality, that $n = 1$.

We now demonstrate how each of the four channels of interest can be decomposed into a binary erasure channel with constant erasure probability ($e = 1/2$ in parts (i), (ii), (iv) and $e = 1 - \sqrt{2/3}$ in part (iii)) and some other fixed channel. The Lemma then follows from Fact 16 and Theorem 15 with $q = 2 - e$.

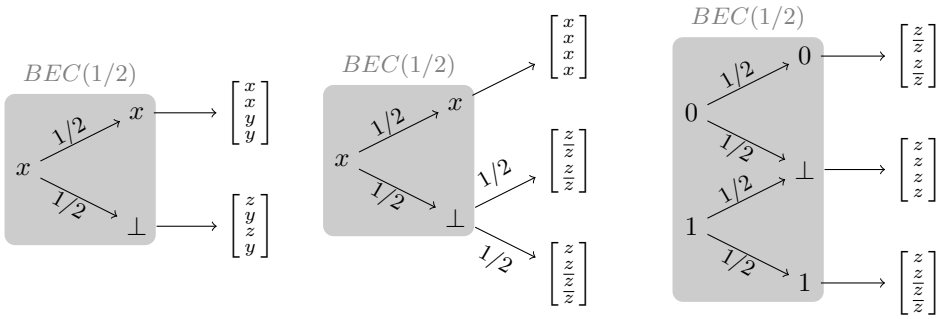

Figure 2 Channels (i) $x \to \textsc{queries}(\pi, x_\pi z_{\overline{\pi}}, y)$; (ii) $x \to \textsc{queries}(\pi \oplus \sigma, x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}})$; (iv) $\pi \to \textsc{queries}(\pi, z, w)$. y and z are random bits.

(i) The channel $x \to \text{QUERIES}(\pi; x_\pi z_{\overline{\pi}}, y) = (x_\pi z_{\overline{\pi}}, x_\pi y_{\overline{\pi}}, y_\pi z_{\overline{\pi}}, y)$ from $\Sigma = \{0,1\}$ to $\{0,1\}^4$ can be decomposed in the following way: On input x the channel samples a random bit π and outputs $xxyy$ if $\pi = 1$, and $zyzy$ if $\pi = 0$ for random y and z. This channel can be alternatively described as $BEC(1/2)$ composed with a second channel that outputs $xxyy$ if there is no erasure and the independent symbol $zyzy$ otherwise. See Figure 2 (i).

(ii) The channel from $\Sigma = \{0,1\}$ to $\{0,1\}^4$ is of the form

$$x \to \text{QUERIES}(\pi \oplus \sigma, x_\sigma z_{\overline{\sigma}}, z_\sigma x_{\overline{\sigma}}) = \begin{pmatrix} x_{\pi\sigma} z_{\pi\overline{\sigma}} x_{\overline{\pi}\sigma} z_{\overline{\pi\sigma}} \\ z_{\pi\sigma} z_{\pi\overline{\sigma}} x_{\overline{\pi}\sigma} x_{\overline{\pi\sigma}} \\ x_{\pi\sigma} x_{\pi\overline{\sigma}} z_{\overline{\pi}\sigma} z_{\overline{\pi\sigma}} \\ z_{\pi\sigma} x_{\pi\overline{\sigma}} z_{\overline{\pi}\sigma} x_{\overline{\pi\sigma}} \end{pmatrix} = \begin{cases} xzxz, & \text{if } \pi\sigma = 1, \\ zzxx, & \text{if } \pi\overline{\sigma} = 1, \\ xxzz, & \text{if } \overline{\pi}\sigma = 1, \\ zxzx, & \text{if } \overline{\pi\sigma} = 1, \end{cases}$$

where π, σ, z are random bits. We can alternatively describe it like this: If $z = x$, then output $xxxx$. If $z \neq x$ and $\pi \oplus \sigma = 1$, then output $zz\overline{z}\overline{z}$. If $z \neq x$ and $\pi \oplus \sigma = 0$, then output $zzzz$.

This channel can be factored through $BEC(1/2)$ as in Figure 2 (ii). If there is no erasure, the second channel outputs $xxxx$. If there is an erasure, then the second channel outputs $zz\overline{z}\overline{z}$ with probability $1/2$ and $z\overline{z}z\overline{z}$ with probability $1/2$.

(iii) The channel from $\Sigma = \{0,1\}^3$ to $\{0,1\}^4$ is of the form

$$\begin{pmatrix} \pi \\ x \\ y \end{pmatrix} \to \text{QUERIES}(\pi \oplus \sigma; x_\sigma z, y_\sigma w) = \begin{pmatrix} x_{\pi\sigma} z_{\pi\overline{\sigma}} x_{\overline{\pi}\sigma} z_{\overline{\pi\sigma}} \\ y_{\pi\sigma} z_{\pi\overline{\sigma}} x_{\overline{\pi}\sigma} w_{\overline{\pi\sigma}} \\ x_{\pi\sigma} w_{\pi\overline{\sigma}} y_{\overline{\pi}\sigma} z_{\overline{\pi\sigma}} \\ y_{\pi\sigma} w_{\pi\overline{\sigma}} y_{\overline{\pi}\sigma} w_{\overline{\pi\sigma}} \end{pmatrix} = \begin{cases} xyxy, & \text{if } \pi\sigma = 1, \\ zzww, & \text{if } \pi\overline{\sigma} = 1, \\ xxyy, & \text{if } \overline{\pi}\sigma = 1, \\ zwzw, & \text{if } \overline{\pi\sigma} = 1. \end{cases}$$

Consider the composition of the following two channels. The first channel views the symbol πxy as three bits and independently applies $BEC(1/4)$ to π and $BEC(1 - \sqrt{2/3})$ to x and y. The second channel is described in Figure 3.

- If π is erased, the second channel outputs $zzzz$, for a uniform bit z. This corresponds to the event $z = w$ and $\sigma = 0$.
- If π is not erased but one of x, y is erased, the second channel samples a uniform bit $z \in \{0,1\}$ and outputs $z\overline{z}z\overline{z}$ if $\pi = 0$ and $zz\overline{z}\overline{z}$ if $\pi = 1$. This corresponds to the event $z \neq w$ and $\sigma = 0$.
- If there are no erasures, then the second channel outputs $xyxy$ if $\pi = 1$, and $xxyy$ if $\pi = 0$. This corresponds to the event $\sigma = 1$.

The first channel is $BEC(\frac{1}{4}) \otimes BEC(1 - \sqrt{2/3}) \otimes BEC(1 - \sqrt{2/3})$. Since $1 - \sqrt{2/3} \leq 1/4$, by Fact 14 it inherits the hypercontractivity parameters of $BEC(1 - \sqrt{2/3})$.

(iv) The channel $\pi \to \text{QUERIES}(\pi, z, w)$ from $\Sigma = \{0,1\}$ to $\{0,1\}^4$ outputs $zzww$ if $\pi = 1$ and $zwzw$ if $\pi = 0$ for random bits z and w. Alternatively, the channel can be described as a uniform choice between $zzzz$ and $zz\overline{z}\overline{z}$ when $\pi = 1$ and a uniform choice between $zzzz$ and $z\overline{z}z\overline{z}$ when $\pi = 0$. This can be modeled as the composition of $BEC(1/2)$ and a second channel that outputs $zzzz$ if there is an erasure, and either $zz\overline{z}\overline{z}$ or $z\overline{z}z\overline{z}$ depending on the value of π_i otherwise. See Figure 2 (iv). ◀

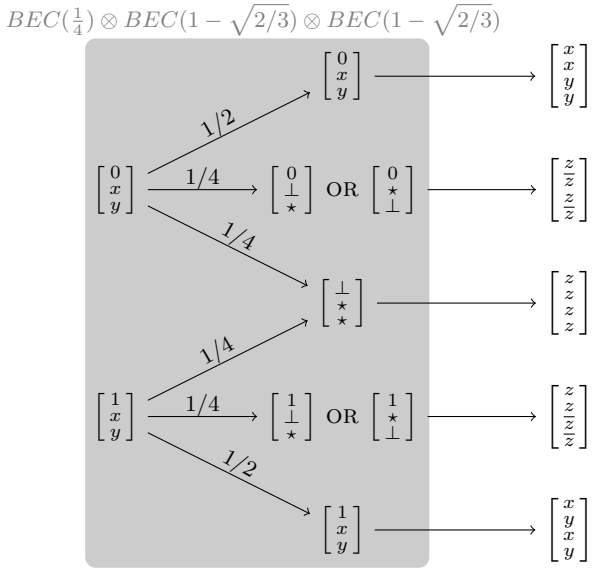

Figure 3 (iii) Channel $(\pi, x, y) \to \text{QUERIES}(\pi \oplus \sigma, x_\sigma z, y_\sigma w)$. A $\star$ represents any of $\{0, 1, \perp\}$ and z is a random bit.

4 Testing $\oplus$-Partitionability

Recall that a function $f : \mathcal{D} = \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{G}$ is *k-$\oplus$-partitionable* if there exists a k-partition $S_1, \ldots, S_k$ of $[n]$, and functions $f_1, \ldots, f_k$ such that $f(x) = f_1(x_{S_1}) + \ldots + f_k(x_{S_k})$, for all $x \in \mathcal{D}$.

Recall that for disjoint sets $S, T \subseteq [n]$,

$$D_f(S, T; x, y) \doteq f(x) - f(y_S x) - f(y_T x) + f(y_{S \cup T} x)$$

The following claim is an immediate consequence of Theorem 1, and allows us to determine whether a function f is $\oplus$-partitionable with respect to a fixed partition $S_1, \ldots, S_k$.

▷ Claim 18. Let $(S, \overline{S})$ be a random coarsening of a k-partition $(S_1, \ldots, S_k)$ obtained by adding each S_i to S with probability $1/2$. If f is ϵ-far from $\oplus$-partitionable with respect to $S_1, \ldots, S_k$, then $D_f(S, \overline{S}; x, y)$ is nonzero with probability $\Omega(\epsilon)$.

To determine whether a function is k-$\oplus$-partitionable, our testers use the 4-query test D_f to group together variables that cannot occur in different partition components. If the tester finds fewer than k groups, it rejects, otherwise it accepts.

4.1 Adaptive Test for $\oplus$-Partitionability

Our test for k-$\oplus$-partitionability (Algorithm 3) seeks to identify a pair of *contractable* variables s, t that must fall in the same component of a partition. Variables s and t are then contracted and the test is repeated until either fewer than k variables are left (giving a certificate of non-partionability) or no contractable candidates can be found.

A sufficient condition for contractability is that $D_f(\{s\}, \{t\}; x, y)$ is nonzero for some assignment x, y. We start by splitting the variables into k components $S_1, \ldots, S_k$ arbitrarily and zero-testing $D_f(S, \bar{S}; x, y)$ for a random coarsening of the components into $S, \bar{S}$. By Claim 18, the zero-test fails with probability at least $\Omega(\epsilon)$, where ϵ is the distance between f and the set of functions that are $\oplus$-partitionable with respect to $S_1, \ldots, S_k$.

Once such a bipartition $S, \bar{S}$ is identified, s and t can be identified via binary search using Algorithm 2 below. The same idea was used by Blais [3] to identify an influential variable in his junta test. Our t is in fact the influential variable in the function $g(x_{[n]\setminus S}) = f(x) - f(y_S x)$, for fixed x_S, y_S, returned by Blais' test.

Algorithm 2 Violating pair adaptive search.

Oracle : $f\colon \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{G}$
Input : $(S, T; x, y)$ such that $D_f(S, T; x, y) \neq 0$.
Output : $(\{s\}, \{t\})$ such that $D_f(\{s\}, \{t\}; x', y') \neq 0$ for some x', y'.

If $|S| = |T| = 1$, output S, T.
If $|T| = 1$, swap S and T.
do
  Split T into two subsets T' and T'' of (almost) equal size.
  If $D_f(S, T'; x, y) \neq 0$, recursively run on input $(S, T'; x, y)$.
  Otherwise, recursively run on input $(S, T''; y, x)$.

The correctness of Algorithm 2 is based on the following identity.

▷ Claim 19. $D_f(S, T \cup T'; x, y) = D_f(S, T; x, y) + D_f(S, T'; y, x)$ for disjoint sets S, T, T'.

Proof. Without loss of generality take $S = \{1\}$, $T = \{2\}$, $T' = \{3\}$ and assume there are no other inputs (they are all fixed). By the definition of D_f,

$$\begin{aligned} D_f(\{1\}, \{2\}; x, y) &= f(x_1x_2x_3) + f(y_1y_2x_3) - f(x_1y_2x_3) - f(y_1x_2x_3) \\ D_f(\{1\}, \{3\}; y, x) &= f(y_1y_2y_3) + f(x_1y_2x_3) - f(y_1y_2x_3) - f(x_1y_2y_3) \\ -D_f(\{1\}, \{2,3\}; x, y) &= -f(x_1x_2x_3) - f(y_1y_2y_3) + f(x_1y_2y_3) + f(y_1x_2x_3). \end{aligned}$$

The terms on the right hand side cancel out. ◁

▶ **Lemma 20.** *Algorithm 2 is correct and has query complexity at most* $4(\lceil \log |S| \rceil + \lceil \log |T| \rceil)$.

Proof. The correctness follows from Claim 19 and from the symmetry of D_f in the S, T inputs. As for the query complexity, the algorithm makes four queries (in fact at most two additional queries) in each iteration, and each iteration shrinks one of the original inputs S, T by half. ◀

In the following algorithm we let $\mathcal{P}(S_1, \ldots, S_k)$ be the distribution on disjoint pairs of sets $(S, \bar{S})$ from Claim 18.

Algorithm 3 Adaptive tester for k-$\oplus$-paritionability.

Oracle : $f\colon \mathcal{D}_1 \times \ldots \times \mathcal{D}_n \to \mathcal{G}$
Input : Size k of partition

If f has fewer than k variables, output "not partitionable".
Otherwise, partition variables arbitrarily into k sets $S_1, \ldots, S_k$.
repeat
  Choose sets $(S, \bar{S})$ at random from $\mathcal{P}(S_1, \ldots, S_k)$.
  Choose random inputs x, y.
until $D_f(S, T; x, y) \neq 0$;
Run violating pair adaptive search on input $(S, \bar{S}; x, y)$ to obtain outputs $\{s\}, \{t\}$.
Contract variables s and t in the oracle and repeat.

Proof of Theorem 2. We analyze Algorithm 3. First assume f is k-$\oplus$-partitionable. By Lemma 20, f only contracts variables s, t that are not split by the partition (otherwise $D_f(\{s\}, \{t\}; x', y')$ always vanishes). Therefore f cannot be contracted down to $k-1$ inputs and the tester accepts with probability one.

Now assume f is ϵ-far from partitionable. We will argue that Algorithm 3 outputs "not partitionable" after $O((n-k+1)(\log n + 1/\epsilon))$ queries in expectation by induction on n. Assume $n \geq k$. By Claim 18, Loop 6 takes $O(1/\epsilon)$ iterations to complete in expectation, and each iteration costs four queries to f. By Lemma 20, line 7 takes another $O(\log n)$ queries. After merging s and t the resulting function on $n-1$ inputs can only be farther from partitionable, so by inductive assumption the expected query complexity $Q(n)$ is at most $Q(n-1) + O(\log n + 1/\epsilon)$. This gives the desired bound. By Markov's inequality, Algorithm 3 makes at most twice this number of queries with probability at least half.

The query complexity can be improved slightly to the stated bound $O((n-k)(\log n + 1/\epsilon) + 1/\epsilon)$ by observing that the violating pair search in line 7 can be bypassed when $n = k$ since a proof of non-partitionability has already been discovered in line 6. ◀

5 Testing $\otimes$-Partitionability

Recall that a function $f : \mathcal{D} = \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{R}^k$ is *k-$\otimes$-partitionable* if there exists a k-partition $S_1, \ldots, S_k$ of $[n]$, and functions $f_1, \ldots, f_k$ such that $f(x) = (f_1(x_{S_1}), \ldots, f_k(x_{S_k}))$ for all $x \in \mathcal{D}$.

In this section we present a $O((n/\epsilon)\log^2(n/\epsilon))$-query non-adaptive one-sided error test for $\otimes$-partitionability (see Theorem 3). We begin with an overview of the construction.

First, some notation. For a function $f : \mathcal{D} \to \mathcal{R}^k$ and a subset $T \subseteq [k]$ we write f_T to refer to the function obtained by projecting the output of f onto the coordinates in T. We often write x_i instead of $x_{\{i\}}$ and f_j instead of $f_{\{j\}}$.

For simplicity, suppose that $k = 2$. Then f is 2-$\otimes$-partitionable if and only if every variable has non-zero influence on at most one of the two coordinates of f. So our task boils down to determining whether there is a variable that is influential in both coordinates of the output of f. The key observation that allows us to find such a coordinate with a small number of queries is that if f is ϵ-far from $\otimes$-partitionable, then

$$\sum_{i \in [n]} \min(\mathrm{Inf}(i; f_1), \mathrm{Inf}(i; f_2)) \geq \epsilon. \tag{4}$$

Therefore, if f is ϵ-far from $\otimes$-partitionable, there must be a coordinate that has influence at least ϵ/n in both coordinates. This immediately suggests an $O(n^2/\epsilon)$ query test: for each variable use $O(n/\epsilon)$ queries to determine whether it is influential in both coordinates.

We obtain an improvement in the query complexity by exploiting a trade-off between the number of samples, $i \in [n]$, required to find a variable that is influential in both coordinates, and the number of samples required to certify that a variable is indeed influential in both coordinates.

Given subsets $S_1, \ldots, S_k$ of $[n]$, let $\Delta_f(S_1, \ldots, S_k)$ be the distance from $f = (f_1, \ldots, f_k)$ to the closest function $g = (g_1, \ldots, g_k)$ in which g_j does not depend on the inputs in S_j, and define the *influence* of $(S_1, \ldots, S_k)$ on f as

$$\mathrm{Inf}(S_1, \ldots, S_k; f) = \Pr[f_j(x) \neq f_j(y_{S_j} x) \text{ for some } j],$$

where x, y is an independent pair of inputs.

▶ **Proposition 21.** $\mathrm{Inf}(S_1,\dots,S_k;f) \le \sum_{i=1}^n \mathrm{Inf}(i;f_{J(i)})$, *where* $J(i)$ *is the set of output coordinates* $j \in [k]$ *for which* S_j *contains* i.

Proof. Let E be the event "$f_j(x) \neq f_j(y_{S_j}x)$ for some j". Let h^i be the hybrid input in which $h^i_t = y_t$ for $t \le i$ and x_t for $t > i$. Then $h^0 = x$ and $h^n = y$. If the event "$f_j(x) \neq f_j(y_{S_j}x)$" occurs, then one of the events "$f_j(h^{i-1}_{S_j}x) \neq f_j(h^i_{S_j}x)$" must occur for some i between 1 and n. By the union bound, $\Pr(E) \le \sum_{i=1}^n \Pr(E_i)$, where E_i is the event "$f_j(h^{i-1}_{S_j}x) \neq f_j(h^i_{S_j}x)$ for some j." The inputs $h^{i-1}_{S_j}x$ and $h^i_{S_j}x$ are identical unless $i \in S_j$, in which case they differ only in the i-th coordinate where they are independent. Therefore

$$\Pr(E_i) = \Pr[f_j(x) \neq f_j(x^i) \text{ for some } j \in J(i)],$$

where x^i is x with its i-th input resampled independently. The right hand side is precisely the influence of i in $f_{J(i)}$. ◀

▷ Claim 22. $\Delta_f(S_1,\dots,S_k) \le \mathrm{Inf}(S_1,\dots,S_k;f)$.

Proof. By averaging, there must exist an assignment a to y such that

$$\mathrm{Inf}(S_1,\dots,S_k;f) \ge \Pr[f_j(x) \neq f_j(a_{S_j}x) \text{ for some } j].$$

Define $g_j(x) = f_j(a_{S_j}x)$ (on all inputs). Then g_j does not depend on the inputs in S_j, so

$$\Delta_f(S_1,\dots,S_k) \le \Pr[f_j(x) \neq g_j(x) \text{ for some } j] = \Pr[f_j(x) \neq f_j(a_{S_j}x) \text{ for some } j] \le \Pr(E).$$

◁

▷ Claim 23. Let $k \ge 2$ and $f(x_i) = (f_1(x_i),\dots,f_k(x_i))$ be a possibly randomized univariate function. Let d an the output coordinate that maximizes $\mathrm{Inf}(i;f_d)$. There exists a partition $(P,\overline{P})$ of the output coordinates such that $\mathrm{Inf}(i;f_P)$ and $\mathrm{Inf}(i;f_{\overline{P}})$ are both at least $\mathrm{Inf}(i;f_{[n]\setminus\{d\}})/3$.

Proof. Let I_j be the event $f_j(x) \neq f_j(y)$ for random independent x and y. Then $\mathrm{Inf}(i;f_T) = \Pr(\cup_{j\in T} I_j)$. Let $\delta_i = \Pr(\cup_{j\neq d} I_j)$. If $\Pr(I_d) \ge \delta_i/3$ then the partition $(\{d\},[n]\setminus\{d\})$ satisfies the conclusion. Otherwise, $\Pr(I_j) \le \delta_i/3$ for all j. Then some partition of type $(I_1 \cup \cdots \cup I_j, I_{j+1} \cup \cdots \cup I_k)$ works: If j is the first set for which $\Pr(I_1 \cup \cdots \cup I_j)$ exceeds $\delta_i/3$, then

$$\Pr(I_1 \cup \cdots \cup I_j) \le \Pr(I_1 \cup \cdots \cup I_{j-1}) + \Pr(I_j) \le 2\delta_i/3.$$

Since

$$\Pr(I_1 \cup \cdots \cup I_j) + \Pr(I_{j+1} \cup \cdots \cup I_k) \ge \Pr(\cup_j I_j) \ge \delta_i,$$

the event $I_{j+1} \cup \cdots \cup I_k$ also has probability at least $\delta_i/3$. ◁

▶ **Lemma 24.** *If* f *is* δ*-far from* $\otimes$*-partitionable then there exist partitions* $(P(1),\overline{P(1)}),\dots,(P(n),\overline{P(n)})$ *of* $[k]$ *such that*

$$\sum_{i=1}^n \min\{\mathrm{Inf}(i;f_{P(i)}),\mathrm{Inf}(i;f_{\overline{P(i)}})\} \ge \frac{\delta}{3}.$$

Proof. Let $j^*(i)$ be the maximizer of $\mathrm{Inf}(i; f_j)$ (breaking ties arbitrarily), and S_j be the set of all i such that $j^*(i) \neq j$. Then $J(i) = \{j \colon i \in S_j\} = [n] \setminus \{j^*(i)\}$. By Proposition 21 and Claim 22, $\delta \leq \Delta_f(S_1, \ldots, S_k) \leq \sum \mathrm{Inf}(i; f_{[n]\setminus\{j^*(i)\}})$. By Claim 23 applied to f as a function of x_i only (randomized over the other inputs), $\mathrm{Inf}(i; f_{[n]\setminus\{j^*(i)\}})/3 \leq \min\{\mathrm{Inf}(i; f_{P(i)}), \mathrm{Inf}(i; f_{\overline{P(i)}})\}$. ◀

Algorithm 4 Non-adaptive tester for $\otimes$-partitionability.

Oracle: $f : \mathcal{D} = \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{R}^k$
Input : Proximity parameter ϵ
1 **foreach** $r \in \{0, \ldots, \lceil \log(3n/\epsilon) \rceil\}$ **do**
2 Let $S \subseteq [n]$ be a set of $3 \cdot \lceil \frac{6n \log(3n/\epsilon)}{2^r \epsilon} \rceil$ indices sampled uniformly at random from $[n]$.
3 **foreach** $i \in S$ **do**
4 Sample $3 \cdot 2^{r+1}$ independent pairs of inputs from $\mathcal{D}$.
5 **if** $\exists$ *samples* $(x, y), (x', y')$, *and* $j \neq j' \in [k]$ *such that* $f_j(x) \neq f_j(y_{\{i\}}x)$ *and* $f_{j'}(x') \neq f_{j'}(y'_{\{i\}}x')$ **then**
6 Reject.
7 Accept.

Proof of Theorem 3. We show that Algorithm 4 satisfies the statement of the theorem. In each iteration of the outer loop, $O(n/\epsilon \log(n/\epsilon))$ queries are made to f. Thus, in total the algorithm makes $O((n/\epsilon)\log^2(n/\epsilon))$ queries.

The test has perfect completeness because the condition on Line 5 is never triggered if f is a direct product.

We now argue soundness. If f is ϵ-far from being a direct product, then by Lemma 24, for every $i \in [n]$ there exist partitions $(P(i), \overline{P(i)})$ such that

$$\sum_{i \in [n]} M_i \geq \epsilon/3, \tag{5}$$

where $M_i = \min\{\mathrm{Inf}(i; f_{P(i)}), \mathrm{Inf}(i; f_{\overline{P(i)}})\}$.

For $r \in \{0, \ldots, \lceil \log(3n/\epsilon) \rceil\}$, let A_r denote the set $\{i \mid M_i \in [1/2^r, 1/2^{r+1})\}$. By (5) and an averaging argument, we know that there exists an ℓ such that $|A_\ell| \geq \lceil \frac{2^\ell \epsilon}{6 \log(3n/\epsilon)} \rceil$. For such an ℓ, we show that the probability that the algorithm rejects in the ℓ-th iteration is at least $2/3$.

Consider the ℓ-th iteration of the outer loop. The probability that no index in A_ℓ is picked at Line 2 is at most $(1 - \frac{|A_\ell|}{n})^{3 \cdot \frac{n}{|A_\ell|}} \leq 1/e^3$.

In an iteration of the inner loop corresponding to an index $i \in A_\ell$, the probability that either $f_{P(i)}(x) = f_{P(i)}(y)$ for all sampled pairs (x, y), or $f_{\overline{P(i)}}(x) = f_{\overline{P(i)}}(y)$ for all sampled pairs (x, y) is at most $2 \cdot (1 - 1/2^{\ell+1})^{3 \cdot 2^{\ell+1}} \leq 2/e^3$. This tells us that the probability that the algorithm rejects in the ℓ-th iteration of the outer loop conditioned on $A_\ell \cap S \neq \emptyset$ is at least $(1 - 2/e^3)$. Since $A_\ell \cap S$ is empty with probability at most $1/e^3$, the probability that the algorithm rejects in the ℓ-th iteration is at least $(1 - 3/e^3) \geq 2/3$. ◀

Abstract

We show, assuming the Strong Exponential Time Hypothesis, that for every $\varepsilon > 0$, approximating undirected unweighted Diameter on n-vertex m-edge graphs within ratio $7/4 - \varepsilon$ requires $m^{4/3-o(1)}$ time, even when $m = \tilde{O}(n)$. This is the first result that conditionally rules out a near-linear time 5/3-approximation for undirected Diameter.

1 Introduction

The diameter of a graph is the length of a longest shortest path between two of its vertices. We write Diameter for the algorithmic task of computing the diameter of an input graph. Throughout the paper, n implicitly denotes the number of vertices of a graph, and m, its number of edges. We will often prefix Diameter with *undirected/directed* to indicate whether or not edges may be oriented[1], and *unweighted/weighted* to indicate whether or not non-negative edge weights are allowed.

A fairly recent and active line of work aims to determine the best runtime for an algorithm approximating Diameter within a given ratio. First, there is an exact algorithm running in time[2] $\tilde{O}(mn)$, which computes n shortest-path trees from every vertex of the graph. Secondly, there is a 2-approximation running in time $\tilde{O}(m)$, which computes a shortest-path tree from an arbitrary vertex and outputs the largest distance found. There are an $\tilde{O}(m^{3/2})$ time 3/2-approximation for directed weighted Diameter [1, 15, 6], and for every non-negative integer k, an $\tilde{O}(mn^{\frac{1}{k+1}})$ time $(2-2^{-k})$-approximation[3] for *undirected* weighted Diameter [4]. We refer the interested reader to the survey of Rubinstein and Vassilevska Williams [16].

We will now focus on sparse graphs, for which $m = \tilde{O}(n)$. This is because the current paper deals with conditional lower bounds on approximating Diameter, and all such results even work with that restriction. Observe that, on sparse graphs, the first result of the previous paragraph is a near-quadratic 1-approximation, while the second result is a near-linear 2-approximation. One can represent these ratio-runtime trade-offs in the two-dimensional plane. The ultimate goal of fine-grained complexity, in that particular context, is to obtain a

[1] In directed Diameter, we are to compute the length of a longest shortest path taken from any vertex to any vertex.

complete curve of algorithms linking these two extreme points, matched by tight conditional lower bounds. We now present one way of deriving conditional lower bounds for polytime problems.

Lower bounds based on the Strong Exponential Time Hypothesis

The Strong Exponential Time Hypothesis (SETH, for short) asserts that for every $\varepsilon > 0$, there is an integer k such that k-SAT cannot be solved in time $(2-\varepsilon)^n$ on n-variable instances [11]. At first glance, this assumption should only be useful to rule out some specific running time for NP-hard problems which, like the satisfiability problem, seems to require superpolynomial time. Such conditional lower bounds to classical [7] or parameterized algorithms [8] are overviewed in a survey [14] on the consequences of the SETH (as well as the weaker assumption ETH) on solving computationally hard problems.

Interestingly, using the SETH to rule out a given running time for a polynomial-time solvable problem took more time. In a survey of fine-grained complexity [18], Vassilevska Williams dates the first reduction (albeit used positively) from SAT to a problem in P back to 2005 [17]. We will see that this reduction to 2-Orthogonal Vectors, where one wants to find two orthogonal 0, 1-vectors within a given list, is very relevant to the fine-grained complexity of Diameter. As it turns out, the first SETH-based lower bound for a polytime graph problem occurred almost a decade later, on the very unweighted undirected Diameter [15].

There might have been a psychological barrier in reducing a "hard" problem to an "easy" one, in order to derive a conditional lower bound. However this makes perfect sense. Let us give an apropos example. Suppose (as it is actually the case) that one can create in time $O(n)$ a list of n 0,1-vectors with $n = O(2^{N/2})$, from an N-variable SAT formula, such that there is pair of orthogonal vectors in the list if and only if the formula is satisfiable. Now a truly subquadratic algorithm, that is in time $n^{2-\varepsilon}$ for some $\varepsilon > 0$, for 2-Orthogonal Vectors would enable to solve SAT in time $O(2^{(1-\varepsilon/2)N}) = O((2-\delta)^N)$ for some $\delta > 0$, contradicting the SETH. We thus say that 2-Orthogonal Vectors is *SETH-hard* at time n^2, and more generally a problem Π is *SETH-hard* at time T if it requires time $T^{1-o(1)}$ under the SETH.

SETH lower bounds for Diameter

There is a handful of SETH-hardness results on approximating Diameter [15, 2, 3, 9, 12, 13]. Unless the SETH fails, any $3/2-\varepsilon$-approximation for sparse undirected unweighted Diameter, with $\varepsilon > 0$, requires time $n^{2-o(1)}$ [15] (this is the above-mentioned seminal result to the fine-grained complexity within P), whereas any $5/3-\varepsilon$-approximation requires time $n^{3/2-o(1)}$ [12] (an early version of [13]). Since a 5/3-approximation of Diameter running in near-linear time was consistent with the then knowledge (up until mid-August 2020, even in weighted directed graphs) Rubinstein and Vassilevska Williams [16] and Li [12] ask for such an algorithm or some lower bounds with a ratio closer to 2.

In the last few months, there were several developments on directed graphs. The author showed that, under the SETH, $7/4-\varepsilon$-approximating sparse directed weighted Diameter requires time $n^{4/3-o(1)}$ [3]. Then Wein and Dalirrooyfard [9], and independently, Li [13] (an updated version of [12]) both show that not only this result holds on directed *unweighted* graphs but they generalize it in the following way: Unless the SETH fails, for every $\varepsilon > 0$ and every integer $k \geqslant 4$, $\frac{2k-1}{k} - \varepsilon$-approximating directed unweighted Diameter requires time $n^{\frac{k}{k-1}-o(1)}$.

Despite these advances, a near-linear time 5/3-approximation for the *undirected* Diameter may still have existed. In this paper, we rule out this possibility by showing the following (see Figure 1 for a visual summary of what is now known on approximating undirected Diameter).

▶ **Theorem 1.** *Unless the SETH fails, for any $\varepsilon > 0$, $7/4 - \varepsilon$-approximating Diameter on undirected unweighted n-vertex $\tilde{O}(n)$-edge graphs requires $n^{4/3-o(1)}$ time.*

In particular we resolve [16, Open Question 2.2.], on the existence of a near-linear time 5/3-approximation for *undirected* Diameter, by the negative.

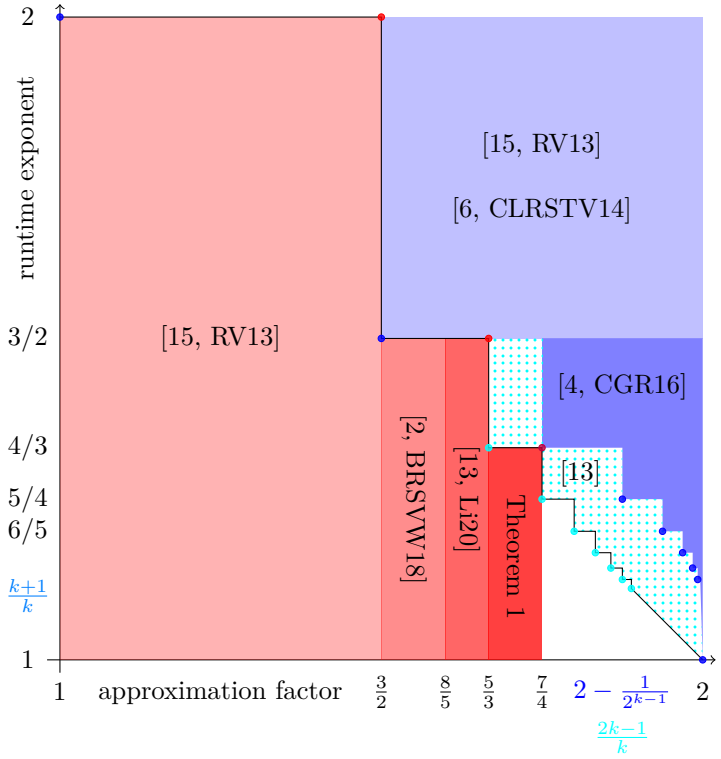

Figure 1 Approximability of sparse undirected unweighted Diameter. Blue areas are feasible, as witnessed by algorithms at bottom-left corners (blue dots). The red regions are SETH-hard, as witnessed by reductions at top-right corners (red dots). Dotted cyan areas are not SETH-hard, unless the NSETH fails. The current landscape for the sparse undirected *weighted* Diameter is the same, except the middle red region is entirely due to Backurs et al. [2] instead of [13]. The axis-parallel black curve represents the tractability frontier as foreseen by Conjecture 2.

In light of the recent results (see in particular the paragraph on barriers to SETH-hardness), it is reasonable to conjecture that the four variants of sparse Diameter (undirected/directed unweighted/weighted) are equally approximable. More precisely, we venture the following optimistic prediction.

▶ **Conjecture 2.** *Sparse (un)directed (un)weighted Diameter is $2 - \frac{1}{k}$-approximable in time $\tilde{O}(n^{\frac{k+1}{k}})$ for every $k \in \mathbb{N}^+ \cup \{\infty\}$. Furthermore unless the SETH fails, approximating sparse (un)directed (un)weighted Diameter within ratio better than $2 - \frac{1}{k+1}$ requires time $n^{\frac{k+1}{k}-o(1)}$ for every $k \in \mathbb{N}^+$.*

Conjecture 2 is naturally equivalent to obtaining the algorithms for the directed weighted Diameter and the SETH-hardness for the undirected unweighted Diameter. Settling the conjecture would give a complete landscape of the approximability of Diameter, where if one represents the results in the two-dimensional space of approximation factor vs runtime exponent, the feasible and infeasible regions are separated by a rectilinear curve with infinitely many corners (the black curve drawn in Figure 1). In that respect, our contribution is to give the third lower bound on the curve (i.e., North-East corner) after Roditty and Vassilevska Williams gave the first [15], and Li, the second [12]. Perhaps our new ideas (together with the recent constructions in the directed case of Wein and Dalirrooyfard [9], and Li [13]) will also help in generalizing the lower bound predicted by Conjecture 2 to every positive integer k.

Barriers to SETH lower bounds

Conjecture 2 is partly prompted by intriguing results due to Li [13]. To state them, we need to recall the definition of a strengthening of SETH introduced by Carmosino et al. [5]. It is called NSETH for Nondeterministic SETH. NSETH asserts that for every $\varepsilon > 0$, there is an integer k such that the k-Taut problem cannot be solved in *non-deterministic* time $(2-\varepsilon)^n$, where k-Taut asks, given a k-DNF formula whether every truth assignment satisfies it (in other words, if it is a tautology). Li shows, for all four variants of Diameter *but* the directed weighted one, that no point positioned strictly above the rectilinear black curve of Figure 1 can be shown SETH-hard, under the NSETH (and, if randomized reductions are permitted, under a stronger assumption, called NUNSETH for Non-Uniform NSETH).

Conjecture 2 is very optimistic since it predicts that every such point will be explained by an algorithm. There are many alternatives to that event. For instance NSETH could be false[4], or the intractability region could extend further North via a non SETH-based reduction, or via a deterministic SETH-based reduction in the directed weighted case. Besides it would require significant progress in approximating the sparse directed Diameter, when currently no algorithm running in time $n^{\frac{3}{2}-\varepsilon}$ achieves approximation factor better than 2.

The second half of Conjecture 2 shown for every $k \geqslant 4$ on directed graphs [9, 13], and for $k = 1, 2, 3$ on undirected graphs, is much easier to believe in.

Techniques

Like every mentioned Diameter lower bound (for more details, see the paragraphs on k-OV and Diameter in the surveys [18, 16]), we reduce from k-Orthogonal Vectors, where one seeks, in a given set of N 0, 1-vectors of dimension ℓ, k vectors such that at every index, at least one of these k vectors has a 0 entry. Under the SETH, k-Orthogonal Vectors requires time $N^{k-o(1)}$ [17], even when ℓ is polylogarithmic in N.

Here we will reduce from 4-Orthogonal Vectors. We thus wish to build a graph on $\tilde{O}(N^3)$ vertices and edges with diameter 7 if there is an orthogonal quadruple (i.e., a solution to the 4-Orthogonal Vectors instance), and diameter 4 otherwise. Following a reduction to ST-Diameter[5] by Backurs et al. [2] (arguably also following [15]) most of the reductions (as in [3, 9, 13]) feature layers $L_0, L_1, \ldots, L_{k-1}, L_k$, with only (forward) edges between two consecutive L_i. The vertices within the same layer share the same number of "vector attributes" and "index attributes". The interplay between vector and index attributes

[4] If we are totally honest, even the weaker SETH does not gather such a wide consensus, and is false if quantum computation is allowed.

[5] where one seeks the length of a longest shortest path from a vertex of S to a vertex of T

in defining the vertices and edges is made so that if there are no k orthogonal vectors, then there are paths of "optimal" length k between every pair in $L_0 \times L_k$, whereas if there is set X of k orthogonal vectors, a pair in $L_0 \times L_k$ jointly encoding X is suddenly very far apart (usually and ideally at distance $2k-1$).

Then the challenge is to make sure that, on NO-instances, the other pairs (not in $L_0 \times L_k$) are at distance at most k, without destroying the previous property. The core of our reduction is similar to our previous construction for directed weighted Diameter [3]. However we simplify and streamline it in the following way. As in the first construction of Li [12], we collapse some layers into one. We will have $L_0 = L_4 (= T)$ and $L_1 = L_3 (= C)$, while L_2 is called P. This makes the case analyses simpler (fewer kinds of pairs to consider).

At this point, we face the same issue as in [3]: There are pairs in $T \times P$ that are too far apart. On directed graphs, this can be fixed by adding parallel layers and appropriate "back" edges [3, 9] or simply "back" edges [13]. This is no longer an option. Instead we add a set I of vertices with only index attributes. These vertices link the right pairs of $T \times P$ with path of length 4 (we are back to the first variation on the theme [15]). To emphasize that the situation is somewhat delicate, we observe that not all the pairs of $T \times P$ can be at distance 4, since otherwise every pair in $T \times T$ is at distance at most 6. We set I at distance 3 of T (by initially putting edges of weight 3). This permits to cliquify I without creating TT-paths of length at most 6. In turn, this puts every pair involving I at distance at most 4, as well as pairs of $(C \cup P) \times P$. Note that as long as $d(T,X) + d(T,Y) \geqslant 3$ (or $k-1$), one can have *all* the pairs of $X \times Y$ at distance 4 (or k), without creating undesired TT-paths of length at most 6 (or $2k-2$).

We then remove the weight-3 edges between T and I. This involves some vertex splits transforming T into T, T', T'', and a simpler echo of the idea of having the clique I, with a clique I' connecting appropriately the pairs in $T \times T''$.

2 Preliminaries

We use standard graph-theoretic notations. If G is a graph, $V(G)$ denotes its vertex set, and $E(G)$, its edge set. We denote the edge set between $X \subseteq V(G)$ and $Y \subseteq V(G)$ by $E(X,Y)$. If $S \subseteq V(G)$, $G[S]$ denotes the subgraph of G induced by S. *Weighted graphs* have positive edge weights. (Throughout the paper, we will only need edges of weight 1 and 3.) We exclusively deal with undirected graphs (for which the distance function is symmetric). For $u, v \in V(G)$, $d_G(u,v)$ denotes the distance between u and v in G, that is, the number of edges in a shortest path between u and v. For every positive integer r and every vertex $u \in V(G)$, $N^r_G[u]$ denotes the set of vertices v such that $d_G(u,v) \leqslant r$. In unweighted graphs, the closed neighborhood of u, denoted $N_G[u]$, coincides with $N^1_G[u]$. However in a weighted graph $N^1_G[u]$ would for instance not contain the neighbors of u via an edge of weight greater than 1. This subtlety will arise only once, and we will remind the reader in due time. For every positive integer r and every vertex $S \subseteq V(G)$, $N^r_G[S]$ denotes the set of vertices $v \in V(G)$ such that $d_G(u,v) \leqslant r$ for some $u \in S$. We observe that, in unweighted graphs, $N^r_G[S]$ coincides with $N_G[N_G[\cdots N_G[N_G[S]]\cdots]]$ where $N_G[\cdot]$ is applied r times and $N_G[S]$ is the closed neighborhood of S. We drop the subscript in the above notations, if the graph G is clear from the context.

We denote by $\mathrm{diam}(G)$ the diameter of G, that is, $\max_{u,v \in V(G)} d(u,v)$. The Diameter problem asks, given a graph G, for the value of $\mathrm{diam}(G)$. We call uv-path, a path going from vertex u to vertex v, and ST-path (with possibly $S = T$), any path going from some vertex $u \in S$ to some vertex $v \in T$.

If ℓ is a positive integer, $[\ell]$ denotes the set $\{1, 2, \ldots, \ell\}$. If v is a vector and i is a positive integer, then $v[i]$ denotes the i-th coordinate of v. We use $\mathrm{maj}(a_1, \ldots, a_h)$ to denote the value with the largest number of occurrences in the tuple $(a_1, \ldots, a_h)$.

For every fixed positive integer k, the k-Orthogonal Vectors (k-OV for short) problem is as follows. It asks, given a set S of 0,1-vectors in $\{0,1\}^\ell$, if there are k vectors $v_1, \ldots, v_k \in S$ such that for every $i \in [\ell]$, $\Pi_{h\in[k]} v_h[i] = 0$, or equivalently, $v_1[i] = v_2[i] = \cdots = v_k[i] = 1$ does not hold. Williams [17] showed that, assuming the SETH, k-OV requires $N^{k-o(1)}$ time with $N := |S|$. Furthermore, using the Sparsification Lemma [10], this lower bound holds even when, say, $\ell = \lceil \log^2 N \rceil$. Here we will leverage this lower bound for $k = 4$. This is, in the context of the SETH-hardness of approximating Diameter, a usual opening step: For example, Roditty and Vassilevska Williams [15] uses this lower bound for $k = 2$, Li [12], for $k = 3$ and general $k \geqslant 3$, the author [3], for $k = 4$, Wein and Dalirrooyfard [9], for general $k \geqslant 5$ and $k = 4$.

3 A simpler reduction with edge weights

From any set S of N vectors in $\{0,1\}^\ell$, we build an undirected weighted graph $G = \rho(S)$ (with edge weights 1 and 3, only) with $O(N^3 + N^2\ell^3 + \ell^5)$ vertices and $O(N^3\ell^5 + N^2\ell^6 + \ell^{10})$ edges such that if S admits an orthogonal quadruple then the diameter of G is (at least) 7, whereas if S has no orthogonal quadruple then the diameter of G is (at most) 4. We recall that 4-OV requires $N^{4-o(1)}$ time, unless the SETH fails, even when $\ell = \lceil \log^2 N \rceil$ [17]. In that case, the graph G has $O(N^3)$ vertices and $\tilde{O}(N^3)$ edges. Hence any algorithm approximating sparse undirected weighted Diameter within ratio better than $7/4$ in time $n^{4/3-\delta}$, with $\delta > 0$, would refute the SETH.

3.1 Construction

We first describe the vertex set of G, then its edge set, and finally check that the number of vertices and edges are as announced.

Vertex set

Every vertex of G is the concatenation of a possibly empty tuple of vectors of S, called *vector tuple*, followed by a possibly empty tuple of possibly equal indices of $[\ell]$, called *index tuple*. Each coordinate of the vector tuple is called a *vector field*, while each coordinate of the index tuple is called an *index field*. The set $V(G)$ is partitioned into four sets: T (for **t**riples), C (for **c**ouples), P (for **p**airs), and I (for **i**ndices). The names behind T, C, P reflect the number and the nature (ordered or unordered) of the vector fields. Each of these sets comprise vertices with up to three vector fields and five index fields. They are defined in the following way.

- T: for every ordered triple $a, b, c \in S$ with a, b, c pairwise distinct, we add vertex (a, b, c) to T. Thus vertices of T have three vector fields and no index field.
- C: for every $a \neq b \in S$ and $i, j, k \in [\ell]$ such that $a[i] = a[j] = a[k] = 1$ and $\mathrm{maj}(b[i], b[j], b[k]) = 1$, we add vertex (a, b, i, j, k) to C. Thus vertices of C have two vector fields and three index fields.
- P: for every $a, b \in S$ and $i, j, k \in [\ell]$ such that $a[i] = a[j] = a[k] = 1$ and $b[i] = b[j] = b[k] = 1$, we add vertex $(\{a, b\}, i, j, k)$ to P. We will still see a and b as filling the *two* vector fields of the vertex, without a *first* vector field and a *second* vector field. Contrary to vertices of C, $(\{a, b\}, i, j, k)$ and $(\{b, a\}, i, j, k)$ are two names for the same vertex

(whereas (a, b, i, j, k) and (b, a, i, j, k) are two distinct vertices, whose existence implies slightly different properties). Thus vertices of P also have two vector fields and three index fields. Note also that $\{a, b\}$ is a multiset, since a may be equal to b.

- I: for every $p_1, p_2, i, j, k \in [\ell]$, we add vertex (p_1, p_2, i, j, k) to I. The chosen labels for the five index fields anticipate that, to build the edge set, it is convenient to imagine a separation after the first two index fields of the tuple. The vertices of I have no vector field and five index fields.

Edge set

We will put some edges between T and C, C and P, P and I, and I and T. In addition, we put *index-switching edges* within I and within C. An index-switching edge is between two vertices of the same set (I or C) with the same vector tuple (which is always the case in I) and distinct index tuples. The only edges with a weight different than 1 are the edges between I and T, which all have weight 3. Thus, unless specified otherwise, an edge has weight 1.

The total list of edges is as follows.

- We add all the index-switching edges within I and C. Thus $G[I]$ is a clique and $G[C]$ is a disjoint union of cliques (while $G[T]$ and $G[P]$ remain independent sets). More explicitly, we have an edge between every pair of distinct vertices $(p_1, p_2, i, j, k) \in I$ and $(p'_1, p'_2, i', j', k') \in I$, and for every $a \neq b \in S$ between every pair of distinct vertices $(a, b, i, j, k) \in C$ and $(a, b, i', j', k') \in C$.
- $E(T, C)$: We add an edge between every $(a, b, c) \in T$ and $(a, b, i, j, k) \in C$ provided that there is an $h \in \{i, j, k\}$ such that $b[h] = c[h] = 1$.
- $E(C, P)$: We add an edge between every $(a, b, i, j, k) \in C$ and $(\{c, d\}, i, j, k) \in P$ whenever $a \in \{c, d\}$.
- $E(T, I)$: We add an edge of weight 3 between every $(a, b, c) \in T$ and $(p_1, p_2, i, j, k) \in I$ whenever $a[p_1] = b[p_1] = c[p_1] = a[p_2] = b[p_2] = c[p_2] = 1$.
- $E(I, P)$: We add an edge between every $(p_1, p_2, i, j, k) \in I$ and $(\{a, b\}, i, j, k) \in P$ whenever $a[p_1] = b[p_2] = 1$ or $a[p_2] = b[p_1] = 1$.

This ends the construction. See Figure 2 for an illustration.

Vertex and edge count

There are $O(N^3)$ vertices in T, $O(N^2\ell^3)$, in $C \cup P$, and ℓ^5, in I, hence $O(N^3 + N^2\ell^3 + \ell^5) = O(N^3)$ in total. There are $O(N^3\ell^3)$ edges in $E(T, C) \cup E(C, P)$, $O(N^2\ell^6)$, in $E(C)$, $O(N^3\ell^5)$, in $E(T, I)$, $O(N^2\ell^5)$, in $E(I, P)$, and $O(\ell^{10})$ in $E(I)$, hence $O(N^3\ell^5 + N^2\ell^6 + \ell^{10}) = \tilde{O}(N^3)$ edges in total. Furthermore G can be built in time $\tilde{O}(N^3)$.

3.2 The absence of orthogonal quadruple implies diameter at most 4

Assuming that there is no orthogonal quadruple, we show that every pair of vertices of G is at distance at most 4. For that we repeatedly use that, for every $a, b, c, d \in S$, $\mathrm{ind}(a, b, c, d) := \min\{i \in [\ell] \mid a[i] = b[i] = c[i] = d[i] = 1\}$ is a well-defined index in $[\ell]$. We only take the minimum index to have a deterministic notation, but there is nothing particular with it, and any index of the non-empty $\{i \in [\ell] \mid a[i] = b[i] = c[i] = d[i] = 1\}$ would work all the same.

We first observe that every vertex is at distance at most 3 from I.

▶ **Lemma 3.** *$N^1[I] \supseteq I \cup P$, $N^2[I] \supseteq I \cup P \cup C$, and $N^3[I] = V(G)$.*

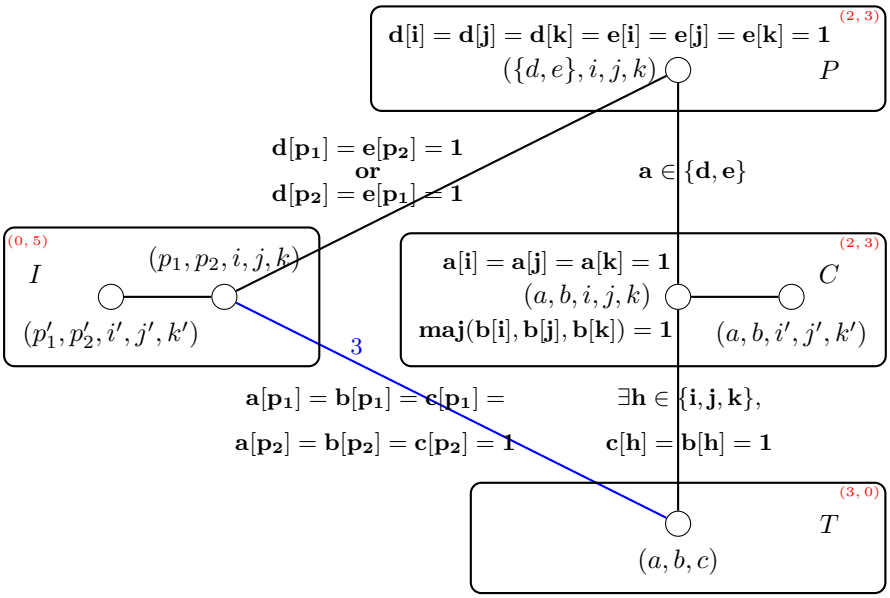

Figure 2 The weighted construction G. In bold, the conditions for the existence of a vertex or of an edge. The edge in blue, and more generally every edge of $E(T, I)$, has weight 3, while all other edges have weight 1. The pairs in red recall, for vertices of the corresponding set, the length of their vector tuple followed by the length of their index tuple.

Proof. The first and second inclusions are actually equalities but we will not need those facts. $N^1[I] \supseteq I \cup P$ since every $(\{a, b\}, i, j, k) \in P$ is adjacent (with an edge of weight 1) to $(i, i, i, j, k) \in I$. Then, $N^2[I] \supseteq N^1[I \cup P] \supseteq I \cup P \cup C$ since every $(a, b, i, j, k) \in C$ is adjacent to $(\{a, a\}, i, j, k) \in P$. Finally, $N^3[I] \supseteq N^1[I \cup P \cup C] = V(G)$ since every $(a, b, c) \in T$ is adjacent to $(a, b, i, i, i) \in C$ for some $i \in [\ell]$, for otherwise a, b, c is an orthogonal triple. ◀

We now exhibit paths of length at most 4 between every pair of vertices of G. For the case disjunction, initially imagine the K_4 with loops on vertices T, C, P, I, where edges correspond to kinds of pairs that are left to check. The following paragraphs remove all its edges in the order: all edges incident to I, all remaining edges incident to P but TP, all remaining edges incident to C, the loop on T, and finally the edge TP.

Between $u \in I$ and $v \in V(G)$

As $G[I]$ is a clique and, by Lemma 3, $N^3[I] = V(G)$, every vertex $u \in I$ is at distance at most 4 from every vertex $v \in V(G)$.

Between $u \in P$ and $v \in P \cup C$

For every $u \in P$, $N^2[u] \supset I$ and so $N^4[u] \supset P \cup C$, by Lemma 3. In particular there is a path of length at most 4 between u and any vertex $v \in P \cup C$.

Between $u \in C$ and $v \in T \cup C$

Let (a, b) be the two vector fields of $u \in C$, (c, d) be the first two vector fields of $v \in T \cup C$, and e be the third vector field of v if $v \in T$. Let $i = \text{ind}(a, b, c, d)$, $j = \text{ind}(a, c, d, e)$ if $v \in T$, and $j = i$ if $v \in C$. We observe that $(a, b, i, i, j), (\{a, c\}, i, i, j), (c, d, i, i, j)$ are (existing) vertices

of C, P, and C, respectively, and that $u-(a,b,i,i,j)-(\{a,c\},i,i,j)-(c,d,i,i,j)$ is a path of length 3 in G. The existence of these vertices is implied by $a[i]=b[i]=c[i]=d[i]=1$, $a[j]=c[j]=d[j]=1$. The first edge of the path is an index-switching edge within C. The existence of the other edges is implied by $a\in\{a,c\}$, $c\in\{a,c\}$, and the fact that the index tuple (i,i,j) does not change.

Finally if $v\in C$, then the index-switching edge $(c,d,i,i,j)-v$ completes the uv-path of length 4. If instead $v\in T$, then the edge $(c,d,i,i,j)-(c,d,e)=v$ completes the uv-path of length 4. This edge exists since $d[j]=e[j]=1$.

Between $u\in T$ and $v\in T$

Let $u=(a,b,c),v=(d,e,f)\in T$, $i=\mathrm{ind}(a,b,c,d)$, $j=\mathrm{ind}(a,b,d,e)$ and $k=\mathrm{ind}(a,d,e,f)$. Then $u=(a,b,c)-(a,b,i,j,k)-(\{a,d\},i,j,k)-(d,e,i,j,k)-(d,e,f)=v$ is a path of length 4 in G. These vertices exist since a and d have value 1 on indices i,j,k, b, on indices i,j, and e, on indices j,k. The first edge exists since $b[i]=c[i]=1$, the next two edges exist for similar reasons as invoked in the previous paragraph, and the fourth edge exists since $e[k]=f[k]=1$.

Between $u\in T$ and $v\in P$

Let $u=(a,b,c)\in T$ and $v=(\{d,e\},i,j,k)\in P$. We set $p_1=\mathrm{ind}(a,b,c,d)$, $p_2=\mathrm{ind}(a,b,c,e)$, and exhibit a uv-path of length 4 via I. Indeed $u=(a,b,c)-(p_1,p_2,i,j,k)-(\{d,e\},i,j,k)=v$ is a path of length 4 in G (recall that the first edge of the path has weight 3). Edge $(a,b,c)-(p_1,p_2,i,j,k)\in E(T,I)$ exists since $a[p_1]=b[p_1]=c[p_1]=a[p_2]=b[p_2]=c[p_2]=1$. Edge $(p_1,p_2,i,j,k)-(\{d,e\},i,j,k)\in E(I,P)$ exists since $d[p_1]=e[p_2]=1$ and the three last indices (i,j,k) remain unchanged.

3.3 The presence of orthogonal quadruple implies diameter at least 7

Let $a,b,c,d\in S$ be an orthogonal quadruple, that is, such that there is *no* index $i\in[\ell]$ satisfying $a[i]=b[i]=c[i]=d[i]=1$. We may further assume that a,b,c,d are all distinct since checking for an orthogonal triple can be done in time $\tilde{O}(N^3)$. We will now show that there is no path $\mathcal{P}$ of length at most 6 between $u=(a,b,c)\in T$ and $v=(d,c,b)\in T$.

Since the distance between every pair of vertices in $T\times I$ is at least 3, a TT-path of length at most 6 cannot contain an edge of the clique $G[I]$, nor more generally intersects I at least twice. We thus distinguish two cases: (case A) $\mathcal{P}$ visits I exactly once, and (case B) $\mathcal{P}$ remains within $T\cup C\cup P$. Before proving that no uv-path $\mathcal{P}$ of length at most 6 visits I, thereby ruling out case A, we state a couple of useful observations.

▶ **Observation 4.** *There is at most one path of length 2 between $(\{d,e\},i,j,k)\in P$ and $(a,b,c)\in T$, namely $(\{d,e\},i,j,k)-(a,b,i,j,k)-(a,b,c)$, which in particular implies that $a\in\{d,e\}$.*

More basically, the only neighbors of $(a,b,c)\in T$ (at distance 1, so not in I) are of the form $(a,b,i,j,k)\in C$. We can generalize this observation to paths contained in $T\cup C$.

▶ **Observation 5.** *For every path within $G[T\cup C]$, all the vertices of the path have the same first two vector fields.*

Case A: $\mathcal{P}$ visiting I

As $\mathcal{P}$ cannot visit I twice, if it visits I then it has length exactly 6 and is one of the following kinds: (case 1) $T-I-T$, (case 2) $T-C-P-I-P-C-T$, or (case 3) $T-I-P-C-T$ (recall that the edges in $E(I,T)$ have weight 3). An important feature of such paths is that no index-switching edge can be used, thus the three last index fields (when they exist) have to remain the same.

Case 1. A path $(a,b,c)-(p_1,p_2,i,j,k)-(d,c,b)$ would in particular imply that $a[p_1]=b[p_1]=c[p_1]=d[p_1]=1$, contradicting the orthogonality of a,b,c,d.

Case 2. By Observation 4 applied to both ends of the path, $\mathcal{P}$ is of the form $(a,b,c)-(a,b,i,j,k)-(\{a,e\},i,j,k)-(p_1,p_2,i,j,k)-(\{d,f\},i,j,k)-(d,c,i,j,k)-(d,c,b)$ with some $e,f\in S$. The existence of the vertices $(a,b,i,j,k),(d,c,i,j,k)\in C$ implies that $a[i]=a[j]=a[k]=d[i]=d[j]=d[k]=1$, and that b and c have value 1 on at least two indices (with multiplicity) of multiset $\{i,j,k\}$. In particular, there is an $h\in\{i,j,k\}$ such that $a[h]=b[h]=c[h]=d[h]=1$, a contradiction to a,b,c,d being orthogonal.

Case 3. By Observation 4 applied to the second half of the path, $\mathcal{P}$ has then the form $(a,b,c)-(p_1,p_2,i,j,k)-(\{d,e\},i,j,k)-(d,c,i,j,k)-(d,c,b)$. The first three vertices yield a contradiction. Indeed, the existence of edge $(p_1,p_2,i,j,k)-(\{d,e\},i,j,k)$ implies that $d[p_z]=1$ for some $z\in\{1,2\}$, while the existence of $(a,b,c)-(p_1,p_2,i,j,k)$ implies that $a[p_z]=b[p_z]=c[p_z]=1$.

Case B: paths $\mathcal{P}$ within $T\cup C\cup P$

We now consider paths $\mathcal{P}$ in $G[T\cup C\cup P]$. Since $a\neq d$, $\mathcal{P}$ has to visit P, since otherwise the first vector field cannot change, by Observation 5. We then observe that no shortest uv-path visits T a third time (one more time than the two endpoints u and v). A TT-path visiting T a third time would contain a segment $C-T-C$ that can be shortcut into $C-C$. Indeed, $(a,b,i,j,k)-(a,b,c)-(a,b,i',j',k')$ has a chord $(a,b,i,j,k)-(a,b,i',j',k')$ which is an index-switching edge of C.

We further distinguish two cases: (case 1) $\mathcal{P}$ does not contain any index-switching edge, or (case 2) $\mathcal{P}$ contains at least one index-switching edge.

Case 1. In that case, $\mathcal{P}$ is of the form $T-C-P-C-T$ or $T-C-P-C-P-C-T$. Either way, we consider the unique neighbors of u and v in $\mathcal{P}$. These neighbors have to be $(a,b,i,j,k)\in C$ and $(d,c,i,j,k)\in C$ for some $i,j,k\in[\ell]$. Indeed no index-switching edge nor return to T is allowed here. Thus we conclude as in case A.2.

Case 2. We now assume that $\mathcal{P}$ contains at least one index-switching edge (of C). In that case, as $\mathcal{P}$ has length at most 6, it can visit P only once. Hence $\mathcal{P}$ is of the kind $T-C-C-P-C-C-T$, where one of the two edges $C-C$ is optional. We consider the last vertex $u'\in C$ before visiting P, and the first vertex $v'\in C$ after visiting P. There is, by design, no index-switching edge between u' and v' on path $\mathcal{P}$. Thus by Observation 5, there are $i,j,k\in[\ell]$ such that $u'=(a,b,i,j,k)$ and $v'=(d,c,i,j,k)$. We then conclude as in case A.2.

4 Removing the weights

So far we showed the announced lower bound for sparse undirected *weighted* Diameter. We show how to tune the previous construction to get the same lower bound for sparse undirected unweighted Diameter. The weighted graph G had only non-trivial edge weights in $E(T,I)$. We now describe how to replace these weighted edges, to get an unweighted graph $G'=\rho'(S)$.

4.1 Unweighted construction

We start with a short summary of the changes. We will replace T by three copies T, T', T'' with an induced perfect matching between T and T', and between T' and T''. We link T'' to I as we linked T to I, and T and C, and T' and C, as we linked T and C. We finally add a set I' of vertices with empty vector tuple (like I) that we link to T'' and I only.

Addition to the vertex set

We add three sets to $V(G)$ to get $V(G')$: two identical copies of T, denoted by T' and T'', and a set I' isomorphic to $[\ell]$. More precisely, for every $i \in [\ell]$, we add vertex (i) to I'. Thus I' has no vector field and a unique index field. We use a subscript to distinguish the *homologous* vertices in T, T', T''. Vertices $(a,b,c)_T \in T, (a,b,c)_{T'} \in T', (a,b,c)_{T''} \in T''$ are the three vertices of G' corresponding to the same vertex (a,b,c) of G.

Edition of the edge set

We first remove the edges of G with weight 3 (between T and I). For every $\{a,b,c\} \in \binom{S}{3}$, we add the edges $(a,b,c)_T - (a,b,c)_{T'}$ and $(a,b,c)_{T'} - (a,b,c)_{T''}$. We also add edges between T' and C, the same way we have defined edges between T and C. That is, $(a,b,c)_{T'} - (a,b,i,j,k)$ is an edge if and only if $(a,b,c)_T - (a,b,i,j,k)$ is an edge. Let us recall that the existence of this edge (and of its endpoint in C) implies that a,b,c have value 1 on indices $\{i,j,k\}$, three times, at least twice, and at least once, respectively, and that there is an $h \in \{i,j,k\}$ such that $a[h] = b[h] = c[h]$.

We add edges (of weight 1) between T'' and I, the same way we defined the weight-3 edges of G between T and I. Thus there is an edge $(a,b,c)_{T''} - (p_1,p_2,i,j,k)$ whenever $a[p_1] = b[p_1] = c[p_1] = a[p_2] = b[p_2] = c[p_2] = 1$. We further add an edge between $(i) \in I'$ and $(a,b,c)_{T''}$ whenever $a[i] = b[i] = 1$. Finally we add all the index-switching edges in I', and we make I and I' fully adjacent, that is, we turn $G'[I' \cup I]$ into a clique.

This finishes the edition to the unweighted construction. See Figure 3 for an illustration.

New vertex and edge count

We added to $V(G)$ $O(N^3)$ vertices in $T' \cup T''$, and ℓ, in I'. Thus G' has also $O(|V(G)|) = O(N^3 + N^2\ell^3 + \ell^5) = O(N^3)$ vertices. We added to $E(G)$ $O(N^3 + N^3\ell^3)$ edges incident to T', and $O(N^3\ell + \ell^6 + \ell^2)$ edges incident to I'. (The edges between T'' and I were already counted in G between T and I.) Thus G' has $O(|E(G)|) = O(N^3\ell^5 + N^2\ell^6 + \ell^{10}) = \tilde{O}(N^3)$ edges. Again G' can be computed in time $\tilde{O}(N^3)$.

4.2 The absence of orthogonal quadruple implies diameter at most 4

In case S has no orthogonal quadruple, we use similar arguments as in G to find paths of length at most 4 between every pair of vertices in G'. We first show that I' is at distance at most 3 of every vertex of G'.

▶ **Lemma 6.** *$N[I'] \supseteq I' \cup I \cup T''$, $N^2[I'] \supseteq I' \cup I \cup T'' \cup P \cup T'$, and $N^3[I'] = V(G')$.*

Proof. The inclusions are actually equalities. $N[I'] \supseteq I' \cup I \cup T''$ since I is fully adjacent to I' and every $(a,b,c)_{T''} \in T''$ is adjacent to some $(i) \in I'$, for otherwise a,b is an orthogonal pair. $N^2[I'] \supseteq N[I' \cup I \cup T''] \supseteq I' \cup I \cup T'' \cup P \cup T'$ since every $(\{a,b\},i,j,k) \in P$ is adjacent to $(i,i,i,j,k) \in I$ and every $(a,b,c)_{T'} \in T'$ is adjacent to $(a,b,c)_{T''} \in T''$. Finally, $N^3[I'] \supseteq N[I' \cup I \cup T'' \cup P \cup T'] = V(G')$ since every $(a,b,i,j,k) \in C$ is adjacent to $(\{a,a\},i,j,k) \in P$ and every $(a,b,c)_T \in T$ is adjacent to $(a,b,c)_{T'} \in T'$. ◀

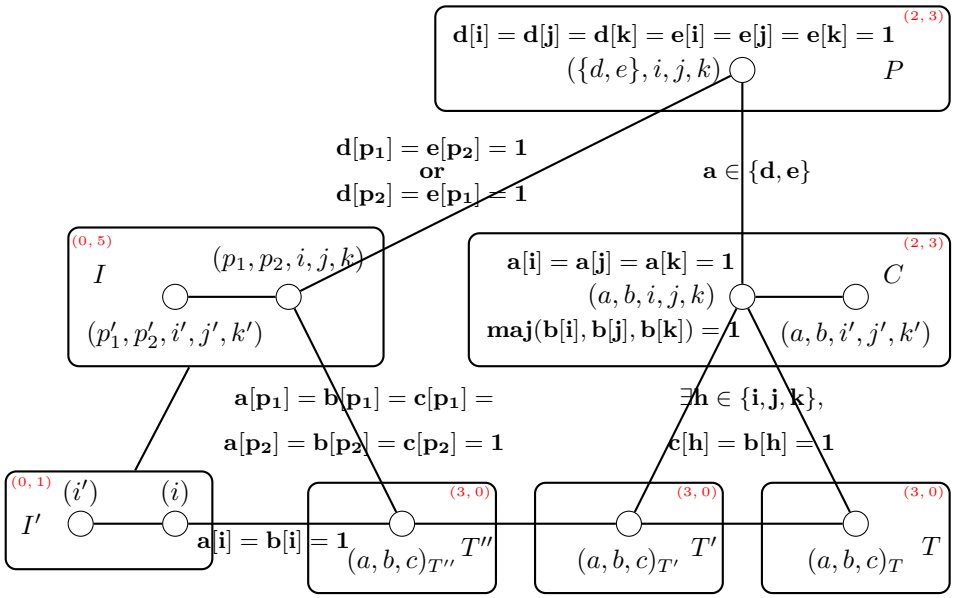

Figure 3 The unweighted construction G'. In bold, the conditions for the existence of a vertex or of an edge. The pairs in red recall, for vertices of the corresponding set, the length of their vector tuple followed by the length of their index tuple.

We also show the following inclusions.

▶ **Lemma 7.** *$N[I] \supset P \cup T''$, and $N^2[I] \supset P \cup C \cup T'' \cup T'$.*

Proof. $N[I] \supset P$, $N^2[I] \supset C$, and $N[T''] \supset T'$ have all been shown in Lemma 6. Therefore we shall just prove that $N[I] \supset T''$. Indeed every vertex $(a, b, c)_{T''} \in T''$ is adjacent to some $(i, i, i, i, i) \in I$, since otherwise a, b, c is an orthogonal triple. ◀

For the case disjunction, initially imagine the K_7 with loops on vertices T, T', T'', C, P, I, I', where edges correspond to the kinds of pairs that are left to check. The following paragraphs remove all its edges in the order: all edges incident to I and to I', all remaining edges incident to P and to T'' but TP and TT'', all remaining edges incident to C, all remaining edges incident to T' as well the loop on T, the edge TP, and finally the edge TT''.

Between $u \in I \cup I'$ and $v \in V(G')$

As $G'[I \cup I']$ is a clique and, by Lemma 6, $N^3[I'] = V(G')$, then $N^4[u] = V(G')$ holds for every vertex $u \in I \cup I'$.

Between $u \in P \cup T''$ and $v \in P \cup C \cup T'' \cup T'$

For every $u \in P \cup T''$, by Lemma 7 and the fact that $G'[I]$ is a clique, $N^2[u] \supset I$ and, again by Lemma 7, $N^4[u] \supset P \cup C \cup T'' \cup T'$. In particular there is a path of length at most 4 from u to any vertex $v \in P \cup C \cup T'' \cup T'$.

The following two cases work as in G, since $(a, b, c)_T$ and $(a, b, c)_{T'}$ are twins in $G'[T \cup T' \cup C \cup P]$.

Between $u \in C$ and $v \in T \cup T' \cup C$

This holds by replacing the occurrence of (c,d,e) by $(c,d,e)_T$ or $(c,d,e)_{T'}$, and every occurrence of T by $T \cup T'$, in the paragraph *Between $u \in C$ and $v \in T \cup C$* of the weighted construction.

Between $u \in T \cup T'$ and $v \in T \cup T'$

Again this holds by replacing occurrences of (a,b,c) (resp. (c,d,e)) by $(a,b,c)_T$ or $(a,b,c)_{T'}$ (resp. $(c,d,e)_T$ or $(c,d,e)_{T'}$).

Between $u \in T$ and $v \in P$

This works as in G by following three edges of weight 1 from T to I, instead of a single edge of weight 3. For every $u = (a,b,c)_T \in T$ and $v = (\{d,e\},i,j,k) \in P$, there is a path $u = (a,b,c)_T - (a,b,c)_{T'} - (a,b,c)_{T''} - (p_1,p_2,i,j,k) - (\{d,e\},i,j,k) = v$ in G', with $p_1 = \mathrm{ind}(a,b,c,d)$ and $p_2 = \mathrm{ind}(a,b,c,e)$.

Between $u \in T$ and $v \in T''$

This case is the real novelty compared to G, and the reason for introducing I'. For every $u = (a,b,c)_T \in T$ and $v = (d,e,f)_{T''} \in T''$, there is a path $u = (a,b,c)_T - (a,b,c)_{T'} - (a,b,c)_{T''} - (i) - (d,e,f)_{T''} = v$ in G', with $i = \mathrm{ind}(a,b,d,e)$. The last two edges exist since $a[i] = b[i] = d[i] = e[i] = 1$.

4.3 The presence of orthogonal quadruple implies diameter at least 7

Again we assume that there is an orthogonal quadruple $a,b,c,d \in S$ such that a,b,c,d are pairwise distinct. We claim that there is no path of length at most 6 in G' between $u = (a,b,c)_T$ and $v = (d,c,b)_T$. Since the distance between T and $I \cup I'$ is at least 3, any TT-path of length at most 6 visits $I \cup I'$ at most once. For the sake of contradiction, let $\mathcal{P}$ be such a path that we further assume shortest (hence in particular chordless) and, among shortest uv-paths, having the fewest edges in $E(T',C)$. We will show that $\mathcal{P}$ cannot visit I', nor use any edge of $E(T',C)$. Finally we observe that TT-paths of length at most 6 in G' respecting these two interdictions are in length-preserving one-to-one correspondence with TT-paths in G.

$\mathcal{P}$ cannot visit I'

The only possible kind of a TT-path of length at most 6 visiting I' is $T - T' - T'' - I' - T'' - T' - T$. This forces $\mathcal{P}$ to be of the form $(a,b,c)_T - (a,b,c)_{T'} - (a,b,c)_{T''} - (i) - (d,c,b)_{T''} - (d,c,b)_{T'} - (d,c,b)_T$ for some $i \in [\ell]$. However the third and fourth edges imply that there is an $i \in [\ell]$ such that $a[i] = b[i] = c[i] = d[i] = 1$, a contradiction to the orthogonality of a,b,c,d.

$\mathcal{P}$ cannot use any edge of $E(T',C)$

Assuming that $\mathcal{P}$ contains at least one edge in $E(T',C)$, we first show that it has to contain a subpath $C - T' - T'' - I \cup I'$ or $I \cup I' - T'' - T' - C$. Let $w = (a',b',c')_{T'} \in T' \cap V(\mathcal{P})$ be a vertex of $\mathcal{P}$ with one neighbor $x \in C \cap V(\mathcal{P})$ on $\mathcal{P}$. The other neighbor y of w on $\mathcal{P}$ is necessarily in T''. Indeed if $y \in T$, then $y = (a',b',c')_T$, and $xy \in E(G')$ is a chord. If

instead $y \in C$, then one can replace the subpath $x - (a', b', c')_{T'} - y$ by $x - (a', b', c')_T - y$, contradicting the minimality of the number of used edges in $E(T', C)$ (since this number decreases by 2).

Thus the only possibility is that $y \in T''$. Then the other neighbor of y on $\mathcal{P}$ (other than w) has to be in $I \cup I'$, since otherwise $\mathcal{P}$ is not a *simple* path. Hence $\mathcal{P}$ contains a subpath of the kind $C - T' - T'' - I \cup I'$ (or the reverse, $I \cup I' - T'' - T' - C$). Now we observe that C is at distance at least 1 from T, while $I \cup I'$ is at distance at least 3 from T. Therefore such a path $\mathcal{P}$ would have length at least 7.

Such a path $\mathcal{P}$ would also exist in G

We can now assume that $\mathcal{P}$ does not use any vertex of I' nor any edge of $E(T', C)$. Every such *simple* TT-path (visiting I at most once) also *exists* in the weighted graph G, with the same length. To see it, we notice that if $\mathcal{P}$ contains an edge $(a', b', c')_T - (a', b', c')_{T'}$, then it has to contain a subpath of the form $(a', b', c')_T - (a', b', c')_{T'} - (a', b', c')_{T''} - (p_1, p_2, i, j, k) \in I$, and is emulated in G by taking the weight-3 edge $(a', b', c') - (p_1, p_2, i, j, k)$. However we showed in the previous section that no uv-path of length at most 6 exists in G.

Abstract

We recently introduced the notion of twin-width, a novel graph invariant, and showed that first-order model checking can be solved in time $f(d,k)n$ for n-vertex graphs given with a witness that the twin-width is at most d, called d-contraction sequence or d-sequence, and formulas of size k [Bonnet et al., FOCS '20]. The inevitable price to pay for such a general result is that f is a tower of exponentials of height roughly k. In this paper, we show that algorithms based on twin-width need not be impractical. We present $2^{O(k)}n$-time algorithms for k-Independent Set, r-Scattered Set, k-Clique, and k-Dominating Set when an $O(1)$-sequence of the graph is given in input. We further show how to solve the weighted version of k-Independent Set, Subgraph Isomorphism, and Induced Subgraph Isomorphism, in the slightly worse running time $2^{O(k \log k)}n$. Up to logarithmic factors in the exponent, all these running times are optimal, unless the Exponential Time Hypothesis fails. Like our FO model checking algorithm, these new algorithms are based on a dynamic programming scheme following the sequence of contractions forward.

We then show a second algorithmic use of the contraction sequence, by starting at its end and rewinding it. As an example of such a reverse scheme, we present a polynomial-time algorithm that properly colors the vertices of a graph with relatively few colors, thereby establishing that bounded twin-width classes are χ-bounded. This significantly extends the χ-boundedness of bounded rank-width classes, and does so with a very concise proof. It readily yields a constant approximation for Max Independent Set on K_t-free graphs of bounded twin-width, and a $2^{O(\mathrm{OPT})}$-approximation for Min Coloring on bounded twin-width graphs. We further observe that a constant approximation for Max Independent Set on bounded twin-width graphs (but arbitrarily large clique number) would actually imply a PTAS.

The third algorithmic use of twin-width builds on the second one. Playing the contraction sequence backward, we show that bounded twin-width graphs can be edge-partitioned into a linear number of bicliques, such that both sides of the bicliques are on consecutive vertices, in a fixed vertex ordering. This property is trivially shared with graphs of bounded average degree. Given that biclique edge-partition, we show how to solve the unweighted Single-Source Shortest Paths and hence All-Pairs Shortest Paths in time $O(n \log n)$ and time $O(n^2 \log n)$, respectively. In sharp contrast, even Diameter does not admit a truly subquadratic algorithm on bounded twin-width graphs, unless the Strong Exponential Time Hypothesis fails.

The fourth algorithmic use of twin-width builds on the so-called *versatile tree of contractions* [Bonnet et al., SODA '21], a branching and more robust witness of low twin-width. We present constant-approximation algorithms for Min Dominating Set and related problems, on bounded twin-width graphs, by showing that the integrality gap is constant. This is done by going down the versatile tree and stopping accordingly to a problem-dependent criterion. At the reached node, a greedy approach yields the desired approximation.

1 Introduction

As the title suggests, this is the third paper of a series [4, 3] devoted to a new graph invariant called *twin-width*. All the results presented in this paper are self-contained as the relevant background is given in Section 2. In the same section, the reader can find the definitions of *contraction sequences* and *twin-width*. For now, we are content with some intuition on these notions. This will be enough to sketch the ideas and techniques leading to our results, while sparing this introduction from too much formalism.

The twin-width of a graph is a non-negative integer measuring its distance to being a cograph. Among the several characterizations of cographs, a possible definition goes as follows. A graph is a *cograph* if one can find therein two twins,[1] identify them, and iterate this process until there is only one vertex left. This corresponds to what we define as a 0-sequence in Section 2, witnessing that cographs have twin-width 0. Conversely it is also true that graphs with twin-width 0 are cographs. We generalize this identification process by allowing a controlled error on the contracted pairs of vertices. An error graph or *red graph* keeps the faulty adjacencies appearing between a contracted pair and the vertices that are neighbor of only one vertex of the pair. A d-sequence is an indentification or contraction sequence such that the maximum degree of the error graph never exceeds d. The existence of such a sequence entails that the initial graph has twin-width at most d.

As it turns out, many graph classes have bounded twin-width: planar graphs and more generally proper minor-closed classes, bounded rank-width or clique-width graphs, proper hereditary subclasses of permutation graphs, unit interval graphs, and some particular class of cubic expanders, to name only a few.[2] Considering the wide variety of these classes, it might seem that our cograph generalization has gone too far to allow for a unified algorithmic treatment of bounded twin-width graphs. The first paper of the series [4] and the current one show that this is not the case. Graphs of bounded twin-width admit algorithms whose running times are provably unattainable in general graphs. We will now detail that point.

After defining any graph parameter κ, a natural question is whether some computationally hard problems can be solved more efficiently on graphs where κ is bounded. When this turns out to be the case for several problems, it may sometimes lead to a powerful meta-theorem. A standard way of capturing a large set of problems within the same framework is through the use of logic formulas over graphs, or more generally over relational structures. In the language of parameterized algorithms, one may ask for the existence of a Fixed-Parameter Tractable (FPT) algorithm parameterized by κ and the size of the graph formula φ to be tested: More precisely, an algorithm deciding in time $f(|\varphi|, \kappa(G))n^{O(1)}$, or better

[1] i.e., two vertices with the same neighborhood beside them
[2] A more exhaustive list is given in Theorem 7.

$f(|\varphi|, \kappa(G))n$, whether an n-vertex graph G satisfies φ, where f is some computable function. Certainly the most famous result of that kind is the celebrated Courcelle's theorem, where the parameter κ is tree-width, and the formula φ ranges over Monadic Second Order logic (MSO_2) formulas [5]. On a slightly less general logic (namely MSO_1, where quantification over edge sets is disallowed), the result holds for the smaller parameter clique-width [6]. It implies, for instance, that deciding whether a graph on n vertices contains a subset of k pairwise non-adjacent vertices (i.e., solving k-Independent Set) can be done in linear time on graphs of constant clique-width, while in general graphs it cannot be solved in polynomial time unless P=NP, nor in time $f(k)n^{O(1)}$ unless FPT=W[1]. Such a result is unlikely for twin-width as k-Independent Set remains NP-hard in planar graphs, which have constant twin-width. Nevertheless, when parameterized by the solution size k, an FPT algorithm is known in planar graphs, and more generally in any proper minor-closed graph class. Actually, on the latter class, every problem expressible by a first-order (FO) formula φ can be solved in FPT time parameterized by $|\varphi|$ [9]. In the first paper of our series [4], we extended this result and obtained the following meta-theorem for twin-width.

▶ **Theorem 1** ([4]). *Given an n-vertex graph G, a d-sequence of G, and a first-order formula φ, one can decide $G \models \varphi$ in time $f(|\varphi|, d)n$ for some computable function f.*

The main drawback of this kind of algorithm is the obtained running time: The function f is a tower of exponentials whose height depends on the size of the formula. This is an unavoidable price to pay to solve at once all graph problems expressible in first-order logic. Indeed, it is known that testing first-order formulas on trees requires a running time whose dependence in the size of the formula is a non-elementary function, unless P = NP [10]. Furthermore the running time of our FO model checking algorithm does not get better on "seemingly simpler" formulas, such as for instance, with few quantifier alternations.

Our results

We show that twin-width and its associated contraction sequence can also give rise to practical algorithms for some individual classic graph problems. In particular, we consider the following NP-complete problems, given a graph G and an integer k, decide if:

- k-Independent Set: there are k pairwise non-adjacent vertices.
- k-Clique: there are k pairwise adjacent vertices.
- (k, r)-Scattered Set: there are k vertices pairwise at distance at least r.
- k-Dominating Set: there is a set S of k vertices such that for every vertex v of G, either $v \in S$ or v has a neighbor in S.
- (k, r)-Dominating Set: there is a set S of k vertices such that every vertex of G is at distance at most r of some vertex in S.

These problems, parameterized by k, are W[1]-hard (the last two are even W[2]-complete), thus unlikely to admit an FPT algorithm, i.e., one with running time $f(k)n^{O(1)}$, on general graphs. We obtain single-exponential parameterized algorithms for all these problems when a contraction sequence witnessing "twin-width at most d" is given. When considering the unparameterized optimization variant, we denote these five problems by Max Independent Set (and MIS for short), Max Clique, Distance-$(r-1)$ MIS, Min Dominating Set, and Min r-Dominating Set, respectively.

▶ **Theorem 2.** *Given an n-vertex graph G and a d-sequence $G = G_n, \ldots, G_1 = K_1$, the above-mentioned five problems can be solved in time $2^{O_d(k)}n$.*

We then consider some W[1]-complete generalizations of k-Independent Set or of k-Clique. Namely:

- Weighted Max Independent Set: given a graph G with a weight function on vertices $w : V(G) \to \mathbb{R}$ and an integer k, decide whether there exists a set S of size exactly k of pairwise non-adjacent vertices such that $\sum_{v \in S} w(v)$ is maximum.
- Induced Subgraph Isomorphism: given a graph H on k vertices and a graph G, decide whether there exists a set $S \subseteq V(G)$ such that $G[S]$, the subgraph of G induced by S, is isomorphic to H.
- Subgraph Isomorphism: given a graph H on k vertices and a graph G, decide whether there exists a set $S \subseteq V(G)$ such that H is isomorphic to a subgraph of $G[S]$.

Unlike the other two problems, Subgraph Isomorphism is *not* a generalization of k-Independent Set. Though it does generalize k-Clique. Once the formal definition of a contraction sequence is given, it will be clear that a d-sequence for G readily yields a d-sequence for its complement, $\overline{G}$. Thus in the context of bounded twin-width graphs, an algorithm solving Subgraph Isomorphism can be used to solve k-Independent Set. For these three problems, we now get slightly superexponential parameterized algorithms.

▶ **Theorem 3.** *Given an n-vertex graph G and a d-sequence $G = G_n, \ldots, G_1 = K_1$, the above-mentioned three problems can be solved in time $2^{O_d(k \log k)} n$.*

The algorithms behind Theorems 2 and 3 follow the same general plan. Let us consider the n successive red graphs $R_n, \ldots, R_1$ (error graphs) obtained after each vertex contraction.[3] R_n is the edgeless n-vertex graph (since there are initially no errors) and R_1 is the 1-vertex graph. We maintain optimum partial solutions populating connected subgraphs of bounded size in each R_i. Initially in R_n, the connected subgraphs are only made of single vertices (there are no edges). So the optimum partial solutions are trivial to compute. The partial solutions for R_i are built from the partial solutions of R_{i+1} in the following way. Every partial solution *not* involving the newly contracted vertex is simply kept. Every partial solution involving the newly contracted vertex is computed by merging a bounded number of previous partial solutions on pairwise disconnected sets. The key is that, by design, there is no error between the latter partial solutions. Thus the presence or absence of edges can be decided regardless of the forgotten choices of precise vertices within the solution. Eventually a (partial) solution is computed in R_1, which constitutes an actual solution in the entire initial graph G. In a nutshell, the algorithms may be summarized as dynamic programming over connected sets of the red graphs.

For k-Independent Set there is not much more to it than the previous sketch. For (Induced) Subgraph Isomorphism the algorithms become more technical. Also conceptually, partial solutions are no longer necessarily feasible. For k-Dominating Set some new challenges appear. The partial solutions and their actual specification are not straightforward to define, as it is for k-Independent Set.

One may wonder if subexponential parameterized algorithms are possible for any of the eight problems considered so far. We will observe that even k-Independent Set cannot be solved in time $2^{o(k/\log k)} n^{O(1)}$ on graphs given with an $O(1)$-sequence, unless the Exponential Time Hypothesis fails. With a similar argument, the same lower bound applies to k-Dominating Set. Thus, up to logarithmic factors in the exponent, the running times of Theorems 2 and 3 are optimal. Actually we will see that even algorithms running in time $2^{o(n/\log n)}$ are unlikely.

[3] A reader who would want precise definitions at this point is welcome to read first the couple of paragraphs of Section 2.1.

All the previous algorithms exploit the contraction sequence forward. They follow the identification process from the initial graph G to the 1-vertex graph. What if we would start at the end, and maintain solutions as the vertices are iteratively split until the initial graph G is formed? We exemplify the idea of using the contraction sequence backward with an essentially greedy coloring procedure that is not optimal but still uses relatively few colors.

Let us be more specific. A proper k-coloring of a graph G is a mapping $c : V(G) \to \{1, \dots, k\}$ such that $c(u) \neq c(v)$ whenever $uv \in E(G)$. The chromatic number, denoted by $\chi(G)$, is the smallest integer k such that G admits a proper k-coloring. It can be seen that $\chi(G) \geqslant \omega(G)$, where $\omega(G)$ denotes the size of a largest clique in G, whereas many constructions of triangle-free (that is, with $\omega(G) \leqslant 2$) graphs G with arbitrarily large $\chi(G)$ are known. A class of graphs $\mathcal{C}$ is *χ-bounded* if there is a function f such that for any graph $G \in \mathcal{C}$, we have $\chi(G) \leqslant f(\omega(G))$. Our coloring algorithm $(d+2)$-colors any triangle-free graph of twin-width at most d, and more generally $(d+2)^{\omega(G)-1}$-colors any graph G given with a d-sequence. In particular, it shows the following.

▶ **Theorem 4.** *Every graph class with bounded twin-width is χ-bounded.*

Algorithmically this has some direct consequences for approximating the chromatic number, as well as, in the subcase of K_t-free graphs, the independence number.

The same idea of considering the contraction sequence backward is then used to show that every graph given with an $O(1)$-sequence admits an edge partition into $O(n)$ bicliques, each side of which is on consecutive vertices, for a fixed vertex ordering. We use this edge partition to tackle the unweighted version of some classic polynomial-time solvable problems:

- Single-Source Shortest Paths: given a graph G and a source s, find a shortest-path tree rooted at s, spanning the connected component of s.
- All-Pairs Shortest Paths: given a graph G, find the distances in G between every pair of vertices.
- Diameter: given a graph G, report the largest distance in G between two vertices.

We show how breadth-first search (BFS) can be mimicked, when replacing "traversing an edge" by "traversing a biclique all at once". A subtlety of the algorithm, beside the necessary data structures to get Single-Source Shortest Paths sublinear in the total number of edges, lies in the fact that bicliques, contrary to single edges, can be traversed twice (once in both directions) before being discarded.

▶ **Theorem 5.** *If the input graph comes with an $O(1)$-sequence, Single-Source Shortest Paths can be solved in $O(n \log n)$ time, thus All-Pairs Shortest Paths and Diameter can be solved in $O(n^2 \log n)$ time. In contrast, Diameter cannot be solved in $O(n^{2-\varepsilon})$ for any $\varepsilon > 0$, even in that scenario, unless the Strong Exponential Time Hypothesis fails.*

Our algorithm inherently relies on unweighted edges. Nonetheless vertex-weights can be supported with the same running time.

Min Dominating Set is known to be as approximable as the Set Cover problem. Thus, by classic papers by Johnson [14] and by Lovász [15], it admits a $\ln n$-approximation and the integrality gap (i.e., the ratio between the optimum of the original problem and the optimum of the LP relaxation) of its standard LP formulation is also $\ln n$. In sharp contrast, unless P=NP, Min Dominating Set cannot be approximated in polynomial-time within factor $(1 - o(1)) \ln n$ on n-vertex general graphs [7].

We show that, on bounded twin-width classes, the integrality gap of Min Dominating Set is constant. This uses the *versatile trees of contractions* developed in the second paper of the series [3]. These are more robust witnesses of low twin-width which, instead of providing

a single contraction in a given trigraph, give linearly many disjoint ones. Placing ourselves at a right node of the versatile tree, we show that a greedy strategy in the corresponding trigraph yields a constant approximation in the original graph.

▶ **Theorem 6.** *If the input graph comes with an $O(1)$-sequence, Min Dominating Set, Distance-2 MIS, and more generally Min r-Dominating Set, Distance-$2r$ MIS for every positive r, admit $O(1)$-approximation algorithms.*

These results are particular cases of the fact that when the twin-width of a matrix A is bounded, there is a linear gap between the packing number and the minimum hitting set of the hypergraph with incidence matrix A. Bounded twin-width matrices might more generally provide linear programs with bounded duality gap. It is noteworthy that Max Independent Set (which corresponds to Distance-1 MIS) is *not* covered by the previous theorem. We further give some evidence that MIS may have a very different approximability status than Min Dominating Set on bounded twin-width graphs.

2 Preliminaries

We denote by $[i, j]$ the set of integers $\{i, i+1, \ldots, j-1, j\}$, and by $[i]$ the set of integers $[1, i]$. If $\mathcal{X}$ is a set of sets, we denote by $\cup\mathcal{X}$ their union. The notation $O_d(\cdot)$ gives an asymptotic behavior when d is seen as a constant. The notation $O^*(\cdot)$ suppresses polynomial factors.

Unless stated otherwise, all graphs are assumed undirected and simple, that is, they do not have parallel edges or self-loops. We denote by $V(G)$ and $E(G)$ the set of vertices and edges respectively of a graph G. For $S \subseteq V(G)$, we denote the *open neighborhood* (or simply *neighborhood*) of S by $N_G(S)$, i.e., the set of neighbors of S deprived of S, and the *closed neighborhood* of S by $N_G[S]$, i.e., the set $N_G(S) \cup S$. We may omit the subscript if the graph is clear from the context. We denote by $G[S]$ the subgraph of G induced by S, and $G - S := G[V(G) \setminus S]$. A *connected subset* (or *connected set*) $S \subseteq V(G)$ is one such that $G[S]$ is connected. Two distinct vertices u, v such that $N(u) = N(v)$ are called *false twins*, and *true twins* if $N[u] = N[v]$. Two vertices are *twins* if they are false twins or true twins.

A graph is *H-free* if it does not contain H as an induced subgraph. However we make an exception for $H = K_{t,t}$. A $K_{t,t}$-free graph is a graph with no biclique $K_{t,t}$ *as a subgraph*. A class[4] $\mathcal{C}$ of graphs *has property Π* if every graph of $\mathcal{C}$ has property Π. A class is *hereditary* if it is closed under taking induced subgraphs.

2.1 Trigraphs, contraction sequences, and twin-width of a graph

A *trigraph* G has vertex set $V(G)$, (black) edge set $E(G)$, and red edge set $R(G)$ (the error edges), with $E(G)$ and $R(G)$ being disjoint. The *set of neighbors* $N_G(v)$ of a vertex v in a trigraph G consists of all the vertices adjacent to v by a black or red edge. A d-trigraph is a trigraph G such that the *red graph* $(V(G), R(G))$ has degree at most d. In that case, we also say that the trigraph has *red degree* at most d. A (vertex) *contraction* or *identification* in a trigraph G consists of merging two (non-necessarily adjacent) vertices u and v into a single vertex z, and updating the edges of G in the following way. Every vertex of the symmetric difference $N_G(u) \triangle N_G(v)$ is linked to z by a red edge. Every vertex x of the intersection $N_G(u) \cap N_G(v)$ is linked to z by a black edge if both $ux \in E(G)$ and $vx \in E(G)$, and by a red

[4] That is, a set of graphs closed under isomorphism.

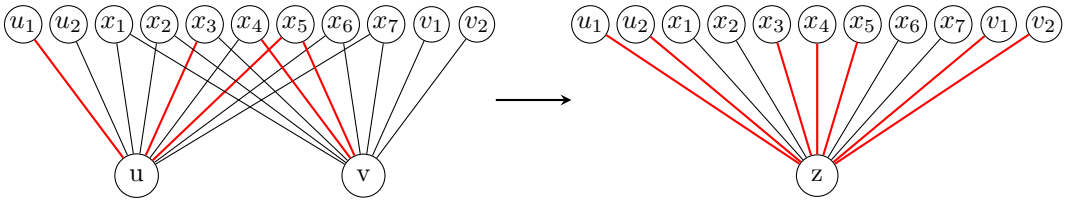

Figure 1 Contraction of vertices u and v, and how the edges of the trigraph are updated.

edge otherwise. The rest of the edges (not incident to u or v) remain unchanged. We insist that the vertices u and v (together with the edges incident to these vertices) are removed from the trigraph. See Figure 1 for an illustration.

A *d-sequence* (or *contraction sequence*) is a sequence of d-trigraphs $G_n, G_{n-1}, \dots, G_1$, where $G_n = G$, $G_1 = K_1$ is the graph on a single vertex, and G_{i-1} is obtained from G_i by performing a single contraction of two (non-necessarily adjacent) vertices. We observe that G_i has precisely i vertices, for every $i \in [n]$. The twin-width of G, denoted by $tww(G)$, is the minimum integer d such that G admits a d-sequence.

For $u \in V(G_i)$, we denote by $u(G)$ the subset of $V(G)$ that was contracted to the single vertex u in $G_n, G_{n-1}, \dots, G_i$. Twin-width and d-sequences can be equivalently seen as a partition refinement process on $V(G)$. We start with the finest partition $\mathcal{P}_n = \{\{v\} : v \in V(G)\}$, and end with the coarsest partition $\mathcal{P}_1 = \{V(G)\}$. There is a *partition sequence* $\mathcal{P}_n, \mathcal{P}_{n-1}, \dots, \mathcal{P}_2, \mathcal{P}_1$ mimicking the contraction sequence, where the contraction of $u, v \in V(G_i)$ corresponds to the merge of parts $u(G_i), v(G_i) \in \mathcal{P}_i$ to form the part $u(G_i) \cup v(G_i) = z(G_{i-1}) \in \mathcal{P}_{i-1}$, while all the other parts are unchanged from P_i to P_{i-1}. The red degree (bounded by d) of a part $P \in \mathcal{P}_i$ now corresponds to the number of other parts $P' \in \mathcal{P}_i$ which are not fully adjacent nor fully non-adjacent to P in G. We may denote by $G_{\mathcal{P}}$ the trigraph corresponding to partition $\mathcal{P}$ over $V(G)$. Thus $G_i = G_{\mathcal{P}_i}$.

2.2 Classes with bounded twin-width and how the sequences are given

The current paper is devoted to presenting efficient algorithms when the input has bounded twin-width, and the contraction sequence is given. It is therefore important to know how realistic this scenario is. Fortunately, in the first two papers of the series [4, 3] we showed that many central sparse and dense (di)graph classes have bounded twin-width.

▶ **Theorem 7** ([4, 3]). *The following classes have bounded twin-width, and $O(1)$-sequences for n-vertex members can be computed in $O(n^2)$ time.*

- *Bounded clique-width/rank-width, and more generally, boolean-width graphs,*
- *every hereditary proper subclass of permutation graphs,*
- *posets of bounded antichain size (seen as digraphs),*
- *unit interval graphs,*
- *K_t-minor free graphs,*
- *map graphs (given with an embedding),*
- *subgraphs of d-dimensional grids,*
- *K_t-free unit d-dimensional ball graphs,*
- *$\Omega(\log n)$-subdivisions of all the n-vertex graphs,*
- *cubic expanders defined by iterative random 2-lifts from K_4,*
- *strong products of two bounded twin-width classes one of which has also bounded degree,*
- *any subgraph closure of a $K_{t,t}$-free bounded twin-width class, and*
- *any first-order transduction of a bounded twin-width class.*

2.3 Selected results for the short version

Due to space constraints, we select a representative sample of the results announced in the introduction. This sample covers at least partially Theorems 2–4 and 6. We present the following four items on bounded twin-width classes, where the input graph comes with an $O(1)$-sequence; each item sharply contrasting with what is possible on general graphs.

- In Section 3 we give a linear FPT algorithm for k-Independent Set.
- In Section 4 we give a linear FPT algorithm for k-Dominating Set.
- In Section 5 we show a constant approximation for Min Dominating Set.
- In Section 6 we show that bounded twin-width graphs are χ-bounded.

That selection presents our new conceptual ideas in their simplest form, while echoing the title of the paper. For more details on these results or for the proofs *not* covered in the short version, we refer the reader to the long version in appendix.

3 Practical algorithm for k-Independent Set

The running time analysis of the forthcoming algorithm is based on a folklore bound on the number of connected subsets of size at most k in a bounded-degree graph.

▶ **Lemma 8.** *The number of connected vertex sets of size at most k, intersecting a set X, in a graph of maximum degree d is at most $(d^{2k-2}+1)|X|$. Furthermore they can be enumerated in time $O(d^{2k-2}|X|)$.*

We show how to solve k-Independent Set by dynamic programming on the connected subsets of size at most k in the red graphs of a d-sequence given with the input graph.

▶ **Theorem 9.** *Given an n-vertex graph G, a positive integer k, and a d-sequence $G = G_n, \dots, G_1 = K_1$, k-Independent Set can be solved in time $O(k^2 d^{2k} n) = 2^{O_d(k)} n$.*

Proof. Our algorithm maintains a set of *optimum partial solutions* in the current trigraph, starting from G, and progressively going along the d-sequence. Let us start with a definition of the partial solutions and of their optimality.

A *partial solution* in the trigraph G_i is a pair (T, S) where $T \subseteq V(G_i)$ is a vertex set inducing a connected subgraph in the red graph $(V(G_i), R(G_i))$, and $S \subseteq V(G)$ is an independent set of G such that $S \subseteq \bigcup_{u \in T} u(G)$ and for every $u \in T$, $S \cap u(G) \neq \emptyset$. A partial solution (T, S) is said *optimum* if there is no partial solution (T, S') such that $|S| < |S'|$. A set $T \subseteq V(G_i)$ is said *realizable* (in G_i) if there is an $S \subseteq V(G)$ such that (T, S) is a partial solution in G_i. Notice that *not* every connected subset in the red graph is realizable. For instance, it is easy to engineer a situation where there is no independent set intersecting the three vertices of a 3-vertex red path. Initially, in G, the only connected subgraphs of the red graph are singletons (since there is no red edge). So there are exactly n (optimum) partial solutions in $G = G_n$: Each vertex v of G induces a partial solution $(\{v\}, \{v\})$. We denote by $\mathcal{S}_n$ this set of n optimum partial solutions. It boils down to determining if there is a partial solution $(_, S)$ in G_1 (or actually in any G_i) with $|S| \geqslant k$. For i going from $n-1$ down to 1, we will build a set of optimum partial solutions $\mathcal{S}_i$ in G_i from the set $\mathcal{S}_{i+1}$, keeping the invariant that for every realizable set $T \subseteq V(G_i)$, there is a unique optimum partial solution (T, S) stored in $\mathcal{S}_i$ (and no other partial solution in $\mathcal{S}_i$).

We shall then describe how we update the set of optimum partial solutions after a single contraction. Two partial solutions $(T, _)$ and $(T', _)$ in G_i are *disjoint* if $T \cap T' = \emptyset$, and *separate*, if they are disjoint and there is no red edge $uu' \in R(G_i)$ with $u \in T$ and

$u' \in T'$. Two separate partial solutions $(T, _)$ and $(T', _)$ are *compatible* if there is no edge $uu' \in E(G_i) \cup R(G_i)$ with $u \in T$ and $u' \in T'$. The *union* of two compatible partial solutions (T_1, S_1) and (T_2, S_2) as $(T_1, S_1) \cup (T_2, S_2) := (T_1 \cup T_2, S_1 \cup S_2)$. By definition, such a union is *not* a partial solution since T induces two connected components in its current red graph. Nevertheless we will build the new (connected) partial solutions of G_i by making unions of up to $d+2$ pairwise compatible partial solutions in G_{i+1}. These unions will be connected in G_i, hence will correspond to partial solutions as well.

Let us be more specific. Say $u, v \in V(G_{i+1})$ are contracted into $z \in V(G_i)$ to form G_i. We say that a partial solution $(T, _)$ in G_i *intersects* a set $X \subseteq V(G_i)$ if $T \cap X \neq \emptyset$. We initialize $\mathcal{S}_i$ with all the partial solutions of $\mathcal{S}_{i+1}$ not intersecting $\{u, v\}$. We now add one partial solution in $\mathcal{S}_i$ per realizable set $T \ni z$ in G_i, of size at most k. For every $T \subseteq V(G_i)$ such that $z \in T$ and T induces a connected subgraph on at most k vertices in the red graph $(V(G_i), R(G_i))$, we observe three possibilities for a potential partial solution (T, S). Either S intersects $u(G)$ and $v(G)$, or it intersects only $u(G)$, or it intersects only $v(G)$. (It is not possible that $S \cap (u(G) \cup v(G)) = \emptyset$ since T contains z.) Therefore we take the best (meaning with the largest S, breaking ties arbitrarily) of the potential partial solutions $\bigcup \mathrm{dec}(T \setminus \{z\} \cup \{u, v\}), \bigcup \mathrm{dec}(T \setminus \{z\} \cup \{u\}), \bigcup \mathrm{dec}(T \setminus \{z\} \cup \{v\})$, where $\mathrm{dec}(X)$ is the set with one partial solution per connected component of X in its red graph (here $(V(G_{i+1}), R(G_{i+1}))$. See Figure 2 for an illustration of this decomposition.

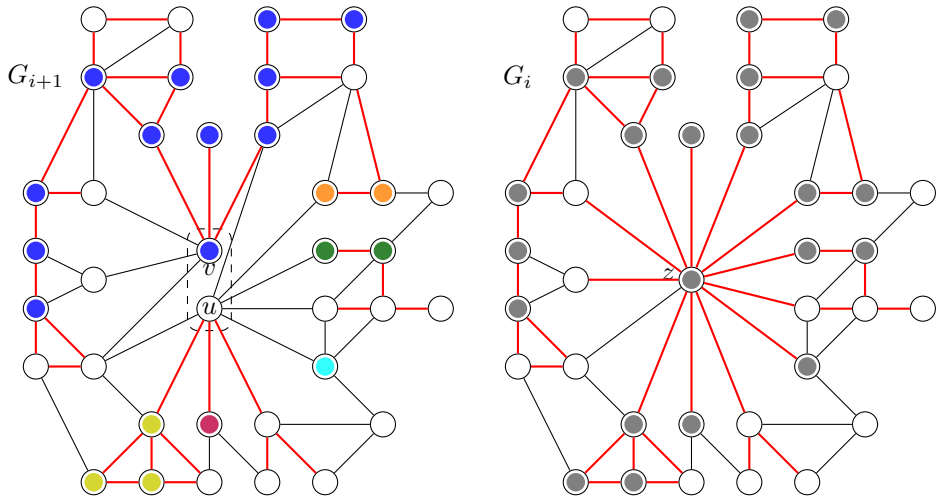

Figure 2 Right: In gray, a connected vertex set T in the red graph of G_i in the vicinity of the just contracted vertex $z \in T$. Left: The decomposition $\mathrm{dec}(T \setminus \{z\} \cup \{v\})$ in the previous trigraph G_{i+1}, where each color represents a connected component. If every color class is a realizable set in G_{i+1}, then T is realizable in G_i, with (optimum) partial solution $\bigcup \mathrm{dec}(T \setminus \{z\} \cup \{v\})$. Note that, due to black edges between u and some vertices of T, the partial solutions in $\mathrm{dec}(T \setminus \{z\} \cup \{u, v\})$ and in $\mathrm{dec}(T \setminus \{z\} \cup \{u\})$ cannot be pairwise compatible.

In the very possible event that at least one such connected component of X is not realizable, $\mathrm{dec}(X) = \text{None}$. The union $\bigcup \mathrm{dec}(X)$ of all the partial solutions of $\mathrm{dec}(X)$ is None if $\mathrm{dec}(X) = \text{None}$ or if there is at least one black edge between two connected components. Otherwise $\bigcup \mathrm{dec}(X)$ is a pair (T, S) as defined in the previous paragraph, since the partial solutions of $\mathrm{dec}(X)$ are pairwise compatible. Since T is chosen connected in $(V(G_i), R(G_i))$, (T, S) is indeed a partial solution in G_i. If $\bigcup \mathrm{dec}(T \setminus \{z\} \cup \{u, v\}), \bigcup \mathrm{dec}(T \setminus \{z\} \cup \{u\}), \bigcup \mathrm{dec}(T \setminus \{z\} \cup \{v\})$ all three evaluate to None, then $\mathrm{best}\{\bigcup \mathrm{dec}(T \setminus \{z\} \cup \{u, v\}), \bigcup \mathrm{dec}(T \setminus \{z\} \cup \{u\}), \bigcup \mathrm{dec}(T \setminus$

$\{z\} \cup \{v\})\}$ also returns None. This would mean that T is not realizable. If instead T is realizable, we get a partial solution (T, S) that we put in $\mathcal{S}_i$. If $|S| \geqslant k$, we already have a large enough independent set; the algorithm outputs it and terminates.

If we finally build $\mathcal{S}_1$, and no independent set of size at least k was found, we output S, the unique set such that $(_, S) \in \mathcal{S}_1$. $\mathcal{S}_1$ is indeed a singleton since there is only one realizable set in G_1. That finishes the description of the algorithm.

Details on the correctness and running time can be found in the long version. The correctness uses the classic inductive arguments for an algorithm based on dynamic programming. The claimed running time for `k-IndSet` essentially follows from Lemma 8.

Optimizations. We suggest some improvements or variations of `k-IndSet` to generally improve over the worst-case running time of the inner for loop. A lot of sets T will trivially be *not* realizable because they induce a black edge. When enumerating the walks starting at z of length at most $2k-3$, one can abort every branch $zv_1 \dots v_h$ inducing at least one black edge. It can even be done in a way that the enumeration takes time $O(t)$ where t is the number of sets $T \ni z$ of size at most k, such that T is connected in the red graph, and an independent set in the black graph.

Even if a set T satisfies those properties, we have no guarantee that T is realizable. In very dense instances, it is imaginable that the realizable sets are very rare. In that case, we will lose a lot of time generating sets T to observe immediately after that there is no associated partial solution (T, S). An alternative to `k-IndSet` is to build the new partial solutions of $\mathcal{S}_i$ directly as unions of pairwise compatible partial solutions of $\mathcal{S}_{i+1}$, without anticipating the nature of the possibly realizable set $T \subseteq V(G)$.

Let us be more precise. Let R_z be the set of red neighbors of z in G_i. For every set of at most $\max(2, d+1)$ partial solutions $(T_1, S_1), \dots, (T_h, S_h) \in \mathcal{S}_{i+1}$ intersecting R_z, at least one of which intersects $\{u, v\}$, if the partial solutions are pairwise compatible, we update the realizable set $\bigcup_{i\in[h]} T_i$ with the partial solution $\bigcup_{i\in[h]}(T_i, S_i)$ if $\bigcup_{i\in[h]} S_i$ is larger than the current best solution. Following the first improvement, we can only generate the sets that are pairwise compatible. As we know, there are at most three ways to reach a given set $T \subseteq V(G_i)$ as a union of pairwise compatible partial solutions in $\mathcal{S}_{i+1}$. The running time of this variation of `k-IndSet` is $O^*(\Sigma_{i\in[n]}|\mathcal{S}_i^{\text{new}}|)$, where $S_i^{\text{new}} := \mathcal{S}_i \setminus \mathcal{S}_{i-1}$ (and $S_n^{\text{new}} := \mathcal{S}_n$) represents the new partial solutions computed at step i. In practice, this can be significantly better than $O(k^2 d^{2k} n)$. Such a dynamic programming, only generating "positive" subinstances, dubbed *positive-instance driven* by Tamaki, led to a breakthrough and current state-of-the-art practical algorithm for computing optimally the treewidth of a graph [17]. ◀

Without too many changes, `k-IndSet` may support weights, that is, find an independent set of size exactly $\min(k, \alpha(G))$ with largest total weight. Instead of keeping one solution S per realizable set T, we keep up to k solutions, one per pair (T, j) with $j \in [|T|, k]$. A partial solution (T, j, S) is defined as before except S is required to have size exactly j. To compute the new partial solutions, we add a third nested for loop after line 6: We iterate over all the ways of distributing $j \leqslant k$ units between the red connected components induced by $T' \in \{T \setminus \{z\} \cup \{u, v\}, T \setminus \{z\} \cup \{u\}, T \setminus \{z\} \cup \{v\}\}$ so that each connected component gets a positive integer (at least equal to its size). We then add to $\mathcal{S}_i$ one partial solution (T, j, S) (if at least one exists) maximizing the weight of S for fixed T and j. We also skip lines 8 and 9 of `k-IndSet`.

This comes with a slight increase in the running time. Namely, there is an extra $2^{O(k \log k)}$ factor accounting for the ordered partition of integer $j \leqslant k$ into positive integers. Thus the overall running time with weights is $2^{O(k \log k)} d^{2k} n$.

As twin-width and d-sequences are preserved when complementing the graph, we also solve k-Clique in the same running time. One may wonder if the dependency in k of our $2^{O_d(k)}n$-time algorithm can be improved. It turns out that this running time is essentially optimal. Due to the Sparsification Lemma [13] and folklore reductions, MIS restricted to subcubic n-vertex graphs cannot be solved in $2^{o(n)}$, under the Exponential Time Hypothesis[5] (ETH) [12]. Thus, by the classic self-reduction consisting of performing an even subdivision of each edge [16], MIS cannot be solved in time $2^{o(n/\log n)}$ on $2\lceil \log n \rceil$-subdivisions of n-vertex subcubic graphs, unless the ETH fails. In [3], we show how to find $O(1)$-sequences in polynomial time for $2\lceil \log n \rceil$-subdivisions of n-vertex graphs. Therefore this lower bound holds even if we are given the d-sequence. In particular, no algorithm solves k-Independent Set in time $2^{o_d(k/\log k)}n^{O(1)}$, unless the ETH fails.

4 A practical algorithm for k-Dominating Set

We solve k-Dominating Set with a more involved instantiation of the scheme of the previous section. We face some new conceptual difficulties compared to the algorithm for k-Independent Set. For one thing, the partial solutions that we maintain are not feasible solutions in the whole graph. Also we now consider balls of radius $f(d)k$ in the red graphs, and not merely of radius k. In general, the arguments are more subtle to handle partially and fully dominated vertex sets, as well as the solution trace. This entails a worse dependency in d, but the same essentially optimal $2^{O(k)}n$ when d is treated as a constant.

▶ **Theorem 10.** *Given an n-vertex graph G, a positive integer k, and a d-sequence $G = G_n, \dots, G_1 = K_1$, k-Dominating Set can be solved in time $O(2^{2(d^2+1)(2+\log d)k}n) = 2^{O_d(k)}n$.*

Proof. As was the case with k-Independent Set, the algorithm sequentially considers each trigraph in the d-sequence $G_n, \dots, G_1$ starting from G_n, and inductively updates a set of optimal partial solutions of the trigraph G_i to yield the next set for G_{i-1}. We recall that $E(G_i)$ and $R(G_i)$ respectively refer to the black and red edge set of the trigraph G_i. The ball of radius at most r in the red graph $(V(G_i), R(G_i))$ centered at a vertex $x \in V(G_i)$ is denoted as $B_i^r(x)$.

Profile of a partial solution. A *profile (of a partial solution)* of G_i is a triple (T, D, M) of vertex sets of $V(G_i)$ such that (i) T forms a connected set in the red graph $(V(G_i), R(G_i))$, (ii) $D, M \subseteq T$, and (iii) $\bigcup_{x\in D} B_i^2(x) \subseteq T$. The first entry T of a profile $P = (T, D, M)$ is called the *ground set* of P, and the size of P is defined as the size of its ground set. A profile (T, D, M) is said to be a *k-profile* if $|D| \leqslant k$. When the profile under consideration is clear from the context, we denote $T \setminus D$ and $T \setminus M$ by $\bar{D}$ and $\bar{M}$ respectively.

We say that *a profile (T, D, M) is realizable with $S \subseteq V(G)$* if the following conditions hold.

1. $S \subseteq \bigcup_{x\in T} x(G)$,
2. for every $x \in V(G_i)$, $x \in D$ if and only if $x(G) \cap S \neq \emptyset$, and
3. for every $x \in V(G_i)$, $x \in M$ if and only if $x(G)$ is (fully) dominated by S.

A profile is said to be *realizable* if there exists S with which it is realizable.

Suppose that $x, y \in V(G_{i+1})$ are contracted to yield G_i with z being the new vertex. For a vertex set $T \subseteq V(G_i)$ connected in the red graph $V(G_i, R_i)$ and containing z, let $T_1, \dots, T_\ell$ be the red connected components of $T' = (T \setminus z) \cup \{x, y\}$ in G_{i+1}, i.e. the partition of T'

[5] The assumption that there is a constant $\delta > 0$, such that 3-SAT cannot be solved in time $2^{\delta n}$.

into maximal vertex sets each of which is connected in $V(G_{i+1}, R_{i+1})$. The number of these red subgraphs does not exceed $d+2$ because each T_i either contains x or y, or one of the newly created red neighbors of z. Notice also that ℓ can be equal to 1, which means that x and y belong to the same connected component of $(V(G_{i+1}), R(G_{i+1}))$.

For a k-profile (T, D, M) of G_i such that $z \in T$, we say that a set $\mathcal{P} = \{(T_1, D_1, M_1), \ldots, (T_\ell, D_\ell, M_\ell)\}$ of k-profiles of G_{i+1} is *consistent with* (T, D, M) if the following holds. Let $T' := (T \setminus z) \cup \{x, y\}$, $D' := \bigcup_{j=1}^{\ell} D_j$ and $M' := \bigcup_{j=1}^{\ell} M_j$.

1. The ground sets of the profiles in $\mathcal{P}$ are precisely the red components of T' in G_{i+1}.
2. $D \setminus z = D' \setminus \{x, y\}$.
3. $z \in D$ if and only if $x \in D'$ or $y \in D'$.
4. For every $u \in T \setminus z$, $u \in M$ if and only if $u \in M'$ or there exists $v \in D'$ such that uv is a black edge in G_{i+1}.
5. $z \in M$ if and only if for each $u \in \{x, y\}$, it holds that: $u \in M'$ or there exists $v \in D'$ such that uv is a black edge in G_{i+1}.

Algorithm, and how to compute τ_i from τ_{i+1}. At each iteration along the d-sequence, we maintain one mapping τ_i from k-profiles $P = (T, D, M)$ of G_i with $|T| < (d^2+1)k$ to a subset of $\bigcup_{t \in T} t(G)$. The assignment $\tau_i(P) = nil$ is interpreted as that P is not realizable whereas $\tau_i(P) \neq nil$ is intended to be a minimum-size vertex set of $V(G)$ realizing P. Again let G_i be obtained by contracting the vertices $x, y \in V(G_{i+1})$ and z be the new vertex. Our goal is to compute τ_i from τ_{i+1}, assuming τ_{i+1} has been computed correctly. Note that a k-profile $P = (T, D, M)$ of G_i such that $z \notin T$ is also a profile of G_i, and trivially one is realizable with S if and only if the other is realizable with S. Therefore, τ_i simply inherits the assignment of τ_{i+1} in this case as depicted in lines 6-7.

If $P = (T, D, M)$ has z in its ground set, the algorithm `k-DomSet` inspects all sets $\mathcal{P}$ of k-profiles of G_{i+1} consistent with (T, D, M) and among the unions $\bigcup_{P \in \mathcal{P}} \tau_{i+1}(P)$ over all such $\mathcal{P}$, outputs the best one as $\tau_i(T, D, M)$, that is, the one of minimum cardinality is chosen. If $\bigcup_{P \in \mathcal{P}} \tau_{i+1}(P) = nil$ for each consistent $\mathcal{P}$, the algorithm concludes that (T, D, M) is not realizable and assigns nil. The case when $\mathcal{P}$ contains a k-profile P with ground set of size at least $(d^2+1)k$, a special step is taken as τ_{i+1} is not defined on such P. In this situation, a vertex $v \in T' \setminus \bigcup_{t \in D'} B^2_{i+1}(t)$ is chosen, and the query at $(T' \setminus v, D' \setminus v, M' \setminus v)$ is made instead. Lines 15-18 handle this case. The uniqueness of k-profile in $\mathcal{P}$ in line 16 and the existence of such v in line 17 will be discussed in the correctness proof.

Correctness. To show the correctness of Algorithm 1, it suffices to prove the following.

> ($\star$) For every $i \in [n]$ and every k-profile P of G_i, we have $\tau_i(P) \neq nil$ if and only if P is realizable with a set of size at most k. Furthermore, if $\tau_i(P) \neq nil$, then $\tau_i(P)$ is a set of minimum size with which P is realizable.

We prove ($\star$) by induction. In the base case when $i = n$, the claim trivially holds. Assume $i < n$ and let x, y be the vertices of G_{i+1} which were contracted to yield G_i, where z is the newly obtained vertex of G_i. By induction hypothesis, for any k-profile (T, D, M) of G_i with $z \notin T$ the claim holds as it is a k-profile of G_{i+1} as well.

Therefore, we assume that $z \in T$ and let $T' = (T \setminus z) \cup \{x, y\}$.

▷ Claim 11. Assume that ($\star$) holds for all $i' > i$ and let $P = (T, D, M)$ be a k-profile of G_i. If P is realizable with a set of size at most k, then $\tau_i(P) \neq nil$.

Proof. Suppose that $P = (T, D, M)$ is realizable with $S \subseteq V(G)$ of size at most k. Let $T_1, \ldots, T_\ell$ be the red connected components of T' in G_i, and let $S_j = S \cap \bigcup_{t \in T_j} t(G)$ for every $j \in [\ell]$. The pairs T_j and S_j for $j = 1, \ldots, \ell$ define a set of ℓ k-profiles (T_j, D_j, M_j) of G_{i+1} in a canonical way: D_j is precisely the set of vertices $t \in T_j$ such that $t(G) \cap S_j$ and M_j is the set of vertices $t \in T_j$ such that $t(G)$ is (fully) dominated by S_j. By construction, each k-profile (T_j, D_j, M_j) is realizable with S_j.

We argue that the set $\mathcal{P} = \{(T_j, D_j, M_j) : j \in [\ell]\}$ is consistent with $P = (T, D, M)$. The first and the second conditions for consistency are clearly satisfied. To verify the third condition, consider a vertex $u \in T$ distinct from z and without loss of generality we assume $u \in T_{j^*}$. If $u \in M$ and $u \notin M_{j^*}$, this means that S_{j^*} does not dominate $u(G)$ because S_{j^*} realizes $(T_{j^*}, D_{j^*}, M_{j^*})$. From $u \in M$ and the fact that S realizes (T, D, M), we know that S dominates $u(G)$ and thus there is at least one vertex $S \setminus S_{j^*}$ which is adjacent (in G) with some vertex of $u(G)$. Consider an arbitrary vertex $v \in T$ to which some of $S \setminus S_{j^*}$ contracts to, and observe that $v \notin T_{j^*}$. This means that uv is a black edge. The converse direction of the third condition is clearly met. The fourth condition of consistency can be verified similarly as the third condition. If $\mathcal{P}$ does not contain any k-profile whose ground set has size at least $(d^2 + 1)k$, now the claim is immediate because each (T_j, D_j, M_j) is realizable with S_j: by induction hypothesis, we have $\tau_{i+1}(T_j, D_j, M_j) \neq nil$, and thus $\tau_i(T, D, M)$ is set to $\neq nil$ at line 14.

Suppose that $\mathcal{P}$ contains a k-profile whose ground set has size at least $(d^2 + 1)k$. One can easily see that in this case, $\ell = 1$ or equivalently T' is a red connected component in $(V(G_{i+1}), R(G_{i+1}))$ consisting of exactly $(d^2+1)k$ vertices. Since the union of at most k balls of radius at most 2 which is connected in $(V(G_{i+1}), R(G_{i+1}))$ have less than $(d^2+1)k$ vertices, there exists $v \in T' \setminus \bigcup_{t \in D'} B^2_{i+1}(t)$. Moreover, by the choice of v, $(T' \setminus v, D' \setminus v, M' \setminus v)$ is now a k-profile of G_{i+1}. To conclude that $\tau_i(T, D, M) \neq nil$, it suffices to prove that $\tau_{i+1}(T' \setminus v, D' \setminus v, M' \setminus v) \neq nil$. We do this by showing that (T, D, M), (T', D', M') and $(T' \setminus v, D' \setminus v, M' \setminus v)$ are equivalent in regards to realizability.

The equivalence of the first two is obvious. For the equivalence of the last two, note that if S realizes (T', D', M'), S does not intersect $v(G)$, and thus S trivially realizes $(T' \setminus v, D' \setminus v, M' \setminus v)$. Conversely, suppose that $(T' \setminus v, D' \setminus v, M' \setminus v)$ is realizable with S'. The crucial observation is that v has no red neighbor in D' since otherwise, v belongs to the union $\bigcup_{t \in D'} B^2_{i+1}(t)$, contradicting the choice of v. Therefore, we know that $v \in M'$ if and only if there exists $u \in D' \setminus v$ such that uv is a black edge. In the case when $v \in M'$, there exists a black neighbor $u \in D' \setminus v$ of v, and any S' realizing $(T' \setminus v, D' \setminus v, M' \setminus v)$ intersects $u(G)$. If follows that S' fully dominates $v(G)$ and S' realizes (T', D', M'). Else if $v \notin M'$, this means that not only the red neighbors of v are disjoint from D' but also no black neighbor of v is contained in D'. As a consequence $v(G)$ is not dominated by S', thus S' realizes (T', D', M'). This proves the equivalence of (T', D', M') and $(T' \setminus v, D' \setminus v, M' \setminus v)$, and completes the proof of the claim. ◁

To establish the other direction, suppose that $\tau_i(T, D, M) \neq nil$ and let $\mathcal{P}^*$ be the set consistent with P such that $\tau_i(T, D, M) = \bigcup_{P \in \mathcal{P}^*} \tau_{i+1}(P)$ or $\tau_i(T, D, M) = \tau_{i+1}(T' \setminus v, D' \setminus v, M' \setminus v)$ for some v. Such $\mathcal{P}^*$ clearly exists since otherwise only nil can be output. In the former case, it is tedious to verify that if each (T_i, D_i, M_i) of $\mathcal{P}^*$ is realizable with S_i, then $\bigcup_{i \in [\ell]} S_i$ realizes (T, D, M). In the latter case, we simply recall that (T, D, M) and $(T' \setminus v, D' \setminus v, M' \setminus v)$ are equivalent in regards to realizability. This completes the proof of the first statement of $(\star)$. The second statement immediately follows.

Algorithm 1 `k-DomSet`.

Input : A graph G, a positive integer k, and a d-sequence $G = G_n, \dots, G_1 = K_1$.
Output : A dominating set of G of size at most k, or report *nil* (No-instance).

1 **for** $v \in V(G_n)$ **do**
2 $\tau_n(\{v\},\{v\},\{v\}) = \{v\}$, $\tau_n(\{v\},\emptyset,\emptyset) = \emptyset$, $\tau_n(P) = nil$ for all other k-profiles P
3 **for** $i = n-1 \to 1$ **do**
4 $x, y \leftarrow$ contracted pair in $G_{i+1} \to G_i$
5 $z \leftarrow$ contraction of x and y in G_i
6 **for** *every k-profile (T, D, M) of G_i of size less than $(d^2+1)k$ s.t. $z \notin T$* **do**
7 $\tau_i(T, D, M) \leftarrow \tau_{i+1}(T, D, M)$
8 **for** *every k-profile (T, D, M) of G_i of size less than $(d^2+1)k$ s.t. $z \in T$* **do**
9 $\tau_i(T, D, M) \leftarrow nil$
10 $T' \leftarrow (T \setminus z) \cup \{x, y\}$
11 **for** *every set $\mathcal{P}$ of k-profiles of G_{i+1} consistent with (T, D, M)* **do**
12 **if** *each k-profile of $\mathcal{P}$ has size less than $(d^2+1)k$* **then**
13 **if** *$\tau_{i+1}(P) \neq nil$ for all $P \in \mathcal{P}$* **then**
14 $\tau_i(T, D, M) \leftarrow \text{best}\{\tau_i(T, D, M), \bigcup_{P\in\mathcal{P}} \tau_{i+1}(P)\}$
15 **else**
16 Let (T', D', M') be the unique k-profile contained in $\mathcal{P}$.
17 Choose $v \in T' \setminus \bigcup_{t\in D'} B^2_{i+1}(t)$
18 $\tau_i(T, D, M) \leftarrow \text{best}\{\tau_i(T, D, M), \tau_{i+1}(T' \setminus v, D' \setminus v, M' \setminus v)\}$
19 **if** *$\tau_i(T, D, M) \neq nil$ and has size larger than k* **then**
20 $\tau_i(T, D, M) \leftarrow nil$
21 **return** $\tau_1(V(G_1), V(G_1), V(G_1))$

Running time. In an actual implementation of Algorithm 1, we maintain a single mapping τ. As we proceed from G_{i+1} to G_i, we modify the domain of τ consisting of k-profiles so that new k-profiles involving z are added and after calculating the assignments for the new k-profiles, all the domains and corresponding assignments involving x or y shall be discarded. Therefore, it suffices to check the running time for updating τ, which is performed in the inner loop of lines 6-20. By Lemma 8, there are $O(d^{2(d^2+1)k-2} \cdot 2^{2(d^2+1)k})$ new profiles of G_i to compute. For each k-profile (T, D, M) with $z \in T$, the ground sets $T_1, \dots, T_\ell$ of a potentially consistent set $\mathcal{P}$ is already determined. Hence, we exhaust all possibilities of appending each T_i by M_i and D_i to form a k-profile and the inner loop of 8-20 will consider at most $2^{(d^2+1)k} \cdot 2^{(d^2+1)k}$ sets $\mathcal{P}$. The consistency of $\mathcal{P}$ with (T, D, M) can be routinely verified. This establishes the claimed running time. ◀

5 Approximation algorithms

5.1 Constant approximation for Min Dominating Set

In this section, we prove that Min Dominating Set has bounded integrality gap in classes of bounded twin-width. A constant factor approximation algorithm readily follows. We will use the following technical lemma from the second paper of the series.

▶ **Theorem 12** (Section 3, Lemma 20 in [3]). *For every integer t, there are integers s and t' such that every graph G with a t-sequence admits a rooted tree $\mathcal{T}$ with the following properties.*

- *Every node of $\mathcal{T}$ is labeled by a t'-trigraph.*
- *The root of $\mathcal{T}$ is labeled by G.*
- *All the leaves of $\mathcal{T}$ are labeled by the 1-vertex graph K_1.*
- *If a node x of $\mathcal{T}$ is labeled by H, and a child node of x is labeled by H', there is a t'-contraction in H that yields H'. In particular $|V(H)| = |V(H')| + 1$.*
- *Every internal node of $\mathcal{T}$ labeled by H has at least $|V(H)|/s$ children coming from t'-contractions on pairwise disjoint pairs of vertices of H.*

Such a tree is called an *s-versatile tree of t'-contractions*. Informally Theorem 12 says that, by degrading the twin-width bound, one can move away from the "linear nature" of the contraction sequence to a profusely branching contraction witness.

Theorem 12 is effective: The s-versatile tree of t'-contractions can be computed in polynomial time, if a t-sequence for G is provided.

▶ **Theorem 13.** *In classes of bounded twin-width, Min Dominating Set has bounded integrality gap.*

Proof. Let G be a graph of twin-width at most t. By Theorem 12, there exist t', s functions of t only such that G admits an s-versatile tree of t'-contraction. Let $w^* : V(G) \to [0,1]$ be the weight function of a minimum fractional dominating set, with total weight γ^*. Thus w^* is an optimum solution of the linear program

$$\text{minimize} \sum_{x \in V(G)} w(x)$$
$$\text{with } \forall x \in V(G), \sum_{y \in N[x]} w(y) \geqslant 1, \text{ and } 0 \leqslant w(x) \leqslant 1,$$

and $\gamma^* = \sum_{x \in V(G)} w^*(x)$. The weight function w^* is extended to subsets of vertices by sum. We assume that G has at least one vertex, so $\gamma^* \geqslant 1$.

We now greedily perform contractions in G following the versatile tree of contractions with a restriction: contractions involving a part of total weight at least $\frac{1}{2(t'+1)}$ are forbidden. Let us explain what this means in more detail. We start at the root, labeled G, of the versatile tree. We move to a(ny) child node along an edge corresponding to a non-forbidden t'-contraction. A *non-forbidden* contraction is one of u, v with $w^*(u(G)) < \frac{1}{2(t'+1)}$ and $w^*(v(G)) < \frac{1}{2(t'+1)}$. We iterate that until we get stuck (every child of the current node entails a forbidden contraction).

We adopt the partition viewpoint of the t'-sequence. Let $\mathcal{P}$ be the partition of $V(G)$ obtained when this process finishes, and let $G_{\mathcal{P}}$ be the corresponding trigraph (that is, the label of the node where we stop). We observe that we cannot end at a leaf of the versatile tree. Indeed that would mean that the last contraction merged a bipartition $\{X, Y\}$ of $V(G)$ into $\{V(G)\}$. As $\gamma^* \geqslant 1$, this would imply that $w^*(X) \geqslant 1/2$ or $w^*(Y) \geqslant 1/2$, contradicting $\max(w^*(X), w^*(Y)) < \frac{1}{2(t'+1)}$.

▷ Claim 14. The partition $\mathcal{P}$ has at most $2s(t'+1)\gamma^*$ classes.

Proof. As we explained, we cannot end up with a partition $\mathcal{P}$ at a leaf of the versatile tree. Thus at least $|\mathcal{P}|/s$ disjoint pairs of vertices are t'-contractions in $G_{\mathcal{P}}$. Therefore all these contractions must be forbidden by our restriction imposed on the weights. It follows that at least $|\mathcal{P}|/s$ parts of $\mathcal{P}$ have weight at least $\frac{1}{2(t'+1)}$. Since the sum of all weights in $\mathcal{P}$ is γ^*, it follows that $|\mathcal{P}| \leqslant 2s(t'+1)\gamma^*$. ◁

▷ Claim 15. Let $P \in \mathcal{P}$ be any part. Either $w^*(P) < \frac{1}{t'+1}$ or P is a singleton.

Proof. Let $P \in \mathcal{P}$, and assume that P is not a singleton. Then P has been obtained by contracting two parts P_1, P_2 during the contraction sequence leading to $\mathcal{P}$. The restriction on the contraction sequence ensures that $w^*(P_1) < \frac{1}{2(t'+1)}$ and $w^*(P_2) < \frac{1}{2(t'+1)}$. Therefore $w^*(P) = w^*(P_1) + w^*(P_2) < \frac{1}{t'+1}$. ◁

Let $D \subseteq V(G)$ be obtained by picking arbitrarily one vertex x_P in each part $P \in \mathcal{P}$. By Claim 14, $|D| \leqslant 2s(t'+1)\gamma^*$, which is linear in γ^* when t is fixed. Let us prove that D is a dominating set. We let $P \in \mathcal{P}$, and prove that all vertices of P are dominated by D.

Suppose first that there exists $P' \in \mathcal{P}$ such that P, P' is a black edge in $G_{\mathcal{P}}$. Then $x_{P'} \in P'$ is adjacent to all vertices of P, which are thus dominated by D.

Hence we may instead assume that P does not have any black neighbor in $G_{\mathcal{P}}$. Consider any vertex $y \in P$, and let $P_1, \dots, P_k$ the parts of $\mathcal{P} \setminus \{P\}$ such that there exists an edge between y and some vertex of P_i. Then $P_1, \dots, P_k$ are neighbors of P in $G_{\mathcal{P}}$, and must be red neighbors since P has no black neighbor. Since $G_{\mathcal{P}}$ is a t'-trigraph, it follows that $k \leqslant t'$.

We now claim that one of the parts $P, P_1, \dots, P_k$ must be a singleton. Indeed, since w^* is a fractional dominating set, and since $P \cup \bigcup_{i=1}^{k} P_i$ contains y and its neighborhood, it must be that $w^*(P) + \sum_{i=1}^{k} w^*(P_i) \geqslant 1$. Because $k \leqslant t'$, it follows that one part among $P, P_1, \dots, P_k$ has weight at least $\frac{1}{t'+1}$. By Claim 15, that same part P_h must be a singleton. Let z be the single vertex in P_h. Necessarily $z \in D$. If this singleton part is P, then $z = y$. Otherwise z is a neighbor of y by definition of $P_1, \dots, P_k$. In either case y is dominated in D by z. ◀

5.2 A constant approximation for MIS would imply a PTAS

A pessimistic stance on the result of this section is that, perhaps surprisingly, the constant approximation of Min Dominating Set is unlikely to be generalizable to the closely related MIS. We indeed observe that the self-improving reduction of Feige et al. [8] preserves the twin-width. As a consequence a constant approximation for MIS would provide a polynomial-time approximation scheme (PTAS).

▶ **Theorem 16.** *If Max Independent Set on graphs of twin-width at most d has a constant-approximation algorithm, then it admits a PTAS.*

For G_1 and G_2 two non-empty graphs, and $u \in V(G_1)$, we denote by $G_1(u \leftarrow G_2)$ the substitution in G_1 of u by G_2. That is, u is replaced by G_2, and every vertex of $V(G_1) \setminus \{u\}$ initially adjacent to u is made adjacent to the whole $V(G_2)$.

▶ **Lemma 17.** $tww(G_1(u \leftarrow G_2)) = \max(tww(G_1), tww(G_2))$.

For G a graph, let G^t be the graph on the vertex set $V(G)^t$, such that for $\bar{x} = (x_1, \dots, x_t)$, $\bar{y} = (y_1, \dots, y_t)$ distinct vertices, $\bar{x}\bar{y} \in E(G^t)$ if and only if $x_i y_i \in E(G)$ where i is the smallest index such that $x_i \neq y_i$. This definition can be restated inductively: G^0 is the 1-vertex graph, and G^t is obtained from G by substituting each vertex by a copy of G^{t-1}. With the notations of the initial definition, for $x \in V(G)$, the set of vertices of G^t of the form $(x, x_2, \dots, x_t)$ is a copy isomorphic to G^{t-1}.

The following holds as a direct consequence of Lemma 17.

▶ **Lemma 18.** *For any graph G and integer $t > 0$, $tww(G^t) = tww(G)$.*

We now show that the independence number of G^t is tightly related to the one of G.

▶ **Lemma 19.** *For any graph G, both following conditions hold.*

1. *Given any independent set of size k in G, one can compute an independent of size k^t in G^t, in time $O(k^t)$.*
2. *Given any independent set of size k' in G^t, one can compute an independent of size at least $\sqrt[t]{k'}$ in G, in time $O(k')$.*

As an immediate corollary, $\alpha(G^t) = \alpha(G)^t$ where, we recall, $\alpha(H)$ denotes the size of a maximum independent set in H.

Proof of Theorem 16. Assume there is a polynomial-time β-approximation for MIS on graphs of twin-width at most d. Let G be a graph with twin-width at most d. By Lemma 18 the algorithm can be ran on G^t to obtain an independent set of size at least $\frac{\alpha(G^t)}{\beta} = \frac{\alpha(G)^t}{\beta}$. By Lemma 19, this independent set in G^t can be turned into an independent set in G of size at least $\alpha(G)/\sqrt[t]{\beta}$. This gives a polynomial-time $\sqrt[t]{\beta}$-approximation for arbitrary t. Thus the approximation ratio can be made arbitrarily close to 1. ◀

6 Bounded twin-width classes are χ-bounded

So far, our algorithms use the contraction sequence (or tree) "forward". This is the original scheme of Guillemot and Marx [11], and of our model checking algorithm [4]. We now see how it can be useful to consider the contraction process "backward". We start with the case of triangle-free graphs, which will be the base case for the proof of the χ-boundedness.

▶ **Theorem 20.** *Every triangle-free graph with twin-width at most d is $(d+2)$-colorable.*

Proof. Let G be an n-vertex triangle-free graph of twin-width at most d, and let $G = G_n, \dots, G_1 = K_1$ be a d-sequence of G. We show how to color G with $d+2$ colors starting from G_1, and iteratively coloring G_{i+1} based on the coloring of G_i. We give the unique vertex of $G_1 = K_1$ color 1. This defines coloring C_1. For every i from 1 to $n-1$, let z be the vertex of G_i split into $u, v \in V(G_{i+1})$. In coloring C_{i+1}, every vertex of $V(G_{i+1}) \setminus \{u, v\}$ keeps the color it received by C_i. Vertex u receives color $C_i(z)$. Finally, v receives color $C_i(z)$ if uv is a non-edge in G_{i+1}, and the smallest positive integer *not* appearing in its neighborhood (black *and* red neighbors) in G_{i+1}, otherwise. We will now show that C_n is a proper coloring of G using at most $d+2$ distinct colors.

We show by induction on i that C_i is a proper $(d+2)$-coloring of the *graph* $G'_i := (V(G_i), E(G_i) \cup R(G_i))$. Coloring C_1 is indeed proper in G'_1 and uses $1 \leqslant d+2$ color. We assume that C_i is a proper $(d+2)$-coloring of G'_i, and distinguish two cases. If there is a black edge $yz \in E(G_i)$ (recall that z is the vertex split into u, v), then uv has to be a non-edge in G_{i+1}. Otherwise there is at least one edge between $u(G)$ and $v(G)$, and this edge forms a triangle with any vertex in $y(G)$. Thus in that case, $C_{i+1}(u) = C_{i+1}(v) = C_i(z)$. So the number of distinct colors given by C_{i+1} is still at most $d+2$ (see Figure 3).

And C_{i+1} is a proper coloring of G'_{i+1} since $N_{G'_{i+1}}(\{u, v\}) = N_{G'_i}(z)$. If instead z has only red neighbors in G_i, then z has at most d neighbors in G'_i. Furthermore let us assume that $uv \in E(G'_{i+1})$, otherwise we conclude as previously. In that case, v is properly colored by C_{i+1} in G'_{i+1} by construction, and vertex u as well, since $N_{G'_{i+1}}(u) \setminus \{v\} \subseteq N_{G'_i}(z)$. Finally $C_{i+1}(v)$ is the smallest positive integer not appearing in a set of at most $d+1$ positive integers. Thus $C_{i+1}(v) \leqslant d+2$, and C_{i+1} is overall a proper $(d+2)$-coloring of G'_{i+1} (see Figure 4).

In particular, C_n is a proper $(d+2)$-coloring of $G'_n = G_n = G$. ◀

As a side note, it is, to our knowledge, possible that every triangle-free K_t-minor free graph has twin-width $O(t)$. If this turns out to be true, it offers a seemingly different approach to getting improved bounds in the triangle-free case of the Hadwiger's conjecture:

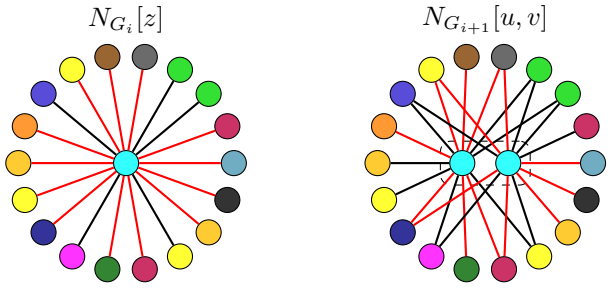

Figure 3 Split, when z is incident to a black edge in G_i. As G is triangle-free, there cannot be an edge (red or black) between u and v. Thus both u and v can take the color of z, which does not appear in their neighborhood.

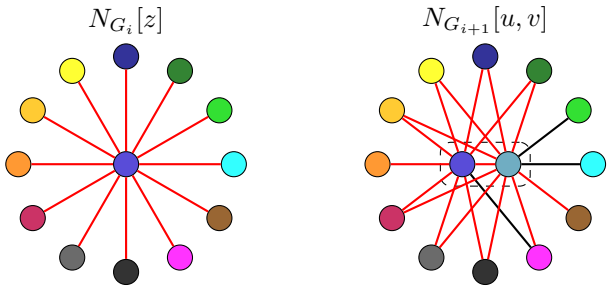

Figure 4 Split, when z is only incident to red edges. Even if the red neighbors of z have d distinct colors, vertex v can find a color in $[d+2]$ which avoids these d colors plus the color of z and u.

Instead of trying to color these graphs, one could try to design contraction sequences for them. We now show how to color any K_t-free graph G given with a d-sequence, with at most $(d+2)^{t-2}$ colors.

▶ **Theorem 21.** *For every integer $t \geqslant 3$, every K_t-free graph with twin-width at most d is $(d+2)^{t-2}$-colorable.*

Proof. Let $G_n, \dots, G_1$ be a d-sequence of a K_t-free graph G with $t \geqslant 3$. In Theorem 20, whenever a vertex $x \in V(G_{i+1})$ was incident to a black edge for the first time (going from G_1 to G_n), the color of all the vertices in $x(G)$ was eventually set to the same value, namely $C_{i+1}(x)$. Now such a set $x(G)$ is not necessarily an independent set, but rather induces a K_{t-1}-free graph. Indeed, a K_{t-1} in $G[x(G)]$ would form a K_t in G with any vertex of $y(G)$, where $xy \in E(G_{i+1})$. By induction on t, we may color $G[x(G)]$ with tuples of at most $t-3$ integers of $[d+2]$, and prepends $C_{i+1}(x)$ to these tuples. The base case $t=3$ is Theorem 20. We make the general idea a bit more precise.

For every $i \in [n]$, we define G_i^* as the *graph* obtained from G_i by blowing every vertex $x \in V(G_i)$ into $G[x(G)]$ whenever x is incident to a black edge, and then turning every red edge into a black edge. We define the successive colorings $C'_1, \dots, C'_n$ of $G_1^*, \dots, G_n^*$, respectively, following the algorithm of Theorem 20. While there are no black edge in the current trigraph G_i, we set $C'_i := C_i$, where C_i is the coloring in the triangle-free case. Say, at least one black edge appears for the first time in G_{i+1} (this is well-defined since G_n has only black edges). Again we adopt the convention that $z \in V(G_i)$ was split into $u, v \in V(G_{i+1})$. Let S be the set of (at most $d+2$) vertices with an incident black edge in G_{i+1}. (One may notice that $S \subseteq \{u,v\} \cup N_{G_i}(z)$ and $S \cap \{u,v\} \neq \emptyset$.) Every vertex $w \in V(G_{i+1}) \setminus S$ receives

color $C_{i+1}(w)$. As we observed, for every $x \in S$, $G[x(G)]$ is K_{t-1}-free. By induction there is a coloring C^x of $G[x(G)]$ with tuples of at most $t-3$ integers from $[d+2]$. We *permanently* color every vertex $y \in x(G)$ by $(C_{i+1}(x), C^x(y))$. This defines the coloring C'_{i+1} of G^*_{i+1}.

We continue to follow Theorem 20, with the ensuing precisions. We go through all the splits, including the ones between two permanently colored vertices, since they may make some other vertices incident to a black edge for the first time. If the split vertex $z \in V(G_j)$ is *not* such that $z(G)$ was already permanently colored, the colors of the new vertices $u, v \in V(G_{j+1})$ are chosen according to the rules of Theorem 20 where we consider the trigraphs G_j and G_{j+1} (and not the graphs G^*_j and G^*_{j+1}), and the coloring C_j of $V(G_j)$ is defined as: $C_j(y)$ is the first coordinate of $C'_j(y)$ (or $C'_j(y)$ itself if it is not a tuple) if $y \in V(G^*_j)$, and the first coordinate of the color of any vertex in $y(G)$, otherwise. (One may observe that C_j is *not* necessarily a proper coloring of $(V(G_j), E(G_j) \cup R(G_j))$, but all the conflict edges lie within a permanently colored subgraph.) Every time a vertex x becomes incident to a black edge, we permanently color $x(G)$. This defines the sequence of colorings $C'_1, \dots, C'_n$.

We show by induction on i that C'_i properly colors G^*_i. Coloring C'_1 is indeed a proper coloring of $G^*_1 = K_1$. We assume that C'_i is a proper coloring of G^*_i, and let xy be any edge in $E(G^*_{i+1})$. By the outermost induction on t, if xy lies within a K_{t-1}-free graph permanently colored, then $C'_{i+1}(x) \neq C'_{i+1}(y)$. If instead x and y belong to two distinct vertices of G_{i+1}, by the proof of Theorem 20 and the fact that C'_i is a proper coloring of G^*_i, the first coordinate of $C'_{i+1}(x)$ and of $C'_{i+1}(y)$ differ. In particular C'_n is a proper coloring of $G^*_n = G_n = G$. We pad every tuple $C'_n(x)$ of length $t' < t$ with $t - t'$ entries 1. From the previous proof, it can be observed that this new coloring of G is still proper, and uses at most $(d+2)^{t-2}$ colors. ◀

Theorem 21 directly implies that, provided $O(1)$-sequences are given, Min Coloring can be $2^{O(\mathrm{OPT})}$-approximated on bounded twin-width graphs, and Max Independent Set can be $O(1)$-approximated on K_t-free graphs of bounded twin-width. It would be interesting to determine if bounded twin-width classes are polynomially χ-bounded, that is, satisfies for some constant c, $\chi(G) = O(\omega(G)^c)$ for every graph G in the class. Bounded clique-width or rank-width classes were shown polynomially χ-bounded only recently [2]. We show however that bounded twin-width classes satisfy the related *strong Erdős-Hajnal property*. We recall that a class $\mathcal{C}$ of graphs satisfies the *strong Erdős-Hajnal property* if there exists an $\varepsilon > 0$ such that every $G \in \mathcal{C}$ contains two disjoint subsets of vertices X, Y, both of size at least $\varepsilon|V(G)|$, with either all edges or no edges between X and Y. The strong Erdős-Hajnal property of a hereditary class implies the existence of a clique or a stable set of polynomial size, that is, the Erdős-Hajnal property [1].

▶ **Theorem 22.** *The class of graphs with twin-width at most d satisfies the strong Erdős-Hajnal property with $\varepsilon = 1/(d+4)$.*

Proof. Let G be an n-vertex graph with twin-width at most d. Consider in a fixed d-sequence $G_n, \dots, G_1$ the maximum index i such that there is a vertex $z \in V(G_i)$ satisfying $|z(G)| \geqslant n/(d+4)$. Since $X := z(G)$ is the union of $u(G)$ and $v(G)$ for some $u, v \in V(G_{i+1})$, its size is at most $2n/(d+4)$. Vertex z has at most d red neighbors in G_i. These neighbors constitute a set $S \subseteq V(G)$ of at most $d \cdot n/(d+4)$ vertices. Thus $|V(G) \setminus (z(G) \cup S)| \geqslant n - 2n/(d+4) - dn/(d+4) = 2n/(d+4)$. By construction, every vertex in $V(G) \setminus (z(G) \cup S)$ is fully adjacent to X or fully non-adjacent to X. Let $Y \subseteq V(G) \setminus (z(G) \cup S)$ be the subset of all vertices in the majority regarding these two outcomes. Set Y has size at least $n/(d+4)$ vertices and X, Y is therefore an appropriate pair. ◀

Abstract

A mobile agent navigating along edges of a simple connected graph, either finite or countably infinite, has to find an inert target (treasure) hidden in one of the nodes. This task is known as treasure hunt. The agent has no *a priori* knowledge of the graph, of the location of the treasure or of the initial distance to it. The cost of a treasure hunt algorithm is the worst-case number of edge traversals performed by the agent until finding the treasure. Awerbuch, Betke, Rivest and Singh [3] considered graph exploration and treasure hunt for finite graphs in a restricted model where the agent has a fuel tank that can be replenished only at the starting node s. The size of the tank is $B = 2(1+\alpha)r$, for some positive real constant α, where r, called the radius of the graph, is the maximum distance from s to any other node. The tank of size B allows the agent to make at most $\lfloor B \rfloor$ edge traversals between two consecutive visits at node s.

Let $e(d)$ be the number of edges whose at least one extremity is at distance less than d from s. Awerbuch, Betke, Rivest and Singh [3] conjectured that it is impossible to find a treasure hidden in a node at distance at most d at cost nearly linear in $e(d)$. We first design a deterministic treasure hunt algorithm working in the model without any restrictions on the moves of the agent at cost $\mathcal{O}(e(d) \log d)$, and then show how to modify this algorithm to work in the model from [3] with the same complexity. Thus we refute the above twenty-year-old conjecture. We observe that no treasure hunt algorithm can beat cost $\Theta(e(d))$ for all graphs and thus our algorithms are also almost optimal.

1 Introduction

The background. A mobile agent has to find an inert target (treasure) in some environment that can be a network modeled by a graph or a terrain in the plane. This task, known as *treasure hunt*, has important applications when the environment is dangerous for humans. When a miner is lost in a contaminated mine, it may have to be found by a robot, and the length of the robot's trajectory should be as short as possible, in order to minimize rescuing

time. In this example, a graph models the corridors of the mine with nodes representing crossings. Another application of treasure hunt in graphs is searching for a data item in a communication network modeled by a graph.

The models and the problem. We consider a simple connected undirected locally finite graph $\mathcal{G} = (V_{\mathcal{G}}, E_{\mathcal{G}})$, i.e., a graph with nodes of finite degrees. Such a graph can be either finite or countably infinite. A mobile agent (robot) starts at a node s of $\mathcal{G}$, called the *source node*, and moves along its edges. The maximum distance of any node from s is denoted by r and called the *radius* of the graph (the radius of countably infinite graphs is infinite). We make the same assumption as in [3] that the agent has unbounded memory and can recognize already visited nodes and traversed edges. This is formalized as follows. Nodes of $\mathcal{G}$ have distinct labels that are positive integers. Each edge has ports at both of its extremities. Ports corresponding to edges incident to a node of degree δ are numbered $0, 1, \ldots, \delta - 1$ in an arbitrary way. At the beginning, the agent situated at node s sees its degree. The agent executes a deterministic algorithm: at each step, it selects a port number on the basis of currently available information, and traverses the corresponding edge. When the agent enters the adjacent node, it learns its label, its degree, and the incoming port number. Each node of $V_{\mathcal{G}}$ will be identified with its label, and each edge of $E_{\mathcal{G}}$ will be identified as the quadruple (v, w, p, q), where $v < w$ are labels of the edge extremities, p is its port number at node v and q is its port number at node w.

The above simple model will be called *unrestricted*. However, some authors imposed additional restrictions, in the case when the graph is finite. The authors of [3] used a restriction of moves of the agent that we will call the *fuel-restricted model*. They assumed that the agent has a fuel tank that can be replenished only at the starting node s of the agent. The size of the tank is $B = 2(1+\alpha)r$, for some positive real constant α, where r is the radius of the graph. The tank of size B allows the agent to make at most $\lfloor B \rfloor$ edge traversals between two consecutive visits at node s. The restriction used in [11] was of a different kind. We will call it the *rope-restricted model*. It was assumed in [11] that the agent is *tethered*, i.e., attached to s by a rope that it unwinds by a length 1 with every forward edge traversal and rewinds by a length of 1 with every backward edge traversal. The rope is infinitely extendible but has to satisfy the following constraint: the segment of the rope unwinded by the agent must never be longer than $L = (1 + \alpha)r$, for some positive real constant α. Hence the agent is forced to match every forward edge traversal of an edge with a backward edge traversal, rewinding the rope, in a first-in last-out stack order.

The task of treasure hunt, in any of the above three models, is defined as follows. An adversary hides the treasure in some node of the underlying graph $\mathcal{G}$. The agent has no *a priori* knowledge of the graph, of the location of the treasure or of the initial distance to it, and has to find the treasure. The *cost* of a treasure hunt algorithm is the worst-case number of edge traversals performed by the agent until finding the treasure.

In order to state our problem we need the notion of a *ball*. Given a non-negative integer k, a graph G, and a node u, the ball $B_k(G, u)$ is defined as the subgraph $K = (V_K, E_K)$ of G, where V_K is the set of all nodes at distance at most k from u in G, and E_K is the set of all edges of G whose at least one extremity is at distance smaller than k from u in G. (Thus $B_k(G, u)$ is the subgraph of G induced by nodes at distance at most k without edges joining nodes at distance exactly k from u in G). The number of edges in ball $B_k(\mathcal{G}, s)$, where s is the source node, will be denoted by $e(k, \mathcal{G})$. Whenever the graph $\mathcal{G}$ is clear from the context, we will write $e(k)$ instead of $e(k, \mathcal{G})$.

The main problem considered in this paper is inspired by the following conjecture of Awerbuch, Betke, Rivest and Singh [3], formulated for their fuel-restricted model:

Is it possible (we conjecture not) to find a treasure in time nearly linear in the number of those vertices and edges whose distance to the source is less than or equal to that of the treasure? [1]

Our results. Our main result refutes the above twenty-year-old conjecture. Let d be any integer such that $1 < d \leq r$, where r is the radius of the underlying graph $\mathcal{G}$. We first design a deterministic treasure hunt algorithm working in the unrestricted model and always finding a treasure located at distance at most d from the source node, at cost $\mathcal{O}(e(d) \log d)$. We then show how to modify this algorithm to work in the fuel-restricted and rope-restricted models with the same complexity. Since $d \leq e(d)$, the cost of our algorithms differs from $e(d)$ only by a logarithmic factor, and hence it is nearly linear in $e(d)$, contrary to the conjecture. Due to the ignorance of the agent concerning the graph in which it operates, it can be easily shown that no treasure hunt algorithm can beat cost $\Theta(e(d))$ for all graphs and thus our algorithms are also almost optimal. The main difficulty is to design the algorithm for the unrestricted model. This algorithm is then suitably modified for each of the two restricted models.

Solving the problem of treasure hunt at a cost quasi-linear in $e(d)$ required to respect two fundamental principles, whose joint implementation seemed precarious in the light of the existing literature.

The first one is a *prudence principle*. It consists in never getting "for too long" beyond the unknown distance d in order to guarantee a cost that depends on $e(d)$. This can be ideally achieved by emulating BFS. However, since in such an emulation the agent must physically move from one node to the next, it may be forced to traverse $\Omega(e(d)^2)$ edges before finding the treasure, in some graphs. In particular, this could be the case when $\mathcal{G}$ is an infinite line.

The second principle is what we could call an *efficiency principle*. It consists in getting a cost that is asymptotically close to the number of edges of the subgraph that has been explored till finding the treasure, if the treasure is far away. This can be ideally achieved using the treasure hunt algorithm of [11], the cost of which is linear in the number of edges of the explored subgraph. However, using this algorithm, the agent may go for too long beyond the unknown distance d and consequently the cost of treasure hunt could not be upper bounded by any function of $e(d)$. The key challenge overcome by our work was combining these two principles within the same algorithm. It is precisely the combination of prudence with efficiency that finally made possible the design of an almost-optimal treasure hunt algorithm.

Due to lack of space, the proofs of several results are omitted.

Related work. The task of treasure hunt, i.e., finding an inert target hidden in some environment, has been studied for over fifty years [5, 6, 7]. The environment where the target is hidden may be a graph or a plane, and the search may be deterministic or randomized. The book [1] surveys both treasure hunt and the related rendezvous problem, where the target and the searching agent are both mobile and they cooperate to meet. This book is concerned mostly with randomized search strategies. In [23, 26] the authors studied relations between treasure hunt and rendezvous in graphs. The authors of [4] studied the task of treasure hunt on the line and in the grid, and initiated the study of the task of searching for an unknown line in the plane. This research was continued, e.g., in [16, 21].

Several papers considered treasure hunt in the plane, see surveys [14, 15]. In [20], the author designs an optimal algorithm to sweep the plane in order to locate an unknown fixed target, where locating means getting the agent originating at point O to a point P such that the target is in the segment OP. In [13], the authors generalized the search problem in the

[1] Here time is what we call cost, i.e., the worst-case number of edge traversals until finding the treasure.

plane to the case of several searchers. Efficient treasure hunt in the plane, under complete ignorance of the searching agent, was studied in [24]. Treasure hunt on the line (called the cow-path problem [17]) has been also generalized to the environment consisting of multiple rays originating at a single point [2, 10, 22, 25].

In [12], the authors considered treasure hunt in several classes of graphs including trees. Treasure hunt in trees was studied in [8, 9, 18]. In [8, 9], the authors considered complete b-ary trees, and in [18], treasure hunt was studied in symmetric trees, with possibly multiple treasures.

In [19, 23], treasure hunt in graphs was considered under the advice paradigm, where a given number of bits of advice can be given to the agent, and the issue is to minimize this number of bits. The impact of different types of knowledge on the efficiency of the treasure hunt problem restricted to symmetric trees was studied in [18].

The two papers closest to the present work are [3, 11]. Both of them are mainly interested in exploration of finite unknown graphs but they both get interesting corollaries for the treasure hunt problem. [3] adopts the fuel-restricted model and [11] adopts the rope-restricted model. In [3], the authors get a treasure hunt algorithm working at cost $O(E + V^{1+o(1)})$, where E (resp. V) is the number of edges (resp. nodes) in a ball $B_\Delta(\mathcal{G}, s)$, with $\Delta \leq d + o(d)$, if the treasure is at distance at most d from the starting node of the agent. Since $e(\Delta)$ may be a lot larger than $e(d)$, this does not permit to bound the cost of the algorithm by any function of $e(d)$. This impossibility may be the reason for their conjecture that we refute in this paper. In [11], the authors design, for any constant $0 < \alpha < 1$, a treasure hunt algorithm whose cost is linear in $e((1 + \alpha)d)$. Again, since $e((1 + \alpha)d)$ may be much larger than $e(d)$, this does not permit to bound the cost of the algorithm by any function of $e(d)$.

2 Preliminaries

In this section we introduce some conventions, definitions and procedures that will be used to describe and analyze our algorithm.

Consider any graph $H = (V_H, E_H) \subseteq \mathcal{G}$. If H is finite, its size i.e., its number of edges is denoted by $|H|$. A graph is said to be *empty* if it contains no node. In the rest of this section, we assume that H is not empty.

Let u and v be two (not necessarily distinct) nodes of H. We say that a sequence of i integers $(x_1, x_2, \ldots, x_i)$ is a *path* (of length i) in H from node u to v iff (1) $i = 0$ and $u = v$, or (2) there exists an edge e in H between node u and a node w of H such that the port number of edge e at node u is x_1 and $(x_2, \ldots, x_i)$ is a path from node w to v in H. The lexicocraphically smallest shortest path from node u to v in H, if any, is denoted by $P_H(u, v)$, and the length of this path is denoted by $|P_H(u, v)|$. The distance between u and v in H is denoted by $d_H(u, v)$ and is equal to $|P_H(u, v)|$ if $P_H(u, v)$ exists, ∞ otherwise. If H is finite and connected, the eccentricity $\epsilon_H(u)$ of node u is defined as $\max_{w \in V_H} d_H(u, w)$. The degree of u in H will be denoted by $deg_H(u)$, or simply by $deg(u)$ if $H = \mathcal{G}$. We say that node u is *incomplete* (resp. *complete*) in H if $deg_H(u) < deg(u)$ (resp. $deg_H(u) = deg(u)$). We also say that a port p is free at node u in H, if $p \leq deg(u) - 1$ and there is no edge $(u, *, p, *)$ or $(*, u, *, p)$ in E_H.

We will often need to handle subgraphs of $\mathcal{G}$ through union and intersection operations. More precisely, given two subgraphs $H' = (V_{H'}, E_{H'})$ and $H'' = (V_{H''}, E_{H''})$ of $\mathcal{G}$, the union of (resp. the intersection of) H' and H'' is denoted by $H' \sqcup H''$ (resp. $H' \sqcap H''$) and is equal to $(V_{H'} \cup V_{H''}, E_{H'} \cup E_{H''})$ (resp. $(V_{H'} \cap V_{H''}, E_{H'} \cap E_{H''})$).

We define the boundary of a ball $B_f(\mathcal{G}, s)$, where s is the source node, as the set of nodes of $B_f(\mathcal{G}, s)$ that are incomplete in $B_f(\mathcal{G}, s)$.

To design our algorithm, we will also make use of three basic routines presented below. The first routine is `MoveTo`(H, v). Assuming that the agent currently occupies a node w of H and $P_H(w, v)$ exists, this routine moves the agent from node w to node v by following path $P_H(w, v)$. The second routine is `IncompleteNodes`(v, H, l) where l is a positive integer. This routine returns the set of all nodes w of H such that $d_H(v, w) \leq l$ and w is incomplete in H. The third routine is `Nodes`$(\mathcal{S})$, where $\mathcal{S}$ is a finite set of finite subgraphs of $\mathcal{G}$. This routine returns the union of all nodes in all subgraphs from $\mathcal{S}$.

Given an execution $\mathcal{E}$ of a series of instructions, the cost of $\mathcal{E}$ is the number of edge traversals performed by the agent during $\mathcal{E}$.

We will use the following convention. The agent will sometimes need to use Depth First Search traversal of graphs (not performed physically, but performed as a computation in the memory of the agent). Such a traversal depends on the order in which edges incident to a given node are traversed for the first time. We fix this order as the increasing order of port numbers at the given node. In this way the traversal is unambiguous, and we call it DFS.

3 Intuition

The purpose of this section is to sketch an intuitive overview of our algorithm that allows to find the treasure at an almost-optimal cost in the unrestricted model. To this end and to simplify the discussion, we will assume that the underlying graph $\mathcal{G}$ is countably infinite with nodes of finite degrees. We will rely on the notion of *largest explored ball*. By "largest explored ball", at a given phase of treasure hunt, we mean the ball $B_f(\mathcal{G}, s)$ where f is the largest integer such that each edge of $B_f(\mathcal{G}, s)$ has been traversed at least once. This largest integer f is the radius of the largest explored ball.

At a high level, our algorithm works in phases $i = 1, 2, 3, \ldots$ and immediately stops as soon as the treasure is found. At the beginning of phase i, the agent is located at node s and the radius of the largest explored ball is equal to f_i. The goal for the agent is to terminate the phase at node s while satisfying at least one of the following three conditions unless, of course, the treasure has been found before.

- *Condition 1.* The agent has entirely explored ball $B_{f_i+1}(\mathcal{G}, s)$, $e(f_i + 1) \geq 2e(f_i)$ and the cost of the phase is $\mathcal{O}(e(f_i + 1))$.
- *Condition 2.* The agent has entirely explored ball $B_{2f_i}(\mathcal{G}, s)$, $f_i \geq 1$ and the cost of the phase is $\mathcal{O}(e(f_i))$.
- *Condition 3.* The agent has entirely explored ball $B_{f_i+k}(\mathcal{G}, s)$ for some positive integer k, $e(f_i + k + 1) \geq 2e(f_i)$, $f_i \geq 2$, and the cost of the phase is $\mathcal{O}(e(f_i) \log f_i)$.

Actually, the conditions we really seek to meet in our algorithm are a little more intricate than those presented above, because we needed stronger technical requirements to refute the conjecture of Awerbuch, Betke, Rivest and Singh [3]. However, this would add an unnecessary level of complexity to understand the intuition, hence we omit these technical details here.

Before seeing how we implement our strategy, let us briefly examine why it permits us to get a cost quasi-linear in $e(d)$. Since $f_1 = 0$ and the radius of the largest explored ball increases by at least one during each phase in which the treasure is not found, the agent necessarily finds the treasure by the end of some phase $\lambda \leq d$, and $f_i < f_\lambda < d$ for every $1 \leq i < \lambda$. During each phase satisfying Condition 1, the size of the largest explored ball at least doubles, which means that the total cost of these phases is upper bounded by twice the

worst-case cost of the last phase satisfying Condition 1 i.e., $\mathcal{O}(e(f_\lambda + 1))$. Concerning the phases fulfilling Condition 2, their number is at most $\mathcal{O}(\log(f_\lambda + 1))$ and the cost of each of them cannot be more than $\mathcal{O}(e(f_\lambda))$, which implies that their total cost is $\mathcal{O}(e(f_\lambda)\log(f_\lambda+1))$. It remains to consider the case of the phases satisfying Condition 3. Given such a phase i, we have the guarantee that the size of the largest explored ball at least doubles between the beginning of phase i and the end of phase $i+1$, provided phase $i+1$ exists and is not prematurely interrupted by the discovery of the treasure. Indeed, at the end of phase i, the agent has at least entirely explored ball $B_{f_i+k}(\mathcal{G}, s)$ for some positive integer k and $e(f_i + k + 1) \geq 2e(f_i)$, while at the end of the (not prematurely interrupted) phase $i+1$ the agent has at least entirely explored ball $B_{f_{i+1}+1}(\mathcal{G}, s)$ with $f_{i+1} \geq f_i + k$. Using this, it can be shown that the total cost of the phases satisfying Condition 3 is at most four times the worst-case cost of the last phase satisfying this condition i.e., $\mathcal{O}(e(f_\lambda)\log(f_\lambda + 1))$. Given that the last phase λ can be viewed as a truncated phase that should have normally satisfied one of the three conditions, our sketch of analysis leads to the conclusion that the cost incurred by the agent till the discovery of the treasure is in $\mathcal{O}(e(f_\lambda + 1)\log(f_\lambda + 1))$, which is $\mathcal{O}(e(d)\log d)$ and is in line with our expectations.

Having justified the pertinence of such a strategy, we can turn our attention to its implementation. To do so, we need to introduce a technical building block, which we call `GlobalExpansion`(l, m) and to which we will go back at the end of this section to give additional details. Always executed from the source node s, it is a function that returns a boolean and whose two input parameters are positive integers except m that may be sometimes equal to the special symbol $\perp$. Assuming that $B_f(\mathcal{G}, s)$ is the largest explored ball, the execution of `GlobalExpansion`$(l, \perp)$ permits the agent to traverse all the edges of $B_{f+l}(\mathcal{G}, s)$ that are outside of $B_f(\mathcal{G}, s)$ before coming back to node s. Under the same assumption, the execution of `GlobalExpansion`(l, m), when m is a positive integer, consists for the agent in acting as if m was $\perp$ but with the following extra requirement: as soon as more than m distinct edges outside of $B_f(\mathcal{G}, s)$ have been traversed during the execution of the function, the agent backtracks to node s and aborts this execution. If m is $\perp$ or at least large enough to avoid an aborted execution, the agent ends up exploring $B_{f+l}(\mathcal{G}, s)$ and the function returns true. Otherwise, the function returns false. It should be stressed that all of this is made while guaranteeing two properties. The first one is that the agent is always in $B_{f+2l-1}(\mathcal{G}, s)$ during the execution of `GlobalExpansion`(l, m). The second is that the cost of the execution of `GlobalExpansion`(l, m) is $\mathcal{O}(e(f + 2l - 1))$ (resp. $\mathcal{O}(\min\{e(f) + m, e(f + 2l - 1)\})$) when $m = \perp$ (resp. $m \neq \perp$). Both these properties will turn out to be crucial to ensure a proper design of the phases. Finally, even if by chance the agent could explore a larger ball, we will assume for the ease of our intuitive explanations that $B_{f+l}(\mathcal{G}, s)$ (resp. $B_f(\mathcal{G}, s)$) is the largest ball explored by the agent at the end of `GlobalExpansion`(l, m) in the case where the returned value is true (resp. false).

Let us consider a phase i of our algorithm and, in order not to burden the text with a lot of "unless the treasure is found", let us assume that the treasure will not be found by the end of it. Phase i is made of at most three successive attempts, each of them aiming at fulfilling at least one of the three conditions described earlier, with the help of our building block. In the first attempt, the agent executes `GlobalExpansion`$(1, \perp)$ from node s, the cost of which is $\mathcal{O}(e(f_i + 1))$. At the end of this execution, the agent is at node s and $B_{f_i+1}(\mathcal{G}, s)$ has been entirely explored by the agent. If $e(f_i + 1) \geq 2e(f_i)$ or $f_i \leq 1$, the first attempt is a success as Condition 1 or Condition 2 is verified, and the agent directly switches to phase $i + 1$. Otherwise, the attempt is a failure, but we can nonetheless observe that the cost incurred because of the attempt is just $\mathcal{O}(e(f_i))$ because $e(f_i + 1) < 2e(f_i)$.

If the first attempt has failed, the agent starts the second attempt of phase i that consists of an execution of function `GlobalExpansion`$(f_i - 1, e(f_i))$. The hope here is to expand by a distance of $f_i - 1$ the radius of the largest explored ball, which is $B_{f_i+1}(\mathcal{G}, s)$. According to the properties of `GlobalExpansion` and the fact that $e(f_i + 1) < 2e(f_i)$, the cost of this execution, and thus of the second attempt, is $\mathcal{O}(e(f_i))$. If `GlobalExpansion`$(f_i - 1, e(f_i))$ returns true, then at the end of the second attempt, the radius of the largest explored ball is $2f_i$. Hence, the cost of the first two attempts being equal to $\mathcal{O}(e(f_i))$ and f_i being at least 2, Condition 2 is satisfied and the agent starts phase $i + 1$ without making the third attempt.

On the other hand, if `GlobalExpansion`$(f_i - 1, e(f_i))$ returns false, it is a different story. Indeed, the largest explored ball is still only $B_{f_i+1}(\mathcal{G}, s)$ and we cannot ensure the fulfillment of Condition 1 or Condition 2. This is exactly where Condition 3 comes into the picture. In order to remedy the failures of the two previous attempts, the agent will start a third and last attempt which consists of a dichotomic process that is described in Algorithm 1. At the end of this process, Condition 3 is guaranteed to be satisfied.

Algorithm 1 Third attempt.

```
1 floor := f_i + 1; ceil := 3f_i − 2; l := ⌊(ceil − floor)/2⌋;
2 while l ≥ 1 and |B_floor(G, s)| < 2e(f_i) do
3     success := GlobalExpansion(l, e(f_i));
4     if success = true then
5         floor := floor + l; l := ⌊(ceil − floor)/2⌋;
6     else
7         ceil := floor + 2l − 1; l := ⌊l/2⌋;
```

In order to better understand why we can get such a guarantee, let us take a look at the properties that are satisfied during the third attempt and at its end.

Since the execution of `GlobalExpansion`$(f_i - 1, e(f_i))$ returned false, the agent has explored at least $e(f_i)$ distinct edges outside of ball $B_{f_i+1}(\mathcal{G}, s)$ during the second attempt. Moreover, during this execution, the agent was always in $B_{3f_i-2}(\mathcal{G}, s)$ according to the properties of `GlobalExpansion`. As a result, in view of line 1 of Algorithm 1, we necessarily have the following feature before the execution of the while loop of Algorithm 1: $B_{floor}(\mathcal{G}, s)$ is the largest explored ball and $e(ceil) \geq 2e(f_i)$. Actually, by carefully examining the pseudocode of the while loop and using again the properties of `GlobalExpansion`, it can be inductively proven that this feature is a loop invariant. Alone, this loop invariant is not enough to bring the sought guarantee, but as highlighted below, it is of precious help to do the job.

The number of iterations of the while loop can be shown to be $\mathcal{O}(\log f_i)$. Furthermore, at the beginning of each iteration, $B_{floor}(\mathcal{G}, s)$ has size smaller than $2e(f_i)$ in view of the condition of the while loop, and is the largest explored ball in view of the loop invariant. Hence, according to the cost property of `GlobalExpansion`, each execution of `GlobalExpansion`$(l, e(f_i))$ costs at most $\mathcal{O}(e(f_i))$ like the previous two attempts, which gives a total cost of $\mathcal{O}(e(f_i) \log f_i)$ of the whole phase. This corresponds exactly to the target value of Condition 3. Along with this, at the end of the while loop, the size of $B_{floor}(\mathcal{G}, s)$ is at least $2e(f_i)$, or $l < 1$. In the first case, we immediately have $e(floor + 1) \geq 2e(f_i)$, while in the second case it can be shown that $ceil \leq floor + 1$. This, combined with the fact that $e(ceil)$ is always at least $2e(f_i)$ (by the loop invariant) and the fact that $floor$ is always at

least $f_i + 1$, allows us to show the last missing piece of the puzzle, which is precisely this: when Algorithm 1 terminates, ball $B_{f_i+k}(\mathcal{G}, s)$ is entirely explored and $e(f_i + k + 1) \geq 2e(f_i)$ for some integer $k \geq 1$.

To conclude with the intuitive explanations, let us give, as promised, some more insight concerning the building block `GlobalExpansion`(l, m). At first glance, one might think that `GlobalExpansion` could be directly derived from the exploration algorithm `CFX`(v, r, α) of [11], which permits to explore a ball $B_r(\mathcal{G}, v)$ at a cost of $\mathcal{O}\left(\frac{|B_{(1+\alpha)r}(\mathcal{G},v)|}{\alpha}\right)$ for any given real $\alpha > 0$ (this corresponds to a cost of $\mathcal{O}\left(\frac{e((1+\alpha)r)}{\alpha}\right)$ when $v = s$) provided $\alpha r \geq 1$. Indeed, the task of `GlobalExpansion`(l, m) that consists in expanding the radius f of the largest explored ball by a distance l in the case where m is appropriately set, can be done with `CFX`$(s, f + l, \alpha)$. However, in this case we want the cost of this expansion to be $\mathcal{O}(e(f + 2l - 1))$, which is an important property of our strategy. This cannot be guaranteed using `CFX`$(s, f + l, \alpha)$ because, in order to get a cost depending on $e(f + 2l - 1)$, we would have to set α to a value lower than $\frac{l-1}{f+l}$, which cannot lead to a cost that is linear in $e(f + 2l - 1)$, as $\frac{l-1}{f+l}$ can be arbitrarily small. True, during the design we could have been "less demanding" about some of the properties of `GlobalExpansion`(l, m), but not significantly enough to permit the use of `CFX`$(s, f + l, \alpha)$ without spoiling the validity or the cost complexity of our strategy. Another solution that may come to mind would be to apply `CFX`(v, l, α) from each node v located on the boundary of the largest explored ball $B_f(\mathcal{G}, s)$. Visiting each node of the boundary can be done in $\mathcal{O}(e(f))$. Hence, this solution looks attractive because by setting α to $\frac{1}{2}$ or less (which overcomes the above problem of the arbitrarily small value) and provided the zones explored by the different executions of `CFX` do not overlap, we would get a cost that is linear in $e(f + 2l - 1)$. The bad news is that there may be overlaps. Of course, some overlaps can be easily avoided, especially those appearing within $B_f(\mathcal{G}, v)$, but some others cannot without running the risk of missing some nodes of $B_{f+l}(\mathcal{G}, s)$ that are outside of $B_f(\mathcal{G}, s)$. These "necessary overlaps" may be pernicious and may occur in a way that prevents us from guaranteeing a cost of $\mathcal{O}(e(f + 2l - 1))$.

So, what did we do? Although it was not possible to use `CFX` as a black box, we managed to tailor `GlobalExpansion` by adapting to our needs an elegant algorithmic technique used in `CFX`. Through a set of judiciously pruned trees spanning some already explored area, it allowed us to satisfy the desired cost property of `GlobalExpansion` by controlling and amortizing efficiently the number of times the same edges are traversed. The technique in question is detailed in the next section that presents the pseudocode of our treasure hunt algorithm.

4 Algorithm

Solving the treasure hunt problem in the unrestricted model can be done by executing Algorithm `TreasureHunt`(x) described below in Algorithm 2 and by interrupting it as soon as the treasure is found.

Algorithm 2 `TreasureHunt`(x).

```
1 v := the current node;
2 M := ({v}, ∅); /* M is a global variable                    */
3 repeat
4     Search(x);
```

The input parameter x is a positive real constant. It is a technical ingredient that will have an impact on the maximal distance at which the agent can be from node s. In our present context, parameter x does not really matter and it can be fixed as *any* positive real constant. In fact, it will show its full significance in Section 6 that is dedicated to the same problem in restricted models: there, we will reuse `TreasureHunt`(x) in a context where x will have to be carefully chosen. The variable $\mathcal{M}$ in line 2 of Algorithm 2 is a global variable that will always correspond to some explored subgraph of $\mathcal{G}$. For this reason, it will recurrently appear in most of the pseudocodes of the functions described thereafter.

As the reader can see, the execution of Algorithm `TreasureHunt`(x) essentially consists of a series of executions of procedure `Search`(x), whose pseudocode is described in Algorithm 3: these executions correspond to what we called "phases" in our intuitive explanations of Section 3. Procedure `Search`(x) should be seen as the organizer of our solution. At the beginning of each call to `Search`(x), $\mathcal{M}$ is some explored ball $B_f(\mathcal{G}, s)$ and the goal of the call is to make this ball grow while satisfying some conditions. These conditions, whose simplified version we gave at the beginning of Section 3, are formally described in Lemma 4.

Algorithm 3 `Search`(x).

```
1  v := the current node; m := |M|;
2  floor := ε_M(v); ceil := ⌊(1 + x) · floor⌋;
3  success := GlobalExpansion(1, ⊥);
4  floor := floor + 1; i := 0; l := ⌊(ceil − floor)/2⌋;
5  while l ≥ 1 and |M| < 2m and (i ≠ 1 or success = false) do
6      success := GlobalExpansion(l, m);
7      if success = true then
8          floor := floor + l; l := ⌊(ceil − floor)/2⌋;
9      else
10         ceil := floor + 2l − 1; l := ⌊l/2⌋;
11     M := B_floor(M, v);
12     i := i + 1;
```

Although there are some technical differences, we can discern, throughout the lines of Algorithm 3, the three attempts outlined in Section 3 that rely on function `GlobalExpansion`. Roughly speaking, line 3 of Algorithm 3 relates to the first attempt, the first iteration of the while loop of Algorithm 3 relates to the second attempt, and the other iterations relate to the third attempt.

The pseudocode of function `GlobalExpansion`(l, m) is given by Algorithm 4. It has primarily the same specifications as those given in Section 3 except that we did not implement the case where $m = \perp$ and $l \geq 2$ as it was not necessary for our purpose. Hence, the function precisely handles the case where $l = 1$ and $m = \perp$, and the case where $l \geq 1$ and $m \neq \perp$. The general scheme of the function is as follows. At the beginning, the agent knows a ball $B_f(\mathcal{G}, s)$ that is stored in variable $\mathcal{M}$ and the objective is to expand the radius of this ball by a distance l, without exploring more than m edges outside of $B_f(\mathcal{G}, s)$, if $m \neq \perp$. To do this, the agent visits the nodes $L[1], L[2], \ldots$ (stored in the array L) of the boundary of $B_f(\mathcal{G}, s)$ and executes from these nodes function `CDFS` (described in Algorithm 5 and whose name stands for Constrained DFS) or function `LocalExpansion` (described in Algorithm 6) depending on the initial values of l and m. Each of these executions, which starts and ends at the same node, locally contributes to the global expansion of the ball. In the case where

$m \neq \perp$, variable b of Algorithm 4 is updated with the return value of the two aforementioned functions, and corresponds at each stage to the remaining number of new edges the agent is authorized to traverse outside of $B_f(\mathcal{G}, s)$. If b becomes negative before the end of the while loop of Algorithm 4, the objective of expansion is simply not reached. Note that, in order to avoid that the moves from one node of the boundary of $B_f(\mathcal{G}, s)$ to the next get too costly, they are made according to a precise order that results from the definition of L given in line 2 of Algorithm 4.

Algorithm 4 `GlobalExpansion`(l, m).

```
1  v := the current node;
2  L := the array containing all the nodes of the boundary of M sorted in the order of
     the first visit through the DFS traversal of M from node v;
3  T := the tree produced by the DFS traversal of M from node v;
4  i := 1; b := m; T := ∅; /* T is a global variable                              */
5  while i ≤ |L| and (b ≥ 0 or b = ⊥) do
6      MoveTo(T, L[i]);
7      if l = 1 then
8          if b = ⊥ then
               /* We run CDFS(1, deg(L[i])) without using its return value.   */
9              (∗, ∗) := CDFS(1, deg(L[i]));
10         else
               /* We run CDFS(1, b) without using the second term of its
                  return value.                                                */
11             (b, ∗) := CDFS(1, b);
12     else
13         b := LocalExpansion(l, b);
14     i := i + 1;
15 MoveTo(T, v);
16 return the logical value of "b ≥ 0 or b = ⊥";
```

As one can see in lines 9 and 11 of Algorithm 4, the implementation of the case $l = 1$ in Algorithm 4 directly relies on function `CDFS`. We will see below that this function is also involved in the trickier case where $l \geq 2$ and $m \neq \perp$ through the calls to function `LocalExpansion`. Function `CDFS`(l, b) permits the agent to perform a depth-first search in the zone that does not belong to $\mathcal{M}$ when it starts executing it. During the execution of this function $\mathcal{M}$ grows, augmented with the edges that are traversed by the agent. The two input parameters $l \geq 1$ and $b \geq 0$ are integers that bring constraints to the execution of the depth-first search. The first indicates the limit depth of the search, while the second indicates an upper bound on the number of distinct edges the agent can traverse during the search: when this bound is violated, the agent stops the search and goes back to the node it occupied at the beginning of the search. The return value of `CDFS`(l, b) is a couple (n, T). The first term n is an integer such that $b - n$ is the number of distinct edges that have been traversed during the execution of `CDFS`(l, b). If the bound b has been respected then $n \geq 0$, otherwise $n = -1$. Concerning the second term T of the return value, it simply corresponds to the resulting DFS tree of the execution of `CDFS`(l, b). If $n \geq 0$ and v is the occupied node at the start of `CDFS`(l, b), then for every node u such that $d_T(u, v) < l$, u is complete in $\mathcal{M}$ at the end of `CDFS`(l, b). Note that in the particular case where $l = 1$ and $m = \perp$ in Algorithm 4,

the second argument of each call to `CDFS` is always set to the degree of the node from which the function is executed (cf. line 9 of Algorithm 4) in order to ensure that this node becomes complete in $\mathcal{M}$ at the end of the call.

Algorithm 5 `CDFS`(l, b).

```
1  v := the current node; T := ({v}, ∅); bound := b;
2  if l > 0 then
3      Mark node v;
4      while node v is incomplete in M and bound ≥ 0 do
5          pt_1 := the smallest free port at node v in M;
6          Take port pt_1;
7          w := the current node;
8          pt_2 := the port by which the agent has just entered node w;
9          if v < w then
10             K := ({v, w}, {(v, w, pt_1, pt_2)});
11         else
12             K := ({v, w}, {(w, v, pt_2, pt_1)});
13         M := M ⊔ K; bound := bound − 1;
14         if w is not marked then
15             (bound, T') := CDFS(l − 1, bound);
16             T := T ⊔ T' ⊔ K;
17         Take port pt_2;
18     Unmark node v;
19 return (bound, T);
```

The case where $l \geq 2$ and $m \neq \perp$ in Algorithm 4 relies on function `LocalExpansion`. It is exactly here that we make use of the algorithmic technique of [11] mentioned at the end of Section 3, which is based on a set of adequately pruned trees. In our solution, this set corresponds to the variable $\mathcal{T}$. It is a global variable like $\mathcal{M}$ and it is initialized to $\emptyset$ at the beginning of each call to `GlobalExpansion` (cf. line 4 of Algorithm 4). Let us consider the ith call LE_i to `LocalExpansion`(l, b) made from node $L[i]$ during an execution of `GlobalExpansion`(l, m). At the end of LE_i, the return value of `LocalExpansion`(l, b) is an integer $n \geq -1$ such that $b - n$ is the number of distinct edges that have been traversed during LE_i and that were not in $\mathcal{M}$ at the start of LE_i. Besides, in the case where $n \geq 0$, at the end of LE_i we can guarantee that for each incomplete node u of $\mathcal{M}$, $d_{\mathcal{M}}(L[i], u) > l$ or u is one of the last $|L| - i$ nodes of L (i.e., a node of L from which the agent has not yet executed `LocalExpansion`(l, b)).

To see the algorithmic technique in question at work, let us focus on an iteration I of the first while loop of Algorithm 6 occuring in LE_i. This iteration starts at node $L[i]$ and we can show that at the beginning of I, we necessarily have the following properties.

- $\mathcal{T}$ is a set of node disjoint trees that are all subgraphs of $\mathcal{M}$.
- For each tree Tr of $\mathcal{T}$, $|Tr| \geq \lfloor \frac{l}{8} \rfloor$ if Tr contains a node different from $L[i]$.
- Every incomplete node of $\mathcal{M}$ belongs to a tree of $\mathcal{T}$ or is one of the last $|L| - i$ nodes of L.

Algorithm 6 `LocalExpansion`(l, b).

1 $bound := b$; $v :=$ the current node;
2 **if** *v is incomplete in $\mathcal{M}$* **and** *no tree of $\mathcal{T}$ contains node v* **then**
3 $\mathcal{T} := \mathcal{T} \cup \{(\{v\}, \emptyset)\}$;
4 **while** $\texttt{IncompleteNodes}(v, \mathcal{M}, l) \cap \texttt{Nodes}(\mathcal{T}) \neq \emptyset$ **and** $bound \geq 0$ **do**
5 $u :=$ the node with the smallest label in $\texttt{IncompleteNodes}(v, \mathcal{M}, l) \cap \texttt{Nodes}(\mathcal{T})$;
6 $\texttt{MoveTo}(\mathcal{M}, u)$;
7 $\texttt{Prune}(l)$;
8 $bound := \texttt{Explore}(l, bound)$;
9 Remove from $\mathcal{T}$ every tree for which all the nodes are complete in $\mathcal{M}$;
10 **while** *there are two trees T and T' in $\mathcal{T}$ having a common node* **do**
11 $T'' :=$ the spanning tree produced by the BFS traversal of $T \sqcup T'$ from the node having the smallest label in $T \sqcup T'$;
12 $\mathcal{T} := (\mathcal{T} \setminus \{T, T'\}) \cup \{T''\}$;
13 Execute in the reverse order all the edge traversals that have been made since the beginning of the current iteration of the while loop;
14 **return** *bound*;

Let us examine what happens during iteration I. At the beginning of I, the agent follows a path of length at most l from node $L[i]$ to a node u that is incomplete in $\mathcal{M}$ (cf. line 5 of Algorithm 6). By the first and third properties and the condition at line 4 of Algorithm 6, node u belongs to a unique tree $T_u \subseteq \mathcal{G}$ of $\mathcal{T}$. Once the agent occupies node u, the tree T_u is pruned via the procedure $\texttt{Prune}(l)$ at line 7 of Algorithm 6. The pseudocode of procedure `Prune` is detailed in Algorithm 7.

Algorithm 7 `Prune`(l).

1 $v :=$ the current node;
2 $T_v :=$ the tree of $\mathcal{T}$ containing node v;
3 $\mathcal{T} := \mathcal{T} \setminus \{T_v\}$;
4 Root T_v at node v;
5 **foreach** *node u of T_v such that $d_{T_v}(u, v) = \max\{1, \lfloor \frac{l}{4} \rfloor\}$* **do**
6 $T_u :=$ the subtree of T_v rooted at u;
7 **if** $\epsilon_{T_u}(u) \geq \lfloor \frac{l}{4} \rfloor - 1$ **then**
8 $\mathcal{T} := \mathcal{T} \cup \{T_u\}$;
9 Remove from T_v all nodes that belong to T_u and all edges that are incident to a node of T_u;
10 $\mathcal{T} := \mathcal{T} \cup \{T_v\}$;

In the context of iteration I, the pruning operation will transform T_u into a tree T'_u such that $\epsilon_{T'_u}(u) \leq \lfloor \frac{l}{2} \rfloor - 1$, while preserving the three properties listed above: this offers two important advantages to which we will return at the end of this section. Once the pruning is done, the agent applies function $\texttt{Explore}(l, bound)$, whose pseudocode is given in Algorithm 8.

Algorithm 8 `Explore`(l, b).

```
1 bound := b; i := 1; v := the current node;
2 T := the tree of 𝒯 containing node v;
3 V := array containing all the nodes of T sorted in the order of the first visit through
    the DFS traversal of T from node v;
4 while i ≤ |V| and bound ≥ 0 do
5     MoveTo(T, V[i]);
6     if node V[i] is incomplete in ℳ then
7         (bound, T') := CDFS(⌊l/2⌋, bound);
8         𝒯 := 𝒯 ∪ {T'};
9 return bound;
```

In the pseudocodes of `LocalExpansion` and of `Explore`, variable *bound* corresponds at any stage to the number of remaining edges the agent is authorized to traverse outside of $B_f(\mathcal{G}, s)$. In the context of iteration I, function `Explore`$(l, bound)$ permits the agent to explore tree T'_u and to execute function `CDFS`$(\lfloor \frac{l}{2} \rfloor, bound)$ from the nodes of T'_u that are incomplete in $\mathcal{M}$, as long as variable *bound* remains non-negative. These executions of `CDFS` occuring during the exploration of T'_u create in turn trees that are added to $\mathcal{T}$ (cf. line 8 of Algorithm 8) and that contain the new incomplete nodes of $\mathcal{M}$. If the return value of function `Explore`$(l, bound)$ is non-negative, we can show that all the nodes of T'_u have become complete in $\mathcal{M}$. Under the same condition, we will also guarantee that each tree Tr, which has been added to $\mathcal{T}$ during the execution of function `Explore`, contains an incomplete node only if $|Tr| \geq \lfloor \frac{l}{8} \rfloor$. Both these guarantees combined with lines 9 to 12 of Algorithm 6 will allow us to show that our three properties will be satisfied for the next iteration I', if any, even if it occurs in another call to `LocalExpansion` (in the same execution of `GlobalExpansion`(l, m)). In particular, this is made possible by the fact that $\mathcal{T}$ is never reset between the calls to `LocalExpansion` during the execution of the while loop of Algorithm 4.

To fully appreciate the process accomplished during I, we need to come back to the two aforementioned advantages that are brought by the pruning operation. The first advantage concerns the height of T'_u. The fact that $\epsilon_{T'_u}(u) \leq \lfloor \frac{l}{2} \rfloor - 1$ is a key element to control the maximal distance between the agent and node s. Without this, the agent could go too far from node s and we would not be able to guarantee that the agent explores only edges of $B_{f+2l-1}(\mathcal{G}, s)$ during the execution of `GlobalExpansion`(l, m) (which is a crucial property as pointed out in Section 3). The second advantage concerns the size of T'_u. The pruning operation preserves the second property, and thus (1) T'_u corresponds to a tree containing only node $L[i]$ or (2) $|T'_u| \geq \lfloor \frac{l}{8} \rfloor$. This implies that the cost resulting from the moves of line 6 of Algorithm 6 and line 5 of Algorithm 8 is linear in the size of T'_u. Besides, if *bound* is still non-negative at the end of `Explore`$(l, bound)$, all the nodes of T'_u have become complete (it is in particular the case for node u) and the tree is removed from $\mathcal{T}$ through line 9 of Algorithm 6. After this removal, no edge of T'_u will be an edge of another tree of $\mathcal{T}$ till the end of the execution of `GlobalExpansion`(l, m). As a result, if the return value of `Explore`$(l, bound)$ is non-negative in I, we can associate the moves of line 6 of Algorithm 6 and line 5 of Algorithm 8 to at least one node that becomes complete during I and to at least $\lfloor \frac{l}{8} \rfloor$ edges that will no longer be edges of any tree of $\mathcal{T}$ till the end of the execution of `GlobalExpansion`(l, m). In our analysis, this association will enable us to amortize efficiently the number of times the agent retraverses the edges that have been already explored during any previous iteration of the considered while loop. This will be a decisive argument to show the cost of $\mathcal{O}(e(f) + m)$ for the execution of `GlobalExpansion`(l, m) in the case where $l \geq 2$ and $m \neq \perp$.

5 Correctness and complexity analysis

In this section, we give a sketch of the proof of correctness and of complexity of Algorithm `TreasureHunt`(x) in the unrestricted model. `TreasureHunt`(x) is an exploration algorithm that can be executed also if there is no treasure in $\mathcal{G}$. We first establish several exploration properties of our algorithm or of its components assuming that there is no treasure in $\mathcal{G}$. In fact, this assumption concerns all the lemmas (and only them) of this section. After the series of lemmas, we show the main result of this section, namely Theorem 6, which specifies that our algorithm allows to find the treasure at a cost quasi-linear in $e(d)$.

Throughout the proof of correctness, we will often have to consider the value of the global variable $\mathcal{M}$ before or after some executions. To this end, we introduce the following convention: given an execution $\mathcal{E}$ of Algorithm `TreasureHunt`(x) or some part of it, we denote by $M_1(\mathcal{E})$ the value of $\mathcal{M}$ at the beginning of $\mathcal{E}$ and by $M_2(\mathcal{E})$ the value of $\mathcal{M}$ at the end of $\mathcal{E}$.

We start by giving two lemmas concerning the function `CDFS`(l, b). They list some properties that are useful to prove Lemma 3. They are direct consequences of Algorithm 5 and can be easily proved by induction on l.

▶ **Lemma 1.** *Consider an execution $\mathcal{E}$ of function* `CDFS`(l, b) *from a node u of $\mathcal{G}$ where $l \geq 1$ and $b \geq 0$ are integers. Assume that $M_1(\mathcal{E}) \subseteq \mathcal{G}$. Execution $\mathcal{E}$ terminates at node u, and the agent always knows a path of length at most l from node u to its current node during $\mathcal{E}$.*

▶ **Lemma 2.** *Consider an execution $\mathcal{E}$ of function* `CDFS`(l, b) *from a node u of $\mathcal{G}$ where $l \geq 1$ and $b \geq 0$ are integers. Assume that $M_1(\mathcal{E}) \subseteq \mathcal{G}$. Function* `CDFS`$(l, b)$ *returns a couple (i, Tr) such that the following properties are satisfied.*

- *Let G be the subgraph of $\mathcal{G}$ that has been explored during $\mathcal{E}$. $G \subseteq B_l(\mathcal{G}, u)$, $|M_1(\mathcal{E}) \sqcap G| = 0$, $M_1(\mathcal{E}) \sqcup G = M_2(\mathcal{E})$, Tr is a spanning tree of G and $i = b - |G| \geq -1$.*
- *The cost of $\mathcal{E}$ is $2|G|$ and $\epsilon_{Tr}(u) \leq l$.*
- *If $i \geq 0$ then for every node v of Tr such that $d_{Tr}(u, v) < l$, v is complete in $M_2(\mathcal{E})$. If $i = -1$, then there exists a node v of Tr such that $d_{Tr}(u, v) \leq l - 1$ and v is incomplete in $M_2(\mathcal{E})$.*

The following lemma establishes the properties of function `GlobalExpansion`(l, m). It is prerequisite to prove Lemma 4 that concerns procedure `Search`(x).

▶ **Lemma 3.** *Consider an execution $\mathcal{E}$ of function* `GlobalExpansion`(l, m) *from the source node s, where l is a positive integer and m is either a positive integer or $\perp$. Assume that $M_1(\mathcal{E}) = B_f(\mathcal{G}, s)$ for some integer $f \geq 0$.*

- *if $m \neq \perp$, or $m = \perp$ and $l = 1$, then $\mathcal{E}$ terminates at node s and during $\mathcal{E}$ the agent always knows a path in $\mathcal{G}$ of length at most $f + 2l - 1$ from node s to its current node.*
- *If $m = \perp$ and $l = 1$ then the cost of $\mathcal{E}$ is $\mathcal{O}(e(f + 1))$ and $B_{f+1}(\mathcal{G}, s) = M_2(\mathcal{E})$.*
- *If $m \neq \perp$ and function* `GlobalExpansion`(l, m) *returns true (resp. false) then $B_{f+l}(\mathcal{G}, s) \subseteq M_2(\mathcal{E})$ (resp. $B_f(\mathcal{G}, s) \subseteq M_2(\mathcal{E})$ and $e(f + 2l - 1) > e(f) + m$) and the cost of $\mathcal{E}$ is $\mathcal{O}(e(f) + m)$.*

Below is the lemma establishing the properties of procedure `Search`(x).

▶ **Lemma 4.** *Consider an execution $\mathcal{E}$ of procedure* `Search`(x) *from the source node s, for any real constant $x > 0$. Assume that $M_1(\mathcal{E}) = B_f(\mathcal{G}, s)$ for some integer $f \geq 0$.*

- *The execution terminates at node s and during the execution the agent always knows a path in $\mathcal{G}$ of length at most $\max\{f + 1, \lfloor (1 + x)f \rfloor\}$ from node s to its current node.*
- *There exists an integer $f' > f$ such that $M_2(\mathcal{E}) = B_{f'}(\mathcal{G}, s)$ and at least one of the following properties holds:*

1. *The cost of* $\mathcal{E}$ *is* $\mathcal{O}(e(f+1))$ *and* $xf < 3$.
2. *The cost of* $\mathcal{E}$ *is* $\mathcal{O}(e(f))$ *and* $f' > (1+\frac{x}{3})f$.
3. *The cost of* $\mathcal{E}$ *is* $\mathcal{O}(e(f)\log(f+2))$ *and* $e(f'+1) \geq 2e(f)$.
4. *The cost of* $\mathcal{E}$ *is* $\mathcal{O}(e(f+1))$ *and* $e(f+1) \geq 2e(f)$.

If we put aside the initial assignments of lines 1 and 2 in Algorithm 2, the execution of procedure `TreasureHunt`(x) from the source node s in $\mathcal{G}$ can be viewed as a sequence of consecutive executions of procedure `Search`(x): the i*th* execution of `Search`(x) in this sequence will be denoted by S_i.

The following lemma is a small technical observation concerning the execution of `TreasureHunt`(x) from the source node s. Since, at the beginning of this execution, variable $\mathcal{M}$ is equal to $B_0(\mathcal{G}, s)$, the lemma can be easily proved by induction on i using Lemma 4.

▶ **Lemma 5.** *Consider an execution of procedure* `TreasureHunt`(x) *from the source node* s*, for any real constant* $x > 0$*. For every integer* $i \geq 1$*,* S_i *starts and ends at node* s*, and there are two integers* $f_{i+1} > f_i \geq i-1$ *such that* $M_1(S_i) = B_{f_i}(\mathcal{G}, s)$ *and* $M_2(S_i) = B_{f_{i+1}}(\mathcal{G}, s)$.

Using Lemmas 4 and 5, we can prove the main result of this section that is stated in the following theorem.

▶ **Theorem 6.** *Consider a graph* $\mathcal{G}$ *of unknown radius* r *in which a treasure is located at an unknown distance at most* $1 < d \leq r$ *from the starting node* s *of an agent. For any real constant* $x > 0$*, procedure* `TreasureHunt`(x) *allows the agent to find the treasure at cost* $\mathcal{O}(e(d)\log d)$.

6 Treasure hunt with restrictions

Theorem 6 holds for the task of treasure hunt without any restrictions on the moves of the agent, for all locally finite graphs, both finite and infinite. In this section we show how to modify our treasure hunt algorithm to make it work under the fuel-restricted and the rope-restricted models for finite graphs.

Strictly speaking, the fuel-restricted model was defined in [3] assuming that both the constant $\alpha > 0$ and the radius r were known to the agent. On the other hand, the rope-restricted model was defined in [11] for any known constant $\alpha > 0$ and for unknown radius r. We will show that, for each of these restrictive models and for any known constant $\alpha > 0$, we can design a treasure hunt algorithm with the promised efficiency even when r is unknown. To this end, we need to modify the restriction of the fuel-restricted model from [3], avoiding to reveal r to the agent by showing it the size of the tank. We fix a positive constant α, known to the agent, and we proceed as follows. For the restricted tank case from [3], we assume that at any visit of s the agent can put as much fuel in the tank as it wants, but we show that if the (unknown) radius of the graph is r then the tank is never filled to more than $B = 2(1+\alpha)r$. The formalization of the rope-restricted model corresponds to its definition in [11]. Recall that the agent is attached at s by an infinitely extendible rope that it unwinds by a length 1 with every forward edge traversal and rewinds by a length of 1 with every backward edge traversal. Whenever the agent completely backtracks to s, the unwinded segment of the rope is of length 0. We show that if the (unknown) radius of the graph is r then the initial segment of the rope unwinded by the agent executing our algorithm will never be longer than $L = (1+\alpha)r$.

▶ **Theorem 7.** *Consider a graph $\mathcal{G}$ of unknown radius r in which a treasure is located at an unknown distance at most $1 < d \leq r$ from the starting node s of the agent. For any positive constant α, procedure* `TreasureHunt`$(\frac{\alpha}{2})$ *can be transformed into a procedure allowing the agent to find the treasure at cost $\mathcal{O}(e(d)\log d)$ in the rope-restricted model (resp. fuel-restricted model) without ever using a segment of the rope longer than $(1+\alpha)r$ (resp. without filling the tank to more than $2(1+\alpha)r$ at any visit of s).*

Proof. The execution of procedure `TreasureHunt`$(\frac{\alpha}{2})$ from node s corresponds to a sequence $S = (S_1, S_2, \ldots, S_{|S|})$ of executions of `Search`$(\frac{\alpha}{2})$, in which the $|S|$th execution of `Search`$(\frac{\alpha}{2})$ is interrupted prematurely because of the discovery of the treasure.

We denote by G_0 the graph consisting only of node s, and for every $1 \leq i \leq |S|$, we denote by G_i the subgraph of $\mathcal{G}$ that has been explored from the beginning of S_1 to the end of S_i. For every $1 \leq i \leq |S|$, the cost of S_i will be denoted by c_i.

According to Lemma 5, for every $1 \leq i \leq |S|$, S_i starts and ends at node s (except $S_{|S|}$ that ends at the node containing the treasure), there is an integer $f_i \geq 0$ such that $M_1(S_i) = B_{f_i}(\mathcal{G}, s)$ and if $i < |S|$, $M_2(S_i) = M_1(S_{i+1})$. Moreover, the value of $\mathcal{M}$ is always a subgraph of $\mathcal{G}$ whose nodes and edges have been all explored by the agent, and thus, for every $1 \leq i \leq |S|$, $B_{f_i}(\mathcal{G}, s)$ is a subgraph of G_{i-1}, f_i is unique and $f_i < d$ (or otherwise the treasure would have been found before the start of S_i which leads to a contradiction with the existence of this execution). Hence, from the fact that $d \leq r$, we get the following claim.

▷ Claim 8. For every $1 \leq i \leq |S|$, $\max\{f_i + 1, \lfloor(1+\alpha)f_i\rfloor\} \leq (1+\alpha)r$

First, we describe a new algorithm $\mathcal{A}$ that permits to find the treasure, in the model without constraints, with asymptotically the same cost as that of `TreasureHunt`$(\frac{\alpha}{2})$. This new algorithm consists in executing `TreasureHunt`$(\frac{\alpha}{2})$ with some changes in order to guarantee an extra property that will be important for our purpose. More precisely, an execution of $\mathcal{A}$ from node s is a sequence of executions $(S'_1, S'_2, \ldots, S'_{|S|})$ in which each S'_i has cost $\mathcal{O}(c_i)$ and corresponds to an emulation of execution S_i. In particular, for every $1 \leq i \leq |S|$, S'_i starts and ends at node s (except $S'_{|S|}$ that ends at the node containing the treasure), $M_1(S'_i) = M_1(S_i) = B_{f_i}(\mathcal{G}, s)$, and at the end of S'_i, G_i has been entirely explored. Obviously, all of this would not be interesting without the additional crucial property brought by S'_i that will be called the *frequent return property* and that is the following. Let Sk be the stack initially empty in which we push (resp. pop) the last traversed edge if it corresponds to a forward (resp. backward) edge traversal. During S'_i, the size of Sk is 0 at least once during any block of $2\max\{f_i + 1, \lfloor(1+\alpha)f_i\rfloor\}$ consecutive edge traversals, and is never greater than $\max\{f_i + 1, \lfloor(1+\alpha)f_i\rfloor\}$. Moreover, at the beginning of S'_i, the size of Sk is 0, and if $i < |S|$, it is also 0 at the end of S'_i.

Note that Algorithm $\mathcal{A}$ is a solution with the desired cost in the rope-restricted model, that will never use a segment of the rope longer than $(1+\alpha)r$, as for all $1 \leq i \leq |S|$, we have $\max\{f_i+1, \lfloor(1+\alpha)f_i\rfloor\} \leq (1+\alpha)r$ according to Claim 8. By requiring the agent, each time the size of Sk is 0 in S'_i, to refuel its tank up to the limit of $2 \cdot \max\{f_i + 1, \lfloor(1+\alpha)f_i\rfloor\}$ (when the size of Sk is 0, the agent is at node s), we also get our objective with algorithm $\mathcal{A}$ in the fuel-restricted model, as the agent never runs out of fuel and $2\cdot\max\{f_i+1, \lfloor(1+\alpha)f_i\rfloor\} \leq 2(1+\alpha)r$.

Let us describe how we can construct our emulations while ensuring the features mentioned above. Consider the emulation S'_i of S_i. Assume that at the beginning of S'_i, G_{i-1} has been entirely explored, the size of Sk is 0 and $M_1(S'_i) = M_1(S_i) = B_{f_i}(\mathcal{G}, s)$. These assumptions are trivially satisfied if $i = 1$. We will show below that, at the end of S'_i, G_i is entirely explored and if $i < |S|$ the size of Sk is 0. We will also show that if $i < |S|$ then $M_1(S'_{i+1}) = B_{f_{i+1}}(\mathcal{G}, s)$. We consider two cases.

The first case is when $\alpha f_i \geq 2$. We assume for simplicity that the number of edge traversals in S_i is a positive multiple of $\lfloor \frac{\alpha f_i}{2} \rfloor$. As we will explain in detail, in this case the agent executes S_i but interrupts it after each block of $\lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals, except the last one, to make a "return trip" to node s before resuming S_i from where it was interrupted. The goal of these return trips is to satisfy the frequent return property. Once the agent has executed all instructions of S_i, it is either at the node containing the treasure or at node s. In the first case, we know that $i = |S|$ and S'_i is simply over. In the second case $i < |S|$, but we do not have the guarantee that the size of Sk is 0. Hence, if the agent occupies node s once it has executed all instructions of S_i, it then finishes S'_i with what we call a *close period* in which it executes in the reverse order some of the last edge traversals so that the size of Sk becomes 0 at the end of S'_i.

Denote by v_k the node in which the kth interruption occurs, and by P_k the path of length at most $\lfloor (1 + \frac{\alpha}{2}) f_i \rfloor$ from node s to v_k that is known by the agent when the interruption occurs. Note that P_k necessarily exists in view of Lemma 4, of the initial assumptions concerning S'_i and of the fact that no edge traversal of S_i has been skipped before the kth interruption. Also note that if there are several paths that can play the role of P_k, we simply choose the lexicographically smallest shortest path among them.

Each interruption is composed of two parts. In the first interruption, the first part consists in backtracking to node s by executing in the reverse order the last $\lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals. The second part consists in going back to node v_1 using path P_1 to resume S_i. For the kth interruption with $k > 1$, the first part consists in backtracking to node s by executing in the reverse order the last $|P_{k-1}| + \lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals, and the second part consists in going back to node v_k using path P_k to resume S_i. Finally, the close period simply consists in backtracking to node s by executing in the reverse order the last $\lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals if S_i is made of only one block of $\lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals. Otherwise, it consists in backtracking to node s by executing in the reverse order the last $|P_{k^*-1}| + \lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals where $k^* = \frac{c_i}{\lfloor \frac{\alpha f_i}{2} \rfloor}$ is the number of blocks of $\lfloor \frac{\alpha f_i}{2} \rfloor$ edge traversals in S_i.

It follows by induction on the number of interruptions that the size of Sk is 0 at the end of the first part of each interruption. Using this, the fact that Sk is empty at the beginning of S'_i and the fact that for every $1 < k \leq \frac{c_i}{\lfloor \frac{\alpha f_i}{2} \rfloor}$, $|P_{k-1}| + \lfloor \frac{\alpha f_i}{2} \rfloor \leq \lfloor (1 + \alpha) f_i \rfloor$, it follows that the frequent return property is satisfied during S'_i.

Moreover, it follows from the above explanation that at the end of S'_i, G_i is entirely explored and the agent is at the node containing the treasure, if $i = |S|$. If $i < |S|$, it also follows that the size of Sk is 0 at the beginning of the next emulation S'_{i+1}, and $M_1(S'_{i+1}) = M_1(S_{i+1}) = B_{f_{i+1}}(\mathcal{G}, s)$ because $M_2(S'_i) = M_2(S_i) = M_1(S_{i+1})$. Finally, concerning the cost of S'_i observe that the number of interruptions is $\frac{c_i}{\lfloor \frac{\alpha f_i}{2} \rfloor} - 1$ and during each interruption as well as during the close period the agent makes at most $2\lfloor (1+\alpha) f_i \rfloor$ edge traversals. The cost of S'_i is then upper bounded by $c_i + \frac{c_i}{\lfloor \frac{\alpha f_i}{2} \rfloor} 2 \lfloor (1+\alpha) f_i \rfloor \leq (1 + \frac{2(1+\alpha) f_i}{\lfloor \frac{\alpha f_i}{2} \rfloor}) c_i$. If $2 \leq \alpha f_i < 4$, then $\frac{2}{\alpha} \leq f_i < \frac{4}{\alpha}$, which implies that the cost is at most $(1 + \frac{8(1+\alpha)}{\alpha}) c_i$. Otherwise, $\alpha f_i \geq 4$ and the cost is then upper bounded by $(1 + \frac{2(1+\alpha) f_i}{\frac{\alpha f_i}{2} - 1}) c_i \leq (1 + \frac{2(1+\alpha)}{\frac{\alpha}{2} - \frac{1}{f_i}}) c_i$ which is also at most $(1 + \frac{8(1+\alpha)}{\alpha}) c_i$, as $\frac{1}{f_i} \leq \frac{\alpha}{4}$. Hence, the cost of S'_i is $\mathcal{O}(c_i)$ as α is a constant, which concludes the first case.

The second case is when $\alpha f_i < 2$. Here, we could not apply the same strategy as that of the first case because we have $\lfloor \frac{\alpha f_i}{2} \rfloor = 0$. Consequently, we adopt a slightly different strategy in which the agent executes S_i but interrupts it before each of its edge traversals. As explained in detail below, the kth interruption either consists of a return trip to node s before resuming S_i and making the kth edge traversal of S_i, or it consists in going to the node the agent should occupy at the end of the kth edge traversal of S_i but without

taking the corresponding edge: the agent then resumes S_i as if it had just performed the kth edge traversal of S_i (essentially it just makes some computations before interrupting again S_i for the next edge traversal, if any). We will show that the latter situation will occur only when the "skipped edge" has already been traversed before by the agent. Once S_i has been entirely processed, S'_i is simply over if the agent is located at the node containing the treasure. Otherwise, the agent is at node s and $i < |S|$. In this case, it executes (similarly as in the previous case) a close period in order to guarantee that the size of Sk is 0 at the end of S'_i.

Let us first focus on the interruptions. We denote by $(u_1, u_2, u_3, \ldots, u_{c_i+1})$ the sequence (with repetitions), in the chronological order, of the nodes that are visited during S_i, and by $(e_1, e_2, e_3, \ldots, e_{c_i})$ the sequence (with repetitions), in the chronological order, of the edges that are traversed during S_i. Consider the kth interruption occuring at node u_k just before the kth edge traversal of S_i and assume that at the beginning of this interruption, the property $H(k)$, consisting of the following three conditions, is satisfied:

- The agent has made $D_k \leq f_i + 1$ edge traversals since the last time when Sk was empty (this could be the current time).
- The sequence of edges $(e_1, e_2, \ldots, e_{k-1})$ has been previously explored by the agent.
- The size of Sk has been 0 at least once during any previous block of $2(f_i + 1)$ consecutive edge traversals and has never been greater than $f_i + 1$.

Note that at the beginning of the first interruption, property $H(1)$ immediately holds. We will show below that property $H(k + 1)$ is satisfied at the beginning of the $(k + 1)$th interruption, if any.

In the kth interruption, the agent first checks whether it knows a path of length at most f_i from node s to node u_k. If this is the case, the agent executes in the reverse order the last D_k edge traversals, at the end of which it is at node s and Sk is empty. Then, the agent comes back to u_k using the known path of length at most f_i from node s to node u_k (as when $\alpha f_i \geq 2$, if there are several such paths, the agent chooses the lexicographically smallest shortest among them). Once this is done, the interruption is over: the agent resumes S_i and makes the kth edge traversal to reach node u_{k+1}. We can easily show that at the end of this edge traversal, and thus at the beginning of the next interruption if any, property $H(k + 1)$ is satisfied.

So, assume that at the beginning of the kth interruption, the agent does not know a path of length at most f_i from node s to node u_k. In view of the fact that $D_k \leq f_i + 1$, the shortest path from node s to node u_k that is known by the agent has actually length exactly $f_i + 1$. Before explaining what the agent does, let us give some properties that necessarily hold in this situation. We have the following claim, whose proof is omitted.

▷ Claim 9. e_k belongs to G_{i-1} or to the sequence $(e_1, e_2, \ldots, e_{k-1})$.

From the above claim, it follows that at the beginning of the kth interruption the agent has already traversed edge e_k before, and already knows which edge of G_{i-1} or of $(e_1, e_2, \ldots, e_{k-1})$ corresponds to it. Thus, at the beginning of the kth interruption, the agent can already determine a path of length at most $f_i + 1$ from node s to node u_{k+1} because in view of Lemma 4 it must know such a path when reaching node u_{k+1} and because the traversal of e_k does not bring extra topological information on $\mathcal{G}$.

Now we are are able to formulate what the agent does, when it has noticed that it does not know a path of length at most f_i from node s to node u_k. It executes in the reverse order the last D_k edge traversals, at the end of which it is at node s and Sk is empty. Then, instead of coming back to u_k, it goes directly to node u_{k+1} using the known path (highlighted

in the previous paragraph) of length at most $f_i + 1$ from node s to node u_{k+1}. Once this is done, the interruption is over: the agent resumes S_i and acts as if it had just traversed edge e_k (as previously mentioned, it just performs some computations before interrupting again S_i for the next edge traversal, if any). It follows that at the end of the interruption, and thus at the beginning of the following one if any, $H(k+1)$ is satisfied. We have shown by induction on k that, at the beginning of the kth interruption, for any $k \geq 1$, the property $H(k)$ is satisfied. This closes the description of the interruptions.

It remains to deal with the close period. At the beginning of it, property $H(c_i + 1)$ is satisfied, which implies that the agent has performed $D_{c_i+1} \leq f_i + 1$ edge traversals since the last time when Sk was empty. Hence, during the close period, the agent simply executes in the reverse order the last D_{c_i+1} edge traversals, at the end of which Sk is empty. In view of this, of the fact that Sk is empty at the beginning of S'_i, and of property $H(c_i + 1)$, the frequent return property is satisfied during S'_i.

It follows from the above explanation that at the end of S'_i, G_i is entirely explored and the agent is at the node containing the treasure if $i = |S|$. If $i < |S|$, it also follows that the size of Sk is 0 at the beginning of the next emulation S'_{i+1}, and $M_1(S'_{i+1}) = M_1(S_{i+1}) = B_{f_{i+1}}(\mathcal{G}, s)$ because $M_2(S'_i) = M_2(S_i) = M_1(S_{i+1})$. Finally, concerning the cost of S'_i, observe that the number of interruptions is c_i and during the close period as well as during each interruption the agent makes at most $2(f_i + 1)$ edge traversals. The cost of S'_i is then upper bounded by $2(f_i + 1)c_i + 2f_i + 2$ which is at most $2(\frac{2}{\alpha} + 1)c_i + \frac{4}{\alpha} + 2$, as $f_i < \frac{2}{\alpha}$ in the currently analysed case. Hence, the cost of S'_i is $\mathcal{O}(c_i)$. This concludes the second case and thus concludes the proof of the theorem. ◀

Abstract

Promise Constraint Satisfaction Problems (PCSPs) are a generalization of Constraint Satisfaction Problems (CSPs) where each predicate has a strong and a weak form and given a CSP instance, the objective is to distinguish if the strong form can be satisfied vs. even the weak form cannot be satisfied. Since their formal introduction by Austrin, Guruswami, and Håstad [1], there has been a flurry of works on PCSPs, including recent breakthroughs in approximate graph coloring [4, 24, 35]. The key tool in studying PCSPs is the algebraic framework developed in the context of CSPs where the closure properties of the satisfying solutions known as *polymorphisms* are analyzed.

The polymorphisms of PCSPs are significantly richer than CSPs – even in the Boolean case, we still do not know if there exists a dichotomy result for PCSPs analogous to Schaefer's dichotomy result [32] for CSPs. In this paper, we study a special case of Boolean PCSPs, namely Boolean *Ordered* PCSPs where the Boolean PCSPs have the predicate $x \leq y$. In the algebraic framework, this is the special case of Boolean PCSPs when the polymorphisms are *monotone functions*. We prove that Boolean Ordered PCSPs exhibit a computational dichotomy assuming the Rich 2-to-1 Conjecture [9] which is a perfect completeness surrogate of the Unique Games Conjecture.

In particular, assuming the Rich 2-to-1 Conjecture, we prove that a Boolean Ordered PCSP can be solved in polynomial time if for every $\epsilon > 0$, it has polymorphisms where each coordinate has *Shapley value* at most ϵ, else it is NP-hard. The algorithmic part of our dichotomy result is based on a structural lemma showing that Boolean monotone functions with each coordinate having low Shapley value have arbitrarily large threshold functions as minors. The hardness part proceeds by showing that the Shapley value is consistent under a uniformly random 2-to-1 minor. As a structural result of independent interest, we construct an example to show that the Shapley value can be inconsistent under an adversarial 2-to-1 minor.

1 Introduction

Constraint satisfaction problems (CSP) have played a very influential role in the theory of computation, providing an excellent testbed for the development of both algorithmic and hardness techniques, which then extend to more general settings. A CSP over domain D is specified by a finite collection $\mathbb{A}$ of predicates over D, and is denoted as CSP($\mathbb{A}$). Given an input containing n variables with constraints on the variables using these predicates, the objective is to identify if we can assign values from D to the variables that satisfies all the constraints. Examples of CSPs include classical problems such as 3-SAT and 3-Coloring of graphs.

When the domain is Boolean, Schaefer [32] proved that every CSP is either in P or is NP-Complete. Feder and Vardi [15] conjectured that the same should hold over arbitrary domains as well. They also showed that the then known algorithmic results all follow by the algebraic closure properties of the CSPs. This notion was formalized by Jeavons, Cohen, and Gyssens [17, 18] and other works [11] that crystallized the *(universal) algebraic approach* to CSPs. In the algebraic approach, the higher-order closure properties obeyed by the predicates, namely their *polymorphisms*, are studied. A polymorphism is a function that when applied coordinate-wise to arbitrary satisfying assignments to the predicate, is guaranteed to produce an output that satisfies the predicate. For example, consider an arbitrary instance I of the 2-SAT problem over n variables, and suppose that $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \{0,1\}^n$ are three assignments that satisfy all the constraints in I. Now, if we compute $\mathbf{u} \in \{0,1\}^n$ that is obtained by setting $u_i = \mathsf{MAJ}(x_i, y_i, z_i)$ for all $i \in [n]$, the assignment $\mathbf{u}$ also satisfies all the constraints of I. Thus, the majority function on 3 bits is a polymorphism of the 2-SAT CSP. On the other hand, for the 3-SAT problem, it is not hard to prove that the only polymorphisms are the dictator functions. The algebraic approach has been immensely successful and culminated in the recent resolution of Feder-Vardi conjecture by Bulatov [10] and Zhuk [36]. Further, these proofs yield a precise understanding of the mathematical structure underlying efficient algorithms: if the CSP has a "non-trivial" polymorphisms, the CSP is polytime solvable, and otherwise, it is NP-complete.

In this paper, we study Promise Constraint Satisfaction Problems (PCSPs) that vastly generalize the CSPs. In the PCSPs, each predicate has a weak and a strong form–given an instance of PCSP containing n variables with the constraints, the goal is to distinguish between the case that the stronger form can be satisfied vs. even the weaker one cannot be satisfied. A classical example of PCSP is the approximate graph coloring, where given a graph G, the goal is to distinguish between the cases that G can be colored with c colors vs. it cannot be colored with s colors for some $c \leq s$. Another example is the (1-in-3 SAT, NAE-3-SAT), wherein given a 1-in-3-SAT instance that is promised to be satisfiable, the objective is to assign $0, 1$ values to the variables such that each constraint is satisfied as a NAE-3-SAT instance, i.e., both 0 and 1 occur in every constraint. While the individual CSPs, namely 1-in-3-SAT and NAE-3-SAT are both NP-hard, the above PCSP is in P. The study of PCSPs was formally initiated by Austrin, Guruswami, and Håstad [1]. and since then, there has been a lot of recent interest in PCSPs, including the development of a systematic theory in [4, 6] and leading to breakthroughs in approximate graph coloring [4, 24, 35].

The central question in the study of PCSPs is whether there exists a complexity dichotomy for PCSPs i.e. if every PCSP is either in P or is NP-complete. As is the case with CSPs, the key tool towards establishing such a dichotomy result is the algebraic approach. The Galois correspondence from the CSP world extends to PCSPs, i.e., the polymorphisms fully capture the computational complexity of the underlying PCSP [6, 30]. This has been extended to show

that just the identities satisfied by the polymorphisms suffice to capture the computational complexity of the underlying PCSP [4]. However, the polymorphisms of PCSPs are much richer, and characterizing which polymorphisms lead to algorithms and which ones lead to hardness has been a challenging problem. Conceptually, the principal difficulty is that the polymorphisms for CSPs are closed under composition (hence referred to as *clones*), whereas for PCSPs, this is no longer the case.

As a result, even in the Boolean case, we do not have a dichotomy theorem for PCSPs. Towards establishing a potential Boolean PCSP dichotomy, progress has been made by Ficak, Kozik, Olsák and Stankiewicz [16], who obtained a dichotomy result when each predicate is symmetric. In this paper, we study Boolean PCSPs that contain the *simplest non-symmetric predicate*, $x \to y$. We call such Boolean PCSPs *Ordered* as we can also view the implication constraint as an ordering requirement $x \leq y$.

Ordered Boolean PCSPs have come under recent study. The work of Petr [29] (inspired by work of Barto [2, 3]) considered a special class of Ordered Boolean PCSPs which have an additional predicate $x \neq y$ (this corresponds to allowing negations in the constraints) as well as the requirement that the majority on three bits is *not* a polymorphism. In this setting Petr was able to show that such Ordered Boolean PCSPs are NP-hard. However, the approach considered does not seem immediately extendable to analyzing general Ordered Boolean PCSPs [3].

The main motivation for studying these PCSPs comes from the fact that adding the additional $x \leq y$ predicate is equivalent to restricting the polymorphisms of the PCSPs to be *monotone functions*. Monotonicity is an influential theme in the study of Boolean functions and complexity theory, and understanding the structure of polymorphisms in the monotone case is an important (and certainly necessary) subcase towards a general characterization of polymorphisms vs. tractability for arbitrary Boolean PCSPs. For the special case of Boolean Ordered PCSPs which include negation constraints, it was conjectured in [3] that polynomial time tractability is characterized by the existence of majority polymorphisms of arbitrarily large arity.

Our main result is that Boolean Ordered PCSPs exhibit a dichotomy, under the recently introduced *Rich 2-to-1 Conjecture* of Braverman, Khot, and Minzer [9].

▶ **Theorem 1.** *Assuming the Rich 2-to-1 Conjecture, every Ordered Boolean PCSP is either in P or is NP-Complete. Furthermore, an Ordered PCSP Γ is in P if and only if for every $\epsilon > 0$, there are polymorphisms of Γ with every coordinate having Shapley value at most ϵ. Equivalently, Γ is in P if and only if it has threshold polymorphisms of arbitrarily large arity.*

As a concrete example, recall the earlier mentioned example of (1-in-3-SAT, NAE-3-SAT). As it has threshold polymorphisms of arbitrarily large arity, it remains polynomial time solvable even after adding the predicate $x \to y$. However, if we also add another two-variable predicate $x \neq y$, the PCSP no longer has threshold polymorphisms, and by our above result, it becomes NP-Complete.

We obtain the conditional dichotomy result by analyzing the polymorphisms of the Ordered PCSPs. The key idea in the algebraic approach to PCSPs is that the PCSP is tractable if the polymorphisms are close to symmetric, and the PCSP is hard if all the polymorphisms have a small number of "important" coordinates. More concretely, on the algorithmic front, it has been proved that symmetric polymorphisms of arbitrarily large arities lead to polynomial time algorithms for PCSPs [8]. On the hardness side, if all the polymorphisms depend on a bounded number of coordinates, then the underlying PCSP is NP-hard [1]. This has been extended to various other notions, including combinatorial ones

such as C-fixing [5], and topological ones such as having a bounded number of coordinates with non-zero winding number [24]. In this paper, we study the monotone polymorphisms using analytical techniques.

In particular, we use Shapley value to analyze the monotone polymorphisms. For a monotone function $f : \{0,1\}^n \to \{0,1\}$, Shapley value of a coordinate i is the probability that on a random path from $\{0,0,\ldots,0\}$ to $\{1,1,\ldots,1\}$, the function value turns from 0 to 1 when we switch the ith coordinate to 1. Initially studied to understand the power of an individual in voting systems [33], Shapley value has now found applications in various settings, especially in game theory [26, 27]. In our setting, there are two advantages of using Shapley value to study the polymorphisms. First, it is a relative measure of the importance of a coordinate, as opposed to other notions of Influence which are absolute. This helps in bounding the number of coordinates with Shapley value above a certain threshold. Second, it is a versatile measure with combinatorial and analytical interpretations [12] which helps in proving that Shapley value stays consistent under function minors[1], a key property necessary in both the algorithm and the hardness.

Algorithm Overview. We obtain our algorithmic result by using the Basic Linear Programming with Affine relaxation (BLP+Affine relaxation), combined with a structural result regarding the monotone functions with bounded Shapley value. As mentioned earlier, PCSPs with symmetric polymorphisms of arbitrarily large arities can be solved in polynomial time using the BLP+Affine relaxation algorithm [8]. Our main structural result is that Boolean functions with bounded Shapley value have arbitrarily large threshold functions as minors. Since the set of polymorphisms of a PCSP are closed under taking minors, this proves that the underlying PCSP Γ has arbitrarily large threshold functions as polymorphisms, which then implies that Γ is in P. The key tool underlying our structural result is a result of Kalai [19] that states that under certain conditions, monotone Boolean functions with arbitrarily small Shapley value have a sharp threshold.

Hardness Overview. We obtain our hardness result assuming the Rich 2-to-1 Conjecture. Braverman, Khot, and Minzer [9] introduced the conjecture as a perfect completeness surrogate of the well known Unique Games Conjecture [21]. They also proved that the conjecture is equivalent to Unique Games Conjecture when we relax the perfect completeness requirement. The reduction from the Rich 2-to-1 Conjecture to PCSPs follows using the standard Label Cover-Long Code paradigm. The key ingredient in this reduction is a decoding of the Long Codes to a bounded number of coordinates that is consistent under function minors. We decode each Long Code function to the coordinates with $\Omega(1)$ Shapley value – as the sum of Shapley values of all the coordinates of any monotone function is equal to 1, there is a bounded number of such coordinates. We argue about the consistency of this decoding using a structural result that states that under a uniformly random minor, Shapley value is roughly preserved.

On the necessity of "richness" in 2-to-1 Conjecture. A natural question is whether our hardness result can be obtained using a weaker assumption such as the 2-to-1 conjecture (whose imperfect completeness version was recently established [13, 14, 22, 23]). We shed some light on this question by showing that there are monotone Boolean functions $f : \{0,1\}^{2n} \to \{0,1\}$ and $g : \{0,1\}^n \to \{0,1\}$ such that g is a minor of f with respect to the

[1] A minor(formally defined in Section 2) of a function $f : \{0,1\}^m \to \{0,1\}$ is a function $g : \{0,1\}^n \to \{0,1\}$ of smaller arity $n \leq m$ obtained from f by identifying sets of variables together.

2-to-1 function π, both the functions f and g have exactly one coordinate i_1, i_2 respectively, with $\Omega(1)$ Shapley value, and yet $\pi(i_1) \neq i_2$. Such an adversarial example is interesting from two angles: first, it shows that even using the 2-to-1 conjecture, the Shapley value based decoding is not consistent. Second, it gives an example of agents pairing up maliciously to completely alter the Shapley value. The underlying phenomenon is that the rich 2-to-1 games have "subcode-covering" property, which is absent in the standard 2-to-1 games, helping in preserving the consistency of any biased influence measure such as the Shapley value.

Organization. In Section 2, we formally define PCSPs, polymorphisms, and Shapley value. We present the algorithmic and hardness parts of our dichotomy result in Section 3 and Section 4 respectively. We present the adversarial example of a 2-to-1 minor that alters the Shapley value in Section 5.

2 Preliminaries

Notations. We use $[n]$ to denote the set $\{1, 2, \ldots, n\}$. For a k-ary relation $A \subseteq [q]^k$, we abuse the notation and use A both as a subset of $[q]^k$, and also as a predicate $A : [q]^k \to \{0, 1\}$. For a vector $\mathbf{x} = (x_1, x_2, \ldots, x_n) \in \{0, 1\}^n$, we use $\mathsf{hw}(\mathbf{x})$ to denote $\sum_{i=1}^{n} x_i$. For two vectors $\mathbf{x}, \mathbf{y} \in \{0, 1\}^n$, we say that $\mathbf{x} \leq \mathbf{y}$ if $x_i \leq y_i$ for all $i \in [n]$. A Boolean function $f : \{0, 1\}^n \to \{0, 1\}$ is called monotone if $f(\mathbf{x}) \leq f(\mathbf{y})$ for all $\mathbf{x} \leq \mathbf{y}$.

PCSPs and Polymorphisms. We first define Constraint Satisfaction Problems (CSP).

▶ **Definition 2** (CSP). *Given a k-ary relation $A : D^k \to \{0, 1\}$ over a domain D, the Constraint Satisfaction Problem (CSP) associated with the predicate A takes a set of variables $V = \{v_1, v_2, \ldots, v_n\}$ as input which are to be assigned values from D. There are m constraints $(e_1, e_2, \ldots, e_m)$ each consisting of $e_i = ((e_i)_1, (e_i)_2, \ldots, (e_i)_k) \subseteq V^k$ that indicate that the corresponding assignment should belong to A. The objective is to identify if there is an assignment $V \to D$ that satisfies all the constraints.*

In general, we can have multiple relations $A_1, A_2, \ldots, A_l$, and different constraints can use different relations. We denote such a CSP by $CSP(A_1, A_2, \ldots, A_l)$.

We formally define Promise Constraint Satisfaction Problems (PCSP).

▶ **Definition 3** (PCSP). *In a Promise Constraint Satisfaction Problem $PCSP(\Gamma)$ over a pair of domains D_1, D_2, we have a set of pairs of relations $\Gamma = \{(A_1, B_1), (A_2, B_2), \ldots, (A_l, B_l)\}$ such that for every $i \in [l]$, A_i is a subset of $D_1^{k_i}$ and B_i is a subset of $D_2^{k_i}$. Furthermore, there is a homomorphism $h : D_1 \to D_2$ such that for all $i \in [l]$ and $x \in D_1^{k_i}$, $x \in A_i$ implies $h(x) \in B_i$. Given a $CSP(A_1, A_2, \ldots, A_l)$ instance, the objective is to distinguish between the two cases:*

1. *There is an assignment to the variables from D_1 that satisfies every constraint when viewed as $CSP(A_1, A_2, \ldots, A_l)$.*
2. *There is no assignment to the variables from D_2 that satisfies every constraint when viewed as $CSP(B_1, B_2, \ldots, B_l)$.*

We now define Boolean Ordered PCSPs.

