In the bounded degree model Goldreich and Ron [9] observed that it is possible to test triangle freeness with query complexity $O(1/\epsilon)$ in graphs of maximum degree bounded by some constant.

The problem of testing triangle freeness in the general graph model was first studied by Alon, Kaufman, Krivelevich, Ron [3]. The query complexity of their algorithms dependent on n and $\bar{d}$, the number of vertices in the graph and the average degree, respectively. They provided sublinear upper bounds for almost the entire range of parameters. Moreover, their upper bounds are at most quadratic in their lower bounds. Specifically, their upper bound, which is combined from several upper bounds is $\tilde{O}(\min\{(n\bar{d})^{1/2}/\epsilon^{3/2}, (n^{4/3}/\bar{d}^{2/3})/\epsilon^2\})$. Their lower bound, which is also combined from several lower bounds, is $\Omega(\max\{(n/\bar{d})^{1/2}, \min\{\bar{d}, n/\bar{d}\}, \min\{\bar{d}^{1/2}, n^{2/3}/\bar{d}^{1/3}\} \cdot n^{-o(1)}\})$.

Rast [13] improved the upper bound of [3] for graphs with average degree in the range $[c_1 n^{1/5}, c_2 n^{1/2}]$ where c_1 and c_2 are some constants. The upper bound in [13] is $O(\max\{(n\bar{d})^{4/9}, n^{2/3}/\bar{d}^{1/3}\})$.

Gugelmann [10] provided a lower bound which improves the lower bound in [3] for graphs with average degree in the range $[c_1 n^{2/5}, c_2 n^{4/5}]$ where c_1 and c_2 are some constants. The lower bound in [10] is $\Omega(\min\{(n\bar{d})^{1/3}, n/\bar{d}\})$.

1.2.2 Sublinear algorithms that receive the arboricity of the graph as a parameter

Eden, Ron and Rosenbaum [5] designed an algorithm that given n, the number of edges of the input graph and an upper bound on the arboricity of the input graph, Γ, the algorithm makes $O(\Gamma/\bar{d} + \log^3 n/\epsilon)$ queries on expectation and samples an edge of the graph almost uniformly. More specifically, each edge in the graph is sampled with probability in the range $[(1-\epsilon)m, (1+\epsilon)m]$.

Eden, Ron and Seshadhri [6] estimate the degree distribution moments of an undirected graph. In particular, for estimating the average degree of a graph, their algorithm has query complexity of $\tilde{O}(\Gamma/\bar{d})$. As they show in their paper, if Γ is not given as an input to the algorithm then estimating the average degree is not possible in general with this query complexity.

In another paper, Eden, Ron and Seshadhri [7] give a $(1 \pm \epsilon)$-approximation for the number of k-cliques in a graph given a bound on the arboricity of the graph Γ. In particular for triangles they provide an upper bound with expected running time, in terms of n, Γ and the number of triangles in the graph, n_3, of $\min\{n\Gamma^2/n_3, n/n_3^{1/3} + (m\Gamma)/n_3\} \cdot \text{poly}(\log n, 1/\epsilon)$.

1.2.3 Testing graphs for bounded arboricity

Eden, Levi and Ron [4] provided an algorithm for testing whether a graph has bounded arboricity. Specifically, they provide a tolerant tester that distinguished graphs that are ϵ-close to having arboricity Γ from which are $c \cdot \epsilon$-far from having arboricity 3Γ, where c is an absolute constant. The query complexity and the running time of their algorithm is in terms of n, m and Γ is $\tilde{O}(n/\sqrt{m} + n\Gamma/m)$ and is quasi-polynomial in $1/\epsilon$.

1.3 Comparison between our upper bound and upper bounds in previous work

As mentioned before, Alon et al. [3] provide tight bounds only in two cases. The first case is when $d_{\max} = O(\bar{d})$ and $\bar{d} \leq \sqrt{n}$, where $d_{\max}$ denotes the maximum degree and $\bar{d}$ denotes the average degree of the graph. In this case, it follows that $\Gamma = \Theta(d_{\max}) = \Theta(\bar{d})$ an so our upper bounds essentially match. Additionally we note that a bound on the arboricty of the graph does not imply a bound on the maximum degree of the graph. In fact, the maximum degree could be $\Theta(n)$ while the arboricity is $\Theta(1)$ (as it is the case in the star graph). Consequently, the tightness of our upper bound is not restricted for graphs which have bounded maximum degree.

The second case is when $\bar{d} = \Theta(1)$, for these graphs the running time complexity of their algorithm is $\tilde{\Theta}(n^{1/2})$. For this case, the running time complexity of our upper bound is $\tilde{O}(\Gamma)$. We note that in graphs in which $\bar{d} = \Theta(1)$, Γ could range between $\Theta(1)$ and $\Theta(n^{1/2})$. Therefore when $\bar{d} = \Theta(1)$ the complexity of our upper bound is not worse than the complexity of the upper bound in [3] but could be much better, depending on Γ.

For average degree in the range between $\Omega(1)$ and $O(n^{2/5})$ and in the range between $\Omega(n^{1/2})$ and $O(n^{2/3})$ the upper bound of $O(m^{1/2})$ queries of Alon et al. achieves the best running time, in terms of n and m. For these ranges, the running time of our algorithm is $\tilde{O}(\Gamma)$. Since $m^{1/2} \geq \Gamma$, we obtain that for this ranges as well the performances of our algorithm are at least as good (up to $O(\log \log n)$ and $\text{poly}(1/\epsilon)$ factors) but could be significantly better.

For average degree in the range between $\Omega(n^{2/5})$ and $O(n^{1/2})$ the upper bound of $O(\max\{(n\bar{d})^{4/9}, n^{2/3}/\bar{d}^{1/3}\})$ queries of Rast [13] achieves the best running time. In this range our upper bound is always better than the upper bound of [13] for graphs of arboricity $O(n^{12/21})$.

1.4 High-level of Our Algorithm

It is well known that a graph which is ϵ-far from being triangle free has $\Omega(\epsilon m)$ edge-disjoint triangles (see Claim 1). Therefore if we were able to sample edges uniformly from the graph then after sampling $O(1/\epsilon)$ edges we would sample an edge $\{u, v\}$ which belongs to a triangle. Thus, if we revealed the entire neighborhood of u and the entire neighborhood of v then we would find a triangle in the graph. Our algorithm is based on this simple approach. There are only two problems that need to be addressed. The first problem is that sampling edges uniformly in a graph in which the degrees have high variability is too costly. The second problem, which also stems from the variability of the degrees in the graph, is that revealing the entire neighborhood of a vertex can be too costly, depending on its degree.

This is where the arboricity of the graph comes into play. For a graph of arboricity Γ, as was shown in [4], the fraction of edges in the subgraph induced on *heavy* vertices, that is, vertices with degree greater than $c\Gamma/\epsilon$ where c is some absolute constant, is at most $\epsilon/2$.

Therefore, if Γ was given to us as a parameter then we could, in some sense, ignore the subgraph induced on vertices of degree greater than $\Theta(\Gamma/\epsilon)$ since a graph which is ϵ-far from being triangle free still have $\Omega(\epsilon m)$ violating edges (and $\Omega(\epsilon m)$ edge-disjoint triangles) even after we remove this subgraph entirely. Ignoring this subgraph allows us on one hand to sample edges almost uniformly from the resulting graph while making only $\Omega(\Gamma/\bar{d})$ queries, and also guarantees that there are $\Omega(\epsilon m)$ violating edges for which both endpoints are not heavy. This solves the two problems we had with taking the simple approach.

However a bound on the arboricty of the graph is not given to the algorithm as a parameter. Since approximating the arboricity of a graph up to a constant factor is not possible in sublinear time (to see this consider a graph with a hidden clique), we estimate a different parameter which we informally refer to as the *effective arboricity* of the graph. We show that this parameter suffices for our needs. In fact, this parameter could be much smaller than Γ, in which case the complexity of our algorithm is better than $O(\Gamma/\bar{d}+\Gamma)$. We reduce the problem of approximating the effective arboricity of the graph to the problem of estimating the number of edges in the graph in which we remove the subgraph induced on heavy vertices, where heavy vertices are defined with respect to increasing thresholds. We stop increasing our threshold once the estimation of the number of edges is sufficiently large. As we prove, with high constant probability, our approximation to the effective arboricity is bounded by $O(\Gamma)$ which leads to a tester with running time $O(\Gamma/\bar{d}+\Gamma)$, as claimed.

1.5 Lower Bounds

Our first lower bound of $\Omega(\Gamma/\bar{d})$ for graphs in which $\bar{d} \leq 1$ is based on a simple hitting argument. Specifically, construct a graph which is 1/3-far from being triangle free in which $\Omega(\Gamma/\bar{d}+\Gamma) = \Omega(\Gamma/\bar{d})$ queries are required in order to sample a vertex which is not isolated with probability that is at least 1/3.

Our other two lower bounds are simple adaptations of the lower bound of $\Omega(\min\{\bar{d}, n/\bar{d}\})$ queries presented in Alon et al. [3].

2 Preliminaries

Let $G = (V, E)$ be an undirected graph and let $\bar{d} = 2m/n$ denote the average degree of G where $n = |V|$ and $m = |E|$. For each vertex $v \in V$, let $\deg(v)$ denote the number of neighbors of v. For a subset of vertices $S \subseteq V$ we denote by $G([S])$ the subgraph induced on S. For a directed graph D we denote by $\bar{d}_{out}(D)$ the average out-degree of D.

A graph G is triangle free if for every three vertices, u, v, w in G at least one pair in $\{\{u, v\}, \{v, w\}, \{w, u\}\}$ is not an edge of G. A graph G is ϵ-far from being triangle free if more than ϵm edges need to be removed in order to make G triangle free.

In the general graph model the tester accesses the graph via the following oracle queries.

1. Degree queries: on query v the oracle returns $\deg(v)$.
2. Neighbor queries: on query (v, i) where $i \in [\deg(v)]$, the oracle returns the i-th neighbor of v.
3. Vertex-pair queries: on query $\{v, u\}$ the oracle returns whether there is an edge between u and v.

An algorithm is a tester for the property of triangle freeness if given a proximity parameter ϵ and access to an input graph G, it accepts G with probability at least 2/3 if G is triangle free and rejects G with probability at least 2/3 if G is ϵ-far from being triangle free. If the tester always accepts graphs which are triangle free we say it has one-side error. Otherwise we say it has two-sided error.

▷ Claim 1. A graph $G = (V, E)$ which is ϵ-far from being triangle free has at least $\epsilon m/3$ edge-disjoint triangles.

Proof. Consider a procedure that given a graph G, as long as there is triangle, t in G it deletes all the edges of t and proceeds in this manner until there are no triangles in the graph. The number of edges which are deleted by this process is at least ϵm. Therefore the number of edge disjoint triangles that are deleted is at least $\epsilon m/3$. The claim follows. ◁

The *arboricity* of an undirected graph G, denoted by $\Gamma(G)$, is the minimum number of forests into which its edges can be partitioned. Equivalently it is the minimum number of spanning forests needed to cover all the edges of the graph.

3 The Algorithm

3.1 First Step: computing the threshold for defining heavy vertices

As described above, for an input graph G, the number of edges in the subgraph induced on the heavy vertices w.r.t. the threshold $4\Gamma(G)/\epsilon$ is at most $(\epsilon/2)|E(G)|$ (see Claim 4). Therefore, when testing triangle freeness, we may, roughly speaking, ignore this subgraph with the hope of obtaining better complexity. Since $\Gamma(G)$ is not given to the algorithm as a parameter, we compute, in Algorithm 1, a different parameter of the graph, denoted by Γ^*, which is, roughly speaking, an approximation of the *effective* arboricity of the graph. In order to specify the guarantees on Γ^* we shall need a couple of definitions.

▶ **Definition 2.** *For a graph $G = (V, E)$ and a threshold t we define the set of* heavy vertices with respect to t *as $H_t(G) = \{v \in V : d(v) > t\}$ and the set of* light vertices with respect to t *as $L_t(G) = V \setminus H_t(G)$.*

When G is clear from the context we may simply use H_t and L_t. Using the definition of $H_t(G)$, we next define the graph $H(G, t)$ which is defined w.r.t. G and a threshold t.

▶ **Definition 3** (The undirected graph $H(G, t)$)**.** *For a graph $G = (V, E)$ and a threshold t, the graph $H(G, t)$ is an undirected graph defined as follows. The set of vertices of $H(G, t)$ is V and the set of edges of $H(G, t)$ is $E(G) \setminus \{\{u, v\} : u \in H_t(G)$ and $v \in H_t(G)\}$. Namely, $H(G, t)$ is the graph G after removing the edges for which both endpoints are heavy with respect to t.*

▷ Claim 4. For a graph G, $\Gamma' \geq \Gamma(G)$ and $\eta \in (0, 1]$ it holds that $|E(H(G, \Gamma'/\eta))| \geq (1 - 2\eta)|E(G)|$.

Proof. We shall prove the claim about $\Gamma' = \Gamma$. The general claim will follow from the fact that $|E(H(G, x)|$ is monotonically non-decreasing in x. Let $G([H_t])$ denote the sub-graph induced on $H_t(G)$ where $t = \Gamma/\eta$ and let k denote the number of edges of this graph. Our goal is to show that $k < 2\eta m$ where $m = |E(G)|$. The sum of the degrees of vertices in $H_t(G)$ is greater than $t \cdot |H_t(G)|$, therefore $m > t \cdot |H_t(G)|/2$. On the other hand, since the arboricity of $G([H_t])$ is also bounded by Γ it follows that $k \leq |H_t(G)| \cdot \Gamma$. Therefore $k < 2m/t \cdot \Gamma = 2\eta m$, as desired. ◁

The guarantees on Γ^*, which is the return value of Algorithm 1 (that will be described next), are as described in the following claim.

▷ Claim 5. With probability at least 5/6, Γ^* returned by Algorithm 1 is such that:

1. $|E(H(G,t))| \geq (1-(\epsilon/6))m$ where $t = \Gamma^*/(48\epsilon)$,
2. $\Gamma^* \leq 2\Gamma(G)$.

Algorithm 1 proceeds in iterations where in each iteration it multiplies Γ^* by a factor of 2, where initially Γ^* is set to 1. It stops when the estimated number of edges in $E(H(G,t))$, for t which is $\Theta(\Gamma^*/\epsilon)$, is at least $|E(G)|(1-\Theta(\epsilon))$. In order to estimate the number of edges in $E(H(G,t))$, Algorithm 1 calls Algorithm 2.

In turn, Algorithm 2 uses the directed graph $D(G,t)$, which we defined momentarily, that is constructed from G and can be accessed by making a constant number of queries to G.

▶ **Definition 6** (The directed graph $D(G,t)$)**.** *The graph $D(G,t)$ is a directed version of the graph $H(G,t)$ in which we orient the edges as follows. For every edge $\{u,v\}$ of $H(G,t)$, we orient the edge from u to v if: (a) $u \in L_t$ and $v \in H_t$ or (b) both $u \in L_t$ and $v \in L_t$ and $id(u) < id(v)$. Otherwise, we orient it from v to u.*

Algorithm 1 Compute Γ^*.

Input: Access to a graph G and parameters n, m and $\epsilon \in (0,1]$
Output: Γ^* as described in Lemma 5

Set $\Gamma_1 = 1$
for $i = 1$ ***to*** $\log n$ **do**
  Run Algorithm 2 on G with parameters n, m, $\epsilon/24$, t_i and $\delta = \Theta(\log\log n)$ where $t_i \stackrel{\text{def}}{=} \Gamma_i/(24\epsilon)$. Let Z_i denote the returned value.
  If $Z_i \leq (1-\epsilon/12)m$ then set $\Gamma_{i+1} = 2\Gamma_i$, otherwise, return Γ_i

Algorithm 2 Estimate the number of edges of $H(G,t)$.

Input: Access to an undirected graph G and parameters parameters n, m, ϵ, t and δ, where $n = |V(G)|$ and $m = |E(G)|$
Output: Estimation to the number of edges of $H(G,t)$

Sample $r = \Theta(\delta^{-1}\epsilon^{-2}t/\bar{d})$, where $\bar{d} = m/n$, vertices $v_1,\ldots,v_r$, uniformly at random from $V(G)$.
For each $i \in [r]$:
  1. Sample a random neighbor of v_i, u. If the edge between u and v_i is oriented from v_i to u in D then set $Y_i = 1$, otherwise set $Y_i = 0$
  2. Set $X_i = \frac{(d_{\text{out}}(v)+d_{\text{in}}(v))\cdot Y_i}{t}$

Return $X = \frac{t\cdot|V(G)|}{r} \cdot \sum_{i\in[r]} X_i$

The following claim specifies the guarantees of Algorithm 2.

▷ Claim 7. Given a query access to a graph G and parameters n, m, ϵ, t and δ where $n = |V(G)|$ and $m = |E(G)|$, Algorithm 2 outputs X such that w.p. at least $1-2^{1/\delta}$, $(1-\epsilon)m' \leq X \leq (1+\epsilon)m'$ if $m' \geq (1-2\epsilon)m$, and $X < (1-\epsilon)m$, otherwise, where $m' = |E(H(G,t))|$.

Proof. First observe that Y_i is an indicator variable to the event that the edge selected in the i-th iteration of Algorithm 2, $\{v_i,u\}$ is an out-edge of v_i in $D(G,t)$. Since $V(G) = V(D(G,t))$ we obtain the following.

$$\mathrm{E}(Y_i) = \frac{1}{|V(D(G,t))|} \cdot \Sigma_{v \in V(D(G,t))} \frac{d_{\mathrm{out}}(v)}{d_{\mathrm{out}}(v) + d_{\mathrm{in}}(v)} \ . \tag{1}$$

Similarly,

$$\begin{aligned} \mathrm{E}(X_i) &= \frac{1}{|V(D(G,t))|} \cdot \Sigma_{v \in V(D(G,t))} \frac{d_{\mathrm{out}}(v) + d_{\mathrm{in}}(v)}{t} \cdot \frac{d_{\mathrm{out}}(v)}{d_{\mathrm{out}}(v) + d_{\mathrm{in}}(v)} \\ &= \frac{1}{|V(D(G,t))|} \cdot \Sigma_{v \in V(D(G,t))} \frac{d_{\mathrm{out}}(v)}{t} = \frac{\bar{d}_{\mathrm{out}}(D(G,t))}{t} \ . \end{aligned} \tag{2}$$

Observe that if $v_i \in H_t(G)$ then $d_{\mathrm{out}}(v) = 0$ and so $Y_i = X_i = 0$. On the other hand, if $v_i \in L_t(G)$ then $d_{\mathrm{out}}(v) + d_{\mathrm{in}}(v) \leq t$. Therefore, in both cases $X_i \in [0,1]$. Thus, for r which is $\Theta(1/(\delta\epsilon^2 E(X_1)))$ it follows by Multiplicative Chernoff's bound that with probability at least $1 - 2^{1/\delta}$,

$$(1-\epsilon)E(X_1) \leq \sum_{i \in [r]} X_i/r \leq (1+\epsilon)E(X_1) \ .$$

And so

$$t \cdot |V(G)| \cdot (1-\epsilon)E(X_1) \leq X \leq t \cdot |V(G)| \cdot (1+\epsilon)E(X_1) \ .$$

Since $t \cdot |V(G)| \cdot E(X_1) = |E(H(G,t))|$ we obtain that

$$(1-\epsilon) \cdot |E(H(G,t))| \leq X \leq (1+\epsilon) \cdot |E(H(G,t))| \ .$$

Hence, if $|E(H(G,t))| \geq (1-2\epsilon)m$ then $\bar{d}_{\mathrm{out}}(D(G,t)) = \Theta(\bar{d}(G))$ and so $\mathrm{E}(X_1) = \Theta(\bar{d}(G)/t)$, implying that $r = \Theta(1/(\delta\epsilon^2 E(X_1)))$, as desired. On the other hand, if $|E(H(G,t))| < (1-2\epsilon)m$, then it is not hard to see that the claim follows by a straightforward coupling argument. More specifically, first assume that $|E(H(G,t))| = (1-2\epsilon)m$ and so by the above, with probability at least $1 - 2^{1/\delta}$,

$$X \leq (1+\epsilon)|E(H(G,t))| = (1+\epsilon)(1-2\epsilon)m < (1-\epsilon)m.$$

Therefore, it follows by a coupling argument that with probability at least $1 - 2^{1/\delta}$, $X < (1-\epsilon)m$ also in the case that $|E(H(G,t))| < (1-2\epsilon)m$. ◁

▷ Claim 8. For an input graph G and parameters n, m, ϵ, t and δ, where $n = |V(G)|$ and $m = |E(G)|$, the time complexity and query complexity of Algorithm 2 is $O(\delta^{-1}\epsilon^{-2}t/\bar{d}(G))$.

Proof. The claim follows from the fact that in order to implement Steps 2.1 and 2.2 of Algorithm 2 the algorithm makes a constant number of queries to G. Specifically, for each v_i the algorithm either performs a single degree query (in case $v_i \in H_t(G)$ then $Y_i = X_i = 0$) or a single adjacency-list query and 2 degree queries in case $v_i \in L_t(G)$ (the orientation of the edge $\{v_i, u\}$ can be determined by the degrees and ids of v_i and u). The implementation of Step 2.2 does not require additional queries as $d_{\mathrm{out}}(v_i) + d_{\mathrm{in}}(v_i) = d_G(v_i)$. ◁

We are now ready to prove Claim 5.

Proof of Claim 5. For the sake of analysis assume that Algorithm 1 performs all $\log n$ iterations of the for-loop. Let E_i denote the event that Z_i is as claimed in Claim 7. By Claim 7, for a fixed i, the probability that E_i occurs is at least $1/(6\log n)$ for an appropriate setting of δ. Therefore, by the union bound the probability that E_i occurs for all $i \in [\log n]$ is at least $5/6$. From this point on we condition on the event that indeed E_i occurs for all $i \in [\log n]$.

Let $m_i = |E(H(G,t_i))|$ for every $i \in [\log n]$. Let j denote the iteration in which Algorithm 1 returns a value. By Step 4 of Algorithm 1, $Z_j > (1-\epsilon/12)m$. By Claim 7, it follows that $m_j \geq (1-\epsilon/6)m$, as desired (to see this note that if $m_j < (1-\epsilon/6)m$ then By Claim 7, $Z_j < (1-\epsilon/12)m$).

To prove the claim about Γ^* we consider the minimum $j' \geq 1$, for which $2^{j'-1} \geq \Gamma$. If $j < j'$ then clearly $\Gamma^* < \Gamma$, as desired. Otherwise, we claim that $j = j'$ (namely, that $\Gamma^* = 2^{j'-1}$) which implies that $\Gamma^* \leq 2\Gamma$, as desired. To see this, first note that by Claim 4, for any $\Gamma' \geq \Gamma$ and $\eta \in (0,1]$, $|E(H(G,\Gamma'/\eta))| \geq (1-2\eta)m$. Therefore $m'_j \geq (1-\epsilon/24)m$. Therefore, by Claim 7, $Z_{j'} \geq (1-\epsilon/24)m'_j \geq (1-\epsilon/24)^2 m > (1-\epsilon/12)m$, which implies that the algorithms stops at the j'-th iteration. ◁

3.2 Second Step: sampling edges almost uniformly given a threshold for heavy vertices

Given a threshold t, Algorithm 3 samples an edge from $H(G,t)$ almost uniformly as described in the next claim.

▷ Claim 9. Algorithm 3 samples an edge from $H(G,t)$ such that for each edge, e, of $H(G,t)$, the probability to sample e is in $\left[\frac{c_1}{m'}, \frac{c_2}{m'}\right]$, where c_1 and c_2 are absolute constants and $m' \stackrel{\text{def}}{=} |E(H(G,t))|$. If t is such that $m' \geq |E(G)|/2$ then the expected running time of the algorithm is $O(t/\bar{d}(G))$.

Proof. Consider a single iteration of the while loop of Algorithm 3. For an edge e in $H(G,t)$ let $p(e)$ denote the probability that e is returned in this iteration of Algorithm 3. If e is an edge such that both endpoints are in $L_t(G)$, then $p(e) = \frac{2}{n} \cdot \frac{1}{t}$. If e is an edge such that one endpoint in $L_t(G)$ and the other endpoint is in $H_t(G)$, then $p(e) = \frac{1}{n} \cdot \frac{1}{t}$. Therefore for any two edges e_1 and e_2 in $H(G,t)$ the probability that e_1 is picked by the algorithm is at most twice the probability that e_2 is picked by the algorithm. Since Algorithm 3 only returns edges in $H(G,t)$, the claim about the probability to sample an edge follows.

For a fixed iteration of the while loop, the probability that the algorithm returns one of the edges of $E(H(G,t))$ is at least $m' \cdot \frac{1}{n} \cdot \frac{1}{t}$ which is at least $\bar{d}(G)/(2t)$ in the case that $m' \geq |E(G)|/2$. Therefore in this case the expected number of iterations of the while loop is at most $(2t/\bar{d}(G))$. Hence the claim about the expected running time follows. ◁

Algorithm 3 Sample an edge from $H(G,t)$ almost uniformly.

Input: Access to a graph G and a parameter t.
1 **while do**
2 Pick u.a.r. a vertex v from $V(G)$
3 Pick u.a.r. $j \in [t]$
4 If $v \in L_t(G)$ and v has a j-th neighbor, u, then return $\{v,u\}$.

▶ Remark 10. We remark that Algorithm 3 is stated as a Las Vegas algorithm. Moreover, if $m < |E(G)|/2$ then we can not obtain from Claim 9 any bound on the expected running time of the algorithm. However, we note that since t and $\bar{d}(G)$ are known then we can set a timeout for the algorithm (specifically $ct/\bar{d}(G)$ for some constant c) and incorporate the event that we were forced to stop the algorithm in the failure probability of the tester.

3.3 Putting things together - the algorithm for testing triangle freeness

Using Algorithms 2 and 3 we are now ready to describe our tester (Algorithm 4).

Algorithm 4 Testing Triangle-Freeness.

Input: Access to a graph G and parameters n, m, and ϵ.
1 Execute Algorithm 2 with parameters n, m and ϵ and let Γ^* denote the returned value
2 Let $t = \Gamma^*/\epsilon$
3 **for** $i = 1$ ***to*** $s = \Theta(\epsilon^{-1})$ **do**
4 Execute Algorithm 3 on G with parameter t and let $\{u, v\}$ denote the edge returned by the algorithm.
5 If both $u \in L_t(G)$ and $v \in L_t(G)$ then return REJECT if $N(u) \cap N(v) \neq \emptyset$
6 Return ACCEPT

Since the tester has one-sided error (it rejects only if it finds a witness for violation, i.e., a triangle) its correctness follows from the following claim.

▷ Claim 11. If G is ϵ-far from being triangle free then **Test Triangle Freeness** finds a triangle with probability at least 2/3. The expected running time of the algorithm is $\tilde{O}\left(\Gamma/\bar{d}(G) + \Gamma\right) \cdot \text{poly}(\epsilon^{-1})$.

Proof. Let $G = (V, E)$ be an input graph which is ϵ-far from being triangle free. There are at least $\epsilon m/3$ edge-disjoint triangles in G (see Claim 1). Let E_1 denote the event that for Γ^* that is return by Algorithm 1 it holds that $|E(H(G,t))| \geq (1 - (\epsilon/6))m$ where $t = \Gamma^*/\epsilon$. By Claim 5 E_1 occurs with probability at least 5/6. Given that E_1 occurred, it follows that there are at least $(\epsilon/3)m - (\epsilon/6)m = (\epsilon/6)m$ edge-disjoint triangles in $H(G,t)$. Let $\{t_1, \ldots, t_k\}$ be an arbitrary subset of these edge-disjoint triangles where $k \stackrel{\text{def}}{=} (\epsilon/6)m$. By the definition of $H(G,t)$ it holds that for every edge $\{u, v\} \in E(H(G,t))$ either $u \in L_t(G)$ or $v \in L_t(G)$. Thus, for every $i \in [k]$ the triangle t_i includes an edge $\{x_i, y_i\}$ such that both x_i and y_i are in $L_t(G)$. Therefore, there are at least k edges in $H(G,t)$ such that if Algorithm 3 returns one of these edges in Step 4 of Algorithm 4 then Algorithm 4 rejects. For every $i \in [s]$, let $E_{2,i}$ denote the event that Algorithm 3 returns one of these edges in the i-th iteration of Algorithm 4.

By Claim 9, given that E_1 occurred, the probability that $E_{2,i}$ occurs (given that the algorithm did not return REJECT before the i-th iteration) is at least $c\epsilon$ for some absolute constant c. Therefore the probability that both E_1 and $E_{2,i}$ occur for some $i \in [s]$ is at least 2/3 for an appropriate setting of s. Thus the algorithm rejects with probability at least 2/3 as desired. ◁

4 Lower Bounds

4.1 Lower bound of $\Omega((\Gamma n)/m)$ for any Γ and any feasible $m \geq 1$

▶ **Theorem 12.** *For any $\Gamma \leq n - 1$ and any $m \geq 1$ which is feasible w.r.t. Γ, any algorithm for testing triangle-freeness must perform $\Omega((\Gamma n)/m)$ queries where n, m and Γ denote the number of vertices, the number of edges and the arboricity of the input graph, receptively. This lower bound holds even if the algorithm is allowed two-sided error.*

Proof. We consider the following graph G over n vertices, m edges and of arboricity Γ. V_1 and V_2 are subsets of $2m/(3\Gamma)$ vertices each and V_3 is a subset of $\Gamma/2$ vertices. V_1, V_2 and V_3 are pairwise disjoint. The edges of the graph are as follows. The sub-graph induced on V_1 and V_3 is a complete bipartite graph with V_1 on one side and V_3 on the other side. Similarly the subgraph induced on V_2 and V_3 is also a complete bipartite graph. Between V_1 and V_2 we take $\Gamma/2$ edge disjoint prefect matchings. Consequently the degree of every node in V_1 and V_2, as well as the arboricity of the graph, is exactly Γ. The number of edge disjoint triangles in the graph is at least $m/3$. To see this consider the following correspondence between an edge $\{u, v\}$ such that $u \in V_1$ and $v \in V_2$ and a triangle in the graph. Let $i \in [\Gamma/2]$ denote the matching for which $\{u, v\}$ belongs to, then triangle that corresponds to $\{u, v\}$ is $\{u, v, w_i\}$.

Therefore the graph is $(1/3)$-far from being triangle free (if $t_1, \ldots, t_{m/3}$ are edge disjoint triangles of G then we need to delete at least one edge per triangle in order to make G triangle free). The number of queries we need to make to hit either V_1 or V_2 is $\Omega((\Gamma n)/m)$. The number of queries we need to make to hit V_3 is $\Omega(n/\Gamma)$. Since $m = \Omega(\Gamma^2)$, we obtain a lower bound of $\Omega((\Gamma n)/m)$ queries in order to hit a vertex from $V_1 \cup V_2 \cup V_3$. Therefore unless the tester makes $\Omega((\Gamma n)/m)$ queries, it can not distinguish between G and the empty graph. The theorem follows. ◀

4.2 Lower bound of $\Omega(\Gamma)$ for any Γ and any feasible $m \geq \Gamma^3$

We adapt the following lower bound of Alon et al. [3].

▶ **Theorem 13.** *Any algorithm for testing triangle-freeness must perform* $\Omega(\min\{\bar{d}, n/\bar{d}\})$ *queries. This lower bound holds even if the algorithm is allowed two-sided error and even for* $d_{\max} = O(\bar{d})$.

Using Theorem 13, we shall prove the following claims.

▷ Claim 14. For any Γ and any feasible m w.r.t. Γ such that $m \geq \Gamma^3$, any algorithm for testing triangle-freeness must perform $\Omega(\Gamma)$ queries, where m and Γ denote the number of edges and the arboricity of the input graph, respectively. This lower bound holds even if the algorithm is allowed two-sided error.

Proof. Assume towards contradiction that there exists an algorithm $\mathcal{A}$ for testing triangle-freeness that is allowed two-sided error and performs $o(\Gamma)$ queries even for input graphs for which $m \geq \Gamma^3$, where m and Γ denote the number of edges and the arboricity of the input graph of $\mathcal{A}$, respectively. We will show that there exists an algorithm $\mathcal{B}$ for testing triangle-freeness (with two-sided error) for graphs in which $M/N = \Gamma$, $N = m/\Gamma$ and the maximum degree is Γ, whose query complexity is $o(\Gamma)$, where M and N denote the number of edges and the number of vertices of the input graph of $\mathcal{B}$, respectively. This will contradict the lower bound in Theorem 13 as $\min\{M/N, N^2/M\} = \min\{\Gamma, m/\Gamma^2\} = \Gamma$, where the last inequality follows from the fact that $m \geq \Gamma^3$.

Let m, n and Γ be such that m is feasible w.r.t. Γ and $m \geq \Gamma^3$. Therefore $\Gamma^3 \leq m \leq \Gamma n$. Let G be a graph over N vertices and M edges for which $M/N = \Gamma$, $N = m/\Gamma$ and the maximum degree is Γ. Given such an input graph G, the algorithm $\mathcal{B}$ simulates $\mathcal{A}$ on another graph, G', that will be described momentarily, and returns the output of $\mathcal{A}$ on G'. The graph G' is constructed from G and has the following properties:

1. G' has arboricity Γ.
2. Any query on G' can be answered by performing at most a single query to G
3. If G is triangle free then G' is triangle free as well.
4. If G is ϵ-far from being triangle free then G' is ϵ-far from being triangle free as well.

G' is simply the graph G with $n - N$ isolated vertices (observe that $n \geq N$ since $m \leq \Gamma n$). Since $M = m$, Item 4 follows. Items 1 and 3 follow from construction and the bound on the maximum degree of G. Item 2 follows from the fact that any query to the graph G' is can be answered either by performing a single query the graph G' or to without performing any query to G (in case the algorithm queries the subgraph induced on the additional $n - N$ isolated vertices of G').

The completeness and soundness of algorithm $\mathcal{B}$ follows from the correctness of algorithm $\mathcal{A}$ and Items 3 and 4, respectively. The claim about the query complexity of algorithm $\mathcal{B}$ follows from Item 2 and the assumption on the query complexity of algorithm $\mathcal{A}$. This completes the proof of the claim. ◁

4.3 Lower bound of $\Omega(m^{1/3})$ for any $\Gamma \leq (n/2)^{1/2}$ and any feasible $n \leq m \leq \Gamma^3$

▷ Claim 15. For any $\Gamma \leq (n/2)^{1/2}$ and any feasible m w.r.t. Γ such that $n \leq m \leq \Gamma^3$, any algorithm for testing triangle-freeness must perform $\Omega(m^{1/3})$ queries, where m, n and Γ denote the number of edges, number of vertices and the arboricity of the input graph, respectively. This lower bound holds even if the algorithm is allowed two-sided error.

Proof. The proof of this claim follows the same lines as the proof of Claim 14. Assume towards contradiction that there exists an algorithm $\mathcal{A}$ for testing triangle-freeness that is allowed two-sided error and performs $o(m^{1/3})$ queries even for input graphs for which $n \leq m \leq \Gamma^3$, where m, n and Γ denote the number of edges, number of vertices and the arboricity of the input graph, respectively. We will show that there exists an algorithm $\mathcal{B}$ for testing triangle-freeness (with two-sided error) for graphs in which $M = N^{3/2} = \Theta(m)$ and the maximum degree is M/N, whose query complexity is $o(M/N)$, where M and N denote the number of edges and the number of vertices of the input graph of $\mathcal{B}$, respectively. This will contradict the lower bound in Theorem 13 as $\min\{M/N, N^2/M\} = M/N$, where the last inequality follows from the fact that $M = N^{3/2}$.

Let m, n and Γ be such that m is feasible w.r.t. Γ and $n \leq m \leq \Gamma^3$. Let G be a graph over N vertices and M edges for which $M = N^{3/2} = m/2$ and for which the maximum degree is M/N. Given such an input graph G, the algorithm $\mathcal{B}$ simulates $\mathcal{A}$ on another graph, G', that will be described momentarily, and returns the output of $\mathcal{A}$ on G'. The graph G' is constructed from G and has the following properties:

1. G' has arboricity Γ.
2. Any query on G' can be answered by performing at most a single query to G
3. If G is triangle free then G' is triangle free as well.
4. If G is ϵ-far from being triangle free then G' is at least $\epsilon/2$-far from being triangle free as well.

G' is composed of the graph G, a complete bipartite graph A over 2Γ vertices and a graph I of $n - N - 2\Gamma$ isolated vertices. Observe that $n - N \geq 2\Gamma$ since $\Gamma^2 \leq n/2$ and $N = M^{2/3} \leq \Gamma^2/2^{2/3} \leq n/2$. The graph A has Γ vertices on each side, A_1 and A_2 and Γ^2 edges. Item 4 follows from the fact that $M = m - \Gamma^2 \geq m - n/2 \geq m/2$. Observe that maximum degree of G is at most Γ since $M/N \leq m^{1/3} \leq \Gamma$. Therefore, Items 1 and 3 follow from the fact that the arboricity of A is Γ and the bound on the maximum degree of G. Item 2 follows from the fact that any query to the graph G' is can be answered either by performing a single query the graph G' or to without performing any query to G (in case the algorithm queries the subgraphs A or I).

The completeness and soundness of algorithm $\mathcal{B}$ follows from the correctness of algorithm $\mathcal{A}$ and Items 3 and 4, respectively. The claim about the query complexity of algorithm $\mathcal{B}$ follows from Item 2 and the assumption on the query complexity of algorithm $\mathcal{A}$. This completes the proof of the claim. ◁

An Efficient Coding Theorem via Probabilistic Representations and Its Applications

Zhenjian Lu
University of Warwick, Coventry, UK

Igor C. Oliveira
University of Warwick, Coventry, UK

Abstract

A *probabilistic representation* of a string $x \in \{0,1\}^n$ is given by the code of a randomized algorithm that outputs x with high probability (Oliveira, ICALP 2019, [30]). We employ probabilistic representations to establish the first unconditional Coding Theorem in *time-bounded* Kolmogorov complexity. More precisely, we show that if a distribution ensemble $\mathcal{D}_m$ can be uniformly sampled in time $T(m)$ and generates a string $x \in \{0,1\}^*$ with probability at least δ, then x admits a time-bounded probabilistic representation of complexity $O(\log(1/\delta) + \log(T) + \log(m))$. Under mild assumptions, a representation of this form can be computed from x and the code of the sampler in time polynomial in $n = |x|$.

We derive consequences of this result relevant to the study of data compression, pseudodeterministic algorithms, time hierarchies for sampling distributions, and complexity lower bounds. In particular, we describe an *instance-based* search-to-decision reduction for Levin's Kt complexity (Levin, Information and Control 1984, [23]) and its probabilistic analogue rKt [30]. As a consequence, if a string x admits a succinct time-bounded representation, then a near-optimal representation can be generated from x with high probability in polynomial time. This partially addresses in a time-bounded setting a question from [23] on the efficiency of computing an optimal encoding of a string.

1 Introduction

Shannon's information theory provides a foundation for the study of data transmission and data compression. However, it inherently considers *probability distributions* and *random variables*, and for this reason it does not apply to an *individual* object. The theory of Kolmogorov complexity on the other hand captures the information or computational content of an individual string or message. Despite significant conceptual differences between the two theories, results obtained in one setting sometimes admit an analogue in the other (see e.g. the textbooks [12, 24, 34]).

A fundamental result connecting the distributional framework of Shannon and the information of an individual object x is the *Coding Theorem* in Kolmogorov complexity [22].[1] This theorem states that if a randomized machine A generates a string x with probability δ, then its Kolmogorov complexity $\mathsf{K}(x)$ is at most $\log(1/\delta) + O_A(1)$. The result is part of a deep and beautiful theory that we will not be able to survey here. For a complexity-theoretic perspective that is closer to our work, we refer to [21], where the coding theorem is referred to as one of the four pillars of Kolmogorov complexity.

An issue with this result and with Kolmogorov complexity more broadly is that many aspects of the theory are *nonconstructive*. For instance, computing or even estimating $\mathsf{K}(x)$ of an input string x is known to be undecidable. This limits the applicability of Kolmogorov complexity and of the aforementioned coding theorem in algorithms and complexity theory.

In order to import methods of Kolmogorov complexity from computability to complexity theory, a number of works have introduced *time-bounded* variants of Kolmogorov complexity (cf. [1, 2, 13, 3] for a survey of results). In other words, one considers the minimum description length of a string x with respect to machines that operate *under a time constraint*. Among many applications, this idea has led Sipser [35] to a proof that BPP is contained in the polynomial hierarchy, and Levin [23, Section 1.3] to further develop universal search and optimal search algorithms.

Naturally, many authors have investigated time-bounded variants of the main results in Kolmogorov complexity.[2] Unfortunately, under standard hardness assumptions some of its most powerful theorems do not survive in time-bounded settings. Two notable examples are the language compression theorem (see [8] and references therein) and the principle of symmetry of information (see [26, 27]).

Our focus in this work is on the coding theorem and its applications. Interestingly, there is no barrier to proving certain versions of the coding theorem in a time-bounded setting. For instance, Fortnow and Antunes [5] have implicitly established a form of this result, *under a strong computational assumption*. While their results are conditional and currently beyond reach without an assumption, they indicate that a useful time-bounded version of the coding theorem might be true.

Before proceeding with our discussion, we recall Levin's time-bounded Kolmogorov complexity. Let M be a deterministic machine and $|M|$ be its description length. For a string $x \in \{0,1\}^*$,

$$\mathsf{Kt}(x) \stackrel{\text{def}}{=} \min_{\text{TM } M,\, t \geq 1} \{|M| + \log t \mid M(\varepsilon) \text{ outputs } x \text{ in } t \text{ steps}\},$$

where $M(\varepsilon)$ denotes the computation of M over the empty string.[3] An important advantage of this definition over Kolmogorov complexity $\mathsf{K}(x)$ is that an encoding of minimal Kt complexity can be computed in exponential time via exhaustive search. Moreover, given an encoding w of x of Kt complexity at most k, we can recover x from w in time at most 2^k. Beyond its established applications in topics such as optimal search algorithms and pseudorandomness, Levin's Kt complexity plays an important role in a few other areas. Recent examples include hardness magnification (e.g. [31, 10]) and the investigation of non-disjoint promise problems [18].

---

[1] Some authors also refer to it as the Source Compression Theorem or Source Coding Theorem.

[2] Troy Lee's PhD thesis [21] contains a particularly nice exposition of the contrast between Kolmogorov complexity and its time-bounded variants, including pointers to relevant references.

[3] To obtain precise results about the encoding lengths, it is necessary to fix a universal machine and to consider short inputs for this machine that produce x, as done by Levin. Since our techniques are not sensitive to encoding choices and our results incur a constant factor overhead in the encoding length, this is not relevant for our discussion.

A *probabilistic version* of Levin's Kt complexity has been recently investigated in [30]. In this definition, we minimize over *randomized* machines that output x with probability at least $2/3$ after computing for at most t steps. In other words,

$$\mathsf{rKt}(x) \stackrel{\text{def}}{=} \min_{\text{RTM } M,\, t\geq 1}\{|M| + \log t \mid M(\varepsilon) \text{ outputs } x \text{ in } t \text{ steps with probability} \geq 2/3\}.$$

Consequently, an rKt description w of a string x provides a *probabilistic representation* of x, in the sense that x can be recovered with high probability from w. (Note that the description itself is a deterministic object.)

Under a mild derandomization assumption, $\mathsf{Kt}(x) = \Theta(\mathsf{rKt}(x))$ for every string x [30, Theorem 5]. If so, this would show that any object that can be succinctly described in a probabilistic way can also be succinctly described in a deterministic way, and that results about rKt can be transferred to Kt. However, we appear to be far from establishing this relation, and it is consistent with our knowledge that there is an infinite sequence $\{x_n\}_{n\geq 1}$ where each x_n is an n-bit string satisfying $\mathsf{rKt}(x) = O(\log n)$ and $\mathsf{Kt}(x) = \Omega(n)$.

We do know without assumptions that various natural objects such as certain n-bit prime numbers can have rKt complexity $n^{o(1)}$ [30, 32], while establishing even an upper bound of $o(n)$ on the Kt complexity of a sequence of n-bit primes would lead to a breakthrough in the deterministic generation of primes [37]. It seems therefore that probabilistic representations are useful to represent data, given our current knowledge of algorithms and complexity.

Another interesting aspect of rKt is that, despite its conjectured equivalence to Kt, we are able to settle basic questions about rKt that remain longstanding conjectures in the case of Kt. For instance, a natural computational problem is to approximate, given a string x, the value $\mathsf{rKt}(x)$. In other words, we would like to decide if a string has a short probabilistic representation. [30] proved *unconditionally* that this problem cannot be solved in probabilistic polynomial time. In contrast, showing that computing Kt cannot be done in deterministic polynomial time (i.e., proving $\mathsf{MKtP} \notin \mathsf{P}$) is an important problem in time-bounded Kolmogorov complexity (cf. [4]).

We are motivated by these intriguing recent results and by the possibility of studying algorithmic information theory from the vantage point of probabilistic descriptions. The following questions are particularly relevant in this context.

1. Is it possible to employ rKt to establish new results in time-bounded Kolmogorov complexity? Specifically, can we establish an *unconditional* version of the coding theorem discussed above?
2. We have natural examples where probabilistic representations might be helpful, but no positive algorithmic results about *finding* such descriptions. Is it possible to compute a probabilistic representation of a string in some non-trivial way?
3. Can we further develop the theory of probabilistic representations and show stronger results for natural objects, such as prime numbers?

1.1 Contributions

We make progress in the context of these questions, obtaining results that suggest new research directions connected to data compression, time-bounded Kolmogorov complexity, search-to-decision reductions, and related areas. In particular, our results highlight the usefulness of *probabilistic representations* in algorithms and complexity. We describe these contributions in detail next.

1.1.1 Main results

For an algorithm or machine A, recall that we use $|A|$ to denote its description length under a fixed encoding scheme. One of our main contributions in this work is to show that an important result in Kolmogorov complexity survives in the time-bounded setting.

▶ **Theorem 1** (Efficient Coding Theorem for rKt). *Suppose there is a randomized algorithm A for sampling strings such that $A(1^m)$ runs in time $T(m)$ and outputs a string $x \in \{0,1\}^*$ of length $n \leq T(m)$ with probability at least $\delta > 0$. Then*

$$\mathsf{rKt}(x) \;=\; O\big(\log(1/\delta) + \log(T(m)) + \log(m)\big),$$

where the constant behind the $O(\cdot)$ depends on $|A|$ and is independent of the remaining parameters. Moreover, given x, m, the code of A, and δ, it is possible to compute with probability ≥ 0.99 some rKt *encoding of x of at most this complexity in time* $\mathsf{poly}(|A|, \log(m), |x|, \log(1/\delta))$.

A few comments are in order. It is not hard to prove an effective coding theorem for a distribution whose *cumulative probability function* is computable in polynomial time (cf. [24]). Other works have established incomparable results under the assumption that deciding if a string is in the support of the distribution is easy (see e.g. [39]). Crucially, the theorem above only assumes that the distribution is *samplable*, which makes it more broadly applicable. To our knowledge, Theorem 1 is the first result that provides a general approach to constructing a probabilistic encoding of a string.

It follows from Shannon's Coding Theorem that the expected encoding length in Theorem 1 is essentially optimal up to a constant factor. An interesting feature of the result is that the algorithm computing the rKt encoding runs in polynomial time regardless of the time complexity of the sampler $A(1^m)$. Furthermore, producing the encoding of a string x only requires knowledge of a lower bound on its probability weight, in contrast to encoding algorithms such as Huffman coding where knowledge of the probabilities of all elements in the support of the distribution is necessary.

Using an argument of Levin (see [16] and [21, Section 5.3] or [28, Section A.3]), under the existence of one-way functions there is a polynomial-time samplable source $\mathcal{D}_n$ supported over $\{0,1\}^n$ such that every $x \in \mathsf{Support}(\mathcal{D}_n)$ has probability weight $\mathcal{D}_n(x) \geq 2^{-n^\varepsilon}$, but $\mathcal{D}_n$ does not admit a pair $(\mathsf{Enc}_n, \mathsf{Dec}_n)$ of efficient (probabilistic) encoding and decoding algorithms such that each $x \in \mathsf{Support}(\mathcal{D}_n)$ is assigned a description of length $\leq n - 3$. In contrast, Theorem 1 is able to sidestep this limitation by using an efficient encoding algorithm whose associated decoding procedure (provided by the rKt representation itself) is not necessarily efficient. There are applications where this trade-off might be acceptable, i.e., where it is crucial to achieve high compression rates and fast (or low energy) encoding, but for which decoding is allowed to take more resources.[4]

Similarly to the coding theorem in Kolmogorov complexity, it is possible to derive a variety of consequences from Theorem 1. We cover in more detail one of its most unexpected implications, deferring the discussion of a couple of other results to Section 1.1.2 below.

A *search-to-decision reduction* is an efficient procedure that allows one to find solutions to a problem from the mere ability to decide when a solution exists. These reductions are particularly important in algorithms and complexity. On the one hand, theories of computational complexity are often easier to develop in the context of *decision problems*.

[4] As a speculative scenario, one can imagine data transmission for deep space exploration.

On the other hand, in practice solving a *search problem* tends to be the relevant task. A search-to-decision reduction for a given problem shows that the complexities of its search and decision versions are similar.

It is well known that any NP-complete problem admits a search-to-decision reduction. However, there are problems of interest for which such reductions are still unknown. A notable example in the realm of time-bounded Kolmogorov complexity is whether MCSP, the Minimum Circuit Size Problem, admits a search-to-decision reduction (cf. [19] for a discussion and a recent result).

We establish the existence of the following search-to-decision reductions for rKt and Kt complexities.

▶ **Theorem 2** (Instance-based search-to-decision reductions). *The following results hold:*

(i) *There is a randomized polynomial-time algorithm that, when given an input string $x \in \{0,1\}^n$ and a value $k \geq \mathsf{rKt}(x)$, outputs with probability ≥ 0.99 a valid* rKt *representation of x of complexity $O(k)$.*

(ii) *Similarly, there is a randomized polynomial-time algorithm that, when given an input string $x \in \{0,1\}^n$ and a value $k \geq \mathsf{Kt}(x)$, outputs with probability ≥ 0.99 a valid* Kt *representation of x of complexity $O(k)$.*

We note that [4] established that any language in deterministic exponential time E can be non-uniformly reduced via polynomial-size circuits to the problem of deciding Kt complexity (or even of just approximating Kt on a large fraction of inputs). Since the problem of finding a minimal Kt representation of an input string can be encoded as a language in E, it follows from their work that there is a polynomial-size search-to-decision reduction for Kt. Observe that the reduction given by [4] finds a description of minimum length, while Theorem 2 only provides a description that is within a constant factor of the optimal description length.

There are now a number of search-to-decision reductions in the context of time-bounded Kolmogorov complexity with respect to a variety of string complexity measures (e.g. [9, 17, 19, 20, 25]). We are not aware, however, of a previous *instance-based* search-to-decision reduction in the sense of Theorem 2. In other words, Theorem 2 shows that it is possible to produce a near-optimal Kt representation of x from a decision oracle for Kt *that is only queried on x*.[5] In contrast, the aforementioned reductions require an oracle to the decision problem that is correct on all or at least on a large fraction of inputs. More broadly, search-to-decision reductions for problems in other domains such as circuit satisfiability and graph theory tend to query inputs that modify the original input x.

As a result of the property described above, we are able to derive consequences from Theorem 2 that do not follow from other reductions. Unsurprisingly, our approach employs significantly different techniques compared to the papers cited above. In particular, it departs from the PRG-based approach of [4] and of a few other subsequent works.

We elaborate next on some aspects of Theorem 2 that make it particularly interesting, at least to the authors. Note that Kt (similarly for rKt and probabilistic algorithms) is a *universal* complexity measure for data compression, in the following precise sense. If a string x can be encoded/decoded by *some* uniform compression scheme in time $\leq T$ and using a description of length $\leq \log T$, then its Kt complexity is at most $O(\log T)$. As a consequence, compressing a string x to $O(\mathsf{Kt}(x))$ bits is not far from optimal *in a strong sense*.

[5] A binary search is sufficient to compute $\mathsf{rKt}(x) \in \mathbb{N}$ from a decision oracle that checks if $\mathsf{rKt}(x) \leq \gamma$ for a given threshold γ.

Now suppose we have a string x of length n, and we estimate its Kt complexity to be at most, say, $O(\sqrt{n})$. Then finding a valid Kt representation of this complexity via *exhaustive search* would take time $2^{O(\sqrt{n})}$. Assuming the widely believed hardness of estimating the Kt complexity of a string (which is provably true for rKt by [30]), one is tempted to conjecture that nothing better can be done. Still, Theorem 2 tells us that there is an algorithm that can produce a valid Kt representation of x of complexity $O(\sqrt{n})$ in time just $\mathsf{poly}(n)$.[6] This result addresses to some extent in the time-bounded setting a question from [23, Page 5] on the efficiency of generating programs of length close to the optimal description length.

It is unclear to us whether there are *deterministic* search-to-decision reductions for Items (i) and (ii) of Theorem 2. Although this requires more investigation, it is possible that these reductions provide natural examples of randomized algorithms that cannot be replaced by deterministic ones with only a polynomial overhead.[7]

1.1.2 Further applications and open problems

Efficient construction of time-bounded programs and complexity lower bounds for estimating rKt. By executing the efficient search-to-decision reduction from Theorem 2 with all values of $k = O(n)$ that are powers of 2, the following corollary is immediate.

▶ **Corollary 3** (Effective short lists with short programs in short time)**.** *Given an arbitrary string x of length n, it is possible to compute with high probability and in polynomial time a collection of at most $d = \log(n) + O(1)$ strings $w_1, \ldots, w_d$ such that at least one of these strings is a valid rKt encoding of x of complexity $O(\mathsf{rKt}(x))$.*

The same result can be obtained for Kt complexity. Corollary 26 should be contrasted with the results from [7, 6] in the context of (time-unbounded) Kolmogorov complexity. They achieve optimal compression rates, by mapping a string of Kolmogorov complexity k to a collection of strings that contains a valid representation of length $k + O(1)$. While we are not able to achieve this level of compression, our setting is more stringent, since we need to construct a short representation that can be decompressed under a time constraint. It would be interesting to explore connections between our techniques and those employed in Kolmogorov complexity to see if our parameters can be further improved.

In light of Corollary 3 and the complexity lower bound for estimating the rKt complexity of a string ([30]; see Theorem 14), it follows that the intractability of estimating rKt does not lie in the exhaustive search required to *find* a succinct representation. Instead, the hardness is a consequence of the intractability of *checking* if a given rKt representation is valid for a string x.

It is unlikely that circuit minimization of a given truth-table (MCSP) admits a search-to-decision reduction of the form given by Theorem 2. This would allow one to construct in time polynomial in the size of the input truth-table a collection of circuits that contains a circuit of near-optimal size for the truth-table. As opposed to rKt, checking if a circuit correctly encodes a string can be done in polynomial time, which implies that such a search-to-decision reduction provides a natural property in the sense of [33]. Consequently, under cryptographic assumptions, minimizing circuit size and minimizing Kt/rKt behave differently with respect to instance-based search-to-decision reductions.

---

[6] This does not contradict the intractability result from [30]. Indeed, it implies that *checking* if a given representation generates a particular string is the problem that requires super-polynomial time.

[7] Note that this is not inconsistent with $\mathsf{P} = \mathsf{BPP}$ because these are not decision problems.

Hardness of approximately sampling distributions. It is not hard to show that if Promise-BPP $\subseteq$ Promise-P then BPTIME[$\cdot$] admits a time hierarchy theorem. This easily follows from the deterministic time hierarchy theorem for decision problems. As a consequence of our results, we observe that a similar derandomization hypothesis for *decision problems* implies a strong time hierarchy theorem for *sampling distributions*.

To our knowledge, a uniform time hierarchy theorem for sampling distributions was first established in [41]. While the results of his work are *unconditional*, [41] left open the problems of proving an *almost-everywhere* lower bound and of achieving a *larger statistical gap* [41, Section 5]. Our next result provides a conditional solution to these questions.

▶ **Theorem 4** (A strong time hierarchy theorem for sampling distributions)**.** *Under the assumption that* Promise-BPE $\subseteq$ Promise-E*, there is a constant $\zeta > 0$ for which the following holds. Let $n^{1/\zeta} \leq T(n) \leq 2^n$ be any constructive time bound. There is an ensemble $\{\mathcal{D}_n\}_{n\geq 1}$ of distributions $\mathcal{D}_n$ such that:*

- **(i)** *Each distribution $\mathcal{D}_n$ is supported over a single string $z_n \in \{0,1\}^n$.*
- **(ii)** *There is a deterministic algorithm $A(1^n)$ that samples $\mathcal{D}_n$ and runs in time $O(T(n))$.*
- **(iii)** *For each randomized algorithm $B(1^n)$ that runs in time $O(T(n)^\zeta)$ and for every large enough n, the statistical distance of $\mathcal{D}_n$ and $B(1^n)$ is at least $1 - 1/T(n)^\zeta$.*

We are not aware of a previous time hierarchy theorem for sampling distributions able to produce hard distributions of support size one, even under computational assumptions. (Interestingly, the unconditional results of [41] hold for support size $k \geq 2$.) Note that Theorem 4 exploits *uniformity* in a crucial way: each distribution $\mathcal{D}_n$ can be sampled by a (non-uniform) linear-size circuit C_n that ignores its random input and outputs the unique string z_n in the support of $\mathcal{D}_n$.

Computational patterns in prime numbers. We now step back and revisit one of the most basic questions associated with the power of probabilistic representations. The problem stated below is concerned with the computational (in)compressibility of n-bit prime numbers.

▶ **Problem 5** (Primes with short descriptions)**.** *Is there an infinite sequence $\{p_n\}_{n\geq 1}$ of prime numbers $p_n \in [2^{n-1}, 2^n - 1]$ such that $\mathsf{rKt}(p_n) = o(n)$?*

This would show that there are primes of *every* large length that admit effective short encodings, i.e., such primes possess computational patterns that translate into effective representations (e.g. Mersenne primes). A partial result appears in [32], where this is proved for *infinitely* many n. Consequently, some primes can have short descriptions. *Is this a rare phenomenon, or does it happen for primes of all lengths?* This is the question captured by Problem 5.

We note that obtaining a solution to Problem 5 is necessary before showing the existence of a deterministic algorithm that generates n-bit primes in time $2^{o(n)}$. We refer to [37] for more background on this problem.

Theorem 1 offers a path to solving this problem. In other words, it shows that it is enough to sample n-bit numbers in time $2^{o(n)}$ in a way that assigns enough weight to some (possibly unknown) prime. Given that many advances to our understanding of prime numbers employ *probabilistic ideas* (see e.g. [38, 29] and references therein), this perspective could be fruitful.

Our last result shows that the existence of a sampler of this form is in fact *equivalent* to a positive solution to Problem 5.

▶ **Theorem 6** (Equivalence between faster samplability and improved time-bounded descriptions)**.** *The following statements are equivalent:*

- **(i)** Sampling Algorithm. *For every $\varepsilon > 0$, there is a randomized algorithm $A(1^n)$ sampling strings in $\{0,1\}^*$ that runs in time $T(n) = O(2^{\varepsilon n})$ and for which the following holds. For every large n, there is an n-bit prime q_n such that $\Pr[A(1^n)$ outputs $q_n] \geq 2^{-\varepsilon n}$.*
- **(ii)** Short Descriptions. *Let $\delta > 0$ be an arbitrary constant. For every large n, there is an n-bit prime p_n such that $\mathsf{rKt}(p_n) \leq \delta n$.*

We stress that the equivalence in Theorem 6 is not particular to prime numbers and to exponential time bounds. It can be seen as the analogue for rKt of Levin's fundamental insight that a sequence of objects (such as n-bit primes or solutions to search problems) can be deterministically generated in time $T(n)$ if and only if they have Kt complexity of order $\log(T(n))$.

Finally, complementing the applications and open problems mentioned above, it would be interesting to understand when a mathematical method employed to show the existence of certain combinatorial objects also implies the existence of objects of bounded rKt complexity. This is particularly interesting in settings where the desired objects are "rare" and the probability of producing them is small (e.g. Lovász local lemma and techniques from discrepancy theory). Extracting rKt upper bounds from existential proofs offers an alternate way of designing non-trivial algorithms for generating the corresponding objects, since it is sufficient to exhaustively search for objects of bounded description length.[8]

1.2 Techniques

In this section, we describe the main conceptual ideas behind Theorems 1 and 2. Since our goal is to establish a coding theorem in a time-bounded setting and our applications require an algorithm that produces a valid encoding in polynomial time, it is not clear if arguments employed in the context of (unbounded) Kolmogorov complexity can be adapted to our setting. For instance, it is not hard to construct an encoding given all strings in the support of the distribution and their corresponding probabilities, but we cannot assume in the time-bounded setting that this is available. Similarly, under additional assumptions on the distribution, such as the ability to compute its cumulative probability function, producing an encoding is easier. However, we are aiming for a result that applies to the larger class of samplable distributions.

Sketch of the proof of Theorem 1. We are given a randomized algorithm $A(1^m)$ that runs in time T and samples from a distribution $\mathcal{D}_m$. Fix a string $x \in \mathsf{Support}(\mathcal{D}_m)$, and assume that its probability weight $\mathcal{D}_m(x) \geq \delta$. Our goal is to (efficiently) produce a succinct probabilistic representation of x in the sense of rKt complexity. The first thing to notice is that there are at most $1/\delta$ strings $y \in \mathsf{Support}(\mathcal{D}_m)$ such that $\mathcal{D}_m(y) \geq \delta$. Let $S_\delta \stackrel{\text{def}}{=} \{y \in \{0,1\}^* \mid \mathcal{D}_m(y) \geq \delta\}$ be the set of such strings, which includes our target string x. We assume for simplicity of the exposition that $S_\delta \subseteq \{0,1\}^n$, where $n = |x|$ is the length of x.

Let's pretend for now that we know the set S_δ. Note that this is not really a realistic assumption, since we are aiming to output a valid rKt description of x in a number of steps that might not even allow us to sample a single string from $\mathcal{D}_m$. We will revisit this assumption later on, and argue that explicit knowledge of S_δ is not needed to produce a probabilistic representation of x.

[8] In some applications, one might need to consider *conditional* rKt complexity. The techniques employed in this work also extend in this direction.

Our current goal is to be able to identify x among the elements of S_δ, ideally with an advice string of length close to $O(\log |S_\delta|) = O(\log(1/\delta))$. A natural way to try to achieve this goal is by producing a "fingerprint" or "hash value" from x that uniquely specifies this string. In other words, we would like to have a function $h\colon S_\delta \to \{0,1\}^*$ such that $h(x) \neq h(y)$ for every $y \in S_\delta \backslash \{x\}$. Then we can identify x in S_δ using h and the value $z = h(x)$. Assuming that we know S_δ, the total description length of x would be upper bounded by roughly $|h| + |z|$, where $|h|$ is the description length of h and $|z|$ is the length of z.

This is a basic algorithmic problem, and one way to achieve this goal with a reasonable upper bound on the description length is as follows. Given an explicit polynomial-time computable error-correcting code $E\colon \{0,1\}^n \to \{0,1\}^{O(n)}$, let $T_\delta \stackrel{\text{def}}{=} E(S_\delta)$, i.e., each string $y' \in T_\delta$ is obtained by applying E to a string $y \in S_\delta$. Consequently, for every distinct pair $y', y'' \in T_\delta$, their relative hamming distance $d(y', y'') = \Omega(1)$. For this reason, it follows by a simple probabilistic analysis that if we *randomly project* about $O(\log(1/\delta))$ coordinates of the strings in T_δ, we are likely to produce a "fingerprint" that uniquely specifies each string. Thus to specify x in S_δ it is enough to compute $E(x)$ and to store $O(\log(1/\delta))$ random pairs (i, b_i), where $i \sim [O(n)]$ and $b_i \stackrel{\text{def}}{=} E(x)_i$, the i-th bit of the string $E(x)$. Following our notation from above, one can think of h as being given by the sequence of coordinates, and z by the bits obtained from the projection of $E(x)$.[9]

There are two potential issues with this approach:

(a) In order to store x's fingerprint information (h and z), we still need $O(|h| + |z|) = O(\log(1/\delta) \cdot \log(n) + \log(1/\delta))$ bits, instead of just $O(\log(1/\delta))$.

(b) We have assumed explicit knowledge of S_δ to recover x from h and z.

The first issue is of a quantitative nature, and it can be handled via standard techniques. By projecting coordinates of $E(x)$ according to a random walk on an explicit constant-degree expander graph on $O(n)$ vertices, the total description length can be reduced to $O(\log(n) + \log(1/\delta))$.

Regarding the more challenging issue (b), first notice that the argument we have described so far uses randomness only to produce h. In particular, it gives a *randomized* algorithm that with high probability produces a *deterministic* representation of x from h, $z = h(x)$, and S_δ. Therefore, we have not yet exploited the power of *probabilistic representations*.

A simple but crucial idea is that we can use the *code* of the sampler A and m to efficiently *compute a valid* rKt *representation* of x, without ever running $A(1^m)$. More precisely, the rKt *instructions* to output x include running $A(1^m)$ about $O((1/\delta) \cdot \log(1/\delta))$ times to collect (with high probability) a superset $W_\delta \supseteq S_\delta$. Let's assume for simplicity that $W_\delta = S_\delta$ (it is possible to take care of extra elements by a more delicate argument). Given the set W_δ, $n = |x|$, and an independently generated h obtained before we compute the rKt representation, h and the hash value $z = h(x)$ are likely to isolate x among the elements in W_δ. A careful implementation of these ideas allows us in randomized polynomial-time to generate an rKt representation of x whose description length is $O(\log(m) + \log(1/\delta) + \log(n))$ and whose logarithm of the running time is $O(\log(T(m)) + \log(1/\delta))$. Since generating an n-bit string x takes time $T \geq n$, the overall rKt complexity (description length + log of the running time) is $O(\log(1/\delta) + \log(T(m)) + \log(m))$. ◀

[9] Notice that an *explicit* error-correcting code together with a bounded number of random coordinates of the string $E(x)$ were used to minimize the description length of x's fingerprint. We can also generate a fingerprint by collecting the value of random XORs χ_S applied to x, but storing the relevant sets S would have been expensive.

Sketch of the proof of Theorem 2. First, we discuss a reduction for rKt. Given a string x and a parameter $k \geq \mathsf{rKt}(x)$, we need to output a valid rKt representation of x of complexity $O(k)$. This is not a lot of information, but we have a general tool at our disposal: the Coding Theorem for rKt (Theorem 1). In particular, if we could sample x in time $2^{O(k)}$ and with probability $2^{-\Omega(k)}$ using an *explicit* algorithm A, we would be done by the moreover part of this result. The only challenge is to uniformly construct an explicit sampler of this form.

Fortunately, there is a *universal* sampler U that works for all strings of rKt complexity at most k. In more detail, the sampler randomly selects the code of a randomized machine M of length at most k, simulates M with its internal randomness for at most 2^k steps, and outputs whatever is left on the output tape of M after this simulation. Using that $\mathsf{rKt}(x) \leq k$, which implies that some randomized machine of length at most k outputs x within 2^k steps with probability at least $2/3$, it is easy to see that x has probability weight at least $2^{-\Omega(k)}$ under U. Given that the code of U is explicit and we know x and k, the desired representation of x can be generated with high probability in polynomial time via Theorem 1.

We now consider a search-to-decision reduction for Kt. Recall that, under a derandomization assumption, $\mathsf{Kt}(x) = \Theta(\mathsf{rKt}(x))$ [30, Theorem 5]. Moreover, it is not hard to adapt the proof to give an efficient deterministic algorithm that converts a probabilistic representation in the sense of rKt into a deterministic one in the sense of Kt. For this reason, it is possible to show, under a plausible computational assumption, that there is an instance-based search-to-decision reduction for Kt.

The most interesting aspect of Item (ii) of Theorem 2 is that it is possible to *unconditionally* establish the result. This is obtained by a more careful investigation of the elements employed in the proofs of Theorem 1 and Theorem 2 Item (i), which reveals that the derandomization assumption is not really needed. We refer the reader to the main body of the paper for the details. ◀

Organization. The proof of Theorem 1 appears in Section 3, while the remaining results are established in Section 4. Due to lack of space, the proof of the strong time hierarchy theorem for sampling distributions (Theorem 4) appears in the full version of the paper [28].

2 Preliminaries

2.1 Basic notions

We use $|x|$ to denote the length of a binary string $x \in \{0,1\}^*$. We abuse notation and use $|M|$ denote the length of the binary encoding of a machine M with respect to a fixed universal machine. Although this will not be essential, we assume a prefix-free encoding of machines, and remark that our statements are robust with respect to encoding choices.

Probabilistic machines have an extra tape with random bits. We use $\boldsymbol{M_{\leq t}}$ to denote a random variable that represents the content of the output tape of M when it computes for t steps over the empty string ε (or its final content if the machine halts before that).

▶ **Definition 7** (rKt_δ Complexity). *For $\delta \in [0,1]$ and a string $x \in \{0,1\}^*$, we let*

$$\mathsf{rKt}_\delta(x) = \min_{M,t} \left\{ |M| + \lceil \log t \rceil \;\middle|\; \Pr[\boldsymbol{M_{\leq t}} = x] \geq \delta \right\}.$$

The randomized time-bounded Kolmogorov complexity of x is given by $\mathsf{rKt}(x) \stackrel{\text{def}}{=} \mathsf{rKt}_{2/3}(x)$.

Levin's complexity $\mathsf{Kt}(x)$ can be defined similarly, either by taking $\delta = 1$ in the definition above or by restricting the minimization over M and t to deterministic machines. For more information about rKt, see [30].

We will assume from our encoding that for every string x of length n, $\mathsf{rKt}(x) \leq \gamma \cdot n$, where $\gamma \in \mathbb{N}$ is a universal constant. This is achieved by a trivial machine that simply stores x and prints it when given an empty string. Since printing a string x takes time at least $|x|$, we have $\mathsf{Kt}(x) \geq \mathsf{rKt}(x) \geq \log |x|$. We might implicitly use this fact to omit certain $\log n$ additive factors in our upper bounds.

These definitions and conventions are sufficient for the formalization of our results, given that the proof of Theorem 1 incurs a constant factor overhead in the resulting rKt upper bound. For the interested reader, we present a careful discussion of the parameters of Theorem 1 in the full version [28, Section A]. For more background in time-bounded Kolmogorov complexity, see [24].

For a discrete probability distribution $\mathcal{D}$, we use $\mathsf{Support}(\mathcal{D})$ to denote its support. For $x \in \mathsf{Support}(\mathcal{D})$, we let $\mathcal{D}(x)$ denote its probability weight under $\mathcal{D}$. We extend this definition to a set T in the natural way, i.e., $\mathcal{D}(T) = \sum_{x \in T} \mathcal{D}(x)$. If $\mathcal{D}$ and $\mathcal{D}'$ are distributions with support contained in a set S, their statistical distance $|\mathcal{D} - \mathcal{D}'|$ is defined as $\max_{T \subseteq [S]} |\mathcal{D}(T) - \mathcal{D}'(T)|$.

▶ **Definition 8** (Entropy). *The entropy $H(\mathcal{D})$ of a discrete probability distribution $\mathcal{D}$ is defined as*

$$H(\mathcal{D}) \;=\; \sum_{x \in \mathsf{Support}(\mathcal{D})} \mathcal{D}(x) \cdot \log \frac{1}{\mathcal{D}(x)},$$

where log *is the binary logarithm function.*

We will also require a standard application of expander graphs in order to minimize the amount of randomness in one of our constructions.

▶ **Definition 9** (Expander Graph). *An m-vertex undirected graph G is an (m, d, λ)-expander if G is d-regular and $\lambda(G) \leq \lambda$, where $\lambda(G)$ denotes the second largest eigenvalue (in absolute value) of the normalized adjacency matrix of G (i.e., the adjacency matrix of G divided by d).*

2.2 Technical tools

The version of the concentration bound appearing below can be found for instance in [40].

▶ **Theorem 10** (Chernoff Bound). *Let $X = \sum_{i=1}^{n} X_i$, where each X_i is an independent $0/1$-valued random variable. The following inequalities hold.*

- **(i)** *For every $\gamma > 0$, if $\mu \geq \mathbf{E}[X]$ then $\mathbf{Pr}[X \geq (1+\gamma)\mu] \leq \left(\frac{e^{\gamma}}{(1+\gamma)^{(1+\gamma)}}\right)^{\mu}$.*
- **(ii)** *For every $0 < \gamma \leq 1$, if $\mu \leq \mathbf{E}[X]$ then $\mathbf{Pr}[X \leq (1-\gamma)\mu] \leq \left(\frac{e^{-\gamma}}{(1-\gamma)^{(1-\gamma)}}\right)^{\mu}$.*

▶ **Theorem 11** (Explicit ECCs; see e.g. [36]). *There is a constant $C \in \mathbb{N}$ and a polynomial-time computable function $E_n \colon \{0,1\}^n \to \{0,1\}^{Cn}$ such that for each $n \geq 1$ and for any distinct strings $a, b \in \{0,1\}^n$, the relative hamming distance between $E_n(a)$ and $E_n(b)$ is at least $1/10$.*

We will rely on the following explicit construction of expander graphs.

▶ **Theorem 12** ((Strongly) Explicit Expander Graphs [14]). *There are constants $d \in \mathbb{N}$ and $0 < \lambda < 1$ for which the following holds. There is an (m, d, λ)-expander family $\{G_m\}$ of m-vertex graphs and a deterministic algorithm A that on inputs $m \in \mathbb{N}$, $v \in [m]$, and $i \in [d]$ outputs the i-th neighbor of v in G_m in time polynomial in $\log(m)$.*

We will also need the following well-known property of a random walk on an expander graph.

▶ **Theorem 13** (Expander Chernoff Bound [15]). *Let $G_m = (V, E)$ be an (m, d, λ)-expander, $f\colon V \to \{0,1\}$ be an arbitrary function, and $\mu \stackrel{\text{def}}{=} \mathbf{E}_{v\sim V}[f(v)]$. Let $v_1 \sim V$ be a uniformly chosen vertex and $v_1, \ldots, v_t$ be a random walk on G of length t. Then, for any $\alpha > 0$,*

$$\Pr_{v_1,\ldots,v_t}\left[\frac{1}{t}\sum_{i=1}^{t} f(v_i) < \mu - \alpha\right] \;\le\; e^{-(1-\lambda)\alpha^2 t/4}.$$

It is known that estimating the rKt complexity of an input string is intractable.

▶ **Theorem 14** (Hardness of estimating rKt [30]). *Let $\varepsilon \in (0,1)$ and $C \in \mathbb{N}$. There is no randomized algorithm A running in time $T(n) = O(n^{(\log n)^C})$ such that for every large enough n:*

- *For every $x \in \{0,1\}^n$ such that $\mathsf{rKt}(x) \le n^{\varepsilon}$, $\Pr_A[A(x) = 1] \ge 2/3$.*
- *For every $x \in \{0,1\}^n$ such that $\mathsf{rKt}(x) \ge n - 10$, $\Pr_A[A(x) = 0] \ge 2/3$.*

3 A Coding Theorem via Probabilistic Representations

3.1 An efficient String Isolation Lemma

The next lemma allows us to efficiently isolate a string x from a collection W of strings using a short advice string v whose length depends on the logarithm of the size of W. We follow a construction described in the proof of [11, Lemma 6.1].

▶ **Lemma 15** (String Isolation Lemma). *There is a deterministic algorithm M for which the following holds. For any set $W \subseteq \{0,1\}^n$ of size ℓ, there exists a string $u \in \{0,1\}^{O(\log(n\cdot\ell))}$ such that $M(1^n, u)$ runs in $\mathsf{poly}(n)$ time and outputs a Boolean circuit that computes a function $H\colon \{0,1\}^n \to \{0,1\}^{O(\log \ell)}$ with the following property:*

$$H(w) \neq H(w') \text{ for every distinct pair } w, w' \in W.$$

Moreover, the same guarantee is achieved by a random string u of the same length with probability at least 0.99.

Proof. Let $E_n\colon \{0,1\}^n \to \{0,1\}^{Cn}$ be the error-correcting code from Theorem 11. Moreover, let $t = c_1 \log \ell$, where c_1 is a large enough universal constant. Finally, let G_{Cn} be the expander graph from Theorem 12, where $m = Cn$.

Given a walk $\gamma = (v_1, \ldots, v_t)$ in G_{Cn}, we define the function $H_\gamma\colon \{0,1\}^n \to \{0,1\}^t$ as follows. On a string z, let $z' = E_n(z)$, and set $H_\gamma(z)_i = z'_{v_i}$, where $v_i \in [Cn]$ is given by γ and z'_j denotes the j-th bit of z'.

For distinct strings $z^1, z^2 \in \{0,1\}^n$, $E_n(z^1)$ and $E_n(z^2)$ have relative distance at least $1/10$. As a consequence, if $\boldsymbol{\gamma}$ is a length-t *random walk* on G_{Cn}, it follows from the Expander Chernoff Bound (Theorem 13) that

$$\Pr_{\boldsymbol{\gamma}}\left[H_{\boldsymbol{\gamma}}(z^1) = H_{\boldsymbol{\gamma}}(z^2)\right] \;\le\; \Pr_{\boldsymbol{\gamma}}\left[\frac{1}{t}\cdot\sum_{i=1}^{t} 1_{[H_{\boldsymbol{\gamma}}(z^1)_i \neq H_{\boldsymbol{\gamma}}(z^2)_i]} < \frac{1}{20}\right] \;\le\; e^{-\Omega(t)} \;<\; \frac{1}{100\ell^2},$$

where we have used that c_1 is a large enough constant in the definition of t. By a union bound over all distinct pairs of strings in W, there is some length-t random walk such that the corresponding function H satisfies the condition of the lemma.

Note that any length-t walk $\gamma = (v_1, \ldots, v_t)$ can be described by a string of length $\log(Cn) + O(t) = O(\log(n \cdot \ell))$, given that G_{Cn} is an m-vertex d-regular graph with $d = O(1)$ and $m = Cn$.

Finally, given 1^n and a description u of a length-t walk γ, it is possible to produce a circuit that computes as the function H_γ in time polynomial in n. This is because E_n, G_{Cn} and the walk encoded by u can be computed in time $\mathsf{poly}(n,t) = \mathsf{poly}(n, \log \ell) = \mathsf{poly}(n)$, where the last step uses that $\ell \leq 2^n$. This completes the proof of the lemma. ◀

The power of Lemma 15 comes from the fact that we don't need to know the set W, i.e., an upper bound on its size is sufficient. We remark that it is possible to achieve better parameters in Lemma 15 if we do not consider the efficiency of M. However, we need an efficient M for our applications in time-bounded Kolmogorov complexity. We also note that in our proofs we will only need that for a particular string $x \in W$ fixed in advance the value $H(x)$ is not contained in the image of H on $W \backslash \{x\}$.

3.2 An efficient Coding Theorem for rKt

We prove Theorem 1 in this section, restated below for convenience of the reader.

▶ **Theorem 16** (Efficient Coding Theorem for rKt)**.** *Suppose there is a randomized algorithm A for sampling strings such that $A(1^m)$ runs in time $T(m)$ and outputs a string $x \in \{0,1\}^*$ of length $n \leq T(m)$ with probability at least $\delta > 0$. Then*

$$\mathsf{rKt}(x) = O(\log(1/\delta) + \log(T(m)) + \log(m)),$$

where the constant behind the $O(\cdot)$ depends on $|A|$ and is independent of the remaining parameters. Moreover, given x, m, the code of A, and δ, it is possible to compute with probability ≥ 0.99 some rKt *encoding of x of at most this complexity in randomized time* $\mathsf{poly}(|A|, \log(m), |x|, \log(1/\delta))$.

Proof. Let x be a string generated with probability at least δ by a sampler $A(1^m)$. Since we only need a *lower bound* on the probability and our rKt upper bound is stated asymptotically, for representation purposes we assume without loss of generality that δ is of the form $2^{-\ell}$ for some $\ell \in \mathbb{N}$. We now show how to obtain an rKt description of x.

With the binary descriptions of m and $1/\delta$, we first run the sampler $A(1^m)$ for $t = 64 \cdot (1/\delta) \cdot \log(1/\delta)$ times to obtain a multi-set of strings S_0 of size t. Let V be the set

$$V \stackrel{\text{def}}{=} \{y \mid A(1^m) \text{ outputs } y \text{ with probability at least } \delta\}.$$

Note that $x \in V$ and that $|V| \leq 1/\delta$. Also, without loss of generality, we assume $\delta < 2/3$; otherwise the sampler $A(1^m)$ yields a desired rKt description of x.

▷ Claim 17. With probability at least $5/6$ *(over S_0)*, every $y \in V$ appears in S_0 at least $\alpha = 32 \cdot \log(1/\delta)$ times.

Proof of Claim 17. Fix a $y \in V$. Note that the expected number of times that y appears in S_0 is at least

$$\mu \stackrel{\text{def}}{=} t \cdot \delta \;=\; 64 \cdot \log(1/\delta).$$

By the Chernoff bound (Item (*ii*) of Theorem 10), we have

$$\Pr_{S_0}[y \text{ appears in } S_0 \text{ less than } \alpha \text{ times}] \;\leq\; \left(\frac{e^{-1/2}}{(1/2)^{(1/2)}}\right)^{64 \cdot \log(1/\delta)} \;<\; \delta^6.$$

By a union bound over the strings in V, where $|V| \leq 1/\delta$, we have that the probability that there exists a $y \in V$ such that y appears in S_0 less than α times is less than $\delta^5 < 1/6$. ◁

▷ Claim 18. With probability at most 1/6 *(*over S_0*)*, there exists a string z in S_0 such that z appears at least $\alpha = 32 \cdot \log(1/\delta)$ times in S_0 and that $A(1^m)$ outputs z with probability less than $\delta/32$.

Proof of Claim 18. Let's view S_0 as an ordered multi-set $(z_1, z_2, \ldots, z_t)$. For $z_i \in S_0$, we say "z_i is bad" if that $A(1^m)$ outputs z_i with probability less than $\delta/32$ and that it appears in S_0 at least α times. Let $\mathcal{E}$ be the event that there exists some $z_i \in S_0$ such that z_i is bad. Then we have

$$\mathbf{Pr}[\mathcal{E}] \;\leq\; \sum_{i=1}^{t} \mathbf{Pr}[z_i \text{ is bad}]. \tag{1}$$

Fix an $i \in [t]$, we have

$$\begin{aligned}
\mathop{\mathbf{Pr}}_{z_1,z_2,\ldots,z_t \sim A}[z_i \text{ is bad}] \;&=\; \sum_{\substack{z \,:\, A \text{ outputs } z \\ \text{w.p. less than } \delta/32}} \mathbf{Pr}[z_i = z \text{ AND } z_i \text{ appears in } S_0 \text{ at least } \alpha \text{ times}] \\
&\leq \sum_{z \text{ as above}} \mathbf{Pr}[z_i \text{ appears in } S_0 \text{ at least } \alpha \text{ times} \mid z_i = z] \cdot \mathbf{Pr}[z_i = z] \\
&\leq \max_{z \text{ as above}} \mathbf{Pr}[z_i \text{ appears in } S_0 \text{ at least } \alpha \text{ times} \mid z_i = z] \\
&\leq \max_{z \text{ as above}} \mathbf{Pr}[z \text{ appears } S_0 \backslash \{z_i\} \text{ at least } \alpha - 1 \text{ times}]. \qquad (2)
\end{aligned}$$

Note that if for a string z, A outputs z with probability less than $\delta/32$, then the expected number of times that z appears in the multi-set $S_0 \backslash \{z_i\}$ is less than

$$\mu \stackrel{\text{def}}{=} (t-1) \cdot \delta/32 \;=\; 2 \cdot \log(1/\delta) - \delta/32,$$

and hence $\alpha - 1 > 11 \cdot \mu$. Then by the Chernoff bound (Item (i) of Theorem 10), we have

$$\textit{Equation (2)} \;\leq\; \left(\frac{e^9}{10^{10}}\right)^{\log(1/\delta)} \;<\; \delta^{18}.$$

Therefore, we have

$$\textit{Equation (1)} \;\leq\; t \cdot \delta^{18} \;<\; 64 \cdot (1/\delta)^2 \cdot \delta^{18} \;<\; 1/6,$$

as desired. ◁

Next, from S_0, we build a set S by removing every string in S_0 that appears less than $\alpha = 32 \cdot \log(1/\delta)$ times in S_0, and keeping only one copy for each of the remaining strings. Let W be the set

$$W \stackrel{\text{def}}{=} \{w \mid A(1^m) \text{ outputs } w \text{ with probability at least } \delta/32\}.$$

Note that $|W| \leq 32/\delta$. From Claim 17 and Claim 18, we get that with probability at least 2/3 over the choices of S_0, we obtain a "good" set S in the sense that $V \subseteq S$ (hence $x \in S$) and $S \subseteq W$.

Consider the algorithm in the String Isolation Lemma (Lemma 15), and let $n = |x| \leq T(m)$. Let u be a string of length $O(\log(n \cdot |W|)) = O(\log(T(m)) + \log(1/\delta))$ such that the algorithm in Lemma 15 running on u produces a good hash function $H\colon \{0,1\}^n \to \{0,1\}^\tau$ for all length-n strings in W, where $\tau = O(\log(|W|)) = O(\log(1/\delta))$. That is, for every distinct

$w, w' \in W \cap \{0,1\}^n$, we have $H(w) \neq H(w')$. Then for every "good" set S, H maps the strings in S of length n into different buckets. Therefore, given u, n, and the hash value for x, $H(x)$, we can recover x from a good set S.

The whole algorithm runs in randomized time $\mathrm{poly}(m, T(m), 1/\delta)$ and requires an advice of length $O(\log(1/\delta) + \log(m) + \log(n))$, which gives the desired upper bound for $\mathsf{rKt}(x)$.

For the moreover part of the theorem, first observe that to output a description of x it is not necessary to run the sampling algorithm $A(1^m)$ nor to know an upper bound on its running time. We need instead the following information: the code of A, the input parameter m, the probability lower bound δ, the length $n = |x|$, the advice string u given by Lemma 15, and the hash value $H(x)$. Crucially, the proof of Lemma 15 shows that a *random* string u (encoding a random walk) satisfies the conditions of the lemma with probability ≥ 0.99. Furthermore, the same proof shows that, given u and x, we can compute $H(x)$ in time $\mathsf{poly}(n) = \mathsf{poly}(|x|)$. Therefore, by sampling a random string u of an appropriate length that depends on n and δ, it is possible to compute a correct description of x with probability at least 0.99. The necessary information can be computed from x, the code of A, n, and δ in time $\mathsf{poly}(|A|, \log(m), |x|, \log(1/\delta))$. ◀

4 Applications

4.1 Equivalence between samplability and succinct probabilistic descriptions

It will be useful in the proof of some results to introduce the following sampler.

Definition of $U(1^m)$.

1. Given 1^m, U samples an integer $\ell \sim [m]$ uniformly at random. It then samples a uniformly random string z of length ℓ, and an independent uniformly random string r of length 2^m.
2. U interprets z as the code of a randomized machine M_z, simulates M_z on the empty input string with randomness r for 2^m steps, and outputs the string y that is left on the output tape of M_z after this simulation.

This sampler satisfies the following properties.

▷ Claim 19. On every input 1^m and for every choice of its randomness, $U(1^m)$ runs in time at most $2^{O(m)}$.

Proof. This is immediate from the definition. ◁

▷ Claim 20. Suppose $x \in \{0,1\}^*$ is a string such that $\mathsf{rKt}(x) \leq k$. Then the probability of x under $U(1^k)$ is at least $(1/k) \cdot 2^{-k} \cdot (2/3)$.

Proof. Since $\mathsf{rKt}(x) \leq k$, there is a randomized machine M running in time at most t such that

$$\Pr[\boldsymbol{M}_{\leq \boldsymbol{t}} = x] \geq 2/3 \quad \text{and} \quad |M| + \log t \leq k.$$

Let $\ell = |M| \leq k$, and note that $t \leq 2^k$. It is clear that x is output by $U(1^k)$ with probability at least $(1/\ell) \cdot 2^{-\ell} \cdot (2/3) \geq (1/k) \cdot 2^{-k} \cdot (2/3)$. ◁

We state next an immediate consequence of the coding theorem for rKt and the existence of universal time-bounded samplers. For concreteness, we focus on the generation of prime numbers in the context of Problem 5.

▶ **Theorem 21** (Equivalence between fast samplability and short time-bounded descriptions)**.** *The following statements are equivalent:*

- **(i)** Sampling Algorithm. *For every $\varepsilon > 0$, there is a randomized algorithm $A(1^n)$ sampling strings in $\{0,1\}^*$ that runs in time $T(n) = O(2^{\varepsilon n})$ and for which the following holds. For every large n, there is an n-bit prime q_n such that $\Pr[A(1^n) \text{ outputs } q_n] \geq 2^{-\varepsilon n}$.*
- **(ii)** Short Descriptions. *Let $\delta > 0$ be an arbitrary constant. For every large n, there is an n-bit prime p_n such that $\mathsf{rKt}(p_n) \leq \delta n$.*

Proof. That samplability as in the first item leads to short descriptions follows immediately from Theorem 16 by taking $\varepsilon > 0$ small enough as a function of the given $\delta > 0$. For the other direction, for a given $\varepsilon > 0$, we consider the sampler $A(1^n) \stackrel{\text{def}}{=} U(1^m)$ with $m = \varepsilon' n$, where $\varepsilon' = \varepsilon/C$ for a large constant C. By Claim 19, $A(1^n)$ runs in time $O(2^{\varepsilon n})$. Under the assumption that (ii) holds, Claim 20 guarantees that for large n there is an n-bit prime q_n that is output by $A(1^n)$ with probability at least $2^{-\varepsilon n}$. ◀

This should be contrasted with the equivalence between the existence of primes of bounded Kt complexity and fast deterministic generation of primes. As mentioned in Section 1.1.2, the equivalence in Theorem 21 also holds in a broader sense.

4.2 Instance-based search-to-decision reduction for rKt and its consequences

In this section, we show that there is a *uniform* polynomial-time "approximate" search-to-decision reduction for rKt. More precisely, we show that given a *linear* approximation of the rKt complexity of the input string, it is possible to output a valid rKt representation that is optimal up to a *constant factor*.

We will need the following definition.

▶ **Definition 22.** *Let $\gamma\colon \mathbb{N} \to \mathbb{R}$. We say that a function $\mathcal{O}\colon \{0,1\}^* \to \mathbb{N}$ γ-approximates rKt complexity if for every string $x \in \{0,1\}^*$,*

$$\frac{\mathsf{rKt}(x)}{\gamma(|x|)} \;\leq\; \mathcal{O}(x) \;\leq\; \gamma(|x|) \cdot \mathsf{rKt}(x).$$

If this holds for a constant $\gamma \in \mathbb{N}$, we say that $\mathcal{O}$ linearly approximates rKt.

▶ **Theorem 23** (An instance-based search-to-decision reduction for rKt)**.** *Let $\mathcal{O}$ be a function that linearly approximates rKt complexity. There is a randomized polynomial-time algorithm with access to $\mathcal{O}$ that, when given an input string x, outputs with probability ≥ 0.99 a valid rKt representation of x of complexity $O(\mathsf{rKt}(x))$. Furthermore, this algorithm makes a single query q to $\mathcal{O}$, where $q = x$.*

Proof. Given an input $x \in \{0,1\}^*$, let $\widetilde{k} \stackrel{\text{def}}{=} \mathcal{O}(x)$ be the estimate provided by the oracle, and recall that $\mathsf{rKt}(x)/C \leq \widetilde{k} \leq C \cdot \mathsf{rKt}(x)$ for a universal constant C. By Claim 20, we get that the universal sampler $U(1^{C\cdot\widetilde{k}})$ outputs x with probability at least $\delta \stackrel{\text{def}}{=} (1/(C\cdot\widetilde{k}))\cdot 2^{-C\cdot\widetilde{k}}\cdot(2/3)$. In addition, by Claim 19, the running time of this sampler is bounded by $2^{O(C\cdot\widetilde{k})}$. It then follows from the "moreover" part of Theorem 16 that it is possible to efficiently compute with probability at least 0.99 a valid rKt representation of x of complexity $O(C \cdot \widetilde{k}) = O(C^2 \cdot \mathsf{rKt}(x)) = O(\mathsf{rKt}(x))$. ◀

As explained in Section 1, an interesting aspect of this reduction is that it works on an *input by input* basis. In other words, if we are able to linearly approximate the rKt complexity of the input string, then we can compute a near-optimal representation for the same string.

We note that a reduction that works on an input by input basis is easy to come up with in the setting of (time-unbounded) Kolmogorov complexity: from an upper bound on $K(x)$, it is possible to compute a string that represents x of complexity at most $K(x)$ simply by running in parallel all machines of at most this description length. Theorem 23 can be interpreted as an analogue result in the more challenging setting of time-bounded Kolmogorov complexity.

Using ideas from the proof of the coding theorem for rKt, we can also show an *unconditional* instance-based search-to-decision reduction for Kt.

▶ **Theorem 24** (An instance-based search-to-decision reduction for Kt)**.** *Let $\mathcal{O}$ be a function that linearly approximates Kt complexity. There is a randomized polynomial-time algorithm with access to $\mathcal{O}$ that, when given an input string x, outputs with probability ≥ 0.99 a valid Kt representation of x of complexity $O(\mathsf{Kt}(x))$. Furthermore, this algorithm makes a single query q to $\mathcal{O}$, where $q = x$.*

Proof. We are given an input $x \in \{0,1\}^*$ where $|x| = n$, and $\mathsf{Kt}(x)/C \leq \widetilde{k} \leq C \cdot \mathsf{Kt}(x)$ for a universal constant C, where $\widetilde{k}$ is obtained via a single query to $\mathcal{O}$ on x. Our encoding algorithm is as follows:

1. Pick $u \in \{0,1\}^d$ uniformly at random, where $d = O\Big(\log\Big(n \cdot 2 \cdot 2^{C \cdot \widetilde{k}}\Big)\Big) = O(\widetilde{k} + \log(n))$.
2. Invoke the deterministic algorithm $M(1^n, u)$ from Lemma 15 to obtain a hash function $H\colon \{0,1\}^n \to \{0,1\}^{O(\widetilde{k})}$, and compute $z = H(x)$.
3. Output $(n, \widetilde{k}, u, z)$.

It is easy to verify that the output of the above procedure has length

$$O(\log(\widetilde{k}) + \log(n)) = O(\mathsf{Kt}(x) + \log(n)) = O(\mathsf{Kt}(x)).$$

Next, we claim that with probability at least 0.99 over the choice of u, the tuple generated in Step 3 can be easily converted into a valid Kt representation of x. (Note that the randomness is only over the encoding algorithm that generates the Kt representation, which provides a deterministic description.) To decode x from this information, we first run $M(1^n, u)$ from Lemma 15 to recover the hash function H. We then enumerate each deterministic machine of description length at most $C \cdot \widetilde{k}$ and simulate it for at most $2^{C \cdot \widetilde{k}}$ steps. For each output y of these machines that is in $\{0,1\}^n$, we compute $H(y)$ and output the first y such that $H(y) = z$. Note that there are at most $\ell = 2 \cdot 2^{C \cdot \widetilde{k}}$ distinct machines of length at most $C \cdot \widetilde{k}$, and each machine produces at most one output string. By the fact that $\mathsf{Kt}(x) \leq C \cdot \widetilde{k}$, at least one of them will output x. Also, by Lemma 15, for at least a fraction of .99 of the u's, the hash function H obtained from u isolates every n-bit string in the set of outputs of these ℓ machines, and x is the only string such that $H(x) = z$. Therefore, for any such "good" u, the string x can be decoded correctly from n, $\widetilde{k}$, u, and z. It is easy to see that the running time of the decoding algorithm is $\mathrm{poly}(n) \cdot 2^{O(\widetilde{k})}$, so the Kt complexity of the resulting representation for x is $O(\mathsf{Kt}(x))$. ◀

Note that Theorem 23 (search-to-decision reduction for rKt) and Theorem 24 (search-to-decision reduction for Kt) complete the proof of Theorem 2 from Section 1.

The next result should be contrasted with the unconditional lower bound of [30] for estimating the rKt complexity of an input string x.

▶ **Theorem 25** (Efficient generation of rKt descriptions). *There is a randomized polynomial-time algorithm E such that on any input string $x \in \{0,1\}^n$, given as advice a string $\alpha = \alpha(x)$ of length $\leq \log\log n + O(1)$, $E(x,\alpha)$ outputs with probability ≥ 0.99 an* rKt *description of x of complexity $O(\mathsf{rKt}(x))$.*

Proof. Algorithm E computes on $x \in \{0,1\}^n$ as follows. It expects $\alpha \in \{0,1\}^{\log\log n + O(1)}$ to encode a tight approximation $\tilde{k}$ to the value $k \stackrel{\text{def}}{=} \mathsf{rKt}(x) \in [\gamma \cdot n]$, where $\gamma \in \mathbb{N}$ is a universal constant, and $\gamma \cdot n$ is an upper bound on $\max\{\mathsf{rKt}(x) \mid x \in \{0,1\}^n\}$. Since we are only aiming for a constant factor approximation of $\mathsf{rKt}(x)$, we use α to encode the smallest integer β such that $2^\beta \geq \mathsf{rKt}(x)$. Since $\beta \leq \log n + O_\gamma(1)$, α can be encoded with just $\log\log n + O(1)$ bits, and a value $\tilde{k}$ such that $k \leq \tilde{k} \leq 2k$ can be obtained from α. $E(x,\alpha)$ considers the universal sampler $U(1^{\tilde{k}})$ as the algorithm $A(1^{\tilde{k}})$ in Theorem 16. Furthermore, it sets $\delta \stackrel{\text{def}}{=} (1/\tilde{k}) \cdot 2^{-\tilde{k}} \cdot (2/3)$. By Claims 19 and 20, $A(1^{\tilde{k}}) \equiv U(1^{\tilde{k}})$ outputs x with probability at least δ and in time at most $T = 2^{O(\tilde{k})}$. As a consequence, from the "moreover" part of Theorem 16 it follows that $E(x,\alpha)$ can compute with probability at least 0.99 a valid rKt representation of x of complexity $O(\log(\tilde{k}) + \log(T) + \log(1/\delta)) = O(\tilde{k}) = O(\mathsf{rKt}(x))$ in time $\mathsf{poly}(|U|, \log(\tilde{k}), n, \log(1/\delta)) = \mathsf{poly}(n)$. ◀

The next corollary is immediate from Theorem 23.

▶ **Corollary 26** (Time-bounded short lists with short programs in short time). *Given an arbitrary string x of length n, it is possible to compute with high probability and in polynomial time a collection of at most $d = \log(n) + O(1)$ strings $w_1, \ldots, w_d$ such that at least one of these strings is a valid* rKt *encoding of x of complexity $O(\mathsf{rKt}(x))$.*

Proof. We can enumerate all values of $k \in [O(n)]$ that are a power of 2, and run the instance-based search-to-decision reduction from Theorem 23 on x using k as the query answer. One of such k will be a linear approximation of $\mathsf{rKt}(x)$, and the output of the search-to-decision reduction for this k will be a rKt description of x with complexity $O(\mathsf{rKt}(x))$. ◀

Abstract

In the General Factor problem, we are given an undirected graph G and for each vertex $v \in V(G)$ a finite set B_v of non-negative integers. The task is to decide if there is a subset $S \subseteq E(G)$ such that $\deg_S(v) \in B_v$ for all vertices v of G. Define the max-gap of a finite integer set B to be the largest $d \geq 0$ such that there is an $a \geq 0$ with $[a, a+d+1] \cap B = \{a, a+d+1\}$. Cornuéjols showed in 1988 that if the max-gap of all sets B_v is at most 1, then the decision version of General Factor is polynomial-time solvable. This result was extended 2018 by Dudycz and Paluch for the optimization (i.e. minimization and maximization) versions. We present a general algorithm counting the number of solutions of a certain size in time $(M+1)^{\mathrm{tw}} n^{\mathcal{O}(1)}$, given a tree decomposition of width tw, where M is the maximum integer over all B_v. By using convolution techniques from van Rooij (2020), we improve upon the previous $(M+1)^{3\mathrm{tw}} n^{\mathcal{O}(1)}$ time algorithm by Arulselvan et al. from 2018.

We prove that this algorithm is essentially optimal for all cases that are not trivial or polynomial time solvable for the decision, minimization or maximization versions. Our lower bounds show that such an improvement is not even possible for B-Factor, which is General Factor on graphs where all sets B_v agree with the fixed set B. We show that for every fixed B where the problem is NP-hard, our $(\max B + 1)^{\mathrm{tw}} n^{\mathcal{O}(1)}$ algorithm cannot be significantly improved: assuming the Strong Exponential Time Hypothesis (SETH), no algorithm can solve B-Factor in time $(\max B + 1 - \epsilon)^{\mathrm{tw}} n^{\mathcal{O}(1)}$ for any $\epsilon > 0$. We extend this bound to the counting version of B-Factor for arbitrary, non-trivial sets B, assuming #SETH.

We also investigate the parameterization of the problem by cutwidth. Unlike for treewidth, having a larger set B does not appear to make the problem harder: we give a $2^{\mathrm{cutw}} n^{\mathcal{O}(1)}$ algorithm for any B and provide a matching lower bound that this is optimal for the NP-hard cases.

1 Introduction

Matching problems for graphs are widely studied in computer science [1, 7, 11, 18, 19, 24, 27, 31, 32, 34]. The most prominent ones are Perfect Matching (PerfMatch) and Maximum-Weight Matching. Both problems have long known polynomial-time algorithms [19, 32] and various generalizations were investigated in the graph-theory literature. These range from simple extensions such as the k-factor problem for a positive integer k (every vertex has to be incident to exactly k edges) [2, 27], to more complex ones, where the vertices are assigned intervals [34]. These problems are generally solved by a reduction to PerfMatch by replacing the vertices of the original instance with suitable gadgets. Lovász introduced a general version of these problems which we call General Factor [31]:

▶ **Definition 1.1** (General Factor (GenFac)). *Let $G = (V, E)$ be an undirected node labeled graph where the label of a vertex v is a set $B_v \subseteq \mathbb{N}$. We say $S \subseteq E$ is a* solution *if $\deg_S(v) \in B_v$ for all $v \in V$. GenFac is the problem of deciding whether G has a solution.*

The minimization and maximization versions of GenFac are the problems of finding the size of the solution with smallest and largest cardinality, respectively.

Polynomial-Time Solvable Cases. For several cases (e.g. k-factor, sets are intervals) reductions to PerfMatch are known, leading directly to polynomial-time algorithms. Cornuéjols analyzed the complexity of the general problem to identify properties of the sets that make the problem easier to solve [7]. For this he introduced the *gap* of a set: A gap is a finite sequence of consecutive integers not contained in the set but whose boundaries are contained in the set (cf. Definition 2.2). For example, the set $\{1, 5, 6, 8\}$ has gaps of size 3 and 1. For a set S, max-gap S denotes the size of its largest gap. Cornuéjols showed that if the max-gaps of all sets are at most 1, then the problem is polynomial-time solvable. Later this result was extended to the maximization and minimization (optimization) versions of GenFac.

▶ **Theorem 1.2** ([7, 18]). *The decision, maximization, and minimization version of GenFac can be solved in polynomial time on arbitrary graphs if for all nodes v,* max-gap $B_v \leq 1$.

On the other side Cornuéjols proved GenFac to be NP-complete if there are nodes with a gap of size two, namely $\{1\}$ and $\{0, 3\}$, by a reduction from *exact* 3*-cover*. More generally, it can be deduced from the work of Feder [22] that GenFac becomes NP-complete whenever every set B_v is restricted to be the same fixed set B having gap size at least two.

Treewidth. This paper is part of a long sequence of works studying problems parameterized by treewidth and related metrics like cutwidth or cliquewidth. Treewidth received significant attention as many NP-hard problems like Colouring, Independent Set, or Dominating Set (see [4] for a survey) are polynomial-time solvable on bounded-treewidth graphs. Courcelle's Theorem [8, 9] shows that a large class of graph problems can be solved in linear time on graphs of bounded treewidth. Recent developments on the algorithmic side include various techniques such as Cut & Count [15, 33], rank-based dynamic programming [3, 14, 23] and fast subset convolution [37, 38]. On the negative side, there have been a large number of results showing lower bounds based on complexity assumptions such as the Exponential Time Hypothesis (ETH) and the Strong Exponential Time Hypothesis (SETH) [5, 12, 29, 30]. For many such problems, their optimal algorithms utilize some form of dynamic programming, where a "state" is stored for every node in the tree decomposition. The number of such states determines the running time of the algorithms, seemingly suggesting

that this number is a natural barrier to the running time of any algorithm. Typically, the conditional lower bounds confirm this intuition by showing that no algorithm can break this barrier.

New Faster Algorithms. One of the first algorithmic results for GenFac parameterized by treewidth was given by Arulselvan et al. [1]. They present an algorithm for a restricted version of the problem where the sets contain zero and an interval of integers. This algorithm can be easily extended to handle arbitrary instances while preserving the running time of $(M+1)^{3\mathrm{tw}}n^{\mathcal{O}(1)}$ where M is the maximum over all sets assigned to the vertices. Their algorithm is based on the standard dynamic programming approach when parameterizing by treewidth, i.e. it considers all possible states for each node of the tree decomposition. The number of states in the dynamic programming is about $(M+1)^{\mathrm{tw}+1}$: one needs to keep track of the degree of the partial solution at each of the at most $\mathrm{tw}+1$ vertices of a bag of the tree decomposition, and this degree can be between 0 and M. Therefore, a natural question is whether the algorithm can be improved to obtain an $(M+1)^{\mathrm{tw}}n^{\mathcal{O}(1)}$ running time, matching the number of states. Such improvements are known for other problems, for example for Dominating Set and #PerfMatch in [38]. We base our algorithm on the same dynamic programming idea, but instead of processing all combination of states at join nodes, we make use of the technique of van Rooij [37] to compute fast convolutions, avoiding this bottle-neck of the computation. The algorithm can be easily generalized to the optimization and counting versions as well; to unify the results, we present the algorithm in a way that counts all solutions of a certain given size.

▶ **Theorem 1.3.** *Given a GenFac instance G and a tree decomposition of width* tw*. Let $M = \max_{v\in V(G)} \max B_v$. Then for all s, we can count the solutions of size exactly s in time $(M+1)^{\mathrm{tw}}n^{\mathcal{O}(1)}$.*

As we shall see, this algorithm is essentially optimal for every fixed B where B-Factor is NP-hard. Note that in order to obtain this optimal running time, we have to use a well-known, but non-trivial technique; beyond that, our algorithm does not provide new insights into the problem. Due to space constraints, we omit the algorithm here and refer the reader instead to the full version.

Tight Lower Bounds for the Decision Version. To investigate how the properties of the sets B_v influence the complexity of the problem, we give conditional lower bounds based on SETH for the restrictive B-Factor problem, where all sets have to be the same fixed set B. By a careful design our lower bounds also hold for a parameterization by *pathwidth*. Note that if the set is not fixed, Arulselvan et al. showed that GenFac is W[1]-hard when parameterizing only by treewidth [1]. Thus, it is reasonable to focus only on the cases with fixed sets to prove tight lower bounds.

▶ **Theorem 1.4** (Lower Bound for Decision Version)**.** *Let $B \subseteq \mathbb{N}$ be a fixed, finite set with $0 \notin B$ and* max-gap $B > 1$*. If, given a path decomposition of width* pw*, B-Factor can be solved in time $(\max B + 1 - \epsilon)^{\mathrm{pw}}n^{\mathcal{O}(1)}$ for some $\epsilon > 0$ even on graphs with degree at most $2\max B$, then SETH is false.*

The same result immediately follows for treewidth as for all graphs the pathwidth forms an upper-bound for the treewidth [13]. Hence, our algorithm is optimal not only for GenFac but also for B-Factor parameterized by treewidth and does not allow major improvements.

Tight Lower Bounds for the Optimization Version. It suffices to consider the maximization version with max-gap $B > 1$ and $0 \in B$ for the optimization version. The other cases are either polynomial-time solvable (max-gap $B \leq 1$ or $0 \in B$ for Min-B-Factor) [18] or the hardness directly follows from the lower bound for the decision version. Observe that the assumption $0 \in B$ does not make the problem trivially solvable. For these cases, we give essentially the same lower bound as for the decision version. Again the bound rules out that we can improve the given algorithm substantially; the running time is essentially optimal.

▶ **Theorem 1.5** (Lower Bound for Maximization Version). *Let $B \subseteq \mathbb{N}$ be a fixed, finite set with* max-gap $B > 1$. *If, given a path decomposition of width* pw, Max-B-Factor *can be solved in time* $(\max B + 1 - \epsilon)^{\mathrm{pw}} n^{\mathcal{O}(1)}$ *for some $\epsilon > 0$ even on graphs with degree at most* $2 \max B$, *then SETH is false.*

Counting. It is well known that PerfMatch can be solved in polynomial time [19]. Surprisingly, Valiant showed in [35] that *counting* the number of perfect matchings of a graph is as hard as counting satisfying assignment of a boolean formula. This is curious as (presumably) no polynomial-time algorithm for the decision version of the latter problem exists. The observation then led to the definition of the complexity class #P containing the counting problems whose corresponding decision version lies in NP. Indeed, this feature that some structures are easy to find but hard to count appears in our work as well. Apart from #PerfMatch, which itself is #$\{1\}$-Factor, our results imply that #B-Factor is #P-hard for any finite, fixed B. This contrasts with the decision version, where the problem is easy when max-gap $B \leq 1$. Over and above showing #P-hardness, we show a tight lower bound for #B-Factor, assuming #SETH, the counting version of SETH. There have been several results [10, 11, 17] based on #SETH and #ETH. Some of our constructions were inspired by one such work by Curticapean and Marx [11], where they show a lower bound of $(2 - \epsilon)^{\mathrm{pw}} n^{\mathcal{O}(1)}$ for #PerfMatch on graphs assuming #SETH. We prove a wide generalization of this result by providing a tight lower bound for every #B-Factor problem. As for the optimization and decision version, our algorithm shows the tightness of this lower bound.

▶ **Theorem 1.6** (Lower Bound for Counting Version). *Let $B \subseteq \mathbb{N}$ be a nonempty, fixed, and finite set such that $B \neq \{0\}$. If, given a path decomposition of width* pw, #B-Factor *can be solved in time* $(\max B + 1 - \epsilon)^{\mathrm{pw}} n^{\mathcal{O}(1)}$ *for some $\epsilon > 0$ even on graphs with degree at most* $2 \max B + 6$, *then #SETH is false.*

We also investigate #Max-B-Factor, the problem of counting maximum-sized solutions. The following argument shows that #$\{\max B\}$-Factor can be reduced to #Max-B-Factor without increasing pathwidth, hence Theorem 1.6 gives a lower bound of $(\max B + 1 - \epsilon)^{\mathrm{pw}} n^{\mathcal{O}(1)}$. Consider an instance of #$\{\max B\}$-Factor on a graph G of pathwidth pw. In polynomial time, check if G has some $\{\max B\}$-Factor [7]. If it does not, then output 0. If it does, then solve #Max-B-Factor on G. As now every maximum-sized B-factor is actually a $\{\max B\}$-factor, this indeed solves the #$\{\max B\}$-Factor problem.

▶ **Corollary 1.7.** *Let $B \subseteq \mathbb{N}$ be a fixed, finite set such that $B \neq \{0\}$. If, given a path decomposition of width* pw, #Max-B-Factor *can be solved in time* $(\max B + 1 - \epsilon)^{\mathrm{pw}} n^{\mathcal{O}(1)}$ *for some $\epsilon > 0$ even on graphs with degree at most* $2 \max B + 6$, *then SETH is false.*

We leave open the question of a tight lower bound for the minimization version.

Parameterizing by Cutwidth. As previously mentioned, pathwidth and treewidth are not the only parameters used in parameterized complexity. Cutwidth, cliquewidth, genus, and crossing number are only a few more examples of a vast class of possible parameters. For cutwidth, we consider linear layouts of graphs with n vertices, which are just enumerations $v_1, \ldots, v_n$ of all graph vertices. Then the cut after vertex v_i consists of all edges in G with one end in $\{v_1, \ldots, v_i\}$ and the other end in $\{v_{i+1}, \ldots, v_n\}$. The *cutwidth* of a linear layout is the maximum over the size of the cut after every v_i. The cutwidth cutw of a graph is the minimum over the cutwidths of all possible linear layouts. As $\mathrm{tw} \leq \mathrm{pw} \leq \mathrm{cutw}$, it is not completely surprising that we get different upper bounds for cutwidth. But now a simple dynamic program suffices to prove the upper bound for this case. Further, the running time of the algorithm is independent from the maximum of the set B.

▶ **Theorem 1.8.** *Given a linear layout of a* GenFac *instance G with width* cutw*, for all s we can count the number of solutions of size exactly s in time $2^{\mathrm{cutw}} n^{\mathcal{O}(1)}$,.*

This again matches the number of states for each cut of the linear layout. Like before, we omit the algorithm here and refer the reader to the full version. Note that the running times appearing in Theorems 1.3 and 1.8 cannot be directly compared: the base is lower when parameterized by cutwidth, but cutwidth can be larger than treewidth.

By a modified high-level construction, we show matching lower bounds based on SETH for the decision and optimization versions, and, based on #SETH, for the counting version.

▶ **Theorem 1.9** (Lower Bounds for Cutwidth)**.** *Let $B \subseteq \mathbb{N}$ be a fixed, nonempty set of finite size. If, given a linear layout of width* cutw*, the following problems can be solved in time $(2-\epsilon)^{\mathrm{cutw}} n^{\mathcal{O}(1)}$ for any $\epsilon > 0$ even on graphs with degree at most $2 \max B + 6$, then SETH (resp. #SETH) fails: (1) B-Factor and Min-B-Factor if $0 \notin B$ and $\text{max-gap}\, B > 1$, (2) Max-B-Factor if $\text{max-gap}\, B > 1$, and (3) #B-Factor if $B \neq \{0\}$.*

2 Preliminaries

We introduce homogeneous graphs to formally define B-Factor.

▶ **Definition 2.1** (Homogeneous Graphs and B-Factor)**.** *Let $B \subseteq \mathbb{N}$ be some fixed, finite set. We say a node-labeled graph is* B-homogeneous *if for each node $v \in V$ it holds that $B_v = B$. Then B-Factor is the restriction of* GenFac *to B-homogeneous graphs.*

This definition directly transfers to the optimization and counting version. We now formally introduce the max-gap of integer sets along with some other properties.

▶ **Definition 2.2.** *Let $B \subseteq \mathbb{N}$ be finite. We define* $\text{max-gap}\, B$ *as the largest non-negative integer d such that there is an $a \in B$ with $[a, a+d+1] \cap B = \{a, a+d+1\}$.*

In this paper we regularly insert graphs into other graphs. To make this operation formal, we make use of *dangling edges*: these are edges that have only one endpoint. We denote a dangling edge with endpoint v by $(?, v)$. For the sake of completeness we now formally define this procedure of replacing the relations, i.e. the insertion of a graph into another graph.

▶ **Definition 2.3** (Insertion)**.** *Let $G = (V, E)$ be a graph and $v \in V$ be of degree k, with incident edges $e_1 = (v_1, v), \ldots, e_k = (v_k, v)$ that are ordered in some fixed way. Let $H = (W, F)$ be a graph with dangling edges $d_1 = (?, u_1), \ldots, d_k = (?, u_k)$ where the u_i are not necessarily pairwise distinct.* Inserting *H in G at v gives us a new graph $G' = (V', E')$ where:*

$$V' = (V \cup W) \setminus \{v\} \quad \text{and} \quad E' = (E \cup F) \setminus \{e_1, \ldots, e_k, d_1, \ldots, d_k\} \cup \{(v_1, u_1), \ldots, (v_k, u_k)\}$$

All lower bounds we prove in this paper are based on the Strong Exponential Time Hypothesis. But instead of using the original statement we use a formulation which is more useful to work with.

▶ **Conjecture 2.4** (Strong Exponential Time Hypothesis (SETH) [6, 25]). *For all $\delta > 0$, there is a $k \geq 3$ such that satisfiability of k-CNF formulas on n variables requires more than $(2-\delta)^n$ time.*

About Relations. A relation $R : \{0,1\}^k \to \{0,1\}$ can also be seen as a set $R' \subseteq \{0,1\}^k$ such that $x \in R'$ iff $R(x) = 1$. We can also identify R with a set $R'' \subseteq 2^{[k]}$, where each element of R'' contains the positions of the 1s of an accepted input. Precisely, $x' = \{i \mid x[i] = 1\} \in R''$ iff $R(x) = 1$. We switch between these definitions depending on the context. Recall, a relation is *symmetric* if its output only depends on the Hamming weight of its input.

To simplify notation, we introduce the following generic classes of symmetric relations.

▶ **Definition 2.5.** *For a vector $x \in \{0,1\}^k$, we define $\mathrm{hw}(x)$ as the number of 1s in x, i.e. the Hamming weight of x. We define the following for $S \subseteq \mathbb{N}$, and $i, j \in \mathbb{N}$:*

$$\mathtt{HW}^{(j)}_{\in S} \coloneqq \{x \in \{0,1\}^j \mid \mathrm{hw}(x) \in S\} \qquad \mathtt{EQ}_j \coloneqq \mathtt{HW}^{(j)}_{\in \{0,j\}} \qquad \mathtt{HW}^{(j)}_{=i} \coloneqq \mathtt{HW}^{(j)}_{\in \{i\}}$$

$\mathtt{EQ}_j$ is the equality *relation on j inputs. We use $\mathtt{HW}_{\in S}$ to denote $\mathtt{HW}^{(j)}_{\in S}$ when the arity j of the relation is implicit. We also use this as the set of the relations $\mathtt{HW}^{(j)}_{\in S}$ for all $j \in \mathbb{N}$. We transfer this abuse of notation to $\mathtt{HW}_{=i}$.*

Note that assigning the relations $\mathtt{HW}_{\in B}$ to a vertex corresponds to assigning the set B to the vertex. Which notation is used depends on the context we are in.

3 Lower Bound when Parameterizing by Pathwidth

We show the lower bounds in two steps. The first step is a reduction from CNF-SAT to the intermediate problem B-Factor with Relations. In the second step, we reduce to the actual version of B-Factor for which we want to show the lower bound. As the lower bounds are for pathwidth they immediately hold for treewidth as it can be upper-bounded by pathwidth for all graphs.

▶ **Definition 3.1** (B-Factor with Relations (B-Factor$^{\mathcal{R}}$)). *Let $B \subseteq \mathbb{N}$ be fixed of finite size. $G = (V_S \dot\cup V_C, E)$ is an instance of B-Factor with Relations if all nodes in V_S are labeled with set B and all nodes $v \in V_C$ are labeled with a relation R_v that is given as a truth table such that the following holds:*

1. *Let $I(v)$ be the set of edges incident to v in G. Then $R_v \subseteq 2^{I(v)}$.*
2. *There is an even $c_v > 0$ such that for all $x \in R_v$ we have $\mathrm{hw}(x) = c_v$.*

A set $\widehat{E} \subseteq E$ is a solution *for G if (1) for $v \in V_S$: $\deg_{\widehat{E}}(v) \in B$ and (2) for $v \in V_C$: $I(v) \cap \widehat{E} \in R_v$. B-Factor$^{\mathcal{R}}$ is the problem of deciding if such an instance has a solution. We call V_S the set of* simple *nodes and V_C the set of* complex *nodes.*

Using this intermediate problem, we can formally state the first part of the reduction. The lower bound needs a careful formulation: when we reduce B-Factor$^{\mathcal{R}}$ to B-Factor by inserting gadgets realizing the relations at the complex nodes, the size and pathwidth of the graph can increase significantly. Therefore, we state a stronger lower bound that can tolerate additional terms to take care of such increases. The key point is that this increase is mainly influenced by the total degree of the complex nodes in a bag of the path decomposition.

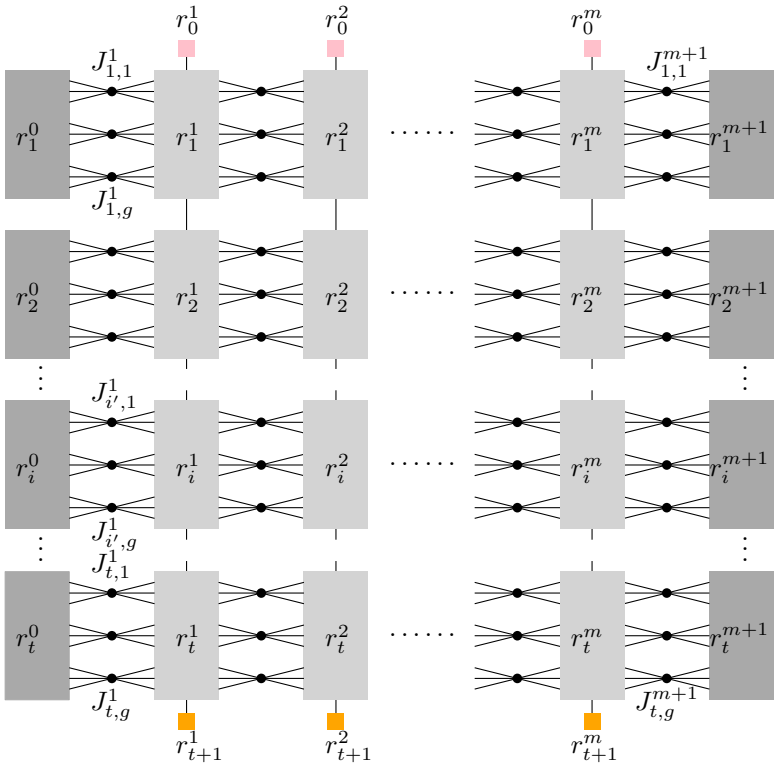

Figure 1 An example illustrating the construction from the proof of Theorem 3.2. The simple nodes are represented by circles while the complex nodes are represented by boxes.

▶ **Theorem 3.2.** *Let $B \subseteq \mathbb{N}$ be a fixed set of finite size with $B \neq \{0\}$. Given a B-Factor$^{\mathcal{R}}$ instance along with a path decomposition of width* pw *such that $\Delta^* = \max_{bag\ X} \sum_{v \in X \cap V_C} \deg(v)$. Assume B-Factor$^{\mathcal{R}}$ can be solved in $(\max B + 1 - \epsilon)^{\mathrm{pw}+f_B(\Delta^*)} n^{\mathcal{O}(1)}$ time on graphs with n vertices for some $\epsilon > 0$ and some function $f_B : \mathbb{N} \to \mathbb{R}^+$ that may depend on the set B. Then SETH fails.*

High Level Idea. We follow the ideas of previous lower bound reductions from [30] and combine them with the concept of using relations from [11]. From now on let $M := \max B$. Let ϕ be the given CNF formula with n variables and clauses $C_1, \ldots, C_m$. Instead of encoding each variable separately, we group q variables together and encode (partial) assignments to these groups. For each partial assignment, we define a vector in $[0, M]^g$, where g is chosen such that $2^q \leq (M+1)^g$. For each group we define a *layer* with g parallel *rows*, where each row corresponds to one dimension of the vector. The layers consist of an alternation of g parallel simple nodes and a complex node that is related to a clause. All simple nodes are connected to their neighboring complex nodes by M parallel edges. The vector from above then corresponds to the number of selected edges from a simple node to the following shared complex node. The complex nodes check whether the assignment represented by the selected edges of a layer satisfies the related clause. For each clause we connect the related complex nodes by a path. This path is used to propagate the information whether the clause is already satisfied by some partial assignment or whether it still needs to be satisfied. We ensure that each clause is initially not satisfied and eventually all clauses must be satisfied.

Constructing the B-FACTOR$^{\mathcal{R}}$ Instance. See Figure 1 for an example of the following construction. Split the variables of ϕ into $t \coloneqq \lceil n/q \rceil$ groups $F_1, \ldots, F_t$ of size at most q, where q is chosen later. For each of the t groups we encode the 2^q partial assignments by vectors from $[0, M]^g$ for some g chosen later. Instead of using all $(M+1)^g$ possible encodings we only use those vectors where the total weight of the coordinates is equal to $gM/2$ (we will choose g as a multiple of 4, hence $gM/2$ is an even number). It can easily be shown that there are more than $(M+1)^g/(gM+1)$ vectors with exactly this weight. Thus, after setting $q = \lfloor \log((M+1)^g) - \log(gM+1) \rfloor$, we can map each of the 2^q assignments of a group F_i to a distinct vector $[0, M]^g$ with weight exactly $gM/2$. We say that an partial assignment τ to a group F_i satisfies a clause C_j if at least one literal in the clause is satisfied under the assignment τ. Note, that a group F_i does not have to cover all variables of C_j to satisfy the clause.

We define the graph now as follows:

1. For all $i \in [t]$, $\ell \in [g]$, and $j \in [m]$: create a simple node $J^j_{i,\ell}$.
2. For all $i \in [t]$ and $j \in [m]$: create complex nodes r^j_i with relation R^j_i to be defined later.
3. For all $i \in [t]$: create complex nodes r^0_i and r^{m+1}_i with relation R^0.
4. For all $j \in [m]$: create complex nodes r^j_0 (resp. r^j_{t+1}) with relation $\texttt{HW}_{=0}$ (resp. $\texttt{HW}_{=1}$).
5. For all $i \in [t]$, $\ell \in [g]$, and $j \in [m]$: make $J^j_{i,\ell}$ adjacent to r^j_{i-1} and r^j_i by M parallel edges each. We call these edges backwards and forwards edges, respectively.
6. For all $i \in [t]$ and $j \in [m]$, make r^j_i additionally adjacent to r^j_{i-1} and r^j_{i+1} by one edge each. The degree of the nodes is now $2gM + 2$.

We call the set of nodes $\{r^j_i, J^j_{i,\ell}\}_{j,\ell}$ the ith *layer*. The set $\{J^j_{i,\ell}\}_j$ forms the ℓth *row* of the ith layer. For a fixed $j \in [m]$, the set of nodes $\{r^j_i\}_i$ is called the jth *column*.

The idea is now the following: For each partial assignment τ to a group F_i, we define a vector $v_\tau \in [0, M]^g$ of weight $gM/2$ as its *encoding*.[1] Then $v_\tau[\ell]$ corresponds to the number of selected forward edges of the simple nodes in the ℓth row of the ith layer. The vertical edges encode whether a clause was already satisfied. That is, if the edge between r^j_i and r^j_{i+1} is selected, then there is some group F_k with $k \leq i$ where the corresponding assignment satisfies the clause C_j. By the relation of the nodes r^j_0 every clause is initially not satisfied. But the relation of the r^j_{t+1} nodes ensures that every clause is eventually satisfied.

Defining the Relations. R^0 accepts exactly those inputs of Hamming weight exactly $gM/2$, an even number by assumption, where the selected edges for each row must precede the unselected edges, i.e. the first k edges are selected, the next $M - k$ are not selected.

The relation $R^j_i \subseteq \{0,1\}^{2Mg+2}$ of node r^j_i is defined as follows:

- For $\ell \in [g]$, let x_ℓ (resp. y_ℓ) be the number of selected incident edges to $J^j_{i,\ell}$ (resp. $J^{j+1}_{i,\ell}$).
- $\sum_{\ell \in [g]} x_\ell = gM/2 = \sum_{\ell \in [g]} y_\ell$.
- $\langle x_1, \ldots, x_g \rangle$ describes a valid encoding, i.e. it corresponds to a partial assignment for F_i.
- $x_\ell + y_\ell = M$. Further, the x_ℓ (resp. y_ℓ) selected edges precede the $M - x_\ell$ (resp. $M - y_\ell$) unselected edges of the M parallel edges going to a simple node.
- If the ingoing top edge is selected, then the outgoing bottom edge is also selected.
- If the ingoing top edge is not selected:
  - If C_j does not contain a variable of F_i, then the outgoing bottom edge is not selected.
  - If C_j contains at least one variable of F_i, then the outgoing bottom edge is selected if and only if the selected edges correspond to a valid partial assignment satisfying C_j.

[1] Note that for different groups the encoding of the same partial assignment do not need to be the same.

Final Modifications. Due to parity issues, we can only realize relations where the Hamming weight of the accepted inputs is an *even* constant for each relation. Thus, we slightly have to modify this construction. We leave the exact details to the full version.

▶ **Lemma 3.3.** *ϕ is satisfiable if and only if there is a solution to the B-Factor$^{\mathcal{R}}$ instance.*

To obtain a tight lower bound, we need to analyze the pathwidth of our construction and have to bound the degree of the complex nodes.

▶ **Lemma 3.4.** *The graph has $\mathcal{O}(tgm)$ simple and $\mathcal{O}(tm)$ complex nodes. The degree of the complex nodes is bounded by $2gM + 4$. The degree of the simple nodes is bounded by $2M$. We can efficiently construct a path decomposition of width $tg + \mathcal{O}(1)$ where at most three complex nodes are simultaneously in one bag.*

Now we have everything ready to prove the lower bound for the intermediate problem B-Factor$^{\mathcal{R}}$ based on the previous construction. Recall, we defined Δ^* as the maximum total degree of the complex nodes appearing in one bag, that is $\Delta^* = \max_{\text{bag } X} \sum_{v \in X \cap V_C} \deg(v)$.

Proof of Theorem 3.2 (Sketch). As $(M+1)^g \approx 2^q$ and $t \approx n/q$, we intuitively get

$$(M+1-\epsilon)^{tg} n^{\mathcal{O}(1)} = ((M+1-\epsilon)^g)^{\frac{n}{q}} n^{\mathcal{O}(1)} \ll ((M+1)^g)^{\frac{n}{q}} n^{\mathcal{O}(1)} = (2^q)^{\frac{n}{q}} n^{\mathcal{O}(1)} = 2^n n^{\mathcal{O}(1)},$$

showing that the reduction and the assumed algorithm would solve the SAT instance too fast. Note that due to rounding and other issues the calculation has to be done way more carefully and is thus deferred to the full version. ◀

4 Decision Version

In this section we prove the lower bound for the decision version of B-Factor by a reduction from the intermediate B-Factor$^{\mathcal{R}}$ problem. For this we formally define the concept of realizations and show that we can realize all relations of a B-Factor$^{\mathcal{R}}$ instance. Replacing the nodes and their relations by these realizations yields the final lower bound.