▶ **Definition 4** (Boolean Ordered PCSP). *A PCSP $PCSP(\Gamma)$ over a pair of domains D_1, D_2 with the set of pairs of relations $\Gamma = \{(A_1, B_1), (A_2, B_2), \ldots, (A_l, B_l)\}$ is said to be Boolean Ordered if the following hold.*

1. *The domains are both Boolean i.e., $D_1 = D_2 = \{0, 1\}$.*
2. *There exists $i \in [l]$ such that $A_i = B_i = \{(0, 0), (0, 1), (1, 1)\}$.*

Associated with every PCSP, there are polymorphisms that capture the closure properties of the satisfying solutions to the PCSP. More formally, we can define polymorphisms of a PCSP as follows.

▶ **Definition 5** (Polymorphisms). *For $PCSP(\Gamma)$ with $\Gamma = \{((A_1, B_1), (A_2, B_2), \ldots, (A_l, B_l))\}$ where for every $i \in [l]$, $A_i : [q_1]^{k_i} \to \{0,1\}, B_i : [q_2]^{k_i} \to \{0,1\}$, a polymorphism of arity n is a function $f : [q_1]^n \to [q_2]$ that satisfies the below property for all $i \in [l]$. For all $(\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_{k_i})$ such that for all $j \in [n], ((\boldsymbol{v}_1)_j, (\boldsymbol{v}_2)_j, \ldots, (\boldsymbol{v}_{k_i})_j) \in A_i$, we have*

$$(f(\boldsymbol{v}_1), f(\boldsymbol{v}_2), \ldots, f(\boldsymbol{v}_{k_i})) \in B_i$$

We use $\mathrm{Pol}(\Gamma)$ *to denote the family of all the polymorphisms of $PCSP(\Gamma)$.*

A crucial property satisfied by $\mathrm{Pol}(\Gamma)$ is that the family of functions is closed under taking minors. We first define the minor of a function formally.

▶ **Definition 6** (Minor of a function). *For a Boolean function $f : [q]^n \to [q']$, the function $g : [q]^m \to [q']$ is said to be a minor of f with respect to the function $\pi : [n] \to [m]$ if*

$$g(x_1, x_2, \ldots, x_m) = f(x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}) \, \forall x_1, x_2, \ldots, x_m \in [q]$$

We say that a function g is a minor of f if there exists some π such that g is a minor of f with respect to π.

We are often interested in 2-to-1 minors. A function g is said to be a 2-to-1 minor of f if there exists a 2-to-1 function π such that g is a minor of f with respect to π, where 2-to-1 function is defined below.

▶ **Definition 7** (2-to-1 function). *A function $\pi : [2n] \to [n]$ is said to be a 2-to-1 function if*

$$|\pi^{-1}(i)| = 2 \ \forall i \in [n]$$

We use $\mathcal{F}_{2\to1}(n)$ to denote the set of all the 2-to-1 functions from $[2n]$ to $[n]$.

By the definition of the polymorphisms, we can infer that if $f \in \mathrm{Pol}(\Gamma)$ for a PCSP Γ, then for all functions g such that g is a minor of f, we have $g \in \mathrm{Pol}(\Gamma)$. Such a family of functions that is closed under taking minors is called as a *minion*. We often refer to the family of polymorphisms of a PCSP as the polymorphism minion.

We refer the reader to [4] for an extensive introduction to PCSPs and polymorphisms.

Shapley value. Let $f : \{0,1\}^n \to \{0,1\}$ be a monotone Boolean function. We can view the monotone Boolean function f as a voting scheme between two parties, and n agents: the winner of the voting scheme when the ith agent votes for $\mathbf{x}_i \in \{0,1\}$ is $f(\mathbf{x})$. The relative power of an agent in a voting scheme is typically measured using the Shapley-Shubix Index, also known as Shapley Value.

Informally speaking, the Shapley Value of a coordinate i is the probability that the ith agent is the altering vote when we start with all zeroes and flip the votes in a uniformly random order. More formally,

▶ **Definition 8** (Shapley value). *Let $f : \{0,1\}^n \to \{0,1\}$ be a monotone Boolean function. Let $\sigma \in S_n$ be a uniformly random permutation of $[n]$. For an integer $j \in [n]$, let P_j denote the set of first j elements of σ i.e., $P_j := \{\sigma(1), \sigma(2), \ldots, \sigma(j)\}$. The Shapley value $\Phi_f(i)$ of the coordinate $i \in [n]$ is defined as*

$$\Phi_f(i) := Pr_\sigma \{\exists j \in [n] : \sigma(j) = i, f(P_{j-1}) = 0, f(P_j) = 1\}$$

We also give an alternate definition of Shapley value using the notion of boundary of a coordinate. For a monotone Boolean function $f : \{0,1\}^n \to \{0,1\}$ and coordinate $i \in [n]$, let $\mathcal{B}_f(i)$ denote the boundary of the coordinate i i.e.

$$\mathcal{B}_f(i) := \{S \subseteq [n] \setminus \{i\} : f(\{i\} \cup S) = 1, f(S) = 0\}$$

By the monotonicity of f, we can infer that $\mathcal{B}_f(i)$ satisfies the following sandwich property that will be useful later.

▶ **Proposition 9.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a monotone Boolean function and let $i \in [n]$. Then, for every pair of sets $S_1, S_2 \in \mathcal{B}_f(i)$ with $S_1 \subseteq S_2$, we have $S \in \mathcal{B}_f(i)$ for all S such that $S_1 \subseteq S \subseteq S_2$.*

Proof. By the monotonicity of f, we have $f(S \cup \{i\}) \geq f(S_1 \cup \{i\}) = 1$, and thus, $f(S \cup \{i\}) = 1$. Similarly, we have $f(S) \leq f(S_2) = 0$, and thus, $f(S) = 0$. ◀

For an index $j \in \{0, 1, \ldots, n-1\}$, let $\mu_f(j)^{(i)}$ denote the fraction of subsets of $[n]$ of size j that are in $\mathcal{B}_f(i)$ i.e.

$$\mu_f(j)^{(i)} := \left|\mathcal{B}_f(i) \cap \tbinom{[n]}{j}\right| \Big/ \tbinom{n}{j}.$$

We can rewrite the definition of Shapley value of the ith coordinate as the following [34]:

$$\Phi_f(i) = \frac{\sum_{j=0}^{n-1} \mu_f(j)^{(i)}}{n}. \tag{1}$$

3 Algorithm when Shapley values are small

In this section, we show that monotone Boolean functions where each coordinate has bounded Shapley value has arbitrarily large threshold functions as minors, thereby proving the algorithmic part of our dichotomy result.

Let L be a positive integer and $0 \leq \tau \leq L$ be a non-negative integer. We let $\mathsf{THR}_{L,\tau} : \{0,1\}^L \to \{0,1\}$ be the threshold function on L variables with threshold τ. More formally,

$$\mathsf{THR}_{L,\tau}(\mathbf{x}) := \begin{cases} 1 \text{ if } \mathsf{hw}(\mathbf{x}) \geq \tau \\ 0 \text{ otherwise.} \end{cases}$$

For a monotone Boolean function $f : \{0,1\}^n \to \{0,1\}$ and real number $p \in [0,1]$, let $P_p(f)$ denote the expected value of $f(x)$ where each element $x_i, i \in [n]$ is independently set to be 1 with probability p and 0 with probability $1-p$. For every monotone function f, the function $P_p(f)$ is a strictly monotone continuous function in p on the interval $[0,1]$. The value $p_c = p_c(f)$ at which $P_{p_c}(f) = \frac{1}{2}$ is called the *critical probability* of f.

Using the Russo-Margulis Lemma [25, 31] and Poincaré Inequality, we can show the following lemma that we need later.

▶ **Lemma 10** (Exercise 8.29(e) in [28]). *Let f be a non-constant monotone Boolean function with critical probability $p_c \leq \frac{1}{2}$. Let $p_1 := \frac{1}{(2\nu)^2} p_c$ for $\nu > 0$. If $p_1 \leq \frac{1}{2}$, then $P_{p_1}(f) \geq 1 - \nu$.*

We now define the threshold interval of f.

▶ **Definition 11.** *For a monotone function f and $0 < \epsilon < \frac{1}{2}$, we define $T_\epsilon(f) := p_2 - p_1$, where p_2 and p_1 are such that $P_{p_1}(f) = \epsilon, P_{p_2}(f) = 1 - \epsilon$.*

Kalai [19] proved the following result regarding monotone Boolean functions.

▶ **Theorem 12.** *For every $a, \epsilon, \gamma > 0$, there exists $\delta := \delta(a, \epsilon, \gamma) > 0$ such that for every monotone Boolean function $f : \{0,1\}^n \to \{0,1\}$ with $\Phi_f(i) \leq \delta$ for all $i \in [n]$ and $a \leq p_c(f) \leq 1 - a$, then $T_\epsilon(f) \leq \gamma$.*

We will use this result to show that for every monotone function where each coordinate has bounded Shapley value has arbitrarily large threshold functions as minor.

▶ **Lemma 13.** *For every $L \geq 2$, there exists a $\delta := \delta(L) > 0$ such that the following holds. For any monotone Boolean function $f : \{0,1\}^n \to \{0,1\}$ with*

$$\Phi_f(i) \leq \delta \ \ \forall i \in [n]$$

there exists a positive integer $L' \in \{L, L+1\}$ and a non-negative integer τ such that $\mathsf{THR}_{L',\tau}$ is a minor of f.

Proof. We obtain $\delta := \delta(L) > 0$ from Theorem 12 by setting $\epsilon = \frac{1}{2^{L+1}}, \gamma = a = \frac{1}{L^3}$. Our goal is to show that for this parameter δ, for every monotone Boolean function f with each coordinate having Shapley value at most δ, there exists $L' \in \{L, L+1\}$ and τ such that $\mathsf{THR}_{L',\tau}$ is a minor of f.

We assume that f is a non-constant function, else we have a trivial minor by setting $\tau = 0$ or $\tau = L'$. Let p_c be the critical probability of f.

Case 1: $p_c < a = \frac{1}{L^3}$. Let $p_1 = L^2 p_c < \frac{1}{L}$. Using Lemma 10, we can conclude that $P_{p_1}(f) \geq 1 - \frac{1}{2L}$. As $P_p(f)$ is monotone, we get that $P_{\frac{1}{L}}(f) > 1 - \frac{1}{2L}$. We let $g : \{0,1\}^L \to \{0,1\}$ be a uniformly random minor of f i.e. we choose the function $\pi : [n] \to [L]$ by choosing each value $\pi(i)$ uniformly and independently at random from $[L]$, and we let g to be the minor of f with respect to π.

Note that for every $i \in [L]$, the distribution of $g(\{i\})$ over the random minor g is the same as sampling a random input to f where we set each bit to 1 with probability $\frac{1}{L}$. As $P_{\frac{1}{L}}(f) \geq 1 - \frac{1}{2L}$, we get that for each $i \in [L]$, $g(\{i\}) = 1$ with probability at least $1 - \frac{1}{2L}$. By union bound, with probability at least $\frac{1}{2}$, $g(\{i\}) = 1$ for all $i \in [L]$. As $f(0, 0, \ldots, 0) = 0$, $g(\phi) = 0$ as well. Thus, with probability at least $\frac{1}{2}$, $g = \mathsf{THR}_{L,1}$. Hence, $\mathsf{THR}_{L,1}$ is a minor of f.

Case 2: $p_c > 1 - a = 1 - \frac{1}{L^3}$. Let $f^\dagger$ be the Boolean dual of f defined as $f^\dagger(x) = 1 - f(\overline{x})$. Note that $P_p(f^\dagger) = 1 - P_{1-p}(f)$ for all $p \in [0,1]$. Thus, $p_c(f^\dagger) = 1 - p_c < a$. Using the previous case, we can infer that $\mathsf{THR}_{L,1}$ is a minor of $f^\dagger$ with respect to a funtion $\pi : [n] \to [L]$. The same function π proves that $\mathsf{THR}^\dagger_{L,1} = \mathsf{THR}_{L,L}$ is a minor of f.

Case 3: $a \leq p_c \leq 1 - a$. Using Theorem 12, we obtain p_1 such that $P_{p_1}(f) \leq \epsilon$, and $P_{p_1+\gamma} \geq 1 - \epsilon$, where $\epsilon = \frac{1}{2^{L+1}}, \gamma = \frac{1}{L^3}$. As $\gamma < \frac{1}{L(L+1)}$, there exists $L' \in \{L, L+1\}$ and $\tau \in [L']$ such that $p_1 + \gamma < \frac{\tau}{L'}$ and $p_1 > \frac{\tau-1}{L'}$. Thus, we get that $P_{\frac{\tau}{L'}}(f) > 1 - \epsilon$ and $P_{\frac{\tau-1}{L'}} < \epsilon$. Let $g : \{0,1\}^{L'} \to \{0,1\}$ be a uniformly random minor of f i.e. we choose $\pi : [n] \to [L']$ by setting each value uniformly and independently at random from $[L']$ and set g to be the minor of f with respect to π. For a vector $\mathbf{x} \in \{0,1\}^{L'}$ with $\mathsf{hw}(\mathbf{x}) = \tau$, with probability greater than $1 - \frac{1}{2^{L+1}}$, $g(\mathbf{x}) = 1$. Similarly, for $\mathbf{x} \in \{0,1\}^{L'}$ with $\mathsf{hw}(\mathbf{x}) = \tau - 1$, with probability greater than $1 - \frac{1}{2^{L+1}}$, $g(\mathbf{x}) = 0$. Thus, with non-zero probability, $g(\mathbf{x}) = 1$ for all $x \in \{0,1\}^{L'}$ with $\mathsf{hw}(\mathbf{x}) = \tau$ and $g(\mathbf{x}) = 0$ for all $\mathbf{x} \in \{0,1\}^{L'}$ with $\mathsf{hw}(\mathbf{x}) = \tau - 1$. In other words, with non-zero probability, g is equal to $\mathsf{THR}_{L',\tau}$. Thus, $\mathsf{THR}_{L',\tau}$ is a minor of f. ◀

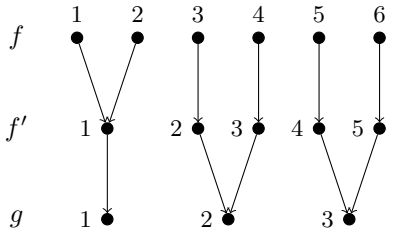

Figure 1 An illustration of the two step minor approach: Here $f : \{0,1\}^6 \to \{0,1\}$ is a Boolean function, $f' : \{0,1\}^5 \to \{0,1\}$ is a minor of f with respect to the function $\pi_1 : [6] \to [5]$ with $\pi_1(i) = \max(i-1, 1)$, and g is a minor of f' with respect to the function $\pi_2 : [5] \to [3]$ with $\pi_2(i) = \lceil \frac{i+1}{2} \rceil$.

Using the existence of arbitrarily large arity threshold minors, the algorithmic part of our Dichotomy result follows immediately.

▶ **Theorem 14.** *Let Γ be a Promise CSP template. Suppose that for every $\epsilon > 0$, there exists a function $f \in \mathrm{Pol}(\Gamma), f : \{0,1\}^n \to \{0,1\}$ such that $\Phi_i(f) \leq \epsilon$ for all $i \in [n]$. Then,* $\mathrm{PCSP}(\Gamma) \in \mathsf{P}$.

Proof. Using Lemma 13, we can conclude that there are infinitely many positive integers L such that there exists $\tau \in \{0, 1, \ldots, L\}$ with $\mathsf{THR}_{L,\tau} \in \mathrm{Pol}(\Gamma)$. As the threshold functions are symmetric[2], $\mathrm{Pol}(\Gamma)$ has symmetric polymorphisms of infinitely many arities. Thus, using the BLP+Affine algorithm of [8], $\mathrm{PCSP}(\Gamma)$ can be solved in polynomial time. ◀

We remark that the above result is inspired by a special case shown by Barto [2] that a Boolean Ordered PCSP is polytime tractable if it has cyclic polymorphisms of arbitrarily large arities.

4 Hardness Assuming Rich 2-to-1 Conjecture

In this section, we prove the hardness part of our dichotomy result. First, we prove that Shapley value is preserved under uniformly random 2-to-1 minors, and then we use this to show the hardness assuming the Rich 2-to-1 Conjecture.

4.1 Shapley value under random 2-to-1 minor

Let $f : \{0,1\}^{2n} \to \{0,1\}$ be a monotone Boolean function with $\Phi_f(1) \geq \lambda$ for some absolute constant $\lambda > 0$. Let $g : \{0,1\}^n \to \{0,1\}$ be a minor of f with respect to the uniformly random 2-to-1 function $\pi : [2n] \to [n]$. Our goal in this subsection is to show that $\mathbb{E}_\pi[\Phi_g(\pi(1))] \geq \gamma$ for some function $\gamma := \gamma(\lambda) > 0$. We prove this in two steps. (See Figure 1)

1. First, we consider the minor of f, $f' : \{0,1\}^{2n-1} \to \{0,1\}$ obtained with respect to $\pi_1 : [2n] \to [2n-1]$ where $\pi_1(1) = \pi_1(2) = 1, \pi_1(i) = i - 1 \, \forall i \in \{3, 4, \ldots, 2n\}$. We show that $\Phi_{f'}(1) \geq \frac{\lambda}{2}$.
2. Next, we consider a minor g of f' obtained with respect to the function $\pi_2 : [2n-1] \to [n]$ which has $\pi_2(1) = 1$ while the rest $2n-2$ values are chosen using a uniformly random partition of $[2n-2]$ into $n-1$ pairs. We show that $\mathbb{E}_{\pi_2}[\Phi_g(1)] \geq \gamma$ for some function $\gamma := \gamma(\lambda) > 0$.

[2] A function $f : \{0,1\}^n \to \{0,1\}$ is said to be symmetric if it is unchanged by any permutation of the input variables.

Note that the process of first taking the f' minor and then obtaining g by partitioning $[2n-2]$ into $n-1$ uniformly random pairs is equivalent to taking a uniformly random 2-to-1 minor of f. Thus, the two steps together prove the required Shapley value property of the uniformly random 2-to-1 minor.

The first step is captured by the following pair of lemmas, which we prove in the full version.

▶ **Lemma 15.** *Let $f : \{0,1\}^{2n} \to \{0,1\}$ and $f' : \{0,1\}^{2n-1} \to \{0,1\}$ be monotone Boolean functions such that f' is a minor of f with respect to the function $\pi_1 : [2n] \to [2n-1]$ defined as $\pi_1(i) = \max(i-1, 1)$. If $\Phi_f(1) \geq \lambda$, then $\Phi_{f'}(1) \geq \frac{\lambda}{2}$.*

▶ **Lemma 16.** *Let $f' : \{0,1\}^{2n-1} \to \{0,1\}$ be a monotone Boolean function such that $\Phi_{f'}(1) = \lambda$ with $\lambda \geq \frac{1}{n}$. For an integer $j \in \{0, 1, \ldots, 2n-2\}$, let $\mu'(j) = \mu_{f'}(j)^{(1)}$. Then, there exists an absolute constant $\gamma := \gamma(\lambda) > 0$ such that*

$$\frac{\sum_{j=0}^{n-1} \mu'(2j)}{n} \geq \gamma$$

We now prove the second step in the proof.

▶ **Lemma 17.** *Suppose that $f' : \{0,1\}^{2n-1} \to \{0,1\}$ is a monotone Boolean function such that $\Phi_{f'}(1) \geq \lambda$ with $\lambda \geq \frac{1}{n}$. Let g be a random minor of f' with respect to $\pi_2 : [2n-1] \to [n]$ which is obtained by setting $\pi_2(1) = 1$, and for every $i > 1$, we randomly choose $j_1, j_2 \in [2n-1] \setminus \{1\}$ (without replacements) and set $\pi_2(j_1) = \pi_2(j_2) = i$. In other words, we choose a uniformly random partition of $[2n-1] \setminus \{1\}$ into $n-1$ pairs $P_2, P_3, \ldots, P_n$ and set $\pi_2(j) = i \, \forall j \in P_i$. Then, there exists $\gamma := \gamma(\lambda) > 0$ such that*

$$\mathbb{E}_{\pi_2}[\Phi_g(1)] \geq \gamma \ .$$

Proof. For ease of notation, we let $\mu'(j) = \mu_{f'}(j)^{(1)}$ and $\mu_g(j) = \mu_g(j)^{(1)}$. For a set $S \subseteq [n] \setminus \{1\}$ and a function $\pi_2 : [2n-1] \to [n]$ with $\pi_2(1) = 1$, and $|\pi_2^{-1}(i)| = 2$ for all $i \in \{2, 3, \ldots, n\}$, let $\pi_2^{-1}(S)$ be the $2|S|$ sized subset of $\{2, 3, \ldots, 2n-1\}$ defined as follows:

$$\pi_2^{-1}(S) := \{\pi_2^{-1}(i) : i \in S\}$$

For every set $S \subseteq \{2, 3, \ldots, n\}$, when $\pi_2 : [2n-1] \to [n]$ is a uniformly random 2-to-1 minor with $\pi_2(1) = 1$, and the rest $2n-2$ elements are partitioned into $n-1$ pairs uniformly at random, the set $\pi_2^{-1}(S)$ is distributed uniformly in $\binom{[2n-1]\setminus\{1\}}{2|S|}$. Also note that $S \in \mathcal{B}_g(1)$ if and only if $\pi^{-1}(S) \in \mathcal{B}_{f'}(1)$. Thus, for every set $S \subseteq \{2, 3, \ldots, n\}$, the probability that $S \in \mathcal{B}_g(1)$ (over the choice of π_2) is equal to $\mu'(2|S|)$. Summing over all such sets of size j, we get that for every $j \in \{0, 1, \ldots, n-1\}$, the expected value of $\mu_g(j)$ is equal to $\mu'(2j)$.

$$\mathbb{E}_{\pi_2}[\mu_g(j)] = \mu'(2j) \, \forall j \in \{0, 1, \ldots, n-1\}$$

By using Lemma 16, we can infer that there exists $\gamma = \gamma(\lambda) > 0$ such that $\sum_{j=0}^{n-1} \mathbb{E}_{\pi_2}[\mu_g(j)] = \sum_{j=0}^{n-1} \mu'(2j) \geq \gamma n$. Using Equation (1), we get

$$\mathbb{E}_{\pi_2}[\Phi_g(1)] = \mathbb{E}_{\pi_2}\left[\frac{\sum_{j=0}^{n-1} \mu_g(j)}{n}\right] = \frac{\sum_{j=0}^{n-1} \mathbb{E}_{\pi_2}[\mu_g(j)]}{n} \geq \gamma. \qquad \blacktriangleleft$$

Lemma 15 and Lemma 17 together prove that Shapley value behaves well under uniformly random 2-to-1 minors for monotone Boolean functions.

▶ **Lemma 18.** *Suppose that* $f : \{0,1\}^{2n} \to \{0,1\}$ *is a monotone Boolean function such that* $\Phi_f(1) \geq \lambda$ *for some absolute constant* $\lambda > 0$ *with* $\lambda \geq \frac{1}{n}$*. Then, there exists* $\gamma := \gamma(\lambda) > 0$ *such that*

$$\mathbb{E}_\pi[\Phi_g(\pi(1))] \geq \gamma$$

where g *is a minor of* f *with respect to the uniformly random* 2*-to-*1 *function* π*.*

Proof. Combining Lemma 15 and Lemma 17, we can conclude that for every $i \in [2n], i > 1$, when $\pi : [2n] \to [n]$ is a uniformly random 2-to-1 minor conditioned on the fact that $\pi(1) = \pi(i)$, we have $\mathbb{E}_\pi[\Phi_g(\pi(1))] \geq \gamma$. Taking average over all the $i \in [2n], i > 1$, we get a proof that the same inequality holds when π is a uniformly random 2-to-1 minor. ◀

4.2 Reduction

We first formally define the Label Cover problem and state the Rich 2-to-1 Conjecture.

▶ **Definition 19** (Label Cover)**.** *In the Label Cover problem* $\mathcal{G} = (G, \Sigma_L, \Sigma_R, \Pi)$*, the input is a bipartite graph* $G = (L \cup R, E)$ *with projection constraint* $\Pi_e : \Sigma_L \to \Sigma_R$ *on every edge* $e \in E$*. A labeling* σ *which assigns values from* Σ_L *to* L *and from* Σ_R *to* R *satisfies the constraint* Π_e *on the edge* $e = (u, v)$ *if* $\Pi_e(\sigma(u)) = \sigma(v)$*. The objective is to identify if there is a labeling that satisfies all the constraints.*

For every constant $\epsilon > 0$, it is NP-hard to distinguish between the case that a given Label Cover instance has a labeling that satisfies all the constraints vs. no labeling can satisfy more than ϵ fraction of the constraints. This hardness result for Label Cover has been instrumental in showing numerous strong, and sometimes optimal, inapproximability results for various computational problems. However, standard Label Cover seems insufficient as a starting point towards proving hardness results for approximate graph coloring and other 2-variable PCSPs. To circumvent this, the hardness of Label Cover on structured instances such as Unique Games, smooth Label Cover, etc. has been studied.

In his celebrated work proposing the Unique Games Conjecture [20], Khot also proposed the "2-to-1 conjecture" that the strong hardness of Label Cover holds when all the constraints of the Label Cover are 2-to-1 functions. The imperfect completeness version of this conjecture was recently established in a striking sequence of works [13, 14, 22, 23]. Braverman, Khot, and Minzer [9] put forth a stronger conjecture that states that the hardness of Label Cover holds when the distribution of 2-to-1 functions on edges incident on every vertex $u \in L$ is uniform over $\mathcal{F}_{2\to1}$.

▶ **Definition 20** (Rich 2-to-1 Label Cover instances)**.** *We call a Label Cover instance* $\mathcal{G} = (G, \Sigma_L, \Sigma_R, \Pi)$ *with* $G = (L \cup R, E)$ *a rich* 2*-to-*1 *instance if the following hold.*

1. *There exists an integer* Σ *such that* $\Sigma_L = [2\Sigma]$*,* $\Sigma_R = [\Sigma]$*, and every projection constraint* Π_e*,* $e \in E$ *is a* 2*-to-*1 *function.*
2. *For every vertex* $u \in L$*, the distribution of* 2*-to-*1 *functions* $\mathcal{P}_u$ *obtained by first sampling a uniformly random neighbor* v *of* u*, and then picking* $\Pi_e, e = (u, v)$*, is uniform over* $\mathcal{F}_{2\to1}(\Sigma)$*.*

▶ **Conjecture 21** (Rich 2-to-1 Conjecture with Perfect Completeness, [9])**.** *For every* $\epsilon > 0$*, there exists an integer* $\Sigma = \Sigma(\epsilon)$ *such that given a rich* 2*-to-*1 *Label Cover instance* $\mathcal{G}$*, it is NP-Hard to distinguish between the following.*

1. *There is a labeling that satisfies all the constraints of* $\mathcal{G}$*.*
2. *No labeling can satisfy more than* ϵ *fraction of the constraints of* $\mathcal{G}$*.*

We are now ready to state the hardness part of our dichotomy. It is proved using the Label Cover-Long Code framework. This reduction is standard in the PCSP literature, see e.g., [4], and we include the proof in the full version of the paper.

▶ **Theorem 22.** *Assume the Rich 2-to-1 Conjecture. Let PCSP*(Γ) *be a Boolean Ordered PCSP such that there exists an absolute constant* $\lambda > 0$ *with* $\max_{i\in[n]} \Phi_f(i) \geq \lambda$ *for all functions* $f : \{0,1\}^n \to \{0,1\}$, $f \in \mathrm{Pol}(\Gamma)$. *Then PCSP*$(\Gamma)$ *is NP-Hard.*

5 Adversarial 2-to-1 minor

We construct an example of a 2-to-1 minor where the Shapley value alters completely after taking the minor.

▶ **Theorem 23.** *Let* $n \geq 2$ *be a positive integer. There exist two monotone Boolean functions* $f : \{0,1\}^{2n} \to \{0,1\}$ *and* $g : \{0,1\}^n \to \{0,1\}$ *such that* g *is a 2-to-1 minor of* f *with respect to the 2-to-1 function* $\pi : [2n] \to [n]$ *defined as* $\pi(i) = \lceil \frac{i}{2} \rceil$. *Furthermore,*

1. $\Phi_g(1) = \Omega(1)$, *and* $\Phi_g(j) = o(1)$ *for all* $j > 1$.
2. $\Phi_f(3) = \Omega(1)$, *and* $\Phi_f(i) = o(1)$ *for all* $i \in [2n], i \neq 3$.

Proof. Similar to the proof of Theorem 22, we construct the minor function pair in two steps.

1. First, we construct Boolean monotone functions $f : \{0,1\}^{2n-1} \to \{0,1\}$ and $g : \{0,1\}^n \to \{0,1\}$ such that g is a minor of f with respect to the function $\pi : [2n-1] \to [n]$ defined as $\pi(1) = 1, \pi(i) = \lceil \frac{i+1}{2} \rceil$ for all $i > 1$. Furthermore, $\Phi_g(1) = \Omega(1)$, and $\Phi_g(j) = o(1)$ for all $j > 1$. We also have $\Phi_f(2) = \Omega(1)$, and $\Phi_f(i) = o(1)$ for all $i \in [2n-1], i \neq 2$.
2. We define the function $f' : \{0,1\}^{2n} \to \{0,1\}$ as

   $$f'(y_1, y_2, \ldots, y_{2n}) = f(y_1, y_3, \ldots, y_{2n})$$

   Note that g is a minor of f' with respect to the 2-to-1 function $\pi : [2n] \to [n]$ defined as $\pi(i) = \lceil \frac{i}{2} \rceil$. Furthermore, by definition, we have $\Phi_{f'}(3) = \Omega(1)$, and $\Phi_{f'}(i) = o(1)$ for all $i \in [2n], i \neq 3$.

Henceforth, our goal is to construct a pair of functions as in the first step above.

We define a partial Boolean function to be a function from $\{0,1\}^n \to \{0,1,?\}$. A partial Boolean function on n variables is monotone if for all $\mathbf{p} \in \{0,1\}^n$ and $\mathbf{q} \in \{0,1\}^n$ such that $\mathbf{p} \leq \mathbf{q}$, if $f(\mathbf{p}) = 1$, then $f(\mathbf{q}) = 1$, and if $f(\mathbf{q}) = 0$, then $f(\mathbf{p}) = 0$.

Now, consider $g : \{0,1\}^n \to \{0,1\}$ to be

$$g(\mathbf{x}) = \begin{cases} 1 \text{ if } \sum_{j=2}^{n} x_j \geq \frac{51n}{100} \\ 0 \text{ if } \sum_{j=2}^{n} x_j \leq \frac{49n}{100} \\ x_1 \text{ if } \frac{49n}{100} < \sum_{j=2}^{n} x_j < \frac{51n}{100} \end{cases}$$

By definition, g is a monotone function, and using Equation (1), we can infer that $\Phi_g(1) = \frac{1}{50}$, and $\Phi_g(j) < \frac{1}{n}$ for all $j > 1$.

We now construct f in three steps. Start with $f = '?'$.

1. (Preserving the minor) First, set the value of entries of f that are of the form $(x_1, x_2, x_2, \cdots, x_n, x_n)$ as

   $$f(x_1, x_2, x_2, \ldots, x_n, x_n) = g(x_1, x_2, \ldots, x_n) \ \forall \mathbf{x} \in \{0,1\}^n$$

   We then extend it both upwards and downwards i.e. if $f(\mathbf{p})$ is set to 1 and $\mathbf{p} \leq \mathbf{q}$, then set $f(\mathbf{q}) = 1$ as well, and similarly, if $f(\mathbf{q})$ is set to 0, and $\mathbf{p} \leq \mathbf{q}$, then we set $f(\mathbf{p}) = 0$. This ensures that g is a minor of f and that the partial function f is monotone.

2. (Destroying the influence of 1) Next, we ensure that the Shapley value of the coordinate 1 is low by the following operation: consider all $\mathbf{y}$ such that $f(\mathbf{y})$ has not been set in the first step, $y_1 = 0$ and $f(1, y_2, \cdots, y_{2n-1})$ is already set to 1 in the first step. Then set $f(\mathbf{y})$ to be 1. Similarly, if $\mathbf{y}$ satisfies $y_1 = 1$ and $f(0, y_2, \cdots, y_{2n-1})$ is already set to 0 in the first step, set $f(\mathbf{y})$ to be 0 if it has not been set in the first step.
   We claim that the updated partial function f is still a monotone partial function. Consider $\mathbf{p}, \mathbf{q} \in \{0,1\}^{2n-1}$ such that $\mathbf{p} \leq \mathbf{q}$. Suppose that $f(\mathbf{p})$ is set to be 1. If it is set in the first step, as we extended the partial function upwards in the first step, $f(\mathbf{q}) = 1$ as well. If $f(\mathbf{p})$ is set to be 1 in the second step, it implies that $f(\mathbf{p}')$ has been set to 1 in the first step, where $\mathbf{p}'$ is obtained from $\mathbf{p}$ by setting p_1 to be 1. Let $\mathbf{q}' \in \{0,1\}^{2n-1}$ be obtained from $\mathbf{q}$ by setting $q_1 = 1$. As $\mathbf{p}' \leq \mathbf{q}'$, $f(\mathbf{q}')$ has been set to 1 in the first step as well. Thus, $f(\mathbf{q})$ is set to be 1 in the second step. The same argument can be used to show that if $f(\mathbf{q}) = 0$, then $f(\mathbf{p}) = 0$ as well.
3. (Adding influence to 2) For all $\mathbf{y}$ for which $f(\mathbf{y}) =' ?'$ set $f(\mathbf{y}) = y_2$. The fact that the final function f is monotone follows from observing that any completion of a partial monotone function using a monotone function results in a monotone function.

Finally, our goal is to argue about the Shapley value of the coordinates of the function f. First, we show that the Shapley value of the coordinate 1 in f is $o(1)$. Suppose there exists $\mathbf{p} = (0, y_2, y_3, \cdots, y_{2n-1})$ and $\mathbf{q} = (1, y_2, y_3, \cdots, y_{2n-1})$ such that $f(\mathbf{p}) = 0$ and $f(\mathbf{q}) = 1$. We claim that both the values $f(\mathbf{p})$ and $f(\mathbf{q})$ are set in the first step of the above procedure. Suppose for contradiction that this is not the case. If neither of them is set in the first step, then they will not be set in the second step either, and in the third step, both of them will be assigned the same value, a contradiction. If exactly one of them is set in the first step, then in the second step, the other value would be set to be equal to it, a contradiction as well. Thus, both the values $f(\mathbf{p})$ and $f(\mathbf{q})$ are set in the first step.

Let $B = \mathcal{B}_g(1) \subseteq \{0,1\}^{n-1}$ be the boundary of the coordinate 1 in g. As $f(\mathbf{q})$ is set to be 1 in the first step, there exists $\mathbf{x} \in \{0,1\}^n$ such that $g(\mathbf{x}) = 1$ and $(x_1, x_2, x_2, \cdots, x_n, x_n) \leq \mathbf{q}$. As $\mathbf{x}$ is not less than or equal to $\mathbf{p}$, we can conclude that $x_1 = 1$ and $g(0, x_2, x_3, \cdots, x_n) = 0$. In other words, $(x_2, x_3, \cdots, x_n) \in B$. Similarly, there exists $\mathbf{x}'$ such that $g(\mathbf{x}') = 0$ and $(x'_1, x'_2, x'_2, \cdots, x'_n, x'_n) \geq \mathbf{p}$. By the same argument as above, we can conclude that $(x'_2, x'_3, \cdots, x'_n) \in B$. Combining the both, we can conclude that there exist $\mathbf{x}, \mathbf{x}' \in B$ such that $(x_2, x_2, x_3, x_3, \ldots, x_n, x_n) \leq (y_2, y_3, \cdots, y_{2n-2}) \leq (x'_2, x'_2, x'_3, x'_3, \ldots, x'_n, x'_n)$. Note that if the above inequality is true for a $(y_2, y_3, \cdots, y_{2n-2})$, we directly get that $(y_2, y_3, \cdots, y_{2n-2})$ is in the boundary of the coordinate 1 in f.

Observe that the boundary of coordinate 1 in g is the set of vectors $(x_2, x_3, \cdots, x_n)$ such that $\frac{49}{100}n \leq \sum_{j=2}^{n} x_j \leq \frac{51}{100}n$. By the previous argument, we can deduce that the boundary $B' = \mathcal{B}_f(1)$ of the coordinate 1 in f is the set of vectors $\mathbf{y} = (y_2, y_3, \cdots, y_{2n-1})$ that satisfy the following property: The number of $i \in [n-1]$ such that both $y_{2i} = y_{2i+1} = 1$ is at least $\frac{49}{100}n$. Similarly, the number of $i \in [n-1]$ such that $y_{2i} = y_{2i+1} = 0$ is at least $\frac{49}{100}n$. Observe that this implies that we require that $\frac{49}{50}n \leq \sum_{j=2}^{2n-1} y_j \leq \frac{51}{50}n$. However, for every integer l such that $\frac{49}{50}n \leq l \leq \frac{51}{50}n$, when we sample a uniformly random vector $\mathbf{y} = (y_2, y_3, \ldots, y_{2n-1})$ with $\sum_{j=2}^{2n-1} y_j = l$, the probability that the number of $i \in [n-1]$ such that both $y_{2i} = y_{2i+1} = 1$ is at least $\frac{49}{100}n$ is $o(\frac{1}{n})$. Thus, using Equation (1), we can infer that the Shapley value of the coordinate 1 in f is $o(1)$.

We now show that the coordinate 2 has $\Omega(1)$ Shapley value in f. Consider $\mathbf{y} = (y_1, y_2, \ldots, y_{2n-1})$ such that $\frac{49n}{50} < \mathsf{hw}(\mathbf{y}) \leq \frac{51n}{50}$. If the number of i such that both $y_{2i} = y_{2i+1} = 1$ is less than $\frac{49}{100}n$, we have $(y_1, y_3, \ldots, y_{2n-1}) \in \mathcal{B}_f(2)$. However, for every integer l such that $\frac{49}{50}n \leq l \leq \frac{51}{50}n$, when we sample a uniformly random $\mathbf{y}$ with

$\mathsf{hw}(\mathbf{y}) = l$, with probability $1 - o(1)$, the number of i such that both $y_{2i} = y_{2i+1} = 1$ is less than $\frac{49}{100}n$. Thus, using Equation (1), we can infer that the Shapley value of the coordinate 2 is $\Omega(1)$ in the function f. Finally, by symmetry, we can observe that $\Phi_f(i) = \Phi_f(3)$ for all $i \geq 3$, and thus, $\Phi_f(i) = o(1)$ for all $i \geq 3$. ◀

Parameterized Applications of Symbolic Differentiation of (Totally) Multilinear Polynomials

Cornelius Brand

Kevin Pratt
Carnegie Mellon University, Pittsburgh, PA, USA

Abstract

We study the following problem and its applications: given a homogeneous degree-d polynomial g as an arithmetic circuit C, and a $d \times d$ matrix X whose entries are homogeneous linear polynomials, compute $g(\partial/\partial x_1, \ldots, \partial/\partial x_n) \det X$. We show that this quantity can be computed using $2^{\omega d}|C|\operatorname{poly}(n,d)$ arithmetic operations, where ω is the exponent of matrix multiplication. In the case that C is skew, we improve this to $4^d|C|\operatorname{poly}(n,d)$ operations, and if furthermore X is a Hankel matrix, to $\varphi^{2d}|C|\operatorname{poly}(n,d)$ operations, where $\varphi = \frac{1+\sqrt{5}}{2}$ is the golden ratio.

Using these observations we give faster parameterized algorithms for the matroid k-parity and k-matroid intersection problems for linear matroids, and faster deterministic algorithms for several problems, including the first deterministic polynomial time algorithm for testing if a linear space of matrices of logarithmic dimension contains an invertible matrix. We also match the runtime of the fastest deterministic algorithm for detecting subgraphs of bounded pathwidth with a new and simple approach. Our approach generalizes several previous methods in parameterized algorithms and can be seen as a relaxation of Waring rank based methods [Pratt, FOCS19].

1 Introduction

Let $\mathcal{S}_d^n := \mathbb{Q}[x_1, \ldots, x_n]_d$ denote the vector space of homogeneous polynomials of degree d in n variables with rational coefficients. We define the *apolar inner product* $\langle \cdot, \cdot \rangle : \mathcal{S}_d^n \times \mathcal{S}_d^n \to \mathbb{Q}$ via

$$\langle f, g \rangle := f\left(\frac{\partial}{\partial x_1}, \ldots, \frac{\partial}{\partial x_n}\right) g. \tag{1}$$

Explicitly, if $f = \sum_{i_1,\ldots,i_n} a_{i_1,\ldots,i_n} x_1^{i_1} \cdots x_n^{i_n}$ and $g = \sum_{i_1,\ldots,i_n} b_{i_1,\ldots,i_n} x_1^{i_1} \cdots x_n^{i_n}$, then

$$\langle f, g \rangle = \sum_{i_1,\ldots,i_n} i_1! \cdots i_n! a_{i_1,\ldots,i_n} b_{i_1,\ldots,i_n}.$$

This inner product originated in 19th century invariant theory [39] and has become a source of interest in computer science due to algorithmic applications. In a typical application, one first identifies some easy-to-evaluate generating polynomial g whose coefficients encode solutions to a combinatorial problem. This information can then be recovered by computing $\langle f, g\rangle$ for a suitable choice of f. While this quantity can be $\#P$ hard to compute exactly, in special cases it can be efficiently approximated. This approach has led to new algorithms for problems as disparate as approximating permanents and mixed discriminants [25], sampling from determinantal point processes [3], Nash social welfare maximization [5], and approximately counting subgraphs [37].

As a motivating example, given a directed graph G with n vertices, let A_G be the $n \times n$ matrix with entry (i, j) equal to the variable x_i if there is an edge from vertex v_i to vertex v_j, and zero otherwise. By the trace method,

$$\operatorname{tr}(A_G^d) = \sum_{\substack{(v_{i_1}, v_{i_2}, \ldots, v_{i_d}) \in G, \\ v_{i_d} = v_{i_1}}} x_{i_1} \cdots x_{i_d} \in \mathcal{S}_d^n.$$

Now let $A \in \mathbb{Q}^{d \times n}$ be a matrix any d columns of which are linearly independent. Let $X = A \cdot \operatorname{diag}(x_1, \ldots, x_n) \cdot A^{\mathrm{T}}$. By the Cauchy-Binet formula,

$$\det X = \sum_{S \in \binom{[n]}{d}} \det(A_S)^2 \prod_{i \in S} x_i.$$

(Here A_S refers to the $d \times d$ submatrix of A with columns indexed by the set S.) Since any d columns in A are linearly independent, $\det(A_S)^2 > 0$ for all $S \in \binom{[n]}{d}$. Then note that $\langle \det(A_S)^2 \prod_{i \in S} x_i, \operatorname{tr}(A_G^d)\rangle$ is positive if there is a simple cycle on the vertices $\{v_i : i \in S\}$, and zero otherwise. It follows by linearity that $\langle \det X, \operatorname{tr}(A_G^d)\rangle > 0$ if and only if G contains a simple cycle of length d.

Motivated by this and other applications, we consider in our Theorems 7, 13, and 25 the algorithmic task of computing the inner product (1) when f is the determinant of a symbolic matrix (a matrix whose entries are homogeneous linear polynomials) and g is given as an arithmetic circuit. As one consequence, starting from the observation of the above example we give a deterministic $\varphi^{2d} \operatorname{poly}(n) < 2.62^d \operatorname{poly}(n)$-time algorithm for detecting simple cycles of length d in an n vertex graph. Here $\varphi := \frac{1+\sqrt{5}}{2}$ is the golden ratio. Our algorithm generalizes to detecting subgraphs of bounded pathwidth, unexpectedly matching the runtime of the fastest known algorithm for this problem of [20].

Our main conceptual contribution is the observation that the following algebraic question is central to a handful of methods in parameterized algorithms. It is motivated by the observation that in order to obtain a (possibly randomized) algorithm for detecting cycles, it would suffice to compute $\langle f, \operatorname{tr}(A_G^d)\rangle$ for any $f \in \mathcal{S}_d^n$ that is supported exactly on the set of all degree-d square-free monomials; $\det X$ is just one such polynomial. We call such polynomials *totally multilinear*, and denote the set of all such polynomials in $\mathcal{S}_d^n$ by $\mathcal{T}_{n,d}$.

▶ **Question 1.** *Let $\mathcal{T}_{n,d}$ be the set of all $f \in \mathcal{S}_d^n$ such that $f = \sum_{S \in \binom{[n]}{d}} c_S \prod_{i \in S} x_i$, where $c_S \neq 0$ for all S. What is $B(d, n) := \min(\dim \operatorname{Diff}(f) : f \in \mathcal{T}_{n,d})$? Here $\operatorname{Diff}(f)$ denotes the vector space spanned by the partial derivatives of all orders of f, including f itself.* [1]

Our algorithms, color coding [1], the group algebra approach [31], and the exterior algebra methods of [12, 11] are all closely related to the existence of polynomials in $\mathcal{T}_{n,d}$ (or related sets) with "unusually small" spaces of partial derivatives (see Section 5). In [37] it was shown

[1] For example, $\operatorname{Diff}(x_1x_2)$ is the vector space spanned by x_1x_2, x_1, x_2, and 1.

that a related quantity, namely the minimum *Waring rank* of any $f \in \mathcal{T}_{n,d}$, gives upper bounds on the complexity of certain parameterized problems. In general, the Waring rank of $f \in \mathcal{S}_d^n$ is lower bounded by $\frac{1}{d} \dim \mathrm{Diff}(f)$, and this bound is almost never optimal [32, Section 3.2]. In this paper, we exploit that fact that, provided f can be "efficiently differentiated," this lower bound can be used to *upper bound* the complexity of these parameterized problems! For instance, our $\varphi^{2d}\,\mathrm{poly}(n)$-time cycle detection algorithm relies on the fact that there is a spanning set of size $\varphi^{2d} < 2.62^d$ for the space of partial derivatives of the polynomial $\det X$ above, when A is a Vandermonde matrix, that we can differentiate $\det X$ "efficiently" with respect to. In contrast, the best best-known upper bound on the Waring rank of this polynomial is 6.75^d [37, Theorem 41].

We show in Proposition 10 that $B(n,d) \leq O(2.6^d)$. Additionally, it is not difficult to show that $B(n,d) \geq 2^d$. A proof of this fact is as follows. First, observe that $\dim \mathrm{Diff}(f)$ does not increase under setting variables to zero. Hence for any $f \in \mathcal{T}_{n,d}$, $\dim \mathrm{Diff}(f) \geq \dim \mathrm{Diff}(c \cdot x_1 x_2 \cdots x_d)$ for some nonzero constant c. As $\mathrm{Diff}(c \cdot x_1 x_2 \cdots x_d)$ has as a basis the collection of products of subsets of the variables $x_1, \ldots, x_d$, the claim follows.

1.1 Previous approaches to computing the apolar inner product

One special case of (1) that has been the source of several recent breakthroughs is when f and g are *real stable* polynomials with nonnegative coefficients; see e.g. [27, 4]. In this case $\langle f, g \rangle$ can be approximated (up to a factor of $e^{d+\varepsilon}$) in polynomial time [2, Theorem 1.2]. For the cases we consider, however, f and g will not both be real stable.

Another approach is based on Waring rank upper bounds [9, 26, 23, 37]. The Waring rank of $f \in \mathcal{S}_d^n$, denoted $\mathbf{R}(f)$, is defined as the minimum r such that $f = \sum_{i=1}^r c_i \ell_i^d$ for linear forms $\ell_1, \ldots, \ell_r \in \mathcal{S}_1^n$ and scalars $c_1, \ldots, c_r$. For example, the identity

$$x_1 x_2 x_3 = \frac{1}{24}\left[(x_1 + x_2 + x_3)^3 - (x_1 + x_2 - x_3)^3 - (x_1 - x_2 + x_3)^3 - (-x_1 + x_2 + x_3)^3\right]$$

shows that $\mathbf{R}(x_1 x_2 x_3) \leq 4$. Waring rank has been studied since the 1850's [29, Introduction] and has gained recent attention for its applications to algebraic complexity, see e.g. [13, 14]. Its relevance to the inner product (1) is due to the following fact, which can be verified by a straightforward calculation: if $f = \sum_{i=1}^r c_i (a_{i,1} x_1 + \cdots + a_{i,n} x_i)^d$, then for all $g \in \mathcal{S}_d^n$,

$$\langle f, g \rangle = d! \sum_{i=1}^r c_i g(a_{i,1}, \ldots, a_{i,n}).$$

Hence upper bounds on $\mathbf{R}(f)$ yield black-box algorithms for computing $\langle f, g \rangle$. Furthermore, it was shown in [37, Theorem 6] that with only evaluation access to g, $\mathbf{R}(f)$ queries are *required* to compute this inner product. Unfortunately, $\mathbf{R}(f)$ is usually prohibitively large; for instance, the Waring rank of almost all $f \in \mathcal{S}_d^n$ is at least $\lceil \binom{n+d-1}{d} / n \rceil$ [32, Section 3.2].

It is also worth pointing out the very recent works of Arvind et al. [7, 6], in particular, [7, Remark 4.3.], which set up a very similar framework based on non-commutative polynomials and algebraic branching programs, on which they prove bounds that also follow from bounds on spaces of partial derivatives.

1.2 Our approach

Given g as an arithmetic circuit C, we compute $\langle f, g \rangle$ symbolically. Our algorithms inductively compute at each gate in C the result of differentiating f by the polynomial computed by C at that gate[2]. At the output gate of C we will therefore have computed $\langle g, f \rangle = \langle f, g \rangle$.

[2] By "differentiating f by g," we mean applying the differential operator $g(\partial/\partial x_1, \ldots, \partial/\partial x_n)$ to f.

At intermediate gates we compute and store elements of $\mathrm{Diff}(f)$, the vector space of partial derivatives of f, which we represent with respect to some spanning set for this space. This kind of symbolic manipulation of partial derivatives is reminiscent of the Baur-Strassen Theorem and its applications (see for example [17]).

We will be particularly interested in the case when f is the determinant of a symbolic matrix X. The advantage of this case is that for a symbolic $d \times d$ matrix X, the vector space spanned by the partial derivatives of $\det X$ of all orders has dimension at most 4^d, and in some algorithmically relevant cases this bound can be significantly improved. So while one might naïvely represent an element in this space as a linear combination of $\binom{n+d}{d}$ monomials, doing so generally includes a significant amount of unnecessary information. Instead, we represent elements in this space as linear combinations of minors (determinants of submatrices) of X, which are specified by pairs of increasing sequences.

We will start by giving in our Theorem 7 a simple algorithm for the special but important case when g is computed by a *skew* circuit, meaning one of the two operands to each multiplication gate is a variable or a scalar:

▶ **Theorem 7.** *Let C be a skew arithmetic circuit computing $g \in \mathcal{S}_d^n$, and let $X = (\ell_{i,j})_{i,j\in[d]}$ be a symbolic matrix with entries in $\mathcal{S}_1^n$. Then we can compute $\langle \det X, g\rangle$ with $4^d|C|\operatorname{poly}(n,d)$ arithmetic operations.*

Our algorithm for Theorem 7 only uses linear algebra and basic properties of differentials.

Of particular interest will be the case of Theorem 7 when X is a Hankel matrix, meaning that $X_{i,j} = X_{i+k,j-k}$ for all $k = 0, \dots, j-i$. For example, the generic 3×3 Hankel matrix is

$$\begin{bmatrix} x_1 & x_2 & x_3 \\ x_2 & x_3 & x_4 \\ x_3 & x_4 & x_5 \end{bmatrix}.$$

This has applications to problems such as detecting cycles in graphs and more generally detecting square-free monomials in arithmetic circuits (Corollary 19). We show the following improvement in this case:

▶ **Theorem 13.** *Let C be a skew arithmetic circuit computing $g \in \mathcal{S}_d^n$, and let $X = (\ell_{i,j})_{i,j\in[d]}$ be a symbolic Hankel matrix with entries in $\mathcal{S}_1^n$. Then we can compute $\langle \det X, g\rangle$ with $\varphi^{2d}|C|\operatorname{poly}(n,d)$ arithmetic operations. Here $\varphi := \frac{1+\sqrt{5}}{2}$ is the golden ratio.*

The improvement in Theorem 13 over Theorem 7 is facilitated by the fact that the space of partial derivatives of the determinant has dimension about 4^d, whereas the dimension of the space of partial derivatives of the determinant of a Hankel matrix is upper bounded by φ^{2d} (Proposition 10).

Let us point out that Hankel matrices (in their guise as squares of the Vandermonde) made appearances already in the exterior-algebraic framework [12, 11], so that their usefulness in our applications might perhaps not come as a complete surprise. Before this work, however, any connections between the exterior and the partial-differential approach remained unclear, and their exact nature remains to be determined.

Still, we do gain one such connection here: For general (not necessarily skew) circuits, we exploit a connection between the *apolar algebra* of the determinant and the exterior algebra (Lemma 24) to show the following:

▶ **Theorem 25.** *Let C be an arithmetic circuit computing $g \in \mathcal{S}_d^n$, and let $X = (\ell_{i,j})_{i,j\in[d]}$ be a symbolic matrix with entries in $\mathcal{S}_1^n$. Then we can compute $\langle \det X, g\rangle$ with $2^{\omega d}|C|\operatorname{poly}(n,d)$ arithmetic operations, where $\omega < 2.373$ is the exponent of matrix multiplication.*

1.3 Applications

Theorem 7 yields faster algorithms for the k-matroid intersection and matroid k-parity problems:

▶ **Problem 1** (Matroid k-Parity). *Suppose we are given a matrix $B \in \mathbb{Q}^{km \times kn}$ representing a matroid M with groundset $[kn]$, and a partition π of $[kn]$ into parts of size k. Decide if the union of any m parts in π are independent in M.*

▶ **Problem 2** (k-Matroid Intersection). *Suppose we are given matrices $B_1, \ldots, B_k \in \mathbb{Q}^{m \times n}$ representing matroids $M_1, \ldots, M_k$ with the common groundset $[n]$. Decide if $M_1, \ldots, M_k$ share a common base.*

We show in Theorems 17 and 18 that these can be solved in time $4^{km}\,\mathrm{poly}(N)$, where N denotes the size of the input. When $k = 2$ these are the classic matroid parity and intersection problems and can be solved in polynomial time, but for $k > 2$ they are NP-hard. The first algorithms for general k faster than naïve enumeration were given by Barvinok in [8], and had runtimes $(km)^{2k+1}4^{km}\,\mathrm{poly}(N)$ and $(km)^{2k}4^{k^2m}\,\mathrm{poly}(N)$, respectively. A parameterized algorithm for Problem 1 was also given by Marx in [36] where it was used to give fixed-parameter tractable algorithms for several other problems, including Problem 2. The fastest algorithms prior to our work were due to Fomin et al. [20] and had runtime $2^{km\omega}\,\mathrm{poly}(N)$, where $\omega < 2.373$ is the exponent of matrix multiplication [33].

By combining Theorem 7 with a known construction of the determinant as a skew circuit [35], we obtain a faster deterministic algorithm for the following problem:

▶ **Problem 3** (SING). *Given matrices $A_1, \ldots, A_n \in \mathbb{Q}^{d \times d}$, decide if their span contains an invertible matrix. Equivalently, decide if $\det \sum_{i=1}^{n} x_i A_i \not\equiv 0$.*

We show that SING can be solved in $4^d\,\mathrm{poly}(N)$ time in our Corollary 16. In particular, this establishes that SING $\in \mathcal{P}$ for subspaces of matrices of logarithmic dimension. The fastest previous deterministic algorithm, due to an observation of Gurvits in [24], had runtime $2^d d!\,\mathrm{poly}(N)$ and made use of an upper bound of $2^d d!$ on $\mathbf{R}(\det_d)$. This problem was originally studied by Edmonds for its application to matching problems [18]. While it is known to admit a simple randomized polynomial time algorithm as was first observed by Lovász [34], a *deterministic* polynomial time algorithm would imply circuit lower bounds that seem far beyond current reach [30]. As a result, variants of SING have attracted attention, leading to a recent breakthrough in the non-commutative setting [22].

Using Theorem 13, we give in Corollary 19 a deterministic $\varphi^{2d}\,\mathrm{poly}(|C|)$-time algorithm for detecting square-free monomials of degree-d in a polynomial with non-negative coefficients computed by a skew arithmetic circuit. Combining this with observations in [11], we obtain the following applications:

▶ **Corollary 20.** *The following problems admit deterministic algorithms running in time $\varphi^{2d}\,\mathrm{poly}(n)$:*

1. *Deciding whether a given directed n-vertex graph has a directed spanning tree with at least d non-leaf vertices,*
2. *Deciding whether a given edge-colored, directed n-vertex graph has a directed spanning tree containing at least d colors,*
3. *Deciding whether a given planar, edge-colored, directed n-vertex graph has a perfect matching containing at least d colors.*

The previous fastest algorithms for these problems had runtimes $3.19^d\,\mathrm{poly}(n)$, $4^d\,\mathrm{poly}(n)$, and $4^d\,\mathrm{poly}(n)$, respectively [11]. This built upon work of Gutin et al. [28] Problem (1) is the best studied among these, with [28, Table 1] listing eleven articles on this problem in the last fourteen years. It is worth noting that our improvements do not rely on any problem-specific adaptations.

Theorem 13 also yields a $\varphi^{2d}\,\mathrm{poly}(n)$-time deterministic algorithm for detecting simple cycles of length d in an n vertex directed graph (and paths, and more generally subgraphs of bounded pathwidth). While it is known that simple cycles of length d can be detected in randomized time $2^d\,\mathrm{poly}(n)$ [41] ($1.66^d\,\mathrm{poly}(n)$ for undirected graphs [10]), it is a major open problem to achieve the same runtime deterministically. Finding a better upper bound on $B(n,d)$ witnessed by a polynomial with nonnegative coefficients seems to us a promising approach for obtaining faster deterministic algorithms for this problem.

Our cycle detection algorithm brushes up against the fastest known deterministic algorithm for this problem which has runtime $2.55^d\,\mathrm{poly}(n)$ [40], and unexpectedly matches the runtime of a previous algorithm [20] while using a different (shorter) approach. Our approach differs from those of previous algorithms which have been based on paradigms such as *color coding*, *divide and color*, and *representative families* [16, Chapter 5] [43]. Whereas these methods make use of explicit constructions of pseudorandom objects such as perfect hash families, universal sets, and representative sets, our algorithm makes use of algebraic-combinatorial identities. This approach was foreshadowed in [12, Theorem 2]. It is important to note that our algorithm only works for unweighted graphs (or weighted graphs with integer weights bounded by $\mathrm{poly}(n)$), while several previous algorithms work for weighted graphs. The algorithm of [20] also extends more generally to detect subgraphs of bounded treewidth.

1.4 Algebraic considerations; the potential for improvement

In Section 4 we note that our algorithms for computing special cases of (1) yield algorithms for performing arithmetic in a certain algebra $\mathcal{A}_f$ associated to f, namely the *apolar algebra* of f. We show in our Lemma 24 that the apolar algebra of the determinant is isomorphic to the diagonal subalgebra of the tensor square of the exterior algebra. This algebra was previously identified in [12] for its applications to detecting subgraphs of bounded pathwidth. By combining this observation with known algorithms for arithmetic in the exterior algebra, we derive our general algorithm for computing $\langle \det X, g\rangle$.

To obtain faster deterministic algorithms for several problems such as detecting simple cycles, we ask Question 1. Our Corollary 11 shows that $B(d,n)$ is at most $(\sqrt{27}/2)^d d$. This upper bound is witnessed by the polynomial

$$\sum_{1\le i_1<\cdots<i_d\le n}\prod_{j<k}(i_j-i_k)^2\prod_{j=1}^{d}x_{i_j}.$$

▶ Remark 4. The discrepancy between $(\sqrt{27}/2)^d d \le O(2.6^d)$ and the base of the exponent $\varphi^{2d} > 2.6^d$ in our runtimes is due to the fact that we do not know how to differentiate in nearly-linear time with respect to a basis for the above polynomial; see Further Questions (6). Instead, we compute them with respect to a larger spanning set.

1.5 Paper outline

In the next section we prove Theorems 7 and 13. We will motivate them with the running application of detecting simple cycles, giving in Corollary 14 our $\varphi^{2d}\,\mathrm{poly}(n)$-time algorithm. The rest of our applications can be found in Section 3, and follow quickly from Theorems 7

and 13, using little more than the Cauchy-Binet formula. In Section 4 we define the apolar algebra of a polynomial. We relate the apolar algebra of the determinant to the tensor square of the exterior algebra in Lemma 24, and use this to prove Theorem 25. We then explain the connection to other methods in parameterized algorithms in Section 5.

2 Computing the apolar inner product for skew circuits

We start by giving an algorithm for computing (1) in the case that g is the determinant of a symbolic matrix and f is computed by a skew arithmetic circuit C. This is a warmup for the special case when g is the determinant of a symbolic Hankel matrix.

We fix the following notation for the rest of the paper. We denote by $|C|$ the total number of gates in the circuit C. Let $I(d,k) \subseteq [d]^k$ be the set of strictly increasing sequences of length k with elements in $[d]$; when $k=0$ we include the empty sequence in this set. Given a $d \times d$ matrix X and tuples $\alpha, \beta \in I(d,k)$, we denote by $X[\alpha|\beta]$ the minor (determinant of a submatrix) of X with rows indexed by α and columns indexed by β. We declare the "empty minor" $X[\,|\,]$ to equal one. We use the convention of writing $\alpha_1, \ldots, \widehat{\alpha_i}, \ldots, \alpha_k$ to denote the sequence $\alpha_1, \ldots, \alpha_{i-1}, \alpha_{i+1}, \ldots, \alpha_k$ obtained from α by omitting α_i. We call a monomial $x_1^{a_1} \cdots x_n^{a_n}$ *square-free* if $a_i \in \{0,1\}$ for all i.

For $f \in \mathcal{S}_d^n$, $\mathrm{Diff}(f)$ denotes the vector space spanned by the partial derivatives of f of all orders (this includes f itself). For example, $\mathrm{Diff}(x_1x_2)$ is the vector space spanned by x_1x_2, x_1, x_2, and 1. The next observation is a simple bound on this quantity for determinants of symbolic matrices, and has been essentially observed several times previously (e.g. [38, Lemma 1.3]).

▶ **Proposition 5.** *Let $X = (\ell_{i,j})_{i,j\in[d]}$ be a symbolic matrix with entries in $\mathcal{S}_1^n$. Then $\mathrm{Diff}(\det X)$ is contained in the space of minors of X. Hence*

$$\dim \mathrm{Diff}(\det X) \leq \sum_{i=0}^{d} \binom{d}{i}^2 = \binom{2d}{d} < 4^d.$$

Proof. Let $\mathfrak{S}_d$ denote the symmetric group on d elements. By the Leibniz formula for the determinant and the product rule, for any $l \in [n]$,

$$\begin{aligned}\frac{\partial \det X}{\partial x_l} &= \sum_{\sigma\in\mathfrak{S}_d} \mathrm{sgn}(\sigma) \sum_{i=1}^{d} \frac{\partial \ell_{i,\sigma(i)}}{\partial x_l} \prod_{j\neq i} \ell_{j,\sigma(j)} = \sum_{1\leq i,j\leq d} \frac{\partial \ell_{i,j}}{\partial x_l} \sum_{\sigma\in\mathfrak{S}_d,\sigma(i)=j} \mathrm{sgn}(\sigma) \prod_{m\neq i} \ell_{m,\sigma(m)} \\ &= \sum_{1\leq i,j\leq d} (-1)^{i+j} \frac{\partial \ell_{i,j}}{\partial x_l} X[1,\ldots,\widehat{i},\ldots,d|1,\ldots,\widehat{j},\ldots,d].\end{aligned}$$

Note that $\frac{\partial \ell_{i,j}}{\partial x_l}$ is just a scalar. To see the last equality, consider the matrix $X^{(ij)}$ obtained by setting the (i,j)th entry of X to 1, and all other entries in the ith row of X to 0. Then $\det X^{(ij)} = \sum_{\sigma\in\mathfrak{S}_d,\sigma(i)=j} \mathrm{sgn}(\sigma) \prod_{m\neq i} \ell_{m,\sigma(m)}$, but at the same time by Laplace expansion along the ith row of $X^{(ij)}$, $\det X^{(ij)} = (-1)^{i+j} X[1,\ldots,\widehat{i},\ldots,d|1,\ldots,\widehat{j},\ldots,d]$.

This shows that the space of order-1 partial derivatives of $\det X$ is contained in the span of the degree-$(d-1)$ minors of X. That $\mathrm{Diff}(\det X)$ is contained in the space of minors of X follows by repeated application of this fact. Furthermore, since square $k \times k$ submatrices of X can be identified by pairs of elements in $I(d,k)$ (their row and column indices), the vector space spanned by all minors of X has dimension at most $\sum_{k=0}^{d} |I(d,k)|^2 = \sum_{k=0}^{d} \binom{d}{k}^2 = \binom{2d}{d}$. ◀

▶ **Lemma 6.** *Given as input a symbolic matrix $X = (\ell_{i,j})_{i,j\in[d]}$ with entries in $\mathcal{S}_1^n$, a linear combination P of minors of X, and $l \in [n]$, we can compute a representation for $\frac{\partial P}{\partial x_l}$ as a linear combination of minors of X with $4^d \operatorname{poly}(n,d)$ arithmetic operations.*

Proof. Let $P = \sum_{k=0}^{d} \sum_{\alpha,\beta\in I(d,k)} c_{\alpha,\beta} X[\alpha|\beta]$ and let $a_{i,j}^{(l)}$ be the coefficient of x_l in $\ell_{i,j}$ (so the input consists of l and the vectors $(c_{\alpha,\beta}) \in \mathbb{Q}^{\binom{2d}{d}}$, $(a_{i,j}^{(l)}) \in \mathbb{Q}^{d^2 n}$). Then by the same considerations as in the proof of Proposition 5,

$$\frac{\partial P}{\partial x_l} = \sum_{k=1}^{d} \sum_{\alpha,\beta\in I(d,k)} \sum_{1\le i,j\le k} c_{\alpha,\beta}(-1)^{i+j} a_{i,j}^{(l)} X[\alpha_1,\dots,\widehat{\alpha}_i,\dots,\alpha_k|\beta_1,\dots,\widehat{\beta}_j,\dots,\beta_k].$$

Note that for $\alpha,\beta \in I(d,k)$, the coefficient of $X[\alpha|\beta]$ in the above equals

$$\sum_{1\le i,j\le k} \sum_{\substack{\alpha',\beta'\in I(d,k+1)\\ \alpha=\alpha'_1,\dots,\widehat{\alpha'_i},\dots,\alpha'_{k+1}\\ \beta=\beta'_1,\dots,\widehat{\beta'_j},\dots,\beta'_{k+1}}} (-1)^{i+j} a_{i,j}^{(l)} c_{\alpha',\beta'}.$$

The numbers of pairs of sequences α',β' considered by the inner sum is naïvely bounded by d^4 (there are d positions in α where we could try to insert a number in $[d]$ into to get an increasing sequence, and similarly for β), and hence the coefficient of each minor can be computed with $O(d^6)$ arithmetic operations. Since there are $\binom{2d}{d}$ minors, all coefficients can be computed with the stated number of operations. ◀

▶ **Theorem 7.** *Let C be a skew arithmetic circuit computing $g \in \mathcal{S}_d^n$, and let $X = (\ell_{i,j})_{i,j\in[d]}$ be a symbolic matrix with entries in $\mathcal{S}_1^n$. Then we can compute $\langle \det X, g\rangle$ with $4^d|C|\operatorname{poly}(n,d)$ arithmetic operations.*

Proof. Say that gate v in C computes the polynomial C_v. We will compute the inner product (1) inductively: at gate v we will compute and store C_v^∂, a representation for $C_v(\frac{\partial}{\partial x_1},\dots,\frac{\partial}{\partial x_n})\det X$ as a linear combination of minors of X. C_v^∂ will be stored as a vector of length $\binom{2d}{d}$ indexed by pairs of row and column sets. At the end of the algorithm we will have computed $f(\frac{\partial}{\partial x_1},\dots,\frac{\partial}{\partial x_n})\det X$ (which by symmetry of the apolar inner product equals $\langle \det X, f\rangle$) at the output gate.

We start by computing and storing $\frac{\partial}{\partial x_l}\det X$ at input gate x_l, which by Lemma 6 can be done in $4^d \operatorname{poly}(n,d)$ time. Now suppose that gate v takes input from gates v' and v'', and that we have already computed $C_{v'}^\partial$ and $C_{v''}^\partial$. To compute C_v^∂, there are two cases to consider:

1. $C_v = x_i \cdot C_{v'}$. Then $C_v^\partial = \frac{\partial}{\partial x_i} C_{v'}(\frac{\partial}{\partial x_1},\dots,\frac{\partial}{\partial x_n})\det X = \frac{\partial}{\partial x_i} C_{v'}^\partial$. Using Lemma 6 this can be computed with $4^d \operatorname{poly}(n,d)$ operations.
2. $C_v = C_{v'} + C_{v''}$. Since differentiation is linear, $C_v^\partial = C_{v'}^\partial + C_{v''}^\partial$. Since $C_{v'}^\partial$ and $C_{v''}^\partial$ are vectors of length $\binom{2d}{d}$, it takes $\binom{2d}{d}$ operations to add them.

Hence at each gate we use at most $4^d \operatorname{poly}(n,d)$ arithmetic operations, for a total of $4^d \operatorname{poly}(n,d)|C|$. ◀

We now show how Theorem 7 can be applied to obtain a deterministic algorithm for detecting simple cycles in graphs. This motivates the following improvement.

▶ **Proposition 8.** *Let G be a graph on n vertices. We can decide in $4^d \operatorname{poly}(n)$ time if G contains a simple cycle of length d.*

Proof. Let $V \in \mathbb{Q}^{d\times n}$ be the Vandermonde matrix with $V_{i,j} = j^i$. Let $X = V \cdot \operatorname{diag}(x_1, \ldots, x_n) \cdot V^{\mathrm{T}}$. By the Cauchy-Binet formula,

$$\det X = \sum_{\alpha \in I(n,d)} V[1, \ldots, d|\alpha]^2 \prod_{i\in\alpha} x_i.$$

Since any d columns in V are linearly independent, $V[1, \ldots, d|\alpha]^2 > 0$ for all $\alpha \in I(n, d)$. Furthermore, observe that $\operatorname{tr}(A_G^d)$ has nonnegative coefficients and contains a square-free monomial if and only if G contains a simple cycle of length d. It follows that $\langle \det X, \operatorname{tr}(A_G^d)\rangle \neq 0$ if and only if G contains such a cycle. In addition, $\operatorname{tr}(A_G^d)$ can be naïvely computed by a skew circuit of size $O(dn^3)$. The theorem follows by applying Theorem 7, noting that we only perform arithmetic with $\operatorname{poly}(n)$-bit integers. ◀

Note that the (i, j)th entry in the matrix X in the proof of Proposition 8 equals $\sum_{k=1}^n k^{i+j} x_k$, and therefore X is Hankel. We now show how this additional structure can be exploited.

Fix linear forms $\ell_1, \ldots, \ell_{2d-1} \in \mathcal{S}_1^n$, and let C_d be the symbolic matrix

$$\begin{bmatrix} \ell_1 & \ell_2 & \ell_3 & \cdots & \cdots & \cdots & \ell_{2d-2} & \ell_{2d-1} \\ \ell_2 & \ell_3 & \iddots & \iddots & \iddots & \iddots & \iddots & 0 \\ \ell_3 & \iddots & \iddots & \iddots & \iddots & \iddots & \iddots & 0 \\ \vdots & \iddots & \iddots & \iddots & \iddots & \iddots & \iddots & \vdots \\ \ell_{2d-2} & \iddots & \iddots & \iddots & \iddots & \iddots & \iddots & \vdots \\ \ell_{2d-1} & 0 & 0 & \cdots & \cdots & \cdots & \cdots & 0 \end{bmatrix}. \tag{2}$$

The minors of the form $C_d[1, 2, \ldots, k|b_1, \ldots, b_k]$, where $k \leq d$ and $b_k \leq 2d - k$, are called *maximal*. For brevity we will let $[\alpha|\beta] \coloneqq C_d[\alpha|\beta]$, and if $[\alpha|\beta]$ is maximal (so $\alpha = 1, \ldots, k$) we further simplify this to $[\beta]$. Let H_d be the submatrix of C_d with row and column subscripts $1, \ldots, d$. It is readily seen that H_d is a Hankel matrix.

We will need the following fact of Conca [15, Lemma 2.1(a)]. For a subset I, we let $e(I)$ be its indicator vector.

▶ **Lemma 9.** *Let $\alpha = \alpha_1, \ldots, \alpha_t$ and $\beta = \beta_1, \ldots, \beta_t$ be sequences of positive integers. Then for all $k = 1, \ldots, t$,*

$$\sum_{I\subseteq[t],|I|=k} [\alpha + e(I)|\beta] = \sum_{J\subseteq[t],|J|=k} [\alpha|\beta + e(J)].$$

Proof. We denote by α_I the subsequence of α indexed by the set I, and by $\alpha^{\hat{I}}$ the subsequence indexed by the complement of I in $[t]$. We let $\alpha + 1 = \alpha_1 + 1, \ldots, \alpha_t + 1$.

First, expanding $[\alpha + e(I)|\beta]$ with respect to the rows indexed by $\alpha_I + 1$:

$$\sum_I [\alpha + e(I)|\beta] = \sum_I \sum_J (-1)^{|I|}(-1)^{|J|}[\alpha_I + 1|\beta_J][\alpha^{\hat{I}}|\beta^{\hat{J}}].$$

Since C_d is Hankel, $[\alpha_I + 1|\beta_J] = [\alpha_I|\beta_J + 1]$. So

$$\sum_I [\alpha + e(I)|\beta] = \sum_J \sum_I (-1)^{|I|}(-1)^{|J|}[\alpha_I|\beta_J + 1][\alpha^{\hat{I}}|\beta^{\hat{J}}] = \sum_J [\alpha|\beta + e(J)]$$

where in the final equality we recognize that the middle equation equals $[\alpha|\beta + e(J)]$ expanded with respect to the columns indexed by $\beta_J + 1$. ◀

▶ **Corollary 10.** $\mathrm{Diff}(\det H_d)$ *is contained in the space of maximal minors of* C_d*. Furthermore, the number of maximal minors of* C_d *is at most* φ^{2d}*.*

Proof. By Proposition 5, the space of partial derivatives of $\det H_d$ is spanned by the minors of C_d. We now show that the maximal minors of C_d span the space of minors of H_d. We will follow the proof of Corollary 2.2 in [15].

Let $[\alpha_1, \ldots, \alpha_t | \beta_1, \ldots, \beta_t]$ be a minor of C_d, where $t \leq d$ and $\alpha_1 = 1$. Note that any minor of H_d can be expressed in this form by shifting the corresponding submatrix in C_d up and to the right. We also assume α and β are strictly increasing sequences (if this is not the case then $[\alpha|\beta]$ vanishes). We now give an inductive procedure that expresses $[\alpha|\beta]$ as a linear combination of maximal minors.

If $\alpha_t = t$, then this minor is maximal and we are done. Otherwise, let h be the smallest index where $\alpha_h > h$. We now apply Lemma 9 to the minor $[\alpha_1, \ldots, \alpha_{h-1}, \alpha_h - 1, \ldots, \alpha_t - 1 | \beta]$ with $k = t - h + 1$. Doing so we obtain an expression for $[\alpha|\beta]$ as a linear combination of minors of C_d, each of which in turn have a larger "h." We conclude by induction.

Finally, note that the number of maximal minors of degree k is $|I(2d-k, k)| = \binom{2d-k}{k}$. Hence the total number of maximal minors equals $\sum_{k=0}^{d} \binom{2d-k}{k} < \varphi^{2d}$. In the last step we used the facts that the dth Fibonacci number satisfies $F_d = \sum_{k=0}^{\lfloor \frac{d-1}{2} \rfloor} \binom{d-k-1}{k}$, and that $F_d \leq \varphi^{d-1}$. ◀

The next observation was noted in [37, Theorem 43].

▶ **Corollary 11.**

$$\dim \mathrm{Diff}(\det H_d) \leq \sum_{i=0}^{d} \min \left\{ \binom{d+i}{d-i}, \binom{2d-i}{i} \right\} \leq (\sqrt{27}/2)^d \cdot d.$$

Proof. By Corollary 10, for $i \leq d/2$ the degree-i piece of $\mathrm{Diff}(H_d)$ has dimension at most $\binom{2d-i}{i}$. We conclude by the fact that $\mathrm{Diff}(H_d)_i \cong \mathrm{Diff}(H_d)_{d-i}$, i.e., the sequence of dimensions of space of partial derivatives is symmetric about $d/2$ [29, Definition 1.9]. The inequality on the right follows from Stirling's formula. ◀

▶ **Lemma 12.** *Given as input a linear combination* P *of maximal minors of* C_d *and* $l \in [n]$*, we can compute a representation for* $\frac{\partial P}{\partial x_l}$ *as a linear combination of maximal minors of* C_d *with* $\varphi^{2d} \operatorname{poly}(n, d)$ *arithmetic operations.*

Proof. For brevity we will write $[\alpha]$ for the minor $C_d[1, \ldots, |\alpha| | \alpha]$. Let $P = \sum_{k=0}^{d} \sum_{\beta \in I(2d-k,k)} c_\beta [\beta]$, and say that the coefficient of x_l in $(C_d)_{i,j}$ is $a_{i,j}^{(l)}$. As in Lemma 6,

$$\frac{\partial P}{\partial x_l} = \sum_{k=1}^{d} \sum_{\beta \in I(2d-k,k)} c_\beta \sum_{1 \leq i,j \leq k} (-1)^{i+\beta_j} a_{i,\beta_j}^{(l)} [1, \ldots, \widehat{i}, \ldots, k | \beta_1, \ldots, \widehat{\beta}_j, \ldots, \beta_k].$$

Note that the only minors with nonzero coefficient in this expression are of the form $[1, \ldots, \widehat{i}, \ldots, k|\gamma]$ for $k \in [d], i \in [k]$ and $\gamma \in I(2d-k, k-1)$. Call the coefficient of this minor in the above $b(i, \gamma)$. Then

$$b(i, \gamma) = \sum_{1 \leq j \leq k} \sum_{\substack{\beta \in I(2d-k,k) \\ \gamma = (\beta_1, \ldots, \widehat{\beta}_j, \ldots, \beta_k)}} c_\beta (-1)^{i+\beta_j} a_{i,\beta_j}^{(l)}.$$

The number of sequences β considered by the inner sum is at most $O(d^2)$, and hence $b(i,\gamma)$ can be computed with $O(d^3)$ additions and multiplications. We can thus compute

$$\frac{\partial P}{\partial x_l} = \sum_{k=1}^{d}\sum_{i=1}^{k}\sum_{\gamma\in I(2d-k,k-1)} b(i,\gamma)[1,\ldots,\widehat{i},\ldots,k|\gamma] \tag{3}$$

with $d^4\sum_{k=1}^{d}|I(2d-k,k-1)| \le \varphi^{2d}\operatorname{poly}(n,d)$ arithmetic operations. Note that this expresses $\frac{\partial P}{\partial x_l}$ as a linear combination of minors that are not necessarily maximal. We now fix this.

We first claim that for all $i\in[k]$ and $\beta\in I(2d-k,k-1)$,

$$[1,\ldots,\widehat{i},\ldots,k|\beta] = \sum_{J\subseteq[k-1],|J|=k-i}[e(J)+(1,\ldots,k-1)|\beta]$$

where $e(J)$ is the indicator vector of the set J. This holds since when $J=\{i,\ldots,k-1\}$, $e(J)+(1,\ldots,k-1)=(1,\ldots,\widehat{i},\ldots,k)$, and for all other J, $e(J)+(1,\ldots,k-1)$ will have a repeated value and hence $[e(J)+(1,\ldots,k-1)|\beta]=0$.

Given this claim, it follows from Lemma 9 that

$$[1,\ldots,\widehat{i},\ldots,k|\beta] = \sum_{J\subseteq[k-1],|J|=k-i}[\beta+e(J)],$$

and so letting Q_k be the degree-k part of Equation 3,

$$Q_k = \sum_{i=1}^{k+1}\sum_{\beta\in I(2d-k-1,k)} b(i,\beta)\sum_{J\subseteq[k],|J|=k+1-i}[\beta+e(J)].$$

We now show how to efficiently compute the coefficients of the maximal minors in this expression from the already computed $b(i,\gamma)$'s.

Let $0\le k\le d-1$ be fixed. For $\beta\in I(2d-k-1,k)$ and integers i,j where $0\le i\le j\le k$, let $D(\beta,i,j,k)\subseteq\{0,1\}^k$ be the set of binary vectors of length k containing exactly i ones, whose last $k-j$ entries are zero, and whose summation with β is strictly increasing everywhere except possibly at positions j and $j+1$ (that is, we may have $w_j+\beta_j=w_{j+1}+\beta_{j+1}$). Define

$$A^k(i,j) \coloneqq \sum_{\beta\in I(2d-k-1,k)} b(k+1-i,\beta)\sum_{w\in D(\beta,i,j,k)}[\beta+w].$$

Note that $\sum_{i=0}^{k}A^k(i,k)=Q_k$, so it suffices to show how to compute $A^k(i,j)$ for all i,j. We do this with a dynamic program. When we store $A^k(i,j)$ we will store all coefficients of maximal minors arising in the above definition, even though such a minor might contain a repeated column and hence equal zero. The minors arising in this definition are specified by sequences of length k with maximum value $2d-k$ that are strictly increasing everywhere but possibly at one position. Hence the number of such sequences is at most $k\binom{2d-k}{k}$.

For the base cases, we have

$$A^k(0,j) = \sum_{\beta\in I(2d-k-1,k)} b(k+1,\beta)[\beta],$$

$$A^k(i,i) = \sum_{\beta\in I(2d-k-1,k)} b(k+1-i,\beta)[\beta+e(\{1,\ldots,i\})].$$

Now suppose we have computed $A^k(i, j-1)$ and $A^k(i-1, j-1)$. Then

$$\begin{aligned} A^k(i,j) &= \sum_{\beta \in I(2d-k-1,k)} b(k+1-i,\beta) \left(\sum_{\substack{w \in B(\beta,i,j,k),\\ w_j=0}} [\beta + w] + \sum_{\substack{w \in D(\beta,i,j,k),\\ w_j=1}} [\beta + w] \right) \\ &= \sum_{\beta \in I(2d-k-1,k)} b(k+1-i,\beta) \sum_{\substack{w \in D(\beta,i,j-1,k),\\ \beta+w \text{ is strictly increasing}}} [\beta + w] \\ &\quad + \sum_{\beta \in I(2d-k-1,k)} b(k+1-i,\beta) \sum_{w \in D(\beta,i-1,j-1,k)} [\beta + w + e(\{j\})]. \end{aligned}$$

The first part of the sum can be computed from $A^k(i, j-1)$ by setting the coefficient of any maximal minor with a repeated column equal zero, and the second sum can be computed from $A^k(i-1, j-1)$ by setting the coefficient of $[\beta]$ to that of $[\beta - e(\{j\})]$. Hence $A^k(i, j)$ can be computed with $O(k\binom{2d-k}{k})$ arithmetic operations. It follows that we can represent $\frac{\partial P}{\partial x_l} = \sum_{i=0}^{d-1} Q_i$ in the space of maximal minors using $\varphi^{2d} \operatorname{poly}(n, d)$ arithmetic operations. ◀

With this we have the following analog of Theorem 7. We omit the proof as it is almost exactly the same, we just work in the space of maximal minors rather than minors, using Lemma 12 to differentiate instead of Lemma 6.

▶ **Theorem 13.** *Let C be a skew arithmetic circuit computing $g \in \mathcal{S}_d^n$, and let $X = (\ell_{i,j})_{i,j\in[d]}$ be a symbolic Hankel matrix with entries in $\mathcal{S}_1^n$. Then we can compute $\langle \det X, g \rangle$ with $\varphi^{2d}|C| \operatorname{poly}(n, d)$ arithmetic operations. Here $\varphi := \frac{1+\sqrt{5}}{2}$ is the golden ratio.*

▶ **Corollary 14.** *Let G be a graph on n vertices. We can decide in $\varphi^{2d} \operatorname{poly}(n)$ time if G contains a simple cycle of length d.*

Proof. Let $V \in \mathbb{Q}^{d\times n}$ be the Vandermonde matrix with $V_{i,j} = j^i$, and $X = V \cdot \operatorname{diag}(x_1, \ldots, x_n) \cdot V^{\mathrm{T}}$. By the same argument of Proposition 8, $\langle \det X, \operatorname{tr}(A_G^d) \rangle \neq 0$ if and only if G contains a simple cycle of length d. Note that the (i, j)th entry in X equals $\sum_{k=1}^n k^{i+j} x_k$, and therefore X is Hankel. We conclude by applying Theorem 13 to compute $\langle \det X, \operatorname{tr}(A_G)^d \rangle$, as $\operatorname{tr}(A_G^d)$ can be computed by a skew circuit of size $\operatorname{poly}(n)$. ◀

▶ Remark 15. This algorithm extends to detecting subgraphs of bounded pathwidth on d vertices by using the construction of the subgraph generating polynomial given in [12, Appendix B].

3 Applications

In this section we give our applications of Theorems 1 and 2.

▶ **Corollary 16.** *Given matrices $A_1, \ldots, A_n \in \mathbb{Q}^{d\times d}$, we can decide if their span contains an invertible matrix in time $4^d \operatorname{poly}(N)$, where N denotes the size of the input.*

Proof. Let $X = \sum_{i=1}^n x_i A_i$. First note that $\operatorname{span}(A_1, \ldots, A_n)$ contains an invertible matrix if and only if $\det X \not\equiv 0$. Writing $\det X = \sum_{\alpha\in[d]^n} c_\alpha x^\alpha$ for some coefficients c_α (at least one of which will be nonzero iff the answer is "yes"), observe that $\langle \det X, \det X \rangle = \sum_\alpha c_\alpha^2 \alpha!$. It follows that $\operatorname{span}(A_1, \ldots, A_n)$ contains an invertible matrix if and only if this quantity is nonzero.

It is shown in [35] that $\det_d$ can be expressed as a skew circuit of size $O(d^4)$, and the construction of this circuit is linear in the output size. Hence we can construct a circuit for $\det X$ by replacing the input variable x_{ij} in this circuit with the (i,j)th entry of X. The theorem follows by applying Theorem 7 to the matrix X and this circuit, noting that all numbers have bit-length $\mathrm{poly}(N)$ throughout the algorithm. ◀

▶ **Corollary 17.** *Suppose we are given a matrix $A \in \mathbb{Q}^{km \times kn}$, where $n \geq m$, representing a matroid M with groundset $[kn]$, and a partition π of $[kn]$ into parts of size k. Then we can decide if the union of any m parts in π are independent in M in time $4^{km}\,\mathrm{poly}(N)$, where N is the size of the input.* [3]

Proof. Let $g \coloneqq (\sum_{S \in \pi} \prod_{i \in S} x_i)^m$. It is easily seen that the square-free monomials appearing in g correspond to unions of m elements in π, and that g can be computed by a skew circuit of size $\mathrm{poly}(n)$. Next, let $X = A \cdot \mathrm{diag}(x_1, \ldots, x_n) \cdot A^{\mathrm{T}}$. By the Cauchy-Binet formula,

$$\det X = \sum_{S \in \mathrm{Bases}(M)} \det(B_S)^2 \prod_{i \in S} x_i,$$

Note that the same monomial appears in the expansion of g and $\det X$ exactly when there is such an independent set in M, and then since g and $\det X$ have non-negative coefficients, $\langle \det X, g \rangle \neq 0$ if and only if an independent set in M is the union of m blocks in π. We conclude by applying Theorem 7. ◀

Using the same trick as in [36] we can use Corollary 17 to solve the k-matroid intersection problem.

▶ **Corollary 18** (k-Matroid Intersection). *Suppose we are given matrices $B_1, \ldots, B_k \in \mathbb{Q}^{m \times n}$ representing matroids $M_1, \ldots, M_k$ with the common groundset $[n]$. We can decide if $M_1, \ldots, M_k$ share a common base in time $4^{km}\,\mathrm{poly}(N)$, where N is the size of the input.*

Proof. Let $M = \bigoplus_{i=1}^{k} B_k$ be the direct sum of the input matrices. We first partition $[kn]$ into n parts of size k as follows: for $i \in [n]$, let $S_i \coloneqq \{i, i+n, i+2n, \ldots, i+kn\}$. If a union of m of the blocks $S_1, \ldots, S_n$ are independent in the matroid represented by M, then $M_1, \ldots, M_k$ share a common base. Conversely, if these matroids share a common base, some union of the S_i's are independent in the matroid represented by M. We conclude by applying Corollary 17 to the matrix $M \in \mathbb{Q}^{km \times kn}$ and the partition $S_1, \ldots, S_n$. ◀

Finally, we have our applications of Theorem 13. These follow immediately by a reduction given in [11, Theorem 1] to the following "square-free monomial detection" algorithm.

▶ **Corollary 19.** *Let $g \in \mathbb{Q}[x_1, \ldots, x_n]_d$ be a homogeneous degree-d polynomial with nonnegative coefficients, computed by a skew arithmetic circuit C. Given as input C, we can decide in deterministic $\varphi^{2d}|C|\,\mathrm{poly}(n)$ time whether g contains a degree-d square-free monomial.*

Proof. Let $V \in \mathbb{Q}^{d \times n}$ be the Vandermonde matrix with $V_{i,j} = j^i$, and $X = V \cdot \mathrm{diag}(x_1, \ldots, x_n) \cdot V^{\mathrm{T}}$. By the Cauchy-Binet formula,

$$\det X = \sum_{S \subseteq \binom{[n]}{d}} \det(V_S)^2 \prod_{i \in S} x_i.$$

[3] Similar to the Theorem 1.1 of [36], this algorithm can be modified to work for finite fields of sufficiently large size with the addition of randomness.

Since any d columns in V are linearly independent, $\det(V_S)^2 > 0$ for all S. It follows that since g has nonnegative coefficients, $\langle \det X, g\rangle \neq 0$ if and only if g contains a square-free monomial. Note that the (i,j)th entry in X equals $\sum_{k=1}^{n} k^{i+j} x_k$, and therefore X is Hankel. The theorem follows by invoking Theorem 13. ◀

By [11, Theorem 1], we then have:

▶ **Corollary 20.** *The following problems admit deterministic algorithms running in time* $\varphi^{2d}\operatorname{poly}(n)$*:*

1. *Deciding whether a given directed n-vertex graph has a directed spanning tree with at least d non-leaf vertices,*
2. *Deciding whether a given edge-colored, directed n-vertex graph has a directed spanning tree containing at least d colors,*
3. *Deciding whether a given planar, edge-colored, directed n-vertex graph has a perfect matching containing at least d colors.*

4 A general algorithm: the apolar algebra of the determinant

4.1 Algebraic preliminaries

Let $\mathcal{R}^n := \mathbb{Q}[\partial_1, \ldots, \partial_n]$ be the ring of partial differential operators. Elements of this ring are just multivariate polynomials in the variables $\partial_1, \ldots, \partial_n$. For an n-tuple $\alpha \in \mathbb{N}^n$, we let ∂^α be the monomial $\partial_1^{\alpha_1} \cdots \partial_n^{\alpha_n}$, and let $|\alpha| = \sum_{i=1}^{n} \alpha_i$. For $h \in \mathcal{R}$ and $f \in \mathcal{S}$, we denote by $h \circ f$ the result of applying the differential operator h to f. For example,

$$(3 \cdot \partial_1\partial_2 + \partial_1^2) \circ x_1^2 x_2 = 3 \cdot \partial_1\partial_2 \circ x_1^2 x_2 + \partial_1^2 \circ x_1^2 x_2 = 6x_1 + 2x_2.$$

When h and f are homogeneous of the same degree, $h \circ f$ is a scalar. In this case $f(\partial_1, \ldots, \partial_n) \circ g = \langle f, g\rangle$, so computing $h \circ f$ is equivalent to computing the apolar inner product.

▶ **Definition 21.** *For $f \in \mathcal{S}_d^n$, we define* $\operatorname{Ann}(f)$ *as the ideal of elements in $\mathcal{R}^n$ annihilating f under differentiation. We define the* apolar algebra $\mathcal{A}_f$ *as the quotient* $\mathcal{R}^n / \operatorname{Ann}(f)$.

In other words, $\mathcal{A}_f$ is the ring of representatives of equivalence classes of differential operators subject to the equivalence relation $\sim$, where $h \sim h'$ if and only if $h \circ f = h' \circ f$. It follows that there is a vector space isomorphism $\mathcal{J}$ between $\mathcal{A}_f$ and $\operatorname{Diff}(f)$, sending $h \in \mathcal{A}_f$ to $h \circ f$. In particular, $(\mathcal{A}_f)_i \cong \operatorname{Diff}(f)_{d-i}$, where we denote by $(\mathcal{A}_f)_i$ the vector space of degree-i elements in $\mathcal{A}_f$.

▶ Remark 22. Multiplication in $\mathcal{A}_f$ corresponds to differentiating by f: for $h_1, h_2 \in \mathcal{A}_f$, $\mathcal{J}(h_1 \cdot h_2) = h_1 \circ (h_2 \circ f)$. It follows that Lemmas 6 and 12 are algorithms for multiplication by ∂_l in $\mathcal{A}_{\det X}$, with respect to the spanning sets of $\mathcal{A}_{\det X}$ given by the inverse images of the minors (or maximal minors) of X.

▶ **Definition 23.** $\Lambda(\mathbb{Q}^n) \otimes \Lambda(\mathbb{Q}^n)$ *is the algebra with the basis of formal variables* $\{(I|J) : I, J \subseteq [n]\}$*, and where multiplication is given by extending bilinearly the rule*

$$(I|J) \cdot (I'|J') = \begin{cases} 0 \text{ if } I \cap I' \neq \emptyset \text{ or } J \cap J' \neq \emptyset, \\ \operatorname{sgn}(I, I') \operatorname{sgn}(J, J')(I \cup I' | J \cup J') \text{ else} \end{cases}$$

where $\operatorname{sgn}(I, I') = (-1)^{|\{i \in I, i' \in I' : i > i'\}|}$.

▶ **Lemma 24.** *$\mathcal{A}_{\det_n}$ is isomorphic to the subalgebra of $\Lambda(\mathbb{Q}^n) \otimes \Lambda(\mathbb{Q}^n)$ generated by $\{v \otimes v : v \in \Lambda(\mathbb{Q}^n)\}$.*

Proof. We first claim that the set of monomials of the form $(I|J) \coloneqq \partial_{I_1,J_1} \cdots \partial_{I_k,J_k}$, where $I, J \in I(n,k)$ and $0 \leq k \leq n$, are a basis for $\mathcal{A}_{\det_n}$. This follows from the fact that there are $\binom{2n}{n}$ such monomials, $\dim \mathrm{Diff}(\det_n) = \binom{2n}{n}$, and the polynomials of the form $(I|J) \circ \det_n$ are linearly independent. The latter claim can be seen by noting that if $(I|J) \neq (I'|J')$, $(I|J) \circ \det_n$ and $(I'|J') \circ \det_n$ have disjoint sets of monomials appearing in their expansion.

Next we claim that the product of two basis elements $(I|J)$ and $(I'|J')$ is given by the rule

$$(I|J) \cdot (I'|J') = \begin{cases} 0 \text{ if } I \cap I' \neq \emptyset \text{ or } J \cap J' \neq \emptyset, \\ \operatorname{sgn}(I, I') \operatorname{sgn}(J, J')(I \cup I'|J \cup J') \text{ else} \end{cases}$$

where $\operatorname{sgn}(I, I')$ denotes the sign of the permutation that brings the sequence $I_1, \ldots, I_{k'}$ into increasing order, and $I \cup I'$ denotes the resulting sorted sequence. Indeed, if $I \cap I' \neq \emptyset$, then $(I|J)(I'|J')$ is divisible by the product of two variables that have the same first (row) index. But then $(I|J)(I'|J') \circ \det_n = 0$, since all monomials in the determinant have different row indices. The second case follows from the fact that for $I, J \in I(n,k)$ and $\tau \in \mathfrak{S}_k$, $(I|J) \circ \det_n = \operatorname{sgn} \tau^{-1} \cdot (\tau(I)|J) \circ \det_n$, which follows from the Leibniz formula for the determinant.

It follows from these observations that $\mathcal{A}_{\det_n}$ is the claimed subalgebra of $\Lambda(\mathbb{Q}^n) \otimes \Lambda(\mathbb{Q}^n)$. ◀

▶ **Theorem 25.** *Let C be an arithmetic circuit computing $g \in \mathcal{S}_d^n$, and let $X = (\ell_{i,j})_{i,j \in [d]}$ be a symbolic matrix with entries in $\mathcal{S}_1^n$. Then we can compute $\langle \det X, g \rangle$ with $2^{\omega d}|C| \operatorname{poly}(n,d)$ arithmetic operations, where $\omega < 2.373$ is the exponent of matrix multiplication.*

Proof. Assume that the entries of X are linearly independent. If this is not the case, add a new variable $x_{i,j}$ to the (i,j)th entry of X. Note that since these variables do not appear in g, this does not change the value of $\langle \det X, g \rangle$.

Let $A : \mathcal{S}_1^n \to \mathbb{Q}[y_{1,1}, \ldots, y_{d,d}]_1$ be the linear transformation sending the linear form $X_{i,j}$ to the variable $y_{i,j}$. By [19, Corollary 3.1], $\langle \det X, g \rangle = \langle \det Y, g((A^{-1})^T(x_1, \ldots, x_n)) \rangle$, where $Y_{i,j} = y_{i,j}$. So we will first modify C by applying the linear transformation $(A^{-1})^T$ to the input gates, obtaining a new circuit C'. We then will evaluate C' over $\mathcal{A}_{\det Y}$, using the monomial basis of Lemma 24. Additions in $\mathcal{A}_{\det Y}$ can be done in time linear in the number of basis elements, which is bounded above by 4^d. By identifying $\mathcal{A}_{\det_d}$ with the subalgebra of diagonal elements in $\Lambda(\mathbb{Q}^d) \otimes \Lambda(\mathbb{Q}^d)$, and using the $2^{\omega d} \operatorname{poly}(d)$-time algorithm of [42, Theorem 14] for multiplying elements in $\Lambda(\mathbb{Q}^d) \otimes \Lambda(\mathbb{Q}^d)$, we can multiply elements in $\mathcal{A}_{\det_d}$ with $2^{\omega d} \operatorname{poly}(d)$ operations. Note that the highest degree element in this basis is $q \coloneqq \partial_{1,1}\partial_{2,2} \cdots \partial_{d,d}$. The output gate of of C' therefore equals $(A^{-1})^T \cdot g \bmod \operatorname{Ann}(\det Y) = \frac{\langle \det X, g \rangle q}{\langle \det Y, q \rangle} = \langle \det X, g \rangle q$. ◀

5 Totally Multilinear Polynomials and Previous Methods

We now explain how previous algorithms relate to answers to Question 1. Recall for comparison that Proposition 10 implies that $B(n,d) \leq O(2.6^d)$, and is witnessed by the polynomial

$$f = \sum_{1 \leq i_1 < \cdots < i_d \leq n} \prod_{j<k} (i_j - i_k)^2 \prod_{j=1}^{d} x_{i_j}.$$

Furthermore, we showed in Lemma 12 that given an element of $\mathrm{Diff}(f)$, the linear map $\partial_i : \mathrm{Diff}(f) \to \mathrm{Diff}(f)$ could be computed in time $\varphi^{2d}\,\mathrm{poly}(n)$ with respect to the spanning set of maximal minors.

5.1 Color coding

Let $\mathcal{F}$ be an (n, d) *perfect hash family*, that is, a family of functions from $[n]$ to $[d]$ such that for any subset of $[n]$ of size d, some function in $\mathcal{F}$ is injective on $[d]$. It can be shown by a straightforward random argument that there exists such an $\mathcal{F}$ with size at most $e^d\,\mathrm{poly}(n)$ [1].

Now for $\pi \in \mathcal{F}$ and $i \in [d]$, define the linear forms $\ell_{\pi,i} = \sum_{j \in \pi^{-1}(i)} x_j$. Let $f = \sum_{\pi \in \mathcal{F}} \prod_{i=1}^{d} \ell_{\pi,i}$. Then from the definition of a perfect hash family it follows that $f \in \mathcal{T}_{n,d}$. As the space of partial derivatives of a product of d linear forms has dimension at most 2^d, $\dim \mathrm{Diff}(f) \leq |\mathcal{F}| 2^d \leq (2e)^d\,\mathrm{poly}(n)$.

Explicitly, $\mathrm{Diff}(f)$ is spanned by $\prod_{i \in S} \ell_{\pi,i}$ for all $S \subseteq [d]$ and $\pi \in \mathcal{F}$. In addition, the operator ∂_j can efficiently be computed with respect to this spanning set; this follows from the fact that $\partial_j \prod_{i \in S} \ell_{\pi,i} = \prod_{i \in S : j \notin \pi^{-1}(i)} \ell_{\pi,i}$ (i.e., the matrix representing ∂_i is sparse). Hence color coding can be interpreted in our framework as using the polynomial f.

5.2 Waring rank

In [37] an improvement to the color-coding construction was given. Let $\mathcal{F}$ be an $(n, d, 1.55d)$-*splitter*, that is, a family of functions from $[n]$ to $[1.55d]$ such that for any subset S of $[1.55d]$ of size d, there exists some $\pi \in \mathcal{F}$ that is injective on S.

Let $e_{n,d}$ denote the elementary symmetric polynomial of degree d in n variables. For $\pi \in \mathcal{F}$ and $i \in [1.55d]$, define the linear forms $\ell_{\pi,i} = \sum_{j \in \pi^{-1}(i)} x_j$. Let

$$f = \sum_{\pi \in \mathcal{F}} e_{1.55d,d}(\ell_{\pi,1}, \ldots, \ell_{\pi,1.55d}).$$

Since $\mathcal{F}$ is a splitter it follows that $f \in \mathcal{T}_{n,d}$. By using bounds on $|\mathcal{F}|$ and the Waring rank of $e_{n,d}$, it was shown in [37][Theorem 7] that the Waring rank of f is at most $4.075^d\,\mathrm{poly}(n)$. Since in general $\dim \mathrm{Diff}(f) \leq \mathbf{R}(f)/(d+1)$, we conclude that $B(n,d) \leq \dim \mathrm{Diff}(f) \leq 4.075^d\,\mathrm{poly}(n)$.

5.3 Abelian 2 Groups

Let k be a field of characteristic 2 of size at least n, and let A be a $d \times n$ matrix, any d columns of which are linearly independent. It was shown in Section 3.3 of [37] that the polynomial $f = \sum_{S \in \binom{[n]}{d}} \det(A_S)^2 \prod_{i \in S} x_i$ has Waring rank at most $2^d - 1$, and hence $\dim \mathrm{Diff}(f) \leq (d+1)(2^d - 1)$.

6 Further questions

1. We showed that $2^d \leq B(n,d) < (\sqrt{27}/2)^d d$. Can these bounds be improved?
2. Let X be a generic Hankel matrix. Can the bound $\dim \mathrm{Diff}(\det X) \leq (\sqrt{27}/2)^d d$ be improved? We suspect that the base of the exponent is optimal.
3. Let X be a generic Hankel matrix. Can the linear map $A_i : \mathrm{Diff}(\det X) \to \mathrm{Diff}(\det X)$ given by differentiation with respect to the any variable x_i be computed in linear time with respect to a spanning set of size $(\sqrt{27}/2)^d d$ (rather than φ^{2d})?
4. Do the methods of [21, 43, 40] have an interpretation in our framework?

A Linear-Time $n^{0.4}$-Approximation for Longest Common Subsequence

Abstract

We consider the classic problem of computing the Longest Common Subsequence (LCS) of two strings of length n. While a simple quadratic algorithm has been known for the problem for more than 40 years, no faster algorithm has been found despite an extensive effort. The lack of progress on the problem has recently been explained by Abboud, Backurs, and Vassilevska Williams [FOCS'15] and Bringmann and Künnemann [FOCS'15] who proved that there is no subquadratic algorithm unless the Strong Exponential Time Hypothesis fails. This major roadblock for getting faster exact algorithms has led the community to look for subquadratic *approximation* algorithms for the problem.

Yet, unlike the edit distance problem for which a constant-factor approximation in almost-linear time is known, very little progress has been made on LCS, making it a notoriously difficult problem also in the realm of approximation. For the general setting (where we make no assumption on the length of the optimum solution or the alphabet size), only a naive $O(n^{\varepsilon/2})$-approximation algorithm with running time $\widetilde{O}(n^{2-\varepsilon})$ has been known, for any constant $0 < \varepsilon \leq 1$. Recently, a breakthrough result by Hajiaghayi, Seddighin, Seddighin, and Sun [SODA'19] provided a linear-time algorithm that yields a $O(n^{0.497956})$-approximation in expectation; improving upon the naive $O(\sqrt{n})$-approximation for the first time.

In this paper, we provide an algorithm that in time $O(n^{2-\varepsilon})$ computes an $\widetilde{O}(n^{2\varepsilon/5})$-approximation with high probability, for any $0 < \varepsilon \leq 1$. Our result (1) gives an $\widetilde{O}(n^{0.4})$-approximation in linear time, improving upon the bound of Hajiaghayi, Seddighin, Seddighin, and Sun, (2) provides an algorithm whose approximation scales with any subquadratic running time $O(n^{2-\varepsilon})$, improving upon the naive bound of $O(n^{\varepsilon/2})$ for any ε, and (3) instead of only in expectation, succeeds with high probability.

1 Introduction

The longest common subsequence (LCS) of two strings x and y is the longest string that appears as a subsequence of both strings. The length of the LCS of x and y, which we denote by $L(x, y)$, is one of the most fundamental measures of similarity between two strings and has drawn significant interest in last five decades, see, e.g. [35, 6, 26, 27, 30, 32, 10, 31, 11, 36, 22, 16, 28, 2, 19, 4, 20, 3, 33, 34, 24]. On strings of length n, the LCS problem can be solved exactly in quadratic time $O(n^2)$ using a classical dynamic programming approach [35]. Despite an extensive line of research the quadratic running time has been improved only by logarithmic factors [30]. This lack of progress is explained by a recent result showing that any truly subquadratic algorithm for LCS would falsify the Strong Exponential Time Hypothesis (SETH); this has been proven independently by Abboud et al. [2] and by Bringmann and Künnemann [19]. Further work in this direction shows that even a high polylogarithmic speedup for LCS would have surprising consequences [4, 3]. For the closely related edit distance the situation is similar, as the classic quadratic running time can be improved by logarithmic factors, but any truly subquadratic algorithm would falsify SETH [12].

These strong hardness results naturally bring up the question whether LCS or edit distance can be efficiently *approximated* (namely, whether an algorithm with truly subquadratic time $O(n^{2-\varepsilon})$ for any constant $\varepsilon > 0$, can produce a *good* approximation in the worst-case). In the last two decades, significant progress has been made towards designing efficient approximation algorithms for edit distance [14, 13, 15, 9, 7, 21, 23, 29, 17]; the latest achievement is a constant-factor approximation in almost-linear[1] time [8].

For LCS the picture is much more frustrating. The LCS problem has a simple $\widetilde{O}(n^{\varepsilon/2})$-approximation algorithm with running time $O(n^{2-\varepsilon})$ for any constant $0 < \varepsilon < 1$, and it has a trivial $|\Sigma|$-approximation algorithm with running time $O(n)$ for strings over alphabet Σ. Yet, improving upon these naive bounds has evaded the community until very recently, making LCS a notoriously hard problem to approximate. In 2019, Rubinstein et al. [33] presented a subquadratic-time $O(\lambda^3)$-approximation, where λ is the ratio of the string length to the length of the optimal LCS. For binary alphabet, Rubinstein and Song [34] recently improved the 2-approximation. In the general case (where λ and the alphabet size are arbitrary), the naive $O(\sqrt{n})$-approximation in near-linear[2] time was recently beaten by Hajiaghayi et al. [24], who designed a linear-time algorithm that computes an $O(n^{0.497956})$-approximation *in expectation*.[3] Nonetheless, the gap between the upper bound provided by Hajiaghayi et al. [24] and the recent results on hardness of approximation [1, 5] remains huge.

1.1 Our Contribution

We present a randomized $\widetilde{O}(n^{0.4})$-approximation for LCS running in linear time $O(n)$, where the approximation guarantee holds *with high probability*[4]. More generally, we obtain a tradeoff between approximation guarantee and running time: For any $0 < \varepsilon \leq 1$ we achieve approximation ratio $\widetilde{O}(n^{2\epsilon/5})$ in time $O(n^{2-\varepsilon})$. Formally we prove the following:

---

[1] By *almost-linear* we mean time $O(n^{1+\varepsilon})$ for a constant $\varepsilon > 0$ that can be chosen arbitrarily small.

[2] By *near-linear* we mean time $\widetilde{O}(n)$, where $\widetilde{O}$ hides polylogarithmic factors in n.

[3] While the SODA proceedings version of [24] claimed a high probability bound, the newer corrected Arxiv version [25] only claims that the algorithm outputs an $O(n^{0.497956})$-approximation in expectation. Personal communications with the authors confirm that the result indeed holds only in expectation, see also Remark 14.

[4] We say that an event happens *with high probability* (w.h.p.) if it has probability at least $1 - n^{-c}$, where the constant $c > 0$ can be chosen in advance.

▶ **Theorem 1.** *There is a randomized algorithm that, given strings x, y of length $n \geq 1$ and a time budget $T \in [n, n^2]$, with high probability computes a multiplicative $\widetilde{O}(n^{0.8}/T^{0.4})$-approximation of the length of the LCS of x and y in time $O(T)$.*

The improvement over the state of the art can be summarized as follows:

1. An improved approximation ratio for the linear time regime: from $O(n^{0.497956})$ [24] to $\widetilde{O}(n^{0.4})$;
2. The first algorithm which improves upon the naive bound *with high probability*[4];
3. A generalization to running time $O(n^{2-\varepsilon})$, breaking the naive approximation ratio $\widetilde{O}(n^{\varepsilon/2})$ in general.

2 Technical Overview

We combine classic exact algorithms for LCS with different subsampling strategies to develop several algorithms that work in different regimes of the problem. A combination of these algorithms then yields the full approximation algorithm.

Our Algorithm 1 covers the regime of short LCS, i.e., when the LCS has length at most n^γ for an appropriate constant $\gamma < 1$ depending on the running time budget. In this regime, we decrease the length of the string x by subsampling. This naturally allows to run classic exact algorithms for LCS on the subsampled string x (which now has significantly smaller size) and the original string y, while not deteriorating the LCS between the two strings too much.

For the remaining parts of the algorithm, the strings x and y are split into substrings $x_1, \ldots, x_{n/m}$ and $y_1, \ldots, y_{n/m}$ of length $m = n/\sqrt{T}$ where T denotes the total running time budget. For any block (i, j) we write L_{ij} for the length of the LCS of x_i and y_j. We call a set $\mathcal{S} = \{(i_1, j_1), \ldots, (i_k, j_k)\}$ with $i_1 < \ldots < i_k$ and $j_1 < \ldots < j_k$ a *block sequence*. Since we can assume the LCS of x and y to be long, it follows that there exists a good "block-aligned LCS", more precisely there exists a block sequence with large LCS sum $\sum_{(i,j)\in\mathcal{S}} L_{ij}$.

Now, a natural approach is to compute estimates $0 \leq \widetilde{L}_{ij} \leq L_{ij}$ for all blocks (i, j) and to determine the maximum sum $\widetilde{L} = \sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ over all block sequences $\mathcal{S}$. Once we have estimates $\widetilde{L}_{ij}$, the maximum $\widetilde{L}$ can be computed by dynamic programming in time $O((n/m)^2)$, which is $O(T)$ for our choice of m. In the following we describe three different strategies to compute estimates $\widetilde{L}_{ij}$. The major difficulty is that on average per block (i, j) we can only afford time $\widetilde{O}(1)$ to compute an estimate $\widetilde{L}_{ij}$.

The first strategy focuses on *matching pairs*. A matching pair of strings s, t is a pair of indices (a, b) such that $s[a] = t[b]$. We write M_{ij} for the number of matching pairs of the strings x_i and y_j. Our Algorithm 2 works well if some block sequence $\mathcal{S}$ has a large total number of matching pairs $\mu = \sum_{(i,j)\in\mathcal{S}} M_{ij}$. Here the key observation (Lemma 7) is that for each block (i, j) there exists a symbol that occurs at least $\frac{M_{ij}}{2m}$ times in both x_i and y_j. If M_{ij} is large, matching this symbol provides a good approximation for L_{ij}. Unfortunately, since we can afford only $\widetilde{O}(1)$ running time per block, finding a frequent symbol is difficult. We develop as a new tool an algorithm that w.h.p. finds a frequent symbol in each block with an above-average number of matching pairs, see Lemma 8.

For our remaining two strategies we can assume the optimal LCS L to be large and μ to be small (i.e., every block sequence has a small total number of matching pairs). In our Algorithm 3, we analyze the case where $\lambda = \sum_{i,j} L_{ij}$ is large. Here we pick some diagonal and run our basic approximation algorithm on each block along the diagonal. Since there are $O(n/m)$ diagonals, an above-average diagonal has a total LCS of $\Omega(\lambda/(n/m))$. If λ is

large then this provides a good estimation of the LCS. The main difficulty is how to find an above-average diagonal. A random diagonal has a good LCS sum in expectation, but not necessarily with good probability. Our solution is a non-uniform sampling, where we first test random blocks until we find a block with large LCS, and then choose the diagonal containing this seed block. This sampling yields an above-average diagonal with good probability.

Recall that there always exists a block sequence $\mathcal{G}$ with large LCS sum (see Lemma 11). The idea of our Algorithm 4 is to focus on a uniformly random subset of all blocks, where each block is picked with probability p. Then on each picked block we can spend more time (specifically time $\widetilde{O}(1/p)$) to compute an estimate $\widetilde{L}_{ij}$. Moreover, we still find a p-fraction of $\mathcal{G}$. We analyze this algorithm in terms of μ and λ (the choice of p depends on these two parameters) and show that it works well in the complementary regimes of Algorithms 1-3.

Comparison with the Previous Approach of Hajiaghayi et al. [24]. The general approach of splitting x and y into blocks and performing dynamic programming over estimates $\widetilde{L}_{ij}$ was introduced by Hajiaghayi et al. [24]. Moreover, our Algorithm 1 has essentially the same guarantees as [24, Algorithm 1], but ours is a simple combination of generic parts that we reuse in our later algorithms, thus simplifying the overall algorithm.

Our Algorithm 2 follows the same idea as [24, Algorithm 3], in that we want to find a frequent symbol in x_i and y_j and match only this symbol to obtain an estimate $\widetilde{L}_{ij}$. Hajiaghayi et al. find a frequent symbol by picking a *random* symbol σ in each block x_i, y_j; in expectation σ appears at least $\frac{M_{ij}}{2m}$ times in x_i and y_j. In order to obtain with high probability guarantees, we need to develop a new tool for finding frequent symbols not only in expectation but even with high probability, see Lemma 8 and Remark 14.

The remainder of the approach differs significantly; our Algorithms 3 and 4 are very different compared to [24, Algorithms 2 and 4]. In the following we discuss their ideas. In [24, Algorithm 2], they argue about the alphabet size, splitting the alphabet into frequent and infrequent letters. For infrequent letters the total number of matching pairs is small, so augmenting a classic exact algorithm by subsampling works well. Therefore, they can assume that every letter is frequent and thus the alphabet size is small. We avoid this line of reasoning. Finally, [24, Algorithm 4] is their most involved algorithm. Assuming that their other algorithms have failed to produce a sufficiently good approximation, they show that each part x_i and y_j can be turned into a *semi-permutation* by a little subsampling. Then by leveraging Dilworth's theorem and Tuŕan's theorem they show that most blocks have an LCS length of at least $n^{1/6}$; this can be seen as a *triangle inequality* for LCS and is their most novel contribution. This results in a highly non-trivial algorithm making clever use of combinatorial machinery.

We show that these ideas can be completely avoided, by instead relying on classic algorithms based on matching pairs augmented by subsampling. Specifically, we replace their combinatorial machinery by our Algorithms 3 and 4 described above (recall that Algorithm 3 considers a non-uniformly sampled random diagonal while Algorithm 4 subsamples the set of blocks to be able to spend more time per block). We stress that our solution completely avoids the concept of semi-permutation or any heavy combinatorial machinery as used in [24, Algorithm 4], while providing a significantly improved approximation guarantee.

Organization of the Paper. Section 3 introduces notation and a classical algorithm by Hunt and Szymanski. In Section 4 we present our new tools, in particular for finding frequent symbols. Section 5 contains our main algorithm, split into four parts that are presented in Sections 5.1, 5.3, 5.4, and 5.5, and combined in Section 5.6.

3 Preliminaries

For $n \in \mathbb{N}$ we write $[n] = \{1, 2, \ldots, n\}$. By the notation $\widetilde{O}$ and $\widetilde{\Omega}$ we hide factors of the form polylog(n). We use "with high probability" (w.h.p.) to denote probabilities of the form $1 - n^{-c}$, where the constant $c > 0$ can be chosen in advance.

String Notation. A string x over alphabet Σ is a finite sequence of letters in Σ. We denote its length by $|x|$ and its i-th letter by $x[i]$. We also denote by $x[i..j]$ the substring consisting of letters $x[i] \ldots x[j]$. For any indices $i_1 < i_2 < \ldots < i_k$ the string $z = x[i_1] \ldots x[i_k]$ forms a *subsequence* of x. For strings x, y we denote by $L(x, y)$ the length of the longest common subsequence of x and y. In this paper we study the problem of approximating $L(x, y)$ for given strings x, y of length n. We focus on the length $L(x, y)$, however, our algorithms can be easily adapted to also reconstruct a subsequence attaining the output length. If x, y are clear from the context, we may replace $L(x, y)$ by L. Throughout the paper we assume that the alphabet is $\Sigma \subseteq [O(n)]$ (this is without loss of generality after a $\widetilde{O}(n)$-time preprocessing).

Matching Pairs. For a symbol $\sigma \in \Sigma$, we denote the number of times that σ appears in x by $\#_\sigma(x)$, and call this the *frequency* of σ in x. For strings x and y, a *matching pair* is a pair (i, j) with $x[i] = y[j]$. We denote the number of matching pairs by $M(x, y)$. If x, y are clear from the context, we may replace $M(x, y)$ by M. Observe that $M = \sum_{\sigma \in \Sigma} \#_\sigma(x) \cdot \#_\sigma(y)$. Using this equation we can compute M in time $O(n)$.

Hunt and Szymanski [27] solved the LCS problem in time $\widetilde{O}(n + M)$. More precisely, their algorithm can be viewed as having a preprocessing phase that only reads y and runs in time $\widetilde{O}(|y|)$, and a query phase that reads x and y and takes time $\widetilde{O}(|x| + M)$.

▶ **Theorem 2** (Hunt and Szymanski [27]). *We can preprocess a string y in time $\widetilde{O}(|y|)$. Given a string x and a preprocessed string y, we can compute their LCS in time $\widetilde{O}(|x| + M)$.*

4 New Basic Tools

4.1 Basic Approximation Algorithm

Throughout this section we abbreviate $L = L(x, y)$ and $M = M(x, y)$. We start with the basic approximation algorithm that is central to our approach; most of our later algorithms use this as a subroutine. This algorithm subsamples the string x and then runs Hunt and Szymanski's algorithm (Theorem 2).

▶ **Lemma 3** (Basic Approximation Algorithm). *Let $x, y \in \Sigma^n$. We can preprocess y in time $\widetilde{O}(n)$. Given x, the preprocessed string y, and $\beta \geq 1$, in expected time $\widetilde{O}((n + M)/\beta + 1)$ we can compute a value $\widetilde{L} \leq L$ that w.h.p. satisfies $\widetilde{L} > \frac{L}{\beta} - 1$.*

Proof. In the preprocessing phase, we run the preprocessing of Theorem 2 on y.

Fix a constant $c \geq 1$. If $\beta \geq 1/(8c \log n)$, then in the query phase we simply run Theorem 2, solving LCS exactly in time $\widetilde{O}(|x| + M) = \widetilde{O}((n + M)/\beta + 1)$.

Otherwise, denote by x' a random subsequence of x, where each letter $x[i]$ is removed independently with probability $1 - p$ (i.e., kept with probability p) for $p := 8c \log(n)/\beta$. Note that $p \leq 1$ by our assumption on β. We can sample x' in expected time $O(|x'| + 1)$, since the difference from one unremoved letter to the next is geometrically distributed, and geometric random variates can be sampled in expected time $O(1)$, see, e.g., [18]. Note that this subsampling yields $\mathbb{E}[|x'|] = p|x| = \widetilde{O}(|x|/\beta)$ and $\mathbb{E}[M(x', y)] = p\,M = \widetilde{O}(M/\beta)$.

In the query phase, we sample x' and then run the query phase of Theorem 2 on x' and y. This runs in time $\widetilde{O}(|x'| + M(x', y) + 1)$, which is $\widetilde{O}((|x| + M)/\beta + 1)$ in expectation.

Finally, consider a fixed LCS of x and y, namely $z = x[i_1] \dots x[i_L] = y[j_1] \dots y[j_L]$ for some $i_1 < \dots < i_L$ and $j_1 < \dots < j_L$. Each letter $x[i_k]$ survives the subsampling to x' with probability p. Therefore, we can bound $L(x', y)$ from below by a binomial random variable $\mathrm{Bin}(L, p)$ (the correct terminology is that $L(x', y)$ statistically dominates $\mathrm{Bin}(L, p)$). Since $Z = \mathrm{Bin}(L, p)$ is a sum of independent $\{0, 1\}$-variables, multiplicative Chernoff applies and yields $\Pr[Z < \mathbb{E}[Z]/2] \leq \exp(-\mathbb{E}[Z]/8)$. If $L \geq \beta$ then $\mathbb{E}[Z] = Lp \geq 2L/\beta$ and $\mathbb{E}[Z] \geq 8c \log n$, and thus $\Pr[L(x', y) \geq L/\beta] \geq 1 - n^{-c}$. Otherwise, if $L < \beta$, then we can only bound $L(x', y) \geq 0$. In both cases, we have $L(x', y) > L/\beta - 1$ with high probability. ◀

The above lemma behaves poorly if $L \leq \beta$, due to the "-1" in the approximation guarantee. We next show that this can be avoided, at the cost of increasing the running time by an additive $\widetilde{O}(n)$.

▶ **Lemma 4** (Generalised Basic Approximation Algorithm). *Given $x, y \in \Sigma^n$ and $\beta \geq 1$, in expected time $\widetilde{O}(n + M/\beta)$ we can compute a value $\widetilde{L} \leq L$ that w.h.p. satisfies $\widetilde{L} \geq L/\beta$.*

Proof. We run the basic approximation algorithm from Lemma 3, which computes a value $\widetilde{L} \leq L$. Additionally, we compute the number of matching pairs $M = M(x, y)$ in time $\widetilde{O}(n)$. If $M > 0$, then there exists a matching pair, which yields a common subsequence of length 1. Therefore, if $M > 0$ we set $\widetilde{L} := \max\{\widetilde{L}, 1\}$.

In the proof of Lemma 3 we showed that if $L \geq \beta$ then w.h.p. we have $\widetilde{L} \geq L/\beta$. We now argue differently in the case $L < \beta$. If $L = 0$, then $\widetilde{L} \geq 0 = L/\beta$ and we are done. If $0 < L < \beta$, then there must exist at least one matching pair, so $M > 0$, so the second part of our algorithm yields $\widetilde{L} \geq 1 > L/\beta$. Hence, in all cases w.h.p. we have $\widetilde{L} \geq L/\beta$. ◀

We now turn towards the problem of deciding for given x, y and ℓ whether $L(x, y) \geq \ell$. To this end, we repeatedly call the basic approximation algorithm with geometrically decreasing approximation ratio β. Note that with decreasing approximation ratio we get a better approximation guarantee at the cost of higher running time. The idea is that if the LCS $L = L(x, y)$ is much shorter than the threshold ℓ, then already approximation ratio $\beta \approx \ell/L$ allows us to detect that $L < \ell$. This yields a running time bound depending on the gap L/ℓ.

▶ **Lemma 5** (Basic Decision Algorithm). *Let $x, y \in \Sigma^n$. We can preprocess y in time $\widetilde{O}(n)$. Given x, the preprocessed y, and a number $1 \leq \ell \leq n$, in expected time $\widetilde{O}((n + M)L/\ell + n/\ell)$ we can w.h.p. correctly decide whether $L \geq \ell$. Our algorithm has no false positives (and w.h.p. no false negatives).*

Proof. In the preprocessing phase, we run the preprocessing of Lemma 3. In the query phase, we repeatedly call the query phase of Lemma 3, with geometrically decreasing values of β:

1. Preprocessing: Run the preprocessing of Lemma 3.
2. For $\beta = n, n/2, n/4, \dots, 1$:
   3. Run the query phase of Lemma 3 with parameter β to obtain an estimate $\widetilde{L}$.
   4. If $\widetilde{L} \geq \ell$: return "$L \geq \ell$"
   5. If $\widetilde{L} \leq \ell/\beta - 1$: return "$L < \ell$"

Let us first argue correctness. Since Lemma 3 computes a common subsequence of x, y, we have $\widetilde{L} \leq L$. Thus, if $\widetilde{L} \geq \ell$, we correctly infer $L \geq \ell$. Moreover, w.h.p. $\widetilde{L}$ satisfies $\widetilde{L} > L/\beta - 1$. Therefore, if $\widetilde{L} \leq \ell/\beta - 1$, we can infer $L < \ell$, and this decision is correct with high probability. Finally, in the last iteration (where $\beta = 1$), we have $\ell/\beta - 1 = \ell - 1$, and thus one of $\widetilde{L} \geq \ell$ or $\widetilde{L} \leq \ell/\beta - 1$ must hold, so the algorithm indeed returns a decision.

The expected time of the query phase of Lemma 3 is $\widetilde{O}((n+M)/\beta+1)$. Since β decreases geometrically, the total expected time of our algorithm is dominated by the last call.

If $L \geq \ell$, the last call is at the latest for $\beta = 1$. This yields running time $\widetilde{O}(n+M) \leq \widetilde{O}((n+M)L/\ell)$.

If $L < \ell$, note that for any $\beta \leq \frac{\ell}{L+1}$ we have $\widetilde{L} \leq L \leq \ell/\beta - 1$, and thus we return "$L < \ell$". Because we decrease β by a factor 2 in each iteration, the last call satisfies $\beta \geq \frac{\ell}{2(L+1)}$. Hence, the expected running time is $\widetilde{O}((n+M)(L+1)/\ell + 1)$. If $L \geq 1$ then this time bound simplifies to $\widetilde{O}((n+M)L/\ell + 1)$. If $L = 0$, then also $M = 0$, and the time bound becomes $\widetilde{O}(n/\ell + 1)$. In both cases we can bound the expected running time by the claimed $\widetilde{O}((n+M)L/\ell + n/\ell)$, since $\ell \leq n$. ◀

4.2 Approximating the Number of Matching Pairs

Recall that for given strings x, y of length n the number of matching pairs $M = M(x,y)$ can be computed in time $O(n)$, which is linear in the input size. However, later in the paper we will split x into substrings $x_1, \ldots, x_{n/m}$ and y into substrings $y_1, \ldots, y_{n/m}$, each of length m, and we will need estimates of the numbers of matching pairs $M_{ij} = M(x_i, y_j)$. In this setting, the input size is still n (the total length of all strings x_i and y_j) and the output size is $(n/m)^2$ (all numbers M_{ij}), but we are not aware of any algorithm computing the numbers M_{ij} in near-linear time in the input plus output size $\widetilde{O}(n + (n/m)^2)$.[5] Therefore, we devise an approximation algorithm for estimating the number of matching pairs.

▶ **Lemma 6.** *For $x_1, \ldots, x_{n/m}, y_1, \ldots, y_{n/m} \in \Sigma^m$ write $M_{ij} = M(x_i, y_j)$ and $M = \sum_{i,j} M_{ij}$. Given $x_1, \ldots, x_{n/m}, y_1, \ldots, y_{n/m}$ and $q > 0$, we can compute values $\widetilde{M}_{ij}$ that w.h.p. satisfy $M_{ij}/8 - q \leq \widetilde{M}_{ij} \leq 4M_{ij}$, in total expected time $\widetilde{O}(n + M/q)$.*

This yields a near-linear-time constant-factor approximation of all *above-average* M_{ij}: By setting $q := \Theta(\frac{Mm^2}{n^2})$, in expected time $\widetilde{O}(n + (n/m)^2)$ we obtain a constant-factor approximation of all values M_{ij} with $M_{ij} \gg q$.

Proof. The algorithm works as follows.

1. *Graph Construction:* Build a three-layered graph G on vertex set $V(G) = L \cup U \cup R$, where L has a node i for every string x_i, R has a node j for every string y_j, and U has a node (σ, ℓ, r) for any $\sigma \in \Sigma$ and $0 \leq \ell, r \leq \log m$. Put an edge from $i \in L$ to $(\sigma, \ell, r) \in U$ iff $\#_\sigma(x_i) \in [2^\ell, 2^{\ell+1})$. Similarly, put an edge from $j \in R$ to $(\sigma, \ell, r) \in U$ iff $\#_\sigma(y_j) \in [2^r, 2^{r+1})$. Note that all frequencies and thus all edges of this graphs can be computed in total time $\widetilde{O}(n)$. For $i \in L$ and $j \in R$, we denote by $U_{ij} \subseteq U$ their common neighbors. Note that any $(\sigma, \ell, r) \in U_{ij}$ represents all matching pairs of symbol σ in x_i and y_j, and the number of these matching pairs is $\#_\sigma(x_i) \cdot \#_\sigma(y_j) \in [2^{\ell+r}, 2^{\ell+r+2})$.
2. *Subsampling:* We sample a subset $\widetilde{U} \subseteq U$ by removing each node $(\sigma, \ell, r) \in U$ independently with probability $1 - p_{\ell,r}$, where $p_{\ell,r} := \min\{1, 2^{\ell+r+3}/q\}$.
3. *Determine Common Neighbors:* For each $(\sigma, \ell, r) \in \widetilde{U}$ enumerate all pairs of neighbors $i \in L$ and $j \in R$. For each such 2-path, add (σ, ℓ, r) to an initially empty set $\widetilde{U}_{ij}$. This step computes the sets $\widetilde{U}_{ij} := U_{ij} \cap \widetilde{U}$ in time proportional to their total size.
4. *Output:* Return the values $\widetilde{M}_{ij} := \sum_{(\sigma,\ell,r) \in \widetilde{U}_{ij}} 2^{\ell+r}/p_{\ell,r}$.

[5] In fact, one can show conditional lower bounds from Boolean matrix multiplication that rule out near-linear time for computing all M_{ij}'s unless the exponent of matrix multiplication is $\omega = 2$.

Correctness. To analyze this algorithm, we consider the numbers $\overline{M}_{ij} := \sum_{(\sigma,\ell,r)\in U_{ij}} 2^{\ell+r}$. Observe that we have $\overline{M}_{ij} \leq M_{ij} \leq 4\overline{M}_{ij}$, since each $(\sigma,\ell,r) \in U_{ij}$ corresponds to at least $2^{\ell+r}$ and at most $2^{\ell+r+2}$ matching pairs of x_i and y_j. It therefore suffices to show that $\widetilde{M}_{ij}$ is close to $\overline{M}_{ij}$. Using Bernoulli random variables $\mathrm{Ber}(p_{\ell,r})$ to express whether (σ,ℓ,r) survives the subsampling, we write

$$\widetilde{M}_{ij} = \sum_{(\sigma,\ell,r)\in U_{ij}} \frac{2^{\ell+r}}{p_{\ell,r}} \cdot \mathrm{Ber}(p_{\ell,r}).$$

This yields an expected value of $\mathbb{E}[\widetilde{M}_{ij}] = \overline{M}_{ij}$, so by Markov's inequality we obtain $\widetilde{M}_{ij} \leq 4\overline{M}_{ij} \leq 4M_{ij}$ with probability at least 3/4. Since $\widetilde{M}_{ij}$ is a linear combination of independent Bernoulli random variables, we can also easily express its variance as

$$\mathbb{V}[\widetilde{M}_{ij}] = \sum_{(\sigma,\ell,r)\in U_{ij}} \left(2^{\ell+r}/p_{\ell,r}\right)^2 \cdot p_{\ell,r}(1-p_{\ell,r}) = \sum_{(\sigma,\ell,r)\in U_{ij}} 2^{\ell+r} \cdot 2^{\ell+r}\Big(\frac{1}{p_{\ell,r}} - 1\Big).$$

We now use the definition of $p_{\ell,r} := \min\{1, 2^{\ell+r+3}/q\}$ to bound

$$2^{\ell+r}\Big(\frac{1}{p_{\ell,r}} - 1\Big) = 2^{\ell+r}\Big(\max\Big\{1, \frac{q}{2^{\ell+r+3}}\Big\} - 1\Big) = \max\{0, q/8 - 2^{\ell+r}\} \leq q/8.$$

This yields $\mathbb{V}[\widetilde{M}_{ij}] \leq \overline{M}_{ij}q/8$. We now use Chebychev's inequality $\Pr[X < \mathbb{E}[X] - \lambda] \leq \mathbb{V}[X]/\lambda^2$ on $\lambda = 0.5\mathbb{E}[X]$ and $X = \widetilde{M}_{ij}$ to obtain

$$\Pr[\widetilde{M}_{ij} < \overline{M}_{ij}/2] \leq \frac{q}{2\overline{M}_{ij}}.$$

In case $M_{ij} \geq 8q$, we have $\overline{M}_{i,j} \geq M_{ij}/4 \geq 2q$ and hence $\Pr[\widetilde{M}_{ij} \geq M_{ij}/8] \geq \Pr[\widetilde{M}_{ij} \geq \overline{M}_{ij}/2] \geq 3/4$. Otherwise, in case $M_{ij} < 8q$, we can only use the trivial $\widetilde{M}_{ij} \geq 0 > M_{ij}/8 - q$.

Hence, each inequality $\widetilde{M}_{ij} \leq 4M_{ij}$ and $\widetilde{M}_{ij} \geq M_{ij}/8 - q$ individually holds with probability at leat 3/4. Finally, we boost the success probability by repeating the above algorithm $O(\log n)$ times and returning for each i, j the median of all computed values $\widetilde{M}_{ij}$.

Running Time. Steps 1 and 2 can be easily seen to run in time $\widetilde{O}(n)$. Steps 3 and 4 run in time proportional to the total size of all sets $\widetilde{U}_{ij}$, which we claim to be at most $8M/q$ in expectation. Over $O(\log n)$ repetitions, we obtain a total expected running time of $\widetilde{O}(n + M/q)$. (We remark that here we consider a succinct output format, where only the non-zero numbers $\widetilde{M}_{ij}$ are listed; otherwise additional time of $\widetilde{O}((n/m)^2)$ is required to output the numbers $\widetilde{M}_{ij} = 0$.)

It remains to prove the claimed bound of $\mathbb{E}[\sum_{i,j} |\widetilde{U}_{ij}|] \leq 8M/q$. Since $2^{\ell+r}/p_{\ell,r} = \max\{2^{\ell+r}, q/8\} \geq q/8$, from the definition of $\widetilde{M}_{ij} = \sum_{(\sigma,\ell,r)\in\widetilde{U}_{ij}} 2^{\ell+r}/p_{\ell,r}$ we infer $\widetilde{M}_{ij} \geq \frac{q}{8}|\widetilde{U}_{ij}|$. Therefore,

$$\mathbb{E}\Big[\sum_{i,j} |\widetilde{U}_{ij}|\Big] \leq \mathbb{E}\Big[\frac{8}{q}\sum_{i,j} \widetilde{M}_{ij}\Big] = \frac{8}{q}\sum_{i,j} \overline{M}_{ij} \leq \frac{8}{q}\sum_{i,j} M_{ij} = \frac{8M}{q}. \qquad \blacktriangleleft$$

4.3 Single Symbol Approximation Algorithm

For strings x, y that have a large number of matchings pairs $M = M(x,y)$, some symbol must appear often in x and in y. This yields a common subsequence using (several repetitions of) a single alphabet symbol.

▶ **Lemma 7** (Cf. Lemma 6.6.(ii) in [20] or Algorithm 3 in [24]). *For any $x, y \in \Sigma^n$ there exists a symbol $\sigma \in \Sigma$ that appears at least $\frac{M}{2n}$ times in x and in y. Therefore, in time $\widetilde{O}(n)$ we can compute a common subsequence of x, y of length at least $\frac{M}{2n}$. In particular, we can compute a value $\widetilde{L} \leq L$ that satisfies $\widetilde{L} \geq \frac{M}{2n}$.*

Proof. Let k be maximal such that some symbol $\sigma \in \Sigma$ appears at least k times in x and at least k times in y. Let $\Sigma^w := \{\sigma \in \Sigma \mid \#_\sigma(w) \leq k\}$ for $w \in \{x, y\}$. Since no symbol appears more than k times in x and in y, we have $\Sigma^x \cup \Sigma^y = \Sigma$. We can thus bound

$$M = M(x,y) = \sum_{\sigma\in\Sigma} \#_\sigma(x) \cdot \#_\sigma(y) \leq \sum_{\sigma\in\Sigma^x} k \cdot \#_\sigma(y) + \sum_{\sigma\in\Sigma^y} \#_\sigma(x) \cdot k \leq 2kn,$$

since the frequencies $\#_\sigma(x)$ sum up to at most n, and similarly for $\#_\sigma(y)$. It follows that $k \geq \frac{M}{2n}$. Computing k, and a symbol $\sigma \in \Sigma$ attaining k, in time $\widetilde{O}(n)$ is straightforward. ◀

We devise a variant of Lemma 7 in the following setting. For strings $x_1, \ldots, x_{n/m}$, $y_1, \ldots, y_{n/m} \in \Sigma^m$ we write $L_{ij} = L(x_i, y_j)$, $M_{ij} = M(x_i, y_j)$ and $M = \sum_{i,j} M_{ij}$. We want to find for each block (i, j) a frequent symbol in x_i and y_j, or equivalently we want to find a common subsequence of x_i and y_j using a single alphabet symbol. Similarly to Lemma 6, we relax Lemma 7 to obtain a fast running time.

▶ **Lemma 8.** *Given $x_1, \ldots, x_{n/m}, y_1, \ldots, y_{n/m} \in \Sigma^m$ and any $q > 0$, we can compute for each i, j a number $\widetilde{L}_{ij} \leq L_{ij}$ such that w.h.p. $\widetilde{L}_{ij} \geq \frac{M_{ij}-q}{16m}$. The algorithm runs in total expected time $\widetilde{O}(n + M/q)$.*

Proof. We run the same algorithm as in Lemma 6, except that in Step 4 for each i, j with non-empty set $\widetilde{U}_{ij}$ we let $\widetilde{L}_{ij}$ be the maximum of $2^{\min\{\ell,r\}}$ over all $(\sigma, \ell, r) \in \widetilde{U}_{ij}$. For each empty set $\widetilde{U}_{ij}$, we implicitly set $\widetilde{L}_{ij} = 0$, i.e., we output a sparse representation of all non-zero values $\widetilde{L}_{ij}$.

The running time analysis is the same as in Lemma 6.

For the upper bound on $\widetilde{L}_{ij}$, since σ appears at least 2^ℓ times in x_i and at least 2^r times in y_j, there is a common subsequence of x_i and y_j of length at least $\widetilde{L}_{ij}$. Thus, we have $\widetilde{L}_{ij} \leq L_{ij}$.

For the lower bound on $\widetilde{L}_{ij}$, fix i, j and order the tuples $(\sigma, \ell, r) \in U_{ij}$ in ascending order of $2^{\min\{\ell,r\}}$, obtaining an ordering $(\sigma_1, \ell_1, r_1), \ldots, (\sigma_k, \ell_k, r_k)$. For $h \in [k]$ we let $\mathcal{S} := \{(\sigma_1, \ell_1, r_1), \ldots, (\sigma_h, \ell_h, r_h)\}$ and $\mathcal{L} := \{(\sigma_h, \ell_h, r_h), \ldots, (\sigma_k, \ell_k, r_k)\}$. Recall that $\overline{M}_{ij} = \sum_{(\sigma,\ell,r)\in U_{ij}} 2^{\ell+r}$, and observe that we can pick h with

$$\sum_{(\sigma,\ell,r)\in\mathcal{S}} 2^{\ell+r} \geq \overline{M}_{ij}/2 \qquad \text{and} \qquad \sum_{(\sigma,\ell,r)\in\mathcal{L}} 2^{\ell+r} \geq \overline{M}_{ij}/2. \tag{1}$$

Then we have

$$\frac{\overline{M}_{ij}}{2} \leq \sum_{(\sigma,\ell,r)\in\mathcal{S}} 2^{\ell+r} = \sum_{(\sigma,\ell,r)\in\mathcal{S}} 2^{\min\{\ell,r\}} \cdot 2^{\max\{\ell,r\}} \leq 2^{\min\{\ell_h,r_h\}} \sum_{(\sigma,\ell,r)\in\mathcal{S}} 2^{\max\{\ell,r\}}.$$

Note that for any $(\sigma, \ell, r) \in \mathcal{S}$ the symbol σ appears at least $2^{\max\{\ell,r\}}$ times in x_i or in y_j, and thus the sum on the right hand side is at most $2m$. Rearranging, this yields $2^{\min\{\ell_h,r_h\}} \geq \frac{\overline{M}_{ij}}{4m} \geq \frac{M_{ij}}{16m}$, where we used $\overline{M}_{ij} \geq M_{ij}/4$ as in the proof of Lemma 6. In particular, due to our ordering we have for any $(\sigma, \ell, r) \in \mathcal{L}$:

$$2^{\min\{\ell,r\}} \geq 2^{\min\{\ell_h,r_h\}} \geq \frac{M_{ij}}{16m}. \tag{2}$$

Consider the number of nodes in $\mathcal{L}$ surviving the subsampling, i.e., $Z := |\mathcal{L} \cap \widetilde{U}_{ij}|$. If $Z > 0$, then some node in $\mathcal{L}$ survived, and thus by (2) the computed value $\widetilde{L}_{ij}$ is at least $\frac{M_{ij}}{16m}$. It thus remains to analyze $\Pr[Z > 0]$.

In case some $(\sigma, \ell, r) \in \mathcal{L}$ has $p_{\ell,r} = 1$, we have $Z > 0$ with probability 1. Otherwise all $(\sigma, \ell, r) \in \mathcal{L}$ have $p_{\ell,r} < 1$ and thus $p_{\ell,r} = 2^{\ell+r+3}/q$. In this case, we write Z as a sum of independent Bernoulli random variates in the form $Z = \sum_{(\sigma,\ell,r)\in\mathcal{L}} \mathrm{Ber}(p_{\ell,r})$. In particular,

$$\mathbb{E}[Z] = \sum_{(\sigma,\ell,r)\in\mathcal{L}} 2^{\ell+r+3}/q \overset{(1)}{\geq} \frac{4\overline{M}_{ij}}{q} \geq \frac{M_{ij}}{q}.$$

Since Z is a sum of independent $\{0,1\}$-variables, multiplicative Chernoff applies and yields $\Pr[Z < \mathbb{E}[Z]/2] \leq \exp(-\mathbb{E}[Z]/8)$. We thus obtain

$$\Pr[Z > 0] \geq 1 - \Pr\left[Z < \mathbb{E}[Z]/2\right] \geq 1 - \exp\left(-\mathbb{E}[Z]/8\right) \geq 1 - \exp\left(-\frac{M_{ij}}{8q}\right).$$

In case $M_{ij} \geq q$, we obtain $\Pr[Z > 0] \geq 1 - \exp(-1/8) \geq 0.1$, and thus we have $\widetilde{L}_{ij} \geq \frac{M_{ij}}{16m}$ with probability at least 0.1. Otherwise, in case $M_{ij} < q$, we can only use the trivial bound $\widetilde{L}_{ij} \geq 0 > \frac{M_{ij}-q}{16m}$. In any case, we have $\widetilde{L}_{ij} \geq \frac{M_{ij}-q}{16m}$ with probability at least 0.1. Similar to the proof of Lemma 6, we run $O(\log n)$ independent repetitions of this algorithm and return for each i, j the maximum of all computed values $\widetilde{L}_{ij}$, to boost the success probability and finish the proof. ◀

5 Main Algorithm

In this section we prove Theorem 1. First we show that Theorem 9 implies Theorem 1, and then in the remainder of this section we prove Theorem 9.

▶ **Theorem 9** (Main Result, Relaxation). *Given strings x, y of length n and a time budget $T \in [n, n^2]$, in expected time $\widetilde{O}(T)$ we can compute a number $\widetilde{L}$ such that $\widetilde{L} \leq L := L(x, y)$ and w.h.p. $\widetilde{L} \geq \widetilde{\Omega}(LT^{0.4}/n^{0.8})$.*

Recall Theorem 1:

▶ **Theorem 1.** *There is a randomized algorithm that, given strings x, y of length $n \geq 1$ and a time budget $T \in [n, n^2]$, with high probability computes a multiplicative $\widetilde{O}(n^{0.8}/T^{0.4})$-approximation of the length of the LCS of x and y in time $O(T)$.*

Proof of Theorem 1 assuming Theorem 9. Note that the difference between Theorems 1 and 9 is that the latter allows *expected* running time and has an additional slack of logarithmic factors in the running time.

In order to remove the *expected* running time, we abort the algorithm from Theorem 9 after $\widetilde{O}(T)$ time steps. By Markov's inequality, we can choose the hidden constants and logfactors such that the probability of aborting is at most 1/2. We boost the success probability of this adapted algorithm by running $O(\log n)$ independent repetitions and returning the maximum over all computed values $\widetilde{L}$. This yields an $\widetilde{O}(n^{0.8}/T^{0.4})$-approximation with high probability in time $\widetilde{O}(T)$.

To remove the logfactors in the running time, as the first step in our algorithm we subsample the given strings x, y, keeping each symbol independently with probability $p = 1/\mathrm{polylog}(n)$, resulting in subsampled strings $\tilde{x}, \tilde{y}$. Since any common subsequence of $\tilde{x}, \tilde{y}$ is also a common subsequence of x, y, the estimate $\widetilde{L}$ that we compute for $\tilde{x}, \tilde{y}$ satisfies

$\widetilde{L} \leq L(\tilde{x}, \tilde{y}) \leq L(x, y)$. Moreover, if $L(x, y) \geq \text{polylog}(n)$ then by Chernoff bound with high probability we have $L(\tilde{x}, \tilde{y}) = \widetilde{\Omega}(L(x, y))$, so that an $\widetilde{O}(n^{0.8}/T^{0.4})$-approximation on $\tilde{x}, \tilde{y}$ also yields an $\widetilde{O}(n^{0.8}/T^{0.4})$-approximation on x, y. Otherwise, if $L(x, y) \leq \text{polylog}(n)$, then in order to compute a $\widetilde{O}(1)$-approximation it suffices to compute an LCS of length 1, which is just a matching pair and can be found in time $O(n)$ (assuming that the alphabet is $[O(n)]$).

This yields an algorithm that computes a value $\widetilde{L} \leq L$ such that w.h.p. $\widetilde{L} \geq \widetilde{\Omega}(LT^{0.4}/n^{0.8})$. The algorithm runs in time $O(T)$, and this running time bound holds deterministically, i.e., with probability 1. Hence, we proved Theorem 1. ◀

It remains to prove Theorem 9. Our algorithm is a combination of four methods that work well in different regimes of the problem, see Sections 5.1, 5.3, 5.4, and 5.5. We will combine these methods in Section 5.6.

5.1 Algorithm 1: Small L

Algorithm 1 works well if the LCS is short. It yields the following result.

▶ **Theorem 10** (Algorithm 1). *We can compute in expected time $\widetilde{O}(T)$ an estimate $\widetilde{L} \leq L$ that w.h.p. satisfies $\widetilde{L} \geq \min\{L, \sqrt{LT/n}\}$.*

Proof. Our Algorithm 1 works as follows.

1. Run Lemma 7 on x and y.
2. Run Lemma 4 on x and y with $\beta := \max\{1, \frac{M}{2T}\}$.
3. Output the larger of the two common subsequence lengths computed in Steps 1 and 2.

Running Time. Step 1 runs in time $\widetilde{O}(n) = \widetilde{O}(T)$. Step 2 runs in expected time $\widetilde{O}(n+M/\beta)$. Since $\beta \geq \frac{M}{2T}$ we have $M/\beta \leq 2T$, so the expected running time is $\widetilde{O}(n + T) = \widetilde{O}(T)$.

Upper Bound. Steps 1 and 2 compute common subsequences, so the computed estimate $\widetilde{L}$ satisfies $\widetilde{L} \leq L$.

Approximation Guarantee. Note that Step 1 guarantees $\widetilde{L} \geq \frac{M}{2n}$ and Step 2 guarantees w.h.p. $\widetilde{L} \geq L/\beta$. If $M \leq 2T$ then $\beta = 1$ and $\widetilde{L} = L$, so we solved the problem exactly. Otherwise we have $M > 2T$ and $\beta = \frac{M}{2T}$, so Step 2 guarantees w.h.p. $\widetilde{L} \geq 2LT/M$. By multiplying the two guarantees on $\widetilde{L}$ and taking square roots, we obtain w.h.p.

$$\widetilde{L} \geq \sqrt{\frac{M}{2n} \cdot \frac{2LT}{M}} = \sqrt{\frac{LT}{n}}.$$

It follows that w.h.p. $\widetilde{L} \geq \min\{L, \sqrt{LT/n}\}$. ◀

5.2 Block Sequences and Parameter Guessing

This section introduces some general notation and structure for the remaining algorithms.

Block Sequences. We split x into substrings $x_1, \ldots, x_{n/m}$ of length $m = n/\sqrt{T}$. Similarly, we split y into $y_1, \ldots, y_{n/m}$. A pair $(i, j) \in [n/m]^2$, corresponding to the substrings x_i, y_j, is called a *block*. For any block we write $M_{ij} = M(x_i, y_j)$ and $L_{ij} = L(x_i, y_j)$. Moreover, we write $(i, j) < (i', j')$ if and only if $i < i'$ and $j < j'$. A *block sequence* is a set $\mathcal{S} = \{(i_1, j_1), \ldots, (i_k, j_k)\}$ with $\mathcal{S} \subseteq [n/m]^2$ satisfying the monotonicity property $(i_1, j_1) < \ldots <$

(i_k, j_k). In what follows, every algorithm will compute estimates $0 \le \widetilde{L}_{ij} \le L_{ij}$ and then choose a block sequence $\mathcal{S}$ to produce an overall estimate $\widetilde{L} = \sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$. Note that this guarantees $\widetilde{L} \le L$, as the sum $\sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ corresponds to some (block-aligned) common subsequence of x and y. In order to get bounds in the other direction, we need to show that there always exists a block sequence of large LCS sum, i.e., a long "block-aligned common subsequence". This is shown by the following lemma.

▶ **Lemma 11.** *There exists a block sequence $\mathcal{G}$ of size $|\mathcal{G}| = \frac{L\sqrt{T}}{8n}$ such that for any $(i,j) \in \mathcal{G}$ we have $L_{ij} \ge \frac{L}{4\sqrt{T}}$ and $M_{ij} \le \frac{8\mu n}{L\sqrt{T}}$. In particular, we have $\sum_{(i,j)\in\mathcal{G}} L_{ij} \ge \frac{L^2}{32n}$.*

▶ Remark 12. This is analogous to [24, Lemma 8.2], but we improve the size of $\mathcal{G}$.

Proof. Let L^*_{ij} be the *contribution of block* (i,j) to the LCS. More precisely, fix an LCS z of x and y, and write $z = x[a_1]\dots x[a_L] = y[b_1]\dots y[b_L]$ for $(a_1,b_1) < \dots < (a_L,b_L)$. Then for any block (i,j), the number L^*_{ij} counts all indices k with $a_k \in ((i-1)m, im]$ and $b_k \in ((j-1)m, jm]$. Consider the set $\mathcal{A} := \{(i,j) \mid L^*_{ij} > 0\}$ consisting of all contributing blocks. From the monotonicity $(a_1,b_1) < \dots < (a_L,b_L)$ it follows that also the contributing blocks form a monotone sequence, in the sense that for any $(i,j),(i',j') \in \mathcal{A}$ we have $i \le i'$ and $j \le j'$, or $i' \le i$ and $j' \le j$. (However, these inequalities are not necessarily strict, so $\mathcal{A}$ is not necessarily a block sequence.) This monotonicity implies that there are $|\mathcal{A}| \le 2n/m$ contributing blocks. Also note that $\sum_{(i,j)\in\mathcal{A}} L^*_{ij} = L$. Now consider the subset $\mathcal{B} = \{(i,j) \mid L^*_{ij} > \frac{Lm}{4n}\} \subseteq \mathcal{A}$. Note that the remaining blocks in total contribute

$$\sum_{(i,j)\in\mathcal{A}\setminus\mathcal{B}} L^*_{ij} \le |\mathcal{A}| \cdot \frac{Lm}{4n} \le \frac{2n}{m} \cdot \frac{Lm}{4n} = \frac{L}{2},$$

and thus $\mathcal{B}$ contributes $\sum_{(i,j)\in\mathcal{B}} L^*_{ij} \ge L/2$.

We now greedily pick a subset $\mathcal{C} \subseteq \mathcal{B}$ as follows. Pick any $(i,j) \in \mathcal{B}$, add (i,j) to $\mathcal{C}$, and then remove each $(i',j') \in \mathcal{B}$ with $i' = i$ or $j' = j$ from $\mathcal{B}$. Repeat until $\mathcal{B}$ is empty.

By construction, $\mathcal{C}$ is a block sequence and for any $(i,j) \in \mathcal{C}$ we have $L_{ij} \ge \frac{Lm}{4n} = \frac{L}{4\sqrt{T}}$. We claim that $|\mathcal{C}| \ge \frac{L}{4m} = \frac{L\sqrt{T}}{4n}$. To see this, observe that all blocks $(i',j') \in \mathcal{B}$ with $i' = i$ in total contribute at most m, since they describe a subsequence of x_i, which has length m. Similarly, all blocks $(i',j') \in \mathcal{B}$ with $j' = j$ in total contribute at most m. Therefore, one step of the greedy procedure removes a contribution of at most $2m$. Since the total contribution is $\sum_{(i,j)\in\mathcal{B}} L^*_{ij} \ge L/2$, there are at least $\frac{L}{4m} = \frac{L\sqrt{T}}{4n}$ greedy steps. Finally, we consider the number of matching pairs. Since $\mathcal{C}$ is a block sequence, we have $\sum_{(i,j)\in\mathcal{C}} M_{ij} \le \mu$. Thus, on average each $(i,j) \in \mathcal{C}$ has a number of matching pairs of at most $\mu/|\mathcal{C}| = \frac{4\mu n}{L\sqrt{T}}$. By Markov's inequality, at least half of the blocks $(i,j) \in \mathcal{C}$ have $M_{ij} \le \frac{8\mu n}{L\sqrt{T}}$. We denote the set of these blocks by $\mathcal{G} \subseteq \mathcal{C}$. The set $\mathcal{G}$ satisfies all claimed bounds. This finishes the proof. ◀

Parameter Guessing. We analyze our algorithms in terms of n (the length of the strings), T (the running time budget), L (the length of the LCS), as well as λ and μ, defined as

$$\lambda := \sum_{i,j} L_{ij} \qquad \text{and} \qquad \mu := \max_{\text{block seq. } \mathcal{S}} \sum_{(i,j)\in\mathcal{S}} M_{ij},$$

where the maximum goes over all block sequences $\mathcal{S}$. Note that λ is the total LCS length over all blocks and μ is the maximum total number of matching pairs along any block sequence.

The numbers n and T are part of the input, and we can assume to know M, since it can be computed in time $O(n)$. However, in order to set some parameters in our algorithms, it would be convenient to also know L, λ, μ up to constant factors (which seemingly is a contradiction, as our goal is to compute a polynomial-factor approximation of L).

We therefore run our algorithms $O(\log^3 n)$ times, once for each guess $\hat{L} = 2^i$, $\hat{\lambda} = 2^j$, and $\hat{\mu} = 2^k$. Then for at least one call we have $L/2 \leq \hat{L} \leq L$, $\lambda/2 \leq \hat{\lambda} \leq \lambda$, and $\mu/2 \leq \hat{\mu} \leq \mu$, that is, we know L, λ, μ up to constant factors. For this correct guess, we prove that our algorithms have the promised approximation guarantee and running time bound. For the wrong guesses, the approximation guarantee can fail, but we always ensure the upper bound $\widetilde{L} \leq L$, by ensuring that the estimate corresponds to some common subsequence of x and y. Hence, returning the maximum computed value $\widetilde{L}$ over all guesses $\hat{L}, \hat{\lambda}, \hat{\mu}$ yields the promised approximation guarantee. For this reason, in the following we assume to know estimates $\hat{L} \approx L$, $\hat{\lambda} \approx \lambda$, $\hat{\mu} \approx \mu$ up to constant factors; we will only use them to set certain parameters.

We remark that for the wrong guesses, not only the approximation guarantee but also the running time bound can fail, so we need to abort each of the $O(\log^3 n)$ calls after time $\widetilde{O}(T)$.

Diagonals. A *diagonal* is a set of the form $\mathcal{D}_d = \{(i,j) \in [n/m]^2 \mid i - j = d\}$. Each diagonal is a block sequence, so we have $\sum_{(i,j)\in\mathcal{D}_d} M_{ij} \leq \mu$. Note that there are $2n/m - 1 < 2\sqrt{T}$ (non-empty) diagonals. Moreover, we have $\sum_d \sum_{(i,j)\in\mathcal{D}_d} M_{ij} = M$. This yields the inequality

$$M < 2\mu\sqrt{T}. \tag{3}$$

5.3 Algorithm 2: Large L, Large μ

In this section we present Algorithm 2, which works well if μ is large, i.e., if some block sequence has a large total number of matching pairs. The algorithm makes use of the single symbol approximation that we designed in Lemma 8. This yields estimates $0 \leq \widetilde{L}_{ij} \leq L_{ij}$, over which we then perform dynamic programming to determine the maximum of $\sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ over all block sequences $\mathcal{S}$. (This is similar to [24, Algorithm 3], but we obtain concentration in a wider regime, see Remark 14 for a comparison.)

▶ **Theorem 13** (Algorithm 2). *We can compute in expected time $\widetilde{O}(T)$ an estimate $\widetilde{L} \leq L$ that w.h.p. satisfies*

$$\widetilde{L} = \Omega\Big(\frac{\mu\sqrt{T}}{n}\Big).$$

Proof. Algorithm 2 works as follows.

1. Run Lemma 8 with $q := \frac{M}{4T}$ to compute values $\widetilde{L}_{ij}$.
2. Perform dynamic programming over $[n/m]^2$ to determine the maximum $\sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ over all block sequences $\mathcal{S}$. Output this maximum value $\widetilde{L}$. More precisely:
   - Initialize $D[i,0] = D[0,i] = 0$ for any $0 \leq i \leq n/m$.
   - For $i = 1, \ldots, n/m$ and $j = 1, \ldots, n/m$: $D[i,j] = \max\big\{\widetilde{L}_{ij} + D[i-1, j-1],\ D[i-1, j],\ D[i, j-1]\big\}$.
   - Output $D[n/m, n/m]$.

We analyze this algorithm in the following.

Upper Bound. Since Lemma 8 ensures $\widetilde{L}_{ij} \leq L_{ij}$, the dynamic programming step ensures $\widetilde{L} \leq L$.

Approximation Guarantee. Let $\mathcal{S}$ be a block sequence achieving $\sum_{(i,j)\in\mathcal{S}} M_{ij} = \mu$. Step 2 computes an estimate $\widetilde{L} \geq \sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$, and Lemma 8 yields w.h.p.

$$\widetilde{L} \geq \sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij} \geq \sum_{(i,j)\in\mathcal{S}} \frac{M_{ij} - q}{16m} = \frac{\mu}{16m} - |\mathcal{S}|\frac{q}{16m}.$$

By the monotonicity property of block sequences, we have $|\mathcal{S}| \leq n/m$. Using our definitions of $q = \frac{M}{4T}$ and $m = n/\sqrt{T}$ as well as inequality (3), we obtain

$$|\mathcal{S}|\frac{q}{16m} \leq \frac{qn}{16m^2} = \frac{M}{64n} \leq \frac{\mu\sqrt{T}}{32n}.$$

Plugging this into our bound for $\widetilde{L}$ yields

$$\widetilde{L} \geq \frac{\mu\sqrt{T}}{16n} - \frac{\mu\sqrt{T}}{32n} = \frac{\mu\sqrt{T}}{32n}.$$

Running Time. For Step 1 note that Lemma 8 runs in expected time $\widetilde{O}(n + M/q) = \widetilde{O}(T)$. Step 2 can be easily seen to run in time $O((n/m)^2) = O(T)$ by our choice of $m = n/\sqrt{T}$. This finishes the proof. ◀

▶ Remark 14. Our Algorithm 2 is similar to [24, Algorithm 3], which works as follows. For each block (i, j), their algorithm selects a random symbol σ and uses the minimum of the frequencies $\#_\sigma(x_i), \#_\sigma(y_j)$ as the estimate $\widetilde{L}_{ij}$. It can be shown that this yields $\mathbb{E}[\widetilde{L}_{ij}] = M_{ij}/(2m)$, which is a similar lower bound as provided by Lemma 8, but only in expectation. The summation $\sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ over a block sequence $\mathcal{S}$ then allows to apply concentration inequalities to obtain a w.h.p. error guarantee, assuming $\mu \gg m^2$.

However, in the regime $\mu \leq m^2$ the value μ could be dominated by a single block with $M_{ij} \approx \mu$. In this case, we cannot hope to get concentration by summing over many blocks. Thus, picking a random symbol per block does not suffice to obtain a w.h.p. error guarantee.

Since our improved approximation ratio makes it necessary to use Algorithm 2 in the regime $\mu \ll m^2$, their algorithm is not sufficient in our context. Thus, we replace sampling a single symbol by our new Lemma 8.

5.4 Algorithm 3: Large L, Small μ and Large λ

Our next algorithm works well if μ is small (i.e., every block sequence has a small total number of matching pairs) and λ is large (i.e., on average every block has a large LCS).

Let us start with the intuition. The idea is to *pick some diagonal $\mathcal{D}_d$ and run the basic approximation algorithm (Lemma 4) with approximation ratio $\beta = \max\{1, \mu/T\}$ on each block along the diagonal.* Since every diagonal is a block sequence, we have $\sum_{(i,j)\in\mathcal{D}_d} M_{ij} \leq \mu$, which bounds the running time of this algorithm by $\widetilde{O}(n + \sum_{(i,j)\in\mathcal{D}_d} M_{ij}/\beta) = \widetilde{O}(T)$. Moreover, this algorithm produces an estimate $\widetilde{L} \leq L$ that w.h.p. satisfies

$$\widetilde{L} \geq \sum_{(i,j)\in\mathcal{D}_d} L_{ij}/\beta.$$

Since $\sum_d \sum_{(i,j)\in\mathcal{D}_d} L_{ij} = \sum_{i,j} L_{ij} = \lambda$ and there are $O(n/m)$ diagonals, on average a diagonal $\mathcal{D}_d$ satisfies $\sum_{(i,j)\in\mathcal{D}_d} L_{ij} = \Omega(\lambda m/n) = \Omega(\lambda/\sqrt{T})$. If we pick an above-average diagonal, then we obtain an estimate

$$\widetilde{L} \geq \sum_{(i,j)\in\mathcal{D}_d} L_{ij}/\beta = \Omega\Big(\frac{\lambda}{\sqrt{T}\beta}\Big) = \Omega\Big(\min\Big\{\frac{\lambda}{\sqrt{T}}, \frac{\lambda\sqrt{T}}{\mu}\Big\}\Big).$$

If λ is large and μ is small, then this is a good estimate.

The main difficulty in translating this idea to an actual algorithm is how to pick the diagonal. A natural approach is to pick a random diagonal, as then the *expected* LCS sum of the diagonal is sufficiently large. However, in situations where the diagonal sums are highly

unbalanced, so that λ is dominated by very few diagonals that have a very large LCS sum, a random diagonal is unlikely to have an above-average LCS sum. In this situation, a random diagonal works only with negligible probability.

Therefore, we need a sampling process that favors diagonals with large LCS sum. To this end, we first "guess" a value g such that the sum λ is dominated by summands $L_{ij} = \Theta(g)$. We call blocks (i,j) with $L_{ij} = \Omega(g)$ *good*. Next we sample a random good block (i_0, j_0); for this we simply keep sampling random i, j until we find a good block. Finally, we pick the diagonal $\mathcal{D}_d$ containing the "seed" block (i_0, j_0) and run the above algorithm on this diagonal. This sampling procedure favors diagonals with large LCS sum, because such diagonals contain more good blocks (i,j) to start from, and thus we are more likely to pick the "seed" (i_0, j_0) in a diagonal with large LCS sum. This yields the following result.

▶ **Theorem 15** (Algorithm 3). *We can compute in expected time $\widetilde{O}(T)$ an estimate $\widetilde{L} \le L$ that w.h.p. satisfies*

$$\widetilde{L} = \widetilde{\Omega}\Big(\min\Big\{\frac{\lambda}{\sqrt{T}}, \frac{\lambda\sqrt{T}}{\mu}\Big\}\Big).$$

Proof. Note that the theorem statement is trivial if $\lambda \le \sqrt{T}$. Indeed, in time $O(n)$ we can compute $M = M(x,y)$. If $M = 0$ then $L = \lambda = 0$ and we return $\widetilde{L} = 0$. If $M \ge 1$, then we return $\widetilde{L} = 1$. This ensures $\widetilde{L} \le L$, since any matching pair gives a common subsequence of length 1. Moreover, in case $\lambda \le \sqrt{T}$ the returned value $\widetilde{L} = 1$ satisfies the approximation guarantee $\widetilde{L} = \Omega(\lambda/\sqrt{T})$. Therefore, we can assume

$$\lambda > \sqrt{T}. \tag{4}$$

Algorithm 3 repeats the following procedure $O(\log n)$ times to boost its success probability.

1. Repeat the following for g being any power of two with $\max\{1, \hat{\lambda}/(4T)\} \le g \le m$:
   2. *Sampling a good block:* Pick a random set of blocks $\mathcal{R} \subseteq [n/m]^2$ of size $O\big((gT/\hat{\lambda})\log^2 n\big)$. For each block $(i,j) \in \mathcal{R}$, test whether $L_{ij} \ge g$ using our basic decision algorithm (Lemma 5). If no test was successful, then set $\widetilde{L}(g) = 0$ and continue with the next value of g. Otherwise, pick a random successfully tested block (i_0, j_0) and proceed to Step 3.
   3. *Approximating along a diagonal:* Let $\mathcal{D}$ be the diagonal containing the block (i_0, j_0). For each $(i,j) \in \mathcal{D}$: Run our basic approximation algorithm (Lemma 4) with approximation ratio $\beta = \max\{1, \hat{\mu}/T\}$ on x_i, y_j to obtain an estimate $\widetilde{L}_{ij}$. Finally, $\widetilde{L}(g) = \sum_{(i,j)\in\mathcal{D}} \widetilde{L}_{ij}$ is the result of iteration g.
4. Return $\widetilde{L} = \max_g \widetilde{L}(g)$.

Upper Bound. Again it is easy to see that $\widetilde{L} \le L$, since Lemma 4 yields $\widetilde{L}_{ij} \le L_{ij}$.

Approximation Guarantee. Let $\mathcal{B}_g$ be the set of all blocks (i,j) with $g \le L_{ij} \le 2g$.

▷ Claim 16. If $\lambda/2 \le \hat{\lambda} \le \lambda$ then for some power of two g with $\max\{1, \hat{\lambda}/(4T)\} \le g \le m$ we have

$$g \cdot |\mathcal{B}_g| = \Omega(\lambda/\log m). \tag{5}$$

Proof. Write G for the set of all powers of two g with $\max\{1, \hat{\lambda}/(4T)\} \leq g \leq m$. Note that blocks (i,j) with $L_{ij} \leq \frac{\lambda}{2T}$ in total contribute at most $\lambda/2$ to $\lambda = \sum_{i,i} L_{ij}$, since the total number of blocks is $(n/m)^2 = T$. Hence, the blocks with $L_{ij} > \frac{\lambda}{2T}$ contribute at least $\lambda/2$, that is,

$$\frac{\lambda}{2} \leq \sum_{\substack{i,j \\ L_{ij} > \lambda/(2T)}} L_{ij}.$$

Note that the sets $\mathcal{B}_g$ for powers of two $g \geq \max\{1, \lambda/(4T)\} \geq \max\{1, \hat{\lambda}/(4T)\}$ cover all blocks with $L_{ij} > \frac{\lambda}{2T}$. Moreover, the sets $\mathcal{B}_g$ are empty for $g > m$. Therefore, the blocks with $L_{ij} > \frac{\lambda}{2T}$ are covered by the sets $\mathcal{B}_g$ with $g \in G$, that is,

$$\frac{\lambda}{2} \leq \sum_{\substack{i,j \\ L_{ij} > \lambda/(2T)}} L_{ij} \leq \sum_{g \in G} \sum_{(i,j) \in \mathcal{B}_g} L_{ij} \leq \sum_{g \in G} 2g|\mathcal{B}_g|.$$

If for all g appearing in the sum on the right hand side we would have $g \cdot |\mathcal{B}_g| < \lambda/(4 \log m + 4)$ then the right hand side would be less than $\lambda/2$, so we would obtain a contradiction. This proves the claim. ◁

In the following we focus on an iteration of Step 1 in which we pick a value of g as promised by Claim 16.

We call a block (i,j) *good* if $L_{ij} \geq g$, and *bad* otherwise. Note that any $(i,j) \in \mathcal{B}_g$ is good, but not every good block is in $\mathcal{B}_g$. In Step 2, we claim that the set $\mathcal{R}$ w.h.p. contains at least one good block, assuming that our guess $\hat{\lambda}$ is correct up to constant factors. Indeed, since the set $\mathcal{B}_g$ is a subset of the good blocks, the probability that $\Theta((gT/\lambda)\log^2 n)$ sampled blocks do not contain any good block is at most

$$\left(1 - \frac{|\mathcal{B}_g|}{(n/m)^2}\right)^{\Theta((gT/\lambda)\log^2 n)} \overset{(5)}{\leq} \left(1 - \frac{\lambda}{gT \log m}\right)^{\Theta((gT/\lambda)\log^2 n)} \leq \exp(-\Theta(\log n)),$$

which is negligible. For any bad block $(i,j) \in \mathcal{R}$ the test $L_{ij} \geq g$ is unsuccessful, as Lemma 5 has no false positives. For any good block $(i,j) \in \mathcal{R}$ w.h.p. the test is successful, and w.h.p. there is at least one good block in $\mathcal{R}$. It follows that w.h.p. Step 2 finds a good block (i_0, j_0) and proceeds to Step 3. Observe that (i_0, j_0) is chosen uniformly at random from all good blocks.

We call a diagonal *good* if it contains at least $\frac{|\mathcal{B}_g|m}{4n}$ good blocks, and *bad* otherwise. Since there are $< 2n/m$ non-empty diagonals, the number of good blocks contained in bad diagonals is at most $|\mathcal{B}_g|/2$, which is at most half of all good blocks. Therefore, at least half of all good blocks are contained in good diagonals. It follows that the uniformly random good block (i_0, j_0) lies in a good diagonal with probability at least $1/2$.

Hence, with probability at least $1/2 - o(1)$ the diagonal $\mathcal{D}$ considered in Step 3 is good, that is, it contains at least $\frac{|\mathcal{B}_g|m}{4n}$ blocks (i,j) with $L_{ij} \geq g$. Since the approximations $\widetilde{L}_{ij}$ computed in Step 3 w.h.p. satisfy $\widetilde{L}_{ij} \geq L_{ij}/\beta$, we obtain

$$\widetilde{L} \geq \widetilde{L}(g) \geq \frac{|\mathcal{B}_g|m}{4n} \cdot \frac{g}{\beta}.$$

Inequality (5) and the definitions $m = n/\sqrt{T}$ and $\beta = \max\{1, \hat{\mu}/T\}$ now yield

$$\widetilde{L} = \widetilde{\Omega}\Big(\min\Big\{\frac{\lambda}{\sqrt{T}}, \frac{\lambda\sqrt{T}}{\hat{\mu}}\Big\}\Big).$$

If our guess $\hat{\mu} \approx \mu$ is correct up to a constant factor, then this yields the claimed approximation guarantee. Returning the maximum over $O(\log n)$ independent repetitions of this algorithm improves the success probability from $1/2 - o(1)$ to w.h.p.

Running Time. By Lemma 5, the test $L_{ij} \geq g$ runs in expected time $\widetilde{O}((m + M_{ij})L_{ij}/g + m/g) = \widetilde{O}(m^2 L_{ij}/g + m/g)$. Note that in expectation for random i, j we have $\mathbb{E}[L_{ij}] = \lambda/(n/m)^2 = \lambda/T$. Therefore, the expected running time of one test is bounded by $\widetilde{O}\big(\frac{m^2\lambda}{gT} + m/g\big)$. As Step 2 performs $O\big((gT/\hat{\lambda})\log^2 n\big)$ such tests, its expected running time is $\widetilde{O}(m^2 + mT/\lambda)$, assuming that our guess $\hat{\lambda} \approx \lambda$ is correct up to a constant factor. We now use $m^2 = n^2/T \leq T$ from $n \leq T$ and $\lambda \geq \sqrt{T} \geq n/\sqrt{T} = m$ from (4) and $n \leq T$, to bound the expected running time of Step 2 by $\widetilde{O}(T)$.

For Step 3, the expected running time is $\widetilde{O}(n + \sum_{(i,j)\in\mathcal{D}} M_{ij}/\beta)$. Since $\mathcal{D}$ is a block sequence, we have $\sum_{(i,j)\in\mathcal{D}} M_{ij} \leq \mu$. Using $\beta \geq \hat{\mu}/T = \Omega(\mu/T)$ (if our guess $\hat{\mu} \approx \mu$ is correct up to a constant factor) we can bound the expected time by $\widetilde{O}(n + T) = \widetilde{O}(T)$.

Over the $O(\log n)$ iterations of Step 1 and the $O(\log n)$ repetitions for boosting the success probability, the expected running time is still $\widetilde{O}(T)$. ◀

5.5 Algorithm 4: Large L, Small μ, and Small λ

Our next algorithm works well if μ is small (i.e., every block sequence has a small total number of matching pairs), λ is small (i.e., on average every block has a small LCS), and L is large (i.e., there is a long LCS). The goal of this algorithm is to detect a sufficiently large random subset of the block sequence $\mathcal{G}$ from Lemma 11. To this end, we first sample a random set of blocks $\mathcal{R}$ containing each block $(i, j) \in [n/m]^2$ with probability p. Then we use our basic decision algorithm to detect the blocks $(i, j) \in \mathcal{R}$ with $L_{ij} \geq \frac{\hat{L}}{4\sqrt{T}}$, and for these blocks we set $\widetilde{L}_{ij} = \frac{\hat{L}}{4\sqrt{T}}$, while for the remaining blocks we set $\widetilde{L}_{ij} = 0$. Finally, we perform dynamic programming to determine the maximum $\sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ over all block sequences $\mathcal{S}$.

Observe that for each block in $\mathcal{G} \cap \mathcal{R}$ this algorithm sets $\widetilde{L}_{ij} = \frac{\hat{L}}{4\sqrt{T}}$, so it detects a random subset of $\mathcal{G}$. We thus obtain a p-fraction of the LCS guaranteed by the block sequence $\mathcal{G}$.

Note that in this algorithm we may focus on blocks with $M_{ij} = O(\frac{\mu n}{L\sqrt{T}})$, since this holds for all blocks in $\mathcal{G}$. Moreover, since λ is small, most blocks outside of $\mathcal{G}$ have small LCS L_{ij}. These bounds on L_{ij} and M_{ij} for the considered blocks allow us to bound the running time of the basic decision algorithm. We elaborate this algorithm in the following theorem.

▶ **Theorem 17** (Algorithm 4). *We can compute in expected time $\widetilde{O}(T)$ an estimate $\widetilde{L} \leq L$ that w.h.p. satisfies*

$$\widetilde{L} = \Omega\Big(\min\Big\{\frac{L^3}{n^2}, \frac{L^3 T}{\lambda n^2}, \frac{L^4 T}{\lambda\mu n^2}\Big\}\Big), \quad \textit{assuming that} \quad \frac{L^2 T^{0.5}}{n^2}, \frac{L^2 T^{1.5}}{\lambda n^2}, \frac{L^3 T^{1.5}}{\lambda\mu n^2} = n^{\Omega(1)}.$$

Proof. Algorithm 4 works as follows.

1. Run Lemma 6 with $q := \frac{M}{T}$ to compute values $\widetilde{M}_{ij}$. Initialize $\widetilde{L}_{ij} = 0$ for all i, j.
2. Run the preprocessing of the basic decision algorithm (Lemma 5) on each string y_j.
3. Sample a set $\mathcal{R} \subseteq [n/m]^2$ by including each block (i, j) independently with probability

$$p := \min\Big\{\frac{\hat{L}}{n}, \frac{\hat{L}T}{\hat{\lambda}n}, \frac{\hat{L}^2 T}{\hat{\lambda}\hat{\mu}n}\Big\}.$$

4. For each $(i,j) \in \mathcal{R}$ with $\widetilde{M}_{ij} \leq 64\hat{\mu}n/(\hat{L}\sqrt{T})$: Run the query of the basic decision algorithm (Lemma 5) to test whether $L_{ij} \geq \frac{\hat{L}}{4\sqrt{T}}$. If this test is successful then set $\widetilde{L}_{ij} := \frac{\hat{L}}{4\sqrt{T}}$.
5. Perform dynamic programming over $[n/m]^2$ to determine the maximum $\sum_{(i,j)\in\mathcal{S}} \widetilde{L}_{ij}$ over all block sequences $\mathcal{S}$. Output this maximum value $\widetilde{L}$.

Upper Bound. Since Lemma 5 has no false positives, we ensure $\widetilde{L}_{ij} \leq L_{ij}$ and thus $\widetilde{L} \leq L$.

Approximation Guarantee. The values $\widetilde{M}_{ij}$ computed in Step 1 w.h.p. satisfy $M_{ij}/8 - q \leq \widetilde{M}_{ij} \leq 4M_{ij}$. For all blocks $(i,j) \in \mathcal{G}$ we have $M_{ij} \leq \frac{8\mu n}{L\sqrt{T}}$ (by Lemma 11) and thus w.h.p. $\widetilde{M}_{ij} \leq \frac{32\mu n}{L\sqrt{T}}$. We may assume that our guesses $\hat{L}, \hat{\mu}$ satisfy $L/2 \leq \hat{L} \leq L$ and $\mu/2 \leq \hat{\mu} \leq \mu$; then we obtain $\widetilde{M}_{ij} \leq \frac{64\hat{\mu}n}{\hat{L}\sqrt{T}}$.

Therefore, each block in $\mathcal{G} \cap \mathcal{R}$ satisfies the property checked in Step 4, that is, for each such block we run the basic decision algorithm. Since for each $(i,j) \in \mathcal{G}$ we have $L_{ij} \geq \frac{L}{4\sqrt{T}} \geq \frac{\hat{L}}{4\sqrt{T}}$, in Step 4 for each block in $\mathcal{G} \cap \mathcal{R}$ w.h.p. we obtain an estimate $\widetilde{L}_{ij} = \frac{\hat{L}}{4\sqrt{T}}$. Since $\mathcal{G}$ is a block sequence, also $\mathcal{G} \cap \mathcal{R}$ is a block sequence, and thus the dynamic programming in Step 5 returns an estimate of

$$\widetilde{L} \geq \sum_{(i,j)\in\mathcal{G}\cap\mathcal{R}} \widetilde{L}_{ij} = |\mathcal{G} \cap \mathcal{R}| \cdot \frac{\hat{L}}{4\sqrt{T}}.$$

Note that the size $|\mathcal{G} \cap \mathcal{R}|$ is distributed as a binomial random variable $\mathrm{Bin}(|\mathcal{G}|, p)$, with expectation $p|\mathcal{G}|$. Assuming that our guesses $\hat{L}, \hat{\lambda}, \hat{\mu}$ are correct up to constant factors, we have

$$p|\mathcal{G}| = \Omega\Big(\min\Big\{\frac{L}{n}, \frac{LT}{\lambda n}, \frac{L^2T}{\lambda\mu n}\Big\} \cdot \frac{L\sqrt{T}}{n}\Big) = \Omega\Big(\min\Big(\frac{L^2T^{0.5}}{n^2}, \frac{L^2T^{1.5}}{\lambda n^2}, \frac{L^3T^{1.5}}{\lambda\mu n^2}\Big)\Big) = n^{\Omega(1)},$$

by the assumption in the theorem statement. By Chernoff bound, we have

$$\Pr[|\mathcal{G} \cap \mathcal{R}| < p|\mathcal{G}|/2] \leq \exp(-p|\mathcal{G}|/8) = \exp(-n^{\Omega(1)}),$$

and thus w.h.p. we have $|\mathcal{G} \cap \mathcal{R}| \geq p|\mathcal{G}|/2$. Plugging this into our lower bound for $\widetilde{L}$ yields w.h.p.

$$\widetilde{L} \geq \frac{p|\mathcal{G}|\hat{L}}{8\sqrt{T}} = \Omega\Big(\min\Big\{\frac{L^3}{n^2}, \frac{L^3T}{\lambda n^2}, \frac{L^4T}{\lambda\mu n^2}\Big\}\Big),$$

assuming that our guesses $\hat{L}, \hat{\lambda}, \hat{\mu}$ are correct up to constant factors. This shows the claimed lower bound.

Running Time. The expected running time of Step 1 is $\widetilde{O}(n + M/q) = \widetilde{O}(T)$ since $q = \frac{M}{T}$. Step 2 runs in time $\widetilde{O}(\sum_j |y_j|) = \widetilde{O}(n)$. Steps 3 and 5 take time $O((n/m)^2) = O(T)$. In the remainder we show that Step 4 also runs in expected time $\widetilde{O}(T)$, assuming that our guesses $\hat{L}, \hat{\lambda}, \hat{\mu}$ are correct up to constant factors. Recall that w.h.p. $M_{ij}/8 - q \leq \widetilde{M}_{ij} \leq 4M_{ij}$; we condition on this event in the following.[6] Then $\widetilde{M}_{ij} = O(\frac{\mu n}{L\sqrt{T}})$ implies $M_{ij} = O(q + \frac{\mu n}{L\sqrt{T}})$.

[6] In the error event we bound the running time of Step 4 by $O(n^2)$. This has a negligible contribution to the expected running time of Step 4.

Using inequality (3) we have $q = \frac{M}{T} \leq \frac{2\mu}{\sqrt{T}} \leq \frac{2\mu n}{L\sqrt{T}}$, so $M_{ij} = O(\frac{\mu n}{L\sqrt{T}})$. Since only blocks (i,j) with $\widetilde{M}_{ij} = O(\frac{\mu n}{L\sqrt{T}})$ are tested, each invocation of the basic approximation algorithm in Step 4 runs in expected time $\widetilde{O}((|x_i| + M_{ij})L_{ij}\sqrt{T}/L + |x_i|\sqrt{T}/L) = \widetilde{O}((m + \frac{\mu n}{L\sqrt{T}})L_{ij}\sqrt{T}/L + m\sqrt{T}/L)$. Since each block is tested with probability at most p, Step 4 has an expected running time of

$$O\Big(\sum_{i,j} p \cdot \Big(\Big(m + \frac{\mu n}{L\sqrt{T}}\Big)L_{ij}\frac{\sqrt{T}}{L} + \frac{m\sqrt{T}}{L}\Big)\Big) = O\Big(\Big(\frac{n}{\sqrt{T}} + \frac{\mu n}{L\sqrt{T}}\Big)\frac{p\lambda\sqrt{T}}{L} + \frac{pnT}{L}\Big)$$
$$= \widetilde{O}\Big(\frac{p\lambda n}{L} + \frac{p\lambda\mu n}{L^2} + \frac{pnT}{L}\Big).$$

Note that our choice of $p = \Theta(\min\{\frac{L}{n}, \frac{LT}{\lambda n}, \frac{L^2T}{\lambda\mu n}\})$ ensures that this running time is $\widetilde{O}(T)$. ◀

5.6 Combining the Algorithms

We conclude the proof of Theorem 9 by verifying that for any input at least one of Algorithms 1-4 computes an estimate $\widetilde{L} = \widetilde{\Omega}(LT^{0.4}/n^{0.8})$. The proof of this claim is a case distinction that is deferred to the full version of this paper.

Abstract

The Subgraph Isomorphism problem is of considerable importance in computer science. We examine the problem when the pattern graph H is of bounded treewidth, as occurs in a variety of applications. This problem has a well-known algorithm via color-coding that runs in time $O(n^{\mathrm{tw}(H)+1})$ [Alon, Yuster, Zwick'95], where n is the number of vertices of the host graph G. While there are pattern graphs known for which Subgraph Isomorphism can be solved in an improved running time of $O(n^{\mathrm{tw}(H)+1-\varepsilon})$ or even faster (e.g. for k-cliques), it is not known whether such improvements are possible for all patterns. The only known lower bound rules out time $n^{o(\mathrm{tw}(H)/\log(\mathrm{tw}(H)))}$ for any class of patterns of unbounded treewidth assuming the Exponential Time Hypothesis [Marx'07].

In this paper, we demonstrate the existence of maximally hard pattern graphs H that require time $n^{\mathrm{tw}(H)+1-o(1)}$. Specifically, under the Strong Exponential Time Hypothesis (SETH), a standard assumption from fine-grained complexity theory, we prove the following asymptotic statement for large treewidth t:

> For any $\varepsilon > 0$ there exists $t \geq 3$ and a pattern graph H of treewidth t such that Subgraph Isomorphism on pattern H has no algorithm running in time $O(n^{t+1-\varepsilon})$.

Under the more recent 3-uniform Hyperclique hypothesis, we even obtain tight lower bounds for each specific treewidth $t \geq 3$:

> For any $t \geq 3$ there exists a pattern graph H of treewidth t such that for any $\varepsilon > 0$ Subgraph Isomorphism on pattern H has no algorithm running in time $O(n^{t+1-\varepsilon})$.

In addition to these main results, we explore **(1)** colored and uncolored problem variants (and why they are equivalent for most cases), **(2)** Subgraph Isomorphism for $\mathrm{tw} < 3$, **(3)** Subgraph Isomorphism parameterized by pathwidth instead of treewidth, and **(4)** a weighted variant that we call Exact Weight Subgraph Isomorphism, for which we examine pseudo-polynomial time algorithms. For many of these settings we obtain similarly tight upper and lower bounds.

1 Introduction

The Subgraph Isomorphism problem is commonly defined as follows: Given a graph H on k vertices, and a graph G on n vertices, is there a (not necessarily induced) subgraph of G which is isomorphic to H?

© Karl Bringmann and Jasper Slusallek;
licensed under Creative Commons License CC-BY 4.0

Subgraph Isomorphism generalizes many problems of independent interest, such as the k-path and k-clique problems. The problem is also of considerable interest when H is less structured, with applications to discovering patterns in graphs that, for example, arise from biological processes such as gene transcription or food networks, from social interaction, from electronic circuits, from neural networks [42], from chemical compounds [47] or from control flow in programs [19]. In some fields, the problem is sometimes referred to as the search for "network motifs", i.e. subgraphs that appear more often than would normally be expected.

In its general form, the problem is NP-hard. We are interested in solving the problem when the pattern graph H is "tree-like" or "path-like", i.e. when the treewidth $\mathrm{tw}(H)$ or the pathwidth $\mathrm{pw}(H)$ of H is bounded. Such pattern graphs of low treewidth or pathwidth often arise in practice when considering the structure of chemical compounds, the control flow of programs, syntactic relations in natural language, or many other graphs from practical applications (see e.g. [14, 16]). On the theoretical side, many restricted classes of graphs have bounded treewidth, see also [15]. Restricting NP-hard problems to graphs of bounded tree- and pathwidth often yields polynomial-time algorithms, and Subgraph Isomorphism is no exception. Most notably, the classic Color-Coding algorithm by Alon, Yuster and Zwick [9] solves the problem by a Las Vegas algorithm in expected time $O(n^{\mathrm{tw}(H)+1}g(k))$, or by a deterministic algorithm in time $\widetilde{O}(n^{\mathrm{tw}(H)+1}g(k))$, where g is a computable function (and $\widetilde{O}(\cdot)$ is used to suppress factors that are polylogarithmic in the input size). In other words, if the pattern graph H has treewidth bounded by some constant, the problem is fixed-parameter tractable when parameterized by k. The Color-Coding algorithm is also relevant for practical purposes: Recently, it has received an efficient implementation, which tested well against state-of-the-art programs for Subgraph Isomorphism [39].

Many researchers wondered whether the Color-Coding algorithm can be improved. This question has been studied in many different directions, including the following:

- Marx [40] showed that no algorithm solves the Subgraph Isomorphism problem in time $O(n^{o(\mathrm{tw}(H)/\log(\mathrm{tw}(H)))}g(k))$ unless the Exponential Time Hypothesis (ETH) fails, and this even holds when restricted to any class of pattern graphs of unbounded treewidth.
- A series of work has improved the computable function g, see e.g. [10, 29, 44].
- For many special pattern graphs faster algorithms have been found; the most famous example is the k-Clique problem, which can be solved in time $O(n^{k\omega/3}g(k))$ [43][1].

In this paper, we use a different angle to approach the question whether Color-Coding can be improved. We ask whether there exist "hard" pattern graphs:

Do there exist pattern graphs H for which Subgraph Isomorphism cannot be solved in time $O(n^{\mathrm{tw}(H)+1-\varepsilon})$ for any constant $\varepsilon > 0$?

To the best of our knowledge, this question has not been previously studied. As our main result, we (conditionally) give a positive answer to this question. More precisely, we show that for every $t \geq 3$ there exists a pattern graph H with $\mathrm{tw}(H) = t$ for which Subgraph Isomorphism cannot be solved in time $O(n^{\mathrm{tw}(H)+1-\varepsilon})$ for any constant $\varepsilon > 0$, assuming the 3-uniform k-Hyperclique hypothesis; see Section 1.3 for details on this hypothesis. We also show a slightly weaker statement under the Strong Exponential Time Hypothesis. This conditionally shows that the Color-Coding algorithm by Alon, Yuster and Zwick cannot be significantly improved while still working for all pattern graphs.

[1] This bound assumes that k is divisible by 3; there are similar results for general k [27].

For the case of $\mathrm{tw}(H) = 2$, an algorithm of Curticapean, Dell and Marx [24] can be adapted such that it solves Subgraph Isomorphism in time $\widetilde{O}(n^\omega g(k))$. We unify this with the algorithm of Alon, Yuster and Zwick by showing that both time bounds can be achieved within a simple framework. In particular, we use so-called k-wise matrix products, an operation which was introduced in its general form in [31] and studied further in [38].

We also study the Subgraph Isomorphism problem when the pathwidth of H is bounded, and specialize our framework to show slight improvements in running time compared to the case of bounded treewidth. Here, we use rectangular matrix products, for which faster-than-naive algorithms are known [30].

In further results, our focus is on the weighted variant Exact Weight Subgraph Isomorphism, where the subgraph must also have total weight equal to zero. In this work, we consider both the node-weighted and the edge-weighted variant of this problem, for both bounded treewidth and bounded pathwidth, allowing the maximum absolute weight W to appear in the running time (i.e. the pseudopolynomial-time setting). We show that our algorithms for the unweighted case can be adapted to the weighted case. We also speed up the weighted algorithms by using the fact that fast convolution (or rather, sumset computation), a folklore technique that lies at the core of many fast algorithms for problems with weights (e.g. [20, 18, 35, 34, 17, 12] and [23, exercise 30.1.7]), can easily be adapted to work with rectangular matrices and tensors. We furthermore show tight conditional lower bounds in many cases. Last but not least, we show that our algorithms can be slightly improved for the case of node-weighted instances for which either the pathwidth of H is bounded, or H is a tree. These algorithms also rely on fast rectangular matrix products.

1.1 Related Work

Additional to the conditional lower bound of $O(n^{o(\mathrm{tw}(H)/\log(\mathrm{tw}(H)))}g(k))$ by Marx [40], there is an unconditional lower bound of $O(n^{\kappa(H)})$ for the size of any AC^0-circuit, for some graph parameter $\kappa(H) = \Omega(\mathrm{tw}(H)/\log(\mathrm{tw}(H)))$, which holds even when considering the average case [37]. Interestingly, the factor of $1/\log(\mathrm{tw}(H))$ does not seem to be an artefact of the proof: There is an AC^0-circuit of size $O(n^{o(\mathrm{tw}(H))}g(k))$ that solves the problem on certain unbounded-treewidth classes in the average case [45].

In a different direction, Dalirrooyfard et al. [25] design various reductions from k-Clique to Subgraph Isomorphism, among other results. They also present results on the detection of induced subgraphs (we focus on non-induced subgraphs).

For the weighted variant of Subgraph Isomorphism, lower bounds under the k-Sum hypothesis for stars, paths, cycles and some other pattern graphs are presented in [5]. Edge-weighted triangle detection has a by-now classic $O(n^{3-\varepsilon})$ lower bound under both the 3Sum hypothesis and the APSP hypothesis [7]. On the other hand, in [6], it is proven that finding node-weighted k-cliques can be done almost as quickly as finding unweighted k-cliques. We are not aware of any results on the Exact Weight Subgraph Isomorphism problem when W may appear in the running time (i.e. a pseudopolynomial-time algorithm), which is what we focus on here.

In our work, we pose no restrictions on the host graph G. For an extensive classification of Subgraph Isomorphism with respect to various parameters of both G and H, see [41].

1.2 Hardness Assumptions

The most standard hypothesis from fine-grained complexity theory is the Strong Exponential Time Hypothesis (SETH) [32], which postulates that for any $\varepsilon > 0$ there exists $k \geq 3$ such that k-Sat on n variables cannot be solved in time $O^*(2^{(1-\varepsilon)n})$.

More recent is the Hyperclique hypothesis. In the h-uniform k-Hyperclique problem, for a given h-uniform hypergraph we want to decide whether there exist a set of k vertices such that every size-h subset of these vertices forms a hyperedge. For any $k > 3$, the 3-uniform k-Hyperclique hypothesis postulates that this problem cannot be solved in time $O(n^{k-\varepsilon})$ for any $\varepsilon > 0$. This hypothesis has also been formulated when replacing 3 with any $h < k$, getting progressively more believable with larger h. For a more in-depth discussion of the believability of this hypothesis we refer to [38, Section 7].

Note that we will also use the h-uniform Hyperclique hypothesis for various h, which is simply the conjecture that the h-uniform k-Hyperclique hypothesis is true for all $k > h$.

Related to this is the k-Clique conjecture, which postulates that the k-Clique problem (which is the 2-uniform k-Hyperclique problem) cannot be solved in time $O(n^{\omega k/3-\varepsilon})$ for any constant $\varepsilon > 0$, where $\omega < 2.373$ [36] is the exponent of matrix multiplication.

1.3 Our Results

Unweighted Subgraph Isomorphism with Bounded Treewidth. First, consider the case of the unweighted Subgraph Isomorphism problem for bounded-treewidth pattern graphs H. As was said, and as we will re-prove with a unified algorithm later, this problem has an algorithm running in time $\widetilde{O}(n^{\mathrm{tw}(H)+1})$ for $\mathrm{tw}(H) \geq 3$. We show tight conditional lower bounds by proving the following obstacles to faster algorithms, which use the k-clique hypothesis and the h-uniform k-hyperclique hypothesis. Note that when we say, for some x, that an algorithm has running time $O(n^{x-\varepsilon})$, what we mean is that the algorithm runs in time $O(n^{x-\varepsilon})$ for some constant $\varepsilon > 0$.

▶ **Theorem 1.** *The following statements are true.*

1. *For each $t \geq 3$ and each $3 \leq h \leq t$, there exists a connected, bipartite pattern graph $\mathcal{H}_{t,h}$ of treewidth t such that there cannot be an algorithm solving the Subgraph Isomorphism problem on pattern graph $\mathcal{H}_{t,h}$ in time $O(n^{t+1-\varepsilon})$ unless the h-uniform $h(t+1)$-hyperclique hypothesis fails.*
2. *For each $t \geq 2$ and each $h \geq 3$, there exists a connected, bipartite pattern graph $\mathcal{H}_{t,h}$ of treewidth t such that there cannot be an algorithm solving the Subgraph Isomorphism problem on pattern graph $\mathcal{H}_{t,h}$ in time $O(n^{t-\varepsilon})$ unless the h-uniform ht-hyperclique hypothesis fails.*
3. *For each $t \geq 2$, there exists a connected, bipartite pattern graph $\mathcal{H}_t$ of treewidth t such that there cannot be an algorithm solving the Subgraph Isomorphism problem on pattern graph $\mathcal{H}_t$ in time $O(n^{(t+1)\omega/3-\varepsilon})$ unless the $(t+1)$-Clique hypothesis fails.*

Indeed, with the very same reduction, we also get an obstacle from SETH. However, the lower bound it provides is not as tight as the above, and in the case of the second part does not work for each target treewidth t.

▶ **Theorem 2.** *Assuming SETH, the following two statements are true.*

1. *For any $t \geq 3$ and any $\varepsilon > 0$ there exists a pattern graph $\mathcal{H}_{t,\varepsilon}$ of treewidth t such that there cannot be an algorithm solving all instances of Subgraph Isomorphism with pattern graph $\mathcal{H}_{t,\varepsilon}$ in time $O(n^{t-\varepsilon})$.*
2. *For any $\varepsilon > 0$ there exists a $t \geq 3$ and a pattern graph $\mathcal{H}_\varepsilon$ of treewidth t such that there cannot be an algorithm solving all instances of Subgraph Isomorphism with pattern graph $\mathcal{H}_\varepsilon$ in time $O(n^{t+1-\varepsilon})$.*

On the algorithmic side, we present an algorithm that achieves matching running times (as listed in Theorem 3 below). As was said, the results in the following theorem are not new. Part 1 was shown via Color-Coding in [9] and part 2 follows from techniques in [24].

We unify these two results by providing a single, relatively simple algorithmic technique achieving both, based on k-wise matrix products. These techniques are later expanded to also work for the weighted version, where they then achieve new results. In the following, $\omega < 2.373$ [36] is the exponent of matrix multiplication.

▶ **Theorem 3.** *There are algorithms which, given an arbitrary instance $\phi = (H, G)$ of* Subgraph Isomorphism *where H has treewidth $\mathrm{tw}(H)$, solve ϕ in*

1. *time $\widetilde{O}(n^{\mathrm{tw}(H)+1}g(k))$ when $\mathrm{tw}(H) \geq 3$,*
2. *time $\widetilde{O}(n^{\omega}g(k))$ when $\mathrm{tw}(H) = 2$, and*
3. *time $\widetilde{O}(n^{2}g(k))$ when $\mathrm{tw}(H) = 1$,*

where $k := |V(H)|, n := |V(G)|$ and g is a computable function.

Semi-Equivalence of Hyperclique and Subgraph Isomorphism. In the full version of the paper, we also discuss how our results not only show a reduction from Hyperclique to Subgraph Isomorphism with bounded treewidth, but also in the other direction. For this, we show that calculating the boolean k-wise matrix products, which is the bottleneck in our algorithm for bounded-treewidth Subgraph Isomorphism, is actually equivalent to the k-uniform $(k+1)$-Hypergraph problem. Hence we have a reduction in the second direction. This gives an interesting intuition for why the Hyperclique hypothesis is the "correct" conjecture to prove conditional hardness of Subgraph Isomorphism for bounded treewidth.

We remark that this does not lead to a full equivalence of these problems because the uniformity (i.e. the size of hyperedges) of the Hyperclique problem we reduce from in the first reduction is much smaller than the size of the hypercliques we search for. Hence we only have a reduction from a Hyperclique instance with small edge uniformity to Subgraph Isomorphism, and a reduction from Subgraph Isomorphism to Hyperclique instances with large edge uniformity.

Weighted Subgraph Isomorphism with Bounded Treewidth. Now consider the weighted version of Subgraph Isomorphism for bounded-treewidth graphs H. Recall that the weighted version can be either node- or edge-weighted and is defined such that the weights in the solution subgraph must have total weight zero. A trivial dynamic programming algorithm on the tree decomposition achieves a running time of $\widetilde{O}(n^{\mathrm{tw}(H)+1} \cdot W \log W)$ for $\mathrm{tw}(H) \geq 3$.

Note that these results show conditional lower bounds even when the maximum weight is restricted to $W = \Theta(n^{\gamma})$, for any constant $\gamma > 0$.

▶ **Theorem 4.** *For both the node- and edge weighted variant of the problems, the following statements are true.*

1. *For each $t \geq 3$, each $\gamma \in \mathbb{R}^+$ and each $3 \leq h \leq t$, there exists a connected, bipartite graph $\mathcal{H}_{t,h,\gamma}$ of treewidth t such that there cannot be an algorithm solving the Exact Weight Subgraph Isomorphism problem on pattern graph $\mathcal{H}_{t,h,\gamma}$ for instances with maximum weight $W = \Theta(n^{\gamma})$ in time $O(n^{t+1-\varepsilon}W)$, unless the h-uniform Hyperclique hypothesis fails.*
2. *For each $t \geq 1$, each $\gamma \in \mathbb{R}^+$ and each $h \geq 3$, there exists a connected, bipartite graph $\mathcal{H}_{t,h,\gamma}$ of treewidth t such that there cannot be an algorithm solving the Exact Weight Subgraph Isomorphism problem on pattern graph $\mathcal{H}_{t,h,\gamma}$ for instances with maximum weight $W = \Theta(n^{\gamma})$ in time $O(n^{t-\varepsilon}W)$, unless the h-uniform Hyperclique hypothesis fails.*
3. *For each $t \geq 1$ and each $\gamma \in \mathbb{R}^+$, there exists a connected, bipartite graph $\mathcal{H}_{t,\gamma}$ of treewidth t such that there cannot be an algorithm solving the Exact Weight Subgraph Isomorphism problem on pattern graph $\mathcal{H}_{t,\gamma}$ for instances with maximum weight $W = \Theta(n^{\gamma})$ in time $O(n^{(t+1)\omega/3-\varepsilon}W^{\omega/3})$, unless the Clique hypothesis fails.*

Similar lower bounds also hold when trying to reduce the exponent of W instead of n. Meaning there is also no algorithm of running time $O(n^{t+1}W^{1-\varepsilon})$ in part 1, etc.

On the algorithmic side, we present an algorithm that achieves matching running times for $\mathrm{tw}(H) \geq 3$, and almost matching running times for $\mathrm{tw}(H) = 1, 2$. Note that in terms of exponents, the first algorithm below is not better than the naive one with running time $O(n^{\mathrm{tw}+1}W \log W)$. However, it avoids a factor of $\log W$ in the largest term, and instead appends it to a smaller term, so in a way it presents an improvement of $\log W$ in the running time. Specifically, we show

▶ **Theorem 5.** *There are algorithms which, given an arbitrary instance $\phi = (H, G, w)$ of the* Exact Weight Subgraph Isomorphism *problem where H has treewidth $\mathrm{tw}(H)$, solve ϕ in*
1. *time $\widetilde{O}((n^{\mathrm{tw}(H)+1}W + n^{\mathrm{tw}(H)}W \log W)g(k))$ when $\mathrm{tw}(H) \geq 3$,*
2. *time $\widetilde{O}((n^{\omega}W + n^2 W \log W)g(k))$ when $\mathrm{tw}(H) = 2$, or*
3. *time $\widetilde{O}((n^2 W + nW \log W)g(k))$ when $\mathrm{tw}(H) = 1$,*

where $n := |V(G)|, k := |V(H)|$, g is a computable function, and W is the maximum absolute weight in the image of w.

Comparing these upper bounds with the lower bounds from Theorem 5, we have a tight lower bound for the weighted case with $\mathrm{tw}(H) \geq 3$. For weighted $\mathrm{tw}(H) = 2$, we have a lower bound which is tight except for the exponent of $\omega/3$ to W; it is unclear whether this can be strengthened. The lower bound for weighted graphs with $\mathrm{tw}(H) = 1$ is obviously not tight: We have an upper bound of $\widetilde{O}(n^2 W + nW \log W)$, but our lower bounds only states that it requires time $O(n^{1-o(1)}W^{1-o(1)})$ and $O(n^{2\omega/3-o(1)}W^{\omega/3-o(1)})$. Tighter lower bounds for this case remain an important open problem.

Unweighted Subgraph Isomorphism with Bounded Pathwidth. So far we have only looked at the case of bounded treewidth. However, similar results hold for the case of bounded pathwidth. Let us start with the unweighted Subgraph Isomorphism problem.

Note that we do not get any lower bounds for the current setting. This is because we prove all our lower bounds by showing an equivalence of the standard Subgraph Isomorphism problem to a colored variant (see also Section 1.4), and then proving a lower bound for the colored version. We do not know how to prove such an equivalence for the current setting, therefore we do not get lower bounds in this case; we leave this as an open problem.

Since a path decomposition is always also a tree decomposition, we trivially get upper bounds as in Theorem 3 (when replacing treewidth by pathwidth). However, we can do better by using rectangular matrix multiplication to speed up the computation. For $z \in \mathbb{R}^+$, let $\omega(z)$ be the smallest real number such that multiplying a $n \times n$ matrix with a $n \times n^z$ matrix can be done in time $O(n^{\omega(z)})$[2]. We prove the following upper bounds.

▶ **Theorem 6.** *There are algorithms which, given an arbitrary instance $\phi = (H, G)$ of* Subgraph Isomorphism *where H has pathwidth p, solve ϕ in*
1. *time $\widetilde{O}(n^{\omega(p-1)}g(k))$ when $p \geq 2$, and*
2. *time $\widetilde{O}(n^2 g(k))$ when $p = 1$*

where $k := |V(H)|$ and $n := |V(G)|$.

[2] Le Gall [30] has shown that there are fast algorithms for rectangular matrix multiplication based on the Coppersmith-Winograd method [22, 36] used for square matrix multiplication. Among other values, he shows $\omega(0.31) = 2$, $\omega(2) < 3.26$, $\omega(3) < 4.2$, $\omega(4) < 5.18$ and $\omega(5) < 6.16$. See [30] for an extensive table of such values.

We certainly have $p \leq \omega(p-1) < p+1$, so these results represent only a minor improvement, which is nonetheless important because it "beats" the lower bound for treewidth. Hence the lower bound for pathwidth cannot be the same as for treewidth.

Weighted Subgraph Isomorphism with Bounded Pathwidth. We also analyze the bounded-pathwidth pattern graph version of Weighted Subgraph Isomorphism. Specifically, we get the following lower bound.

▶ **Theorem 7** (Theorem 4 for pathwidth)**.** *Parts 2 and 3 of Theorem 4 also hold when replacing the treewidth t by the pathwidth p. Part 1 does not hold.*

And on the algorithmic side, we can again use rectangular matrix multiplication to improve on the algorithms from the case of bounded treewidth. Specifically, we get:

▶ **Theorem 8.** *There are algorithms which, given an arbitrary instance $\phi = (H, G, w)$ of the Exact Weight Subgraph Isomorphism problem, solve ϕ in*

1. *time $\widetilde{O}((n^{\omega(\mathrm{pw}(H)-1)}W + n^{\mathrm{pw}(H)}W \log W)g(k))$ when $\mathrm{pw}(H) \geq 2$,*
2. *time $\widetilde{O}((n^2W + nW \log W)g(k))$ when $\mathrm{pw}(H) = 1$*

where $n := |V(G)|, k := |V(H)|$, and W is the maximum absolute weight in the image of w.

For $\mathrm{pw}(H) \geq 3$, the lower bounds are therefore obviously not tight (at least for current algorithms), unless significant advances in matrix multiplication techniques are made. For $\mathrm{pw}(H) = 1, 2$, the situation is the same as with treewidth, see the discussion of Theorem 5.

Improvements to Special Cases of Weighted Subgraph Isomorphism. It is natural to think that the exponents $\frac{\omega}{3}$ to W in the lower bounds of Theorems 4 and 7 are only artefacts of the reduction, and that with more advanced methods, this exponent can be improved to 1. However, the following two theorems show that this notion is false for $\mathrm{tw}(H) = 1$ and $\mathrm{pw}(H) = 1, 2$, at least when considering the node-weighted case. Indeed, for $\mathrm{tw}(H) = 1$ (or $\mathrm{pw}(H) = 1$) and $W = n$, these bounds are tight, so further general improvements on the exponent are impossible.

Specifically, Theorems 9 and 10 show the following improvements of the algorithms from Theorems 5 and 8 for small tree- or pathwidth. Let $\mathrm{MM}(n, n, x)$ be the time in which a $n \times n$ matrix can be multiplied with with a $n \times x$ matrix.

▶ **Theorem 9.** *There is an algorithm which, given an arbitrary instance $\phi = (H, G, w)$ of the node-weighted Exact Weight Subgraph Isomorphism problem where H is a tree, solves ϕ in time $\widetilde{O}((\mathrm{MM}(n, n, W) + nW \log W)g(k))$.*

▶ **Theorem 10.** *There is an algorithms which, given an arbitrary instance $\phi = (H, G, w)$ of the node-weighted Exact Weight Subgraph Isomorphism problem, solves ϕ in time $\widetilde{O}(\mathrm{MM}(n, n, n^{\mathrm{pw}(H)-1}W)g(k))$.*

For $W = O(n^\gamma)$, the running time of Theorem 9 is $\widetilde{O}(n^{\omega(\gamma)}\,\mathrm{poly}(k))$. This implies several interesting facts. One such fact is that due to the known convergence $\lim_{\gamma\to\infty} \omega(\gamma) - \gamma = 1$ [21], we have that for node-weighted trees, there cannot be a lower bound of $O(n^{(1+\varepsilon-o(1)}W)$ for any $\varepsilon > 0$ that holds for any constant $\gamma > 0$. A similar result holds for bounded-pathwidth graphs. Other implications are discussed in the full version.

1.4 Equivalence of the Colored and Uncolored Problems

All mentioned algorithms and conditional lower bounds are shown for the restricted problem of Colored Subgraph Isomorphism, where the nodes of G and H are colored with $|V(H)|$ colors and the isomorphism must preserve colors, as also studied in [40]. In the full version of the paper, we prove that the standard and the colored variant of Subgraph Isomorphism can be solved in essentially the same running time in almost all cases. Specifically, we show the following lemma.

▶ **Lemma 11.** *Let ρ be any graph parameter.*

1. *If there is a $T(n,k,\rho(H))$ time algorithm for Colored Subgraph Isomorphism, then there is a $\widetilde{O}(T(kn,k,\rho(H))g(k))$ time algorithm for Subgraph Isomorphism, where g is some computable function.*
2. *If there is a $T(n,k,\rho(H),W)$ time algorithm for Exact Weight Colored Subgraph Isomorphism, then there is a $\widetilde{O}(T(kn,k,\rho(H),W)g(k))$ time algorithm for Exact Weight Subgraph Isomorphism, where g is some computable function.*
3. *Let $\mathrm{tw}(H) \geq 2$. If there is a $T(n,k,\mathrm{tw}(H))$ time algorithm for Subgraph Isomorphism, then there is a $O(T(\mathrm{poly}(k)n,\mathrm{poly}(k),\mathrm{tw}(H)) + \mathrm{poly}(k)n^2)$ time algorithm for Colored Subgraph Isomorphism.*
4. *If there is a $T(n,k,\rho(H),W)$ time algorithm for Exact Weight Subgraph Isomorphism, then there is a $O(T(2n,2k,\rho(H),2^kW) + \mathrm{poly}(k)n^2)$ time algorithm for Exact Weight Colored Subgraph Isomorphism.*

This lemma enables us to prove results for (Exact Weight) Subgraph Isomorphism while only talking about the more structured colored variants of the problem.

2 Technical Overview of Our Main Results

We now give proof sketches of our main lower bound results. We do not give proofs for the upper bound results due to their technicality. The full version of this paper contains all proofs with full detail.

2.1 Lower Bound for Subgraph Isomorphism

Our main result is the existence of the hard pattern graphs for bounded-treewidth Subgraph Isomorphism. We now prove their existence for treewidth at least 3 under the Hyperclique hypothesis, i.e. part 1 of Theorem 1.

The exact statement we prove is that for each $t \geq 3$ and each $3 \leq h \leq t$, there exists a pattern graph of treewidth t such that Subgraph Isomorphism cannot be solved in time $O(n^{t+1-\varepsilon})$ on that pattern graph unless the h-uniform $h(t+1)$-hyperclique hypothesis fails. Note that the proof actually shows this for the colored variant of Subgraph Isomorphism, after which we can use Lemma 11 to transfer the lower bound to the uncolored problem.

Proof sketch. See Figure 1 for a sketch of the reduction. Let $t \geq 3$ and $3 \leq h \leq t$ be given and assume that Subgraph Isomorphism can be solved in time $O(n^{t+1-\varepsilon})$ on pattern graphs of treewidth t. We show that the h-uniform $h(t+1)$-hyperclique hypothesis fails.

Construction of H. We construct a pattern graph H as a bipartite graph with vertex set $A \cup B$ as follows. Writing $[c] := \{1,\dots,c\}$, we set $A := [t+1]$ and $B := \binom{A \times [h]}{h}$. We connect a vertex $b = ((a_1,j_1),..,(a_h,j_h))$ in B to a vertex a in A if $a = a_\ell$ for some ℓ. Set $k := |A| + |B|$.

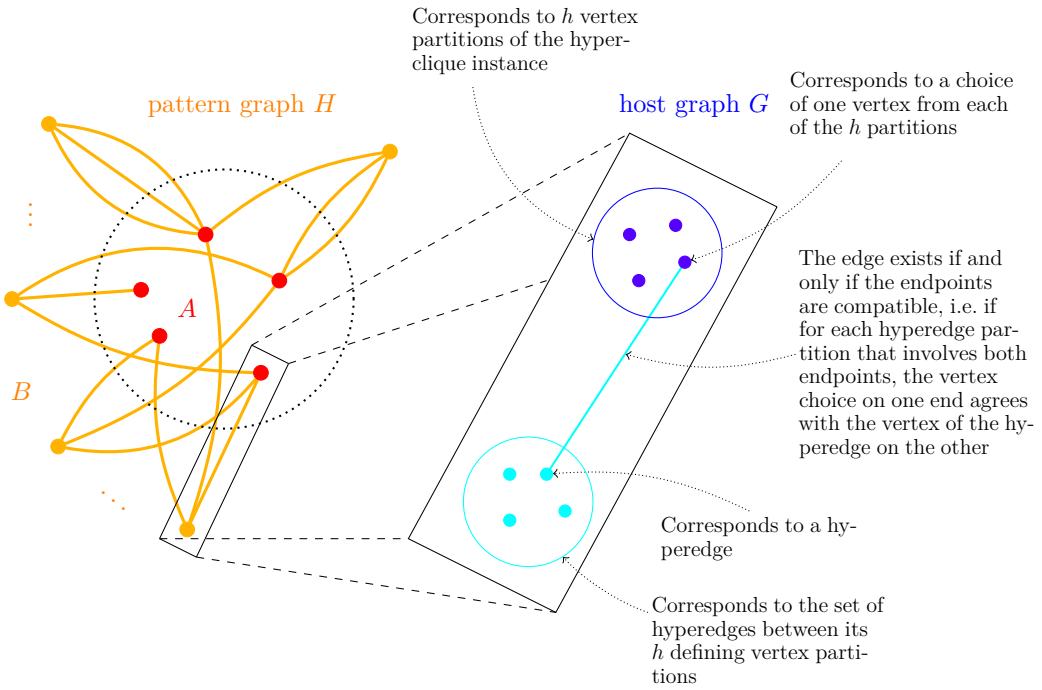

Figure 1 A sketch of the reduction we use to prove part 1 of Theorem 1 where $h = 3$ and $t = 4$. Note that this is only a partial sketch of the pattern graph. We use multiedges to signify that for the endpoints $a \in A$ and $b = ((a_1, j_1), \ldots, (a_h, j_h)) \in B$ there exists more than one ℓ such that $a = a_\ell$.

We show that this pattern has a treewidth of t, via a well-known characterization of treewidth as a graph-theoretic game: A graph F has treewidth $\leq t$ if and only if $t + 1$ cops can catch[3] a robber on F [46]. To show the bound on the treewidth of H, initially place a cop on each vertex of A. No matter on which vertex of B the robber starts, they are surrounded by cops. Since every vertex in B has $h \leq t < t + 1$ neighbors in A, there must exist some cop which is not adjacent to the robber, so this cop can catch the robber in a single step. This concludes the proof that the pattern graph H has treewidth t.

Construction of G. Now given a $h(t + 1)$-partite hypergraph H', i.e. an instance of the h-uniform k'-Hyperclique problem for $k' := h(t + 1)$, we write the vertex set of H' as $U_{1,1} \cup \ldots \cup U_{1,h} \cup \ldots \cup U_{t+1,1} \cup \ldots \cup U_{t+1,h}$. Let N_H be the number of vertices vertices in each partition and $n_H = O(N_H)$ the number of vertices overall.

We construct a k-partite graph G as follows. For a in A we set $V_a := U_{a,1} \times \ldots \times U_{a,h}$. For $b = ((a_1, j_1), .., (a_h, j_h))$ in B, we set $V_b := E(H') \cap (U_{a_1,j_1} \times \ldots \times U_{a_h,j_h})$. This describes the k parts of the k-partite vertex set $V(G)$. Note that each part has size at most $N_G := N_H^h$. Now we construct the edges. For any a in A and $b = ((a_1, j_1), .., (a_h, j_h))$ in B with (a, b) in $E(H)$, consider an arbitrary $u = (u_1, .., u_h)$ in V_a and $u' = (u'_1, ..., u'_h)$ in V_b. We say that u and u' are "compatible" if for every ℓ with $a_\ell = a$ we have $u'_\ell = u_{j_\ell}$; in this case we connect u and u' by an edge. This finishes the construction of G.

[3] The game works as follows: The $k + 1$ cops select their starting vertices in the graph. Then the robber may choose their starting vertex. The cops can always see the robber and adapt their strategy accordingly. Similarly, the robber can see the cops. The game now proceeds in steps, where in each step, one of the cops chooses an arbitrary destination vertex and takes off via helicopter in the direction of that vertex. While the cop is travelling, the robber sees where they will land and may now move arbitrarily along edges of the graph, as long as they do not pass through stationary cops. When the robber has finished moving, the cop lands. The cops win if and only if they are guaranteed to catch the robber after a finite number of moves, and lose otherwise.

Correctness. Note that any colored subgraph isomorphism of H in G chooses vertices v_a in V_a for all a in A. This corresponds to choosing vertices $u_{i,j}$ in $U_{i,j}$ for all i in $[t+1]$, Moreover, the edges of a $h(t+1)$-hyperclique are in one-to-one correspondence with the set B. Since for each b in B the colored subgraph isomorphism of H in G needs to choose a vertex v_b in V_b, which corresponds to an edge between certain vertices $u_{i,j}$, we indeed check that the chosen vertices $u_{i,j}$ form an h-uniform $h(t+1)$-hyperclique.

Running Time. Trivially, the construction time and output size are $O(N_H^{2h})$ (actually, it is slightly better, but this is not important in this proof sketch), and G has $n = O(N_G) = O(N_H^h)$ vertices. Now if we can solve Subgraph Isomorphism in time $O(n^{t+1-\varepsilon})$, we solve the h-uniform $h(t+1)$-Hyperclique instance in time $O(N_H^{2h} + (N_H^h)^{t+1-\varepsilon}) = O(N_H^{h(t+1)-h\varepsilon}) = O(N_H^{h(t+1)-\varepsilon'}) = O(n_H^{h(t+1)-\varepsilon'})$. ◀

This shows part 1 of Theorem 1. Part 2 can be shown by the almost the exact same proof, except that now we choose the size of A to be t instead of $t+1$, and we start with an ht-hyperclique instead of an $h(t+1)$-hyperclique. It can be seen that in this case, the pattern graph still has treewidth t. The third part of the theorem can be seen by simply taking an instance of $(t+1)$-Clique and subdividing the edges in the obvious way to make the graph bipartite.

Let us also quickly mention how the proof of the slightly weaker bounds under SETH, i.e. Theorem 2, works. The split-and-list technique from [48] allows one to reduce the Satisfiability problem to Hyperclique. Using this technique, the following result was shown in [38, Lemma 9.1].

▶ **Lemma 12** ([38]). *Assuming SETH, for any $\varepsilon > 0$ there exists $h \geq 3$ such that for all $k > h$, the h-uniform k-Hyperclique problem is not in time $O(n^{k-\varepsilon})$.*

The SETH result now follows by using essentially the same reduction as above, but we prefix it by the reduction from SAT to Hyperclique.

2.2 Lower Bound for Exact Weight Subgraph Isomorphism

We also give lower bounds for the exact weight variant of the Subgraph Isomorphism problem. In particular, we prove the existence of hard pattern graphs for the bounded-treewidth Exact Weight Subgraph Isomorphism problem for any polynomial weight bound. We give this result for any treewidth which is at least 3, and under the Hyperclique hypothesis. This is part 1 of Theorem 4.

The exact statement we prove is that for each $t \geq 3$, $\gamma \in \mathbb{R}^+$ and $3 \leq h \leq t$, there exists a pattern graph of treewidth t such that Exact Weight Subgraph Isomorphism with maximum weight $W = \Theta(n^\gamma)$ cannot be solved in time $O(n^{t+1-\varepsilon}W)$ unless the h-uniform Hyperclique hypothesis fails. Again, we show this statement for the colored problem and transfer the lower bound via Lemma 11.

To do this, we will encode part of a hyperclique instance in the edges of the Exact Weight Subgraph Isomorphism problem, and the rest of the instance in the weights. To do the latter, we need to encode certain equality constraints only via weights. This can be done using so-called k-average free sets[4], which we define below.

[4] These k-average-free sets are a tool which are very useful for weighted problems, especially when they have additive elements. Such problems include k-sum, Subset Sum, Bin Packing, various scheduling problems, Tree Partitioning, Max-Cut, Maximum/Minimum Bisection, a Dominating Set variant with capacities, and similar [3, 4, 6, 11, 28, 33, 26]. Other uses of k-average-free sets in computer science include constructions in extremal graph theory, see e.g. [1, 2, 8].

▶ **Definition 13** (k-average free sets). *A set $S \subseteq \mathbb{Z}$ is called k-average-free if, for any $s_1, \dots, s_{k'+1} \in S$ with $k' \leq k$, we have $s_1 + \dots + s_{k'} = k' \cdot s_{k'+1}$ if and only if $s_1 = \dots = s_{k'+1}$. In other words, the average of $s_1, \dots, s_{k'} \in S$ is in S if and only if all s_i are equal.*

We use the following construction for k-average free sets, originally proven in [13], modified into a more useful version in [6] and formulated in this form in [3].

▶ **Lemma 14.** *There exists a universal constant $c > 0$ such that, for all constants $\varepsilon \in (0,1)$ and $k \geq 2$, a k-average-free set S of size n with $S \subseteq [0, k^{c/\varepsilon} n^{1+\varepsilon}]$ can be constructed in time* $\mathrm{poly}(n)$.

Let us now prove the statement about Exact Weight Subgraph Isomorphism. We will construct an instance that is node-weighted, however this can easily be converted into an edge-weighted version by moving the weight of each vertex to all of its incident edges.

Proof sketch. Let $t \geq 3$, $3 \leq h \leq t$ and $\gamma \in \mathbb{R}$ be given and assume that Exact Weight Subgraph Isomorphism can be solved in time $O(n^{t+1-\varepsilon}W)$ on instances where the pattern graph has treewidth t and all weights are bounded by $W = \Theta(n^\gamma)$. We show that the h-uniform k-hyperclique hypothesis fails for some large enough k.

Construction of H. We construct a pattern graph H as a graph with vertex set $(A_1 \cup A_2) \cup B$ as follows. We set $A_1 := [t+1]$, $A_2 := [r]$ (for some r large enough) and $B := \binom{(A_1 \cup A_2) \times [h]}{h}$. We connect a vertex $b = ((a_1, j_1), \dots, (a_h, j_h))$ in B to a vertex a in A_1 (not in A_2) if $a = a_\ell$ for some ℓ. Set $k := |A_1| + |A_2| + |B|$. By almost the same proof as in the unweighted version, it can be shown that this pattern H has treewidth t.

Grouping partitions. Now let an instance of the h-uniform k'-Hyperclique problem be given, and write the vertex set of H' as $U_1 \cup \dots \cup U_k$. Let N_H be the number of vertices vertices in each partition and $n_H = O(N_H)$ the number of vertices overall.

We construct the k-partite graph G with at most some number N_G of vertices in each partition as follows. We will encode a β-fraction of the Hyperclique instance in the weights of the final Exact Weight Subgraph Isomorphism instance, and a $(1-\beta)$-fraction in the edges, for some β chosen appropriately. To do this, we will choose β such that $\frac{\beta k'}{hr}, \frac{(1-\beta)k'}{h(t+1)} \in \mathbb{N}$ and then group the sets $U_1, \dots, U_{\beta k'}$ into hr groups and the sets $U_{\beta k'+1}, \dots, U_{k'}$ into $h(t+1)$ groups. Specifically, for each $(x,y) \in [r] \times [h]$, we create the set $U^1_{x,y} = U_{(xr+y-1)\frac{\beta k'}{hr}+1} \times \dots \times U_{(xr+y)\frac{\beta k'}{hr}}$, and for each $(x,y) \in [t+1] \times [h]$, we create the set $U^2_{x,y} = U_{\beta k' + (x(t+1)+y-1)\frac{(1-\beta)k'}{h(t+1)}+1} \times \dots \times U_{\beta k' + (x(t+1)+y)\frac{(1-\beta)k'}{h(t+1)}}$.

Vertices of G. Now for each a in A_1 we set $V_a := U^1_{a,1} \times \dots \times U^1_{a,h}$ and for each a in A_2 we set $V_a := U^2_{a,1} \times \dots \times U^2_{a,h}$. Finally, for each $b = ((a_1, j_1), \dots, (a_h, j_h))$ in B, where for each ℓ we have $a_\ell \in A_{i_\ell}$, we set $V_b := E(H') \cap (U^{i_1}_{a_1,j_1} \times \dots \times U^{i_h}_{a_h,j_h})$. This describes the k parts of the k-partite vertex set $V(G)$. We choose r large enough so that the maximum size of each part is $N_G := N_H^{(1-\beta)k'/(t+1)}$.

Edges of G Now we construct the edges and weights of the graph. Let us start with the edges. The construction here is basically the same as the construction of the edges in the unweighted proof in the last section. For each a in A_2 and $b = ((a_1, j_1), \dots, (a_h, j_h))$ in B with (a,b) in $E(H)$, consider an arbitrary $u = (u_1, \dots, u_h)$ in V_a and $u' = (u'_1, \dots, u'_h)$ in V_b. We say that u and u' are "compatible" if for every ℓ with $a_\ell = a$ we have $u'_\ell = u_{j_\ell}$; in this case we connect u and u' by an edge. This finishes the construction of the edges of G.

Weights of G. Now we construct the weights. We want to encode the same edge constraints as we just encoded for A_2, but now for A_1, and we have to use weights instead of edges. To do this, we use $|B|$-average free sets via the construction of Lemma 14. We simplify the usage in this shortened proof to avoid dealing with too many variables. We use the lemma to obtain in polynomial time (which we will treat as negligible here) a $|B|$-average free set S of size $N_H^{\beta k'/(hr)}$ such that $S \subseteq [0, C]$, where $C \approx O(N_H^{\beta k'/(hr)})$ (up to a factor of $(1+\varepsilon)$ in the exponent, but we will ignore this here for simplicity). From this, we can construct an arbitrary bijection $\varrho_S : [N_H^{\beta k'/(hr)}] \to S$.

To simplify our construction, we specify a target weight T (instead of the default target zero). We can easily get rid of this again later by subtracting T from the weights of all vertices of some set of the partition. The binary representation of T consists of hr blocks of $\lceil 2|B|C \rceil$ bits, indexed by pairs $(i,j) \in [r] \times [h]$, each containing the binary representation of $|B|C$. The block (i,j) represents the group $U^1_{i,j}$. The size of the blocks is large enough to prevent overflow between the blocks. Note that the maximum weight W now satisfies $\log_2(W) = \Theta(hr \log_2(2|B|C))$ and hence $W \approx O(N_H^{\beta k'})$.

Let us now actually specify the weights of the vertices, beginning with the vertices in V_a for $a \in A_1$. For each $(i,j) \in [r] \times [h]$, we relabel the elements of each $U^1_{i,j}$ as $\{1, \ldots, N_H^{\beta k'/(hr)}\}$. Now we define the weight of the vertex $V_a \ni u = (u_1, \ldots, u_h)$ to have, for each $i \in [h]$, the value $|B|C - |N(a)| \cdot \varrho_S(u_i)$ in the block (a,i) of its binary representation. Now we move on to the vertices in V_b for $b = ((a_1, j_1), \ldots, (a_h, j_h))$. We define the weight of the vertex $V_b \ni u' = (u'_1, \ldots, u'_h)$ to have, for each $i \in [h]$ such that $a_i \in A_1$, the value $\varrho_S(u'_i)$ in the block (a_i, j_i) of its binary representation.

All blocks and vertices which have not been assigned a weight yet are assigned a value of zero. This concludes the construction of G.

Correctness. Note that any colored subgraph isomorphism of H in G chooses vertices v_a in V_a for all a in $A_1 \cup A_2$. This corresponds to choosing vertices u_i in U_i for each $i \in [k']$. Moreover, the edges of a k'-hyperclique are in one-to-one correspondence with the set B. We simply need to show that the choice of hyperclique vertices induced by the choice of vertices in $A_1 \cup A_2$ agrees with the choice of hyperclique edges induced by the choice of vertices in B. For the vertices in A_2, this is easily seen to be ensured by the edges. For the vertices in A_1, we need to prove that the weights encode the same constraint. This, however, is simply the definition of a $|B|$-average free set: Consider the block (i,j) (where $(i,j) \in [r] \times [h]$) in the binary representation of the total weight of the subgraph. Suppose that for $i \in A_1$ the vertex $V_i \ni u = (u_1, \ldots, u_h)$ was selected, and that for each $B \ni b = ((a_1, j_1), \ldots, (a_h, j_h))$ with $\exists \ell : (a_\ell, j_\ell) = (i,j)$ the vertex $V_b \ni u' = (u'_1, \ldots, u'_h)$ was selected. Then by construction, the total value in the block (i,j) is the value $|B|C - |N(i)|\varrho_S(u_j)$ (where $N(i)$ is the neighbourhood of $i \in A_1$), plus the value $\varrho_S(u'_\ell)$ for all b as above. Note that the latter term has exactly $|N(i)|$ summands, hence in order for the value in the block to be equal to $|B|C$ as specified by the target weight, we must have that the value of $\varrho_S(u_j)$ is equal to the value of each of the $\varrho_S(u'_\ell)$ by the definition of $|B|$-average free sets. Since ϱ_S is a bijection, this ensures that the choice of hyperclique vertices in the sets appearing in the Cartesian product defining $U^1_{i,j}$ – i.e. $U_{(ir+j-1)\frac{betak'}{hr}+1}, \ldots, U_{(ir+j)\frac{\beta k'}{hr}}$ – agree with the choice of hyperclique edges. This is true for all i,j and hence for each U_ℓ for $\ell \in [k']$.

The other direction is easy to see via a similar, simpler argument. This concludes the correctness proof.

Running Time. It can be seen that the running time of this reduction is $O(N_H^{2h})$, up to the running time of the algorithm for the construction of the $|B|$-average free set, which we will ignore here for sake of simplicity. Now suppose we can solve Exact Weight

Subgraph Isomorphism in time $O(n^{t+1-\varepsilon}W)$. We use the reduction above to convert a Hyperclique instance with $n_H = O(N_H)$ nodes to an Exact Weight Subgraph Isomorphism instance where $W \approx \Theta(N_H^{\beta k'})$ and $n = O(N_H^{(1-\beta)k'/(t+1)})$. Choosing β carefully, we get $W = \Theta(N_H^{\gamma})$; note that we are ignoring some intricacies in the choice of β that arise when you consider the running time of the algorithm that constructs the $|B|$-average free set – the details are available in the full version of this paper. Now via the algorithm for Exact Weight Subgraph Isomorphism, we can solve this instance and hence the original Hyperclique problem in time $O(N_H^{2h}+N_H^{((1-\beta)k'/(t+1))(t+1-\varepsilon)}\cdot N_H^{\beta k'}) = O(N_H^{k'-\varepsilon'}) = O(n_H^{k'-\varepsilon'})$. ◀

It is easy to see that the same proof also rules out algorithms running in time $O(n^{t+1}W^{1-\varepsilon})$. Similar as with the proof for the unweighted problem, basically the same techniques can be used to prove the other parts of Theorem 4.

3 Open Problems

In this paper we discussed many different variants of the Subgraph Isomorphism problem. For some of these variants we leave gaps, which gives rise to several open problems:

1. Can the algorithms for weighted trees be improved? We have shown that some improvements can be made for node-weighted trees (see Theorem 9), but are these optimal? What about edge-weighted trees?
2. Are there fast algorithms for unweighted Subgraph Isomorphism on graphs of bounded pathwidth that do not use rectangular matrix multiplication? Can the gap between exponent $\omega(p-1)$ and exponent p be closed? Similar questions apply to the weighted case; see Theorems 6 and 8.
3. Relatedly, are there good lower bounds for unweighted Subgraph Isomorphism on graphs of bounded pathwidth? Recall that Lemma 11 does not allow us to transfer our lower bounds for the colored case to the uncolored case.

We conclude with some more general open problems:

1. Do our algorithms and lower bounds also work for other types of graph homomorphisms, and for counting the number of solutions? Techniques from [24] seem applicable.
2. In this work we demonstrated the existence of maximally hard patterns for which Subgraph Isomorphism requires time $n^{\mathrm{tw}(H)+1-o(1)}$. Can we classify which (classes of) patterns are maximally hard?
3. Changing our focus from hard patterns to easy patterns, we can ask: do classes of patterns of unbounded treewidth exist for which Subgraph Isomorphism can be solved in time $n^{o(\mathrm{tw}(H))}$? Recall that a conditional lower bound rules out $n^{o(\mathrm{tw}(H)/\log \mathrm{tw}(H))}$ [40].

Abstract

We consider the problem of computing the Boolean convolution (with wraparound) of n vectors of dimension m, or, equivalently, the problem of computing the sumset $A_1 + A_2 + \ldots + A_n$ for $A_1, \ldots, A_n \subseteq \mathbb{Z}_m$. Boolean convolution formalizes the frequent task of combining two subproblems, where the whole problem has a solution of size k if for some i the first subproblem has a solution of size i and the second subproblem has a solution of size $k - i$. Our problem formalizes a natural generalization, namely combining solutions of n subproblems subject to a modular constraint. This simultaneously generalises Modular Subset Sum and Boolean Convolution (Sumset Computation). Although nearly optimal algorithms are known for special cases of this problem, not even tiny improvements are known for the general case.

We almost resolve the computational complexity of this problem, shaving essentially a factor of n from the running time of previous algorithms. Specifically, we present a *deterministic* algorithm running in *almost* linear time with respect to the input plus output size k. We also present a *Las Vegas* algorithm running in *nearly* linear expected time with respect to the input plus output size k. Previously, no deterministic or randomized $o(nk)$ algorithm was known.

At the heart of our approach lies a careful usage of Kneser's theorem from Additive Combinatorics, and a new deterministic almost linear output-sensitive algorithm for non-negative sparse convolution. In total, our work builds a solid toolbox that could be of independent interest.

1 Introduction

In this paper we study n-fold variants of the following fundamental 2-fold problems.

1.1 2-Fold Case

Boolean Convolution and Sumset Computation. In Boolean convolution we are given vectors $A, B \in \{0,1\}^m$ and the task is to compute the vector $C = A \circledast B \in \{0,1\}^m$ defined by $C[k] = \bigvee_i A[i] \wedge B[k-i]$. This formalizes a situation in which we split a computational problem into two subproblems, so that in total there is a solution of size k if and only if for some i there is a solution of the left subproblem of size i and there is a solution of the right subproblem of size $k - i$. This is a natural task that frequently arises in algorithm design. There are two variants of this problem: *Without wraparound* the $\bigvee_i$-quantifier goes

© Karl Bringmann and Vasileios Nakos;
licensed under Creative Commons License CC-BY 4.0

over $0 \leq i \leq k$; *with wraparound* the quantifier goes over all $i \in [m]$ and the entry $B[k-i]$ means $B[(k-i) \bmod m]$. Algorithmically the two variants are equivalent, and throughout this paper we study the latter variant.

An equivalent problem is *sumset computation*: Given sets $A, B \subseteq \mathbb{Z}_m$, compute their sumset $A + B$, which denotes the set of all sums $a + b$ modulo m with $a \in A, b \in B$. This corresponds to Boolean convolution with wraparound[1].

Standard Convolution and Polynomial Multiplication. In (standard) convolution we are given vectors $A, B \in \mathbb{R}^m$ and the task is to compute the vector $C = A \star B \in \mathbb{R}^m$ with $C[k] = \sum_i A[i] \cdot B[k-i]$. For instance, if $A[i]$ and $B[i]$ count the number of size-i solutions of the left and right subproblem, then $C[k]$ counts the number of size-k solutions of the whole problem. Again one can consider variants with or without wraparound. A typical restriction are *non-negative* entries, which is well-motivated in case that A, B, C represent numbers of solutions.

This problem is equivalent to *polynomial multiplication*: Given the coefficients of polynomials $P(X) = \sum_{i=0}^{m} A[i] \cdot X^i$ and $Q(X) = \sum_{i=0}^{m} B[i] \cdot X^i$, compute the coefficients of their product $P \cdot Q$.

State of the Art. Using Fast Fourier Transform (FFT), all of the above problems can be solved in time $O(m \log m)$. A long line of work has considered these problems in a sparse setting, called sparse convolution or sparse polynomial multiplication, see, e.g., [23, 16, 25, 21, 28, 5, 15, 26, 24, 18, 11]. Here the task is to compute the convolution of two sparse vectors much faster than performing FFT, ideally in near-linear time in terms of the input plus output size (i.e., the number of non-zero entries of the input and output vectors). Near-linear in the input plus output size running time was achieved for vectors with non-negative entries by Cole and Hariharan [16] and for general vectors in [24], see also [18] for additional $\log m$ factors improvements. Very recently, a Monte Carlo $O(k \log k)$-time algorithm has been achieved in [11] for non-negative convolution, where k is the input plus output size. Sparse convolution techniques are crucially used in [3, 4, 2, 15, 8, 12], and are also relevant to the study of sparse wildcard matching, a fundamental string problem [14, 16].

However, all known algorithms for these sparse problems are randomized, and thus an open problem is to *close the gap between deterministic and randomized algorithms*. This was explicitly posed as an open problem in [15, Remark 8.2].

Our Contribution to the 2-Fold Case. We present a deterministic algorithm for convolution of non-negative vectors (and thus also for Boolean convolution) running in time $k \cdot m^{o(1)}$, where k is the input plus output size. This matches up to the $m^{o(1)}$ term the best known algorithms in the randomize case [16]. Our algorithm heavily builds upon an algorithm by Chan and Lewenstein [15], which operates under the additional assumption that a small superset of the non-negative terms is known in advance. We remove their assumption by gradually building the sumset using calls to their algorithm.

[1] By removing the modulo operation and thus working over $\mathbb{Z}$ we can also pose a problem variant corresponding to Boolean convolution without wraparound. Again, algorithmically these variants are equivalent, since for any $A, B \subseteq \{0, 1, \ldots, m-1\}$, on the one hand computing $A + B$ over $\mathbb{Z}$ and taking the result modulo m yields $A + B$ over $\mathbb{Z}_m$, and on the other hand computing $A + B$ over $\mathbb{Z}_{2m}$ yields $A + B$ over $\mathbb{Z}$.

▶ **Theorem 1** (Deterministic Non-Negative Sparse Convolution, Section 6). *Denote by $\|x\|_0$ the number of non-zero entries of a vector x. Given vectors $A, B \in \mathbb{R}^m_{\geq 0}$, we can compute their convolution $A \star B$ (with wraparound) in time $\|A \star B\|_0 \cdot m^{o(1)}$ by a deterministic algorithm. More precisely, the running time is $\|A \star B\|_0 \cdot 2^{O(\sqrt{\log \|A \star B\|_0 \log\log m})}$.*

Observe that $\|A\|_0, \|B\|_0 \leq \|A \star B\|_0$, and thus rather than bounding the running time in terms of the input plus output size $\|A\|_0 + \|B\|_0 + \|A \star B\|_0$, it suffices to bound the running time in terms of only the output size $\|A \star B\|_0$. Moreover, note that since $\|A \star B\|_0 \leq m$ the above running time is bounded by $m^{1+o(1)}$. As an additional bonus, our approach gives a quite simple $\|A \star B\|_0 \cdot \operatorname{polylog}(m)$-time Las Vegas algorithm for the 2-fold case of non-negative sparse convolution, see Theorem 17.

We leave it as an open problem whether similarly efficient deterministic algorithms exist under the presence of negative entries.

1.2 n-Fold Case

The focus of this paper is on n-fold generalizations of the above problems. Indeed, in typical applications we do not only split a problem into two subproblems, but these subproblems are recursively split into further subproblems. If the recursion tree has n leaves, we therefore want to compute Boolean convolutions of the form $A_1 \circledast \ldots \circledast A_n$ for vectors $A_1, \ldots, A_n$.

Note that now the "gold standard" would be linear running time in terms of the total input plus output size $k = \|A_1\|_0 + \ldots + \|A_n\|_0 + \|A_1 \circledast \ldots \circledast A_n\|_0$. Note that in contrast to the 2-fold case, the size of the output is incomparable to the size of the input.

A Special Case: Modular Subset Sum. As an example, consider the Modular Subset Sum problem, where we are given $x_1, \ldots, x_n \in \mathbb{Z}_m$ and a target t, and the task is to decide whether for some subset $I \subseteq [n]$ we have $\sum_{i \in I} x_i \equiv t \pmod m$. Observe that the sumset $\{0, x_1\} + \ldots + \{0, x_n\} \subseteq \mathbb{Z}_m$ denotes the set of all attainable subset sums modulo m, and thus Modular Subset Sum can be solved by a direct application of n-fold sumset computation, which is equivalent to n-fold Boolean convolution (with wraparound).

The state of the art for Modular Subset Sum is as follows. A standard dynamic programming approach solves the problem in time $O(n \cdot m)$. After the first improvements by Koiliaris and Xu [20], Axiotis et al. [8] designed an algorithm running in time $O((n+m)\operatorname{polylog}(n+m))$, which was further simplified, sped up and made deterministic in [7, 13]. Those running times match a conditional lower bound based on the Strong Exponential Time Hypothesis [1, 8]. Moreover, all of the above algorithms can be analyzed to run in time $O(k \operatorname{polylog} m)$, where k is the total input plus output size [8].

In other words, for the special case $|A_1| = \ldots = |A_n| = 2$ of n-fold sumset computation near-optimal algorithms are known. Furthemore, the techniques crucially exploit the fact that all sets A_i have constant cardinality. The goal of this paper is to investigate the general case without any restrictions on $|A_i|$. Can one move beyond the problem-specific techniques in [20, 8, 7, 13] which seem to apply solely to Modular Subset Sum?

Naive Approach. As it is already known how to compute $A \star B$ (and thus $A \circledast B$) in time near-linear in the output size [16, 24, 11], is there an easy generalization to compute the n-fold Boolean convolution $A_1 \circledast \ldots \circledast A_n$? Naively, if we compute the n-fold convolution in a linear fashion as $(((A_1 \circledast A_2) \circledast A_3) \star \ldots \circledast A_{n-1}) \circledast A_n$, then each intermediate convolution has input plus output size at most k, so using [16] we can bound the total expected running time by $O(nk \operatorname{polylog} m)$. Unfortunately, this running time analysis is tight. The issue is that up to $\widetilde{\Omega}(n)$ intermediate results may have size $\Omega(k)$.

The same is true if we compute the n-fold convolution in a bottom-up tree-like fashion as $((A_1 \circledast A_2) \circledast (A_3 \circledast A_4)) \circledast \ldots$, as shown by the following example. Pick $b = \lfloor \frac{\log m}{\log \log m} \rfloor$ and $\ell = \lceil \log_b(m) \rceil = \Theta(b)$, and set A_i to the indicator vector of $b^{i \bmod \ell} \cdot \{0, 1, 2, \ldots, b-1\}$. Then the Boolean convolution of any ℓ consecutive A_i's is the all-ones vector and thus has size m, and this holds for $\Omega(n/\ell) = \Omega\big(n \frac{\log \log m}{\log m}\big)$ intermediate convolutions. On the other hand, the input size is $O(n \frac{\log m}{\log \log m})$ and the output size is $O(m)$.

Analyzing the time only in terms of n, m, the naive approach yields time $O(nm \operatorname{polylog} m)$. A simple algorithm using $n-1$ FFTs also yields time $O(nm \log m)$. Before this work it was open whether n-fold Boolean convolution can be solved in time close to linear in $n+m$, and close to linear in k, or whether the additional factor $\widetilde{\Theta}(n)$ of the naive approach is necessary.

n-Fold Boolean Convolution versus n-Fold Convolution. We note that n-fold Boolean convolution is quite different from n-fold convolution, and we focus on the former in this paper. The reason is that n-fold convolution results in exponentially large entries. Indeed, assuming that $A_1, \ldots, A_n$ are non-negative integer vectors, each with at least two non-zero entries, one can check that $\|A_1 \star \ldots \star A_n\|_1 = \|A_1\|_1 \cdot \ldots \cdot \|A_n\|_1 \geq 2^n$ (here $\|x\|_1 = \sum_i |x[i]|$), and thus at least one output entry requires $\Omega(n)$ bits to represent exactly. Possible ways to handle this situation are (1) to let k be the total number of input plus output *bits*, (2) assume that entries come from a finite field, or (3) relax to approximation. We leave these as open problems and focus on Boolean convolution in this paper.

Our Contribution to n-Fold Boolean Convolution. We show that the multiplicative factor n in the naive running times $O(nk \operatorname{polylog} m)$ and $O(s + nm \log m)$ is not necessary (here s is the size of the input). Specifically, our approach yields two new results for n-fold Boolean convolution: a randomized Las Vegas algorithm running in expected time $O(k \cdot \operatorname{polylog} m)$, and a deterministic algorithm running in time $k \cdot m^{o(1)}$. Morally, we show that one can convolve n Boolean vectors in a much better way than doing $n-1$ FFTs. In particular, in terms of m, n and the size of the input s, the known algorithms would run in time $\widetilde{O}(s + mn)$, whereas our approach yields time $\widetilde{O}(s+m)$. Thus, in instances where the size of the input does not dominate (as in Modular Subset Sum where $s = 2n$) our approach yields a substantial improvement.

Our algorithm falls in a line of research that tries to apply results from Additive Combinatorics in algorithm design, such as [17, 15, 6, 9, 22, 12]. Quite interestingly, this is the first time that such a connection has produced an (almost) optimal result. Previous algorithms [17, 15, 6, 9, 22, 12] had less clean running time bounds and are thus likely to be suboptimal, partly because of the Additive Combinatorics machinery used.

We now state our results more formally. The main result of this paper is the following.

▶ **Theorem 2** (n-Fold Boolean Convolution)**.** *Given vectors $A_1, A_2, \ldots, A_n \in \{0,1\}^m$ we can compute their Boolean convolution with wrap-around $A_1 \circledast A_2 \circledast \ldots \circledast A_n$*
(1) *by a randomized Las Vegas algorithm in $O(k \cdot \operatorname{polylog}(mk))$ expected time, or*
(2) *by a deterministic algorithm in $k \cdot 2^{O(\sqrt{\log k \cdot \log\log m})}$ time*
Here, $k := \|A_1\|_0 + \ldots + \|A_n\|_0 + \|A_1 \circledast A_2 \circledast \ldots \circledast A_n\|_0$ is the total input plus output size.

▶ Remark 3. It might seem confusing that for very small k, specifically for $k \leq \log^{O(1)} m$, our deterministic time is faster than our randomized time. However, as we will discuss later, it is easy to solve the problem deterministically in time $k^{O(1)}$. In fact our time bounds are $\min\{k^3, k \cdot \operatorname{polylog}(mk))\}$ expected time, and $\min\left\{k^3, k \cdot 2^{O(\sqrt{\log k \cdot \log\log m})} \cdot \operatorname{polylog}(mk)\right\}$ deterministically; the latter can be simplified to the expression in Theorem 2.

In order to employ Additive Combinatorics machinery, it will be convenient to phrase the problem in terms of sets and sumsets, making the connection more clear. To this end, we replace every vector $A_i \in \{0,1\}^m$ by a set $A'_i \subseteq \mathbb{Z}_m$ such that $x \in A'_i$ if and only the x-th entry of A_i is 1. Then, it can easily be seen that the Boolean convolution $A_1 \circledast A_2 \circledast \ldots \circledast A_n$ is equivalent to computing the sumset $A'_1 + A'_2 + \ldots + A'_n$. Written in a more Additive-Combinatorics-friendly way, our main result can be rephrased in the following way.

▶ **Theorem 4** (Theorem 2 restated, Section 5). *Given sets $A_1, \ldots A_n \subseteq \mathbb{Z}_m$, we can compute their sumset $A_1 + A_2 + \ldots + A_n$*
(1) *by a randomized Las Vegas algorithm in $O(k \cdot \text{polylog}(mk))$ expected time, or*
(2) *by a deterministic algorithm in $k \cdot 2^{O(\sqrt{\log k \cdot \log\log m})}$ time.*
Here, $k := |A_1| + \ldots + |A_n| + |A_1 + \ldots + A_n|$ is the total input plus output size.

We remark that further improvements over Theorem 1 would directly improve Theorems 2 and 4. In particular, our factor $m^{o(1)} = 2^{O(\sqrt{\log m \log\log m})}$ stems entirely from the application of Theorem 1, and thus indirectly from a tool called the FFT Lemma [15] that we use to prove Theorem 1.

We also remark that Theorem 4 is formulated for sumsets over $\mathbb{Z}_m$, but by setting m sufficiently large (like $1 + \sum_i \max(A_i)$) we can also compute sumsets $A_1 + \ldots + A_n \subseteq \mathbb{Z}$ over the integers in time close to the input plus output size. However, this is a much simpler result that can also be achieved by elementary means, without any Additive Combinatorics.

2 Preliminaries and Technical Toolkit

For any positive integer m, we let $\mathbb{Z}_m$ be the group of residues modulo m. For two sets $A, B \subseteq \mathbb{Z}_m$, we define $A + B := \{x \mid \exists a \in A, b \in B \colon a + b = x\}$. Unless explicitly stated otherwise, all sumsets throughout the paper are computed in the underlying group $\mathbb{Z}_m$, i.e., $A + B \subseteq \mathbb{Z}_m$. We also write $A \bmod q := \{a \bmod q \mid a \in A\}$.

Throughout the paper we use the notation of sumset computation instead of the equivalent Boolean convolution.

2.1 Randomized Sumset Computation

Cole and Hariharan's sparse convolution algorithm [16] implies that the sumset $A + B$ can be computed in Las Vegas time $O(|A + B| \cdot \log^2 m + \text{poly}(\log m))$. Very recently, this was improved to $O(|A + B| \cdot \log |A + B| + \text{poly}(\log m))$ [11] with a Monte Carlo algorithm.

▶ **Theorem 5** (Randomized Sumset Computation, [16], see also Section 6). *Given sets $A, B \subseteq \mathbb{Z}_m$, their sumset $A + B$ can be computed in expected time $O(|A + B| \,\text{poly}(\log m))$.*

2.2 The Symmetry Group and its Properties

▶ **Definition 6** (Symmetry group of a set). *Let $A \subseteq \mathbb{Z}_m$. We define the symmetry group of A as $Sym(A) = \{h \in \mathbb{Z}_m \mid A + \{h\} = A\}$.*

It is easy to check that $Sym(A)$ satisfies the group properties with respect to addition, and thus $Sym(A)$ is a subgroup of $\mathbb{Z}_m$. In particular, we have $Sym(A) = d \cdot \mathbb{Z}_{m/d}$, where d is the minimum non-zero element of $Sym(A)$ (to see this, note that the minimum non-zero element of a cyclic subgroup is also a generator of it).

One can check that $Sym(A) \subseteq Sym(A+B)$ holds for any sets $A, B \subseteq \mathbb{Z}_m$. This property will be of great importance to us. Moreover, for any non-empty set A and any $x \in A$ we have $Sym(A) \subseteq A + \{-x\}$. This holds since any $h \in Sym(A)$ maps x to some $x' \in A$, which means $x' = x + h \pmod m$, hence $h = x' - x \pmod m$. In particular, the symmetry group of a non-empty set A has size at most $|A|$.

We show that the symmetry group can be computed in linear time.

▶ **Theorem 7** (Computing the Symmetry Group, Section 7)**.** *Given a sorted non-empty set $A \subseteq \mathbb{Z}_m$, we can compute $Sym(A)$ in time $O(|A|)$.*

2.3 Kneser's Theorem

The following theorem lies at the core of our algorithms.

▶ **Theorem 8** (Kneser's Theorem, see, e.g., Theorem 5.5 in [27])**.** *Let $A, B \subseteq \mathbb{Z}_m$ be non-empty. Then*

$$|A + B| \geq \min\{|A| + |B| - |Sym(A + B)|, m\}.$$

We will use the following simple corollary.

▶ **Corollary 9.** *Let $A, B \subseteq \mathbb{Z}_m$ be non-empty. If $|A+B| < |A|+|B|-1$ then $|Sym(A+B)| > 1$.*

Proof. For $m = 1$ it cannot happen that $|A + B| < |A| + |B| - 1$, so assume $m \geq 2$.

If $|A + B| = m$, then $A + B = \mathbb{Z}_m$. This implies $Sym(A + B) = \mathbb{Z}_m$ and thus $|Sym(A + B)| = m > 1$. Otherwise, if $|A + B| < m$, we can simplify the bound obtained from Kneser's Theorem to

$$|A + B| \geq |A| + |B| - |Sym(A + B)|.$$

Together with $|A + B| < |A| + |B| - 1$, this implies $|Sym(A + B)| > 1$. ◀

3 Overview and Comparison with Previous Approaches

We start by giving a rough overview of our algorithm, leaving out several details. Our improvements are obtained by delving deeper into the additive structure of sumset computation over $\mathbb{Z}_m$ than previous work. Our algorithms compute the sumset $A_1 + \ldots + A_n$ in a bottom-up tree-like fashion as $((A_1 + A_2) + (A_3 + A_4)) + \ldots$. For any two sets X, Y for which we compute $X + Y$ during the execution of this algorithm, we check whether $|X+Y| < |X|+|Y|-1$. If this is the case, Kneser's Theorem (specifically Corollary 9) implies that $X + Y$ has a non-trivial symmetry group, and hence $A_1 + \ldots + A_n$ has a non-trivial symmetry group. A non-trivial symmetry group of a set $Z = X + Y \subseteq \mathbb{Z}_m$ implies that the set is *periodic*: there exists a divisor d of m and a set $Z' \subseteq \{0, \ldots, d-1\}$ such that $Z = Z' + d \cdot \mathbb{Z}_{m/d} = Z' + \{0, d, 2d, \ldots, m-d\}$, i.e., Z is a rotation (by multiples of d) of a subset of $\{0, \ldots, d-1\}$. This allows us to reduce to the smaller universe $\mathbb{Z}_d$, which is progress (it might seem from this discussion that we require a factorization of m, but this is not the case: if we reduce to a smaller universe $\mathbb{Z}_d$, then d is a divisor of m that can be easily read off the sumset $Z = X + Y$, by computing the symmetry group $Sym(X + Y)$ and taking its smallest non-zero element). It remains to argue about the situation in which every computed sumset satisfies $|X + Y| \geq |X| + |Y| - 1$. Using this inequality, we can control at any intermediate step of the algorithm the total size of all sumsets computed so far. When the computation arrives at the root, the running time that we spent on computing these sumsets is almost linear in the input plus output size.

Why Previous Approaches Cannot Solve the Generalized Problem. A natural question to ask is whether previous algorithms for Subset Sum or Modular Subset Sum were also able to tackle the more general problem of n-fold sumset computation. The techniques underlying the algorithms for Subset Sum in [10, 20, 19] are inherently non-modular, and hence cannot facilitate n-fold sumset computation problem over the group $\mathbb{Z}_m$. More relevant is the Modular Subset Sum problem, which is a standard variant of Subset Sum, where one works over $\mathbb{Z}_m$ rather than $\mathbb{Z}$. This problem has seen two interesting developments in the last few years.

The deterministic algorithm of Koiliaris and Xu [20] uses multiple interesting problem-specific tricks for Modular Subset Sum, but it is unclear how to generalize them to n-fold sumset computation. In fact, their algorithm can be viewed as a reduction from Modular Subset Sum to $\min\{\sqrt{n}, m^{1/4}\}$-fold sumset computation, which they then solve by the straightforward repeated Fast Fourier Transform. Hence, also for the general case of n-fold sumset computation their approach does not seem to yield time $o(nm)$.

All known algorithms for Modular Subset Sum [8, 7, 13] compute the set of attainable subset sums $\mathcal{S}(A) = \{0, a_1\} + \ldots + \{0, a_n\} \subseteq \mathbb{Z}_m$ for $A = \{a_1, \ldots, a_n\}$. The main idea is to compute $\mathcal{S}(A)$ from $\mathcal{S}(A \setminus \{a\})$ by forming the vector $1_{a+\mathcal{S}(A\setminus\{a\})} - 1_{\mathcal{S}(A\setminus\{a\})}$. It can be easily seen that this vector consists of an equal number of positive and negative entries, and the positive entries correspond to the "new" sums $\mathcal{S}(A) \setminus \mathcal{S}(A \setminus \{a\})$. Using hashing-based arguments or appropriate data structures for string manipulation, they show how to recover the support of the aforementioned vector in near-linear output-sensitive time. A possibility to generalize this approach to n-fold sumset computation $A_1 + \ldots + A_n$ would be to consider the vector $\sum_{a\in A_n}(1_{a+A_1+\ldots+A_{n-1}} - 1_{A_1+\ldots+A_{n-1}})$. However, measuring this vector would incur time $\Omega(|A_n|)$, and thus an immediate generalization of their approach would at least pay a factor $\max_i |A_i|$ on top of the output size.

Symmetry Manifestations in Higher Dimensions. It would be interesting to understand whether the symmetry considerations of our algorithm manifest themselves in other abelian groups, most notably in $\mathbb{Z}_m^D$. The characterization of subgroups over $\mathbb{Z}_m^D$ with $D > 1$ is less convenient for our purposes than the characterization in the one-dimensional case, so it seems that a different treatment and notion of progress is needed in that case. We leave this to potential future work. Even if one does worry about the n-fold case and concentrates in the simplest case of $n = 2$, i.e. 2-fold d-dimensional sparse convolution, the best algorithm we are aware of solves the problem with a multiplicative 2^d multiplicative factor on top of output size. We leave as an open question the problem of avoiding the exponential dependence of 2-fold d-dimensional sparse convolution.

4 Warmup: n-Fold Sumset Computation over Prime Universe

As a warmup, we consider universe $\mathbb{Z}_m = \mathbb{Z}_p$ for prime p. For simplicity, we analyze our algorithm only in terms of the input size and the universe size p, that is, we defer the output-sensitive analysis to the general algorithm in Section 5.

Suppose we are given sets $A_1, \ldots, A_n \subseteq \mathbb{Z}_p$. We may assume that n is a power of 2, since otherwise we can add an appropriate number of sets $A_i = \{0\}$ without affecting the sumset. Consider Algorithm 1. We compute $A_1 + \ldots + A_n$ in a tree-like bottom-up fashion, by first computing $A_1 + A_2, A_3 + A_4, \ldots$, then computing $A_1 + A_2 + A_3 + A_4, \ldots$, and so on. The intermediate sets in round r are called $X_{r,1}, \ldots, X_{r,n/2^r}$. The termination criterion is that the sets that we computed so far in the current round r have total size significantly more

Algorithm 1 Computing the n-fold sumset $A_1 + \ldots + A_n$ over $\mathbb{Z}_p$ for prime p.

```
1: procedure nFoldSumsetInPrimeUniverse(A_1, A_2, ..., A_n, p)
2:                          ▷ n is a power of 2; p is prime; non-empty sets A_1, ..., A_n ⊆ Z_p
3:     X_{0,i} ← A_i, for all i ∈ [n]
4:     for r = 1 to log n do
5:         for i = 1 to n/2^r do
6:             X_{r,i} ← X_{r-1,2i-1} + X_{r-1,2i}        ▷ sumset computation via Theorem 1
7:             if Σ_{j≤i} |X_{r,j}| > p + i - 1 then
8:                 return Z_p
9:     return X_{log n,1}
```

than p, more precisely, $\sum_{j\leq i} |X_{r,j}| > p + i - 1$. If this criterion is satisfied, then we return the complete universe $\mathbb{Z}_p$. If the termination criterion is never satisfied, then in the end we return $X_{\log n,1}$.

It remains to analyze correctness and running time of this algorithm. To analyze correctness of the termination criterion, we need the following lemma.

▶ **Lemma 10.** *Let p be a prime, and let $A_1, A_2, \ldots, A_n \subseteq \mathbb{Z}_p$ be non-empty. If $\sum_{j=1}^{n} |A_j| \geq p + n - 1$, then $A_1 + A_2 + \ldots + A_n = \mathbb{Z}_p$.*

Proof. Suppose that the symmetry group has size $|Sym(A_1 + \ldots + A_n)| > 1$. Since $\mathbb{Z}_p$ has no non-trivial subgroups, this yields $Sym(A_1 + \ldots + A_n) = \mathbb{Z}_p$. Since $|Sym(A)| \leq |A|$ holds for any set A, we obtain $A_1 + \ldots + A_n = \mathbb{Z}_p$.

It remains to consider the case $|Sym(A_1 + \ldots + A_n)| = 1$. Since $Sym(A) \subseteq Sym(A + B)$ holds for any sets A, B, it follows that $|Sym(A_1 + \ldots + A_i)| = 1$ for all $1 \leq i \leq n$. We now inductively prove that $|A_1 + \ldots + A_i| \geq \min\{\sum_{j=1}^{i} |A_j| - i + 1, p\}$, from which the corollary follows. The induction base for $i = 1$ is trivial. For $i > 1$, we use Kneser's theorem on $A := A_1 + \ldots + A_{i-1}$ and $B := A_i$ to obtain

$$|A_1 + \ldots + A_i| \geq \min\left\{|A_1 + \ldots + A_{i-1}| + |A_i| - |Sym(A_1 + \ldots + A_i)|, p\right\}.$$

Plugging in $|Sym(A_1 + \ldots + A_i)| = 1$ and the induction hypothesis on $|A_1 + \ldots + A_{i-1}|$, and simplifying $\min\{\min\{a, p\} + b, p\}$ to $\min\{a + b, p\}$, yields

$$|A_1 + \ldots + A_i| \geq \min\left\{\left(\sum_{j=1}^{i-1} |A_j| - (i-1) + 1\right) + |A_i| - 1, p\right\} = \min\left\{\sum_{j=1}^{i} |A_j| - i + 1, p\right\},$$

which finishes the inductive proof.[2] ◀

▶ **Lemma 11** (Analysis of Algorithm 1)**.** *Given non-empty sets $A_1, \ldots, A_n \subseteq \mathbb{Z}_p$, where p is prime and n is a power of 2, Algorithm 1 correctly computes $A_1 + \ldots + A_n$ and runs in deterministic time $O((p+n)^{1+o(1)} + \sum_{i=1}^{n} |A_i|)$.*

Proof. If the termination criterion $\sum_{j\leq i} |X_{r,j}| > p + i - 1$ is satisfied, then Lemma 10 implies that $X_{r,1} + \ldots + X_{r,i} = \mathbb{Z}_p$, and hence $A_1 + \ldots + A_n = \mathbb{Z}_p$, so we correctly return $\mathbb{Z}_p$. Otherwise we reach the last line of Algorithm 1, and we correctly computed $X_{\log n,1} = A_1 + \ldots + A_n$. This shows correctness.

[2] We remark that for this lemma it would be sufficient to use the Cauchy-Davenport theorem (see, e.g., [27, Theorem 5.4]) instead of Kneser's theorem. Only for the generalization to non-prime m we need the more general theorem by Kneser.

To analyze the running time, let (r^*, i^*) be the values of r and i at the end of the execution of the algorithm. In particular, if $r^* = \log n$ we have $i^* = 1$. By our use of Theorem 1, the total running time of the algorithm is

$$\sum_{r<r^*} \sum_{i=1}^{n/2^r} |X_{r,i}| \cdot p^{o(1)} + \sum_{i \le i^*} |X_{r^*,i}| \cdot p^{o(1)}.$$

We use the fact that the termination criterion was not satisfied before step (r^*, i^*) to obtain:

$$\sum_{i=1}^{n/2^r} |X_{r,i}| \le p + \frac{n}{2^r} - 1 \qquad \text{for any } r < r^*,$$
$$\sum_{i<i^*} |X_{r^*,i}| \le p + \frac{n}{2^{r^*}} - 1.$$

Moreover, we have $|X_{r^*,i^*}| \le p$. Combining these observations allows us to further bound the running time by

$$\left(\sum_{r<r^*} \left(p + \frac{n}{2^r} - 1\right) + \left(p + \frac{n}{2^{r^*}} - 1\right) + p \right) \cdot p^{o(1)} = (p \log n + n) \cdot p^{o(1)} = (p+n)^{1+o(1)}. \blacktriangleleft$$

5 Algorithm for n-Fold Sumset Computation

This section proves Theorem 4. The main idea is that whenever we detect a non-trivial symmetry group we reduce to a problem over a smaller universe $\mathbb{Z}_d$, for a divisor d of m.

Consider Algorithm 2. Suppose we are given sets $A_1, \ldots, A_n \subseteq \mathbb{Z}_p$. We may assume that n is a power of 2, since otherwise we can add an appropriate number of sets $A_i = \{0\}$ without affecting the sumset. We maintain a guess s of the outputsize $|A_1 + \ldots + A_n|$. Specifically, s loops over all powers of 2 starting from $2^0 = 1$, and the algorithm returns the correct result once we reach the first iteration with $s \ge |A_1 + \ldots + A_n|$. Thus, in iteration s we know that the output size is more than $s/2$, and our primary goal is to test whether $|A_1 + \ldots + A_n| \le s$. If this is true then we want to compute the set $A_1 + \ldots + A_n$. We compute $A_1 + \ldots + A_n$ in a tree-like bottom-up fashion, by first computing $A_1 + A_2, A_3 + A_4, \ldots$, then computing $A_1 + A_2 + A_3 + A_4, \ldots$, and so on. The intermediate sets in round r are called $X_{r,1}, \ldots, X_{r,n/2^r}$. Our two main ideas now are as follows.

First, due to the presence of non-trivial subgroups in $\mathbb{Z}_m$ when m is not a prime, an intermediate set $X_{r,i}$ can have a non-trivial symmetry group $Sym(X_{r,i})$. As a criterion for a non-trivial symmetry group we test whether $|X_{r,i}| < |X_{r-1,2i}| + |X_{r-1,2i+1}| - 1$ (cf. Corollary 9 of Kneser's Theorem). Once we have found a non-trivial symmetry group $Sym(X_{r,i})$, then also $Sym(A_1 + \ldots + A_n) \supseteq Sym(X_{r,i})$ is non-trivial, and thus the output set $A_1 + \ldots + A_n$ is periodic, with period length $d = m/|Sym(X_{r,i})|$. It therefore suffices to compute $A_1 + \ldots + A_n$ modulo d. Hence, we reduce to a problem over a smaller universe $\mathbb{Z}_d$. This case is handled in lines 8-12. Note that d may not be the smallest period length for $A_1 + A_2 + \ldots + A_n$, but since we only need to reduce the problem size, any period suffices for us.

Second, if the criterion $|X_{r,i}| < |X_{r-1,2i}| + |X_{r-1,2i+1}| - 1$ is never satisfied, then we can use it to bound the output size. Specifically, we obtain a lower bound for $|X_{\log n,1}|$ in terms of the total intermediate size $\sum_j |X_{r,j}|$. In particular, if the total intermediate size is much larger than s, then also the output size is more than s. However, we cannot move to the next guess $2s$ yet, since we do not know whether the criterion $|X_{r,i}| < |X_{r-1,2i}| + |X_{r-1,2i+1}| - 1$ will

Algorithm 2 Computing the n-fold sumset $A_1 + \ldots + A_n$ over $\mathbb{Z}_m$ for general m.

```
1:  procedure nFoldSumset(A_1, ..., A_n, m)
2:                                  ▷ n is a power of 2; non-empty A_1, ..., A_n ⊆ Z_m
3:      for s = 1, 2, 4, ..., 2^⌈log m⌉ do
4:          X_{0,i} ← A_i, for all i ∈ [n]

9:                      Compute Sym(X_{r,i})    ▷ symmetry group computation via Theorem 7
10:                     d ← m/|Sym(X_{r,i})|                ▷ Sym(X_{r,i}) = d · Z_{m/d}
11:                     A'_i ← A_i mod d, for all i ∈ [n]
12:                     return nFoldSumset(A'_1, ..., A'_n, d) + d · {0, 1, 2, ..., m/d - 1}
13:                 if Σ_{j≤i} |X_{r,j}| ≥ s + n/2^r then
14:                     X_{r,j} ← {0}, for all i < j ≤ n/2^r
15:                     break
16:         if |X_{log n,1}| ≤ s then
17:             return X_{log n,1}
```

be satisfied in future rounds $r' > r$. Nevertheless, we argue that once we have intermediate set size $\sum_{j \le i} |X_{r,j}| \gg s$, then we can ignore the remaining sets $X_{r,j}$, $j > i$, by setting them to $\{0\}$, cf. lines 13-15. This allows us to bound the total size of all intermediate sets to be linear in the input plus output size.

We next prove correctness and then analyze the running time of Algorithm 2.

▶ **Lemma 12** (Correctness of Algorithm 2). *Given non-empty sets $A_1, \ldots, A_n \subseteq \mathbb{Z}_m$, where n is a power of 2, Algorithm 2 correctly computes $A_1 + \ldots + A_n$.*

Proof. Note that without lines 13-15, we would compute the sumset in a straightforward bottom-up tree-like fashion as $((A_1 + A_2) + (A_3 + A_4)) + \ldots$, and thus the intermediate set $X_{r,i}$ would be equal to $A_x + A_{x+1} + \ldots + A_y$ for $x = (i-1)2^r + 1$ and $y = i2^r$. In the additional lines 13-15, we set some intermediate sets $X_{r,i}$ to $\{0\}$. Thus, we may lose some summands, but any intermediate set $X_{r,i}$ still corresponds to the sumset of a subset of its summands $A_x, A_{x+1}, \ldots, A_y$. More precisely, the set $X_{r,i}$ satisfies $X_{r,i} = A_{z_1} + A_{z_2} + \ldots + A_{z_\ell}$ for some $\{z_1, \ldots, z_\ell\} \subseteq \{x, x+1, \ldots, y\}$, with the understanding that $X_{r,i} = \{0\}$ if $\ell = 0$. (This property holds initially in line 4 and it continues to hold when we set $X_{r,i}$ in lines 7 and 14.) In particular, we always have

$$Sym(X_{r,i}) = Sym(A_{z_1} + A_{z_2} + \ldots + A_{z_\ell}) \subseteq Sym(A_1 + \ldots + A_n). \tag{1}$$

Moreover, we also infer

$$|X_{r,i}| = |A_{z_1} + A_{z_2} + \ldots + A_{z_\ell}| \le |A_1 + \ldots + A_n|. \tag{2}$$

We shall perform induction on the universe size m. For the base case $m = 1$, the result is obvious. For larger m, we consider the following two cases.

Case 1: *At some point in the execution, the criterion $|X_{r,i}| < |X_{r-1,2i-1}| + |X_{r-1,2i}| - 1$ in line 8 is satisfied.* Then by Corollary 9, $Sym(X_{r,i})$ is non-trivial and hence $Sym(A_1 + \ldots + A_n) \supseteq Sym(X_{r,i})$ is also non-trivial. We make use of the fact that all subgroups of

$\mathbb{Z}_m$ are of the form $d \cdot \mathbb{Z}_{m/d}$, where d divides m. In particular, $Sym(X_{r,i}) = d \cdot \mathbb{Z}_{m/d}$ for $d := m/|Sym(X_{r,i})|$. This means that $A_1 + \ldots + A_n$ is cyclic with period length d. It follows that for $A'_i := A_i \bmod d$ we have (using the induction hypothesis on d)

$$A_1 + \ldots + A_n = \textsc{nFoldSumset}(A'_1, \ldots, A'_n, d) + d \cdot \{0, 1, \ldots, \tfrac{m}{d} - 1\}.$$

This shows correctness of lines 8-12.

Case 2: *Lines 8-12 are never executed.* That is, for each computed set $X_{r,i}$ in line 7 we have

$$|X_{r,i}| \geq |X_{r-1,2i-1}| + |X_{r-1,2i}| - 1. \tag{3}$$

We use inequality (3) to analyze line 13. Fix any $s \in \{1, 2, 4, \ldots, 2^{\lceil \log m \rceil}\}$, and consider iteration s.

▷ Claim 13. In iteration s, we have $|X_{\log n,1}| > s$ if and only if $|A_1 + \ldots + A_n| > s$. Moreover, if $|X_{\log n,1}| \leq s$ then $X_{\log n,1} = A_1 + \ldots + A_n$.

Comparing this claim with lines 16-17, we see that if our guess s for the output size is too small, i.e., $|A_1 + \ldots + A_n| > s$, then the algorithm proceeds with the next larger guess. Otherwise, the algorithm correctly computes $X_{\log n,1} = A_1 + \ldots + A_n$ and returns this set. It remains to prove the claim.

Proof. The "only if" part follows from the bound $|X_{\log n,1}| \leq |A_1 + \ldots + A_n|$ by (2).

For the "if" part, we consider two cases:

Case A: If the criterion $\sum_{j \leq i} |X_{r,j}| \geq s + n/2^r$ in line 13 is never satisfied, then the algorithm computes $X_{\log n,1} = A_1 + \ldots + A_n$ in a straightforward manner, and thus $|X_{\log n,1}| = |A_1 + \ldots + A_n|$.

Case B: If the criterion $\sum_{j \leq i} |X_{r,j}| \geq s + n/2^r$ in line 13 is satisfied in some iteration r, then the following bound shows that it will also be satisfied in iteration $r + 1$ for some value of i:

$$\sum_{j=1}^{n/2^{r+1}} |X_{r+1,j}| \overset{(3)}{\geq} \sum_{j=1}^{n/2^r} |X_{r,j}| - \frac{n}{2^{r+1}} \geq \left(s + \frac{n}{2^r}\right) - \frac{n}{2^{r+1}} = s + \frac{n}{2^{r+1}}.$$

This nearly proves that the criterion is satisfied in iteration $r + 1$, but it ignores that some of the sets $X_{r+1,j}$ could be set to $\{0\}$ by lines 13-15. However, when this happens then by the criterion in line 13 we nevertheless have $\sum_{j=1}^{n/2^{r+1}} |X_{r+1,j}| \geq s + n/2^{r+1}$.

Therefore, if the criterion in line 13 is satisfied in some iteration r, then it is also satisfied for $r = \log n$, which yields $|X_{\log n,1}| \geq s + 1 > s$.

In either case, we obtain $|X_{\log n,1}| > s$ if $|A_1 + \ldots + A_n| > s$. This proves the equivalence.

For the second claim, note that $|X_{\log n,1}| \leq s$ only happens in Case A, and in this case we showed that $X_{\log n,1} = A_1 + \ldots + A_n$. ◁

In summary, if at any point during the course of the algorithm the criterion $|X_{r,i}| < |X_{r-1,2i-1}| + |X_{r-1,2i}| - 1$ in line 8 is satisfied (Case 1), then we have found a non-trivial symmetry group, and we can move to a problem over a smaller universe $\mathbb{Z}_d$, where $d < m$

is a divisor of m. Correctness then follows by induction on m. If this never happens (Case 2), then the algorithm behaves as follows. We have an increasing guess s for the output size $|A_1 + \ldots + A_n|$. When this guess is too small, at some point the criterion $\sum_{j \le i} |X_{r,j}| \ge s + n/2^r$ in line 13 is satisfied, from which point on we set some of the sets $X_{r,i}$ to $\{0\}$, but we ensure that we end up with $|X_{\log n,1}| > s$. This allows us to conclude that our guess s was too small, so we increase it. When our guess s reaches the smallest power of 2 that is at least $|A_1 + \ldots + A_n|$, then the algorithm correctly computes $X_{\log n,1} = A_1 + \ldots + A_n$ and returns this set. ◀

▶ **Lemma 14** (Running Time of Algorithm 2). *Let $k := |A_1| + \ldots + |A_n| + |A_1 + \ldots + A_n|$ be the total input plus output size. Depending on whether we use Theorem 1 or Theorem 5 for sumset computation, Algorithm 2 is*

1. *deterministic and runs in time $k \cdot 2^{O(\sqrt{\log k \log\log m})} \cdot \log m$, or*
2. *randomized and runs in expected time $O(k \cdot \mathrm{polylog}(mk))$.*

Proof. Let $T(k, m)$ be the running time of our algorithm. Note that we have at most one call to a recursive subproblem in line 12, incurring time $T(k, d)$, where d is a divisor of m and thus $d \le m/2$.

Let s^* be the smallest power of 2 that is at least $|A_1 + \ldots + A_n|$. Similarly as in the proof of correctness, we see that the algorithm only performs iterations s from 1 to at most s^*, since we return the correct output in iteration s^*, unless we call a recursive subproblem before that.

We bound the running time in iteration s as follows. For any iteration r, let $X_{r,i(r)}$ be the last set that we computed in line 7. (That is, after computing $X_{r,i(r)}$ we either move to a recursive call, or we set all remaining sets $X_{r,j} \leftarrow \{0\}$, for any $j > i(r)$.) Note that $\sum_{j<i(r)} |X_{r,j}| < s + n/2^r$, since otherwise we would have set $X_{r,i(r)} \leftarrow \{0\}$ and not computed it in line 7. Moreover, $|X_{r,i(r)}| \le |A_1 + \ldots + A_n| \le k$ by (2). By Theorem 1, computing $X_{r,i}$ takes time

$$|X_{r,i}| \cdot 2^{O(\sqrt{\log |X_{r,i}| \log\log m})} \le |X_{r,i}| \cdot 2^{O(\sqrt{\log k \log\log m})}.$$

Therefore, the total time spent in iteration r is bounded by

$$\left(s + \frac{n}{2^r} + k\right) \cdot 2^{O(\sqrt{\log k \log\log m})} \le k \cdot 2^{O(\sqrt{\log k \log\log m})},$$

for any $1 \le s \le s^* = O(k)$. Summing over all iterations r adds a factor $\log n \le \log k \le 2^{O(\sqrt{\log k})}$, which can be ignored. Summing over all iterations s adds a factor $\log s^* = O(\log k)$, which can also be ignored. Adding the potential recursive call, the total running time is

$$T(k, m) \le k \cdot 2^{O(\sqrt{\log k \log\log m})} + T(k, m/2).$$

This solves to total time $k \cdot 2^{O(\sqrt{\log k \log\log m})} \cdot \log(m)$.

The analysis of the randomized variant is analogous. ◀

Proof of Theorem 4. Algorithm 2 almost proves the theorem, except that the deterministic running time shown in Lemma 14 is $k \cdot 2^{O(\sqrt{\log k \log\log m})} \cdot \log m$ instead of the promised $k \cdot 2^{O(\sqrt{\log k \log\log m})}$. Note that the former can be bounded by the latter unless $k \le \log^c m$, for some absolute constant c. In the case $k \le \log^c m$ we switch to a different algorithm. Specifically, we simply compute $((A_1 + A_2) + A_3) + \ldots + A_n$ in a linear fashion, in each step using a naive sumset computation that computes $A + B$ in time $\widetilde{O}(|A| \cdot |B|)$. Since

each intermediate result has size at most k, each sumset computation takes time $O(k^2)$. Since $n \leq k$, in total this simple algorithm runs in time $O(k^3)$. Finally, since $k \leq \log^c m$ we can bound $O(k^3) \leq 2^{O(\sqrt{\log k \log\log m})}$. This shows the promised running time also in case $k \leq \log^c m$. We obtain the promised guarantees even if we do not know k, by running both algorithms in parallel until the first one finishes. ◀

6 Output-sensitive Sumset Computation

Recall that in sumset computation we are given sets $A, B \subseteq \mathbb{Z}_m$ and the task is to compute $A + B$. In this section we present a deterministic algorithm for sumset computation. We also show a generalization to convolution of non-negative vectors, proving Theorem 1.

Chan and Lewenstein [15] designed very efficient algorithms for sumset computation in a specialized setting, in which the input additionally contains a set T promised to be a superset of $A + B$. Their running time is close to linear in $|T|$. Specifically, they proved the following lemma.

▶ **Lemma 15** (FFT Lemma from [15]). *Given sets $A, B \subseteq \{0, 1, \ldots, m-1\}$ and given a set T which is known to be a superset of $A + B$, we can compute $A + B$ (over $\mathbb{Z}$)*
(1) *by a randomized Las Vegas algorithm in $O(|T| \operatorname{polylog} m)$ expected time, or*
(2) *by a deterministic algorithm in $|T| \cdot 2^{O(\sqrt{\log |T| \log\log m})}$ time*
The running time bounds are taken from [15, Section 8].

Here we show a trick that yields the same time bounds in the standard setting (without the additional set T). We note that it makes no significant difference whether we compute $A + B$ over $\mathbb{Z}_m$ or over $\mathbb{Z}$, as discussed also in the introduction. We choose to work over $\mathbb{Z}_m$, for consistency with the rest of this paper.

▶ **Lemma 16.** *Given sets $A, B \subseteq \mathbb{Z}_m$, we can compute $A + B$ (over $\mathbb{Z}_m$)*
(1) *by a randomized Las Vegas algorithm in $O(|A + B| \operatorname{polylog} m)$ expected time, or*
(2) *by a deterministic algorithm in $|A + B| \cdot 2^{O(\sqrt{\log |A+B| \log\log m})}$ time.*

Note that bullet point (1) reproves Theorem 5 by Cole and Hariharan [16], and bullet point (2) answers an open problem by Chan and Lewenstein [15].

Proof. First note that we can assume m to be a power of 2. Indeed, if m is not a power of 2, we let m' be the smallest power of 2 greater than $2m$. Given $A, B \subseteq \{0, 1, \ldots, m-1\}$ we compute $A + B$ over $\mathbb{Z}_{m'}$ and take the resulting set modulo m to obtain $A + B$ over $\mathbb{Z}_m$. This assumption is not necessary, but shall make the exposition cleaner, avoiding using the ceil and floor functions.

So assume that m is a power of 2, and set $m' := m/2$. Let $A' := A \bmod m'$ and $B' := B \bmod m'$ and recursively compute $S := A' + B'$ over $\mathbb{Z}_{m'}$. Then we have $S = (A+B) \bmod m'$. Thus, since $\max(A) + \max(B) < 2m \leq 4m'$, the set $T := S + \{0, m', 2m', 3m'\}$ covers $A + B$. In other words, T is a superset of $A + B$ over $\mathbb{Z}$. We can thus use the FFT Lemma to compute $A + B$ over $\mathbb{Z}$. Reducing the resulting set modulo m yields $A + B$ over $\mathbb{Z}_m$. This leads to the recursive Algorithm 3.

Since we can bound $|T| \leq 4|S| \leq 4|A + B|$, the expected running time of one recursive step is $O(|A + B| \cdot \operatorname{polylog} m)$, and there are $O(\log m)$ recursive steps. This yields the claimed randomized running time. For the deterministic variant we obtain running time $|A + B| \cdot 2^{O(\sqrt{\log |A+B| \log\log m})} \cdot \operatorname{polylog} m$ from the FFT Lemma, times an additional $\log m$ factor due to the recursion.

Algorithm 3 A deterministic algorithm for computing the sumset $A + B$ over $\mathbb{Z}_m$.

```
1: procedure DeterministicSumset(A, B, m)
2:                ▷ m is a power of 2; non-empty A, B ⊆ Z_m; computes A + B over Z_m
3:     m' := m/2
4:     S ← DeterministicSumset(A mod m', B mod m', m')
5:     T ← S + {0, m', 2m', 3m'} over Z                    ▷ T ⊇ A + B over Z
6:     Compute R := A + B over Z via the FFT Lemma using additional input T
7:     return R mod m
```

Now, to get rid of the additional polylog(m) factor and obtain the promised guarantee, we shall observe the following. If $|A + B| \geq \log m$, then this running time is bounded by the claimed $|A + B| \cdot 2^{O(\sqrt{\log |A+B| \log\log m})}$. If $|A + B| < \log m$, then the naive approach which computes $A + B$ in time $\tilde{O}(|A| \cdot |B|) = \tilde{O}(|A + B|^2) = 2^{O(\sqrt{\log |A+B| \log\log m})}$. Running both algorithms in parallel until the first one finishes yields the claimed bound. ◀

A similar result also holds for convolution of non-negative vectors. We denote by $\|x\|_0$ the number of non-zero entries of a vector x.

▶ **Lemma 17.** *Given vectors $A, B \in \mathbb{R}^m_{\geq 0}$, we can compute their convolution $A \star B$ (with wraparound)*
(1) *by a randomized Las Vegas algorithm in $O(\|A \star B\|_0 \operatorname{polylog} m)$ expected time, or*
(2) *by a deterministic algorithm in $\|A \star B\|_0 \cdot 2^{O(\sqrt{\log \|A\star B\|_0 \log\log m})}$ time.*
Again bullet point (1) reproves a result by Cole and Hariharan [16], and bullet point (2) proves Theorem 1.

Proof. Denote by I and J the indicator vectors of the non-zero entries of A and B, respectively. Observe that $|I + J| = \|A \star B\|_0$. We can thus compute $I + J$ in expected time $O(\|A \star B\|_0 \operatorname{polylog} m)$ by Lemma 16. We now make use of a variant of the FFT Lemma from [15, Remark 8.2], stating that if we know a superset $T \supseteq I + J$ then we can compute $A \star B$ in expected time $O(|T| \operatorname{polylog} m)$. Using this for $T = I + J$ yields expected time $O(\|A \star B\|_0 \operatorname{polylog} m)$, or time $\|A \star B\|_0 \cdot 2^{O(\sqrt{\log \|A\star B\|_0 \log\log m})} \cdot \operatorname{poly}(\log m)$ for the deterministic variant. Now, we can get rid of the polylog(m) factors in the deterministic variant using the same argument as the one in Lemma 16. ◀

7 Computing the Symmetry Group

In this section, we show how to compute the symmetry group $Sym(A)$ for any given non-empty set $A \subseteq \mathbb{Z}_m$ in time $O(|A|)$, proving Theorem 7. Let $n := |A|$ and denote by $a_1 < a_2 < \ldots < a_n$ the elements of A. For simplicity of notation, we set

$$a_{n+1} := a_1, \quad a_{n+2} := a_2, \quad \ldots, \quad a_{2n} := a_n.$$

Note that for our applications of this Theorem, a_i correspond to residue classes modulo m. We construct a string P (the pattern) of length n by setting for any $1 \leq i \leq n$:

$$P_i := (a_{i+1} - a_i) \bmod m.$$

Similarly, we construct a string T (the text) of length $2n - 1$ by setting for any $1 \leq i \leq 2n - 1$:

$$T_i := (a_{i+1} - a_i) \bmod m.$$

Note that the text is constructed by repeating the pattern twice and removing the last letter.

We say that there is a match of pattern P in text T at position i if $P_j = T_{i-1+j}$ holds for any $1 \leq j \leq n$. The following lemma shows that the matches of P in T are in one-to-one correspondence with the symmetry group $Sym(A)$. Since all matches of P in T can be computed in time $O(n)$ by the classic Knuth-Morris-Pratt pattern matching algorithm, this finishes the proof of Theorem 7.

▶ **Lemma 18.** *If there is a match of P in T at position i, then $a_i - a_1 \in Sym(A)$. Moreover, for any $x \in Sym(A)$, we have $x = a_i - a_1$ for some $1 \leq i \leq n$ and there is a match of P in T at position i.*

Proof. Note that there is a match at position i if and only if for all $1 \leq j \leq n$

$$a_{j+1} - a_j = a_{i+j} - a_{i+j-1} \pmod{m}.$$

Summing this equation in a telescoping sum over all $j \in \{1, \ldots, \ell-1\}$, for any fixed $1 \leq \ell \leq n$, yields

$$a_\ell - a_1 = a_{i+\ell-1} - a_i \pmod{m},$$

or, equivalently,

$$a_\ell + (a_i - a_1) = a_{i+\ell-1} \pmod{m}.$$

This establishes $a_i - a_1 \in Sym(A)$.

For the second part, recall that $Sym(A) \subseteq A - \{a_1\}$, as discussed in Section 2.2. Therefore for any $x \in Sym(A)$ we have $x = a_i - a_1$ for some i. Now consider the values $a'_j := (a_j - x) \bmod m$ for $1 \leq j \leq n$. Observe that the sequence $a'_1, \ldots, a'_n$ is monotonically increasing up to some point, where the modulo operation reduces by an additional $-m$, and then is again monotonically increasing. In particular, for some $1 \leq r \leq n$ we have

$$a'_r < a'_{r+1} < \ldots < a'_{n-1} < a'_n < a'_1 < a'_2 < \ldots < a'_{r-2} < a'_{r-1}.$$

Since $x \in Sym(A)$ and $Sym(A)$ is a group, also $-x \in Sym(A)$, and thus $a'_j \in A$ for all j. Hence, the n different values a'_j must correspond to the elements of A. It follows that $a'_{r-1+j} = a_j$ for all $1 \leq j \leq n$.

Observing that $a'_i = a_i - x = a_i - (a_i - a_1) = a_1 \pmod{m}$, we see that $r = i$. In other words, we have for all $1 \leq j \leq n$

$$a_{i-1+j} - (a_i - a_1) = a_j \pmod{m}.$$

Subtracting this equation for j from this equation for $j+1$ yields, for any $1 \leq j \leq n$,

$$a_{i+j} - a_{i+j-1} = a_{j+1} - a_j \pmod{m}.$$

As noted in the beginning of this proof, this means that there is a match of P in T at position i. ◀

Abstract

We formalize the concept of *additive approximation schemes* and apply it to load balancing problems on identical machines. Additive approximation schemes compute a solution with an absolute error in the objective of at most ϵh for some suitable parameter h and any given $\epsilon > 0$. We consider the problem of assigning jobs to identical machines with respect to common load balancing objectives like *makespan minimization*, the *Santa Claus* problem (on identical machines), and the *envy-minimizing Santa Claus* problem. For these settings we present additive approximation schemes for $h = p_{\max}$, the maximum processing time of the jobs.

Our technical contribution is two-fold. First, we introduce a new relaxation based on integrally assigning slots to machines and *fractionally* assigning jobs to the slots. We refer to this relaxation as the *slot-MILP*. While it has a linear number of integral variables, we identify structural properties of (near-)optimal solutions, which allow us to compute those in polynomial time. The second technical contribution is a local-search algorithm which rounds any given solution to the slot-MILP, introducing an additive error on the machine loads of at most $\epsilon \cdot p_{\max}$.

1 Introduction

Typically, when constructing an approximation algorithm, one provides a multiplicative approximation ratio ρ such that the respective algorithm finds a solution of value at most (or at least, in case of maximization problems) $\rho \cdot \mathrm{OPT}$, where OPT is the optimal solution value. Then, an approximation scheme is a family with an algorithm for each ratio $\rho = 1 + \epsilon$ with $\epsilon > 0$ (or $\rho = 1 - \epsilon$ for maximization problems).

In this paper, we study approximation algorithms and schemes for which we measure their performance as the absolute difference between the value of their computed solution and OPT. We measure this difference with respect to some problem depending quantity h (which might be much smaller than OPT).

▶ **Definition 1.** *For a given optimization problem, consider a quantity defined by $h(I)$ for each instance I. An algorithm is an* additive approximation algorithm w.r.t. *h if for any instance I it computes in polynomial time a solution with value $A(I)$ satisfying $|A(I) - \mathrm{OPT}(I)| \leq h(I)$. An* additive approximation scheme w.r.t. *h is a family of algorithms containing an additive approximation algorithm w.r.t $\epsilon \cdot h$ for each $\epsilon > 0$.*

Studying additive approximation algorithms is particularly interesting in the following two scenarios.

1. If $h(I) \ll (\rho - 1)\mathrm{OPT}(I)$ for some $\rho > 1$ then an additive approximation algorithm w.r.t. h gives a much stronger guarantee than a (multiplicative) ρ-approximation algorithm. In particular, if $h(I) \ll \mathrm{OPT}(I)$ an additive approximation schemes then gives a much stronger guarantee than a PTAS.
2. When there cannot exist a PTAS, or even any multiplicative guarantee for a given problem, additive approximation algorithms give an alternative notion for approximating it. A notable example is the case when it is NP-hard to decide whether $\mathrm{OPT} = 0$, as then no multiplicative approximation guarantee can be obtained.

While a lot of research has focused on traditional multiplicative approximation guarantees, additive approximation guarantees are relatively unexplored in the literature. Notable exceptions include Vizing's algorithm that finds an edge coloring with at most $\Delta + 1$ colors, where Δ is the maximum degree of a graph [36], which is hence an additive approximation for $h \equiv 1$. Also, for bin packing there is an algorithm known that uses at most $\mathrm{OPT} + O(\log \mathrm{OPT})$ bins [17] (improving earlier results in [25] and [33]) which is thus an additive approximation for $h \equiv O(\log \mathrm{OPT})$.

In this paper, we present additive approximation schemes for scheduling and load balancing problems which are among the classical problems in the literature on approximation algorithms, starting with the seminal work of Graham [14]. In these problems, n jobs need to be processed by m machines such that each job is completely processed by one single machine. Each job j has a given processing time p_j and the load of a machine i is the sum of the processing times of the jobs assigned to i. The goal is to find a schedule (represented by an assignment of jobs to the machines) that optimizes some objective function over the machine loads. Since it is strongly NP-hard to decide whether there is a schedule that assigns the same load to each machine (see [13]), most non-trivial load balancing problems of this form are also strongly NP-hard. This observation has led to extensive research on approximation algorithms. In the following, we consider three variations of load balancing problems.

Objective functions. Our first objective function is to minimize the maximum machine load, i.e., to minimize the *makespan*. This is the one of the most classical scheduling problems on parallel machines and has led to the first approximation algorithms [14,15]. Sahni [34] showed that the problem admits an FPTAS for constant number of machines and Hochbaum and Shmoys [19] found a PTAS if the number of machines is part of the input. Since then, there has been lively research in improving the running time, e.g., to an EPTAS [1, 8, 18, 20, 21].

The second objective function that we consider yields the *max-min allocation* problem [7]. Here, the goal is to maximize the load of the least loaded machine. Bansal and Sviridenko [5] called it the Santa Claus problem when they studied it in the restricted assignment setting. This objective is considered to measure the fairness of the allocation. The case of identical machines was also considered by Woeginger [37] who presents a PTAS.

As a third and final objective function, we consider to minimize the *maximum envy*, which is defined as the maximum load minus the minimum load. This objective has been considered by Lipton et. al [30]. While in the Santa Claus problem fairness is measured

by the minimum load of a machine, in this setting fairness is considered by the difference between the maximum and minimum load. Note that it is strongly NP-hard to decide whether or not the envy is 0. Therefore, unless P = NP, there cannot exist any polynomial time approximation algorithm with any (multiplicative) performance guarantee.

For all three variants there is a simple greedy algorithm, which assigns the jobs iteratively to the respective least loaded machine, and which gives an additive error of $p_{\max} := \max_{j \in J} p_j$. Such an additive approximation w.r.t. $p_{\max}$ exists even for unrelated machines, i.e., when the processing time of a job depends on the machine [29]. Note that this guarantee is incomparable to the error of ϵOPT of a PTAS. In particular, in the regime where $p_{\max} = o(\mathrm{OPT})$ the greedy algorithm is still the best algorithm we know.

Our contribution. In this paper, we present additive approximation schemes w.r.t. $p_{\max}$ for the three load balancing problems defined above on identical machines. For the makespan and Santa Claus objective this gives a significant improvement over the greedy algorithm mentioned above while also dominating the guarantees of the known PTASes[1]; for minimizing the maximum envy this demonstrates how additive approximation schemes can lead to non-trivial guarantees when no multiplicative guarantees are possible.

Since $p_{\max}$ can be much smaller than OPT, the main approach of the known (multiplicative) PTASes does not work when aiming for an additive approximation guarantee of $\epsilon p_{\max}$. In those results, a job j is typically considered as small if $p_j \leq \epsilon\mathrm{OPT}$ and otherwise as large. Then there is only a constant number of large jobs on each machine in the optimal solution which allows methods based on enumeration or integer programming in constant dimension (after rounding or grouping the job sizes according to, e.g., powers of $(1+\epsilon)$). The small jobs are finally assigned greedily. However, if $p_{\max} < \epsilon\mathrm{OPT}$ then these algorithms would simply assign all jobs greedily which yields an additive error of up to $p_{\max} > \epsilon \cdot p_{\max}$. Given this, it seems natural to define a job j to be large if $p_j > \epsilon \cdot p_{\max}$; however, then it is not guaranteed that there are only a constant number of large jobs on each machine and thus the aforementioned techniques are not applicable anymore. Moreover, we cannot even afford to round all job sizes to powers of $1+\epsilon$ since this might yield a total error of $\epsilon \sum_j p_j$, which can be much larger than $\epsilon \cdot p_{\max}$. Therefore, there is need for new (non-trivial) machinery.

To this end, we present a new fractional relaxation for this general class of load balancing problems, which we call the *slot-MILP*. This slot-MILP can be interpreted as a strengthened variant of the assignment-LP. The assignment-LP is a relaxation in which each job is assigned separately (fractionally) to a machine. In the slot-MILP we first group jobs of similar sizes, but we do not round the job sizes (unlike most previous PTASes). In particular, different jobs belonging to the same group may have different job sizes. In addition to the constraints of the assignment-LP we require an *integral* number of jobs of each group to be assigned to each machine (which can be implemented using a linear number of integer variables). Our relaxation can be thought of as assigning slots (for the groups of jobs) *integrally* to machines and then assigning the jobs *fractionally* to the slots.

Due to the many integer variables, it is not obvious how to solve the slot-MILP efficiently. This contrasts our approach to many other approximation algorithms which are based on purely fractional relaxations or on MILP-relaxations with only few integral variables which can be solved with Lenstra's algorithm (e.g., as done in some EPTASes for minimizing the

[1] While for makespan minimization $p_{\max} \leq \mathrm{OPT}$ always holds, for Santa Claus this can be assumed essentially w.l.o.g., since the optimum does not change if job sizes are capped at OPT and the latter can be guessed by binary search.

makespan [20, 21]). Instead, we manage to solve it using non-trivial structural properties combined with dynamic programming. While the additive integrality gap of the assignment-LP can be as large as $p_{\max}$, for the slot-MILP this gap is only $\epsilon \cdot p_{\max}$. We show this using a rounding procedure inspired by a local search method for the restricted assignment problem [23, 24, 35]. The local search algorithm repeatedly moves jobs between machines, eventually converging to a good solution. Although in the restricted assignment problem no polynomial running time bound is known for the local search procedure, in our case we obtain such a bound for our local search.

We remark that our slot-MILP is stronger than the known configuration-LP, e.g., since for minimizing the makespan on identical machines, the latter has a multiplicative integrality gap of at least $1+\frac{1}{1023}$ [28] and hence an additive integrality gap of at least $\mathrm{OPT}\cdot\frac{1}{1023} \geq p_{\max}\cdot\frac{1}{1023}$.

Other related work. The case of small values of $p_{\max}$ has also been considered from a parameterized point of view: If all processing times are integers, then it is possible to obtain a running time that is fixed-parameter tractable (FPT) for the parameter $k = p_{\max}$ [26, 27, 31]. In other words, there is an algorithm that finds an exact solution in time $f(k) \cdot |I|^{O(1)}$ for some computable function f.

Other variants of load balancing problems on identical machines have been considered by Alon et al. [1]. They identify some conditions on the objective function, e.g. makespan minimization and the Santa Claus problem, so that the load balancing or machine scheduling problem admits an (E)PTAS. The Santa Claus problem has been considered in the restricted assignment setting in which each job is only allowed to be processed on a subset of the machines, starting with [5]. In a series of papers [3, 4, 9, 12, 16], the approximation ratio was further and further improved, and the currently best known result is a polynomial time $(4+\epsilon)$-approximation algorithm [9, 10] and an upper bound of $3+\frac{21}{26} \approx 3.808$ for the integrality gap of the configuration-LP [9] (which can be solved in polynomial time to any desired accuracy).

For the bin packing problem, Jansen et al. [22] present an additive approximation algorithm w.r.t $h \equiv 1$ in time exponential in the optimal number of bins plus a polynomial in the number of items to be packed. Ophelders et al. [32] showed that a simple local search algorithm for the so-called Equitable Hamiltonian Cycle finds a solution that is at most 1 away from the optimal solution value. Alon et al. [2] present an additive approximation algorithm w.r.t. $h = \epsilon n^2$ for every $\epsilon > 0$ for the edge deletion problem to obtain a graph with a monotone property. This is hence an additive approximation scheme for $h = n^2$ (which is in fact an upper bound on the minimum number of edges to be deleted).

2 Slot-MILP

We introduce an alternative relaxation for a general class of load balancing problems on identical machines. We first formally define this class of load balancing problems as the *target load balancing problem.*

▶ **Definition 2.** *In the* target load balancing problem *we are given a set of jobs $\mathcal{J}$ with a processing time p_j for each $j \in \mathcal{J}$ and a set of machines $\mathcal{M}$ with values ℓ, u. The goal is to assign each job $j \in \mathcal{J}$ to a machine $i \in \mathcal{M}$ such that every machine load satisfies the target load interval $[\ell, u]$.*

This generalizes the load balancing settings mentioned earlier, e.g., for makespan minimization we choose $\ell = 0$ and $u = T$, where T is a guess on the optimal makespan.

Let $\epsilon > 0$ and assume w.l.o.g. that $1/\epsilon \in \mathbb{N}$. Our task is to either assert that there is no solution for the given instance or to find a solution in which the load of each machine i is in the interval $[\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$ with $p_{\max} := \max_{j \in J} p_j$. First we partition the jobs into sets $\mathcal{J}_1, \ldots, \mathcal{J}_{1/\epsilon}$, where for $k = 1, ..., 1/\epsilon$ the set $\mathcal{J}_k$ contains all jobs $j \in \mathcal{J}$ with $p_j \in ((k-1)\epsilon \cdot p_{\max}, k\epsilon \cdot p_{\max}]$. We define a new relaxation for this problem in which for each machine i and each $k = 1, ..., 1/\epsilon$ we specify integrally how many jobs from $\mathcal{J}_k$ are assigned to i (one may imagine that this defines slots for jobs from $\mathcal{J}_k$ on i). Then the jobs from $\mathcal{J}_k$ are assigned fractionally to these slots.

$$\begin{aligned} \sum_{i \in \mathcal{M}} x_{i,j} &= 1 && \forall j \in \mathcal{J} \\ \ell \leq \sum_{j \in \mathcal{J}} p_j x_{i,j} &\leq u && \forall i \in \mathcal{M} \\ \sum_{j \in \mathcal{J}_k} x_{i,j} &= y_{i,k} && \forall i \in \mathcal{M}, \forall k \in \{1, \ldots, 1/\epsilon\} \\ x_{i,j} &\geq 0 && \forall j \in \mathcal{J}, i \in \mathcal{M} \\ y_{i,k} &\in \mathbb{N}_0 && \forall i \in \mathcal{M}, k \in \{1, \ldots, 1/\epsilon\} \end{aligned} \tag{1}$$

We refer to this relaxation as the slot-MILP. The integer variables define exactly how many jobs of a type are assigned to a machine but do not imply a specific load based on rounded processing times. The load of a machine is based on an assignment that satisfies the distribution of slots among the machines.

Since the slot-MILP contains $1/\epsilon \cdot |\mathcal{M}|$ integral variables, it is not clear how to solve it in polynomial time. Nevertheless, we present two methods of efficiently solving the slot-MILP. The first method gives an exact solution while the second method gives a solution that slightly violates the target load intervals. Afterwards, we show how to round a fractional solution of the slot-MILP to an integral solution, while violating the load interval $[\ell, u]$ for each machine $i \in \mathcal{M}$ by at most $\epsilon \cdot p_{\max}$.

2.1 Exact solution method for the relaxation

We make use of a structural property to find an exact solution to the slot-MILP. Note that in this case an exact solution is one that satisfies (1). This structure allows us to guess the values of the integral variables in polynomial time and then the remaining problem is only a linear program.

Given a solution (x, y), we write y_i for the $(1/\epsilon)$-tuple $(y_{i,1}, \ldots, y_{i,1/\epsilon})$. Using similar arguments to [11] we show that there exist solutions in which there are not too many different vectors y_i.

▶ **Lemma 3.** *There is a solution (x, y) to the slot-MILP such that for all $i, i' \in \mathcal{M}$ with $y_i \equiv y_{i'} \bmod 2$ it follows that $y_i = y_{i'}$.*

Proof. Let (x, y) be a solution to the slot-MILP and assume that x is the solution which minimizes

$$\sum_{i \in \mathcal{M}} \sum_{k=1}^{1/\epsilon} \|y_{i,k}\|_2. \tag{2}$$

Now suppose toward contradiction that there are i_1, i_2 with $y_{i_1} \equiv y_{i_2} \bmod 2$, but $y_{i_1} \neq y_{i_2}$. We construct a new solution x', which has a lower value of (2). We set $x'_{i,j} = x_{i,j}$ for all $i \notin \{i_1, i_2\}$ and $x'_{i_1,j} = x'_{i_2,j} = (x_{i_1,j} + x_{i_2,j})/2$. In other words, we evenly distribute all jobs between i_1 and i_2. Let us first check that the solution remains feasible. Let $j \in \mathcal{J}$. Then

$$\begin{aligned}\sum_{i\in\mathcal{M}} x'_{i,j} &= x'_{i_1,j} + x'_{i_2,j} + \sum_{i\notin\{i_1,i_2\}} x'_{i,j} \\ &= \frac{x_{i_1,j} + x_{i_2,j}}{2} + \frac{x_{i_1,j} + x_{i_2,j}}{2} + \sum_{i\notin\{i_1,i_2\}} x_{i,j} \\ &= \sum_{i\in\mathcal{M}} x_{i,j} = 1.\end{aligned}$$

For all machines $i \notin \{i_1, i_2\}$ the load does not change and, hence, the load of machine i remains within $[\ell, u]$. For i_1 and i_2, we argue

$$\begin{aligned}\sum_{j\in\mathcal{J}} p_j x'_{i_1,j} = \sum_{j\in\mathcal{J}} p_j x'_{i_2,j} &= \sum_{j\in\mathcal{J}} p_j \frac{x_{i_1,j} + x_{i_2,j}}{2} \\ &= \frac{1}{2}\sum_{j\in\mathcal{J}} p_j x_{i_1,j} + \frac{1}{2}\sum_{j\in\mathcal{J}} p_j x_{i_2,j} \\ &\leq \frac{u}{2} + \frac{u}{2} = u\end{aligned}$$

and

$$\begin{aligned}\sum_{j\in\mathcal{J}} p_j x'_{i_1,j} = \sum_{j\in\mathcal{J}} p_j x'_{i_2,j} &= \sum_{j\in\mathcal{J}} p_j \frac{x_{i_1,j} + x_{i_2,j}}{2} \\ &= \frac{1}{2}\sum_{j\in\mathcal{J}} p_j x_{i_1,j} + \frac{1}{2}\sum_{j\in\mathcal{J}} p_j x_{i_2,j} \\ &\geq \frac{\ell}{2} + \frac{\ell}{2} = \ell.\end{aligned}$$

Hence, the solution remains optimal. As for the integrality constraints, again the machines $i \notin \{i_1, i_2\}$ do not change. Let $k \in \{1, \ldots, 1/\epsilon\}$. Since $y_{i_1,k} \equiv y_{i_2,k}$, we have that $y_{i_1,k} + y_{i_2,k}$ is even. It follows that

$$\sum_{j\in\mathcal{J}_k} x'_{i_1,j} = \sum_{j\in\mathcal{J}_k} x'_{i_2,j} = \frac{y_{i_1} + y_{i_2}}{2}$$

is integral. Now it remains to show that (2) has decreased. Notice that by triangle inequality

$$\|y'_{i_1,k}\|_2 + \|y'_{i_2,k}\|_2 = 2\left\|\frac{y_{i_1,k} + y_{i_2,k}}{2}\right\|_2 \leq \|y_{i_1,k}\|_2 + \|y_{i_2,k}\|_2$$

and strict inequality holds when $y_{i_1,k} \neq y_{i_2,k}$. Since this is the case for at least one k and all machines $i \notin \{i_1, i_2\}$ do not change, we have that (2) has decreased. A contradiction. ◀

Using Lemma 3 we can solve the slot-MILP in polynomial time.

▶ **Lemma 4.** *We can solve the slot-MILP in time* $m^{O(2^{1/\epsilon})} \cdot n^{O(1/\epsilon \cdot 2^{1/\epsilon})}$.

Proof. Lemma 3 implies that there are only $2^{1/\epsilon}$ many machine types denoted by the $1/\epsilon$-tuples y_i. This allows us to guess all values of $y_{i,k}$ (up to permutations of machines) of the optimal solution as follows. For each of the $2^{1/\epsilon}$ types we guess (1) the number of machines

having this type and (2) for each $k \in \{1, ..., 1/\epsilon\}$ we guess the value of $y_{i,k}$ for each machine $i \in \mathcal{M}$ of this type. Note that the machines are identical and hence it suffices to guess the number of machines of each type, rather than guessing which exact machine is of which type. The total number of guesses is bounded by $m^{O(2^{1/\epsilon})} \cdot n^{O(1/\epsilon \cdot 2^{1/\epsilon})}$. Then the remaining problem is only a linear program since all integral variables of the slot-MILP are already fixed. If our guess was correct then the LP must have a feasible solution. ◀

2.2 Faster (approximate) solution to the relaxation

The solution based on Lemma 3 can be found in double exponential time with respect to the number of job types $1/\epsilon$ and is an exact solution to the slot-MILP. Using a different (slightly more complicated) structural property one can find an additive δ-approximate solution to the slot-MILP in single exponential time with respect to $1/\epsilon$ and polynomial in $1/\delta$, i.e., even with $\delta := 1/n^{O(1)}$ we obtain polynomial running time. Here, δ-approximate means that we find a solution to a weaker version of slot-MILP with lower and upper bounds $\ell' = \ell - \delta \cdot p_{\max}$ and $u' = u + \delta \cdot p_{\max}$ for the load of every machine i. We refer to this weaker MILP the slot-MILP'.

The algorithm is based on a different structural property than the one proved in Lemma 3. Given a solution (x, y) of the slot-MILP, for each machine $i \in \mathcal{M}$ and each $k \in \{1, \dots, 1/\epsilon\}$, we denote by $z_{i,k}$ the average size of the jobs type k on machine i defined by

$$z_{i,k} \cdot y_{i,k} = \sum_{j \in \mathcal{J}_k} p_j x_{i,j}.$$

In the case that $y_{i,k} = 0$ this allows us to freely choose the value of $z_{i,k}$ which is important for the structural property in the following lemma. We prove that there is always a solution to the slot-MILP and an ordering of the machines such that for each $k \in \{1, \dots, 1/\epsilon\}$ the values $z_{i,k}$ are non-decreasing and on each prefix of length ℓ of the machines the total size of the slots for the jobs in $\mathcal{J}_k$ is at least as large as the $y_{\sigma(1),k} + \cdots + y_{\sigma(\ell),k}$ smallest jobs in $\mathcal{J}_k$. For each integer n' let $\mathcal{J}_k^{\min}(n') \subseteq \mathcal{J}_k$ be the n' smallest jobs in $\mathcal{J}_k$.

▶ **Lemma 5.** *There is an optimal solution (x, y) for the slot-MILP, a corresponding vector $\{z_{i,k}\}_{i \in \mathcal{M}, k \in \{1,\dots,1/\epsilon\}}$, and an ordering $\sigma : \{1, ..., |\mathcal{M}|\} \to \mathcal{M}$ such that*

$$\sum_{\ell'=1}^{\ell} y_{\sigma(\ell'),k} z_{\sigma(\ell'),k} \geq \sum_{j \in \mathcal{J}_k^{\min}(y_{\sigma(1),k} + \cdots + y_{\sigma(\ell),k})} p_j \qquad \begin{matrix} \forall k \in \{1, \dots, 1/\epsilon\} \\ \forall \ell \in \{1, ..., |\mathcal{M}|\} \end{matrix} \tag{3}$$

$$\sum_{i \in \mathcal{M}} y_{i,k} z_{i,k} = \sum_{j \in \mathcal{J}_k} p_j \qquad \forall k \in \{1, \dots, 1/\epsilon\} \tag{4}$$

$$z_{\sigma(\ell),k} \leq z_{\sigma(\ell+1),k} \qquad \begin{matrix} \forall k \in \{1, \dots, 1/\epsilon\} \\ \forall \ell \in \{1, ..., |\mathcal{M}| - 1\}. \end{matrix} \tag{5}$$

Proof. Condition (3) and (4) follow directly from feasibility of the solution.

To show condition (5), let x, y be a solution with corresponding average load vector $\{z_{i,k}\}_{i \in \mathcal{M}, k \in 1,\dots,1/\epsilon\}}$, where the values $z_{i,k}$ when $y_{i,k} = 0$ are chosen appropriately. Let $\hat{z}_1 \leq \cdots \leq \hat{z}_{\bar{n}}$ be an ordering of the $\bar{n} = |\{(i,k) : y_{ik} > 0\}|$ values $z_{i,k}$ for all $i \in \mathcal{M}, k \in \{1, \dots, 1/\epsilon\}$ with $y_{ik} > 0$. Assume that (x, y) is the solution maximizing the following potential function

$$\sum_{i=1}^{\bar{n}} n^{2(m/\epsilon - i)} \hat{z}_i. \tag{6}$$

We will now show that in this case we can iteratively find an ordering of machines such that condition (5) holds and otherwise get a contradiction with respect to the potential function. Let i be the machine minimizing $\sum_{k=1}^{1/\epsilon} z_{i,k}$. All other machines i' must satisfy one of the following two cases: (1) $z_{i,k} \leq z_{i',k}$ for all $k \in \{1, ..., 1/\epsilon\}$ or (2) $z_{i,k} > z_{i',k}$ for some k. If (1) holds for all machines i' we relabel machine i as machine 1. Otherwise, let $i' \neq i$ be a machine such that for some k

$$z_{i,k} > z_{i',k}. \tag{7}$$

Then, as i minimizes $\sum_{k=1}^{1/\epsilon} z_{i,k}$ we know that there must exist $\overline{k} \neq k$ with

$$z_{i,\overline{k}} < z_{i',\overline{k}}. \tag{8}$$

As we can freely choose the value of $z_{\overline{i},k'}$, whenever $y_{\overline{i},k'} = 0$, we know that $y_{i,k}, y_{i,\overline{k}}, y_{i',k}, y_{i',\overline{k}} > 0$. We now gradually exchange jobs of $\mathcal{J}_k$ and $\mathcal{J}_{\overline{k}}$ between i and i' without changing the total load on either of the machines. Indeed, there must be some $j, j' \in \mathcal{J}_k$ with $x_{i,j} > 0$, $x_{i',j'} > 0$, and $p_j > p_{j'}$. Conversely, there are $\overline{j}, \overline{j}' \in \mathcal{J}_{\overline{k}}$ with $x_{i,\overline{j}} > 0$, $x_{i',\overline{j}'} > 0$, and $p_{\overline{j}} < p_{\overline{j}'}$. For some $\delta, \overline{\delta} > 0$ we now augment the solution in the following way.

$$\begin{aligned} x_{i,j'} &\leftarrow x_{i,j'} + \delta & \qquad x_{i,\overline{j}'} &\leftarrow x_{i,\overline{j}'} + \overline{\delta} \\ x_{i,j} &\leftarrow x_{i,j} - \delta & \qquad x_{i,\overline{j}} &\leftarrow x_{i,\overline{j}} - \overline{\delta} \\ x_{i',j'} &\leftarrow x_{i',j'} - \delta & \qquad x_{i',\overline{j}'} &\leftarrow x_{i',\overline{j}'} - \overline{\delta} \\ x_{i',j} &\leftarrow x_{i',j} + \delta & \qquad x_{i',\overline{j}} &\leftarrow x_{i',\overline{j}} + \overline{\delta} \end{aligned}$$

It is easy to see that for δ and $\overline{\delta}$ sufficiently small each variable remains non-negative. Moreover, each job remains fully assigned and the number of jobs of $\mathcal{J}_k$ and $\mathcal{J}_{\overline{k}}$ assigned to i and i' remains the same.

By setting $\overline{\delta} = \delta(p_j - p_{j'})/(p_{\overline{j}'} - p_{\overline{j}})$ the load over each of the two machines stays the same. Furthermore, as $p_j > p_{j'}$ and $p_{\overline{j}'} > p_{\overline{j}}$ we have that $\delta, \overline{\delta} > 0$. We choose δ maximal such that all x variables remain non-negative and the inequalities (7) and (8) still hold or turn to equality. This means that we decreased $z_{i,k}$ by $\frac{\delta(p_j - p'_j)}{y_{i,k}}$ and $z_{i',\overline{k}}$ by $\frac{\delta(p_j - p_{j'})}{y_{i,\overline{k}}}$. At the same time we increased $z_{i,\overline{k}}$ by $\frac{\delta(p_j - p_{j'})}{y_{i,\overline{k}}}$ and $z_{i',k}$ by $\frac{\delta(p_j - p'_j)}{y_{i',k}}$. Since $z_{i',k}$ and $z_{i,\overline{k}}$ (the respective smaller z-variables for i and i' that we change) increase by at least $\frac{\delta(p_j - p'_j)}{n}$ and $z_{i,k}$ and $z_{i',\overline{k}}$ decrease by at most $\delta(p_j - p'_j)$, we have that (6) increases. This gives a contradiction.

As we can repeat this argument iteratively assuming that machines $\{1, \ldots, i_0\}$ are correctly sorted for some $i_0 \in \{1, \ldots, m\}$, we have that there exists a solution (x, y) with vector $\{z_{i,k}\}_{i \in \mathcal{M}, k \in 1, \ldots, 1/\epsilon\}}$ such that condition (5) holds. ◀

We introduce a dynamic program that uses the property from Lemma 5. Intuitively, our DP guesses the machines in the ordering σ one after the other. When it guesses the next machine i, it guesses for each $k \in \{1, \ldots, 1/\epsilon\}$ the value $z_{i,k}$ and the number of jobs $y_{i,k}$ from $\mathcal{J}_k$ on machine i. In order to bound the running time we need to consider rounded values of $z_{i,k}$. Therefore, the DP ensures that the conditions (3) and (5) on the vectors y, z from Lemma 5 are satisfied and that condition (4) as well as the upper and lower target load bounds are only violated to a small extent. The following lemma shows that this is sufficient in order to compute an approximate solution to the slot-MILP based on the vectors y, z.

▶ **Lemma 6.** *Suppose that we are given an ordering* $\sigma : \{1, ..., |\mathcal{M}|\} \to \mathcal{M}$ *and vectors* $\{y_{i,k}, z_{i,k}\}_{i\in\mathcal{M},k\in\{1,...,1/\epsilon\}}$ *such that conditions* (3) *and* (5) *hold. Moreover, assume that for each* $i \in \mathcal{M}$ *it holds that*

$$\ell \leq \sum_{k=1}^{1/\epsilon} y_{i,k} z_{i,k} \leq u + \delta p_{\max} \tag{9}$$

and for each $k \in \{1, \cdots, 1/\epsilon\}$ *we have that condition* (4) *is slightly violated as follows*

$$\sum_{j\in\mathcal{J}_k} p_j \leq \sum_{i\in\mathcal{M}} y_{i,k} z_{i,k} \leq \sum_{j\in\mathcal{J}_k} p_j + \delta\epsilon \cdot p_{\max}. \tag{10}$$

Then we can compute a vector $\{x_{i,j}\}_{i\in\mathcal{M},j\in\mathcal{J}}$ *such that* (x, y) *is a solution to slot-MILP' in time* $O(mn^2)$.

Proof. We first show that there exists an assignment vector $\{x_{i,j}\}_{i\in\mathcal{M},j\in\mathcal{J}}$ satisfying

$$\sum_{j\in\mathcal{J}_k} p_j x_{i,j} \leq y_{i,k} z_{i,k} \tag{11}$$

for all $i \in \mathcal{M}$ and $k \in \{1, \ldots, 1/\epsilon\}$. In order to do so we use condition (3) of Lemma 5. We find this assignment independently for all k. We start by assigning $\mathcal{J}_k^{\min}(y_{1,k})$ (completely) to machine 1, then $\mathcal{J}_k^{\min}(y_{1,k} + y_{2,k}) \setminus \mathcal{J}_k^{\min}(y_{1,k})$ to machine 2, etc. This assignment does not necessary have the desired property (11). Hence, we repair the property iteratively for $i = 2, \ldots, m$. Machine 1 clearly satisfies (11) because of (3)). Let $i \in \{2, \ldots, m-1\}$ such that all machines $1, \ldots, i$ satisfy (11). In each iteration i we do not touch any of the machines $i+1, \ldots, m$. Hence, when repairing machine i we may assume that machines $1, \ldots, i$ contain only $\mathcal{J}_k^{\min}(y_{1,k} + \cdots + y_{i,k})$. If machine i satisfies (11) we are done and continue with $i+1$. Otherwise, we know that there is a job j with $p_j > z_{i,k}$ and $x_{i,j} > 0$. Moreover, because of condition (3) we have

$$\sum_{i'=1}^{i} \sum_{j\in\mathcal{J}_k^{\min}(y_{1,k}+\cdots+y_{i,k})} p_j x_{i',j} = \sum_{j\in\mathcal{J}_k^{\min}(y_{1,k}+\cdots+y_{i,k})} p_j \leq y_{1,k} z_{1,k} + \cdots + y_{i,k} z_{i,k}. \tag{12}$$

Since i violates (11) there must be some $i' < i$ satisfying (11) with strict inequality. In particular, there is a job j' with $p_{j'} < z_{i',k} \leq z_{i,k} < p_j$ and $x_{i',j'} > 0$. We now choose an $\alpha > 0$ and exchange j' and j between i and i' as follows

$$x_{i,j'} \leftarrow x_{i,j'} + \alpha \qquad x_{i',j'} \leftarrow x_{i',j'} - \alpha$$
$$x_{i,j} \leftarrow x_{i,j'} - \alpha \qquad x_{i',j'} \leftarrow x_{i',j'} + \alpha$$

Clearly, the solution remains feasible. We choose α maximal such that either i' satisfies (11) with equality, i satisfies (11), $x_{i,j} = 0$, or $x_{i',j'} = 0$. The choice of α makes sure that each pair j, j' that can be exchanged like this will only be exchanged once. This procedure is repeated until i satisfies (11). As the procedure is repeated for all i and possibly has to check all pairs of every job type in each exchange we have a running time of $O(mn^2)$.

Next, we claim that for all i and k, we have that (13) holds, that is,

$$\sum_{j\in\mathcal{J}_k} p_j x_{i,j} \geq y_{i,k} z_{i,k} - \delta\epsilon \cdot p_{\max}. \tag{13}$$

To prove this claim, assume by contradiction that for some machine i' (13) does not hold. Then by (11) and condition (4), we have that

$$\sum_{j\in\mathcal{J}_k}\sum_{i\in\mathcal{M}} x_{i,j}p_j < \sum_{i\in\mathcal{M}} y_{i,k}z_{i,k} - \delta\epsilon\cdot p_{\max} < \sum_{j\in\mathcal{J}_k} p_j. \tag{14}$$

This contradicts the fact that all jobs are fully assigned and thus $\sum_{j\in\mathcal{J}_k} p_j x_{i,j} = \sum_{j\in\mathcal{J}_k} p_j$. Hence, we have that

$$\sum_{k=1}^{1/\epsilon}\sum_{k\in\mathcal{J}_k} p_j x_{ij} \geq \sum_{k=1}^{1/\epsilon} y_{i,k}z_{i,k} - \delta p_{\max} \geq \ell - \delta p_{\max}, \tag{15}$$

where the last inequality follows by condition (9). ◀

The goal of our DP is to compute vectors $\{y_{i,k}, z_{i,k}\}_{i\in\mathcal{M},k\in\{1,\dots,1/\epsilon\}}$ that satisfy the conditions due to Lemma 6. The key insight is now that when we consider the next machine i' in the ordering, we do not need to remember all vectors $\{y_{i,k}, z_{i,k}\}_{i\in\mathcal{M},k\in\{1,\dots,1/\epsilon\}}$ for all previously considered machines i, but it suffices to remember the number of previously assigned jobs from each set $\mathcal{J}_k$, the current left hand side of inequality (3) for each k and the vector $\{z_{i'',k}\}_{k\in\{1,\dots,1/\epsilon\}}$ of the previously considered machine i''. At each iteration the DP then guesses the vectors $\{y_{i,k}, z_{i,k}\}_{i\in\mathcal{M},k\in\{1,\dots,1/\epsilon\}}$ such that the new solution consisting of the guess for machine i and the remembered solution for the previous machines satisfies the conditions stated in Lemma 7. If none of the guesses satisfies these conditions the DP cell corresponding to this iteration remains empty.

To give a more detailed description, we introduce a DP-table with one cell for each combination of

- a value $i \in \{0, ..., m\}$ indicating the number of machines that have already been considered,
- a vector $\{z_{i,k}\}_{k\in\{1,\dots,1/\epsilon\}}$ where $z_{i,k} \in \left\{0, \frac{\delta\epsilon}{n}p_{\max}, \frac{2\delta\epsilon}{n}p_{\max}, ..., p_{\max}\right\}$ for $k \in \{1, \dots, 1/\epsilon\}$. The vector $z_{i,k}$ corresponds to the average loads on the currently considered machine,
- a vector $\{y_{i,k}\}_{k\in\{1,\dots,1/\epsilon\}}$ where $y_{i,k} \in \{0, 1, 2, ..., n_k\}$ for each $k \in \{1, \dots, 1/\epsilon\}$. The vector $y_{i,k}$ corresponds to the number of jobs on the currently considered machine,
- for each $k \in \{1, ..., 1/\epsilon\}$
  - a value $n'_k \in \{0, ..., |\mathcal{J}_k|\}$ indicating the number of slots for jobs of $\mathcal{J}_k$ that have already been assigned to machines,
  - a value S_k with $S_k \in \left\{0, \frac{\delta\epsilon}{n}p_{\max}, \frac{2\delta\epsilon}{n}p_{\max}, ..., np_{\max}\right\}$ which corresponds to the value $\sum_{i'=1}^{i} y_{i',k}z_{i',k}$.

Each cell corresponds to the subproblem of checking whether there is a solution using machines $\{1, \dots, i\}$ such that machine i is assigned $y_{i,k}$ jobs of each type k with average load $z_{i,k}$ and for each type k a total number of n'_k slots is assigned of a total volume of S_k. Due to the dimension of the values corresponding to a DP-cell, the dimension of the DP table is given by $m^2 \cdot (\frac{n}{\delta\epsilon})^{O(1/\epsilon)}$.

When considering cell

$$\left(i, \{z_{i,k}\}_{k\in\{1,\dots,1/\epsilon\}}, \{y_{i,k}\}_{k\in\{1,\dots,1/\epsilon\}}, \{n'_k\}_{k\in\{1,\dots,1/\epsilon\}}, \{S_k\}_{k\in\{1,\dots,1/\epsilon\}}\right)$$

the DP checks whether for some $\{\tilde{z}_{i-1,k}\}_{k\in\{1,\dots,1/\epsilon\}}$ and $\{\tilde{y}_{i-1,k}\}_{k\in\{1,\dots,1/\epsilon\}}$ the entry of the DP is true in cell

$$\left(i-1, \{\tilde{z}_{i-1,k}\}_{k\in\{1,\dots,1/\epsilon\}}, \{\tilde{y}_{i-1,k}\}_{k\in\{1,\dots,1/\epsilon\}}, \{\tilde{n}'_k\}_{k\in\{1,\dots,1/\epsilon\}}, \left\{\tilde{S}_k\right\}_{k\in\{1,\dots,1/\epsilon\}}\right),$$

where $\tilde{n}'_k = n'_k - y_{i,k}$ for each $k \in \{1, \dots, 1/\epsilon\}$, and $\tilde{S}_k = S_k - y_{i,k} z_{i,k}$ for each $k \in \{1, \dots, 1/\epsilon\}$. Then we need to check if the following conditions are true for all $k \in \{1, ..., 1/\epsilon\}$:

$$S_k \leq \delta\epsilon \cdot p_{\max} + \sum_{j \in \mathcal{J}_k} p_j \tag{16}$$

$$z_{i,k} \geq \tilde{z}_{i-1,k}. \tag{17}$$

If these conditions are true, then there exists a solution corresponding to the considered DP cell. Filling each cell takes $(\frac{n}{\delta\epsilon})^{O(1/\epsilon)}$.

Finally, for each possible value of $\{z_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}$ we check whether there exists a solution for the DP cell

$$\left(m, \{z_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}, \{y_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}, \{n'_k\}_{k \in \{1,\dots,1/\epsilon\}}, \{S_k\}_{k \in \{1,\dots,1/\epsilon\}}\right),$$

where all jobs are assigned and for every $k \in \{1, \dots, 1/\epsilon\}$ we have that

$$\sum_{j \in \mathcal{J}_k} p_j \leq S_k \leq \sum_{j \in \mathcal{J}_k} p_j + \delta\epsilon \cdot p_{\max}.$$

If this is the case we use standard backward recursion to find vectors $\{z_{i,k}\}_{k \in \{1,\dots,1/\epsilon\}}$ and $\{y_{i,k}\}_{k \in \{1,\dots,1/\epsilon\}}$ for all $i \in \{1, ..., m\}$ and an assignment of machine types to machine indices and use Lemma 6 to obtain a solution (x, y) to slot-MILP'. If there is no such solution we assert that there is no solution to the original relaxation, i.e., to slot-MILP.

▶ **Lemma 7.** *For each $\delta > 0$ there is an algorithm with a running time of $m^2(\frac{n}{\delta\epsilon})^{O(1/\epsilon)}$ which either finds a δ-approximate solution to the slot-MILP (and thus a feasible solution to slot-MILP') or asserts that the slot-MILP is infeasible.*

Proof. The running time follows from the dimension of the DP table and the time it takes to validate a specific DP cell. This amounts to a running time of $m^2(\frac{n}{\delta\epsilon})^{O(1/\epsilon)}$.

For the correctness of the DP we need two observations: (1) due to conditions (16) and (17) and the way we check whether a solution corresponding to a DP cell exists we have that there exists a solution for machine i if and only if there is a solution for machine $i-1$. Hence, we can indeed find a solution via backward recursion and (2) if for some $\{z_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}$ and $\{y_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}$ there is a solution for the cell

$$\left(m, \{z_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}, \{y_{m,k}\}_{k \in \{1,\dots,1/\epsilon\}}, \{n'_k\}_{k \in \{1,\dots,1/\epsilon\}}, \{S_k\}_{k \in \{1,\dots,1/\epsilon\}}\right),$$

then we can apply Lemma 6 to find a solution to slot-MILP'. If there is no such solution, we know that due to our rounding of the z-values there is also no solution satisfying Lemma 5. This implies that there is no solution to the slot-MILP. ◀

3 Rounding the relaxation

We assume that we are given an exact solution to the slot-MILP via the algorithm due to Lemma 4 or an approximate solution via the algorithm due to Lemma 7. In this section, we describe an algorithm with a running time of $n^{O(1)}$ that computes an integral solution to the slot-MILP (or slot-MILP') which for each machine $i \in \mathcal{M}$ violates the target load intervals by at most $\epsilon \cdot p_{\max}$. For a solution to the slot-MILP this implies that $\sum_{j \in \mathcal{J}} p_j x_{i,j} \in$

$[\ell-\epsilon\cdot p_{\max}, u+\epsilon\cdot p_{\max}]$. For a solution to slot-MILP' this implies that the target load violation is given by the error made due to the approximate solution and due to the rounding, i.e., after rounding the solution it holds that $\sum_{j\in\mathcal{J}} p_j x_{i,j} \in [\ell-\delta\cdot p_{\max}-\epsilon\cdot p_{\max}, u+\delta\cdot p_{\max}+\epsilon\cdot p_{\max}]$. In the following we describe the rounding procedure based on an exact solution to the slot-MILP as the same arguments hold for an approximate solution.

We imagine that each machine $i \in \mathcal{M}$ has $y_{i,k}$ slots for the jobs in $\mathcal{J}_k$, for each $k \in \{1, ..., 1/\epsilon\}$. We say that these slots are of *type* k. Notice that $\sum_{i\in\mathcal{M}} y_{i,k} = |\mathcal{J}_k|$. We compute an initial solution by assigning each job $j \in \mathcal{J}_k$ to an arbitrary slot of type k. In this solution there might be a machine i whose load is not in $[\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$, i.e., the load is too small or too large. We present a local search algorithm that repeatedly swaps pairs of jobs from the same set $\mathcal{J}_k$ such that eventually each machine $i \in \mathcal{M}$ has a load in $[\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$ while maintaining the number of jobs from each set $\mathcal{J}_k$ on each machine.

3.1 Local search

We describe how to perform one iteration of the local search algorithm. Each iteration aims at finding a pair of jobs that can be swapped. Let $\mathcal{M}_1$ be the set of machines $i \in \mathcal{M}$ that have a load strictly greater than $u + \epsilon \cdot p_{\max}$. Consider a $k \in \{1, ..., 1/\epsilon\}$ such that a job $j \in \mathcal{J}_k$ is assigned to a machine $i \in \mathcal{M}_1$. We would like to exchange j for a smaller job $j' \in \mathcal{J}_k$ that is assigned to a machine $i' \notin \mathcal{M}_1$. Thus, consider all jobs $j' \in \mathcal{J}_k$ with $p_{j'} < p_j$ which are assigned to a machine $i' \notin \mathcal{M}_1$. If the load of i' is at most u then we exchange j and j' which completes the swap. We try to perform such a swap for each $k \in \{1, ..., 1/\epsilon\}$ such that a job $j \in \mathcal{J}_k$ is assigned to a machine in $\mathcal{M}_1$. If we did not perform a swap then let $\mathcal{M}_2$ denote the set of machines $i' \in \mathcal{M}$ having a job j' which we tried to swap with a job j on a machine $i \in \mathcal{M}_1$, i.e., $\mathcal{M}_2$ contains all machines $i' \in \mathcal{M} \setminus \mathcal{M}_1$ for which there exists a machine $i \in \mathcal{M}_1$ and a $k \in \{1, ..., 1/\epsilon\}$ such that there is a job $j \in \mathcal{J}_k$ assigned to i and a job $j' \in \mathcal{J}_k$ assigned to i' with $p_{j'} < p_j$. Observe that each machine $i' \in \mathcal{M}_2$ has a load of more than u.

Now we repeat this procedure: Suppose that we constructed sets of machines $\mathcal{M}_1, ..., \mathcal{M}_\ell$. For each $k \in \{1, ..., 1/\epsilon\}$ such that there is a job $j \in \mathcal{J}_k$ assigned to a machine $i \in \mathcal{M}_\ell$ consider all jobs $j' \in \mathcal{J}_k$ with $p_{j'} < p_j$, which are assigned to a machine $i' \notin \mathcal{M}_1 \cup \ldots \cup \mathcal{M}_\ell$. If the load on one such machine i' is at most u, then we exchange j and j' which completes the swap. In particular, we do not reuse the constructed sets $\mathcal{M}_1, \ldots, \mathcal{M}_\ell$ for the next swap but we forget these sets before the next swap starts. Otherwise, if each considered machine i' has a load strictly more than u we construct a set $\mathcal{M}_{\ell+1}$ consisting of all these machines i' and continue in the current iteration.

Suppose that at the beginning of a swap there is no machine $i \in \mathcal{M}$ that has a load strictly greater than $u + \epsilon \cdot p_{\max}$. Then, a second stage of the local search algorithm takes place. We take the current solution and perform an analogous procedure in order to ensure that each machine $i \in \mathcal{M}$ has a load of at least $\ell - \epsilon \cdot p_{\max}$. Initially define $\mathcal{M}_1$ to be the set of all machines $i \in \mathcal{M}$ with a load strictly less than $\ell - \epsilon \cdot p_{\max}$. Suppose that we constructed sets of machines $\mathcal{M}_1, ..., \mathcal{M}_\ell$. For each $k \in \{1, ..., 1/\epsilon\}$ such that there is a job $j \in \mathcal{J}_k$ assigned to a machine $i \in \mathcal{M}_\ell$ consider all jobs $j' \in \mathcal{J}_k$ with $p_{j'} > p_j$, which are assigned to a machine $i' \notin \mathcal{M}_1 \cup \ldots \cup \mathcal{M}_\ell$. If the load on one such machine i' is at least ℓ, then we exchange j and j' which completes the swap. Otherwise, if each such machine i' has a load of strictly less than ℓ we construct a set $\mathcal{M}_{\ell+1}$ consisting of all these machines i' and continue. As we never increase the load of a machine with load at least $\ell - \epsilon \cdot p_{\max}$ we do not introduce new violations of the upper bound on the load. The algorithm terminates if the load of each machine $i \in \mathcal{M}$ is within $[\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$.

3.2 Correctness and running time

We show now that the algorithm terminates in $n^{O(1)}$ time. Then, by construction it outputs a solution in which each machine $i \in \mathcal{M}$ has a load in the interval $[\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$. In the following we prove this for the first stage of the local search, i.e., when at least one machine has as a load higher than $u + \epsilon p_{\max}$. We first show that in each iteration of the first stage we can find a pair of jobs j, j' to swap. Using a similar argument the same can be shown for the second stage.

▶ **Lemma 8.** *In each iteration the algorithm finds two jobs j, j' that it swaps and finding such a pair can be done in time $O(n^2)$.*

Proof. Suppose towards contradiction that the algorithm does not find two jobs $j, j' \in \mathcal{J}_k$ such that j is assigned to a machine $i \in \mathcal{M}_\ell$ with load more than $u + \epsilon \cdot p_{\max}$ and job j' is assigned to a machine $i' \notin \mathcal{M}_1 \cup \ldots \cup \mathcal{M}_\ell$ and $p'_j < p_j$. This means that the machines in $\mathcal{M}_1 \cup \ldots \cup \mathcal{M}_\ell$ are assigned the smallest jobs of type k while each machine having load at least u. Hence, even a fractional assignment of jobs cannot reduce the total load on these machines. Hence, in a fractional assignment at least one machine must have a load greater than u. This gives a contradiction. When finding a pair of jobs to swap each pair of type k is considered exactly once as each job is assigned fully to a machine. As the existence of a pair was shown for an arbitrary k this gives a worst case running time of $O(n^2)$. ◀

Next, we show that the first stage of the algorithm always terminates after at most $O(n^3)$ swaps. As Lemma 8 states that each swap can be done in time $O(n^2)$, this shows that the first stage finishes in time $n^{O(1)}$. To this end, we give an alternative formulation of the first stage of the algorithm as a repeated breadth-first search (BFS). We construct a weighted, directed graph. It contains one special vertex, the source s, and one vertex for each slot, that is $|\mathcal{J}| + 1$ vertices in total. Each non-source vertex is associated with a machine and a size class. The slots of the same machine form a clique: There is an edge from each slot to the other with weight 0. Furthermore, there is an edge of weight 1 from slot v to w, when (1) v and w are not on the same machine, (2) v and w belong to the same size class, and (3) v is currently assigned a larger job than w. Additionally, there is an edge of weight 0 from the source to every slot on a machine with load more than $u + \epsilon \cdot p_{\max}$. The algorithm performs a BFS on the graph above starting in s. Once it reaches a machine with load at most u, it selects the edge (v, w) over which the machine was reached and swaps the jobs assigned to the slots v and w. This is continued until every machine i is assigned a load at most $u + \epsilon \cdot p_{\max}$. The following lemma shows that the distance between s and other slots does not decrease by a swap.

▶ **Lemma 9.** *The distance from s to any slot does not decrease by a swap in the first stage of the algorithm.*

Proof. Note that when we make a swap, we actually reverse the direction of an edge. To get the main idea of the proof, consider an edge (v, w) that is "swapped". As the search is a BFS, we know that the distance in the original graph to w is equal to the shortest path to v plus 1. When we make the swap, this shortest path is eliminated, whereas all other paths from s to w remain. Therefore, the distance from s to w will not decrease. Furthermore, the distance from s to v did not change due to the swap.

Formally, we observe how the graph changes when swapping two jobs. Throughout the proof the distance $d(w)$ of a slot w is the distance from s to w before the swap is executed. Clearly, removing any edges from the graph cannot decrease the distances of vertices. Edges

between slots of the same machine do not change and no new edges can be added from the source, since during the execution of the algorithm a machine with load at most $u + \epsilon \cdot p_{\max}$ will never exceed $u + \epsilon \cdot p_{\max}$. Hence, it suffices to look at the changes in edges of weight 1. Although such an edge (v, w) might be added to the graph, we will show that this happens only when $d(w) \leq d(v) + 1$. Adding this edges cannot decrease any distances, since the first part of a shortest path using (v, w) could always be replaced by a path to w without this edge.

Now we have to check that these are the only changes made to the graph. Let v, w be the slots in which we exchange the jobs. The size of the job in v decreases; the size of the job in w increases. We only need to look at the incoming and outgoing edges of v and w, since all other edges remain the same.

Consider the incoming edges of v. Since the size of the job in v decreases, there could be new incoming edges. Let (w', v) be an edge of weight 1 that is added. This means the job in slot w' has a larger size than the job on v. Either w' is a slot on the same machine as w or (w', w) is in the graph before the swap. The former case implies that $d(w') = d(w) = d(v)+1$. In the latter case we have $d(v) = d(w) - 1 \leq d(w')$. No outgoing edge from v can be added, since the size of v's job decreases.

Now consider w. Since the size of its job increases, no incoming edge can be added. As for the outgoing edges, let (w, w') be an outgoing edge added by the swap. Then either v and w' are slots on the same machine or (v, w') was is in the graph before the swap. In the former case, $d(w') = d(v) = d(w) - 1$. In the latter case, $d(w') \leq d(v) + 1 = d(w)$. ◀

Using Lemmas 8 and 10 we can bound the maximum number of swaps necessary in the first stage of the algorithm.

▶ **Lemma 10.** *The first stage of the algorithm terminates after at most $O(n^3)$ swaps.*

Proof. Let $j_1, \ldots, j_n$ be the jobs $\mathcal{J}$ in increasing order of size. We claim that the potential

$$\sum_{i=1}^{n} i \cdot d(j_i)$$

increases with every swap. Here $d(j_i)$ denotes the distance from s to the slot to which j_i is assigned. Since the function is integral and bounded by n^3, the claim follows. Let j_k, j_h be the jobs that are swapped. Assume that $k < h$, i.e., $p_{j_k} < p_{j_h}$. Let d, d' be the distance functions before and after the swap. Based on Lemma 9 we have $d'(j_i) \geq d(j_i)$ for all $i \notin \{k, h\}$, $d'(j_h) \geq d(j_k)$ and $d'(j_k) \geq d(j_h)$, since these jobs swapped their slots. It follows that

$$\begin{aligned} k \cdot d'(j_k) + h \cdot d'(j_h) &\geq k \cdot d(j_h) + h \cdot d(j_k) \\ &= k \cdot d(j_h) + (h - k) \cdot \underbrace{d(j_k)}_{> d(j_h)} + k \cdot d(j_k) > h \cdot d(j_h) + k \cdot d(j_k). \end{aligned}$$ ◀

In order to complete the running time analysis we consider the second stage. Again, we construct a graph on $|\mathcal{J}| + 1$ vertices with the difference that we add an edge from s to every slot on a machine with load less than $\ell - \epsilon p_{\max}$ and an edge (v, w) between two slots of the same job type associated to different machines if v is currently assigned a smaller job than w. Following the same ideas as the proofs for the first stage, the running time of the second stage can be shown. For the detailed proofs for the second stage of the algorithm we refer to [6].

▶ **Lemma 11.** *The distance from s to any slot does not decrease by a swap in the second stage of the algorithm.*

▶ **Lemma 12.** *The second stage of the algorithm terminates after at most $O(n^3)$ swaps.*

Together, Lemmas 10 and 12 give the running time of the local search procedure.

▶ **Lemma 13.** *Given a solution to the slot-MILP, in time $n^{O(1)}$ we can compute an integral solution to slot-MILP such that $\sum_{j\in\mathcal{J}} p_j x_{i,j} \in [\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$ for each machine $i \in \mathcal{M}$.*

The main theorem follows from Lemmas 7 and 13.

▶ **Theorem 14.** *There is an algorithm for the target load balancing problem with a running time of $m^2 n^{O(1/\epsilon)}$ that computes a solution in which the load of each machine $i \in \mathcal{M}$ is in $[\ell - \epsilon \cdot p_{\max}, u + \epsilon \cdot p_{\max}]$, or asserts that there is no feasible solution.*

4 Applications

We can use Theorem 14 to obtain additive approximation schemes for *makespan minimization*, the *Santa Claus* problem and the *envy-minimizing Santa Claus* problem on identical machines. The idea is to guess the target load intervals up to multiples of $\epsilon \cdot p_{\max}$ and then applying the algorithm due to Theorem 14.

For $P||C_{\max}$ and the *Santa Claus* problem the guessing procedure can be done in time $O(1/\epsilon)$. For $P||C_{\max}$ we set $\ell = 0$ and guess u as a multiple of $\epsilon \cdot p_{\max}$ within the interval $[\frac{1}{m}\sum_{j=1}^{n} p_j, \frac{1}{m}\sum_{j=1}^{n} p_j + p_{\max}]$.

▶ **Corollary 15.** *There is an algorithm for $P||C_{\max}$ with a running time of $m^2 n^{O(1/\epsilon)}$ that computes a solution with makespan at most $OPT + \epsilon \cdot p_{\max}$.*

For the *Santa Claus* problem we set $u = \sum_{j=1}^{n} p_j$ and guess ℓ within the interval $[\frac{1}{m}\sum_{j=1}^{n} p_j - p_{\max}, \frac{1}{m}\sum_{j=1}^{n} p_j]$.

▶ **Corollary 16.** *There is an algorithm for the Santa Claus problem on identical machines with a running time of $m^2 n^{O(1/\epsilon)}$ that computes a solution in which each machine has a load of at least $OPT - \epsilon \cdot p_{\max}$.*

For the *envy-minimizing* Santa Claus problem we need to guess both ℓ and u simultaneously from the intervals above with a total number of $O(1/\epsilon^2)$ guesses.

▶ **Corollary 17.** *There is an algorithm for envy-minimization on identical machines with a running time of $m^2 n^{O(1/\epsilon)}$ which computes a solution with envy at most $OPT + \epsilon \cdot p_{\max}$.*

5 Conclusion

In this paper, we formalized the concept of additive approximation schemes and presented such algorithms for makespan minimization, the Santa Claus problem, and minimizing the maximum envy on identical machines with respect to the parameter $p_{\max}$. For the former two problems, additive approximation schemes are particularly interesting when $p_{\max} \ll \mathrm{OPT}$. For the latter, a multiplicative approximation guarantee is not possible for polynomial time algorithms (unless P=NP); therefore, an additive approximation scheme is a suitable alternative way to obtain non-trivial approximation guarantees.

For $P||C_{\max}$ and the Santa Claus problem on identical machines there is an EPTAS [2,21]. We leave as an open question to find additive approximation schemes for these problems with a running time of this form or to rule out that such schemes exists. Note that using similar techniques as in [34], one can easily show that all three versions admit even an additive FPTAS in case that m is a constant.

Abstract

Genome assembly asks to reconstruct an unknown string from many shorter substrings of it. Even though it is one of the key problems in Bioinformatics, it is generally lacking major theoretical advances. Its hardness stems both from practical issues (size and errors of real data), and from the fact that problem formulations inherently admit multiple solutions. Given these, at their core, most state-of-the-art assemblers are based on finding non-branching paths (*unitigs*) in an assembly graph. While such paths constitute only partial assemblies, they are likely to be correct. More precisely, if one defines a genome assembly solution as a *closed arc-covering walk* of the graph, then unitigs appear in all solutions, being thus *safe* partial solutions. Until recently, it was open what are *all* the safe walks of an assembly graph. Tomescu and Medvedev (RECOMB 2016) characterized all such safe walks (*omnitigs*), thus giving the first safe and *complete* genome assembly algorithm. Even though omnitig finding was later improved to quadratic time, it remained open whether the crucial linear-time feature of finding unitigs can be attained with omnitigs.

We answer this question affirmatively, by describing a surprising $O(m)$-time algorithm to *identify* all maximal omnitigs of a graph with n nodes and m arcs, notwithstanding the existence of families of graphs with $\Theta(mn)$ total maximal omnitig size. This is based on the discovery of a family of walks (*macrotigs*) with the property that all the non-trivial omnitigs are univocal extensions of subwalks of a macrotig. This has two consequences: (1) A *linear-time output-sensitive* algorithm enumerating all maximal omnitigs. (2) A *compact* $O(m)$ *representation* of all maximal omnitigs, which allows, e.g., for $O(m)$-time computation of various statistics on them. Our results close a long-standing theoretical question inspired by practical genome assemblers, originating with the use of unitigs in 1995. We envision our results to be at the core of a reverse transfer from theory to practical and *complete* genome assembly programs, as has been the case for other key Bioinformatics problems.

1 Introduction

Theoretical and practical background of genome assembly. Genome assembly is one of the flagship problems in Bioinformatics, along with other problems originating in – or highly motivated by – this field, such as edit distance computation, reconstructing and comparing phylogenetic trees, text indexing and compression. In genome assembly, we are given a collection of strings (or *reads*) and we need to reconstruct the unknown string (the genome) from which they originate. This is motivated by sequencing technologies that are able to read either "short" strings (100-250 length, Illumina technology), or "long" strings (10.000-50.000 length, Pacific Biosciences or Oxford Nanopore technologies) in huge amounts from the genomic sequence(s) in a sample. For example, the SARS-CoV-2 genome was obtained in [58] from short reads using the MEGAHIT assembler [39].

Other leading Bioinformatics problems have seen significant theoretical progress in major Computer Science venues, culminating (just to name a few) with both positive results, see e.g. [17, 57] for phylogeny problems, [22, 6, 34] for text indexing, [23, 7, 35] for text compression, and negative results, see e.g. [4, 1, 5, 21] for string matching problems. However, the genome assembly problem is generally lacking major theoretical advances.

One reason for this stems from practice: the huge amount of data (e.g. the 3.1 Billion characters long human genome is read 50 times over) which impedes slower than linear-time algorithms, errors of the sequencing technologies (up to 15% for long reads), and various biases when reading certain genomic regions [47]. Another reason stems from theory: historically, finding an optimal genome assembly solution is considered NP-hard under several formulations [49, 33, 32, 43, 46, 29, 48], but, more fundamentally, even if one outputs a 3.1 Billion characters long string, this is likely incorrect, since problem formulations inherently admit a large number of solutions of such length [36].

Given all these setbacks, most state-of-the-art assemblers, including e.g. MEGAHIT [39] (for short reads), or wtdbg2 [52] (for long reads), generally employ a very simple and *linear-time* strategy, dating back to 1995 [32]. They start by building an assembly graph encoding the overlaps of the reads, such as a *de Bruijn graph* [50] or an *overlap graph* [45] (graphs are directed in this paper). After some simplifications to this graph to remove practical artifacts such as errors, at their core they find strings labeling paths whose internal nodes have in-degree and out-degree equal to 1 (called *unitigs*), approach dating back to 1995 [32]. That is, they do not output *entire* genome assemblies, but only shorter strings that are likely to be present in the sequenced genome, since unitigs do not branch at internal nodes.

Safe and complete algorithms: A theoretical framing of practical genome assembly. With the aim of enhancing the widely-used practical approach of assembling just unitigs – as those walks considered to be present in any possible assembly solution – a result in a major Bioinformatics venue [55] asked *what is the "limit" of the correctly reconstructible information from an assembly graph.* Moreover, is all such reconstructible information still obtainable in *linear time*, as in the case of the popular unitigs? Variants of this question also appeared in [27, 8, 46, 53, 37, 9], while other works already considered simple linear-time generalizations of unitigs [51, 44, 30, 36], without knowing if the "assembly limit" is reached.

To make this question precise, [55] introduced the following *safe and complete* framework. Given a notion of solution to a problem (e.g. a type of walk in a graph), a partial solution (e.g. some shorter walk in the graph) is called *safe* if it appears (e.g. is a subwalk) in all solutions. An algorithm reporting only safe partial solutions is called a *safe algorithm*. A safe algorithm reporting *all* safe partial solutions is called *safe and complete*. A safe and complete algorithm outputs all and only what is likely part of the unknown object to be reconstructed, *synthesizing all solutions from the point of view of correctness.* Safety generalizes the existing notion of *persistency*: a *single* node or edge was called *persistent* if it appears in all solutions [28, 16, 13], for example persistent edges for maximum bipartite matchings [16]. It also has roots in other Bioinformatics works [56, 14, 24, 59] considering the aligned symbols appearing in all optimal (and sub-optimal) alignments of two strings.

There are many theoretical formulations of genome assembly as an optimization problem, e.g. a shortest common superstring of all the reads [49, 33, 32], or some type of shortest walk covering all nodes or arcs of the assembly graph [51, 43, 44, 31, 29, 48, 46]. However, it is widely acknowledged [46, 48, 42, 47, 41, 36] that, apart from some being NP-hard, these formulations are lacking in several aspects, for example they collapse repeated regions of a genome. At present, given the complexity of the problem, there is no definitive notion of a "good" genome assembly solution. Therefore, [55] considered as genome assembly solution *any* closed arc-covering walk of a graph, where *arc-covering* means that it passes through each arc *at least* once. The main benefit of considering *any* arc-covering walk is that safe walks for them are safe also for any possible restriction of such covering walks (e.g. by some additional optimality criterion[1]). Put otherwise, safe walks for *all* arc-covering walks are more likely to be correct than safe walks for some peculiar type of arc-covering walks.

Prior results on safety in closed arc-covering walks. It is immediate to see that unitigs are safe walks for closed arc-covering walks. A first safe generalization of unitigs consisted of those paths whose internal nodes have only out-degree equal to 1 (with no restriction on their in-degree) [51]. Further, these safe paths have been generalized in [44, 30, 36] to those partitionable into a prefix whose nodes have in-degree equal to 1, and a suffix whose nodes have out-degree equal to 1. *All* safe walks for closed arc-covering walks were characterized by [55, 54] as being exactly those that are *omnitigs*, see Definition 1, Figure 1, and Theorem 8. This leads to the first *safe and complete* genome assembly algorithm (obtained thus 20 years after unitigs were first considered), outputting all *maximal* omnitigs in polynomial time (maximal omnitigs are those which are not sub-walks of other omnitigs).

▶ **Definition 1** (Omnitig). *Let $W = e_0 \dots e_\ell$ be a walk. We say that a non-empty path P is a j-i* forbidden path *for W, for some $1 \leq i \leq j \leq \ell$, if the first arc of P has the same tail as e_j and is different from e_j, and the last arc of P has the same head as e_{i-1} and is different from e_{i-1}. We say that W is an* omnitig *if for no $1 \leq i \leq j \leq \ell$ there exists a j-i forbidden path for W.*

Furthermore, through experiments on "perfect" human read datasets, [55] also showed that strings labeling omnitigs are about 60% longer on average than unitigs, and contain about 60% more biological content on average. Thus, once other issues of real data (e.g. errors)

[1] For example, closed arc-covering walks are a common relaxation of the fundamental notions of closed Eulerian walk (we now pass through each arc *at least once*), and of closed Chinese postman walk (i.e. a closed arc-covering walk *of minimum length*) [26], which were mentioned in [46] as unsatisfactory models of genome assembly.

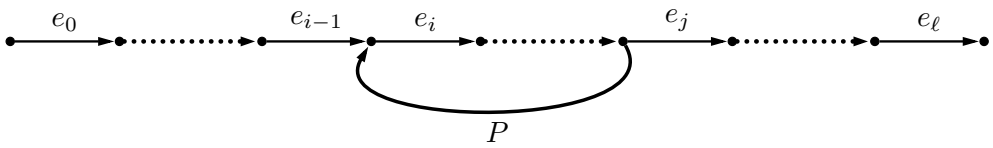

Figure 1 Walk $e_0 \dots e_\ell$ is *not* an omnitig because there is a forbidden path P.

are added to the problem formulation, omnitigs (and the safe walks for such extended models) have the potential to significantly improve the quality of genome assembly results. Nevertheless, for this to be possible, one first needs the best possible results for omnitigs (given e.g. the sheer size of the read datasets), and a full comprehension of them, otherwise, such extensions are hard to solve efficiently.

Cairo et al. [11] recently proved that the length of all maximal omnitigs of any graph with n nodes and m arcs is $O(nm)$, and proposed an $O(nm)$-time algorithm enumerating all maximal omnitigs. This was also proven to be optimal, in the sense that they constructed families of graphs where the total length of all maximal omnitigs is $\Theta(nm)$. However, it was left open if it is necessary to pay $O(nm)$ even when the total length of the output is smaller. Moreover, that algorithm cannot break this barrier, because e.g. $O(m)$-time traversals have to be done for $O(n)$ cases.

Our results. Our main result is an $O(m)$-size representation of all maximal omnitigs[2], based on a careful structural decomposition of the omnitigs of a graph. This is surprising, given that there are families of graphs with $\Theta(nm)$ total length of maximal omnitigs [11].

▶ **Theorem 2.** *Given a strongly connected graph G with n nodes and m arcs, there exists a $O(m)$-size representation of all maximal omnitigs, consisting of a set $\mathcal{M}$ of walks (*maximal macrotigs*) of total length $O(n)$ and a set $\mathcal{F}$ of arcs, such that every maximal omnitig is the univocal extension[3] of either a subwalk of a walk in $\mathcal{M}$, or of an arc in $\mathcal{F}$.*

Moreover, $\mathcal{M}$, $\mathcal{F}$, and the endpoints of macrotig subwalks univocally extending to maximal omnitigs can be computed in time $O(m)$.

Since the univocal extension $U(W)$ of a walk W can be trivially computed in time linear in the length of $U(W)$, we immediately get the linear-time output sensitive algorithm:

▶ **Corollary 3.** *Given a strongly connected graph G, it is possible to enumerate all maximal omnitigs of G in time linear in their total length.*

We obtain Theorem 2 using two interesting ingredients. The first is a novel graph structure (*macronodes*), obtained after a *compression* operation of "easy" nodes and arcs (Section 4). The second is a connection to a recent result by Georgiadis et al. [25] showing that it is possible to answer in $O(1)$-time strong connectivity queries under a *single* arc removal, after linear-time preprocessing (notice that a forbidden path is defined w.r.t. *two* arcs to avoid).

Theorem 2 has additional practical implications. First, omnitigs are also representable in the same (linear) size as the commonly used unitigs. Second, maximal macrotigs enable various $O(m)$-time operations on maximal omnitigs (without listing them explicitly), by pre-computing the univocal extensions from any node, needed in Theorem 2. For example, given that the number of maximal omnitigs is $O(m)$ [11], this implies the following result:

[2] Note that the total length of the maximal omnitigs is at least m, since every arc is an omnitig.
[3] The *univocal extension* $U(W)$ of a walk W is obtained by appending to W the longest path whose nodes (except for the last one) have out-degree 1, and prepending to W the longest path whose nodes (except for the first one) have in-degree 1; see Section 2 for the formal definition.

▶ **Corollary 4.** *Given a strongly connected graph G with m arcs, it is possible to compute the lengths of all maximal omnitig in total time $O(m)$.*

Corollary 4 leads to a linear-time computation of various statistics about maximal omnitigs, such as minimum, maximum, and average length (useful e.g. in [15]). One can also use this to filter out subfamilies of them (e.g. those of length smaller and/or larger than a given value) before enumerating them explicitly.

Significance of our results. This paper shows that *all* the strings that can be correctly assembled from a graph can be obtained in output-sensitive linear time, a time feasible for being implemented in practical genome assemblers. It closes the issue of finding safe walks for a fundamental model of genome assembly (*any* closed arc-covering walk), a long-standing theoretical question and originating with the use of unitigs in 1995 [32].

This theoretical question is crucial also from the practical point of view: assembly graphs have the number of nodes and arcs in the order of millions, and yet the total length of the maximal omnitigs is almost linear in the size of the graph. For example, the compressed (see Section 4) de Bruijn graph of human chromosome 10 (length 135 million) has 467 thousand arcs [11, Table 1], and the length of all maximal omnitigs (i.e. their total number of arcs, not their total string length) is 893 thousand. Moreover, even though this chromosome is only about 4% of the full human genome, the running time of the *quadratic* algorithm of [11] on its compressed de Bruijn graph is about 30 minutes.

We envision a reverse transfer from theory to practical and *complete* genome assembly programs, as in other Bioinformatics problems. For example, trivially, safe walks for all closed arc-covering walks are also safe for more specific types of arc-covering walks. Moreover, while a genome solution defined as a single closed arc-covering walk does not incorporate several practical issues of real data, in a follow-up work [10] we show that omnitigs are the basis of more advanced models handling many practical aspects. For example, to allow more types of genomes to be assembled, one can define an assembly solution as a *set* of closed walks that together cover all arcs [2], which is the case in *metagenomic* sequencing of bacteria. For linear chromosomes (as in eukaryotes such as human), or when modeling missing sequencing coverage, one can analogously consider one, or many, such *open* walks [54, 55]. Safe walks for all these models are subsets of omnitigs [2, 10]. Moreover, when modeling sequencing errors, or mutations present e.g. only in the mother copy of a chromosome (and not in the father's copy), one can require some arcs not to be covered by a solution walk, or even to be "invisible" from the point of view safety. Finding safe walks for such models is also based on first finding omnitigs-like walks [10].

Notice that such separation between theoretical formulations and their practical embodiments is common for many classical problems in Bioinformatics. For example, computing edit distance is often replaced with computing edit distance under affine gap costs [18], or enhanced with various heuristics as in the well-known BLAST aligner [3]. Also text indexes such as the FM-index [22] are extended in popular read mapping tools (e.g. [40, 38]) with many heuristics handling errors and mutations in the reads.

Finally, our results show that safe partial solutions enjoy interesting combinatorial properties, further promoting the persistency and safety frameworks. For real-world problems admitting multiple solutions, safe and complete algorithms are more pragmatic than the classical approach of outputting an arbitrary optimal solution. They are also more efficient than enumerating all, or only the first k-best, solutions [19, 20], because they already *synthesize all that can be correctly reconstructed from the input data.*

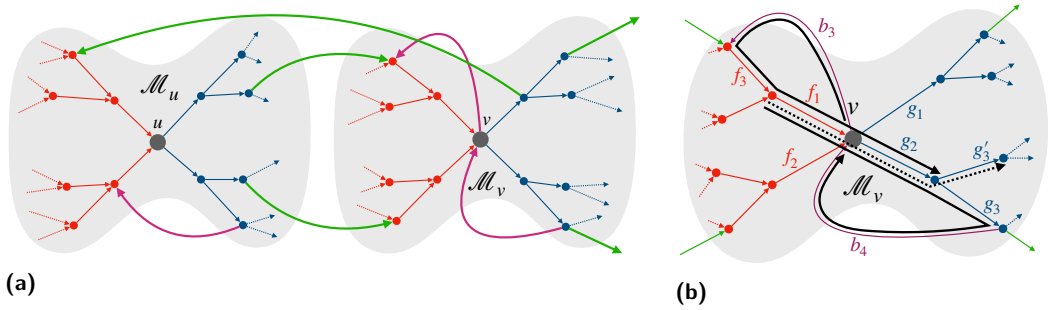

Figure 2 Figure 2a: Given a bivalent node v, the macronode $\mathcal{M}_v$ is the subgraph of G induced by the nodes reaching v with a split-free path (in red), and the nodes reachable from v with a join-free path (in blue). These two types of nodes induce the two trees of the macronode. By definition, every arc with endpoints in different macronodes is bivalent (in green, denoted *cross-bivalent arcs*). The remaining bivalent arcs have endpoints in the same macronode (in purple, denoted *self-bivalent arcs*). Figure 2b: The only omnitig traversing the bivalent node v is f_1g_2; e.g., by the X-intersection Property neither f_2g_2 is an omnitig ($b_3f_3f_1$ is a forbidden path) nor f_1g_1 is an omnitig ($g_2g_3b_4$ is a forbidden path). Extending the micro-omnitig f_1g_2 to the right we notice that $f_1g_2g_3$ is an omnitig and by the Y-intersection Property $f_1g_2g_3'$ is not an omnitig (g_3b_4 is a forbidden path). Hence, the only maximal right-micro omnitig is $f_1g_2g_3b_4$, and the only maximal left-micro omnitig is $b_3f_3f_1g_2$. Merging the two on f_1g_2, we obtain the maximal microtig $b_3f_3f_1g_2g_3b_4$.

2 Overview of the proofs

We highlight here our key structural and algorithmic contributions, and give more formal details in Sections 4 and 5. We start with the minimum terminology needed to understand this section, and defer the rest of the notation to Section 3.

Terminology. Functions $t(\cdot)$ and $h(\cdot)$ denote the *tail* node and the *head* node, respectively, of an arc or walk. We classify the nodes and arcs of a strongly connected graph as follows (see Figure 2a): (i) A node v is a *join node* if its *in-degree* $d^-(v)$ satisfies $d^-(v) > 1$, and a *join-free node* otherwise. An arc f is called a *join arc* if $h(f)$ is a join node, and a *join-free arc* otherwise. (ii) A node v is a *split node* if its *out-degree* $d^+(v)$ satisfies $d^+(v) > 1$, and a *split-free node* otherwise. An arc g is called a *split arc* if $t(g)$ is a split node, and a *split-free arc* otherwise. (iii) A node or arc is called *bivalent* if it is both join and split, and it is called *biunivocal* if it is both split-free and join-free. A walk W is *split-free* (resp., *join-free*) if all its arcs are split-free (resp., join-free). Given a walk W, its *univocal extension* $U(W)$ is defined as W^-WW^+, where W^- is the longest join-free path to $t(W)$ and W^+ is the longest split-free path from $h(W)$ (observe that they are uniquely defined).

Structure. The main structural insight of this paper is that omnitigs enjoy surprisingly limited freedom, in the sense that any omnitig can be seen as a concatenation of walks in a very specific set. In order to give the simplest exposition, we first simplify the graph by contracting biunivocal nodes and arcs. The nodes of the resulting graph can now be partitioned into *macronodes* (see Figure 2a and Definition 12), where each macronode $\mathcal{M}_v$ is uniquely identified by a bivalent node v (its *center*). We can now split the problem by first finding omnitigs inside each macronode, and then characterizing the ways in which omnitigs from different macronodes can combine.

We discover a key combinatorial property of how omnitigs can be extended: there are at most two ways that any omnitig can traverse a macronode center (see also Figure 2b):

▶ **Theorem 5** (X-intersection Property). *Let v be a bivalent node. Let $f_1 \neq f_2$ be join arcs with $h(f_1) = h(f_2) = v$; let $g_1 \neq g_2$ be split arcs with $t(g_1) = t(g_2) = v$.*

(i) *If f_1g_1 and f_2g_2 are omnitigs, then $d^+(v) = d^-(v) = 2$.*

(ii) *If f_1g_1 is an omnitig, then there are no omnitigs f_1g' with $g' \neq g_1$, nor $f'g_1$ with $f' \neq f_1$.*

In order to prove the X-intersection Property, we prove an even more fundamental property: once an omnitig traverses a macronode center, for any node it meets after the center node, there is at most one way of continuing from that node (Y-intersection Property), see Figure 2b. The basic intuition is that if there is more than one possibilities, then strong connectivity creates forbidden paths.

Given an omnitig fg traversing the bivalent node v, we define the *maximal right-micro omnitig* as the longest extension fgW in the macronode $\mathcal{M}_v$ (see Figure 2b and Definition 14). The *maximal left-micro omnitig* is the symmetrical omnitig Wfg. By Theorem 5, there are at most two maximal right-micro omnitigs and two maximal left-micro omnitigs. The merging of a maximal left- and right-micro omnitig on fg is called a *maximal microtig* (see Figure 2b and Definition 14; notice that a microtig is not necessarily an omnitig). These *at most two* maximal microtigs represent "forced tracks" to be followed by omnitigs crossing v.

We now describe how omnitigs can advance from one macronode to another. We prove that any arc having endpoints in different macronodes is a bivalent arc, and moreover, for every maximal microtig ending with a bivalent arc b, there is at most one maximal microtig starting with b. As such, when an omnitig track exits a macronode, there is at most one way of connecting it with an omnitig track from another macronode. It is natural to merge all omnitig tracks (i.e. maximal microtigs) on all bivalent arcs between *different* macronodes, and thus obtain *maximal macrotigs* (Definition 17 and Figure 5). The total size of all maximal macrotigs is $O(n)$ (Theorem 20), and they are a representation of all maximal omnitigs, except for those that are univocal extensions of the arcs of $\mathcal{F}$, see below and Theorem 21.

Algorithms. Our algorithms first build the set $\mathcal{M}$ of maximal macrotigs, and then identify maximal omnitigs inside them. The set $\mathcal{F}$ of arcs univocally extending to the remaining maximal omnitigs will be the set of bivalent arcs not appearing in $\mathcal{M}$ (Theorem 21).

Crucial to the algorithms is an *extension* primitive deciding what new arc (if any) to choose when extending an omnitig (recall that the X- and Y-intersection Properties limits the *number* of such arcs to one). Suppose we have an omnitig fW, with f a join arc, and we need to decide if it can be extended with an arc g out-going from $h(W)$. Naturally, this extension can be found by checking that there is no forbidden path from $t(g) = h(W)$. However, this forbidden path can potentially end in any node of W. Up to this point, [54, 55, 11] need to do an entire $O(m)$ graph traversal to check if any node of W is reachable by a forbidden path. We prove here a new key property:

▶ **Theorem 6** (Extension Property). *Let fW be an omnitig in G, where f is a join arc. Then fWg is an omnitig if and only if g is the only arc with $t(g) = h(W)$ such that there exists a path from $h(g)$ to $h(f)$ in $G \setminus f$.*

Thus, for each arc g with $t(g) = h(W)$, we can do a *single* reachability query under one arc removal: "does $h(g)$ reach $h(f)$ in $G \setminus f$?" Since the target of the reachability query is also the head of the arc excluded f, then we can apply an immediate consequence of [25]:

▶ **Theorem 7** ([25]). *Let G be a strongly connected graph with n nodes and m arcs. After $O(m)$-time preprocessing, one can build an $O(n)$-space data structure that, given a node w and an arc f, tests in $O(1)$ worst-case time if there is a path from w to $h(f)$ in $G \setminus f$.*

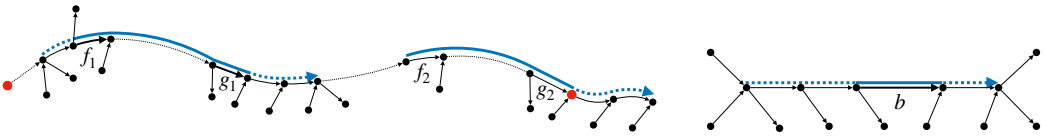

Figure 3 Any maximal omnitig is identified (in solid blue) either by a macrotig interval (from a join arc f to a split arc g; left), or by a bivalent arc b not appearing in any macrotig (right). The full maximal omnitig is obtained by univocal extension (dotted blue), extension which may go outside of the maximal macrotig.

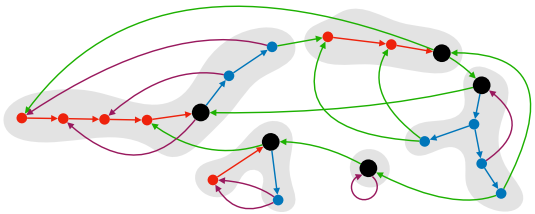
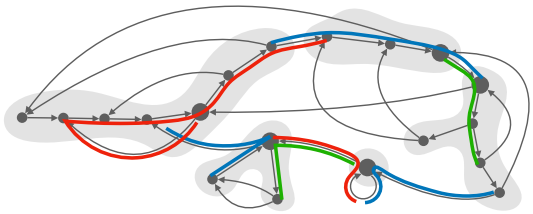
Using the Extension Property and Theorem 7, we can thus pay $O(1)$ time to check each out-outgoing arc g, before discovering the one (if any) with which to extend fW. In the full version of this paper we describe how to transform the graph to have constant degree, so that we pay $O(1)$ per node. This transformation also requires slight changes to the maximal omnitig enumeration algorithm to maintain the linear-time output sensitive complexity. We use the Extension Property when building the left- and right-maximal micro omnitigs, and when identifying maximal omnitigs inside macrotigs, as follows.



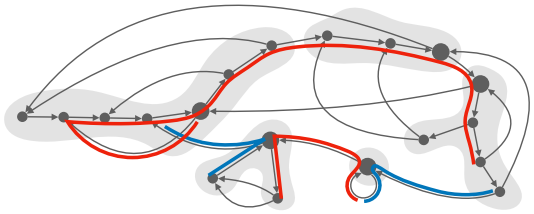
Once we have the set $\mathcal{M}$ of maximal macrotigs, we scan each macrotig with two pointers, a left one always on a join arc f, and a right one always on a split arc g (see Figure 3 and Algorithm 2). Both pointers move from left to right in such a way that the subwalk between them is always an omnitig. The subwalk is grown to the right by moving the right pointer as long as it remains an omnitig (checked with the Extension Property). When growing to the right is no longer possible, the omnitig is shrunk from the left by moving the left pointer. This technique runs in time linear to the total length of the maximal macrotigs, namely $O(n)$. In Figure 4 we work out all these notions on a concrete example.

Comparison with previous techniques. The algorithm of [55] exhaustively extends an omnitig with every edge outgoing from its head, as long as the resulting walk remained an omnitig, and did not use any insights on the structure of omnitigs. The $O(nm)$-time algorithm of [11] was obtained using two structural results: there can be only one left-maximal omnitig ending with a split arc (which we do not use here, since we prove deeper insights on the structure of omnitigs, e.g. the X- and Y-intersection Properties) and the existence of an acyclic order between split arcs connected by "simple" omnitigs. In [11], these allow computation to be memoized when recursively computing the left-maximal omnitig ending with a given split arc. The two-pointer technique was used also in [2] for a related problem, to test the safety of intervals of an *entire solution*. Our surprising discovery of macrotigs allow for a "small search space" of total size to $O(n)$, and eliminate the need of recursion, while the Extension Property enables the use of [25], thus the pay of $O(1)$ per omnitig extension, instead of $O(m)$ as in [54, 55, 11].

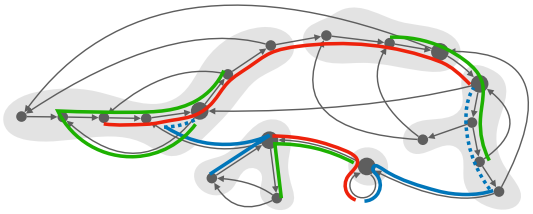


3 Basics

In this paper, a *graph* is a tuple $G = (V, E)$, where V is a finite set of *nodes*, E is a finite multi-set of ordered pairs of nodes called *arcs*. Parallel arcs and self-loops are allowed. For an arc $e \in E(G)$, we denote $G \setminus e = (V, E \setminus \{e\})$. The *reverse graph* G^R of G is obtained by reversing the direction of every arc. In the rest of this paper, we assume a fixed strongly connected graph $G = (V, E)$, with $|V| = n$ and $|E| = m \geq n$.



A *walk* in G is a sequence $W = (v_0, e_1, v_1, e_2, \ldots, v_{\ell-1}, e_\ell, v_\ell)$, $\ell \geq 0$, where $v_0, v_1, \ldots, v_\ell \in V$, and each e_i is an arc from v_{i-1} to v_i. Sometimes we drop the nodes $v_0, \ldots, v_\ell$ of W, and write W more compactly as $e_1 \ldots e_\ell$. If an arc e appears in W, we write $e \in W$. We say



(a) Nodes and arcs color-coded as in Figure 2a.

(b) Maximal microtigs.

(c) Maximal macrotigs.

(d) The maximal omnitigs obtained from maximal macrotigs (univocal extensions are dotted). All other maximal omnitigs are univocal extensions of the bivalent arcs not appearing in macrotigs.

Figure 4 A concrete example of the main notions of this paper. In Figures 4b–4d walks have different colors for visual distinguishability.

that W goes *from* $t(W) = v_0$ *to* $h(W) = v_\ell$, has *length* ℓ, contains $v_1, \ldots, v_{\ell-1}$ as *internal nodes*, *starts with* e_1, *ends with* e_ℓ, and contains $e_2, \ldots, e_{\ell-1}$ as *internal arcs*. A walk W is called *empty* if it has length zero, and *non-empty* otherwise. There exists exactly one empty walk $\epsilon_v = (v)$ for every node $v \in V$, and $t(\epsilon_v) = h(\epsilon_v) = v$. A walk W is called *closed* if it is non-empty and $t(W) = h(W)$, otherwise it is *open*. The concatenation of walks W and W' (with $h(W) = t(W')$) is denoted WW'. A walk $W = (v_0, e_1, v_1, \ldots, e_\ell, v_\ell)$ is called a *path* when the nodes $v_0, v_1, \ldots, v_\ell$ are all distinct, with the exception that $v_\ell = v_0$ is allowed (in which case we have either a closed or an empty path). To simplify notation, we may denote a walk $W = (v_0, e_1, v_1, \ldots, e_\ell, v_\ell)$ as a sequence of arcs, i.e. $W = e_1 \ldots e_\ell$. Subwalks of open walks are defined in the standard manner. For a closed walk $W = e_0 \ldots e_{\ell-1}$, we say that $W' = e'_0 \ldots e'_j$ is a subwalk of W if there exists $i \in \{0, \ldots, \ell - 1\}$ such that for every $k \in \{0, \ldots, j\}$ it holds that $e'_k = e_{(i+k) \bmod \ell}$.

A closed *arc-covering* walk (i.e. passing through every arc at least once) exists if and only if the graph is strongly connected. We are interested in the (safe) walks that are subwalks of all closed arc-covering walks:

▶ **Theorem 8** ([55]). *Let G be a strongly connected graph different from a closed path. Then a walk W is a subwalk of all closed arc-covering walks of G if and only if W is an* omnitig.

Observe that W is an omnitig in G if and only if W^R is an omnitig in G^R. Moreover, any subwalk of an omnitig is an omnitig. For every arc e, its univocal extension $U(e)$ is an omnitig. A walk W satisfying a property $\mathcal{P}$ is *right-maximal* (resp., *left-maximal*) if there is no walk We (resp., eW) satisfying $\mathcal{P}$. A walk satisfying $\mathcal{P}$ is *maximal* if it is left- and right-maximal w.r.t. $\mathcal{P}$. Notice that if G is a closed path, then every *walk* of G is an omnitig. As such, it is relevant to find the maximal omnitigs of G only when G is different from a closed path. Thus, in the rest of this paper our strongly connected graph G is considered to be different from a closed path, even when we do not mention it explicitly.

4 Macronodes and macrotigs

We summarize here the key results about macronodes and macrotigs, and refer the reader to the full version of this paper for the full details and proofs. Unless otherwise stated, we assume that the input graph is *compressed*, in the sense that it has no biunivocal nodes and arcs. In some algorithms we will also require that the graph has constant in- and out-degree. In the full version of this paper we show how these properties can be guaranteed, by transforming any strongly connected graph G with m arcs, in time $O(m)$, into a compressed graph of constant degree and with $O(m)$ nodes and arcs. Observe that in a compressed graph all arcs are split, join or bivalent. Moreover, the following properties hold.

▶ **Observation 9.** *Let G be a compressed graph. Let f and g be a join and a split arc, respectively, in G. The following holds:*

(i) *if fWg is a walk, then W has a node which is a bivalent node;*

(ii) *if gWf is a walk, then gWf contains a bivalent arc.*

▶ **Lemma 10.** *Every maximal omnitig of a compressed graph contains both a join arc and a split arc. Moreover, it has a bivalent arc or an internal bivalent node.*

▶ **Lemma 11.** *Let u be a bivalent node. No omnitig contains u twice as an internal node.*

Macronodes. We introduce a natural partition of the nodes of a compressed graph; each class of such a partition (i.e. a *macronode*) contains precisely one bivalent node. We identify each class with the unique bivalent node they contain. All other nodes belonging to the same class are those that either reach the bivalent node with a join-free path or those that are reached by the bivalent node with a split-free path (recall Figure 2a).

▶ **Definition 12** (Macronode). *Let v be a bivalent node of G. Consider the following sets:*

- $R^+(v) := \{u \in V(G) : \exists$ *a join-free path from v to $u\}$;*
- $R^-(v) := \{u \in V(G) : \exists$ *a split-free path from u to $v\}$.*

The subgraph $\mathcal{M}_v$ induced by $R^+(v) \cup R^-(v)$ is called the macronode centered in v.

▶ **Lemma 13.** *In a compressed graph G, the following properties hold:*

i) *The set $\{V(\mathcal{M}_v) : v$ is a bivalent node of $G\}$ is a partition of $V(G)$.*

ii) *In a macronode $\mathcal{M}_v$, $R^+(v)$ and $R^-(v)$ induce two trees with common root v, but oriented in opposite directions. Except for the common root, the two trees are node-disjoint, all nodes in $R^-(v)$ being join nodes and all nodes in $R^+(v)$ being split nodes.*

iii) *The only arcs with endpoints in two different macronodes are bivalent arcs.*

To analyze how omnitigs can traverse a macronode and the degrees of freedom they have in choosing their directions within the macronode, we introduce the following definitions. *Central-micro omnitigs* are the smallest omnitigs that cross the center of a macronode. *Left- and right-micro omnitigs* start from a central-micro omnitig and proceed to the periphery of a macronode. Finally, we combine left- and right-micro omnitigs into microtigs (which are not necessarily omnitigs themselves); recall Figure 2b.

▶ **Definition 14** (Micro omnitigs, microtigs). *Let f be a join arc and g be a split arc, such that fg is an omnitig.*

- *The omnitig fg is called a* central-micro omnitig.
- *An omnitig fgW (Wfg, resp.) that does not contain a bivalent arc as an internal arc is called a* right-micro omnitig *(respectively,* left-micro omnitig*).*
- *A walk $W = W_1fgW_2$, where W_1fg and fgW_2 are, respectively, a left-micro omnitig, and a right-micro omnitig, is called a* microtig.

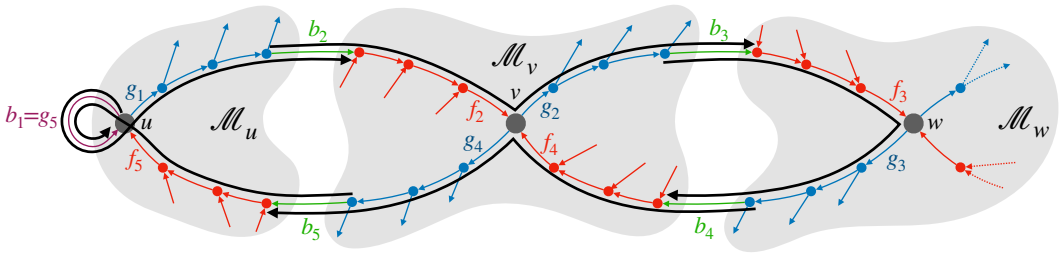


Figure 5 Three macronodes $\mathcal{M}_u, \mathcal{M}_v, \mathcal{M}_w$ (as gray areas) with arcs color-coded as in Figure 2a. Black walks mark their five maximal microtigs: $b_1 g_1 \dots b_2$, $b_i \dots f_i g_i \dots b_{i+1}$ ($i \in \{2,3,4\}$), $b_5 \dots f_5 g_5$ ($g_5 = b_1$). The maximal macrotig M is obtained by overlapping them on the cross-bivalent arcs b_2, b_3, b_4, b_5, i.e. $M = b_1 \dots b_2 \dots b_3 \dots b_4 \dots b_5 \dots b_1$. Notice that no arc is contained twice in M, with the exception of the self-bivalent arc b_1, appearing as the first and last arc of M.

▶ **Theorem 15** (Maximal microtigs). *The maximal microtigs of any strongly connected graph G with n nodes, m arcs, and arbitrary degree have total length $O(n)$, and can be computed in time $O(m)$.*

Macrotigs. Macronodes are connected with each other by bivalent arcs (Lemma 13), but merging microtigs on all possible bivalent arcs may create too complicated structures. However, this can be avoided by a simple classification of bivalent arcs: those that connect a macronode with itself (*self-bivalent*) and those that connect two different macronodes (*cross-bivalent*), recall Figure 2a.

▶ **Definition 16** (Self-bivalent and cross-bivalent arcs). *A bivalent arc b is called a* self-bivalent arc *if $U(b)$ goes from a bivalent node to itself. Otherwise it is called a* cross-bivalent arc.

A macrotig is now obtained by merging those microtigs from different macronodes which overlap only on a cross-bivalent arc, see also Figure 5.

▶ **Definition 17** (Macrotig). *Let W be any walk. W is called a* macrotig *if*

1. *W is an microtig, or*
2. *By writing $W = W_0 b_1 W_1 b_2 \dots b_{k-1} W_{k-1} b_k W_k$, where $b_1, \dots, b_k$ are all the internal bivalent arcs of W, the following conditions hold:*
   - **a.** *the arcs $b_1, \dots, b_k$ are all cross-bivalent arcs, and*
   - **b.** *$W_0 b_1$, $b_1 W_1 b_2$, …, $b_{k-1} W_{k-1} b_k$, $b_k W_k$ are all microtigs.*

Our structural results (including Lemmas 18 and 19 below) show that we can construct all *maximal* macrotigs by repeatedly joining microtigs overlapping on cross-bivalent arcs, as long as possible, and obtain Theorem 20.

▶ **Lemma 18.** *For any macrotig W there exists a unique maximal macrotig containing W.*

▶ **Lemma 19.** *Let W be a macrotig and let e be an arc of W. If e is self-bivalent, then e appears at most twice in W (as first or as last arc of W). Otherwise, e appears only once.*

▶ **Theorem 20** (Maximal macrotigs). *The maximal macrotigs of any strongly connected graph G with n nodes, m arcs, and arbitrary degree have total length $O(n)$, and can be computed in time $O(m)$.*

5 Maximal omnitig representation and enumeration

In the algorithms of this section we assume that the graph has constant degree. In the full version of this paper we explain how to handle the non-constant degree case.

We begin by proving the first part of Theorem 2. Theorem 20 guarantees that the total length of maximal macrotigs is $O(n)$. Thus, it remains to prove the following lemma, since since any macrotig is a subwalk of a maximal macrotig (Lemma 18).

▶ **Theorem 21** (Maximal omnitig representation)**.** *Let W be a maximal omnitig.*

- **i)** *If W contains an internal bivalent node, then W is of the form $U(fW'g)$, where f is the first join arc of W and $g \neq f$ is the last split arc of W, and W' is a possibly empty walk. Moreover, $fW'g$ is a macrotig.*
- **ii)** *Otherwise, W is of the form $U(b)$, where b is a bivalent arc, and b does not belong to any macrotig.*

Proof. To prove i), let u be an internal bivalent node of W, and let f_u and g_u be, respectively, the join arc and the split arc of W with $h(f_u) = u = t(g_u)$; both such f_u and g_u exist, since u is an internal node of W. Therefore, since W contains at least f_u and g_u, let f and g be, respectively the first join arc and the last split arc of W. Observe that f is either f_u or it appears before f_u in W; likewise, g is either g_u or it appears after g_u in W. Thus, f comes before g, and we can write $W = W^- fW'gW^+$, where W' is the subwalk of W, possibly empty, from $h(f)$ to $t(g)$. Therefore, by the maximality of W, we have $W = W^- fW'gW^+ = U(fW'g)$.

To prove that the subwalk $fW'g$ of W is a macrotig, we prove by induction that *any* walk of the form $fW'g$, where f is a join arc and g is a split arc, is a macrotig. The induction is on the length of W'.

Case 1: W' contains no internal bivalent arcs. Since $fW'g$ contains a bivalent node (Observation 9), it is of the form $fW'g = W_1' f' g' W_2'$, with $h(f') = t(g') = u$ bivalent node. Notice that $W_1' f' g' W_2'$ is an microtig and thus it is a macrotig, by definition.

Case 2: $fW'g$ contains an internal bivalent arc b, i.e. $fW'g = W_1' b W_2'$, with W_1', W_2' non empty. By induction, $W_1'b$ and bW_2' are macrotigs and both contain a bivalent node as internal node. Suppose b is a self-bivalent arc, then both $W_1'b$ and bW_2' would contain the same bivalent node u as internal node, contradicting Lemma 11. Thus, b is a cross-bivalent arc and $W_1' b W_2'$ is also a macrotig, by definition.

For ii), notice that if W contains no internal bivalent node then it contains a unique bivalent arc b, by Lemma 10 and Observation 9. Thus, by the maximality of W, it holds that $W = U(b)$. It remains to prove that there is no macrotig containing b.

Suppose for a contradiction that there is a maximal left-micro omnitig M containing b. By definition, M is of the form $bW_M f_M g_M$. Notice that Wg_M is an omnitig, because M is an omnitig and the arcs of W before b are join-free, so Wg_M can have no forbidden path. This contradicts the fact that W is maximal.

Symmetrically, we have that there is no maximal right-micro omnitig containing b. Thus, by definition, b appears in no microtig, and thus in no macrotig. ◀

▶ Remark 22. The number of maximal omnitigs containing an internal bivalent node is $O(n)$. This follows by Theorem 21(i), by maximality, and by the fact that the total length of maximal macrotigs is $O(n)$ (Theorem 20).

Algorithm 1 Function IsOmnitigRightExtension.

Function IsOmnitigRightExtension(G, f, g)
  Input : The compressed graph G. A join arc f and a split arc g such that there exists a walk fWg where fW is an omnitig.
  Output : Whether fWg is also an omnitig.
  $S \leftarrow \{g' \in E(G) \mid t(g') = t(g)$ and there is a path from $h(g')$ to $h(f)$ in $G \setminus f\}$
  Return : **True** if $S = \{g\}$ and **False** otherwise

Next, we are going to prove the second, algorithmic, part of Theorem 2. By Theorem 20 we can compute the maximal macrotigs of G in time $O(m)$. We can trivially obtain in $O(m)$ time the set $\mathcal{F}$ of arcs not appearing in the maximal macrotigs. It remains to show how to obtain the subwalks of the maximal macrotigs univocally extending to maximal omnitigs.

We first prove an auxiliary lemma needed for the proof of the Extension Property (Theorem 6).

▶ **Lemma 23.** *Let fW be an omnitig, where f is a join arc. Let P be a path from $t(P) = h(W)$ to a node in W, such that the last arc of P is not an arc of fW. Then no internal node of P is a node of W.*

Proof. Consider P_W the longest suffix of P, such that no internal node of P_W is a node of W. If $P_W = P$, the lemma trivially holds. Let now $W = (u_0, e_1, u_1, e_2, \ldots, e_k, u_k)$. Let $u_i = t(P_W)$ and $u_j = h(P_W)$. If $i \geq j$, then P_W is a forbidden path for fW,a contradiction. Hence, assume $i < j < k$. Let $f'WQ$ be a closed path. Consider the walk $Z = P_W e_{j+1} \ldots e_k Q$. Notice that $e_{i+1} \notin Z$ and $f \notin Z$. Thus Z can transformed in a forbidden path for fW, from u_i to $h(f)$. ◀

▶ **Theorem 6** (Extension Property). *Let fW be an omnitig in G, where f is a join arc. Then fWg is an omnitig if and only if g is the only arc with $t(g) = h(W)$ such that there exists a path from $h(g)$ to $h(f)$ in $G \setminus f$.*

Proof. To prove the existence of an arc g, which satisfies the condition, consider any closed path Pf' in G, where f' is an arbitrary sibling join arc of f. Notice that W is a prefix of Pf', since fW is an omnitig, since otherwise one can easily find a forbidden path for the omnitig fW as a subpath of Pf', from the head of the very first arc of Pf' that is not in W to $h(f')$. Therefore, let g be the the first arc of Pf' after the prefix W, in such a way that the suffix of Pf' starting from $h(g)$ is a path to $h(f)$ in $G \setminus f$. Moreover, assume g is a split arc, otherwise the statement trivially holds.

First, assume that there is a g' sibling split arc of g and a path P from $h(g')$ to $h(f)$ in $G \setminus f$. We prove that there exists a forbidden path for fWg. Let P_W be the prefix of P ending in the first occurrence of a node in W (i.e., no node of P_W belongs to W, except for $h(P_W)$). Notice that $g'P_W$ is a forbidden path for the omnitig fWg (it is possible, but not necessary, that $h(P_W) = h(f)$).

Second, take any forbidden path P for the omnitig fWg. We prove that there exists a g' sibling split arc of g and a path from $h(g)$ to $h(f)$ in $G \setminus f$. Notice that $t(P) = h(W) = t(g)$, otherwise P would be a forbidden path for fW. As such, P starts with a split arc $g' \neq g$ and, by Lemma 23, P does not contain f. Thus, the suffix of P from $h(g')$ is a path in $G \setminus f$ from $h(g')$ to $h(f)$. ◀

Algorithm 2 Computing all maximal omnitigs.

Input : The compressed strongly connected graph G of constant degree.
Output : All maximal omnitigs of G.

▷Assume that AllMaximalMacrotigs(G) returns all the maximal macrotigs in G.
▷Recall that $U(W)$ is the univocal extension of the walk W.

1 $B \leftarrow \{b \mid b$ bivalent arc that does not occur in any $W \in$ AllMaximalMacrotigs$(G)\}$
2 **foreach** $b \in B$ **do output** $U(b)$
3 **foreach** $f^*Xg^* \in$ AllMaximalMacrotigs(G) **do**
  ▷With the notation $X[f..g]$, we refer to the subwalk of f^*Xg^* starting with the occurrence of f in f^*X (unique by Lemma 19) and ending with the occurrence of g in Xg^* (unique by Lemma 19).
4 $f \leftarrow f^*$, $g \leftarrow$ **nil**, $g' \leftarrow$ first split arc in Xg^*
5 **while** $g' \neq$ **nil** **do**
6 **while** $g' \neq$ **nil and** IsOmnitigRightExtension(f, g') **do**
    ▷Grow $X[f..g]$ to the right as long as possible
7 $g \leftarrow g'$
8 $g' \leftarrow$ next split arc in Xg^* after g
  ▷$X[f..g]$ cannot be grown to the right anymore
9 **output** $U(X[f..g])$
10 **while** $g' \neq$ **nil and not** IsOmnitigRightExtension(f, g') **do**
    ▷Shrink $X[f..g]$ from the left until it can be grown to the right again
11 $f \leftarrow$ next join arc in f^*X after f

To describe the algorithm that identifies all maximal omnitigs (Algorithm 2), we first introduce an auxiliary procedure (Algorithm 1), which uses the Extension Property (Theorem 7) and Theorem 6 to find the unique possible extension of an omnitig.

▶ **Corollary 24.** *Algorithm 1 is correct. Assuming that the graph has constant degree, we can preprocess it in time $O(m + n)$ time, so that Algorithm 1 runs in constant time.*

Maximal omnitigs are identified with a two-pointer scan of maximal macrotigs (Algorithm 2): a left pointer always on a join arc f and a right pointer always on a split arc g, recall Figure 3. For completeness, Algorithm 2 also outputs the maximal omnitigs.

▶ **Theorem 25** (Maximal omnitig enumeration)**.** *Algorithm 2 is correct and, if the compressed graph has constant degree, it runs in time linear in the size of the graph and of its output.*

Proof. By Theorem 21, any maximal omnitig W is either of the form $U(fW'g)$ (where $fW'g$ is a macrotig, and thus also a subwalk of a maximal macrotig, by Lemma 18), or of the form $W = U(b)$, where b is a bivalent arc not appearing in any macrotig. In the latter case, such omnitigs are outputted in Line 2. In the former case, it remains to prove that the external *while* cycle outputs all the maximal omnitigs of the form $U(fW'g)$ where $fW'g$ is contained in a maximal macrotig f^*Xg^*. At the beginning of the first iteration, $W = U(X[f..g'])$ is left-maximal since $f = f^*$. The first internal *while* cycle ensures that $W = U(X[f..g])$ is also right-maximal, at which point it is printed in output. Then, the second internal *while* cycle ensures that $W = U(X[f..g'])$ is a left-maximal omnitig, and the external cycle repeats.

For the running time analysis, note that AllMaximalMacrotigs(G) runs in $O(m)$ time, by Theorem 20. Each iteration of the *foreach* cycle takes time linear in the total size of the maximal macrotig X and of its output (by Corollary 24), and that the total size of all maximal macrotigs is linear, by Theorem 20. ◀

Abstract

Lifting arguments show that the complexity of a function in one model is essentially that of a related function (often the composition of the original function with a small function called a *gadget*) in a more powerful model. Lifting has been used to prove strong lower bounds in communication complexity, proof complexity, circuit complexity and many other areas.

We present a lifting construction for constant depth unbounded fan-in circuits. Given a function f, we construct a function g, so that the depth $d+1$ circuit complexity of g, with a certain restriction on bottom fan-in, is controlled by the depth d circuit complexity of f, with the same restriction. The function g is defined as f composed with a parity function. With some quantitative losses, average-case and general depth-d circuit complexity can be reduced to circuit complexity with this bottom fan-in restriction. As a consequence, an algorithm to approximate the depth d (for any $d > 3$) circuit complexity of given (truth tables of) Boolean functions yields an algorithm for approximating the depth 3 circuit complexity of functions, i.e., there are quasi-polynomial time mapping reductions between various gap-versions of AC^0-MCSP. Our lifting results rely on a *blockwise* switching lemma that may be of independent interest.

We also show some barriers on improving the efficiency of our reductions: such improvements would yield either surprisingly efficient algorithms for MCSP or stronger than known AC^0 circuit lower bounds.

1 Introduction

Determining the circuit complexity of a given Boolean function (presented by its truth table) is a fundamental algorithmic problem with a long history. One can view the whole area of circuit synthesis as consisting of variants of this problem. Historically, this is an apparently intractable search problem that motivated early thought on the P vs. NP problem; both Karp [21] and Levin [30] were thinking about this problem. It is also a fundamental problem from the point of view of computational complexity, where its complexity in different models has been related to cryptography, learning theory, derandomization, and circuit lower bounds.

Its decision version, known as the Minimum Circuit Size Problem (MCSP), asks to decide for a given truth table of a function f and a parameter s whether there is a circuit with at most s gates computing the function f. The high-level overview is that while any algorithmic improvement for MCSP would have dramatic consequences, thus making MCSP very likely to be extremely difficult, there are also many barriers to showing that MCSP is NP-complete [20, 24, 17, 5, 16, 4, 15, 29].

Intuitively, both algorithms for MCSP and completeness results for MCSP would require a better understanding of circuits, and in particular, would seem to be connected to proving lower bounds for circuit complexity. We could then hope to understand variants of MCSP where we restrict the class of circuits considered. However, MCSP remains mysterious even for the best understood circuit classes, such as constant depth unbounded fan-in circuits, where strong lower bounds are known. One aspect that adds to the mystery is that there is no known general relation between the minimum circuit size problems for various circuit classes, even when one class is stronger than the other, or even when they are almost identical in computational power.

Recently, Ilango [18] made break-through progress by showing NP-completeness for the constant-depth formula size version of MCSP under randomized quasi-polynomial time Turing reductions. He used a *lifting* argument to reduce the depth d formula complexity of a function f to the depth $d+1$ formula complexity of a related function f'. *Lifting arguments* show that the complexity of a function in one model is essentially that of a related function (often the composition of the original function with a small function called a *gadget*) in a more powerful model. Lifting has been used to prove strong lower bounds in communication complexity, proof complexity, circuit complexity and many other areas [26, 12, 25, 10]. As in the work of Ilango, lifting results can also be viewed as a *reduction* from the problem of computing the complexity of functions in the first model to that in the second model.

This intriguing result also raises a number of questions. In particular, what is the strength of lifting arguments as reductions between MCSP variants? Are the restrictions in Ilango's argument (formulas rather than circuits, randomization, quasi-polynomial time, and Turing rather than mapping) essential, or can at least some of these be eliminated? How general is the lifting technique, i.e., could there be natural reductions between these problems that do not use lifting? Our work is a first step towards answering some of these questions.

1.1 Our Results

To answer these questions, we present a lifting construction for constant depth unbounded fan-in circuits that given a function f, constructs a function g, so that the depth $d+1$ complexity of g is controlled by the depth d complexity of f. Our construction is very simple: g is f composed with a suitable sized parity function. Given that there are strong constant depth lower bounds using the properties of the parity function, the form of our construction is quite natural (and can be traced back to the classical Andreev function construction [6]).

However, converting this intuition into a formal lifting theorem is delicate. First, tight lifting for this construction seems to require that we look at circuits with restricted bottom gate fan-in, rather than general circuits. Even with this restriction, we need to get both lower bounds and upper bounds on the complexity of the constructed function g, that are very close together. So we need to take extra care for both parts of the argument. In particular, for the upper bound, it is not sufficient to compose the circuit for f with an optimal depth 2 circuit for the parity; instead, we show that the bottom level of the circuit for f applied to parities has a relatively small depth 2 circuit. For the lower bound, we need a variant of the classical Switching Lemma [13], because we cannot afford to have even a small probability that an input to f is removed by the restriction. Our Switching Lemma variant (Lemma 10) is actually both as easy or easier to prove than the standard one, and implies the standard switching lemma, so could have independent pedagogical value.

Our main lifting theorem (Theorem 18) shows that if a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ is computable by a size s depth $d+1$ circuit with bottom gate fan-in at most $\log s$ (we term such circuits to be of depth $d + 1/2$), then the new "lifted" function $g = f \circ \oplus_\ell$ (f composed with parity on $\ell < n$ inputs) will have its depth $((d+1) + 1/2)$ circuit complexity sandwiched between $s^{1/2}$ and s^6.

We apply this lifting theorem to give reductions between approximately computing the constant-depth circuit complexity of a given function at depth d and any higher constant depth d'. Because our lifting theorems control the circuit complexity only approximately, we phrase these reductions as reductions between gap-versions of MCSP; these are promise problems to distinguish between functions of circuit complexity at most s_{yes} and of circuit complexity greater than s_{no}, for some parameters $s_{yes} < s_{no}$.

We first observe that the restriction on circuits we have in our lifting theorem does not change their average-case complexity substantially. This gives a reduction from small depth "tolerant" gap-MCSP to tolerant gap-MCSP for larger depths.

Also, by giving a non-trivial size/bottom fan-in trade-off for constant depth circuits, loosely based on the size-width trade-offs in proof complexity [8], we show that hardness for approximation of MCSP for weakly exponential sizes at one depth can be translated to similar hardness for higher depths.

Since the input to MCSP is the entire truth table of the function, the operation we give yields a quasi-polynomial, rather than polynomial time reduction, between MCSP for smaller depths and larger. Under a suitable assumption about the difficulty of MCSP, we show that any natural (in the sense of [20]) polynomial time reduction would either implicitly contain a stronger lifting theorem or yield a subexponential-time algorithm for small-depth MCSP.

Finally, we note that our lifting results are a step towards proving the NP-completeness of AC^0_d-MCSP for any constant depth $d \geq 3$: one just needs to prove that depth 3 circuit complexity is NP-hard to approximate to within the factors needed by our lifting theorems.

1.2 Related Work

The most closely related to our work is the recent result by Ilango [18] that there is a quasi-polytime randomized Turing reduction from the AC^0_d minimum formula size problem to the AC^0_{d+1} minimum formula size problem. The main theorem used for this reduction is a kind of lifting theorem, where for any f and a sufficiently hard to compute g relative to f, the AC^0_{d+1} formula complexity of $f \wedge g$ is close to the AC^0_d formula complexity of f plus the AC^0_{d+1} formula complexity of g. With this, they were able to show that AC^0 minimum formula size problem is NP-hard under such reductions. Their proof crucially relied on the model being *formulas*, whereas our work gives similar depth-increasing reductions for *circuits*, along with some barriers to improving these reductions.

Khot and Saket [22] proved essentially optimal hardness of approximation for DNF-GapMCSP, under the assumption that NP $\not\subseteq$ QuasiP, via a connection shown by Feldman [11] between the gap problem and a hypercube covering problem. Under this same assumption, Hirahara, Oliveira, and Santhanam [15] showed that DNF $\circ$ MOD$_m$-GapMCSP was hard for $O(\log n)$ gaps. Both of these gap problems are known to be easy for $O(n)$ gaps [9, 15]. These results rely on the existing geometric characterization of the classes in question, the former being a union of subcubes, the latter a union of affine subspaces. For general fixed-depth circuits, we no longer have these characterizations; the bottom levels, being CNFs or DNFs, can represent any subset of the hypercube.

Allender and Hirahara [4] show that under modest cryptographic assumptions (the existence of a one-way function), GapMCSP for general circuits and $N^{1-o(1)}$ gaps is NP-intermediate. Their arguments depend heavily on being able to compose functions to large depths. See a recent survey by Allender [1] for more on MCSP-related results.

Remainder of the paper. We give basic definitions and prove our blockwise switching lemma in Section 2. We prove our lifting theorem for the worst-case AC^0 circuit complexity in Section 3, and for the average-case AC^0 circuit complexity in Section 4. We discuss the barriers to improving our lifting reductions in Section 5, and state some open questions in Section 6.

2 Preliminaries

2.1 General

▶ **Definition 1** (Boolean function composition). *The composition of boolean functions* $f : \{0,1\}^n \to \{0,1\}$ *and* $g : \{0,1\}^m \to \{0,1\}$ *is the function* $f \circ g : \{0,1\}^{nm} \to \{0,1\}$ *obtained by dividing the input* z *into* n *consecutive blocks* $z_1, \ldots, z_n$ *of length* m*, applying* g *to each block, and then computing* $f(g(z_1), g(z_2), \ldots, g(z_n))$.

▶ **Definition 2** (Time $t(n)$ many-one reductions). *We say that* $A \leq_m^t B$ *if there is a time* $t = t(n)$*-computable function* $g\colon \{0,1\}^n \to \{0,1\}^{n'}$ *such that* $x \in A \iff f(x) \in B$*. We denote the polynomial* $t(n) = n^{O(1)}$ *by* poly*, and quasipolynomial* $t(n) = n^{(\log n)^{O(1)}}$ *by* qpoly.

2.2 Complexity Measures

We denote the set of n-input Boolean functions by $\mathcal{F}_n$, and the set of all Boolean functions by $\mathcal{F}$. A *complexity measure* is a function $\Lambda : \mathcal{F} \to \mathbb{N}$ that maps Boolean functions to the natural numbers, quantifying some aspect of their complexity relative to a concrete computational model. The most basic such quantity is number of gates in a circuit C, denoted by $|C|$. We assume every circuit has at least one gate for each input bit.

▶ **Definition 3** (Constant-Depth Alternating Circuits: AC^0_d). *The* depth-d alternating circuit complexity *of* f*, denoted* $\mathsf{AC}^0_d(f)$*, is the minimum number of gates in any unbounded-fanin circuit computing* f *where gates are from the set* $\{\wedge, \vee, \neg\}$*, layers alternate, and the depth is at most* d.

▶ **Definition 4** (Bounded Bottom-Fanin Alternating Circuits: $\mathsf{AC}^0_{d+1/2}$). *The* bounded bottom fan-in depth-d alternating circuit complexity *of* f*, denoted* $\mathsf{AC}^0_{d+1/2}(f)$*, is the minimum number* s *of gates in any depth-*$d+1$ *circuit computing* f *with bottom fan-in at most* $\log s$*. Equivalently, it is the minimum over all depth-*$d+1$ *circuits* C *computing* f *of* $\max\{|C|, 2^{w_C}\}$*, where* w_C *denotes the bottom fan-in of* C.

We measure average-case complexity by expanding what counts as "computing" f.

▶ **Definition 5** (Tolerance Operator: $\widehat{\Lambda}$). *Let Λ be a complexity measure. Denote by* $\mathrm{dist}(f,\epsilon)$ *the Hamming ball of radius $\epsilon \cdot 2^n$ around the truth-table of f. The* ϵ-relaxation *of Λ is* $\widehat{\Lambda}[\epsilon] = \min_{f' \in \mathrm{dist}(f,\epsilon)} \Lambda(f')$.

2.3 Meta-Complexity Problems

Every meta-complexity problem is defined relative to a complexity measure.

▶ **Definition 6** (MCSP). *For a complexity measure Λ, Λ-$\mathtt{MCSP} = \{(f,s) \mid \Lambda(f) \leq s\}$.*

▶ **Definition 7** (GapMCSP). *For a complexity measure Λ, Λ-$\mathtt{GapMCSP}_n[s_{yes}, s_{no}]$ is the following promise problem, where f_n denotes an n-variate Boolean function:*

$$\mathcal{Y} = \{f_n \mid \Lambda(f_n) \leq s_{yes}\} \quad \text{and} \quad \mathcal{N} = \{f_n \mid \Lambda(f_n) > s_{no}\}$$

▶ **Definition 8** (Tolerant GapMCSP). *For a complexity measure Λ, $\widehat{\Lambda}[\epsilon_1,\epsilon_2]$-$\mathtt{GapMCSP}_n[s_{yes}, s_{no}]$ is the following promise problem:*

$$\mathcal{Y} = \{f_n \mid (\widehat{\Lambda}[\epsilon_1])(f_n) \leq s_{yes}\} \quad \text{and} \quad \mathcal{N} = \{f_n \mid (\widehat{\Lambda}[\epsilon_2])(f_n) > s_{no}\}$$

2.4 Blockwise Switching Lemma

We will need a strengthening of Håstad's Switching Lemma [13] for the case of *structured* random restrictions that leave exactly one variable unset in every block of variables.

▶ **Definition 9** (Blockwise Restrictions, $\mathcal{B}_n^\ell$). *A binary string of length $n \cdot \ell$ can naturally be divided into n consecutive "blocks" of ℓ bits each. Variables $\{y_{i,j} : i \in [n],\ j \in [\ell]\}$ index into these strings. Denote by $\mathcal{B}_n^\ell$ the set of all restrictions ρ that place* ***exactly one*** $\star$ *in each block of an n-block, ℓ-block-size string. Formally, we have $\rho : [n] \times [k] \to \{0,1,\star\}$ and $\forall i \in [n]\ \exists! j \in [k]$ such that $\rho(i,j) = \star$.*

▶ **Lemma 10** (Blockwise Switching Lemma). *Let φ be a k-CNF on $n \cdot \ell$ variables. For any $s \geq 0$, $\Pr_{\rho \sim \mathcal{B}_n^\ell}[\varphi \restriction_\rho$ cannot be expressed as an 2^s-term s-DNF$] \leq \left(\frac{8k}{\ell}\right)^s$.*

▶ Remark 11. While the proof of Lemma 10 is actually slightly simpler than that of the standard Switching Lemma [27, 7], this Blockwise Switching Lemma implies the standard Switching Lemma (as stated in [7]). A uniformly random subset of pn out of n variables can be chosen as follows: Randomly uniformly permute the n variables, then partition them into pn consecutive disjoint blocks of size $1/p$ each, and, finally, randomly uniformly choose exactly one variable from each of the pn blocks. For each fixed permutation of n variables, Lemma 10 applies with $\ell = 1/p$. We get that the probability that a given k-CNF fails to simplify to an s-DNF when hit with a random restriction that leaves exactly pn variables unset is upper-bounded by $(8pk)^s$.

▶ Remark 12. Our blockwise restrictions are different from Håstad's blockwise random restrictions used in the context of the AC^0 depth hierarchy theorem [13] (later improved to the average-case depth hierarchy theorem in [14]). Håstad's blockwise restrictions were designed to preserve the structure of Sipser's function; ours will allow us to recover a circuit for f from a higher-depth circuit for the composition $f \circ \oplus_\ell$ of f with parities over disjoint blocks of ℓ variables, for any Boolean function f. Because of this, the two random restriction distributions are very different, and the Switching Lemmas that result are quantitatively quite different.

We prove the Switching Lemma (Lemma 10) below, via a modification of the "compression"-based proof of the Switching Lemma due to Razborov [27, 7].

Canonical Decision Trees & Notation

We write assignments to a set of variables $\{x_i | i \in [n]\}$ as functions $\alpha : [n] \to \{0,1\}$. A k-CNF $\varphi(x_1, \ldots, x_n)$ is a conjunction of m clauses, where each clause is a disjunction over at most k literals. A **Decision Tree** is a binary tree where nodes are labeled by variables $x_1, \ldots, x_n$, and leaves and edges are labeled by constants $\{0,1\}$.

To evaluate a Decision Tree on an assignment α, begin at the root, labeled by some x_i. Move down the edge labeled by $\alpha(i)$. Repeat until you arrive at a leaf and report the constant labeling that leaf as the value of the tree.

Given a k-CNF $\varphi(x_1, \ldots, x_n) = C_1 \wedge \cdots \wedge C_m$ we can create a ***Canonical* Decision Tree**. Fix a lexical ordering on variables and use it to sort and de-duplicate clauses; let $i \in [m]$ index the clauses of φ in this sorted order. We define $\mathrm{CDT}(\varphi)$ recursively:

> Transform $C_1 \in \varphi$ to a depth $\leq k$ tree T querying all variables of C_1 in lexical order. For each branch b of T, follow b to induce a partial assignment α_b; set $\varphi_b \leftarrow$ Simplify φ/α_b. If φ_b is empty, terminate b with leaf labeled 1; if φ_b is falsified, terminate b with leaf labeled 0; otherwise, if φ_b is undetermined, extend b with $\mathrm{CDT}(\varphi_b)$.

A restriction is a *partial assignment*: a map $\rho : [n] \to \{0, 1, \star\}$. The result of applying a restriction to a Boolean function f is written $f \restriction_\rho$ where we substitute each occurrence of x_i by $\rho(i)$ for every $\rho(i) \neq \star$. We will need to define restrictions that *extend* other restrictions. Let $\mathcal{E}_D(\rho)$ denote the set of restrictions that are identical to ρ, except for replacing D star locations with constants. Let $\mathcal{E}(\rho)$ denote the set of restrictions that replace *all* $\star$-locations of ρ with constants. We will be concerned with the blockwise restrictions of Definition 9.

Coding and Decoding Large-Depth Restrictions

Suppose all we know about ρ is that it produces a large-depth canonical decision tree when applied to φ. We can witness this with some "long" path σ through the tree. Our code will consist of a restriction $\tilde{\rho}_c$ that extends ρ and a short bitstring "hint" that allows us to implicitly navigate "down" a long path of the CDT and guess ρ by un-setting variables of ρ_c.

Algorithm 1 `ENC`.

```
Let σ be a long path (≥ depth D) through T;
foreach clause along σ, C_i^σ do
    foreach variable η_ij appearing in C_i^σ do
        record the following hint: begin
            η_ij as an index into C_i^σ (log k bits);
            Assignment to η_ij along σ (single bit);
            Is this the last variable queried in C_i^σ? (single bit);
    Record τ_i as an assignment to η_i that falsifies C_i^σ;
ρ_c = ρ ∘ τ_1 ∘ ··· ∘ τ_D
return ρ̃_c ← ρ_c completed to a full assignment uniformly at random, all hints
```

▷ Claim 13 (Decoding from `ENC` output). Suppose $\rho \in \mathcal{B}_n^\ell$ fails to simplify a particular k-CNF φ, so that $\mathrm{CDT}(\varphi \restriction_\rho) \geq D$. Then, $\Pr_{\tilde{\rho}_c \sim \mathtt{ENC}(\rho)} [\mathtt{DEC}(\tilde{\rho}_c) = \rho] \geq \left(\frac{1}{\ell}\right)^{(n-D)}$.

Proof of Claim 13. Fix $\rho \in \mathcal{B}_n^\ell$ and suppose $T = \mathrm{CDT}(\varphi \restriction_\rho)$ has depth $\geq D$. Let σ be a witnessing path of length at least D through T. We'll require some notation; denote by C_i^σ the ith clause traversed along the path σ, in the sense that the recursive CDT construction

Algorithm 2 DEC.

Initialize: $\rho_1 \leftarrow \rho_c = \rho \circ \tau_1 \circ \cdots \circ \tau_D$ and $i \leftarrow 1$
for $i = 1$ *to* D **do**
  Simplify $\varphi_i \restriction_{\rho_i}$;
  Find first falsified clause of $\varphi_i = C_i^\sigma$;
  Read hint to find τ_i and σ_i (stop-bit tells you when to stop).;
  $\rho_{i+1} \leftarrow \rho_i$ with τ_i replaced by σ_i (so $\rho_{i+1} = \rho \circ \sigma_1 \circ \sigma_{i-1} \circ \sigma_i \circ \tau_{i+1} \ldots \tau_D$)
return ρ_D *with* $\sigma_1 \circ \ldots \sigma_D$ *unset, and* $\star$*'s* guessed *uniformly at random for all other blocks*

worked on clause C to produce that section of the decision tree. Note, this may well be smaller than m, due to simplifications applied during construction of the CDT. Further, let σ_i be the section of σ that traverses C_i^σ and let η_i be the variables queried along σ_i. We can think of σ_i as a sequence of assignments to these variables.

Now, consider the operation of DEC on $\tilde{\rho}_c \sim \mathtt{ENC}(\rho)$. First observe that no clauses of φ were falsified by ρ alone, by our assumption that $\mathrm{CDT}(\varphi \restriction_\rho) \geq D$ – a falsified clause would give a depth-1 decision tree with a single 0 leaf. Therefore, any falsified clause is due to variables set by some τ_i or a randomly set variable.

Because the CDT is constructed in lexical-clause-order and ENC follows this order, the *first* falsified clause of $\varphi \restriction_{\tilde{\rho}_c}$ must be C_1^σ. We wish to recover which variables τ_1 set; the trick is that now we know they must reside in a uniquely identified clause of at most k variables. So, we spend $\log k$ bits of the hint per variable to name *which* variables of C_1^σ were along σ and thus set in τ_1.

Iterating this argument, we see that lexical ordering of the canonical decision tree ensures recovery of D $\star$ locations of ρ. So, after running the main loop of DEC on $\tilde{\rho}_c$ we have a candidate that matches ρ exactly in D blocks. For each remaining block, DEC will simply guess at random which variable in the block was a $\star$ in ρ. Each block has ℓ bits, so we have a $(1/\ell)$ chance of guessing correctly – that is, in agreement with the original location of the $\star$ in ρ. The number of blocks that must be guessed (instead of recovered using deterministic decoding, DEC) is $(n - D)$. Every guess must be correct to successfully decode ρ. This gives the claimed probability of decoding. ◁

Given instead a *random* completion ρ_r of blockwise restriction ρ and a *random* hint h_r, can any algorithm decode ρ? We can upper bound this probability.

▷ Claim 14 (Decoding from random information). For any algorithm $\mathcal{A}$, for every blockwise restriction ρ, $\Pr_{\rho_r \sim \mathcal{E}(\rho)}[\mathcal{A}(\rho_r, h_r) = \rho] \leq \left(\frac{1}{\ell}\right)^n$.

Proof of Claim 14. The hint h_r is clearly useless, because it is a random string. Furthermore, the random variables ρ_r and ρ are conditionally independent, given that ρ_r is a randomly sampled completion of ρ. This means that observing ρ_r provides *no information* regarding the $\star$-locations of ρ. Therefore, no algorithm can do better than to randomly guess which location, in each block, was a star, for every block of the received ρ_r. There are n blocks of ℓ bits each and every guess must be correct, for the overall probability $(1/\ell)^n$. ◁

Completing the proof

We are now ready to prove Lemma 10, re-stated below in a more general form.

▶ **Lemma 15** (Blockwise Switching Lemma). *Let φ be a k-CNF. Pick ρ from $\mathcal{B}_n^\ell$ uniformly at random. Then* $\Pr[\mathrm{CDT}(\varphi \restriction_\rho) \geq D] \leq \left(\frac{8k}{\ell}\right)^D$.

Proof. We can lower-bound the probability of decoding from random completion ρ_r: if we are lucky enough that the randomly sampled completion agrees with ρ_c in the "special" blocks set by ENC, then we can significantly narrow down the number of blocks whose $\star$ must be guessed at random! That is, the non-trivial probability of recovery for DEC can be exploited. Formally,

$$\begin{aligned}\left(\frac{1}{\ell}\right)^n &\geq \Pr[\mathtt{DEC}(\rho_r, h_r) = \rho] && \text{(by Claim 14)}\\ &\geq \Pr[\mathrm{CDT}(\varphi \restriction_\rho) \geq D] \times \Pr[h_r = h] \times \Pr[\rho_r \text{ extends } \rho_c] \times \Pr[\mathtt{DEC} \text{ decodes } \star\text{'s}]\end{aligned}$$

Taking each event in turn:

1. $|h| = D(\log(k) + 2)$ so there are $(4k)^D$ possible strings. Flipping h_r uniformly at random, $\Pr[h_r = h] = (4k)^{-D}$.
2. To extend ρ_c, the randomly chosen ρ_r must agree in D locations. One of these settings is correct, so $\Pr[\rho_r \text{ extends } \rho_c] = 2^{-D}$.
3. Given a correct hint and randomly completed ρ_c, the probability of DEC recovering ρ is $\left(\frac{1}{\ell}\right)^{(n-D)}$ by Claim 13.

Plugging in, we get

$$\left(\frac{1}{\ell}\right)^n \geq \Pr[\mathrm{CDT}(\varphi \restriction_\rho) \geq D] \times (4k)^{-D} \times 2^{-D} \times \left(\frac{1}{\ell}\right)^{(n-D)}.$$

The proof of the lemma follows. ◀

3 Constant-Depth GapMCSP Reductions

The focus of this section is "hardness lifting" for circuits of depth $(d+1)$ to circuits of depth $(d+2)$, and its applications to GapMCSP for the respective classes. Theorem 18 shows how to lift hardness for bounded-fan-in AC^0 circuits from depth d to depth $d+1$ (also bounded fan-in). Here, a function of a not much larger size yet higher depth is constructed by replacing input variables of the original function by disjoint relatively small parities. This theorem is then applied to reduce GapMCSP for AC^0_d circuits to GapMCSP for AC^0_{d+1} circuits.

The reduction proceeds in three steps, with the middle step potentially repeated multiple times for a larger depth increase. The first step converts unbounded bottom fan-in circuits of depth $(d+1)$ to bounded (by log of the circuit size) fan-in circuits of the same depth, at the cost of increasing the size from s to $2^{O(\sqrt{n \log n \log s})}$; see Corollary 17. This rebalancing only needs to be done once.

The second step, which relies on the hardness lifting theorem, is the quasi-polynomial time reduction from GapMCSP for bounded bottom fan-in circuits of depth $(d+1)$, to GapMCSP for bounded bottom fan-in circuits of depth $(d+2)$. The quasi-polynomial running time of this reduction comes from the blow-up in the size of the output truth table of the new function. Then, we show that for this setting GapMCSP for depth $d+1$ circuits reduces to GapMCSP for depth $d+2$ circuits (both bounded bottom fan-in), with a small loss in the gap size. See Theorem 19 for the exact statement.

The last step is a polytime reduction from GapMCSP for bounded bottom fan-in circuits of depth $(d+2)$, to GapMCSP for unbounded bottom fan-in circuits of the same depth; see Theorem 21.

3.1 Depth $d+1$ to $d+1/2$

▶ **Lemma 16** (Fanin vs Size Tradeoff). *For any $d \geq 3$, let C be any depth-d size-s circuit over n inputs. Then, for any $w \geq 1$, there is an equivalent depth-d circuit C' with bottom fan-in at most w, and the size at most $s^{(4n\log n)/w}$.*

Proof. Assume WLOG that all the bottom gates of C are disjunctions. We will recursively define a decision tree T such that each leaf ℓ is associated with a restriction ρ_ℓ resulting in $C\restriction_{\rho_\ell}$ having bottom fan-in at most w.

Initially, T consists of a single leaf node corresponding to the empty restriction. While there is a leaf v in T corresponding to a restriction ρ such that $C\restriction_\rho$ has some nonempty set S of bottom gates of fan-in greater than w, do the following. Let $t = |S| \leq s$. Let z be the literal that occurs in the most gates of S. Since there are more than tw literal occurrences among the gates in S and there are $2n$ literals, z must appear in more than $(tw)/(2n)$ bottom gates. Branch on z, with the left child v_1 of v corresponding to $z=1$, and the right child v_0 to $z=0$. Note that the restriction corresponding to v_1 satisfies all bottom gates containing z, and the restriction corresponding to v_0 reduces their fan-in by 1.

Every left branching we take in the decision tree results in t shrinking by more than a factor $\left(1-\frac{w}{2n}\right)$. So after k left branchings, there are fewer than $t\left(1-\frac{w}{2n}\right)^k$ large fan-in gates left. Setting $k = (2n/w)\ln s$, we have that after k left branchings there are no large fan-in gates left. If $k \geq n/2$ (i.e., $w \leq 4\ln s$), then we can use the trivial upper bound 2^n on the size of T; note that, in this case, $2^n \leq 2^{4n\cdot(\ln s)/w}$, as required.

Otherwise, for $k < n/2$, we can upper-bound the size of T as follows. Since each branch of T is of length at most n, and it may contain at most k left branchings, we get that the size of T is at most

$$\sum_{r=0}^{k}\binom{n}{r} \leq k\cdot\binom{n}{k} \leq k\cdot\left(\frac{ne}{k}\right)^k \leq k\cdot\left(\frac{we}{2\ln s}\right)^k \leq 2^{(1.5)k\cdot\log(w/\ln s)} \leq s^{\frac{3n\log n}{w}},$$

where for the last inequality we used the definition of k and the bound $(w/\ln s) \leq w \leq n$.

Suppose without loss of generality that the top gate of C is a disjunction, i.e., $C = \bigvee_i \bigwedge_j g_{i,j}$. We can rewrite $C(x)$ as $\bigvee_{\text{leaves } \ell\in T}\left(\phi(x,\rho_\ell)\wedge C\restriction_{\rho_\ell}(x)\right)$, where, for a fixed restriction ρ_ℓ, the formula $\phi(x,\rho_\ell)$ indicates whether x is consistent with ρ_ℓ (i.e., whether x ends up at leaf ℓ of our decision tree T). It is easy to see that $\phi(x,\rho_\ell)$ can be written as a conjunction of at most n literals.

As written, the circuit above is a depth-$(d+2)$ size at most $(1+|T|+|T|\cdot s)$ circuit with fan-in at most w. By distributivity, we can rewrite each $\phi(x,\rho_\ell)\wedge C\restriction_{\rho_\ell}(x)$ as $\bigvee_i\left(\phi(x,\rho_\ell)\wedge\bigwedge_j\left(g_{i,j}\restriction_{\rho_\ell}(x)\right)\right)$. Plugging this into (3.1), we obtain a depth-d circuit C' with fan-in at most w, computing the same function as C, and the size of C' is at most $|T|\cdot s \leq s^{(4n\log n)/w}$, as required. ◀

▶ **Corollary 17** (Depth $(d+1)\to(d+1/2)$). *For any $d\geq 2$, n, and s_{yes}, s_{no} such that $\log s_{yes} \leq \frac{\log^2(s_{no}/4)}{n\log n}$, we have*

$$\mathsf{AC}^0_{d+1}\text{-}\mathtt{GapMCSP}_n[s_{yes},s_{no}] \leq^{\mathsf{poly}}_m \mathsf{AC}^0_{d+1/2}\text{-}\mathtt{GapMCSP}_n[2^{4\cdot\sqrt{n(\log n)(\log s_{yes})}},s_{no}]$$

with the identity functions as a reduction.

Proof. The "NO→NO" case is immediate: if $f\colon\{0,1\}^n\to\{0,1\}$ doesn't have size-s_{no} circuits with no restriction on the bottom fan-in, then f doesn't have size-s_{no} circuits with restricted bottom fan-in.

For the "YES→YES" case, we apply Lemma 16 to a depth-$(d+1)$ size-s_{yes} circuit for f, with $w = \sqrt{n(\log n)(\log s_{yes})}$. This results in a circuit for f of size at most $2^{4\cdot\sqrt{n(\log n)(\log s_{yes})}}$, with bottom fan-in at most $\sqrt{n(\log n)(\log s_{yes})}$. ◀

3.2 Depth $d + 1/2$ to $(d+1) + 1/2$

▶ **Theorem 18** (Hardness lifting). *Let f have $\mathsf{AC}^0_{d+1/2}$ circuit complexity s. Fix $s_0 > 0$. Then there is a function f' on $n' = n \cdot 16 \log s_0$ inputs with $\mathsf{AC}^0_{(d+1)+1/2}$ circuit complexity s' where $s' \le 2s2^{\sqrt{16 \log s \log s_0}}\sqrt{16 \log s \log s_0}$. Moreover, if $s_0 < \sqrt{s/3}$, then $s_0 \le s'$.*

Proof. The construction is as follows: given the truth table of $f\colon \{0,1\}^n \to \{0,1\}$, output the truth table of $f' = f \circ \oplus_\ell$ for $\ell = 16 \log s_0$. This takes time $2^{n\ell} = N^{16 \log s_0} \le N^{O(\log N)}$, quasi-polynomial in N since $s_0 \le N$. We argue the correctness next.

Bounding s' from below. Note that the parameter ℓ must be sufficiently larger than $\log s_0$ so that we can apply the Blockwise Switching Lemma to a depth-$(d+2)$ size-s_0 circuit with bottom fan-in $\log s_0$ that presumably computes $f \circ \oplus_\ell$ to obtain a depth-$(d+1)$ size-s circuit with bottom fan-in $\log s$ that computes f. We prove that if f' has a $\mathsf{AC}^0_{(d+1)+1/2}$ of size s_0, then f has a $\mathsf{AC}^0_{d+1/2}$ circuit of size $s \le 3(s_0)^2$.

Suppose $f \circ \oplus_\ell$ has a depth-$(d+2)$ circuit C' of size s_0 and bottom fan-in at most $\log s_0$. We shall hit C' with a blockwise random restriction ρ, where the blocks are the inputs to each $\oplus_\ell$. Since exactly one bit is left unset in each block, $C' \restriction_\rho$ computes f with some of the input bits potentially negated. For $C' \restriction_\rho$ to simplify to a depth-$(d+1)$ circuit with bottom fan-in at most $k \le \log(3s_0^2) \le \log s$, we need to argue that there exists a blockwise restriction ρ which makes every depth-2 bottom circuit of C' into a decision tree of depth at most k. By the Blockwise Switching Lemma (Lemma 10), this is implied if $s_0 \left(\frac{8 \log s_0}{\ell}\right)^k < 1$, which is equivalent to $2^{\log s_0 - k} < 1$, for our choice of $\ell = 16 \log s_0$. Thus, setting $k = \log s_0 + 1$ satisfies this inequality. Moreover, each bottom CNF or DNF of C' is turned into a DNF or CNF with 2^k clauses. So the size of $C' \restriction_\rho$ is at most $s_0 + s_0 \cdot 2^k \le 3(s_0)^2 \le s$, as required.

Bounding s' from above. Next we need to show that if f has a small depth-$(d+1/2)$ circuit, then $f \circ \oplus_\ell$ has a small depth-$(d+1+1/2)$ circuit. Note that computing the ℓ-bit parities by naive depth-2 circuits of size 2^ℓ is prohibitively expensive, as this would make the size of the new circuit for $f \circ \oplus_\ell$ at least $(s_0)^{16} > s'$, for our choice of $\ell = 16 \log s_0$ (which was dictated by the "NO→NO" case analysis above). Instead we will compute each $\oplus_\ell$ by a depth-3 circuit, as a parity of parities, adapting the standard construction of optimal size-$(\ell 2^{\sqrt{\ell}})$ depth-3 circuits. To get a final circuit for $f \circ \oplus_\ell$ to be of depth $d+1+1/2$, we will need to carefully balance the parameters of our partition of ℓ bits into ℓ_1 blocks of size ℓ_2 each, for ℓ_1 and ℓ_2 such that $\ell = \ell_1 \cdot \ell_2$.

Suppose f has a depth-$(d+1)$ circuit C of size s and bottom fan-in at most $\log s$, with all negations at the leaves; this at most doubles the size. Without loss of generality, assume that the bottom layer of gates consists of disjunctions with fan-in $\log s$. To obtain a circuit for $f \circ \oplus_\ell$, we will compose $\oplus_\ell$ with each of the bottom CNFs of C. Consider a particular CNF $h_i = \bigwedge_{j=1}^{k} g_{i,j}$ at the bottom of C, where $k \le s$ and each $g_{i,j}$ is a disjunction of at most $\log s$ literals.

For ℓ_1 to be chosen later, let $\ell_2 = \ell/\ell_1$. Using the trivial 2^{ℓ_1}-size CNF for computing $\oplus_{\ell_1}$, we can compute each $g_{i,j} \circ \oplus_{\ell_1}$ by an OR-AND-OR circuit, where the top OR gate has fan-in $\log s$ and the AND gates each have fan-in 2^{ℓ_1}. By distributivity, we can rewrite $g_{i,j} \circ \oplus_{\ell_1}$ as a CNF with $2^{\ell_1 \log s}$ clauses, each of width at most $\ell_1 \log s$.

Since C is a layered circuit, we can merge this CNF into h_i to obtain a depth-2 circuit computing $h_i \circ \oplus_{\ell_1}$. Finally, composing this with the DNF for $\oplus_{\ell_2}$, we get a depth-3 circuit with bottom fan-in ℓ_2 computing $h_i \circ \oplus_\ell$. Replacing each h_i in C with circuits constructed in this way, we obtain a depth-$(d+2)$ circuit for $f \circ \oplus_\ell$ with bottom fan-in ℓ_2. The subcircuit for computing each $g_{i,j} \circ \oplus_\ell$ is of size at most $\sigma = 1 + 2^{\ell_1 \log s} + 2^{\ell_2} \cdot \ell_1 \log s$. So the total size of the circuit for $f \circ \oplus_\ell$ is at most $s + s \cdot \sigma = s(\sigma + 1)$. If we set $\ell_2 = \sqrt{\ell \log s}$ and $\ell_1 = \sqrt{\frac{\ell}{\log s}}$, then the total size is at most

$$s\left(2 + 2^{\sqrt{\ell \log s}} + 2^{\sqrt{\ell \log s}} \cdot \sqrt{\ell \log s}\right) \leq (2s) \cdot 2^{\sqrt{\ell \log s}} \cdot \sqrt{\ell \log s} \leq s'.$$

Since the bottom fan-in is at most $\sqrt{\ell \log s} \leq \log s'$, this concludes the proof. ◀

▶ **Theorem 19** (Depth $(d + 1/2) \to ((d+1) + 1/2)$ GapMCSP)**.** *For any $d \geq 1$, n, s_{yes}, s'_{yes}, s'_{no}, and s_{no} such that $s_{yes} < s_{no}$, $s'_{yes} < s'_{no}$, $s_{no} \geq 3(s'_{no})^2$ and*

$$s'_{yes} \geq 2(s_{yes}) 2^{\sqrt{16(\log s_{yes})(\log s'_{no})}} \sqrt{16(\log s_{yes})(\log s'_{no})},$$

we have $\mathsf{AC}^0_{d+1/2}\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}] \leq^{\mathsf{qpoly}}_m \mathsf{AC}^0_{(d+1)+1/2}\text{-}\mathtt{GapMCSP}_{n'}[s'_{yes}, s'_{no}]$, *where* $n' = 16n \log s'_{no} \leq O(n^2)$.

Proof. We use the construction in Theorem 18 as the reduction function, with $s_0 = s'_{no}$. For the YES $\to$ YES side, if $AC^0_{d+1/2}(f) \leq s_{yes}$, then

$$\mathsf{AC}^0_{d+1+1/2}(f') \leq 2(s_{yes}) 2^{\sqrt{16(\log s_{yes})(\log s'_{no})}} \sqrt{16(\log s_{yes})(\log s'_{no})}$$

as desired. For the NO $\to$ NO side, if $AC^0_{d+1/2}(f) > s_{no}$, then $\mathsf{AC}^0_{d+1+1/2}(f') \geq s_0 = s'_{no}$. ◀

▶ Remark 20. If we apply this to succinct MCSP, we actually get a polytime reduction instead; constructing the naïve $f \circ \oplus_\ell$ circuit given a circuit for f takes polytime, it just makes the truth table too large.

3.3 Depth $d + 1/2$ to $d + 1$

▶ **Theorem 21** (Depth $(d + 1/2) \to (d+1)$)**.** *For any $d \geq 1$, $n, s_{yes}, s_{no}, s'_{yes}, s'_{no}$, such that $s_{yes} < s_{no}$, $s'_{yes} < s'_{no}$, $s_{no} \geq (s'_{no})^5$ and $s'_{yes} \geq 2(s_{yes})^3$, we have*

$$\mathsf{AC}^0_{d+1/2}\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}] \leq^{\mathsf{poly}}_m \mathsf{AC}^0_{d+1}\text{-}\mathtt{GapMCSP}_{2n}[s'_{yes}, s'_{no}]$$

Proof. The reduction is as follows: given the truth table of $f\colon \{0,1\}^n \to \{0,1\}$, output the truth table of $g = f \circ \oplus_2$. The size of the input for g is $2n$. The runtime of the reduction is $\mathsf{poly}(N)$. Next we argue the correctness of this reduction.

NO $\to$ NO. Suppose $f \circ \oplus_2\colon \{0,1\}^{2n} \to \{0,1\}$ is computable by a size-s'_{no} circuit C' of depth $d+1$. Without loss of generality, we may assume that the bottom gates of C' are ANDs. We will hit C' with a random blockwise restriction ρ. Consider a particular bottom AND-gate of fan-in t, for some $1 \leq t \leq n$. Since each block in a blockwise restriction is of size two, there must be at least $t/2$ variables from distinct blocks that feed into this AND gate. Each one of these variables will be chosen as a non-star variable by ρ with probability $1/2$, and then independently set to 0 with probability $1/2$. This would simplify the AND gate to the constant 0, with probability $1/4$. This happens independently for each of these

$t/2$ variables. Thus the probability that the AND gate of fan-in at least t survives a random restriction is at most $(3/4)^{t/2}$. By the union bound, the probability that any such AND gate survives is at most $s'_{no} \cdot (3/4)^{t/2}$, which is less than 1 for $t = 5(\log s'_{no})$. Thus there exists a blockwise restriction ρ which simplifies C' to a depth-$(d+1)$ circuit computing f, with size at most $s'_{no} \le s_{no}$ and bottom fan-in at most $5(\log s'_{no}) \le \log s_{no}$.

YES $\to$ YES. Suppose $f\colon \{0,1\}^n \to \{0,1\}$ is computable by a size-s_{yes} circuit C of depth $d+1$, with bottom fan-in at most $\log s_{yes}$. WLOG, assume the bottom gates of C are ANDs. Note that we can express the XOR and the negated XOR of two variables as the following 2-CNFs:

$$y \oplus z = (\bar{y} \vee \bar{z}) \wedge (y \vee z) \qquad \text{and} \qquad \neg(y \oplus z) = (\bar{y} \vee z) \wedge (y \vee \bar{z}).$$

Replacing the input literals of C by these circuits for (possibly negated) $\oplus_2$, and merging the bottom AND gate of C with the top AND gate of these parity circuits, we get a depth-$(d+2)$ circuit C' for $f \circ \oplus_2$, with 2-CNFs on $t = (2 \log s_{yes})$ clauses as the bottom depth-2 sub-circuits. By distributivity, we can rewrite each 2-CNF on t clauses as a t-DNF on 2^t terms. Then merge the OR gates of these DNFs with the OR gates at the preceding level in C', obtaining an equivalent depth-$(d+1)$ circuit C'' for $f \circ \oplus_2$, of size at most $s_{yes} + s_{yes} \cdot (s_{yes})^2 \le 2(s_{yes})^3 \le s'_{yes}$ (and bottom fan-in at most $(2 \log s_{yes}) \le \log s'_{yes}$). ◀

3.4 Combining the steps: Depth $d+1$ to $d+c$ for any constant $c > 1$

The reduction in Theorem 19 can be repeated multiple times, resulting in the overall reduction lifting hardness to constantly many levels. The following theorem shows how the parameters evolve over all steps of the reduction.

▶ **Theorem 22** (Depth $(d+1) \to (d+c)$)**.** *For any $d \ge 2$, $c > 1$, $n \ge n_0(\alpha, \delta, c)$, and $0 < \alpha < \delta < 1$ where $1 + \alpha < 2\delta$, we have*

$$\mathsf{AC}^0_{d+1}\text{-}\mathtt{GapMCSP}_n[2^{n^\alpha}, 2^{n^\delta}] \le_m^{\mathsf{qpoly}} \mathsf{AC}^0_{(d+c)}\text{-}\mathtt{GapMCSP}_{n'}[2^{(n')^\beta}, 2^{(n')^\gamma}],$$

where $n' = n^{(c-1)\delta+1}$, $\gamma \approx \frac{1}{c-1}$, $\beta \approx \frac{1}{c-1} - \frac{1}{(c-1)2^{c-1}} \cdot (1 - \frac{1+\alpha}{2\delta})$.

Proof. As outlined at the beginning of the section, we will create this reduction via composing the reductions in Corollary 17 and Theorems 19 and 21. Let $a = \frac{1+\alpha+\frac{\log\log n+4}{\log n}}{2}$.

Step 1. $\mathsf{AC}^0_{d+1}\text{-}\mathtt{GapMCSP}_n[2^{n^\alpha}, 2^{n^\delta}] \le_m^{\mathsf{poly}} \mathsf{AC}^0_{d+1/2}\text{-}\mathtt{GapMCSP}_n[2^{n^a}, 2^{n^\delta}]$
This follows immediately from Corollary 17 with $s_{yes} = 2^{n^\alpha}$ and $s_{no} = 2^{n^\delta}$.

Step 2.
$\mathsf{AC}^0_{d+1/2}\text{-}\mathtt{GapMCSP}_n[2^{n^a}, 2^{n^\delta}] \le_m^{\mathsf{qpoly}} \mathsf{AC}^0_{(d+c-1)+1/2}\text{-}\mathtt{GapMCSP}_{n^{(c-1)\delta+1}/2}[\exp_2\left(5n^{\frac{a+(2^{c-1}-1)\delta}{2^{c-1}}}\right),$
$\exp_2(\frac{n^\delta}{2^{c-1}} - \frac{2^{c-1}-1}{2^{c-1}} \log 3)]$
We will show each of n, s_{yes}, and s_{no} map to the corresponding values after $c-1$ applications of the reduction in Theorem 19. Define $n^{(i)}$, $s^{(i)}_{yes}$, and $s^{(i)}_{no}$ to be each value after applying i iterations of the reduction, with $n^{(0)}$, $s^{(0)}_{yes}$, and $s^{(0)}_{no}$ set to the initial values.

We will first show that $s^{(i)}_{no} = 2^{\frac{n^\delta}{2^i} - \frac{2^i-1}{2^i}\log 3}$; this is true for $i = 0$, and for larger i we have $s^{(i+1)}_{no} = \sqrt{\frac{s^{(i)}_{no}}{3}} = 2^{\frac{n^\delta}{2^{i+1}} - \frac{2^i-1}{2^{i+1}}\log 3 - \frac{\log 3}{2}} = 2^{\frac{n^\delta}{2^{i+1}} - \frac{2^{i+1}-1}{2^{i+1}}\log 3}$.

Next, we show that $n^{(i)} = 16^i n \prod_{j=1}^{i} [\frac{n^\delta}{2^j} - \frac{2^j-1}{2^j} \log 3]$; via padding, we can increase the number of variables to $n^{(c-1)\delta+1}/2$ at the end. Again, this is true for $i = 0$. For larger i,

$$n^{(i+1)} = 16 n^{(i)} \log s_{no}^{(i+1)} = 16^{i+1} n \prod_{j=1}^{i+1} \left[\frac{n^\delta}{2^j} - \frac{2^j - 1}{2^j} \log 3 \right].$$

Finally, for $s_{yes}^{(i)}$, we show that after i iterations of the Theorem 19 reduction, $s_{yes} = 2^{n^a}$, $s_{no} = 2^{n^\delta}$ would be mapped to at most $s'_{yes} = \exp_2(5n^{\frac{a+(2^i-1)\delta}{2^i}})$. For $i > 0$, assuming $s_{yes}^{(i)} \leq \exp_2(5n^{\frac{a+(2^i-1)\delta}{2^i}})$, we have $s_{yes}^{(i+1)}$ is at most

$$\exp_2\left(1 + 5n^{\frac{a+(2^i-1)\delta}{2^i}} + \sqrt{\frac{80}{2^i} n^{\frac{a+(2^i-1)\delta}{2^i}} (n^\delta - \Theta(2^i))} + O(\log n)\right) \leq \exp_2\left(5n^{\frac{a+(2^{i+1}-1)\delta}{2^{i+1}}}\right),$$

fixing n_0 sufficiently large. For $i = 0$, note that $n^a < 5n^{\frac{a+(2^0-1)\delta}{2^0}}$.

Step 3.

$\mathsf{AC}^0_{(d+c-1)+1/2}$-$\mathtt{GapMCSP}_{n^{(c-1)\delta+1}/2}[\exp_2\left(5n^{\frac{a+(2^{c-1}-1)\delta}{2^{c-1}}}\right), \exp_2(\frac{n^\delta}{2^{c-1}} - \frac{2^{c-1}-1}{2^{c-1}} \log 3)] \leq_m^{\mathsf{poly}}$
AC^0_{d+c}-$\mathtt{GapMCSP}_{n^{(c-1)\delta+1}}[2^{n^\beta}, 2^{n^\gamma}]$
This follows immediately from Theorem 21, setting

$$s_{yes} = \exp_2\left(5n^{\frac{a+(2^{c-1}-1)\delta}{2^{c-1}}}\right) \text{ and } s_{no} = \exp_2\left(\frac{n^\delta}{2^{c-1}} - \frac{2^{c-1}-1}{2^{c-1}} \log 3\right). \quad \blacktriangleleft$$

4 Constant-Depth Tolerant GapMCSP Reductions

We will show an analogous "hardness lifting" reduction from the GapMCSP problem for average-case circuits of depth d to depth $d+1$.

In this average case setting, instead of applying the machinery of Lemma 16, we can instead make use of the observation that bottom gates of large fan-in are almost always equal to their bias; see Theorem 23. Thus we get smaller gaps on the output side of the reduction, at a small cost to the tolerance parameter.

4.1 Tolerant depth $d+1$ to $d+1/2$ and reverse

▶ **Theorem 23** (Tolerant depth $(d+1) \to (d+1/2)$). *For any $0 \leq \epsilon_1, \epsilon_2 < 1/2$, $d \geq 1$, $n \geq 1$, and $s_{yes} < s_{no}$, we have*

$$\widehat{\mathsf{AC}}^0_{d+1}[\epsilon_1, \epsilon_2]\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}] \leq_m^{\mathsf{poly}} \widehat{\mathsf{AC}}^0_{d+1/2}[\epsilon_1 + 1/n, \epsilon_2]\text{-}\mathtt{GapMCSP}_n[(s_{yes})^2, s_{no}]$$

with the identity functions as a reduction.

Proof. The "NO"→"NO" case is obvious. For the "YES"→"YES" case, suppose C is a depth $d+1$ circuit of size s_{yes} that disagrees with f on at-most an ϵ_1-fraction of inputs. For each bottom gate of C with fan-in larger than $2 \log |C|$, replace the gate with a 1 if it is an OR, or a 0 if it is an AND. Call this new circuit with the replaced gates C'. For a uniformly-random sampled input, any of the replaced gates would disagree with this bit with probability at most $|C|^{-2}$, and so the probability C' disagrees with C on a uniformly-random input is at most $1/|C|$, via a union bound. Since $|C| \geq n$, this is at most $1/n$, and so C' disagrees with f on at most an $(\epsilon_1 + 1/n)$-fraction of inputs. Note that $|C'| \leq |C| \leq (s_{yes})^2$ and the bottom fan-in of C' is at most $2 \log s_{yes} \leq \log(s_{yes})^2$, as required. $\blacktriangleleft$

▶ **Theorem 24** (Tolerant depth $(d+1/2) \to (d+1)$)**.** *For any $0 \le \epsilon_1, \epsilon_2 < 1/2$, $d \ge 1$, $n \ge 1$, $s_{yes}, s_{no}, s'_{yes}, s'_{no}$ such that $s_{yes} < s_{no}$, we have, via the the identity functions as a reduction,*

$$\widehat{\mathsf{AC}}^0_{d+1/2}[\epsilon_1, \epsilon_2 + 1/n]\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}] \le^{\mathsf{poly}}_m \widehat{\mathsf{AC}}^0_{d+1}[\epsilon_1, \epsilon_2]\text{-}\mathtt{GapMCSP}_n[s_{yes}, \sqrt{s_{no}}].$$

Proof. The "YES"→"YES" case is obvious. For the "NO"→"NO" case, let C' be depth-$(d+1)$ circuit of size at most $s'_{no} = \sqrt{s_{no}}$ that ϵ_2-approximates f. As in the proof of Theorem 23 above, we replace by constants all bottom gates of C' that have fan-in larger than $2\log|C'|$, getting a new circuit C that computes f on all but at most $\epsilon_2 + (1/n)$ fraction of inputs. The size of C is at most $s'_{no} \le s_{no}$, and the bottom fan-in is at most $2\log s_{no}^{1/2} = \log s_{no}$, as required. ◀

4.2 Tolerant depth $d + 1/2$ to $(d+1) + 1/2$

▶ **Theorem 25** (Tolerant depth $(d+1/2) \to ((d+1)+1/2)$)**.** *For any $d \ge 1$, $n \ge 1$, $0 \le \epsilon_1, \epsilon_2 < 1/2$, s_{yes}, s'_{yes}, s'_{no}, and s_{no} such that $s_{yes} < s_{no}$, $s'_{yes} < s'_{no}$, $s_{no} \ge 3(s'_{no})^2(\epsilon_2 n + 1)$ and $s'_{yes} \ge 2(s_{yes})2^{\sqrt{16(\log s_{yes})(\log s'_{no})}}\sqrt{16(\log s_{yes})(\log s'_{no})}$, we have*

$$\widehat{\mathsf{AC}}^0_{d+1/2}[\epsilon_1, \epsilon_2 + 1/n]\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}] \le^{\mathsf{qpoly}}_m \widehat{\mathsf{AC}}^0_{(d+1)+1/2}[\epsilon_1, \epsilon_2]\text{-}\mathtt{GapMCSP}_{n'}[s'_{yes}, s'_{no}],$$

where $n' = 16n\log s'_{no} \le O(n^2)$.

Proof. We shall use the same reduction as in Theorem 19, outputting $f \circ \oplus_\ell$ on input f, where $\ell = 16\log s'_{no}$.

NO → NO. Let C' be a depth-$(d+2)$ circuit of size s'_{no} and bottom fan-in at most $\log s'_{no}$ that ϵ_2-approximates $f \circ \oplus_\ell$. We shall hit C' with a blockwise random restriction, as before. Here, we simultaneously require that $C' \restriction \rho$ simplifies to a depth-$(d+1)$ circuit with bounded bottom fan-in, and that its truth table is $(\epsilon_2 + 1/n)$-close to (some fixed shift of) f.

For any $x \in \{0,1\}^n$ and a blockwise restriction ρ, we denote by $\langle x, \rho\rangle$ the $(n \cdot \ell)$-tuple of bits obtained by placing x in the star positions of ρ. Clearly, picking x and ρ uniformly at random results in $\langle x, \rho\rangle$ being the uniform distribution on $\{0,1\}^{n\cdot\ell}$. By our assumption on C', we have $\mathsf{Exp}_{x,\rho}[C'(\langle x,\rho\rangle) \ne (f \circ \oplus_\ell)(\langle x,\rho\rangle)] \le \epsilon_2$. By Markov's Inequality,

$$\Pr_\rho\left[\mathsf{Exp}_x[C'(\langle x,\rho\rangle) \ne (f\circ\oplus_\ell)(\langle x,\rho\rangle)] > \epsilon_2 + \frac{1}{n}\right] < \frac{\epsilon_2}{\epsilon_2 + (1/n)}.$$

Hence, with probability at least $(\epsilon_2 \cdot n + 1)^{-1}$, for a randomly chosen blockwise restriction ρ

$$\begin{aligned}\mathsf{Exp}_x[C'(\langle x,\rho\rangle) \ne (f\circ\oplus_\ell)(\langle x,\rho\rangle)] &= \mathsf{Exp}_x[C' \restriction_\rho (x) \ne (f\circ\oplus_\ell)\restriction_\rho (x)] \\ &= \mathsf{Exp}_x[C' \restriction_\rho (x) \ne f(x \oplus b^\rho)] \le \epsilon_2 + \frac{1}{n},\end{aligned}$$

for $b^\rho = b_1 \dots b_n \in \{0,1\}^n$ such that b_i is the parity of assigned values in the ith block of ρ.

So, if $C' \restriction_\rho$ fails to simplify with probability less than $(\epsilon_2 \cdot n + 1)^{-1}$, then we are guaranteed there is some ρ such that $C' \restriction_\rho (x)$ agrees with $f(x \oplus b^\rho)$, a shift of f, on all but at most $(\epsilon_2 + (1/n))$-fraction of inputs $x \in \{0,1\}^n$, and is a depth-$(d+1)$ circuit with bounded bottom fan-in.

By the Blockwise Switching Lemma (Lemma 10), the probability that $C' \restriction \rho$ fails to simplify to depth $(d+1)$ circuit with bottom fan-in at most k is at most $s'_{no}\left(\frac{8\log s'_{no}}{\ell}\right)^k = 2^{\log s'_{no} - k}$, which is less than $(\epsilon_2 \cdot n + 1)^{-1}$ if we choose $k = \log(2s'_{no}(1+\epsilon_2 n))$.

Thus, there must exist a blockwise restriction ρ such that $C' \restriction_\rho$ is simplified and agrees with $f(x \oplus b^\rho)$ on all but at most $(\epsilon_2 + (1/n))$ fraction of inputs. We have that $C' \restriction_\rho$ is of size at most $s'_{no}(1+2^k) \leq s'_{no}(1+2s'_{no}(1+\epsilon_2 n)) \leq 3(s'_{no})^2(1+\epsilon_2 n) \leq s_{no}$. Also, the bottom fan-in is at most $k \leq \log s_{no}$ for our choice of k. Then the circuit $C(x) = C' \restriction_\rho (x \oplus b^\rho)$ agrees with $f(x)$ on all but at most $(\epsilon_2 + (1/n))$ fraction of inputs, and C has depth $(d+1)$, size at most s_{no}, and bottom fan-in at most $\log s_{no}$, as required.

YES $\to$ YES. Suppose f is ϵ_1-approximated by a depth-$(d+1)$ circuit C with size s_{yes} and bottom fan-in $\log s_{yes}$. Let g be the Boolean function computed by C. Using the same techniques as in the "YES$\to$YES" case analysis in the proof of Theorem 19, we construct a depth-$(d+1)$ circuit C' computing $g \circ \oplus_\ell$, with size at most s'_{yes} and bottom fan-in at most $\log s'_{yes}$.

We will argue that C' computes $f \circ \oplus_\ell$ on all but at most ϵ_1 fraction of inputs. Indeed, since the parity of a uniformly random string of bits is a uniformly random bit, we get that

$$\Pr_{z \in \{0,1\}^{n\ell}}[(f \circ \oplus_\ell)(z) = (g \circ \oplus_\ell)(z)] = \Pr_{x \in \{0,1\}^n}[f(x) = g(x)],$$

which is at most ϵ_1 by our assumption. This concludes the proof. ◀

4.3 Combining the steps: Tolerant depth $d+1$ to $d+2$

Using the above reductions, we can obtain a reduction from tolerant depth $d+1$ gap-MCSP to tolerant depth $d+2$ gap-MCSP. Extending this to depth $d+c$ can be done via repeatedly composing this reduction with itself.

▶ **Corollary 26.** *For any $d \geq 1, 0 \leq \epsilon_1, \epsilon_2 < 1/2, s_{yes}, s_{no}, s'_{yes}, s'_{no}$ where $s_{no} \geq (2\epsilon n+1){s'_{no}}^4$ and $s'_{yes} \geq 2(s_{yes})^2 \cdot 2^{\sqrt{16\log({s_{yes}}^2)\log({s'_{no}}^2)}}\sqrt{16\log({s_{yes}}^2)\log({s'_{no}}^2)}$, we have*

$$\widehat{\mathsf{AC}}^0_{d+1}[\epsilon_1, \epsilon_2 + \frac{2}{n}]\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}] \leq_m^{\mathsf{qpoly}} \widehat{\mathsf{AC}}^0_{d+2}[\epsilon_1 + \frac{1}{n}, \epsilon_2]\text{-}\mathtt{GapMCSP}_{32n\log s'_{no}}[s'_{yes}, s'_{no}].$$

Proof. We obtain the desired reduction by composing the reductions from Theorems 23, 25, and 24. Using $\langle \epsilon_1, \epsilon_2, s_{yes}, s_{no}\rangle_{d,n}$ as a shorthand for $\widehat{\mathsf{AC}}^0_d[\epsilon_1, \epsilon_2]\text{-}\mathtt{GapMCSP}_n[s_{yes}, s_{no}]$, the reductions operate as follows:

$$\begin{aligned}
\langle \epsilon_1, \epsilon_2 + \frac{2}{n}, s_{yes}, s_{no}\rangle_{d+1,n} &\leq_m^{\mathsf{poly}} \langle \epsilon_1 + \frac{1}{n}, \epsilon_2 + \frac{2}{n}, (s_{yes})^2, s_{no}\rangle_{d+1/2,n} && \text{Theorem 23}\\
&\leq_m^{\mathsf{qpoly}} \langle \epsilon_1 + \frac{1}{n}, \epsilon_2 + \frac{1}{n}, s'_{yes}, (s'_{no})^2\rangle_{d+1+1/2,32n\log s'_{no}} && \text{Theorem 25}\\
&\leq_m^{\mathsf{poly}} \langle \epsilon_1 + \frac{1}{n}, \epsilon_2, s'_{yes}, s'_{no}\rangle_{d+2,32n\log s'_{no}} && \text{Theorem 24}
\end{aligned}$$ ◀

5 Barriers to More Efficient Natural Reductions

Our reductions are deterministic, many-one, and "simple" in the original size parameter. However, they require quasi-polynomial time. Here, we give evidence that improving such "nice" reductions to run in polynomial time for the *exact* MCSP is difficult: such reductions would immediately give breakthrough circuit lower bounds or non-trivial MCSP algorithms, and either outcome seems like dramatic progress.[2] To begin, observe that every reduction we present is qpoly-Natural in the following sense.

[2] Similar arguments apply to the gap-versions of the problem that we study above, but we argue about the exact version here to facilitate exposition.

▶ **Definition 27** (Natural Reductions between Parametric Problems). *Let A and B be* parametric problems, *that is, inputs are of the form: $\{\langle x, s\rangle : x \in \{0,1\}^n,\ s \in \mathbb{N}\}$. We call a* parametric reduction $R = \langle R_I, R_P\rangle$ *where R_I outputs instances and R_P outputs parameters, $t(\cdot)$-*natural *if it is:*

- ***Parametric Many-one:*** $\langle x, s\rangle \in A \iff \langle R_I(x,s),\ R_P(x,s)\rangle \in B$
- ***Parameter-Value Uniform:*** $R_P(x,s)$ *depends* ***only*** *on the size of the input and value of the parameter; we will treat R_P as a function from $\mathbb{N}\times\mathbb{N}$ in this case.*
- ***$t(\cdot)$-Efficient:*** *The combined runtime of R_I and R_P is bounded by $t(|x|,\ s)$.*

A natural reduction R from Λ-MCSP to Γ-MCSP is many-one, so a Λ-MCSP algorithm follows by brute-force search through Γ-circuits, and Λ-to-Γ lifting follows by mapping a Λ-hard function h through R. This gives the next two lemmas. Kabanets and Cai used the same reasoning to prove that NP-hardness of MCSP under poly-time natural reductions would imply breakthrough circuit lower bounds (Theorem 15 of [20]). Removing NP-hardness from the picture, we instead obtain the following:

▶ **Lemma 28** (Black-Box MCSP Algorithms from Natural MCSP-Redux). *If there is a* poly*-Natural Reduction from Λ-MCSP to Γ-MCSP, then there is a fixed constant $k \in \mathbb{N}$ such that $\Lambda\text{-MCSP}_n \in \mathsf{TIME}[\mathsf{poly}(nk) \times \Gamma\text{-count}(R_P(2^n, s))]$*

Proof. Fix a reasonable encoding of Γ-circuits that admits efficient evaluation. Then write Γ-count(s) for the total number of circuits so encoded that witness Γ-measure at most s. On input (f, s) to $\Lambda\text{-MCSP}_n$ we first run (f, s) through the natural reduction R to obtain (f', s'). Just as above, because R is poly-time, there is a fixed k such that $t(n) = 2^{kn}$. This means $|f'| \le 2^{kn}$, so we obtain an instance of Γ-MCSP with new size parameter $s' = R_P(2^n, s)$ on at most kn input variables.

Then, because R is parametric many-one, a (yes, no)-instance of $\Lambda\text{-MCSP}_n$ becomes a (yes, no)-instance of $\Gamma\text{-MCSP}_{kn}$ (respectively). So, we can solve the resulting instance of Γ-MCSP by brute-force search over the set of all s'-measure-witnessing Γ-circuits, and answer accordingly. We must evaluate a s'-size Γ-circuit on $\le kn$ bits at most Γ-count(s') times. This takes $\mathsf{poly}(nk) \cdot \Gamma$-count$(s')$ time in total. ◀

Lifting begins with pre-existing lower bounds for Λ, which we formalize below. Many concrete circuit lower bounds are *far more* explicit, but this weak notion will suffice for lifting via natural and efficient inter-MCSP reductions.

▶ **Definition 29** (Explicit Complexity Lower Bounds). *Let $H = \{h_n\}_{n\in\mathbb{N}}$ be a sequence of Boolean functions in* E*, and let $s_\Lambda : \mathbb{N} \to \mathbb{N}$ be a function in* FP*. We call the pair $\langle H, s_\Lambda\rangle$ an* explicit Λ-complexity lower bound *if $\forall n\ \Lambda(h_n) > s_\Lambda(n)$.*

▶ **Lemma 30** (Black-Box Lifting from Natural MCSP-Redux). *Let $\langle H, s\rangle$ be a Λ-complexity lower bound. If there is a* poly*-Natural Reduction R from Λ-MCSP to Γ-MCSP, then there exists a constant k and sequence of m-input Boolean functions H' such that $\langle H', R_P(2^{m/k}, s(m/k))\rangle$ is an explicit Γ-complexity lower bound.*

Proof. Fix an explicit Λ-complexity lower bound $\langle H, s\rangle$ and poly-natural reduction $R = \langle R_I, R_P\rangle$ from Λ-MCSP to Γ-MCSP. Now run the reduction: let H' be the sequence $h'_n = R_I(h_n, s(n))$ and let $s'(n) = R_P(h_n, s(n))$. We know $(h_n, s(n)) \notin \Lambda$-MCSP by the hardness assumption about H. Then, because R is parametric many-one, $(h'_n, s'(n)) \notin \Gamma$-MCSP and thus $\Gamma(h'_n) > s'(n)$. To make this explicit, we bound the runtime of answering queries according to h' on inputs x of m bits. This amounts to re-indexing the sequence H' to ensure that a Γ-hard function is defined everywhere and computable in E.

First, because R is poly-time, there is a fixed k such that $t(n) = 2^{kn}$. This means $|h'_n| \leq 2^{kn}$, so we send each input length n through the reduction to a new input length of at most kn. We evaluate h at m/k input bits and pad to fill in the gaps. Propagating this padded sequence of functions through the parameter-map R_P, we obtained the claimed Γ-complexity lower bound. ◀

5.1 Efficient Natural Reductions Between AC^0_d-, AC^0_{d+1}-MCSP: Win/Win

Notice how both applications of poly-Natural reductions depend quantitatively on R_P, the size parameter of the reduction. For lifting, we want $R_P(\cdot)$ *large enough* to improve the best known Γ-complexity lower bound by starting with a stronger lower bound for Λ. For solving Λ-MCSP by brute-force on Γ-MCSP, we want $R_P(\cdot)$ *small enough* such that searching all relevant Γ-circuits is faster than trivial brute-force over all relevant Λ-circuits. This observation suggests a case analysis of the function R_P, to obtain either a non-trivial MCSP algorithm or improved circuit lower bounds. For poly-Natural reductions from AC^0_d-MCSP to AC^0_{d+1}-MCSP, such a win/win argument succeeds. Informally, we have the following:

▶ **Theorem 31** (poly-Natural MCSP Reduction Win/Win)**.** *Suppose there is a* poly*-Natural reduction from* AC^0_d-MCSP *to* $\mathsf{AC}^0_{d'}$-MCSP*, for* $d' > d$*. Then, either:*

- *There is a surprisingly fast algorithm for* AC^0_d-MCSP*, or*
- *There are breakthrough explicit circuit lower bounds against* $\mathsf{AC}^0_{d'}[2^{\Omega(n^{1/d})}]$ *for* $d < d'$ *!*

We spend the remainder of this section formalizing and proving variations on the above.

5.2 Quantitative Consequences of a Hardness Hypothesis for MCSP

We first formulate an appropriate hypothesis about the hardness of MCSP.

▶ **Definition 32** (Weak Exponential Time Hypothesis (WETH) for Λ-MCSP)**.** *There exists an* $\epsilon > 0$ *such that for all "nice" size functions* $s(n)$*,* $\Lambda\text{-MCSP}_n[s(n)] \notin \mathsf{TIME}[2^{s(n)^\epsilon}]$.

For the general MCSP (when Λ is the class of unrestricted Boolean circuits), it can be shown that the WETH for MCSP is implied by the cryptographic conjecture that exponentially-strong one-way functions exist (using the ideas of [28, 20, 2]). One can also show that if WETH for general MCSP is false, then $\mathsf{NEXP} \not\subset \mathsf{P/poly}$ (using the ideas of [19]). For every $d \geq 2$, the WETH for AC^0_d-MCSP is also reasonable to assume, although we don't seem to have any strong evidence to support it yet (see [3] for some cryptographic hardness of AC^0_d-MCSP for large d).

Under this hypothesis, we establish barriers to giving poly-Natural reductions from AC^0_d-MCSP to AC^0_{d+c}-MCSP. We begin by recalling the best-known AC^0_d circuit lower bounds.

▶ **Theorem 33** (Håstad [13])**.** *Any depth* $(d+1)$ *alternating circuit computing* $\oplus_n$ *requires* $2^{\Omega(n^{1/d})}$ *gates. Furthermore, this bound is clearly* explicit *as in Definition 29.*

▶ **Theorem 34.** *Suppose there is a* poly*-Natural reduction from* AC^0_d-MCSP *to* $\mathsf{AC}^0_{d'}$-MCSP*, for* $d' > d$*. Then, either:*

- *The WETH for* AC^0_d-MCSP *is* ***false****, or*
- *There is an explicit circuit lower bound with* $s(n) = 2^{\Omega(n^{1/(d-1)})}$ *against* $\mathsf{AC}^0_{d'}$.

Proof. Assume such a poly-Natural reduction $R = \langle R_I, R_P \rangle$ exists, with run-time 2^{kn}. We reason by cases on bounds for R_P.

Suppose R_P is small. That is, $\forall\epsilon.R_P(2^n, s(n)) < s(n)^\epsilon$. Substituting into the black-box MCSP algorithm above, we have that $\forall\epsilon.\mathsf{AC}^0_d\text{-}\mathtt{MCSP}_n \in \mathsf{TIME}[\mathsf{poly}(nk) \times \mathsf{AC}^0_{d'}\text{-}\,\mathrm{count}(s(n)^\epsilon)] \in \mathsf{TIME}[2^{s(n)^{2\epsilon}}]$, where the first inclusion is by Lemma 28, and second by counting $\mathsf{AC}^0_{d'}$ circuits. This contradicts the MCSP-WETH for AC^0_d.

Suppose R_P is large. That is, $\exists\epsilon.R_P(2^n, s(n)) > s(n)^\epsilon$. Lifting $\oplus$ through R we have that there is an explicit sequence of Boolean functions H on m-bit inputs such that we have the following explicit $\mathsf{AC}^0_{d'}$-complexity bounds: $R_P(2^{m/k}, s(m/k)) > s(m/k)^\epsilon > 2^{\Omega(m^{1/(d-1)})}$. Here, the lower bound is by Lemma 30, the first inequality by size assumption about R_P, and the last by application of Håstad's bound. ◀

When $d' > d$, the lower-bound case above would be a breakthrough in circuit complexity.