▶ **Definition 4.1** (Realization). *Let $R \subseteq \{0,1\}^k$ be a relation. Let G be a node-labeled graph with dangling edges $D = \{d_1, \ldots, d_k\} \subseteq E(G)$. We say that graph G* realizes *R if for all $D' \subseteq D$: $D' \in R$ if and only if there is a solution $S \subseteq E(G)$ with $S \cap D = D'$. We say that G B-*realizes *R if G is B-homogeneous. The endpoints of the dangling edges are called* portals.

The crucial part of the reduction is the proof of the following theorem. We postpone its proof and first show the lower bound.

▶ **Theorem 4.2.** *Let $B \subseteq \mathbb{N}$ be a fixed set of finite size with* max-gap $B > 1$ *and $0 \notin B$. There is a $f : \mathbb{N} \to \mathbb{N}$ such that the following holds. Let $R \subseteq \{0,1\}^e$ be an even relation (i.e.* $\mathrm{hw}(x)$ *is even for all $x \in R$). Then we can B-realize R by a simple graph with $f(e)$ vertices of degree at most* $\max B + 2$*, the portal nodes are pairwise distinct.*

Now we can prove the lower bound under SETH. We assume that $B \subseteq \mathbb{N}$ is a fixed, finite set such that $0 \notin B$ and max-gap $B > 1$.

Proof of Theorem 1.4 (Sketch). Replace every complex node v and its relation R_v in the B-Factor$^{\mathcal{R}}$ instance H by its B-realization of size at most $f(\deg(v))$ according to Theorem 4.2. This increases the size of the graph at most by a factor of $f(\Delta^*)$. As we can bound the pathwidth of the inserted graphs by their size, we modify each bag of the path decomposition

of H by replacing all complex nodes with the nodes of their realization. Thus, the pathwidth of the new graph is bounded by $\mathrm{pw}_H + \Delta^* f(\Delta^*)$. Assuming the faster algorithm, this already contradicts SETH by Theorem 3.2. ◀

From now on let $B \subseteq \mathbb{N}$ be our fixed, finite set with $\min B \geq 1$ and max-gap $B = d > 1$ such that $[a, a+d+1] \cap B = \{a, a+d+1\}$ for some $a \geq 1$. We first realize three quite basic relations which we use later to realize the more complex relations.

▶ **Lemma 4.3.** *We can B-realize each of the relations $\mathtt{HW}^{(2)}_{=2}$, $\mathtt{EQ}_{d+1}$, and $\mathtt{EQ}_2$ by a simple graph with $\mathcal{O}(\mathrm{poly}(\max B))$ vertices of degree at most $\max B$.*

Proof.

1. Define a $\min B + 1$-clique with new vertices. Split an arbitrary edge (u, v) into two dangling edges $(?, u)$ and $(?, v)$. The construction of the clique and the fact that we chose $\min B$ as degree forces the two dangling edges to be selected in any solution.
2. We start with two new vertices u, v and connect each to a many common $\mathtt{HW}^{(2)}_{=2}$ nodes. We add $d+1$ dangling edges to u and zero to v. Finally the nodes are replaced by their realization. Observe that u has a forced edges and $d+1$ dangling edges. Thus we must select none or all of the dangling edges since $[a, a+d+1] \cap B = \{a, a+d+1\}$.
3. Define a $d+2$-clique with $\mathtt{EQ}_{d+1}$ nodes. Split an arbitrary edge (u, v) into two dangling edges $(?, u)$ and $(?, v)$. Replace the nodes by their realization.
   Either both dangling edges are selected in which case all nodes have $d+1$ incident edges in the solution, or neither is selected in which case every node has zero incident edges in the solution. ◀

The following lemma helps us to keep the later constructions simple. Instead of constructing the relations for arbitrary degree, only the very low degree cases are necessary.

▶ **Lemma 4.4.** *If we can realize $\mathtt{HW}^{(a)}_{=1}$ for $a \in \{1, 2, 3\}$ by a simple graph with at most N vertices of degree at most D, then we can realize $\mathtt{HW}^{(k)}_{=1}$ for all $k \geq 1$ by a simple graph using $\mathcal{O}(kN)$ nodes of degree at most D.*

Proof. We construct the graph for the realization inductively starting with the basis for $k = 1, 2, 3$. See Figure 2 for an example.

For the inductive step from k to $k+1$ we start with a node u with relation $\mathtt{HW}^{(k)}_{=1}$. Connect one dangling edge of u to a new node v with $\mathtt{HW}^{(2)}_{=1}$. Connect the other dangling edge of v to a node w with relation $\mathtt{HW}^{(3)}_{=1}$. Observe that the final graph has $k+1$ dangling edges.

Assume one dangling edge of u is selected, then the edge between u and v is not selected but the edge from v to w is. Hence, no dangling edge of w can be selected. The analogue holds if one of the dangling edges of w is selected. It cannot be the case that more than one or zero dangling edges are selected, as then the relation of one of the three nodes u, v, or w would not be satisfied. ◀

Due to parity issues, the construction of the realizations depends on the set B. Each of the possible cases (B contains only even numbers, only odd number, or even and odd numbers) is treated separately. We focus on the all even case and refer the reader to the full version for the other cases.

▶ **Lemma 4.5.** *If B contains only even numbers, we can B-realize the following relations by simple graphs:*

1. $\mathtt{EQ}_k$ *for even $k \geq 2$ using $\mathcal{O}(k \,\mathrm{poly}(\max B))$ vertices of degree at most $\max B$.*
2. $\mathtt{HW}^{(k)}_{=1}$ *together with $\mathtt{HW}^{(\ell)}_{=1}$ for all $k, \ell \geq 1$ using $\mathcal{O}((k+\ell)\,\mathrm{poly}(\max B))$ vertices of degree at most $\max B + 2$.*

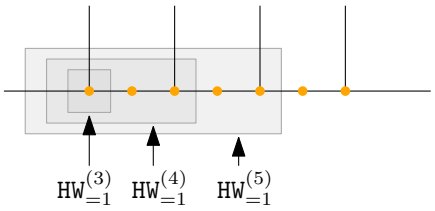

Figure 2 Example of the inductive construction from Lemma 4.4 for $\mathtt{HW}_{=1}^{(6)}$ using $\mathtt{HW}_{=1}^{(3)}$ and $\mathtt{HW}_{=1}^{(2)}$.

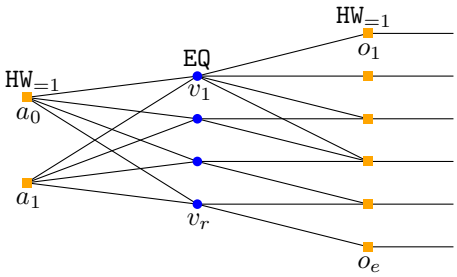

Figure 3 An example illustrating the construction from the proof of Theorem 4.2 for the relation R with $R(000011) = R(110011) = R(111001) = R(111100) = 1$ and zero otherwise.

Proof.

1. For $k = 2$ we can use the construction of Lemma 4.3. For the other case we first realize $\mathtt{EQ}_4$. Then we use a chain of these relations to realize $\mathtt{EQ}_k$ for even $k \geq 6$.
   Start with a $\mathtt{EQ}_{d+1}$ node u and make it adjacent to $\frac{d+1-4}{2}$ many $\mathtt{EQ}_2$ nodes (note that an even B can have only gaps of odd size, hence d is odd). Then we add four dangling edges to u. hence the construction actually works. The graph is simple as the dangling edges in the realization of $\mathtt{EQ}_2$ are different.
2. To use Lemma 4.4 for the general construction, observe that the number of $\mathtt{HW}_{=1}$ nodes used in the construction is odd. Hence, we will always realize two nodes. For this we show how to realize $\mathtt{HW}_{=1}^{(k)}$ together with $\mathtt{HW}_{=1}^{(\ell)}$ for all $k, \ell \in \{1, 2, 3\}$.
   Start with two vertices u, v. Make u and v adjacent to $\max B - 1$ common $\mathtt{HW}_{=2}^{(2)}$ nodes. We add k dangling edges to u and ℓ dangling edges to v. As B does not contain $\max B - 1$, the correctness follows. ◀

Now we have everything ready to prove that even relations can be realized.

Proof of Theorem 4.2. See Figure 3 for an example of the following construction. We use essentially the construction from Lemma 3.3 in [11]. Let $R = \{x_1, \ldots, x_r\} \subseteq \{0,1\}^e$ be the even relation for some r. Let further $P = \{(1 + e \mod 2), 0\}$.

1. Create nodes $o_1, \ldots, o_e$ with relation $\mathtt{HW}_{=1}$.
2. Create vertices a_j for all $j \in P$ with relation $\mathtt{HW}_{=1}$.
3. For all $i \in [r]$:
   a. Let $O_i = \{n_1^{(i)}, \ldots, n_{h_i}^{(i)}\} = \{k \in [e] \mid x_i[k] = 0\}$ for $h_i = e - \mathrm{hw}(x_i)$.
   b. Create the node v_i with relation $\mathtt{EQ}$ and connect it to $o_{n_j^{(i)}}$ for all $j \in [h_i]$.
   c. Connect v_i to all a_j.
4. Replace all nodes by their realization.

There are $|P| + e$ many $\mathtt{HW}_{=1}$ nodes. Since $|P| = 1 + (1 + e \mod 2)$, we can replace pairs of these nodes by their realization. Every v_i is connected to $|P| + |O_i|$ nodes, where $|O_i| = e - \mathrm{hw}(x_i)$. Thus, v_i has even degree as the relation R is even, i.e. $\mathrm{hw}(x)$ is even. Hence, we can replace these nodes by their realization according to the previous lemmas.

To show that the construction actually realizes the relation, assume the selected dangling edges corresponds to some element $x \in R$, let it w.l.o.g. be x_1. Then we can select all edges incident to x_1, the dangling edges, and the extension of this to all nodes as a solution. As x_1 is adjacent to all a_j they are in a valid state. Further x_1 is adjacent to those o_k where $x_1[k] = 0$ and hence every o_k is incident to exactly one edge in the solution.

Now assume we are given a solution. As the nodes a_j have exactly one incident edge in the solution, there is exactly one node v_i where all incident edges are in the solution. Let O be the set of nodes o_k to which v_i is adjacent. By construction v_i corresponds to some $x \in R$ with $x[k] = 0$ iff $k \in O$. As all selected dangling edges must be in the solution, let O' be the set of nodes incident to the selected dangling edges. But as we are given a solution we get $O \dot\cup O' = \{o_1, \dots, o_e\}$. Hence, the dangling edges correspond to x. ◀

5 Optimization Version

In the previous section we have seen the realization of the relations for the decision version. As we are interested in the largest solution for Max-B-Factor, we also allow $0 \in B$ since this does not make the problem trivially solvable. This makes it necessary to change the definition of a realization, as the pure existence of a solution is not sufficient anymore. We change it such that if the relation is satisfied (i.e. the dangling edges are selected in a good way), then there is a *large* solution. Otherwise, there must be a gap by which any solution is *smaller* compared to the solutions in the good cases. We call this gap the penalty (of the realization).

▶ **Definition 5.1** (Realization). *Let $R \subseteq \{0,1\}^k$ be a relation. Let G be a node labeled graph, with dangling edges $D = \{d_1, \dots, d_k\}$. We say that graph G* realizes *R with* penalty *β if we can efficiently construct/find a target value $\alpha > 0$ such that for all $D' \subseteq D$:*

- *If $D' \in R$, then there is a solution $S \subseteq E(G)$ with $S \cap D = D'$ and $|S| = \alpha$.*
- *If $D' \notin R$, then for all solutions $S \subseteq E(G)$ with $S \cap D = D'$ we have $|S| \leq \alpha - \beta$.*

We say that G B-realizes R if G is additionally B-homogeneous. We call the endpoints of the dangling edges portal nodes.

In the main part of this section we show how to realize the relations of B-Factor$^{\mathcal{R}}$. The following theorem corresponds to Theorem 4.2 for the decision version.

▶ **Theorem 5.2** (Realization of Relations). *Let $B \subseteq \mathbb{N}$ be a fixed, finite set with* max-gap $B > 1$ *and $0 \in B$. There is a $f : \mathbb{N}^2 \to \mathbb{N}$ such that the following holds. Let $R \subseteq \{0,1\}^e$ be a relation with a constant $c_R \in 2\mathbb{N}$ such that for all $x \in R$ we have* $\mathrm{hw}(x) = c_R$.

We can B-realize the relation R with arbitrary penalty $\beta > 0$ by a simple graph with $f(e, \beta)$ vertices of degree at most $\max B + 2$.

It remains to compute the target value by which we decide if the B-Factor$^{\mathcal{R}}$ instance has a solution or not.

▶ **Lemma 5.3.** *Let G be a B-Factor$^{\mathcal{R}}$ instance from Section 3. Let G' be a B-Factor instance resulting from G by replacing every complex nodes with degree δ by its realization with penalty 2δ. Then, there is an efficiently computable constant α such that G has a solution if and only if the largest solution for G' has size α.*

Proof (Sketch). The target value α is essentially the sum of the target values α_v for the realizations of the complex nodes $v \in V_C$. But we have to take care that the edges between complex nodes are not counted twice. ◀

Now we are ready to prove the conditional lower bound for Max-B-Factor when $0 \in B$.

Proof of Theorem 1.5. Use Lemma 5.3 to construct the final graph and the target value. Then the proof goes analogous to the proof for the decision version (cf. Theorem 1.4). ◀

High Girth Graphs. We know that there is a gap of size at least two between a and $a+d+1$ in B. This allows us to define relatively simple conditions of the form "if one incident edge of a vertex with degree $a+d+1$ is not selected, then another edge is also not selected". In other words, this propagates the penalty to a neighboring vertex. We combine this with high girth graphs to introduce an arbitrary large penalty for not selecting an edge.

The construction of r regular graphs with girth g is a long studied problem in graph theory. Erdős and Sachs proved the existence of such graphs for all combinations of r and g.

▶ **Lemma 5.4** (Theorem 1 in [20]). *For all $r \geq 2$ and $g \geq 3$, there is a r-regular graph $G_{r,g}$ of girth g with at most $4gr^g$ vertices.*

Finding the smallest graph for each r, g is a non-trivial task and known as the (r, g)-cage problem. For several cases (e.g. r is a prime power) constructions are known reducing the number of vertices in the graph. See [16, 21, 26, 28] for more results.

Realizing Relations. From now on let $d \coloneqq \text{max-gap}\, B > 1$ such that $[a, a+d+1] \cap B = \{a, a+d+1\}$ for some $a \geq 0$. As we allow $0 \in B$, we can always find a trivial solution. Thus, we cannot force edges as we did for the decision version. Instead we construct a gadget where we can select many edges when the "forced" edges are selected. Otherwise we ensure that the solution is small. We use the graphs with high girth for this.

▶ **Lemma 5.5.** *There is a $f : \mathbb{N} \to \mathbb{N}$ such that the following holds. We can B-realize $\mathtt{HW}^{(2)}_{=2}$ (with distinct portal vertices) with arbitrary penalty β by simple graphs using at most $f(\beta)$ vertices of degree at most* $\max B$.

Proof. We use Lemma 5.4 to get an $a+d+1$-regular graph $G_{a+d+1,\beta}$ of girth at least β. Split an arbitrary edge (u, v) into two dangling edges for u and v each and assign the set B to every vertex.

The graph has the claimed properties: If both dangling edges are selected, then we can use the set of all edges in the graph as a solution since $a+d+1 \in B$.

It remains to check the case when at least one dangling edge is not selected, let it w.l.o.g. be the one incident to u. Assume S is the optimal solution. We show that this solution does not contain more than $|E_{a+d+1,\beta}| - \beta$ edges.

By assumption $\deg_S(u) \leq a$. Hence, there must be at least one other incident edge to u that is not in the solution, because $a+d-1 \geq a+1 \notin B$. Then we can apply this argument always to the next vertex. Observe that this sequence can only stop if we reach another vertex w we have already visited because for this vertex we already know that two incident edges were not selected in the solution. The length of this path, i.e. the number of not selected edges from w to w, is at least the girth of the graph. Hence the number of edges that are not selected in the solution is at least the girth of the graph which is at least β. ◀

The remaining part follows mainly the constructions from the decision version. However, as we care about the size of the solution a more careful construction and analysis is needed. The detailed construction of the realization is given in the full paper.

6 Counting Version

From a certain perspective the optimization version can be seen as a relaxation of the decision version: The assumption $\min B > 0$ is dropped while still assuming max-gap $B > 1$. For the counting version we now even drop this last assumption such that there might be no gap at all in B. Thus the only polynomial-time solvable cases for the counting version are $B = \{0\}$ and $B = \emptyset$ with one and zero solutions, respectively. This implies that we additionally must realize equality relations. Surprisingly this also reduces to realizing $\mathtt{HW}^{(1)}_{=1}$ nodes in the end, i.e. forcing edges.

We use the Holant framework and lemmas and definitions analogous to those from [11]. A signature graph Ω is a graph with weights w_e for all edges e and all vertices are labeled by *signatures* $f_v : \{0,1\}^{I(v)} \to \mathbb{Q}$, which are rational functions on the incidence vector $I(v)$ of the edges incident to v. We define Holant(Ω) to be the quantity

$$\sum_{x \in \{0,1\}^{E(\Omega)}} \prod_{e \in x} w_e \prod_{v \in V(\Omega)} f_v(x|_{I(v)}).$$

The Holant framework can be seen as a natural generalization of GenFac. If each signature f_v is a symmetric Boolean function and each edge weight is 1, then it is exactly #GenFac. If additionally each vertex has signature $\mathtt{HW}_{\in B}$, this corresponds to #B-Factor.

▶ **Definition 6.1** (Holant(F)). *If F is a set of rational functions, we say that* Holant(F) *is the set of all Holant problems where the signature graph has signatures only from F.*

▶ **Definition 6.2** (Gate). *A gate is a signature graph Γ, possibly containing a set $D \subseteq E(\Gamma)$ of dangling edges, all of which have edge weight 1. The signature realized by Γ is the function* $\mathtt{SIG}(\Gamma) : \{0,1\}^D \to \mathbb{Q}$ *that maps an assignment of dangling edges $x \in \{0,1\}^D$ to*

$$\mathtt{SIG}(\Gamma, x) = \sum_{y \in \{0,1\}^{E(\Gamma) \setminus D}} \left(\prod_{e \in E(\Gamma)} w(e) \prod_{v \in V(\Gamma)} f_v\Big((x \cup y)|_{I(v)}\Big) \right)$$

Note that unless mentioned otherwise, we restrict ourselves to signature graphs with unit edge weights and hence they are usually omitted.

In essence, gates in the Holant framework play the role of realizations in the previous sections. Given these definitions, we are now ready to state our main theorem, which can then be used to prove Theorem 1.6. Observe for this that the reduction in Theorem 3.2 is parsimonious.

▶ **Theorem 6.3.** *For all fixed, finite $B \subseteq \mathbb{N}$ with $B \neq \{0\}$ there is a $f : \mathbb{N} \to \mathbb{N}$ such that the following holds. Let $G = (V_S \dot\cup V_C, E)$ be an instance of #B-Factor$^{\mathcal{R}}$ with a path decomposition of width* pw *such that $\Delta^* = \max_{bag\ X} \sum_{v \in X \cap V_C} \deg(v)$. Then there is a $f(\Delta^*)n^{\mathcal{O}(1)}$ time Turing reduction from #B-Factor$^{\mathcal{R}}$ to #B-Factor such that for every constructed instance of #B-Factor pathwidth and cutwidth increase at most by $f(\Delta^*)$.*

We can think of #B-Factor$^{\mathcal{R}}$ as a Holant problem where the allowed signatures are either $\mathtt{HW}_{\in B}$ or restricted even relations. We first use a lemma from [11] to realize these relations through nodes with signature $\mathtt{HW}_{=1}$. Since their constructions are in the perfect matching setting, they can equivalently be seen as gates that use vertices with signature $\mathtt{HW}_{=1}$. After using this lemma to reduce from #B-Factor$^{\mathcal{R}}$ to a Holant problem, we give a chain of reductions (see Figure 4) that ends at #B-Factor and preserves the pathwidth up to an additive constant.

▶ **Lemma 6.4** (Informal, Lemma 3.3 from [11]). *Every even relation can be realized through a graph whose vertices have signature $\mathtt{HW}_{=1}$ and whose edges have weights in $\{-1, \frac{1}{2}, 1\}$.*

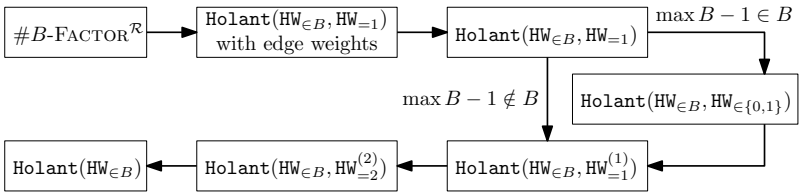

Figure 4 The chain of reductions that starts with B-Factor$^{\mathcal{R}}$ and ends at $\#B$-Factor (i.e. $\texttt{Holant}(\texttt{HW}_{\in B})$). Arrows show the direction of Turing or many-one reductions.

Main Ideas. The next step is to remove the edge weights. We do this through polynomial interpolation, which was first used by Valiant [36]. The idea is that we can recover a polynomial $P(\cdot)$ if we know the value of $P(x)$ for sufficiently many x. We represent the solution of one problem as the value of a polynomial $P(\cdot)$ and the second problem as a function $f(P)$ of the polynomial itself. Then, we recover the value of the second problem by using an oracle of the first problem, giving a Turing reduction from the second problem to the first.

For the removal of the edge weight it suffices by the polynomial interpolation to consider edge weights that are a power of two. Assume for simplicity, we just have edge weight 2. Replace such edges by two parallel edges of unit weight. This leaves the output unchanged, as we duplicated the number of solutions, which compensates for the unit edge weight.

The main difficulty is to realize $\texttt{HW}_{=1}$ nodes using $\texttt{HW}_{\in B}$ nodes. To replace the $\texttt{HW}_{=1}$ nodes, we distinguish between the case where $\max B - 1$ is in B or not. In the latter case, the construction from the decision version works. But in the former case we use an argument similar to the procedure for the final step. The last step replaces $\texttt{HW}^{(2)}_{=2}$ nodes by $\texttt{HW}_{\in B}$ nodes. For this we "separate" the case where the forced edges are selected and where they are not. We define a pathlike gadget with many solutions if the dangling edges are not selected and significantly fewer otherwise. Each vertex on this long path is connected to many fresh vertices. We choose their number to be higher than the maximum element of B. Then, if an incident edge of the path is already selected, there are fewer solutions as if the edge is not selected. Combining this with the interpolation we arrive at a point, where all nodes have relation $\texttt{HW}_{\in B}$.

We now describe one case in the final step in the chain of reductions, where we realize $\texttt{HW}^{(2)}_{=2}$ nodes by $\texttt{HW}_{\in B}$ nodes. For the remaining cases and steps, we refer the reader to the full version of this paper.

For the interpolation we make use of the following result which is proven in the full version.

▶ **Proposition 6.5.** *Suppose we have two non-zero sequences* $\{A_n\}_{n\in\mathbb{N}}, \{B_n\}_{n\in\mathbb{N}}$ *that are related as*

$$\begin{bmatrix} A_n \\ B_n \end{bmatrix} = M \begin{bmatrix} A_{n-1} \\ B_{n-1} \end{bmatrix} = M^n U \qquad \text{, where } U = \begin{bmatrix} A_0 \\ B_0 \end{bmatrix}$$

and M *is a symmetric and invertible* 2×2 *matrix such that* U *is not an eigenvector of* M*. Then* $\{\frac{B_n}{A_n}\}_{n\in\mathbb{N}}$ *is a sequence which does not contain any repetitions.*

▶ **Lemma 6.6.** *Let* $B \subseteq \mathbb{N}$ *be a fixed finite set. There is a polynomial-time Turing reduction from* $\texttt{Holant}(\texttt{HW}_{\in B}, \texttt{HW}^{(2)}_{=2})$ *to* $\texttt{Holant}(\texttt{HW}_{\in B})$ *increasing pathwidth and cutwidth only by a fixed constant and leaving the max degree unaffected, or increasing it to* $2 \max B + 6$*.*

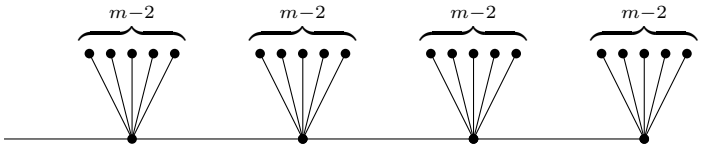

Figure 5 The gadget for case 1: Black nodes are $\mathtt{HW}_{\in B}$ nodes.

Proof. If $0 \notin B$, we can use the construction from Lemma 4.3 to get a $\mathtt{HW}^{(2)}_{=2}$ node. For the case when $0 \in B$, we do a case-by-case analysis depending on B. In either case, we attach a subgraph with a constant pathwidth and cutwidth to vertices. This does not affect either of them by more than $2 \max B + 6$, a fixed constant.

Case 1: B contains 1. Define $m \geq 2$ to be the smallest integer not in B. Consider the gadget in Figure 5. Suppose there are d such vertices with $m-2$ pendant nodes each. Let all of them have the relation $\mathtt{HW}_{\in B}$. Let $P_1(d)$ be the number of solutions of the gadget where the dangling edge is selected in the solution. Similarly define $P_0(d)$ when the dangling edge is not selected. We claim that the gadget described can be effectively used to force edges, i.e. a $\mathtt{HW}^{(1)}_{=1}$ node. Two such gadgets will give us a $\mathtt{HW}^{(2)}_{=2}$ node. Suppose any graph G contains t such gadgets. We have

$$\text{Holant}(G) = \sum_{i=0}^{t} A_i (P_0(d))^{t-i} (P_1(d))^i = (P_0(d))^t \sum_{i=0}^{t} A_i \left(\frac{P_1(d)}{P_0(d)}\right)^i$$

where A_i is the number of ways of extending the solution in G when i of the gadgets choose to match their dangling edge. Through standard interpolation techniques, we can recover the A_is, and thus A_t will give us the solution where each gadget behaves like a $\mathtt{HW}^{(1)}_{=1}$. Now, we can replace $\mathtt{HW}^{(2)}_{=2}$ nodes in the $\mathtt{Holant}(\mathtt{HW}_{\in B}, \mathtt{HW}^{(2)}_{=2})$ instance with pairs of $\mathtt{HW}^{(1)}_{=1}$ nodes.

To argue that we can do the interpolation, we need to show that $\frac{P_1(d)}{P_0(d)}$ will take at least t unique values, and that these are computable in polynomial time. Since we can define such a gadget for any integer d we have

$$P_0(d) = kP_0(d-1) + kP_1(d-1) \qquad \text{and} \qquad P_1(d) = kP_0(d-1) + (k-1)P_1(d-1)$$

for $k = 2^{m-2}$. We now apply Proposition 6.5 with $M = \left[\begin{smallmatrix} k & k \\ k & k-1 \end{smallmatrix}\right]$ and $U = \left[\begin{smallmatrix} k \\ k \end{smallmatrix}\right]$.

This completes the realization for the case when B contains 1. The remaining cases when B does not contain 1 but some odd number and when B only consists of even numbers can be found in the full version. ◀

Proof of Theorem 6.3 (Sketch). Given any instance of $\#B$-Factor$^{\mathcal{R}}$, we can sequentially apply the reductions from Figure 4 to get a polynomial number of instances of $\#B$-Factor such that the pathwidth is affected only by some function of Δ^*. ◀

7 Lower Bound when Parameterizing by Cutwidth

The algorithmic result from Theorem 1.8 shows that the pathwidth lower bound breaks when parameterizing by cutwidth. Nevertheless, we can show that this "improved" running time is the best we can hope for assuming SETH and #SETH. For this we use the same high level ideas Curticapean and Marx presented in Figure 6 of [11] where they reduce from #SAT to computing the Holant and then reduce to counting perfect matchings. But the construction

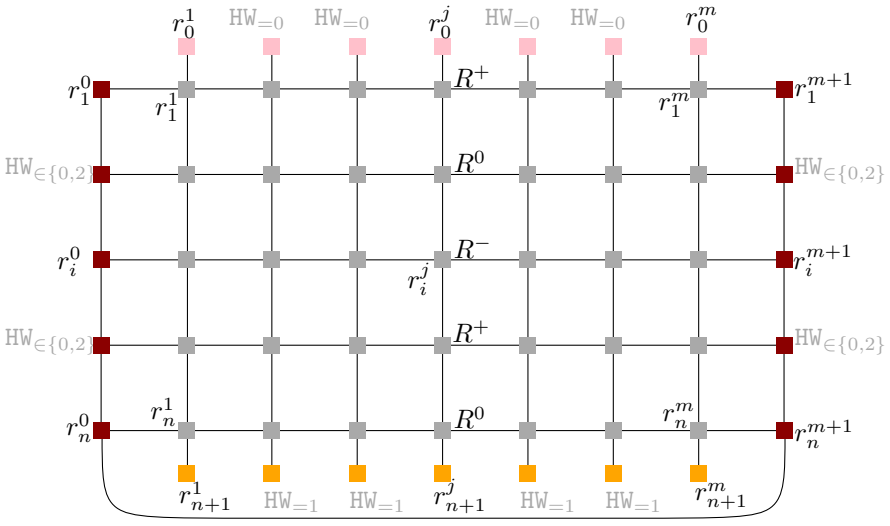

Figure 6 The example graph for a formula containing the clause $(x_1 \vee \bar{x}_3 \vee x_4)$.

can also be seen as a modification of our reduction for the pathwidth lower bound. We again first reduce to the intermediate problem B-Factor$^{\mathcal{R}}$ and then to B-Factor. By this we can reuse the results of realizing relations that we have seen in the previous sections.

▶ **Theorem 7.1.** *Let $B \subseteq \mathbb{N}$ be a fixed set of finite size. Given a CNF-formula ϕ with n variables and m clauses. We can construct a (simple) B-Factor$^{\mathcal{R}}$ instance G with $\mathcal{O}(nm)$ vertices, bounded degree and a linear layout of width* cutw $\leq n + \mathcal{O}(1)$ *in time linear in the output size. Further, the number of solutions for ϕ is equal to the number of solutions for G.*

Recall, that for the pathwidth lower bound we grouped variables together. This was needed to keep the pathwidth of the construction low. But this increased the cutwidth of the graph. Now, we do not group variables together but encode each variable on its own. See Figure 6 for an example of the construction we describe formally in the following.

Let $x_1, \ldots, x_n$ be the variables and $C_1, \ldots, C_m$ the clauses of ϕ. For each $i \in [n]$ and every $j \in [m]$ we create a vertex r_i^j. We assign the relation R^+ to r_i^j if x_i appears positively in C_j, R^- if it appears negatively, and otherwise R^0, where R^0, R^+, and R^- are defined later. Additionally add vertices r_i^0 and r_i^{m+1} with relation $\mathtt{HW}_{\in\{0,2\}}$ for all $i \in [n]$. We say that the vertices $r_i^0, \ldots, r_i^{m+1}$ form the ith *row*, i.e. the row of variable x_i. Create new nodes r_0^j and r_{n+1}^j and assign the relations $\mathtt{HW}_{=0}$ and $\mathtt{HW}_{=1}$ to them for all $j \in [m]$, respectively. We say the vertices $\{r_i^j\}_i$ form the jth *column*. We connect two nodes r_i^j and $r_{i'}^{j'}$ by an edge if $|i - i'| \leq 1$ and $|j - j'| \leq 1$ for all $i, i' \in [0, n+1]$ and $j, j' \in [0, m+1]$, i.e. if they are neighbors in the grid.

The idea is the same as for the pathwidth construction, except that selecting the edges of the ith row corresponds to setting the variable x_i to true. The edges between the nodes of a column represent if a clause is already satisfied. The relation $\mathtt{HW}_{=0}$ ensures that we start with an initially unsatisfied clause. At each node r_i^j we check whether the assignment to this variable x_i satisfies the clause C_j and then force the output edge (i.e. the bottom edge) to be selected. Otherwise we propagate the current state (i.e. the selection of edges). Eventually we reach r_{n+1}^j with relation $\mathtt{HW}_{=1}$ where the edge has to be selected and thus the clause must be satisfied.

The relations R^0, R^+, and R^- accept exactly those inputs that satisfy all of the following conditions:

1. The left edge is selected if and only if the right edge is selected.
2. If the top edge is selected, the bottom edge is selected.
3. Only for R^+: If the top edge is unselected and the left edge is selected, then the bottom edge is selected.
4. Only for R^-: If the top edge is unselected and the left edge is not selected, then the bottom edge is selected.

For the proofs of the lower bounds, i.e. Theorem 1.9, we follow the ideas from the pathwidth lower bounds in Section 3. Thus we also have to modify the graph a bit such that we obtain a B-Factor$^{\mathcal{R}}$ instance and can replace all relations by their realizations. The details can be found in the full version of the paper.

High-Girth Near-Ramanujan Graphs with Lossy Vertex Expansion

Theo McKenzie

Abstract

Kahale proved that linear sized sets in d-regular Ramanujan graphs have vertex expansion at least $\frac{d}{2}$ and complemented this with construction of near-Ramanujan graphs with vertex expansion no better than $\frac{d}{2}$. However, the construction of Kahale encounters highly local obstructions to better vertex expansion. In particular, the poorly expanding sets are associated with short cycles in the graph. Thus, it is natural to ask whether the vertex expansion of *high-girth* Ramanujan graphs breaks past the $\frac{d}{2}$ bound. Our results are two-fold:

1. For every $d = p + 1$ for prime $p \geq 3$ and infinitely many n, we exhibit an n-vertex d-regular graph with girth $\Omega(\log_{d-1} n)$ and vertex expansion of sublinear sized sets bounded by $\frac{d+1}{2}$ whose nontrivial eigenvalues are bounded in magnitude by $2\sqrt{d-1} + O\left(\frac{1}{\log_{d-1} n}\right)$.
2. In any Ramanujan graph with girth $C \log_{d-1} n$, all sets of size bounded by $n^{0.99C/4}$ have near-lossless vertex expansion $(1 - o_d(1))d$.

The tools in analyzing our construction include the nonbacktracking operator of an infinite graph, the Ihara–Bass formula, a trace moment method inspired by Bordenave's proof of Friedman's theorem [8], and a method of Kahale [16] to study dispersion of eigenvalues of perturbed graphs.

1 Introduction

This paper is concerned with expander graphs, which are ubiquitous in theoretical computer science. A natural and highly well-studied quantity associated with a d-regular graph is its *edge expansion* defined as

$$\min_{|S| \leq \epsilon n} E(S, \overline{S})/|S|,$$

for some constant ϵ. Namely it is the minimum ratio of edges leaving a set S to the size of S for all S of appropriately bounded size. While edge expansion is known to be intractable to compute, there are explicit constructions of good edge expanders, and it is closely related to the second largest magnitude eigenvalue of its adjacency matrix, also known as *spectral*

expansion of a graph, via the expander mixing lemma and Cheeger's inequality [1]. Spectral expansion is easily computable. In particular, an application of the expander mixing lemma proves that small enough sets in graphs with spectral expansion $o(d)$ have near-optimal edge expansion of $(1 - o_d(1))d$.

A natural analog to edge expansion is *vertex expansion*, defined as

$$\min_{|S| \leq \epsilon n} |\Gamma(S)|/|S|$$

for some constant ϵ, where $\Gamma(S)$ is the neighborhood of the set S (potentially containing vertices of S). However, as difficult as edge expansion is to ascertain, vertex expansion has proven far more challenging.

As witnessed by the neighborhood of a vertex, we cannot hope for vertex expansion greater than $d-1$. Therefore we call a graph a *lossless vertex expander* if for every δ, there exists an ϵ such that there is vertex expansion $d - 1 - \delta$ for sets of size ϵn. Lossless vertex expanders exist since a random d-regular graph is one with high probability (see [15, Theorem 4.16] for a proof). However no deterministic construction of such graphs is known. In an effort to understand lossless vertex expansion better and give explicit constructions, a natural question to ask is: *what properties of random graphs leads to lossless vertex expansion*?

Since a random d-regular graph is near-Ramanujan with high probability [11], and since near-Ramanujan graphs have near-optimal edge expansion, it is natural to inquire if spectral expansion has any implications for vertex expansion as well. Kahale [16] showed that the spectral expansion gives a bound on the vertex expansion. Specifically, Ramanujan graphs (namely graphs with optimal spectral expansion) have vertex expansion at least $d/2$. While this is a nontrivial implication, it falls short of achieving the coveted *losslessness* property. Kahale also proved that the bound of $d/2$ is tight. In particular, he exhibited an infinite family of near-Ramanujan graphs with vertex expansion $d/2$, which means spectral expansion alone is not sufficient for lossless vertex expansion.

The occurrence of a copy of $K_{2,d}$[1] as a subgraph is the obstruction to lossless vertex expansion in Kahale's example. Kahale's example deviates from a random graph in that it is highly unlikely for a random graph to contain a copy of $K_{2,d}$ as a subgraph. More generally, random graphs have the property that with high probability any two "short" cycles are far apart, which Kahale's example doesn't satisfy. Thus, it is natural to ask if the "near-Ramanujan" property in conjunction with the "separatedness of cycles" property of random graphs break past the $d/2$ barrier of Kahale. The "separatedness of cycles" property is especially interesting to consider since it is a key property of random graphs exploited in proofs of Alon's conjecture [11, 8]. A concrete question we can ask is: *Do Ramanujan graphs with $\Omega(\log_{d-1} n)$ girth have lossless vertex expansion?*

An affirmative answer to the above question would prove that the Ramanujan graphs of Lubotzky, Phillips, and Sarnak [18] are lossless vertex expanders. Towards answering the above question, we prove the following negative result:

▶ **Theorem 1.** *For every $d = p + 1$ for prime $p \geq 3$, there is an infinite family of d-regular graphs G on n vertices of girth $\geq \left(\frac{2}{3} - o_n(1)\right) \log_{d-1} n$ where there is a set of vertices U such that $|\Gamma(U)| \leq (d+1)|U|/2$, $|U| \leq n^{1/3}$, and $\max\{\lambda_2(G), -\lambda_n(G)\} \leq 2\sqrt{d-1} + O(1/\log_{d-1} n)$.*

We also complement the above with a positive result which can be summarized as "small enough sets in Ramanujan graphs expand nearly losslessly":

[1] complete bipartite graph with 2 vertices on one side and d vertices on the other

▶ **Theorem 2.** *Let G be a d-regular Ramanujan graph with girth $C \log_{d-1} n$, then every set of S of size $\leq n^{\kappa}$ for $\kappa < \frac{C}{4}$ has vertex expansion $(1 - o_d(1))d$.*

After posting our preprint, Amitay Kamber informed us that a theorem in an alternative version of [16] gives the same bound by a different argument. Moreover, his theorem does not depend on the spectral expansion of the graph. However, our proof may be of interest as an alternate method.

1.1 Technical Overview

We give a brief description of how Theorem 1 and Theorem 2 are proved.

1.1.1 Overview of Proof of Theorem 1

Our proof is inspired by that of Kahale's. At a high level, Kahale embeds a copy of $K_{2,d}$ within a Ramanujan graph. We proceed similarly to Kahale, but instead of embedding a $K_{2,d}$, we embed a single subgraph H that is high girth but a lossy vertex expander and show that if H has size n^{α} for some $0 < \alpha \leq 1/3$, the overall graph is still near-Ramanujan.

Our proof involves two steps: the first step is in proving that the subgraph H being embedded has spectral radius bounded by $2\sqrt{d-1}$, and the second step is in proving that planting H within a Ramanujan graph results in a near-Ramanujan graph. For the first step, we describe an infinite graph containing H and bound its spectral radius via a trace moment method. The trace moment method involves bounding the number of closed walks satisfying certain properties within a graph, and is inspired by an encoding argument from Bordenave's proof of Friedman's theorem [8].

The second step is in proving that our method of embedding a copy of H within a Ramanujan graph does not perturb the eigenvalues by a large amount. Towards doing so, we use the fact that the spectral radius of H is bounded by $2\sqrt{d-1}$ in conjunction with Kahale's argument about dispersion of eigenvalues in high-girth graphs.

1.1.2 Overview of Proof of Theorem 2

We first prove that if a set S in a Ramanujan graph has "lossy" vertex expansion, then we can construct a graph H on vertex set S such that (i) the girth of H is at least half the girth of G, and (ii) the average degree of H is "high" (in particular, the worse the vertex expansion of S, the higher the average degree of H). We then employ the irregular Moore bound, which gives a quantitative tradeoff between the average degree of a graph and its girth. In particular, this would imply that a Ramanujan graph with "lossy" vertex expansion necessarily must have "low" girth.

1.2 Related Work

1.2.1 Applications of Vertex Expanders

There are many applications of expander graphs where having vertex expansion is particularly useful. For example, lossless expanders are particularly of interest in the field of error correcting codes [19, 26, 27]. Lossless vertex expanders give linear error correcting codes that are decodable in linear time [26]. Guruswami, Lee and Razborov [14] use bipartite vertex expanders to construct large subspaces of $\mathbb{R}^n$ where all vectors x in the subspace satisfy $(\log n)^{-O(\log\log\log n)}||x||_2 \leq ||x||_1 \leq \sqrt{n}||x||_2$.

1.2.2 Explicit Constructions

Constructions of Ramanujan graphs of [18, 20, 22] of all degrees that are of the form $p^r + 1$ for p prime, as well as the construction of near-Ramanujan graphs of every degree of [21] have vertex expansion $\sim \frac{d}{2}$ just by virtue of being Ramanujan via Kahale's result. In fact no deterministic construction has improved upon the $d/2$ bound obtained from solely spectral information. In a remarkable work, Capalbo et al. [10] exhibited an explicit construction of a bipartite graph where subsets of one side of the bipartite graph expand losslessly to the other, using a zig-zag product so the the losslessness of a small, random-like graph boosts the expansion from a large, potentially lossy vertex expanding graph.

1.2.3 Quantum Ergodicity

Quantum ergodicity is another area where both local and global properties of random-like graphs are used. In particular, Anantharaman and Le Masson [6] proved that graphs that have few short cycles (and are therefore close to high girth) and spectral expansion are quantum ergodic, which in this context means the eigenvectors are equidistributed across vertices. Anantharaman, as well as Brooks, Le Masson, and Lindenstrauss exhibited alternative proofs [5, 9]. The proof from [9] shows that quantum ergodicity is equivalent to the mixing of a certain graphical operator. They then use high girth to show that this is equivalent to showing mixing on the infinite tree, then expansion to show the nonbacktracking operator mixes on the tree.

1.2.4 Eigenvector Delocalization

Ganguly and Srivastava, and later Alon, Ganguly and Srivastava [12, 3] give a perturbation of the LPS graph similar to Kahale's argument, but instead of individual vertices, two trees are added and connected to the graph. By assuming the tree is sufficiently deep and carefully connecting the tree to the rest of the graph, the authors create a graph that is high girth but contains eigenvectors that are localized. These graphs are also lossy vertex expanders. However, they show that these graphs cannot be Ramanujan, but rather have spectral radius at least $(2 + c)\sqrt{d - 1}$ where $c > 0$ is a constant. Alon [2] used eigenvector delocalization to create near-Ramanujan expanders of every degree by perturbing known constructions of Ramanujan or near-Ramanujan graphs. Paredes [23] used similar techniques to remove short cycles in a graph while preserving expansion and uses this to algorithmically create graphs that are near-Ramanujan and also have girth at least $\Omega(\sqrt{\log n})$.

1.2.5 Complexity of Constraint Satisfaction Problems

Proofs that it is hard for even linear degree Sum-of-Squares to refute random 3XOR and 3SAT instances on n variables [13, 25] rely on lossless vertex expansion of some sets in a graph underlying a random instance, which suggests a connection between deterministic algorithms for constructing lossless vertex expanders and algorithms for explicit hard instances for Sum-of-Squares.

2 Preliminaries

2.1 Elementary Graph Theory

▶ **Definition 3.** *The girth $g(G)$ of a graph G is the length of the smallest cycle in G.*

▶ **Definition 4.** *For $G = (V, E)$, the valency of $a \in V$ to $B \subset V$ is $|\Gamma(a) \cap B|$, where $\Gamma(S)$ for $S \subset V$ is the set of neighbors of S in G.*

▶ **Definition 5.** *The ball of radius h around a set $U \subset V$, denoted* $\mathrm{Ball}_h(U)$*, is the set of vertices of distance at most h from U.*

▶ **Definition 6.** *The vertex expansion of a set $U \subset V$ is*

$$\Psi(U) := \frac{|\Gamma(U)|}{|U|}.$$

Similarly, the ϵ-vertex expansion of a graph G is:

$$\Psi_\epsilon(G) = \min_{|U| \leq \epsilon |V|} \Psi(U)$$

where U ranges over subsets of V, and ϵ is an arbitrary constant.

▶ **Definition 7.** *Given a graph G, we use A_G to denote its adjacency matrix. When G is a finite graph on n vertices, the eigenvalues of A_G can be ordered as $\lambda_1(G) \geq \lambda_2(G) \geq \cdots \geq \lambda_n(G)$.*

▶ **Definition 8.** *We use B_G to denote the* nonbacktracking matrix *of a graph G which is a matrix with rows and columns indexed by directed edges of G defined as follows:*

$$B[(u,v),(w,x)] = \begin{cases} 1 & \text{if } v = w \text{ and } u \neq x \\ 0 & \text{otherwise.} \end{cases}$$

▶ **Definition 9.** *The* spectral expansion *of a finite graph G, denoted $\lambda(G)$ is defined as $\max\{\lambda_2(G), -\lambda_n(G)\}$, which can equivalently be described as the "second largest absolute eigenvalue".*

We now state the following standard fact known as the *expander mixing lemma* (see [15, Lemma 2.5]).

▶ **Lemma 10** (Expander Mixing Lemma)**.** *Let G be a d-regular graph on n vertices. For any two subsets of vertices, $S, T \subseteq V(G)$, let $e(S,T)$ be the number of pairs of vertices (x,y) such that $x \in S, y \in T$ and $\{x,y\}$ is an edge in G. Then:*

$$\left| e(S,T) - \frac{d}{n}|S| \cdot |T| \right| \leq \lambda(G)\sqrt{|S| \cdot |T|}.$$

And finally, we state the "irregular Moore bound" of [4] which articulates a tradeoff between the average degree of a graph and its girth.

▶ **Lemma 11.** *Let G be a n-vertex graph with average degree-d. Then*

$$g(G) \leq 2\log_{d-1} n + 2.$$

2.2 Operator Theory

In this section, let V be a countable set and $T : \ell_2(V) \to \ell_2(V)$ be a bounded linear operator.

▶ **Definition 12.** *The* spectrum *of T, which we denote* $\mathsf{spec}(T)$*, is the set of all $\lambda \in$ such that $\lambda I - T$ is not invertible.*

▶ **Definition 13.** *The* spectral radius *of T, which we denote $\rho(T)$ is defined as* $\sup\{|\lambda| : \lambda \in \mathsf{spec}(T)\}$.

▶ **Observation 14.** *The* operator norm *of T, which we write as $\|T\|$ is equal to $\sqrt{\rho(TT^*)}$ where T^* is the adjoint of T.*[2]

▶ **Observation 15.** $\rho(T) = \lim_{\ell\to\infty} \|T^\ell\|^{1/\ell}$.

▶ **Observation 16** (Consequence of [24, Theorem 6])**.** *Suppose T is a self-adjoint operator, and Φ is a basis of $\ell_2(V)$. Then:*

$$\rho(T) = \sup_{\phi\in\Phi} \limsup_{k\to\infty} |\langle \phi, T^k\phi\rangle|^{1/k}.$$

▶ **Observation 17.** *Let A be any principal submatrix of T. Then $\rho(A) \le \rho(T)$.*

▶ **Corollary 18.** *If H is a subgraph of (possibly infinite) graph G, then $\rho(A_H) \le \rho(A_G)$.*

3 Infinite Trees Hanging from a Biregular Graph

Let H be any $(2, d-1)$-biregular graph where the partition with degree-$(d-1)$ vertices is called U and the partition with degree-2 vertices is called V. Let X be the infinite graph constructed from H as follows:

At every vertex in U, the $(d-1)$-regular partition, glue an infinite tree where the root has degree-1 and the remaining vertices have degree-d. At every vertex in V, the 2-regular partition, glue an infinite tree where the root has degree-$(d-2)$ and every other vertex has degree-d.

Note that X is a d-regular infinite graph. The main result of this section is:

▶ **Lemma 19.** $\rho(A_X) \le 2\sqrt{d-1}$.

To prove Lemma 19, we instead turn our attention to the nonbacktracking matrix of X, called B_X. In particular, we bound $\rho(B_X)$ and then employ the Ihara–Bass formula of [7] for infinite graphs to translate the bound on $\rho(B_X)$ into a bound on $\rho(A_X)$.

Thus, we first prove:

▶ **Lemma 20.** $\rho(B_X) \le \sqrt{d-1}$.

We use the following version of the Ihara–Bass formula of [7] for infinite graphs.

▶ **Theorem 21.** *Let G be a (possibly infinite) graph. Then*

$$\mathsf{spec}(B_G) = \{\pm 1\} \cup \{\lambda : (D_G - I) - \lambda A_G + \lambda^2 I \text{ is not invertible}\}.$$

An immediate corollary that we will use is:

▶ **Corollary 22.** *Let G be a d-regular graph. Then $\rho(B_G) \le \sqrt{d-1}$ implies that $\rho(A_G) \le 2\sqrt{d-1}$.*

Proof. If there is μ in $\mathsf{spec}(A_G)$ such that $|\mu| > 2\sqrt{d-1}$, then $\mu I - A_G$ is not invertible. Consequently, by Theorem 21 $\lambda = \frac{\mu+\sqrt{\mu^2-4(d-1)}}{2}$, which is greater than $\sqrt{d-1}$, is in $\mathsf{spec}(B_G)$. ◀

In light of Corollary 22, we see that Lemma 20 implies Lemma 19.

Towards proving Lemma 20, we first make a definition.

---

[2] Since $\ell_2(V)$ comes equipped with the inner product $\langle f, g\rangle := \sum_{v\in V} f(v)g(v)$, T^* is simple the "transpose" of T.

▶ **Definition 23.** *We call a walk W a $(a \times b)$-linkage if it can be split into a segments, each of which is a length-b nonbacktracking walk.*

Proof of Lemma 20. By Observation 15

$$\rho(B_X) = \limsup_{\ell \to \infty} \|B_X^\ell\|^{1/\ell}.$$

Since $\|B_X^\ell\| = \sqrt{\rho(B_X^\ell (B_X^*)^\ell)}$ it suffices to bound $\rho(T)$ where $T := B_X^\ell (B_X^*)^\ell$ is a bounded self-adjoint operator, and hence by Observation 16:

$$\rho(T) = \max_{uv \in \vec{E}(X)} \limsup_{k \to \infty} |\langle 1_{uv}, T^k 1_{uv} \rangle|^{1/k}.$$

The quantity $\langle 1_{uv}, T^k 1_{uv} \rangle$ is bounded by the number of $(2k \times (\ell+1))$-linkages that start and end at vertex u, which we can bound via an encoding argument. In particular, we will give an algorithm to uniquely encode such linkages and bound the total number of possible encodings.

3.1 Encoding Linkages

Each length-$(\ell+1)$ nonbacktracking segment can be broken into 3 consecutive phases (of which some can possibly be empty): the phase where distance to H decreases on each step (Phase 1), the second phase where distance to H does not change on each step (Phase 2), and the third phase where distance to H increases on each step (Phase 3). We further break the third phase into two (possibly empty) subphases – the first subphase where the distance to u decreases on each step (Phase 3a), and the second subphase where the distance to u increases on each step (Phase 3b).

To encode the linkage, for each length-$(\ell+1)$ nonbacktracking we specify four numbers denoting the lengths of Phases 1, 2, 3a, and 3b. Note that Phase 2 is nonempty only if it is contained in H. For each step ab in Phase 2 that goes from U (the $(d-1)$-regular partition) to V (the 2-regular partition) we specify a number i in $[d-1]$ such that b is the ith neighbor of a within H. If the first step ab in Phase 2 is from V to U we specify a number in $[2]$ denoting if b is the first or second neighbor of a. For each step ab in Phase 3b we specify a number i in $[d-1]$ such that b is the ith neighbor of a that does not lie in the path between between u and H.

3.2 Recovering Linkages from Encodings

We recover a linkage from its encoding "segment-by-segment". Suppose the first t segments have been recovered, we show how to recover the $(t+1)$-th segment. Let x be the vertex the walk is at after it has traversed the first t segments. The steps taken in Phase 1 can be recovered from the length of the Phase since there is a unique path from any vertex to H. The steps in Phase 2 alternate between stepping from V to U and from U to V. It is easy to recover the first step of Phase 2 as well as any step from U to V; a step ab from V to U that is not the first step of Phase 2 is uniquely determined by the previous step, since a has 2 neighbors in U and by the nonbacktracking nature of the walk there is only one choice for b. Note that Phase 3a is nonempty only if u is not in H and all the steps are contained in the same branch as u. Since there is a unique shortest path between the start vertex of Phase 3a and u, the steps taken in Phase 3a can be recovered from its length. Finally, it is easy to recover the steps taken in Phase 3b since they are explicitly given in the encoding.

3.3 Counting Encodings

Now we turn our attention to bounding the total number of encodings. For given $\alpha, \beta \geq 0$ such that $\alpha + \beta = 2k(\ell+1)$ we first bound the number of walks such that α steps occur in Phase 2 (i.e. are within H) and β steps occur outside Phase 2 (i.e. are outside H). Let $v_1, v_2, \ldots, v_{2k(\ell+1)}$ be the sequence of vertices visited by the walk in order. By $d(x,y)$ we denote the graphical distance between vertices x and y, and for a set of vertices A, we write $d(x,A) := \min_{y \in A} d(x,y)$. Since $d(v_1, H) = d(v_{2k(\ell+1)}, H)$, $|d(v_i, H) - d(v_{i+1}, H)| \leq 1$ always and $|d(v_i, H) - d(v_{i+1}, H)| = 0$ for every step in Phase 2, the number of steps of the walk that occur in Phase 3 of their respective segments is at most $\frac{\beta}{2}$. In particular, the number of steps that occur in Phase 3b of their respective segments is bounded by $\frac{\beta}{2}$. The following bounds hold:

- The number of possible encodings of the lengths of phases is at most $(\ell+1)^{8k}$.
- The number of possible encodings of the first step of Phase 2 of each segment is at most 2^{2k}.
- The number of possible encodings of the list of U-to-V steps in Phase 2 is at most $(d-1)^{\frac{\alpha+1}{2}}$ because the steps taken in Phase 2 alternate between going from V to U and from U to V.
- The number of possible encodings of the list of steps in Phase 3b is at most $(d-1)^{\frac{\beta}{2}}$.

The above bounds combine to give a bound of

$$(\ell+1)^{8k} 2^{2k} (d-1)^{\frac{\alpha+1}{2}} (d-1)^{\frac{\beta}{2}} \leq (\ell+1)^{8k} 2^{2k} \sqrt{d-1}^{2k(\ell+1)+1}.$$

As there are at most $2k\ell$ choices for (α, β) pairs, the number of $(2k \times (\ell+1))$-linkages is at most

$$2k\ell(\ell+1)^{8k} 2^{2k} \sqrt{d-1}^{2k(\ell+1)+1}.$$

Thus,

$$\rho(T) \leq \limsup_{k \to \infty} \left(2k\ell(\ell+1)^{8k} 2^{2k} \sqrt{d-1}^{2k(\ell+1)+1}\right)^{1/k} = 4(\ell+1)^8 \sqrt{d-1}^{2(\ell+1)}.$$

Consequently,

$$\rho(B_X) \leq \limsup_{\ell \to \infty} \rho(T)^{1/2\ell} \leq \limsup_{\ell \to \infty} \left(4(\ell+1)^8 \sqrt{d-1}^{2(\ell+1)}\right)^{1/2\ell} = \sqrt{d-1}. \qquad \blacktriangleleft$$

4 High-Girth Near-Ramanujan graphs with Lossy Vertex Expansion

We will plant a high girth graph with low spectral radius within a d-regular Ramanujan graph. We will show that such a construction is a spectral expander, but has low vertex expansion. By $u \sim_G v$, we mean that u and v are adjacent in the graph G. We will write $u \sim v$ when the graph is clear from context.

Consider a $(2, d-1)$ biregular bipartite graph $H = (U, V, E)$, with vertex components U and V. U is the degree-$(d-1)$ component and V the degree-2 component. Therefore if we define $\gamma := |U|$, requiring γ to be even, then $|V| = (d-1)\gamma/2$. Call the vertices of U and V $\{u_1, \ldots, u_\gamma\}$ and $\{v_1, \ldots, v_{\gamma(d-1)/2}\}$, respectively. We connect U and V in such a way to maximize the girth of H.

▶ **Lemma 24.**

$$g(H) \geq 2 \log_{d-1} \gamma.$$

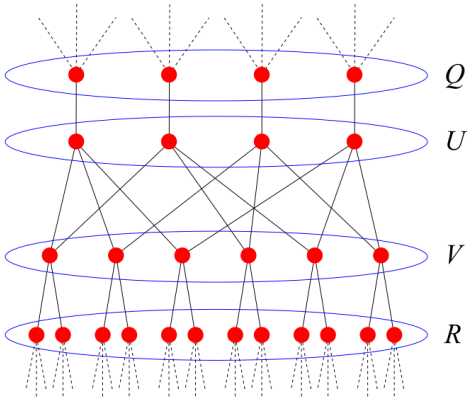

Figure 1 H', with labeled components for $d = 4$, $\gamma = 4$. Note that $\Psi(U) = (d+1)/2$. To create G', we connect Q and R to a well spaced matching in G.

Proof. Because of the valency conditions on H, there is a graph $\tilde{H}$ on γ vertices $\{\tilde{u}_1, \ldots, \tilde{u}_\gamma\}$, where $\tilde{u}_i \sim_{\tilde{H}} \tilde{u}_j$ if and only if $\exists v_k \in H$ such that $u_i \sim_H v_k$ and $u_j \sim_H v_k$. Namely, U corresponds to the vertex set of $\tilde{H}$, and V corresponds to the edge set. $\tilde{H}$ is $d-1$ regular, and, as paths in $\tilde{H}$ of length r correspond to paths of length $2r$ in H, $g(H) = 2g(\tilde{H})$.

By a result of Linial and Simkin [17], there exists a graph $\tilde{H}$ that has girth at least $c \log_{d-2} \gamma$, for any $c \in (0,1)$, assuming γ is even. Therefore by setting $c = \log(d-2)/\log(d-1)$, we have that $g(\tilde{H}) \geq \log_{d-1} \gamma$ and $g(H) \geq 2 \log_{d-1} \gamma$. ◀

We add a new set of vertices $Q = \{q_1, \ldots, q_\gamma\}$ and add a matching between Q and U, adding the edge $q_i u_i$ for $1 \leq i \leq \gamma$. Similarly, we add another set of vertices $R = \{r_{i,j}\}, 1 \leq i \leq \gamma(d-1)/2, 1 \leq j \leq d-2$. For each $1 \leq i \leq \gamma(d-1)/2$, we then add an edge from v_i to each of $r_{i,j}$ for $1 \leq j \leq (d-2)$.

We call H' the graph on $U \cup V \cup Q \cup R$. At this point vertices of U and V have degree-d, and vertices of Q and R have degree-1. Also, note $\Psi(U) = (d+1)/2$. We wish to embed H' into a larger, high girth expander, and show that this new graph maintains high girth and expansion, even though the set U is a lossy vertex expander. Our argument follows that of [16, Section 5], but instead of embedding individual vertices, we will embed H'.

▶ **Theorem 25** (Theorem 1 in more detail). *For every $d = p+1$ for prime $p \geq 3$, there is an infinite family of d-regular graphs $G_m = (V_m, E_m)$ on m vertices, such that $\exists U_m \subset V_m$ with $\Psi(U_m) = (d+1)/2$ for $|U_m| \leq m^{1/3}$, $g(G_m) = (\frac{2}{3} - o_m(1)) \log_{d-1} m$, and such that $\lambda(G_m) \leq 2\sqrt{d-1} + O(1/\log_{d-1} m)$.*

Proof. By the result of Lubotzky, Phillips and Sarnak [18], for such d, there exists an infinite family of d-regular graphs, where graphs of n vertices have girth $(\frac{4}{3} - o_n(1)) \log_{d-1} n$ and have spectral expansion $\leq 2\sqrt{d-1}$.

For a given graph $G = (V, E)$ of this type of size n, we attach H' by removing a matching $M \subset E$, $M = \{(a_{1,1}, a_{1,2}), \ldots, (a_{k,1}, a_{k,2})\}$ for

$$k := \gamma(d-1)(2 + (d-1)(d-2))/4. \tag{1}$$

We take a matching such that the pairwise distance between edges in the matching is maximized in G.

▶ **Lemma 26.** *In a d-regular graph on n vertices, there exists a matching M of size k such that for every pair of edges $(a_{i_1,1}, a_{i_1,2}), (a_{i_2,1}, a_{i_2,2}) \in M$, $i_1 \neq i_2$,*

$$d((a_{i_1,1}, a_{i_1,2}), (a_{i_2,1}, a_{i_2,2})) \geq \log_{d-1} n - \log_{d-1} \gamma - O_n(1).$$

Proof. For a given pair of adjacent vertices $(a_{i,1}, a_{i,2})$, as our graph is d regular, there are at most $1 + d\frac{(d-1)^r - 1}{d-2}$ vertices at distance at most r from $a_{i,1}$, and at most $(d-1)^r$ vertices at distance r from $a_{i,2}$ and distance $r+1$ from $a_{i,1}$. Therefore for any $d \geq 4$, the number of edges at distance at most r from a given edge is less than $4(d-1)^r$. We then greedily add edges by choosing an arbitrary edge with vertices at distance at least r away from all already chosen edges. A kth such edge will exist as long as $4k(d-1)^r \leq n$. For our k given in (1) we can set $r = \log_{d-1} n - \log_{d-1} \gamma - O_n(1)$. ◀

To connect H' to G, we first delete the matching M. Then for every vertex of Q and R, we add $d-1$ edges to the set of vertices of M, connecting to each vertex of M exactly once. Namely, the induced subgraph on $(Q \cup R) \cup M$ is a $(d-1, 1)$ biregular bipartite graph. Call $G' = (V', E')$ the new graph formed from G and H'.

We wish to show that G' remains high girth and a good spectral expander. For the girth of G', cycles are either completely contained in H', completely contained in G, or a mix between the two. Cycles in H' have length at least $2\log_{d-1} \gamma$ by Lemma 24. Cycles in G have length at least $(\frac{4}{3} - o_n(1)) \log_{d-1} n$ by the construction of [18]. For cycles that are a mix of H' and G, we must go from one vertex of H' to another vertex of H' through G. Therefore by Lemma 26, the length of such a cycle is at least $\log_{d-1} n - \log_{d-1} \gamma - O_n(1)$, giving

$$g(G') \geq \min\{2\log_{d-1} \gamma, \log_{d-1} n - \log_{d-1} \gamma - O_n(1)\}.$$

To show that the spectrum is not adversely affected, we follow the argument of [16, Theorem 5.2], with some adjustments. For our new graph, assume that there is an eigenvector $g \perp \mathbf{1}$ corresponding to an eigenvalue $|\mu| > 2\sqrt{d-1}$.

Call A the adjacency matrix of G', and A_G the adjacency matrix of G padded with zeros so it is of the same size as A. Then we have

$$g^* A g = g_G^* A_G g_G + g_{H'}^* A g_{H'} - 2\sum_{i=1}^{k} g(a_{i,1}) g(a_{i,2}) + \sum_{\substack{u \in Q \cup R \\ a_{i,j} \in M \\ u \sim a_{i,j}}} g(u) g(a_{i,j})$$

where g_G and $g_{H'}$ are the projections of g onto G and H', respectively.

We know that

$$|g_G^* A_G g_G| \leq 2\sqrt{d-1}||g_G||^2 + \frac{d}{n}\left(\sum_{u \in G} g(u)\right)^2$$

by decomposing g into parts parallel and perpendicular to the all ones vector.

By a combination of Lemma 19 and Corollary 18, the spectral radius of H' is at most $2\sqrt{d-1}$, and therefore we have

$$|g_G^* A_G g_G| + |g_{H'}^* A g_{H'}| \leq 2\sqrt{d-1}||g||^2 + \frac{d}{n}\left(\sum_{u \in H'} g(u)\right)^2$$

as $\sum_G g(u) = -\sum_{H'} g(u)$, considering $g \perp \mathbf{1}$.

To show that $|\mu| = 2\sqrt{d-1} + O(1/\log n)$, we then need to show

$$\frac{1}{\|g\|^2}\left(\frac{d}{n}\left(\sum_{H'} g_{H'}(u)\right)^2 - 2\sum_{i=1}^{k} g(a_{i,1})g(a_{i,2}) + \sum_{\substack{u\in Q\cup R\\ a_{i,j}\in M\\ u\sim a_{i,j}}} g(u)g(a_{i,j})\right) = O\left(\frac{1}{\log n}\right). \quad (2)$$

The first term of (2) can be bounded as

$$\frac{d}{n}\left(\sum_{H'} g_{H'}(u)\right)^2 \leq \frac{d}{n}|H'|\,\|g_{H'}\|^2 \leq \frac{\gamma(2+(d-1)(d-2))d}{2n}\|g_{H'}\|^2. \quad (3)$$

The second term we can bound as

$$\left|2\sum_{i=1}^{k} g(a_{i,1})g(a_{i,2})\right| \leq \sum_{a_{i,j}\in M} g(a_{i,j})^2. \quad (4)$$

Now we will bound the last term of (2) using the Cauchy-Schwarz inequality.

$$\left|\sum_{\substack{u\in Q\cup R\\ a_{i,j}\in M\\ u\sim a_{i,j}}} g(u)g(a_{i,j})\right| \leq \sqrt{(d-1)\sum_{u\in Q\cup R} g(u)^2}\sqrt{\sum_{a_{i,j}\in M} g(a_{i,j})^2}. \quad (5)$$

We use the following lemma to bound the right hand sides of (4) and (5). The lemma is a generalized version of [16, Lemma 5.1]. The result follows from the same proof, which we reproduce for completeness. Here, for two vectors $a, b \in \mathbb{R}^n$, $a \leq b$ if $\forall i \in [n], a(i) \leq b(i)$.

▶ **Lemma 27** (Lemma 5.1 of [16]). *Consider a graph on a vertex set W, a subset X of W, a positive integer h, and $s \in L^2(W)$. Let X_i be the set of nodes at distance i from X. Assume the following conditions hold:*

(1) *For $h-1 \leq i, j \leq h$, all nodes in X_i have the same number of neighbors in X_j.*

(2) *If $u \in X_{h-1}$ and $v \in X_h$ and $u \sim v$, then $s(u)/s(v)$ does not depend on the choices of u and v.*

(3) *s is nonnegative and $As \leq \mu s$ on $\mathrm{Ball}_{h-1}(X)$, where μ is a positive real number.*

Proof. Let A be the adjacency matrix of W. Let P_{h-1} and $P_h(X)$ be the orthogonal projections onto X_{h-1} and onto X_h, respectively. Let $P_{\leq h-1}$ and $P_{\leq h}(X)$ be the orthogonal projections onto $\mathrm{Ball}_{h-1}(X)$ and $\mathrm{Ball}_h(X)$, respectively. We need to show that

$$\frac{\|P_h g\|^2}{\|P_h s\|^2} \geq \frac{\|P_{h-1} g\|^2}{\|P_{h-1} s\|^2}.$$

Call $A_h = P_{\leq h} A P_{\leq h}$ (so A_h performs the adjacency operator on $\mathrm{Ball}_h(X)$). By the conditions of the lemma, we know that there are constants α, β and γ such that

$$P_h A_h s = \gamma P_h s \quad (6)$$

and

$$A_h P_h s = \alpha P_h s + \beta P_{h-1} s. \quad (7)$$

By assumption,

$$A_h s \le \mu P_{\le h-1} s + \gamma P_h s. \tag{8}$$

Therefore by applying $P_{\le h-1}$ to both sides of (8),

$$\begin{aligned} P_{\le h-1} A_h s &\le \mu P_{\le h-1} s \\ &\le \mu P_{\le h} s - \mu P_h s. \end{aligned}$$

Now we apply A_h to both sides:

$$\begin{aligned} A_h P_{\le h-1} A_h s &\le \mu A_h s - \mu A_h P_h s \\ &\le \mu A_h s - \mu(\alpha P_h s + \beta P_{h-1} s) && \text{by (7)} \\ &\le \left(\mu^2 P_{\le h-1} + \mu(\gamma-\alpha) P_h - \mu\beta P_{h-1}\right) s. && \text{by (8)} \end{aligned}$$

Define the matrix $B := \mu^2 P_{\le h-1} + \mu(\gamma-\alpha)P_h - \mu\beta P_{h-1} - A_h P_{h-1} A_h$. B has no positive entries on the off-diagonal. Take any eigenvector ψ of B. Without loss of generality assume that ψ has a positive entry. Then take $i = \operatorname{argmax}_u \psi(u)/s(u)$. As $\psi \le (\psi(i)/s(i))s$, $(B\psi)(i) \ge (B(\psi(i)/s(i))s)(i)$. The quantity on the right is nonnegative, meaning that the eigenvalue with eigenvector ψ is nonnegative. As ψ was arbitrary, B is positive semidefinite.

Because B is positive semidefinite,

$$g^* A_h P_{\le h-1} A_h g \le g^* \left(\mu^2 P_{\le h-1} + \mu(\gamma-\alpha)P_h - \mu\beta P_{h-1}\right) g. \tag{9}$$

For any orthogonal projection P, $P^2 = P$. Therefore $g^* A_h P_{\le h-1} A_h g = \|P_{\le h-1} A_h g\|^2$. Moreover (9) becomes

$$\|P_{\le h-1} A_h g\|^2 \le \mu^2 \|P_{\le h-1} g\|^2 + \mu(\gamma-\alpha)\|P_h g\|^2 - \mu\beta\|P_{h-1} g\|^2.$$

By assumption, $\|P_{\le h} A_h g\| = \mu \|P_{\le h} g\|$. Therefore

$$(\gamma-\alpha)\|P_h g\|^2 \ge \beta \|P_{h-1} g\|^2. \tag{10}$$

As A_h and P_h are self adjoint, $s^* A_h P_h s = s^* P_h A_h s$, so $\alpha\|P_h s\|^2 + \beta\|P_{h-1}\|^2 = \gamma\|P_h s\|^2$. Combining this with (10), we obtain (11). ◀

For any $g \in L^2(W)$ such that $|Ag(u)| = \mu|g(u)|$ for $u \in \mathrm{Ball}_{h-1}(X)$, we have

$$\frac{\sum_{v\in X_h} g(v)^2}{\sum_{v\in X_h} s(v)^2} \ge \frac{\sum_{v\in X_{h-1}} g(v)^2}{\sum_{v\in X_{h-1}} s(v)^2}. \tag{11}$$

To use the lemma, we set $X_0 = U \cup V$, and h will vary from $2 \le h \le \lfloor r/2 \rfloor$. Assuming that the girth of G' is at least r, the $\lfloor r/2 \rfloor$ neighborhoods of each vertex do not overlap.

Our test vector decays exponentially, with a small adjustment.

$$s(y) = \begin{cases} \frac{1}{(d-1)^{h/2}} & y \in X_{h,U} \\ \frac{2}{\sqrt{d-1}} - \frac{1}{(d-1)^{3/2}} & y \in X_{0,V} \\ \left(\frac{2}{d-2} - \frac{2}{(d-1)(d-2)}\right)\frac{1}{(d-1)^{(h-1)/2}} & y \in X_{h,V}, h \ge 1. \end{cases}$$

For this assignment of values we have $As \le (2\sqrt{d-1})s$. In fact, this inequality is sharp at all coordinates except for $y \in X_{1,V}$.

For this s, we have that $\sum_{y\in X_h} s(y)^2$ is constant for $h = 1,\dots,\lfloor r/2\rfloor$. Also, recall $Q\cup R = X_1$ and $M = X_2$. By Lemma 27, as g corresponds to an eigenvalue $|\mu| > 2\sqrt{d-1}$, the mass on each of first 2 layers of X can only be at most $2/(r-2)$ of the total mass.

Combining (3), (4), and (5), we can bound (2) as

$$\begin{aligned}(2) &\le \frac{\gamma(2+(d-1)(d-2))d}{2n}\|g_{H'}\|^2 + \sum_{a\in X_2} g(a)^2 + \sqrt{(d-1)\sum_{u\in X_1} g(u)^2}\sqrt{\sum_{a\in X_2} g(a)^2}\\ &\le \left(\frac{\gamma(2+(d-1)(d-2))d}{2n} + (1+\sqrt{d-1})\frac{2}{r-2}\right)\|g\|^2.\end{aligned}$$

If we set $\gamma = n^{1/3}$ and $r = \frac{2}{3}\log_{d-1} n - O_n(1)$, for fixed d this becomes

$$O\left(\frac{1}{\log n}\right)\|g\|^2,$$

meaning that $\mu \le 2\sqrt{d-1} + O(1/\log n)$. This also gives the desired bounds on vertex expansion and girth, by setting $U = U_m$. Because $|V'| = (1+o_n(1))n$, the bounds on $\Psi(U_m)$, $g(G')$ and $\lambda(G')$ given in terms of n do not change when they are given in terms of m. ◀

5 Lossless Expansion of Small Sets

In this section, we prove that sufficiently small sets in a high-girth spectral expander expand losslessly.

▶ **Theorem 28** (Theorem 2 in detail). *Let G be a d-regular graph on n vertices with girth at least $2\alpha\log_{d-1} n + 4$. Then for any set S with n^κ vertices,*

$$\frac{|\Gamma(S)|}{|S|} \ge d - \lambda(G) - \frac{d^{2\kappa/\alpha}}{2} - \frac{d}{n^{1-\kappa}}.$$

Proof. Let S be a set of vertices of size n^κ in G. Let e_S denote the number of internal edges within S. Let n_i denote the number of vertices in $\Gamma(S)$ that have i edges from S incident to it. Then: $|\Gamma(S)| = n_1 + n_2 + \cdots + n_d$ and $|E(S,\Gamma(S))| = n_1 + 2n_2 + \cdots + dn_d$. Note that $|E(S,\Gamma(S))|$ is also equal to $d|S| - 2e_S$. Now consider the graph H_S on vertex set S and edge set given by induced edges on S along with new edges introduced by adding an arbitrary spanning tree for every set of i vertices that are neighbors of a vertex in $\Gamma(S)$ with exactly i neighbors in S. The number of edges in H_S is equal to

$$e_S + n_2 + 2n_3 + \cdots + (d-1)n_d = e_S + |E(S,\partial S)| - |\Gamma(S)| = d|S| - e_S - |\Gamma(S)|.$$

The edges in H_S that are not in G correspond to paths of length at most 2 in G. Therefore $g(H_S) \ge \frac{1}{2}g(G) \ge \alpha\log_{d-1} n + 2$. As a consequence of the expander mixing lemma (Lemma 10), $e_S \le \left(\lambda(G) + \frac{d|S|}{n}\right)|S|$. Consequently,

$$|E(H_S)| \ge \left(d - \lambda(G) - \frac{d|S|}{n}\right)|S| - |\Gamma(S)|,$$

which means the average degree is lower bounded by

$$2\left(d - \lambda(G) - \frac{d|S|}{n} - \frac{|\Gamma(S)|}{|S|}\right).$$

Thus by the irregular Moore bound (Lemma 11),

$$g(H_S) \leq \frac{2\log n^\kappa}{\log\left(2\left(d-\lambda(G)-\frac{d|S|}{n}-\frac{|\Gamma(S)|}{|S|}\right)-1\right)}+2$$

and hence

$$\frac{\alpha}{\log(d-1)} \leq \frac{2\kappa}{\log\left(2\left(d-\lambda(G)-\frac{d|S|}{n}-\frac{|\Gamma(S)|}{|S|}\right)-1\right)}.$$

This implies

$$d-\lambda(G)-\frac{d|S|}{n}-\frac{|\Gamma(S)|}{|S|}-\frac{1}{2} \leq \frac{d^{2\kappa/\alpha}}{2},$$

and finally by rearranging the above and plugging in $|S| = n^\kappa$

$$\frac{|\Gamma(S)|}{|S|} \geq d-\lambda(G)-\frac{d^{2\kappa/\alpha}-1}{2}-\frac{d}{n^{1-\kappa}}.$$ ◀

▶ Remark 29. If G is a n-vertex d-regular Ramanujan graph with girth $\frac{4}{3}\log_{d-1} n$ (which is a condition satisfied by the Ramanujan graphs of [18]) then for every set S of size n^κ for $\kappa < 1/3$,

$$\frac{|\Gamma(S)|}{|S|} \geq d(1-o_d(1)).$$

Abstract

This paper gives a k-means approximation algorithm that is efficient in the *relational algorithms model*. This is an algorithm that operates directly on a relational database without performing a join to convert it to a matrix whose rows represent the data points. The running time is potentially exponentially smaller than N, the number of data points to be clustered that the relational database represents.

Few relational algorithms are known and this paper offers techniques for designing relational algorithms as well as characterizing their limitations. We show that given two data points as cluster centers, if we cluster points according to their closest centers, it is NP-Hard to approximate the number of points in the clusters on a general relational input. This is trivial for conventional data inputs and this result exemplifies that standard algorithmic techniques may not be directly applied when designing an efficient relational algorithm. This paper then introduces a new method that leverages rejection sampling and the k-means++ algorithm to construct a $O(1)$-approximate k-means solution.

1 Introduction

Kaggle surveys [2] show that the majority of learning tasks faced by data scientists involve *relational data*. Conventional formats usually represent data with multi-dimensional points where each dimension corresponds to a feature of the data. In contrast, a **relational database** consists of tables $T_1, T_2, \ldots, T_m$ where the features could be stored partially in the tables. The columns in each table are a subset of features[1] and the rows are data records for

[1] In relational database context the columns are also referred to as *attributes* but here we call them features per the tradition of broader communities.

these features. The underlying data is represented by the **design matrix** $J = T_1 \bowtie \cdots \bowtie T_m$ where each row in J can be interpreted as a data point. Here the **join** ($\bowtie$) is a binary operator on two tables T_i and T_j. The result of the join is the set of all possible concatenations of two rows from T_i and T_j such that they are equal in their common columns/features. If T_i and T_j have no common columns their join is the cross product of all rows. See Table 1 for an example of join operation on two tables.

Table 1 A join of tables T_1 and T_2. Each has 5 rows and 2 features, sharing f_2. The join has all features from both tables. The rows with $f_2 = x$ in the join is the cross product of all rows with $f_2 = x$ from T_1 and T_2. For example, for $f_2 = 1$, the four rows in $T_1 \bowtie T_2$ has (f_1, f_3) values $\{(1,1),(1,2),(2,1),(2,2)\}$, this is the cross product of $f_1 \in \{1,2\}$ from T_1 and $f_3 \in \{1,2\}$ from T_2.

Almost all learning tasks are designed for data in matrix format. The current standard practice for a data scientist is the following.

Standard Practice:

1. Extract the data points from the relational database by taking the join of all tables to find the design matrix $J = T_1 \bowtie \cdots \bowtie T_m$.
2. Then interpret each row of J as a point in a Euclidean space and the columns as the dimensions, corresponding to the features of data.
3. Import this design matrix J into a standard algorithm.

A relational database is a highly compact data representation format. The size of J can be exponentially larger than the input size of the relational database [10]. Extracting J makes the standard practice inefficient. Theoretically, there is a potential for exponential speed-up by running algorithms *directly* on the tables in relational data. We call such algorithms **relational algorithms** if their running time is polynomial in the size of tables when the database is *acyclic*. Acyclic databases will be defined shortly. This leads to the following exciting algorithmic question.

The Relational Algorithm Question:

A. Which standard algorithms can be implemented as relational algorithms?

B. For standard algorithms that are *not* implementable by relational algorithms, is there an alternative efficient relational algorithm that has similar performance?

This question has recently been of interest to the community. However, few algorithmic techniques are known. Moreover, we do not have a good understanding of which problems can be solved on relational data and which cannot. Relational algorithm design has a interesting combinatorial structure that requires a deeper understanding.

We design a relational algorithm for k-means. It has a polynomial time complexity for **acyclic** relational databases. The relational database is acyclic if there exists a tree with the following properties. There is exactly one node in the tree for each table. Moreover, for any feature (i.e. column) f, let $V(f)$ be the set of nodes whose corresponding tables contain feature f. The subgraph induced on $V(f)$ must be a connected component. Acyclicity can be easily checked, as the tree can be found in polynomial time if it exists [27].

Luckily, most of the natural database schema are acyclic or nearly acyclic. Answering seemingly simple questions on general (cyclic) databases, such as if the join is empty or not is NP-Hard. For general databases, efficiency is measured in terms of the **fractional hypertree width** of the database (denoted by "fhtw"). The parameter measures how close the database structure is to being acyclic. It is 1 for acyclic databases and larger as the database is farther from being acyclic.

State-of-the-art algorithms for queries as simple as counting the number of rows in the design matrix have linear dependency on n^{fhtw} where n is the *maximum* number of rows in all input tables [7]. Running in time linear in n^{fhtw} is the goal, as fundamental barriers need to be broken to be faster. Notice that this is polynomial time when fhtw is a fixed constant (i.e. nearly acyclic). Our algorithm has linear dependency on n^{fhtw}, matching the state-of-the-art.

Relational Algorithm for k-means. k-means is perhaps the most widely used data mining algorithm (e.g. k-means is one of the few models in Google's BigQuery ML package [1]). The input to the k-means problem consists of a collection S of points in a Euclidean space and a positive integer k. A feasible output is k points $c_1, \ldots, c_k$, which we call **centers**. The objective is to choose the centers to minimize the aggregate squared distance from each original point to its nearest center.

Recall extracting all data points could take time exponential in the size of a relational database. Thus, the problem is to find the cluster centers without fully realizing all of the data points the relational data represents.

[15] was the first paper to give a non-trivial k-means algorithm that works on relational inputs. The paper gives an $O(1)$-approximation. The algorithm's running time has superlinear dependency on k^d when the tables are acyclic and thus is not polynomial. Here k is the number of cluster centers and d is the dimension (a.k.a number of features) of the points. This is equivalently the number of distinct columns in the relational database. For a small number of dimensions, this algorithm is a large improvement over the standard practice and they showed the algorithm gives up to 350x speed up on real data versus performing the query to extract the data points (not even including the time to cluster the output points).

Several questions remain. Is there a relational algorithm for k-means? What algorithmic techniques can we use as building blocks to design relational algorithms? Moreover, how can we show some problems are hard to solve using a relational algorithm?

Overview of Results. The main result of the paper is the following.

▶ **Theorem 1.** *Given an acyclic relational database with tables $T_1, T_2, \ldots T_m$ where the design matrix J has N rows and d columns. Let n be the maximum number of rows in any table. Then there is a randomized algorithm running in time polynomial in d, n and k that computes an $O(1)$ approximate k-means clustering solution with high probability.*

The discussion about the algorithm's time complexity for cyclic databases is left out due to space limits. To illustrate the challenges for finding such an algorithm as described in the prior theorem, even when the database is acyclic, consider the following theorem.

▶ **Theorem 2.** *Given an acyclic relational database with tables $T_1, T_2, \ldots T_m$ where the design matrix J has N rows and d columns. Given k centers $c_1, \ldots, c_k$, let J_i be the set of points in J that are closest to c_i for $i \in [k]$. It is #P-Hard to compute $|J_i|$ for $k \geq 2$ and NP-Hard to approximate $|J_i|$ to any factor for $k \geq 3$.*

We show the proof in Section 2.1. We prove it by reducing a NP-Hard problem to the problem of determining if J_i is empty or not. Counting points closest to a center is a fundamental building block in almost all k-means algorithms. Moreover, we note that performing one iteration of the classic Lloyd's algorithm, that is, to re-compute the centroids of all J_i's, is also $\#P$-Hard. The proof is omitted here.

Together this necessitates the design of new techniques to address the main theorem, shows that seemingly trivial algorithms are difficult relationally, and suggests computing a coreset is the right approach for the problem as it is difficult to cluster the data directly.

Overview of Techniques. We first compute a **coreset** of all points in J. That is, a collection of points with weights such that if we run an $O(1)$ approximation algorithm on this weighted set, we will get a $O(1)$ approximate solution for all of J. To do so, we sample points according to the principle in k-means++ algorithm and assign weights to the points sampled. The number of points chosen will be $\Theta(k \log N)$. Any $O(1)$-approximate weighted k-means algorithm can be used on the coreset to give Theorem 1.

k-means++. k-means++ is a well-known k-means algorithm [9, 8]. The algorithm iteratively chooses centers $c_1, c_2, \ldots$. The first center c_1 is picked uniformly from J. Given that $c_1, \ldots, c_{i-1}$ are picked, a point x is picked as c_i with probability $P(x) = \frac{L(x)}{Y}$ where $L(x) = \min_{j \in [i-1]}(\|x - c_j\|_2^2)$ and $Y = \sum_{x \in J} L(x)$. Here $[i-1]$ denotes $\{1, 2, \ldots, i-1\}$.

Say we sample $\Theta(k \log N)$ centers according to this distribution, which we call the ***k*-means++ distribution**. It was shown in [8] that if we cluster the points by assigning them to their closest centers, the total squared distance between points and their cluster centers is at most $O(1)$ times the optimal k-means cost with high probability. Note that this is not a feasible k-means solution because more than k centers are used. However, leveraging this, the work showed that we can construct a coreset by weighting these centers according to the number of points in their corresponding clusters.

We seek to mimic this approach with a relational algorithm. Let's focus on one iteration where we want to sample the center c_i given $c_1, \ldots, c_{i-1}$ according to the k-means++ distribution. Consider the assignment of every point to its closest center in $c_1, \ldots, c_{i-1}$. Notice that the k-means++ probability is determined by this assignment. Indeed, the probability of a point being sampled is the cost of assigning this point to its closest center $(\min_{j \in [i-1]} \|x - c_j\|_2^2)$ normalized by Y. Y is the summation of this cost over all points.

The relational format makes this distribution difficult to compute without the design matrix J. It is hard to efficiently characterize which points are closest to which centers. The assignment *partitions* the data points according to their closest centers, where each partition may not be easily represented by a compact relational database (unlike J).

A Relational k-means++ Implementation. Our approach will sample every point according to the k-means++ distribution without computing this distribution directly. Instead, we use **rejection sampling** [13], which allows one to sample from a "hard" distribution P using an "easy" distribution Q. Rejection sampling works by sampling from Q first, then reject the sample with another probability used to bridge the gap between Q and P. The process is repeated until a sample is accepted. In our setting, P is the k-means++ distribution, and we need to find a Q which could be sampled from efficiently with a relational algorithm (without computing J). Rejection sampling theory shows that for the sampling to be efficient, Q should be close to P point-wise to avoid high rejection frequency. In the end, we will *perfectly simulate* the k-means++ algorithm.

We now describe the intuition for designing such a Q. Recall that P is determined by the assignment of points to their closest centers. We will approximate this assignment up to a factor of $O(i^2d)$ when sampling the i^{th} center c_i, where d is the number of columns in J. Intuitively, the approximate assignment makes things easier since for any center we can easily find the points assigned to it using an efficient relational algorithm. Then Q is found by normalizing the squared distance between each point and its assigned center.

The approximate assignment is designed as follows. Consider the d-dimensional Euclidean space where the data points in J are located. The algorithm divides space into a **laminar** collection of **hyper-rectangles**[2] (i.e., $\{x \in \mathcal{R}^d : v_j \leq x_j \leq w_j, j = 1, \ldots, d\}$, here x_j is the value for feature f_j). We assign each hyper-rectangle to a center. A point assigns itself to the center that corresponds to the *smallest* hyper-rectangle containing the point.

The key property of hyper-rectangles that benefits our relational algorithm is: we can efficiently represent all points from J inside any hyper-rectangle by removing some entries in each table from the original database and taking the join of all tables. For example, if a hyper-rectangle has constraint $v_j \leq x_j \leq w_j$, we just remove all the rows with value outside of range $[v_j, w_j]$ for column f_j from the tables containing column f_j. The set of points assigned to a given center can be found by adding and subtracting a laminar set of hyper-rectangles, where each hyper-rectangle can be represented by a relational database.

Weighting the Centers. We have sampled a good set of cluster centers. In order to get a coreset we need to assign weights to them. As we have already mentioned, assuming $P \neq \#P$, the weights cannot be computed relationally. In fact, they cannot be approximated up to any factor in polynomial time unless $P = NP$. Rather, we design an alternative relational algorithm for computing the weights. Each weight will not be an approximate individually, but we prove that the weighted centers form an $O(1)$-approximate coreset in aggregate.

The main algorithmic idea is that for each center c_i we generate a collection of hyperspheres around c_i containing geometrically increasing numbers of points. The space is then partitioned using these hyperspheres where each partition contains a portion of points in J. Using the algorithm from [3], we then sample a poly-log sized collection of points from each partition, and use this subsample to estimate the fraction of the points in this partition which are closer to c_i than any other center. The estimated weight of c_i is aggregated accordingly.

Paper Organization. As relational algorithms are relatively new, we begin with some special cases which help the reader build intuition. In Section 2 we give a warm-up by showing how to implement 1-means++ and 2-means++ (i.e. initialization steps of k-means++). In this section, we also prove Theorem 2 as an example of the limits of relational algorithms. In Section 3 we go over background on relational algorithms that our overall algorithm will leverage. In Section 4 we give the k-means++ algorithm via rejection sampling. Section 5 shows an algorithm to construct the weights and then analyze this algorithm.

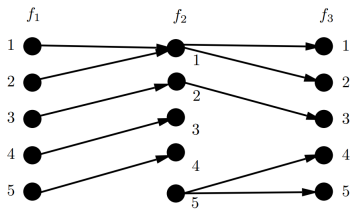
2 Warm-up: Efficiently Implementing 1-means++ and 2-means++

This section is a warm-up to understand the combinatorial structure of relational data. We will show how to do k-means++ for $k \in \{1, 2\}$ (referred to as 1- and 2-means++) on a simple join structure. We will also show the proof of Theorem 2 which states that counting the number of points in a cluster is a hard problem on relational data.

[2] A laminar set of hyper-rectangles means any two hyper-rectangles from the set either have no intersection, or one of them contains the other.

First, let us consider relationally implementing 1-means++ and 2-means++. For better illustration, we consider a special type of acyclic table structure named **path join**. The relational algorithm used will be generalized to work on more general join structures when we move to the full algorithm in Section 4.

In a path join each table T_i has two features/columns f_i, and f_{i+1}. Table T_i and T_{i+1} then share a common column f_{i+1}. Assume for simplicity that each table T_i contains n rows. The design matrix $J = T_1 \bowtie T_2 \bowtie \ldots \bowtie T_m$ has $d = m + 1$ features, one for each feature (i.e. column) in the tables.



Even with this simple structure, the size of the design matrix J could still be exponential in the size of database - J could contain up to $n^{m/2}$ rows , and $dn^{m/2}$ entries. Thus the standard practice could require time and space $\Omega(mn^{m/2})$ in the worst case.

Table 2 A path join instance where the two tables T_1 and T_2 have $m = 2$ and $n = 5$. This shows T_1, T_2, the design matrix J, and the resulting layered directed graph G. *Every* path from the left most layer to the right most layer of this graph G corresponds to one data point for the clustering problem (i.e. a row of the design matrix).

Graph Illustration of the Design Matrix. Conceptually consider a directed acyclic graph G, where there is one layer of nodes corresponding to each feature $f_i (i = 1, \ldots, d)$, and edges only point from nodes in layer f_i to layer f_{i+1}.

The nodes in G correspond to feature values, and edges in G correspond to rows in tables. There is one vertex v in layer f_i for each value that appears in column f_i in table T_{i-1} or T_i, and one edge pointing from u in layer f_i to v in layer f_{i+1}, if (u, v) is a row in table T_i. Then, there is a one-to-one correspondence between **full paths** in G (paths from layer f_1 to layer f_d) and rows in the design matrix.

A Relational Implementation of 1-means++. Implementing the 1-means++ algorithm is equivalent to *generating a full path uniformly at random from* G. We generate this path by iteratively picking a row from table $T_1, \ldots, T_m$, corresponding to picking an arc pointing from layer f_1 to f_2, f_2 to f_3, ..., such that concatenating all picked rows (arcs) will give a point in J (full path in G).

To sample a row from T_1, for every row $r \in T_1$, consider $r \bowtie J$, which is all rows in J whose values in columns (f_1, f_2) are equivalent to r. Let the function $F_1(r)$ denote the total number of rows in $r \bowtie J$. This is also the number of full paths passing arc r. Then, every $r \in T_1$ is sampled with probability $\frac{F_1(r)}{\sum_{r' \in T_1} F_1(r')}$, notice $\sum_{r' \in T_1} F_1(r')$ is the total number of full paths. Let the picked row be r_1.

After sampling r_1, we can conceptually throw away all other rows in T_1 and focus only on the rows in J that uses r_1 to concatenate with rows from other tables (i.e., $r_1 \bowtie J$). For any row $r \in T_2$, let the function $F_2(r)$ denote the number of rows in $r \bowtie r_1 \bowtie J$, also equivalent to the total number of full paths passing arc r_1 and r. We sample every r with probability

$\frac{F_2(r)}{\sum_{r' \in T_2} F_2(r')}$. Notice that $\sum_{r' \in T_2} F_2(r') = F_1(r_1)$, the number of full paths passing arc r_1. Repeat this procedure until we have sampled a row in the last table T_m: for table T_i and $r \in T_i$, assuming we have sampled $r_1, \ldots, r_{i-1}$ from $T_1, \ldots, T_{i-1}$ respectively, throw away all the other rows in previous tables and focus on $r_1 \bowtie \ldots \bowtie r_{i-1} \bowtie J$. $F_i(r)$ is the number of rows in $r \bowtie r_1 \bowtie \ldots \bowtie r_{i-1} \bowtie J$ and r is sampled with probability proportional to $F_i(r)$. It is easy to verify that every full path is sampled uniformly.

For every table T_i we need to find the function $F_i(\cdot)$ which is defined on all its rows. There are m such functions. For each $F_i(\cdot)$, we can find all $F_i(r)$ values for $r \in T_i$ using a one-pass dynamic programming and then sample according to the values. Repeating this procedure m rounds completes the sampling process. This gives a polynomial time algorithm.

A Relational Implementation for 2-means++. Assume $x = (x_1, \ldots, x_d)$ is the first center sampled and now we want to sample the second center. By k-means++ principles, any row $r \in J$ is sampled with probability $\frac{\|r-x\|^2}{\sum_{r' \in J} \|r'-x\|^2}$. For a full path in G corresponding to a row $r \in J$ we refer to $\|r - x\|^2$ as the **aggregated cost** over all d nodes/features.

Similar to 1-means++, we pick one row in each table from T_1 to T_m and putting all the rows together gives us the sampled point. Assume we have sampled the rows $r_1, r_2, \ldots, r_{i-1}$ from the first $i-1$ tables and we focus on all full paths passing $r_1, \ldots, r_{i-1}$ (i.e., the new design matrix $r_1 \bowtie \ldots \bowtie r_{i-1} \bowtie J$). In 1-means++, we compute $F_i(r)$ which is the total number of full paths passing arc $r_1, \ldots, r_{i-1}, r$ (i.e., $r \bowtie r_1 \bowtie \ldots \bowtie r_{i-1} \bowtie J$.) and sample $r \in T_i$ from a distribution normalized using $F_i(r)$ values. In 2-means++, we define $F_i(r)$ to be the summation of aggregated costs over all full paths which pass arcs $r_1, \ldots, r_{i-1}, r$. We sample $r \in T_i$ from a distribution normalized using $F_i(r)$ values.

It is easy to verify the correctness. Again, each $F_i(\cdot)$ could be computed using a one-pass dynamic programming which gives the values for all rows in T_i when we sample from T_i. This would involve m rounds of such computations and give a polynomial relational algorithm.

2.1 Hardness of Relationally Computing the Weights

Here we prove Theorem 2. We first show that given a set of centers, counting the number of points in J that is closest to any of them is $\#P$-hard. We prove $\#P$-Hardness by a reduction from the well known $\#P$-hard Knapsack Counting problem. The input to the Knapsack Counting problem consists of a set $W = \{w_1, \ldots, w_h\}$ of nonnegative integer weights, and a nonnegative integer L. The output is the number of subsets of W with aggregate weight at most L. To construct the relational instance, for each $i \in [h]$, we define the tables T_{2i-1} and T_{2i} as follows:

T_{2i-1}	
f_{2i-1}	f_{2i}
0	0
0	w_i

T_{2i}	
f_{2i}	f_{2i+1}
0	0
w_i	0

Let centers c_1 and c_2 be arbitrary points such that points closer to c_1 than c_2 are those points p for which $\sum_{i=1}^{d} p_i \leq L$. Then there are 2^h rows in J, since w_i can either be selected or not selected in feature $2i$. The weight of c_1 is the number of points in J closer to c_1 than c_2, which is in turn exactly the number of subsets of W with total weight at most L.

Now we prove the second part of Theorem 2: given an acyclic database and a set of centers $c_1, \ldots, c_k$, it is NP-Hard to approximate the number of points assigned to each center when $k \geq 3$. We prove it by reduction from Subset Sum. In Subset Sum problem, the input

is a set of integers $A = w_1, \ldots, w_m$ and an integer L, the output is true if there is a subset of A such that its summation is L. We create the following acyclic schema. There are m tables. Each table T_i has a single unique column x_i with two rows $w_i, 0$. Then the join of the tables has 2^m rows, and it is a cross product of the rows in different tables in which each row represents one subset of A.

Then consider the following three centers: $c_1 = (\frac{L-1}{m}, \frac{L-1}{m}, \ldots, \frac{L-1}{m})$, $c_2 = (\frac{L}{m}, \ldots, \frac{L}{m})$, and $c_1 = (\frac{L+1}{m}, \frac{L+1}{m}, \ldots, \frac{L+1}{m})$. The Voronoi diagram that separates the points assigned to each of these centers consists of two parallel hyperplanes: $\sum_i x_i = L-1/2$ and $\sum_i x_i = L+1/2$ where the points between the two hyperplanes are the points assigned to c_2. Since all the points in the design matrix have integer coordinates, the only points that are between these two hyperplanes are those points for which $\sum_i x_i = L$. Therefore, the approximation for the number of points assigned to c_2 is non-zero if and only if the answer to Subset Sum is True.

3 Related Work and Background

Related Work on K-means. Constant approximations are known for the k-means problem in the standard computational setting [20, 18]. Although the most commonly used algorithm in practice is a local search algorithm called Lloyd's algorithm, or sometimes confusingly just called "the k-means algorithm". The k-means++ algorithm from [9] is a $\Theta(\log k)$ approximation algorithm, and is commonly used in practice to seed Lloyd's algorithm. Some coreset construction methods have been used before to design algorithms for the k-means problem in other restricted access computational models, including steaming [17, 12], and the MPC model [16, 11], as well as speeding up sequential methods [21, 25].

Relational Algorithms for Learning Problem. Training different machine learning models on relational data has been studied; however, many of the proposed algorithms are not efficient under our definition of a relational algorithm. It has been shown that using repeated patterns in the design matrix, linear regression, and factorization machines can be implemented [23] more efficiently. [19, 24, 5] has improved the relational linear regression and factorization machines for different scenarios. A unified relational algorithm for problems such as linear regression, singular value decomposition and factorization machines proposed in [6]. Algorithms for training support vector machine is studied in [26, 4]. In [14], a relational algorithm is introduced for Independent Gaussian Mixture Models, and they have shown experimentally that this method will be faster than materializing the design matrix.

Relational Algorithm Building Blocks. In the path join scenario, the 1- and 2-means++ sampling methods introduced in subsection 2 have similar procedures: starting with the first table T_1, iteratively evaluate some general function $F_i(\cdot)$ defined on all rows in the table T_i, sample one row r_i according to the distribution normalized from $F_i(\cdot)$. The function $F_i(\cdot)$ for table T_i is defined on the matrix $r_1 \bowtie \ldots \bowtie r_{i-1} \bowtie J$ where J is the design matrix. This matrix is also the design matrix of a new relational database, constructed by throwing away all rows in previous tables apart from the sampled $r_1, \ldots, r_{i-1}$.

We can generalize the computation of $F_i(\cdot)$ functions into a broader class of queries that we know could be implemented efficiently on *any* acyclic relational databases, namely **SumProd queries**. See [7] for more details. In the following lemmas assume the relational database has tables $T_1, \ldots, T_m$ and their design matrix is J, let n be the maximum number of rows in each table T_i, m be the number of tables and d be the number of columns in J.

▶ **Definition 3.** *For the j^{th} feature ($j \in [d]$) let $q_j : \mathbb{R} \to S$ be an efficiently computable function that maps feature values to some set S. Let the binary operations $\oplus$ and $\otimes$ be any operators such that $(S, \oplus, \otimes)$ forms a commutative semiring. The value of $\bigoplus_{x \in J} \bigotimes_{j \in [d]} q_j(x_j)$ is a SumProd query.*

▶ **Lemma 4** ([7])**.** *Any SumProd query can be computed efficiently in time $O(md^2 n^{fhtw} \log(n))$ where fhtw is the fractional hypertree width of the database. For acyclic databases fhtw=1 so the running time is polynomial.*

Despite the cumbersome formal definition of SumProd queries, below we list their key applications used in this paper. With a little abuse of notation, throughout this paper we use $\Psi(n, d, m)$ to denote the worst-case time bound on any SumProd queries.

▶ **Lemma 5.** *Given a point $y \in \mathcal{R}^d$ and a hyper-rectangle $b = \{x \in \mathcal{R}^d : v_i \leq x_i \leq w_i, i = 1, \ldots, d\}$ where v and w are constant vectors, we let $J \cap b$ denote the data points represented by rows of J that also fall into b. Pick any table T_j. Using one single SumProd query we can compute for all $r \in T_j$ the value $\sum_{p \in r \bowtie J \cap b} \|p - y\|_2^2$. The time required is at most that required by one SumProd query, $\Psi(n, d, m)$,*

Lemma 5 is intuitively based on the fact that we can efficiently represent all points in $J \cup b$ by a new relational database, which is constructed by removing some entries in each table from the original database. The following lemma follows by an application of the main result in [3].

▶ **Lemma 6** ([3])**.** *Given a hypersphere $\{x \in \mathcal{R}^d : \|x - y_0\|^2 \leq z_0^2\}$ where y_0 is a given point and z_0 is the radius, a $(1 + \epsilon)$-approximation of the number of points in J that lie inside this hypersphere could be computed in $O\left(\frac{m^6 \log^4 n}{\epsilon^2} \Psi(n, d, m)\right)$ time.*

Notice that a SumProd query could be used to output either a scalar (similar to Lemma 6) or a vector whose entries are function values for every row r in a chosen table T_j (in Lemma 5). We say the SumProd query is **grouped by** T_j in the latter case.

4 The k-means++ Algorithm

In this section, we describe a relational implementation of the k-means++ algorithm. It is sufficient to explain how center c_i is picked given the previous centers $c_1, \ldots, c_{i-1}$. Recall that the k-means++ algorithm picks a point x to be c_i with probability $P(x) = \frac{L(x)}{Y}$ where $L(x) = \min_{j \in [i-1]} \|x - c_j\|_2^2$ and $Y = \sum_{x \in J} L(x)$ is a normalizing constant.

The implementation consists of two parts. The first part, described in Section 4.1, shows how to partition the d-dimensional Euclidean space into a laminar set of hyper-rectangles (referred to as **boxes** hereafter) that are generated around the previous centers. The second part, described in Section 4.2, samples according to the "hard" distribution P using rejection sampling and an "easy" distribution Q.

Conceptually, we assign every point in the design matrix J to an *approximately* nearest center among $c_1, \ldots, c_{i-1}$. This is done by assigning every point in J to one of the centers contained in the *smallest* box this point belongs to. Then Q is derived using the squared distance between the points in J and their assigned centers.

4.1 Box Construction

Here we explain the algorithm for constructing a set of laminar boxes given the centers sampled previously. The construction is completely combinatorial. It only uses the given centers and we don't need any relational operation for the construction.

Algorithm Description. Assume we want to sample the i^{th} point in k-means++. The algorithm maintains two collections $\mathcal{G}_i$ and $\mathcal{B}_i$ of tuples. Each tuple consists of a box and a point in that box, called the **representative** of the box. This point is one of the previously sampled centers. One can think of the tuples in $\mathcal{G}_i$ as "active" ones that are subject to changes and those in $\mathcal{B}_i$ as "frozen" ones that are finalized, thus removed from $\mathcal{G}_i$ and added to $\mathcal{B}_i$. When the algorithm terminates, $\mathcal{G}_i$ will be empty, and the boxes in $\mathcal{B}_i$ will be a laminar collection of boxes that we use to define the "easy" probability distribution Q.

The initial tuples in $\mathcal{G}_i$ consist of one *unit hyper-cube* (side length is 1) centered at each previous center c_j, $j \in [i-1]$, with its representative point c_j. Up to scaling of initial unit hyper-cubes, we can assume that initially no pair of boxes in $\mathcal{G}_i$ intersect. This property of $\mathcal{G}_i$ is maintained throughout the process. Initially $\mathcal{B}_i$ is empty. Over time, the implementation keeps growing the boxes in $\mathcal{G}_i$ in size and moves tuples from $\mathcal{G}_i$ to $\mathcal{B}_i$.

The algorithm repeats the following steps in rounds. At the beginning of each round, there is no intersection between any two boxes in $\mathcal{G}_i$. The algorithm performs a doubling step where it **doubles** every box in $\mathcal{G}_i$. Doubling a box means each of its $d-1$ dimensional face is moved twice as far away from its representative. Mathematically, a box whose representative point is $y \in \mathcal{R}^d$ may be written as $\{x \in \mathcal{R}^d : y_i - v_i \le x_i \le y_i + w_i, i = 1, \ldots, d\}$ $(v_i, w_i > 0)$. This box becomes $\{x \in \mathcal{R}^d : y_i - 2v_i \le x_i \le y_i + 2w_i, i = 1, \ldots, d\}$ after doubling.

After doubling, the algorithm performs the following operations on intersecting boxes until there are none. The algorithm iteratively picks two arbitrary intersecting boxes from $\mathcal{G}_i$. Say the boxes are b_1 with representative y_1 and b_2 with representative y_2. The algorithm executes a **melding** step on (b_1, y_1) and (b_2, y_2), which has the following procedures:

- Compute the smallest box b_3 in the Euclidean space that contains both b_1 and b_2.
- Add (b_3, y_1) to $\mathcal{G}_i$ and delete (b_1, y_1) and (b_2, y_2) from $\mathcal{G}_i$.
- Check if b_1 (or b_2) is a box created by the doubling step at the beginning of the current round and hasn't been melded with other boxes ever since. If so, the algorithm computes a box b_1' (resp. b_2') from b_1 (resp. b_2) by **halving** it. That is, each $d-1$ dimensional face is moved so that its distance to the box's representative is halved. Mathematically, a box $\{x \in \mathcal{R}^d : y_i - v_i \le x_i \le y_i + w_i, i = 1, \ldots, d\}$ $(v_i, w_i > 0)$, where vector y is its representative, becomes $\{x \in \mathcal{R}^d : y_i - \frac{1}{2}v_i \le x_i \le y_i + \frac{1}{2}w_i, i = 1, \ldots, d\}$ after halving. Then (b_1', y_1) (or (b_2', y_2)) is added to $\mathcal{B}_i$. Otherwise do nothing.

Notice that melding decreases the size of $\mathcal{G}_i$.

The algorithm terminates when there is one tuple (b_0, y_0) left in $\mathcal{G}_i$, at which point the algorithm adds a box that contains the whole space with representative y_0 to $\mathcal{B}_i$. Note that during each round of the doubling and melding, the boxes which are added to $\mathcal{B}_i$ are the ones that after doubling were melded with other boxes, and they are added at their shapes before the doubling step.

▶ **Lemma 7.** *The collection of boxes in $\mathcal{B}_i$ constructed by the above algorithm is laminar.*

Proof. Note that right before each doubling step, the boxes in $\mathcal{G}_i$ are disjoint and that is because the algorithm in the previous iteration melds all the boxes that have intersection with each other. We prove by induction that at all time, for every box b in $\mathcal{B}_i$ there exist a box b' in $\mathcal{G}_i$ such that $b \subseteq b'$. Since the boxes added to $\mathcal{B}_i$ in each iteration are a subset of the boxes in $\mathcal{G}_i$ before the doubling step and they do not intersect each other, laminarity of $\mathcal{B}_i$ is a straight-forward consequence.

Initially $\mathcal{B}_i$ is empty and therefore the claim holds. Assume in some arbitrary iteration ℓ this claim holds right before the doubling step, then after the doubling step since every box in $\mathcal{G}_i$ still covers all of the area it was covering before getting doubled, the claim holds.

Furthermore, in the melding step every box b_3 that is resulted from melding of two boxes b_1 and b_2 covers both b_1 and b_2; therefore, b_3 will cover b_1 and b_2 if they are added to $\mathcal{B}_i$, and if a box in $\mathcal{B}_i$ was covered by either of b_1 or b_2, it will be still covered by b_3. ◀

The collection of boxes in $\mathcal{B}_i$ can be thought of as a tree where every node corresponds to a box. The root node is the entire space. In this tree, for any box b', among all boxes included by b', we pick the inclusion-wise *maximal* boxes and let them be the **children** of b'. Thus the number of boxes in $\mathcal{B}_i$ is $O(i)$ since the tree has i leaves, one for each center.

4.2 Sampling

To define our easy distribution Q, for any point $x \in J$, let $b(x)$ be the minimal box in $\mathcal{B}_i$ that contains x and $y(x)$ be the representative of $b(x)$. Define $R(x) = \|x - y(x)\|_2^2$, and $Q(x) = \frac{R(X)}{Z}$ where $Z = \sum_{x \in J} R(x)$ normalizes the distribution. We call $R(x)$ the **assignment cost** for x. We will show how to sample from target distribution $P(\cdot)$ using $Q(\cdot)$ and rejection sampling, and how to implement the this designed sampling step relationally.

Rejection Sampling. The algorithm repeatedly samples a point x with probability $Q(x)$, then either (A) rejects x and resamples, or (B) accepts x as the next center c_i and finishes the sampling process. After sampling x, the probability of accepting x is $\frac{L(x)}{R(x)}$, and that of rejecting x is $1 - \frac{L(x)}{R(x)}$. Notice that here $\frac{L(x)}{R(x)} \leq 1$ since $R(x) = \|x - y(x)\|_2^2 \geq \min_{j \in [i-1]} \|x - c_j\|_2^2$.

If $S(x)$ is the the event of initially sampling x from distribution Q, and $A(x)$ is the event of subsequently accepting x, the probability of choosing x to be c_i in one given round is:

$$\Pr[S(x) \text{ and } A(x)] = \Pr[A(x) \mid S(x)] \Pr[S(x)] = \frac{L(x)}{R(x)} Q(x) = \frac{L(x)}{Z}$$

Thus the probability of x being the accepted sample is proportional to $L(x)$, as desired.

We would like $Q(\cdot)$ to be close to $P(\cdot)$ point-wise so that the algorithm is efficient. Otherwise, the acceptance probability $\frac{L(x)}{R(x)}$ is low and it might keep rejecting samples.

Relational Implementation of Sampling. We now explain how to relationally sample a point x with probability $Q(x)$. The implementation heavily leverages Lemma 5, which states for given box b^* with representative y^*, the cost of assigning all points in $r \bowtie J \cap b^*$ to y^* for each row $r \in T_i$ can be computed in polynomial time using a SumProd query grouped by T_i. Recall that we assign all points in J to the representative of the smallest box they belong to. We show that the total assignment cost is computed by evaluating SumProd queries on the boxes and then adding/subtracting the query values for different boxes.

Following the intuition provided in Section 2, the implementation generates a single row from table $T_1, T_2, \ldots, T_m$ sequentially. The concatenation of these rows (or the join of them) gives the sampled point x. It is sufficient to explain assuming we have sampled $r_1, \ldots, r_{\ell-1}$ from the first $\ell - 1$ tables, how to implement the generation of a row from the next table T_ℓ. Just like 1- and 2-means++ in subsection 2, the algorithm evaluates a function $F_\ell(\cdot)$ defined on rows in T_ℓ using SumProd queries, and samples r with probability $\frac{F_\ell(r)}{\sum_{r' \in T_\ell} F_\ell(r')}$. Again, we focus on $r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J$, denoting the points in J that uses the previously sampled rows. The value of $F_\ell(r)$ is determined by points in $r \bowtie r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J$.

To ensure we generate a row according to the correct distribution Q, we define the function $F_\ell(\cdot)$ as follows. Let $F_\ell(r)$ be the total assignment cost of all points in $r \bowtie r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J$. That is, $F_\ell(r) = \sum_{x \in r \bowtie r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J} R(x)$. Notice that the definition of function $F_\ell(\cdot)$ is very similar to 2-means++ apart from that each point is no longer assigned to a given center, but the representative of the smallest box containing it.

Let $G(r, b^*, y^*)$ denote the cost of assigning all points from $r \bowtie r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J$ that lies in box b^* to a center y^*. By replacing the J in Lemma 5 by $r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J$, we can compute all $G(r, b^*, y^*)$ values in polynomial time using one SumProd query grouped by T_ℓ. The value $F_\ell(r)$ can be expanded into subtraction and addition of $G(r, b^*, y^*)$ terms. The expansion is recursive. For a box b_0, let $H(r, b_0) = \sum_{x \in r \bowtie r_1 \bowtie \ldots \bowtie r_{\ell-1} \bowtie J \cap b_0} R(x)$. Notice that $F_\ell(r) = H(r, b_0)$ if b_0 is the entire Euclidean space. Pick any row $r \in T_\ell$. Assume we want to compute $H(r, b_0)$ for some tuple $(b_0, y_0) \in \mathcal{B}_i$.

Recall that the set of boxes in $\mathcal{B}_i$ forms a tree structure. If b_0 has no children this is the base case - $H(r, b_0) = G(r, b_0, y_0)$ by definition since all points in b_0 must be assigned to y_0. Otherwise, let $(b_1, y_1), \ldots, (b_q, y_q)$ be the tuples in $\mathcal{B}_i$ where $b_1, \ldots, b_q$ are children of b_0. Notice that, by definition all points in $b_0 \setminus (\bigcup_{j \in [q]} b_j)$ is assigned to y_0. Then, one can check that the following equation holds for any r:

$$H(r, b_0) = G(r, b_0, y_0) - \sum_{j \in [q]} G(r, b_j, y_0) + \sum_{j \in [q]} H(r, b_j)$$

Starting with setting b_0 as the entire Euclidean space, the equation above could be used to recursively expand $H(\cdot, b_0) = F_\ell(\cdot)$ into addition and subtraction of $O(|\mathcal{B}_i|)$ number of $G(\cdot, \cdot, \cdot)$ terms, where each term could be computed with one SumProd query by Lemma 5.

Runtime Analysis of the Sampling. We now discuss the running time of the sampling algorithm simulating k-means++. These lemmas show how close the probability distribution we compute is as compared to the k-means++ distribution. This will help bound the running time.

▶ **Lemma 8.** *Consider the box construction algorithm when sampling the i^{th} point in the k-means++ simulation. Consider the end of the j^{th} round where all melding is finished but the boxes have not been doubled yet. Let b be an arbitrary box in $\mathcal{G}_i$ and $h(b)$ be the number of centers in b at this time. Let c_a be an arbitrary one of these $h(b)$ centers. Then:*
A. *The distance from c_a to any $d-1$ dimensional face of b is at least 2^j.*
B. *The length of each side of b is at most $h(b) \cdot 2^{j+1}$.*

Proof. The first statement is a direct consequence of the definition of doubling and melding since at any point of time the distance of all the centers in a box is at least 2^j. To prove the second statement, we define the assignment of the centers to the boxes as following. Consider the centers inside each box b right before the doubling step. We call these centers, the centers assigned to b and denote the number of them by $h'(b)$. When two boxes b_1 and b_2 are melding into box b_3, we assign their assigned centers to b_3.

We prove each side length of b is at most $h'(b)2^{j+1}$ by induction on the number j of executed doubling steps. Since $h'(b) = h(b)$ right before each doubling, this will prove the second statement. The statement is obvious in the base case, $j = 0$. The statement also obviously holds by induction after a doubling step as j is incremented and the side lengths double and the number of assigned boxes don't change. It also holds during every meld step because each side length of the newly created larger box is at most the aggregate maximum side lengths of the smaller boxes that are moved to $\mathcal{B}_i$, and the number of assigned centers in the newly created larger box is the aggregate of the assigned centers in the two smaller boxes that are moved to $\mathcal{B}_i$. Note that since for any box b all the assigned centers to b are inside b at all times, $h'(b)$ is the number of centers inside b before the next doubling. ◀

This lemma bounds the difference of the two probability distributions.

▶ **Lemma 9.** *Consider the box generation algorithm when sampling the ith point in the k-means++ simulation. For all points x, $R(x) \leq O(i^2 d) \cdot L(x)$.*

Proof. Consider an arbitrary point x. Let c_ℓ, $\ell \in [i-1]$, be the center that is closest to x under the 2-norm distance. Assume j is minimal such that just before the $(j+1)$-th doubling round, x is contained in a box b in $\mathcal{G}_i$. We argue about the state of the algorithm at two times, the time s just before doubling round j and the time t just before doubling round $j+1$. Let b be a minimal box in $\mathcal{G}_i$ that contains x at time t, and let y be the representative for box b. Notice that we assign x to the representative of the smallest box in $\mathcal{B}_i$ that contains it, so x will be assigned to y. Indeed, none of the boxes added into $\mathcal{B}_i$ before time t contains x by the minimality of j, and when box b gets added into $\mathcal{B}_i$ (potentially after a few more doubling rounds) it still has the same representative y. By Lemma 8 the squared distance from from x to r is at most $(i-1)^2 d 2^{2j+2}$. So it is sufficient to show that the squared distance from x to c_ℓ is $\Omega(2^j)$.

Let b' be the box in $\mathcal{G}_i$ that contains c_ℓ at time s. Note that x could not have been inside b' at time s by the definition of t and s. Then by Lemma 8 the distance from c_ℓ to the edge of b' at time t is at least 2^{2j-2}, and hence the distance from c_ℓ to x is also at least 2^{2j-2} as x is outside of b'. ◀

The following theorem bounds the running time.

▶ **Theorem 10.** *The expected time complexity for running k' iterations of this implementation of k-means++ is $O(k'^4 dm\Psi(n,d,m))$.*

Proof. When picking center c_i, a point x can be sampled with probability $Q(x)$ in time $O(mi\Psi(n,m,d))$. This is because the implementation samples one row from each of the m tables. To sample one row we evaluate $O(|\mathcal{B}_i|)$ SumProd queries, each in $O(\Psi(n,m,d))$ time. As mentioned earlier $\mathcal{B}_i$ can be thought of as a tree of boxes with $i-1$ leaves, so $|\mathcal{B}_i| = O(i)$.

By Lemma 9, the probability of accepting any sampled x is $\frac{L(x)}{R(x)} = \frac{1}{O(i^2 d)}$. The expected number of sampling from Q until getting accepted is $O(i^2 d)$. Thus the expected time of finding c_i is $O(i^3 dm\Psi(n,m,d))$. Summing over $i \in [k']$, we get $O(k'^4 dm\Psi(n,m,d))$. ◀

5 Weighting the Centers

Our algorithm samples a collection C of $k' = \Theta(k \log N)$ centers using the k-means++ sampling described in the prior section. We give weights to the centers to get a coreset.

Ideally, we would compute the weights in the standard way. That is, let w_i denote the number of points that are closest to point c_i among all centers in C. These pairs of centers and weights (c_i, w_i) are known to form a coreset. Unfortunately, as stated in Theorem 2, computing such w_i's even approximately is NP hard. Instead, we will find a different set of weights which still form a coreset and are computable.

Next we describe a relational algorithm to compute a collection W' of weights, one weight $w'_i \in W'$ for each center $c_i \in C$. The proof that the centers with these alternative weights (c_i, w'_i) also form a coreset is postponed until Section 6.

Algorithm for Computing Alternative Weights. Initialize the weight w'_i for each center $c_i \in C$ to zero. In the d-dimensional Euclidean space, for each center $c_i \in C$, we generate a collection of hyperspheres (also named **balls**) $\{B_{i,j}\}_{j \in [\lg N]}$, where $B_{i,j}$ contains approximately 2^j points from J. The space is then partitioned into $\{B_{i,0}, B_{i,1} - B_{i,0}, B_{i,2} - B_{i,1}, \ldots\}$. For each partition, we will sample a small number of points and use this sample to estimate

the number of points in this partition that are closer to c_i than any other centers, and thus aggregating w'_i by adding up the numbers. Fix small constants $\epsilon, \delta > 0$. The following steps are repeated for $j \in [\lg N]$:

- Let $B_{i,j}$ be a ball of radius $r_{i,j}$ centered at c_i. Find a $r_{i,j}$ such that the number of points in $J \cap B_{i,j}$ lies in the range $[(1-\delta)2^j, (1+\delta)2^j]$. This is an application of Lemma 6.
- Let τ be a constant that is at least 30. A collection $T_{i,j}$ of $\frac{\tau}{\epsilon^2} k'^2 \log^2 N$ "test" points are independently sampled following the same **approximately uniform** distribution with replacement from every ball $B_{i,j}$. Here an "approximately uniform" distribution means one where every point p in $B_{i,j}$ is sampled with a probability $\gamma_{p,i,j} \in [(1-\delta)/|B_{i,j}|, (1+\delta)/|B_{i,j}|]$ on each draw. This can be accomplished efficiently similar to the techniques used in Lemma 6 from [3]. We leave out the details due to space limit.
- Among all sampled points $T_{i,j}$, find $S_{i,j}$, the set of points that lie in the **"donut"** $D_{i,j} = B_{i,j} - B_{i,j-1}$. Then the cardinality $s_{i,j} = |S_{i,j}|$ is computed.
- Find $t_{i,j}$, the number of points in $S_{i,j}$ that are closer to c_i than any other center in C.
- Compute the ratio $f'_{i,j} = \frac{t_{i,j}}{s_{i,j}}$ (if $s_{i,j} = t_{i,j} = 0$ then $f'_{i,j} = 0$).
- If $f'_{i,j} \geq \frac{1}{2k'^2 \log N}$ then w'_i is incremented by $f'_{i,j} \cdot 2^{j-1}$, else w'_i stays the same.

At first glance the algorithm appears naive: w'_i can be significantly underestimated if in some donuts only a small portion of points are closest to c_i, making the estimation inaccurate based on sampling. However, we prove the following theorem which shows that the alternative weights computed by our algorithm actually form a coreset.

▶ **Theorem 11.** *The centers C, along with the computed weights W', form an $O(1)$-approximate coreset with high probability.*

The running time of a naive implementation of this algorithm would be dominated by sampling of the test points. Sampling a single test point can be accomplished with m applications of the algorithm from [3] and setting the approximation error to $\delta = \epsilon/m$. Recall the running time of the algorithm from [3] is $O\left(\frac{m^6 \log^4 n}{\delta^2} \Psi(n,d,m)\right)$. Thus, the time to sample all test points is $O\left(\frac{k'^2 m^9 \log^6 n}{\epsilon^4} \Psi(n,d,m)\right)$. Substituting for k', and noting that $N \leq n^m$, we obtain a total time for a naive implementation of $O\left(\frac{k^2 m^{11} \log^8 n}{\epsilon^4} \Psi(n,d,m)\right)$.

6 Analysis of the Weighting Algorithm

The goal in this subsection is to prove Theorem 11 which states that the alternative weights form an $O(1)$-approximate coreset with high probability. Throughout our analysis, "with high probability" means that for any constant $\rho > 0$ the probability of the statement not being true can be made less than $\frac{1}{N^\rho}$ asymptotically by appropriately setting the constants in the algorithm.

Intuitively, if a decent fraction of the points in each donut are closer to center c_i than any other center, then Theorem 11 can be proven by using a straight-forward application of Chernoff bounds to show that each alternate weight w'_i is likely close to the true weight w_i. The conceptual difficultly is if only a very small portion of points in a donut $D_{i,j}$ are closer to c_i than any other points, in which case the estimated $f'_{i,j} < \frac{1}{2k'^2 \log N}$ and thus the "uncounted" points in $D_{i,j}$ would contribute no weight to the computed weight w'_i. We call this the **undersampled** case. If many donuts around a center i are undersampled, the computed weight w'_i may well poorly approximate the actual weight w_i.

To address this, we need to prove that omitting the weight from these uncounted points does not have a significant impact on the objective value. We break our proof into four parts. The first part, described in subsubsection 6.1, involves conceptually defining a fractional weight w_i^f for each center $c_i \in C$. Each point has a weight of 1, and instead of giving all this weight to its closest center, we allow fractionally assigning the weight to various "near" centers. w_i^f is then the aggregated weight over all points for c_i. The second part, described in subsubsection 6.2, establishes various properties of the fractional weight that we will need. The third part, described in subsubsection 6.3, shows that each fractional weight w_i^f is likely to be closely approximated the computed weight w_i'. The fourth part, described in subsubsection 6.4, shows that the fractional weights of the centers in C form a $O(1)$-approximate coreset. Subsubsection 6.4 also contains the proof of Theorem 11.

6.1 Defining the Fractional Weights

To define the fractional weights we first define an auxiliary directed acyclic graph $G = (S, E)$ where there is one node in S corresponding to each row in J. For the rest of this section, with a little abuse of notation, we use S to denote both the nodes in graph G, and the set of d-dimensional data points in the design matrix. Let p be an arbitrary point in $S - C$. Let $\alpha(p)$ denote the subscript of the center closest to p, i.e., if $c_i \in C$ is closest to p then $\alpha(p) = i$. Let $D_{i,j}$ be the donut around c_i that contains p. If $D_{i,j}$ is not undersampled then p will have one outgoing edge (p, c_i). Therefore, let us now assume that $D_{i,j}$ is undersampled. Defining the outgoing edges from p in this case is a bit more complicated.

Let $A_{i,j}$ be the points $q \in D_{i,j}$ that are closer to c_i than any other center in C (i.e., $\alpha(q) = i$). If $j = 1$ then $D_{i,1}$ contains only the point p, and the only outgoing edge from p goes to c_i. Therefore, let us now assume $j > 1$. Let c_h the center that is closest to the most points in $D_{i,j-1}$, the next donut in toward c_i from $D_{i,j}$. That is $c_h = \arg\max_{c_j \in C} \sum_{q \in D_{i,j-1}} \mathbb{1}_{\alpha(q)=c_j}$. Let $M_{i,j-1}$ be points in $D_{i,j-1}$ that are closer to c_h than any other center. That is, $M_{i,j-1}$ is the collection of $q \in D_{i,j-1}$ such that $\alpha(q) = h$. Then there is a directed edge from p to each point in $M_{i,j-1}$. Before defining how to derive the fractional weights from G, let us take a detour to note that G is acyclic.

▶ **Lemma 12.** *G is acyclic.*

Proof. Consider a directed edge $(p, q) \in E$, and c_i be the center in C that p is closest to, and $D_{i,j}$ the donut around c_i that contains p. Then, since $p \in D_{i,j}$ it must be the case that $\|p - c_i\|_2^2 > r_{i,j-1}$. Since $q \in B_{i,j-1}$ it must be the case that $\|q - c_i\|_2^2 \leq r_{i,j-1}$. Thus $\|p - c_i\|_2^2 > \|q - c_i\|_2^2$. Thus, the closest center to q must be closer to q than the closest center to p is to p. Thus as one travels along a directed path in G, although identify of the closest center can change, the distance to the closest center must be monotonically decreasing. Thus, G must be acyclic. ◀

We explain how to compute a fractional weight w_p^f for each point $p \in S$ using the network G. Initially, each w_p^f is set to 1. Then conceptually these weights flow toward the sinks in G, splitting evenly over all outgoing edges at each vertex. More formally, the following flow step is repeated until is no longer possible to do so:

Flow Step. Let $p \in S$ be an arbitrary point that currently has positive fractional weight and that has positive outdegree h in G. Then for each directed edge (p, q) in G increment w_q^f by w_p^f/h. Finally, set w_p^f to zero.

As the sinks in G are exactly the centers in C, the centers in C will be the only points that end up with positive fractional weight. Thus, we use w_i^f to refer to the resulting fractional weight on center $c_i \in C$.

6.2 Properties of the Fractional Weights

Let $f_{i,j}$ be the fraction of points that are closest to c_i among all centers in C in this donut $D_{i,j} = B_{i,j} - B_{i,j-1}$. We show in Lemma 13 and 14 that with high probability, either the estimated ratio is a good approximation of $f_{i,j}$, or the real ratio $f_{i,j}$ is very small.

We show in Lemma 16 that the maximum flow through any node is bounded by $1+\epsilon$ when N is big enough. This follows by induction because each point has $\Omega(k' \log N)$ neighbors and every point can have in degree from one set of nodes per center. We further know every point that is not uncounted actually contributes to their centers' weight.

▶ **Lemma 13.** *With high probability, either* $|f_{i,j} - f'_{i,j}| \leq \epsilon f_{i,j}$ *or* $f'_{i,j} \leq \frac{1}{2k'^2 \log N}$.

▶ **Lemma 14.** *If* $f_{i,j} > \frac{1+\epsilon}{2k'^2 \log N}$ *then with high probability* $f'_{i,j} \geq \frac{1}{2k'^2 \log N}$.

The proofs of Lemmas 13 and 14 are omitted; see [22] for the full version of this work.

We now seek to bound the fractional weights computed by the algorithm. Let $\Delta_i(p)$ denote the total weight received by a point $p \in S \setminus C$ from other nodes (including the initial weight one on p). Furthermore, let $\Delta_o(p)$ denote the total weight sent by p to all other nodes. Notice that in the flow step $\Delta_o(p) = \Delta_i(p)$ for all p in $S \setminus C$.

▶ **Lemma 15.** *Let* $\Delta_i(p)$ *denote the total weight received by a point* $p \in S \setminus C$ *from other nodes (including the initial weight one on* p*). Furthermore, let* $\Delta_o(p)$ *denote the total weight sent by* p *to all other nodes. With high probability, for all* $q \in S$, $\Delta_i(q) \leq 1 + \frac{1+2\epsilon}{\log N} \max_{p:(p,q)\in E} \Delta_o(p)$.

Proof. Fix the point q that redirects its weight (has outgoing arcs in G). Consider its direct predecessors: $P(q) = \{p : (p, q) \in E\}$. Partition $P(q)$ as follows: $P(q) = \bigcup_{i=1,\ldots,k'} P_{c_i}(q)$, where $P_{c_i}(q)$ is the set of points that have flowed their weights into q, but c_i is actually their closest center in C. Observe the following. The point q can only belong to one donut around c_i. Due to this, $P_{c_i}(q)$ is either empty or contains a set of points in a single donut around c_i that redirect weight to q.

Fix $P_{c_i}(q)$ for some c_i. If this set is non-empty suppose this set is in the j-th donut around c_i. Conditioned on the events stated in Lemma 13 and 14, since the points in $P_{c_i}(q)$ are undersampled, we have $|P_{c_i}(q)| \leq \frac{(1+\epsilon)2^{j-1}}{2k'^2 \log N}$. Consider any $p \in P_{c_i}(q)$. Let β_i be the number of points that p charges its weight to (this is the same for all such points p). It is the case that β_i is at least $\frac{(1-\delta)2^{j-1}}{2k'}$ since p flows its weights to the points that are assigned to the center that has the most number of points assigned to it from c_i's $(j-1)$th donut.

Thus, q receives weight from $|P_{c_i}(q)| \leq \frac{(1+\epsilon)2^{j-1}}{2k'^2 \log N}$ points and each such point gives its weight to at least $\frac{(1-\delta)2^{j-1}}{2k'}$ points with equal split. The total weight that q receives from points in $P_{c_i}(q)$ is at most the following.

$$\begin{aligned} &\frac{2k'}{(1-\delta)2^{j-1}} \sum_{p \in P_{c_i}(q)} \Delta_o(p) \\ \leq &\frac{2k'}{(1-\delta)2^{j-1}} \sum_{p \in P_{c_i}(q)} \max_{p \in P_{c_i}(q)} \Delta_o(p) \end{aligned}$$

$$\leq \frac{2k'}{(1-\delta)2^{j-1}} \cdot \frac{(1+\epsilon)\cdot 2^{j-1}}{2k'^2 \log N} \max_{p\in P_{c_i}(q)} \Delta_o(p) \qquad [|P_{c_i}(q)| \leq \tfrac{(1+2\epsilon)2^{j-1}}{2k'^2 \log N}]$$
$$\leq \frac{1+2\epsilon}{k' \log N} \max_{p\in P_{c_i}(q)} \Delta_o(p) \qquad [\delta \leq \tfrac{\epsilon}{2} \leq \tfrac{1}{10}]$$

Switching the max to $\max_{p:(p,q)\in E} \Delta_o(p)$, summing over all centers $c_i \in C$ and adding the original unit weight on q gives the lemma. ◀

The following crucial lemma bounds the maximum weight that a point can receive.

▶ **Lemma 16.** *Fix η to be a constant smaller than $\frac{\log(N)}{10}$ and $\epsilon < 1$. Say that for all $q \in S \setminus C$ it is the case that $\Delta_o(q) = \eta\Delta_i(q)$. Then, with high probability for any $p \in S \setminus C$ it is the case that $\Delta_i(p) \leq 1 + \frac{2\eta}{\log N}$.*

Proof. We can easily prove this by induction on nodes. The lemma is true for all nodes that have no incoming edges in G. Now assume it is true for all nodes whose longest path that reaches them in G has length $t-1$. Now we prove it for nodes whose longest path that reaches then in G is t. Fix such a node q. For any node p such that $(p,q) \in E$, by induction we have $\Delta_i(p) \leq 1 + \frac{2\eta}{\log N}$, so $\Delta_o(p) \leq 2(1 + \frac{2\eta}{\log N})$. By Lemma 15, $\Delta_i(q) \leq 1 + \frac{1+2\epsilon}{\log N} \max_{p:(p,q)\in E} \Delta_o(p) \leq 1 + \left(\frac{\eta(1+2\epsilon)}{\log N}\right)\left(1 + \frac{2\eta}{\log N}\right) = 1 + \frac{\eta}{\log N} + \frac{\eta}{\log N} \cdot \frac{2(1+2\epsilon)\eta+2\epsilon}{\log N} \leq 1 + \frac{2\eta}{\log N}$. ◀

6.3 Comparing Alternative Weights to Fractional Weights

It only remains to bound the cost of mapping points to the centers they contribute weight to. This can be done by iteratively charging the total cost of reassigning each node with the flow. In particular, each point will only pass its weight to nodes that are closer to their center. We can charge the flow through each node to the assignment cost of that node to its closest center, and argue that the cumulative reassignment cost bounds the real fractional assignment cost. Further, each node only has $1+\epsilon$ flow going through it. This will be sufficient to bound the overall cost in Lemma 18.

▶ **Lemma 17.** *With high probability, for every center c_i, it is the case that the estimated weight w'_i computed by the weighting algorithm is $(1 \pm 2\epsilon)w_i^f$ where w_i^f is the fractional weight of i.*

The proofs of Lemmas 17 is omitted; see [22] for the full version of this work.

6.4 Comparing Fractional Weights to Optimal

Next, we bound the total cost of the fractional assignment defined by the flow. According to the graph G, any point $p \in S$ and $c_i \in C$, we let $\omega(p, c_i)$ be the fraction of weights that got transferred from p to c_i. Naturally we have $\sum_{c_i\in C} \omega(p, c_i) = 1$ for any $p \in S$ and the fractional weights $w_i^f = \sum_{p\in S} \omega(p, c_i)$ for any $c_i \in C$.

▶ **Lemma 18.** *Let ϕ_{opt} be the optimal k-means cost on the original set S. With high probability, it is the case that:*

$$\sum_{p\in S} \sum_{c_i\in C} \omega(p, c_i)\|p - c_i\|^2 \leq 160(1+\epsilon)\phi_{opt}$$

Proof. Let $\phi^* = \sum_{p \in S} \|p - c_{\alpha(p)}\|^2$. Consider any $p \in S$ and center c_i such that $\omega(p, c_i) > 0$. Let P be any path from p to c_i in G. If node p's only outgoing arc is to its closest center $c_{\alpha(p)} = c_i$, then $P = p \to c_i$, we have $\sum_{c \in C} \omega(p, c)\|p - c\|^2 = \|p - c_{\alpha(p)}\|^2$. Otherwise assume $P = p \to q_1 \to q_2 \to \ldots \to q_\ell \to c_i$. Note that the closest center to q_ℓ is c_i. Let $\Delta(P)$ be the fraction of the original weight of 1 on p that is given to c_i along this path according to the flow of weights. As we observed in the proof of Lemma 12, we have $\|p - c_{\alpha(p)}\| > \|q_1 - c_{\alpha(p)}\| \geq \|q_1 - c_{\alpha(q_1)}\| > \|q_2 - c_{\alpha(q_1)}\| \geq \|q_2 - c_{\alpha(q_2)}\| > \ldots > \|q_\ell - c_{\alpha(q_\ell)}\|$. This follows because for any arc (u, v) in the graph, v is in a donut closer to $c_{\alpha(u)}$ than the donut u is in, and v is closer to $c_{\alpha(v)}$ than $c_{\alpha(u)}$.

We use the relaxed triangle inequality for squared ℓ_2 norms. For any three points x, y, z, we have $\|x - z\|^2 \leq 2(\|x - y\|^2 + \|y - z\|^2)$. Thus, we bound $\|p - c_i\|^2$ by

$$\begin{aligned}
\|p - c_i\|^2 &= \|p - c_{\alpha(p)} + c_{\alpha(p)} - q_1 + q_1 - c_i\|^2 \\
&\leq 2\|p - c_{\alpha(p)} + c_{\alpha(p)} - q_1\|^2 + 2\|q_1 - c_i\|^2 && \text{[relaxed triangle inequality]} \\
&\leq 2(\|p - c_{\alpha(p)}\| + \|c_{\alpha(p)} - q_1\|)^2 + 2\|q_1 - c_i\|^2 && \text{[triangle inequality]} \\
&\leq 8\|p - c_{\alpha(p)}\|^2 + 2\|q_1 - c_i\|^2 && [\|p - c_{\alpha(p)}\| \geq \|c_{\alpha(p)} - q_1\|].
\end{aligned}$$

Applying the prior steps to each q_i gives the following.

$$\|p - c_i\|^2 \leq 8(\|p - c_{\alpha(p)}\|^2 + \sum_{j=1}^{\ell} 2^j \|q_j - c_{\alpha(q_j)}\|^2)$$

Let $\mathcal{P}_q(j)$ be the set of all paths P that reach point q using j edges. If $j = 0$, it means P starts with point q. We seek to bound $\sum_{j=0}^{\infty} 2^j \sum_{P \in \mathcal{P}_q(j)} \Delta(P)\|q - c_{\alpha(q_j)}\|^2$. This will bound the charge on point q above over all path P that contains it.

Define a weight function $\Delta'(p)$ for each node $p \in S \setminus C$. This will be a new flow of weights like Δ, except now the weight increases at each node. In particular, give each node initially a weight of 1. Let $\Delta'_o(p)$ be the total weight leaving p. This will be evenly divided among the nodes that have outgoing edges from p. Define $\Delta'_i(p)$ to be the weight incoming to p from all other nodes plus one, the initial weight of p. Set $\Delta'_o(p)$ to be $2\Delta'_i(p)$, twice the incoming weight.

Lemma 16 implies that the maximum weight of any point p is $\Delta'_i(p) \leq 1 + \frac{4}{\log N}$. Further notice that for any q it is the case that $\Delta'_i(q) = \sum_{j=0}^{\infty} 2^j \sum_{P \in \mathcal{P}_q(j)} \Delta(P)$. Letting $\mathcal{P}(p, c_i)$ be the set of all paths that start at p to center c_i. Notice such paths correspond to how p's unit weight goes to c_i. We have $\omega(p, c_i) = \sum_{P \in \mathcal{P}(p, c_i)} \Delta(P)$. Let $\mathcal{P}$ denote the set of all paths, $\ell(P)$ denote the length of path P (number of edges on P) , and let $P(j)$ denote the jth node on path P. Thus we have the following.

$$\begin{aligned}
&\sum_{p \in S} \sum_{c_i \in C} \omega(p, c_i)\|p - c_i\|^2 = \sum_{p \in S} \sum_{c_i \in C} \sum_{P \in \mathcal{P}(p, c_i)} \Delta(P)\|p - c_i\|^2 \\
\leq\ & 8 \sum_{p \in S} \sum_{c_i \in C} \sum_{P \in \mathcal{P}(p, c_i)} \Delta(P)\Big(\sum_{j=0}^{\ell(p)-1} 2^j \|P(j) - c_{\alpha(P(j))}\|^2\Big) \\
=\ & 8 \sum_{P \in \mathcal{P}} \Delta(P)\Big(\sum_{j=0}^{\ell(p)-1} 2^j \|P(j) - c_{\alpha(P(j))}\|^2\Big) \\
=\ & 8 \sum_{q \in S} \sum_{j=0}^{+\infty} \sum_{P \in \mathcal{P}_q(j)} 2^j \Delta(P)\|q - c_{\alpha(q)}\|^2 = 8 \sum_{q \in S} \Delta'_i(q)\|q - c_{\alpha(q)}\|^2 \\
\leq\ & \sum_{q \in S} 8(1 + \frac{4}{\log N})\|q - c_{\alpha(q)}\|^2 = 8(1 + \frac{4}{\log N})\phi^*
\end{aligned}$$

Lemma 18 follows because if $k' \geq 1067k \log N$, $\phi^* \leq 20\phi_{opt}$ with high probability by Theorem 1 in [8]. ◀

Finally, we prove that finding any $O(1)$-approximation solution for optimal weighted k-means on the set (C, W') gives a constant approximation for optimal k-means for the original set S. Let $W^f = \{w_1^f, \ldots, w_{k'}^f\}$ be the fractional weights for centers in C. Let $\phi^*_{W^f}$ denote the optimal weighted k-means cost on (C, W^f), and $\phi^*_{W'}$ denote the optimal weighted k-means cost on (C, W'). We first prove that $\phi^*_{W^f} = O(1)\phi_{\text{OPT}}$, where ϕ_{OPT} denote the optimal k-means cost on set S.

▶ **Lemma 19.** *Let (C, W^f) be the set of points sampled and the weights collected by fractional assignment ω. With high probability, we have $\phi^*_{W^f} = O(1)\phi_{\text{OPT}}$.*

Proof. Consider the cost of the fractional assignment we've designed. For $c_i \in C$, the weight is $w_i^f = \sum_{p\in S} \omega(p, c_i)$. Denote the k-means cost of ω by $\phi_\omega = \sum_{p\in S}\sum_{c\in C} \omega(p, c)\|p - c\|^2$. By Lemma 18, we have that $\phi_\omega \leq 160(1 + \epsilon)\phi_{\text{OPT}}$.

Intuitively, in the following we show $\phi^*_{W^f}$ is close to ϕ_ω. As always, we let C_{OPT} denote the optimal centers for k-means on set S. For a set of points X with weights $Y : X \to \mathbb{R}^+$ and a set of centers Z, we let $\phi_{(X,Y)}(Z) = \sum_{x\in X} Y(x) \min_{z\in Z} \|x - z\|^2$ denote the cost of assigning the weighted points in X to their closest centers in Z. Note that $\phi^*_{W^f} \leq \phi_{(C,W^f)}(C_{\text{OPT}})$ since C_{OPT} is chosen with respect to S.

$$\begin{aligned}
\phi^*_{W^f} \leq \phi_{(C,W^f)}(C_{\text{OPT}}) &= \sum_{c_i\in C}\sum_{p\in S} \min_{c\in C_{\text{OPT}}} \omega(p, c_i)\|c_i - c\|^2 && [w_i^f = \textstyle\sum_{p\in S}\omega(p, c_i)] \\
&\leq \sum_{c_i\in C}\sum_{p\in S} \min_{c\in C_{\text{OPT}}} \omega(p, c_i) \cdot 2(\|p - c_i\|^2 + \|p - c\|^2) && [\text{relaxed triangle inequality}] \\
&= 2\phi_\omega + 2\phi_{\text{OPT}} \leq 322(1 + \epsilon)\phi_{\text{OPT}} &&
\end{aligned}$$ ◀

Using the mentioned lemmas, we can prove the final approximation guarantee.

Proof of Theorem 11. Using Lemma 17, we know $w'_i = (1 \pm 2\epsilon)w_i^f$ for any center c_i. Let C'_k be k centers for (C, W') that is a γ-approximate for optimal weighted k-means. Let C^f_{OPT} be the *optimal* k centers for (C, W^f), and C'_{OPT} optimal for (C, W'). We have $\phi_{(C,W^f)}(C'_k) \leq (1 + 2\epsilon)\phi_{(C,W')}(C'_k)$ for the reason that the contribution of each point grows by at most $(1+2\epsilon)$ due to weight approximation. Using the same analysis, $\phi_{(C,W')}(C^f_{\text{OPT}}) \leq (1+2\epsilon)\phi^*_{W^f}$. Combining the two inequalities, we have

$$\begin{aligned}
\phi_{(C,W^f)}(C'_k) &\leq (1 + 2\epsilon)^2\phi_{(C,W')}(C'_k) \leq (1 + 2\epsilon)^2\gamma\phi^*_{W'} && \\
&\leq (1 + 2\epsilon)^2\gamma\phi_{(C,W')}(C^f_{\text{OPT}}) && [\text{by optimality of } \phi^*_{W'}] \qquad (1) \\
&\leq (1 + 2\epsilon)^3\gamma\phi^*_{W^f} \leq 322\gamma(1 + 2\epsilon)^4\phi_{\text{OPT}} && [\text{using Lemma 19}]
\end{aligned}$$

Let $\phi_S(C'_k) = \sum_{p\in S} \min_{c\in C'_k} \|p - c\|^2$. For every point $p \in S$, to bound its cost $\min_{c\in C'_k} \|p - c\|^2$, we use multiple relaxed triangle inequalities for every center $c_i \in C$, and take the weighted average of them using $\omega(p, c_i)$.

$$\begin{aligned}
\phi_S(C'_k) &= \sum_{p\in S} \min_{c\in C'_k} \|p - c\|^2 = \sum_{p\in S}\sum_{c_i\in C} \omega(p, c_i) \min_{c\in C'_k} \|p - c\|^2 && [\textstyle\sum_{c_i\in C}\omega(p, c_i) = 1] \\
&\leq \sum_{p\in S}\sum_{c_i\in C} \omega(p, c_i) \min_{c\in C'_k} 2(\|p - c_i\|^2 + \|c_i - c\|^2) && [\text{relaxed triangle inequality}] \\

Testing Dynamic Environments: Back to Basics

Yonatan Nakar
Tel Aviv University, Israel

Dana Ron
Tel Aviv University, Israel

Abstract

We continue the line of work initiated by Goldreich and Ron (*Journal of the ACM, 2017*) on testing dynamic environments and propose to pursue a systematic study of the complexity of testing basic dynamic environments and local rules. As a first step, in this work we focus on dynamic environments that correspond to elementary cellular automata that evolve according to threshold rules.

Our main result is the identification of a set of conditions on local rules, and a meta-algorithm that tests evolution according to local rules that satisfy the conditions. The meta-algorithm has query complexity $\text{poly}(1/\epsilon)$, is non-adaptive and has one-sided error. We show that all the threshold rules satisfy the set of conditions, and therefore are $\text{poly}(1/\epsilon)$-testable. We believe that this is a rich area of research and suggest a variety of open problems and natural research directions that may extend and expand our results.

1 Introduction

Property testing [12, 5] is the study of algorithms that distinguish between objects that have a given property and those that are far from having the property, by performing a small number of queries to the object. Goldreich and Ron [6] initiated the study of testing *dynamic environments*, which introduces a temporal aspect to property testing. In this context, the entity being tested changes with time, and is referred to as an *environment*.

Starting from some initial *configuration* (say, a vector or a matrix), the environment is supposed to evolve according to a prespecified *local* rule. The rule is local in the sense that the value associated with each location in the environment at time t is determined by the values of nearby locations at time $t-1$. The goal of the testing algorithm is then to distinguish between the case that the environment indeed evolves according to the rule, and the case in which the evolution significantly strays from obeying the rule. To this end, the algorithm can query the value of any location of the environment at any of the available time steps, as long as it does not "go back in time". Namely, the algorithm cannot choose to query a location at time t after it has queried some location at time $t' > t$. We refer to this as the *time-conforming* requirement. The aim is to design time-conforming algorithms with low query complexity.

Goldreich and Ron [6] investigate the complexity landscape of testing dynamic environments from multiple angles. From a hardness perspective, they show that there are dynamic environments whose testing requires high query complexity and running time, and that adaptivity and time-conformity are relevant constraints which can significantly impact the query complexity. However, as we discuss in Section 1.4, relatively little is known regarding positive results for testing specific rules.

In our quest for understanding which natural families of dynamic environments can be tested efficiently, we propose to first "go back to the basics" and study testing in the simplest of dynamic environments. Namely, in this work we consider environments defined by one-dimensional configurations, which evolve according to local rules that are functions of the current location and its two immediate neighbors. These dynamic environments, originally introduced by von Neumann [13], have been extensively studied under the name of *Elementary Cellular Automata* [14] (see definition in Section 1.1). While these environments can be described in simple terms, they are nevertheless able to capture complex behavior.[1] Cellular automata have played a role in various research fields and applications. Examples include modeling physical [2] and chemical [7] systems, VLSI design [3], music generation [1], analyzing plant population dynamics [15], forest fire spread [17], city traffic [11], urban sprawl [8], and more.

As we discuss in Section 1.4, there are several hardness results (both regarding the query complexity and the running time) for testing dynamic environments that correspond to one-dimensional cellular automata (over non-binary alphabets) [6]. Hence, in order to obtain efficient algorithms, it is necessary to restrict the rules considered. In the current work, our main focus is on perhaps the most basic and natural rules, defined by threshold functions. Such functions have received much attention within the study of propagation of information/influence in networks (see, e.g., the review paper of Peleg [10], and the recent Ph.D. thesis of Zehmakan [16] and references within).

Our testers are based on a general meta-algorithm which works for rules that satisfy a set of conditions that we define. In essence, the conditions capture a certain type of behavior leading to ultimate convergence. This behavior induces a global structure on the environment which we exploit in our meta-algorithm.

We hope this work can serve as a basis for further extensions and generalizations, some of which we discuss shortly in Section 1.5.

1.1 Testing basic evolution rules

We now formally define the problems we study. We use $[m]$ to denote the set $\{0, ..., m-1\}$. For two integers n and m, let $\texttt{ENV} : [m] \times \mathbb{Z}_n \to \{0,1\}$ denote the evolving environment, and for any $t \in [m]$ let $\texttt{ENV}_t : \mathbb{Z}_n \to \{0,1\}$ (the environment at time t) be defined by $\texttt{ENV}_t(i) = \texttt{ENV}(t,i)$. In general, we refer to a function $\sigma : \mathbb{Z}_n \to \{0,1\}$ as a *configuration*. When convenient, we may view σ as a (cyclic) binary string of length n.

For a function (evolution rule) $\rho : \{0,1\}^3 \to \{0,1\}$, we say that $\texttt{ENV}$ *evolves according to* ρ, if for every $i \in \mathbb{Z}_n$ and $t > 0$, we have that $\texttt{ENV}_t(i) = \rho(\texttt{ENV}_{t-1}(i-1), \texttt{ENV}_{t-1}(i), \texttt{ENV}_{t-1}(i+1))$, where all operations are modulo n. We use $\mathcal{E}^{\rho}_{m,n}$ to denote the set of environments $\texttt{ENV} : [m] \times \mathbb{Z}_n \to \{0,1\}$ that evolve according to ρ. As in [6], we employ the standard notion of distance used in property testing and say that $\texttt{ENV} : [m] \times \mathbb{Z}_n \to \{0,1\}$ is ϵ-*far from evolving according to* ρ (ϵ-far from $\mathcal{E}^{\rho}_{m,n}$) if $|\{(t,i) : \texttt{ENV}(t,i) \neq \texttt{ENV}'(t,i)\}| > \epsilon mn$ for every $\texttt{ENV}' \in \mathcal{E}^{\rho}_{m,n}$.[2]

[1] Some rules are even Turing complete [4].

[2] In the context of dynamic environments, this notion of distance can be interpreted as capturing "measurement errors" due to some noise process. Namely, it can be viewed as allowing the testing algorithm to accept not only "perfect" environments, but also environments that correspond to a correct evolution with a bounded fraction of corruptions. Also note that being ϵ-far from evolving according to ρ does not simply translate to there being an ϵ-fraction of pairs (t,i) for which $\texttt{ENV}_t(i) \neq \rho(\texttt{ENV}_{t-1}(i-1), \texttt{ENV}_{t-1}(i), \texttt{ENV}_{t-1}(i+1))$ (which would be trivial to test).

Given n, m, and a distance parameter $\epsilon \in (0,1)$, a testing algorithm for evolution according to a rule ρ should distinguish with constant success probability between the case that an environment ENV belongs to $\mathcal{E}^{\rho}_{m,n}$ and the case that it is ϵ-far from $\mathcal{E}^{\rho}_{m,n}$. To this end, the algorithm is given query access to ENV, where a query on a pair (t,i) cannot follow any query on (t',i') for $t' > t$. We are interested in bounding both the total number of queries performed by the algorithm (as a function of ϵ, and possibly m and n) and the maximum number of queries it performs at any time step (which we refer to as its *temporal query complexity*).

1.2 Our results

We identify several conditions on local rules (which are formally stated in Section 3), such that if a rule ρ satisfies these conditions, then evolution according to ρ can be tested with query complexity $\text{poly}(1/\epsilon)$ with one-sided error. Our testers have the advantage that they are non-adaptive, and therefore, in particular, time-conforming.

▶ **Theorem 1.** *Let Ψ be the set of conditions specified in Section 3. For every rule ρ that satisfies the conditions in Ψ, it is possible to test evolution according to ρ by performing $O(1/\epsilon^4)$ queries. Furthermore, the testing algorithm is non-adaptive and has one-sided error.*

To establish Theorem 1, we present a *meta-algorithm* for testing evolution and prove its correctness for rules that satisfy the aforementioned conditions (the set Ψ). It is a meta-algorithm in the sense that it is based on certain subroutines that are rule-specific (but have a common functionality of detecting violations of evolution according to the tested rule). We provide a high-level discussion of the conditions and the algorithm in Section 1.3.

Our main application of the meta-algorithm is to the natural family of threshold rules.

▶ **Definition 1.** *We say that a rule $\rho : \{0,1\}^3 \to \{0,1\}$ is a* threshold *rule if there exist a threshold integer $0 \leq b \leq 3$ and a bit $\alpha \in \{0,1\}$ such that $\rho(\beta_1,\beta_2,\beta_3) = \alpha$ if and only if $\beta_1 + \beta_2 + \beta_3 \geq b$.*

We prove:

▶ **Theorem 2.** *For each threshold rule ρ, evolution according to ρ can be tested with query complexity $O(1/\epsilon^4)$. Furthermore, the testing algorithm is non-adaptive and has one-sided error.*

We also show that the conditions hold for two additional (non-threshold) rules, so the applicability of our meta-algorithm is more general (for details, see full version of this paper [9]). We believe that appropriate (perhaps more complex) variants of our algorithm can be used to test an even larger variety of basic local rules (see Section 1.5), where we conjecture that this is true for all rules that ultimately converge. Interestingly, while the two additional rules are not threshold rules as per Definition 1, they can be represented as weighted threshold rules (which are a subclass of ultimately converging rules).

1.3 The high-level ideas behind our results

In this high-level discussion, we assume for simplicity that $m \geq n$ (the case $m < n$ can be essentially reduced to this case).

1.3.1 Convergence, final/non-final locations and prediction functions

To give an intuition on the convergence behavior that our conditions capture, it is useful to first discuss the notion of *ultimate convergence*. A rule ρ ultimately converges if, for any initial configuration $\texttt{ENV}_0$, an environment evolving according to ρ converges after a bounded number of steps to either a single final configuration or to a constant number of configurations between which it alternates. For example, consider the majority rule (threshold 2). Unless the initial configuration is $(01)^{n/2}$, the environment ultimately converges to some configuration that consists of blocks of 0s and 1s of size at least 2 each (and if it is $(01)^{n/2}$, then it alternates between $(01)^{n/2}$ and $(10)^{n/2}$).

Once an environment converges, testing is straightforward since we can easily predict the values of locations in future time steps and then verify that indeed they hold the predicted values (or else we reject). The issue, however, is that convergence is not ensured to be reached after a small number of time steps.[3] In other words, knowing that a rule ultimately converges cannot be exploited directly. Hence, the challenge is to identify and formalize conditions that allow for "pre-convergence prediction". Namely, conditions that imply the ability to predict future values of locations based on the current values of these and other locations (before convergence is reached).

In this context, our conditions try to formalize the idea that rules exhibit a certain *local* convergence, which "expands" with time. The first ingredient of our approach is the observation that, in the case of the majority rule, if at any time step t, $\texttt{ENV}_t(i) \in \{\texttt{ENV}_t(i-1), \texttt{ENV}_t(i+1)\}$, then $\texttt{ENV}_{t'}(i) = \texttt{ENV}_t(i)$ for any $t' > t$ (operations are modulo n). We say in such a case that location i is *final* at time t (in $\texttt{ENV}$). Otherwise it is *non-final*. Crucially for us, whether a location i is final or not at a certain time step depends solely on its local neighborhood at that time (and can hence be verified with a constant number of queries).

An important property of a location being final at time t (in addition to converging to their final value, up to alternations), is the aforementioned expansion (or "transmission of finality"). Namely, a location i that is non-final at time t becomes final at time $t+1$ if either $i-1$ or $i+1$ is final at time t (possibly both). Furthermore, it cannot become final if both its neighbors are non-final. Another related property of final locations is that (under certain circumstances), they can be used to predict the values of locations that become final in the future, based on a (rule-specific) *prediction function*. A similar statement holds for non-final locations (though the circumstances are different).

1.3.2 The meta-algorithm: the grid and violating pairs

Based on these properties (which are formalized in the conditions we introduce), our (meta) algorithm works in two stages. In the first stage, it queries the environment at time $t_1 = \Theta(\epsilon m)$ on $O(1/\epsilon^2)$ equally spaced locations, which we refer to as *the grid locations*, and their local neighborhoods. This allows the algorithm to determine which of the grid locations are final at time t_1 and which are non-final. If the answers it gets are not consistent with any environment that evolves according to ρ (in which case we say that the grid is *not feasible*), then it rejects.

In its second stage, the algorithm uniformly samples $O(1/\epsilon)$ random time-location pairs (t, i) and queries $\texttt{ENV}_t$ on i and its local neighborhood. It then checks whether the answers are consistent with the answers to queries in the first stage (on the grid locations and their neighborhoods) or constitute a *violation*. The definition of consistency/violation is based on the aforementioned prediction functions of the tested rule.

---

[3] In fact, there are initial configurations that require $\Omega(n)$ steps before they ultimately converge.

One may have hoped that such a consistency check is sufficient, in the sense that all (or almost all) pairs (t, i) can be predicted based on the answers to the queried grid locations. Unfortunately, this is not the case. There are (possibly many) pairs (t, i) whose 0/1 values are not determined given the first-stage answers. However, we show that such pairs are constrained in a different way (in environments that evolve according to ρ): their location must have become final by time $t_2 = t_1 + \Delta$, where Δ is the distance between grid location. Hence, for each selected pair (t, i), the algorithm also queries $\texttt{ENV}_{t_2}$ on location i (and its neighborhood) and checks consistency with the queried locations at time t_2.

1.3.3 On the analysis of the algorithm and "backward prediction"

To show that the algorithm always accepts environments that evolve according to the tested rule ρ, we prove that our definition of violation is such that there are no violations in such environments (assuming ρ satisfies the aforementioned conditions). The more involved part of the analysis is proving that if the environment $\texttt{ENV}$ is ϵ-far from evolving according to ρ, then the algorithm will detect this with probability at least 2/3. To this end, we prove the contrapositive statement. Namely, we show that if the algorithm accepts with probability at least 2/3, then there exists an environment that evolves according to ρ and is ϵ-close to $\texttt{ENV}$. This is done by showing that we can construct an initial configuration $\texttt{ENV}'_0$, such that if we let it evolve according to ρ, resulting in an environment $\texttt{ENV}' \in \mathcal{E}^{\rho}_{m,n}$, then we can upper bound the number of pairs (t, i) such that $\texttt{ENV}_t(i) \neq \texttt{ENV}'_t(i)$ by ϵmn.

Here we build on a useful property of the prediction functions, by which they allow us a certain "prediction back in time". Namely (for t_1 and t_2 as mentioned above), we use the queried grid locations at time t_1 as well as some locations at time t_2 (which have not been queried) to determine values of locations at the earlier time 0 in $\texttt{ENV}'$. We prove that this can be done in a way that ensures that $\texttt{ENV}'$ agrees with $\texttt{ENV}$ on all pairs (t, i) that are not violating.

1.4 A short overview of the results in [6]

As stated earlier, the study of testing dynamic environments was initiated by Goldreich and Ron [6], who present several general results as well as analyze two natural specific rules. We first provide a short overview of their main general results.

They prove that the query complexity of testing (one-dimensional) rules may have high query complexity. Specifically, they show that there exists a constant $c > 0$ and an evolution rule $\rho : \Sigma^3 \to \Sigma$ such that any tester of evolution according to ρ requires $\Omega(n^c)$ queries.[4] They also prove that testing dynamic environments may be NP-Hard, provided that the temporal query complexity is "significantly sublinear" (where $f(x)$ is significantly sublinear if $f(x) < x^{1-\Omega(1)}$). More precisely, they show that for every constant $c > 0$ there exists an evolution rule $\rho : \Sigma^3 \to \Sigma$ such that no (time-conforming) polynomial-time testing algorithm with temporal query complexity n^{1-c} can test whether n-sized environments evolve according to ρ (assuming $\mathcal{NP} \not\subseteq \mathcal{BPP}$). Their general results also include a theorem concerning the usefulness of adaptivity in testing dynamic environments, a study of the relation between testing and learning dynamic environments, and a result on the power of being non time-conforming.

[4] Observe that it is possible to test the evolution according to any rule ρ over configurations of size n by performing $O(n + 1/\epsilon)$ queries (n queries to the initial configuration and $O(1/\epsilon)$ uniformly selected queries elsewhere). To get sublinear temporal query complexity, a total of $O(n/\epsilon)$ uniformly selected queries suffice (by applying a simple union bound over all possible initial configurations).

Goldreich and Ron [6] also provide testers for evolution according to two specific (classes of) rules. The first is the class of linear rules, which in the binary 1-dimensional case corresponds to the XOR rule in elementary cellular automata. They show that for any $d \geq 1$ and any field Σ of prime order, there exists a constant $\gamma < d$ such that the following holds. For any linear rule $\rho : \Sigma^{3^d} \to \Sigma$ there exists a time-conforming oracle machine of (total) time complexity $\text{poly}(1/\epsilon) \cdot n^\gamma$ that tests the consistency of an evolving environment with respect to ρ. Furthermore, the tester is non-adaptive and has one-sided error.

Their second specific positive result, loosely stated, captures fixed-speed movement of objects in one-dimension such that colliding objects stop forever. They present a (time-conforming) algorithm of (total) time complexity $\text{poly}(1/\epsilon)$ that tests the consistency of evolving environments with respect to that rule.

1.5 Future directions

Basic dynamic environments. A natural question that arises is whether a more nuanced version of the set of conditions formalized in this paper and the meta-algorithm can be defined and proved to work for other rules in the realm of basic dynamic environments. Indeed, preliminary results suggest that several other rules that ultimately converge exhibit behaviors that "resemble" the ones captured by our conditions. This leads us to the following conjecture.

▶ **Conjecture.** *If a rule ρ ultimately converges, then it is poly$(\frac{1}{\epsilon})$-testable.*

While our meta-algorithm does not apply to rules that do not ultimately converge, there are natural rules that fall under this category (the XOR rule for instance). This raises the question of whether $\text{poly}(1/\epsilon)$ testers exist for such rules. The answer is that there are $\text{poly}(1/\epsilon)$-testable rules that do not ultimately converge, but as we'll see, the question should be slightly rephrased.[5] To give one example, for the rule ρ defined as $\rho(x, y, z) = x$, each configuration is simply a copy of the previous configuration, shifted one location to the right. That is, while an environment evolving according to this rule does not, technically, ultimately converge, this rule is trivially $\text{poly}(1/\epsilon)$-testable. However, this particular rule and other rules that are capable of producing such "shifting behaviors" also have the property of not being *symmetric* (i.e., it does not hold that $\rho(x, y, z) = \rho(z, y, x)$ for every x, y, z). Hence, one way to rephrase the question is restricting it to symmetric rules.

▶ **Open Problem 1.** *Are there any symmetric rules that do not ultimately converge and are poly$(1/\epsilon)$-testable?*

Another way to rephrase this question is to define a more general notion of ultimate convergence. Specifically, we say that a rule ρ *ultimately converges up to a shift* if, for any initial configuration $\texttt{ENV}_0$, an environment evolving according to ρ converges after a bounded number of steps to a constant number of configuration *equivalence classes* between which it alternates, where two configurations are *equivalent* if they are equal *up to a shift*.

▶ **Open Problem 2.** *Are there any non-symmetric rules that do not ultimately converge up to a shift and are poly$(1/\epsilon)$-testable?*

As mentioned in Section 1.4, it has been shown in [6] that the XOR rule is sublinearly testable. However, the query complexity of the tester depends on the size of the environment and is only mildly sublinear (the complexity is $O(n^{0.8})$ for an environment of size n). This

[5] We thank one of the anonymous reviewers of this paper for pointing this out.

raises the question of whether there exists a tester for the XOR rule with significantly lower query complexity (maybe even polylogarithmic). Another question that can be raised is whether there are other symmetric rules, ones that do not ultimately converge, that can be tested with a sublinear query complexity that depends on the size of the environment.

▶ **Open Problem 3.** *Which symmetric rules that do not ultimately converge can be tested with query complexity that is sublinear in (but strictly grows with) the size of the environment?*

More general dynamic environments. Building on the ideas for testing basic dynamic environments, it may be possible to venture into more general environments. One such generalization is to consider rules that depend on more than just the three locations constituting the immediate neighborhood. Other generalizations are to environments and rules over non-binary values, higher dimensions, and environments that evolve on more general graphs.

Non-deterministic rules. We also suggest considering local rules that are non-deterministic in the sense that given some configuration, the rule allows several configurations to follow. An example of one such rule, which can be thought of as a relaxation of the OR rule, is the rule in which each value is restricted to be monotonically non-decreasing with respect to the previous values at the location's neighborhood.

Missing details

Due to space constraints, not all details appear in this extended abstract, and can be found in the full version of this paper [9].

2 Preliminaries

In addition to the basic definitions provided in Section 1.1 regarding testing dynamic environments, here we introduce several more definitions and notations.

In all that follows, when performing operations on locations $i \in \mathbb{Z}_n$, these operations are modulo n. For a pair of locations $i, j \in \mathbb{Z}_n$ we use $[i, j]$ to denote the sequence $i, i+1, \ldots, j$ (so that it is possible that $j < i$).

▶ **Definition 2.** *For a location $i \in \mathbb{Z}_n$ and an integer r, the r-neighborhood of i, denoted $\Gamma_r(i)$, is the sequence $[i-r, i+r]$. For a set of locations $I \subseteq \mathbb{Z}_n$, we let $\Gamma_r(I)$ denote the set of locations in the union of sequences $[i-r, i+r]$ taken over all $i \in I$.*

▶ **Definition 3.** *For an integer n and a local rule ρ, let $\mathcal{M}_\rho(n)$ denote the (deterministic) state machine that is defined as following. Each state of $\mathcal{M}_\rho(n)$ corresponds to a different configuration $\sigma : \mathbb{Z}_n \to \{0,1\}$. If a state corresponds to a configuration σ, then it has a single transition going to the state corresponding to the configuration that results from applying ρ to σ.*

The period of $\mathcal{M}_\rho(n)$, denoted $p_\rho(n)$, is the longest size of a (directed) cycle in $\mathcal{M}_\rho(n)$. If there exists a constant p such that $p_\rho(n) = p$ ($p_\rho(n) \leq p$) for every sufficiently large n, then we say that ρ has period (at most) p, and that ρ ultimately converges.

Observe that for every $\mathcal{M}_\rho(n)$, each strongly connected component in $\mathcal{M}_\rho(n)$ is either a single state with no edges in the component or a cycle (where in particular, the cycle may be a self-loop). For example, if ρ is the OR function, then it has period 1 (as it contains

only two cycles: one is a self-loop for the state corresponding to the configuration 1^n and the other is a self loop for the state corresponding to the configuration 0^n). On the other hand, there are rules, such as XOR, for which $p_\rho(n) = \Omega(n)$.

▶ **Definition 4.** *For two locations $i, i' \in \mathbb{Z}_n$, we let $\overrightarrow{\text{dist}}(i, i') = i' - i$ denote the directed distance from i to i, and let $\text{dist}(i, i') = \min\{\overrightarrow{\text{dist}}(i, i'), \overrightarrow{\text{dist}}(i', i)\}$ denote the (undirected) distance.*

Note that since operations on locations are modulo n, we have that $\overrightarrow{\text{dist}}(i, i') \leq n - 1$, while $\text{dist}(i, i') \leq n/2$ for all $i, i' \in \mathbb{Z}_n$.

▶ **Definition 5.** *For $t \in [m]$ and $i \in \mathbb{Z}_n$, we refer to (t, i) as a time-location pair (or simply pair).*

Given two locations, $i, i' \in \mathbb{Z}_n$ and two time steps $t, t' \in [m]$ where $t > t'$, we say that the pair (t, i) descends from the pair (t', i') if $\text{dist}(i, i') \leq t - t'$. We say that (t, i) is a descendant of (t', i') and that (t', i') is an ancestor of (t, i).

▶ **Definition 6.** *For an integer r, an r-pattern is a string in $\{0, 1\}^r$.*

3 The Conditions

Let $\rho : \{0, 1\}^3 \to \{0, 1\}$ be a local rule. We present several conditions, such that if they all hold, then the rule ρ can be tested with $\text{poly}(1/\epsilon)$ queries. These conditions capture properties of local rules that can be exploited by our (meta) algorithm.

The conditions are defined with respect to a constant (integer) k (which depends on ρ, but for the sake of simplicity we suppress the dependence on ρ and use k rather than k_ρ), and a partition of all $(2k + 1)$-patterns.[6] The partition is denoted by $(\mathcal{F}_\rho, \overline{\mathcal{F}}_\rho)$, where $\mathcal{F}$ stands for *final* and $\overline{\mathcal{F}}$ for *non-final*.

We shall say that a pair (t, i) is final (respectively, non-final) *with respect to* ENV *and* ρ if $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$ (respectively, $\overline{\mathcal{F}}_\rho$). Roughly speaking, if (t, i) is final (with respect to ENV and ρ), then location i does not change from time t and onward (or, more generally, $\texttt{ENV}_{t'}(i)$ for $t' > t$ can be predicted based on $\texttt{ENV}_t(i)$). Furthermore, if (t, i) is non-final, then $(t + 1, i)$ is final if and only if $(t, i - 1)$ or $(t - 1, i + 1)$ is final (so that finality is "infectious").

In our statements of the conditions, we make use of the parity function, which we denote by $\text{parity} : \mathbb{N} \to \{0, 1\}$ (so that $\text{parity}(x) = 1$ if x is odd and $\text{parity}(x) = 0$ if x is even).

Before each of the conditions is stated formally, we give a short, informal description. It will also be useful to have a running example of a specific rule ρ, which is the majority rule. Namely, $\text{MAJ}(\beta_1, \beta_2, \beta_3) = 1$ for any three bits $\beta_1, \beta_2, \beta_3$, if and only if $\beta_1 + \beta_2 + \beta_3 \geq 2$. For the majority rule, $k = 1$, and $\mathcal{F}_{\text{MAJ}} = \{111, 110, 011, 000, 001, 100\}$ (so that $\overline{\mathcal{F}}_{\text{MAJ}} = \{101, 010\}$).

The first condition says that if a location is final, then it remains final.

▶ **Condition 1.** *Let $\texttt{ENV} \in \mathcal{E}^\rho_{m,n}$ be an environment that evolves according to ρ. For any time step $t \in [m - 1]$ and location $i \in \mathbb{Z}_n$, if $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$, then $\texttt{ENV}_{t+1}(\Gamma_k(i)) \in \mathcal{F}_\rho$.*

Indeed, for the majority rule, if $\texttt{ENV}_t(\Gamma_1(i)) = 111$, then $\texttt{ENV}_{t+1}(\Gamma_1(i)) = 111 \in \mathcal{F}_{\text{MAJ}}$, if $\texttt{ENV}_t(\Gamma_1(i)) = 110$, then $\texttt{ENV}_{t+1}(\Gamma_1(i)) \in \{110, 111\} \subset \mathcal{F}_{\text{MAJ}}$, and if $\texttt{ENV}_t(\Gamma_1(i)) = 110$, then $\texttt{ENV}_{t+1}(\Gamma_1(i)) \in \{110, 111\} \subset \mathcal{F}_{\text{MAJ}}$ (analogous statements hold for $\texttt{ENV}_t(\Gamma_1(i)) \in \{000, 001, 100\}$).

[6] For the local rules we apply our conditions to, k is either 0 or 1, but using a variable parameter k will hopefully allow to extend our results more easily.

The second condition says that if a location is non-final, then it can become final in one time step if and only if it has a final neighbor.

▶ **Condition 2.** *Let* $\texttt{ENV} \in \mathcal{E}^{\rho}_{m,n}$ *be an environment that evolves according to* ρ*. For any time step* $t \in [m-1]$ *and location* $i \in \mathbb{Z}_n$*, if* $\texttt{ENV}_t(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$*, then* $\texttt{ENV}_{t+1}(\Gamma_k(i)) \in \mathcal{F}_\rho$ *if and only if* $\texttt{ENV}_t(\Gamma_k(i-1)) \in \mathcal{F}_\rho$ *or* $\texttt{ENV}_t(\Gamma_k(i+1)) \in \mathcal{F}_\rho$ *(or both).*

For the majority rule, consider the case that $\texttt{ENV}_t(\Gamma_1(i)) = 101$ (so that it belongs to $\overline{\mathcal{F}}_{\text{MAJ}}$). In this case, $\texttt{ENV}_t(\Gamma_1(i-1)) \in \{110, 010\}$ and $\texttt{ENV}_t(\Gamma_1(i+1)) \in \{011, 010\}$. If $\texttt{ENV}_t(\Gamma_1(i-1)) = 110$ (which belongs to $\mathcal{F}_{\text{MAJ}}$), then $\texttt{ENV}_{t+1}(\Gamma_1(i)) \in \{110, 111\} \subset \mathcal{F}_{\text{MAJ}}$, and the case that $\texttt{ENV}_t(\Gamma_1(i+1)) = 011$ is analogous. On the other hand, if both $\texttt{ENV}_t(\Gamma_1(i-1)) = 010$ and $\texttt{ENV}_t(\Gamma_1(i+1)) = 010$ (so that they both belong to $\overline{\mathcal{F}}_{\text{MAJ}}$), then $\texttt{ENV}_{t+1}(\Gamma_1(i)) = 010$ (and it belongs to $\overline{\mathcal{F}}_{\text{MAJ}}$ as well). Note that, if for every location $i \in \mathbb{Z}_n$, it holds that $\texttt{ENV}_0(\Gamma_1(i)) \in \{010, 101\}$ (that is, every location in the initial configuration is non-final), then no location would ever become final throughout the evolution of the rule. In particular, in this case the environment alternates between $(01)^{n/2}$ and $(10)^{n/2}$, where all the locations are non-final.

The first two conditions intuitively imply that one can determine whether certain locations are final or non-final using particular "past" locations that are known to be final or non-final. The next two conditions capture the idea that the actual *values* at certain locations (and not only whether or not they are final) can also be determined based on past locations.

In particular, the third condition captures how values at locations that are final at a certain time step can be predicted using a function that depends on "past" final locations from which they descend (and to which they are closest).

▶ **Condition 3.** *Let* $\texttt{ENV} \in \mathcal{E}^{\rho}_{m,n}$ *be an environment that evolves according to* ρ*. There exists a function* $f_\rho : \{0,1\}^3 \to \{0,1\}$ *for which the following holds. First,* f_ρ *is the XOR of its first argument and a subset of the other two arguments. Second, let* (t,i) *and* (t',i') *be any two pairs such that* (t,i) *descends from* (t',i')*,* $\texttt{ENV}_t(\Gamma_k(i)), \texttt{ENV}_{t'}(\Gamma_k(i')) \in \mathcal{F}_\rho$*, and for every* $i'' \neq i'$ *satisfying* $\text{dist}(i,i'') \leq \text{dist}(i,i')$ *it holds that* $\texttt{ENV}_{t'}(\Gamma_k(i'')) \in \overline{\mathcal{F}}_\rho$*. Then*

$$\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_{t'}(i'), \mathit{parity}(t-t'), \mathit{parity}(\text{dist}(i,i'))) \ .$$

For the majority rule, f_{MAJ} is simply the identity function on its first argument, namely, $f_{\text{MAJ}}(\beta, \cdot, \cdot) = \beta$.

The fourth condition captures how locations that are non-final at a certain time step can be predicted using a function that depends on "past" non-final locations from which they descend (conditioned on there not being any final location among its ancestors in that past time step).

▶ **Condition 4.** *Let* $\texttt{ENV} \in \mathcal{E}^{\rho}_{m,n}$ *be an environment that evolves according to* ρ*. There exists a function* $h_\rho : \overline{\mathcal{F}}_\rho \times \{0,1\} \times \mathbb{Z}_n \to \overline{\mathcal{F}}_\rho$ *for which the following holds. First,* h_ρ *is reversible in the sense that for each fixed* $\tau \in \overline{\mathcal{F}}_\rho$*,* $\beta \in \{0,1\}$ *and* $\ell \in \mathbb{Z}_n$*, there exists a unique* τ' *such that* $h_\rho(\tau', \beta, \ell) = \tau$*. Second, let* (t,i) *and* (t',i') *be any two pairs such that* (t,i) *descends from* (t',i')*,* $\texttt{ENV}_t(\Gamma_k(i)), \texttt{ENV}_{t'}(\Gamma_k(i')) \in \overline{\mathcal{F}}_\rho$*, and* $\texttt{ENV}_{t'}(\Gamma_k(i'')) \in \overline{\mathcal{F}}_\rho$ *for every* i'' *such that* (t,i) *descends from* (t',i'')*. Then*

$$\texttt{ENV}_t(\Gamma_k(i)) = h_\rho(\texttt{ENV}_{t'}(\Gamma_k(i')), \mathit{parity}(t-t'), \overrightarrow{\text{dist}}(i',i)) \ .$$

For the majority rule, $h_{\text{MAJ}}(010, \beta, x) = 010$ if $\beta \oplus \mathsf{parity}(x) = 0$ and $h_{\text{MAJ}}(010, \beta, x) = 101$ if $\beta \oplus \mathsf{parity}(x) = 0$. Similarly, $h_{\text{MAJ}}(101, \beta, x) = 101$ if $\beta \oplus \mathsf{parity}(x) = 0$ and $h_{\text{MAJ}}(101, \beta, x) = 010$ if $\beta \oplus \mathsf{parity}(x) = 1$.

The additional two conditions presented below are a bit more involved than Conditions 1–4, and perhaps initially less intuitive. They do not play a role in the definition of the meta algorithm, but are applied in the proof of Lemma 2 (and we recommend that the reader return to them in that context). In a nutshell, they allow us to show that if our testing algorithm accepts the environment $\texttt{ENV}$ with high constant probability, then there exists an environment $\texttt{ENV}'$ that evolves according to ρ and is relatively close to $\texttt{ENV}$. In particular, they aid us in defining the initial configuration $\texttt{ENV}'_0$ based on $\texttt{ENV}_t$ for some appropriate time step t.

▶ **Condition 5.** *Let $\sigma : \mathbb{Z}_n \to \{0,1\}$ be a configuration and let $[x,y]$ be an interval of locations such that $\sigma(\Gamma_k(x)) \in \mathcal{F}_\rho$ and $\sigma(\Gamma_k(y)) \in \mathcal{F}_\rho$. There exists a configuration $\widetilde{\sigma} \in \mathbb{Z}_n$, which differs from σ only on locations inside $[x,y]$, for which the following holds: For every $i \in [x,y]$ we have that $\widetilde{\sigma}(\Gamma_k(i)) \in \mathcal{F}_\rho$, and if $\sigma(\Gamma_k(i)) \in \mathcal{F}_\rho$, then $\widetilde{\sigma}(i) = \sigma(i)$.*

This condition also covers the special case in which $y = x$ and we interpret $[x,y]$ as $x, x+1, \ldots, x+n$ (with a slight abuse of notation).

▶ **Condition 6.** *Let $\sigma : \mathbb{Z}_n \to \{0,1\}$ be a configuration and $z \in \mathbb{Z}_n$ such that $\sigma(\Gamma_k(z)) \in \overline{\mathcal{F}}_\rho$. Let $\nu \in \{\tau_{k+1} : \tau \in \mathcal{F}_\rho\}$ and $\gamma, \gamma' \in \{0,1\}$. There exists a configuration $\widetilde{\sigma} : \mathbb{Z}_n \to \{0,1\}$ for which the following hold. There is a location $z' \in [z+1, z+2k+1]$ where $\widetilde{\sigma}(\Gamma_k(z')) \in \mathcal{F}_\rho$, and $f_\rho(\widetilde{\sigma}(z'), \gamma, \mathsf{parity}(z'-z) \oplus \gamma') = \nu$. Furthermore, for every $i \in [z+1, z'-1]$ it holds that $\widetilde{\sigma}(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$, and for every $i \notin [z+k, z'+k]$, $\widetilde{\sigma}(i) = \sigma(i)$.*

A (symmetric) variant of the above should also hold if we replace $z' \in [z+1, z+2k+1]$ by $z' \in [z-2k-1, z-1]$, $i \in [z+1, z'-1]$ by $i \in [z'+1, z-1]$, and $i \notin [z+k, z'+k]$ by $i \notin [z'-k, z-k]$.

4 The Meta-Algorithm

In this section, we present a meta-algorithm for testing evolution of local rules that satisfy the sufficient conditions (specified in Section 3). Here we give an algorithm whose complexity is $\lceil n/m \rceil \cdot \mathrm{poly}(1/\epsilon)$ and, in the full version of this paper [9], we explain how to remove the dependence on n/m.

In order to precisely describe our meta-algorithm, we need to first define a particular set of locations that we designate as *the 1-dimensional grid* and the notion of *violating time-location pairs* with respect to the 1-dimensional grid. The 1-dimensional grid is defined in Section 4.1 and the notion of violating pairs is defined in Section 4.2. Then, in Section 4.3, we describe our meta-algorithm.

In the full version of this paper [9], we show that these conditions hold for all (non-trivial) threshold rules, as well as a couple of additional rules.

4.1 The grid

In this subsection we introduce the notion of a one-dimensional "grid", which will be a central building block of the meta algorithm (and its analysis). Recall that a configuration is a function $\sigma : \mathbb{Z}_n \to \{0,1\}$. A *partial* configuration is a function $\sigma' : \mathbb{Z}_n \to \{0,1\} \cup \perp$, which will serve us to denote restrictions of configurations to a subset of the locations.

Let $\Delta = \frac{\epsilon^2}{b_0} \cdot \min\{n, m\}$ where b_0 is a sufficiently large constant. We assume for simplicity that Δ and n/Δ are both integers. Let $G \subseteq \mathbb{Z}_n$ (the *grid*) be the set of locations $\{j \cdot (n/\Delta)\}_{j=0}^{n/\Delta - 1}$.

As we shall see in Section 4.3, our algorithm queries the tested environment on all grid locations and their k-neighborhoods at a specific time step t_1 (which will be set subsequently).

Let $\texttt{ENV}_t[G]$ be the partial configuration that agrees with $\texttt{ENV}_t$ on all locations in $\{\Gamma_k(g) : g \in G\}$ and is $\perp$ elsewhere.

▶ **Definition 7.** *Given a time step $t > 0$, we say that the partial configuration $\texttt{ENV}_t[G]$ induced by the k-neighborhoods of the grid locations at time t is* feasible *with respect to a rule ρ, if there exists an environment $\texttt{ENV}'$ that evolves according to ρ and such that $\texttt{ENV}'_t(i) = \texttt{ENV}_t(i)$ for every $i \in \Gamma_k(G)$. We say in such a case that $\texttt{ENV}'$ is a* feasible completion *of $\texttt{ENV}_t[G]$ with respect to ρ.*

▶ **Definition 8.** *Given a pair of grid locations $g_1, g_2 \in G$, a time step t and a subset $\mathcal{S} \subset \{0,1\}^{2k+1}$, if for every grid location $g \in G \cap [g_1, g_2]$ it holds that $\texttt{ENV}_t(\Gamma_k(g)) \in S$, then we say that the interval $[g_1, g_2]$ is an S grid interval with respect to $\texttt{ENV}_t$. We say that $[g_1, g_2]$ is a maximal $\mathcal{S}$ grid interval with respect to $\texttt{ENV}_t$, if both $\texttt{ENV}_t(g_1 - \Delta)$ and $\texttt{ENV}_t(g_2 + \Delta)$ do not belong to $\mathcal{S}$.*

In particular, we shall be interested in the case that $\mathcal{S}$ is $\mathcal{F}_\rho$ or $\overline{\mathcal{F}}_\rho$. Note that a grid interval $[g_1, g_2]$ contains all the locations between g_1 and g_2, and not just the grid locations. Also note that if $\texttt{ENV}_t(\Gamma_k(g)) \in S$ for every $g \in G$, then by Definition 8, there is no maximal $\mathcal{S}$ grid interval with respect to $\texttt{ENV}_t$ (we shall deal with such cases separately).

4.2 Violating Pairs

Let ρ be a fixed local rule that satisfies all the conditions stated in Section 3. Let $t_1 = \frac{b_1 \Delta}{\epsilon}$, where b_1 is a sufficiently large constant and Δ is as defined in Section 4.1. Let $t_2 = t_1 + \Delta$. We now define the concept of a violating pair $(t, i) \in [m] \times \mathbb{Z}_n$ with respect to $\texttt{ENV}_{t_1}$. Generally speaking, these are pairs in the environment $\texttt{ENV}$ whose values are inconsistent with evolving according to the rule ρ given the values at the grid locations at time t_1. The definition of a violating pair serves us later by allowing our algorithm to reject when it encounters one, which, as we prove, happens with high constant probability if $\texttt{ENV}$ is ϵ-far from evolving according to the rule ρ.

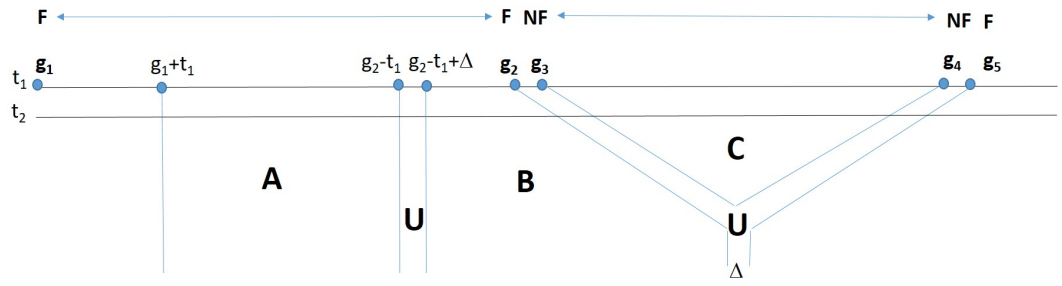

Figure 4.1 An illustration for the sets A, B, C, and U. Here $[g_1, g_2]$ is a maximal $\mathcal{F}_\rho$ grid interval, $g_3 = g_2 + \Delta$, where $[g_3, g_4]$ is a maximal $\overline{\mathcal{F}}_\rho$ grid interval, and $g_5 = g_4 + \Delta$ is an endpoint of a maximal $\mathcal{F}_\rho$ grid-interval. The area marked by A corresponds to pairs (t, i) such that $t > t_2$ and $i \in [g_1 + t_1, g_2 - t_1]$. These pairs are supposed to be final. The area marked by B corresponds to pairs (t, i) such that $t > t_2$, $i \in [g_2 - t_1 + \Delta, g_2 + (t - t_1)]$, and $\text{dist}(g_2, i) < \text{dist}(g_5, i) - \Delta$. These pairs are supposed to be final too. The area marked by C corresponds to pairs (t, i) such that $t > t_2$, $i \in [g_3, g_4]$, and (t, i) neither descends from $(t_1, g_3 + 1)$ nor from $(t_1, g_4 - 1)$. These pairs are supposed to be non-final. Finally, the areas marked by U correspond to pairs (t, i) such that $t > t_2$ and one of the following holds: **(1)** $i \in [g_2 - t_1 + 1, g_2(i) - t_1 + \Delta]$; **(2)** $i \in [g_3, g_4]$ and either **(a)** (t, i) descend from $(t_1, g_3 - \Delta)$ or $(t_1, g_4 + \Delta)$ and $|\text{dist}(g_3, i) - \text{dist}(g_4, i)| \leq \Delta$, or **(b)** (t, i) does not descend from either $(t_1, g_3 - \Delta)$ or $(t_1, g_4 + \Delta)$ but it descends from either (t_1, g_3) or (t_1, g_4).

We next define three disjoint sets of time-location pairs, denoted A, B and C, and for each of these three sets we state conditions under which the pair is considered to be a violating pair with respect to $\texttt{ENV}_{t_1}[G]$. The proof that the three sets are pairwise disjoint appears in Section 5, and for an illustration, see Figure 4.1.

If $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \mathcal{F}_\rho$ for every $g \in G$, then $A = \{(t,i) : t_2 < t < m,\ i \in \mathbb{Z}_n\}$. Otherwise, A is the set of pairs (t,i) where $t_2 < t < m$ and $i \in \mathbb{Z}_n$ such that there exists a maximal $\mathcal{F}_\rho$ grid interval $[g_1(i), g_2(i)]$ with respect to $\texttt{ENV}_{t_1}$ for which $i \in [g_1(i) + t_1, g_2(i) - t_1]$.

▶ **Definition 9.** *A pair $(t,i) \in A$ is said to be a violating pair with respect to $\texttt{ENV}_{t_1}[G]$, if at least one of the following requirements does not hold. (1) $\texttt{ENV}_{t_2}(\Gamma_k(i)) \in \mathcal{F}_\rho$. (2) $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$. (3) $\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_{t_2}(i), \mathit{parity}(t-t_2), 0)$ where f_ρ is the function referred to in Condition 3.*

Let B be the set of pairs (t,i), where $t_2 < t < m$ and $i \in \mathbb{Z}_n$ for which the following holds. First, there exists a maximal $\mathcal{F}_\rho$ grid interval $[g_1(i), g_2(i)]$ with respect to $\texttt{ENV}_{t_1}$ such that either $i \in [g_1(i) - (t - t_1), g_1(i) + t_1 - \Delta - 1]$ or $i \in [g_2(i) - t_1 + \Delta + 1, g_2(i) + (t - t_1)]$. Second, for every other maximal $\mathcal{F}_\rho$ grid interval $[g_1', g_2']$ (with respect to $\texttt{ENV}_{t_1}$), if $i \in [g_1(i) - (t - t_1), g_1(i) + t_1 - \Delta - 1]$, then $\mathrm{dist}(g_1(i), i) < \mathrm{dist}(g_2', i) - \Delta$, and if $i \in [g_2(i) - t_1 + \Delta + 1, g_2(i) + (t - t_1)]$, then $\mathrm{dist}(g_2(i), i) < \mathrm{dist}(g_1', i) - \Delta$.

▶ **Definition 10.** *A pair $(t,i) \in B$ is said to be a violating pair with respect to $\texttt{ENV}_{t_1}[G]$, if at least one of the following requirements does not hold. (1) $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$. (2) Let $[g_1(i), g_2(i)]$ be the maximal $\mathcal{F}_\rho$ grid interval ensured by the definition of B given (t,i). Let $g(i)$ be the grid location in $G \cap ([g_1(i), g_1(i) + t_1 - \Delta] \cup [g_2(i), g_2(i) - t_1 + \Delta])$ that is closest to i (if there are two such grid locations, then select the one closer to $g_1(i)$). Then $\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_{t_1}(g(i)), \mathit{parity}(t - t_1), \mathit{parity}(\mathrm{dist}(i, g(i))))$, where f_ρ is the function referred to in Condition 3.*

If $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \overline{\mathcal{F}}_\rho$ for every $g \in G$, then $C = \{(t,i) : t_2 < t < m,\ i \in \mathbb{Z}_n\}$. Otherwise, C is the set of pairs (t,i) where $t_2 < t < m$ and $i \in \mathbb{Z}_n$ for which the following holds. First, there exists a maximal $\overline{\mathcal{F}}_\rho$ grid interval $[g_1(i), g_2(i)]$ with respect to $\texttt{ENV}_{t_1}$ such that $i \in [g_1(i), g_2(i)]$. Second, the pair (t,i) neither descends from the pair $(t_1, g_1(i) + 1)$ nor from the pair $(t_1, g_2(i) - 1)$.

▶ **Definition 11.** *A pair $(t,i) \in C$ is said to be a violating pair with respect to $\texttt{ENV}_{t_1}$, if at least one of the following requirements does not hold. (1) $\texttt{ENV}_t(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$. (2) Let $g(i) \in G$ be a grid location satisfying $\mathrm{dist}(g(i), i) < \Delta$ (if there are two such grid locations, then select the one closer to $g_1(i)$). Then $\texttt{ENV}_t(\Gamma_k(i)) = h_\rho(\texttt{ENV}_{t_1}(\Gamma_k(g(i))), \mathit{parity}(t - t_1), \overrightarrow{\mathrm{dist}}(g(i), i))$.*

Finally, we define the set U of *uncertain* pairs (t,i), for which we cannot determine, given $\texttt{ENV}_{t_1}[G]$ and the corresponding pairs (t_2, i), whether they are violating or not.

▶ **Definition 12.** *The set U consists of all pairs $(t,i) \in \mathbb{Z}_n \times [m]$ such that $t > t_2$ and $(t,i) \notin A \cup B \cup C$.*

In Section 5 show that the number of pairs (t,i) belonging to the set U is relatively small, provided that $\texttt{ENV}_{t_1}[G]$ is feasible.

4.3 The testing algorithm

Recall that Let $\Delta = \frac{\epsilon^2}{b_0} \cdot \min\{n, m\}$, $t_1 = \frac{b_1 \Delta}{\epsilon}$, and $t_2 = t_1 + \Delta$ (where b_0 and b_1 are constants that will be set in the analysis).

Algorithm 1 The testing algorithm.

Tester for evolution according to a rule ρ

1. Query $\texttt{ENV}_{t_1}$ on all locations in $\Gamma_k(G)$. If $\texttt{ENV}_{t_1}[G]$ is infeasible with respect to ρ, reject.
2. Select uniformly at random $\Theta(\frac{1}{\epsilon})$ pairs (t,i) where $i \in \mathbb{Z}_n$ and $t_2 < t < m$.
   For each selected pair (t,i), query $\texttt{ENV}_t(\Gamma_k(i))$ and $\texttt{ENV}_{t_2}(\Gamma_k(i))$.
3. If some pair selected in Step 2 is a violating pair with respect to ρ, then reject.
   Otherwise, accept.

▶ **Theorem 3.** *Let ρ be any local rule that satisfies Conditions 1–6. Algorithm 1 is a one-sided error non-adaptive testing algorithm for evolution according to ρ whose query complexity is $O(\lceil n/m \rceil/\epsilon^2)$.*

The bound on the query complexity of the algorithm follows from the fact that the number of queries performed in Step 1 is $O(n/\Delta) = O(\lceil n/m \rceil/\epsilon^2)$ (recall that k is a constant), and the number of queries performed in Step 3 is $O(1/\epsilon)$. The correctness of the algorithm follows from the next two lemmas. We prove Lemma 1 in Section 6 and Lemma 2 in Section 7.

▶ **Lemma 1** (Completeness of the meta-algorithm)**.** *Let ρ be any local rule that satisfies Conditions 1–6. If the environment* ENV *evolves according to ρ, then the algorithm accepts with probability 1.*

▶ **Lemma 2** (Soundness of the meta-algorithm)**.** *Let ρ be any local rule that satisfies Conditions 1–6. If the environment* ENV *is ϵ-far from evolving according to ρ, then the algorithm rejects with probability at least $2/3$.*

5 Observations and simple claims

In this subsection we present several observations and simple claims that will be used in our proofs of Lemma 1 and Lemma 2.

The first two observations are directly implied by Conditions 1 and 2.

▶ **Observation 1.** *Let ρ be a local rule that satisfies Conditions 1 and 2, $\texttt{ENV} \in \mathcal{E}^{\rho}_{m,n}$ an environment that evolves according to ρ and $(t,i) \in [m] \times \mathbb{Z}_n$. If (t,i) has an ancestor (t',i') such that $\texttt{ENV}_{t'}(\Gamma_k(i')) \in \mathcal{F}_\rho$, then $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$.*

Note that Observation 1 implies that if $\texttt{ENV}_t(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$, then $\texttt{ENV}_{t'}(\Gamma_k(i')) \in \overline{\mathcal{F}}_\rho$ for every ancestor (t',i') of (t,i).

▶ **Observation 2.** *Let ρ be a local rule that satisfies Conditions 1 and 2, $\texttt{ENV} \in \mathcal{E}^{\rho}_{m,n}$ an environment that evolves according to ρ and $(t,i) \in [m] \times \mathbb{Z}_n$, $t \leq n/2$. If $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$, then the location i belongs to an interval whose size is at least $2t$ such that $\texttt{ENV}'_t(\Gamma_k(j)) \in \mathcal{F}_\rho$ for every location j in this interval.*

The observation below directly follows from Observation 2 (as well as the definition of the grid G and Definitions 7 and 8).

▶ **Observation 3.** *Let ρ be a local rule that satisfies Conditions 1 and 2. Suppose that $\texttt{ENV}_t[G]$ for $t \leq n/2$ is feasible with respect to ρ. Then for every $[g_1,g_2]$ that is a maximal $\mathcal{F}_\rho$ grid interval with respect to $\texttt{ENV}_t$, the number of locations in $[g_1,g_2]$ is at least $2t - \Delta$.*

The next observation follows directly from Observation 1 (as well as the definition of G and Definitions 7 and 8).

▶ **Observation 4.** *Let ρ be a local rule that satisfies Conditions 1 and 2. Suppose that $\texttt{ENV}_t[G]$ for $t \leq n/2$ is feasible with respect to ρ and let $g \in G$ be such that $\texttt{ENV}_t(\Gamma_k(g)) \in \mathcal{F}_\rho$. If $\texttt{ENV}'$ is a feasible completion of $\texttt{ENV}_t[G]$ (with respect to ρ), then $\texttt{ENV}'_{t'}(\Gamma_k(i)) \in \mathcal{F}_\rho$ for every $t' \geq t + \Delta$ and $i \in [g - \Delta, g + \Delta]$.*

Claim 5, stated next, also deals with feasible completions.

▷ Claim 5. Let ρ be a local rule that satisfies Conditions 1 and 2. Suppose that $\texttt{ENV}_t[G]$ is feasible with respect to ρ for $t \geq \Delta$ and let $g \in G$ be such that both $\texttt{ENV}_t(\Gamma_k(g)) \in \overline{\mathcal{F}}_\rho$ and $\texttt{ENV}_t(\Gamma_k(g + \Delta)) \in \overline{\mathcal{F}}_\rho$. If $\texttt{ENV}'$ is a feasible completion of $\texttt{ENV}_t[G]$ (with respect to ρ), then $\texttt{ENV}'_t(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$ for every $i \in [g, g + \Delta]$.

Recall the definitions of the sets A, B and C from Section 4.2.

▷ Claim 6. The sets A, B, and C are pairwise disjoint.

In the last claim of this subsection, we bound the size of the set U of uncertain pairs (as defined in Definition 12).

▷ Claim 7. If $\texttt{ENV}_{t_1}[G]$ is feasible (with respect to ρ), then $|U| \leq \frac{5\epsilon}{b_1}mn$ (where b_1 is the constant in the setting of $t_1 = \frac{b_1 \Delta}{\epsilon}$).

We note that Claim 7 does not depend on the setting of Δ, but only on the definition of t_1 as a function of Δ (as well as the definition of the grid G, which, too is defined based on Δ, and in turn is used to determine U).

6 Proof of Lemma 1: Completeness of the meta-algorithm

Let ρ be any local rule that satisfies Conditions 1–6 (where in this proof we do not make use of Conditions 5 and 6, which are provided in the next subsection), and let $\texttt{ENV} \in \mathcal{E}^\rho_{m,n}$ be a dynamic environment that evolves according to ρ. The only steps in which our algorithm may reject are Step 1 and Step 3. The grid is feasible by definition, and hence the algorithm does not reject in Step 1. To show that it also does not reject in Step 3, we show that there are no violating pairs with respect to $\texttt{ENV}_{t_1}[G]$. Recall that each violating pair belongs to one of the three sets A, B, or C (as defined in Section 4.2). Specifically, we next show that in each of the three cases ($(t,i) \in A$, $(t,i) \in B$, and $(t,i) \in C$), the requirements (specified in Section 4.2) for (t,i) being a non-violating pair hold. In what follows, if we say that a pair (t,i) is final (similarly, non-final), then we mean with respect to $\texttt{ENV}$, and when we refer to maximal grid intervals, it is always with respect to $\texttt{ENV}_{t_1}$, and violations are always with respect to $\texttt{ENV}_{t_1}[G]$.

Pairs $(t,i) \in A$. By the definition of A, $t > t_2$ and there exists a grid location $g(i) \in G$ such that $\text{dist}(i, g(i)) \leq \Delta$ and $\texttt{ENV}_{t_1}(\Gamma_k(g(i))) \in \mathcal{F}_\rho$ (this holds both in the case that $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \mathcal{F}_\rho$ for every $g \in G$ and in the case that there exists a maximal $\mathcal{F}_\rho$ grid interval $[g_1(i), g_2(i)]$ such that $i \in [g_1(i) + t_1, g_2(i) - t_1]$.) By Observation 4, both $\texttt{ENV}_{t_2}(\Gamma_k(i)) \in \mathcal{F}_\rho$ and $\texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$. Turning to the third requirement, by Condition 3, applied with $t' = t_2$ and $i' = i$, we get that $\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_{t_2}(i), \mathsf{parity}(t - t_2), 0)$. Therefore, all three requirements on pairs in A hold, and hence (t,i) is not a violating pair.

Pairs $(t,i) \in B$. By the definition of B, $t > t_2$ and there exists a maximal $\mathcal{F}_\rho$ grid interval $[g_1(i), g_2(i)]$ with respect to $\texttt{ENV}_{t_1}$ such that either $i \in [g_1(i) - (t-t_1), g_1(i) + t_1 - \Delta - 1]$ or $i \in [g_2(i) - t_1 + \Delta + 1, g_2(i) + (t-t_1)]$. Furthermore, for every other maximal $\mathcal{F}_\rho$ grid interval $[g'_1, g'_2]$ (with respect to $\texttt{ENV}_{t_1}$), if $i \in [g_1(i) - (t-t_1), g_1(i) + t_1 - \Delta - 1]$, then $\text{dist}(g_1(i), i) < \text{dist}(g'_2, i) - \Delta$, and if $i \in [g_2(i) - t_1 + \Delta + 1, g_2(i) + (t-t_1)]$, then $\text{dist}(g_2(i), i) < \text{dist}(g'_1, i) - \Delta$. Let $g(i)$ be the grid location closest to i in $G \cap ([g_1(i), g_1(i) + t_1 - \Delta] \cup [g_2(i) - t_1 + \Delta, g_2(i)])$ (as defined in the second requirement concerning (non-)violating pairs $(t,i) \in B$).

We claim that (t,i) descends from $(0, g(i))$. To see why, first consider the case in which $i \in [g_1(i) - (t-t_1), g_1(i)] \cup [g_2(i), g_2(i) + (t-t_1)]$. In this case, either $g(i) = g_1(i)$ or $g(i) = g_2(i)$, which means that $\text{dist}(i, g(i)) \leq t - t_1 \leq t$. Second, consider the case in which $i \in [g_1(i), g_1(i) + t_1 - \Delta - 1] \cup [g_2(i) - t_1 + \Delta + 1, g_2(i)]$. In this case, the grid location closest to i in $G \cap ([g_1(i), g_1(i) + t_1 - \Delta] \cup [g_2(i) - t_1 + \Delta, g_2(i)])$ is within a distance of at most Δ from the location i. Hence, $\text{dist}(i, g(i)) \leq \Delta \leq t$. Therefore, in any case, $\text{dist}(i, g(i)) \leq t$, and thus the pair (t,i) descends from the pair $(0, g(i))$.

Assume (without loss of generality) that $g(i) \in [g_2(i) - t_1 + \Delta, g_2(i)]$. Since $\texttt{ENV}_{t_1}(\Gamma_k(g_2(i) + \Delta)) \in \overline{\mathcal{F}}_\rho$ (as $[g_1(i), g_2(i)]$ is a maximal final grid interval), we know (by Observation 1) that $\texttt{ENV}_0(\Gamma_k(j)) \in \overline{\mathcal{F}}_\rho$ for every $j \in [g_2(i) + \Delta - t_1, g_2(i) + \Delta + t_1]$. However, since $\texttt{ENV}_{t_1}(\Gamma_k(g_2(i)) \in \mathcal{F}_\rho$, there must be some location $\ell \in [g_2(i) - t_1, g_2(i) + \Delta - t_1 - 1]$ such that $\texttt{ENV}_0(\Gamma_k(\ell)) \in \mathcal{F}_\rho$. Among the locations ℓ that satisfy these conditions, let ℓ^* be the one that minimizes $\text{dist}(\ell, g_2(i) + \Delta - t_1)$, so that for every $\ell' \in [\ell^* + 1, g_2(i) + \Delta - t_1]$ we have that $\texttt{ENV}_0(\Gamma_k(\ell')) \in \overline{\mathcal{F}}_\rho$. Hence, for every $i'' \neq g(i)$ satisfying $\text{dist}(g(i), i'') \leq \text{dist}(g(i), \ell^*)$ it holds that $\texttt{ENV}_0(i'') \in \overline{\mathcal{F}}_\rho$. Additionally, since $g(i) \in [g_2(i) - t_1 + \Delta, g_2(i)]$ and $\ell^* \in [g_2(i) - t_1, g_2(i) + \Delta - t_1 - 1]$, it must hold that $\text{dist}(g(i), \ell^*) \leq t_1$, which means that the pair $(t_1, g(i))$ descends from the pair $(0, \ell^*)$. Also, both $\texttt{ENV}_{t_1}(g(i)) \in \mathcal{F}_\rho$ and $\texttt{ENV}_0(\ell^*) \in \mathcal{F}_\rho$. Thus, we can apply Condition 3 for the two pairs $(0, \ell^*)$ and $(t_1, g(i))$ to get that $\texttt{ENV}_{t_1}(g(i)) = f_\rho(\texttt{ENV}_0(\ell^*), \mathsf{parity}(t_1), \mathsf{parity}(\text{dist}(\ell^*, g(i))))$.

Since the pair (t,i) descends from the pair $(t_1, g(i))$, and the pair $(t_1, g(i))$ descends from the pair $(0, \ell^*)$, it holds that the pair (t,i) must also descend from the pair $(0, \ell^*)$. Additionally, both both $\texttt{ENV}_t(i) \in \mathcal{F}_\rho$ and $\texttt{ENV}_0(\ell^*) \in \mathcal{F}_\rho$. Also, by the second requirement on (t,i), involving other maximal $\mathcal{F}_\rho$ grid intervals $[g'_1, g'_2]$, for every $i'' \neq i$ satisfying $\text{dist}(i, i'') \leq \text{dist}(i, \ell^*)$ it holds that $\texttt{ENV}_0(i'') \in \overline{\mathcal{F}}_\rho$. Thus, we can apply Condition 3 for the two pairs $(0, \ell^*)$ and (t,i) to get that $\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_0(\ell^*), \mathsf{parity}(t), \mathsf{parity}(\text{dist}(\ell^*, i)))$. But then, since f_ρ is the XOR of its first argument and a subset of the other two, and $\mathsf{parity}(t - t_1) = \mathsf{parity}(t_1) \oplus \mathsf{parity}(t)$ as well as $\mathsf{parity}(\text{dist}(g(i), i))) = \mathsf{parity}(\text{dist}(\ell^*, g(i))) \oplus \mathsf{parity}(\text{dist}(\ell^*, i))$, we get that $\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_{t_1}(g(i)), \mathsf{parity}(t - t_1), \mathsf{parity}(\text{dist}(g(i), i)))$.

Pairs $(t,i) \in C$. There are two cases (where in both $t > t_2$). The first is that $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \overline{\mathcal{F}}_\rho$ for every $g \in G$ (so that i may be any location in $\mathbb{Z}_n$). In the second case there exists a maximal $\overline{\mathcal{F}}_\rho$ grid interval $[g_1(i), g_2(i)]$ such that $i \in [g_1(i), g_2(i)]$, and (t,i) does not descend from either $(t_1, g_1(i) - 1)$ or $(t_1, g_2(i) + 1)$, which implies that for every $j \in \mathbb{Z}_n$, if the pair (t,i) descends from (t_1, j), then $j \in [g_1(i), g_2(i)]$. In both cases, by Claim 5, all ancestors (t_1, j) of (t,i) satisfy $\texttt{ENV}_{t_1}(\Gamma_k(j)) \in \overline{\mathcal{F}}_\rho$. By Observation 1 this implies that $\texttt{ENV}_t(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$, so that the first requirement is met. As for the second requirement, since the grid location $g(i)$ defined in the second requirement is such that $(t_1, g(i))$ is an ancestor of (t,i) (and $\texttt{ENV}_{t_1}(\Gamma_k(g(i))) \in \overline{\mathcal{F}}_\rho$), we can apply Condition 4 (with $t' = t_1$ and $i' = g$) to get that $\texttt{ENV}_t(\Gamma_k(i)) = h_\rho(\texttt{ENV}_{t_1}(\Gamma_k(g(i))), \mathsf{parity}(t - t_1), \overrightarrow{\text{dist}}(g(i), i)$, as required.

We've shown that under the premise of the lemma, there is no pair $(t,i) \in A \cup B \cup C$ that is a violating pair. Thus, our algorithm cannot reject at Step 3.

7 Proof of Lemma 2: Soundness of the meta-algorithm

Let $\texttt{ENV}$ be any environment that is ϵ-far from evolving according to ρ, where ρ is a local rule that satisfies Conditions 1–6. If $\texttt{ENV}_{t_1}[G]$ is infeasible with respect to ρ, then the algorithm rejects (in Step 1). Hence, we assume from now on that $\texttt{ENV}_{t_1}[G]$ is feasible.

We claim that the number of violating pairs with respect to $\texttt{ENV}_{t_1}[G]$ is at least $\frac{\epsilon}{b_2}mn$, where $b_2 > 1$ is a constant. Lemma 2 follows, since the algorithm selects $s = \Theta(1/\epsilon)$ pairs (in Step 2), and rejects if any of them is found to be a violating pair (in Step 3). Hence, the probability that the algorithm rejects is at least $1 - (1 - \epsilon/b_2)^s$, which is at least $2/3$ for $s \geq 2b_2/\epsilon$.

Suppose by way of contradiction that there are less than $\frac{\epsilon}{b_2}mn$ violating pairs. We show how, based on $\texttt{ENV}$ (to be precise, $\texttt{ENV}_{t_1}[G]$ and $\texttt{ENV}_{t_2}$) we can define an environment $\texttt{ENV}'$ for which the following holds. First, $\texttt{ENV}'$ evolves according to ρ. Second, $\texttt{ENV}'$ differs from $\texttt{ENV}$ on at most ϵmn pairs $(t, i) \in \mathbb{Z}_n \times [m]$. But this contradicts the premise that $\texttt{ENV}$ is ϵ-far from evolving according to ρ. Details follow in the next subsections.

We first provide all details (in Section 7.1 and Section 7.2) under the assumption that there exist grid locations $g \in G$ for which $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \mathcal{F}_\rho$ as well as grid locations $g' \in G$ for which $\texttt{ENV}_{t_1}(\Gamma_k(g')) \in \overline{\mathcal{F}}_\rho$. We discuss (in the full version of this paper [9]) the two special cases for which either $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \mathcal{F}_\rho$ for every $g \in G$ or $\texttt{ENV}_{t_1}(\Gamma_k(g)) \in \overline{\mathcal{F}}_\rho$ for every $g \in G$, which we refer to as the *homogeneous* cases.

7.1 The definition of $\texttt{ENV}'$

To construct the dynamic environment $\texttt{ENV}'$, we define its initial configuration $\texttt{ENV}'_0$, and then apply the local rule ρ for $m - 1$ steps. Hence, $\texttt{ENV}'$ evolves according to ρ by construction. The initial configuration $\texttt{ENV}'_0$ is defined with respect to a configuration σ on which we perform several transformations to obtain $\texttt{ENV}'_0$. We define the configuration σ by specifying the value of $\sigma(i)$ for each location $i \in \mathbb{Z}_n$ as explained next. In what follows, whenever we refer to maximal $\overline{\mathcal{F}}_\rho$ grid intervals (similarly, maximal $\mathcal{F}_\rho$ grid intervals), it is with respect to $\texttt{ENV}_{t_1}$.

We shall make use of a function $h_\rho^{\leftarrow} : \overline{\mathcal{F}}_\rho \times \{0,1\} \times \mathbb{Z}_n$ (based on h_ρ – see Condition 4). Recall that by Condition 4, for each fixed $\tau \in \overline{\mathcal{F}}_\rho$, $\beta \in \{0,1\}$ and $\ell \in \mathbb{Z}_n$, there exists a unique τ' such that $h_\rho(\tau', \beta, \ell) = \tau$.

▶ **Definition 8.** *For any $\tau \in \overline{\mathcal{F}}_\rho$, $\beta \in \{0,1\}$ and $\ell \in \mathbb{Z}_n$, $h_\rho^{\leftarrow}(\tau, \beta, \ell)$ equals the (unique) pattern τ' for which $h_\rho(\tau', \beta, \ell) = \tau$.*

We also make the following observation, based on Condition 3, by which f_ρ is the XOR of its first argument and a subset of the other two.

▶ **Observation 9.** *For any $\beta_1, \beta_2, \beta_3 \in \{0,1\}$, if $f_\rho(\beta_1, \beta_2, \beta_3) = \beta'_1$, then $f_\rho(\beta'_1, \beta_2, \beta_3) = \beta_1$. Furthermore, for any $\beta'_2, \beta'_3 \in \{0,1\}$, $f_\rho(f_\rho(\beta_1, \beta_2, \beta_3), \beta'_2, \beta'_3) = f_\rho(\beta_1, \beta_2 \oplus \beta'_2, \beta_3 \oplus \beta'_3)$, and in particular, $f_\rho(f_\rho(\beta_1, \beta_2, \beta_3), \beta_2, \beta_3) = \beta_1$.*

For each maximal $\overline{\mathcal{F}}_\rho$ grid interval $[g_1, g_2]$, let $J(g_1, g_2) = [g_1 - t_1 - k, g_2 + t_1 + k]$ and let J be the union over all such sets. We also define $J_1(g_1, g_2) = [g_1 - t_1, g_2 + t_1]$ (for each $\overline{\mathcal{F}}_\rho$ grid interval $[g_1, g_2]$), and let $J_1 \subset J$ be the union over all such sets.

We first establish two simple claims.

▷ Claim 10. Let ρ be any local rule that satisfies Conditions 1–4. For every two maximal $\overline{\mathcal{F}}_\rho$ grid interval $[g_1, g_2]$ and $[g'_1, g'_2]$, we have that $J(g_1, g_2) \cap J(g'_1, g'_2) = \emptyset$.

▷ Claim 11. Let ρ be any local rule that satisfies Conditions 1–4. Let $\texttt{ENV}''$ be any environment that is a feasible extension of $\texttt{ENV}_{t_1}[G]$ with respect to ρ, and let $[g_1, g_2]$ be a maximal $\overline{\mathcal{F}}_\rho$ grid interval (with respect to $\texttt{ENV}_{t_1}[G]$). Then $\texttt{ENV}''_0(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$ for every $i \in J_1(g_1, g_2)$. Furthermore, $\texttt{ENV}''_0(\Gamma_k(i)) = h^{\leftarrow}_\rho(\texttt{ENV}_{t_1}(\Gamma_k(g)), \mathsf{parity}(t_1), \overrightarrow{\mathrm{dist}}(i, g))$ for any $g \in G \cap [g_1, g_2]$ and every ancestor $(0, i)$ of (t_1, g).

Observe that Claim 11 implies that $\texttt{ENV}''_0$ is *uniquely* determined by $\texttt{ENV}_{t_1}[G]$ on all location in J for every $\texttt{ENV}''$ that is a feasible extension of $\texttt{ENV}_{t_1}[G]$ (with respect to ρ). Based on this observation, we start by setting the locations of σ that belong to J as in such $\texttt{ENV}''_0$. In particular we have that $\sigma(\Gamma_k(i)) \in \overline{\mathcal{F}}_\rho$ for every $i \in J_1$, and furthermore,

$$\forall i \in J_1, g \in G \text{ s.t. } (t_1, g) \text{ descends from } (0, i) \text{ and,}$$
$$\sigma(\Gamma_k(i)) = h^{\leftarrow}_\rho(\texttt{ENV}_{t_1}(\Gamma_k(g)), \mathsf{parity}(t_1), \overrightarrow{\mathrm{dist}}(i, g)) \ . \tag{7.1}$$

Turning to the locations not yet set in σ, for each location $i \in \mathbb{Z}_n \setminus J$, $\sigma(i) = f_\rho(\texttt{ENV}_{t_2}(i), \mathsf{parity}(t_2), 0)$. Note that by Observation 9, $f_\rho(\sigma(i), \mathsf{parity}(t_2), 0) = \texttt{ENV}_{t_2}(i)$.

We next explain how we modify σ so as to obtain $\texttt{ENV}'_0$ using Condition 5 and Condition 6. The modifications are performed (strictly) within the following set of intervals $\mathcal{S}$.

$$\mathcal{S} = \left\{ \left[a = g_1 - \Delta + t_1, b = g_2 + \Delta - t_1\right] \ : \ [g_1, g_2] \text{ is a maximal } \mathcal{F}_\rho \text{ grid interval} \right\} \ . \tag{7.2}$$

The intervals in $\mathcal{S}$ are clearly disjoint (as each is a sub-interval of a different maximal $\mathcal{F}_\rho$ grid interval), and by Observation 3, each is non-empty. Note that for each maximal $\mathcal{F}_\rho$ grid interval $[g_1, g_2]$, we have that $g_1 - \Delta$ and $g_2 + \Delta$ are endpoints of maximal $\overline{\mathcal{F}}_\rho$ grid interval. Therefore, $a, b \in J_1$ for each interval $[a, b] \in \mathcal{S}$, and by the setting of σ and Claim 11, $\sigma(\Gamma_k(a)), \sigma(\Gamma_k(b)) \in \overline{\mathcal{F}}_\rho$.

For each $[a, b] \in \mathcal{S}$ and the corresponding $[g_1, g_2]$, let $\alpha(a, b) = \texttt{ENV}_{t_1}(g_1)$, $\beta(a, b) = \texttt{ENV}_{t_1}(g_2)$, $\gamma(a, b) = \mathsf{parity}(t_1)$, $\gamma'(a, b) = \mathsf{parity}(t_1 - \Delta)$. We shall apply Condition 5 and Condition 6 to modify σ on all $[a, b] \in \mathcal{S}$ "in parallel" as described next, and set $\texttt{ENV}'_0$ to be the resulting configuration.

For each $[a, b] \in \mathcal{S}$ we first apply Condition 6 with $z = a$, $\nu = \alpha(a, b)$, $\gamma = \gamma(a, b)$ and $\gamma' = \gamma'(a, b)$. We let $a' = z'$ (recall that $z' \in [z + 1, z + 2k + 1]$ and $\widetilde{\sigma}(\Gamma_k(z')) \in \mathcal{F}_\rho$). Next we apply Condition 6 in its second (symmetric) variant with $z = b$, $\nu = \beta(a, b)$, $\gamma = \gamma(a, b)$ and $\gamma' = \gamma'(a, b)$. We let $b' = z'$ (recall that in this variant, $z' \in [z - 2k - 2, z - 1]$, and here too $\widetilde{\sigma}(\Gamma_k(z')) \in \mathcal{F}_\rho$). Finally we apply Condition 5 on the modified configuration with $x = a'$ and $y = b'$.

7.2 The distance between ENV and ENV′

In this subsection we show that based on the counter-assumption regarding the number of violating pairs, the number of pairs $(t, i) \in \mathbb{Z}_n \times [m]$ on which $\texttt{ENV}$ and $\texttt{ENV}'$ differ is at most ϵmn. To this end we show that each (t, i) such that $\texttt{ENV}_t(i) \neq \texttt{ENV}'_t(i)$ belongs to one of the following sets:

1. The set of pairs (t, i) for which $0 \leq t \leq t_2$.
2. The uncertainty set U.
3. The set of (t, i) pairs where (t, i) is a violation with respect to $\texttt{ENV}_{t_1}[G]$.

By the setting of t_2 (t_1) and Δ, the number of pairs in the first set is at most $\frac{(b_1+1)\epsilon}{b_0} mn$. By Claim 7, $|U| \leq \frac{5\epsilon}{b_1} mn$. By our counter-assumption, the number of violating pairs is at most $\frac{\epsilon}{b_2} mn$. Setting $b_1 = 15$, $b_0 = 48$ and $b_2 = 3$, we get a total of at most ϵmn pairs, as claimed.

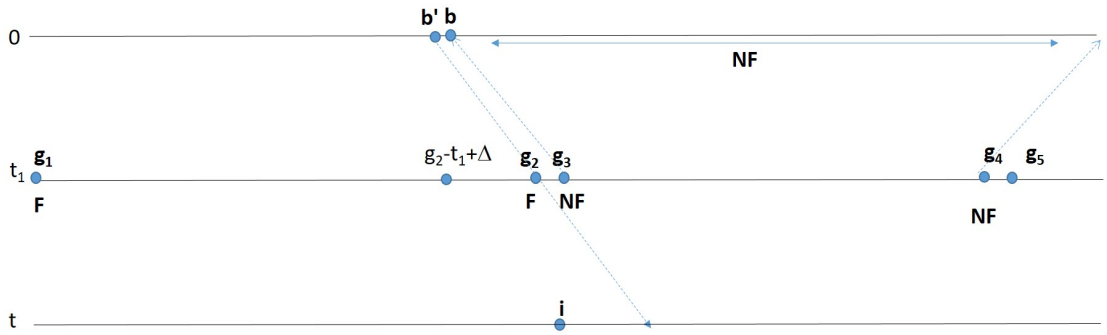

Figure 7.1 An illustration for the setting of $\texttt{ENV}_0$. As in Figure 4.1, $[g_1, g_2]$ is a maximal $\mathcal{F}_\rho$ grid interval, $g_3 = g_2 + \Delta$, where $[g_3, g_4]$ is a maximal $\overline{\mathcal{F}}_\rho$ grid interval, and $g_5 = g_4 + \Delta$ is an endpoint of a maximal $\mathcal{F}_\rho$ grid-interval. The maximal $\overline{\mathcal{F}}_\rho$ grid interval $[g_3, g_4]$ is used to set the locations between $g_3 - t_1 = g_2 - t_1 + \Delta$ and $g_4 + t_1$ (more precisely, between $g_3 - t_1 - k$ and $g_4 + t_1 + k$ based on Claim 11. The location $b = g_2 - t_1 + \Delta$ is an endpoint of an interval in $\mathcal{S}$, and the location b' is determined by the application of Condition 6. The values in the k-neighborhood of b' are set so that the evolution of ρ will result in the $\texttt{ENV}_{t_1}(g_2)$ at time t_1. The pair (t, i) belongs to the set B.

To establish the claim that each (t, i) for which $\texttt{ENV}_t(i) \neq \texttt{ENV}'_t(i)$ belongs to one of the above three sets, we prove the contrapositive. Suppose the pair (t, i) is not in the uncertainty set U and that $t > t_2$. It follows that $(t, i) \in A \cup B \cup C$. We show that for each of the three types of pairs ($(t, i) \in A$, $(t, i) \in B$, and $(t, i) \in C$), if the pair (t, i) is not a violating pair with respect to $\texttt{ENV}_{t_1}[G]$, it must hold that $\texttt{ENV}_t(i) = \texttt{ENV}'_t(i)$.

Pairs $(t, i) \in A$. By the definition of A, there exists a maximal $\mathcal{F}_\rho$ grid interval $[g_1(i), g_2(i)]$ (with respect to $\texttt{ENV}_{t_1}$) for which $i \in [g_1(i) + t_1, g_2(i) - t_1]$. Since (t, i) is not a violating pair with respect to $\texttt{ENV}_{t_1}[G]$, it must hold that $\texttt{ENV}_{t_2}(\Gamma_k(i)), \texttt{ENV}_t(\Gamma_k(i)) \in \mathcal{F}_\rho$ and that $\texttt{ENV}_t(i) = f_\rho(\texttt{ENV}_{t_2}(i), \mathsf{parity}(t - t_2), 0)$. Since $i \in [g_1(i) + t_1, g_2(i) - t_1]$, we know that $i \notin J$. Hence, by the definition of the configuration σ, we have that $\sigma(i) = f_\rho(\texttt{ENV}_{t_2}(i), \mathsf{parity}(t_2), 0)$ and that $\sigma(\Gamma_k(i)) \in \mathcal{F}_\rho$. Let $[a(i), b(i)] = [g_1(i) - \Delta + t_1, g_2(i) + \Delta - t_1]$, so that $i \in I(a(i), b(i))$. By the definition of E'_0, based on Condition 5 we have that $\texttt{ENV}'_0(i) = \sigma(i)$ and $\texttt{ENV}'_0(\Gamma_k(i)) \in \mathcal{F}_\rho$. Since $\texttt{ENV}'$ evolves according to ρ, by Condition 3,

$$\texttt{ENV}'_{t_2}(i) = f_\rho(\texttt{ENV}'_0(i), \mathsf{parity}(t_2), 0) = f_\rho(f_\rho(\texttt{ENV}_{t_2}(i), \mathsf{parity}(t_2), 0), \mathsf{parity}(t_2), 0) = \texttt{ENV}_{t_2}(i)$$

where the last equality follows from (the second part of) Observation 9. Additionally, by Condition 1, $\texttt{ENV}'_{t_2}(i) \in \mathcal{F}_\rho$. Therefore, by Condition 3,

$$\texttt{ENV}'_t(i) = f_\rho(\texttt{ENV}'_{t_2}(i), \mathsf{parity}(t - t_2), 0) = f_\rho(\texttt{ENV}_{t_2}(i), \mathsf{parity}(t - t_2), 0) = \texttt{ENV}_t(i)\ .$$

Pairs $(t, i) \in B$. By the definition of B, there exists a maximal $\mathcal{F}_\rho$ grid interval $[g_1(i), g_2(i)]$ with respect to $\texttt{ENV}_{t_1}$ such that either $i \in [g_1(i) - (t - t_1), g_1(i) + t_1 - \Delta - 1]$ or $i \in [g_2(i) - t_1 + \Delta + 1, g_2(i) + (t - t_1)]$. Assume (without loss of generality) that the latter holds. By the definition of B we also know that for every other maximal $\mathcal{F}_\rho$ grid interval $[g'_1, g'_2]$ it holds that $\mathrm{dist}(i, g_2(i)) < \mathrm{dist}(i, g'_1), \mathrm{dist}(i, g'_2) - \Delta$. Let $g(i)$ be the grid location closest to i in $[g_2(i) - t_1 + \Delta, g_2(i)]$. Since $i \in [g_2(i) - t_1 + \Delta + 1, g_2(i) + (t - t_1)]$, necessarily, $g(i) \in [g_2(i) - t_1, g_2(i)]$. For the sake of conciseness, in what follows we shall use g_1, g_2, and g as a shorthand for $g_1(i)$, $g_2(i)$ and $g(i)$, respectively.

Since $[g_1, g_2]$ is a maximal $\mathcal{F}_\rho$ grid interval, $[a = g_1 - \Delta + t_1, b = g_2 + \Delta - t_1] \in \mathcal{S}$. Hence, to obtain $\texttt{ENV}'_0$ from the configuration σ, we invoked Condition 6 (the symmetric version) with $z = b$, $\nu = \texttt{ENV}_{t_1}(g_2)$, $\gamma = \mathsf{parity}(t_1)$, and $\gamma' = \mathsf{parity}(t_1 - \Delta) = \mathsf{parity}(\mathrm{dist}(g_2, b))$. By Condition 6, letting $b' = z'$, $\texttt{ENV}_{t_1}(g_2) = f_\rho(\texttt{ENV}'_0(b'), \mathsf{parity}(t_1), \mathsf{parity}(\mathrm{dist}(g_2, b')))$. By Observation 9,

$$\texttt{ENV}'_0(b') = f^{\leftarrow}_\rho(\texttt{ENV}_{t_1}(g_2), \mathsf{parity}(t_1), \mathsf{parity}(\mathrm{dist}(g_2, b'))) \ . \tag{7.3}$$

As $b' \in [b - 2k - 1, b - 1]$, which by the setting of b implies that $b' \in [g_2 + \Delta - t_1 - 2k - 1, g_2 + \Delta - t_1 - 1]$, we have that $(0, b')$ is an ancestor of (t_1, j) for every $j \in [g_2 - t_1, g_2]$. In particular this holds for the grid location g (that is closest to i in $G \cap [g_2 - t_1, g_2]$). Since (t, i) descends from (t_1, g), we get that (t, i) also descends from $(0, b')$.

We claim that for every $b'' \neq b'$ with $\mathrm{dist}(i, b'') < \mathrm{dist}(i, b')$ it holds that $\texttt{ENV}'_0(b'') \in \overline{\mathcal{F}}_\rho$. To verify this, let $[g_3, g_4]$ be the maximal $\overline{\mathcal{F}}_\rho$ grid interval where $g_3 = g_2 + \Delta$, and let $g_5 = g_4 + \Delta$, so that g_5 is the endpoint of a maximal $\mathcal{F}_\rho$ grid interval. By the definition of $\texttt{ENV}'_0$ (based on σ and Condition 6) we have that $\texttt{ENV}'_0(\Gamma_k(j)) \in \overline{\mathcal{F}}_\rho$ for every $j \in [b' + 1, b - 1] \cup J_1(g_3, g_4) = [b' + 1, g_4 + t_1]$. Since (by the second requirements on pairs in B), $\mathrm{dist}(i, g_2) < \mathrm{dist}(i, g_5) - \Delta$ and $b' \in [g_2 - t_1 + \Delta - 2k - 1, g_2 - t_1 + \Delta - 1]$, we have that $\texttt{ENV}'_0(b'') \in \overline{\mathcal{F}}_\rho$ for every $b'' \neq b'$ with $\mathrm{dist}(i, b'') < \mathrm{dist}(i, b')$. Therefore, we can apply Condition 3 to obtain that

$$\begin{aligned}
&\texttt{ENV}'_t(i) = f_\rho(\texttt{ENV}_0(b'), \mathsf{parity}(t), \mathsf{parity}(\mathrm{dist}(i, b'))) \\
&= f_\rho(f_\rho(\texttt{ENV}_{t_1}(g_2), \mathsf{parity}(t_1), \mathsf{parity}(\mathrm{dist}(g_2, b'))), \mathsf{parity}(t), \mathsf{parity}(\mathrm{dist}(i, b'))) &(7.4)\\
&= f_\rho(\texttt{ENV}_{t_1}(g_2), \mathsf{parity}(t - t_1), \mathsf{parity}(\mathrm{dist}(i, g_2))) &(7.5)
\end{aligned}$$

where the last equality follows from Observation 9.

Consider first the case that $g = g_2$. Since the pair (t, i) is not a violating pair,

$$\texttt{ENV}_t(i) \ = \ f_\rho(\texttt{ENV}_{t_1}(g_2), \mathsf{parity}(t - t_1), \mathsf{parity}(\mathrm{dist}(i, g_2))) \ , \tag{7.6}$$

and hence in this case, $\texttt{ENV}_t(i) = \texttt{ENV}'_t(i)$, as desired. We next turn to the case that $g \neq g_2$. We claim that since $\texttt{ENV}_{t_1}[G]$ is feasible,

$$\texttt{ENV}_{t_1}(g) = f_\rho(\texttt{ENV}'_0(b'), \mathsf{parity}(t_1), \mathsf{parity}(\mathrm{dist}(g, b'))) \ . \tag{7.7}$$

Conditioned on Equality 7.7 holding, the argument is the same as for the case that $g = g_2$ (replacing g_2 with g in Equations (7.4)–(7.6)).

To verify Equation (7.7), we introduce the notion of a *source* for a final pair. Let $\texttt{ENV}''$ be an environment that evolves according to ρ, and (t', i') a final pair with respect to $\texttt{ENV}''$ and ρ. We say that $(0, b'')$ is the *source* of (t', i') (at time 0) in $\texttt{ENV}''$ if $(0, b'')$ is an ancestor of (t', i'), is final, and $\mathrm{dist}(b'', i') < \mathrm{dist}(j, i')$ for every other final $(0, j)$. Consider any feasible extension E'' of $\texttt{ENV}_{t_1}[G]$. By Claim 11 and the discussion above, the source $(0, b'')$ of (t_1, g_2) (at time 0 in $\texttt{ENV}''$) must satisfy $b'' \in [g_2 - t_1, g_2 - t_1 + \Delta - 1]$. Furthermore, $(0, b'')$ must also be the source of (t_1, g') for every grid location $g' \in [g_2 - t_1, g_2]$. Therefore, for each such grid location, $\texttt{ENV}_{t_1}(g') = \texttt{ENV}''_{t_1}(g') = f_\rho(\texttt{ENV}''_0(b''), \mathsf{parity}(t_1), \mathsf{parity}(\mathrm{dist}(g', b'')))$, where $\texttt{ENV}''_0(b'') = f^{\leftarrow}_\rho(\texttt{ENV}_{t_1}(g_2), \mathsf{parity}(t_1), \mathsf{parity}(\mathrm{dist}(g_2, b'')))$. If f_ρ and $f^{\leftarrow}_\rho$ do no depend on their third argument, then, by Equation (7.3), $\texttt{ENV}'_0(b') = \texttt{ENV}''_0(b'')$ and if they do, then $\texttt{ENV}'_0(b') = \texttt{ENV}''_0(b'') \oplus \mathsf{parity}(\mathrm{dist}(b', b''))$. In either case, Equation (7.7) follows.

Pairs $(t, i) \in C$. By the definition of C, there exists a maximal $\overline{\mathcal{F}}_\rho$ grid interval $[g_1(i), g_2(i)]$ such that $g_1(i) \leq i \leq g_2(i)$. Additionally, the pair (t, i) does not descend from either the pair $(t_1, g_1(i) - 1)$ or from the pair $(t_1, g_2(i) + 1)$. Let $g(i)$ be the grid location defined in Definition 11 (of violating pairs in C), so that $g(i) \in G \cap [g_1(i), g_2(i)]$ and $\mathrm{dist}(i, g(i)) < \Delta$.

By the definition of $\texttt{ENV}'_0$ (based on σ – recall Equation (7.1)), we have that $\texttt{ENV}'_0(\Gamma_k(i)) = h^{\leftarrow}_\rho(\texttt{ENV}_{t_1}(\Gamma_k(g(i))), \mathsf{parity}(t_1), \overrightarrow{\mathrm{dist}}(i, g(i)))$. By the definition of $h^{\leftarrow}_\rho$ (Definition 8), this implies that $\texttt{ENV}_{t_1}(\Gamma_k(g(i))) = h_\rho(\texttt{ENV}'_0(\Gamma_k(i)), \mathsf{parity}(t_1), \overrightarrow{\mathrm{dist}}(i, g(i)))$. Since $\texttt{ENV}'_0(\Gamma_k(j)) \in \overline{\mathcal{F}}_\rho$ for every location $j \in J(g_1(i)), g_2(i))$, and the environment $\texttt{ENV}'$ evolves according to ρ where ρ satisfies Condition 4, we know that $\texttt{ENV}'_{t_1}(\Gamma_k(g(i))) = h_\rho(\texttt{ENV}'_0(\Gamma_k(i)), \mathsf{parity}(t_1), \overrightarrow{\mathrm{dist}}(i, g(i)))$. Hence, $\texttt{ENV}'_{t_1}(\Gamma_k(g(i))) = \texttt{ENV}_{t_1}(\Gamma_k(g(i)))$. Furthermore, using in addition the fact that (t, i) does not descend from either $(t_1, g_1(i) - 1)$ or $(t_1, g_2(i) + 1)$, we get all ancestors of (t_1, j) of (t, i) satisfy $\texttt{ENV}'_{t_1}(\Gamma_k(j)) \in \overline{\mathcal{F}}_\rho$, so that $\texttt{ENV}'_t(\Gamma_k(i)) = h_\rho(\texttt{ENV}'_{t_1}(\Gamma_k(g(i))), \mathsf{parity}(t - t_1), \overrightarrow{\mathrm{dist}}(g(i), i)))$. Since (t, i) is not a violating pair, $\texttt{ENV}_t(\Gamma_k(i)) = h_\rho(\texttt{ENV}_{t_1}(\Gamma_k(g(i))), \mathsf{parity}(t - t_1), \overrightarrow{\mathrm{dist}}(g(i), i))$, and using $\texttt{ENV}'_{t_1}(\Gamma_k(g(i))) = \texttt{ENV}_{t_1}(\Gamma_k(g(i)))$ we get that $\texttt{ENV}'_t(i) = \texttt{ENV}_t(i)$.

Abstract

We study decision problems for sequences which obey a second-order holonomic recurrence of the form $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ with rational polynomial coefficients, where P is non-constant, Q is non-zero, and the degree of Q is smaller than or equal to that of P. We show that existence of infinitely many zeroes is decidable. We give partial algorithms for deciding the existence of a zero, positivity of all sequence terms, and positivity of all but finitely many sequence terms. If Q does not have a positive integer zero then our algorithms halt on almost all initial values $(f(1), f(2))$ for the recurrence. We identify a class of recurrences for which our algorithms halt for all initial values. We further identify a class of recurrences for which our algorithms can be extended to total ones.

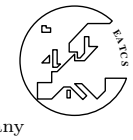
1 Introduction



A sequence $(f(n))_{n\geq 1}$ of real numbers is called *holonomic* or *P-finite* if its terms satisfy an algebraic equation of the form

$$P_r(n)f(n+r) + P_{r-1}(n)f(n+r-1) + \cdots + P_0(n)f(n) = 0,$$

where $P_0, \ldots, P_r \in \mathbb{R}[X]$ are polynomials, not all zero. The number r is called the *order* of the recurrence. When all polynomials $P_r, \ldots, P_0$ are constant we recover the familiar example of ordinary linear recurrence sequences. Alternatively, holonomic sequences are characterised as the coefficients of formal power series which satisfy a non-trivial homogeneous linear ordinary differential equation with polynomial coefficients [10]. Strikingly, holonomic sequences with rational polynomial coefficients can be tested for equality automatically [11]. This allows for automatic proving of highly non-trivial special function identities with numerous applications in mathematics and the sciences [7].

It is natural to ask if holonomic sequences can be automatically tested for inequality as well. This reduces to the problem of deciding whether all terms of a given holonomic sequence $(f(n))_n$ are positive. In full generality this question seems to be completely out of reach, even in the case where the polynomials $P_r, \ldots, P_0$ are all constant. While this problem, often called the Positivity Problem, is widely believed to be decidable in the constant coefficient

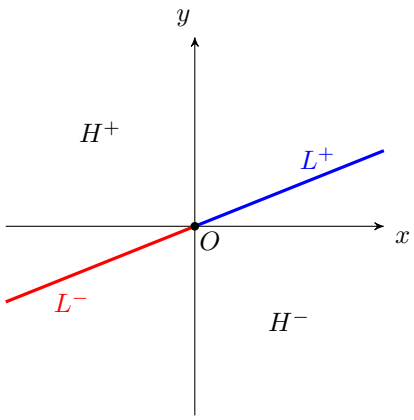

Figure 1 Example of a partition of the space of initial values into the five regions identified in Theorem 1. The asymptotic dynamic behaviour of the signs of a sequence is completely determined by the region containing the initial values.

case, a feasible decision method for linear recurrences of order six or higher would entail major breakthroughs in Diophantine approximation [6]. Nonetheless, decision methods are known for constant coefficient linear recurrence sequences of order up to five.

There is hence some hope that one can obtain decidability results on the Positivity Problem for low-order holonomic sequences as well. In this paper we investigate the problem for sequences satisfying a second-order holonomic recurrence of the form

$$f(n+2) = P(n)f(n+1) + Q(n)f(n) \tag{1}$$

with P non-constant and $0 \leq \deg Q \leq \deg P$. This constitutes arguably the simplest class of non-trivial instances of the Positivity Problem. By a straightforward reduction, our results extend to the larger class of holonomic recurrences of the form

$$R(n)f(n+2) = P(n)f(n+1) + Q(n)f(n)$$

with P non constant, R without positive integer zeroes, and $0 \leq \deg R + \deg Q \leq \deg P$.

We study the possible behaviours that a sequence satisfying a recurrence of the form (1) may exhibit as $n \to \infty$. Up to shifting the recurrence by finitely many terms we may assume that Q does not have any positive integer zeroes. We then show that the plane of initial values $(f(1), f(2)) \in \mathbb{R}^2$ decomposes into five disjoint pieces – the origin O, two rays L^+ and L^-, and two open half-planes H^+ and H^- – such that the behaviour of the sequence $(f(n))_{n\geq 1}$ for large n depends only on the piece that contains the initial values and the signs of the leading coefficients of P and Q. See Figure 1 for a graphical illustration. Depending on these data, unless the sequence is identically zero, it will be eventually strictly positive, strictly negative, or alternating between strictly positive and strictly negative. Moreover, we can compute on each of the five pieces for any initial value a number N such that the sequence $(f_n)_n$ has the described behaviour for all $n \geq N$.

Up to potentially shifting the recurrence by finitely many terms, the line $L = L^+ \cup L^- \cup O$ has a well-defined slope, given by the (necessarily convergent) continued fraction $-\mathrm{K}_{n=1}^{\infty} \frac{Q(n)}{P(n)}$. This allows us to approximate the line L numerically to any given finite precision. We can hence determine, by means of a potentially non-terminating algorithm, if a given pair of rational initial values $(f(1), f(2)) \in \mathbb{Q}^2$ is outside the line and in that case determine the behaviour of the sequence for large n. This yields a partial algorithm for deciding the Positivity Problem and related problems on the class of sequences satisfying recurrences of the form (1).

While we do not obtain a total algorithm for all second-order holonomic recurrences of the form (1), we identify a class of recurrences for which the slope of the line L is an effectively computable rational number. In this case we can extend our algorithm to a total one. One can effectively check if a given recurrence belongs to this class.

Our algorithm is also total for the class of all recurrences such that the slope of the line L is irrational. We establish non-trivial effective criteria that guarantee this.

Related Work. Decidability of the Positivity Problem for second-order holonomic sequences is investigated in [4]. It is shown that for sequences with linear polynomial coefficients, the Positivity Problem reduces to the problem of deciding the equality of certain effectively given quantities, closely related to periods [5] whose equality is conjectured to be decidable [5, Conjecture 1].

Gerhold and Kauers [2] give a partial algorithm for deciding Positivity for general holonomic sequences based on symbolic methods from real algebraic geometry. To the best of our knowledge its precise termination behaviour is not known, even for low-order sequences. Further practical partial algorithms in the spirit of [2] are introduced in [3, 8, 9]. In those papers sufficient termination criteria are given for recurrences of the form

$$P_r(n)f(n+r) + \cdots + P_0(n)(f) = 0$$

with $\deg P_0 = \deg P_r$ and $\deg P_j \leq \deg P_0$ for all $j \leq r$. This situation is disjoint from the one we investigate. Similarly to our main result, one of the algorithms in [3] is shown to terminate for all second-order recurrences of the above form on almost all initial values. All further termination criteria established in the aforementioned papers put restrictions on the eigenvalues of the holonomic recurrence but no restrictions on the initial values. The algorithms may fail to converge for all initial values of a recurrence that does not meet the restrictions on the eigenvalues.

Key contributions. There remains a dearth of algorithmic results on positivity and inequality problems for second-order (and higher) holonomic sequences. The present paper makes two substantial contributions to these outstanding open problems: (i) we identify a large class of second-order holonomic recurrences for which we can precisely characterise all the possible asymptotic behaviours (Theorem 1); and (ii) building upon this, we identify a substantial subclass of holonomic sequences for which we exhibit total algorithms for the Positivity and Skolem problems.

2 Results

Let us first introduce the decision problems we seek to investigate. The Skolem Problem is the problem of deciding for a given recurrence of the form (1) and for given initial values $f(1), f(2)$ if the induced recurrence sequence $(f(n))_n$ has a zero. The Infinite Zero Problem asks if the sequence $(f(n))_n$ thus given has infinitely many zeroes. The Positivity Problem asks if all terms of the sequence $(f(n))_n$ are positive. The Ultimate Positivity Problem is the problem of deciding if there exists an index N such that all terms $f(n)$ with $n \geq N$ are positive.

Our results are best stated for holonomic recurrences that are normalised in the following sense. A second-order holonomic recurrence $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ with P non-constant and $0 \leq \deg Q \leq \deg P$ is said to be *in normal form* if $P, Q \in \mathbb{Z}[X]$ are integer polynomials such that P has a positive leading coefficient, P and Q have no positive real zeroes, $P(n)^2 + 4Q(n) > 0$ for all positive integers n, and there is no prime number p such that p divides all coefficients of P and p^2 divides all coefficients of Q.

For the most part, the above assumptions on P and Q do not present essential restrictions: Given any second-order holonomic recurrence of the form (1) we can effectively compute integers c and N such that the holonomic recurrence $g(n+2) = cP(N+n)g(n+1)+c^2Q(N+n)g(n)$ is in normal form. For any given pair of initial values $f(1), f(2) \in \mathbb{Q}$, we can effectively compute $g(1) = c^{N+1}f(N+1)$ and $g(2) = c^{N+2}f(N+2)$. The sequence $(g(n))_n$ is then equal to $(c^n f(n))_{n>N}$. Thus, the behaviour of $(f(n))_n$ is easily deduced from that of $(g(n))_n$ and the finite sequence $f(1), \dots, f(N)$. In particular, the above mentioned decision problems reduce in this way to their specialisation to recurrences in normal form. However, since in general there may exist initial values for which our algorithm is not guaranteed to terminate, we also need to understand which initial values for the original recurrence get mapped to such ones. We will discuss this below, after we have stated our main results.

It is worth pointing out that our results extend to holonomic recurrences of the form $R(n)f(n+2) = P(n)f(n+1) + Q(n)f(n)$ with P non constant, R without positive integer zeroes, and $0 \leq \deg R + \deg Q \leq \deg P$. Indeed, if $(f(n))_n$ satisfies a recurrence of this form then the sequence $g(n) = R(1) \cdot \dots \cdot R(n)f(n)$ satisfies the recurrence $g(n+2) = R(n+2)P(n)f(n+2) + R(n+2)R(n+1)Q(n)$, which falls within the class we investigate. Note that up to shifting the recurrence appropriately we may assume that $R(n)$ has constant (non-zero) sign, so that the behaviour of $(f(n))_n$ is easily deduced from that of $(g(n))_n$.

Our first result is a complete classification of the possible behaviours that a holonomic recurrence of the form (1) may exhibit for large n. We say that a sequence $(x_n)_n$ of real numbers is *eventually positive* if there exists an $N \in \mathbb{N}$ such that $x_n > 0$ for all $n \geq N$. We say that it is *eventually negative* if there exists an $N \in \mathbb{N}$ such that $x_n < 0$ for all $n \geq N$. We say that it is *eventually alternating* if there exists an $N \in \mathbb{N}$ such that $x_N \neq 0$ and $\operatorname{sgn}(x_{n+1}) = -\operatorname{sgn}(x_n)$ for all $n \geq N$. We say that it is *eventually zero* if there exists an $N \in \mathbb{N}$ such that $x_N = 0$ for all $n \geq N$. In each of these cases we call any admissible choice for N a *witness* for the respective behaviour.

▶ **Theorem 1.** Let $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ be a holonomic recurrence in normal form. Then there exists a partition of $\mathbb{R}^2$ into five pieces, the origin O, two rays L^+ and L^-, and two open half-planes H^+ and H^-, such that for all pairs of initial values $(f(1), f(2)) \in \mathbb{R}^2$ we have:

1. If $(f(1), f(2)) \in O$ then the sequence is constant equal to zero.
2. If $(f(1), f(2)) \in H^+$ then the sequence is eventually positive.
3. If $(f(1), f(2)) \in H^-$ then the sequence is eventually negative.
4. If $(f(1), f(2)) \in L^+$ then the sequence is eventually positive if the leading coefficient Q is negative, and eventually alternating if the coefficient is positive.
5. If $(f(1), f(2)) \in L^-$ then the sequence is eventually negative if the leading coefficient Q is negative, and eventually alternating if the coefficient is positive.

We will call the line $L = O \cup L^+ \cup L^-$ the *critical line* of the holonomic recurrence. We can compute its slope to any given finite precision thanks to the following continued fraction representation:

▶ **Proposition 2.** Let $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ be a holonomic recurrence in normal form. Then we can compute a number N such that for the shifted recurrence $g(n+2) = P(n+N)g(n+1) + Q(n+N)g(n)$, in the notation of Theorem 1, the line $L = O \cup L^+ \cup L^-$ has slope

$$-\operatorname*{K}_{n=N}^{\infty} \frac{Q(n)}{P(n)} = -\cfrac{Q(N)}{P(N) + \cfrac{Q(N+1)}{P(N+1) + \dots}}.$$

Theorem 1 suggests the following computational problem: given a holonomic recurrence in normal form and initial values $(f(1), f(2)) \in \mathbb{Q}^2$, report whether the sequence $(f(n))_n$ thus defined is eventually positive, eventually negative, eventually alternating, or eventually zero and output a witness N for this. Let us call this the *Ultimate Sign Problem*. By Theorem 1 this problem is well-defined. It is clear that the Skolem Problem, the Positivity Problem, the Ultimate Positivity Problem, and the Infinite Zero Problem reduce to this.

Unfortunately we only obtain a partial computability result:

▶ **Theorem 3.** There exists an algorithm which takes as input a holonomic recurrence $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ in normal form, together with a pair $(f(1), f(2)) \in \mathbb{Q}^2$ of rational initial values and halts if and only if $(f(1), f(2)) \notin L^+ \cup L^-$. Upon halting the algorithm reports if $(f(1), f(2))$ is zero, belongs to H^+, or belongs to H^-, and in the latter two cases returns a number N such that the sequence $(f(n))_n$ has constant sign for all $n \geq N$.

Theorem 3 yields a total algorithm for deciding the Infinite Zero Problem and partial algorithms for deciding the Skolem Problem, the Positivity Problem, and the Ultimate Positivity Problem. The set of problem instances where the algorithm does not halt is "small" in the sense that it is contained in a set of codimension one.

While we do not obtain a total algorithm in general, there are special instances for which we do. To describe these instances we need to introduce further concepts. The *companion matrix* of the holonomic recurrence (1) is the matrix

$$M(n) = \begin{pmatrix} 0 & 1 \\ Q(n) & P(n) \end{pmatrix}.$$

Note that we have

$$\begin{pmatrix} f(n) \\ f(n+1) \end{pmatrix} = \prod_{j=1}^{n-1} M(j) \begin{pmatrix} f(1) \\ f(2) \end{pmatrix}.$$

Its n^{th} *characteristic polynomial* is given by

$$z^2 - P(n)z - Q(n).$$

For holonomic recurrences in normal form, the discriminant of this polynomial is by definition strictly positive for all $n \in \mathbb{N}$. Hence the characteristic polynomial has two distinct real roots

$$\lambda_1(n) = \tfrac{1}{2}\left(P(n) + \left(P(n)^2 + 4Q(n)\right)^{1/2}\right)$$

and

$$\lambda_2(n) = \tfrac{1}{2}\left(P(n) - \left(P(n)^2 + 4Q(n)\right)^{1/2}\right).$$

In the case where $\lambda_2(n)$ is a constant function of n we can compute the slope of the line L, yielding a total algorithm.

▶ **Proposition 4.** Let $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ be a holonomic recurrence in normal form. If $\lambda_2(n) = \lambda_2$ is a constant function of n then, in the notation of Theorem 1,

$$L^+ \cup L^- \cup O = \left\{(x, y) \in \mathbb{R}^2 \mid y = \lambda_2 x\right\}.$$

▶ **Corollary 5.** The Ultimate Sign Problem is computable for the class of all holonomic recurrences in normal form which have the additional property that $\lambda_2(n)$ is a constant function of n.

The following criterion allows us to check whether λ_2 is constant, increasing, or decreasing:

▶ **Proposition 6.** Write $P(n) = a_d n^d + \cdots + a_0$, $Q(n) = b_d n^d + \cdots + b_0$ with $a_d > 0$. Let

$$\chi_j = \det \begin{pmatrix} b_d & b_j \\ a_d & a_j \end{pmatrix}$$

for $j = 1, \ldots, d-1$. Let

$$\chi_0 = \det \begin{pmatrix} b_d & b_0 \\ a_d & a_0 \end{pmatrix} + b_d^2/a_d$$

The function λ_2 is either constant, strictly monotonically increasing for sufficiently large n, or strictly monotonically decreasing for large n. It is constant if and only if $\chi_0 = \cdots = \chi_d = 0$. It is decreasing if and only if there exists a j_0 such that $\chi_{j_0} > 0$ and $\chi_j = 0$ for $j > j_0$. It is increasing if and only if there exists a j_0 such that $\chi_{j_0} < 0$ and $\chi_j = 0$ for $j > j_0$.

We also obtain a total algorithm for the Ultimate Sign Problem in the case where the critical line contains no rational points. We collect some sufficient conditions that guarantee this.

▶ **Theorem 7.** Let $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ be a holonomic recurrence in normal form with integer polynomial coefficients $P(n) = a_d n^d + \cdots + a_1 n + a_0$ and $Q(n) = b_d n^d + \cdots + b_1 n + b_0$. Then the critical line L contains no non-trivial rational points if any of the following sufficient conditions is met:

1. $b_d = 0$.
2. $|\operatorname{lcof}(Q)/\operatorname{lcof}(P)| < 1$.
3. $|\operatorname{lcof}(Q)/\operatorname{lcof}(P)| = 1$ and $\lambda_2(n)$ is non-constant, positive and increasing for large n.
4. $|\operatorname{lcof}(Q)/\operatorname{lcof}(P)| = 1$ and $\lambda_2(n)$ is non-constant, negative and decreasing for large n.
5. $|\operatorname{lcof}(Q)/\operatorname{lcof}(P)| = 1$ and $\lambda_2(n)$ is non-constant, positive, decreasing for large n, and

$$\begin{cases} |a_0 + b_0 - 1| < 3a_1 & \text{if } d = 1, \\ |a_{d-1} + b_{d-1}| < (d+2)a_d & \text{otherwise.} \end{cases}$$

6. $|\operatorname{lcof}(Q)/\operatorname{lcof}(P)| = 1$ and $\lambda_2(n)$ is non-constant, negative, increasing for large n, and

$$\begin{cases} |a_0 - b_0 + 1| < 3a_1 & \text{if } d = 1, \\ |a_{d-1} - b_{d-1}| < (d+2)a_d & \text{otherwise.} \end{cases}$$

Finally, let us discuss how the reduction to normal form affects the termination behaviour of our algorithm. Let $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ be a holonomic recurrence of the form (1), and let $g(n+2) = cP(n+N)g(n+1) + c^2Q(n+N)g(n)$ be a recurrence in normal form as above. The map which sends initial values $(f(1), f(2))$ for the original recurrence to the initial values $(c^{N+1}f(N+1), c^{N+2}f(N+2))$ for the recurrence in normal form is a linear map $A\colon \mathbb{R}^2 \to \mathbb{R}^2$. The map A is bijective if and only if Q does not have any positive integer zeroes. If Q does have positive integer zeroes then the kernel of A is one-dimensional. In the cases where we have a total algorithm for the Ultimate Sign Problem for the recurrence in normal form the reduction of course yields a total algorithm. Assume that we only have a

partial algorithm that halts outside the union of the two rays L^+ and L^-. If Q does not have any positive integer zeroes, then applying the partial algorithm for the Ultimate Sign Problem after the reduction yields an algorithm that halts outside the union of the two rays $A^{-1}(L^+)$ and $A^{-1}(L^-)$. Thus, the behaviour of the algorithm is unchanged. If Q has positive integer zeroes then either A sends all initial values outside its kernel into the union of the rays L^+ and L^-, or it sends all such initial values into the union of H^+ and H^-. In the latter case we obtain a total algorithm, but in the former case we obtain an algorithm that only halts on the one-dimensional kernel of A. Thus, in the former scenario the dimension of the set of inputs which lead to termination decreases by one.

Let us illustrate some of our results with the help of a simple example.

▶ **Example 8.** Consider the holonomic recurrence

$$f(n+2) = (n-1)f(n+1) + nf(n).$$

We have $\lambda_1(n) = n$ and $\lambda_2(n) = -1$ for all $n \in \mathbb{N}$. Proposition 4 allows us to easily compute the critical line:

$$L = \left\{(x, y) \in \mathbb{R}^2 \mid x = -y\right\}.$$

Using elementary linear algebra we can explicitly compute the n^{th} term of the sequence:

$$f(n) = (-1)^n \frac{f(1) - f(2)}{2} + \left(\frac{n!}{n+1} + \sum_{k=1}^{n-1} \frac{(-1)^{n-k} k!}{(k+1)(k+2)}\right) \frac{f(1) + f(2)}{2}.$$

We hence have $H^+ = \left\{(x, y) \in \mathbb{R}^2 \mid x > -y\right\}$ and $H^- = \left\{(x, y) \in \mathbb{R}^2 \mid x < -y\right\}$.

Thus, if we fix $f(1) > 0$ and let $f_t(2) = -f(1) + t$ with $t \in [0, 1]$ the sequence with initial values $(f(1), f_t(2))$ is eventually positive for all $t > 0$. For sufficiently small $t > 0$ the sequence will alternate between positive and negative values a finite number $N(t)$ of times before attaining only positive values. We have $N(t) \to \infty$ as $t \to 0$. For $t = 0$ the sequence alternates between positive and negative values forever, a witness for this being given by $N(0) = 1$.

If we let the sequence start at the index $n = 0$ then the matrix product has the following closed form:

$$\prod_{j=0}^{n} M(j) = \begin{pmatrix} 0 & 1 \\ 0 & -1 \end{pmatrix}.$$

Thus, every initial value gets mapped onto the critical line for the same recurrence with starting index $n = 1$. The sequence is alternating for all initial values. Since λ_2 is a constant function our algorithm is total and hence able to detect this.