▶ **Corollary 35** (Breakthrough Circuit Lower Bounds for Alternating Constant-Depth)**.** *Suppose the WETH for* $\mathsf{AC}^0_d\text{-}\mathtt{MCSP}$ *holds, for every* $d \geq 2$*. Then, if* $\forall d > d_0$ *we have a* poly*-Natural reduction* R_d *from* $\mathsf{AC}^0_d\text{-}\mathtt{MCSP}$ *to* $\mathsf{AC}^0_{(d+1)}\text{-}\mathtt{MCSP}$*, then there is a fixed constant* α *such that, for each depth* $d > d_0$*, there is a Boolean function* $f^d \in E$ *such that any depth-*d *alternating circuit computing* f^d_n *requires* $2^{\Omega_d(n^\alpha)}$ *gates.*

Proof. Fix any constant $d > d_0$. We first compose R_d with itself sufficiently many times to obtain a many-one reduction R'_d all the way from $\mathsf{AC}^0_{d_0}\text{-}\mathtt{MCSP}$ to $\mathsf{AC}^0_d\text{-}\mathtt{MCSP}$. Observe that R'_d remains poly-Natural, because all the polynomial resource bounds are closed under a constant number of compositions – though the leading constant exponent of runtime for R'_d certainly increases proportional to the gap between d and d_0; this is precisely what is hidden by Ω_d in the bound. To conclude, we apply black box lifting (Lemma 30) to the composed poly-Natural reduction R'_d, with Håstad's lower bound for $\oplus$ at depth d_0, getting $\alpha = 1/d_0$ in the theorem. ◀

Combining with a simulation of shallow formulas by constant-depth circuits, we get

▶ **Lemma 36** (Folklore)**.** *Any sequence* f_n *of Boolean functions on* n *inputs computable by formulas of depth* $c\log(n)$ *is computable by depth-*d *alternating* circuits *of size* $2^d \times 2^{n^{(c/d)}}$*.*

▶ **Theorem 37** (Breakthrough Circuit Lower Bounds for Formulas)**.** *Suppose the WETH for* $\mathsf{AC}^0_d\text{-}\mathtt{MCSP}$ *holds, for every* $d \geq 2$*. Then, if* $\forall d > d_0$ *we have a* poly*-Natural reduction* R_d *from* $\mathsf{AC}^0_d\text{-}\mathtt{MCSP}$ *to* $\mathsf{AC}^0_{(d+1)}\text{-}\mathtt{MCSP}$*, for every fixed* k *there exists* f^k *a sequence of Boolean functions in* E*, such that* f^k *does not have size-*n^k *formulas.*

Proof. Fix constant k, and let $c \in \mathbb{N}$ be the leading constant that results from re-balancing an arbitrary n^k-size formula to log-depth. Any function computed by such a formula will have – for every d – AC^0_d circuits of size $\approx 2^{n^{c/d}}$ by Lemma 36. Therefore, if we choose d such that $1/d_0 > c/d$, the size bound that results from lifting $\oplus$ through iterated composition of R_d exceeds the constant-depth simulation-size of any n^k-size formula. The rest of this argument is identical to the proof of Corollary 35 above. ◀

6 Open Questions

One obvious question is whether one can show the NP-completeness of AC^0_d-MCSP for any constant depth $d \geq 3$ by proving that depth 3 circuit complexity is NP-hard to approximate to within the factors needed by our lifting theorems? Note that while we have hardness of approximation result for DNFs [23, 3], the (almost tight) approximation gap there is not strong enough for our lifting theorems to apply. For depth-3 circuits, on the other hand, there are no known hardness of approximation results.

Another natural question is to tighten the gap (the approximation factor) of our lifting theorems. Finally, can one provide more evidence supporting the Weak Exponential Time Hypothesis for AC^0_d-MCSP?

Abstract

In this paper, we consider the problem of designing cut sparsifiers and sketches for directed graphs. To bypass known lower bounds, we allow the sparsifier/sketch to depend on the *balance* of the input graph, which smoothly interpolates between undirected and directed graphs. We give nearly matching upper and lower bounds for both *for-all* (cf. Benczúr and Karger, STOC 1996) and *for-each* (Andoni et al., ITCS 2016) cut sparsifiers/sketches as a function of cut balance, defined the maximum ratio of the cut value in the two directions of a directed graph (Ene et al., STOC 2016). We also show an interesting application of digraph sparsification via cut balance by using it to give a very short proof of a celebrated maximum flow result of Karger and Levine (STOC 2002).

1 Introduction

Graph sparsification, originally introduced by Benczúr and Karger as a means of obtaining faster maximum flow algorithms [8], has become a fundamental tool in graph algorithms. The goal of graph sparsification is to replace an arbitrary graph with a sparse graph (called the graph sparsifier) on the same set of n vertices but with only $O(n \cdot \text{poly}(\log n, 1/\epsilon))$ edges, while approximately preserving the value of every cut up to a factor of $1 \pm \epsilon$ for any given $\epsilon > 0$. Since their work, several graph sparsification techniques have been discovered (e.g., [17]), the idea has been extended to other models of computation such as data streaming (e.g., [1]) and sketching (e.g., [6]), stronger notions such as spectral sparsification that preserves all quadratic forms have been proposed (e.g., [43]), and far-reaching generalizations such as the Kadison-Singer conjecture have been established [37]. On the applications front, graph sparsification has been heavily used to obtain a tradeoff between algorithmic accuracy and efficiency for a variety of "cut-based" problems such as maximum flows, minimum cuts, balanced separators, etc.

In spite of its widespread use, one restriction is that most sparsification techniques only apply to undirected graphs. There is a fundamental reason for this restriction – there are directed graphs that *cannot* be sparsified (see Fig. 1 for an example). Indeed, the lower

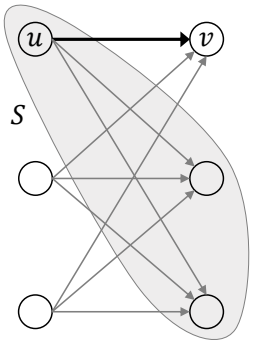

Figure 1 The graph is a complete bipartite graph where all edges go from the left vertices L to the right vertices R. For any $u \in L$ and $v \in R$, the only edge that leaves the set $S = \{u\} \cup (R \setminus \{v\})$ is the edge (u, v). Consequently, if we want to preserve the value of all directed cuts in this graph, we have to (approximately) store the weight of every edge.

bound holds even for *cut sketches*, where one does not insist on a graph being output as the sparsifier, but simply a succinct data structure from which the cut values of the original graph can be (approximately) retrieved.

A qualitative distinction between directed and undirected graphs is in terms of the *balance* of cuts, i.e., the ratio between incoming and outgoing edges in any given cut. An equivalent view of an undirected graph is by bi-directing its edges, which results in a graph with perfect balance, i.e., every cut has exactly the same number of incoming and outgoing edges.[1] Cut balance, therefore, smoothly interpolates between undirected and directed graphs, which leads to the question: *can we design cut sparsifiers/sketches for directed graphs that depend on cut balance?* We answer this question in the affirmative in this paper, and show that this view of sparsification leads to interesting consequences.

We note that the use of cut balance to bridge between undirected and directed graphs predates our work. Ene et al. [15] introduced the notion of parameterizing digraphs by their cut balance (or simply balance) and defined it as the largest ratio between the value of a cut in its two directions. Using this view, they extended two classic operations on undirected graphs – oblivious routing and fast approximate maximum flows – to directed graphs with a dependence on the balance. In this paper, we show that this phenomenon is exhibited by cut sparsification as well.

1.1 Our Results

We consider the two canonical forms of cut sparsification considered in the literature. The first is the classic version introduced by Benczúr and Karger [8], where all cuts must simultaneously be approximately preserved *whp*;[2] we call this *for-all* sparsification. The second, more relaxed, notion is due to Andoni et al. [6], where *any* cut must be approximately preserved *whp* instead of all cuts simultaneously; we call this *for-each* sparsification. For both these notions of sparsification, previous results on undirected graphs can be extended to β-balanced graphs by boosting sampling probabilities in undirected sparsification algorithms by a factor of β, thereby losing an additional factor of β in the size of the sparsifier/sketch (see also Ikeda and Tanigawa [20]). Is it possible to do better than losing a factor of β?

[1] Note that all Eulerian digraphs, whether or not derived from undirected graphs, exhibit perfect cut balance.

[2] with high probability

Our first result sharpens this naïve bound in for-each sparsification, by constructing cut sketches that improve the dependence on β to $\sqrt{\beta}$. We also show that this dependence is tight by constructing a matching lower bound. This pair of results resolves the precise dependence of for-each sparsification in directed graphs on the balance of the graph.

▶ **Theorem 1** (Upper Bound). *For any β-balanced graph with n vertices, m edges, and polynomially-bounded edge weights, there is an $\widetilde{O}(m + \sqrt{\beta}n/\epsilon)$-time algorithm[3] that constructs a $(1 \pm \epsilon)$ for-each cut sketch of size $\widetilde{O}(\sqrt{\beta}n/\epsilon)$ bits.*

(Lower Bound) Fix any $\beta \geq 1$, $0 < \epsilon < 1$, and n such that $(\beta/\epsilon)^{1/2} \leq n/2$. Any $(1 \pm \epsilon)$ for-each cut sketching algorithm for β-balanced graphs with n vertices must output at least $\Omega(\sqrt{\beta}n/\sqrt{\epsilon})$ bits in the worst case.

In for-all sparsification, we are not as lucky; we show that the linear dependence on β is tight in this case. (In fact, Ikeda and Tanigawa [20] had conjectured that better for-all sparsifiers can be constructed by sampling edges according to directed connectivity parameters; our lower bound construction refutes this conjecture and shows that such more aggressive sampling may not produce a sparsifier at all.)

▶ **Theorem 2.** *Fix any $\beta \geq 1$, $0 < \epsilon < 1$, and n such that $\beta/\epsilon \leq n/2$. Any $(1 \pm \epsilon)$ for-all cut sketching algorithm for n-node β-balanced graphs must output at least $\Omega(n\beta/\epsilon)$ bits.*

But, we note that the upper bound only applies to digraphs where *all* cuts are β-balanced. In general, the balance parameter for different cuts in a digraph may be highly non-uniform: some cuts could be very balanced and some others very unbalanced. For such graphs, we show a more refined result: for *any* value $\beta \geq 1$, we construct a sparsfier that approximately preserves all β-balanced cuts losing only an additional factor β in the size of the sparsifier. Note that this result holds for any value of β irrespective of the balance parameter of the graph; if β is the balance parameter, then it recovers the tight bound for β-balanced graphs.

▶ **Theorem 3.** *For any directed graph with n vertices, m edges, and non-negative edge weights, and any $\beta \geq 1$, there is an $\widetilde{O}(m)$-time algorithm that returns a (weighted) subgraph with $\widetilde{O}(\beta n/\epsilon^2)$ edges and preserves the values of all β-balanced cuts up to a factor of $1 \pm \epsilon$.*

We remark that digraph sparsification using cut balance has interesting consequences. In particular, note that for residual graphs produced by s-t maximum flow algorithms in undirected graphs, we can precisely bound the balance parameter on all cuts separating the source and the sink. Using this observation, we give a very short proof of the celebrated maximum flow result of Karger and Levine [27] via the digraph sparsification results.

1.2 Our Techniques

First, we outline the main ideas in our for-each cut sketch. In previous results on for-each cut sketches of undirected graphs [6, 21], the main idea was to (recursively) partition the graph into "sparse" and "dense" parts, and then maintain the sparse parts exactly along with a sample of the dense parts. A directed subgraph, however, can simultaneously be too dense to preserve exactly but also not amenable to sampling (e.g., a complete bipartite digraph). Of course, the balance parameter helps bridge this gap, but the cut balance of a subgraph that the algorithm encounters during recursion can be much worse than that of the original

[3] This runtime bound assumes that the value of β is known. If not, then β can be computed using an algorithm of Ene et al. [15] in $\widetilde{O}(\beta^2 m)$ time.

graph. Indeed, individual subgraphs might not even be strongly connected (i.e., have balance ∞), even if the original graph were Eulerian (i.e., has balance 1). This makes the (recursive) local sketching techniques in previous works unusable for directed graphs.

Our main technical contribution is a new *global* cut sketch construction. We design a cut sketch whose variance can be large on individual dense regions of the input digraph that are well-connected in an undirected sense, but we crucially show that the *cumulative variance of our estimator across all these well-connected regions of the digraph is small*. This helps eliminate the need for local cut sketches in each dense subgraph, and simplifies the recovery algorithm to the natural estimator that appropriately scales the number of sampled edges in the queried cut. Moreover, to obtain the right dependence on β, we need to carefully analyze the variance of our estimator. Our new variance analysis works for undirected graphs as well, which tightens the analysis of [6] and consequently leads to undirected cut sketching algorithms that do not require downsampling or low-accuracy for-all sparsifiers.

Next, we turn to for-all sparsification. Our first result is the lower bound on for-all sparsifiers and cut sketches. For any β and n, we construct a family $\mathcal{G}$ of β-balanced graphs on n vertices that satisfies two conflicting properties: $\mathcal{G}$ is a large family, yet for each graph $G \in \mathcal{G}$, the number of graphs in $\mathcal{G}$ that approximate all cuts of G is small. For any graph G and cut S, let $\delta_G(S)$ denote the value of S and $E_G(S)$ denote the edges crossing S. Notice that there are many possible graphs H such that $\delta_H(S) \approx \delta_G(S)$, because $E_H(S)$ and $E_G(S)$ could differ in numerous ways. Thus, to ensure that the number of cut approximators is small, we carefully design $\mathcal{G}$ such that for any $G, H \in \mathcal{G}$ and cut S, if $\delta_H(S) \approx \delta_G(S)$, then $E_H(S) \approx E_G(S)$. We show that this can be done by considering a large family of bipartite graphs that all contain a fixed (directed) matching. Consequently, any sketching algorithm must produce a large number of different cut sketches for the graphs in $\mathcal{G}$, which translates to a lower bound on the size of the cut sketches using standard information theory.

Finally, we refine for-all sparsification in digraphs by showing that we can preserve all balanced cuts, irrespective of the balance parameter of the entire graph G. More specifically, at a cost of an additional factor of β in the size of the sparsifer, we can preserve all β-balanced cuts, and provide an approximation for α-balanced cuts with $\alpha > \beta$ that degrades gracefully as α gets larger. For this purpose, we adopt a (recursive) graph decomposition due to Benczúr and Karger [8] that expresses a graph as a weighted sum of subgraphs, each of which corresponds to a particular edge sampling rate. Now we can boost the (undirected) sampling rate by a factor of β. If the balance of every subgraph in the decomposition is also β, then the undirected analysis carries over to the directed case. However, in general, each subgraph can be very unbalanced, so we cannot bound the estimation error in each individual subgraph. Our main technical contribution is to show that even though we do not preserve the cut values in individual subgraphs, we do so globally across all the subgraphs.

1.3 Related Work

Graph Sparsification. Graph sparsification was introduced by Benczúr and Karger [8] ("for-all" cut sparsification), and has led to research in a number of directions: Fung et al. [17] and Kapralov and Panigrahy [26] gave new algorithms for preserving cuts in a sparsifier; Spielman and Teng [43] generalized to spectral sparsfiers that preserved all quadratic forms, which led to further research both in reducing the size of the sparsifier [42, 7] and developing faster algorithms (e.g., [34, 5, 35, 11, 33, 30, 32, 31]); faster algorithms for fundamental graph problems such as maximum flow utilized sparsification results (e.g., [8, 40]); Ahn and Guha [1] introduced sparsification in the streaming model, which has led to a large body of work for both cut (e.g., [2, 3, 18]) and spectral sparsifiers (e.g., [25, 24, 23, 4]) in graph

streams; both cut [29, 38] and spectral [41] sparsification have been studied in hypergraphs. For lower bounds, Andoni et al. [6] showed that any data structure that $(1\pm\epsilon)$-approximately stores the sizes of all cuts in an undirected graph must use $\Omega(n/\epsilon^2)$ bits. Carlson et al. [10] improved this lower bound to $\Omega(n\log n/\epsilon^2)$ bits, matching existing upper bounds.

Andoni et al. [6] first proposed the notion of "for-each" cut (and spectral) sketches, where the sparsifier preserves the value of *any* cut rather than all cuts simultaneously. They showed that for any undirected graph with n vertices, a $(1\pm\epsilon)$ for-each cut sketch of size $\widetilde{O}(n/\epsilon)$ exists and can be computed in polynomial time. Subsequently, Jambulapati and Sidford [21] gave the first nearly-linear time algorithm for constructing $(1\pm\epsilon)$ for-each graph sketches of size $\widetilde{O}(n/\epsilon)$. Their sketch not only approximates cut values, but also approximately preserves the quadratic form of any undirected Laplacian matrix (and its pseudoinverse). Chu et al. [11] showed how to construct a *graph* containing $\widetilde{O}(n^{1+o(1)}/\epsilon)$ edges that satisfies the "for-each" requirement for spectral queries.

Directed Graphs. Cohen et al. [14, 13] proposed a directed notion of spectral sparsifiers and used it to obtain nearly-linear time algorithms for solving directed Laplacian linear systems and computing various properties of directed random walks. However, their directed spectral sparsifiers only work for Eulerian graphs, i.e., for $\beta = 1$. Zhang et al. [44] proposed a notion of spectral sparsification that works for all directed graphs, but their definition does not preserve cut values. More generally, there have been attempts at bridging the divide between directed and undirected graphs for other problems. For instance, Lin [36] defined the imbalance of a graph as the sum of the absolute difference of in- and out-capacities at all vertices, and used it to generalize the max-flow algorithm of Karger and Levine [27] from undirected graphs to digraphs. Digraphs have also been parameterized by directed extensions of treewidth [22], and similar notions of DAG-width [9, 39] and Kelly-width [19], which led to FPT algorithms based on these parameters, much like for undirected bounded treewidth graphs. In spectral graph theory, directed analogs of Cheeger's inequality have been defined [12], particularly in the context of analyzing the spectrum of digraphs. Closest to our work is that of Ene et al. [15] who proposed cut balance of digraphs that we use in this paper, although in the context of oblivious routing and max-flow algorithms.

2 Preliminaries

Basic Notations. Let $G = (V, E, w)$ be a weighted *directed* graph with $n = |V|$ vertices and $m = |E|$ edges. Every edge $e \in E$ has a given non-negative weight $w_e \geq 0$. When working with unweighted graphs, (i.e., $w_e = 1$ for all $e \in E$), we will omit the edge weights w_e.

For two sets of vertices $S \subseteq V$ and $T \subseteq V$, we use $E(S,T) = \{(u,v) \in E : u \in S, v \in T\}$ to denote the set of edges in E that go from S to T. We use $w(S,T) = \sum_{e\in E(S,T)} w_e$ to denote the total weight of the edges from S to T. For a vertex $u \in V$ and a set of vertices $S \subseteq V$, we write $E(u,S)$ for $E(\{u\},S)$, and we define $E(S,u)$, $w(u,S)$, and $w(S,u)$ similarly.

We often write $\overline{S}$ as a shorthand for $V \setminus S$. Given a component V_i and a subset of its vertices $S_i \subseteq V_i$, we can similarly define $\overline{S_i} = V_i \setminus S_i$. For example, using this notation, we write $w(S,\overline{S})$ for $w(S, V\setminus S)$ and similarly $w(S_i,\overline{S_i}) = w(S_i, V_i \setminus S_i)$.

The *conductance* of an undirected graph $G = (V, E, w)$ is defined as

$$\phi(G) = \min_{\varnothing\neq S\subset V} \frac{w(S,\overline{S})}{\min\big(w(S,V), w(\overline{S},V)\big)}. \tag{1}$$

▶ **Definition 4** (β-Balanced). *A strongly connected digraph $G = (V, E, w)$ is* β-balanced *if, for all $\varnothing \subseteq S \subseteq V$, it holds that $w(S,\overline{S}) \leq \beta \cdot w(\overline{S}, S)$.*

Directed Cut Sparsifiers and Cut Sketches. We consider two notions of sparsification. The first is the classic "for-all" sparsifier that approximately preserves the values of all cuts.

▶ **Definition 5** (For-All Cut Sparsifier). *Let $G = (V, E_G, w_G)$ and $H = (V, E_H, w_H)$ be two weighted directed graphs. Fix $0 < \epsilon < 1$. We say H is a $(1 \pm \epsilon)$ for-all cut sparsifier of G iff the following holds for all $S \subseteq V$:*

$$(1 - \epsilon) \cdot w_G(S, V \setminus S) \leq w_H(S, V \setminus S) \leq (1 + \epsilon) \cdot w_G(S, V \setminus S).$$

Instead of a graph that preserves cut values, if we allow any data structure from which the cut values can be (approximately) recovered, we call it a cut sketch.

▶ **Definition 6** (For-All Cut Sketch). *Let $G = (V, E, w)$ be a weighted directed graph. Fix $0 < \epsilon < 1$. A (deterministic) function g outputs a $(1 \pm \epsilon)$ for-all cut sketch of G if there exists a recovering function f such that, for all $S \subseteq V$:*

$$(1 - \epsilon) \cdot w(S, V \setminus S) \leq f(S, \mathrm{sk}(G)) \leq (1 + \epsilon) \cdot w(S, V \setminus S).$$

Next we consider a weaker notion of graph sparsification, where instead of approximating the value of all cuts, we only require the value of any individual cut to be approximately preserved with (high) constant probability.

▶ **Definition 7** (For-Each Cut Sketch). *Let $G = (V, E, w)$ be a weighted directed graph. Fix $0 < \epsilon < 1$. A function g outputs a for-each $(1 \pm \epsilon)$-cut sketch of G if there exists a recovering function f such that, for each $S \subseteq V$, with probability at least $2/3$,*

$$(1 - \epsilon) \cdot w(S, V \setminus S) \leq f(S, g(G)) \leq (1 + \epsilon) \cdot w(S, V \setminus S).$$

3 For-All Sparsification: $\widetilde{O}(n \cdot \beta/\epsilon^2)$ Upper Bound

In this section, we extend the seminal work of Bencúr and Karger [8] to directed graphs using cut balance. For undirected graphs, they showed that sampling every edge inversely proportional to a quantity known as its strength (see Definition 11) preserves all cuts with high probability. We show that, by boosting this sampling probability by a factor of β, this procedure can preserve the value of β-balanced cuts in any directed graph.

We then show that this sampling theorem can be applied in a black-box manner to recover the analysis of a celebrated maximum flow algorithm for undirected graphs given by Karger and Levine [27]. At each step of the algorithm, they sample edges from the residual network (which is directed) of an undirected graph. Using a customized version of the sparsification result from Benczúr and Karger [8], they show that with high probability, the sample contains an augmenting path. In contrast, our sampling procedure can be applied directly to the residual network, which simplifies the analysis of the algorithm.

The following theorem is our main result of this section:

▶ **Theorem 8.** *Let $G = (V, E)$ be a directed graph where each edge e has weight $u_e \geq 0$, and let ϵ, β be parameters. There is an $\widetilde{O}(m)$-time algorithm that returns a weighted subgraph H that satisfies the following with high probability: for every α-balanced cut U,*

$$\left(1 - \epsilon\sqrt{\frac{\alpha+1}{\beta+1}}\right) \cdot \delta_G(U) \leq \delta_H(U) \leq \left(1 + \epsilon\sqrt{\frac{\alpha+1}{\beta+1}}\right) \cdot \delta_G(U).$$

where $\delta_G(U)$ and $\delta_H(U)$ denote the cut value of U in G and H, respectively. Furthermore, H contains $O(\beta n \log n/\epsilon^2)$ edges in expectation.

Note that for the special case where the graph G is β-balanced, Theorem 3 is implied by Theorem 8: all cut values are preserved. This is the main result of Ikeda and Tanigawa [20].

▶ **Corollary 9** (Ikeda and Tanigawa [20]). *Consider the same setting as Theorem 8. If G is β-balanced, then with high probability, H approximates every cut of G up to a $(1 \pm \epsilon)$ factor.*

Before proving Theorem 8, we give an application of digraph sparsification to the maximum flow problem. In particular, we prove the correctness of the $\widetilde{O}(m + nv)$-time maximum flow algorithm given by Karger and Levine [27], where v is the value of the maximum flow. This algorithm is an adaptation of the classic augmenting paths algorithm of Ford and Fulkerson [16], but with the following crucial observation. Let f denote the current flow value in any iteration, and $\gamma = (v - f)/v$ denote the fraction of remaining flow in the residual network. Karger and Levine [27] show that, by boosting the undirected sampling procedure of Benczúr and Karger [8] by a factor of $1/\gamma$ and applying it to the residual network, the resulting sample contains an augmenting path with high probability. This saves on running time since the search for an augmenting path can then be performed on the sampled graph instead of the entire residual network. (See the full paper for more details.)

In contrast, we show that we can directly apply digraph sparsification to the residual network, with $\beta = 2/\gamma$ to obtain a short proof of the Karger-Levine theorem:

▶ **Theorem 10** (Karger and Levine [27]). *Suppose we apply the algorithm in Theorem 8 to the residual network in a maximum flow computation, with $\epsilon = 0.1$ and $\beta = 2/\gamma$, where $\gamma = (v - f)/v$ is the fraction of flow remaining in the residual network. Then with high probability, there is an augmenting path in the sample.*

Proof. We claim that every s-t cut S in the residual graph is β-balanced, where $\beta = 2/\gamma$. Suppose S initially contains capacity $c \geq v$, and currently, x units of flow are entering S. Since the flow value is $(1 - \gamma)v$, the amount of flow leaving S is $x + (1 - \gamma)v$. At the same time, the x units of flow entering S create a residual capacity of x leaving S. Thus, the total residual capacity leaving S is $c - x - (1 - \gamma)v + x = c - (1 - \gamma)v$. We can similarly show that the residual capacity entering S is $c + x + (1 - \gamma)v - x = c + (1 - \gamma)v$. Thus, in the residual graph, the balance of S is at most $\frac{c+(1-\gamma)v}{c-(1-\gamma)v} \leq \frac{2-\gamma}{\gamma} \leq \frac{2}{\gamma}$.

Now by setting $\epsilon = 0.1$ and $\beta = 2/\gamma$, Theorem 8 implies that the sparsifier H preserves all $(2/\gamma)$-balanced cuts up to a (1 ± 0.1) factor with high probability. Since every s-t cut is $(2/\gamma)$-balanced, this implies that there exists an augmenting path in H, as desired. ◀

In the rest of this section, we prove Theorem 8. Before we give our algorithm, we state the definitions and results that we need from previous work.

▶ **Definition 11** (Strength and strong components). *The* strength *of an edge e, denoted by k_e, is the largest k such that there exists a k-edge-connected vertex-induced subgraph of G containing e. A* k-strong component *is the subgraph induced by edges with strength at least k.*

▶ **Lemma 12** (Benczúr and Karger [8]). *The strong components of an undirected graph form a laminar family, and a graph on n vertices has at most $n - 1$ nontrivial strong components.*

▶ **Lemma 13** (Benczúr and Karger [8]). *In any graph with edge weights u_e and strengths k_e, we have $\sum_e u_e/k_e \leq n - 1$. Furthermore, there exists an $O(m \log^3 n)$-time algorithm that returns, for every edge e, an estimate $\widetilde{k}_e$ of k_e satisfying $\widetilde{k}_e \leq k_e$ and $\sum_e u_e/\widetilde{k}_e = O(n)$.*

We now describe our algorithm (Algorithm 1). The input is a directed graph where each edge e has weight u_e. We first compute approximate edge strengths $\widetilde{k}_e$ as given in Lemma 13. Then we sample each edge e proportional to $(\beta+1)u_e/\widetilde{k}_e$, where $\beta \geq 1$ is a chosen parameter. We choose the weight of the sampled edges so that we get an unbiased estimator.

Algorithm 1 For-all sparsification for directed graphs.

Input : An n-vertex directed graph $G = (V, E, u)$ with edge weights u_e, $0 < \epsilon < 1$, $\beta \geq 1$, and a constant $d > 2$.
Output : A subgraph H that satisfies Theorem 8.

```
Use Lemma 13 to compute an estimated edge strength k̃_e ≤ k_e for every edge e ∈ E.
Let ρ = 3d(β + 1) log n/ε².
for each edge e ∈ E do
    Sample e with probability p_e = ρ · u_e/k̃_e.
    if e is sampled then add e to H with weight w_e = k̃_e/ρ.
return H.
```

Now we analyze the output H of Algorithm 1. Without loss of generality, we assume that the algorithm uses the actual edge strengths k_e rather than the estimates $\widetilde{k}_e$. This is because $\widetilde{k}_e \leq k_e$ and it does not hurt to oversample in importance sampling.

For each strong component G_i of G (see Definition 11), let H_i denote the corresponding component in H. Because the way we choose sampling probabilities and edge weights in H, we have $\mathbb{E}[H_i] = G_i$. Let $\alpha_i = (k_i - k_{p(i)})/\rho$ where $p(i)$ is G_i's parent in the laminar family formed by strong components (see Lemma 12). As shown by Benczúr and Karger [8], this results in a decomposition of G into its strong components, that is, $G = \sum_i \alpha_i G_i$.

For a component G_i and a cut U, let $\delta_{G_i}(U)$ be the total capacity of edges leaving U in G_i, and let $\delta^{\text{un}}_{G_i}(U)$ be the corresponding value for the undirected version of G_i. The following lemma shows that for every strong component G_i, with high probability, $\delta_{G_i}(U)$ is preserved in H up to a relative error for every cut U.

▶ **Lemma 14.** *Let H be the output of Algorithm 1. For each strong component G_i (defined in Definition 11), the following holds with probability at least $1 - O(n^{-d+2})$: for any cut U, we have $\left|\delta_{H_i}(U) - \delta_{G_i}(U)\right| \leq \zeta(U) \cdot \delta_{G_i}(U)$ where $\zeta(U) = \epsilon\sqrt{\delta^{\text{un}}_{G_i}(U)/(\delta_{G_i}(U)(\beta+1))}$.*

Proof. For any cut U, let $\delta_p(U)$ denote the sum of u_e/k_e over the (undirected) edges crossing U_j in G_i. Order the r cuts intersecting G_i such that $1 = \delta_p(U_1) \leq \cdots \leq \delta_p(U_r)$, and let

$$q_j = \Pr\left(\left|\delta_{H_i}(U_j) - \delta_{G_i}(U_j)\right| > \zeta(U) \cdot \mathbb{E}\left[\delta_{H_i}(U_j)\right]\right).$$

By a Chernoff bound, we have

$$q_j \leq 2\exp\left(-\frac{(\zeta(U))^2 \cdot \delta_{G_i}(U_j)}{3}\right) = 2\exp\left(-\frac{\epsilon^2 \cdot \delta^{\text{un}}_{G_i}(U_j)}{3(\beta+1)}\right), \tag{2}$$

where the equality follows substituting the definition of $\zeta(U)$. Let $E(i,j)$ denote the set of edges crossing U_j in G_i. Since each edge e in G_i has weight p_e, we have

$$\delta^{\text{un}}_{G_i}(U_j) = \sum_{e \in E(i,j)} p_e = \sum_{e \in E(i,j)} \frac{3d(\beta+1)u_e}{\epsilon^2 k_e} \cdot \log n,$$

Substituting this into Eq. (2) shows

$$q_j \le 2\exp\left(-d\sum_{e\in E(i,j)}\frac{u_e}{k_e}\cdot\log n\right) = 2n^{-d\cdot\delta_p(U_j)}.$$

Since $\delta_p(U_j)\ge 1$, we have $q_j \le 2n^{-d}$, so

$$\sum_{j\le n^2} q_j \le n^2\cdot 2n^{-d} = 2n^{-d+2} = O(n^{-d+2}). \tag{3}$$

For $j\ge n^2$, we express j as $j = n^{2\lambda}$. The number of λ-minimum cuts is at most j (see, e.g., Karger and Stein [28]) and $\delta_p(U_1)=1$, so $\delta_p(U_j)\ge\lambda$, so $\delta_p(U_j)\ge\frac{\log j}{2\log n}$. This implies, for $j\ge n^2$, $q_j\le 2n^{-(d\log j)/(2\log n)} = 2j^{-d/2}$. Combining this with Eq. (3), we can conclude

$$\sum_{j\ge 1} q_j \le O(n^{-d+2}) + 2\int_{n^2}^{\infty} j^{-d/2}dj = O(n^{-d+2}). \qquad \blacktriangleleft$$

Now we are ready to prove Theorem 8.

Proof of Theorem 8. By Lemma 13, the expected number of edges in H is $\sum_e p_e = O(\beta n\log n/\epsilon^2)$, as claimed. Now consider an α-balanced cut U. We have

$$\left|\delta_H(U)-\delta_G(U)\right| = \left|\sum_i \alpha_i\delta_{H_i}(U)-\alpha_i\delta_{G_i}(U)\right| \le \sum_i \alpha_i\left|\delta_{H_i}(U)-\delta_{G_i}(U)\right|.$$

Taking a union bound over all strong components, we know that with high probability, Lemma 14 holds for every strong component. Thus, the quantity above is at most

$$\begin{aligned}\sum_i \alpha_i\zeta(U)\cdot\delta_{G_i}(U) &= \sum_i \alpha_i\epsilon\sqrt{\delta^{\mathrm{un}}_{G_i}(U)\delta_{G_i}(U)/(\beta+1)}\\ &\le \frac{\epsilon}{\sqrt{\beta+1}}\sqrt{\sum_i \alpha_i\delta^{\mathrm{un}}_{G_i}(U)\sum_i\alpha_i\delta_{G_i}(U)} && \text{(Cauchy-Schwarz)}\\ &= \frac{\epsilon}{\sqrt{\beta+1}}\sqrt{\delta^{\mathrm{un}}_G(U)\delta_G(U)}. && (\textstyle\sum_i\alpha_i\delta_{G_i}(U)=\delta_G(U))\end{aligned}$$

We conclude the proof by noting that $\delta^{\mathrm{un}}_G(U)\le(\alpha+1)\cdot\delta_G(U)$, since U is α-balanced. $\blacktriangleleft$

4 For-All Sparsification: $\Omega(n\cdot\beta/\epsilon)$ Lower Bound

Our goal in this section to prove a lower bound whose dependence on β matches the linear upper bound given by Ikeda and Tanigawa [20] on the size of for-all cut sketches:

▶ **Theorem 15.** *Fix $\beta\ge 1$ and $0<\epsilon<1$ where $\beta/\epsilon\le n/2$. Any $(1\pm\epsilon)$ for-all cut sketching algorithm for n-node β-balanced graphs must output $\Omega(n\cdot\beta/\epsilon)$ bits in the worst case.*

We prove a special case of our lower bound for $\beta=\Theta(n)$ and $\epsilon=\Theta(1)$ (Lemma 16). The proof for this special case contains the main ideas of our lower-bound construction for general values of β and ϵ. We defer the proof of Theorem 15 to the full paper.

▶ **Lemma 16.** *Let $\beta=8n$ and let ϵ be a sufficiently small universal constant. Any $(1\pm\epsilon)$ for-all cut sketching algorithm for n-node β-balanced graphs must output $\Omega(\beta n)$ bits in the worst case.*

We give an overview of how we prove Lemma 16. We can w.l.o.g focus on deterministic cut sketching algorithms, because running time is not a concern in Lemma 16, any randomized sketching algorithm can be derandomized by enumerating all possible coin flips.

We will choose a set of graphs $\mathcal{G}$ such that the following conditions hold:

- Every graph in $\mathcal{G}$ is β-balanced.
- The size of $\mathcal{G}$ is large (Lemma 17).
- There exists a ℓ with $|\mathcal{G}|/\ell = 2^{\Omega(\beta n)}$ such that, for every graph $G \in \mathcal{G}$, there are at most ℓ graphs in $\mathcal{G}$ that can share a $(1 \pm \epsilon)$-cut sketch with G (Lemma 18).

This way, each cut sketch works for at most ℓ graphs in $\mathcal{G}$, so any algorithm must produce at least $|\mathcal{G}|/\ell = 2^{\Omega(\beta n)}$ different cut sketches for all graphs in $\mathcal{G}$, which implies that the algorithm must output at least $\log_2(|\mathcal{G}|/\ell) = \Omega(\beta n)$ bits.

Formally, consider the set of graphs $\mathcal{G}_{2n}$ with $2n$ vertices defined as follows: every graph $G \in \mathcal{G}_{2n}$ is an unweighted bipartite graph with bipartitions L, R satisfying $|L| = |R| = n$. Fix a perfect matching from L to R. The set $\mathcal{G}_{2n}$ is defined to contain all graphs G such that the edges from L to R is exactly this perfect matching (and the set of edges from R to L are arbitrary). Let $\mathcal{G}_{2n,\beta} \subseteq \mathcal{G}_{2n}$ be the subset of graphs in $\mathcal{G}_{2n}$ that are β-balanced.

As described above, Lemma 17 gives a lower bound on the size of $\mathcal{G}_{2n,\beta}$.

▶ **Lemma 17.** *Let n_0 be a sufficiently large universal constant. If $n \geq n_0$ and $\beta = 8n$, then $|\mathcal{G}_{2n,\beta}| \geq 2^{n^2/2}$.*

The next lemma upper bounds the maximum number of graphs in $\mathcal{G}$ that can share an $(1 \pm \epsilon)$-cut sketch. Notice that if G and H have the same $(1 \pm \epsilon)$-cut sketch, then H must be a $(1 \pm 3\epsilon)$-cut sparsifier of G.

▶ **Lemma 18.** *Let $\epsilon > 0$ be a sufficiently small universal constant. For every $G \in \mathcal{G}_{2n}$, the number of graphs in $\mathcal{G}_{2n}$ that are $(1 \pm 3\epsilon)$-cut sparsifiers of G is at most $2^{n^2/4}$.*

We now prove Lemma 16 and defer the proofs of Lemmas 17 and 18 to the full paper.

Proof of Lemma 16. We work with graphs with $2n$ vertices (rather than n vertices) to make the presentation easier. This is equivalent because we aim to prove a lower bound of $\Omega(\beta n)$.

Fix any $(1 \pm \epsilon)$ for-all cut sketching algorithm. Consider running this algorithm on all graphs in $\mathcal{G}_{2n,\beta}$. Every graph in $\mathcal{G}_{2n,\beta}$ is β-balanced, so the algorithm must map every $G \in \mathcal{G}_{2n,\beta}$ to a bit string (i.e., cut sketch), and graphs that are not $(1 \pm 3\epsilon)$-cut sparsifiers of each other must be mapped to different strings. By Lemma 17, there are at least $2^{n^2/2}$ graphs in $\mathcal{G}_{2n,\beta}$, and by Lemma 18, at most $2^{n^2/4}$ graphs can be mapped to the same bit string. Therefore, the algorithm must output at least $\frac{2^{n^2/2}}{2^{n^2/4}} = 2^{n^2/4}$ distinct bit strings. This implies that the algorithm must output at least $\frac{n^2}{4} = \frac{1}{32}\beta n$ bits in the worst case. ◀

5 For-Each Cut Sketch: $\widetilde{O}(n \cdot \sqrt{\beta}/\epsilon)$ Upper Bound

In this section, we give an upper bound on the size of cut sketches in the for-each setting.

▶ **Theorem 19.** *Let G be an n-vertex β-balanced graph with edge weights in $[1, \mathrm{poly}(n)]$. There exists a $(1 \pm \epsilon)$ for-each cut sketch of size $O(n\beta^{1/2}\log^3 n/\epsilon)$ bits that approximates the value $w(S, V \setminus S)$ of every directed cut $S \subseteq V$ with high probability.*

We will prove a lower bound of $\Omega(n \cdot (\beta/\epsilon)^{1/2})$ bits in Section 6.

Overview of Our Approach. Our approach is inspired by the cut sketching algorithm for undirected graphs by Andoni et al. [6]. We first partition the edges into $\ell = O(\log n)$ disjoint sets $(E_i)_{i=1}^{\ell}$ based on their weights. Edges in $G_i = (V, E_i, w)$ have roughly the same weight and we can essentially treat G_i as an unweighted graph. For each graph G_i, we ignore edge directions, and iteratively remove and store edges belonging to sparse cuts.

Note that G_i may not be balanced. Even when G_i is balanced, the dense components of G_i may not be balanced. Despite this, we show that we can estimate the dense components' contribution to the cut value via random sampling. This is because we can bound the variance within each component, and in the end, upper bound their sum (i.e., the overall variance) using the β-balance condition.

One of our main technical contributions is to derive a tighter upper bound on the variance of random sampling. If we trace our analysis back to the undirected case, we remove some redundant terms in the analysis of [6]. This tighter variance bound is critical, because we cannot obtain the right space dependence on β without it (see the full paper). In addition, our new analysis can be traced back to the undirected case, which will simplify the algorithm of [6]. We can obtain a for-each sketching algorithms for undirected graphs without downsampling or low-accuracy for-all sparsifiers, and the output is a graph.

5.1 Sketching and Recovery Algorithms

Let $G = (V, E, w)$ be an n-node β-balanced directed graph with edge weights $w_e \in [1, \text{poly}(n)]$. It is worth noting that, when constructing the cut sketch, we do not know the cut query $S \subseteq V$. The cut query S is only given as input to the recovery algorithm.

The Sketching Algorithm. We describe our overall cut sketching algorithm (Algorithm 2). We partition the edges into $O(\log n)$ weight classes. For each weight class, we iteratively store and remove all edges that belong to some λ-sparse cut (defined in Equation 4). When there are no λ-sparse cuts remain, we sample α incoming and outgoing edges at each vertex among the remaining edges. The values of λ and α will be specified later in our analysis.

For a directed graph $G = (V, E, w)$, we say a cut $(S, \overline{S})$ is λ-*sparse* if the following holds:

$$|E(S, \overline{S})| + |E(\overline{S}, S)| \leq \lambda \cdot \min\big(|S|, |\overline{S}|\big). \tag{4}$$

The Recovery Algorithm. Algorithm 3 is our recovery algorithm that queries the cut sketch $\text{sk}(G)$ (i.e., the output of Algorithm 2). We first establish some notation. Recall that Algorithm 2 decomposes G into $(G_i)_{i=1}^{\ell}$ according to the edge weights. Let $V_i = (V_{ij})_j$ denote the set of dense components in G_i after we iteratively remove the sparse cuts in G_i.

Algorithm 3 approximates $w(S, \overline{S})$ by adding the total contribution of the sparse-cut edges and the dense-component edges. Let J_S denote the total weight of sparse-cut edges that go from S to $\overline{S}$ in all of the graphs G_i (which we store deterministically). Let I_S be the estimator for the total weight of dense-component edges leaving S in all G_i as defined in Algorithm 3. Algorithm 3 returns $I_S + J_S$ as the final answer.

Correctness and Size Guarantees. We state the correctness of our recovery algorithm (Algorithm 3) in Lemma 20 and the output size of our sketching algorithm (Algorithm 2) in Lemma 21. Theorem 19 follows immediately from Lemmas 20 and 21; we prove the latter before proving the former.

▶ **Lemma 20** (Correctness of Algorithm 3). *Let* $\text{sk}(G)$ *be the output of Algorithm 2. Fix a cut query* $S \subseteq V$*. With probability at least* $2/3$*, the value* $(I_S + J_S)$ *returned by Algorithm 3 on input* $(S, \text{sk}(G))$ *satisfies* $\Big|(I_S + J_S) - w(S, \overline{S})\Big| \leq O(\epsilon) \cdot w(S, \overline{S})$.

Algorithm 2 Compute a $(1 \pm O(\epsilon))$ for-each cut sketch.

Input : An n-vertex β-balanced graph $G = (V, E, w)$ with edge weights $w_e \in [1, \text{poly}(n)]$, and $0 < \epsilon < 1$.
Output : A $(1 \pm O(\epsilon))$ for-each cut sketch $\text{sk}(G)$ of size $\widetilde{O}(n\beta^{1/2}/\epsilon)$.

Set $\alpha = \lambda = \beta^{1/2}/\epsilon$.
Partition the edges into $\ell = O(\log n)$ weight classes $E_1, \ldots, E_\ell$ where $E_i = \{e : w_e \in [2^{i-1}, 2^i)\}$.
Each weight class E_i defines a (possibly unbalanced) graph $G_i = (V, E_i, w)$.
for $i = 1$ **to** ℓ **do**
  while *there exists a λ-sparse cut (defined in Equation (4)) in G_i* **do**
    Remove all edges (in both directions) in this cut and store them in $\text{sk}(G_i)$.
  In $\text{sk}(G_i)$, store the (dense) components $\{V_{ij}\}_j$ of G_i.
  For every V_{ij} and every $u \in V_{ij}$, store the number of (remaining) incoming and outgoing edges at u in G_i, i.e., $d^{\text{in}}_{ij}(u) = |E_i(V_{ij}, u)|$ and $d^{\text{out}}_{ij}(u) = |E_i(u, V_{ij})|$.
  At each vertex $u \in V$, sample with replacement α edges from the (remaining) outgoing edges (u, v) and store them in $\text{sk}(G_i)$. Do the same for incoming edges.
return $\text{sk}(G) = \bigcup_i \text{sk}(G_i)$.

Algorithm 3 Query the cut value $w(S, \overline{S})$ from $\text{sk}(G)$.

Input : A cut query $S \subseteq V$ and a cut sketch $\text{sk}(G)$ (output of Algorithm 2).

for *each* $\text{sk}(G_i)$ *in* $\text{sk}(G)$ **do**
  for *each dense component V_{ij} in G_i* **do**
    Let S_{ij} denote the smaller set of $(V_{ij} \cap S)$ and $(V_{ij} \cap \overline{S})$.
    if $S_{ij} = V_{ij} \cap S$ **then**
      Estimate the total weight of edges leaving S_{ij}: For every $u \in S_{ij}$, set

$$I_{S_{ij}}(u) = \frac{d^{\text{out}}_{ij}(u)}{\alpha} \sum_{q=1}^{\alpha} \chi_{ij}(u, q) w_{ij}(u, q) \tag{5}$$

      where $d^{\text{out}}_{ij}(u)$ is the out-degree of u in V_{ij}, $\chi_{ij}(u, q) = 1$ if the q-th sampled outgoing edge at u crosses S and $\chi_{ij}(u, q) = 0$ otherwise, and $w_{ij}(u, q)$ is the weight of the q-th sampled edge.
    else
      Estimate the total weight of edges entering $S_{ij} = V_{ij} \cap \overline{S}$ instead:
      For every $u \in S_{ij}$, set $I_{S_{ij}}(u)$ as in (5), using $d^{\text{in}}_{ij}(u)$ instead of $d^{\text{out}}_{ij}(u)$, and $\chi_{ij}(u, q)$ indicates if the q-th sampled incoming edge at u crosses S.
    The estimated contribution from V_{ij} is $I_{V_{ij}} = \sum_{u \in S_{ij}} I_{S_{ij}}(u)$.
  The estimated contribution from G_i is $I_{G_i} = \sum_{V_{ij} \in G_i} I_{V_{ij}}$.
Compute $I_S = \sum_i I_{G_i}$, the estimate of the cut value from all dense-component edges.
Compute J_S, the total weight of λ-sparse cut edges that leaves S in all G_i's.
return $I_S + J_S$.

▶ **Lemma 21** (Output Size of Algorithm 2). *The output* $\mathrm{sk}(G)$ *of Algorithm 2 has size* $\widetilde{O}(n(\lambda+\alpha)) = \widetilde{O}(n\beta^{1/2}/\epsilon)$.

Proof. Without loss of generality, we assume $\epsilon = \Omega(1/n)$, otherwise we can store all edges exactly using $\widetilde{O}(n/\epsilon)$ bits. Algorithm 2 produces $\ell = O(\log n)$ weight classes; each weight class defines a graph G_i. In every G_i:

- First we iteratively store and remove edges in λ-sparse cuts. We can upper bound the total number of edge removed using the following charging argument: When a λ-sparse cut is removed, we charge the cut size evenly to the vertices on the smaller side of the cut. Since the cut is λ-sparse, every vertex on the smaller side gets charged at most λ edges. Each vertex can be charged at most $O(\log n)$ times because it can be in the smaller side $O(\log n)$ times. Therefore, $\mathrm{sk}(G)$ stores at most $O(\lambda n \log n)$ sparse edges, which takes $O(\lambda n \log^2 n)$ bits.
- On the remaining graph, the connected components are disjoint, so we can also store the partition of vertices into these dense components in $O(n \log n)$ bits.
- We can store the (remaining) in- and out-degree of every vertex in $O(n \log n)$ bits.
- We sample $O(\alpha)$ edges at each vertex in V, which requires $O(\alpha n \log n)$ bits.

Thus, for every G_i we store $O(\lambda n \log^2 n + n \log n + \alpha n \log n) = O(n(\lambda+\alpha)\log^2 n)$ bits. Since $\alpha = \lambda = \beta^{1/2}/\epsilon$, the size of $\mathrm{sk}(G_i)$ is $O(n\beta^{1/2}\log^2 n/\epsilon)$. The size of $\mathrm{sk}(G) = \bigcup_i \mathrm{sk}(G_i)$ is

$$O(\log n) \cdot O(n\beta^{1/2}\log^2 n/\epsilon) = O(n\beta^{1/2}\log^3 n/\epsilon). \qquad \blacktriangleleft$$

Now we prove Lemma 20 (the correctness of Algorithm 3). Note that it follows immediately from the following lemma and Chebyshev's inequality.

▶ **Lemma 22.** *The estimator returned in Algorithm 3 is unbiased, i.e.,* $\mathbb{E}[I_S] + J_S = w(S,\overline{S})$. *Moreover, the variance of* I_S *is* $\mathrm{Var}[I_S] \le O(\beta/\alpha\lambda)w(S,\overline{S})^2$.

Proof of Lemma 20. Algorithm 2 sets $\alpha = \lambda = \beta^{1/2}\epsilon^{-1}$, so Lemma 22 implies $\mathrm{Var}[I_S] \le O(\epsilon^2)\cdot w(S,\overline{S})^2$. By Chebyshev's inequality, with probability at least $2/3$,

$$\left|(I_S + J_S) - w(S,\overline{S})\right| \le O(\epsilon)\cdot w(S,\overline{S}). \qquad \blacktriangleleft$$

To prove Theorem 19, all that remains is to prove Lemma 22.

Proof of Lemma 22. Recall that our estimator is

$$I_S = \sum_{G_i}\sum_{V_{ij}}\sum_{u\in S_{ij}} I_{S_{ij}}(u),$$

where i sums over the graphs G_i defined according to the edge weights, j sums over the dense components in each G_i after all sparse cuts are removed, and u sums over the vertices of S_{ij}. Without loss of generality, we can assume $|V_{ij}\cap S| \le |V_{ij}\cap\overline{S}|$ and hence $S_{ij} = V_{ij}\cap S$. Otherwise, Algorithm 3 works with $V_{ij}\cap\overline{S}$ and queries for the incoming edges instead. Under this assumption, we always work with outgoing edges:

$$I_{S_{ij}}(u) = \frac{d_{ij}^{\mathrm{out}}(u)}{\alpha}\sum_{q=1}^{\alpha}\chi_{ij}(u,q)w_{ij}(u,q).$$

Every edge $e \in E(S,\overline{S})$ belongs to exactly one G_i, and in that G_i it is either a sparse-cut edge, or a dense-component edge in exactly one V_{ij}. Consequently, to prove $I_S + J_S$ is unbiased, it suffices to prove that $I_{S_{ij}}(u)$ is unbiased. In the dense component V_{ij} of G_i, the

total contribution of edges leaving u to $w(S,\overline{S})$ is $\sum_{r=1}^{d_{ij}^{\text{out}}(u)} \chi(u,r)\cdot w(u,r)$, where r indexes the edges leaving u, $w(u,r)$ is the weight of the r-th edge leaving u, and $\chi(u,r)$ indicates if this edge goes from S to $\overline{S}$. Let $e(u,r)$ denote the r-th edge leaving u and $e_{ij}(u,q)$ denote the q-th sampled edge leaving u within V_{ij}. Summing over the α sampled edges, we have

$$\begin{aligned}\mathbb{E}\left[I_{S_{ij}}(u)\right] &= \frac{d_{ij}^{\text{out}}(u)}{\alpha}\cdot\sum_{q=1}^{\alpha}\mathbb{E}\left[\chi_{ij}(u,q)\cdot w_{ij}(u,q)\right]\\ &= \frac{d_{ij}^{\text{out}}(u)}{\alpha}\cdot\sum_{q=1}^{\alpha}\sum_{r=1}^{d_{ij}^{\text{out}}(u)}\Pr[e_{ij}(u,q)=e(u,r)]\cdot\chi(u,r)\cdot w(u,r)\\ &= \sum_{r=1}^{d_{ij}^{\text{out}}(u)}\chi(u,r)\cdot w(u,r),\end{aligned}$$

where the last equality holds because each sample has the same variance, and the q-th sample is drawn uniformly among all outgoing edges at u, i.e., $\Pr[e_{ij}(u,q)=e(u,r)]=\frac{1}{d_{ij}^{\text{out}}(u)}$. The expectation of $I_{S_{ij}}(u)$ is exactly the contribution of edges leaving u to $w(S,\overline{S})$, so $I_{S_{ij}}(u)$ is unbiased.

For the rest of the proof, we upper bound the variance of I_S. We assume without loss of generality that $J_S=0$, i.e., no sparse edges were ever stored and removed by Algorithm 2. This is because we are trying to prove the statement

$$\text{Var}\left[I_S\right]\le O\left(\frac{\beta}{\alpha\lambda}\right)w(S,\overline{S})^2 = O\left(\frac{\beta}{\alpha\lambda}\right)\cdot\left(\mathbb{E}\left[I_S\right]+J_S\right)^2,$$

so setting $J_S=0$ only makes the right-hand side smaller and hence, the proof more difficult.

We introduce some notation: recall that $(V_{ij})_j$ is the set of dense components of G_i and $S_{ij}=V_{ij}\cap S$. We use $X_{ij}=|E_i(S_{ij},\overline{S_{ij}})|$ to denote the *number* of edges from S_{ij} to $V_{ij}\cap\overline{S}$ in G_i, and $\overline{X_{ij}}=|E_i(\overline{S_{ij}},S_{ij})|$ the number of edges in the reverse direction. Let $X_i=\sum_j X_{ij}$ and $\overline{X_i}=\sum_j\overline{X_{ij}}$, so that X_i is the total number of dense-component edges that go from S to $\overline{S}$ in G_i.

Since there are no λ-sparse cuts (defined in (4)) at the end of Algorithm 2, we have $X_{ij}+\overline{X_{ij}}>\lambda\min(|S_{ij}|,|\overline{S_{ij}}|)$. Since we assume $|S_{ij}|\le|\overline{S_{ij}}|$, this condition implies the following for every dense component V_{ij}, $\lambda\left|S_{ij}\right|\le X_{ij}+\overline{X_{ij}}$.

Fix any $u\in S_{ij}$. We first upper bound $\text{Var}\left[I_{S_{ij}}(u)\right]$ and then work our way up the definition of I_S. Since $\chi_{ij}(u,q)$ is a Bernoulli random variable with mean $\left|E_i(u,\overline{S_{ij}})\right|/d_{ij}^{\text{out}}(u)$, its variance is

$$\text{Var}\left[\chi_{ij}(u,q)\right]=\frac{\left|E_i(u,\overline{S_{ij}})\right|}{d_{ij}^{\text{out}}(u)}\cdot\frac{\left|E_i(u,S_{ij})\right|}{d_{ij}^{\text{out}}(u)}.$$

Now from the definition of $I_{S_{ij}}(u)$, we have

$$\begin{aligned}
\operatorname{Var}\left[I_{S_{ij}}(u)\right] &= \frac{d_{ij}^{\text{out}}(u)^2}{\alpha^2}\sum_{q=1}^{\alpha}\operatorname{Var}\left[\chi_{ij}(u,q)\right]w_{ij}(u,q)^2 \\
&\le \frac{d_{ij}^{\text{out}}(u)^2}{\alpha^2}\cdot\alpha\cdot\frac{\left|E_i(u,\overline{S_{ij}})\right|}{d_{ij}^{\text{out}}(u)}\cdot\frac{\left|E_i(u,S_{ij})\right|}{d_{ij}^{\text{out}}(u)}\cdot 2^{2i} && (w_e \le 2^i \text{ for all } e\in E_i) \\
&= \frac{2^{2i}}{\alpha}\left|E_i(u,\overline{S_{ij}})\right|\cdot\left|E_i(u,S_{ij})\right| \\
&\le \frac{2^{2i}}{\alpha}\left|E_i(u,\overline{S_{ij}})\right|\cdot\left|S_{ij}\right|. && (\left|E_i(u,S_{ij})\right| \le |S_{ij}|)
\end{aligned}$$

In Algorithm 3, we set $I_{V_{ij}} = \sum_{u\in S_{ij}} I_{S_{ij}}(u)$, so

$$\begin{aligned}
\operatorname{Var}\left[I_{V_{ij}}\right] = \sum_{u\in S_{ij}}\operatorname{Var}\left[I_{S_{ij}}(u)\right] &\le \sum_{u\in S_{ij}}\frac{2^{2i}}{\alpha}\left|S_{ij}\right|\cdot\left|E_i(u,\overline{S_{ij}})\right| \\
&= \frac{2^{2i}}{\alpha}\cdot\left|S_{ij}\right|\cdot X_{ij} && (X_{ij} = \left|E_i(S_{ij},\overline{S_{ij}})\right|) \\
&\le \frac{2^{2i}}{\alpha\lambda}\left(X_{ij}+\overline{X_{ij}}\right)X_{ij}. && ((S_{ij},\overline{S_{ij}}) \text{ is not } \lambda\text{-sparse})
\end{aligned}$$

Summing across every dense component V_{ij} in G_i, we get

$$\begin{aligned}
\operatorname{Var}\left[I_{G_i}\right] = \sum_j \operatorname{Var}\left[I_{V_{ij}}\right] &\le \frac{2^{2i}}{\alpha\lambda}\sum_j\left(X_{ij}+\overline{X_{ij}}\right)X_{ij} \\
&\le \frac{2^{2i}}{\alpha\lambda}\left(X_i+\overline{X}_i\right)X_i. && (X_i = \textstyle\sum_j X_{ij} \text{ and } \overline{X_i} = \sum_j \overline{X_{ij}})
\end{aligned}$$

Finally, we sum across the weight classes indexed by i to obtain

$$\begin{aligned}
\operatorname{Var}\left[I_S\right] &= \sum_i \operatorname{Var}\left[I_{G_i}\right] \\
&\le \frac{1}{\alpha\lambda}\sum_i\left(2^i\right)^2\left(X_i+\overline{X}_i\right)X_i \\
&= \frac{1}{\alpha\lambda}\left[\sum_i\left(2^iX_i\right)^2+\sum_i 2^i\overline{X}_i\cdot\sum_i 2^iX_i\right] \\
&\le \frac{4}{\alpha\lambda}\left[w(S,\overline{S})^2+w(\overline{S},S)\cdot w(S,\overline{S})\right] && (w_e \ge 2^{i-1} \text{ for all } e\in E_i) \\
&\le \frac{4}{\alpha\lambda}\left[w(S,\overline{S})^2+\beta w(S,\overline{S})^2\right] && (w(\overline{S},S)\le\beta w(S,\overline{S})) \\
&= O\left(\frac{\beta}{\alpha\lambda}\right)w(S,\overline{S})^2. && \blacktriangleleft
\end{aligned}$$

5.2 For-Each Cut Sketch: Faster Algorithms

We can speed up the algorithms in the previous section and prove the following theorem.

▶ **Theorem 23.** *Consider the same setting as in Theorem 19. That is, a $(1\pm\epsilon)$ for-each cut sketch of size $O(\beta^{1/2}n\log^5 n/\epsilon)$ bits exists for any n-vertex β-balanced graph G. Now in addition, we can compute such a cut sketch in time $\widetilde{O}(m+\beta^{1/2}n/\epsilon)$.*

For undirected graphs, Jambulapati and Sidford [21] showed how to construct for-each cut sketches in nearly-linear time. Instead of trying to repeatedly find sparse cuts, they showed how to sketch expander graphs (graphs with high conductance) and then decompose the input graph using expander partitioning algorithms.

Intuitively, we should be able to speed up our algorithm using a similar approach, because when we partition the graph by removing sparse cuts, we do not look at the direction of the edges. However, the analysis in [21] does not apply to our setting because they focus on sketching quadratic forms. The quadratic form of a directed Laplacian ignores edge directions and hence does not preserve the directed cut values. On a more technical level, their analysis relies heavily on the notion of conductance, which is not canonically defined for directed graphs. In our setting, we cannot bound the variance of our estimator even if we have a directed graph whose undirected version is an expander (see the full paper for more details).

Because our main focus in this paper is to derive cut sketches with *optimal size* (especially with a tight dependence on β) rather than to obtain best runtime of computing such cut sketches, we defer the proof of Theorem 23 to the full paper.

6 For-Each Cut Sketch: $\Omega(n \cdot \sqrt{\beta/\epsilon})$ Lower Bound

In this section, we prove that the size of for-each cut sketches must scale with $\sqrt{\beta}$.

▶ **Theorem 24.** *Fix $\beta \geq 1$ and $0 < \epsilon < 1$ with $\left(\beta/\epsilon\right)^{1/2} \leq \frac{n}{2}$. A $(1 \pm \epsilon)$ for-each cut sketching algorithm for n-node β-balanced graphs must output $\Omega(n \cdot (\beta/\epsilon)^{1/2})$ bits in the worst case.*

To prove this, we will need the following folklore result from communication complexity:

▶ **Lemma 25.** *Given a bit string $s \in \{0,1\}^N$, if there is a data structure D that allows one to recover each bit of s with marginal probability at least $2/3$, then D must use $\Omega(N)$ bits.*

We first prove a special case of our lower bound for specific values of $\beta = \Theta(n^2)$ and $\epsilon = \Theta(1)$ (Lemma 26). The proof for this special case is easier to explain and it contains the key ingredients of our construction for the general lower bound.

▶ **Lemma 26.** *For $\beta = n^2$ and $\epsilon = \frac{1}{10}$, any $(1 \pm \epsilon)$ for-each cut sketching algorithm for n-node β-balanced graphs must output $\Omega(n \cdot \beta^{1/2})$ bits in the worst case.*

Proof. At a high level, we will encode a bit string s of length $\Omega(n^2)$ into an n-node β-balanced graph, such that given a $(1 \pm \epsilon)$ for-each cut sketch, we can recover each bit of s with high constant probability. Then by Lemma 25, the cut sketch must have use $\Omega(|s|) = \Omega(n^2) = \Omega(n\beta^{1/2})$ bits.

Given a bit string s of length $\frac{n^2}{4}$, we construct a graph as follows. We start with an $\frac{n}{2} \times \frac{n}{2}$ complete bipartite digraph where edges go from left to right. We set the weight of the i-th bipartite edge to $s_i + 1$ (so either 1 or 2). We add a unit-weight cycle that leaves each side exactly once. See Fig. 2 for an example of our construction.

We first show that the graph is β-balanced for $\beta = n^2$. The graph is strongly connected because it contains a cycle. Note that all edge weights are in $[1, 2]$ and there are in total $\frac{n^2}{4} + n \leq \frac{n^2}{2}$ edges in the graph. Therefore, for every non-empty set $S \subset V$, the total weight of edges leaving (or entering) S is at least 1 and at most n^2, so the graph is (n^2)-balanced.

It remains to show that we can recover each bit of s from a $(1 \pm \epsilon)$ cut sketch. Let L denote the left vertices and R the right vertices. Fix any coordinate of s and suppose it corresponds to the edge (u, v) for some $u \in L$ and $v \in R$. To recover this bit of s, we need to decide whether $w(u, v)$ is 1 or 2. Consider the cut value leaving $S = \{u\} \cup R \setminus \{v\}$. The cycle contributes a fixed amount to this cut (independent of the weights of the bipartite

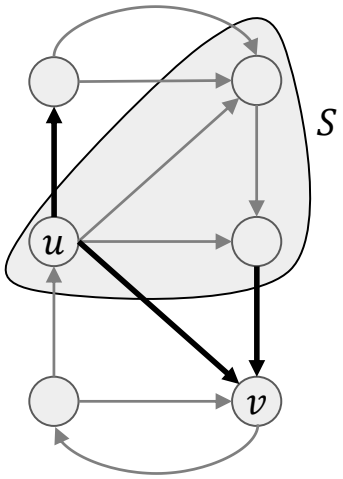

Figure 2 In this example, the cut value $w(S, \overline{S})$ is 2 or 3, depending on the value of $w(u, v)$. Thus, a (1 ± 0.1)-approximation to $w(S, \overline{S})$ allows us to decode the bit in s corresponding to edge (u, v). (For readability we omit other bipartite edges from L to R.)

edges), which is at most 3. More importantly, (u, v) is the only bipartite edge leaving S. Since $\epsilon = \frac{1}{10}$ and the sketch returns this cut value within a factor of $(1 \pm \epsilon)$ with probability at least $2/3$, we can recover $w(u, v)$ with probability at least $2/3$. ◀

Our lower bound construction for general values of β and ϵ builds on the one in the proof of Lemma 26. At a high level, instead of using a bipartite graph with two clusters, we will use multiple clusters where the size of each cluster depends on β and ϵ.

Proof of Theorem 24. Let $k = \sqrt{\beta/\epsilon}$. We will encode a bit string s of length $\Omega(nk)$ into an n-node graph G such that (1) G is (3β)-balanced, and (2) we can recover each bit of s with high constant probability given a $(1 \pm c \cdot \epsilon)$ for-each cut sketch of G where $c = 10^{-2}$. By Lemma 25, the cut sketch must have at least $\Omega(nk) = \Omega(n \cdot (\beta/\epsilon)^{1/2})$ bits.

Without loss of generality, we assume k is an integer and n is a multiple of k. We partition n vertices into $t = n/k$ clusters of size k, which we denote by $V_1, \ldots, V_t$. Since we assume $n \geq 2k$, there are at least two clusters.

Let s be a bit string of length $k^2(t-1) = \Omega(nk)$. We partition s into $(t-1)$ blocks where each block has length k^2. We encode the i-th block of s in a $k \times k$ complete bipartite digraph where edges go from V_i to V_{i+1}. As in the proof of Lemma 26, a bipartite edge (u, v) for $u \in V_i$ and $v \in V_{i+1}$ has weight $s_{i,(u,v)} + 1$ (so either 1 or 2). For every $1 \leq i \leq t-1$, we add a cycle between V_i and V_{i+1} that leaves V_i and V_{i+1} exactly once. Now, in contrast to the previous construction, these cycle edges have weight $1/\epsilon$.

We first show that G is (3β)-balanced. Fix any non-empty set $S \subset V$. Let G_i denote the subgraph between V_i and V_{i+1} which contains k^2 bipartite edges and one cycle. Let $w_i(S, \overline{S})$ denote the total weight of edges leaving S in G_i. We will show that $w_i(S, \overline{S})$ and $w_i(S, \overline{S})$ are within a factor of 3β of each other. Because G is strongly connected and $w(S, \overline{S}) = \sum_{i=1}^{t-1} w_i(S, \overline{S})$, we can conclude that G is (3β)-balanced.

Without loss of generality, we assume both $w_i(S, \overline{S})$ and $w_i(\overline{S}, S)$ are positive. The cut value $w_i(S, \overline{S})$ remains the same if we restrict G_i on vertices $(V_i \cup V_{i+1})$ and consider the cut query $S \cap (V_i \cup V_{i+1})$. The cycle contributes equally in both directions, so without loss of generality, we can assume the cycle has minimum contribution, which is $\frac{1}{\epsilon}$. (If the cycle

contributes more, the cut is more balanced.) The total weight of the bipartite edges is at most $2k^2 = \frac{2\beta}{\epsilon}$. Therefore, the ratio between the cut values in both directions is at most $\frac{(2\beta/\epsilon)+(1/\epsilon)}{1/\epsilon} = 2\beta + 1 \leq 3\beta$.

It remains to show that we can recover every bit of s from a cut sketch. Fix any bit of s. Suppose this bit $s_{i,(u,v)}$ corresponds to the edge (u, v) for some $u \in V_i$ and $v \in V_{i+1}$, we query the cut value leaving $S_{(u,v)} = \{u\} \cup \left(V_{i+1} \setminus \{v\}\right) \bigcup_{j=i+2}^{t-1} V_j$. The only bipartite edge leaving $S_{(u,v)}$ is the edge (u, v), which has weight either 1 or 2. There are at most 5 cycle edges leaving $S_{(u,v)}$ (at most 1 from G_{i-1}, 3 from G_i, and 1 from G_{i+1}), whose total weight is fixed and at most $\frac{5}{\epsilon}$. Therefore, if we can compute an $(1 \pm c \cdot \epsilon)$ approximation to the cut value for $c = 10^{-2}$, we can recover the corresponding bit of s. ◀

7 Conclusion

In this paper, we considered the question of sparsifying directed graphs. We focused on graphs that are β-balanced, where the ratio between the cut value in two directions is at most β. We gave upper and lower bounds on the size of the cut sketch with almost tight dependence on β, under both the standard "for-all" notion (i.e., simultaneously preserving the value of all cuts) and the "for-each" notion (introduced by Andoni *et. al* [6]) of cut sparsification. More specifically, we showed that under the "for-all" notion, the linear dependence on β obtained by Ikeda and Tanigawa [20] is tight. For the "for-each" notion, we gave a data structure that preserves cut values whose size scales as $\sqrt{\beta}$, thereby beating the "for-all" lower bound. We also showed that this dependence on $\sqrt{\beta}$ is tight. Our lower bounds hold not only for sparsifiers (i.e., graph encodings), but also for arbitrary data structures.

An interesting direction for future work is to consider the *spectral* sparsification of directed graphs. Cohen et al. [14, 13] (see also Chu et al. [11]) introduced a novel definition of directed sparsification and leveraged it to solve directed Laplacian linear systems. However, their work is not immediately relevant to ours because their directed spectral sparsifiers do not necessarily preserve directed cut values. This motivates the following natural question: *is there a notion of spectral sparsification that generalizes cut sparsification in directed graphs?* (Note that this is indeed the case for undirected graphs, where spectral sparsifiers also preserve cut values.) A natural candidate would be a sparse graph that preserves $\sum_{(u,v)\in E} \left((x_u - x_v)^+\right)^2$ for all real vectors x, where $y^+ = \max(0, y)$. Note that if $x \in \{0, 1\}^{|V|}$, then this sum represents directed cut values, which is analogous to the correspondence between cut and spectral sparsification in undirected graphs. It would be interesting to explore if preserving this sum in directed graphs has interesting applications beyond preserving cuts, and if so, whether there exist sparse graphs that preserve this sum approximately for balanced directed graphs.

Abstract

In this work, we initiate the study of fault tolerant Max-Cut, where given an edge-weighted undirected graph $G = (V, E)$, the goal is to find a cut $S \subseteq V$ that maximizes the total weight of edges that cross S even after an adversary removes k vertices from G. We consider two types of adversaries: an adaptive adversary that sees the outcome of the random coin tosses used by the algorithm, and an oblivious adversary that does not. For any constant number of failures k we present an approximation of $(0.878-\epsilon)$ against an adaptive adversary and of $\alpha_{GW} \approx 0.8786$ against an oblivious adversary (here α_{GW} is the approximation achieved by the random hyperplane algorithm of [Goemans-Williamson J. ACM '95]). Additionally, we present a hardness of approximation of α_{GW} against both types of adversaries, rendering our results (virtually) tight.

The non-linear nature of the fault tolerant objective makes the design and analysis of algorithms harder when compared to the classic Max-Cut. Hence, we employ approaches ranging from multi-objective optimization to LP duality and the ellipsoid algorithm to obtain our results.

1 Introduction

In this work, we initiate the study of *fault tolerant Max-Cut*. In the classic Max-Cut problem, we are given an undirected graph $G = (V, E)$ equipped with non-negative edge weights $w : E \to \mathbb{R}_+$. The goal is to find a cut $S \subseteq V$ that maximizes the total weight of edges that cross S. Max-Cut is one of Karp's 21 NP-complete problems [37] and has been for close to three decades a case study for the introduction of new approaches both in the theory of algorithms and the complexity theory. Perhaps the two most prominent examples of the above are: (1) the random hyperplane rounding method of Goemans and Williamson for semi-definite programs [29], which yields an approximation of $\alpha_{GW} \approx 0.8786$ for Max-Cut; and (2) the Unique Games Conjecture of Khot [38]. The former has opened an entirely new area in the field of approximation algorithms with applications to a wide range of problems, *e.g.*, Max-DiCut [26,42,44], Max-Bisection [5,53], Max-Agreement [20,56], Max-2SAT [26,42],

Max-SAT [4, 7], and Cut Norm [2], to name a few. The latter has been a dominant method for proving hardness of approximation results in the last two decades, *e.g.*, the celebrated tight hardness for Max-Cut [39, 45], and Vertex Cover [40].

Motivated by large scale real life systems, fault tolerant algorithms seek to find a solution to a given optimization problem that is resilient to failures of some parts of the input. The above can be intuitively formulated as a two step process: (1) the algorithm finds a solution to the problem at hand; and (2) an adversary removes parts of the input. The goal of the algorithm is that no matter which part of the input the adversary removes, the remaining solution after removal still retains some desired properties despite the removal. Typically, the focus of fault tolerance has been network design problems, *e.g.*, BFS [33, 48, 50–52] and spanners [15–17, 25, 41, 47, 55]. Additional related algorithmic problems for which fault tolerant algorithms were studied include, *e.g.*, single source reachability [9, 10], connected dominating set [18, 59], and facility location [23, 32, 36, 57].

In this work, we initiate the study of fault tolerant Max-Cut, where the adversary can remove vertices from the graph (all edges touching the removed vertices are also deleted). Intuitively, fault tolerant Max-Cut can be seen as a two players game, in which one player (the algorithm) chooses a cut and the other player (the adversary) removes up to a prespecified number k of vertices. The algorithm desires to maximize the total weight of edges crossing the cut, while the adversary aims to minimize the total weight of edges crossing the cut.

We study two types of adversaries. The first is an *adaptive adversary* that chooses which k vertices to fail *after* seeing the cut the algorithm produces. Specifically, the adaptive adversary knows the input, how the algorithm operates, and if the algorithm is randomized, the adaptive adversary also knows the outcome of all random coin tosses used by the algorithm. The second type of adversary is an *oblivious adversary*. Similarly to the adaptive adversary, the oblivious adversary knows the input and how the algorithm operates. However, in contrast to the adaptive adversary, the oblivious adversary does not know the outcome of the random coin tosses used by the algorithm, in case the latter is randomized (equivalently, the oblivious adversary only knows the distribution over cuts the algorithm produces). Thus, the oblivious adversary is required to choose which k vertices to fail without the knowledge of which cut was sampled. To the best of our knowledge only adaptive adversaries were studied in the fault tolerance literature.

The Challenges. The fault tolerant Max-Cut problem differs considerably from classic Max-Cut for several reasons. First, the structure of the solutions may be different. Specifically, there are instances for which an optimal solution to fault tolerant Max-Cut is not an optimal solution to classic Max-Cut, and vice versa (refer to [19] for details). Furthermore, it might be the case that the ratio between the values of the optimal solutions is large or even unbounded.

Second, the application of known techniques (which can be successfully applied to Max-Cut) to fault tolerant Max-Cut imposes some obstacles that arise from the non-linear nature of the fault tolerant objective. For example, the random hyperplane rounding method of Goemans and Williamson cannot be analyzed in a straightforward manner as one is required to lower bound the expectation of the minimum value (over all possible actions of the adversary) of the cut the random hyperplane defines, as opposed to just the expected value of the cut the random hyperplane defines. Moreover, even analyzing the simplest known algorithm for Max-Cut, *i.e.*, choosing a uniform random cut, requires great care (refer to [19] for further details). Hence, the design and analysis of algorithms for fault tolerant Max-Cut requires some new insights into the problem.

1.1 Our Contributions

Adaptive Adversary. When focusing on an adaptive adversary, our main result is an (almost) tight approximation of $0.878-\epsilon$, for any constant number k of failures and unweighted graphs. This is summarized in the following theorem (it is important to note that the constant in the theorem is slightly smaller than the Goemans-Williamson approximation factor α_{GW}).

▶ **Theorem 1.1.** *For every constant $k > 0$ and $\epsilon > 0$, there is a polynomial time $(0.878-\epsilon)$-approximation algorithm for fault tolerant Max-Cut on unweighted graphs against an adaptive adversary and k faults.*

Our algorithm is based on viewing fault tolerant Max-Cut against an adaptive adversary as a multi-objective optimization problem, where for every possible subset of k vertices the adversary can fail, one can define a different objective. The goal is to maximize the worst, *i.e.*, minimum, objective. This approach does not suffice, since all known results for the multi-objective variant of Max-Cut (formally known as Simultaneous Max-Cut [12, 13]) can handle only a constant number of objectives. In our case, even when a single failure is allowed, the number of objectives equals n. Hence, to overcome this difficulty, we incorporate local search into the above multi-objective approach to obtain the claimed result in Theorem 1.1.

Oblivious Adversary. When focusing on an oblivious adversary, our main result is a tight approximation of α_{GW} for any constant number k of failures. However, in contrast to the adaptive adversary setting, this result holds for general weighted graphs and achieves the α_{GW}-approximation guarantee exactly. This is summarized in the following theorem.

▶ **Theorem 1.2.** *For every constant $k > 0$, there is a polynomial time α_{GW}-approximation algorithm for fault tolerant Max-Cut on general weighted graphs against an oblivious adversary and k faults.*

The approach we adopt for approximating fault tolerant Max-Cut against an oblivious adversary significantly differs from the approach taken against an adaptive adversary. Surprisingly, our algorithm is based on an approximation-preserving reduction from fault tolerant Max-Cut to the classic Max-Cut problem. This reduction uses LP duality alongside the ellipsoid algorithm and is achieved by presenting a suitable approximate dual separation oracle for a configuration LP that encodes the distribution over cuts that the algorithm produces.

Hardness of Approximation. We prove that fault tolerant Max-Cut in unweighted graphs, against both adaptive and oblivious adversaries, cannot be approximated better than α_{GW} without breaking well-known hardness assumptions. It is important to note that this settles the approximability of the oblivious adversary setting (see Theorem 1.2 above), and almost settles the approximability of the adaptive adversary setting (see Theorem 1.1 above) as the constant in Theorem 1.1 is slightly smaller than α_{GW}.

▶ **Theorem 1.3.** *Assuming the Unique Games Conjecture and $NP \nsubseteq BPP$, there is no polynomial time $(\alpha_{GW}+\epsilon)$-approximation algorithm for fault tolerant Max-Cut in unweighted graphs, for any constant $\epsilon > 0$. This holds for both adaptive and oblivious adversaries.*

Simple Purely Combinatorial Algorithms. While Theorem 1.1 provides an (almost) tight result against an adaptive adversary, and Theorem 1.2 provides a tight result against an oblivious adversary, the techniques we employ yield algorithms which are polynomial but

not simple. For example, the work of [12] for approximating Simultaneous Max-Cut, an important ingredient in the design of our algorithm against an adaptive adversary, is based on SDP hierarchies and the running time is exponential in the number of objectives. In contrast, the classic Max-Cut problem admits some very simple and fast heuristics, *e.g.*, choosing a random uniform cut. Thus, we also aim to study simple and purely combinatorial algorithms for fault tolerant Max-Cut.

We prove that fault tolerant Max-Cut does yield a simple purely combinatorial local search algorithm with a provable approximation guarantee against an adaptive adversary. Unfortunately, the classic local search for Max-Cut, that in each step moves a single vertex from one side of the cut to the other side, fails in the fault tolerant setting. Nonetheless, we prove that a local search that allows for a slightly richer family of local improvement steps suffices. This is summarized in the following theorem (refer to Section 3.2 for additional details).

▶ **Theorem 1.4.** *There is a purely combinatorial polynomial time* $1/2$*-approximation algorithm for fault tolerant Max-Cut on unweighted input graphs against an adaptive adversary and a single fault.*

We further study how a *uniform random cut* performs against both types of adversaries (deferred to the full version [19]), and prove that this performance depends on the type of the adversary. Specifically, for an oblivious adversary an approximation of $1/2$ is achieved, by a uniform random cut. However, this is not the case when considering an adaptive adversary, since we prove that a uniform random cut cannot achieve an approximation better than $1/4$.

1.2 Related Work

The weighted version of Max-Cut is one of Karp's NP-complete problems [37], and the unweighted version is also known to be NP-complete [27]. In general graphs, one cannot obtain an approximation factor better than $16/17$ for the undirected version, or better than $12/13$ for the directed version, unless $P = NP$ [34, 58]. The best known approximation for Max-Cut is the celebrated random hyperplane algorithm of Goemans and Williamson that obtains an approximation factor of roughly 0.8786 by rounding the natural semi-definite programming relaxation [29]. This is the best approximation that one can achieve, assuming the Unique Games Conjecture of Khot [39] and $P \neq NP$.

The problem of fault tolerant Max-Cut against an adaptive adversary that we introduce in this paper can be viewed as a special case of Simultaneous Max-Cut, in which the input is a collection of τ weighted graphs on the same vertex set and the goal is to partition the vertices into two parts, such that the size of the cut is large in every given graph. In a straightforward manner, our problem would imply $\tau = \binom{n}{k}$, which is unacceptable since the known approximations for Simultaneous Max-Cut are for a constant number of instances only [3, 12, 13]. Nonetheless, we do use the algorithm from [12] to obtain an algorithm that achieves an approximation of 0.878 for fault tolerant Max-Cut against an adaptive adversary. The state-of-the-art for Simultaneous Max-Cut is a polynomial 0.878-approximation for any constant number of input graphs [12], which is nearly optimal since assuming the Unique Games conjecture, Simultaneous Max-Cut cannot be approximated better than $(\alpha_{GW} - \delta)$ (where $\delta \geq 10^{-5}$) [11].

One more notion of resilience is that of robust submodular maximization, see, *e.g.*, [6, 46]. Given a submodular function f and, *e.g.*, a cardinality constraint k, a set A is robust against τ failures if $A = \arg\max_{A \subseteq V, |A| \leq k} \min_{Z \subseteq A, |Z| \leq \tau} f(A - Z)$, i.e., a subset of size at most k that achieves the maximal value after at most τ elements are removed from the solution.

Note that this notion of robustness differs from fault tolerance. The reason is that the failed elements are removed from the solution, as opposed to removed from the instance. Specifically, when considering the cut function of an undirected graph (which is submodular) the removal of a vertex from S (as in robust) differs from removing the same vertex from the graph (as in fault tolerant).

Due to the importance of coping with failures, the fault tolerance of many additional fundamental problems has been extensively studied. Prime examples are replacement paths [1, 21, 22, 30, 54], BFS trees [33, 48, 50–52], spanners [15–17, 25, 41, 47, 55], connected dominating sets [18, 59], and more [8–10, 14, 23, 32, 36, 57]

Fault tolerance was also studied in the distributed setting, such as for BFS trees [28], MST [28], and spanners [25, 49].

Paper Organization. Section 2 contains all required formal definitions and preliminary lemmas used throughout the paper. Section 3 deals with the adaptive adversary, whereas Section 4 deals with the oblivious adversary. In Section 5 we show a hardness of approximation result. Missing proofs and the analysis of a random cut appear in the full version [19].

2 Preliminaries

Graph Notations. We consider only edge-weighted graphs $G = (V, E, w)$ with positive integer weights w_e assigned to the edges $e \in E$. By *unweighted* graphs we mean graphs with $w_e = 1$, for all $e \in E$. A *cut* S in a graph $G = (V, E, w)$ is a subset of vertices $S \subseteq V$. We let $\delta(S, G) = \{e \in E : |e \cap S| = 1\}$ denote the set of all *crossing edges* of S in the graph G. The *size* or *weight* of a cut S, denoted by $C_{S,G}$, is the total weight of the crossing edges: $C_{S,G} = \sum_{e \in \delta(S,G)} w_e$. When G is clear from the context, we use C_S and $\delta(S)$.

For a set $F \subseteq V$ of vertices, the *degree* $d(F)$ of F is the total weight of edges adjacent to F: $d(F) = \sum_{e \in E : e \cap F \neq \emptyset} w_e$. For a subset $F \subseteq V$ and cut $S \subseteq V$, the *crossing degree* $d_S(F)$ of F is the total weight of edges adjacent to F that cross S: $d_S(F) = \sum_{e \in \delta(S) : e \cap F \neq \emptyset} w_e$. We use $d(v)$ and $d_S(v)$, if $F = \{v\}$. We also let $n = |V|$, $m = |E|$, and $\Delta = \max_{v \in V} d(v)$. Finally, we let 2^V and $\binom{V}{k}$ denote the collection of all and all size-k subsets of V, respectively.

The Adaptive Adversary. We define the *k-FT value of a cut against an adaptive adversary* to be the minimal size of the cut, subsequent to a failure of any k vertices. Formally, for a cut S in a graph $G = (V, E, w)$ and a constant $k > 0$, the k-FT value of S is defined as $\varphi(S, k, G) = \min_{F \in \binom{V}{k}} C_{S-F, G-F}$.

▶ **Definition 2.1** (*k-AFTcut*). *Given an edge-weighted graph $G = (V, E, w)$ and a number $k \in \mathbb{N}$, a cut S is a* k-adaptive fault tolerant cut*, or k-AFTcut for short, if $\varphi(S, k, G) = \max_{S' \subseteq V} \{\varphi(S', k, G)\}$.*

We usually omit G and/or k from $\varphi(S, k, G)$ when G is clear from the context and $k = 1$. The *Max-Cut* problem, i.e., that of finding a cut with the largest size, corresponds to the special case $k = 0$, but will always be denoted by Max-Cut.

The Oblivious Adversary. We represent a randomized algorithm that finds a cut in a graph $G = (V, E, w)$ by a probability distribution $\mathcal{D}$ over all possible cuts 2^V. For a distribution $\mathcal{D}$ over cuts, we define the *k-FT value of $\mathcal{D}$* to be the minimal expected size of the cut, subsequent to the failure of any k vertices. Formally, for a graph $G = (V, E, w)$, a distribution $\mathcal{D}$ over cuts and a constant $k > 0$, we define the k-FT value of $\mathcal{D}$, denoted by $\mu(\mathcal{D}, k, G)$, as $\mu(\mathcal{D}, k, G) = \min_{F \in \binom{V}{k}} \mathop{\mathbb{E}}_{S \sim \mathcal{D}} [C_{S-F, G-F}]$.

▶ **Definition 2.2** (*k-OFTcut*). *Given an edge-weighted graph $G = (V, E, w)$ and a number $k \in \mathbb{N}$, a distribution $\mathcal{D}$ over all cuts 2^V is a k-oblivious fault tolerant cut, or k-OFTcut for short, if $\mu(\mathcal{D}, k, G) = \max_{\mathcal{D}'} \{\mu(\mathcal{D}', k, G)\}$.*

Note that here we assume the adversary chooses the set F of faults deterministically; it easily follows from the linearity of expectation that the adversary always has a deterministic best choice – a subset that has the largest expected crossing degree.

Greedy steps and stable cuts. We assume here that we are given an *unweighted* graph $G = (V, E)$. A key observation in our algorithms against an adaptive adversary is that any solution can be transformed into another one where each vertex contributes *many* of its edges to the cut. If a vertex contributes too little, we can just move it to the opposite side of the cut: while this could increase the crossing degree of some vertices (negative contribution to the FT value), it increases the cut size by more, giving a positive net contribution to the FT value. We prove this formally in Lemma 2.4, after some formal definitions.

For every $v \in V$ and $S \subseteq V$, let $S \oplus v$ denote the cut obtained from S by switching v to its opposite side, that is, $S \oplus v = S - v$, if $v \in S$, and $S \oplus v = S \cup \{v\}$, otherwise. Given a subset $S \subseteq V$, a constant $k \in \mathbb{N}$, and a vertex $v \in V$, we say that replacing S with $S \oplus v$, i.e., moving v to its opposite side w.r.t. S, is a *k-greedy step* if $d_S(v) \leq (d(v) - k)/2$. A cut S is *k-stable* if it has no k-greedy step, that is, for every $v \in V$, it holds that $d_S(v) > (d(v) - k)/2$. For $k = 1$, we use *stable* instead of 1-stable.

▶ **Observation 2.3.** *For every cut S and a vertex v, it holds that $C_{S\oplus v} - C_S = d_{S\oplus v}(v) - d_S(v)$.*

▶ **Lemma 2.4.** *Let $v \in V$ be a vertex, $S \subseteq V$ be a cut, and $k > 0$ be an integer, such that $d_S(v) \leq (d(v) - k)/2$; then $C_{S\oplus v} \geq C_S + k$, and $\varphi(S \oplus v, k) \geq \varphi(S, k)$.*

Proof. Assume, without loss of generality, that $v \in S$ (otherwise, we swap S and $V - S$). Observation 2.3 implies that $C_{S\oplus v} \geq C_S + k$, since $d_S(v) + k \leq d(v) - d_S(v) = d_{S\oplus v}(v)$.

For the second claim, we show that for every $F \in \binom{V}{k}$, $C_{S-F,G-F} \leq C_{S\oplus v-F,G-F}$. Assume that $v \notin F$, as otherwise $S - F = S \oplus v - F$, and the claim holds trivially. Recall that $C_{S\oplus v} \geq C_S + k$. In addition, $d_{S\oplus v}(F) \leq d_S(F) + k$, since for every $u \in F$, at most one crossing edge is added to the cut (the edge $\{u, v\}$). Putting those together, we have that: $C_{S-F,G-F} = C_S - d_S(F) \leq C_{S\oplus v} - d_{S\oplus v}(F) = C_{S\oplus v-F,G-F}$. Since this holds for every F, we have that $\varphi(S \oplus v, k) \geq \varphi(S, k)$. ◀

By repeatedly applying a k-greedy step to a cut, we keep increasing the cut value, while not decreasing the k-FT value; thus, after at most m greedy steps, we have a k-stable cut with a k-FT value at least as good as the original one. We let StabilizeCut(G,S,k) denote this procedure, which takes as input a graph G, a cut S in G, and a number k, then starting with S, repeatedly applies a (arbitrary) k-greedy step, while there is one, and returns the obtained k-stable cut. The following corollary follows from the reasoning above (the second claim follows by applying StabilizeCut to an optimal *k-AFTcut*).

▶ **Corollary 2.5.** *Let S be a cut in graph $G = (V, E)$, and let k be a positive integer. Let $S' = \textsc{StabilizeCut}(G, S, k)$. It holds that S' is k-stable, $C_{S'} \geq C_S$ and $\varphi(S', k) \geq \varphi(S, k)$. In particular, every unweighted graph $G = (V, E)$ has a k-stable optimal k-AFTcut.*

3 Fault Tolerance Against an Adaptive Adversary

3.1 A 0.878-Approximation for Multiple Faults

In this section, we give a $(0.878-\epsilon)$-approximation algorithm for k-*AFTcut* on unweighted graphs, for constants $k, \epsilon > 0$. A core tool that we use in our algorithm is an algorithm for the *Simultaneous Max-Cut* problem, where given several graphs defined over the same vertex set, the goal is to find a cut that is large for all graphs simultaneously. A 0.878-approximation algorithm for this problem with a *constant* number of graphs has been given in [12]. The algorithm is based on semidefinite programming techniques.

The main idea behind our algorithm is to separate a constant number of "heavy" (high-degree) vertices for which the following holds; given a cut which is large subsequent to any failure of k *heavy* vertices, the cut is large even if light (non-heavy) vertices fail as well. For such a heavy set, a good approximation for Simultaneous Max-Cut on the instances obtained by removing each possibility of k heavy vertices from G, should be a good approximation for k-*AFTcut* on G. We give a greedy algorithm that selects the set of heavy vertices. We then consider two cases. We show that if the heavy vertices do not cover most of the edges in the graph (the "non-shallow" case), then an approximate solution for Simultaneous Max-Cut with respect to the heavy set gives an approximate solution for k-*AFTcut*. Otherwise (the "shallow" case), we identify a set of "super-heavy" vertices, which is shown to fail in any near-optimal solution. Therefore, finding a near-optimal solution for the original graph reduces to finding a near-optimal solution on the graph remaining by removing the "super-heavy" vertices. We show that it can be solved via brutforce, or by finding a good solution to Max-Cut (e.g., obtained via [29]). We prove the following theorem.

▶ **Theorem 1.1.** *For every constant $k > 0$ and $\epsilon > 0$, there is a polynomial time $(0.878-\epsilon)$-approximation algorithm for fault tolerant Max-Cut on unweighted graphs against an adaptive adversary and k faults.*

Before proceeding to the algorithm, we introduce the Simultaneous Max-Cut framework.

▶ **Definition 3.1** (Simultaneous Max-Cut). *Let V be a vertex set. We are given k edge-weighted graphs, $G_i = (V, E_i)$, $i = 1, \ldots, k$, on the vertex set V, where the weights are normalized, so that $\sum_{e \in E_i} w_e = 1$, for each i. In the (Pareto)* Simultaneous Max-Cut *problem, given the graphs G_i together with thresholds $c_i \in [0, 1]$, the goal is to find a cut $S^* \subseteq V$ such that $C_{S^*, G_i} \geq c_i$, for every i. We say that an algorithm is an α-approximation algorithm for the problem if for every input G_i, c_i, $i = 1, \ldots, k$, where there exists a cut S^* such that $C_{S^*, G_i} \geq c_i$ for every i, the algorithm returns a cut $\widetilde{S}$ such that $C_{\widetilde{S}, G_i} \geq \alpha c_i$, for every i.*

▶ **Theorem 3.2.** *[12] For every constant $k \geq 1$ and parameter $n \geq 1$, there is a polynomial-in-n algorithm that computes an α_{SMC}-approximate solution to any Simultaneous Max-Cut instance with k weighted graphs on a vertex set of size n, in which all non-zero edge-weights are lower-bounded by $\exp(n^{-c})$, for constants k and c, and $\alpha_{SMC} = 0.878$.*

We apply the Simultaneous Max-Cut framework for unweighted graphs G_i. We let SimultaneousMC denote the algorithm that gets as input a constant number of unweighted graphs G_i, $i = 1, \ldots, k$, and returns a cut $\widetilde{S}$ with the following property: for every cut S^* and number c such that $C_{S^*, G_i} \geq c$, for all i, it holds that $C_{\widetilde{S}, G_i} \geq \alpha_{SMC} \cdot c$, for all i. This can be achieved by combining the algorithm given in Theorem 3.2 (by appropriately scaling the edge-weights and the thresholds) with a binary search on c.

Algorithm 1 $(\alpha_{SMC} - \epsilon)$-approximation for k-*AFTcut*.

Input: $G = (V, E)$, k, ϵ
Output: $(\alpha_{SMC} - \epsilon)$-approximation for k-*AFTcut*
$H \leftarrow$ HeavyVertices(G, k, ϵ)
$\widetilde{S} \leftarrow$ SimultaneousMC($\{G_{\neg F} : F \in \binom{H}{k}\}$)
if $(H, \widetilde{S})$ *is shallow* **then**
  return ShallowFTCut(G, H, $\widetilde{S}$, k, ϵ)
else
  return $\widetilde{S}$

In addition to the Simultaneous Max-Cut algorithm, we use the α_{GW}-approximation for Max-Cut due to Goemans and Williamson [29], for $\alpha_{GW} \approx 0.8786$. We use Goemans-Williamson (with input G) to denote this algorithm. Note that the actual value of the approximation factor α_{SMC} is slightly larger than 0.878 but is less than α_{GW}.

The Main Algorithm. The inputs to the algorithm (see the pseudocode in Algorithm 1) are an unweighted graph G, and parameters k (number of faults) and ϵ (precision). First, it computes the set H of heavy vertices via the subroutine HeavyVertices, then applies SimultaneousMC on a collection $\{G_{\neg F} : F \in \binom{H}{k}\}$ of subgraphs containing one subgraph for every failure of k heavy vertices. The following notation is used: for a subset $F \subseteq V$ of vertices, we let $G_{\neg F} = (V, E_{\neg F})$, where $E_{\neg F} = \{e \in E : e \cap F = \emptyset\}$. Note that in $G_{\neg F}$, we do not remove the vertices of F from the graph, as opposed to $G - F$, but only the edges adjacent to F.

The pair $(H, \widetilde{S})$ is *shallow* if all vertices in $V - H$ have degree at most $3k$, and there are k vertices in H whose removal reduces the weight of $\widetilde{S}$ below $3k^2/\epsilon$. To state this formally, let us introduce a notation that will be useful later too. For a cut $S \subseteq V$, we use $C_{S-k\times H}$ to denote the smallest size of the cut after the failure of any k vertices from H, i.e., $C_{S-k\times H} = \min\{C_{S-F,G-F} : F \in \binom{H}{k}\}$. Thus, $(H, \widetilde{S})$ is shallow if we have $\max_{v\in V-H} d(v) \leq 3k$ and $C_{\widetilde{S}-k\times H} < 3k^2/\epsilon$. If $(H, \widetilde{S})$ is not shallow, the algorithm simply returns $\widetilde{S}$. Otherwise, we recompute the cut via ShallowFTCut, using alternative methods.

The proof of Theorem 1.1 is split into two parts, addressing shallow and non-shallow cases separately. The running time is dominated by Simultaneous Max-Cut. Before giving further details, let us mention how the proof follows from the main lemmas addressing those cases.

Proof of Theorem 1.1. Let G be a graph and let S^* be an optimal k-*AFTcut* on G. Let $\widetilde{S}$ be the output of Algorithm 1 on G, k, ϵ. We show that $\varphi(\widetilde{S}, k) \geq (\alpha_{SMC} - \epsilon) \cdot \varphi(S^*, k)$. Lemma 3.4 provides this for the non-shallow case, while Lemma 3.5 provides it in the shallow case. The algorithm is indeed polynomial, since the sub-routines are such, and the input to SimultaneousMC consists of $\binom{|H|}{k} = O(k/\epsilon)^k = O(1)$ subsets, where $|H| = O(k^2/\epsilon)$ is proven in Lemma 3.3. ◀

The selection of heavy vertices (Algorithm 2) is done by a simple greedy procedure, where we sequentially select vertices in the heavy set H in a non-increasing order by degree. The selection stops either when the remaining vertices $(V - H)$ have a small degree (at most $3k$) or when H has sufficiently many incident edges (used in Lemma 3.4). By Corollary 2.5, any cut can be transformed into one with a similar k-FT value, where every vertex v has crossing

Algorithm 2 HeavyVertices.

```
1 Input: G = (V, E), k, ε
2 Output: H ⊆ V, the set of heavy vertices
3 Let v_1, ..., v_n be an ordering of vertices by non-increasing degree
4 σ ← 0, i ← 1, H ← {v_1, ..., v_k}
5 while d(v_{k+i}) > (ε · α_SMC/k) · σ and d(v_{k+i}) > 3k do
6     σ ← σ + (d(v_{k+i}) − 3k)/4
7     H ← H ∪ {v_{k+i}}
8     i ← i + 1
9 return H
```

degree at least $(d(v)-k)/2$, and at least $(d(v)-3k)/2$, after k failures. Thus, heavy vertices are guaranteed to contribute σ in the "stable version" of every cut. The degree constraint ensures that we do not select vertices that are unnecessary, according to this logic, which helps us keep the size of H bounded.

▶ **Lemma 3.3.** *Algorithm 2 terminates within $t = 4(3k^2+k)/(\epsilon \cdot \alpha_{SMC})$ iterations. In particular, $|H| \leq t + k$.*

Proof. If $d(v_{k+t}) \leq 3k$, then by the condition in Line 5, the algorithm terminates before the t-th iteration; therefore, assume $d(v_{k+t}) > 3k$. For every $i \leq t$, after the i-th iteration, it holds that $\sigma_i = \sum_{j=1}^{i} (d(v_{k+j}) - 3k)/4$; thus, after t iterations,

$$\sigma_t = \sum_{j=1}^{t} \frac{d(v_{k+j})-3k}{4} \geq t \cdot \frac{d(v_{k+t})-3k}{4} = \frac{3k^2+k}{\epsilon \cdot \alpha_{SMC}} \cdot (d(v_{k+t})-3k)$$
$$= \frac{k}{\epsilon \cdot \alpha_{SMC}} \cdot d(v_{k+t}) + \frac{3k^2}{\epsilon \cdot \alpha_{SMC}} \cdot d(v_{k+t}) - \frac{3k^2(3k+1)}{\epsilon \cdot \alpha_{SMC}} \geq \frac{k}{\epsilon \cdot \alpha_{SMC}} d(v_{k+t}) \ ,$$

where in the first inequality, we use the fact that the vertices are processed in a non-increasing order of degrees, and in the last inequality, we use the assumption that $d(v_{k+t}) \geq 3k+1$. It follows that $d(v_{k+t}) \leq (\epsilon \cdot \alpha_{SMC}/k) \cdot \sigma_t$, and using $d(v_{k+t+1}) \leq d(v_{k+t})$, we get that the algorithm terminates within the first t iterations, by the condition in Line 5. ◀

Non-Shallow Case. In this case, we have either $\max_{v \in V-H} d(v) > 3k$ or $C_{\widetilde{S}-k\times H} \geq 3k^2/\epsilon$. If the former holds, we see from Algorithm 2 that for all light vertices $v \notin H$, $d(v) \leq (\epsilon \cdot \alpha_{SMC}/k) \cdot \sigma$. As it was observed earlier, Corollary 2.5 implies that every cut can be turned into another one with no smaller FT value, such that H contributes σ edges to the cut, even after k failures. In such a cut, a failure of k light vertices would affect only an ϵ fraction of the cut. A similar reasoning applies in the other case, when $\max_{v \in V-H} d(v) \leq 3k$: here we have $C_{\widetilde{S}-k\times H} \geq 3k^2/\epsilon$, which leads to similar conclusions as above. Putting these together with the near-optimality of $\widetilde{S}$, we obtain the main lemma of the non-shallow case (see [19]).

▶ **Lemma 3.4.** *If $(H, \widetilde{S})$ is not shallow, then it holds that $\varphi(\widetilde{S}, k) \geq (\alpha_{SMC} - \epsilon)\varphi(S^*_{ft}, k)$, for an optimal k-AFTcut S^*_{ft}.*

Shallow Case. Recall that in this case, we have that $\max_{v \in V-H} d(v) \leq 3k$, and $C_{\widetilde{S}-k\times H} < 3k^2/\epsilon$. The subroutine ShallowFTCut (Algorithm 3) constructs another cut, $\hat{S}$, which we prove in Lemma 3.5 is a $(\alpha_{SMC} - \epsilon)$-approximation for k-$AFTcut$. A key role in this case is played by the following (possibly empty) set $\hat{H}$ of *super-heavy* vertices, where $\hat{H} = \left\{v \in V : (d(v) - 3k)/2 > C_{\widetilde{S}-k\times H}/\alpha_{SMC}\right\}$. We show that $\hat{H}$ is contained in *every worst-case failure set* of a cut where there is no k-greedy step of a vertex in $\hat{H}$. We let $G_R = G - \hat{H}$, and let m_R be the number of edges in G_R. Note that the degree of every $v \notin \hat{H}$ is bounded by some constant ℓ.

Algorithm 3 ShallowFTCut.

```
Input: G = (V, E), H, S̃, k, ε
Output: Cut Ŝ ⊆ V
if m_R < 2kℓ/(α_SMC ε) then
    for every S' ⊆ V_R (V_R is of constant size) do
        Compute φ(S', k − |Ĥ|)
    Ŝ ← arg max_{S'⊆V_R} φ(S', k − |Ĥ|)
else
    Ŝ ← Goemans-Williamson(G_R)
while ∃v ∈ Ĥ such that d_Ŝ(v) ≤ (d(v) − k)/2 do
    Ŝ ← Ŝ ⊕ v
return Ŝ
```

First, we compute a near-optimal $(k-|\hat{H}|)$-$AFTcut$, $\hat{S}$, on G_R, then add $\hat{H}$ and repeatedly apply k-greedy steps to the vertices in $\hat{H}$, while there are any. To compute a cut in G_R, we distinguish between two cases. If there are many edges, i.e., $m_R \geq ck\ell/\epsilon$, for a constant c, then we let $\hat{S}$ =Goemans-Williamson(G_R). This suffices, since the cut is of size at least $m_R/2 = \Omega(k\ell/\epsilon)$, and the degrees are bounded by ℓ , so failures do not affect the cut size significantly, and we get an $(\alpha_{GW} - \epsilon)$-approximation. If, on the other hand, there are few edges, i.e., $m_R < ck\ell/\epsilon$, then we can compute an optimal $(k - |\hat{H}|)$-$AFTcut$ in G_R via brute-force. Also using that $\hat{H}$ belongs to every worst-cast failure set of a cut not having a k-greedy step of a vertex in $\hat{H}$ (including the one we constructed, and the optimal ones that exist by Corollary 2.5), we get the following main lemma (proved in the full version [19]).

▶ **Lemma 3.5.** *If $(H, \widetilde{S})$ is shallow, then it holds that $\varphi(\hat{S}, k) \geq (\alpha_{SMC} - \epsilon) \cdot \varphi(S^*_{ft}, k)$, for an optimal k-$AFTcut$ S^*_{ft}.*

3.2 A Combinatorial 1/2-Approximation for a Single Fault

In the case of a single fault, we have the following result, that is, a simple and efficient 1/2-approximation for the case of a single fault. Moreover, we show that an FT value of $(m - \Delta)/2$ can be achieved, for $\Delta \geq 3$, while $m - \Delta$ is an (easy) upper bound.

▶ **Theorem 1.4.** *There is a purely combinatorial polynomial time 1/2-approximation algorithm for fault tolerant Max-Cut on unweighted input graphs against an adaptive adversary and a single fault.*

In the discussion below, we call a vertex v *critical* for a cut S if $C_{S-v,G-v} = \varphi(S)$. It is well-known (and easy to show) that every stable cut is a 1/2-approximate Max-Cut. This even holds for $AFTcut$, with $\Delta = 2$ (see [19]). However, in general, while we know

Algorithm 4 Combinatorial 1/2-approximation for *AFTcut*.

Input: $G = (V, E)$
if $\Delta \leq 2$ **then return** $\textsc{StabilizeCut}(G, \emptyset, 1)$
$\widetilde{S} \leftarrow \emptyset$
while $\varphi(\widetilde{S}) < (m - \Delta)/2$ **do**
  if $\exists v, \varphi(\widetilde{S} \oplus v) \geq (m - \Delta)/2$ **then**
    $\widetilde{S} \leftarrow \widetilde{S} \oplus v$ `// type-0 step`
  else if $\exists v, d_{\widetilde{S}}(v) < d(v)/2$ **then**
    $\widetilde{S} \leftarrow \widetilde{S} \oplus v$ `// type-1 step`
  else if $\exists v, w, \left(d_{\widetilde{S}}(v) = \frac{d(v)}{2}$ **and** $\varphi(\widetilde{S} \oplus v) \geq \varphi(\widetilde{S})$ **and** $d_{\widetilde{S} \oplus v}(w) < \frac{d(w)}{2}\right)$ **then**
    $\widetilde{S} \leftarrow \widetilde{S} \oplus v$ `// build-up for another type-1 step`
  else
    $v \leftarrow$ a vertex such that $d_{\widetilde{S}}(v) = d(v)/2$ and $\varphi(\widetilde{S} \oplus v) > \varphi(\widetilde{S})$
    $\widetilde{S} \leftarrow \widetilde{S} \oplus v$ `// type-2 step`
return $\widetilde{S}$

that greedy steps (moving a vertex v with $d(v) < d_S(v)/2$) never decrease the FT value (Lemma 2.4), a stable cut can be a poor approximation for *AFTcut*. Consider, for example, a graph that consists of t triangles with a single common vertex u. Note that $d(u) = \Delta = 2t$, $d(v) = 2$, for every $v \neq u$, and $m = 3t$. The cut $S' = \{u\}$ is a stable cut, with $\varphi(S') = 0$. In order to transform S' into a 1/2-approximation, we have to decrease the crossing degree of the critical vertex u without decreasing the size of the cut. This can be done by moving a neighbor v of u from the opposite side of the cut, since $d_{S'}(v) = d(v)/2$.

In general, moving such vertex v (which we call a *neutral* move below) does not change the size of the cut, and decreases the crossing degree of u. Nevertheless, it does not always imply that the FT value increases, as there can be an additional critical vertex u' in S that is not affected, or that moving v creates a new critical vertex u'' with the same crossing degree as u.

Our algorithm (see Algorithm 4) is based on some key structural properties of stable cuts that we prove. Essentially, we show that any given cut S with FT value less than $(m - \Delta)/2$ either admits a *greedy step*, or a *neutral move followed by a greedy step*, or a *neutral move that increases the FT value*. Our algorithm is then a repeated application of such steps until the cut has the desired FT value; thus, it can be seen as a local search over two-move combinations, for maximizing the *sum* of the cut size and FT value.

Our key technical observation is that in a balanced cut S with an FT value less than $(m - \Delta)/2$, the critical vertex is unique. Moreover, letting $x_S(v) = d_S(v) - d(v)/2$ denote the *excess* contribution of a vertex v to the cut, it holds for the critical vertex u that $x_S(u) > \sum_{v \neq u} x_S(v) + \Delta - d(u)$, as proved in the following lemma.

▶ **Lemma 3.6.** *Let S be a stable cut in a graph $G = (V, E)$ such that $\varphi(S) < (m - \Delta)/2$. Then S has a unique critical vertex vertex u, and u satisfies*

$$d_S(u) > \sum_{v \neq u} x_S(v) + \Delta - d(u)/2 \ . \tag{1}$$

Moreover, u has a neighbor w in its opposite side of the cut, which satisfies $x_S(w) = 0$.

Proof. First, we show that S has a unique critical vertex. Since for every vertex v, $d_S(v) = d(v)/2 + x_S(v)$ and $\sum_{v\in V} d(v)/2 = m$, we get that

$$C_S = \frac{1}{2}\sum_{v\in V} d_S(v) = \frac{1}{2}\sum_{v\in V}\left(\frac{d(v)}{2} + x_S(v)\right) = \frac{m}{2} + \sum_{v\in V}\frac{x_S(v)}{2} \ . \tag{2}$$

Let u be a critical vertex, and assume, without loss of generality, that $u \in S$ (otherwise we swap S and $V-S$). On one hand, we have $\varphi(S) = C_S - d_S(u) = m/2 + \sum_{v\in V} x_S(v)/2 - d_S(u)$, and on the other hand, we have $\varphi(S) < (m-\Delta)/2$, which together imply:

$$m/2 + \sum_{v\in V} x_S(v)/2 - d_S(u) < (m-\Delta)/2 \ .$$

After a rearrangement, the latter implies (1). Using $d_S(u) = d(u)/2 + x_S(u)$ in (1) and simplifying, we get $x_S(u) > \sum_{v\neq u} x_S(v) + \Delta - d(u) \geq \sum_{v\neq u} x_S(v)$. Since u is an arbitrary critical vertex, this implies that u is the only critical vertex of S.

Next, let us show that there is a neighbor $w \in V - S$ of u (recall that $u \in S$) with $x_S(w) = 0$. Assume to the contrary that for every $v \notin S$ such that $\{u, v\} \in E$, it holds that $x_S(v) \geq 1/2$ (recall that S is stable, and hence $x_S(v)$ is a non-negative integer multiple of $1/2$). Using (2), this implies:

$$\begin{aligned} C_S = \frac{m}{2} + \sum_{v\in V}\frac{x_S(v)}{2} &\geq \frac{m}{2} + \frac{1}{2}\left(x_S(u) + \sum_{v:\{u,v\}\in\delta(S)} x_S(v)\right) \\ &\geq \frac{m}{2} + \frac{1}{2}\left(x_S(u) + \frac{d_S(u)}{2}\right) \geq \frac{m}{2} + x_S(u) \ , \end{aligned}$$

where we use $d_S(u) = |\{v : \{u, v\} \in \delta(S)\}|$ in the second inequality, and $d_S(u) = d(u)/2 + x_S(u) \geq 2x_S(u)$, in the third one. Since u is the critical vertex of S, this gives that

$$\varphi(S) = C_S - d_S(u) \geq \frac{m}{2} + x_S(u) - d_S(u) = \frac{m}{2} - \frac{d(u)}{2} \geq (m-\Delta)/2 \ ,$$

in contradiction to $\varphi(S) < (m-\Delta)/2$. This completes the proof. ◀

Note that in a stable cut S, $x_S(v)$ is a non-negative multiple of $1/2$, for all v. In most typical cases (e.g., when $d(u) < \Delta$, or when there are not too few nodes v with $x_S(v) > 0$), the inequality from the lemma quickly gives us the properties we claimed. However, covering all cases turns out to be quite tedious. The complete analysis can be found in the full version [19].

4 Fault Tolerance Against an Oblivious Adversary

We give an algorithm that approximates the fault tolerant Max-Cut against the oblivious adversary with (constant) k faults within an α_{GW}-approximation factor. The main idea is to frame the problem as a linear program (LP) with an exponential number of variables, then reduce the number of variables using a solution of its dual (with an exponential number of constraints but a polynomial number of variables). The dual is approximately solved by the ellipsoid algorithm together with an approximate separation oracle that is given by a Max-Cut algorithm. A similar approach has been used, e.g. in [35], for an unrelated problem.

▶ **Theorem 1.2.** *For every constant $k > 0$, there is a polynomial time α_{GW}-approximation algorithm for fault tolerant Max-Cut on general weighted graphs against an oblivious adversary and k faults.*

For simplicity, we present the algorithm for a single fault. In the full version [19], we show how to extend it to any constant number k of faults. The $OFTcut$ problem can be formulated as the following LP, $(Primal_1)$, with an exponential number of variables.

$$\max \quad \sum_{S\subseteq V} P_S \cdot \sum_{e\in\delta(S)} w_e - Z \qquad (Primal_1)$$

$$\text{s.t.} \quad \sum_{S\subseteq V} P_S \cdot \sum_{v:\{u,v\}\in\delta(S)} w_{\{u,v\}} \le Z \qquad \forall u \in V \qquad (3)$$

$$\sum_{S\subseteq V} P_S \le 1 \qquad (4)$$

$$0 \le P_S \qquad \forall S \subseteq V \qquad (5)$$

The variable P_S represents the probability assigned to the cut $S \subseteq V$. The variable Z represents the expected weight that the adversary removes from the graph. Constraints (4-5) make P_S a probability distribution. In (3), for each vertex u, we bound by Z the expected weight that is removed from the cut when u fails. To see that the left hand side is indeed the expected removed weight, note that it equals $\sum_{S\subseteq V} P_S \cdot d_S(u)$.

Consider the dual problem of the LP above, $(Dual_1)$:

$$\min \quad Y \qquad (Dual_1)$$

$$\text{s.t.} \quad \sum_{\{u,v\}\in\delta(S)} w_{\{u,v\}} - \sum_{u\in V} X_u \sum_{v:\{u,v\}\in\delta(S)} w_{\{u,v\}} \le Y \qquad \forall S \subseteq V \qquad (6)$$

$$\sum_{u\in V} X_u \le 1 \qquad (7)$$

$$0 \le X_u \qquad \forall u \in V \qquad (8)$$

The dual LP captures the following problem: The adversary picks a distribution over the vertices, and the algorithm picks a cut (depending on the choice of the adversary). The goal of the adversary is to choose its distribution (without knowing the cut choice of the algorithm) so as to minimize the expected cut size after a random failure from its distribution.

The dual LP $(Dual_1)$ has an exponential number of constraints but only $|V|+1$ variables. Such LPs can be solved efficiently via the *ellipsoid method* [31], given an efficient *separation oracle*. The latter is an algorithm that given an assignment of values to the variables of the LP, reports a violated constraint if the assignment is infeasible, or otherwise reports that it is feasible. For the particular case of $(Dual_1)$, the ellipsoid algorithm can be viewed as a binary search over the values of Y, such that in each stage (fixed Y), a black-box procedure does a polynomial number of queries to a given separation oracle, and either reports the first solution $\{X_u\}_{u\in V}$ it finds such that $\{X_u\}_{u\in V}, Y$ is feasible according to the oracle, or reports that there is no such solution.

Let us see what a separation oracle looks like in our case. For given values $\{X_u\}_{u\in V}, Y$, let $G' = (V', E', w')$ be the graph with weights $w'_{\{u,v\}} = (1-X_u-X_v)w_{\{u,v\}}$. With this notation, constraint (6) becomes $C_{S,G'} \le Y$. In order to see if a given assignment of variables is feasible, it thus suffices to find a maximum weight cut S^* in G' and test if $C_{S^*,G'} \le Y$. Since Max-Cut

is hard to solve exactly, we use an *approximate separation oracle*. Given $\{X_u\}_{u\in V}, Y$, it immediately returns the constraint (7), if it is violated, and otherwise computes a cut S_{ALG} in G' using a derandomized variant of the Goemans-Williamson algorithm [43], which we denote by Derandomized-Goemans-Williamson. Given an assignment $\{X_u\}_{u\in V}, Y$ to the variables in the LP, the oracle either outputs `feasible` or a violated constraint. If the size of the cut is larger than Y, it returns the violated constraint (6) corresponding to S_{ALG}, otherwise it reports that the solution is feasible (see Algorithm 5).

Algorithm 5 Approximate separation oracle.

Input: $\{X_u\}_{u\in V}, Y, G$
if $\sum_{u\in V} X_u > 1$ **then**
  return violated constraint $\sum_{u\in V} X_u \leq 1$
$S_{ALG} \leftarrow$ Derandomized-Goemans-Williamson(G')
if $C_{S_{ALG},G'} > Y$ **then**
  return violated constraint for subset S_{ALG}
else
  return `feasible`

We show (Lemma 4.1) that if $\{X_u\}_{u\in V}, Y$ is feasible, then the oracle reports that it is feasible, and otherwise, it either reports a violated constraint, or incorrectly reports that it is feasible, in which case, however, $\{X_u\}_{u\in V}, Y/\alpha_{GW}$ is feasible.

▶ **Lemma 4.1.** *Given an assignment $\{X_u\}_{u\in V}, Y$ to the variables in $(Dual_1)$ as input to the separation oracle in Algorithm 5, it holds that:*

1. *if the assignment is feasible, then the oracle returns* `feasible`*,*
2. *if the assignment is infeasible, then either the oracle outputs a violated constraint, or reports* `feasible`*, in which case $\{X_u\}_{u\in V}, Y/\alpha_{GW}$ is feasible.*

Proof. Let $\{X_u\}_{u\in V}, Y$ be an assignment to the variables of $(Dual_1)$. If it is feasible, then it holds that $\sum_{u\in V} X_u \leq 1$, and in addition every $S \subseteq V$ satisfies $C_{S,G'} \leq Y$, therefore the oracle returns `feasible`.

If the assignment is infeasible, there are two cases. If $\sum_{u\in V} X_u > 1$, the oracle returns this violated constraint. Otherwise, there is a subset $S' \subseteq V$ such that $C_{S',G'} > Y$. Let S^* be an optimal solution for Max-Cut on G', and note that $C_{S^*,G'} > Y$. If $\alpha_{GW} \cdot C_{S^*,G'} > Y$, then we also have that $C_{S_{ALG},G'} > Y$ (since S_{ALG} is an α_{GW}-approximate Max-Cut), and the oracle returns the violated constraint for S_{ALG}. Otherwise, $C_{S^*,G'} \leq Y/\alpha_{GW}$. Since S^* is an optimal solution for Max-Cut on G', it follows that for every $S \subseteq V$, it holds that $C_{S,G'} \leq Y/\alpha_{GW}$, i.e., the solution $\{X_u\}_{u\in V}, Y/\alpha_{GW}$ is feasible. ◀

It is not hard to see that the application of the ellipsoid algorithm on $(Dual_1)$ takes a polynomial time (i.e., at most as much time as it would take with an exact separation oracle), since our approximate oracle is (possibly) incorrect only on *the last* call from the ellipsoid algorithm (for a given Y), when it incorrectly reports a solution as feasible.

The output of the ellipsoid algorithm/binary search is an assignment $\{X_u\}_{u\in V}, Y$ to the variables of $(Dual_1)$ such that $\{X_u\}_{u\in V}, Y$ is feasible according to the oracle, while $Y - \epsilon$ is infeasible with every assignment to the X variables, where ϵ is the precision of the binary search. As observed above, we have that $\{X_u\}_{u\in V}, Y/\alpha_{GW}$ is feasible, and it follows that if

Y^* is the optimal value of $(Dual_1)$, then $Y - \epsilon \leq Y^* \leq Y/\alpha_{GW}$. Since the ellipsoid algorithm queries the oracle a polynomial number of times, there is a set $\mathcal{H} \subseteq 2^V$ of a polynomial number of cuts S, for which constraint (6) is queried. Consider a modified variant of $(Dual_1)$, called $(Dual_2)$, where only constraints of cuts in $\mathcal{H}$ are present. Let Y_2^* be the optimal value of $(Dual_2)$. Note that $Y_2^* \leq Y^*$. Note also that the ellipsoid algorithm returns exactly the same solution $\{X_u\}_{u \in V}, Y$, when executed on $(Dual_1)$ and $(Dual_2)$ (since our algorithm is deterministic, and only constraints in $\mathcal{H}$ are queried); hence, we have $Y - \epsilon \leq Y_2^*$. Finally, let us consider the primal LP corresponding to $(Dual_2)$ it is obtained from $(Primal_1)$ by removing variables P_S with $S \notin \mathcal{H}$ (i.e., setting $P_S = 0$).

The new primal has polynomially many constraints and variables, so can be solved in polynomial time. From the arguments above, we have that its optimal value Y_2^* satisfies $Y - \epsilon \leq Y_2^* \leq Y^* \leq Y/\alpha_{GW}$. Recalling that Y^* is the optimal value for the original LP, we see that Y_2^* is a α_{GW}-approximation (with any polynomial precision ϵ).

5 Hardness of Approximation

In this section we show that assuming the Unique Games Conjecture, one cannot approximate *AFTcut* and *OFTcut* within a factor greater than α_{GW}. Formally, we prove the following:

▶ **Theorem 1.3.** *Assuming the Unique Games Conjecture and NP $\not\subseteq$ BPP, there is no polynomial time $(\alpha_{GW} + \epsilon)$-approximation algorithm for fault tolerant Max-Cut in unweighted graphs, for any constant $\epsilon > 0$. This holds for both adaptive and oblivious adversaries.*

In both cases, given an unweighted instance G of Max-Cut, we construct an unweighted graph G', as follows: we take the disjoint union of G with a star with $n = |V|$ leaves and a center u^*, and add an edge joining u^* to an arbitrary vertex $v_1 \in V$. This completes the construction of G'. Clearly, this is a polynomial construction.

We show for each kind of adversary how to translate a given (approximate) solution to *AFTcut* or *OFTcut* in G' into a solution to Max-Cut in G, which would imply the corresponding inapproximability results, using the fact that Max-Cut is hard to approximate within a factor better than α_{GW} [39]. We only present the proof for *OFTcut*, leaving *AFTcut* to the full version. We use the following simple observation.

▶ **Observation 5.1.** *Let $S \subseteq V$ be a cut in G, and $S' = S \cup \{u^*\}$. It holds that in G', u^* is a critical vertex of S', i.e., $\varphi(S') = C_{S'-u^*,G'-u^*}$. For every cut $S'' \subseteq V'$, we have $C_{S''-u^*,G'} = C_{S'' \cap V,G}$.*

The proof follows from the fact that for every vertex $v \in V'$, $d_{S'}(v) \leq n \leq d_{S'}(u^*)$, and that all edges in $G' - u^*$ belong to G.

We show first that the optimal values for *OFTcut* in G' and Max-Cut in G are equal.

▶ **Lemma 5.2.** *Let $\mathcal{D}^*$ be the distribution of an optimal OFTcut in G', and S^*_{mc} be an optimal Max-Cut in G. It holds that $\mu(\mathcal{D}^*, G') = C_{S^*_{mc},G}$.*

Proof. Let $\widetilde{S} = S^*_{mc} \cup \{u^*\}$, and let $\mathcal{D}$ be the distribution that assigns probability 1 to $\widetilde{S}$ and probability 0 to all other cuts. By Observation 5.1, u^* is a critical vertex, hence for every vertex $v \in G'$, we have $\mathop{\mathbb{E}}_{S \sim \mathcal{D}}[C_{S-u^*,G'-u^*}] = C_{\widetilde{S}-u^*,G'-u^*} \leq C_{\widetilde{S}-v,G'-v} = \mathop{\mathbb{E}}_{S \sim \mathcal{D}}[C_{S-v,G'-v}]$. Using Observation 5.1 again, we have $\mu(\mathcal{D}^*, G') \geq \mu(\mathcal{D}, G') \geq C_{\widetilde{S}-u^*,G'-u^*} = C_{S^*_{mc},G}$. Next, by Observation 5.1, we have $C_{S-u^*,G'-u^*} = C_{S \cap V,G} \leq C_{S^*_{mc},G}$, for every cut S from the support of $\mathcal{D}^*$, which implies that $\mu(\mathcal{D}^*, G') \leq \mathop{\mathbb{E}}_{S \sim \mathcal{D}^*}[C_{S-u^*,G'-u^*}] \leq C_{S^*_{mc},G}$. This completes the proof. ◀

Proof of Theorem 1.3 for an Oblivious Adversary. Assume, for a contradiction, that we have an α-approximation algorithm for $OFTcut$, for $\alpha = \alpha_{GW} + \epsilon > \alpha_{GW}$. We design a randomized approximation algorithm for Max-Cut. Let G be an input to Max-Cut. Construct the graph G' as described above. Let $\mathcal{D}$ be the distribution of an α-approximate $OFTcut$ in G'. By Lemma 5.2, we have $\mathop{\mathbb{E}}_{S\sim\mathcal{D}}[C_{S-u^*,G'-u^*}] \geq \mu(\mathcal{D},G') \geq \alpha \cdot C_{S^*_{mc},G}$, where S^*_{mc} is a Max-Cut in G. By Observation 5.1, it holds that $C_{S_{ft}-u^*,G'-u^*} = C_{S_{ft}\cap V,G} \leq C_{S^*_{mc}}$ for every cut S_{ft} in the support of $\mathcal{D}$. Letting $p = \mathbb{P}\left[C_{S-u^*,G'-u^*} \geq (\alpha-\epsilon/2)C_{S^*_{mc}}\right]$, we have

$$\alpha \cdot C_{S^*_{mc},G} \leq \mathop{\mathbb{E}}_{S\sim\mathcal{D}}[C_{S-u^*,G'-u^*}] \leq p \cdot C_{S^*_{mc},G} + (1-p)\cdot(\alpha-\epsilon/2)C_{S^*_{mc},G} \ ,$$

implying that $p \geq \epsilon/2$. Thus, for a random cut S_{ft} sampled from $\mathcal{D}$, it holds that $S_{ft}\cap V$ is an $(\alpha-\epsilon/2)$-approximation to Max-Cut, with probability $\epsilon/2$, where $\alpha-\epsilon/2 > \alpha_{GW}$. This contradicts to our assumption about the Unique Games Conjecture and $NP \not\subseteq BPP$. ◀

6 Discussion

Our work leaves several open questions regarding fault tolerant Max-Cut. An immediate question is to bridge the (rather small) gap between our approximation of $(0.8780-\epsilon)$ and our hardness of α_{GW} for k-$AFTcut$.

The central bottleneck is that Simultaneous Max-Cut, a main ingredient in our algorithm, has hardness of approximation that is slightly below α_{GW} and equals $(\alpha_{GW}-\delta)$ (where $\delta \geq 10^{-5}$) [11]. Thus, either one finds a different algorithm for k-$AFTcut$ that does not rely on Simultaneous Max-Cut and achieves an approximation of α_{GW}, or one can extend the hardness result of [11] to k-$AFTcut$ and thus rule out an approximation of α_{GW} for k-$AFTcut$. Another question is what approximation factors can be obtained for $AFTcut$ on general weighted graphs.

Another interesting question is how to deal with a non-constant number of faults, for both of the adversaries. Since the number of all possible cases of failure is not polynomial, a new approach may be needed. There are techniques that are used to deal with a non-constant number of faults, e.g., failure sampling, that is presented in [24]. It would be interesting to see whether these techniques can be used for fault tolerant Max-Cut as well.

One more important and intriguing open question is what happens in other fault tolerant problems when an oblivious adversary is considered. We are unaware of previous algorithms for an oblivious adversary in the fault-tolerance literature. Since an oblivious adversary is arguably more realistic in its nature, and since it is likely that one can get improved algorithms for this case, pursuing this line of research could be crucial for many additional fundamental problems involving fault tolerance.

Abstract

All-Pairs Shortest Paths (APSP) is one of the most well studied problems in graph algorithms. This paper studies several variants of APSP in unweighted graphs or graphs with small integer weights.

APSP with small integer weights in undirected graphs [Seidel'95, Galil and Margalit'97] has an $\tilde{O}(n^\omega)$ time algorithm, where $\omega < 2.373$ is the matrix multiplication exponent. APSP in directed graphs with small weights however, has a much slower running time that would be $\Omega(n^{2.5})$ even if $\omega = 2$ [Zwick'02]. To understand this $n^{2.5}$ bottleneck, we build a web of reductions around directed unweighted APSP. We show that it is *fine-grained equivalent* to computing a rectangular Min-Plus product for matrices with integer entries; the dimensions and entry size of the matrices depend on the value of ω. As a consequence, we establish an equivalence between APSP in directed unweighted graphs, APSP in directed graphs with small ($\tilde{O}(1)$) integer weights, All-Pairs Longest Paths in DAGs with small weights, cRed-APSP in undirected graphs with small weights, for any $c \geq 2$ (computing all-pairs shortest path distances among paths that use at most c red edges), $\#_{\leq c}$APSP in directed graphs with small weights (counting the number of shortest paths for each vertex pair, up to c), and approximate APSP with additive error c in directed graphs with small weights, for $c \leq \tilde{O}(1)$.

We also provide fine-grained reductions from directed unweighted APSP to All-Pairs Shortest Lightest Paths (APSLP) in undirected graphs with $\{0, 1\}$ weights and $\#_{\bmod c}$APSP in directed unweighted graphs (computing counts mod c), thus showing that unless the current algorithms for APSP in directed unweighted graphs can be improved substantially, these problems need at least $\Omega(n^{2.528})$ time.

We complement our hardness results with new algorithms. We improve the known algorithms for APSLP in directed graphs with small integer weights (previously studied by Zwick [STOC'99]) and for approximate APSP with sublinear additive error in directed unweighted graphs (previously studied by Roditty and Shapira [ICALP'08]). Our algorithm for approximate APSP with sublinear additive error is optimal, when viewed as a reduction to Min-Plus product. We also give new algorithms for variants of #APSP (such as $\#_{\leq U}$APSP and $\#_{\bmod U}$APSP for $U \leq n^{\tilde{O}(1)}$) in unweighted graphs, as well as a near-optimal $\tilde{O}(n^3)$-time algorithm for the original #APSP problem in unweighted graphs (when counts may be exponentially large). This also implies an $\tilde{O}(n^3)$-time algorithm for Betweenness Centrality, improving on the previous $\tilde{O}(n^4)$ running time for the problem. Our techniques also lead to a simpler alternative to Shoshan and Zwick's algorithm [FOCS'99] for the original APSP problem in undirected graphs with small integer weights.

1 Introduction

All-Pairs Shortest Paths (APSP) is one of the oldest and most studied problems in graph algorithms. The fastest known algorithm for general n-node graphs runs in $n^3/2^{\Theta(\sqrt{\log n})}$ [31]. In unweighted graphs, or graphs with small integer weights, faster algorithms are known.

For APSP in *undirected* unweighted graphs (u-APSP), Seidel [21] and Galil and Margalit [12, 13] gave $\tilde{O}(n^\omega)$ time algorithms where $\omega \leq 2.373$ is the exponent of matrix multiplication [2, 27, 16]; the latter algorithm works for graphs with small integer weights[1] in $[\pm c_0]$ for $c_0 = \tilde{O}(1)$. The hidden dependence on c_0 was improved by Shoshan and Zwick [22].

For *directed* unweighted graphs or graphs with weights in $[\pm c_0]$, the fastest APSP algorithm is by Zwick [34], running in $O(n^{2.529})$ time. This running time is achieved using the best known bounds for rectangular matrix multiplication [17] and would be $\Omega(n^{2.5})$ even if $\omega = 2$.

There is a big discrepancy between the running times for undirected and directed APSP. One might wonder, why is this? Are directed graphs inherently more difficult for APSP, or is there some special graph structure we can uncover and then use it to develop an $\tilde{O}(n^\omega)$ time algorithm for directed APSP as well? (Note that matrix multiplication seems necessary for APSP since APSP is known to capture Boolean matrix multiplication.)

The first contribution in this paper is a fine-grained equivalence between directed unweighted APSP (u-APSP) and a certain rectangular version of the Min-Plus product problem.

The *Min-Plus product* of an $n \times m$ matrix A by an $m \times p$ matrix B is the matrix C with entries $C[i,j] = \min_{k=1}^{m}(A[i,k] + B[k,j])$. Let us denote by $\mathrm{M}^\star(n_1, n_2, n_3 \mid M)$ the problem of computing the Min-Plus product of an $n_1 \times n_2$ matrix by an $n_2 \times n_3$ matrix where both matrices have integer entries in $[M]$. Let $\mathcal{M}^\star(n_1, n_2, n_3 \mid M)$ be the best running time for $\mathrm{M}^\star(n_1, n_2, n_3 \mid M)$.

Zwick's algorithm [34] for u-APSP can be viewed as making a logarithmic number of calls to the Min-Plus product $\mathrm{M}^\star(n, n/L, n \mid L)$ for all $1 \leq L \leq n$ that are powers of $3/2$. The running time of Zwick's algorithm is thus, within polylogarithmic factors, $\max_L \mathcal{M}^\star(n, n/L, n \mid L)$.

Let $\mathcal{M}(a, b, c)$ denote the running time of the fastest algorithm to multiply an $a \times b$ by a $b \times c$ matrix over the integers. Let $\omega(a, b, c)$ be the smallest real number r such that $\mathcal{M}(n^a, n^b, n^c) \leq O(n^{r+\varepsilon})$ for all $\varepsilon > 0$.

The best known upper bound for the Min-Plus product running time $\mathcal{M}^\star(n, n/L, n \mid L)$ is the minimum of $O(n^3/L)$ (the brute force algorithm) and $\tilde{O}(L \cdot \mathcal{M}(n, n/L, n))$ [3]. For $L = n^{1-\ell}$, $\mathcal{M}^\star(n, n/L, n \mid L)$ is thus at most $\tilde{O}(\min\{n^{2+\ell}, n^{1-\ell+\omega(1,\ell,1)}\})$. Over all $\ell \in [0, 1]$, the runtime is maximized at $\tilde{O}(n^{2+\rho})$ where ρ is such that $\omega(1, \rho, 1) = 1 + 2\rho$.

Hence in particular, the running time of Zwick's algorithm is $\tilde{O}(n^{2+\rho})$. This running time has remained unchanged (except for improvements on the bounds on ρ) for almost 20 years. The current best known bound on ρ is $\rho < 0.529$, and if $\omega = 2$, then $\rho = 1/2$.

[1] In this paper, $[\pm c_0] = \{-c_0, \ldots, c_0\}$ and $[c_0] = \{0, \ldots, c_0\}$. The $\tilde{O}$ notation hides polylogarithmic factors (although conditions of the form $c_0 = \tilde{O}(1)$ may be relaxed to $c_0 \leq n^{o(1)}$ if we allow extra $n^{o(1)}$ factors in the $\tilde{O}$ time bounds).

Our first result is that u-APSP is sub-$n^{2+\rho}$ fine-grained equivalent to $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$:

▶ **Theorem 1.** *If $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ is in $O(n^{2+\rho-\varepsilon})$ time for $\varepsilon > 0$, then u-APSP can also be solved in $O(n^{2+\rho-\varepsilon'})$ time for some $\varepsilon' > 0$. If u-APSP can be solved in $O(n^{2+\rho-\varepsilon})$ time for some $\varepsilon > 0$, then $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ can also be solved in $O(n^{2+\rho-\varepsilon})$ time.*

The Min-Plus product of two $n \times n$ matrices with *arbitrary* integer entries is known to be equivalent to APSP with *arbitrary* integer entries [10], so that their running times are the same, up to constant factors. All known algorithms for directed unweighted APSP (including [34, 3] and others), make calls to Min-Plus product of rectangular matrices with integer entries that can be as large as say $n^{0.4}$. It is completely unclear, however, why a problem in *unweighted* graphs such as u-APSP should require the computation of Min-Plus products of matrices with such large entries. Theorem 1 surprisingly shows that it does. Moreover, it shows that unless we can improve upon the known approaches for Min-Plus product computation, there will be no way to improve upon Zwick's algorithm for u-APSP. The latter is an algebraic problem in disguise.

The main proof of Theorem 1 is simple – what is remarkable are the numerous consequences on equivalences and conditional hardness that follow from this idea. We first use Theorem 1 to build a class of problems that are all equivalent to u-APSP, via $(n^{2+\rho}, n^{2+\rho})$-fine-grained reductions (see [29] for a survey of fine-grained complexity). In particular, if $\omega = 2$ (or more generally when $\omega(1, \frac{1}{2}, 1) = 2$), these are all problems that are $n^{2.5}$-fine-grained equivalent.

Recall that in the *All-Pairs Longest Paths (APLP)* problem, we want to output for every pair of vertices s, t the weight of the longest path from s to t. While APLP is NP-hard in general, it is efficiently solvable in DAGs. In the *cRed-APSP* problem, for a given graph in which some edges can be colored red, we want to output for every pair of vertices s, t the weight of the shortest path from s to t that uses at most c red edges. For convenience, we call all non-red edges blue.

We use the following convention for problem names: the prefix "u-" is for unweighted graphs; the prefix "$[c_0]$-" is for graphs with weights in $[c_0]$ (similarly for "$[\pm c_0]$-" and for other ranges). Input graphs are directed unless stated otherwise.

▶ **Theorem 2.** *The following problems either all have $O(n^{2+\rho-\varepsilon})$ time algorithms for some $\varepsilon > 0$, or none of them do, assuming that $c_0 = \tilde{O}(1)$:*

- $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$,
- *u-APSP,*
- *$[\pm c_0]$-APSP for directed graphs without negative cycles,*
- *u-APLP for DAGs,*
- *$[\pm c_0]$-APLP for DAGs,*
- *u-cRed-APSP for* undirected *graphs for any $2 \le c \le \tilde{O}(1)$.*

Interestingly, while u-2Red-APSP in undirected graphs above is equivalent to u-APSP and hence improving upon its $\tilde{O}(n^{2+\rho})$ runtime would be difficult, we show that u-1Red-APSP in undirected graphs can be solved in $\tilde{O}(n^\omega)$ time via a modification of Seidel's algorithm, and hence there is a seeming jump in complexity in u-cRed-APSP from $c = 1$ to $c = 2$.

Besides the above equivalences we provide some interesting reductions from u-APSP to other well-studied matrix product and shortest paths problems.

Lincoln, Polak and Vassilevska W. [18] reduce u-APSP to some matrix product problems such as All-Edges Monochromatic Triangle and the $(\min, \max)$-Product studied in [24, 26] and [25, 9] respectively. Using the equivalence of u-APSP and $\mathrm{M}^\star(n, n/\ell, n \mid \ell^{1-p})$, we can reduce

u-APSP to another matrix product called Min Witness Equality Product (MinWitnessEq), where we are given $n \times n$ integer matrices A and B, and are required to compute $\min\{k \in [n] : A[i,k] = B[k,j]\}$ for every pair of (i,j). This can be viewed as a merge of the Min Witness product [8] [2] and Equality Product problems [15, 28].

Another natural variant of APSP is the problem of *approximating* shortest path distances. Zwick [34] presented an $\tilde{O}(n^\omega \log M)$ time algorithm for computing a $(1+\varepsilon)$-multiplicative approximation for all pairwise distances in a directed graph with integer weights in $[M]$, for any constant $\varepsilon > 0$.[3] This is essentially optimal assuming no $o(n^\omega)$ time algorithm can multiple $n \times n$ Boolean matrices since any such approximation algorithm can be used to multiply Boolean matrices.

An arguably better notion of approximation is to provide an additive approximation, i.e. outputting for every u, v an estimate $D'[u,v]$ for the distance $D[u,v]$ such that $D[u,v] \leq D'[u,v] \leq D[u,v] + E$, where E is an error that can depend on u and v.

At ICALP'08, Roditty and Shapira [20] studied the following variant: given an unweighted directed graph and a constant $p \in [0,1]$, compute for all u, v an estimate $D'[u,v]$ with $D[u,v] \leq D'[u,v] \leq D[u,v] + D[u,v]^p$. They gave an algorithm with running time $\tilde{O}(\max_\ell \min\{n^3/\ell, \mathcal{M}^\star(n, n/\ell^{1-p}, n \mid \ell^{1-p})\})$. For example, for $p = 0$, this matches the time complexity of Zwick's exact algorithm for u-APSP; for $p = 1$, this matches Zwick's $\tilde{O}(n^\omega)$-time algorithm with constant multiplicative approximation factor. For $p = 0.5$, with the current rectangular matrix multiplication bounds [17], the running time is $O(n^{2.447})$.

We obtain an improved running time:

▶ **Theorem 3.** *For any $p \in [0,1]$, given a directed unweighted graph, one can obtain additive $D[u,v]^p$ approximations to all distances $D[u,v]$ in time $\tilde{O}(\max_\ell \mathcal{M}^\star(n, n/\ell, n \mid \ell^{1-p}))$.*

The improvement over Roditty and Shapira's running time is substantial. For example, for all $p \geq 0.415$, the time bound is $O(n^{2.373})$ (the current matrix multiplication running time), whereas their algorithm only achieves $O(n^{2.373})$ for $p = 1$. Our result also answers one of Roditty and Shapira's open question (on whether $\tilde{O}(n^\omega)$ time is possible for any $p < 1$), if $\omega > 2$.

The new algorithm is also *optimal* (ignoring logarithmic factors) in a strong sense, as our reduction technique shows that for all ℓ, $\mathrm{M}^\star(n, n/\ell, n \mid \ell^{1-p})$ can be tightly reduced to the additive $D[u,v]^p$ approximation of APSP. In particular, u-APSP with constant additive error is fine-grained equivalent to exact u-APSP.

The *All-Pairs Lightest Shortest Paths (APLSP)* problem studied in [6, 33] asks to compute for every pair of vertices s, t the distance from s to t (with respect to the edge weights) and the smallest number of edges over all shortest paths from s and t. Traditional shortest-path algorithms can be easily modified to find the lightest shortest paths, but not the faster matrix-multiplication-based algorithms. Our reduction for u-cRed-APSP can be easily modified to reduce $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ to $\{0,1\}$-APLSP in undirected graphs, which can be viewed as a conditional lower bound of $n^{2+\rho-o(1)}$ for the latter problem.

▶ **Corollary 4.** *If $\{0,1\}$-APLSP in undirected graphs is in $O(n^{2+\rho-\varepsilon})$ time for $\varepsilon > 0$, then so is $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$.*

---

[2] Recently, there has been renewed interest in studying the Min Witness product, due to a breakthrough [14] on the All-Pairs LCA in DAGs problem, which was one of the original motivations for studying Min Witness.

[3] Bringmann et al. [5] considered the more unusual setting of very large M, where the $\log M$ factor is to be avoided.

The fastest known algorithm to date for $\{0,1\}$-APLSP, or more generally, $[c_0]$-APLSP for $c_0 = \tilde{O}(1)$, for directed or undirected graphs is by Zwick [33] from STOC'99 and runs in $O(n^{2.724})$ time with the current best bounds for rectangular matrix multiplication (the running time would be $\tilde{O}(n^{8/3})$ if $\omega = 2$). Chan [6] (STOC'07) improved this running time to $\tilde{O}(n^{(3+\omega)/2}) \leq O(n^{2.687})$ but only if the weights are *positive*, i.e., for $([c_0] - \{0\})$-APLSP (and so his result does not hold for $\{0,1\}$-APLSP).

Both Zwick's and Chan's algorithms solve a more general problem, Lex_2-APSP, in which one is given a directed graph where each edge e is given two weights $w_1(e), w_2(e)$ and one wants to find for every pair of vertices u, v the lexicographic minimum over all u-v paths π of $(\sum_{e\in\pi} w_1(e), \sum_{e\in\pi} w_2(e))$. Then APLSP is Lex_2-APSP when all w_2 weights are 1, and the related *All-Pairs Shortest Lightest Paths (APSLP)* problem is when all w_1 weights are 1.

To complement the conditional lower bound for APLSP, and hence Lex_2-APSP, we present new algorithms for $[c_0]$-Lex_2-APSP for $c_0 = \tilde{O}(1)$, both (slightly) improving Chan's running time and also allowing zero weights, something that Chan's algorithm couldn't support.

▶ **Theorem 5.** *$[c_0]$-Lex_2-APSP can be solved in $O(n^{2.66})$ time for any $c_0 = \tilde{O}(1)$.*

If $\omega = 2$, the above running time would be $\tilde{O}(n^{2.5})$, improving Zwick's previous $\tilde{O}(n^{8/3})$ bound [33] and matching our conditional lower bound $n^{2+\rho-o(1)}$. For undirected graphs with *positive* weights in $[c_0] - \{0\}$, we further improve the running time to $O(n^{2.58})$ under the current matrix multiplication bounds.

We next consider the natural problem, *#APSP*, of counting the number of shortest paths for every pair of vertices in a graph. This problem needs to be solved, for example, when computing the so-called *Betweenness Centrality (BC)* of a vertex. BC is a well-studied measure of vertex importance in social networks. If we let $C[s,t]$ be the number of shortest paths between s and t, and $C_v[s,t]$ be the number of shortest paths between s and t that go through v, then $\text{BC}(v) = \sum_{s,t\neq v} C_v[s,t]/C[s,t]$ and the BC problem is to compute $\text{BC}(v)$ for a given graph and a given node v.

Prior work [4] showed that #APSP and BC in m-edge n-node unweighted graphs can be computed in $O(mn)$ time via a modification of Breadth-First Search (BFS).[4] However, all prior algorithms assumed a model of computation where adding two integers of arbitrary size takes constant time. In the more realistic word-RAM model (with $O(\log n)$ bit words), these algorithms would run in $\tilde{\Theta}(mn^2)$ time, as there are explicit examples of graphs with m edges (for any m, a function of n) for which the shortest paths counts have $\Theta(n)$ bits.[5] In particular, the best running time in terms of n so far has been $\tilde{O}(n^4)$.

We provide the first genuinely $\tilde{O}(n^3)$ time algorithm for #APSP, and thus Betweenness Centrality, in directed unweighted graphs.

▶ **Theorem 6.** *u-#APSP can be solved in $\tilde{O}(n^3)$ time by a combinatorial algorithm.*

This runtime cannot be improved since there are graphs for which the output size is $\Omega(n^3)$.

Since the main difficulty of the #APSP problem comes from the counts being very large, it is interesting to consider variants that mitigate this. Let $U \leq n^{\tilde{O}(1)}$. Let $\#_{\bmod U}$APSP be the problem of computing all pairwise counts modulo U. Let $\#_{\leq U}$APSP be the problem of

[4] Brandes presented further practical improvements as well.

[5] One example is an $(n/3+2)$-layered graph where the first $n/3$ layers have 2 vertices each and the last 2 layers have $n/6$ vertices each. The i-th layer and the $(i+1)$-th layer are connected by a complete bipartite graph for each $1 \leq i \leq n/3$, while the last two layers are connected by $O(m)$ edges.

computing for every pair of nodes u, v the minimum of their count and U (think of U as a "cap"). Finally, let $\#_{\text{approx-}U}$APSP be the problem of computing a $(1 + 1/U)$-approximation of all pairwise counts (think of keeping the $\log U$ most significant bits of each count).

We obtain the following result for u-$\#_{\leq U}$APSP in directed graphs:

▶ **Theorem 7.** *u-$\#_{\leq U}$APSP (in directed graphs) can be solved in $n^{2+\rho}\text{polylog } U \leq n^{2+\rho+o(1)}$ time.*

Furthermore, for any $U \geq 2$, if u-$\#_{\leq U}$APSP can be solved in $O(n^{2+\rho-\varepsilon})$ time for some $\varepsilon > 0$, then so can u-APSP (with randomization). For any $2 \leq U \leq \tilde{O}(1)$, the converse is true as well.

Thus, we get a conditionally optimal algorithm for u-$\#_{\leq U}$APSP. For $2 \leq U \leq \tilde{O}(1)$, the theorem above gives a fine-grained equivalence between u-$\#_{\leq U}$APSP and u-APSP; in particular, for $U = 2$, the problem corresponds to testing *uniqueness* for the shortest path of each pair. (For large U, however, it is not a fine-grained equivalence since the algorithm for u-$\#_{\leq U}$APSP does not go through Min-Plus product, but rather directly uses fast matrix multiplication.)

Our algorithm from Theorem 7 is based on Zwick's algorithm for u-APSP. We show that one can also modify Seidel's algorithm for u-APSP in undirected graphs to obtain $\tilde{O}(n^\omega)$ time algorithms for u-$\#_{\leq U}$APSP and u-$\#_{\bmod U}$APSP in undirected graphs.

▶ **Theorem 8.** *u-$\#_{\leq U}$APSP and u-$\#_{\bmod U}$APSP in undirected graphs can be solved in $\tilde{O}(n^\omega \log U)$ time.*

Furthermore, we show that u-$\#_{\text{approx-}U}$APSP in undirected graphs can be solved in $O(n^{2.58}\text{polylog } U)$ time, somewhat surprisingly, by a slight modification of our undirected Lex_2-APSP algorithm (despite the apparent dissimilarity between the two problems).

Paper Organization and Techniques. In Section 3, we show the web of reductions around u-APSP, proving Theorem 1, Theorem 2, the hardness of additive $D[u, v]^p$ approximate u-APSP and the hardness of u-$\#_{\leq U}$APSP in Theorem 7.

In Section 4, we give our algorithms for approximating APSP with additive errors, proving Theorem 3. In Section 5, we describe our algorithms for Lex_2-APSP. Due to space limitation, we defer our algorithms for various versions of #APSP to the full paper (including an algorithm for u-$\#_{\leq U}$APSP to complete the proof of Theorem 7, the proof of Theorem 8, and the algorithm for u-$\#_{\text{approx-}U}$APSP). An exception is our near-cubic algorithm for exact u-#APSP (proof of Theorem 6), which is simple and is described in Section 6.

For approximating APSP with additive error, we propose an interesting *two-phase* variant of Zwick's algorithm [34]. Zwick's algorithm computes distance products of $n \times (n/\ell)$ with $(n/\ell) \times n$ matrices for ℓ in a geometric progression. Our idea is to do less during the first phase, computing products of $(n/\ell) \times (n/\ell)$ with $(n/\ell) \times n$ matrices instead. We complete the work during a second phase. The observation is that for the APSP approximation problem, we can afford to perform the distance computation in the first phase *exactly*, but use approximation to speed up the second phase. The resulting approximation algorithm is even simpler than Roditty and Shapira's previous (slower) algorithm [20].

Our Lex_2-APSP algorithm for directed graphs also uses this two-phase approach, but in a more sophisticated way to control the size of the numbers in the rectangular matrix products. A number of interesting new ideas are needed.

To further illustrate the power of this two-phase approach, we also show (in the full version) how the idea can lead to an alternative $\tilde{O}(c_0 n^\omega)$ time algorithm for the standard $[c_0]$-APSP problem for undirected graphs, rederiving Shoshan and Zwick's result [22] in an arguably simpler way. This may be of independent interest (as Shoshan and Zwick's algorithm has complicated details).

Our Lex_2-APSP algorithm for *undirected* graphs uses small dominating sets for high-degree vertices, an idea of Aingworth et al. [1]. Originally, this idea was for developing combinatorial algorithms for *approximate* shortest paths that avoid matrix multiplication. Interestingly, we show that this idea can be combined with (rectangular) matrix multiplication to compute *exact* Lex_2 shortest paths.

2 Preliminaries

The computation model of all algorithms and reductions in this paper is the word-RAM model with $O(\log n)$ bit words.

We let $\mathcal{M}(n_1, n_2, n_3)$ denote the best known running time for multiplying an $n_1 \times n_2$ by an $n_2 \times n_3$ matrix over the integers. We use $\omega(a, b, c)$ to denote the rectangular matrix multiplication exponent, i.e. the smallest real number z such that $\mathcal{M}(n^a, n^b, n^c) \leq O(n^{z+\varepsilon})$ for all $\varepsilon > 0$. In particular, let $\omega = \omega(1, 1, 1)$. It is known that $\omega \in [2, 2.373)$ [2, 27, 16]. The best known bounds for $\omega(a, b, c)$ are in [17].

Let $\mathcal{M}^\star(n_1, n_2, n_3 \mid \ell_1, \ell_2)$ be the time to compute the Min-Plus product of an $n_1 \times n_2$ matrix A with an $n_2 \times n_3$ matrix B, where all finite entries of A are from $[\ell_1]$ and all finite entries of B are from $[\ell_2]$. Let us also denote $\mathcal{M}^\star(n_1, n_2, n_3 \mid \ell) := \mathcal{M}^\star(n_1, n_2, n_3 \mid \ell, \ell)$. It is known [3] that $\mathcal{M}^\star(n_1, n_2, n_3 \mid \ell) \leq \tilde{O}(\ell \cdot \mathcal{M}(n_1, n_2, n_3))$. This algorithm in [3] first replaces each entry e in both matrices A, B by $(n_2 + 1)^e$, then uses fast rectangular matrix multiplication to compute the product of the new matrices A, B. Since each arithmetic operation takes $\tilde{O}(\ell)$ time, the running time follows.

More generally, let $\mathcal{M}^\star(n_1, n_2, n_3 \mid m_1, m_2, m_3 \mid \ell_1, \ell_2)$ be the time to compute m_3 given entries of the Min-Plus product of an $n_1 \times n_2$ matrix A with an $n_2 \times n_3$ matrix B, where A has at most m_1 finite entries, all from $[\ell_1]$, and B has at most m_2 finite entries, all from $[\ell_2]$.

3 Directed APSP and Rectangular Min-Plus with Bounded Weights

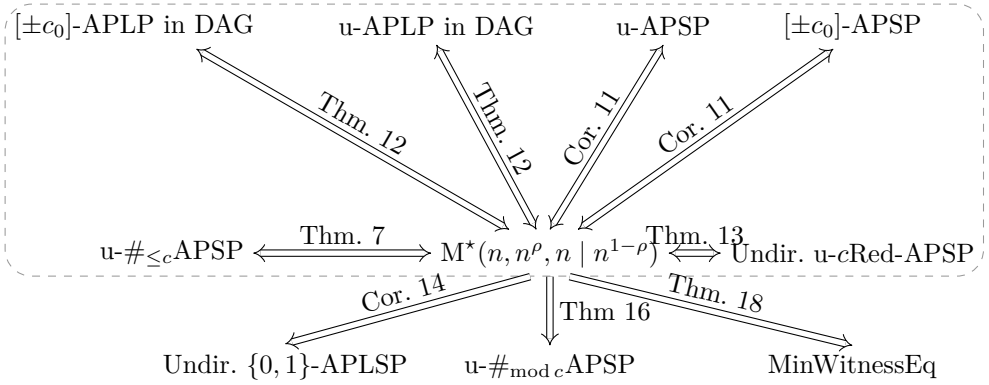

Figure 1 The web of (a subset of) the reductions in this paper. All reductions are $(n^{2+\rho}, n^{2+\rho})$-fine grained reductions, where ρ is such that $\omega(1, \rho, 1) = 1 + 2\rho$. The problems in the bounding box are sub $n^{2+\rho}$-equivalent. Here, $c_0 = \tilde{O}(1)$, and $2 \leq c \leq \tilde{O}(1)$. For the current best bounds on rectangular matrix multiplication [17], ρ is roughly 0.529.

Here we consider the All-Pairs Shortest Paths (APSP) problem in unweighted directed graphs, or more generally in directed graphs with integer weights in $[\pm c_0]$ with $c_0 = \tilde{O}(1)$ and no negative cycles. Zwick [34] showed that this problem in n-node graphs can be solved in time $\tilde{O}(n^{2+\rho})$ time where ρ is such that $\omega(1, \rho, 1) = 1 + 2\rho$. For the current best bounds on rectangular matrix multiplication [17], ρ is roughly 0.529.

Zwick's algorithm can be viewed as a reduction to rectangular Min-Plus matrix multiplication. The algorithm proceeds in stages, for each ℓ from 0 to $\log_{3/2}(n^{1-\rho})$.

In stage ℓ, up to logarithmic factors, one needs to compute the Min-Plus product of two matrices A_ℓ and B_ℓ where A_ℓ has dimensions $n \times n/(3/2)^\ell$ and B_ℓ has dimensions $n/(3/2)^\ell \times n$ and both matrices have entries bounded by $(3/2)^\ell$. Intuitively, this computes the pairwise distances that are roughly $(3/2)^\ell$. After stage $\log_{3/2}(n^{1-\rho})$, the algorithm also runs Dijkstra's algorithm[6] to and from $\tilde{O}(n^\rho)$ nodes S sampled randomly and uses $\tilde{O}(n^{2+\rho})$ extra time to complete the computation of the distances by considering for every $u, v \in V$, $\min_{s \in S}\{D[u, s] + D[s, v]\}$. This can also be viewed as using the brute-force algorithm to compute the Min-Plus products when $(3/2)^\ell \geq n^{1-\rho}$.

The total running time is within logarithmic factors of

$$n^{2+\rho} + \sum_{\ell=0}^{\log_{3/2}(n^{1-\rho})} \mathcal{M}^\star(n, n/(3/2)^\ell, n \mid (3/2)^\ell),$$

where $\mathcal{M}^\star(n_1, n_2, n_3 \mid M)$ is the Min-Plus product running time for matrices with entries in $\{0, \ldots, M\}$ and dimensions $n_1 \times n_2$ by $n_2 \times n_3$. With the known bounds for Min-Plus product, $\mathcal{M}^\star(n, n^\tau, n \mid M) \leq \tilde{O}(Mn^{\omega(1,\tau,1)})$, and the running time of Zwick's algorithm becomes $\tilde{O}(n^{2+\rho} + n^{1-\rho+\omega(1,\rho,1)})$, which is $\tilde{O}(n^{2+\rho})$ when $\omega(1, \rho, 1) = 1 + 2\rho$.

If $\omega = 2$, then ρ is 1/2 and the running time of Zwick's algorithm becomes $\tilde{O}(n^{2.5})$. This running time is a seeming barrier for the APSP problem in directed graphs.

In the full version we prove the following technical theorem which rephrases Zwick's algorithm [34] as a reduction.

▶ **Theorem 9.** *Let ρ be the solution to $\omega(1, \rho, 1) = 1 + 2\rho$. If the Min-Plus product of an $n \times n^\rho$ matrix by an $n^\rho \times n$ matrix where both matrices have integer entries bounded by $n^{1-\rho}$ (denoted as $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$) can be computed in $O(n^{2+\rho-\epsilon})$ time for some $\epsilon > 0$, then APSP in directed n node graphs with integer edge weights in $[\pm c_0]$ for $c_0 = \tilde{O}(1)$ can be solved in $O(n^{2+\rho-\epsilon'})$ time for $\epsilon' > 0$.*

If $\omega = 2$, the above theorem statement becomes: If the Min-Plus problem of an $n \times \sqrt{n}$ matrix by a $\sqrt{n} \times n$ matrix where both matrices have integer entries bounded by $\sqrt{n}$ can be computed in $O(n^{2.5-\delta})$ time for some $\delta > 0$, then APSP in directed n node graphs with integer edge weights in $[\pm c_0]$ for $c_0 = \tilde{O}(1)$ can be solved in $O(n^{2.5-\delta'})$ time for $\delta' > 0$.

We will show a reduction in the reverse direction as well, showing that rectangular Min-Plus product with suitably bounded entries can be reduced back to unweighted directed APSP.

▶ **Theorem 10.** *For any fixed $k \in (0, 1)$, $\mathrm{M}^\star(n, n^k, n \mid n^{1-k})$ can be reduced in $O(n^2)$ time to APSP in a directed unweighted graph with $O(n)$ vertices.*

[6] If there are negative weights, one also needs to run single source shortest paths (SSSP) from a node, as in Johnson's algorithm and then reweight the edges so that they are nonnegative. SSSP can be solved in $\tilde{O}((m + n^{1.5}) \log^2(c_0)) = \tilde{O}(n^2)$ time [23].

A consequence of Theorem 9, and the fact that u-APSP is a special case of $[\pm c_0]$-APSP for directed graphs without negative cycles, is the following equivalence.

▶ **Corollary 11.** *Let ρ be such that $\omega(1,\rho,1) = 1+2\rho$. Then u-APSP, $[\pm c_0]$-APSP for directed graphs without negative cycles, and $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ are sub-$n^{2+\rho}$ fine-grained equivalent for $c_0 = \tilde{O}(1)$.*

In particular, if $\omega = 2$, APSP in directed unweighted graphs is sub-$n^{2.5}$ fine-grained equivalent to the Min-Plus problem of an $n \times \sqrt{n}$ matrix by a $\sqrt{n} \times n$ matrix where both entries have integer entries bounded by $\sqrt{n}$.

Proof of Theorem 10. Let A be an $n \times n^k$ matrix and let B be an $n^k \times n$ matrix, both with entries in $\{1, \ldots, n^{1-k}\}$.

We will create a directed graph as follows. Let I be a set of n nodes, which represent the rows of A. Let J be a set of n nodes, which represent the columns of B.

For every $p \in [n^k]$ corresponding to a column of A (or row of B), create a path of $2n^{1-k}+1$ nodes:

$$X(p) := x_{p,n^{1-k}} \to x_{p,n^{1-k}-1} \to \ldots \to x_{p,0} \to y_{p,1} \to y_{p,2} \to \ldots \to y_{p,n^{1-k}}.$$

For every $i \in [n]$ and $p \in [n^k]$, consider $t = A[i,p] \in [n^{1-k}]$. Add an edge from $i \in I$ to $x_{p,t}$. Similarly, for every $j \in [n]$ and $p \in [n^k]$, consider $t' = B[p,j] \in [n^{1-k}]$. Add an edge from $y_{p,t'}$ to $j \in J$.

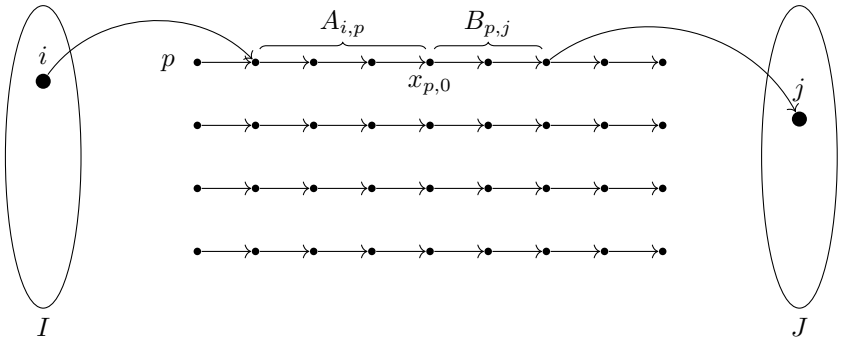

Figure 2 Sketch of the construction in proof of Theorem 10. For each vertex i and path p, we add an edge from i to a vertex on the path p whose distance to the middle point $x_{p,0}$ on the path is $A_{i,p}$. For each path p and vertex j, we add an edge from a vertex on the path whose distance from the middle point $x_{p,0}$ on the path is $B_{p,j}$ to vertex j.

Now, consider some $i \in [n], p \in [n^k], j \in [n]$ and $A[i,p] + B[p,j]$. If we consider the path consisting of $(i, x_{p,A[i,p]})$, $(y_{p,B[p,j]}, j)$ and the subpath of $X(p)$ between $x_{p,A[i,p]}$ and $y_{p,B[p,j]}$, its length is exactly $2 + A[i,p] + B[p,j]$. Also, any path from i to j is of this form. Thus, the shortest path from $i \in I$ to $j \in J$ in the created graph is exactly of length $2 + \min_p\{A[i,p] + B[p,j]\}$, and thus computing APSP in the directed unweighted graph we have created computes the Min-Plus product of A and B.

The number of vertices in the graph is $O(n^k \cdot n^{1-k}) = O(n)$. ◀

One consequence of Corollary 11 is that u-APSP and computing the predecessor matrix in unweighted directed APSP are also sub-$n^{2+\rho}$ fine-grained equivalent. It was known that Zwick's algorithm [34] can compute the predecessor matrix for unweighted directed APSP, which can also be viewed as a sub-$n^{2+\rho}$ time reduction from computing the predecessor

matrix to $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$. Also, if we can compute the predecessor matrix for the graph constructed in the above proof, we would know which path $X(p)$ the shortest path from i to j uses, which in turn solves $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$. Thus, computing the predecessor matrix for unweighted directed APSP is sub-$n^{2+\rho}$ fine-grained equivalent to $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$, and thus also equivalent to u-APSP.

Zwick's algorithm is general enough to apply to some variants of APSP. One example is the All-Pairs Longest Paths (APLP) problem in DAGs. To compute APLP in a DAG, we first negate the weight of every edge, then the problem becomes APSP, on which we can directly apply Zwick's algorithm. Therefore, Zwick's algorithm show reductions from u-APLP and $[\pm c_0]$-APLP in DAGs to $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$.

Perhaps more surprisingly, the other direction of the reduction also holds. Therefore, APLP in DAG and APSP in graphs with weights bounded by $\tilde{O}(1)$ are sub-$O(n^{2+\rho})$ equivalent.

▶ **Theorem 12.** *Let ρ be such that $\omega(1, \rho, 1) = 1 + 2\rho$. Then u-APLP in DAGs, $[\pm c_0]$-APLP in DAGs and $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ are sub-$n^{2+\rho}$ fine-grained equivalent.*

The proof of Theorem 12 follows from the same approach and is deferred to the full version.

All problems shown equivalent to u-APSP above are problems on directed graphs. One natural question is that whether some problems on undirected graphs are also in this equivalence class, or whether we can show some undirected graph problems require $n^{2+\rho-o(1)}$ time if we assume problems in this equivalence class also require $n^{2+\rho-o(1)}$ time. To answer these questions, we first consider the u-cRed-APSP problem.

▶ **Theorem 13.** *Let ρ be such that $\omega(1, \rho, 1) = 1 + 2\rho$. u-cRed-APSP for $2 \le c = \tilde{O}(1)$ and $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ are sub-$n^{2+\rho}$ fine-grained equivalent.*

The proof of Theorem 13 uses a similar graph construction and is in the full version.

By slightly modifying the proof of Theorem 13, we can show conditional hardness for APLSP on undirected graphs where the edge weights are in $\{0, 1\}$. The proof is in the full version.

▶ **Corollary 14.** *Let ρ be such that $\omega(1, \rho, 1) = 1 + 2\rho$. Suppose $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ requires $n^{2+\rho-o(1)}$ time. Then APLSP on undirected graphs where the edge weights can be $\{0, 1\}$ also requires $n^{2+\rho-o(1)}$ time.*

Using similar ideas we also show hardness for *Vertex-Weighted APSP* in undirected graphs, where the vertex weights may be large. (The current best algorithms for Vertex-Weighted APSP for directed graphs [6, 32] had running time about $O(n^{2.85})$; the bound is $\tilde{O}(n^{11/4})$ if $\omega = 2$. No better algorithms were known in the undirected graphs – which our conditional lower bound attempts to explain.) The proof is in the full version.

▶ **Corollary 15.** *Let ρ be such that $\omega(1, \rho, 1) = 1 + 2\rho$. Suppose $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ requires $n^{2+\rho-o(1)}$ time. Then vertex-weighted APSP on undirected graphs where the vertex weights are in $[O(n^{1-\rho})]$ also requires $n^{2+\rho-o(1)}$ time.*

The conditional hardness for u-$\#_{\mathrm{mod}\, U}$APSP and u-$\#_{\le U}$APSP for any $U \ge 2$ can be proved by combining our graph construction with randomized techniques for a unique variant of Min-Plus product; see the proof in the full version.

▶ **Theorem 16.** *Let ρ be such that $\omega(1, \rho, 1) = 1 + 2\rho$. Suppose $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ requires $n^{2+\rho-o(1)}$ time (with randomization). Then u-$\#_{\mathrm{mod}\, U}$APSP and u-$\#_{\le U}$APSP for any $U \ge 2$ requires $n^{2+\rho-o(1)}$ time.*

In Section 4, we will give an algorithm for approximating APSP with sublinear additive errors. Using the same technique as our reductions from Rectangular Min-Plus product to APSP problems, we can show a conditional lower bound for this problem.

▶ **Theorem 17.** *Given a directed unweighted graph $G = (V, E)$ with n vertices and a function $f > 0$ where $\frac{\ell}{f(\ell)}$ is nondecreasing. Suppose we can approximate the shortest-path distance $D[u, v]$ with additive error $f(D[u, v])$, for all $u, v \in V$ in $T(n)$ time, then $\max_{1\le\ell\le n} \mathcal{M}^\star\left(n, n/\ell, n \mid \frac{\ell}{f(\ell)}\right) \le O(T(n))$.*

Proof. Fix any $1 \le \ell \le n$. First, note that $\mathcal{M}^\star\left(n, n/\ell, n \mid \frac{\ell}{f(\ell)}\right) = \Theta\left(\mathcal{M}^\star\left(n, n/\ell, n \mid \frac{\ell}{Cf(\ell)}\right)\right)$ for any constant C. Here, we take $C = 12$ to be a large enough constant.

Suppose we are given an $n \times n/\ell$ matrix A and an $n/\ell \times n$ matrix B, whose entries are positive integers bounded by $\frac{\ell}{12f(\ell)}$, and we want to compute their Min-Plus product $A \star B$. We use a similar reduction as the one in the proof of Theorem 10, but stretching the length of the middle paths. Specifically, we create vertex set I of size n, vertex set J of size n, and n/ℓ paths of the form $X(p) := x_{p,\frac{\ell}{3f(\ell)}} \rightsquigarrow \cdots \rightsquigarrow x_{p,0} \rightsquigarrow y_{p,0} \rightsquigarrow \cdots \rightsquigarrow y_{p,\frac{\ell}{3f(\ell)}}$. From $x_{p,i}$ to $x_{p,i-1}$ and $y_{p,j}$ to $y_{p,j+1}$, we embed paths of length $6f(\ell)$; from $x_{p,0}$ to $y_{p,0}$, we embed a path of length $\ell - 2$. Similar to previous reductions, for every $i \in [n] = I$ and $p \in [n/\ell]$, we add an edge from i to $x_{p,A[i,p]}$; for every $j \in [n] = J$ and $p \in [n/\ell]$, we add an edge from j to $y_{p,B[p,j]}$. Then the distance from $i \in I$ to $j \in J$ in this graph equals $\ell + 6f(\ell)(A \star B)[i, j]$.

Since $0 \le (A \star B)[i, j] \le \frac{\ell}{6f(\ell)}$, we must have $\ell \le \ell + 6f(\ell)(A \star B)[i, j] \le 2\ell$. Since $\frac{\ell}{f(\ell)}$ is nondecreasing, we must have $f(t\ell) \le tf(\ell)$ for any $t \ge 1$, and thus $f(\ell + 6f(\ell)(A \star B)[i, j]) \le 2f(\ell)$. Therefore, an $f(\ell + 6f(\ell)(A \star B)[i, j])$-additive approximation of APSP can determine that the distance from $i \in I$ to $j \in J$ is in $\ell + 6f(\ell)(A \star B)[i, j] \pm 2f(\ell)$, from which we can compute $(A \star B)[i, j]$ easily since $(A \star B)[i, j]$ must be an integer. ◀

Finally, we give a reduction from u-APSP to Min Witness Equality, where we are given $n \times n$ integer matrices A and B, and are required to compute $\min\{k \in [n] : A[i, k] = B[k, j]\}$ for every pair of (i, j). Reductions from u-APSP to matrix product problems are considered by Lincoln et al. [18], where they show reductions from u-APSP to the All-Edges Monochromatic Triangle problem and $(\min, \max)$-product problem, but their techniques do not seem to apply to Min Witness Equality.

The proof of the following theorem is deferred to the full version.

▶ **Theorem 18.** *Let ρ be such that $\omega(1, \rho, 1) = 1 + 2\rho$. Suppose $\mathrm{M}^\star(n, n^\rho, n \mid n^{1-\rho})$ requires $n^{2+\rho-o(1)}$ time. Then Min Witness Equality requires $n^{2+\rho-o(1)}$ time.*

4 Additive Approximation Algorithms for APSP

In this section, we give an algorithm for approximate APSP with additive errors in directed unweighted graphs, to match the lower bound that we have just proved in Theorem 17 (ignoring logarithmic factors). Namely, our algorithm achieves running time $\tilde{O}(\max_\ell \mathcal{M}^\star(n, n/\ell, n \mid \ell^{1-p}))$, which improves Roditty and Shapira's previous algorithm [20] with running time $\tilde{O}(\max_\ell \min\{n^3/\ell, \mathcal{M}^\star(n, n/\ell^{1-p}, n \mid \ell^{1-p})\})$.

Let $D[u, v]$ denote the shortest-path distance from u to v.

Overview. The new algorithm is a variation of Zwick's exact u-APSP algorithm [34], and is actually simpler than Roditty and Shapira's algorithm. The idea is to compute as many as the shortest-path distances *exactly* as we can in $\tilde{O}(n^\omega)$ time in an initial phase. In the second phase, we apply rectangular matrix multiplication to submatrices computed from the first phase, where entries are approximated by rounding and rescaling.

Preliminaries. For every ℓ that is a power of $3/2$, let $R_\ell \subseteq V$ be a subset of $\tilde{O}(n/\ell)$ vertices that hits all shortest paths of length $\ell/2$ [34]. (For example, a random sample works with high probability.) We may assume that $R_{(3/2)^i} \supseteq R_{(3/2)^{i+1}}$ (because otherwise, we can add $R_{(3/2)^j}$ to $R_{(3/2)^i}$ for all $j > i$ and the size bound would still hold). For subsets $S_1, S_2 \subseteq V$, let $D(S_1, S_2)$ denote the submatrix of D containing the entries for $(u, v) \in S_1 \times S_2$.

Phase 1. We first solve the following subproblem: compute $D[u, v]$ (exactly) for all $(u, v) \in R_\ell \times V$ with $D[u, v] \le \ell$, and similarly for all $(u, v) \in V \times R_\ell$ with $D[u, v] \le \ell$.

Suppose we have already computed $D[u, v]$ for all $(u, v) \in R_{2\ell/3} \times V$ with $D[u, v] \le 2\ell/3$, and similarly for all $(u, v) \in V \times R_{2\ell/3}$ with $D[u, v] \le 2\ell/3$.

We take the Min-Plus product $D(R_\ell, R_{2\ell/3}) \star D(R_{2\ell/3}, V)$. For each $(u, v) \in R_\ell \times V$, if its output entry is smaller than the current value of $D[u, v]$, we reset $D[u, v]$ to the smaller value. Similarly, we take the Min-Plus product $D(V, R_{2\ell/3}) \star D(R_{2\ell/3}, R_\ell)$. For each $(u, v) \in V \times R_\ell$, if its output entry is smaller than the current value of $D[u, v]$, we reset $D[u, v]$ to the smaller value. We reset all entries greater than ℓ to ∞.

To justify correctness, observe that for any shortest path π of length between $2\ell/3$ and ℓ, the middle $(2\ell/3)/2 = \ell/3$ vertices must contain a vertex of $R_{2\ell/3}$, which splits π into two subpaths each of length at most $\ell/2 + \ell/6 \le 2\ell/3$.

We do the above for all ℓ's that are powers of $3/2$. The total cost is

$$\tilde{O}\left(\max_\ell \mathcal{M}^\star(n/\ell, n/\ell, n \mid \ell)\right) \le \tilde{O}\left(\max_\ell \ell \cdot \mathcal{M}^\star(n/\ell, n/\ell, n)\right) \le \tilde{O}\left(\max_\ell \ell^2 (n/\ell)^\omega\right) = \tilde{O}(n^\omega).$$

Phase 2. Next we approximate all shortest-path distances $D[u, v]$ where $D[u, v]$ is between $2\ell/3$ and ℓ, with additive error $O(f(\ell))$ for a given function f, as follows:

We compute the Min-Plus product $D(V, R_{2\ell/3}) \star D(R_{2\ell/3}, V)$, keeping only entries bounded by $O(\ell)$. As we allow additive error $O(f(\ell))$, we round entries to multiples of $f(\ell)$. This takes $\tilde{O}(\mathcal{M}^\star(n, n/\ell, n \mid \frac{\ell}{f(\ell)}))$ time.

To justify correctness, observe as before that in any shortest path π of length between $2\ell/3$ and ℓ, some vertex in $R_{2\ell/3}$ splits the path into two subpaths of length at most $2\ell/3$.

We repeat for all ℓ's that are powers of $3/2$. The total cost is $\tilde{O}\left(\max_\ell \mathcal{M}^\star(n, n/\ell, n \mid \frac{\ell}{f(\ell)})\right)$.

Standard techniques for generating witnesses for matrix products can be applied to recover the shortest paths (e.g., see [11, 34]).

▶ **Theorem 19.** *Given a directed unweighted graph $G = (V, E)$ with n vertices and a function f where $\frac{\ell}{f(\ell)}$ is nondecreasing, we can approximate the shortest-path distance $D[u, v]$ with additive error $O(f(D[u, v]))$ for all $u, v \in V$, in $\tilde{O}\left(\max_\ell \mathcal{M}^\star(n, n/\ell, n \mid \frac{\ell}{f(\ell)})\right)$ time.*

▶ Remark. For $f(\ell) = \ell^p$, we can upper-bound the running time by

$$\begin{aligned}\tilde{O}\left(\max_\ell \mathcal{M}^\star(n, n/\ell, n \mid \ell^{1-p})\right) &\le \tilde{O}\left(L^{1-p} \cdot \mathcal{M}(n, n/L, n) + n^3/L\right) \\ &\le \tilde{O}\left(L^{1-p}(n^{2+o(1)} + n^\omega / L^{(\omega-2)/(1-\alpha)}) + n^3/L\right)\end{aligned}$$

for any choice of L, where α is the rectangular matrix multiplication exponent (satisfying $\omega(1,1,\alpha)=2$). For example, we can set $L=n^{3-\omega}$, and for $p>1-\min\{\frac{\omega-2}{1-\alpha},\frac{\omega-2}{3-\omega}\}$, get optimal $\tilde{O}(n^\omega)$ running time. In fact, with the current rectangular matrix multiplication bounds we get $\tilde{O}(n^{2.373})$ time for $p\geq 0.415\geq(\omega(1,0.373,1)-2\cdot 0.373-1)/(1-0.373)$. Roditty and Shapira [20] specifically asked whether there exists $p<1$ for which $\tilde{O}(n^\omega)$ time is possible; we have thus answered their question affirmatively if $\omega>2$.

▶ Remark. For directed graphs with weights from $[c_0]$, the running time is

$$\tilde{O}\left(c_0 n^\omega+\max_\ell \mathcal{M}^\star(n,n/\ell,n\mid c_0\tfrac{\ell}{f(\ell)})\right).$$

5 Algorithms for All-Pairs Lightest Shortest Paths

In this section, we describe algorithms for the following problem, which includes both All-Pairs Lightest Shortest Paths (APLSP) and Shortest Lightest Paths (APSLP) as special cases:

▶ **Problem 20. (Lex_2-APSP)** *We are given a graph $G=(V,E)$ with n vertices, where each edge $(u,v)\in E$ has a "primary" weight $w_1(u,v)$ and a "secondary" weight $w_2(u,v)$. For every pair of vertices $u,v\in V$, we want to find a path π from u to v that minimizes $(\sum_{e\in\pi}w_1(e),\sum_{e\in\pi}w_2(e))$ lexicographically.*

Let $D[u,v]$ be the lexicographical minimum of $(\sum_{e\in\pi}w_1(e),\sum_{e\in\pi}w_2(e))$. Let $D_1[u,v]$ be the minimum of $\sum_{e\in\pi}w_1(e)$ (the shortest-path distance) and let $D_2[u,v]$ be the second coordinate of $D[u,v]$. APLSP corresponds to the case when all secondary edge weights are 1, whereas APSLP corresponds to the case when all primary edge weights are 1.

The following lemma, which will be important in the analysis of our Lex_2-APSP algorithm, bounds the complexity of Min-Plus product of an $n_1\times n_2$ matrix A and an $n_2\times n_3$ matrix B in the case when the finite entries of A come from a small range $[\ell_1]$ (but the finite entries of B may come from a large range $[\ell_2]$). The bound can be made sensitive to the number m_2 of finite entries of B and the number m_3 of output entries we want. The lemma is a variant of [6, Theorem 3.5] (the basic approach originates from Matoušek's dominance algorithm [19], but this variant requires some extra ideas). It also generalizes and improves (using rectangular matrix multiplication) Theorem 1.2 in [30].

▶ **Lemma 21.** $\mathcal{M}^\star(n_1,n_2,n_3\mid\ell_1,\ell_2)=\tilde{O}\left(\min_t(\mathcal{M}^\star(n_1,n_2,n_2n_3/t\mid\ell_1)+tn_1n_3)\right)$. *More generally,* $\mathcal{M}^\star(n_1,n_2,n_3\mid m_1,m_2,m_3\mid\ell_1,\ell_2)=\tilde{O}\left(\min_t(\mathcal{M}^\star(n_1,n_2,m_2/t\mid\ell_1)+tm_3)\right)$.

Proof. Divide each column of B into groups of t entries by rank: the first group contains the t smallest elements, the second group contains the next t smallest, etc. (ties in ranks can be broken arbitrarily). Each column may have at most t leftover entries. The total number of groups is at most m_2/t.

For each $i\in[n_1]$ and $j'\in[m_2/t]$, let $C[i,j']$ be true iff there exists $k\in[n_2]$ such that $A[i,k]<\infty$ and group j' contains an element with row index k. Computing C reduces to taking a Boolean matrix product and has cost $O(\mathcal{M}(n_1,n_2,m_2/t))$.

For each $i\in[n_1]$ and $j'\in[m_2/t]$, suppose that group j' is part of column j and the maximum element in group j' is x; let $\widehat{C}[i,j']=\min_{k:B[k,j]\in[x,x+\ell_1]}(A[i,k]+B[k,j])$. Since entries in A are from the range $[\ell_1]\cup\{\infty\}$, and we only keep a size ℓ_1+1 range of values for matrix B, computing $\widehat{C}$ reduces to taking a Min-Plus product with entries in $[\ell_1]$ (after shifting) and has cost $O(\mathcal{M}^\star(n_1,n_2,m_2/t\mid\ell_1))$.

To compute the output entry at each of the m_3 positions (i, j), we find the group j' in column j with the smallest rank such that $C[i, j']$ is true. Let x be the maximum element in group j'. The answer $\min_k(A[i, k] + B[k, j])$ is at most $x + \ell_1$. Thus, the answer is defined by an index k that (i) corresponds to an element in group j', or (ii) corresponds to a leftover element in column j, or (iii) has $B[k, j] \in [x, x + \ell_1]$. Cases (i) and (ii) can be handled by linear search in $O(t)$ time; case (iii) is handled by looking up $\widehat{C}[i, j']$. The total time to compute m_3 output entries is $O(tm_3)$. ◀

5.1 $[c_0]$-Lex$_2$-APSP

Let $c_0 = \tilde{O}(1)$. For directed graphs, Zwick [33] presented a variant of his u-APSP algorithm that solves $[c_0]$-Lex$_2$-APSP (and thus $[c_0]$-APLSP and $[c_0]$-ALPSP) in time $\tilde{O}(\max_\ell \mathcal{M}^\star(n, n/\ell, n \mid \ell^2)) \leq \tilde{O}(\min_L(L^2\mathcal{M}(n, n/L, n) + n^3/L))$. This is $O(n^{2.724})$ by the current bounds on rectangular matrix multiplication [17] (and is $\tilde{O}(n^{8/3})$ if $\omega = 2$).

Chan [6] gave a faster algorithm for $([c_0] - \{0\})$-Lex$_2$-APSP (and in fact a special case of Vertex-Weighted APSP that includes $([c_0] - \{0\})$-Lex$_k$-APSP for an arbitrary constant k) in time $\tilde{O}(n^{(3+\omega)/2})$, which is $O(n^{2.687})$ by the current matrix multiplication exponent (and is $\tilde{O}(n^{2.5})$ if $\omega = 2$). Zwick's algorithm works even when zero primary weights are allowed, but Chan's algorithm does not (part of the difficulty is that the secondary distance of a path may be much larger than the primary distance). A more general version of Chan's algorithm [6] can handle zero primary weights (and $[c_0]$-Lex$_k$-APSP for constant k) but has a worse time bound of $\tilde{O}(n^{(9+\omega)/4})$, which can be slightly reduced using rectangular matrix mutiplication [32].

We describe an $O(n^{2.6581})$-time algorithm to solve $[c_0]$-Lex$_2$-APSP for directed graphs, which can handle zero weights and is faster than Zwick's $O(n^{2.724})$-time algorithm; it is also slightly faster than Chan's algorithm. The algorithm uses rectangular matrix multiplication (without which the running time would be $\tilde{O}(n^{(\omega+3)/2})$). It should be noted that Chan's previous algorithm can't be easily sped up using rectangular matrix multiplication, besides being inapplicable when there are zero primary weights.

Overview. The new algorithm can be viewed as an interesting variant of Zwick's u-APSP algorithm [34]. Zwick's algorithm uses rectangular Min-Plus products of dimensions around $n \times n/\ell$ and $n/\ell \times n$, in geometrically increasing parameter ℓ. Our algorithm proceeds in two phases. In both phases, we use the rectangular products of dimensions around $n/\ell \times n/\ell$ and $n/\ell \times n$. In the first phase, we consider ℓ in increasing order; in the second, we consider ℓ in decreasing order. In these Min-Plus products, entries of the first matrix in each product come from a small range; this enables us to use Lemma 21.

Preliminaries. Let L be a parameter to be set later. Let $\lambda[u, v]$ denote the length of a lexicographical shortest path between u and v. In this section, the *length* of a path refers to the number of edges in the path.

For every ℓ that is a power of $3/2$, as in Section 4, let $R_\ell \subseteq V$ be a subset of $\tilde{O}(n/\ell)$ vertices that hits all shortest paths of length $\ell/2$ [33, 34]. We may assume that $R_{(3/2)^i} \supseteq R_{(3/2)^{i+1}}$ (as before). Set $R_1 = V$.

For $S_1, S_2 \subseteq V$, let $D(S_1, S_2)$ denote the submatrix of D containing the entries for $(u, v) \in S_1 \times S_2$.

Phase 1. We first solve the following subproblem for a given $\ell \leq L$: compute $D[u,v]$ for all $(u,v) \in R_\ell \times V$ with $\lambda[u,v] \leq \ell$, and similarly for all $(u,v) \in V \times R_\ell$ with $\lambda[u,v] \leq \ell$. (We don't know $\lambda[u,v]$ in advance. More precisely, if $\lambda[u,v] \leq \ell$, the computed value should be correct; otherwise, the computed value is only guaranteed to be an upper bound.)

Suppose we have already computed $D[u,v]$ for all $(u,v) \in R_{2\ell/3} \times V$ with $\lambda[u,v] \leq 2\ell/3$, and similarly for all $(u,v) \in V \times R_{2\ell/3}$ with $\lambda[u,v] \leq 2\ell/3$.

We take the Min-Plus product $D(R_\ell, R_{2\ell/3}) \star D(R_{2\ell/3}, V)$ (where elements are compared lexicographically). For each $(u,v) \in R_\ell \times V$, if its output entry is smaller than the current value of $D[u,v]$, we reset $D[u,v]$ to the smaller value. Similarly, we take the Min-Plus product $D(V, R_{2\ell/3}) \star D(R_{2\ell/3}, R_\ell)$. For each $(u,v) \in V \times R_\ell$, if its output entry is smaller than the current value of $D[u,v]$, we reset $D[u,v]$ to the smaller value. We reset all entries greater than $c_0\ell$ to ∞.

To justify correctness, observe that for any shortest path π of length between $2\ell/3$ and ℓ, the middle $(2\ell/3)/2 = \ell/3$ vertices must contain a vertex of $R_{2\ell/3}$, which splits π into two subpaths each of length at most $\ell/2 + \ell/6 \leq 2\ell/3$.

To take the product, we map each entry $D[u,v]$ of $D(R_{2\ell/3}, V)$ to a number $D_1[u,v] \cdot c_0\ell + D_2[u,v] \in [\tilde{O}(\ell^2)]$. It is more efficient to break the product into ℓ separate products, by putting entries of $D(R_\ell, R_{2\ell/3})$ with a common D_1 value into one matrix. Then after shifting, the finite entries of each such matrix are in $[\tilde{O}(\ell)]$. (The entries of $D(R_{2\ell/3}, V)$ are still in $[\tilde{O}(\ell^2)]$.) Hence, the computation takes time $\tilde{O}(\ell \cdot \mathcal{M}^\star(n/\ell, n/\ell, n \mid \ell, \ell^2))$.

We do the above for all $\ell \leq L$ that are powers of $3/2$ (in increasing order).

Phase 2. Next we solve the following subproblem for a given $\ell \leq L$: compute $D[u,v]$ for all $(u,v) \in R_{2\ell/3} \times V$ with $\lambda[u,v] \leq L$.

Suppose we have already computed $D[u,v]$ for all $(u,v) \in R_\ell \times V$ with $\lambda[u,v] \leq L$.

We take the Min-Plus product $D(R_{2\ell/3}, R_\ell) \star D(R_\ell, V)$, keeping only entries bounded by $\tilde{O}(\ell)$ in the first matrix and $\tilde{O}(L)$ in the second matrix. For each $(u,v) \in V \times R_\ell$, if its output entry is smaller than the current value of $D[u,v]$, we reset $D[u,v]$ to the smaller value.

To justify correctness, recall that for $(u,v) \in R_{2\ell/3} \times V$, if $\lambda[u,v] < 2\ell/3$, then $D[u,v]$ is already computed in Phase 1. On the other hand, in any shortest path π of length between $2\ell/3$ and L, the first $\ell/2$ vertices of the path must contain a vertex of R_ℓ.

To take the product, we map each entry $D[u,v]$ of $D(R_{2\ell/3}, V)$ to a number $D_1[u,v] \cdot c_0 L + D_2[u,v] \in [\tilde{O}(\ell L)]$. As before, it is better to perform ℓ separate products, by putting entries of $D(R_{2\ell/3}, R_\ell)$ with a common D_1 value into one matrix. Then after shifting, the finite entries of each such matrix are in $[\tilde{O}(\ell)]$. (The entries of $D(R_{2\ell/3}, V)$ are still in $[\tilde{O}(\ell L)]$.) Hence, the computation takes time $\tilde{O}(\ell \cdot \mathcal{M}^\star(n/\ell, n/\ell, n \mid \ell, \ell L))$.

We do the above for all $\ell \leq L$ that are powers of $3/2$ (in decreasing order).

Last step. By the end of Phase 2 (when ℓ reaches 1), we have computed $D[u,v]$ for all (u,v) with $\lambda[u,v] \leq L$. To finish, we compute $D[u,v]$ for all (u,v) with $\lambda[u,v] > L$, as follows:

We run Dijkstra's algorithm $O(|R_L|)$ times to compute $D[u,v]$ for all $(u,v) \in R_L \times V$ and for all $(u,v) \in V \times R_L$. This takes $O(|R_L|n^2) = \tilde{O}(n^3/L)$ time. We then compute $D(V, R_L) \star D(R_L, V)$ by brute force in $O(|R_L|n^2) = \tilde{O}(n^3/L)$ time.

Correctness follows since every shortest path of length more than L must pass through a vertex in R_L.

As before, standard techniques for generating witnesses for matrix products can be applied to recover the shortest paths [11, 34].

Total time. The cost of Phase 2 dominates the cost of Phase 1. By Lemma 21, the total cost is

$$\tilde{O}\left(\max_{\ell \le L} \ell \cdot \mathcal{M}^\star(n/\ell, n/\ell, n \mid \ell, \ell L) \,+\, n^3/L\right)$$
$$\leq \quad \tilde{O}\left(\max_{\ell \le L} \ell \cdot \min_t \left(\mathcal{M}^\star(n/\ell, n/\ell, n^2/(\ell t) \mid \ell) + t n^2/\ell\right) \,+\, n^3/L\right).$$

We set $t = n/L$ and obtain

$$\tilde{O}(\max_{\ell \le L} \ell^2 \cdot \mathcal{M}(n/\ell, n/\ell, Ln/\ell) \,+\, n^3/L).$$

Intuitively, the maximum occurs when $\ell = 1$, and so we should choose L to minimize $\tilde{O}(\mathcal{M}(n, n, Ln) + n^3/L)$. With the current bounds on rectangular matrix multiplication [17], we choose $L = n^{0.342}$ and get running time $O(n^{2.6581})$. (Formally, we can verify this time bound using the convexity of the function $2x + \omega(1-x, 1-x, 1.342-x)$.)

▶ **Theorem 22.** *$[c_0]$-Lex$_2$-APSP (and thus $[c_0]$-APLSP and $[c_0]$-APSLP) can be solved in $O(n^{2.6581})$ time for any $c_0 = \tilde{O}(1)$.*

Remarks. Without rectangular matrix multiplication, the above still gives a time bound of $\tilde{O}(Ln^\omega + n^3/L)$, yielding $\tilde{O}(n^{(3+\omega)/2})$.

The same algorithm works even with negative weights (i.e., for $[\pm c_0]$-Lex$_2$-APSP), like Zwick's previous algorithm [33], assuming no negative cycles.

In the full version, we describe an alternative algorithm that has the same running time, though it does not allow zero primary edge weights (or negative weights).

5.2 Undirected $([c_0] - \{0\})$-Lex$_2$-APSP

A natural question is whether APLSP or APSLP is easier for undirected graphs. We now describe a faster $O(n^{2.58})$-time algorithm for $([c_0] - \{0\})$-Lex$_2$-APSP for undirected graphs. Zero primary weights are not allowed, but zero secondary weights are. (In particular, the algorithm can solve $[c_0]$-APSLP, when all primary weights are 1.)

Overview. We follow an idea of Aingworth et al. [1], to divide into two cases: when the source vertex has high degree or low degree. For high-degree vertices, there exists a small dominating set, and so these vertices can be covered by a small number of "clusters"; sources in the same cluster are close together, and so distances from one fixed source give us good approximation to distances from other sources in the same cluster, by the triangle inequality (since the graph is undirected). On the other hand, for low-degree vertices, the relevant subgraph is sparse, which enables faster algorithms. Originally, Aingworth et al.'s approach was intended for the design of approximation algorithms (with $O(1)$ additive error for unweighted graphs). We will adapt it to find *exact* shortest paths. (Chan [7] previously had also applied Aingworth et al.'s approach to exact APSP, but the goal there was in logarithmic-factor speedup, which was quite different.) In order to handle the high-degree case for Lex$_2$-APSP, we need further ideas to use approximate primary shortest-path distances to compute exact lexicographical shortest-path distances; in particular, we will need Min-Plus products on secondary distances (as revealed in the proof of Lemma 23 below). The combination of Aingworth et al.'s approach with matrix multiplication appears new, and interesting in our opinion.

Preliminaries. We first compute $D_1[u,v]$ for all (u,v) by running a known $[c_0]$-APSP algorithm on the primary distances in $O(n^\omega)$ time [3, 21].

Assume that we have already computed $D[u,v]$ for all (u,v) with $D_1[u,v] \le 2\ell/3$ for a given ℓ. We want to compute $D[u,v]$ for all (u,v) with $D_1[u,v] \le \ell$.

Define $D_2^{(\ell)}[u,v] = D_2[u,v]$ if $D_1[u,v] = \ell$, and $D_2^{(\ell)}[u,v] = \infty$ otherwise. For subsets $S_1, S_2 \subseteq V$, let $D_2^{(\ell)}(S_1,S_2)$ denote the submatrix of $D_2^{(\ell)}$ containing the entries for $(u,v) \in S_1 \times S_2$.

▶ **Lemma 23.** *Let $G=(V,E)$ be an undirected graph with edge weights in $[c_0]-\{0\}$. Assume that we have already computed $D[u,v]$ for all (u,v) with $D_1[u,v] \le 2\ell/3$. Given a set S of vertices that are within primary distance $c = \tilde{O}(1)$ from each other, we can compute $D[u,v]$ for all $u \in S$ and $v \in V$ with $D_1[u,v] \le \ell$ in $O(\mathcal{M}^\star(|S|, n/\ell, n \mid \ell))$ total time.*

Proof. Fix $s \in S$. Let $V_i = \{v \in V : D_1[s,v] \in i \pm c\}$. Note that $\sum_i |V_i| = \tilde{O}(n)$. Also note that if $u \in S$ and $D_1[u,v] = i$, then we must have $v \in V_i$ (by the triangle inequality, because the graph is undirected).

Pick an index $m \in [0.4\ell, 0.6\ell]$ with $|V_{m-c_0} \cup \cdots \cup V_m| = \tilde{O}(n/\ell)$.

For $i \le m$, we have already computed $D_2^{(i)}(S,V_i)$.

For $i = m+1, \ldots, \ell$, we will compute $D_2^{(i)}(S,V_i)$ as follows: For each $\Delta \in [c_0]$, we take the Min-Plus product $D_2^{(m-\Delta)}(S,V_{m-\Delta}) \star D_2^{(i-m+\Delta)}(V_{m-\Delta},V_i)$. Note that $D_2^{(i-m+\Delta)}(V_{m-\Delta},V_i)$ is already known, since $i-m+\Delta < 2\ell/3$. We take the minimum over all $\Delta \in [c_0]$ for those $(u,v) \in S \times V_i$ with $D_1[u,v] = i$.

Instead of doing the product individually for each i, it is more efficient to combine all the matrices $D_2^{(i-m+\Delta)}(V_{m-\Delta},V_i)$ over all $i > m$. This gives a single matrix (per Δ) with $|V_{m-\Delta}| = \tilde{O}(n/\ell)$ rows and $\sum_{i>m} |V_i| = \tilde{O}(n)$ columns. So, the entire product can be computed in $O(\mathcal{M}^\star(|S|, n/\ell, n \mid \ell))$ time. ◀

Let L be a parameter to be set later. Let V_{high} be the set of all vertices of degree more than n/L, and V_{low} be the set of all vertices of degree at most n/L.

Phase 1. We will first compute $D[u,v]$ for all $u \in V_{\text{high}}$ and $v \in V$ with $D_1[u,v] \le \ell$, as follows:

Let $X \subseteq V$ be a dominating set for V_{high} of size $\tilde{O}(L)$, such that every vertex in V_{high} is in the (closed) neighborhood of some vertex in X. Such a dominating set can be constructed (for example, by the standard greedy algorithm) in $\tilde{O}(n^2)$ time [1].

Let $X = \{x_1, x_2, \ldots, x_{\tilde{O}(L)}\}$. For each $x_i \in X$, we divide $N(x_i) \setminus \left(\bigcup_{j<i} N(x_j)\right)$ – its neighborhood excluding previous neighborhoods – into groups of size $O(n/L)$. The total number of groups is $\tilde{O}(L)$, and the groups cover all vertices in V_{high}. For each such group, we apply Lemma 23 (with $c = 2c_0$). The total time is $\tilde{O}(L \cdot \mathcal{M}^\star(n/L, n/\ell, n \mid \ell))$.

Phase 2. Next, for each $u \in V_{\text{low}}$, we will compute $D[u,v]$ for all $v \in V$ with $D_1[u,v] \le \ell$, as follows:

Define a graph G_u containing all edges (x,y) with $x \in V_{\text{low}}$ or $y \in V_{\text{low}}$; for each $z \in V_{\text{high}}$, we add an extra edge (u,z) with weight $D[u,z]$, which has been computed in Phase 1. Then the lexicographical shortest-path distance from u to v in G_u matches the lexicographical shortest-path distance in G, because if $\langle u_1, \ldots, u_k\rangle$ is a lexicographical shortest path in G with $u_1 = u$, and i is the largest index with $u_i \in V_{\text{high}}$ (set $i=1$ if none exists), then $\langle u_1, u_i, \ldots, u_k\rangle$ is a path in G_u. We run Dijkstra's algorithm on G_u from the source u. Since G_u has $O(n^2/L)$ edges, this takes $\tilde{O}(n^2/L)$ time per u. The total over all u is $\tilde{O}(n^3/L)$.

As before, standard techniques for generating witnesses for matrix products can be applied to recover the shortest paths [11, 34].

Total time. We do the above for all ℓ's that are powers of 3/2. The overall cost is

$$\begin{aligned}
&\tilde{O}\left(\max_{\ell} L\cdot\mathcal{M}^{\star}(n/L,n/\ell,n\mid\ell)\ +\ n^3/L\right)\\
&\leq\ \tilde{O}\left(\max_{\ell} L\cdot\min\left\{n^3/(L\ell),\ \ell\cdot\mathcal{M}(n/L,n/\ell,n)\right\}\ +\ n^3/L\right)\\
&=\ \tilde{O}\left(\max_{\ell\leq L} L\ell\cdot\mathcal{M}(n/L,n/\ell,n)\ +\ n^3/L\right)\ =\ \tilde{O}(L^2\cdot\mathcal{M}(n/L,n/L,n)\ +\ n^3/L).
\end{aligned}$$

With the current bounds on rectangular matrix multiplication, we choose $L=n^{0.4206}$ and get running time $O(n^{2.5794})$.

▶ **Theorem 24.** *($[c_0]-\{0\}$)-Lex$_2$-APSP (and thus -APLSP and -APSLP) for undirected graphs can be solved in $O(n^{2.5794})$ time for any $c_0=\tilde{O}(1)$.*

▶ Remarks. Without rectangular matrix multiplication, the above still gives a time bound of $\tilde{O}(L^3(n/L)^{\omega}+n^3/L)$, yielding $\tilde{O}(n^{2+1/(4-\omega)})$.

One could adapt the algorithm to solve Undirected ($[c_0]-\{0\}$)-Lex$_k$-APSP for a larger constant k, but the running time appears worse than the bound $\tilde{O}(n^{(3+\omega)/2})$ by Chan [6] (because of the need to compute a Min-Plus product between matrices with larger entries in Lemma 23).

6 Exact u-#APSP

We defer most of our algorithms for #APSP to the full paper. An exception is our algorithm for exact u-#APSP, which is simple and is described below. Interestingly, some of our #APSP algorithms are obtained by modifying our Lex$_2$-APSP algorithms, even though the #APSP and Lex$_2$-APSP problems appear very different.

For exact counts that could be exponentially large, we will describe a combinatorial $\tilde{O}(n^3)$-time algorithm to solve u-#APSP for directed unweighted graphs, in the standard word RAM model (with $(\log n)$-bit words). The idea behind the algorithm is actually related to the Lex$_2$-APSP algorithm in Section 5.2, but simplified with $L=1$ and without matrix multiplication and dominating sets.

Recall that the goal is to compute the number $C[u,v]$ of shortest paths from u to v, for all $u,v\in V$ for a given directed unweighted graph $G=(V,E)$.

We first compute $D[u,v]$ for all $u,v\in V$ in $O(n^3)$ time by known APSP algorithms. There are of course faster APSP algorithms for directed unweighted graphs, but we use the slower $O(n^3)$ time algorithm to keep the whole algorithm combinatorial.

Assume we have already computed $C[u,v]$ for all u,v with $D[u,v]\leq 2\ell/3$ for a given ℓ. Fix a source vertex $s\in V$. We will compute $C[s,v]$ for all v with $D[s,v]\leq\ell$, as follows:

Let $V_i=\{v\in V: D[s,v]=i\}$. Note that $\sum_i|V_i|=n$, so there exist an index $m\in[0.4\ell,0.6\ell]$ with $|V_m|=O(n/\ell)$.

For $i\leq m$, we have already computed $C[s,v]$ for all $v\in V_i$.

For $i=m+1,\ldots,\ell$, by setting $C[s,v]=\sum_{u\in V_m:D[u,v]=i-m}C[s,u]\cdot C[u,v]$, we compute $C[s,v]$ for all $v\in V_i$. Note that $C[s,u]$ and $C[u,v]$ have been computed from the previous iteration, since $i-m<2\ell/3$. The total number of arithmetic operations is $O(\sum_i|V_i|\cdot|V_m|)=O(n^2/\ell)$. Since the counts are bounded by $O(n^{\ell})$ and are $\tilde{O}(\ell)$-bit numbers, the total cost is $\tilde{O}(n^2/\ell\cdot\ell)=\tilde{O}(n^2)$.

We do this for every source $s \in V$. The overall cost is $\tilde{O}(n^3)$.
We do the above for all ℓ's that are powers of 3/2. The final time bound is $\tilde{O}(n^3)$.

▶ **Theorem 25.** *u-#APSP can be solved in $\tilde{O}(n^3)$ time.*

▶ Remarks. This is worst-case optimal up to polylogarithmic factors, as the total number of bits in the answers could be $\Omega(n^3)$.

Recall the Betweenness Centrality of a vertex v is defined as $\mathrm{BC}(v) = \sum_{s,t \neq v} C_v[s,t]/C[s,t]$ where $C_v[s,t]$ is the number of shortest paths between s and t that go through v. As an immediate corollary, we can compute the Betweenness Centrality of a given vertex exactly in a directed unweighted graph in $\tilde{O}(n^3)$ time.

▶ **Corollary 26.** *The betweenness centrality of a vertex can be computed in $\tilde{O}(n^3)$ time in a directed unweighted graph.*

Abstract

We consider the problem of preprocessing two strings S and T, of lengths m and n, respectively, in order to be able to efficiently answer the following queries: Given positions i, j in S and positions a, b in T, return the optimal alignment score of $S[i\,..\,j]$ and $T[a\,..\,b]$. Let $N = mn$. We present an oracle with preprocessing time $N^{1+o(1)}$ and space $N^{1+o(1)}$ that answers queries in $\log^{2+o(1)} N$ time. In other words, we show that we can efficiently query for the alignment score of every pair of substrings after preprocessing the input for almost the same time it takes to compute just the alignment of S and T. Our oracle uses ideas from our distance oracle for planar graphs [STOC 2019] and exploits the special structure of the alignment graph. Conditioned on popular hardness conjectures, this result is optimal up to subpolynomial factors. Our results apply to both edit distance and longest common subsequence (LCS).

The best previously known oracle with construction time and size $\mathcal{O}(N)$ has slow $\Omega(\sqrt{N})$ query time [Sakai, TCS 2019], and the one with size $N^{1+o(1)}$ and query time $\log^{2+o(1)} N$ (using a planar graph distance oracle) has slow $\Omega(N^{3/2})$ construction time [Long & Pettie, SODA 2021]. We improve both approaches by roughly a $\sqrt{N}$ factor.

1 Introduction

String alignment is arguably the most popular problem in combinatorial pattern matching. Given two strings S and T of length m and n, the problem asks to compute the similarity between the strings according to some similarity measure. The two most popular similarity measures are edit distance and longest common subsequence (LCS). In both cases, the classical solution is essentially the same: Compute the shortest path from vertex $(0, 0)$ to vertex (m, n) in the so called *alignment graph* of the two strings. As taught in almost every elementary course on algorithms, computing this shortest path (and hence the optimal alignment of the two strings) can easily be done in $\mathcal{O}(N)$ time where $N = mn$, via dynamic programming. Interestingly, this time complexity cannot be significantly improved assuming popular conjectures such as the strong exponential time hypothesis (SETH) [1, 6, 8]. In fact,

by now we seem to have a rather good understanding of the complexity of this problem for different similarity measures and taking other parameters than the length of the strings into account, see [8].

Substring queries. A natural direction after having determined the complexity of a particular problem on strings is to consider the more general version in which we need to answer queries on substrings of the input string. This has been done for alignment [34, 36], pattern matching [24, 28], approximate pattern matching [17], dictionary matching [14, 15], compression [24], periodicity [27, 28], counting palindromes [33], longest common substring [3], computing minimal and maximal suffixes [5, 26], and computing the lexicographically k-th suffix [4].

Alignment oracles. Consider the shortest path from vertex (i, a) to vertex (j, b) in the alignment graph. It corresponds to the optimal alignment of two substrings: the substring of S between indices i and j and the substring of T between indices a and b. An *alignment oracle* is a data structure that, after preprocessing, can report the optimal alignment score of any two substrings of S and T. That is, given positions i, j in S and positions a, b in T, the oracle returns the optimal alignment score of $S[i\,..\,j]$ and $T[a\,..\,b]$ (or equivalently, the $(i-1, a-1)$-to-(j, b) distance in the alignment graph).

Tiskin [36, 37] considered a restricted variant of the problem, in which the queries are either the entire string S vs. a substring of T or a prefix of S vs. a suffix of T. For such queries, Tiskin gave an $\tilde{\mathcal{O}}(n+m)$-size oracle, that can be constructed in $\tilde{\mathcal{O}}(N)$ time, and answers queries in $\mathcal{O}(\log N/\log\log N)$ time [36]. For the general problem, Sakai [34] (building on Tiskin's work [36]) showed how to construct in $\mathcal{O}(N)$ time an alignment oracle with $\mathcal{O}(n+m)$ query time. In this work we show that, perhaps surprisingly, obtaining such an oracle can be done essentially for free! That is, at almost the same time it takes to compute just the alignment of S and T. More formally, our main result is:

▶ **Theorem 1.** *For two strings of lengths m and n, with $N = mn$, we can construct in $N^{1+o(1)}$ time an alignment oracle achieving either of the following tradeoffs:*

- *$N^{1+o(1)}$ space and $\log^{2+o(1)} N$ query time,*
- *$N \log^{2+o(1)} N$ space and $N^{o(1)}$ query time.*

Planar distance oracles and Voronoi diagrams. The starting point of our work is the recent developments in *distance oracles* for planar graphs. A distance oracle is a compact representation of a graph that allows to efficiently query the distance between any pair of vertices. Indeed, since the alignment graph is a planar graph, the state-of-the-art distance oracle for planar graphs of Long and Pettie [30] (which builds upon [13, 19, 21]) is an alignment oracle with space $N^{1+o(1)}$ and query time $\mathcal{O}(\log^{2+o(1)} N)$. However, the construction time of this oracle is $\Omega(N^{3/2})$. Our main contribution is an improved $N^{1+o(1)}$ construction time when the underlying graph is not just a planar graph but an alignment graph.

Our oracle has the same recursive structure as the planar graph oracles in [13, 21, 30] (in fact, the alignment graph, being a grid, greatly simplifies several technical, but standard, difficulties of the recursive structure). These oracles (inspired by Cabello's use of Voronoi diagrams for the diameter problem in planar graphs [10]) use the recursive structure in order to apply (at different levels of granularity) an efficient mechanism for *point location on Voronoi diagrams*. At a high level, a *Voronoi diagram* with respect to a subset S of vertices (called sites) is a partition of the vertices into $|S|$ parts (called Voronoi cells), where the cell of site $s \in S$ contains all vertices that are closer to s than to any other site in S. A *point*

location query, given a vertex v, returns the site s such that v belongs to the Voronoi cell of s. Our main technical contribution is a polynomially faster construction of the point location mechanism when the underlying graph is an alignment graph. We show that, in this case, the special structure of the Voronoi cells facilitates point location via a non-trivial divide and conquer. Unlike the planar oracles, which use planar duality to represent Voronoi diagrams, the representation and point location mechanisms we develop in this paper are novel and achieve the same query time, while being arguably simpler than those of Long and Pettie.[1]

It is common that techniques are originally developed for pattern matching problems (and in particular alignment problems) and later extended to planar graphs. A concrete example is the use of Monge matrices and unit-Monge matrices. However, it is much less common that techniques are first developed for planar graphs (in our case, the use of Voronoi diagrams) and only then translated to pattern matching problems.

Conditional lower bounds. Any lower bound on the time required to compute an optimal alignment of two strings directly implies an analogous lower bound for the sum of the preprocessing time and the query time of an alignment oracle. In particular, the existence of an oracle for which this sum is $\mathcal{O}(N^{1-\epsilon})$, for a constant $\epsilon > 0$, would refute SETH [6, 8].

In the *Set Disjointness* problem, we are given a collection of m sets $A_1, A_2, \ldots, A_m$ of total size M for preprocessing. We then need to report, given any query pair A_i, A_j, whether $A_i \cap A_j = \emptyset$. The Set Disjointness conjecture [18, 22, 32] states that any data structure with constant query time must use $M^{2-o(1)}$ space. Goldstein et al. [22] stated the following stronger conjecture.

▶ **Conjecture 2** (Strong Set Disjointness Conjecture [22]). *Any data structure for the Set Disjointness problem that answers queries in time t must use space $M^2/(t^2 \cdot \log^{\mathcal{O}(1)} M)$.*

The following theorem implies that, conditioned on the above conjecture, our alignment oracle is optimal up to subpolynomial factors; its proof is identical to that of [3, Theorem 1] as explained in [12].

▶ **Theorem 3** ([3, 12]). *An alignment oracle for two strings of length at most n with query time t must use $n^2/(t^2 \cdot \log^{\mathcal{O}(1)} n)$ space, assuming the Strong Set Disjointness Conjecture.*

Even though the main point of interest is in oracles that achieve fast (i.e. constant, polylogarithmic, or subpolynomial) query-time, the above lower bound suggests to study other tradeoffs of space vs. query-time. In Section 5 we show oracles with space sublinear in N. More formally, we prove the following theorem.

▶ **Theorem 4.** *Given two strings of lengths m and n with $N = mn$, integer alignment weights upper-bounded by w, and a parameter $r \in [\sqrt{N}, N]$ we can construct in $\tilde{\mathcal{O}}(N)$ time an $\tilde{\mathcal{O}}(Nw/\sqrt{r} + m + n)$-space alignment oracle that answers queries in time $\tilde{\mathcal{O}}(\sqrt{N} + r)$.*

For example, if the alignment weights are constant integers, by setting $r = \sqrt{N}$ we obtain an $\mathcal{O}(N^{3/4} + m + n)$-space oracle that answers queries in time $\tilde{\mathcal{O}}(\sqrt{N})$.

[1] We believe that our efficient construction can also be made to work, for alignment graphs, with the dual representation of Voronoi diagrams used in [13, 21, 30], but we think the new representation makes the presentation more approachable as it exploits the structure of the alignment graph more directly.

Other related works. When the edit distance is known to be bounded by some threshold k, an efficient edit distance oracle can be obtained via the Landau-Vishkin algorithm [29]. Namely, after $\mathcal{O}(n+m)$ time preprocessing of the input strings (oblivious to the threshold k), given a substring of S, a substring of T, and a threshold k, in $\mathcal{O}(k^2)$ time one can decide whether the edit distance of these substrings is at most k, and if so, return it.

Further, after an $\mathcal{O}(n+m)$-time preprocessing, given a substring X of S and a substring Y of T, the starting positions of substrings of Y that are at edit distance at most k from X can be returned in $\mathcal{O}(k^4 \cdot |Y|/|X|)$ time [17].

In a recent work [16] on dynamic string alignment, it was shown that, in the case where the alignment weights are small integers, two strings of total length at most n can be maintained under edit operations in $\tilde{\mathcal{O}}(n)$ time per operation so that an alignment of any pair of substrings can be queried in $\tilde{\mathcal{O}}(n)$ time.

2 Preliminaries

The alignment oracle presented in this paper applies to both edit distance and longest common subsequence (LCS). To simplify the presentation we focus on LCS but the extension to edit distance is immediate.

The LCS of two strings S and T is a longest string that is a subsequence of both S and T. We denote the length of an LCS of S and T by $\texttt{LCS}(S,T)$.

▶ **Example 5.** An LCS of $S = \texttt{acbcddaaea}$ and $T = \texttt{abbbccdec}$ is $\texttt{abcde}$; $\texttt{LCS}(S,T) = 5$.

For strings S and T, of lengths m and n respectively (we will assume that $n \geq m$), the alignment graph G of S and T is a directed acyclic graph of size $N = \mathcal{O}(mn)$. For every $0 \leq x \leq m$ and $0 \leq y \leq n$, the alignment graph G has a vertex (x,y) and the following unit-length edges (defined only if both endpoints exist):

- $((x,y),(x+1,y))$ and $((x,y),(x,y+1))$,
- $((x,y),(x+1,y+1))$, present if and only if $S[x] = T[y]$.

Intuitively, G is an $(m+1) \times (n+1)$ grid graph augmented with diagonal edges corresponding to matching letters of S and T. See Figure 1. We think of the vertex $(0,0)$ as the top-left vertex of the grid and the vertex (m,n) as the bottom-right vertex of the grid. We shall refer to the rows and columns of G in a natural way. It is easy to see that $\texttt{LCS}(S,T)$ equals $n+m$ minus the length of the shortest path from $(0,0)$ to (m,n) in G.

Multiple-source shortest paths. Given a planar graph with N vertices and a distinguished face h, the multiple-source shortest paths (MSSP) data structure represents all shortest path trees rooted at the vertices of h. It can be constructed in $\mathcal{O}(N \log N)$ time, requires $\mathcal{O}(N \log N)$ space, and can report the distance between any vertex u of h and any other vertex v in the graph in $\mathcal{O}(\log N)$ time. These bounds were first obtained for alignment graphs [35] and then extended to arbitrary planar graphs [11, 25].

The MSSP data structure can be augmented at no asymptotic overhead (cf. [23, Section 5]), to allow for the following. First, to report a shortest u-to-v path ρ in time $\mathcal{O}(|\rho| \log\log \Delta)$, where Δ is the maximum degree of a vertex in G. Second, to support the following queries in $\mathcal{O}(\log N)$ time [21]: Given two vertices $u, v \in G$ and a vertex x of h report whether u is an ancestor of v in the shortest path tree rooted at x, and whether u occurs before v in a preorder traversal of this tree. (We consider shortest path trees as ordered trees with the order inherited from the planar embedding.)

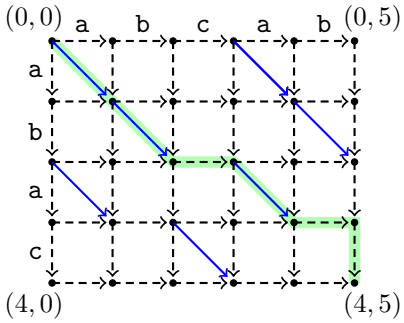

Figure 1 The alignment graph for $S = \texttt{abac}$ and $T = \texttt{abcab}$. We represent the horizontal and vertical edges by dashed black arrows, and the diagonal edges by blue arrows. A lowest scoring $(0, 0)$-to-$(4, 5)$ path is highlighted in green, it has weight 6 and corresponds to the LCS $\texttt{aba}$ of length $3 = 9 - 6 = |T| + |S| - 6$.

Recursive decomposition. We assume without loss of generality that the length of each of the two strings is a power of 2, and hence the alignment graph is a $(2^a + 1) \times (2^b + 1)$ grid. We consider a recursive decomposition $\mathcal{A}$ of G such that in each level all pieces are of the same rectangular shape. At each level, each piece will be of size $(2^c + 1) \times (2^d + 1)$ for non-negative integers c and d. Consider a piece P of size $(2^c + 1) \times (2^d + 1)$, with $c + d \neq 0$. Assuming without loss of generality that $c \geq d$, in the next level we will partition P to two pieces, each of size $(2^{c-1} + 1) \times (2^d + 1)$, that share the middle row of P. See Figure 2. We view $\mathcal{A}$ as a binary tree and identify a piece P with the node corresponding to it in $\mathcal{A}$.

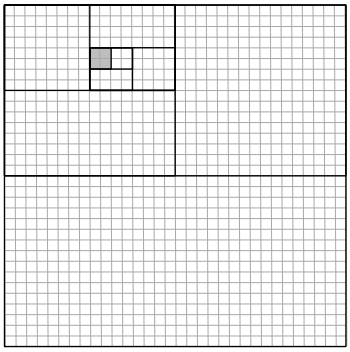

Figure 2 Illustration of pieces in a recursive decomposition of the alignment graph. Diagonal edges are not show to avoid clutter. All rectangular pieces that contain the gray square form a single root-to-leaf path in the tree $\mathcal{A}$.

Consider a piece $P \in \mathcal{A}$. The set ∂P of *boundary vertices* of a piece P consists of those vertices who have neighbours that are not in P. We call the vertices in $P \setminus \partial P$ the *internal vertices* of P. We denote by $\lrcorner(P)$ the set of boundary vertices of P that are either rightmost or bottommost in P, and by $\ulcorner(P)$ the set of boundary vertices of P that are either leftmost or topmost in P. We consider each of $\lrcorner(P)$ and $\ulcorner(P)$ to be ordered, such that adjacent vertices are consecutive and the earliest vertex is the bottom-left one. Therefore, whenever convenient, we refer to subsets of $\lrcorner(P)$ and $\ulcorner(P)$ as sequences. We define the *outside* of P, denoted by P^{out}, to be the set of vertices of $G \setminus (P \setminus \partial P)$ that are reachable from some vertex in P, i.e. the vertices of G that are not internal in P and are to the right or below some vertex of P. Note that any path from a vertex $u \in P$ to a vertex $v \in P^{out}$ must contain at least one vertex from $\lrcorner(P)$, and any path from a vertex $u \notin P$ to a vertex $u \in P$ must contain at least one vertex from $\ulcorner(P)$.

For any $r \in [1, nm]$, an *r-division* of G is a decomposition of G to pieces of size $\mathcal{O}(r)$, each with $\mathcal{O}(\sqrt{r})$ boundary vertices. Clearly, such a decomposition can be retrieved from $\mathcal{A}$, with all nodes being of the same depth. In particular, we will use recursive $(r_t, \ldots, r_1)$-divisions, where for every $i < t$, each piece of the r_i-division must be contained in some piece of the r_{i+1}-division. By convention, we will have r_t being a single piece consisting of the entire graph G. Such a recursive division can be materialized as follows: First, we select the appropriate depth of $\mathcal{A}$ for each r_i-division and mark all nodes of this depth. Then, we contract every edge of $\mathcal{A}$ of the form $(\mathsf{parent}(u), u)$ such that u is unmarked. Such a recursive $(r_t, \ldots, r_1)$-division can thus also be represented by a tree, which we will denote by $\mathcal{T}$.

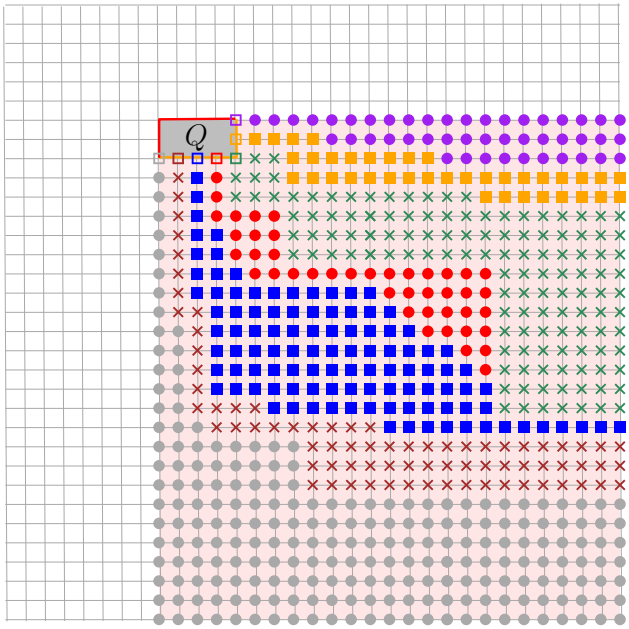

Figure 3 A piece Q (shaded gray). $\ulcorner(Q)$ is indicated by a red line, and $\lrcorner(Q)$ by an orange line. Q^{out} is shaded pink. The Voronoi diagram for Q^{out} with sites $\lrcorner(Q)$ (boxes) is also illustrated. Each site has a distinct color. Vertices in each Voronoi cell are indicated by a matching color.

Voronoi diagrams. Let H be a directed planar graph with real edge-lengths, and no negative-length cycles. Let h be a face of H, and let S be the set of vertices (called *sites*) of h. Each site $s \in S$ has a weight $\omega(s) \geq 0$ associated with it. The additively weighted distance $d^{\omega}(s, v)$ between a site $s \in S$ and a vertex $v \in H$ is defined as $\omega(s)$ plus the length of the shortest s-to-v path in H.

The *additively weighted Voronoi diagram* $\mathsf{VD}(S, \omega)$ of H is a partition of the vertices of H into pairwise disjoint sets, one set $\mathsf{Vor}(s)$ for each site $s \in S$. The set $\mathsf{Vor}(s)$, called the *Voronoi cell* of s, contains all vertices of H that are closer (w.r.t. $d^{\omega}(.,.)$) to s than to any other site in S. If $v \in \mathsf{Vor}(s)$ then we call s the site of v, and say that v belongs to the site s. Throughout the paper, we will only consider additively weighted Voronoi diagrams for the outside P^{out} of a piece $P \in \mathcal{A}$ with sites $S \subseteq \lrcorner(P)$. We next discuss the structure of such Voronoi diagrams.

We resolve ties between sites in favor of the site $s = (x, y)$ for which $(\omega(s), x, y)$ is lexicographically largest. Since the alignment graph is planar, this guarantees that the vertices in $\mathsf{Vor}(s)$ are spanned by a subtree of a shortest paths tree rooted at s: for every

vertex $v \in \mathsf{Vor}(s)$, for any vertex u on a shortest s-to-v path, we must have $u \in \mathsf{Vor}(s)$. Hence, each Voronoi cell is a simply connected region of the plane. The structure of the alignment graph dictates that any shortest path is monotone in the sense that it only goes right and/or down. This property immediately implies the following lemma.

▶ **Lemma 6.** *For any $a \leq c$ and $d \leq f$, if $u = (a, f)$ and $v = (c, d)$ both belong to $\mathsf{Vor}(s)$ then every vertex $w = (b, e)$ with $a \leq b \leq c$ and $d \leq e \leq f$ also belongs to $\mathsf{Vor}(s)$.*

Proof. Suppose $w = (b, e)$ belongs to $\mathsf{Vor}(s')$ for some $s' \neq s$. Since shortest paths only go right and down, the shortest s'-to-w path must cross either the s-to-u path or the s-to-v path, which is a contradiction. ◀

Lemma 6 together with the fact that $\mathsf{Vor}(s)$ is connected implies the following characterization of the structure of $\mathsf{Vor}(s)$, which roughly says that $\mathsf{Vor}(s)$ has the form of a double staircase, as illustrated in Figure 3.

▶ **Corollary 7.** *For any row a and any site s, the vertices of row a that belong to $\mathsf{Vor}(s)$ form a contiguous interval of columns $[i_a, j_a]$. Furthermore, the sequences i_a and j_a are monotone non-decreasing, $i_a \leq i_{a+1} \leq j_a + 1$, and $j_a \leq j_{a+1}$.*

▶ **Corollary 8.** *There is a rightmost vertex $s_{\searrow}$ in $\mathsf{Vor}(s)$ that is also a bottommost one.*

▶ **Corollary 9.** *For every $v \in \mathsf{Vor}(s)$, $\mathsf{Vor}(s)$ contains a path from v to $s_{\searrow}$.*

Our representation of a Voronoi diagram for P^{out} with sites $\lrcorner(P)$ consists of the following. For each $s \in \lrcorner(P)$, we store:

1. the rightmost bottommost vertex $s_{\searrow}$ of $\mathsf{Vor}(s)$, defined in Corollary 8,
2. a vertex $\mathsf{last}(s, s_{\searrow})$ on a shortest s-to-$s_{\searrow}$ path, whose definition will be given later.

3 The Alignment Oracle

In this section, we describe our oracle and prove that its space and query time are as in Theorem 1. In the next section we will show how to construct the oracle in $N^{1+o(1)}$ time.

Consider a recursive $(r_t, \ldots, r_1)$-division of G for some $N = r_t > \cdots > r_1 = \mathcal{O}(1)$ to be specified later. Recall that our convention is that the r_t-division consists of G itself. Further, we set the r_1-division to consist of pieces of size 2×2. We also consider an r_0-division, in which each vertex v of G is a singleton piece. Let us denote the set of pieces of the r_i-division by $\mathcal{R}_i$. Let $\mathcal{T}$ denote the tree representing this recursive $(r_t, \ldots, r_0)$-division, where each singleton piece $\{v\}$ at level 0 is attached as a child of a piece P at level 1 such that $v \in \lrcorner(P)$ – this is well-defined for all singletons apart from $\{(0, 0)\}$ and $\{(m, n)\}$, each of which is attached to the single level-1 piece containing it.

The oracle consists of the following. For each $0 \leq i \leq t - 1$, for each piece $P \in \mathcal{R}_i$ whose parent in $\mathcal{T}$ is $Q \in \mathcal{R}_{i+1}$:

1. If $i > 0$, we store an MSSP with sources $\lrcorner(P)$ for the graph obtained from P by flipping the orientation of all edges; we call this the *reverse MSSP of P*.
2. If $i > 0$, we store an MSSP with sources $\lrcorner(P)$ for $Q \setminus (P \setminus \partial P)$.
3. If $i < t - 1$, for each vertex $u \in \lrcorner(P)$ we store $\mathsf{VD}(u, Q)$: the Voronoi diagram for Q^{out} with sites $\lrcorner(Q)$ and additive weights the distances in G from u to these sites.

To complete the description of the oracle it remains to specify the definition of $\mathsf{last}(s, s_{\searrow})$. Before doing so, let us distinguish, for a (source) vertex u and a (target) vertex v, two levels of the recursive division that are of interest. Let R_0 be the singleton piece $\{u\}$. Let

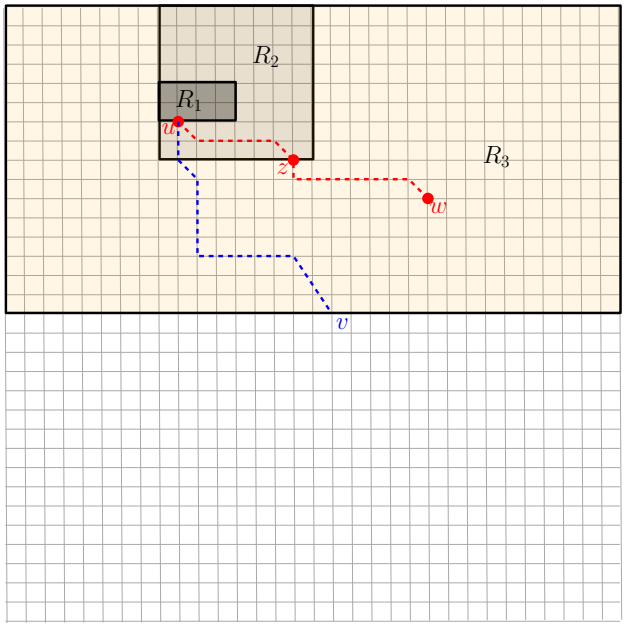

Figure 4 A vertex u and all the pieces of a recursive $(r_4, r_3, r_2, r_1, r_0)$-division that contain u. The piece R_0 consists of just u, and the piece R_4 is the entire alignment graph. Note that $u \in \lrcorner(R_1)$. In this example, $\mathsf{lev}(u) = 1$, $\mathsf{anc}(u, w) = 3$, and $\mathsf{anc}(u, v) = 4$ (because $v \in \partial R_3$). A u-to-w shortest path ρ is shown in dashed red. $\mathsf{last}(u, w)$ is the last vertex of ρ that belongs to $\lrcorner(R_2)$, which is the vertex z. The distance from u to w is $\mathsf{dist}(u, z) + \mathsf{dist}(z, w)$. $\mathsf{dist}(u, z)$ is stored in the reverse MSSP of R_2. $\mathsf{dist}(z, w)$ is stored in the MSSP of $R_3 \setminus (R_2 \setminus \partial R_2)$. Similarly, a u-to-v shortest path ρ is shown in dashed blue. Because $v \in \partial R_3$, $\mathsf{last}(u, v)$ is v itself.

$R_1, R_2, \ldots, R_t$ be the ancestors of R_0 in $\mathcal{T}$. Note that $u \in \lrcorner(R_i)$ for a non-empty prefix of the sequence of ancestors $R_0, R_1, \ldots, R_t$. Let $\mathsf{lev}(u) = \operatorname{argmax}_i\{u \in \lrcorner(R_i)\}$. Further, let $\mathsf{anc}(u, v) = \operatorname{argmin}_i\{v \in R_i \setminus \partial R_i\}$. Note that $\mathsf{anc}(u, v)$ is well defined since $v \in R_t = G$ and $\partial G = \emptyset$. Also note that if v is reachable from u then $\mathsf{lev}(u) < \mathsf{anc}(u, v)$. This is because all vertices in $R_{\mathsf{lev}(u)} \setminus \partial R_{\mathsf{lev}(u)}$ are unreachable from u.

Denote $H = R_{\mathsf{anc}(u,v)-1}$. We define $\mathsf{last}(u, v)$ as any boundary vertex of $\lrcorner(H)$ that lies on a shortest u-to-v path ρ. The idea behind this definition is that $\mathsf{last}(u, v)$ partitions this u-to-v path into a prefix and a suffix, each of which is represented in one of the MSSP data structures stored for H; The prefix of ρ ending at $\mathsf{last}(u, v)$ is represented in the shortest path tree rooted at $\mathsf{last}(u, v)$ in the reverse MSSP of H. The suffix of ρ starting at $\mathsf{last}(u, v)$ is represented in the shortest path tree rooted at $\mathsf{last}(u, v)$ in the MSSP for $H' \setminus (H \setminus \partial H)$ with sources $\lrcorner(H)$, where $H' = R_{\mathsf{anc}(u,v)}$ is the parent of H in $\mathcal{T}$. This allows us to efficiently compute $\mathsf{dist}(u, v)$ (the u-to-v distance) given $\mathsf{last}(u, v)$. See Figure 4. This concludes the description of the oracle.

▶ **Lemma 10.** *The oracle occupies space* $\mathcal{O}\left(N \log^2 N + N \log N \cdot \sum_{i=0}^{t-1} r_{i+1}/r_i\right)$.

Proof. The reverse MSSPs over all pieces of $\mathcal{A}$ require $\mathcal{O}(N \log^2 N)$ space, since $\sum_{P \in \mathcal{A}} |P| = \mathcal{O}(N \log N)$ and since the reverse MSSP of a piece P requires space $\mathcal{O}(|P| \log |P|)$.

For each $i \in (0, t-1]$, for each of the $\mathcal{O}(N/r_i)$ pieces in $\mathcal{R}_i$, we store an MSSP of size $\mathcal{O}(r_{i+1} \log r_{i+1})$. For each $i \in [0, t-1)$, for each of the $\mathcal{O}(N/r_i)$ pieces in $\mathcal{R}_i$, we store $\mathcal{O}(\sqrt{r_i})$ Voronoi diagrams each of size $\mathcal{O}(\sqrt{r_{i+1}})$. The stated bound follows. ◀

Query. We now describe how to answer a distance query $\mathsf{dist}(u, v)$. First, note that if u and v are in the same piece P in $\mathcal{R}_1$ we can report $\mathsf{dist}(u, v)$ in $\mathcal{O}(1)$ time using brute force.