3 Proof of the Results

3.1 Preliminaries

Consider a second-order holonomic recurrence $f(n+2) = P(n)f(n+1) + Q(n)f(n)$ in normal form. Let $M(n)$ be its companion matrix. Using that $M(n)$ has two distinct real eigenvalues for all n, write $M(n) = S(n)D(n)S(n)^{-1}$, where

$$D(n) = \begin{pmatrix} \lambda_2(n) & 0 \\ 0 & \lambda_1(n) \end{pmatrix}, \qquad S(n) = \begin{pmatrix} 1 & 1 \\ \lambda_2(n) & \lambda_1(n) \end{pmatrix},$$

$$S(n)^{-1} = \frac{1}{\lambda_1(n) - \lambda_2(n)} \begin{pmatrix} \lambda_1(n) & -1 \\ -\lambda_2(n) & 1 \end{pmatrix}.$$

Then we have:

$$M(n)M(n-1)\cdot\cdots M(k) = S(n)D(n)S(n)^{-1}S(n-1)D(n-1)S(n-1)^{-1}\cdot\cdots S(k)D(k)S(k)^{-1}.$$

Intuitively, the products $S(n+1)^{-1}S(n)$ are very close to the identity matrix for large n, but we need to study the error terms precisely. Thus, define real-valued functions $\varepsilon_{i,j}(n)$ by:

$$S(n+1)^{-1}S(n) = \begin{pmatrix} 1+\varepsilon_{1,1}(n) & \varepsilon_{1,2}(n) \\ \varepsilon_{2,1}(n) & 1+\varepsilon_{2,2}(n) \end{pmatrix}.$$

More explicitly:

$$\varepsilon_{1,1}(n) = \frac{\lambda_2(n+1)-\lambda_2(n)}{\lambda_1(n+1)-\lambda_2(n+1)} \qquad \varepsilon_{1,2}(n) = \frac{\lambda_1(n+1)-\lambda_1(n)}{\lambda_1(n+1)-\lambda_2(n+1)}$$
$$\varepsilon_{2,1}(n) = \frac{\lambda_2(n)-\lambda_2(n+1)}{\lambda_1(n+1)-\lambda_2(n+1)} \qquad \varepsilon_{2,2}(n) = \frac{\lambda_1(n)-\lambda_1(n+1)}{\lambda_1(n+1)-\lambda_2(n+1)}$$

We want to study the product $M(n)M(n-1)\cdot\cdots\cdot M(k)$. To this end, define functions $a(k,n), b(k,n), c(k,n)$, and $d(k,n)$ via:

$$\prod_{j=k}^{n} M(j) = S(n)\begin{pmatrix} a(k,n) & b(k,n) \\ c(k,n) & d(k,n) \end{pmatrix} S(k)^{-1}.$$

Define functions `stay-small`, `switch-big`, `switch-small`, and `stay-big` as follows:

$$\texttt{stay-small}(n) = \lambda_2(n+1)(1+\varepsilon_{1,1}(n)) \qquad \texttt{switch-big}(n) = \lambda_2(n+1)\varepsilon_{1,2}(n)$$
$$\texttt{switch-small}(n) = \lambda_1(n+1)\varepsilon_{2,1}(n) \qquad \texttt{stay-big}(n) = \lambda_1(n+1)(1+\varepsilon_{2,2}(n)).$$

A straightforward calculation then shows that we have recursive equations:

$$\begin{aligned} a(k,n+1) &= \texttt{stay-small}(n)a(k,n) + \texttt{switch-big}(n)c(k,n) \\ b(k,n+1) &= \texttt{stay-small}(n)b(k,n) + \texttt{switch-big}(n)d(k,n) \\ c(k,n+1) &= \texttt{stay-big}(n)c(k,n) + \texttt{switch-small}(n)a(k,n) \\ d(k,n+1) &= \texttt{stay-big}(n)d(k,n) + \texttt{switch-small}(n)b(k,n). \end{aligned} \tag{2}$$

By definition we have the following initial values:

$$a(k,k) = \lambda_2(k) \qquad b(k,k) = 0 \qquad c(k,k) = 0 \qquad d(k,k) = \lambda_1(k).$$

The next three lemmas constitute the key steps in the proof of Theorem 1. We defer their technical proof to Section 3.4.

▶ **Lemma 9.**

1. The function $\lambda_1(n)$ is positive, strictly monotonically increasing, and satisfies $\lambda_1(n) = \Theta(P(n))$ as $n \to \infty$.
2. The function $\lambda_2(n)$ is either positive for all n or negative for all n. It is either constant, strictly monotonically decreasing for large n, or strictly monotonically increasing for large n. It satisfies $\lambda_2(n) = \Theta(n^{\deg Q - \deg P})$ as $n \to \infty$.
3. We have $\texttt{stay-big}(n) = \Theta(P(n))$ as $n \to \infty$.
4. We have $\texttt{switch-big}(n) = \Theta(n^{\deg Q - \deg P - 1})$ as $n \to \infty$.
5. We have $\texttt{stay-small}(n) = \Theta(n^{\deg Q - \deg P})$ as $n \to \infty$.
6. If λ_2 is constant then $\texttt{switch-small} = 0$ for all n. Otherwise $\texttt{switch-small} = O(n^{-2})$ and $\texttt{switch-small} = \Omega(n^{1-3\deg P})$ as $n \to \infty$.

▶ **Lemma 10.** We can compute a number $K \in \mathbb{N}$ such that for all $k \geq K$ there exists $N \in \mathbb{N}$ such that $d(k,n) > 0$ for all $n \geq N$.

▶ **Lemma 11.** Let K be as in Lemma 10. Let $k \geq K$ be fixed and $n \geq k+5$ such that $d(k,n') > 0$ for all $n' \geq n$. Then $|a(k,n)/d(k,n)| \in O(1/nP(n))$ and $|b(k,n)/d(k,n)| \in O(1/nP(n))$.

▶ **Lemma 12.** Let K be as in Lemma 10. Let $k \geq K$ be fixed and $n \geq k+3$ such that $d(k,n') > 0$ for all $n' \geq n$. Then the sequence $c(k,n)/d(k,n)$ converges to a limit $L(k)$ as $n \to \infty$. We have $L(k) = O(1/k^2P(k)^2)$ as $k \to \infty$. The number $L(k)$ is equal to zero if λ_2 is constant. If λ_2 is decreasing and positive or increasing and negative then the number $L(k)$ is positive. If λ_2 is increasing and positive or decreasing and negative then the number $L(k)$ is negative. Moreover, for any given $p \in \mathbb{N}$ we can compute a rational number $\tilde{L} \in \mathbb{Q}$ with $|\tilde{L} - L(k)| < 2^{-p}$.

3.2 Proof of Theorem 1

With the asymptotic behaviour of the matrix entries being established, we can study the asymptotic behaviour of the sequence $(f(n))_n$. Using Lemmas 10 and 12 we can compute a number K such that for all $k \geq K$, the number $L(k)$ is defined and $1 - L(k) > 0$. By definition of $M(n)$ we have for all $k \geq K$:

$$\begin{aligned}\begin{pmatrix} f(n) \\ f(n+1) \end{pmatrix} &= \prod_{j=k}^{n-1} M(j) \begin{pmatrix} f(k) \\ f(k+1) \end{pmatrix} \\ &= S(n) \begin{pmatrix} a(k,n-1) & b(k,n-1) \\ c(k,n-1) & d(k,n-1) \end{pmatrix} S(k)^{-1} \begin{pmatrix} f(k) \\ f(k+1) \end{pmatrix}.\end{aligned}$$

By calculating the right hand side explicitly we obtain:

$$\begin{aligned}&(\lambda_1(k) - \lambda_2(k))f(n) = \\ &\quad \big(a(k,n-1)\,(\lambda_1(k)f(k) - f(k+1)) \qquad + b(k,n-1)\,(f(k+1) - \lambda_2(k)f(k)) \\ &\quad + c(k,n-1)\,(\lambda_1(k)f(k) - f(k+1)) \qquad + d(k,n-1)\,(f(k+1) - \lambda_2(k)f(k))\big).\end{aligned}$$

Using Lemma 11 we obtain:

$$(\lambda_1(k) - \lambda_2(k))\tfrac{f(n)}{d(k,n-1)} = \tag{3}$$

$$\tfrac{c(k,n-1)}{d(k,n-1)}\,(\lambda_1(k)f(k) - f(k+1)) + (f(k+1) - \lambda_2(k)f(k)) + O(1/nP(n)) \tag{4}$$

Passing to the limit as $n \to \infty$ we obtain, using Lemma 12:

$$\lim_{n\to\infty} (\lambda_1(k) - \lambda_2(k))\tfrac{f(n)}{d(k,n-1)} = (1 - L(k))f(k+1) + (\lambda_1(k)L(k) - \lambda_2(k))f(k). \tag{5}$$

Let $\ell(k) = (1 - L(k))f(k+1) + (\lambda_1(k)L(k) - \lambda_2(k))f(k)$. Note that this defines a straight line for all k, since $1 - L(k) \neq 0$ by assumption.

Now there are two cases:

1. There exists a $k \geq K$ such that $\ell(k) \neq 0$. In this case the sign $f(n)$ is eventually constant and the same as that of $\ell(k)$. It follows from Lemma 12 that $\ell(k)$ is computable. This together with the estimate (4) with an effective constant for the $O(1/nP(n))$ term allows us to compute an index N such that the sign of $f(n)$ is equal to that of $\ell(k)$ for all $n \geq N$.

2. We have $\ell(k) = 0$ for all $k \geq K$. Then the sequence satisfies the first-order recurrence relation

$$f(k+1) = \frac{\lambda_2(k) - \lambda_1(k)L(k)}{1 - L(k)} f(k)$$

for all $k \geq K$. In particular, if λ_2 is negative for all k then the sequence $(f(n))_{n \geq K}$ is zero or alternating, and if λ_2 is positive then the sign of every sequence element $f(n)$ with $n \geq K$ is equal to that of $f(K)$.

Now, since $Q(n)$ is assumed to have no integer zeroes, the matrices $M(n)$ are non-singular for all n. It follows with the above that if $\ell(n) \neq 0$ then the behaviour of the sequence as $n \to \infty$ is robust under small perturbations, while if $\ell(n) \neq 0$ then the behaviour changes under arbitrarily small perturbations of the initial values. It follows that for all $n \geq K$, the matrix $M(n)$ sends the line $L_n = \{(x, y) \in \mathbb{R}^2 \mid (1 - L(n))y + (\lambda_1(n)L(n) - \lambda_2(n))x\}$ to the line L_{n+1}. Hence $\ell(k) = 0$ for some $k \geq K$ if and only if $\ell(k) = 0$ for all $k \geq K$. Thus, the first case in the above case alternative occurs if and only if $\ell(K) \neq 0$. Also note that since the matrices $M(j)$ are all invertible, if the sequence $(f(n))_n$ is eventually zero then it is everywhere zero. It follows that in the second case alternative above the sequence is either eventually alternating or eventually has constant sign.

Let $h = M(K-1) \cdot \cdots \cdot M(1)$. Let

$$\begin{aligned}
H^+ &= h^{-1}\left(\{(x, y) \in \mathbb{R}^2 \mid (1 - L(K))y + (\lambda_1(K)L(K) - \lambda_2(K))x > 0\}\right) \\
H^- &= h^{-1}\left(\{(x, y) \in \mathbb{R}^2 \mid (1 - L(K))y + (\lambda_1(K)L(K) - \lambda_2(K))x < 0\}\right) \\
L^+ &= h^{-1}\left(\{(x, y) \in \mathbb{R}^2 \mid (1 - L(K))y + (\lambda_1(K)L(K) - \lambda_2(K))x = 0, x > 0\}\right) \\
L^- &= h^{-1}\left(\{(x, y) \in \mathbb{R}^2 \mid (1 - L(K))y + (\lambda_1(K)L(K) - \lambda_2(K))x = 0, x < 0\}\right).
\end{aligned}$$

Theorems 1 and 3 follow.

Proposition 2 is now proved as follows: For $n \geq K$, let $S(n)$ denote the slope of the line $L_n = \{(x, y) \in \mathbb{R}^2 \mid (1 - L(n))y + (\lambda_1(n)L(n) - \lambda_2(n))x\}$. Using that $M(n)$ maps L_n onto L_{n+1} we obtain the equation $S(n) = -\frac{Q(n)}{P(n) - S(n+1)}$. This yields $S(K) = -\mathrm{K}_{m=K}^{\infty} \frac{Q(m)}{P(m)}$, and this is the slope of the critical line of the recurrence shifted by K.

If λ_2 is a constant function of n then $L_n = 0$ for all n, as is readily seen from the recursive equation (2) for $c(n, k)$. Thus, $\ell(K) = y - \lambda_2 x$. Since the vector $(1, \lambda_2)$ is an eigenvector for all matrices $M(1), \ldots, M(K-1)$ we have $h^{-1}(\{(x, y) \mid y - \lambda_2 x = 0\}) = \{(x, y) \mid y - \lambda_2 x = 0\}$. It follows that we have $L^+ \cup L^- \cup O = \{(x, y) \mid y = \lambda_2 x\}$. This establishes Proposition 4. Corollary 5 follows together with the above discussion.

Let us now prove Proposition 6. Write $P(n) = a_d n^d + \cdots + a_0$ and $Q(n) = b_d n^d + \cdots + b_0$ with $a_d > 0$. Then the limit of $\lambda_2(n)$ as $n \to \infty$ is equal to $-b_d/a_d$. This follows for instance from the series representation (10) in Section 3.4. We have seen in Lemma 9 that λ_2 is either constant or strictly monotone. It follows that λ_2 is decreasing or constant if and only if $\lambda_2(n) \geq -b_d/a_d$ for all sufficiently large n, with λ_2 being decreasing if and only if the inequality is strict. By writing out the definition of $\lambda_2(n)$ and applying basic algebra we obtain that this is equivalent to:

$$P(n) + 2b_d/a_d \geq \left(P(n)^2 + 4Q(n)\right)^{\frac{1}{2}}.$$

For sufficiently large n the expressions on both sides are positive, so the inequality is equivalent to the same inequality with both sides squared:

$$P(n)^2 + 4P(n)b_d/a_d + 4b_d^2/a_d^2 \geq P(n)^2 + 4Q(n).$$

This is further equivalent to the inequality:

$$P(n)b_d - a_dQ(n) + b_d^2/a_d \geq 0.$$

Proposition 6 follows.

3.3 Proof of Theorem 7

By the proof of Theorem 1 the critical line is, up to potentially shifting the recurrence, given by the equation

$$(1 - L(1))f(2) + (\lambda_1(1)L(1) - \lambda_2(1))f(2).$$

If the equation has a non-zero rational solution then it has a non-zero integer solution. Thus, assume that the equation has an integer solution $(f(1), f(2))$ with $f(1)$ and $f(2)$ not both zero. Then the recurrence sequence $(f(n))_n$ satisfies

$$f(n+1) = \frac{\lambda_2(n) - L(n)\lambda_1(n)}{1 - L(n)} f(n). \tag{6}$$

If $\deg Q < \deg P$ or $\deg Q = \deg P$ and $|\operatorname{lcof}(Q)| < |\operatorname{lcof}(P)|$ then it follows from Lemma 9 that $|\lambda_2(n)| \to c$ with $0 \geq c < 1$ as $n \to \infty$. It follows from (6) that $f(n) \in o(1)$. But since $(f(n))_n$ is an integer sequence it follows that $f(n) = 0$ for all large n. But then $f(n) = 0$ for all n by Theorem 1. Hence, the only integer solution is $(0, 0)$.

It remains to consider the cases where $\deg Q = \deg P$ and $|\operatorname{lcof}(Q)| = |\operatorname{lcof}(P)|$.

We claim that in the case where λ_2 is negative and decreasing or positive and increasing the sequence $(f(n))_n$ is bounded. In this case $|\lambda_2(n)| < 1$ for all n. It follows from (6) and Lemma 12 that there exists a constant c such that $|f(n)| \leq \prod_{k=1}^{n}(1 + \frac{c}{k^2})|f(1)|$. Boundedness of the sequence follows by taking logarithms on both sides and noting that the sequence $\sum_{n=1}^{\infty} n^{-2}$ converges.

We claim that if λ_2 is positive and decreasing and $d \geq 2$ then $|f(n)| \leq Cn^{\left|\frac{a_{d-1}+b_{d-1}}{a_d}\right|}$. By assumption on λ_2 and Lemma 12 the number $L(n)$ is positive, so that we have for all sufficiently large n:

$$\left|\frac{\lambda_2(n) - L(n)\lambda_1(n)}{1 - L(n)}\right| \leq \lambda_2(n)$$

There exist constants c and c' such that for all sufficiently large n we have:

$$|\lambda_2(n)| \leq 1 + \left|\frac{b_{d-1} + a_{d-1}}{a_d}\right| \frac{1}{n - c'} + \frac{c}{n^2}.$$

It follows that, for sufficiently large M and all $N \geq M$ we have:

$$f(N) \leq |f(M)| \prod_{n=M}^{N} \left(1 + \left|\frac{b_{d-1} + a_{d-1}}{a_d}\right| \frac{1}{n - c'} + \frac{c}{n^2}\right).$$

Taking logarithms on both sides we obtain:

$$\log f(N) \leq \log |f(M)| + \sum_{n=M}^{N} \log \left(1 + \left|\frac{b_{d-1} + a_{d-1}}{a_d}\right| \frac{1}{n - c'} + \frac{c}{n^2}\right)$$

Using $\log(1+x) = x + O(x^2)$ we obtain:

$$\log f(N) \le \log|f(M)| + \sum_{n=M}^{N} \left(\left| \frac{b_{d-1}+a_{d-1}}{a_d} \right| \frac{1}{n-c'} + \frac{c}{n^2} + O(1/n^2) \right) \tag{7}$$

$$\le \log|f(M)| + \left| \frac{b_{d-1}+a_{d-1}}{a_d} \right| \log(N) + C', \tag{8}$$

where C' is a constant.

We have used in (7) that $\sum_{n=1}^{N} \frac{1}{n} \le \log(N) + \gamma + 1$ for all large N, where $\gamma \approx 0.5572\ldots$ is the Euler-Mascheroni constant. Since $\sum_{n=1}^{N} \frac{1}{n}$ diverges, it follows that $\sum_{n=M}^{N} \frac{1}{n} \le \log(N)$ for large M. Now apply the exponential function to both sides of (8):

$$f(N) \le |f(M)| N^{\left| \frac{b_{d-1}+a_{d-1}}{a_d} \right|} e^{C'}.$$

This proves the claim. An analogous argument shows that $f(N) \in O\left(N^{\left| \frac{b_{d-1}+a_{d-1}}{a_d} \right|}\right)$ if λ_2 is negative and increasing and $d \ge 2$. Analogous claims hold for the case that $d = 1$. Now, by assumption we have

$$L(n) = \frac{\lambda_2(n) f(n) - f(n+1)}{\lambda_1(n) f(n) - f(n+1)}. \tag{9}$$

By our previous considerations, the denominator of this expression is in $O(\frac{1}{P(n)})$ if $\lambda_2(n)$ is positive and increasing or if $\lambda_2(n)$ is negative and decreasing. If $\lambda_2(n)$ is, say, positive and decreasing and $d \ge 2$ then the expression is in $O\left(n^{\left| \frac{b_{d-1}+a_{d-1}}{a_d} \right|} P(n)\right)$. Similarly for the other cases we consider. Thus, if $\lambda_2(n)$ is positive and increasing or negative and decreasing, or for instance if $d \ge 2$ and it is positive and decreasing and $\left| \frac{b_{d-1}+a_{d-1}}{a_d} \right| < \deg P + 2$, then the numerator of (9) has to be in $o(1)$.

In other words, we have a sequence of pairs of non-zero integers (x_n, y_n) with $|x_n|, |y_n| \le n^p$ for some positive integer p such that $|\lambda_2(n) x_n - y_n| \to 0$ as $n \to \infty$. We may assume that $p \ge 2$. Now use the series representation (10) of $\lambda_2(n)$ computed in Section 3.4:

$$\begin{aligned}
&|\lambda_2(n) x_n - y_n| \\
&= \left| -x_n \sum_{m=1}^{\infty} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1} (1-2j)\, P(n)^{1-2m} - y_n \right| \\
&= \left| x_n \sum_{m=1}^{2p} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1} (1-2j)\, P(n)^{1-2m} + y_n + O\left(n^p Q(n)^{2p} / P(n)^{4p-1}\right) \right| \\
&= \left| P(n)^{1-4p} \left(x_n \left(\sum_{m=1}^{2p} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1} (1-2j)\, P(n)^{4p-2m} \right) + y_n P(n)^{4p-1} \right) \right| \\
&\qquad + O\left(n^p Q(n)^{2p} / P(n)^{4p-1}\right).
\end{aligned}$$

In order for this to converge to zero we must have

$$x_n \left(\sum_{m=1}^{2p} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1} (1-2j)\, P(n)^{4p-2m} \right) + y_n P(n)^{4p-1} \in o(P(n)^{4p-1}).$$

But the left hand side is an integer linear combination of two polynomials of degree $(4p-1)\deg P$. By assumption, their leading coefficients are either equal or additive inverses of each other – depending on the sign of $\lambda_2(n)$. It follows that $x_n = y_n$ or $x_n = -y_n$ for all sufficiently large n. Let us without loss of generality assume that the former holds true.

Then, for all sufficiently large n the lines

$$L_n = \{(x,y) \mid (\lambda_1(n)L(n) - \lambda_2(n))x + (1 - L(n)) = 0\}$$

are all equal to the diagonal $x = y$. Since the matrix $M(n)$ sends the line L_n line onto the line L_{n+1}, it follows that the vector $(1,1)$ is an eigenvector for every $M(n)$. The corresponding eigenvalue must be $\lambda_2(n)$. But since the vector gets mapped to itself it follows that $\lambda_2(n) = 1$ for all n, contradicting our initial assumption.

3.4 Proof of Lemmas 11 and 12

We will expand the terms $a(k,n)$, $b(k,n)$, $c(k,n)$, and $d(k,n)$ into large sums based on the above recursive equations. It will be convenient to describe these sums with the help of a finite automaton. Consider the finite automaton $\mathcal{A}$ over the alphabet $\Sigma = \{\texttt{stay-big}, \texttt{switch-small}, \texttt{stay-small}, \texttt{switch-big}\}$ defined in Figure 2.

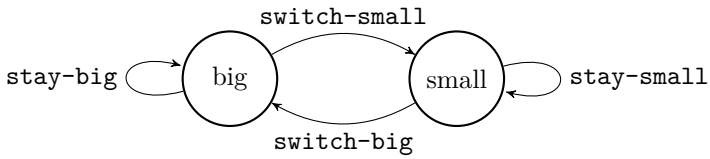

Figure 2 The automaton $\mathcal{A}$.

Let $[\text{small} \to \text{small}] \subseteq \Sigma^*$ denote the set of all words that are accepted by $\mathcal{A}$ with initial state "small" and accepting state "small". Define the sets $[\text{small} \to \text{big}]$, $[\text{big} \to \text{small}]$, and $[\text{big} \to \text{big}]$ analogously.

For each symbol $s \in \Sigma$, let $[\![s]\!] \colon \mathbb{N} \to \mathbb{R}$ be the obvious function associated with it. For a word $w = w_1 \cdot \cdots \cdot w_s$ over the alphabet Σ and $n \geq s$, let $[\![w]\!](n) = [\![w_1]\!](n) \cdot \cdots \cdot [\![w_s]\!](n-s+1)$.

For $k \leq n$, let

$$A(k,n) = [\text{small} \to \text{small}] \cap \Sigma^{n-k} \qquad B(k,n) = [\text{small} \to \text{big}] \cap \Sigma^{n-k}$$
$$C(k,n) = [\text{big} \to \text{small}] \cap \Sigma^{n-k} \qquad D(k,n) = [\text{big} \to \text{big}] \cap \Sigma^{n-k}$$

From the above recursive equations and initial values we obtain for all $n > k$:

$$a(k,n) = \lambda_2(k) \sum_{w \in A(k,n)} [\![w]\!](n-1) \qquad b(k,n) = \lambda_1(k) \sum_{w \in B(k,n)} [\![w]\!](n-1)$$
$$c(k,n) = \lambda_2(k) \sum_{w \in C(k,n)} [\![w]\!](n-1) \qquad d(k,n) = \lambda_1(k) \sum_{w \in D(k,n)} [\![w]\!](n-1).$$

We study the asymptotic behaviour of the quotients $a(k,n)/d(k,n)$, $b(k,n)/d(k,n)$, and $c(k,n)/d(k,n)$. In order to do so, we first need to study the asymptotic behaviour of the functions $\texttt{stay-big}, \texttt{switch-small}, \texttt{stay-small}, \texttt{switch-big}$. In the sequel we will denote these functions by $\texttt{stb}, \texttt{sws}, \texttt{sts}, \texttt{swb}$ for short.

Recall that we have

$$\lambda_1(n) = \tfrac{1}{2}\left(P(n) + \left(P(n)^2 + 4Q(n)\right)^{1/2}\right)$$

and

$$\lambda_2(n) = \tfrac{1}{2}\left(P(n) - \left(P(n)^2 + 4Q(n)\right)^{1/2}\right)$$

The Taylor series expansion of $h(x) = x^{1/2}$ about $x = P(n)^2$ is

$$x^{1/2} = \sum_{m=0}^{\infty} \frac{(x - P(n)^2)^m}{2^m m!} \left(\prod_{j=1}^{m-1}(1-2j)\right) P(n)^{1-2m}.$$

Hence:

$$\left(P(n)^2 + 4Q(n)\right)^{1/2} = \sum_{m=0}^{\infty} \frac{2^m Q(n)^m}{m!} \left(\prod_{j=1}^{m-1}(1-2j)\right) P(n)^{1-2m}. \tag{10}$$

Let

$$\rho(n) = \sum_{m=1}^{\infty} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1}(1-2j)\, P(n)^{1-2m}.$$

Then we have

$$\lambda_1(n) = P(n) + \rho(n),$$

and

$$\lambda_2(n) = -\rho(n).$$

Note that the series

$$\sum_{m=1}^{\infty} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1}(1-2j)\, P(n)^{1-2m}$$

is majorised by the geometric series $P(n)\sum_{m=1}^{\infty}\left(\frac{4Q(n)}{P(n)^2}\right)^m$. In particular we have

$$\sum_{m=k}^{\infty} \frac{2^{m-1} Q(n)^m}{m!} \prod_{j=1}^{m-1}(1-2j)\, P(n)^{1-2m} = O\left(\frac{Q(n)^k}{P(n)^{2k-1}}\right).$$

Let us now prove Lemma 9.

Proof of Lemma 9. It is clear that $\lambda_1(n)$ is positive and monotonically increasing. It follows easily from the series representation (10) that $\lambda_1(n)$ has the claimed asymptotic behaviour.

If $Q(n)$ is negative for all n then $\left(P(n)^2 + 4Q(n)\right)^{1/2} < P(n)$ and $\lambda_2(n)$ is positive for all n. If $Q(n)$ is positive for all n then $\left(P(n)^2 + 4Q(n)\right)^{1/2} > P(n)$ and $\lambda_2(n)$ is negative for all n. It follows easily from the series representation (10) that $\lambda_2(n)$ has the claimed asymptotic behaviour.

The claimed asymptotic behaviour of the functions `stb`, `swb`, and `sts` is easily verified.

It remains to prove that λ_2 is either constant or monotone and to study the asymptotic behaviour of $\mathtt{sws}$. To this end we compute the derivative of $\lambda_2(z)$ for $z \in \mathbb{R}$:

$$\lambda_2'(z) = \frac{P'(z)(P(z)^2 + 4Q(z))^{1/2} - P(z)P'(z) - 2Q'(z)}{2(P(z)^2 + 4Q(z))^{-1/2}}.$$

Let $A(z) = P'(z)(P(z)^2 + 4Q(z))^{1/2}$ and $B(z) = P(z)P'(z) - 2Q'(z)$. Then $A(z)^2$ and $B(z)^2$ are polynomials. Hence, if the functions $A(z)$ and $B(z)$ are not equal everywhere, then there exists a positive constant c such that $|A(z)^2 - B(z)^2| \geq c$ for all sufficiently large z. Thus,

$$|A(z) - B(z)| = |A(z)^2 - B(z)^2|/|A(z) + B(z)| \geq c/|A(z) + B(z)|.$$

This already establishes that λ_2 is either constant or monotone.

We have $\mathtt{sws} \in \Theta(\lambda_2(n) - \lambda_2(n+1))$. If λ_2 is constant then clearly $\mathtt{sws} = 0$. Assume now that λ_2 is not constant. The upper bound $\mathtt{sws} \in O(n^{-2})$ can be deduced from the easily established fact that if the degree of P and Q is bounded by d, then the degree of $Q(n)P(n+1) - Q(n+1)P(n)$ is bounded by $2d - 2$.

From the series representation (10) we obtain $|A(z)+B(z)| \in O(z^{2\deg P - 1})$ and $2(P(z)^2 - 4Q(z))^{-1/2} \in O(z^{\deg P})$. It follows that $|\lambda_2'(z)| \in \Omega(z^{1-3\deg P})$. Then, by the mean value theorem, $|\lambda_2(n) - \lambda_2(n+1)| \in \Omega(n^{1-3\deg P})$. ◀

The signs of the coefficients $\mathtt{stb}, \mathtt{sws}, \mathtt{swb}, \mathtt{sts}$ can be easily deduced from Lemma 9. They depend on the behaviour of the function $\lambda_2(n)$. Recall that this function is either constant, positive, or negative and either increasing or decreasing. This leads to four possible sign configurations, indicated in Figures 3 - 7.

We will treat the case where λ_2 is constant and the case where λ_2 is non-constant separately. Let us focus on the latter case for now. Let $D(k,n)^+$ denote the set of words in $D(k,n)$ which contain each of the symbols $\mathtt{sws}$ and $\mathtt{sts}$ an even number of times. Let $D(k,n)^-$ denote its complement. Clearly, for every word $w \in D(k,n)^+$, the number $[\![w]\!](n)$ is positive.

The following proposition is trivial but useful when comparing sums over large index sets:

▶ **Proposition 13.** Let A and B be finite sets of positive real numbers. Let $\mu\colon A \to B$ be a function. Assume that $a/\mu(a) < \varepsilon$ for some $\varepsilon > 0$ and $\mu^{-1}(b)$ contains at most c elements. Then

$$\sum_{a \in A} a / \sum_{b \in B} b < c\varepsilon.$$

▶ **Lemma 14.** Assume that λ_2 is non-constant. For all sufficiently large k and $n \geq k$ we have

$$\sum_{w \in D(k,n)^+} [\![w]\!](n-1) > 2 \sum_{w \in D(k,n)^-} |[\![w]\!](n-1)|$$

Proof. Let $D(k,n)_1$ denote the set of words with an odd number of $\mathtt{sws}$. Let $D(k,n)_2$ denote the set of words with an even number of $\mathtt{sws}$. Consider the map $\mu\colon D(k,n)_1 \to D(k,n)_2$ defined as follows: For a word $w \in D(k,n)_1$ there exist unique words p, r such that $w = p \cdot \mathtt{sws} \cdot r$ with $\mathtt{sws}$ not occurring in r. Let $\mu(w) = p \cdot \mathtt{stb}^{|r|+1}$.

For $w = p \cdot \mathtt{sws} \cdot r$ we have

$$\mu^{-1}(\mu(w)) = \left\{ p \cdot \mathtt{sws} \cdot \mathtt{sts}^j \cdot \mathtt{swb} \cdot \mathtt{stb}^{|r|-j-1} \mid j \in \{0, \ldots, |r|-1\} \right\}.$$

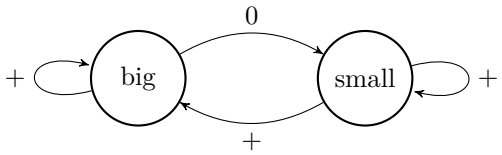

Figure 3 λ_2 constant.

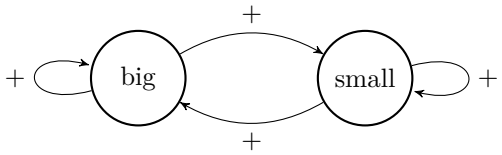

Figure 4 λ_2 positive and decreasing.

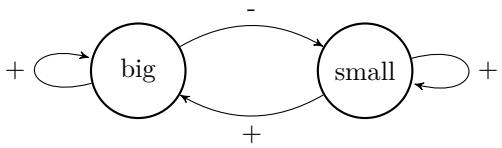

Figure 5 λ_2 positive and increasing.

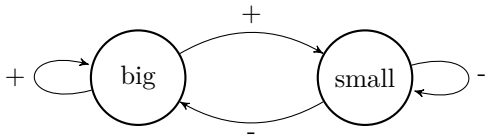

Figure 6 λ_2 negative and increasing.

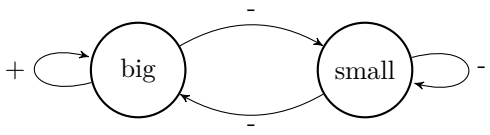

Figure 7 λ_2 negative and decreasing.

We have

$$\begin{aligned}
&\sum_{v\in\mu^{-1}(\mu(w))} |[\![v]\!](n-1)|/|[\![\mu(w)]\!](n-1)| \\
&= \sum_{j=0}^{n-k-|p|-2} \left| \frac{\mathtt{sws}(n-|p|-1)\cdot\prod_{l=1}^{j}\mathtt{sts}(n-|p|-l-1)\cdot\mathtt{swb}(n-|p|-j-2)\cdot\prod_{l=k}^{n-|p|-j-3}\mathtt{stb}(l)}{\mathtt{stb}(n-|p|-1)\cdot\cdots\cdot\mathtt{stb}(k)} \right| \\
&\leq \sum_{j=0}^{n-k-|p|-2} \left| \frac{c/(n-|p|-1)^2\cdot c^j\cdot c/(n-|p|-j-2)}{P(n-|p|-1)\cdot\cdots\cdot P(n-|p|-j-2)} \right|
\end{aligned}$$

for some constant c. Now, for large k we have $P(k) > c$ and we can estimate:

$$\sum_{j=0}^{n-k-|p|-2} \left| \frac{c/(n-|p|-1)^2 \cdot c^j \cdot c/(n-|p|-j-2)}{P(n-|p|-1)\cdot\dots\cdot P(n-|p|-j-2)} \right|$$
$$\leq \frac{c^2}{k(n-|p|-1)^2} \sum_{j=0}^{n-k-|p|-2} \left(\frac{c}{P(k)}\right)^j$$
$$\leq \frac{c^2}{k^3} \frac{P(k)}{P(k)-c}.$$

It follows that

$$\sum_{w\in D(k,n)_1} |[\![w]\!](n-1)| / \sum_{w\in D(k,n)_2} |[\![w]\!](n-1)| \leq \frac{c^2}{k^3}\frac{P(k)}{P(k)-c}.$$

Define a map $\sigma\colon D(k,n)_2 \to D(k,n)^+$ as follows: For a word $w \in D(k,n)_2$, if w contains the symbol $\mathtt{sts}$ an even number of times, let $\sigma(w) = w$. If w contains the symbol $\mathtt{sts}$ an odd number of times then there exists a unique integer $e \geq 1$ and unique words p, q such that

$$w = p \cdot \mathtt{sws} \cdot \mathtt{sts}^e \cdot q$$

and q does not contain the symbol $\mathtt{sts}$. Now, let

$$\sigma(w) = p \cdot \mathtt{stb} \cdot \mathtt{sws} \cdot \mathtt{sts}^{e-1} \cdot q.$$

Then σ is a well-defined map of type $D(k,n)_2 \to D(k,n)^+$. Every word in $D(k,n)^+$ has at most two preimages under σ.

Let $w = p \cdot \mathtt{sws} \cdot \mathtt{sts}^e \cdot q \in D(k,n)_2$ be a word which contains the symbol $\mathtt{sts}$ an odd number of times. Then

$$|[\![w]\!](n-1)| / [\![\sigma(w)]\!](n-1) = \frac{|\mathtt{sws}(n-|p|-1)\cdot\mathtt{sts}(n-|p|-2)|}{|\mathtt{stb}(n-|p|-1)\cdot\mathtt{sws}(n-|p|-2)|} \leq \frac{c}{P(k)}$$

with the same constant $c > 0$ as above. It follows that

$$\sum_{w\in D(k,n)_2} |[\![w]\!](n-1)| / \sum_{w\in D(k,n)^+} [\![w]\!](n-1) \leq 2.$$

Further, letting $D(k,n)_2^-$ denote the set of words in $D(k,n)_2$ which contain the symbol $\mathtt{sts}$ an odd number of times, the same estimate shows that

$$\sum_{w\in D(k,n)_2^-} |[\![w]\!](n-1)| / \sum_{w\in D(k,n)^+} [\![w]\!](n-1) \leq \frac{c}{P(k)}.$$

Thus, in total, we have:

$$\frac{\sum_{w\in D(k,n)^-} |[\![w]\!](n-1)|}{\sum_{w\in D(k,n)^+} [\![w]\!](n-1)}$$
$$\leq \frac{\sum_{w\in D(k,n)_2^-} |[\![w]\!](n-1)| + \sum_{w\in D(k,n)_1} |[\![w]\!](n-1)|}{\sum_{w\in D(k,n)^+} [\![w]\!](n-1)}$$
$$= \frac{\sum_{w\in D(k,n)_2^-} |[\![w]\!](n-1)|}{\sum_{w\in D(k,n)^+} [\![w]\!](n-1)} + \frac{\sum_{w\in D(k,n)_1} |[\![w]\!](n-1)|}{\sum_{w\in D(k,n)_2} |[\![w]\!](n-1)|} \cdot \frac{\sum_{w\in D(k,n)_2} |[\![w]\!](n-1)|}{\sum_{w\in D(k,n)^+} [\![w]\!](n-1)}$$
$$\leq \frac{c}{P(k)} + 2\frac{c^2}{k^3}\frac{P(k)}{P(k)-c}.$$

The right hand side converges to zero as $k \to \infty$. In particular it is smaller than $1/2$ for all sufficiently large k, which yields the claim. ◀

Lemma 14 immediately implies Lemma 10. The computability of the constant K is obtained by observing that we can effectively find all constants that appear in the estimates in the proof. We are now ready to prove Lemmas 11 and 12.

Proof of Lemma 11. We only prove the claim for $b(k,n)$. The claim for $a(k,n)$ is proved analogously.

Let us first assume that λ_2 is non-constant. Then by Lemma 14 it suffices to show that

$$\sum_{w\in B(k,n)} |[\![w]\!](n-1)| / \sum_{w\in D(k,n)} |[\![w]\!](n-1)| = O(1/nP(n)).$$

By Lemma 9 we have $\mathtt{sws} \in \Omega(n^{1-3\deg P})$. Define a map $\mu\colon B(k,n) \to D(k,n)$ as follows: for a word $w = p\cdot q$ in $B(k,n)$ with $|p| = 5$, let $\mu(w) = \mathtt{stb}^4 \cdot s \cdot q$, where $s = \mathtt{sws}$ if $q \in [\text{small} \to \text{big}]$ and $s = \mathtt{stb}$ if $q \in [\text{big} \to \text{big}]$. Then the set $\mu^{-1}(\mu(w))$ contains at most 16 elements. By Proposition 13 it suffices to show that $|[\![w]\!](n-1)|/|[\![\mu(w)]\!](n-1)| \in O(1/nP(n))$.

Consider two cases. The first case is that $w = p\cdot q$ with $p \in [\text{small} \to \text{small}]$, $|p| = 5$. Note that $|[\![p]\!](n-1)|$ is smaller than $[\![\mathtt{sts}^5]\!](n-1)$ or $[\![\mathtt{swb}\cdot\mathtt{stb}^3\cdot\mathtt{sws}]\!](n-1)$. Now, $\mu(\mathtt{sts}^5\cdot q) = \mathtt{stb}^4\cdot\mathtt{sws}\cdot q$, with

$$\begin{aligned}\frac{[\![\mathtt{sts}^5\cdot q]\!](n-1)}{[\![\mathtt{stb}^4\cdot\mathtt{sws}\cdot q]\!](n-1)} &= \frac{\mathtt{sts}(n-1)\cdot\cdots\cdot\mathtt{sts}(n-5)}{\mathtt{stb}(n-1)\cdot\cdots\cdot\mathtt{stb}(n-4)\cdot\mathtt{sws}(n-5)}\\ &= \frac{\Theta(n^{5(\deg P-\deg Q)})}{\Theta(n^{4\deg P}n^{1-3\deg P})}\\ &= O\left(\frac{1}{nP(n)}\right).\end{aligned}$$

It remains to check the other possibility. $\mu(\mathtt{swb}\cdot\mathtt{stb}^3\cdot\mathtt{sws}\cdot q) = \mathtt{stb}^4\cdot\mathtt{sws}\cdot q$, with

$$\frac{[\![\mathtt{swb}\cdot\mathtt{stb}^3\cdot\mathtt{sws}\cdot q]\!](n-1)}{[\![\mathtt{stb}^4\cdot\mathtt{sws}\cdot q]\!](n-1)} = \frac{\mathtt{swb}(n-1)}{\mathtt{stb}(n-1)} = \frac{O(1/n)}{\Theta(P(n))} = O\left(\frac{1}{nP(n)}\right).$$

The second case is that $w = p\cdot q$ with $p \in [\text{small} \to \text{big}]$, $|p| = 5$. Again, $|[\![p]\!](n-1)|$ is smaller than $[\![\mathtt{swb}\cdot\mathtt{stb}^4]\!](n-1)$ or $[\![\mathtt{sts}^4\cdot\mathtt{swb}]\!](n-1)$. We have $\mu(\mathtt{swb}\cdot\mathtt{stb}^4\cdot q) = \mathtt{stb}^5\cdot q$ with

$$\frac{[\![\mathtt{swb}\cdot\mathtt{stb}^4\cdot q]\!](n-1)}{[\![\mathtt{stb}^5\cdot q]\!](n-1)} = \frac{\mathtt{swb}(n-1)}{\mathtt{stb}(n-1)} = O\left(\frac{1}{nP(n)}\right)$$

and $\mu(\mathtt{sts}^4\cdot\mathtt{swb}\cdot q) = \mathtt{stb}^5\cdot q$ with

$$\frac{[\![\mathtt{sts}^4\cdot\mathtt{swb}\cdot q]\!](n-1)}{[\![\mathtt{stb}^5\cdot q]\!](n-1)} = \frac{\mathtt{sts}(n-1)\cdot\cdots\cdot\mathtt{sts}(n-4)\cdot\mathtt{swb}(n-5)}{\mathtt{stb}(n-1)\cdot\cdots\cdot\mathtt{stb}(n-5)} = O\left(\frac{1}{nP(n)}\right).$$

This proves the claim.

It remains to examine the case where λ_2 is constant. In this case, $\mathtt{sws} = 0$, so that

$$d(k,n) = \mathtt{stb}(n-1)\cdot\cdots\cdot\mathtt{stb}(k)\lambda_1(k).$$

We have

$$B(k,n) = \left\{\mathtt{sts}^e\cdot\mathtt{swb}\cdot\mathtt{stb}^{n-k-e} \mid e\in\{0,\dots,n-k\}\right\},$$

so that

$$b(k,n) = \lambda_2(k)\sum_{e=0}^{n-k}\left(\prod_{j=1}^{e}\mathtt{sts}(n-j)\right)\mathtt{swb}(n-e-1)\left(\prod_{j=e+1}^{n-k}\mathtt{stb}(n-j-1)\right).$$

It follows that

$$b(k,n)/d(k,n) = \frac{\lambda_2(k)}{\lambda_1(k)} \sum_{e=0}^{n-k} \frac{\left(\prod_{j=1}^{e} \mathtt{sts}(n-j)\right) \mathtt{swb}(n-e-1)}{\prod_{j=0}^{e} \mathtt{stb}(n-j-1)}.$$

Now, by Lemma 9 there exists a positive constant c such that $|\mathtt{sts}(n-j)| \leq c$, $|\mathtt{swb}(n-e-1)| \leq c/(n-e)$, and $|\mathtt{stb}(n-j-1)| \geq P(n)/c$. Thus:

$$\begin{aligned}
|b(k,n)/d(k,n)| &\leq \sum_{e=0}^{n-k} \frac{c^{2e+1}}{(n-e)P(n)\cdot P(n-1)\cdot\dots\cdot P(n-e)} \\
&\leq \frac{c}{nP(n-k)} \sum_{e=0}^{n-k} \frac{(c^2)^e}{(n-1)\cdot\dots\cdot(n-e)} \\
&\leq \frac{c}{nP(n-k)} \sum_{e=0}^{n-k} \frac{(c^2)^e}{e!} \\
&\leq \frac{c\exp(c^2)}{nP(n-k)} \\
&= O(1/nP(n)).
\end{aligned}$$

◀

Proof of Lemma 12. If $\mathtt{sws} = 0$ then $c(k,n) = 0$ for all k and n, so that the claim is trivial.

Let us hence assume that $\mathtt{sws} \neq 0$. Define a map $\mu\colon C(k,n) \to D(k,n)$ as follows: Let $w = p \cdot q \in C(k,n)$ with $|q| = 3$. If $p \in [\text{big} \to \text{big}]$ then let $\mu(w) = p \cdot \mathtt{stb}^3$. If $p \in [\text{big} \to \text{small}]$ then let $\mu(w) = p \cdot \mathtt{swb} \cdot \mathtt{stb}^2$. One easily verifies that $|[\![w]\!](n-1)/[\![\mu(w)]\!](n-1)| \in O(1/k^2P(k))$ with a constant that does not depend on n. It follows from Lemma 14, Lemma 9, and Proposition 13 that

$$|c(k,n)/d(k,n)| = O(1/k^2P(k)^2) \tag{11}$$

with a constant that does not depend on n. In particular, for all fixed k the sequence $(c(k,n)/d(k,n))_n$ is bounded.

Now, by (2) we have:

$$\begin{aligned}
\frac{c(k,n+1)}{d(k,n+1)} &= \frac{\mathtt{stb}(n)c(k,n) + \mathtt{sws}(n)a(k,n)}{\mathtt{stb}(n)d(k,n) + \mathtt{sws}(n)b(k,n)} \\
&= \frac{\mathtt{stb}(n)c(k,n)}{\mathtt{stb}(n)d(k,n) + \mathtt{sws}(n)b(k,n)} + \frac{\mathtt{sws}(n)a(k,n)}{\mathtt{stb}(n)d(k,n) + \mathtt{sws}(n)b(k,n)}.
\end{aligned}$$

Thus,

$$\begin{aligned}
&\left|\frac{c(k,n+1)}{d(k,n+1)} - \frac{c(k,n)}{d(k,n)}\right| \\
&\leq \frac{\mathtt{swb}(n)c(k,n)}{\mathtt{swb}(n)d(k,n)} \frac{\mathtt{sws}(n)b(k,n)}{\mathtt{stb}(n)d(k,n) + \mathtt{sws}(n)b(k,n)} + \frac{\mathtt{sws}(n)a(k,n)}{\mathtt{stb}(n)d(k,n)} \\
&= O(1)O\left(\tfrac{1}{nP(n)^2}\right) + O\left(\tfrac{1}{nP(n)^2}\right) \\
&= O\left(\tfrac{1}{nP(n)^2}\right).
\end{aligned}$$

It follows that the distance $\left|\frac{c(k,n+m)}{d(k,n+m)} - \frac{c(k,n)}{d(k,n)}\right|$ is majorised by the tail of a convergent series. The convergence of $\left(\frac{c(k,n)}{d(k,n)}\right)_n$ follows.

The asymptotics of $L(k)$ follow from (11). The computability of $L(k)$ to any given finite precision is obtained by observing that we can make all implicit constants in the above estimates into explicit ones, yielding explicit error estimates.

It remains to compute the sign of $L(k)$. The case where λ_2 is constant is trivial. For the other cases, note that essentially the same argument as in Lemma 14 shows that the sum $\sum_{w\in C(k,n)}[\![w]\!](n-1)$ is dominated by the terms with an even number of `sts` and an odd number of `sws`. The number of `swb` is even in all such terms, so that the sign of the sum $\sum_{w\in C(k,n)}[\![w]\!](n-1)$ for sufficiently large n is the sign of $\mathtt{sws}(k)$. Since $c(k,n) = \lambda_2(k)\sum_{w\in C(k,n)}[\![w]\!](n-1)$, the sign of $c(k,n)$ is the sign of $\lambda_2(k)\cdot\mathtt{sws}(k)$. Since $d(k,n)$ is positive for large n it follows that the sign of $L(k)$ is the sign of $\lambda_2(k)\cdot\mathtt{sws}(k)$. ◀

University of Haifa, Israel

Abstract

Estimating the length of the longest increasing subsequence (LIS) in an array is a problem of fundamental importance. Despite the significance of the LIS estimation problem and the amount of attention it has received, there are important aspects of the problem that are not yet fully understood. There are no better lower bounds for LIS estimation than the obvious bounds implied by testing monotonicity (for adaptive or nonadaptive algorithms). In this paper, we give the first nontrivial lower bound on the complexity of LIS estimation, and also provide novel algorithms that complement our lower bound.

Specifically, we show that for every $\epsilon \in (0, 1)$, every nonadaptive algorithm that outputs an estimate of the LIS length in an array of length n to within an additive error of ϵn has to make $\log^{\Omega(\log(1/\epsilon))} n$ queries. Next, we design nonadaptive LIS estimation algorithms whose complexity decreases as the number of distinct values, r, in the array decreases. We first present a simple algorithm that makes $\tilde{O}(r/\epsilon^3)$ queries and approximates the LIS length with an additive error bounded by ϵn. This algorithm has better complexity than the best previously known adaptive algorithm (Saks and Seshadhri; 2017) for the same problem when $r \ll \operatorname{poly}\log(n)$. We use our algorithm to construct a nonadaptive algorithm with query complexity $\tilde{O}(\sqrt{r} \cdot \operatorname{poly}(1/\lambda))$ that, when the LIS is of length at least λn, outputs a multiplicative $\Omega(\lambda)$-approximation to the LIS length. Our algorithm improves upon the state of the art nonadaptive LIS estimation algorithm (Rubinstein, Seddighin, Song, and Sun; 2019) in terms of the approximation guarantee.

Finally, we present a $O(\log n)$-query nonadaptive erasure-resilient tester for monotonicity. Our result implies that lower bounds on erasure-resilient testing of monotonicity does not give good lower bounds for LIS estimation. It also implies that nonadaptive tolerant testing is strictly harder than nonadaptive erasure-resilient testing for the natural property of monotonicity.

1 Introduction

Estimating the length of the longest increasing subsequence (LIS) in an array is a problem of fundamental importance. For arrays of length n, one can solve this problem exactly in time $O(n \log n)$ using dynamic programming [9] or patience sorting [2]. Approximating the length of the LIS has also been well-studied, and there are several sublinear-time

algorithms [15, 1, 19, 18] for this task. In the approximation task, for a real-valued array A of size n, the goal is to estimate the length of the LIS within an additive error (of ϵn) or multiplicative error. An additive ϵn-approximation algorithm for this problem can also be used to estimate, with the same approximation guarantee, the Hamming distance of A to the closest sorted array[1] (a.k.a. distance to monotonicity).

Early sublinear-time algorithms for LIS estimation [15, 1] provided multiplicative $(2+o(1))$-approximation for the distance to monotonicity, and thereby, additive $\frac{n}{2}$-approximation to the length of the LIS. Saks and Seshadhri [19] made a major improvement to the state of the art, and presented an algorithm that approximates the LIS length to within an additive error of ϵn for arbitrary $\epsilon \in (0,1)$. All these algorithms have query complexity polylogarithmic[2] in n for constant ϵ. Subsequently, Rubinstein, Seddighin, Song, and Sun [18] presented a nonadaptive algorithm that computes a multiplicative $\Omega(\lambda^3)$-approximation to the LIS length, with query complexity $\tilde{O}(\sqrt{n}\cdot\text{poly}(1/\lambda))$, where λ is the ratio of the LIS length to n. In a very recent work (independent and parallel to ours), Mitzenmacher and Seddighin [11] developed a sublinear algorithm for LIS estimation with query complexity $\tilde{O}(n^{1-\Omega(\epsilon)}\cdot\text{poly}(1/\lambda))$ that obtains an approximation ratio of $\Omega(\lambda^\epsilon)$ for arbitrary $\epsilon \in (0,1)$.

Despite the significance of the LIS estimation problem and the amount of attention it has received, there are important aspects of the problem that are not yet fully understood. There is no better lower bound on the query complexity of LIS estimation, for adaptive or nonadaptive algorithms, other than the obvious bound of $\Omega(\log n)$ implied by monotonicity testing [8]. Another issue is to investigate whether the input length n is the right parameter to express the complexity of LIS estimation algorithms. In other words, it is unknown whether there are other input parameters that capture the fine-grained complexity of LIS estimation by making use of the underlying combinatorics of the problem.

In this paper we address both these issues. We prove the first nontrivial lower bound on the query complexity of nonadaptive algorithms for additive error LIS estimation. We also design nonadaptive LIS estimation algorithms whose query complexity is parameterized in terms of the number of distinct values in the input array.

Lower Bound for LIS Estimation. We show that there is no nonadaptive algorithm that approximates the LIS length to arbitrary additive error and has query complexity polylogarithmic in n. Specifically, for arbitrary constant $\epsilon \in (0,1)$, every nonadaptive LIS estimation algorithm that has an additive error bounded by ϵn has to make $\log^{\Omega(\log(1/\epsilon))} n$ queries. Interestingly, our lower bound construction uses ideas from the lower bound [4] on the query complexity of 1-sided error nonadaptive testers for the property of $(k,\ldots,2,1)$-freeness. This is the first lower bound that improves upon the obvious lower bound of $\Omega(\log n)$.

One general approach for proving lower bounds on the complexity of LIS estimation was proposed by Dixit, Raskhodnikova, Thakurta, and Varma [6], who showed that lower bounds for erasure-resilient testing of monotonicity provides lower bounds for estimating the distance to monotonicity up to an additive error. We prove that this method cannot provide a nontrivial lower bound for LIS estimation, by showing a $O(\log n)$-query *nonadaptive* algorithm for erasure-resilient monotonicity testing.

---

[1] It is necessary and sufficient to modify the values that do not belong to an LIS to make the array sorted.

[2] The query complexity of the algorithm by Saks and Seshadhri [19] depends on the approximation parameter ϵ as $O((1/\epsilon)^{1/\epsilon})$ and hence is within aforementioned bound only if ϵ is constant. In particular, the query complexity ceases to be sublinear as as soon as ϵ is $O(1/\log(n))$.

Sublinear Algorithms for LIS Estimation. Our starting point here is to understand the dependence of the query complexity of LIS estimation on the range size of an input array. This is a major direction of study for the simpler problem of monotonicity testing, since the only tight lower bound [8] holds for exponential range. Recently, Pallavoor, Raskhodnikova, and Varma [14], and Belovs [3], gave efficient algorithms for monotonicity testing whose query complexity beats the above lower bound when range size is small. There were no explicit results on LIS estimation for limited range size before our work.[3] In this paper, we give efficient *nonadaptive* LIS estimation algorithms whose complexity is parameterized by r, the number of distinct values in the array, which is always at most the range size. Our algorithms improve upon the state of the art algorithms in both complexity and approximation guarantee when the range is small.

We first show a $\tilde{O}(r/\epsilon^3)$-query nonadaptive algorithm for LIS estimation, of additive error ϵn, for arbitrarily small ϵ. In particular, when the LIS length is a constant fraction of n, our algorithm can be used to get a multiplicative $(1 \pm \epsilon)$-approximation for the LIS length. We add that our algorithm is the only sublinear nonadaptive algorithm giving this approximation guarantee when $r = o(n)$. Furthermore, when $r = o(\log^k n)$ (for an appropriate power k), our algorithm outperforms the adaptive algorithm of Saks and Seshadhri [19], not only in terms of the dependence of query complexity on the input size n, but also in terms of its dependence on the approximation parameter ϵ. Hence, our algorithm bridges the gap between the known $\Omega(\text{poly} \log n)$-query algorithm for the general range and the $O(1)$-query algorithm for the Boolean range.

An additional main result of this paper is a $\tilde{O}(\sqrt{r})$-query nonadaptive algorithm that gives a multiplicative approximation to the LIS length even when the LIS is relatively small. Namely, the algorithm makes $\tilde{O}(\sqrt{r} \cdot \text{poly}(1/\lambda))$ queries and outputs a multiplicative $\Omega(\lambda)$-aproximation to the LIS length, where λ denotes the LIS length normalized by the input length. This is an improvement over the algorithm by Rubinstein, Seddighin, Song, and Sun [18], which makes $\tilde{O}(\sqrt{n} \cdot \text{poly}(1/\lambda))$ nonadaptive queries and outputs a multiplicative $\Omega(\lambda^3)$-approximation to the LIS length. Our algorithm improves upon [18] in terms of approximation guarantee (even in the general case of $r = n$) as well as query complexity (when $r \ll n$), and further, works for any value of r. Finally, the query complexity of our algorithm is always better than that of the recent LIS estimation algorithm by Mitzenmacher and Seddighin [11] that outputs a multiplicative $\Omega(\lambda^\epsilon)$-approximation to the LIS length for arbitrary $\epsilon \in (0, 1)$.[4]

Separating Distance Estimation from Erasure-Resilient Testing. As mentioned before, a general method for proving lower bounds on distance estimation (or tolerant testing [15]) is via proving lower bounds on erasure-resilient testing [6].

Our nonadaptive erasure-resilient tester for monotonicity with complexity $O(\log n)$ and our lower bound on the query complexity of nonadaptive algorithms for LIS estimation imply that nonadaptive tolerant testing is strictly harder than nonadaptive erasure-resilient testing for the natural property of monotonicity, thereby making progress towards solving an open question raised by Raskhodnikova, Ron-Zewi, and Varma [16].

[3] For the case of Boolean arrays, Berman, Raskhodnikova, and Yaroslavtsev [5] showed that one can approximate the LIS length to within an additive error of ϵn by making $O(1/\epsilon^2)$ queries.

[4] We point out that the LIS estimation algorithm of Mitzenmacher and Seddighin [11] uses the algorithm of Rubinstein et al. [18] as a subroutine. By using our algorithm instead, the query complexity of the algorithm of Mitzenmacher and Seddighin [11] can be improved.

1.1 Discussion of Results and Overview of Techniques

In this section, we state our results more formally, and provide an overview of the techniques used to prove them. We use ideas from [18], [12] and [4]. Given a real-valued array A of length n, an LIS in A is the longest nondecreasing sequence of values in A. In other words, the LIS is a largest cardinality set $\mathcal{L}$ of indices such that for $u, v \in \mathcal{L}$, we have $u < v$ if and only if $A[u] \leq A[v]$. We abuse notation and also use the term LIS to denote $|\mathcal{L}|$ when this is clear from the context. A real-valued array of length n can be equivalently viewed as a function from $[n]$ to the reals. Adopting this view, we use the term *monotone array* to refer to a sorted array. Throughout, we denote by r, the number of (or a guaranteed upper bound on) distinct values in the array. That is, $r = |R|$ for $R = \{A[i] : \ i \in [n]\}$. Thus, for the unrestricted case it is assumed that $r = n$.

1.1.1 Lower bound on the query complexity of nonadaptive LIS estimation algorithms

Our first result proves that there is no nonadaptive algorithm that approximates the LIS length in an array of length n to within an additive error of ϵn and has query complexity polylogarithmic in n, for arbitrary constant $\epsilon \in (0, 1)$.

▶ **Theorem 1.1.** *For every $\epsilon \in (0, 1)$, every nonadaptive algorithm that on an array A of length n, outputs an additive ϵn-approximation to the length of the LIS in A, has to make $\log^{\Omega(\log(1/\epsilon))} n$ queries.*

We note that this is the first lower bound on LIS estimation that is not directly implied by the lower bound for testing monotonicity [8].

To prove our lower bound, we construct two distributions with different LIS lengths such that every deterministic nonadaptive algorithm distinguishing the distributions with probability at least 2/3, has query complexity $\log^{\omega(1)}(n)$. More specifically, for every natural number h, we construct distributions $\mathcal{D}_0^{(h)}$ and $\mathcal{D}_1^{(h)}$ that are supported on inputs whose LIS lengths differ by $\exp(-h)$. We then prove that every deterministic nonadaptive algorithm that takes input from the union of the supports of $\mathcal{D}_0^{(h)}$ and $\mathcal{D}_1^{(h)}$, and aims to correctly identify the distribution from which the input is taken, either fails for most inputs or makes $\Omega(\log^h n)$ queries. Interestingly, our lower bound construction uses ideas from the lower bound of Ben-Eliezer, Canonne, Letzter, and Waingarten [4] on the query complexity of 1-sided error nonadaptive testers for the property of $(k, \ldots, 2, 1)$-freeness, where an array A of length n is $(k, \ldots, 2, 1)$-free if there are no k indices $i_1 < i_2 < \cdots < i_k$ such that $A[i_1] > A[i_2] > \cdots > A[i_k]$.

Using reductions from erasure-resilient testing

As mentioned before, a general method for proving lower bounds on distance estimation is via proving lower bounds on erasure-resilient testing [6].

▶ **Definition 1.2** (Erasure-resilient monotonicity tester). *Given $\epsilon, \alpha \in (0, 1)$ and a real-valued array A containing at most α-fraction of* erased *values*[5]*, the goal of an α-erasure-resilient ϵ-tester for monotonicity is to determine whether A can be completed to a monotone array or whether every completion of A has Hamming distance at least ϵn to monotonicity.*

[5] Erasures are made adversarially before the tester makes its queries and the tester is unaware of the location of the erasures. A tester that queries the value at an erased location is returned a special symbol $\perp$.

Dixit, Raskhodnikova, Thakurta and Varma [6] observed that the complexity of erasure-resilient (ER) testing a property, falls in between the complexity of standard testing the property and estimating the distance to that property (with additive error). Hence, a lower bound on the complexity of ER testing monotonicity implies the same lower bound for estimating the LIS length up to an additive error. The only previously known ER tester for monotonicity [6] is adaptive and has query complexity $O(\log(n)/\epsilon)$. Hence, a nontrivial lower bound for (adaptive) LIS estimation cannot be obtained this way.

We present a *nonadaptive* ER tester that makes $O(\log n)$ queries and works for all fraction of erasures. This makes the results on ER testing monotonicity tight, and also shows that one cannot obtain a lower bound for LIS estimation via ER testing.

▶ **Theorem 1.3.** *Let $\epsilon, \alpha \in (0,1)$ such that $\alpha + \epsilon < 1$. There exists a nonadaptive α-erasure-resilient ϵ-tester for monotonicity that makes $O\left(\frac{\log n}{\epsilon^2} + \frac{1}{\epsilon^3}\right)$ queries for n-length arrays.*

The ER testers designed by Dixit et al. [6] for various properties, are all either adaptive, or obtained by repeating a (standard) tester that makes independent and uniformly distributed queries. Our tester is different, and is in this sense, the first nontrivial nonadaptive ER tester for a natural property. Consider an array A of length n with at most α fraction of erasures, where $\alpha \in [0,1)$. Our tester samples an index $s \in [n]$ uniformly at random and does a randomized binary search for s on the array as if it were monotone. It queries the array values on these indices, and looks for violations to monotonicity on the search path to s. In case there are no erasures, this is a good strategy to detect a violation to monotonicity [7]. However, when values at a constant fraction of indices are erased, it could be the case that most of the values on the search path are erased. We show that a slightly modified version of this tester can be used for testing monotonicity. Specifically, our tester, in addition to querying the values along the binary search path, also queries the indices in a small constant-sized interval around the search point s. To analyze this modified tester, we rely on a combinatorial lemma by Newman, Rabinovich, Rajendraprasad, and Sohler [12]. A nonerased index $x \in [n]$ is γ-deserted for $\gamma \in (0,1)$ if there exists an interval $I \subseteq [n]$ such that $x \in I$ and at most γ fraction of the values in I are nonerased. Roughly speaking, the lemma implies that the fraction of γ-deserted indices in A is proportional to $\gamma \cdot \alpha$. Using this, we are able to argue that, with high probability, the index s that we sample as the search point is not γ-deserted (for an appropriate choice of γ) and that it forms a violation with enough other nonerased indices, so as to ensure a high probability of success.

1.1.2 Parameterized and nonadaptive algorithms for LIS estimation

We present efficient nonadaptive LIS estimation algorithms. The novelty is that we parameterize the complexity of LIS estimation algorithms in terms of the number of distinct values r in an array. We first show an LIS estimation algorithm with query complexity $\tilde{O}(r)$.

▶ **Theorem 1.4.** *There exists a nonadaptive algorithm that, given a real-valued array A of length n containing at most r distinct values, and a parameter $\epsilon \in (0,1)$, makes $\tilde{O}(r/\epsilon^3)$ queries and outputs, with probability at least $2/3$, an estimate for the LIS size that is accurate to within additive ϵn-error. Moreover, the queries of the algorithm are uniformly and independently distributed, and the algorithm runs in time $\tilde{O}(r/\epsilon^3)$.*

We mention that the approximation guarantee provided by the algorithm is quite strong and holds even for non-constant error parameter ϵ. It matches the approximation guarantee of the adaptive LIS estimation algorithm by Saks and Seshadhri [19], which makes polylog(n)

queries when $\epsilon = \theta(1)$. In particular, when the length of the LIS $\mathcal{L}$ is a constant fraction of n, our algorithm can be used to get a multiplicative $(1 \pm \epsilon)$-approximation for the LIS length. We add that our algorithm is the only nonadaptive sublinear algorithm giving this approximation guarantee as soon as $r = o(n)$. Furthermore, when $r = o(\log^k n)$ (for an appropriate power k), our algorithm performs much better than the algorithm of Saks and Seshadhri, not only in terms of the dependence of query complexity on the input size n, but also in terms of the dependence on the approximation parameter ϵ.

The high level idea of the algorithm is that it is enough to restrict attention to special subarrays that are *dense* and *nice*, as elaborated in the following. Let $\mathcal{L}$ be a fixed unknown LIS in the input array. A subarray is dense if a constant fraction of its indices belong to $\mathcal{L}$, and it is nice if the LIS takes at most one distinct value in the subarray. Informally, we divide the array into $O(r/\epsilon)$ subarrays. This will make most dense subarrays nice with respect to $\mathcal{L}$ (for an appropriate density parameter). We then sample $O(\log r)$ indices in each subarray to find the values that are "typical" in each subarray.

Our goal is to output as an estimate for $|\mathcal{L}|$, the size of $\mathcal{L}'$, which is the restriction of $\mathcal{L}$ to such typical values. This will naturally be an underestimate, but with a small additive error. To estimate the size of $\mathcal{L}'$, we consider all possible increasing sequences of the typical values, taking one value from each subarray. Since most subarrays are nice, the size of $\mathcal{L}'$ restricted to such a sequence of values is quite close to $|\mathcal{L}'|$. Finally, for a given nice subarray A_i, the largest subsequence in A_i that takes one given value v can be easily determined – this is just the distance to the array taking the value v everywhere.

Next, we use the above $\tilde{O}(r)$-query algorithm to obtain a nonadaptive LIS estimation algorithm with query complexity $\tilde{O}(\sqrt{r})$.

▶ **Theorem 1.5.** *There exists a nonadaptive algorithm that, given a real-valued array A of length n containing at most r distinct values and $|\mathrm{LIS}(A)| = \lambda \cdot n$, makes $\tilde{O}(\sqrt{r} \cdot \mathrm{poly}(1/\lambda))$ queries and outputs, with probability at least $2/3$, an estimate est such that $\Omega(\lambda \cdot |\mathrm{LIS}(A)|) \leq \mathsf{est} \leq O(|\mathrm{LIS}(A)|)$. Moreover, the algorithm runs in time $\tilde{O}(r \cdot \mathrm{poly}(1/\lambda))$.*

As mentioned before, this result is an improvement over a recent LIS estimation algorithm by Rubinstein, Seddighin, Song and Sun [18], in terms of the approximation guarantee. Additionally, the complexity of our algorithm improves as the number of distinct values in the input array decreases. Another advantage of our algorithm (also that of [18]) is that its query complexity is sublinear, even if λ is sub-constant.

Our $\tilde{O}(\sqrt{r})$-query nonadaptive algorithm is somewhat complicated. In the following, we present a high-level description of the algorithm. We denote the input array by A and use $\mathcal{L}$ to denote a fixed LIS in A. We visualize the array values as points in an $r \times n$ grid G_n. The vertical axis of G_n represents the range R of the array and is labeled with the at most r distinct array values in increasing order and the horizontal axis is labeled with the indices in $[n]$. We refer to an index-value pair in the grid as a point. The grid has n points, to which we do not have direct access. We use queries to the array to form some *approximate* picture of the location of points in this grid, and use it to estimate $|\mathcal{L}|$.

The main idea is to build, in $\tilde{O}(\sqrt{r})$ queries, a data structure that possesses enough information to compute an estimate est, which is a lower bound on $|\mathcal{L}|$ and is also a reasonably good approximation. Roughly speaking, the first step in building this data structure is the following. We divide the $r \times n$ grid G_n into y^* rows and x columns that partitions G_n into a $y^* \times x$ grid G' of boxes, where $y^* = \Theta(\sqrt{r})$ and $x = \Theta(\sqrt{r})$. Specifically, we divide the interval $[n]$ into x contiguous subarrays. For $i \in [x]$, let D_i denote the i-th subarray. Additionally, we divide the range R into y^* contiguous intervals of array values, where for $j \in [y^*]$, we use I_j to denote the j-th interval when the intervals are sorted in the nondecreasing order of values. The set of boxes in G' is then $\{(D_i, I_j) : \ i \in [x], j \in [y^*]\}$.

For simplicity, we assume that $r = n$ for the rest of the high-level description. The $y^* \times x$ grid of boxes G' induces a poset on the y^*x boxes, which is similar to the natural poset defined on G_n. Namely, for two boxes in G' (or for two points in G_n), we have $(D_i, I_j) \preceq (I_t, D_s)$ (or $(i, j) \leq (t, s)$) if $i \leq s$ and $j \leq t$. The points in $\mathcal{L}$ form a chain in the above poset in G_n. Conversely, each chain in the poset G_n forms an increasing subsequence in the array A. Further, the boxes in G' through which $\mathcal{L}$ passes also forms a chain in the poset in G'. On the other hand, every chain of boxes in the poset in G' induces a number of chains in the poset in G_n, but of possibly quite different lengths. Our strategy is to find a small collection of chains in the poset in G' that cover all boxes through which the fixed $\mathcal{L}$ passes, and then to estimate the length of an LIS in each of these chains of boxes.

Let $I \subseteq R$ be a subset of the range R of values and B be a subarray of A. The density of the box (B, I), denoted by $\mathsf{den}(B, I)$, is defined to be the fraction of indices in the subarray B whose values belong to the interval I. In other words, for each box $(D_i, I_j) \in G'$, its density $\mathsf{den}(D_i, I_j)$ is the fraction of indices in the subarray D_i whose values land in the interval I_j. For $\beta < 1$, a box (D_i, I_j) is said to be β-dense, if $\mathsf{den}(D_i, I_j) \geq \beta$. There can be at most $\frac{1}{\beta}$ boxes that are β-dense in any particular subarray D_i.

Suppose that we know (a good approximation of) the density of every box in G' (this is what we require from our data structure, and this will be achieved via sampling). Then, we may restrict our attention to the at most x/β dense boxes in G' and compute the LIS only in the corresponding part of G_n. This is obviously an underestimate of the size of $\mathcal{L}$, but one that can be afforded; deleting every box that is not β-dense from the chain of boxes that $\mathcal{L}$ passes through causes the deletion at most βn points from $\mathcal{L}$.

We note that the same global idea is also used in the algorithms of [18] and (implicitly) also of [19], but in a completely different setting (and grid sizes) which makes the first one weaker in term of approximation guarantees, and the second one necessarily adaptive.

Next, in order to further reduce the number of possible chains of boxes in which we need to compute LIS, we note that we can delete large antichains of boxes from G', while not decreasing the LIS size by much. For this, we first consider a finer partition of each dense box into dense cells of nearly equal densities, and then define a poset on the set of all dense cells in the whole array. We then remove large antichains from this latter poset and argue that the removal of dense cells participating in these antichains does not *hurt* the LIS too much. Finally, by using Dilworth's theorem, we are able to obtain a collection of a *constant* number of chains in G', that covers the restriction of $\mathcal{L}$ to the undeleted boxes.

The next idea is to estimate the LIS in each of the constantly many remaining chains. This results in a loss of a multiplicative constant factor in the LIS size estimation.

At this point, we have reduced the problem to the estimation of the LIS in a given fixed chain of β-dense boxes in G'. Such a chain can be partitioned into two chains, one that contains only strictly horizontal chains on disjoint subarrays, and the other that contains only strictly vertical chains on disjoint interval ranges (see Figure 3). We will estimate the LIS in each, losing possibly another multiplicative 2-factor, which we are prepared to accept.

The final idea is the following. For the vertical going chain, one can just sample a constant number of vertically going subchains, estimate the LIS length in each one of them, and use these estimates to estimate the LIS length in the vertical chain. By the Hoeffding bound, this will be a good approximation. When $r = n$, estimating the LIS in a single vertical going subchain is trivial; we just query all $n/x = \tilde{O}(\sqrt{n})$ points in the subarray D_i corresponding to that subchain. For smaller r, this is not possible, and what we do is to reduce to the algorithm implied in Theorem 1.4, using the fact that most vertically going chains span a small range (this later fact will have to be argued from the way the data structure is formed).

For horizontally going chains, we will need a bit more from our data structure. The partition G' of G_n will be such that every layer formed by $i \in [y^*]$ contains either a small fraction of points from $\mathcal{L}$, or it contains only one range value. This is the only place in which we actually make use of the fact that $y^* = \Omega(\sqrt{n})$, which lower bounds the query complexity of the algorithm. Having this guarantee on the grid G', it would have been enough to sample a constant number of horizontally going subchains, and estimate the LIS within. Further, by the guarantee above, each horizontal layer in G' contains only a small number of distinct values. This implies that we could again employ our algorithm of Theorem 1.4. However, this will make the whole algorithm adaptive (as one has to "locate" the horizontal segments). Instead, we show that we can concentrate on short (spanning a constant number of boxes) subchains, which will allow us to employ the algorithm given by Theorem 1.4 nonadaptively.

1.1.3 Separating erasure-resilient testing from tolerant testing

Tolerant testing is a generalization of property testing [17, 10] defined by Parnas, Ron and Rubinfeld [15]. Specifically, a $(\delta, \epsilon + \delta)$-tolerant tester of monotonicity distinguishes, with probability at least $2/3$, between the cases that the distance of A to monotonicity is less than δn and at least $(\epsilon + \delta)n$, where $\epsilon, \delta \in (0, 1)$.

It has been observed [15] that a tolerant tester for a property is equivalent to an algorithm for estimating the distance to that property with an additive error guarantee. Hence, the task of estimating the LIS up to an additive error is equivalent to tolerant monotonicity testing. This allows us to restate Theorem 1.1 in terms of tolerant testing as follows.

▶ **Theorem 1.6.** *For every $\epsilon \in (0, 1)$, there exists a constant $\delta \in (0, 1)$ such that every nonadaptive 2-sided error $(\delta, \delta + \epsilon)$-tolerant tester of monotonicity has query complexity $\log^{\Omega(\log(1/\epsilon))} n$.*

Theorem 1.6 and Theorem 1.3 together imply that for the property of monotonicity, nonadaptive tolerant testing is strictly harder than nonadaptive ER testing, and also significantly less efficient than adaptive tolerant testing. Our results make progress towards answering the open question raised by Raskhodnikova, Ron-Zewi, and Varma [16] on the existence of natural properties for which one can show a separation between tolerant testing and ER testing in terms of query complexity.

1.2 Organization

We set our notations in Section 2. The proof for an important special case of our lower bound on the query complexity of nonadaptive LIS estimation (Theorem 1.6) is presented in Section 3 and the proof in its full generality is deferred to the full version [13]. Our nonadaptive and parameterized algorithm for multiplicative error LIS estimation (Theorem 1.5) and its analysis are presented in Section 4. Our algorithm for additive error LIS estimation (Theorem 1.4), and our nonadaptive erasure-resilient monotonicity tester (Theorem 1.3) can both be found in the full version [13]. All omitted proofs can also be found in the full version [13].

2 Notations and Preliminaries

For a natural number n, we use $[n]$ to denote the set $\{1, 2, \ldots, n\}$. For a real-valued array A of length n, we use $A[i]$ to denote the i-th entry of A for $i \in [n]$. For $x \leq y \in [n]$ we denote by $[x, y]$ the set $\{x, x + 1, \ldots, y\}$. The array A is monotone if for every two indices $u, v \in [n]$

such that $u < v$, we have $A[u] \leq A[v]$. If A is not monotone, two indices $u, v \in [n]$ are said to violate monotonicity if $u < v$ and $A[u] > A[v]$. For $\epsilon \in (0, 1)$, we say that A is ϵ-far from monotone if the values on at least $\epsilon \cdot n$ indices need to be modified to get a monotone array. A is ϵ-close to monotone if there is a way to modify the values on fewer than $\epsilon \cdot n$ indices to get a monotone array. For a parameter $\alpha \in [0, 1)$, we say that A is α-erased, if at most α fraction of the array values evaluate to a special symbol $\perp$. An assignment of values to the erased points in an array is called a completion. An α-erased array is monotone if there exists a completion that is monotone; it is ϵ-far from monotone if every completion is ϵ-far from monotone. We assume that algorithms accesses an input array A via an oracle; that is when the algorithm makes a query $i \in [n]$, the oracle returns a special symbol $\perp$ if the array value at index i is erased, and $A[i]$ otherwise. An algorithm is *adaptive* if its queries depend on the answers to its previous queries, and is *nonadaptive* otherwise. A partially ordered set (poset) is a set $\mathcal{P}$ associated with a reflexive, transitive, antisymmetric order relation $\preceq$ on its elements. We denote the poset by $\langle \mathcal{P}, \preceq \rangle$. A chain in $\langle \mathcal{P}, \preceq \rangle$ of length k is a sequence of elements $x_1 \preceq x_2 \preceq \cdots \preceq x_k$. An antichain is a set $S \subseteq \mathcal{P}$ such that for $u, v \in S$ neither $u \preceq v$ nor $v \preceq u$.

3 Lower Bounds for Nonadaptive LIS Estimation

In this section, we prove our lower bounds (Theorem 1.1) on the query complexity of 2-sided error nonadaptive algorithms for estimating the distance of real-valued arrays of length n from monotonicity up to an additive error of $\epsilon \cdot n$ for some constant $\epsilon \in (0, 1)$. Equivalently, our lower bounds also hold for algorithms that $(\delta, \epsilon + \delta)$-tolerant test monotonicity for constants $\delta, \epsilon \in (0, 1)$. Interestingly, our lower bounds use ideas from the lower bound on the query complexity of 1-sided error nonadaptive testers for the property of $(k, \ldots, 2, 1)$-freeness [4], where an array A of length n is $(k, \ldots, 2, 1)$-free if there are no k indices $i_1 < i_2 < \cdots < i_k$ such that $A[i_1] > A[i_2] > \cdots > A[i_k]$.

An algorithm is said to be *comparison-based* if its decisions are based only on the ordering relation between the queried values, and not on the values themselves. The following Lemma 3.1, which follows from the work of Fischer [8], states that it is enough to restrict our attention to comparison-based algorithms.

▶ **Lemma 3.1** ([8]). *There is an optimal comparison-based algorithm for computing an additive ϵn-approximation to the LIS in real-valued arrays of length n for all constant $\epsilon \in (0, 1)$.*

Even though Fischer [8] proves the above statement in the context of testing monotonicity in the standard model, his proof also works for the case of tolerant testing monotonicity, and in turn for LIS estimation. In the rest of this section, we restrict our attention to comparison-based algorithms for LIS estimation.

3.1 An $\Omega(\log^2 n)$ Lower Bound

As a starting point, we prove an $\Omega(\log^2 n)$ lower bound. Throughout this section, we assume that n is of the form 2^{2^x} for some natural number x. We prove the lower bound using Yao's method. Specifically, we describe two distributions $\mathcal{D}_0$ and $\mathcal{D}_1$ over real-valued arrays of length n, with different distances to monotonicity (Lemma 3.2), and show that every deterministic nonadaptive comparison-based algorithm distinguishing these distributions with probability at least $2/3$, has to make $\Omega(\log^2 n)$ queries (Lemma 3.3).

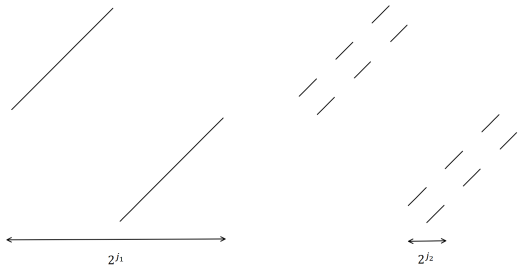

Figure 1 The relative values in j_1-blocks of $\mathcal{D}_0$ either look like the left or right diagrams above, with equal probability.

For ease in describing our distributions, we first define some notation. We think of the indices of an array of length n as the leaves of an ordered binary tree $\mathcal{T}$ of height $\log(n)+1$. We associate bit positions in the $\log n$-bit representation of the numbers in $[n]$ with the non-leaf nodes of $\mathcal{T}$. The root is associated with the most significant bit (or the bit position $\log n$). Every node at distance $i \in [\log(n)-1]$ from the root is associated with bit position $\log(n)-i$. The bit position associated with a node is also referred to as its *level* (and the level of the root is $\log n$). The edges connecting a node with its left and right children are labeled 0 and 1, respectively. Clearly, the string obtained by concatenating all the edge labels on a root-to-leaf path in $\mathcal{T}$ gives the binary representation of the index corresponding to the leaf. For two indices $x, y \in [n]$ (which are, by definition, the leaves in $\mathcal{T}$), we use $\mathsf{LCA}(x,y)$ to denote the lowest common ancestor of x and y in $\mathcal{T}$. For $j \in [\log n]$ there are obviously $n/2^j$ subtrees of $\mathcal{T}$, each rooted at level j. In a left to right ordering, these $n/2^j$ subtrees partition $[n]$ into blocks of size 2^j. The "the ℓ-th j-block" is the ℓ-th block from left with size 2^j.

The distributions $\mathcal{D}_0$ and $\mathcal{D}_1$

We first describe the steps that are common to constructing the distributions $\mathcal{D}_0$ and $\mathcal{D}_1$. Sample numbers $j_1, j_2 \in [\log n]$ such that $j_1 < \log(n) - 14$, and $j_2 < j_1 - 14$. We refer to the numbers j_1, j_2 as the *scales* of the distributions.

We start with the monotone array A in which $A[u] = u$ for all $u \in [n]$. Swap the array values between the left and right halves of every j_1-block. See the left part of Figure 1 to see how the relative values in each j_1-block of the array will look like at this point. For $\ell \in [n/2^{j_1}]$, let B_ℓ denote the ℓ-th j_1-block.

- **Distribution** $\mathcal{D}_0$: Independently for each $\ell \in [n/2^{j_1}]$:
  1. with probability $\frac{1}{2}$, for each j_2-block inside B_ℓ, swap the array values between the left and right halves of that j_2-block.
- **Distribution** $\mathcal{D}_1$: Independently for each $\ell \in [n/2^{j_1}]$:
  1. with probability $\frac{1}{2}$, for each j_2-block inside the left half of B_ℓ, swap the array values between the left and right halves of that j_2-block,
  2. with the remaining probability $\frac{1}{2}$, for each j_2-block inside the right half of B_ℓ, swap the array values between the left and right halves of that j_2-block.

The relative values taken by the array A on indices in an arbitrary j_1-block in distributions $\mathcal{D}_0$ and $\mathcal{D}_1$ can be visualized as in Figures 1 and 2. We note that in both $\mathcal{D}_0, \mathcal{D}_1$, all values in the ℓ-th j_1-block are smaller than the values in the $(\ell+1)$-th j_1-block for all $\ell \in [(n/2^{j_1})-1]$.

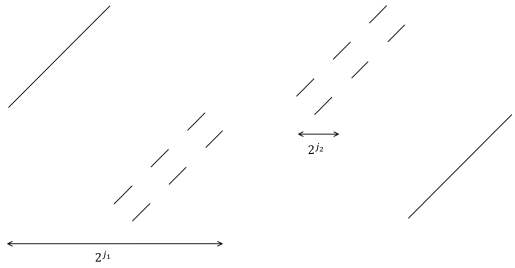

Figure 2 The relative values in j_1-blocks of $\mathcal{D}_1$ either look like the left or right diagrams above, with equal probability.

▶ **Lemma 3.2.** *The distance to monotonicity of every array sampled from $\mathcal{D}_0$ is, with probability $1 - \delta/2$, within $\frac{5}{8} \pm \delta$, where $\delta \leq \frac{1}{2^6}$. The distance to monotonicity of every array sampled from $\mathcal{D}_1$ is equal to $1/2$.*

Proof. Consider an array A sampled from one of the distributions. Let $j_1 > j_2$ be the scales used. First, observe that there are no violations to monotonicity across j_1-blocks. Therefore, it is enough to focus on repairing individual j_1-blocks and making them monotone (without inducing new violations). Consider a j_1-block B_ℓ for $\ell \in [n/2^{j_1}]$.

Assume that A is constructed from $\mathcal{D}_0$, and that B_ℓ is such that the values in the left and right halves of every j_2-block in B_ℓ are swapped (happens with probability $\frac{1}{2}$ for that block). Then we need to modify the values of at least $3/4$ fraction of indices in B_ℓ to make it monotone, since B_ℓ contains an exact cover by disjoint decreasing subsequences, each of size 4. Further, it is easy to see that by correcting a $3/4$ fraction of indices we can make B_ℓ monotone. In case swapping of values is done for none of the j_2-blocks in B_ℓ (happens with probability $\frac{1}{2}$), then we can repair B_ℓ if and only if we modify the values on half the indices in B_ℓ. Therefore, the expected distance to monotonicity of each block B_ℓ, and thereby, of A is equal to $5/8$. Note that the specific values of the scales did not matter in the above.

Let $\delta = 1/2^6$. We now show that the distance of A from monotonicity is $\frac{5}{8} \pm \delta$, with high probability. For a block $B_\ell, \ell \in [n/2^{j_1}]$, let $\mathsf{dist}(B_\ell)$ denote the distance of the block from monotonicity, normalized by the block length 2^{j_1}. We can see that the random variable $(\sum_\ell \mathsf{dist}(B_\ell))/(n/2^{j_1})$ corresponds to the normalized Hamming distance of A from monotonicity. By Hoeffding's bound, we have, $\Pr\left[\left|\frac{\sum_\ell \mathsf{dist}(B_\ell)}{n/2^{j_1}} - \frac{5}{8}\right| > \frac{1}{2^6}\right] \leq \frac{2}{\exp(8)} \leq \frac{1}{2^7} = \frac{\delta}{2}$.

Assume now that A is constructed from $\mathcal{D}_1$. For $\ell \in [n/2^{j_1}]$, if the swap of values happens within every j_2-block in the left half of B_ℓ, then we can repair B_ℓ by setting every value in the left half of that block to the smallest value in the right half of the same block. An analogous repair can be done if the swap happens in the right hand side of the block. In both cases, we only change values of at most half the number of indices in each block. The reader can easily convince themselves that at least half the values per block need to be changed to make a j_1-block monotone, which concludes the proof for the given scales. As before, the argument is independent of the choice of the scales. ◀

▶ **Lemma 3.3.** *Every comparison-based nonadaptive deterministic algorithm that, with probability at least $2/3$, distinguishes the distributions $\mathcal{D}_0$ and $\mathcal{D}_1$ has to make $\Omega(\log^2 n)$ queries.*

Proof. Consider an arbitrary deterministic comparison-based nonadaptive algorithm T that makes $o(\log^2 n)$ queries and aims to distinguish $\mathcal{D}_0$ and $\mathcal{D}_1$. Let $Q \subseteq [n]$ denote the set of queries that T makes.

Consider an array A sampled according to one of the distributions. Recall that $\mathcal{T}$ denotes an ordered binary tree whose leaves are the indices of A. Let $j_1, j_2 \in [\log n]$ such that $j_2 < j_1$ denote the scales used while constructing A. Let E denote the (bad) event that Q contains four indices $w < x < y < z \in [n]$ such that for some $\ell \in [n/2^{j_1}]$, (1) Each of $\{w, x, y, z\}$ belongs to the same ℓ-th j_1-block, (2) $\mathsf{LCA}(w, x)$ and $\mathsf{LCA}(y, z)$ are both nodes in $\mathcal{T}$ at level j_2, and (3) $\mathsf{LCA}(x, y)$ is at level j_1. By an argument of Ben-Eliezer, Canonne, Letzter, and Waingarten [4], the probability, over the choice of the scales j_1, j_2, of the event E is at most $1/3$. In the rest of the proof, we fix the scales (j_1, j_2) for which E does not happen.

Let $x, y \in Q$ be such that $\mathsf{LCA}(x, y)$ is at level j_2 in $\mathcal{T}$. In the rest of the proof, for simplicity, we refer to such queries as being j_2-*cousins*. Let B be a j_1-block, and let $Q_L(B)$ be the queries in Q that are in the left half of B, and $Q_R(B)$ the queries in Q that are in the right half of B. By our conditioning, for each j_1-block B, either all j_2-cousins in B belong to $Q_L(B)$ or to $Q_R(B)$ but not both. Consider the half of B that does not contain any j_2-cousins. In the algorithm's view, the array values in that half are increasing, whether A is sampled from $\mathcal{D}_0$ or $\mathcal{D}_1$.

Assume that A is sampled from $\mathcal{D}_0$. We show that there is a way to sample an array A' from $\mathcal{D}_1$ such that the algorithm's view on A and A' are identical. The scales of A' have to be identical to those of A. We only need to specify how swapping of values is done inside the j_1-blocks, as part of constructing A'.

Note that we only need to consider the j_1-blocks in which at least two queries fall. Consider such a block B, and assume that $Q_R(B)$ contains no j_2-cousins. Consider the case that swapping of values was done within every j_2-block inside the block B while constructing A. Then, in A', we swap the values only within the j_2-blocks inside the left half of B. In the other case that no swapping of values (within j_2-blocks) was done while constructing A, we swap the values only within the j_2-blocks inside the right half of B. It is easy to see that the relative values within block B in the array A' are consistent with that of an array sampled from $\mathcal{D}_1$. One can make similar arguments about coupling the arrays A and A' on blocks B such that the only occurrences of indices $x, y \in Q \cap B$ that are j_2-cousins are in the right half of B.

We conclude that for any scales j_1, j_2 for which E does not happen, the view of the algorithm making queries Q is identical on A' and A. Hence the algorithm cannot distinguish between the case that the array is sampled from $\mathcal{D}_0$ or from $\mathcal{D}_1$ for such scales. As this is true for any scales for which E does not happen, this concludes the proof.

Observe that the only place in the analysis where we made use of the bound on the number of queries is in arguing that the event E happens with low probability. ◀

3.2 A $\log^{\omega(1)} n$ Lower Bound

Next, we strengthen the $\Omega(\log^2 n)$ lower bound and prove Theorem 1.1. We make use of the idea of Ben-Eliezer et al. [4] for lower bounding query complexity of nonadaptive detection of larger forbidden order patterns. The idea is to use more than just two scales. This, in turn, makes the difference between the distances of arrays sampled from the two distributions smaller, which is why we only get a $\log^{\omega(1)} n$ lower bound.

Let $h \geq 2$ be an integer parameter. We describe the two distributions $\mathcal{D}_0^{(h)}$ and $\mathcal{D}_1^{(h)}$ on real-valued arrays, such that no comparison-based deterministic nonadaptive algorithm that makes $o(\log^h n)$ queries can distinguish between the distributions with high probability. Further, the distance to monotonicity of each array sampled from $\mathcal{D}_0^{(h)}$ will be significantly different than that of arrays sampled from $\mathcal{D}_1^{(h)}$.

The distributions are defined recursively, where, for the base case $h = 2$, let $\mathcal{D}_0^{(2)}$ and $\mathcal{D}_1^{(2)}$ be equal to $\mathcal{D}_0$ and $\mathcal{D}_1$ defined with scales j_1, j_2 as in Section 3.1, respectively. The details of the distributions and the proof of lower bound for the general case is much more technical and it is deferred to the full version [13].

4 Parameterized and Nonadaptive Algorithm for LIS Estimation

Our final goal in this paper is to present a sublinear algorithm that, for an array of length n containing at most r distinct values, approximates the LIS length within a bounded multiplicative error (Theorem 1.5). Our algorithm is described in the following subsections, and it uses as a subroutine, the algorithm guaranteed by Theorem 1.4 that approximates the LIS length within a bounded additive error. The description and analysis of the latter algorithm can be found in the full version of the paper [13].

4.1 $\tilde{O}(\sqrt{r})$-Query Nonadaptive Algorithm

Let $\mathcal{L}$ denote the set of points in an arbitrary and fixed LIS in the input array A. For simplicity of the presentation, we assume that our algorithm knows a lower bound λn on $|\mathcal{L}|$. Disregarding this assumption, the algorithm will output, with high probability, a lower bound estimate of the size of an increasing sequence in A. If λn is indeed a bound as assumed, it will be guaranteed that the estimate is within the multiplicative error that is stated. Hence λ can be checked by running the algorithm, in parallel, for a geometrically decreasing sequence of λ's. The reader may think of $\lambda < 1$ as a small constant (although the algorithm works for $\lambda = o(1)$ as well).

Throughout this section, we visualize the array values as points in an $r \times n$ grid G_n. The vertical axis of G_n represents the range R of the array and is labeled with the at most r distinct array values in increasing order and the horizontal axis is labeled with the indices in $[n]$. We refer to an index-value pair in the grid as a point. The grid has n points, to which we do not have direct access.

We divide the $r \times n$ grid G_n into y^* rows and x columns that partitions G_n into a $y^* \times x$ grid G' of boxes, where $y^* = \Theta(\sqrt{r})$ and $x = \Theta(\sqrt{r})$. Specifically, we divide the interval $[n]$ into x contiguous subintervals. For $i \in [x]$, let D_i denote the subarray induced by the indices in the i-th subinterval. Additionally, we divide the range R into y^* contiguous intervals of array values, where for $j \in [y^*]$, we use I_j to denote the j-th interval when the intervals are sorted in the nondecreasing order of values. The set of boxes in G' is then $\{(D_i, I_j) : \ i \in [x], j \in [y^*]\}$.

The $y^* \times x$ grid of boxes G' induces a poset $\langle \mathcal{P}, \preceq \rangle$ on the $y^* x$ boxes, which is similar to the natural poset defined on G_n. Namely, for two boxes in G' (or for two points in G_n), we have $(D_i, I_j) \preceq (D_s, I_t)$ (or $(i, j) \leq (s, t)$) if $i \leq s$ and $j \leq t$. The points in $\mathcal{L}$ form a chain in the above poset in G_n. Further, each chain in the poset in G_n forms an increasing subsequence in the array A. The boxes in G' through which $\mathcal{L}$ passes also forms a chain in the poset in G'. Every chain of boxes in the poset in G' induces a number of chains in the poset in G_n, but of possibly quite different lengths.

▶ **Definition 4.1** (Density of a box). *Let $I \subseteq R$ be a subset of the range R of values and B be a subarray of A. The density of the box (B, I), denoted by $\mathsf{den}(B, I)$, is defined to be the fraction of indices in the subarray B whose values belong to the interval I.*

In other words, for each box $(D_i, I_j) \in G'$, its density $\mathsf{den}(D_i, I_j)$ is the fraction of points in the subarray D_i that land in the box (D_i, I_j). For $\beta < 1$ (that the reader can think of as a small constant), a box (D_i, I_j) is said to be β-dense, if $\mathsf{den}(D_i, I_j) \geq \beta$.

4.1.1 Forming the grid G' of boxes

Our goal in this section is to describe a procedure that determines the grid G' of boxes. Specifically, as we do not know the range R and only know an upper bound r on its size $|R|$, we start by forming an approximation of R and an approximation of the densities of subinterval ranges in R in the array A. To do this, we first partition R into $\tilde{O}(\sqrt{r})$ sub-ranges called *layers*. For the sake of generality, we describe the procedure for a subarray B of A.

More generally, given a subarray B, and a parameter y, our goal is to partition the range R into roughly y intervals of roughly equal densities, where the densities are with respect to B. We note that although the size r of the range R might be relatively large, it is possible that some values appear in B much more frequently than others. One of our goals is to identify such values and well-approximate their densities. We now define a "nice" partition as follows. Given y and B, a nice y-partition of the values in B is a partition $R = \cup_{i=1}^{y^*} I_i$, if for each $i \in [y^*]$, either I_i contains only one value v_i and $\mathsf{den}(B, I_i) \geq \frac{1}{2y}$, or $\mathsf{den}(B, I_i) \leq \frac{2}{y}$. In the former case, we call I_i a single-valued layer. In the latter, we say that I_i is a multi-valued layer (although in an extreme case it might contain only one value). We also require $y^* \leq 2y$.

Next, we describe our procedure $\textsc{Layering}(B, y, t)$ that forms a y-nice partition of a subarray B, along with a good approximation of the densities of the single-valued layers. This is quite technical, although standard. We advise the reader to avoid it on first reading, and assume that, when needed, we have a nice partition along with a good approximation to the densities of layers.

Algorithm 1 Layering.

procedure $\textsc{Layering}(B, y, t)$

Goal: To divide the set of array values in the subarray B into roughly y contiguous intervals of roughly equal densities. The parameter t is used to control the success probability.

Sample a set of $\ell = t \cdot y \log y$ indices S from B, uniformly at random and independently. ▷ Note that a value v is expected to appear in proportion to its density in the array. Hence the collection of values obtained is a multiset of size ℓ.

We sort the multiset of values $V = \{B[p] : p \in S\}$ to form a strictly increasing sequence $\mathsf{seq} = (v'_1 < \ldots < v'_q)$, where with each $i \in [q]$ we associate a weight w_i that equals the multiplicity of v'_i in the multiset V of values. ▷ Note that $\sum_{i \in [q]} w_i = \ell$.

We now partition the sequence $W = (w_1, \ldots, w_q)$ into maximal disjoint contiguous subsequences $W_1, \ldots W_{y^*}$ such that for each $j \in [y^*]$, either $\sum_{w \in W_j} w < 2t \log y$, or W_j contains only one member w for which $w > t \log y$.

Note that this can be done greedily as follows. If $w_1 > t \log y$ then W_1 will contain only w_1, otherwise W_1 will contain the maximal subsequence $(w_1, \ldots, w_i)$ whose sum is at most $2t \log y$. We then delete the members of W_1 from W and repeat the process. For $i \in [y^*]$, let $w(W_i)$ denote the total weight in W_i.

Correspondingly, we obtain a partition of the sequence seq of sampled values into at most y^* subsequences $\{S_i\}_{i \in [y^*]}$. Some subsequences contain only one value of weight at least $t \log y$ and are called *single-valued*. The remaining subsequences are called *multi-valued*.

For a subsequence S_i, let $\alpha_i = \min(S_i)$ and $\beta_i = \max(S_i)$. Let $\beta_0 = -\infty$. Note that $\alpha_i \leq \beta_i$ and $\beta_{i-1} < \alpha_i$ for all $i \in [y^*]$.

For $i \in [y^*]$, we associate with the subsequence S_i, an interval (layer) $I_i \subseteq R$, where $I_i = (\beta_{i-1}, \beta_i]$, and an approximate density $\widetilde{\mathsf{den}}(B, I_i) = w(W_i)/\ell$.

end procedure

Let $\{I_i\}_{i=1}^{y^*}$ be the set of layers that are created by a call to LAYERING(B, y, t). Recall that $w(W_i) \geq t \log y$ if I_i is a single-valued layer and $w(W_i) < 2t \log y$ if I_i is multi-valued, where W_i denotes the sum of multiplicities of the values in the sample S_i.

For a multi-valued layer I_i, let E_i denote the event that $\mathsf{den}(B, I_i) < \frac{4}{y}$. For a single-valued layer I_i such that $\mathsf{den}(B, I_i) \geq \frac{1}{2y}$, let E_i denote the event that $\frac{\mathsf{den}(B,I_i)}{2} \leq \widetilde{\mathsf{den}}(B, I_i) \leq \frac{3}{2}\mathsf{den}(B, I_i)$. For a single-valued layer I_i such that $\mathsf{den}(B, I_i) < \frac{1}{2y}$, let E_i be the event that $\widetilde{\mathsf{den}}(B, I_i) \leq \frac{3}{2}\mathsf{den}(B, I_i)$. Let $E = \bigcap_{i=1}^{y^*} E_i$. The following claim asserts that the layering above well-represents the structure of the range w.r.t. B.

▷ Claim 4.2. LAYERING(B, y, t) returns a collection of intervals $\{I_i\}_{i=1}^{y^*}$ such that, $y^* \leq 2y$, and $\Pr(E) = 1 - \exp(\Omega(-t))$.

We now define the grid G' of boxes as follows. We first use the procedure LAYERING on the original array, $B = A$, with parameters $y = \frac{\sqrt{r}}{\epsilon}$ and $t = O(1)$, where the value of t is set to ensure a success probability of 99/100 in Claim 4.2. This defines the set of y^* layers that partitions R as $R = \bigcup_{i \in y^*} I_i$. Next we partition $[n]$ into $x = \epsilon \cdot \sqrt{r}$ contiguous intervals $D_1, \ldots D_x$ each of size n/x, which defines G' as the grid of boxes $\{(D_i, I_j) : (j, i) \in [y^*] \times [x]\}$ in the $r \times n$ grid, some of which may be empty, while some may contain many points.

We set $\beta = \epsilon^3 \lambda$. Next, our goal is to find all the β-dense boxes in G' by making $\tilde{O}(\sqrt{r})$ queries and then restrict our attention only to these boxes. As described in the high level overview Introduction, doing this will not make the LIS in this restricted array too short. This is made formal in the following claim.

▷ Claim 4.3. The number of points in $\mathcal{L}$ that belong to boxes that are not β-dense is at most $\beta n \cdot (1 + 2y/x)$.

We do not know which boxes are β-dense. We approximate this by sampling, and this is formally presented below as algorithm GRIDDING. The algorithm assumes the partition of $[n]$ and of the range R as above. As before, $t = O(1)$ in this procedure can be set appropriately to ensure a large constant success probability.

Algorithm 2 GRIDDING.

```
1: procedure GRIDDING(A, {I_j}_{j∈[y*]}, {D_i}_{i∈[x]}, β)
2:     for i ∈ [x] do
3:         Sample ℓ = t · (1/β) · log(x/β) indices from D_i uniformly and independently at random.
4:         for j ∈ [y*] do
5:             Label box (D_i, I_j) as dense if and only if the values on at least (3/4)βℓ points
   from the sample fall into the box; namely, if for at least (3/4)βℓ indices sampled from D_i,
   the values are in I_j.
6:         end for
7:     end for
8: end procedure
```

Let D be the event that all β-dense boxes are tagged as *dense* by the procedure, and that every box that is not $\beta/8$-dense is not tagged as dense.

▷ Claim 4.4. $\Pr[D] \geq 1 - \exp(-\Omega(t))$.

From now on, we assume that we have the grid G' for which the events E and D hold. This is the initialization of our data structure as described in the Introduction. We now refine the data structure as follows.

A β-dense box may have density that is anything in $[\beta, 1]$. For a better approximation guarantee, we need to identify the regions with density nearly equal to β. To achieve this, we perform the following finer layering using the procedure LAYERING on each dense box.

Finer layering of each dense box. For each $i \in [x]$, call LAYERING on the array D_i with $y = 1/\beta$ and $t' = \Theta(\log(x/\beta))$. Here, we do not collapse the single-valued intervals into a single layer, but rather just leave them as different layers of the same value and density β.

Let $\{I'_k\}_{k \in [y_i^*]}$ be the set of intervals returned by the procedure. We restrict our attention to the boxes (D_i, I'_k) contained in some β-dense box (D_i, I_j), and call them β-dense cells.

Fix D_i. The number of β-dense cells in D_i is at most $2y = 2/\beta$. Claim 4.2 asserts that, with probability $1 - \exp(-\Omega(t')) = 1 - \frac{\beta}{100x}$, each D_i is layered so that each β-dense cell has true density at most $3\beta/2$ and at least $\beta/8$. Additionally, the portion of a β-dense box that is not covered by β-dense cells has true density smaller than β. This implies that for all $i \in [x]$ this event happens with probability at least $99/100$. We denote this event by F, and assume in what follows that F happens.

4.1.2 Chain reduction

In this section, we define a poset over dense cells and argue that in order to well-approximate the LIS, it is enough to restrict our attention to LIS's in a few chains in this poset.

Since dense cells, by definition, are contained inside dense boxes, we denote dense cells using triplets (D_i, I_j, k), where this triplet denotes the k-th dense cell inside the dense box $(D_i, I_j), i \in [\epsilon\sqrt{r}], j \in [\sqrt{r}/\epsilon]$.

Recall that there is a poset $\langle \mathcal{P}, \preceq \rangle$ on the dense boxes. Now, we define another poset $\langle \mathcal{P}^\star, \preceq^\star \rangle$ whose elements are the (at most) $2x/\beta$ dense cells. The order relation $\preceq^\star$ is defined by $(D_i, I_j, k) \preceq^\star (D_{i'}, I_{j'}, k')$ if and only if either $(D_i, I_j) \neq (D_{i'}, I_{j'})$ and $(D_i, I_j) \preceq (D_{i'}, I_{j'})$, or if $j' = j, i' = i$ and $k \leq k'$. Note that the poset $\preceq^\star$ is not consistent with a grid poset, it rather inherits the order from $\mathcal{P}$ for cells in different boxes.

Let $\mathcal{L}_1$ be the LIS $\mathcal{L}$ restricted to dense boxes, let $C(\mathcal{L}_1, \mathcal{P})$ be the set of dense boxes in which $\mathcal{L}_1$ passes, and let $C(\mathcal{L}_1, \mathcal{P}^\star)$ be the set of dense cells in which $\mathcal{L}_1$ passes. We observe that $C(\mathcal{L}_1, \mathcal{P})$ and $C(\mathcal{L}_1, \mathcal{P}^\star)$ are chains in the corresponding posets.

Our goal now is to show that there are a small number of chains in $\mathcal{P}^\star$ that cover $C(\mathcal{L}_1, \mathcal{P}^\star)$. This is done as follows.

- For parameter $\tau = 5/\lambda$, repeatedly remove antichains of size larger than τ from $\mathcal{P}^\star$. Here, by removing, we mean the deletion of the points in the cells of the corresponding antichain from the array[6].

Let the resulting poset be denoted by $\mathcal{P}^{\star\star}$. The maximum antichain in this poset has size at most τ, and Dilworth's theorem implies that there is a decomposition of $\mathcal{P}^{\star\star}$ into at most τ chains. These chains, being made of dense cells, is naturally extended to at most τ (possibly intersecting) chains of the poset $\mathcal{P}$. Let these chains be $C_1, \ldots, C_\tau$. We bound the "loss" to the LIS incurred by chain reduction in Claim 4.5.

▷ Claim 4.5. Conditioned on the events $E \cup D \cup F$, the number of points in $\mathcal{L}_1$ that does not belong to $\cup_{i=1}^{\tau} C_i$ is at most $4n/\tau$.

[6] For a single-valued cell $a = (D_i, I_j, k)$ taking the value v, there might be other points with value v in the dense box containing a. When we remove a from $\mathcal{P}^\star$, we "mentally" remove some $\beta n/x$ points of value v from the box (D_i, I_j). This is not algorithmically done, but will just be used in the analysis.

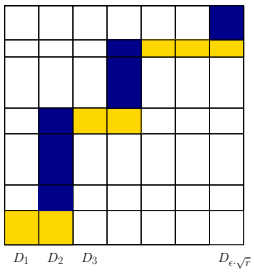

Figure 3 A staircase like chain, and its decomposition into two chains, one that contains only horizontal blocks and one that contains only vertical blocks. In each of the chains, no two blocks share a layer or a subarray.

Let $\mathcal{L}_2$ denote the LIS $\mathcal{L}_1$ after chain reduction. The following claim is straightforward.

▷ Claim 4.6. There exists $i \in [\tau]$ such that $|\text{LIS}(C_i)| \geq \frac{|\mathcal{L}_2|}{\tau}$.

We point out that no query is made at this stage.

4.1.3 Estimating the LIS restricted to poset chains

Let $\mathcal{P}'$ denote the poset obtained from $\mathcal{P}$ after removing the large antichains in $\mathcal{P}^\star$. At this point, we have covered the poset $\mathcal{P}'$ using at most τ chains $C_1, \ldots, C_\tau$. This reduces the LIS estimation to estimating the LIS in one of these chains.

In what follows, we fix such one chain C, and denote by $\mathcal{L}(C)$, the LIS in the array restricted to C. The chain C is composed of a sequence of horizontal and vertical blocks, arranged in a staircase manner (see Figure 3), where a horizontal block is a sequence of contiguous boxes in the chain from the same layer, and a vertical block is a sequence of contiguous dense boxes in the chain that belong to the same subarray.

Let H_1, H_2 be two maximal horizontal blocks in C. Blocks H_1, H_2 have a subarray D_i in common if there are boxes $(D_i, I_j) \in H_1$ and $(D_i, I_s) \in H_2$. In particular, there is a vertical block between them. Two horizontal chains have at most one subarray in common, and if this happens, then the common subarray D_i defines the rightmost box of the "lower" horizontal chain (the horizontal chain in the lower layer) and the leftmost box of the "upper" horizontal chain. We conclude that if we arrange the horizontal blocks from bottom to top as $H_1, \ldots H_s$, and remove the rightmost box from H_i if it has a common subarray with H_{i+1}, we get a sequence of horizontal blocks in which no two share a subarray. We use C_H to denote this subchain of C. Notice that $C_V = C \setminus C_H$ is a chain that contains only vertical blocks, where no two share a layer (see Figure 3, as how the whole chain C decomposes into a chain of horizontal blocks and a chain of vertical blocks).

To estimate the size of $\mathcal{L}(C)$, we estimate the LIS within C_H and C_V separately, and use the larger for the size estimate for $\mathcal{L}(C)$. In the following, we denote $\mathcal{L}_H$ and $\mathcal{L}_V$ for $\text{LIS}(C_H)$ and $\text{LIS}(C_V)$, respectively. The main advantage of this decomposition of C into C_H and C_V is given by the following observation.

▶ **Observation 4.7.** *For any chain C, we have $|\mathcal{L}_H| = \sum_{B \in C_H} |LIS(B)|$, where the sum is over the horizontal blocks B in C_H. A similar statement holds for C_V in which case, horizontal blocks are replaced with vertical blocks.*

The observation leads to an immediate adaptive way to approximate the lengths of $\mathcal{L}_H$ and $\mathcal{L}_V$. We sample a constant number of blocks from the chain, estimate the LIS in each block, and normalize to estimate the LIS in the entire chain. By the Hoeffding bound, we can

see that the estimate is accurate enough with high probability. The adaptivity is needed to locate each block, and to estimate the LIS within a block (horizontal and vertical), which we did not yet specify how to do. To avoid adaptivity, we will rely on the fact that if $\mathcal{L}_V$ is large, then it must contain a large number of small vertical blocks. Thus, sampling uniformly in $[n]$ will hit such blocks frequently enough to facilitate the Hoeffding bound above. Further, for the estimation of LIS within a short vertical block, we will use the algorithm guaranteed by Theorem 1.4. For horizontal blocks, we need some further relaxations. We will show below that we may restrict ourselves to short horizontal blocks, due to the choice of parameters in the formation of the grid G'. This again will facilitate the use of the algorithm guaranteed by Theorem 1.4. The details now follow.

Estimating the length of LIS in a horizontal chain. A horizontal block belonging to a multi-valued layer is referred to as a multi-valued horizontal block, and a horizontal block belonging to a single-valued layer is a single-valued horizontal block. We treat these horizontal blocks separately.

Let $m = \epsilon/\lambda^2$. Let $\mathcal{L}'_H$ denote the restriction of $\mathcal{L}_H$ after deleting multi-valued horizontal blocks containing more than m boxes. We first show that the length of $\mathcal{L}'_H$ is not much smaller than $\mathcal{L}_H$.

▷ Claim 4.8. $|\mathcal{L}'_H| \leq |\mathcal{L}_H| - 4\lambda^2\epsilon n$.

Let C'_H denote the chain obtained after removing multi-valued horizontal blocks containing more than m boxes. If there are at most $\phi = \epsilon\lambda^2 y$ multi-valued horizontal blocks in the chain C'_H, then, by removing all of them, we end up losing only $\phi \cdot \frac{4n}{y} \leq 4n\epsilon\lambda^2$ points (as each multi-valued layer has density at most $4/y$). If there are at least ϕ multi-valued horizontal blocks in C'_H, then the average number of values in such a horizontal block is at most $\frac{r}{\phi} \leq \frac{r}{\epsilon\lambda^2 y} = \frac{\sqrt{r}}{\lambda^2}$ by our choice of y. That is, with probability at least $1 - \frac{1}{100\log(\tau)}$, a uniformly random multi-valued horizontal block in C'_H contains at most $\frac{100\sqrt{r}\log(\tau)}{\lambda^2}$ values. Thus, we have reduced the problem to estimating the LIS in a collection of (possibly very long) single-valued horizontal blocks and several short multi-valued horizontal blocks containing $O(\frac{\sqrt{r}\log(\tau)}{\lambda^2})$ values.

In the following, we use the term *segment* to denote a subarray composed of $2m$ subarrays $\{D_i, D_{i+1}, \ldots, D_{i+2m-1}\}$ for some $i \in [x-2m+1]$. A segment is said to contain a multi-valued horizontal block H if all the subarrays forming H are contained in the segment.

Fix $r' = \frac{100\sqrt{r}\log(\tau)}{\lambda^2}$. Our algorithm for estimating the length of $\mathcal{L}_H$ is as follows:

1. Sample $t\log^2(\tau)$ uniformly random segments.
2. For each sampled segment B, query $s = \Theta\left(\frac{m\log(\tau)}{\beta} \cdot \frac{r'}{\epsilon^3\lambda^6}\log\left(\frac{r'^2}{\epsilon\lambda}\right)\right)$ points uniformly and independently at indexes from B and run the algorithm given by Theorem 1.4 with parameters r' (for the number of distinct values) and $\epsilon\lambda^2$ (for approximation guarantee) using the samples that fall into the multi-valued horizontal block H contained in the segment B, if any.
3. Estimate the contribution to the LIS from multi-valued horizontal blocks by summing the answers returned by the algorithm in the previous steps and then normalizing appropriately.
4. Estimate the contribution to the LIS from single-valued horizontal blocks by summing the estimates of the densities of all single-valued horizontal blocks in C_H (as we already know these estimates from the Gridding stage).
5. Output an estimate L_H of the length of $\mathcal{L}_H$ by summing the above two estimates.

Clearly, the contribution to $\mathcal{L}_H$ from single-valued horizontal blocks is estimated within multiplicative $(1 \pm \frac{1}{2})$-error, by our conditioning on the event F. We show the following.

▷ Claim 4.9. With probability $1 - O(\frac{\log(\tau)}{\tau^2})$, the contribution to $\mathcal{L}_H$ from multi-valued horizontal blocks is estimated within an additive error of $\epsilon\lambda^2 n$.

Estimating the length of the LIS in a vertical chain. Let $\nu = \epsilon\lambda^2$. We may assume that the vertical chain is composed of at least $\nu \cdot x$ vertical blocks, for otherwise, we can abandon the entire vertical chain by incurring a "loss" to the LIS amounting to at most $\nu \cdot n$ points. Additionally, since the boxes from different vertical blocks belong to different layers, using a similar averaging argument as before, we can show that with probability at least $1 - \frac{1}{100\log(\tau)}$, a uniformly random vertical block contains at most $\frac{100\sqrt{\tau}\log(\tau)}{\lambda^2}$ distinct values.

Therefore, in order to estimate the length of the LIS in the vertical chain, we sample $O(\log(\tau))$ subarrays $D_i, i \in [x]$ and run the pseudo-solution-based LIS estimation algorithm, restricted to the vertical box, if any, that belongs to this subarray while making sure that the success probability is at least $1 - \frac{1}{100\log\tau}$ and the error parameter is $\epsilon\lambda^2$. The details of how to implement this procedure nonadaptively are identical to how we implemented the estimation of the LIS in C_H in the preceding section. The query complexity is also identical.

▷ Claim 4.10. With probability $1 - O(\frac{\log(\tau)}{\tau^2})$, we estimate the contribution of vertical blocks to within an additive error of $\epsilon\lambda^2 n$.

4.1.4 Correctness, approximation guarantee, and query complexity

In this section, we complete the analysis of our algorithm and finish the proof of Theorem 1.5.

Success probability. The probability that any of Layering, Gridding and Finer Gridding fail is at most 3/100. For a specific chain of boxes, by Claims 4.9 and 4.10, we know that estimating the length of LIS within them is within the approximation guarantee with probability at least $1 - O(\frac{\log(\tau)}{\tau^2})$. By a union bound over all τ chains, we can see that the probability of incorrectly estimating the LIS length in some chain is at most 1/100. Thus, overall, the failure probability is at most a small constant.

Query complexity. The query complexity is clearly $\tilde{O}(\sqrt{r} \cdot \text{poly}(1/\lambda))$ from the description of the algorithm.

Approximation guarantee. Consider a fixed true LIS $\mathcal{L}$. The loss to $\mathcal{L}$ due to ignoring boxes that are not β-dense ($\beta = \epsilon^2\lambda$) is at most $\epsilon^3\lambda n + \epsilon\lambda n$. The loss to $\mathcal{L}$ due to antichain removal is at most $4n/\tau$, which is equal to $4\lambda n/5$. The resulting increasing sequence has length at least $|\mathcal{L}| - \epsilon^3\lambda n - \epsilon\lambda n - 4\lambda n/5$, which is at least $(1 - \epsilon^3 - \epsilon - 4/5) \cdot |\mathcal{L}|$, since, by our assumption $|\mathcal{L}| \geq \lambda n$. After chain decomposition, the length of the LIS in the best chain is at least $(1 - \epsilon^3 - \epsilon - 4/5) \cdot |\mathcal{L}|/\tau$, which is equal to $\frac{\lambda}{5} \cdot |\mathcal{L}| \cdot (1/5 - \epsilon^3 - \epsilon)$. Since we split the chains into horizontal and vertical chains, we further lose a factor of 2, and the resulting LIS length becomes $\frac{\lambda}{10} \cdot |\mathcal{L}| \cdot (1/5 - \epsilon^3 - \epsilon)$. In case of horizontal chains, we additionally lose a $9\epsilon\lambda^2 n$ and in the case of vertical chains, we additionally lose $\epsilon\lambda^2 n$. That is the length of LIS in the (best) horizontal chain is at least $\frac{\lambda}{10} \cdot |\mathcal{L}| \cdot (1/5 - \epsilon^3 - 11\epsilon)$. Finally, using Claims 4.9 and 4.10, we can see that we estimate the lengths of the best horizontal and vertical chains to within a constant multiplicative factor. Overall, the approximation guarantee is multiplicative $\Omega(\lambda)$.

Optimal-Time Queries on BWT-Runs Compressed Indexes

Abstract

Indexing highly repetitive strings (i.e., strings with many repetitions) for fast queries has become a central research topic in string processing, because it has a wide variety of applications in bioinformatics and natural language processing. Although a substantial number of indexes for highly repetitive strings have been proposed thus far, developing compressed indexes that support various queries remains a challenge. The *run-length Burrows-Wheeler transform* (RLBWT) is a lossless data compression by a reversible permutation of an input string and run-length encoding, and it has received interest for indexing highly repetitive strings. LF and ϕ^{-1} are two key functions for building indexes on RLBWT, and the best previous result computes LF and ϕ^{-1} in $O(\log \log n)$ time with $O(r)$ words of space for the string length n and the number r of runs in RLBWT. In this paper, we improve LF and ϕ^{-1} so that they can be computed in a constant time with $O(r)$ words of space. Subsequently, we present *OptBWTR (optimal-time queries on BWT-runs compressed indexes)*, the first string index that supports various queries including locate, count, extract queries in optimal time and $O(r)$ words of space.

1 Introduction

A string index represents a string in a compressed format that supports locate queries (i.e., computing all the positions at which a given pattern appears in a string). The *FM-index* [10, 11] is an efficient string index on a lossless data compression called the *Burrows-Wheeler transform (BWT)* [5], which is a reversible permutation of an input string. In particular, locate queries can be efficiently computed on an FM-index by performing a *backward search*, which is an iterative algorithm for computing an interval corresponding to the query on a *suffix array* (SA) [19] storing all the suffixes of an input string in lexicographical order. The FM-index performs locate queries in $O(m + occ)$ time with $O(n(\frac{\log \sigma}{\log n} + \frac{1}{s}))$ words of space for a string T of length n, query string of length m, alphabet size σ, parameter s, and number occ of occurrences of a query in T [3].

A *highly repetitive string* is a string including many repetitions. Examples include the human genome, version-controlled documents, and source code in repositories. A significant number of string indexes on various compressed formats for highly repetitive strings have been proposed thus far (e.g., SLP-index [8], LZ-indexes [6, 12], BT-indexes [7, 21]). For a large collection of highly repetitive strings, the most powerful and efficient compressed format is the run-length (RL) Burrows Wheeler transform (RLBWT) [5], which is a BWT compressed

by run-length encoding. Mäkinen et al. [18] presented an RLBWT-based string index, named the RLFM-index, that solves locate queries by executing a backward search algorithm on RLBWT. While the RLFM-index can solve locate queries in $O(r + n/s)$ words of space in $O((m + s \cdot occ)(\frac{\log \sigma}{\log \log r} + (\log \log n)^2))$ time for the number r of runs in the RLBWT of T and parameter $s \geq 1$, the size of the index depends on the string length. Recently, Gagie et al. [13] presented the r-index, which can reduce the space usage of the RLFM-index to one linearly proportional to the number of runs in RLBWT. The r-index can solve locate queries space efficiently with only $O(r)$ words of space and in $O(m \log \log_w(\sigma + (n/r)) + occ \log \log_w(n/r))$ time for a machine word size $w = \Theta(\log n)$. If the r-index allows $O(r \log \log_w(\sigma + n/r))$ words of space to be used, it can solve locate queries in the optimal time, $O(m + occ)$. Although there are other important queries including count query, extract query, decompression and prefix search for various applications to string processing, no previous string index can support various queries in addition to locate queries based on RLBWT in an optimal time with only $O(r)$ words of space. That is, developing a string index for various queries in an optimal time with $O(r)$ words of space remains a challenge.

Contribution. In this paper, we present *OptBWTR (optimal-time queries on BWT-runs compressed indexes)*, the first string index that supports various queries including locate, count, extract queries in optimal time and $O(r)$ words of space for the number r of runs in RLBWT. LF and ϕ^{-1} are important functions for string indexes on RLBWT. The best previous data structure computes LF and ϕ^{-1} in $O(\log \log_w(n/r))$ time with $O(r)$ words of space [13]. In this paper, we present a novel data structure that can compute LF and ϕ^{-1} in constant time and $O(r)$ words of space. Subsequently, we present OptBWTR that supports the following five queries in optimal time and $O(r)$ words of space.

- **Locate query:** OptBWTR can solve a locate query on an input string in $O(r)$ words of space and $O(m \log \log_w \sigma + occ)$ time, which is optimal for strings with polylogarithmic alphabets (i.e., $\sigma = O(\text{polylog } n)$).
- **Count query:** OptBWTR can return the number of occurrences of a query string on an input string in $O(r)$ words of space and $O(m \log \log_w \sigma)$ time, which is optimal for polylogarithmic alphabets.
- **Extract query:** OptBWTR can return substrings starting at a given position bookmarked beforehand in a string in $O(1)$ time per character and $O(r + b)$ words of space, where b is the number of bookmarked positions. Resolving extract queries is sometimes called the *bookmarking problem* [12, 9].
- **Decompression:** OptBWTR decompresses the original string of length n in optimal time (i.e., $O(n)$). This is the first linear-time decompression algorithm for RLBWT in $O(r)$ words of working space.
- **Prefix search:** OptBWTR can return the strings in a set D that include a given pattern as their prefixes in optimal time (i.e., $O(m + occ')$) and $O(r')$ words of space, where occ' is the number of output strings and r' is the number of runs in the RLBWT of a string made by concatenating the strings in D.

The state-of-the-art string indexes for each type of query are summarized in Table 1.

This paper is organized as follows. In Section 2, we introduce the important notions used in this paper. Section 3 presents novel data structures for computing LF and ϕ^{-1} in constant time. Section 4 presents a data structure supporting a modified version of a backward search on RLBWT. The backward search leverages the two data structures introduced in Section 3. Sections 5 and 6 present OptBWTR that supports all five queries mentioned above by leveraging the modified backward search, LF, and ϕ^{-1}.

Table 1 Summary of space and time for (i) locate and (ii) count queries, (iii) extract queries (a.k.a the bookmarking problem), (iv) decompression of BWT or RLBWT and (v) prefix searches for each query, where n is the length of the input string T, m is the length of a given string P, occ is the number of occurrences of P in T, σ is the alphabet size of T, $w = \Theta(\log n)$ is the machine word size, r is the number of runs in the RLBWT of T, s is a parameter, g is the size of a compressed grammar deriving T, b is the number of input positions for the bookmarking problem, $G = \max\{1, \log^* g - \log^*(\frac{g}{b} - \frac{b}{g})\}$, D is a set of strings of total length n, occ' is the number of strings in D such that each string has P as a prefix and r' is the number of runs in the RLBWT of a string made by concatenating the strings in D.

(i) Locate query	Space (words)	Time
RLFM-index [18]	$O(r + n/s)$	$O((m + s \cdot occ)(\frac{\log \sigma}{\log \log r} + (\log \log n)^2))$
r-index [13]	$O(r)$	$O(m \log \log_w(\sigma + (n/r)) + occ \log \log_w(n/r))$
	$O(r \log \log_w(\sigma + (n/r)))$	$O(m + occ)$
	$O(rw \log_\sigma \log_w n)$	$O(\lceil m \log(\sigma)/w \rceil + occ)$
OptBWTR	$O(r)$	$O(m \log \log_w \sigma + occ)$

(ii) Count query	Space (words)	Time
RLFM-index [18]	$O(r)$	$O(m(\frac{\log \sigma}{\log \log r} + (\log \log n)^2))$
r-index [13]	$O(r)$	$O(m \log \log_w(\sigma + (n/r)))$
	$O(r \log \log_w(\sigma + (n/r)))$	$O(m)$
	$O(rw \log_\sigma \log_w n)$	$O(\lceil m \log(\sigma)/w \rceil)$
OptBWTR	$O(r)$	$O(m \log \log_w \sigma)$

(iii) Extract query	Space (words)	Time per character	Overhead
Gagie et al.[12]	$O(g + b \log^* n)$	$O(1)$	-
Gagie et al.[13]	$O(r \log(n/r))$	$O(\log(\sigma)/w)$	$O(\log(n/r))$
Cording et al.[9]	$O((g + b)G)$	$O(1)$	-
OptBWTR	$O(r + b)$	$O(1)$	-

(iv) Decompression	Space (words)	Time
Lauther and Lukovszki [17]	$O(n(\log \log n + \log \sigma)/w)$	$O(n)$
Golynski et al.[14]	$O((n \log \sigma)/w)$	$O(n \log \log \sigma)$
Predecessor queries [4]	$O(r)$	$O(n \log \log_w(n/r))$
OptBWTR	$O(r)$	$O(n)$

(v) Prefix search	Space (words)	Time
Compact trie [20]	$(n \log \sigma)/w + O(\lvert D \rvert)$	$O(m + occ')$
Z-fast trie [2]	$(n \log \sigma)/w + O(\lvert D \rvert)$	expected $O(\lceil \frac{m \log(\sigma)}{w} \rceil + \log m + \log \log \sigma + occ')$
Packed c-trie [25]	$(n \log \sigma)/w + O(\lvert D \rvert)$	expected $O(\lceil \frac{m \log(\sigma)}{w} \rceil + \log \log n + occ')$
c-trie++ [26]	$(n \log \sigma)/w + O(\lvert D \rvert)$	expected $O(\lceil \frac{m \log(\sigma)}{w} \rceil + \log \log_\sigma w + occ')$
OptBWTR	$O(r' + \lvert D \rvert)$	$O(m + occ')$

2 Preliminaries

Let $\Sigma = \{1, 2, \ldots, \sigma\}$ be an ordered alphabet of size σ, T be a string of length n over Σ, and $|T|$ be the length of T. Let $T[i]$ be the i-th character of T (i.e., $T = T[1], T[2], \ldots, T[n]$) and $T[i..j]$ be the substring of T that begins at position i and ends at position j. For two strings, T and P, $T \prec P$ means that T is lexicographically smaller than P. Let ε be the empty string, i.e., $|\varepsilon| = 0$. We assume that (i) $\sigma = n^{O(1)}$ and (ii) the last character of string T is a special character \$ not occurring on substring $T[1..n-1]$ such that $\$ \prec c$ holds for any character $c \in \Sigma \setminus \{\$\}$. For two integers, b and e ($b \leq e$), *interval* $[b, e]$ is the set $\{b, b+1, \ldots, e\}$. $Occ(T, P)$ denotes all the occurrence positions of a string P in a string T, i.e., $Occ(T, P) = \{i \mid i \in [1, n-|P|+1] \text{ s.t. } P = T[i..(i+|P|-1)]\}$. A *count query* on a string T returns the number of occurrences of a given string P in T, i.e., $|Occ(T, P)|$. Similarly, a *locate query* on string T returns all the starting positions of P in T, i.e., $Occ(T, P)$.