Let R_0 be the singleton piece $\{u\}$. As before, let $R_1, R_2, \ldots, R_t$ be the ancestors of R_0 in $\mathcal{T}$. Since the distance query originates from an LCS query, v must be reachable from u. Let $\ell = \mathsf{lev}(u)$ and $h = \mathsf{anc}(u, v)$. We then have $u \in \lrcorner(R_\ell)$ and $v \in R_\ell^{out}$. We will answer $\mathsf{dist}(u, v)$ by identifying $\mathsf{last}(u, v)$, which lies on $\lrcorner(R_{h-1})$. As explained above, we can then obtain $\mathsf{dist}(u, v)$ from the MSSP data structures stored for R_{h-1}. See Algorithm 1.

Algorithm 1 DIST(u, v).

```
if u and v belong to the same piece in R_1 then
    return the answer by brute force
w ← GetLast(u, v)
return dist(u, w) + dist(w, v)
```

We now show how to implement the procedure GETLAST for finding $\mathsf{last}(u, v)$; see Algorithm 2 for a pseudocode. First, note that if $h = \ell + 1$ we can simply return u as $\mathsf{last}(u, v)$. Hence, in what follows, we assume that $h > \ell + 1$. The procedure GETLAST proceeds in iterations for $i = \ell+1, \ldots, h-1$. At the beginning of the iteration with value i, the procedure has a subset W_{i-1} of $\lrcorner(R_{i-1})$ such that some $w \in W_{i-1}$ belongs to a shortest u-to-v path. We initially set $W_\ell := \{u\}$, which trivially satisfies the requirement for $i = \ell + 1$. For each $w \in W_{i-1}$ the iteration uses a procedure GETNEXTCANDIDATES that adds at most two vertices of $\lrcorner(R_i)$ to W_i. The guarantee is that, if w is a vertex of $\lrcorner(R_{i-1})$ that belongs to a shortest u-to-v path, then at least one of the two added vertices also belongs to a shortest u-to-v path. Since $|W_i| \leq 2|W_{i-1}|$, at the end of the last iteration (the one for $h - 1$), we have a subset W_{h-1} of at most 2^t vertices of $\lrcorner(R_{h-1})$, one of which can be returned as $\mathsf{last}(u, v)$. To figure out which one, for each such vertex w, we use the MSSP data structures to compute $\mathsf{dist}(u, w) + \mathsf{dist}(w, v)$, and return a vertex for which the minimum is attained.

Algorithm 2 GETLAST(u, v).

```
ℓ ← lev(u)
h ← anc(u, v)
W_ℓ ← {u}
for i = ℓ + 1 to h − 1 do
    W_i ← ∅
    for each w ∈ W_{i−1} do
        W_i ← W_i ∪ GetNextCandidates(w, i, v)
return argmin_{w∈W_{h−1}} dist(u, w) + dist(w, v)
```

It remains to describe the procedure GETNEXTCANDIDATES. Consider any $w \in W_{i-1}$. To reduce clutter, let us denote R_i by Q. Since $w \in \lrcorner(R_{i-1})$, the Voronoi diagram $\mathsf{VD}(w, Q)$ for Q^{out} is stored by the oracle. The procedure GETNEXTCANDIDATES finds two sites of $\mathsf{VD}(w, Q)$, one of which is the site of v. Indeed, if w is a vertex on a u-to-v shortest path then the site of v in $\mathsf{VD}(w, Q)$ is a vertex of $\lrcorner(Q)$ on a shortest u-to-v path.

Let $(x_\lrcorner, y_\lrcorner)$ be the bottom-right vertex of Q. Every vertex $v = (x_v, y_v)$ of $Q^{out} \setminus \partial Q$ either has $x_v > x_\lrcorner$ or $y_v > y_\lrcorner$. We describe the case when $x_v > x_\lrcorner$; the case when $y_v > y_\lrcorner$ is analogous. Let Γ denote the set of $s \to s_\searrow$ paths ρ_s stored in $\mathsf{VD}(w, Q)$ according to the order of the sites s along $\lrcorner(Q)$. For every row $x > x_\lrcorner$, let Γ_x denote the subset of paths in Γ that intersect row x, ordered according to the order of the intersection vertices along row x.

▶ **Lemma 11.** *For every x, x' with $x > x'$, Γ_x is a subsequence of $\Gamma_{x'}$.*

Proof. This is a direct consequence of the fact that each path ρ_s goes monotonically down and right, and from the fact that ρ_s and $\rho_{s'}$ are disjoint for $s \neq s'$. ◀

We define the set of *critical rows* to be all rows x such that $(x, y) = s_{\searrow}$ for some $y \in [0, n]$ and $s \in \lrcorner(Q)$. Lemma 11 implies that if we consider the evolution of the sequences Γ_x as x increases from $x_{\lrcorner}$ to m as a dynamic process, changes occur only at critical rows. More precisely, if the row of $s_{\searrow}$ is x for some site s, then $\rho_s \in \Gamma_x$ but $\rho_s \notin \Gamma_{x+1}$. We can therefore maintain the sequences Γ_x in a persistent binary search tree. (A binary search tree can be made partially persistent at no extra asymptotic cost in the update and search times using a general technique for pointer-machine data structures of bounded degree [9].) Initially, the BST stores the sequence $\Gamma_{x_{\lrcorner}+1}$. Then, we go over the critical rows in increasing order, and remove the path ρ_s from the BST when we reach the row of $s_{\searrow}$.

For any $x_{\lrcorner} < x \leq m$, we can access the BST representation of Γ_x by finding the predecessor x' of x among the critical rows, and accessing the persistent BST at time x'.

Let $v = (x, y)$. We say that v is right (left) of a path $\rho_s \in \Gamma_x$ if y is greater (smaller) than any vertex of ρ_s at row x. We will either find a path $\rho_s \in \Gamma_x$ to which v belongs, or identify the last path $\rho_s \in \Gamma_x$ such that v is right of ρ_s. In the former case the site of v is s, and in the latter case the site of v is either s or the successor of s in Γ_x.

Recall that (1) the MSSP data structure, given a root vertex r and two vertices w, z, can determine in $\mathcal{O}(\log N)$ time whether w is left/right/ancestor/descendant of z in the shortest path tree rooted at r, (2) for each shortest path ρ_s represented in $\mathsf{VD}(w, Q)$, the representation contains $\mathsf{last}(s, s_{\searrow})$, and (3) the prefix of ρ_s ending at $\mathsf{last}(s, s_{\searrow})$ is represented in the shortest path tree rooted at $\mathsf{last}(s, s_{\searrow})$ in the reverse MSSP of H (recall that $H = R_{\mathsf{anc}(u,v)-1}$), while the suffix of ρ_s starting at $\mathsf{last}(s, s_{\searrow})$ is represented in the shortest path tree rooted at $\mathsf{last}(s, s_{\searrow})$ in the MSSP for $H' \setminus (H \setminus \partial H)$, where H' is the parent of H.

We perform binary search on Γ_x to identify the path ρ_s such that either $v \in \rho_s$ or ρ_s is the last path of Γ_x that is left of v. Focus on a step of the binary search that considers a path ρ_s. Denote $\mathsf{last}(s, s_{\searrow}) = (x_b, y_b)$. If $y < y_b$, we query the MSSP structure that contains the prefix of ρ_s, and otherwise we query the MSSP data structure that contains the suffix of ρ_s. In either case, the query either returns that v is on ρ_s or tells us whether v is left or right of ρ_s. In the former case we conclude that the site of v is s. In the latter case we continue the binary search accordingly. Each step of the binary search takes $\mathcal{O}(\log n)$ time. Note that $\log n = \mathcal{O}(\log N)$. Thus, the binary search takes $\mathcal{O}(\log^2 N)$ time, and when it terminates we have a site s that is either the site of v or the site such that ρ_s is the last path of Γ_x that is left of v. This implies that the site of v is either s or the successor of s in Γ_x, and concludes the description of GetNextCandidates.

▶ **Lemma 12.** *The oracle answers distance queries in time $\mathcal{O}(2^t \log^2 N)$.*

Proof. First, $\mathsf{lev}(u)$ and $\mathsf{anc}(u, v)$ can be (naively) computed in $\mathcal{O}(\log N)$ time by going over the ancestors of $\{u\}$ in $\mathcal{T}$: for each (rectangular) ancestor piece R of $\{u\}$, in $\mathcal{O}(1)$ time, we can retrieve the coordinates of R's corners and check whether $v \in R \setminus \partial R$ using v's coordinates. Overall, for a $\mathsf{dist}(u, v)$ query, we make $\mathcal{O}(2^t)$ calls to GetNextCandidates, each requiring $\mathcal{O}(\log^2 N)$ time, for a total of $\mathcal{O}(2^t \log^2 N)$ time. Finally, we make $\mathcal{O}(2^t)$ queries to the MSSP data structures, requiring $\mathcal{O}(2^t \log N)$ time in total. ◀

▶ Remark 13. Since our query procedure computes $\mathsf{last}(u, v)$, and we have MSSP data structures that capture the u-to-$\mathsf{last}(u, v)$ and the $\mathsf{last}(u, v)$-to-v shortest paths, an optimal alignment can be returned in time proportional to the total length of the two substrings.

By setting the r_i's appropriately, we obtain the following tradeoffs, which are identical to those of Pettie and Long for arbitrary planar graphs [30].

▶ **Proposition 14.** *For two strings of lengths m and n, with $N = mn$, there is an alignment oracle achieving either of the following tradeoffs:*
- $N \log^{2+o(1)} N$ *space and* $N^{o(1)}$ *query time,*
- $N^{1+o(1)}$ *space and* $\log^{2+o(1)} N$ *query time.*

Proof. The space of the oracle is $\mathcal{O}\left(N \log^2 N + N \log N \cdot \sum_{i=0}^{t-1} r_{i+1}/r_i\right)$ by Lemma 10. We will choose r_i's for $i \geq 1$ to be a geometric progression with common ratio p to be specified below. In that case, $t = \mathcal{O}(\log_p N)$ and the space becomes $\mathcal{O}(N \log^2 N + N \log N \cdot p \log_p N)$. First, let us set $p = N^{1/g(N)}$ for some $g(N)$ which is $\omega(\log N / \log\log N)$ and $o(\log N)$. Then, $p = 2^{\log N/g(N)} = 2^{o(\log\log N)} = \log^{o(1)} N$. We get $\mathcal{O}(N \log N \cdot 2^{\log N/g(N)} \log N) = N \log^{2+o(1)} N$ space and $N^{o(1)}$ query time. Second, let us set $p = N^{1/f(N)}$, for some $f(N)$ which is $\omega(1)$ and $o(\log\log N)$. We get $N^{1+o(1)}$ space and $\log^{2+o(1)} N$ query time. ◀

The following observation will prove useful in the efficient construction algorithm of the oracle that will be presented in the next section.

▶ **Observation 15.** *The query algorithm for $\mathsf{dist}(u, v)$ takes $\mathcal{O}(2^{t-\mathsf{lev}(u)} \log^2 N)$ time and uses only Voronoi diagrams $\mathsf{VD}(u, Q)$ for $Q \in \mathcal{R}_i$ with $i > \mathsf{lev}(u)$.*

4 An Efficient Construction Algorithm

In this section, we present an algorithm for constructing the alignment oracle in $N^{1+o(1)}$ time (thus completing the proof of Theorem 1). The computation of the recursive decomposition, the recursive $(r_t, \ldots, r_0)$-division and all of the MSSP structures stored for all pieces in $\mathcal{A}$ can be done in $\mathcal{O}(N \log^2 N)$ time. It therefore only remains to analyze the time it takes to construct all the representations of Voronoi diagrams stored by the oracle.

Consider some additively weighted Voronoi diagram for Q^{out} with sites a subsequence U of $\lrcorner(Q)$ – we will only build Voronoi diagrams with $U = \lrcorner(Q)$, but during the analysis, we will also consider Voronoi diagrams with sites $U \subseteq \lrcorner(Q)$. In what follows, when we talk about a piece $H \neq Q$, we will really mean its intersection with Q^{out}, assuming that it is non-empty. Similarly, when we talk about ∂H, $\ulcorner(H)$, and $\lrcorner(H)$ we will really mean the intersection of ∂H, $\ulcorner(H)$, and $\lrcorner(H)$ with Q^{out}, respectively. See Figure 5 for an illustration.

▶ **Lemma 16.** *Let $X \in \{\ulcorner(H), \lrcorner(H)\}$. Let $u, v \in X$ belong to distinct Voronoi cells. If u precedes v (in X) then the site $s_u \in U$ of u precedes (in U) the site $s_v \in U$ of v.*

Proof. For any vertex $a \in X$, that belongs to the cell of a site s_a, all vertices in the shortest s_a-to-a path belong to $\mathsf{Vor}(s_a)$. Towards a contradiction, suppose that s_u succeeds s_v in U. By the planarity of the graph and the fact that paths can go only down and right it follows that the shortest s_u-to-u path must cross the shortest s_v-to-v path in some vertex b. Then $b \in \mathsf{Vor}(s_u) \cap \mathsf{Vor}(s_v)$, which is a contradiction as Voronoi cells are disjoint. ◀

The above lemma means that the vertices of each of $\ulcorner(H)$ and $\lrcorner(H)$ can be partitioned into maximal contiguous intervals of vertices belonging to the Voronoi cell of the same site in U. When we say that we compute the partition of $\ulcorner(H)$ or $\lrcorner(H)$ with respect to U, we mean that we compute these intervals, specified by their endpoints, and, for each interval, the site from U to which the vertices of the interval belong.

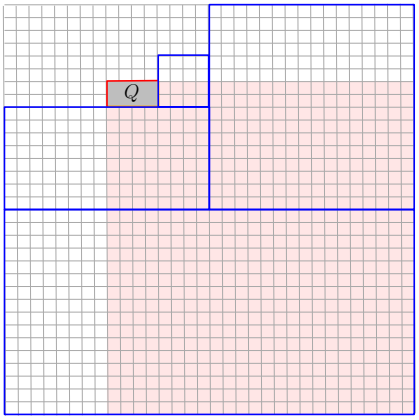

Figure 5 Covering Q^{out} (shaded pink) with siblings of ancestors of Q in $\mathcal{A}$ (blue boxes). When we refer to a piece H (e.g. a blue box), we only refer to the portion of H that belongs to Q^{out}.

The following simple observation allows us to compute partitions using binary search. It says that a piece H contains $s_{\searrow}$ if and only if s is the site of some vertex in $\ulcorner(H)$, and s is not the site of any vertex in $\lrcorner(H)$.

▶ **Lemma 17.** *For any $s \in S$ and any level ℓ, there is a unique level-ℓ piece $H \in \mathcal{A}$ for which $\mathsf{Vor}(s) \bigcap \ulcorner(H) \neq \emptyset$ and $\mathsf{Vor}(s) \bigcap \lrcorner(H) = \emptyset$, and this piece contains $s_{\searrow}$.*

Proof. By Corollary 9, for all $v \in \mathsf{Vor}(s)$, there exists a v-to-$s_{\searrow}$ path all of whose vertices are in $\mathsf{Vor}(s)$. Hence, for every level-ℓ piece H for which $\mathsf{Vor}(s) \bigcap \ulcorner(H) \neq \emptyset$ and $s_{\searrow} \notin H$, we must also have that $\mathsf{Vor}(s) \bigcap \lrcorner(H) \neq \emptyset$. We can thus focus on the at most four level-ℓ pieces that contain $s_{\searrow}$. It is readily verified that the bottom-right of those pieces is the only one for which $\mathsf{Vor}(s) \bigcap \lrcorner(H) = \emptyset$. ◀

▶ Remark 18. The condition in the statement of Lemma 17 is equivalent to: $s_{\searrow} \in H \setminus \lrcorner(H)$.

Lemma 17 provides a criterion on the partitions of $\ulcorner(H)$ and $\lrcorner(H)$ for determining whether a piece H contains any vertex $s_{\searrow}$. The following lemma describes a binary search procedure, Partition, which gets as input a sequence U of candidate sites, and returns the partition of $\ulcorner(H)$ or $\lrcorner(H)$; i.e., the subsequence of sites in U whose Voronoi cells contain the vertices of $\ulcorner(H)$ or $\lrcorner(H)$. The procedure Partition will be a key element in the overall construction algorithm. The following lemma describes an implementation of Partition using distance queries $\mathsf{dist}(u, v)$ with $u \in \lrcorner(Q)$ and $v \in \partial H$. We will ensure that such queries can be answered efficiently whenever Partition is called by the main algorithm.

▶ **Lemma 19.** *Given a sequence $U \subseteq \lrcorner(Q)$ of sites and their additive weights, we can perform the procedure Partition (that computes a partition of $\ulcorner(H)$ or $\lrcorner(H)$ w.r.t. U) in the time required by $\mathcal{O}(|U| \cdot \log n)$ distance queries $\mathsf{dist}(u, v)$ with $u \in \lrcorner(Q)$ and $v \in \partial H$.*

Proof. We will only prove the statement for $\ulcorner(H)$ as the case of $\lrcorner(H)$ is analogous. We start with a single interval, which is all of $\ulcorner(H)$. We will call an interval *active* if we have not concluded that all of its vertices belong to the same Voronoi cell. For each active interval L, we have a set C_L of *candidate sites*. Thus, initially, the single interval $\ulcorner(H)$ is active, and U is the set of its candidate sites.

The algorithm proceeds by divide and conquer. As long as we have an active interval L, we perform the following: we compute the site $u \in C_L$ with the minimum additively weighted distance to the midpoint of L. This is done in the time required by C_L distance queries of the form specified in the statement of the lemma. Then, we split L at this midpoint: for the

left part of L the set of candidate sites is now $\{v \in C_L : v \leq u\}$, while for the right part of L the set of candidate sites is now $\{v \in C_L : v \geq u\}$. If either of these two sets is of size 1, the corresponding interval becomes inactivate. That is, we recurse on at most two active intervals of roughly half the length. In the end, in a left-to-right pass, we merge consecutive intervals all of whose vertices belong to the same Voronoi cell.

Let us now analyze the time complexity of the above algorithm. First, observe that the sequences of candidates of any two intervals at the same level of the recursion are internally disjoint. Thus, each site is a candidate for at most two active intervals at the same recursive level. Second, at level j of the recursion, the length of every active interval is $\mathcal{O}(|\ulcorner(H)|/2^j)$. Hence, the total time required to process all intervals is proportional to the time required by $\mathcal{O}(|U| \cdot \log n)$ distance queries $\mathsf{dist}(u, v)$, with $u \in \lrcorner(Q)$ and $v \in \partial H$. ◀

We now present the algorithm for computing the representations of the Voronoi diagrams stored by the oracle. The algorithm performs the computation in order of decreasing levels of the recursive $(r_t, \ldots, r_0)$-division.

Consider some level i, and assume that we have already computed all Voronoi diagrams $\mathsf{VD}(u, R)$ for pieces $R \in \bigcup_{j>i} \mathcal{R}_j$. Consider any piece $P \in \mathcal{R}_{i-1}$. Let $Q \in \mathcal{R}_i$ be the parent of P in $\mathcal{T}$. Our goal is to compute, for every $u \in \lrcorner(P)$, the representation of $\mathsf{VD}(u, Q)$, the Voronoi diagram of Q^{out} with sites $\lrcorner(Q)$ and additive weights $\mathsf{dist}(u, \lrcorner(Q))$. Recall that this representation consists of the vertices $s_{\searrow}$ and $\mathsf{last}(s, s_{\searrow})$ for every site $s \in \lrcorner(Q)$. We would like to compute this representation in time roughly proportional to its size $|\lrcorner(Q)|$. By Observation 15, using the already computed parts of the oracle for levels $j > i$, we can already answer any distance query $\mathsf{dist}(s, v)$ for any $s \in \lrcorner(Q)$ and any $v \in Q^{out}$ in $\mathcal{O}(2^t \log^2 n)$ time. These are precisely the distance queries required for computing partitions of pieces H in Q^{out} w.r.t. sites in $\lrcorner(Q)$ (Lemma 19).

The computation is done separately for each $u \in \lrcorner(P)$. First, we compute the additive weights $\mathsf{dist}(u, \lrcorner(Q))$ in $\mathcal{O}(|\lrcorner(Q)| \cdot \log n)$ time using the MSSP data structure stored for $Q \setminus (P \setminus \partial P)$ with sites $\lrcorner(P)$. Next, we cover Q^{out} using $\mathcal{O}(\log N)$ pieces from $\mathcal{A}$ that are internally disjoint from Q (i.e. they may only share boundary vertices). These pieces are the $\mathcal{O}(\log N)$ siblings of the (weak) ancestors of Q in $\mathcal{A}$ that have a non-empty intersection with Q^{out} (see Figure 5). Notice that these pieces are in $\mathcal{A}$ but not necessarily in $\mathcal{T}$.

We shall find the vertices $s_{\searrow}$ of $\mathsf{VD}(u, Q)$ in each such piece H separately. We invoke Partition on $\ulcorner(H)$ and on $\lrcorner(H)$, and use Lemma 17 to determine whether H contains any vertices $s_{\searrow}$. If so, we zoom in on each of the two child pieces of H in $\mathcal{A}$ until, after $\mathcal{O}(\log N)$ steps, we get to a constant-size piece, in which we can find $s_{\searrow}$ by brute force. Note, however, that we are aiming for a running time that is roughly proportional to $|\lrcorner(Q)|$, but that the running time of Partition depends on the number of sites U w.r.t. which we partition. This is problematic since, e.g., when H contains $s_{\searrow}$ just for a single site s, we can only afford to invest $\tilde{\mathcal{O}}(1)$ time in locating $s_{\searrow}$ in H. In this case, computing the partition w.r.t. $|\lrcorner(Q)|$ is too expensive. Even computing the partition just w.r.t. the sites whose Voronoi cell has non-empty intersection with H, which is bounded by $|\ulcorner(H)|$, is too expensive. To overcome this problem we will show that it suffices to compute the partition w.r.t. a smaller sequence of sites, whose size is proportional to the number of sites s with $s_{\searrow}$ in H (actually in $H \setminus \lrcorner(H)$), rather than to the size of H or of $\ulcorner(H)$. We call such a sequence a *safe* sequence of sites for H, which we now define formally. Recall that the Voronoi diagram $\mathsf{VD}(u, Q)$ of Q^{out} has sites $\lrcorner(Q)$. Let U be a subsequence of $\lrcorner(Q)$. Consider the Voronoi diagram VD' of Q^{out} whose sites are the elements of U (with the same additive distances as in $\mathsf{VD}(u, Q)$). We say that U is *safe for* H if and only if the sets $\{(s, s_{\searrow}) : s \text{ is a site and } s_{\searrow} \in H \setminus \lrcorner(H)\}$ are identical for VD' and $\mathsf{VD}(u, Q)$.

▶ **Observation 20.** *A sequence that is safe for H is also safe for any child H' of H in $\mathcal{A}$.*

We will discuss the details of safe sequences after first providing the pseudocode of the procedure Zoom for finding the vertices $s_{\searrow}$ in a piece H.

Algorithm 3 Zoom(U, ω, H).

Input: The additive weight $\omega(s)$ for each $s \in \lrcorner(Q)$, a piece H in $\mathcal{A}$ that is internally disjoint from Q and has a non-empty intersection with Q^{out}, and a sequence $U \subseteq \lrcorner(Q)$ that is safe for H.

Output: All vertices $s_{\searrow}$ for $s \in \lrcorner(Q)$ that belong to H.

1: **if** $|H| = 4$ **then**
2: Find all vertices $s_{\searrow}$ in H for all $s \in U$ by computing $\omega(s) + \mathsf{dist}(s, v)$ for all $s \in U$ and all v adjacent to some vertex of H.
3: **for** each child H' of H in $\mathcal{A}$ **do**
4: $Z \leftarrow$ Partition$(U, \omega, \ulcorner(H'))$
5: $Z' \leftarrow$ Partition$(U, \omega, \lrcorner(H'))$
6: $L \leftarrow Z \setminus Z'$
7: **if** $L \neq \emptyset$ **then**
8: $V \leftarrow Z \setminus \{z \in Z \setminus L :$ both the predecessor and successor of z in Z are not in $L\}$
9: Zoom(V, ω, H')

The procedure Zoom takes as input a piece H and a sequence $U \subseteq \lrcorner(Q)$ that is safe for H. In order to compute $\mathsf{VD}(u, Q)$, we call the procedure Zoom$(\lrcorner(Q), \omega, H)$ for each of the $\mathcal{O}(\log N)$ pieces H that we use to cover Q^{out}. Clearly, in each of those initial $\mathcal{O}(\log N)$ calls $\lrcorner(Q)$ is a safe sequence of the respective piece. For each child H' of H in $\mathcal{A}$, we check whether the condition of Lemma 17 is satisfied in lines 4-7. Note that since U is a safe sequence for H, U is also a safe sequence for H' and hence our computation of the set $L = \{s \in \lrcorner(Q) : s_{\searrow} \in H' \setminus \lrcorner(H')\}$ is correct. If L is non-empty, we recurse on H' (cf. line 7). In line 8, we construct a safe sequence V for H', of size proportional to $|L|$ and then, in line 9, we call Zoom(V, ω, H'). In order to prove the correctness of procedure Zoom, it remains to show that V is indeed safe. The following two lemmas show this (see also Figure 6).

▶ **Lemma 21.** *Let U be safe for a piece H, such that* Partition$(U, \omega, \ulcorner(H)) = U$. *Suppose that there are three elements u_1, u_2, u_3 of U that appear consecutively (in this order) in both* Partition$(U, \omega, \ulcorner(H))$ *and* Partition$(U, \omega, \lrcorner(H))$. *Then, $U \setminus \{u_2\}$ is also safe for H.*

Proof. To avoid confusion we denote the Voronoi diagram of Q^{out} with sites U by VD and the one with sites $U \setminus \{u_2\}$ by VD'. We denote the Voronoi cells of VD by $\mathsf{Vor}(\cdot)$, and those of VD' by $\mathsf{Vor}'(\cdot)$. Note that for every $u \in U \setminus \{u_2\}$, $\mathsf{Vor}(u) \subseteq \mathsf{Vor}'(u)$. By Lemma 17, in VD, $u_{1\searrow}, u_{2\searrow}, u_{3\searrow} \notin H \setminus \lrcorner(H)$. Hence, in VD', $u_{1\searrow}, u_{3\searrow} \notin H \setminus \lrcorner(H)$.

▷ Claim. Every vertex y of $\mathsf{Vor}(u_2) \cap H$ belongs either to $\mathsf{Vor}'(u_1)$ or to $\mathsf{Vor}'(u_3)$.

Proof. Consider the last vertex z_1 of $\lrcorner(H)$ that is in $\mathsf{Vor}(u_1)$, and the first vertex z_3 of $\lrcorner(H)$ that is in $\mathsf{Vor}(u_3)$. Let ρ_1 be a shortest u_1-to-z_1 path, and ρ_3 be a shortest u_3-to-z_3 path. Note that all vertices of ρ_1 belong to $\mathsf{Vor}(u_1)$ and all vertices of ρ_3 belong to $\mathsf{Vor}(u_3)$. Consider any vertex y of $\mathsf{Vor}(u_2) \cap H$. The vertex y lies to the right of ρ_1 and to the left of ρ_3. In VD', the vertices of ρ_1 belong to $\mathsf{Vor}'(u_1)$ and the vertices of ρ_3 belong to $\mathsf{Vor}'(u_3)$. Hence, by Lemma 16, in VD', y can only belong to a site $s \neq u_2$ that is weakly between u_1 and u_3. Since u_1, u_2, u_3 appear consecutively in Partition$(U, \omega, \ulcorner(H)) = U$, the only such sites are u_1 and u_3, and the claim follows. ◁

By the above claim, the sets $\{(s, s_{\searrow}) : s$ is a site and $s_{\searrow} \in H \setminus \lrcorner(H)\}$ are identical for VD and VD'. Since U is safe for H, so is $U \setminus \{u_2\}$. ◀

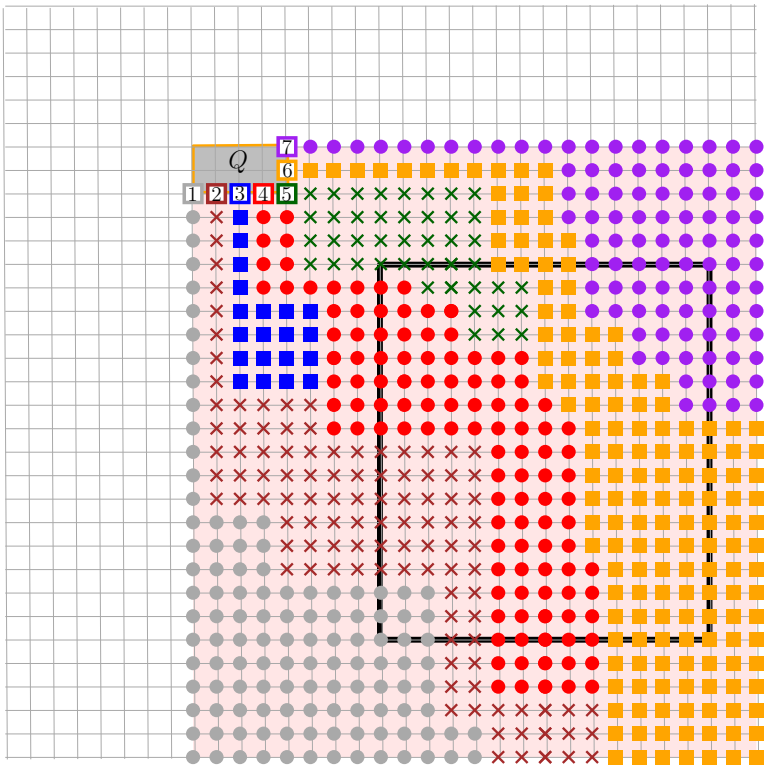

Figure 6 Illustration for Lemma 21. Part of Q^{out} (pink) for some piece Q (gray) is shown. A piece H is indicated by a black rectangle. The sites of $\lrcorner(Q)$ are numbered 1 through 7. The partition of $\ulcorner(H)$ w.r.t. $\lrcorner(Q)$ is $U = (1, 2, 4, 5, 6, 7)$. Hence, U is safe for H. The partition of $\lrcorner(H)$ w.r.t. $\lrcorner(Q)$ is $(1, 2, 4, 6, 7)$. Since sites $1, 2, 4$ are consecutive in both partitions, $(1, 4, 5, 6, 7)$ is also safe for H. Further, $\lrcorner(Q)$ is also clearly safe for H. However, $(1, 3, 4, 5, 6, 7)$ may not be safe for H, as $3_{\searrow}$ could be in $H \setminus \partial H$ in the Voronoi diagram with sites $1, 3, 4, 5, 6, 7$ and the same additive weights.

▶ **Lemma 22.** *Suppose that U is safe for H. Then, in each recursive call $\textsc{Zoom}(V, \omega, H')$ made by procedure $\textsc{Zoom}(U, \omega, H)$ for a child H' of H in $\mathcal{A}$, V is a safe sequence for H'.*

Proof. Since U is a safe sequence for H, U is also a safe sequence for H' (cf. Observation 20). Hence, L is the set of sites s such that $s_{\searrow} \in H' \setminus \lrcorner(H')$.

Z is the set of sites in U whose Voronoi cells have non-empty intersection with H'. In line 8, we remove from Z all vertices of $Z \setminus L$ that are not preceded or succeeded by a vertex in L. Therefore, by considering the removal of these sites one at a time, and directly applying Lemma 21 to each such removal, the resulting sequence V is safe for H'. ◀

This establishes the correctness of our construction algorithm. Let us now analyze its time complexity. Initially, we make $\mathcal{O}(\log N)$ calls to $\textsc{Zoom}(U, \omega, H)$, each with $U = \lrcorner(Q)$. In each recursive call, for a child H' of a piece H, the set U of sites is of size proportional to the size of the set $\{s \in \lrcorner(Q) : s_{\searrow} \in H' \setminus \lrcorner(H')\}$. Note that in each level of the tree $\mathcal{A}$ each $s \in \lrcorner(Q)$ is an element of exactly one such set. Hence, each $s \in \lrcorner(Q)$ contributes to $\mathcal{O}(\log N)$ calls to Zoom: the $\mathcal{O}(\log N)$ initial ones and at most one more per level of $\mathcal{A}$ (which is of depth $\mathcal{O}(\log N)$).

Thus, by Lemma 19, computing $s_{\searrow}$ for all $s \in \lrcorner(Q)$ reduces to $\mathcal{O}(|\lrcorner(Q)| \cdot \log^2 N)$ distance queries $\mathsf{dist}(u, v)$, with $u \in \lrcorner(Q)$ and $v \in Q^{out}$. We can answer each such query with the portion of the oracle that has already been computed in $\mathcal{O}(2^t \log^2 N)$ time. Now, recall that

a $\mathsf{dist}(s, s_{\searrow})$ query also computes $\mathsf{last}(s, s_{\searrow})$, and hence these values can also be retrieved in $\mathcal{O}(2^t \log^2 N)$ time. Thus, $\mathsf{VD}(u, Q)$, which is of size $\mathcal{O}(|\lrcorner(Q)|)$ can be computed in time $\mathcal{O}(|\lrcorner(Q)| \cdot 2^t \log^4 N)$, which is $|\lrcorner(Q)| \cdot N^{o(1)}$ for both choices of t in Proposition 14. Therefore, the time to compute $\mathsf{VD}(u, Q)$ for all pieces is $N^{o(1)} \cdot \sum_Q |\lrcorner(Q)| = N^{o(1)} \cdot \sum_{i=0}^{t-1} \frac{N}{r_i}\sqrt{r_i}$, which is $N^{1+o(1)}$ for both choices of t. This concludes the proof of Theorem 1.

5 Tradeoffs with $o(N)$ space

In this section we prove Theorem 4. Recall that for this result we consider integer alignment weights upper-bounded by w: A weight w_{match} for aligning a pair of matching letters, w_{mis} for aligning a pair of mismatching letters, and w_{del} for letters that are not aligned. One may assume without loss of generality that $2w_{match} > 2w_{mis} \geq w_{del}$ [36]. Given w_{match}, w_{mis} and w_{del}, we define $w'_{match} = 0$, $w'_{mis} = w_{match} - w_{mis}$ and $w'_{del} = \frac{1}{2}w_{match} - w_{del}$. These weights are also upper-bounded by w. Then, a shortest path (of length W) in the alignment grid with respect to the new weights, corresponds to a highest scoring path with respect to the original weights (of score $\frac{1}{2}(m+n)w_{match} - W$).

FR-Dijkstra. We define the *dense distance graph* (DDG) of a piece P as a directed bipartite graph with vertices ∂P and an edge from every vertex $u \in \ulcorner(P)$ to every vertex $v \in \lrcorner(P)$ with weight equal to the length of the shortest u-to-v path in P. We denote this graph as DDG_P.[2] DDG_P can be computed in time $\mathcal{O}((|\partial P|^2 + |P|) \log |P|) = \mathcal{O}(|P| \log |P|)$ using the MSSP data structure. In their seminal paper, Fakcharoenphol and Rao [20] designed an efficient implementation of Dijkstra's algorithm on any union of DDGs – this algorithm is nicknamed FR-Dijkstra. FR-Dijkstra exploits the fact that, due to planarity, the adjacency matrix of each DDG can be decomposed into Monge matrices (defined formally in equation (1) below). In our case, since each DDG is a bipartite graph, the entire adjacency matrix is itself Monge (this will be shown below). Let us now give an interface for FR-Dijkstra that is convenient for our purposes.

▶ **Theorem 23** ([20, 23, 31]). *Dijkstra's algorithm can be run on the union of a set of DDGs with $\mathcal{O}(M)$ vertices in total (with multiplicities) and an arbitrary set of $\mathcal{O}(M)$ extra edges in the time required by $\mathcal{O}(M \log^2 M)$ accesses to edges of this union.*

▶ Remark 24. In our case, the runtime of the algorithm encapsulated in the above theorem can be improved to $\mathcal{O}(M \log\log(nw))$. One of the two $\mathcal{O}(\log M)$ factors stems from the decomposition of the adjacency matrix into Monge submatrices, which is not necessary in our case. The second $\mathcal{O}(\log M)$ comes from the use of binary heaps. In our case, these heaps store integers in $\mathcal{O}(nw)$ and can be thus implemented with $\mathcal{O}(\log\log(nw))$ update and query times using an efficient predecessor structure [38, 39].

A warmup. Let us first show how to construct in $\tilde{\mathcal{O}}(N)$ time an $\tilde{\mathcal{O}}(N)$-size oracle that answers queries in $\tilde{\mathcal{O}}(\sqrt{N})$ time using well-known ideas [20]. We will then improve the size of the data structure by efficiently storing the computed DDGs.

Let us consider an r-division of G, for an r to be specified later. Further, consider the tree $\mathcal{A}'$, obtained from the recursive decomposition tree $\mathcal{A}$ by deleting all descendants of pieces in the r-division. For each piece $P \in \mathcal{A}'$, we compute and store DDG_P. In each of

[2] For general planar graphs, the DDG of a piece is usually defined as a complete directed graph on ∂P.

the $\mathcal{O}(\log N)$ levels of $\mathcal{A}$, for some value y, we have $\mathcal{O}(N/y)$ pieces, each with $\mathcal{O}(y)$ vertices and $\mathcal{O}(\sqrt{y})$ boundary vertices. Hence, both the construction time and the space occupied by these DDGs are $\tilde{\mathcal{O}}(N)$.

We next show how to compute the weight of an optimal alignment of $S[i\,..\,j]$ and $T[a\,..\,b]$, i.e. compute the shortest path ρ from $u = (i-1, a-1)$ to $v = (j, b)$, where $i < j$ and $a < b$. If u and v belong to $P \setminus \partial P$ for a piece P of the r-division, then both $S[i\,..\,j]$ and $T[a\,..\,b]$ are of length $\mathcal{O}(\sqrt{r})$, and we can hence run the textbook dynamic programming algorithm which requires $\mathcal{O}(r)$ time. Henceforth, we consider the complementary case.

Let P_u and P_v be the distinct r-division pieces that contain u and v, respectively. Further, let Q be the lowest common ancestor of P_u and P_v in $\mathcal{A}'$. For $z \in \{u, v\}$, let Q_z be the child of Q that contains z. The set of vertices $Q_u \cap Q_v$ are denoted by $\mathsf{sep}(Q)$ – which stands for separator. Observe that ρ must contain at least one vertex from $\mathsf{sep}(Q)$. Consider the set that consists of P_z and the siblings of weak ancestors of P_z in $\mathcal{A}'$ that are descendants of Q, and call it the *cone of* P_z. The cone of P_z covers Q_z and its elements are pairwise internally disjoint. See Figure 7 for an illustration. Now, observe, that any shortest path ρ between a vertex of ∂P_z and a vertex of $\mathsf{sep}(Q)$ can be partitioned into subpaths $\rho_1, \ldots, \rho_k$ such that each ρ_i lies entirely within some piece R_i in the cone of P_z and both ρ_i's endpoints are boundary vertices of R_i. Using these two observations, we can compute a shortest u-to-v path by running FR-Dijkstra on the cones of P_u and P_v, and, possibly, the following extra edges. In the case where the source u (resp. target v) is not a boundary vertex, we include $\mathcal{O}(\sqrt{r})$ additional edges: for each boundary vertex x of P_u (resp., P_v), an edge from u to x (resp., from x to v) with length equal to that of the shortest path from u to x (resp. from x to v). The weights of such edges can be computed in $\mathcal{O}(r)$ time using dynamic programming. Thus, a query can be answered in time $\tilde{\mathcal{O}}(\sqrt{N} + r)$. By setting $r = \sqrt{N}$ we get the promised complexities.

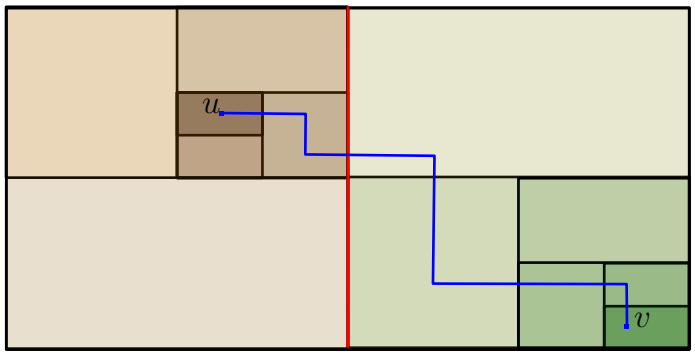

Figure 7 The piece Q is shown. $\mathsf{sep}(Q)$ is denoted by red, while a shortest u-to-v path is shown in blue. The pieces in the cone of P_u are shaded by brown, while the pieces in the cone of P_z are shaded by pink.

The tradeoff. We can now describe the entire tradeoff of Theorem 4. We assume that $r > w^2$, since otherwise $Nw/\sqrt{r} = \Omega(N)$ and Theorem 4 is satisfied by the warmup solution. For a piece P, we will show how to store DDG_P in $\mathcal{O}(|\partial P| \cdot w) = \mathcal{O}(w\sqrt{|P|})$ instead of $\mathcal{O}(|P|)$ space. Our representation will allow retrieving the length of any edge of DDG_P in $\tilde{\mathcal{O}}(1)$ time. Our approach closely follows ideas from [2].

For the remainder, we deviate from our ordering convention of $\ulcorner(P)$; the first vertex is now the top-right vertex of P, and the last is the bottom-left one. $\lrcorner(P)$ is ordered as before where the first vertex is the bottom-left one and the last is the top-right one. We denote

the i-th vertex of $\ulcorner(P)$ by v_i and the j-th vertex of $\lrcorner(P)$ by u_j. Note that we can infer whether any vertex u_j is reachable from a vertex v_i in $\mathcal{O}(1)$ time. For ease of presentation we would like the weights of all edges of DDG_P to be finite. To achieve this, for each edge between two vertices of $\ulcorner(P)$, we introduce (in P) an artificial edge with weight w in the opposite direction. It is readily verified that all v_i-to-u_j distances that were finite before the introduction of such edges remain unchanged. This is because the shortest path between two vertices of this modified graph that lie on the same column (resp. row) consists solely of vertical (resp. horizontal) edges.

Let M be the adjacency matrix of DDG_P with entry $M[i,j]$ storing the distance from v_i to u_j, and let $k = |\ulcorner(P)| = |\lrcorner(P)|$. Matrix M satisfies the Monge property, namely:

$$M[i+1,j] - M[i,j] \leq M[i+1,j+1] - M[i,j+1] \tag{1}$$

for any $i \in [1,k-1]$ and $j \in [1,k-1]$. This is because the shortest v_i-to-u_j and v_{i+1}-to-u_{j+1} paths must necessarily cross.

In addition, for any fixed $j \in [1,k]$, for all $i \in [1,k-1]$, we have

$$|M[i+1,j] - M[i,j]| \leq w. \tag{2}$$

This is because edges v_iv_{i+1} and $v_{i+1}v_i$ both have weight at most w. This implies that $M[i,j] \leq M[i+1,j]+w$, as a shortest v_i-to-u_j path cannot be longer than the concatenation of the edge v_iv_{i+1} with a shortest v_{i+1}-to-u_j path. Similarly, we have $M[i+1,j] \leq M[i,j]+w$.

Our representation of M is as follows, and fairly standard [2, 16, 36]. We define a $(k-1)\times(k-1)$ matrix P, satisfying

$$P[i,j] = M[i,j] + M[i+1,j+1] - M[i,j+1] - M[i+1,j].$$

Equations (1) and (2) imply that, for any $i \in [1,k-1]$, the sequence $M[i+1,j] - M[i,j]$ is nondecreasing and contains only values in $[-w,w]$. Hence, P has $\mathcal{O}(kw)$ non-zero entries. Now, observe that

$$\sum_{r\geq i, c\geq j} P[r,c] = M[i,j] + M[k,k] - M[i,k] - M[k,j]. \tag{3}$$

We store the last row and column of M. By (3), this means that retrieving $M[i,j]$ boils down to computing $\sum_{r\geq i,c\geq j} P[r,c]$. We view the non-zero entries of P as points in the plane and build in $\tilde{\mathcal{O}}(kw)$ time an $\tilde{\mathcal{O}}(kw)$-size 2D-range tree over them [7], which can return $\sum_{r\geq i,c\geq j} P[r,c]$ for any i,j in $\tilde{\mathcal{O}}(1)$ time. The overall space required by our representation of DDG_P is thus $\tilde{\mathcal{O}}(kw) = \tilde{\mathcal{O}}(|\partial P|\cdot w)$, and any entry of M can be retrieved in $\tilde{\mathcal{O}}(1)$ time.

In total, over all $\mathcal{O}(N/r)$ pieces of the r-division, the space required is $\tilde{\mathcal{O}}((N/r)\cdot\sqrt{r}\cdot w) = \tilde{\mathcal{O}}(Nw/\sqrt{r})$. This level dominates the other levels of the decomposition, as the sizes of pieces, as well as their boundaries, decrease geometrically in each root-to-leaf path. Note that, for the dynamic programming part of the query algorithm, we can simply store the strings, which take $\mathcal{O}(m+n)$ space. This concludes the proof of Theorem 4.

Faster Algorithms for Rooted Connectivity in Directed Graphs

Abstract

We consider the fundamental problems of determining the rooted and global edge and vertex connectivities (and computing the corresponding cuts) in *directed* graphs. For rooted (and hence also global) edge connectivity with small integer capacities we give a new randomized Monte Carlo algorithm that runs in time $\tilde{O}\left(n^2\right)$. For rooted edge connectivity this is the first algorithm to improve on the $\Omega(n^3)$ time bound in the dense-graph high-connectivity regime. Our result relies on a simple combination of sampling coupled with sparsification that appears new, and could lead to further tradeoffs for directed graph connectivity problems.

We extend the edge connectivity ideas to rooted and global vertex connectivity in directed graphs. We obtain a $(1+\epsilon)$-approximation for rooted vertex connectivity in $\tilde{O}(nW/\epsilon)$ time where W is the total vertex weight (assuming integral vertex weights); in particular this yields an $\tilde{O}\left(n^2/\epsilon\right)$ time randomized algorithm for unweighted graphs. This translates to a $\tilde{O}(\kappa nW)$ time exact algorithm where κ is the rooted connectivity. We build on this to obtain similar bounds for global vertex connectivity.

Our results complement the known results for these problems in the low connectivity regime due to work of Gabow [8] for edge connectivity from 1991, and the very recent work of Nanongkai et al. [23] and Forster et al. [6] for vertex connectivity.

1 Introduction

Let $G = (V, E)$ be a simple directed graph; that is, a directed graph with no parallel edges. Recall that G is *strongly connected* if there is a path from any vertex $a \in V$ to any vertex $b \in V$. The *edge connectivity* is the minimum number of edges that need to be removed so that G is *not* strongly connected. The corresponding set of edges is called the *minimum edge cut*. The *vertex connectivity* is the minimum number of vertices that need to be removed so that the remaining graph is not strongly connected or has only one vertex. The corresponding set of vertices is called the *minimum vertex cut*. These problems generalize to weighted settings where the edges and vertices are assigned positive weights and the goal is to find the minimum weight edge or vertex cut. Determining the edge and vertex connectivities and finding the corresponding minimum cuts are among the basic problems in graph algorithms.

This work obtains faster randomized algorithms for finding minimum edge and vertex cuts in directed graphs, especially in the dense setting. The algorithms are based on a simple technique which could be of independent interest.

Our interest is actually in the more general *rooted connectivity* problems. Let $r \in V$ be a fixed vertex, called the *root*. The *r-rooted edge connectivity* is the minimum number of edges that have to be removed so that there is some vertex in $V - r$ that r cannot reach. An algorithm for rooted edge connectivity easily implies an algorithm for edge connectivity, by fixing any root and returning the minimum of the rooted connectivity in G and the rooted connectivity in the graph obtained by reversing all the edges in G. Another important motivation for investigating rooted connectivity is the fundamental result by Edmonds [4] that the r-rooted edge connectivity equals the maximum number of edge-disjoint arboresences rooted at r. We refer the reader to [27, 7] for further connections in combinatorial optimization. Similarly, the *r-rooted vertex connectivity* is the minimum number of vertices (excluding r) that have to be removed so that r cannot reach some vertex in the residual graph. Algorithms for rooted vertex connectivity also lead to global vertex connectivity by a similar but somewhat more involved reduction. There is a long and rich history of developing algorithms for determining the edge and vertex connectivity. We first note that all of these connectivity and cut problems reduce to a polynomial number of (s, t)-cut and flow problems by standard reductions. Beyond (s, t)-flow, an interesting algorithmic landscape emerges with different running times depending on whether we are interested in edge or vertex cuts, directed or undirected graphs, and weighted or unweighted graphs.

Rooted and global edge-connectivity. We first discuss edge connectivity in directed graphs. Let λ denote either the rooted or global edge connectivity of the graph depending on the context. One can compute both via $O(n)$ (s, t)-minimum cut computations. For the simple and unweighted directed graph setting, Mansour and Schieber [21] improved on this and gave algorithms that run in $O(mn)$ time or in $O\big(\lambda^2 n^2\big)$ time for global connectivity. It was also observed by Alon (cf. [21]) that this approach can be parameterized by the minimum out-degree δ^+ to obtain a $O(n \log(\delta^+) \operatorname{EC}(m, n)/\delta^+)$ algorithm, where $\operatorname{EC}(m, n)$ denotes the running time for (s, t)-edge connectivity[1]. Gabow [8] then gave a $O\big(m\lambda \log\big(n^2/m\big)\big)$ for rooted connectivity in graphs with integer capacities. Gabow's algorithm is based on Edmonds' theorem described above. Gabow's algorithm is nearly linear time for sparse unweighted graphs, and remains the fastest algorithm for small λ for both rooted and global edge connectivity. It is interesting that Gabow's algorithm is not based on (s, t)-flow. For directed graphs with arbitrary edge capacities, Hao and Orlin [12] gave an $O\big(mn \log\big(n^2/m\big)\big)$ algorithm for rooted connectivity by adapting the push-relabel max flow algorithm; in fact their algorithm computes the (r, v)-connectivity for all $v \in V - r$. Thereafter there have been no direct running time improvements to rooted or global edge connectivity in directed graphs but we point out that there have been numerous breakthroughs in the running times for (s, t)-flow and connectivity [11, 24, 15, 19, 20, 18, 14, 28, 10]. In particular, starting with the work of Goldberg and Rao [11], the running time for (s, t)-flow is $o(mn)$ which breaks the flow-decomposition barrier. Motivated by these developments and several others, there has been a resurgence of interest and literature on faster graph algorithms for several fundamental problems. Despite these developments there has been no algorithm for rooted

[1] Depending on the context, we let $\operatorname{EC}(m, n)$ denote the running time for (s, t)-cut in either a simple or a weighted directed graph with m edges and n vertices.

Table 1 Running times for finding the minimum cut in unweighted directed graphs (i.e., $U = 1$). $\mathrm{EC}(m, n)$ denotes the running time of computing (s, t)-connectivity (in unweighted graphs). See also [27, §15.3a].

	$O(n\,\mathrm{EC}(m,n))$	Trivial. Also holds for rooted connectivity.
	$O(n\,\mathrm{EC}_\lambda(m,n))$	Matula [22]. Also holds for rooted connectivity.
	$O(mn)$, $O\big(\lambda^2 n^2\big)$	Mansour and Schieber [21]
*	$O\Big(\frac{n\log\delta}{\delta}\,\mathrm{EC}(m,n)\Big)$	Alon (cf. Mansour and Schieber [21]). δ is the minimum out-degree in the graph.
*	$O\big(m\lambda\log\big(n^2/m\big)\big)$	Gabow [8]. Also holds for rooted connectivity.
*	$\tilde{O}\big(n^2\big)$	Theorem 1. Randomized. Also holds for rooted connectivity.

edge-connectivity in simple directed graphs that is faster than $O(n^3)$ in the worst case. In this paper we obtain a nearly quadratic time algorithm which also applies to graphs with small integer capacities.[2]

▶ **Theorem 1.** *Let $G = (V, E)$ be a simple directed graph with m edges n, vertices, and integer edge weights $w : E \to [U]$. Then the minimum rooted r-cut can be computed with high probability in $\tilde{O}\big(n^2U\big)$ randomized time.*

This running time is particularly compelling when the rooted edge connectivity λ is high.

Rooted and global vertex-connectivity. We now consider (rooted) vertex connectivity in directed graphs. It is well known that for fast algorithms, global vertex connectivity is more involved than edge connectivity and the running times are more varied. While the rooted vertex connectivity can be reduced to computing $O(n)$ (s, t)-cuts, the global version, if done naively, would require $\Omega(n^2)$ calls to the (s, t)-cut problem since it is not obvious how to find a vertex that is not part of the minimum global vertex cut. There is a large body of literature and we highlight the leading (randomized) running times, where we state running times for randomized algorithms with high probability of success. Let κ denote the weight minimum vertex cut, where we assume the minimum weight of any vertex is 1. For large κ and general capacities, there is a randomized algorithm by Henzinger et al. [13] (extending the directed edge connectivity algorithm of [12]) that runs in $O(mn\log(n))$ time. For small values of κ in the unweighted setting, recent randomized algorithms by Forster et al. [6] based on *local connectivity* have obtained $\tilde{O}\big(m\kappa^2\big)$ and $\tilde{O}\big(n\kappa^3 + \kappa^{3/2}\sqrt{mn}n\big)$ running times. For more intermediate values of κ, there are also randomized $\tilde{O}\big(\kappa m^{2/3}n\big)$ and $\tilde{O}\big(\kappa m^{4/3}\big)$ time algorithms [23] as well as an $O(n^\omega + n\kappa^\omega)$ time algorithm [3], where $\omega \approx 2.3728596$ is the current exponent for fast matrix multiplication [1]. There is also recent interest in obtaining fast $(1 + \epsilon)$-approximation algorithms for minimum vertex cut [23, 6]. In particular [23] obtains a $O\big(n^\omega/\epsilon^2 + m\min\{\kappa, \sqrt{n}\}\big)$ running time (where ω denotes the exponent for matrix multiplication) and [6] obtains a randomized algorithm with running time $\tilde{O}(m\kappa/\epsilon)$. We obtain the following theorem.

[2] Here and throughout $\tilde{O}(\cdots)$ hides polylogarithmic factors in m and n. We note that the ideas introduced in this work are simple and the logarithmic factors they generate are easy to account for. However Theorem 1 also uses the recent (s, t)-flow algorithm of [28] with running time $\mathrm{EC}(m, n) = \tilde{O}\big(m + n^{1.5}\big)$, which has large logarithmic factors.

Table 2 A table of running times for finding the minimum vertex cut in unweighted directed graphs (i.e., $W = n$). $\mathrm{VC}(m, n)$ denotes the running time of computing (s, t)-vertex connectivity, and is at most $\tilde{O}\left(m + n^{1.5}\right)$ [29]. All randomized algorithms above are correct with high probability. See also [27, §15.2a] and [6].

$O\left(n^2\,\mathrm{VC}(m,n)\right)$	Trivial.
$O(n\,\mathrm{VC}(m,n)\log(n))$	Trivial. Randomized. $\kappa \leq .999n$
$O(\kappa n\,\mathrm{VC}(m,n))$	Podderyugin [25], Even and Tarjan [5]
$O(n^\omega + n\kappa^\omega)$	Cheriyan and Reif [3].
$O(\kappa mn)$, $O\left((\kappa^3+n)m\right)$	Henzinger et al. [13].
$O(mn\log(n))$	Henzinger et al. [13]. Randomized.
$O\left(\min\left\{\kappa^{5/2}, \kappa n^{3/4}\right\}m + mn\right)$	Gabow [9].
$\tilde{O}\left(\kappa m^{2/3}n\right)$, $\tilde{O}\left(\kappa m^{4/3}\right)$	Nanongkai et al. [23]. Randomized.
$\tilde{O}\left(m\kappa^2\right)$, $\tilde{O}\left(n\kappa^3 + \kappa^{3/2}m^{1/2}n\right)$	Forster et al. [6]. Randomized.
$\tilde{O}\left(n^2\kappa\right)$	Corollary 3. Randomized.

▶ **Theorem 2.** *Let $G = (V, E)$ be a directed graph with m edges, n vertices, and integer vertex weights $w : V \to \mathbb{N}$. Let $r \in V$ be a fixed root vertex. Let κ be the rooted vertex connectivity from r. Let $W = \sum_{v\in V} w(v)$ be the total weight of the graph. For any $\epsilon > 0$ a $(1+\epsilon)$-approximate rooted minimum vertex cut can be computed with high probability in $\tilde{O}(m + n(W-\kappa)/\epsilon)$ randomized time; for unit weights this is $\tilde{O}(m + n(n-\kappa)/\epsilon)$. The rooted connectivity can be computed with high probability in $\tilde{O}(m + \kappa n(W-\kappa))$ time.*

Note that $W \geq n$ in the above running times. We point out that the approximation algorithm's running time is independent of κ. This large κ regime has been challenging for previous approaches. The rooted connectivity algorithm, when combined with sampling and other ideas, gives the following theorem for global vertex connectivity. As we remarked, the reduction from global to rooted is not as clean for vertex connectivity as it is for edge connectivity.

▶ **Corollary 3.** *Let $G = (V, E)$ be a directed graph with m edges, n vertices, and integer vertex weights $w : V \to \mathbb{N}$. Let $W = \sum_{v\in V} w(v)$ be the total vertex weight of the graph. Let κ be the global vertex connectivity of G. There is a randomized algorithm that for any $\epsilon > 0$ outputs a $(1+\epsilon)$-approximate minimum vertex cut with high probability in time $\tilde{O}(nW/\epsilon)$. There is a $\tilde{O}(\kappa nW)$ time randomized algorithm that computes the (exact) minimum vertex cut with high probability. In particular, for unit weights, the running time is $\tilde{O}\left(\kappa n^2\right)$.*

1.1 Key ideas

Our algorithms are based on a simple but key idea that we briefly outline below. We focus on the edge-connectivity case since the idea for vertex connectivity is essentially the same with some modifications. We would like to take advantage of recent developments on fast algorithms for (s, t)-cut and reduce to solving a small number of such cut problems in a black box fashion (unlike the approach of [12] based on the properties of a specific flow

algorithm). For undirected graph global connectivity there has been very recent exciting progress by Li and Panigrahi [17] reducing to a *logarithmic* number of (s,t)-cuts. However, the technique makes strong use of the symmetry of the edge-cut function which are absent in the directed graph setting. In a different direction the work of Nanongkai, Saranurak, and Yingchareonthawornchai [23] and follow up improvements by Forster et al. [6], developed fast algorithms for global connectivity based on *local connectivity* and *randomization*. At a high-level they use sampling to identify two vertices s,t on the opposite sides of a cut and then reduce to (s,t)-cut, or they use a local-connectivity algorithm from each vertex $v \in V$. This approach is particularly well-suited for *small* connectivity.

For directed graph edge connectivity Gabow's algorithm with running time $\tilde{O}(m\lambda)$ is very good. In order to beat $O(n^3)$ in the worst case, the bottleneck is the dense graph regime with high connectivity. We have two main ideas that are particularly well suited to this regime. First, we focus on the rooted case even though it may appear to be more difficult than the global connectivity case. The global connectivity can be much smaller than the rooted connectivity; for instance the graph may not be strongly connected, in which case the global edge connectivity is 0, while the rooted connectivity for a particular root can still be $\Omega(n)$. Consider rooted connectivity from a given vertex r. In order to reduce to (s,t)-cut we would like to find a node t such that t is the sink side of a minimum r-cut. Let $T \subseteq V$ be a sink side of a minimum r-cut and hence $\lambda = |\delta^-(T)|$; here $\delta^-(T)$ denotes the set of edges entering T. If $|T|$ is large we can randomly sample a small number of vertices and we will succeed with good probability in finding a vertex from T. Therefore the difficult case is when $|T|$ is small and this is the setting in which we make our key observation: if the graph is *simple* (or edge capacities are small) and the sink side of a minimum r-cut is small (but not a singleton!), then T cannot have a high-degree vertex. How can we take advantage of this? Since we are working with the rooted problem, we can shrink all high-degree vertices into the root r! In other words we can *sparsify* the graph if the sink side is small and compensate for the higher sampling rate (and larger number of (s,t)-cut computations) we need to find a vertex on the sink side. Simple in retrospect, this tradeoff between sparsification and sampling rate coupled with guessing the size of the sink component gives us the overall algorithm with some additional technical work. We believe that our high-level idea will find use in other contexts when combined with other techniques.

Recent related work. Several recent papers have obtained results that are relevant to this work. Li et al. [16] obtained an $\tilde{O}\big(mn^{1-1/12+o(1)}\big)$ time algorithm for vertex connectivity in directed and unweighted graphs. A followup work by one of the authors of this paper obtained $(1+\epsilon)$-approximation algorithms for *weighted* graphs, for rooted and global, edge and vertex connectivity, with $\tilde{O}\big(n^2/\epsilon^{O(1)}\big)$ running times [26]. Improved exact algorithms for weighted edge connectivity have also been obtained very recently in [2].

2 Edge connectivity

In this section, we prove the main theorem for edge connectivity, Theorem 1. To this end, we will first introduce the main key lemma, called the *Rooted Sparsification Lemma*, in Section 2.1. In Section 2.2, we give a lemma that applies the Rooted Sparsification Lemma to give a faster algorithm when the number of vertices in the sink component is known to be in a fixed interval between 1 and n. Theorem 1 is then proven in Section 2.4, applying the ideas from Section 2.2 to each of a small family of intervals.

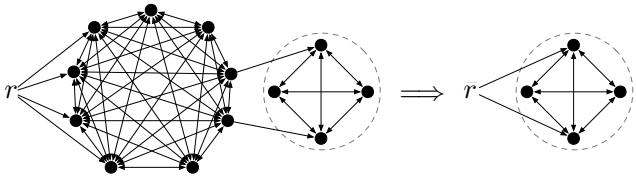

Figure 1 An example of the Rooted Sparsification Lemma in action. In particular, contracting the high in-degree vertices into r leaves the sink component of the minimum r-cut intact.

2.1 The Rooted Sparsification Lemma for Edge Connectivity

We introduce the key technical ingredient that we call the Rooted Sparsification Lemma. This lemma says that if the sink component of the minimum r-cut is small, then unless it is a singleton cut (which is easy to find directly), we can contract all vertices with high in-degree into the root while preserving the minimum rooted cut exactly. The result is a smaller and sparser graph in which we can find the minimum rooted cut faster. Later we will see that the running time saved by operating on a smaller graph makes up for the difficulty in identifying a vertex from a smaller sink component.

▶ **Lemma 4.** *Let $G = (V, E)$ be a simple directed graph with m edges, n vertices, and edge weights $w : E \to [1, U]$. Let $r \in V$ be a fixed root vertex. Let $k \in \mathbb{N}$. Consider the graph $\bar{G}$ obtained by contracting all vertices with weighted in-degree $\geq (1 + U)k$ into r. Let $\bar{r}$ denote the contracted vertex in $\bar{G}$. Then we have the following.*

1. *$\bar{G}$ is a multigraph with less than $(1 + U)nk$ edges.*
2. *If the minimum number of vertices in a sink component of a minimum r-cut has greater than 1 and less than or equal to k vertices, then the minimum r-cut and the minimum $\bar{r}$-cut are the same.*

Note that contraction cannot reduce the value of r-cut. An example illustrating the lemma is given in Figure 1. The proof is in two steps.

Small sinks make small cuts (except for singletons). The first step towards the Rooted Sparsification Lemma for edge connectivity is the following basic observation relating the connectivity to the number of vertices in the sink component of a minimum rooted cut. For simple graphs (i.e., $U = 1$), the following lemma says that *except for the case where the minimum rooted cut is achieved by a singleton*, the rooted connectivity is less than the number of vertices in the sink component of the cut. With capacities between 1 and U, we obtain a similar inequality except scaled by U. See Figure 2 for an illustration of the following lemma.

▶ **Lemma 5.** *Let $G = (V, E)$ be a simple directed graph with m edges, n vertices, and edge weights $w : E \to [1, U]$. Let $r \in V$ be a fixed root vertex. Let λ be the rooted edge connectivity from r. Let k be the minimum number of vertices in a sink component of a minimum r-cut. Then either $k = 1$ or $\lambda < Uk$.*

Proof. Let T be the set of vertices on the sink-side of a cut with λ edges. Suppose $k = |T| > 1$. Every vertex in T has weighted in-degree $> \lambda$. Consider all edges with head in T. Because G has capacities between 1 and U, of all the edges with head in T, at most $k(k-1)U$ total weight have their tail in T as well. Thus $\lambda > k\lambda - k(k-1)U$. Rearranging, we have $k(k-1)U > (k-1)\lambda$, hence $kU > \lambda$. ◀

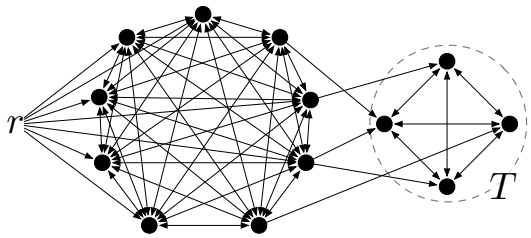

Figure 2 The set of vertices T has 4 vertices and there are 5 edges crossing into T. Lemma 5 implies that T cannot be the sink component of the minimum r-cut. Indeed, there are singleton cuts of degree 4 inside T.

▶ Remark 6. The above argument is simple and (unsurprisingly) we realized that a similar line of reasoning has appeared in previous work [21] (though towards a different algorithmic approach and not in the context of rooted connectivity).

Small sinks are sparse sinks. We now prove the Rooted Sparsification Lemma, Lemma 4. The high level argument is very simple and we first give an informal argument to emphasize the intuition. If the sink component of the minimum r-cut is small, then by Lemma 5, the minimum r-cut is also small. Suppose for the sake of discussion that the graph is simple (i.e., $U = 1$). If both the minimum r-cut and the sink component are small and the graph is simple, then every vertex in the sink component has small in-degree. The contrapositive implies that every high in-degree vertex is on the source side of the cut. Thus the high in-degree vertices can be safely contracted into the root.

Proof of the rooted sparsification lemma. Recalling the statement of the lemma, it is easy to see that contracting all vertices with weighted in-degree $\geq (1+U)k$ into r results in a multigraph $\bar{G}$ in which every vertex has weighted in-degree $< (1+U)k$, and hence there are at most $(1+U)nk$ edges total.

Let T be the sink component of a minimum r-cut. Observe that contracting into r cannot decrease the edge connectivity. If one can show that no vertices in T are contracted into $\bar{r}$, then T is the sink component of a minimum $\bar{r}$-cut as well.

By Lemma 5, the minimum r-cut has size $\lambda < Uk$. Because G is simple and T has $\leq k$ vertices, every vertex in T has in-degree less than $\lambda + k < (1+U)k$. Thus any contracted vertex is outside of T. This completes the proof. ◀

2.2 Rooted connectivity for a fixed range of component sizes

Applying the Rooted Sparsification Lemma usefully requires a fairly tight upper bound on the number of vertices in the sink component of the minimum r-cut. In this section, we assume we are given a lower bound k_1 and an upper bound k_2 on the number of vertices in the sink component, and develop algorithms for the minimum rooted cut in this parametrized regime. The running times are decreasing in k_1 and increasing in k_2; that is, they are better for tighter bounds on the number of vertices in the sink component.

▶ **Lemma 7.** *Let $G = (V, E)$ be a simple directed graph with m edges, n vertices, and edge weights $w : E \to [1, U]$. Let $r \in V$ be a fixed root vertex. Let λ be the rooted edge connectivity from r. Let $k_1, k_2 \in \mathbb{N}$ with $1 \leq k_1 \leq k_2 \leq n$. Suppose the sink component of the minimum r-cut has between k_1 and k_2 vertices. Then the minimum r-cut can be computed with constant probability in*

$$O\left(m + \frac{n}{k_1}(\mathrm{EC}(\min\{m, nk_2U\}, n))\right) \text{ time.}$$

Proof. We first consider the case $k_1 > 1$. By Lemma 4, we can reduce the number of edges to $m' = O(k_2 nU)$ while preserving the r-cut and retaining all k_1 or more vertices in the sink-side component. Let us sample $O(n/k_1)$ sink vertices t in the remaining graph uniformly at random, and compute the minimum (r,t)-cut for each. This takes $\mathrm{EC}(\min\{m,m'\},n) = \mathrm{EC}(\min\{m,k_2nU\},n)$ time for each instance, as desired. With constant probability, at least one sink is sampled out of the sink component of the minimum r-cut, which will return the minimum r-cut.

If $k_1 = 1$, then we must also address the possibility of a singleton cut. We apply the above for $k_1 = 2$ and compare the output to all of the singleton r-cuts, and output the smallest of these cuts. ◀

2.3 Rooted connectivity for small sink components

▶ **Lemma 8.** *Let $G = (V,E)$ be a simple directed graph with m edges, n vertices, and integer edge weights $w : E \to [U]$. Let $r \in V$ be a fixed root vertex. Let $k \in \mathbb{N}$ be a given parameter. There is a deterministic algorithm that runs in $O\big(m + nk^2U^2 \log(\max\{n/kU\})\big)$ time and returns an r-cut with the following guarantee. If the sink component of a minimum r-cut has at most k vertices, then the algorithm will return a minimum r-cut.*

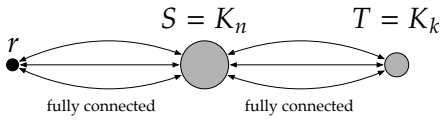
Proof. If the sink side of the minimum cut has less than k vertices, then via Lemma 5, either a singleton induces a minimum r-cut, or the minimum r-cut has size $\lambda < Uk$. For the latter case, we apply the rooted sparsification lemma and reduce the graph to $O(nkU)$ edges while preserving the minimum r-cut. We apply Gabow's algorithm [8] to the sparsified graph and it runs $O\big(nk^2U^2 \log(\max\{1, n/kU\})\big)$ time, and either finds a minimum rooted cut or certifies that the r-cut value in the sparsified graph has value $\geq kU$. We compare the output with all singleton r-cuts. ◀

2.4 Algorithm for rooted edge connectivity

We now prove the main theorem for edge connectivity, Theorem 1. By Lemma 7, if the number of vertices in the sink component is known, then we can reduce very efficiently to (s,t)-connectivity by either sparsifying the graph (if the number is small) or easily guessing a sink (if the number is large). More generally, we can pursue both strategies relative to any given upper and lower bounds on the number of vertices in the sink component. Meanwhile, for small component sizes (that are not singletons), we can still sparsify the graph, while the cut size must be small, which combine to produce fast running times via [8] in Lemma 8. The only unknown is the number of vertices in the sink component. Here we guess the number of vertices up to a constant factor, which only requires enumerating a logarithmic number of guesses. We restate Theorem 1 for the sake of convenience.

▶ **Theorem 1.** *Let $G = (V,E)$ be a simple directed graph with m edges n, vertices, and integer edge weights $w : E \to [U]$. Then the minimum rooted r-cut can be computed with high probability in $\tilde{O}\big(n^2U\big)$ randomized time.*

Proof. Let $\ell \in [n]$ be a parameter to be determined. The sink component of the minimum r-cut either (a) is a singleton, (b) has at most ℓ vertices, or (c) has between 2^i and 2^{i+1} vertices for some $i \geq \lfloor \log \ell \rfloor$. For each of these categories we apply a subroutine and take the minimum of the cut values found.



Singleton cuts are easy to evaluate in $O(m)$ time. Let $i_0 = \lfloor \log \ell \rfloor$ and $i_1 = \max\{\lceil \log m/nU \rceil, i_0 + 1\}$. For $i = i_0, \ldots, i_1 - 1$, let $k_i = 2^i$. Let $k_{i_1} = n$. For (b) we invoke Lemma 8 with maximum sink component k_{i_0}. To address (c), for each $i = i_0, \ldots, i_1 - 1$, we invoke Lemma 7 $O(\log n)$ times with lower bound k_i and upper bound k_{i+1} on the number of vertices in the sink component. We use $\mathrm{EC}(m, n) = \tilde{O}\left(m + n^{1.5}\right)$ [28]. The combined running time is $\tilde{O}\left(n^2 U + \frac{n^{2.5}}{\ell} + n\ell^2 U^2\right)$. For $\ell = \sqrt{n}/U$, this gives the claimed running time. ◀

3 Rooted and global vertex connectivity

In this section, we describe and analyze the approximation algorithms for rooted and global vertex connectivity. The high-level approach is similar to the previously discussed algorithm for edge connectivity. The first step, Lemma 10, is a variant of the Rooted Sparsification Lemma that applies to (approximate) vertex connectivity. It plays a similar role as its counterpart for edge connectivity, allowing one to sparsify the graph when the sink component of the minimum rooted vertex cut is small. The proof of Lemma 10 is given Section 3.1. We then give an algorithm specific to (roughly) the number of vertices in the sink component in Section 3.2. We use this algorithm as a subroutine in the final algorithm for approximate rooted connectivity in Section 3.4. In Section 3.5, we give the reduction from approximate global vertex connectivity to approximate rooted vertex connectivity. The exact global vertex connectivity algorithm for integer weights follows from an appropriate choice of error parameter.

3.1 Rooted sparsification for approximate vertex connectivity

Recall that a key idea in the algorithm for (rooted) edge connectivity was the Rooted Sparsification Lemma, which allows us to substantially decrease the number of edges when the sink component of the minimum rooted cut is small. Underlying the rooted sparsification lemma for edge connectivity was a direct relation between the size of the sink component and the weight of the minimum edge cut – Lemma 5 in Section 2.1. But this relation does not hold for vertex connectivity, even in unweighted and undirected graphs – even if the sink component is small, the vertex in-cut can be very large. For example, for arbitrarily large n and any fixed constant k, let $S = K_n$ be a clique of size n and let $T = K_k$ be a clique of size k. Add edges between all $s \in S$ and all $t \in T$. Let r be an additional root vertex connected to every vertex in S. Then T is the sink component of the minimum vertex r-cut. It has a constant number of vertices, k, while the size of the vertex cut, n, is arbitrarily large.

That said, we show that a useful sparsification is possible if we relax to *approximating* the rooted vertex connectivity, and qualify the lemma by the assumption that no singleton cut already represents a good approximation. To this end, let $u, v \in V$. We say that u is an *in-neighbor* of v if $(u, v) \in E$. We denote the set of in-neighbors of a vertex v by $N^-(v) \stackrel{\text{def}}{=} \{u \in V : (u, v) \in E\}$. The definition of in-neighbors naturally extends to sets of vertices; for $S \subset V$ we define $N^-(S) = (\cup_{v \in S} N^-(v)) \setminus S$. The *weighted in-degree* of v is defined as the total weight of all in-neighbors of v. Similarly we define the set of *out-neighbors* of a vertex v, denoted $N^+(v)$, as $N^+(v) \stackrel{\text{def}}{=} \{u \in V : (u, v) \in E\}$, and the weighted out-degree of v, denoted $\deg^+(v)$, as the sum of weights over $N^+(v)$.

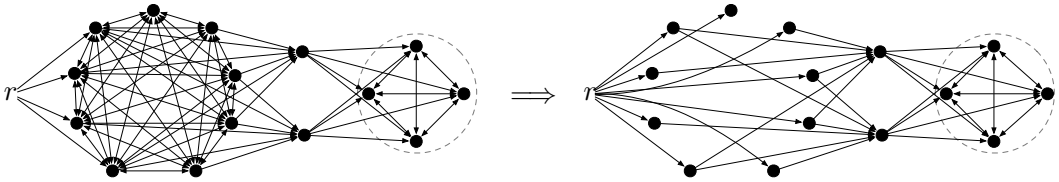


Figure 3 An example of the Rooted Sparsification Lemma for vertex connectivity in action. In the input graph on the left, minimum vertex r-cut has size 2 and the sink component (circled) has 4 vertices. The minimum in-degree (other than r) is 5. On the right hand side, all vertices with in-degree ≥ 9 have all their incoming edges replaced with a single edge from r. The minimum vertex r-cut is again 2 and the sink-component of the minimum r-cut remains unchanged.

Our first lemma gives an approximate relationship between the weight of the minimum weight rooted vertex cut and the weight of the sink component of the minimum weight rooted vertex cut.

▶ **Lemma 9.** *Let $\epsilon > 0$ be fixed. Let $G = (V, E)$ be a directed graph with m edges, n vertices, and vertex weights $w : V \to [1, \infty)$. Let $r \in V$ be a fixed root vertex. Let κ be the rooted vertex connectivity from r. Suppose the in-neighborhood of every non-root vertex has total weight greater tha $(1 + \epsilon)\kappa$. Then the minimum vertex r-cut has more than $\epsilon\kappa$ weight in the sink component.*

Proof. Let the minimum r-cut be of the form $N^-(S)$, where $S \subseteq V - r$. To prove the claim it suffices to show that $w(S) > \epsilon\kappa$.

For any vertex $v \in S$, by assumption, total weight of in-neighbors is more tha $(1 + \epsilon)\kappa$. At most κ weight of these in-neighbors are in the minimum vertex r-cut, $N^-(S)$. This implies that v has more than $\epsilon\kappa$ weight of in-neighors in S, and hence $\sum_{s \in S} w(s) > \epsilon\kappa + 1$ (where the extra 1 is for the weight of v). ◀

▶ **Lemma 10.** *Let $\epsilon > 0$ be fixed. Let $G = (V, E)$ be a directed graph with m edges, n vertices, and vertex weights $w : V \to [1, \infty)$. Let $r \in V$ be a fixed root vertex. Let κ be the rooted vertex connectivity from r. Suppose every vertex (excluding r) has weighted in-degree greater than $(1 + \epsilon)\kappa$. Let $k \in \mathbb{N}$. Consider the graph $\bar{G}$ obtained by replacing, for each vertex $v \in V$ with weighted in-degree $\geq (1 + 1/\epsilon)k$, all of the in-coming edges to v with a single edge from r to v. Then we have the following.*

1. *$\bar{G}$ has maximum weighted in-degree at most $(1 + 1/\epsilon)nk$.*
2. *$\bar{G}$ has at most $(1 + 1/\epsilon)nk$ edges.*
3. *If the sink component of a minimum vertex r-cut in G has weight $\leq k$, then the minimum vertex r-cut in G and $\bar{G}$ are the same.*

Proof. Let T be the sink component of a minimum rooted r-vertex cut, of minimum weight among such sink components. Suppose T has weight less than or equal to k. By Lemma 9, $\kappa < k/\epsilon$. Therefore any vertex v with weighted in-degree greater than $(1 + 1/\epsilon)k$ cannot be in T of the minimum rooted r-vertex cut. We claim that replacing the incoming edges to v does not decrease rooted vertex connectivities for r. As a thought experiment, suppose we make the replacement over two steps, where we first add the edge from r to v, and then remove the other incoming edges to v. The first step does not decrease vertex connectivities, and forces the rooted vertex connectivity from r to v to be $+\infty$. Removing the other incoming

edges to r does not effect the connectivity from r to v, so no other vertex connectivities from r are effected either. Over the two steps, then, we see that no rooted connectivities from r decrease.

On the other hand, since v is not in the sink of the minimum vertex r-cut, the rooted vertex connectivity of r does not change. ◀

3.2 Rooted vertex connectivity parametrized by sink component size

We now give an algorithm for rooted vertex connectivity parametrized by the weight of the vertices in the sink component of the minimum rooted cut. More precisely, we take as additional input two weights $k_1 \leq k_2$ and assume the sink component has weight between k_1 and k_2.

In the following, let $\mathrm{VC}(m, n)$ be the running time for vertex (s, t)-cut.

▶ **Lemma 11.** *Let $\epsilon > 0$ be fixed. Let $G = (V, E)$ be a directed graph with m edges, n vertices, and vertex weights $w : V \to [1, \infty)$. Let $r \in V$ be a fixed root vertex. Let κ be the rooted vertex connectivity from r. Let $W = \sum_{v \in V} w(v)$ be the total weight in the graph. Suppose every vertex (excluding r) has weighted in-degree greater than $(1 + \epsilon)\kappa$. Let $k_1, k_2 \in \mathbb{N}$ with $0 < k_1 < k_2$. Suppose also that the sink component of the minimum r-cut has between k_1 and k_2 total weight. Then the minimum r-cut can be computed with constant probability in*

$$O\left(m + \left(\frac{W - \kappa}{k_1}\right) \mathrm{VC}\left(\min\left\{m, \frac{k_2 n}{\epsilon}\right\}, n\right)\right)$$

randomized time.

Proof. By Lemma 10, in $O(m)$ time, we can reduce the number of edges to at most $O(k_2 n/\epsilon)$ without decreasing the rooted vertex connectivity. We sample vertices from $V' = V \setminus (\{r\} \cup N^+(r))$. Note that V' has weight at most $W - \deg^+(r) \leq W - \kappa$.

We sample $O\big((W - \deg^+(r))/k_1\big) \leq O((W - \kappa)/k_1)$ vertices $t \in V'$ independently in proportion to their weight. For each sampled vertex t, we compute the minimum (r, t)-vertex cut in the sparsified graph. With constant probability, one of these vertices t is in the sink component of the minimum vertex r-cut, and the minimum vertex (r, t)-cut is the minimum vertex r-cut. ◀

▶ Remark 12. The simple observation that the weight of $N^+(r)$ is at least κ is from [13].

3.3 Rooted vertex connectivity for small sink components

This section develops an approximation algorithm for rooted vertex connectivity specifically for the case where the sink component has small weight. The algorithm takes an upper bound k on the weight of the sink component, and guarantees an approximate minimum cut when there is a minimum rooted vertex cut where the sink component has weight at most k. The approach is inspired by the recent local connectivity algorithm of [6], and also integrates the rooted sparsification lemma. This algorithm is developed in two steps. The first step is a local cut algorithm that, given a vertex $t \in V$, searches for a small (r, t)-cut around t in time proportional to a given upper bound on the weight of the sink component. The second step first applies the rooted sparsification lemma, finds a vertex t in the sink component by random sampling, and runs the local cut algorithm for this choice of t.

The following lemma, which describes the local cut algorithm, is nearly identical to [6] except for two small modifications. First, we work with integral capacities, which does not change any arguments. Second is the inclusion of the root r which we want to keep on the opposite side of the local cut. The proof is included for the sake of completeness. In the following, the *in-volume* of a set of vertices T in a directed, edge-capacitated graph is the sum of weighted in-degrees over all vertices in T. Similarly the out-volume is defined as the sum of weighted out-degrees.

▶ **Lemma 13.** *Let $G = (V, E)$ be a directed graph with integral edge capacities. We assume that G is already available in memory in adjacency list format. Let $r, t \in V$, and let $\lambda, \ell > 0$ be given parameters. Then there is a randomized algorithm that runs in $O(\ell\lambda/\epsilon)$ time with the following guarantee.*

Let λ^* be the minimum capacity of all (r, t) cuts where the sink component has in-volume at most ℓ. If $\lambda^* < \lambda$, then with constant probability, the algorithm returns an (r, t)-cut of capacity at most $(1 + \epsilon)\lambda^*$.

Proof. Let T be the sink component of a minimum (r, t)-edge cut among those where the sink component has in-volume at most ℓ. We run a randomized variation of augmenting paths in the reversed graph G_{rev} where t is the source. Note that T now has out-volume at most ℓ in G_{rev}. We run the following subroutine for at most $1 + (1 + \epsilon)\lambda$ iterations, where each iteration routes one unit of flow from t to some chosen v.

Each iteration i runs DFS from t in the residual graph, until it either (a) visits r, (b) has traversed edges of total capacity at least $O(\ell/\epsilon)$, or (c) has explored all the edges reachable from t while failing to satisfy either (a) or (b). In event (a), we route one unit of flow to r. In event (b), we select one of the visited edges randomly in proportion to their capacity, and route one unit of flow to the endpoint of that edge. In either case, after routing, we update the residual graph by reverse (one unit of capacity) of each edge on the path from t to the selected sink. In event (c), we return the entire component of vertices reachable from t which induces an (r, t)-cut in the original graph. If, after $1 + (1 + \epsilon)\lambda$ iterations, we never reach event (c), then the algorithm terminates with failure.

We first argue that we return a $(1 + \epsilon)$-approximate (r, t)-cut with constant probability. We first point out that the total out-volume of T in the residual graph never increases, as we are reversing edges along edges along a path starting from t. Next, we observe that in each instance of event (b), where we randomly sample the endpoint of a visited edge as a sink, there is less than $\epsilon/2$ probability that this endpoint lies in T. This is because the graph search has traversed a total capacity of at least $O(\ell/\epsilon)$, and T has out-volume at most ℓ. That is, the out-volume of T represents at most an $(\epsilon/2)$-fraction of the searched edges.

Now, over the first $(1 + \epsilon)\lambda^*$ iterations, we expect to sample less than $\epsilon\lambda^*/2$ sinks from T. By Markov's inequality, we sample less than $\epsilon\lambda^*$ sinks from T over the first $(1 + \epsilon)\lambda^*$ iterations with probability at least $1/2$. In this event, if the algorithm did not find an (r, t)-cut within the first λ^* iterations, then we must have routed more than λ^* units of flow out of T – a contradiction. Thus the algorithm finds an (r, t)-cut within $(1 + \epsilon)\lambda^*$ iterations with probability at least $1/2$. Since this cut was obtained as the reachable set of t after routing at most $(1 + \epsilon)\lambda^*$ units of flow, the cut has capacity $\leq (1 + \epsilon)\lambda^*$.

It remains to prove the running time. Each iteration takes $O(\ell/\epsilon)$ time to traverse at most $O(\ell/\epsilon)$ edges. The algorithm runs for at most $O(\lambda)$ iterations. ◀

The next lemma presents the approximate rooted vertex cut algorithm that uses Lemma 13 as a subroutine. It also uses the rooted sparsification lemma to reduce the size of the graph and give stronger bounds on the volume of the sink component of the desired vertex cut.

▶ **Lemma 14.** *Let $\epsilon > 0$ be fixed. Let $G = (V, E)$ be a directed graph with m edges, n vertices, and integer vertex weights $w : V \to \mathbb{N}$. Let $r \in V$ be a fixed root vertex. Let $k \in \mathbb{N}$ and suppose that the sink component of the minimum r-cut has weight $\leq k$. Then a $(1+\epsilon)$-approximate minimum r-cut can be computed with high probability in $O\big(m + (W-\kappa)k^2 \log(n) \log(k)/\epsilon^3\big)$ randomized time.*

Proof. By Lemma 9, either a $(1+\epsilon)$-approximate minimum cut is induced by a singleton, or the minimum r-vertex cut has weight at most $O(k/\epsilon)$. The former is addressed by inspecting all singleton cuts. For the rest of the proof, let us assume the latter. By Lemma 10, we can sparsify the graph to have maximum weighted in-degree $O(k/\epsilon)$, hence at most $O(nk/\epsilon)$ total edges.

Let T be the sink component of the minimum r-cut, which has total vertex weight at most $O(k)$, and induces an r-cut with capacity $\kappa \leq O(k/\epsilon)$. Recall the standard auxiliary "split-graph" where vertex capacities are modeled as edge capacities. The high-level idea is to find a vertex $t \in T$ by random sampling and then apply Lemma 13 to the appropriate auxiliary vertices of r and t in the split graph.

To this end, we first bound the volume of the sink-component corresponding to T in the split-graph. We recall that the split graph splits each vertex v into an auxiliary "in-vertex" v^- and an auxiliary "out-vertex" v^+. For each v there is a new edge (v^-, v^+) with capacity equal to the vertex capacity of v. Each edge (u, v) is replaced with an edge (u^+, v^-) with capacity[3] equal to the vertex capacity of u. As a sink component, T maps to a vertex set T' in the split-graph consisting of (a) both copies v^- and v^+ of each vertex $v \in T$, and (b) the out-vertex v^+ of each vertex v in the vertex in-cut $N^-(T)$. For each vertex $v \in T$, v^- has (edge-)weighted in-degree equal to the vertex-weighted in-degree of v in the original graph, which is at most $O(k/\epsilon)$. This sums to $O(|T|k/\epsilon)$ over all $v \in T$. For each $v \in T$, v^+ has weighted in-degree equal to the vertex weight of T, which sums to the total vertex weight of T. Lastly, for each $v \in N^-(T)$, v^+ has weighted in-degree equal to the vertex weight of v. This sums to $\kappa \leq O(k/\epsilon)$ over all $v \in N^-(T)$. All summed up, the total in-volume of T' in the split-graph is at most $O(k/\epsilon)$ times the total vertex weight of T.

Suppose we had a constant factor estimate ℓ for the total vertex weight of T. Then we can sample $O\big((W - \deg^+(r)) \log(n)/\ell\big) \leq O((W-\kappa)\log(n)/\ell)$ vertices by weight from $V \setminus (\{r\} \cup N^+(r))$. With high probability, we sample $O(\log n)$ vertices from T. For each sampled vertex t we invoke Lemma 13 to find an (r,t)-cut, with upper bound $O(\ell k/\epsilon)$ on the volume of the sink component and $O(k/\epsilon)$ as the upper bound on the cut. With high probability, one of these calls returns a $(1+\epsilon)$-approximate cut. The total time, over all calls, would be $O\big((W-\kappa)\log(n)k^2/\epsilon^3\big)$.

Of course, we do not know the vertex weight of T *a priori*. However, we know that it is upper bounded by k, and let ℓ enumerate all powers of 2 between 1 and k. For each ℓ, run the process described above under the hypothesis that ℓ is a constant factor estimate for the total vertex weight of T. Each choice of ℓ takes $O\big((W-\kappa)\log(n)k^2/\epsilon^3\big)$ time. There are $O(\log(k))$ choices of ℓ. One of these choices of ℓ is a constant factor for the total volume of T and produces a $(1+\epsilon)$-approximate minimum (r,t)-cut with high probability. ◀

3.4 Rooted vertex connectivity

We now present the algorithm for approximate rooted vertex connectivity and prove Theorem 2. The algorithm combines the subroutine in Lemma 11 for logarithmically many ranges of weights, and Lemma 14 for sufficiently small weights. We restate Theorem 2 for the sake of convenience.

[3] Usually, this edge is set to capacity ∞, but either the weight of u or the weight of v are also valid.

▶ **Theorem 2.** *Let $G = (V, E)$ be a directed graph with m edges, n vertices, and integer vertex weights $w : V \to \mathbb{N}$. Let $r \in V$ be a fixed root vertex. Let κ be the rooted vertex connectivity from r. Let $W = \sum_{v \in V} w(v)$ be the total weight of the graph. For any $\epsilon > 0$ a $(1+\epsilon)$-approximate rooted minimum vertex cut can be computed with high probability in $\tilde{O}(m + n(W-\kappa)/\epsilon)$ randomized time; for unit weights this is $\tilde{O}(m + n(n-\kappa)/\epsilon)$. The rooted connectivity can be computed with high probability in $\tilde{O}(m + \kappa n(W-\kappa))$ time.*

Proof. Let $\kappa_0 = \epsilon\sqrt{n}$. Let $i_0 = \lfloor \log \kappa_0 \rfloor$, and let $i_1 = \max\{\lceil \log \epsilon m/n \rceil, i_0 + 1\}$ For each $i = \lfloor \log \kappa_0 \rfloor, \lfloor \log \kappa_0 \rfloor + 1, \ldots, i_1 - 1$, let $k_i = 2^i$. Let $k_{i_1} = W - \deg^+(r)$ where we recall that $\deg^+(r)$ is the weighted out-degree of r. For each i, we apply Lemma 11 with lower bound k_i and upper bound k_{i+1} on the weight of the sink component of the minimum vertex r-cut. We repeat this subroutine $O(\log n)$ times for each i to amplify the success probability from constant to high probability. We use $\mathrm{VC}(m, n) = \tilde{O}\big(m + n^{1.5}\big)$ [29]. We also apply Lemma 14 with $\epsilon\kappa_0$ has an upper bound on the sink component size. The set of all cuts obtained by these methods includes a $(1+\epsilon)$-approximate minimum r-cut with high probability, and we return the minimum of these cuts. The combined running time is

$$\tilde{O}\left(m + \frac{(W-\kappa)n}{\epsilon} + \frac{(W-\kappa)n^{1.5}}{\kappa_0} + (W-\kappa)\kappa_0^2/\epsilon^3\right) \leq \tilde{O}(m + (W-\kappa)n/\epsilon),$$

as desired. The exact bound follows by first using the approximation algorithm to obtain a constant factor estimate for κ, and then setting setting $\epsilon \leq 1/\kappa$. ◀

3.5 Global vertex connectivity

We now shift to global vertex connectivity and prove Corollary 3, which we address by reduction to the algorithm for rooted vertex connectivity above. We note that obtaining a root is slightly non-trivial because many vertices may be in the minimum weight vertex cut. We restate Corollary 3 for the sake of convenience.

▶ **Corollary 3.** *Let $G = (V, E)$ be a directed graph with m edges, n vertices, and integer vertex weights $w : V \to \mathbb{N}$. Let $W = \sum_{v \in V} w(v)$ be the total vertex weight of the graph. Let κ be the global vertex connectivity of G. There is a randomized algorithm that for any $\epsilon > 0$ outputs a $(1+\epsilon)$-approximate minimum vertex cut with high probability in time $\tilde{O}(nW/\epsilon)$. There is a $\tilde{O}(\kappa nW)$ time randomized algorithm that computes the (exact) minimum vertex cut with high probability. In particular, for unit weights, the running time is $\tilde{O}\big(\kappa n^2\big)$.*

Proof. Let κ denote the global vertex connectivity. If we sample a single vertex r in proportion to its weight, then with probability $1 - \kappa/W$, r is not in the minimum vertex cut. Then either the rooted vertex connectivity from r, or to r (i.e., from r in the graph G' with all the edges reversed), will give the rooted vertex cut. In principle we would like to apply Theorem 2 with root r in both orientations, which conditional on r not being in the minimum cut, succeeds with high probability. We amplify by repeating $L = O(\frac{W}{W-\kappa} \log n)$ times to obtain the high probability bound. Observe that the running time, via Theorem 2, is

$$\tilde{O}(mL + nW/\epsilon).$$

We would like to remove the mL factor.

To this end, observe that the m term arises from applying the rooted sparsification lemma for various estimates k of the weight of the sink component. Recall that for fixed k and ϵ, the sparsification lemma replaces, for every vertex v with in-degree $> O(k/\epsilon)$, all the incoming edges to v with a single edge from the root. Note that much of the sparsification lemma can be executed without r. In particular, we can remove all incoming edges to the high in-degree vertices without knowing r; once r is given, we add an edge from r to each of these vertices. The key point is that the first part, which takes $O(m)$ time, can be done once for all L sampled roots for each value of k. Thereafter, each of the L roots takes $O(n)$ to complete the sparsification for that root. This replaces the $\tilde{O}(mL)$ term with $\tilde{O}(nL)$, which is dominated by $\tilde{O}(nW/\epsilon)$.

For the exact algorithm, we first apply the approximation algorithm with $\epsilon = 1/2$ obtain a factor-2 approximation to κ within the claimed running time. We then apply the approximation algorithm again with $1/(2\kappa) \leq \epsilon \leq 1/\kappa$. ◀

Isolating Cuts, (Bi-)Submodularity, and Faster Algorithms for Connectivity

Abstract

Li and Panigrahi [37], in recent work, obtained the first deterministic algorithm for the global minimum cut of a weighted undirected graph that runs in time $o(mn)$. They introduced an elegant and powerful technique to find *isolating cuts* for a terminal set in a graph via a small number of s-t minimum cut computations.

In this paper we generalize their isolating cut approach to the abstract setting of symmetric bisubmodular functions (which also capture symmetric submodular functions). Our generalization to bisubmodularity is motivated by applications to element connectivity and vertex connectivity. Utilizing the general framework and other ideas we obtain significantly faster randomized algorithms for computing global (and subset) connectivity in a number of settings including hypergraphs, element connectivity and vertex connectivity in graphs, and for symmetric submodular functions.

1 Introduction

We investigate fast algorithms for several fundamental connectivity problems in (weighted) undirected graphs as well as their generalizations to the abstract setting of submodular and bisubmodular functions. The motivation for this work arose from the recent paper of [37] that described a new algorithmic approach for finding the *global minimum cut* in an undirected graph. For a graph $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_{>0}$, the global minimum cut problem is to find the minimum weight subset of edges whose removal disconnects the graph; alternatively it is to find a set S, where $\emptyset \subsetneq S \subsetneq V$, that minimizes $w(\delta(S))$[1]. When G is unweighted, this is called the edge connectivity of the graph. There has been extensive work on algorithms for this problem, and its study has led to many important theoretical developments. Karger developed a near-linear time randomized algorithm [30] that runs in $O(m \log^3 n)$ time with some recent improvements in the log factors via better data structures [21, 42]. Here m is the number of edges and n is number of nodes in the

[1] For $A \subset V$, $\delta(A)$ denote the set of edges in G with exactly one end point in A. $w(\delta(A))$ is notation for $\sum_{e \in \delta(A)} w(e)$.

graph. However, the best deterministic algorithm until recently was $\tilde{O}(mn)$ via two very different approaches [24, 49]. Li and Panigrahi developed a new approach that improved this bound. Their algorithm runs in time $O(m^{1+o(1)})$ plus the time to compute $O(\text{polylog}(n))$ (s,t)-minimum cut computations in a graph with m edges and n nodes. Their approach uses the (s,t)-minimum cut algorithm as a black box.

Isolating cuts. A key technique in [37] is an algorithm to find *isolating cuts*. To describe this notion, let $R \subseteq V$ be subset of nodes that we call terminals. Given $r \in R$, a set $S \subseteq V$ is an isolating cut for r (with respect to R) if $S \cap R = \{r\}$. Consider the problem of finding, for *each* $r \in R$, a minimum weight isolating cut, that is; a cut $S_r \subseteq V$ where $S_r = \arg\min_{S \subseteq V, S \cap R = \{v\}} w(\delta(S))$. Note that if $R = V$ this is trivial since $S_r = \{r\}$ for each r. However, the problem is non-trivial when $R \subset V$ is a proper subset of V. A naive approach would require $|R|$ (s,t)-minimum cut computations. [37] described a simple and elegant procedure that computes all the isolating cuts for any given R in time proportional to $O(\log |R|)$ (s,t)-minimum cut computations. This, combined with simple random sampling, can be used to easily derive a randomized algorithm for global minimum cut that relies on $O(\text{polylog}(n))$ (s,t)-minimum cut computations. Note that even though the total time corresponds to $O(\text{polylog}(n))$ (s,t)-minimum cuts, the second phase of their algorithm requires computing $|R|$ (s,t)-minimum cuts, but in smaller graphs whose total size is $O(m)$ and thus can be folded into a single (s,t)-minimum cut on roughly the same input size as the original graph. Their algorithm gives a new randomized approach to global minimum cut; however, it does not lead to a faster algorithm than the existing near-linear time algorithm. Instead [37] focuses on deterministic running times and avoids random sampling by relying on several technical tools including deterministic expander decompositions to obtain a deterministic algorithm. We note, however, that the algorithm in [37] applies to the more general problem of finding the Steiner minimum cut: given $X \subseteq V$, the goal is to find a minimum cut separating a pair of nodes in X. See [25, 29] for applications.

Vertex and element connectivity. Our focus here is not on deterministic algorithms per se but rather on the applicability of the isolating cut approach to derive faster (randomized) algorithms in settings beyond edge connectivity. There has been tremendous recent and ongoing progress in fast algorithms for (s,t)-flow and cut problems and leveraging these algorithms for global connectivity is opened up by the new approach. In particular, an important motivating problem is to compute the global *(weighted) vertex connectivity* of a graph which has received substantial recent attention [17, 45]. In this setting we are given a graph $G = (V, E)$ with vertex weights $w : V \to \mathbb{R}_+$ and the goal is to find a minimum weight subset $S \subset V$ such that $G - S$ has at least two non-trivial connected components. However, as is well-known, vertex cuts/separators are not as easy to work with as edge cuts. Despite recent exciting progress via an approach based on local cuts and connectivity, the weighted case had not been addressed and the best known algorithms are from the work of Henzinger, Rao and Gabow [27]. Our starting point is the observation that the isolating cut approach of [37] relies only on the submodularity and symmetry of the edge-cut function of undirected graphs. Recall that a real-valued set function $f : 2^V \to \mathbb{R}$ is *submodular* iff $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$ for all $A, B \subseteq V$. A set function is symmetric if $f(A) = f(V \setminus A)$ for all $A \subseteq V$. The applicability of the isolation cut approach to symmetric submodular set functions already yields faster algorithms for hypergraph connectivity and several other problems that we describe subsequently. However, as we already remarked, vertex cuts do not lend themselves to this approach as vertex cuts, unlike undirected edge cuts, are simply not a symmetric submodular function.

When considering isolating cuts in the context of vertex connectivity one naturally encounters the notion of *element connectivity*, which has been found to have several important connections between edge and vertex connectivity. Element connectivity plays a key role in network design, and in fact, it was introduced by [28] to overcome the difficulty of working with vertex connectivity. We refer the reader to surveys and related papers on network design [16, 14, 15, 23, 33] for extensive literature on this topic. It also plays an important role in packing vertex disjoint Steiner trees and forests among others [13, 5, 1, 8]; [7] surveys this area. We now formally define element connectivity. The input is a graph $G = (V, E)$ and a partition of V into terminals T and non-terminals $N = V \setminus T$. The *elements* of G are the edges and non-terminals; that is, $E \cup N$. For two terminals s, t we define the element connectivity between s and t as the minimum number of elements whose removal disconnects s from t. We emphasize that element connectivity is defined *only* between the terminals. We can generalize this to the weighted setting where edges and non-terminals have non-negative weights. The global element connectivity of $G = (T \cup N, E)$ is the minimum element connectivity between any two terminals. [11] considered algorithms for computing (global) element connectivity. For global element connectivity they obtained an algorithm with running time $O(|T|)$ times the time for (s, t)-minimum cut computation.

Set-pairs and Bisubmodularity. Cuts for element and vertex connectivity do not fall into the setting of symmetric submodular set functions. A vertex separator S induces a partition of $V \setminus S$ into disjoint sets A, B that do not share an edge, and obviously $B \neq V \setminus A$ (for nonempty S). Nevertheless, one of the reasons for the tractability of element connectivity is that it does admit submodularity properties. The natural way to view its submodularity properties is via the more general notion of *bisubmodular* set functions. Given a ground set V a set-pair is (A, B) where $A, B \subseteq V$. Informally speaking a bisubmodular function f assigns a real-value to each set-pair (A, B) in a collection of set-pairs as to satisfy the inequality

$$f(X_1, Y_1) + f(X_2, Y_2) \geq f(X_1 \cup X_2, Y_1 \cap Y_2) + f(X_1 \cap X_2, Y_1 \cup Y_2)$$

for all set-pairs (X_1, Y_1) and (X_2, Y_2) on which it is defined. For this to make sense the collection of set-pairs needs to be closed under the above criss-crossed intersection and union operations for set-pairs. These binary operations can be understood more clearly as the meet and join of an appropriately defined lattice; we defer the formal definitions to Section 2. One can generalize the notion of cuts to set-pairs. Let (S, T) be a set-pair corresponding to a partition of a terminal set R. A set-pair (A, B) cuts (S, T) if $S \subseteq A$ and $T \subseteq B$. One can then define the f-minimum cut problem for (S, T): find the set-pair of minimum f value among all set-pairs that cut (S, T). With this definition in place the notions of global minimum cut for a terminal set $R \subseteq V$, and isolating cuts for R, naturally generalize. In this paper we show that the isolating cut approach of [37] generalizes to the class of symmetric bisubmodular set functions defined over appropriate collections of set-pairs.

1.1 Contributions and Results

We make two contributions at the high-level. The first is conceptual in generalizing the isolating cut approach to the (bi)submodular setting. The second is to apply this abstract framework with additional ideas to derive faster randomized algorithms for several fundamental problems. Together they yield a plethora of new running times for a diverse collection of connectivity problems, both abstract (optimizing over set functions in an oracle model) and concretely in graphs. The multiplicity of results is for the following combination of

reasons. First, by implementing the isolating cut approach at a higher level of abstraction, and abstaining from concrete specificities, we not only expose the isolating cut approach to new problems, but allow for the substitution of different domain specific black box subroutines that, within a domain, can have interesting tradeoffs. Second, and unlike the case of graph edge connectivity, the second phase of the isolating cut approach can often benefit from additional problem specific ideas, especially if one wants to take advantage of certain domain-specific algorithms that can be very powerful if applied carefully.

An important aspect of the isolating cut approach is that it inherently gives an algorithm for the subset connectivity version. In the following we will use m, n to refer to the number of edges and vertices in a given graph and use $\mathrm{EC}(m, n)$ to refer to the running time for computing a minimum (s, t)-cut in an edge-weighted directed graph, and $\mathrm{VC}(m, n)$ for the running time for computing a minimum (s, t)-cut in a vertex-weighted directed graph. We instantiate concrete running times for special cases when needed.

Connectivity of Bisubmodular functions. The precise statement that captures the general isolation cut property in bisubmodular set functions requires stating several technical definitions. Our main results for this are captured by Lemma 11, Lemma 12 and Theorem 13 which are better understood after the technical definitions. Here we state an informal theorem that captures these results.

▶ **Theorem 1** (Informal). *Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function defined over a collection of set-pairs $\mathcal{V}$ over V. Let $R \subseteq V$. Suppose one has an oracle that given a partition (S, T) of R finds the f-minimum set-pair $(A, B) \in \mathcal{V}$ that cuts (S, T). In $O(\log |R|)$ calls to this oracle one can find for each $r \in R$ a set-pair $(X_r, X'_r) \in \mathcal{V}$ such that the following properties hold: (i) for each $r \in R$, (X_r, X'_r) is a $(r, R - r)$ separating set-pair, (ii) there is an f-minimum set-pair (Y_r, Y'_r) separating $(r, R - r)$ such that $Y_r \subseteq X_r$, $X'_r \subseteq Y'_r$ and (iii) $X_r \cap X_q = \emptyset$ for $r \neq q$. The total run time for finding the f-minimum isolating cut (Y_r, Y'_r) for each $r \in R$ can thus be bounded by the $O(\log |R|)$ cut computations and the total time to find the cuts inside each (X_r, X'_r).*

Symmetric submodular functions. We derive the following theorem as a corollary.

▶ **Theorem 2.** *Let $f : 2^V \to \mathbb{R}$ be a symmetric submodular function and $R \subseteq V$ and let $n = |V|$. Suppose there is an algorithm for submodular function minimization in the value oracle model in time $\mathrm{SFM}(n) = g_1(n)EO + g_2(n)$ where EO is the time for the evaluation oracle. Assuming that $g_1(n) = \Omega(n)$ and $g_2(n) = \Omega(n)$, a minimum f-cut that separates some two terminals in R can be found in $O\big(\mathrm{SFM}(n) \log^2(n)\big)$ time.*

▶ **Corollary 3.** *Let f be an integer valued symmetric submodular function with $|f(S)| \leq M$. Using the submodular function minimization algorithms of [35] one can find the global minimum cut of f with high probability in time $\tilde{O}(n^2 \log(nM)EO + n^3 \log^{O(1)}(nM))$.*

The preceding corollary should be compared to Queyranne's well-known combinatorial algorithm that uses $O(n^3\mathrm{EO})$ time [47]. The algorithm from [35] is not strongly polynomial but uses a factor $\tilde{\Omega}(n)$ fewer evaluation calls. Further, our randomized algorithm can handle minimum f-cut for a subset of terminals while Queyranne's algorithm does not generalize. In addition, the black box reduction can take advantage of future improvements to $\mathrm{SFM}(n)$ as well as for special cases as we will see next.

Hypergraph connectivity. A hypergraph $H = (V, E)$ consists of vertices V and hyperedges E where each hyperedge $e \in E$ is a subset of nodes; that is, $e \subseteq V$. We let $p = \sum_{e \in E} |e|$ denote the total size of H and let m, n denote number of hyperedges and vertices. The rank r of a hypergraph is the maximum edge size; graphs are rank 2 hypergraphs. The cut function of a hypergraph is symmetric and submodular and the global minimum cut question for edge connectivity naturally generalizes to hypergraphs. The best deterministic algorithm for this problem runs in $O(pn + n^2 \log n)$ time [32, 47, 41]. The best randomized algorithm runs in time $\tilde{O}(n^r)$ time with high probability in rank r hypergraphs [18] and this is better than $\tilde{O}(pn)$ only for very dense hypergraphs. Via sparsification one can also get an algorithm in unweighted hypergraphs that runs in time $O(p + \lambda n^2)$ where λ is the minimum cut value [12]. We obtain the following theorem that gives significantly better bounds in most settings of interest, and new tradeoffs, while also generalizing to subset minimum cut.

▶ **Theorem 4.** *Let $H = (V, E)$ be a weighted hypergraph with m edges, n nodes and total size $p = \sum_{e \in E} |e|$. Let $R \subseteq V$. The global minimum cut for R in H can be found with high probability in time $\tilde{O}(\mathrm{EC}(p, m + n))$ or in time $\tilde{O}(\sqrt{pn(m+n)^{1.5}})$.*

Now we state our algorithmic results for element connectivity and vertex connectivity that follow via the bisubmodularity framework and problem specific optimizations.

Element connectivity. The fastest known algorithm so far for global element connectivity is from [11] and runs in time $O(|T|\,\mathrm{EC}(m, n))$ for terminal set T, which can be $\Omega(n\,\mathrm{EC}(m, n))$. We obtain the following.

▶ **Theorem 5.** *Let $G = (T \cup N, E)$ be an instance of weighted element connectivity with $|T| = k$ terminals. The global element connectivity can be computed in*

$$\tilde{O}\left(\mathrm{EC}(m, n) + \max_{m_1, \ldots, m_k} \left\{ \sum_{i=1}^{k} \mathrm{EC}(m_i, n) : m_1 + \cdots + m_k \leq 2m \right\}\right)$$

time with high probability. The algorithm generalizes to subset element connectivity.

In particular, for $\mathrm{EC}(m, n)$ of the form $\mathrm{EC}(m, n) = \tilde{O}(m\,\mathrm{poly}(m, n))$, the running time above is $\tilde{O}(\mathrm{EC}(m, n))$. For instance, via [34], one obtains an $\tilde{O}(m\sqrt{n})$ time algorithm. However, recent breakthrough work of [51] showed that $\mathrm{EC}(m, n) = \tilde{O}(m + n^{1.5})$. This running time bound cannot be directly used in the preceding theorem. Using further ideas we obtain an improved running times that are encapsualted in the following theorem.

▶ **Theorem 6.** *Let $G = (T \cup N, E)$ be an instance of element connectivity with n nodes and m edges. Let $w : V \cup E \to [1..U]$ assign integer (or infinite) weights to each vertex and edge. The global element connectivity can be computed in randomized $\tilde{O}\big(m^{1+o(1)} n^{3/8} U^{1/4} + n^{1.5}\big)$ time or in $\tilde{O}\big(m^{1/2} n^{5/4}\big)$ time where $\tilde{O}(\cdots)$ hides $\mathrm{poly}(\log(n), \log(U))$-factors.*

Vertex connectivity. We now consider global vertex connectivity of both weighted and unweighted graphs. For simplicity we consider the interesting setting where there is a vertex separator of size less than $0.99W$ where W is the total vertex weight. We obtain new and faster randomized $(1 + \epsilon)$-approximation algorithms that improves upon the randomized $\tilde{O}(mn)$ exact algorithm of Henzinger, Rao and Gabow [27]. The algorithms are based on reducing, via sampling, to computing isolating element cuts. The running times we obtain are captured by the following theorem.

▶ **Theorem 7.** *Let $G = (V, E)$ be a* weighted *instance of vertex connectivity. There is a randomized algorithm that gives a $(1+\epsilon)$-approximation with high-probability in $\tilde{O}(\mathrm{EC}(m, n)/\epsilon)$ time; in particular there is a randomized algorithm that runs in time $\tilde{O}(m\sqrt{n}/\epsilon)$. For dense graphs there is a randomized algorithm that runs in $\tilde{O}(m^{1/2}n^{5/4}/\epsilon)$ time.*

There has been exciting recent work on faster algorithms for vertex connectivity via a local connectivity approach [45, 17]. The algorithms are limited to unweighted graphs while our theorem above gives the first constant factor approximation for weighted vertex connectivity in $o(mn)$ time. For unweighted graphs and graphs with small integer capacities we can obtain *exact* algorithms by setting $\epsilon = 1/\kappa$ where κ is the vertex connectivity. We obtain several different tradeoffs depending on m, n, κ. These can be found in Section 4.

Recent related work. There have been several recent papers on the use of isolating cuts and other approaches for connectivity problems in undirected as well as directed graphs. We refer the reader to some of these papers [36, 9, 46, 6]. Others have also observed that the isolating cut approach generalizes to symmetric submodular functions; see [43] for instance.

Organization. Section 2 describes the bisubmodularity framework and the abstract results at a high level; a more detailed description with several examples and formal proofs of the lemmas and theorems stated in Section 2 can be found in the full version [10]. Section 3 describes the algorithms for element-connectivity and Section 4 describes our algorithms for vertex connectivity. Section 5 describes the results for hypergraph connectivity. The proofs for Section 5 have been omitted due to space constraints and can be found in the full version [10].

2 Isolating Cuts, Symmetric Bisubmodular Functions, and Lattices

Our goal in this section to define the relevant machinery to explore and make explicit the generality of the isolating cut idea. As discussed in the introduction, this framework is motivated by the necessity of going beyond symmetric submodular set functions to capture concrete applications of interest such as element and vertex connectivity. Given the abstract nature of this discussion, in constrast to the concrete algorithmic applications, we have elected to give a brief and minimal discussion of the bisubmodular framework here. A more comprehensive description, including many more examples as well as the proofs of all lemmas and theorems stated here, can be found in the full version [10].

Let V be a finite set of elements. An ordered pair $(A, B) \in 2^V \times 2^V$ is a *set-pair* over V. For a family of set-pairs $\mathcal{V} \subseteq 2^V \times 2^V$ over V, we say that $\mathcal{V}$ is a *crossing lattice*[2] over V if it is closed under the following two operators.

$$(X_1, Y_1) \vee (X_2, Y_2) = (X_1 \cup X_2, Y_1 \cap Y_2).$$
$$(X_1, Y_1) \wedge (X_2, Y_2) = (X_1 \cap X_2, Y_1 \cup Y_2).$$

If $\mathcal{V}$ is closed under these operations, then $\mathcal{V}$ is a lattice under the partial order

$$(X_1, Y_1) \preceq (X_2, Y_2) \iff X_1 \subseteq X_2,\ Y_2 \subseteq Y_1.$$

[2] This notion is analogous to the definition of a crossing family of sets.

The binary operator $\vee$ returns the unique least upper bound of its arguments (a.k.a. the *meet*) and the binary operator $\wedge$ returns the unique greatest lower bound of its arguments (a.k.a. the *join*).

For a pair of sets $(X, Y) \in 2^V \times 2^V$, the *transpose* of (X, Y), denoted $(X, Y)^T$, is the reversed pair of sets $(X, Y)^T \stackrel{\text{def}}{=} (Y, X)$. A crossing lattice $\mathcal{V} \subseteq 2^V \times 2^V$ is *symmetric* if is closed under taking the transpose. We have the following identities relating the transpose with the lattice operations $\vee$ and $\wedge$. Observe that for $\mathcal{X}, \mathcal{Y} \in \mathcal{V}$, we have $\left(\mathcal{X}^T\right)^T = \mathcal{X}$, $(\mathcal{X} \vee \mathcal{Y})^T = \mathcal{X}^T \wedge \mathcal{Y}^T$, and $(\mathcal{X} \wedge \mathcal{Y})^T = \mathcal{X}^T \vee \mathcal{Y}^T$. Lastly, A crossing lattice $\mathcal{V} \subseteq 2^V \times 2^V$ is *pairwise disjoint* if $X \cap Y = \emptyset$ for all $(X, Y) \in \mathcal{V}$.

We now define an abstract, lattice-based notion of cuts that unifies the various different families of cuts of interest in graphs. Let V be a set. For two set-pairs $\mathcal{S} = (S, T) \in 2^V \times 2^V$ and $\mathcal{X} = (X, Y) \in 2^V \times 2^V$, we denote

$$\mathcal{S} \subseteq \mathcal{X} \stackrel{\text{def}}{\iff} S \subseteq X, T \subseteq Y.$$

If $\mathcal{S} \subseteq \mathcal{X}$, then we say that $\mathcal{X}$ *cuts* $\mathcal{S}$ or that $\mathcal{X}$ is an $\mathcal{S}$*-cut*. If $\mathcal{V}$ is a crossing lattice over V, $R \subset V$ is a subset, and $\mathcal{R}$ is a crossing lattice over R, then we say that $\mathcal{V}$ *separates* $\mathcal{R}$ if for every $\mathcal{S} \in \mathcal{R}$, there is an $\mathcal{S}$-cut $\mathcal{X} \in \mathcal{V}$. The following lemma observes that cuts are closed under the two lattice operations.

▶ **Lemma 8.** *Let V be a set and let $R \subseteq V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be a crossing lattice over R. Suppose that $\mathcal{V}$ separates $\mathcal{R}$. Let $\mathcal{S}_1, \mathcal{S}_2 \in \mathcal{R}$, let $\mathcal{X}_1 \in \mathcal{V}$ be an $\mathcal{S}_1$-cut, and let $\mathcal{X}_2 \in \mathcal{V}$ be an $\mathcal{S}_2$-cut. Then $\mathcal{X}_1 \vee \mathcal{X}_2$ is an $\mathcal{S}_1 \vee \mathcal{S}_2$-cut and $\mathcal{X}_1 \wedge \mathcal{X}_2$ is an $\mathcal{S}_1 \wedge \mathcal{S}_2$-cut.*

Now, let $\mathcal{V}$ be a lattice. A real-valued function $f : \mathcal{V} \to \mathbb{R}$ is *submodular* if for all $\mathcal{X}, \mathcal{Y} \in \mathcal{V}$,

$$f(\mathcal{X}) + f(\mathcal{Y}) \geq f(\mathcal{X} \vee \mathcal{Y}) + f(\mathcal{X} \wedge \mathcal{Y}).$$

Bisubmodular functions can be interpreted as submodular functions over particular crossing lattices. There are at least two definitions of bisubmodular function in the literature. These definitions are similar and we discuss both.

In one definition (e.g., in [48]), a function $f : 2^V \times 2^V \to \mathbb{R}$ is called *bisubmodular* if for all $X_1, Y_1, X_2, Y_2 \subseteq V$, we have

$$f(X_1, Y_1) + f(X_2, Y_2) \geq f(X_1 \cup X_2, Y_1 \cap Y_2) + f(X_1 \cap X_2, Y_1 \cup Y_2). \tag{1}$$

A bisubmodular function $f : 2^V \times 2^V \to \mathbb{R}$ is submodular over the crossing lattice of all set-pairs, $\mathcal{V} = 2^V \times 2^V$.

Another definition (e.g., [4, 3, 2, 19]) of a bisubmodular function f is that $f(X_1, Y_1)$ is only defined for disjoint sets X_1 and Y_1, and otherwise satisfies inequality (1) for these inputs. In this version, f is bisubmodular iff it is a submodular function over the lattice of disjoint sets, $\mathcal{V} = \{(X, Y) : X, Y \subseteq V, X \cap Y = \emptyset\}$.

Now, let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric crossing lattice. A function $f : \mathcal{V} \to \mathbb{R}$ is *symmetric* if for all $\mathcal{X} \in \mathcal{V}$, $f(\mathcal{X}) = f\left(\mathcal{X}^T\right)$. This is a different definition than for symmetric submodular *set* functions and generalizes the (more standard) set-based definition. Both undirected edge cuts and vertex cuts are examples of symmetric submodular functions over appropriate symmetric crossing lattices.

There is an important relationship between the sets of terminals being separated and *minimal* minimum cuts that separate them, highlighted in the following lemma.

▶ **Lemma 9.** *Let V be a set and $R \subset V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be a symmetric crossing lattice over R, such that $\mathcal{V}$ separates $\mathcal{R}$. Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function. Consider the function $h : \mathcal{R} \to \mathcal{V}$ where $h(\mathcal{S})$ is defined as $\preceq$-minimum, f-minimum $\mathcal{S}$-cut. Then h is well-defined and carries the partial orders on $\mathcal{R}$ to $\mathcal{V}$; that is, $\mathcal{S}_1 \preceq \mathcal{S}_2 \implies h(\mathcal{S}_1) \preceq h(\mathcal{S}_2)$.*

The following is a particularly convenient form of Lemma 9, and the one applied directly in the sequel.

▶ **Lemma 10.** *Let V be a set and $R \subset V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be a symmetric crossing lattice over R, such that $\mathcal{V}$ separates $\mathcal{R}$. Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function. Let $\mathcal{S}_1, \ldots, \mathcal{S}_k \in \mathcal{R}$ and $\mathcal{X}_1, \ldots, \mathcal{X}_k \in \mathcal{V}$ such that for all $i \in [k]$, $\mathcal{X}_i$ is an f-minimum $\mathcal{S}_i$-cut. Then for any $\mathcal{S} \in \mathcal{R}$ such that $\mathcal{S} \preceq \mathcal{S}_i$ for all i, there is an f-minimum $\mathcal{X}$-cut with $\mathcal{X} \preceq \mathcal{X}_1 \wedge \cdots \wedge \mathcal{X}_k$.*

We now come to the issue of computing isolating cuts. We formalize this as follows. Let V be a set and $R \subset V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric and *pairwise disjoint* crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be the symmetric and *pairwise disjoint* crossing lattice over R consisting of all partitions of R; i.e., $\mathcal{R} = \{(S,T) : S \cup T = R,\ S \cap T = \emptyset\}$. Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function. For each $r \in R$ we wish to find an f-minimum cut $\mathcal{Y}_r$ for the set-pair $(\{r\}, R - \{r\})$ (which we abbreviate as $(r, R - r)$ for notational simplicity). The main property that leads to efficiency is captured by the next lemma.

▶ **Lemma 11.** *Let V be a set and $R \subset V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric and* pairwise disjoint *crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be the symmetric and* pairwise disjoint *crossing lattice over R consisting of all partitions of R; i.e., $\mathcal{R} = \{(S,T) : S \cup T = R,\ S \cap T = \emptyset\}$. Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function. Suppose we had access to an oracle that, given $\mathcal{S} \in \mathcal{R}$, returns a minimum $\mathcal{S}$-cut $\mathcal{W} \in \mathcal{V}$. Let $k = \lceil \log |R| \rceil$. Then with k calls to the oracle, one can compute k cuts $\mathcal{W}_1, \ldots, \mathcal{W}_k \in \mathcal{V}$ such that the following holds.*

For each $r \in R$, let $\mathcal{X}_r = \left(\bigwedge_{i:(r,V-r) \preceq \mathcal{W}_i} \mathcal{W}_i\right) \wedge \left(\bigwedge_{i:(r,V-r) \preceq \mathcal{W}_i^T} \mathcal{W}_i^T\right)$ be the intersection of cuts transposed to always include r in the first component. Then we have the following. (1) For all $r \in R$, $\mathcal{X}_r$ is an $(r, R-r)$-cut. (2) For all $r \in R$, there is a minimum $(r, R-r)$-cut $\mathcal{Y}_r$ such that $\mathcal{Y}_r \preceq \mathcal{X}_r$. (3) For any two distinct elements $r, q \in R$, $\mathcal{X}_r \wedge \mathcal{X}_q \preceq (\emptyset, R)$. (That is, the first components of the set pairs $\mathcal{X}_r$ are pairwise disjoint.)

Using the preceding lemma the problem of computing the f-minimum r-isolating cuts is reduced to finding such a cut in $\mathcal{X}_r$. The advantage, in terms of running time, is captured by the disjointness property: for distinct $r, q \in R$ we have $\mathcal{X}_r \wedge \mathcal{X}_q \preceq (\emptyset, R)$. For each r let $\mathcal{X}_r = (A_r, B_r)$. Thus we have $\sum_r |A_r| \leq |V|$. Given r and $\mathcal{X}_r$, the problem of computing the f-minimum cut $\mathcal{Y}_r \preceq \mathcal{X}_r$ can in several settings be reduced to solving a problem that depends only on $|A_r|$ and $|V|$. We capture this in the following lemma.

▶ **Lemma 12.** *Let V be a set and $R \subset V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric and* pairwise disjoint *crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be the symmetric and* pairwise disjoint *crossing lattice over R consisting of all partitions of R; i.e., $\mathcal{R} = \{(S,T) : S \cup T = R,\ S \cap T = \emptyset\}$. Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function. Suppose we had access to an oracle that, given $\mathcal{S} \in \mathcal{R}$, returns a minimum $\mathcal{S}$-cut $\mathcal{W} \in \mathcal{V}$ and let $\mathrm{SM}(n)$ denote its running time where $n = |V|$. Moreover, suppose we have an oracle that given any $u \in R$ and $(A_u, B_u) \in \mathcal{V}$ with $u \in A_u$ outputs an f-minimum cut $\mathcal{Y}_u \preceq (A_u, B_u)$ in time $\mathrm{SMI}(|A_u|, n)$. Let $k = \lceil \log |R| \rceil$. Then, one can compute for each $r \in R$ an f-minimium r-isolating cut in in total time $O(k\,\mathrm{SM}(n) + \max_{0 \leq n_1, n_2, \ldots, n_{|R|} : \sum_i n_i = n} \sum_{i=1}^{|R|} \mathrm{SMI}(n_i, n))$.*

A simple random sampling approach combined with isolating cuts, as shown in [37] for edge cuts in graphs, yields the following theorem in a much more abstract setting.

▶ **Theorem 13.** *Let V be a set and $R \subset V$. Let $\mathcal{V} \subseteq 2^V \times 2^V$ be a symmetric and pairwise disjoint crossing lattice over V and let $\mathcal{R} \subseteq 2^R \times 2^R$ be the symmetric and pairwise disjoint crossing lattice over R consisting of all disjoint subsets of R; i.e., $\mathcal{R} = \{(S,T) : S,T \subseteq R,\, S \cap T = \emptyset\}$. Let $f : \mathcal{V} \to \mathbb{R}$ be a symmetric bisubmodular function. Suppose we had access to an oracle that, given $\mathcal{S} \in \mathcal{R}$, returns a minimum $\mathcal{S}$-cut $\mathcal{W} \in \mathcal{V}$ and let $\mathrm{SM}(n)$ denote its running time where $n = |V|$. Moreover, suppose we have an oracle that given any $u \in R$ and $(A_u, B_u) \in \mathcal{V}$ with $u \in A_u$ outputs an f-minimum cut $\mathcal{Y}_u \preceq (A_u, B_u)$ in time $\mathrm{SMI}(|A_u|, n)$. Then one can compute the minimum (nontrivial) $\mathcal{R}$-cut with constant probability in $O\Big(\mathrm{SM}(n)\log^2|R| + \max_{0\le n_1,n_2,\ldots,n_{|R|}:\sum_i n_i = n} \log(|R|)\sum_{i=1}^{|R|}\mathrm{SMI}(n_i,n)\Big)$ time.*

We derive the following corollary for symmetric submodular set functions.

▶ **Corollary 14.** *Let $f : 2^V \to \mathbb{R}$ be a symmetric submodular function and $R \subseteq V$ and let $n = |V|$. Suppose there is an algorithm for submodular function minimization in the value oracle model in time $\mathrm{SFM}(n) = g_1(n)EO + g_2(n)$ where EO is the time for the evaluation oracle. Assuming that $g_1(n) = \Omega(n)$ and $g_2(n) = \Omega(n)$, a minimum f-cut that separates some two terminals in R can be found in $O\big(\mathrm{SFM}(n)\log^2(n)\big)$ time.*

3 Element connectivity

Let $G = (V, E)$ be an undirected graph with m edges and n vertices. Let $T \subseteq V$ be a set of terminals and let $N = V \setminus T$ be the non-terminal set. For any two distinct terminals $u, v \in T$, the element connectivity between u and v is defined as the maximum number of paths from u to v that are edge-disjoint and vertex-disjoint in the non-terminal vertices $V \setminus T$. That is, only terminal vertices may be reused across paths. This notion can be easily generalized to the weighted setting where edges and non-terminals have non-negative weights/capacities. For any two terminals $s, t \in T$, we denote by $\kappa'(s,t)$ the element connectivity between them. One can compute $\kappa'(s,t)$ via a simple reduction to s-t maximum flow in a directed graph which takes $\mathrm{EC}(m,n)$ time. In this section we are concerned with the problem of computing the global element connectivity which is defined as $\kappa' = \min_{s,t\in T, s\neq t}\kappa'(s,t)$. In fact we are also interested in computing the more general problem of computing $\kappa'(R) = \min_{s,t\in R, s\neq t}\kappa'(s,t)$ where $R \subseteq T$; note that $\kappa' = \kappa'(T)$. Here we apply our general framework that obtains a randomized algorithm with running time $O(\mathrm{EC}(m,n)\log^2|R|)$. In addition to the global minimum cut for R, as we will see in the next section, finding all the isolating cuts can be used with other ideas for vertex connectivity.

Let $G = (T \uplus N, E)$ be an instance of a weighted element connectivity problem. Let $w : N \cup E \to \mathbb{R}_{\ge 0}$ assign weights to the elements. Let $R \subseteq T$ be a subset of terminals with $|R| \ge 2$. We reduce the problem of computing $\kappa'(R)$ to Theorem 13 as follows.

For ease of notation, let $\overline{V} = V \cup E$ denote the elements. Consider the family of pairs of sets $\mathcal{V} \subseteq 2^{\overline{V}} \times 2^{\overline{V}}$ defined as the set of pairs $(X, Y) \in \overline{V} \times \overline{V}$ with the following properties: (i) X and Y are disjoint, (ii) no edge in X is adjacent to a vertex in Y, and no edge in Y is adjacent to a vertex in X, and (iii) $T \subseteq X \cup Y$. $\mathcal{V}$ describes the disjoint sets that are element-wise disconnected and cover T. Clearly $\overline{V}$ is symmetric and pairwise disjoint. It is also straightforward to verify that $\overline{V}$ is a crossing lattice.

We define a function $f : \mathcal{V} \to \mathbb{R}$ by $f(X, Y) = \sum_{x \in \overline{V} - (X \cup Y)} w(x)$. $f(\mathcal{X})$ gives the total weight of elements that are not a member of either of the two sets in $\mathcal{X}$. This function f is submodular and in fact it is modular. One can easily verify that $f(X_1, Y_1) + f(X_2, Y_2) = f(X_1 \cup X_2, Y_1 \cap Y_2) + f(X_1 \cap X_2, Y_1 \cup Y_2)$. Thus $\mathcal{V}$ is a symmetric and pairwise disjoint crossing lattice, and $f : \mathcal{V} \to \mathbb{R}$ is a symmetric submodular function over $\mathcal{V}$.

Isolating (weighted) element cuts and global connectivity Let $R \subseteq T$ and let $\mathcal{R}$ be the crossing lattice consisting of all pairwise disjoint subsets of R. Given a partition of R into two sets (A, B), an f-minimum (A, B)-cut, which corresponds to the minimum element cut separating A from B, can be computed via directed (s, t)-maxflow, in $\mathrm{EC}(m, n)$-time. By Lemma 11, we can compute disjoint sets of elements $\left\{\overline{U}_r \subset \overline{V} : r \in R\right\}$ where for each $r \in R$, $\overline{U}_r$ contains the r-side component of a minimum $(r, R - r)$-element cut. Moreover, because the $\overline{U}_r$'s are obtained as intersections of sides of element cuts, for any distinct $r, q \in R$, there is no edge from $\overline{U}_r$ incident to a vertex from $\overline{U}_q$ and (symmetrically) vice-versa.

For each r, let $\overline{U}'_r \subset \overline{V}$ be the set of vertices outside $\overline{U}_r$ and incident to an edge in $\overline{U}_r$, and the edges outside $\overline{U}_r$ incident to vertices in $\overline{U}_r$. Informally speaking, $\overline{U}'_r$ is the "boundary" of $\overline{U}_r$ in an element connectivity sense. Let $n_r = \left|V \cap \left(\overline{U}_r \cup \overline{U}'_r\right)\right|$ be the number of vertices in $\overline{U}_r \cup \overline{U}'_r$ and let $m_r = \left|E \cap \left(\overline{U}_r \cup \overline{U}'_r\right)\right|$ be the number of edges in $\overline{U}_r \cup \overline{U}'_r$. Note that $\sum_r m_r \leq 2m$ since each edge can either appear in $\overline{U}_r$ for a unique choice of r or in $\overline{U}'_r$ for two choices of r.

To find an isolating cut for r we need to find the cheapest element cut contained in $\overline{U}_r$. We can do this via a flow computation as described below. For each r, consider the graph G_r where we first take the graph $\overline{U}_r \cup \overline{U}'_r$ and introduce an auxiliary vertex $\bar{t}$. We connect $\bar{t}$ to all vertices in $\overline{U}'_r$ with infinite capacity. For every edge $e \in \overline{U}'_r$ with exactly one endpoint in $\overline{U}_r$, we replace the opposite endpoint with $\bar{t}$. Observe that the minimum $(r, \bar{t})$-element cut in G_r coincides with the minimum $(r, R - r)$-element cut in G. G_r has $O(m_r)$ edges and $O(n_r)$ vertices, and the element $(r, \bar{t})$-cut problem can be solved in $\mathrm{EC}(m_r, n_r)$ time. Summing over all $r \in R$ gives the following theorem.

▶ **Theorem 15.** *Let $G = (T \cup N, E)$ be an instance of element connectivity with n nodes and m edges and let $R \subseteq T$. Let $w : V \cup E \to (-\infty, \infty]$ assign positive weight to each vertex and edge. Let $k = |T|$. Then one can compute, for all $r \in R$, the minimum weight element $(r, R - r)$-cut in $O\Big(\mathrm{EC}(m, n) \log k + \max_{m_1, \ldots, m_k} \Big\{\sum_{i=1}^{k} \mathrm{EC}(m_i, n) : m_1 + \cdots + m_k \leq 2m\Big\}\Big)$, where $\mathrm{EC}(m, n)$ is the running time for element (S, T)-cut with m edges and n vertices.*

With Theorem 15 in place we can reduce the global mincut problem for R to the isolating cut computation via sampling [37], and captured in the abstract setting Theorem 13, to obtain the following theorem to compute $\kappa'(R)$.

▶ **Theorem 16.** *Let $G = (T \cup N, E)$ be an instance of element connectivity with n nodes and m edges and let $R \subseteq T$. Let $w : V \cup E \to (-\infty, \infty]$ assign positive weight to each vertex and edge. Let $k = |R|$. Then one can compute $\kappa'(R)$ with constant probability in time $O((\mathrm{EC}(m, n) \log(k) + \max_{m_1, \ldots, m_n} \{\sum_{i=1}^{n} \mathrm{EC}(m_i, n) : m_1 + \cdots + m_n \leq 2m\}) \log n)$.*

3.1 Refined running times for element connectivity

Until recently, the leading running times for $\mathrm{EC}(m, n)$ (e.g., $\mathrm{EC}(m, n) = \tilde{O}(m\sqrt{n})$ [34]) plug directly into Theorem 16 to give running times of the form $\tilde{O}(\mathrm{EC}(m, n))$ to compute the global element connectivity. A recent breakthrough work by [50] has obtained a running

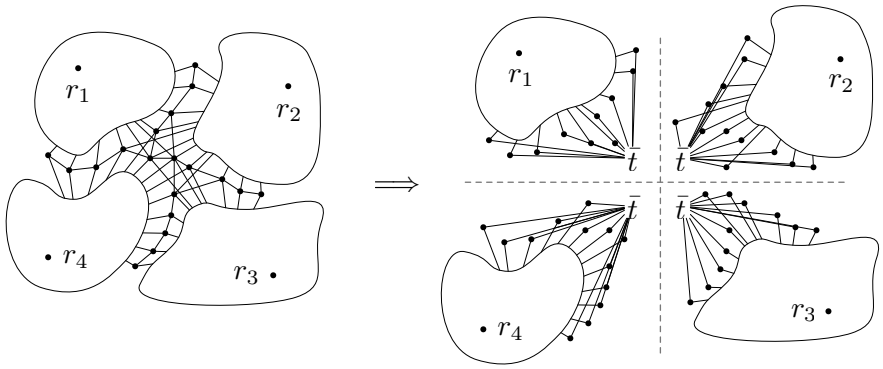

Figure 1 Applying the uncrossing framework to vertex connectivity reduces vertex isolating cuts to edge disjoint cut problems. Note that the separating vertices may appear in multiple subproblems, which is an obstruction towards a direct $\tilde{O}(\mathrm{EC}(m,n))$ overall running time for isolating vertex cuts.

time of $\mathrm{EC}(m,n) = \tilde{O}\big(m + n^{1.5}\big)$ for polynomially bounded and integral capacities. However, Theorem 16 does not directly benefit from this running time because the vertices are not partitioned across subproblems. See Figure 1 for an illustration in the concrete setting of vertex cuts. Consequently, plugging $\mathrm{EC}(m,n) = \tilde{O}\big(m + n^{1.5}\big)$ directly into Theorem 16 generates a running time of $\tilde{O}\big(m + n^{1.5}k\big)$, where $k = |T|$. The additional factor of k (to a certain extent) defeats the purpose of the isolating cuts framework.

In this section, we develop more advanced algorithms that take the isolating cut framework as a starting point, and incorporates additional ideas to take advantage of $\mathrm{EC}(m,n) = \tilde{O}\big(m + n^{1.5}\big)$. In addition to obtaining faster algorithms, these results point to a general algorithm design space where additional ideas can be introduced to obtain even better running times. The first algorithm we present leverages the fact that the edges are partitioned across subproblems, even if the vertices are not.

▶ **Theorem 17.** *Let $G = (T \cup N, E)$ be an instance of element connectivity with n nodes and m edges and let $R \subseteq T$. Let $w : V \cup E \to [1..U]$ assign integer (or infinite) weights to each vertex and edge. For $R \subseteq T$, the minimum R-isolating vertex cut can be computed in*

$$\tilde{O}\Big(m^{1+o(1)}n^{3/8}U^{1/4} + n^{1.5}\Big)$$

time.

Proof. Let $k = |R|$. We apply Theorem 15 and give concrete upper bounds using known upper bounds for $\mathrm{EC}(m,n)$. Let $m_1, \ldots, m_k \in \mathbb{N}$ with $m_1 + \cdots + m_k \le m$. Recall that $\mathrm{EC}(m,n) = \tilde{O}\big(m^{4/3+o(1)}U^{1/3}\big)$ by [31] and $\mathrm{EC}(m,n) = \tilde{O}\big(m + n^{3/2}\big)$ by [50]. Let $\alpha > 0$ be a parameter to be determined. We apply the first running time when $m_i < m\alpha/k$ and the second running time then $m_i \ge m\alpha/k$. At most k/α indices i have $m_i \ge m\alpha/k$. Thus,

$$\begin{aligned}\sum_{i=1}^{k}\mathrm{EC}(m_i,n) &= \sum_{i:m_i \ge m\alpha/k}\mathrm{EC}(m_i,n) + \sum_{i:m_i<m\alpha/k}\mathrm{EC}(m_i,n)\\ &\le \tilde{O}\left(m + \frac{k}{\alpha}n^{1.5} + \sum_{i:m_i<m\alpha/k} m_i^{4/3+o(1)}U^{1/3}\right)\\ &\overset{(a)}{\le} \tilde{O}\left(m + \frac{k}{\alpha}\left(n^{1.5} + \Big(\frac{\alpha m}{k}\Big)^{4/3+o(1)}U^{1/3}\right)\right).\end{aligned}$$

Here (a) is by convexity: the quantity $\sum_{i:m_i<m\alpha/k} m_i^{4/3+o(1)}$ subject to the condition that $\sum_i m_i \leq m$ is at most $(k/\alpha)(\alpha m/k)^{4/3+o(1)}$. Balancing terms at $\alpha = kn^{9/8}/m$, this gives an upper bound of $\tilde{O}\big(m^{1+o(1)}n^{3/8}U^{1/4}\big)$, hence the claimed running time. ◀

We point out that other running time tradeoffs between m and U can be obtained by instead applying the flow alogrithms from [39, 40].

The next theorem, which is particularly good for dense graphs, leverages the fact that while the vertices are not necessarily partitioned across subproblems, at least the "inner" vertex sets $\overline{U}_r \cap V$ are disjoint and all of the repeating "boundary" vertices are guaranteed to be outside the r-component of each $(r, R-r)$-minimum cut. The following algorithm balances a tradeoff between the recent algorithm with [51] with blocking flows [22]. In the application of blocking flows, we argue that with an appropriate construction of the auxiliary graph in the components given by the decomposition by isolating cuts, the maximum length of any augmenting paths is proportional to the number of inner vertices (rather than the total number of vertices) for that component.

▶ **Theorem 18.** *Let $G = (T \cup N, E)$ be an instance of element connectivity with n nodes and m edges and let $R \subseteq T$. Let $w : V \cup E \to [0, U]$ assign positive (or infinite) weights to each vertex and edge. For $R \subseteq T$, the minimum R-isolating cut can be computed in*

$$\tilde{O}\Big(m^{1/2}n^{5/4}\Big)$$

randomized time, where $\tilde{O}(\cdots)$ hides $\mathrm{poly}(\log(n), \log(U))$-factors.

Proof. We recall the construction from Theorem 15, adopting the same notation. In addition, for each r, let $\tilde{n}_r$ be the number of vertices in $\overline{U}_r$. Note that as the $\bar{U}_r$'s are disjoint, we have $\sum_{r\in R} \tilde{n}_r \leq n$.

For each r, we employ two different approaches to computing the minimum $(r, \bar{t})$-element cut. On one hand we can apply any max flow algorithm in $\mathrm{EC}(m_r, n_r)$ time. As remarked above we have $\mathrm{EC}(m_r, n_r) \leq \tilde{O}\big(m_r + n_r^{1.5}\big)$ by [50]. The second approach is to apply blocking flows with the following additional observations. Element connectivity can be modeled as maximum flow in undirected graphs with edge and vertex capacities, which in turn can be reduced to maximum flow in edge capacitated directed graphs. Recall the directed graph representation of vertex capacities, sometimes called the "split graph". We remind the reader that in the split graph, each non-terminal vertex $v \in V_r \setminus \big\{r, \bar{t}\big\}$ is split into two vertices – an "in-vertex" v^- and an "out-vertex" v^+ – and there is an edge (v^-, v^+) with capacity equal to $w(v)$. Each edge $(u, v) \in E_r$ is replaced with an edge (u^+, v^-) with the same capacity. From this split graph, we contract the edges $(v^+, \bar{t})$ for all $v \in V \cap \overline{U}'_r$, which is safe because $\bar{t}$ is the sink and each edge $(v^+, \bar{t})$ has infinite capacity. Now, in this directed auxiliary graph, we have $O(m_r)$ edges and $O(n_r)$ vertices. We now observe that the auxiliary vertices corresponding to $\overline{U}'_r \cap V$, $\Big\{v^- : v \in \overline{U}'_r \cap V\Big\}$, do not have any edges between them. Then any $(s, \bar{t})$ path in this graph or in any residual graph that may arise cannot have consecutive auxiliary vertices from $\overline{U}'_r$. Therefore, every augmenting path has length at most $2\tilde{n}_r$. In turn, $O(\tilde{n}_r)$ iterations of blocking flows suffice to find the minimum $(r, \bar{t})$ cut in G_r, which takes $O(m_r \log(m_r/n_r))$ time per iteration [22] and $O(m_r\tilde{n}_r \log(m_r/n_r))$ time overall.

Let $\alpha > 0$ be a parameter to be determined. We have $\tilde{n}_r \geq \alpha n/k$ for at most k/α vertices $r \in R$. We have

$$\begin{aligned} O\left(\sum_r \min\{\mathrm{EC}(m_r, n_r), m_r \tilde{n}_r \log(m)\}\right) &\leq \tilde{O}\left(\sum_{r:\tilde{n}_r \leq \alpha n/k} m_r \tilde{n}_r + \sum_{r:\tilde{n}_r \geq \alpha n/k} \left(m_r + n_r^{1.5}\right)\right) \\ &\leq \tilde{O}\left(m + \left(\frac{\alpha}{k}\right) mn + \left(\frac{k}{\alpha}\right) n^{1.5}\right) \\ &\overset{(a)}{\leq} \tilde{O}\left(m + m^{1/2} n^{5/4}\right) = \tilde{O}\left(m^{1/2} n^{5/4}\right), \end{aligned}$$

as desired. Here, in step (a), we substituted $\alpha = kn^{1/4}/m^{1/2}$. ◀

4 Vertex connectivity

In this section we consider the problem of computing the vertex connectivity in weighted and unweighted graphs. Let $G = (V, E)$ be an undirected graph with m edges and n vertices. Let $w : V \to [1, U]$ be positive vertex weights. Given distinct nodes $s, t \in V$ such that $st \notin E$, the minimum weight vertex separator between s and t can be computed via flow techniques. Recently there has been significant improvement in the running time of vertex capacitated flow to $\tilde{O}(m+n^{1.5})$ [51]. We use $\mathrm{VC}(m, n)$ to denote the complexity of computing such a separator. We let $\kappa(s, t)$ denote the weight of the separator between s, t with the understanding that $\kappa(s, t) = \infty$ if $\{s, t\} \in E$. Here we are interested in the minimum vertex weight separator of G which can be defined as $\min_{s,t \in V, s \neq t} \kappa(s, t)$.

Let $R \subset V$ such that R is an *independent set* in G; that is, no two vertices in R share an edge. One can then define $\kappa(R)$ to be $\min_{s,t \in R, s \neq t} \kappa(s, t)$. We observe that $\kappa(R)$ is the same as the element connectivity of R in the graph where R is the set of terminals and $V \setminus R$ are the non-terminals and edge weights are set to ∞; i.e., only vertices are allowed to be removed. We have already seen algorithms for element connectivity, which immediately convert to isolating cut algorithms for vertex connectivity. For instance, one can compute the minimum isolating cut in $\tilde{O}\left(m^{1+o(1)} n^{3/8} U^{1/4} + n^{1.5}\right)$ time with integral vertex weights between 1 and U, or in $\tilde{O}\left(\sqrt{m} n^{5/4}\right)$ time for polynomially bounded weights.

These running times for isolating cuts do not, however, immediately convert to running times for vertex cuts. To obtain the minimum vertex cut as an isolating cut, we must initialize the algorithm with a set of vertices R for which the minimum vertex cut is also an isolating cut. Let (S, T) be opposite sides of a minimum vertex cut $N(S) = N(T)$. Without loss of generality suppose S has weight less than or equal to T. We would like a set R that samples exactly one point from S, at least one point from T, and avoids $N(S)$ altogether. Even in the unweighted setting, uniform sampling is thwarted by the fact that $N(S)$ may be much larger than S, and it is difficult to hit S without hitting $N(S)$ too. In the following lemma, we observe that if we relax our problem to an $(1 + \epsilon)$-approximately minimum vertex cut, then we can sample a useful set R with reasonably good probability.

▶ **Lemma 19.** *Let $\epsilon > 0$ be fixed. Let $G = (V, E)$ be an undirected graph with m edges and n vertices. Let $w : V \to [1, U]$ be positive vertex weights and let $W = \sum_{v \in V} w(v)$ be the total weight. Let κ be the weight of the minimum weight vertex cut. Suppose the minimum weighted degree is greater than $(1 + \epsilon)\kappa$. Then one can compute a randomized independent set $R \subset V$ such that the minimum vertex cut is an R-isolating set with probability at least $\Omega((\epsilon/\log(nU)) \max\{\epsilon, (1 - \kappa/W)\})$.*

Proof. For ease of notation, let

$$\epsilon_0 = \max\left\{\epsilon, \frac{1}{2}\left(1 - \frac{\kappa}{W}\right)\right\}$$

Let (S, T) be opposite sides of the minimum vertex cut $N(S) = N(T)$. Without loss of generality suppose $w(S) \leq w(T)$ where we use the notation $w(A)$ to denote the total weight of vertices in A, that is, $w(A) = \sum_{v \in A} w(v)$. Since $N(S)$ is the minimum weight vertex separator we have $w(N(S)) = \kappa$. We would like a independent set $R \subset V$ that has exactly one point from S, at least one point from T, and avoids $N(S)$ altogether. Then (S, T) would isolate the lone vertex in $R \cap S$ from $R - r \subseteq T$, as desired. We can achieve this via a sampling procedure that we described below.

First we claim that $w(S) \geq \epsilon\kappa$. Fix an arbitrary vertex $v \in S$. By assumption, $w(N(v)) \geq (1 + \epsilon)\kappa$. Since $N(v) \subseteq S \cup N(S)$ and $S \cap N(S) = \emptyset$, we have $w(S) \geq \epsilon\kappa$.

Let μ be any value in the range $[2\max\{w(S), \kappa\}, 4\max\{w(S), \kappa\}]$. Since $\max\left\{\sum_{v \in S} w(v), \kappa\right\}$ lies in the range $[1, \text{poly}(n, U)]$, we can sample a value μ that lies in the above range with probability $\Omega(1/\log(nU))$ by randomly picking a power of 2 in the range $[1, \text{poly}(n, U)]$. Once we fix μ, let R be a random subset of vertices obtained by independently sampling each vertex v with probability $w(v)/\mu$. Then, as long as R has an adjacent pair of vertices, we remove one of them from R. We claim that the intial sample for R has one point from S, no points from $N(S)$, and at least one point from T with probability $\geq \Omega(\epsilon\epsilon_0)$. If so, then since S and T are independent from one another, dropping vertices in the second phase will not remove any vertices from S, and retain at least one vertex in T, as desired. Observe that the three events are independent.

The probability that R avoids $N(S)$ is $\prod_{v \in N(S)}(1 - w(v)/\mu)$. Since $w(N(S)) = \kappa$ and $\mu \geq 2\kappa$, for any $v \in N(S)$, $w(v)/\mu \leq 1/2$. For $x \in (0, 1/2]$ the inequality $(1 - x) \geq e^{-2x}$ holds. Hence, $\prod_{v \in N(S)}(1 - w(v)/\mu) \geq \prod_{v \in N(S)} e^{-2w(v)/\mu} \geq e^{-2\kappa/\mu} \geq 1/e$.

Recall that $w(S) \geq \epsilon\kappa$ and hence the probability that R samples exactly one vertex from S is

$$\sum_{v \in S} \frac{w(v)}{\mu} \prod_{u \in S - \{v\}} (1 - \frac{w(u)}{\mu}) \geq \sum_{v \in S} \frac{w(v)}{\mu} e^{-2(w(S) - w(v))/\mu} \geq \frac{1}{e} \sum_{v \in S} \frac{w(v)}{\mu} \geq \frac{\epsilon}{4e}.$$

In the preceding set of inequalities we used the fact that $1 - x \geq e^{-2x}$ for $x \in [0, 1/2]$ since $w(S)/\mu \leq 1/2$. In the final inequality we used the fact that $w(S) \geq \epsilon\kappa$ which implies that $w(S) \geq \epsilon\mu/4$.

We claim that $w(T) \geq \epsilon_0\mu/4$. Assuming the claim, the probability that R samples at least one vertex from T is $\geq 1 - e^{-w(T)/\mu} \geq 1 - e^{\epsilon_0/4} = \Omega(\epsilon_0)$. To see the claim, recall that $w(T) \geq w(S) \geq \epsilon\kappa$. We also have $w(S) + w(T) + w(N(S)) = W$ which implies that $w(T) \geq \frac{1}{2}(W - \kappa) \geq \frac{1}{2}(1 - \frac{\kappa}{W})W \geq \frac{1}{2}(1 - \frac{\kappa}{W})w(S)$. Since $\mu \leq 4\max\{w(S), \kappa\}$, we have $w(T) \geq \epsilon_0\mu/4$.

Thus, given μ lies in the range $[2\max\{w(S), \kappa\}, 4\max\{w(S), \kappa\}]$ which happens with probability $\Omega(1/\log(nU))$ we have the desired sample R with probability $\Omega(\epsilon \cdot \epsilon_0)$. ◀

4.1 Approximate vertex connectivity

By combining the isolating cut algorithms with the sampling lemma above (for the case where no singleton already induces a good enough vertex cut), we obtain the following approximation algorithm for vertex connectivity. We point out that in the running time below, the trailing factor $(\min\{1/\epsilon, W/(W - \kappa)\})$ is simply a constant except in the relatively

uninteresting setting where the minimum weight vertex cut is almost all of the weight of the graph. In the regime of interest, the following is a $\tilde{O}(1/\epsilon)$ factor greater than the running time to compute an isolating vertex cut.

▶ **Theorem 20.** *Let $\epsilon > 0$ be fixed. Let $G = (V, E)$ be an undirected graph with m edges and n vertices. Let $w : V \to \mathbb{R}_{>0}$ be positive vertex weights and let $W = \sum_{v \in V} w(v)$ be the total weight. Let κ be the weight of the minimum weight vertex cut. Then a minimum vertex cut can be computed with high probability in $\tilde{O}((1/\epsilon)\,\mathrm{IsoVC}(m, n)\min\{(1/\epsilon), W/(W-\kappa)\})$ randomized time, where $\mathrm{IsoVC}(m, n)$ is the running time to compute the minimum isolating vertex cut in a weighted graph of m edges and n vertices.*

Proof. Let

$$\ell = \tilde{O}\left(\frac{1}{\epsilon}\min\left\{\frac{1}{\epsilon}, \frac{W}{W-\kappa}\right\}\right)$$

The algorithm first repeats the following subroutine $O(\ell)$ times. This subroutine first generates an set $R \subset V$ by Lemma 19, and then it computes a minimum R-isolating cut. It compares the ℓ isolating cuts generated above with the singleton cuts in the graph, returning the minimum overall.

We argue that the algorithm returns a $(1+\epsilon)$-approximate minimum weight cut with high probability by the following simple analysis. In one case, some singleton cut is an approximate minimum cut, in which case the algorithm always succeeds. In the second case, the minimum weighted degree is at least an $(1+\epsilon)$-multiplicative factor greater than the vertex connectivity. In that case, the minimum weight vertex cut is a minimum R-isolating cut for at least one of the random sets R with high probability, in which case we return the minimum weight vertex cut. ◀

We briefly compare our bound above to previous work. As mentioned previously Henzinger, Rao and Gabow [27] obtain a randomized algorithm that gives the exact vertex connectivity in $\tilde{O}(mn)$ time for weighted graphs. We obtain a $(1+\epsilon)$-approximation in $\tilde{O}(m\sqrt{n}/\epsilon)$ time or in $\tilde{O}\big(m^{1/2}n^{5/4}/\epsilon\big)$ time; other bounds are outlined in previous subsection. We are thus able to obtain substantially faster algorithm if we settle for a small approximation. There have been past works on approximation for vertex connectivity but as far as we know they have been limited to unweighted graphs. Henzinger [26] obtained a 2-approximation in $O(n^2\min(\sqrt{n}, \kappa))$. Forster et al. obtained a $(1+\epsilon)$-approximation in randomized time $\tilde{O}\big(m + n\kappa^2/\epsilon\big)$ which is near-linear for small connectivity, and combining various other results they improve upon Henzinger's result. We refer the reader to [17] for detailed bounds. Our running times are useful for the larger connectivity regime and we can obtain improved bounds in various other regimes of interest. We leave a more detailed comparison to a future version of the paper.

4.2 Exact vertex connectivity

Now, for integral weights, the approximation algorithm above gives the following exact algorithm for vertex connectivity by suitable choice of ϵ. Again we highlight that in the running time below, the trailing factor $(\min\left\{\kappa, \frac{W}{W-\kappa}\right\})$ is simply a constant except in the relatively uninteresting setting where κ is almost $\sum_{v \in V} w(v)$, in which case the remaining factors of $O(\kappa\,\mathrm{IsoVC}(m, n))$ are not as compelling anyway.

Table 1 A table of running times for finding the minimum vertex cut in an *unweighted* and undirected graph. $\mathrm{VC}(m,n)$ denotes the running time of computing (s,t)-vertex connectivity. $\mathrm{EC}(m,n)$ denotes the running time computing (s,t)-edge connectivity. See also [48, Section 15.2a].

$O\big(n^2\,\mathrm{VC}(\kappa n, n)\big)$	Combines trivial algorithm with sparsification [44].
$O(n\,\mathrm{VC}(\kappa n, n))$	Combines randomized trivial algorithm with sparsification [44]. $\kappa \leq .99n$
$O(n^\omega + n\kappa^\omega)$.	[38].
$\tilde{O}\big(\kappa n^2\big)$	[27]. Randomized.
$O\big(\min\big\{n^{3/4}, \kappa^{3/2}\big\}\kappa^2 n + \kappa n^2\big)$	[20].
$\tilde{O}\big(m + \kappa^{7/3} n^{4/3}\big)$	[45]. Randomized.
$\tilde{O}\big(m + n\kappa^3\big)$	[17]. Randomized.
$\tilde{O}\big(m + \kappa^{7/3} n^{4/3}\big)$	Corollary 22. Randomized. $\kappa \leq .99n$
$\tilde{O}\big(m + \kappa^2 n^{11/8+o(1)} + \kappa n^{3/2}\big)$	Corollary 22. Randomized. $\kappa \leq .99n$
$\tilde{O}\big(m + \kappa^{1.5} n^{7/4}\big)$	Corollary 22. Randomized. $\kappa \leq .99n$.

▶ **Theorem 21.** *Let $G = (V, E)$ be an undirected graph with m edges and n vertices. Let $w : V \to \mathbb{N}$ be integer vertex weights and let $W = \sum_{v \in V} w(v)$ be the total weight. Let κ be the weight of the minimum weight vertex cut. Then the minimum vertex cut can be computed with high probability in $\tilde{O}(\kappa\,\mathrm{IsoVC}(m,n)\min\{\kappa, W/(W-\kappa)\})$ randomized time, where $\mathrm{IsoVC}(m,n)$ is the running time to compute the minimum isolating vertex cut in a weighted graph of m edges and n vertices.*

Proof. For integral capacities, a $(1 + 1/(\kappa+1))$-approximation is an exact solution. Thus the result follows from Theorem 20. ◀

For the unweighted case, combining the above with sparsification [44] gives the following.

▶ **Corollary 22.** *Let $G = (V, E)$ be a simple unweighted graph. Then the minimum vertex cut can be computed with high probability in $\tilde{O}(m + \kappa\,\mathrm{IsoVC}(n\kappa, n)\min\{\kappa, n/(n-\kappa)\})$ randomized time, where $\mathrm{IsoVC}(m,n)$ is the running time to compute the minimum isolating vertex cut in a graph of m edges and n vertices.*

Proof. For unweighted graphs we can assume we know κ (via exponential search which adds an additional $O(\log \kappa)$ overhead). We apply the well-known linear-time sparsification algorithm of Nagamochi and Ibaraki [44] to reduce the number of edges to $O(n\kappa)$ and then run the algorithm in the preceding theorem on the sparsified graph which gives the claimed bound. ◀

The reduction from exact vertex connectivity to isolating vertex cut above, mixed with the algorithms for isolating vertex cuts, and optionally including the sparsification step from Corollary 22, produces a number of new running times that are optimal for different ranges of κ. In general, the running times obtained here have a lower dependence on κ then other

algorithms for vertex connectivity with a poly(κ) dependence (which is common for the unweighted setting), so the running times here are particularly good for moderate to large κ. For a more detailed comparison between the literature and new running times for the unweighted setting (where we restrict to unweighted for simplicity), see Table 1.

5 Hypergraph Connectivity

Let $H = (V, E)$ be a weighted hypergraph and let $R \subseteq V$. The cut function of a hypergraphs is symmetric and submodular. Given disjoint sets $S, T \subset V$ the minimum S-T cut in H can be computed in $\mathrm{EC}(p, m+n)$ time via standard reductions[3]. We can use Lemma 11 and Corollary 14 to understand the running time to compute R-connectivity in H. Up to logarithmic factors it suffices to estimate the time to find R-isolating cuts. Recall that the running time consists of two parts. The first part is $O(\log |R|)$ calls to S-T cut problem in H. After this we have the following situation. For each $r \in R$ we obtain a set $U_r \subset V$ such that $r \in R$ and $U_r \cap (R - r) = \emptyset$. Furthermore the sets U_r over $r \in R$ are pairwise disjoint. For each r the goal is to find a set $Y_r \subseteq U_r$ with minimum $w(\delta(Y_r))$ where $\delta(Y_r)$ is set of hyperedges crossing Y_r. Let $n_r = |U_r|$. We can compute Y_r by solving a cut problem in an auxiliary hypergraph G_r on $n_r + 1$ vertices obtained by shrinking $V \setminus U_r$ into a single vertex. Let p_r be the total size of the hyperedges in G_r. It is not hard to see that $\sum_{r \in R} p_r = O(p)$. Thus each cut problem in G_r can be computed in either $\mathrm{EC}(p_r, m + n_r + 1)$. This implies the following.

▶ **Theorem 23.** *The minimum isolating cuts over a set of vertices R of size $k = |R|$ in a hypergraph with m edges, n vertices, and total size p can be computed*

$$\tilde{O}\left(\mathrm{EC}(p, m+n) + \max_{n_1,\ldots,n_k,p_1,\ldots,p_k} \left\{ \sum_{i=1}^{k} \mathrm{EC}(p_i, m+n_i) : n_1 + \cdots + n_k \leq n,\ p_1 + \cdots + p_k \leq 2p \right\}\right)$$

time with high probability.

In particular $\mathrm{EC}(p, m+n)$ is $\tilde{O}(p\sqrt{m+n}\log U)$ [34] and for unweighted case we have $\mathrm{EC}(p, m+n) = \tilde{O}(p^{4/3})$ [39]. We can obtain two other run times for hypergraphs that provide different tradeoffs. These are obtained by more carefully solving the second part of the isolating cut framework, and transfer ideas from vertex connectivity to hypergraphs.

1. $\sqrt{pn(m+n)^{1.5}}$.
2. $\tilde{O}\left(p(m+n)^{\frac{3\alpha}{2(1+\alpha)}}\beta^{\frac{1}{1+\alpha}}\right)$ for any α, β where $\mathrm{EC}(m, n) \leq m^{1+\alpha}\beta$ (e.g., [31] gives $\mathrm{EC}(m, n) \leq \tilde{O}\left(m^{4/3}U^{1/3}\right)$, which we interpret as $\alpha = 1/3$ and $\beta = U^{1/3}$).

We sketch the proofs of theorems that obtain the preceding bounds.

▶ **Theorem 24.** *The minimum isolating cut in a hypergraph can be computed in*

$$\tilde{O}\left(\sqrt{pn(m+n)^{1.5}}\right)$$

randomized time.

The proof is omitted due to space constraints, and can be found in [10]. We mention that the approach is similar to the the algorithm for element isolating cuts that had a running time of $\tilde{O}\left(\sqrt{m}n^{5/4}\right)$.

[3] One can also reduce to computing s-t cut in a vertex capacitated undirected graph with p edges and $m + n$ nodes, although there does not seem to be any particular advantage with current running time bounds for $\mathrm{EC}(p, m+n)$.

▶ **Theorem 25.** *Suppose* $\mathrm{EC}(m,n) \leq \tilde{O}\left(m^{1+\alpha}\beta\right)$ *for fixed* $\alpha, \beta > 0$. *Then minimum isolating cuts can be computed in* $\tilde{O}\left(p(m+n)^{\frac{3\alpha}{2(1+\alpha)}}\beta^{\frac{1}{1+\alpha}} + p + (m+n)^{1.5}\right)$.

The proof is omitted due to space constraints, and can be found in [10]. We mention that the approach is similar to the algorithm for element isolating cuts that obtained a running time of $\tilde{O}\left(m^{1+o(1)}n^{3/8}U^{1/4} + n^{1.5}\right)$.

Abstract

We develop a general framework that characterizes strong average-case lower bounds against circuit classes $\mathcal{C}$ contained in NC^1, such as $\mathsf{AC}^0[\oplus]$ and ACC^0. We apply this framework to show:

- *Generic seed reduction*: Pseudorandom generators (PRGs) against $\mathcal{C}$ of seed length $\leq n-1$ and error $\varepsilon(n) = n^{-\omega(1)}$ can be converted into PRGs of *sub-polynomial* seed length.
- *Hardness under natural distributions*: If E (deterministic exponential time) is average-case hard against $\mathcal{C}$ under *some* distribution, then E is average-case hard against $\mathcal{C}$ under the *uniform* distribution.
- *Equivalence between worst-case and average-case hardness*: Worst-case lower bounds against $\mathsf{MAJ} \circ \mathcal{C}$ for problems in E are *equivalent* to strong average-case lower bounds against $\mathcal{C}$. This can be seen as a certain converse to the Discriminator Lemma [Hajnal et al., JCSS'93].

These results were not known to hold for circuit classes that do not compute majority. Additionally, we prove that classical and recent approaches to *worst-case* lower bounds against ACC^0 via communication lower bounds for NOF multi-party protocols [Håstad and Goldmann, CC'91; Razborov and Wigderson, IPL'93] and Torus polynomials degree lower bounds [Bhrushundi et al., ITCS'19] also imply *strong average-case hardness* against ACC^0 under the uniform distribution.

Crucial to these results is the use of *non-black-box* hardness amplification techniques and the interplay between ***Majority*** (MAJ) and ***Approximate Linear Sum*** ($\widetilde{\mathsf{SUM}}$) gates. Roughly speaking, while a MAJ gate outputs 1 when the sum of the m input bits is at least $m/2$, a $\widetilde{\mathsf{SUM}}$ gate computes a real-valued bounded weighted sum of the input bits and outputs 1 (resp. 0) if the sum is close to 1 (resp. close to 0), with the promise that one of the two cases always holds. As part of our framework, we explore ideas introduced in [Chen and Ren, STOC'20] to show that, for the purpose of proving lower bounds, a top layer MAJ gate is *equivalent* to a (weaker) $\widetilde{\mathsf{SUM}}$ gate. Motivated by this result, we extend the algorithmic method and establish stronger lower bounds against bounded-depth circuits with layers of MAJ and $\widetilde{\mathsf{SUM}}$ gates. Among them, we prove that:

- *Lower bound*: NQP does not admit fixed quasi-polynomial size $\mathsf{MAJ} \circ \widetilde{\mathsf{SUM}} \circ \mathsf{ACC}^0 \circ \mathsf{THR}$ circuits.

This is the first explicit lower bound against circuits with distinct layers of MAJ, $\widetilde{\mathsf{SUM}}$, and THR gates. Consequently, if the aforementioned equivalence between MAJ and $\widetilde{\mathsf{SUM}}$ as a *top gate* can be extended to *intermediate layers*, long sought-after lower bounds against the class $\mathsf{THR} \circ \mathsf{THR}$ of depth-2 polynomial-size threshold circuits would follow.

Acknowledgements We would like to thank William Hoza for asking whether PRGs for $\mathcal{C}$ imply average-case lower bounds against $\mathcal{C}$ under the uniform distribution. We are also grateful to Roei Tell for the observation that part of our equivalence theorem extends to the constant-error case as well.

1 Introduction

1.1 Overview

Establishing the *intractability of computations* and understanding the *power of randomness* in algorithms are among the most basic open problems in theoretical computer science. The theory of computational pseudorandomness provides a firm link between these two research directions. One of the most celebrated developments in this area is a proof that if E (deterministic exponential time $2^{O(n)}$) requires Boolean circuits of exponential size then $\mathsf{P} = \mathsf{BPP}$ [30, 43]. This result and its underlying techniques provide a robust mathematical theory that connects *worst-case lower bounds*, *average-case hardness*, and the construction of *pseudorandom generators*.

Unfortunately, a large part of this beautiful and far-reaching theory is not known to survive in *restricted* computational settings. For instance, while we know since the eighties that E cannot be $(1/2 + n^{-1/2+\Omega(1)})$-approximated by $\mathsf{AC}^0[\oplus]$ [40], it is an important open problem to obtain *strong* average-case hardness results of the form $1/2 + n^{-k}$ for all k and pseudorandom generators against this circuit class. The fact that existing connections between hardness and pseudorandomness do not apply in restricted settings is significant, given that known unconditional results and existing lower bound frontiers lie within weak sub-classes of NC^1, such as ACC^0.

Several works (e.g. [45, 23, 42, 36, 5, 22, 47, 29]) have investigated the difficulty of extending the hardness vs. randomness theory and its consequences to restricted circuit classes. Roughly speaking, these results show that standard "black-box" techniques to amplify computational hardness and construct pseudorandom generators *require* the underlying circuit class $\mathcal{C}$ to be closed under *majority*. However, obtaining lower bounds against circuit classes that are closed under majority is a notorious open problem. This leaves us in this unsatisfying situation where many benefits of the theory mentioned above only apply to settings where current circuit-analysis techniques do not hold. In other words, we have the following "lose-lose" scenario: above TC^0 we have no lower bounds, while below it we have lower bounds but no hardness amplification.

In this work, we explore *non-black-box* techniques to overcome this difficulty, obtaining a general connection between worst-case lower bounds, strong average-case hardness, and pseudorandomness for *weak circuit classes*. Our results build on recent ideas of Chen and Ren [14] employed in the context of the algorithmic method. Using our techniques, we are able to establish fundamental equivalences that were previously only known for circuit classes containing TC^0. As a consequence, the new results are widely applicable and can affect *current frontiers in circuit complexity theory*.

A crucial ingredient in our proofs is the interplay between Majority (MAJ) and Approximate Linear Sum ($\widetilde{\mathsf{SUM}}$) gates. Roughly speaking, while a MAJ gate outputs 1 when the sum of the m input bits is at least $m/2$, a $\widetilde{\mathsf{SUM}}$ gate computes a real-valued bounded weighted sum of the input bits and outputs 1 (resp. 0) if the sum is close to 1 (resp. close to 0), with

the promise that one of the two cases always holds. $\widetilde{\mathsf{SUM}}$ gates are significantly simpler than MAJ gates (e.g. MAJ has approximate degree [38] of order $\Omega(m)$), but still powerful enough to implement useful computations, such as hardness amplification for *specific* problems (a non-black-box element).

Complementing our results about the average-case complexity of restricted circuit classes, we obtain the first unconditional lower bounds against bounded-depth circuits with distinct layers of MAJ, $\widetilde{\mathsf{SUM}}$, and THR gates. These results suggest that further investigating the relation between MAJ and $\widetilde{\mathsf{SUM}}$ might be a path to lower bounds against depth-2 threshold circuits, a long-standing open problem in complexity theory (cf. [18, 9]).

1.2 Results and techniques

To begin with, we recall some definitions for linear sums of functions. Our notation is taken from previous work [50, 15, 14, 13] on lower bounds via the algorithmic method. Let $\mathcal{C}$ be a class of functions from $\{0,1\}^n \to \{0,1\}$.

$\mathsf{SUM} \circ \mathcal{C}$-circuits. A $\mathsf{SUM} \circ \mathcal{C}$-circuit $C\colon \{0,1\}^n \to \mathbb{R}$ is a circuit that can be written as $C(x) = \sum_{i=1}^{\ell} \alpha_i \cdot C_i(x)$, where each α_i is a real, and each $C_i \in \mathcal{C}$. Here ℓ is called the *sparsity* of C, and is denoted as $\mathsf{sparsity}(C)$. We also use $\mathsf{complexity}(C)$ to denote $\max(\ell, \sum_{i=1}^{\ell} |\alpha_i|)$. Furthermore, if a $\mathsf{SUM} \circ \mathcal{C}$-circuit C always outputs values in the interval $[0,1]$, we say it is a $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$-circuit.

$\widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}$-circuits. Let $\delta \in [0, 0.5)$. A $\widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}$-circuit $C\colon \{0,1\}^n \to \{0,1\}$ is defined by a $\mathsf{SUM} \circ \mathcal{C}$-circuit $L\colon \{0,1\}^n \to \mathbb{R}$ satisfying the following promise: for every $x \in \{0,1\}^n$, either $|L(x) - 1| \leq \delta$ or $|L(x)| \leq \delta$. (We stress that this promise is only required over inputs x to the $\mathsf{SUM} \circ \mathcal{C}$-circuit L, and not over all possible input values to the top SUM gate.) We say $C(x) = 1$ if $|L(x) - 1| \leq \delta$ and $C(x) = 0$ otherwise. The sparsity and the complexity of C is defined as the sparsity and the complexity of L, respectively.

For a circuit class $\mathcal{C}$, we use $\mathsf{SUM} \circ \mathcal{C}$, $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$, and $\widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}$ to denote the collection of such circuit families with at most $\mathrm{poly}(n)$ complexity. When $\mathcal{C}$ has a clear notion of complexity, such as circuit size, this also means that the involved $\mathcal{C}$-subcircuits are of polynomial size. In some statements we might refer to classes such as $\widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}[s]$ to emphasize a specific upper bound s on the complexities of $\mathcal{C}$-subcircuits and of the top gate.

Notation for standard concepts. A $\mathsf{MAJ}\colon \{0,1\}^m \to \{0,1\}$ gate $\mathsf{MAJ}(y_1, \ldots, y_m)$ outputs 1 if and only if $\sum_i y_i \geq m/2$. A $\mathsf{THR}\colon \{0,1\}^m \to \{0,1\}$ gate is described by weights $w_1, \ldots, w_m, \theta \in \mathbb{R}$ and outputs 1 if and only if $\sum_i w_i y_i \geq \theta$.

For a probability distribution $\mathcal{D}$ over $\{0,1\}^n$ and Boolean functions $f, g\colon \{0,1\}^n \to \{0,1\}$, we say that f is γ-approximated by g over $\mathcal{D}$ if $\Pr_{x \sim \mathcal{D}}[f(x) = g(x)] \geq \gamma$. For convenience, circuit lower bounds involving approximations of the form $1/2 + 1/n^{\omega(1)}$ might be informally referred to as *strong average-case lower bounds* or simply *strong correlation bounds*.

Our results refer to non-uniform circuit classes, and we use $\mathcal{C}_1 \circ \mathcal{C}_2$ to refer to circuit families consisting of a top circuit from $\mathcal{C}_1$ composed with bottom circuits from $\mathcal{C}_2$.[1]

We use $\mathcal{U}_n$ to denote the uniform distribution over $\{0,1\}^n$. A distribution $\mathcal{D}$ *ε-fools* a function $f\colon \{0,1\}^n \to \{0,1\}$ if $|\Pr[f(\mathcal{D}) = 1] - \Pr[f(\mathcal{U}_n) = 1]| \leq \varepsilon$. We say that a sequence $G_n\colon \{0,1\}^{\ell(n)} \to \{0,1\}^n$ is an infinitely often PRG against a circuit class $\mathcal{C}$ with error ε

[1] As usual, in the case of $\mathcal{C}_2 = \mathsf{ACC}^0$, where $\mathsf{ACC}^0 = \bigcup_{m \in \mathbb{N}} \mathsf{AC}^0[m]$ with m here representing the modulo, we require that each $\mathcal{C}_2$-subcircuit of a circuit D from $\mathcal{C}_1 \circ \mathcal{C}_2$ uses the same fixed m.

(i.e. ε-PRG) and seed length ℓ if G_n is computable in time $2^{O(\ell(n))}$ and for infinitely many values of n, the induced distribution $G_n(\mathcal{U}_{\ell(n)})$ $\varepsilon(n)$-fools each function $f\colon \{0,1\}^n \to \{0,1\}$ in $\mathcal{C}$.

1.2.1 Equivalences for worst-case and strong average-case hardness

Our first contribution is a general result that tightly connects worst-case lower bounds, strong average-case hardness, and pseudorandomness in *restricted computational models*.

▶ **Theorem 1** (Non-black-box equivalences for worst-case and strong average-case hardness)**.** *Let $\mathcal{C}$ be a circuit class contained in NC^1 that is closed under negations and under a bottom layer of juntas over $O(1)$ input bits. The following statements are equivalent:*

1. *There is $L \in \mathsf{E}$ such that $L \notin \widetilde{\mathsf{SUM}}_{1/3} \circ \mathcal{C}$.*
2. *There is $L \in \mathsf{E}$ and $\delta \geq 1/\mathsf{poly}(n)$ such that $L \notin \widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}$.*
3. *There is $L \in \mathsf{E}$ such that $L \notin \mathsf{MAJ} \circ \mathcal{C}$.*
4. *There is $L \in \mathsf{E}$ such that, for every $k \geq 1$, L cannot be computed by probabilistic $\mathcal{C}$-circuits with error $1/2 - 1/n^k$.*[2]
5. *There is $L \in \mathsf{E}$ and a distribution ensemble $\mathfrak{D}$ such that for every $k \geq 1$, L cannot be $(1/2 + n^{-k})$-approximated by $\mathcal{C}$ under $\mathfrak{D}$.*
6. *There is $L \in \mathsf{E}$ such that for every $k \geq 1$, L cannot be $(1/2 + n^{-k})$-approximated by $\mathcal{C}$ under the uniform distribution.*
7. *There is $L \in \mathsf{E}$ that cannot be approximated by $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$ within ℓ_1 distance $1/3$.*[3]
8. *There is $L \in \mathsf{E}$ and $\delta \geq 1/\operatorname{poly}(n)$ such that L cannot be approximated by $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$ within ℓ_1 distance δ.*
9. *There is an i.o. ε-PRG G against $\mathcal{C}$ with seed length $n-1$ and error $\varepsilon(n) \leq n^{-\omega(1)}$.*[4]
10. *For each $\gamma > 0$, there is an i.o. ε-PRG against $\mathcal{C}$ with seed length n^γ and $\varepsilon(n) \leq n^{-\omega(1)}$.*

This result can be applied to a variety of natural circuit classes, such as $\mathsf{AC}^0[\oplus]$, ACC^0, and constant-degree polynomial threshold functions (PTFs). We stress that while Theorem 1 requires the circuit class $\mathcal{C}$ to be contained in NC^1, in circuit complexity this is the most interesting case for the result. More precisely, for circuit classes that are above NC^1, it is well known that worst-case hardness for a problem in E can be converted into average-case hardness and PRGs. (Furthermore, NC^1 is closed under a top MAJ or $\widetilde{\mathsf{SUM}}$ gate.) We remark that Theorem 1, with appropriate modifications, can be adapted to other uniform complexity classes, such as $\mathsf{BPE} = \mathsf{BPTIME}[2^{O(n)}]$ and PSPACE. For simplicity, we restrict our discussion to E.

We observe that a connection between worst-case hardness and *weak* average-case hardness for functions in E has been established in [20], under the assumption that the circuit class $\mathcal{C}$ contains AC^0 and is closed under composition. In contrast to their work, we have a much weaker assumption on $\mathcal{C}$, and our setting of parameters allows us to obtain equivalences to PRGs and to derive consequences that do not follow from their results.

We now highlight three fundamental consequences of Theorem 1. Note that, while our proof employs $\widetilde{\mathsf{SUM}}$ gates in important ways, none of these results refer to such gates.

---

[2] Following standard terminology, a probabilistic $\mathcal{C}$-circuit F is simply a distribution of $\mathcal{C}$-circuits. We say that F computes a Boolean function g with error ε if for every input x we have $\Pr_F[F(x) \neq g(x)] \leq \varepsilon$.

[3] In other words, there is no family of circuits $F_n \in [0,1]$-$\mathsf{SUM} \circ \mathcal{C}$ such that $\mathsf{E}_{x \sim \{0,1\}^n}[|L(x) - F_n(x)|] \leq 1/3$ for all large n. This notion plays a crucial role in [13] and other related works.

[4] More precisely, for each choice of k, there is an infinite set $S_k \subseteq \mathbb{N}$ such that G fools circuits from $\mathcal{C}[n^k]$ on inputs of length $n \in S_k$ with error $\varepsilon(n) \leq n^{-k}$.

1. Seed reduction for PRGs. Perhaps surprisingly, the equivalence between Items 9 and 10 of Theorem 1 shows the existence of a *generic seed reduction phenomenon* for weak circuit classes. Thus to construct i.o. PRGs of sub-polynomial seed length for a class $\mathcal{C}$ satisfying the conditions of this result it is enough to construct a non-trivial i.o. PRG (i.e. of seed length $\leq n-1$) with small error. In particular, improving the error parameter of the PRG against $\mathsf{AC}^0[\oplus]$ described in [16] to inverse-super-polynomial would lead to major consequences for $\mathsf{AC}^0[\oplus]$-circuits.

2. Hardness under some distribution implies hardness under the uniform distribution. Theorem 1 also has important implications to our understanding of the average-case hardness of problems in E with respect to weak circuit classes. This is an immediate consequence of Items 5 and 6, which establish the result for strong average-case hardness of the form $1/2 + 1/n^{\omega(1)}$. In the full version of this paper [11], we observe that our techniques can also translate constant-error average-case hardness under an arbitrary distribution to constant-error average-case hardness under the uniform distribution. An interesting application of these results is that the existence of a PRG against $\mathcal{C}$, which was only known to imply hardness under some distribution (see e.g. Section 3 of [46]), also implies hardness with respect to the uniform distribution (which in turn is sufficient to construct PRGs).

3. Equivalence between worst-case and average-case hardness. The well-known Discriminator Lemma from Hajnal et al. [24] has found numerous applications in circuit complexity lower bounds. It shows that if a Boolean function f cannot be $(1/2+1/\operatorname{poly}(n))$-approximated by a class $\mathcal{C}$ then f is not in $\mathsf{MAJ} \circ \mathcal{C}$. In other words, one can lift an average-case lower bound against $\mathcal{C}$ to a worst-case lower bound against the stronger class $\mathsf{MAJ} \circ \mathcal{C}$. Interestingly, the equivalence between Items 3 and 6 in Theorem 1 shows that, for the purpose of proving lower bounds for a problem in E, a worst-case lower bound against $\mathsf{MAJ} \circ \mathcal{C}$ is actually *equivalent* to a strong average-case lower bound against $\mathcal{C}$. To our knowledge, this was previously unknown for weak computational models.[5]

A consequence of Theorem 1 relevant to the study of $\widetilde{\mathsf{SUM}}$ gates is that if $\mathsf{E} \not\subseteq \widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}$ for some $\delta(n) = 1/n^c$ then $\mathsf{E} \not\subseteq \widetilde{\mathsf{SUM}}_{1/3} \circ \mathcal{C}$.[6] Another interesting implication is that the average-case lower bounds against $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$ under ℓ_1 distance investigated in [13] are *necessary* and *sufficient* for strong average-case hardness against $\mathcal{C}$.

Next, we discuss some of the techniques behind Theorem 1.

Theorem 1: Techniques. As alluded to above, the proof of Theorem 1 relies on non-black-box hardness amplification techniques explored by Chen and Ren [14] and on a careful balance between the *strength* and *weakness* of $\widetilde{\mathsf{SUM}}$ gates. To give some intuition, we discuss the main ingredients behind a more direct proof of the following equivalence, which also explains the assumptions on the circuit class $\mathcal{C}$:

$$\text{Worst-case hardness against } \widetilde{\mathsf{SUM}} \circ \mathcal{C} \iff \text{i.o. PRGs against } \mathcal{C} \text{ with error } \varepsilon = n^{-\omega(1)}.$$

[5] We also remark that it was known [19, 28, 33] before that for general circuit class $\mathcal{C}$, weak average-case hardness against $\mathsf{MAJ} \circ \mathcal{C}$ implies strong average-case hardness against $\mathcal{C}$.

[6] We note that a simple error amplification technique for $\widetilde{\mathsf{SUM}}$ (see [11]) blows up the complexity of the involved $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$-circuits to quasi-polynomial when amplifying from constant-error approximation to inverse polynomial. For this reason, it does not establish this implication.

While it is possible to show that a $\widetilde{\mathsf{SUM}}$ gate can be efficiently simulated by a MAJ gate,[7] the opposite simulation does not hold (e.g. consider approximate degree). In this sense, $\widetilde{\mathsf{SUM}}$ gates are indeed weak. Still, it is possible to show essentially that, for a certain *specific* NC^1-hard problem L contained in P, a $\widetilde{\mathsf{SUM}}$ gate of polynomial complexity can implement a hardness amplification proof: roughly speaking, a weak approximator circuit for L can be transformed into a correct circuit for L by incurring only a top $\widetilde{\mathsf{SUM}}$ gate overhead. This allows us to employ the following win-win analysis. Either the NC^1-hard problem L is $1/2 + n^{-k}$-hard against $\mathcal{C}$ on infinitely many input lengths for every choice of k, in which case an i.o. PRG against $\mathcal{C}$ can be constructed from L using standard techniques under the assumption that $\mathcal{C}$ is closed under bottom layer $O(1)$-juntas, or there is a choice of k such that L can be $1/2 + n^{-k}$ approximated by $\mathcal{C}$-circuits on large enough input lengths. The latter implies via the hardness amplification reconstruction routine that $L \in \widetilde{\mathsf{SUM}} \circ \mathcal{C}$, which in turns yields $\mathsf{NC}^1 \subseteq \widetilde{\mathsf{SUM}} \circ \mathcal{C}$ using the NC^1-hardness of L (which in fact admits ultra efficient reductions). Now under our assumption that $\mathcal{C} \subseteq \mathsf{NC}^1$, it is easy to see that $\mathsf{NC}^1 = \widetilde{\mathsf{SUM}} \circ \mathcal{C}$. As a consequence, a worst-case lower bound against $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$ provides a worst-case lower bound against NC^1, and again, PRGs can be constructed from such an assumption via standard methods (since NC^1 admits black-box worst-case to average-case amplification).

For the other direction, we start with an i.o. PRG G against $\mathcal{C}$ that might have a large seed length but guarantees *low error* $\varepsilon(n) = n^{-\omega(1)}$. Here the important insight is that a low error PRG that fools $\mathcal{C}$ also fools linear combinations of functions in $\mathcal{C}$ with bounded coefficients. This implies that G fools $\widetilde{\mathsf{SUM}} \circ C$. Another standard argument shows that from such a PRG one can define a function in E that is worst-case hard against $\widetilde{\mathsf{SUM}} \circ C$.

We stress that two crucial ingredients of our equivalence theorem are the existence of the hard problem L mentioned above and the use of $\widetilde{\mathsf{SUM}}$ gates. The hard language L is actually a pair of problems CMD and DCMD with very useful structural properties (see Section 2.2). They have been explored in a few other works (e.g. [31, 4, 20, 1]), and are tightly connected to *decomposable randomized encodings*, which are well-studied in cryptography (see [3]). The fruitful interaction between these problems and $\widetilde{\mathsf{SUM}}$ gates was first noticed by [14] in the context of the algorithmic method and is a crucial ingredient in their proof that NQP is strongly average-case hard against ACC^0.

While the proof of Theorem 1 avoids the black-box "barrier" and applies to circuit classes that are not assumed to be closed under majority, our techniques come with certain limitations. As a consequence of our indirect analysis via a win-win argument, Theorem 1 does not provide almost-everywhere equivalences for some items and does not scale to large circuit size bounds above quasi-polynomial. These are important directions for future work.

Applications to ACC^0-circuits lower bound approaches. As a concrete application of Theorem 1 to current frontiers in circuit complexity, we explore its consequences to the average-case complexity of ACC^0. We use our framework to show that existing "combinatorial" approaches to worst-case lower bounds would also provide *strong average-case hardness* against ACC^0. Before stating this result, we briefly recall some concepts.

[7] It is possible to approximate all coefficients of the bounded linear sum using sums of powers of 2^i with $i \in \mathbb{Z}$, then multiply the linear sum by an appropriate power of 2 to obtain integer coefficients, and finally simulate the resulting sum by an appropriate THR gate with polynomial weights, which can be translated to a MAJ gate using duplicated input wires and by negating input variables if necessary.

Let $\mathbb{T} = \mathbb{R}/\mathbb{Z}$ be the one-dimensional torus. A *torus polynomial* [7] (see also [34]) is a real polynomial $p(x_1, \ldots, x_n)$ restricted to the domain $\{0,1\}^n$ and evaluated modulo one.[8] For the purpose of representing the output of a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ as a value in $\mathbb{T}$, we map the output bit $f(x)$ to $f(x)/2$. For $\delta < 1/4$, we say that f is δ-approximated by a degree-d torus polynomial if there is a degree-d real polynomial $p(x_1, \ldots, x_n)$ such that if $f(x) = 1$ then $p(x) - \lfloor p(x) \rfloor \in [1/2 - \delta, 1/2 + \delta]$ and if $f(x) = 0$ then $p(x) - \lfloor p(x) \rfloor \in [0, \delta] \cup [1 - \delta, 1)$. A recent approach proposed by [7] shows that ACC^0 lower bounds follow from torus polynomial degree lower bounds for approximating a Boolean function.

The number-on-forehead (NOF) multi-party communication model was introduced by [8], and work of [26, 41] show that explicit communication lower bounds in this model (even in the single-round model where all players simultaneously communicate to a referee) imply lower bounds against SYM^+-circuits, which are known to simulate ACC^0 [6].

▶ **Theorem 2** (Lifting worst-case ACC^0 lower bound approaches to strong correlation bounds)**.** *Consider the following statements:*

1. **Torus Polynomials:** *There is a language $L \in \mathsf{E}$ and a function $\delta(n) \geq 1/\operatorname{poly}(n)$ such that L does not have δ-approximation torus polynomials of degree $\operatorname{polylog}(n)$.*
2. **NOF Protocols:** *There is a language in E that does not admit (single-round) NOF multi-party protocols with $\operatorname{polylog}(n)$ parties of communication cost $\operatorname{polylog}(n)$.*

In each case, if the corresponding statement holds then there is a language in E that cannot be $(1/2 + 1/\operatorname{poly}(n))$-approximated under the uniform distribution by ACC^0.

As a consequence, lower bounds against these models provide i.o. PRGs of sub-polynomial seed length against ACC^0.

Theorem 2: Techniques. It is not hard to adapt classical techniques to show that if a Boolean function can be approximated by torus polynomials of bounded degree, then it can also be computed by NOF protocols of low complexity. For this reason, in order to prove Theorem 2 it is sufficient to obtain average-case hardness against ACC^0 from degree lower bounds for torus polynomials approximating Boolean functions.[9] To achieve this, we refine the argument of [7] and invoke our framework. In more detail, we show the stronger result that even functions families in $\widetilde{\mathsf{SUM}} \circ \mathsf{ACC}^0$ can be approximated by low-degree torus polynomials. This yields the result using the equivalence between Items 6 and 2 in Theorem 1.

To establish this claim, we make use of low degree "middle-bit polynomials" [21], a sub-class of SYM^+-circuits that is strong enough to simulate ACC^0. By a careful adaptation of the argument of [7], we are able to show that a linear sum (with bounded coefficients) of middle-bit polynomials with a special structure can be converted into a torus polynomial. The argument is somewhat subtle, and involves the manipulation of universal circuits for depth-d $\mathsf{ACC}^0[s]$ in order to enforce similar parameters for all middle-bit polynomials feeding the top $\widetilde{\mathsf{SUM}}$ gate. The details appear in the full version of this paper [11].

[8] By a value y (mod 1) we mean its fractional part given by $y - \lfloor y \rfloor$, where the floor function $\lfloor y \rfloor$ denotes the largest integer less than or equal to y. For instance, 1.37 (mod 1) is 0.37 and -2.21 (mod 1) is 0.79.

[9] Alternatively, earlier work on ACC^0 already showed that $\mathsf{MAJ} \circ \mathsf{ACC}^0$-circuits can be simulated by NOF protocols of low communication. Therefore, the NOF protocols part of Theorem 2 follows directly from our Theorem 1.

1.2.2 Lower bounds against circuits with layers of $\widetilde{\mathsf{SUM}}$ and MAJ gates

Observe that Theorem 1 (via Items 1, 2, and 3) establishes the following equivalence: for the purpose of proving circuit lower bounds for a function in E, a top layer MAJ gate is *equivalent* to a top layer $\widetilde{\mathsf{SUM}}$ gate. Given that $\widetilde{\mathsf{SUM}}$ is simpler than MAJ, and lower bounds against $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$ offer a path to correlation bounds and PRGs against $\mathcal{C}$, obtaining a better understanding of $\widetilde{\mathsf{SUM}}$ gates in Boolean circuits might have significant benefits.

In this section, we explore *unconditional* lower bounds against circuits with layers of MAJ and $\widetilde{\mathsf{SUM}}$ gates. Our results are connected to the long-standing problem of showing explicit lower bounds against $\mathsf{THR} \circ \mathsf{THR}$, the class of polynomial-size depth-2 threshold circuits (where size is measured by number of gates). For convenience of the reader, we review below some results related to this frontier.

Threshold circuits. Recall that a threshold gate THR over m input bits is described by weights $w_1, \ldots, w_m, \theta \in \mathbb{R}$. It outputs 1 on an input $y \in \{0,1\}^m$ if and only if $\sum_i w_i y_i \geq \theta$. It is known that every such gate can be implemented with integer weights of magnitude $2^{O(m \log m)}$ (see [25]). In the context of polynomial size circuits, by duplicating input wires a MAJ gate can be equivalently defined as the restriction of a THR gate to polynomially bounded integer weights. It was shown that $\mathsf{MAJ} \circ \mathsf{THR} = \mathsf{MAJ} \circ \mathsf{MAJ}$ and $\mathsf{THR} \circ \mathsf{THR}$ is contained in $\mathsf{MAJ} \circ \mathsf{MAJ} \circ \mathsf{MAJ}$ [18]. Exponential lower bounds are known against $\mathsf{THR} \circ \mathsf{MAJ}$-circuits [17], and $\mathsf{THR} \circ \mathsf{MAJ}$ is strictly contained in $\mathsf{THR} \circ \mathsf{THR}$ [9]. Recently, [32] described a function in P that requires $\mathsf{THR} \circ \mathsf{THR}$-circuits of size (measured by the number of gates) nearly $n^{3/2}$. This is the strongest known lower bound against this class (see their work for extensions to other circuit size measures) for a function in P. It is also known that E^{NP} does not have $n^{2-\varepsilon}$-size $\mathsf{THR} \circ \mathsf{THR}$-circuits for every constant $\varepsilon > 0$ [2, 44].

$\mathsf{LTF}^s \circ \mathcal{C}$-circuits: An intermediary class between $\mathsf{MAJ} \circ \mathcal{C}$ and $\mathsf{THR} \circ \mathcal{C}$. In order to make progress toward showing super-polynomial lower bounds against $\mathsf{THR} \circ \mathsf{THR}$-circuits, we study a newly defined gate LTF^s whose power lies between MAJ and THR.[10] Let $\mathsf{SUM}^{\infty} \circ \mathcal{C}$ be the relaxation of $\mathsf{SUM} \circ \mathcal{C}$ to an *unrestricted* top SUM gate (i.e. the top gate can use arbitrary real coefficients that might not be polynomially bounded). For a given function s and a circuit class $\mathcal{C}$, we say that a function f admits a $\mathsf{LTF}^s \circ \mathcal{C}$-circuit of size S if there is a circuit $D \in \mathsf{SUM}^{\infty} \circ \mathcal{C}$ such that the following hold: (1) $f(x) = 1$ if and only if $D(x) \geq 0$; (2) $|D(x)| \in (1/s, s)$ for every $x \in \{0,1\}^n$; (3) the total size of the $\mathcal{C}$-subcircuits of D is at most S. Note that unrestricted weights are allowed in the top gate, but we are promised that on each input x the value $D(x)$ is neither too close to 0 nor too large in magnitude.[11]

We are able to extend the algorithmic method [49] to show that #SAT algorithms for a circuit class $\mathcal{C}$ imply worst-case lower bounds against $\mathsf{LTF}^s \circ \mathcal{C}$ and average-case lower bounds against $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$. Let $\mathsf{NQP} = \mathsf{NTIME}[2^{\mathrm{polylog}(n)}]$ be the class of languages computable in non-deterministic quasi-polynomial time. We say that a circuit class $\mathcal{C}$ is *nice* if $\mathcal{C}$ is closed under negation, (bottom) projections, and a top AND gate of unbounded fan-in, and in addition $\mathcal{C}$-circuits of size s admit general circuits of depth $O(\log s)$. Examples of nice circuit classes include AC^0, ACC^0, and $\mathsf{AC}^0[\oplus] \circ \mathsf{THR}$.

[10] LTF denotes linear threshold function, another standard name for THR. We employ both names in this paper to make a clear distinction between the new gates and THR.

[11] Note that we only impose this constraint for each input x of the combined $\mathsf{SUM}^{\infty} \circ \mathcal{C}$-circuit, and not over all possible input strings for the top gate.

▶ **Theorem 3** (Stronger lower bounds from #SAT algorithms). *Let $\mathcal{C}$ be a nice circuit class. Suppose there is a constant $\varepsilon > 0$ such that, given a $\mathcal{C}$-circuit of size 2^{n^ε} over n input variables, its number of satisfying assignments can be deterministically computed in time 2^{n-n^ε}. Then the following statements hold:*

1. *For every constant $k > 0$, NQP does not have $\mathsf{LTF}^{2^{\log^k n}} \circ \mathcal{C}$-circuits of size $2^{\log^k n}$.*
2. *For every choice of constants $k > 0$ and $\delta \in (0, 0.5)$, NQP cannot be $(1/2 + 2^{-\log^k n})$-approximated by $\widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-circuits where both the sparsity of the top SUM-gate and the size of the bottom layer $\mathcal{C}$-circuits are at most $2^{\log^k n}$.*[12]

To our knowledge, these two circuit lower bound consequences are incomparable. By combining Theorem 3 with existing #SAT algorithms for $\mathcal{C} = \mathsf{ACC}^0 \circ \mathsf{THR}$-circuits [51], we obtain the following unconditional lower bounds.

▶ **Corollary 4** (Lower bounds against circuits with $\widetilde{\mathsf{SUM}}$, THR, and MAJ gates). *The following results hold:*

1. *For every constant $k > 0$, NQP does not admit $\mathsf{LTF}^{2^{\log^k n}} \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-circuits of size $2^{\log^k n}$.*
2. *For every choice of constants $k > 0$ and $\delta \in (0, 0.5)$, NQP cannot be $(1/2 + 2^{-\log^k n})$-approximated by $\widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-circuits where the top sum has sparsity $2^{\log^k n}$ and all $\mathsf{ACC}^0 \circ \mathsf{THR}$-subcircuits have size $2^{\log^k n}$.*
3. *For every choice of constants $k > 0$ and $\delta \in (0, 0.5)$, NQP cannot be computed by $\mathsf{MAJ} \circ \widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-circuits where the top MAJ gate has fan-in $2^{\log^k n}$ and all $\widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-subcircuits have size and sparsity $2^{\log^k n}$.*

To contrast these results with previous work, we note that [15, Theorem 15] gave a *worst-case* lower bound against $\widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-circuits with any *constant* error δ less than $1/2$. Also, [14, Section 5.2] showed a strong average-case lower bound against $\widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-circuits, where the top sum gate has *zero error* (i.e., $\delta = 0$). Consequently, Corollary 4 Item 2 simultaneously strengthens both results. On the other hand, Corollary 4 Item 3 shows the first lower bound against circuits combining layers of $\widetilde{\mathsf{SUM}}_{1/3}$, MAJ, and THR gates.

Before discussing our techniques in more detail, we mention an open problem and its connection to $\mathsf{THR} \circ \mathsf{THR}$ lower bounds. Recall that this class is contained in $\mathsf{MAJ} \circ \mathsf{MAJ} \circ \mathsf{MAJ}$. In light of the super-polynomial lower bound against $\mathsf{MAJ} \circ \widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0 \circ \mathsf{THR}$ from Corollary 4 Item 3, it would be very interesting to understand the relation between MAJ gates and $\widetilde{\mathsf{SUM}}$ gates appearing in *internal layers* of Boolean circuits. In particular, we note that if MAJ can be simulated by $\widetilde{\mathsf{SUM}}_{1/3} \circ \mathsf{ACC}^0$-circuits of quasi-polynomial size (or THR can be simulated by $\mathsf{MAJ} \circ \widetilde{\mathsf{SUM}}_\delta \circ \mathsf{ACC}^0$-circuits of quasi-polynomial size), then $\mathsf{NQP} \not\subseteq \mathsf{THR} \circ \mathsf{THR}$. On the other hand, if this is not the case, strong average-case lower bounds against ACC^0 follow from Theorem 1.

Theorem 3 and Corollary 4: Techniques. The proofs of the first two items of Corollary 4 are immediate from the corresponding items of Theorem 3 via the #SAT algorithm for $\mathcal{C} = \mathsf{ACC}^0 \circ \mathsf{THR}$ given by [51]. On the other hand, Item 3 of Corollary 4 can be established in different ways. The first proof is just a standard application of the Discriminator Lemma [24] together with the lower bound from Item 2. A second proof follows from Item 1, via a

[12] For the interested reader, we notice that the coefficients of the top $\widetilde{\mathsf{SUM}}$ gate can be unbounded in this lower bound.

simulation of a $\mathsf{MAJ} \circ \widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-circuit of quasi-polynomial complexity by a $\mathsf{LTF}^{2^{\log^k n}} \circ \mathsf{ACC}^0 \circ \mathsf{THR}$-circuit of size size $2^{\log^k n}$, for some constant k. This can be done by first reducing the error δ of each $\widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-subcircuit (see [11]), then rewriting the corresponding $\mathsf{MAJ} \circ \widetilde{\mathsf{SUM}}_\varepsilon$ top layers as an LTF^s gate via an appropriate collapse. We omit the details.

The proofs of Items 1 and 2 of Theorem 3 are essentially independent. We discuss each of them next, starting with Item 1.

An extension of the algorithmic method [49] obtained by [37] shows that SAT algorithms for a circuit class $\mathcal{C}$ of sub-exponential size circuits (satisfying minor closure conditions) that run in time 2^{n-n^ε} imply that $\mathsf{NQP} \not\subseteq \mathcal{C}$. In a more recent work that builds on [50], [15] established (in particular) that #SAT algorithms of similar running time provide the stronger lower bound $\mathsf{NQP} \not\subseteq \widetilde{\mathsf{SUM}} \circ \mathcal{C}$. Our proof of Item 1 of Theorem 3 relies on the latter result and on a win-win argument inspired by [14]. In more detail, and oversimplifying a bit, we argue that if a special NC^1-hard problem L (contained in NQP) is not in $\mathsf{LTF}^{2^{\log^k n}} \circ \mathcal{C}$, then we are done. Otherwise, we explore LTF^s gates and the special form of the NC^1-hardness of L to show that NC^1 can be simulated by $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$-circuits of quasi-polynomial complexity. Given this lemma and the corresponding simulation, we can reduce the derivation of the desired lower bound to previous work, i.e., we invoke the aforementioned connection between #SAT algorithms and lower bounds against $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$. This provides a language in NQP that is not in $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$ of complexity $2^{\log^\ell n}$, where $\ell = \ell(k)$ is large enough. Now by simulating $\mathsf{LTF}^{2^{\log^k n}} \circ \mathcal{C}$-circuits using quasi-polynomial size Boolean formulas, and using the collapse of NC^1 to quasi-polynomial size $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$, it is possible to argue that L is also hard against $\mathsf{LTF}^{2^{\log^k n}} \circ \mathcal{C}$.

The proof of Item 2 of Theorem 3 shares some similarities with the argument above, but the technical details are different. From a high-level perspective, we also employ a win-win argument, though this time it is based on the *average-case* complexity of the language L mentioned above. Moreover, we cannot rely on previous connections between #SAT algorithms and lower bounds in a *black-box* way. Given that explaining the relevant details would be fairly technical, we refer the interested reader to the full version of this paper [11]. We mention that a conceptual contribution is that while our proof of Theorem 3 Part 2 follows the strategy of previous works, such as [10, 15, 14], on obtaining lower bounds from meta-algorithms, it does not use PCPs of proximity (PCPP), which was a key ingredient in the proofs of those works. For this, we rely in part on a PCP stated in [48], combined with other ideas.

Organization. In Section 2 we introduce the necessary technical preliminaries for proving our results. In Section 3 we prove our main equivalence result (Theorem 1). Due to space constraints, the remaining proofs are deferred to the full version of this paper [11].

2 Preliminaries

2.1 Notation

We use $\mathbb{N}$ to denote the set of all non-negative integers and $\mathbb{N}_{\geq 1}$ to denote $\mathbb{N} \setminus \{0\}$. For every $n \in \mathbb{N}_{\geq 1}$, we let $\mathcal{U}_n$ denote the uniform distribution over $\{0,1\}^n$. For convenience, in some settings a Boolean function $f\colon \{0,1\}^n \to \{0,1\}$ will be viewed as a function with output in $\{-1,1\}$, where -1 and 1 are interpreted as True and False, respectively.

For a predicate $P(x)$, we use $\mathbb{1}_{P(x)}$ to denote its corresponding Boolean value on x. That is, $\mathbb{1}_{P(x)} = 1$ if $P(x)$ is true, and 0 otherwise. For a real v, we define $\mathrm{sign}(v) := (-1) \cdot \mathbb{1}_{v<0} + 1 \cdot \mathbb{1}_{v \geq 0}$.

For two strings $\alpha, \beta \in \{0,1\}^*$, we write $\alpha \circ \beta$ to denote the concatenation of α and β.

A projection of a function $f(x_1, \ldots, x_n)$ is a function $g(y_1, \ldots, y_m)$ with a projection mapping $P\colon \{0,1\}^m \to \{0,1\}^n$ such that $g(y_1, \ldots, y_m) = f(P(y_1, \ldots, y_m))$. By "projection" we mean that each output bit of $P(y_1, \ldots, y_m)$ is either an input bit y_i, its negation, or a constant.

Let a be a positive integer. For an arbitrary $\ell \geq 1$ and a function $h\colon \{0,1\}^\ell \to \{0,1\}$, we say that $h \in \mathsf{JUNTA}_a$ if the output of h depends on at most a input coordinates.

For a circuit class $\mathcal{C}$ and $s \geq 1$, we use $\widetilde{\mathsf{SUM}} \circ \mathcal{C}[s]$ to denote the class of $\widetilde{\mathsf{SUM}} \circ \mathcal{C}$-circuits where the top SUM gate has complexity at most s and the bottom layer $\mathcal{C}$-circuits have size at most s.

For a function $f\colon \{0,1\}^n \to \{0,1\}$, we let $f_\pm\colon \{0,1\}^n \to \{-1,1\}$ be the $\{-1,1\}$-version of f where we map the output of f from 0 to 1 and 1 to -1. Also, for a circuit class $\mathcal{C}$ where the circuits in $\mathcal{C}$ output values in $\{0,1\}$, we denote by $\mathcal{C}_\pm$ the $\{-1,1\}$-version of $\mathcal{C}$ where the circuits in $\mathcal{C}_\pm$ output values in $\{-1,1\}$.

2.2 A $\oplus$L-complete problem with good properties

The existence of $\oplus$L-complete problems with good reducibility properties will be important for us. (Recall that $\oplus$L is the class of problems solvable by a nondeterministic logspace Turing machine that accepts the input if the number of accepting paths is odd.) We define the following two problems, called Connected Matrix Determinant (CMD) and Decomposed Connected Matrix Determinant (DCMD):

▶ **Definition 5.** *An instance of* CMD *is an* $n \times n$ *matrix over* $\mathbb{F}_2$ *where the main diagonal and above may contain either* 0 *or* 1*, the second diagonal (i.e. the one below the main diagonal) contains* 1*, and other entries are* 0*. In other words, the matrix is of the following form (where* $*$ *represents any element in* $\mathbb{F}_2$*):*

$$\begin{pmatrix} * & * & * & \cdots & * & * \\ 1 & * & * & \cdots & * & * \\ 0 & 1 & * & \cdots & * & * \\ 0 & 0 & 1 & \cdots & * & * \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & * \end{pmatrix}.$$

The instance is an $(n(n+1)/2)$*-bit string specifying elements on and above the main diagonal. We define* $x \in \mathsf{CMD}$ *if and only if the determinant (over* $\mathbb{F}_2$*) of the matrix corresponding to* x *is* 1*.*

An instance of DCMD *is a string of length* $n^3(n+1)/2$*. For an input* x*,* $\mathsf{DCMD}(x)$ *is computed as follows: we partition* x *into blocks of length* n^2*, let* y_i $(1 \leq i \leq n(n+1)/2)$ *be the parity of the* i*-th block, and define* $\mathsf{DCMD}(x) := \mathsf{CMD}(y_1 \circ y_2 \circ \cdots \circ y_{n(n+1)/2})$*.*

The precise definitions of CMD and DCMD are not important here, as we only need the following two important results about them.

▶ **Theorem 6** ([4, 20])**.** *There is a function* $P : \{0,1\}^{n(n+1)/2} \times \{0,1\}^{O(n^4)} \to \{0,1\}^{n^3(n+1)/2}$ *such that the following hold.*

- *For any input* $x \in \{0,1\}^{n(n+1)/2}$*, the random variable* $P(x, \mathcal{U}_{O(n^4)})$ *is uniformly distributed in* $\{0,1\}^{n^3(n+1)/2}$*.*
- *For any* $x \in \{0,1\}^{n(n+1)/2}$ *and* $r \in \{0,1\}^{O(n^4)}$*, let* $P(x,r) = y$*, then* $\mathsf{CMD}(x) = \mathsf{DCMD}(y) \oplus r_0$*, where* r_0 *is the first bit of* r*.*
- *For each fixed randomness* r*,* $P(x,r)$ *is a projection over* x*, computable in polynomial time given* r*.*

▶ **Theorem 7** ([31]). CMD *is* $\oplus$L*-complete under projections.*

Observe that if CMD is in a circuit class $\mathcal{C}$ closed under projections then all problems in (non-uniform) NC^1 are also in $\mathcal{C}$, given that the problem of evaluating an input Boolean formula is solvable with logarithmic space.

We refer the reader to the full version of [14] for a self-contained exposition of these problems and their relevant properties, including pointers to related work.

2.3 Pseudorandomness

We need the following Hardness vs. Randomness framework for constructing PRGs.

▶ **Lemma 8** (Hardness vs. Randomness [39], see also [14, Appendix E.3] for the proof). *There is a function* $G\colon \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ *such that the following holds. Let* n, ℓ, a *be integers such that* $a \le \ell$*, and* $t = O\big(\ell^2 \cdot n^{1/a}/a\big)$*. Let* $\mathcal{C}$ *be a circuit class closed under negation. For any function* $Y\colon \{0,1\}^\ell \to \{0,1\}$ *represented as a length-*2^ℓ *truth table, if* Y *cannot be* $(1/2 + \varepsilon/n)$*-approximated by* $\mathcal{C} \circ \mathsf{JUNTA}_a$*-circuits where the top circuit has size* S*, then for every circuit* $C \in \mathcal{C}$ *of size* S*,*

$$\left| \mathop{\mathbf{Pr}}_{z \sim \{0,1\}^t}[C(G(Y,z)) = 1] - \mathop{\mathbf{Pr}}_{x \sim \{0,1\}^n}[C(x) = 1] \right| \le \varepsilon.$$

Moreover, the function G *is computable in* $\mathrm{poly}(n, 2^t)$ *time.*

The following simple fact says PRGs imply worst-case hardness.

▶ **Proposition 9** (Worst-case hardness from PRGs). *Let* $\mathcal{F}$ *be a class of functions. If there is an i.o.* ε*-PRG* $G\colon \{0,1\}^r \to \{0,1\}^n$ *with seed length* $r(n)$ *against* $\mathcal{F}_n$*, where* $\varepsilon < 1 - 2^{r(n)-n}$*, then there is a language* $L \in E$ *such that* L *cannot be computed by* $\mathcal{F}$*.*

Proof. Please see the full version [11] for details. ◀

2.4 Hardness amplification

The following result allows us to amplify hardness against NC^1.

▶ **Lemma 10** (Hardness amplification against NC^1, see e.g. [43, 20]). *Suppose there is a language* $L \in \mathsf{E}$ *such that* $L \notin \mathsf{NC}^1$*. Then there is a language* $L' \in \mathsf{E}$ *such that for every constant* $k \ge 1$*,* L' *cannot be* $(1/2 + 1/n^k)$*-approximated by formulas of size* n^k*.*

The following notion of ℓ_1-approximation by SUM-circuits plays a crucial role in some recent results on average-case lower bounds via the algorithmic method (e.g. [13, 12, 27]).

▶ **Definition 11** (ℓ_1-approximation by SUM-circuits). *Let* $\delta \in (0,1)$ *and let* $\mathcal{C}$ *be a circuit class. We say that a function* $f\colon \{0,1\}^n \to \{0,1\}$ *is approximated by a* $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$*-circuit* C *within* ℓ_1 *distance* δ *if*

$$\mathop{\mathbf{E}}_{x \sim \mathcal{U}_n}[\,|f(x) - C(x)|\,] \le \delta.$$

For functions $f, g\colon \{0,1\}^n \to \mathbb{R}$, we let $\langle f, g \rangle := \mathbf{E}_{x \in \{0,1\}^n}[f(x) \cdot g(x)]$.

▶ **Proposition 12.** *Let* $\delta \in (0,1)$*,* $f\colon \{0,1\}^n \to \{0,1\}$*, and* $\mathcal{C}$ *be a circuit class.*

1. *If* f *can be approximated by* $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$*-circuits of complexity* s *within* ℓ_1 *distance* δ*, then there is a* $\mathsf{SUM} \circ \mathcal{C}_\pm$*-circuit* C *of complexity* $O(s)$ *such that* $\|C\|_\infty \le 1$ *and* $\langle f_\pm, C \rangle \ge 1 - 2\delta$*.*

2. *If there is a* $\mathsf{SUM} \circ \mathcal{C}_{\pm}$*-circuit* C *of complexity* s *such that* $\|C\|_{\infty} \leq 1$ *and* $\langle f_{\pm}, C\rangle \geq 1 - 2\delta$*, then* f *can be approximated by* $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}$*-circuits of complexity* $O(s)$ *within* ℓ_1 *distance* δ*.*

Proof. Please see the full version [11] for details. ◀

Given a set X and a Boolean function $f\colon X \to \{-1,1\}$, for and integer $t \geq 1$ and $X^t = X \times \ldots \times X$ (t times) we let $f^{\oplus t}\colon X^t \to \{-1,1\}$ be the Boolean function defined as $f^{\oplus t}(x_1,\ldots,x_t) \coloneqq \prod_{i\in[t]} f(x_i)$. We will need the following XOR lemma from [13].

▶ **Theorem 13** ([35] and [13, Lemma 3.8], see also [12, Lemma 1.7])**.** *Let* $\mathcal{F}$ *be a class of Boolean functions that is closed under negation and restriction. For every* $\delta, \varepsilon \in (0,1)$ *and every function* $f\colon \{0,1\}^n \to \{-1,1\}$*, if*

$$\langle f, C\rangle \leq 1 - \delta$$

for every $\mathsf{SUM} \circ \mathcal{F}$*-circuit* C *where the top* SUM *has complexity* $10 \cdot n/\varepsilon^2$ *and* $\|C\|_{\infty} \leq 1$*, then*

$$\langle f^{\oplus t}, D\rangle \leq (1-\delta)^t + \varepsilon/\delta$$

for any Boolean function $D\colon \{0,1\}^{tn} \to \{-1,1\}$ *in* $\mathcal{F}$*.*

3 Equivalences for worst-case and strong average-case lower bounds

In this section, we prove our equivalence results for worst-case hardness, strong average-case hardness and pseudorandomness.

▶ **Reminder of Theorem 1.** *Let* $\mathcal{C}$ *be a circuit class that satisfies the following:*

- $\mathcal{C}$ *is closed under negation and projection.*
- $\mathcal{C}$ *is closed under a bottom layer of juntas over* $O(1)$ *input bits. That is*

$$\bigcup_{k\geq 1} \mathcal{C}[n^k] \circ \mathsf{JUNTA}_k \subseteq \bigcup_{k\geq 1} \mathcal{C}[n^k].$$

- $\bigcup_{k\geq 1} \mathcal{C}[n^k] \subseteq \mathsf{NC}^1$.

Then the following statements are equivalent:

1. *There is* $L \in \mathsf{E}$ *such that for every* $k \geq 1$*,* $L \notin \widetilde{\mathsf{SUM}}_{1/3} \circ \mathcal{C}[n^k]$*.*
2. *There is* $L \in \mathsf{E}$ *and* $\delta \geq 1/\mathsf{poly}(n)$ *such that for every* $k \geq 1$*,* $L \notin \widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}[n^k]$*.*
3. *There is* $L \in \mathsf{E}$ *such that for every* $k \geq 1$*,* $L \notin \mathsf{MAJ} \circ \mathcal{C}[n^k]$*.*
4. *There is* $L \in \mathsf{E}$ *such that, for every* $k \geq 1$*,* L *cannot be computed by a probabilistic* $\mathcal{C}[n^k]$*-circuit with error* $1/2 - 1/n^k$*.*
5. *There is* $L \in \mathsf{E}$ *and a distribution* $\mathcal{D}$ *such that for every* $k \geq 1$*,* L *cannot be* $(1/2 + n^{-k})$*-approximated by* $\mathcal{C}[n^k]$ *under* $\mathcal{D}$*.*
6. *There is* $L \in \mathsf{E}$ *such that for every* $k \geq 1$*,* L *cannot be* $(1/2 + n^{-k})$*-approximated by* $\mathcal{C}[n^k]$ *under the uniform distribution.*
7. *There is* $L \in \mathsf{E}$ *such that for every* $k \geq 1$*,* L *cannot be approximated by* $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}[n^k]$ *within* ℓ_1 *distance* $1/3$*.*
8. *There is* $L \in \mathsf{E}$ *and* $\delta \geq 1/\operatorname{poly}(n)$ *such that for every* $k \geq 1$*,* L *cannot be approximated by* $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}[n^k]$ *within* ℓ_1 *distance* δ*.*

Proof. We will first show Item 2 ⇒ Item 6 ⇒ Item 10 ⇒ Item 1 ⇒ Item 2, establishing the equivalence of Items 1, 2, 6, and 10. We then show Item 6 ⇒ Item 5 ⇒ Item 4 ⇒ Item 1, which adds Items 4 and 5 to the list of equivalent items. Next, we show Item 6 ⇒ Item 3 ⇒ Item 4, which adds Item 3, and Item 10 ⇒ Item 9 ⇒ Item 2, which adds Item 9. Finally, we show Item 6 ⇒ Item 7 ⇒ Item 8 ⇒ Item 6, adding Items 7 and 8 to the list and completing the proof.

Item 2 ⇒ Item 6. We consider two cases. If DCMD cannot be $\left(1/2 + 1/n^k\right)$-approximated by $\mathcal{C}[n^k]$ for every $k \geq 1$ under the uniform distribution, then we are done.

Now consider the case that there is some $k \geq 1$ such that DCMD can be $\left(1/2 + 1/n^k\right)$-approximated by $\mathcal{C}[n^k]$. By the random self-reducibility of $\mathsf{DCMD}/\mathsf{CMD}$ (see Theorem 6 and also [14, Section 3]), for any $\delta = 1/\operatorname{poly}(n)$, CMD can be computed by a $\widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-circuit where the top SUM-gate has polynomial complexity and the bottom-layer $\mathcal{C}$-circuits have polynomial size. By Theorem 7, for every polynomial-size parity branching program B, there is a projection $p\colon \{0,1\}^n \to \{0,1\}^{n^{O(1)}}$ such that for every $x \in \{0,1\}^n$, $B(x) = \mathsf{CMD}(p(x))$. Since $\mathcal{C}$ is closed under projection, this means that every polynomial-size parity branching program has a $\widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-circuit of polynomial complexity and size, which then implies that every function in NC^1 also has such a $\widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-circuit. On the other hand, by Item 2, there is a function $L \in \mathsf{E}$ that has no $\widetilde{\mathsf{SUM}}_\delta \circ \mathcal{C}$-circuit of polynomial complexity and size, so L is not in NC^1. Using hardness amplification against NC^1 (Lemma 10), it follows that there is a function in E that is strongly average-case hard against NC^1, which by assumption contains polynomial-size $\mathcal{C}$-circuits.

Item 6 ⇒ Item 10. We construct the PRG using the hardness vs. randomness framework. Consider Lemma 8 with the following setting of parameters: $a := 2/\gamma$ and $\ell := n^{\gamma/4}$. Let $G_{L_\ell}\colon \{0,1\}^t \to \{0,1\}^n$ be the PRG defined as $G_{L_\ell}(z) := G(L_\ell, z)$, where $L \in \mathsf{E}$ is the language from Item 6. Note that the seed length t is at most $O\left(\ell^2 \cdot n^{1/a}/a\right) \leq n^\gamma$ and G_{L_ℓ} can be computed in time $\operatorname{poly}(n, 2^t) = 2^{O(n^\gamma)}$. Let $k \geq 1$ be any constant and consider any ℓ-variate $\mathcal{C} \circ \mathsf{JUNTA}_a$-circuit C where the top circuit has size $n^k = \ell^{4k/\gamma}$. Since $\mathcal{C}$ is closed under a bottom layer of juntas, we have that $C \in \mathcal{C}\left[\ell^{k'}\right]$ for some large enough $k' > 4k/\gamma$. Also, let $\varepsilon = 1/n^k$, which implies $\varepsilon/n = 1/n^{k+1} = 1/\ell^{4(k+1)/\gamma} \geq 1/\ell^{k'}$. From Item 6, we have that L_ℓ cannot be $\left(1/2 + 1/\ell^{k'}\right)$-approximated by any circuit from $\mathcal{C}[\ell^{k'}]$, for infinitely many values of ℓ. Then by Lemma 8, we conclude that G_{L_ℓ} $\left(1/n^k\right)$-fools any circuit from $\mathcal{C}[n^k]$, for infinitely many values of n.

Item 10 ⇒ Item 1. Let $G\colon \{0,1\}^r \to \{0,1\}^n$ be an i.o. PRG as in Item 10, where $r \leq n-2$. That is, for each choice of k', G fools circuits from $\mathcal{C}[n^{k'}]$ on input length n with error $\varepsilon(n) \leq n^{-k'}$, for infinitely many values of n.

Let $k \geq 1$ and let $C \in \widetilde{\mathsf{SUM}}_{1/3} \circ \mathcal{C}[n^k]$. By Proposition 9, it suffices to show that G is an i.o. $\left(< \frac{3}{4}\right)$-PRG against C. Let $\tilde{C}$ be the corresponding linear sum for C. That is,

$$\tilde{C}(x) := \sum_i \alpha_i \cdot C_i(x),$$

where $C_i \in \mathcal{C}[n^k] \subseteq \mathcal{C}[n^{k':=k+1}]$ and $\sum_i |\alpha_i| \leq n^k$. Since $\tilde{C}$ (1/3)-approximates C in a pointwise manner, we have

$$\left|\mathbf{E}[C(\mathcal{U})] - \mathbf{E}[\tilde{C}(\mathcal{U})]\right| \leq 1/3 \text{ and } \left|\mathbf{E}[C(G)] - \mathbf{E}[\tilde{C}(G)]\right| \leq 1/3.$$

Therefore, if we can show that

$$\left|\mathbf{E}[\tilde{C}(\mathcal{U})] - \mathbf{E}[\tilde{C}(G)]\right| \leq \delta,$$

for some $\delta < 1/12$ (infinitely often), then G δ'-fools C (infinitely often), where $\delta' = 2/3 + \delta < 3/4$. We have

$$\begin{aligned}
\left|\mathbf{E}[\tilde{C}(\mathcal{U})] - \mathbf{E}[\tilde{C}(G)]\right| &= \left|\mathbf{E}\left[\sum_i \alpha_i \cdot C_i(\mathcal{U})\right] - \mathbf{E}\left[\sum_i \alpha_i \cdot C_i(G)\right]\right| \\
&= \left|\sum_i \alpha_i \cdot \mathbf{E}[C_i(\mathcal{U})] - \mathbf{E}[C_i(G)]\right| \\
&\leq \max_i |\mathbf{E}[C_i(\mathcal{U})] - \mathbf{E}[C_i(G)]| \cdot \sum_i |\alpha_i| \\
&\leq n^{-k'} \cdot n^k \leq 1/n,
\end{aligned}$$

as desired.

Item 1 ⇒ Item 2. This implication is straightforward.

Item 6 ⇒ Item 5 ⇒ Item 4. The first implication is obvious. The contrapositive of the second implication follows from an averaging argument.

Item 4 ⇒ Item 1. It suffices to show that for every $k \geq 1$, every function in $\widetilde{\mathsf{SUM}}_{1/3} \circ \mathcal{C}[n^k]$ has a probabilistic $\mathcal{C}[n^k]$-circuit with error $1/2 - 1/n^{O(k)}$.

For the simplicity of presentation, we will consider Boolean functions that take inputs from $\{0,1\}^n$ and output values in $\{-1,1\}$. Let $f_{\pm}\colon \{0,1\}^n \to \{-1,1\} \in \widetilde{\mathsf{SUM}}_{1/3} \circ \mathcal{C}_{\pm}[n^k]$. Then there is a linear sum of $\mathcal{C}_{\pm}[n^k]$-circuits

$$f_1(x) := \sum_i \alpha_i \cdot \left(\frac{1 - C_i(x)}{2}\right),$$

where $C_i\colon \{0,1\}^n \to \{-1,1\} \in \mathcal{C}_{\pm}[n^k]$ and $\sum_i |\alpha_i| \leq n^k$, such that

- if $f_{\pm}(x) = 1$, then $f_1(x) \leq 1/3$, and
- if $f_{\pm}(x) = -1$, then $f_1(x) \geq 2/3$.

Next, let

$$f_2(x) := 1/2 - f_1(x).$$

It is easy to see that

- if $f_{\pm}(x) = 1$, then $f_2(x) \geq 1/6$, and
- if $f_{\pm}(x) = -1$, then $f_2(x) \leq -1/6$.

Now note that since $\mathcal{C}_{\pm}$ is closed under negation, f_2 can be written as

$$f_2(x) := \sum_j \beta_j \cdot D_j(x),$$

where for each j, $D_j\colon \{0,1\}^n \to \{-1,1\} \in \mathcal{C}_{\pm}[n^k]$, $\beta_j \geq 0$, and $T := \sum_j \beta_j \leq n^{O(k)}$. Finally, let

$$f_3(x) := \frac{f_2(x)}{T}.$$

Let $\mathcal{D}$ be the probabilistic $\mathcal{C}_{\pm}[n^k]$-circuit where D_j is sampled with probability β_j/T. Then for every x we have $\mathbf{E}_{\mathcal{D}}[\mathcal{D}(x)] = f_3(x)$. Moreover, if $f_{\pm}(x) = 1$, then

$$\begin{aligned}\frac{1}{6T} &\leq \mathop{\mathbf{E}}_{\mathcal{D}}[\mathcal{D}(x)] \\ &= \mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = 1] - \mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = -1] \\ &= \mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = 1] - (1 - \mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = 1]) \\ &= 2 \cdot \mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = 1] - 1,\end{aligned}$$

which implies

$$\mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = 1] \geq \frac{1}{2} + \frac{1}{12T}.$$

Similarly, we can show that if $f_{\pm}(x) = -1$, then

$$\mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = -1] \geq \frac{1}{2} + \frac{1}{12T}.$$

Therefore, $\mathcal{D}$ is a probabilistic $\mathcal{C}_{\pm}[n^k]$-circuit for $f_{\pm}$ with error $1/2 - 1/n^{O(k)}$.

Item 6 ⇒ Item 3. This follows from the standard Discriminator Lemma [24].

Item 3 ⇒ Item 4. We will show that for every $k \geq 1$, every function that has a probabilistic $\mathcal{C}[n^k]$-circuit with error $1/2 - 1/n^k$ is contained in $\mathsf{MAJ}_{n^{O(k)}} \circ \mathcal{C}[n^{O(k)}]$.

Let $f\colon \{0,1\}^n \to \{0,1\}$ and $\mathcal{D}$ be the probabilistic $\mathcal{C}[n^k]$-circuit for f with error $1/2 - 1/n^k$. That is, for every x,

$$\mathop{\mathbf{Pr}}_{\mathcal{D}}[\mathcal{D}(x) = f(x)] \geq 1/2 + 1/n^k.$$

By the Chernoff bound, if we sample $t := O(n^{2k} \cdot n)$ circuits $C_1, \ldots, C_t$ from $\mathcal{D}$, then

$$\mathop{\mathbf{Pr}}_{C_1,\ldots,C_t \sim \mathcal{D}}\left[\mathop{\mathbf{Pr}}_{i \in [t]}[C_i(x) = f(x)] \geq 1/2 + 1/(2n^k)\right] \geq 1 - 2^{-2n}.$$

By a union bound over $x \in \{0,1\}^n$, there exist t circuits $C_1, \ldots, C_t$ such that for every x,

$$\mathop{\mathbf{Pr}}_{i \in [t]}[C_i(x) = f(x)] \geq 1/2 + 1/(2n^k).$$

Therefore, by taking the majority of these t circuits, we obtain a $\mathsf{MAJ}_{n^{O(k)}} \circ \mathcal{C}[n^{O(k)}]$-circuit that computes f.

Item 10 ⇒ Item 9 ⇒ Item 2. This first implication is obvious. The proof of the second implication is essentially the same as that of "Item 10 ⇒ Item 1". From Item 9, we get an i.o. PRG with seed length $n - 1$ that $\left(< \frac{1}{2}\right)$-fools $\widetilde{\mathsf{SUM}}_{\delta} \circ \mathcal{C}$-circuits for some $\delta = 1/\operatorname{poly}(n)$, which by Proposition 9 implies Item 2. We omit the details here.

Item 6 ⇒ Item 7. Let $L\colon \{0,1\}^* \to \{0,1\}$ be the language from Item 6. For the sake of contradiction, suppose there is a $k \geq 1$ such that L can be approximated by $[0,1]$-$\mathsf{SUM} \circ \mathcal{C}[n^k]$-circuits within ℓ_1 distance $1/3$. Then by Item 1 of Proposition 12, we have that for every n, there is a $\mathsf{SUM} \circ \mathcal{C}_{\pm}[O\left(n^k\right)]$-circuit C such that $\|C\|_\infty \leq 1$ and

$$\langle (L_{\pm})_n, C\rangle \geq 1/3.$$

Suppose

$$C(x) := \sum_i |\alpha_i| \cdot C_i(x),$$

where $C_i \in \mathcal{C}_{\pm}[O\left(n^k\right)]$ and $\sum_i |\alpha_i| \leq O\left(n^k\right)$. Then

$$\begin{aligned}
1/3 &\leq \left\langle (L_{\pm})_n, \sum_i \alpha_i \cdot C_i \right\rangle \\
&= \sum_i \alpha_i \cdot \langle (L_{\pm})_n, C_i\rangle \\
&\leq \sum_i |\alpha_i| \cdot \langle (L_{\pm})_n, C_i\rangle \\
&\leq \max_i \langle (L_{\pm})_n, C_i\rangle \cdot \sum_i |\alpha_i| \\
&\leq \max_i \langle (L_{\pm})_n, C_i\rangle \cdot O\left(n^k\right),
\end{aligned}$$

which implies that there exists some i such that

$$\langle (L_{\pm})_n, C_i\rangle \geq \frac{1}{O(n^k)}.$$

This contradicts Item 6.

Item 7 ⇒ Item 8. This implication is obvious.

Item 8 ⇒ Item 6. By Item 2 of Proposition 12, we have that Item 8 implies that there is a language $L\colon \{0,1\}^* \to \{-1,1\}$ in E and $\delta = 1/\ell^b$, where $b \geq 1$ is a constant, such that for every $k' \geq 1$, on infinitely many input lengths there is no $\mathsf{SUM} \circ \mathcal{C}_{\pm}[\ell^{k'}]$-circuit C with $\|C\|_\infty \leq 1$ such that

$$\langle L_\ell, C\rangle \leq 1 - 2\delta. \tag{1}$$

Now consider the following language $L'\colon \{0,1\}^* \to \{-1,1\}$: on input x of length n, let ℓ be the largest integer such that $\ell \cdot \ell^b \log^2(\ell) \leq n$ and view the input as $x = (x_1, \ldots, x_t, y)$, where $t := \ell^b \log^2(\ell)$ and $x_i \in \{0,1\}^\ell$ for $i \in [t]$. Then let

$$L'(x) := \prod_{i \in [t]} L(x_i).$$

Note that for large enough n we have

$$n < 2\ell \cdot t < \ell^{b+2}.$$

We claim that L' is strongly average-case hard against $\mathcal{C}_{\pm}$-circuits. For the sake of contradiction, suppose there is $k \geq 1$ and an n-variate circuit $C' \in \mathcal{C}_{\pm}[n^k]$ such that, for all large enough n,

$$\langle L'_n, C' \rangle > \frac{1}{n^k}.$$

By an averaging argument, where we fix the y-part of the input to some value, there exists some $(\ell \cdot t)$-variate $\mathcal{C}_{\pm}$-circuit C' of size $n^k \leq \ell^{k(b+2)}$ such that

$$\left\langle L_{\ell}^{\oplus t}, C'' \right\rangle > \frac{1}{n^k}.$$

Note that for $\delta = 1/\ell^b$ and our choice of $t = \ell^b \log^2(\ell)$, we have

$$\frac{1}{n^k} > (1-2\delta)^t + \frac{1}{2\delta \cdot \ell^{k(b+2)} \cdot \ell^b}.$$

By Theorem 13, there is a $\mathsf{SUM} \circ \mathcal{C}_{\pm}$ C where $\|C\|_{\infty} \leq 1$, the top SUM has complexity $10 \cdot \ell \cdot \left(\ell^{k(b+2)} \cdot \ell^b\right)^2 \leq \ell^{O(kb)}$ and the bottom layer $\mathcal{C}_{\pm}$-circuits have size $\ell^{k(b+2)}$ such that

$$\langle L_{\ell}, C \rangle > 1 - 2\delta,$$

for all large enough ℓ. This contradicts Equation (1). ◀

Abstract

For a directed graph G with n vertices and a start vertex u_{start}, we wish to (approximately) sample an L-step random walk over G starting from u_{start} with minimum space using an algorithm that only makes few passes over the edges of the graph. This problem found many applications, for instance, in approximating the PageRank of a webpage. If only a single pass is allowed, the space complexity of this problem was shown to be $\widetilde{\Theta}(n \cdot L)$. Prior to our work, a better space complexity was only known with $\widetilde{O}(\sqrt{L})$ passes.

We essentially settle the space complexity of this random walk simulation problem for *two-pass* streaming algorithms, showing that it is $\widetilde{\Theta}(n \cdot \sqrt{L})$, by giving almost matching upper and lower bounds. Our lower bound argument extends to every constant number of passes p, and shows that any p-pass algorithm for this problem uses $\widetilde{\Omega}(n \cdot L^{1/p})$ space. In addition, we show a similar $\widetilde{\Theta}(n \cdot \sqrt{L})$ bound on the space complexity of any algorithm (with *any* number of passes) for the related problem of sampling an L-step random walk from *every* vertex in the graph.

1 Introduction

1.1 Background and Motivation

Graph streaming algorithms. *Graph streaming algorithms* have been the focus of extensive study over the last two decades, mainly due to the important practical motivation in analyzing potentially *huge structured data* representing the relationships between a set of entities (*e.g.*, the link graph between webpages and the friendship graph in a social network). In the graph streaming setting, an algorithm gets access to a sequence of graph edges given in an arbitrary order and it can read them one-by-one in the order in which they appear in the sequence. The goal here is to design algorithms solving important graph problems that only make one or few passes through the edge sequence, while using as little memory as possible.