A *rank* query $\mathsf{rank}(T, c, i)$ on a string T returns the number of occurrences of a character c in $T[1..i]$, i.e., $\mathsf{rank}(T, c, i) = |Occ(T[1..i], c)|$. A *select* query $\mathsf{select}(T, c, i)$ on a string T returns the i-th occurrence of c in T (i.e., it returns the smallest integer $j \geq 1$ such that $|Occ(T[1..j], c)| = i$) if T contains c; otherwise it returns -1. Assume that $T[b..e]$ contains a character c for an interval $[b, e] \subseteq [1, n]$. Let $\hat{b}$ and $\hat{e}$ be the first and last occurrences of a character c in $T[b..e]$ (i.e., $\hat{b} = \min\{i \mid i \in [b, e] \text{ s.t. } T[i] = c\}$ and $\hat{e} = \max\{i \mid i \in [b, e] \text{ s.t. } T[i] = c\}$). Then, we can compute $\hat{b}$ and $\hat{e}$ by the following lemma.

▶ **Lemma 1.** *The following statements hold: (i) $T[b..e]$ contains a character c if and only if $\mathsf{rank}(T, c, e) - \mathsf{rank}(T, c, b-1) \geq 1$ holds. (ii) $\hat{b} = \mathsf{select}(T, c, \mathsf{rank}(T, c, b-1) + 1)$ and $\hat{e} = \mathsf{select}(T, c, \mathsf{rank}(T, c, e))$ hold if $T[b..e]$ contains c.*

A suffix array (SA) of a string T is an integer array of size n such that $\mathsf{SA}[i]$ stores the starting position of the i-th suffix of T in lexicographical order. Formally, SA is a permutation of $[1, n]$ such that $T[\mathsf{SA}[1]..n] \prec \cdots \prec T[\mathsf{SA}[n]..n]$ holds. Each value in SA is called an *sa-value*.

The *suffix array interval* (*sa-interval*) of a string P is an interval $[b, e] \subseteq [1, n]$ such that $\mathsf{SA}[b..e]$ represents all the occurrence positions of P in string T, i.e., $Occ(T, P) = \{\mathsf{SA}[b], \mathsf{SA}[b+1], \ldots, \mathsf{SA}[e]\}$. The sa-interval of the empty string ε is defined as $[1, n]$.

LF is a function that returns the position with sa-value $\mathsf{SA}[i] - 1$ on SA (i.e., $\mathsf{SA}[\mathsf{LF}(i)] = \mathsf{SA}[i] - 1$) for a given integer $i \in [1, n]$ if $\mathsf{SA}[i] \neq 1$; otherwise, it returns the position with sa-value n (i.e., $\mathsf{SA}[\mathsf{LF}(i)] = n$). ϕ^{-1} [15] is a function that returns $\mathsf{SA}[i+1]$ for a given sa-value $\mathsf{SA}[i] \in [1, n]$ (i.e., $\phi^{-1}(\mathsf{SA}[i]) = \mathsf{SA}[i+1]$) if $i \neq n$; otherwise, it returns $\mathsf{SA}[1]$.

We will use base-2 logarithms throughout this paper unless indicated otherwise. Our computation model is a unit-cost word RAM with a machine word size of $w = \Theta(\log n)$ bits. We evaluate the space complexity in terms of the number of machine words. A bitwise evaluation of space complexity can be obtained with a $\log n$ multiplicative factor.

2.1 Rank-select data structure

We describe a set $\{c_1, c_2, \ldots, c_{\sigma'}\}$ and function γ for a string T. $c_1, c_2, \ldots, c_{\sigma'}$ are all the distinct characters in T, i.e., $\{c_1, c_2, \ldots, c_{\sigma'}\} = \{T[i] \mid i \in [1, |T|]\}$ ($c_1 < c_2 < \cdots < c_{\sigma'}$). The function γ returns the rank of a given character $c \in \Sigma$ in a string T; i.e., $\gamma(T, c) = j$ if there exists an integer j such that $c = c_j$ holds; otherwise $\gamma(T, c) = -1$.

A rank-select data structure $R(T)$ consists of three data structures R_{rank}, R_{select}, and R_{map}. R_{rank} is a *rank data structure* for solving a rank query on a string T in $O(\log \log_w \sigma)$ time and with $O(|T|)$ words of space [4]. R_{select} consists of σ' arrays $H_1, H_2, \ldots, H_{\sigma'}$. The size of H_j is $|Occ(T, c_j)|$ for each $j \in \{1, 2, \ldots, \sigma'\}$, and $H_j[i]$ stores $\mathsf{select}(T, c_j, i)$ for each $i \in [1, |Occ(T, c_j)|]$. R_{map} is a *deterministic dictionary* [24] storing the mapping function γ for T. The deterministic dictionary can compute $\gamma(T, c)$ for a given character c in constant time, and its space usage is $O(\sigma')$ words. The space usage of the rank-select data structure is $O(|T|)$ words in total, because $\sigma' \leq |T|$ holds. We can compute a given select query $\mathsf{select}(T, c, i)$ in two steps: (i) compute $j = \gamma(T, c)$; and (ii) return -1 if $j = -1$ or $|H_j| < i$; otherwise, return $H_j[i]$. Hence, the rank-select data structure can support rank and select queries on T in $O(\log \log_w \sigma)$ and $O(1)$ time, respectively.

2.2 BWT and run-length BWT (RLBWT)

The BWT [5] of a string T is a string L of length n built by permuting T as follows: (i) all n circular strings of T (i.e., $T[1..n]$, $T[2..n]T[1]$, $T[3..n]T[1..2]$, …, $T[n]T[2..n-1]$) are sorted in lexicographical order; (ii) $L[i]$ is the last character at the i-th circular string in

			Sorted circular strings		
i	SA	LF	F		L
1	15	10	$	baababaabaaba	b
2	7	11	a	abaabab$baaba	b
3	10	12	a	abab$baababaa	b
4	2	13	a	ababaabaabab$	b
5	13	14	a	b$baababaabaa	b
6	5	15	a	baabaabab$baa	b
7	8	2	a	baabab$baabab	a
8	11	3	a	bab$baababaab	a
9	3	4	a	babaabaabab$b	a
10	14	5	b	$baababaabaab	a
11	6	6	b	aabaabab$baab	a
12	9	7	b	aabab$baababa	a
13	1	1	b	aababaabaabab	$
14	12	8	b	ab$baababaaba	a
15	4	9	b	abaabaabab$ba	a

Figure 1 Table illustrating the BWT (L), SA, LF function, F, and the sorted circular strings of $T = baababaabaabab\$$.

the sorted order for $i \in [1, n]$. Similarly, F is a string of length n such that $F[i]$ is the first character at the i-th circular string in the sorted order. Formally, let $L[i] = T[\mathsf{SA}[\mathsf{LF}(i)]]$ and $F[i] = T[\mathsf{SA}[i]]$.

Let C be an array of size σ such that $C[c]$ is the number of occurrences of characters lexicographically smaller than $c \in \Sigma$ in string T i.e., $C[c] = |\{i \mid i \in [1, n] \text{ s.t. } T[i] \prec c\}|$. The BWT has the following property. For any integer $i \in [1, n]$, $\mathsf{LF}(i)$ is equal to the number of characters that are lexicographically smaller than the character $L[i]$ plus the rank of $L[i]$ on the BWT. Thus, $\mathsf{LF}(i) = C[c] + \mathsf{rank}(L, c, i)$ holds for $c = L[i]$. This is because $\mathsf{LF}(i) < \mathsf{LF}(j)$ if and only if either of the following conditions holds: (i) $L[i] \prec L[j]$ or (ii) $L[i] = L[j]$ and $i < j$ for two integers $1 \leq i < j \leq n$.

Let $[b, e]$ be the sa-interval of a string P and $[b', e']$ be the sa-interval of cP for a character c. Then, the following relation holds between $[b, e]$ and $[b', e']$ on the BWT L.

▶ **Lemma 2** (e.g., [10]). *Let $\hat{b}$ and $\hat{e}$ be the first and last occurrences of c in $L[b..e]$ (i.e., $\hat{b} = \min\{i \mid i \in [b, e] \text{ s.t. } L[i] = c\}$ and $\hat{e} = \max\{i \mid i \in [b, e] \text{ s.t. } L[i] = c\}$). Then, $b' = \mathsf{LF}(\hat{b})$, $e' = \mathsf{LF}(\hat{e})$, and $\mathsf{SA}[b'] = \mathsf{SA}[\hat{b}] - 1$ hold if P and cP are substrings of T.*

Figure 1 illustrates the BWT, SA, LF function, F, L and sorted circular strings of a string $T = baababaabaabab\$$. For example, let $P = ab$, $c = b$. Then $[b, e] = [5, 9]$, $[b', e'] = [14, 15]$, $\hat{b} = 5$, and $\hat{e} = 6$ (see also Figure 1). Moreover, $b' = \mathsf{LF}(\hat{b})$ and $e' = \mathsf{LF}(\hat{e})$ hold by Lemma 2.

The RLBWT of T is a BWT encoded by run-length encoding; i.e., it is a partition of L into r substrings $\mathsf{rlbwt}(L) = L_1, L_2, \ldots, L_r$ such that each substring L_i is a maximal repetition of the same character in L (i.e., $L_i[1] = L_i[2] = \cdots = L_i[|L_i|]$ and $L_{i-1}[1] \neq L_i[1] \neq L_{i+1}[1]$). Each L_i is called a *run*. Let ℓ_i be the starting position of the i-th run of BWT L, i.e., $\ell_1 = 1$, $\ell_i = \ell_{i-1} + |L_{i-1}|$ for $i \in [2, r]$. Let $\ell_{r+1} = n + 1$. The RLBWT is represented as r pairs $(L_1[1], \ell_1)$, $(L_2[1], \ell_2)$, …, $(L_r[1], \ell_r)$ using $2r$ words. For example, $\mathsf{rlbwt}(L) = bbbbbb, aaaaaa, \$, aa$ for BWT L illustrated in Figure 1. The RLBWT is represented as $(b, 1), (a, 7), (\$, 13)$, and $(a, 14)$.

Let δ be a permutation of $[1, r]$ satisfying $\mathsf{LF}(\ell_{\delta[1]}) < \mathsf{LF}(\ell_{\delta[2]}) < \cdots < \mathsf{LF}(\ell_{\delta[r]})$. The LF function has the following properties on RLBWT.

▶ **Lemma 3** (e.g., Lemma 2.1 in [16]). *The following two statements hold: (i) Let x be the integer satisfying $\ell_x \leq i < \ell_{x+1}$ for some $i \in [1, n]$. Then, $\mathsf{LF}(i) = \mathsf{LF}(\ell_x) + (i - \ell_x)$; (ii) $\mathsf{LF}(\ell_{\delta[1]}) = 1$ and $\mathsf{LF}(\ell_{\delta[i]}) = \mathsf{LF}(\ell_{\delta[i-1]}) + |L_{\delta[i-1]}|$ for all $i \in [2, r]$.*

Proof. (i) Let $y = (i - \ell_x)$ and $c = L[\ell_x + (i - \ell_x)]$. $\mathsf{LF}(\ell_x + y) = C[c] + \mathsf{rank}(L, c, \ell_x + y)$ holds by the BWT property. $\mathsf{rank}(L, c, \ell_x + y) = \mathsf{rank}(L, c, \ell_x) + y$ holds because the x-th run L_x is a repetition of the character c. Hence $\mathsf{LF}(\ell_x + y) = C[c] + \mathsf{rank}(L, c, \ell_x + y) = C[c] + \mathsf{rank}(L, c, \ell_x) + y = \mathsf{LF}(\ell_x) + y$ holds. By $i = \ell_x + y$, $\mathsf{LF}(i) = \mathsf{LF}(\ell_x) + (i - \ell_x)$ holds.

(ii) Clearly, $\mathsf{LF}(\ell_{\delta[1]}) = 1$. Next, $\mathsf{LF}(\ell_{\delta[i]}) = \mathsf{LF}(\ell_{\delta[i-1]}) + |L_{\delta[i-1]}|$ holds for any $i \in [2, r]$, because (a) the LF function maps the interval $[\ell_{\delta[i]}, \ell_{\delta[i]} + |L_{\delta[i]}| - 1]$ into the interval $[\mathsf{LF}(\ell_{\delta[i]}), \mathsf{LF}(\ell_{\delta[i]}) + |L_{\delta[i]}| - 1]$ by Lemma 3(i) for any $i \in [1, r]$, (b) LF is a bijection from $[1, n]$ to $[1, n]$, and (c) $\mathsf{LF}(\ell_{\delta[1]}) < \mathsf{LF}(\ell_{\delta[2]}) < \cdots < \mathsf{LF}(\ell_{\delta[r]})$ holds. ◀

The sequence $u_1, u_2, \ldots, u_{r+1}$ consists of sa-values such that (i) $\{u_1, u_2, \ldots, u_r\} = \{\mathsf{SA}[\ell_1 + |L_1| - 1], \mathsf{SA}[\ell_2 + |L_2| - 1], \ldots, \mathsf{SA}[\ell_r + |L_r| - 1]\}$, and (ii) $u_1 < u_2 < \cdots < u_r$. Let δ' be a permutation of $[1, r]$ satisfying $\phi^{-1}(u_{\delta'[1]}) < \phi^{-1}(u_{\delta'[2]}) < \cdots < \phi^{-1}(u_{\delta'[r]})$, and let $u_{r+1} = n + 1$. ϕ^{-1} has the following properties on RLBWT.

▶ **Lemma 4** (Lemma 3.5 in [13]). *The following three statements hold: (i) Let x be the integer satisfying $u_x \leq i < u_{x+1}$ for some integer $i \in [1, n]$. Then $\phi^{-1}(i) = \phi^{-1}(u_x) + (i - u_x)$; (ii) $\phi^{-1}(u_{\delta'[1]}) = 1$ and $\phi^{-1}(u_{\delta'[i]}) = \phi^{-1}(u_{\delta'[i-1]}) + d$ for all $i \in [2, r]$, where $d = u_{\delta'[i-1]+1} - u_{\delta'[i-1]}$; (iii) $u_1 = 1$.*

Proof. (i) Lemma 4(i) clearly holds for $i = u_x$. We show that Lemma 4(i) holds for $i \neq u_x$ (i.e., $i > u_x$). Let s_t be the position with sa-value $u_x + t$ for an integer $t \in [1, y]$ (i.e., $\mathsf{SA}[s_t] = u_x + t$), where $y = i - u_x$. s_t is not the ending position of a run (i.e., $(u_x + t) \notin \{u_1, u_2, \ldots, u_r\}$), and thus, two adjacent positions s_t and $s_t + 1$ are contained in an interval $[\ell_v, \ell_v + |L_v| - 1]$ on SA (i.e., $s_t, s_t + 1 \in [\ell_v, \ell_v + |L_v| - 1]$), which corresponds to the v-th run L_v of L. The LF function maps s_t into s_{t-1}, where s_0 is the position with sa-value u_x. LF also maps $s_t + 1$ into $s_{t-1} + 1$ by Lemma 3(i). The two mapping relationships established by LF produce y equalities $\phi^{-1}(\mathsf{SA}[s_1]) = \phi^{-1}(\mathsf{SA}[s_0]) + 1$, $\phi^{-1}(\mathsf{SA}[s_2]) = \phi^{-1}(\mathsf{SA}[s_1]) + 1$, …, $\phi^{-1}(\mathsf{SA}[s_y]) = \phi^{-1}(\mathsf{SA}[s_{y-1}]) + 1$. The equalities lead to $\phi^{-1}(\mathsf{SA}[s_y]) = \phi^{-1}(\mathsf{SA}[s_0]) + y$, which represents $\phi^{-1}(i) = \phi^{-1}(u_x) + (i - u_x)$ by $\mathsf{SA}[s_y] = i$, $\mathsf{SA}[s_0] = u_x$, and $y = i - u_x$.

(ii) Clearly, $\phi^{-1}(u_{\delta'[1]}) = 1$. $\phi^{-1}(u_{\delta'[i]}) = \phi^{-1}(u_{\delta'[i-1]}) + d$ holds for any $i \in [2, r]$, because (a) ϕ^{-1} maps the interval $[u_{\delta'[i]}, u_{\delta'[i]} + d - 1]$ into the interval $[\phi^{-1}(u_{\delta'[i]}), \phi^{-1}(u_{\delta'[i]}) + d - 1]$ by Lemma 4(i) for any $i \in [1, r]$, (b) ϕ^{-1} is a bijection from $[1, n]$ to $[1, n]$, and (c) $\phi^{-1}(u_{\delta'[1]}) < \phi^{-1}(u_{\delta'[2]}) < \cdots < \phi^{-1}(u_{\delta'[r]})$ holds.

(iii) Let p be the integer satisfying $L_p = \$$. Then there exists an integer q' such that $u_{q'}$ is the sa-value at position ℓ_p, because the length of L_p is 1. Hence, $u_1 = u_{q'} = 1$ holds. ◀

Here, we give an example of Lemma 3. In Figure 1, $(\ell_1, \ell_2, \ell_3, \ell_4) = (1, 7, 13, 14)$ and $(\mathsf{LF}(\ell_1), \mathsf{LF}(\ell_2), \mathsf{LF}(\ell_3), \mathsf{LF}(\ell_4)) = (10, 2, 1, 8)$. Hence, $\mathsf{LF}(3) = \mathsf{LF}(\ell_1) + (3 - \ell_1) = 12$ and $\mathsf{LF}(8) = \mathsf{LF}(\ell_2) + (8 - \ell_2) = 3$ hold by Lemma 3(i).

Next, we give an example of Lemma 4. In Figure 1, $(u_1, u_2, u_3, u_4) = (1, 4, 5, 9)$ and $(\phi^{-1}(u_1), \phi^{-1}(u_2), \phi^{-1}(u_3), \phi^{-1}(u_4)) = (12, 15, 8, 1)$. Hence $\phi^{-1}(3) = \phi^{-1}(u_1) + (3 - u_1) = 14$ and $\phi^{-1}(8) = \phi^{-1}(u_3) + (8 - u_3) = 11$ hold by Lemma 4(i).

3 Novel data structures for computing LF and ϕ^{-1} functions

In this section, we present two new data structures for computing LF and ϕ^{-1} functions in constant time with $O(r)$ words of space. Our key idea is to (i) divide the domains and ranges of two functions into at least r non-overlapping intervals on RLBWT and (ii) compute two

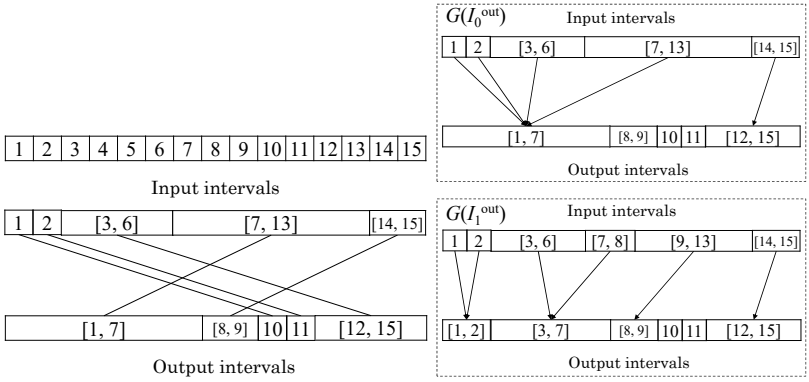

Figure 2 Left figure illustrates input and output intervals created by $I = (1, 10), (2, 11), (3, 12), (7, 1), (14, 8)$. The i-th input and output intervals are connected by a black line. Right figure illustrates two permutation graphs $G(I_0^{\text{out}})$ and $G(I_1^{\text{out}})$ for I.

functions for each domain and range by a linear search in constant time. First, we introduce a notion named *disjoint interval sequence* that is used for a function with non-overlapping intervals for its domain and range. Then, we present a *move query* for computing a function on each disjoint interval sequence and a novel data structure for efficiently computing move queries. Finally, we show that LF and ϕ^{-1} can be computed on two disjoint interval sequences using move queries.

3.1 Disjoint interval sequence and move query

Let $I = (p_1, q_1), (p_2, q_2), \ldots, (p_k, q_k)$ be a sequence of k pairs of integers. We introduce a permutation π of $[1, k]$ and sequence $d_1, d_2, \ldots, d_k$ for I. π satisfies $q_{\pi[1]} \leq q_{\pi[2]} \leq \cdots \leq q_{\pi[k]}$, and $d_i = p_{i+1} - p_i$ for $i \in [1, k]$, where $p_{k+1} = n + 1$. We call the sequence I a *disjoint interval sequence* if it satisfies the following three conditions: (i) $p_1 = 1 < p_2 < \cdots < p_k \leq n$ holds, (ii) $q_{\pi[1]} = 1$, and (iii) $q_{\pi[i]} = q_{\pi[i-1]} + d_{\pi[i-1]}$ holds for each $i \in [2, k]$.

We call the two intervals $[p_i, p_i + d_i - 1]$ and $[q_i, q_i + d_i - 1]$ the i-th *input and output intervals* of the disjoint interval sequence I, respectively, for each $i \in [1, k]$. The input intervals $[p_1, p_1 + d_1 - 1]$, $[p_2, p_2 + d_2 - 1]$, …, $[p_k, p_k + d_k - 1]$ do not overlap, i.e., $[p_i, p_i + d_i - 1] \cap [p_j, p_j + d_j - 1] = \emptyset$ holds for any pair of two distinct integers $i, j \in [1, k]$. Hence, the union of the input intervals is equal to the interval $[1, n]$, i.e., $\bigcup_{i=1}^{k} [p_i, p_i + d_i - 1] = [1, n]$. Similarly, the output intervals $[q_1, q_1 + d_1 - 1]$, $[q_2, q_2 + d_2 - 1]$, …, $[q_k, q_k + d_k - 1]$) do not overlap, and their union is equal to $[1, n]$.

A move query $\mathsf{Move}(I, i, x)$ returns a pair (i', x') on a disjoint interval sequence I for a position $i \in [1, n]$ and the index x of the input interval of I containing the position i (i.e., x is the integer satisfying $i \in [p_x, p_x + d_x - 1]$). Here, $i' = q_x + (i - p_x)$ and x' is the index of the input interval of I containing i'. We can represent a bijective function using a disjoint interval sequence and move query. Formally, let $f_I(i) = i'$ for an integer $i \in [1, n]$, where i' is the first value of the pair outputted by $\mathsf{Move}(I, i, x)$. f_I maps the j-th input interval into the j-th output interval (i.e., $f_I(i) = q_j + (i - p_j)$ for $i \in [p_j, p_j + d_j - 1]$). Hence, f_I is a bijective function from $[1, n]$ to $[1, n]$.

In Figure 2, the left figure illustrates the input and output intervals of the disjoint interval sequence $I = (1, 10), (2, 11), (3, 12), (7, 1), (14, 8)$, where $n = 15$. The input intervals created by I are $[1, 1], [2, 2], [3, 6], [7, 13]$, and $[14, 15]$. The output intervals created by I are $[10, 10], [11, 11], [12, 15], [1, 7]$, and $[8, 9]$. For example, $\mathsf{Move}(I, 3, 3) = (12, 4)$, $\mathsf{Move}(I, 5, 3) = (14, 5)$, and $\mathsf{Move}(I, 8, 4) = (2, 2)$.

3.2 Move data structure

In this section, we present a data structure called *move data structure* for computing move queries in constant time. To do so, we introduce three notions, i.e., the *permutation graph*, *split interval sequence*, and *balanced interval sequence*. A permutation graph $G(I)$ is a directed graph for a disjoint interval sequence I. The number of nodes in $G(I)$ is $2k$, and the nodes correspond one-by-one with the input and output intervals of I. Each input interval $[p_i, p_i + d_i - 1]$ has a single outgoing edge pointing to the output interval $[q_j, q_j + d_j - 1]$ containing p_i; i.e., j is the integer satisfying $p_i \in [q_j, q_j + d_j - 1]$. Hence, $G(I)$ has k edges. We say that I is *out-balanced* if every output interval has at most three incoming edges.

A split interval sequence I_t^{out} is a disjoint interval sequence for a disjoint interval sequence I and an integer $t \geq 0$. Let $I_0^{\mathsf{out}} = I$. For $t \geq 1$, we define I_t^{out} using I_{t-1}^{out} and two integers j, d if I_{t-1}^{out} is not out-balanced. Let (i) $I_{t-1}^{\mathsf{out}} = (p'_1, q'_1), (p'_2, q'_2), \ldots, (p'_{k'}, q'_{k'})$, (ii) j be the smallest integer such that the j-th output interval of I_{t-1}^{out} has at least four incoming edges in $G(I_{t-1}^{\mathsf{out}})$, and (iii) d be the largest integer satisfying $|[q_j, q_j + d - 1] \cap \{p_1, p_2, \ldots, p_{k'}\}| = 2$. Then, I_t^{out} is defined as (p'_1, q'_1), (p'_2, q'_2), …, (p'_{j-1}, q'_{j-1}), (p'_j, q'_j), $(p'_j + d, q'_j + d)$, …, $(p'_{k'}, q'_{k'})$. In other words, I_t^{out} is created by splitting the j-th pair (p'_j, q'_j) of I_{t-1}^{out} into two pairs (p'_j, q'_j) and $(p'_j + d, q'_j + d)$. Let $\tau \geq 0$ be the smallest integer such that I_τ^{out} is out-balanced.

In Figure 2, the right figure illustrates two permutation graphs $G(I_0^{\mathsf{out}})$ and $G(I_1^{\mathsf{out}})$, where I is the disjoint interval sequence illustrated in the left figure, i.e., $I = (1, 10)$, $(2, 11)$, $(3, 12)$, $(7, 1)$, $(14, 8)$. The fourth output interval $[1, 7]$ of I_0^{out} has four incoming edges, and the other output intervals have at most one incoming edge in $G(I_0^{\mathsf{out}})$. Hence, $I_1^{\mathsf{out}} = (1, 10)$, $(2, 11)$, $(3, 12)$, $(7, 1)$, $(9, 3)$, $(14, 8)$ holds by $j = 4$ and $d = 2$. I_1^{out} is out-balanced, and hence $\tau = 1$ holds.

The split interval sequence has the following four properties for each $t \in [0, \tau]$: (i) I_t^{out} consists of $k + t$ pairs. (ii) I_t^{out} consists of at least $2t$ pairs. (iii) Let $d'_i = p'_{i+1} - p'_i$ for $i \in [1, k']$ and $p'_{k'+1} = n + 1$. Both output intervals $[q'_j, q'_j + d - 1]$ and $[q'_j + d, q'_j + d'_j - 1]$ have at least two incoming edges in $G(I_t^{\mathsf{out}})$. (iv) Let f_I and f_I^t be the two bijective functions represented by I and I_t^{out}, respectively. Then, $f_I(i) = f_I^t(i)$ holds for $i \in [1, n]$. Formally, we obtain the second property from the following lemma.

▶ **Lemma 5.** *$|I_t^{\mathsf{out}}| \geq 2t$ holds for any $t \in [0, \tau]$.*

Proof. Let $\mathcal{Q}(I_{t-1}^{\mathsf{out}})$ be the set of the starting positions of input intervals in $G(I_{t-1}^{\mathsf{out}})$ (i.e., $\mathcal{Q}(I_{t-1}^{\mathsf{out}}) = \{p'_1, p'_2, \ldots, p'_{k'}\}$). Then $\mathcal{Q}(I_t^{\mathsf{out}}) = \mathcal{Q}(I_{t-1}^{\mathsf{out}}) \cup \{p'_j + d\}$ holds from the definition of I_t^{out}. Next, let $\mathsf{Edge}_2(I_{t-1}^{\mathsf{out}})$ be the set of output intervals such that each output interval has at least two incoming edges in $G(I_{t-1}^{\mathsf{out}})$, i.e., $\mathsf{Edge}_2(I_{t-1}^{\mathsf{out}}) = \{[q'_i, q'_i + d'_i - 1] \mid i \in [1, k'] \text{ s.t. } |[q'_i, q'_i + d'_i - 1] \cap \mathcal{Q}(I_{t-1}^{\mathsf{out}})| \geq 2\}$, where $d'_i = p'_{i+1} - p'_i$. $[q'_i, q'_i + d'_i - 1] \in \mathsf{Edge}_2(I_t^{\mathsf{out}})$ holds if $[q'_i, q'_i + d'_i - 1] \in \mathsf{Edge}_2(I_{t-1}^{\mathsf{out}})$ for any integer $i \in [1, k'] \setminus \{j\}$. This is because (i) $[q'_i, q'_i + d'_i - 1]$ is also an output interval of I_t^{out}, and (ii) $([q'_i, q'_i + d'_i - 1] \cap \mathcal{Q}(I_{t-1}^{\mathsf{out}})) \subseteq ([q'_i, q'_i + d'_i - 1] \cap \mathcal{Q}(I_t^{\mathsf{out}}))$ holds by $\mathcal{Q}(I_{t-1}^{\mathsf{out}}) \subseteq \mathcal{Q}(I_t^{\mathsf{out}})$. $[q'_j, q'_j + d - 1], [q'_j + d, q'_{j+1} - 1] \in \mathsf{Edge}_2(I_t^{\mathsf{out}})$ also holds by the third property of I_t^{out}. Hence, we obtain an inequality $|\mathsf{Edge}_2(I_t^{\mathsf{out}})| \geq |\mathsf{Edge}_2(I_{t-1}^{\mathsf{out}})| + 1$ for any integer $t \in [1, \tau]$. The inequality $|\mathsf{Edge}_2(I_t^{\mathsf{out}})| \geq |\mathsf{Edge}_2(I_{t-1}^{\mathsf{out}})| + 1$ guarantees that $|\mathsf{Edge}_2(I_t^{\mathsf{out}})| \geq t$ holds for any integer $t \in [0, \tau]$. The inequality $|\mathsf{Edge}_2(I_t^{\mathsf{out}})| \geq t$ indicates that I_t^{out} consists of at least $2t$ pairs, because each output interval in $\mathsf{Edge}_2(I_t^{\mathsf{out}})$ has at least two incoming edges from distinct input intervals. Hence, Lemma 5 holds. ◀

A balanced interval sequence $B(I)$ is defined as I_τ^{out} for a disjoint interval sequence I. We obtain the lemma below from the four properties of I_τ^{out}.

▶ **Lemma 6.** *Let f_I and $f_{B(I)}$ be the two bijective functions represented by I and $B(I)$, respectively for a disjoint interval sequence I of length k. The following three statements hold: (i) $|B(I)| \leq 2k$, (ii) $B(I)$ is out-balanced, and (iii) the two disjoint interval sequences I and $B(I)$ represent the same bijective function, i.e., $f_I(i) = f_{B(I)}(i)$ for $i \in [1, n]$.*

Proof. (i) We obtain an inequality $\tau \leq k$ from the first and second properties of I_t^{out}, because $k + t \geq 2t$ must hold for any $t \in [0, \tau]$. Hence, I_τ^{out} consists of at most $2k$ pairs; i.e., $|B(I)| \leq 2k$ holds. (ii) I_τ^{out} is out-balanced, and thus, $B(I)$ is out-balanced. (iii) $f_I(i) = f_I^0(i) = f_I^1(i) = \cdots = f_I^\tau(i) = f_{B(I)}(i)$, and thus, $f_I(i) = f_{B(I)}(i)$ for $i \in [1, n]$. ◀

The move data structure $F(I)$ is built on a balanced interval sequence $B(I) = (p_1, q_1)$, (p_2, q_2), …, $(p_{k'}, q_{k'})$ for a disjoint interval sequence I, and it supports move queries on $B(I)$. The move data structure consists of two arrays D_{pair} and D_{index} of size k'. $D_{\mathsf{pair}}[i]$ stores the i-th pair (p_i, q_i) of $B(I)$ for each $i \in [1, k']$. $D_{\mathsf{index}}[i]$ stores the index j of the input interval containing q_i. Hence, the space usage is $O(k')$ words in total.

Now let us describe an algorithm for solving a move query $\mathsf{Move}(B(I), i, x) = (i', x')$ on $B(I)$, where x and x' are the indexes of the two input intervals of $B(I)$ containing i and i', respectively, and $i' = q_x + (i - p_x)$. The algorithm consists of three steps. In the first step, the algorithm computes $i' = q_x + (i - p_x)$. In the second step, the algorithm finds the x'-th input interval by a linear search on the input intervals of $B(I)$. Let $b = D_{\mathsf{index}}[x]$. The linear search starts at the b-th input interval $[p_b, p_{b+1} - 1]$, reads the input intervals in the left-to-right order, and stops if the input interval containing position i' is found (i.e., the x'-th input interval). The linear search is always successful (i.e., $x' \geq b$), because $i' \geq q_x$ holds. In the third step, the algorithm returns the pair (i', x'). The running time of the algorithm is $O(x' - b + 1)$ in total.

The running time is computed as follows. Let i_{beg} and i_{end} be the indexes of the first and last input intervals that are connected to the x-th output interval in $G(B(I))$. The x-th output interval has at most three incoming edges, and hence, $i_{\mathsf{end}} - i_{\mathsf{beg}} + 1 \leq 3$ holds. Since b is the index of an input interval that overlaps the x-th output interval, $i_{\mathsf{beg}} - 1 \leq b \leq i_{\mathsf{end}}$. Similarly, $i_{\mathsf{beg}} - 1 \leq x' \leq i_{\mathsf{end}}$. Therefore, $x' - b \leq 3$ and we can solve the move query in constant time.

3.3 Computing LF and ϕ^{-1} functions using move data structures

Here, we show that we can compute the LF function using a move data structure. Recall that ℓ_i is the starting position of the i-th run on BWT L for $i \in [1, r]$, and δ is the permutation of $[1, r]$ introduced in Section 2.2. The sequence I_{LF} is defined as r pairs $(\ell_1, \mathsf{LF}(\ell_1))$, $(\ell_2, \mathsf{LF}(\ell_2))$, …, $(\ell_r, \mathsf{LF}(\ell_r))$. I_{LF} satisfies the three conditions of a disjoint interval sequence by Lemma 3, i.e., (i) $\ell_1 = 1 < \ell_2 < \cdots < \ell_r \leq n$, (ii) $\mathsf{LF}(\ell_{\delta[1]}) = 1$, and (iii) $\mathsf{LF}(\ell_{\delta[i]}) = \mathsf{LF}(\ell_{\delta[i-1]}) + |L_{\delta[i-1]}|$ holds for each $i \in [2, r]$. Hence I_{LF} is a disjoint interval sequence.

Let f_{LF} be the bijective function represented by the disjoint interval sequence I_{LF}. Then, $f_{\mathsf{LF}}(i) = \mathsf{LF}(\ell_x) + (i - \ell_x)$ holds, where x is the integer such that $\ell_x \leq i < \ell_{x+1}$ holds. On the other hand, we have $\mathsf{LF}(i) = \mathsf{LF}(\ell_x) + (i - \ell_x)$ by Lemma 3(i). Hence, f_{LF} and LF are the same function, i.e., $\mathsf{LF}(i) = f_{\mathsf{LF}}(i)$ for $i \in [1, n]$.

Let $F(I_{\mathsf{LF}})$ be the move data structure built on the balanced interval sequence $B(I_{\mathsf{LF}})$ for I_{LF}. By Lemma 6, the move data structure requires $O(r)$ words of space, and $\mathsf{LF}(i) = i'$ holds for a move query $\mathsf{Move}(B(I), i, x) = (i', x')$ on $B(I_{\mathsf{LF}})$. Hence, we have proven the following theorem.

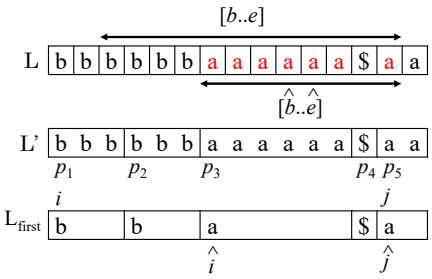

Figure 3 Example of modified toehold lemma.

▶ **Theorem 7.** *Let x and x' be the indexes of the two input intervals of $B(I_{\mathsf{LF}})$ containing an integer $i \in [1, n]$ and $\mathsf{LF}(i)$, respectively. We can compute $\mathsf{LF}(i)$ and x' in constant time by using $F(I_{\mathsf{LF}})$ and (i, x).*

Similarly, we can show that we can compute ϕ^{-1} by using a move data structure. A sequence I_{SA} consists of r pairs $(u_1, \phi^{-1}(u_1))$, $(u_2, \phi^{-1}(u_2))$, ..., $(u_r, \phi^{-1}(u_r))$, where $u_1, u_2, \ldots, u_r$ are the integers introduced in Section 2.2. I_{SA} has the following three properties: (i) $u_1 = 1 < u_2 < \cdots < u_r \leq n$ holds by Lemma 4(iii), (ii) $\phi^{-1}(u_{\delta'[1]}) = 1$ by Lemma 4(ii), and (iii) $\phi^{-1}(u_{\delta'[i]}) = \phi^{-1}(u_{\delta'[i-1]}) + (u_{\delta'[i-1]+1} - u_{\delta'[i-1]})$ holds by Lemma 4(ii) for each $i \in [2, r]$, where δ' is the permutation of $[1, r]$ introduced in Section 2.2. Hence, I_{SA} satisfies the three conditions of a disjoint interval sequence by Lemma 4.

Let f_{SA} be the bijective function represented by the disjoint interval sequence I_{SA}. Then $f_{\mathsf{SA}}(i) = \phi^{-1}(u_x) + (i - u_x)$ holds, where x is the integer such that $u_x \leq i < u_{x+1}$ holds. On the other hand, $\phi^{-1}(i) = \phi^{-1}(u_x) + (i - u_x)$ holds by Lemma 4(i). Hence f_{SA} and $\phi^{-1}(i)$ are the same function.

Let $F(I_{\mathsf{SA}})$ be the move data structure built on the balanced interval sequence $B(I_{\mathsf{SA}})$ for I_{SA}. Then, the result of a move query on $B(I_{\mathsf{SA}})$ contains $\phi^{-1}(i)$ for $i \in [1, n]$, and hence, we have proven (i) of the following theorem.

▶ **Theorem 8.** *Let x, x', $\hat{x}$ be the indexes of the three input intervals of $B(I_{\mathsf{SA}})$ containing an integer $i \in [1, n]$, $\phi^{-1}(i)$, and $i - 1$, respectively. Then, the following two statements hold: (i) We can compute $\phi^{-1}(i)$ and x' in constant time using data structure $F(I_{\mathsf{SA}})$ and the pair (i, x). (ii) We can compute the index $\hat{x}$ using $F(I_{\mathsf{SA}})$ and (i, x).*

Proof. (ii) Let $B(I_{\mathsf{SA}}) = (p_1, q_1), (p_2, q_2), \ldots, (p_{k'}, q_{k'})$. The x-th input interval is $[p_x, p_{x+1} - 1]$, which contains i. $\hat{x} = x$ holds if $p_x \neq i$; otherwise, $\hat{x} = x - 1$. We can verify $p_x \neq i$ holds in constant time by using $F(I_{\mathsf{SA}})$. ◀

Theorems 7 and 8 indicate that we can compute the position obtained by recursively applying LF and ϕ^{-1} to a position $i \in [1, n]$ t times in $O(t)$ time if we know the index of the input interval containing i. For example, let x, x', x'', and x''' be the indexes of the four input intervals of $B(I_{\mathsf{LF}})$ containing i, $\mathsf{LF}(i)$, $\mathsf{LF}(\mathsf{LF}(i))$, and $\mathsf{LF}(\mathsf{LF}(\mathsf{LF}(i)))$, respectively. $\mathsf{LF}(\mathsf{LF}(\mathsf{LF}(i)))$ can be computed by computing three move queries $\mathsf{Move}(B(I_{\mathsf{LF}}), i, x) = (\mathsf{LF}(i), x')$, $\mathsf{Move}(B(I_{\mathsf{LF}}), \mathsf{LF}(i), x') = (\mathsf{LF}(\mathsf{LF}(i)), x'')$, and $\mathsf{Move}(B(I_{\mathsf{LF}}), \mathsf{LF}(\mathsf{LF}(i)), x'') = (\mathsf{LF}(\mathsf{LF}(\mathsf{LF}(i))), x''')$.

4 New data structure for backward searches

Here, we present a modified version of the *backward search* [10, 1], which we call *backward search query for OptBWTR* (BSR query), for computing the sa-interval of cP for a given string P and character c. To define the BSR query, we will introduce a new tuple: a *balanced*

sa-interval of a string P is a 6-tuple $(b, e, \mathsf{SA}[b], i, j, v)$. Here, (i) $[b, e]$ is the sa-interval of P; (ii) i and j are the indexes of the two input intervals of $B(I_{\mathsf{LF}})$ containing b and e, respectively; (iii) v is the index of the input interval of $B(I_{\mathsf{SA}})$ containing $\mathsf{SA}[b]$. The balanced sa-interval of P is undefined if the sa-interval of P is $\emptyset$ (i.e., P is not a substring of T). The input of the BSR query is the balanced sa-interval $(b, e, \mathsf{SA}[b], i, j, v)$ of a string P and a character c. The output of the BSR query is the balanced sa-interval $(b', e', \mathsf{SA}[b'], i', j', v')$ of string cP if the sa-interval of cP is not the empty set; otherwise BSR outputs a mark $\perp$.

Now, we will present a data structure called the *BSR data structure*. The BSR data structure supports BSR queries in $O(\log \log_w \sigma)$ time. It consists of five data structures $F(I_{\mathsf{LF}})$, $F(I_{\mathsf{SA}})$, $R(L_{\mathsf{first}})$, SA^+, and $\mathsf{SA}^+_{\mathsf{index}}$. Here, $F(I_{\mathsf{LF}})$ and $F(I_{\mathsf{SA}})$ are the two move data structures introduced in Section 3.3. Let $B(I_{\mathsf{LF}}) = (p_1, q_1), (p_2, q_2), \ldots, (p_k, q_k)$. Then L_{first} is the string satisfying $L_{\mathsf{first}} = L[p_1], L[p_2], \ldots, L[p_k]$. $R(L_{\mathsf{first}})$ is a rank-select data structure built on L_{first}, which is defined in Section 2. $R(L_{\mathsf{first}})$ requires $O(|L_{\mathsf{first}}|)$ words of space, and it supports rank and select queries on L_{first} in $O(\log \log_w \sigma)$ and $O(1)$ time, respectively. SA^+ is an array of size k such that $\mathsf{SA}^+[x]$ stores the sa-value at the starting position of the x-th input interval of $B(I_{\mathsf{LF}})$ for each $x \in [1, k]$ (i.e., $\mathsf{SA}^+[x] = \mathsf{SA}[p_x]$). Let $B(I_{\mathsf{SA}}) = (p'_1, q'_1), (p'_2, q'_2), \ldots, (p'_{k'}, q'_{k'})$. $\mathsf{SA}^+_{\mathsf{index}}$ is an array of size k such that $\mathsf{SA}^+_{\mathsf{index}}[x]$ stores the index y of the input interval of $B(I_{\mathsf{SA}})$ containing the position $\mathsf{SA}^+[x]$ (i.e., y is the integer satisfying $\mathsf{SA}^+[x] \in [p'_y, p'_{y+1} - 1]$). The space usage of the five data structures is $O(|B(I_{\mathsf{LF}})| + |B(I_{\mathsf{SA}})|)$ words, and $|B(I_{\mathsf{LF}})|, |B(I_{\mathsf{SA}})| = O(r)$ holds by Lemma 6(i).

Next, we will present a key observation on BSR queries, which is based on the toehold lemma (see, e.g., [23, 13, 1]). Let L' be a sequence of k substrings $L[p_1..p_2 - 1], L[p_2..p_3 - 1], \ldots, L[p_k..p_{k+1} - 1]$ of BWT L, where $p_{k+1} = n + 1$. Then, L' has the following properties: (i) L' represents a partition of L. (ii) Each string of L' consists of a repetition of the same character. (iii) Each character $L_{\mathsf{first}}[t]$ corresponds to the first character of the t-th string of L'. (iv) The i-th and j-th strings of L' contain the b-th and e-th characters of BWT L, respectively. (v) Let $\hat{b}$ and $\hat{e}$ be the first and last occurrences of c in $L[b..e]$ (i.e., $\hat{b} = \min\{t \mid t \in [b, e] \text{ s.t. } L[t] = c\}$ and $\hat{e} = \max\{t \mid t \in [b, e] \text{ s.t. } L[t] = c\}$). Similarly, let $\hat{i}$ and $\hat{j}$ be the indexes of the two strings of L' containing the $\hat{b}$-th and $\hat{e}$-th characters of BWT L, respectively. Then $\hat{i}$ and $\hat{j}$ are equal to the first and last occurrences of c in $L_{\mathsf{first}}[i..j]$. We obtain the following relations among the four positions b, $\hat{b}$, e, and $\hat{e}$ by using the above five properties: (i) $\hat{b} = b$ if $L_{\mathsf{first}}[i] = c$; otherwise, $\hat{b} = p_{\hat{i}}$. (ii) Similarly, $\hat{e} = e$ if $L_{\mathsf{first}}[j] = c$; otherwise $\hat{b} = p_{\hat{j}+1} - 1$. We call these two relations the *modified toehold lemma*.

Let $\hat{v}$ be the index of the input interval of $B(I_{\mathsf{SA}})$ containing position $\mathsf{SA}[\hat{b}]$. $\hat{v} = v$ and $\mathsf{SA}[\hat{b}] = \mathsf{SA}[b]$ hold if $\hat{b} = b$; otherwise, $\hat{v} = \mathsf{SA}^+_{\mathsf{index}}[\hat{i}]$ and $\mathsf{SA}[\hat{b}] = \mathsf{SA}^+[\hat{i}]$ by the modified toehold lemma. We can compute the balanced sa-interval of cP by using $F(I_{\mathsf{LF}})$ and $F(I_{\mathsf{SA}})$ after computing the six integers $\hat{b}, \hat{e}, \hat{i}, \hat{j}, \hat{v}, \mathsf{SA}[\hat{b}]$, because $b' = \mathsf{LF}(\hat{b})$, $e' = \mathsf{LF}(\hat{e})$, and $\mathsf{SA}[b'] = \mathsf{SA}[\hat{b}] - 1$ hold by Lemma 2.

Figure 3 illustrates an example of the modified toehold lemma for a BWT $L = bbbbbb\ aaaaaa\$aa$. In this example, $c = a$ and $L' = bbb, bbb, aaaaaa, \$, aa$. (i) $k = 5$, (ii) $(p_1, p_2, p_3, p_4, p_5) = (1, 4, 7, 13, 14)$, (ii) $L_{\mathsf{first}} = bba\$a$, (iii) $(b, e) = (3, 14)$, (iv) $(\hat{b}, \hat{e}) = (7, 14)$, (v) $(i, j) = (1, 5)$, and (vi) $(\hat{i}, \hat{j}) = (3, 5)$. The i-th string of L' is not a repetition of the character c, and the $\hat{i}$-th string of L' contains the $\hat{b}$-th character of L. Hence $\hat{b} = p_{\hat{i}} = 7$ holds by the modified toehold lemma. Similarly, the j-th string of L' is a repetition of c, and hence $\hat{e} = e$ holds by the modified toehold lemma.

We solve a BSR query in four steps. In the first step, we verify whether $L_{\mathsf{first}}[i..j]$ contains character c by computing two rank queries $\mathsf{rank}(L_{\mathsf{first}}, c, j)$ and $\mathsf{rank}(L_{\mathsf{first}}, c, i)$. By Lemma 1(i), $L_{\mathsf{first}}[i..j]$ contains c if $\mathsf{rank}(L_{\mathsf{first}}, c, j) - \mathsf{rank}(L_{\mathsf{first}}, c, i) \geq 1$; otherwise, cP is not a substring

of T, and hence BSR outputs a mark $\perp$. In the second step, we compute two integers $\hat{i}$ and $\hat{j}$ using rank and select queries on the string L_{first}. $\hat{i} = \mathsf{select}(L_{\mathsf{first}}, c, \mathsf{rank}(L_{\mathsf{first}}, c, i-1)+1)$ and $\hat{j} = \mathsf{select}(L_{\mathsf{first}}, c, \mathsf{rank}(L_{\mathsf{first}}, c, j))$ hold by Lemma 1(ii). In the third step, we compute $\hat{b}$, $\hat{e}$, $\hat{v}$, and $\mathsf{SA}[\hat{b}]$ by the modified toehold lemma. In the fourth step, we compute the balanced sa-interval of cP by processing the six integers $\hat{b}, \hat{e}, \hat{i}, \hat{j}, \hat{v}, \mathsf{SA}[\hat{b}]$, i.e., we compute (i) the pair (b', i') using a move query on $B(I_{\mathsf{LF}})$ for the pair $(\hat{b}, \hat{i})$, (ii) the pair (e', j') using a move query on $B(I_{\mathsf{LF}})$ for the pair $(\hat{e}, \hat{j})$, and (iii) the pair $(\mathsf{SA}[v'], v')$ by Theorem 8(ii). The running time is $O(\log \log_w \sigma)$ in total.

5 OptBWTR

Here, we present OptBWTR, which supports optimal-time queries for polylogarithmic alphabets by leveraging data structures for computing LF and ϕ^{-1} functions. Let P be a string of length m in a count or locate query and $occ = |Occ(T, P)|$. The goal of this section is to prove the following theorem.

▶ **Theorem 9.** *OptBWTR requires $O(r)$ words, and it supports count and locate queries on a string T in $O(m \log \log_w \sigma)$ and $O(m \log \log_w \sigma + occ)$ time, respectively. We can construct OptBWTR in $O(n + r \log r)$ time and $O(r)$ words by processing the RLBWT of T.*

Proof. See the full version of this paper [22] for the proof of the construction time and working space in Theorem 9. ◀

OptBWTR consists of the five data structures composing the BSR data structure, i.e., $F(I_{\mathsf{LF}})$, $F(I_{\mathsf{SA}})$, $R(L_{\mathsf{first}})$, SA^+, and $\mathsf{SA}^+_{\mathsf{index}}$. First, we present an algorithm for a count query using OptBWTR that consists of two phases. In the first phase, the algorithm computes the balanced sa-interval of P by iterating BSR query m times. The input of the i-th BSR query is the $(m-i+1)$-th character of P (i.e., $P[m-i+1]$) and the balanced sa-interval of $P[m-i+2..m]$ for each $i \in [1, m]$. Here, $P[m+1..m]$ is defined as the empty string ε. The balanced sa-interval of ε is $(1, n, n, 1, |B(I_{\mathsf{LF}})|, |B(I_{\mathsf{SA}})|)$, because (i) the sa-interval of the empty string is $[1, n]$, and (ii) $\mathsf{SA}[1] = n$. The i-th BSR query outputs the balanced sa-interval of $P[m-i+1..m]$ if $P[m-i+1..m]$ is a substring of T; otherwise it outputs a mark $\perp$. If a BSR query outputs $\perp$, the pattern P does not occur in T. In this case, the algorithm stops and returns 0 as the solution for the count query. In the second phase, the algorithm returns the length of the sa-interval $[b, e]$ of P (i.e., $e-b+1$) as the solution for the count query, because $occ = e-b+1$ holds. The sa-interval of P is contained in the balanced sa-interval of P; hence, the running time is $O(m \log \log_w \sigma)$ in total.

Next, we present an algorithm for a locate query using OptBWTR. Assume that we already computed the balanced sa-interval of P by the algorithm for the count query. Let v_t be the index of the input interval of $B(I_{\mathsf{SA}})$ containing $\mathsf{SA}[b+t]$ for $t \in [0, e-b]$. Then $\mathsf{SA}[b+1..e]$ can be computed by computing $(e-b)$ move queries $\mathsf{Move}(B(I_{\mathsf{SA}}), \mathsf{SA}[b], v_0) = (\mathsf{SA}[b+1], v_1)$, $\mathsf{Move}(B(I_{\mathsf{SA}}), \mathsf{SA}[b+1], v_1) = (\mathsf{SA}[b+2], v_2)$, …, $\mathsf{Move}(B(I_{\mathsf{SA}}), \mathsf{SA}[e-1], v_{e-b}) = (\mathsf{SA}[e], v_{e-b+1})$ on $B(I_{\mathsf{SA}})$. The first sa-value $\mathsf{SA}[b]$ and the index v_0 are stored in the balanced sa-interval of P.

The algorithm for a locate query also consists of two phases. In the first phase, the algorithm computes the balanced sa-interval of P by iterating BSR query m times. In the second phase, it computes $(e-b)$ move queries $\mathsf{Move}(B(I_{\mathsf{SA}}), \mathsf{SA}[b], v_0)$, $\mathsf{Move}(B(I_{\mathsf{SA}}), \mathsf{SA}[b+1], v_1)$, …, $\mathsf{Move}(B(I_{\mathsf{SA}}), \mathsf{SA}[e-1], v_{e-b})$ by using the move data structure $F(I_{\mathsf{SA}})$, and outputs $\mathsf{SA}[b..e]$. Hence, we can solve a locate query in $O(m \log \log_w \sigma + occ)$ time.

6 Applications

In this section, we show that OptBWTR can support extract, decompression, and prefix search queries in optimal time.

Extract query. Let a string T of length n have b marked positions $i_1, i_2, \ldots, i_b \in [1, n]$. An extract query (also called the bookmarking problem) is to return substring $T[i_j..i_j + d - 1]$ for a given integer $j \in [1, b]$ and $d \in [1, n - i_j + 1]$.

We will use *FL function* to solve extract queries. FL is the inverse function of LF function, i.e., $\mathsf{FL}(\mathsf{LF}(i)) = i$ holds for $i \in [1, n]$. We will also use the function FL_x and integers $h_1, h_2, \ldots, h_b$. $\mathsf{FL}_x(i)$ returns the position obtained by recursively applying the FL function to a given integer i x times, i.e., $\mathsf{FL}_0(i) = i$ and $\mathsf{FL}_x(i) = \mathsf{FL}_{x-1}(\mathsf{FL}(i))$ for $x \geq 1$. h_j is the position with sa-value i_j on SA (i.e., $\mathsf{SA}[h_j] = i_j$). The FL function returns the position with the sa-value $y + 1$ on SA for a given position with sa-value y, and hence $T[i_j..i_j + d - 1] = F[\mathsf{FL}_0(h_j)], F[\mathsf{FL}_1(h_j)], \ldots, F[\mathsf{FL}_{d-1}(h_j)]$ holds for $j \in [1, b]$, where F is the string described in Section 2.2. We can construct a data structure of $O(r)$ words to compute FL function in constant time by modifying Theorem 7 and can solve an extract query in linear time by using the data structure. See the full version of this paper [22] for details of our data structure for solving extract queries.

▶ **Theorem 10.** *There exists a data structure of $O(r + b)$ words that solves the bookmarking problem for a string T and b positions $i_1, i_2, \ldots, i_b$ ($1 \leq i_1 < i_2 < \cdots < i_b \leq n$). This data structure supports an exact query in constant time per character. We can construct the data structure in $O(n)$ time and $O(r + b)$ words of space by processing the RLBWT and positions $i_1, i_2, \ldots, i_b$.*

Proof. See the full version of this paper [22]. ◀

Decompression of RLBWT. We apply Theorem 10 to $T[1..n]$ with marked position 1. Then, our data structure for extract queries can return the string T in $O(n)$ time (i.e., the data structure can recover T from the RLBWT of T in linear time to n). The $O(n)$ time decompression is the fastest among other decompression algorithms on compressed indexes in $O(r)$ words of space, as the following theorem shows.

▶ **Theorem 11.** *We can compute the characters of T in left-to-right order (i.e., $T[1], T[2], \ldots, T[n]$) in $O(n)$ time and $O(r)$ words of space by processing the RLBWT of string T.*

Prefix search. The prefix search for a set of strings $D = \{T_1, T_2, \ldots, T_d\}$ returns the indexes of the strings in D that include a given string P as their prefixes (i.e., $\{i \mid i \in [1, d]$ s.t. $T_i[1..|P|] = P\}$). We can construct a data structure supporting the prefix search by combining Theorem 10 with *compact trie* [20].

A compact trie for a set of strings D is a trie for D such that all unary paths are collapsed, and each node represents the string by concatenating labels on the path from the root to the node. For simplicity, we assume that the set D is *prefix-free*, i.e., T_i is not a prefix of $T_{i'}$ for any pair of two strings T_i and $T_{i'}$ in D. Each leaf in the compact trie represents a distinct string in D by the assumption. Let v be the node such that (i) P is a prefix of the string represented by the node and (ii) P is not a prefix of the string represented by its parent. Then, the leaves under v are the output of the prefix search query for P.

To find v, we decode the string on the path from the root to the node v in linear time using exact queries for the path. After we find v, we traverse the subtree rooted at v and output all the leaves in the subtree. This procedure runs in $O(|P| + occ')$ time, where occ' is the number of leaves under the lowest node. See the full version of this paper [22] for the details of our data structure for solving prefix search queries.

▶ **Theorem 12.** *Let r' be the number of runs in the RLBWT of a string T containing all the strings in $D = \{T_1, T_2, \ldots, T_d\}$. There exists a data structure that supports a prefix search on D in $O(|P| + occ')$ time and $O(r' + d)$ words of space for a string P. The data structure also returns the number of the strings in D that include P as their prefixes in $O(|P|)$ time.*

Proof. See the full version of this paper [22]. ◀

7 Conclusion

We presented OptBWTR, the first string index that can support count and locate queries on RLBWT in optimal time with $O(r)$ words of space for polylogarithmic alphabets. OptBWTR also supports extract queries and prefix searches on RLBWT in optimal time for any alphabet size. In addition, we presented the first decompression algorithm working in optimal time and $O(r)$ words of working space. This is the first optimal-time decompression algorithm working in $O(r)$ words of space.

We presented a new data structure of $O(r)$ words for computing LF and ϕ^{-1} functions in constant time by using a new data structure named move data structure, provided that we use an additional input. We also showed that the backward search works in optimal time for polylogarithmic alphabets with $O(r)$ words of space using the data structure. The two functions and the backward search are general and applicable to various queries on RLBWT.

The following problems remain open: Does there exist a string index of $O(r)$ words supporting locate queries in optimal time for any alphabet size? We assume $\sigma = O(\text{polylog}\, n)$ for supporting locate queries in optimal time with $O(r)$ words. As mentioned in Section 1, a faster version of r-index can support locate queries in optimal time with $O(r \log \log_w(\sigma + (n/r)))$ words. Thus, improving OptBWTR so that it can support locate queries in optimal time with $O(r)$ words for any alphabet size is an important future work. For this goal, one needs to solve a rank query on a string of length $\Theta(r)$ in constant time and $O(r)$ words of space. However, this seems impossible because any data structure of $O(r)$ words requires $\Omega(\log \log_w \sigma)$ time to compute a rank query on a string of length r [4]. Perhaps, we may be able to compute the sa-interval of a given pattern in $O(m)$ time and $O(r)$ words of space without using rank queries. After computing the sa-interval of the pattern, we can solve the locate query in optimal time by using our data structure for the ϕ^{-1} function.

Application of the Level-2 Quantum Lasserre Hierarchy in Quantum Approximation Algorithms

Ojas Parekh

Kevin Thompson
Sandia National Laboratories, Albuquerque, NM, USA

Abstract

The Lasserre Hierarchy, [18, 19], is a set of semidefinite programs which yield increasingly tight bounds on optimal solutions to many NP-hard optimization problems. The hierarchy is parameterized by levels, with a higher level corresponding to a more accurate relaxation. High level programs have proven to be invaluable components of approximation algorithms for many NP-hard optimization problems [3, 7, 26]. There is a natural analogous quantum hierarchy [5, 8, 24], which is also parameterized by level and provides a relaxation of many (QMA-hard) quantum problems of interest [5, 6, 9]. In contrast to the classical case, however, there is only one approximation algorithm which makes use of higher levels of the hierarchy [5]. Here we provide the first ever use of the level-2 hierarchy in an approximation algorithm for a particular QMA-complete problem, so-called Quantum Max Cut [2, 9]. We obtain modest improvements on state-of-the-art approximation factors for this problem, as well as demonstrate that the level-2 hierarchy satisfies many physically-motivated constraints that the level-1 does not satisfy. Indeed, this observation is at the heart of our analysis and indicates that higher levels of the quantum Lasserre Hierarchy may be very useful tools in the design of approximation algorithms for QMA-complete problems.

1 Introduction

The study of many body quantum systems, and their corresponding spectra is of utmost importance in many sub-fields of physics [4]. These systems generally have an exponentially large dimension, so a direct calculation is intractable. Indeed, determining the highest or lowest energy of a quantum state is the canonical QMA-hard problem [4, 17], so we should not expect to solve the problem even with access to a quantum computer. Hence, the study of algorithms which produce approximate solutions emerges as an interesting direction of study. These problems are made even more interesting by the fact that, in contrast to the classical case [29, 30], there are relatively few known rigorous approximation algorithms known.

Prior work. The 2-Local Hamiltonian problem has been a cornerstone of quantum complexity theory; however, it has been recently studied in the context of approximation algorithms [2, 5, 6, 9, 12, 22]. Many of these algorithms draw inspiration from the seminal Goemans-Williamson Max Cut approximation algorithm [10] or other appropriate classical counterparts [26]. For classical approximation algorithms, an effective meta-algorithm is to solve a linear or semidefinite program (SDP) which relaxes the (NP-hard) optimization problem, followed by a rounding procedure which seeks to turn the optimal SDP variable into a solution in the appropriate domain (binary, integral, etc.). The SDP provides a polynomial-time-computable bound on the optimization problem hence bounding the loss in objective allows one to bound the ratio of the objective obtained to the optimal solution (this quantity is called the approximation factor). In the quantum case, the SDP variable is polynomial size, and the goal is to produce a (classical description) of an exponentially large quantum state, again with quantifiable loss. Most such results use the same quantum generalization [5, 6, 9] of a semidefinite programming hierarchy discovered independently by several authors in the classical case [11, 18, 23]. Variations in the aforementioned results [6, 9, 12, 22] derive from differences in either the SDP used to relax the problem [12], changing the rounding algorithm [6, 9, 12, 22], or in some cases by slightly modifying the approximation algorithm and providing a better analysis for the formal proof of the approximation factor [22].

With only one exception, [2], these results all have a rounding step which produces a product state. Since there are upper bounds on the performance of product states [9], these results all have necessarily limited performance, and it is desireable to produce non-product states for a better objective. Another common thread in many of these works is the use of the level-1 instance of the quantum Lasserre Hierarchy. As we will demonstrate in Section 3, this is a relatively loose relaxation which does not satisfy important physical constraints that a consistent quantum state would satisfy. Hence, to get a better objective it is important to use a higher level of Lasserre, for a tighter bound on the optimal quantum state.

There are two works of particular interest in the current context: [2] and [5], which we comment on. We will first need to formally describe a specific 2-Local Hamiltonian problem, introduced as a quantum analog of Max Cut [9]. Note that here and throughout the paper, we will use the notation σ_i to mean the 2×2 matrix σ acting on i tensored with the $\mathbb{I} \in \mathbb{C}^{2\times 2}$ acting on each of the other qubits (the total number of qubits, n, will be clear from context when this notation is used). The formal definition of Quantum Max Cut, $QMC(G, w)$ is:

▶ **Definition 1** ($QMC(G, w)$)**.** *Given a graph $G = (V, E)$ with $|V| = n$, let $H \in \mathbb{C}^{2^n \times 2^n}$ such that:*

$$H = \sum_{ij \in E} w_{ij}(\mathbb{I} - X_i X_j - Y_i Y_j - Z_i Z_j)$$

Then, we define $QMC(G, w)$ to be the largest eigenvalue of H. Ideally, one also seeks to produce a (description) of a state achieving this value.

Gharibian and Parekh [9] introduced this problem as a maximization version of the well-known problem of finding ground states for the quantum Heisenberg model. They give a classical 0.498-approximation using product states, where a $\frac{1}{2}$-approximation is the best possible in the product state regime. Anshu, Gosset, and Morenz [2] present a classical rounding algorithm that outputs a description of an entangled state and are able to deliver a 0.531-approximation. To the best of our knowledge, this is the first approximation algorithm for a 2-Local Hamiltonian problem to move beyond product states. Likewise, the analysis in [2] differs from the analysis in the other related works. Instead of using SDPs to upper

bound the optimal quantum objective, [2] uses physical considerations for the particular kind of Hamiltonian they study [20]. The key technical component is an upper bound on $QMC(G, w)$ where G is a star graph. The rounding algorithm is also fundamentally different in that the output quantum state is produced from direct consideration of the Hamiltonian and its weights, rather than a solution to an SDP.

Another important work for understanding our contribution is that of Brandão and Harrow [5], since this paper makes use of higher levels of the quantum Lasserre Hierarchy. Essentially the relevant rounding algorithm from this paper proceeds in the same way as the classical counterpart by Barak, Raghavendra, and Steurer [26], where a set of subsystems is sampled and all other density matrices are sampled according to single qubit density matrices conditioned on this set. There are additional issues that arise in the analysis from the quantum-ness of the problem, but the rounding algorithm is semantically similar. Additionally, all of the results presented in [5] make strong non-local assumptions on the particular "topology" or structure of the instance.

Our contributions. In contrast to previous approaches, we make only local assumptions on the 2-Local terms, and apply the second level of the Lasserre Hierarchy in a radical new way which makes crucial use of "monogamy of entanglement" inequalities. Indeed, we believe that the methods we introduce constitute the most interesting contribution of this work.

We bridge the gap between [2] and more traditional SDP-based approximation algorithms by showing that the monogamy of entanglement bound derived in [2], based on a seminal result of Lieb and Mattis [20], is a consequence of the second level of a quantum analog [5,8,24] of the classical Lasserre Hierarchy [18,19]. To the best of our knowledge this is a first explicit example of such a connection. This establishes the second level of the quantum Lasserre Hierarchy as the source of the best upper bound for Quantum Max Cut that is amenable to analysis. We show that weaker versions of this SDP relaxation, including the first level, fail to yield the monogamy of entanglement bound. In addition we slightly improve upon the best-known approximation factor for QMC [2] through a simple rounding algorithm that uses an SDP solution to guide construction of an entangled solution. This is a significant departure from existing approximation algorithms for 2-Local Hamiltonian problems, requiring new connections between quantum SDP relaxations and the convex hull of matchings in a graph. Quantum Max Cut has emerged as a vehicle for advancement of approximation algorithms for 2-Local Hamiltonian problems, since it maintains the hardness and essence of more general problems while hiding technical details that hinder progress [2, 9, 22]. We expect that the insights we develop here for Quantum Max Cut may be generalized for other problems.

Our methods. As stated previously, our rounding algorithm begins by formulating and solving an appropriate SDP, which comes from the quantum generalization of the Lasserre Hierarchy. The SDP assigns a "value" for each edge, roughly corresponding to "how close" the parameters of the edge are to a singlet. An edge with *large* value has parameters nearly matching the singlet. Loosely speaking, if an edge has large value then the SDP "thinks" an optimal quantum solution is nearly a singlet along the edge. The rounding algorithm proceeds by picking a threshold and adding every edge with value over the threshold to the large edge set (denoted L in the paper). In a legitimate quantum state, the concept of monogamy of entanglement implies that we cannot have too many large edges attached to the same vertex. Since the SDP relaxation we use is relatively strong (Section 3), this implies the graph induced by the small edges must have low degree. Hence, if we find a maximum matching on this graph, and place a singlet (the state in Equation (1)) on each edge in the matching, we obtain a quantum state with performance approximately comparable to the SDP on this subgraph. For the remainder of the qubits we place the maximally mixed state.

Intuitively, this technique of thresholding the edges and then finding a matching has poor performance when all the edges have small values. However, in this case a product state gives a good approximation to the objective: if all the edges are small then the state does not align well with the singlet along the edges in the Hamiltonian, hence entanglement is not really needed to emulate the state. The rounding algorithm checks the value of both of these strategies (singlets on large edges vs. product state rounding) and takes whichever is better.

Future work. Our analysis is not optimal, and it is possible to obtain improvements. For example, we may consider stronger valid inequalities for Quantum Max Cut solutions arising from our relaxation, which we know exist through numerical experiments. How far can such an improvement be pushed? Can we significantly improve the approximation ratio for Quantum Max Cut beyond ≈ 0.53? Our analysis shows that the second level of the quantum Lasserre Hierarchy is exact for star graphs. Can similar results be achieved for more interesting classes of graphs?

Another important direction is the search for upper bounds on achievable approximation factors. For classical optimization problems there are many such bounds known [15, 16]. Most of these rely on a complexity theoretic conjecture referred to as the Unique Games Conjecture (UGC) [14], i.e. if UGC holds then we have the corresponding upper bound on the approximation factor. No analogous results are known for quantum optimization problems.

2 Preliminaries

We use standard quantum information and graph theory notation, highlighting a few specific definitions below.

For an integer $l \geq 1$, we let $[l] := \{1, \ldots, l\}$. For a set S, $\mathbb{R}^S$ refers to $\mathbb{R}^{|S|}$, where the dimensions of the Euclidean space are associated with the elements of S. We generally refer to the elements of a vector $x \in \mathbb{R}^S$ as x_l for $l \in S$; however, we will also refer to x_l as variables comprising a solution x in the context of semidefinite and linear programs.

Quantum information. The Pauli matrices take their usual definition:

$$\mathbb{I} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Y = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}, \text{ and } \quad Z = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}.$$

We follow the standard practice of using subscripts to indicate quantum subsystems among n qubits, and we use the notation σ_i to denote a Pauli matrix $\sigma \in \{X, Y, Z\}$ acting on qubit i, i.e. $\sigma_i := \mathbb{I} \otimes \mathbb{I} \otimes \ldots \otimes \sigma \otimes \ldots \otimes \mathbb{I} \in \mathbb{C}^{2^n \times 2^n}$, where the σ occurs at position i. The sets $\mathcal{S}(\mathcal{X})$ and $\mathcal{H}(\mathcal{X})$ refer to the symmetric and Hermitian matrices, respectively, acting on the (complex) Euclidean space $\mathcal{X}$.

Graph theory. We deal with only finite and simple graphs $G = (V, E)$, with vertex set V and edge set E. The notation $E(G)$ is the edge set of a graph G. We will refer to an edge e with endpoints $i, j \in V$ as $ij \in E$, or simply as $e \in E$ when endpoints are immaterial. We generally consider weighted graphs where a weight $w_e \geq 0$ is specified for each edge $e \in E$.

For a graph $G = (V, E)$, and a set of vertices $S \subseteq V$, we denote the *induced subgraph* on S, consisting of all edges in E with both endpoints in S, as $G[S]$. For a set of vertices and edges $S \subseteq V$ and $F \subseteq E$, respectively, the edge set $\delta_F(S)$ is defined as $\{ij \in F \mid |\{i, j\} \cap S| = 1\}$, and $E_F(S) := \{ij \in F \mid |\{i, j\} \cap S| = 2\}$. We drop the subscript F when $F = E$, and for a vertex $i \in V$, we abbreviate $\delta_F(\{i\})$ as $\delta_F(i)$.

A graph is *k-vertex connected* if it has at least k vertices and deleting any set of fewer than k vertices (and any incident edges) leaves a connected graph. A *matching* M is a set of edges such that no two distinct $e, f \in M$ share a common vertex. A *perfect matching* in G is a matching of size $\frac{|V|}{2}$.

2.1 Approximation Algorithm Overview

The formal rounding algorithm we propose is presented in Algorithm 1.

Algorithm 1 Approximation Algorithm for Quantum Max Cut.

1. Given as input a graph $G = (V, E)$ with weights $w = \{w_e \geq 0\}_{e \in E}$, solve $\text{Lasserre}_2(G, w)$ (Definition 4). Let the matrix M be an optimal solution.
2. For each $ij \in E$ calculate $v_{ij} := [M(X_iX_j, \mathbb{I}) + M(Y_iY_j, \mathbb{I}) + M(Z_iZ_j, \mathbb{I})]/3$, where $M(\Gamma, \Phi)$ refers to the (Γ, Φ) entry of the matrix M. Set $x_{ij} := -v_{ij}$.
3. Pick an integer $d \geq 1$, and define $L := \{e \in E \mid x_e > \alpha(d) := \frac{d+3}{3(d+1)}\}$. Find a maximum-weight matching F in the graph $G_L := (V, L)$ with respect to the weights $\{w_e\}_{e \in L}$. Let U be the vertices unmatched by F.
4. Define a quantum state:[1]

$$\rho_F := \prod_{ij \in F} \left(\frac{\mathbb{I} - X_iX_j - Y_iY_j - Z_iZ_j}{4} \right) \prod_{v \in U} \frac{\mathbb{I}_v}{2}. \tag{1}$$

5. Execute the randomized approximation algorithm for Quantum Max Cut from [9], yielding a product state ρ_{PS} from a Lasserre_1 solution.
6. Output the better of ρ_F and ρ_{PS}.

To understand the significance of the parameter d in Step 3, recall that we find a set of "large" edges L based on a threshold. The strength of Lasserre_2 implies that G_L has bounded degree. d is the degree upper bound we prove (Lemma 14) corresponding to threshold $\alpha(d) = (d+3)/(3(d+1))$. In particular, if $d = 1$ then no vertex has two adjacent edges and we may select all edges in L for our matching. The problem with this strategy, however, is that if all the edges have small values then the product state rounding algorithm (Step 5) has relatively poor performance. Hence, we obtain the result for $d = 2$. This allows us to get better performance for product state rounding but requires more work to show a maximum matching has good performance with respect to the SDP.

Analysis outline. The main theorem of this work (Theorem 2) proves the stated approximation factor of Algorithm 1. The proof of this theorem requires first demonstrating (in Section 3) several inequalities on the optimal solution of the second level of the quantum Lasserre Hierarhcy (demonted Lasserre_2). Roughly there are two sets of techniques we use to prove the inequalities we need. The first set (Section 3.2) involves using invariance of the the objective function under certain permutations of the SDP variable and Schur complements. The second set of bounds follows from sum-of-squares proof techniques Section 3.3.

Understanding the performance of the thresholding (Step 3 in the algorithm) involves showing that constraints satisfied by the SDP (Section 3) imply that the "large" edges L can be scaled by a not too small constant and brought into the convex hull of matchings

[1] Recall X_i is a tensor product of identity operators and a single X operator in the ith position. So, $((\mathbb{I} + X)/2) \otimes ((\mathbb{I} + X)/2)$ is expressed as $\prod_{i=1}^{2}(\mathbb{I} + X_i)/2$ rather than $\bigotimes_{i=1}^{2}(\mathbb{I} + X_i)/2$

(Theorem 16). This provides a lower bound on the performance of the state ρ_F, then we may appeal to [9] to lower bound the performance of ρ_{PS}. We will prove the main theorem first, using components proved subsequently. The reader is encouraged to come back to this proof after reading the document

▶ **Theorem 2** (Main Theorem). *Let $G = (V, E)$ be a graph and $\{w_e\}_{e\in E}$ be a set of weights with $w_e \geq 0$ for all $e \in E$. Let H be the QMC Hamiltonian in Definition 1, and let ρ be the density matrix output by Algorithm 1. Then,*

$$\frac{\mathbb{E}[\mathrm{Tr}(H\rho)]}{QMC(G,w)} \geq 0.533,$$

where the numerator is the expected objective value obtained by Algorithm 1

Proof. Let $d = 2$, let $\{x_e\}_{e\in E}$ be the values obtained from the SDP as in Item 2, let L be the set of edges found in Item 3, let $S := E - L$, and let $\{y_e^*\}_{e\in E}$ be such that $\{0, 1\} \ni y_e^* = 1$ if and only if edge e is chosen in the matching for ρ_F (see Lemma 17).

Define:

$$s := \frac{\sum_{e\in S} w_e(1+3x_e)}{\sum_{e\in S} w_e(1+3x_e) + \sum_{e\in L} w_e(1+3x_e)},$$

and note that $s \in [0, 1]$ since the comment below Lemma 12 implies that $(1 + 3x_e) \geq 0$ for $e \in E$. It holds that

$$\frac{\sum_{e\in S} w_e(1+3y_e^*) + \sum_{e\in L} w_e(1+3y_e^*)}{\sum_{e\in S} w_e(1+3x_e) + \sum_{e\in L} w_e(1+3x_e)} = \frac{\sum_{e\in S} w_e(1+3y_e^*)}{\sum_{e\in S} w_e(1+3x_e)}s + \frac{\sum_{e\in L} w_e(1+3y_e^*)}{\sum_{e\in L} w_e(1+3x_e)}(1-s)$$

Now we can apply Lemma 17,

$$\frac{\sum_{e\in S} w_e(1+3y_e^*)}{\sum_{e\in S} w_e(1+3x_e)}s + \frac{\sum_{e\in L} w_e(1+3y_e^*)}{\sum_{e\in L} w_e(1+3x_e)}(1-s) \geq \frac{3}{8}s + \frac{3}{4}(1-s).$$

A similar argument for ρ_{PS} using Lemma 18 yields:

$$\frac{\mathbb{E}[\mathrm{Tr}(H\rho_{PS})]}{\sum_{e\in S} w_e(1+3x_e) + \sum_{ij\in L} w_e(1+3x_e)} \geq 0.557931s + 0.498766(1-s)$$

A lower bound on the expected approximation factor is

$$\min_{s\in[0,1]} \max\left\{\frac{3}{8}s + \frac{3}{4}(1-s),\ 0.557931s + 0.498766(1-s)\right\},$$

which is calculated by the linear program,

$$\begin{aligned} &0.533 \leq \min r \\ &\quad s.t.\ \ \left\{\frac{3}{8}s + \frac{3}{4}(1-s) \leq r,\ 0.557931s + 0.498766(1-s) \leq r,\ 1 \geq s \geq 0\right\}. \end{aligned}$$

◀

3 The Level-2 Quantum Lasserre Hierarchy

3.1 Definitions

The classical or commutative Lasserre Hierarchy (and the dual Sum-of-Squares Hierarchy) is a set of semidefinite programs which relaxes the notion of a probability distribution to a pseudo-distribution [3]. A pseudo-distribution is an assignment of values to low order moments which

respects some, but not all, of the properties that a fully consistent probability distribution would satisfy. To understand this consider n binary random variables $(A_1, ..., A_n)$. We will be interested in expectations of polynomials in the A_i. For each monomial of degree $t \leq 2k$ in these variables, the level-k instance of the hierarchy assigns value: $v_k(A_{i_1}A_{i_2}\dots A_{i_t}) \in [0,1]$. The value v_k is meant to represent the expectation $\mathbb{E}_{\mathcal{D}}[A_{i_1}A_{i_2}\dots A_{i_t}]$ for a valid probability distribution $\mathcal{D}$, but it is also possible that it assigns values in such a way that it is impossible to have $v_k(A_{i_1}A_{i_2}\dots A_{i_t}) = \mathbb{E}_{\mathcal{D}}[A_{i_1}A_{i_2}\dots A_{i_t}]$ for any valid distribution $\mathcal{D}$. The level-k SDP assigns values so that polynomials of degree at most k behave as they should for a valid distribution. In particular the SDP assigns values to monomials in such a way that if one expanded $p(A_1, \dots, A_n)^2$ as a linear combination of monomials and applied v_k to the individual terms, the resulting value $v_k(p(A_1, \dots, A_n)^2) \geq 0$. Note that the expected behavior for random variables is the same: $\mathbb{E}_{\mathcal{D}}[p(A_1, \dots, A_n)^2] \geq 0$ for a distribution $\mathcal{D}$. The level k can be thought of as checking that the distribution looks valid from the perspective of low order polynomials.

A quantum analog of the Lasserre Hierarchy [5, 8, 24] is essentially the same except that it is checking the validity of low order polynomials in the Pauli matrices with respect to an overall quantum distribution (density matrix). The values we will assign are meant to represent values of $\mathrm{Tr}(\Gamma\rho)$ for Γ a "low-order" tensor product of Pauli matrices and ρ a valid density matrix. However, the relaxation will likely assign values $v(\Gamma)$ in such a way that it is impossible for $v(\Gamma) = \mathrm{Tr}(\Gamma\rho)$ to hold for any density matrix (and for all Γ)[2]. In this context, by "low-order monomial" we mean the following:

▶ **Definition 3** ($\mathcal{P}_n(k)$)**.** *Given k, n define $\mathcal{P}_n(k)$ as the set of Pauli operators of weight $\leq k$. Formally, $\Gamma \in \mathcal{P}_n(k)$ if Γ is a tensor product of n operators, each of which is in $\{\mathbb{I}, X, Y, Z\}$ such that at most k are not $\mathbb{I}$.*

Lasserre$_k$ will assign values to monomials (elements of $\mathcal{P}_n(2k)$) in such a way that if $p = \sum_{\Phi\in\mathcal{P}_n(k)} c_\Phi \Phi$, then $v(p^2) = \sum_{\Phi,\Phi'} c_\Phi c_{\Phi'} v(\Phi\Phi') \geq 0$. A value assignment which respects low order statistics is equivalent to a positive-semidefinite (PSD) constraint on a "moment matrix". To understand this imagine we had a PSD matrix M with rows and columns indexed by elements of $\mathcal{P}_n(k)$, and we assigned values so that $v(\Gamma) := M(\Phi, \Psi)$ if $\Phi\Psi = \Gamma$. Then, given some polynomial p,

$$v(p^2) = v\left(\left(\sum_{\Phi\in\mathcal{P}_n(k)} c_\Phi \Phi\right)^2\right) = \sum_{\substack{\Phi,\Phi' \\ \in\mathcal{P}_n(k)}} c_\Phi c_{\Phi'} v(\Phi\Phi') = \sum_{\substack{\Phi,\Phi' \\ \in\mathcal{P}_n(k)}} c_\Phi c_{\Phi'} M(\Phi,\Phi') = c^T M c,$$

where $c \in \mathbb{R}^{\mathcal{P}_n(k)}$ is the vector of monomial coefficients. Since M was assumed PSD we are guaranteed that the RHS is ≥ 0. Indeed, if we assign values based on a PSD matrix subject to appropriate constraints, we are guaranteed that Lasserre$_k$ will respect low degree polynomials:

[2] Indeed, if we were able to constrain the low order statistics to be *globally consistent* with some (physical) density matrix, then we could find the largest eigenvalue and solve a QMA-complete problem [21].

▶ **Definition 4** (Lasserre$_k(G,w)$)**.** *Given k, a graph $G = (V, E)$ on n vertices, as well as a vector of non-negative weights $\{w_e\}_{e\in E}$ let $\gamma := |\mathcal{P}_n(k)|$. For each $ij \in E$, define $C_{ij} \in \mathcal{S}(\mathbb{R}^{\gamma\times\gamma})$ where rows and columns are indexed by elements of $\mathcal{P}_n(k)$ such that*

$$C_{ij}(\sigma_i, \sigma_j) := -\frac{1}{2} \quad \text{for } \sigma \in \{X, Y, Z\},$$
$$C_{ij} := 0 \qquad \text{otherwise.}$$

Let $M \in \mathcal{S}(\mathbb{R}^{\gamma\times\gamma})$ be an SDP variable with rows and columns indexed by elements of $\mathcal{P}_n(k)$. We define Lasserre$_k(G,w)$ as the following SDP:

$$\max \sum_{ij\in E} w_{ij}\,(1 + \mathrm{Tr}(C_{ij}M)) \tag{2}$$

$$\begin{aligned}
s.t. \quad & M(\Gamma,\Gamma) = 1 && \forall\,\Gamma \in \mathcal{P}_n(k), && (3)\\
& M(\Gamma,\Phi) = 0 && \forall\,\Gamma,\Phi \in \mathcal{P}_n(k) \text{ s.t. } \Gamma\Phi \text{ is not Hermitian}, && (4)\\
& M(\Gamma,\Phi) = M(\Gamma',\Phi') && \forall\,\Gamma,\Phi,\Gamma',\Phi' \in \mathcal{P}_n(k) \text{ s.t. } \Gamma\Phi = \Gamma'\Phi', && (5)\\
& M(\Gamma,\Phi) = -M(\Gamma',\Phi') && \forall\,\Gamma,\Phi,\Gamma',\Phi' \in \mathcal{P}_n(k) \text{ s.t. } \Gamma\Phi = -\Gamma'\Phi', && (6)\\
& M \succeq 0, && && (7)\\
& M \in \mathcal{S}(\mathbb{R}^{\gamma\times\gamma}). && && (8)
\end{aligned}$$

We will denote Lasserre$_k(G)$ as the above problem with uniform weights (set all $w_{ij} = 1$). Note that we employ a real version of the Lasserre Hierarchy rather than the usual complex version. This still provides an upper bound on the optimal quantum state as shown below in Theorem 7.

Since in Lasserre$_2$ we have constraints $M(\sigma_i, \sigma_j) = M(\sigma_i\sigma_j, \mathbb{I})$, we could have equivalently defined the objective matrix using these moment matrix entries, i.e. taking $C_{ij}(\sigma_i\sigma_j, \mathbb{I}) \neq 0$.

▶ **Definition 5** (Lasserre$_k$ Edge Values)**.** *From a solution M to Lasserre$_k$(G,w) (Definition 4), we define edge values that are used by the rounding algorithm, Algorithm 1. Such values are defined for every pair of distinct vertices i, j, hence we assume, when referring to these values, that E is edge set of a complete graph, denoted K_n. We may set $w_e = 0$ for edges $e \in E$ that do not contribute to the objective value. We define:*

$$v_{ij} := \frac{M(X_iX_j,\mathbb{I}) + M(Y_iY_j,\mathbb{I}) + M(Z_iZ_j,\mathbb{I})}{3}, \text{ and } x_{ij} := -v_{ij},$$

for all $ij \in E := E(K_n)$. We say an edge is large *if $x_{ij} \approx 1$ (and $v_{ij} \approx -1$).*

We will also need to define a modified version of Lasserre$_1$. This is simply Lasserre$_1$ supplemented with positivity of 2-qubit marginals. This is a relaxation of intermediate strength between Lasserre$_1$ and Lasserre$_2$, so we have denoted is Lasserre$_{1.5}$. The additional marginal constraints are crucial for the analysis presented in [22], so a precise understanding of its strength is very interesting. We will define it only for unweighted graphs, since it will not be used in the context of the approximation algorithm.

▶ **Problem 6** (Lasserre$_{1.5}(G)$). *Given a graph $G = (V, E)$ on n vertices, for each $ij \in E$ let C_{ij} be as defined in Lasserre$_1$. Solve the following SDP:*

$$\max \sum_{ij \in E} (1 + \mathrm{Tr}(C_{ij} M)) \tag{9}$$

$$\begin{aligned}
s.t. \quad M(\Gamma, \Gamma) &= 1 && \forall \Gamma \in \mathcal{P}_n(1), && (10)\\
M(\Gamma, \Phi) &= 0 && \forall \Gamma, \Phi \in \mathcal{P}_n(1) \text{ s.t. } \Gamma\Phi \text{ is not Hermitian}, && (11)\\
M(\sigma_i, \eta_j) &= \mathrm{Tr}[\sigma \otimes \eta\ \rho_{ij}] && \forall ij \in E \text{ and } \sigma, \eta \in \{X, Y, Z\}, && (12)\\
M(\sigma_i, \mathbb{I}) &= \mathrm{Tr}[\sigma_i \otimes \mathbb{I}\ \rho_{ij}] && \forall ij \in E \text{ and } \sigma \in \{X, Y, Z\}, && (13)\\
M(\sigma_j, \mathbb{I}) &= \mathrm{Tr}[\mathbb{I} \otimes \sigma_j\ \rho_{ij}] && \forall ij \in E \text{ and } \sigma \in \{X, Y, Z\}, && (14)\\
\mathrm{Tr}[\rho_{ij}] &= 1 && \forall ij \in E, && (15)\\
\rho_{ij} &\succeq 0 && \forall ij \in E, && (16)\\
\rho_{ij} &\in \mathcal{H}(\mathbb{C}^{4\times 4}) && \forall ij \in E, && (17)\\
M &\succeq 0, && && (18)\\
M &\in \mathcal{S}(\mathbb{R}^{(3n+1)\times(3n+1)}). && && (19)
\end{aligned}$$

Note that the main difference between Lasserre$_{1.5}$ and Lasserre$_1$ is the presence of constraints Equation (12)-Equation (14). As stated previously, their intent is to force consistency of 2-local moment matrices by forcing them to correspond to physical 2-qubit density matrices. These relaxations are important because they relax quantum states, hence can be used as upper bounds on 2-Local Hamiltonian problems:

▶ **Theorem 7.** *For any constant k Lasserre$_k$ is an efficiently computable semidefinite program that provides an upper bound on $QMC(G, w)$.*

Proof. Except for $M \succeq 0$, the constraints and objective are affine on the entries of M, hence we do indeed have an SDP. Since M is of polynomial size (it has length $O(n^k)$ on one side), and there are polynomially many linear constraints ($O(n^{2k})$ many), the usual considerations show computational efficiency: All feasible M have bounded norm since moment matrices are constrained to be 1 along the diagonal, the identity matrix is feasible so strong duality holds, and there is a "ball" of operators around the identity which are feasible. Hence, the program can be solved to arbitrary additive precision in polynomial time via the ellipsoid or interior point methods (e.g., [28]).

Let $|\psi\rangle$ be an eigenvector corresponding to $\lambda_{max}(H)$ where H is the 2-Local Hamiltonian in QMC (Definition 1). Set $M(\Phi, \Gamma) = \mathrm{Tr}(\Phi\Gamma\rho)$. M is PSD since for a complex vector v, $v^\dagger M v = \mathrm{Tr}(S^2\rho)$ for S some polynomial as previously described. The remaining issue is that if $\Phi\Gamma$ is not Hermitian then the corresponding value of M is purely imaginary, so we may not be satisfying Equation (4). The solution is simply to set a new moment matrix M' as $M' = (M + M^*)/2$ where M^* is the same as M but with complex conjugate entries. Note that M' is PSD since M^* must also be PSD. For the objective, note that

$$\mathrm{Tr}\left(w_{ij}(\mathbb{I} - X_iX_j - Y_iY_j - Z_iZ_j)\,|\psi\rangle\,\langle\psi|\right) = w_{ij}(1 + \mathrm{Tr}(MC_{ij})).$$

Hence we have established that the optimal quantum state has the same energy as the objective for *some* feasible M. It follows that the optimal M has objective which upper bounds the optimal quantum solution. ◀

$$M(\sigma_i, \eta_k) = \begin{cases} 1 \text{ if } i = k \text{ and } \sigma = \eta \\ -1 \text{ if } i = 0 \text{ and } \sigma = \eta \\ 1 \text{ if } i \neq 0 \neq k, \text{ and } \sigma = \eta \\ 1 \text{ if } \sigma_i = \mathbb{I} = \sigma_k \\ 0 \text{ otherwise} \end{cases}$$

(a) Formal Description of Optimal Moment Matrix.

$$M = \begin{array}{c} \\ 0 \\ 1 \\ 2 \\ \vdots \\ n \\ \mathbb{I} \end{array} \begin{array}{c} \begin{array}{ccccccc} 0 & 1 & 2 & \dots & n & \mathbb{I} \end{array} \\ \begin{bmatrix} \mathbb{I} & -\mathbb{I} & -\mathbb{I} & \dots & -\mathbb{I} & \mathbf{0} \\ -\mathbb{I} & \mathbb{I} & \mathbb{I} & \dots & \mathbb{I} & \mathbf{0} \\ -\mathbb{I} & \mathbb{I} & \mathbb{I} & \dots & \mathbb{I} & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ -\mathbb{I} & \mathbb{I} & \mathbb{I} & \dots & \mathbb{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & 1 \end{bmatrix} \end{array}$$

(b) Informal Description of Optimal Moment Matrix.

$$\begin{bmatrix} 1 & -1 & -1 & \dots & -1 \\ -1 & 1 & 1 & \dots & 1 \\ -1 & 1 & 1 & \dots & 1 \\ \vdots & \vdots & & \ddots & \vdots \\ -1 & 1 & 1 & \dots & 1 \end{bmatrix}$$

(c) One of the Diagonal Blocks of M.

$$\begin{bmatrix} 1 & 1 \dots & 1 \\ \vdots & \vdots & \vdots \\ 1 & 1 \dots & 1 \end{bmatrix} - \begin{bmatrix} -1 \\ -1 \\ \vdots \\ -1 \end{bmatrix} \begin{bmatrix} -1 & -1 & \dots & -1 \end{bmatrix} \succeq 0$$

(d) Schur Complement to complete the proof.

Figure 1 Matrices Needed For Proof of Theorem 9.

3.2 Relative Strength of Relaxations

An important contribution of this work is that the level-2 instances of the Lasserre Hierarchy satisfy important physical constraints which are not satisfied by the first level, even when the first level is further constrained with positive 2-qubit marginals (Lasserre$_{1.5}$). The physical property of interest can be thought of as a "monogamy of entanglement" with respect to specific partitions of the quantum state. Let $G = (V, E)$ be a graph on $n + 1$ vertices with vertex set $\{0, 1, ..., n\}$. Further, let the edge set be $E = \{(0, 1), (0, 2), ..., (0, n)\}$. This graph is easily visualized as n "leaves" connected to a central vertex 0. The Hamiltonian for $QMC(G)$, H, can be thought of as "testing" entanglement along the edges since it is testing overlap with respect to a maximally entangled state. If a state $|\psi\rangle$ had value $\langle\psi|H|\psi\rangle = 4n$, then $|\psi\rangle$ would appear to be maximally entangled along all the edges in E. Indeed, this is impossible, and the value of the maximum possible $\langle\psi|H|\psi\rangle$ (or the maximum eigenvalue of H) is an important result for the analysis presented in [2]:

▶ **Theorem 8** (Star Bound [2, 20]). *If G is a star graph with n leaves, $QMC(G) = 2(n + 1)$.*

This was proven by Anshu, Gosset, and Morenz [2] using a well-known monogamy of entanglement result for the Heisenberg model on complete bipartite interaction graphs by Lieb and Mattis [20].

The first observation we have is that the Lasserre$_1$ SDP violates this property in a maximal sense. By this, we mean that the optimal solution has objective $4n$, rather than $2(n + 1)$. Using the informal language we used to describe Lasserre$_k$, if we only tracked 1-local Pauli polynomials, we would think it is possible to have a state which is maximally entangled along many overlapping edges:

▶ **Theorem 9.** *For G a star graph on n vertices, Lasserre$_1(G)$ has optimal objective $4n$.*

Proof. We can demonstrate an optimal solution to $\text{Lasserre}_1(G)$ by showing that the solution which "picks up" all the edges is feasible. Since the moment matrix must be PSD, and since the diagonal blocks are forced to be $\mathbb{I}$, this is the maximum possible solution for any SDP variable and a solution with this objective value must be optimal. Define moment matrix M as in Figure 1a. We can describe this matrix pictorially by partitioning the rows and columns into blocks corresponding to individual qubits, i.e. block i would correspond to indices $\{X_i, Y_i, Z_i\}$, as well as a block corresponding to the $\mathbb{I}$ index. With these partitions, we can write M as in Figure 1b where $\mathbf{0}$ denotes the zero vector $[0, 0, 0]$. It is easy to see that M satisfies all the linear constraints on the matrix elements, the remaining task is to prove it is PSD. We may reshuffle the rows/columns to write M in block diagonal form as four blocks, where one of the blocks is 1 and three of the blocks have the form Figure 1c. Using the method of Schur complements [31], PSDness of this matrix above is equivalent to Figure 1d, which holds trivially. Hence M is block diagonal with PSD blocks so it must be PSD. ◀

One direction for fixing this problem is to note that many of the low-order statistics present in the optimal moment matrix (see Figure 1a) are non-sensical even for very small states. The submatrix corresponding to qubits 1 and 2, for instance, has the form:

$$\begin{array}{c} \\ X_1 \\ Y_1 \\ Z_1 \\ X_2 \\ Y_2 \\ Z_2 \end{array} \begin{array}{c} \begin{array}{cccccc} X_1 & Y_1 & Z_1 & X_2 & Y_2 & Z_2 \end{array} \\ \left[\begin{array}{cccccc} 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \end{array}\right] \end{array}$$

which is impossible for any (reduced) two qubit density martrix ρ_{12} [13]. This can be remedied in the SDP by adding variables $\rho_{ij} \in \mathbb{C}^{4\times 4}$ for every pair of vertices i, j which force submatrices of the above form to conform to moment matrices of legitimate 2-qubit quantum states, as in [22] and as in in $\text{Lasserre}_{1.5}$.

Unfortunately, this relaxation is still not strong enough to enforce the star bound (Theorem 8):

▶ **Theorem 10.** *If G is a star graph on n vertices, then $\text{Lasserre}_{1.5}(G)$ has optimal objective:*

$$n + 3\sqrt{n(1 + (n-1)/3)}.$$

Proof. Let M be the optimal moment matrix. We may permute the leaves without changing the objective since the graph is unweighted, which corresponds to $M \to UMU^T$ for U some orthogonal matrix. Formally, if $f : [n] \to [n]$ is some permutation on the leaves, then define U as in Figure 2d for all $\sigma \in \{X, Y, Z\}$. Then, the set of marginal density matrix variables can be redefined using UMU^T. Similarly, we can permute $\{X, Y, Z\}$ within each block. We will assume that each $\{X_i, Y_i, Z_i\}$ is permuted in the same way so as to not change the objective. By taking convex combinations of the described permutations (setting M to be a convex combination of terms of the form UMU^T for U orthogonal matrices), we can then assume WLOG that M has been fully symeterized and hence it is invariant to such permutations. We can also assume that the entries $M(\sigma_i, \mathbb{I})$ are zero for $\sigma \in \{X, Y, Z\}$. To see this observe that these terms do not participate in the objective, and that if they are non-zero in the optimal M they can be set to zero without altering positivity. We have shown that M has the form Figure 2a where the rows/columns are

$$M = \begin{array}{c} \\ 0 \\ 1 \\ 2 \\ \vdots \\ n \\ \mathbb{I} \end{array} \begin{array}{c} \begin{array}{cccccc} 0 & 1 & 2 & \dots & n & \mathbb{I} \end{array} \\ \begin{bmatrix} \mathbb{I} & P_1 & P_1 & \dots & P_1 & \mathbf{0} \\ P_1^T & \mathbb{I} & P_2 & \dots & P_2 & \mathbf{0} \\ P_1^T & P_2 & \mathbb{I} & \dots & P_2 & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ P_1^T & P_2 & \dots & P_2 & \mathbb{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & 1 \end{bmatrix} \end{array}$$

(a) Symmeterized Optimal Moment Matrix.

$$Q := \begin{bmatrix} 1 & \alpha & \alpha & \dots & \alpha \\ \alpha & 1 & \beta & \dots & \beta \\ \alpha & \beta & 1 & & \beta \\ \vdots & \vdots & & \ddots & \vdots \\ \alpha & \beta & \dots & \beta & 1 \end{bmatrix}$$

(b) One Block of M.

$$\begin{bmatrix} 1 & \beta & \dots & \beta \\ \beta & 1 & & \beta \\ \vdots & & \ddots & \vdots \\ \beta & \dots & \beta & 1 \end{bmatrix} - \begin{bmatrix} \alpha \\ \alpha \\ \alpha \\ \vdots \\ \alpha \end{bmatrix} \begin{bmatrix} \alpha & \alpha & \alpha & \dots & \alpha \end{bmatrix} \succeq 0$$

(c) Schur Complement for Proof.

$$U(\sigma_j, \sigma_i) = \begin{cases} 1 \text{ if } f(i) = j \text{ or } \sigma_i = \mathbb{I} = \sigma_j \\ 0 \text{ otherwise} \end{cases}$$

(d) Permutation Matrix for Symmeterization.

Figure 2 Matrices Needed For Proof of Theorem 10.

indexed according to $\{X_0, Y_0, Z_0, X_1, Y_1, Z_1, ..., X_n, Y_n, Z_n, \mathbb{I}\}$. Further, according to the symmeterization argument we can assume P_1 has the same entry on each diagonal, P_2 has the same entry on each diagonal and P_2 is symmetric. Consider the submatrix corresponding to just the X operators, and denote if Q as in Figure 2b where $\alpha = M(X_0, X_i)$ and $\beta = M(X_1, X_2)$. We know this matrix is PSD because it is a submatrix of a PSD matrix. Further, since the submatrix corresponding to qubits 1 and 2 must correspond to the (valid) density matrix ρ_{12}, by [13, 22] $-1 \leq \beta \leq 1/3$. Writing Q in block diagonal form $\begin{bmatrix} A & B \\ B^T & C \end{bmatrix}$ with A equal to the top left entry, and we can apply the method of Schur complements [31] to obtain Figure 2c.

We can take the inner product with the all ones vector to obtain the inequality $n(1+(n-1)\beta)-\alpha^2 n^2 \geq 0$. Observe that this is a concave (down) parabola, to so to get a uniform bound on α we must set β to the largest possible value. Hence we derive $\alpha \geq -\sqrt{(1+(n-1)/3)/n}$ with $\beta = 1/3$. The objective is $n + (3n\alpha)$, so far we have shown the optimal solution is at most $n + 3\sqrt{n(1+(n-1)/3)}$. To see the SDP achieves this upper bound note we can take $P_1 \propto \alpha\mathbb{I}$ and $P_2 \propto \beta\mathbb{I}$ for α and β saturating the upper bound. Just as in Theorem 9, M decomposes into a block diagonal form where every block is PSD. ◀

Lasserre$_2$, on the other hand, does satisfy the star bound, which will be an important fact for the analysis of our rounding algorithm.

▶ **Theorem 11.** *Let $G = (V, E)$ be a star graph with n leaves. If G is a subgraph of a larger graph G' on n' vertices, and if M is any feasible solution to Lasserre$_2(G')$, then the values $\{x_e\}_{e \in E}$ (as in Algorithm 1) satisfy $\sum_{e \in E}(1 + 3x_e) \leq 2(n+1)$. Additionally, Lasserre$_2(G)$ has optimal solution with objective $2(n+1)$.*

Proof. This proof is very similar to Theorem 10. Let M be the optimal solution to Lasserre$_2(G')$. We will once again permute the leaves. Consider some permutation of the leaves of G $f : [n] \to [n]$. Let $U \in \mathbb{C}^{2^{n'} \times 2^{n'}}$ be the (Clifford) unitary which satisfies $U\sigma_i U^\dagger = \sigma_j$ if $\sigma \in \{X, Y, Z\}$ and $f(i) = j$. Then, define the $|\mathcal{P}_{n'}(2)| \times |\mathcal{P}_{n'}(2)|$ permutation matrix W as:

$$W(\Gamma, \Phi) = \begin{cases} 1 \text{ if } U\Phi U^\dagger = \Gamma \\ 0 \text{ otherwise} \end{cases}$$

and define $M' = WMW^T$. Constraint Equation (5) holds because if $\Gamma\Phi = \Theta\Pi$ then $(U^\dagger \Gamma U)(U^\dagger \Phi U) = (U^\dagger \Theta U)(U^\dagger \Pi U)$ so

$$M'(\Gamma, \Phi) = M(U^\dagger \Gamma U, U^\dagger \Phi U) = M(U^\dagger \Theta U, U^\dagger \Pi U) = M'(\Theta, \Pi)$$

The other constraints are similar. Just as in Theorem 10, we can also permute $\{X, Y, Z\}$ in each block. Note that by permuting the leaves we have potentially reduced the objective value of M overall (including the edges outside of the star graph), however we have not changed the sum of the values of edges in the star: $\sum_{e \in E}(1 + 3x_e)$.

Now extract the submatrix corresponding to the 2-local terms along the edges corresponding to the G, as well as the identity. Denote this as Q. Formally, Q is the submatrix induced by the index set

$$\{X_0X_1, Y_0Y_1, Z_0Z_1, X_0X_2, ..., X_0X_n, Y_0Y_n, Z_0Z_n, \mathbb{I}\}. \tag{20}$$

By symmeterization, we may assume Q has the following block form[3]:

$\begin{matrix} 1 & -\alpha & -\alpha \\ -\alpha & 1 & -\alpha \\ -\alpha & -\alpha & 1 \end{matrix}$	$\beta\mathbb{I}$	$\cdots$	$\beta\mathbb{I}$	$\begin{matrix} \alpha \\ \alpha \\ \alpha \end{matrix}$
$\beta\mathbb{I}$	$\begin{matrix} 1 & -\alpha & -\alpha \\ -\alpha & 1 & -\alpha \\ -\alpha & -\alpha & 1 \end{matrix}$	$\ddots$	$\vdots$	$\begin{matrix} \alpha \\ \alpha \\ \alpha \end{matrix}$
$\vdots$	$\ddots$	$\ddots$	$\beta\mathbb{I}$	$\vdots$
$\beta\mathbb{I}$	$\cdots$	$\beta\mathbb{I}$	$\begin{matrix} 1 & -\alpha & -\alpha \\ -\alpha & 1 & -\alpha \\ -\alpha & -\alpha & 1 \end{matrix}$	$\begin{matrix} \alpha \\ \alpha \\ \alpha \end{matrix}$
$\begin{matrix} \alpha & \alpha & \alpha \end{matrix}$	$\begin{matrix} \alpha & \alpha & \alpha \end{matrix}$	$\begin{matrix} \alpha & \alpha & \alpha \end{matrix}$	$\begin{matrix} \alpha & \alpha & \alpha \end{matrix}$	1

(21)

Note that rows and columns are indexed as the same order as the set in Equation (20). By Lemma 12, $-1 \leq \beta \leq 1/3$.

Now observe that $Q \succeq 0$ since it is a submatrix of a PSD matrix. Consider this matrix in 2×2 block form $\begin{bmatrix} A & B \\ C & D \end{bmatrix}$ where $D = 1$ is the bottom right entry. Exactly as in previous proofs we can then use the method of Schur complement to derive a necessary condition for positivity:

$$-3n\alpha^2 - 2\alpha + (1 + (n-1)\beta) \geq 0.$$

[3] Note that off-diagonal elements of off-diagonal blocks are imaginary for a quantum state: $X_0X_j \cdot Y_0Y_k \propto iZ_0X_jY_k$. So, those entries correspond to non-Hermitain matrices and are set to zero by constraint Equation (4)

Observe that this is a concave down parabola in α, so to get a uniform bound we need to take β as large as possible. Setting $\beta = 1/3$ and solving for the zeros of the polynomial yields the bounds $-(n+2)/(3n) \leq \alpha \leq 1/3$. The lower bound yields the star bound for the sum of the edge values.

To show $\text{Lasserre}_2(G)$ has optimal solution meeting the star bound note from the previous analysis we have that the optimal objective is upper bounded by the star bound. Further, by Theorem 8 and the fact that we are considering a relaxation on the 2-Local Hamiltonian problem (Theorem 7) the optimal objective must be at least the star bound. The result follows. ◀

3.3 Valid Inequalities for Lasserre_2

We now turn our attention to deriving inequalities that any Lasserre_2 solution must satisfy. These will be used in the subsequent analysis of Algorithm 1. Let M be a feasible solution to $\text{Lasserre}_2(G, w)$. Consider a Cholesky decomposition $U^T U = M \succeq 0$; we will refer to the vectors obtained from the columns of U as $u(\Gamma) \in \mathbb{R}^l$, corresponding to $\Gamma \in \mathcal{P}_n(k)$ and the rows or columns of M. Thus we have

$$u(\Gamma)^T u(\Phi) = M(\Gamma, \Phi) \quad \forall \Gamma, \Phi \in \mathcal{P}_n(k), \tag{22}$$

and in particular each $u(\Gamma)$ is a unit vector by Equation (3). We will establish linear inequalities on the values v_e of Definition 5, as these are the input to the rounding portion of Algorithm 1. First we establish bounds on the v_e.

▶ **Lemma 12.** *For all $ij \in E$, $0 \leq 1 - M(X_iX_j, \mathbb{I}) - M(Y_iY_j, \mathbb{I}) - M(Z_iZ_j, \mathbb{I}) \leq 4$.*

Proof. We will use properties of the vectors $u(\Gamma)$ and M. In particular suppose $\sigma, \eta, \tau \in \{X, Y, Z\}$ are distinct Paulis, giving us:

$$\begin{aligned} u(\sigma_i\sigma_j)^T u(\eta_i\eta_j) &= M(\sigma_i\sigma_j, \eta_i\eta_j) && \text{[by Equation (22)]} \\ &= M(\sigma_i\eta_i\sigma_j\eta_j, \mathbb{I}) && \text{[by Equation (5)]} \\ &= -M(\tau_i\tau_j, \mathbb{I}) && \text{[by Equation (6)].} \end{aligned}$$

The above in conjunction with $u(\Gamma)^T u(\Gamma) = 1$ and $u(\sigma_i\sigma_j)^T u(\mathbb{I}) = M(\sigma_i\sigma_j, \mathbb{I})$ yields the lower bound we seek to prove:

$$\begin{aligned} 0 &\leq [u(\mathbb{I}) - u(X_iX_j) - u(Y_iY_j) - u(Z_iZ_j)]^T [u(\mathbb{I}) - u(X_iX_j) - u(Y_iY_j) - u(Z_iZ_j)] \\ &= 4[1 - M(X_iX_j, \mathbb{I}) - M(Y_iY_j, \mathbb{I}) - M(Z_iZ_j, \mathbb{I})]. \end{aligned}$$

For the upper bound, let the vector $z(1) := u(\mathbb{I}) - u(X_iX_j) + u(Y_iY_j) + u(Z_iZ_j)$. Analogously to above, we have

$$0 \leq \frac{1}{4} z(1)^T z(1) = 1 - M(X_iX_j, \mathbb{I}) + M(Y_iY_j, \mathbb{I}) + M(Z_iZ_j, \mathbb{I}). \tag{23}$$

If we let $z(2) := u(\mathbb{I}) + u(X_iX_j) - u(Y_iY_j) + u(Z_iZ_j)$ and $z(3) := u(\mathbb{I}) + u(X_iX_j) + u(Y_iY_j) - u(Z_iZ_j)$, then

$$0 \leq \sum_{l \in [3]} \frac{1}{4} z(l)^T z(l) = 3 + M(X_iX_j, \mathbb{I}) + M(Y_iY_j, \mathbb{I}) + M(Z_iZ_j, \mathbb{I}),$$

by the analogs of Equation (23) for $z(2)$ and $z(3)$. The above inequality is equivalent to the upper bound we seek to prove. ◀

The lemma implies that $-1 \leq v_e \leq \frac{1}{3}$ and $-\frac{1}{3} \leq x_e \leq 1$, for all $e \in E$. We next derive inequalities for odd cycles in G.

▶ **Lemma 13.** *For an odd-length cycle $C \subseteq E$, $\sum_{e \in C} v_e \geq 2 - |C|$.*

Proof. We take the same basic approach as the proof of Lemma 12, namely the inequality will follow from a positive combination of inequalities derived from $z^T z \geq 0$, for appropriately chosen vectors z. First we consider the case when $|C| = 3$; let C consist of $ij, ik, jk \in E$, and let $\sigma \in \{X, Y, Z\}$. Letting the vector $z(\sigma) := u(\mathbb{I}) + u(\sigma_i\sigma_j) + u(\sigma_i\sigma_k) + u(\sigma_j\sigma_k)$, we see:

$$0 \leq \frac{1}{4} z(\sigma)^T z(\sigma) = 1 + M(\sigma_i\sigma_j, \mathbb{I}) + M(\sigma_i\sigma_k, \mathbb{I}) + M(\sigma_j\sigma_k, \mathbb{I}),$$

since $u(\sigma_p\sigma_q)^T u(\sigma_q\sigma_r) = M(\sigma_p\sigma_q, \sigma_q\sigma_r) = M(\sigma_p\sigma_r, \mathbb{I})$, for $p, q, r \in V$. Averaging the above inequality over $\sigma \in X, Y, Z$ yields:

$$0 \leq \frac{1}{3} \sum_{\sigma \in \{X,Y,Z\}} \frac{1}{4} z(\sigma)^T z(\sigma) = 1 + v_{ij} + v_{ik} + v_{jk}, \tag{24}$$

establishing the lemma for $|C| = 3$. We establish another flavor of the triangle inequality above in order to extend the $|C| = 3$ bound to larger cycles. This time we let $z(\sigma) := u(\mathbb{I}) + u(\sigma_i\sigma_j) - u(\sigma_i\sigma_k) - u(\sigma_j\sigma_k)$, ultimately yielding:

$$0 \leq \frac{1}{3} \sum_{\sigma \in \{X,Y,Z\}} \frac{1}{4} z(\sigma)^T z(\sigma) = 1 + v_{ij} - v_{ik} - v_{jk}. \tag{25}$$

Let us derive the bound for $|C| = 5$. Suppose the vertices of C are in $[5]$. We sum three instances of the above inequalities: Equation (24) for triangles on $\{1, 2, 5\}$ and $\{2, 3, 4\}$, and $1 + v_{45} - v_{24} - v_{25} \geq 0$ for the triangle on $\{2, 4, 5\}$. The sum is $3 + v_{12} + v_{23} + v_{34} + v_{45} + v_{15} \geq 0$, as desired. More generally, for $|C| = 2k+1$ with $k > 2$, we may sum k instances of Equation (24) and $k - 1$ instances of Equation (25) to derive the desired inequality. These $2k - 1$ triangles represent a triangulation of the cycle C; chords introduced by the triangulation appear in exactly two triangles, and edges of C appear in exactly one triangle. The $k - 1$ instances of Equation (25) are used to cancel out variables on such chords. ◀

The inequalities of the above lemma are actually implied by level 2 of the classical Lasserre Hierarchy for the classical Max Cut problem. This is captured by restricting $\mathcal{P}_n(2)$ to only contain tensor products of at most two Pauli Z's and setting $v_{ij} := M(Z_i Z_j, \mathbb{I})$.

4 Analysis of Lasserre$_2$ Rounding

Our goal is to provide bounds on the quality of the rounded solutions produced by Algorithm 1, ρ_F and ρ_{PS}, relative to our Lasserre$_2$ relaxation. For each of these solutions, we consider both the contribution of the edges selected by Algorithm 1 to be in L as well as those in $S := E - L$.

4.1 Bounding the Quality of the Matching-Based Solution

Algorithm 1 leverages a matching on a graph obtained by keeping only edges with high-magnitude fractional SDP values. Here we show that the resulting graph has bounded degree and why this approach produces a matching of relatively large weight.

We consider the values x_e for $e \in E = E(K_n)$ (Definition 5) obtained from the Lasserre$_2(G, w)$ SDP (Definition 4), so that the SDP's objective value is $1 + 3x_e$ for each $e \in E$. Recall from Algorithm 1 that we threshold these variables so that $L = \{e \in E \mid x_e > \alpha(d) \geq 0\}$, where $\alpha(d) = \frac{d+3}{3(d+1)}$. The star bound allows us to bound the maximum degree in the resulting graph, $G_L = (V, L)$.

▶ **Lemma 14.** *The graph G_L, as defined above, has maximum degree at most d.*

Proof. Suppose a vertex $i \in V$ in has degree at least $d+1$ in G_L. Let $D \subseteq \delta(i)$ be a set of $d+1$ edges. We then have

$$\sum_{e \in D} (1 + 3x_e) > (d+1)(1 + 3\alpha(d)) = 2(d+2),$$

violating Theorem 11 for the star rooted at vertex i and containing the edges in D. ◀

Algorithm 1 finds a matching F^* in G_L that maximizes $\sum_{e \in F} w_e$ over matchings F in G_L. The algorithm obtains a quantum state ρ_{F^*} from F^* by putting a singlet, $\frac{1}{4}(\mathbb{I} - X_iX_j - Y_iY_j - Z_iZ_j)$, on each edge in F^* and a maximally mixed state, $\frac{1}{2}\mathbb{I}$, on each vertex unmatched by F^*. Since the objective is $w_{ij}(\mathbb{I} - X_iX_j - Y_iY_j - Z_iZ_j)$ for each edge $ij \in E$, this earns a weight of $4w_{ij}$ for every $ij \in F^*$ and a weight of w_{ij} for every $ij \in E - F^*$. If we define $y^*_e = 1$ for $e \in F^*$ and $y^*_e = 0$ otherwise, then we may express the weight earned by ρ_{F^*} on an edge $e \in E$ as: $4w_e y^*_e + w_e(1 - y^*_e) = w_e(1 + 3y^*_e)$. We would like to show that the total weight of F^* on the edges in L is approximately the weight earned by the SDP on L: $\sum_{e \in L} w_e(1 + 3x_e)$. The following lemma suggests a strategy for accomplishing this.

▶ **Lemma 15.** *If, for some $\beta \in [0, 1]$, the vector $\beta x \in \mathbb{R}^{|E|}$ is a convex combination of matchings, then $\sum_{e \in L} w_e(1 + 3y^*_e) \geq \sum_{e \in L} w_e(1 + 3\beta x_e)$.*

Proof. Write $\beta x = \sum_l \mu_l M_l$, where the latter is a convex combination of incidence vectors of matchings. We have, for the vector of weights w, $\beta w^T x = \sum_l \mu_l w^T M_l$, so there is some l' with $w^T M_{l'} \geq \beta w^T x$. Since y^* is the incidence vector of a maximum-weight matching with respect to w, we get $w^T y^* \geq w^T M_{l'} \geq \beta w^T x$, completing our proof. ◀

The hypothesis of the above lemma is equivalent to showing that βx is in the convex hull of matchings for our graph G, and the convex hull of matchings in a graph is well understood.

▶ **Theorem 16** (Pulleyblank and Edmonds [25]; see [27], Section 25.2)**.** *The convex hull of matchings in a graph $G = (V, E)$ is defined by the following linear inequalities:*

$$\sum_{e \in \delta(i)} y_e \leq 1 \qquad \forall i \in V, \tag{26}$$

$$\sum_{e \in E(S)} y_e \leq \frac{|S| - 1}{2} \qquad \forall S \in \mathcal{F}, \tag{27}$$

$$y_e \geq 0 \qquad \forall e \in E, \tag{28}$$

where $\mathcal{F} := \{S \subseteq V \mid |S| \geq 3$, and $G[S]$ is factor critical and 2-vertex connected$\}$. A graph H is called factor critical (or hypomatchable) if deleting any vertex in H leaves a graph containing a perfect matching (hence $|H|$ must be odd).

We obtain our main lemma by determining a relatively large $\beta \in [0, 1]$ for which $y_e = \beta x_e$ is a feasible solution for the inequalities above, when we take $d = 2$.

▶ **Lemma 17.** *Suppose v_e for $e \in E$ is a feasible solution to the SDP Definition 4, and set $x_e := -v_e$. Let $L := \{e \in E \mid x_e > \frac{5}{9} = \alpha(2)\}$ and $G_L := (V, L)$ be the graph consisting of the edges in L. If F^* is an maximum-weight matching in G_L with respect to the weights $w_e \geq 0$ for $e \in L$, then*

$$\frac{\sum_{e\in L} w_e(1+3y_e^*)}{\sum_{e\in L} w_e(1+3x_e)} > \frac{3}{4}, \tag{29}$$

where $\{0,1\} \ni y_e^* = 1$ if and only if $e \in F^*$. If $S := E - L$, then

$$\frac{\sum_{e\in S} w_e(1+3y_e^*)}{\sum_{e\in S} w_e(1+3x_e)} \geq \frac{3}{8}. \tag{30}$$

Proof. We begin by considering Equation (29) and first showing that the variables βx_e satisfy the inequalities of Theorem 16 for G_L with $\beta = \frac{9}{14}$. Then, Lemma 15 gives us

$$\frac{\sum_{e\in L} w_e(1+3y_e^*)}{\sum_{e\in L} w_e(1+3x_e)} \geq \frac{\sum_{e\in L} w_e(1+3\beta x_e)}{\sum_{e\in L} w_e(1+3x_e)}, \tag{31}$$

and we may focus our attention on bounding the latter, which only depends on the x_e.

Satisfying the inequalities of Theorem 16. Inequality (28) is satisfied since $e \in L$ implies $x_e \geq 0$. To see that the vector $\frac{9}{14}x$ is feasible for the inequality (26), first note that since we take $d = 2$, G_L has maximum degree at most 2 by Lemma 14. Inequality (26) is satisfied for vertices of degree 1 since SDP Definition 4 gives us $x_e \leq 1$ for all e. Now another application of the star bound (Theorem 11) to a degree-2 vertex, i in G_L with neighbors j and k, gives us that

$$(1+3x_{ij}) + (1+3x_{ik}) \leq 6 \;\Rightarrow\; x_{ij} + x_{ik} \leq \frac{4}{3}, \tag{32}$$

hence $\frac{9}{14}x_{ij} + \frac{9}{14}x_{ik} \leq \frac{3}{4}x_{ij} + \frac{3}{4}x_{ik} \leq 1$.

Next we will show that Inequality (27) is satisfied. For these inequalities, we may assume that the induced subgraph on $S \in \mathcal{F}$ in G_L, $G_L[S]$, is an odd cycle. The set $\mathcal{F}$ contains only odd-sized sets that are (2-vertex) connected, and G_L has degree at most 2; hence, $G_L[S]$ must be a path or a cycle. The graph $G_L[S]$ cannot be a path since it must be factor critical, and removing a penultimate vertex in a path leaves a graph with no perfect matching.

Pick some $S \in \mathcal{F}$, and sum the inequalities of (26) over $i \in S$. This yields

$$\sum_{e\in\delta_L(S)} y_e + \sum_{e\in E_L(S)} 2y_e \leq |S| \;\Rightarrow\; \sum_{e\in E_L(S)} y_e \leq \frac{|S|}{2},$$

since $y_e \geq 0$ by Inequality (28). This shows that any vector y that satisfies Inequality (26) gives a RHS of $\frac{|S|}{2}$ instead of the desired value, $\frac{|S|-1}{2}$ for Inequality (27). To make such a vector feasible for Inequality (27), we must scale it by $\max_{k\geq 1} \frac{2k}{2k+1} = \frac{2}{3}$. In our case, $\frac{3}{4}x$ satisfies Inequality (26), hence $\frac{2}{3}\cdot\frac{3}{4}x = \frac{1}{2}x$ is feasible for the inequalities of Theorem 16. However, we can do better by considering additional inequalities satisfied by the x_e that are implied by our Lasserre$_2$ SDP relaxation. Lemma 13 gives us that $x_{ij} + x_{ik} + x_{jk} \leq 1$ for $ij, ik, jk \in E$, hence the inequalities of (27) for $|S| = 3$ are satisfied by the vector x (in fact, since $x_e > \frac{5}{9}$ for all $e \in L$, G_L contains no triangles).

For any cycle $C \subseteq L$ on 5 vertices, Lemma 13 yields $\sum_{e\in C} x_e \leq 3$, so that $\sum_{e\in C} \frac{3}{4}x_e \leq \frac{9}{4}$. Hence, $\frac{3}{4}x$ must be scaled by an additional factor of $\frac{8}{9}$ in order satisfy the inequalities of (27) for $|S| = 5$. For $|S| \geq 7$, an additional factor of $\max_{k\geq 3} \frac{2k}{2k+1} = \frac{6}{7}$ suffices. Thus $\frac{6}{7}\cdot\frac{3}{4}x = \frac{9}{14}x$ is a feasible solution for the inequalities of *Theorem* 16, and it is consequently a convex combination of incidence vectors of matchings in G_L.

Establishing Equation 29. For the RHS of Equation (31), we have

$$\frac{\sum_{e\in L} w_e(1+3\beta x_e)}{\sum_{e\in L} w_e(1+3x_e)} \geq \min_{\{e\in L|w_e>0\}} \frac{w_e(1+3\beta x_e)}{w_e(1+3x_e)}, \tag{33}$$

since $1+3x_e > 0$ for all $e \in L$, and the LHS above is a convex combination of the ratios $(1+3\beta x_e)/(1+3x_e)$ for $e \in L$ with $w_e > 0$. This reduces our task to bounding $(1+3\beta x_e)/(1+3x_e)$, for a worst-case value of x_e achieving the minimum above. If e is an isolated edge in G_L (i.e. it is not incident to any other edges in L), then we may assume e is in the maximum-weight matching F^* without loss of generality, since we can apply the arguments of this section to each connected component of G_L. For such an edge e, we may simply take $\beta = 1$, yielding $(1+3\beta x_e)/(1+3x_e) = 1$. If e is not isolated in G_L, then it is incident to another edge f at a vertex of degree 2 in G_L. Since $x_f > \frac{5}{9}$, by Equation (32) we see that $x_e \leq \frac{4}{3} - x_f < \frac{7}{9}$. We consequently have, for $\beta = \frac{9}{14}$:

$$\min_{\{e\in L|w_e>0\}} \frac{w_e(1+3\beta x_e)}{w_e(1+3x_e)} \geq \min_{x_e\in(\frac{5}{9},\frac{7}{9})} \frac{1+3\beta x_e}{1+3x_e} = \beta + \min_{x_e\in(\frac{5}{9},\frac{7}{9})} \frac{1-\beta}{1+3x_e} > \frac{3}{10} + \frac{7}{10}\beta = \frac{3}{4},$$

demonstrating Equation (29).

Establishing Equation 30. We now turn our attention to the edges in $S = E - L$. Since F^* includes no edges in S, we have $y^*_e = 0$ for $e \in S$. By the definition of S, $x_e \leq \frac{5}{9}$ for $e \in S$. These facts yield Equation (30). ◀

Finding a maximum-weight matching in G_L. We note that since each vertex in G_L has degree at most 2 when $d = 2$, each connected component of G_L is a path or cycle. In this case a maximum-weight matching may be found in linear time by a dynamic programming algorithm.

4.2 Bounding the Quality of the Product State Solution

We have established performance bounds on the matching part of the rounding algorithm. The only remaining piece is a performance bound on the product state solution produced by the rounding algorithm, ρ_{PS}.

▶ **Lemma 18.** *Suppose v_e for $e \in E$ are values derived from the optimal solution to Lasserre$_2$, and set $x_e := -v_e$. Let $L := \{e \in E \mid x_e > \frac{5}{9} = \alpha(2)\}$ and let $S := E - L$. Then, with respect to the weights $w_e \geq 0$, the approximation algorithm from [9] produces a random product state ρ satisfying:*

$$\frac{\sum_{ij\in L} w_{ij}\mathbb{E}[\mathrm{Tr}((\mathbb{I} - X_iX_j - Y_iY_j - Z_iZ_j)\rho)]}{\sum_{ij\in L} w_{ij}(1+3x_{ij})} \geq 0.498766, \tag{34}$$

and

$$\frac{\sum_{ij\in S} w_{ij}\mathbb{E}[\mathrm{Tr}((\mathbb{I} - X_iX_j - Y_iY_j - Z_iZ_j)\rho)]}{\sum_{ij\in S} w_{ij}(1+3x_{ij})} \geq 0.557931. \tag{35}$$

Proof. Let M be the optimal solution to Lasserre$_2(G, w)$ produced by Algorithm 1. The product state approximation algorithm of [9] relies on a feasible solution to Lasserre$_1(G, w)$, which we may obtain from M. In particular the [9] algorithm takes as input the vectors $u(\Phi)$, from Equation (22), for $\Phi \in \mathcal{P}_n(1)$ and rounds them to a product state solution.

Let Γ and ${}_2F_1$ be the Gamma and Hyergeometric functions as they are normally defined [1]. The analysis of the [9] algorithm considers a worst-case edge $ij \in E$ and depends on the value $v_{ij} = -x_{ij}$. The worst-case approximation ratio is determined by the quantity

$$\min_{v_{ij} \in [-1, \frac{1}{3}]} \frac{1 - F(v_{ij})}{1 - 3v_{ij}}, \text{ where } F(t) = \frac{2}{3} \left(\frac{\Gamma(2)}{\Gamma(3/2)} \right)^2 {}_2F_1 \begin{bmatrix} 1/2 & 1/2 \\ 5/2 & \end{bmatrix} ; t^2 \Bigg]. \tag{36}$$

For more details see the paragraph above Section 4.1 in [9], where t in that paper is equal to v_{ij} in our terminology. The first inequality, Equation (34) is immediate because it is the worst case approximation factor for their algorithm.

The worst-case value of v_{ij} in Equation (36) is close to -1. We take advantage of the fact that $v_{ij} \geq -\alpha(2)$ for $ij \in S$, avoiding the worst case. In particular we get a ratio of:

$$\min_{v_{ij} \in [-\frac{5}{9}, \frac{1}{3}]} \frac{1 - F(v_{ij})}{1 - 3v_{ij}} = \frac{3}{8} (1 - F(5/9)) \geq 0.557931. \qquad \blacktriangleleft$$

Matching on the Line Admits No $o(\sqrt{\log n})$-Competitive Algorithm

Enoch Peserico

Michele Scquizzato ✉
Università degli Studi di Padova, Italy

Abstract

We present a simple proof that the competitive ratio of any randomized online matching algorithm for the line exceeds $\sqrt{\log_2(n+1)}/15$ for all $n = 2^i - 1 : i \in \mathbb{N}$, settling a 25-year-old open question.

1 Online matching, on the line

In *online metric matching* [7, 9] n points of a metric space are designated as *servers*. One by one n *requests* arrive at arbitrary points of the space; upon arrival each must be matched to a yet unmatched server, at a cost equal to their distance. Matchings should minimize the ratio between the total cost and the *offline* cost attainable if all requests were known beforehand. A matching algorithm is $c(n)$-*competitive* if it keeps this ratio no higher than $c(n)$ for all possible placements of servers and requests.

It is widely acknowledged [1, 10, 14] that the line is the most interesting metric space for the problem. Matching on the line models many scenarios, like a shop that must rent to customers skis of approximately their height, where a stream of requests must be serviced with minimally mismatched items from a known store. Despite matching being specifically studied on the line since at least 1996 [8], no tight competitiveness bounds are known.

As for upper bounds, the line is a doubling space and thus admits an $O(\log n)$-competitive randomized algorithm [5]; a sequence of recent developments [1, 12, 13] yielded the same ratio without randomization. Better bounds have been obtained only by algorithms with additional power, such as that to re-assign past requests [6, 11] or predict future ones [2].

As for lower bounds, the competitive ratio is at least 4.591 for randomized algorithms and 9 for deterministic ones since the *cow-path* problem is a special case of matching on the line [8]. These bounds were conjectured tight [8] until a complex adversarial strategy yielded a lower bound of 9.001 for deterministic algorithms [4]. Beyond some $\Omega(\log n)$ bounds for restricted classes of algorithms [3, 10, 12], there has been no further progress on the lower-bound side before this work.