Much of the streaming literature was devoted to the study of *one-pass* algorithms and an $\Omega(n^2)$ space lower bound for such algorithms was shown for many fundamental graph problems. A partial list includes: maximum matching and minimum vertex cover [15, 19], s-t reachability and topological sorting [7, 15, 22], shortest path and diameter [15, 16], maximum and (global or s-t) minimum cut [39], maximal independent set [3, 13], and dominating set [4, 14].

Recently, the *multi-pass* streaming setting received quite a bit of attention. For some graph problems, allowing a few passes instead of a single pass can reduce the memory consumption of a streaming algorithm dramatically. In fact, even a single additional pass over the input can already greatly enhance the capability of the algorithms. For instance, minimum cut and s-t minimum cut in undirected graphs can be solved in two passes with only $\widetilde{O}(n)$ and $O(n^{5/3})$ space, respectively [33] (as mentioned above, any one-pass algorithm for these problems must use $\Omega(n^2)$ space). Additional multi-pass algorithms include an $O(1)$-pass algorithm for approximate matching [17, 19, 28, 29], an $O(\log \log n)$-pass algorithm for maximal independent set [3, 13, 18], and $O(\log n)$-pass algorithms for approximate dominating set [4, 8, 21] and weighted minimum cut [30].

Simulating random walks on graphs. Simulating random walks on graphs is a well-studied algorithmic problem with may applications in different areas of computer science, such as connectivity testing [32], clustering [1, 2, 10, 36], sampling [26], generating random spanning tree [35], and approximate counting [25]. Since most applications of random-walk simulation are concerned with huge networks that come from practice, it is of practical interest to design low-space graph streaming algorithms with few passes for this problem.

In an influential paper by Das Sarma, Gollapudi and Panigrahy [34], an $\widetilde{O}(\sqrt{L})$-pass and $\widetilde{O}(n)$ space algorithm for simulating L-step random walks on directed graphs was established. (Streaming algorithms with almost linear space complexity, like this one, are often referred to as *semi-streaming* algorithms). Using this algorithm together with some additional ideas, [34] obtained space-efficient algorithms for estimating *PageRank* on graph streams. Recall that the PageRank of a webpage corresponds to the probability that a person that randomly clicks on web links arrives at this particular page[1]. However, scanning the sequence of edges $\widetilde{O}(\sqrt{L})$ times may be time-inefficient in many realistic settings.

In the one-pass streaming setting, a folklore algorithm with $\widetilde{O}(n \cdot L)$ space complexity for simulating L-step random walks is known [34] (see Subsection 2.1 for a description of this algorithm), and it is proved to be optimal [27]. We mention that the work of [27]

[1] Given a web-graph $G = (V, E)$ representing the webpages and links between them, the PageRank of the vertices satisfy $\mathsf{PageRank}(u) = \sum_{(v,u)\in E} \mathsf{PageRank}(v)/d(v)$, simultaneously for all u, where $d(\cdot)$ denotes the out-degree, [6].

also considers random walks on *undirected graphs*, and shows that $\widetilde{\Theta}(n \cdot \sqrt{L})$ space is both necessary and sufficient for simulating L-step random walks on undirected graphs with n vertices in one pass.

Both of these known algorithms for general directed graphs have their advantages and disadvantage (either requiring many passes or more space). A natural question is whether one can interpolate between these two results and obtain an algorithm with pass complexity much smaller than $\sqrt{L}$, yet with a space complexity much smaller than $n \cdot L$. Prior to our work, it was not even known if an $o(\sqrt{L})$-pass streaming algorithm with $n \cdot L^{0.99}$ space is possible.

1.2 Our Results

We answer the above question in the affirmative by giving a two-pass streaming algorithm with $\widetilde{O}(n \cdot \sqrt{L})$ space for sampling a random walk of length L on a directed graph with n vertices. We complement this result by an almost matching $\widetilde{\Omega}(n \cdot \sqrt{L})$ lower bound on the space complexity of every two-pass streaming algorithm for this problem. In fact, our two-pass lower bound generalizes to an $\widetilde{\Omega}(n \cdot L^{1/p})$ lower bound on the space consumption of any p-pass algorithm, for a constant p.

1.2.1 Two-Pass Algorithm for Random Walk Sampling

For a directed graph $G = (V, E)$, a vertex $u_{\mathsf{start}} \in V$ and a non-negative integer L, we use $\mathsf{RW}_L^G(u_{\mathsf{start}})$ to denote the distribution of L-step random walks $(v_0, \ldots, v_L)$ in G starting from $v_0 = u_{\mathsf{start}}$ (see Subsection 3.2 for formal definitions). For a distribution $\mathcal{D}$ over a finite domain Ω, we say that a randomized algorithm *samples* from $\mathcal{D}$ if, over its internal randomness, it outputs an element $\omega \in \Omega$ distributed according to $\mathcal{D}$. We give a space-efficient streaming algorithm for (approximate) sampling from $\mathsf{RW}_L^G(u_{\mathsf{start}})$ with small error:

▶ **Theorem 1** (Two-pass algorithm). *There exists a streaming algorithm $\mathbb{A}_{\mathsf{two\text{-}pass}}$ that given an n-vertex* directed *graph $G = (V, E)$, a starting vertex $u_{\mathsf{start}} \in V$, a non-negative integer L indicating the number of steps to be taken, and an error parameter $\delta \in (0, 1/n)$, satisfies the following conditions:*

1. *$\mathbb{A}_{\mathsf{two\text{-}pass}}$ uses at most $\widetilde{O}(n \cdot \sqrt{L} \cdot \log \delta^{-1})$ space*[2] *and makes two passes over the input graph G.*
2. *$\mathbb{A}_{\mathsf{two\text{-}pass}}$ samples from some distribution $\mathcal{D}$ over V^{L+1} satisfying $\|\mathcal{D} - \mathsf{RW}_L^G(u_{\mathsf{start}})\|_{\mathrm{TV}} \leq \delta$.*

Our algorithm can also be generalized to the *turnstile* model, paying a $\operatorname{poly}\log n$ factor in the space usage. See Subsection 4.4.

Observe that our algorithm $\mathbb{A}_{\mathsf{two\text{-}pass}}$ allows for a considerable saving in space compared to the folklore single-pass algorithm ($\widetilde{O}(n \cdot \sqrt{L})$ vs $\widetilde{O}(n \cdot L)$) and considerable saving in the number of passes compared to [34] (2 vs $\widetilde{O}(\sqrt{L})$), at least if we allow some small error δ.

We mention that $\mathbb{A}_{\mathsf{two\text{-}pass}}$ can also be used to sample a random path from *every* vertex[3] of G with the same storage cost of $\widetilde{O}(n \cdot \sqrt{L} \cdot \log \delta^{-1})$ and two passes[4]. This is because $\mathbb{A}_{\mathsf{two\text{-}pass}}$ satisfies the useful property of *obliviousness to the starting vertex* u_{start}, meaning

[2] The $\widetilde{O}$ hides logarithmic factors in n. We may assume without loss of generality that $L \leq n^2$, as otherwise $n \cdot \sqrt{L} > n^2$ and that algorithm can store the entire input graph.

[3] Note, however, that the random walks from different vertices in the graph may be correlated.

[4] We count towards the space complexity only the space on the work tape used by the algorithm and do not count space on the output tape (otherwise an $\Omega(n \cdot L)$ lower bound is trivial).

that it scans the input graph before the start vertex is revealed. More formally, we say that an algorithm $\mathbb{A}$ is oblivious to the starting vertex if it first runs a *preprocessing* algorithm $\mathbb{P}$ and then a *sampling* algorithm $\mathbb{S}$; the algorithm $\mathbb{P}$ reads the input graph stream *without* knowing the starting vertex u_{start} (if $\mathbb{A}$ is a p-pass streaming algorithm, $\mathbb{P}$ makes p passes over the input graph stream), and outputs a string; $\mathbb{S}$ takes both the string outputted by $\mathbb{P}$ and a starting vertex u_{start} as an input, and outputs a walk on the input graph G.

1.2.2 Lower Bounds

We prove the following lower bound:

▶ **Theorem 2** (Multi-pass lower bound). *Fix a constant $\beta \in (0,1]$ and an integer $p \geq 1$. Let $n \geq 1$ be a sufficiently large integer and let $L = \lceil n^{\beta} \rceil$. Any randomized p-pass streaming algorithm that, given an n-vertex* directed *graph $G = (V,E)$ and a starting vertex $u_{\mathsf{start}} \in V$, samples from a distribution $\mathcal{D}$ such that $\|\mathcal{D} - \mathsf{RW}_L^G(u_{\mathsf{start}})\|_{\mathrm{TV}} \leq 1 - \frac{1}{\log^{10} n}$ requires $\widetilde{\Omega}(n \cdot L^{1/p})$ space.*

We remark that the theorem above shows that no low-space algorithms can achieve sampling error $1 - 1/\mathrm{poly}\log(n)$, which is quite strong as usual applications of simulating random walks would require at least a small constant sampling error. Plugging in $p = 2$ in Theorem 2, implies that our two-pass algorithm from Theorem 1 is essentially optimal. Also, with $p = 1$, the theorem reproduces the one-pass lower bound by [27]. In addition, Theorem 2 rules out the possibility of a semi-streaming algorithm with any constant number of passes.

Recall from Subsubsection 1.2.1, that our two-pass algorithm $\mathbb{A}_{\mathsf{two\text{-}pass}}$ utilizes $\widetilde{O}(n \cdot \sqrt{L})$ space and is oblivious to the starting vertex. Interestingly, we are able to show that *any* oblivious algorithm for random walk sampling (with any number of passes) requires $\widetilde{\Omega}(n \cdot \sqrt{L})$ space. Thus, any algorithm for random walk sampling with significantly less space than ours, has to be inherently different and have its storage depend on the starting vertex. Our lower bound for oblivious algorithms also implies that $\mathbb{A}_{\mathsf{two\text{-}pass}}$ gives an almost optimal algorithm for sampling a pass from every start vertex, even if any number of passes are allowed.

▶ **Theorem 3** (Lower bound for oblivious algorithms). *Let $n \geq 1$ be a sufficiently large integer and let L denote an integer satisfying that $L \in [\log^{40} n, n]$. Any randomized algorithm that is* oblivious to the start vertex *and given an n-vertex* directed *graph $G = (V,E)$ and a starting vertex $u_{\mathsf{start}} \in V$, samples from a distribution $\mathcal{D}$ such that $\|\mathcal{D} - \mathsf{RW}_L^G(u_{\mathsf{start}})\|_{\mathrm{TV}} \leq 1 - \frac{1}{\log^{10} n}$ requires $\widetilde{\Omega}(n \cdot \sqrt{L})$ space*[5].

1.3 Discussions and Open Problems

Better space complexity with more passes? Our results leave open a couple of interesting directions for future work. The most significant open question is to understand the streaming space complexity of sampling random walks with more than two passes. In particular, Theorem 2 implies that a three-pass streaming algorithm has space complexity at least $\widetilde{\Omega}(n \cdot L^{1/3})$. Can one get $\widetilde{O}(n \cdot L^{1/3})$ space with three passes, or at least $O(n \cdot L^{1/2-\varepsilon})$ space, for some constant $\varepsilon > 0$? Note that, as explained in Subsubsection 1.2.2, such an algorithm must utilize its knowledge of the starting vertex when it reads the graph stream.

[5] In fact, we show that Theorem 3 holds even if the preprocessing algorithm $\mathbb{P}$ and the sampling algorithm $\mathbb{S}$ are allowed to use an arbitrarily large amount of memory, as long as $\mathbb{P}$ passes a string of length at most (roughly) $n \cdot \sqrt{L}$ to $\mathbb{S}$.

Theorem 2 does not rule out semi-streaming $\widetilde{O}(n)$ space algorithms even when p is a moderately growing function of n and L. In [34], it is shown that such an $\widetilde{O}(n)$ space algorithm exists with $p = \widetilde{O}(\sqrt{L})$ passes. Does a semi-streaming algorithm with, say, $\operatorname{poly}\log(L)$ passes exist?

Undirected graphs? It would also be interesting to see what is the best two-pass streaming algorithm for simulating random walks on *undirected graphs*. Specifically, is it possible to combine our algorithm with the algorithm from [27] to obtain an improvement over the optimal $\widetilde{O}(n \cdot \sqrt{L})$ space complexity of a one-pass streaming algorithm for this problem?

Only outputting the end vertex? Finally, our lower bounds only apply to the case where the algorithms need to output an entire random path $(v_0, \ldots, v_L)$. If instead only the last vertex v_L in the random walk is required, can one design better two-pass algorithms or prove a non-trivial lower bound?

2 Techniques

2.1 The Two-Pass Algorithm

We next overview our two-pass algorithm from Theorem 1, that simulates random walks with only $\widetilde{O}(n \cdot \sqrt{L})$ space.

The folklore one-pass algorithm. Before discussing our algorithm, it would be instructive to review the folklore $\widetilde{O}(n \cdot L)$-space one-pass algorithm for simulating L-step random walks in a directed graph $G = (V, E)$ (for simplicity, we will always assume $L \leq n$ in the discussions). The algorithm is quite simple:

1. For every vertex $v \in V$, sample L of its outgoing neighbors *with replacement* and store them in a list L_v^{save} of length L (that is, for each $j \in [L]$, the j-th element of L_v^{save} is an *independent uniformly random* outgoing vertex of v). This can be done in a single pass over input graph stream using reservoir sampling [37].
2. Given a starting vertex $u_{\mathsf{start}} \in V$, our random walk starts from u_{start} and repeats the following for L steps: suppose we are currently at vertex v and it is the k-th time we visit this vertex, then we go from v to the k-th vertex in the list L_v^{save}.

It is not hard to see that the above algorithm works: whenever we visit a vertex $v \in V$, the next element in the list L_v^{save} will always be a uniformly random outgoing neighbor of v, *conditioned on* the walk we have produced so far; and we will never run out of the available neighbors of v as $|L_v^{\mathsf{save}}| = L$.

A naive attempt and the obstacles. Since we are aiming at only using $\widetilde{O}(n \cdot \sqrt{L})$ space, a naive attempt to improve the above algorithm is to just sample and store $\tau = O(\sqrt{L})$ outgoing neighbors instead of L neighbors, and simulate the walk starting from u_{start} in the same way. The issue here is that, during the simulation of an L-step walk, whenever one visits a vertex v more than τ times, one would run out of available vertices in the list L_v^{save}, and the algorithm can no longer produce a legit random walk. For a simple example, imagine we have a star-like graph where $n - 1$ vertices are connected to a center vertex via two-way edges. An L-step random walk starting at the center would require at least $\Omega(L)$ samples from the center's neighbors, and our naive algorithm completely breaks.

Our approach: heavy and light vertices. Observe, however, that in the above example of a star-like graph, we are only at risk of not storing enough random neighbors of the center node, as an L-step *random* walk would only visit the other non-center vertices a very small number of times. Thus, the algorithm may simply record all edges from the center with only $O(n)$ space. This observation inspires the following approach for a two-pass algorithm:

1. In the first pass, we identify all the vertices that are likely to be visited many times by a random walk (starting from *some* vertex). We call such vertices *heavy*, while all other vertices are called *light*.
2. In the second pass, we record *all* outgoing neighbors of all heavy vertices, as well as $O(\tau)$ random outgoing neighbors with replacement of each of the light vertices.

Observe that the obtained algorithm is indeed *oblivious to the starting vertex*: the two passes described above do not use the starting vertex. Still, given the set of outgoing neighbors stored by the second pass, we are able to sample a random walk from any start vertex.

First pass: how do we detect heavy vertices? The above approach requires that we detect, in a single pass, all vertices v that with a decent probability (say, $1/\text{poly}(n)$), are visited more than $O(\tau)$ times by an L-step random walk. To this end, we observe that if a random walk visits a vertex v more than τ times, this random walk must follow more than $\tau - 1$ self-circles around v in L steps. This, in turn, implies that a random walk that starts from v is likely to return to v in roughly $L/\tau = O(\sqrt{L})$ steps.

The above discussion suggests the following definition of heavy vertices: a vertex v is *heavy*, if a random walk starting from v is likely (say, with probability at least $1/3$) to revisit v in $O(\sqrt{L})$ steps. Indeed, this property is much easier to detect: we can run $O(\log n)$ independent copies of the folklore one-pass streaming algorithms to sample $O(\log n)$ $O(\sqrt{L})$-step random walks starting from v, and count how many of them return to v at some step.

Second pass: can we afford to store the neighbors? In Lemma 18, we show that for a light vertex v, an L-step random walk starting at any vertex visits v $O(\sqrt{L})$ times with high probability. Therefore, in the second pass, we can safely record only $O(\sqrt{L})$ outgoing neighbors for all light vertices. Still, we have to record all the outgoing neighbors for heavy vertices.

The crux of our analysis is a *structural result* about directed graphs, showing that the total outgoing degree of all heavy vertices is bounded by $O(n \cdot \sqrt{L})$, and therefore we can simply store all of their outgoing neighbors. This is proved in Lemma 10, which may also be of independent interest.

Intuition behind the structure lemma. Finally, we discuss the insights behind the above structure lemma for directed graphs. We will use $d_{\mathsf{out}}(v)$ to denote the number of outgoing neighbors of v. For concreteness, we now say a vertex v is heavy if a random walk starting from v revisits v in $\sqrt{L}$ steps with probability at least $1/3$.

Let $V_{\mathsf{heavy}} \subseteq V$ be the set of heavy vertices and let $v \in V_{\mathsf{heavy}}$. By a simple calculation, one can see that for at least a $1/6$ fraction of outgoing neighbors u of v, a random walk starting from u visits v in $\sqrt{L}$ steps with probability at least $1/6$. The key insight is to consider the number of pairs $(u, v) \in V^2$ such that a random walk starting from u visits v in $\sqrt{L}$ steps with probability at least $1/6$. We will use $\mathcal{S}$ to denote this set.

- By the previous discussions, we can see that for each heavy vertex v, it adds at least $1/6$ $d_{\mathsf{out}}(v)$ pairs to the set $\mathcal{S}$. Hence, we have

$$|\mathcal{S}| \geq \frac{1}{6} \cdot \sum_{v \in V_{\mathsf{heavy}}} d_{\mathsf{out}}(v). \tag{1}$$

- On the other hand, it is not hard to see that for each vertex v, there are at most $O(\sqrt{L})$ many pairs of the form $(v, u) \in \mathcal{S}$, since a $\sqrt{L}$-step walk can visit only $\sqrt{L}$ vertices. So we also have

$$|\mathcal{S}| \leq O(n\sqrt{L}). \tag{2}$$

Putting the above (Equation 1 and Equation 2) together, we get the desired bound

$$\sum_{v \in V_{\mathsf{heavy}}} d_{\mathsf{out}}(v) \leq O(n\sqrt{L}).$$

2.2 Lower Bound for p-Pass Algorithms

We now describe the ideas behind the proof of Theorem 2, our $\widetilde{\Omega}(n \cdot L^{1/p})$ space lower bound for p-pass randomized streaming algorithms for sampling random walks. We mention that many of the tools developed for proving space lower bounds are not directly applicable when one wishes to lower bound the space complexity of a *sampling* task and are more suitable for proving lower bounds on the space required to compute a function or a search problem[6].

From sampling to function computation. Our way around this is to first prove a reduction from streaming algorithms that sample a random walk from u_{start} to streaming algorithms that compute the $(p+1)$-neighborhood of the vertex u_{start}. This is done by considering a graph where a random walk returns to the vertex u_{start} every $p+2$ steps. If p is a constant, then a random walk of length L on such a graph can be seen as $L/(p+2) = O(L)$ copies of a random walk of length $p+2$. Observe that if the $(p+1)$-neighborhood of the vertex u_{start} has (almost) L vertices (and the probability of visiting each vertex is more or less uniform), then a random walk of length L is likely to visit all the vertices in the neighborhood and an algorithm that samples a random walk also outputs the entire neighborhood with high probability.

A lower bound for computing the $(p+1)$-neighborhood via pointer-chasing. Having reduced sampling a random walk to outputting the $(p+1)$-neighborhood, we now need to prove that a space efficient p-pass streaming algorithms cannot output the $(p+1)$-neighborhood of u_{start}, if this neighborhood has roughly L vertices. This is reminiscent of the "*pointer-chasing*" lower bounds found in the literature.

Pointer-chasing results are typically concerned with a graph with $p+1$ layers of vertices (p layers of edges) and show that given a vertex in the first layer, finding a vertex that is reachable from it in the last layer cannot be done with less than p passes, unless the memory is huge. Classical pointer-chasing lower bounds (*e.g.*, [31]), consider graphs where the out-degree of each vertex is 1, thus the start vertex reaches a unique vertex in the last layer. Unfortunately, this type of pointer-chasing instances are very *sparse* and a streaming algorithm can simply remember the entire graph in one pass using $\widetilde{O}(n)$ memory.

[6] One such tool that cannot be used directly for our purpose is the very useful *Yao's minimax principle* [38] that allows proving randomized communication lower bounds by proving the corresponding distributional (deterministic) communication lower bounds.

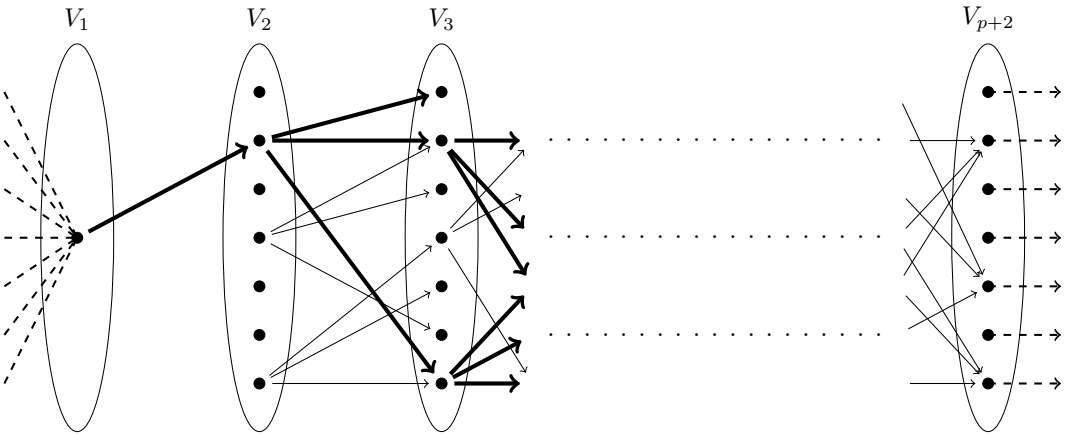

Figure 1 A depiction of our hard instance for p-pass streaming algorithms. Some edges omitted.

Since we wish to have roughly L vertices in a $(p+1)$-neighborhood of u_{start}, the out-degree of each vertex should be roughly $\Omega(L^{\frac{1}{p+1}})$ (assuming uniform degrees). Pointer-chasing lower bounds for this type of *dense* graphs were also proved (*e.g.*, [20] and [16]), showing that p-pass algorithms essentially need to store an entire layer of edges, which is $\Omega(n \cdot L^{\frac{1}{p+1}})$ in our case. However, this still does not give us the $\Omega(n \cdot L^{\frac{1}{p}})$ lower bound we aspire for (and which is tight, at least for two passes).

Towards a tight lower bound: combining dense and sparse. To get a better lower bound, we construct a hard instance that is a combination of the two above mentioned types of pointer-chasing instances, the dense and the sparse. Specifically, for a p-pass lower bound, we construct a layered graph with $p+2$ layers of vertices $V_1, \ldots, V_{p+2}$, where the first layer has only one vertex u_{start} and all the other layers are of equal size (see Figure 1). To ensure that vertex u_{start} is reached every $p+2$ steps, we connect all vertices in the last layer to u_{start}. Every vertex in layers $V_2, \ldots, V_{p+1}$ connects to a random set of roughly $L^{\frac{1}{p}}$ vertices in the next layer. Using Guruswami and Onak style arguments ([20]), it can be shown that when the edges are presented to the algorithm from right to left, finding a vertex in layer V_{p+2} that is reachable form a given vertex in V_2 with a $(p-1)$-pass algorithm requires $\Omega(n \cdot L^{\frac{1}{p}})$ space. We "squeeze out" an extra pass in the algorithm by connecting the start vertex u_{start} in V_1 to a single random vertex in V_2. Note that with this construction, it is indeed the case that a $(p+1)$-neighborhood of u_{start} consists of only roughly L vertices, but still, the out-degrees of vertices in $V_2, \ldots, V_{d+1}$ are roughly $L^{\frac{1}{p}}$ instead of only $L^{\frac{1}{p+1}}$.

2.3 Lower bounds for Oblivious Algorithms

Finally, we discuss the intuitions behind the proof of Theorem 3, showing that any algorithm that is oblivious to the starting vertex must use $\widetilde{\Omega}(n \cdot \sqrt{L})$ space space. Our proof is based on a reduction from a multi-output generalization of the well-studied INDEX problem for one-way communication protocols, denoted by $\mathsf{INDEX}_{m,\ell}$. In $\mathsf{INDEX}_{m,\ell}$, Alice gets ℓ strings $X_1, \ldots, X_\ell \in \{0,1\}^m$ and Bob gets an index $i \in [\ell]$. Alice sends a message to Bob and then Bob is required to output the string X_i. (Note that when $m = 1$ it becomes the original INDEX problem).

It is not hard to show that any one-way communication protocol solving $\mathsf{INDEX}_{m,\ell}$ with non-trivial probability (say, $1/\operatorname{poly}\log(m)$) requires Alice to send at least $\widetilde{\Omega}(m\ell)$ bits to Bob (see the full version of this paper [11] for details).

Our key observation here is that if there is a starting vertex oblivious algorithm $\mathbb{A} = (\mathbb{P}, \mathbb{S})$ with S space for approximate simulation of an $L = \widetilde{O}(m)$-step random walk on a graph with $n = O(\sqrt{m} \cdot \ell)$ vertices, then it implies a one-way communication protocol for $\mathsf{INDEX}_{m,\ell}$ with communication complexity S and a decent success probability. Recall the lower bound for $\mathsf{INDEX}_{m,\ell}$, we immediately have $S = \widetilde{\Omega}(m\ell) = \widetilde{\Omega}(n\sqrt{L})$.

In more detail, given an m-bit string X, we will build an $O(\sqrt{m})$-vertex graph $H(X)$ by encoding all bits of X as *existence/non-existence* of edges in H (this is possible since there are more than m potential edges in H). We also add some artificial edges to H to make sure it is strongly connected. Our construction will make sure that an $L = \widetilde{O}(m)$ steps random walk in H will reveal all edges in H with high probability, which in turn reveals all bits of X (see the proof of Theorem 3 in the full version of this paper for more details).

Now the reduction can be implemented as follows: given ℓ strings $X_1, \ldots, X_\ell \in \{0,1\}^m$, Alice constructs a graph $G = \bigsqcup_{i=1}^{\ell} H(X_i)$, as the joint union of ℓ graphs. Note that G has $n = O(\sqrt{m} \cdot \ell)$ vertices. Alice then runs the preprocessing algorithm $\mathbb{P}$ on G to obtain a string M, and sends it to Bob. Given an index $i \in [\ell]$, Bob simply runs $\mathbb{S}$ with M together with a suitable starting vertex inside the $H(X_i)$ component of G. By previous discussions, this reveals the string X_i with high probability and proves the correctness of this reduction. Hence, the space complexity of $\mathbb{A}$ must be $\widetilde{\Omega}(m\ell) = \widetilde{\Omega}(n\sqrt{L})$.

Organization of this paper

In Section 3 we introduce the necessary preliminaries for this paper. In Section 4 we present our nearly optimal two-pass streaming algorithm for simulating random walks and prove Theorem 1. See the full version of this paper [11] for the proof of Theorem 2 and Theorem 3.

3 Preliminaries

3.1 Notation

Let $n \in \mathbb{N}$. We use $[n]$ to denote the set $\{1, \ldots, n\}$. We often use sans-serif letters (*e.g.*, X) to denote random variables, and calligraphic font letters (*e.g.*, $\mathcal{X}$) to denote distributions. For two random variables X and Y, and for $Y \in \mathrm{supp}(\mathsf{Y})$, we use $(X|\mathsf{Y} = Y)$ to denote X conditioned on $\mathsf{Y} = Y$. For two lists a and b, we use $a \circ b$ to denote their concatenation.

For two distributions $\mathcal{D}_1$ and $\mathcal{D}_2$ on set $\mathcal{X}$ and $\mathcal{Y}$ respectively, we use $\mathcal{D}_1 \otimes \mathcal{D}_2$ to denote their product distribution over $\mathcal{X} \times \mathcal{Y}$, and $\|\mathcal{D}_1 - \mathcal{D}_2\|_{\mathrm{TV}}$ to denote the total variation distance between them.

3.2 Graphs

In this paper we will always consider directed graphs without multi-edges. A directed G is a pair (V, E), where V is the vertex set and $E \subseteq V \times V$ is the set of all edges.

For a vertex u in a graph $G = (V, E)$, we let $N^G_{\mathsf{out}}(u) \coloneqq \{v : (u, v) \in E\}$ and $N^G_{\mathsf{in}}(u) \coloneqq \{v : (v, u) \in E\}$. We also use $d^G_{\mathsf{out}}(u)$ and $d^G_{\mathsf{in}}(u)$ to denote its out and in degrees (*i.e.*, $|N^G_{\mathsf{out}}(u)|$ and $|N^G_{\mathsf{in}}(u)|$). For an edge $(u, v) \in E$, we say v is the *out-neighbor* of u and u is the *in-neighbor* of v.

Random walks on directed graphs. For a vertex u in a graph $G = (V, E)$ and an non-negative integer L, an L-step random walk $(v_0, v_1, \ldots, v_L)$ starting at u is generated as follows: set $v_0 = u$, for each $i \in [L]$, we draw v_i uniformly random from $N^G_{\mathsf{out}}(u)$. We say that $v_0 = u$ is the 0-th vertex on the walk, and v_i is the i-th vertex for each $i \in [L]$. We use $\mathsf{RW}^G_L(u)$ to denote the distribution of an L-step random walk starting from u in G.

We use $\mathsf{visit}^G_{[a,b]}(u,v)$ to denote the probability of a b-step random walk starting from u visits v between the a-th vertex and b-th vertex on the walk.

We often omit the superscript G when the graph G is clear from the context.

Starting vertex oblivious algorithms. Now we formally define a starting vertex oblivious streaming algorithm for simulating random walks.

▶ **Definition 4.** *We say a p-pass S-space streaming algorithm $\mathbb{A}$ for simulating random walks is starting vertex oblivious, if $\mathbb{A}$ can be decomposed into a preprocessing subroutine $\mathbb{P}$ and a sampling subroutine $\mathbb{S}$, such that:*

1. *(**Starting vertex oblivious preprocessing phase**) $\mathbb{P}$ makes p passes over the input graph stream, using at most S words of space. After that, $\mathbb{P}$ outputs at most S words, denoted as M.*
2. *(**Sampling phase**) $\mathbb{S}$ takes both the starting vertex u_{start} and M as input, and outputs a desired walk starting from u_{start}, using at most S words of space.*

3.3 Useful Concentration Bounds on Random Variables

The following standard concentration bounds will be useful for us.

▶ **Lemma 5** (Multiplicative Chernoff bound, [12])**.** *Suppose $X_1, \cdots, X_n$ are independent random variables taking values in $[0,1]$. Let X denote their sum and let $\mu = \mathbb{E}[X]$ denote the sum's expected value. Then,*

$$\Pr\left(X \geq (1+\delta)\mu\right) \leq \mathrm{e}^{-\frac{\delta^2\mu}{2+\delta}}, \qquad \forall 0 \leq \delta,$$

$$\Pr\left(X \leq (1-\delta)\mu\right) \leq \mathrm{e}^{-\frac{\delta^2\mu}{2}}, \qquad \forall 0 \leq \delta \leq 1.$$

In particular, we have that:

$$\Pr\left(X \geq (1+\delta)\mu\right) \leq \mathrm{e}^{-\frac{\delta\mu}{3}\cdot\min(\delta,1)}, \qquad \forall 0 \leq \delta,$$

$$\Pr\left(|X-\mu| \geq \delta\mu\right) \leq 2\cdot\mathrm{e}^{-\frac{\delta^2\mu}{3}}, \qquad \forall 0 \leq \delta \leq 1.$$

We also need the following Azuma-Hoeffding inequality.

▶ **Lemma 6** (Azuma-Hoeffding inequality, [5, 23])**.** *Let $Z_0, \ldots, Z_n$ be random variables satisfying (1) $\mathbb{E}[|Z_i|] < \infty$ for every $i \in \{0, \ldots, n\}$ and $\mathbb{E}[Z_i | Z_0, \ldots, Z_{i-1}] \leq Z_{i-1}$ for every $i \in [n]$ (i.e., $\{Z_i\}$ forms a supermartingale) and (2) for every $i \in [n]$, $|Z_i - Z_{i-1}| \leq 1$, then for all $\lambda > 0$, we have*

$$\Pr[Z_n - Z_0 \geq \lambda] \leq \exp(-\lambda^2/2n).$$

In particular, the following corollary will be useful for us.

▶ **Corollary 7** (Azuma-Hoeffding inequality for Boolean random variables, [5, 23])**.** *Let $X_1, \ldots, X_n$ be random variables satisfying $X_i \in \{0,1\}$ for each $i \in [n]$. Suppose that $\mathbb{E}[X_i | X_1, \ldots, X_{i-1}] \leq p_i$ for all i. Then for any $\lambda > 0$,*

$$\Pr\left[\sum_{i=1}^{n} X_i \geq \lambda + \sum_{i=1} p_i\right] \leq \exp(-\lambda^2/2n).$$

Proof. For $i \in \{0, \ldots, n\}$, let $Z_i = \sum_{j=1}^{i}(X_j - p_j)$. From the assumption one can see that all the Z_i form a supermartingale and $|Z_i - Z_{i-1}| \leq 1$, hence the corollary follows directly from Lemma 6. ◀

4 Two-Pass Streaming Algorithms for Simulating Directed Random Walk

In this section, we present our two-pass streaming algorithms for simulating random walks on directed graphs.

4.1 Heavy and Light Vertices

We first define the notion of heavy and light vertices.

▶ **Definition 8** (Heavy and light vertices). *Given a directed graph $G = (V, E)$ with n vertices and $\ell \in \mathbb{N}$.*

- *(**Heavy vertices**.) We say a vertex u is ℓ-heavy in G, if $\mathsf{visit}_{[1,\ell]}(u, u) \geq 1/3$ (i.e., if a random walk starting from u will revisit u in at most ℓ steps with probability at least $1/3$.)*
- *(**Light vertices**.) We say a vertex u is ℓ-light in G, if $\mathsf{visit}_{[1,\ell]}(u, u) \leq 2/3$ (i.e., if a random walk starting from u will revisit u in at most ℓ steps with probability at most $2/3$.)*

We also let $V^{\ell}_{\mathsf{heavy}}(G)$ and $V^{\ell}_{\mathsf{light}}(G)$ be the sets of ℓ-heavy and ℓ-light vertices in G. When G and ℓ are clear from the context, we simply refer to them as V_{heavy} and V_{light}.

▶ Remark 9. Note that if the revisiting probability is between $[1/3, 2/3]$, then the vertex is considered to be both heavy and light.

The following lemma is crucial for the analysis of our algorithm.

▶ **Lemma 10** (Upper bounds on the total out-degrees of heavy vertices). *Given a directed graph G with n vertices and $\ell \in \mathbb{N}$, it holds that*

$$\sum_{u \in V^{\ell}_{\mathsf{heavy}}(G)} d_{\mathsf{out}}(u) \leq O(n \cdot \ell).$$

Proof. We define a set $\mathcal{S}$ of pairs of vertices as follows:

$$\mathcal{S} \coloneqq \{(u, v) \in V^2 : \mathsf{visit}_{[0,\ell]}(u, v) \geq 1/6\}.$$

That is, a pair of vertices u and v belongs to $\mathcal{S}$ if and only if an ℓ-step random walk starting from u visits v with probability at least $1/6$.

For each fixed vertex u, we further define

$$\mathcal{S}_u \coloneqq \big\{v \in N_{\mathsf{out}}(u) \mid \mathsf{visit}_{[0,\ell]}(v, u) \geq 1/6\big\},$$

and

$$\mathcal{H}_u \coloneqq \big\{v \in V \mid \mathsf{visit}_{[0,\ell]}(u, v) \geq 1/6\big\}.$$

The following claim will be useful for the proof.

▷ Claim 11. The following two statements hold:

1. For every $u \in V$, it holds that $|\mathcal{H}_u| \leq O(\ell)$.
2. For every $u \in V_{\mathsf{heavy}}$, it holds that $|\mathcal{S}_u| \geq 1/6 \cdot d_{\mathsf{out}}(u)$.

Proof. Fixing $u \in V$, the first item follows from the simple fact that

$$\sum_{v \in V} \mathsf{visit}_{[0,\ell]}(u, v) \leq \ell + 1.$$

Now we move to the second item, and fix $u \in V_{\mathsf{heavy}}$. For the sake of contradiction, suppose that $|\mathcal{S}_u| < 1/6 \cdot d_{\mathsf{out}}(u)$. We have

$$\begin{aligned}\mathsf{visit}_{[1,\ell]}(u,u) &= \mathop{\mathbb{E}}_{v \in N_{\mathsf{out}}(u)}[\mathsf{visit}_{[0,\ell-1]}(v,u)] \\ &\leq \mathop{\mathbb{E}}_{v \in N_{\mathsf{out}}(u)}[\mathsf{visit}_{[0,\ell]}(v,u)] \\ &< \Pr_{v \in N_{\mathsf{out}}(u)}[v \in \mathcal{S}_u] \cdot 1 + \Pr_{v \in N_{\mathsf{out}}(u)}[v \notin \mathcal{S}_u] \cdot 1/6 < 1/6 + 1/6 < 1/3,\end{aligned}$$

a contradiction to the assumption that u is heavy. ◁

Finally, note that by definition of $\mathcal{H}_u$ and $\mathcal{S}_u$ we immediately have

$$|\mathcal{S}| = \sum_{u \in V} |\mathcal{H}_u| \geq \sum_{u \in V} |\mathcal{S}_u|.$$

By Claim 11, we have

$$\sum_{u \in V_{\mathsf{heavy}}} d_{\mathsf{out}}(u) \leq 6 \cdot \sum_{u \in V} |\mathcal{S}_u| \leq 6 \cdot \sum_{u \in V} |\mathcal{H}_u| \leq O\left(n \cdot \ell\right),$$

which completes the proof. ◀

4.2 A Simple One-Pass Algorithm for Simulating Random Walks

We first describe a simple one-pass algorithm for simulating random walks, which will be used as a sub-routine in our two-pass algorithm. Moreover, this one-pass algorithm is starting vertex oblivious, which will be crucial for us later.

Reservoir sampling in one pass. Before describing our one-pass subroutine, we need the following basic reservoir sampling algorithm.

▶ **Lemma 12** ([37]). *Given input access to a stream of n items such that each item can be described by $O(1)$ words, we can uniformly sample m of them without replacement using $O(m)$ words of space.*

Using m independent reservoir samplers each with capacity 1, one can also sample m items from the stream *with replacement* in a space-efficient way.

▶ **Corollary 13.** *Given input access to a stream of n items such that each item can be described by $O(1)$ words, we can uniformly sample m of them with replacement using $O(m)$ words of space.*

Description of the one-pass algorithm. Now we describe our one-pass algorithm for simulating random walks. Our algorithm $\mathbb{A}_{\mathsf{one\text{-}pass}}$ is starting vertex oblivious, and can be described by a preprocessing subroutine $\mathbb{P}_{\mathsf{one\text{-}pass}}$ and a sampling subroutine $\mathbb{S}_{\mathsf{one\text{-}pass}}$. Recall that as defined in Definition 4, $\mathbb{P}_{\mathsf{one\text{-}pass}}$ takes a single pass over the input graph streaming without knowing the starting vertex u_{start}, and $\mathbb{S}_{\mathsf{one\text{-}pass}}$ takes the output of $\mathbb{P}_{\mathsf{one\text{-}pass}}$ together with u_{start}, and outputs a desired sample fo the random walk.

Algorithm 1 Preprocessing phase of $\mathbb{A}_{\text{one-pass}}$: $\mathbb{P}_{\text{one-pass}}(G, \tau, V_{\text{full}})$.

Input: One pass streaming access to a directed graph $G = (V, E)$. A parameter $\tau \in \mathbb{N}$. A subset $V_{\text{full}} \subseteq V$, and we also let $V_{\text{samp}} = V \setminus V_{\text{full}}$.

1: For each vertex $v \in V_{\text{full}}$, we record all its out-neighbors in the list L_v^{save}. (That is, V_{full} stands for the set of vertices that we keep all its edges.)

2: For each vertex $v \in V_{\text{samp}}$, using Corollary 13, we sample τ of its out-neighbors uniformly at random with replacement in the list L_v^{save}. (That is, V_{samp} stands for the set of vertices that we sample some of its edges.)

3: For a big enough constant $c_2 > 1$, whenever the number of out-neighbors stored exceeds $c_2 \cdot \tau \cdot n$, the algorithm stops recording them. If this happens, we say the algorithm *operates incorrectly* and otherwise we say it *operates correctly*.

Output: A collection of lists $\vec{L}^{\text{save}} = \{L_v^{\text{save}}\}_{v \in V}$.

Algorithm 2 Sampling phase of $\mathbb{A}_{\text{one-pass}}$: $\mathbb{S}_{\text{one-pass}}(V, u_{\text{start}}, L, V_{\text{full}}, \vec{L}^{\text{save}} = \{L_v^{\text{save}}\}_{v \in V})$.

Input: A starting vertex u_{start}. The path length $L \in \mathbb{N}$. A subset $V_{\text{full}} \subseteq V$, and we also let $V_{\text{samp}} = V \setminus V_{\text{full}}$.

1: Let $v_0 = u_{\text{start}}$. For each $v \in V$, we set $k_v = 1$.
2: **for** $i \coloneqq 1 \to L$ **do**
3: **if** $v_{i-1} \in V_{\text{full}}$ **then**
4: v_i is set to be a uniformly random element from $L_{v_{i-1}}^{\text{save}}$
5: **else if** $k_{v_{i-1}} > |L_{v_{i-1}}^{\text{save}}|$ **then**
6: **return** failure
7: **else**
8: $v_i \leftarrow (L_{v_{i-1}}^{\text{save}})_{k_{v_{i-1}}}$.
9: $k_{v_{i-1}} \leftarrow k_{v_{i-1}} + 1$.
10: **end if**
11: **end for**

Output: The walk $(v_0, v_1, \ldots, v_L)$.

Analysis of the one-pass algorithm. Now we analyze the correctness of our one-pass algorithm. We first observe its space complexity can be easily bounded.

▶ **Observation 14** (Space complexity of $\mathbb{A}_{\text{one-pass}}$). *Given a directed graph $G = (V, E)$ with n vertices. For every $\tau \in \mathbb{N}$ and subset $V_{\text{full}} \subseteq V$, $\mathbb{P}_{\text{one-pass}}(G, \tau, V_{\text{full}})$ always takes at most $O(\tau \cdot n)$ words of space.*

Next we bound the statistical distance between its output distribution and the correct distribution of the random walk by the following lemma.

▶ **Lemma 15** (Correctness of $\mathbb{A}_{\text{one-pass}}$). *Given a directed graph $G = (V, E)$ with n vertices. For every integers $\tau, L \in \mathbb{N}$ and subset $V_{\text{full}} \subseteq V$ such that $\tau \cdot (n - |V_{\text{full}}|) + \sum_{v \in V_{\text{full}}} d_{\text{out}}(v) \leq c_2 \cdot \tau \cdot n$, let $\vec{\mathsf{L}}^{\text{save}}$ be random variable of the output of $\mathbb{P}_{\text{one-pass}}(G, \tau, V_{\text{full}})$. For every $u_{\text{start}} \in V$, the output distribution of $\mathbb{S}_{\text{one-pass}}(V, u_{\text{start}}, L, V_{\text{full}}, \vec{\mathsf{L}}^{\text{save}})$ has statistical distance β to $\mathsf{RW}_L^G(u_{\text{start}})$, where β is the probability that $\mathbb{S}_{\text{one-pass}}(V, u_{\text{start}}, L, V_{\text{full}}, \vec{\mathsf{L}}^{\text{save}})$ outputs failure.*

Proof. Conclude from $\tau \cdot (n - |V_{\mathsf{full}}|) + \sum_{v \in V_{\mathsf{full}}} d_{\mathsf{out}}(v) \leq c_2 \cdot \tau \cdot n$ that $\mathbb{P}_{\mathsf{one\text{-}pass}}(G, \tau, V_{\mathsf{full}})$ always operates correctly.

To bound the statistical distance between the distribution of $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, \vec{\mathsf{L}}^{\mathsf{save}})$ and $\mathsf{RW}_L^G(u_{\mathsf{start}})$. We construct another random variable $(\vec{\mathsf{L}}^{\mathsf{save}})'$, in which for every vertex u, we sample another L out-neighbors of u uniformly at random with replacement, and add them to the end of the list L_v^{save} in $\vec{\mathsf{L}}^{\mathsf{save}}$.

Note that $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, (\vec{\mathsf{L}}^{\mathsf{save}})')$ never outputs failure, and distributes exactly the same as $\mathsf{RW}_L^G(u_{\mathsf{start}})$. On the other hand, $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, (\vec{\mathsf{L}}^{\mathsf{save}})')$ and $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, \vec{\mathsf{L}}^{\mathsf{save}})$ are the same as long as $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, \vec{\mathsf{L}}^{\mathsf{save}})$ does not output failure, which completes the proof. ◀

The following corollary follows immediately from the lemma above. (Note that this special case exactly corresponds to the folklore one-pass streaming algorithm for simulating random walks.)

▶ **Corollary 16.** *Given a directed graph $G = (V, E)$ with n vertices and an integer $L \in \mathbb{N}$. Let $\vec{\mathsf{L}}^{\mathsf{save}}$ be random variable of the output of $\mathbb{P}_{\mathsf{one\text{-}pass}}(G, L, \emptyset)$. For every $u_{\mathsf{start}} \in V$, the output distribution of $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, \emptyset, \vec{\mathsf{L}}^{\mathsf{save}})$ distributes identically as $\mathsf{RW}_L^G(u_{\mathsf{start}})$.*

4.3 Two-Pass Streaming Algorithm for Simulating Random Walks

Description of the two-pass algorithm. Now we are ready to describe our two pass algorithm $\mathbb{A}_{\mathsf{two\text{-}pass}}$, which is also starting vertex oblivious, and can be described by the following two sub-routines $\mathbb{P}_{\mathsf{two\text{-}pass}}$ and $\mathbb{S}_{\mathsf{two\text{-}pass}}$.

Algorithm 3 Preprocessing phase of $\mathbb{A}_{\mathsf{two\text{-}pass}}$: $\mathbb{P}_{\mathsf{two\text{-}pass}}(G, L, \delta)$.

Input: A directed graph $G = (V, E)$ with n vertices. An integer $L \in \mathbb{N}$. A failure parameter $\delta \in (0, 1/n)$. We also let $\ell = \sqrt{L}$, and $\gamma = c_1 \cdot \log \delta^{-1}$ where $c_1 \geq 1$ is a sufficiently large constant to be specified later.

1: **First pass: estimation of heavy and light vertices.**

1. Run γ independent instances of $\mathbb{P}_{\mathsf{one\text{-}pass}}(G, \ell, \emptyset)$ and let $(L^{\mathsf{save}})^{(1)}, \ldots, (L^{\mathsf{save}})^{(\gamma)}$ be the corresponding collections of lists.
2. For each vertex $u \in V$, by running $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u, \ell, \emptyset, (L^{\mathsf{save}})^{(j)})$ for each $j \in [\gamma]$, we take γ independent samples from RW_ℓ^G. Let w_u be the fraction of these random walks that revisit u in ℓ steps.
3. Let $\widetilde{V}_{\mathsf{heavy}}$ be the set of vertices with $w_u \geq 0.5$, and $\widetilde{V}_{\mathsf{light}}$ be the set of vertices with $w_u < 0.5$.

2: **Second Pass: heavy-light edge recording**

1. Let $V_{\mathsf{full}} = \widetilde{V}_{\mathsf{heavy}}$.
2. Run $\mathbb{P}_{\mathsf{one\text{-}pass}}(G, \gamma \cdot \ell, V_{\mathsf{full}})$ to obtain a collection of lists $\vec{L}^{\mathsf{save}}$.

Output: The set V_{full} and the collection of lists $\vec{L}^{\mathsf{save}}$.

Algorithm 4 Sampling phase of $\mathbb{A}_{\mathsf{two\text{-}pass}}$: $\mathbb{S}_{\mathsf{two\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, \vec{L}^{\mathsf{save}} = \{L_v^{\mathsf{save}}\}_{v \in V})$.

Input: A starting vertex u_{start}. The path length $L \in \mathbb{N}$. A subset $V_{\mathsf{full}} \subseteq V$, and a collection of lists $\vec{L}^{\mathsf{save}}$.

Output: Simulate $\mathbb{S}_{\mathsf{one\text{-}pass}}(V, u_{\mathsf{start}}, L, V_{\mathsf{full}}, \vec{L}^{\mathsf{save}})$ and return its output.

Analysis of the algorithm. We first show that with high probability, $\widetilde{V}_{\mathsf{light}}$ and $\widetilde{V}_{\mathsf{heavy}}$ are subsets of V_{light} and V_{heavy} respectively.

▶ **Lemma 17.** *Given a directed graph $G = (V, E)$ with n vertices, $L \in \mathbb{N}$ and $\delta \in (0, 1/n)$, letting $\ell = \sqrt{L}$, with probability at least $1-\delta/2$ over the internal randomness of $\mathbb{P}_{\mathsf{two\text{-}pass}}(G, L, \delta)$, it holds that $\widetilde{V}_{\mathsf{light}} \subseteq V_{\mathsf{light}}$ and $\widetilde{V}_{\mathsf{heavy}} \subseteq V_{\mathsf{heavy}}$.*

Proof. Setting c_1 in Algorithm 3 to be a large enough constant and applying Corollary 16 and the Chernoff bound, with probability at least $1 - n \cdot \delta^3 \geq 1 - \delta/2$, $|w_u - \mathsf{visit}_{[1,\ell]}(u, u)| \leq 0.1$ for every $u \in V$. The lemma then follows from the definition of heavy and light vertices. ◀

Next, we show that with high probability, a random walk does not visit a light vertex too many times.

▶ **Lemma 18.** *Given a directed graph $G = (V, E)$ with n vertices, $L \in \mathbb{N}$ and $\delta \in (0, 1/n)$, letting $\ell = \sqrt{L}$ and $\gamma = c_1 \cdot \log \delta^{-1}$, where $c_1 > 1$ is the sufficiently large constant, for every vertex $u_{\mathsf{start}} \in V$ and vertex $v \in V^{\ell}_{\mathsf{light}}(G)$, an L-step random walk starting from u_{start} visits v more than $\gamma \cdot \ell$ times with probability at most $\delta/2n$.*

Proof. Suppose we have an infinite random walk W starting from u_{start} in G. Letting $\tau = \gamma\ell$, the goal here is to bound the probability that during the first L steps, W visits v more than τ times. We denote this as the bad event $\mathcal{E}_{\mathsf{bad}}$.

Let Z_i be the random variable representing the step at which W visits v for the i-th time (if W visits v less than i times in total, we let $\mathsf{Z}_i = \infty$). $\mathcal{E}_{\mathsf{bad}}$ is equivalent to that $\mathsf{Z}_{\tau+1} \leq L$.

$\mathsf{Z}_{\tau+1} \leq L$ further implies that for at least $(\tau - \ell)$ $i \in [\tau]$, $\mathsf{Z}_{i+1} - \mathsf{Z}_i \leq \ell$ and $\mathsf{Z}_i < \infty$. In the following we denote this event as $\mathcal{E}_1$ and bounds its probability instead.

For each $i \in [\tau]$, let Y_i be the random variable which takes value 1 if both $Z_i < \infty$ and $\mathsf{Z}_{i+1} - \mathsf{Z}_i \leq \ell$ hold, and 0 otherwise. Letting $\mathsf{Y}_{<i} = (\mathsf{Y}_1, \ldots, \mathsf{Y}_{i-1})$, the following claim is crucial for us.

▷ Claim 19. For every $i \in [\tau]$ and every possible assignments $Y_{<i} \in \{0, 1\}^{i-1}$, we have

$$\mathbb{E}[\mathsf{Y}_i | \mathsf{Y}_{<i} = Y_{<i}] \leq 2/3.$$

Proof. By the Markov property of the random walk, and noting that Y_i is always 0 when $\mathsf{Z}_i = \infty$, we have.

$$\begin{aligned}\mathbb{E}[\mathsf{Y}_i | \mathsf{Y}_{<i} = Y_{<i}] &= \sum_{j=0}^{\infty} \Pr[\mathsf{Z}_i = j | \mathsf{Y}_{<i} = Y_{<i}] \cdot \mathbb{E}[\mathsf{Y}_i | \mathsf{Y}_{<i} = Y_{<i}, \mathsf{Z}_i = j] \\ &= \sum_{j=0}^{\infty} \Pr[\mathsf{Z}_i = j | \mathsf{Y}_{<i} = Y_{<i}] \cdot \mathbb{E}[\mathsf{Y}_i | \mathsf{Z}_i = j].\end{aligned}$$

To further bound the quantity above, recall that the event $\mathsf{Z}_i = j$ means that the random walk W starting from u_{start} visits the light vertex v for the i-th time at W's j-th step, and we have

$$\mathbb{E}[\mathsf{Y}_i | \mathsf{Z}_i = j] = \Pr[\mathsf{Y}_i = 1 | \mathsf{Z}_i = j] = \Pr[\mathsf{Z}_{i+1} \leq j + \ell | \mathsf{Z}_i = j].$$

By the Markov property of the random walk W, $\Pr[\mathsf{Z}_{i+1} \leq j + \ell | \mathsf{Z}_i = j]$ equals the probability that a random walk starting from v revisits v in at most ℓ steps. By the definition of light vertices, we can bound that by $2/3$, which completes the proof. ◁

Then by the Azuma-Hoeffding inequality (Corollary 7),

$$\begin{aligned}\Pr_{\mathsf{W}}[\mathcal{E}_{\mathsf{bad}}] &\leq \Pr_{\mathsf{W}}[\mathcal{E}_1] \\ &= \Pr_{\mathsf{W}}\left[\sum_{i=1}^{\tau} \mathsf{Y}_i \geq (\tau - \ell)\right] \\ &\leq \exp(-\Omega(\tau - \ell - 2/3 \cdot \tau)) \leq \delta/2n,\end{aligned}$$

the last inequality follows from the fact that $\Omega(\tau - \ell - 2/3 \cdot \tau) = \Omega(\gamma)$, $\gamma = c_1 \cdot \log \delta^{-1}$ for a sufficiently large constant c_1, and $\delta \leq 1/n$. ◀

The correctness of the algorithm is finally completed by the following theorem.

▶ **Theorem 20** (Formal version of Theorem 1). *Given a directed graph $G = (V, E)$ with n vertices, $L \in \mathbb{N}$ and $\delta \in (0, 1/n)$. Let $\vec{\mathsf{L}}^{\mathsf{save}}$ and $\mathsf{V}_{\mathsf{full}}$ be the two random variables of the output of $\mathbb{P}_{\mathsf{two\text{-}pass}}(G, L, \delta)$. For every $u_{\mathsf{start}} \in V$, the following hold:*

- *The output distribution of $\mathbb{S}_{\mathsf{two\text{-}pass}}(V, u_{\mathsf{start}}, L, \mathsf{V}_{\mathsf{full}}, \vec{\mathsf{L}}^{\mathsf{save}})$ has statistical distance at most δ from $\mathsf{RW}_L^G(u_{\mathsf{start}})$.*
- *Both of $\mathbb{P}_{\mathsf{two\text{-}pass}}(G, L, \delta)$ and $\mathbb{S}_{\mathsf{two\text{-}pass}}(V, u_{\mathsf{start}}, L, \mathsf{V}_{\mathsf{full}}, \vec{\mathsf{L}}^{\mathsf{save}})$ use at most $O(n \cdot \sqrt{L} \cdot \log \delta^{-1})$ words of space.*

Proof. Note that we can safely assume $L \leq n^2$, since otherwise one can always use $O(n^2)$ words to store all the edges in the graph. In this case, we have that $L \leq n \cdot \sqrt{L}$ and the space for restoring the L-step output walk can be ignored.

Let $\widetilde{\mathsf{V}}_{\mathsf{heavy}} = \mathsf{V}_{\mathsf{full}}$ and $\widetilde{\mathsf{V}}_{\mathsf{light}} = V \setminus \widetilde{\mathsf{V}}_{\mathsf{heavy}}$. Let $\mathcal{E}_{\mathsf{good}}$ be the event that $\widetilde{\mathsf{V}}_{\mathsf{light}} \subseteq V_{\mathsf{light}}$ and $\widetilde{\mathsf{V}}_{\mathsf{heavy}} \subseteq V_{\mathsf{heavy}}$. By Lemma 17, we have that $\Pr[\mathcal{E}_{\mathsf{good}}] \geq 1 - \delta/2$.

Now we condition on the event $\mathcal{E}_{\mathsf{good}}$. In this case, it follows from Lemma 10 that $\mathbb{P}_{\mathsf{one\text{-}pass}}(G, \gamma \cdot \ell, \widetilde{\mathsf{V}}_{\mathsf{heavy}})$ operates correctly (by setting the constant c_2 in Algorithm 1 to be sufficiently large).

By Lemma 18 and a union bound, the probability of $\mathbb{S}_{\mathsf{two\text{-}pass}}(V, u_{\mathsf{start}}, L, \widetilde{\mathsf{V}}_{\mathsf{heavy}}, \vec{\mathsf{L}}^{\mathsf{save}})$ outputs failure is at most $\delta/2$. By Lemma 15, it follows that the statistical distance between the output distribution of $\mathbb{S}_{\mathsf{two\text{-}pass}}(V, u_{\mathsf{start}}, L, \widetilde{\mathsf{V}}_{\mathsf{heavy}}, \vec{\mathsf{L}}^{\mathsf{save}})$ and $\mathsf{RW}_L^G(u_{\mathsf{start}})$ is at most $\delta/2$.

The theorem follows by combing the above with the fact that $\Pr[\mathcal{E}_{\mathsf{good}}] \geq 1 - \delta/2$. ◀

4.4 Two-pass Streaming in the Turnstile Model

Similar to the algorithm in [27], our algorithms can also be easily adapted to work for the *turnstile graph streaming model*, where both insertions and deletions of edges are allowed. Note that our two-pass algorithm $\mathbb{A}_{\mathsf{two\text{-}pass}}$ only accesses the input graph stream via the one-pass preprocessing subroutine $\mathbb{P}_{\mathsf{one\text{-}pass}}$. Hence, it suffices to implement $\mathbb{P}_{\mathsf{one\text{-}pass}}$ in the turnstile model as well. There are two distinct tasks in $\mathbb{P}_{\mathsf{one\text{-}pass}}$: (1) for light vertices, we need to sample their outgoing neighbors with replacement and (2) for heavy vertices, we need to record all their outgoing neighbors.

Uniformly sampling via ℓ_1 sampler. For light vertices, uniformly sampling some out-neighbors from each vertex without replacement can be implemented via the following ℓ_1 sampler in the turnstile model.

▶ **Lemma 21** (ℓ_1 sampler in the turnstile model [24]). *Let $n \in \mathbb{N}$, failure probability $\delta \in (0, 1/2)$ and $f \in \mathbb{R}^n$ be a vector defined by a streaming of updates to its coordinates of the form $f_i \leftarrow f_i + \Delta$, where $\Delta \in \{-1, 1\}$. There is a randomized algorithm which reads the stream, and with probability at most δ it outputs FAIL, otherwise it outputs an index $i \in [n]$ such that:*

$$\Pr(i = j) = \frac{|f_j|}{\|f\|_1} + O(n^{-c}), \qquad \forall j \in [n]$$

where $c \geq 1$ is some arbitrarily large constant.

The space complexity of this algorithm is bounded by $O(\log^2(n) \cdot \log(1/\delta))$ bits in the random oracle model, and $O(\log^2(n) \cdot (\log\log n)^2 \cdot \log(1/\delta))$ bits otherwise.

▶ Remark 22. To get error in the statistical distance also to be at most δ, one can simply set n to be larger than $1/\delta$. And in that case the space complexity can be bounded by $O(\log^4(n/\delta))$.

Recording all outgoing neighbors via ℓ_1 heavy hitter. For heavy vertices, recording all their outgoing neighbors can be implemented using the following ℓ_1 heavy hitter in the turnstile model. (Recall that we assumed our graphs is a simple graph without multiple edges.)

▶ **Lemma 23** (ℓ_1 heavy hitter in the turnstile model [9]). *Let $n, k \in \mathbb{N}$, $\delta \in (0, 0.1)$ and $f \in \mathbb{R}^n$ be a vector defined by a streaming of updates to its coordinates of the form $f_i \leftarrow f_i + \Delta$, where $\Delta \in \{-1, 1\}$. There is an algorithm which reads the stream and returns a subset $L \subset [n]$ such that $i \in L$ for every $i \in [n]$ such that $|f_i| \geq \|f\|_1/k$ and $i \notin L$ for every $i \in [n]$ such that $|f_i| \leq \|f\|_1/2k$. The failure probability is at most δ, and the space complexity is at most $O(k \cdot \log(n) \cdot \log(n/\delta))$.*

Algorithm in the turnstile model. Modifying $\mathbb{P}_{\text{one-pass}}$ with Lemma 21 and Lemma 23, we can generalize our two-pass streaming algorithm to work in two-pass turnstile model.[7]

▶ Remark 24 (Two-pass algorithm in the turnstile model). There exists a streaming algorithm $\mathbb{A}_{\text{turnstile}}$ that given an n-vertex *directed* graph $G = (V, E)$ via a stream of both edge insertions and edge deletions, a starting vertex $u_{\text{start}} \in V$, a non-negative integer L indicating the number of steps to be taken, and an error parameter $\delta \in (0, 1/n)$, satisfies the following conditions:

1. $\mathbb{A}_{\text{turnstile}}$ uses at most $\widetilde{O}(n \cdot \sqrt{L} \cdot \log \delta^{-1})$ space and makes two passes over the input graph G.
2. $\mathbb{A}_{\text{turnstile}}$ samples from some distribution $\mathcal{D}$ over V^{L+1} satisfying $\|\mathcal{D} - \mathsf{RW}_L^G(u_{\text{start}})\|_{\text{TV}} \leq \delta$.

Abstract

The problem of sparsifying a graph or a hypergraph while approximately preserving its cut structure has been extensively studied and has many applications. In a seminal work, Benczúr and Karger (1996) showed that given any n-vertex undirected weighted graph G and a parameter $\varepsilon \in (0,1)$, there is a near-linear time algorithm that outputs a weighted subgraph G' of G of size $\tilde{O}(n/\varepsilon^2)$ such that the weight of every cut in G is preserved to within a $(1\pm\varepsilon)$-factor in G'. The graph G' is referred to as a $(1\pm\varepsilon)$-*approximate cut sparsifier* of G. Subsequent recent work has obtained a similar result for the more general problem of hypergraph cut sparsifiers. However, all known sparsification algorithms require $\Omega(n+m)$ time where n denotes the number of vertices and m denotes the number of hyperedges in the hypergraph. Since m can be exponentially large in n, a natural question is if it is possible to create a hypergraph cut sparsifier in time polynomial in n, *independent of the number of edges*. We resolve this question in the affirmative, giving the first sublinear time algorithm for this problem, given appropriate query access to the hypergraph.

Specifically, we design an algorithm that constructs a $(1\pm\varepsilon)$-approximate cut sparsifier of a hypergraph $H(V,E)$ in polynomial time in n, independent of the number of hyperedges, when given access to the hypergraph using the following two queries:

1. given any cut $(S,\bar{S})$, return the size $|\delta_E(S)|$ (*cut value queries*); and
2. given any cut $(S,\bar{S})$, return a uniformly at random edge crossing the cut (*cut edge sample queries*).

Our algorithm outputs a sparsifier with $\tilde{O}(n/\varepsilon^2)$ edges, which is essentially optimal. We then extend our results to show that cut value and cut edge sample queries can also be used to construct hypergraph *spectral sparsifiers* in poly(n) time, independent of the number of hyperedges.

We complement the algorithmic results above by showing that any algorithm that has access to only one of the above two types of queries can not give a hypergraph cut sparsifier in time that is polynomial in n. Finally, we show that our algorithmic results also hold if we replace the cut edge sample queries with a *pair neighbor sample query* that for any pair of vertices, returns a random edge incident on them. In contrast, we show that having access only to cut value queries and queries that return a random edge incident on a given single vertex, is not sufficient.

1 Introduction

In many applications, the underlying graphs are too large to fit in the main memory, and one typically builds a compressed representation that preserves relevant properties of the graph. Cuts in graphs are a fundamental object of study, and play a central role in the study of graph algorithms. Consequently, the problem of *sparsifying* a graph while approximately preserving its cut structure has been extensively studied (see, for instance, [17, 6, 18, 25, 1, 2, 13, 5, 3, 21, 15, 4, 16], and references therein). A cut-preserving sparsifier not only reduces the space requirement for any computation, but it can also reduce the time complexity of solving many fundamental cut, flow, and matching problems as one can now run the algorithms on the sparsifier which may contain far fewer edges. In a seminal work, Benczúr and Karger [6] showed that given any n-vertex undirected weighted graph G and a parameter $\varepsilon \in (0,1)$, there is a near-linear time algorithm that outputs a weighted subgraph G' of G of size $\tilde{O}(n/\varepsilon^2)$ such that the weight of every cut in G is preserved to within a multiplicative $(1\pm\varepsilon)$-factor in G'. The graph G' is referred to as the $(1\pm\varepsilon)$-*approximate cut sparsifier* of G.

In this work, we consider the problem of cut sparsification for hypergraphs. A hypergraph $H(V,E)$ consists of a vertex set V and a set E of hyperedges where each edge $e \in E$ is a subset of vertices. The rank of a hypergraph is the size of the largest edge in the hypergraph, that is, $\max_{e\in E}|e|$. Hypergraphs are a natural generalization of graphs and many applications require estimating cuts in hypergraphs (see, for instance, [8, 9, 14, 26]). Note that unlike graphs, an n-vertex hypergraph may contain exponentially many (in n) hyperedges. It is thus natural to ask if cut-preserving sparsifiers in the spirit of graph sparsifiers can also be created for hypergraphs as this would allow algorithmic applications to work with hypergraphs whose size is polynomially bounded in n.

Kogan and Krauthgamer [19] initiated a study of this basic question and showed that given any weighted hypergraph H, there is an $O(mn^2)$ time algorithm to find a $(1\pm\varepsilon)$-approximate cut sparsifier of H of size $\tilde{O}(\frac{nr}{\varepsilon^2})$ where r denotes the rank of the hypergraph. Similar to the case of graphs, the *size* of a hypergraph sparsifier refers to the number of edges in the sparsifier. Since r can be as large as n, in general, this gives a hypergraph cut sparsifier of size $\tilde{O}(n^2/\varepsilon^2)$, which is a factor of n larger than the Benczúr-Karger bound for graphs. Chekuri and Xu [10] designed a more efficient algorithm for building a hypergraph sparsifier. They gave a near-linear time algorithm in the total representation size (sum of the sizes of all hyperedges) to construct a hypergraph sparsifier of size $\tilde{O}(nr^2/\varepsilon^2)$ in hypergraphs of rank r, thus speeding up the run-time obtained in the work of Kogan and Krauthgamer [19] by at least a factor of n, but at the expense of an increased sparsifier size. Until recently, it was an open question if the Benczúr-Karger bound is also achievable on hypergraphs, that is, do there exist hypergraph sparsifiers with $\tilde{O}(n/\varepsilon^2)$ edges. In a very recent work [11], we were able to resolve this question in the affirmative by giving a $\tilde{O}(mn + n^{10}/\varepsilon^7)$ time algorithm for creating hypergraph sparsifiers of size $\tilde{O}(n/\varepsilon^2)$.

All known results for creating poly(n) size hypergraph sparsifiers have at least one thing in common – the running time of these algorithms has at least a linear dependence on both n and m. All known algorithms are essentially based on sampling edges in proportion to their importance, and they primarily differ in how the importance of an edge is defined and computed. A linear dependence on n is unavoidable since the hypergraph size itself is $\Omega(n)$.

However, since the number of hyperedges can be exponential in n, even a linear dependence on m means that the running time of a sparsification algorithm can be exponentially large in n in the worst-case. This motivates the following natural question: is there an algorithm for building a hypergraph sparsifier that runs in time that is polynomial in n? In other words, is there a sublinear time algorithm for creating hypergraph sparsifiers?

In order to tackle this question, we need to first define our model for accessing the input hypergraph $H = (V, E)$. The most basic requirement is to have the ability to efficiently evaluate the size or weight of any cut in a given hypergraph. We assume here access to a *cut value oracle*, denoted as O_{value}, which takes as input a cut $C = (S, \bar{S})$, returns the size of the cut $|\delta_H(S)|$. This is akin to the standard assumption in submodular function minimization, namely, the algorithm has an oracle access to the value of the submodular function on any set S since the cut function is a submodular function. However, as it turns out, it is easy to show that the access to a cut value oracle is provably not sufficient to construct a sparsifier, regardless of the time allowed as this oracle can not differentiate between hypergraphs where all edges have size 2 from hypergraphs where all edges have size 3[1]. So we also need a mechanism for accessing edges of the underlying graph. We thus introduce a second oracle, referred to as the *cut edge oracle*, denoted as O_{edge}, which takes as input a cut $C = (S, \bar{S})$, returns a random edge crossing the cut. Given access to both these oracles, we are indeed able to solve the problem of hypergraph sparsification in polynomial time in n.

▶ **Theorem 1.** *Suppose we are given an unweighted hypergraph $H = (V, E)$ that can be accessed using the oracles O_{value} and O_{edge}. Then for any $0 < \varepsilon < 1$, a $(1 \pm \varepsilon)$-approximate sparsifier with $\tilde{O}(n/\varepsilon^2)$ hyperedges can be constructed in $O(n^{10}/\varepsilon^7)$ time, independent of the number of hyperedges.*

At a high-level, graph and hypergraph sparsification algorithms work by estimating the importance of each edge in preserving cut sizes, and then sampling edges with probability proportional to their importance and assigning them an appropriately scaled weight. The main technical challenge in proving the above theorem is that the cut value oracle on the original graph cannot be used to estimate cut sizes in the vertex-induced subgraphs of the original graph – a step that is implicit in determining importance of edges in preserving the cut structure. This issue does not arise in normal graphs where each edge contains 2 vertices, and the cut value oracle on the original graph indeed suffices to recover cut values in any induced subgraph. But once we consider hypergraphs with even edges of size 3, it is easy to show that the cut value oracle on the original graph can not distinguish between induced subgraphs that have minimum cut value 0 and induced subgraphs where the minimum cut value is polynomially large. We refer the reader to Section 3 for a more detailed discussion of this. We get around this issue by introducing for any subset of vertices X, a weaker notion of *pseudo cut size* for approximating cut sizes in the subgraph induced by X. The new cut size function remains submodular, and we show that it suffices to approximate the importance of each edge to within a factor n of its true importance. We then use the O_{edge} oracle to sample edges in accordance with their approximate importance. The resulting sparsifier H' has poly(n) edges which we further sparsify to $\tilde{O}(n/\varepsilon^2)$ edges in poly(n) time by applying the result of [11] to H'.

[1] For instance, the cut value oracle can not distinguish between a copy of K_4 and the hypergraph that contains all possible hyperedges of size 3 on 4 vertices. Note that this does not rule out the possibility of efficiently constructing a data structure/sketch that can be used to answer cut queries. Our focus in this paper, however, is on constructing sparsifiers, namely, sparse subgraphs of the original graph that preserve all cuts.

We complement the algorithmic result above by showing that just like the oracle O_{value} alone is not sufficient to achieve the result above, the oracle O_{edge} alone is also not sufficient to create a poly(n) size hypergraph sparsifier in poly(n) time.

▶ **Theorem 2.** *There is no polynomial time randomized algorithm that can use O_{edge} queries alone to construct a $(1 \pm \varepsilon)$-approximate sparsifier of an underlying hypergraph H with probability better than $o(1)$.*

One may wonder if the oracle O_{edge} can be replaced with another access oracle that is used in sublinear algorithms for standard graphs, namely, ability to access the i_{th} neighbor of a vertex v for any integer i that is at most the degree of v. It is easy to see that this is essentially same as the ability to access a random edge incident on a vertex v. We can generalize this idea to the setting of hypergraphs as follows. A neighbor query oracle in a hypergraph takes as input a set $S \subseteq V$, and returns a random edge that contains all vertices in S if there is such an edge, and returns NIL if there is no edge. We say that a neighbor query is a *single vertex neighbor query* if $|S| = 1$, and it is a *vertex pair neighbor query* if $|S| = 2$. We denote the oracles that answer a single vertex neighbor query and a vertex pair neighbor query as O^1_{nbr} and O^2_{nbr} respectively. We next show that the oracle O_{edge} can be replaced with the oracle O^2_{nbr}, to obtain an alternate poly(n) time implementation of the result in Theorem 1.

▶ **Theorem 3.** *Given an unweighted hypergraph $H = (V, E)$, suppose the algorithm can access the hypergraph using O_{value} and O^2_{nbr}, then for any $0 < \varepsilon < 1$, a $(1 \pm \varepsilon)$-approximate sparsifier with $\tilde{O}(n/\varepsilon^2)$ hyperedges can be constructed in $O(n^1 0/\varepsilon^7)$ time in n, independent of the number of hyperedges.*

In contrast to the result above, we show any algorithm that has access only to oracles O_{value} and O^1_{nbr}, requires exponentially many queries in the worst-case to construct a poly(n) size sparsifier.

▶ **Theorem 4.** *There is no polynomial time randomized algorithm that can use O_{value} and O^1_{nbr} queries alone to construct a $(1 \pm \varepsilon)$-approximate sparsifier of an underlying hypergraph H with probability better than $o(1)$.*

Hypergraph Spectral Sparsification. We also consider the problem of hypergraph spectral sparsification, a notion that strengthens cut sparsification. A $(1 \pm \varepsilon)$-approximate *spectral sparsifier* of a graph $G(V, E)$ is a weighted graph $G'(V, E')$ such that for every vector $x \in \mathbb{R}^n$, we have

$$|x^T L_{G'}\ x - x^T L_G\ x| \leq \varepsilon(x^T L_G\ x),$$

where L_G and $L_{G'}$ denote the Laplacian matrices of G and G', respectively. To see that the notion of spectral sparsifier only strengthens the notion of a cut sparsifier, observe that the cut sparsification requirement for any cut $(S, \bar{S})$ is captured by the definition above when we choose x to be the 0/1-indicator vector of the set S. Batson, Spielman, and Srivastava [5] gave a polynomial-time algorithm that for every graph G, gives a weighted graph G' with $O(n/\varepsilon^2)$ edges such that G' is a $(1 \pm \varepsilon)$-approximate spectral sparsifier of G. Subsequently, Lee and Sun [21] gave an $O(m/\varepsilon^{O(1)})$ time algorithm to construct a spectral graph sparsifier with $O(n/\varepsilon^2)$ edges.

The notion of spectral sparsification can be extended to hypergraphs [22, 27] as follows. The *Laplacian* L_H of a hypergraph H is a function $\mathbb{R}^n \to \mathbb{R}^n$, such that for any n-dimensional vector x, we have

$$x^T L_H(x) = \sum_{e \in E} w(e) \max_{u,v \in e} (x(u) - x(v))^2.$$

Given a weighted hypergraph H with n vertices, a $(1 \pm \varepsilon)$-spectral sparsifier H' is a subgraph of H such that for any n-dimensional vector x, we have

$$(1 - \varepsilon) x^T L_{H'}(x) \leq x^T L_H(x) \leq (1 + \varepsilon) x^T L_{H'}(x).$$

Soma and Yoshida [23] give a polynomial-time algorithm that outputs a weighted spectral sparsifier with $\tilde{O}(n^3)$ hyperedges. The algorithm of [23] is also based on sampling edges based on a suitable notion of importance, and in their work, the importance of a hyperedge e is measured by $\min_{u,v \in e} |E(\{u, v\})|$ where $E(\{u, v\})$ is the set of edges that contains both u and v. If we assume access to the underlying hypergraph using O^2_{nbr} queries, then we can sample a random hyperedge in $E(\{u, v\})$ for any pair of vertices u and v, which makes it in turn straightforward to simulate the algorithm of [23].

▶ **Theorem 5.** *Given an unweighted hypergraph $H = (V, E)$, suppose the algorithm can access the hypergraph using O_{value} and O^2_{nbr} queries. Then for any $0 < \varepsilon < 1$, a $(1 \pm \varepsilon)$-spectral sparsifier with $\tilde{O}(n^3/\varepsilon^2)$ hyperedges can be constructed in polynomial time in n, independent of the number of hyperedges.*

The more interesting case is when we can only access the hypergraph using O_{value} and O_{edge} queries. It is now provably impossible to get a handle on $|E(\{u, v\})|$ using only polynomially many queries, and thus there is no direct way to simulate the algorithm in [23]. Recently, Bansal, Svensson, and Trevisan [4] designed another hypergraph spectral sparsification algorithm that in polynomial-time algorithm creates a weighted spectral sparsifier with $\tilde{O}(nr^3)$ hyperedges; here r denotes the maximum arity of any hyperedge. Unlike the algorithm of [23], their measure of importance of a hyperedge is derived from an auxiliary standard graph created by converting every hyperedge into a clique. The importance of a hyperedge is then given by the maximum effective resistance among all the edges in the clique associated with that hyperedge. We show that we can simulate this process using only $\text{poly}(n)$ many O_{value} and O_{edge} queries.

▶ **Theorem 6.** *Given an unweighted hypergraph $H = (V, E)$, suppose the algorithm can access the hypergraph using only O_{value} and O_{edge} queries. Then for any $0 < \varepsilon < 1$, a $(1 \pm \varepsilon)$-spectral sparsifier with $\tilde{O}(n^3/\varepsilon^2)$ hyperedges can be constructed in polynomial time in n, independent of the number of hyperedges.*

The idea is to associate the strength of a hyperedge with the resistance of the edges inside the clique associated with this hyperedge. We first show that in any standard graph the effective resistance of an edge f is at most n/k_f where k_f denote the strength of the edge f. We then show that the strength of a hyperedge e is at most the strength of any edge in the clique associated with the hyperedge e. With this pair of relationships, we are able to simulate the algorithm in [4] by the algorithm in Theorem 1, except that we will sample somewhat larger number of hyperedges to meet the sampling probability requirement for the sparsification algorithm in [4].

Note that unlike hypergraph cut sparsification which is now well-understood [11], the problem of determining the optimal size of a hypergraph spectral sparsifier is still open. However, note that any further improvements on the size of hypergraph spectral sparsifiers can be used in a black-box manner with our sparsification algorithms – we can simply apply the improved sparsification algorithm to the sparsifier generated by our algorithm.

Finally, we note that since any spectral sparsifier is also a cut sparsifier, the lower bounds in Theorem 2 and Theorem 4 also hold for spectral sparsifiers.

Extension to weighted hypergraphs. All our algorithmic results stated thus far are for sparsifying unweighted hypergraphs. We note that all algorithms can be extended in a straightforward manner to sparsifying weighted hypergraphs assuming natural weighted versions of the access oracles used in proving these results. Specifically, it suffices to assume that the oracle O_{value} returns the *weight* of a cut, and the oracles O_{edge} and O^2_{nbr} return an edge with probability *proportional to its weight*.

Organization. We set up our notation and state some useful background results in Section 2. In Section 3, we give a poly(n) time algorithm for creating a $\tilde{O}(n/\varepsilon^2)$ size sparsifier using the cut value and cut edge sample oracles, proving Theorem 1. In Section 4, we give a poly(n) time algorithm for creating a $\tilde{O}(n/\varepsilon^2)$ size sparsifier using the cut value and the vertex pair neighbor oracles, proving Theorem 3. Then in Section 5, we present poly(n) time algorithms for hypergraph spectral sparsification proving Theorems 5 and 6. We show in Section 6 that any weakening of the oracles assumed in Theorems 1 and 3 necessarily requires worst-case exponential time for creating a poly(n) size hypergraph cut sparsifier, proving Theorems 2 and 4. In Section 7, we briefly describe how the results of Theorems 1 and 3 can be extended to weighted hypergraphs. Finally, we conclude in Section 8 with some directions for future work.

2 Preliminaries

2.1 Notation

Given an integer n and a probability p, let $B(n,p)$ be the Bernoulli distribution with n trials where each trial succeeds with probability p. Suppose a set has n elements, and given a probability p. Then the following process will sample each element in the set with probability p: we first sample a number $N \sim B(n,p)$, then randomly sample N elements in the set.

Given any weight function $w : S \to \mathbb{R}_{\geq 0}$, we extend it to also be a function on subsets of S so that $w(S') = \sum_{e \in S'} w(e)$ for $S' \subseteq S$.

Given a graph $H = (V, E)$ and a subset of vertices $V' \subseteq V$, we define $G[V']$ to be the weighted subgraph/subhypergraph of G induced by the vertices in V'. We identify an edge/hyperedge e with the set of vertices that are contained in e. A hyperedge e has *rank* k *if* $|e| = k$. *The* rank of a hypergarph is the maximum rank of its hyperedges.

Given a weighted hypergraph $H = (V, E, w)$ and a cut $C = (S, \bar{S})$, we say an edge e crosses the cut if $e \cap S \neq \emptyset$ and $e \cap \bar{S} \neq \emptyset$. We denote by $\delta_H(S)$ the set of the edges crossing the cut C in H. By definition, $|\delta_H(S)|$ is the number of edges crossing C and $w(\delta_H(S))$ is the weight of C. For any $\varepsilon > 0$, a $(1 \pm \varepsilon)$-*approximate cut sparsifier* of H is a hypergraph $H' = (V, E', w')$ with $E' \subseteq E$ such that

$$\forall S \subseteq V, \quad |w'(\delta_{H'}(S)) - w(\delta_H(S))| \leq \varepsilon w(\delta_H(S)).$$

Given a weighted normal graph G with n vertices, the *Laplacian* $L_G \in \mathbb{R}^{n\times n}$ is defined as follows: for any u, $L_G(u,u)$ is the total weight edges incident on u, and for any $u \neq v$, $L_G(u,v)$ is minus the weight of edges between u and v. For any n-dimensional vector $x \in \mathbb{R}^n$, $x^T L_G x = \sum_{(u,v)\in e} w(e)(x(u)-x(v))^2$. A $(1\pm\varepsilon)$-spectral sparsifier G' is a subgraph of G such that for any vector x,

$$(1-\varepsilon)x^T L_{G'} x \leq x^T L_G x \leq (1+\varepsilon)x^T L_{G'} x.$$

The notion of spectral sparsification can be extended to hypergraphs as follows. The *Laplacian* L_H of a hypergraph H is a function $\mathbb{R}^n \to \mathbb{R}^n$, such that for any n-dimensional vector x, we have

$$x^T L_H(x) = \sum_{e\in E} w(e) \max_{u,v\in e}(x(u)-x(v))^2.$$

Given a weighted hypergraph H with n vertices, a $(1\pm\varepsilon)$-spectral sparsifier H' is a subgraph of H such that for any n-dimensional vector x, we have

$$(1-\varepsilon)x^T L_{H'}(x) \leq x^T L_H(x) \leq (1+\varepsilon)x^T L_{H'}(x).$$

2.2 Hypergraph Cut Sparsification

In this section, we review some important concepts and results of hypergraph cut sparsification.

Given a weighted hypergraph $H=(V,E,w)$, a *k-strong component* of H is a maximal induced subgraph of G that has minimum cut at least k. For any edge e, the *strength* of e, denoted by k_e, in H is the maximum value of k such that e is *fully* contained in a k-strong component of H. Alternatively, the strength of an edge $e \in E$ is the largest minimum cut size among all induced subgraphs $H[X]$ that contain e, where X ranges over all subsets of V. The sum of w_e/k_e is at most $n-1$.

▶ **Lemma 7** ([19]). *Given a weighted hypergraph $H=(V,E,w)$, we have $\sum_{e\in E} w_e/k_e \leq n-1$.*

Benczúr and Karger [6, 7] showed that when we are dealing with a normal graph where each edge contains exactly two vertices, if we sample each edge e independently with probability $p_e = O(\log n/\varepsilon^2 k_e)$, and give it weight $1/p_e$ if sampled, then the resulting graph will be a $(1\pm\varepsilon)$-approximate cut sparsifier of G with high probability.

Kogan and Krauthgamer [19] generalized this approach to hypergraphs. They showed that given a hypergraph $H=(V,E)$ with rank r, for each hyperedge e, if we sample e with probability $p_e = O((\log n + r)/\varepsilon^2 k_e)$, and has weight $1/p_e$ if get sampled, the resulting graph will be a cut sparsifier of H with high probability.

▶ **Theorem 8** ([19]). *Let H be a hypergraph with rank r, and let $\varepsilon > 0$ be an error parameter. Consider the hypergraph H' obtained by sampling each hyperedge e in H independently with probability $p_e = \min\{1, \frac{3((d+2)\log n + r)}{k_e \varepsilon^2}\}$, giving it weight $1/p_e$ if included. Then with probability at least $1 - O(n^{-d})$*

1. *the hypergraph H' has $O(\frac{n}{\varepsilon^2}(r+\log n))$ edges, and*
2. *H' is a $(1\pm\varepsilon)$-approximate cut sparsifier of H.*

In fact, if for each edge e, the sampling proability p_e is at least $\frac{3((d+2)\log n + r)}{k_e\varepsilon^2}$, then the resulting graph is still a $(1\pm\varepsilon)$-approximate cut sparsifier. This is because in the proof of Theorem 8, the authors showed that each cut has a very small probability that the cut size

in H' is not within a factor of $(1 \pm \varepsilon)$ of the cut size in H, and the probability that there is no such cut is also very small by taking a union bound over all possible cuts. To bound the probability that a cut has a similar size in H' and H, the authors use the Chernoff bound. However, we can also use the following concentration bound to prove the same result.

▶ **Lemma 9** (Theorem 2.2 in [12]). *Let $\{x_1, \ldots, x_k\}$ be a set of random variables, such that for $1 \leq i \leq k$, each x_i independently takes value $1/p_i$ with probability p_i and 0 otherwise, for some $p_i \in [0, 1]$. Then for all $N \geq k$ and $\varepsilon \in (0, 1]$,*

$$\Pr\left(\left|\sum_{i\in[k]} x_i - k\right| \geq \varepsilon N\right) \leq 2e^{-0.38\varepsilon^2 \cdot \min_i p_i \cdot N}$$

So if we replace the probability of sampling an edge e with $q_e \geq p_e$, the concentration bound in Lemma 9 still holds. In other words, if we sample according to q_e then the probability that each cut in the sampled graph H' has size close to the cut size in H is at least as large as the probability when edges are sampled according to p_e.

▶ **Lemma 10.** *Let H be a hypergraph with rank r, and let $\varepsilon > 0$ be an error parameter. Consider the hypergraph H' obtained by sampling each hyperedge e in H independently with probability $p_e \geq \min\{1, \frac{3((d+2)\log n + r)}{k_e \varepsilon^2}\}$, giving it weight $1/p_e$ if included. Then with probability at least $1 - O(n^{-d})$, H' is a $(1 \pm \varepsilon)$-approximate cut sparsifier of H.*

Recently, [11] showed that for every n-vertex hypergraph, there is a $(1 \pm \varepsilon)$-approximate cut sparsifier with $\tilde{O}(n)$ edges. Moreover, this sparsifier can be constructed in polynomial time in the number of vertices and the number of hyperedges.

▶ **Theorem 11** ([11]). *Given a weighted hypergraph H, for any $0 < \varepsilon < 1$, there exists an randomized algorithm that constructs a $(1 \pm \varepsilon)$-approximate cut sparsifier of H with $O(\frac{n \log n}{\varepsilon^2})$ hyperedges in $O(mn + n^{10}/\varepsilon^7)$ time with high probability.*

2.3 Hypergraph Spectral Sparsification

In this section, we review some important concepts and results on spectral sparsification in both normal graphs and hypergraphs.

Given a weighted normal graph G, the *effective resistance* r_e of an edge $e = (u, v)$ is defined to be the electrical effective resistance between u and v if we view G as a electrical network on n nodes in which each edge e corresponds to a resistor with conductance $w(e)$.

Spielman and Srivastava [24] showed that given an unweighted graph G, if we sample each edge e independently with probability $p_e = O(r_e \log n/\varepsilon^2)$ and give it a weight of w_e/p_e if sampled, then the resulting graph is a $(1 \pm \varepsilon)$-spectral sparsifier.

In the case of hypergraphs, Soma and Yoshida [23] showed that if we sample each hyperedge e with probability proportional to $n \log n/(\varepsilon^2 \min_{u,v\in e} |E(\{u, v\})|)$ where $E(\{u, v\})$ is the set of hyperedges that contains both u and v, then the resulting graph is a $(1 \pm \varepsilon)$-spectral sparsifier.

▶ **Theorem 12** ([23]). *Given an unweighted hypergraph H, if we sample each edge e with probability $p_e = \min\{1, \frac{Cn \log n}{\varepsilon^2 \min_{u,v\in e} |E(\{u,v\})|}\}$ where C is a universal constant, and give weight $1/p_e$ if sampled, then the resulting hypergraph H' is a $(1 \pm \varepsilon)$-spectral sparsifier of H with high probability. The sparsifier has $\tilde{O}(n^3/\varepsilon^2)$ hyperedges. The running time of this algorithm is $\tilde{O}(mn^2 + m + n^3/\varepsilon^2)$.*

Bansal et al. [4] take a different approach to hypergraph spectral sparsification. For any hypergraph H, define the auxiliary graph G_H as a normal graph that is obtained by, for each hyperedge e, transforming e into a clique F_e over the vertices in e. For any hyperedge e, we now define $r_e = \max_{f \in F_e} r_f$. Bansal et al. showed that if we sample each hyperedge e with probability proportional to $r^4 r_e \log n/\varepsilon^2$ where r is the maximum size of any hyperedge in H, then the resulting graph is a $(1 \pm \varepsilon)$-spectral sparsifier.

▶ **Theorem 13** ([4]). *Given an unweighted hypergraph H, if we sample each edge e with probability $p_e = \min\{1, \frac{Cr^4 r_e \log n}{\varepsilon^2}\}$ where C is a universal constant, and assign it weight $1/p_e$ if sampled, then the resulting hypergraph H' is a $(1 \pm \varepsilon)$-spectral sparsifier of H with high probability. The sparsifier has $\tilde{O}(nr^3/\varepsilon^2)$ hyperedges.*

Similar to the case of Theorem 8, Theorem 12 and Theorem 13 both work when we sample each edge with a probability $q_e \geq p_e$ instead of p_e and give weight $1/q_e$ if sampled.

2.4 Minimizing a Submodular Function Using Value Queries

A set function $f : 2^\Omega \to \mathbb{R}$ is a *submodular function* if for every $S, T \subseteq \Omega$, $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$. Given a graph/hypergraph, for any vertex set S, the cut function $f(S)$, defined as the weight of edges crossing cut $(S, \bar{S})$ is easily shown to be submodular. There is an algorithm that for any submodular function f finds a set S that minimizes the value of function f using $\tilde{O}(n^3)$ value queries and in $\tilde{O}(n^4)$ time.

▶ **Theorem 14** ([20]). *There is an algorithm for submodular function minimization with $O(n^3 \log^2 n)$ value queries and $O(n^4 \log^{O(1)} n)$ time where n is the size of the ground set.*

3 Sublinear Time Cut Sparsification with Cut Size and Cut Edge Sampling Queries

We now present an algorithm that, given access to a hypergraph H through cut size queries (oracle O_{value}) and queries to sample a random edge crossing a cut (oracle O_{edge}), outputs a $(1 \pm \varepsilon)$-approximate sparsifier with $\tilde{O}(n/\varepsilon^2)$ hyperedges in poly(n) time. At a high-level, our algorithm will first create a poly(n) size sparsifier H_1 by indirectly implementing the algorithm underlying Theorem 8. We then use the algorithm in Theorem 11 to construct a sparsifier H_2 of H_1 which has $\tilde{O}(n/\varepsilon^2)$ hyperedges. By the definition of cut sparsifier, H_2 is also a cut sparsifier of H. We can thus focus on the construction of the sparsifier H_1.

The primary challenge in simulating the algorithm of Theorem 8 is to sample edges according to their strength with a small number of queries. Consider the following recursive algorithm. We start with the graph H, and then at each step, we find the minimum cut of the connected graph, and sample $\Theta((r + \log n)/\varepsilon^2)$ edges from the cut. We then recursively execute this algorithm on each side of the cut. Algorithm 1 gives an implementation of this idea.

It is easy to see that this algorithm samples each edge independently, and that the sampling probability is at least that of Kogan-Krauthgamer in Theorem 8. The challenge is that unlike cut queries in the normal graph, it is hard to compute the cut size in an induced subgraph of a hypergraph using only cut queries on the original graph, which is crucial as the algorithm proceeds recursively.

We first note that this task is straightforward to do in graphs where each edge has exactly two vertices. For any two disjoint subsets of vertices S, T, the number of edges in $S \times T$ is $\frac{1}{2}(|\delta(S)| + |\delta(T)| - |\delta(S \cup T)|)$.

Algorithm 1 Sampling edges with probability proportional to their strength.

Input : A subset of vertices $V' \subseteq V$.

Let $(S, \bar{S})$ be a minimum cut of the induced graph $G[V']$;
Let c be the number of edges crossing $(S, \bar{S})$ in $G[V']$;
Sample an integer $N \sim B(c, \frac{10(\log n + r)}{\epsilon^2 c})$;
Sample N edges from $\delta_{G[V']}(S)$ uniformly at random, and assign each of them a weight of $\frac{\epsilon^2 c}{10(\log n + r)}$;
Delete all edges in $\delta_{G[V']}(S)$ and recurse on each of the newly created connected components;

However, this is far from true in the hypergraph setting. The problem is that there may be some hyperedges that intersect with each of S, T, and $V \setminus (S \cup T)$. These edges are inside all of $\delta(S)$, $\delta(T)$ and $\delta(S \cup T)$. We have

$$\begin{aligned}
&|\delta(S)| + |\delta(T)| - |\delta(S \cup T)| \\
=&2\left|\{e | e \cap S \neq \emptyset, e \cap T \neq \emptyset, e \cap (\overline{S \cup T}) = \emptyset\}\right| + \left|\{e | e \cap S \neq \emptyset, e \cap T \neq \emptyset, e \cap (\overline{S \cup T}) \neq \emptyset\}\right| \\
=&|\{e | e \cap S \neq \emptyset, e \cap T \neq \emptyset\}| + \left|\{e | e \cap S \neq \emptyset, e \cap T \neq \emptyset, e \cap (\overline{S \cup T}) = \emptyset\}\right|
\end{aligned}$$

▶ **Example 15.** Consider a hypergraph H that consists of three equal size sets of vertices A, B, C, such that each hyperedge has a non-empty intersection with each of A, B, and C. Then there are no hyperedges in $H[A \cup B]$. But the quantity $\frac{1}{2}(|\delta(A)| + |\delta(B)| - |\delta(A \cup B)|)$ is half the total number of hyperedges which could be exponentially large in n.

▶ **Example 16.** Consider the following pair of hypergraphs on 4 vertices, say $\{v_1, v_2, v_3, v_4\}$: the graph H_1 is a (rank 2) clique on 4 vertices while the graph H_2 contains every possible edge of size 3 on these 4 vertices. It is easy to verify that the answer to every cut query is the same on the graphs H_1 and H_2. Now consider the subgraph of these graphs induced by the vertices $X = \{v_1, v_2\}$. In case of H_1, the minimum cut in the induced subgraph is 1 while in H_2, the minimum cut in the graph induced by X is 0. We can amplify this gap to 0 versus $\Omega(n)$ by taking $n/4$ copies of H_1 in one case, and $n/4$ copies of H_2 in the other case, and defining X to be union of arbitrarily chosen pairs of vertices from each copy. This means that O_{value} queries can not be used to estimate cut size in induced subgraphs to any multiplicative factor or to better than a polynomial additive error.

To get around the challenge highlighted by examples above, we next introduce notions of *pseudo cut size* over a subset of vertices and *pseudo strength* of hyperedges, such that the pseudo cut sizes are easy to compute by cut queries and pseudo strength of any hyperedge is at most a factor n larger than the strength of the hyperedge. We develop these ideas in detail in the next subsection.

3.1 Pseudo Cuts and Pseudo Strengths

Given a set of vertices X, we define $\Delta_X(S)$, the *pseudo cut* size of a set $S \subset X$ as $\frac{1}{2}(|\delta(S)| + |\delta(X \setminus S)| - |\delta(X)|)$, and define the *pseudo min cut* over X as a cut $(S, X \setminus S)$ that minimizes $\Delta_X(S)$. Note that $\Delta_X(S)$ is at most the number of edges that intersect both S and $X \setminus S$. The following lemma shows that $\Delta_X(S)$ is a submodular function, so we can compute the pseudo min cut over any vertex set in $\text{poly}(n)$ time by Theorem 14.

▶ **Lemma 17.** *For any vertex set $X \subseteq V$, $\Delta_X(S)$ is a submodular function.*

Proof. Let $f_1(S)$ be the number of edges that intersect both S and $X \setminus S$, and let $f_2(S)$ be the number of edges that intersect both S and $X \setminus S$ but are fully contained in X. By definition, we have $\Delta_X(S) = \frac{1}{2}(f_1(S) + f_2(S))$, so to prove that $\Delta_X(S)$ is a submodular function, it is sufficient to prove that both f_1 and f_2 are submodular.

Since f_2 is the cut function in the induced graph $H[X]$, it is submodular. In fact, f_1 is also the cut function of the hypergraph whose vertex set is X and edge set is $\{e \cap X | e \in E\}$. So f_1 is also a submodular function. ◀

For any edge e, we define the *pseudo strength* k'_e as the largest pseudo min-cut size among all sets X that contain e, where X ranges over all subsets of V. It is easy to see that for any edge e, k'_e is at least k_e since for any set of vertices X, the minimum cut size of $H[X]$ is at most the pseudo min-cut size of set X. More interestingly, although Example 15 showed that the pseudo min-cut size of a set X may be arbitrarily larger than the minimum cut size of $H[X]$, the lemma below shows that the pseudo strength of an edge is at most a factor n larger than its strength.

▶ **Lemma 18.** *For any edge e, $k'_e \leq nk_e$.*

Proof. Let X be any set of vertices that contains the edge e and has pseudo min-cut size k'_e in H. To prove the lemma, it is sufficient to prove that the pseudo min-cut size of X in H is at most nk_e.

Let $Y = V$ and $E_c = \emptyset$. Consider the following iterative process: we find the minimum cut $(S, Y \setminus S)$ in $H[Y]$. If either S or $Y \setminus S$ fully contains the set X, we add all edges crossing the cut into E_c, and set Y to be S or $Y \setminus S$ (whichever fully contains X), and repeat. Otherwise, we stop the process.

After the process terminates, suppose $(S, Y \setminus S)$ is the minimum cut in $H[Y]$. Since the process terminated, $(S, Y \setminus S)$ must partition X. Let $S' = S \cap X$, and consider the pseudo cut $(S', X \setminus S')$. We prove that the number of edges in H that intersect both S' and $X \setminus S'$ (which is an upper bound on $\Delta_X(S')$) is at most nk_e.

First, note that no edge e' such that $e' \not\subseteq Y$ and $e' \notin E_c$ can intersect with the set Y; hence any such edge e' also does not intersect with S' or $X \setminus S'$. Therefore every edge that intersects with both S' and $X \setminus S'$ either belongs to E_c or is completely contained in Y. During the iterative process, the set Y always fully contains e, so by the definition of strength, the minimum cut size of $H[Y]$ is at most k_e. This implies during each step, at most k_e edges are added into E_c. On the other hand, the process repeats at most $n - 2$ times, since each time the size of Y is reduced by at least 1. So $|E_c| \leq (n-2)k_e$. Finally, any edge that is fully contained in Y and intersects with both S' and $X \setminus S'$ crosses the cut $(S, Y \setminus S)$ in $H[Y]$, and the number of such edges is at most the minimum cut size of $H[Y]$, which is at most k_e. So in total, there are at most $|E_c| + k_e \leq (n-1)k_e$ edges that intersect both S' and $X \setminus S'$. ◀

3.2 Sampling the Edges

We are now ready to present an algorithm that uses the cut size queries and cut edge sample queries to sample each edge with probability inversely proportional to its strength. Specifically, we will ensure that each edge e gets sampled with probability at least n^2/k'_e which is at least n/k_e by Lemma 18. The algorithm is similar to Algorithm 1, but uses pseudo cuts and pseudo strengths instead. To sample the edges, we call Algorithm 2 on set V.

Algorithm 2 Sampling edges with probability proportional to their pseudo strength.

Input : A subset of vertices $V' \subseteq V$
1 Find the pseudo min-cut $(S, V' \setminus S)$ within the set V';
2 Let c be $|\delta(S)|$, the cut size of $(S, V \setminus S)$;
3 Sample an integer $N \sim B(c, \min\{1, \frac{10n^3}{\epsilon^2 c}\})$;
4 Keep sampling edges in cut $(S, \bar{S})$ until we get N different hyperedges. ;
5 Recurse on both S and $V' \setminus S$;

We now prove that each edge gets sampled with probability at least as large as the sampling probability in Theorem 8. Fix an edge e, let S_1 be the last input set that fully contains e. For any $i \geq 1$, if S_i is not V, we define S_{i+1} to be the input set in the recursion that generates a recursive call of the algorithm on the set S_i. In other word, $(S_i, S_{i+1} \setminus S_i)$ is the pseudo min cut within set S_{i+1}. Let $(S_0, S_1 \setminus S_0)$ be the pseudo min cut within S_1, by definition, $e \cap S_0 \neq \emptyset$ and $e \cap S_1 \setminus S_0 \neq \emptyset$. When the algorithm works on set S_1, e gets sampled with probability $\min\{1, \frac{10n^3}{\varepsilon^2 |\delta(S_0)|}\}$. If e gets sampled with probability 1, then it is clearly as large as the probability in Theorem 8. Otherwise we need to prove that $n^3/|\delta(S_0)| = \Omega((\log n + r)/k_e)$. Since $n = \Omega(\log n + r)$, by Lemma 18, it is sufficient to prove that $|\delta(S_0)| \leq nk'_e$.

▶ **Lemma 19.** $|\delta(S_0)| \leq nk'_e$.

Proof. We partition the edges crossing the cut $(S_0, \overline{S_0})$ into sets $E_1, E_2, \ldots$ such that for any $i \geq 0$, E_i is the set of edges that are fully contained in S_{i+1} but not in S_i. Note that $|\delta(S_0)| = \sum_i |E_i|$. Since the algorithm has at most n levels of recursion, to prove the lemma, it is sufficient to prove $|E_i| \leq k'_e$ for all $i \geq 0$.

For any edge $e' \in E_i$, $e' \cap S_i \neq \emptyset$ since e' crosses the cut $(S_0, \overline{S_0})$ and $S_0 \subseteq S_i$. We also have $e' \cap S_{i+1} \setminus S_i \neq \emptyset$ and $e' \cap \overline{S_{i+1}} = \emptyset$ since e' is fully contained in S_{i+1} but not S_i. So $|E_i| \leq \Delta_{S_{i+1}}(S_i)$. On the other hand, by definition of pseudo strength, $k'_e \geq \Delta_{S_{i+1}}(S_i)$ since e is fully contained in S_{i+1}. Therefore, $|E_i| \leq k'_e$. ◀

By Lemma 19, we proved that each edge e is sampled with probability at least the required probability in Theorem 8. Next, we need to assign weights to each sampled edge.

We do this after we finish sampling. For each edge e that gets sampled, we need to know the probability that it gets sampled. Since we sample edges from each cut independently, we only need to know the probability that e gets sampled during each recursive call, and that probability depends only on the size of the cut and whether e crosses the cut. So we can compute the probability that e gets sampled during Algorithm 2.

To complete the proof of Theorem 1, we need to show that the running time of the whole process is polynomial in n.

Proof of Theorem 1. During each call to Algorithm 2, we need $\tilde{O}(n^3)$ queries to cut size query oracle and $\tilde{O}(n^4)$ time to figure out the pseudo min-cut within the set V' by Theorem 14 and Lemma 17. At line 4, we call cut edge sample query $10n^3/\varepsilon^2$ times in expectation. Total number of recursive calls to Algorithm 2 is $O(n)$, since each time, the input set gets partitioned into two sets, and there are n sets in the end. Thus the running time of Algorithm 2 is $\tilde{O}(n^5 + n^4/\varepsilon^2)$.

We sample the edges in $O(n)$ cuts, so when assigning the weights, we only need to query the size of these $O(n)$ cuts and calculate the probability of each sampled edge, which can also be done in $O(n)$ time for each edge. So the running time of assigning the weights is $\tilde{O}(n^5/\varepsilon^2)$.

After sampling the edges and assigning weights, we get a $(1\pm\varepsilon)$-approximate cut sparsifier H_1 of H with polynomial size in n. Then we run the algorithm in Theorem 11 to find a $(1+\varepsilon)$-approximate cut sparsifier H_2 of H_1 with $\tilde{O}(n/\varepsilon^2)$ number of edges in polynomial time in n. By definition of cut sparsifier, H_2 is a $(1\pm\varepsilon)^2$-approximate cut sparsifier of H. Since H_1 contains $\tilde{O}(n^4/\varepsilon^2)$ edges, by Theorem 11, the running time is $O(n^{10}/\varepsilon^7)$.

So the total running time is $O(n^{10}/\varepsilon^7)$. ◀

4 Sublinear Time Cut Sparsification with Cut Size and Pair Neighbor Queries

In this section, we show that cut edge queries can be simulated by a $\text{poly}(n)$ number of cut size queries (oracle O_{value}) and pair neighbor queries (oracle O^2_{nbr}), establishing that cut size query oracle and pair neighbor query oracle are also sufficient to compute a $(1\pm\varepsilon)$-approximate cut sparsifier in $\text{poly}(n)$ time.

Given a pair of vertices u and v, let $E(\{u,v\})$ be the set of edges that contain both u and v. We first show how to approximate $|E(\{u,v\})|$ to within a factor of $(1\pm\varepsilon)$ with probability $1-\xi$, for some small ξ. Note that we can compute $2\Delta_{\{u,v\}}(\{u\}) = |E(\{u,v\})| + |E\cap\{u,v\}|$, where $|E\cap\{u,v\}|$ is the number of copies of the edge $\{u,v\}$. We now describe an algorithm to approximate $|E(\{u,v\})|$:

Algorithm 3 Approximating $|E(\{u,v\})|$.

Input : A pair of vertices $u,v\in V$, ε, ξ.
Output : An approximation $\hat{E}(\{u,v\})$ of $|E(\{u,v\})|$.

1 Define $k = 12\log(2/\xi)/(\varepsilon^2)$.
2 Call the oracle O^2_{nbr} k times on (u,v), and let $\hat{\alpha}$ be the fraction of returned edges that were $\{u,v\}$.
3 Return $\hat{E}(\{u,v\}) := 2\Delta_{\{u,v\}}(\{u\})\cdot\frac{1}{1+\hat{\alpha}}$.

Note that this algorithm makes $k = O(\frac{\log(1/\xi)}{\varepsilon^2})$ queries.

▶ **Lemma 20.** *With probability at least $1-\xi$, $\hat{E}(\{u,v\})$ is an approximation of $|E(\{u,v\})|$ to within a factor of $(1\pm\varepsilon)$.*

Proof. Let $\alpha := \frac{|E\cap\{u,v\}|}{|E(\{u,v\})|}$ be the fraction of hyperedges that are $\{u,v\}$. The algorithm runs a Monte Carlo simulation to approximate α by the ratio $\hat{\alpha}$. In order to prove concentration of $\hat{\alpha}$ around α, let k' be the total number of $\{u,v\}$ edges returned, and observe that k' is the sum of k independent Bernoulli random variables each having probability equal to α. By Chernoff bound, $\Pr[|k'-\alpha k| > \varepsilon k/2] \le 2\exp(-\alpha k\varepsilon^2/12\alpha) \le 2\exp(-k\varepsilon^2/12) = 2\exp(\log(\xi/2)) = \xi$. Therefore with probability at least $1-\xi$, $|\hat{\alpha}-\alpha|\le\varepsilon/2$. This implies that $\frac{1}{1+\hat{\alpha}} \in \frac{1}{1+\alpha\pm\varepsilon/2} \subseteq \frac{1}{(1\pm\varepsilon/2)(1+\alpha)}$. Finally, we use that $\frac{1}{(1\mp\varepsilon/2)} \subseteq (1\pm\varepsilon)$ to conclude that $\frac{1}{1+\hat{\alpha}} \in \frac{1\pm\varepsilon}{1+\alpha}$, so

$$\frac{2\Delta_{\{u,v\}}(\{u\})}{1+\hat{\alpha}} \in (1\pm\varepsilon)\frac{2\Delta_{\{u,v\}}(\{u\})}{1+\alpha} = (1\pm\varepsilon)|E(\{u,v\})|.$$ ◀

We now describe an algorithm to sample a random edge from $\delta(S)$, simulating a response to O_{edge}. We first approximate the size of $E(\{u,v\})$ for each pair of vertices $u\in S$ and $v\in\bar{S}$. Then we sample a pair of u,v with probability proportional to $|E(\{u,v\})|$, sample an edge in $E(\{u,v\})$, and then decide whether we keep it or not with probability proportional to its size. If we decide not to pick the edge, we repeat the whole process again.

Algorithm 4 Sampling an edge in $\delta(S)$.

Input : A subset $S \subseteq V$
Output : An edge $e \in \delta(S)$

1 For each pair of vertices u, v such that $u \in S$ and $v \in \bar{S}$, call Algorithm 3 with $\xi = 1/n^{20}$, and let $\hat{E}(\{u,v\})$ be the output;
2 Sample a pair of vertices $(u,v) \in S \times \bar{S}$ with probability proportional to $\hat{E}(\{u,v\})$;
3 Use the oracle O^2_{nbr} to sample an edge e in $E(\{u,v\})$;
4 With probability $\frac{1}{|e\cap S|\cdot|e\cap\bar{S}|}$, return e. Otherwise go to Step 2.

▶ **Lemma 21.** *With probability at least $1 - 1/n^{-10}$, Algorithm 4 samples each edge in $\delta(S)$ gets with probability $\frac{1\pm\varepsilon}{|\delta(S)|}$. The expected running time is $\tilde{O}(n^2/\varepsilon^2)$.*

Proof. We first condition on the $|S| \cdot |\bar{S}| \le n^2$ events that for each pair u, v with $u \in S$ and $v \in \bar{S}$, the estimate $\hat{E}(\{u,v\})$ was indeed in $(1 \pm \varepsilon) \cdot |E(\{u,v\})|$, which happens with probability at least $1 - n^2\xi > 1 - 1/n^{-10}$. Now fix an edge $e \in \delta(S)$. The probability that it was sampled at a particular iteration of Algorithm 4 is

$$\sum_{u\in S\cap e, v\in\bar{S}\cap e} \frac{\hat{E}(\{u,v\})}{\sum_{(u',v')\in S\times\bar{S}}\hat{E}(\{u',v'\})} \cdot \frac{1}{|E(\{u,v\})|} \cdot \frac{1}{|e\cap S|\cdot|e\cap\bar{S}|}$$

$$\in \frac{1}{\sum_{(u',v')\in S\times\bar{S}}\hat{E}(\{u',v'\})} \sum_{u\in S\cap e, v\in\bar{S}\cap e} \frac{(1\pm\varepsilon)}{|e\cap S|\cdot|e\cap\bar{S}|} = \frac{(1\pm\varepsilon)}{\sum_{(u',v')\in S\times\bar{S}}\hat{E}(\{u',v'\})}$$

That is, the probability of sampling each edge at any given iteration of Algorithm 4 is within $(1 \pm \varepsilon)$ of every other edge. Therefore the probability of sampling each edge is within a factor of $(1 \pm \varepsilon)$ of every other edge.

Step 1 calls Algorithm 3 $O(n^2)$ times, so the running time is $\tilde{O}(n^2/\varepsilon^2)$. At step 4, the probability that we keep the edge and finish the algorithm is at least $1/n^2$, so the expected number of iterations through step 2 to 4 is at most n^2. So the total running time on step 2 to 4 is $\tilde{O}(n^2)$ in expectation. ◀

Proof of Theorem 3. We run Algorithm 2, but each time it calls O_{edge}, we instead run Algorithm 4 twice. With high probability, each time we simulate O_{edge} by Algorithm 4, the probability of any edge in the cut being sampled is within a $(1 \pm \varepsilon)$ factor of the uniform distribution. Denote by q'_e be the probability that an edge e is sampled by this algorithm, and let q_e be the probability that the edge e is sampled in Algorithm 2. We have $q'_e \in 2(1 \pm \varepsilon)q_e$, which is larger than p_e the probability of sampling an edge in Theorem 8. Also we cannot directly compute q'_e, but we can approximate it to within a factor of $(1 \pm \varepsilon)$, which only adds another $(1 \pm \varepsilon)$ factor to the approximation achieved by the cut sparsifier.

Since the number of calls to O_{edge} oracle in Algorithm 2 is $\tilde{O}(n^4/\varepsilon^2)$. So we need $\tilde{O}(n^6/\varepsilon^2) = o(n^10/\varepsilon^7)$ queries to simulate these calls. So the running time of the algorithm is still $O(n^10/\varepsilon^7)$. ◀

5 Sublinear Time Hypergraph Spectral Sparsification

In this section, we consider the problem of hypergraph spectral sparsification in the access models considered in the previous sections. We will focus on unweighted hypergraphs here, and show that these results can be extended to the weighted case in Section 7. We first consider the setting when we can access the underlying hypergraph using O_{value} and O^2_{nbr}

queries. It is easy to simulate the approach in Theorem 12 since O^2_{nbr} allows us to sample from $E(\{u,v\})$ for any u and v. For any pair of vertices u and v, we sample $Cn\log n/\varepsilon^2$ edges in $E(\{u,v\})$. For any hyperedge e, e gets sampled with probablity q_e which is at least the required value p_e. Next we need to assign weights to the sampled edges. For any pair of vertices u and v, we use Algorithm 3 to approximate $|E(\{u,v\})|$. Then for any e, we approximate q_e by the approximation of $|E(\{u,v\})|$ for all pair u and v in e, and then assign the weight of e as $1/q_e$.

Proof of Theorem 5. For each pair of vertices u and v, we sample $\tilde{O}(n)$ edges in $E(\{u,v\})$, and also use Algorithm 3 to approximate $|E(\{u,v\})|$. The total number of edges in the sparsifier and the total number of queries we perform is $\tilde{O}(n^3)$. For every sampled edge e, we need to calculate q_e, which costs at most $O(n^2)$ time as we need to combine the probabilities of sampling e through any pair of vertices inside e. So the total time complexity of the algorithm is $\tilde{O}(n^5)$. ◀

We next consider the case when we are given access to hypergraph via O_{value} and O_{edge} queries only. We observe that we cannot simulate the algorithm in Theorem 12. Consider the following hypergraph H: there is a pair of vertices u and v, such that H contains all possible hyperedges that do not contain both u and v. H also contains an edge $\{u,v\}$. Since $\{u,v\}$ is the only edge that contains both u and v, we need to sample this edge with probability 1 in the algorithm of Theorem 12. However, any cut in the hypergraph has exponential (in n) size. So we need an exponential number of queries to sample the edge $\{u,v\}$.

Given the obstacle above, we will instead simulate Theorem 13. Our approach is to show that the task of implementing Theorem 13 can be accomplished by our algorithm in Section 3, except that we will sample poly(n) times more hyperedges. By doing so, we will guarantee that the probability that each hyperedge e gets sampled is larger than the p_e in Theorem 13. We now develop the ideas needed to establish this coupling between Theorem 13 and our algorithm in Section 3.

We first observe a relationship between the effective resistance and strength of an edge in a normal graph.

▶ **Lemma 22.** *For any edge f in a normal (weighted) graph G, we have $r_f \le \frac{n}{k_f}$.*

Proof. Suppose the edge $f=(u,v)$, and let c denote the min-cut size between u and v. Since for any vertex-induced subgraph of G that contains both u and v, the min-cut size is at most c, it follows that $k_f \le c$. So it is sufficient to prove that $r_f \le \frac{n}{c}$.

Since the min-cut size between u and v is c, the max-flow size between u and v is also c, which means we have a set of c edge-disjoint paths from u to v. As each path can have length at most n, this set of edge-disjoint paths can be interpreted as c parallel resistors each with resistance at most n. By Rayleigh's monotonicity law, it then follows that $r_f \le \frac{n}{c}$. ◀

We now briefly review the approach underlying Theorem 13 (see Section 2.3). Recall that for any hyperedge e in a hypergraph H, F_e is the clique associated with e in the auxiliary graph G_H, and $r_e = \max_{f\in F_e} r_f$. Define $\kappa_e = \min_{f\in F_e} k_f$. Then by Lemma 22, we have $r_e \le \frac{n}{\kappa_e}$. The following lemma shows a relationship between κ_e and k_e.

▶ **Lemma 23.** *For any hyperedge e in a hypergraph H, $\kappa_e \ge k_e$.*

Proof. For any subset of vertices X, consider the corresponding vertex-induced subgraphs of H and G_H, which we denote by $H[X]$ and $G_H[X]$, respectively. For any cut defined by a partition of X, and for any hyperedge e crossing this cut in $H[X]$, at least one edge in F_e

must cross this cut in $G_H[X]$. So the min-cut size of $H[X]$ is at most the min-cut size of $G_H[X]$. Let X_e be the set of vertices such that $e \subseteq X_e$ and the min-cut size of $H[X_e]$ equals k_e. The min-cut size of $G_H[X_e]$ is at least k_e. For any edge $f \in F_e$, f is contained in X_e and so $k_f \geq k_e$, which means $\kappa_e = \min_{f \in F_e} k_f \geq k_e$. ◀

By Lemma 22 and Lemma 23, we have $\frac{n}{k_e} \geq r_e$ for any hyperedge e. So by Theorem 13, if we sample each hyperedge with probability q_e which is at least $\min\{1, \frac{Cn^5 \log n}{\varepsilon^2 k_e}\}$, and assign it weight $1/q_e$ if sampled, then the resulting hypergraph is a $(1 \pm \varepsilon)$-spectral sparsifier. So we can use the same process as described in Section 3, except that we oversample hyperedges by a factor of n^4. The resulting hypergraph will then be a $(1 \pm \varepsilon)$-spectral hypergraph sparsifier.

Proof of Theorem 6. We run Algorithm 2, except that in line 3, we set $N \sim B(c, \min\{1, \frac{Cn^7}{\varepsilon^2 c}\})$ where C is the constant in Theorem 13. By the same argument as in Section 3, we sample each edge with probability at least $\min\{1, \frac{Cn^5 \log n}{\varepsilon^2 k_e}\}$, which means the resulting graph is a $(1 \pm \varepsilon)$-spectral sparsifier if we assign the weight of each edge also using the same process in Section 3. The number of hyperedges sampled is $\tilde{O}(n^8/\varepsilon^2)$. We then run the algorithm in Theorem 12 on our sparsifier and get a $(1 \pm 2\varepsilon)$-spectral sparsifier with $\tilde{O}(n^3/\varepsilon^2)$ hyperedges. The time taken by running Algorithm 2 and assigning weights is $\tilde{O}(n^9/\varepsilon)$ since there are n^4 times more hyperedges being sampled. The running time of the algorithm in Theorem 12 is $\tilde{O}(n^{10})$ since there are $\tilde{O}(n^8)$ hyperedges sampled by Algorithm 2. So the overall running time is $\tilde{O}(n^{10})$. ◀

6 Lower Bounds

In this section we show that any natural relaxation of the assumptions underlying Theorem 1 and 3 rules out poly(n) time sparsification algorithms, proving Theorem 2 and 4.

6.1 Queries O_{value} and O^1_{nbr} Together are not Sufficient

In this section, we prove that if any randomized algorithm can only access the underlying hypergraph via O_{value} and O^1_{nbr}, it is not possible to find with probability better than $o(1)$ a $(1 \pm \varepsilon)$-approximate cut sparsifier with only poly(n) queries, proving Theorem 4. We start by showing a weaker result, as stated in the lemma below, which shows that the failure probability of a poly(n) time algorithm must be at least $1/2 - o(1)$, and then show how to amplify the failure probability to $1 - o(1)$.

▶ **Lemma 24.** *There is no polynomial time algorithm that can use O_{value} and O^1_{nbr} queries alone to construct a $(1 \pm \varepsilon)$-approximate sparsifier of an underlying hypergraph H with probability at least $1/2 + \xi$ for any constant $\xi > 0$.*

Proof. Suppose the runtime of the algorithm is bounded by some polynomial $f(n)$. We will construct two graphs $H_1 = (V \cup V', E_1)$ and $H_2 = (V \cup V', E_2)$ with $|V| = |V'| = n$ and the algorithm is shown with probability $1/2$ the graph H_1 and with probability $1/2$ the graph H_2. We will then show that (a) any algorithm that can only access the underlying graph using O_{value} and O^1_{nbr} cannot distinguish between these two graphs with probability at least $1/2 + \xi$ for any constant $\xi > 0$, and (b) there exists a non-empty cut such that H_1 and H_2 do not have any common edges crossing the cut. Together, these properties immediately imply the lemma .

Let $u, v \in V$ and $u', v' \in V'$ be two arbitrary pairs of vertices. Let $E = 2^V \cup 2^{V'}$ be the union of the complete hypergraphs on V and V'. We define E_1 as E along with all possible edges of size two among $\{u, v, u', v'\}$. We define E_2 as E along with all possible edges of

size 3 among $\{u, v, u', v'\}$. It is easy to verify that for any cut, the number of edges in E_1 crossing the cut equals the number of edges in E_2 crossing the cut. So any cut size query O_{value} has the same answer in H_1 and H_2, and hence can not distinguish between these two graphs, no matter the number of queries allowed.

The algorithm can additionally make at most $f(n)$ calls to O^1_{nbr}. But since each vertex $w \in V \cup V'$ has at least 2^n edges incident on it, the probability that a uniformly random edge incident on w is not in E is at most $3/2^n$. Using a union bound over all $f(n)$ queries along with the fact that $3f(n)/2^n \leq \xi$ for sufficiently large n, we get that for both hypergraphs, with probability at least $1 - 3f(n)/2^n \geq 1 - \xi$, all sampled edges are in E.

Thus conditioned on the event that all of the sampled edges are in E, the algorithm cannot distinguish between H_1 and H_2. On the other hand, there are no common edges crossing the cut (V, V') in H_1 and H_2, so to output a proper $(1 \pm \varepsilon)$-approximate cut sparsifier, the algorithm must distinguish between H_1 and H_2. Hence the probability that algorithm succeeds is at most $1/2 + \xi$. ◀

To amplify the failure probability to $1 - o(1)$, we can independently generate $\log n$ instances from the distribution above with each instance containing $n/\log n$ vertices. We now let our underlying graph be a union of these $\log n$ instances. Any algorithm that outputs a $(1 \pm \varepsilon)$-approximate sparsifier, must successfully identify for each of the $\log n$ instances whether it is an instance of H_1 or H_2. Thus the probability of success is at most $(1/2 + o(1))^{\log n} = o(1)$. This completes the proof of Theorem 4.

6.2 O_{edge} Queries Alone are not Sufficient

In this section, we prove that if the algorithm can access the hypergraph through only O_{edge} queries, it is not possible to find a proper $(1 \pm \varepsilon)$-approximate cut sparsifier with $\text{poly}(n)$ queries with success probability better than $o(1)$, proving Theorem 2. As above, we start by showing a weaker result, which shows that the failure probability of a $\text{poly}(n)$ time algorithm must be at least $1/2 - o(1)$, and then show how to amplify the failure probability to $1 - o(1)$.

We first define two distributions of hypergraphs $\mathcal{H}_1$ and $\mathcal{H}_2$ such that for any sequence of the queries the algorithm asks to O_{edge}, the distribution of the answers are almost identical regardless of whether the graph was chosen from $\mathcal{H}_1$ or $\mathcal{H}_2$.

A graph in each of the distributions $\mathcal{H}_1$ and $\mathcal{H}_2$ is generated as follows. There are $n + 1$ vertices $v_0, v_1, \ldots, v_n$ and the generated graph will have $2^n - n - 1$ edges. If the graph is generated by $\mathcal{H}_1$, then we randomly choose $2^{n/2}$ subsets of $\{v_1, \ldots, v_n\}$ with size at least 2. If the graph is generated by $\mathcal{H}_2$, then we randomly choose $2^{n/4}$ subsets of $\{v_1, \ldots, v_n\}$ with size at least 2. Then for any subset S of $\{v_1, \ldots, v_n\}$ of size at least 2, if S is chosen in the previous step, then the edge $S \cup \{v_0\}$ is in the graph, otherwise the edge S is in the graph.

The algorithm is presented with probability $1/2$ a graph H generated by $\mathcal{H}_1$, and with probability $1/2$ a graph H generated by $\mathcal{H}_2$, that is, the algorithm sees a graph H generated by the distribution $1/2\mathcal{H}_1 + 1/2\mathcal{H}_2$. Since the cut sizes of $(\{v_0\}, \overline{\{v_0\}})$ in the graph generated by $\mathcal{H}_1$ and $\mathcal{H}_2$ are $2^{n/2}$ and $2^{n/4}$ respectively, any algorithm that outputs a $(1 \pm \varepsilon)$-approximate cut sparsifier with $\varepsilon < 1$ must be able to distinguish between the graphs generated by $\mathcal{H}_1$ and $\mathcal{H}_2$. However, the following lemma shows that unless the algorithm makes exponential number of queries, it cannot distinguish between the graphs generated by $\mathcal{H}_1$ and $\mathcal{H}_2$. The proof of this lemma is deferred to the full version of this paper.

▶ **Lemma 25.** *Any algorithm that only makes k O_{edge} queries where $k = \text{Poly}(n)$ cannot determine with probability better than $\frac{1}{2} + \frac{k^2}{2^{n/4}}$ if the underlying graph H is generated from $\mathcal{H}_1$ or $\mathcal{H}_2$.*

Thus any algorithm that makes only $\text{poly}(n)$ O_{edge} queries, fails with probability at least $1/2 - o(1)$. To amplify the failure probability to $1 - o(1)$, we can as before independently generate $\log n$ instances from the distribution above with each instance containing $n/\log n$ vertices. We now let our underlying graph be a union of these $\log n$ instances. Any algorithm that outputs a $(1 \pm \varepsilon)$-approximate sparsifier, must successfully identify for each of the $\log n$ instances whether it was generated from the first distribution or the second. Thus the probability of success is at most $(1/2 + o(1))^{\log n} = o(1)$. This completes the proof of Theorem 2.

7 Weighted Hypergraphs

In this section, we describe how to extend the results of Theorem 1, Theorem 3, Theorem 5, and Theorem 6 to weighted hypergraphs. Given a weighted hypergraph $H = (V, E, w)$, we consider access to this graph by weighted generalizations of oracles O_{value}, O_{edge}, and O^2_{nbr}: the oracle O_{value} now returns the weight of a cut rather than its size, and instead of sampling uniformly, the oracles O_{edge} and O^2_{nbr} sample edges with probability proportional to their weight.

We first note that all the Theorems we use to derive these results (Theorem 8, Theorem 12, and Theorem 13) can be modified to work when the input hypergraph is weighted.

▶ **Lemma 26** (Weighted version of Theorem 8). *Let $H = (V, E, w)$ be a weighted hypergraph with rank r, and let $\varepsilon > 0$ be an error parameter. Consider the hypergraph H' obtained by sampling each hyperedge e in H independently with probability $p_e \geq \min\{1, w(e) \cdot \frac{3((d+2)\log n + r)}{k_e \varepsilon^2}\}$, giving it weight $w(e)/p_e$ if included. Then with probability at least $1 - O(n^{-d})$, H' is a $(1 \pm \varepsilon)$-approximate cut sparsifier of H, and has $O(\frac{n}{\varepsilon^2}(r + \log n))$ hyperedges.*

▶ **Lemma 27** (Weighted version of Theorem 12). *Let $H = (V, E, w)$ be a weighted hypergraph, and let $\varepsilon > 0$ be an error parameter. Consider the hypergraph H' obtained by sampling each hyperedge e in H independently with probability $p_e \geq \min\{1, w(e) \cdot \frac{Cn \log n}{\varepsilon^2 \min_{u,v \in e} w(E(\{u,v\}))}\}$, giving it weight $w(e)/p_e$ if included. Then with high probability, H' is a $(1 \pm \varepsilon)$-approximate spectral sparsifier of H, and has $\tilde{O}(n^3/\varepsilon^2)$ hyperedges.*

▶ **Lemma 28** (Weighted version of Theorem 13). *Let $H = (V, E, w)$ be a weighted hypergraph with rank r, and let $\varepsilon > 0$ be an error parameter. Consider the hypergraph H' obtained by sampling each hyperedge e in H independently with probability $p_e \geq \min\{1, w(e) \cdot \frac{Cr^4 r_e \log n}{\varepsilon^2}\}$, giving it weight $w(e)/p_e$ if included. Then with high probability, H' is a $(1 \pm \varepsilon)$-approximate spectral sparsifier of H, and has $\tilde{O}(nr^3/\varepsilon^2)$ hyperedges.*

Most of our arguments and definitions for the unweighted case of Theorem 1 and Theorem 6 translate directly to the weighted case once we replace every mention of the cardinality of an edge set by the weight of that edge set. In particular, if we generalize the definition of pseudo cut size to be $\Delta_X(S) = \frac{1}{2}(w(\delta(S)) + w(\delta(X \setminus S)) - w(\delta(X)))$, then the proofs for Lemma 17, Lemma 18, and Lemma 19 are completely analogous. The only difference in the analysis of Algorithm 2 is that the probability that a sample from the cut $(S_0, \bar{S_0})$ returns an edge e in the cut is now $w(e)/w(\delta(S))$, implying that the probability that e is sampled by Algorithm 2 is at least $\min\{1, \frac{10w(e)n^3}{\epsilon^2 w(\delta(S_0))}\}$. Since this is at least the requisite sampling probability in Lemma 26, the hypergraph H_1 is a sparsifier of H with high probability. In the case of Theorem 6, we still have that for every hyperedge e, $\frac{n}{k_e} \geq r_e$, so Algorithm 2 can be applied to sample each hyperedge e with the desired probability of at least $\min\{1, w(e) \cdot \frac{Cr^4 r_e \log n}{\varepsilon^2}\}$.

Similarly for Theorem 3 and Theorem 5, the proof of correctness of Algorithm 3 is almost completely analogous (although this time, the algorithm outputs an estimate of the total weight of hyperedges containing both u and v). The proof of correctness of Algorithm 4 is modified to assert that the probability of sampling an edge $e \in E(\{u,v\})$ is $w(e)/w(E(\{u,v\}))$, implying that the probability that the algorithm samples e in each iteration is proportional to $(1 \pm \varepsilon) \cdot w(e)$.

Note that the running time of our algorithms are independent of the number of edges in the unweighted setting. Similarly, in the weighted setting, our running times have no dependence on the weights of the edges, and the running time and the size of sparsifier are the same as in the unweighted cases.

8 Concluding Remarks

We presented the first sublinear time algorithms for creating a hypergraph sparsifier. Given access to a hypergraph through cut size and suitable edge sampling queries, our algorithm outputs a $(1 \pm \varepsilon)$-approximate sparsifier with $\tilde{O}(n/\varepsilon^2)$ hyperedges in polynomial time in n, independent of the number of hyperedges. We also showed that for any natural weakening of our query access assumptions, there is no poly(n) time algorithm for building a hypergraph sparsifier of poly(n) size. An intriguing question is if an information-theoretic cut sparsifier can be constructed using cut value queries alone. Cut value queries alone can not distinguish between hypergraphs which only contain edges of rank 2 from hypergraphs which only contain edges of rank 3, making it impossible for them to output a proper sparsifier. But this does not rule out the possibility that a suitable data structure can be created using these queries alone that can recover the value of any cut to within a $(1 \pm \varepsilon)$-approximation.

Abstract

The *edit distance* (ED) and *longest common subsequence* (LCS) are two fundamental problems which quantify how similar two strings are to one another. In this paper, we first consider these problems in the asymmetric streaming model introduced by Andoni, Krauthgamer and Onak [11] (FOCS'10) and Saks and Seshadhri [64] (SODA'13). In this model we have random access to one string and streaming access the other one. Our main contribution is a constant factor approximation algorithm for ED with memory $\tilde{O}(n^{\delta})$ for any constant $\delta > 0$. In addition to this, we present an upper bound of $\tilde{O}_{\epsilon}(\sqrt{n})$ on the memory needed to approximate ED or LCS within a factor $1 \pm \epsilon$. All our algorithms are deterministic and run in polynomial time in a single pass.

We further study small-space approximation algorithms for ED, LCS, and *longest increasing sequence* (LIS) in the non-streaming setting. Here, we design algorithms that achieve $1 \pm \epsilon$ approximation for all three problems, where $\epsilon > 0$ can be any constant and even slightly sub-constant. Our algorithms only use poly-logarithmic space while maintaining a polynomial running time. This significantly improves previous results in terms of space complexity, where all known results need to use space at least $\Omega(\sqrt{n})$. Our algorithms make novel use of triangle inequality and carefully designed recursions to save space, which can be of independent interest.

1 Introduction

We consider *edit distance* (ED) and *longest common subsequence* (LCS) which are classic problems measuring the similarity between two strings. Edit distance is defined on two strings s and $\bar{s}$ and seeks the smallest number of character insertions, character deletions, and character substitutions to transform s into $\bar{s}$. While in edit distance the goal is to make a transformation, longest common subsequence asks for the largest string that appears as a subsequence in both s and $\bar{s}$.

Edit distance and longest common subsequence have applications in various contexts, such as computational biology, text processing, compiler optimization, data analysis, image analysis, among others. As a result, both problems have been subject to a plethora of studies since 1950 (e.g. see [19, 20, 2, 14, 13, 11, 47, 17, 32, 34, 46, 57, 33, 42, 54, 23, 6, 26, 63, 24, 62, 48, 40, 38, 59, 3, 25, 45, 8, 10, 9, 7, 15, 39, 29, 53, 64, 43, 4, 21, 44, 26]).

Both problems are often used to measure the similarity of long strings. For example, a human genome consists of almost three billion base pairs that are modeled as a string for similarity testing. Classic algorithms for the problems require quadratic runtime as well as linear memory to find a solution. These bounds might be impractical for some real-world applications. Therefore, recent work on ED and LCS focus on obtaining fast algorithms [61, 44, 20, 13, 11, 8, 9, 60, 22, 52, 26] as well as solutions with small memory [45, 20, 28, 41].

As can be seen from the aforementioned references, while there have been a lot of previous works on obtaining fast algorithms, the equally important question of achieving algorithms using small space has not been studied in depth. In this paper our focus is to design algorithms with significantly improved space complexity for these string measures, in several different models.

Our first model is related to the *streaming* setting studied in most previous works on space complexity for ED and LCS. This is an increasingly popular framework to model memory constraints. In this setting, the input arrives as a data stream while only sublinear memory is available to the algorithm. The goal is to design an algorithm that solves/approximates the solution by taking a few passes over the data. While several works have studied ED and LCS in the streaming model (see Section 1.1 for a detailed discussion), positive results are known only for the low-distance regime [56, 66, 18, 28, 27]. In addition to this, strong lower bounds are given for the streaming variant of LCS [56, 66].

Inspired by the work of [11] (FOCS'10), Saks and Seshadhri [64] (SODA'13) studied the problem of approximating $n -$ LCS (which is half of the the edit distance between two strings of length n when only insertions and deletions are allowed) in the asymmetric model. In this model we have random access to one of the strings (say $\bar{s}$) and streaming access to the other string (say s). They showed that $(1+\epsilon)$ approximation of $n -$ LCS can be found with a memory of $\tilde{O}_\epsilon(\sqrt{n})$. Another work by Saha [63] gives an algorithm for ED in this setting, using a memory of $O(\frac{\sqrt{n}}{\epsilon})$, and achieving an ϵn *additive* approximation.

In this work, we study ED and LCS in the asymmetric streaming model. We present a single-pass deterministic constant factor approximation algorithm for ED that uses only $\tilde{O}(n^\delta)$ memory for any constant $\delta > 0$. In addition to this, we show that with the memory of $\tilde{O}_\epsilon(\sqrt{n})$ one can approximate both ED and LCS within a factor of $1 \pm \epsilon$. All our algorithms

are deterministic and run in a single-pass and in polynomial time. Moreover, the memory bound of our algorithm for LCS is tight due to a lower bound given in [37]. It is also worth mentioning that the lower bound of $\Omega(\log^2 n/\epsilon)$ is known for computing $1+\epsilon$ approximation of $n-$ LCS due to the result of [58].

LIS and distance to monotonicity (DTM) are special cases of LCS and ED that are also studied in the streaming model [41, 64]. In these two problems, one of the strings is a length n string over the alphabet $[n]$ and the second string is the sorted permutation $\langle 1, 2, \ldots, n\rangle$. Therefore, any asymmetric streaming algorithm for LCS and ED also implies a classical streaming algorithm for LIS and DTM, since we can assume that we have random access to the sorted permutation $\langle 1, 2, \ldots, n\rangle$. As a result, our algorithms for ED and LCS can be seen as a generalization of [41, 64] on streaming LIS and distance to monotonicity.

More generally, we also study the memory requirements of ED, LCS, and LIS in the non-streaming model, where we have random access to all input strings. Even in this setting, classic algorithms that compute ED and LCS exactly using dynamic programming need linear space. A recent work [50] slightly improves the space complexity to $O(\frac{n\log^{1.5} n}{2^{\sqrt{\log n}}})$ while preserving a polynomial running time, however achieving strongly sublinear space (i.e., space $n^{1-\alpha}$ for some constant $\alpha > 0$) with a polynomial running time for ED and LCS still seems out of reach. Therefore, in this paper we turn to the relaxed goal of approximating ED and LCS using significantly smaller space while preserving a polynomial running time.

The only previous positive results in this setting we are aware of, are the previously mentioned works on streaming algorithms and the work of Saha [63]. Again, for ED the streaming results only work in the low-distance regime, except the work of Saks and Seshadhri [64] which gives a $(1+\epsilon)$ approximation of $n-$ LCS using $\tilde{O}_\epsilon(\sqrt{n})$ space. Additionally, [64] also gives a randomized algorithm that achieves an ϵn additive approximation of LCS in this model, using space $O(k\log^2 n/\epsilon)$ where k is the maximum number of times any symbol appears in y. [63] gives a small space algorithm for ED, although the result only works for constant alphabet size and only provides an additive approximation instead of multiplicative approximation. Further the space needed is at least $\Omega(n^{2/3})$. For LIS the situation is slightly better. In particular, the work of Gopalan, Jayram, Krauthgamer and Kumar [41] provides a deterministic streaming algorithm that approximates LIS to within a $1-\epsilon$ factor, using time $O(n\log n)$ and space $O(\sqrt{n/\epsilon}\log n)$; while a very recent work by Kiyomi, Ono, Otachi, Schweitzer and Tarui [51] obtains a deterministic algorithm that computes LIS *exactly* using $O(n^{1.5}\log n)$ time and $O(\sqrt{n}\log n)$ space. [63] in addition provides an algorithm for LIS using space $O(\frac{\log n}{\epsilon})$ that achieves an ϵn additive approximation. Thus here we seek to obtain an $1-\epsilon$ approximation of LIS using space much smaller than $\sqrt{n}$.

More broadly, the questions studied in this paper are closely related to the general question of *non-deterministic small space computation* vs. *deterministic small space computation*. Specifically, the decision versions of all three problems (ED, LCS, and LIS) can be easily shown to be in the class NL (i.e., non-deterministic log-space), and the question of whether NL = L (i.e., if non-deterministic log-space computation is equivalent to deterministic log-space computation) is a major open question in complexity theory. Note that if NL = L, this would trivially imply polynomial time algorithms for *exactly* computing ED, LCS, and LIS in logspace. However, although we know that NL $\subseteq$ P and NL $\subseteq$ SPACE$(\log^2 n)$ (by Savitch's theorem [65]), it is not known if every problem in NL can be solved simultaneously in polynomial time and polylog space, i.e., if NL $\subseteq$ SC where SC is Steve's class. In fact, it is not known if an NL-complete language (e.g., directed s-t connectivity) can be solved simultaneously in polynomial time and strongly sub linear space (i.e., space $n^{1-\alpha}$ for some fixed constant $\alpha > 0$). Thus, studying special problems such as ED, LCS, and LIS, and the relaxed version of approximation is a reasonable first step towards major open problems.

In the non-streaming setting, for all three problems ED, LCS, and LIS, we give efficient *deterministic* approximation algorithms that can achieve $1 \pm \epsilon$ approximation, using even polylog(n) space while maintaining a polynomial running time. By relaxing the space complexity to n^δ for any constant $\delta > 0$, we obtain algorithms whose running time is comparable to the standard dynamic programming approach. This is in sharp contrast to the time complexity of ED, LCS, where we only know how to beat the standard dynamic programming significantly by using *randomized* algorithms and with much worse approximation guarantees.

Last but not least, it turns out that we can also use our techniques developed for the non-streaming model to significantly reduce the running time of our algorithm in the asymmetric streaming model, resulting in a polynomial time algorithm.

1.1 Related work

Quadratic time solutions for ED and LCS have been known for many decades [55]. Recently, it has been shown that a truly subquadratic time solution for either ED or LCS refutes *Strong Exponential Time Hypothesis* (SETH), a conjecture widely believed in the community (see [14, 2, 25]). Therefore, much attention is given to approximation algorithms for the two problems. For edit distance, a series of works [54], [16], [17], and [13] improve the approximation factor culminating in the seminal work of Andoni, Krauthgamer, and Onak [11] that finally obtains a polylogarithmic approximation factor in near-linear time. More recently constant factor approximation algorithms with truly subquadratic runtimes are obtained for edit distance (a question which was open for a few decades): first a quantum algorithm [20], then a classic solution [26], and finally near linear time solutions are given [22, 52, 12]. LCS has also received tremendous attention in recent years [44, 60, 61, 1, 4, 30]. Only trivial solutions were known for LCS until very recently: a 2 approximate solution when the alphabet is 0/1 and an $O(\sqrt{n})$ approximate solution for general alphabets in linear time. Both these bounds are recently improved by [44] and Rubinstein and Song [60] (see also a recent approximation algorithms given by [61]).

Streaming algorithms for edit distance have been limited to the case that the distance between the two strings is *bounded* by a parameter k which is substantially smaller than n. In particular, [28] gives a randomized one-pass algorithm in a variant of the streaming model where one can scan the two strings s and $\bar{s}$ simultaneously in the coordinated fashion, using space $O(k^6)$ and time $O(n + k^6)$. This was later improved to space $O(k)$ and time $O(n + k^2)$ in [27, 18]. [18] further gives a randomized one-pass algorithm in the standard streaming model using space $O(k^8 \operatorname{polylog} n)$ and time $\tilde{O}(k^2 n)$. It is improved to $O(k^3 \operatorname{polylog} n)$ space recently in [49]. Note that in all these algorithms the space can be as large as n.

1.2 Our Results

We summarize our main theorems in this section and in Table 1. In the next subsection we demonstrate our main techniques and general ideas in details. Formal proofs are deferred to the appendix. First we start with the following results for the asymmetric streaming model.

▶ **Theorem 1.** *Given online string s and offline string $\bar{s}$ both in Σ^n, for any constant $\delta > 0$, there exists a deterministic algorithm that, making one pass through s, outputs a $O(2^{1/\delta})$ approximation of $\mathsf{ED}(s, \bar{s})$ using $\tilde{O}(n^\delta/\delta)$ space and $\tilde{O}_\delta(n^4)$ time.*

▶ **Theorem 2.** *Given online string s and offline string $\bar{s}$ both in Σ^n, for any constant $\epsilon \in (0, 1)$, there is a deterministic algorithm that, making one pass through s, outputs a $(1-\epsilon)$-approximation of $\mathsf{LCS}(s, \bar{s})$ using $\tilde{O}(\frac{\sqrt{n}}{\epsilon})$ space, or $(1+\epsilon)$-approximation of $\mathsf{ED}(s, \bar{s})$ using $\tilde{O}(\sqrt{\frac{n}{\epsilon}})$ space, in polynomial time.*

Theorem 1 is surprising in the sense that by allowing random access to one string, we can design an efficient deterministic one pass streaming algorithm achieving a constant approximation of ED with space n^δ for any constant $\delta > 0$. Previously no such positive results with sublinear space are known in the full streaming model even for randomized algorithms. The proof of this theorem makes novel uses of triangle inequality, and combines the techniques we develop for the non-streaming model. Theorem 2 further shows that we can in fact achieve an $(1+\epsilon)$-approximation of ED, albeit using a larger space $(\tilde{O}(\sqrt{\frac{n}{\epsilon}}))$. The result also extends to give the first $(1-\epsilon)$-approximation of LCS with sublinear space in the asymmetric streaming model, and the space matches the lower bound implied from the lower bound for LIS in [37].

Next we bring our results for the (non-streaming) small space model.

▶ **Theorem 3.** *Given any strings x and y each of length n, there are deterministic algorithms that approximate $\mathsf{ED}(x, y)$ with the following parameters:*

1. *For any constants $\delta \in (0, \frac{1}{2})$ and $\epsilon \in (0, 1)$, an algorithm that outputs a $1+\epsilon$ approximation of $\mathsf{ED}(x, y)$ using $\tilde{O}_{\epsilon,\delta}(n^\delta)$ space and $\tilde{O}_{\epsilon,\delta}(n^2)$ time.*
2. *An algorithm that outputs a $1 + O(\frac{1}{\log\log n})$ approximation of $\mathsf{ED}(x, y)$ using $O(\frac{\log^4 n}{\log\log n})$ space and $n^{7+o(1)}$ time.*

Note that our first algorithm for ED uses roughly the same running time as the standard dynamic programming, but much smaller space. Indeed, we can use space n^δ for any constant $\delta > 0$. This also significantly improves the previous result of [64], which needs to use space $\Omega(\sqrt{n}\log n)$ and only provides a $2+\epsilon$ approximation for standard ED. With a larger (but still polynomial) running time, we can achieve space complexity $O(\frac{\log^4 n}{\log\log n})$.

▶ **Theorem 4.** *Given any strings x and y each of length n, there are deterministic algorithms that approximate $\mathsf{LCS}(x, y)$ with the following parameters:*

1. *For any constants $\delta \in (0, \frac{1}{2})$ such that $\frac{1}{\delta}$ is an integer, and $\epsilon \in (0, 1)$,an algorithm that outputs a $1-\epsilon$ approximation of $\mathsf{LCS}(x, y)$ using $\tilde{O}_{\epsilon,\delta}(n^\delta)$ space and $\tilde{O}_{\epsilon,\delta}(n^{3-\delta})$ time.*
2. *An algorithm that outputs a $1 - O(\frac{1}{\log\log n})$ approximation of $\mathsf{LCS}(x, y)$, using $O(\frac{\log^4 n}{\log\log n})$ space and $n^{6+o(1)}$ time.*

To the best of our knowledge, Theorem 4 (together with Theorem 2) is the first $1-\epsilon$ approximation of LCS using truly sub-linear space, and in fact we can achieve space n^δ for any constant $\delta > 0$ with only a slightly larger running time than the standard dynamic programming approach. We can achieve space $O(\frac{\log^4 n}{\log\log n})$ with an even larger (but still polynomial) running time. For LIS, we have a similar theorem.

▶ **Theorem 5.** *Given any string x of length n, there are deterministic algorithms that approximate $\mathsf{LIS}(x)$ with the following parameters:*

1. *For any constants $\delta \in (0, \frac{1}{2})$ such that $\frac{1}{\delta}$ is an integer, and $\epsilon \in (0,1)$, an algorithm that computes a $1-\epsilon$ approximation of $\mathsf{LIS}(x)$ using $\tilde{O}_{\epsilon,\delta}(n^{\delta})$ space and $\tilde{O}_{\epsilon,\delta}(n^{2-2\delta})$ time.*
2. *An algorithm that outputs a $1 - O(\frac{1}{\log\log n})$ approximation of $\mathsf{LIS}(x)$ using $O(\frac{\log^4 n}{\log\log n})$ space and $n^{5+o(1)}$ time.*

2 Preliminaries

Let Σ be an alphabet. For a string $s \in \Sigma^n$, we use $s[i]$ to denote the i^{th} character in s. We use $s[i,j]$ to denote the substring of s from the i^{th} character to the j^{th} character. We also use $s[i,j)$ to denote the substring of s from the i^{th} character to $(j-1)^{\text{th}}$ character ($s[i,i)$ is an empty string). We denote the concatenation of two strings x and y by $x \circ y$. We use two special symbols ∞ and $-\infty$ with $\infty > i$ and $-\infty < i$ for any character $i \in \Sigma$.

Given two strings s and $\bar{s}$ in Σ^n, the longest common subsequence (LCS) of s and $\bar{s}$ is a string t with the maximum length such that t is a subsequence of both s and $\bar{s}$. In other words, t can be obtained from both s and $\bar{s}$ by removing some of the characters. We use $\mathsf{LCS}(s,\bar{s})$ to denote the length of the LCS of two strings s and $\bar{s}$. The edit distance (ED) between two strings s and $\bar{s}$, denoted by $\mathsf{ED}(s,\bar{s})$, is the minimum number of character insertions, deletions, and substitutions needed to transform one string to the other string. The longest increasing subsequence (LIS) problem is defined as follows. We assume there is a given total order on the alphabet set Σ. We say the string $x \in \Sigma^t$ is an *increasing subsequence* of $s \in \Sigma^n$ if there exists indices $1 \le i_1 < i_2 < \cdots < i_t \le n$ such that $x = s_{i_1} s_{i_2} \cdots s_{i_t}$ and $s_{i_1} < s_{i_2} < \cdots < s_{i_t}$. We denote the length of the longest increasing subsequence of string s by $\mathsf{LIS}(s)$.

Asymmetric streaming model. Throughout this paper, we assume that the input of the algorithm consists of two strings $\bar{s}$ and s. We assume for simplicity and without loss of generality that the two strings have equal length n. We call the string $\bar{s}$ the *offline* string and assume that the algorithm has random access to the characters of $\bar{s}$ via making a query. The other string s arrives as a stream of characters. We call s the *online* string.

3 Constant Approximation for Streaming Edit distance

Our main results in the asymmetric streaming setting is an algorithm that given any constant $\delta > 0$ finds a constant approximation of the edit distance using $\tilde{O}(n^{\delta})$ memory. As we discussed in the previous section, instead of directly solving the edit distance, we aim to find a substring of s such that its edit distance is smallest to $\bar{s}$. We can this problem *Closest Substring*. It is defined as follows. It takes two inputs: an offline string $\bar{s}$ and an online string s. The goal is to find two indices l, r and $\mathsf{ED}(\bar{s}[l,r],s)$ such that $\mathsf{ED}(\bar{s}[l,r],s) \le \mathsf{ED}(\bar{s}[i,j],s)$ for every $1 \le i \le j \le n$.

We first show that how solving the closest substring problem can give us a good approximation of the edit distance. Let $\bar{s}[l,r]$ be the substring of $\bar{s}$ with the minimum edit distance to s. We know by the definition of edit distance that it satisfies the *triangle inequality*[1].

[1] $\mathsf{ED}(s_1,s_3) \le \mathsf{ED}(s_1,s_2) + \mathsf{ED}(s_2,s_3)$ for any strings s_1, s_2, s_3.

Therefore, we have

$$\mathsf{ED}(\bar{s}, s) \leq \mathsf{ED}(\bar{s}, \bar{s}[l, r]) + \mathsf{ED}(\bar{s}[l, r], s)\,. \tag{1}$$

We also have,

$$\begin{aligned}
&\mathsf{ED}(\bar{s}, \bar{s}[l, r]) + \mathsf{ED}(\bar{s}[l, r], s) \\
&\quad \leq \mathsf{ED}(\bar{s}, s) + \mathsf{ED}(\bar{s}[l, r], s) + \mathsf{ED}(\bar{s}[l, r], s) && \text{By the triangle inequality.} \\
&\quad \leq 3\mathsf{ED}(\bar{s}, s) && \text{Since } \bar{s}[l, r] \text{ has the minimum ED to } s.
\end{aligned} \tag{2}$$

It follows from (1) and (2) that $\mathsf{ED}(\bar{s}, \bar{s}[l, r]) + \mathsf{ED}(\bar{s}[l, r], s)$ is a 3-approximation of the edit distance between $\bar{s}$ and s. Therefore, if we design a streaming algorithm that finds $\bar{s}[l, r]$ and its edit distance from s, we can then estimate the edit distance of s and $\bar{s}$ by computing $\mathsf{ED}(\bar{s}, \bar{s}[l, r]) + \mathsf{ED}(\bar{s}[l, r], s)$. In the following theorem which directly implies from Savitch's theorem [65], we show that $\mathsf{ED}(\bar{s}, \bar{s}[l, r]) + \mathsf{ED}(\bar{s}[l, r], s)$ can be computed using a poly-logarithmic memory. In specific, we show that the edit distance between any two substrings of the offline string can be computed using a very small memory of $O(\log^2 n)$. The proof is deferred to the full version [36]

▶ **Theorem 6.** *Suppose that we have random access to two given strings s and $\bar{s}$ of length n. Then $\mathsf{LCS}(s, \bar{s})$ and $\mathsf{ED}(s, \bar{s})$ can be computed using $O(\log^2 n)$ memory.*

Therefore, by finding the substring that has the minimum edit distance to s, we can get a good approximation of the edit distance. Nonetheless, we do not know any streaming algorithm with the memory of $O(n^\delta)$ for finding closest substring, and our algorithm only finds an approximate solution for this problem. In other words, it finds a substring of $\bar{s}$ such that its approximate edit distance to s is close to the minimum. In the rest of the section, we show that how we can approximately solve the closest substring problem with the memory of $\tilde{O}(n^\delta)$. Given an online string, we divide the online string into $n^{1-\delta}$ windows of size n^δ. Our algorithm (formally as Algorithm 1), then recursively finds substrings of $\bar{s}$ that have the minimum edit distance from each of these windows. Note that for each window we can store the result of solving the closest substring problem in $O(\log n)$ (We can store only three numbers which are the start and the end of the interval and the approximate edit distance to the online string). Therefore, by the end of all recursive calls our algorithm needs to store $O(n^\delta)$ values.

In order to find the solution of the closest substring problem using these partial solutions, our algorithm considers all different substrings $\bar{s}[l, r]$ of $\bar{s}$ and all different mappings between the windows of the s and the substrings of $\bar{s}[l, r]$. Then, for any mapping it estimates the edit distance between a window of s and its mapped substring of $\bar{s}[l, r]$ using the solution of the closest substring problem that we have found in the recursive call.

In order to analyze our algorithm, we first show that finding any approximation of the closest substring problem, can yield us an approximation for the edit distance. We first define an approximate version of the closest substring problem as follows.

▶ **Definition 7.** *Given an offline string $\bar{s}$ and online string s, we say that the substring $\bar{s}[l, r]$ along with its approximate edit distance d is an α-approximation for the closest substring problem if for any substring $\bar{s}[l^*, r^*]$ we have*

$$\mathit{ED}(\bar{s}[l, r], s) \leq d \leq \alpha \cdot \mathit{ED}(\bar{s}[l^*, r^*], s)\,. \tag{3}$$

Algorithm 1 Algorithm APPROXIMATE-CLOSEST-SUBSTR for approximating ED.

Data: An offline string $\bar{s}$ of length n, a stream of characters of the online string s, and a parameter $\delta > 0$.

if $|s| \leq n^{\delta}$ **then**
  Store all characters of s in the memory.
  Find a substring of $\bar{s}$ that has the minimum edit distance to s. Let $\bar{s}[l, r]$ be this substring and d be its edit distance.
  return l, r and d.
else
  $\xi \leftarrow n^{\delta}$.
  Divide s into ξ windows $s_1^*, s_2^*, \ldots, s_{\xi}^*$ of size $|s|/\xi$.
  for $i \in [\xi]$ **do**
    Recursively find the closest substring of $\bar{s}$ from s_i^* . Let l_i, r_i be the start and the end of this substring respectively, and d_i be the approximate edit distance of this substring to s_i^*.
  $min_dist \leftarrow \infty$.
  for $1 \leq p_0 \leq p_1 \leq \ldots \leq p_{\xi} \leq n + 1$ **do**
    $dist = \sum_{i=1}^{\xi} d_i + \mathsf{ED}\big(\bar{s}[p_{i-1}, p_i), \bar{s}[l_i, r_i]\big)$.
    if $dist < min_dist$ **then**
      $min_dist \leftarrow dist$.
      $l \leftarrow p_0$.
      $r \leftarrow p_{\xi} - 1$.
  return l, r and min_dist.

In the following claim we show that we can use any α-approximation of the closest substring problem to get a $O(\alpha)$-approximation for the edit distance.

▷ Claim 8. Let $\bar{s}[l, r]$ be an α approximation of the closest substring problem and let d be its approximate edit distance to s. Then for any substring $\bar{s}[l^*, r^*]$, $d + \mathsf{ED}\big(\bar{s}[l, r], \bar{s}[l^*, r^*]\big)$ is a $(2\alpha + 1)$-approximation for the edit distance between $\bar{s}[l^*, r^*]$ and s.

Proof. First we show that $\big(d + \mathsf{ED}\big(\bar{s}[l, r], \bar{s}[l^*, r^*]\big)\big)$ is not less than the edit distance between $\bar{s}[l^*, r^*]$ and s.

$$\begin{aligned} d + \mathsf{ED}\big(\bar{s}[l, r], \bar{s}[l^*, r^*]\big) &\geq \mathsf{ED}(\bar{s}[l, r], s) + \mathsf{ED}\big(\bar{s}[l, r], \bar{s}[l^*, r^*]\big) && \text{By (3).} \\ &\geq \mathsf{ED}\big(\bar{s}[l^*, r^*], s\big)\,. && \text{By the triangle inequality.} \end{aligned}$$

We now show that the value of $\big(d + \mathsf{ED}\big(\bar{s}[l, r], \bar{s}[l^*, r^*]\big)\big)$ is at most $(2\alpha + 1) \cdot \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big)$. Thus, it gives us a $(2\alpha + 1)$-approximation of the edit distance. We have

$$\begin{aligned} d + \mathsf{ED}\big(\bar{s}[l, r], \bar{s}[l^*, r^*]\big) &\leq d + \mathsf{ED}\big(s, \bar{s}[l, r]\big) + \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big) && \text{By the triangle inequality.} \\ &\leq d + \alpha \cdot \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big) + \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big) && \text{By (3).} \\ &= d + (\alpha + 1) \cdot \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big) \\ &\leq \alpha \cdot \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big) + (\alpha + 1) \cdot \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big) && \text{By (3).} \\ &= (2\alpha + 1) \cdot \mathsf{ED}\big(s, \bar{s}[l^*, r^*]\big)\,, \end{aligned}$$

which completes the proof of the claim. ◁

Based on our discussion above, we design an algorithm that finds a constant approximation of the edit distance using $\tilde{O}(n^\delta)$ memory for any $\delta > 0$. The algorithm first divides the online string into n^δ windows with the equal length. Therefore, the length of each window is $n^{1-\delta}$. It then finds an approximate solution of the closest substring problem for each window recursively. By Claim 8, we can use the approximate solution of the closest substring problem for each window, to find its edit distance from every other substring of the offline string. The algorithm uses these approximate solutions to approximate the edit distance between the entire online string and any substring of the offline string.

Note that by each recursive call the length of the online string will get smaller by a multiplicative factor of $n^{-\delta}$. Therefore, when the depth of the recursive calls becomes $1/\delta$, the length of the remaining online string is bounded by $O(n^\delta)$ and we can store all of this remaining online string in the memory and find the exact solution of the closest substring problem. Thus, the depth of the recursion is bounded by $O(1/\delta)$. In the following theorem we show that the approximation ratio of our algorithm is $O(2^{1/\delta})$.

▶ **Theorem 9.** *Given an offline string $\bar{s}$, an online string s and any constant $\delta > 0$, let n be the length of the offline string and n^γ be the length of the online string where $\gamma > 0$. Then, Algorithm 1 finds a $O\left(2^{\gamma/\delta}\right)$ approximation for the closest substring problem.*

The full proof of Theorem 9 is deferred to the full version [36]. Now we are ready to prove a version of Theorem 1 without the time complexity bound. We introduce how to achieve polynomial runtime in Section 5.2.

Proof of Theorem 1 without the time complexity bound. By Theorem 9, Algorithm 1 finds a $O(2^{1/\delta})$ approximation of the closest substring problem. Recall that by Theorem 6, we can find the edit distance of any two substrings of $\bar{s}$ using a very small memory. Therefore by Claim 8, we can find a $O(2^{1/\delta})$ approximation of the edit distance between s and $\bar{s}$.

Now we show that the memory of Algorithm 1 is at most $\tilde{O}(n^\delta/\delta)$. While the length of the online string is larger than n^δ, Algorithm 1 divides the online string into n^δ windows and recursively solves the closest substring problem for each window. Therefore, by each recursive call the length of the online string will decrease by a multiplicative factor of $n^{-\delta}$. Thus, the maximum depth of the recursive calls is bounded by $O(1/\delta)$. At each call the algorithm acquires a memory of $\tilde{O}(n^\delta)$ which is the memory needed for storing the result of the recursive calls and iterating over all possible mappings. Therefore, the memory of the algorithm is bounded by $\tilde{O}(n^\delta/\delta)$. ◀

4 $1+\epsilon$-Approximation of Streaming ED

A previous work by Saks and Seshadri [64] studied the approximation algorithm for deletion distance in the asymmetric streaming model. Here, the deletion distance (DD) is defined as the minimum number of insertions and deletions required to transform s to $\bar{s}$. Thus, assuming $|s| = |\bar{s}| = n$, $\mathsf{DD}(s, \bar{s}) = 2(n - \mathsf{LCS}(s, \bar{s}))$. [64] gives an algorithm that outputs a $(1+\epsilon)$ approximation of $\mathsf{DD}(s, \bar{s})$ for any constant $\epsilon > 0$ with $\tilde{O}_\epsilon(\sqrt{n})$ space.

▶ **Theorem 10** ([64])**.** *Given an offline string $\bar{s}$, an online string s, both with length n, and any constant $\epsilon \in (0, 1]$, there is a deterministic algorithm that outputs a $1+\epsilon$ approximation of $DD(\bar{s}, s)$ with $O(\sqrt{n \log n/\epsilon})$ space in polynomial time.*

Although deletion distance is not equivalent to edit distance we study in this paper, there is a simple transformation that reduces edit distance to deletion distance. The transformation can be found in previous works (see example 6.9 of [67] for example). More specifically,

for any given string s, we can obtain a new string s' by prepending a special symbol \$ (\$ is not the in the alphabet set) to each character of s. Thus, say $s = s_1 s_2 \cdots s_n$, we let $s' = \$s_1\$s_2 \cdots \$s_n \in (\Sigma \cup \{\$\})^{2n}$. We can obtain a string $\bar{s}'$ from $\bar{s}$ with the same transformation. The following lemma shows that the above transformation reduces computing edit distance to computing deletion distance.

▶ **Lemma 11.** *$DD(s', \bar{s}') = 2ED(s, \bar{s})$.*

Proof. We first show that $2\mathsf{ED}(s, \bar{s}) \geq \mathsf{DD}(s', \bar{s}')$. Assume we can transform s to $\bar{s}$ with d edit operations (insertion, deletion, and substitution), we show that it is possible to transform s' to $\bar{s}'$ with $2d$ insdel operations (insertion and deletion). To see this, if we delete one symbol from s, we delete the corresponding symbol in s' together with the \$ prepended to it. If we insert one symbol to s, we insert the corresponding symbol to s' together with a \$ prepended to it. If we substitute one symbol with another in s, we can first delete the corresponding symbol in s' and insert the new symbol at the same position.

We now show that $2\mathsf{ED}(s, \bar{s}) \leq \mathsf{DD}(s', \bar{s}')$. We consider an LCS between s' and $\bar{s}'$, and consider each pair of adjacent matches of \$ in this LCS. Without loss of generality, we can assume that in at least one side (say s'), this pair looks like $\$a\$$ where a is a symbol (we can also append a \$ at the end if needed), because otherwise if both sides have at least two symbols between the \$'s, then there is another pair of \$'s in the middle that can be matched and added to the LCS. Suppose now in $\bar{s}'$ there are t non-\$ symbols between the two \$'s. We have two cases: 1. If in the LCS, a is matched to one of the t symbols in $\bar{s}$. Then the number of insdel operations between s' and $\bar{s}'$ we need for this part is $2t - 2$, while for the corresponding part of s and $\bar{s}$, we only need $t - 1$ deletions. 2. If in the LCS a is not matched to any of the t symbols in $\bar{s}$. Then the number of insdel operations between s' and $\bar{s}'$ we need for this part is $2t$, while for s and $\bar{s}$ we need $t - 1$ deletions and one substitution (we can substitute a for any of the t symbols in $\bar{s}$), so that's t operations. Thus, if we can transform s' to $\bar{s}'$ with d insdel operations, we can transform s to $\bar{s}$ with $\frac{d}{2}$ edit operations. ◀

Note that the reduction can be implemented in a streaming manner, thus the following theorem is a direct result of the reduction and Theorem 10.

▶ **Theorem 12.** *Given an offline string $\bar{s}$, an online string s, both with length n, and any constant $\epsilon > 0$, there is a deterministic algorithm that outputs a $1 + \epsilon$ approximation of $ED(\bar{s}, s)$ with $\tilde{O}(\sqrt{\frac{n}{\epsilon}})$ space in polynomial time.*

5 Space Efficient Algorithms for ED in the Non-Streaming Model

5.1 Space Efficient algorithms for ED

In this section, we present our algorithm for approximating ED with small space. The pseudocode for our algorithm is given in Algorithm 2. Our algorithm is based on recursion. In each level of recursion, we use an idea from [45] to approximate the edit distance between certain pairs of substrings. We start by giving a brief description of the algorithm in [45].

Let x and y be two input strings such that $|x| = n$ and $|y| = m$. We assume a value Δ is given to us. If Δ is a $(1+\epsilon)$-approximation of $\mathsf{ED}(x, y)$, then the algorithm will output a good approximation of $\mathsf{ED}(x, y)$. Otherwise, the algorithm will output a value at least $\mathsf{ED}(x, y)$. Thus, we can try every $\Delta = \lceil (1 + \epsilon)^i \rceil \leq n$ for some integer i and take the minimum. This only increases the running time by a $\log_{1+\epsilon} n$ factor.

Given such a Δ, we first divide x into b blocks each of length $\frac{n}{b}$. [45] showed that, for each block of x that is not matched to a too large or too small interval in y, there is a way to choose $O(\frac{b}{\epsilon} \log_{1+\epsilon} n) = O(\frac{b}{\epsilon^2} \log n)$ candidate intervals such that one of them is close enough to the

Algorithm 2 Algorithm SpaceEfficientApproxED.

Data: Two strings x and y, parameters $b \leq \sqrt{n}$ and $\epsilon \in (0,1)$

```
if |x| ≤ b then
    compute ED(x, y) exactly.
    return ED(x, y).
ed ← ∞.
set n = |x| and m = |y|.
divide x into b block each of length at most ⌈n/b⌉ such that x = x^1 ∘ x^2 ∘ ··· ∘ x^b.
for all Δ = 0 or ⌈(1+ε)^j⌉ for some integer j and Δ ≤ max{|x|, |y|} do
    for i = 1 to b do
        for all (a, b) ∈ CandidateSet(n, m, (l_i, r_i), ε, Δ) do
            M(i, (a, b)) ← SpaceEfficientApproxED(x^i, y[a, b], b, ε).
    e ← min{e, DPEditDistance(n, m, b, ε, Δ, M)}.
return e.
```

optimal alignment. We compute the edit distance between each block and all of its candidate intervals, which gives $O(\frac{b^2}{\epsilon^2}\log n)$ values. After this, a simple dynamic programming gives $(1+O(\epsilon))$-approximation of the edit distance if Δ is a $(1+\epsilon)$-approximation of $\mathsf{ED}(x,y)$. The dynamic programming algorithm takes $O(\frac{b^3\log n}{\epsilon^3})$ time.

Since each block has length $\frac{n}{b}$, computing the edit distance of each block with one of its candidate intervals in y takes at most $O(\frac{n}{b}\log n)$ space (we assume each symbol can be stored with space $O(\log n)$). We can run this algorithm sequentially and reuse the space for each computation. Storing the edit distance of each pair takes $O(\frac{b^2}{\epsilon^2}\log^2 n)$ bits of space. Thus, if we take $b = n^{1/3}$, the above algorithm uses a total of $\tilde{O}_\epsilon(n^{2/3})$ space.

We now run the above algorithm recursively to further reduce the space required. Algorithm 2 takes four inputs: two strings $x, y \in \Sigma^n$, two parameters b, ϵ such that $b \leq \sqrt{n}$ and $\epsilon \in (0,1)$. The goal is to output a good approximation of $\mathsf{ED}(x,y)$ with small space (related to parameters b and ϵ). Similarly, we first divide x into b blocks. We try every Δ that is equal to $\lceil(1+\epsilon)^i\rceil$ for some integer i, and for each Δ there is a set of candidate intervals for each block of x. Then, for each block of x, we use a sub algorithm called *CandidateSet* to return all its $O(\frac{b}{\epsilon^2}\log n)$ candidate intervals. Instead of computing the edit distance between each block of x and its candidate intervals exactly, we recursively call our space efficient approximation algorithm with this pair as input, while keeping b and ϵ unchanged. After getting the results from the recursive calls, we combine these results with a dynamic programming (the sub algorithm *DPEditDistance*). We argue that if the recursive call outputs a $(1+\gamma)$-approximation of the actual edit distance, the output of the dynamic programming increases by at most a $(1+\gamma)$ factor. Thus if Δ is a $(1+\epsilon)$-approximation of $\mathsf{ED}(x,y)$, the output of the dynamic programming is guaranteed to be a $(1+O(\epsilon))(1+\gamma)$-approximation. The recursion stops whenever one of the input strings has length smaller than b, where we compute the edit distance exactly with $O(b\log n)$ space.

Notice that at each level of the recursion, the first input string is divided into b blocks if it has length larger than b. Thus the length of first input string at the i-th level of recursion is at most $\frac{n}{b^{i-1}}$. The depth of recursion is at most $d = \log_b n$.

At the d-th level, Algorithm 2 computes the edit distance exactly. Using this as a base case, we can show that the output of the i-th level of recursion is a $(1+O(\epsilon))^{d-i}$ approximation of the edit distance by induction on i from d to 1. Thus, the output in the first level is guaranteed to be a $(1+O(\epsilon))^d$-approximation. Since $d \leq \log_b n$, we get a $(1+O(\epsilon))^d = 1+O(\epsilon d) = 1+O(\epsilon\log_b n)$ approximation of $\mathsf{ED}(x,y)$.

To analyze the time and space complexity, we study the recursion tree in our algorithm. Notice that for each block x^i and each choice of Δ, we consider $O(\frac{b}{\epsilon^2}\log n)$ candidate intervals. Since there are b blocks and $O(\log_{1+\epsilon} n)$ choices of Δ, we need to solve $O(\frac{b^2}{\epsilon^3}\log^3 n)$ subproblems by recursion. Thus, the degree of the recursion tree is $O(\frac{b^2}{\epsilon^3}\log^3 n)$.

The dynamic programming at each level can be divided into b steps. At the j-th step, the inputs are the edit distances between block x^j and each of its candidate intervals. The information we need to maintain is an approximation of edit distances between the first $j-1$ blocks of x and the substrings $y[1,l]$ of y, where l is chosen from the set of starting points of the candidate intervals of x^j. There are $O(\frac{b}{\epsilon})$ choices for l and we query the approximated edit distance between x^j and each of its candidate intervals by recursively applying our algorithm. Thus, we only need to maintain $O(\frac{b}{\epsilon})$ values at any time for the dynamic programming.

At the i-th level of recursion, we either invoke one more level of recursion and maintain $O(\frac{b}{\epsilon})$ values where each value takes $O(\log n)$ space, or do an exact computation of edit distance when one of the input strings has length at most b, which takes $O(b\log n)$ space. Hence, the space used at each level is bounded by $O(\frac{b}{\epsilon}\log n)$. There are at most $d=\log_b n$ levels. The aggregated space used by our recursive algorithm is still $O(\frac{b\log^2 n}{\epsilon\log b})$.

We compute the running time by counting the number of nodes in the recursion tree. Notice that the number of nodes at level i is at most $(O(\frac{b^2}{\epsilon^3}\log^3 n))^{i-1}$. For each leaf node, we do exact computation with time $O(\frac{b^2}{\epsilon})$, and the number of leaf nodes is bounded by $(O(\frac{b^2}{\epsilon^3}\log^3 n))^{d-1}$. For each inner node, we run the dynamic programming $O(\log_{1+\epsilon} n)$ times (the number of choices of Δ) which takes $O(\frac{b^3\log^2 n}{\epsilon^4})$ time, and the number of inner nodes is bounded by $(d-1)(O(\frac{b^2}{\epsilon^3}\log^3 n))^{d-2}$.

If we take $b=\log n$ and $\epsilon=\frac{1}{\log n}$, we get a $(1+O(\frac{1}{\log\log n}))$-approximation using $O(\frac{\log^4 n}{\log\log n})$ space and $n^{7+o(1)}$ time. If we take $b=n^\delta$ for $\delta\in(0,\frac{1}{2})$ and ϵ a small constant, we get a $(1+O(\epsilon))$-approximation using $\tilde{O}_{\epsilon,\delta}(n^\delta)$ space and $\tilde{O}_{\epsilon,\delta}(n^2)$ time.

5.2 Improving the Runtime of Streaming ED

We can now use our techniques for small space approximation of ED to reduce the runtime of our algorithm for ED in the asymmetric streaming model proposed in Section 3. Recall that the most time consuming part of our streaming algorithm is finding the optimal window-compatible solution given a series of windows. More specifically, this can be formulated as follows. Suppose we divide the online string s into $b=n^\delta$ windows $\{s^i\}$, and in the recursion our algorithm already finds b windows $\{\bar{s}[l_i,r_i]\}$ in the offline string $\bar{s}$, that are approximately the closest to $\{s^i\}$. We now need to use the windows $\{\bar{s}[l_i,r_i]\}$ to find a substring in $\bar{s}$ that is approximately the closest to s. Previously, this is done by a brute force approach: we try all possible $1\le p_0\le p_1\le\ldots\le p_b\le n+1$ to find the set of p_i's that minimizes $\sum_{i=1}^b \mathsf{ED}(\bar{s}[p_{i-1},p_i),\bar{s}[l_i,r_i])$. Let the optimal set be $\{p_i^*\}$ and record the substring $\bar{s}[l,r]$ of $\bar{s}$ where $l=p_0^*$ and $r=p_b^*-1$. The exponential running time comes from two parts: First, the step of trying all possible $1\le p_0\le p_1\le\ldots\le p_b\le n+1$ needs to examine $\binom{n}{n^\delta+1}$ such choices. Second, when computing $\mathsf{ED}(\bar{s}[p_{i-1},p_i),\bar{s}[l_i,r_i])$, the $O(\log^2 n)$ algorithm from Savitch's theorem uses quasi-polynomial time.

Our main observation now is that, the step of trying all possible $1\le p_0\le p_1\le\ldots\le p_b\le n+1$ to find the set of p_i's that minimizes $\sum_{i=1}^b \mathsf{ED}(\bar{s}[p_{i-1},p_i),\bar{s}[l_i,r_i])$, is equivalent to finding the substring of $\bar{s}$ that minimizes the edit distance to the concatenation of $\bar{s}[l_i,r_i]$ from $i=1$ to b. Thus, instead of trying all possible p_i's, we can try all substrings of y (there

are only $O(n^2)$ such substrings) and compute the edit distance between each substring and the concatenation of the $\bar{s}[l_i, r_i]$'s. Furthermore, instead of an exact computation which either uses $\Omega(n)$ space or $2^{\Omega(\log^2 n)}$ time, we can use our $(1+\epsilon)$-approximation for ED with $\tilde{O}(n^\delta)$ space and $\tilde{O}(n^2)$ time. The approximation factor is now increased to $O((2+\epsilon)^{\frac{1}{\delta}})$, which is still $O(2^{\frac{1}{\delta}})$ if we take ϵ to be small enough. But the running time decreases to $\tilde{O}(n^4)$, and the space complexity remains $\tilde{O}(n^\delta/\delta)$.

6 $1-\epsilon$-Approximation of Streaming LCS

In this section, we design a streaming algorithm for finding a $(1-\epsilon)$ approximation of the LCS using $\tilde{O}(\sqrt{n}/\epsilon)$ memory. We first define the LCSPosition function as below. Given the online string s and the offline string $\bar{s}$, it takes a position p in $\bar{s}$ and a non-negative integer k as inputs. The output is the smallest position q such that $\mathsf{LCS}(\bar{s}[p,q], s[l,r]) \geq k$. If no such q exists, the output is ∞.

For a position p in $\bar{s}$, a substring $s[l,r]$ of s, and a non-negative integer k, we use $\text{LCSPosition}_{l,r}(p,k)$ to denote the result of the mentioned function.[2] It is easy to verify that the LCS of two strings $\bar{s}$ and s is equal to the largest k such that $\text{LCSPosition}_{1,n}(1,k) < \infty$. Therefore, instead of solving the LCS problem, we can solve the $\text{LCSPosition}_{1,n}$ problem and report the largest k such that $\text{LCSPosition}_{1,n}(1,k) < \infty$.

Algorithm 3 Algorithm for approximating the LCS in streaming model.

Data: An offline string $\bar{s}$ of length n, an online string s, and an $\epsilon^* > 0$.
1: Divide s into $\sqrt{n}$ windows $s^*_1, s^*_2, \ldots, s^*_{\sqrt{n}}$ of size $\sqrt{n}$.
2: $D \leftarrow$ an array of size $\lfloor \log_{1+\epsilon^*} n \rfloor$ initially containing ∞ in all cells.
3: **for** $i \in \lceil \sqrt{n} \rceil$ **do**
4: $\quad T \leftarrow$ an array of size $\lfloor \log_{1+\epsilon^*} n \rfloor$ initially containing ∞ in all cells.
5: $\quad$ **for** $0 \leq k \leq \lfloor \log_{1+\epsilon^*} n \rfloor$ **do**
6: $\quad\quad T[k] \leftarrow \text{LCSPosition}_{(i-1)\sqrt{n}+1, i\sqrt{n}}\left(1, \lfloor (1+\epsilon^*)^k \rfloor\right)$.
7: $\quad\quad$ **for** $0 \leq k_1 \leq k$ **do**
8: $\quad\quad\quad$ **if** $D[k_1] < \infty$ **then**
9: $\quad\quad\quad\quad$ Find $\text{LCSPosition}_{(i-1)\sqrt{n}+1, i\sqrt{n}}\left(D[k_1]+1, \lfloor (1+\epsilon^*)^k \rfloor - \lfloor (1+\epsilon^*)^{k_1} \rfloor\right)$ using any offline algorithm. Let q be this result.
10: $\quad\quad\quad\quad T[k] \leftarrow \min\{T[k], q\}$.
11: $\quad D \leftarrow T$.
12: **return** The largest value $\lfloor (1+\epsilon^*)^k \rfloor$ such that $D[k] < \infty$.
13: $\quad$ **return** 0 if no such k exists.

We now describe our algoirthm. The pseudocode is given in algorithm 3. It first divides the online string into $\sqrt{n}$ windows of equal sizes. We assume w.l.o.g., that length of the strings is divisible by $\sqrt{n}$. Otherwise we can always pad offline and online strings with different characters that are not in Σ such that their new length get divisible by $\sqrt{n}$. The algorithm divides s into $\sqrt{n}$ windows $s^*_1, s^*_2, \cdots, s^*_{\sqrt{n}}$ each with the size of $\sqrt{n}$ where s^*_i is the substring $s[(i-1)\sqrt{n}+1, i\sqrt{n}]$. Given an $\epsilon^* > 0$, the algorithm keeps an array D of the size $\lfloor \log_{1+\epsilon^*} n \rfloor$ where $D[k]$ is an estimation of $\text{LCSPosition}(1, \lfloor (1+\epsilon^*)^k \rfloor)$ in the subsequence of the online string that has arrived so far in the stream. Specifically, after arrival of the window

[2] We also define $\text{LCSPosition}_{l,r}(p,0)$ to be $p-1$.

s_i^* in the stream, the algorithm keeps an estimation of $\text{LCSPosition}_{1,i\sqrt{n}}(1, \lfloor(1+\epsilon^*)^k\rfloor)$ in $D[k]$. Please see the full version [36] for more details on how we update the array D upon arrival of a new window and why we can achieve the approximation guarantee. We have the following Theorem. The full proof is deferred to [36].

▶ **Theorem 13.** *There exists a single-pass deterministic streaming algorithm that finds a $(1-\epsilon)$ approximation of the LCS between $\bar{s}$ and s using $\tilde{O}(\sqrt{n}/\epsilon)$ memory and polynomial time.*

7 Space Efficient Algorithms for LIS in the Non-Streaming Model

We now consider approximating the LIS of a string $x \in \Sigma^n$ where the alphabet Σ has a total order. We assume each symbol in Σ can be stored with $O(\log n)$ space. Let ∞ and $-\infty$ be two special symbols such that for any symbol $\sigma \in \Sigma$, $-\infty < \sigma < \infty$. We denote the length of the longest increasing subsequence of x by $\mathsf{LIS}(x)$.

Again our algorithm is a recursive one, and in each recursion we use an approach similar to the deterministic streaming algorithm from [41] that gives a $1-\epsilon$ approximation of $\mathsf{LIS}(x)$ with $O(\sqrt{n/\epsilon}\log n)$ space. Before describing their approach, we first give a brief introduction to a classic algorithm for LIS, known as *PatienceSorting*. The algorithm initializes a list P with n elements such that $P[i] = \infty$ for all $i \in [n]$, and then scans the input sequence x from left to right. When reading a new symbol x_i, we find the smallest index l such that $P[l] \geq x_i$ and set $P[l] = x_i$. After processing the string x, for each i such that $P[i] < \infty$, we know $\sigma = P[i]$ is the smallest possible character such there is an increasing subsequence in x of length i ending with σ. Finally the algorithm returns the largest index l such that $P[l] < \infty$. This computes LIS exactly in $O(n \log n)$ time and $O(l \log n)$ space (see [5] for more details).

In the streaming algorithm from [41], we maintain a set S and a list Q, such that, $Q[i]$ is stored only for $i \in S$ and $S \subseteq [n]$ is a set of size $O(\sqrt{n})$. We use S and Q as an approximation to the list P in *PatienceSorting* in the sense that for each $s \in S$, there is an increasing subsequence in x of length s ending with $Q[s]$. More specifically, we can generate a list P' from S and Q such that $P'[i] = Q[j]$ for the smallest $j \geq i$ that lies in S. For i larger than the maximum element in S, we set $P'[i] = \infty$. Each time we read a new element, we update Q and S accordingly, which is equivalent to doing *PatienceSorting* on the list P'. When S gets larger than $2\sqrt{n}$, we do a cleanup to S by only keeping $\sqrt{n}/\epsilon$ evenly picked values from 1 to $\max S$ and storing $Q[s]$ for $s \in S$. This loses at most $\frac{\epsilon}{\sqrt{n}}\mathsf{LIS}(x)$ in the length of the longest increasing subsequence detected. Since we only do $O(\sqrt{n})$ cleanups, we are guaranteed an increasing subsequence of length at least $(1-\epsilon)\mathsf{LIS}(x)$.

We now modify the above algorithm into another form. This time we first divide x evenly into many small blocks. Meanwhile, we also maintain a set S and a list Q. We now process x from left to right, and update S and Q each time we have processed one block of x. If the number of blocks in x is small, we can get the same approximation as in [41] with S and Q having smaller size. For example, we can divide x into $n^{1/3}$ blocks each of size $n^{2/3}$, and we update S and Q once after processing each block. If we do exact computation within each block, we only need to maintain the set S and the list Q of size $O(\frac{n^{1/3}}{\epsilon})$. We can still get a $(1-\epsilon)$ approximation, because we do $n^{1/3}$ cleanups and for each cleanup, we lose about $\frac{\epsilon}{n^{1/3}}\mathsf{LIS}(x)$ in the length of the longest increasing subsequence detected.

This almost already gives us an $\tilde{O}_\epsilon(n^{1/3})$ space algorithm, except the exact computation within each block needs $O(n^{2/3}\log n)$ space. A natural idea to reduce the space complexity is to replace the exact computation with an approximation. When each block x^i has size $n^{2/3}$, running the approximation algorithm from [41] takes $O(\frac{n^{1/3}}{\epsilon}\log n)$ space and thus we

can hope to reduce the total space required to $O(\frac{n^{1/3}}{\epsilon}\log n)$. However, a problem here is that the approximation algorithm on each block x^i only gives us an approximation of $\mathsf{LIS}(x^i)$. This alone does not give us enough information on how to update S and Q. Also, for a longest increasing subsequence of x, say τ, the subsequence of τ that lies in the block x^i may be much shorter than $\mathsf{LIS}(x^i)$. This subsequence of τ may be ignored if we run the approximation algorithm instead of using exact computation.

We now give some intuition of our approach to fix these issues. Let us consider a longest increasing subsequence τ of x such that τ can be divided into many parts, where the i-th part τ^i lies in x^i. We denote the length of τ^i by d_i. Let the first symbol of τ^i be α_i and the last symbol be β_i if τ^i is not empty. When we process the block x^i, we want to make sure that our algorithm can detect an increasing subsequence of length very close to d_i in x^i, where the first symbol is at least α_i and the last symbol is at most β_i. We can achieve this by running a bounded version of the approximation algorithm which only considers increasing subsequences no longer than d_i. Since we do not know α_i or d_i in advance, we can guess α_i by trying every symbol in $Q[s]$ where one of them is close enough to α_i. For d_i, we can try $O(\log_{1+\epsilon} n)$ different values of l such that one of them is close enough to d_i. In this way, we are guaranteed to detect a good approximation of τ_i.

Based on the above intuition, we now introduce our space-efficient algorithm for LIS called **ApproxLIS**. The pseudocode is given in Algorithm 4. It takes three inputs, a string $x \in \Sigma^*$, two parameters b and ϵ. We also introduce a slightly modified version of **ApproxLIS** called **ApproxLISBound**. It takes an additional input l, which is an integer at most n. We want to guarantee that if the string x has an increasing subsequence of length l ending with $\alpha \in \Sigma$, then **ApproxLISBound**(x, b, ϵ, l) can detect an increasing subsequence of length close to l ending with some symbol no larger than α. The idea is to run **ApproxLIS** but only consider increasing subsequence of length at most l. **ApproxLISBound** has the same space and time complexity as **ApproxLIS**.

We now describe **ApproxLIS**. When the input string x has length at most b^2, we compute an $(1-\epsilon)$-approximation of LIS using the algorithm in [41] with $O(\frac{b}{\epsilon}\log n)$ space. Otherwise, we divide the input string into b blocks each of length $\frac{n}{b}$. Similar to the streaming algorithm in [41], we maintain two sets S and Q of size $O(\frac{b}{\epsilon})$ as an approximation of the list P when running *PatienceSorting*. We will show that it is enough to use $O(\frac{b}{\epsilon}\log n)$ bits for S and Q, because we only update them b times and we lose about $O(\frac{\epsilon}{b})\,\mathsf{LIS}(x)$ after each update. Initially, S contains only one element 0 and $Q[0] = -\infty$. We update S and Q after processing each block of x as follows.

For simplicity, we denote S and Q after processing the t-th block by S_t and Q_t. To see how S and Q are updated, we take the t-th update as an example. Given S_{t-1} and Q_{t-1}, we first determine the length of the LIS in $x^1 \circ \cdots \circ x^t$ that can be detected based on S_{t-1} and Q_{t-1}. We denote this length by k_t. Notice that, for each $s \in S_{t-1}$, we know there is an increasing subsequence in $x^1 \circ \cdots \circ x^{t-1}$ of length s ending with $Q_{t-1}[s] \in \Sigma$. This gives us $|S_{t-1}|$ increasing subsequences. The idea is to find the best extension of these increasing subsequences in the block x^t and see which one gives us the longest increasing subsequence of $x^1 \circ \cdots \circ x^t$. Since each block is of size $\frac{n}{b}$, we cannot always afford to do exact computation. Thus we compute an approximation of the LIS by recursively calling **ApproxLIS** itself. For each $s \in S_{t-1}$, we run **ApproxLIS**(z^s, b, ϵ) where z^s is the subsequence of x^t with only symbols larger than $Q_{t-1}[s]$. Finally, we let $k_t = \max_{s\in S_{t-1}}(s + \textbf{ApproxLIS}(z^s, b, \epsilon))$. Given k_t, we then set S_t to be the $\frac{b}{\epsilon}$-th evenly picked integers from 0 to k_t.

The next step is to compute Q_t. We first set $Q_t[s] = \infty$ for all $s \in S_t$ except $s = 0$, and we set $Q_t[0] = -\infty$. Then, for each $s \in S_{t-1}$ and $l = 1, 1+\epsilon, (1+\epsilon)^2, \ldots, k_t - s$, we run **ApproxLISBound**(z^s, b, ϵ, l). For each $s' \in S_t$ such that $s \le s' \le s + l$, we update $Q_t[s']$

Algorithm 4 Algorithm **ApproxLIS** (**ApproxLISBound**) for approximating LIS.

Data: A string x , parameters b and ϵ. And an additional parameter l for **ApproxLISBound**

if $|x| \leq b^2$ **then**
  compute an $(1-\epsilon)$-approximation of $\mathsf{LIS}(x)$ with the streaming algorithm from [41] using $O(\frac{b}{\epsilon}\log n)$ space. (For **ApproxLISBound**, we only consider LIS of length at most l.)
  return
divide x evenly into b blocks such that $x = x^1 \circ x^2 \circ \cdots \circ x^b$. ▷ $|x^i| \leq \lceil n/b \rceil$
initialize $S = \{0\}$ and $Q[0] = -\infty$.
for $i = 1$ **to** b **do**
  $k = 0$.
  for all $s \in S$ **do**
    let z be the subsequence of x^i by only considering the elements larger than $Q[s]$.
    $d =$ **ApproxLIS**(z, b, ϵ).
    $k = \max\{k, s+d\}$. (For **ApproxLISBound**, we let $k = \min\{l, \max\{k, s+d\}\}$) .
  if $k \leq b/\epsilon$ **then**
    let $S' = \{0, 1, 2, \ldots, k\}$.
  else
    let $S' = \{0, \frac{\epsilon}{b}k, 2\frac{\epsilon}{b}k, \ldots, k\}$. ▷ *evenly pick* $b/\epsilon + 1$ *integers from* 0 *to* k *(including* 0 *and* k*).*
  $Q'[s] = \infty$ for all $s' \in S'$ except $Q'[0] = -\infty$.
  for all $s \in S$ **do**
    let z be the subsequence of x^i by only considering the elements larger than $Q[s]$.
    for all $l = 1, 1+\epsilon, (1+\epsilon)^2, \ldots, k-s$ **do**
      $\tilde{S}, \tilde{Q} \leftarrow$ **ApproxLISBound**(z, b, ϵ, l) .
      for each $s' \in S'$ such that $s \leq s' \leq s+l$, let $\tilde{s}$ be the smallest element in $\tilde{S}$ that is larger than $s'-s$ and set $Q'[s'] = \min\{\tilde{Q}[\tilde{s}], Q'[s']\}$.
  $S \leftarrow S'$, $Q \leftarrow Q'$.
return $\max S$. (for **ApproxLISBound**, we return the set S and Q)

if **ApproxLISBound**(z^s, b, ϵ, l) detects an increasing subsequence of length at least $s'-s$ ending with a symbol smaller than the old $Q_t[s']$. The intuition is that, with the bound l, we may be able to find a smaller symbol in Σ such that there is an increasing subsequence of length l ending with it. This information can be easily ignored if l is a lot smaller than the actual length of LIS in x^t. To see why this is important, let τ be a longest increasing subsequence of x, and let τ^t be the part of τ that lies in the block x^t. The length of τ^t may be much smaller than the length of LIS in x^t. When the bound l is close to $|\tau^t|$, we will be able to detect a good approximation of τ^t by running **ApproxLISBound**(z^s, b, ϵ, l) on z^s for each $s \in S_{t-1}$. Since we do not know the length of τ^t, we will guess it by trying $O_\epsilon(\log n)$ values of l and always record the optimal $Q_t[s]$ for $s \in S_t$.

Continue doing this, we get S_b and Q_b. **ApproxLIS** outputs the largest element in S_b.

ApproxLIS is recursive. We denote the depth of recursion by d, and it can be seen that d is at most $\log_b n - 1$. To see the correctness of our algorithm, given fixed b, ϵ, we show the output at the r-th recursive level is a $(1 - O((d-r)\epsilon))$-approximation. Thus, the final output will be a $(1 - O(\epsilon \log_b n))$-approximation to $\mathsf{LIS}(x)$.

The proof is by induction on r from d to 1. For the base case of $r = d$, the statement follows from [41]. Now consider the computation at the r-th level. For convenience, we denote the input string by x, which has length at most $\frac{n}{b^{r-1}}$. Let τ be an increasing subsequence of x where τ^i lies in x^i. For our analysis, let P'_t be the list generated by S_t and Q_t in the following way: for every i let $P'_t[i] = Q_t[j]$ for the smallest $j \geq i$ that lies in S_t. If no such j exists, set $P'_t[i] = \infty$. Correspondingly, P_t is the list P after running *PatienceSorting* with input $x^1 \circ x^2 \circ \cdots \circ x^t$.

Let $h_t = \sum_{j=1}^{t} |\tau^j|$ and $k_t = \max S_t$, our main observation is the following inequality:

$$P'_t[(1 - 3(d - (r+1)\epsilon - \epsilon)h_t - 2t\frac{\epsilon}{b}k_t] \leq P_t[h_t] \tag{4}$$

Note that $h_b = |\tau| = \mathsf{LIS}(x)$. We have $P_b[h_b] < \infty$ by the correctness of *PatienceSorting*. If inequality 4 holds, then by $k_t \leq h_t$, there must exist an element in S_b larger than $(1 - 3(d-r)\epsilon)\,\mathsf{LIS}(x)$ which gives the correctness of the computation at the r-th level.

We prove inequality 4 by induction on t. The intuition is that, at the t-th update, if inequality 4 holds for $t-1$, we know that there must exist an $s \in S_{t-1}$ that is close to h_{t-1} and $Q_{t-1}[s] \leq P_{t-1}[h_{t-1}] = \beta_{t-1} < \alpha_t$. By trying $l = 1, 1+\epsilon, (1+\epsilon), \ldots, k_t - s$, one l is close enough to $|\tau^t|$. Thus we are guaranteed to detect a good approximation of τ_t in x^t and the inequality also holds for t.

At each recursive level, we need to maintain the sets S and Q with space $O(\frac{b}{\epsilon}\log n)$. Thus the total space is $O(d\frac{b}{\epsilon}\log n) = O(\frac{b\log^2 n}{\epsilon \log b})$. The analysis of time complexity is similar to the case of edit distance, where we analyze the recursion tree and bound the number of nodes.

If we take $b = \log n$ and $\epsilon = \frac{1}{\log n}$, we get a $(1 - O(\frac{1}{\log\log n}))$-approximation algorithm using $O(\frac{\log^4 n}{\log\log n})$ space and $O(n^{5+o(1)})$ time. Let $\delta \in (0, \frac{1}{2})$ be a constant such that $\frac{1}{\delta}$ is an integer. If we take $b = n^\delta$ and ϵ a small constant, we get a $(1 + O(\epsilon))$-approximation algorithm using $\tilde{O}_{\epsilon,\delta}(n^\delta)$ space and $\tilde{O}_{\epsilon,\delta}(n^{2-2\delta})$ time.

8 Space Efficient ALgorithms for LCS in the Non-Streaming Model

Our algorithm for LCS is based on a reduction to LIS. Given input strings x and y, for each $i \in [n]$ let $b^i \in [m]^*$ be the sequence consisting of all distinct indices j in $[m]$ such that $x_i = y_j$, arranged in descending order. Note that b^i may be empty. Let $z = b^1 \circ b^2 \circ \cdots \circ b^n$, which has length $O(mn)$ since each sequence b^i is of length at most m. We claim that $\mathsf{LIS}(z) = \mathsf{LCS}(x, y)$. This is because for every increasing subsequence of z, say $t = t_1 t_2 \cdots t_d$, the corresponding subsequence $y_{t_1} y_{t_2} \cdots y_{t_d}$ of y also appears in x. Conversely, for every common subsequence of x and y, we can find an increasing subsequence in z with the same length. We call this procedure ReduceLCStoLIS. Note that in our algorithms, z need not be stored, since we can compute each element in z as necessary in logspace by querying x and y. Thus our reduction is a logspace reduction.

Based on the reduction, we can use similar techniques as we used for LIS. Specifically, let $z = \textbf{ReduceLCStoLIS}(x, y)$. We call our space efficient algorithm for LCS **ApproxLCS**. If one input string is shorter than the parameter b, we know $\mathsf{LCS}(x, y) \leq b$ and we can compute $\mathsf{LIS}(z)$ using *PatienceSorting* with $O(b \log n)$ space. Otherwise, the goal is to compute an approximation of $\mathsf{LIS}(z)$. One difference here is, instead of dividing z evenly into b blocks, we divide z according to x. That is, we first divide x evenly into b blocks, and then divide z into b blocks such that $z^i = \text{ReduceLCStoLIS}(x^i, y)$. This gives us a slight improvement on running time over the naive approach of running our LIS algorithm on z. Note that $\mathsf{LIS}(z^i)$ is at most $\frac{n}{b}$ since the length of x^i is $\frac{n}{b}$. We compute an approximation of $\mathsf{LIS}(z^i)$ by recursively calling **ApproxLCS** with inputs x, y, b, ϵ. The input size to the next recursive level is decreased by a factor of b. The remaining analysis is similar to the case of LIS.

Abstract

We study quantum algorithms that learn properties of a matrix using queries that return its action on an input vector. We show that for various problems, including computing the trace, determinant, or rank of a matrix or solving a linear system that it specifies, quantum computers do not provide an asymptotic speedup over classical computation. On the other hand, we show that for some problems, such as computing the parities of rows or columns or deciding if there are two identical rows or columns, quantum computers provide exponential speedup. We demonstrate this by showing equivalence between models that provide matrix-vector products, vector-matrix products, and vector-matrix-vector products, whereas the power of these models can vary significantly for classical computation.

1 Introduction

Algorithms for linear algebra problems – for example, solving linear systems and determining basic properties of matrices such as rank, trace, determinant, eigenvalues, and eigenvectors – constitute a fundamental research area in applied mathematics and theoretical computer science. Such tasks have widespread applications in scientific computation, statistics, operations research, and many other related areas. Algorithmic linear algebra also provides a fundamental toolbox that can inspire the design of algorithms in general.

There are several possible models of access to a matrix, and linear-algebraic algorithms can depend significantly on how the input is represented (as discussed further below). One natural model is the *matrix-vector product* (Mv) oracle. For a matrix $M \in \mathbb{F}^{n\times m}$ in a given field $\mathbb{F}$, the Mv oracle takes $x \in \mathbb{F}^m$ as input and outputs $Mx \in \mathbb{F}^n$. Matrix-vector products arise, for example, as the elementary step of the power method (and the related Lanczos method) for computing the largest eigenvector of a matrix. Matrix-vector products also commonly appear in streaming algorithms, especially in the technique of sketching (see the survey [22] for more information).

Recent work has studied the classical complexity of various basic problems in the Mv model. Specifically, Sun, Woodruff, Yang, and Zhang [21] studied the complexities of various linear algebra, statistics, and graph problems using matrix-vector products, and Braverman, Hazan, Simchowitz, and Woodworth [8] proved tight bounds on maximum eigenvalue computation and linear regression in this model. Rashtchian, Woodruff, and Zhu [19] considered a generalization to the vector-matrix-vector product (vMv) oracle, which returns $x^\top My$ for given input vectors $x \in \mathbb{F}^n, y \in \mathbb{F}^m$, and studied the complexity of various linear algebra, statistics, and graph problems in this setting. Table 1 includes a partial summary of these results.

Quantum computers can solve certain problems much faster than classical computers, so it is natural to study quantum query complexity with matrix-vector products. Lee, Santha, and Zhang recently studied the quantum query complexity of graph problems with cut queries [17], which are closely related to matrix-vector queries. For a weighted graph $G = (V, w)$ where $|V| = n$ and w assigns a nonnegative integer weight to each edge, the input of a cut query is a subset $S \subseteq V$ and the output is $|w(S, V \setminus S)|$, the total weight of the edges between S and $V \setminus S$. This can be viewed as a version of the vMv model over $\mathbb{Z}$, with the extra assumptions that $x \in \{0,1\}^n, y \in \{0,1\}^m$ are both boolean and M is a symmetric matrix with nonnegative integer entries. Reference [17] gives quantum algorithms for determining all connected components of G with $O(\log^6 n)$ quantum cut queries, and for outputting a spanning forest of G with $O(\log^8 n)$ quantum cut queries. Both problems require $\Omega(n/\log n)$ classical cut queries, so the quantum algorithms provide exponential speedups.

In other recent work on structured queries for graph problems, Montanaro and Shao studied the problem of learning an unknown graph with "parity queries" [18]: for an unknown graph with adjacency matrix A, the parity oracle takes as input a string x that encodes a subset of the vertices, and returns $x^\top Ax \bmod 2$. This query model is the vMv model over $\mathbb{F}_2$ with the extra restriction that the left and right vectors are identical.

Van Apeldoorn and Gribling studied Simon's problem for linear functions over a prime field $\mathbb{F}_p$ [4]. In this problem, the oracle encodes a linear function $f\colon \mathbb{F}_p \to \mathbb{F}_p$, and the task is to determine if the function is one-to-one, or if there is a one-dimensional subspace $H \subset \mathbb{F}_p$ such that for every $x, x' \in \mathbb{F}_p^n$, $f(x) = f(x')$ if and only if $x - x' \in H$. Such a function can be represented by a square matrix over $\mathbb{F}_p$, and the problem is equivalent to determining whether that matrix is full rank or has nullity 1 using matrix-vector product queries.

Other past work has developed linear algebraic quantum algorithms using different input models. Quantum algorithms for high-dimensional linear algebra have been studied extensively since Harrow, Hassidim, and Lloyd introduced a method for generating a quantum state proportional to the solution of a large, sparse system of linear equations [14]. This algorithm assumes a quantum oracle that determines the locations and values of the nonzero entries of a matrix in any given row or column, and the ability to generate a quantum state that encodes the right-hand side of the linear system. Subsequent work has led to improved and generalized algorithms under similar assumptions. However, it is challenging to find practical applications that achieve speedup over classical computation [2,11]. Recent work by Apers and de Wolf [5] gives polynomial quantum speedup for producing an explicit classical description of the solution of a Laplacian linear system, assuming adjacency-list access to the underlying graph of the Laplacian. Note also that for various problems including determinant estimation, rank testing, linear regression, etc., there is a large separation between the classical query complexities under Mv and entrywise queries ($\tilde{\Theta}(n)$ [21] and $\Theta(n^2)$, respectively). These results show how the model of access to a matrix can significantly impact the complexity of solving linear-algebraic problems. A better understanding of the quantum matrix-vector oracle could therefore provide a useful tool for the design of future quantum algorithms.

Contributions. We conduct a systematic study of quantum query complexity with a matrix-vector oracle for a matrix $M \in \mathbb{F}_q^{m\times n}$, where $\mathbb{F}_q$ is a given finite field. Using this model, we provide results on the quantum query complexities of linear algebra and statistics problems.

First, we prove that various linear algebra problems, including

- computing the trace $\mathrm{tr}(M)$ of $M \in \mathbb{F}_q^{n\times n}$;
- computing the determinant $\det(M)$ of $M \in \mathbb{F}_q^{n\times n}$;
- solving the linear system $Ax = b$ for $A \in \mathbb{F}_q^{n\times n}$; and
- testing whether $\mathrm{rank}(M) = n$ or $\mathrm{rank}(M) \le n/2$ for a matrix $M \in \mathbb{F}_q^{m\times n}$;

require $\Omega(n)$ quantum queries to the Mv oracle. Since $O(n)$ queries suffice to determine the entire matrix, even classically, these results show that no quantum speedup is possible. (As a side effect, we improve the $\Omega(n/\log n)$ classical lower bound for trace computation [21] to $\Omega(n)$.)

Our quantum lower bound for trace computation applies results of Copeland and Pommersheim [12] by viewing the problem as a special case of *coset identification*. Our lower bounds for other linear algebra problems are all proved by the polynomial method [1,6]. We show how to symmetrize the success probability to a univariate polynomial, and then give a lower bound on the polynomial degree using an observation of Koiran, Nesme, and Portier [16].

On the other hand, we determine the matrix-vector quantum query complexity of several statistics problems, including

- computing the row and column parities of $M \in \mathbb{F}_2^{m\times n}$;
- deciding if there exist two identical columns in $M \in \mathbb{F}_2^{m\times n}$; and
- deciding if there exist two identical rows in $M \in \mathbb{F}_2^{m\times n}$.

Specifically, we prove that their quantum query complexities with an Mv oracle are $O(1)$, $O(\log n)$, and $O(\log m)$, respectively. Compared to the classical bounds using either the Mv oracle [21] or the vMv oracle [19], our quantum algorithms achieve *exponential* quantum speedups.

Technically, these results build upon our observation that the quantum query complexities in the Mv model under left or right multiplication are *identical* (Theorem 5). In particular, one right Mv query can be simulated using one left Mv query, and vice versa. In contrast,

classically there is a significant difference between matrix-vector (Mv) and vector-matrix (vM) queries – for example, computing the parity of rows over $\mathbb{F}_2$ only takes $O(1)$ Mv queries, but computing the parity of columns over $\mathbb{F}_2$ requires $\Theta(n)$ Mv queries. In contrast, for both problems a quantum computer can achieve the smaller query complexity by switching to the easier side.

Table 1 Comparison of classical and quantum query complexities with matrix-vector (Mv) and vector-matrix-vector (vMv) product oracles for an $m \times n$ matrix. For trace and linear regression, $m = n$. Known query complexities over $\mathbb{R}$ and $\mathbb{F}_q$ are included for completeness; results over different fields are incomparable in general.

Problem	Classical Mv	Classical vMv	Quantum (this paper)
Trace	$O(n), \Omega(n/\log n)$ for matrix with entries in $\{0, 1, \ldots, n^3\}$ & queries with entries in $\{0, 1, \ldots, n^C\}$, $C \in \mathbb{N}$ [21]; $\Theta(n)$ over $\mathbb{F}_q$ (Theorem 16)	$O(n), \Omega(n/\log n)$ for matrix with entries in $\{0, 1, \ldots, n^3\}$ & queries with entries in $\{0, 1, \ldots, n^C\}$, $C \in \mathbb{N}$ [19]; $\Theta(n)$ over $\mathbb{F}_q$ (Theorem 16)	$\Theta(n)$ over $\mathbb{F}_q$ (Theorem 16)
Linear regression	$\Theta(n)$ over $\mathbb{R}$ [8]; $\Theta(n)$ over $\mathbb{F}_q$ (Theorem 24)	$\Theta(n^2)$ over $\mathbb{F}_q$ (Corollary 25)	$\Theta(n)$ over $\mathbb{F}_q$ (Theorem 24)
Rank testing	$k+1$ to distinguish rank $\leq k$ from $k' > k$ over $\mathbb{R}$ [21]; $\Theta(n)$ over $\mathbb{F}_q$ (Theorem 27)	$\Omega(k^2)$ to distinguish rank k from $k+1$ over $\mathbb{F}_q$ [19]; $\Omega(n^{2-O(\epsilon)})$ for non-adaptive $(1 \pm \epsilon)$-approximation over $\mathbb{R}$ [19]	$\Theta(\min\{m, n\})$ to distinguish rank $\min\{m, n\}$ from $\leq \frac{1}{2}\min\{m, n\}$ over $\mathbb{F}_q$ (Theorem 27)
Two identical columns	$O(n/m)$, $m = \Omega(\log(n/\epsilon))$ over $\mathbb{F}_2$ [21]	$O(n \log n), \Omega(n)$ over $\mathbb{F}_2$ [19]	$O(\log n)$ over $\mathbb{F}_2$ (Corollary 8)
Two identical rows	$O(\log m)$ over $\mathbb{F}_2$ [21]	$O(n \log n), \Omega(n)$ over $\mathbb{F}_2$ [19]	$O(\log m)$ over $\mathbb{F}_2$ (Corollary 8)
Majority of columns	$\Omega(n/\log n)$ for binary matrices over $\mathbb{R}$ [21]	$\Theta(n^2)$ over $\mathbb{F}_2$ [19]	$O(1)$ for binary matrices over $\mathbb{R}$ (Corollary 10)
Majority of rows	$O(1)$ for binary matrices over $\mathbb{R}$ [21]	$\Theta(n^2)$ over $\mathbb{F}_2$ [19]	$O(1)$ for binary matrices over $\mathbb{R}$ (Corollary 10)
Parity of columns	$\Theta(n)$ over $\mathbb{F}_2$ [21]	$\Theta(n)$ over $\mathbb{F}_2$ (Lemma 7)	$O(1)$ over $\mathbb{F}_2$ (Corollary 6)
Parity of rows	$O(1)$ over $\mathbb{F}_2$ [21]	$\Theta(m)$ over $\mathbb{F}_2$ (Lemma 7)	$O(1)$ over $\mathbb{F}_2$ (Corollary 6)

Our results are summarized in Table 1, including some implications of our results for classical query complexity and a few additional results over $\mathbb{R}$. Note that there can be large gaps between the classical query complexities with Mv and vMv queries, but they are the same in the quantum setting due to an equivalence between quantum Mv and vMv queries (Theorem 11), which follows along similar lines to the equivalence between Mv and vM queries. The Mv–vMv equivalence is closely related to a similar equivalence shown in the work of Lee, Santha, and Zhang [17], as we discuss further in Section 3.2.

Open questions. Our paper leaves several natural open questions for future investigation:

- For linear algebra problems such as those we studied, can we also prove quantum query lower bounds for matrices over the real field $\mathbb{R}$? Our proofs rely on the polynomial method, and it is unclear how to adapt them to a setting with continuous input.
- Can we prove a quantum lower bound for the task of minimizing a quadratic form $f(x) = \frac{1}{2}x^\top Ax + b^\top x$, where $A \in \mathbb{R}^{n\times n}$ and $b \in \mathbb{R}^n$? Note that f is minimized at $x = -A^{-1}b$, and we can determine the vector b and implement Mv queries to the matrix A using fast quantum gradient computation [15], so this is closely related to the previous open question. Quadratic form minimization is a special case of optimizing a convex function $f\colon \mathbb{R}^n \to \mathbb{R}$ by quantum evaluation queries, where previous works [3, 10, 13] left a quadratic gap between the best known quantum upper and lower bounds of $\tilde{O}(n)$ and $\Omega(\sqrt{n})$, respectively.
- For the finite field case, can we identify other problems with quantum speedup over the classical matrix-vector oracle, or find advantage compared to other quantum oracles such as entrywise queries?

Organization. We review necessary background in Section 2. We prove the equivalence of quantum matrix-vector and vector-matrix-vector product oracles in Section 3. In Section 4, we prove tight quantum query complexity lower bounds on various linear algebra problems, including trace, determinant, linear systems, and rank.

2 Preliminaries

2.1 The quantum query model

Given a set X and an abelian group G, let $f\colon X \to G$ be a function. Access to f is provided by a black-box unitary operation $U_f\colon |x, y\rangle \mapsto |x, y + f(x)\rangle$ for all $x \in X$ and $y \in G$. We call an application of U_f a (standard) query.

For a finite abelian group G, the Fourier transform over G is

$$F_G := \frac{1}{|G|^{1/2}} \sum_{x\in G} \sum_{y\in \hat{G}} \chi_y(x)|y\rangle\langle x|, \tag{1}$$

where $\hat{G}$ is a complete set of characters of G, and $\chi_y\colon G \to \mathbb{C}$ denotes the y^{th} character of G. Since $\hat{G} \cong G$, we label elements of $\hat{G}$ using elements of G. Note that χ_y is a group homomorphism, i.e., $\chi_y(x + z) = \chi_y(x)\chi_y(z)$. In addition, the characters satisfy the orthogonality condition

$$\frac{1}{|G|} \sum_{z\in G} \chi_y(z)^* \chi_w(z) = \delta_{yw}. \tag{2}$$

A phase query is defined as a standard query conjugated by the Fourier transform acting on the output register. In other words, for $x \in X$ and $y \in G$, a phase query acts as

$$\begin{aligned} |x, y\rangle &\xmapsto{\mathbb{1}\otimes F_G^\dagger} \frac{1}{|G|^{1/2}} \sum_{z\in G} \chi_y(z)^* |x, z\rangle \\ &\xmapsto{U_f} \frac{1}{|G|^{1/2}} \sum_{z\in G} \chi_y(z)^* |x, z + f(x)\rangle \\ &\xmapsto{\mathbb{1}\otimes F_G} \frac{1}{|G|} \sum_{z\in G} \chi_y(z)^* \chi_w(z + f(x))|x, w\rangle = \chi_y(f(x))|x, y\rangle. \end{aligned} \tag{3}$$

The equality in (3) follows from the orthogonality condition in (2). Since one can simulate a phase query using a single standard query and vice versa, the query complexities of any problem are equal with these two models.

Over a finite field $\mathbb{F}_q$ for prime power $q = p^r$, the Fourier transform over $\mathbb{F}_q$ is the unitary transformation $|x\rangle \mapsto q^{-1/2} \sum_{y \in \mathbb{F}_q} e(xy)|y\rangle$, where the exponential function $e\colon \mathbb{F}_q \to \mathbb{C}$ is defined as $e(z) := e^{2\pi i \mathrm{Tr}_{\mathbb{F}_q/\mathbb{F}_p}(z)/p}$ and the trace function $\mathrm{Tr}_{\mathbb{F}_q/\mathbb{F}_p}\colon \mathbb{F}_q \to \mathbb{F}_p$ is defined as $\mathrm{Tr}_{\mathbb{F}_q/\mathbb{F}_p}(z) := z + z^p + z^{p^2} + \cdots + z^{p^{r-1}}$.

Over the field of real numbers, the quantum Fourier transform is

$$F_{\mathbb{R}} := \int_{\mathbb{R}} \mathrm{d}y \int_{\mathbb{R}} \mathrm{d}x \, e^{2\pi i y x} |y\rangle\langle x|. \tag{4}$$

The basis states $\{|x\rangle : x \in \mathbb{R}\}$ are normalized to the Dirac delta function, i.e., for $x, x' \in \mathbb{R}$, $\langle x'|x\rangle = \delta(x - x')$. Here the Dirac delta function δ satisfies $\int_{\mathbb{R}} \mathrm{d}x' \, \delta(x - x') f(x') = f(x)$ for any function f. Furthermore, we have $\int_{\mathbb{R}} \mathrm{d}y \, e^{2\pi i y(x - x')} = \delta(x - x')$. By direct calculation using these facts, $F_{\mathbb{R}}^\dagger F_{\mathbb{R}} = \int_{\mathbb{R}} \mathrm{d}x \, |x\rangle\langle x| = \mathbb{1}$.

While we can formally consider a model of query complexity over $\mathbb{R}$ with arbitrary precision, its practical instantiation requires discrete approximation. We can achieve precision ϵ by approximating real numbers with $s = O(\log(1/\epsilon))$ bits, and can then replace the continuous Fourier transform with the discrete Fourier transform over $\mathbb{Z}_{2^s}$. It is straightforward to show that a discretized phase query over $\mathbb{Z}_{2^s}$ can be implemented by Fourier transforming a standard query that maps discretized inputs to discretized function values.

2.2 The coset identification problem

Copeland and Pommersheim studied a kind of quantum query problem that they call the *coset identification problem* [12]. They define this problem in a generalized query model where the black box does not necessarily perform a standard or phase query, although their definition includes those cases. In the coset identification problem, we fix a finite group G and a subgroup $H \leq G$. The algorithm is given access to a unitary transformation $\pi(g)$, where π is a representation of G on vector space V. When π is given, the vector space V is called the representation space (or simply, the representation) of G [20, Chapter 1]. The goal is to determine which coset of H the unknown element $g \in G$ belongs to.

▶ **Definition 1** (Coset identification problem [12]). *A coset identification problem for a finite group G and subgroup $H \leq G$ is a 3-tuple (π, V, F) such that*

- *π is a unitary representation of G in the complex vector space V, and*
- *F is a function constant on left cosets of $H \leq G$ and distinct on distinct cosets, i.e., $F(g) = F(g')$ if and only if $g' = gh$ for some $h \in H$.*

Given a black box that performs the unitary transformation $\pi(g)$, the goal is to compute $F(g)$.

Copeland and Pommersheim show that the optimal success probability of a t-query algorithm for a coset identification problem can be calculated by taking, over all irreps Y of H, the maximum of the fraction of the induced representation $Y^\uparrow$ of G shared with $V^{\otimes t}$. Furthermore, the optimal algorithm can be non-adaptive. For a representation V, let $I(V)$ denote the set of irreducible characters of G appearing in V.

▶ **Theorem 2** (Optimal success probability of coset identification [12, Corollary 5.7]). *The optimal success probability of any t-query quantum algorithm $\mathcal{A}$ for the coset identification problem (π, V, F) for finite group G and subgroup $H \leq G$, under uniformly random inputs in G, is*

$$\Pr[\mathcal{A}^{\pi(g)} = F(g)] = \max_Y \frac{\dim Y^\uparrow_{V^{\otimes t}}}{\dim Y^\uparrow}, \tag{5}$$

where the probability is maximized over all irreducible representations Y of H, $Y^{\uparrow}$ is the induced representation of G, and A_B is the maximal subrepresentation of A such that $I(A_B) \subseteq I(B)$ for representations A, B.

The *oracle discrimination problem* is the special case of the coset identification problem where H is the trivial group, i.e., the function F is injective. In this case, $Y^{\uparrow} = \mathrm{span}\{|g\rangle : g \in G\}$.

▶ **Corollary 3** (Optimal success probability of oracle discrimination [12, Theorem 4.2])**.** *The optimal success probability of the oracle discrimination problem is*

$$\frac{1}{|G|} \sum_{i \in I(V^{\otimes t})} d_i^2, \tag{6}$$

where $I(V^{\otimes t})$ is the irrep content of $(\pi^{\otimes t}, V^{\otimes t})$ and d_i is the dimension of irrep $i \in I(V^{\otimes t})$.

We consider the complexity of standard queries in the matrix-vector model. In this model, oracle access to a matrix $M \in \mathbb{F}^{m \times n}$ for field $\mathbb{F}$ and positive integers m, n is the unitary operation $U(M)\colon |x, y\rangle \mapsto |x, y + Mx\rangle$. The map U is a representation of the additive group of matrices since it is a group homomorphism satisfying $U(M)U(N) = U(M + N)$ for all matrices M, N of the same dimensions. A phase query is also a unitary representation since it is a standard query conjugated by a fixed unitary matrix (the quantum Fourier transform).

2.3 The polynomial method

We will use the polynomial method to obtain quantum lower bounds. Here we state a version for non-boolean functions as used in [1].

▶ **Lemma 4.** *Let $\mathcal{A}$ be a t-query quantum algorithm given access to the input $x \in [m]^n$ for $m, n \in \mathbb{Z}$ through oracle $U_x\colon |i, j\rangle \mapsto |i, j + x_i\rangle$ for $i \in [n]$ and $j \in [m]$. The acceptance probability of $\mathcal{A}$ on input x is a degree-$(2t)$ polynomial in $x_1, \ldots, x_n$.*

3 Equivalence of matrix-vector and vector-matrix-vector products

In this section, we show that the matrix-vector and vector-matrix-vector models are equivalent, i.e., for any problem, the quantum query complexities in these models differ by at most a constant factor. Furthermore, we show that in the matrix-vector model, left matrix-vector products and right matrix-vector products are equivalent. This is in stark contrast to the classical case where these query complexities can differ significantly, as mentioned in Section 1 and discussed further below.

3.1 Left and right matrix-vector queries

We first show that left matrix-vector products and right matrix-vector products are equivalent.

▶ **Theorem 5.** *Quantum query complexities in the left and right matrix-vector models over a finite field are identical. In particular, one right* Mv *query can be simulated using one left* Mv *query, and vice versa.*

Proof. For input matrix $M \in \mathbb{F}_q^{n \times m}$, a matrix-vector (Mv) query applies the unitary transformation

$$U^{\mathsf{Mv}}(M)\colon |x, y\rangle \mapsto |x, y + Mx\rangle \tag{7}$$

for every $x \in \mathbb{F}_q^m$ and $y \in \mathbb{F}_q^n$. Conjugating by a quantum Fourier transform on the output register yields a phase query

$$\begin{aligned}
|x,y\rangle &\xmapsto{\mathbb{1}\otimes F_{\mathbb{F}_q^n}^\dagger} q^{-1/2}\sum_z e(-y^\top z)|x,z\rangle \\
&\xmapsto{U^{\mathsf{Mv}}(M)} q^{-1/2}\sum_z e(-y^\top z)|x,z+Mx\rangle \\
&\xmapsto{\mathbb{1}\otimes F_{\mathbb{F}_q^n}} q^{-1}\sum_{z,w} e(-y^\top z + w^\top(z+Mx))|x,w\rangle \\
&= \sum_w \delta[y=w] e(-y^\top z + w^\top(z+Mx))|x,w\rangle \\
&= e(y^\top Mx)|x,y\rangle. \qquad (8)
\end{aligned}$$

We denote this unitary transformation by $U^{\widetilde{\mathsf{Mv}}}(M)$.

Conjugating a phase query by a swap gate, we have

$$\begin{aligned}
|x,y\rangle &\xmapsto{\mathsf{SWAP}} |y,x\rangle \\
&\xmapsto{U^{\widetilde{\mathsf{Mv}}}(M)} e(x^\top My)|y,x\rangle \\
&\xmapsto{\mathsf{SWAP}} e(x^\top My)|x,y\rangle \\
&= e(y^\top M^\top x)|x,y\rangle. \qquad (9)
\end{aligned}$$

This yields $U^{\widetilde{\mathsf{Mv}}}(M^\top)$, which in turn gives $U^{\mathsf{Mv}}(M^\top)$ upon conjugation by an inverse quantum Fourier transform on the output register. Thus one can simulate the oracle $U^{\mathsf{Mv}}(M^\top)$ using one query to $U^{\mathsf{Mv}}(M)$, showing equivalence of the two models. ◀

In contrast to Theorem 5, Sun, Woodruff, Yang, and Zhang show that for the task of computing the row parities of an $m \times n$ matrix M over $\mathbb{F}_2$, the left query complexity is $\Omega(m)$, whereas the right query complexity is 1 [21]. Thus we have shown that computing column parities over $\mathbb{F}_2$ in the Mv model has quantum query complexity 1, significantly less than the classical query complexity of $\Omega(n)$.

▶ **Corollary 6.** *The query complexity of computing the row parities and the column parities of an $m \times n$ matrix over $\mathbb{F}_2$ is 1.*

Note that it is easy to understand the randomized query complexities of these problems in the vMv model.

▶ **Lemma 7.** *The randomized query complexities of computing the row parities and the column parities of an $m \times n$ matrix over $\mathbb{F}_2$ are $\Theta(m)$ and $\Theta(n)$, respectively.*

Proof. Each query reveals one bit of information, while the row parities convey m bits, giving a lower bound of $\Omega(m)$. An algorithm querying $(e_1, 1^n), \ldots, (e_m, 1^n)$ learns the row parities with probability 1, giving an upper bound of m. The query complexity of column parities follows immediately from the symmetry of the vMv oracle. ◀

The randomized query complexities of determining if there exist identical columns or identical rows are $\Theta(n/m)$ and $\Theta(\log m)$, respectively [21]. Theorem 5 implies that for identical columns, there is an exponential quantum speedup.

▶ **Corollary 8.** *The query complexities of deciding if there exist two identical columns and rows in a $m \times n$ matrix over $\mathbb{F}_2$ are $O(\log n)$ and $O(\log m)$, respectively.*

Proof. By Theorem 5, it suffices to give an algorithm for determining if there are two identical rows. To make the proof self-contained, we describe the algorithm of Sun, Woodruff, Yang, and Zhang [21, Section 4.2]. The algorithm makes q random queries $v_1, \ldots, v_q$, the entries of which are sampled uniformly. The algorithm outputs 1 if and only if there exist two entries i, j such that $(Mv_k)_i = (Mv_k)_j$ for $k \in [q]$.

To analyze the performance, for any two identical rows $m_i^\top, m_j^\top$, $\Pr_v[m_i^\top v = m_j^\top v] = 1$. For $m_i \neq m_j$, $\Pr_v[m_i^\top v = m_j^\top v] \leq 1/2$. Therefore for a matrix that has two identical rows, the algorithm outputs 1 with probability 1. On the other hand, for a matrix that has no identical rows, the algorithm outputs 1 with probability

$$\begin{aligned}\Pr_{v_1,\ldots,v_q}[\exists i,j \in [m],\ \forall \ell \in [q], m_i^\top v_\ell = m_j^\top v_\ell] &\leq \sum_{i,j\in[m],i\neq j} \Pr_{v_1,\ldots,v_q}[\forall \ell \in [q], m_i^\top v_\ell = m_j^\top v_\ell] \\ &\leq \binom{m}{2} 2^{-q}. \end{aligned} \tag{10}$$

Taking $q = 2\log m$, the probability is no more than $\frac{1}{2} - \frac{1}{2m}$. ◀

The equivalence of left and right queries also holds over the reals.

▶ **Theorem 9.** *Quantum query complexities in the left and the right matrix-vector models over $\mathbb{R}$ are identical. In particular, one right* Mv *query can be simulated using one left* Mv *query, and vice versa.*

Proof. The same idea as in the proof of Theorem 5 applies. First, a phase query can be simulated by conjugating a standard query by the quantum Fourier transform. This yields $U^{\widetilde{\mathsf{Mv}}}(M)$. Conjugating a phase query by a swap gate gives $U^{\widetilde{\mathsf{Mv}}}(M^\top)$ with the same calculation as in (9). This in turn yields $U^{\mathsf{Mv}}(M^\top)$ upon conjugating $U^{\widetilde{\mathsf{Mv}}}(M^\top)$ by an inverse quantum Fourier transform. ◀

Note that with finite precision, a phase query can be simulated using the quantum Fourier transform over an integer modulus (see Section 2.1 for details).

As an example, we determine the query complexity of the majority of rows or columns: given a binary matrix $M \in \{0,1\}^{m\times n}$, compute the majority of each row or column over $\mathbb{R}$, i.e., for each row or column, determine if there are more 1s than 0s.

▶ **Corollary 10.** *In the matrix-vector model, the query complexities of computing the majorities of rows and columns of an $m \times n$ matrix over $\mathbb{R}$ are 1.*

Proof. By Theorem 9, it suffices to show the query complexity of the majority of rows is 1. With a single query $(1, 1, \ldots, 1)^\top$, the majority of each row is determined. ◀

This result is not significantly affected by considering computation with finite precision. The number of 1s in each row and each column is an integer in $[0, k]$ for $k = \max\{m, n\}$. Thus a truncation with $O(\log k)$ bits suffices to perform the computation with no error.

3.2 The vector-matrix-vector model

We now relate the power of the matrix-vector and vector-matrix-vector query models. In the vector-matrix-vector model, the algorithm is given access to M via $U^{\mathsf{vMv}}\colon |x, y, a\rangle \mapsto |x, y, a + y^\top Mx\rangle$. We can simulate one vMv query using two Mv queries and an ancilla space storing a matrix-vector product:

$$\begin{aligned}|x,y,a\rangle &\xmapsto{U^{\mathsf{Mv}}(M)} |x,y,a\rangle|Mx\rangle \\ &\mapsto |x,y,a+y^\top Mx\rangle|Mx\rangle \\ &\xmapsto{U^{\mathsf{Mv}}(M)^\dagger} |x,y,a+y^\top Mx\rangle|0\rangle. \end{aligned} \tag{11}$$

On the other hand, an Mv phase query (defined previously in (8)) can be simulated using a vMv phase query by setting $a = 1$:

$$|x,y,1\rangle \mapsto e(y^\top Mx)|x,y,1\rangle. \tag{12}$$

Such a vMv phase query can be constructed using one application of U^{vMv}:

$$\begin{aligned}|x,y,a\rangle &\xmapsto{\mathbb{1}\otimes\mathbb{1}\otimes F_{\mathbb{F}_q}^\dagger} \sum_b e(-ab)|x,y,b\rangle \\ &\xmapsto{U^{\mathsf{vMv}}(M)} \sum_b e(-ab)|x,y,b+y^\top Mx\rangle \\ &\xmapsto{\mathbb{1}\otimes\mathbb{1}\otimes F_{\mathbb{F}_q}} \sum_{bc} e(-ab+c(b+y^\top Mx))|x,y,c\rangle \\ &= e(ay^\top Mx)|x,y,a\rangle. \end{aligned} \tag{13}$$

Thus we have shown the following.

▶ **Theorem 11.** *Quantum query complexities in the matrix-vector and vector-matrix-vector models differ by at most a constant factor. In particular, one* vMv *query can be simulated using two* Mv *queries, and one* Mv *query can be simulated using one* vMv *query.*

This is again in stark contrast to the classical case, where the Mv model can be much more powerful than the vMv model. For example, for distinguishing a full-rank matrix from a rank-$(n-1)$ matrix, the randomized query complexity in the vMv model is $\Omega(n^2)$ [19], while the randomized query complexity in the Mv model is $O(n)$ [21].

Note that Lee, Santha, and Zhang [17] previously studied the equivalence between quantum Mv and vMv oracles. They focus on the special case where the matrix M is the adjacency matrix of a graph with nonnegative integer weights and the inputs $x \in \{0,1\}^n, y \in \{0,1\}^m$ are boolean. In that setting, they prove equivalence between the vMv oracle and the additive oracle $a\colon 2^{[n]} \to \mathbb{Z}$ that returns $a(S) = \sum_{(u,v)\in S^{(2)}} w(u,v)$ for $S \subseteq [n]$, where $S^{(2)}$ denotes the set of cardinality-2 subsets of S. They also study relationships with other oracles that encode specific information about graphs (cuts, disjoint cuts, etc.; see Section 4 of [17]). In contrast, our Theorem 5, Theorem 9, and Theorem 11 work for inputs and matrices in fields, and do not apply to other graph oracles. While these results are, strictly speaking, incomparable, they are closely related, both following from a generalization of the Bernstein-Vazirani algorithm [7].

4 Linear algebra over finite fields

We now consider the quantum query complexity of particular linear algebra problems in the matrix-vector query model. Specifically, we consider learning the trace (Section 4.1), computing the null space and determinant (Section 4.2), solving linear systems (Section 4.3), and estimating the rank (Section 4.4).

4.1 Trace

In this section, we show that the quantum query complexity of computing the trace of an $n \times n$ matrix over $\mathbb{F}_q$ is $\Theta(n)$. Since there is a trivial algorithm that computes the trace by learning the entire matrix using n queries, we focus on the lower bound.

Learning the trace can be regarded as a coset identification problem (defined in Section 2.2) in the group $G = \mathbb{F}_q^{n\times n}$ with subgroup $H = \{M \in \mathbb{F}_q^{n\times n} : \mathrm{tr}M = 0\} \cong \mathbb{F}_q^{n^2-1}$. The irreducible characters χ_Z of H are indexed by $Z \in \mathbb{Z}_m^{n\times n}$ with $Z_{nn} = 0$, and satisfy $\chi_Z(M) = e(\langle Z, M\rangle)$ where $\langle Z, M\rangle \coloneqq \sum_{i,j=1}^n Z_{ij}M_{ij}$.

4.1.1 Learning the trace over $\mathbb{F}_2$

First we consider the case $q = 2$. Then the irreducible characters χ_Z of H for $Z \in \mathbb{Z}_m^{n\times n}$ (with $Z_{nn} = 0$) satisfy

$$\chi_Z(M) = (-1)^{\langle Z,M\rangle}. \tag{14}$$

For irredicible character Z, the induced representation can be decomposed into two irreducible characters of G:

$$\chi_{Z,0}(M) = (-1)^{\langle Z,M\rangle}; \qquad \chi_{Z,1}(M) = (-1)^{\langle Z,M\rangle+\mathrm{tr}M}. \tag{15}$$

It is easy to check that for $M \in G$, $\chi_{Z,0}(M + E^{(nn)}) = \chi_{Z,0}(M)$ and $\chi_{Z,1}(M + E^{(nn)}) = -\chi_{Z,1}(M)$, where $E^{(ij)}$ is an $n \times n$ matrix whose entries are zero except that $(E^{(ij)})_{ij} = 1$. We emphasize that in (15), $M \in G$ (rather than in H since we are now looking at the representations of the entire group), and $Z_{nn} = 0$.

On the other hand, recall that the phase query oracle is $U(M)\colon |x, y\rangle \mapsto (-1)^{y^\top Mx}|x, y\rangle$, which is a unitary representation of M with character $\xi(M) \coloneqq \mathrm{tr}(U(M)) = \sum_{x,y\in\mathbb{F}_2^n}(-1)^{y^\top Mx}$. To determine the optimal success probability, we calculate the irrep content of $U^{\otimes t}$. The character of $U^{\otimes t}$ is ξ^t, satisfying

$$\begin{aligned}\mathrm{tr}(U^{\otimes t}(M)) &= \mathrm{tr}(U(M))^t = (\xi(M))^t \\ &= \left(\sum_{x,y\in\mathbb{F}_2^n}(-1)^{y^\top Mx}\right)^t = \sum_{x_1,\ldots,x_t,y_1,\ldots,y_t\in\mathbb{F}_2^n}(-1)^{\sum_i y_iMx_i}.\end{aligned} \tag{16}$$

Thus it has non-zero Fourier coefficient at W if and only if $W \in R_t$, where R_t is the set of matrices of rank no more than t.

We now check containment of the irreps (15) in $U^{\otimes t}$. We find

$$m_{Z,0}^{(t)} = \langle \xi^t, \chi_{Z,0}\rangle > 0 \iff Z \in R_t, \qquad m_{Z,1}^{(t)} = \langle \xi^t, \chi_{Z,0}\rangle > 0 \iff Z + \mathbb{1}_n \in R_t. \tag{17}$$

By Theorem 2, to succeed with probability better than $1/2$, we must choose a Z such that both $m_{Z,0}^{(t)} > 0$ and $m_{Z,1}^{(t)} > 0$. However, now we show this is impossible with $t < n/2$.