2 An $\Omega(\sqrt{\log n})$-competitiveness bound

We prove a simple $\Omega(\sqrt{\log n})$ lower bound on the competitive ratio of randomized online matching algorithms for the line.

For any $n = 2^i - 1$ with $i \in \mathbb{N}$ consider the $[0, n{+}1]$ interval; for each positive integer $j \leq n$ place a server at point j, and place n requests over $\log_2(n{+}1)$ rounds as follows. On the r^{th} round (for $1 \leq r \leq \log_2(n{+}1)$) partition the interval into $(n{+}1)/2^r$ subintervals of length 2^r, choose within each uniformly and independently at random an *origin* point, and place a request on the closest integer multiple of 2^{-n} breaking ties arbitrarily. "Discretizing" requests instead of directly using the corresponding origins prevents some technical difficulties – see our remark at the end.

We prove in Lemma 1 that the expected distance between the ℓ^{th} leftmost server and the ℓ^{th} leftmost origin is $O(\sqrt{\log n})$, so servers and requests can be matched with an expected offline cost $O(n\sqrt{\log n})$. Conversely, we prove in Lemma 2 that *any* online matching algorithm ALG incurs an expected $\Omega(n)$ cost in any given round, for a total cost $\Omega(n \log n)$. The two results can be combined to prove that on *some* request sequence ALG incurs $\Omega(\sqrt{\log n})$ times the offline cost.

▶ **Lemma 1.** *The expected distance between the ℓ^{th} leftmost origin and the ℓ^{th} leftmost server is at most $\sqrt{\log_2(n{+}1)} + 3$.*

Proof. Let S_ℓ be ℓ^{th} leftmost server and g_ℓ be the number of origins to its left. Note that if g_ℓ equals respectively ℓ or $\ell - 1$, the ℓ^{th} origin is the first immediately to the left, or to the right of S_ℓ; and since the first round placed one origin in every subinterval of size 2, such an origin is within distance 3 of S_ℓ. By the same token, denoting by δ_ℓ the quantity $|g_\ell - (\ell - \frac{\ell}{n+1})|$, the ℓ^{th} leftmost origin is within distance $2\delta_\ell + 3$ of S_ℓ. Note that δ_ℓ is the absolute deviation from the mean of r_ℓ, since r_ℓ is the sum of n independent indicator random variables each denoting whether a given origin was placed to the left of S_ℓ, with total expectation $\frac{n}{n+1}\ell = \ell - \frac{\ell}{n+1}$ (by construction, the expected density of origins is constant throughout the main interval). At most one such variable in a given round has variance greater than 0, albeit obviously at most 1/4: that corresponding to the origin placed in a subinterval holding S_ℓ strictly in its interior. Adding the individual variances we obtain that the variance of r_ℓ, i.e. the expectation of δ_ℓ^2, is at most $\log_2(n{+}1)/4$; and since by Jensen's inequality $E[\delta_\ell] \leq E[\delta_\ell^2]^{\frac{1}{2}}$, the expected distance between S_ℓ and the ℓ^{th} leftmost origin is at most $\sqrt{\log_2(n{+}1)} + 3$. ◀

▶ **Lemma 2.** *Any randomized online matching algorithm incurs an expected cost greater than $(n{+}1)/12$ in each round.*

Proof. Consider an origin placed uniformly at random in a subinterval of size 2^r during the r^{th} round. Assume m unmatched servers in the interior points of that subinterval divide it into $m + 1$ segments of (integer) length $d_0, \ldots, d_m$. Then the probability the corresponding *request* falls within a segment of length d is $d/2^r$, in which case the expected distance of the *request* from the segment's closer endpoint is $d/4$. Adding over all the s_r segments in all the round's subintervals, applying Jensen's inequality, and noting that s_r does not exceed the number of subintervals (i.e. $(n{+}1)/2^r$) plus the total number of unmatched servers (i.e. $(n{+}1)/2^{r-1} - 1$), the expected cost to service all requests in the round is at least:

$$\sum_{h=1}^{s_r} \frac{d_h}{4} \cdot \frac{d_h}{2^r} \geq \frac{1}{4 \cdot 2^r} s_r \left(\frac{n{+}1}{s_r}\right)^2 > \frac{(n{+}1)^2}{4 \cdot 2^r} \cdot \frac{2^r}{3(n{+}1)} = \frac{n{+}1}{12}.$$ ◀

We can then easily prove the following:

▶ **Theorem.** *The competitive ratio of any randomized online matching algorithm for the line exceeds* $\sqrt{\log_2(n+1)}/15$ *for all* $n = 2^i - 1 : i \in \mathbb{N}$.

Proof. Let $C_A(\sigma)$ be the expected cost incurred by a randomized online matching algorithm ALG on a request sequence σ, and $C_O(\sigma)$ the offline cost; and let p_σ be the probability of generating σ through the origin-request process described earlier. Since $\forall a_i, b_i > 0$ we have that $(\sum_i a_i)/(\sum_i b_i)$ is a convex linear combination of the individual ratios a_i/b_i, focusing on the case $\sqrt{\log_2(n+1)}/15 \geq 1$ for which $\sqrt{\log_2(n+1)} + 3 + 2^{-n} < (5/4)\sqrt{\log_2(n+1)}$:

$$\max_{\sigma:p_\sigma\neq 0} \frac{C_A(\sigma)}{C_O(\sigma)} \geq \frac{\sum_{\sigma:p_\sigma\neq 0} C_A(\sigma)p_\sigma}{\sum_{\sigma:p_\sigma\neq 0} C_O(\sigma)p_\sigma} > \frac{(n+1)\log_2(n+1)/12}{n(\sqrt{\log_2(n+1)} + 3 + 2^{-n})} > \frac{\sqrt{\log_2(n+1)}}{15}. \qquad \blacktriangleleft$$

▶ Remark. Without discretized requests the term $\sum_{\sigma:p_\sigma\neq 0} C_A(\sigma)p_\sigma$ in the theorem's proof would have been an integral, potentially ill-defined (for example, if ALG serviced requests for rational points in an interval with one server and for irrational points with another).

Non-Mergeable Sketching for Cardinality Estimation

Seth Pettie
University of Michigan, Ann Arbor, MI, USA

Dingyu Wang
University of Michigan, Ann Arbor, MI, USA

Longhui Yin
Tsinghua University, Beijing, China

Abstract

Cardinality estimation is perhaps the simplest non-trivial statistical problem that can be solved via sketching. Industrially-deployed sketches like HyperLogLog, MinHash, and PCSA are *mergeable*, which means that large data sets can be sketched in a distributed environment, and then merged into a single sketch of the whole data set. In the last decade a variety of sketches have been developed that are *non-mergeable*, but attractive for other reasons. They are *simpler*, their cardinality estimates are *strictly unbiased*, and they have substantially *lower variance*.

We evaluate sketching schemes on a reasonably level playing field, in terms of their *memory-variance product* (MVP). E.g., a sketch that occupies $5m$ bits and whose relative variance is $2/m$ (standard error $\sqrt{2/m}$) has an MVP of 10. Our contributions are as follows.

- Cohen [14] and Ting [35] independently discovered what we call the *Martingale transform* for converting a mergeable sketch into a non-mergeable sketch. We present a simpler way to analyze the limiting MVP of Martingale-type sketches.
- Pettie and Wang proved that the Fishmonger sketch [31] has the best MVP, $H_0/I_0 \approx 1.98$, among a class of mergeable sketches called "linearizable" sketches. (H_0 and I_0 are precisely defined constants.) We prove that the Martingale transform is optimal in the non-mergeable world, and that Martingale Fishmonger in particular is optimal among linearizable sketches, with an MVP of $H_0/2 \approx 1.63$. E.g., this is circumstantial evidence that to achieve 1% standard error, we cannot do better than a 2 kilobyte sketch.
- Martingale Fishmonger is neither simple nor practical. We develop a new mergeable sketch called Curtain that strikes a nice balance between simplicity and efficiency, and prove that Martingale Curtain has limiting MVP ≈ 2.31. It can be updated with $O(1)$ memory accesses and it has lower empirical variance than Martingale LogLog, a practical non-mergeable version of HyperLogLog.

1 Introduction

Cardinality estimation[1] is a fundamental problem in streaming and sketching with diverse applications in databases [12, 21], network monitoring [5, 8, 39, 11], nearest neighbor search [33], caching [37], and genomics [30, 17, 38, 2]. In the ***sequential*** setting of this problem, we receive the elements of a multiset $\mathcal{A} = \{a_1, a_2, \ldots, a_N\}$ one at a time. We

[1] (aka F_0 estimation or *Distinct Elements*)

© Seth Pettie, Dingyu Wang, and Longhui Yin;
licensed under Creative Commons License CC-BY 4.0

maintain a small *sketch* S of the elements seen so far, such that the true cardinality $\lambda = |\mathcal{A}|$ is estimated by some $\hat{\lambda}(S)$. The ***distributed*** setting is similar, except that $\mathcal{A}$ is partitioned arbitrarily among several machines, the shares being sketched separately and combined into a sketch of $\mathcal{A}$. Only ***mergeable*** sketches are deployed in distributed settings; see Definition 2 below.

▶ **Definition 1.** *In the* RANDOM ORACLE MODEL $\mathcal{A} \subseteq [U]$ *and we have oracle access to a uniformly random permutation* $h : [U] \to [U]$ *(or a uniformly random hash function* $h : [U] \to [0, 1]$*). In the* STANDARD MODEL *we can generate random bits as necessary, but must explicitly store any hash functions in the sketch.*

▶ **Definition 2.** *Suppose* $\mathcal{A}^{(1)}, \mathcal{A}^{(2)}$ *are multisets such that* $\mathcal{A} = \mathcal{A}^{(1)} \cup \mathcal{A}^{(2)}$*. A sketching scheme is* **mergeable** *if, whenever,* $\mathcal{A}^{(1)}, \mathcal{A}^{(2)}$ *are sketched as* $S^{(1)}, S^{(2)}$ *(using the same* RANDOM ORACLE h *or the same source of random bits in the* STANDARD MODEL*), the sketch* S *of* $\mathcal{A}$ *can be computed from* $S^{(1)}, S^{(2)}$ *alone.*

STANDARD MODEL sketches [1, 3, 4, 6, 22, 27] usually make an (ϵ, δ)-guarantee, i.e.,

$$\Pr\left(\hat{\lambda} \notin [(1-\epsilon)\lambda, (1+\epsilon)\lambda]\right) < \delta.$$

The state-of-the-art STANDARD MODEL sketch [6, 27] uses $O(\epsilon^{-2} \log \delta^{-1} + \log U)$ bits, which is optimal at this level of specificity, as it meets the space lower bounds of $\Omega(\log U)$, $\Omega(\epsilon^{-2})$ (when $\delta = \Theta(1)$), and $\Omega(\epsilon^{-2} \log \delta^{-1})$ [1, 25, 26]. However, the leading constants hidden by [6, 27] are quite large.

In the RANDOM ORACLE MODEL the cardinality estimate $\hat{\lambda}$ typically has negligible bias, and errors are expressed in terms of the *relative variance* $\lambda^{-2} \cdot \mathrm{Var}(\hat{\lambda} \mid \lambda)$ or *relative standard deviation* $\lambda^{-1}\sqrt{\mathrm{Var}(\hat{\lambda} \mid \lambda)}$, also called the *standard error*. Sketches that use $\Omega(m)$ bits typically have relative variances of $O(1/m)$. Thus, the most natural way to measure the quality of the *sketching scheme* itself is to look at its limiting *memory-variance product* (MVP), i.e., the product of its memory and variance as $m \to \infty$.

Until about a decade ago, all STANDARD/RANDOM ORACLE sketches were mergeable, and suitable to both distributed and sequential applications. For reasons that are not clear to us, the idea of ***non-mergeable*** sketching was discovered independently by multiple groups [10, 24, 14, 35] at about the same time, and quite *late* in the 40-year history of cardinality estimation. Chen, Cao, Shepp, and Nguyen [10] invented the S-Bitmap in 2011, followed by Helmi, Lumbroso, Martínez, and Viola's[24] Recordinality in 2012. In 2014 Cohen [14] and Ting [35] independently invented what we call the *Martingale transform*, which is a simple, mechanical way to transform any mergeable sketch into a (better) non-mergeable sketch.[2]

In a companion paper [31], we analyzed the MVPs of *mergeable* sketches under the assumption that the sketch was compressed to its entropy bound. Fishmonger (an entropy compressed variant of PCSA with a different estimator function) was shown to have MVP $= H_0/I_0 \approx 1.98$, where

$$H_0 = (\ln 2)^{-1} + \sum_{k=1}^{\infty} k^{-1} \log_2(1 + 1/k) \qquad \text{and} \quad I_0 = \zeta(2) = \pi^2/6.$$

[2] Cohen [14] called these *Historical Inverse Probability* (HIP) sketches and Ting [35] applied the prefix *Streaming* to emphasize that they can be used in the single-stream setting, not the distributed setting.

Furthermore, H_0/I_0 was shown to be the minimum MVP among *linearizable* sketches, a subset of *mergeable* sketches that includes all the popular sketches (HyperLogLog, PCSA, MinHash, etc.).

Our aim in *this* paper is to build a useful framework for designing and analyzing *non-mergeable* sketching schemes, and, following [31], to develop a theory of space-variance optimality in the non-mergeable world. We work in the RANDOM ORACLE MODEL. Our results are as follows.

- Although the *Martingale transform* itself is simple, analyzing the variance of these sketches is not. For example, Cohen [14] and Ting [35] estimated the standard error of Martingale LogLog to be about $\approx \sqrt{3/(4m)} \approx 0.866/\sqrt{m}$ and about $\approx 1/(2\alpha_m m)$, respectively, where the latter tends to $\sqrt{\ln 2/m} \approx 0.8326/\sqrt{m}$ as $m \to \infty$.[3] We give a general method for determining the limiting relative variance of Martingale sketches that is strongly influenced by Ting's perspective.
- What is the most efficient (smallest MVP) non-mergeable sketch for cardinality estimation? The best Martingale sketches perform better than the *ad hoc* non-mergeable S-Bitmap and Recordinality, but perhaps there is a completely different, better way to systematically build non-mergeable sketches. We prove that up to some natural assumptions[4] the best non-mergeable sketch is a Martingale X sketch, for some X. Furthermore, we prove that Martingale Fishmonger, having MVP of $H_0/2 \approx 1.63$, is optimal among all Martingale X sketches, where X is *linearizable*. This provides some circumstantial evidence that Martingale Fishmonger is optimal, and that if we want, say, 1% standard error, we need to use a $H_0/2 \cdot (0.01)^{-2}$-bit sketch, ≈ 2 kilobytes.
- Martingale Fishmonger has an attractive MVP, but it is slow and cumbersome to implement. We propose a new mergeable sketch called Curtain that is "naturally" space efficient and easy to update in $O(1)$ memory accesses, and prove that Martingale Curtain has a limiting MVP ≈ 2.31.

1.1 Prior Work: Mergeable Sketches

Let S_i be the state of the sketch after processing $(a_1, \ldots, a_i)$.

The state of the PCSA sketch [20] is a 2D matrix $S \in \{0,1\}^{m \times \log U}$ and the hash function $h : [U] \to [m] \times \mathbb{Z}^+$ produces two indices: $h(a) = (j,k)$ with probability $m^{-1}2^{-k}$. $S_i(j,k) = 1$ iff $\exists i' \in [i].h(a_{i'}) = (j,k)$. Flajolet and Martin [20] proved that a certain estimator has standard error $0.78/\sqrt{m}$, making the MVP around $(0.78)^2 \log U \approx 0.6 \log U$.

Durand and Flajolet's LogLog sketch [16] consists of m counters. It interprets h exactly as in PCSA, and sets $S_i(j) = k$ iff k is maximum such that $\exists i' \in [i].h(a_{i'}) = (j,k)$. Durand and Flajolet's estimator is of the form $\hat{\lambda}(S) \propto m 2^{m^{-1}\sum_j S(j)}$ and has standard error $\approx 1.3/\sqrt{m}$. Flajolet, Fusy, Gandouet, and Meunier's HyperLogLog [19] is the same sketch but with the estimator $\hat{\lambda}(S) \propto m^2(\sum_j 2^{-S(j)})^{-1}$. They proved that it has standard error tending to $\approx 1.04/\sqrt{m}$. As the space is $m \log\log U$ bits, the MVP is $\approx 1.08 \log\log U$.

The MinCount sketch (aka MinHash or Bottom-m [13, 15, 7]) stores the smallest m hash values, which we assume requires $\log U$ bits each. Using an appropriate estimator [23, 9, 29], the standard error is $1/\sqrt{m}$ and MVP $= \log U$.

---

[3] Here $\alpha_m = \left(m \int_0^\infty \left(\log_2\left(\frac{2+u}{1+u}\right)\right)^m du\right)^{-1}$ is the coefficient of Flajolet et al.'s HyperLogLog estimator.

[4] (the sketch is insensitive to duplicates, and the estimator is unbiased)

It is straightforward to see that the entropy of PCSA and LogLog are both $\Theta(m)$. Scheuermann and Mauve [34] experimented with entropy compressed versions of PCSA and HyperLogLog and found PCSA to be slightly superior. Rather than use the given estimators of [20, 19, 16], Lang [28] used Maximum Likelihood-type Estimators and found entropy-compressed PCSA to be significantly better than entropy-compressed LogLog (with MLE estimators). Pettie and Wang [31] defined the Fisher-Shannon (Fish)[5] number of a sketch as the ratio of its Shannon entropy (controlling its entropy-compressed size) to its Fisher information (controlling the variance of a statistically efficient estimator), and proved that the Fish-number of any base-q PCSA is H_0/I_0, and that the Fish-number of base-q LogLog is worse, but tends to H_0/I_0 in the limit as $q \to \infty$. (The constants H_0, I_0 were defined earlier.)

Table 1 A selection of results on composable sketches (top) and non-composable Martingale sketches (bottom) in terms of their limiting memory-variance product (MVP). Logarithms are base 2.

Mergeable Sketch		Limiting MVP	Notes
PCSA	[20]	$.6 \log U \approx 38.9$	For $U = 2^{64}$
LogLog	[16]	$1.69 \log\log U \approx 10.11$	For $U = 2^{64}$
MinCount	[23, 9, 29]	$\log U = 64$	For $U = 2^{64}$
HyperLogLog	[19]	$1.08 \log\log U \approx 6.48$	For $U = 2^{64}$
Fishmonger	[31]	$H_0/I_0 \approx 1.98$	
Non-Mergeable Sketch			
S-Bitmap	[10]	$O(\log^2(U/m))$	
Recordinality	[24]	$O(\log(\lambda/m) \log U)$	
Martingale PCSA	**new**	$0.35 \log U \approx 22.4$	For $U = 2^{64}$
Martingale LogLog	[14, 35]	$0.69 \log\log U \approx 4.16$	For $U = 2^{64}$
Martingale MinCount	[14, 35]	$0.5 \log U = 32$	For $U = 2^{64}$
Martingale Fishmonger	**new**	$H_0/2 \approx 1.63$	$H_0 = (\ln 2)^{-1} + \sum_{k\geq 1} \frac{\log_2(1+1/k)}{k}$
Martingale Curtain	**new**	≈ 2.31	Theorem 4 with $(q, a, h) = (2.91, 2, 1)$
Non-Mergeable Lower Bound			
Martingale X	**new**	$\geq H_0/2$	X is a *linearizable* sketch

1.2 Prior Work: Non-Mergeable Sketches

Chen, Cao, Shepp, and Nguyen's S-Bitmap [10] consists of a bit string $S \in \{0,1\}^m$ and m known constants $0 \leq \tau_0 < \tau_1 < \cdots < \tau_{m-1} < 1$. It interprets $h(a) = (j, \rho) \in [m] \times [0,1]$ as an index j and real ρ and when processing a, sets $S(j) \leftarrow 1$ iff $\rho > \tau_{\text{HammingWeight}(S)}$. One may confirm that S is insensitive to duplicates in the stream $\mathcal{A}$, but its state depends on the *order* in which $\mathcal{A}$ is scanned. By setting the τ-thresholds and estimator properly, the standard error is $\approx \ln(eU/m)/(2\sqrt{m})$ and $\text{MVP} = O(\log^2(U/m))$.

Recordinality [24] is based on MinCount; it stores (S, cnt), where S is the m smallest hash values encountered and cnt is the *number of times* that S has changed. The estimator looks only at cnt, not S, and has standard error $\approx \sqrt{\ln(\lambda/em)/m}$ and $\text{MVP} = O(\log(\lambda/m) \log U)$.

[5] Fish is essentially the same as MVP, under the assumption that the sketch state is compressed to its entropy.

Cohen [14] and Ting [35] independently described how to turn any sketch into a non-mergeable sketch using what we call the Martingale transform. Let S_i be the state of the original sketch after seeing $(a_1, \ldots, a_i)$ and $P_{i+1} = \Pr(S_{i+1} \neq S_i \mid S_i, a_{i+1} \notin \{a_1, \ldots, a_i\})$ be the probability that it changes state upon seeing a *new* element a_{i+1}.[6] The state of the Martingale sketch is $(S_i, \hat{\lambda}_i)$. Upon processing a_{i+1} it becomes $(S_{i+1}, \hat{\lambda}_{i+1})$, where

$$\hat{\lambda}_{i+1} = \hat{\lambda}_i + P_{i+1}^{-1} \cdot \left[\!\left[S_{i+1} \neq S_i \right]\!\right].$$

Here $\left[\!\left[\mathcal{E}\right]\!\right]$ is the indicator variable for the event $\mathcal{E}$. We assume the original sketch is insensitive to duplicates, so

$$\mathbb{E}(\hat{\lambda}_{i+1}) = \begin{cases} \hat{\lambda}_i & \text{when } a_{i+1} \in \{a_1, \ldots, a_i\} \text{ (and hence } S_{i+1} = S_i) \\ \hat{\lambda}_i + 1 & \text{when } a_{i+1} \notin \{a_1, \ldots, a_i\}. \end{cases}$$

Thus, with $\hat{\lambda}_0 = \lambda_0 = 0$, $\hat{\lambda}_i$ is an unbiased estimator of the true cardinality $\lambda_i = |\{a_1, \ldots, a_i\}|$ and $(\hat{\lambda}_i - \lambda_i)_i$ is a *martingale*. The Martingale-transformed sketch requires the same space, plus just $\log U$ bits to store the estimate $\hat{\lambda}$.

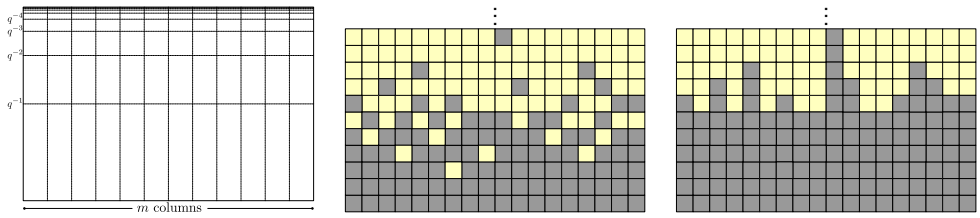
Cohen and Ting [14, 35] both proved that Martingale MinCount has standard error $1/(2\sqrt{m})$ and MVP $= (\log U)/2$. They gave different estimates for the standard error of Martingale LogLog. Ting's estimate is quite accurate, and tends to $\sqrt{\ln 2/m}$ as $m \to \infty$, giving it an MVP $= \ln 2 \log\log U \approx 0.69 \log\log U$.

▶ Remark 3. We call Martingale sketches *non-mergeable* because, in a distributed environment, there is no obvious way to merge the cardinality estimates $(\hat{\lambda})$. On the other hand, Ting [36] has shown that if $(S^A, \hat{\lambda}^A)$ and $(S^B, \hat{\lambda}^B)$ are Martingale MinCount sketches obtained by sequentially processing A and B, that $\hat{\lambda}^A, \hat{\lambda}^B$ carry useful information for estimating $|A \cup B|$ and $|A \cap B|$ beyond that contained in S^A, S^B.

1.3 The Dartboard Model

The ***dartboard model*** [31] is useful for describing cardinality sketches with a single, uniform language. The dartboard model is essentially the same as Ting's [35] *area cutting* process, but with a specific, discrete cell partition and state space fixed in advance.

The *dartboard* is the unit square $[0,1]^2$, partitioned into a set $\mathcal{C} = \{c_0, \ldots, c_{|\mathcal{C}|-1}\}$ of *cells* of various sizes. Every cell may be either *occupied* or *unoccupied*; the *state* is the set of occupied cells and the state space some $\mathcal{S} \subseteq 2^{\mathcal{C}}$.



We process a stream of elements one by one; when a *new* element is encountered we throw a *dart* uniformly at random at the dartboard and update the state in response. The relationship between the state and the dart distribution satisfies two rules:

(R1) Every cell with at least one dart is occupied; occupied cells may contain no darts.

(R2) If a dart lands in an occupied cell, the state does not change.

As a consequence of (R1) and (R2), if a dart lands in an empty cell the state *must* change, and occupied cells may never become unoccupied. Dart throwing is merely an intuitive way of visualizing the hash function. Base-q PCSA and LogLog use the same cell partition but with different state spaces; see Figure 1.

[6] These probabilities are over the choice of $h(a_{i+1})$, which, in the RANDOM ORACLE MODEL, is independent of all other hash values.

(a) (b) (c)

Figure 1 The unit square is partitioned into m columns. Each column is partitioned into cells. Cell j covers the vertical interval $[q^{-(j+1)}, q^{-j})$. (b) The state of a PCSA sketch records precisely which cells contain a dart (gray); all others are empty (yellow). (c) The state of the corresponding LogLog sketch.

It was observed [31] that the dartboard model includes all mergeable sketches, and some non-mergeable ones like S-Bitmap. Recordinality and the Martingale sketches obey rules (R1),(R2) but are not strictly dartboard sketches as they maintain some small state information (cnt or $\hat{\lambda}$) outside of the set of occupied cells. Nonetheless, it is useful to speak of the *dartboard part* of their state information.

1.4 Linearizable Sketches

The lower bound of [31] applies to *linearizable* sketches, a subset of mergeable sketches. A sketch is called linearizable if it is possible to encode the occupied/unoccupied status of its cells in some fixed linear order $(c_0, \ldots, c_{\mathcal{C}-1})$, so whether c_i is occupied only depends on the status of $c_0, \ldots, c_{i-1}$ and whether c_i has been hit by a dart. (Thus, it is independent of $c_{i+1}, \ldots, c_{\mathcal{C}-1}$.) Specifically, let Y_i, Z_i be the indicators for whether c_i is occupied, and has been hit by a dart, respectively, and $\mathbf{Y}_i = (Y_0, \ldots, Y_i)$. The state of the sketch is $\mathbf{Y}_{\mathcal{C}-1}$; it is called linearizable if there is some monotone function $\phi : \{0,1\}^* \to \{0,1\}$ such that

$$Y_i = Z_i \vee \phi(\mathbf{Y}_{i-1}).$$

I.e., if $\phi(\mathbf{Y}_{i-1}) = 1$, c_i is forced to be occupied and the state is forever independent of Z_i.

PCSA-type sketches [20, 18] are linearizable, as are (Hyper)LogLog [19, 16], and all MinCount, MinHash, and Bottom-m type sketches [13, 7, 23, 9, 29]. It is very easy to engineer non-linearizable sketches; see [31]. The open problem is whether this is ever a *good idea* in terms of memory-variance performance.

1.5 Organization

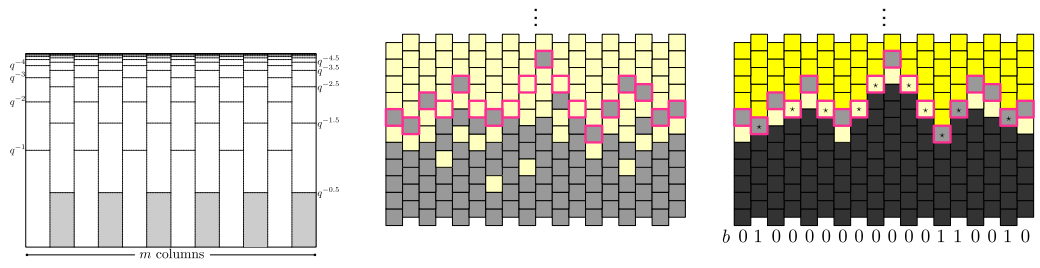
In Section 2 we introduce the Curtain sketch, which is a linearizable (hence mergeable) sketch in the dartboard model. In Section 3 we prove some general theorems on the bias and asymptotic relative variance of Martingale-type sketches, and in Section 4 we apply this framework to bound the limiting MVP of Martingale PCSA, Martingale Fishmonger, and Martingale Curtain.

In Section 5 we prove some results on the optimality of the Martingale transform itself, and that Martingale Fishmonger has the lowest variance among those based on linearizable sketches.

Section 6 presents some experimental findings that demonstrate that the conclusions drawn from the asymptotic analysis of Martingale sketches are extremely accurate in the pre-asymptotic regime as well, and that Martingale Curtain has lower variance than Martingale LogLog.

All the missing proofs can be found in the full version [32].

2 The Curtain Sketch



Design Philosophy

Our goal is to strike a nice balance between the simplicity and time-efficiency of (Hyper)LogLog, and the superior information-theoretic efficiency of PCSA, which can only be fully realized under extreme (and time-inefficient) compression to its entropy bound [31, 28]. Informally, if we are dedicating at least 1 bit to encode the status of a cell, the *best* cells to encode have mass $\Theta(\lambda^{-1})$ and we should design a sketch that maximizes the number of such cells encoded.

We assume the dartboard is partitioned into m columns; define $\mathrm{Cell}(j,i)$ to be the cell in column i covering the vertical interval $[q^{-(j+1)}, q^{-j})$. In a PCSA sketch, the occupied cells are precisely those with at least one dart. In LogLog, the occupied cells in each column are contiguous, extending to the highest cell containing a dart. In Figure 1, cells are drawn with uniform sizes for clarity.

Consider the vector $v = (g_0, g_1, \ldots, g_{m-1})$ where $\mathrm{Cell}(g_i, i)$ is the highest occupied cell in LogLog/PCSA. The *curtain* of v w.r.t. allowable offsets $\mathcal{O}$ is a vector $v_{\mathrm{curt}} = (\hat{g}_0, \hat{g}_1, \ldots, \hat{g}_{m-1})$ such that (i) $\forall i \in [1, m-1].\ \hat{g}_i - \hat{g}_{i-1} \in \mathcal{O}$, and (ii) v_{curt} is the minimal such vector dominating v, i.e., $\forall i.\ \hat{g}_i \geq g_i$. Although we have described v_{curt} as a function of v, it is clearly possible to maintain v_{curt} as darts are thrown, without knowing v.

We have an interest in $|\mathcal{O}|$ being a power of 2 so that curtain vectors may be encoded efficiently, as a series of offsets. On the other hand, it is most efficient if $\mathcal{O}$ is symmetric around zero. For these reasons, we use a base-q "sawtooth" cell partition of the dartboard; see Figure 2. Henceforth $\mathrm{Cell}(j,i)$ is defined as usual, except j is an integer when i is even and a half-integer when i is odd. Then the allowable offsets are $\mathcal{O}_a = \{-(a-1/2), -(a-3/2), \ldots, -1/2, 1/2, \ldots, a-3/2, a-1/2\}$, for some a that is a power of 2.

(a) (b) (c)

Figure 2 (a) The base-q "sawtooth" cell partition. (b) and (c) depict a Curtain sketch w.r.t. $\mathcal{O} = \{-3/2, -1/2, 1/2, 3/2\}$ and $h = 1$. (b) Gray cells contain at least one dart; light yellow cells contain none. The curtain $v_{\mathrm{curt}} = (\hat{g}_i)$ is highlighted with a pink boundary. (c) Columns that are in *tension* have a $\star$ in their curtain cell. All *dark* gray cells are occupied and all *dark* yellow cells are free according to Rule 3. All other cells are occupied/free (light gray, light yellow) according to Rules 1 and 2.

Let $\mathrm{Cell}(g_i, i)$ be the highest cell containing a dart in column i in the *sawtooth* cell partition and $v_{\mathrm{curt}} = (\hat{g}_i)$ be the curtain vector of $v = (g_i)$ w.r.t. offsets $\mathcal{O} = \mathcal{O}_a$. We say column i is *in tension* if $(\cdots, \hat{g}_{i-1}, \hat{g}_i - 1, \hat{g}_{i+1}, \cdots)$ is not a valid curtain, i.e., if $\hat{g}_i - \hat{g}_{i-1} = \min(\mathcal{O})$ or $\hat{g}_{i+1} - \hat{g}_i = \max(\mathcal{O})$. In particular, if column i is *not* in tension, then $\mathrm{Cell}(\hat{g}_i, i)$ must contain at least one dart, for if it contained no darts the curtain would be dropped to $\hat{g}_i - 1$ at column i. However, if column i *is* in tension, then $\mathrm{Cell}(\hat{g}_i, i)$ might not contain a dart.

The Curtain sketch encodes $v_{\mathrm{curt}} = (\hat{g}_i)$ w.r.t. the base-q sawtooth cell partition and offsets $\mathcal{O}_a$, and a bit-array $b = \{0,1\}^{h \times m}$. This sketch designates each cell *occupied* or *free* as follows.

Rule 1. If column i is not in tension then $\mathrm{Cell}(\hat{g}_i, i)$ is occupied, and $b(\cdot, i)$ encodes the status of the h cells below the curtain, i.e., $\mathrm{Cell}(\hat{g}_i - (j+1), i)$ is occupied iff $b(j,i) = 1$, $j \in \{0, \ldots, h-1\}$.

Rule 2. If column i is in tension, then $\mathrm{Cell}(\hat{g}_i - j, i)$ is occupied iff $b(j,i) = 1$, $j \in \{0, \ldots, h-1\}$.

Rule 3. Every cell above the curtain is free ($\mathrm{Cell}(\hat{g}_i + j, i)$, when $j \geq 1$) and all remaining cells are occupied.

Figure 2 gives an example of a Curtain sketch, with $\mathcal{O} = \{-3/2, -1/2, 1/2, 3/2\}$ and $h = 1$. (The base q of the cell partition is unspecified in this example.)

▶ **Theorem 4.** *Consider the Martingale Curtain sketch with parameters q, a, h (base q, $\mathcal{O}_a = \{-(a-1/2), \ldots, a-1/2\}$, and $b \in \{0,1\}^{h \times m}$), and let $\hat{\lambda}$ be its estimate of the true cardinality λ.*

1. *$\hat{\lambda}$ is an unbiased estimate of λ.*
2. *The relative variance of $\hat{\lambda}$ is:*

$$\frac{1}{\lambda^2}\operatorname{Var}(\hat{\lambda} \mid \lambda) = \frac{(1 + o_{\lambda/m}(1) + o_m(1))q \ln q}{2m(q-1)} \left(\frac{q-1}{q} + \frac{2}{q^h(q^{a-1/2}-1)} + \frac{1}{q^{h+1}} \right),$$

As a result, the limiting MVP of Martingale Curtain is

$$\mathit{MVP} = (\log_2(2a) + h) \times \frac{q \ln q}{2(q-1)} \left(\frac{q-1}{q} + \frac{2}{q^h(q^{a-1/2}-1)} + \frac{1}{q^{h+1}} \right).$$

Proof. Follows from Theorems 11 and 17. ◀

Here $o_{\lambda/m}(1)$ and $o_m(1)$ are terms that go to zero as m and λ/m get large. Recall that for practical reasons we want to parameterize Theorem 4 with a a power of 2 and h an integer, but it is realistic to set $q > 1$ to be any real. Given these constraints, the optimal setting is $q = 2.91$, $a = 2$, and $h = 1$, exactly as in the example in Figure 2. This uses $\log\log U + 3(m-1)$ bits to store the sketch proper, $\log U$ bits[7] to store $\hat{\lambda}$, and achieves a limiting MVP ≈ 2.31. In other words, to achieve a standard error $1/\sqrt{b}$, we need about $2.31b$ bits.

Implementation Considerations

We encode a curtain $(\hat{g}_0, \hat{g}_1, \ldots, \hat{g}_{m-1})$ as $\hat{g}_0$ and an offset vector $(o_1, o_2, \ldots, o_{m-1})$, $o_i = \hat{g}_i - \hat{g}_{i-1}$, where $\hat{g}_0$ takes $\log_2 \log_q U \leq 6$ bits and o_i takes $\log_2 |\mathcal{O}| = \log_2(2a)$ bits. Clearly, to evaluate $\hat{g}_i$ we need to compute the prefix sum $\hat{g}_0 + \sum_{i' \leq i} o_{i'}$.

[7] It is fine to store an approximation $\tilde{\lambda}$ of $\hat{\lambda}$ with $O(\log m)$ bits of precision.

▶ **Lemma 5.** *Let $(x_0, \ldots, x_{\ell-1})$ be a vector of t-bit unsigned integers packed into $\lceil t\ell/w \rceil$ words, where each word has $w = \Omega(\log(t\ell))$ bits. The prefix sum $\sum_{j\in[0,i]} x_j$ can be evaluated in $O(t\ell/w + \log w)$ time.*

Proof. W.l.o.g. we can assume $i = \ell - 1$, so the task is to sum the entire list. In $O(\lceil (t\ell)/w \rceil)$ time we can halve the number of summands, by masking out the odd and even summands and adding these vectors together. After halving twice in this way, we have a vector of $\ell/4$ $(t+2)$-bit integers, each allocated $4t$ bits. At this point we can halve the number of words by adding the $(2i+1)$th word to the $2i$th word. Thus, if $T_w(\ell, t)$ is the time needed to solve this problem, $T_w(\ell, t) = T_w(\ell/8, 4t) + O(\lceil (t\ell)/w \rceil)$, which is $O((t\ell)/w + \log w)$. ◀

In our context $t = \log_2(2a) = 2$, so even if m is a medium-size constant, say at most 256 or 512, we only have to do prefix sums over 8 or 16 consecutive 64-bit words. If m is much larger then it would be prudent to partition the dartboard into m/c independent curtains, each with $c = 256$ or 512 columns. This keeps the update time independent of m and increases the space overhead negligibly.

We began this section by highlighting the design philosophy, which emphasizes conceptual simplicity and efficiency. Our encoding uses fixed-length codes for the offsets, and can be decoded very efficiently by exploiting bit-wise operations and word-level parallelism. That said, we are mainly interested in analyzing the *theoretical* performance of sketches, and will not attempt an exhaustive experimental evaluation in this work.

3 Foundations of the Martingale Transform

In this section we present a simple framework for analyzing the limiting variance of Martingale sketches, which is strongly influenced by Ting's [35] work. Theorem 7 gives simple unbiased estimators for the cardinality and the variance of the the cardinality estimator. The upshot of Theorem 7 is that to analyze the variance of the estimator, we only need to bound $\mathbb{E}(P_k^{-1})$, where P_k is the probability the kth distinct element changes the sketch. Theorem 11 further shows that for sketches composed of m subsketches (like Curtain, HyperLogLog, and PCSA), the limiting variance tends to $\frac{1}{2\kappa m}$, where κ is a constant that depends on the sketch scheme. Section 4 analyzes the constant κ for each of PCSA, LogLog, and Curtain. Using results of [31] on the entropy of PCSA we can calculate the limiting MVP of PCSA, LogLog, Curtain, and Fishmonger.

3.1 Martingale Estimators and Retrospective Variance

Consider an arbitrary sketch with state space $\mathcal{S}$. We assume the sketch state does not change upon seeing duplicated elements, hence it suffices to consider streams of *distinct* elements. We model the evolution of the sketch as a Markov chain $(S_k)_{k\geq 0} \in \mathcal{S}^*$, where S_k is the state after seeing k *distinct* elements. Define $P_k = \Pr(S_k \neq S_{k-1} \mid S_{k-1})$ to be the *state changing probability*, which depends only on S_{k-1}. In the dartboard terminology P_k is the total size of all unoccupied cells in S_{k-1}.

▶ **Definition 6.** *Let* $[\![\mathcal{E}]\!]$ *be the indicator variable for event* $\mathcal{E}$*. For any* $\lambda \geq 0$*, define:*

$$E_\lambda = \sum_{k=1}^{\lambda} [\![S_k \neq S_{k-1}]\!] \cdot \frac{1}{P_k}, \qquad \textit{the martingale estimator,}$$

$$\textit{and } V_\lambda = \sum_{k=1}^{\lambda} [\![S_k \neq S_{k-1}]\!] \cdot \frac{1-P_k}{P_k^2}, \qquad \textit{the "retrospective" variance.}$$

Note that $E_0 = V_0 = 0$*.*

The Martingale transform of this sketch stores $\hat{\lambda} = E_\lambda$ in one machine word and returns it as a cardinality estimate. It can also store V_λ in one machine word as well. Theorem 7 shows[8] that the retrospective variance V_λ is a good running estimate of the empirical squared error $(E_\lambda - \lambda)^2$.

▶ **Theorem 7.** *The martingale estimator* E_λ *is an unbiased estimator of* λ *and the retrospective variance* V_λ *is an unbiased estimator of* $\mathrm{Var}(E_\lambda)$*. Specifically, we have,*

$$\mathbb{E}(E_\lambda) = \lambda, \textit{ and } \mathrm{Var}(E_\lambda) = \mathbb{E}(V_\lambda) = \sum_{k=1}^{\lambda} \mathbb{E}\left(\frac{1}{P_k}\right) - \lambda.$$

▶ Remark 8. Theorem 7 contradicts Ting's claim [35], that V_λ is unbiased *only at "jump" times*, i.e., those λ for which $S_\lambda \neq S_{\lambda-1}$, and therefore inadequate to estimate the variance. In order to correct for this, Ting introduced a Bayesian method for estimating the time that has passed since the last jump time. The reason for thinking that jump times are different is actually quite natural. Suppose we record the list of *distinct* states $s_0, \ldots, s_k$ encountered while inserting λ elements, λ being unknown, and let p_i be the probability of changing from s_i to some other state. The amount of time spent in state s_i is a geometric random variable with mean p_i^{-1} and variance $(1-p_i)/p_i^2$. Furthermore, these waiting times are independent. Thus, $\sum_{i\in[0,k)} p_i^{-1}$ and $\sum_{i\in[0,k)}(1-p_i^{-1})/p_i^2$ are unbiased estimates of the cardinality λ' and squared error *upon entering state* s_k. These exactly correspond to E_λ and V_λ, but they *should* be biased since they do not take into account the $\lambda - \lambda'$ elements that had no effect on s_k. As Theorem 7 shows, this is a mathematical optical illusion. The history is a random variable, and although the last $\lambda - \lambda'$ elements did not change the state, *they could have*, which would have altered the observed history $s_0, \ldots, s_k$ and hence the estimates E_λ and V_λ.

3.2 Asymptotic Relative Variance

3.2.1 The ARV Factor

We consider classes of sketches composed of m *subsketches*, which controls the size and variance. In LogLog, PCSA, and Curtain these subsketches are the m columns. When considering a sketch with m subsketches, instead of using λ as the total number of insertions, we always use λ to denote the number of insertions *per subsketch* and therefore the total number of insertions is λm. We care about the *asymptotic relative variance* (ARV) as m and λ both go to infinity (defined below). A reasonable sketch should have relative variance $O(1/m)$. Informally, the ARV factor is just the leading constant of this expression.

[8] The proof can be found in the full version [32].

▶ **Definition 9** (ARV factor). *Consider a class of sketches whose size is parameterized by m. For any $k \geq 0$, define $P_{m,k}$ to be the probability the sketch changes state upon the kth insertion and $E_{m,k}$ the martingale estimator. The* ARV factor *of this class of sketches is defined as*

$$\lim_{\lambda\to\infty} \lim_{m\to\infty} m \cdot \frac{\mathrm{Var}(E_{m,\lambda m})}{(\lambda m)^2}. \tag{1}$$

3.2.2 Scale-Invariance and the Constant κ

Few sketches have *strictly* well-defined ARV factors. In Martingale LogLog, for example, the quantity $\left(\lim_{m\to\infty} m\frac{\mathrm{Var}(E_{m,\lambda m})}{(\lambda m)^2}\right)$ is not constant, but periodic in $\log_2 \lambda$; it does not converge as $\lambda \to \infty$. We explain how to fix this issue using *smoothing* in Section 3.2.3. *Scale-invariant* sketches must have well-defined ARV factors.

▶ **Definition 10** (scale-invariance and constant κ). *A combined sketch is* scale-invariant *if*

1. *For any λ, there exists a constant κ_λ such that $\lambda \cdot P_{m,\lambda m}$ converges to κ_λ almost surely as $m \to \infty$.*
2. *The limit of κ_λ as $\lambda \to \infty$ exists, and $\kappa \stackrel{\text{def}}{=} \lim_{\lambda\to\infty} \kappa_\lambda$.*

The constant of a sketch A is denoted as κ_A, where the subscript A is often dropped when the context is clear.

The next theorem proves that under mild regularity conditions, all scale-invariant sketches have well defined ARV factors and there is a direct relation between the ARV factor and the constant κ.

▶ **Theorem 11** (ARV factor of a scale-invariant sketch). *Consider a sketching scheme satisfying the following properties.*

1. *It is scale-invariant with constant κ.*
2. *For any $\lambda > 0$, the limit operator and the expectation operator of $\{\frac{1}{P_{m,\lambda m}}\}_m$ can be interchanged.*

Then the ARV factor of the sketch exists and equals $\frac{1}{2\kappa}$.

The constant κ together with Theorem 11 is useful in that it gives a simple and systematic way to evaluate the asymptotic performance of a well behaved (scale-invariant) sketch scheme.

MinCount [23, 9, 29] is an example of a scale-invariant sketch. The function $h(a) = (i, v) \in [m] \times [0, 1]$ is interpreted as a pair containing a bucket index and a real hash value. A (k, m)-MinCount sketch stores the smallest k hash values in each bucket.

▶ **Theorem 12.** *(k, m)-MinCount is scale-invariant and $\kappa_{(k,m)\text{-MinCount}} = k$.*

Proof. When a total of λm elements are inserted to the combined sketch, each subsketch receives $(1 + o(1))\lambda$ elements as $\lambda \to \infty$. Since we only care the asymptotic behavior, we assume for simplicity that each subsketch receives exactly λ elements.

Let $P_\lambda^{(i)}$ be the probability that the sketch of the ith bucket changes after the λth element is thrown into the ith bucket. Then by definition, we have

$$P_{m,\lambda m} = \frac{\sum_{i=1}^m P_\lambda^{(i)}}{m}.$$

Since all the subsketches are i.i.d., by the law of large numbers, $\lambda \cdot P_{m,\lambda} \to \lambda \cdot \mathbb{E}\left(P_\lambda^{(1)}\right)$ almost surely as $m \to \infty$.

Let X be the kth smallest hash value among λ uniformly random numbers in $[0,1]$, which distributes identically with $P_\lambda^{(1)}$. By standard order statistics, X is a Beta random variable $\mathrm{Beta}(k, \lambda - 1 + k)$ which has mean $\frac{k}{\lambda+1}$. Thus $\kappa_\lambda = \lambda \cdot \mathbb{E}(X) = \frac{k\lambda}{\lambda+1}$. We conclude that

$$\kappa = \lim_{\lambda\to\infty} \kappa_\lambda = \lim_{\lambda\to\infty} \frac{k\lambda}{\lambda+1} = k. \qquad \blacktriangleleft$$

Applying Theorem 11 to (k,m)-MinCount, we see its ARV is $\frac{1}{2km}$,[9] matching Cohen [14] and Ting [35]. Technically its MVP is unbounded since hash values were real numbers, but any realistic implementation would store them to $\log U$ bits of precision, for a total of $km \log U$ bits. Hence we regard its MVP to be $\frac{1}{2} \cdot \log_2 U$.

3.2.3 Smoothing Discrete Sketches

Sketches that partition the dartboard in some exponential fashion with base q (like LogLog, PCSA, and Curtain) have the property that their estimates and variance are periodic in $\log_q \lambda$. Pettie and Wang [31] proposed a simple method to *smooth* these sketches and make them truly scale-invariant as $m \to \infty$.

We assume that the dartboard is partitioned into m columns. The base-q *smoothing* operation uses an *offset vector* $\vec{r} = (r_0, \ldots, r_{m-1})$. We scale down all the cells in column i by the factor q^{-r_i}, then add a dummy cell spanning $[q^{-r_i}, 1)$ which is always occupied. (Phrased algorithmically, if a dart is destined for column i, we filter it out with probability $1 - q^{-r_i}$ and insert it into the sketch with probability q^{-r_i}.) When analyzing variants of (Hyper)LogLog and PCSA, we use the uniform offset vector $(0, 1/m, 2/m, \ldots, (m-1)/m)$. The Curtain sketch can be viewed as having a built-in offset vector of $(0, 1/2, 0, 1/2, 0, 1/2, \ldots)$ which effects the "sawtooth" cell partition. To smooth it, we use the offset vector[10]

$$(0,\ 1/2,\ 1/m,\ 1/2+1/m,\ 2/m,\ 1/2+2/m,\ \ldots,\ 1/2-1/m,\ 1-1/m).$$

As $m \to \infty$, $\vec{r}$ becomes uniformly dense in $[0,1]$.

The smoothing technique makes the empirical estimation more scale-invariant (see [31, Figs. 1& 2]) but also makes the sketch theoretically scale-invariant according to Definition 10. Thus, in the analysis, we will always assume the sketches are smoothed. However, in practice it is probably not necessary to do smoothing if $q < 3$.

In the next section, we will prove that *smoothed* q-LL, q-PCSA, and Curtain are all scale-invariant.

4 Analysis of Dartboard Based Sketches

Consider a dartboard cell that covers the vertical interval $[q^{-(t+1)}, q^{-t})$. We define the *height* of the cell to be t. In a smoothed cell partition, no two cells have the same height and all heights are of the form $t = j/m$, for some integer j. Thus, we may refer to it unambiguously as *cell* t. Note that cell t is an $m^{-1} \times \frac{1}{q^t}\frac{q-1}{q}$ rectangle.

[9] For simplicity, we assume the second condition of Theorem 4 holds for all the sketches analyzed in this paper.

[10] In [31], the smoothing was implemented via *random* offsetting, instead of the *uniform* offsetting. In Curtain we need to use uniform offsetting so that the offset values of columns are similar to their neighbors.

4.1 Poissonized Dartboard

Since we care about the asymptotic case where $\lambda \to \infty$, we model the process of "throwing darts" by a Poisson point process on the dart board (similar to the "poissonization" in the analysis of HyperLogLog [19]). Specifically, after throwing λm darts (events) to the dartboard, we assume the number of darts in cell t is a Poisson random variable with mean $\lambda \frac{1}{q^t}\frac{q-1}{q}$ and the number of darts in different cells are independent. For the poissonized dartboard, the range of height of cells naturally extend to the whole set of real numbers, instead of just having cells with positive height.

For any $t \in \mathbb{R}$, let $Y_{t,\lambda}$ be the indicator whether cell t contains at least one dart. Note that the probability that a Poisson random variable with mean λ' is zero is $e^{-\lambda'}$. Thus we have,

$$\Pr(Y_{t,\lambda} = 0) = e^{-\frac{\lambda}{q^t}\frac{q-1}{q}}.$$

Here, we note some simple identities for integrals that we will use frequently in the analysis.

▶ **Lemma 13.** *For any $q > 1$, we have*

$$\int \frac{1}{q^t} e^{-\frac{1}{q^t}}\, dt = \frac{1}{\ln q} e^{-\frac{1}{q^t}} + C.$$

Furthermore, let c_0, c_1 be any positive numbers, we have

$$\int_{-\infty}^{\infty} \frac{c_0}{q^t} e^{-\frac{c_1}{q^t}}\, dt = \frac{c_0}{c_1}\frac{1}{\ln q}.$$

4.2 The Constant κ

Let $Z_{t,\lambda}$ be the indicator of whether the cell t is *free*. Unlike $Y_{t,\lambda}$, $Z_{t,\lambda}$ depends on which sketching algorithm we are analyzing. Since the state changing probability is equal to the sum of the area of free cells, we have

$$P_{m,\lambda m} = \sum_{j=0}^{\infty} \frac{1}{m}\left(\frac{1}{q^{j/m}} - \frac{1}{q^{j/m+1}}\right) Z_{j/m,\lambda}. \tag{2}$$

If $P_{m,\lambda m}$ converges to κ_λ/λ almost surely as $m \to \infty$, then $\mathbb{E}(P_{m,\lambda m})$ also converges to κ_λ/λ as $m \to \infty$. Thus we have, from (2),

$$\begin{aligned}\kappa_\lambda/\lambda &= \lim_{m\to\infty} \mathbb{E}(P_{m,\lambda m}) = \lim_{m\to\infty} \sum_{j=0}^{\infty} \frac{1}{m}\left(\frac{1}{q^{j/m}} - \frac{1}{q^{j/m+1}}\right)\mathbb{E}(Z_{j/m,\lambda}) \\ &= \int_0^{\infty}\left(\frac{1}{q^t} - \frac{1}{q^{t+1}}\right)\mathbb{E}(Z_{t,\lambda})dt \approx \int_{-\infty}^{\infty}\left(\frac{1}{q^t} - \frac{1}{q^{t+1}}\right)\mathbb{E}(Z_{t,\lambda})dt, \end{aligned} \tag{3}$$

where we can extend the integration range to negative infinity without affecting the limit of κ_λ as $\lambda \to \infty$.[11] We conclude that

$$\kappa = \lim_{\lambda\to\infty} \kappa_\lambda = \lim_{\lambda\to\infty} \lambda \int_{-\infty}^{\infty}\left(\frac{1}{q^t} - \frac{1}{q^{t+1}}\right)\mathbb{E}(Z_{t,\lambda})dt. \tag{4}$$

The formula (4) is novel in the sense that, in order to evaluate κ, we now only need to understand the probability that $Z_{t,\lambda}$ is 1 for fixed t and λ.[12]

[11] See [32].

[12] Technically, to apply formula (4) one needs to first prove that the state changing probability $P_{m,\lambda m}$ converges almost surely to some constant κ_λ/λ for any λ, which is a mild regularity condition for any reasonable sketch. Thus in this paper we will assume the sketches in the analysis all satisfy this regularity condition and claim that a sketch is scale-invariant if formula (4) converges.

4.3 Analysis of Smoothed q-PCSA and q-LL

The sketches q-PCSA and q-LL are the natural smoothed base-q generalizations of PCSA [20] and LogLog [16].

▶ **Theorem 14.** *q-PCSA and q-LL are scale-invariant. In particular, we have,*

$$\kappa_{q\text{-PCSA}} = \frac{1}{\ln q}, \text{ and } \kappa_{q\text{-LL}} = \frac{1}{\ln q}\frac{q-1}{q}.$$

Proof. For q-LL, cell t is free iff both itself and all the cells above it in its column contain no darts. Thus we have

$$\mathbb{E}(Z_{t,\lambda}) = \prod_{i=0}^{\infty} \Pr(Y_{t+i,\lambda} = 0) = \prod_{i=0}^{\infty} e^{-\frac{\lambda}{q^{t+i}}\frac{q-1}{q}} = e^{-\frac{\lambda}{q^t}}.$$

Insert it to formula (4) and we get

$$\kappa_{q\text{-LL}} = \lim_{\lambda\to\infty} \lambda \int_{-\infty}^{\infty} \left(\frac{1}{q^t} - \frac{1}{q^{t+1}}\right) e^{-\frac{\lambda}{q^t}} dt = \frac{1}{\ln q}\frac{q-1}{q}.$$

For q-PCSA, cell t is free iff it has no dart. Thus $Z_{t,\lambda} = 1 - Y_{t,\lambda}$ and by formula (4) we have

$$\kappa_{q\text{-PCSA}} = \lim_{\lambda\to\infty} \lambda \int_{-\infty}^{\infty} \left(\frac{1}{q^t} - \frac{1}{q^{t+1}}\right) e^{-\frac{\lambda}{q^t}\frac{q-1}{q}} dt = \frac{1}{\ln q}. \quad ◀$$

The Fishmonger [31] sketch is based on a smoothed, entropy compressed version of base-e PCSA. The memory footprint of Fishmonger approaches its entropy as $m \to \infty$, which was calculated to be mH_0 [31, Lemma 4]. From Theorem 14, we know $\kappa_{e\text{-PCSA}} = 1$.

▶ **Corollary 15.** *Fishmonger has limiting MVP $H_0/2 \approx 1.63$.*

Proof. By Theorem 11, limiting MVP equals $mH_0 \cdot \frac{1}{2m} = \frac{H_0}{2}$. ◀

4.4 Asymptotic Local View

For any t and λ, since we want to evaluate $Z_{t,\lambda}$, whose value may depend on its "neighbors" on the dartboard, we need to understand the configurations of the cells near cell t. Since we consider the case where m goes to infinity, we may ignore the effect of smoothing to the cells in the immediate vicinity of cell t.

After taking these asymptotic approximations, we can index the cells near cell t as follows.

▶ **Definition 16** (neighbors of cell t)**.** *Fix a cell t. Let $i \in \mathbb{Z}$ and $c \in \mathbb{R}$. The (i, c)-neighbor of cell t is a cell whose column index differs by i (negative i means to the left, positive to the right) and has height $t + c$, it covers the vertical interval $[q^{-(t+c+1)}, q^{-(t+c)})$. In the sawtooth partition, c is an integer when i is even and a half-integer when i is odd. (Note that we are locally ignoring the effect of smoothing.)*

Once cell t is fixed, define $W(i, c)$ to be the indicator for whether the (i, c)-neighbor of cell t has at least one dart in it. Thus, for fixed t, λ, we have

$$\Pr(W(i,c) = 0) = \Pr(Y_{t+c,\lambda} = 0) = e^{-\frac{\lambda}{q^{t+c}}\frac{q-1}{q}}.$$

In the asymptotic local view, we lose the property that a cell can be uniquely identified by its height, hence the need to refer to nearby cells by their position *relative* to cell t.

4.5 Analysis of Curtain

We first briefly state some properties of curtain. For any $a \geq 1$, recall that $\mathcal{O}_a = \{-(a-1/2), -(a-3/2), \ldots, -1/2, 1/2, \ldots, a-3/2, a-1/2\}$. It is easy to see that for any vector $v = (g_0, g_1, \ldots, g_{m-1})$, $v_{\text{curt}} = (\hat{g}_i)$ can be expressed as

$$\hat{g}_i = \max_{j \in [0,m-1]} \{g_j - |i-j|(a-1/2)\}.$$

For each i, we define the *tension point* τ_i to be the lowest allowable value of $\hat{g}_i$, given the context of its neighboring columns.

$$\tau_i = \max_{j \in [0,m-1] \setminus \{i\}} \{g_j - |i-j|(a-1/2)\},$$

and thus we have $\hat{g}_i = \max(g_i, \tau_i)$. We see that the column i is *in tension* iff $g_i \leq \tau_i$, that is, $\hat{g}_i = \tau_i$.

▶ **Theorem 17.** *Curtain is scale-invariant with*

$$\kappa_{\textsf{Curtain}} = \frac{1}{\ln q} \frac{q-1}{q} \frac{1}{\frac{q-1}{q} + \frac{2}{q^h(q^{a-1/2}-1)} + \frac{1}{q^{h+1}}}.$$

Proof. Fix cell t and λ. Define $W_1(k)$ to be the height of the highest cell containing darts in the column k away from t's column. I.e., define $\iota = \left[\!\left[k \text{ is odd}\right]\!\right]/2$ to be $1/2$ if k is odd and zero if k is even, and $W_1(k) \stackrel{\text{def}}{=} \max\{t+i+\iota \mid i \in \mathbb{Z} \text{ and } W(k, i+\iota) = 1\}$.

We have for any $i \in \mathbb{Z}$,

$$\Pr(W_1(k) \leq t+i+\iota) = \prod_{j=1}^{\infty} \Pr(W(k, i+j+\iota) = 0) = e^{-\frac{\lambda}{q^{t+1+i+\iota}}}.$$

Let T_1 be the tension point of the column of cell t, which equals $\max_{j \in \mathbb{Z}\setminus\{0\}} \{W_1(j) - |j|(a-1/2)\}$. We have for any $i \in \mathbb{Z}$,

$$\begin{aligned}
\Pr(T_1 \leq i+t) &= \Pr\left(\max_{j \in \mathbb{Z}\setminus\{0\}} \{W_1(j) - |j|(a-1/2)\} \leq i+t\right) \\
&= \prod_{j \in \mathbb{Z}\setminus\{0\}} \Pr(W_1(j) - |j|(a-1/2) \leq i+t) \\
&= \left(\prod_{j=1}^{\infty} e^{-\lambda \frac{1}{q^{t+i+1+j(a-1/2)}}}\right)^2 = e^{-\lambda \frac{2}{q^{t+i+1}} \frac{1}{q^{a-1/2}-1}}.
\end{aligned}$$

From the rules of Curtain, we know that a cell is free iff it contains no dart, it is at most $h-1$ below its column's tension point, and at most h below the highest cell in its column containing darts. Thus,

$$Z_{t,\lambda} = \left[\!\left[Y_{t,\lambda} = 0\right]\!\right] \cdot \left[\!\left[t \geq T_1 - (h-1)\right]\!\right] \cdot \left[\!\left[t \geq W_1(0) - h\right]\!\right],$$

Note that T_1 is independent from $Y_{t,\lambda}$ and $W_1(0)$. In addition, $Y_{t,\lambda}$ is also independent from $\left[\!\left[t \geq W_1(0) - h\right]\!\right]$, since the latter only depends on $Y_{t',\lambda}$ with $t' \geq h+t+1$. Thus, we have

$$\begin{aligned}
\mathbb{E}(Z_{t,\lambda}) &= \Pr(Y_{t,\lambda} = 0) \cdot \Pr(T_1 \leq t+h-1) \cdot \Pr(W_1(0) \leq t+h) \\
&= e^{-\frac{\lambda}{q^t}\frac{q-1}{q}} e^{-\lambda \frac{2}{q^{t+h}} \frac{1}{q^{a-1/2}-1}} e^{-\frac{\lambda}{q^{t+h+1}}} \\
&= \exp\left(-\frac{\lambda}{q^t}\left(\frac{q-1}{q} + \frac{2}{q^h(q^{a-1/2}-1)} + \frac{1}{q^{h+1}}\right)\right).
\end{aligned}$$

Thus by formula (4), we have

$$\kappa_{\mathsf{Curtain}} = \lim_{\lambda\to\infty} \lambda \int_{-\infty}^{\infty} \left(\frac{1}{q^t} - \frac{1}{q^{t+1}}\right) \exp\left(-\frac{\lambda}{q^t}\left(\frac{q-1}{q} + \frac{2}{q^h(q^{a-1/2}-1)} + \frac{1}{q^{h+1}}\right)\right) dt$$
$$= \frac{1}{\ln q}\frac{q-1}{q}\frac{1}{\frac{q-1}{q} + \frac{2}{q^h(q^{a-1/2}-1)} + \frac{1}{q^{h+1}}}. \qquad \blacktriangleleft$$

5 Optimality of Martingale Fishmonger

Martingale sketches have several attractive properties, e.g., being strictly unbiased and insensitive to duplicate elements in the data stream. In Section 5.1 we argue that any sketch that satisfies these natural assumptions can be systematically transform into a Martingale X sketch with equal or lesser variance, where X is a dartboard sketch. In other words, the Martingale *transform* is optimal.

In Section 5.2 we prove that within the class of *linearizable* dartboard sketches, Martingale Fishmonger is optimal. The class of linearizable sketches is broad and includes state-of-the-art sketches, which lends strong *circumstantial* evidence that the memory-variance product of Martingale Fishmonger cannot be improved.

5.1 Optimality of the Martingale Transform

Consider a non-mergeable sketch processing a stream $\mathcal{A} = (a_1, a_2, \ldots)$. Let S_i be its state after seeing $(a_1, \ldots, a_i)$, $\lambda_i = |\{a_1, \ldots, a_i\}|$, and $\hat{\lambda}(S_i)$ be the estimate of cardinality λ_i when in state S_i. We make the following natural assumptions.

Randomness. The random oracle h is the only source of randomness. In particular, S_i is a function of $(h(a_1), h(a_2), \ldots, h(a_i))$.

Duplicates. If $a_i \in \{a_1, \ldots, a_{i-1}\}$, $S_i = S_{i-1}$, i.e., duplicates do not trigger state transitions.

Unbiasedness. Suppose one examines the data structure at time i and sees $S_i = \mathbf{s}_i$ and then examines it at time j. Then $\hat{\lambda}(S_j) - \hat{\lambda}(\mathbf{s}_i)$ is an unbiased estimate of $\lambda_j - \lambda_i$.

In the full version [32], we show that as a consequence of the *Randomness*, *Duplicates*, and *Unbiased* assumptions, the Martingale estimator has minimum variance.

▶ Remark 18. We should note that under some circumstances it is possible to achieve smaller variance by violating the *duplicates* and *unbiasedness* assumptions. For example, suppose the sketch state after seeing i elements were $(\hat{\lambda}_i, S_i, i)$. If the stream is duplicate-heavy, "i" carries no useful information, but if nearly all elements are distinct, i is also a good cardinality estimate. Since $\lambda_i \le i$, the cardinality estimate $\min\{\hat{\lambda}_i, i\}$ is never worse than $\hat{\lambda}_i$ alone, but when $\lambda_i \approx i$, it is biased and has a constant factor lower variance.

5.2 Optimality of Martingale Fishmonger

Given an abstract linearizable sketching scheme X, its space is minimized by compressing it to its entropy. On the other hand, by Theorem 11 the variance of Martingale X is controlled by the normalized expected probability of changing state: $2\lambda \cdot \mathbb{E}(P_\lambda)$. Theorem 19 lower bounds the ratio of these two quantities for any sketch that behaves well over a sufficiently large interval of cardinalities $\lambda \in [e^a, e^b]$. The proof technique is very similar to [31], as is the take-away message (that X=Fishmonger is optimal up to some assumptions). However, the two proofs are mathematically distinct as [31] focuses on Fisher information while Theorem 19 focuses on the *probability of state change*.

▶ **Theorem 19.** *Fix reals $a < b$ with $d = b - a > 1$. Let $\bar{H}, \bar{R} > 0$. For any linearizable sketch, let $H(\lambda)$ be the entropy of its state and P_λ be the probability of state change*[13] *at cardinality λ satisfies that*

1. *for all $\lambda > 0$, $H(\lambda) \le \bar{H}$, and*
2. *for all $\lambda \in [e^a, e^b]$, $2\lambda \mathbb{E}(P_\lambda) \ge \bar{R}$, then*

$$\frac{\bar{H}}{\bar{R}} \ge \frac{H_0}{2} \frac{1 - \max(8d^{-1/4}, 5e^{-d/2})}{1 + \frac{(344+4\sqrt{d})}{d} \frac{H_0}{I_0} \left(1 - \max(8d^{-1/4}, 5e^{-d/2})\right)} = \frac{H_0}{2}(1 - o_d(1)).$$

▶ **Corollary 20.** *The MVP of any linearizable and scale-invariant sketch is at least $\frac{H_0}{2}$.*

6 Experimental Validation

Throughout the paper we have maintained a possibly unhealthy devotion to asymptotic analysis, taking $m \to \infty$ whenever it was convenient. In practice m will be a constant, and possibly a smallish constant. How do the sketches perform in the pre-asymptotic region?

In turns out that the theoretical analysis predicts the performance of Martingale sketches pretty well, even whem m is small. In the experiment of Figure 3, we fixed the sketch size at a tiny 128 bits. Therefore HyperLogLog uses $m_1 = \lfloor 128/6 \rfloor = 21$ counters. The Martingale LogLog and Martingale Curtain sketches encode the martingale estimator with a floating point *approximation* of $\hat{\lambda}$ in 14 bits, with a 6-bit exponent and 8-bit mantissa. Thus, Martingale LogLog uses $m_2 = (128 - 14)/6 = 19$ counters, and Martingale Curtain uses $m_3 = 37$.[14]

For larger sketch sizes, the distribution of $\hat{\lambda}/\lambda$ is more symmetric, and closer to the predicted performance. Figure 4 gives the empirical distribution of $\hat{\lambda}/\lambda$ over 100,000 runs when $\lambda = 10^6$ and the sketch size is fixed at 1,200 bits. Here MartingaleCurtain uses $m = 400$, and both Martingale LogLog and HyperLogLog use $m = 200$. The experimental and predicted relative variances and standard errors are given in Table 2.

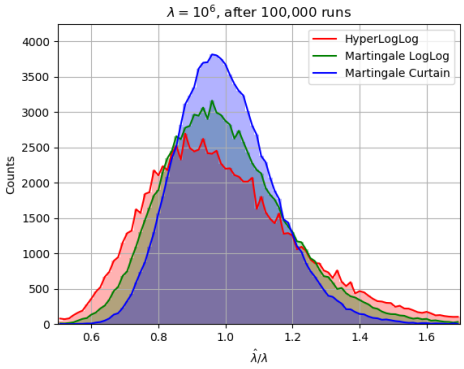


Figure 3 The sketch size is fixed at 128 bits.

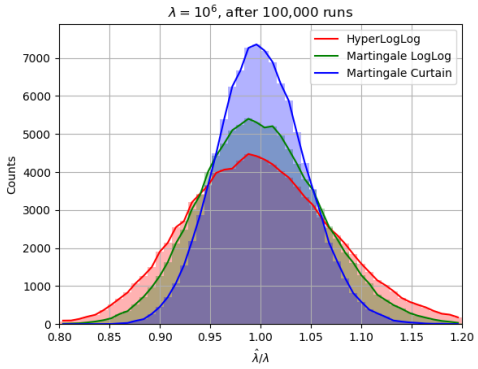

Figure 4 The sketch size is fixed at 1200 bits.

[13] The probability of state change P_λ is itself a random variable.
[14] It uses the optimal parameterization $(q, a, h) = (2.91, 2, 1)$ of Theorem 4.

Table 2 The relative variance is $\frac{1}{\lambda^2}\operatorname{Var}(\hat{\lambda} \mid \lambda)$ and standard error is $\frac{1}{\lambda}\sqrt{\operatorname{Var}(\hat{\lambda} \mid \lambda)}$. The predictions for Martingale LogLog and Martingale Curtain use Theorems 11, 14, and 17. The predictions for HyperLogLog are from Flajolet et al. [19, p. 139].

Sketch	Using 128 bits				Using 1200 bits			
	Experiment		Prediction		Experiment		Prediction	
	Var	StdErr	Var	StdErr	Var	StdErr	Var	StdErr

7 Conclusion

The Martingale transform is attractive due to its simplicity and low variance, but it results in *non*-mergeable sketches. We proved that under natural assumptions,[15] it generates optimal estimators automatically, allowing one to design structurally more complicated sketches, without having to worry about designing or analyzing *ad hoc* estimators. We proposed the Curtain sketch, in which each subsketch only needs a constant number of bits of memory, for *arbitrarily large* cardinality U.[16]

The analytic framework of Theorems 7 and 11 simplifies Cohen [14] and Ting [35], and gives a user-friendly formula for the asymptotic relative variance (ARV) of the Martingale estimator, as a function of the sketch's constant κ. We applied this framework to Martingale Curtain as well as the Martingale version of the classic sketches (MinCount, HLL and PCSA).

Assuming perfect compression, one gets the *memory-variance product* (MVP) of an sketch by multiplying its entropy and ARV. It is proved that for linearizable sketches, Fishmonger is optimal for mergeable sketches [31] (limiting MVP $= H_0/I_0 \approx 1.98$). In this paper we proved that in the sequential (non-mergeable) setting, if we restrict our attention to linearizable sketches, that Martingale Fishmonger is optimal, with limiting MVP $= H_0/2 \approx 1.63$ (Section 5.2). We conjecture that these two lower bounds hold for general, possibly *non*-linearizable sketches.

The Structure of Minimum Vertex Cuts

Seth Pettie
University of Michigan, Ann Arbor, MI, USA

Longhui Yin
Tsinghua University, Beijing, China

Abstract

In this paper we continue a long line of work on representing the *cut structure* of graphs. We classify the types of minimum *vertex* cuts, and the possible relationships between multiple minimum vertex cuts.

As a consequence of these investigations, we exhibit a simple $O(\kappa n)$-space data structure that can quickly answer pairwise $(\kappa+1)$-connectivity queries in a κ-connected graph. We also show how to compute the "closest" κ-cut to every vertex in near linear $\tilde{O}(m + \text{poly}(\kappa)n)$ time.

1 Introduction

One of the strong themes running through graph theory is to understand the *cut structure* of graphs and to apply these structural theorems to solve algorithmic and data structural problems. Consider the following exemplars of this line of work:

Gomory-Hu Tree. Gomory and Hu (1961) [31] proved that any weighted, undirected graph $G = (V, E)$ can be replaced by a weighted, undirected tree $T = (V, E_T)$ such that for every $s, t \in V$, the minimum s-t cut partition in T (removing a single edge, partitioning V into two sets) corresponds to a minimum s-t cut partition in G. These are sometimes called *cut-equivalent trees* [1].

Cactus Representations. Dinitz, Karzanov, and Lomonosov (1976) [13] proved that all the *global* minimum edge-cuts of any weighted, undirected graph $G = (V, E)$ could be succinctly encoded as an (unweighted) *cactus graph*. A cactus is a connected multigraph in which every edge participates in exactly one cycle. It was proved that there exists a cactus $C = (V_C, E_C)$ and an embedding $\phi : V \to V_C$ such that the minimum edge-cuts in C (2 edges in a common cycle) are in 1-1 correspondence with the minimum edge-cuts of G. A corollary of this theorem is that there are at most $\binom{n}{2}$ minimum edge-cuts.

Picard-Queyrenne Representation. In a *directed* s-t flow network there can be exponentially many min s-t cuts. Picard and Queyrenne (1980) [56] proved that the family $\mathcal{S} = \{S \mid (S, \overline{S})$ is a min s-$t\}$ corresponds 1-1 with the downward-closed sets of a partial order, and is therefore closed under union and intersection.

Block Trees, SPQR Trees, and Beyond. Whitney (1932) [61, 62] proved that the cut vertices (articulation points) of an undirected graph $G = (V, E)$ partition E into single edges and 2-edge connected components (blocks). This yields the *block tree* representation. Di

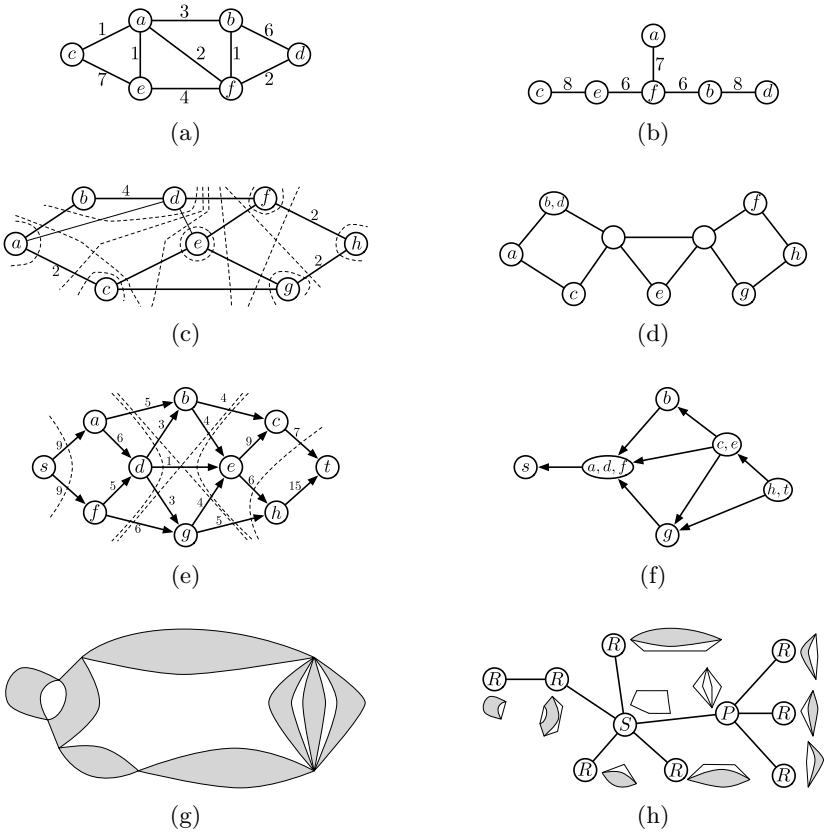

Figure 1 (a) A weighted undirected graph; (b) Its Gomory-Hu (cut-equivalent) tree [31]. (c) A weighted undirected graph (unmarked edges have unit weight); (d) the Cactus representation [13] of its minimum edge cuts. (e) A directed s-t flow network; (f) A dag whose downward-closed sets (that include s but not t) correspond to min s-t cuts (Picard-Queyrenne [56]). (g) An abstract representation of a 2-connected graph; (h) The representation of its 3-connected components as an SPQR tree (Di Battista-Tamassia [4]).

Battista and Tamassia (1989) [5, 4] formally defined the *SPQR tree*, which succinctly encodes all 2-vertex cuts in a biconnected graph, and Kanevsky, Tamassia, Di Battista, and Chen [42] extended this structure to represent 3-vertex cuts in a triconnected graph.[1]

It is natural to ask how, and to what extent, these structures can be extended and generalized. Gusfield and Naor [34] combined the Gomory-Hu tree and the Picard-Queyrenne representation for edge-connetivity. They [33] also described an analogue of Gomory-Hu trees (cut-equivalent trees) for vertex connectivity, i.e., a tree that compactly represents a minimum s-t *vertex* cut for every $s, t \in V$. It used a result of Schnorr [57] on an analogue of Gomory-Hu trees for "roundtrip" flow-values in directed networks. These claims were refuted by Benczur [6], who illustrated that Schnorr's and Gusfield and Naor's proofs were incorrect and could not be rectified. In particular, there are no *cut-equivalent* trees for s-t vertex connectivity and directed s-t cuts. Benczur [6, p. 505-506] suggested a way to construct a *flow-equivalent* tree for vertex connectivity (vertex capacitated s-t flows) using a result of

[1] Many of the structural insights behind [4, 42] were latent in prior work. See, for example. Mac Lane [48], Tutte [59, 60] (1961-6), Hopcroft and Tarjan [36], and Cunningham and Edmonds [12].

Cheng and Hu [9]. This, too, turned out to be incorrect. Hassin and Levin [35] proved that a graph can have $\Omega(n^2)$ s-t vertex-capacitated cut values, which cannot be captured by a flow-equivalent tree. We take these episodes as a reminder that having published proofs (*even incorrect ones*) is essential for facilitating self-correction in science.

The inspiration for this paper is an extended abstract of Cohen, Di Battista, Kanevsky, and Tamassia [11] from STOC 1993. Their goal was to find a cactus-analogue for global minimum vertex cuts, or from a different perspective, to extend SPQR trees [4] and [42] from $\kappa \in \{2, 3\}$ vertex cuts to arbitrarily large κ. As an application of their ideas, they described a data structure for κ-connected graphs occupying space $O(\kappa^3 n)$ that, given u, v, decided whether u, v are separated by a κ-cut or $(\kappa + 1)$-connected. There are no suspect claims in [11]. On the other hand, the paper is 7 pages and leaves many of its central claims unproven.[2] We believe that understanding the *structure* of minimum vertex cuts is a fundamental problem in graph theory, and deserving of a complete, formal treatment.

In this paper we investigate the structure of the set of all minimum vertex cuts and classify the relationships between different minimum vertex cuts. Our work reveals some structural features of minimum κ-cuts not evident in Cohen, Di Battista, Kanevsky, and Tamassia [11], and ultimately allows us to develop a simpler data structure to answer pairwise κ-cut queries in a κ-connected graph. It occupies (optimal) $O(\kappa n)$ space and can be constructed in randomized $\tilde{O}(m + \text{poly}(\kappa)n)$ time, in contrast to [11], which occupies $O(\kappa^3 n)$ space and is constructed in $\exp(\kappa)n^5$ time.[3]

1.1 Related Work

Dinitz and Vainshtein [17, 18] combined elements of the cactus [13] and Picard-Queyrenne [56] representations, which they called the *connectivity carcass*. Given an undirected, unweighted $G = (V, E)$ and $S \subseteq V$ of terminals, λ_S is the size of the minimum edge-cut that separates S. The carcass represents *all* size-λ_S separating cuts in $O(\min\{m, \lambda_S n\})$ space and answers various cut queries in $O(1)$ time.[4]

Benczur and Goemans [7] generalized the cactus representation [13] in a different direction, by giving a compact representation of all cuts that are within a factor 6/5 of the global minimum edge-cut.

Dinitz and Nutov [14] generalized the cactus representation [13] in another direction, by giving an $O(n)$-space representation of all λ and $\lambda + 1$ edge cuts, where λ is the edge-connectivity of the undirected, unweighted graph. Another feature of representations in [17, 18, 14] worth to mention is that they answer connectivity queries with supporting edge insertions in the graph. Unpublished manuscripts [15, 16] give detailed treatments of the λ odd and λ even cases separately.

Georgiadis et al. [30, 22, 28, 29] investigated various notions of 1- and 2-edge and vertex connectivity in *directed* graphs, and the compact representation of edge/vertex cuts.

Gabow [25] provided a $O(m \log n^2/m)$ data structure for all mincuts of a directed graph by drawing a correspondence between cuts and intersecting set families.

---

[2] The full version of this paper was never written (personal communication with R. Tamassia, 2011, and R. Di Battista, 2016).

[3] The algorithm enumerates *all* minimum κ-cuts, which can be as large as $\Omega(2^\kappa(n/\kappa)^2)$; modern vertex connectivity algorithms [23, 27, 26] may reduce the exponent of n in the running time.

[4] The carcass was introduced in extended abstracts [17, 18] and the (simpler) case of odd λ_S was analyzed in detail in a journal article [19]. We are not aware of a full treatment of the case when λ_S is even.

Granot and Hassin [32] generalized the Gomory-Hu tree into node- and arc-capacitated case and gave an algorithm for finding a cut-tree over a set of terminals K by solving $|K|-1$ minimum-cut problems.

Sparsification

One general way to compactly represent connectivity information is to produce a *sparse* graph with the same cut structure. Nagamochi and Ibaraki [50] proved that every unweighted, undirected graph $G = (V, E)$ contains a subgraph $H = (V, E_H)$ with $|E_H| < (k+1)n$ (arboricity $k+1$) such that H is computable in $O(m)$ time and contains exactly the same k'-vertex cuts and k'-edge cuts as G, for all $k' \in \{1, \ldots, k\}$. Benczur and Karger [8] proved that for any capacitated, undirected graph $G = (V, E)$, there is another capacitated graph $H = (V, E_H)$ with $|E_H| = O(\epsilon^{-2} n \log n)$ such that the capacity of *every* cut in G is preserved in H up to a $(1 \pm \epsilon)$-factor. This bound was later improved to $O(\epsilon^{-2} n)$ by Batson, Spielman, and Srivastava [3], which is optimal.

In directed graphs, Baswana, Choudhary, and Roditty [2] considered the problem of finding a sparse subgraph that preserves reachability from a single source, even if d vertices are deleted. They proved that $\Theta(2^d n)$ edges are necessary and sufficient for $d \in [1, \log n]$.

d-Failure Connectivity

An undirected graph can be compactly represented such that connectivity queries can be answered after the deletion of any d vertices/edges (where d could be much larger than the underlying connectivity of the graph). Improving on [54, 43, 20], Duan and Pettie [21] proved that d vertex failures could be processed in $\tilde{O}(d^2)$ time such that connectivity queries are answered in $O(d)$ time, and d edge failures could be processed in $O(d \log d \log \log n)$ time such that connectivity queries are answered in $O(\log \log n)$ time. The size of the [21] structure is $\tilde{O}(m)$ for vertex failures and $\tilde{O}(n)$ for edge failures. Choudhary [10] gave an optimal $O(n)$-space data structure that could answer directed reachability queries after $d \in \{1, 2\}$ vertex or edge failures.

Labeling Schemes

Benczur's refutation [6] of [57, 33] shows that all pairwise vertex connectivities cannot be captured in a *tree* structure, but it does not preclude other representations of this information. Hsu and Lu [37] designed a $O(k \log n)$-bit labeling scheme to determine whether $\kappa(u, v) \geq k$, given just the labels of u and v. This improved [45] and matched an $\Omega(k \log n)$-bit lower bound of Katz, Katz, Korman, and Peleg [44]. By applying it to all $k \in \{1, \ldots, \overline{\kappa}\}$, the Hsu-Lu labeling has size $O(\overline{\kappa}^2 \log n)$ and reports $\min\{\kappa(u, v), \overline{\kappa}\}$. Using a different approach, Izsak and Nutov [38] gave a $O(\overline{\kappa} \log^3 n)$-bit labeling scheme for computing $\min\{\kappa(u, v), \overline{\kappa}\}$. The schemes [37, 45, 44, 38] have large polynomial construction times, and cannot report a u-v cut of size $\kappa(u, v)$

Vertex Connectivity Algorithms

In optimal linear time we can decide whether the connectivity of a graph is $\kappa = 1, \kappa = 2$, or $\kappa \geq 3$ [58, 36]. For larger κ, the state-of-the-art in vertex connectivity has been improved substantially in the last few years. Forster, Nanongkai, Yang, Saranurak, and Yingchareonthawornchai [23] gave a *Monte Carlo* algorithm for computing the vertex connectivity κ of an undirected graph in $\tilde{O}(m + n\kappa^3)$ time, w.h.p.[5] A new result of Li, Nanongkai,

[5] The algorithm does not produce a witness, and hence may err with small probability.

Panigrahi, Saranurak, and Yingchareonthawornchai [46] gave a randomized algorithm running in $O(m^{4/3+o(1)})$ time. The best deterministic algorithm, due to Gao, Li, Nanongkai, Peng, Saranurak, and Yingchareonthawornchai [27], computes the connectivity $\kappa < n^{1/8}$ in $O((m+n^{7/4}\kappa^{O(\kappa)})n^{o(1)})$ time or $O((m+n^{19/20}\kappa^{5/2})n^{o(1)})$ time. For $\kappa > n^{1/8}$, Gabow's algorithm [26] runs in $O(\kappa n^2 + \kappa^2 n \cdot \min\{n^{3/4}, \kappa^{3/2}\})$ time.

The connectivity augmentation problem is to *improve* the global vertex connectivity or specific pairwise connectivities by adding few edges. See, for example, Frank and Jordán [24], Jordán [40], Jackson and Jordán [39], and Nutov [52] for positive results, and Nutov [51] for a hardness of approximation result.

1.2 Organization

In Section 2 we review basic definitions and lemmas regarding vertex cuts. Section 3 gives the basic classification theorem for minimum vertex cuts, and lists some useful corollaries. In short, every pair of cuts have *laminar*, *wheel*, *crossing matching*, or *small* relation. Sections 3.1–3.4 analyze these four categories in more detail. Section 4 exhibits a new $O(\kappa n)$-space[6] data structure that, given two vertices, answers $(\kappa+1)$-connectivity queries in $O(1)$ time, and produces a separating κ-cut (if one exists) in $O(\kappa)$ time. We conclude with some remarks and open problems in Section 5. All missing proofs appear in the full version of the paper [55].

2 Preliminaries

The input is a simple, connected, undirected graph $G=(V,E)$ with $n=|V|$ and $m=|E|$.

Let the subgraph of G induced by A be denoted $G|_A$. We call $U \subset V$ a *cut* if the graph $G|_{V\setminus U}$ is disconnected. A *side* of the cut U is a connected component of $G|_{V\setminus U}$. If P is a side of U and $A \subseteq P$, we say A is *within a side of* U, and let $\mathrm{Side}_U(A) = P$ denote the side containing A. A *region* of a cut U is a side, or the union of several sides of U. Denote $\mathrm{Region}_U(A)$ as the region containing the sides of U that intersects with A. [7] We say a cut *disconnects* or *separates* A and B if they are in distinct sides of U. In particular, if $B = V\setminus(A\cup U)$, we say U *disconnects* or *separates* B *from the rest of the graph*.

A path $\pi = v_1 v_2 \cdots v_l$ is *from* A *to* B, if $v_1 \in A$ and $v_l \in B$. Two paths π, π' from v_1 to v_l are *internally* vertex disjoint if they have no common vertices, except for v_1, v_l. We say U *blocks* π if $U \cap \{v_2, \ldots, v_{l-1}\} \neq \emptyset$.

A k-*cut* is a cut of size k. Define $\kappa(u,v)$ to be the minimum k such that there exists a k-cut separating u and v, where $\{u,v\} \neq E(G)$. Define $\kappa = \kappa(G)$ to be the minimum of $\kappa(u,v)$ over all pairs $\{u,v\} \in \binom{V(G)}{2}\setminus E(G)$. We say G is k-*connected* if $\kappa(G) \geq k$.

In this paper we assume that $\kappa < n/4$ and consider the set of *all* (minimum) κ-cuts.

▶ Remark 1. There is some flexibility in defining the corner cases. Some authors leave $\kappa(u,v)$ undefined when $\{u,v\} \in E(G)$ or define it to be $n-1$. Other authors define connectivity as the maximal number of vertex-disjoint paths. In [11] a k-cut is defined to be a mixed set of edges and vertices whose removal disconnects the graph. Under this definition, when $\{u,v\} \in E(G)$, $\kappa(u,v) = k$ if removing $k-1$ vertices and $\{u,v\}$ disconnects u and v. The last two definitions are equivalent and are compatible with Menger's theorem.

▶ **Theorem 2** (Menger [49]). *Let $G=(V,E)$ be an undirected graph and $\{u,v\}$ a pair* not *in E. Let $U \subset V$ be a minimum size cut disconnecting u and v and Π be a maximum size set of internally vertex disjoint paths from u to v. Then $\kappa(u,v) = |U| = |\Pi|$.*

[6] Formally speaking, this is $O(\kappa n)$ words of space, where a word store the index of a vertex, and takes up $O(\log n)$ bits of space.

[7] Note when A is a singleton set $\{u\}$, $\mathrm{Region}_U(A) = \mathrm{Side}_U(A)$.

The following categories make sense when applied to *non*-minimal vertex cuts, but we are only interested in applying them to *minimum* vertex cuts. Henceforth *cut* usually means *minimum cut*.

Laminar Cuts

Let U be a cut and P be a side of U. If W is a cut and $W \subset U \cup P$, we say W is a *laminar cut* of U in side P.[8]

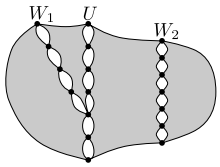

Figure 2 A 7-cut U with two sides, and two 7-cuts W_1, W_2 that are laminar w.r.t. U.

Small Cuts

Informally, when a side of a cut is tiny we call the cut *small*. We define three levels of small cuts. Let U be a cut with sides $A_1, A_2, \ldots, A_a$. We say that

1° U is (I, t)-*small* if there exists an index $i^\sharp$ such that $\sum_{i \neq i^\sharp} |A_i| \leq t$. $A_{i^\sharp}$ is called the *large side* of U and the others the *small sides* of U.

2° U is (II, t)-*small* if there exists $i^\sharp$ such that for every $i \neq i^\sharp$, $|A_i| \leq t$.

3° U is (III, t)-*small*, if there exists $i^\sharp$ such that $|A_{i^\sharp}| \leq t$. In this case $A_{i^\sharp}$ is the *small side* of U.

Note that for any t, I-small cuts are II-small, and II-small cuts are III-small. We typically apply this definition with $t = \kappa$, $t = \Theta(\kappa)$, or $t = \lceil \frac{n-\kappa}{2} \rceil$.

Wheel Cuts

Suppose V can be partitioned into a series of disjoint sets T, $\{C_i\}, \{S_i\}$ ($1 \leq i \leq w, w \geq 4$, subscripts are taken module w), such that the $\{C_i\}$ and $\{S_i\}$ are nonempty (T may be empty), and $C_i \cup T \cup C_{i+2}$ disconnects $S_i \cup C_i \cup S_{i+1}$ from the rest of the graph. We say $(T; C_1, C_2, \ldots, C_w)$ forms a *w-wheel* with *sectors* $S_1, S_2, \ldots, S_w$. We call T the *center* of the wheel, $\{C_i\}$ the *spokes* of the wheel, and $C(i,j) = C_i \cup T \cup C_j$ the *cuts* of the wheel. Define $D(i,j) = S_i \cup C_{i+1} \cup \cdots \cup C_{j-1} \cup S_{j-1}$.

Recall that we are only interested in wheels whose cuts are minimum κ-cuts. The cut of the wheels discussed in this paper are all κ-cuts. It is proved in Lemma 10 that, if $(T; C_1, C_2, \ldots, C_w)$ forms a wheel, then for every i, j such that $j - i \notin \{1, w-1\}$, $C(i,j)$ is a κ-cut with exactly two sides, namely $D(i,j)$ and $D(j,i)$. Note that a w-wheel $(T; C_1, C_2, \ldots, C_w)$ contains x-wheels, $x \in [4, w-1]$. Specifically, for *any* subset $\{i_1, i_2, \ldots, i_x\} \subseteq \{1, 2, \ldots, w\}$ with $x \geq 4$, $(T; C_{i_1}, C_{i_2}, \ldots, C_{i_x})$ forms an x-wheel called a *subwheel* of the original. If a wheel is not a subwheel of any other wheel, it is a *maximal wheel*. If there exists an index $i^\sharp$ such that, $\sum_{i \neq i^\sharp} |S_i| \leq \kappa$, then we say this is a *small wheel*.[9]

[8] These are sometimes called *parellel cuts*.

[9] For a small wheel, all its cuts $C(i,j)$ are (II, $O(\kappa^2)$)-small.

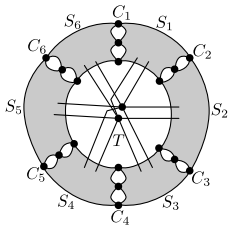

Figure 3 A 6-wheel of 8-cuts with a center of size $|T| = 2$.

Note that wheel cuts resemble the "cycle cuts" of a cactus, or the set of 2−cuts of a cycle.

Matching Cuts and Crossing Matching Cuts

Let U be a cut, A be a side of U, and $P \subseteq U$ be a subset of the cut. We call a cut W a *matching cut of U in side A w.r.t. P* if (i) $U \backslash P \subseteq W \subseteq U \cup A$, (ii) $A \backslash W \neq \emptyset$, and (iii) W disconnects $P \cup (V \backslash (U \cup A))$ from $A \backslash W$. The set $\text{Match}_{U;A}(P) \stackrel{\text{def}}{=} W \backslash U$ is the neighborhood of P restricted to A. Note that a matching cut is a type of laminar cut.

Now suppose U is a cut with exactly two sides A and B, and let $P \subseteq U$ be a non-empty subset of U. We call W a *crossing matching cut of U in side A w.r.t. P* if (i) $W \cap B \neq \emptyset$, (ii) $(U \backslash P) \cup (W \cap A)$ is a matching cut of U in side A w.r.t. P,

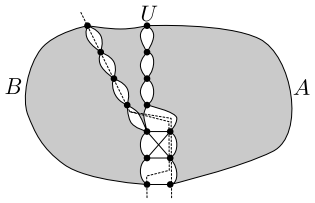

Figure 4 A cut U (drawn vertically) with two sides A and B. Dotted lines indicate two crossing matching cuts w.r.t. P_1 (bottom 3 vertices of U) and P_2 (top 2 vertices of P_1).

One could view U and a crossing matching cut W as a degenerate 4-wheel, in which one sector $S_1 = \emptyset$ is empty. Such cuts should *not* be regarded as wheels, as they do not possess key properties of wheels, e.g., that when U and W are (minimum) κ-cuts, that $|C_1| = \cdots = |C_4| = \frac{\kappa - |T|}{2}$, because $C_1 \cup T \cup C_2$ is not a cut.

Lemmas 3 and 4 are used throughout the paper. Recall here $\kappa = \kappa(G)$ is the vertex connectivity of G.

▶ **Lemma 3.** *Suppose U is a κ-cut and P a side of U. For every $p \in P$ and $u \in U$, there exists a path from p to u that is not blocked by $V \backslash P$.*

▶ **Lemma 4.** *Suppose U and W are two cuts, P is disconnected by U from the rest of the graph G and Q is disconnected by W from the rest of the graph G. Then we have the following two rules:*

- *(Intersection Rule) If $P \cap Q \neq \emptyset$, then $P \cap Q$ is disconnected by $(U \cap Q) \cup (U \cap W) \cup (W \cap P)$ from the rest of the graph G;*
- *(Union Rule) If $V \backslash (U \cup P \cup W \cup Q) \neq \emptyset$, then $P \cup Q$ is disconnected by $(U \backslash Q) \cup (W \backslash P)$ from the rest of the graph G.*

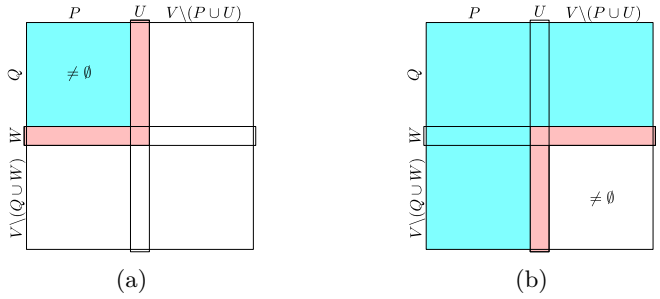

Figure 5 (a) Intersection rule; (b) Union rule.

3 The Classification of Minimum Vertex Cuts

The main *binary* structural theorem for vertex connectivity is, informally, that every two minimum vertex cuts have a relationship that is *Laminar*, *Wheel*, *Crossing Matching*, or *Small*; cf. [11]. Moreover, any strict subset of this list would be inadequate to capture all possible relationships between two vertex cuts.[10]

▶ **Theorem 5.** *Fix a minimum κ-cut U with sides $A_1, A_2, \ldots, A_a$, $a \geq 2$, and let W be any other κ-cut with sides $B_1, B_2, \ldots, B_b$, $b \geq 2$. Denote $T = U \cap W$, $W_i = W \cap A_i$ and $U_j = U \cap B_j$. Then W may be classified w.r.t. U as follows:*

Laminar type. *W is a laminar cut of U, and in particular, there exists indices i^* and j^* such that $B_{j^*} \backslash A_{i^*} = (U \backslash W) \cup (\cup_{i \neq i^*} A_i)$ and $A_{i^*} \backslash B_{j^*} = (W \backslash U) \cup (\cup_{j \neq j^*} B_j)$.*

Wheel type. *$a = b = 2$, and $(T; U_1, W_1, U_2, W_2)$ forms a 4-wheel with sectors $A_1 \cap B_1$, $A_1 \cap B_2$, $A_2 \cap B_2$ and $A_2 \cap B_1$.*

Crossing Matching type. *$a = b = 2$, and w.l.o.g., $A_1 \cap B_1 \neq \emptyset$, $A_2 \cap B_2 \neq \emptyset$, but $A_1 \cap B_2 = \emptyset$. We have $|W_2| = |U_1| > 0$, $|W_1| = |U_2| > 0$, and W is a crossing matching cut of U in side A_1 w.r.t. U_2. Furthermore, if $A_2 \cap B_1 \neq \emptyset$, then $|U_1| \geq |U_2|$.*

Small type. *U is $(I, \kappa - 1)$-small, and the small sides of U are within W, or W is $(I, \kappa - 1)$-small, and the small sides of W are within U.*

▶ Remark 6. Minimum cuts with at least three sides (i.e., $a \geq 3$ or $b \geq 3$) are sometimes called *shredders*. It it known that there are $O(n)$ shredders [41, 47] and that, in the terminology of Theorem 5, two shredders have a *laminar* or *small* relationship.

Proof of Theorem 5. Suppose there is a single index i^* such that $W_{i^*} \neq \emptyset$ and $W_i = \emptyset$ for all $i \neq i^*$. It follows that $W \subseteq A_{i^*} \cup U$ is a laminar cut of U in side A_{i^*}. It remains to prove the other properties of the laminar type. By Lemma 3 there exists paths from any vertex in A_i, $i \neq i^*$, to $U \backslash W$ that are not blocked by W, so they all lie within one side of W; let us denote this side by B_{j^*}. Then $(U \backslash W) \cup (\cup_{i \neq i^*} A_i) \subseteq B_{j^*}$, and because $V = U \cup (\cup_{i=1}^{a} A_i)$, we obtain $B_{j^*} \backslash A_{i^*} = (U \backslash W) \cup (\cup_{i \neq i^*} A_i)$. Now that $U \subseteq W \cup B_{j^*}$ is laminar w.r.t. W, so based on the same reasoning we have $A_{i^*} \backslash B_{j^*} = (W \backslash U) \cup (\cup_{j \neq j^*} B_j)$.

We proceed under the assumption that such indices i^*, j^* do not exist, and without loss of generality assume that $W_1, W_2, U_1, U_2 \neq \emptyset$. We now wish to prove that *all* U_i, W_i are non-empty. Suppose $W_i \stackrel{\text{def}}{=} W \cap A_i = \emptyset$ were empty, then A_i would be contained within a side of W, say $A_i \subseteq B_j$. By Lemma 4 (intersection rule), whenever $A_i \cap B_j \neq \emptyset$, the set $W_i \cup T \cup U_j$ disconnects $A_i \cap B_j$ from the rest of the graph. It follows that

[10] The existence of *Small* cuts as a category – an *a priori* unnatural class – indicates that there may be other ways to capture all minimum vertex cuts through an entirely different classification system.

$$|W_i| + |T| + |U_j| = |T| + |U_j| \geq \kappa = |T| + \sum_{l=1}^{b} |U_l|\,,$$

which implies that U_j is the *only* non-empty U_*-set, contradicting $U_1, U_2 \neq \emptyset$. Therefore, $W_i \neq \emptyset$ for all i and similarly, $U_j \neq \emptyset$ for all j.

Define $\Omega = \{(i,j) \mid A_i \cap B_j \neq \emptyset\}$ to be the side-pairs whose intersections are non-empty. We consider the following possibilities, which are exhaustive.

1° There exist $(i,j),(i',j') \in \Omega$ such that $i \neq i'$, $j \neq j'$. Then by Lemma 4 (intersection rule)

$$\begin{aligned} &|W_i| + |T| + |U_j| \geq \kappa \\ \text{and}\quad &|W_{i'}| + |T| + |U_{j'}| \geq \kappa. \end{aligned}$$

On the other hand,

$$\begin{aligned} &|U_j| + |U_{j'}| + |T| \leq |U| = \kappa \\ \text{and}\quad &|W_i| + |W_{i'}| + |T| \leq |W| = \kappa. \end{aligned}$$

Thus all these inequalities must be equalities, and, adding the fact that all $W_i, U_j \neq \emptyset$, we conclude that $a = b = 2$, $|W_i| = |U_{j'}|$, $|W_{i'}| = |U_j|$. W.l.o.g. we fix $i = j = 1$, $i' = j' = 2$. See Figure 6.

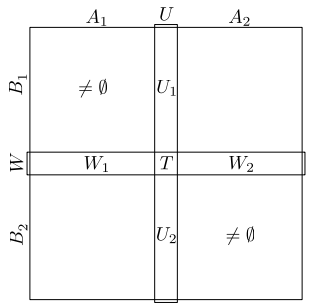

Figure 6 A depiction of cuts U, W in case 1°.

1.1° Suppose $A_1 \cap B_2 \neq \emptyset$ and $A_2 \cap B_1 \neq \emptyset$. Then $|W_i| + |U_j| \geq \kappa - |T|$ for every $\hat{\imath}, \hat{\jmath} \in \{1,2\}$, so we conclude that

$$|U_1| = |U_2| = |W_1| = |W_2| = \frac{\kappa - |T|}{2}.$$

Now that $W_i \cup T \cup U_j$ disconnects $A_i \cap B_j$ from the rest of the graph, $U_1 \cup T \cup U_2 = U$ disconnects $(A_1 \cap B_1) \cup W_1 \cup (A_1 \cap B_2) = A_1$ from $(A_2 \cap B_1) \cup W_2 \cup (A_2 \cap B_2) = A_2$, $W_1 \cup T \cup W_2 = W$ disconnects $(A_1 \cap B_1) \cup U_1 \cup (A_2 \cap B_1) = B_1$ from $(A_1 \cap B_2) \cup U_2 \cup (A_2 \cap B_2) = B_2$, we conclude that $(T; U_1, W_1, U_2, W_2)$ forms a 4-wheel.

1.2° Suppose $A_1 \cap B_2 = \emptyset$ (or symmetrically, that $A_2 \cap B_1 = \emptyset$). Then $A_1 = A_1 \cap (B_1 \cup W) = (A_1 \cap B_1) \cup W_1$. By Lemma 4, $W_1 \cup T \cup U_1$ separates $A_1 \cap B_1$ from the rest of the graph. Since $U_2 \subseteq V \setminus ((A_1 \cap B_1) \cup (U_1 \cup T \cup W_1))$, it follows that $W_1 \cup T \cup U_1$ disconnects U_2 from $A_1 \cap B_1 = A_1 \setminus (W_1 \cup T \cup U_1)$, i.e., it is a matching cut of U in side A_1 w.r.t. U_2. See Figure 7. Because $W_2 = W \cap A_2 \neq \emptyset$ and $(W \cap A_1) \cup (U \setminus U_2) = W_1 \cup T \cup U_1$, W is a crossing matching cut of U in side A_1 w.r.t. U_2.

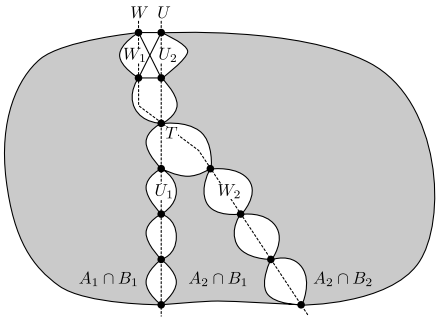

Figure 7 A depiction of the cuts U, W in case 1.2°.

If $A_2 \cap B_1 \neq \emptyset$, by Lemma 4 (intersection rule) $|U_1|+|W_2|+|T| \geq \kappa = |W_1|+|T|+|W_2|$, so $|U_1| \geq |U_2|$.

2° Suppose there exists a $j^\sharp$ such that $\forall i.\forall j \neq j^\sharp.(i,j) \notin \Omega$, i.e., $A_i \cap B_j = \emptyset$. This implies that $\cup_{j \neq j^\sharp} B_j \subseteq U$, and because $U_{j^\sharp} \neq \emptyset$, $\left|\cup_{j \neq j^\sharp} B_j\right|$ is *strictly* smaller than κ. Therefore W is a (I, $\kappa - 1$)-small cut, and all the small sides of W are within U.

3° There exists $i^\sharp$ such that $\forall i \neq i^\sharp.\forall j.(i,j) \notin \Omega$. Symmetric to case 2°; U is (I, $\kappa - 1$)-small, and all the small sides of U are within W.

4° $\Omega = \emptyset$. Then $\cup_{i=1}^{a} A_i \subseteq W$, so $|V| = |U \cup (\cup_{i=1}^{a} A_i)| \leq |U \cup W| \leq 2\kappa$. This is possible, but not one we consider as it contradicts our initial assumption that $n > 4\kappa$. ◀

▶ **Corollary 7** (cf. [41, 47, 53])**.** *If U is a κ-cut that is not (I, $\kappa - 1$)-small and has at least 3 sides, then all other κ-cuts have a laminar type relation with U, or are themselves (I, $\kappa - 1$)-small cuts.*

▶ **Corollary 8.** *Suppose U is a κ-cut that is not (I, $\kappa - 1$)-small, with exactly two sides A and B. Suppose W is a κ-cut with sides K, L (and possibly others), such that $W \cap A \neq \emptyset$, $W \cap B \neq \emptyset$, $A \subseteq K \cup W$, and $L \cap U \neq \emptyset$. Then W only has two sides, and W is a crossing matching cut of U in side A w.r.t. $L \cap U$.*

▶ **Corollary 9.** *Define* $\text{Cuts}_{C;D}$ *to be the set of all κ-cuts that disconnect disjoint, non-empty vertex sets C and D. If* $\text{Cuts}_{C;D} \neq \emptyset$*, it contains a unique minimal element* $\text{MinCut}_{C;D}$*, such that for any cut $U \in \text{Cuts}_{C;D}$,* $\text{Region}_{\text{MinCut}_{C;D}}(C) \subseteq \text{Region}_U(C)$.

Theorem 5 classifies the pairwise relationship between two minimum κ-cuts. In Sections 3.1–3.4 we further explore the properties of wheel cuts, (crossing) matching cuts, laminar cuts, and small cuts.

3.1 Wheels and Wheel Cuts

Recall that a w-wheel $(T; C_1, \ldots, C_w)$ satisfied, by definition, the property that $C_i \cup T \cup C_{i+2}$ formed a κ-cut, but did not say anything explicitly about $C(i,j) = C_i \cup T \cup C_j$. Lemma 10 proves that these are also cuts, and bounds their number of sides.

▶ **Lemma 10.** *Suppose $(T; C_1, C_2, \ldots, C_w)$ forms a w-wheel with sectors $S_1, S_2, \ldots, S_w$. (Subscripts are modulo w.) For any $i \neq j$, $C(i,j)$ is a κ-cut that disconnects $D(i,j)$ from the rest of the graph. Moreover, when $j - i \notin \{1, w-1\}$, $C(i,j)$ has exactly two sides, which are $D(i,j)$ and $D(j,i)$. Furthermore, $|C_i| = \frac{\kappa - |T|}{2}$.*

▶ **Theorem 11.** *Suppose $(T; C_1, C_2, \ldots, C_w)$ forms a w-wheel with sectors $S_1, S_2, \ldots, S_w$. (Subscripts are given by modulo w.) Let X be any minimum κ-cut. Then one of the following is true:*

1° *$X = C(i,j)$ for some $i \neq j$.*

2° *$X \subseteq C(i,i+1) \cup S_i$ for some i, i.e., X is a laminar cut of $C(i,i+1)$.*

3° *X has crossing matching type relation with some $C(i,i+1)$ or some $C(i,i+2)$.*

4° *X is a $(I, \kappa-1)$-small cut.*

5° *$(T; C_1, C_2, \ldots, C_w)$ is a small wheel.*

6° *There exists $i < j$, such that $X \subseteq S_i \cup T \cup S_j$, and $(T; C_1, \ldots, C_i, X \cap S_i, C_{i+1}, \ldots, C_j, X \cap S_j, C_{j+1}, \ldots, C_w)$ forms a $(w+2)$-wheel; or there exists $i \neq j$, $X \subseteq S_i \cup T \cup C_j$, and $(T; C_1, \ldots, C_i, X \cap S_i, C_{i+1}, \ldots, C_w)$ forms a $(w+1)$-wheel. In other words, the wheel $(T; C_1, C_2, \ldots, C_w)$ is a subwheel of some other wheel.*

3.2 Matching Cuts and Crossing Matching Cuts

Define $N(P)$ to be the neighborhood of $P \subset V$ and $N_A(P) \stackrel{\text{def}}{=} N(P) \cap A$.

▶ **Theorem 12.** *Let U be an arbitrary κ-cut and A a side of U.*

1° *If there exists a matching κ-cut of U in side A w.r.t. P, then it is $W = (U \backslash P) \cup N_A(P)$, and $|P| = |N_A(P)| < |A|$. In particular, $\mathrm{Match}_{U;A}(P) = N_A(P)$.*

2° *When there is such a matching cut W, G contains a matching between P and its neighborhood $N_A(P) = \mathrm{Match}_{U;A}(P)$ in side A.*

3° *Suppose $\mathrm{Match}_{U;A}(P)$ and $\mathrm{Match}_{U;A}(Q)$ exist. If $P \cap Q \neq \emptyset$, then $\mathrm{Match}_{U;A}(P \cap Q)$ exists, and*

$$\mathrm{Match}_{U;A}(P \cap Q) = \mathrm{Match}_{U;A}(P) \cap \mathrm{Match}_{U;A}(Q).$$

If $|A| > |P \cup Q|$, then $\mathrm{Match}_{U;A}(P \cup Q)$ exists, and

$$\mathrm{Match}_{U;A}(P \cup Q) = \mathrm{Match}_{U;A}(P) \cup \mathrm{Match}_{U;A}(Q).$$

Fix a κ-cut U and a side A of U. Define $\Theta = \{P \mid \mathrm{Match}_{U;A}(P) \text{ exists}\}$. According to Part 3° of Theorem 12, Θ is closed under union and intersection, and is therefore characterized by its minimal elements. Define $\Theta^* = \{\cap_{u \in P, P \in \Theta} P \mid u \in U\}$. It can be seen from the definition that $\cap_{u \in P, P \in \Theta} P$ corresponds to the minimum matching cut for vertex u.

In the most extreme case Θ may have $2^\kappa - 1$ elements (e.g., if the graph induced by $U \cup N_A(U)$ is a matching), which may be prohibitive to store explicitly. From definition we know that $|\Theta^*| \leq \kappa$, so it works as a good compression for Θ. Lemmas 13 and 14 also highlights some ways in which Θ^* is a sufficient substitute for Θ.

▶ **Lemma 13.** *Let U be a κ-cut and let Θ be defined w.r.t. the matching cuts of U in a side A. Suppose that $P \in \Theta^*$ and $P \subseteq Q \in \Theta$, and that W is a crossing matching cut of U in side A w.r.t. Q. Then $(W \setminus \mathrm{Match}_{U;A}(Q)) \cup (Q \backslash P) \cup \mathrm{Match}_{U;A}(P)$ is also a crossing matching cut of U in A w.r.t. P. Moreover, if $Q = P_1 \cup P_2 \cup \cdots \cup P_\ell$ where each $P_i \in \Theta^*$, then any pair disconnected by W is also disconnected by some $(W \setminus \mathrm{Match}_{U;A}(Q)) \cup (Q \backslash P_i) \cup \mathrm{Match}_{U;A}(P_i)$.*

▶ **Lemma 14.** *Let U be a κ-cut with two sides A and B, and let Θ be defined w.r.t. its matching cuts in side A. For $P \in \Theta^*$, define $U^*(P)$ to be the cut separating P from $A \setminus \mathrm{Match}_{U;A}(P)$ minimizing $\left|\mathrm{Side}_{U^*(P)}(P)\right|$.*

1° *$U^*(P)$ is either a crossing matching cut of U in side A w.r.t. P, or else there is no such crossing matching cut and $U^*(P) = (U \backslash P) \cup \mathrm{Match}_{U;A}(P)$ is a matching cut.*

2° *Suppose X is a crossing matching cut of U in side A w.r.t. P. If u, v are separated by X, then they are also separated by either $U^*(P)$ or $(X \setminus \mathrm{Match}_{U;A}(P)) \cup P$, which is a laminar cut of U.*

3.3 Laminar Cuts

In this section we analyze the structure of laminar cuts. Throughout this section, U refers to a cut that is *not* (I, $\kappa-1$)-small, *not* a wheel cut $C(i,j)$ in some wheel, and has a side A with $|A| > 2\kappa$.

Consider the set of all cuts W that are laminar w.r.t. U, contained in $U \cup A$ and not (I, $\kappa-1$)-small. It follows that W has a side, call it $S(W)$, that contains $U \backslash W$ and all other sides of U.[11] Define $R(W)$ to be the region containing all other sides of W beside $S(W)$. We call W a *maximal* laminar cut of U if there does not exist another laminar cut W' such that $R(W) \subseteq R(W')$.

▶ **Theorem 15.** *Let U be the reference cut.*

1. *If there exist matching cuts of U in side A, define Θ^* w.r.t. U, A, define $Q = \cup_{P\in\Theta^*} P$, and let $X = (U \backslash Q) \cup \mathrm{Match}_{U;A}(Q)$ be the matching cut in side A having the smallest intersection with U. Then every laminar cut W of U in side A is*
   - **(i)** *a laminar cut of X in region $A \backslash \mathrm{Match}_{U;A}(Q)$, or*
   - **(ii)** *a matching cut of U, or*
   - **(iii)** *a crossing matching cut of X.*
2. *If there are no matching cuts of U in side A, every laminar cut of U in side A is a maximal laminar cut, or a laminar cut of some maximal laminar cut W_i in a side of $R(W_i)$. Moreover, whenever W_i, W_j are distinct maximal laminar cuts, $R(W_i) \cap R(W_j) = \emptyset$.*

3.4 Small Cuts

Fix a vertex u and a threshold $t \leq \lceil \frac{n-\kappa}{2} \rceil$. Define $\mathrm{Sm}_t(u)$ to be a cut U minimizing $|\mathrm{Side}_U(u)|$ with $|\mathrm{Side}_U(u)| \leq t$. We show that $\mathrm{Sm}_t(u)$, if it exists, is unique. Also, note this is not immediately derived using intersection-union(submodularity) property of cuts, or lemma 4.

▶ **Theorem 16.** *If there exists a (III, t)-small cut that is small w.r.t. u, then there exists a* unique *such cut, denoted $\mathrm{Sm}_t(u)$, such that for any other cut U, $u \notin U$, $\mathrm{Side}_{\mathrm{Sm}_t(u)} \subseteq \mathrm{Side}_U(u)$.*

4 A Data Structure for $(\kappa+1)$-Connectivity Queries

In this section we design an efficient data structure that, given u, v, answers $(\kappa+1)$-connectivity queries, i.e., reports that $\kappa(u,v) = \kappa$ and produces a minimum κ-cut separating u, v, or reports that $\kappa(u,v) \geq \kappa+1$.

We work with the mixed-cut definition of $\kappa(u,v)$ (see Remark 1), which is the minimum size set of vertices and edges that need to be removed to disconnect u and v, or equivalently, the maximum size set of internally vertex-disjoint paths joining u and v.[12]

▶ **Theorem 17.** *Given a κ-connected graph G, we can construct in $\tilde{O}(m + \mathrm{poly}(\kappa)n)$ time a data structure occupying $O(\kappa n)$ space that answers the following queries. Given $u, v \in V(G)$, report whether $\kappa(u,v) = \kappa$ or $\geq \kappa+1$ in $O(1)$ time. If $\kappa(u,v) = \kappa$, report a κ-cut separating u, v in $O(\kappa)$ time.*

---

[11] $S(W)$ is exactly B_{j^*} of Theorem 5, if using its notation on U and W.

[12] If $\{u,v\} \notin E(G)$ and $\kappa(u,v) = \kappa$, then there exists $U \subset V$, $|U| = \kappa$, such that removing U disconnects u, v. If $\{u,v\} \in E(G)$ then there exists $U \subset V$, $|U| = \kappa - 1$, such that removing U and $\{u,v\}$ disconnects u, v. In this case the single-edge path $\{u,v\}$ would count for one of the κ internally vertex disjoint paths, the other $\kappa-1$ passing through distinct vertices of U.

In $O(m)$ time, the Nagamochi-Ibaraki [50] algorithm produces a subgraph G' that has arboricity $\kappa+1$[13] and hence at most $(\kappa+1)n$ edges, such that $\kappa_{G'}(u,v)=\kappa_G(u,v)$ whenever $\kappa_G(u,v)\le\kappa+1$, and $\kappa_{G'}(u,v)\ge\kappa+1$ whenever $\kappa_G(u,v)\ge\kappa+1$. Without loss of generality we may assume G is the *output* of the Nagamochi-Ibaraki algorithm.

Data Structure

Throughout this section we fix the threshold $t=\lceil\frac{n-\kappa}{2}\rceil$. Define $\mathrm{Sm}(u)=\mathrm{Sm}_t(u)$ to be the unique minimum κ-cut with $\mathrm{Side}_{\mathrm{Sm}(u)}(u)\le t$, if any such cut exists, and $\mathrm{Sm}(u)=\perp$ otherwise. The data structure stores, for each $u\in V(G)$, $\mathrm{Sm}(u)$, $|\mathrm{Side}_{\mathrm{Sm}(u)}(u)|$, a $O(\log n)$-bit identifier for $\mathrm{Side}_{\mathrm{Sm}(u)}(u)$, and for each vertex $v\in N(u)\cap\mathrm{Sm}(u)$, a bit $b_{u,v}$ indicating whether $\{\{u,v\}\}\cup\mathrm{Sm}(u)\backslash\{v\}$ is a mixed cut disconnecting u and v. Furthermore, when $|\mathrm{Side}_{\mathrm{Sm}(u)}(u)|\le\kappa-1$, we store $\mathrm{Side}_{\mathrm{Sm}(u)}(u)$ explicitly. When $\mathrm{Sm}(u)=\perp$ we will say $\mathrm{Side}_{\mathrm{Sm}(u)}(u)=G$ and hence $\left|\mathrm{Side}_{\mathrm{Sm}(u)}\right|=n$. The total space is $O(\kappa n)$.

Connectivity Queries

The query algorithm proceeds to the first applicable case. Note in the following, $\mathrm{Sm}(u)$ may be $\perp$, and for all vertices v, we define $v\notin\perp$.

Case I: $\mathrm{Sm}(u)=\mathrm{Sm}(v)$ and $\mathrm{Side}_{\mathrm{Sm}(u)}(u)=\mathrm{Side}_{\mathrm{Sm}(v)}(v)$. Then $\kappa(u,v)\ge\kappa+1$.

Case II: $u\notin\mathrm{Sm}(v)$ and $v\notin\mathrm{Sm}(u)$. Then $\kappa(u,v)=\kappa$. Without loss of generality suppose that $\left|\mathrm{Side}_{\mathrm{Sm}(u)}(u)\right|\le\left|\mathrm{Side}_{\mathrm{Sm}(v)}(v)\right|$. Then $\mathrm{Sm}(u)$ is a κ-cut separating u and v.

Case III: $v\in\mathrm{Sm}(u)\cap N(u)$, or the reverse. The bit $b_{u,v}$ indicates whether $\kappa(u,v)\ge\kappa+1$ or $\kappa(u,v)=\kappa$, in which case $\{\{u,v\}\}\cup\mathrm{Sm}(u)\backslash\{v\}$ is the κ-cut.

Case IV: $v\in\mathrm{Sm}(u),u\in\mathrm{Sm}(v)$. Then $\kappa(u,v)\ge\kappa+1$.

Case V: $v\in\mathrm{Sm}(u),u\notin\mathrm{Sm}(v)$, or the reverse. If $\left|\mathrm{Side}_{\mathrm{Sm}(v)}(v)\right|\le\kappa-1$, directly check whether $u\in\mathrm{Side}_{\mathrm{Sm}(v)}(v)$. If so then $\kappa(u,v)\ge\kappa+1$; if not then $\mathrm{Sm}(v)$ disconnects them. Thus $\left|\mathrm{Side}_{\mathrm{Sm}(v)}(v)\right|\ge\kappa$. If $\left|\mathrm{Side}_{\mathrm{Sm}(v)}(v)\right|\le\left|\mathrm{Side}_{\mathrm{Sm}(u)}(u)\right|$ then $\mathrm{Sm}(v)$ is a κ-cut separating u and v, and otherwise $\kappa(u,v)\ge\kappa+1$.

Lemmas 18, 19, and Theorem 20 establish the *correctness* of the query algorithm. Its construction algorithm is described and analyzed in Section 4.1.

▶ **Lemma 18.** *If $v\in\mathrm{Side}_{\mathrm{Sm}(u)}(u)$, then either $\mathrm{Sm}(v)=\mathrm{Sm}(u)$ or $\mathrm{Sm}(v)$ is a laminar cut of $\mathrm{Sm}(u)$ with $\mathrm{Side}_{\mathrm{Sm}(v)}(v)\subset\mathrm{Side}_{\mathrm{Sm}(u)}(u)$.*

▶ **Lemma 19.** *Suppose u and v are not $(\kappa+1)-$connected, i.e., $\kappa(u,v)=\kappa$. If $\{u,v\}\notin E(G)$, then they are disconnected by $\mathrm{Sm}(u)$ or $\mathrm{Sm}(v)$, and if $\{u,v\}\in E(G)$, then they are disconnected by $\{(u,v)\}\cup\mathrm{Sm}(u)\backslash\{v\}$ or $\{(u,v)\}\cup\mathrm{Sm}(v)\backslash\{u\}$.*

Proof. First suppose $\{u,v\}\notin E(G)$ and let X be any cut separating u and v. When $t=\lceil\frac{n-\kappa}{2}\rceil$ either $|\mathrm{Side}_X(u)|\le t$ or $|\mathrm{Side}_X(v)|\le t$. W.l.o.g. suppose it is the former, then $\mathrm{Sm}(u)$ exists and by Theorem 16, $\mathrm{Side}_{\mathrm{Sm}(u)}(u)\subseteq\mathrm{Side}_X(u)$, so $\mathrm{Sm}(u)$ also separates u and v.

If $\{u,v\}\in E(G)$, suppose $(\kappa-1)$ vertices $W=\{w_1,w_2,\ldots,w_{\kappa-1}\}$ and $\{u,v\}$ disconnect u and v. After removing W from the graph, $G\backslash W$ is still connected. By deleting the edge $\{u,v\}$, the graph breaks into exactly two connected components, say A and B with $u\in A$ and $v\in B$. Then $W\cup\{u\}$ forms a κ-cut with $\mathrm{Side}_{W\cup\{u\}}(v)=B$, and $W\cup\{v\}$

[13] Namely, G' is a union of k forests, as mentioned before.

also forms a κ-cut with $\text{Side}_{W\cup\{v\}}(u) = A$. Clearly we have $n = |W| + |A| + |B| = \kappa - 1 + |A| + |B|$. W.l.o.g. suppose $|A| \leq |B|$, then $|A| \leq \lfloor \frac{n-\kappa+1}{2} \rfloor = \lceil \frac{n-\kappa}{2} \rceil = t$. Thus $\text{Sm}(u)$ exists, $\text{Side}_{\text{Sm}(u)}(u) \subseteq \text{Side}_{W\cup\{v\}}(u)$, and $\text{Sm}(u)$ is either $W \cup \{v\}$ or a laminar cut of $W \cup \{v\}$ in side A. Since $\{u, v\} \in E(G)$, we have $v \in \text{Sm}(u)$. If we remove $\{u, v\}$ from G, then any path from u to v goes through a vertex in W, but any path from u to a vertex in W goes through a vertex in $\text{Sm}(u)\backslash\{v\}$. Therefore, $\{\{u, v\}\} \cup \text{Sm}(u)\backslash\{v\}$ is a mixed cut separating u, v as it blocks all u-v paths. ◀

▶ **Theorem 20.** *The query algorithm correctly answers $(\kappa + 1)$-connectivity queries.*

Proof. Suppose the algorithm terminates in Case I. It follows that $u \notin \text{Sm}(v), v \notin \text{Sm}(u)$, and neither $\text{Sm}(u)$ nor $\text{Sm}(v)$ disconnect u and v. Lemma 19 implies that $\kappa(u, v) \geq \kappa + 1$.

In Case II, if $\text{Sm}(u) \neq \perp$ but $\text{Sm}(v) = \perp$ then $\text{Sm}(u)$ is the cut separating u, v and since $\left|\text{Side}_{\text{Sm}(u)}(u)\right| < \left|\text{Side}_{\text{Sm}(v)}(v)\right| = n$, then the query is answered correctly. If both $\text{Sm}(u), \text{Sm}(v) \neq \perp$, then by Lemma 18, $v \notin \text{Side}_{\text{Sm}(u)}(u)$ and once again the query is answered correctly.

In Case III, by Lemma 19, if u and v are separated by a κ-cut, they are separated by $\{\{u, v\}\} \cup \text{Sm}(u)\backslash\{v\}$ (if $\text{Sm}(u) \neq \perp$) or $\{\{u, v\}\} \cup \text{Sm}(v)\backslash\{u\}$ (if $\text{Sm}(v) \neq \perp$), and this information is stored in the bit $b_{u,v}, b_{v,u}$.

If we get to Case IV then $\{u, v\} \notin E(G)$ and neither $\text{Sm}(u)$ nor $\text{Sm}(v)$ separate u, v, hence by Lemma 19, $\kappa(u, v) \geq \kappa + 1$ and the query is answered correctly.

Case V is the most subtle. Because $v \in \text{Sm}(u)$ and $\{u, v\} \notin E(G)$, Lemma 19 implies that *if* $\kappa(u, v) = \kappa$, then u, v must be separated by $\text{Sm}(v)$. If $\text{Sm}(v) = \perp$ then $\kappa(u, v) \geq \kappa + 1$ and the query is answered correctly. If $|\,\text{Side}_{\text{Sm}(v)}(v)| \leq \kappa - 1$ then the query explicitly answers the query correctly by direct lookup. Thus, we proceed under the assumption that $\text{Sm}(v) \neq \perp$ exists and is not small.

If $u \in \text{Side}_{\text{Sm}(v)}(v)$ then $\text{Sm}(v)$ does not disconnect u and v, and by Lemma 18, $\left|\text{Side}_{\text{Sm}(v)}(v)\right| > \left|\text{Side}_{\text{Sm}(u)}(u)\right|$, so the query is handled correctly in this case.

If $u \notin \text{Side}_{\text{Sm}(v)}(v)$ then $\text{Sm}(v)$ separates u and v, so we must argue that $\left|\text{Side}_{\text{Sm}(v)}(v)\right| \leq \left|\text{Side}_{\text{Sm}(u)}(u)\right|$ for the query algorithm to work correctly. It cannot be that $\text{Sm}(v)$ and $\text{Sm}(u)$ have a laminar relation, so by Theorem 5 they must have a crossing matching, wheel, or small type relation. If they have the small-type relation then the small sides of $\text{Sm}(u)$ are contained in $\text{Sm}(v)$ (contradicting $u \notin \text{Sm}(v)$) or the small sides of $\text{Sm}(v)$ are contained in $\text{Sm}(u)$, but we have already ruled out this case. Thus, the remaining cases to consider are wheel and crossing matching type.

Suppose $\text{Sm}(u), \text{Sm}(v)$ form a 4-wheel $(T; C_1, C_2, C_3, C_4)$. Then $u \notin \text{Sm}(v)$ appears in a sector of the wheel, say S_1. Then $C(1, 2)$ is a cut violating the minimality of $\text{Sm}(u) = C(1, 3)$.