▶ **Lemma 12.** *The set* $\{Z : m_{Z,0}^{(t)} > 0 \wedge m_{Z,1}^{(t)} > 0\}$ *is empty for* $t < n/2$.

Proof. We show that the set is non-empty only if $t \geq n/2$. Suppose there exists Z such that $m_{Z,0} > 0$ and $m_{Z,1} > 0$. By (17), $Z \in R_t$ and $Z + \mathbb{1}_n \in R_t$. Since the ranks of Z and $Z + \mathbb{1}_n$ are no more than t, we conclude that the rank of $\mathbb{1}_n = Z + Z + \mathbb{1}_n$ is no more than $2t$. Therefore $t \geq n/2$. ◀

This implies an $n/2$ lower bound, formally stated as follows.

▶ **Lemma 13.** *For $t < n/2$, any t-query quantum algorithm computing the trace of an $n \times n$ matrix over $\mathbb{F}_2$ succeeds with probability at most $1/2$.*

Proof. By Theorem 2 and Lemma 12, the optimal success probability for a uniformly random matrix in $\mathbb{F}_2^{n\times n}$ is

$$\frac{1}{2}\max_Z \sum_{b=0}^{1} \delta[m_{Z,b} > 0] \leq \frac{1}{2} \tag{18}$$

for $t < n/2$. ◀

On the upper bound side, we present an $\lceil n/2 \rceil$-query quantum algorithm, showing that the above lower bound is achievable.

▶ **Lemma 14.** *In the matrix-vector query model, there exists an $\lceil n/2 \rceil$-query quantum algorithm that computes the trace of an $n \times n$ matrix over $\mathbb{F}_2$ with probability 1.*

Proof. First we pad the matrix with one extra zero row and one extra zero column if n is odd, and denote the padded matrix by M'. Let $\ell = \lceil n/2 \rceil$. It is clear that one query to $M' \in \mathbb{F}_2^{2\ell\times 2\ell}$ can be simulated using one query to M. By Theorem 2, it suffices to find an irreducible character such that both $m_{Z,0} > 0$ and $m_{Z,1} > 0$. Now consider

$$Z = \begin{bmatrix} \mathbb{1}_\ell & 0 \\ 0 & 0 \end{bmatrix} = \sum_{i=1}^{\ell} e_i e_i^\top, \qquad Z + \mathbb{1}_{2\ell} = \begin{bmatrix} 0 & 0 \\ 0 & \mathbb{1}_\ell \end{bmatrix} = \sum_{i=\ell+1}^{2\ell} e_i e_i^\top. \tag{19}$$

The algorithm first prepares the state

$$|\psi_0\rangle = \frac{1}{\sqrt{2}}|e_1,\ldots,e_\ell\rangle|e_1,\ldots,e_\ell\rangle + \frac{1}{\sqrt{2}}|e_{\ell+1},\ldots,e_{2\ell}\rangle|e_{\ell+1},\ldots,e_{2\ell}\rangle. \tag{20}$$

Making ℓ phase queries in parallel, we have

$$\begin{aligned} |\psi_M\rangle &= \widetilde{U^{\mathsf{Mv}}}(M')|\psi_0\rangle \\ &= \frac{1}{\sqrt{2}}(-1)^{\sum_{i=1}^{\ell} M'_{ii}}|e_1,\ldots,e_\ell\rangle|e_1,\ldots,e_\ell\rangle \\ &\quad + \frac{1}{\sqrt{2}}(-1)^{\sum_{i=\ell+1}^{2\ell} M'_{ii}}|e_{\ell+1},\ldots,e_{2\ell}\rangle|e_{\ell+1},\ldots,e_{2\ell}\rangle. \end{aligned} \tag{21}$$

Measuring in the basis $\{|\psi_0\rangle\langle\psi_0|, |\psi_1\rangle\langle\psi_1|\}$, where

$$|\psi_1\rangle = \frac{1}{\sqrt{2}}|e_1,\ldots,e_\ell\rangle|e_1,\ldots,e_\ell\rangle - \frac{1}{\sqrt{2}}|e_{\ell+1},\ldots,e_{2\ell}\rangle|e_{\ell+1},\ldots,e_{2\ell}\rangle, \tag{22}$$

the algorithm outputs the trace with probability 1. ◀

The results of this section are summarized in the following theorem.

▶ **Theorem 15.** *In the matrix-vector query model, no quantum algorithm can compute the trace of an $n \times n$ matrix over $\mathbb{F}_2$ with probability better than 1/2 using fewer than $n/2$ queries, and there exists a quantum algorithm that succeeds with probability 1 using $\lceil n/2 \rceil$ queries.*

4.1.2 Learning the trace over $\mathbb{F}_q$

Now we prove a linear lower bound for the task of learning the trace over $\mathbb{F}_q$. The proof idea is the same as in the case $q = 2$, generalized to any finite field.

▶ **Theorem 16.** *In the matrix-vector query model over $\mathbb{F}_q$, computing the trace of an $n \times n$ matrix with probability more than $1/q$ requires at least $n/2$ queries.*

Proof. The induced representation of Z (defined in the second paragraph of Section 4.1) can be decomposed into q 1-dimensional irreps whose characters are

$$\chi_{Z,s}(M) = e(\langle Z, M\rangle + s \cdot \mathrm{tr}M) = e(\langle Z + s\mathbb{1}_n, M\rangle) \tag{23}$$

for $s \in \mathbb{F}_q$. Again, recall that a phase query oracle $U(M)\colon |x, y\rangle \mapsto e(y^\top Mx)|x, y\rangle$ is a unitary representation of M. The character of U is the trace $\xi(M) \coloneqq \mathrm{tr}(U(M)) = \sum_{x,y\in\mathbb{F}_q^n} e(y^\top Mx)$. The optimal success probability is determined by the irrep content of $U^{\otimes t}$, and the character of $U^{\otimes t}$ is ξ^t, satisfying

$$\mathrm{tr}(U^{\otimes t}(M)) = \xi^t(M) = \sum_{x_1,\ldots,x_t,y_1,\ldots,y_t\in\mathbb{F}_q^n} e\left(\sum_{i=1}^t y_i^\top Mx_i\right). \tag{24}$$

Thus for every $s \in \mathbb{Z}_m$,

$$m_{Z,s}^{(t)} = \langle \xi^t, \chi_{Z,s}\rangle > 0 \iff Z + s \cdot \mathbb{1}_n \in R_t, \tag{25}$$

where R_t is the set of matrices of rank no more than t. Since $\mathbb{1}_n \notin R_{n-1}$, we conclude for $t < n/2$ the success probability is at most $1/q$, as claimed. ◀

4.2 Null space

In this section, we show a linear lower bound on the matrix-vector quantum query complexity of computing the rank of a matrix $M \in \mathbb{F}_q^{m\times n}$ for $m \geq n$. This is without loss of generality since for $m < n$, by Theorem 5, we can simulate oracle access to $M^\top$ using one query to M.

The rank problem is an instance of the hidden subgroup problem (HSP) over $\mathbb{F}_q^m$ since two vectors map to the same value if and only if their difference is in the null space. However, the lower bound for the abelian HSP [16] does not directly apply to this problem since the instance is more structured – specifically, the subgroup hiding function is a linear transformation.

We recall some standard facts from linear algebra over finite fields. For $\ell \geq m$, let $\binom{\ell}{m}_q \coloneqq \frac{\prod_{i=0}^{m-1}(q^\ell - q^i)}{\prod_{i=0}^{m-1}(q^m - q^i)}$ denote a Gaussian binomial coefficient.

▶ **Lemma 17.** *The number of m-dimensional subspaces of an ℓ-dimensional space over $\mathbb{F}_q$ is $\binom{\ell}{m}_q$.*

▶ **Lemma 18.** *For integers $k \leq m \leq \ell$ and any k-dimensional space V over $\mathbb{F}_q$, the number of m-dimensional subspaces of an ℓ-dimensional space containing V is $\binom{\ell-k}{m-k}_q$.*

For proofs of these facts, see for example [9, Lemma 9.3.2].

Computing the rank. Now we consider the problem of computing the rank of a matrix $M \in \mathbb{F}_q^{m\times n}$ for $m \geq n$. A matrix M has rank r if and only if its null space is $(n - r)$-dimensional.

By Lemma 4, the success probability of a t-query algorithm is a degree-$2t$ polynomial in δ_{xy}. This polynomial P can be written as

$$P(\delta) = \sum_{S \subseteq \mathbb{F}_q^n \times \mathbb{F}_q^m} c_S \prod_{(x,y)\in S} \delta_{xy}, \tag{26}$$

with $c_S = 0$ for $|S| > \deg(P)$. For an input M, the assignments to these variables are $\delta_{xy} = \delta[Mx = y]$; we will sometimes write $\delta_{xy} = \delta_{xy}(M)$ to emphasize that δ is a function of M.

Now symmetrize by averaging over all matrices with nullity d, giving

$$\begin{aligned} Q(d) &\coloneqq \mathop{\mathbb{E}}_{M\sim Y_d}[P(\delta(M))] \\ &= \sum_{S \subseteq \mathbb{F}_q^n \times \mathbb{F}_q^m} c_S \mathop{\mathbb{E}}_{M\sim Y_d}\left[\prod_{(x,y)\in S} \delta_{xy}(M)\right] \\ &= \sum_{S \subseteq \mathbb{F}_q^n \times \mathbb{F}_q^m} c_S \Pr_{M\sim Y_d}[Mx = y \ \forall (x,y) \in S], \end{aligned} \tag{27}$$

where Y_d is the set of matrices of nullity d. Here M is drawn uniformly from Y_d. Since $0 \le P(\delta(M)) \le 1$, we have $0 \le Q(d) \le 1$. The following lemma states that we can approximate $Q(d)$ with a low-degree polynomial. Van Apeldoorn and Gribling previously showed the same statement in their proof of a lower bound for Simon's problem for linear functions [4, Lemma 3]. That problem can be viewed as a special case of our problem with $m = n$. We observe that essentially the same proof establishes this lemma for $m \ge n$.

▶ **Lemma 19.** *There exists a polynomial R of degree at most $2t$ such that for each $d \in [n]$, $R(q^d) = Q(d)$.*

We emphasize that we do not bound the degree of $Q(d)$ because we do not know how to represent it as a polynomial in d. Instead, the lower bound is established by showing (i) a lower bound on the degree of the polynomial R and (ii) that the degree of R is no more than $2t$.

Next, recall a lemma by Koiran, Nesme, and Portier [16, Lemma 5].

▶ **Lemma 20.** *Let $c > 0$ and $\xi > 1$ be constants and let f be a real polynomial with the following properties:*
1. *for any integer $0 \le i \le n$, $|f(\xi^i)| \le 1$;*
2. *for some real number $1 \le x_0 \le \xi$, $|f'(x_0)| \ge c$.*

Then $\deg f = \Omega(n)$.

Lemma 19 and Lemma 20 imply an $\Omega(\min\{m,n\})$ lower bound for distinguishing a matrix is full-rank or has nullity 1. The case $m = n$ was previously shown by van Apeldoorn and Gribling [4, Theorem 1]. We briefly explain the main ideas for completeness. By Lemma 19, for $d \in \{0, 1, \ldots, n-1\}$, $R(q^d) = Q(d)$ and $\deg(R) \le 2t$. For distinguishing a full-rank matrix (i.e., $d = 0$) from a rank $n-1$ matrix (i.e, $d = 1$), we set $R(1) \ge 1 - \epsilon$ and $R(q) \le \epsilon$. There exists $x_0 \in [1, q]$ such that $R'(x_0) \ge \frac{|R(q)-R(1)|}{q-1} \ge \frac{1-2\epsilon}{q-1}$. By Lemma 20, $t = \Omega(n)$ for $m \ge n$. For $m < n$, an $\Omega(m)$ lower bound follows from Theorem 5. Overall, this gives the following.

▶ **Theorem 21.** *The bounded-error matrix-vector quantum query complexity of deciding if an $m \times n$ matrix over $\mathbb{F}_q$ is full-rank is $\Omega(\min\{m,n\})$. In particular, $\Omega(\min\{m,n\})$ queries are needed to decide whether the matrix is full-rank or has nullity 1.*

There is a trivial algorithm that learns an entire $m \times n$ matrix using $\min\{m, n\}$ queries. Thus the query complexity of computing the rank is $\Theta(\min\{m, n\})$.

▶ **Corollary 22.** *The bounded-error query matrix-vector quantum complexity of computing the rank of an $m \times n$ matrix over $\mathbb{F}_q$ is $\Theta(\min\{m, n\})$.*

With the same argument, the quantum query complexity of computing the determinant of an $n \times n$ matrix over $\mathbb{F}_q$ is $\Theta(n)$. Moreover, the classical query complexity is $\Theta(n^2)$, implied by the $\Omega(n^2)$ lower bound for rank testing by Rashtchian, Woodruff, and Zhu [19, Theorem 3.3].

▶ **Corollary 23** (Determinant). *The bounded-error classical and quantum query complexities of computing the determinant of an $n \times n$ matrix over $\mathbb{F}_q$ through matrix-vector products are $\Theta(n^2)$ and $\Theta(n)$, respectively.*

4.3 Solving linear systems

In this section, we consider the quantum query complexity of solving the linear system $Ax = b$ for $A \in \mathbb{F}_q^{n \times n}$ is $\Theta(n)$. Since there is an n-query algorithm learning the entire matrix using n matrix-vector queries, we focus on the lower bound.

Our proof is based on a randomized reduction from deciding whether a submatrix is full rank. For a square matrix A, let A^{ij} be the submatrix obtained by deleting the i^{th} row and the j^{th} column, and let A_{ij} denote the (i, j) element of A. The elements of A^{-1} can be computed as

$$(A^{-1})_{ij} = \frac{\det A^{ij}}{\det A}. \tag{28}$$

Given an invertible A, one can use a linear system solver to decide whether $(A^{-1})_{11}$ is non-zero, and thus decide if the minor A^{11} is full-rank.

In our reduction, to decide whether $M \in \mathbb{F}_q^{n \times n}$ is full-rank given access to matrix-vector products, we pad M with one extra random row and one extra random column, giving a matrix $A \in \mathbb{F}_q^{(n+1)\times(n+1)}$. We show that with sufficiently high probability, the padded matrix is full-rank. Thus, invoking a linear system solver with $b = e_1$, we learn whether $\det M = 0$. Thus the linear regression lower bound follows from Theorem 21.

▶ **Theorem 24.** *The bounded-error matrix-vector quantum query complexity of solving an $n \times n$ linear system is $\Omega(n)$.*

Proof. Assume toward contradiction that $\mathcal{A}$ is a t-query quantum algorithm for determining whether $(A^{-1})_{11}$ is non-zero for any invertible $A \in \mathbb{F}_q^{(n+1)\times(n+1)}$, succeeding with probability $p \geq 1/3$ with $t = o(n)$. We present a t-query algorithm for determining whether an $n \times n$ matrix is full-rank with probability $p(1 - 1/q)^2 \geq 1/12$.

Given access to $M \in \mathbb{F}_q^{n \times n}$, the algorithm first samples two random vectors $u, v \in \mathbb{F}_q^n$ and a random element $a \in \mathbb{F}_q$ to give the padded matrix

$$A = \begin{bmatrix} a & u^\top \\ v & M \end{bmatrix}. \tag{29}$$

The matrix-vector product $A(x_0, x^\top)^\top$ for $x_0 \in \mathbb{F}_q, x \in \mathbb{F}_q^n$ can be computed using one Mv query to Mx since

$$A \begin{bmatrix} x_0 \\ x \end{bmatrix} = \begin{bmatrix} a_0 + u^\top x \\ x_0 v + Mx \end{bmatrix}. \tag{30}$$

We show that with probability at least $(1-1/q)^2$, the matrix A is invertible (i.e., $\det A \neq 0$) given that $\operatorname{rank}(M) \geq n-1$. If M is invertible, the submatrix $B = (v, M)$ is full-rank. If $\operatorname{rank}(M) = n-1$, then without loss of generality, we consider the case that the first $n-1$ rows of M are linearly independent, and the last row is a linear combination of the first $n-1$ rows, since other cases can be handled accordingly by rearranging the rows. We let

$$M = \begin{bmatrix} M' \\ w^\top \end{bmatrix}. \tag{31}$$

for an $(n-1) \times n$ matrix M' and an $n \times 1$ vector w. Since $w^\top$ is a linear combination of the first $n-1$ rows, we write $w^\top = c^\top M'$ for an $(n-1) \times 1$ vector c. Since M' is full-rank, the vector c satisfying $w^\top = c^\top M'$ is unique. Now write the vector

$$v = \begin{bmatrix} z \\ b \end{bmatrix} \tag{32}$$

for an $(n-1) \times 1$ matrix z and $b \in \mathbb{F}_q$. The matrix B is not full rank if and only if the last row is a linear combination of the first $n-1$ rows, i.e., $c^\top z = b$, since the first $n-1$ rows of B are linearly independent. Since v is a random vector with each element chosen independently, we have

$$\Pr[B \text{ is not full-rank}] = \Pr_{z,b}[c^\top z = b] = 1/q. \tag{33}$$

Thus with probability at least $1 - 1/q$ the matrix B is full-rank.

Conditioned on B being full-rank, the matrix A is not full-rank if and only if the vector $(a, u^\top)$ is in the vector space spanned by the rows of B. The number of vectors in the vector space is $q^{(n-1)}$. Thus

$$\Pr_{a,u,v}[A \text{ is not full-rank} \mid B \text{ is full-rank}] = 1/q. \tag{34}$$

Therefore with probability at least $1 - 1/q$, A is invertible. Conditioned on successfully simulating Mv queries of an invertible A, the algorithm $\mathcal{A}$ determines whether $(A^{-1})_{11}$ is nonzero with probability p. Thus the algorithm succeeds with probability at least $p(1-1/q)^2 \geq 1/12$ using $t = o(n)$ queries to M. By Theorem 21 we have a contradiction. ◀

The same proof idea shows that a lower bound for rank testing implies a lower bound for linear regression in the vMv model. Rashtchian, Woodruff, and Zhu show that the query complexity of distinguishing rank-n matrices from rank-$(n-1)$ matrices over $\mathbb{F}_q$ is $\Omega(n^2)$ [19, Theorem 3.3].

▶ **Corollary 25.** *The bounded-error classical* vMv *query complexity of solving an* $n \times n$ *linear system over* $\mathbb{F}_q$ *is* $\Omega(n^2)$.

Proof. By the same idea as in the proof of Theorem 24, it suffices to show that one vMv query to the $(n+1) \times (n+1)$ matrix A in (29) can be simulated with one vMv query to the $n \times n$ matrix M. For any query x, y, we let $x = (x_0, x_1^\top)^\top$ and $y = (y_0, y_1^\top)^\top$ for $n \times 1$ matrices x_1, y_1. The product $y^\top A x$ can be computed using one vMv query to M since $y^\top A x = a y_0 x_0 + y_0 u^\top x_1 + y_1^\top v x_0 + y_1^\top M x_1$. Since no $o(n^2)$-query classical algorithm can distinguish rank-n matrices from rank-$(n-1)$ matrices [19, Theorem 3.3], the bounded-error query complexity of solving linear systems is $\Omega(n^2)$. ◀

4.4 Rank testing

In this section, we show a linear lower bound on distinguishing whether an $m \times n$ matrix M has $\mathrm{rank}(M) = n$ or $\mathrm{rank}(M) \leq n/2$, where $m \geq n$. First we show the following lemma using ideas from [16].

▶ **Lemma 26.** *Let $\xi \geq 2$ and let n be an even integer. Then any polynomial f satisfying*
1. $0 \leq f(\xi^i) \leq 1$ *for* $i \in \{0, 1, \ldots, n-1\}$ *and*
2. $f(1) \leq 1/3$ *and* $f(\xi^i) \geq 2/3$ *for* $i \in \{n/2, n/2+1, \ldots, n-1\}$

has $\deg(f) = \Omega(n)$.

Proof. Let $d = \deg(f)$. Toward contradiction, we assume $d = o(n)$. For intervals $S_i := [\xi^i, \xi^{i+1})$, since $\deg(f'), \deg(f'') = o(n)$, there exists an index $a \in \{9n/10, \ldots, n-3, n-2\}$ such that none of the roots of f' and f'' has its real part in S_a. This implies that f' is monotonically increasing or decreasing in S_a, i.e., f is concave or convex. In each case, $f(\frac{\xi^a+\xi^{a+1}}{2}) \in [0, 1]$. If f is convex in S_a,

$$\left|f'\Big(\frac{\xi^a+\xi^{a+1}}{2}\Big)\right| \leq \frac{1}{\xi^{a+1} - \frac{\xi^{a+1}+\xi^a}{2}} = \frac{2}{\xi^{a+1}-\xi^a} \leq \frac{2}{\xi^a} \leq 2\xi^{-9n/10}. \tag{35}$$

If f is concave in S_a, reflecting about the x-axis gives the same bound.

By the second constraint, there exists $x_0 \in [1, \xi^{n/2}]$ such that

$$|f'(x_0)| \geq \frac{|f(\xi^{n/2}) - f(1)|}{\xi^{n/2}-1} \geq \xi^{-n/2}/3. \tag{36}$$

Therefore

$$\left|\frac{f'(\frac{\xi^a+\xi^{a+1}}{2})}{f'(x_0)}\right| \leq 6\xi^{-2n/5} \leq \xi^{3-2n/5}. \tag{37}$$

On the other hand, since $\deg(f') = d-1$, denoting the roots $a_1, \ldots, a_{d-1} \in \mathbb{C}$, we write

$$f'(x) = \lambda \prod_{i=1}^{d-1}(x - a_i). \tag{38}$$

Thus

$$\left|\frac{f'(\frac{\xi^a+\xi^{a+1}}{2})}{f'(x_0)}\right| = \prod_{i=1}^{d-1}\left|\frac{\frac{\xi^a+\xi^{a+1}}{2} - a_i}{x_0 - a_i}\right| = \prod_{i=1}^{d-1}|g(a_i)|, \tag{39}$$

where

$$g(x) = \frac{x - \frac{\xi^a+\xi^{a+1}}{2}}{x - x_0}. \tag{40}$$

Our goal is to show that for each i, $|g(a_i)| \geq \frac{1}{2\xi}$. Recall that for each i, $\Re(a_i) \notin S_a$. Also for real $x \notin S_a$, $x \geq x_0$, we have $|g(x)| \geq \frac{\xi-1}{2\xi} \geq \frac{1}{2\xi}$. For real roots, $|g(a_i)| \geq \frac{1}{2\xi}$. Now we consider the case where $a_i = \alpha + \beta i$ for $\beta \neq 0$, giving

$$|g(\alpha+\beta i)|^2 = \frac{(\alpha - \frac{\xi^a+\xi^{a+1}}{2})^2 + \beta^2}{(\alpha - x_0)^2 + \beta^2}. \tag{41}$$

If $(\alpha - \frac{\xi^a+\xi^{a+1}}{2})^2 \geq (\alpha - x_0)^2$, then $|g(\alpha+\beta i)| \geq 1$. Otherwise,

$$|g(\alpha+\beta i)| \geq \left| \frac{\alpha - \frac{\xi^a+\xi^{a+1}}{2}}{\alpha - x_0} \right| \geq \frac{1}{2\xi}. \tag{42}$$

We have shown that $|g(a_i)| \geq \frac{1}{2\xi}$ for every root a_i. Now we have

$$\left| \frac{f'(\frac{\xi^a+\xi^{a+1}}{2})}{f'(x_0)} \right| = \prod_{i=1}^{d-1} |g(a_i)| \geq (2\xi)^{-d+1} \geq \xi^{2-2d}. \tag{43}$$

Thus by (37), we have $\xi^{3-2n/5} \geq \xi^{2-2d}$ and conclude $d \geq n/5 - 1/2 = \Omega(n)$ – a contradiction. ◀

Lemma 19 and Lemma 26 imply the following theorem.

▶ **Theorem 27.** *The bounded-error matrix-vector quantum query complexity of determining whether a matrix* $M \in \mathbb{F}_q^{m\times n}$ *has* $\operatorname{rank}(M) = n$ *or* $\operatorname{rank}(M) \leq n/2$ *is* $\Omega(n)$.

Truthful Allocation in Graphs and Hypergraphs

George Christodoulou

Abstract

We study truthful mechanisms for allocation problems in graphs, both for the minimization (i.e., scheduling) and maximization (i.e., auctions) setting. The minimization problem is a special case of the well-studied unrelated machines scheduling problem, in which every given task can be executed only by two pre-specified machines in the case of graphs or a given subset of machines in the case of hypergraphs. This corresponds to a multigraph whose nodes are the machines and its hyperedges are the tasks. This class of problems belongs to multidimensional mechanism design, for which there are no known general mechanisms other than the VCG and its generalization to affine minimizers. We propose a new class of mechanisms that are truthful and have significantly better performance than affine minimizers in many settings. Specifically, we provide upper and lower bounds for truthful mechanisms for general multigraphs, as well as special classes of graphs such as stars, trees, planar graphs, k-degenerate graphs, and graphs of a given treewidth. We also consider the objective of minimizing or maximizing the L^p-norm of the values of the players, a generalization of the makespan minimization that corresponds to $p = \infty$, and extend the results to any $p > 0$.

1 Introduction

This work belongs to the area of mechanism design, one of the most researched branches of Game Theory and Microeconomics with numerous applications in environments where a protocol of conduct of selfish participants is required. The goal is to design an algorithm, called mechanism, which is robust under selfish behavior and that produces a social outcome with a certain guaranteed quality. The mechanism solicits the preferences of the participants over the outcomes, in forms of bids, and then selects one of the outcomes. The challenge stems from the fact that the real preferences of the participants are private, and the participants care only about maximizing their private utilities and hence they will lie if a false report is profitable. A *truthful* mechanism provides incentives such that a truthful bid is the best action for each participant.

Despite the importance of the problem the only general positive result for multi-dimensional domains is the celebrated Vickrey-Clarke-Groves (VCG) mechanism [43, 15, 26] and its affine extensions, known as affine maximizers.

In their seminal paper on algorithmic mechanism design, Nisan and Ronen [39] proposed the scheduling problem on unrelated machines as a central problem to understand the algorithmic aspects of mechanism design. The objective is to incentivize n machines to execute m tasks, so that the maximum completion time of the machines, i.e. the makespan, is minimized. Scheduling, a problem that has been extensively studied from the classical algorithmic perspective, proved to be the perfect ground to study the limitations that truthfulness imposes on algorithm design.

Nisan and Ronen applied the VCG mechanism, the most successful generic machinery in mechanism design, which truthfully implements the outcome that maximizes the social welfare. In the case of scheduling, the allocation of the VCG is the greedy allocation in which each task is assigned to the machine with minimum processing time. This mechanism is truthful, but has a poor approximation ratio of n for the makespan. They conjectured that this is the best guarantee that can be achieved by any deterministic (polynomial-time or not) truthful mechanism and this conjecture, known as the Nisan-Ronen conjecture, is widely perceived as the holy grail in algorithmic mechanism design.

An interesting special case of the scheduling problem, which is well-understood, is the single-dimensional mechanism design in which the values of each player are linear expressions of a single parameter. The principal representative is the problem of scheduling *related* machines, where the cost of each machine can be expressed via a single parameter, its *speed*. This was first studied by Archer and Tardos [1], who showed that in contrast to the unrelated machines version, an algorithm that minimizes the makespan can be truthfully implemented – albeit in exponential time. It was subsequently shown that truthfulness has essentially no impact on the computational complexity of the problem. Specifically, a randomized truthful-in-expectation[1] PTAS was given in [18] and a deterministic PTAS was given in [14]; a PTAS is the best possible algorithm even for the pure algorithmic problem (unless $P = NP$).

1.1 Summary of Results

In this work, we show how to combine these two main positive results of VCG and single-dimensional mechanisms into a single mechanism, which we call the *Hybrid Mechanism*. This new mechanism applies to domains in which some players are multidimensional and some players are single-dimensional. A typical example is to schedule m tasks, such that task i can only be executed by player 0 and player i. In this case, player 0 is multidimensional and the other m players are single-dimensional. We call this the *star balancing* problem. This is a multidimensional mechanism design problem for which the VCG mechanism, as well as every other known mechanism, performs very poorly. However, as we show in Section 3.1, the Hybrid Mechanism has approximation ratio 2, optimal among all truthful mechanisms. We generalize the star balancing problem in three directions: *graphs/multigraphs*, *hyperstars* and also to objectives other than makespan minimization. Due to space limitations, omitted proofs are presented in the full version.

(Multi)Graphs. A generalization of the star balancing problem to graphs and multigraphs is the Unrelated Graph Balancing problem (Section 3). This is a special case of unrelated machines scheduling in which there is a (multi)graph whose nodes represent the machines

[1] This is one of the two main definitions of truthfulness for randomized mechanisms, where truth-telling maximizes the expected utility of each player.

and whose edges represent tasks that can be executed only by the incident nodes. For general graphs, all machines are multiparameter, but we can still apply the Hybrid Mechanism, if we first decompose the graph into stars and then apply the Hybrid Mechanism to each one of them. The combined mechanism, which we call the *Star-Cover Mechanism*, has surprisingly good approximation ratio for certain classes of graphs – ratio 4 for trees, 8 for planar graphs, and $2k+2$ for k-degenerate graphs (Corollary 15). These results use as ingredient the analysis of star graphs, in which the Hybrid Mechanism has approximation ratio 2.

Hyperstars. In the hyperstar version, there are k multidimensional players/machines and every task can be executed by any one of these k players or by a task-specific single-dimensional player. Specifically, there are k different *root players* (players $1, 2, \ldots, k$ with bids $(r_{ij})_{k\times m}$) and each of them are allowed to process all tasks. In addition, for each task there is one *leaf player*, which can process only this single task (players $k+1, k+2, \ldots, k+m$ with bids $(\ell_1, \ell_2, \ldots \ell_m)$). Note that the root players without the leaves form a classic input for unrelated scheduling mechanisms with k players and m-tasks. We can now state the Hybrid Mechanism for this case.

▶ **Definition 1** (Hybrid Mechanism). *The Hybrid Mechanism minimizes*

$$\min_T \left\{ \left(\min_{x^T} \sum_{i=1}^{k} \lambda_i r_i \cdot x_i^T \right) + g_T(\ell) \right\},$$

where the λ_i can be arbitrary non-negative real numbers and $(g_T)_{T\subseteq M}$ can be any functions that guarantee that the leaf players are truthful. The output of the mechanism is the subset of tasks T that are allocated to the multidimensional root players together with their allocation matrix x^T. The remaining tasks, $M \setminus T$, are allocated to the leaf players.

VCG fairs poorly, yielding approximation ratio m in this domain, but the Hybrid Mechanism has approximation ratio $k+1$, as stated in the next theorem. Due to space limitations, we provide details and proofs in the full version of the paper.

▶ **Theorem 2.** *For the hyperstar scheduling problem, the Hybrid Mechanism with $g_T(\ell) = \max_{j\notin T} \ell_j$, and with $\lambda_i = 1$, for every i, is $(k+1)$-approximate.*

In Section 4 we provide general definitions as well as necessary and sufficient conditions for truthfulness of the Hybrid Mechanism.

Mechanisms for L^p-norm optimization. In Section 5, we consider the much more general objective of minimizing or maximizing the L^p-norm of the values of the players, for $p > 0$. The scheduling problem is the special case of minimizing the L^∞-norm. We show that the Hybrid Mechanism performs very well for this much more general problem, and in some cases it has the optimal approximation ratio among all truthful mechanisms. This illustrates the applicability and usefulness of the Hybrid Mechanism in applications with various domains and objectives. We emphasize that for all these cases, even for stars, all known mechanisms such as the VCG and affine maximizers have very poor performance.

Relation to the Nisan-Ronen conjecture. Our results on (multi)graphs show that this domain may provide an easier way to attack the Nisan-Ronen conjecture. In a recent work [12], we showed a $\Omega(\sqrt{n})$ lower bound for multistars with edge multiplicity only 2, when the root player has submodular or supermodular valuations. In contrast, our results in this

work show that for additive valuations, the Star-Cover Mechanism has approximation ratio 4 on the very same multigraphs. However, the Hybrid and the Star-Cover Mechanisms have high approximation for multistars with high edge-multiplicity or for simple clique graphs. It is natural to ask whether there are other, better mechanisms for these cases. Recently we have proved a $\Omega(\sqrt{n})$ lower bound for the former case, which is the first super-constant lower bound for the Nisan-Ronen problem [11], and we conjecture that the latter case admits similarly a high, perhaps even linear, lower bound.

We remark that all previous lower bound proofs use inherently either (multi)graphs [13, 29, 11] or, recently, hypergraphs with hyperedges of small size [24, 20]. Our work provides new methodological tools to study these objects, that can help to identify certain (hyper)graph structures as good candidates for high lower bounds and to avoid those where low upper bounds exist. For example, the 2.755 lower bound construction of [24] uses a hyperstar with $k = 2$, for which the Hybrid Mechanism achieves an upper bound of 3 (Thm 2).

All our lower bounds are information theoretic and hold independently of the computational time of the mechanisms. Conversely, all upper bounds are polynomial time algorithms when the star decomposition is given. We leave it open whether computing an optimal star decomposition of a graph is in P, although it follows from our results that it can be approximated with an additive term of 1 in polynomial time (actually in linear time).

1.2 Related Work

The Nisan-Ronen conjecture [39] has become one of the central problems in Algorithmic Game Theory, and despite intensive efforts it remains open. The original paper showed that no truthful deterministic mechanism can achieve an approximation ratio better than 2 for two machines, which was later improved to 2.41 [13] for three machines, and finally to 2.618 [29] which was the best known bound for over a decade. Recent progress improved this bound to 2.755 [24], to 3 [20] and finally to the first non-constant lower bound of $1 + \sqrt{n-1}$ [11]. The best known upper bound is n [39].

The purely algorithmic problem of makespan minimization on unrelated machines is one of the most important scheduling problems. The seminal paper of Lenstra, Shmoys and Tardos [32], gave a 2-approximation algorithm, and also showed that it is NP-hard to approximate within a factor of 3/2. Closing this gap has remained open for 30 years, and is considered one of the most important open questions in scheduling.

In this work we consider the design of truthful mechanisms for the *Unrelated Graph Balancing* problem, a special but quite rich case of the unrelated machines problem, which was previously studied by Verschae and Wiese [42], for which each task can only be assigned to two machines. This can be formulated as a graph problem, where given an undirected (multi)-graph $G = (V, E)$, each vertex corresponds to a machine, and each edge corresponds to a task. The goal is to allocate each edge to one of its nodes, in a way that minimizes the maximum (weighted) in-degree.

The special case of this problem where each direction of an edge corresponds to the same processing time $t(e)$ is known as Graph Balancing, and was introduced by Ebenlendr, Krcál, and Sgall [21] who showed an 1.75-approximate algorithm and also demonstrated that the problem retains the hardness of the unrelated machines problem, by showing that it is NP-hard to approximate within a factor better than 3/2.

Graph Balancing. As was already mentioned, for the pure graph balancing problem, the best approximation ratio for classical polynomial time algorithms is 1.75 by [21]. Wang and Sitters [44] showed a different LP-based algorithm with a higher ratio of $11/6 \approx 1.83$, while Huang and Ott [27] designed a purely combinatorial approximation algorithm but with also a higher guarantee of 1.857.

Jansen and Rohwedder [28] studied the so-called *configuration LP* which was introduced by Bansal and Sviridenko [6]. They showed that it has an integrality gap of at most 1.749 breaking the 1.75 barrier of the integrality gaps of the previous LP formulations. This leaves open the possibility of using this LP to produce an approximation algorithm with a ratio better than 1.75.

Verschae and Wiese [42] studied the *unrelated* version of graph balancing (whose strategic variant we consider in this paper) and showed that the integrality gap of the configuration LP is equal to 2, which is much higher comparing to graph balancing. They also showed a 2-approximation algorithm for the problem of maximizing the minimum load, which is the best possible unless P=NP.

The problem has been studied for various special graph classes. For the case of simple graphs (also known as Graph Orientation), Asahiro et al [2] showed that the problem is in P for the case of trees, while Asahiro, Miyano and Ono [3] showed that it becomes strongly NP-hard for planar and bipartite graphs. Finally, Lee, Leung and Pinedo [31] concluded the case of trees in the case of multiple edges, showing an FPTAS which is the best possible, given that the problem in multi-graphs is immediately NP-hard even for the simple case of two vertices (due to reduction from Subset Sum).

Truthful Scheduling. The lack of progress in the original unrelated machine problem led to the study of special cases where progress has been made. Ashlagi et al.[4], resolved a restricted version of the Nisan-Ronen conjecture, for the special but natural class of *anonymous* mechanisms. Lavi and Swamy [30] studied a restricted input domain which however retains the multi-dimensional flavour of the setting. They considered inputs with only two possible values "low" and "high", that are publicly known to the designer. For this case they showed an elegant deterministic mechanism with an approximation factor of 2. They also showed that even for this setting achieving the optimal makespan is not possible under truthfulness, and provided a lower bound of 11/10. Yu [45] extended the results for a range of values, and Auletta et al. [5] studied multi-dimensional domains where the private information of the machines is a single bit.

Randomization has led to mildly improved guarantees. There are two extensions of truthfulness for randomized mechanisms; *universal truthfulness* if the mechanism is described as a probability distribution over deterministic truthful mechanisms, and *truthfulness-in-expectation*, if in expectation no player can benefit by lying. The former notion was first considered in [39] for two machines, it was later extended to n machines by Mu'alem and Schapira [38] and finally Lu and Yu [35] showed a $0.837n$-approximate mechanism, which is currently the best known. Lu and Yu [36] showed a truthful-in-expectation mechanism with an approximation guarantee of $(m+5)/2$. Mu'alem and Schapira [38], showed a lower bound of $2-1/m$, for both notions of randomization. Christodoulou, Koutsoupias and Kovács [10] extended this lower bound for fractional mechanisms, where each task can be split to multiple machines, and they also showed a fractional mechanism with a guarantee of $(m+1)/2$. The special case of two machines [34, 36] is still unresolved; currently, the best upper bound is 1.587 due to Chen, Du, and Zuluaga [9].

The case of *related* machines is well understood. It falls into the so-called *single-dimensional* mechanism design in which the valuations of a player are linear expressions of a single parameter. In this case, the cost of each machine is expressed via a single parameter, its *(inverse) speed* multiplied by the workload allocated to the machine, instead of an m-valued vector, as it is the case for the unrelated machines and the Graph Balancing setting. Archer and Tardos [1] showed that, in contrast to the unrelated machines version, the optimal

makespan can be achieved by an (exponential-time) truthful algorithm, while [14] gave a deterministic truthful PTAS which is the best possible even for the pure algorithmic problem (unless P=NP).

Truthful implementation of other objectives was considered by Mu'alem and Schapira [38] for multi-dimensional problems and by Epstein, Levin and van Stee [22] for single-dimensional ones. Leucci, Mamageishvili and Penna [33] demonstrated high lower bounds for other min-max objectives on some combinatorial optimization problems on graphs, showing essentially that VCG is the best mechanism for these problems. Minooei and Swamy [37] considered a multi-dimensional vertex cover problem, and approached in by decomposition into single parameter problems.

The Bayesian setting, where the players costs are drawn from a probability distribution has also been studied. Daskalakis and Weinberg [17] showed a mechanism that is at most a factor of 2 from the *optimal truthful mechanism*, but not with respect to the optimal makespan. Chawla et al. [8] provided bounds of prior-independent mechanisms (where the input distribution is unknown to the mechanism), while Giannakopoulos and Kyropoulou [25] showed that the VCG mechanism achieves a factor of $O(\log n/\log\log n)$ under some distributional and symmetry assumptions.

Recently Christodoulou, Koutsoupias, and Kovács [12] showed a lower bound of $\sqrt{n-1}$ for all deterministic truthful mechanisms, when the cost of processing a subset of tasks is given by a submodular (or supermodular) set function, instead of an additive function which is assumed in the standard scheduling setting.

2 Preliminaries

Scheduling. In the classical *unrelated machines scheduling* there is a set N of n machines and a set M of m tasks that need to be scheduled on the machines. The input is given by a nonnegative matrix $t = (t_{ij})_{n\times m}$: machine i needs time $t_{ij} \in \mathbb{R}_{\geq 0}$ to process task j, and her *costs* are additive, i.e., the processing time for machine i for a set of tasks $X_i \subset M$ is $t_i(X_i) := \sum_{j\in X_i} t_{ij}$. The objective is to minimize the makespan (min-max objective). An allocation to all machines $X = (X_1, X_2, \ldots, X_n)$, (which is a partition of M) can also be denoted by the characteristic matrix $x = (x_{ij})$ where $x_{ij} = 1$ if $j \in X_i$, and $x_{ij} = 0$ otherwise.

The current work essentially considers a special case of unrelated scheduling, in which every task can be processed by two designated machines. The tasks can thus be modelled by the edges of a graph, and the associated problem is also known as *Unrelated Graph Balancing*. More formally, in the Unrelated Graph Balancing problem, there is a given undirected graph $G = (V, E)$; the vertices correspond to a set of machines $N = V$ and the edges to a set of tasks $M = E$. For each edge $e \in E$ only its two incident vertices can process the job e, and they have in general different processing times $t_i(e)$, and $t_{i'}(e)$. The goal is to assign a direction to each edge $e = (i, i')$ (allocate the corresponding task) of the graph, to one of the incident vertices (machines). The *completion time* of each vertex i is then the total processing time of the jobs X_i assigned to it $t_i(X_i) = \sum_{e\in X_i} t_i(e)$. The objective is to find an allocation that minimizes the *makespan*, i.e. the maximum completion time over all vertices.

Mechanism design setting. We assume that each machine $i \in N$ is controlled by a selfish agent that is reluctant to process the tasks and the cost function t_i is private information (also called the *type* of agent i). A *mechanism* asks the agents to report *(bid)* their types t_i, and based on the collected bids it allocates the jobs, and gives payments to the agents. A player may report a false cost function $b_i \neq t_i$, if this serves her interests.

Formally, a mechanism (X, P) consists of two parts:

An allocation algorithm: The allocation algorithm X allocates the tasks to the machines depending on the players' bids $b = (b_1, \ldots, b_n)$. We denote by $X_i(b)$ the subset of tasks assigned to machine i in the bid profile b.

A payment scheme: The payment scheme $P = (P_1, \ldots, P_n)$ determines the payments also depending on the bid values b. The functions $P_1, \ldots, P_n$ stand for the payments that the mechanism hands to each agent.

The *utility* u_i of a player i is the payment that she gets minus the *actual* time that she needs to process the set of tasks assigned to her, $u_i(b) = P_i(b) - t_i(X_i(b))$. We are interested in *truthful* mechanisms. A mechanism is truthful, if for every player, reporting his true type is a *dominant strategy*. Formally,

$$u_i(t_i, b_{-i}) \geq u_i(t'_i, b_{-i}), \qquad \forall i \in N, \;\; t_i, t'_i \in \mathbb{R}^m_{\geq 0}, \;\; b_{-i} \in \mathbb{R}^{(n-1)\times m}_{\geq 0},$$

where b_{-i} denotes the reported bidvectors of all players disregarding i.

We are looking for *truthful* mechanisms with *low approximation ratio* of the allocation algorithm for the makespan irrespective of the running time to compute X and P. In other words, our lower bounds are information-theoretic and do not take into account computational issues.

A useful characterization of truthful mechanisms in terms of the following monotonicity condition, helps us to get rid of the payments and focus on the properties of the allocation algorithm.

▶ **Definition 3** (Weak Monotonicity). *An allocation algorithm X is called* weakly monotone (WMON) *if it satisfies the following property: for every two inputs $t = (t_i, t_{-i})$ and $t' = (t'_i, t_{-i})$, the associated allocations X and X' satisfy $t_i(X_i) - t_i(X'_i) \leq t'_i(X_i) - t'_i(X'_i)$.*

It is well known that the allocation function of every truthful mechanism is WMON [7], and also that this is a sufficient condition for truthfulness in convex domains [41].

The following lemma was essentially shown in [39] and has been a useful tool to show lower bounds for truthful mechanisms for several variants (see for example [13, 38]).

▶ **Lemma 4.** *Let t be a bid vector, and let $S = X_i(t)$ be the subset assigned to player i by a weakly monotone allocation X. For any bid vector $t' = (t'_i, t_{-i})$ such that only the bid of machine i has changed and in such a way that for every task in S it has decreased (i.e., $t'_{ij} < t_{ij}, j \in S$) and for every other task it has increased (i.e., $t'_{ij} > t_{ij}, j \in M \setminus S$). Then the mechanism does not change the allocation to machine i, i.e., $X_i(t') = X_i(t) = S$.*

In general, when the values of a machine change, the allocation of the other machines may change, this issue being the pivotal difficulty of truthful unrelated scheduling. Allocation algorithms that "promise" not to change the allocation of other machines as long as changing (only) t_i does not affect the set X_i, are less problematic. These allocation rules are called *local* in [39], where it is shown that local truthful mechanisms cannot have a better than n approximation.

▶ **Definition 5** (Local mechanisms). *A mechanism is* local *if for every $i \in N$, for every t_{-i}, and t_i, t'_i for which $X_i(t_i, t_{-i}) = X_i(t'_i, t_{-i})$ also holds that $X_j(t_i, t_{-i}) = X_j(t'_i, t_{-i}) \quad (\forall j \in N)$.*

There are several special classes of mechanisms that satisfy this property, perhaps the most prominent one is the class of *affine minimizers* (see, e.g., [13]).

3 Graph Balancing

In this section we focus on the (Unrelated) Graph Balancing problem, which is a special case of makespan minimization of scheduling unrelated machines. The Graph Balancing is a multi-parameter mechanism design problem that retains most of the difficulty of the Nisan-Ronen conjecture, yet has certain features that make it more amenable.

One of the difficulties in dealing with truthful mechanisms is that while truthfulness is a local property (i.e., independent truthfulness conditions, one per player), the allocation algorithm is a global function (that involves all players). Local algorithms attempt to reconcile this tension by insisting that the allocation is also "local", but they take this notion too far. The results of this work show that locality in mechanisms is very restrictive in some domains, where the Hybrid Mechanism outperforms every local mechanism.

The Graph Balancing problem is more amenable than the general scheduling problem because it exhibits another kind of locality, *domain locality*: when a machine does not get a task, we know which machines gets it. Yet, this locality is not very restrictive and the problem retains most of its original difficulty.

In this section, we take advantage of domain locality to obtain an optimal mechanism for stars. It turns out that this mechanism, the Hybrid Mechanism, is a special case of a more general mechanism. But since the Hybrid Mechanism does not apply to general graphs, we also propose the Star-Cover mechanism for general graphs: decompose the graph into stars and apply the Hybrid Mechanism independently to each star. In this way, we obtain a 4-approximation algorithm for trees and similar positive results for other types of graphs.

Makespan minimization is the special case, when $p = \infty$, of minimizing the L^p-norm of the values of the players. Other special cases of the L^p-norm optimization is the case $p = 1$, which corresponds to welfare maximization, and the case $p = 0$, which is related to Nash Social Welfare [16]. We deal with this more general problem in another section (Section 5). Most of the results and proofs of this section generalize to any $p \geq 1$. We provide almost all the proofs in this section, because we believe that the Graph Balancing problem is an important problem in its own right and because the treatment is simpler and more intuitive, and we omit most of the (more general) results of Section 5 that deals with the L^p-norm minimization, due to space limitations.

3.1 Stars and the Hybrid Mechanism

In this subsection, we focus on star graphs, where there are $n = m + 1$ players and m tasks. Player 0 is the root of the star, and has processing times given by a vector $r = (r_1, r_2, \dots r_m)$. We also refer to this player as the *root player* or *r-player*. For given bids r of the root player, and task set $T \subseteq M$ we use the short notation $r(T) = \sum_{j \in T} r_j$.

There are also m *leaf-players*, one for each leaf of the star with processing times $\ell = (\ell_1, \dots, \ell_m)$ respectively. Each task j can only be assigned to two players; either to the root, with processing time r_j, or to the leaf with processing time ℓ_j.

As usual, we denote by r_{-i} the vector of bids of the root player except for the bid for task i, and similarly ℓ_{-i} denotes the bids of all leaf-players, except for player i. The vector of all input bids is given by $t = (r, \ell)$.

As we show later in the Lower Bound section (Section 3.3), all previously known mechanisms for the Unrelated Graph Balancing problem, e.g. affine minimizers and task independent mechanisms, have approximation ratio at least $\sqrt{n-1}$ for graphs, even for stars.

In contrast, we now show that the Hybrid Mechanism has constant approximation ratio for stars.

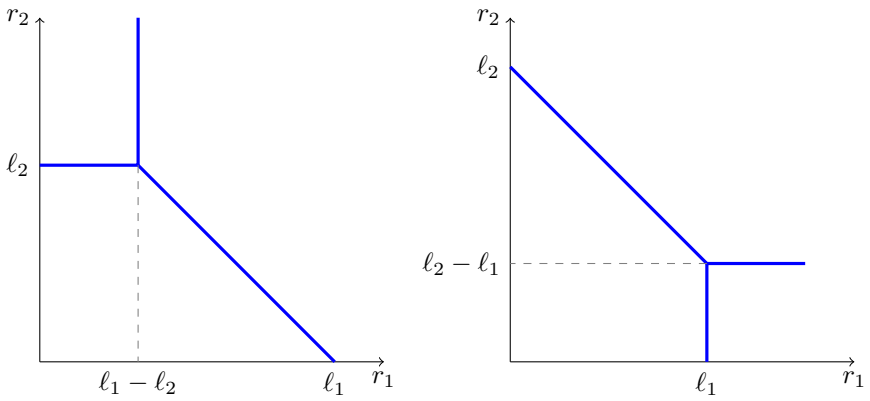

Figure 1 An instance of the Hybrid Mechanism, for the star of $m = 2$ leaves. It shows the partition of bid-space of the root player induced by the allocation of the Hybrid Mechanism when $\ell_1 \geq \ell_2$ (left) and when $\ell_2 \geq \ell_1$ (right). In the left case, the root gets both tasks in the area near $(0, 0)$, it gets only task 1 when $r_1 \leq \ell_1 - \ell_2$ and $r_2 \geq \ell_2$, and it gets neither task otherwise. Note that, in contrast to VCG, for every set of fixed values for the leaves, only three allocations are possible.

▶ **Definition 6** (Hybrid Mechanism for Graph Balancing). *Consider an instance of the Unrelated Graph Balancing problem on a star of n nodes and set of tasks M. Let*

$$S \in \arg\min_{T \subseteq M} \{r(T) + \max_{i \notin T} \ell_i\}. \tag{1}$$

The mechanism assigns a set of tasks S to the root and the remaining tasks to leaves. Ties are broken in a deterministic way (e.g., lexicographically).

Figure 1 shows the partition of the space of the root player induced by the Hybrid Mechanism for a star of two leaves.

The argmin expression that defines the Hybrid Mechanism and a corresponding expression that defines the VCG mechanism are similar: in the definition of VCG, instead of $\max_{i \notin T} \ell_i$, we have $\sum_{i \notin T} \ell_i$. It is a happy coincidence that replacing the operator sum with max preserves the truthfulness of the mechanism, a fact that rarely holds.

▶ **Lemma 7.** *The Hybrid Mechanism for Graph Balancing on stars is truthful and has approximation ratio 2.*

Proof. The root player has no incentive to lie since $-\max_{i \notin T} \ell_i$ can be interpreted as its payments. The reason that leaf players have no incentive to lie comes essentially from the fact that the expression in (1) is monotone in ℓ_i (see Section 4, for a more rigorous and extensive treatment of the truthfulness of the general Hybrid Mechanism).

Let $S^* = \arg\min_{T \subseteq M} \max\{r(T), \max_{i \notin T} \ell_i\}$ be the subset assigned to the root in the optimal allocation, OPT be the optimal makespan, and ALG be the makespan achieved by the Hybrid Mechanism. Then we have

$$ALG \leq \min_{T \subseteq M} \{r(T) + \max_{i \notin T} \ell_i\} \leq r(S^*) + \max_{i \notin S^*} \ell_i \leq 2 \max\{r(S^*), \max_{i \notin S^*} \ell_i\} = 2OPT. \quad \blacktriangleleft$$

3.2 Upper bound for general graphs and multigraphs

We now turn our attention to positive (upper bound) results for general graphs and multigraphs. We will need a few definitions first.

▶ **Definition 8** (Star decomposition). *A* star decomposition *of a (multi)graph $G(V, E)$ is a partition $T = \{T_1, \ldots, T_k\}$ of its edges into stars (see Figure 2 for an example). Let $V(T_i)$ denote the vertex set of the star spanned by T_i. The star contention number of a star decomposition is the maximum number of stars that include a node either as a root or as a leaf: $c(T) = \max_{v \in V} |\{i : v \in V(T_i), i = 1, \ldots, k\}|$. The* star contention number of a (multi)graph *is the minimum star contention number among all its star decompositions.*

In an optimal star decomposition of a graph (but not multigraph), we can assume that every node is the root of at most one star, otherwise we can merge stars with common root without changing the star contention number.

A related notion to star decomposition that has been studied extensively is the notion of edge orientation of a multigraph (or of load balancing when we consider multigraphs).

▶ **Definition 9** (Edge orientation number). *Define the orientation number of a given orientation of the edges of a multigraph G, as its maximum in-degree. The* edge orientation number $o(G)$ *of a multigraph G is the minimum orientation number among all its possible orientations.*

Indeed the two notions are closely related: every star decomposition corresponds to a graph orientation by orienting the edges in all stars from roots to leaves, and vice versa a graph orientation gives rise to a star decomposition in which every node with its outgoing edges defines a star. Given that in an optimal star decomposition of a graph, each node is the root of at most one star, we get that for *every graph G*:

$$o(G) \leq c(G) \leq o(G) + 1.$$

This relation for *multigraphs* is similar only that in the right hand side we add the maximum edge multiplicity w instead of 1, i.e., $o(G) \leq c(G) \leq o(G) + w$.

The following definition utilizes the Hybrid Mechanism on stars to obtain a general mechanism for arbitrary graphs (and multigraphs).

▶ **Definition 10** (Star-Cover Mechanism). *Let $G = (V, E)$ be a multigraph and let $T = \{T_1, \ldots, T_k\}$ be a fixed star decomposition. The Star-Cover mechanism runs the Hybrid Mechanism on every star of T independently. That is, if $S_{i,h}$ is the subset of tasks allocated to a player i by the Hybrid Mechanism when applied to a star T_h, the set of tasks allocated to player i is $S_i = \cup_{h=1}^{k} S_{i,h}$.*

We can now state and prove the general positive theorem of this section.

▶ **Theorem 11.** *The Star-Cover mechanism for a given multigraph G that uses the Hybrid Mechanism on every star of a fixed star decomposition $T = \{T_1, \ldots, T_k\}$ is truthful and has an approximation ratio at most $2c(T)$.*

Proof. Fix some player i and let $S_{i,h}$ be the subset of tasks allocated to player i by the Star Mechanism when applied to a star T_h, $h = 1, \ldots, k$. Truthfulness is an immediate consequence of the following two observations. First, since the fixed star decomposition is independent of player i's processing times, player i cannot affect it by lying. Second, $S_{i,h}$ is independent of player i's processing times $t_i(e)$ for all edges $e \notin T_h$, therefore player i cannot alter the assignment on T_h by changing its values outside T_h.

To see the approximation guarantee, let OPT, $OPT(T_h)$ be the optimal makespan on G and T_h respectively, and let ALG and $ALG(T_h)$ be the makespan achieved by the Star-Cover mechanism on G and T_h.

$$ALG \leq \max_{h=1,\ldots,k} c(T) \cdot ALG(T_h) \leq \max_{h=1,\ldots,k} c(T) \cdot 2OPT(T_h) \leq 2c(T) \cdot OPT. \qquad \blacktriangleleft$$

Due to the connection between star decompositions and edge orientations in graphs, we get

▶ **Corollary 12.** *The approximation ratio for graphs with edge orientation number $o(G)$ is at most $2o(G) + 2$.*

In the sequel, we consider particular bounds for certain classes of graphs. It is known that the edge orientation number of a given graph can be computed in polynomial time [2]. In fact, by an application of the max-flow-min-cut theorem it can be shown that $o(G) \leq \gamma$ iff for every subgraph H of G it holds that $|E(H)| \leq \gamma|V(H)|$. Since this equivalent condition[2] holds for planar graphs with $\gamma = 3$, we immediately obtain:

▶ **Theorem 13.** *For every planar graph, there exists a truthful mechanism with approximation ratio 8.*

A natural class of graphs fulfilling this property (with $\gamma = k$) is k-degenerate graphs. A graph $G(V, E)$ is called *k-degenerate* [23] (or *k-inductive*) if there is an ordering $v_1, \ldots, v_n$ of its nodes such that the number of neighbors of v_i in $\{v_{i+1}, \ldots, v_n\}$ is at most k. Many interesting classes of graphs are k-degenerate for some small k. Besides planar graphs (with $k = 5$), another example is given by k-trees [40]: by definition, a k-tree is a degenerate graph with an ordering such that every v_i (except for the last k nodes of the ordering) has exactly k neighbors in $\{v_{i+1}, \ldots, v_n\}$ and these k neighbors form a clique. Since graphs of treewidth k are subgraphs of k-trees [40], they are also k-degenerate. In particular, trees are 1-degenerate. We give here a direct proof and illustration of a star decomposition for k-degenerate graphs:

▶ **Theorem 14.** *For every k-degenerate graph, there is a truthful mechanism with approximation ratio $2k + 2$.*

Proof. Consider a k-degenerate graph G. It suffices to show that it admits a star decomposition with contention number $k + 1$. Let $v_1, \ldots, v_n$ be an inductive ordering of the nodes of G. We consider the star covering $\{T_2, \ldots, T_n\}$ where T_i is the star with root v_i and leaves all its neighbors in $\{v_1, \ldots, v_{i-1}\}$. Note that stars are created in the opposite direction of the inductive order (see Figure 2). This star decomposition has contention number $k + 1$ since every node belongs to at most one star as a root and to at most k stars as a leaf. ◀

▶ **Corollary 15.** *There exist truthful mechanisms with approximation ratio at most 4 for trees, and generally of ratio at most $2k + 2$ for graphs of treewidth k.*

3.3 Lower Bounds for Graph Balancing

In this subsection, we show corresponding negative results for the positive results of the previous subsection. We first observe that the natural candidate mechanisms for the Graph Balancing problem have very poor performance, in stark contrast to the Hybrid Mechanism.

▶ **Theorem 16.** *All local mechanisms for stars, including VCG, affine minimizers and task-independent mechanisms, have approximation ratio at least $\sqrt{m} = \sqrt{n-1}$.*

[2] This characterization of the orientation number $o(G)$ implies that a truthful mechanism with constant approximation ratio exists for any minor-closed class of graphs, because for every class of graphs with forbidden minors, there exists some constant γ that satisfies the property (see Theorems 7.2.3, 7.2.4 and Lemma 12.6.1. in [19]). We are grateful to an anonymous referee for pointing this out.

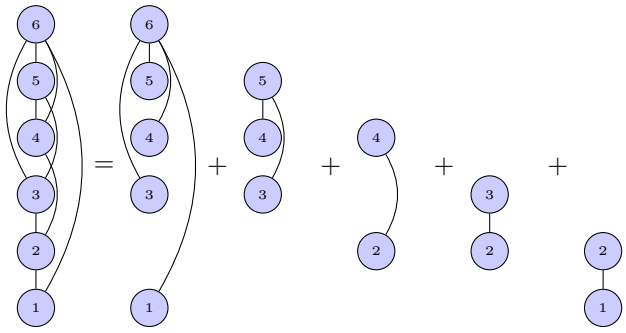

Figure 2 The star decomposition used in Theorem 14 of a 2-degenerate graph. The inductive order is upwards, while the stars are "pointing" downwards.

Proof. Consider the following input

$$t = \begin{pmatrix} \frac{1}{\sqrt{m}} & \frac{1}{\sqrt{m}} & \cdots & \frac{1}{\sqrt{m}} \\ 1 & \infty & \cdots & \infty \\ \infty & 1 & \cdots & \infty \\ \infty & \infty & \cdots & 1 \end{pmatrix}.$$

If, in the allocation of the mechanism, the root player takes all the tasks, then this allocation has approximation $\sqrt{m}$, as the optimal allocation is to assign the tasks to the leaves with makespan equal to 1. Otherwise, assume that (at least) one of the tasks, is given to some other player, say w.l.o.g. task 1 is given to player 1. By a series of applications of Lemma 4, and by exploiting the locality of the mechanism, we set the value of the owner of task j to 0 for every $j \neq 1$.

In particular, let S be the set of tasks assigned to the root player, and $M \setminus S$ be the tasks assigned to their respective leaf-player. Let $t^1 = (r', \ell_1, \ldots, \ell_m)$, with r' defined as follows for some arbitrarily small ϵ.

$$r'_j = \begin{cases} 0 & j \in S \\ \frac{1}{\sqrt{m}} + \epsilon & \text{otherwise.} \end{cases}$$

By applying Lemma 4, the root player receives again the set S, and therefore, the set $M \setminus S$ is assigned to the leaves. We proceed by changing the bids of the leaf-players for the tasks in $M \setminus S$ to 0, i.e., defining a sequence t^j for $j \in M \setminus S$, with $t^j = (r', \ell'_j = 0, \ell_{-j}^{j-1})$

Again, by Lemma 4 and by locality, we get that the allocation of the tasks remains the same for the leaf j, *and* for all the other players as well.

We end up with an instance t' where player 1 still takes the first task, while the rest of the tasks are assigned to a player with 0 processing time. For t', the optimal makespan is $1/\sqrt{m}$, while the mechanism achieves makespan equal to 1. We illustrate the case when $S = \emptyset$, that is, the allocation gives all the tasks to the leaves of the star.

$$t = \begin{pmatrix} \frac{1}{\sqrt{m}} & \frac{1}{\sqrt{m}} & \cdots & \frac{1}{\sqrt{m}} \\ \textcircled{1} & \infty & \cdots & \infty \\ \infty & \textcircled{1} & \cdots & \infty \\ \infty & \infty & \cdots & \textcircled{1} \end{pmatrix} \rightarrow t' = \begin{pmatrix} \frac{1}{\sqrt{m}} & \frac{1}{\sqrt{m}} & \cdots & \frac{1}{\sqrt{m}} \\ \textcircled{1} & \infty & \cdots & \infty \\ \infty & \textcircled{0} & \cdots & \infty \\ \infty & \infty & \cdots & \textcircled{0} \end{pmatrix}$$

◀

In the previous subsection, we showed that the Hybrid Mechanism outperforms all known mechanisms and has approximation ratio at most 2. The next theorem shows that this ratio is the best possible among all possible mechanisms for stars.

▶ **Theorem 17.** *There is no deterministic mechanism for stars that can achieve an approximation ratio better than 2.*

This is a special case of a more general lower bound for the L^p-norm objective (Theorem 30), but we give the proof here anyway, since it will be an ingredient of the proof of the following theorem (Theorem 18).

Proof. Let's assume that the mechanism takes an input where the processing time of the root player is $r_j = a^{j-1}$, for each task j, where $a > 1$ is a parameter, and the processing time of the corresponding leaf player for task j is $\ell_j = a^j$, as also shown in the following table.

$$t = \begin{pmatrix} 1 & a & \cdots & a^{m-2} & a^{m-1} \\ a & \infty & \cdots & \infty & \infty \\ \infty & a^2 & \cdots & \infty & \infty \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \infty & \infty & \cdots & a^{m-1} & \infty \\ \infty & \infty & \cdots & \infty & a^m \end{pmatrix}$$

If the mechanism assigns all tasks to the root player, then the makespan for this input is $(a^m-1)/(a-1)$, while the optimal makespan is a^{m-1}, yielding a ratio of $(a^m-1)/((a-1)a^{m-1})$. Otherwise, let X be the nonempty set of tasks assigned to the leaf players. Let k be the task with the maximum index in X. Since it is processed by the leaf player, its processing time is a^k. Now consider the input in which we change the processing times of the root player to

$$r'_j = \begin{cases} 0 & j \notin X \\ r_j + \epsilon & \text{otherwise} \end{cases}$$

for some arbitrarily small $\epsilon > 0$. By weak monotonicity (Lemma 4), the set of tasks assigned to the root player remains the same, and as a result the whole allocation stays the same. Therefore task k is still assigned to the leaf player k and the makespan of the mechanism is at least a^k. Notice that the optimum allocation for this input is $a^{k-1} + \epsilon$ which yields an approximation ratio of a, as ϵ tends to 0.

In conclusion, the approximation ratio is $\min\{(a^m-1)/((a-1)a^{m-1}), a\}$, for every $a > 1$. By choosing $a = 2$, we see that the ratio is $2 - 1/2^{m-1}$, which shows that for the class of stars no mechanism can have approximation ratio better than 2. For fixed m, the lower bound is slightly better than $2 - 1/2^{m-1}$, by selecting a to be the positive root of the equation $(a^m - 1)/((a-1)a^{m-1}) = a$. ◀

We now show how to extend the previous result to get a lower bound of $1+\varphi \approx 2.618$ for trees, and thus for graphs. This matches the best lower bound for the Nisan-Ronen setting [29] that was known until the recent improvements [24, 20, 11], suggesting that studying the special case of scheduling in graphs may be useful in attacking the Nisan-Ronen conjecture.

▶ **Theorem 18.** *No mechanism for trees can achieve approximation ratio* $1 + \varphi \approx 2.618$.

Proof. The proof mimics the proof of Theorem 17 on the tree shown in Figure 3. The tree consists of a star with root 0 and leaves $1, \ldots, k$ in which we add a new node $\overline{v}$ for each node v of the star and connect it to v. These new nodes (players), which we call dummy will not

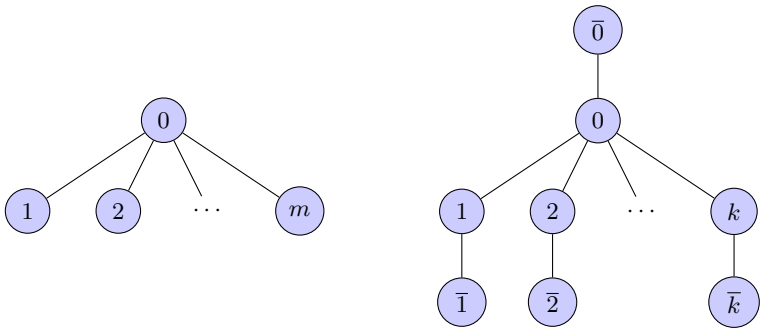

Figure 3 A star with root 0 and leaves $1, \ldots, m$ and its extension to a tree with dummy nodes.

be assigned any task by any efficient mechanism since we set their processing times to an arbitrarily high value H. The processing times of the edges of the star are exactly the same as in the proof of Theorem 17: $r_j = a^{j-1}$ and $\ell_j = a^j$, for some $a > 1$. The processing times for all edges are given below:

$$r_j = a^{j-1} \qquad \ell_j = a^j \qquad j = 1, \ldots, k$$
$$\overline{r} = 0 \qquad \overline{\ell}_j = 0$$

where $\overline{r}$ and $\overline{\ell}_j$ are the processing times of the star vertices of their respective dummy tasks. The dummy nodes themselves have a very large processing time $H \gg 1$ on these tasks.

We consider two cases. In the first case, all tasks of the star are assigned to the root player 0. We then consider a new instance in which we slightly lower the processing time of the root on the tasks of the star (i.e., $r_j = a^{j-1} - \epsilon$ for some $\epsilon > 0$) and increase the processing time of its dummy task $\overline{r} = a^k$. By weak monotonicity (Lemma 4), the r-player will take this task and all tasks of the star with a total processing time slightly less than $1 + a + \ldots + a^k = (a^{k+1} - 1)/(a - 1)$. It is easy to see that the optimal allocation for this instance is a^k, and the approximation ratio $(a^{k+1} - 1)/((a - 1)a^k)$.

In the second case, at least one task of the star is allocated to a leaf. Let p be the star task allocated to a leaf with the maximum index (that is, task p of the star is allocated to leaf-player p and tasks $p + 1, \ldots, k$ are allocated to the root). We consider the instance in which we change the processing times of the root player as follows: all processing times of the tasks allocated to the root become 0 and all processing times of the root player for the remaining tasks increase slightly. By weak monotonicity (Lemma 4), the r-player will still get the same set of tasks. We now create a new instance by increasing the processing time of the p-th dummy task: $\overline{\ell}_p = a^{p-1}$ and slightly decreasing the processing time of the leaf p for its task in the star: $\ell_p = a^p - \epsilon$, for some $\epsilon > 0$. Then again by weak monotonicity (Lemma 4), player p will get these two tasks. Although the allocation of the other tasks may change, the cost for the mechanism is at least $a^p + a^{p-1} - \epsilon$, while the optimal allocation has cost a^{p-1}. Therefore, in this case the mechanism has approximation ratio $(a^p + a^{p-1})/a^{p-1} = a + 1$, as $\epsilon \to 0$. In any case, the mechanism has approximation ratio $\min\{((a^{k+1} - 1)/((a - 1)a^k), a + 1\}$. By selecting $a = \varphi$, we get a ratio at least $1 + \varphi$ (as $k \to \infty$). ◀

Closing the gap between the above lower bound 2.618 of Theorem 18 and the upper bound 4 (Corollary 15) for mechanisms for trees is a crisp intriguing question.

4 Hybrid Mechanisms

Here we provide the general definitions related to Hybrid Mechanisms, and show necessary and sufficient conditions for truthfulness on stars (and hyper-stars[3]). We emphasize that this is a multi-dimensional mechanism design setting. Each leaf j has a single dimensional valuation, given by the scalar ℓ_j but a root has multi-dimensional preferences, given by the vector of values. For the sake of convenience, we call non-decreasing real functions *increasing*, and non-increasing functions *decreasing*. We say *strictly increasing/decreasing* if we want to emphasize strict monotonicity.

It is known, that an allocation rule can be equipped by a truthful payment scheme iff it is *weakly monotone* [41]. The next two propositions give a characterization of the weak monotonicity property in our case, for the leaf-players, and for the root player, respectively:

▶ **Proposition 19.** *An allocation rule is weakly monotone for a leaf-player i, iff for every r and every ℓ_{-i}, whenever leaf-player i gets task i with bid ℓ_i, then he also gets the task with every smaller bid $\ell_i' < \ell_i$.*

▶ **Proposition 20.** *An allocation rule is weakly monotone for the root player if and only if for every fixed bid vector ℓ of the other players, and every $T \subseteq M$ a constant $g_T(\ell)$ (i.e., independent of r) exists, such that for every r the root player is allocated a set $S \in \arg\min_T \{r(T) + g_T(\ell)\}$.*

The canonical choice for truthful payments to the r-player is then $P_S^0(\ell) = g_\emptyset(\ell) - g_S(\ell)$, and all other truthful payments can be obtained by an additive shift by an arbitrary $c(\ell)$.

We assume w.l.o.g. that for every fixed ℓ the payments P_S^0 correspond to an increasing set-function of S,[4] because a set of tasks with higher cost and less payments can not be allocated to player 0 by a truthful mechanism.[5] Motivated by Proposition 20 we restrict our search for truthful mechanisms on star graphs as follows:

▶ **Definition 21** (Hybrid Mechanism). *Assume that an m-variate function $g_T : \mathbb{R}^m \to \mathbb{R}$ is given for every $T \subseteq M$, so that for every fixed vector $\ell \geq 0$ the values $\{g_T(\ell)\}_{T \subseteq M}$ correspond to a decreasing setfunction of T. For any input (r, ℓ), a* Hybrid Mechanism (for the functions $\{g_T\}_{T \subseteq M}$) *allocates a set S to the root player such that*

$$S \in \arg\min_T \{r(T) + g_T(\ell)\};$$

if there are more than one such sets S, the mechanism breaks ties according to the lexicographic order over all subsets of M. The items in $M \setminus S$ are assigned to the leaves.

Now for any $i \in M$ fix all bids in the input except for r_i, i.e., fix the vectors r_{-i} and ℓ. The following function $\psi_i[r_{-i}, \ell]$ defines the so called *critical value* for the bid r_i. We omit the argument r_{-i}, ℓ whenever they are obvious from the context.

▶ **Definition 22.**

$$\psi_i = \psi_i[r_{-i}, \ell] = \min_{T: i \notin T} \{r(T) + g_T(\ell)\} - \min_{T: i \in T} \{r(T \setminus \{i\}) + g_T(\ell)\}$$

[3] For simplicity of presentation we give here all definitions and lemmata for the case of stars, and discuss the necessary changes for hyper-stars in the full version.

[4] We call a setfunction P *increasing*, if $P(S') \leq P(S)$ whenever $S' \subset S$; we call it *strictly increasing* if the inequality is strict.

[5] See also the *virtual payments* in [12].

The next lemma states that ψ_i is nonnegative, and is, indeed, a critical value function. The proofs are straightforward, and due to space limitations are deferred to the full version.

▶ **Lemma 23.** *Let $i \in M$, and arbitrary nonnegative bid vectors r_{-i} and ℓ be fixed. Then $\psi_i[r_{-i}, \ell] \geq 0$, furthermore for every $r_i < \psi_i$ the root player receives task i, and for every $r_i > \psi_i$ the leaf player with bid ℓ_i receives task i.*

The following lemma provides various necessary or sufficient conditions for the truthfulness of Hybrid Mechanisms in terms of monotonicity of the critical value function ψ_i as a function of ℓ_i. For the proof of the lemma see the full version. There we also present an example mechanism showing that conditions (b) and (c) are both not necessary for the Hybrid Mechanism to be truthful.

▶ **Lemma 24.** *For the truthfulness of the Hybrid Mechanism with given $\{g_T\}_{T \subseteq M}$ functions (i.e., for a truthful payment scheme to exist),*

(a) *it is necessary that for every $i \in M$ and every fixed (r_{-i}, ℓ_{-i}) the function $\psi_i(\ell_i) = \psi_i[r_{-i}, \ell_{-i}](\ell_i)$ is an increasing function of ℓ_i;*

(b) *it is sufficient that for every $i \in M$ and every fixed (r_{-i}, ℓ_{-i}) the function $\psi_i(\ell_i) = \psi_i[r_{-i}, \ell_{-i}](\ell_i)$ is a* strictly *increasing function of ℓ_i;*

(c) *it is sufficient that for every i and ℓ_{-i} the $g_T(\ell_i, \ell_{-i})$ is an increasing function of ℓ_i whenever $i \notin T$, and decreasing function of ℓ_i whenever $i \in T$.*

▶ **Corollary 25.** *The Hybrid Mechanism for Graph Balancing and the Hybrid L^p Mechanism on stars are truthful.*

Proof. The first statement follows from the fact that the Hybrid Mechanism for Graph Balancing fulfils (c). Clearly, $g_T(\ell) = \max_{i \notin T}\{\ell_i\} = \max_{i \in M \setminus T}\{\ell_i\}$ is an increasing setfunction of the sets $M \setminus T$, and therefore a decreasing setfunction of the sets T, for fixed ℓ. For fixed T, $\max_{i \notin T}\{\ell_i\}$ is an increasing function of ℓ_i for every $i \notin T$, and it is independent of ℓ_i (constant function) if $i \in T$. Finally, it is easy to see that the Hybrid L^p Mechanism (see Section 5) fulfils (b) as well as (c). ◀

5 Mechanisms for L^p-norm optimization

In this section we generalize some of the results of Section 3 to the objective of minimizing the L^p-norm of the values of the agents, i.e., minimizing, over all allocations X the expression

$$\left(\sum_{i=1}^{n} t_i(X)^p \right)^{1/p}. \tag{2}$$

The makespan scheduling problem is the special case of $p = \infty$. We consider all positive values of p, but we deal separately with the case $p \geq 1$, in which L^p is a proper norm, and the case $p \in (0, 1)$, where the L^p function is not subadditive (i.e., the triangle inequality does not hold). Due to space limitations we postpone most of the results and their proofs to the full version of the paper. There we also consider the *maximization* case, which for $p = 1$ corresponds to auctions.

Consider an instance of the Unrelated Graph Balancing problem on a star of n nodes and set of tasks M. Notice that for stars the objective of minimizing the L^p-norm corresponds to minimizing $(r(T)^p + \sum_{i \notin T} \ell_i^p)^{\frac{1}{p}}$ over all task sets $T \subseteq M$ given to the r-player.

▶ **Definition 26** (Hybrid L^p Mechanism for stars). *For a given $0 < p \leq \infty$, and an instance of the Unrelated Graph Balancing problem on a star of n nodes and set M of tasks, let*

$$S \in \arg\min_{T \subseteq M} \left\{ r(T) + \left(\sum_{i \notin T} \ell_i^p \right)^{1/p} \right\}. \tag{3}$$

The mechanism assigns S to the root and the remaining tasks to leaves. Ties are broken in a deterministic way (e.g., lexicographically).

The argmin expression that defines the Hybrid L^p Mechanism coincides with the VCG mechanism for $p = 1$ and with the Hybrid Mechanism of Section 3 for $p \to \infty$. As it is shown in Corollary 25, the Hybrid L^p mechanism is truthful.

Next we show two upper bound results for the approximation ratio (for the L^p-norm objective) separately in case $p \geq 1$, and in case $0 < p \leq 1$, respectively. We summarize here the inequalities that we will use:

▶ **Lemma 27.** *For any $p \geq 1$ it holds*

$$\sum_{i=1}^{k} x_i^p \leq \left(\sum_{i=1}^{k} x_i \right)^p \leq k^{p-1} \sum_{i=1}^{k} x_i^p. \tag{4}$$

Similarly for any $0 < p \leq 1$ it holds

$$\sum_{i=1}^{k} x_i^{1/p} \leq \left(\sum_{i=1}^{k} x_i \right)^{1/p} \leq k^{1/p-1} \sum_{i=1}^{k} x_i^{1/p}. \tag{5}$$

▶ **Theorem 28.** *For the problem of minimizing the L^p-norm, the Hybrid L^p Mechanism for stars has approximation ratio of at most $2^{(p-1)/p}$, when $p \geq 1$, and $2^{(1-p)/p}$, when $0 < p < 1$.*

Proof. Let $S^* = \arg\min_{T \subseteq M} (r(T)^p + \sum_{i \notin T} \ell_i^p)^{\frac{1}{p}}$ be the subset assigned to the root in the optimal allocation, S be the subset assigned to the root by the L^p Mechanism, OPT be the optimal L^p-norm, and ALG be the L^p-norm achieved by the Hybrid L^p Mechanism.

We first consider the case $p \geq 1$. We have

$$\begin{aligned} ALG = \left(r(S)^p + \sum_{i \notin S} \ell_i^p \right)^{1/p} &\leq r(S) + \left(\sum_{i \notin S} \ell_i^p \right)^{1/p} \\ &\leq r(S^*) + \left(\sum_{i \notin S^*} \ell_i^p \right)^{1/p} \\ &\leq 2^{(p-1)/p} \left(r(S^*)^p + \sum_{i \notin S^*} \ell_i^p \right)^{1/p} = 2^{(p-1)/p} OPT, \end{aligned}$$

where the first inequality follows from the triangle inequality, the second from the definition of the Hybrid L^p Mechanism, while the last one from Jensen's inequality (Lemma 27, Equation (4)) for $k = 2$, $x_1 = r(S^*)$, and $x_2 = (\sum_{i \notin S^*} \ell_i^p)^{1/p}$.

The case of $p < 1$, is essentially the same, but the proof is slightly different.

$$\begin{aligned} ALG = \left(r(S)^p + \sum_{i \notin S} \ell_i^p \right)^{1/p} &\leq 2^{\frac{1}{p}-1} \left(r(S) + \left(\sum_{i \notin S} \ell_i^p \right)^{1/p} \right) \\ &\leq 2^{\frac{1}{p}-1} \left(r(S^*) + \left(\sum_{i \notin S^*} \ell_i^p \right)^{1/p} \right) \\ &\leq 2^{\frac{1}{p}-1} \left(r(S^*)^p + \sum_{i \notin S^*} \ell_i^p \right)^{1/p} = 2^{\frac{1}{p}-1} OPT. \end{aligned}$$

The first inequality follows from Jensen's inequality for $x_1 = (r(S))^p$, and $x_2 = \sum_{i \notin S} \ell_i^p$; the second from the definition of the L^p Mechanism, while the last one from the fact that $(\alpha + \beta)^p \leq \alpha^p + \beta^p$, when $0 < p \leq 1$. ◀

As in the case of makespan, we can use the mechanism to other domains by decomposing them. We can apply the Star-Cover mechanism (Definition 10) to get good approximation ratios for general domains:

▶ **Theorem 29.** *For $p \geq 1$, the Star-Cover mechanism for a given multigraph G that uses the Hybrid L^p Mechanism on every star of a fixed star decomposition $T = \{T_1, \ldots, T_k\}$ is truthful and has an approximation ratio at most $(2c(T))^{(p-1)/p}$ of the L^p-norm of the machines' costs, where $c(T)$ is the star contention number of the decomposition.*

We also provide corresponding negative results for mechanisms. For the case, of $p \geq 1$, the next theorem shows that the Hybrid L^p Mechanism has optimal approximation ratio.

▶ **Theorem 30.** *For any $p \geq 1$, there is no deterministic mechanism for stars that can achieve an approximation ratio better than $2^{1-1/p}$ for the L^p-objective.*

We point out that all known (local) mechanisms perform much worse that the Hybrid Mechanism. Observe that for $p = 1$, the VCG is optimal, but for large p the inefficiency of all local mechanisms grows and tends to $\sqrt{m}$:

▶ **Theorem 31.** *For minimizing the L^p-norm on stars, all* local *mechanisms, including affine minimizers and task-independent mechanisms, have approximation ratio of at least $m^{\frac{1}{2}(1-1/p)} = (n-1)^{\frac{1}{2}(1-1/p)}$, when $p \geq 1$.*

The lower bound that we give for the case of $p < 1$ does not match exactly the upper bound, which leaves open the possibility that there exists a mechanism with better approximation ratio than the Hybrid L^p Mechanism. Notice that the following approximation ratio tends to infinity as p tends to 0.

▶ **Theorem 32.** *For any $0 < p \leq 1$ and every $a > 1$, there is no deterministic mechanism for stars that can achieve an approximation ratio better than*

$$\min\left\{a, \frac{(a+1)^{1/p}}{a^{1/p} + a)}\right\}. \tag{6}$$

By selecting an appropriate a, this is $\Omega(p^{-1}/\ln(p^{-1}))$.

Towards the k-Server Conjecture: A Unifying Potential, Pushing the Frontier to the Circle

Christian Coester
CWI, Amsterdam, The Netherlands

Elias Koutsoupias
University of Oxford, UK

Abstract

The k-server conjecture, first posed by Manasse, McGeoch and Sleator in 1988, states that a k-competitive deterministic algorithm for the k-server problem exists. It is conjectured that the work function algorithm (WFA) achieves this guarantee, a multi-purpose algorithm with applications to various online problems. This has been shown for several special cases: $k = 2$, $(k + 1)$-point metrics, $(k + 2)$-point metrics, the line metric, weighted star metrics, and $k = 3$ in the Manhattan plane.

The known proofs of these results are based on potential functions tied to each particular special case, thus requiring six different potential functions for the six cases. We present a *single* potential function proving k-competitiveness of WFA for all these cases. We also use this potential to show k-competitiveness of WFA on multiray spaces and for $k = 3$ on trees. While the DoubleCoverage algorithm was known to be k-competitive for these latter cases, it has been open for WFA. Our potential captures a type of lazy adversary and thus shows that in all settled cases, the worst-case adversary is lazy. Chrobak and Larmore conjectured in 1992 that a potential capturing the lazy adversary would resolve the k-server conjecture.

To our major surprise, this is not the case, as we show (using connections to the k-taxi problem) that our potential fails for three servers on the circle. Thus, our potential highlights laziness of the adversary as a fundamental property that is shared by all settled cases but violated in general. On the one hand, this weakens our confidence in the validity of the k-server conjecture. On the other hand, if the k-server conjecture holds, then we believe it can be proved by a variant of our potential.

1 Introduction

The k-server problem, introduced by Manasse, McGoech and Sleator [23], is one of the most fundamental problems in online optimization and contains other problems like paging or weighted paging as important special cases. It is defined as follows: k servers are located in a metric space. One by one, points of the metric space are requested, and each request must be served upon arrival by moving one of the servers to the requested point. The problem is typically considered *online*, where the choice of this server has to be made without knowledge of future requests. The goal is to minimize the total distance traveled by all servers.

When Manasse, McGeoch and Sleator [23] introduced the k-server problem, they showed that on any metric space with $n \geq k+1$ points[1], every deterministic online algorithm has competitive ratio at least k. They showed that this lower bound is tight when $k = 2$ or $k = n - 1$ by giving a k-competitive algorithm for these cases and boldly conjectured that a k-competitive online algorithm exists for the general case. This conjecture became known as the famous *k-server conjecture* and has been a driving force in online optimization, making the k-server problem perhaps the most studied problem in the field. It has often been referred to as "the holy grail of competitive analysis", and many techniques developed for the k-server problem have later found applications to other problems.

Chrobak, Karloff, Payne, and Vishwanathan [10] designed the elegant *Double Coverage* algorithm to achieve the optimal competitive ratio of k on the line metric. Shortly after, Chrobak and Larmore [11] extended this algorithm to tree metrics, again matching the lower bound of k. The first algorithm for general metrics with a competitive ratio depending only on k was found by Fiat, Rabani and Ravid [16], achieving a competitive ratio exponential in k. Significant progress was made by Koutsoupias and Papadimitriou [21], showing that a competitive ratio of $2k - 1$ is achievable on general metric spaces.

While this reduces the gap between the upper and lower bound to a factor of 2, it remains open to determine the exact competitive ratio. The lack of a proof of the k-server conjecture is even more puzzling given that the algorithm conjectured to achieve the competitive ratio of k has been known for 30 years: The *work function algorithm (WFA)*. It is this algorithm that achieves the aforementioned upper bound of $2k - 1$ [21]. Its definition is generic[2], with applications reaching far beyond the k-server problem. For instance, WFA achieves the optimal competitive ratio for metrical task systems [7, 6], the closely related *generalized WFA* has been applied successfully to the weighted k-server problem [3], the generalized 2-server problem [26] and layered graph traversal [9], and work functions have also played a crucial role in recent breakthroughs for convex body chasing [1, 25]. Given these connections, an exact understanding of the WFA for the k-server problem is likely to have a wider impact on online optimization in general.

WFA is known to achieve the tight competitive ratio of k for the following special cases, which impose restrictions on the number of servers and/or the type of metric space:

- $k = 2$ [12]
- $k = n - 1$ (folklore; see e.g. [19])
- $k = n - 2$ [20, 4]
- line metric [4]
- weighted star metrics [4]
- $k = 3$ in the Manhattan plane [5]

While there has been a lack of progress on the k-server conjecture for about two decades, tremendous progress has been achieved for the *randomized* k-server problem in recent years [2, 8, 22], leading to algorithms with polylogarithmic competitive ratios.

1.1 Our contribution

Our contribution consists of three parts.

(a) The known proofs of the aforementioned six special cases where WFA is k-competitive all use a different potential function, and thus do not seem to point towards a potential function that can solve the k-server conjecture in the general case. We present a single potential function that proves the k-server conjecture for all these cases.

[1] On metric spaces with $n \leq k$ points, the k-server problem is trivial.

[2] WFA always chooses the action that would be best if the future were a mirror image of the past.

(b) Tree metrics are the only special case of the k-server problem where WFA is not known to be k-competitive but another algorithm is (namely, the Double Coverage algorithm [11]). In [4], the question whether WFA is k-competitive on trees was raised as an intermediate step towards solving the k-server conjecture. In this direction, we use our potential function to show that WFA is k-competitive on multiray spaces (a type of tree metrics that generalizes the line and weighted star metrics) and for $k = 3$ on general trees. Our proofs employ the quasi-convexity property of work functions in several new ways.

(c) Chrobak and Larmore [12] formulated three conjectures which say, essentially, that the "adversary is lazy" in the sense that at any time, the worst-case continuation of the request sequence begins with many requests to the k offline server locations (forcing any sensible algorithm to converge to this configuration) before other points are requested. They verified their conjectures on tens of thousands of small metric spaces. In [5], a stronger statement was considered (ignoring the question what kind of work functions are "reachable"), which fails in general but which they conjectured to be true on the circle metric. We reject all these conjectures by showing that for $k = 3$, our potential captures exactly this lazy adversary (and a more restricted adversary for general k), but that it fails on the circle by giving an explicit request sequence as a counterexample. This highlights an important conceptual separation between all cases where k-competitiveness of WFA has been shown and the general case. We believe this property constitutes the main difficulty in resolving the k-server conjecture, and it suggests the circle as the main testing ground for further progress. Our method of constructing the counterexample is based on a connection with the k-taxi problem [13], which we use to generate phenomena of large metric spaces on a much smaller metric space.

1.2 Overview

We provide various definitions and lemmas in Section 2. In Section 3 we formally define our potential in two equivalent ways and show the basic way to use it to prove k-competitiveness. In Section 4, we relate our potential to the lazy adversary potential that was defined implicitly by Chrobak and Larmore. We prove k-competitiveness on multiray spaces in Section 5. This is our most involved proof, and implies the previously known k-competitiveness on the line and weighted stars as special cases. The proof for $k = 3$ on trees and proofs for previously known special cases using our potential can be found in the full version of our paper [14]. In Section 6, we describe ideas of a counter-example to our potential for $k = 3$ on the circle, implying that the adversary is not lazy in this case, unlike the cases where WFA is known to be k-competitive. Details of this construction are given in the full version [14].

2 Preliminaries

Basic notation and abuse of notation. We use (M, d) to denote the metric space, where d is the distance function. We denote by $n = |M|$ its size and by $\Delta = \max_{x,y} d(x, y)$ its diameter. For $x, y \in M$, we will often use the shorthand notation $xy := d(x, y)$. A multiset $C \subseteq M$ of k points is called a *configuration*, representing the location of k servers. We denote by $\mathcal{C}_M^k$ the set of all configurations. For two configurations, X and Y, we denote by $d(X, Y)$ the value of their minimum matching. For notational convenience, we often use the empty space as a union operator on elements of M. For example, we often write $x_1x_2 \dots x_i$ instead of $\{x_1, x_2, \dots, x_i\}$ when it is clear from the context that the set is meant. Similarly, given also a multiset C, we may write $Cx_1 \dots x_i$ instead of $C \cup \{x_1, \dots, x_i\}$. For $x \in M$ and $i \in \mathbb{N}_0$, we write x^i for the multiset containing i copies of x.

For a set $S \subseteq M$, let clique(S) be the sum of pairwise distances of the points in S.

The k-server problem. An instance of the k-server problem is defined by a metric space (M, d), an initial configuration $C_0 \in \mathcal{C}_M^k$ and a sequence $r_1, r_2, \ldots, r_T \in M$ of requests. A feasible solution is a sequence $C_1, C_2, \ldots C_T$ of configurations such that $r_t \in C_t$ for all $t = 1, \ldots, T$. The cost of this solution is the sum $\sum_{t=1}^{T} d(C_{t-1}, C_t)$.

The work function algorithm (WFA). Given an instance of the k-server problem, the *work function* w_t at time t is the function that maps any configuration C to the minimal cost of serving the first t requests and subsequently ending in configuration C. Formally,

$$w_t(C) := \min_{\substack{C_1,\ldots,C_t \\ \forall \tau\colon r_\tau \in C_\tau}} \sum_{\tau=1}^{t} d(C_{\tau-1}, C_\tau) + d(C_t, C).$$

The work function algorithm (WFA) selects $C_t \ni r_t$ so as to minimize $d(C_{t-1}, C_t) + w_t(C_t)$, with ties broken arbitrarily.

Quasiconvexity. A function $w\colon \mathcal{C}_M^k \to \mathbb{R}$ is called *quasiconvex* if for any configurations X and Y there exists a bijection $\mu\colon X \to Y$ such that for any $A \subseteq X$,

$$w(X) + w(Y) \geq w(A \cup \mu(X \setminus A)) + w(\mu(A) \cup (X \setminus A)).$$

It was shown in [21] that if w is quasiconvex, then μ can be chosen such that $\mu(x) = x$ for all $x \in X \cap Y$. More importantly, it was shown in [21] that any work function is quasiconvex.

Fundamentals about work functions. A function $w\colon \mathcal{C}_M^k \to \mathbb{R}$ is 1-*Lipschitz* if

$$w(X) - w(Y) \leq d(X, Y) \tag{1}$$

for all configurations X and Y. By triangle inequality, every work function is 1-Lipschitz.

Let $\mathcal{Q}_M^k$ be the set of functions $w\colon \mathcal{C}_M^k \to \mathbb{R}$ that are quasiconvex. Let $\mathcal{W}_M^k \subseteq \mathcal{Q}_M^k$ be the subset of functions that are additionally 1-Lipschitz. We may drop k and/or M from the notation when they are clear from the context or immaterial. For $w \in \mathcal{W}$ and configurations X and Y, we say that Y *supports* X if (1) holds with equality. Note that if Y supports X in w_t, then the cheapest way of serving the first t requests and ending in configuration X is equal to the cheapest way of serving the first t requests and then first going to Y and then to X. Thus, if Y supports X, then there is no reason for an offline algorithm to be in configuration X because it is at least as good to be in configuration Y and delay the move from Y to X until later.

The *support* of w, denoted supp(w), is the set of all configurations that are *not* supported by any other configuration. Intuitively, supp(w_t) are the possible configurations where an optimal offline algorithm might be at time t. Clearly,

$$w(X) = \min_{Y \in \mathrm{supp}(w)} w(Y) + d(X, Y)$$

for any configuration X. In particular, any work function is fully specified by its support and the values it takes on support configurations.

For $r \in M$, let $\mathcal{W}_M^k(r) \subseteq \mathcal{W}_M^k$ be the subset of 1-Lipschitz, quasiconvex functions with the property that every support configuration contains r. Again, we may drop k and/or M from the notation. Note that the work function w_t at time t is in $\mathcal{W}(r_t)$.

There exists a simple update rule to compute the new work function when a new request is issued. For $w \in \mathcal{W}_M$ and $r \in M$, the updated work function $w \wedge r \in \mathcal{W}(r)$ is defined by

$$w \wedge r(C) = \min_{X \ni r} w(X) + d(X, C).$$

It is easy to see that $w_t = w_{t-1} \wedge r_t$. A basic observation is that if $r_t \in C$, then $w_{t-1}(C) = w_t(C)$. Another basic property is that $w_t(C) \geq w_{t-1}(C)$.

2.1 Extended cost, minimizers and duality

The following lemma was proved by Chrobak and Larmore [12] (see also [19]):

▶ **Lemma 1** (Extended cost lemma). *If for every k-server instance on a metric space M it holds that*

$$\sum_{t=1}^{T} \max_X [w_t(X) - w_{t-1}(X)] \leq (\rho + 1) \cdot \min_X w_T(X) + c_M$$

for some constant c_M independent of the request sequence, then WFA is ρ-competitive on M.

The power of this lemma is that it reduces the task of proving competitiveness of WFA to a property of work functions. In particular, we do not need to keep track of the actual configurations of the online and offline algorithm. The quantity $\max_X [w_t(X) - w_{t-1}(X)]$ is also called the *extended cost* of the tth request, and the proof of the lemma is based on the fact that the total extended cost over all requests is an upper bound on the sum of WFA's cost and the optimal offline cost.

For a work function $w \in \mathcal{W}_M^k$ and a point $y \in M$, we call a configuration $X \in \arg\min w(X) - d(y^k, X)$ a *minimizer of w with respect to y*. There is a direct connection between minimizers and the configurations X maximizing the extended cost. This is captured by the duality lemma, which was first proved in [21]. We give a slightly stronger version of the duality lemma by stating it as an equivalence rather than an implication.

▶ **Lemma 2** (Duality lemma). *Let $w \in \mathcal{W}_M$ and $r \in M$. Define $w' = w \wedge r$. Then $A \in \arg\min_X w(X) - d(r^k, X)$ if and only if the following two conditions hold:*

$$A \in \arg\max_X w'(X) - w(X) \tag{2}$$

$$A \in \arg\min_X w'(X) - d(r^k, X) \tag{3}$$

Proof. The "only if" direction is the duality lemma of [21], where it was shown that if $A \in \arg\min_X w(X) - d(r^k, X)$ then for every configuration B

$$w'(A) + w(B) \geq w(A) + w'(B), \quad \text{and} \tag{4}$$

$$w'(B) - d(r^k, B) \geq w'(A) - d(r^k, A). \tag{5}$$

By summing these two constraints we get $w(B) - d(r^k, B) \geq w(A) - d(r^k, A)$, which shows the other direction. ◀

It is interesting that the proof of the duality lemma does not use the fact that d is a distance, i.e., it satisfies the triangle inequality.

2.2 Additional properties of work functions

In this section, we provide additional properties of work functions that follow from the quasiconvexity property. We will use these properties to prove k-competitiveness on multiray spaces and for $k = 3$ on trees.

The notion of quasiconvex or quasiconcave functions appears in many different areas and was discovered independently a few times. As a result, they appear with different terminology in literature. For example, in the early 1980s Celso and Crawford [17] defined a related notion as a sufficient condition to the existence of Walrasian Equilibria and called a similar notion gross substitute functions[3]; in 1990, Dress and Wenzel [15] related them to a variant of the greedy algorithm and called them valuated matroids; Koutsoupias and Papadimitriou [21] defined them in the context of online algorithms for the k-server problem and called them quasiconvex. They have also played a central role in discrete optimization [24].

▶ **Lemma 3.** *Let $w \in \mathcal{Q}$. Let $X \in \arg\min w(X)$, and let $x \in X$. Then there exists $Y \in \arg\min_{Y \not\ni x} w(Y)$ such that $X - x \subset Y$.*

Proof. Let Y be chosen such that $X \cap Y$ is maximal under inclusion. Suppose towards a contradiction that there exists $x' \in (X - x) \setminus Y$. By quasiconvexity, there exists $y' \in Y \setminus X$ such that $w(X) + w(Y) \geq w(X - x' + y') + w(Y - y' + x')$. By choice of X, we have $w(X - x' + y') \geq w(X)$. Combining these last two inequalities, we get $w(Y) \geq w(Y - y' + x')$. But $Y - y' + x' \not\ni x$ and $X \cap Y \subsetneq X \cap (Y - y' + x')$, so this contradicts the choice of Y. ◀

▶ **Lemma 4.** *Let $w \in \mathcal{Q}^k_M$. Let $X \in \arg\min w(X)$, and let $A \subset M$ be a (multi)set of cardinality $|A| < k$. Then there exists $Y \in \arg\min_{Y \supset A} w(Y)$ such that $Y - A \subseteq X - A$.*

Proof. Let Y be chosen such that $(Y - A) \setminus (X - A)$ is minimal under inclusion and suppose towards a contradiction that there exists $y \in (Y - A) \setminus (X - A)$. By quasiconvexity, there exists $x \in X \setminus Y$ such that $w(X) + w(Y) \geq w(X - x + y) + w(Y - y + x)$. By choice of X, we have $w(X - x + y) \geq w(X)$. Combining these inequalities, we get $w(Y) \geq w(Y - y + x)$. But this contradicts the choice of Y since we would rather have chosen $Y - y + x$. ◀

▶ **Lemma 5.** *Let $w \in \mathcal{W}^k_M(r)$, let $X \subseteq M$ be a k-point multiset and $x, y \in X$. If X resolves[4] from x in w, then also $X - y + x$ resolves from x in w.*

Proof. Suppose that instead, $X - y + x$ resolves from some $z \in X - y - x$. Consider the $(k-3)$-point multiset $C := X - y - x - z$. Then

$$\begin{aligned} w(X) + w(X - y + x) &= w(Cxyz) + w(Cx^2z) \\ &= w(Cyzr) + w(Cx^2r) + rx + rz \\ &\geq w(Cxyr) + w(Cxzr) + rx + rz \\ &\geq w(Cxyz) + w(Cx^2z), \end{aligned}$$

where the first inequality is by quasiconvexity and the last by 1-Lipschitzness of w. Since the second and the last expression are the same, we have equality in all steps. But then the last step shows that Cx^2z resolves from x. Since $Cx^2z = X - y + x$, the lemma follows. ◀

[3] Gross substitute functions are real functions defined for all subsets of a ground set V, whose restriction to subsets of each size k are quasiconvex.

[4] When $w(X) = w(X - x + y) + xy$, we say that X "resolves from x to y". If $y = r$ is the last request, we simply say that X resolves from x.

3 The potential

We provide two different, but equivalent definitions of our potential function. The first formulation views the potential through the lens of the *m-evader problem*, which is equivalent to the k-server problem when $m = n - k$. Thereafter, we will give a more compact and equivalent formulation of the same potential in the k-server view based on extending the metric space by adding antipodal points.

3.1 The evader potential

The m-evader problem is defined similarly to the k-server problem, but instead of k servers there are m evaders in the metric space, which must occupy m different points at all times. When a point r is requested, rather than moving a server towards r, an evader that might be located at r has to move to a different point. The equivalence between the k-server problem and the $(n-k)$-evader problem follows by identifying a server configuration C with the evader configuration $M \setminus C$.[5] Given a k-server work function w, we denote by $\hat{w}$ the corresponding evader work function, defined by $\hat{w}(C) := w(M \setminus C)$.

In the evader view, the potential $\hat{\Phi}$ is defined as follows. Let $y = (y_1, \dots, y_n)$ be a permutation of the points of the metric space M. Let

$$\hat{\Phi}_y(\hat{w}) := \operatorname{clique}(y_1 \dots y_{n-k-1}) + \sum_{i=n-k}^{n} \min_{\substack{C \subseteq \{y_1,\dots,y_i\} \\ |C|=n-k}} \left(\hat{w}(C) + d(C, y_i^{n-k})\right)$$

$$\hat{\Phi}(\hat{w}) := \min_y \hat{\Phi}_y(\hat{w}). \tag{6}$$

▶ **Theorem 6.** *Let (M, d) be an n-point metric space. If for every $r \in M$ and every work function $w \in \mathcal{W}_M^k(r)$ it holds that $\hat{\Phi}(\hat{w}) = \hat{\Phi}_y(\hat{w})$ for a permutation y of M with $y_n = r$, then WFA is k-competitive on M.*

Proof. Consider a k-server instance on M with a request sequence $r_1, \dots, r_T$ and associated sequence of work functions $w_0, \dots, w_T$. We first show that at each time t, the change in potential is an upper bound on the extended cost.

By the premise of the lemma, $\hat{\Phi}(\hat{w}_t) = \hat{\Phi}_y(\hat{w}_t)$ for some y with $y_n = r_t$. Thus,

$$\begin{aligned}
\hat{\Phi}(\hat{w}_t) - \hat{\Phi}(\hat{w}_{t-1}) &\geq \hat{\Phi}_y(\hat{w}_t) - \hat{\Phi}_y(\hat{w}_{t-1}) \\
&\geq \min_{\substack{C \subseteq M \\ |C|=n-k}} \left(\hat{w}_t(C) + d(C, r_t^{n-k})\right) - \min_{\substack{C \subseteq M \\ |C|=n-k}} \left(\hat{w}_{t-1}(C) + d(C, r_t^{n-k})\right) \\
&= \min_{\substack{X \subseteq M \\ |X|=k}} \left(w_t(X) - d(X, r_t^k)\right) - \min_{\substack{X \subseteq M \\ |X|=k}} \left(w_{t-1}(X) - d(X, r_t^k)\right) \\
&= \max_X w_t(X) - w_{t-1}(X),
\end{aligned}$$

where the first inequality uses $\hat{\Phi}(\hat{w}_{t-1}) \leq \hat{\Phi}_y(\hat{w}_{t-1})$, the second inequality uses $y_n = r_t$ and the fact that $\hat{w}_{t-1}(C) \leq \hat{w}_t(C)$ for each C, the first equation translates evader work functions to server work functions and uses $d(C, r_t^{n-k}) = d(M, r_t^n) - d(M \setminus C, r_t^k)$, and the second equation is due to the duality lemma, which says that the same X can be chosen in both minima and the maximum. So indeed, the potential change upper bounds the extended cost.

[5] This identification requires the server configuration to be a set rather than a multiset. This is no restriction on the power of k-server algorithms (online or offline).

Now, we can bound the total extended cost by

$$\sum_{t=1}^{T} \max_X [w_t(X) - w_{t-1}(X)] \le \hat{\Phi}(\hat{w}_T) \le (k+1) \cdot \min_X w_T(X) + c_M,$$

where the last inequality is due to the fact that $\hat{\Phi}(\hat{w}_T)$ is a sum of distances (which are absorbed by the constant c_M) and $k+1$ work function values, each of which differs from $\min_X w_T(X)$ by at most k times the diameter of M due to 1-Lipschitzness of w_T (and the diameters are also absorbed by c_M). The theorem follows from the extended cost lemma. ◀

3.2 The k-server potential

We now derive an equivalent but simpler expression for the aforementioned potential. To formulate it, we need the notion of antipodal points.

Let Δ be the diameter of M. A point $\bar{p} \in M$ is called the *antipode* of another point $p \in M$ if for each $x \in M$, $px + x\bar{p} = p\bar{p} = \Delta$. On some metric spaces such as the circle, each point has an antipode. As mentioned in [18], every metric space can be extended so that each point has an antipode: To achieve this, add to M another copy of the same points, $\bar{M} = \{\bar{p} \colon p \in M\}$, and define distances by $\bar{p}\bar{q} = pq$ and $\bar{p}q = 2\Delta - pq$ for $p, q \in M$. It is easy to check that $M \cup \bar{M}$ is a metric space where $\bar{p}$ and p are antipodes of each other.

Consider a metric space M where every point has an antipode. Let $x_1, \dots, x_k \in M$. We define the k-server potential Φ via

$$\Phi_{x_1,\dots,x_k}(w) := \sum_{i=0}^{k} w(\bar{x}_i^i x_{i+1} \dots x_k)$$
$$\Phi(w) := \min_{x_1,\dots,x_k} \Phi_{x_1,\dots,x_k}(w). \tag{7}$$

The following lemma states that the two potential functions differ by a fixed constant depending on M and are therefore equivalent.

▶ **Lemma 7.** *Let M be a pseudo-metric space of diameter Δ where every point has an antipode and there are k copies of each point.*[6] *For any work function $w \in \mathcal{W}_M^k$ and any permutation $y = (y_1, \dots, y_n)$ of M,*

$$\Phi_{y_{n-k+1}\dots y_n}(w) = \hat{\Phi}_y(\hat{w}) - \text{clique}(M) + \frac{k(k+1)}{2}\Delta.$$

Proof. Subtracting clique(M) from the evader potential and using server work functions instead of evader work functions, we have

$$\hat{\Phi}_y(\hat{w}) - \text{clique}(M) = \sum_{i=n-k}^{n} \min_{\substack{C \supseteq \{y_{i+1},\dots,y_n\} \\ |C|=k}} \left(w(C) - \sum_{p \in C \cap \{y_1,\dots,y_i\}} p y_i \right).$$

[6] It is only a pseudo-metric because the distance between two copies of the same point is 0. We use the assumption of several copies of the same point because the definition of $\Phi_{x_1,\dots,x_k}$ allows points to repeat, whereas Φ_y requires y to be a permutation.

Notice that the minimum in the summand for i is achieved when $C \setminus \{y_{i+1}, \dots, y_n\}$ consists of $k - n + i$ copies of the antipodal point $\bar{y}_i$. Thus, the expression is equal to

$$\sum_{i=n-k}^{n} \left(w(\bar{y_i}^{k-n+i} y_{i+1} \dots y_n) - (k-n+i)\Delta\right) = \sum_{i=n-k}^{n} w(\bar{y_i}^{k-n+i} y_{i+1} \dots y_n) - \frac{k(k+1)}{2}\Delta$$
$$= \Phi_{y_{n-k+1} \dots y_n}(w) - \frac{k(k+1)}{2}\Delta. \quad \blacktriangleleft$$

▶ **Corollary 8.** *Let (M, d) be a metric space where every point has an antipode. If for every $r \in M$ and every work function $w \in \mathcal{W}_M^k(r)$ it holds that $\Phi(w) = \Phi_{x_1 \dots x_k}(w)$ for some $x_1, \dots x_k \in M$ with $x_k = r$, then WFA is k-competitive on M.*

4 Interpretation as a lazy adversary potential

4.1 The implicitly defined potential by Chrobak and Larmore

Chrobak and Larmore [12] gave an *implicit* definition of a potential that they conjectured to prove the k-server conjecture. This potential captures exactly a type of lazy adversary. To give a precise definition, we first need some additional notation.

For $r \in M$ and a work function $w \in \mathcal{W}$, denote by $\nabla(w, r) := \max_A (w \wedge r)(A) - w(A)$ the extended cost of request r on w. For a request sequence $\rho = (r_1, \dots, r_T) \in M^*$, let

$$\nabla(w, \rho) := \sum_{t=1}^{T} \nabla(w_{t-1}, r_t)$$

be the total extended cost, where $w_t = w \wedge r_1 \wedge r_2 \wedge \dots \wedge r_t$ is the updated work function after the first t requests. The potential conjectured by Chrobak and Larmore is given by

$$\tilde{\Phi}(w) := \min_X \tilde{\Phi}_X(w)$$

where the maximum is taken over configurations X and

$$\tilde{\Phi}_X(w) := -\operatorname{clique}(X) + (k+1)w(X) - \sup_{\rho \in X^*} \nabla(w, \rho).$$

Because of the term $\sup_{\rho \in X^*} \nabla(w, \rho)$, this potential captures exactly the worst-case extended cost when the future request sequence consists only of points in X, until the work function is a cone[7] with support $\{X\}$. An adversary constructing such a request sequence can be thought of as "lazy" because it wants to force the online algorithm to the offline configuration X before it requests different points. The additional term $\operatorname{clique}(X)$ is needed because of extended cost being incurred when passing from one cone to a different cone. The definition of $\tilde{\Phi}$ is only implicit because of the supremum over request sequences $\rho \in X^*$. It was conjectured in [12] that $\tilde{\Phi}(w \wedge r) - \tilde{\Phi}(w) \geq \nabla(w, r)$ for any (reachable) work function w and request r. This would imply the k-server conjecture similarly to the proof of Theorem 6. They also conjectured that $\tilde{\Phi}_X(w \wedge r)$ is minimized for a configuration X containing r, and more specifically that it is minimized by a configuration $X \in \operatorname{supp}(w \wedge r)$. This would imply the previous conjectures. We show that for $k = 3$, the potential $\tilde{\Phi}$ matches our potential Φ. For $k \geq 4$, our potential captures a more restricted type of lazy adversary. As we will

[7] A work function is a *cone* if its support contains only a single configuration.

show in Section 6 that our potential fails to bound the extended cost for $k = 3$ on the circle, this disproves the conjectures from [12] and yields the surprising insight that the worst-case adversary on the circle is not lazy – unlike the adversary for all cases where WFA is known to be k-competitive.

4.2 Relationship to our potential

Our next lemma shows that our potential Φ captures a more restricted adversarial strategy, where the configuration X is ordered as $x_1, \dots, x_k$ and the next request in ρ is always to the point x_i with i maximal that leads to a change of the work function. We will show later that for $k = 3$, this imposes no additional restriction.

For fixed $x_1, \dots, x_k \in M$ and a work function $w \in \mathcal{W}_M^k$, define a request sequence $r_1, r_2, \dots, r_T$ as follows. Let $w_t = w \wedge r_1 \wedge r_2 \wedge \dots \wedge r_t$ be the updated work function after the first t requests. We define $r_t = x_i$ for i maximal such that $w_{t-1} \wedge x_i \neq w_{t-1}$; if no such i exists, the request sequence ends, $T = t - 1$, and w_T is a cone with support $\{\{x_1, \dots, x_k\}\}$.

▶ **Lemma 9.**

$$\Phi_{x_1,\dots,x_k}(w) = \frac{k(k+1)}{2}\Delta - \text{clique}(x_1, \dots, x_k) + (k+1)w(x_1 \dots x_k) - \sum_{t=1}^{T} \nabla(w_{t-1}, r_t).$$

Proof. It suffices to show

$$\Phi_{x_1,\dots,x_k}(w_t) = \Phi_{x_1,\dots,x_k}(w_{t-1}) + \nabla(w_{t-1}, r_t) \tag{8}$$

$$\Phi_{x_1,\dots,x_k}(w_T) = (k+1)w(x_1 \dots x_k) + \frac{k(k+1)}{2}\Delta - \sum_{1 \le i < j \le k} x_i x_j. \tag{9}$$

For equation (9), we have

$$\begin{aligned}
\Phi_{x_1,\dots,x_k}(w_T) &= \sum_{j=0}^{k} w_T(\bar{x}_j^j x_{j+1} \dots x_k) \\
&= (k+1)w_T(x_1, \dots, x_k) + \sum_{1 \le i \le j \le k} x_i \bar{x}_j \\
&= (k+1)w(x_1, \dots, x_k) + \sum_{1 \le i \le j \le k} (\Delta - x_i x_j) \\
&= (k+1)w(x_1, \dots, x_k) + \frac{k(k+1)}{2}\Delta - \sum_{1 \le i < j \le k} x_i x_j.
\end{aligned}$$

We now show equation (8). Let i be such that $r_t = x_i$. Then,

$$\begin{aligned}
\Phi_{x_1,\dots,x_k}(w_t) &= \sum_{j=0}^{k} (w_{t-1} \wedge x_i)(\bar{x}_j^j x_{j+1} \dots x_k) \\
&= \sum_{j=0}^{i-1} w_{t-1}(\bar{x}_j^j x_{j+1} \dots x_k) + \sum_{j=i}^{k} (w_{t-1} \wedge x_i)(\bar{x}_j^j x_{j+1} \dots x_k).
\end{aligned} \tag{10}$$

By maximality of i, $x_{j+1} \dots x_k$ is contained in every support configuration of w_{t-1}. Thus, $\bar{x}_i^i x_{i+1} \dots x_k$ is a minimizer of w_{t-1} with respect to x_i and hence

$$(w_{t-1} \wedge x_i)(\bar{x}_i^i x_{i+1} \dots x_k) = w_{t-1}(\bar{x}_i^i x_{i+1} \dots x_k) + \nabla(w_{t-1}, r_t) \tag{11}$$

by the duality lemma.

We claim that

$$(w_{t-1} \wedge x_i)(\bar{x}_j^j x_{j+1} \dots x_k) = w_{t-1}(\bar{x}_j^j x_{j+1} \dots x_k) \qquad \forall j = i+1, \dots, k. \tag{12}$$

Assuming this is true, we obtain (8) by substituting (11) and (12) into (10).

It remains to show (12). Since $w_{t-1} \wedge x_i \geq w_{t-1}$, the direction "$\geq$" is obvious. For the other direction, since $x_j x_{j+1} \dots x_k$ is contained in every support configuration of w_{t-1},

$$\begin{aligned} w_{t-1}(\bar{x}_j^j x_{j+1} \dots x_k) &= w_{t-1}(\bar{x}_j^{j-1} x_j x_{j+1} \dots x_k) + \bar{x}_j x_j \\ &\geq w_{t-1}(\bar{x}_j^{j-1} x_i x_{j+1} \dots x_k) - x_i x_j + \bar{x}_j x_j \\ &= (w_{t-1} \wedge x_i)(\bar{x}_j^{j-1} x_i x_{j+1} \dots x_k) + x_i \bar{x}_j \\ &\geq (w_{t-1} \wedge x_i)(\bar{x}_j^j x_{j+1} \dots x_k). \end{aligned}$$

◀

▶ **Lemma 10.** *Let $X \subset M$ with $|X| = 3$ and $r \in X$ be fixed and let $w \in \mathcal{W}_M^3(r)$. For a bijection $\pi \colon \{1, \dots, 3\} \to X$, write $\Phi_\pi := \Phi_{\pi(1)\pi(2)\pi(3)}$. Then*

$$\min_{\pi \colon \pi(3)=r} \Phi_\pi(w) = \min_{\pi} \Phi_\pi(w).$$

Proof. Let π be a minimizer of the right hand side. If $\pi(k) = r$, we are done. The case $\pi(k-1) = r$ is also easy, using the fact that r is contained in every support configuration. The remaining case $\pi(k-2) = r$ is non-trivial. Let $y := \pi(k-1)$ and $z := \pi(k)$. We will construct a permutation π' with $\pi'(3) = r$ and $\Phi_\pi(w) \geq \Phi_{\pi'}(w)$. This will only affect the last three terms in the sum of the definition of Φ,

$$w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-1} z) + w(\bar{z}^k).$$

If $w(\bar{y}^{k-1} z) = w(\bar{y}^{k-2} rz) + \bar{y}r$, then

$$\begin{aligned} w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-1} z) + w(\bar{z}^k) &= w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-2} rz) + w(\bar{z}^k) + \bar{y}r \\ &\geq w(\bar{y}^{k-2} rz) + w(\bar{r}^{k-1} z) + w(\bar{z}^k) \end{aligned}$$

where the inequality uses $\bar{y}r = y\bar{r}$. This corresponds to a permutation with r in the next-to-last position, and it is easy to push it from there to the last position.

So we can assume $w(\bar{y}^{k-1} z) = w(\bar{y}^{k-1} r) + zr$. Thus

$$\begin{aligned} w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-1} z) + w(\bar{z}^k) &= w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-1} r) + w(\bar{z}^{k-1} r) + zr + \bar{z}r \\ &= w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-1} r) + w(\bar{z}^{k-1} r) + \Delta. \end{aligned} \tag{13}$$

In the last expression, y and z are symmetric, so we can assume

$$w(\bar{r}^{k-2} yz) = w(\bar{r}^{k-2} rz) + yr. \tag{14}$$

By quasi-convexity and Lipschitzness of the work function (and $\bar{y}\bar{r} = yr$, $\bar{r}r = \Delta$),

$$\begin{aligned} w(\bar{y}^{k-1} r) + w(\bar{r}^{k-2} rz) &\geq w(\bar{y}^{k-2} zr) + w(\bar{r}^{k-2} \bar{y}r) \\ &\geq w(\bar{y}^{k-2} zr) + w(\bar{r}^k) - yr - \Delta \end{aligned} \tag{15}$$

Combining (13), (14) and (15), we get

$$w(\bar{r}^{k-2} yz) + w(\bar{y}^{k-1} z) + w(\bar{z}^k) \geq w(\bar{y}^{k-2} zr) + w(\bar{z}^{k-1} r) + w(\bar{r}^k),$$

corresponding to the permutation $(\pi(1), \pi(2), \pi(3)) = (y, z, r)$. ◀

We remark (without proof) that the above lemma fails for $k = 4$.

By the following corollary, for $k = 3$ it holds that Φ is an explicit expression for the implicit potential of [12].

▶ **Corollary 11.** *For $k = 3$,*

$$\Phi(w) = 6\Delta + \min_{\substack{X\colon |X|=3 \\ r_1,\dots,r_T \in X}} \left[4w(X) - \text{clique}(X) - \sum_{t=1}^{T} \nabla(w \wedge r_1 \dots r_{t-1}, r_t) \right]. \tag{16}$$

Proof. The direction "$\geq$" follows from Lemma 9. For direction "$\leq$", select X and $r_1, \dots, r_T$ to minimize the right hand side. Let $w_t = w \wedge r_1 \dots r_t$. By minimality of the right hand side, w_T is a cone at X. Let $\Phi_X = \min \Phi_{x_1x_2x_3}$, with the minimum taken over permutations x_1, x_2, x_3 of X. By Lemma 10, we have $\Phi_X(w_t) = \Phi_{xyr_t}(w_t)$ for some $x, y \in X$. Thus,

$$\begin{aligned} \Phi_X(w_t) - \Phi_X(w_{t-1}) &\geq \Phi_{xyr_t}(w_t) - \Phi_{xyr_t}(w_{t-1}) \\ &= w_t(\bar{r}_t^3) - w_{t-1}(\bar{r}_t^3) \\ &= \nabla(w_{t-1}, r_t). \end{aligned}$$

Hence,

$$\begin{aligned} \Phi(w) \leq \Phi_X(w) = \Phi_X(w_T) - \sum_{t=1}^{T} [\Phi_X(w_t) - \Phi_X(w_{t-1})] \\ \leq \Phi_X(w_T) - \sum_{t=1}^{T} \nabla(w_{t-1}, r_t), \end{aligned}$$

which is equal to the right hand side of (16) by Lemma 9 and since w_T is a cone at X. ◀

5 Multi-ray spaces

A multi-ray space is a tree of depth 1 whose edges have infinite length and where requests can appear at arbitrary locations along the edges. We call these edges rays.

We will show in this section that WFA is k-competitive on multiray spaces. Note that a multiray space with only 2 rays is equal to the line metric. A subset of a multi-ray space containing only one point from each ray is a weighted star. Our proof therefore recovers the known proofs that WFA is k-competitive on the line and on weighted stars as special cases.

We denote by c the center/root of the multi-ray space, i.e., the origin of the rays. We can assume that every ray has finite length by considering only a sufficiently long part that all requests fall into. We call the endpoint of a ray that is not the center a *leaf*. Denote by $\mathcal{L}$ the set of leaves. For $w \in \mathcal{W}^k$, define $m_w(X) := w(X) - d(c^k, X)$. Note that m_w is also quasiconvex. As we use the server definition of the potential, we augment the multi-ray space by adding antipodes as discussed earlier. In the definition (6), we require the points $x_1, \dots, x_k$ to be chosen from the original metric space M. This corresponds to requiring the permutation in the evader potential to end with k points from the original metric space, which does not affect the proof of Theorem 6.

The proof that WFA is k-competitive on multi-ray spaces proceeds along the following three main steps:

1. First we establish properties of $\Phi_{x_1\dots x_k}$ when $x_i = \ell_i$ are leaves. In particular, we express $\Phi_{\ell_1\dots\ell_k}$ in terms of m_w, and show that $\ell_1, \dots, \ell_k$ can be permuted under certain conditions.
2. We then show by induction on k that $\Phi_{x_1\dots x_k}(w)$ is indeed minimized when $x_1, \dots, x_k$ are leaves and $\min_X m_w(X) = m_w(x_1 \dots x_k)$.
3. Finally, we show that $\Phi_{x_1\dots x_k}(w)$ is also minimized for some $x_1, \dots, x_k$ where only $x_1, \dots, x_{k-1}$ are leaves whereas $x_k = r$ is the last request.

Step 1: Properties of $\Phi_{x_1 \dots x_k}$ when x_i are leaves

▶ **Lemma 12.** *Let $w \in \mathcal{W}^k$. There exist leaves $\ell_1, \dots, \ell_k$ such that $\min_X m_w(X) = m_w(\ell_1 \dots \ell_k)$.*

Proof. Follows from the fact that since w is 1-Lipschitz, $m_w(X)$ cannot increase when a point in X moves away from c towards a leaf. ◀

▶ **Lemma 13.** *For any $w \in \mathcal{W}^k$, a leaf $\ell \in \mathcal{L}$ and $x_{i+1}, \dots, x_k \in M$,*

$$w(\bar{\ell}^i x_{i+1} \dots x_k) = \min_{\substack{X \supseteq x_{i+1} \dots x_k : \\ X - x_{i+1} \dots x_k \subseteq \mathcal{L} - \ell}} m_w(X) + i(\Delta - c\ell) + \sum_{j=i+1}^{k} c x_j.$$

Proof.

$$\begin{aligned} w(\bar{\ell}^i x_{i+1} \dots x_k) &= \min_{X \supseteq x_{i+1} \dots x_k} w(X) + d(X - x_{i+1} \dots x_k, \bar{\ell}^i) \\ &= \min_{X \supseteq x_{i+1} \dots x_k} w(X) + i\Delta - d(X - x_{i+1} \dots x_k, \ell^i) \end{aligned}$$

We claim that the minimum is achieved by some X with $X - x_{i+1} \dots x_k \subseteq \mathcal{L} - \ell$: Indeed, if there is some $x \in X - x_{i+1} \dots x_k$ that is not in $\mathcal{L} - \ell$, sliding x away from ℓ along a path to some other leaf increases $d(X - x_{i+1} \dots x_k, \ell^i)$ by the distance moved, and it increases $w(X)$ by at most this distance, so the whole term cannot increase.

This also means that every distance in $d(X - x_{i+1} \dots x_k, \ell^i)$ goes across the center, i.e.,

$$d(X - x_{i+1} \dots x_k, \ell^i) = i \cdot c\ell + d(X - x_{i+1} \dots x_k, c^i).$$

The lemma now follows by definition of m_w. ◀

As a consequence of Lemma 13, we obtain the following expression for $\Phi_{\ell_1 \dots \ell_k}$ whenever $\ell_1, \dots, \ell_k$ are leaves:

$$\Phi_{\ell_1 \dots \ell_k}(w) = \frac{k(k+1)}{2}\Delta + \sum_{i=0}^{k} \min_{\substack{X_i \supseteq \ell_{i+1} \dots \ell_k : \\ X_i - \ell_{i+1} \dots \ell_k \subseteq \mathcal{L} - \ell_i}} m_w(X_i). \tag{17}$$

The following symmetry and monotonicity properties allow us to reorder $\ell_1, \dots, \ell_k$ under certain circumstances.

▶ **Lemma 14** (Symmetry and Monotonicity Lemma)**.** *Let $w \in \mathcal{W}^k$ and let $\ell_1, \dots, \ell_k$ be leaves such that $\min_X m_w(X) = m_w(\ell_1 \dots \ell_k)$. The following properties hold:*
Symmetry: *$\Phi_{\ell_1 \dots \ell_k}(w)$ is constant under permutation of $\ell_1, \dots, \ell_k$.*
Monotonicity: *For any leaf ℓ, $\Phi_{\ell_1 \dots \ell_{k-1} \ell}(w) \geq \Phi_{\ell \ell_1 \dots \ell_{k-1}}(w) \geq \Phi_{\ell_1 \dots \ell_k}(w)$.*

Proof. For the symmetry property and the first inequality of the monotonicity property, we proceed by induction on k. The base case $k = 1$ is trivial. For the induction step, it suffices to show that $\Phi_{\ell_1 \dots \ell_{k-1} \ell}(w) \geq \Phi_{\ell_1 \dots \ell_{k-2} \ell \ell_{k-1}}(w)$, with equality if $\ell = \ell_k$. The lemma then follows by invoking the induction hypothesis on $\tilde{w} = w(\,\cdot\, \ell_{k-1}) \in \mathcal{W}^{k-1}$, observing that $\min_X m_{\tilde{w}}(X) = m_{\tilde{w}}(\ell_1 \dots \ell_{k-2} \ell_k)$, and that $\Phi_{x_1 \dots x_{k-1} \ell_{k-1}}(w) - \Phi_{x_1 \dots x_{k-1}}(\tilde{w}) = w(\bar{\ell}^k_{k-1})$ is a constant function of $x_1, \dots, x_{k-1}$ (and thus $\Phi_{x_1 \dots x_{k-1} \ell_{k-1}}(w)$ and $\Phi_{x_1 \dots x_{k-1}}(\tilde{w})$ are affected in the same way when $x_1, \dots, x_{k-1}$ are permuted).

Note that only the two terms involving X_{k-1} and X_k in (17) are affected when the last two leaves are swapped. For two leaves y and z, let

$$f(y,z) := \min_{\substack{Y \ni z:\\ Y-z \subseteq \mathcal{L}-y}} m_w(Y) + \min_{Z \subseteq \mathcal{L}-z} m_w(Z)$$

We only need to show that $f(\ell_{k-1},\ell) \geq f(\ell,\ell_{k-1})$, and that this holds with equality if $\ell = \ell_k$. Assume $\ell_{k-1} \neq \ell$ as otherwise there is nothing to show. Then

$$\begin{aligned}
&f(\ell_{k-1},\ell) - f(\ell,\ell_{k-1})\\
&\quad= \min_{\substack{Y_1 \ni \ell:\\ Y_1 \subseteq \mathcal{L}-\ell_{k-1}}} m_w(Y_1) + \min_{Z_1 \subseteq \mathcal{L}-\ell} m_w(Z_1) - \min_{\substack{Y_2 \ni \ell_{k-1}:\\ Y_2 \subseteq \mathcal{L}-\ell}} m_w(Y_2) - \min_{Z_2 \subseteq \mathcal{L}-\ell_{k-1}} m_w(Z_2)\\
&\quad\geq \min_{Z_1 \subseteq \mathcal{L}-\ell} m_w(Z_1) - \min_{\substack{Y_2 \ni \ell_{k-1}:\\ Y_2 \subseteq \mathcal{L}-\ell}} m_w(Y_2)\\
&\quad= 0,
\end{aligned}$$

where the last equation follows by applying Lemma 3 to the quasi-convex function m_w. If $\ell = \ell_k$, then the same argument shows that the inequality can be replaced by equality.

It remains to show the second inequality of the monotonicity property. Due to the symmetry property, and by a renaming of leaves, it suffices to show that $\Phi_{\ell\ell_2\dots\ell_k}(w) \geq \Phi_{\ell_1\ell_2\dots\ell_k}(w)$. Assume $\ell \neq \ell_1$, otherwise we are done. In (17), the only terms affected when the first leaf is replaced are the ones involving X_0 and X_1. Let X_0 and X_1 be these sets in $\Phi_{\ell_1\ell_2\dots\ell_k}(w)$ and X_0' and X_1' those in $\Phi_{\ell\ell_2\dots\ell_k}(w)$. Then $X_0 = \ell_1\dots\ell_k$, $X_0' = \ell\ell_2\dots\ell_k$, and since $\min_X m_w(X) = m_w(\ell_1\dots\ell_k)$, we can choose $X_1' = \ell_1\dots\ell_k$. Moreover, X_0' satisfies the requirements of X_1 (apart from minimality, possibly), hence $m_w(X_1) \leq m_w(X_0')$. Thus,

$$\Phi_{\ell\ell_2\dots\ell_k}(w) - \Phi_{\ell_1\ell_2\dots\ell_k}(w) = m_w(X_0') + m_w(X_1') - m_w(X_0) - m_w(X_1) \geq 0. \qquad \blacktriangleleft$$

Step 2: $x_1, \dots, x_k$ are indeed leaves

▶ **Lemma 15.** *Let $w \in \mathcal{W}^k$. Let $\ell_1,\dots,\ell_k$ be leaves such that $\min_X m_w(X) = m_w(\ell_1\dots\ell_k)$. Then $\Phi(w) = \Phi_{\ell_1\dots\ell_k}(w)$.*

Proof. By induction on k. The base case $k = 0$ is trivial. For the induction step, fix x such that $\Phi(w) = \Phi_{x_1\dots x_{k-1}x}(w)$ for some $x_1,\dots,x_{k-1}$. Consider the function $\tilde{w} = w(\cdot x) \in \mathcal{W}^{k-1}$. By Lemma 4, $\min m_{\tilde{w}}(X) = m_{\tilde{w}}(\ell_1\dots\ell_k - \ell')$ for some $\ell' \in \ell_1\dots\ell_k$. By Lemma 14, we can assume without loss of generality that $\ell' = \ell_k$, i.e., $\min m_{\tilde{w}}(X) = m_{\tilde{w}}(\ell_1\dots\ell_{k-1})$. By the induction hypothesis, $\Phi(\tilde{w}) = \Phi_{\ell_1\dots\ell_{k-1}}(\tilde{w})$. Hence,

$$\begin{aligned}
\Phi(w) &= \min_{x_1\dots x_{k-1}} \Phi_{x_1\dots x_{k-1}x}(w)\\
&= \min_{x_1\dots x_{k-1}} \Phi_{x_1\dots x_{k-1}}(\tilde{w}) + w(\bar{x}^k)\\
&= \Phi_{\ell_1\dots\ell_{k-1}}(\tilde{w}) + w(\bar{x}^k)\\
&= \Phi_{\ell_1\dots\ell_{k-1}x}(w).
\end{aligned}$$

We will now transform the last expression in several steps with the goal of eventually replacing x by ℓ_k.

Denote by ℓ the leaf below x. The goal of the following transformations is to replace x by ℓ. For some $a \in \{0,1,\dots,k\}$ we have

$$w(\bar{x}^k) = w(\bar{\ell}^a \ell^{k-a}) + a \cdot x\ell + (k-a) \cdot x\bar{\ell}.$$

The symmetry property of Lemma 14 allows us to assume that $\ell_1, \dots, \ell_{s-1}$ are all different from ℓ and $\ell_s = \ell_{s+1} = \cdots = \ell_{k-1} = \ell$ for some $s \in \{1, \dots, k\}$.

As an intermediate step, we show by (backwards) induction on $j = k, k-1, \dots, \max\{s, a\}$ that

$$\Phi(w) \geq \sum_{i=0}^{j-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} x) + \sum_{i=j}^{k-1} w(\bar{\ell}_i^{i+1} \ell_{i+1} \dots \ell_{k-1}) + w(\bar{\ell}^a \ell^{j-a} \ell_j \dots \ell_{k-1}) + a \cdot x\ell + (j-a) \cdot x\bar{\ell} \tag{18}$$

The base case $k = j$ follows from the previous equation. Suppose now that (18) holds for some $j > \max\{s, a\}$. From $\ell_{j-1} = \ell$ we get

$$w(\bar{\ell}_{j-1}^{j-1} \ell_j \dots \ell_{k-1} x) \geq w(\bar{\ell}_{j-1}^{j} \ell_j \dots \ell_{k-1}) - x\bar{\ell}$$

and

$$w(\bar{\ell}^a \ell^{j-a} \ell_j \dots \ell_{k-1}) = w(\bar{\ell}^a \ell^{j-1-a} \ell_{j-1} \dots \ell_{k-1}).$$

The induction step of (18) follows by plugging these in to (18).

If $a \geq s$, then (18) for $j = a$ yields

$$\begin{aligned}
\Phi(w) &\geq \sum_{i=0}^{a-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} x) + \sum_{i=a}^{k-1} w(\bar{\ell}_i^{i+1} \ell_{i+1} \dots \ell_{k-1}) + w(\bar{\ell}^a \ell_a \dots \ell_{k-1}) + a \cdot x\ell \\
&\geq \sum_{i=0}^{a-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} \ell) + \sum_{i=a}^{k-1} w(\bar{\ell}_i^{i+1} \ell_{i+1} \dots \ell_{k-1}) + w(\bar{\ell}^a \ell_a \dots \ell_{k-1}) \\
&= \Phi_{\ell_1 \dots \ell_{k-1} \ell}(w),
\end{aligned}$$

where we have used that $\ell_i = \ell$ for $i \geq a \geq s$. The lemma then follows from the monotonicity property of Lemma 14.

Otherwise, $a < s$, and from (18) for $j = s$ we get

$$\begin{aligned}
\Phi(w) &\geq \sum_{i=0}^{s-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} x) + \sum_{i=s}^{k-1} w(\bar{\ell}_i^{i+1} \ell_{i+1} \dots \ell_{k-1}) \\
&\qquad + w(\bar{\ell}^a \ell^{s-a} \ell_s \dots \ell_{k-1}) + a \cdot x\ell + (s-a) \cdot x\bar{\ell} \\
&\geq \sum_{i=0}^{s-a-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} x) + \sum_{i=s-a}^{s-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} \ell) + \sum_{i=s+1}^{k} w(\bar{\ell}^i \ell^{k-i}) \\
&\qquad + w(\bar{\ell}^a \ell^{s-a} \ell_s \dots \ell_{k-1}) + (s-a) \cdot x\bar{\ell}.
\end{aligned}$$

By Claim 16 below, replacing a by $a+1$ does not increase the latter quantity. Inductively we may therefore replace a by s to obtain

$$\begin{aligned}
\Phi(w) &\geq \sum_{i=0}^{s-1} w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_{k-1} \ell) + \sum_{i=s+1}^{k} w(\bar{\ell}^i \ell^{k-i}) + w(\bar{\ell}^s \ell^{k-s}) \\
&= \Phi_{\ell_1 \dots \ell_{k-1} \ell}(w).
\end{aligned}$$

The monotonicity property of Lemma 14 completes the proof. ◀

▷ Claim 16. Let $0 \leq a < s \leq k$ and $w \in \mathcal{W}^k$. Let $\ell_{s-a-1}, \dots, \ell_{k-1}$ and ℓ be leaves such that $\ell_i \neq \ell$ for $i < s$, and let x be a point on the ray of ℓ. Then

$$\begin{aligned}
&w(\bar{\ell}_{s-a-1}^{s-a-1} \ell_{s-a} \dots \ell_{k-1} x) + w(\bar{\ell}^a \ell^{s-a} \ell_s \dots \ell_{k-1}) + x\bar{\ell} \\
&\qquad \geq w(\bar{\ell}_{s-a-1}^{s-a-1} \ell_{s-a} \dots \ell_{k-1} \ell) + w(\bar{\ell}^{a+1} \ell^{s-a-1} \ell_s \dots \ell_{k-1}).
\end{aligned}$$

Proof. Consider the bijection from the definition of quasiconvexity between the two configurations on the left hand side.[8] By the pigeonhole principle, at least one of the $s-a$ copies of ℓ in the second configuration maps to some point $p \in \ell_{s-a} \dots \ell_{s-1} x$ in the first configuration. Quasiconvexity gives

$$w(\bar{\ell}^{s-a-1}_{s-a-1}\ell_{s-a}\dots\ell_{k-1}x) + w(\bar{\ell}^{a}\ell^{s-a}\ell_s\dots\ell_{k-1}) \\ \geq w(\bar{\ell}^{s-a-1}_{s-a-1}\ell_{s-a}\dots\ell_{k-1}\ell x - p) + w(\bar{\ell}^{a}\ell^{s-a-1}\ell_s\dots\ell_{k-1}p).$$

By 1-Lipschitzness of w, we get

$$w(\bar{\ell}^{s-a-1}_{s-a-1}\ell_{s-a}\dots\ell_{k-1}\ell x - p) \geq w(\bar{\ell}^{s-a-1}_{s-a-1}\ell_{s-a}\dots\ell_{k-1}\ell) - px$$

and

$$w(\bar{\ell}^{a}\ell^{s-a-1}\ell_s\dots\ell_{k-1}p) \geq w(\bar{\ell}^{a+1}\ell^{s-a-1}\ell_s\dots\ell_{k-1}) - p\bar{\ell}.$$

Since $\ell_i \neq \ell$ for $i < s$ and $p \in \ell_{s-a}\dots\ell_{s-1}x$, the point x lies on the path from p to ℓ, i.e., $px + x\ell = p\ell$. Equivalently, $x\bar{\ell} = px + p\bar{\ell}$. The claim follows by combining these inequalities. ◁

Step 3: Alternatively, $x_k = r$

▶ **Lemma 17.** *For any $w \in \mathcal{W}^k(r)$, there exist leaves $\ell_1, \dots, \ell_{k-1}$ such that $\Phi(w) = \Phi_{\ell_1\dots\ell_{k-1}r}(w)$.*

Proof. Since $w \in \mathcal{W}^k(r)$, we can choose $X \in \arg\min_X m_w(X)$ of the form $X = r\ell_2\dots\ell_k$ for $\ell_2, \dots, \ell_k \in \mathcal{L}$. If $\ell := \ell_1$ is the leaf of the ray containing r, then clearly $\ell_1\dots\ell_k$ is also a minimizer of m_w and $\ell_1\dots\ell_k$ resolves from ℓ_1. Let $\ell_2, \dots, \ell_k$ be ordered such that $\ell = \ell_1 = \dots = \ell_s$ for some $s \geq 1$ and $\ell_i \neq \ell$ for $i > s$.

The main part of this proof is to show that there exists $a \in \{1, \dots, s\}$ such that

$$w(\bar{\ell}^i_i\ell_{i+1}\dots\ell_k) = \begin{cases} w(\bar{\ell}^i_i\ell_{i+2}\dots\ell_k r) + r\ell & \text{if } i < a \\ w(\bar{\ell}^{i-1}_i\ell_{i+1}\dots\ell_k r) + r\bar{\ell}_i & \text{if } i \geq a. \end{cases} \tag{19}$$

Before we prove this, let us see why it implies the lemma. By Lemma 15 and the fact that $\ell = \ell_1 = \dots = \ell_a$, we have

$$\begin{aligned} \Phi(w) &= \Phi_{\ell_1\dots\ell_k}(w) \\ &= \sum_{i=0}^{k} w(\bar{\ell}^i_i\ell_{i+1}\dots\ell_k) \\ &= \sum_{i=0}^{a-1} w(\bar{\ell}^i_i\ell_{i+2}\dots\ell_k r) + \sum_{i=a}^{k} w(\bar{\ell}^{i-1}_i\ell_{i+1}\dots\ell_k r) + a\cdot r\ell + \sum_{i=a}^{k} r\bar{\ell}_i \\ &= \sum_{i=0}^{k-1} w(\bar{\ell}^i_{i+1}\ell_{i+2}\dots\ell_k r) + w(\bar{\ell}^{a-1}\ell_{a+1}\dots\ell_k r) + (a-1)\cdot r\ell + \sum_{i=a+1}^{k} \bar{r}\ell_i + \Delta \\ &\geq \sum_{i=0}^{k-1} w(\bar{\ell}^i_{i+1}\ell_{i+2}\dots\ell_k r) + w(\bar{r}^k) \\ &= \Phi_{\ell_2\dots\ell_k r}(w). \end{aligned}$$

[8] We remark that earlier proofs about competitiveness of the work function algorithm only used a weaker form of quasi-convexity and did not actually use the existence of such a bijection.

It remains to show (19). We choose a maximal such that $\bar{\ell}_{a-1}^{a-1}\ell_a \dots \ell_k$ resolves from ℓ. Recall from the start of this proof that $\ell_1 \dots \ell_k$ resolves from ℓ_1, so $a \geq 1$. Moreover, $a \leq s$ since $\ell_i \neq \ell$ for $i > s$. So $a \in \{1, \dots, s\}$ as required. The case "$i < a$" of (19) now follows by backwards induction on i, where the induction step is due to Lemma 5.

Consider now some $i > s$. Letting $\tilde{w} = w(\cdot\, \ell_{i+1} \dots \ell_k) \in \mathcal{W}^i_{\mathcal{L}+r}$, we have

$$w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_k) = \tilde{w}(\bar{\ell}_i^i) = \min_{X \subseteq \mathcal{L}+r-\ell_i} m_{\tilde{w}}(X) + i(\Delta - c\ell_i),$$

where the last equation is proved similarly to Lemma 13, but we may allow X to contain the non-leaf r since it is on a different ray than ℓ_i (thanks to $i > s$). Since $\min_X m_w(X) = m_w(r\ell_2 \dots \ell_k)$, we have $\min_X m_{\tilde{w}}(X) = m_{\tilde{w}}(r\ell_2 \dots \ell_i)$, so by Lemma 3 the minimum under the restriction $X \subseteq \mathcal{L} + r - \ell_i$ is achieved for some X with $r \in X$. Thus,

$$\begin{aligned}
w(\bar{\ell}_i^i \ell_{i+1} \dots \ell_k) &= \min_{Y \subseteq \mathcal{L}-\ell_i} \tilde{w}(Yr) - d(Y, c^{i-1}) - r\ell_i + i(\Delta - c\ell_i) \\
&= \min_{Y \subseteq \mathcal{L}-\ell_i} \tilde{w}(Yr) + d(Y, \bar{\ell}_i^{i-1}) + \bar{\ell}_i r \\
&\geq \tilde{w}(\bar{\ell}_i^{i-1} r) + \bar{\ell}_i r \\
&= w(\bar{\ell}_i^{i-1} r \ell_{i+1} \dots \ell_k) + r\bar{\ell}_i.
\end{aligned}$$

Note that the inequality between the first and last expression cannot be strict due to 1-Lipschitzness of w, and their equality reveals that $\bar{\ell}_i^i \ell_{i+1} \dots \ell_k$ resolves from $\bar{\ell}_i$, as desired.

Finally, consider $i \in \{a, a+1, \dots, s\}$. Then $\ell_i = \ell$, and we need to show that $\bar{\ell}^i \ell_{i+1} \dots \ell_k$ resolves from $\bar{\ell}$. Suppose that it instead resolves from ℓ_h for some $h > i$. Since $a \leq s$ was chosen maximal, we know that $\ell_h \neq \ell$. By Lemma 13,

$$\begin{aligned}
w(\bar{\ell}^i \ell_{i+1} \dots \ell_k) &= w(\bar{\ell}^i \ell_{i+1} \dots \ell_{h-1} \ell_{h+1} \dots \ell_k r) + r\ell_h \\
&= \min_{\substack{X \supseteq \ell_{i+1} \dots \ell_{h-1} \ell_{h+1} \dots \ell_k r \\ X - \ell_{i+1} \dots \ell_{h-1} \ell_{h+1} \dots \ell_k r \subseteq \mathcal{L} - \ell}} m_w(X) + i(\Delta - c\ell) + \sum_{\substack{j=i+1 \\ j \neq h}}^{k} c\ell_j + cr + r\ell_h. \\
&= \min_{Y \not\ni \ell} m_{\tilde{w}}(Y) + i(\Delta - c\ell) + r\ell_h,
\end{aligned}$$

where $\tilde{w} = w(\cdot\, \ell_{i+1} \dots \ell_{h-1} \ell_{h+1} \dots \ell_k r) \in \mathcal{W}^i_{\mathcal{L}}$. Since $\min_X m_w(X) = m_w(r\ell_2 \dots \ell_k)$, we have that $\min_X m_{\tilde{w}}(X) = m_{\tilde{w}}(\ell_2 \dots \ell_i \ell_h)$, so by Lemma 3 the minimum under the restriction $Y \not\ni \ell$ is achieved for some Y with $\ell_h \in Y$. Letting $Y' = Y - \ell_h$, we get

$$\begin{aligned}
w(\bar{\ell}^i \ell_{i+1} \dots \ell_k) &= m_{\tilde{w}}(Y) + i(\Delta - c\ell) + r\ell_h \\
&= w(Y' \ell_{i+1} \dots \ell_k r) - d(Y, c^i) + i(\Delta - c\ell) + (rc + c\ell_h) \\
&= w(Y' \ell_{i+1} \dots \ell_k r) - \sum_{y \in Y'} y\ell + i\Delta - c\ell + rc \\
&\geq w(Y' \ell_{i+1} \dots \ell_k r) + \sum_{y \in Y'} y\bar{\ell} + \Delta - r\ell \\
&\geq w(\bar{\ell}^{i-1} \ell_{i+1} \dots \ell_k r) + r\bar{\ell},
\end{aligned}$$

where the second equation uses that $\ell \neq \ell_h$ and therefore c lies on the path from r to ℓ_h, and the third equation uses that y and ℓ are different leaves and therefore $yc + c\ell = y\ell$. Again, the inequality between the first and last expression cannot be strict due to 1-Lipschitzness of w, and their equality reveals that $\bar{\ell}^i \ell_{i+1} \dots \ell_k$ resolves from $\bar{\ell}$, completing the proof. ◀

▶ **Theorem 18.** *WFA is k-competitive on multiray spaces.*

Proof. Follows from Lemma 17 and Corollary 8. ◀

6 Non-laziness of the worst-case adversary on the circle

▶ **Theorem 19.** *For $k = 3$ servers on the circle, there exists a reachable work function from where the worst-case adversarial continuation of the request sequence is not lazy. More precisely, there exists a request sequence such that the induced work functions w_t and w_{t+1} after time steps t and $t+1$ and the WFA configuration C_t after time step t satisfy $w_{t+1}(C_t) - w_t(C_t) > \Phi(w_{t+1}) - \Phi(w_t)$.*

In other words, the extended cost is strictly greater than the change in potential. Due to the interpretation of our potential (Section 4), this means that the worst-case continuation of the request sequence after time t is not lazy. If Theorem 19 could be strengthened such that the request sequence to reach w_t has extended cost equal to its induced change in potential, then this would disprove the premise of the extended cost lemma (because one could create a cyclic request sequence where extended cost is always at least the change in potential and exceeds it infinitely often; we remark that one can go from a cone work function to any other cone via a request sequence whose extended cost equals its potential change).

Note that Theorem 19 holds even if in the extended cost $\max_X w_{t+1}(X) - w_t(X)$ we replace X by the configuration C_t of WFA at time t. The significance of this is that the sum of the terms $w_{t+1}(C_t) - w_t(C_t)$ over all time steps is *equal* to the sum of WFA's cost and the optimal offline cost (up to a bounded additive error). Thus, proving violation of the premise of the extended cost lemma with X replaced by C_t would imply that WFA's competitive ratio is strictly greater than k.

The proof of Theorem 19 is given in the full version of our paper [14]. It is based on a tight connection between the k-server problem and the "easy" version of the k-taxi problem observed in [13]. The k-taxi problem is the generalization of the k-server problem where each request is not a single point, but a pair (s, t) of two points, representing the start s and destination t of a taxi request. To serve it, the algorithm has to select a server that first goes to s and then to t. In the "easy" version relevant for us, the cost is defined as the total distance traveled by servers.[9] As shown in [13], the easy k-taxi problem has exactly the same competitive ratio as the k-server problem. The idea of this reduction is that a k-taxi request (s, t) can be simulated by a sequence of many k-server requests along the shortest path from s to t. We extend this idea to show that we can use k-taxi requests to reach work functions that are arbitrarily close to work functions reachable via k-server requests. We then give an explicit counter-example using k-taxi requests.

We remark that up to symmetry and shift by an additive constant, for $k = 3$ there exist over 280,000 different work functions reachable by taxi requests with starts/destinations at the points on the circle considered in our construction (8 equally spaced points for the destinations and 16 equally spaced points for the starts – the aforementioned 8 points as well as the 8 intermediate points). Among these over 280,000 work functions, the pair of w_t and w_{t+1} from our construction is the *only* counterexample to laziness of the adversary. Using only k-server requests and no k-taxi requests, we were unable to find any counterexamples for n equally spaced points on the circle for the values of n that were computationally feasible for us to try. Of course, though, our approximability argument of k-taxi requests via k-server requests implies that such counterexamples do exist for n sufficiently large. Given the rarity of these counterexamples, it is not surprising that Chrobak and Larmore [12] who reported testing their conjecture on tens of thousands of small metric spaces in the early 90s did not find any counterexample.

[9] In contrast, the "hard" k-taxi problem defines the cost as only the overhead distance traveled while *not* carrying a passenger, i.e., the distance from s to t is excluded from the cost.

7 Conclusion

Our potential gives a unified perspective on all cases where WFA is known to be k-competitive. Unlike previous potentials, which were specific to their special case and had no clear intuition, our potential has a natural interpretation as capturing a lazy adversary. We remark that our potential also proves k-competitiveness on 6-point metric spaces. Since work functions, the WFA, and the generalized WFA are central to various online problems, similar potential functions may also prove useful to analyze different problems.

Since it was a major belief that a lazy adveresary would capture the worst case, our insights yield a qualitative explanation of the shortcomings of previous approaches and may point in a direction to overcome these shortcomings.

Our proof for $k = 3$ on trees relies on the fact that if (M, d) is a tree metric, then d is quasiconcave (i.e., $-d$ is quasiconvex). We are puzzled by the question whether this has any deeper connection to the quasiconvexity property of work functions and whether it is crucial for the existence of k-competitive algorithms. While the k-server problem is also k-competitive on some non-quasiconcave metrics (such as the cases $k = 2$ and $n = k - 2$), the reason for this might simply be due to the fact that the subspaces relevant in all proof steps are small (note that any 3-point metric is quasiconcave).

Abstract

We want to efficiently find a specific object in a large unstructured set, which we model by a *random n-permutation*, and we have to do it by revealing just a single element. Clearly, without any help this task is hopeless and the best one can do is to select the element at random, and achieve the success probability $\frac{1}{n}$. Can we do better with some small amount of advice about the permutation, even without knowing the object sought? We show that by providing advice of just one integer in $\{0, 1, \ldots, n-1\}$, one can improve the success probability considerably, by a $\Theta(\frac{\log n}{\log \log n})$ factor.

We study this and related problems, and show asymptotically matching upper and lower bounds for their optimal probability of success. Our analysis relies on a close relationship of such problems to some intrinsic properties of random permutations related to the rencontres number.

1 Introduction

Understanding basic properties of random permutations is an important concern in modern data science. For example, a preliminary step in the analysis of a very large data set presented in an unstructured way is often to model it assuming the data is presented in a random order. Understanding properties of random permutations would guide the processing of this data and its analysis. In this paper, we consider a very natural problem in this setting. You are given a set of n objects ($[n-1]$, say[1]) stored in locations $x_0, \ldots, x_{n-1}$ according to a random permutation σ of $[n-1]$. This is the *haystack*, and you want to find one specific object, not surprisingly called the *needle*, by drawing from just one location.

Clearly, the probability of finding the right object in a single draw is always $\frac{1}{n}$ (whichever location you choose, since the permutation σ is random, the probability that your object is there is exactly $\frac{1}{n}$). But can I give you any advice or *hint* about σ – *without knowing which object you are seeking* – to improve the chance of you finding the specific object? If I could

[1] Throughout the paper we use the standard notation $[n-1] := \{0, \ldots, n-1\}$, and we write log for $\log_2$.

tell you the entire σ (which can be encoded with $\log(n!) = \Theta(n \log n)$ bits) then this task is trivial and you would know the location of the object sought. But what if I give you just a small hint (on the basis of σ), one number $\mathfrak{h}$ from $[n-1]$ (or equivalently, one $\log n$-bit sequence) – even when I know nothing about the object sought?

Formally, the goal is to design a strategy to choose a *hint* $\mathfrak{h} = \mathfrak{h}(\sigma)$ and an *index* $\mathfrak{i} = \mathfrak{i}(\mathfrak{h}, \mathfrak{s})$, with both $\mathfrak{h}, \mathfrak{i} \in [n-1]$, such that for a given $\mathfrak{s} \in [n-1]$, $\mathbf{Pr}[\sigma(\mathfrak{i}) = \mathfrak{s}]$ is maximized, where the probability is over the random choice of σ and over the randomness in the choice of the strategy (since $\mathfrak{h} = \mathfrak{h}(\sigma)$ and $\mathfrak{i} = \mathfrak{i}(\mathfrak{h}, \mathfrak{s})$ may be randomized functions), see also Section 2.2.

1.1 Related puzzle: *communication in the locker room*

The *needle in a haystack* problem is closely related to the following *locker room* problem (see Figure 1): The locker room has n lockers, numbered $0, \ldots, n-1$. A set of n cards, numbered $0, \ldots, n-1$, is inserted in the lockers according to a uniformly random permutation σ. Alice and Bob are a team with a task. Alice enters the locker room, opens all the lockers and can swap the cards between just two lockers, or may choose to leave them unchanged. She closes all the lockers and leaves the room. Bob is given a number $\mathfrak{s} \in [n-1]$ and his task is to find card $\mathfrak{s}$. He can open at most two lockers. Before the game begins, Alice and Bob may communicate to decide on a strategy. What is their optimal strategy, and how efficient is it?

As in the *needle in a haystack* problem, without help from Alice, Bob can do no better than open lockers at random. If he opens one locker his probability of success is $\frac{1}{n}$ and if he opens two lockers this probability is $\frac{2}{n}$. With the help of Alice, he can do better when opening one locker. E.g., their strategy could be that Bob will open locker $\mathfrak{s}$, where $\mathfrak{s}$ is his given number. Alice would then try to increase the number of fixed points in the permutation above the expected number of 1. If there is a transposition she can reverse it, increasing the number of fixed points by two, and if not she can produce one more fixed point (unless the permutation is the identity). This strategy succeeds with probability just under $\frac{12}{5n}$. When Bob can open two lockers, the challenge is to increase the success probability to $\omega(\frac{1}{n})$.

The answer involves viewing Bob's first locker opening in a different way: not as looking for his card but as receiving a communication from Alice. The interest is in finding what kind of information Alice can send about the permutation which could help Bob in his search.

Now, we invite the reader to stop for a moment: to think about this puzzle, to find any strategy that could ensure the success probability would be $\omega(\frac{1}{n})$.

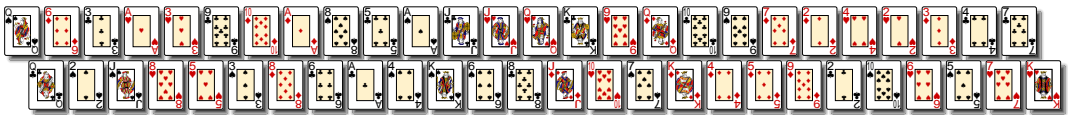

Figure 1 Consider the following randomly shuffled deck, one card per locker. What advice should Alice give to Bob – just by swapping the locations of at most one pair of cards – to increase the probability that Bob will find his randomly chosen card by opening at most two lockers?

It is easy to see that a solution to the *needle in a haystack* search problem immediately yields a solution to the *locker room* problem: Alice just takes the card corresponding to the advice and swaps it into the first locker. For example, the shuffled deck from Figure 1 corresponds to the following permutation σ of 52 numbers:

$$\begin{aligned}\sigma(0, 1, \ldots, 51) = \langle &49, 17, 1, 38, 27, 7, 21, 25, 45, 3, 51, 9, 35, 36, 11, 33, 23,\\ &8, 46, 18, 13, 28, 26, 14, 2, 5, 10, 39, 48, 32, 29, 40, 19, 4,\\ &50, 43, 6, 22, 34, 44, 24, 15, 16, 20, 0, 47, 30, 42, 31, 37\rangle\end{aligned}$$

with mapping: ♣: 0–12 (in order *2,3,4,5,6,7,8,9,10,J,Q,K,A*), ♢: 13–25, ♡: 26–38, ♠: 39–51. We see, for example, that ♠Q, card number 49 is in locker 0. If in the *needle in a haystack* search problem the advice is a number $\mathfrak{h} \in [n-1]$, then Alice swaps the contents of locker 0 and the locker containing the card corresponding to number $\mathfrak{h}$. This way, Bob gets the advice $\mathfrak{h}$ by opening locker 0.

For the strategy we propose in Theorem 5, Alice would swap ♠Q and ♡5. But can we do better?

1.2 Results for the *needle in a haystack* and *locker room* problems

We present a tight analysis of the *needle in a haystack* search problem. While some basic examples suggest that it is difficult to ensure success probability $\omega(\frac{1}{n})$, we will show that one can improve this probability considerably. Our main results are tight (up to lower order terms) lower and upper bounds for the maximum probability that with a single number hint one can find the object sought. First, we will show that for any strategy, the probability that one can find the sought object is at most $\frac{(1+o(1))\log n}{n\log\log n}$ (Theorem 5). Next, as the main result of this paper, we will complement this by designing a simple strategy that with a hint ensures that the sought object is found with probability at least $\frac{(1+o(1))\log n}{n\log\log n}$ (Theorem 6).

Further, we demonstrate essentially the same results for the *locker room* problem. Theorem 6 for the *needle in a haystack* search problem immediately implies that there is a simple strategy for Alice and Bob which ensures that Bob finds his card with probability at least $\frac{(1+o(1))\log n}{n\log\log n}$. We will complement this claim and extend in Theorem 21 the result from Theorem 5 for the *needle in a haystack* search problem to prove that for any strategy for Alice and Bob, the probability that Bob finds the required card is at most $O\left(\frac{\log n}{n\log\log n}\right)$.

Techniques. Our analysis exploits properties of random permutations to ensure that some short advice can reveal information about the input permutation, which can be used to increase the success probability substantially. Our approach relies on a close relationship between the *needle in a haystack* search problem and some intrinsic properties of random permutations related to the *rencontres number*, the number of n-permutations with a given number of fixed points. The two parts of our analysis for the *needle in a haystack* problem, the upper bound and the lower bound for the success probability, use quite different techniques.

To show the upper bound for the success probability (Theorem 5), we first observe that every deterministic strategy corresponds to a unique partition of $\mathbb{S}_n$ (set of all permutations of $[n-1]$) into n parts, with part $\mathfrak{h}$ containing exactly those permutations that cause the choice of hint $\mathfrak{h}$. By a careful analysis of the properties of this partition, we devise a metric for the best possible accuracy of the prediction counting instances in each part of the partition in which a permutation maps a given choice $\mathfrak{i}$ to $\mathfrak{s}$. By combining these estimation with the bounds for the rencontres number, we prove the desired upper bound for the success probability in the *needle in a haystack* search problem. An application of Yao's principle shows that our results are also valid for randomized strategies.

To show the lower bound for the success probability (Theorem 6), we first present a simple *shift strategy*, and then provide a non-trivial analysis of random permutations that demonstrates desirable properties of this strategy. The analysis here is related to the maximum load problem for balls and bins, where one allocates n balls into n bins, chosen independently and uniformly at random (*i.u.r.*). However, the dependencies between locations of distinct elements in the random permutations make this analysis more complex (cf. Remark 11 for more detailed discussion).

Finally, while a solution to the *needle in a haystack* search problem immediately yields a solution to the *locker room* problem with the same success probability, we complement our analysis by showing (Theorem 21) that no strategy of Alice and Bob can do much better. We show that Alice can do little more than just to send a few numbers to Bob, which is essentially the setup of the *needle in a haystack* search problem.

1.3 Background: Permutations, puzzles, and locker rooms

Our *locker room* problem follows a long line of the study of combinatorial puzzles involving the analysis of properties of permutations. One such example is the following locker problem involving prisoners and lockers: There are n lockers into which a random permutation of n cards are inserted. Then n prisoners enter the locker room one at a time and are allowed to open half of the lockers in an attempt to find their own card. The team of prisoners wins if every one of them is successful. The surprising result is that there is a strategy which wins with probability about $1 - \ln 2$. This problem was initially considered by Peter Bro Miltersen and appeared in his paper with Anna Gál [7], which won a best paper award at ICALP 2003. In that paper they refer to a powerful strategy approach suggested by Sven Skyum but it was left to the readers to find it for themselves. This is the idea of using the number contained in each locker as a pointer to another locker. Thus using a sequence of such steps corresponds to following a cycle in the permutation. Solutions to these problems are of a *combinatorial and probabilistic flavor* and involve an *analysis of the cycle structure of random permutations*. The original paper [7] stimulated many subsequent papers considering different variants (see, e.g., [4, 8]), including a matching upper bound provided in [5]. An early version giving the problem where each prisoner can open half of the lockers was published by [14] (see also [15, p. 18]). If each prisoner begins with the locker corresponding to the number they seek then they will all succeed provided that there is no cycle in the permutation which is longer than $\frac{n}{2}$. It is easy to show that a helpful prison warder, Alice, can always find an appropriate transposition of the contents of two lockers so that the resulting permutation has no cycle longer than $\frac{n}{2}$. We were told of this observation recently by Kazuo Iwama and this stimulated the current paper, in which we subvert the locker problem tradition with a problem which has little to do with the cycle structure of permutations and is more concerned with some basic communication complexity and rather different properties of permutations.

Various results about permutations have found diverse applications in computer science, especially for sorting algorithms (for example, see [10, Chapter 5]). In this paper, we are particularly interested in two such questions. Firstly, to apply known results concerning the asymptotic growth of the rencontres numbers, in order to approximate the optimal success probabilities in both the *needle in a haystack* problem and the *locker room* problem. Secondly, to use the concept of the rencontres numbers to examine the way in which the sizes of "shift sets" (sets of elements which a permutation displaces by the same number of positions "to the right") are distributed in permutations of $\mathbb{S}_n$ for a fixed natural number n. In particular, to determine the mean size of the largest shift set of a permutation chosen uniformly at random from $\mathbb{S}_n$, as well as to show that it is typical, i.e., that the variance of the size of the largest shift set is small. These results are useful for providing a concrete optimal strategy for both of the titular search problems.

2 Preliminaries

In this section, we prepare a framework for the study of strategies to prove an upper bound for the success probability for the *needle in a haystack* search problem (cf. Section 3). For the simplicity of the analysis, we will consider (in Sections 2, 3, and 6) the setting when $\mathfrak{s}$

is chosen i.u.r. from $[n-1]$; see Section 2.2 for justification that this can be done without loss of generality. First, let us rephrase the original problem in a form of an equivalent communication game between Alice and Bob: Bob, the *seeker*, has as his input a (random) number $\mathfrak{s} \in [n-1]$. Alice, the *adviser*, sees a permutation σ chosen i.u.r. from $\mathbb{S}_n$, and uses σ to send advice to Bob in the form of a number $\mathfrak{h} \in [n-1]$. Bob does not know σ, but on the basis of $\mathfrak{s}$ and $\mathfrak{h}$, he picks some $\mathfrak{i} \in [n-1]$ trying to maximize the probability that $\sigma(\mathfrak{i}) = \mathfrak{s}$.

First we will consider *deterministic strategies* (we will later argue separately that randomized strategies cannot help much here). Since we consider deterministic strategies, the advice sent is a function $\mathbb{S}_n \to [n-1]$, which can be defined by a partition of $\mathbb{S}_n$ into n sets. This naturally leads to the following definition of a *strategy*.

▶ **Definition 1.** *A* ***strategy*** $\mathbb{C}$ *for* $\mathbb{S}_n$ *is a partition of* $\mathbb{S}_n$ *into* n *sets* $C_0, C_1, \ldots, C_{n-1}$*. Such a strategy* $\mathbb{C}$ *is denoted by* $\mathbb{C} = \langle C_0, C_1, \ldots, C_{n-1} \rangle$*.*

Given a specific strategy $\mathbb{C}$, we examine the success probability. Let $\mathcal{V}$ be the event that the sought number is found, $\mathcal{A}_\mathfrak{h}$ the event that $\mathfrak{h}$ is the received advice, and $\mathcal{B}_\mathfrak{s}$ the event that $\mathfrak{s}$ is the sought number. Notice that for every $\mathfrak{h} \in [n-1]$ we have $\mathbf{Pr}[\mathcal{A}_\mathfrak{h}] = \frac{|C_\mathfrak{h}|}{n!}$ and for every $\mathfrak{s} \in [n-1]$ we have $\mathbf{Pr}[\mathcal{B}_\mathfrak{s}] = \frac{1}{n}$. Therefore, since the events $\mathcal{A}_\mathfrak{h}$ and $\mathcal{B}_\mathfrak{s}$ are independent,

$$\mathbf{Pr}[\mathcal{V}] = \sum_{\mathfrak{s}=0}^{n-1} \sum_{\mathfrak{h}=0}^{n-1} \mathbf{Pr}[\mathcal{V}|\mathcal{A}_\mathfrak{h} \cap \mathcal{B}_\mathfrak{s}] \cdot \mathbf{Pr}[\mathcal{A}_\mathfrak{h} \cap \mathcal{B}_\mathfrak{s}] = \sum_{\mathfrak{s}=0}^{n-1} \sum_{\mathfrak{h}=0}^{n-1} \mathbf{Pr}[\mathcal{V}|\mathcal{A}_\mathfrak{h} \cap \mathcal{B}_\mathfrak{s}] \cdot \mathbf{Pr}[\mathcal{A}_\mathfrak{h}] \cdot \mathbf{Pr}[\mathcal{B}_\mathfrak{s}]$$
$$= \frac{1}{n} \sum_{\mathfrak{h}=0}^{n-1} \frac{|C_\mathfrak{h}|}{n!} \cdot \sum_{\mathfrak{s}=0}^{n-1} \mathbf{Pr}[\mathcal{V}|\mathcal{A}_\mathfrak{h} \cap \mathcal{B}_\mathfrak{s}] \ . \tag{1}$$

▶ **Definition 2.** *Let* $\mathbb{C} = \langle C_0, C_1, \ldots, C_{n-1} \rangle$ *be a strategy. The* ***magneticity*** *of an element* i *for an element* k *in the class* C_j *is defined as* $\mathsf{mag}(C_j, i, k) = |\{\sigma \in C_j : \sigma(i) = k\}|$*.*

The element with the greatest magneticity for k *in the class* C_j *is called the* ***magnet in*** C_j ***of*** k *and is denoted* $\mathsf{max\text{-}mag}(C_j, k)$*; ties are broken arbitrarily. The magneticity of* $\mathsf{max\text{-}mag}(C_j, k)$ *is called the* ***intensity of*** k ***in*** C_j*, denoted by* $\mathsf{int}(C_j, k)$*; that is,* $\mathsf{int}(C_j, k) = \max_{i \in [n-1]} \{\mathsf{mag}(C_j, i, k)\}$*.*

This can be extended in a natural way to any $C = \langle A_0, A_1, \ldots, A_{n-1} \rangle$ of n subsets of $\mathbb{S}_n$.

Let us discuss the intuitions. Firstly, the *magneticity* in the class C_j of an element i for an element k, $\mathsf{mag}(C_j, i, k)$, denotes the number of permutations in C_j with k in position i. Therefore, the *magnet* in C_j of k is an index $i \in [n-1]$ such that among all permutations in C_j, k is most likely to be in position i. The *intensity* in C_j of k denotes just the number of times (among all permutations in C_j) that k appears in the position of the magnet i.

In the *needle in a haystack* search problem, Alice sends to Bob a message $\mathfrak{h}$ which points to a class $C_\mathfrak{h}$ of their agreed strategy $\mathbb{C}$, and Bob has to choose a number $\mathfrak{i}$ in order to find whether $\sigma(\mathfrak{i})$ is the number $\mathfrak{s} \in [n-1]$ which he seeks. The maximum probability that they succeed is $\frac{\mathsf{int}(C_\mathfrak{h}, \mathfrak{s})}{|C_\mathfrak{h}|}$, realized if Bob opts for the magnet of $\mathfrak{s}$ in $C_\mathfrak{h}$. Thus, by (1), we obtain

$$\mathbf{Pr}[\mathcal{V}] \leq \frac{1}{n} \cdot \frac{1}{n!} \sum_{\mathfrak{s},\mathfrak{h} \in [n-1]} \mathsf{int}(C_\mathfrak{h}, \mathfrak{s}) \ .$$

▶ **Definition 3.** *Let the* ***field*** *of* $\mathbb{S}_n$ *be* $F(n) = \max_{\mathbb{C}=\langle C_0, C_1, \ldots, C_{n-1} \rangle} \sum_{\mathfrak{s},\mathfrak{h} \in [n-1]} \mathsf{int}(C_\mathfrak{h}, \mathfrak{s})$*.*

With this definition, a strategy which yields the field of $\mathbb{S}_n$ is called *optimal*, and

$$\mathbf{Pr}[\mathcal{V}] \leq \frac{1}{n} \cdot \frac{1}{n!} \sum_{\mathfrak{s},\mathfrak{h} \in [n-1]} \mathsf{int}(C_\mathfrak{h}, \mathfrak{s}) \leq \frac{1}{n} \cdot \frac{F(n)}{n!} \ . \tag{2}$$

We will use this bound to prove Theorem 5 in Section 3, that whatever the strategy, we always have $\mathbf{Pr}[\mathcal{V}] \leq \frac{(1+o(1)) \cdot \log n}{n \log \log n}$.

2.1 Derangements

We use properties of random permutations related to derangements and rencontres numbers.

▶ **Definition 4.** *A permutation $\sigma \in \mathbb{S}_n$ with no fixed points is called a* ***derangement****. The number of derangements in $\mathbb{S}_n$ is denoted D_n. A permutation $\sigma \in \mathbb{S}_n$ with exactly r fixed points is called an* ***r-partial derangement****. The number of r-partial derangements in $\mathbb{S}_n$ (also known as the* rencontres number*) is denoted $D_{n,r}$.*

Definition 4 yields $D_{n,0} = D_n$ and it is easy to see that $D_{n,r} = \binom{n}{r} \cdot D_{n-r}$. It is also known (see, e.g., [9, p. 195]) that $D_n = \lfloor \frac{n!}{e} + \frac{1}{2} \rfloor$, and hence one can easily show $D_{n,r} \leq \frac{n!}{r!}$.

2.2 Formal framework and justification about worst-case vs. random $\mathfrak{s}$

We consider the problem with two inputs: a number $\mathfrak{s} \in [n-1]$ and a permutation $\sigma \in \mathbb{S}_n$. We are assuming that σ is a random permutation in $\mathbb{S}_n$; no assumption is made about $\mathfrak{s}$.

For the *needle in a haystack* search problem (a similar framework can be easily set up for the *locker room* problem), a *strategy* (or an *algorithm*) is defined by a pair of (possibly randomized) functions, $\mathfrak{h} = \mathfrak{h}(\sigma)$ and $\mathfrak{i} = \mathfrak{i}(\mathfrak{h}, \mathfrak{s})$, with both $\mathfrak{h}, \mathfrak{i} \in [n-1]$.

For a fixed strategy, let $\mathfrak{p}(\mathfrak{s})$ be the success probability for a given $\mathfrak{s}$ and for a randomly chosen $\sigma \in \mathbb{S}_n$. That is,

$$\mathfrak{p}(\mathfrak{s}) = \mathbf{Pr}[\sigma(\mathfrak{i}) = \mathfrak{s}] \ ,$$

where the probability is over σ taken i.u.r. from $\mathbb{S}_n$, and over the randomness in the choice of the strategy (since both $\mathfrak{h} = \mathfrak{h}(\sigma)$ and $\mathfrak{i} = \mathfrak{i}(\mathfrak{h}, \mathfrak{s})$ may be randomized functions).

The goal is to design an algorithm (find a strategy) that will achieve some success probability for every $\mathfrak{s} \in [n-1]$. That is, we want to have a strategy which maximizes

$$\mathbf{Pr}[\mathcal{V}] = \min_{\mathfrak{s} \in [n-1]} \{\mathfrak{p}(\mathfrak{s})\} \ .$$

In our analysis for the upper bounds in Sections 2 and 3 (Theorem 5) and Section 6 (Theorem 21), for simplicity, we will be making the assumption that $\mathfrak{s}$, the input to the *needle in a haystack* search problem and to the *locker room* problem, is random, that is, is chosen i.u.r. from $[n-1]$. (We do not make such assumption in the lower bound in Section 4 (Theorem 6), where the analysis is done explicitly for arbitrary $\mathfrak{s}$.) Then the main claim (Theorem 5) is that if we choose $\mathfrak{s}$ i.u.r. then $\mathfrak{p}(\mathfrak{s}) \leq \frac{(1+o(1)) \log n}{n \log \log n}$, though in fact, one can read this claim as that $\sum_{\mathfrak{s} \in [n-1]} \frac{\mathfrak{p}(\mathfrak{s})}{n} \leq \frac{(1+o(1)) \log n}{n \log \log n}$. However, notice that this trivially yields

$$\mathbf{Pr}[\mathcal{V}] = \min_{\mathfrak{s} \in [n-1]} \{\mathfrak{p}(\mathfrak{s})\} \leq \sum_{\mathfrak{s} \in [n-1]} \frac{\mathfrak{p}(\mathfrak{s})}{n} \ ,$$

and therefore Theorem 5 yields $\mathbf{Pr}[\mathcal{V}] \leq \frac{(1+o(1)) \log n}{n \log \log n}$, as required.

Observe that such arguments hold only for the upper bound. Indeed, since $\min_{\mathfrak{s} \in [n-1]} \{\mathfrak{p}(\mathfrak{s})\}$ may be much smaller than $\sum_{\mathfrak{s} \in [n-1]} \frac{\mathfrak{p}(\mathfrak{s})}{n}$, in order to give a lower bound for the success probability, Theorem 6 proves that there is a strategy that ensures that $\mathfrak{p}(\mathfrak{s}) \geq \frac{(1+o(1)) \log n}{n \log \log n}$ for every $\mathfrak{s} \in [n-1]$; this clearly yields $\mathbf{Pr}[\mathcal{V}] \geq \frac{(1+o(1)) \log n}{n \log \log n}$, as required.

3 Upper bound for the success probability for needle in a haystack

We will use the framework set up in the previous section, in particular the tools in Definition 2 and inequality (2) and that $\mathfrak{s}$ is chosen i.u.r. from $[n-1]$, to bound from above the best possible success probability in the *needle in a haystack* search problem.

▶ **Theorem 5.** *For any strategy in the* needle in a haystack *problem, the success probability is*

$$\mathbf{Pr}[\mathcal{V}] \leq \frac{(1+o(1))\cdot \log n}{n \log\log n} \ .$$

Proof. We will first consider only *deterministic* strategies and, only at the end, we will argue that this extends to randomized strategies.

Consider an optimal strategy $\mathbb{C} = \langle C_0, \ldots, C_{n-1}\rangle$. First, we will modify sets $C_0, \ldots, C_{n-1}$ to ensure that each C_j has n distinct magnets.

Fix $j \in [n-1]$. Suppose that there are two elements $k_1 < k_2 \in [n-1]$ with the same magnet i_1 in C_j. Since there are exactly n elements and n possible magnets, there is some $i_2 \in [n-1]$ which is not a magnet in C_j of any element. For every $\sigma \in C_j$ with $\sigma(i_1) = k_2$, calculate $\sigma' = \sigma(i_1 i_2)$ (that is, σ' is the same as σ, except that the images of i_1 and i_2 are exchanged). Now, if $\sigma' \notin C_j$, then remove σ from C_j and add σ' to C_j. We notice the following properties of the resulting set C'_j in the case that some σ is replaced by σ':

(i) $|C'_j| = |C_j|$.

(ii) i_2 can be chosen as the new magnet of k_2. Indeed, for every $i \neq i_1, i_2$, we have

$$\mathsf{mag}(C'_j, i_2, k_2) > \mathsf{mag}(C_j, i_1, k_2) = \mathsf{int}(C_j, k_2) \geq \mathsf{mag}(C_j, i, k_2) = \mathsf{mag}(C'_j, i, k_2), \text{ so}$$
$$\mathsf{mag}(C'_j, i_2, k_2) = \mathsf{int}(C'_j, k_2) > \mathsf{int}(C_j, k_2) \ .$$

(iii) None of the intensities decreases. Indeed the only differences are due to changes to permutations $\sigma \in C_j$ with $\sigma(i_1) = k_2$. Such a permutation where $\sigma(i_2) = k_3$, say, is replaced by σ', where $\sigma'(i_2) = k_2$ and $\sigma'(i_1) = k_3$, if σ' is not already in C_j. As shown in (ii), the intensity of k_2 increases. For k_3, only $\mathsf{mag}(C_j, i_2, k_3)$ decreases, but since i_2 was not a magnet in C_j, the magnet in C'_j of k_3, and hence $\mathsf{int}(C_j, k_3)$, is unchanged.

We repeat this operation for every remaining pair of elements which share a magnet in C_j until we arrive at a set of permutations which has n distinct magnets. Then, we perform the same process for every other class in $\mathbb{C}$.

To see that this algorithm indeed terminates, (ii) shows that if in any iteration the magnet of an element i changes, then $\mathsf{int}(C'_j, i) > \mathsf{int}(C_j, i)$. As the maximum intensity of any element within a class C_j is $|C_j|$ and the minimum is 1, the algorithm terminates after $n \cdot n!$ iterations.

Let us consider the collection $C = \langle A_0, \ldots, A_{n-1}\rangle$ obtained. From (i), we see that the sets of C contain a total of $n!$ permutations of $\mathbb{S}_n$. Permutations belonging to the same set A_j are necessarily distinct, but two different sets of C may have non-trivial intersection. Hence, C may not be a strategy. Every A_j has n distinct magnets, one for each element of $[n-1]$. Most importantly, by (iii), we have

$$\sum_{i,j\in[n-1]} \mathsf{int}(A_j, i) \geq \sum_{i,j\in[n-1]} \mathsf{int}(C_j, i) = F(n) \ .$$

Hence, calculating an upper bound for $\sum_{i,j\in[n-1]} \mathsf{int}(A_j, i)$ yields an upper bound for $F(n)$.

The set A_j has exactly n magnets, one for each element of $[n-1]$. For a permutation $\sigma \in A_j$ to contribute r to $\sum_{i\in[n-1]} \mathsf{int}(A_j, i)$, σ^{-1} must map exactly r elements to their magnets in A_j. Hence, (cf. Definition 4) there are at most $D_{n,r}$ permutations in A_j which contribute exactly r to $\sum_{i\in[n-1]} \mathsf{int}(A_j, i)$. Recall that $D_{n,r} \leq \frac{n!}{r!}$ and thus for any natural ℓ,

$$\sum_{i\in[n-1]} \mathsf{int}(A_j, i) \leq \ell \cdot |A_j| + \sum_{r=\ell+1}^{n} r \cdot D_{n,r} = \ell \cdot |A_j| + \sum_{r=\ell+1}^{n} \frac{n!}{(r-1)!} \leq \ell \cdot |A_j| + \frac{en!}{\ell!} \ .$$

We will choose some $\ell = \frac{(1+o(1))\log n}{\log\log n}$ to ensure that $\ell! = \omega(n)$, giving

$$F(n) \le \sum_{i,j\in[n-1]} \mathsf{int}(A_j, i) \le \sum_{j\in[n-1]} (\ell \cdot |A_j| + o((n-1)!)) = (\ell + o(1))n! = \frac{(1+o(1))\log n}{\log\log n} n! \quad (3)$$

We can combine (2) and (3) to obtain the following,

$$\mathbf{Pr}[\mathcal{V}] \le \frac{1}{n} \cdot \frac{F(n)}{n!} \le \frac{(1+o(1))\log n}{n\log\log n} \ .$$

The upper bound of $\frac{(1+o(1))\log n}{n\log\log n}$ is valid not only for deterministic strategies, but also for *randomized strategies*. Let $c(\mathbb{C}, (\sigma, i))$ be the indicator function of the event that the strategy $\mathbb{C}$ fails to guess the image of i under the permutation σ. Let us consider a probability measure P over the set D of all deterministic strategies, and the distribution $U = (U_{\mathbb{S}_n}, U_{[n-1]})$ over $\mathbb{S}_n \times [n-1]$, where U_S denotes the uniform probability measure over the set S. Let S be a random strategy chosen according to P, and let X be a random set-up chosen according to U. Then, by Yao's principle, $\max_{(\sigma,i)\in\mathbb{S}_n\times[n-1]} \mathbf{E}[c(S,(\sigma,i))] \ge \min_{\mathbb{C}\in D} \mathbf{E}[c(\mathbb{C}, X)]$. That is, the probability that a randomized strategy fails for the worst-case input exceeds the probability that an optimal deterministic strategy fails. Hence, the worst-case probability that a randomized strategy succeeds is also bounded above by $\frac{(1+o(1))\log n}{n\log\log n}$. ◀

4 Lower bound: solution for the needle in a haystack search problem

In Theorem 5, we showed that whatever strategy we use in the *needle in a haystack* problem, the best success probability we can hope for is $\frac{(1+o(1))\log n}{n\log\log n}$. In this section we will show that such success probability is achievable by a simple strategy, which we call the *shift strategy*.

- Let $\mathfrak{h} \in [n-1]$ maximize $|\{\ell \in [n-1] : \ell = \sigma(\ell + \mathfrak{h} \pmod n)\}|$.
- In order to find number $\mathfrak{s} \in [n-1]$ in σ, check $\sigma(\mathfrak{s} + \mathfrak{h} \pmod n)$.

(Our choice of $\mathfrak{h}$ is equivalent to maximizing $|\{\ell \in [n-1] : (\ell - \mathfrak{h} \pmod n) = \sigma(\ell)\}|$.)

We will prove that the shift strategy ensures a success probability of at least $\frac{(1+o(1))\log n}{n\log\log n}$. Notice that this is equivalent to saying that $\mathbf{Pr}[\sigma(\mathfrak{s} + \mathfrak{h} \pmod n) = \mathfrak{s}] \ge \frac{(1+o(1))\log n}{n\log\log n}$, and hence, by the definition of $\mathfrak{h}$, that with probability $1 - o(1)$,

$$\max_{s\in[n-1]} \left\{ \left| \{\ell \in [n-1] : \ell - \sigma(\ell) = s \pmod n\} \right| \right\} \ge \frac{(1+o(1))\log n}{\log\log n} \ .$$

This also implies, by Theorem 5 in Section 3, that the shift strategy is asymptotically optimal.

▶ **Theorem 6.** *For any $\mathfrak{s} \in [n-1]$, the shift strategy satisfies $\mathbf{Pr}[\mathcal{V}] \ge \frac{(1+o(1))\log n}{n\log\log n}$.*

In order to prove Theorem 6, we introduce some notation. For every $i \in [n-1]$, let $v(i) = i - \sigma(i) \pmod n$. Since σ is random, $v(i)$ has uniform distribution over $[n-1]$.

Let $S_\ell = |\{i \in [n-1] : v(i) = \ell\}|$. Notice that in the shift strategy $\mathbb{C} = \langle C_0, C_1, \ldots, C_{n-1}\rangle$, if $\sigma \in C_\mathfrak{h}$ then $S_\mathfrak{h} = \max_{\ell\in[n-1]}\{S_\ell\}$. Therefore, our goal is to study basic properties of the distribution of $S_\mathfrak{h}$, and in particular, to estimate the largest value of S_j over all $j \in [n-1]$.

▶ **Example 7.** Using the example presented in Figure 1 with

$$\sigma(0,1,\ldots,51) = \langle 49,17,1,38,27,7,21,25,45,3,51,9,35,36,11,33,23,8,46,18,13,28,26,$$
$$14,2,5,10,39,48,32,29,40,19,4,12,41,50,43,6,22,34,44,24,15,16,20,0,47,30,42,31,37\rangle,$$

we have

$$v(0,1,\ldots,51) = \langle 3,36,1,17,29,50,37,34,15,6,11,2,29,29,3,34,45,9,24,1,7,45,48,9,$$
$$22,20,16,40,32,49,1,43,13,29,22,46,38,46,32,17,6,49,18,28,28,25,46,0,18,7,19,14\rangle.$$

Then

$$S_{0,1,2,\ldots,50,51} = \langle 1,3,1,2,0,0,2,2,0,2,0,1,0,1,1,1,1,2,2,1,1,0,2,0,1,1,$$
$$0,0,2,4,0,0,2,0,2,0,1,1,1,0,1,0,0,1,0,2,3,0,1,2,1,0\rangle,$$

so $\mathfrak{h} = 29$ and $S_{\mathfrak{h}} = 4$. Alice delivers this hint to Bob by exchanging cards ♡5 and ♠Q. Then, over all $\mathfrak{s} \in [n-1]$, $\mathbf{Pr}[\sigma(\mathfrak{s}+29 \pmod{52}) = \mathfrak{s}] = \frac{4}{52}$. ⊠

Let us first notice the following simple auxiliary lemma which should give the *intuition* behind our approach (see the end of this section for a standard and elementary proof).

▶ **Lemma 8.** *The expected number of values $j \in [n-1]$ with $S_j \geq \frac{(1+o(1))\cdot\log n}{\log\log n}$ is at least one.*

Lemma 8 tells us that in expectation, there is at least one value j such that $S_j \geq \frac{(1+o(1))\log n}{\log\log n}$. Notice however that in principle, we could have that the expectation is high but only because with small probability the random variable takes a very high value. Therefore the bound in Lemma 8 is fairly weak. We will now prove, using the second moment method, that with high probability there is some j such that $S_j \geq \frac{(1+o(1))\log n}{\log\log n}$. This yields Theorem 6.

▶ **Lemma 9.** *With probability $1-o(1)$ there is some $j \in [n-1]$ such that $S_j \geq \frac{(1+o(1))\log n}{\log\log n}$.*

Proof. Let Z_j^t be the indicator random variable that $S_j = t$. Let $R_t = \sum_{j=0}^{n-1} Z_j^t$. With this notation, our goal is to show that $R_t = 0$ is unlikely for our choice of some $t = \frac{(1+o(1))\log n}{\log\log n}$ (since if $R_t > 0$ then $\max_{j\in[n-1]} S_j \geq t$, and hence $\mathbf{Pr}\big[\max_{j\in[n-1]} S_j \geq t\big] \geq \mathbf{Pr}[R_t > 0]$). We use the second moment method relying on a standard implication of Chebyshev's inequality,

$$\mathbf{Pr}\big[\max_{j\in[n-1]} S_j < t\big] \leq \mathbf{Pr}\big[R_t = 0\big] \leq \frac{\mathbf{Var}[R_t]}{\mathbf{E}[R_t]^2} \ . \tag{4}$$

Let us recall that

$$\mathbf{Var}[R_t] = \mathbf{Var}[\sum_{j=0}^{n-1} Z_j^t] = \sum_{j=0}^{n-1} \mathbf{Var}[Z_j^t] + \sum_{i,j\in[n-1],i\neq j} \mathbf{Cov}[Z_i^t, Z_j^t] \ . \tag{5}$$

Next, since every Z_j^t is a 0-1 random variable, we obtain the following,

$$\mathbf{Var}[Z_j^t] = \mathbf{Pr}[Z_j^t = 1]\cdot\mathbf{Pr}[Z_j^t = 0] \leq \mathbf{Pr}[Z_j^t = 1] = \mathbf{E}[Z_j^t] \ . \tag{6}$$

Our main technical claim is that the covariance of random variables Z_j^t, Z_i^t is small. Although the proof of Lemma 10 is the *main technical contribution* of this section, for the clarity of the presentation, we defer its proof to Section 5.

▶ **Lemma 10.** *Let $t \leq O(\log n)$. Then, the following holds for any $i \neq j$, $i,j \in [n-1]$:*

$$\mathbf{Cov}[Z_i^t, Z_j^t] = \mathbf{E}\big[Z_i^t \cdot Z_j^t\big] - \mathbf{E}\big[Z_i^t\big]\cdot\mathbf{E}[Z_j^t] \leq o(1)\cdot\mathbf{E}\big[Z_i^t\big]\cdot\mathbf{E}[Z_j^t] \ . \tag{7}$$

Therefore, if we combine (6) and Lemma 10 in identity (5), then (assuming $t \le O(\log n)$)

$$\begin{aligned}\mathbf{Var}[R_t] &= \sum_{j=0}^{n-1} \mathbf{Var}[Z_j^t] + \sum_{i,j\in[n-1],i\neq j} \mathbf{Cov}[Z_i^t, Z_j^t] \le \sum_{j=0}^{n-1} \mathbf{E}[Z_j^t] + o(1) \sum_{i,j\in[n-1],i\neq j} \mathbf{E}\big[Z_i^t\big]\mathbf{E}[Z_j^t] \\ &= \mathbf{E}[R_t] + o(1)\cdot \mathbf{E}[R_t]^2 \ .\end{aligned}$$

If we plug this in (4), then we will get the following (assuming $t \le O(\log n)$),

$$\mathbf{Pr}\big[R_t = 0\big] \le \frac{\mathbf{Var}[R_t]}{\mathbf{E}[R_t]^2} \le \frac{1}{\mathbf{E}[R_t]} + o(1) \ . \tag{8}$$

Therefore, if for some $\varsigma > 0$ we have $\mathbf{E}[R_t] \ge \varsigma$ (with $t \le O(\log n)$) then the bound above yields $\mathbf{Pr}\big[\max_{i\in[n-1]} S_i < t\big] \le \frac{1}{\varsigma} + o(1)$. Hence we can combine this with (9) to obtain $\mathbf{E}[R_t] = \sum_{j=0}^{n-1} \mathbf{E}[Z_j^t] = \sum_{j=0}^{n-1} \mathbf{Pr}[S_j = t] > \frac{n}{2et!}$, which is $\omega(1)$ for any t such that $t! = o(n)$. This in particular holds for some $t = \frac{(1+o(1))\log n}{\log\log n}$, and thus concludes Lemma 9. ◀

▶ Remark 11. A reader may notice a close similarity of the problem of estimating $\max_{i\in[n-1]} S_i$ to the maximum load problem for balls and bins, where one allocates n balls into n bins i.u.r. Indeed, random variables $S_0, \ldots, S_{n-1}$ have similar distribution to the random variables $B_0, \ldots, B_{n-1}$, where B_i represents the number of balls allocated to bin i. However, the standard approaches used in the analysis of balls-and-bins processes seem to be more complicated in our setting. The main reason is that while every single random variable S_i has approximately Poisson distribution with mean 1, as has B_i too, the analysis of $\max_{i\in[n-1]} S_i$ is more complicated than the analysis of $\max_{i\in[n-1]} B_i$ because of the intricate *correlation* of random variables $S_0, \ldots, S_{n-1}$. For example, one standard approach to show that $\max_{i\in[n-1]} B_i \ge \frac{(1+o(1))\log n}{\log\log n}$ with high probability relies on the fact that the load of a set of bins B_i with $i \in I$ decreases if we increase the load of bins B_j with $j \in J$, $I \cap I = \emptyset$. However, the same property holds only *approximately* for $S_0, \ldots, S_{n-1}$ (and in fact, the $o(1)$ error term in Lemma 10 corresponds to this notion of "approximately"; for balls and bins the covariance is known to be always non-positive). To see the difficulty (see also the classic reference for permutations [13, Chapters 7–8]), notice that, for example, if $\sigma(i) = i + \ell$ then we cannot have $\sigma(i+1) = i+\ell$, meaning that there is a special correlation between S_ℓ (which counts i with $\sigma(i) = i + \ell$) and $S_{\ell-1}$ (which counts i with $\sigma(i+1) = i + \ell$). In particular, from what we can see, random variables $S_0, \ldots, S_{n-1}$ are not negatively associated [6]. In a similar way, we do not expect the Poisson approximation framework from [1] (see also [11, Chapter 5.4]) to work here. Our approach is therefore closer to the standard second moment method, see, e.g., [2, Chapter 3] and [12].

Elementary proof of Lemma 8. Let us recall Definition 4 for derangements and r-partial derangements. The probability that a random permutation in $\mathbb{S}_n$ is a derangement is $D_n/n! = \lfloor \frac{n!}{e} + \frac{1}{2} \rfloor / n! \sim \frac{1}{e}$. Let $u(n) = \lfloor \frac{n!}{e} + \frac{1}{2} \rfloor / \frac{n!}{e}$ and note that $D_n = u(n)\, n!/e$, that $u(n) = 1 + o(1)$, and $u(n) > 0.9$ for all $n > 1$. Since the permutation $\sigma \in \mathbb{S}_n$ is chosen i.u.r.,

$$\mathbf{Pr}[S_0 = k] = \frac{D_{n,k}}{n!} = \frac{\binom{n}{k} D_{n-k}}{n!} = \frac{\binom{n}{k}\frac{(n-k)!}{e} u(n-k)}{n!} = \frac{u(n-k)}{ek!} \ .$$

The same bound can be obtained for S_j for every $j \ge 0$. For any permutation $\sigma \in \mathbb{S}_n$ and any integer $\ell \in [n-1]$, define permutation $\sigma_\ell \in \mathbb{S}_n$ such that $\sigma_\ell(i) = \sigma(i) + \ell \pmod n$. For any permutation $\sigma \in \mathbb{S}_n$ and any ℓ, the operator $\sigma \mapsto \sigma_\ell$ is a bijection from $\mathbb{S}_n$ to $\mathbb{S}_n$, and a

permutation $\sigma \in \mathbb{S}_n$ with $\ell \in [n-1]$ has exactly k fixed points if and only if permutation σ_ℓ has exactly k points with $\sigma_\ell(i) = i + \ell \pmod n$. Hence for every $j, j' \in [n-1]$ and $k \in [n]$, we have $\mathbf{Pr}[S_j = k] = \mathbf{Pr}[S_{j'} = k]$. Therefore, for any integers $j \in [n-1]$ and $k \in [n-2]$,

$$\mathbf{Pr}[S_j = k] = \frac{u(n-k)}{ek!} > \frac{1}{2ek!} \ . \tag{9}$$

Let $k(n)$ be the largest k such that $2ek! \le n$. Then $\mathbf{Pr}[S_j = k(n)] > 1/n$. Hence, if we let Q_j be the indicator random variable that $S_j = k(n)$, then $\mathbf{Pr}[Q_j = 1] > 1/n$, and hence $\mathbf{E}[\sum_{j=0}^{n-1} Q_j] = \sum_{j=0}^{n-1} \mathbf{E}[Q_j] = \sum_{j=0}^{n-1} \mathbf{Pr}[Q_j = 1] > 1$. Therefore, in expectation, there is at least one value j such that $S_j = k(n)$. It is easy to show that $k(n) = \frac{\log n}{\log \log n}(1 + o(1))$. ◀

5 Proof of Lemma 10: bounding the covariance of Z_i^t and Z_j^t

The main technical part of the analysis of the lower bound for the *needle in a haystack* search problem in Section 4 (cf. Theorem 6) relies on the proof Lemma 9. This proof, in turn, is quite simple except for one central claim, Lemma 10, bounding the covariance of Z_i^t and Z_j^t. The proof of Lemma 10 is rather lengthly, and because of space considerations, some proofs are deferred to the full version of the paper (cf. `https://arxiv.org/abs/2008.11448`).

Let Z_j^t be the indicator random variable that $S_j = t$. Since Z_i^t and Z_j^t are 0-1 random variables, we have $\mathbf{E}\left[Z_i^t \cdot Z_j^t\right] = \mathbf{Pr}[S_i = t, S_j = t]$, $\mathbf{E}\left[Z_i^t\right] = \mathbf{Pr}[S_i = t]$ and $\mathbf{E}[Z_j^t] = \mathbf{Pr}[S_j = t]$. Since $\mathbf{Pr}[S_i = t] = \mathbf{Pr}[S_j = t] = \frac{u(n-t)}{et!} = \frac{1+o(1)}{et!}$ by (9), to complete the proof of Lemma 10, we only have to show that, for $i \neq j$,

$$\mathbf{Pr}[S_i = t, S_j = t] \le (1 + o(1)) \cdot \frac{1}{(et!)^2} \ . \tag{10}$$

We will prove this claim in Lemma 19 in Section 5.2.4 below.

5.1 Notation and key intuitions

For any set $I \subseteq [n-1]$ and any integer $\ell \in [n-1]$, let $\mathcal{F}_{I,\ell} = \{\sigma \in \mathbb{S}_n : \sigma(i) = i + \ell \pmod n \text{ iff } i \in I\}$ and $\mathcal{F}^*_{I,\ell} = \{\sigma \in \mathbb{S}_n : \forall_{i \in I}\ \sigma(i) = i + \ell \pmod n\}$. Notice that $\mathcal{F}_{I,\ell} \subseteq \mathcal{F}^*_{I,\ell}$. Further, $|\mathcal{F}_{I,\ell}| = D_{n-t,0}$ where $t = |I|$, and

$$\mathbf{Pr}[S_i = t] = \frac{|\bigcup_{I \subseteq [n-1], |I|=t} \mathcal{F}_{I,i}|}{n!} = \frac{\sum_{I \subseteq [n-1], |I|=t} |\mathcal{F}_{I,i}|}{n!} = \frac{\binom{n}{t} \cdot D_{n-t,0}}{n!} \ .$$

Next, with this notation and for $i \neq j$, we also have

$$\mathbf{Pr}[S_i = t, S_j = t] = \frac{1}{n!} \left| \bigcup_{I,J \subseteq [n-1], |I|=|J|=t} \mathcal{F}_{I,i} \cap \mathcal{F}_{J,j} \right| = \frac{1}{n!} \sum_{I,J \subseteq [n-1], |I|=|J|=t} |\mathcal{F}_{I,i} \cap \mathcal{F}_{J,j}| \ .$$

Notice that in the sum above one can restrict attention only to $I \cap J = \emptyset$, since $\mathcal{F}_{I,i} \cap \mathcal{F}_{J,j} = \emptyset$ otherwise. In view of this, our goal is to estimate $|\mathcal{F}_{I,i} \cap \mathcal{F}_{J,j}|$ for disjoint sets $I, J \subseteq [n-1]$.

In what follows, we will consider sets S_i and S_j with $i = 0$ and $j = s$ for some $s \in [n-1] \setminus \{0\}$. By symmetry, we can consider the first shift to be 0 without loss of generality; s is an arbitrary non-zero value. As required in our analysis (cf. Lemma 10), we will consider $t \le O(\log n)$.

Our approach now is to focus on a typical pair I and J, and consider some atypical pairs separately. We will show in Lemma 13 that almost all pairs of disjoint sets I and J are so-called *compatible for shift* s. As a result, the contribution of pairs I and J that

are not compatible for s is negligible, and so we will focus solely on pairs compatible for s. Then, for the pair of indices I and J we will estimate $|\mathcal{F}_{I,i} \cap \mathcal{F}_{J,j}|$ using the Principle of Inclusion-Exclusion. For that, we will have to consider the contributions of all possible sets $K \subseteq [n-1] \setminus (I \cup J)$ to the set of permutations in $\mathcal{F}^*_{I,i} \cap \mathcal{F}^*_{J,j}$. As before, contributions of some sets are difficult to be captured and so we will show in Lemma 15 that almost all sets $K \subseteq [n-1] \setminus (I \cup J)$ are so-called *feasible for I, J, and s*. As a result, the contribution of sets K that are not feasible for I, J, and s is negligible, and so we will focus on sets that are feasible for I, J, and s. The final simplification follows from the fact that we do not have to consider all such sets K, but only small sets K, of size $O(\log n)$. Once we have prepared our framework, we will be able to use the Principle of Inclusion-Exclusion to estimate $|\bigcup_{I,J\subseteq[n-1],|I|=|J|=t} \mathcal{F}_{I,i} \cap \mathcal{F}_{J,j}|$ in Lemmas 18 and 19.

5.2 The analysis

For any integer ℓ and any subset $L \subseteq [n-1]$ we write $L + \ell$ to denote the set of elements in L shifted by ℓ, in the arithmetic modulo n, that is, $L + \ell = \{i + \ell \pmod n : i \in L\}$. Similarly, $L - \ell = \{i - \ell \pmod n : i \in L\}$.

Let $\Phi_{0,s}(I, J) = \mathcal{F}_{I,0} \cap \mathcal{F}_{J,s} = \{\sigma \in \mathbb{S}_n : \sigma(i) = i \text{ iff } i \in I \text{ and } \sigma(j) = j+s \pmod n \text{ iff } j \in J\}$. Let $\Phi^*_{0,s}(I, J) = \mathcal{F}^*_{I,0} \cap \mathcal{F}^*_{J,s} = \{\sigma \in \mathbb{S}_n : \forall_{i\in I}\ \sigma(i) = i \text{ and } \forall_{j\in J}\ \sigma(j) = j + s \pmod n\}$.

It is easy to compute the size of $\Phi^*_{0,s}(I, J)$. Notice first that if $I \cap J \neq \emptyset$ or $I \cap (J + s) \neq \emptyset$, then $\Phi^*_{0,s}(I, J) = \Phi_{0,s}(I, J) = \emptyset$. Otherwise, if $I \cap J = \emptyset$ and $I \cap (J + s) = \emptyset$, then $|\Phi^*_{0,s}(I, J)| = (n - |I \cup J|)!$ (see also Lemma 12).

However, our main goal, that of computing the size of $\Phi_{0,s}(I, J)$, is significantly more complicated, because this quantity cannot be reduced to an intersection test and a simple formula over n, $|I|$, $|J|$, and s.

5.2.1 Disjoint sets $I \subseteq [n-1]$ and $J \subseteq [n-1] \setminus I$ compatible for shift s

Let I and J be two arbitrary subsets of $[n-1]$ of size t each. We say *I and J are compatible for shift s* if the four sets I, J, $I - s$, and $J + s$ are all pairwise disjoint. With this notation, we have the following lemma.

▶ **Lemma 12.** *If I and J are compatible for shift s then $\Phi_{0,s}(I, J) \neq \emptyset$ and $|\Phi^*_{0,s}(I, J)| = (n - |I \cup J|)!$.*

Proof. If I and J are compatible for shift s then any permutation $\sigma \in \mathbb{S}_n$ with $\sigma(i) = i$ for all $i \in I$, $\sigma(j) = j + s \pmod n$ for all $j \in J$ and complemented by an arbitrary permutation $[n-1] \setminus (I \cup J)$ is in $\Phi^*_{0,s}(I, J)$. Hence the claim follows from the fact that since I, J, and $J + s$ are pairwise disjoint, such permutations always exist. ◀

The following lemma shows that almost all pairs of disjoint sets of size $t \leq O(\log n)$ are compatible.

▶ **Lemma 13.** *Let s be an arbitrary non-zero integer in $[n-1]$. If we choose two disjoint sets $I, J \subseteq [n-1]$ of size t i.u.r., then the probability that I and J are compatible for shift s is at least $\left(1 - \frac{4t}{(n-2t)}\right)^{2t}$. In particular, if $t \leq O(\log n)$, then this probability is at least $1 - O\left(\frac{\log^2 n}{n}\right)$.*

Because of Lemma 13, our goal will be to compute the sizes of sets $\Phi_{0,s}(I, J)$ only for compatible sets I and J. Next, for given disjoint sets I and J compatible for shift s, we will consider all sets $K \subseteq [n-1] \setminus (I \cup J)$ and argue about their contributions to $|\Phi^*_{0,s}(I, J)|$ using the Principle of Inclusion-Exclusion.

5.2.2 Properties of sets $K \subseteq [n-1]$ feasible for I, J, and s

Define $\mathcal{P}_{I,J,0,s}(K) = \{\sigma \in \Phi^*_{0,s}(I,J) : \text{ for every } \ell \in K \text{ it holds that: } \sigma(\ell) \in \{\ell, \ell+s \pmod n\}\}$. While it is difficult to study $\mathcal{P}_{I,J,0,s}(K)$ for all sets $K \subseteq [n-1] \setminus (I \cup J)$, we will want to focus our attention only on subsets with some good properties. We call a *set* $K \subseteq [n-1]$ *feasible for* I, J, *and* s, if I and J are compatible for shift s, $K \cap (K+s) = \emptyset$, and $K \cap (I \cup J \cup (I-s) \cup (J+s)) = \emptyset$.

To justify the definition of feasible sets, we begin with the following simple lemma.

▶ **Lemma 14.** *If $K \subseteq [n-1]$ is feasible for I, J, and s, then $|\mathcal{P}_{I,J,0,s}(K)| = 2^{|K|} \cdot (n - |I \cup J \cup K|)!$.*

Next, similarly to Lemma 13, we argue that almost all suitably small sets are feasible for pairs of disjoint small sets.

▶ **Lemma 15.** *Let s be an arbitrary non-zero integer in $[n-1]$. Let I and J be a pair of compatible sets for s with $|I| = |J| = t$. Let k be a positive integer with $2k \le n - 4t$. If we choose set $K \subseteq [n-1] \setminus (I \cup J)$ of size k i.u.r., then the probability that K is feasible for I, J, and s is at least $\left(1 - \frac{2t+k}{n-2t-k}\right)^k$. In particular, if $t, k \le O(\log n)$, then this probability is at least $1 - O\left(\frac{\log^2 n}{n}\right)$.*

5.2.3 Approximating $|\Phi_{0,s}(I,J)|$ for compatible sets I, J for s

In this section we will complete our analysis to provide a tight bound for the size of $\Phi_{0,s}(I,J)$ for any pair I and J of compatible sets for shift s with $|I| = |J| \le O(\log n)$. Our analysis relies on properties of sets feasible for I, J, and s, as proven in Lemmas 14 and 15.

We begin with the two auxiliary claims. For both, let r be the smallest integer such that $2r \ge \log n$ and let $t = |I| = |J| \le O(\log n)$.

▷ Claim 16.

$$\sum_{k=1}^{2r} (-1)^{k+1} \sum_{\substack{K \subseteq [n-1]\setminus(I\cup J), |K|=k \\ K \text{ feasible for } I,\ J,\text{ and } s}} |\mathcal{P}_{I,J,0,s}(K)| \ge \left(1 - O\left(\frac{\log^2 n}{n}\right)\right) \cdot (n-2t)! \cdot (1 - e^{-2}) \ . \quad (11)$$

▷ Claim 17.

$$\sum_{k=1}^{2r} (-1)^{k+1} \sum_{\substack{K \subseteq [n-1]\setminus(I\cup J), |K|=k \\ K \textit{ not} \text{ feasible for } I,\ J,\text{ and } s}} |\mathcal{P}_{I,J,0,s}(K)| \ge -O\left(\frac{\log^2 n}{n}\right) \cdot (n-2t)! \ .$$

In order to approximate the size of $\Phi_{0,s}(I,J)$ for compatible sets I and J for shift s, let us first notice that

$$\Phi_{0,s}(I,J) = \Phi^*_{0,s}(I,J) \setminus \bigcup_{\ell \in [n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\}) \ . \quad (12)$$

Therefore, since we know that $|\Phi^*_{0,s}(I,J)| = (n - (|I| + |J|))!$ by Lemma 12, we only have to approximate $|\bigcup_{\ell \in [n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})|$; we need a good lower bound.

We compute $|\bigcup_{\ell\in[n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})|$ using the Principle of Inclusion-Exclusion,

$$\begin{aligned}
|\bigcup_{\ell\in[n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})| &= \sum_{K\subseteq[n-1]\setminus(I\cup J),K\neq\emptyset} (-1)^{|K|+1}|\bigcap_{\ell\in K} \mathcal{P}_{I,J,0,s}(\{\ell\})| \\
&= \sum_{K\subseteq[n-1]\setminus(I\cup J),K\neq\emptyset} (-1)^{|K|+1}|\mathcal{P}_{I,J,0,s}(K)| \\
&= \sum_{k=1}^{n-(|I|+|J|)} (-1)^{k+1} \sum_{K\subseteq[n-1]\setminus(I\cup J),|K|=k} |\mathcal{P}_{I,J,0,s}(K)| \ .
\end{aligned}$$

We will make further simplifications; since computing $|\mathcal{P}_{I,J,0,s}(K)|$ for arbitrary non-empty sets $K \subseteq [n-1] \setminus (I \cup J)$ is difficult, we restrict our attention only to *small* sets K which are *feasible for I, J, and s*. For that, we will need to show that by restricting only to small sets K feasible for I, J, and s, we will not make too big errors in the calculations.

Let r be the smallest integer such that $2r \geq \log n$. We can use the Bonferroni inequality [3] to obtain the following,

$$\begin{aligned}
|\bigcup_{\ell\in[n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})| &\geq \sum_{k=1}^{2r}(-1)^{k+1} \sum_{K\subseteq[n-1]\setminus(I\cup J),|K|=k} |\mathcal{P}_{I,J,0,s}(K)| \\
&= \sum_{k=1}^{2r}(-1)^{k+1}\left(\sum_{\substack{K\subseteq[n-1]\setminus(I\cup J),|K|=k \\ K \text{ feasible for } I,\ J, \text{ and } s}} |\mathcal{P}_{I,J,0,s}(K)| + \sum_{\substack{K\subseteq[n-1]\setminus(I\cup J),|K|=k \\ K \textit{ not} \text{ feasible for } I,\ J, \text{ and } s}} |\mathcal{P}_{I,J,0,s}(K)| \right) \\
&\geq -O\left(\frac{\log^2 n}{n}\right)(n-2t)! + \left(1 - O\left(\frac{\log^2 n}{n}\right)\right)(n-2t)!\cdot(1-e^{-2}) \\
&= \left(1 - O\left(\frac{\log^2 n}{n}\right)\right)(n-2t)!\cdot(1-e^{-2}) \ , \qquad (13)
\end{aligned}$$

where the last inequality follows from the auxiliary Claims 16 and 17.

If we combine (12) and (13), then we get the following lemma.

▶ **Lemma 18.** *If I and J are compatible for shift s and $|I| = |J| = t = O(\log n)$, then*

$$|\Phi_{0,s}(I,J)| = |\Phi^*_{0,s}(I,J)| - |\bigcup_{\ell\in[n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})| \leq \frac{(n-2t)!}{e^2}\left(1 + O\left(\frac{\log^2 n}{n}\right)\right) \ .$$

Proof. Indeed, by (12), we have

$$|\Phi_{0,s}(I,J)| = |\Phi^*_{0,s}(I,J)| - |\bigcup_{\ell\in[n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})| \ ,$$

by Lemma 12 we get

$$|\Phi^*_{0,s}(I,J)| = (n - (|I| + |J|))! \ ,$$

and by (13) we have

$$|\bigcup_{\ell\in[n-1]\setminus(I\cup J)} \mathcal{P}_{I,J,0,s}(\{\ell\})\ | \geq \left(1 - O\left(\frac{\log^2 n}{n}\right)\right)\cdot(n-2t)!\cdot(1-e^{-2}) \ .$$

Putting these three bounds together yields the promised bound. ◀

5.2.4 Completing the proof of inequality (10)

Now, with Lemma 18 at hand, we are ready to complete our analysis in the following lemma.

▶ **Lemma 19.** *For any $i, j \in [n-1]$, $i \neq j$, and for $t \leq O(\log n)$, we have,*

$$\mathbf{Pr}[S_i = t, S_j = t] \leq \left(1 + O\left(\frac{\log^2 n}{n}\right)\right) \frac{1}{(et!)^2} \ .$$

Proof. Without loss of generality we assume that $i = 0$ and $j \in [n-1] \setminus \{0\}$.

First, let us recall the following

$$\sum_{I,J\subseteq[n-1],|I|=|J|=t,I\cap J=\emptyset} |\mathcal{F}_{I,0} \cap \mathcal{F}_{J,j}| = \sum_{I,J\subseteq[n-1],|I|=|J|=t,I\cap J=\emptyset} |\Phi_{0,j}(I,J)|$$
$$= \sum_{\substack{I,J\subseteq[n-1],|I|=|J|=t,I\cap J=\emptyset \\ I \text{ and } J \textit{ not} \text{ compatible for } j}} |\Phi_{0,j}(I,J)| + \sum_{\substack{I,J\subseteq[n-1],|I|=|J|=t \\ I \text{ and } J \text{ compatible for } j}} |\Phi_{0,j}(I,J)| \ .$$

Next, let us notice that if I and J are *not* compatible for shift j and $I \cap J = \emptyset$, then we clearly have $|\Phi_{0,s}(I,J)| \leq (n-2t)!$ (since once we have fixed $2t$ positions, we can generate at most $(n-2t)!$ distinct n-permutations). Further, by Lemma 18, we know that if I and J are compatible for shift j, then $|\Phi_{0,s}(I,J)| \leq \frac{(n-2t)!}{e^2} \cdot \left(1 + O\left(\frac{\log^2 n}{n}\right)\right)$. Next, we notice that by Lemma 13, we have,

$$|\{I, J \subseteq [n-1] : |I| = |J| = t, I \cap J = \emptyset \text{ and } I, J \textit{ not} \text{ compatible for } j\}|$$
$$= O\left(\frac{\log^2 n}{n}\right) \left|\{I, J \subseteq [n-1] : |I| = |J| = t, I \cap J = \emptyset\}\right| = O\left(\frac{\log^2 n}{n}\right) \binom{n}{t}\binom{n-t}{t} \ .$$

This immediately gives,

$$\sum_{\substack{I,J\subseteq[n-1],|I|=|J|=t,I\cap J=\emptyset \\ I \text{ and } J \textit{ not} \text{ compatible for } j}} |\Phi_{0,j}(I,J)| \leq O\left(\frac{\log^2 n}{n}\right) \binom{n}{t}\binom{n-t}{t}(n-2t)! = O\left(\frac{\log^2 n}{n}\right) \frac{n!}{(t!)^2}$$

and

$$\sum_{\substack{I,J\subseteq[n-1],|I|=|J|=t \\ I \text{ and } J \text{ compatible for } j}} \Phi_{0,j}(I,J)| \leq \binom{n}{t}\binom{n-t}{t} \frac{(n-2t)!}{e^2} \left(1 + O\left(\frac{\log^2 n}{n}\right)\right)$$
$$= \left(1 + O\left(\frac{\log^2 n}{n}\right)\right) \frac{n!}{(et!)^2} \ .$$

Therefore,

$$\sum_{\substack{I,J\subseteq[n-1],I\cap J=\emptyset \\ |I|=|J|=t}} |\mathcal{F}_{I,0} \cap \mathcal{F}_{J,j}| = \sum_{\substack{I,J\subseteq[n-1],|I|=|J|=t,I\cap J=\emptyset \\ I \text{ and } J \textit{ not} \text{ compatible for } j}} |\Phi_{0,j}(I,J)| + \sum_{\substack{I,J\subseteq[n-1],|I|=|J|=t \\ I \text{ and } J \text{ compatible for } j}} |\Phi_{0,j}(I,J)|$$
$$\leq \left(1 + O\left(\frac{\log^2 n}{n}\right)\right) \frac{n!}{(et!)^2} \ .$$

Hence, we can conclude that for $i \neq j$ we have,

$$\mathbf{Pr}[S_i = t, S_j = t] = \frac{1}{n!} \sum_{\substack{I,J\subseteq[n-1],I\cap J=\emptyset \\ |I|=|J|=t}} |\mathcal{F}_{I,i} \cap \mathcal{F}_{J,j}| \leq \left(1 + O\left(\frac{\log^2 n}{n}\right)\right) \cdot \frac{1}{(et!)^2} \ . \quad \blacktriangleleft$$

6 Analysis of the *communication in the locker room* setting

A lower bound for the success probability in the *locker room* problem is provided by a straightforward adaptation of the *shift strategy*: Alice enters her message relaying the most common shift $\mathfrak{h}$ to locker 0, and Bob opens locker 0 and uses Alice's message to check location $(\mathfrak{s}+\mathfrak{h})$ mod n for his card. This strategy ensures a success probability of $\frac{(1+o(1))\log n)}{n\log\log n}$.

As in Sections 2 and 3, we will consider the case when $\mathfrak{s}$ is chosen i.u.r. from $[n-1]$(cf. Section 2.2). In order to obtain an upper bound for the success chance in the *locker room* problem, we shall introduce some intermediate settings, or "protocols". In the *CLR* protocol Alice views the contents of all the lockers, interchanges the contents of two lockers, then Bob is given a number and can open two lockers in search of it (i.e., the *CLR* protocol is the set of rules which govern the *locker room* problem). In the *NH* protocol Alice views the contents of all the lockers, communicates a message of length $\log n$ to Bob, then Bob is given a number and can open one locker in search of it (i.e., the *NH* protocol is the set of rules which govern the *needle in a haystack* game). Moreover, we can append the modifier "-with-r-bits" to NH, which substitutes r for $\log n$ in the above description.

We write $\mathbf{Pr}[\mathcal{V}(\mathcal{P})]$ for the optimal probability of success in protocol $\mathcal{P}$ and $\mathbf{Pr}[\mathcal{V}(\mathbb{C},\mathcal{P})]$ for the probability of success for strategy $\mathbb{C}$ in protocol $\mathcal{P}$. For example, we have already shown that $\mathbf{Pr}[\mathcal{V}(NH)] = \frac{(1+o(1))\log n}{n\log\log n}$.

▶ **Lemma 20.** $\mathbf{Pr}[\mathcal{V}(CLR)] \leq \mathbf{Pr}[\mathcal{V}(\textit{NH-with-}4\log n\textit{-bits})]$.

Proof. We will interpolate between CLR and NH-with-$4\log n$-bits with two other protocols.

In the protocol *CLR0*, Alice views the contents of all the lockers, interchanges the contents of two lockers, then Bob is given a number and can open two lockers in search of it, and he can recognize upon seeing the content of the first locker whether it has been altered by Alice.

In the protocol *CLR1*, Alice views the contents of all the lockers, interchanges the contents of two lockers, leaves these two lockers open with their contents visible to Bob, then Bob is given a number and can open one locker in search of it.

Also, let *Sim* be the strategy in *NH-with-*$4\log n$*-bits* in which Alice uses her message to communicate to Bob the cards whose positions she would exchange, and the positions of these cards, if she encountered the permutation σ while working in the *CLR1* protocol, simulating an optimal strategy $\mathbb{C}$ in *CLR1*. Since this is an ordered quadruple in $[n-1]^4$, it can indeed be communicated in at most $4\log n$ bits.

The proof is in four parts:

(i) $\mathbf{Pr}[\mathcal{V}(CLR)] \leq \mathbf{Pr}[\mathcal{V}(CLR0)]$,
(ii) $\mathbf{Pr}[\mathcal{V}(CLR0)] \leq \mathbf{Pr}[\mathcal{V}(CLR1)] + O(\frac{1}{n})$,
(iii) $\mathbf{Pr}[\mathcal{V}(CLR1)] \leq \mathbf{Pr}[\mathcal{V}(\textit{Sim, NH-with-4logn-bits})]$,
(iv) $\mathbf{Pr}[\mathcal{V}(\textit{Sim, NH-with-4logn-bits})] \leq \mathbf{Pr}[\mathcal{V}(\textit{NH-with-4logn-bits})]$.

(i), (iii), (iv) are straightforward and so we only have to show (ii). Let p_t be the maximum probability that Bob finds his sought number in the t^{th} locker that he opens, $t \in \{1,2\}$.

Firstly, we bound p_1. Suppose that Alice and Bob have settled on a specific strategy. Let $e_{x,w}$ be the probability that σ is such that Alice's transposition sends the locker w to card x. Evidently, $0 \leq e_{x,w} \leq \frac{n-1}{n}$ for all $x, w \in [n-1]$ and $\sum_{x,w\in[n-1]} e_{x,w} \leq 2$.

Having received his number $\mathfrak{s}$, Bob has to open a specific locker, let us say $b = b(\mathfrak{s})$. The probability that Bob happens upon the card $\mathfrak{s}$ in the locker b is at most $e_{\mathfrak{s},b(\mathfrak{s})} + \frac{1}{n}$ (either Alice substitutes the content of $b(\mathfrak{s})$ for $\mathfrak{s}$, or the content of $b(\mathfrak{s})$ is initially $\mathfrak{s}$ and Alice does not interfere). Thus, choosing $\mathfrak{s}$ i.u.r. from $[n-1]$, the probability that Bob finds $\mathfrak{s}$ at his first try is at most $\frac{1}{n}(\sum_{\mathfrak{s},b\in[n-1]} e_{\mathfrak{s},b(\mathfrak{s})} + \frac{1}{n}) < \frac{3}{n} = O(\frac{1}{n})$.

Then, we bound p_2. If Bob opens first one of the lockers whose contents have been altered by Alice, then there is one remaining locker for him to open, and he has at most as much information as in the *CLR0* protocol. Hence, in this case, $p_2 \leq \mathbf{Pr}[\mathcal{V}(CLR0)]$.

Alternatively, Bob first opens one of the lockers whose contents have not been altered by Alice. This requires a more detailed analysis of the *CLR0* protocol.

Alice's choice of a transposition is informed solely by the initial permutation σ of the cards inside the lockers. Hence, there should be a function $a : \mathbb{S}_n \to \binom{[n-1]}{2}$ which directs Alice to a pair of lockers. Then, Bob's choice of a first locker to open is informed only by his sought number. Thus, there should be a function $b : [n-1] \to [n-1]$ which directs Bob to his first locker. Finally, Bob chooses his second locker by considering his sought number and the content of the first locker, so there should be a function $b' : \{0,1\} \times [n-1]^2 \to [n-1]$ which directs Bob to his second locker (the binary factor distinguishes whether Bob's first locker has had its content altered by Alice or not). The strategy which Alice and Bob employ in the *CLR0* protocol can therefore be identified with a triple $[a, b, b']$.

Let $E_{u,v} = a^{-1}(\{u, v\})$ be the event that Alice transposes the contents of the u^{th} and v^{th} lockers, and let $F_w = b^{-1}(w)$ be the event that Bob opens the w^{th} locker first. Let $s(y, w) \subseteq \mathbb{S}_n$ be the permutations which map w to y, and let G_y be the event that the initial content of Bob's first locker is y. Notice that $\mathbf{Pr}[E_{u,v}|F_w \cap G_y] = \frac{|a^{-1}(\{u,v\}) \cap s(y,w)|}{(n-1)!}$, $\mathbf{Pr}[F_w] = \frac{|b^{-1}(w)|}{n}$, and $\mathbf{Pr}[G_y] = \frac{1}{n}$. Then, the probability that Bob finds his sought number in his second attempt given that his first locker was not altered by Alice is

$$p_2 \leq \sum_{\substack{u,v,w,y \in [n-1] \\ u,v,w \text{ distinct}}} \mathbf{Pr}[E_{u,v}|F_w \cap G_y] \cdot \mathbf{Pr}[F_w] \cdot \mathbf{Pr}[G_y] \cdot \mathbf{Pr}[\mathcal{V}(CLR0)|E_{u,v} \cap F_w \cap G_y] \ .$$

Observe that

$$\mathbf{Pr}[\mathcal{V}(CLR0)|E_{u,v} \cap F_w \cap G_y] \leq \frac{(n-2)!}{\left|\left(\mathbb{S}_n \setminus \bigcup_{\ell \in [n-1]} a^{-1}(\{w, \ell\})\right) \cap s(y, w)\right|} + \frac{2}{n} \ .$$

This holds because, barring the $\frac{2}{n}$ probability for Bob's sought card to be in a locker whose content was changed by Alice, Bob is only going to find his sought card in his second locker if the permutation σ maps both w to y and Bob's second locker to his sought card. There are exactly $(n-2)!$ such permutations, which yields the numerator. For the denominator, when Bob opens the locker w and views the card inside, he sees that its content is y and that it has not been touched by Alice, so he knows that σ is a permutation which maps w to y and which does not prompt Alice to transpose y with some other card, and there are exactly $\left|\left(\mathbb{S}_n \setminus \bigcup_{\ell \in [n-1]} a^{-1}(\{w, \ell\})\right) \cap s(y, w)\right|$ such permutations.

Also, note that

$$\bigcup_{\substack{u,v \in [n-1] \\ u,v,w \text{ distinct}}} (a^{-1}(\{u, v\}) \cap s(y, w)) = (\mathbb{S}_n \setminus \bigcup_{\ell \in [n-1]} a^{-1}(\{w, \ell\})) \cap s(y, w) \Rightarrow$$

$$\sum_{\substack{u,v \in [n-1] \\ u,v,w \text{ distinct}}} |a^{-1}(\{u, v\}) \cap s(y, w)| = |(\mathbb{S}_n \setminus \bigcup_{\ell \in [n-1]} a^{-1}(\{w, \ell\})) \cap s(y, w)| \ .$$

Combining the above, we obtain that

$$p_2 \leq \sum_{\substack{u,v,w,y \in [n-1] \\ u,v,w \text{ distinct}}} \frac{1}{n} \cdot \frac{|a^{-1}(\{u, v\}) \cap s(y, w)|}{(n-1)!} \cdot \frac{|b^{-1}(w)|}{n} \cdot \left(\mathbf{Pr}[\mathcal{V}(CLR0)|E_{u,v} \cap F_w \cap G_y] + \frac{2}{n}\right)$$

$$\leq \sum_{w,y \in [n-1]} \frac{1}{n} \cdot \frac{1}{n-1} \cdot \frac{|b^{-1}(w)|}{n} + \frac{2}{n} = \frac{1}{n-1} + \frac{2}{n} \ .$$

Thus, in this case, $p_2 \leq \frac{4}{n}$.

Ultimately, $p_2 \leq \mathbf{Pr}[\mathcal{V}(CLR1)] + \frac{4}{n}$, and hence $\mathbf{Pr}[\mathcal{V}(CLR0)] \leq p_1 + p_2 \leq \mathbf{Pr}[\mathcal{V}(CLR1)] + O(\frac{1}{n})$, concluding the proof. ◀

▶ **Theorem 21.** $\mathbf{Pr}[\mathcal{V}(CLR)] \leq \frac{(4+o(1))\log n}{n \log\log n}$.

Proof. We use Lemma 20 along with the fact that $\mathbf{Pr}[\mathcal{V}(\textit{NH-with-4logn-bits})] \leq \frac{(4+o(1))\log n}{n\log\log n}$, which can be immediately derived from Theorem 22 in Section 7.1 by setting $m = n^4$. ◀

7 Conclusions and generalizations

In this paper we presented a new search problem and provided a comprehensive analysis of its optimal strategy. The core of our analysis is a novel study of properties of random permutations with a given number of fixed points.

There are several natural generalizations of the problem studied in this paper and related questions about properties of random permutations, which we will discuss in the full version of the paper (cf. `https://arxiv.org/abs/2008.11448`). Here we discuss a couple of them.

7.1 Simple generalization: longer message

In the *needle in a haystack* problem, when Alice sends the message $\mathfrak{h}$ to Bob, there is no reason why she must choose a number in $[n-1]$; instead, she could transmit a number $\mathfrak{h} \in [m-1]$ for an arbitrary integer m. One can easily generalize the analysis from Theorems 5 and 6 in this setting for a large range of m.

Let us denote the maximum attainable sum of intensities received from partitioning $\mathbb{S}_n$ to m parts the *m-field* of $\mathbb{S}_n$, and denote it by $F(n,m)$. Fields are simply diagonal m-fields (fields of the form $F(n,n)$).

We have $F(n,1) = n!$ (yielding a success probability of $\frac{1}{n}$, corresponding to not receiving advice) and $F(n,m) = n \cdot n!$ for every $m \geq n!$ (yielding a success probability of 1, corresponding to obtaining full information). For other values of m we can follow the approach used in Theorem 5. First, notice that there is $\ell = \frac{(1+o(1))\log m}{\log\log m}$, such that $\frac{m}{\ell!} = o(1)$. Then, using the techniques from the proof of Theorem 5, we obtain

$$\begin{aligned} F(n,m) &\leq \sum_{i\in[n-1], j\in[m-1]} \mathsf{int}(A_j, i) \leq \sum_{j\in[m-1]} \left(\ell \cdot |A_j| + \sum_{r=\ell+1}^{n} r \cdot D_{n,r}\right) \\ &\leq \sum_{j\in[m-1]} \left(\ell \cdot |A_j| + \frac{(1+o(1))n!}{\ell!}\right) \leq n! \cdot \left(\ell + \frac{(1+o(1))m}{\ell!}\right) \\ &\leq \ell \cdot n! \cdot (1+o(1)) = \frac{(1+o(1))\log m}{\log\log m} \cdot n! \ .r \end{aligned}$$

By (2), this yields the success probability of $\frac{(1+o(1))\log m}{n\log\log m}$, giving the following theorem.

▶ **Theorem 22.** *If Alice can choose a number $\mathfrak{h} \in [m]$, then the maximum attainable success probability is at most $\frac{(1+o(1))\log m}{n\log\log m}$. In particular, if $m = poly(n)$, then the maximum attainable success probability is at most $O\left(\frac{\log n}{n\log\log n}\right)$.*

Observe that Theorem 22 implies that since for the algorithm presented in Theorem 6, that is, one using the shift strategy with hint $\mathfrak{h} \in [n]$, the success probability is already $\Omega\left(\frac{\log n}{n\log\log n}\right)$, the shift strategy is asymptotically optimal to within a constant factor for

any hint $\mathfrak{h}$ polynomial in n. A similar conclusion holds also for the communication in the locker room setting: even if Alice leaves Bob a message by altering the contents of a constant number c of lockers rather than just one, this message is $c \log n$ bits long, and hence the success probability is still at most $O(\frac{\log n}{n \log \log n})$.

Asymptotic results for several other interesting domains of m could be found in a similar way. However, for super-polynomial domains, the upper bound derived in the above manner is far away from the lower bound that we currently can provide in Theorem 6. Determining some properties of the rate of growth of $F(n, m)$ for fixed n would be a good step towards determining its values. With this in mind, we have the following natural conjecture.

▶ **Conjecture 23.** *For any fixed n, the function $f(m) = F(n, m)$ is concave.*

7.2 Optimal strategies

Although we have successfully calculated the maximum field and the maximum success probability for the *needle in a haystack* problem, the problem of determining a characterization of, or at least some major properties for, optimal strategies remains. Indeed, the only optimal strategy that we have explicitly described so far is the shift strategy (which is in fact a set of different strategies, since, for permutations which have several $S_{\mathfrak{h}}$'s of maximum size, there are multiple legitimate options for their class). A natural generalization of shift strategies are *latin strategies*; in these, Alice and Bob decide on a $n \times n$ latin square S, and Alice's message indicates the row of S which coincides with σ at the maximum number of places.

We present a couple of interesting questions concerning the optimal strategies for $\mathbb{S}_n$ in *needle in a haystack*.

▶ **Conjecture 24.** *For every natural number n, there is an optimal strategy for $\mathbb{S}_n$ whose parts all contain exactly $(n-1)!$ permutations.*

▶ **Conjecture 25.** *Optimal strategies are exactly latin strategies.*

Abstract

In the *adaptive influence maximization problem*, we are given a social network and a budget k, and we iteratively select k nodes, called seeds, in order to maximize the expected number of nodes that are reached by an influence cascade that they generate according to a stochastic model for influence diffusion. The decision on the next seed to select is based on the observed cascade of previously selected seeds. We focus on the *myopic feedback model*, in which we can only observe which neighbors of previously selected seeds have been influenced and on the *independent cascade* model, where each edge is associated with an independent probability of diffusing influence. While adaptive policies are strictly stronger than non-adaptive ones, in which all the seeds are selected beforehand, the latter are much easier to design and implement and they provide good approximation factors if the adaptivity gap, the ratio between the adaptive and the non-adaptive optima, is small. Previous works showed that the adaptivity gap is at most 4, and that simple adaptive or non-adaptive greedy algorithms guarantee an approximation of $\frac{1}{4}\left(1-\frac{1}{e}\right) \approx 0.158$ for the adaptive optimum. This is the best approximation factor known so far for the adaptive influence maximization problem with myopic feedback.

In this paper, we directly analyze the approximation factor of the non-adaptive greedy algorithm, without passing through the adaptivity gap, and show an improved bound of $\frac{1}{2}\left(1-\frac{1}{e}\right) \approx 0.316$. Therefore, the adaptivity gap is at most $\frac{2e}{e-1} \approx 3.164$. To prove these bounds, we introduce a new approach to relate the greedy non-adaptive algorithm to the adaptive optimum. The new approach does not rely on multi-linear extensions or random walks on optimal decision trees, which are commonly used techniques in the field. We believe that it is of independent interest and may be used to analyze other adaptive optimization problems. Finally, we also analyze the adaptive greedy algorithm, and show that guarantees an improved approximation factor of $1-\frac{1}{\sqrt{e}} \approx 0.393$.

1 Introduction

In the Influence Maximization (IM) problem, we are given a social network, a stochastic model for diffusion of influence over the network, and a budget k, and we ask to find a set of k nodes, called *seeds*, that maximize their *spread of influence*, which is the expected number of nodes reached by a cascade of influence diffusion generated by the seeds according to the given diffusion model. One of the most studied models for influence diffusion is the Independent Cascade (IC), where each edge is associated with an independent probability of transmitting influence from the source node to the tail node. In the IC model the spread of influence is a monotone submodular function of the seed set, therefore a greedy algorithm, which iteratively selects a seed with maximum marginal gain, guarantees a $1 - \frac{1}{e}$ approximation factor for the IM problem [34]. Since its definition by Domingos and Richardson [19, 40] and formalization as an optimization problem by Kempe et al. [33, 34], the IM problem and its variants have been extensively investigated, motivated by applications in viral marketing [13], adoption of technological innovations [24], and outbreak or failure detection [35]. See [10, 36] for surveys on the IM problem.

Recently, Golovin and Krause [25] initiated the study of the IM problem under the framework of adaptive optimization, where, instead of selecting all the seeds at once at the beginning of the process, we can select one seed at a time and observe, to some extent, the portion of the network reached by a new selected seed. The advantage is that the decision on the next seed to choose can be based on the observed spread of previously selected seeds, usually called *feedback*. Two main feedback models have been introduced: in the *full-adoption* feedback the whole spread from each seed can be observed, while, in the *myopic* feedback, one can only observe the direct neighbors of each seed.