Suppose $\text{Sm}(u), \text{Sm}(v)$ have a crossing matching type relation. Let $A_1 = \text{Side}_{\text{Sm}(u)}(u)$ and A_2 be the other side of $\text{Sm}(u)$, and $B_1 = \text{Side}_{\text{Sm}(v)}(v)$ and B_2 be the other side of $\text{Sm}(v)$. Then $u \in A_1 \cap B_2$, and it must be that the diagonal quadrant $A_2 \cap B_1 = \emptyset$. Suppose otherwise, i.e., $A_2 \cap B_1 \neq \emptyset$, and let $X = (\text{Sm}(u) \cap B_2) \cup (\text{Sm}(v) \cap A_1) \cup (\text{Sm}(u) \cap \text{Sm}(v))$. Then by Corollary 9 X is a κ-cut with $\text{Side}_X(u) = A_1 \cap B_2$, contradicting the minimality of $\text{Sm}(u)$. Thus, $\text{Sm}(v)$ is a crossing matching cut of $\text{Sm}(u)$ in side A_2 w.r.t. some $Q \subseteq \text{Sm}(u) \cap B_1$ with $v \in Q$. By Theorem 5 and $u \in A_1 \cap B_2 \neq \emptyset$, we have

$$|A_1 \cap \text{Sm}(v)| = |B_2 \cap \text{Sm}(u)| \geq |A_2 \cap \text{Sm}(v)| = |B_1 \cap \text{Sm}(u)| = |Q|.$$

Thus,

$$|\,\text{Side}_{\text{Sm}(u)}(u)| = |A_1| > |(A_1 \cap B_1) \cup Q| = |\,\text{Side}_{\text{Sm}(v)}(v)|,$$

establishing the correctness in the crossing matching case. (The strictness of the inequality is because $A_1 \cap B_2 \neq \emptyset$.) ◀

Refer to the full version for a $\tilde{O}(m + \text{poly}(\kappa)n)$-time algorithm to construct this data structure, in particular, to find all minimal cuts $\{\text{Sm}(u)\}_{u \in V}$.

4.1 Construction of the Data Structure

We assume Nagamochi-Ibaraki sparsification [50] has already been applied, so G has arboricity $\kappa + 1$ and $O(\kappa n)$ edges. We use the recent Forster et al. [23] algorithm for computing the connectivity $\kappa = \kappa(G)$ in $\tilde{O}(\text{poly}(\kappa)n)$ time and searching for κ-cuts.

▶ **Corollary 21** (Consequence of Forster, Nanongkai, Yang, Saranurak, and Yingchareonthawornchai [23]). *Given $x \in V(G)$ and an integer $s \leq \lceil \frac{n-\kappa}{2} \rceil$, we can, with high probability $1 - 1/\text{poly}(n)$, compute $\text{Sm}_s(x)$ in $\tilde{O}(|\text{Side}_{\text{Sm}_s(x)}(x)| \cdot \kappa^3)$ time, or determine that $\text{Sm}_s(x)$ does not exist in $\tilde{O}(s\kappa^3)$ time.*

We call the procedure of Corollary 21 FindSmall(x, s).

▶ **Definition 22.** *Let U be a cut, A a side of U. We use the notation $\overline{A} = G \backslash (U \cup A)$ to be the region of all other sides of U. Define $G(U, \overline{A})$ to be the graph induced by $U \cup \overline{A}$, supplemented with a κ-clique on U. If W is a cut in $G(U, \overline{A})$, define $\text{Side}_W^{G(U,\overline{A})}(x)$ to be $\text{Side}_W(x)$ in the graph $G(U, \overline{A})$.*

Lemma 23 is useful for constructing the algorithm in lemma 24.

▶ **Lemma 23.** *Let U be a κ-cut, A be a side of U, and W be a set of κ vertices in $G(U, \overline{A})$. Then W is a κ-cut in $G(U, \overline{A})$ if and only if W is a laminar cut of U in one of the sides of $\overline{A}$. Moreover, when W is such a cut, for any vertex $u \in U \backslash W$,*

$$\text{Side}_W(u) = \text{Side}_W^{G(U,\overline{A})}(u) \cup A.$$

Lemma 24 shows how, beginning with a cut X where $\text{Side}_X(u)$ is small, can find another cut Y (if one exists) where $\text{Side}_Y(u)$ is about M, in $\tilde{O}(M\kappa^4)$ time. The difficulty is that there could be an unbounded number of cuts "between" X and Y that would prevent the FindSmall algorithm from finding Y directly.

▶ **Lemma 24.** *For any integer $M \leq t/2$, vertex u, and cut X with $A = \text{Side}_X(u), |A| \leq 2M$, the algorithm* Expand$(u, A, M)$ *runs in time $\tilde{O}(M\kappa^4)$ and, w.h.p., returns a cut Y satisfying the following properties.*

- $\text{Side}_X(u) \subseteq \text{Side}_Y(u)$.
- $|\text{Side}_Y(u)| \leq 2M$.
- *If there exists a cut Z that is (III, M)-small w.r.t. u, then $|\text{Side}_Y(u)| \geq |\text{Side}_Z(u)|$.*

The content of Expand(u, A, M) *is given below.*

Initially $Y \leftarrow X$. While $|\text{Side}_Y(u)| < M$,

a. *For each vertex $v \in Y$, in parallel,*
   i. *In the graph $G(Y, \overline{\text{Side}_Y(u)})$, run* FindSmall$(v, M)$.

b. *The moment any call to* FindSmall *halts in step (i) with a cut W, stop all such calls and set $Y \leftarrow W$. If all $|Y|$ calls to* FindSmall *run to completion without finding a cut, halt and return Y.*

We use Corollary 25 to find $\text{Sm}_t(u)$ for potentially many vertices u in bulk.

▶ **Corollary 25** (Consequence of Picard and Queyrenne [56]). *Fix two disjoint, non-empty vertex sets C and D. In $O(\kappa^2(n - |C| - |D|))$ time, we can output a cut $S(v)$ for every $v \in V \backslash (C \cup D)$, such that if $\text{Sm}(v)$ exists and $C \subseteq \text{Side}_{\text{Sm}(v)}(v)$, then $S(v) = \text{Sm}(v)$.*

We are now ready to present the entire construction algorithm.

Preamble. The algorithm maintains some κ-cut $T(u)$ for each u, which is initially $\perp$, and stores $|\operatorname{Side}_{T(u)}(u)|$. If the algorithm makes no errors, $T(u) = \operatorname{Sm}_t(u) = \operatorname{Sm}(u)$ at the end of the computation. The procedure $\mathsf{Update}(u, U)$ updates $T(u) \leftarrow U$ if U is a better cut, i.e., $|\operatorname{Side}_U(u)| \leq \min\{|\operatorname{Side}_{T(u)}(u)| - 1, t\}$, and does nothing otherwise. $\mathsf{Update}(A, U)$ is short for $\mathsf{Update}(u, U)$ for all $u \in A$.

Step1: very small cuts. For each $u \in V$, let $U \leftarrow \mathsf{FindSmall}(u, 100\kappa)$ and then $\mathsf{Update}(u, U)$. This takes $\tilde{O}(n\kappa^4)$ time.

Step2: unbalanced cuts. For each index i such that $100\kappa < 2^i \leq t$, let $\alpha = 2^i$, and pick a uniform sample $V_i \subset V$ of size $(n \log n)/\alpha$.[14] For each $u \in V_i$, compute $\operatorname{Sm}_\alpha(u) \leftarrow \mathsf{FindSmall}(u, \alpha)$. If $\operatorname{Sm}_\alpha(u) = \operatorname{Sm}(u) \neq \perp$, we first do an $\mathsf{Update}(\operatorname{Side}_{\operatorname{Sm}(u)}(u), \operatorname{Sm}(u))$, then compute $Y \leftarrow \mathsf{Expand}(u, \operatorname{Sm}(u), \alpha)$. For each $v \in Y$, compute $W_v \leftarrow \mathsf{FindSmall}(w, \alpha)$ and then $\mathsf{Update}(v, W_v)$. We then run the algorithm of Corollary 25 with $C = \operatorname{Side}_{\operatorname{Sm}(u)}(u)$ and $D = V \backslash (Y \cup \operatorname{Side}_Y(u))$, which returns a set of cuts $\{S(v)\}_{v \in V \backslash (C \cup D)}$. For each such $v \in \operatorname{Side}_Y(u) \backslash \operatorname{Side}_{\operatorname{Sm}(u)}(u)$, do an $\mathsf{Update}(v, S(v))$. For each index i, the running time is $\tilde{O}(|V_i| \cdot \alpha\kappa^4) = \tilde{O}(n\kappa^4)$, which is $\tilde{O}(n\kappa^4)$ overall.

Step3: balanced cuts. Sample $O(\log n)$ pairs $(x, y) \in V^2$. For each such pair, compute $U \leftarrow \mathsf{FindSmall}(x, t)$. If $U \neq \perp$, apply the algorithm of Corollary 25 to $C = \operatorname{Side}_{\operatorname{Sm}(x)}(x)$ and $D = \{y\}$, which returns a set $\{S(v)\}$. Then do an $\mathsf{Update}(v, S(v))$ for every $v \in V \backslash (C \cup D)$. By Corollary 21 this takes $\tilde{O}(\kappa^3 n)$ time.

Step4: adjacent vertices At this point it should be the case that $T(u) = \operatorname{Sm}(u)$ for all u. For each $v \in T(u) \cap N(u)$ compute and set the bit $b_{u,v}$. (This information can be extracted from the calls to FindSmall and the algorithm of Corollary 25 in the same time bounds.)

▶ **Lemma 26.** *Suppose* $\operatorname{Sm}(u)$ *and* $\operatorname{Sm}(v)$ *exists,* $u \in \operatorname{Side}_{\operatorname{Sm}(v)}(v)$*, and suppose there is a cut* W *such that* $\kappa \leq \left|\operatorname{Side}_{\operatorname{Sm}(v)}(v)\right| < |\operatorname{Side}_W(u)| \leq t$*. Then* $v \in W \cup \operatorname{Side}_W(u)$*.*

Lemma 26 is critical to proving the correctness of the algorithm's search strategy.

▶ **Theorem 27.** *The construction algorithm correctly computes* $\{\operatorname{Sm}(v)\}_{v \in V}$ *and runs in time* $\tilde{O}(n\kappa^4)$*.*

Proof. If $|\operatorname{Side}_{\operatorname{Sm}(v)}(v)| \leq 100\kappa$, then $T(v) = \operatorname{Sm}(v)$ after Step 1, with high probability.

Suppose that $|\operatorname{Side}_{\operatorname{Sm}(v)}(v)| \in [2^j, 2^{j+1}]$ and $2^{j+1} \leq t$. Then with high probability, at least one vertex $x \in V_j$ is sampled in Step 2 such that $x \in \operatorname{Side}_{\operatorname{Sm}(v)}(v)$. Step 2 (Expand) computes a cut Y such that $|\operatorname{Side}_Y(x)| \geq |\operatorname{Side}_{\operatorname{Sm}(v)}(v)|$, so by Lemma 26, either $v \in \operatorname{Side}_Y(x)$ or $v \in Y$. In the former case $\operatorname{Sm}(v)$ is computed using the Corollary 25 algorithm. In the latter case $\operatorname{Sm}(v)$ is computed directly using FindSmall.

Finally, if $\operatorname{Sm}(v)$ is balanced, say $|\operatorname{Side}_{\operatorname{Sm}(v)}(v)| \geq t/4$, then w.h.p. we would pick a pair (x, y) in Step 3 such that $x \in \operatorname{Side}_{\operatorname{Sm}(v)}(v)$ and $y \in V \backslash (\operatorname{Sm}(v) \cup \operatorname{Side}_{\operatorname{Sm}(v)}(v))$. If this holds the algorithm of Corollary 25 correctly computes $\operatorname{Sm}(v)$. ◀

[14] The Forster et al. [23] algorithm samples vertices proportional to their degree. Note that after the Nagamochi-Ibaraki [50] sparsification, the minimum degree is at least κ and the density of every induced subgraph is at most $\kappa + 1$, so it is equally effective to do vertex sampling.

5 Conclusion

This paper was directly inspired by the extended abstract of Cohen, Di Battista, Kanevsky, and Tamassia [11]. Our goal was to substantiate the main claims of this paper, and to simplify and improve the data structure that answers $(\kappa+1)$-connectivity queries.

We believe that our structural theorems can, ultimately, be used to develop even more versatile vertex-cut data structures. For one example, is it possible to succinctly represent *all* minimum vertex cuts so that the following queries can be answered efficiently?
Is-it-a-cut?$(u_1,\ldots,u_\kappa)$**:** Return *true* iff $\{u_1,\ldots,u_\kappa\}$ forms a κ-cut.
List-cuts(u)**:** Return all the κ-cuts containing u.
Note that if all minimum cuts have a wheel or laminar relationship, then they can be represented as a tree, as in [4, 11]. Whether there is a clean representation that *also* captures all *small* and *crossing matching* cuts is an open problem.

We assumed throughout the paper that κ was not too large, specifically $\kappa < n/4$. When $n < 2\kappa$, *all* cuts are (I,κ)-small by our classification, and the classification theorem (Theorem 5) says very little about the structure of such cuts. Understanding the structure of minimum vertex cuts when κ is large, relative to n, is an interesting open problem.

Abstract

Knapsack and Subset Sum are fundamental NP-hard problems in combinatorial optimization. Recently there has been a growing interest in understanding the best possible pseudopolynomial running times for these problems with respect to various parameters.

In this paper we focus on the maximum item size s and the maximum item value v. We give algorithms that run in time $\mathcal{O}(n + s^3)$ and $\mathcal{O}(n + v^3)$ for the Knapsack problem, and in time $\widetilde{\mathcal{O}}(n + s^{5/3})$ for the Subset Sum problem.

Our algorithms work for the more general problem variants with multiplicities, where each input item comes with a (binary encoded) multiplicity, which succinctly describes how many times the item appears in the instance. In these variants n denotes the (possibly much smaller) number of *distinct* items.

Our results follow from combining and optimizing several diverse lines of research, notably proximity arguments for integer programming due to Eisenbrand and Weismantel (TALG 2019), fast structured $(\min, +)$-convolution by Kellerer and Pferschy (J. Comb. Optim. 2004), and additive combinatorics methods originating from Galil and Margalit (SICOMP 1991).

1 Introduction

In the Knapsack problem we are given a (multi-)set consisting of N items, where the i-th item has size s_i and value v_i, and a knapsack capacity t. The task is to find a subset of items with the maximum total value such that its total size does not exceed the capacity t. In the related Subset Sum problem we are given a (multi-)set of N positive integers and a target value t, and the task is to find a subset of integers with the total sum exactly equal to t. The Subset Sum problem can thus be seen as a decision variant of the Knapsack problem with the additional restriction that $s_i = v_i$ for every item i.

Knapsack and Subset Sum are fundamental problems in computer science and discrete optimization. They are studied extensively both from practical and theoretical points of view (see, e.g. [23] for a comprehensive monograph). The two problems are (weakly) NP-hard, and Bellman's seminal work on dynamic programming [7] gives pseudopolynomial $\mathcal{O}(Nt)$ time

algorithms for both of them. Recently there has been a growing interest in understanding the best possible pseudopolynomial running times for these problems with respect to various parameters, see, e.g., [9, 6, 16, 5, 11].

In this paper we consider binary multiplicity encoding of the Knapsack and Subset Sum instances. Each item i given in the input has a (binary encoded) positive integer multiplicity u_i, which denotes that up to u_i copies of this item can be used in a solution. In these variants n denotes the (possibly much smaller) number of distinct items and $N = \sum_{i\in[n]} u_i$.[1] Binary multiplicity encoding can be challenging because one requires the algorithm to run in polynomial time in the input size, which can be exponentially smaller compared to the naive encoding. A notable example of this setting is the breakthrough result of Goemans and Rothvoß [18] showing that Bin Packing with few different item sizes (and binary multiplicity encoding) can be solved in polynomial time.

Formally, Knapsack with multiplicities can be defined as an integer linear program: maximize $\sum_{i\in[n]} v_i x_i$ subject to $0 \leqslant x_i \leqslant u_i$, $x_i \in \mathbb{Z}$, and $\sum_{i\in[n]} s_i x_i \leqslant t$. Similarly, Subset Sum with multiplicities can be defined as a feasibility integer linear program with constraints $0 \leqslant x_i \leqslant u_i$, $x_i \in \mathbb{Z}$, and $\sum_{i\in[n]} s_i x_i = t$. Throughout the paper we use u to denote the maximum item multiplicity $\max_{i\in[n]} u_i$, and w.l.o.g. we assume that $u \leqslant t$.

1.1 Our results

We focus on pseudo-polynomial time algorithms with respect to the maximum item size $s = \max_{i\in[n]} s_i$ (or maximum item value $v = \max_{i\in[n]} v_i$, which is essentially equivalent). We note that s is a stronger parameter compared to t in the sense that s can be much smaller than t, but not vice versa. Yet, s is less well understood than t. In the regime where n is large compared to s, an $\mathcal{O}(n + \mathrm{poly}(s))$ time algorithm would be desirable. We show that the Knapsack problem can indeed be solved in such a time. Prior results (even for 0-1 Knapsack, that is, without multiplicities) only came with the form $\mathcal{O}(\mathrm{poly}(n) \cdot \mathrm{poly}(s))$ or $\mathcal{O}(\mathrm{poly}(s) \cdot \mathrm{poly}(t))$.

This raises the natural question what the best exponent in the polynomial is. In this paper we address the question from the upper bound side. We give algorithms for Knapsack running in $\mathcal{O}(n + s^3)$ and $\mathcal{O}(n + v^3)$ time, and for Subset Sum running in $\widetilde{\mathcal{O}}(n + s^{5/3})$ time[2]. Our algorithms are in the word RAM model, and we assume that each integer in the input fits in one word. In particular, arithmetic operations on integers of size polynomial in the sum of the input's integers require constant time.

Our first result is an algorithm for Knapsack. We use proximity techniques due to Eisenbrand and Weismantel [16] which allow us to prove that there is an efficiently computable solution that differs only very little from an optimal solution. Then we apply a fast algorithm for structured $(\min, +)$-convolution [22] to search for this optimal solution within the limited space. This results in a running time which is cubic in the maximum item size.

▶ **Theorem 1.1.** *Knapsack (with multiplicities) can be solved in deterministic $\mathcal{O}(n + s^3)$ time.*

The definition of (the decision variant of) the Knapsack problem is symmetric with respect to sizes and values. We give a simple transformation that allows us to apply our algorithm also to the case where the maximal item value (and not the maximal item size) is small.

---

[1] We use $[n]$ to denote $\{1, 2, \ldots, n\}$.

[2] Throughout the paper we use a $\widetilde{\mathcal{O}}(\cdot)$ notation to hide polylogarithmic factors.

▶ **Theorem 1.2.** *Knapsack (with multiplicities) can be solved in deterministic* $\mathcal{O}(n + v^3)$ *time.*

Theorem 1.1 already implies that Subset Sum can also be solved in $\mathcal{O}(n+s^3)$. Our algorithm uses as a subprocedure an $\mathcal{O}(n+st)$ time Knapsack algorithm (see Lemma 2.2). If we simply replaced it with a $\widetilde{\mathcal{O}}(N+t)$ time algorithm for Subset Sum [9], we would get a $\widetilde{\mathcal{O}}(n+s^2)$ time algorithm for Subset Sum. We improve on this by introducing a refined proximity argument that lets us further reduce an instance, where the maximum item multiplicity u can be of the order of s, to two instances with $u \ll s$ each. By combining this with additive combinatorics methods, originally developed by Galil and Margalit [17] and recently generalized by Bringmann and Wellnitz [11], we then obtain a subquadratic algorithm.

▶ **Theorem 1.3.** *Subset Sum (with multiplicities) can be solved in randomized* $\widetilde{\mathcal{O}}(n + s^{5/3})$ *time, with a one-sided error algorithm that returns a correct answer with high probability.*

All our algorithms can also retrieve a solution, without increasing the asymptotic running times. This is notable especially for our Subset Sum algorithm, in which we use as a black box the Bringmann-Wellnitz algorithm that gives only yes/no answers. We can deal with this presumable obstacle because we can afford to spend more time on retrieving a solution than the Bringmann-Wellnitz algorithm could.

A limitation of our algorithms is that they can provide an answer only for a single target value t at a time. Conversely, many (but not all) known Knapsack and Subset Sum algorithms can give answers for all target values between 0 and t at the same time. This limitation is however unavoidable: We aim at running times independent of the target value t, thus we cannot afford output size linear in t, because t cannot be bounded in terms of n and s only.

In the next section we discuss how our results fit a broader landscape of existing Knapsack and Subset Sum algorithms.

1.2 Related work

Pseudopolynomial time algorithms for Knapsack

Bellman [7] was the first to show that the Knapsack problem admits a pseudopolynomial time algorithm. He presented an $\mathcal{O}(Nt)$ time algorithm based on dynamic programming. Pisinger [28] gave an $\mathcal{O}(Nsv)$ time algorithm, which is an improvement for instances with both small sizes and small values. He proved that only *balanced feasible solutions* to Knapsack need to be considered in order to find an optimal solution. Then he used this observation to decrease the number of states of the dynamic program. His arguments may be thought of as an early example of proximity-based arguments.

Kellerer and Pferschy [22] studied approximation algorithms for Knapsack. As a subroutine they developed a $\widetilde{\mathcal{O}}(N+vp)$ time (exact) algorithm, where p denotes the optimal total value. Their algorithm can be easily modified to work in $\widetilde{\mathcal{O}}(N+st)$ time. Their approach, based on fast $(\min,+)$-convolution for structured (convex) instances was rediscovered and improved by Axiotis and Tzamos [5]. Bateni et al. [6] achieved the same $\widetilde{\mathcal{O}}(N+st)$ running time with a different method, which can be seen as a far-reaching refinement of Pisinger's idea [28]. They also developed the *prediction* technique, which let them achieve $\widetilde{\mathcal{O}}(N+vt)$ running time.

Eisenbrand and Weismantel [16] studied more general integer linear programs, and presented a $\widetilde{\mathcal{O}}(ns^2)$ time algorithm for Knapsack with multiplicities, based on proximity-based arguments. To the best of our knowledge they are the first to consider Knapsack with multiplicities. Subsequently Axiotis and Tzamos [5] improved logarithmic factors (in the

non-multiplicity setting) and gave an $\mathcal{O}(Ns^2)$ time algorithm, which they also generalized to $\mathcal{O}(Nv^2)$ time. Bateni et al. [6] also explicitly consider the Knapsack problem with multiplicities and independently designed a $\widetilde{\mathcal{O}}(ns^2 \min\{n,s\})$ time algorithm.

Axiotis and Tzamos suggested [5, Footnote 2] that the fast convex convolution can be combined with proximity-based arguments of Eisenbrand and Weismantel [16] to obtain an algorithm for small items with running time independent of t. However, a direct application of Eisenbrand and Weismantel [16] proximity argument (see [16, Section 4.1]) reduces an instance to $t \leqslant \mathcal{O}(ns^2)$, which, in combination with $\mathcal{O}(N+st)$ algorithm, yields $\mathcal{O}(N+ns^3)$ runtime. Our algorithm improves it to $\mathcal{O}(n+s^3)$ by a more careful proximity argument and a convex convolution that explicitly handles negative items. Moreover, we show how to extend this reasoning to the multiplicity setting.

▶ Remark 1.4. Lawler [26] showed that the variant with multiplicities can be reduced to the 0-1 variant. His reduction transforms a multiset composed of at most u copies of each of n distinct numbers bounded by s into an instance of $\mathcal{O}(n \log u)$ numbers bounded by $\mathcal{O}(us)$. This easily enables us to adapt algorithms with no time dependence on s (e.g., the $\mathcal{O}(Nt)$ time algorithm of Bellman) into the setting with multiplicities (with logarithmic overhead).

▶ Remark 1.5. There is also a folklore reduction that enables us to bound $N \leqslant \widetilde{\mathcal{O}}(t)$ for the variant with multiplicities. For each $x \in [s]$ keep $\lfloor t/x \rfloor$ most profitable items of size $s_i = x$. This leaves us with at most $N \leqslant \mathcal{O}(t \log(t))$ items and does not increase the item sizes.

See Table 1 for a summary of the known results for Knapsack.

Pseudopolynomial time algorithms for Subset Sum

Subset Sum is a special case of Knapsack and we expect significantly faster algorithms for it. Pisinger's algorithm [28] runs in $\mathcal{O}(Ns)$ time for Subset Sum. The first improvement in all parameter regimes over the $\mathcal{O}(Nt)$ time algorithm of Bellman was given by Koiliaris and Xu [24]. They presented $\widetilde{\mathcal{O}}(\sqrt{Nt}+N)$, $\widetilde{\mathcal{O}}(N+t^{5/4})$ and $\widetilde{\mathcal{O}}(\Sigma)$ time deterministic algorithms for Subset Sum, where Σ is the total sum of items. A by now standard method, used by all these algorithms, is to encode an instance of Subset Sum as a convolution problem that can be solved using Fast Fourier Transform. Subsequently, Bringmann [9] presented a $\widetilde{\mathcal{O}}(N+t)$ randomized time algorithm for Subset Sum based on the color-coding technique. Jin and Wu [21] later gave an alternative $\widetilde{\mathcal{O}}(N+t)$ randomized time algorithm based on Newton's iterative method. Their proof is notable for being very compact.

Table 2 Pseudopolynomial time algorithms for **Subset Sum**. N is the total number of items, n is the number of distinct items, t is the target value, Σ is the sum of all items, s is the maximum item, and u is the maximum multiplicity of an item. Symbol (–) means that no non-trivial optimization is given for the respective regime; running times can still be derived from the trivial inequalities $n \leqslant N \leqslant nu$ and $t \leqslant Ns$. In ($\star$) the instance cannot have two items with the same size, the algorithm works only for $u = 1$. We use symbol (‡) when Remark 1.4 applies.

–		$\widetilde{\mathcal{O}}(N+u^{1/2}s^{3/2})$	Bringmann and Wellnitz [11]
–		$\widetilde{\mathcal{O}}(n+s^{5/3})$	**This Paper**

From a different perspective, Galil and Margalit [17] used additive combinatorics methods to prove that Subset Sum can be solved in near linear time when $t \gg \Sigma s/N^2$ and all items are distinct. Very recently Bringmann and Wellnitz [11] generalized that result to multisets. Their algorithm combined with the $\widetilde{\mathcal{O}}(N+t)$ time algorithm [9] yields a $\widetilde{\mathcal{O}}(N+u^{1/2}s^{3/2})$ time algorithm for Subset Sum with multiplicities (cf., Lemma 2.4). For $u = 1$ this gives the currently fastest $\widetilde{\mathcal{O}}(N+s^{3/2})$ time algorithm (in terms of small s). With our $\widetilde{\mathcal{O}}(n+s^{5/3})$ time algorithm we improve upon their result for $u \gg s^{1/3}$. We note that even with the naive (not binary) multiplicity encoding our improvement is nontrivial, since the mentioned case with $u = 1$ requires that each item has a different size. For example, even an $\mathcal{O}(N+s^{1.99})$ time algorithm does not follow immediately from [9] when multiple items can have the same size. We discuss their additive combinatorics methods in more detail in Section 5.2.

See Table 2 for a summary of the known results for Subset Sum.

Lower bounds

Bringmann's Subset Sum algorithm [9], which runs in time $\widetilde{\mathcal{O}}(N+t)$, was shown to be near-optimal by using the modern toolset of fine-grained complexity. More precisely, any $t^{1-\varepsilon}2^{o(N)}$ algorithm for Subset Sum, for any $\varepsilon > 0$, would violate both the Strong Exponential Time Hypothesis [1] and the Set Cover Conjecture [14]. This essentially settles the complexity of the problem in the parameters N and t. These lower bounds use reductions that produce instances with $t = \widetilde{\Theta}(s)$, and therefore they do not exclude a possibility of a $\widetilde{\mathcal{O}}(N+s)$ time algorithm for Subset Sum. The question if such an algorithm exists is still a major open problem [4].

Bringmann and Wellnitz [11] excluded a possibility of a near-linear algorithm for Subset Sum in a *dense* regime. More precisely, they showed that, unless the Strong Exponential Time Hypothesis and the Strong k-Sum Hypothesis both fail, Subset Sum requires $(s\Sigma/(Nt))^{1-o(1)}$ time (where Σ is the total sum of items).

For the Knapsack problem Bellman's algorithm [7] remains optimal for the most natural parametrization by N and t. This was explained by Cygan at el. [15] and Künnemann et al. [25], who proved an $(N+t)^{2-o(1)}$ lower bound assuming the $(\min,+)$-Convolution

Conjecture. Their hardness constructions create instances of 0-1 Knapsack where s and t are $\widetilde{\Theta}(N)$. This is also the best lower bound known for Knapsack with multiplicities. In particular, an $\mathcal{O}(N + s^{2-\varepsilon})$ time algorithm is unlikely, and our $\mathcal{O}(n + s^3)$ upper bound leaves the gap for the best exponent between 2 and 3.

Other variants of Knapsack and Subset Sum

We now briefly overview other variants of Knapsack and Subset Sum, which are not directly related to our results. The Unbounded Knapsack problem is the special case with $u_i = \infty$, for all $i \in [n]$, and one can assume w.l.o.g. $N = n \leqslant s$. For that variant Tamir [31] presented an $\mathcal{O}(n^2 s^2)$ time algorithm. Eisenbrand and Weismantel [16] improved this result and gave an $\mathcal{O}(ns^2)$ time algorithm using proximity arguments. Bateni et al. [6] presented a $\widetilde{\mathcal{O}}(ns + s^2 \min\{n, s\})$ time algorithm. Then, an $\mathcal{O}(n + \min\{s^2, v^2\})$ algorithm for Unbounded Knapsack was given independently by Axiotis and Tzamos [5] and Jansen and Rohwedder [19]. Finally, Chan and He [13] gave a $\widetilde{\mathcal{O}}(ns)$ time algorithm. Unbounded Knapsack seems to be an easier problem than 0-1 Knapsack because algorithms do not need to keep track of which items are already used in partial solutions. Most of the Unbounded Knapsack techniques do not apply to 0-1 Knapsack.

In the polynomial space setting, Lokshtanov and Nederlof [27] presented a $\widetilde{\mathcal{O}}(N^4 sv)$ time algorithm for Knapsack and a $\widetilde{\mathcal{O}}(N^3 t)$ time algorithm for Subset Sum. The latter was subsequently improved by Bringmann [9], who gave a $\widetilde{\mathcal{O}}(Nt^{1+\varepsilon})$ time and $\widetilde{\mathcal{O}}(N \log t)$ space algorithm. Recently, Jin, Vyas and Williams [20] presented a $\widetilde{\mathcal{O}}(Nt)$ time and $\widetilde{\mathcal{O}}(\log(Nt))$ space algorithm (assuming a read-only access to $\widetilde{\mathcal{O}}(\log N \log\log N + \log t)$ random bits).

In the Modular Subset Sum problem, all subset sums are taken over a finite cyclic group $\mathbb{Z}_m$, for some given integer m. Koiliaris and Xu [24] gave a $\widetilde{\mathcal{O}}(m^{5/4})$ time algorithm for this problem, which was later improved by [4] to $\mathcal{O}(m \log^7 m)$. Axiotis et al. [3] independently with Cardinal and Iacono [12] simplified their algorithm and gave an $\mathcal{O}(m \log m)$ time randomized and $\mathcal{O}(m \operatorname{polylog}(m))$ deterministic time algorithms. Recently, Potępa [29] gave the currently fastest $\mathcal{O}(m \log(m)\alpha(m))$ deterministic algorithm for Modular Subset Sum (where $\alpha(m)$ is the inverse Ackerman function).

Bringmann and Nakos [10] designed a near-linear time algorithm for output sensitive Subset Sum by using additive combinatorics methods. Finally, Jansen and Rohwedder [19] considered the Unbounded Subset Sum problem and presented a $\widetilde{\mathcal{O}}(s)$ time algorithm.

2 Techniques

In this section we recall several known techniques from different fields, which we later combine as black boxes in order to get efficient algorithms in the setting with binary encoded multiplicities. We do not expect the reader to be familiar with all of them, and we include their brief descriptions for completeness. Nevertheless, it should be possible to skip reading this section and still get a high-level understanding of our results.

2.1 Proximity arguments

Now we introduce proximity arguments, which will allow us to avoid a dependency on the multiplicities u_i in the running time. Very similar arguments were used by Eisenbrand and Weismantel [16] for more general integer linear programs. We reprove them for our simpler case to make the paper self-contained.

We will show that we can efficiently compute a solution to Knapsack which differs from an optimal solution only in a few items. To this end, we define a ***maximal prefix solution*** to be a solution obtained as follows. We order the items by their efficiency, i.e. by the ratios v_i/s_i, breaking ties arbitrarily. Then, beginning with the most efficient item, we select items in the decreasing order of efficiency until the point when adding the next item would exceed the knapsack's capacity. At this point we stop and return the solution.

Note that a maximal prefix solution can be found in time $\mathcal{O}(n)$: We first select the median of v_i/s_i in time $\mathcal{O}(n)$ [8]. Then, we check if the sum of all the items that are more efficient than the median exceeds t. If so, we know that none of the other items are used in the maximal prefix solution. Otherwise, all the more efficient items are used. In both cases we can recurse on the remaining $n/2$ items. The running time is then of the form of a geometric sequence that converges to $\mathcal{O}(n)$.

▶ **Lemma 2.1** (cf., [16]). *Let p be a maximal prefix solution to Knapsack. There is an optimal solution z that satisfies $\|z-p\|_1 \leqslant 2s$, where $\|z-p\|_1$ denotes $\sum_{i\in[n]} |z_i - p_i|$.*

Proof. Let z be an optimal solution which minimizes $\|z-p\|_1$. If all the items fit into the knapsack, p and z must be equal. Otherwise, we can assume that the total sizes of both solutions, i.e. $\sum_{i\in[n]} s_i z_i$ and $\sum_{i\in[n]} s_i p_i$, are both between $t-s+1$ and t. In particular, we have that

$$-s < \sum_{i\in[n]} s_i(p_i - z_i) < s. \tag{1}$$

For the sake of the proof consider the following process. We start with the vector $z-p$, and we move its components towards zeros, carefully maintaining the bounds of (1). That is, in each step of the process, if the current sum of item sizes is positive, we reduce a positive component by 1; if the sum is negative, we increase a negative component by 1. The crucial idea is that during this process in no two steps we can have the same sum of item sizes. Otherwise, one could apply to z the additions and removals performed between the two steps, and therefore obtain another solution that is closer to p and is still optimal. Indeed, the optimiality follows from the fact that this operation does not increase the total size of the solution, and it also cannot decrease the value of the solution, because every item selected by p but not by z has efficiency no lower than every item selected by z but not by p. Hence, the number of steps, i.e., $\|z-p\|_1$, is bounded by $2s$. ◀

This lemma can be used to avoid the dependency on multiplicities $u_1, u_2, \ldots, u_n$ as follows. We compute a maximal prefix solution p. Then we know that there is an optimal solution z with

$$z_i \in \{0, \ldots, u_i\} \cap \{p_i - 2s, \ldots, p_i + 2s\} \quad \forall i \in [n].$$

Hence, we can obtain an equivalent instance by fixing the choice of some items. Formally, we remove $\max\{0, p_i - 2s\}$ many copies of item i and subtract their total size from t. If some item still has more than $4s$ copies, we can safely remove the excess. This shows that one can reduce a general knapsack instance to an instance with $u_i \leqslant 4s$ for all $i \in [n]$. In particular, a naive application of Bellman's algorithm would run in time $\mathcal{O}(t \cdot \sum_{i=1}^{n} u_i) \leqslant \mathcal{O}(n^2 s^3)$. Later in this paper we will apply the same proximity statement in more involved arguments.

2.2 Fast structured $(\min, +)$-convolution

Another technique that we use in this paper is a fast algorithm for structured instances of the $(\min, +)$-convolution problem. This technique was already applied in several algorithms for Knapsack [22, 6, 5]. We use it to find solutions for all knapsack capacities in $\{0, \dots, t\}$ in time $\mathcal{O}(n + st + t\log^2(t))$. We consider a slightly more general variant, where the values of items may also be negative and the knapsack constraint has to be satisfied with equality. To avoid confusion, we let $\bar{v}_i \in \mathbb{Z}$, $i \in [n]$, denote these possibly negative values of items.

▶ **Lemma 2.2.** *Let $\bar{v}_1, \bar{v}_2, \dots, \bar{v}_n \in \mathbb{Z}$. In time $\mathcal{O}(n + st + t\log^2(t))$ one can solve*

$$\max_{x \in \mathbb{Z}^n} \sum_{i \in [n]} \bar{v}_i x_i \qquad \text{subject to } \sum_{i \in [n]} s_i x_i = t' \qquad \text{and} \quad \forall_{i \in [n]}\ 0 \leqslant x_i \leqslant u_i, \tag{2}$$

for all $t' \in \{0, \dots, t\}$.

Proof. For $h \in [s+1]$ let $w^{(<h)} = \langle w_0^{(<h)}, w_1^{(<h)}, \dots, w_t^{(<h)} \rangle$ where $w_{t'}^{(<h)}$ denotes the value of an optimal solution to (2) for the knapsack capacity t' when restricting the instance to items i with $s_i < h$. If there is no solution satisfying the equality constraint with t', we let $w_{t'}^{(<h)} = -\infty$. Our goal is to compute the vectors $w^{(<1)}, w^{(<2)}, \dots, w^{(<h+1)}$ iteratively. We define the vector $w^{(h)} = \langle w_0^{(h)}, w_1^{(h)}, \dots, w_t^{(h)} \rangle$ which describes the optimal solutions solely of items j with $s_j = h$. For each i, the component $w_{t'}^{(h)}$ for $t' = ih$ is equal to the total value of the i most valuable items of size h, or to $-\infty$ if there are less than i items of size h. All components for indices not divisible by h are $-\infty$.

Hence, to compute $w^{(h)}$ it suffices to find the $\lceil t/h \rceil$ most valuable items of size h in the decreasing order of values. In time $\mathcal{O}(n+s)$ we partition the items by their size s_i. Extracting the t/h most valuable items for all $h \in [s]$ requires in total a time of $\mathcal{O}(n + \sum_{h \in [s]} t/h) \leqslant \mathcal{O}(n + t\log(t))$. Finally, sorting all sets takes in total $\mathcal{O}(\sum_{h \in [s]} t/h \cdot \log(t/h)) \leqslant \mathcal{O}(t\log^2(t))$ time.

Given $w^{(<h)}$ for some h we want to compute the vector $w^{(<h+1)}$ in time $\mathcal{O}(t)$. Then the lemma follows by iteratively applying this step. To this end we notice that $w^{(<h+1)}$ is precisely the $(\max, +)$-convolution of $w^{(h)}$ and $w^{(<h)}$, that is,

$$w_i^{(<h+1)} = \max\left\{ w_j^{(h)} + w_{i-j}^{(<h)} \mid j \in \{0, \dots, i\} \right\}.$$

While in general computing a $(\max, +)$-convolution is conjectured to require quadratic time [15, 25], in this case it can be done efficiently by exploiting the simple structure of $w^{(h)}$. For each remainder $r \in \{0, \dots, h-1\}$ we separately compute the entries of indices that are equal to r modulo h. We define the matrix $M \in \mathbb{Z}^{\lceil t/h \rceil \times \lceil t/h \rceil}$ with

$$M[i, j] = w_{jh+r}^{(<h)} + w_{(i-j)h}^{(h)},$$

where $w_{(i-j)h}^{(h)} = -\infty$ if $j > i$. We do not explicitly construct the matrix, but we can compute any entry of M in the constant time. To produce the vector $w^{(<h+1)}$ it suffices to find the maximum of each row of M. This can be done efficiently, since M is *inverse-Monge*, that is,

$$\begin{aligned} M[i, j] + M[i+1, j+1] &= w_{jh+r}^{(<h)} + w_{(i-j)h}^{(h)} + w_{jh+h+r}^{(<h)} + w_{(i-j)h}^{(h)} \\ &\geqslant w_{jh+r}^{(<h)} + w_{(i-j)h+h}^{(h)} + w_{jh+h+r}^{(<h)} + w_{(i-j)h-h}^{(h)} = M[i+1, j] + M[i, j+1]. \end{aligned}$$

Therefore, we can compute the row maxima in time $\mathcal{O}(t/h)$ with SMAWK algorithm [2]. This implies a total running time of $\mathcal{O}(t)$ for all remainders r and proves the lemma. ◀

2.3 Additive combinatorics

In this section, we introduce a near-linear time algorithm for dense instances of Subset Sum, more precisely, instances with $N^2 \gg us$.

The techniques behind the algorithm were introduced by Galil and Margalit [17], and recently generalized to the multiset setting by Bringmann and Wellnitz [11]. We focus on the modern description of [11], and show in Section 5.3 that in our application we can additionally report a solution.

▶ **Theorem 2.3** (Bringmann and Wellnitz [11]). *There exists $\lambda = \widetilde{\Theta}(us\Sigma/N^2)$ such that in time $\widetilde{\mathcal{O}}(N)$ we can construct a data structure that for any t satisfying $\lambda \leqslant t \leqslant \Sigma/2$ decides in time $\mathcal{O}(1)$ whether t is a subset sum.*

This is non-trivial when $\lambda \leqslant \Sigma/2$, that is when $N^2 \gg us$. We note that in the setting of Subset Sum with multiplicities Theorem 2.3 gives an $\widetilde{\mathcal{O}}(N + u^{1/2}s^{3/2})$ time algorithm. We denote by $\mathcal{S}(I)$ all subset sums of a multiset I, and we write $\Sigma(I) = \sum_{a \in I} a$.

▶ **Lemma 2.4.** *Given a multiset I of size N, in $\widetilde{\mathcal{O}}(N + s^{3/2}u^{1/2})$ time we can construct a data structure that, for any $t \in \mathbb{N}$,*
(a) *determines whether $t \in \mathcal{S}(I)$ in time $\mathcal{O}(1)$, and*
(b) *if $t \in \mathcal{S}(I)$, it finds $X \subseteq I$ with $\Sigma(X) = t$ in time $\widetilde{\mathcal{O}}(N + s^{3/2}u^{1/2})$.*

In order to prove that we can retrieve a solution with the given running time we will need to get into technical details behind the proof of Theorem 2.3. We do it in Section 5.3. Now, we sketch how to use Theorem 2.3 as a blackbox to give an $\widetilde{\mathcal{O}}(N + u^{1/2}s^{3/2})$ time algorithm that can only detect if there is a solution.

Proof of Lemma 2.4 (a). Let λ be defined as in Theorem 2.3. If the total sum of items Σ is bounded by $\widetilde{\mathcal{O}}(s^{3/2}u^{1/2})$, then we can use Bringmann's $\widetilde{\mathcal{O}}(N+t)$ time Subset Sum algorithm [9] to compute $\mathcal{S}(I)$. Therefore from now on we can assume that $s^{3/2}u^{1/2} \leqslant \widetilde{\mathcal{O}}(\Sigma) \leqslant \widetilde{\mathcal{O}}(Ns)$. In particular, this means that $\sqrt{us} \leqslant \widetilde{\mathcal{O}}(N)$. Hence,

$$\lambda \leqslant \widetilde{\mathcal{O}}\left(\frac{us\Sigma}{N^2}\right) \leqslant \widetilde{\mathcal{O}}\left(\frac{us^2}{N}\right) \leqslant \widetilde{\mathcal{O}}(u^{1/2}s^{3/2}).$$

This means that we can afford $\widetilde{\mathcal{O}}(\lambda)$ time. In time $\widetilde{\mathcal{O}}(N + \lambda)$ we find all subset sums in $\mathcal{S}(I) \cap [0, \lambda]$ using Bringmann's algorithm [9]. For $t \in [\lambda, \Sigma/2]$ we use Theorem 2.3 to decide in $\widetilde{\mathcal{O}}(N)$ time if $t \in \mathcal{S}(I)$. For $t > \Sigma/2$ we ask about $\Sigma - t$ instead. ◀

3 Knapsack with small item sizes

In this section we obtain an $\mathcal{O}(n + s^3)$ time algorithm for Knapsack by combining the proximity and convolution techniques.

Proof of Theorem 1.1. Let p be a maximal prefix solution. By Lemma 2.1 there is an optimal solution z with $\|z - p\|_1 \leqslant 2s$. We will construct an optimal solution x that is composed of three parts, that is, $x = p - x^- + x^+$. Our intuition is that x^+ is supposed to mimic the items that are included in z but not in p. We denote these items by $(z - p)_+$, where $(\cdot)_+$ takes for each component the maximum of it and 0. Likewise, x^- intuitively stands for $(p - z)_+$, the items in p but not in z.

To find x^+ and x^- we will invoke twice the $\mathcal{O}(n + st + t\log^2(t))$ time algorithm of Lemma 2.2. Let $\Delta = t - \sum_{i \in [n]} s_i p_i$, that is, the remaining knapsack capacity in the prefix solution. We can assume w.l.o.g. that $\Delta < s$, since otherwise p already includes all items and must be optimal. We use Lemma 2.2 to compute optimal solutions to the following integer programs for every $k \in \{0, \ldots, 2s^2 + \Delta\}$.

$$\max_{x\in\mathbb{Z}^n} \sum_{i\in[n]} v_i x_i \qquad \text{subject to} \qquad \sum_{i\in[n]} s_j x_i \leqslant k \quad \text{and} \quad \forall_{i\in[n]}\ 0 \leqslant x_i \leqslant u_i - p_i \tag{3}$$

$$\max_{x\in\mathbb{Z}^n} \sum_{i\in[n]} -v_i x_i \qquad \text{subject to} \qquad \sum_{i\in[n]} s_i x_i = k \quad \text{and} \quad \forall_{i\in[n]}\ 0 \leqslant x_i \leqslant p_i \tag{4}$$

We denote the resulting solutions by $x^+(k)$ and $x^-(k)$. Note, that formally the algorithm in Lemma 2.2 outputs solutions to the variant of (3) with equality, we can transform it to the above form with a single pass over the solutions.

For any k the solution $x(k) = p - x^-(k) + x^+(k+\Delta)$ is feasible. We compute values of all such solutions and select the best of them. To show that this is indeed an optimal solution, it suffices to show that for one such k the solution is optimal. Let $k = \sum_{i\in[n]} \max\{0, s_i(p_i - z_i)\} \leqslant 2s^2$, then $(x-z)_+$ is feasible for (3) with $k+\Delta$ and $(p-z)_+$ for (4) with k. Thus,

$$\begin{aligned}\sum_{i\in[n]} v_i(x(k))_i &= \sum_{i\in[n]} v_i p_i \quad - \sum_{i\in[n]} v_i (x^-(k))_i \quad + \sum_{i\in[n]} v_i (x^+(k+\Delta))_i \\ &\geqslant \sum_{i\in[n]} v_i p_i \quad - \sum_{i\in[n]} v_i \max\{0, p_i - z_i\} \quad + \sum_{i\in[n]} v_i \max\{0, z_i - p_i\} = \sum_{i\in[n]} v_i z_i.\end{aligned}$$

It remains to bound the running time. The maximal prefix solution can be found in time $\mathcal{O}(n)$. Each of the two calls to the algorithm of Lemma 2.2 takes time $\mathcal{O}(n + s^3 + s^2 \log^2(s)) = \mathcal{O}(n + s^3)$ and selecting the best solution among the $2s^2$ candidates takes time $\mathcal{O}(s^2)$. ◀

4 Knapsack with small item values

In this section we show that it is also possible to solve Knapsack in time $\mathcal{O}(n + v^3)$, proving Theorem 1.2. This can be derived directly from the $\mathcal{O}(n+s^3)$ time algorithm from the previous section. Essentially, we swap the item values and sizes by considering the complementary problem of finding the items that are not taken in the solution. Then our goal is to solve

$$\min_x \sum_{i\in[n]} v_i x_i \qquad \text{subject to} \sum_{i\in[n]} s_i x_i \geqslant \sum_{i\in[n]} u_i s_i - t \qquad \text{and} \qquad \forall_{i\in[n]} 0 \leqslant x_i \leqslant u_i. \tag{5}$$

Suppose we are satisfied with any solution that has value at least some given $v^\star$. Then this can be solved by

$$\max_x \sum_{i\in[n]} s_i x_i \qquad \text{subject to} \sum_{i\in[n]} v_i x_i \leqslant \sum_{i\in[n]} u_i v_i - v^\star \qquad \text{and} \qquad \forall_{i\in[n]} 0 \leqslant x_i \leqslant u_i.$$

Notice that this is now a Knapsack problem with item sizes bounded by v. Hence, our previous algorithm can solve it in time $\mathcal{O}(n + v^3)$. It remains to find the optimum of (5) and use it for the value of $v^\star$. Notice that the maximal prefix solution p gives a good estimate of this $v^\star$, because its value is between $v^\star - v + 1$ and $v^\star$. Thus, one could in a straight-forward way implement a binary search for $v^\star$ and this would increase the running time only by a factor of $\log(v)$, but we can avoid this and get an $\mathcal{O}(n + v^3)$ time algorithm.

It is enough to devise an algorithm that in time $\mathcal{O}(n + v^3)$ computes a solution for each of the v potential values values of $v^\star$ at once. Then we can return the largest $v^\star$ for which the solution requires a knapsack of size at most t. Fortunately, our original Theorem 1.1 can compute solution to every $t' \in \{t - v, t - v + 1, \ldots, t\}$ and the $\mathcal{O}(n + v^3)$ time algorithm for Knapsack follows.

We include a small modification of Knapsack algorithm from Section 3 for completeness.

▷ Claim 4.1. In $\mathcal{O}(n + s^3)$ time we can compute an optimal solution to Knapsack for every $t' \in \{t - s, t - s + 1, \dots, t\}$.

Proof. Recall that the intermediate solutions $x^+(k)$ and $x^-(k)$ depend only on the maximal prefix solution p and the only property of p that is needed is that it differs from the optimal solution by $\mathcal{O}(s)$ items. Notice that the maximal prefix solutions with respect to each of the values t' above differ only by at most s items. Hence, p, the prefix solution for t, differs from each of the optimal solutions only by $\mathcal{O}(s)$. Hence, we only need to compute $x^+(k)$ and $x^-(k)$ once. Given these solutions the remaining computation takes only $\mathcal{O}(s^2)$ for each t'; thus, $\mathcal{O}(s^3)$ in total. ◁

5 Subset Sum

In this section we give a $\widetilde{\mathcal{O}}(n+s^{5/3})$ time algorithm for Subset Sum with multiplicties proving Theorem 1.3. Our algorithm is a combination of additive combinatorics and proximity arguments. Throughout this section, we denote by $\mathcal{S}(A)$ the set of all subset sums of a (multi-)set of integers A. In other words, $t \in \mathcal{S}(A)$ if there exists some $B \subseteq A$ with $\Sigma(B) = t$.

Algorithm 1 $\widetilde{\mathcal{O}}(n + s^{5/3})$ time algorithm for Subset Sum with multiplicties.

Algorithm : `SubsetSum`(I, t).
Output : Multiset $X \subseteq I$ with $\Sigma(X) = t$ or `NO` if such a multiset does not exists.

Preprocess I using Lemma 2.1 so that $u_i \leqslant O(s)$ for all $i \in [n]$
Set $k := \lfloor s^{1/3} \rfloor$
Construct $I^{\uparrow} := \{(\max\{0, \lfloor u_i/k \rfloor - 8\}, s_i) \ : \ (u_i, s_i) \in I\}$
Construct $I^{\downarrow} := \{(u_i - k \cdot \max\{0, \lfloor u_i/k \rfloor - 8\}, s_i) \ : \ (u_i, s_i) \in I\}$
Construct oracle to $\mathcal{S}(I^{\downarrow})$ `// with Lemma 2.4`
Construct set of candidates $\mathcal{C}(I^{\uparrow}) \subseteq \mathcal{S}(I^{\uparrow})$ `// with Lemma 5.1`
foreach $t' \in \mathcal{C}(I^{\uparrow})$ **do**
  if $t - k \cdot t' \in \mathcal{S}(I^{\downarrow})$ **then**
    Recover $A \subseteq I^{\uparrow}$ with $\Sigma(A) = t'$
    Recover $B \subseteq I^{\downarrow}$ with $\Sigma(B) = t - k \cdot t'$
    return $(k \cdot A) \cup B$
return `NO`

We now give a high level overview of the algorithm (see Algorithm 1). In the following we assume w.l.o.g. that $u \leqslant \mathcal{O}(s)$ by using the preprocessing described after Lemma 2.1. First, we split the instance I into two parts $I^{\uparrow}$ and $I^{\downarrow}$: Let $k = \lfloor s^{1/3} \rfloor$. For every item s_i with multiplicity u_i we add $u_i^{\uparrow} = \max\{0, \lfloor u_i/k \rfloor - 8\} = \mathcal{O}(s^{2/3})$ many items of size s_i into multiset $I^{\uparrow}$. The rest of the items of size s_i, i.e., $u_i^{\downarrow} = u_i - k \cdot u_i^{\uparrow} = \mathcal{O}(s^{1/3})$ many, are added to multiset $I^{\downarrow}$. Intuitively, $I^{\uparrow}$ stands for taking bundles of k items. The set $I^{\downarrow}$ consists of the remaining items. In particular, it holds that:

$$\mathcal{S}(I) = \left\{kt^{\uparrow} + t^{\downarrow} \ : \ t^{\uparrow} \in \mathcal{S}(I^{\uparrow}) \text{ and } t^{\downarrow} \in \mathcal{S}(I^{\downarrow})\right\}.$$

Our goal is to decide whether there exists an integer $t' \in \mathcal{S}(I^{\uparrow})$ with the property that $t - kt' \in \mathcal{S}(I^{\downarrow})$. The strategy of the algorithm is as follows: we will use proximity arguments to bound the number of candidates for such a $t' \in \mathcal{S}(I^{\uparrow})$ and efficiently enumerate them in time $\widetilde{\mathcal{O}}(s^{5/3})$.

▶ **Lemma 5.1.** *In time $\widetilde{\mathcal{O}}(s^{5/3})$, we can construct $\mathcal{C}(I^\uparrow) \subseteq \mathcal{S}(I^\uparrow)$ of size $|\mathcal{C}(I^\uparrow)| \leqslant \widetilde{\mathcal{O}}(s^{5/3})$ with the property that if $t \in \mathcal{S}(I)$, then there exists $t' \in \mathcal{C}(I^\uparrow)$ and $t - kt' \in \mathcal{S}(I^\downarrow)$. Moreover, for any $t' \in \mathcal{C}(I^\uparrow)$ we can find $X \subseteq I^\uparrow$ with $\Sigma(X) = t'$ in time $\widetilde{\mathcal{O}}(s^{5/3})$.*

We will prove this lemma in Section 5.1. To check the condition $t - kt' \in \mathcal{S}(I^\downarrow)$ we observe that the set $I^\downarrow$ has bounded multiplicity and large density. To accomplish that we use Lemma 2.4. It uses a recent result of Bringmann and Wellnitz [11] and enables us to decide in constant time if $t - kt' \in \mathcal{S}(I^\downarrow)$ for any t' after a preprocessing that requires time $\widetilde{\mathcal{O}}(|I^\downarrow| + s^{3/2}(u^\downarrow)^{1/2}) \leqslant \widetilde{\mathcal{O}}(s^{5/3})$ because $|I^\downarrow| \leqslant \mathcal{O}(s \cdot u^\downarrow)$ and $u^\downarrow \leqslant \mathcal{O}(s^{1/3})$. We extend their methods to be able to construct the solution within $\widetilde{\mathcal{O}}(s^{5/3})$ time (see Section 5.3 for the proof of Lemma 2.4).

Now, we analyse the correctness of Algorithm 1. The running time is bounded by $\widetilde{\mathcal{O}}(n + s^{5/3})$ because the number of candidates is $|\mathcal{C}(I^\uparrow)| \leqslant \widetilde{\mathcal{O}}(s^{5/3})$ by Lemma 5.1. The algorithm is correct because set $\mathcal{C}(I^\uparrow)$ has the property that if an answer to the Subset Sum is positive, then there exists $t' \in \mathcal{C}(I^\uparrow)$ with $t - k \cdot t' \in \mathcal{S}(I^\downarrow)$

Moreover, when the answer is positive we have $t' \in \mathcal{C}(I^\uparrow)$ with $t - k \cdot t' \in \mathcal{S}(I^\downarrow)$. We use Lemma 5.1 to recover $A \subseteq I^\uparrow$ with $\Sigma(A) = t'$. Then we use Lemma 2.4 to find $B \subseteq I^\downarrow$ with $\Sigma(B) = t - k \cdot t'$. We construct a final solution $(k \cdot A) \cup B$ by unbundling items in A (duplicating them k times) and joining them with set B. This concludes the proof of Theorem 1.3.

5.1 Finding a small set of candidates

In this section we derive a small set of candidates $\mathcal{C}(I^\uparrow)$ and prove Lemma 5.1. This is based on the proximity result (Lemma 2.1). Recall that for p, a maximal prefix solution, we know that there exists some feasible solution that differs only by $\mathcal{O}(s)$ items (if the instance is feasible). Suppose we split p between $I^\uparrow$ and $I^\downarrow$ into $p^\uparrow$ and $p^\downarrow$. As each of the items in $I^\uparrow$ stands for k items in I, one might expect that the part of the optimal solution that comes from $I^\uparrow$ differs from $p^\uparrow$ by only $\mathcal{O}(s/k)$ items. This is not necessarily true if $p^\uparrow$ and $p^\downarrow$ are chosen unfavorably. Fortunately, we can show that with a careful choice of $p^\uparrow$ and $p^\downarrow$ it can be guaranteed.

▶ **Definition 5.2** (Robust split)**.** *Let $p = (p_1, \ldots, p_n) \in \mathbb{N}^n$ be a maximal prefix solution. Let $p^\uparrow, p^\downarrow \in \mathbb{N}^n$ be defined by*

$$p_i^\uparrow = \begin{cases} 0 & \text{if } p_i \leqslant 4k \text{ or } u_i \leqslant 8k, \\ \lfloor u_i/k \rfloor - 8 & \text{if } p_i \geqslant u_i - 4k \text{ and } u_i > 8k, \\ \lfloor p_i/k \rfloor - 2 & \text{if } p_i \in (4k, u_i - 4k) \text{ and } u_i > 8k, \end{cases}$$

and $p_i^\downarrow = p_i - kp_i^\uparrow$, for every $i \in [n]$. We call $p^\uparrow, p^\downarrow$ the robust split *of p.*

An important property of the choice of $p^\uparrow$ and $p^\downarrow$ is that there is some slack for $p_i^\downarrow$. Namely, if we were to change p_i slightly (say, by less than k) then we only need to change $p_i^\downarrow$ (and do not need to change $p_i^\uparrow$) to maintain $p_i = kp_i^\uparrow + p_i^\downarrow$.

▶ **Lemma 5.3.** *Let p be a maximal prefix solution and let $p^\uparrow, p^\downarrow$ be its robust split. If $t \in \mathcal{S}(I)$, then there are solutions $x^\uparrow, x^\downarrow$ of $I^\uparrow$ and $I^\downarrow$ such that:*

$$\sum_{i \in [n]} (kx_i^\uparrow + x_i^\downarrow)s_i = t \quad \text{and} \quad \|x^\uparrow - p^\uparrow\|_1 \leqslant \mathcal{O}(s/k).$$

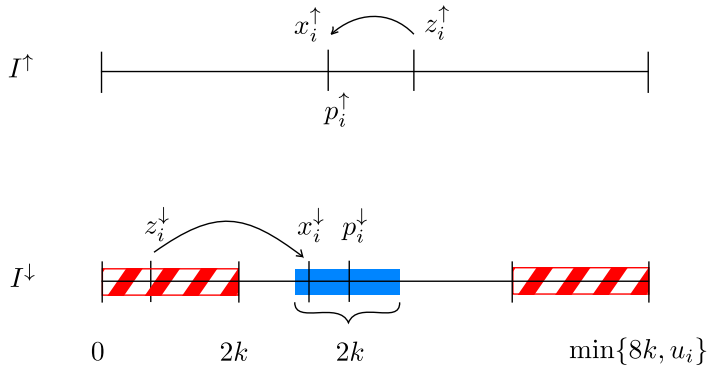

Figure 1 Schematic idea behind the proof of Lemma 5.3 in the case $u_i > 8k$. We select $p_i^\downarrow$ such that it is never in the red hatched regions. The property of $p^\uparrow, p^\downarrow$ is that any solution that differs by at most k elements can take the same elements from $I^\uparrow$ as $p_i^\uparrow$. In that case the situation where the optimal solution is of the form z (in the figure) can always be avoided to instead get the situation with x.

Proof. The proof consists of straightforward, but tedious, calculations; see Figure 1 for an intuition.

By Lemma 2.1 we know that there is a feasible solution x with $\|x - p\|_1 \leqslant \mathcal{O}(s)$. Let us use this solution and construct $x^\uparrow$ and $x^\downarrow$. We consider each index $i \in [n]$ individually and show that there is a split of x_i into $x_i^\uparrow$, $x_i^\downarrow$ which are feasible for $I^\uparrow$, $I^\downarrow$, that is, they satisfy the bounds $[0, u_i^\uparrow]$ and $[0, u_i^\downarrow]$, and we have that $|x_i^\uparrow - p_i^\uparrow| \leqslant 19|x_i - p_i|/k$. This implies the lemma. To this end, consider two cases based on $|x_i - p_i|$.

Case 1: $|x_i - p_i| < k$. In this case we set $x_i^\uparrow = p_i^\uparrow$ and $x_i^\downarrow = x_i - kx_i^\uparrow$. This choice does not contribute anything to the norm $\|x^\uparrow - p^\uparrow\|_1$ because $x_i^\uparrow = p_i^\uparrow$. We need to show that $x_i^\uparrow$ and $x_i^\downarrow$ are feasible solutions to the subset sum instances $I^\uparrow$ and $I^\downarrow$.

Clearly, $x_i^\uparrow$ is between 0 and $u_i^\uparrow = \max\{\lfloor u_i/k \rfloor - 8, 0\}$ in the first two cases of Definition 5.2. In the last case, we have that $4k < p_i < u_i - 4k$ and therefore $0 \leqslant \lfloor p_i/k \rfloor - 2 = p_i^\uparrow$. Furthermore, $p_i^\uparrow = \lfloor p_i/k \rfloor - 2 < p_i/k - 3 < u_i/k - 7 < \lfloor u_i/k \rfloor - 8 = u_i^\uparrow$.

Therefore, it remains to show that $x_i^\downarrow$ is feasible for $I^\downarrow$. More precisely, we will prove that:

$$0 \leqslant x_i - kp_i^\uparrow \leqslant u_i - k \cdot \max\{\lfloor u_i/k \rfloor - 8, 0\}.$$

To achieve that, we will crucially rely on our choice for $p^\uparrow$ in Definition 5.2.

Case 1a: $u_i \leqslant 8k$ **or** $p_i \leqslant 8k$. When $u_i \leqslant 8k$ or $p_i \leqslant 8k$ then the claim follows because $p_i^\uparrow = x_i^\uparrow = 0$.

Case 1b: $p_i \geqslant u_i - 4k$ **and** $u_i > 8k$. In this case we have $p_i^\uparrow := \lfloor u_i/k \rfloor - 8$. Inequality $x_i - kp_i^\uparrow \geqslant 0$ follows from $x_i > p_i - k \geqslant u_i - 5k \geqslant k\lfloor u_i/k \rfloor - 8k = kp_i^\uparrow$. Next, we use the fact $x_i \leqslant u_i$ to conclude $x_i - k\lfloor u_i/k \rfloor + 8k \leqslant u_i - k\lfloor u_i/k \rfloor + 8k$.

Case 1c: $4k < p_i < u_i - 4k$ **and** $u_i > 8k$. In this case we have $p_i^\uparrow := \lfloor p_i/k \rfloor - 2$. The inequality $x_i > p_i - k \geqslant k\lfloor p_i/k \rfloor - k = kp_i^\uparrow + k$ shows that $x_i - kp_i^\uparrow \geqslant 0$. Next, we use inequality $p_i - k\lfloor p_i/k \rfloor < k$ to show that

$$x_i - k\lfloor p_i/k \rfloor \leqslant p_i - k\lfloor p_i/k \rfloor + k \leqslant 2k < \underbrace{u_i - k\lfloor u_i/k \rfloor}_{\geqslant 0} + 8k.$$

Case 2: $|x_i - p_i| \geqslant k$. We set $x_i^{\uparrow} := \min\{\lfloor x_i/k \rfloor, u_i^{\uparrow}\}$ and $x_i^{\downarrow} := x_i - kx_i^{\uparrow}$. Clearly, $0 \leqslant x_i^{\uparrow} \leqslant u_i^{\uparrow}$. Furthermore, $x_i^{\downarrow} \geqslant 0$ and if $x_i^{\uparrow} = u_i^{\uparrow}$ then $x_i^{\downarrow} \leqslant u_i - ku_i^{\uparrow} = u_i^{\downarrow}$; otherwise, $x_i^{\downarrow} = x_i - k\lfloor x_i/k \rfloor < k < u_i^{\downarrow}$.

It remains to bound the difference between $x_i^{\uparrow}$ and $p_i^{\uparrow}$. Note that because of our choice of $p^{\uparrow}$ we have $|p_i^{\uparrow} - \lfloor p_i/k \rfloor| \leqslant 8$. Also, $|u_i^{\uparrow} - \lfloor u_i/k \rfloor| \leqslant 8$. Therefore,

$$|x_i^{\uparrow} - p_i^{\uparrow}| \leqslant \left|\min\{\lfloor x_i/k \rfloor, u_i^{\uparrow}\} - \lfloor p_i/k \rfloor\right| + 8 \leqslant \Big|\underbrace{\min\{\lfloor x_i/k \rfloor, \lfloor u_i/k \rfloor\}}_{=\lfloor x_i/k \rfloor} - \lfloor p_i/k \rfloor\Big| + 16$$
$$\leqslant |x_i - p_i|/k + 18.$$

Recall that we assumed $|x_i - p_i| \geqslant k$. Thus,

$$|x_i^{\uparrow} - p_i^{\uparrow}| \leqslant 19|x_i - p_i|/k. \qquad \blacktriangleleft$$

Now we are ready to proceed with the algorithmic part and prove Lemma 5.1.

Proof of Lemma 5.1. Let t_p be the value of $p^{\uparrow}$ in $I^{\uparrow}$, that is, $t_p := \sum_{i\in[n]} p_i^{\uparrow} s_i$. Let A^- be the multiset of numbers selected in $p^{\uparrow}$. Moreover, let A^+ denote all other elements in $I^{\uparrow}$. We now compute

$$S^+ := \mathcal{S}(A^+) \cap [c \cdot s^{5/3}] \quad \text{and} \quad S^- := \mathcal{S}(A^-) \cap [c \cdot s^{5/3}].$$

Here c is a constant that we will specify later. These sets can be computed in time $\widetilde{\mathcal{O}}(s^{5/3})$ with Bringmann's algorithm [9]. Next, using FFT we compute the sumset

$$\mathcal{C}(I^{\uparrow}) := \{t_p + a - b \mid a \in S^+, b \in S^-\}.$$

Any element in $\mathcal{C}(I^{\uparrow})$ is an integer of the form $t_p + a - b$, integer a is the sum of elements not in $p^{\uparrow}$, and integer $t_p - b$ is the contribution of elements in $p^{\uparrow}$. This operation takes time $\widetilde{\mathcal{O}}(s^{5/3})$ because the range of values of S^+ and S^- is bounded by $\mathcal{O}(s^{5/3})$. We return set $\mathcal{C}(I^{\uparrow})$ as the set of possible values of the candidates. To recover a solution we will use the fact that Bringmann's algorithm can recover solutions and the property that we can find a witness to FFT computation in linear time. Since S^+ and S^- are subsets of $[c \cdot s^{5/3}]$ we know that $\mathcal{C}(I^{\uparrow})$ is a subset of $\{t_p - c \cdot s^{5/3}, \ldots, t_p + c \cdot s^{5/3}\}$. In particular, $|\mathcal{C}(I^{\uparrow})| \leqslant \widetilde{\mathcal{O}}(s^{5/3})$.

It remains to to show that $\mathcal{C}(I^{\uparrow})$ contains some t' such that $t - kt' \in \mathcal{S}(I^{\downarrow})$ if $t \in \mathcal{S}(I)$. By Lemma 5.3 it suffices to show that $\mathcal{C}(I^{\uparrow})$ contains all values $\sum_{i\in[n]} x_i^{\uparrow} s_i$ for $x^{\uparrow}$ with $\|x^{\uparrow} - p^{\uparrow}\|_1 \leqslant c \cdot s/k$, where c is the constant in the lemma. This holds because S^+ contains $\sum_{i\in[n]:x_i^{\uparrow}\geqslant p_i^{\uparrow}} (x_i^{\uparrow} - p_i^{\uparrow}) s_i$ and S^- contains $\sum_{i\in[n]:x_i^{\uparrow}\leqslant p_i^{\uparrow}} (p_i^{\uparrow} - x_i^{\uparrow}) s_i$. $\blacktriangleleft$

5.2 Introduction to additive combinatorics methods

In this section we review the structural ideas behind the proof of Theorem 2.3. Next, in Section 5.3 we show how to use them to recover a solution to Subset Sum with multiplicities.

The additive combinatorics structure that we explore is present in the regime when $N^2 \gg us$. We formalize this assumption as follows:

▶ **Definition 5.4** (Density). *We say that a multiset X is δ-dense if it satisfies $|X|^2 \geqslant \delta us$.*

Note that if all numbers in X are divisible by the same integer d, then the solutions to Subset Sum are divisible by d. Intuitively, this situation is undesirable, because our goal is to exploit the density of the instance. With the next definition we quantify how close we are to the case where almost all numbers in X are divisible by the same number.

▶ **Definition 5.5** (Almost Divisor). *We write $X(d) := X \cap d\mathbb{Z}$ to denote the multiset of all numbers in X that are divisible by d and $\overline{X(d)} := X \setminus X(d)$ to denote the multiset of all numbers in X not divisible by d. We say that an integer $d > 1$ is an α-almost divisor of X if $|\overline{X(d)}| \leqslant \alpha u \Sigma(X)/|X|^2$.*

Bringmann and Wellnitz [11] show that this situation is not the hardest case.

▶ **Lemma 5.6** (Algorithmic Part of [11]). *Given an $\widetilde{\Theta}(1)$-dense multiset X of size N in time $\widetilde{\mathcal{O}}(N)$ we can compute an integer $d \geqslant 1$, such that $X' := X(d)/d$ is $\widetilde{\Theta}(1)$-dense and has no $\widetilde{\Theta}(1)$-almost divisors.*

They achieve that with novel prime factorization techniques. This lemma allows them essentially to reduce to the case that there are no $\widetilde{\Theta}(1)$-almost divisors. We will give more details on this in the end of Section 2.3. In our proofs we use the Lemma 5.6 as a blackbox. Next, we focus on the structural part of their arguments.

Structural part

The structural part of [11] states the surprising property. If we are given a sufficiently dense instance with no almost divisors then every set with target within the given region is attainable.

▶ **Theorem 5.7** (Structural Part of [11]). *If X is $\widetilde{\Theta}(1)$-dense and has no $\widetilde{\Theta}(1)$-almost divisor then $[\lambda_X, \dots, \Sigma(X) - \lambda_X] \subseteq \mathcal{S}(X)$ for some $\lambda_X = \widetilde{\Theta}(us\Sigma(X)/|X|^2))$.*

Therefore, Bringmann and Wellnitz [11] after the reduction to the almost-divisor-free setting can simply output `YES` on every target in the selected region. Our goal is to recover the solution to subset sum and therefore, we need to get into the details of this proof and show that we can efficiently construct it. The crucial insight into this theorem is the following decomposition of a dense multiset.

▶ **Lemma 5.8** (Decomposition, see [11, Theorem 4.35]). *Let X be a $\widetilde{\Theta}(1)$-dense multiset of size n that has no $\widetilde{\Theta}(1)$-almost divisor. Then there exists a partition $X = R \uplus A \uplus G$ and an integer $\kappa = \widetilde{\mathcal{O}}(u\Sigma(X)/|X|^2)$ such that:*

- *set $\mathcal{S}(R)$ is κ-complete, i.e., $\mathcal{S}(R) \bmod \kappa = \mathbb{Z}_\kappa$,*
- *set $\mathcal{S}(A)$ contains an arithmetic progression $\mathcal{P}$ of length $2s$ and step size κ satisfying $\max\{\mathcal{P}\} \leqslant \widetilde{\mathcal{O}}(us\Sigma(X)/|X|^2)$,*
- *the multiset G has sum $\Sigma(G) \geqslant \Sigma(X)/2$.*

Now, we sketch the proof of Theorem 5.7 with the decomposition from Lemma 5.8. This is based on the proof in [11].

Sketch of the proof of Theorem 5.7 assuming Lemma 5.8. We show that any target $t \in [\lambda_X, \dots, \Sigma(X) - \lambda_X]$ is a subset sum of X. For that we will assume without loss of generality that $t \leqslant \Sigma(X)/2$ (note that t is a subset sum if and only if $\Sigma(X) - t$ is). By Lemma 5.8 we get a partition of X into $R \uplus A \uplus G$. We know that $\mathcal{S}(A)$ contains an arithmetic progression $\mathcal{P} \subseteq \mathcal{S}(A)$, with $\mathcal{P} = \{a + \kappa, a + 2\kappa, \dots, a + 2s\kappa\}$. We construct a subset of X that sums to t as follows. First, we greedily pick $G' \subseteq G$ by iteratively adding elements until:

$$t - \Sigma(G') \in [a + \kappa(s+1), a + \kappa(s+1) + s].$$

This is possible because the largest element is bounded by s, t is at most $\Sigma(X)/2 \leqslant \Sigma(G)$, and λ_X is selected such that:

$$t \geqslant \lambda_X \geqslant a + \kappa(s+1).$$

The next step is to select a subset $R' \subseteq R$ that sums up to a number congruent to $(t - \Sigma(G') - a)$ modulo κ. Recall, that set R is κ-complete, hence such a set must exist. Moreover, w.l.o.g. $R' < \kappa$, and $\Sigma(R') < \kappa s$. Therefore, we need extra elements of total sum

$$t - \Sigma(G' \cup R') \in [a + \kappa, a + 2\kappa s], \quad \text{and} \quad t - \Sigma(G' \cup R') \equiv a \mod \kappa.$$

Finally, we note that this is exactly the range of elements of the arithmetic progression $\mathcal{P}$. It means that we can pick a subset $A' \subseteq A$, that gives the appropriate element of the arithmetic progression $\mathcal{P}$ and $t = \Sigma(G' \cup R' \cup A')$. ◀

5.3 Recovering a solution

In this section, we show how to recover a solution to Subset Sum. We need to overcome several technical difficulties. First, we need to reanalyze Lemma 5.8 and show that the partition $X = A \uplus R \uplus G$ can be constructed efficiently. This step follows directly from [11]. However, we do not know of an efficient way to construct κ and a. We show that we do not really need it. Intuitively, for our application we can afford to spend a time $\widetilde{\mathcal{O}}(N + \lambda_I)$. This observation enables us to use the $\widetilde{\mathcal{O}}(N + t)$ time algorithm of Bringmann [9] to reconstruct the solution. We commence with the observation that the decomposition into $R \uplus A \uplus G$ can be constructed within the desired time.

▷ Claim 5.9 (Recovering decomposition). Let X be a $\widetilde{\Theta}(1)$-dense multiset that has no $\widetilde{\Theta}(1)$-almost divisor. Let $K = 42480 \cdot u \cdot \Sigma(X) \log(2u)/|X|^2$. Then in $\widetilde{\mathcal{O}}(N + u\Sigma(X)/|X|^2)$ time we can explicitly find a partition $X = R \uplus A \uplus G$ such that:

- set $\mathcal{S}(R)$ is d-complete for any $d \leqslant K$,
- there exists an integer $\kappa \leqslant K$ such that the set $\mathcal{S}(A)$ contains an arithmetic progression $\mathcal{P}$ of length $2s$ and step size κ satisfying $\max\{\mathcal{P}\} \leqslant \widetilde{\mathcal{O}}(us\Sigma(X)/|X|^2)$,
- the multiset G has sum $\Sigma(G) \geqslant \Sigma(X)/2$.

Proof of Claim 5.9 based on arguments from [11]. We follow the proof of Theorem 4.35 in [11]. We focus on the construction of partition X and present only how the construction follows from [11].

To construct the set R, Bringmann and Wellnitz use [11, Theorem 4.20]. We start by picking an arbitrary subset $R' \subseteq X$ of size $\tau = \widetilde{\Theta}(u\Sigma(X)/|X|^2)$. Next we generate the set S of all prime numbers p with $p \leqslant \tau$. We can do this in $\widetilde{\mathcal{O}}(\tau)$ time by the sieve of Eratosthenes algorithm [30]. Then, we compute the prime factorization of every number in R' by [11, Theorem 3.8] in $\widetilde{\mathcal{O}}(\tau)$ time. This enables us to construct the set P of primes p with $p \leqslant \tau$ such that every $p \in P$ does not divide at least $\tau/2$ numbers in R'. Bringmann and Wellnitz [11] show that $|P| \leqslant 2 \log s$. Next, for every $p \in P$ we select an arbitrary subset $R_p \subseteq \overline{X(p)}$ of size $|R_p| = \tau$. This can be done in $\widetilde{\mathcal{O}}(N)$ time because $|P| = \widetilde{\mathcal{O}}(1)$. Finally Bringmann and Wellnitz [11] construct $R = R' \cup \left(\bigcup_{p \in P} R_p\right)$. See Theorem 4.20 in [11] for a proof that the constructed R is d-complete for any $d \leqslant K$.

To construct set A we do exactly the same as Bringmann and Wellnitz [11] and we pick at most $\lfloor n/4 \rfloor$ smallest elements from $X \setminus R$. At the end we set $G = X \setminus (R \cup A)$. See [11] for a proof that A and G have a desired properties. ◁

Now, we are ready to prove our result about recovering the solution

▶ **Lemma 5.10** (Restatement of Lemma 2.4). *Given a multiset I of N elements, in $\widetilde{\mathcal{O}}(N + s^{3/2}u^{1/2})$ time we can construct a data structure that for any $t \in \mathbb{N}$ can decide if $t \in \mathcal{S}(I)$ in time $\mathcal{O}(1)$. Moreover if $t \in \mathcal{S}(I)$ in $\widetilde{\mathcal{O}}(N + s^{3/2}u^{1/2})$ time we can find $X \subseteq I$ with $\Sigma(X) = t$.*

In the rest of this section we prove Lemma 2.4. We assume that all considered t are at most $\Sigma(I)/2$ because for larger t we can ask about $\Sigma(I) - t$ instead. Let λ_I and be defined as in Theorem 2.3. When the total sum of the elements $\Sigma(I)$ is bounded by $\widetilde{\mathcal{O}}(s^{3/2}u^{1/2})$, Bringmann's algorithm [9] computes $\mathcal{S}(I)$ and retrieves the solution in the declared time. Therefore, we can assume that $s^{3/2}u^{1/2} \leqslant \widetilde{\mathcal{O}}(|I|s)$. In particular, this means that $\sqrt{us} \leqslant \widetilde{\mathcal{O}}(|I|)$ and the set I is $\widetilde{\Theta}(1)$-dense. Hence,

$$\lambda_I \leqslant \widetilde{\mathcal{O}}\left(\frac{us\Sigma(I)}{|I|^2}\right) \leqslant \widetilde{\mathcal{O}}\left(\frac{us^2}{|I|}\right) \leqslant \widetilde{\mathcal{O}}(u^{1/2}s^{3/2}).$$

This means, that we can afford $\widetilde{\mathcal{O}}(\lambda_I)$ time. In time $\widetilde{\mathcal{O}}(|I| + \lambda_I)$ we can find all subset sums in $\mathcal{S}(I)$ that are smaller than $\widetilde{\Theta}(\lambda_I)$ using Bringmann's algorithm. Additionally, when $t \leqslant \widetilde{\Theta}(\lambda_I)$ Bringmann's algorithm can find $X \subseteq I$ in the output sensitive time.

We are left with answering queries about targets greater than λ_I. To achieve that within $\widetilde{\mathcal{O}}(\lambda_I)$-time preprocessing we use the Additive Combinatorics result from [11].

Observe, that if we were interested in a data structure that works in $\widetilde{\mathcal{O}}(N + \lambda_I) \leqslant \widetilde{\mathcal{O}}(N + s^{3/2}u^{1/2})$ and *decides* if $t \in \mathcal{S}(I)$ we can directly use [11] as a blackbox. Therefore, from now, we show that we can also reconstruct the solution in $\widetilde{\mathcal{O}}(N + \lambda_I)$ time.

▷ Claim 5.11. We can find a set $X \subseteq I$ with $\Sigma(X) = t$ in $\widetilde{\mathcal{O}}(N + \lambda_I)$ time for any $t \in [\lambda_I, \Sigma(I)/2]$ if such an X exists.

Proof. First, we use Lemma 5.6 to find an integer $d \geqslant 1$, such that set $I' := I(d)/d$ has no $\widetilde{\Theta}(1)$-almost divisor and is $\widetilde{\Theta}(1)$-dense. Observe, that the integer d can be found in $\widetilde{\mathcal{O}}(N)$ time and set I' can be constructed in $\widetilde{\mathcal{O}}(N)$ time.

Bringmann and Wellnitz [11, Theorem 3.5] prove that (recall that I is $\widetilde{\Theta}(1)$-dense and $t \geqslant \lambda_I$):

$$t \in \mathcal{S}(I) \text{ if and only if } t \bmod d \in (\mathcal{S}(I) \bmod d).$$

Therefore, the first step of our algorithm is to use Axiotis et al. [4] to decide if $t \bmod d \in (\mathcal{S}(I) \bmod d)$ and recover set $D \subseteq I \setminus I(d)$ if such a set exists (Axiotis et al. [4] enables to recover solution and by density assumption it works in $\widetilde{\mathcal{O}}(N)$ time).

If such a set exists by reasoning in [11] we know that a solution must exist (otherwise we output `NO`). We are left with recovering set $K \subseteq I'$ with $\Sigma(K) := (t - \Sigma(D))/d$.

Next, we use Claim 5.9 to find a partition $I' = R \uplus A \uplus G$. We can achieve that in $\widetilde{\mathcal{O}}(u\Sigma(I')/|I'|^2) \ll \widetilde{\mathcal{O}}(N + \lambda_I)$ time. Ideally, we would like to repeat the reasoning presented in the proof of Theorem 5.7. Unfortunately, we do not know how to explicitly construct a and κ within the given time. Nevertheless, Theorem 5.7 guarantees that $t \in \mathcal{S}(I)$ and that such integers a and κ exist.

Based on the properties of sets in Theorem 5.7 we have

$$t \in \mathcal{S}(G \uplus R \uplus A) = \mathcal{S}(G) \oplus (\mathcal{S}(R \cup A) \cap [0, \widetilde{\mathcal{O}}(\lambda_I)]).$$

With a Bringmann's algorithm we can compute the set $T := \mathcal{S}(R \cup A) \cap [0, \widetilde{\mathcal{O}}(\lambda_I)]$ in $\widetilde{\mathcal{O}}(N + \lambda_I)$ time. Now, recall that in the proof of Theorem 5.7 we have chosen set $G' \subseteq G$ greedily to satisfy $\Sigma(G') \geqslant t - a - \kappa(s + 1)$ for some a, κ and s. Therefore it is enough to iterate over every greedily chosen $G' \subseteq G$ and check whether $t - \Sigma(G') \in T$. Notice that there are only N options for G' that can be generated in $\mathcal{O}(N + \lambda_I)$ time. For each of them we can check whether $t - \Sigma(G') \in T$ in $\mathcal{O}(1)$ time because we have access to T. If we find such a set, we just report $K := G' \cup T'$, where $T' \subseteq R \cup A$ with $\Sigma(T') + \Sigma(G') = t$. ◁

This concludes the proof of Lemma 2.4.

Abstract

Random walks on graphs are an essential primitive for many randomised algorithms and stochastic processes. It is natural to ask how much can be gained by running k multiple random walks independently and in parallel. Although the cover time of multiple walks has been investigated for many natural networks, the problem of finding a general characterisation of multiple cover times for *worst-case* start vertices (posed by Alon, Avin, Koucký, Kozma, Lotker, and Tuttle in 2008) remains an open problem.

First, we improve and tighten various bounds on the *stationary* cover time when k random walks start from vertices sampled from the stationary distribution. For example, we prove an unconditional lower bound of $\Omega((n/k)\log n)$ on the stationary cover time, holding for any n-vertex graph G and any $1 \leq k = o(n \log n)$. Secondly, we establish the *stationary* cover times of multiple walks on several fundamental networks up to constant factors. Thirdly, we present a framework characterising *worst-case* cover times in terms of *stationary* cover times and a novel, relaxed notion of mixing time for multiple walks called the *partial mixing time*. Roughly speaking, the partial mixing time only requires a specific portion of all random walks to be mixed. Using these new concepts, we can establish (or recover) the *worst-case* cover times for many networks including expanders, preferential attachment graphs, grids, binary trees and hypercubes.

1 Introduction

A random walk on a graph is a stochastic process that at each time step chooses a neighbour of the current vertex as its next state. The fact that a random walk visits every vertex of a connected, undirected graph in polynomial time was first used to solve the undirected

$s-t$ connectivity problem in logarithmic space [4]. Since then random walks have become a fundamental primitive in the design of randomised algorithms which feature in approximation algorithms and sampling [32, 40], load balancing [23, 42], searching [19, 33], resource location [24], property testing [12, 26, 27], graph parameter estimation [7, 11] and biological applications [8, 20].

The fact that random walks are local and memoryless (Markov property) ensures they require very little space and relatively unaffected by changes in the environment, e.g., dynamically evolving graphs or graphs with edge failures. These properties make random walks a natural candidate for parallelisation, where running parallel walks has the potential of lower time overheads. One early instance of this idea are space-time trade-offs for the undirected $s-t$ connectivity problem [9, 18]. Other applications involving multiple random walks are sublinear algorithms [13], local clustering [6, 43] or epidemic processes on networks [29, 38].

Given the potential applications of multiple random walks in algorithms, it is important to understand fundamental properties of multiple random walks. The *speed up*, first introduced in [5], is the ratio of the worst-case cover time by a single random walk to the cover time of k parallel walks. Following [5] and subsequent works [15, 16, 22, 25, 41] our understanding of when and why a speed up is present has improved. In particular, various results in [5, 15, 16] establish that as long as the lengths of the walks are not smaller than the mixing, the speed-up is linear in k. However, there are still many challenging open problems, for example, understanding the effect of different start vertices or characterising the magnitude of speed-up in terms of graph properties, a problem already stated in [5]: "*...which leads us to wonder whether there is some other property of a graph that characterises the speed-up achieved by multiple random walks more crisply than hitting and mixing times.*" Addressing the previous questions, we introduce new quantities and couplings for multiple random walks, that allow us to improve the state-of-the-art by refining, strengthening or extending results from previous works.

While there is an extensive body of research on the foundations of (single) random walks (and Markov chains), it seems surprisingly hard to transfer these results and develop a systematic theory of *multiple* random walks. One of the reasons is that processes involving multiple random walks often lead to questions about *short* random walks, e.g., shorter than the mixing time. Such short walks may arise in applications including generating random walk samples in massively parallel systems [28, 40], or in applications where random walk steps are expensive or subject to delays (e.g., when crawling social networks like Twitter [11]). The challenge of analysing *short* random walks (shorter than mixing or hitting time) has been mentioned not only in the area of multiple cover times (e.g., [15, Sec. 6]), but also in the contexts of concentration inequalities for random walks [31, p. 863] and property testing [13].

1.1 Our Contribution

Our first set of results provide several tight bounds on $t^{(k)}_{\mathsf{cov}}(\pi)$ in general (connected) graphs, where $t^{(k)}_{\mathsf{cov}}(\pi)$ is the expected time for each vertex to be visited by at least one of k independent walks each started from a vertex independently sampled from the stationary distribution π.

The main findings of Section 3 include:

- Proving general bounds of $\mathcal{O}\big(\big(\frac{|E|}{kd_{\mathsf{min}}}\big)^2 \log^2 n\big)$, $\mathcal{O}\big(\frac{\max_{v\in V} \mathbb{E}_\pi[\,\tau_v\,]}{k} \log n\big)$ and $\mathcal{O}\big(\frac{|E| \log n}{kd_{\mathsf{min}}\sqrt{1-\lambda_2}}\big)$ on $t^{(k)}_{\mathsf{cov}}(\pi)$, where d_{min} is the minimum degree, $\mathbb{E}_\pi[\,\tau_v\,]$ is the single-walk hitting time of $v \in V$ from a stationary start vertex and λ_2 is the second largest eigenvalue of the transition matrix of the walk. All three bounds are tight for certain graphs. The first

bound improves over [9], the second result is a Matthew's type bound for multiple random walks, and the third yields tight bounds for non-regular expanders such as preferential attachment graphs.

- We prove that for any graph G and $1 \leq k = o(n \log n)$, $t_{\mathsf{cov}}^{(k)}(\pi) = \Omega((n/k) \log n)$. Weaker versions of this bound were obtained in [16], holding only for certain values of k or under additional assumptions on the mixing time. Our result matches the fundamental $\Omega(n \log n)$ lower bound for single random walks ($k = 1$) [17], and generalises it in the sense that the total amount of work by all k stationary walks together for covering is always $\Omega(n \log n)$. We establish the $\Omega((n/k) \log n)$ bound by reducing the multiple walk process to a single, reversible Markov chain, and applying a general lower bound on stationary cover times [3].
- A technical tool that provides a bound on the lower tail of the cover time by k walks from stationary for graphs with a large and (relatively) symmetric set of hard to hit vertices (Lemma 9). When applied to 2d tori and binary trees this yields a tight lower bound.

In Section 4 we introduce a novel quantity for multiple walks we call *partial mixing*. Intuitively, instead of mixing all (or at least half) of the k walks, we only need to mix a specified number $\tilde{k}$ of them. We put this idea on a more formal footing and prove min-max theorems which relate worst case cover times $t_{\mathsf{cov}}^{(k)}$ to partial mixing times $t_{\mathsf{mix}}^{(\tilde{k},k)}$ and stationary cover times:

- For any graph G and any $1 \leq k \leq n$, we prove that:

$$t_{\mathsf{cov}}^{(k)} \leq 16 \cdot \min_{1 \leq \tilde{k} < k} \max \left(t_{\mathsf{mix}}^{(\tilde{k},k)}, t_{\mathsf{cov}}^{(\tilde{k})}(\pi) \right).$$

For now, we omit details such as the definition of the partial mixing time $t_{\mathsf{mix}}^{(\tilde{k},k)}$ as well as some max-min characterisations that serve as lower bounds (these can be found in Section 4). Intuitively these characterisations suggest that for any number of walks k, there is an "optimal" choice of $\tilde{k}$ so that one first waits until $\tilde{k}$ out of the k walks are mixed, and then considers only these $\tilde{k}$ stationary walks when covering the remainder of the graph.

This argument involving mixing only some walks extends and generalises previous results that involve mixing all (or at least a constant portion) of the k walks [5, 15, 16]. Previous approaches only imply a linear speed-up as long as the lengths of the walks are not shorter than the mixing time of a *single* random walk. In contrast, our characterisation may still yield tight bounds on the cover time for random walks that are much shorter than the mixing time.

To demonstrate how our insights can be used, we derive worst case cover times for several well-known graph classes. Due to space limitations we could not include this in the main body of this work, however we have summarised our results in Table 1. The corresponding results with full proofs can be found in corresponding section of the full paper [39]. As a first step to calculating $t_{\mathsf{cov}}^{(k)}$, we determine the stationary cover time; this is based on our bounds from Section 3. Secondly, we derive lower and upper bounds on the partial mixing times. Finally, with the stationary cover times and partial mixing times at hand, we can apply the characterisations from Section 4 to infer lower and upper bounds on the worst case stationary times. For some of those graphs the worst case cover times were already known before, while for, e.g., binary trees and preferential attachment graphs, our bounds are new.

- For the graph families of binary trees, cycles, d-dim. tori ($d = 2$ and $d \geq 3$), hypercube, clique, and (possibly non-regular) expanders we determine the cover time up to constants, for both worst-case and stationary start vertices (see Table 1 for the quantitative results).

We believe that this new methodology constitutes some progress towards the open question of Alon et al. [5] about a characterisation of worst-case cover times.

1.2 Novelty of Our Techniques

While a lot of the proof techniques in previous work [5, 15, 16, 41] are based on direct arguments such as mixing time (or relaxation time), our work introduces a number of new methods which, to the best of our knowledge, have not been used in the analysis of cover time of multiple walks before. In particular, one important novel concept is the introduction of the *partial mixing time*. The idea is that instead of waiting for all (or a constant portion of) k walks to mix, we can just mix some $\tilde{k} \leq k$ walks to reap the benefits of coupling these $\tilde{k}$ walks to stationary walks. This then presents a delicate balancing act where one must find an optimal $\tilde{k}$ minimising the overall bound on the cover time, for example in expanders the optimal $\tilde{k}$ is linear in k whereas in binary trees it is approximately $\sqrt{k}$, and for the cycle it is roughly $\log k$. This turning point reveals something about the structure of the graph and our results relating partial mixing to hitting time of sets helps one find this. Another tool we frequently use is a reduction to random walks with geometric resets, similar to a PageRank process, which allows us to relate *multiple* walks from stationary to a *single* reversible Markov chain.

2 Notation & Preliminaries

Throughout $G = (V, E)$ will be a finite undirected, connected graph with $n := |V|$ vertices and $m := |E|$ edges. For any $k \geq 1$, let $X_t = \left(X_t^{(1)}, \ldots, X_t^{(k)}\right)$ be *multiple random walk process*, where each $X_t^{(i)}$ is an independent random walk on G. Let

$$\mathbb{E}_{u_1,\ldots,u_k}[\,\cdot\,] := \mathbb{E}[\,\cdot \mid X_0 = (u_1, \ldots, u_k)\,]$$

denote the conditional expectation where, for each $1 \leq i \leq k$, $X_0^{(i)} = u_i \in V$ is the start vertex of the i^{th} walk. Unless mentioned otherwise, walks will be *lazy*, i.e., at each step the walk stays at its current location with probability $1/2$, and otherwise moves to a neighbour chosen uniformly at random. We let the random variable $\tau_{\mathsf{cov}}^{(k)}(G) = \inf\{t : \bigcup_{i=0}^{t}\{X_i^{(1)}, \ldots, X_i^{(k)}\} = V\}$ be the first time every vertex of the graph has been visited by some walk $X_t^{(i)}$. For $u_1, \ldots, u_k \in V$ let

$$t_{\mathsf{cov}}^{(k)}((u_1, \ldots, u_k), G) = \mathbb{E}_{u_1,\ldots,u_k}\left[\tau_{\mathsf{cov}}^{(k)}(G)\right], \qquad t_{\mathsf{cov}}^{(k)}(G) = \max_{u_1,\ldots,u_k \in V} t_{\mathsf{cov}}^{(k)}((u_1, \ldots, u_k), G)$$

denote the cover time of k walks from $(u_1, \ldots, u_k)$ and the cover time of k walks from worst case start positions respectively. For simplicity, we drop G from the notation if the underlying graph is clear from the context. We shall use π to denote the stationary distribution of a single random walk on on a graph G, for $v \in V$ this is given by $\pi(v) = \frac{d(v)}{2m}$ which is the degree over twice the number of edges. We use π^k, which is a distribution on V^k given by the product measure of π with itself, to denote the stationary distribution of a multiple random walk. For a probability distribution μ on V let $\mathbb{E}_{\mu^k}[\,\cdot\,]$ denote expectation with respect to k walks where each start vertex is sampled independently from μ and

$$t_{\mathsf{cov}}^{(k)}(\mu, G) = \mathbb{E}_{\mu^k}\left[\tau_{\mathsf{cov}}^{(k)}(G)\right].$$

In particular $t_{\mathsf{cov}}^{(k)}(\pi, G)$ denotes the expected cover time from independent stationary start vertices. For a set $S \subseteq V$ we define

$$\tau_S^{(k)} = \inf\{t : \text{ there exists } 1 \leq i \leq k \text{ such that } X_t^{(i)} \in S\}$$

Table 1 All results above are $\Theta(\cdot)$, that is bounded above and below by a multiplicative constant, apart from the mixing time of expanders which is only bounded from above. PA above is the preferential attachment process where each vertex has m initial links, the results hold w.h.p., see [10, 34]. Cells shaded in Yellow are new results proved in this paper with the exception that for $k = \mathcal{O}(\log n)$ upper bounds on the stationary cover time for binary trees, expanders and preferential attachment graphs can be deduced from general bounds for the worst case cover time in [5]. Cells shaded Gray in the second to last column are known results we re-prove in this paper using our partial mixing time results, for the 2-dim grid we only re-prove upper bounds. References for the second to last column are given in the corresponding section in the full version, except for the Barbell, see [15, Page 2]. The Barbell consists of two cliques on $n/2$ vertices connected by single edge; we include this in the table as an interesting example where the speed up by stationary walks is exponential in k. All other results for single walks can be found in [2], for example.

Graph family	Cover t_{cov}	Hitting t_{hit}	Mixing t_{mix}	k-Cover Time, where $2 \le k \le n$	
				Worst case $t_{\mathsf{cov}}^{(k)}$	From π^k, $t_{\mathsf{cov}}^{(k)}(\pi)$
Binary tree	$n \log^2 n$	$n \log n$	n	$(n/k)\log^2 n$ **if** $k \le \log^2 n$. $(n/\sqrt{k})\log n$ **if** $k \ge \log^2 n$.	$\frac{n \log n}{k} \log\left(\frac{n \log n}{k}\right)$
Cycle	n^2	n^2	n^2	$\frac{n^2}{\log k}$	$\left(\frac{n}{k}\right)^2 \log^2 k$
2-Dim. Tori	$n \log^2 n$	$n \log n$	n	$(n/k)\log^2 n$ **if** $k \le \log^2 n$. $\frac{n}{\log(k/\log^2 n)}$ **if** $k \ge \log^2 n$.	$\frac{n \log n}{k} \log\left(\frac{n \log n}{k}\right)$
d-Dim. Tori $d \ge 3$	$n \log n$	n	$n^{2/d}$	$(n/k)\log n$ **if** $k \le n^{1-2/d}\log n$. $\frac{n^{2/d}}{\log(k/(n^{1-2/d}\log n))}$ **if** $k \ge n^{1-2/d}\log n$.	$\frac{n}{k}\log n$
Hypercube	$n \log n$	n	$\log n \log\log n$	$(n/k)\log n$ **if** $k \le n/\log\log n$. $\log n \log\log n$ **if** $k \ge n/\log\log n$.	$\frac{n}{k}\log n$
Expanders	$n \log n$	n	$\mathcal{O}(\log n)$	$\frac{n}{k}\log n$	$\frac{n}{k}\log n$
PA, $m \ge 2$	$n \log n$	n	$\mathcal{O}(\log n)$	$\frac{n}{k}\log n$	
Barbell	n^2	n^2	n^2	n^2/k	$\frac{2^{-k}n^2}{k} + \frac{n \log n}{k}$

as the first time the set S is visited by any of the k independent random walks, if $S = \{v\}$ is a singleton set we use τ_v, dropping brackets. Let

$$t_{\mathsf{hit}}^{(k)}(G) = \max_{u_1,\ldots,u_k \in V} \max_{v \in V} \mathbb{E}_{u_1,\ldots,u_k} \left[\tau_v^{(k)} \right]$$

be the worst case vertex to vertex hitting time. When talking about a single random walk we drop the (1) index, i.e. $t_{\mathsf{cov}}^{(1)}(G) = t_{\mathsf{cov}}(G)$; we also drop G from the notation when the graph is clear. If we wish the graph G to be clear we shall also use the notation $\mathbb{P}_{u,G}[\cdot]$ and $\mathbb{E}_{u,G}[\,\cdot\,]$. For a single random walk X_t with stationary distribution π and $x \in V$, let $d(t)$ and $s_x(t)$ be the total variation and separation distances for X_t given by

$$d(t) = \max_{x \in V} ||P_{x,\cdot}^t - \pi||_{TV} \quad \text{and} \quad s_x(t) = \max_{y \in V} \left[1 - \frac{P_{x,y}^t}{\pi(y)} \right],$$

where $P_{x,\cdot}^t$ is the t-step probability distribution of a random walk starting from x and, for probability measures μ, ν, $||\mu - \nu||_{TV} = \frac{1}{2} \sum_{x \in V} |\mu(x) - \nu(x)|$ is the total variation distance. Let $s(t) = \max_{x \in V} s_x(t)$, then for $0 \le \varepsilon \le 1$ the mixing and separation times [30, (4.32)] are

$$t_{\mathsf{mix}}(\varepsilon) = \inf\{t : d(t) \le \varepsilon\} \qquad \text{and} \qquad t_{\mathsf{sep}}(\varepsilon) = \inf\{t : s(t) \le \varepsilon\}, \tag{1}$$

and $t_{\mathsf{mix}} := t_{\mathsf{mix}}(1/4)$ and $t_{\mathsf{sep}} = t_{\mathsf{sep}}(1/e)$. A strong stationary time (SST) σ, see [30, Ch. 6] or [1], is a randomised stopping time for a Markov chain Y_t on V with stationary distribution π if

$$\mathbb{P}_u[Y_\sigma = v \mid \sigma = k] = \pi(v) \qquad \text{for any } u, v \in V \text{ and } k \ge 0. \tag{2}$$

Let $t_{\mathsf{rel}} = \frac{1}{1-\lambda_2}$ be the relaxation time of G, where λ_2 is the second largest eigenvalue of the transition matrix of the (lazy) random walk on G.

For random variables Y, Z we say that Y dominates Z ($Y \succeq Z$) if $\mathbb{P}[Y \ge x] \ge \mathbb{P}[Z \ge x]$ for all x.

3 Multiple Stationary Cover Times

We shall state our general upper and lower bound results for multiple walks from stationary in Sections 3.1 & 3.2 respectively. All proofs can be found in the full version [39].

3.1 Upper Bounds

Broder, Karlin, Raghavan, and Upfal [9] showed that for any graph G and $k \ge 1$,

$$t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\left(\frac{m}{k} \right)^2 \log^3 n \right).$$

We prove a general bound which improves this bound by a multiplicative factor of $d_{\mathsf{min}}^2 \log n$ which may be $\Omega(n^2 \log n)$ for some graphs.

▶ **Theorem 1.** *For any graph G and any $k \ge 1$,*

$$t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\left(\frac{m}{k d_{\mathsf{min}}} \right)^2 \log^2 n \right).$$

This bound is tight for the cycle if $k = n^{\Theta(1)}$, see Table 1. Theorem 1 is proved by relating the probability a vertex v is not hit up to a certain time t to the expected number of returns to v by a walk of length t from v and applying a bound by Oliveira and Peres [35].

The next bound is analogous to Matthew's bound [2, Theorem 2.26] for the cover time of single random walks from worst case, however it is proved by a different method.

▶ **Theorem 2.** *For any graph G and any $k \geq 1$, we have*

$$t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\frac{\max_{v\in V} \mathbb{E}_\pi\left[\tau_v\right] \log n}{k}\right).$$

This bound is tight for many graphs, see Table 1. Since the acceptance of this paper, the stronger bound $t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}(t_{\mathsf{cov}}/k)$ has been proved by Hermon & Sousi [21]. This bound implies Theorem 2 by a simple application of the aforementioned Matthew's Bound for single random walks. A version of Theorem 2 for $t_{\mathsf{cov}}^{(k)}$ was established by Alon et al. [5] provided $k = \mathcal{O}(\log n)$, the restriction on k is necessary (for worst case) as witnessed by the cycle. Theorem 2 also gives the following explicit bound.

▶ **Corollary 3.** *For any graph G and any $k \geq 1$, we have*

$$t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\frac{m}{k d_{\mathsf{min}}} \sqrt{t_{\mathsf{rel}}} \log n\right).$$

Proof. Use $\max_{v\in V} \mathbb{E}_\pi\left[\tau_v\right] \leq 20m\sqrt{t_{\mathsf{rel}}+1}/d_{\mathsf{min}}$ from [35, Theorem 1] in Theorem 2. ◀

Notice that, for all values $k \geq 1$, this bound is tight for any expander with $d_{\min} = \Omega(m/n)$, such as preferential attachment graphs (see Table 1 and the full version for more details).

We also establish the following two bounds for classes of graphs with "not too large" return probabilities.

▶ **Lemma 4.** *Let G be any graph satisfying $\pi_{\mathsf{min}} = \Omega(1/n)$, $t_{\mathsf{rel}} = o(n)$ and $\sum_{i=0}^{t} P_{vv}^i = \mathcal{O}(1 + t\pi(v))$ for any $t \leq t_{\mathsf{rel}}$. Then for any $1 \leq k \leq n$,*

$$t_{\mathsf{cov}}^{(k)}(\pi) = \Theta\left(\frac{n}{k} \log n\right).$$

The bound above applied to a broad class of graphs with expander like properties but large relaxation time, this includes the hypercube and high dimensional grids. The following bound holds for graphs with sub-harmonic return times, this includes binary trees and 2d-grid/tori.

▶ **Lemma 5.** *Let G be any graph with $\sum_{i=0}^{t} P_{v,v}^i = \mathcal{O}(t/n + \log t)$ for any $t \leq n(\log n)^2$ for all $v \in V$ and $t_{\mathsf{mix}} = \mathcal{O}(n)$. Then for any $1 \leq k \leq (n \log n)/3$,*

$$t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\frac{n \log n}{k} \log\left(\frac{n \log n}{k}\right)\right).$$

3.2 Lower Bounds

Generally speaking, lower bounds for random walks are more challenging to derive than upper bounds. In particular, the problem of obtaining a lower bound for the cover time of a simple random walk on an undirected graph was open for many years [2]. This was finally resolved by Feige [17] who proved $t_{\mathsf{cov}} \geq (1 - o(1))n \log n$. We prove a generalisation of this bound, up to constants, that holds for k random walks which start from stationarity (thus also for worst case).

▶ **Theorem 6.** *There exists a constant $c > 0$ such that for any graph G and $1 \le k \le c \cdot n \log n$,*

$$t_{\mathsf{cov}}^{(k)}(\pi) \ge c \cdot \frac{n}{k} \cdot \log n.$$

We remark that in this section all results hold (and are proven) for *non-lazy* random walks, which by stochastic domination implies that the same result also holds for *lazy* random walks. Theorem 6 is tight, uniformly for all $1 \le k \le n$, for the hypercube, expanders and high-dimensional tori, see Table 1. We note that [16] proved this bound for any start vertices under the additional assumption that $k \ge n^{\epsilon}$, for some constant $\varepsilon > 0$. One can track the constants in the proof of Theorem 6 and show that $c > 2 \cdot 10^{-11}$, we have not optimised this but note that $c \le 1$ must hold in either condition of Theorem 6 due to the complete graph.

To prove this result we introduce the *geometric reset graph*, which allows us to couple the multiple random walk to a single walk to which we can apply a lower bound by Aldous [3]. The random reset graph is a small modification to a graph G which gives an edge-weighted graph $\widehat{G}(x)$ such that the simple random walk on $\widehat{G}(x)$ emulates a random walk on G with $\mathrm{Geo}(x)$ resets to stationarity, where $\mathrm{Geo}(x)$ is a geometric random variable with expectation $1/x$.

▶ **Definition 7** (The Geometric Reset Graph $\widehat{G}(x)$)**.** *For any graph G the undirected, edge-weighted graph $\widehat{G}(x)$, where $0 < x \le 1$, consists of all vertices $V(G)$ and one extra vertex z. All edges from G are included with edge-weight 1. Further, z is connected to each vertex $u \in G$ by an edge with edge-weight $x \cdot d(u)/(1-x)$, where $d(u)$ is the degree of vertex u in G.*

Given a graph with edge weights $\{w_e\}_{e \in E}$ the probability a *non-lazy* random walk moves from u to v is given by $w_{uv} / \sum_{w \in V} w_{uw}$. Thus the walk on $\widehat{G}(x)$ behaves as a random walk in G, apart from that in any step, it may move to the extra vertex z with probability $\frac{x \cdot d(u)/(1-x)}{x \cdot d(u)/(1-x) + d(u)} = x$. Once the walk is at z it moves back to a vertex $u \in V \backslash \{z\}$ with probability proportional to $d(u)$. Hence the stationary distribution $\widehat{\pi}$ of the random walk on $\widehat{G}(x)$ is proportional to π on G, and for the extra vertex z we have

$$\widehat{\pi}(z) = \frac{\sum_{v \in V} x d(u)/(1-x)}{\sum_{v \in V} d(u) + \sum_{v \in V} x d(u)/(1-x)} = \frac{x/(1-x)}{1 + x/(1-x)} = x.$$

Using the next lemma we can then obtain bounds on the multiple stationary cover time by simply bounding the cover time in the augmented graph $\widehat{G}(x)$ for some x.

▶ **Lemma 8.** *Let G be any graph G, $k \ge 1$ and $x = Ck/T$ where $C > 30$ and $T \ge 5Ck$. Then*

$$\mathbb{P}_{\pi^k, G}\left[\tau_{\mathsf{cov}}^{(k)} > \frac{T}{10Ck}\right] > \mathbb{P}_{\widehat{\pi}, \widehat{G}(x)}[\tau_{\mathsf{cov}} > T] - \exp\left(-\frac{Ck}{50}\right).$$

The coupling above will also be used later in the paper to prove a lower bound for the stationary cover time of the binary tree and 2-dimensional grid when k is small.

The next result we present utilises the second moment method to obtain a lower bound which works very well for $k = n^{\Theta(1)}$ walks on symmetric (e.g., transitive) graphs. In particular, we apply this to get tight lower bounds for cycles, 2-dim. tori and binary trees (see the corresponding section of the full version).

▶ **Lemma 9.** *Let G be any graph. Let $\alpha \in (0,1)$ be a fixed real constant and define $p_v(t) = \mathbb{P}_\pi[\tau_v \le t]$ for $t \ge 1$. Suppose there exists a subset $S \subseteq V$, and real numbers $p > 0$ and $0 \le \varepsilon < 1$ such that for all $v \in S$ we have $p(1-\varepsilon) \le p_v(t) \le p$, with $p \le \alpha(\log n)/k$, and that $\min_{v \in S} \pi(v) = \Omega(1/|S|)$. If in addition $p^2 k = o(1)$, then*

$$\mathbb{P}_{\pi^k}\left[\tau_{\mathsf{cov}}^{(k)} < t\right] = \mathcal{O}\left(\frac{(\log n)^2 n^{\alpha(1+\varepsilon)}}{k}\right).$$

4 Mixing Few Walks to Cover Many Vertices

In this section we present several bounds on $t_{\mathsf{cov}}^{(k)}$, the multiple cover time from worst case start vertices, based on $t_{\mathsf{cov}}^{(k)}(\pi)$, the multiple cover time from stationarity, and a new notion that we call *partial* mixing time. The intuition behind this is that on many graphs such as cycles or binary trees, only a certain number, say $\tilde{k}$ out of k walks will be able to reach vertices that are "far away" from the initial distribution. That means covering the whole graph hinges on how quickly these $\tilde{k}$ "mixed" walks cover the graph G, however, we also need to take into account the number of steps needed to "mix" those. Theorem 16 (see Subsection 4.2) makes this intuition more precise and suggests that the best strategy for covering a graph might be when $\tilde{k}$ is chosen so that the time to mix $\tilde{k}$ out of k walks and the stationary cover time of $\tilde{k}$ walks are approximately equal. The first subsection (Subsection 4.1) contains details of our new notions of mixing for multiple random walks, the second contains the bounds on worst-case cover times we derive from these and the third contains some bounds on the multiple mixing times.

4.1 Two Notions of Mixing for Multiple Random Walks

Recall the definition of strong stationary time (SST) given by (2) in Section 2. Then, for any graph G, and any $1 \leq \tilde{k} < k$, we define the *partial mixing time*:

$$\begin{aligned} t_{\mathsf{mix}}^{(\tilde{k},k)}(G) &= \inf\left\{ t \geq 1 : \textit{there exists an SST } \tau \text{ such that } \min_{v \in V} \mathbb{P}_v[\tau \leq t] \geq \tilde{k}/k \right\} \\ &= \inf\left\{ t \geq 1 : s(t) \leq 1 - \tilde{k}/k \right\}. \end{aligned} \tag{3}$$

Note that the two definitions above are equivalent by the following result.

▶ **Proposition 10** ([1, Proposition 3.2]). *If σ is an SST then $\mathbb{P}[\sigma > t] \geq s(t)$ for any $t \geq 0$. Furthermore there exists an SST for which equality holds.*

This notion of mixing, based on the idea of separation distance and strong stationary times for single walks, will be useful for establishing an upper bound on the worst case cover time. For lower bounds on the cover time we will now introduce another notion of mixing for multiple random walks based on a different property of mixing times of single walks.

For single random walks, there is a fundamental connection between mixing times and hitting times of sets. In particular if we let

$$t_{\mathsf{H}}(\alpha) = \max_{u \in V, S \subseteq V\,:\,\pi(S) \geq \alpha} \mathbb{E}_u[\tau_S], \qquad \text{and} \qquad t_{\mathsf{H}} := t_{\mathsf{H}}(1/4),$$

then the following theorem shows this *large-set hitting time* is equivalent to the mixing time.

▶ **Theorem 11** ([36] and independently [37]). *Let $\alpha < 1/2$. Then there exist positive constants $c(\alpha)$ and $C(\alpha)$ so that for every reversible chain*

$$c(\alpha) \cdot t_{\mathsf{H}}(\alpha) \leq t_{\mathsf{mix}}(\alpha) \leq C(\alpha) \cdot t_{\mathsf{H}}(\alpha).$$

In order to prove a lower bounds on the cover time we seek to replace the partial mixing time by an analogue of hitting times of large sets, adapted to multiple walks:

$$t_{\mathsf{large-hit}}^{(\tilde{k},k)}(G) := \min\left\{ t \geq 1 : \min_{u \in V, S \subseteq V\,:\,\pi(S) \geq 1/4} \mathbb{P}_u[\tau_S \leq t] \geq \frac{\tilde{k}}{k} \right\}. \tag{4}$$

Note that both of our mixing times, (4) and (3), are only defined for $\tilde{k} < k$. However, by the union bound, there exists a $C < \infty$ such that if we run k walks for $Ct_{\mathsf{mix}} \log k$ steps then all k walks will be close to uniform in total variation norm.

In the following four results, we present some simple relations between $t_{\mathsf{mix}}^{(\tilde{k},k)}$ and $t_{\mathsf{large-hit}}^{(\tilde{k},k)}$, and t_{mix}, where t_{mix} is the total variation mixing time for a single random walk given by (1).

First we show a simple upper bound in terms of the single walk mixing time.

▶ **Lemma 12.** *There exists a constant $C < \infty$ such that for any graph and $1 \le \tilde{k} < k$ we have*

(i) $t_{\mathsf{mix}}^{(\tilde{k},k)} \le 2 \cdot t_{\mathsf{mix}} \cdot \log\left(\frac{4k}{k-\tilde{k}}\right)$,

(ii) $t_{\mathsf{large-hit}}^{(\tilde{k},k)} \le C \cdot t_{\mathsf{mix}} \cdot \log\left(\frac{k}{k-\tilde{k}}\right)$.

The partial mixing time can be bounded from below quite simply by mixing time.

▶ **Lemma 13.** *For any graph and $1 \le \tilde{k} < k$ we have*

$$t_{\mathsf{mix}}^{(\tilde{k},k)} \ge t_{\mathsf{mix}}\left(1 - \frac{\tilde{k}}{k}\right).$$

We would prefer a bound in terms of $t_{\mathsf{mix}} := t_{\mathsf{mix}}(1/4)$ instead of $t_{\mathsf{mix}}(1 - \tilde{k}/k)$ as the former is easier to compute for most graphs. The following Lemma establishes such a lower bound for both notions of mixing time at the cost of a $\tilde{k}/k$ factor.

▶ **Lemma 14.** *There exists some constant $c > 0$ such that for any graph and $1 \le \tilde{k} < k$ we have*

(i) $t_{\mathsf{mix}}^{(\tilde{k},k)} \ge c \cdot \frac{\tilde{k}}{k} \cdot t_{\mathsf{mix}}$,

(ii) $t_{\mathsf{large-hit}}^{(\tilde{k},k)} \ge c \cdot \frac{\tilde{k}}{k} \cdot t_{\mathsf{mix}}$.

We leave as an open problem whether our two notions of mixing for multiple random walks are equivalent up to constants, but the next result gives partial progress in one direction.

▶ **Lemma 15.** *For any graph and $1 \le \tilde{k} < k/4$ we have*

$$t_{\mathsf{large-hit}}^{(\tilde{k},k)} \le t_{\mathsf{mix}}^{(4\tilde{k},k)} + 1 \le 2t_{\mathsf{mix}}^{(4\tilde{k},k)}.$$

4.2 Upper and Lower Bounds by Partial Mixing

Armed with our new notions of mixing time for multiple random walks from Section 4.1, we can now use them to prove upper and lower bounds on the worst case cover time in terms of stationary cover times and partial mixing times. We begin with the upper bound.

▶ **Theorem 16.** *For any graph G and any $1 \le k \le n$,*

$$t_{\mathsf{cov}}^{(k)} \le 16 \cdot \min_{1 \le \tilde{k} < k} \max\left(t_{\mathsf{mix}}^{(\tilde{k},k)}, t_{\mathsf{cov}}^{(\tilde{k})}(\pi)\right).$$

Proof. Fix any $1 \le \tilde{k} < k$. It suffices to prove that with k walks starting from arbitrary positions running for

$$t := t_{\mathsf{mix}}^{(\tilde{k},k)} + 2t_{\mathsf{cov}}^{(\tilde{k})}(\pi) \le 4 \cdot \max\left(t_{\mathsf{mix}}^{(\tilde{k},k)}, t_{\mathsf{cov}}^{(\tilde{k})}(\pi)\right)$$

steps, we cover G with probability at least $1/4$. Consider a single walk $X_1(t)$ on G. From (3), we have that at time $T = t_{\mathsf{mix}}^{(\tilde{k},k)}$ there exists a probability measure ν_v on V such that,

$$P_{v,w}^T = (1 - s_v(T))\pi(w) + s_v(T)\nu_v(w).$$

Therefore, we can generate $X_1(T)$ as follows: with probability $1 - s_v(T) \geq \tilde{k}/k$ we sample from π, otherwise we sample from ν_v. If we now consider k independent walks, the number of walks that are sampled at time T from π has a binomial distribution $\mathrm{Bin}(k, \tilde{k}/k)$ with k trials and probability $\tilde{k}/k$, whose expectation is $\tilde{k}$. Since the expectation $\tilde{k}$ is an integer it is equal to the median, thus with probability at least $1/2$, at least $\tilde{k}$ walks are sampled from the stationary distribution. Now, consider only the $\tilde{k}$ independent walks starting from π. After $2t_{\mathsf{cov}}(\pi, \tilde{k})$ steps, these walks will cover G with probability at least $1/2$, due to Markov's inequality.

We conclude that in t time steps, from any starting configuration of the k walks, the probability we cover the graph is at least $1/4$. Hence in expectation, after (at most) 4 periods of length t we cover the graph. ◀

This theorem improves on various results in [5] and [15] which bound the worst case cover time by mixing all k walks, and it also generalises a previous result in [16, Lemma 3.1], where most walks were mixed, i.e., $\tilde{k} = k/2$.

We also prove a lower bound for cover times, however this involves the related definition of partial mixing time based on the hitting times of large sets.

▶ **Theorem 17.** *For any graph G with $\pi_{\max} = \max_u \pi(u)$ and any $1 \leq k \leq n$,*

$$t_{\mathsf{cov}}^{(k)} \geq \frac{1}{16} \cdot \max_{1 \leq \tilde{k} < k} \min\left(t_{\mathsf{large-hit}}^{(\tilde{k},k)}, \frac{1}{\tilde{k}\pi_{\max}} \right).$$

Further, for any regular graph G any $\delta > 0$ fixed, there is a constant $C = C(\delta) > 0$ such that

$$t_{\mathsf{cov}}^{(k)} \geq C \cdot \max_{n^\delta \leq \tilde{k} < k} \min\left(t_{\mathsf{large-hit}}^{(\tilde{k},k)}, \frac{n \log n}{\tilde{k}} \right).$$

As we will see later, both Theorem 16 and Theorem 17 yield asymptotically tight (or tight up to logarithmic factors) lower and upper bounds for many concrete networks. To explain why this is often the case, note that both bounds include one non-increasing function in $\tilde{k}$ and one non-decreasing in function in $\tilde{k}$. That means both bounds are optimised when the two functions are as close as possible. Then balancing the two functions in the upper bound asks for $\tilde{k}$ such that $t_{\mathsf{mix}}^{(\tilde{k},k)} \approx t_{\mathsf{cov}}^{(\tilde{k})}(\pi)$. Similarly, balancing the two functions in the first lower bound demands $t_{\mathsf{large-hit}}^{(\tilde{k},k)} \approx n/\tilde{k}$ (assuming $\pi_{\max} = O(1/n)$). Hence for any graph G where $t_{\mathsf{mix}}^{(\tilde{k},k)} \approx t_{\mathsf{large-hit}}^{(\tilde{k},k)}$, and also $t_{\mathsf{cov}}^{(\tilde{k})}(\pi) \approx n/\tilde{k}$, the upper and lower bounds will be close. This turns out to be the case for many networks (see the corresponding section in the full version).

One exception where Theorem 17 is far from tight is the cycle, we shall also prove a min-max theorem but with a different notion of partial cover time which is tight for the cycle.

For a set $S \subseteq V$ we let $\tau_{\mathsf{cov}}^{(k)}(S)$ be the first time that every vertex in S has been visited by at least one of the k walks, thus $\tau_{\mathsf{cov}}^{(k)}(V) = \tau_{\mathsf{cov}}^{(k)}$. Then we define the set cover time

$$t_{\mathsf{large-cov}}^{(k)} = \min_{S:\pi(S)\geq 1/4} \max_{\mu} \mathbb{E}_{\mu^k}\left[\tau_{\mathsf{cov}}^{(k)}(S) \right],$$

where the first minimum is over all sets $S \subseteq V$ satisfying $\pi(S) \geq 1/4$ and the second is over all probability distributions μ on the set $\partial S = \{x \in S : \text{exists } y \in S^c,\ xy \in E\}$.

▶ **Theorem 18.** *For any graph G and any $1 \leq k \leq n$,*

$$t_{\mathsf{cov}}^{(k)} \geq \frac{1}{4} \cdot \max_{1 \leq \tilde{k} < k} \min \left(t_{\mathsf{large-hit}}^{(\tilde{k},k)}, t_{\mathsf{large-cov}}^{(k)} \right).$$

4.3 Geometric Lower Bounds on the Large-Hit and Large-Cover Times

We will now derive two useful lower bounds on $t_{\mathsf{large-hit}}^{(\tilde{k},k)}$, one based on the conductance of the graph, and a second one based on the distance to a large set the random walk needs to hit.

For two sets $A, B \subseteq V$ the *ergodic flow* $Q(A,B)$ is defined by $Q(A,B) = \sum_{a \in A, b \in B} \pi(a) P_{a,b}$, where $P_{a,b}$ denotes the transition matrix of a (lazy) single random walk. We define the *conductance* $\Phi(S)$ of a set $S \subseteq V$ with $\pi(S) \in (0, 1/2]$ to be

$$\Phi(S) = \frac{Q(S, S^c)}{\pi(S)} \quad \text{and let} \quad \Phi(G) = \min_{S \subseteq V, 0 < \pi(S) \leq 1/2} \Phi(S).$$

▶ **Lemma 19.** *For any graph G with conductance $\Phi(G)$, any $1 \leq \tilde{k} \leq k$,*

$$t_{\mathsf{large-hit}}^{(\tilde{k},k)} \geq \frac{\tilde{k}}{k} \cdot \frac{2}{\Phi(G)}.$$

We remark that a similar bound was used implicitly in [41, Proof of Theorem 1.1], where $t_{\mathsf{cov}}^{(k)} \geq \sqrt{\frac{n}{k \cdot \Phi(G)}}$ was shown.

The following lemmas will be useful to lower bound worst case cover times on cycles/tori.

▶ **Lemma 20.** *Let G be a d-dimensional torus with constant $d \geq 2$ (or cycle, $d = 1$), $u \in V$ and S be a set with $|S| \geq n/2$. Then for any $\tilde{k} \leq k/2$,*

$$t_{\mathsf{large-hit}}^{(\tilde{k},k)} = \Omega\left((\mathrm{dist}(u,S))^2 / \log(k/\tilde{k}) \right).$$

▶ **Lemma 21.** *Let $S \subseteq V$ be a subset of vertices with $\pi(S) \geq 1/4$, $t \geq 2$ be an integer and $k \geq 100$ such that for every $u \in S$,*

$$\sum_{s=0}^{t} P_{u,u}^s \geq 32 \cdot t \cdot \pi(u) \cdot k.$$

Then for any starting distribution μ of $k/8$ walks,

$$\mathbb{E}_{\mu^k} \left[\tau_{\mathsf{cov}}^{(k)}(S) \right] \geq t/5.$$

5 Conclusion & Open Problems

In this work, we derived several new bounds on multiple stationary and worst-case cover times. We also introduced a new quantity called *partial mixing time*, which extends the definition of mixing time from single random walks to multiple random walks. By means of a min-max characterisation, we proved that the partial mixing time connects the stationary and worst-case cover times, leading to tight lower and upper bounds for many graph classes.

In terms of worst-case bounds, Theorem 1 implies that for any regular graph G and any $k \geq 1$, $t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\left(\frac{n}{k}\right)^2 \log^2 n \right)$. This bound is tight for the cycle when k is polynomial in n but not for smaller k. We suspect that for any $k \geq 1$ the cycle is (asymptotically) the worst case for $t_{\mathsf{cov}}^{(k)}(\pi)$ amongst regular graphs, which suggests $t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}\left(\left(\frac{n}{k}\right)^2 \log^2 k \right)$.

Some of our results have been only proven for the independent stationary case, but it seems plausible they extend to the case where the k random walks start from the *same* vertex. For example, extending the bound $t_{\mathsf{cov}}^{(k)}(\pi) = \Omega((n/k)\log n)$ to this case would be very interesting.

In Theorem 2 we prove $t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}((\max_{v\in V} \mathbb{E}_\pi[\tau_v]\log n)/k)$, can we prove the stronger bound $t_{\mathsf{cov}}^{(k)}(\pi) = \mathcal{O}(1/k \cdot t_{\mathsf{cov}}(\pi, G))$ without assuming anything on the mixing time of G?

Although our min-max characterisations involving partial mixing time yields tight bounds for many natural graph classes, it would be interesting to establish a general approximation guarantee (or find graph classes that serve as counter-examples). For the former, we believe techniques such as Gaussian Processes and Majorising Measures used in the seminal work of Ding, Lee and Peres [14] could be very useful.

Abstract

Given a graph property Φ, we consider the problem EdgeSub(Φ), where the input is a pair of a graph G and a positive integer k, and the task is to decide whether G contains a k-edge subgraph that satisfies Φ. Specifically, we study the parameterized complexity of EdgeSub(Φ) and of its counting problem #EdgeSub(Φ) with respect to both approximate and exact counting. We obtain a complete picture for minor-closed properties Φ: the decision problem EdgeSub(Φ) always admits an FPT ("fixed-parameter tractable") algorithm and the counting problem #EdgeSub(Φ) always admits an FPTRAS ("fixed-parameter tractable randomized approximation scheme"). For exact counting, we present an exhaustive and explicit criterion on the property Φ which, if satisfied, yields fixed-parameter tractability and otherwise #W[1]-hardness. Additionally, most of our hardness results come with an almost tight conditional lower bound under the so-called Exponential Time Hypothesis, ruling out algorithms for #EdgeSub(Φ) that run in time $f(k) \cdot |G|^{o(k/\log k)}$ for any computable function f.

As a main technical result, we gain a complete understanding of the coefficients of toroidal grids and selected Cayley graph expanders in the homomorphism basis of #EdgeSub(Φ). This allows us to establish hardness of exact counting using the Complexity Monotonicity framework due to Curticapean, Dell and Marx (STOC'17). This approach does not only apply to #EdgeSub(Φ) but also to the more general problem of computing weighted linear combinations of subgraph counts. As a special case of such a linear combination, we introduce a parameterized variant of the Tutte Polynomial T_G^k of a graph G, to which many known combinatorial interpretations of values of the (classical) Tutte Polynomial can be extended. As an example, $T_G^k(2,1)$ corresponds to the number of k-forests in the graph G. Our techniques allow us to completely understand the parameterized complexity of computing the evaluation of T_G^k at every pair of rational coordinates (x, y). In particular, our results give a new proof for the #W[1]-hardness of the problem of counting k-forests in a graph.

1 Extended Abstract

Be it searching for cliques in social networks or understanding protein-protein interaction networks, many interesting real-life problems boil down to finding (or counting) small patterns in large graphs. Hence, to no surprise, finding (and counting) small patterns in large graphs are among the most well-studied computational problems in the fields of database theory [12, 40, 32, 13, 27], molecular biology and bioinformatics [38, 1, 56, 59], and network science [60, 52, 53]. In fact, already in the 1970s, the relevance of *finding* patterns became apparent in the context of finding cliques, finding Hamiltonian paths, or finding specific subgraphs in general [19, 18, 62, 12]. However, with the advent of motif counting for the frequency analysis of small structures in complex networks [52, 53], it became evident that detecting the existence of a pattern graph is not enough; we also need to *count* all of the occurrences of the pattern.

In this work, our patterns are (not necessarily induced) edge subgraphs that satisfy a certain graph property: for instance, given a graph, we want to count all occurrences of edge subgraphs that are are planar or connected.

From a classical point of view, often the problem of *finding* patterns is already NP-hard: prime examples include the aforementioned problems of finding (maximum) cliques or Hamiltonian paths. However, for the task of network motif counting, the patterns are (almost) always much smaller than the network itself (see [52, 53, 1]). This motivates a *parameterized* view: can we obtain fast algorithms to compute the number of occurrences of "small" patterns? If we cannot, can we at least obtain fast (randomized) algorithms to compute an *estimate* of this number? And if we cannot even do this, can we at least obtain fast algorithms to *detect* an occurrence? In this work, we completely answer all of the above questions for patterns that are specified by *minor-closed* graph properties (such as planarity) or selected other graph properties (such as connectivity).