Golovin and Krause [25] considered the Independent Cascade model and showed that, under full-adoption feedback, the objective function satisfies the property of *adaptive submodularity* (introduced in the same paper) and therefore an adaptive greedy algorithm achieves a $1 - \frac{1}{e}$ approximation factor for the adaptive IM problem. In their arXiv version, they retracted a claim (appeared in their previous conference version) in which they mistakenly showed that the adaptive submodularity holds even under the myopic feedback model, and this property would have guaranteed that the adaptive greedy is a constant factor approximation algorithm (under the myopic feedback model). Anyway, they conjectured that there exists a constant factor approximation algorithm for the myopic feedback model, which indeed has been found by Peng and Chen [39] who showed that both the adaptive and non-adaptive greedy algorithms guarantee a $\frac{1}{4}\left(1 - \frac{1}{e}\right)$-approximation. In particular, they showed that the adaptivity gap, which is the supremum, over all possible inputs, of the ratio between the spread of an optimal adaptive policy and that of an optimal non-adaptive one, is upper-bounded by 4. By combining this bound with the approximation factor of both the adaptive and non-adaptive greedy algorithms for the non-adaptive problem they obtain a $\frac{1}{4}\left(1 - \frac{1}{e}\right)$-approximation factor. To prove their upper-bound on the adaptivity gap, Peng and Chen use an approach that is inspired by Bradac et al. [6], which in turn is based on the approach introduced by Gupta et al. [29, 30] in the context of stochastic probing. To relate a non-adaptive solution to an optimal adaptive one, they consider the decision tree of an optimal adaptive solution and construct a non-adaptive policy by performing a random root-leaf walk in the tree, according to a probability distribution induced by the tree. Note that computing the non-adaptive policy that guarantees the upper-bound on the adaptivity gap would require to know an optimal decision tree. However, this approach only requires to show the existence of such a non-adaptive policy since it allows us to bound

the adaptivity gap and non-adaptive approximation factor is obtained by combining the non-adaptive approximation factor with the adaptivity gap. In the same paper, Peng and Chen showed that both the adaptive greedy and the non-adaptive greedy algorithms cannot achieve a factor better than $\frac{e^2+1}{(e+1)^2} < 0.607 < 1 - \frac{1}{e}$ of the adaptive optimum, and that the adaptivity gap is at least $\frac{e}{e-1} \approx 1.582$.

In [11], the same authors showed some upper and lower bounds on the adaptivity gap in the case of full-adoption feedback, still under independent cascade, for some particular graph classes. In order to show these bounds, they followed an approach introduced by Asadpour and Nazerzadeh [3] which consists in transforming an adaptive policy into a non-adaptive one by means of multilinear extensions, and constructing a Poisson process to relate the influence spread of the non-adaptive policy to that of the adaptive one. For general graphs, a non-constant upper bound for the adaptivity gap under the full-adoption feedback has been recently shown in [16].

Our Contribution

In this paper, we focus on the myopic model and analyze the approximation factor of the non-adaptive greedy algorithm without passing through the adaptivity gap. We show that the algorithm achieves at least a fraction of $\frac{1}{2}\left(1 - \frac{1}{e}\right) \approx 0.316$ of the adaptive optimum (Theorem 5). By definition, this implies that the adaptivity gap is at most $\frac{2e}{e-1} \approx 3.164$ (Remark 12). For both approximation ratio and adaptivity gap we obtain a substantial improvement with respect to the upper bounds obtained in [39], which are $\frac{1}{4}\left(1 - \frac{1}{e}\right) \approx 0.158$ and 4, respectively.

Non-adaptive policies are strictly weaker than adaptive ones, since the latter can implement the former by simply ignoring any kind of feedback. On the other hand, adaptive policies are difficult to implement as they require to probe suitable seeds and to observe the corresponding feedback, which can be expensive and error-prone. Moreover, they may consist of exponentially-large decision trees that are hard to compute and store. In contrast, non-adaptive policies are easy to design and implement and are independent from the feedback. In particular, the non-adaptive greedy algorithm has been extensively studied and successfully applied in the field of influence maximization. For the non-adaptive setting, several efficient implementation of the greedy algorithm have been devised that allows us to use it in large real-world networks [14, 27, 35, 37, 47, 48]. Our results show that the simple non-adaptive greedy algorithm performs well, even in the adaptive setting where we compare it with the adaptive optimum.

To show our bounds, we introduce a new approach that relate the non-adaptive greedy policy to an optimal adaptive solution. The new approach is not based on multilinear extensions and poisson processes (like, e.g. [3, 7, 9, 11]) neither on random walks on the optimal decision trees (like, e.g. [6, 29, 30, 39]), which are the main tools used so far to relate adaptive and non-adaptive policies, and to bound adaptivity gaps. Previous techniques derive adaptive approximation factors by combining non-adaptive approximation ratios with a bound on the adaptivity gap which is obtained by showing the existence of a "good" non-adaptive policy. However such a policy is hard to compute as it is usually constructed by using an optimal adaptive policy. Our approach, instead, directly analyzes a non-adaptive policy and therefore provides the exact policy that gives the desired adaptivity gap and adaptive approximation factor. We believe that our approach is of independent interest and may be used to bound approximation factors and adaptivity gaps of different adaptive optimization problems.

Our new approach consists in defining a simple randomized non-adaptive policy whose performance is not higher than that guaranteed by the greedy algorithm, and to relate such randomized non-adaptive policy with the optimal adaptive policy. In order to recover good properties of the objective function (like, e.g. submodularity) that usually guarantee good approximations when adopting greedy strategies, we introduce an artificial diffusion process in which each seed has two chances to influence its neighbours. A similar process was introduced by Peng and Chen [39], who consider a diffusion model in which the seeds appear in multiple copies of the influence graphs, so that, roughly speaking, each node has several chances to influence the neighbours, and the main machinery they consider to relate optimal adaptive strategies with optimal non-adaptive ones is that in [6]. Our direct and more refined analysis of the non-adaptive greedy algorithm improves at the same time both the approximation ratio and the adaptivity gap.

To illustrate our approach, in Section 2 we first apply our machinery to the simpler setting of adaptive monotone submodular maximization under cardinality constraint. As observed by Asadpour and Nazerzadeh [3], a constant factor approximation of the non-adaptive greedy policy applied to such setting can be obtained by combining the approximation ratio over the non-adaptive optimum and the adaptivity gap (which is equal to $\left(1-\frac{1}{e}\right)$ [3]); this leads to an approximation guarantee of $\left(1-\frac{1}{e}\right)^2 \approx 0.399$. We give a more refined analysis of the non-adaptive greedy policy and we show that its approximation ratio is at least $\frac{1}{2}\left(1-\frac{1}{e^2}\right) \approx 0.432$. Asadpour and Nazerzadeh [3] also showed that a so-called continuous greedy policy [7, 9] achieves an approximation ratio of $1-\frac{1}{e}-\epsilon$ (in polynomial time w.r.t. $\frac{1}{\epsilon}$). Since the continuous greedy policy is a non-adaptive policy, this bound is strictly better than ours. However, the non-adaptive greedy policy is simpler and deterministic, while the continuous greedy policy is randomized and more complex.

Finally, in Section 5, we analyze the adaptive version of the greedy algorithm applied to the adaptive influence maximization problem; by resorting again to an artificial diffusion process, we show that such adaptive algorithm guarantees an approximation ratio of $1-\frac{1}{\sqrt{e}} \approx 0.393$; thus, we further improve the upper bound shown for the non-adaptive greedy algorithm, and we also give a more refined analysis of the adaptive greedy algorithm than that of Peng and Chen [39], who showed a $\frac{1}{4}\left(1-\frac{1}{e}\right) \approx 0.158$ approximation factor.

Due to the lack of space, some proofs are deferred to the full version of the paper [15].

Related Work

Adaptive Influence Maximization. The adaptive influence maximization problem under the independent cascade model has been studied by [11, 12, 31, 39, 45, 46, 49, 51, 52, 53]. These include studies on several classes of graphs and different feedback models.

The most studied feedback model is the full-adoption feedback, in which the entire influence spread generated by each selected node is observed. Golovin and Krause [25] show that the full-adoption feedback model satisfies the adaptive submodularity property and, by exploiting such property, provide a $(1-1/e)$ approximation adaptive algorithm for the problem of finding the best adaptive policy. Chen and Peng [11] study the adaptivity gap in the full-adoption feedback model under certain restrictions on the graph topology. In particular, they show that the adaptivity gap of in-arborescence (resp. out-arborescence) graphs belongs to $[e/(e-1), 2e/(e-1)]$ (resp. $[e/(e-1), 2]$). For general graphs with n nodes (resp. in-arborescence graphs), an upper bound of $O(n^{1/3})$ (resp. $2e^2/(e^2-1)$) for the adaptivity gap under the full-adoption feedback has been recently shown in [16].

Golovin and Krause [25] conjectured that the influence maximization problem under the myopic feedback model admits a constant approximation algorithm and a constant adaptivity gap, despite the adaptive submodularity does not hold under such feedback model. Since

then, several studies have been conducted on the myopic feedback model. Some recent works include that of Salha et al. [42], in which they consider a modified version of the independent cascade model which gives multiple chances to the seeds to activate their neighbours, and consider a different utility function which needs to maximized. They demonstrate that the myopic feedback model is adaptive submodular under such modified diffusion model, and provide an adaptive greedy policy that achieves a $1 - 1/e$ approximation ratio for the problem of finding the best adaptive policy. The work of Peng and Chen [39] is the first one that provides a constant upper bound on the adaptivity gap under the myopic feedback model. They introduce a policy in which each seed appears in multiple copies of the original graph; furthermore, this hybrid policy connects the adaptive and the non-adaptive policies via a machinery used by [29, 30, 6] in the context of stochastic probing. They show that the adaptivity gap is in $[e/(e-1), 4]$, and the upper bound is turned into $(1 - 1/e)/4$ approximation algorithm.

Other diffusion and feedback models have been also studied, e.g., the multi-round diffusion model [45], the general feedback model [49], and the partial feedback model [53]. Han et al. [31] conduct a study on the batch selection of seeds at each step of the diffusion process. Tong et al. [50] introduce the dynamic independent cascade model, which captures the dynamic nature of real-world social networks. Finally, Singer et al. [5, 41, 43, 44], in their line of research on adaptivity gaps, studied a two-stage process called adaptive seeding, that exhibits some similarities with the influence maximization problem under the myopic feedback model.

Other Topics in Adaptive Optimization. Beyond influence maximization problems, the adaptive optimization and the adaptivity gap have been generally studied for many other stochastic settings [1, 2, 3, 4, 6, 8, 17, 18, 20, 21, 22, 23, 25, 26, 28, 29, 30, 32, 38].

A general adaptive optimization framework deals with the fact that an item will reveal its actual state only when it has been irrevocably included in the final solution, and the main goal is to optimize an objective function under such uncertainty. Stochastic variants of packing integer programs, 0/1 knapsack problems, and covering problems, have been studied under the perspective of adaptive optimization in [17, 18, 23], respectively.

Asadpour et al. [3, 4] study the adaptivity gap of the stochastic submodular maximization problem under a matroid constraint, in which the goal is to select a subset of items satisfying a matroid constraint, that maximizes the value of a monotone submodular value function defined on the random states of the selected items. In [3], the authors consider an adaptive greedy policy (often denoted as myopic policy) to approximate the optimal value of the best adaptive policy, and they show that it achieves a $1/2$ approximation ratio under general matroid constraint, and a $1 - \frac{1}{e}$ approximation ratio under cardinality constraint. Interesting variants or extensions of the above optimization problem have been considered in [6, 29, 30].

Chan and Farias [8] study the efficiency of adaptive greedy policies applied to a general class of stochastic optimization problems, called stochastic depletion problems, in which the adaptive policy, at each step, chooses an action that generates a reward and depletes some of the items; they show that, under certain structural properties, a simple adaptive greedy policy guarantees a constant factor approximation of the best adaptive policy. Hellerstein et al. [32] use an optimal decision tree to build a connection between the adaptive and the non-adaptive policies, and show that the adaptivity gap of stochastic submodular maximization under cardinality constraint is $1 - \frac{1}{e^\tau}$, where τ is the minimum value of the probability that an item is in some state.

Organization of the Paper

In the next section we introduce our new approach by applying it to a simpler setting. In Section 3 we introduce the adaptive influence maximization problem along with the necessary notation and definitions. In Section 4 we give the main results of the paper, that is the improved approximation factor for the non-adaptive greedy algorithm and the upper bound on the adaptivity gap for adaptive influence maximization. In Section 5 we show an improved approximation ratio for the adaptive greedy algorithm. In Section 6 we outline possible research directions.

2 Overview of the Approach: Stochastic Submodular Maximization

In this section, we illustrate our machinery by applying part of it to the problem of maximizing a stochastic submodular set function under cardinality constraints [3].

For two integers h and k, $h \leq k$, let $[k]_h := \{h, h+1, \ldots, k\}$ and $[k] := [k]_1$. A function $f : \mathbb{R}^n_{\geq 0} \to \mathbb{R}_{\geq 0}$ is *a monotone submodular value function* if, for any vectors $x, y \in \mathbb{R}_{\geq 0}$, we get $f(x \vee y) + f(x \wedge y) \leq f(x) + f(y)$, where $x \wedge y$ denotes the componentwise minimum and $x \vee y$ denotes the componentwise maximum.

Let $[n]$ be a finite set of n items, and let $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_n)$ be a vector of n real, non-negative, and independent *state* random variables, where each $\boldsymbol{\theta}_i$ returns the state $\theta_i \in \mathbb{R}_{\geq 0}$ associated to each item i following a certain probability distribution. Let $f : \mathbb{R}^n_{\geq 0} \to \mathbb{R}_{\geq 0}$ be the *objective function*, that is a monotone submodular value function. For any $S \subseteq [n]$, let $\boldsymbol{\theta}(S) := (\boldsymbol{\theta}_1(S), \ldots, \boldsymbol{\theta}_n(S))$ be the *partial state* random variable, that is a random vector defined as $\boldsymbol{\theta}_i(S) = \boldsymbol{\theta}_i$ if $i \in S$, $\boldsymbol{\theta}_i(S) = 0$ otherwise. With a little abuse of notation, we assume that vector $\boldsymbol{\theta}(S)$ gives also information on the set S which $\boldsymbol{\theta}(S)$ is based on.

For a given integer $k \geq 0$, we aim at selecting a subset $S \subseteq [n]$ subject to cardinality constraint $|S| = k$, that maximizes the expected value $\mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S))]$. To guarantee a (possibly) better solution we can resort to an *adaptive policy*, that, at each step, observes the partial state $\xi \sim \boldsymbol{\theta}(U)$, where U denotes the set of items previously selected, and selects another further item $\pi(\xi) \in [n] \setminus U$; after k iterations, the policy returns a set $U_{\boldsymbol{\theta},k}(\pi) \subseteq [n]$ with $|U_{\boldsymbol{\theta},k}(\pi)| = k$, which is a random set depending on the state of $\boldsymbol{\theta}$. The *stochastic monotone submodular maximization problem* (SMSM) takes as input a set of items $[n]$, a random vector $\boldsymbol{\theta}$, a monotone submodular value function f, and an integer $k \in [n]$, and asks to find an adaptive policy π that maximizes the expected value $\mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(U_{\boldsymbol{\theta},k}(\pi)))]$.

In general, computing an optimal adaptive strategy is a computationally hard problem. Furthermore, in many contexts it is difficult to implement adaptive strategies, and non-adaptive strategies (in which the solution is chosen without observing the states of the random variables) is a more feasible choice. Asadpour and Nazerzadeh [3] show that a non-adaptive randomized continuous greedy algorithm guarantees a $\left(1 - \frac{1}{e} - \epsilon\right)$ approximation for the SMSM problem (in polynomial time w.r.t. $1/\epsilon$); however, the proposed approach resorts to a quite sophisticated randomized algorithm. They also consider a simpler and deterministic *non-adaptive greedy algorithm* as approximation algorithm, that starts from an empty set $S := \emptyset$ and, at each iteration $t \in [k]$, adds in S the item $i \in [n] \setminus S$ maximizing $\mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S \cup \{i\}))]$. They show that the greedy algorithm guarantees an approximation factor of $\frac{1}{2}\left(1 - \frac{1}{e}\right) \approx 0.316$ if the chosen subsets are subject to a matroid constraint, that can be reduced to $\left(1 - \frac{1}{e}\right)^2 \approx 0.399$ when considering a cardinality constraint $|S| \leq k$ only (i.e., uniform matroid constraint).

In the following theorem, we give a better analysis of the greedy algorithm under cardinality constraints, and we show that the approximation factor increases to $\frac{1}{2}\left(1 - \frac{1}{e^2}\right) \approx 0.432$.

▶ **Theorem 1.** *The non-adaptive greedy algorithm is a* $\frac{1}{2}\left(1-\frac{1}{e^2}\right)$ *approximation algorithm for the SMSM problem.*

For the proof of Theorem 1 we relate the non-adaptive greedy solution with the optimal adaptive solution. We assume w.l.o.g that $k \geq 2$, otherwise the approximation ratio is equal to 1. For any $t \in [k]_0$, let S_t be the set of t items computed by the greedy algorithm at iteration t (where $S_0 := \emptyset$). Let π be an optimal adaptive policy, and let $x = (x_1, \ldots, x_n) \in [0,1]^n$ be the vector such that x_i is the probability that node $i \in [n]$ is selected by policy π. Let $OPT_A(k)$ denote the value of policy π (i.e., the optimal value of the problem). Given $i \in [n]$, let $\boldsymbol{e}^i := (\boldsymbol{e}^i_1, \ldots, \boldsymbol{e}^i_n)$ be a random vector where $\boldsymbol{e}^i_j$ has the same distribution of $\boldsymbol{\theta}_i$ if $i = j$, and $\boldsymbol{e}^i_j = 0$ otherwise; given a partial state ξ, let $\Delta(i|\xi) := \mathbb{E}_{\boldsymbol{e}^i}[f(\xi \vee \boldsymbol{e}^i) - f(\xi)]$, i.e., the expected increment of the objective function when adding an item i under partial state ξ.

For any $t \in [k-1]_0$, as intermediate step of our analysis, we consider a *randomized non-adaptive policy* Rand_t that, starting from the greedy solution S_t, computes a random set $S_{\boldsymbol{\rho},t} := S_t \cup \{\boldsymbol{\rho}\}$, where $\boldsymbol{\rho} \in [n]$ is a random item such that $\mathbb{P}[\boldsymbol{\rho} = i] = x_i/k$ for any $i \in [n]$ and selected independently from any other event. Observe that the above random variable is well-defined, as $\sum_{v \in V}(x_v/k) = k/k = 1$; furthermore, we observe that the expected value of f under Rand_t is $\mathbb{E}_{\boldsymbol{\theta},\boldsymbol{\rho}}[f(\boldsymbol{\theta}(S_{\boldsymbol{\rho},t})]$. Furthermore, for any $t \in [k-1]_0$, we consider a *hybrid adaptive policy* Hyb_t, that first runs the adaptive policy π, and then merges the items of S_t with the items of $U_{\hat{\boldsymbol{\theta}},k}(\pi)$ selected by π, where $\hat{\boldsymbol{\theta}}$ is a random state that follows the same distribution of $\boldsymbol{\theta}$ but is independent from $\boldsymbol{\theta}$; finally, the expected value of f under Hyb_t is defined as $\mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S_t) \vee \hat{\boldsymbol{\theta}}(U_{\hat{\boldsymbol{\theta}},k}(\pi) \cup S_t))]$. A similar hybrid adaptive policy has been also considered by Asadpour and Nazerzadeh [3], but in place of the randomized non-adaptive policy considered in our work, they resort to a non-adaptive strategy defined by a Poisson process based on the multilinear extension of the expected value function $\mathbb{E}_{\boldsymbol{\theta}}[f(*)]$. Before showing the theorem, we give some preliminary lemmas, which relate the randomized non-adaptive policy with the hybrid adaptive policy.

▶ **Lemma 2.** *We have that* $\mathbb{E}_{\boldsymbol{\theta},\boldsymbol{\rho}}[f(\boldsymbol{\theta}(S \cup \{\boldsymbol{\rho}\}))] - \mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S))] = \sum_{i \in [n]\setminus S} x_i \cdot \mathbb{E}_{\boldsymbol{\theta}}[\Delta(i|\boldsymbol{\theta}(S))]$ *for any* $S \subseteq [n]$.

▶ **Lemma 3.** *For any* $S \subseteq [n]$, *we have* $\mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S) \vee \hat{\boldsymbol{\theta}}(U_{\hat{\boldsymbol{\theta}},k}(\pi) \cup S))] \leq \mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S) \vee \hat{\boldsymbol{\theta}}(S)] + \sum_{i \in [n]\setminus S} x_i \cdot \mathbb{E}_{\boldsymbol{\theta}}[\Delta(i|\boldsymbol{\theta}(S))]$.

▶ **Lemma 4.** *We have that* $OPT_A(k) \leq \mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S) \vee \hat{\boldsymbol{\theta}}(U_{\hat{\boldsymbol{\theta}},k}(\pi) \cup S))]$ *for any* $S \subseteq [n]$.

Armed with the above lemmas, we can prove Theorem 1.

Proof of Theorem 1. For any $t \in [k]_0$, let $GR_N(t) := \mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S_t))]$ denote the expected value of f obtained at the t-th iteration of the non-adaptive greedy algorithm. We have that

$$GR_N(t+1) - GR_N(t) = \max_{v \in V}\left[\mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(\{v\} \cup S_t))]\right] - \mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S_t))] \tag{1}$$

$$\geq \overbrace{\mathbb{E}_{\boldsymbol{\theta},\boldsymbol{\rho}}[f(\boldsymbol{\theta}(S_t \cup \{\boldsymbol{\rho}\}))]}^{\text{Exp. value of } \mathsf{Rand}_t} - \mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S_t))]$$

$$\geq \frac{1}{k} \cdot \sum_{i \in [n]\setminus S_t} x_i \cdot \mathbb{E}_{\boldsymbol{\theta}}[\Delta(i|\boldsymbol{\theta}(S_t))] \tag{2}$$

$$\geq \frac{1}{k} \cdot \left(\overbrace{\mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S_t) \vee \hat{\boldsymbol{\theta}}(U_{\hat{\boldsymbol{\theta}},k}(\pi) \cup S_t))]}^{\text{Exp. value of } \mathsf{Hyb}_t} - \mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S_t) \vee \hat{\boldsymbol{\theta}}(S_t))] \right) \tag{3}$$

$$\geq \frac{1}{k} \cdot \Big(OPT_A(k) - \mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S_t) \vee \hat{\boldsymbol{\theta}}(S_t))] \Big) \tag{4}$$

$$\geq \frac{1}{k} \cdot OPT_A(k) - \frac{1}{k} \cdot \left(\mathbb{E}_{\boldsymbol{\theta},\hat{\boldsymbol{\theta}}}[f(\boldsymbol{\theta}(S_t)) + f(\hat{\boldsymbol{\theta}}(S_t))]\right) \tag{5}$$

$$\geq \frac{1}{k} \cdot OPT_A(k) - \frac{1}{k} \cdot \left(\mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S_t))] + \mathbb{E}_{\hat{\boldsymbol{\theta}}}[f(\hat{\boldsymbol{\theta}}(S_t))]\right) = \frac{1}{k} \cdot OPT_A(k) - \frac{2}{k} \cdot \mathbb{E}_{\boldsymbol{\theta}}[f(\boldsymbol{\theta}(S_t)]$$

$$= \frac{1}{k} \cdot OPT_A(k) - \frac{2}{k} \cdot GR_N(t), \tag{6}$$

where (1) comes from the fact that the greedy strategy, at iteration $t+1$, adds to S_t the item i guaranteeing the best expected value of f, (2) comes from Lemma 2, (3) comes from Lemma 3, (4) comes from Lemma 4, and (5) holds since f is a monotone submodular value function (as $f(\boldsymbol{\theta}(S_t)\vee\hat{\boldsymbol{\theta}}(S_t)) \leq f(\boldsymbol{\theta}(S_t)\vee\hat{\boldsymbol{\theta}}(S_t))+f(\boldsymbol{\theta}(S_t)\wedge\hat{\boldsymbol{\theta}}(S_t)) \leq f(\boldsymbol{\theta}(S_t))+f(\hat{\boldsymbol{\theta}}(S_t))$). Thus, by (6) and some manipulations, we get $GR_N(t+1) \geq \frac{1}{k}\cdot OPT_A(k)+\left(1-\frac{2}{k}\right)\cdot GR_N(t)$ for any $t \in [k-1]_0$. By applying iteratively the above inequality, we get $GR_N(k) \geq \frac{1}{k}\cdot\sum_{t=0}^{k-1}\left(1-\frac{2}{k}\right)^t\cdot OPT_A(k) = \frac{1}{2}\left(1-\left(1-\frac{2}{k}\right)^k\right)\cdot OPT_A(k)$, that leads to $\frac{GR_N(k)}{OPT_A(k)} \geq \frac{1}{2}\left(1-\left(1-\frac{2}{k}\right)^k\right) \geq \frac{1}{2}\left(1-\frac{1}{e^2}\right)$, and this shows the claim. ◀

3 Adaptive Influence Maximization under the Myopic Feedback Model: Preliminaries

Independent Cascade Model. In the *independent cascade model* (IC), we have an *influence graph* $G = (V = [n], E, (p_{uv})_{(u,v)\in E})$, where edges are directed and $p_{uv} \in [0,1]$ is an *activation probability* associated to each edge $(u,v) \in E$. Given a set of *seeds* $S \subseteq V$ which are initially *active*, the diffusion process in the IC model is defined in $t \geq 0$ discrete steps as follows: (i) let A_t be the set of active nodes which are activated at each step $t \geq 0$; (ii) $A_0 := S$; (iii) given a step $t \geq 0$, for any edge (u,v) such that $u \in A_t$, node u can activate node v with probability p_{uv} independently from any other node, and, in case of success, v is included in A_{t+1}; (iv) the diffusion process ends at a step $r \geq 0$ such that $A_r = \emptyset$, i.e., no node can be activated at all. The size of $\bigcup_{t\leq r} A_t$, i.e. the number of nodes activated/reached by the diffusion process, is the *influence spread*.

The above diffusion process can be equivalently defined as follows. The *live-edge graph* $\boldsymbol{L} = (V, \boldsymbol{L}(E))$ is a random graph made from G, such that each edge $(u,v) \in E$ is included in $\boldsymbol{L}(E)$ with probability p_{uv}, independently from the other edges, i.e., $\mathbb{P}[\boldsymbol{L} = L] = \prod_{(u,v)\in L} p_{uv} \prod_{(u,v)\in E\setminus L}(1-p_{uv})$. With a little abuse of notation, we may denote $\boldsymbol{L}(E)$ with $\boldsymbol{L}$. Given $L \subseteq E$, let $R_L(S) := \{v \in V :$ there exists a path from u to v in L for some $u \in S\}$, i.e., the set of nodes reached by nodes in S in the graph L. Informally, if S is the set of seeds, and L is a realisation of the live-edge graph, $R_L(S)$ equivalently denotes the set of nodes which are reached/activated by the above diffusion process. Let $\sigma_L(S) := |R_L(S)|$ denote the *influence spread* generated by the set of seeds S if the realised live-edge graph is L, and let $\sigma(S) := \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(S)]$ be the *expected influence spread* generated by S.

Non-adaptive Influence Maximization. The *non-adaptive influence maximization problem under the IC model* is the computational problem that, given an influence graph G and an integer $k \geq 1$, asks to find a set of seeds $S \subseteq V$ with $|S| \leq k$ such that $\sigma(S)$ is maximized. Without loss of generality, we assume that $k \in [n]$ and, since the objective function is monotone, $|S| = k$ for any solution S.

Kempe et al. [33, 34] showed that function σ is monotone and submodular, therefore the following greedy algorithm achieves a $1-\frac{1}{e}$ approximation factor: (i) start with an empty set of seeds $S := \emptyset$; (ii) at each iteration $t \in [k]$, add to S the node v that maximizes the expected influence spread $\sigma(S \cup \{v\})$. Note that the greedy algorithm requires at each

iteration to compute the value of function σ, for some set of seeds and this has been shown to be computationally intractable as it is $\#P$-hard [13]. However, standard Chernoff bounds allows us estimate the value of σ through a polynomial number of Monte-Carlo simulations by introducing an arbitrarily small additive error $\epsilon > 0$, which depends on the number of simulations [34]. In the reminder of the paper we will omit the additional term ϵ to avoid unnecessary complicated formulas. We will refer to this algorithm as the *non-adaptive greedy algorithm*.

Adaptive Influence Maximization. Differently from the non-adaptive setting, in which all the seeds are selected at the beginning, an *adaptive policy* activates the seeds sequentially in k steps, one seed at each step, and the decision on the next seed to select is based on the feedback resulting from the observed spread of previously selected nodes. The feedback model considered in this work is *myopic*: when a node is selected, the adaptive policy observes the state of its neighbours.

An adaptive policy under the myopic feedback model is formally defined as follows. Given $L \subseteq E$, the *realisation* $\phi_L : V \to 2^V$ associated to L assigns to each node $v \in V$ the value $\{z \in V : (v, z) \in L\} \cup \{v\}$, i.e., the set containing v and the neighbours activated by seed v when $\boldsymbol{L} = L$. Let Φ denote the *random realisation*, i.e., the random variable such that $\mathbb{P}[\Phi = \phi_L] = \mathbb{P}[\boldsymbol{L} = L]$ for any $L \subseteq E$. Given a set $S \subseteq V$, a *partial realisation* $\psi : S \to 2^V$ is the restriction to S of the domain of some realisation, i.e., there exists $L \subseteq E$ such that $\psi(v) = \phi_L(v)$ for any $v \in S$. Given a partial realisation $\psi : S \to 2^V$, let $dom(\psi) := S$, i.e., $dom(\psi)$ is the domain of partial realisation ψ, and let $Im(\psi) := \bigcup_{v \in dom(\psi)} \psi(v)$. A partial realisation ψ' is a *sub-realisation* of a partial realisation ψ (or, equivalently, $\psi' \subseteq \psi$), if $dom(\psi') \subseteq dom(\psi)$ and $\psi'(v) = \psi(v)$ for any $v \in dom(\psi')$. We observe that any partial realisation ψ can be equivalently represented as $\{(v, \phi_L(v)) : v \in dom(\psi)\}$ for some $L \subseteq E$.

An adaptive policy π takes as input a partial realisation ψ and, either returns a node $\pi(\psi) \in V$ and activates it as seed, or interrupts the activation of new seeds, e.g., by returning a string $\pi(\psi) := STOP$. In particular, an adaptive policy π can be run as follows: (i) start from an empty realisation $\psi := \emptyset$; (ii) if $\pi(\psi) \neq STOP$ set $\psi \leftarrow \psi \cup \{(v, \phi_L(v))\}$ and repeat (ii) until $\pi(\psi) = STOP$; (iii) at the end, return $\psi_\pi := \psi$. Let Ψ_π be the random partial realisation returned by the execution of policy π. The *expected influence spread* of an adaptive policy π is defined as $\sigma(\pi) := \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(dom(\Psi_\pi))]$, i.e., it is the expected value of the number of nodes reached by the diffusion process at the end of the execution of policy π. We say that $|\pi| = k$ if policy π always return a partial realisation ψ_π with $|dom(\psi_\pi)| = k$. The *adaptive influence maximization problem (under IC and myopic feedback)* is the computational problem that, given an influence graph G and $k \in [n]$, asks to find an adaptive policy π subject to $|\pi| = k$ that maximizes the expected influence spread $\sigma(\pi)$.

Adaptivity gap. Given an influence graph G and an integer $k \geq 1$, let $OPT_N(G, k)$ (resp. $OPT_A(G, k)$) denote the optimal value of the non-adaptive (resp. adaptive) influence maximization problem with input G and k. Given an integer $k \in [n]$, the *k-adaptivity gap* of G is defined as $AG(G, k) := \frac{OPT_A(G,k)}{OPT_N(G,k)}$, and measures how much an adaptive policy outperforms a non-adaptive solution for the influence maximization problem applied to influence graph G, when the maximum number of seeds is k. The *adaptivity gap* of G is defined as $AG(G) := \sup_{k \in [n]} AG(G, k)$. We observe that for $k = 1$ the k-adaptivity gap and the approximation factors are trivially equal to 1, thus we omit such case in the following.

4 The Efficiency of the Non-adaptive Greedy Algorithm

In this section, we show that a simple non-adaptive algorithm guarantees an approximation ratio of $\frac{1}{2}\left(1-\frac{1}{e}\right) \approx 0.316$ for the adaptive influence maximization problem, thus improving the approximation ratio of $\frac{1}{4}\left(1-\frac{1}{e}\right) \approx 0.158$ given in [39]. The algorithm provided by [39] is the usual *non-adaptive greedy algorithm* given in [34] and reported in the previous section. We observe that such algorithm is non-adaptive, i.e., despite it is used for adaptive optimization, does not resort to the use of any adaptive policy and all the seeds are selected without observing any partial realisation.

▶ **Theorem 5.** *Given an influence graph G with n nodes and $k \in [n]_2$, the non-adaptive greedy algorithm is a $\frac{1}{2}\left(1-\left(1-\frac{1}{k}\right)^k\right) \geq \frac{1}{2}\left(1-\frac{1}{e}\right)$ approximation algorithm for the adaptive influence maximization problem (under IC and myopic feedback) applied to (G,k).*

In the proof of Theorem 5 (see Subsection 4.4) we relate the expected influence spread coming from the non-adaptive greedy algorithm with that of the optimal adaptive policy. We first need some notation and preliminary results. Let $G = (V = [n], E, (p_{uv})_{(u,v)\in E})$ be an influence graph, and let $k \in [n]_2$. For any $t \in [k]_0$, let S_t denote the set of the first t seeds selected by the greedy algorithm, so that $\sigma(S_k)$ is the expected influence spread of the solution returned by the algorithm. Let π be an optimal adaptive policy, and let $x = (x_1, \ldots, x_n)$ be the vector such that x_i is the probability that node i is selected by π. As in Section 2, we resort again to a randomized non-adaptive policy to relate the expected influence spread of the greedy algorithm with that of the adaptive policy.

Randomized Non-adaptive Policy. For any $t \in [k-1]_0$, as intermediate step of our analysis, we consider again the randomized non-adaptive policy Rand_t defined in Section 2: starting from the greedy solution S_t, we compute a random set $S_{\boldsymbol{\rho},t} := S_t \cup \{\boldsymbol{\rho}\}$, where $\boldsymbol{\rho} \in [n]$ is a random item such that $\mathbb{P}[\boldsymbol{\rho} = i] = x_i/k$ for any $i \in [n]$ and selected independently from any other event. We observe that the expected value of f under Rand_t is $\mathbb{E}_{\boldsymbol{\rho}}[\sigma(S_{\boldsymbol{\rho},t})]$.

As a support of our analysis, we also define a new diffusion model and a hybrid adaptive policy. In particular, the new diffusion model will be used to recover certain properties connected with the submodularity that, as in Section 2, will allow us to relate the expected influence spread of the randomized non-adaptive policy with that of the hybrid adaptive policy. Furthermore, following again the approach of Section 2, the hybrid adaptive policy is obtained by combining the greedy (non-adaptive) solution and the optimal adaptive one, and it will be used in our analysis to get an upper bound on the optimal adaptive spread.

2-level Diffusion Model. In the 2-level diffusion model each selected seed $u \in V$ has two chances to influence its neighbours, and all the non-seeds have one chance only, i.e., the activation probability for all the edges (u,v) is $1-(1-p_{u,v})^2$ if u is a seed, and $p_{u,v}$ otherwise. More formally, let $\hat{\boldsymbol{L}}$ be a live-edge graph distributed as $\boldsymbol{L}$ and independent from $\boldsymbol{L}$. Given a set of seeds S, the *2-level live-edge graph* can be defined as $\boldsymbol{L}^2(S) := \boldsymbol{L} \cup \{\hat{\boldsymbol{L}} \cap \{(u,v) \in E : u \in S\}\}$. Given a set of nodes S, let $\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}}}(S) := \sigma_{\boldsymbol{L}^2(S)}(S)$ denote the influence spread induced by S in live-edge graph $\boldsymbol{L}^2(S)$, and let $\sigma^2(S) := \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}}}(S)]$ denote the expected influence spread induced by S under the 2-level diffusion model. Let Φ and $\hat{\Phi}$ denote the random realisations associated to live-edge graphs $\boldsymbol{L}$ and $\hat{\boldsymbol{L}}$, respectively.

2-Level Hybrid Adaptive Policy. For any $t \in [k-1]_0$, let Hyb^2_t be a hybrid adaptive policy defined as follows: (i) Hyb^2_t selects all the nodes in S_t as seeds; (ii) then, Hyb^2_t adds to S_t all the nodes that the optimal adaptive policy π would have select when starting from the

empty realisation, and observing, at each step, partial realisations coming from the live-edge graph $\hat{\boldsymbol{L}}$ only; in other words, for any seed $v \in V$ selected by the policy, the new set of nodes that the policy observes (to choose the next seed) is $\hat{\Phi}(v)$; (iii) finally, denoting with $\hat{\Psi}_\pi$ the random realisation returned by π, the expected influence spread of Hyb_t^2 is defined as $\mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}}}(dom(\hat{\Psi}_\pi) \cup S_t)]$, i.e., it is the expected influence spread determined $dom(\hat{\Psi}_\pi) \cup S_t$, according to the 2-level live-edge graph $\boldsymbol{L}^2(dom(\hat{\Psi}_\pi) \cup S_t)$.

In what follows we give some technical results which are based on the above definitions and will be used in Subsection 4.4 to show the main theorem. In particular, we show that the 2-level diffusion model satisfies certain properties connected with submodular set functions (see Subsection 4.1); then, we use such properties to relate the expected influence spread in the ordinary diffusion model to that of the 2-level diffusion model (see Subsection 4.2); finally, by using a similar approach as in Section 2, we use the above relations to relate the efficiency of the randomized non-adaptive policy with that of the optimal adaptive policy, via the 2-level hybrid adaptive policy (see Subsection 4.3).

4.1 Adaptive Submodularity in the 2-Level Diffusion Model

The adaptive submodularity [25] is a property that extends the well-known concept of submodularity to the adaptive framework, and allows us to design efficient adaptive approximation algorithms. In particular, the adaptive submodularity states that, given two subrealisations $\psi \subseteq \psi'$ and a node $v \in V$, adding node v under partial realisation ψ' causes an expected increment of the influence spread that is not higher than that caused under partial realisation ψ. Unfortunately, as shown in the arXiv version of [25], the myopic feedback model, in general, does not satisfy the adaptive submodularity.

Anyway, by resorting to the 2-level diffusion model, we can recover a similar property as the adaptive submodularity. Given $S \subseteq V$, a partial realisation $\hat{\psi}$, and $v \in V$, let

$$\Delta^2_S(v|\hat{\psi}) := \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}\left[\sigma_{\boldsymbol{L}^2(\{v\}\cup dom(\hat{\psi})\setminus S)}(\{v\} \cup S \cup dom(\hat{\psi})) - \sigma_{\boldsymbol{L}^2(dom(\hat{\psi})\setminus S)}(S \cup dom(\hat{\psi}))|\hat{\psi} \subseteq \hat{\Phi}\right]$$

denote the expected increment of the influence spread w.r.t. the 2-level diffusion model when adding seed v to the set of nodes $S \cup dom(\hat{\psi})$, but assuming that the nodes in S have a unique chance to influence their neighbors, and that partial realisation $\hat{\psi}$ has been observed. We say that the 2-level diffusion model is *adaptive submodular* if, for any $S \subseteq V$, any partial realisations $\hat{\psi}, \hat{\psi}'$ with $\hat{\psi} \subseteq \hat{\psi}'$, and any $v \in V$, we have that $\Delta^2_S(v|\hat{\psi}) \geq \Delta^2_S(v|\hat{\psi}')$.

▶ **Lemma 6.** *The 2-level diffusion model is adaptive submodular.*

4.2 From the Ordinary to the 2-level Diffusion Model

In this subsection, we see how to relate the 2-level diffusion model to the ordinary one.

▶ **Lemma 7.** *We have that $\sigma^2(S) \leq 2 \cdot \sigma(S)$ for any $S \subseteq V$.*

Now, given a set $S \subseteq V$ and $v \in V$, let $\Delta_S(v) := \sigma(S \cup \{v\}) - \sigma(S)$, that is the expected increment under the ordinary diffusion model when adding a new node to a set S, and let $\Delta^2_S(v) := \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma_{\boldsymbol{L}^2(\{v\})}(S \cup \{v\}) - \sigma_{\boldsymbol{L}}(S)]$, that is the above expected increment, with the further assumption that v has two chances to influence its neighbors.

▶ **Lemma 8.** *We have that $\Delta^2_S(v) \leq 2 \cdot \Delta_S(v)$ for any $S \subseteq V$ and $v \in V$.*

4.3 From the Adaptive to the Randomized Non-adaptive Policy

The following three lemmas (Lemma 9, Lemma 10, and 11) relate the randomized non-adaptive policy with the 2-level hybrid adaptive policy, and then with the optimal adaptive policy of the ordinary diffusion model. In particular, the proofs of Lemma 9, Lemma 10, and 11, resort to a similar approach of the proofs of Lemma 2, Lemma 3, and Lemma 4 of Section 2.

▶ **Lemma 9.** *For any $S \subseteq V$, we have that $k \cdot (\mathbb{E}_{\boldsymbol{\rho}}[\sigma(\{\boldsymbol{\rho}\} \cup S)] - \sigma(S)) \geq \sum_{v \in V \setminus S} x_v \cdot \Delta_S(v)$.*

The following lemma relates the adaptive setting with the non-adaptive one, and its proof resorts to the adaptive submodularity defined in Subsection 4.1.

▶ **Lemma 10.** *We have $\mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}}}(dom(\hat{\Psi}_\pi) \cup S)] \leq \sigma^2(S) + \sum_{v \in V \setminus S} x_v \cdot \Delta^2_S(v)$ for any $S \subseteq V$.*

The following lemma shows that the optimal adaptive influence spread is upper bounded by that expected influence spread of the 2-level hybrid adaptive policy.

▶ **Lemma 11.** *We have $OPT_A(G,k) \leq \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}}}(dom(\hat{\Psi}_\pi) \cup S)]$ for any $S \subseteq V$.*

4.4 Proof of Theorem 5

Armed with the above results, we can now prove Theorem 5. For any $t \in [k]_0$, let $GR_N(G,t) := \sigma(S_t)$ denote the expected influence spread $\sigma(S_t)$ obtained when the first t seeds have been selected by the greedy algorithm. We have that

$$
\begin{aligned}
&GR_N(G,t+1) - GR_N(G,t) \\
&= \max_{v \in V} [\sigma(\{v\} \cup S_t)] - \sigma(S_t) \\
&\geq \overbrace{\mathbb{E}_{\boldsymbol{\rho}}[\sigma(\{\boldsymbol{\rho}\} \cup S_t)]}^{\text{Exp. value of } \mathsf{Rand}_t} - \sigma(S_t) && (7)\\
&\geq \frac{1}{k} \sum_{v \in V \setminus S_t} x_v \cdot \Delta_{S_t}(v) && (8)\\
&\geq \frac{1}{2k} \sum_{v \in V \setminus S_t} x_v \cdot \Delta^2_{S_t}(v) && (9)\\
&\geq \frac{1}{2k} (\overbrace{\mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}}}(dom(\hat{\Psi}_\pi) \cup S_t)]}^{\text{Exp. value of } \mathsf{Hyb}^2_t} - \sigma^2(S_t)) && (10)\\
&\geq \frac{1}{2k} (OPT_A(G,k) - \sigma^2(S_t)) && (11)\\
&\geq \frac{1}{2k} (OPT_A(G,k) - 2 \cdot \sigma(S_t)) && (12)\\
&= \frac{1}{2k} OPT_A(G,k) - \frac{1}{k} GR_N(G,t), && (13)
\end{aligned}
$$

where (7) holds since the greedy strategy adds to S_t the node v maximizing $\sigma(S_t \cup \{v\})$, (8) comes from Lemma 9, (9) comes from Lemma 8, (10) comes from Lemma 10, (11) comes from Lemma 11, and (12) comes from Lemma 7. Thus, by (13) and some manipulations we get the following recursive relation: $GR_N(G,t+1) \geq \frac{1}{2k} \cdot OPT_A(G,k) + \left(1 - \frac{1}{k}\right) \cdot GR_N(G,t)$

for any $t \in [k-1]_0$. By applying iteratively the above inequality, we get $GR_N(G,k) \geq \frac{1}{2k} \cdot \sum_{t=0}^{k-1} \left(1-\frac{1}{k}\right)^t \cdot OPT_A(G,k) = \frac{1}{2}\left(1-\left(1-\frac{1}{k}\right)^k\right) \cdot OPT_A(G,k)$, that leads to $\frac{GR_N(G,k)}{OPT_A(G,k)} \geq \frac{1}{2}\left(1-\left(1-\frac{1}{k}\right)^k\right) \geq \frac{1}{2}\left(1-\frac{1}{e}\right)$, and this shows the claim. ◀

▶ Remark 12. By Theorem 5, we can easily show that, for any influence graph G with n nodes, the k-adaptivity gap of G is at most $2\left(1-\left(1-\frac{1}{k}\right)^k\right)^{-1} \leq \frac{2e}{e-1} \approx 3.164$.

5 The Efficiency of the Adaptive Greedy Algorithm

We show that the adaptive version of the greedy algorithm guarantees an even better approximation ratio of $1-\frac{1}{\sqrt{e}} \approx 0.393$ for the adaptive influence maximization problem. The *adaptive greedy algorithm* is an adaptive policy π_k^{GR} that selects k seeds in k steps, and at each step t selects the t-th seed that maximizes the expected influence spread conditioned by the observed realisation.

▶ **Theorem 13.** *Given an influence graph G with n nodes and $k \in [n]_2$, the adaptive greedy algorithm is a $1-\left(1-\frac{1}{2k}\right)^k \geq 1-\frac{1}{\sqrt{e}}$ approximation algorithm for the adaptive influence maximization problem (under IC and myopic feedback) applied to (G,k).*

In the proof of Theorem 13 we relate the expected influence spread coming from the adaptive greedy algorithm with that of the optimal adaptive policy, passing trough a new hybrid adaptive policy. In the same spirit of Theorem 5, we also consider a new diffusion model and a new notion of adaptive submodularity (slightly different from that of Subsection 4.1). To show the main theorem (see Subsection 5.1) we need some notation and preliminary results. Let $G = (V = [n], E, (p_{uv})_{(u,v)\in E})$ be an influence graph, and let $k \in [n]_2$. Let π be an optimal adaptive policy, and let $x = (x_1, \ldots, x_n)$ be the vector such that x_i is the probability that node i is selected by π.

Strong 2-level Diffusion Model. We define $\boldsymbol{L}$, $\hat{\boldsymbol{L}}$, $\boldsymbol{L}^2(S)$, Φ, $\hat{\Phi}$ as in the 2-level diffusion model considered in Section 4. Given a partial realisation ψ and a set $S \subseteq V$, let $\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(S) := \sigma_{\boldsymbol{L}^2(S\setminus dom(\psi))}(S)$ denote the influence spread induced by S in live-edge graph $\boldsymbol{L}^2(S \setminus dom(\psi))$, and let $\sigma^2_\psi(S) := \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(S) | \psi \subseteq \Phi]$ denote the above influence spread in expectation, conditioned by partial realisation ψ.

Strong 2-level Hybrid Adaptive Policy. Given a partial realisation ψ, let Hyb^2_ψ be a hybrid adaptive policy defined as follows: (i) Hyb^2_ψ selects all the nodes in $dom(\psi)$ as seeds; (ii) then, Hyb^2_ψ adds to $dom(\psi)$ all the nodes that policy π would have select when starting from the empty realisation, and observing, at each step, partial realisations coming from the live-edge graph $\hat{\boldsymbol{L}}$ only; (iii) finally, denoting with $\hat{\Psi}_\pi$ the random realisation returned by policy π, the expected influence spread of Hyb^2_ψ is defined as $\mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(dom(\psi) \cup dom(\hat{\Psi}_\pi)) | \ \psi \subseteq \ \Phi]$, i.e., it is the expected influence spread determined $dom(\psi) \cup dom(\hat{\Psi}_\pi)$ in the strong 2-level diffusion model, conditioned by partial realisation ψ. Differently from the 2-level hybrid policy defined in Section 4, the expected influence spread of the hybrid policy defined here is conditioned by partial realisation ψ and the unique seeds that have two chances to influence their neighbors are those in $dom(\hat{\Psi}_\pi) \setminus dom(\psi)$.

Strong Adaptive Submodularity of the Strong 2-level Diffusion Model. Given two partial realisations $\psi, \hat{\psi}$ and $v \in V$, let

$$\Delta^2_{\psi}(v|\hat{\psi}) := \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}\left[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(\{v\} \cup dom(\psi) \cup dom(\hat{\psi})) - \sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(dom(\psi) \cup dom(\hat{\psi}))|\psi \subseteq \Phi, \hat{\psi} \subseteq \hat{\Phi}\right],$$

i.e., $\Delta^2_{\psi}(v|\hat{\psi})$ is the expected increment of the influence spread in the strong 2-level diffusion model when adding seed v to the set of nodes $dom(\hat{\psi}) \cup dom(\psi)$, conditioned by the observation of partial realisations $\hat{\psi}$ and ψ. We say that the strong 2-level diffusion model is *strongly adaptive submodular* if, for any partial realisations $\hat{\psi}, \hat{\psi}'$ with $\hat{\psi} \subseteq \hat{\psi}'$, any partial realisation ψ, and any $v \in V$, we have that $\Delta^2_{\psi}(v|\hat{\psi}) \geq \Delta^2_{\psi}(v|\hat{\psi}')$.

▶ **Lemma 14.** *The strong 2-level diffusion model is strongly adaptive submodular.*

From the Ordinary to the Strong 2-level Diffusion Model. Given a partial realisation ψ, and $v \in V$, let $\Delta_{\psi}(v) := \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(\{v\} \cup dom(\psi)) - \sigma_{\boldsymbol{L}}(dom(\psi))|\psi \subseteq \Phi]$, that is the expected increment under the ordinary diffusion model when adding a new node to the nodes in $dom(\psi)$ conditioned by partial realisation ψ, and let $\Delta^2_{\psi}(v) := \Delta^2_{\psi}(v|\emptyset) = \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(\{v\} \cup dom(\psi)) - \sigma_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(dom(\psi))|\psi \subseteq \Phi]$, that is the above conditional expectation, but w.r.t. the strong 2-level diffusion model. The following lemma can be shown analogously to Lemma 8.

▶ **Lemma 15.** *We have that $\Delta^2_{\psi}(v) \leq 2 \cdot \Delta_{\psi}(v)$ for any partial realisation ψ and $v \in V$.*

From the Optimal to the Greedy Adaptive Policy. The following lemma will be used to relate the strong 2-level hybrid adaptive policy with the adaptive greedy policy; its proof is similar to that of Lemma 10, but uses the concept of strong adaptive submodularity.

▶ **Lemma 16.** *For any partial realisation ψ, we have*

$$\mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(dom(\psi) \cup dom(\hat{\Psi}_{\pi}))|\ \psi \subseteq \Phi] \leq \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(dom(\psi))|\psi\ \subseteq\ \Phi] + \sum_{v \in V \setminus dom(\psi)} x_v \cdot \Delta^2_{\psi}(v).$$

The following lemma shows that the optimal adaptive influence spread is upper bounded by that expected influence spread of the strong 2-level hybrid adaptive policy, and its proof is completely analogue to that of Lemma 11.

▶ **Lemma 17.** *We have $OPT_A(G,k) \leq \mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\psi}(dom(\psi) \cup dom(\hat{\Psi}_{\pi}))|\ \psi \subseteq \Phi]$ for any partial realisation ψ.*

5.1 Proof of Theorem 13

Armed with the above lemmas, and by using a similar approach as in the proof of Theorem 5, we can prove Theorem 13. Given $t \in [k]_0$, let $\boldsymbol{S}_t$ denote the (random) set of the first t seeds selected by the adaptive greedy policy π^{GR}_k, and let Ψ_t be the (random) partial realisation such that $dom(\Psi_t) = \boldsymbol{S}_t$ (i.e., the partial realisation observed by policy π^{GR}_k at the end of step t); let $GR_A(G,t) := \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(\boldsymbol{S}_t)]$ denote the expected influence spread of the adaptive greedy policy after selecting the first t seeds. For any $t \in [k-1]_0$, we have that

$$
\begin{aligned}
&GR_A(G,t+1) - GR_A(G,t) \\
&= \mathbb{E}_{\boldsymbol{L}}[\sigma(\boldsymbol{S}_{t+1}) - \sigma(\boldsymbol{S}_t)] \\
&= \mathbb{E}_{\Psi_t}\left[\max_{v \in V \setminus dom(\Psi_t)} \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(\{v\} \cup dom(\Psi_t)) - \sigma_{\boldsymbol{L}}(dom(\Psi_t))|\Psi_t]\right] && (14) \\
&\geq \mathbb{E}_{\Psi_t}\left[\sum_{v \in V \setminus dom(\Psi_t)} \frac{x_v}{k} \cdot \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(\{v\} \cup dom(\Psi_t)) - \sigma_{\boldsymbol{L}}(dom(\Psi_t))|\Psi_t]\right] \\
&= \frac{1}{k} \cdot \mathbb{E}_{\Psi_t}\left[\sum_{v \in V \setminus dom(\Psi_t)} x_v \cdot \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(\{v\} \cup dom(\Psi_t)) - \sigma_{\boldsymbol{L}}(dom(\Psi_t))|\Psi_t]\right] \\
&= \frac{1}{k} \cdot \mathbb{E}_{\Psi_t}\left[\sum_{v \in V \setminus dom(\Psi_t)} x_v \cdot \Delta_{\Psi_t}(v)\right] \\
&\geq \frac{1}{2k} \cdot \mathbb{E}_{\Psi_t}\left[\sum_{v \in V \setminus dom(\Psi_t)} x_v \cdot \Delta^2_{\Psi_t}(v)\right] && (15) \\
&\geq \frac{1}{2k} \cdot \mathbb{E}_{\Psi_t}\left[\mathbb{E}_{\boldsymbol{L},\hat{\boldsymbol{L}}}[\sigma^2_{\boldsymbol{L},\hat{\boldsymbol{L}},\Psi_t}(dom(\Psi_t) \cup dom(\hat{\Psi}_\pi))|\Psi_t] - \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(dom(\Psi_t))|\Psi_t]\right] && (16) \\
&\geq \frac{1}{2k} \cdot \mathbb{E}_{\Psi_t}\left[OPT_A(G,k) - \mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(dom(\Psi_t))|\Psi_t]\right] && (17) \\
&\geq \frac{1}{2k} \cdot OPT_A(G,k) - \frac{1}{2k} \cdot \mathbb{E}_{\Psi_t}\left[\mathbb{E}_{\boldsymbol{L}}[\sigma_{\boldsymbol{L}}(dom(\Psi_t))|\Psi_t]\right] \\
&= \frac{1}{2k} \cdot OPT_A(G,k) - \frac{1}{2k} \cdot \mathbb{E}_{\boldsymbol{L}}(\sigma_{\boldsymbol{L}}(\boldsymbol{S}_t)) \\
&= \frac{1}{2k} \cdot OPT_A(G,k) - \frac{1}{2k} \cdot GR_A(G,t), && (18)
\end{aligned}
$$

where (14) holds since the adaptive greedy strategy at each step adds the node maximizing the expected influence spread (conditioned by the partial realisation coming from the previous selected seeds), (15) comes from Lemma 15, (16) comes from Lemma 16, (17) comes from Lemma 17. Thus, by (18) and some manipulations we get the following recursive relation:

$$
GR_A(G,t+1) \geq \frac{1}{2k} \cdot OPT_A(G,k) + \left(1 - \frac{1}{2k}\right) \cdot GR_A(G,t), \quad \forall t \in [k-1]_0. \tag{19}
$$

By applying iteratively (19), we get

$$
GR_A(G,k) \geq \frac{1}{2k} \cdot \sum_{t=0}^{k-1} \left(1 - \frac{1}{2k}\right)^t \cdot OPT_A(G,k) = 1 - \left(1 - \frac{1}{2k}\right)^k \cdot OPT_A(G,k),
$$

that leads to

$$
\frac{GR_A(G,k)}{OPT_A(G,k)} \geq 1 - \left(1 - \frac{1}{2k}\right)^k \geq 1 - \frac{1}{\sqrt{e}},
$$

and this shows the claim.

6 Conclusions and Future Work

In the context of adaptive optimization, we have introduced a new approach to relate the solution provided by a simple non-adaptive greedy policy with the adaptive optimum. The new approach allowed us to establish better bounds for the adaptive influence maximization problem under myopic feedback, specifically we improve both the approximation ratio of the non-adaptive greedy policy and the adaptivity gap.

Our results open several research directions in the context of influence maximization and in more general adaptive optimization settings. The approximation factor of the non-adaptive (resp. adaptive) greedy algorithm is between our lower bound of $\frac{1}{2}\left(1-\frac{1}{e}\right) \approx 0.316$ (resp. $1-\frac{1}{\sqrt{e}} \approx 0.393$) and the upper bound of $\frac{e^2+1}{(e+1)^2} \approx 0.606$ [39], and the adaptivity gap is between the lower bound of $\frac{e}{e-1} \approx 1.582$ [39] and our upper bound of $\frac{2e}{e-1} \approx 3.164$. The first problem left open by our result is to close these gaps. Furthermore, the techniques introduced in this paper to relate non-adaptive policies with adaptive ones might be useful to find better bounds in several variants of the adaptive influence maximization problem, like a combination of the following settings: different feedback models (e.g., the full-adoption feedback), different diffusion models (e.g., the general triggering model [33]), and different graph classes. Finally, as shown in Section 2, we believe that our new approach could be efficiently used to analyze non-adaptive greedy algorithms in other adaptive optimization problems, like e.g. the stochastic probing problem [6, 29, 30].

Approximation Algorithms for Min-Distance Problems in DAGs

Mina Dalirrooyfard
MIT, Cambridge, MA, USA

Jenny Kaufmann
Harvard University, Cambridge, MA, USA

Abstract

Graph parameters such as the diameter, radius, and vertex eccentricities are not defined in a useful way in Directed Acyclic Graphs (DAGs) using the standard measure of distance, since for any two nodes, there is no path between them in one of the two directions. So it is natural to consider the distance between two nodes as the length of the shortest path in the direction in which this path exists, motivating the definition of the min-distance. The min-distance between two nodes u and v is the minimum of the shortest path distances from u to v and from v to u.

As with the standard distance problems, the Strong Exponential Time Hypothesis [Impagliazzo-Paturi-Zane 2001, Calabro-Impagliazzo-Paturi 2009] leaves little hope for computing min-distance problems faster than computing All Pairs Shortest Paths, which can be solved in $\tilde{O}(mn)$ time. So it is natural to resort to approximation algorithms in $\tilde{O}(mn^{1-\epsilon})$ time for some positive ϵ. Abboud, Vassilevska W., and Wang [SODA 2016] first studied min-distance problems achieving constant factor approximation algorithms on DAGs, and Dalirrooyfard *et al* [ICALP 2019] gave the first constant factor approximation algorithms on general graphs for min-diameter, min-radius and min-eccentricities. Abboud *et al* obtained a 3-approximation algorithm for min-radius on DAGs which works in $\tilde{O}(m\sqrt{n})$ time, and showed that any $(2-\delta)$-approximation requires $n^{2-o(1)}$ time for any $\delta > 0$, under the Hitting Set Conjecture. We close the gap, obtaining a 2-approximation algorithm which runs in $\tilde{O}(m\sqrt{n})$ time. As the lower bound of Abboud *et al* only works for sparse DAGs, we further show that our algorithm is conditionally tight for dense DAGs using a reduction from Boolean matrix multiplication. Moreover, Abboud *et al* obtained a linear time 2-approximation algorithm for min-diameter along with a lower bound stating that any $(3/2-\delta)$-approximation algorithm for sparse DAGs requires $n^{2-o(1)}$ time under SETH. We close this gap for dense DAGs by obtaining a 3/2-approximation algorithm which works in $O(n^{2.350})$ time and showing that the approximation factor is unlikely to be improved within $O(n^{\omega-o(1)})$ time under the high dimensional Orthogonal Vectors Conjecture, where ω is the matrix multiplication exponent.

1 Introduction

Among the most fundamental graph parameters that have been extensively studied are the diameter, radius and eccentricities [16, 24, 15, 21, 5, 17, 14, 20, 7, 8, 33, 34, 12, 22, 30, 28, 13, 2, 9] (and many others). The eccentricity of a vertex v is the largest distance between v and any other vertex. The diameter is the maximum eccentricity of a vertex in the graph, thus the distance between the two farthest nodes, and the radius is the minimum eccentricity, measuring the maximum distance to the most central node.

All of these parameters depend on the definition of the distance between two nodes. In undirected graphs, the distance between two vertices is just the shortest path distance $d(\cdot,\cdot)$ between them, which is symmetric. However, in directed graphs, this standard measure of distance d is not necessarily symmetric, since for two nodes, $d(u,v)$ may not equal $d(v,u)$.

Several notions of a "symmetric" distance for directed graphs have been studied. Cowen and Wagner [18] define the *roundtrip distance*, which for two vertices u and v is just $d(u,v)+d(v,u)$. Abboud, Vassilevska W., and Wang [3] define the *max-distance*, which is $\max\{d(u,v),d(v,u)\}$, and the *min-distance*, which is $\min\{d(u,v),d(v,u)\}$.

Each of these notions of distance has a particular application [19]. In this paper, we focus on the min-distance $d_{\min}(\cdot,\cdot)$. The min-distance characterizes a quantity of real-world relevance: for instance, a patient may visit a doctor or a doctor may visit a patient, and if they are in a hurry the min-distance between them may matter. Min-distance is a particularly natural notion of distance in directed acyclic graphs (DAGs), where the standard notion of distance is infinite in at least one direction for any given pair of vertices in a DAG. For example, in a topologically ordered DAG where the edges are directed from left to right, the min-diameter is simply the largest distance $d(u,v)$ where u is to the left of v.

More formally, for a vertex $v \in V$, the *min-eccentricity* $\epsilon(v)$ is $\max_{w\in V} d_{\min}(v,w)$, or in other words, the largest min-distance between v and any other vertex. The *min-diameter* of a graph is $\max_{v\in V}\epsilon(v)$. Note that the min-diameter is the only meaningful notion of diameter for DAGs: all other notions are infinite. The *min-radius* of a graph is $\min_{v\in V}\epsilon(v)$. A *center* is a vertex whose min-eccentricity is equal to the min-radius of the graph.

All-Pairs Shortest Paths (APSP) is the problem of computing the distance between u and v for every pair of vertices $u,v\in V$. In a graph G with m edges, n vertices, and nonnegative edge weights polynomial in n, APSP can easily be computed in $\tilde{O}(mn)$ time[1], by running Dijkstra's algorithm from every vertex[2]. Computing eccentricities, diameter, or radius with any of the notions of distance is no harder than computing APSP.

For the standard notion of distance, under the Strong Exponential Time Hypothesis (SETH) [25, 11], there is no *truly subquadratic* time algorithm for diameter (and thus nor for eccentricities) in unweighted graphs: that is, no such algorithm runs in time $O(m^{2-\epsilon})$ for $\epsilon>0$ [28]. This lower bound also holds for the other notions of diameter (and eccentricities) [19]. For radius, the same lower bound holds but under the Hitting Set Conjecture [3].

Since quadratic time is expensive on large graphs, we resort to approximation algorithms. Many constant factor approximation algorithms were known for all notions of diameter, eccentricities and radius, except for the min-distance notion until recently. For example, for the standard diameter and roundtrip diameter there is a folklore linear time 2-approximation algorithm, and for max-diameter and standard diameter, a conditionally tight 3/2-approximation algorithm is known in $\tilde{O}(m\sqrt{n})$ time [28].

Only recently Dalirrooyfard *et al* [19] showed constant factor approximation algorithms for min-distance problems in general graphs that run in $O(mn^{1-\epsilon})$ time for some fixed $\epsilon>0$. More specifically, they obtained a 3-approximation algorithm for min-diameter in $\tilde{O}(m\sqrt{n})$ time, a $(3+\delta)$-approximation algorithm for min-radius in $\tilde{O}(m\sqrt{n}/\delta)$ time, and a $(3+\delta)$-approximation algorithm for min-eccentricities in $\tilde{O}(m\sqrt{n}/\delta^2)$ time, for any $\delta>0$.

The reason it is hard to obtain approximation algorithms for min-diameter, min-radius, and min-eccentricities is that min-distance does not obey the triangle inequality. Hence the typical approaches to find algorithms that work for other notions of distance do not work for min-distance, as they crucially rely on the triangle inequality.

---

[1] The tilde hides polylogarithmic factors.

[2] Faster algorithms are known by Pettie [26] and Pettie and Ramachandran [27] for sparse graphs.

Table 1 Results on min-distance problems on DAGs. The $(*)$ marks lower bounds that are for dense DAGs. Our $(2-\delta)$ lower bound for min-radius is based on Triangle Detection and our $(\frac{3}{2}-\delta)$ lower bound for min-diameter is based on high dimensional OV. Our k and $(k+\delta)$-approximation algorithms are for any integer $k \geq 2$. Conditionally tight bounds are in bold.

Problem	Upper bound	Lower bound	Reference
min-diameter	2 in $O(m)$	$(\frac{\mathbf{3}}{\mathbf{2}}-\delta)$ needs $m^{2-o(1)}$	[3]
	$\frac{\mathbf{3}}{\mathbf{2}}$ in $O(n^{2.350})$ (dense, unweighted)	$(\frac{\mathbf{3}}{\mathbf{2}}-\delta)$ needs $n^{\omega-o(1)}$ $(*)$	this work
min-radius	3 in $\tilde{O}(m\sqrt{n})$	$(\mathbf{2}-\delta)$ needs $m^{2-o(1)}$	[3]
	2 in $\tilde{O}(\min(m\sqrt{n}, m^{2/3}n))$	$(\mathbf{2}-\delta)$ needs $n^{\omega-o(1)}$ $(*)$	this work
	k in $\tilde{O}(\min(mn^{1/k}, m^{\frac{2^{k-1}}{2^k-1}}n))$		this work
min-eccentri.	$3+\delta$ in $\tilde{O}(m\sqrt{n}/\delta^2)$		[19]
	$k+\delta$ in $\tilde{O}(\min(mn^{1/k}/\delta, m^{\frac{2^{k-1}}{2^k-1}}n/\delta))$		this work

On the bright side, since DAGs have more structure, it is easier to find algorithms for them. The best known subquadratic time algorithm for min-diameter in DAGs is a linear time 2-approximation algorithm, and the best subquadratic time algorithm for min-radius is a 3-approximation algorithm in $\tilde{O}(m\sqrt{n})$ time [3]. However, neither of these algorithms were proven to be conditionally tight.

Previously, the only known conditional lower bounds for these problems were due to Abboud, Vassilevska W., and Wang [3]. They showed that under the Orthogonal Vectors Conjecture from fine-grained complexity (and consequently under SETH [31]), there is no $(3/2-\delta)$-approximation algorithm for any $\delta > 0$ for min-diameter which runs in truly subquadratic time on sparse DAGs. Moreover, under the Hitting Set Conjecture, there is no $(2-\delta)$-approximation algorithm for any $\delta > 0$ for min-radius which runs in truly subquadratic time on sparse DAGs.

1.1 Our results

We obtain fast algorithms for min-diameter, min-eccentricities and min-radius with improved approximation factors. Our results can be seen in Table 1.

Min-Eccentricities and Min-Radius

We obtain the first known subquadratic time $(2+\delta)$-approximation algorithm for min-eccentricities in DAGs for any $\delta > 0$, and the first known subquadratic time 2-approximation algorithm for min-radius in DAGs. These algorithms run in time $\tilde{O}(\min(m\sqrt{n}/\delta, m^{2/3}n)/\delta)$ and $\tilde{O}(\min(m\sqrt{n}, m^{2/3}n))$ respectively. Note that our algorithms in this section are combinatorial: they do not exploit fast matrix multiplication and are potentially practical. Our results are *conditionally optimal* in both sparse and dense graphs: For sparse graphs, if the Hitting Set Conjecture is true, then our min-radius result is tight and our min-eccentricity result is essentially tight, in the sense that no approximation factor smaller than 2 can be achieved in subquadratic time for either of these problems [3]. For dense graphs, our 2-approximation algorithm works in $\tilde{O}(n^{7/3})$ time, and we show that there is no $(2-\delta)$-approximation algorithm for min-radius (and hence min-eccentricities) in $O(n^{\omega-\epsilon})$ for $\epsilon > 0$, if the best algorithm for Triangle Detection runs in time $\Omega(n^{\omega-o(1)})$. Here $\omega < 2.37286$ [6] is the exponent of matrix multiplication.

More generally, we obtain a series of algorithms trading off runtime and accuracy.

▶ **Theorem 1.** *For integer $k \geq 2$ and every $\delta > 0$, there is a $(k+\delta)$-approximation algorithm for min-eccentricities in DAGs which runs in $\tilde{O}(\min(mn^{1/k}/\delta, m^{2^{k-1}/(2^k-1)}n/\delta))$ time.*

For every integer $k \geq 2$, there is a k-approximation algorithm for min-radius in DAGs which runs in $\tilde{O}(\min(mn^{1/k}, m^{2^{k-1}/(2^k-1)}n))$ time.

As mentioned earlier, the case $k = 2$ gives a 2-approximation algorithm for min-radius running in time $\tilde{O}(\min(m\sqrt{n}, m^{2/3}n))$. For $m = \tilde{O}(n^{1.5})$, this matches the runtime and improves the approximation factor of the previous best known algorithm for this problem (from [3]). For $m = \omega(n^{1.5+o(1)})$, it improves both the approximation factor and the runtime.

Our min-eccentricity $(2+\delta)$-approximation algorithm borrows a key idea from the 3-approximation algorithm of [3] and combines it with a new binary search technique. The idea is to partition the DAG into intervals and do local APSP searches to find local paths, then combine these local paths with "outer" paths to guarantee a low enough min-distance to any vertex in the graph. In [3], these outer paths were found by using a clever choice of intervals; our algorithm instead applies binary search to find sets which can be used as jumping-off points for the outer paths, allowing us to shorten the lengths of these paths and also allowing us to approximate all min-eccentricities, not only min-radius. Our $(k+\delta)$-approximation algorithm is achieved by recursively running our approximation algorithm on the intervals instead of running local APSP, which allows us to improve the runtime.

For sparse graphs, Abboud, Vassilevska W., and Wang [3] already showed that a $(2-\delta)$-approximation for min-radius needs $\Omega(m^{2-o(1)})$ time under the Hitting Set Conjecture, so our 2-approximation algorithm is conditionally tight for sparse graphs. We show that the approximation factor of our algorithm is conditionally tight for the dense case as well by reducing Triangle Detection to $(2-\delta)$-approximation of min-radius for any $\delta > 0$. The best running time for Triangle Detection in n-node graphs is conjectured to be $\Omega(n^{\omega-o(1)})$ by many papers (see for example [1, 10]), where $\omega < 2.37286$ [6] is the exponent of fast matrix multiplication. Note that, since $m = O(n^2)$, our algorithm runs in $\tilde{O}(n^{7/3})$ time, which is faster than $O(n^\omega)$ for the current best bound on ω. Since the algorithm of Theorem 1 is combinatorial, if we restrict to combinatorial algorithms then there is no *truly subcubic* (meaning $O(n^{3-\epsilon})$ for $\epsilon > 0$) time $(2-\delta)$-approximation algorithm for min-radius provided that there is no truly subcubic time combinatorial algorithm for Boolean matrix multiplication (BMM). This is because BMM and Triangle Detection are subcubic equivalent [32]. Note that our reduction graph in Theorem 2 is an unweighted DAG.

▶ **Theorem 2.** *If there is a $T(n,m)$-time algorithm for $(2-\delta)$-approximation of min-radius in $O(n)$-node $\tilde{O}(m)$-edge DAGs for some $\delta > 0$, then there is an $\tilde{O}(T(n,m)+m)$-time algorithm for Triangle Detection on graphs with n nodes and m edges.*

▶ **Corollary 3.** *Assuming the best algorithm for Triangle Detection runs in time $\Omega(n^{\omega-o(1)})$, there is no algorithm for $(2-\delta)$-approximation of min-radius in n-node dense DAGs that runs in time $O(n^{\omega-\epsilon})$ for any $\delta, \epsilon > 0$.*

Moreover, there is no $O(n^{3-\epsilon})$-time combinatorial algorithm for $(2-\delta)$-approximation of min-radius in n-node dense DAGs with $\epsilon, \delta > 0$ if there is no $O(n^{3-\epsilon'})$-time combinatorial algorithm for BMM with $\epsilon' > 0$.

Improving the running time using Fast Matrix Multiplication

In DAGs with small integer edge weights, we further improve the running times for all k in Theorem 1 by applying a result of Zwick in [36] on the runtime of APSP in such graphs. We describe our result in more detail in Section 2. In particular, in DAGs with constant integer edge weights, including unweighted DAGs, our result in the case $k = 2$ is as follows:

▶ **Theorem 4.** *For every $\delta > 0$, there is an $\tilde{O}(\min(m\sqrt{n}/\delta, m^{0.605}n/\delta))$-time $(2+\delta)$-approximation algorithm for min-eccentricities in DAGs with constant integer edge weights.*

There is an $\tilde{O}(\min(m\sqrt{n}, m^{0.605}n))$-time 2-approximation algorithm for min-radius in DAGs with constant integer edge weights.

Min-Diameter

We obtain a 3/2-approximation algorithm for min-diameter in unweighted DAGs, where the approximation factor is conditionally optimal in dense graphs. Specifically, our algorithm improves on the standard APSP runtime for any graph with $m = \omega(n^{1+o(1)})$ edges. This is the first known 3/2-approximation algorithm for min-diameter in dense DAGs that runs faster than the best constant factor approximation algorithm for APSP, which runs in $\tilde{O}(n^\omega)$ time in unweighted directed graphs [36].

▶ **Theorem 5.** *There is an $O(m^{0.414}n^{1.522} + n^{2+o(1)})$-time 3/2-approximation algorithm for min-diameter in unweighted DAGs.*

This algorithm relies on the sparse matrix multiplication algorithm of Yuster and Zwick [35]. In dense graphs with $m = O(n^2)$, its runtime is $O(n^{2.350})$. In relatively sparse graphs, with $m = O(n^{1.154+o(1)})$, the second term dominates, so the runtime is $O(n^{2+o(1)})$.

Our techniques, which mix known diameter techniques with sparse matrix multiplication, are informally as follows: We first construct a covering set, which will intersect any sufficiently large set. We run BFS from all vertices in the covering set, and check whether any min-distances found were large. If not, then for each vertex u, we will define a set of vertices that are relatively "close" to u on its right; if this set is large it will intersect the covering set, allowing us to find paths from u to some vertices to its right, using a "close" vertex in the covering set as a jumping-off point. The remaining vertices w, for which this method did not construct a $u \to w$ path, must have the property that any $u \to w$ path must intersect a relatively small subset of the set of vertices "close" to u (note that this set may have been small to begin with, in which case we can skip the previous step). Symmetrically, for each vertex w we can construct the corresponding relatively small subset of vertices "close" to w on its left, and then to bound the min-distance between u and w we check whether these two small subsets share a vertex in common. We use sparse matrix multiplication to detect this set intersection.

The conditional lower bound of [3] says that if the Orthogonal Vectors Conjecture is true then min-diameter cannot be $(3/2-\delta)$-approximated in truly subquadratic time in sparse graphs. There is no known 3/2-approximation algorithm for min-diameter on DAGs that works faster than APSP, neither for dense graphs nor for sparse graphs. So the question is: Is 3/2 the right bound for inapproximability of min-diameter in DAGs? We answer this question in the affirmative for dense DAGs. Theorem 5 gives the first 3/2-approximation algorithm that works faster than APSP, and it is optimal conditioned on *high dimensional OV* using the same reduction as [3]. High dimensional OV can be used for obtaining lower bounds for dense graphs. In high dimensional OV, the dimension of the vectors can be as big as $O(n)$, and using a simple reduction to Boolean matrix multiplication, the best known algorithm for it is in time $O(n^\omega)$.

High dimensional OV gives a conditional lower bound of $\Omega(n^{\omega-o(1)})$ time for $(3/2-\delta)$-approximation of min-diameter for any $\delta > 0$. Our algorithm gives an upper bound of $O(n^{2.350})$ for $m = \Theta(n^2)$, which is faster than $O(n^\omega)$ for the current best bound on ω. We note while we provide tight results for dense DAGs, the gap between the lower bound and upper bound for computing min-diameter on sparse DAGs is still open.

1.2 Preliminaries

All graphs in this paper are directed graphs. Given a graph G, n denotes the number of vertices and m denotes the number of edges. We will assume $m \geq n-1$ since otherwise all min-eccentricities are infinite, a case that is easily checked. All edge weights are assumed to be nonnegative and polynomial in n; if w_{max} is the maximum edge weight and w_{min} is the minimum edge weight, we let $M = \max\{w_{max}, 1/w_{min}\}$. We write $G[S]$ to denote the subgraph of G induced by vertex set S. For a vertex v, we write $N_D^{\text{in}}(v)$ (respectively, $N_D^{\text{out}}(v)$) to denote the set of vertices u such that $d(u,v) \leq D$ (respectively, $d(v,u) \leq D$).

For $v \in V$ and $W \subseteq V$, we define $d_{\min}(W,v) = d_{\min}(v,W)$ as $\min_{w \in W} d_{\min}(v,w)$, and we define the min-eccentricity of W as $\epsilon(W) = \max_{v \in V} d_{\min}(W,v)$.

Given two sets $U, W \subseteq V$, if every $u \in U$ appears prior to (respectively, after) every $w \in W$ in a topological ordering of the vertices of G, we say that U is the left (respectively, right) of W with respect to the topological ordering. When U or W consists of a single vertex $\{x\}$, we omit the brackets. If $W \subseteq U \subseteq V$, we denote the subset of vertices in U that lie to the left (right) of W by $L_U(W)$ (respectively, $R_U(W)$). If $U = V$, we omit the subscript. A vertex set W is called *topologically consecutive* with respect to a topological ordering if its vertices are consecutive; i.e., if $W = V \setminus (L(W) \cup R(W))$. In general, the relevant topological ordering will be clear, and we will omit reference to it.

Let $\omega(1,r,1)$ be the exponent of the runtime of multiplying $n \times n^r$ by $n^r \times n$ matrices. Let $\omega = \omega(1,1,1)$ be the square matrix multiplication exponent. [6] showed that $\omega < 2.37286$.

For specifying lower bounds, we use the following problems with their corresponding running time conjectures.

Orthogonal Vectors (OV)

Given two lists A, B of n d-dimensional Boolean vectors, determine whether there are vectors $a \in A$ and $b \in B$ such that a and b are *orthogonal*; i.e. there is no $i \in [d]$ such that the ith bits of both a and b are 1. When $d = \Omega(\log n)$, the *OV Conjecture* [31] says that there is no algorithm that can solve the OV problem in time $O(n^{2-\epsilon})$ for any fixed $\epsilon > 0$. The OV Conjecture is implied by the Strong Exponential Time Hypothesis (SETH) [31].

High Dimensional Orthogonal Vectors

In high dimensional OV, the dimension d can be as high as $O(n)$. There is a simple reduction from high dimensional OV to matrix multiplication: Given two lists $A = \{a_1, \ldots, a_n\}, B = \{b_1, \ldots, b_n\}$ of d-dimensional Boolean vectors, let M and N be two $n \times d$ and $d \times n$ Boolean matrices, where $M[i,j] = 1$ if a_i is 1 in bit j, and $N[j,k] = 1$ if b_k is 1 in bit j, for $j = 1, \ldots, d$ and $i, k = 1, \ldots, n$. If MN has a zero entry, the vector pair corresponding to that entry are orthogonal. This gives a $O(n^\omega)$ algorithm for high dimensional OV, and there are no faster algorithms known for it up to polylogarithmic factors. Moreover, OV is equivalent to the problem of distinguishing diameter 2 vs 3 [28], and so high dimensional OV is equivalent to distinguishing diameter 2 vs 3 in dense graphs. A well-known open problem is whether diameter 2 vs 3 can be solved faster than matrix multiplication (see for example [5]). Hence, it is conjectured that high dimensional OV cannot be solved in $O(n^{\omega-\epsilon})$ time for any $\epsilon > 0$.

Hitting Set (HS)

Given two lists $A, B \in \{0,1\}^d$, determine whether there is a vector $a \in A$ that is not orthogonal to any vector $b \in B$. When $d = \Omega(\log n)$, the *Hitting Set Conjecture* [3] says that there is no algorithm that can solve the Hitting Set problem in time $O(n^{2-\delta})$ for any fixed $\delta > 0$.

Boolean Matrix Multiplication (BMM)

We abbreviate multiplying two Boolean $n \times n$ matrices over the (AND, OR)-semiring by BMM. It is conjectured that there is no combinatorial algorithm solving BMM in $O(n^{3-\epsilon})$ time for any fixed $\epsilon > 0$, and the best algebraic algorithm for it is in $O(n^{\omega+o(1)})$ time for $\omega < 2.37286$ [6].

Triangle Detection [32]

Given a tripartite graph $G(A, B, C, E)$ where A, B and C are the three parts of the vertex set and E is the edge set, determine if there are $a \in A$, $b \in B$, and $c \in C$ such that abc is a triangle. Vassilevska W. and Williams [32] showed that considering only combinatorial algorithms, Triangle Detection and BMM are subcubic equivalent, meaning that a truly subcubic combinatorial algorithm in one results in a truly subcubic combinatorial algorithm in the other. Moreover, the best (algebraic) algorithm for Triangle Detection is through BMM. Thus the best running time for Triangle Detection is $O(n^\omega)$, and it is conjectured (see for example [1, 10]) that there is no algorithm faster than $O(n^\omega)$ for detecting a triangle.

2 Min-Eccentricities and Min-Radius

We present two different versions of our min-eccentricity and min-radius approximation algorithms, one which works in general weighted DAGs and is combinatorial and one with a lower runtime upper bound which only works in DAGs with small integer edge weights. The algorithms are identical except in how they compute APSP; the former computes APSP in the standard combinatorial way, while the latter uses Zwick's fast APSP algorithm for graphs with small integer edge weights. Here, $\mu(t)$ is the value satisfying $\omega(1, \mu(t), 1) = 1 + 2\mu(t) - t$.

▶ **Theorem 6** ([36]). *APSP can be computed in $O(n^{2+\mu(t)})$ time in directed graphs with integer edge weights bounded by n^t, where $t < 3 - \omega$.*

Both versions of our algorithms use a common technique to compute min-distances to and from a vertex set. Given a graph G and a vertex set $W \subseteq V$, we construct a graph G' by adding a vertex y and adding weight-0 edges (w, y) for all $w \in W$. We then run Dijkstra into y in G'. We refer to this procedure as *running Dijkstra into W*. The symmetric procedure, in which the weight-0 edges point out of an added vertex y' and we run Dijkstra out of y', will be referred to as *running Dijkstra out of W*. Then for $x \in V$, $d_{\min}(x, W) = \min(d(x, y), d(y', x))$, a value which we can now compute. We added $|W|$ edges and ran Dijkstra in G', so in total the procedure takes time $O(|W| + m \log n) = O(m \log n)$.

Our min-eccentricity and min-radius approximation algorithms will be based on the following proposition. Let $c_k(\tau) = \frac{2^{k-2}(1+\tau)}{2^{k-1}(1+\tau)-\tau}$.

▶ **Proposition 7.** *For any $k \geq 2$, there is an $O(\min(mn^{1/k} \log^2 n, m^{2^{k-1}/(2^k-1)} n \log^2 n))$-time algorithm which takes as input a DAG G and a parameter r, and certifies for each vertex v that $\epsilon(v) > r$ or that $\epsilon(v) \leq kr$.*

In DAGs with integer edge weights bounded by n^t, where $t < 3 - \omega$, there is a version of this algorithm which runs in $O(\min(mn^{1/k} \log^2 n, m^{c_k(\mu(t))} n \log^2 n))$-time.

In [23], Le Gall and Urrutia showed that $\mu = \mu(0) < 0.529$. Thus in DAGs with constant integer edge weights (so that $t = 0$), the runtime of the algorithm of Proposition 7 is $\tilde{O}(\min(mn^{1/k}, m^{c_k(0.529)} n))$ time. When $k = 2$, $c_k(0.529) < 0.605$, leading to the special case stated in Theorem 4.

The algorithms of Proposition 7 will be described and proven correct in Subsection 2.1, and their runtimes will be analyzed in Lemma 13 in Subsection 2.2. Then by binary searching over $r \in [0, Mn]$, these algorithms can be used to obtain the min-eccentricity approximation algorithms of Theorems 8 and 9 and the min-radius approximation algorithms of Theorems 10 and 11.

▶ **Theorem 8.** *Let $k \geq 2$ be an integer. For any $\delta > 0$, there is an $\tilde{O}(\min(mn^{1/k}/\delta, m^{2^{k-1}/(2^k-1)}n/\delta))$-time algorithm which, given a DAG G, outputs for every vertex $v \in V$ an estimate $\epsilon'(v)$ such that $\epsilon(v) \leq \epsilon'(v) < (k+\delta)\epsilon(v)$.*

▶ **Theorem 9.** *Let $k \geq 2$ be an integer. For any $\delta > 0$, there is an $\tilde{O}(\min(mn^{1/k}/\delta, m^{c_k(\mu(t))}n/\delta))$ time algorithm which, given a DAG G with integer edge weights bounded by n^t for $t < 3 - \omega$, outputs for every vertex $v \in V$ an estimate $\epsilon'(v)$ such that $\epsilon(v) \leq \epsilon'(v) < (k+\delta)\epsilon(v)$.*

Proof. First we have all the vertices as "unmarked." We do binary search in $[0, Mn]$ by starting with $r = 1$ in Proposition 7 and incrementing $r' = (1 + \delta/k)r$ at each step. At each step, we run the algorithm given in Proposition 7, and for each unmarked v that is reported as having $\epsilon(v) \leq kr$, we set $\epsilon'(v) = kr$ and mark v. At the end we set $\epsilon'(v) = \infty$ for any remaining unmarked vertices.

Suppose a vertex v was marked at the step corresponding to r. Then $r/(1+\delta/k) < \epsilon(v) \leq kr$, so $\epsilon(v) \leq \epsilon'(v) = kr < (k+\delta)\epsilon(v)$. The binary search adds an $O(\log_{1+\delta/k} Mn) = O((\log Mn)/\delta)$ factor to the runtime. Since $\log Mn$ is polylogarithmic in n, this gives the time bounds stated. ◀

▶ **Theorem 10.** *Let $k \geq 2$ be an integer. There is an $\tilde{O}(\min(mn^{1/k}, m^{2^{k-1}/(2^k-1)}n))$-time algorithm which, given a DAG G, outputs an approximation R' such that if R is the min-radius of G, $R \leq R' < kR$.*

▶ **Theorem 11.** *Let $k \geq 2$ be an integer. There is an $\tilde{O}(\min(mn^{1/k}, m^{c_k(\mu(t))}n))$-time algorithm which, given a DAG G with integer edge weights bounded by n^t for $t < 3 - \omega$, outputs an approximation R' such that if R is the min-radius of G, $R \leq R' < kR$.*

Proof. We do binary search in $[0, Mn]$, running the algorithm given by Proposition 7 at each step as follows: We keep two numbers A_i and B_i at step i which are the lower bound and upper bound to the min-radius R. At step 1 we have $A_1 = 0$ and $B_1 = Mn$. At step i, we have A_i, B_i such that $A_i < R \leq B_i$. Let $C_i = B_i - kA_i$. If C_i is smaller than the minimum positive edge weight, then any path of length at most B_i must have length at most kA_i, so in this case we terminate the binary search and let $R' = kA_i$. We now have $R \leq R' < kR$ as desired.

If C_i is not smaller than the minimum positive edge weight, let $r = A_i + \frac{C_i}{k+1}$, and run the algorithm given by Proposition 7. If the algorithm reports that there is a vertex v with $\epsilon(v) < kr$, then let $A_{i+1} = A_i$ and $B_{i+1} = kr = kA_i + \frac{k}{k+1}C_i$, as we have the min-radius is between A_{i+1} and B_{i+1}. Note that in this case $C_{i+1} = B_{i+1} - kA_{i+1} = \frac{k}{k+1}C_i$. Otherwise, if the algorithm reports that every vertex has $\epsilon(v) \geq r$, then the min-radius is at least $A_{i+1} := r = A_i + \frac{C_i}{k+1}$ and is less than $B_{i+1} := B_i$. In this case $C_{i+1} = B_i - k(A_i + \frac{C_i}{k+1}) = \frac{k}{k+1}C_i$. Thus, at each step, the size of C_i shrinks by a factor of $\frac{k}{k+1}$. Hence, for constant k, the algorithm will in $O(\log Mn)$ steps find bounds A_i, B_i such that C_i is smaller than the minimum positive edge weight. ◀

2.1 Algorithm Description and Correctness

We now describe and prove the correctness of the algorithm of Proposition 7 by induction on k. For convenience, we use $k = 1$ as a base case; in this case we simply run an APSP computation. Our algorithm for $k > 1$ is as follows.

First, topologically sort the vertices and partition them into p consecutive sets $W_1, \dots W_p$ of size $|W_i| = n/p$. The runtime-minimizing value of p will be chosen later.

For each i, run Dijkstra to and from W_i. If $\epsilon(W_i) > r$, then we can report $\epsilon(w) > r$ for all $w \in W_i$. Otherwise, $\epsilon(W_i) \leq r$. In this case, we will apply Claim 12, below, twice. Recall that for $S \subseteq W \subseteq V$, $L_W(S)$ is the set of vertices in W that are to the left of all vertices in S in the topological ordering.

▷ Claim 12. Let $W \subseteq V$ be a topologically consecutive subset of a topologically ordered DAG G, and let r be a parameter such that $\epsilon(W) \leq r$. In $O(m \log^2 n)$ time, one can find a nonempty topologically consecutive subset $S \subseteq W$ such that:

(a) $\epsilon(S) \leq r$.
(b) If $w \in L_W(S)$, $\epsilon(w) > r$.
(c) If $|S| > 1$, all vertices $s \in S$ satisfy $\epsilon(s) > r$.

Proof. We will use a binary search argument to find S. We will induct on an index j. Let $S^0 = W$. Assume that $S^j \subseteq W$ is topologically consecutive, that $\epsilon(S^j) \leq r$, and that for every $w \in L_W(S^j)$, $\epsilon(w) > r$. These all hold for $j = 0$. If $S^j = \{s\}$ consists of a single vertex, let $S = S^j$; then we are done.

Otherwise, let S^j_L be the subset of S^j containing its first $|S^j|/2$ vertices in the topological ordering and let $S^j_R = S^j \setminus S^j_L$. So S^j_L and S^j_R are the left and right halves of S^j, respectively; hence both S^j_L and S^j_R are topologically consecutive. See Figure 1.

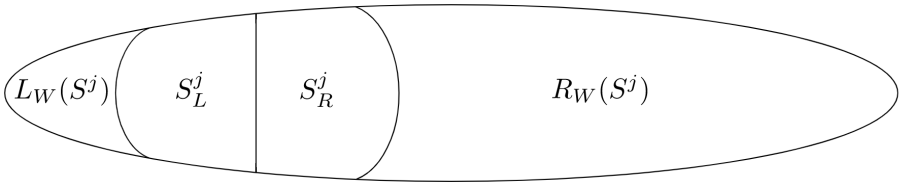

Figure 1 S^j is partitioned into two halves, S^j_L and S^j_R.

Run Dijkstra from S^j_L and from S^j_R. If either of these sets has min-eccentricity at most r, we will continue the induction: If $\epsilon(S^j_L) \leq r$, we let $S^{j+1} = S^j_L$. Then $L_W(S^{j+1}) = L_W(S^j)$, so for every $w \in L_W(S^{j+1})$, $\epsilon(w) > r$. Alternatively, if $\epsilon(S^j_L) > r$ but $\epsilon(S^j_R) \leq r$, we let $S^{j+1} = S^j_R$. Then $L_W(S^{j+1}) = L_W(S^j) \cup S^j_L$, so for every $w \in L_W(S^{j+1})$, $\epsilon(w) > r$.

Otherwise, $\epsilon(S^j_L) > r$ and $\epsilon(S^j_R) > r$. In this case we halt the induction and let $S = S^j$. Every $w \in L_W(S^j) \cup S^j$ satisfies $\epsilon(w) > r$, so S has the properties desired.

At each step, the size of the set S^j halves, so there are at most $\log |W| \leq \log n$ iterations. In each iteration, we perform a constant number of Dijkstras, so the runtime is $O(m \log^2 n)$. ◁

For each i such that $\epsilon(W_i) \leq r$, let S_i be the subset constructed by applying Claim 12 to the set $W = W_i$. For each $w \in L_{W_i}(S_i)$, we report that $\epsilon(w) > r$; this holds by Claim 12b. If S_i consists of a single vertex $\{s\}$, we can determine that for any $v \in L(W_i)$, $d_{\min}(v, s) \leq \epsilon(s) \leq r \leq kr$, by Claim 12a. Otherwise, $|S_i| > 1$, so we report that $\epsilon(s) > r$ for all $s \in S_i$; this holds by Claim 12c.

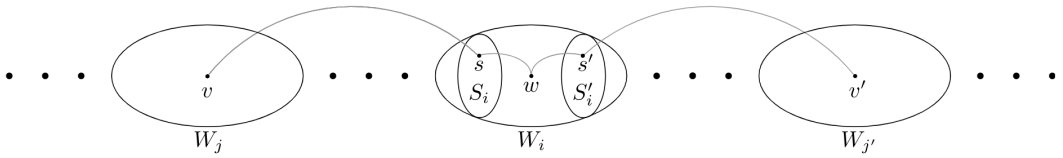

Figure 2 A representation of the $v \to w$ and $w \to v'$ paths, via the sets S_i and S'_i constructed with Claim 12. The outer subpaths are of length $\leq r$, and the inner subpaths are of length $\leq (k-1)r$.

Using a recursive application of our algorithm to the graph $G_i = G[W_i]$, we can certify, for every vertex $w \in W_i$, that $\epsilon_{G_i}(w) > r$ or that $\epsilon_{G_i}(w) \leq (k-1)r$. Consider any $w \in R_{W_i}(S_i)$. If we determined that $\epsilon_{G_i}(w) > r$, we report that $\epsilon(w) > r$; this holds since $\epsilon(w) \geq \epsilon_{G_i}(w)$. Otherwise, consider any $v \in L(W_i)$. Since $\epsilon(S_i) \leq r$, there is some $s \in S_i$ such that $d_{\min}(v, s) = d(v, s) \leq r$. Then since $\epsilon_{G_i}(w) \leq (k-1)r$ and since w is to the right of s in the topological ordering, we have $d_{\min}(v, w) \leq d(v, s) + d(s, w) \leq r + (k-1)r = kr$. See Figure 2.

Thus, our algorithm has certified for each $w \in W_i$ that $\epsilon(w) > r$ or that $d_{\min}(v, w) \leq kr$ for all $v \in L(W_i)$. By a symmetric argument, we can construct the set S'_i obtained by applying Claim 12 to the graph G with the edges reversed; see Figure 2. Then as above we can determine for each $w \in W_i$ that $\epsilon(w) > r$ or that $d_{\min}(w, v') \leq kr$ for all $v' \in R(W_i)$. Since W_i is a topologically consecutive set, $V \setminus W_i = L(W_i) \cup R(W_i)$. So for any $w \in W_i$, if we determine that $d_{\min}(w, v) \leq kr$ for all $v \in L(W_i)$ and for all $v \in R(W_i)$ we report that $\epsilon(w) \leq kr$; otherwise we report $\epsilon(w) > r$.

2.2 Runtime Analysis

In this section we analyze the runtime of the algorithm of Proposition 7, and we give full descriptions of how to prove Theorems 8-11 from Proposition 7 using binary search.

Recall that $c_k(\tau) = \frac{2^{k-2}(1+\tau)}{2^{k-1}(1+\tau)-\tau}$.

▶ **Lemma 13.** *The algorithm of Proposition 7 runs in time* $O(\min(mn^{1/k}\log^2 n, m^{2^{k-1}/(2^k-1)}n\log^2 n))$ *assuming APSP computations are done in* $\tilde{O}(mn)$ *time.*

On graphs with integer edge weights bounded by n^t *for* $t < 3-\omega$*, the algorithm runs in time* $O(\min(mn^{1/k}\log^2 n, m^{mc_k(\mu(t))}n\log^2 n))$*, assuming APSP computations are done in* $O(n^{2+\mu(t)})$ *time using Zwick's fast APSP algorithm [36].*

Proof. To simultaneously analyze both versions of the algorithm, our algorithm's runtime will be described in terms of a placeholder τ, such that APSP computations within the algorithm are done in $O(n^{2+\tau}\log n)$ time. To obtain the runtime bound for general weighted DAGs, we will let $\tau = 1$, and note $c_k(1) = \frac{2^{k-1}}{2^k-1}$. To obtain the runtime bound for DAGs with integer edge weights bounded by n^t for $t < 3-\omega$, we will let $\tau = \mu(t)$.

Topologically sorting the graph takes $O(m\log n)$ time which is absorbed into the final runtime.

In order to use $k = 1$ as a base case, our inductive hypothesis will assume a slightly weaker claim about the runtime: in the inductive step for k, we will assume there is an $O(\min(mn^{1/(k-1)}\log^2 n, n^{2c_{k-1}(\tau)+1}\log^2 n))$-time algorithm which certifies for each $v \in V$ that $\epsilon(v) > r$ or that $\epsilon(v) \leq (k-1)r$. Note that $n^{2c_{k-1}} \geq m^{c_{k-1}}$. Then in the base case where $k = 1$, APSP takes time $O(\min(mn\log n, n^{2+\tau}\log n))$, satisfying the inductive hypothesis.

Consider $k > 1$. Running Dijkstra to and from W_i for each i takes $O(mp \log n)$. It takes time $O(mp \log^2 n)$ to apply Claim 12 twice for each i, to construct sets S_i and symmetric sets S'_i (constructed in the same way as the sets S_i but with left and right swapped, pictured in Figure 2).

We also do recursive calls of our algorithm on at most p subgraphs, induced by sets W_i. Below, we analyze the runtime of the recursive calls in two different ways, giving us two upper bounds on the algorithm's runtime.

Analysis 1. Let $m_i = |E(G[W_i])|$; then note $\sum_i m_i \leq m$. For each i, the recursive call on W_i takes time $O(m_i(n/p)^{1/(k-1)} \log^2 n)$, so in total the recursive calls take time $O(m(n/p)^{1/(k-1)} \log^2 n)$. Let $p = n^{1/k}$, so that $mp = m(n/p)^{1/(k-1)}$. Then the runtime is $O(mn^{1/k} \log^2 n)$.

Analysis 2. Since $|W_i| = n/p$, a recursive call on $G[W_i]$ takes time $O((n/p)^{2c_{k-1}(\tau)+1} \log^2 n)$. We do at most p such calls, so the total runtime of the recursive calls is $O((n/p)^{2c_{k-1}(\tau)} n \log^2 n)$. Now, we choose p so that $mp = (n/p)^{2c_{k-1}(\tau)} n$. Then $m = (n/p)^{2c_{k-1}(\tau)+1}$. Recall that $c_k(\tau) = \frac{2^{k-2}(1+\tau)}{2^{k-1}(1+\tau)-\tau}$ and note that $2c_{k-1}(\tau) + 1 = \frac{2^{k-1}(1+\tau)-\tau}{2^{k-2}(1+\tau)-\tau} = \frac{2c_{k-1}(\tau)}{c_k(\tau)}$. Thus, $m^{c_k(\tau)} = (n/p)^{2c_{k-1}(\tau)}$. So the runtime of the algorithm is $O((n/p)^{2c_{k-1}(\tau)} \cdot n \log^2 n) = O(m^{c_k(\tau)} n \log^2 n)$. Since $m = O(n^2)$, this satisfies the inductive hypothesis. ◀

2.3 Lower Bounds

In this section, using an essentially linear time reduction, we reduce Triangle Detection to $(2-\delta)$-approximation of min-radius.

▶ **Reminder of Theorem 2 .** *If there is a $T(n,m)$-time algorithm for $(2-\delta)$-approximation of min-radius in $O(n)$-node $\tilde{O}(m)$-edge DAGs for some $\delta > 0$, then there is an $\tilde{O}(T(n,m)+m)$-time algorithm for Triangle Detection on graphs with n nodes and m edges.*

Proof. We are going to use two gadgets from previous works:

- DAG gadget [3]: Given a set X of n nodes $v_1, \ldots, v_n$ and a constant integer parameter $t \geq 2$, the gadget creates a DAG $DG_t(X)$ with at most $O(n)$ nodes and $O(n \log n)$ edges such that in the topological order of $DG_t(X)$, $v_i < v_{i+1}$, and for any two nodes of $DG_t(X)$ x, y where $x < y$ in the topological order, $d(x,y) \leq t+1$.
- Connectivity gadget [4]: Let $X = \{v_1, \ldots, v_n\}$, and let $X' = \{v'_1, \ldots, v'_n\}$ be a copy of X, where both X and X' are independent sets. Then we can add a connectivity gadget $U(X)$ along with edges from X to $U(X)$ and from $U(X)$ to X', such that $|U(X)| = O(\log n)$, for all $i \neq j$ we have $d(v_i, v'_j) = 2$, and there is no path from v_i to v'_i.

Now let $G = (A, B, C, E_G)$ be an instance of Triangle Detection, with n nodes and m edges. We create a DAG G^* such that if G has a triangle (YES case), the min-radius of G^* is $t+1$, and if G doesn't have a triangle (NO case), the min-radius of G^* is $2t$. We let t be an integer such that $2 - \delta/2 < \frac{2t}{t+1}$, so that a fast $(2-\delta)$-approximation algorithm is also a fast $(\frac{2t}{t+1} - \delta/2)$-approximation algorithm, and hence it can distinguish min-diameter $t+1$ vs $2t$.

We define G^* as follows: G^* has A, B, and C as part of its vertex set. Let $A'_1, A'_2, \ldots, A'_{t+1}$ be copies of A. Add $E_G(A,B)$ to G^* with edges directed from A to B, and add $E_G(B,C)$ with edges directed from B to C. For any $c \in C$ and $a \in A$, add an edge from c to $a' \in A'_2$ if a and c are attached in G, where a' is the copy of a in A'_2. For each $i = 1, \ldots, t$, connect the copy of a in A'_i to the copy of a in A'_{i+1} for all $a \in A$.

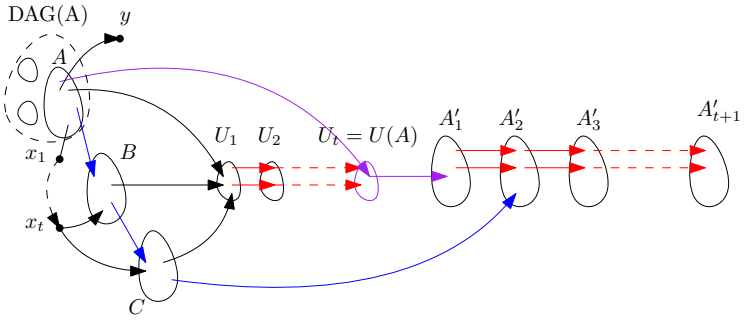

Figure 3 Graph G^* created from the Triangle Detection instance G. Blue edges are edges in G, red edges are between two nodes that are copies of the same vertex. Purple edges are part of the connectivity gadget. Dashed lines are subpaths.

Now we add the two gadgets. Add the connectivity gadget $U(A)$ between A and A'_1. Add two copies of $DG_t(A)$ sharing A, and denote the union of these copies by $DAG(A)$. Also add a node y, and add edges from all nodes in A to y; this guarantees that the center of G^* must be in $DAG(A)$.

To make all nodes in A at distance $t+1$ to A'_1, make $t-1$ copies of $U(A)$, $U_1, \ldots, U_{t-1}$. For each $i = 1, \ldots, t-1$, connect the copy of u in U_i to the copy of u in U_{i+1}, for any $u \in U(A)$, where $U_t = U(A)$. Add edges from all nodes in $A \cup B \cup C$ to all nodes in U_1.

To make all nodes in A at distance $t+1$ to B and C, let $x_1, \ldots, x_t$ be a path of length $t-1$. Connect all nodes of A to x_1, and connect x_t to all nodes of $B \cup C$. See Figure 3 for the construction. Note that G^* is a DAG, with the order of sets of vertices being $DAG(A), y, x_1, \ldots, x_t, B, C, U_1, \ldots, U_{t-1}, U(A), A'_1, \ldots, A'_{t+1}$. Moreover, $G^*[A \cup B \cup C \cup A_2]$ has m edges corresponding to the original edges of G^*, and besides those we only added $O(n \log n)$ edges to G^*. So G^* has $O(n)$ nodes and $O(m + n \log n)$ edges.

We will show that if the Triangle Detection instance is a YES instance, then there is a node $a \in A$ such that $\epsilon(a) = t+1$. If the Triangle Detection instance is a NO instance, then we show that for all nodes in G^*, their min-eccentricity is at least $2t$.

YES case. Let abc be a triangle in G. We show that $\epsilon(a) = t+1$. Note that $d_{\min}(a, \bar{a}) \leq t+1$ for all $\bar{a} \in DAG(A)$. We already know that $d(a, s) \leq t+1$ for any $s \in B \cup C \cup \{x_1, \ldots, x_t, y\}$. For any $u \in U_i$ for $i \leq t+1$, $d(a, u) \leq t+1$ using the path going through $U_1, \ldots U_{i-1}$. Since for any $z' \in A'_1$, there is a $u \in U(A)$ that has an edge to z', we have $d(a, z') \leq t+1$. Now for all $z' \in A'_2$ where z' is a copy of $z \in A$ and $z \neq a$, we have $d(a, z') = 3$ through $U(A)$ and A'_1 (using the edges of the connectivity gadget). For $z = a$, using the triangle edges going from A to B to C, we have that $d(a, z') = 3$. So for all $z' \in A'_2 \cup \ldots \cup A'_{t+1}$, we have $d(a, z') \leq t+1$.

NO case. Suppose that there is no triangle in G. First, note that the min-eccentricities of the vertices outside $DAG(A)$ are infinite, because there is no path between them and y. Moreover, if $z \in DAG(A) \setminus A$, it has a copy $z' \in DAG(A) \setminus A$ (in the other copy of $DG_t(A)$), and there is no path between z and z'. This is because this path must go through A, and since $DAG(A)$ consists of two copies of $DG_t(A)$ sharing A, the set of nodes in A that z has a path to (from) is exactly the same as the set of nodes in A that z' has a path to (from). So there is no $a \in A$ such that that z has a path to a and z' has a path from a.

Now it remains to compute the min-eccentricities of the vertices in A. Let $a \in A$, and let $a'_{t+1} \in A'_{t+1}$ be the copy of a. We show that $d(a, a'_{t+1}) = 2t$. Let P be a shortest path from a to a'_{t+1}. First note that any path from a to a'_{t+1} must go through $a'_2 \in A'_2$, where a'_2

is a copy of a, and we have $d(a'_2, a'_{t+1}) = t - 1$. We also know that there is no path from a to a'_2 using the edges from A to $U(A)$, because this path would need to contain a path between a and $a'_1 \in A_1$ in $G^*[A \cup U(A) \cup A'_1]$, and from the construction of the connectivity gadget there is no such path. If P does not use any $C \times A'_2$ edge, then the path must go through U_i for all i, and hence it is of length $2t$. So if the min-eccentricity of a is smaller than $2t$, the path P uses a $C \times A'_2$ edge ca'_2 for some $c \in C$. If x_1 is on the ac path, then the path goes through x_i for all i, and hence it is of length $2t$. Then x_1 is not on the path, so the ac path must go through B. In particular, there is a $b \in B$ such that $ab, bc \in E(G^*)$. Since $ca'_2 \in E(G^*)$, this implies that abc is a triangle in G, which is a contradiction. So $\epsilon(a) \geq 2t$. ◀

3 Min-diameter

Our min-diameter approximation algorithm relies on Yuster and Zwick's fast sparse matrix multiplication algorithm. Here, we define $\alpha = \max\{0 \leq r \leq 1 \mid \omega(1, r, 1) = 2\}$ and $\beta = \frac{\omega-2}{1-\alpha}$.

▶ **Theorem 14** ([35]). *If A and B are n by n matrices with at most l nonzero entries each, then A and B can be multiplied in $O(l^{\frac{2\beta}{\beta+1}} n^{\frac{2-\alpha\beta}{\beta+1}} + n^{2+o(1)})$ time.*[3]

This sparse matrix multiplication algorithm will be used to prove the following proposition.

▶ **Proposition 15.** *There is an $O(m^{\frac{2\beta}{3\beta+1}} n^{\frac{4\beta+2-\alpha\beta}{3\beta+1}+o(1)} + n^{2+o(1)})$-time algorithm which, given an unweighted DAG G and a parameter D', reports that the min-diameter D of G satisfies $D \leq \frac{3D'}{2}$ or that it satisfies $D > D'$.*

The algorithm of Proposition 15 will be described and proven to work in subsection 3.1, and its runtime will be analyzed in Lemma 18 in subsection 3.2. Then Proposition 15 allows us to obtain the min-diameter approximation algorithm given in Theorem 16 below.

▶ **Theorem 16.** *There is an $O(m^{\frac{2\beta}{3\beta+1}} n^{\frac{4\beta+2-\alpha\beta}{3\beta+1}+o(1)} + n^{2+o(1)})$-time algorithm which, given an unweighted DAG G, outputs an estimate D_0 for its min-diameter D such that $D \leq D_0 < \frac{3D}{2}$.*

Proof. To obtain our approximation D_0, we binary search over D' in $[0, n]$ by applying the algorithm of Proposition 15 logarithmically many times; note that polylogarithmic factors are $n^{o(1)}$ so they do not affect the runtime bound. Let C be the smallest value found in the binary search such that the algorithm reports that $D \leq \frac{3C}{2}$; then $D > C - 1$. Let $D_0 = \frac{3C}{2}$. Then $D \leq D_0 < \frac{3D}{2}$, as desired. ◀

Note that since $\alpha > 0.31389$ [23] and $\omega < 2.37286$ [6], we can use $\beta \simeq 0.5435$. This gives the runtime of $O(m^{0.414} n^{1.522} + n^{2+o(1)})$ stated in Theorem 5.

3.1 Algorithm Description and Correctness

Our algorithm takes as input an unweighted DAG G, an integer D', and a parameter $\epsilon \in [0, 1]$, and reports that $D > D'$ or that $D \leq \frac{3D'}{2}$. (The runtime-minimizing value of ϵ will be determined later.)

[3] To be precise, given known bounds $\alpha \geq a, \omega \leq c$, one can define $b = \frac{c-2}{1-a}$, and then equivalents of Theorem 14 hold for any such pair of values a, b, not just for the "true" values α, β. This is implicit in [35].

If at any point, a BFS finds a pair of vertices at min-distance more than D', the algorithm reports that $D > D'$; hence in what follows we will assume that this does not occur. We initially have all pairs of vertices "unmarked," and mark the pairs for which we know that there is a path from one to the other of length at most $\frac{3D'}{2}$.

The algorithm first takes two preliminary steps: it topologically sorts the graph, and it constructs for each vertex two topologically sorted lists, one of its in-neighbors and one of its out-neighbors.

Our algorithm will then use the greedy set cover algorithm, described in the following lemma. This lemma, and a related randomized version, are standard techniques used in graph distance algorithms (see for example [5, 28, 13, 3]). A proof may be found in [29].

▶ **Lemma 17.** *Let $|V| = n$, let $p = O(n)$, and let $X_1, \ldots X_p \subseteq V$ be sets of size $|X_i| \geq n^\epsilon$ for $\epsilon \in [0, 1]$. Then there is an $O(n^{1+\epsilon})$-time algorithm which constructs a set $S \subseteq V$ of size $\tilde{O}(n^{1-\epsilon})$ such that $S \cap X_i \neq \varnothing$ for all i.*

For any $u \in V$, if $|N^{\text{out}}_{D'/2}(u)| < n^\epsilon$ let $X_u = N^{\text{out}}_{D'/2}(u)$ and otherwise let X_u be the left-most n^ϵ vertices in $N^{\text{out}}_{D'/2}(u)$. So in particular, $|X_u| \leq n^\epsilon$. We can compute X_u as follows: we maintain a list of the $\leq n^\epsilon$ left-most vertices we have found so far that are at distance $< D'/2$ from u. At each step, for each vertex in the list, we consider its left-most out-neighbor that is not yet in our set; we add the left-most such out-neighbor to the set. We halt when there are no more such out-neighbors not in our set, or after adding n^ϵ vertices to our set. Likewise, for any $w \in V$, let $Y_w = N^{\text{in}}_{D'/2}(w)$ if $|N^{\text{in}}_{D'/2}(w)| < n^\epsilon$, and otherwise let Y_w consist of the right-most n^ϵ vertices in $N^{\text{in}}_{D'/2}(w)$. We can compute the sets Y_w in a manner symmetric to how we computed the sets X_u. Then we can use Lemma 17 to construct a set S of size $\tilde{O}(n^{1-\epsilon})$ such that for all u having $|N^{\text{out}}_{D'/2}(u)| \geq n^\epsilon$, $S \cap X_u$ is nonempty, and for all w having $|N^{\text{in}}_{D'/2}(w)| \geq n^\epsilon$, $S \cap Y_w$ is nonempty.

Run BFS into and out of every $s \in S$. We may assume that $d_{\min}(s, x) \leq D'$ for all $s \in S, x \in V$.

We will construct matrices A and B with rows and columns indexed by vertices in V, as follows: For each vertex $t \in X_u$, let $A[u, t] = 1$. For each vertex $t \in Y_w$, let $B[t, w] = 1$. Multiply A and B using the sparse matrix multiplication algorithm of Theorem 14.

Now, we will consider any pair of vertices (u, w) where u is to the left of w, $u \in R(N^{\text{in}}_{D'/2}(w) \cap S)$, and $w \in L(N^{\text{out}}_{D'/2}(u) \cap S)$. We have that $(A \cdot B)[u, w] > 0$ if and only if $d(u, w) \leq D'$. Indeed, if $d(u, w) \leq D'$, then there is some intermediate vertex t such that $d(u, x) \leq D'/2$ and $d(x, w) \leq D'/2$. Suppose that $t \notin X_u$. Then since X_u is defined as the left-most n^ϵ vertices in $N^{\text{out}}_{D'/2}(u)$, this implies that $|N^{\text{out}}_{D'/2}(u)| > n^\epsilon$ and hence that $|X_u| = n^\epsilon$. Then there is some $s \in S \cap X_u$. Since $t \notin X_u$, t is to the right of all vertices in X_u, and in particular t is to the right of s. This implies $t \notin L(N^{\text{out}}_{D'/2}(u) \cap S)$. But since $w \in L(N^{\text{out}}_{D'/2}(u) \cap S)$ and t lies between u and w, this is a contradiction. Thus, t must be in X_u, and by symmetry, t is in Y_w. So $A[u, t] = 1$ and $B[t, w] = 1$, meaning $(A \cdot B)[u, w] > 0$. Likewise, if $(A \cdot B)[u, w] > 0$, then there exists $t \in X_u \cap Y_w$ such that $d(u, t) \leq D'/2$ and $d(t, w) \leq D'/2$, so $d(u, w) \leq D'$. Therefore, we will mark all pairs (u, w) such that $(A \cdot B)[u, w] > 0$.

Now, consider any $u \in V$ and any $w \notin L(N^{\text{out}}_{D'/2}(u) \cap S)$ to the right of u. We mark the pair (u, w). If such a w exists, then there is some $s \in N^{\text{out}}_{D'/2}(u) \cap S$ such that s is to the left of or is equal to w. By assumption, $d(s, w) \leq D'$, so $d(u, w) \leq d(u, s) + d(s, w) \leq D'/2 + D' = \frac{3D'}{2}$. By a symmetric argument, for any $w \in V$ and any $u \notin R(N^{\text{in}}_{D'/2}(w) \cap S)$ to the left of w, we have that $d(u, w) \leq \frac{3D'}{2}$, so again we mark any such pair (u, w). Thus, since we have assumed that $\epsilon(s) \leq \frac{3D'}{2}$ for all $s \in S$, the algorithm will mark all pairs of vertices $u, w \in V$ except those for which we have simultaneously that $u \in R(N^{\text{in}}_{D'/2}(w) \cap S)$ and $w \in L(N^{\text{out}}_{D'/2}(u) \cap S)$.

Finally, check whether there exists an unmarked pair (u, w). If so, report that $D > D'$. Otherwise, report that $D \leq \frac{3D'}{2}$.

3.2 Runtime Analysis

Here we analyze the runtime of the algorithm of Proposition 15.

▶ **Lemma 18.** *The algorithm of Proposition 15 runs in time* $\tilde{O}(m^{\frac{2\beta}{3\beta+1}} n^{\frac{4\beta+2-\alpha\beta}{3\beta+1}+o(1)} + n^{2+o(1)})$.

Proof. Topologically sorting the graph takes $O(m \log n)$ time which is absorbed into the final runtime. Constructing for each vertex topologically ordered lists of its in-neighbors and out-neighbors can be done in time $\tilde{O}(n^2)$.

Computing the covering set S takes time $\tilde{O}(n^{1+\epsilon})$ and running BFS from its vertices takes time $O(n^{1-\epsilon} m \log n)$. Checking for each pair (u, w) whether $u \in L(N^{\text{out}}_{D'/2}(u) \cap S)$ and $w \in L(N^{\text{out}}_{D'/2}(u) \cap S)$ can be done in $\tilde{O}(n^2)$ time.

For a fixed u, to compute X_u, we maintain a list of the at most n^ϵ left-most vertices we have found that are at distance $< D'/2$ from u. For each vertex, we store its left-most out-neighbor that is not yet in our set. At each step, we find the left-most such out-neighbor of any vertex in the list; this takes time $O(n^\epsilon)$, and updating the list to reflect that this out-neighbor has been added to our set takes time $O(n^\epsilon)$. At each step we add a vertex to our set X_u, so there are at most $O(n^\epsilon)$ steps. Hence, constructing X_u for a fixed u takes $O(n^{2\epsilon})$ time. Then constructing all sets X_u, Y_w takes $O(n^{1+2\epsilon})$ time altogether.

Finally, note that there are at most n^ϵ 1s in each row of A, since we only set $A[u, t] = 1$ if $t \in X_u$. Thus, A contains at most $n^{1+\epsilon}$ 1s. By symmetry, the same holds for B. Then multiplying A and B can be done in time $O(n^{(1+\epsilon)\frac{2\beta}{\beta+1}+\frac{2-\alpha\beta}{\beta+1}+o(1)} + n^{2+o(1)})$, using Yuster and Zwick's fast sparse matrix multiplication (Theorem 14).

Then the total runtime is:

$$\tilde{O}(n^{1-\epsilon}m + n^{1+2\epsilon} + n^{(1+\epsilon)\frac{2\beta}{\beta+1}+\frac{2-\alpha\beta}{\beta+1}+o(1)} + n^{2+o(1)})$$

Let γ be the largest value such that $n^\gamma = O(m)$. Let $\epsilon = \frac{\alpha\beta+(\beta+1)(\gamma-1)}{3\beta+1}$; this value is chosen because it sets the first and third terms in the above runtime equal (up to $n^{o(1)}$ factors), hence asymptotically minimizing their sum. Substituting the value of ϵ and simplifying, the runtime of the algorithm is:

$$\tilde{O}(n^{\frac{2\beta}{3\beta+1}\gamma+\frac{4\beta+2-\alpha\beta}{3\beta+1}+o(1)} + n^{\frac{2\beta+2}{3\beta+1}\gamma+\frac{\beta-1+2\alpha\beta}{3\beta+1}} + n^{2+o(1)})$$

We note that $3\beta - 3\alpha\beta > 3(\omega - 2) \geq 0 > -1$, giving:

$$4\beta + 2 - \alpha\beta > 2 + (\beta - 1 + 2\alpha\beta) \geq 2\gamma + (\beta - 1 + 2\alpha\beta)$$

Thus, the first term of the above runtime dominates the second. Substituting $n^\gamma = O(m)$, and noting that the polylogarithmic factors in the runtime are of order $n^{o(1)}$, the runtime is $O(m^{\frac{2\beta}{3\beta+1}} n^{\frac{4\beta+2-\alpha\beta}{3\beta+1}+o(1)} + n^{2+o(1)})$, as desired. ◀

Abstract

Consider a set P of points in the unit square $\mathcal{U} = [1, 0)$, one of them being the origin. For each point $p \in P$ you may draw an axis-aligned rectangle in $\mathcal{U}$ with its lower-left corner being p. What is the maximum area such rectangles can cover without overlapping each other?

Freedman [18] posed this problem in 1969, asking whether one can always cover at least 50% of $\mathcal{U}$. Over 40 years later, Dumitrescu and Tóth [12] achieved the first constant coverage of 9.1%; since then, no significant progress was made. While 9.1% might seem low, the authors could not find any instance where their algorithm covers less than 50%, nourishing the hope to eventually prove a 50% bound. While we indeed significantly raise the algorithm's coverage to 39%, we extinguish the hope of reaching 50% by giving points for which its coverage stays below 43.3%.

Our analysis studies the algorithm's average and worst-case density of so-called tiles, which represent the staircase polygons in which a point can freely choose its maximum-area rectangle. Our approach is comparatively general and may potentially help in analyzing related algorithms.

1 Introduction

The Lower-Left Anchored Rectangle Packing (LLARP) problem considers a finite set $P \subseteq \mathcal{U} := [0, 1)^2$ of *input points* with $(0, 0) \in P$. The goal is to find a set of non-empty, axis-aligned interior-disjoint rectangles $(r_p)_{p \in P}$ with p being the lower-left corner of $r_p \subseteq \mathcal{U}$ and such that their total area $\sum_{p \in P} |r_p|$ is maximized.

This problem was first introduced by Freedman [18, Unsolved Problem 11, page 345] in 1969. He asked the question whether, for any point set P, the rectangles can always be chosen such that they cover at least 50% of $\mathcal{U}$. It is easy to see that this is the best one can hope for, since putting n equally spaced points along the ascending diagonal of $\mathcal{U}$ yields a maximum coverable area of $1/2 + o(1)$ for $n \to \infty$.

Over the years, the LLARP problem reoccurred in the form of geometric challenges [14] and in miscellaneous books and journals about mathematical puzzles [19, 20, 21]. Still, it took more than 40 years until the first constant lower bound was established: Dumitrescu and Tóth [12] considered a natural greedy algorithm, called GreedyPacking, and proved that it achieves a coverage of 9.1%.

This caused a surge of interest in this old problem, resulting in numerous findings for variants or special cases of the problem (see Section 1.1). Since then, no further significant progress was made towards the original question[1], and even the question whether a maximum area covering can be found in polynomial time remains elusive.

While [12] themselves observed that "*a sizable gap to the conjectured* 50% *remains*", they were unable to find instances where their algorithm *does not* reach 50%. This led them and others to conjecture a much better quality of their algorithm, making it a natural candidate to answer Freedman's question positively, albeit [12] also mentioned that "*obtaining substantial improvements probably requires new ideas*".

Our results indeed attest the greedy algorithm a much better coverage of 39%. However, at the same time, we show that there are instances where the coverage stays below 43.3%.

1.1 Related Work

LLARP falls into the class of geometric packing problems, where a typical question is how much of a container can be covered using a set of geometric shapes in two or more dimensions. We concentrate on two-dimensional packing problems with rectangular containers and shapes.

Complexity of LLARP. The GreedyPacking algorithm by Dumitrescu and Tóth [12] considers the input points step by step from top-right to bottom-left, always choosing the maximum-area rectangle. They showed that this achieves the same worst-case coverage as an algorithm called TilePacking. The latter partitions the unit square into staircase-shaped *tiles*, one per input point, and chooses a maximal rectangle within each tile (see Section 2 for the formal algorithm description).

While the complexity of LLARP remains unknown, [12] also showed that there is an order of the input points for which the greedy algorithm achieves an optimal packing (albeit of unknown value); how to find that ordering remains unclear. [7] studied the combinatorial structure of optimal solutions, proving that the worst-case number of maximal rectangle packings is exponential in the number of input points.

LLARP Variants. After [12], a series of papers studied special cases and variants of LLARP. [6] allowed rectangles to be anchored in any of the four corners and showed that here the worst-case coverage lies in $[7/12, 2/3]$ and in $[5/32, 7/27]$ if the rectangles are restricted to squares. [4] showed that the union of all (possibly overlapping) squares covers at least $1/2$ and proved that finding a maximum corner-anchored square packing is NP-hard. Interestingly, there is only one other LLARP-variant known to be NP-hard, namely if the rectangle's anchors lie in their center [5]. Other results consider specific classes of input points, like points with certain ascending/descending structures [8] or points that lie on the unit square's boundary (for corner-anchored rectangles) [9].

Further Related Problems and Applications. Further related problems include the maximum weight independent set of rectangles problem [2, 10, 1] (which was used, e.g., in [5] to derive a PTAS for center-anchored rectangle packings) or geometric knapsack [3, 17] and strip packing problems [15]. In contrast to LLARP and its variants, the size of the objects to be packed is typically part of the input and object placement is less constrained.

[1] A very recent, still unpublished result slightly raised the greedy algorithm's coverage to 10.39% [13].

Note that LLARP-like problems are not of pure theoretical interest, but have applications in, e.g., map labeling. Here, rectangular text labels must be placed under certain constraints (e.g., labels might be scalable but require a fixed ratio and must be placed at a specific anchor) within a given container. We refer to the relatively recent survey [16] for details.

1.2 Our Contribution and Techniques

We analyze the greedy algorithm TilePacking from [12] (formally described in Section 2). From a high-level view, TilePacking partitions the unit square into staircase-shaped *tiles*, each anchored at an input point, and chooses an area-maximal rectangle in each tile. A natural way to analyze such an algorithm is to consider the tiles' densities (the ratio between their area-maximal rectangles and their own area) and prove a lower bound on the *average* tile density (which immediately yields the covering guarantee).

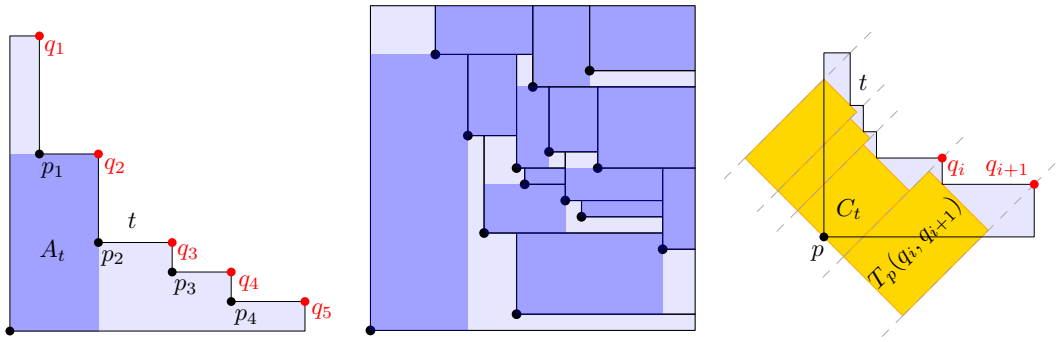
Dumitrescu and Tóth [12] follow this approach by defining suitable charging areas C_t for each tile t (trapezoids below/beneath the tile). We also use such a charging scheme, but rely on a much more complex charging area which we refer to as a tile's *crown*. But instead of directly analyzing a tile's charging area, we first extract the critical properties that determine the charging scheme's quality. This general approach (described in Section 3) requires a bound ξ on the tile's *charging ratio* $|C_t|/|t|$ together with some simple properties (basically a form of local convexity characterizing the average tile density).

We derive such a charging ratio bound ξ_s and describe simple, symmetric tiles for which it is tight (Figures 8 and 9). We then take an arbitrary tile and show how to gradually transform it into one of these tiles without increasing its charging ratio. This establishes that ξ_s is indeed a charging ratio bound and allows us to conclude the following theorem.

▶ **Theorem 1.** *Given any set of input points, TilePacking covers at least* 39% *of* $\mathcal{U}$.

While the aforementioned transformations to worst-case tiles require some care, we showcase the versatility of our approach by first proving a slightly weaker bound of only 25% (Section 4.2). Its analysis is not only much simpler but, in fact, takes us halfway to Theorem 1, as the used charging ratio bound ξ_w (Proposition 11) is tight for high-density tiles and all that remains is to refine our charging ratio bound for low-density tiles (Proposition 15).

Our second major result constructs an input instance (depicted in Figure 14) for which TilePacking covers significantly less than 50% of the unit square.



▶ **Theorem 2.** *There is a set P of input points for which TilePacking covers at most* 43.3% *of the unit square.*

By the aforementioned worst-case equivalence of TilePacking and GreedyPacking, both Theorems 1 and 2 also hold for the latter.

2 Preliminaries and Algorithm Description

Let $\mathcal{U} \coloneqq [0,1)^2$ denote the unit square. For a point $p \in \mathbb{R}^2$ define $x(p)$ and $y(p)$ as the x- and y-coordinates of p, respectively. For two points $p, p' \in \mathbb{R}^2$ we use the notation $p \preceq p'$ to indicate that $x(p) \leq x(p')$ and $y(p) \leq y(p')$. Similarly, $p \prec p'$ means that $x(p) < x(p')$ and $y(p) < y(p')$. The relations "$\succeq$" and "$\succ$" are defined analogously. For a set S we denote its closure by $\overline{S}$. If S is measurable, we use $|S|$ to denote its area.

To simplify some geometric arguments, we use the following line-notation: We define the line $\ell_q^{\diagup} \subseteq \mathbb{R}^2$ as the line through $q \in \mathbb{R}^2$ of slope $+1$. Similarly, we define the lines ℓ_q^{-}, $\ell_q^{\diagdown}$, and $\ell_q^{|}$ through q with slope 0, -1, and ∞, respectively. For lines of type $R \in \{ \diagup, | \}$, we

(a) Staircase points p_i, q_j and rectangle A_t.

(b) A tile packing produced by TilePacking.

(c) A tile t, its crown C_t, and a tower $T_p(q_i, q_{i+1})$.

Figure 1 Tiles, packings, crowns, and towers. In our figures, tiles are shaded light blue. Upper and lower stair case points are shown in red and black, respectively. A dark blue rectangle represents a (maximal) rectangle of a tile. Crowns are shown in yellow and towers are possibly labeled.

write $\ell_q^R < \ell_{q'}^R$ if $\ell_{q'}^R = \ell_q^R + (x, 0)$ (using element-wise addition) with $x > 0$ and say ℓ_q^R *is left of* $\ell_{q'}^R$. Similarly, for lines of type $R \in \{ \diagdown, - \}$ we write $\ell_q^R < \ell_{q'}^R$ if $\ell_{q'}^R = \ell_q^R + (0, y)$ with $y > 0$ and say ℓ_q^R *is below* $\ell_{q'}^R$. Analogous definitions apply for "$>$", "$\leq$", and "$\geq$".

Input Sets in General Position. Remember the problem description from Section 1. We say that the input set P is *in general position* if there are no two (different) points $p, p' \in P$ with $x(p) = x(p')$, $y(p) = y(p')$, or $x(p) + y(p) = x(p') + y(p')$. That is, no two points may share an x- or y-coordinate and may not lie on the same diagonal of slope -1. W.l.o.g., we restrict P to be in general position (see the full version [11] for why this is ok).

Tiles and Tile Packings. A *tile* t is a staircase polygon in $\mathcal{U}$ (see Figure 1a). More formally, t is defined using its *anchor* $p \in \mathcal{U}$ and a set of k *upper staircase points* $\Gamma_t := \{ q_1, q_2, \dots, q_k \} \subseteq \overline{\mathcal{U}}$ ordered by increasing x-coordinate and such that $q_i \succ p$ for all q_i as well as $q_i \not\preceq q_j$ for all $q_i \neq q_j$. With this we define $t = \{ q \in \mathcal{U} \mid q \succeq p \wedge \exists q' \in \Gamma_t \colon q \prec q' \}$. A point $p_i = \big(x(q_{i-1}), y(q_i)\big)$ is called a *lower staircase point*. We define $A_t \subseteq t$ as an (arbitrary) area-maximal rectangle in t and $\rho_t := |A_t|/|t|$ as the tile's *density*. For indexed upper staircase points q_i we often use the shorthands $x_i := x(q_i)$ and $y_i := y(q_i)$.

If p and Γ_t do not adhere to $q_i \succ p$ and $q_i \not\preceq q_j$, but only to the weaker requirements $q_i \succeq p$, $q_i \not\preceq q_j$ for all $q_i \neq q_j$), then we say that t is *degenerate*. We show in Lemma 13 that we can transform such tiles into non-degenerate ones without affecting our arguments.

The *hyperbola* of t is $h_t := \{ (x + x(p), y + y(p)) \in \mathbb{R}^2_{>0} \mid y = |A_t|/x \}$. Note that all upper staircase points lie between p and h_t. Moreover, the points from $\Gamma_t \cap h_t$ span all area-maximal rectangles in t. If, $p = (0, 0)$ and $|A_t| = 1$, then t is called *normalized*.

A *tile packing* of the unit square is a partition of $\mathcal{U}$ into tiles. In particular, $\sum_{t \in \mathcal{T}} |t| = |\mathcal{U}| = 1$. We use $A(\mathcal{T}) := \sum_{t \in \mathcal{T}} |A_t|$ to denote the area covered by choosing an area-maximal rectangle A_t for each tile t (the *area covered by* $\mathcal{T}$).

A Greedy Tile Packing Algorithm. Let us revisit the algorithm TilePacking by Dumitrescu and Tóth [12]. TilePacking processes the points P from top-right to bottom-left. More formally, it orders $P = \{ p_1, p_2, \dots, p_n \}$ such that $\ell^{\diagdown}_{p_i} \geq \ell^{\diagdown}_{p_{i+1}}$. It then defines for each $p_i \in P$ the tile $t_i := \{ q \in \mathcal{U} \mid q \succeq p_i \} \setminus \bigcup_{j=1}^{i-1} t_j$, yielding a tile packing $\mathcal{T} = \{ t_1, t_2, \dots, t_n \}$.

To build its solution to LLARP, TilePacking picks for each $p \in P$ the rectangle r_p as an (arbitrary) area-maximal rectangle $A_t \subseteq t$ in the tile t containing p. Thus, the total area covered by TilePacking is $A(\mathcal{T})$. Figure 1b illustrates the resulting tile packing.

Note that, by this construction, the lower staircase points of each tile t are input points. Moreover, as already mentioned in [12], for each tile we can define a certain *exclusive area* that does not contain an input point.

▶ Observation 3. Consider the tile packing $\mathcal{T}$ produced by TilePacking for a set P of input points. Fix a tile $t \in \mathcal{T}$ and let $p \in P$ denote its anchor point. Then the tile's *exclusive area* $E_t \coloneqq \{\, q \in \mathbb{R}^2 \mid \ell_q^\rangle > \ell_p^\rangle \wedge \exists q' \in \Gamma_t \colon q \prec q' \,\}$ does not contain any point from P.

This observation follows by noting that any such input point $p' \in E_t$ would be processed before p by TilePacking and "shield" at least one upper staircase point $q' \in \Gamma_t$ from p, preventing it from becoming an upper staircase point of tile t.

3 A General Approach for Lower Bounds

Here we present a general approach to derive lower bounds for the area covered by a given tile packing $\mathcal{T}$. Our approach relies on a suitable *charging scheme* $(c_t)_{t\in\mathcal{T}}$ that charges the area of each tile $t \in \mathcal{T}$ to a *charging area* $c_t > 0$.

▶ **Definition 4.** For a given charging scheme, we define $c^* \coloneqq \sum_{t\in\mathcal{T}} c_t$ as the total charged area and $c_t/|t|$ as the *charging ratio* of tile t. We call a function $\xi \colon (0,1] \to \mathbb{R}_{\geq 0}$ a *charging ratio bound* with *critical density* $\rho^* \in (0,1]$ if

1. ξ is point-convex at ρ^* with $\xi'(\rho^*) < 0$,
2. $\xi(\rho^*) \geq c^*$ and
3. for any $t \in \mathcal{T}$: $\xi(\rho_t) \leq c_t/|t|$.

Note that a function $f \colon I \to \mathbb{R}, I \subseteq \mathbb{R}$ is said to be *point-convex* at $x \in I$ if f is differentiable at x and the tangent t of f at x satisfies $t(x) \leq f(x)$ for all $x \in I$.

The following lemma uses a charging ratio bound to show that ρ^* is a lower bound on $A(\mathcal{T})$.

▶ **Lemma 5.** *Consider a tile packing $\mathcal{T}$ with a charging scheme $(c_t)_{t\in\mathcal{T}}$ together with a charging ratio bound ξ with critical density ρ^*. Then $A(\mathcal{T}) \geq \rho^*$.*

Proof. Since ξ is point-convex in ρ^*, the tangent $\tau(\rho) \coloneqq \xi(\rho^*) + \xi'(\rho^*) \cdot (\rho - \rho^*)$ of ξ in ρ^* satisfies $\tau(\rho) \leq \xi(\rho)$ for all $\rho \in (0,1]$. Using $A(\mathcal{T}) = \sum_{t\in\mathcal{T}} |A_t| = \sum_{t\in\mathcal{T}} |t| \cdot \rho_t$ we calculate

$$\tau\big(A(\mathcal{T})\big) = \tau\left(\sum_{t\in\mathcal{T}} |t| \cdot \rho_t\right) \leq \sum_{t\in\mathcal{T}} |t| \cdot \tau(\rho_t) \leq \sum_{t\in\mathcal{T}} |t| \cdot \xi(\rho_t) \leq \sum_{t\in\mathcal{T}} |t| \cdot \frac{c_t}{|t|} = c^* \leq \xi(\rho^*), \quad (1)$$

where the second inequality follows from applying Jensen's Inequality to the convex function τ. Combining $\tau\big(A(\mathcal{T})\big) = \xi(\rho^*) + \xi'(\rho^*) \cdot \big(A(\mathcal{T}) - \rho^*\big)$ with Inequality 1 and rearranging gives $\xi'(\rho^*) \cdot A(\mathcal{T}) \leq \xi(\rho^*) \cdot \rho^*$, which yields the desired result after dividing by $\xi(\rho^*) < 0$. ◀

4 Charging Scheme and Weak Covering Guarantee

This section introduces the charging scheme we will use to derive our lower bounds for TilePacking's coverage (via the approach presented in Section 3). Then we derive a weak charging ratio bound ξ_w, as described in Section 3. While comparatively simple, this already yields that TilePacking covers at least a quarter of the unit square, almost tripling the original guarantee from [12]. Section 5 will refine ξ_w to derive our main result (Theorem 1).

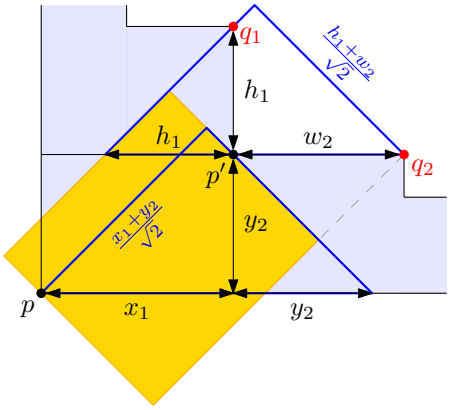


Figure 2 $|T_p(q_1, q_2)|$ is computed via the catheti of the blue triangles.

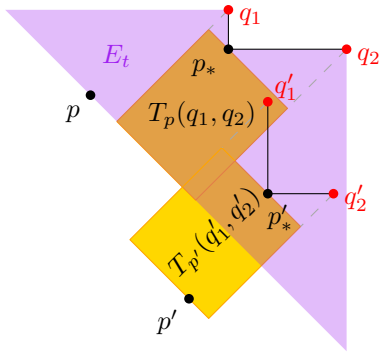

Figure 3 Example for Lemma 8. The shown tower overlap has $p'_* \in E_t$, violating t's exclusive area.

4.1 Charging Scheme

Given a tile packing $\mathcal{T}$ constructed by TilePacking, our charging scheme defines an area C_t for each tile $t \in \mathcal{T}$ and charges t's area to $c_t := |C_t|$. We first explain how C_t is constructed from t. Afterward, we prove useful properties about these areas and their relation to $\mathcal{T}$.

Construction of C_t. Consider three points $p, q_1 = (x_1, y_1), q_2 = (x_2, y_2) \in \mathbb{R}^2$ with $q_1, q_2 \succeq p$, $x_1 \leq x_2$, and $y_1 \geq y_2$. The *tower* $T_p(q_1, q_2)$ with *base point* p and *peak* $p_* = (x_1, y_2)$ is the interior of the rectangle enclosed by the lines $\ell_p^{\searrow}$ (the tower's *base*), $\ell_{q_1}^{\swarrow}$ (the tower's *left side*), $\ell_{q_2}^{\swarrow}$ (the tower's *right side*), and $\ell_{p_*}^{\searrow}$ (the tower's *top*). If the subscript p is omitted, the base point is assumed to be the origin $(0, 0)$.

For a tile t with anchor p and $\Gamma_t = \{q_1, q_2, \ldots, q_k\}$ being ordered by increasing x-coordinate, we define the charging area as the disjoint union of towers, i.e., $C_t := \bigcup_{i=1}^{k-1} T_p(q_i, q_{i+1})$. We refer to C_t as the *crown* of tile t. (See Figure 1c.)

The width and height of a tower $T_p(q_1, q_2)$ correspond to the side lengths of isosceles triangles (see Figure 2), which yields a formula for $|T_p(q_1, q_2)|$. By taking derivatives, we get formulas for the change of the tower's area when moving q_1 or q_2 horizontally or vertically.

▶ Observation 6. Consider $T_p(q_1, q_2)$ with $q_j - p = (x_j, y_j)$, $j \in \{1, 2\}$. Let $w_2 := x_2 - x_1$, and $h_1 := y_1 - y_2$. Then $|T_p(q_1, q_2)| = (x_1 + y_2) \cdot (w_2 + h_1)/2$.

▶ Observation 7. Consider $T_p(q_1, q_2)$ with $q_j - p = (x_j, y_j)$, $j \in \{1, 2\}$. Let $w_2 := x_2 - x_1$, and $h_1 := y_1 - y_2$. Fix $\alpha \in \mathbb{R}$ and consider the change of $|T_p(q_1, q_2)|$ if either q_1 or q_2 are moved horizontally or vertically as a linear function of ε:

(a) If either $q_1(\varepsilon) := q_1 + (0, \alpha \cdot \varepsilon)$ or $q_2(\varepsilon) := q_2 + (\alpha \cdot \varepsilon, 0)$, then $\partial |T_p(q_1, q_2)|/\partial \varepsilon = \alpha \cdot (x_1 + y_2)/2$ and $\partial^2 |T_p(q_1, q_2)|/\partial \varepsilon^2 = 0$.

(b) If either $q_1(\varepsilon) := q_1 + (\alpha \cdot \varepsilon, 0)$ or $q_2(\varepsilon) := q_2 + (0, \alpha \cdot \varepsilon)$, then $\partial |T_p(q_1, q_2)|/\partial \varepsilon = \alpha \cdot \big(w_2 + h_1 - (x_1 + y_2)\big)/2$ and $\partial^2 |T_p(q_1, q_2)|/\partial \varepsilon^2 = -\alpha^2$.

Properties of the Charging Scheme. The following results capture basic properties of our charging scheme. First, we show that the defined crowns are pairwise disjoint.

▶ **Lemma 8.** *Consider the tile packing $\mathcal{T}$ produced by algorithm TilePacking for a set P of input points. For any two different tiles $t, t' \in \mathcal{T}$, we have $C_t \cap C_{t'} = \emptyset$.*

Proof. Fix $t, t' \in \mathcal{T}$ and let $p, p' \in P$ denote their respective anchors. W.l.o.g., assume $\ell^{\searrow}_p > \ell^{\searrow}_{p'}$, such that TilePacking processes p before p'. As crowns consist of towers, it is sufficient to show $T_p(q_1, q_2) \cap T_{p'}(q'_1, q'_2) = \emptyset$ for consecutive $q_1, q_2 \in \Gamma_t$ and $q'_1, q'_2 \in \Gamma_{t'}$. Let $p_*, p'_* \in P$ be the respective peaks of these towers. W.l.o.g., we assume $\ell^{\swarrow}_{p_*} < \ell^{\swarrow}_{p'_*}$ (p_* lies left of $\ell^{\swarrow}_{p'_*}$); the other case follows symmetrically.

If $\ell^{\searrow}_{p'_*} < \ell^{\searrow}_p$, the towers are separated (the top of $T_{p'}(q'_1, q'_2)$ lies below the base of $T_p(q_1, q_2)$) and cannot intersect. So assume $\ell^{\searrow}_{p'_*} > \ell^{\searrow}_p$. Then we cannot have $p'_* \prec q_2$, since this would imply that p'_* lies in the exclusive area of t, violating Observation 3 (see Figure 3).

Let $\Delta_y := q'_1 - p'_*$ and note that $x(\Delta_y) = 0$. Define $\tilde{q}_1 := p_* - \Delta_y$ and note that $p'_* \not\succ \tilde{q}_1$, since otherwise $q'_1 = p'_* + \Delta_y \succ \tilde{q}_1 + \Delta_y = p_*$, which (together with $\ell^{\searrow}_{p_*} > \ell^{\searrow}_p > \ell^{\searrow}_{p'}$) would mean that p_* lies in the exclusive area of t' (again violating Observation 3).

So $\ell^{\swarrow}_{p'_*} > \ell^{\swarrow}_{p_*}$, $p'_* \not\prec q_2$, and $p'_* \not\succ \tilde{q}_1$. Together, these imply $x(p'_*) > x(q_2)$ and $y(p'_*) < y(\tilde{q}_1)$, which in turn imply $\ell^{\swarrow}_{p'_*} > \ell^{\swarrow}_{q_2 - \Delta_y}$. But then, the towers are separated, since $\ell^{\swarrow}_{q'_1} = \ell^{\swarrow}_{p'_* + \Delta_y} > \ell^{\swarrow}_{q_2 - \Delta_y + \Delta_y} = \ell^{\swarrow}_{q_2}$ ($T_p(q_1, q_2)$'s right side lies left of $T_{p'}(q'_1, q'_2)$'s left side). ◀

The next lemma's proof shows that all crowns lie inside a pentagon formed by $\mathcal{U}$ and two isosceles triangles left and below of $\mathcal{U}$ (see Figure 4). With Lemma 8 this implies that the total charging area is bounded by the pentagon's area.

▶ **Lemma 9.** *Consider the tile packing $\mathcal{T}$ produced by algorithm TilePacking for a set P of input points. The total charging area of $\mathcal{T}$ is $c^* \leq 3/2$. Moreover, this bound is tight, since for arbitrarily small $\varepsilon > 0$ there are input points P_ε with $c^* \geq 3/2 - \varepsilon$.*

Proof. Define the points SW $:= (0, 0)$, NW $:= (0, 1)$, and SE $:= (1, 0)$. Let $\pentagon$ denote the pentagon enclosed by the lines $\ell^{\searrow}_{\mathrm{SW}}$, $\ell^{\swarrow}_{\mathrm{NW}}$, $\ell^{\swarrow}_{\mathrm{SE}}$, ℓ^{-}_{NW}, and $\ell^{|}_{\mathrm{SE}}$ (see Figure 4). Since $|\pentagon| = 3/2$ and using Lemma 8, it is sufficient to show that $C_t \subseteq \pentagon$ for any $t \in \mathcal{T}$. For this, in turn, it is sufficient to show that any tower $T_p(q_1, q_2)$ of C_t lies in $\pentagon$.

Fix such a tower $T_p(q_1, q_2)$. Since $p \succeq \mathrm{SW}$, we have $\ell^{\searrow}_p \geq \ell^{\searrow}_{\mathrm{SW}}$ (the base of $T_p(q_1, q_2)$ lies above $\ell^{\searrow}_{\mathrm{SW}}$). Similarly, since $q_1, q_2 \in \overline{\mathcal{U}} \subseteq \pentagon$, we have $\ell^{\swarrow}_{q_1} \geq \ell^{\swarrow}_{\mathrm{NW}}$ (the left side of $T_p(q_1, q_2)$ lies right of the left side of $\pentagon$) and $\ell^{\swarrow}_{q_2} \leq \ell^{\swarrow}_{\mathrm{SE}}$ (the right side of $T_p(q_1, q_2)$ lies left of the right side of $\pentagon$). Finally, the topmost point $q_1 \in \overline{\mathcal{U}}$ of $T_p(q_1, q_2)$ lies below ℓ^{-}_{NW} and the rightmost point $q_2 \in \overline{\mathcal{U}}$ of $T_p(q_1, q_2)$ lies to the left of $\ell^{|}_{SE}$. Together, we get $T_p(q_1, q_2) \subseteq \pentagon$.

For the tightness of the bound, choose $\delta > 0, 1/\delta \in \mathbb{N}$ and define $P^\delta = \{\,\mathrm{SW}\,\} \cup \{\,(k \cdot \delta, 1 - k \cdot \delta^2), (1 - k \cdot \delta^2, k \cdot \delta) \mid k \in \{\,1, 2, \ldots, 1/\delta - 1\,\}\,\}$. As illustrated in Figure 4, the crown C_t of tile t with anchor SW converges towards $\pentagon$ as $\delta \to 0$. Therefore, for each $\varepsilon > 0$, we can choose δ such that, for point set $P_\varepsilon := P^\delta$, we have $c^* \geq |C_t| \geq 3/2 - \varepsilon$. ◀

4.2 Weak Covering Guarantee for Greedy Tile Packings

This section proves the following, slightly weaker version of Theorem 1:

▶ **Theorem 10.** *For any set of input points, TilePacking covers at least 25% of $\mathcal{U}$.*

Proving this not only serves as a warm-up to illustrate our approach before proving our main result, but – as we will see in Section 5 – brings us halfway towards proving Theorem 1.

So consider a tile packing $\mathcal{T}$ produced by algorithm TilePacking for some set P of input points. To prove Theorem 10, we follow the approach outlined in Section 3, using the charging scheme from Section 4.1. That is, the area of $t \in \mathcal{T}$ is charged to $c_t = |C_t|$, where C_t represents the crown of t. To this end, define $\rho^* := 1/4$ and the *weak charging ratio bound*

$$\xi_w \colon (0, 1] \to \mathbb{R}_{\geq 0}, \quad \xi_w(\rho) := 2 \cdot (1 - \rho).$$

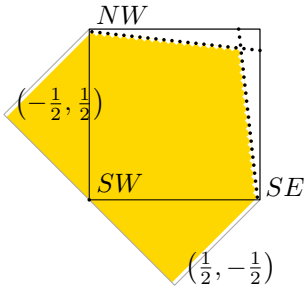

Figure 4 Pentagon $\pentagon$ and point set P_ε from Lemma 9.

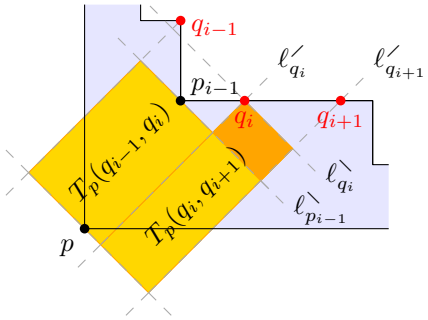

Figure 5 Removing superfluous points from Γ_t reduces $|C_t|$ by the rectangle between $\ell^{\swarrow}_{q_i}$, $\ell^{\swarrow}_{q_{i+1}}$, $\ell^{\searrow}_{q_i}$, and $\ell^{\searrow}_{p_{i-1}}$.

As a linear function, ξ_w is trivially point-convex in ρ^*. Moreover, $\xi_w(\rho^*) = 3/2$ and thus, by Lemma 9, $\xi_w(\rho^*) \geq c^*$. In the remainder of this section we prove the following Proposition 11, stating that ξ_w represents a lower bound on the charging ratio of any $t \in \mathcal{T}$. Once this is proven, Theorem 10 follows immediately by applying Lemma 5.

▶ **Proposition 11.** *For any tile t we have $c_t/|t| \geq \xi_w(\rho_t)$.*

A Lower Bound on the Charging Ratio. To prove that ξ_w bounds from below the charging ratio $c_t/|t|$ of any tile $t \in \mathcal{T}$, we gradually transform t into a "simpler" tile $\tilde{t}$. Our transformations ensure $\rho_{\tilde{t}} = \rho_t$ and $c_{\tilde{t}}/|\tilde{t}| \leq c_t/|t|$. Eventually, $\tilde{t}$ will be simple enough to directly prove $c_{\tilde{t}}/|\tilde{t}| \geq \xi_w(\rho_{\tilde{t}})$. The following notation expresses progress via such a transformation:

$$\tilde{t} \preceq t \quad :\Leftrightarrow \quad \rho_{\tilde{t}} = \rho_t \text{ and } c_{\tilde{t}}/|\tilde{t}| \leq c_t/|t|.$$

As a simple example, note that both a tile's density and charging-ratio are invariant under translation and concentric scaling w.r.t. its anchor. This gives rise to the following transformation, which allows us to restrict our analysis to normalized tiles.

▶ Observation 12. Translate a tile t such that it is anchored in the origin, then scale it by $1/|A_t|$ around the origin. We call the resulting tile $\tilde{t}$ *normalized*. Then $\tilde{t} \preceq t$.

Consider a tile t with anchor p. A transformation may move one of t's upper staircase points to the same x- or y-coordinate as another point from $\Gamma_t \cup \{ p \}$, resulting in a degenerate tile with superfluous points in Γ_t (see Section 2). The next lemma states that removing such superfluous points maintains an equal tile with a smaller crown.

▶ **Lemma 13.** *Consider a degenerate tile t. The tile $\tilde{t}$ with same anchor p but $\Gamma_{\tilde{t}} := \{ q \in \Gamma_t \mid q \succ p \text{ and } \nexists q' \in \Gamma_t \colon q \preceq q' \}$ covers the same points, is non-degenerate, and $\tilde{t} \preceq t$.*

Proof. Order $\Gamma_t = \{ q_1, q_2, \ldots, q_k \}$ by non-decreasing x-coordinate and let $q_0 = q_{k+1} = p$. W.l.o.g. assume there is some $i \in \{ 1, \ldots, k \}$ with $y(q_i) = y(q_{i+1})$; the case of identical x-coordinates follows analogously. Let $\tilde{t}$ denote the (possibly still degenerate) tile with anchor p and $\Gamma_{\tilde{t}} = \Gamma_t \setminus \{ q_i \}$. Note that $\{ q \in \mathcal{U} \mid q \succeq p \wedge q \prec q_i \} \subseteq \{ q \in \mathcal{U} \mid q \succeq p \wedge q \prec q_{i+1} \}$, which implies $\tilde{t} = t$ and, thus, $\rho_t = \rho_{\tilde{t}}$. Removing q_i affects the towers $T_p(q_i, q_{i+1})$ with peak q_i (only if $i < k$) and $T_p(q_{i-1}, q_i)$ with peak p_{i-1}. Figure 5 illustrates the situation.

We now show that $c_{\tilde{t}} \leq c_t$, such that $\tilde{t} \preceq t$; the lemma's statement then follows by iteration. If $i = k$, then $c_{\tilde{t}} = c_t - |T(q_{i-1}, q_i)| \leq c_t$. So assume $i < k$. Then $c_{\tilde{t}} = c_t - |\square| \leq c_t$, where $\square$ is the rectangle enclosed by the lines $\ell^{\swarrow}_{q_i}$, $\ell^{\swarrow}_{q_{i+1}}$, $\ell^{\searrow}_{q_i}$, and $\ell^{\searrow}_{p_{i-1}}$ (see Figure 5). ◀

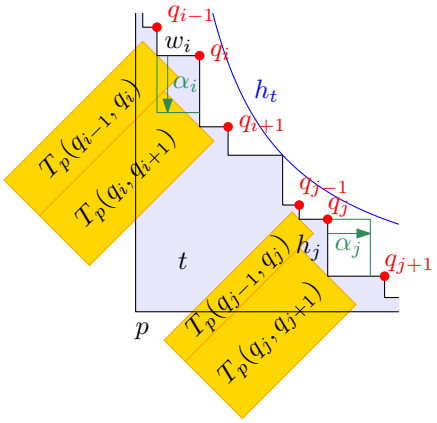

Figure 6 Moving inner points in Lemma 14. Note that $\alpha_j > 0$ and $\alpha_i < 0$ in this case.

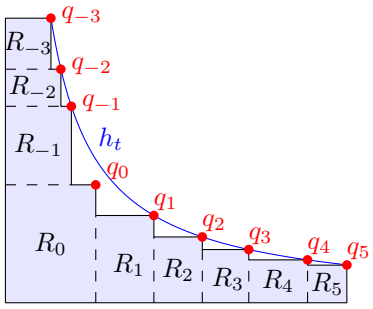

Figure 7 Notation for Proposition 11 with $l = 3$ and $m = 5$.

Note that $h_t \cap \Gamma_t$ consists of the upper staircase points that form maximum rectangles in the tile. We now prove that we can transform t such that at most one $q \in \Gamma_t$ lies not on h_t.

▶ **Lemma 14.** *A normalized tile t can be transformed into a tile $\tilde{t} \preceq t$ with $|\Gamma_{\tilde{t}} \setminus h_{\tilde{t}}| \leq 1$.*

Proof. Assume $|\Gamma_t \setminus h_t| > 1$ and order $\Gamma_t = \{ q_1, q_2, \ldots, q_k \}$ by increasing x-coordinate. To simplify border cases, define $q_0 = q_1$ and $q_{k+1} = q_k$. Choose $q_i, q_j \in \Gamma_t \setminus h_t$ with $i < j$. Consider the transformation $q_i(\varepsilon) := q_i + (0, \alpha_i \cdot \varepsilon)$ and $q_j(\varepsilon) := q_j + (\alpha_j \cdot \varepsilon, 0)$ with $\alpha_i, \alpha_j \in \mathbb{R}$. Then the tile and crown areas become functions $t(\varepsilon)$ and $c_t(\varepsilon)$ of ε. We show that there are non-zero α_i, α_j such that $t(\varepsilon)$ and, thus, $\rho_{t(\varepsilon)}$ remain constant and $c_t(\varepsilon)$ does not increase. Eventually, this results in a tile $\tilde{t} \preceq t$ that has an additional point on h_t or that has a degenerate staircase point which we can remove by Lemma 13. In both cases $|\Gamma_t \setminus h_t|$ is decreased and the lemma follows by iteration. Figure 6 illustrates the transformation.

The transformation changes only the towers $T(q_{i-1}, q_i)$, $T(q_i, q_{i+1})$, $T(q_{j-1}, q_j)$, and $T(q_j, q_{j+1})$. ($i < j$ ensures that these changes do not interfere with each other.) For $l \in \{ 0, 1, \ldots, k+1 \}$ let $q_l = (x_l, y_l)$ and define $w_l := x_l - x_{l-1}$ for $l \neq 0$ and $h_l := y_l - y_{l+1}$ for $l \neq k+1$. Then the transformation changes the area of the tile according to $\partial t(\varepsilon)/\partial\varepsilon = \alpha_i \cdot w_i + \alpha_j \cdot h_j$. To keep $|t|$ constant, we make this zero by setting $\alpha_j = -\alpha_i \cdot w_i / h_j$.

It remains to find a non-zero α_i such that $c_t(\varepsilon)$ is non-increasing in ε. For this let $T_i(\varepsilon) := |T(q_{i-1}, q_i)| + |T(q_i, q_{i+1})|$ and define $T_j(\varepsilon)$ analogously. By Observation 7, $\partial^2 T_l(\varepsilon)/\partial\varepsilon^2 = -\alpha_l^2$ for $l \in \{ i, j \}$. This yields $\partial^2 c_t(\varepsilon)/\partial\varepsilon^2 = -\alpha_i^2 - \alpha_j^2 < -\alpha_i^2$, which is a negative constant. This allows us to choose $\alpha_i \in \{ -1, +1 \}$ such that $c_t(\varepsilon)$ is non-increasing. ◀

With these results, we are ready to prove our first covering guarantee for TilePacking.

Proof of Proposition 11. Let t be a tile. By Observation 12 and Lemma 14, we can assume that t is normalized and $|\Gamma_t \setminus h_t| \leq 1$. If $|\Gamma_t \setminus h_t| = 1$, let $q_0 \in \Gamma_t \setminus h_t$, otherwise let $q_0 \in \Gamma_t$ arbitrary. Relabel the points $\Gamma_t = \{ q_{-l}, \ldots, q_m \}$ in increasing order of their x-coordinates. To simplify border cases, let $q_{-l-1} = q_{-l}$ and $q_{m+1} = q_m$. Let further $w_i := x_i - x_{i-1}$ for $i \neq l - 1$ and $h_i := y_i - y_{i+1}$ for $i \neq m + 1$ (using $q_i = (x_i, y_i)$). For $i = -l, \ldots, m$ inductively define the rectangles $R_i := \{ q \in t \mid q \prec q_i \} \setminus \bigcup_{|j|<|i|} R_j$. Finally, for $i = 1, \ldots, m$, let $T_i := T(q_{i-1}, q_i)$; for $i = -l, \ldots, -1$ let $T_i := T(q_i, q_{i+1})$. See Figure 7 for an illustration.

Note that $c_t = \sum_{i=-l}^{-1} |T_i| + \sum_{i=1}^{m} |T_i|$ and $|t| = \sum_{j=-l}^{m} |R_j|$. We will first show that for $i \in \{-l, \dots, m\} \setminus \{-1, 0, 1\}$ we have $|T_i| \geq 2|R_i|$. Afterward, we show $|T_{-1}| + |T_1| \geq 2(|R_{-1}| + |R_0| + |R_1| - 1)$. With these inequalities and since $\rho_t = |A_t|/|t| = 1/|t|$ due to the normalization, the desired statement follows via

$$c_t = \sum_{i=-l}^{-1} |T_i| + \sum_{i=1}^{m} |T_i| \geq \sum_{i=-l}^{m} 2|R_i| - 2 = 2|t| - 2 = 2|t| \cdot (1 - \rho_t) = |t| \cdot \xi_w(\rho_t).$$

We now show the above bounds, starting with $|T_i| \geq 2|R_i|$ for $|i| \geq 2$. W.l.o.g. we assume $i \geq 2$; the case $i \leq -2$ follows by symmetry. Note that $i \geq 2$ implies $q_i, q_{i-1} \in h_t$ and thus (since t is normalized) $y_j = 1/x_j$ for $j \in \{i-1, i\}$. This yields $x_{i-1}/y_i = x_{i-1} \cdot x_i$ as well as $w_i/h_{i-1} = (x_i - x_{i-1})/(y_{i-1} - y_i) = x_{i-1} \cdot x_i$. We use these identities together with $|R_i| = w_i \cdot y_i$ to bound the formula for $|T_i|$ from Observation 6:

$$\begin{aligned} |T_i| &= 1/2 \cdot (x_{i-1} + y_i)(w_i + h_{i-1}) = w_i \cdot y_i \cdot 1/2 \cdot (1 + x_{i-1}/y_i)(1 + h_{i-1}/w_i) \\ &= |R_i| \cdot \frac{1}{2} \cdot (1 + x_{i-1} \cdot x_i) \cdot \left(1 + \frac{1}{x_{i-1} \cdot x_i}\right) = |R_i| \cdot \frac{1}{2} \cdot \frac{(1 + x_{i-1} \cdot x_i)^2}{x_{i-1} \cdot x_i} \geq 2|R_i|, \end{aligned}$$

using that the function $x \mapsto (1+x)^2/x$ over $[0, \infty)$ has a minimum value of 4 at $x = 1$.

It remains to show that $|T_{-1}| + |T_1| \geq 2(|R_{-1}| + |R_{-1}| + |R_0| - 1)$. Note that, if $m = 0$, we have $q_{m+1} = q_m$ by definition and $|R_1| = 0$ and $|T_1| = 0$ hold. Similarly, if $l = 0$ then $|R_{-1}| = 0$ and $|T_{-1}| = 0$. We assume that $l > 0$ or $m > 0$, as otherwise $\xi_w(\rho_t) = \xi_w(1) = 0$ and the proposition becomes trivial. W.l.o.g. let $m > 0$; the other case follows symmetrically.

For $\alpha \in \{-1, +1\}$ (which we fix later) and $\varepsilon \geq 0$ define the transformation $y_0(\varepsilon) \coloneqq y_0 + \alpha \cdot \varepsilon$, where ε is chosen such that $y_0(\varepsilon) \in [y_1, 1/x_0]$ [2], which moves q_0 either up- or downward, depending on α. Thus, with $f(\varepsilon) \coloneqq |T_{-1}| + |T_1| - 2(|R_{-1}| + |R_1| + |R_0| - 1)$, where the T_i and R_i depend on y_0 and thus ε, our goal becomes to prove $f(0) \geq 0$. To this end, consider how $f(\varepsilon)$ changes with ε. The rectangles $|R_j|$ ($j \in \{-1, 0, 1\}$) change linearly or remain constant. By Observation 7, $\partial^2 |T_1|/\partial \varepsilon^2 = 0$. Similarly, if $l > 0$ we have $\partial^2 |T_{-1}|/\partial \varepsilon^2 = -\alpha^2 = -1$ by Observation 7, and if $l = 0$ we have $\partial^2 |T_{-1}|/\partial \varepsilon^2 = 0$ (because $|T_{-1}|$ remains zero). Thus, in all cases $\partial^2 f(\varepsilon)/\partial \varepsilon^2 \leq 0$, meaning its minimum $f_{\min}$ lies at one of the borders, where either $y_0 = y_1$ or $y_0 = 1/x_0$. We consider both possibilities and show that each time $f_{\min} \geq 0$ (which finishes the proof, since $f(0) \geq f_{\min} \geq 0$).

If at $f_{\min}$ we have $y_0 = 1/x_0$, let t_{high} denote the corresponding tile. Note that q_0 lies on the hyperbola h_t. But then $|R_0| = 1$ and, thus, $f_{\min} = |T_{-1}| + |T_1| - 2(|R_{-1}| + |R_1|)$. Moreover, with $q_0 \in h_t$ we can apply the calculations for $|i| > 1$ to get $|T_{-1}| \geq 2|R_{-1}|$ and $|T_1| \geq 2|R_1|$, such that $f_{\min} \geq 0$.

So assume that at $f_{\min}$ we have $y_0 = y_1$ and let t_{low} denote the corresponding tile. Note that R_0 and R_1 form a rectangle from the origin to the point q_1 on h_t, such that $|R_0| + |R_1| = 1$. Thus, $f_{\min} = |T_{-1}| + |T_1| - 2|R_{-1}|$. Define the (degenerate) tile t' with $\Gamma_{t'} = \{q_{-1}, q_0, q_1\}$ and anchor p, such that its crown area is $c_{t'} = |T_1| + |T_2|$. By Lemma 13, for the (non-degenerate) tile $\tilde{t}'$ with $\Gamma_{\tilde{t}'} = \Gamma_{t'} \setminus \{q_0\}$ we have $c_{\tilde{t}'} \leq c_{t'}$. The crown $c_{\tilde{t}'}$ consists of the single tower $T(q_{-1}, q_1)$. Since $q_{-1}, q_1 \in h_t$, we can apply the calculations for $|i| > 1$ to get $c_{\tilde{t}'} = |T(q_{-1}, q_1)| \geq 2|R_{-1}|$. Putting everything together we get

$$f_{\min} = |T_{-1}| + |T_1| - 2|R_{-1}| = c_{t'} - 2|R_{-1}| \geq c_{\tilde{t}'} - 2|R_{-1}| \geq 0. \qquad \blacktriangleleft$$

[2] These boundaries ensure that the tile remains valid and normalized. Note that if $l = 0$, moving q_0 upward also causes the dummy point q_{-1} to move upward, such that $|R_{-1}|$ and $|T_{-1}|$ remain zero.

5 Strong Covering Guarantee for Greedy Tile Packings

This section proves our strong covering guarantee for TilePacking, namely Theorem 1. We use the same approach as for our weak covering guarantee from Section 4.2 but derive a stronger charging ratio bound. More exactly, instead of ξ_w we use

$$\xi_s\colon (0,1] \to \mathbb{R}_{\geq 0}, \quad \xi_s(\rho) \coloneqq \begin{cases} 1-\rho\cdot\big(1+\sinh(1-1/\rho)\big) & \text{if } \rho \leq 1/2 \\ \xi_w(\rho) = 2\cdot(1-\rho) & \text{if } \rho > 1/2. \end{cases} \tag{2}$$

Most properties required for our approach from Definition 4 are easily verified for ξ_s (whose function graph can be seen in Figure 12). Indeed, for $\rho^* \coloneqq \xi_s^{-1}(3/2) \approx 0.3901$, we have $\partial\xi_s(\rho)/\partial\rho|_{\rho=\rho^*} \approx -5.1 < 0$. Moreover, ξ_s is point-convex at ρ^*, since it is convex on $(0,1/2]$ and on $(1/2,1]$ its tangent t_ξ at ρ^* lies below ξ_s (t_ξ is steeper and $t_\xi(1/2) \approx 0.94 < 1 = \xi_w(1/2)$). Also, by choice of ρ^* and by Lemma 9, we have $\xi_s(\rho^*) = 3/2 \geq c^*$ for the total charged area c^* of a tile packing $\mathcal{T}$ produced by algorithm TilePacking.

The following proposition states the remaining required property of Definition 4.

▶ **Proposition 15.** *For any tile t we have $c_t/|t| \geq \xi_s(\rho_t)$ and this bound is tight.*

With this, Theorem 1 follows by applying Lemma 5. The remainder of this section outlines the analysis of this proposition.

Transformation to Worst-case Tiles. For tiles t of density ρ_t larger than $1/2$, Proposition 15 follows from Proposition 11, since in this regime $\xi_s(\rho_t) = \xi_w(\rho_t)$. The tightness for such high densities follows since for any $\rho_t \in (1/2,1]$ there is a (symmetric) *step tile* $t = t_l(\rho_t)$ of density ρ_t (depicted in Figure 9) with $c_t/|t| = \xi_s(\rho_t)$. Thus, we restrict our further study to tiles of density at most $1/2$. We will show how to gradually transform any such tile t into a (symmetric) *hyperbola tile* $t_h(\rho_t) \preceq t$ (depicted in Figure 8). Again, the tightness follows from the existence of a tile $t = t_h(\rho_t)$ with $c_t/|t| = \xi_s(\rho_t)$.

Before we outline the transformation process into such worst-case low-density tiles, we need to cope with the fact that $t_h(\rho_t)$ is not a staircase polygon and, thus, not captured by our tile definition. However, one can see $t_h(\rho_t)$ as the result of defining Γ_t as k equally spaced points from the hyperbola $\{\,(x,y) \in [0,s) \mid y = 1/x\,\}$ and taking the limit $k \to \infty$. The next paragraph formalizes this intuition by introducing *generalized tiles* and some related notions.

Generalized Tiles and Crown Contribution. A *generalized tile* t is defined equivalently to "normal" tiles, with the only difference that Γ_t may be infinite. All other tile definitions (e.g., point set definition of t, maximum-area rectangle A_t, or density ρ_t) stay intact.

From now on the term *tile* always refers to a normalized and non-degenerate generalized tile. (Note that the points which cause a generalized tile to be degenerate, cannot reside in a slide. As such Observation 12 and Lemma 13 easily transfer to generalized tiles.) We require that the x-coordinates of Γ_t can be partitioned into k inclusion-wise maximal, closed intervals $I_1, I_2, \dots, I_k$, ordered by increasing x-coordinates. For $i \in \{\,1,2,\dots,k\,\}$ let $q_i^-, q_i^+ \in \Gamma_t$ denote the points realizing the left- and rightmost x-coordinate of I_i, respectively. Note that I_i may be a point interval, such that $q_i^- = q_i^+$. A *section* of Γ_t is a tuple as follows:

- a *step* (q_i^+, q_{i+1}^-), if $q_i^+, q_{i+1}^- \in h_t$;
- a *slide* (q_i^-, q_i^+), if $q_i^- \neq q_i^+$ and $\{\,q \in \Gamma_t \mid x(q) \in I_i\,\} \subseteq h_t$;
- a *double step* $(q_{i-1}^+, q_i^-, q_{i+1}^-)$, if $q_{i-1}^+, q_{i+1}^- \in h_t$ and $q_i^- = q_i^+ \notin h_t$; or
- the *corners* (q_1, q_2), if $q_1 \notin h_t$ and $q_2 \in h_t$ as well as (q_{k-1}, q_k) if $q_k \notin h_t$ and $q_{k-1} \in h_t$.

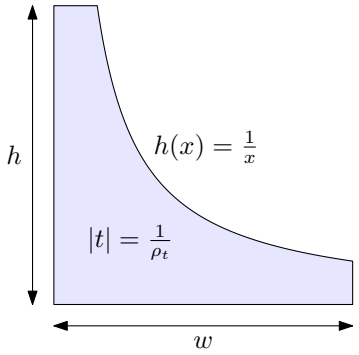

Figure 8 Symmetric ($w = h$) low-density tile $t = t_h(\rho_t)$ for which ξ_s is tight.

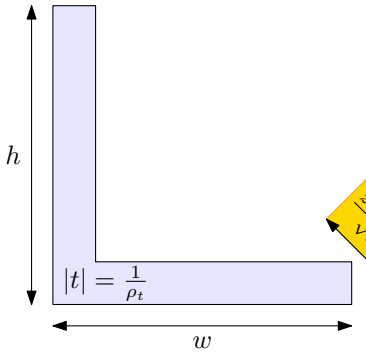

Figure 9 Symmetric ($w = h$) high-density tile $t = t_l(\rho_t)$ for which ξ_s is tight.

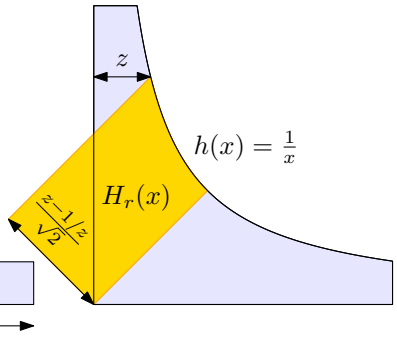

Figure 10 Crown contribution of a slide.

We further define $t(x_L, x_R) = \{ (x, y) \in t \mid x_L \leq x \leq x_R \}$. After applying Lemma 14, all tiles resulting from our transformations can be described as a sequence of such sections. Figure 13 illustrates generalized tiles and the different sections.

Note that a slide can be understood as the limit case of $k \to \infty$ equally spaced upper staircase points. As the slide is the only part of a generalized tile which differs from normal tiles, our charging scheme from Section 4.1 naturally extends to generalized tiles. This yields the following tower complement for slides:

▶ **Definition 16.** For a tile t with a slide (q_1, q_2), rotate the hyperbola by $\pi/4$ around the anchor of t, to obtain the rotated hyperbola $h_r(x) = \sqrt{x^2 + 2}$. The area under h_r between q_1 and q_2 will be denoted as $H(q_1, q_2)$.

▶ Observation 17. For a tile t with slide (q_1, q_2) we get $|H(q_1, q_2)| := \left[\frac{1}{4} \cdot (z^2 - z^{-2}) + \ln z\right]_{x_1}^{x_2}$.

Proof. $|H(q_1, q_2)|$ can be calculated via integration: The indefinite integral under $h_r(x) = \sqrt{x^2 + 2}$ is $H_r(x) := \int h_r(x)\, \mathrm{d}x = x/2 \cdot \sqrt{2 + x^2} + \operatorname{arsinh}(x/\sqrt{2})$, and for $x = (z - 1/z)/\sqrt{2}$, we get $H_r((z - 1/z)/\sqrt{2}) = 1/4 \cdot (z^2 - z^{-2}) + \ln z$, where $z = x_1$ or $z = x_2$ (see Figure 10). ◀

Overview of the Transformation Process.[3] Figure 11 gives an overview of how we gradually transform an arbitrary tile t with density $\rho_t \leq 1/2$ into a worst-case hyperbola tile $t_h(\rho_t)$. Starting with an arbitrary tile t (I), Lemma 18 either enforces $\Gamma_t \subseteq h_t$ or $\Gamma_t \setminus h_t = \{ q \}$.

▶ **Lemma 18.** *Let t be a tile. Then either there exists a tile $\tilde{t} \preceq t$ with $\Gamma_{\tilde{t}} \subset h_{\tilde{t}}$, or t contains a double step (q_1, q_2) with $x_1 \leq 1 \leq x_2$ or a corner (q_1, q_2) with $x_1 < 1$ (if $q_2 \notin h_t$, $x_2 > 1$ if $q_1 \notin h_t$).*

This lemma yields two different cases: In the first case (II), t contains a double-step (q_1, q, q_2) and we can enforce $x(q_1) \leq 1 \leq x(q_2)$. In the second case (III), q is part of a corner where $x(q') \geq 1$ or $x(q') \leq 1$ can be enforced for corners (q, q') or (q', q), respectively. (The case where $\Gamma_{\tilde{t}} \subset h_{\tilde{t}}$ will be dealt with later, in case (VIII).)

The next step from cases (II)/(III) to cases (IV)/(V) is based on smaller transformation/property statements about adjacent sections:

[3] Due to space limitations, the proofs for the following Lemmas 18–29 can only be found in the arXiv version of this paper (see [11]).

▶ **Lemma 19.** *Let t be a tile, $q_1, q_2, q_3 \in \Gamma_t$ the leftmost three points (in order) such that $q_1 = q_2$ or (q_1, q_2) is a step; and $q_2 = q_3$ or (q_2, q_3) is a slide. Then these sections can be replaced by up to one step $s = (q_1, q_2)$ and up to one slide $h = (q_2, q_3)$ such that*

1. *If s exists, then $x_1 x_2 \geq 1/\sqrt{2}$*
2. *If h exists, then $x_1 x_2 \leq 1/\sqrt{2}$*

giving us a tile $\tilde{t} \preceq t$.

Intuitively Lemma 19 states that the leftmost sections will only be a step and hyperbola when they satisfy precise properties and otherwise the tile can be transformed such that one of the sections vanished.

▶ **Lemma 20.** *Let t be a tile with a step (q_1, q_2) and a slide (q_2, q_3). If $x_1 \geq 1/x_3$, then the two sections can be replaced by a slide (q_1, q_4) and a step (q_4, q_2), resulting in a tile $\tilde{t} \preceq t$.*

Lemma 20 describes when "swapping" steps with an adjacent slide lowers c_t.

▶ **Lemma 21.** *Let t be a tile and (q_1, q_2),(q_2, q_3) be steps with $x_3 \leq 1$. Then the two steps can be replaced with a step (q_1, q_4) and a slide (q_4, q_3), resulting in a tile $\tilde{t} \preceq t$.*

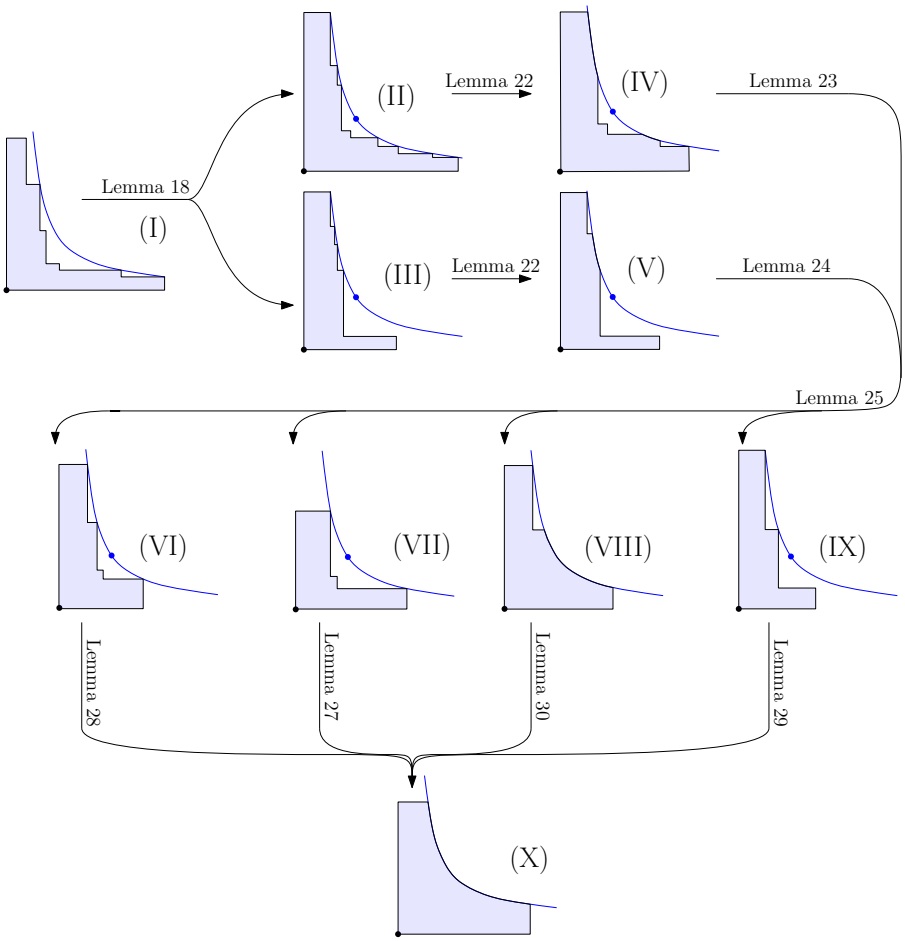

Figure 11 Transforming low-density tiles t with $\rho_t \leq 1/2$ to a corresponding worst-case hyperbola tile $t_h(s) \preceq t$. For the normalized tiles in Cases (II) and later, the blue dot marks the point $(1, 1)$.

Lemma 21 describes when "merging" two adjacent steps into a step and adjacent slide lowers c_t. Note that each of these lemmas hold up to reflection on the x=y axis, due to symmetry. Using the transformations/properties in these lemmas we can show the following Lemma 22, which allows us to only consider tiles containing a single step.

▶ **Lemma 22.** *Consider a tile t with $\rho_t \leq 1/2$. Then there exists a tile $\tilde{t} \preceq t$, containing at most one step. Furthermore, if $\Gamma_t \subseteq h_t$ then $\Gamma_{\tilde{t}} \subseteq h_{\tilde{t}}$.*

Now down to only one step, the following two lemmas (Lemmas 23 and 24) show that we can transform the tiles from (IV) and (V), respectively, such that either $\Gamma_t \subseteq h_t$ or t contains no slides:

▶ **Lemma 23.** *Let t be a tile with a double step (q_1, q_2, q_3) and a slide (q_3, q_4). We can replace both sections by a double step (q_1, q_4) or a sequence of steps and slides between q_1 and q_4, obtaining a tile $t' \preceq t$.*

▶ **Lemma 24.** *Let t be a tile with a slide (q_1, q_2) and a corner (q_2, q_3). We can replace both sections by a corner (q_1, q_2') or a sequence of steps and slides between q_1 and q_2', obtaining a tile $t' \preceq t$.*

These lemmas, together with the following Lemma 25, can then be used to reduce the remaining cases to those illustrated in (VI) to (IX):

▶ **Lemma 25.** *Let t be a tile with $\rho_t \leq 1/2$, then there exists a tile $\tilde{t} \preceq t$ with $\Gamma_{\tilde{t}} \subseteq h_{\tilde{t}}$ or $\tilde{t}$ consists of a step and a corner or a double step and possibly a step.*

The following Lemma 26 allows us to restrict ourselves to tiles t with $\rho_t = 1/2$ or where all points in Γ_t are on t's hyperbola, and is essential to proving the subsequent lemmas.

▶ **Lemma 26.** *Let t be a tile with $\rho_t \leq 1/2$. Then there exists a tile $\tilde{t}$ with $\Gamma_{\tilde{t}} \subseteq h_{\tilde{t}}$ or $\rho_{\tilde{t}} = 1/2$ such that, if $|C_{\tilde{t}}|/|\tilde{t}| \geq \xi_s(\rho_{\tilde{t}})$ then also $|C_t|/|t| \geq \xi_s(\rho_t)$.*

For each of the four cases we then separately show $t_h(\rho) \preceq t$ (Lemmas 27–30).

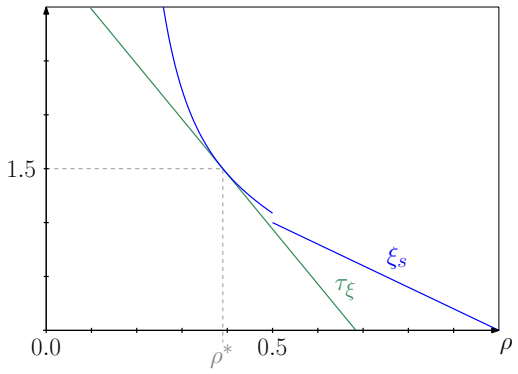

Figure 12 The charging ratio bound ξ_s from Section 5 and its tangent τ_ξ at $\rho^* = \xi_s^{-1}(3/2)$. This illustrates that ξ_s is point-convex at ρ^*.

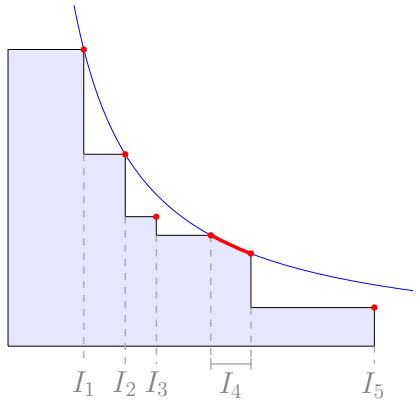

Figure 13 A generalized tile with four sections formed by the five intervals I_1 to I_5 (of which only I_4 is a proper interval). They form a step (between I_1 and I_2), a double-step (between I_2 and I_4), a slide (I_4), and a corner (I_4, I_5).

▶ **Lemma 27.** *Let t be a tile with $\rho_t \leq 1/2$ consisting only of a double-step (q_1, q_2, q_3). Then $|C_t|/|t| \geq \xi_s(\rho_t)$.*

▶ **Lemma 28.** *Let t be a tile with $\rho_t \leq 1/2$ consisting only of a double step (q_1, q_2, q_3) and a step (q_3, q_4). Then $|C_t|/|t| \geq \xi_s(\rho_t)$*

▶ **Lemma 29.** *Let t be a tile with $\rho_t \leq 1/2$ consisting only of a step (q_1, q_2) where $x_1 x_2 \geq 1/\sqrt{2}$ and a corner (q_2, q_3). Then there exists a tile $t' \preceq t$ only consisting of two steps.*

▶ **Lemma 30.** *Let t be a tile with $\rho_t \leq 1/2$ with $\Gamma_t \subseteq h_t$. Then $|C_t|/|t| \geq \xi_s(\rho_t)$.*

Proof. By Lemma 22 we can assume that t contains at most one step. Since $\Gamma_t \subseteq h_t$, t can only consist of steps and slides. Then t must contain at least one slide, as otherwise t consists of exactly one step, contradicting $\rho_t \leq 1/2$. Using Lemma 20, we can then ensure that t has at most one slide: Assuming this is not the case, t has a slide (q_1, q_2), a step (q_2, q_3) and another slide (q_3, q_4). Using the constraints of Lemma 20 we get $x_1 > 1/x_3 > 1/x_4 > x_2 > x_1$, a contradiction, so t has exactly one slide and possibly one step.

It is enough to show $\Delta := |t|\xi_s(\rho_t) - |C_t| < 0$, since the statement follows by rearranging. First assume that t's only section is a slide (q_1, q_2). Then $|t| = |t(0, x_1)| + |t(x_1, x_2)| = 1 + \ln(x_2/x_1)$, and we get:

$$\begin{aligned}
\Delta &= |t|\xi_s(\rho_t) - |H(q_1, q_2)| = |t| - 1 + \sinh(|t| - 1) - \left[1/4 \cdot (z^2 - z^{-2}) + \ln z\right]_{x_1}^{x_2} \\
&= \left(x_2^{-2} - x_2^2 + x_1^2 - x_1^{-2}\right)/4 + \sinh(|t| - 1) + |t| - (1 + \ln(x_2/x_1)) \\
&= \left(x_2^{-2} - x_2^2 + x_1^2 - x_1^{-2}\right)/4 + \sinh(\ln(x_2/x_1)) \\
&= 2\sinh((\ln(x_1) + \ln(x_2))/2)^2 \sinh(\ln(x_1/x_2)) < 0
\end{aligned}$$

where the last inequality directly follows from $x_1 < x_2$.

Now assume that t consists of a step (q_1, q_2) and a slide (q_2, q_3) (w.l.o.g. ordered in this way). In such a case we have $|t| = |t(x_0, x_1)| + |t(x_1, x_2)| + |t(x_2, x_3)| = 1 + (x_2 - x_1)/x_2 + \ln(x_3/x_2)$, or rearranged, $x_3 = x_2 e^{x_1/x_2 + |t| - 2}$. Again we calculate

$$\begin{aligned}
\Delta &= |t|\xi_s(\rho_t) - (|T(q_1, q_2)| + |H(q_2, q_3)|) \\
&= |t| - 1 + \sinh(|t| - 1) - \frac{1}{2}\left(\frac{1}{x_1} - \frac{1}{x_2} + x_2 - x_1\right)\left(x_1 + \frac{1}{x_2}\right) - \left[\frac{z^2 - z^{-2}}{4} + \ln z\right]_{x_2}^{x_3}.
\end{aligned}$$

Taking the derivative of Δ w.r.t. $|t|$ (after inserting $x_3 = x_2 e^{x_1/x_2 + |t| - 2}$), we obtain $\partial\Delta/\partial|t| = -2\cosh(x_1/x_2 + |t| - 2 + \ln x_2)^2 < 0$. This indicates that Δ is maximized for smallest $|t|$. So assume $|t| = 2$ now, or equivalently, $x_3 = x_2 e^{x_1/x_2}$. By Lemma 19 we can further assume that $x_2 = 1/(\sqrt{2}x_1)$. Using the substitution $x_1 = 2^{-3/4}\sqrt{u}$ we get

$$\Delta = \frac{1}{2\sqrt{2}}\left(-3 - \frac{\sqrt{2}}{e} + \sqrt{2}e + \frac{1 - e^u}{u} + u + \frac{u}{2e^u}\right) \quad \text{with the derivative}$$

$$\frac{\partial\Delta}{\partial u} = \frac{(1 - u)(u^2 + 2e^{2u} - 2e^u(1 + u))}{4\sqrt{2}u^2 e^u}.$$

The derivative above has only one zero, namely $u = 1$: From $0 < x_1^2 \leq x_1 x_2 = 1/\sqrt{2}$, we can deduce $u \in (0, 2]$ by the substitution. For the right factor of the derivative's numerator we then get $u^2 + 2e^{2u} - 2e^u(1 + u) > 2e^u(e^u - (1 + u)) > 0$ from the Taylor series of e^u. Hence checking Δ at u's boundaries and $u = 1$ is sufficient, where we get $\lim_{u\to 0}\Delta \approx -0.24 < 0$ (apply L'Hospital's rule on $(1 - e^u)/u$), $\Delta|_{u\to 1} \approx -0.07 < 0$ and $\Delta|_{u\to 2} \approx -0.26 < 0$. ◀

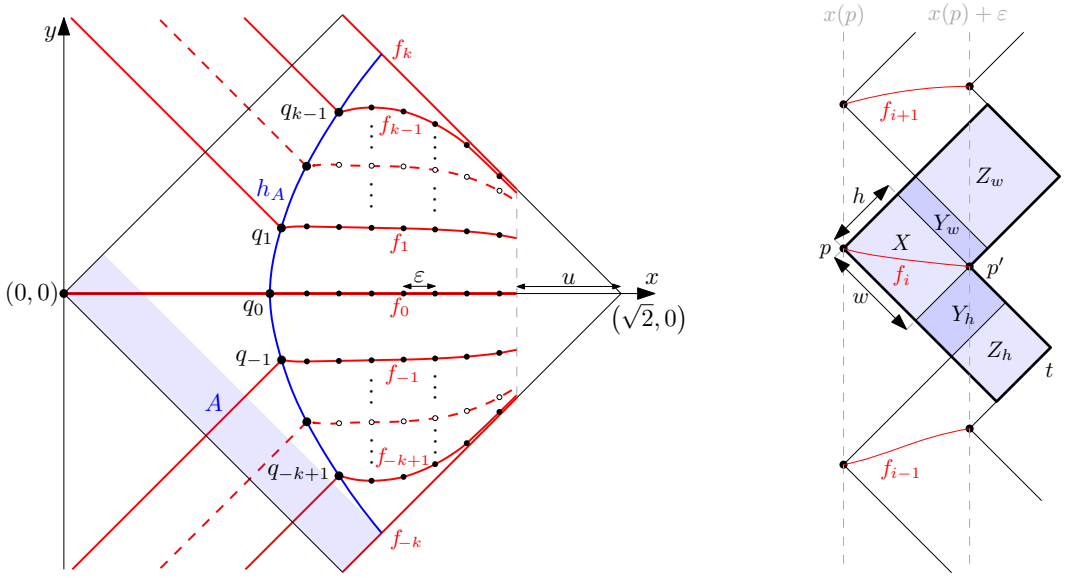

Figure 14 Left: Our construction. Right: A tile anchored at $p \in P_{\varepsilon,k} \setminus \{(0,0)\}$. For demonstration purposes, the areas are not shown to scale; in truth X, Z_w, Z_h are significantly smaller than Y_w, Y_h.

With all previous lemmas combined, we are now ready to give the proof for Proposition 15.

Proof of Proposition 15. By Proposition 11 we already get the result for $\rho_t > 1/2$. It remains to show the result for tiles with $\rho_t \leq 1/2$. Lemma 25 allows us to limit ourselves to certain tiles t: Tiles with $\Gamma_t \subseteq h_t$ (Lemma 30 yields the result), tiles with only a double step (use Lemma 27), tiles with a step and a double step (use Lemma 28) and tiles that consist of a step and a corner (use Lemma 29). As such the bound follows.

It remains to show the tightness. First note that for $\rho_t = 1$, the tightness is trivial (choose an arbitrary tile t with $|\Gamma_t| = 1$). For $\rho < 1$, we show that ξ_s exactly corresponds to the tiles $t_l(\rho)$ and $t_h(\rho)$ shown in Figures 8 and 9.

Let $t = t_l(\rho)$ with $\Gamma_t = \{q_1, q_2\} \subset h_t$, $x_1 = y_2$. We have $|t| = |t(0, x_1)| + |t(x_1, x_2)| = 1 + (1 - x_1^2)$, or rearranged $x_1 = \sqrt{2 - 1/\rho}$ and we get

$$|C_t|/|t| = |T(q_1, q_2)|/|t| = 1/2 \cdot (1/x_1 - x_1 + 1/x_1 - x_1)(x_1 + x_1)/\left(2 - x_1^2\right) = 2 - 2\rho.$$

Now let $t = t_h(\rho)$. t consists of a slide $(q_1, q_2) = ((x_1, 1/x_1), (1/x_1, x_1))$, hence $|t| = |t(0, x_1)| + |t(x_1, x_2)| = 1 + \ln((1/x_1)/x_1) = 1 - 2\ln x_1$, or rearranged, $x_1 = e^{(1-1/\rho)/2}$. So

$$|C_t|/|t| = |H(q_1, q_2)|\rho = \rho\left[\frac{1}{4}\left(z^2 - z^{-2}\right) + \ln z\right]_{e^{(1-1/\rho)/2}}^{e^{(1/\rho-1)/2}} = 1 - \rho(1 + \sinh(1 - \frac{1}{\rho})).$$

Note that t is only valid in the sense of generalized tiles. However, t can be arbitrarily well approximated by a non-generalized tile with area and crown size arbitrarily close to $|t|$ and $|C_t|$, respectively, by densely placing an increasing number of points on the hyperbola. ◀

6 Upper Bound

To show Theorem 2, we construct a point set where TilePacking covers at most roughly $(1 - e^{-2})/2$. Our goal is to construct a tile $\hat{t}$ at the origin where each maximal rectangle has the same size A. We therefore place $2k + 1$ points q_i into $\mathcal{U}$ densely on a hyperbola h_A centered at the origin. The remaining tiles will have a density close to $1/2$.

Such tiles can be realized when they have two nearly equal-sized maximal rectangles with minimum overlap. Hence, we add for each point q_i on h_A a set of (almost) evenly spaced points $p_{i,j}$ with distance roughly ε between each other. To get two maximal rectangles of roughly same area for each such tile, the exact coordinates of the points $p_{i,j}$ must be chosen carefully, as the placement of such points influences the size of maximal rectangles for surrounding points. That is why we place the points on arcs of functions f_i described by differential equations, where each f_i depends on the two neighboring curves f_{i-1} and f_{i+1}.

We may only use finitely many points $q_i \in h_A$ and $p_{i,j} \in f_i$. Both discretizations introduce an error term. Exploiting our choice of the functions f_i and how they relate to each other, we can show that both error terms vanish as k goes to infinity and ε goes to zero.

To aid the analysis, we rotate $\mathcal{U}$ by $\pi/4$ around the origin, obtaining a *rotated unit square* $\mathcal{U}_r$ (see Figure 14). Here, TilePacking processes the points from right to left.

We start by formally defining the point set $P_{\varepsilon,k}$ and the functions f_i. Let $h_A = \{\,(x,y) \in \mathcal{U}_r \mid x^2 - y^2 = 2A\,\}$ be the right branch of a hyperbola centered at the origin that lives in $\mathcal{U}_r$. First we define the upper part of the construction with non-negative y coordinates. For $i = 0, \dots, k-1$, densely choose k points $q_i \in h_A$ such that $y(q_i) \geq 0$ and $\sqrt{2A} = x(q_0) < x(q_1) < \cdots < x(q_{k-1})$. Define further $f_0(x) = 0$ and $f_k(x) = \sqrt{2} - x$. For $0 < i < k$, define $f_i : [0, \sqrt{2}) \to \mathbb{R}$ using

$$f_i(x(q_i)) = y(q_i) \text{ and} \tag{3}$$

$$f_i'(x) = \begin{cases} -1 & \text{for } x \leq x(q_i) \\ 1 - 2\dfrac{f_i(x) - f_{i-1}(x)}{f_{i+1}(x) - f_{i-1}(x)} & \text{for } x > x(q_i). \end{cases} \tag{4}$$

This means, each f_i with $0 < i < k$ has slope -1 in $[0, x(q_i))$, then it intersects h_A at q_i according to Equation (3), and then it has a slope depending on the current values of f_{i-1}, f_i and f_{i+1} according to Equation (4). For the symmetric part with negative y coordinates we define $q_{-i} = (x(q_i), -y(q_i))$ and $f_{-i}(x) = -f_i(x)$ for $0 < i \leq k$. Observe that, for $0 \leq i < k$, we get $q_{-i} \in h_A$ and the f_{-i} adhere to Equation (4). We are now ready to define the point set $P_{\varepsilon,k}$ for $\varepsilon > 0$ and $k \in \mathbb{N}$ as

$$P_{\varepsilon,k} = \{\,(0,0)\,\} \cup \bigcup_{i,j \in \mathbb{Z}} \left\{ \big(j\delta,\ f_i(j\delta)\big) \;\middle|\; -k < i < k, x(q_i) \leq j\delta < \sqrt{2} \right\}.$$

We require that $q_i \in P_{\varepsilon,k}$ for all $-k < i < k$, so we choose ε such that it divides all $x(q_i)$.

In order to be able to choose $P_{\varepsilon,k}$ as shown above, we need that the f_i are well-behaved: They must be defined in $[0, \sqrt{2})$, and should only intersect h_A at q_i. Intuitively, this is true, since the differential equation drives each function f_i to the midpoint of the functions f_{i-1} and f_{i+1}. The proof is given in the following lemma.

▶ **Lemma 31.** *Each function f_i intersects h_A exactly once, namely at q_i. Furthermore, $f_i(x)$ is differentiable for all $i = -k, \dots, k$, and $f_{-k}(x) < \cdots < f_k(x)$ holds for all $x \in [0, \sqrt{2})$.*[4]

We are now able to show Lemma 32: All tiles $t \neq \hat{t}$ have a density of close to $1/2$, unless they are too close to the right corner of $\mathcal{U}_r$, in which case their area is negligible. Afterwards, it only remains to optimize the parameter A, which is done in Theorem 33.

▶ **Lemma 32.** *Let $u, k > 0$ and $\hat{\mathcal{U}} = (\bigcup_{p \in P_{\varepsilon,k}, x(p) \leq \sqrt{2}-u} t_p) \setminus \hat{t}$. Then TilePacking covers $|\hat{\mathcal{U}}|/2 + c_k(\varepsilon)$ area in $\hat{\mathcal{U}}$ for $P_{\varepsilon,k}$ where $\lim_{\varepsilon \to 0} c_k(\varepsilon) = 0$.*

[4] Due to space limitations, the proof can only be found in the arXiv version of this paper (see [11]).

Proof. Consider a point $p \neq (0,0)$, $x(p) \leq \sqrt{2} - u$ that lies on some curve f_i and creates the tile t. Assuming $\varepsilon < u$, there exists another point $p' = (x(p) + \varepsilon, f_j(x(p) + \varepsilon)) \in P_{\varepsilon,k}$. By Lemma 31, we can assume that $f_{i+1}(x) - f_i(x) > \varepsilon$ for all $i = -k, \ldots, k-1$, $x \leq \sqrt{2} - u$. It follows from $|f_i'| \leq 1$ that p' is a lower staircase point of t. (For the same reason there cannot be points further to the right that are lower staircase points.) The tile t is therefore only restricted by the tiles from points with x-coordinate $x(p')$. Therefore, t has exactly two maximal rectangles which TilePacking can choose from (see Figure 14).

TilePacking will choose the larger one of the two maximal rectangles (call them R_1 and R_2). Since there are multiple points with the same x-coordinate as p, any of them can be processed first by TilePacking. This gives rise to areas Z_w,Z_h that may be covered by the tile t or by tiles directly above or below it (see Figure 14). W.l.o.g. we assume that TilePacking covers both Z_w and Z_h when choosing the maximal rectangle for t (since assuming this for all such tiles may only increase the covered area).

Since all f_i are differentiable in $[0, \sqrt{2})$, Taylor's Theorem provides a function $g(x)$ with $\lim_{x \to 0} g(x) = 0$ such that $f_i(x+\varepsilon) = f_i(x) + f_i'(x) \cdot \varepsilon + g(\varepsilon) \cdot \varepsilon$. Denote by w, h the dimensions of the rectangle $X = R_1 \cap R_2$. Then $w = (\varepsilon + f_i(x(p) + \varepsilon) - f_i(x(p)))/\sqrt{2} = (\varepsilon + f_i'(x(p))\varepsilon + g(\varepsilon)\varepsilon)/\sqrt{2} = (1 + f_i'(x(p)) + g(\varepsilon))\varepsilon/\sqrt{2}$ and similarly $h = (1 - f_i'(x(p)) - g(\varepsilon))\varepsilon/\sqrt{2}$.

From $|f_i'| \leq 1$ for all f_i, one can easily see that the rectangles X, Z_w and Z_h have widths and heights in $\mathrm{O}(\varepsilon)$, giving them a total area of $W := X + Z_w + Z_h = \mathrm{O}(\varepsilon^2)$.

The tile t also contains two additional rectangles with an area of $Y_w = w((f_i(x(p)) - f_{i-1}(x(p)))/\sqrt{2} - h)$ and $Y_h = h((f_{i+1}(x(p)) - f_i(x(p)))/\sqrt{2} - w)$. Note that this also holds if $x(q_{i\pm1}) > x(p)$, as we extended $f_{i\mp1}$ with lines of slope ± 1. In this case the two rectangles are restricted by $q_{i\mp1}$'s tile, respectively. Hence, when evaluating the functions at $x(p)$:

$$\begin{aligned}
|Y_w - Y_h| &= |w(f_i - f_{i-1})/\sqrt{2} - h(f_{i+1} - f_i)/\sqrt{2}| \\
&= |(1 + f_i' + g(\varepsilon))(\varepsilon(f_i - f_{i-1}))/2 - (1 - f_i' - g(\varepsilon))(\varepsilon(f_{i+1} - f_i))/2| \\
&= |(f_{i+1}(g(\varepsilon) + f_i' - 1) - f_{i-1}(g(\varepsilon) + f_i' + 1)) + 2f_i| \cdot \varepsilon/2 \\
&= |(g(\varepsilon)(f_{i+1} - f_{i-1}) + f_i'(f_{i+1} - f_{i-1}) - f_{i-1} - f_{i+1} + 2f_i)| \cdot \varepsilon/2 \\
&= |g(\varepsilon)||f_{i+1} - f_{i-1}| \cdot \varepsilon/2 \leq |g(\varepsilon)| \cdot \varepsilon\sqrt{2},
\end{aligned}$$

where the last inequality holds by Lemma 31, which gives us $f_{i+1}(x) - f_{i-1}(x) \leq f_k(x) - f_{-k}(x) \leq 2\sqrt{2}$ for $x \in [0, \sqrt{2})$.

W.l.o.g. assume $Y_w > Y_h$. Then for the tile t with area $|t| = W + Y_w + Y_h$, TilePacking covers at most $W + Y_w \leq W + Y_w/2 + (Y_h + |g(\varepsilon)| \cdot \varepsilon\sqrt{2})/2 = |t|/2 + \mathrm{O}(\varepsilon(|g(\varepsilon)| + \varepsilon))$. As $\hat{\mathcal{U}}$ is the union of such tiles and $|P_{\varepsilon,k}| = \mathrm{O}(k/\varepsilon)$, we have a total coverage of $|\hat{\mathcal{U}}|/2 + \mathrm{O}(k(|g(\varepsilon)| + \varepsilon))$. This immediately gives us the function $c_k(\varepsilon) = \mathrm{O}(k(|g(\varepsilon)| + \varepsilon))$ with $\lim_{\varepsilon \to 0} c_k(\varepsilon) = 0$. ◀

▶ **Theorem 33.** *TilePacking has no better lower bound than* $(1 - e^{-2})/2$.

Proof. We analyze the area ρ covered by TilePacking on $P_{\varepsilon,k}$ for some fixed k and u as ε approaches 0. The bound then follows from letting k go to ∞ and u go to 0.

By Lemma 32, TilePacking covers half of $\hat{\mathcal{U}} = (\bigcup_{p \in P_{\varepsilon,k}, x(p) \leq \sqrt{2} - u} t_p) \setminus \hat{t}$ (plus $c_k(\varepsilon)$ that approaches 0 for $\varepsilon \to 0$) for each $u > 0$. Additionally, at most u^2 area is covered from all tiles at points p with $x(p) > \sqrt{2} - u$. TilePacking covers $A + Q$ area in $\hat{t}$, where an error term Q is introduced because the q_i points only provide an approximation of h_A. Q can easily be bounded by, e.g., $Q \leq \max_i(x(q_i) - x(q_{i-1})) + \max_i(y(q_i) - y(q_{i-1}))$ (the biggest rectangular strip that fits between two consecutive q_i points, in $\mathcal{U}$). (Note that all q_i lie in $P_{\varepsilon,k}$, so no additional error is introduced.) In total, using $E = Q + c_k(\varepsilon) + u^2$,

$$\rho \leq A + |\hat{\mathcal{U}}|/2 + E \leq A + (1 - |\hat{t}|)/2 + E \leq A + (1 - (A + \int_A^1 \frac{A}{x}\,\mathrm{d}x))/2 + E$$
$$\leq (1 + A + A \ln A)/2 + E.$$

Minimizing the last term leads to $\rho \leq (1 - e^{-2})/2 + E$ at $A = e^{-2}$. Q approaches 0 when $k \to \infty$ since the q_i lie densely on h_A. Hence E approaches 0 for large k and small u, ε. ◀

7 Conclusion

We have shown that TilePacking's worst-case coverage lies between 39% and 43.3%. Our lower bound substantially improves over the previous best lower bound of roughly 9.1% [12], while our upper bound is the first non-trivial upper bound for TilePacking. Note that both bounds easily transfer to the (arguably more natural) GreedyPacking algorithm [12].

Our analysis crucially relies on a novel charging scheme and on a new analysis framework. The latter reduces the task of proving good coverage to finding good lower bounds on the tiles' charging ratios (see Section 3). The versatility of this approach shows in the fact that already a comparatively simple and short analysis yields a lower bound of 25%. Moreover, our approach provides structural insights: e.g., it allows us to characterize the exact shape of worst-case tiles as a function of their density (see Figures 8 and 9). We believe that our framework might help to analyze similar algorithms for (variants of) LLARP.

Concerning the remaining gap of size roughly 4 percentage points between our bounds, we believe that both bounds can be improved. For the lower bound, one shortcoming of our analysis is that tiles are analyzed individually, ignoring their local relationships in the unit square. Our lower bound basically predicts that the worst-case instance of TilePacking should consist solely of tiles whose shapes resemble Figure 8, which seems impossible.

Regarding the upper bound, there is still a noticeable gap between the maximal area that is coverable by the crowns (see Figure 4) and the area into which the crowns fall in our upper bound construction (see Figure 14). In particular, our construction uses only one tile (in the origin) with a large charging ratio, while all other tiles can be shown to have a charging ratio of roughly 1. Also note that our upper bound construction might be of interest with respect to the approximation variant of LLARP: an optimal solution should be able to fill most of the unit square, such that our results would imply a corresponding bound on the approximation ratio of TilePacking.

We leave as a major open question to find new algorithms for LLARP that might tackle the 50% conjecture. Note that our upper bound is tailored towards a specific greedy algorithm, so there is reasonable hope that other (possibly also greedy) algorithms might still achieve a coverage of 50%.

Approximately Counting Independent Sets of a Given Size in Bounded-Degree Graphs

Ewan Davies
Department of Computer Science, University of Colorado, Boulder, CO, USA

Will Perkins
Department of Mathematics, Statistics, and Computer Science,
University of Illinois at Chicago, IL, USA

Abstract

We determine the computational complexity of approximately counting and sampling independent sets of a given size in bounded-degree graphs. That is, we identify a critical density $\alpha_c(\Delta)$ and provide (i) for $\alpha < \alpha_c(\Delta)$ randomized polynomial-time algorithms for approximately sampling and counting independent sets of given size at most αn in n-vertex graphs of maximum degree Δ; and (ii) a proof that unless NP=RP, no such algorithms exist for $\alpha > \alpha_c(\Delta)$. The critical density is the occupancy fraction of hard core model on the clique $K_{\Delta+1}$ at the uniqueness threshold on the infinite Δ-regular tree, giving $\alpha_c(\Delta) \sim \frac{e}{1+e}\frac{1}{\Delta}$ as $\Delta \to \infty$.

1 Introduction

Counting and sampling independent sets in graphs are fundamental computational problems arising in several fields including algorithms, statistical physics, and combinatorics. Given a graph G, let $\mathcal{I}(G)$ denote the set of independent sets of G. The independence polynomial of G is

$$Z_G(\lambda) = \sum_{I \in \mathcal{I}(G)} \lambda^{|I|} = \sum_{k \geq 0} i_k(G)\lambda^k \,,$$

where $i_k(G)$ is the number of independent sets of size k in G. The independence polynomial also arises as the partition function of the hard-core model from statistical physics.

With G and λ as inputs, exact computation of $Z_G(\lambda)$ is #P-hard [32, 18], but the complexity of approximating $Z_G(\lambda)$ has been a major topic in recent theoretical computer science research. There is a detailed understanding of the complexity of approximating $Z_G(\lambda)$ for the class of graphs of maximum degree Δ, in particular showing that there is a *computational threshold* which coincides with a certain probabilistic phase transition as one varies the value of λ.

The *hard-core model* on G at fugacity λ is the probability distribution on $\mathcal{I}(G)$ defined by

$$\mu_{G,\lambda}(I) = \frac{\lambda^{|I|}}{Z_G(\lambda)} \,.$$

© Ewan Davies and Will Perkins;
licensed under Creative Commons License CC-BY 4.0

Defined on a lattice like $\mathbb{Z}^d$ (through an appropriate limiting procedure), this is a simple model of a gas (the hard-core lattice gas) and it exhibits an order/disorder phase transition as λ changes. The hard-core model can also be defined on the infinite Δ-regular tree (the *Bethe lattice*). Kelly [23] determined the critical threshold for uniqueness of the infinite volume measure on the tree, namely

$$\lambda_c(\Delta) = \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta}}\,. \tag{1}$$

This value of λ also marks a computational threshold for the complexity of approximating $Z_G(\lambda)$ on graphs of maximum degree Δ. One can approximate $Z_G(\lambda)$ up to a relative error of ε in time polynomial in n and $1/\varepsilon$ with several different methods, provided G is of maximum degree Δ and $\lambda < \lambda_c(\Delta)$. The first such algorithm is based on correlation decay on trees and is due to Weitz [33], but recently alternative algorithms based on polynomial interpolation [3, 27, 28] and Markov chains [2, 6, 7] for this problem have also been given. Conversely, for $\lambda > \lambda_c(\Delta)$ a result of Sly and Sun [31] and Galanis, Štefankovič, and Vigoda [16] (following Sly [30]) states that unless NP=RP there is no polynomial-time algorithm for approximating $Z_G(\lambda)$ on graphs of maximum degree Δ. Counting and sampling are closely related, and by standard reduction techniques the same computational threshold holds for the problem of approximately sampling independent sets from the hard-core distribution.

The hard-core model is an example of the *grand canonical ensemble* from statistical physics, where one studies physical systems that can freely exchange particles and energy with a reservoir. Closely related is the *canonical ensemble*, where one removes the reservoir and considers a system with a fixed number of particles. In the context of independent sets in graphs, this corresponds to the uniform distribution on independent sets of some fixed size k. Here the number $i_k(G)$ of independent sets of size k in G plays the role of the partition function. In this paper we answer affirmatively the natural question of whether there is a similar complexity phase transition for the problem of approximating $i_k(G)$, and the related problem of sampling independent sets of size k approximately uniformly. Analogous to the critical fugacity in the hard-core model, we identify a critical density $\alpha_c(\Delta)$, and for $\alpha < \alpha_c(\Delta)$ we give a fully polynomial-time randomized approximation scheme (FPRAS, defined below) for counting independent sets of size k in n-vertex graphs of maximum degree Δ, where $0 \le k \le \alpha n$. We also show that unless NP=RP there is no such algorithm for $\alpha > \alpha_c(\Delta)$.

In statistical physics the grand canonical ensemble and the canonical ensemble are known to be equivalent in some respects under certain conditions, and the present authors, Jenssen, and Roberts [12] used this idea to give a tight upper bound on $i_k(G)$ for large k in large Δ-regular graphs G (see also [10] for the case of small k). Here, the main idea in our proofs is also to exploit the equivalence of ensembles. For algorithms at subcritical densities we approximately sample independent sets from the hard-core model and show that with sufficiently high probability we get an independent set of the desired size, distributed approximately uniformly. For hardness at supercritical densities we construct an auxiliary graph G' such that $i_k(G')$ is approximately proportional to $Z_G(\lambda)$ for some $\lambda > \lambda_c(\Delta)$, and hence is hard to approximate. Our counting and sampling algorithms for independent sets of size k permit higher densities than previous algorithms for this problem based on Markov chains [5, 1], and an algorithm implicit in [10] based on the cluster expansion.

A pleasant feature of our methods is the incorporation of several advances from recent research on related topics. From the geometry of polynomials we use a state-of-the-art zero-free region for $Z_G(\lambda)$ due to Peters and Regts [28] and a central limit theorem of

Michelen and Sahasrabudhe [26, 25] (though an older result of Lebowitz, Pittel, Ruelle and Speer [24] would also suffice), and we also apply the very recent development that a natural Markov chain (the Glauber dynamics) for sampling from the hard-core model mixes rapidly at fugacities $\lambda < \lambda_c(\Delta)$ on all graphs of maximum degree at most Δ [1, 7]. Finally, our results also show a connection between these algorithmic and complexity-theoretic problems and extremal combinatorics problems for bounded-degree graphs [9, 12, 10], see also the survey [34].

1.1 Preliminaries

Given an error parameter ε and real numbers z, $\hat{z}$, we say that $\hat{z}$ is a *relative ε-approximation* to z if $e^{-\varepsilon} \leq \hat{z}/z \leq e^{\varepsilon}$. A *fully polynomial-time randomized approximation scheme* or *FPRAS* for a counting problem is a randomized algorithm that with probability at least 3/4 outputs a relative ε-approximation to the solution of the problem in time polynomial in the size of the input and $1/\varepsilon$. If the algorithm is deterministic (i.e. succeeds with probability 1) then it is a *fully polynomial-time approximation scheme* (*FPTAS*). An ε-approximate sampling algorithm for a probability distribution μ outputs a random sample from a distribution $\hat{\mu}$ such that the total variation distance $\|\mu - \hat{\mu}\|_{TV} \leq \varepsilon$, and an *efficient sampling scheme* is, for all $\varepsilon > 0$ an ε-approximate sampling algorithm which runs in time polynomial in the size of the input and $\log(1/\varepsilon)$. Note that approximate sampling schemes whose running times are polynomial in $1/\varepsilon$ or in $\log(1/\varepsilon)$ are common in the literature, but we adopt the stronger definition for this paper. The inputs to our algorithms are graphs, and input size corresponds to the number of vertices of the graph.

An *independent set* in a graph $G = (V, E)$ is a subset $I \subset V$ such that no edge of E is contained in I. The *density* of such an independent set I is $|I|/|V|$, and it will be convenient for us to parametrize independent sets by their density instead of their size. We write $\mathcal{I}(G)$ for the set of all independent sets in G, $\mathcal{I}_k(G)$ for the set of independent sets of size k in G, and $i_k(G) = |\mathcal{I}_k(G)|$ for the number of such sets. Recall the hard-core distribution $\mu_{G,\lambda}$ on $\mathcal{I}(G)$ is given by $\mu_{G,\lambda}(I) = \lambda^{|I|}/Z_G(\lambda)$. We also define the *occupancy fraction* $\alpha_G(\lambda)$ of the hard-core model on G at fugacity λ to be the expected density of a random independent set drawn according to $\mu_{G,\lambda}$. Let $\mathcal{G}_\Delta$ be the set of graphs of maximum degree Δ.

The critical density that we show constitutes a computational threshold for the problems of counting and sampling independent sets of a given size in graphs of maximum degree Δ is

$$\alpha_c(\Delta) = \frac{\lambda_c(\Delta)}{1 + (\Delta+1)\lambda_c(\Delta)} = \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta} + (\Delta+1)(\Delta-1)^{\Delta-1}},$$

with λ_c the critical fugacity as in (1). This may seem unexpected at first sight, but has a natural interpretation. The threshold is in fact the quantity $\alpha_{K_{\Delta+1}}(\lambda_c(\Delta))$, the occupancy fraction of the clique on $\Delta + 1$ vertices at the critical fugacity $\lambda_c(\Delta)$. This is a natural threshold because the occupancy fraction is a monotone increasing function of λ, and the clique on $\Delta + 1$ vertices has the minimum occupancy fraction over all graphs of maximum degree Δ. Thus, for any $G \in \mathcal{G}_\Delta$, the value of λ which makes $\alpha_G(\lambda) > \alpha_c(\Delta)$ must be greater than $\lambda_c(\Delta)$. Conversely, if $\alpha < \alpha_c(\Delta)$ then for every graph $G \in \mathcal{G}_\Delta$ there is some $\lambda < \lambda_c(\Delta)$ such that $\alpha_G(\lambda) = \alpha$.

1.2 Our results

We are now ready to state our main result.

▶ **Theorem 1.**

(a) *For every $\alpha < \alpha_c(\Delta)$ there is an FPRAS for $i_{\lfloor \alpha n \rfloor}(G)$ and an efficient sampling scheme for the uniform distribution on $\mathcal{I}_{\lfloor \alpha n \rfloor}(G)$ for n-vertex graphs G of maximum degree Δ.*

(b) *Unless* NP=RP*, for every $\alpha \in (\alpha_c(\Delta), 1/2)$ there is no FPRAS for $i_{\lfloor \alpha n \rfloor}(G)$ for n-vertex, Δ-regular graphs G.*

The assumption NP≠RP, which is that polynomial-time algorithms using randomness cannot solve all problems in NP, is standard in computational complexity theory. Indeed, this assumption is used in [30, 31, 16] to show hardness of approximation for $Z_G(\lambda)$ on regular graphs at supercritical fugacities, which we apply directly. The upper bound of $1/2$ on α in b is required since in a regular graph (of degree ≥ 1) there are no independent sets of density greater than $1/2$ and counting those of density $1/2$ amounts to counting connected components in a bipartite graph (which can be done in polynomial time). For graphs of maximum degree Δ there is no such barrier, and in this case our methods can also be used to prove b for $\alpha \in (\alpha_c(\Delta), 1)$.

On the algorithmic side, Bubley and Dyer [5] showed via path coupling that a natural Markov chain for sampling independent sets of size k in n-vertex graphs of maximum degree Δ mixes rapidly when $k < n/(2\Delta + 2)$, and recently this was slightly improved to $k < n/(2\Delta)$ via the method of high-dimensional expanders by Alev and Lau [1] (who also gave an improved bound in terms of the smallest eigenvalue of the adjacency matrix of G). The fast mixing of this Markov chain provides a randomized algorithm for approximate sampling and an FPRAS for approximate counting for this range of k. Implicit in the work of the present authors and Jenssen [10] is an alternative method based on the cluster expansion that yields an FPTAS for $i_k(G)$ when $k < e^{-5}n/(\Delta + 1)$, and although we did not try to optimize the constant it seems unlikely that without significant extension the cluster expansion approach could yield a sharp result. Considering asymptotics as $\Delta \to \infty$, these previous algorithms work for densities up to $(c + o(1))/\Delta$ with the constant c being $1/2$ or $e^{-5} \approx 0.007$ respectively. Here, our algorithms work for densities α satisfying

$$\alpha < \alpha_c(\Delta) = (1 + o(1))\frac{e}{1+e}\frac{1}{\Delta},$$

as $\Delta \to \infty$. The constant $e/(1 + e)$ is approximately 0.731, and our hardness proof shows that this is tight.

Our sampling algorithm is based on searching over possible values of λ until we find one for which the mean size of an independent set from the hard-core model is close to the target k. We then repeatedly sample from the hard-core model until we obtain an independent set of size k and output this independent set. Our approximate counting algorithm is based on a standard reduction of approximate counting to approximate sampling.

The method of sampling from the canonical ensemble by sampling from the grand canonical ensemble and conditioning on obtaining an object the desired size is quite old and appears in the seminal papers of Jerrum and Sinclair [20, 21]. The key technical step in applying this method is to prove a lower bound on the probability of obtaining the desired size; in [20, 21] this is accomplished by using log-concavity of the specific distribution on sizes. Since the hard-core model does not have this property in general, we need a different argument; our new argument is based on the rapid mixing of Glauber dynamics.

Harris and Kolmogorov [19] have recently investigated the general problem of estimating the coefficients of partition functions given access to samples from the corresponding Gibbs distribution. Applying their ideas and results to this problem could likely lead to more

efficient run times for the problem of approximating the entire sequence $\{i_k(G)\}$, $1 \le k \le \alpha n$. Their ideas could also be applied to improve the efficiency of the reduction from counting to sampling, as they describe a more efficient "cooling schedule" for the simulated annealing technique that we use for this type of reduction.

1.3 Triangle-free graphs

As an additional application of our techniques we find an approximate computational threshold for the class of triangle-free graphs.

▶ **Theorem 2.** *For every $\delta > 0$ there is Δ_0 large enough so that the following is true.*

(a) *For $\Delta \ge \Delta_0$ and $\alpha < \frac{1-\delta}{\Delta}$ there is an FPRAS and efficient sampling scheme for $i_{\lfloor \alpha n \rfloor}(G)$ for the class of triangle-free graphs of maximum degree Δ.*

(b) *For $\Delta \ge \Delta_0$ and $\alpha \in \left(\frac{1+\delta}{\Delta}, 1/2\right)$ there is no FPRAS for $i_{\lfloor \alpha n \rfloor}(G)$ for the class of triangle-free graphs of maximum degree Δ.*

The proof of this theorem uses a result on the occupancy fraction of triangle-free graphs from [11], see Section 4.

1.4 Related work

Counting independent sets of a specified size has arisen in various places as a natural fixed-parameter version of counting independent sets, and is equivalent to counting cliques of a specified size in the complement graph. Exact computation of $i_k(G)$ in an n-vertex graph H is trivially possible in time $O(k^2 n^k)$, though improvements can be made via fast matrix multiplication algorithms (see e.g. [15]). Another branch of research concerns the complexity (in both time and number of queries to the graph data structure) of counting and approximately counting cliques. For example, in [14] the authors gave a randomized approximation algorithm for approximating the number of cliques of size k. Results of this kind perform poorly in our setting, which is equivalent to counting cliques in the complement of bounded-degree graphs, because such graphs are very dense. In particular, the main result of [14] has expected running time $\Omega((nk/e)^k)$ in our setting.

With a focus on bounded-degree graphs and connections to statistical physics, our work is closer in spirit to that of Curticapean, Dell, Fomin, Goldberg, and Lapinskas [8]. There, the authors consider the problem of counting independent sets of size k in bipartite graphs from the perspective of parametrized complexity. They give algorithms for exact computation and approximation of $i_k(G)$ in bipartite graphs (of bounded degree and otherwise), including a fixed parameter tractable randomized approximation scheme, though their running times are exponential in k. We note that the complexity of approximately counting the total number of independent sets in bipartite graphs (a problem known as #BIS) is unknown [13].

1.5 Questions and future directions

For the hard-core model, the algorithm of Weitz [33] gives a deterministic approximation algorithm (FPTAS) for $Z_G(\lambda)$ for $\lambda < \lambda_c(\Delta)$. The approach of Barvinok along with results of Patel and Regts and Peters and Regts give another FPTAS for the same range of parameters [3, 27, 28]. Our algorithm for approximating the number of independent sets of a given size uses randomness, but we conjecture that there is a deterministic algorithm that works for the same range of parameters. (The cluster expansion approach of [10] gives an FPTAS but only for smaller values of α).

▶ **Conjecture 3.** *There is an FPTAS for $i_{\lfloor \alpha n \rfloor}(G)$ for $G \in \mathcal{G}_\Delta$ and all $\alpha < \alpha_c(\Delta)$.*

The Markov chain analyzed in [5, 1] is the "down/up" Markov chain: starting from an independent set $I_t \in \mathcal{I}_k(G)$ at step t, pick a uniformly random vertex $v \in I_t$ and a uniformly random vertex $w \in V$. Let $I' = (I_t \setminus v) \cup w$. If $I' \in \mathcal{I}_k(G)$, let $I_{t+1} = I'$; if not, let $I_{t+1} = I_t$.

▶ **Conjecture 4.** *The down/up Markov chain for sampling from $\mathcal{I}_{\lfloor \alpha n \rfloor}(G)$ mixes rapidly for $\alpha < \alpha_c(\Delta)$ and all $G \in \mathcal{G}_\Delta$.*

One of the steps of our proof leads to a natural probabilistic conjecture concerning the hard-core model in bounded degree graphs.

▶ **Conjecture 5.** *Suppose G is a graph on n vertices of maximum degree Δ. Then if $\lambda < \lambda_c(\Delta)$ and $k = \lfloor \mathbb{E}_{G,\lambda}|\mathbf{I}| \rfloor$, we have*

$$\mathbb{P}_{G,\lambda}[|\mathbf{I}| = k] = \Omega(n^{-1/2}),$$

where the implied constant only depends on Δ and λ and the expectation and probability are with respect to the hard-core model on G at fugacity λ.

Lemma 8 below gives the weaker bound $\Omega(n^{-1}\log^{-1} n)$. A stronger conjecture would be that a local central limit theorem for $|\mathbf{I}|$ holds whenever $\lambda < \lambda_c(\Delta)$.

Finally, our proofs of Theorems 1 and 2 show a close connection between the computational threshold for sampling independent sets of a given size in bounded-degree graphs and the extremal combinatorics problem of minimizing the occupancy fraction in the hard-core model over a class of bounded-degree graphs. We expect that a rigorous connection between the two problems can be proved.

2 Algorithms

In this section, we fix $\Delta \geq 3$ and $\alpha < \alpha_c(\Delta)$. We first give an algorithm that, for $G \in \mathcal{G}_\Delta$ on n vertices and $k \leq \alpha n$, returns an ε-approximate uniform sample from $\mathcal{I}_k(G)$ and runs in time polynomial in n and $\log(1/\varepsilon)$; this proves the sampling part of Theorem 1a. We then use this algorithm to approximate $i_k(G)$ using a standard simulated annealing process to prove the approximate counting part of Theorem 1a.

Given $\lambda \geq 0$, let $\mathbf{I}$ be a random independent set from the hard-core model on G at fugacity λ. We will write $\mathbb{P}_{G,\lambda}$ for probabilities over the hard-core measure $\mu_{G,\lambda}$, so e.g. $\mathbb{P}_{G,\lambda}(|\mathbf{I}| = k)$ is the probability that $\mathbf{I}$ is of size exactly k. Often we will suppress the dependence on G.

A key tool that we use for probabilistic analysis and to approximately sample from $\mu_{G,\lambda}$ is the *Glauber dynamics*. This is a Markov chain with state space $\mathcal{I}(G)$ and stationary distribution $\mu_{G,\lambda}$. Though the algorithm of Weitz [33] was the first to give an efficient approximate sampling algorithm for $\mu_{G,\lambda}$ for $\lambda < \lambda_c(\Delta)$ and all $G \in \mathcal{G}_\Delta$, a randomized algorithm with better running time now follows from recent results showing that the Glauber dynamics mix rapidly for this range of parameters [2, 6, 7]. The *mixing time* $T_{\text{mix}}(\mathcal{M}, \varepsilon)$ of a Markov chain $\mathcal{M}$ is the number of steps from the worst-case initial state I_0 for the resulting state to have a distribution within total variation distance ε of the stationary distribution. We will use the following result of Chen, Liu, and Vigoda [7], and the sampling algorithm that it implies.

▶ **Theorem 6** ([7])**.** *Given $\Delta \geq 3$ and $\xi \in (0, \lambda_c(\Delta))$, there exists $C > 0$ such that the following holds. For all $0 \leq \lambda < \lambda_c(\Delta) - \xi$ and graphs $G \in \mathcal{G}_\Delta$ on n vertices, the mixing time $T_{\text{mix}}(\mathcal{M}, \varepsilon)$ of the Glauber dynamics $\mathcal{M}$ for the hard-core model on G with fugacity λ is at most $Cn\log(n/\varepsilon)$. This implies an ε-approximate sampling algorithm for $\mu_{G,\lambda}$ for $G \in \mathcal{G}_\Delta$ that runs in time $O(n \log n \log(n/\varepsilon))$.*

The sampling algorithm follows from the mixing time bound; the extra factor $\log n$ is the cost of implementing one step of Glauber dynamics (which requires reading $O(\log n)$ random bits to sample a vertex uniformly). Note that the implicit constant in the running time depends on how close λ is to $\lambda_c(\Delta)$, but in applications of this theorem we will have $\lambda \leq \lambda_c(\Delta) - \xi$ for some fixed $\xi > 0$, so that the implicit constant depends only on ξ, which in turn depends on α.

2.1 Approximate sampling

The algorithm Sample-k listed in Algorithm 1 uses Theorem 6 and a binary search on values of λ to generate samples from $\mathcal{I}_k(G)$. The algorithm requires access to distributions $\hat{\mu}_\lambda$ which are meant to be approximate versions of the hard-core model on G at fugacity λ. For the algorithm to work, we require that there is some value of λ such that sampling from the hard-core model at fugacity λ is likely to yield a set of size exactly k, and we will establish that this holds for some λ in a set of size $O(n^2)$ and for a suitable definition of "likely". Quantitatively, these results inform the length $C \log n$ of the for loop and the value of N. An intuitive choice for λ would be the unique value that makes k the expected size of an independent set from the hard-core model on G, and in fact it suffices to find a value sufficiently close to this.

Algorithm 1 Sample-k.

input : $\alpha < \alpha_c$; $\varepsilon > 0$; $G \in \mathcal{G}_\Delta$ of size n; integer $k \leq \alpha n$
output : $I \in \mathcal{I}_k(G)$ with distribution within ε total variation distance of the uniform distribution of $\mathcal{I}_k(G)$

1 Let $\lambda_* = \frac{\alpha}{1-\alpha(\Delta+1)}$
2 For $t = 0, \dots, \lfloor 2\lambda_* n^2 \rfloor$, let $\lambda_t = t/(2n^2)$
3 Let $\Lambda_0 = \{\lambda_t : t = 0, \dots, \lfloor 2\lambda_* n^2 \rfloor\}$
4 **for** $i = 1, \dots, C \log n$, **do**
5 Let λ be a median of the set Λ_{i-1}
6 With $N = C' n^2 \log\left(\frac{\log n}{\varepsilon}\right)$, take N independent samples $I_1, \dots, I_N$ from a distribution $\hat{\mu}_\lambda$ on $\mathcal{I}(G)$
7 Let $\kappa = \frac{1}{N} \sum_{j=1}^{N} |I_j|$
8 If $|\kappa - k| \leq 1/4$ and there exists $j \in \{1, \dots, N\}$ so that $|I_j| = k$, then output I_j for the smallest such j and **halt**
9 If $\kappa \leq k$, let $\Lambda_i = \{\lambda' \in \Lambda_{i-1} : \lambda' > \lambda\}$. If instead $\kappa > k$, let $\Lambda_i = \{\lambda' \in \Lambda_{i-1} : \lambda' < \lambda\}$
10 **end**
11 If no independent set of size k has been obtained by the end of the for loop (or if $\Lambda_j = \emptyset$ at any step), use a greedy algorithm and output an arbitrary $I \in \mathcal{I}_k(G)$

▶ **Theorem 7.** *Let C be the constant in Line 4 and N be as in Line 6 of Sample-k (Algorithm 1). If the distributions $\hat{\mu}_\lambda$ are each within total variation distance $\varepsilon/(2CN \log n)$ of $\mu_{G,\lambda}$, the output distribution of Sample-k is within total variation distance ε of the uniform distribution of $\mathcal{I}_k(G)$. The running time of Sample-k is $O(N \log n \cdot T(n, \varepsilon))$ where $T(n, \varepsilon)$ is the running time required to produce a sample from $\hat{\mu}_\lambda$ satisfying the above guarantee.*

The sampling part of Theorem 1 follows immediately from Theorem 7 since by Theorem 6 we can obtain $\varepsilon/(2CN\log n)$-approximate samples from $\mu_{G,\lambda}$ in time $O(n\log n\log(n\log n\cdot N/\varepsilon))$. Thus, the total running time of Sample-k with this guarantee on $\hat{\mu}_\lambda$ is