As it turns out, the techniques we develop for answering the above questions are quite powerful: they easily generalize to a parameterized version of the Tutte polynomial. Specifically, our techniques allow us to completely understand at which rational points we can evaluate said parameterized Tutte polynomial in reasonable time, and at which rational points this is not feasible. This dichotomy turns out to be similar, but not equal, to the complexity landscape of the classical Tutte polynomial due to Jaeger et al. [42].

Parameterized Counting and Hardness

By now, *counting complexity theory* is a well established subfield of theoretical computer science. Already in the 1970s, Valiant started a formal study of counting problems when investigating the complexity of the permanent [63, 64]: counting the number of perfect matchings in a graph is #P-complete, and hence harder than any problem in the polynomial-time hierarchy PH by Toda's Theorem [61]. In contrast, *detecting* a perfect matching in a graph is much easier and can be done in polynomial time [33]. Hence, counting problems can be much harder than their decision problem counterparts.

As an attempt to overcome the hardness of counting problems in general, the focus shifted to a multivariate or *parameterized* view on these problems. Consider for example the following problem: given a query φ of size k and a database B of size n, we want to count the number of answers to φ in B. If we make the very reasonable assumption that k is much smaller than n, then we may consider an algorithm running in time $O(2^k \cdot n)$ as *tractable*. Note that in particular, such an algorithm may even outperform an algorithm running in time $O(n^2)$. Also consider [39] for a more detailed and formal discussion.
Formally, given a problem P and a *parameterization* κ that maps each instance I of P to a parameter $\kappa(I)$, we say that P is *fixed-parameter tractable* (FPT) with respect to κ, if there is an algorithm that solves each instance I of size n in time $f(\kappa(I)) \cdot n^{O(1)}$, for some computable function f. This notion was introduced by Downey and Fellows in the early 1990s [29, 30] and has itself spawned a rich body of literature (see [35, 31, 23]). In the context of the problems of detecting and counting small patterns in large networks, we parameterize by the size of the pattern: given a pattern of size k and a network of size n, we aim for algorithms that run in time $f(k) \cdot n^{O(1)}$, for some computable function f. However, for some patterns, even this goal is too ambitious: it is widely believed that even finding a clique of size k is not fixed-parameter tractable; in particular, an FPT algorithm for finding a clique of size k would also imply a breakthrough result for the Satisfiability Problem and thereby refute the widely believed Exponential Time Hypothesis [15, 16]. If a problem P is at least as hard as finding a clique (or counting all cliques) of size k, we say that P is $\mathsf{W}[1]$-hard (or $\#\mathsf{W}[1]$-hard, respectively).

For such a $(\#)\mathsf{W}[1]$-hard problem, the hope is to (significantly) improve upon the naive brute-force algorithm, which runs in time $n^{O(k)}$ for the problems considered in this work. However, in view of the aforementioned reduction from the Satisfiability Problem to the problem of finding cliques of size k [14, 15], we can see that for finding cliques this, too, would require a breakthrough for the Satisfiability Problem, which, again, is believed to be unlikely [41]. In our paper, via suitable reductions from the problem of finding cliques, we establish that exact algorithms significantly faster than the brute-force algorithms are unlikely for the problems we study.

Parameterized Detection and Counting of Edge Subgraphs

Vertex-induced subgraphs as patterns are notoriously hard to detect or to count. The long line of research on this problem [47, 17, 43, 44, 51, 45, 21, 57, 28, 58] showed that this holds even if the patterns are significantly smaller than the host graphs, as witnessed by $\mathsf{W}[1]$ and $\#\mathsf{W}[1]$-hardness results and almost tight conditional lower bounds. In case of exact counting, it is in fact an open question whether there are non-trivial instances of induced subgraph counting that admit efficient algorithms; recent work [58] supports the conjecture that no such instances exist.

In search for fast algorithms, in this work, we hence consider a related, but different version of network-motif counting: for a computable graph property Φ, in the problem $\#\textsc{EdgeSub}(\Phi)$ we are given a graph G and a positive integer k, and the task is to compute the number of (not necessarily induced) edge subgraphs[1] with k edges in G that satisfy Φ. Similarly, we write $\textsc{EdgeSub}(\Phi)$ for the corresponding decision problem. Then, in contrast to the case of counting vertex-induced subgraphs, for $(\#)\textsc{EdgeSub}(\Phi)$, we identify non-trivial

[1] Recall that an edge subgraph G' of a graph G may have fewer edges than the subgraph of G that is induced by the vertices of G'.

properties Φ for which (#)EdgeSub(Φ) is fixed-parameter tractable; we discuss this in more detail later. First, however, let us take a detour to elaborate more on what is known already for (#)EdgeSub(Φ).

If the property Φ is satisfied by at most a single graph for each value of the parameter k, the decision problem EdgeSub(Φ) becomes the subgraph isomorphism problem. Hence, naturally there is a vast body of known techniques and results for special properties Φ: for FPT algorithms, think of the Colour-Coding technique by Alon, Yuster and Zwick [3], the "Divide and Colour"-technique [16], narrow sieving [7], representative sets [36], or "extensor-coding" [9] to name but a few. For hardness results, apart from the aforementioned example of detecting a clique, Lin quite recently established that detecting a k-biclique is also W[1]-hard [48]. However, a complete understanding of the parameterized decision version of the subgraph isomorphism is one of the major open problems of parameterized complexity theory [31, Chapter 33.1], that is still to be solved.

In the setting of parameterized *counting*, the situation is much better understood: Flum and Grohe [34] proved #EdgeSub(Φ) to be #W[1]-hard when Φ is the property of being a cycle, or the property of being a path. Curticapean [20] established the same result for the property of being a matching. In [22], Curticapean and Marx established a complete classification in case Φ does not hold on two different graphs with the same number of edges, which is essentially the parameterized subgraph counting problem. In particular, they identified a bound on the matching number as the tractability criterion. In a later work, together with Dell [21], they presented what is now called the framework of Complexity Monotonicity, which can be considered to be one of the most powerful tools in the field of parameterized counting problems. Note that this does not classify the decision version, as #W[1]-hardness for a counting problem does not imply W[1]-hardness for the corresponding decision problem.

In contrast to the parameterized subgraph detection/counting problems, the problem (#)EdgeSub(Φ) allows to search for more general patterns. For example, while the (parameterized) complexity of counting all subgraphs of a graph G isomorphic to a *fixed* connected graph H with k edges is fully understood [22], the case of counting all connected k-edge subgraphs of a graph G remained open so far. As one of our main results, we completely understand the problem #EdgeSub(Φ) for the property Φ = connectivity. In what follows, we present our results, followed by an exposition of the most important techniques. Due to the space constraints, we have to defer the proofs to the full version.

Main Results

In a first part, we present our results on (#)EdgeSub(Φ); we continue with a definition and our results for a parameterized Tutte polynomial in a second part.

Our main results on (#)EdgeSub(Φ) can be categorized in roughly three categories: (1) exact algorithms and hardness results for the counting problem; (2) approximation algorithms for the counting problem; and (3) algorithms for the decision problem. For minor-closed properties Φ, we obtain exhaustive results for all three categories, for other (classes of) properties that we study, we obtain partial criteria. For an overview over our results on #EdgeSub(Φ), also consider Table 1; we go into more detail in the following.

Complete Classification for Minor-Closed Properties

Let us start with the case where the graph property Φ is closed under taking minors, that is, if Φ holds for a graph, then Φ still holds after removing vertices or edges, or after contracting edges. For minor-closed properties Φ, we obtain a complete picture of the complexity of

Table 1 An overview of the complexity of (#)EdgeSub(Φ) for different classes and examples of properties Φ, with respect to exact counting, approximate counting and decision. See further below for the definition of the matching and star criterion. All run-time lower bounds rely on the Exponential Time Hypothesis, and the absence of FPTRASes relies on the assumption that W[1] does not coincide with FPT under randomised parameterized reductions. We write "mixed" whenever the respective classes contain both tractable properties and hard properties. The known results about the clique problem are added for completeness; note that W[1]-hardness of decision immediately rules out an FPTRAS for approximate counting under the previous assumptions.

Property Φ	Exact Counting	Apx. Counting	Decision
Minor-closed[†] (e.g. Φ = planarity)	#W[1]-hard not in $f(k) \cdot \lvert G\rvert^{o(k/\log k)}$ (Main Theorem 1)	FPTRAS (Main Theorem 1)	FPT (Main Theorem 1)
Φ = connectivity	#W[1]-hard not in $f(k) \cdot \lvert G\rvert^{o(k/\log k)}$ (Main Theorem 2)	FPTRAS (follows from [26])	FPT (easy)
Φ = Hamiltonicity	#W[1]-hard not in $f(k) \cdot \lvert G\rvert^{o(k/\log k)}$ (Main Theorem 2)	unknown	unknown
Φ = Eulerianity	#W[1]-hard not in $f(k) \cdot \lvert G\rvert^{o(k/\log k)}$ (Main Theorem 2)	unknown	unknown
Φ = claw-freeness	#W[1]-hard not in $f(k) \cdot \lvert G\rvert^{o(k/\log k)}$ (Main Theorem 2)	unknown	unknown
Bounded matching number	FPT (Proposition 1.2)	FPTRAS (by exact counting)	FPT (by exact counting)
Bounded treewidth	mixed[‡]	FPTRAS (Main Theorem 3)	FPT (follows from [55])
Matching crit. **and** star crit.	mixed[*]	FPTRAS (Main Theorem 3)	FPT (Main Theorem 4)
Matching crit. **or** star crit.	mixed[‡]	mixed[§]	FPT (Main Theorem 4)
$\Phi = \Psi$ (see full version)	#W[1]-hard (full version)	no FPTRAS (full version)	FPT (full version)
Φ = Clique	#W[1]-hard ([34])	no FPTRAS (implicitly by [30])	W[1]-hard ([30])

[†] We assume that the minor-closed property Φ does not have bounded matching number, is not trivially true and that each forbidden minor has a vertex of degree at least 3.

[‡] Φ = true and Φ = false always yield fixed-parameter tractability of exact counting. $\Phi(H) = 1 \Leftrightarrow H$ is a matching yields #W[1]-hardness of exact counting [20]; note that the latter property is of bounded treewidth and satisfies the matching criterion.

[*] Φ = true always yields fixed-parameter tractability of exact counting. $\Phi(H) = 1 \Leftrightarrow (H$ is a matching or a star) yields #W[1]-hardness by Theorem 1.4; note that the latter property satisfies the matching criterion and the star criterion.

[§] Φ = true always yields an FPTRAS for approximate counting. $\Phi = \Psi$ (from the full version) does not allow for an FPTRAS while satisfying the matching criterion.

#EdgeSub(Φ) and EdgeSub(Φ). In what follows, we say that a property Φ has *bounded matching number* if there is a constant bound on the size of a largest matching in graphs satisfying Φ.

▶ **Main Theorem 1.** *Let Φ denote a minor-closed graph property.*

1. Exact Counting*: If Φ is either trivially true or of bounded matching number, then the (exact) counting version #EdgeSub(Φ) is fixed-parameter tractable. Otherwise, the problem #EdgeSub(Φ) is #W[1]-hard. If, additionally, each forbidden minor of Φ has a vertex of degree at least 3, and the Exponential Time Hypothesis holds, then #EdgeSub(Φ) cannot be solved in time $f(k) \cdot |G|^{o(k/\log k)}$, for any function f.*
2. Approximate Counting*: The problem #EdgeSub(Φ) always has a fixed-parameter tractable randomised approximation scheme (FPTRAS).*[2]
3. Decision: *The problem EdgeSub(Φ) is always fixed-parameter tractable.*

Consider for example the property Φ of being planar: planar graphs do not have bounded matching number. Additionally, by Kuratowski's Theorem, the forbidden minors of planar graphs are the 3-biclique $K_{3,3}$ and the 5-clique K_5. Since both $K_{3,3}$ and K_5 contain a vertex of degree at least 3, we conclude that computing the number of planar subgraphs with k edges in a graph G is #W[1]-hard and, assuming ETH, cannot be solved in time $f(k) \cdot |G|^{o(k/\log k)}$ for any function f. In sharp contrast, approximating the number of planar subgraphs with k edges in a graph, as well as deciding whether there is such a planar subgraph can be done efficiently. We obtain Main Theorem 1 as a combination of our (more general) results for each of the three settings that we study; we discuss these results next.

Results for Exact Counting

Let us return to the case of arbitrary graph properties Φ. Without any further assumptions on Φ, the naive algorithm for #EdgeSub(Φ) on the input (k, G) proceeds by enumerating the k-edge subsets of G and counting the number of cases where the corresponding subgraph satisfies Φ. This leads to a running time of the form $f(k) \cdot |V(G)|^{2k+O(1)}$. However, at least the linear constant in the exponent can be substantially improved using the currently fastest known algorithm for counting subgraphs with k edges due to Curticapean, Dell and Marx [21]. In the full version, we show that it easily extends to the case of #EdgeSub(Φ):

▶ **Proposition 1.1.** *Let Φ denote a computable graph property. Then #EdgeSub(Φ) can be solved in time $f(k) \cdot |V(G)|^{0.174k+o(k)}$, where f is some computable function.*

On the other hand, it was shown by Curticapean and Marx [22] that for the property Φ of being a matching, the problem #EdgeSub(Φ) cannot be solved in time $f(k) \cdot |V(G)|^{o(k/\log k)}$ for any function f, unless ETH fails. In other words, asymptotically and up to a factor of $1/\log k$, the exponent of $|V(G)|$ in the running time of #EdgeSub(Φ) cannot be improved without posing any restriction on Φ.

The goal is hence to identify properties Φ for which the algorithm in Proposition 1.1 *can* be (significantly) improved. In the best possible outcome, we hope to identify the properties for which the exponent of $|V(G)|$ does not depend on k; those cases are precisely the fixed-parameter tractable ones. An easy consequence of known results for subgraph counting (see for instance [22]) establishes the following tractability criterion; we include the proof only for the sake of completeness in the full version:

[2] The formal definition is given in the full version; intuitively an FPTRAS is the parameterized equivalent of a fully polynomial-time randomised approximation scheme (FPRAS).

▶ **Proposition 1.2.** *Let Φ denote a computable graph property satisfying that there is $M > 0$ such that for all k either the graphs with k edges satisfying Φ or the graphs with k edges satisfying $\neg\Phi$ have matching number bounded by M. Then #EdgeSub(Φ) is fixed-parameter tractable.*

Examples of properties satisfying the tractability criterion of Proposition 1.2 include, among others, the property of being a star, or the complement thereof. We conjecture that all remaining properties induce #W[1]-hardness and rule out any algorithm running in time $f(k) \cdot |G|^{o(k/\log k)}$ for any function f, unless ETH fails.[3] For the case of minor-closed graph properties, we have seen above that this conjecture holds.

Further, the techniques we develop to prove hardness of #EdgeSub(Φ) for minor-closed properties Φ in Main Theorem 1 can also be applied directly to show hardness for other specific properties Φ. Below, we record several natural examples of such properties which are covered by our methods.

▶ **Main Theorem 2.** *Consider the following graph properties.*

- $\Phi_C(H) = 1$ *if and only if H is connected.*
- $\Phi_H(H) = 1$ *if and only if H is Hamiltonian.*
- $\Phi_E(H) = 1$ *if and only if H is Eulerian.*
- $\Phi_{CF}(H) = 1$ *if and only if H is claw-free.*

For $\Phi \in \{\Phi_C, \Phi_H, \Phi_E, \Phi_{CF}\}$, the problem #EdgeSub($\Phi$) is #W[1]-hard. Further, unless ETH fails, the problem #EdgeSub(Φ) cannot be solved in time $f(k) \cdot |G|^{o(k/\log k)}$ for any function f.

Results for Approximate Counting and Decision

Our results on exact counting indicate that we have to relax the problem if we aim for tractability results for a larger variety of properties. One approach is to only ask for an *approximate* count of the number of k-edge subgraphs satisfying Φ. Tractability of approximation in the parameterized setting is given by the notion of a *fixed-parameter tractable randomized approximation scheme* (FPTRAS) as introduced by Arvind and Raman [5]. While we give the formal definition in full version, it suffices for now to think of an FPTRAS as a fixed-parameter tractable algorithm that can compute an arbitrarily good approximation of the answer with high probability. Readers familiar with the classical notions of approximate counting algorithms should think of an FPTRAS as an FPRAS in which we additionally allow a factor of $f(k)$ in the running time, for any computable function f.

For the statement of our results, we say that a property Φ satisfies the *matching criterion* if it is true for all but finitely many matchings, and we say that it satisfies the *star criterion* if it is true for all but finitely many stars. Furthermore, we say that Φ has bounded treewidth if there is a constant upper bound on the treewidth of graphs that satisfy Φ.

▶ **Main Theorem 3.** *Let Φ denote a computable graph property. If Φ satisfies the matching criterion* ***and*** *the star criterion, or if Φ has bounded treewidth, then #EdgeSub(Φ) admits an FPTRAS.*

For example, the property of being planar satisfies both, the star and the matching criterion. Moreover, we can show that every minor-closed graph property Φ has either bounded treewidth or satisfies matching and star criterion, and thus always admits an

[3] Note that it does not matter whether we choose $|G|$ or $|V(G)|$ for the size of the large graph since we care about the asymptotic behaviour of the exponent.

FPTRAS. Additionally, if not only exact but also approximate counting is intractable, we ask whether we can at least obtain an efficient algorithm for the decision version EdgeSub(Φ). Again, we obtain a tractability criterion; observe the subtle difference in the tractability criterion compared to Main Theorem 3.

▶ **Main Theorem 4.** *Let Φ denote a computable graph property. If Φ satisfies the matching criterion* ***or*** *the star criterion, or if Φ has bounded treewidth, then* EdgeSub(Φ) *is fixed-parameter tractable.*

As an easy corollary, we can conclude that for monotone, that is, subgraph-closed properties Φ, the problem EdgeSub(Φ) is always fixed-parameter tractable.[4]

For many previously studied problems, the complexity analysis of approximate counting and decision were related: often an algorithm solving one setting can be used to solve the other setting [51, 26]. However, in our results Main Theorems 3 and 4 we see an asymmetry between the two settings: it suffices for Φ to satisfy only one of the star and the matching criterion to induce tractability of the decision version, but we require satisfaction of both for approximate counting. One might expect that this reflects a shortcoming of our proof methods (and that in fact it suffices to check one of the criteria to have tractability of approximate counting). Interestingly, this is *not* the case:

▶ **Proposition 1.3.** *There is a computable graph property Ψ (see full version) that satisfies the matching criterion, but not the star criterion, such that* EdgeSub(Ψ) *is fixed-parameter tractable, but* #EdgeSub(Ψ) *does not admit an FPTRAS unless* W[1] *coincides with* FPT *(the class of all fixed-parameter tractable decision problems) under randomised parameterized reductions.*

Dichotomy for Evaluating a parameterized Tutte Polynomial

As a final part of the presentation of our main results, let us discuss our results on a parameterized Tutte polynomial.

The classical Tutte polynomial (as well as its specializations like the chromatic, flow or reliability polynomial) have received widespread attention, both from a combinatorial as well as a complexity theoretic perspective [42, 2, 65, 6, 37, 25, 10, 8]. The classical Tutte polynomial is of special interest from a complexity theoretic perspective, as the Tutte polynomial encodes a plethora of properties of a graph: prominent examples include the chromatic number, the number of acyclic orientations, and the number of spanning trees; we refer the reader to the work of Jaeger et al. [42] for a comprehensive overview. Formally, the Tutte polynomial is a bivariate graph polynomial defined as follows (see [42]):

$$T_G(x,y) := \sum_{A \subseteq E(G)} (x-1)^{k(A)-k(E(G))} \cdot (y-1)^{k(A)+\#A-\#V(G)},$$

where $k(S)$ is the number of connected components of the graph $(V(G), S)$. In the aforementioned work, Jaeger et al. [42] also classified the complexity of evaluating the Tutte Polynomial in every pair of (complex) coordinates, that is, for every pair (a, b), the complexity of computing the function $G \mapsto T_G(a, b)$ is fully understood.

[4] Every graph property has either bounded treewidth or unbounded matching number. In the latter case, if the property is additionally monotone, it must satisfy the matching criterion.

In this work, we consider the following parameterized version of the Tutte Polynomial by restricting to edge-subsets A in G of size k:

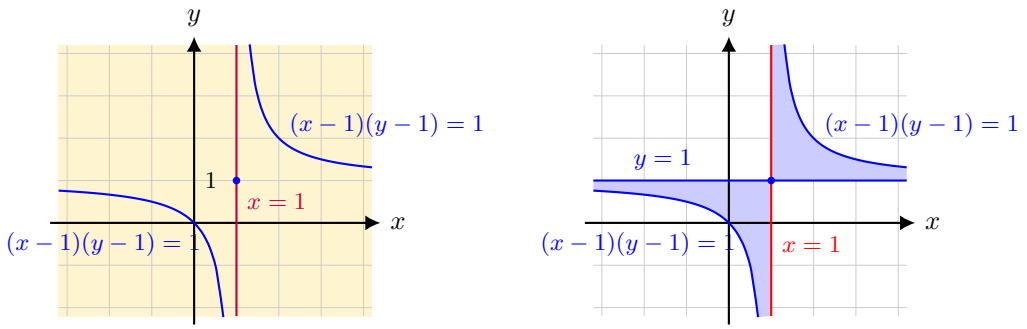
$$T_G^k(x,y) := \sum_{A \in \binom{E(G)}{k}} (x-1)^{k(A)-k(E(G))} \cdot (y-1)^{k(A)+k-\#V(G)} .$$

We observe that the parameterized Tutte polynomial can be seen as a weighted version of counting small k-edge subgraph patterns by assigning to each k-edge subset A of G the weight

$$(x-1)^{k(A)-k(E(G))} \cdot (y-1)^{k(A)+k-\#V(G)} .$$

Moreover, we point out that $T_G^k(x,y)$ is related to a generalization of the bases generating function for matroids [4]. By establishing a so-called deletion-contraction recurrence, we show that $T_G^k(x,y)$ has similar expressive power as its classical counterpart $T_G(x,y)$:

▶ **Main Theorem 5.** *For any graph G and positive integer k, the following graph invariants are encoded in $T_G^k(x,y)$:*



1. *$T_G^k(2,1)$ is the number of k-forests in G. In other words $T_G^k(2,1)$ corresponds to the problem #EdgeSub(Φ) for the property Φ of being a forest.*
2. *For each positive integer c, the values of $T_G^k(1-c,0)$ determine[5] the numbers of pairs (A,σ), where A is a k-edge subset of G, and σ is a proper c-colouring of $(V(G),A)$.*
3. *From $T_G^k(2,0)$ we can compute the numbers of pairs $(A,\vec{\eta})$, where A is a k-edge subset of G, and $\vec{\eta}$ is an acyclic orientation of $(V(G),A)$.*
4. *$T_G^k(2,0)$ also determines the number of k-edge subsets A of G, such that $(V(G),A)$ has even Betti Number (we give a formal definition of the Betti number in the full version).*
5. *$T_G^k(0,2)$ determines the number of k-edge subsets A of G, such that $(V(G),A)$ has an even number of components.*

Note that, while #EdgeSub(Φ) only allows us to count the number of subgraphs with k edges that satisfy Φ, the parameterized Tutte polynomial allows us to count more intricate objects, such as tuples of an edge-subset and a colouring (or acyclic orientation) on the induced graph. From a complexity theoretic point of view, we obtain a similar result as [42], albeit only for rational coordinates: for each *fixed* pair (x,y) of coordinates, we consider the problem receiving as input a graph G and a positive integer k and computing $T_G^k(x,y)$. Following the paradigm of this work, we choose k as a parameter, that is, we consider inputs in which k is significantly smaller than $|G|$.

▶ **Main Theorem 6.** *Let (x,y) denote a pair of rational numbers. The problem of computing $T_G^k(x,y)$ is solvable in polynomial-time if $x=y=1$ or $(x-1)(y-1)=1$, fixed-parameter tractable, but #P-hard, if $x=1$ and $y \neq 1$, and #W[1]-hard otherwise.*

The class #P is the counting version of NP [63, 64] and, in particular, the #P-hard cases in the above classification are not polynomial-time tractable unless the polynomial-time hierarchy collapses to P [61]. Consider Figure 1 for a depiction of the classification. Note that Main Theorem 6 yields #W[1]-hardness for each of the aforementioned problems from Main Theorem 5. Note further, that the tractable cases are similar, but not equal to the classical counterpart [42].

[5] They are equal up to trivial modifications; in particular, their complexities coincide.

(a) Points of the parameterized Tutte polynomial that can be computed in polynomial-time (blue) and that are fixed-parameter tractable, but #P-hard (red). Exact computation at any other point (yellow) is #W[1]-hard.

(b) Points of the parameterized Tutte polynomial that allow for an FPRAS (blue) and for an FPTRAS (red); all points on the boundary of the blue area are included. The complexity of approximation is open for all points outside of the coloured region.

Figure 1 Points of the parameterized Tutte polynomial that can be computed in FPT-time (a) exactly or (b) approximately. We emphasize that a full classification for exact counting is established, while the complexity of approximation remains open outside of the coloured area.

Moreover, our proof uses entirely different tools than [42] and illustrates the power and utility of the method presented in the subsequent discussion of our techniques.

Having fully classified the complexity of exact evaluation of the parameterized Tutte Polynomial, we also consider the complexity of approximate evaluation. We identify two regions bounded by the hyperbola $(x-1)(y-1)=1$ and the lines $x=1$ and $y=1$ as efficiently approximable; consider Figure 1b for a depiction.

▶ **Main Theorem 7.** *Let (x,y) denote a pair of rational numbers. If $0 \leq (x-1)(y-1) \leq 1$, then $T_G^k(x,y)$ has an FPTRAS. If additionally $x \neq 1$ or $y = 1$ then $T_G^k(x,y)$ even has a fully polynomial-time randomized approximation scheme (FPRAS).*

Techniques

Our Main Theorems 3, 4, and 7 are obtained easily: the proof of Main Theorem 3 is a standard application (see for instance [51]) of the Monte-Carlo approach, in combination with Ramsey's theorem, and Arvind and Raman's algorithm for approximately counting subgraphs of bounded treewidth [5]. The proof of Main Theorem 4 uses a standard parameterized Win-Win approach for graphs of bounded treewidth or bounded degree. Finally, the proof of Main Theorem 7 is an easy consequence of the work of Anari et al. [4] on approximate counting via log-concave polynomials.

Hence, in this technical discussion, we want to focus on the technique that enables us to prove the lower bounds for Main Theorems 1 and 2 and, perhaps surprisingly, also for Main Theorem 6.

As a main component, we use the Complexity Monotonicity framework of Curticapean, Dell and Marx [20]. Given a property Φ and a positive integer k, we write $\#\mathsf{EdgeSub}(\Phi, k \to \star)$ for the function that maps a graph G to the number of k-edge subgraphs of G that satisfy Φ. Using a well-known transformation via Möbius inversion [49, Chapter 5.2], we can show that there are rational numbers $a_1, \ldots, a_\ell$ and graphs $H_1, \ldots, H_\ell$ such that for each graph G we have

$$\#\mathsf{EdgeSub}(\Phi, k \to G) = \sum_{i=1}^{k} a_i \cdot \#\mathsf{Hom}(H_i \to G)\,, \tag{1}$$

where $\#\mathsf{Hom}(H_i \to G)$ is the number of graph homomorphisms from H_i to G. In other words, we can express $\#\mathsf{EdgeSub}(\Phi, k \to \star)$ as a finite linear combination of homomorphism counts. Here, we can then apply the Complexity Monotonicity framework [21], which asserts that computing a finite linear combination of homomorphism counts is *precisely as hard as* its hardest term (among the terms with a non-zero coefficient). However, the complexity of computing the number of homomorphisms from small pattern graphs to large host graphs is very well-understood [24, 50]. Roughly speaking, the higher the treewidth of the pattern graph, the harder the problem becomes; we make this formal in the full version.

Instead of our original problem #EdgeSub(Φ), we can thus consider the problem of computing linear combinations of graph homomorphism counts. In particular, to obtain hardness, it suffices to understand for which of the coefficients in equation (1) we have $a_i \neq 0$, depending on k and Φ.

Relying on the well-known fact that the Möbius function of the partition lattice alternates in sign, Curticapean, Dell, and Marx [21] observed that non-trivial cancellations cannot occur in equation (1) if, for each k, every k-edge graph that satisfies Φ must have the same number of vertices. Consequently, if the matching number is unbounded, those properties yield #W[1]-hardness. An example for such a property is the case of $\Phi(H) = 1$ if and only if H is a tree. In contrast, the intractability result for the case of $\Phi =$ acyclicity (that is, being a forest) turned out to be much harder to show [11], indicated by connections to parameterized counting problems in matroid theory.

In later work, the coefficients a_i were shown to have even more interesting structure: the coefficients a_i describe topological and algebraic invariants of the set of pattern graphs. For example, in [57] it was shown that the coefficient of the k-clique in case of counting vertex-induced subgraphs with property Φ is the reduced Euler characteristic of a simplicial complex associated with Φ and can thus, if non-zero, be used to establish evasiveness of certain graph properties [46].

In this work, we prove additional insights into said coefficients a_i.[6] For any graph H we give an explicit formula for its coefficient a_H in terms of a sum over the *fractures* on H, an additional combinatorial structure on a graph H resembling, to some extent, a gadget construction used for the classification of the subgraph counting problem [22] (see full version for details). Our most crucial insight is then that we can drastically simplify the expression of the coefficient a_H modulo a prime ℓ if H admits a vertex-transitive action of a group of order given by a power of ℓ. In this case, we obtain an action of the group on the set of fractures on H and in the formula for a_H all contributions from fractures not fixed by the group cancel out modulo ℓ.

In particular, we consider graphs H which are Cayley graphs of a finite group of prime power order and a symmetric set of generators. Since the Cayley graph of a group always has a natural vertex-transitive action of this group, such Cayley graphs always have the desired symmetry properties. We exploit this by showing that there is a constant number of fractures fixed by the group action. This in turn allows us to write (a_H modulo ℓ) as a finite sum of terms depending on the value of Φ on some explicit graphs.

[6] For technical reasons, the approach we describe below requires us to consider a coloured version of #EdgeSub(Φ), which is, however, shown to be interreducible with the uncoloured one.

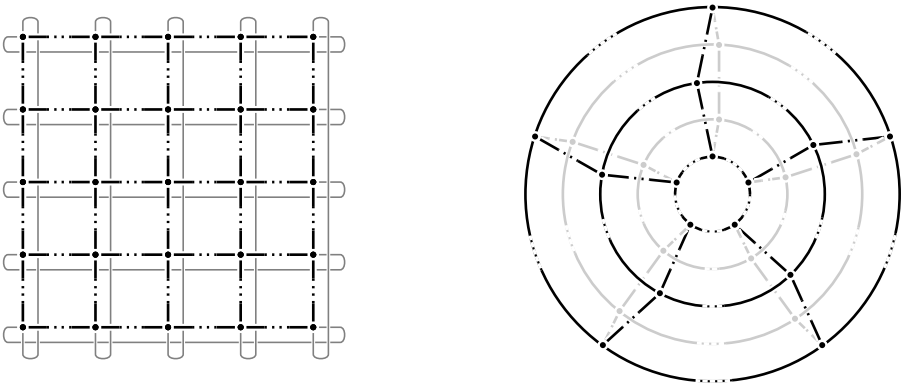


Figure 2 Two isomorphic representations of the toroidal grid $\circledcirc_\ell$: On the left hand side as a grid with connected endpoints, on the right hand side as a stylized torus.

Specifically, the first set of Cayley graphs we consider are the toroidal grids $\circledcirc_\ell$, which are depicted in Figure 2. Since the treewidth of $\circledcirc_\ell$ diverges with ℓ, we thus obtain a #W[1]-hardness result whenever the coefficient $a_{\circledcirc_\ell}$ does not vanish for infinitely many ℓ. Writing M_k for the matching of size k, P_2 for the path consisting of 2 edges, C_k for the cycle of length k, S_k for a sun (a cycle with dangling edges) of size k, and $\circledcirc_k$ for the toroidal grid of size k, our first main technical result reads as follows:

▶ **Theorem 1.4** (Simplified version)**.** *Let Φ denote a computable graph property and assume that infinitely many primes ℓ satisfy the equation*[7]

$$-6\Phi(M_{2\ell^2})+4\Phi(M_{\ell^2}+\ell C_\ell)+8\Phi(\ell^2 P_2)-\Phi(2\ell C_\ell)-2\Phi(\ell C_{2\ell})-4\Phi(\ell S_\ell)+\Phi(\circledcirc_\ell)\neq 0 \mod \ell\,. \quad (2)$$

Then #EdgeSub(Φ) *is* #W[1]*-hard.*

As a toy example for an application of Theorem 1.4, let us consider the property Φ of being connected. Observe that among the graphs in (2), only $\circledcirc_\ell$ is connected, and thus the sum is always 1 for $\ell \geq 2$. Thus, indeed the left-hand side of (2) is nonzero, proving that #EdgeSub(Φ) is #W[1]-hard.

Using Theorem 1.4, we can prove most of the #W[1]-hardness results of Main Theorem 1. However, using the toroidal grid $\circledcirc_\ell$ we cannot prove (almost) tight conditional lower bounds: the treewidth of $\circledcirc_\ell$ grows only with the *square-root* of the parameter k (that is the number of edges of the graph). To address this problem, we consider a second family of 4-regular Cayley graphs, constructed explicitly by Peyerimhoff and Vdovina [54], which have the additional property of being *expander graphs*. In particular, for these graphs, the treewidth grows *linearly* in the number of edges. This allows us to obtain almost tight conditional lower bounds. The variant of Theorem 1.4 for these Cayley graph expanders can be found in the full version of this paper.

The only drawback of the Cayley graphs from [54] is that the corresponding groups always have orders given by powers of 2 (in contrast to having arbitrary primes ℓ in Theorem 1.4). Hence, our criterion for hardness is the nonvanishing of some expression modulo 2. Ultimately, this is the reason why for the conditional lower bounds in Main Theorem 1 we need to exclude forbidden minors having a vertex of degree 2 or less.

[7] We write $+$ for (disjoint) graph union and ℓH for the graph consisting of ℓ disjoint copies of H. Further, we set $\Phi(H) = 1$ if H satisfies Φ and $\Phi(H) = 0$ otherwise.

Finally, to obtain Main Theorem 6, we express the parameterized Tutte polynomial at a rational point (x, y) as a linear combination of (fractures of) toroidal grids; the proof of Theorem 1.4 then essentially shows that this linear combination always contains a graph with unbounded treewidth, yielding #W[1]-hardness.

The Greedy Algorithm Is *not* Optimal for On-Line Edge Coloring

Amin Saberi
Stanford University, CA, USA

David Wajc
Stanford University, CA, USA

Abstract

Nearly three decades ago, Bar-Noy, Motwani and Naor showed that no online edge-coloring algorithm can edge color a graph optimally. Indeed, their work, titled "the greedy algorithm is optimal for on-line edge coloring", shows that the competitive ratio of 2 of the naïve greedy algorithm is best possible online. However, their lower bound required bounded-degree graphs, of maximum degree $\Delta = O(\log n)$, which prompted them to conjecture that better bounds are possible for higher-degree graphs. While progress has been made towards resolving this conjecture for restricted inputs and arrivals or for random arrival orders, an answer for fully general *adversarial* arrivals remained elusive.

We resolve this thirty-year-old conjecture in the affirmative, presenting a $(1.9 + o(1))$-competitive online edge coloring algorithm for general graphs of degree $\Delta = \omega(\log n)$ under vertex arrivals. At the core of our results, and of possible independent interest, is a new online algorithm which rounds a fractional bipartite matching x online under vertex arrivals, guaranteeing that each edge e is matched with probability $(1/2 + c) \cdot x_e$, for a constant $c > 0.027$.

1 Introduction

An edge coloring of a graph is a decomposition of its edge-set into few vertex-disjoint edge-sets (matchings), or *colors*. Edge coloring a graph of maximum degree Δ trivially requires at least Δ colors, and this is tight for bipartite graphs, by the century-old result of König [28]. For general graphs, Δ colors are not always sufficient (e.g., in odd-length cycles), yet $\Delta + 1$ colors are always sufficient, by Vizing's Theorem [35].

Algorithmically matching, or approximating, the optimal $\Delta(+1)$ colors needed to edge color a graph has been the focus of much concentrated effort, for numerous computational models. These include offline, online, distributed, parallel, and dynamic algorithms (see, e.g., [7–9, 11, 13, 25, 31, 34, 36] and references therein). These different models' specific challenges naturally impose limitations on the attainable approximations. For example, Holyer's Theorem [20] rules out efficient offline algorithms for computing an optimal edge coloring in general graphs, unless P=NP.

For online algorithms, the challenge is in making immediate and irrevocable decisions concerning edges' colors after only part of the input is revealed. For example, the input graph can either be revealed edge-by-edge (edge arrivals) or vertex-by-vertex (vertex arrivals), and an online algorithm must assign colors to edges after they are revealed, immediately and irrevocably. The measure of an online algorithm is its competitive ratio, which is the worst-case ratio of the number of colors used by the algorithm to those of the optimal offline algorithm, namely, Δ or $\Delta + 1$.

In both the edge-arrival and vertex-arrival settings, a simple greedy algorithm has competitive ratio 2. The natural question, then, is whether a better online algorithm exists. Some thirty years ago, Bar-Noy, Motwani and Naor [4] showed that this competitive ratio of 2 is best possible, and no online algorithm (randomized or deterministic) can do better, in either arrival model.

However, noting that their result only holds for bounded-degree n-node graphs, of maximum degree $\Delta = O(\log n)$, Bar-Noy et al. conjectured that better algorithms exist for graphs of sufficiently high maximum degree.

▶ **Conjecture 1.1** ([4]). *There exists a $(2 - \Omega(1))$-competitive online edge coloring algorithm under vertex arrivals in n-node graphs of maximum degree $\Delta = \omega(\log n)$.*

Bar-Noy et al. conjectured that the same holds under the more challenging edge-arrival model, and that moreover a $(1+o(1))$-competitive algorithm exists. These conjectures remain out of reach, though progress has been made on them over the years. For edge arrivals, a positive resolution of the stronger conjecture was achieved under the assumption of *random order* arrivals, where the input is generated adversarially, but its arrival order is randomly permuted by nature [1, 3, 5]. For adversarial vertex arrivals, Cohen et al. [9] showed that for *bipartite* graphs under one-sided vertex arrivals (vertices of one side are given, and the other side's vertices arrive), the conjectured $(1 + o(1))$-competitive ratio is achievable for $\Delta = \omega(\log n)$. Whether the competitive ratio of 2 of the greedy algorithm is optimal under *general* vertex arrivals, in *general* graphs, however, remained open.

We answer the above open question, resolving Conjecture 1.1 in the affirmative.

▶ **Theorem 1.2.** *There exists an online edge coloring algorithm which is $(1.897 + o(1))$-competitive w.h.p. on general n-node graphs with maximum degree $\Delta = \omega(\log n)$ under vertex arrivals.*

▶ Remark 1.3. For general Δ, the $o(1)$ term in the above theorem is of the form $\sqrt[\gamma]{\log n/\Delta}$, for some constant $\gamma > 0$. This implies a better than two approximation ratio for sufficiently large $\Delta = O(\log n)$. For simplicity of exposition, we do not elaborate on this point.

1.1 Techniques

To obtain our results, we combine and extend several previous algorithmic ideas.

Our starting point is the following natural recursive approach, due to Karloff and Shmoys [25], which reduces edge coloring a general graph G to edge coloring random bipartite subgraphs. Their idea was to assign each vertex to either side of a random subgraph uniformly, resulting in a bipartite subgraph H of G with maximum degree $\Delta/2 + o(\Delta)$ for $\Delta = \omega(\log n)$,

by standard tail bounds. Consequently, applying an α-approximate algorithm to the random bipartite graph and recursing on the remaining edges is easily shown to result in an edge coloring using $\alpha \cdot \Delta/2 + o(\Delta) + \alpha \cdot \Delta/4 + o(\Delta) \cdots = \alpha \cdot \Delta + o(\Delta)$ colors. Importantly for us, this approach, originally used in the context of NC algorithms by [25], is implementable online, by sampling the random bipartitions in advance. (See Section 5.)

At this point, one might be tempted to use the online algorithm of Cohen et al. [9] for these random bipartite subgraphs. Unfortunately, the reduction of Karloff and Shmoys [25] applied to online edge coloring with general vertex arrivals requires an online algorithm for bipartite graphs with *interleaved* arrivals, and not one-sided arrivals, as handled by [9]. To instantiate the Karloff-Shmoys approach, we therefore present a $(2-c)$-competitive edge coloring algorithm for interleaved vertex arrivals in bipartite graphs, which, when combined with the approach of [25], then extends to general graphs.

To obtain an edge-coloring algorithm for bipartite graphs under interleaved vertex arrival, we extend the approach of Cohen et al. [9], who showed that an $(\alpha + o(1))$-competitive edge coloring can be achieved by repeatedly applying a matching algorithm which matches each edge with probability $(1/\alpha)/\Delta$. For each vertex of degree $\Delta(1 - o(1))$, such a matching results in v being matched with probability $(1/\alpha) \cdot (1 - o(1))$. Repeating the above a super-logarithmic number of times (making use of $\Delta = \omega(\log n)$) therefore decreases the maximum degree of the graph at a rate of roughly one per α colors used. Cohen et al. used this approach with $\alpha = 1 + o(1)$, using an online matching algorithm from [10], on bipartite graphs under one-sided arrivals. We observe that this approach extends to arbitrary α and any arrival model, including interleaved vertex arrivals in bipartite graphs. (See Section 6.)

Motivated by the above discussion, we design an online matching algorithm for bipartite graphs under interleaved arrivals, which matches each edge with probability $(1/2 + c)/\Delta$, for some constant $c > 0$. More generally, and of possible independent interest, we design an online rounding algorithm for bipartite fractional matchings under interleaved vertex arrivals, with a multiplicative factor of $1/2 + c$. That is, we show how, given a bipartite graph G and a fractional matching x in G revealed vertex-by-vertex, one can output a randomized matching which matches each edge e in G with probability $(1/2 + c) \cdot x_e$. This extends a similar online rounding algorithm previously developed by the authors with Papadimitriou and Pollner [33] in the context of online stochastic optimization, but which only works under one-sided vertex arrivals, and is therefore insufficient for our needs. This new rounding algorithm is the technical meat of this paper, and is presented in Section 3.

Combining the above, we obtain Theorem 1.2, and the positive resolution of Conjecture 1.1.

1.2 Related Work

The first positive results for online edge coloring were under random order edge arrivals. In this setting, Aggarwal et al. [1] showed that a $(1 + o(1))$-competitive ratio is achievable in dense multigraphs with maximum degree $\Delta = \omega(n^2)$. Bahmani et al. [3] then showed that the greedy algorithm is sub-optimal for any graph of maximum degree $\Delta = \omega(\log n)$. Achieving the best of both these results, Bhattacharya et al. [5] recently obtained a $(1+o(1))$-competitive algorithm for graphs of maximum degree $\Delta = \omega(\log n)$. As stated above, the only prior algorithm which outperforms the greedy algorithm under *adversarial* arrivals is the algorithm of Cohen et al. [9] for bipartite graphs under one-sided vertex arrivals. In this work, we remove the assumption of bipartiteness and one-sided arrivals, and show how to outperform greedy in general graphs under arbitrary vertex arrivals.

Our work also ties into the long line of work on online matching, initiated by Karp, Vaizrani and Vazirani [26]. (See e.g., [2, 16, 18, 19, 21, 32] and references therein and [29] for a survey of earlier work.) Historically, most research on online matching considered bipartite

graphs with one-sided arrivals, due to applications in Internet advertising [17, 30]. A recent line of work considers such problems subject to interleaved vertex arrivals (motivated by more dynamic two-sided markets), as well as vertex arrivals in general graphs [2, 19, 21, 22, 37]. Our rounding algorithm for bipartite graphs with interleaved arrivals adds to the list of tools for tackling problems in this space.

Few of the works in the online (bipartite) matching literature rely on randomized rounding. At first blush, this seems surprising, given the integrality of the bipartite fractional matching polytope, and the multitude of competitive fractional algorithms for problems in this area [6, 17, 21, 22, 24, 37]. However, as pointed out in [12] and elaborated upon in [10], lossless rounding of a fractional matching x is impossible in online settings. In particular, outputting a matching $\mathcal{M}$ which matches each edge e in a bipartite graph with probability $\Pr[e \in \mathcal{M}] = x_e$ is impossible in online settings, though it is easy to do offline. A natural question, then, is what is the highest value of $\alpha < 1$ for which one can guarantee $\Pr[e \in \mathcal{M}] \geq \alpha \cdot x_e$ when rounding bipartite fractional matchings online. The batched OCRS of Ezra et al. [15] gives $\alpha = 1/2$, unfortunately too low for our purposes. In prior work [33], motivated by a variation of the online Bayesian selection problem, we improve this bound to $\alpha = 0.51$, though only for one-sided arrivals, which is insufficient for our needs here. In this work we generalize this result, achieving a slightly higher $\alpha = 0.527$, subject to *interleaved* vertex arrivals.

2 Preliminaries

The underlying (a priori unknown) input to our problem is an n-node graph $G = (V, E)$ of maximum degree Δ (with n and Δ both known). The vertices of G are revealed over time. For notational convenience, we associate the $n := |V|$ vertices with the numbers in $[n]$ by order of appearance, and denote by $u < v$ the fact that u arrives before v. When a vertex v arrives (at *time* v), all its edges (u, v) to its previously-arrived neighbors $u < v$ are revealed. After v arrives, and before arrival of vertex $v + 1$, an online edge coloring algorithm must decide, irrevocably, which color to assign to all edges (u, v) with $u < v$. The objective is to minimize the number of distinct colors used.

As outlined in the introduction, we will rely on the ability to edge color general graphs by recursively coloring random bipartite subgraphs, as first proposed by Karloff and Shmoys [25], in the context of NC algorithms. The extension and proof for online settings is essentially the same, and is provided, for completeness, in Section 5.

▶ **Lemma 2.1** (Implied by [25]). *Given an online edge coloring algorithm which is α-competitive w.h.p. on bipartite graphs of maximum degree $\Delta = \omega(\log n)$ under interleaved vertex arrivals, there exists an online edge coloring algorithm which is $(\alpha + o(1))$-competitive w.h.p. on* general *graphs of maximum degree $\Delta = \omega(\log n)$ under vertex arrivals.*

The following lemma, implied by the recent work of Cohen et al. [9], reduces α-competitive edge coloring to online matching algorithms which match each edge with probability $(1/\alpha)/\Delta$. The proof is is provided, for completeness, in Section 6.

▶ **Lemma 2.2** (Implied by [9]). *Let $\mathcal{A}$ be an online matching algorithm which on any (bipartite) graph of maximum degree $\Delta \leq \Delta'$ under vertex arrivals, matches each edge with probability at least $1/(\alpha\Delta')$. Then, there exists an online edge coloring algorithm $\mathcal{A}'$ which is $(\alpha + o(1))$-competitive w.h.p. for (bipartite) graphs of maximum degree $\Delta = \omega(\log n)$ under vertex arrivals.*

Motivated by Lemma 2.2, we show how to (approximately) round fractional matchings online. These are assignments of nonnegative $x_e \geq 0$ to edges $e \in E$, satisfying the fractional matching constraint, $\sum_{e \ni v} x_e \leq 1$ for all $v \in V$. This is a fractional relaxation of the

matching constraint, which stipulates that the degree of any vertex in a matching be at most one. Fittingly, we refer to $\sum_{w<v} x_{u,w}$ as the *fractional degree* of u before arrival of v (or at its arrival time, if $u = v$). We shall show how to round fractional matchings up to a multiplicative error of $\alpha < 2$. This rounding subroutine applied to the fractional matching assigning value $1/\Delta$ to each edge of the graph thus matches each edge with probability $1/(\alpha\Delta)$. Combined with lemmas 2.1 and 2.2, this yields our $(\alpha + o(1))\Delta$ coloring algorithm.

2.1 Negative Association

In our work we will need to bound positive correlations between variables. At the core of these proofs will be a use of *negatively associated* random variables. This section introduces this notion of negative dependence and its properties which we use.

▶ **Definition 2.3** ([23, 27]). *Random variables $X_1, \ldots, X_n$ are* negatively associated (NA) *if every two monotone nondecreasing functions f and g defined on disjoint subsets of the variables in $\vec{X}$ are negatively correlated. That is,*

$$\mathbb{E}[f \cdot g] \leq \mathbb{E}[f] \cdot \mathbb{E}[g]. \tag{1}$$

The following simple example of NA variables will prove useful for us.

▶ **Proposition 2.4** (0-1 Principle [14]). *Let $X_1, \ldots, X_n \in \{0, 1\}$ be binary random variables satisfying $\sum_i X_i \leq 1$ always. Then, the variables $X_1, \ldots, X_n$ are NA.*

Negative association is closed under several operations, allowing to construct more elaborate NA distributions from simpler NA distributions as above (see [14, 23, 27]).

▶ **Proposition 2.5** (Independent Union). *Let $X_1, \ldots, X_n$ be NA and $Y_1, \ldots, Y_m$ be NA, with $\{X_i\}_i$ independent of $\{Y_j\}_j$. Then, the variables $X_1, \ldots, X_n, Y_1, \ldots, Y_m$ are all NA.*

▶ **Proposition 2.6** (Function Composition). *Let $X_1, \ldots, X_n$ be NA variables, and let $f_1, \ldots, f_k$ be monotone nondecreasing functions defined on disjoint subsets of the variables in $\vec{X}$. Then the variables $f_1(\vec{X}), \ldots, f_k(\vec{X})$ are NA.*

An immediate corollary of negative association, obtained by considering the functions $f(\vec{X}) = X_i$ and $g(\vec{X}) = X_j$ for $i \neq j$, is pairwise negative correlation.

▶ **Proposition 2.7** (NA implies Negative Correlation). *Let $X_1, \ldots, X_n$ be NA variables. Then, for all $i \neq j$, we have that $\mathrm{Cov}(X_i, X_j) \leq 0$.*

2.2 Probability Basics

Here we include, for completeness, a number of basic probabilistic results used in this paper.

▶ **Proposition 2.8** (Chernoff Bound). *Let $X = \sum_i X_i$ be the sum of independent Bernoulli random variables $X_i \sim$ Bernoulli(p_i), with expectation $\mu := \mathbb{E}[X] = \sum_i p_i$. Then, for any $\epsilon \in (0, 1)$, and $\kappa \geq \mu$,*

$$\Pr[X \geq \kappa \cdot (1 + \epsilon)] \leq \exp\left(\frac{-\kappa \cdot \epsilon^2}{3}\right).$$

$$\Pr[X \leq \mu \cdot (1 - \epsilon)] \leq \exp\left(\frac{-\mu \cdot \epsilon^2}{2}\right).$$

▶ **Proposition 2.9** (Coupling). *Let $X_1, \ldots, X_m$ be binary random variables such that for all i and $\vec{x} \in \{0,1\}^{i-1}$,*

$$\Pr\left[X_i = 1 \,\middle|\, \bigwedge_{\ell \in [i-1]} (X_\ell = x_\ell)\right] \geq p_i.$$

If $\{Y_i \sim Bernoulli(p_i)\}_i$ are independent random variables, then for any $k \in \mathbb{R}$,

$$\Pr\left[\sum_i X_i \leq k\right] \leq \Pr\left[\sum_i Y_i \leq k\right].$$

▶ **Proposition 2.10.** *Let A and B be Bernoulli random variables. Then*

$$\mathrm{Cov}(A, B) = \mathrm{Cov}(1 - A, 1 - B).$$

3 Rounding Bipartite Fractional Matchings Online

In this section we present an online algorithm which (approximately) rounds a bipartite fractional matching under interleaved vertex arrivals. In what follows, we let $c \geq 0.027$ be the largest value below 0.03 satisfying

$$(1/2 - c)(1 - 4c)(1/2 - c - 6c/(1/2 - c)) - 2c \geq 0. \tag{2}$$

We note that this choice of $c \leq 0.03$ also satisfies the following.[1]

$$\min\{1/2 - c,\ 1 - 4c,\ 1 - 6c/(1/2 - c)^2\} \geq 0. \tag{3}$$

We show the following.

▶ **Theorem 3.1.** *There exists an online algorithm which, given an (unknown) bipartite graph G under interleaved vertex arrivals, together with a fractional matching x in G, outputs a random matching $\mathcal{M}$ matching each edge $e \in E$ with probability*

$$\Pr[e \in \mathcal{M}] = (1/2 + c) \cdot x_e \geq 0.527 \cdot x_e. \tag{4}$$

We now turn to describing the algorithm claimed by the above theorem.

3.1 Intuition and Algorithm

Before presenting our algorithm, we describe the approach used to obtain Theorem 3.1 under one-sided arrivals [33], and then discuss the new ideas needed to extend this result to interleaved arrivals.

Naturally, an edge (u, v) with $u < v$ (i.e., v arriving later than u) can only be matched if u is not already matched before the arrival of v. We denote by $F_{u,v}$ the event that u is free (i.e., is not matched in $\mathcal{M}$) prior to the arrival of v. The guarantee of Theorem 3.1 implies the following closed form for the probability of this event.

$$\Pr[F_{u,v}] = g(u, v) := 1 - \sum_{w<v} (1/2 + c) \cdot x_{u,w}. \tag{5}$$

[1] We encourage the reader to think of $c \to 0$, and note that inequalities (2) and (3) hold for sufficiently small constant $c > 0$. Our choice of $c \approx 0.027$ is simply the largest satisfying all these constraints.

To achieve marginal probabilities of $\Pr[(u,v) \in \mathcal{M}] = (1/2+c) \cdot x_{u,v}$, our first step is to have every arriving vertex v pick a random neighbor $u < v$ with probability $x_{u,v}$, and then, if u is free, we match (u,v) with probability $q_{u,v} := \min(1, (1/2+c)/g(u,v))$. For neighbors u of low fractional degree upon arrival of v, i.e., $\sum_{w<v} x_{u,w} \leq \frac{1/2-c}{1/2+c}$, this last probability is precisely $q_{u,v} = (1/2+c)/\Pr[F_{u,v}]$. Consequently, we match each such edge (u,v) with probability $\Pr[(u,v) \in \mathcal{M}] = x_{u,v} \cdot \Pr[F_{u,v}] \cdot (1/2+c)/\Pr[F_{u,v}] = (1/2+c) \cdot x_{u,v}$, as desired. For edges (u,v) for which u has *high* fractional degree, on the other hand, this only gives us $\Pr[(u,v) \in \mathcal{M}] \geq (1/2-c) \cdot x_{u,v}$, and this can be tight.

To increase the probability of an edge (u,v) to be matched to the desired $(1/2+c) \cdot x_{u,v}$, we repeat this process a second time, making a second pick, if v is not matched after its first pick. Here, we must argue that the variables $\{F_{u,v} \mid u < v\}$ do not have strong positive correlation. Indeed, if, as an extreme case, we had $F_{u,v} = F_{w,v}$ always for all $u, w < v$, and v had only high-degree neighbors (for which $q_{u,v} = 1$), then if v is not matched to its first pick, then all its neighbors must be matched, and v is therefore never matched as a second pick. This implies that a second pick does not increase $\Pr[(u,v) \in \mathcal{M}]$ in this case. As shown in [33], under one-sided arrivals, this problematic scenario does not occur, since the matched status of neighbors of v is rather weak. For interleaved arrivals, however, the underlying argument does not carry through, as we now explain.

3.1.1 Extension to Interleaved Arrivals

The key difference between one-sided and interleaved arrivals is that now we require small positive correlation between the matched statuses of every two nodes on the same side of the bipartition, rather than just nodes on the "offline side". For one-sided arrivals, the weak positive correlation between offline vertices was due to two factors. (1) low-degree offline vertices are matched only due to semi-adaptive matching choices, where precisely one neighbor of an arriving online vertex is picked, and at most one is matched. (That is, they are only matched as a first pick.) Therefore, by the 0-1 Principle (Proposition 2.4) and closure properties of NA distributions (propositions 2.5 and 2.6), the indicators for a vertex to be matched when it has low fractional degree are NA, and hence are negatively correlated. (2) On the other hand, the probability of a node to be matched when it has high degree is low, since each edge is matched with probability $(1/2+c) \cdot x_{u,v}$, and the residual fractional degree when v has high degree is $1 - \frac{1/2-c}{1/2+c} = \frac{2c}{1/2+c} \leq 4c$. Putting (1) and (2) together, we find that the matched statuses of any two offline vertices have small correlation.

Unfortunately, under interleaved arrivals, the above is no longer true. In particular, if a vertex v has low fractional degree upon arrival, it may still be matched as a second pick upon arrival (due to its high-degree neighbors). Consequently, the indicators for vertices on the same side of the bipartition being matched when they have low fractional degree are no longer negatively associated, thus undoing the entire argument used to bound $\mathrm{Cov}(F_{u,v}, F_{w,v})$ for vertices $u, w < v$ on the same side of the bipartition.

To overcome this problem, we have each arriving vertex v with low fractional degree upon arrival only pick once, and rely on its low fractional degree to pick each neighbor with higher probability. In particular, when such a vertex v arrives, we pick at most one neighbor with probability $x_{u,v} \cdot \frac{1/2+c}{1/2-c}$. (Since v has low fractional degree on arrival, $\sum_{u<v} x_{u,v} \leq \frac{1/2-c}{1/2+c}$, this is well-defined.) Then, if this picked vertex u is free, we match (u,v) with probability $\frac{1/2-c}{\Pr[F_{u,v}]} = \frac{1/2-c}{g(u,v)} (\leq 1)$, resulting in the edge (u,v) being matched with probability $x_{u,v} \cdot (1/2+c)$. Crucially for our analysis, this now allows us to show that the indicators for vertices (in the same side of the graph) to be matched when they have low

fractional degree is again negatively associated. This then results in the matched status of vertices again being decomposable into two variables, with the first being negatively correlated, and the second having low probability, from which we obtain that vertices on the same side of the bipartition have low correlation.[2]

This discussion gives rise to Algorithm 1, which we prove in this section provides the guarantees of Theorem 3.1.

Algorithm 1 Online rounding scheme.

19: **Output** $\mathcal{M}$

3.2 High-Level Analysis

For our analysis and proof of Theorem 3.1, we will assume, by way of an inductive proof, that Equation (4) holds for all edges (u,w) with $u,w < v$ and therefore that for each $u < v$ we have $\Pr[F_{u,v}] = g(u,v)$, as stated in Equation (5).

Given the inductive hypothesis, it is easy to verify that Algorithm 1 guarantees marginal probabilities of each edge to be matched to be precisely $(1/2+c) \cdot x_e$. Indeed, for an arriving vertex v with low fractional degree, $\sum_{u<v} x_{u,v} \leq \frac{1/2-c}{1/2+c}$ (lines 4-8), since by the inductive hypothesis u is free at time v with probability $\Pr[F_{u,v}] = g(u,v)$, we have that

$$\Pr[(u,v) \in \mathcal{M}] = x_{u,v} \cdot \frac{1/2+c}{1/2-c} \cdot g(u,v) \cdot \frac{1/2-c}{g(u,v)} = (1/2+c) \cdot x_{u,v}.$$

[2] We note that Gamlath et al. [19] followed a superficially similar rounding approach, using two choices. As they only required bounds on the (unweighted) matching's size, their analysis relied on showing that *globally* positive correlation is low. As we desire high matching probability on an edge-by-edge (or at least vertex-by-vertex) basis, we must follow a more delicate approach.

In the alternative case of lines 9-18, we trivially have that each edge (u,v) with $u < v$ is matched with probability precisely $\Pr[(u,v) \in \mathcal{M}] = (1/2+c) \cdot x_e$, due to lines 17-18. The crux of the analysis, then, is in proving that this algorithm is well-defined, and in particular that there exists some probabilities $p_{u,v}$ as stated in Line 17.

We note that all probabilistic lines in the algorithm except for Line 17 are trivially well-defined. First, if v has low fractional degree before time v, i.e., $\sum_{u<v} x_{u,v} \leq \frac{1/2-c}{1/2+c}$, then the probability of any neighbor to be picked in Line 5 is at most $\sum_{u<v} x_{u,v} \cdot \frac{1/2+c}{1/2-c} \leq 1$, and so this line is well-defined. Next, by the fractional matching constraint, we have that $\sum_{u<v} x_{u,v} \leq 1$, and consequently lines 10 and 15 are well-defined. Finally, by the fractional matching constraint, we have that $\sum_{w<v}(1/2+c) \cdot x_{u,w} \leq 1/2+c$, and therefore

$$\Pr[F_{u,v}] = g(u,v) \geq 1/2 - c. \tag{6}$$

Consequently, the term $\frac{1/2-c}{g(u,v)}$ in Line 7 is indeed a probability, by our choice of $c = 0.027 \leq 1/2$. We now turn to proving that probabilities $p_{u,v}$ as stated in Line 17 do indeed exist.

First, to show that $p_{u,v} \geq 0$, we must show that the probability of edge (u,v) to be matched as a first pick in Line 13 does not on its own exceed $(1/2+c) \cdot x_{u,v}$.

▶ **Observation 3.2.** *The probability of an edge (u,v) to be matched in Line 13 is at most*

$$\Pr[(u,v) \text{ added to } \mathcal{M} \text{ in Line 13}] \leq (1/2+c) \cdot x_{u,v}.$$

Proof. By the inductive hypothesis, we have that $\Pr[F_{u,v}] = g(u,v)$. Consequently,

$$\Pr[(u,v) \text{ added to } \mathcal{M} \text{ in Line 13}] = x_{u,v} \cdot \min\left(1, \frac{1/2+c}{g(u,v)}\right) \cdot g(u,v) \leq (1/2+c) \cdot x_{u,v}. \quad \blacktriangleleft$$

▶ **Corollary 3.3.** *The parameter $p_{u,v}$ in Line 17 satisfies $p_{u,v} \geq 0$.*

The core of the analysis will then be in proving that $p_{u,v} \leq 1$. For this, we will need to argue that a second pick in lines 14-18 is likely to result in (u,v) being matched, provided we set $p_{u,v} \leq 1$ high enough. We prove as much in the next section.

3.3 Core of the Analysis

In this section we prove that the second pick is likely to result in a match. To this end, we prove that the matched statuses of neighbors of an arriving vertex v have low positive correlation (if any). More formally, if $G = (V_1, V_2, E)$ is our bipartite graph, we will prove the following.

▶ **Lemma 3.4.** *For any $i = 1, 2$, vertex v and vertices $u, w < v$ with $u, w \in V_i$,*

$$\mathrm{Cov}(F_{u,v}, F_{w,v}) \leq 6c.$$

Since the covariance of two binary variables A and B is equal to that of their complements, $\mathrm{Cov}(A,B) = \mathrm{Cov}(1-A, 1-B)$, we will concern ourselves with bounding $\mathrm{Cov}(M_{u,v}, M_{w,v})$, where $M_{u,v} := 1 - F_{u,v}$ is an indicator for u being matched in $\mathcal{M}$ before v arrives.

For this proof, we write $M_{u,v}$ as the sum of two Bernoulli variables, $M_{u,v} = M^L_{u,v} + M^H_{u,v}$. The indicators $M^L_{u,v}$ and $M^H_{u,v}$ correspond to u being matched to some neighbor w at a time z when u had low or high fractional degree, respectively. That is,

$$M^L_{u,v} := \mathbb{I}\left[(u,w) \in \mathcal{M} \text{ for some } w < v \text{ with } \sum_{z<\min\{u,w\}} x_{u,z} \leq \frac{1/2-c}{1/2+c}\right],$$

with $M^H_{u,v} = M_{u,v} - M^L_{u,v}$ defined analogously.

In what follows, we will show that for any vertex v and index $i = 1, 2$, the variables $\{M^L_{u,v} \mid u \in V_i\}$ are negatively correlated, while the variables $\{M^H_{u,v} \mid u \in V_i\}$ have low probability, which implies that they have low positive correlation with any other binary variable. These bounds will allow us to bound the correlation of the sums $M_{u,v} = M^L_{u,v} + M^H_{u,v}$.

We start by proving the negative correlation between $M^L_{u,v}$ variables, and indeed proving negative association of these variables.

▶ **Lemma 3.5.** *For any $i = 1, 2$ and vertex v, the variables $\{M^L_{u,v} \mid u < v,\ u \in V_i\}$ are NA.*

By Proposition 2.7, this implies that the above variables are negatively correlated.

▶ **Corollary 3.6.** *For any $i = 1, 2$, vertex v and earlier vertices $u, w < v$ with $u, w \in V_i$,*

$$\mathrm{Cov}(M^L_{u,v}, M^L_{w,v}) \leq 0.$$

Proof of Lemma 3.5. Recall that $M^L_{u,v}$ is an indicator for u being matched before arrival of v before it has high fractional degree. By definition of Algorithm 1, this implies that a matching event accounted for by $M^L_{u,v}$ can only occur in lines 8 or 13. Such matches occur due to u picking a neighbor or being picked as a neighbor in line 5 or 10, and the probabilistic test in line 7 or 12 (respectively), passing, if the picked vertex was previously unmatched in $\mathcal{M}$. We imagine we perform the probabilistic tests in lines 7 and 12 *before* testing whether the picked vertex was unmatched in $\mathcal{M}$.

For vertices $w < z$, let $A_{w,z}$ be an indicator for z picking w in line 5 or 10, and the probabilistic test in line 7 or 12 (respectively) passing. Then, by the 0-1 Principle (Proposition 2.4), we have that for any vertex z, the variables $\{A_{w,z} \mid w < z\}$ are NA. Moreover, the families of variables $\{A_{w,z} \mid w < z\}$ for distinct z are NA. Therefore, by closure of NA under independent union (Proposition 2.5), the variables $\{A_{w,z} \mid z,\ w < z\}$ are NA. For notational simplicity, letting $A_{z,w} := A_{w,z}$ for $z > w$ (recall that we only defined $A_{w,z}$ for $w < z$), we find that if z' is the smaller of $v - 1$ and the first time z that u has high fractional degree, the variables $M^L_{u,v}$ are precisely equal to

$$M^L_{u,v} := \bigvee_{w \leq z'} A_{w,u}.$$

Indeed, this is due to u being matched while it has low fractional degree upon the first time that it is picked by a neighbor (or it picks a neighbor) in line 5 or 10, and the corresponding probabilistic test in line 7 or 12 passes. Therefore, by closure of NA under monotone function composition (Proposition 2.6), the variables $\{M^L_{u,v} \mid u \in V_i\}$, which are monotone nondecreasing functions of disjoint subsets of the variables $A_{w,u}$ by bipartiteness, are NA.[3] ◀

We now turn to upper bounding the probability of the event $M^H_{u,v}$.

[3] This is the only place in our analysis where we use bipartiteness.

▶ **Lemma 3.7.** *For any edge (u,v) with $u<v$, we have that* $\Pr[M^H_{u,v}] \le 2c$.

Proof. Recall that by the inductive hypothesis, $\Pr[(u,w)\in\mathcal{M}] = (1/2+c)\cdot x_{u,w}$. On the other hand, by the fractional matching constraint, we have that $\sum_{w<v} x_{u,v} \le 1$, and therefore $\Pr[M_{u,v}] \le 1/2+c$. On the other hand, if we denote by z_u the first time u has high fractional degree, then either $z_u \ge v$, in which case $\Pr[M^H_{u,v}]=0$, or

$$\Pr[M^L_{u,v}] \ge \sum_{w<z_u} x_{u,w}\cdot(1/2+c) \ge \frac{1/2-c}{1/2+c}\cdot(1/2+c) = 1/2-c,$$

in which case we have

$$\Pr[M^H_{u,v}] = \Pr[M_{u,v}] - \Pr[M^L_{u,v}] \le 2c. \qquad \blacktriangleleft$$

We are now ready to prove Lemma 3.4, whereby vertices u,w on the same side of the bipartition have weakly correlated matched statuses, namely $\mathrm{Cov}(F_{u,v},F_{w,v}) \le 6c$.

Proof. By definition of covariance, the binary variables $F_{u,v}$ and $F_{w,v}$ satisfy $\mathrm{Cov}(F_{u,v},F_{w,v}) = \mathrm{Cov}(1-F_{u,v},1-F_{w,v}) = \mathrm{Cov}(M_{u,v},M_{w,v})$ (see Proposition 2.10). We therefore turn to upper bounding the covariance of the variables $M_{u,v}$ and $M_{w,v}$.

By the additive law of covariance, the covariance of the variables $M_{u,v} = M^L_{u,v}+M^H_{u,v}$ and $M_{w,v} = M^L_{w,v}+M^H_{w,v}$, denoted by $(\star)=\mathrm{Cov}(M_{u,v},M_{w,v})$, satisfies

$$\begin{aligned}
(\star) &= \mathrm{Cov}(M^L_{u,v}+M^H_{u,v}\,,\,M^L_{w,v}+M^H_{w,v})\\
&= \mathrm{Cov}(M^L_{u,v},M^L_{w,v}) + \mathrm{Cov}(M^L_{u,v},M^H_{w,v}) + \mathrm{Cov}(M^H_{u,v},M^L_{w,v}) + \mathrm{Cov}(M^H_{u,v},M^H_{w,v})\\
&\le 0 + \Pr[M^L_{u,v},M^H_{w,v}] + \Pr[M^H_{u,v},M^L_{w,v}] + \Pr[M^H_{u,v},M^H_{w,v}]\\
&\le 0 + \Pr[M^H_{w,v}] + \Pr[M^H_{u,v}] + \Pr[M^H_{u,v}]\\
&\le 6c.
\end{aligned}$$

Here, the first inequality follows from Corollary 3.6, the second inequality follows from the trivial bound on covariance of Bernoulli variables A and B given by $\mathrm{Cov}(A,B) = \Pr[A,B] - \Pr[A]\cdot\Pr[B] \le \Pr[A,B] \le \Pr[A]$, and the final inequality follows from Lemma 3.7. ◀

Lemma 3.4 now allows us to argue that if u has high degree upon arrival of v, then $F_{u,v}$ is nearly independent of the event R_v, whereby v is rejected (not matched) after its first pick of u_1 (possibly $u_1=\text{nil}$). In particular, we have the following.

▶ **Lemma 3.8.** *Let $u<v$ be a vertex of high fractional degree, $\sum_{w<v} x_{u,w}$, upon arrival of v. Then, for all $w\neq u$ (including possibly $w=$ nil), we have*

$$\Pr[F_{u,v},R_v,u_1=w] \ge \Pr[F_{u,v}]\cdot\Pr[R_v,u_1=w]\cdot\left(1-\frac{6c}{(1/2-c)^2}\right).$$

Proof. For $w=\text{nil}$ the claim follows from the event $u_1=\text{nil}$ implying R_v, and being independent of $F_{u,v}$.

$$\Pr[F_{u,v},R_v,u_1=\text{nil}] = \Pr[F_{u,v}]\cdot\Pr[R_v,u_1=\text{nil}].$$

Next, let $w<v$ be some neighbor of v. If we denote by $q_{w,v} := \min\left(1,\frac{1/2+c}{g(w,v)}\right)$ the probability that w does not reject v if it is picked first and is free, then the probability that $u_1=w$ and v gets rejected in its first pick is

$$\Pr[R_v,u_1=w] = x_{w,v}\cdot(1-q_{w,v}\cdot\Pr[F_{w,v}]) \ge x_{w,v}\cdot(1/2-c), \tag{7}$$

where the inequality follows from $\Pr[F_{w,v}] = g(w,v)$ by Equation (6), which implies that $q_{w,v} \cdot \Pr[F_{w,v}] \leq 1/2 + c$. Similarly, the probability u is free, $u_1 = w$ and v gets rejected in its first pick is

$$\begin{aligned}
\Pr[F_{u,v}, R_v, u_1 = w] &= x_{w,v} \cdot (\Pr[F_{u,v}] - q_{w,v} \cdot \Pr[F_{w,v}, F_{u,v}]) \\
&\geq x_{w,v} \cdot (\Pr[F_{u,v}] - q_{w,v} \cdot (\Pr[F_{w,v}] \cdot \Pr[F_{u,v}] + 6c)), \\
&\geq x_{w,v} \cdot (\Pr[F_{u,v}] - q_{w,v} \cdot (\Pr[F_{w,v}] \cdot \Pr[F_{u,v}]) - 6c) \\
&\geq x_{w,v} \cdot \Pr[F_{u,v}] \cdot \left(1 - q_{wv} \cdot \Pr[F_{w,v}] - \frac{6c}{1/2 - c}\right) \\
&\geq \Pr[F_{u,v}] \cdot \Pr[R_v, u_1 = w] \cdot \left(1 - \frac{6c}{(1/2-c)^2}\right),
\end{aligned}$$

where the first inequality follows from Lemma 3.4, the second inequality follows from the trivial bound $q_{wv} \leq 1$, the third inequality follows from $\Pr[F_{u,v}] = g(u,v) \geq 1/2 - c$ by Equation (5), and the final inequality follows from Equation (7). ◀

In what follows we denote by $x_{\text{nil},v} := 1 - \sum_{w<v} x_{w,v}$ the probability with which $u_1 = \text{nil}$. From Lemma 3.8 and Equation (7), as well as $\Pr[R_v, u_1 = \text{nil}] = \Pr[u_1 = \text{nil}] = x_{\text{nil},v}$, we obtain the following lower bound on $\Pr[F_{u,v}, R_v, u_1 = w]$ in terms of $x_{w,v}$.

▶ **Corollary 3.9.** *For any vertex v and w (possibly $w = \text{nil}$), we have that*

$$\Pr[F_{u,v}, R_v, u_1 = w] \geq \Pr[F_{u,v}] \cdot x_{w,v} \cdot \left(1/2 - c - \frac{6c}{1/2 - c}\right).$$

Finally, we are ready to prove that $p_{u,v}$ is a probability, and in particular $p_{u,v} \leq 1$.

▶ **Lemma 3.10.** *The parameter $p_{u,v}$ in Line 17 satisfies $p_{u,v} \in [0,1]$.*

Proof. Non-negativity of $p_{u,v}$ was proven in Corollary 3.3. We turn to proving that $p_{u,v} \leq 1$ suffices to guarantee $\Pr[(u,v) \in \mathcal{M}] \geq (1/2 + c) \cdot x_{u,v}$, from which we obtain that there exists some $p_{u,v} \in [0,1]$ which results in $\Pr[(u,v) \in \mathcal{M}] = (1/2 + c) \cdot x_{u,v}$.

By Equation (6) we have that $\Pr[F_{u,v}] = g(u,v) \geq 1/2 - c$, and therefore

$$\Pr[(u,v) \in \mathcal{M} \text{ in Line 13}] = x_{u,v} \cdot \min\left(1, \frac{1/2 + c}{g(u,v)}\right) \cdot g(u,v) \geq (1/2 - c) \cdot x_{u,v}. \tag{8}$$

We therefore wish to prove that the probability of (u,v) being matched in Line 18 is at least $2c \cdot x_{u,v}$, for some choice of $p_{u,v} \leq 1$. And indeed,

$$\begin{aligned}
\Pr[(u,v) \text{ added to } \mathcal{M} \text{ in Line 18}] &= x_{u,v} \cdot \sum_{w \neq u} \Pr[F_{u,v}, R_v, u_1 = w] \cdot p_{u,v} \\
&\geq x_{u,v} \cdot \Pr[F_{u,v}] \cdot \sum_{w \neq u} x_{w,v} \cdot \left(1/2 - c - \frac{6c}{1/2 - c}\right) \cdot p_{u,v} \\
&\geq x_{u,v} \cdot (1/2 - c) \cdot (1 - 4c) \cdot \left(1/2 - c - \frac{6c}{1/2 - c}\right) \cdot p_{u,v} \\
&\geq 2c \cdot x_{u,v},
\end{aligned}$$

where the first inequality follows from Corollary 3.9 and Equation (3). The second inequality holds due to Equation (5) implying $\Pr[F_{u,v}] \geq 1/2 - c$ and due to vertex u having high degree at time v, and therefore by the fractional matching constraint $x_{u,v} \leq 1 - \frac{1/2-c}{1/2+c} = \frac{2c}{1/2+c} \leq 4c$, and hence $\sum_{w \neq u} x_{w,v} \geq 1 - 4c \geq 0$ (again using Equation (3)). The final inequality holds for $p_{u,v} = 1$ and for our choice of c, by Equation (2).

Consequently, combining the above with Equation (8), we find that setting $p_{u,v} = 1$ results in (u, v) being matched in either Line 13 or Line 18 with probability at least

$$\Pr[(u, v) \in \mathcal{M}] \geq (1/2 + c) \cdot x_{u,v}. \tag{9}$$

As the probability of (u, v) being added to $\mathcal{M}$ in Line 18 is monotone increasing in $p_{u,v}$, we conclude that there exists some $p_{u,v} \in [0, 1]$ for which Equation (9) holds with equality. ◀

Conclusion of Algorithm 1's analysis. To conclude, Algorithm 1 is well-defined, and this algorithm outputs a random matching $\mathcal{M}$ which matches each edge e with probability precisely $\Pr[e \in \mathcal{M}] = (1/2 + c) \cdot x_e$. Theorem 3.1 follows.

▶ Remark 3.11. **Computational Aspects:** As described, the only way we are aware of to implement Algorithm 1 exactly (and in particular, computing all $p_{u,v}$ exactly) is using an exponential-time algorithm maintaining the joint distributions as they evolve. However, a simple modification of the algorithm, resulting in a polynomial-time algorithm with a $(1 + o(1))$ additional multiplicative loss in each edge's matching probability, can be readily obtained by approximately estimating the above $p_{u,v}$ up to $(1 \pm o(1))$ multiplicative errors, by standard monte carlo methods. As this results in rather cumbersome descriptions and subsequent calculations, and since running time is not our focus, we do not expand on this.

4 Putting it all Together

In this section we prove our main result, Theorem 1.2, restated below for ease of reference.

▶ **Theorem 1.2.** *There exists an online edge coloring algorithm which is* $(1.897 + o(1))$*-competitive w.h.p. on general* n*-node graphs with maximum degree* $\Delta = \omega(\log n)$ *under vertex arrivals.*

Proof. For a graph of maximum degree at most Δ, assigning x-value $1/\Delta$ to each edge yields a fractional matching. Applying Algorithm 1 to this fractional matching in a bipartite graph under vertex arrivals results in each edge being matched with probability $0.527/\Delta$, by Theorem 3.1. Therefore, by Lemma 2.2, there exists an online edge coloring algorithm whose competitive ratio is $(1/0.527 + o(1)) \approx 1.897 + o(1)$ w.h.p. on bipartite graphs of maximum degree $\Delta = \omega(\log n)$ under (interleaved) vertex arrivals. Finally, Lemma 2.1 together with union bound implies that the same competitive ratio (up to $o(1)$ terms) carries over to general graphs under vertex arrivals. ◀

▶ Remark 4.1. Our analysis extends to prove the slightly tighter result, whereby there exist constants $c_1, c_2 > 0$ and a $(2 - c_1)$-competitive online algorithm for n-node graphs of maximum degree at least $c_2 \cdot \log n$ under vertex arrivals. (See Remark 1.3.) For brevity's sake, we omit the details.

5 The Karloff-Shmoys Approach: Online

Here we substantiate our earlier assertion that α-competitive online edge coloring on high-degree graphs is equivalent (up to $o(1)$ terms) to the same task on high-degree *bipartite* graphs. That is, we outline the proof of Lemma 2.1, restated below for ease of reference.

▶ **Lemma 2.1** (Implied by [25]). *Given an online edge coloring algorithm which is* α*-competitive w.h.p. on bipartite graphs of maximum degree* $\Delta = \omega(\log n)$ *under interleaved vertex arrivals, there exists an online edge coloring algorithm which is* $(\alpha + o(1))$*-competitive w.h.p. on* general *graphs of maximum degree* $\Delta = \omega(\log n)$ *under vertex arrivals.*

Proof. The general graph edge coloring algorithm relies on the following subroutine for sampling balanced random subgraphs in subgraphs of maximum degree $\Delta' \geq 18 \cdot \sqrt{\Delta \log n}$. (Note that $\Delta \geq 18\sqrt{\Delta \log n}$, by the hypothesis, whereby $\Delta = \omega(\log n)$.) Assign each vertex to a set $V_i \subseteq V$ with $i = 1, 2$ chosen uniformly at random. For any vertex $v \in V$, let $d(v)$ denotes the degree of v in G, and D_v denotes the (random) degree of v in the random bipartite subgraph $H = H(V_1, V_2, E \cap (V_1 \times V_2))$. Then, we have that $\mathbb{E}[D_v] = d(v)/2 \leq \Delta'/2$. By Chernoff's Bound (Proposition 2.8), since D_v is the sum of independent Bernoulli(1/2) variables, we have that, for $\epsilon = \sqrt[4]{\log n/\Delta} = o(1)$,

$$\Pr[D_v \geq (\Delta'/2) \cdot (1+\epsilon)] \leq \exp\left(\frac{-(\Delta'/2) \cdot \epsilon^2}{3}\right) \leq \frac{1}{n^3}, \tag{10}$$

using $\Delta' \geq 18 \cdot \sqrt{\Delta \cdot \log n}$, and consequently $\Delta \cdot \epsilon^2 \geq 18 \log n$. The same high-probability bound holds for $d(v) - D_v$, which is identically distributed to D_v.

To achieve an online edge coloring algorithm for G from the above, we apply the α-competitive edge coloring algorithm to the random bipartite H, and recursively apply the same approach to the random subgraph induced by the edges outside of H, namely $G \setminus H = G[E \setminus (V_1 \times V_2)]$, until H is guaranteed to have degree at most $18 \cdot \sqrt{\Delta \cdot \log n}$ w.h.p. We note that this approach can be applied online, by assigning to each vertex v on arrival a side of each of the recursive random bipartitions. Moreover, the colors of each recursive level number ℓ can be associated with a contiguous set of integers of cardinality $\alpha \cdot \Delta \cdot ((1+\epsilon)/2)^\ell$, which is the high probability upper bound on the number of colors used in this recursive call. Repeating the above recursively for $t := \log_{2/(1+\epsilon)}(18\sqrt{\Delta/\cdot \log n}) \leq \log n$ levels results in a random uncolored subgraph of maximum degree at most $18\sqrt{\Delta \cdot \log n} = o(\Delta)$ w.h.p., which we color greedily.

Taking union bound over the $O(n^2)$ bad events (some vertex degree D_v exceeding $\Delta' \cdot ((1+\epsilon)/2)$ in a random bipartite subgraph or its complement in a subgraph whose maximum degree is $\Delta' \geq 18\sqrt{\Delta \cdot \log n}$, or any of the bipartite edge coloring algorithms failing to be α competitive on the subgraph it is applied to), we have that w.h.p., the number of colors C used is, as desired, at most

$$\begin{aligned} C &\leq \alpha \cdot \Delta \cdot \frac{1+\epsilon}{2} + \alpha \cdot \Delta \cdot \left(\frac{1+\epsilon}{2}\right)^2 + \cdots + \alpha \cdot \Delta \cdot \left(\frac{1+\epsilon}{2}\right)^t + 36 \cdot \sqrt{\Delta \cdot \log n} \\ &\leq \alpha \cdot \sum_{i \geq 1} \Delta \cdot \left(\frac{1+\epsilon}{2}\right)^i + 36 \cdot \sqrt{\Delta \cdot \log n} \\ &= \alpha \cdot \Delta \cdot \frac{1+\epsilon}{1-\epsilon} + o(\Delta) \\ &= (\alpha + o(1)) \cdot \Delta. \end{aligned}$$

◀

▶ Remark 5.1. As stated in the introduction, we note that the above reduction from general to bipartite graphs results in bipartite graphs with *interleaved* vertex arrivals.

6 Edge Coloring from Random Matchings

In this section, we show how to reduce edge coloring in (bipartite) graphs under vertex arrivals to computing a random matching which matches each edge with probability $\Omega(1/\Delta)$.

▶ **Lemma 2.2** (Implied by [9]). *Let $\mathcal{A}$ be an online matching algorithm which on any (bipartite) graph of maximum degree $\Delta \leq \Delta'$ under vertex arrivals, matches each edge with probability at least $1/(\alpha\Delta')$. Then, there exists an online edge coloring algorithm $\mathcal{A}'$ which is $(\alpha + o(1))$-competitive w.h.p. for (bipartite) graphs of maximum degree $\Delta = \omega(\log n)$ under vertex arrivals.*

Proof. If $\alpha > 2$, then the claim follows trivially from the greedy algorithm's 2-competitiveness. We therefore assume $\alpha \leq 2$. We give a subroutine which decreases the uncolored degree of a subgraph of maximum degree $\Delta' \geq 48 \cdot \sqrt[4]{\Delta^3 \log n}$ at a rate of one per $\alpha + o(1)$ colors w.h.p. (Note that $\Delta \geq 48\sqrt[4]{\Delta^3 \log n}$, by the hypothesis, whereby $\Delta = \omega(\log n)$.)

Our subroutine is as follows. Let $L := 12\sqrt{\Delta \log n}$ and $\epsilon := \sqrt[4]{(\log n)/\Delta} (= o(1) \leq 1/2)$. We note that by our choice of L and ϵ and our lower bound on Δ', we have that

$$4L/\Delta' \leq 48\sqrt{\Delta \log n}/48\sqrt[4]{\Delta^3 \log n} = \sqrt[4]{(\log n)/\Delta} = \epsilon. \tag{11}$$

For $i = 1, \ldots, \lceil \alpha \cdot L \rceil$, we run Algorithm $\mathcal{A}$, which matches each edge with probability at least $(1/\alpha)/\Delta'$, and color all previously-uncolored matched edges in this run of $\mathcal{A}$ using a new (common) color. Fix a vertex v whose degree in the subgraph is at least $d(v) \geq \Delta' - \lceil \alpha \cdot L \rceil$ and let $X_1, \ldots, X_L$ be indicators of v having an edge colored during application $i = 1, \ldots, \lceil \alpha \cdot L \rceil$ of Algorithm $\mathcal{A}$. Since vertex v can have at most $\lceil \alpha \cdot L \rceil \leq 2 \cdot L$ edges colored during these L applications of Algorithm $\mathcal{A}$, we find that the number of uncolored edges of v at any point during this subroutine is at least $\Delta' - 2\lceil \alpha \cdot L \rceil \geq \Delta' - 4L$, independently of previous random choices. On the other hand, since each uncolored edge is matched (and hence colored) with probability at least $(1/\alpha)/\Delta'$, we have that for any history $\mathcal{H}$ of random choices in applications $1, 2, \ldots, i-1$ of $\mathcal{A}$, application i of $\mathcal{A}$ results in one of the (at least) $\Delta' - 4L$ uncolored edges of v being colored with probability at least

$$\Pr[X_i \mid \mathcal{H}] \geq (1/\alpha) \cdot (\Delta' - 4L)/\Delta' = (1/\alpha) \cdot (1 - 4L/\Delta') \geq (1/\alpha) \cdot (1 - \epsilon), \tag{12}$$

where the last inequality relied on Equation (11). Combining Equation (12) with standard coupling arguments (Proposition 2.9) together with a Chernoff Bound (Proposition 2.8), we find that the number of colored edges of v, denoted by $X := \sum_i X_i$ satisfies

$$\Pr[X \leq L \cdot (1-\epsilon)^2] \leq \exp\left(\frac{-L \cdot (1-\epsilon) \cdot \epsilon^2}{2}\right) \leq \exp\left(\frac{-L \cdot \epsilon^2}{4}\right) = \frac{1}{n^3},$$

where the second inequality follows from $\epsilon \leq 1/2$ and the equality follows from choice of L and ϵ. Union bounding over the n vertices, we obtain the following high probability bound on the maximum degree of the uncolored subgraph H after the $\lceil \alpha \cdot L \rceil$ applications of $\mathcal{A}$:

$$\Pr[\Delta(H) \geq \Delta' - L \cdot (1-\epsilon)^2] \leq \frac{1}{n^2}. \tag{13}$$

We now describe how to make use of this subroutine. For $r = 1, \ldots, \Delta/L$ *phases*, let $\Delta_i := \Delta - (i-1) \cdot L \cdot (1-\epsilon)^2$. If $\Delta_i < 48\sqrt[4]{\Delta^3 \log n}$, apply the greedy coloring. Otherwise, apply the above subroutine with $\Delta' = \Delta_i$. A simple inductive argument together with union bound, relying on Equation (13), shows that for $i = 1, 2, \ldots, \Delta/L (\leq n)$, the uncolored subgraph after the first $i-1$ phases has maximum degree at most $\Delta' \leq \Delta_i$ w.h.p., or alternatively it has maximum degree at most $\Delta' \leq 48 \cdot \sqrt[4]{\Delta^3 \log n} = o(\Delta)$. Moreover, each of these Δ/L phases requires at most $\lceil \alpha \cdot L \rceil \leq \alpha \cdot L + 1$ colors, by definition, and therefore these Δ/L phases require at most $\alpha \cdot \Delta + \Delta/L = (\alpha + o(1)) \cdot \Delta$ colors in total. Finally, after these phases we are guaranteed that the maximum degree of the uncolored subgraph is at most $\min\{48 \cdot \sqrt[4]{\Delta^3 \log n}, \Delta - (\Delta/L) \cdot L \cdot (1-\epsilon)^2\} = o(\Delta)$. Applying the greedy algorithm to this uncolored subgraph after the Δ/L phases thus requires a further $2 \cdot o(\Delta) = o(\Delta)$ colors. This results in a proper edge coloring using $(\alpha + o(1)) \cdot \Delta$ colors w.h.p.

Finally, we note that the above algorithm can be implemented online under vertex arrivals, since $\mathcal{A}$ works under vertex arrivals. In particular, when a vertex arrives, we perform the next steps of the different copies of Algorithm $\mathcal{A}$ (with the different settings of Δ_i) on the

uncolored subgraphs obtained from each phase, simulating the arrival of a vertex in each such uncolored subgraph. Combined with the above, this yields the desired result: an edge coloring algorithm which is $(\alpha + o(1))$-competitive on general n-node graphs of maximum degree $\Delta = \omega(\log n)$ under vertex arrivals. ◀

▶ Remark 6.1. Lemma 2.2 naturally extends to edge arrivals. Unfortunately, no algorithm matching each edge with probability $(1/\alpha)/\Delta$ subject to edge arrivals is currently known for any constant $\alpha < 2$.

▶ Remark 6.2. The approach of Lemma 2.2 only requires matching algorithms which match each edge with probability $(1/\alpha)/\Delta$ for *subgraphs* of the input graph. Consequently, improved matching algorithms, with smaller $\alpha \geq 1$, for any downward-closed family of graphs $\mathcal{F}$ imply a similar improved $(\alpha + o(1))$-competitive edge coloring algorithm for the same family.

7 Conclusion

In this work we resolve the longstanding conjecture of Bar-Noy, Motwani and Naor, namely Conjecture 1.1. That is, we show that, while for bounded-degree graphs the greedy algorithm's competitive ratio of 2 is optimal among online algorithms, for high-degree graphs this is not the case.

Some natural questions remain. What is the best achievable competitive ratio? Is a ratio of $1 + o(1)$ possible, as for one-sided arrivals in bipartite graphs and random-order edge arrivals [5, 9]? Can the same be achieved under adversarial *edge* arrivals? Bar-Noy et al. [4] suggested a candidate algorithm for this latter model, but its analysis seems challenging. Finally, does the online rounding Algorithm 1 have more applications beyond edge coloring?

Abstract

Matrix scaling and matrix balancing are two basic linear-algebraic problems with a wide variety of applications, such as approximating the permanent, and pre-conditioning linear systems to make them more numerically stable. We study the power and limitations of quantum algorithms for these problems. We provide quantum implementations of two classical (in both senses of the word) methods: Sinkhorn's algorithm for matrix scaling and Osborne's algorithm for matrix balancing. Using amplitude estimation as our main tool, our quantum implementations both run in time $\widetilde{O}(\sqrt{mn}/\varepsilon^4)$ for scaling or balancing an $n \times n$ matrix (given by an oracle) with m non-zero entries to within ℓ_1-error ε. Their classical analogs use time $\widetilde{O}(m/\varepsilon^2)$, and every classical algorithm for scaling or balancing with small constant ε requires $\Omega(m)$ queries to the entries of the input matrix. We thus achieve a polynomial speed-up in terms of n, at the expense of a worse polynomial dependence on the obtained ℓ_1-error ε. Even for constant ε these problems are already non-trivial (and relevant in applications). Along the way, we extend the classical analysis of Sinkhorn's and Osborne's algorithm to allow for errors in the computation of marginals. We also adapt an improved analysis of Sinkhorn's algorithm for entrywise-positive matrices to the ℓ_1-setting, obtaining an $\widetilde{O}(n^{1.5}/\varepsilon^3)$-time quantum algorithm for ε-ℓ_1-scaling. We also prove a lower bound, showing our quantum algorithm for matrix scaling is essentially optimal for constant ε: every quantum algorithm for matrix scaling that achieves a constant ℓ_1-error w.r.t. uniform marginals needs $\Omega(\sqrt{mn})$ queries.

1 Introduction

1.1 Matrix scaling and matrix balancing

Matrix scaling is a basic linear-algebraic problem with many applications. A *scaling* of an $n \times n$ matrix $\mathbf{A}$ with non-negative entries is a matrix $\mathbf{B} = \mathbf{XAY}$ where $\mathbf{X}$ and $\mathbf{Y}$ are positive diagonal matrices (everything straightforwardly extends to non-square $\mathbf{A}$). In other words, we multiply the i-th row with X_{ii} and the j-th column with Y_{jj}. We say $\mathbf{A}$ is *exactly scalable* to marginals $\mathbf{r} \in \mathbb{R}^n_+$ and $\mathbf{c} \in \mathbb{R}^n_+$ if there exist $\mathbf{X}$ and $\mathbf{Y}$ such that the vector $\mathbf{r}(\mathbf{B}) = (\sum_{j=1}^n B_{ij})_{i\in[n]}$ of row sums of the scaled matrix $\mathbf{B}$ equals $\mathbf{r}$, and its vector $\mathbf{c}(\mathbf{B})$ of column sums equals $\mathbf{c}$. One typical example would be if $\mathbf{r}$ and $\mathbf{c}$ are the all-1 vectors, which means we want $\mathbf{B}$ to be doubly stochastic: the rows and columns of $\mathbf{B}$ would be probability distributions. In many cases it suffices to find *approximate* scalings. Different applications use different notions of approximation. We could for instance require $\mathbf{r}(\mathbf{B})$ to be ε-close to $\mathbf{r}$ in ℓ_1- or ℓ_2-norm, or in relative entropy (Kullback-Leibler divergence), for some parameter ε of our choice, and similarly require $\mathbf{c}(\mathbf{B})$ to be ε-close to $\mathbf{c}$.

A related problem is *matrix balancing*. Here we do not prescribe desired marginals, but the goal is to find a diagonal $\mathbf{X}$ such that the row and column marginals of $\mathbf{B} = \mathbf{XAX^{-1}}$ are close *to each other*. Again, different notions of closeness $\mathbf{r}(\mathbf{B}) \approx \mathbf{c}(\mathbf{B})$ are possible.

An important application, used in theory as well as in practical linear-algebra software (e.g. LAPACK [6] and MATLAB [40]), is in improving the numerical stability of linear-system solving. Suppose we are given matrix $\mathbf{A}$ and vector $\mathbf{b}$, and we want to find a solution to the linear system $\mathbf{Av} = \mathbf{b}$. Note that $\mathbf{v}$ is a solution iff $\mathbf{Bv'} = \mathbf{b'}$ for $\mathbf{v'} = \mathbf{Xv}$ and $\mathbf{b'} = \mathbf{Xb}$. An appropriately balanced matrix $\mathbf{B}$ will typically be more numerically stable than the original $\mathbf{A}$, so solving the linear system $\mathbf{Bv'} = \mathbf{b'}$ and then computing $\mathbf{v} = \mathbf{X}^{-1}\mathbf{v'}$, is often a better way to solve the linear system $\mathbf{Av} = \mathbf{b}$ than directly computing $\mathbf{A}^{-1}\mathbf{b}$.

Matrix scaling and balancing have surprisingly many and wide-ranging applications. Matrix scaling was introduced by Kruithof for Dutch telephone traffic computation [37], and has also been used in other areas of economics [50]. In theoretical computer science it has been used for instance to approximate the permanent of a given matrix [38], as a tool to get lower bounds on unbounded-error communication complexity [25], and for approximating optimal transport distances [2]. In mathematics, it has been used as a common tool in practical linear algebra computations [39, 12, 46, 42], but also in statistics [49], optimization [47], and for strengthening the Sylvester-Gallai theorem [11]. Matrix balancing has a similarly wide variety of applications, including pre-conditioning to make practical matrix computations more stable (as mentioned above), and approximating the min-mean-cycle in a weighted graph [3]. Many more applications of matrix scaling and balancing are mentioned in [38, 31, 28]. Related scaling problems have applications to algorithmic non-commutative algebra [27, 17], functional analysis [26], and quantum information [29, 18, 16].

1.2 Known (classical) algorithms

Given the importance of good matrix scalings and balancings, how efficiently can we actually find them? For concreteness, let us first focus on scaling. Note that left-multiplying $\mathbf{A}$ with a diagonal matrix $\mathbf{X}$ corresponds to multiplying the i-th row of $\mathbf{A}$ with X_{ii}. Hence it is very easy to get the desired row sums: just compute all row sums $r_i(\mathbf{A})$ of $\mathbf{A}$ and define $\mathbf{X}$ by $X_{ii} = r_i/r_i(\mathbf{A})$, then $\mathbf{XA}$ has exactly the right row sums. Subsequently, it is easy to get the desired column sums: just right-multiply the current matrix $\mathbf{XA}$ with diagonal matrix $\mathbf{Y}$ where $Y_{jj} = c_j/c_j(\mathbf{XA})$, then $\mathbf{XAY}$ will have the right column sums.

The problem with this approach, of course, is that the second step is likely to undo the good work of the first step, changing the row sums away from the desired values; it is not at all obvious how to *simultaneously* get the row sums and column sums right. Nevertheless, the approach of alternating row-normalizations with column-normalizations turns out to work. This alternating algorithm is known as *Sinkhorn's algorithm* [49], and has actually been (re)discovered independently in several different contexts.

For matrix balancing there is a similar method called *Osborne's algorithm* [43, 45]. In each iteration this chooses a row index i and defines X_{ii} such that the i-th row sum and the i-th column sum become equal. Again, because each iteration can undo the good work of earlier iterations, convergence to a balancing of $\mathbf{A}$ is not at all obvious. Remarkably, even though Osborne's algorithm was proposed more than six decades ago and is widely used in linear algebra software, an explicit convergence-rate bound was only proved recently [48, 44]!

At the same time there have been other, more sophisticated algorithmic approaches for scaling and balancing. Just to mention one: we can parametrize $\mathbf{X} = \mathrm{diag}(e^{\mathbf{x}})$ and $\mathbf{Y} = \mathrm{diag}(e^{\mathbf{y}})$ by vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ and consider the following convex potential function:

$$f(\mathbf{x}, \mathbf{y}) = \sum_{i,j=1}^{n} A_{ij} e^{x_i + y_j} - \sum_{i=1}^{n} r_i x_i - \sum_{j=1}^{n} c_j y_j.$$

Note that the partial derivative of this f w.r.t. the variable x_i is $\sum_{j=1}^{n} A_{ij} e^{x_i+y_j} - r_i = r_i(\mathbf{XAY}) - r_i$, and the partial derivative w.r.t. y_j is $c_j(\mathbf{XAY}) - c_j$. A minimizer $\mathbf{x}, \mathbf{y}$ of f will have the property that all these $2n$ partial derivatives are equal to 0, which means $\mathbf{XAY}$ *is exactly scaled!* Accordingly, (approximate) scalings can be obtained by finding (approximate) minimizers using methods from convex optimization. In fact, Sinkhorn's original algorithm can be interpreted as block coordinate descent on this f, and Osborne's algorithm can similarly be derived by slightly modifying f. More advanced methods from convex optimization have also been applied, such as ellipsoid methods [36, 33, 41], box-constrained Newton methods [1, 21] and interior-point methods [21, 19].

Historically, research on matrix scaling and matrix balancing (and generalizations such as operator scaling) has focused on finding ε-ℓ_2-scalings. More recently also algorithms for finding ε-ℓ_1-scalings have been extensively studied, due to their close connection with permanents and finding perfect matchings in bipartite graphs [38, 20], and because the ℓ_1-distance is an important error measure for statistical problems such as computing the optimal transport distance between distributions [22, 2], even already for constant ε. By the Cauchy-Schwarz inequality, an $(\varepsilon/\sqrt{n})$-ℓ_2-scaling for $\mathbf{A}$ is also an ε-ℓ_1-scaling, but often more direct methods work better for finding an ε-ℓ_1-scaling.

Below in Table 1 we tabulate the best known algorithms for finding ε-scalings in ℓ_1-norm for entrywise-positive matrices and general non-negative matrices. We make the standard assumptions that every entry of the target marginals $\mathbf{r}, \mathbf{c}$ is non-zero, and that $\mathbf{A}$ is *asymptotically scalable*: for every $\varepsilon > 0$, there exist $\mathbf{X}$ and $\mathbf{Y}$ such that

$$\|\mathbf{r}(\mathbf{B}) - \mathbf{r}\|_1 \leq \varepsilon \text{ and } \|\mathbf{c}(\mathbf{B}) - \mathbf{c}\|_1 \leq \varepsilon,$$

where $\mathbf{B} = \mathbf{XAY}$ (this implies that the matrix has at least one non-zero entry in every row and column). A sufficient condition for this is that the matrix is entrywise-positive. To state the complexity results, let m be the number of non-zero entries in $\mathbf{A}$ (note that $m \geq n$), assume $\sum_{i,j=1}^{n} A_{ij} = 1$, that its non-zero entries lie in $[\mu, 1]$, and $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$ (so uniform marginal is $\mathbf{1}/n$). We will assume $\varepsilon \in (0, 1)$. The input numbers to the algorithm are all assumed to be rational, with bit size bounded by $\mathrm{polylog}(n)$, unless specified otherwise.[1]

[1] The complexity of our algorithms depends polylogarithmically on the magnitude of the entries; the assumption on the bit size of the entries is made to simplify the presentation.

Note that the table contains both first-order and second-order methods; the former just use the gradient of the potential (or a related potential), whereas the latter also use its Hessian. The second-order methods typically have a polylogarithmic dependence on the inverse of the desired precision ε, whereas the first-order methods have inverse polynomial dependence on ε. For entrywise-positive matrices, second-order methods theoretically outperform the *classical* first-order methods in any parameter regime. However, they depend on non-trivial results for graph sparsification and Laplacian system solving which are relatively complicated to implement, in contrast to the eminently practical (first-order) Sinkhorn and Osborne.

For matrix balancing, Osborne's algorithm has very recently been shown to produce an ε-ℓ_1-balancing in time $\widetilde{O}(m/\varepsilon^2)$ when in each iteration the update is chosen randomly [4]. Algorithms based on box-constrained Newton methods and interior-point methods can find ε-balancings in time $\widetilde{O}(m \log \kappa)$ and $\widetilde{O}(m^{1.5})$, respectively, where κ denotes the ratio between the largest and the smallest entries of the optimal balancing.

Table 1 State-of-the-art time complexity of first- and second-order methods for finding an ε-ℓ_1-scaling, both to uniform marginals and to arbitrary marginals. The boldface lines are from this paper, and the only quantum algorithms for scaling we are aware of. h is the smallest integer such that $h\mathbf{r}$, $h\mathbf{c}$ are integer vectors; m upper bounds the number of non-zero entries of $\mathbf{A}$; κ is the ratio between largest and smallest entries of the optimal scalings $\mathbf{X}$ and $\mathbf{Y}$, which can be exponential in n. Many references use a different error model (e.g., ℓ_2 or Kullback-Leibler), which we convert to guarantees in ℓ_1-norm for comparison. $\widetilde{O}$-notation hides polylogarithmic factors in n, $1/\varepsilon$, $1/\mu$.

	$(\mathbf{1}/n, \mathbf{1}/n)$	$(\mathbf{r}, \mathbf{c})$	References and remarks

1.3 First contribution: quantum algorithms for ℓ_1-scaling and balancing

Because a classical scaling algorithm has to look at each non-zero matrix entry (at least with large probability), it is clear that $\Omega(m)$ is a classical lower bound. This is $\Omega(n^2)$ in the case of a dense or even entrywise-positive matrix $\mathbf{A}$. As can be seen from Table 1, the best classical algorithms also achieve this m lower bound up to logarithmic factors, with various dependencies on ε. The same is true for balancing: $\Omega(m)$ queries are necessary, and this is achievable in different ways, with different dependencies on ε and other parameters.

Our first contribution is to give (in Section 3) quantum algorithms for scaling and balancing that beat the best-possible classical algorithms, at least for relatively large $\varepsilon \in (0, 1)$:

[2] Their proofs work only for input matrices that are exactly scalable. However, with our potential gap bound we can generalize their analysis to work for arbitrary asymptotically-scalable matrices.

Scaling: We give a quantum algorithm that (with probability $\geq 2/3$) finds an ε-ℓ_1-scaling for an asymptotically-scalable $n \times n$ matrix $\mathbf{A}$ with m non-zero entries (given by an oracle) to desired positive marginals $\mathbf{r}$ and $\mathbf{c}$ in time $\widetilde{O}(\sqrt{mn}/\varepsilon^4)$. When $\mathbf{A}$ is entrywise positive (so $m = n^2$), the upper bound can be improved to $\widetilde{O}(n^{1.5}/\varepsilon^3)$.

Balancing: We give a quantum algorithm that (with probability $\geq 2/3$) finds an ε-ℓ_1-balancing for an asymptotically-balanceable $n \times n$ matrix $\mathbf{A}$ with m non-zero entries (given by an oracle) in time $\widetilde{O}(\sqrt{mn}/\varepsilon^4)$.

Our scaling algorithms in fact achieve closeness measured in terms of the relative entropy, and then use Pinsker's inequality ($\|\mathbf{p}-\mathbf{q}\|_1^2 = O(D(\mathbf{p}||\mathbf{q}))$) to convert this to an upper bound on the ℓ_1-error. Our algorithms achieve a *sublinear* dependence on the input size m.

Note that compared to the classical algorithms we have polynomially better dependence on n and m, at the expense of a worse dependence on ε. There have recently been a number of new quantum algorithms with a similar tradeoff: they are better than classical in terms of the main size parameter but worse in terms of the precision parameter. Examples are the quantum algorithms for solving linear and semidefinite programs [14, 8, 13, 7] and for boosting of weak learning algorithms [10, 30, 32].

Conceptually our algorithms are quite simple: we implement the Sinkhorn and Osborne algorithms but replace the exact computation of each row and column sum by *quantum amplitude estimation*; this allows us to approximate the sum of n numbers up to some small multiplicative error δ (with high probability) at the expense of roughly $\sqrt{n}/\delta$ queries to those numbers, and a similar number of other operations.

Our analysis is based on a potential argument (for Sinkhorn we use the above-mentioned potential f). The error δ causes us to make less progress in each iteration compared to an "exact" version of Sinkhorn or Osborne. If δ is too large we may even make backwards progress, while if δ is very small there is no quantum speed-up! We show there is a choice of δ for which the negative contribution due to the approximation errors is of the same order as the progress in the "exact" version, and that choice results in a speed-up. We should caution, however, that it is quite complicated to actually implement this idea precisely and to keep track of and control the various approximation errors and error probabilities induced by the quantum estimation algorithms, as well as by the fact that we cannot represent the numbers involved with infinite precision (this issue of precision is sometimes swept under the rug in classical research on scaling algorithms). Finally, we note that due to the error δ our potential need not decrease monotonically. The standard analysis of Sinkhorn still applies if we can *test* whether the current scaling is an ε-scaling after each full Sinkhorn iteration. We show how to do so efficiently in the quantum setting. However, in Osborne's algorithm one updates only a single (random) row/column per iteration, and the quantum cost of our testing procedure is higher than the cost of updating (classically, this problem is overcome by simply keeping track of the row and column marginals). To circumvent the need for testing every iteration, we give a novel analysis of Osborne's algorithm (and of a randomized version of Sinkhorn) showing uniformly random iterates provide an ε-balancing with high probability.

1.4 Second contribution: quantum lower bound for scaling

A natural question would be whether our upper bounds for the time complexity of matrix scaling and balancing can be improved further. Since the output has length roughly n, there is an obvious lower bound of n even for quantum algorithms. An $\widetilde{O}(n)$ quantum algorithm would, however, still be an improvement over our algorithms, and it would be a quadratic

speed-up over the best classical algorithm. In Section 4 we dash this hope for matrix scaling by showing that our algorithm is essentially optimal for constant ε, even for the special case of $\mathbf{A}$ that is exactly scalable to uniform marginals:

> There exists a constant $\varepsilon > 0$ such that every quantum algorithm that (with probability $\geq 2/3$) finds an ε-ℓ_1-scaling for a given $n \times n$ matrix $\mathbf{A}$ that is exactly scalable to uniform and has m potentially non-zero entries, has to make $\Omega(\sqrt{mn})$ queries to $\mathbf{A}$.

Our proof constructs instances $\mathbf{A}$ that hide permutations, shows how approximate scalings of $\mathbf{A}$ give us information about the hidden permutation, and then uses the adversary method [5] to lower bound the number of quantum queries to the matrix needed to find that information. In particular, we show that for a permutation $\sigma \in S_n$, it takes $\Omega(n\sqrt{n})$ queries to the entries of the associated permutation matrix to learn $\sigma(i) \bmod 2$ for each $i \in [n]$.

2 Preliminaries

2.1 Matrix scaling and balancing

Throughout we use $\mathbf{r}, \mathbf{c} \in \mathbb{R}^n$ as the desired row and column marginals. Unambiguously, we also use $\mathbf{r}\colon \mathbb{R}^{n\times n} \to \mathbb{R}^n$ (resp. $\mathbf{c}\colon \mathbb{R}^{n\times n} \to \mathbb{R}^n$) as the function that sends an $n \times n$-matrix to its row (resp. column) marginal: $\mathbf{r}(\mathbf{A})$ (resp. $\mathbf{c}(\mathbf{A})$) is the vector whose i-th entry equals $r_i(\mathbf{A}) = \sum_{j=1}^n A_{ij}$ (resp. $c_i(\mathbf{A}) = \sum_{j=1}^n A_{ji}$). We use $\mathbf{A}(\mathbf{x}, \mathbf{y}) = (A_{ij}e^{x_i+y_j})_{i,j\in[n]}$ to denote the rescaled matrix $\mathbf{A}$ with scalings given by $e^{\mathbf{x}}$ and $e^{\mathbf{y}}$. We say a non-negative matrix $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ is *exactly scalable* to $(\mathbf{r}, \mathbf{c}) \in \mathbb{R}_+^n \times \mathbb{R}_+^n$, if there exist $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ such that $\mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y})) = \mathbf{r}$ and $\mathbf{c}(\mathbf{A}(\mathbf{x}, \mathbf{y})) = \mathbf{c}$. For an $\varepsilon > 0$, we say $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ is ε-ℓ_1-*scalable* to $(\mathbf{r}, \mathbf{c}) \in \mathbb{R}_+^n \times \mathbb{R}_+^n$, if there exist $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ such that $\|\mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y})) - \mathbf{r}\|_1 \leq \varepsilon$ and $\|\mathbf{c}(\mathbf{A}(\mathbf{x}, \mathbf{y})) - \mathbf{c}\|_1 \leq \varepsilon$. We say $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ is *asymptotically scalable* to $(\mathbf{r}, \mathbf{c}) \in \mathbb{R}_+^n \times \mathbb{R}_+^n$ if it is ε-ℓ_1-scalable to $(\mathbf{r}, \mathbf{c})$ for every $\varepsilon > 0$. In the matrix-balancing setting we require $\mathbf{y} = -\mathbf{x}$, and the marginals are compared to each other. We abbreviate $\mathbf{A}(\mathbf{x}) = \mathbf{A}(\mathbf{x}, -\mathbf{x})$. We say a non-negative matrix $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ is *exactly balanceable*, if there exists a vector $\mathbf{x} \in \mathbb{R}^n$ such that $\mathbf{r}(\mathbf{A}(\mathbf{x})) = \mathbf{c}(\mathbf{A}(\mathbf{x}))$. For an $\varepsilon > 0$, we say $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ is ε-ℓ_1-*balanceable*, if there exists an $\mathbf{x} \in \mathbb{R}^n$ such that $\frac{\|\mathbf{r}(\mathbf{A}(\mathbf{x})) - \mathbf{c}(\mathbf{A}(\mathbf{x}))\|_1}{\|\mathbf{A}(\mathbf{x})\|_1} \leq \varepsilon$. We say $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ is *asymptotically balanceable* if it is ε-ℓ_1-balanceable for every $\varepsilon > 0$. The associated optimization problems are as follows.

▶ **Problem 1** (ε-ℓ_1-scaling problem). *Given $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ and desired marginals $\mathbf{r}, \mathbf{c} \in \mathbb{R}_+^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$, find $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ s.t. $\|\mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y})) - \mathbf{r}\|_1 \leq \varepsilon$ and $\|\mathbf{c}(\mathbf{A}(\mathbf{x}, \mathbf{y})) - \mathbf{c}\|_1 \leq \varepsilon$.*

▶ **Problem 2** (ε-ℓ_1-balancing problem). *Given $\mathbf{A} \in \mathbb{R}_+^{n\times n}$, find $\mathbf{x} \in \mathbb{R}^n$ s.t. $\|\mathbf{r}(\mathbf{A}(\mathbf{x})) - \mathbf{c}(\mathbf{A}(\mathbf{x}))\|_1 / \|\mathbf{A}(\mathbf{x})\|_1 \leq \varepsilon$.*

For matrix scaling, our algorithm is most naturally analyzed with the error measured by the relative entropy, which can be converted to give an upper bound on ℓ_1-distance using (a generalized version of) Pinsker's inequality. We therefore also consider the following problem:

▶ **Problem 3** (ε-relative-entropy-scaling problem). *Given $\mathbf{A} \in \mathbb{R}_+^{n\times n}$ and desired marginals $\mathbf{r}, \mathbf{c} \in \mathbb{R}_+^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$, find $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ such that $D(\mathbf{r}\|\mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y}))) \leq \varepsilon$ and $D(\mathbf{c}\|\mathbf{c}(\mathbf{A}(\mathbf{x}, \mathbf{y}))) \leq \varepsilon$.*

2.2 Computational model

We assume *sparse black-box access* to the elements of $\mathbf{A}$ via lists of the potentially non-zero entries for each row and each column. A quantum algorithm can make such queries also in superposition. We also assume (classical) black-box access to the target marginals $\mathbf{r}, \mathbf{c}$. Our computational model is of a classical computer (say, a Random Access Machine for concreteness) that can invoke a quantum computer as a subroutine. The classical computer can write to a classical-write quantum-read memory ("QCRAM")[3], and send a description of a quantum circuit that consists of one- and two-qubit gates from some fixed discrete universal gate set (say, the H and T gates, Controlled-NOT, and 2-qubit controlled rotations over angles $2\pi/2^s$ for positive integers s; these controlled rotations are used in the circuit for the quantum Fourier transform (QFT), which we invoke later), queries to the input oracles, and queries to the QCRAM to the quantum computer. The quantum computer runs the circuit, measures the full final state in the computational basis, and returns the measurement outcome to the classical computer. See [9, Sec. 2] for details.

3 A Sinkhorn algorithm with approximate updates

We state and analyze Algorithm 1, a variant of the well-known Sinkhorn algorithm. Here we give an overview of its analysis, we refer to [9, Sec. 3] for the proofs. The algorithm's objective is to find scaling vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ such that the matrix $\mathbf{A}(\mathbf{x}, \mathbf{y}) = (A_{ij} e^{x_i + y_j})_{i,j \in [n]}$ has row and column marginals $\mathbf{r}$ and $\mathbf{c}$, respectively. Sinkhorn-type algorithms do so in the following iterative way. Starting from the rational matrix $\mathbf{A} \in [0,1]^{n \times n}$, find a vector $\mathbf{x}$ such that the row marginals of $(A_{ij} e^{x_i})_{i,j \in [n]}$ are $\mathbf{r}$, and then find a $\mathbf{y}$ such that the column marginals of $\mathbf{A}(\mathbf{x}, \mathbf{y})$ are $\mathbf{c}$. The second step may have changed the row marginals, so we repeat the procedure. We can view this as updating the coordinates of $\mathbf{x}$ and $\mathbf{y}$ one at a time, starting from the all-0 vectors. To update the row scaling vectors, we wish to find $\hat{\mathbf{x}} = \mathbf{x} + \mathbf{\Delta}$ such that $\mathbf{r}(\mathbf{A}(\hat{\mathbf{x}}, \mathbf{y})) = \mathbf{r}$. Expanding this equation yields $e^{\Delta_\ell} \cdot r_\ell(\mathbf{A}(\mathbf{x}, \mathbf{y})) = r_\ell$, for $\ell \in [n]$. Every row and column contains at least one non-zero entry, so this has a unique solution:

$$\hat{x}_\ell = x_\ell + \Delta_\ell = x_\ell + \ln\left(\frac{r_\ell}{r_\ell(\mathbf{A}(\mathbf{x}, \mathbf{y}))}\right) = \ln\left(\frac{r_\ell}{\sum_{j=1}^n A_{\ell j} e^{y_j}}\right). \tag{3.1}$$

Similar formulas can be derived for the column-updates. We use the term "one Sinkhorn iteration" to refer to the process of updating all n row scaling vectors, or updating all n column scaling vectors. We state the Sinkhorn algorithm in terms of two subroutines, `ApproxScalingFactor` and `TestScaling`. For both subroutines we provide both classical and quantum implementations in [9, Sec. 4]. A key ingredient of both subroutines is a procedure that computes the logarithm of a sum of exponentials, see Section 3.2 for a high-level explanation of the quantum subroutine. For the analysis of Algorithm 1, we only use the guarantees of the subroutines as stated, and do not refer to their actual implementation.

We study a version of Sinkhorn's algorithm where, instead of computing row and column marginals in each iteration exactly, we use a *multiplicative* approximation of the marginals to compute δ-additive approximations of Equation (3.1) and similar for column-updates. In the classical literature, δ can be chosen to be very small, since the cost per iteration scales as $\mathrm{polylog}(1/\delta)$, and hence that error is essentially a minor technical detail. In the quantum setting, we obtain better dependence in terms of n at the cost of allowing a $\mathrm{poly}(1/\delta)$-dependence, so the required precision δ merits detailed attention in the analysis.

[3] Note that we do not require a full QRAM that can hold qubits as well. We believe QCRAM is a natural assumption since it simply amounts to classical RAM that can be read in superposition.

Algorithm 1 Full Sinkhorn with finite precision and failure probability.

Input: Oracle access to $\mathbf{A} \in [0,1]^{n\times n}$ with $\|\mathbf{A}\|_1 \leq 1$ and non-zero entries at least $\mu > 0$, target marginals $\mathbf{r}, \mathbf{c} \in (0,1]^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$, iteration count $T \in \mathbb{N}$, bit counts $b_1, b_2 \in \mathbb{N}$, estimation precision $0 < \delta < 1$, test precision $0 < \delta' < 1$ and subroutine failure probability $\eta \in [0,1]$

Output: Vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ with entries encoded in (b_1, b_2) fixed-point format

Guarantee: For $\varepsilon \in (0,1]$, with parameters chosen as in Proposition 13, $(\mathbf{x}, \mathbf{y})$ form an ε-relative-entropy-scaling of $\mathbf{A}$ to $(\mathbf{r}, \mathbf{c})$ with probability $\geq 2/3$

$\mathbf{x}^{(0)}, \mathbf{y}^{(0)} \leftarrow \mathbf{0}$; `// entries in` (b_1, b_2) `fixed-point format`
for $t \leftarrow 1, 2, \ldots, T$ **do**
  if *t is odd* **then**
    for $\ell \leftarrow 1, 2, \ldots, n$ **do**
      $x_\ell^{(t)} \leftarrow$ `ApproxScalingFactor`$(\mathbf{A}_{\ell\bullet}, r_\ell, \mathbf{y}^{(t-1)}, \delta, b_1, b_2, \eta, \mu)$;
    end for
    $\mathbf{y}^{(t)} \leftarrow \mathbf{y}^{(t-1)}$;
  else if *t is even* **then**
    for $\ell \leftarrow 1, 2, \ldots, n$ **do**
      $y_\ell^{(t)} \leftarrow$ `ApproxScalingFactor`$(\mathbf{A}_{\bullet\ell}, c_\ell, \mathbf{x}^{(t-1)}, \delta, b_1, b_2, \eta, \mu)$;
    end for
    $\mathbf{x}^{(t)} \leftarrow \mathbf{x}^{(t-1)}$;
  end if
  if `TestScaling`$(\mathbf{A}, \mathbf{r}, \mathbf{c}, \mathbf{x}^{(t)}, \mathbf{y}^{(t)}, \delta', b_1, b_2, \eta, \mu)$ **then**
    return $(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})$;
  end if
end for
return $(\mathbf{x}^{(T)}, \mathbf{y}^{(T)})$;

The Sinkhorn algorithm thus has a number of tunable parameters (precision, error parameters, iteration count). We show how to choose them in such a way that the resulting quantum algorithm obtains an ε-relative-entropy-scaling in time $\widetilde{O}(\sqrt{mn}/\varepsilon^2)$.

▶ **Theorem 4.** *Let $\mathbf{A} \in [0,1]^{n\times n}$ be a matrix with $\|\mathbf{A}\|_1 \leq 1$ and m non-zero entries, each rational and at least $\mu > 0$, let $\mathbf{r}, \mathbf{c} \in (0,1]^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$, and let $\varepsilon \in (0,1]$. Assume $\mathbf{A}$ is asymptotically scalable to $(\mathbf{r}, \mathbf{c})$. Then there exists a quantum algorithm that, given sparse oracle access to $\mathbf{A}$, with probability $\geq 2/3$, computes $(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^n$ such that $\mathbf{A}(\mathbf{x}, \mathbf{y})$ is ε-relative-entropy-scaled to $(\mathbf{r}, \mathbf{c})$, for a total time complexity of $\widetilde{O}(\sqrt{mn}/\varepsilon^2)$.*

A generalization of Pinsker's inequality (cf. [9, Lem. 2.1]) implies the following corollary.

▶ **Corollary 5.** *Let $\mathbf{A}, \mathbf{r}, \mathbf{c}$ and ε be as in Theorem 4. Then there exists a quantum algorithm that with probability $\geq 2/3$ computes $(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^n$ such that $\mathbf{A}(\mathbf{x}, \mathbf{y})$ is ε-ℓ_1-scaled to $(\mathbf{r}, \mathbf{c})$, for a total time complexity of $\widetilde{O}(\sqrt{mn}/\varepsilon^4)$.*

In [9, Thm. C.6], we show that if the matrix $\mathbf{A}$ is entrywise-positive, then the number of iterations to obtain an ε-relative-entropy-scaling can be reduced to roughly $1/\sqrt{\varepsilon}$ rather than roughly $1/\varepsilon$, leading to the following theorem.

Procedure ApproxScalingFactor($\mathbf{a}, r, \mathbf{y}, \delta, b_1, b_2, \eta, \mu$).

Input: Oracle access to rational $\mathbf{a} \in [0,1]^n$, rational $r \in (0,1]$, oracle access to $\mathbf{y} \in \mathbb{R}^n$ encoded in (b_1, b_2) fixed-point format, desired precision $\delta \in (0,1]$, desired failure prob. $\eta \in [0,1]$, lower bound $\mu > 0$ on non-zero entries of $\mathbf{a}$

Output: A number x encoded in (b_1, b_2) fixed-point format

Guarantee: If $b_1 \geq \lceil \log_2(|\ln(r/\sum_{j=1}^n a_j e^{y_j})|) \rceil$ and $b_2 \geq \lceil \log_2(1/\delta) \rceil$, then with prob. $\geq 1-\eta$, x is a δ-additive approximation of $\ln(r/\sum_{j=1}^n a_j e^{y_j})$

Procedure TestScaling($\mathbf{A}, \mathbf{r}, \mathbf{c}, \mathbf{x}, \mathbf{y}, \delta, b_1, b_2, \eta, \mu$).

Input: Oracle access to rational $\mathbf{A} \in [0,1]^{n \times n}$ with $\|\mathbf{A}\|_1 \leq 1$, rational $\mathbf{r}, \mathbf{c} \in (0,1]^n$, oracle access to $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ encoded in (b_1, b_2) fixed-point format, test precision $\delta \in (0,1)$, desired failure probability $\eta \in [0,1]$, lower bound $\mu > 0$ on non-zero entries of $\mathbf{A}$

Output: A bit indicating whether $\mathbf{x}, \mathbf{y}$ forms a δ-relative-entropy-scaling of $\mathbf{A}$ to target marginals $\mathbf{r}, \mathbf{c}$.

Guarantee: If $b_1 \geq \log_2(|\ln(r_\ell/\sum_{j=1}^n A_{\ell j} e^{y_j})|)$ for all $\ell \in [n]$, and similarly for the columns, and furthermore $b_2 \geq \lceil \log_2(1/\delta) \rceil$, then with probability at least $1-\eta$: outputs **False** if $D(\mathbf{r} \| \mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y}))) \geq 2\delta$ or $D(\mathbf{c} \| \mathbf{c}(\mathbf{A}(\mathbf{x}, \mathbf{y}))) \geq 2\delta$, outputs **True** if both are at most δ

▶ **Theorem 6.** *Let $\mathbf{A} \in [\mu, 1]^{n \times n}$ be a matrix with $\|\mathbf{A}\|_1 \leq 1$, each entry rational and at least $\mu > 0$, let $\mathbf{r}, \mathbf{c} \in (0,1]^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$, and let $\varepsilon \in (0,1]$. Then there exists a quantum algorithm that, given sparse oracle access to $\mathbf{A}$, with probability $\geq 2/3$, computes $(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^n$ such that $\mathbf{A}(\mathbf{x}, \mathbf{y})$ is ε-relative-entropy-scaled to $(\mathbf{r}, \mathbf{c})$, at a total time complexity of $\widetilde{O}(n^{1.5}/\varepsilon^{1.5})$.*

The next corollary also follows from the generalization of Pinsker's inequality.

▶ **Corollary 7.** *Let $\mathbf{A}, \mathbf{r}, \mathbf{c}$ and ε be as in Theorem 6. Then there exists a quantum algorithm that with probability $\geq 2/3$ computes $(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^n$ such that $\mathbf{A}(\mathbf{x}, \mathbf{y})$ is ε-ℓ_1-scaled to $(\mathbf{r}, \mathbf{c})$, for a total time complexity of $\widetilde{O}(\sqrt{mn}/\varepsilon^3)$.*

3.1 Potential argument

The analysis uses the convex potential function

$$f(\mathbf{x}, \mathbf{y}) = \sum_{i,j=1}^n A_{ij} e^{x_i + y_j} - \sum_{i=1}^n r_i x_i - \sum_{j=1}^n c_j y_j.$$

This function (already mentioned in the introduction) is often used in the context of matrix scaling, as its gradient is the difference between the current and desired marginals. Many of the more sophisticated algorithms for matrix scaling minimize this function directly. For our purposes, we first bound the potential gap $f(\mathbf{0}, \mathbf{0}) - \inf_{\mathbf{x}, \mathbf{y} \in \mathbb{R}^n} f(\mathbf{x}, \mathbf{y})$ (see [9, App. A]).

▶ **Lemma 8** (Potential gap). *Assume $\mathbf{A} \in [0,1]^{n \times n}$ with $\|\mathbf{A}\|_1 \leq 1$ and non-zero entries at least $\mu > 0$. If $\mathbf{A}$ is asymptotically $(\mathbf{r}, \mathbf{c})$-scalable, then $f(\mathbf{0}, \mathbf{0}) - \inf_{\mathbf{x}, \mathbf{y} \in \mathbb{R}^n} f(\mathbf{x}, \mathbf{y}) \leq \ln(1/\mu)$.*

For matrices $\mathbf{A}$ that are *exactly* $(\mathbf{r}, \mathbf{c})$-scalable, this bound is well-known (see e.g. [34, 20]), but to the best of our knowledge, it has not yet appeared in the literature when $\mathbf{A}$ is only assumed to be asymptotically scalable to $(\mathbf{r}, \mathbf{c})$.

One can show that, for a Sinkhorn iteration in which we update the rows exactly, i.e., $\hat{x}_\ell = \ln(r_\ell / \sum_{j=1}^n A_{\ell j} e^{y_j})$ for $\ell \in [n]$, the potential decreases by exactly the relative entropy:

$$f(\mathbf{x}, \mathbf{y}) - f(\hat{\mathbf{x}}, \mathbf{y}) = D(\mathbf{r} \| \mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y}))), \tag{3.2}$$

and similarly for exact column updates. The next lemma generalizes this to allow for error in the update; it shows that we can lower bound the decrease of the potential function in every iteration in terms of the relative entropy between the target marginal and the current marginal, assuming every call to the subroutine `ApproxScalingFactor` succeeds.

▶ **Lemma 9.** *Let $\mathbf{A} \in \mathbb{R}_+^{n \times n}$, let $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, let $\delta \in [0, 1]$, and let $\hat{\mathbf{x}} \in \mathbb{R}^n$ be a vector such that for every $\ell \in [n]$, we have $|\hat{x}_\ell - \ln(r_\ell / \sum_{j=1}^n A_{\ell j} e^{y_j})| \leq \delta$. Then*

$$f(\mathbf{x}, \mathbf{y}) - f(\hat{\mathbf{x}}, \mathbf{y}) \geq D\big(\mathbf{r} \big\| \mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y}))\big) - 2\delta.$$

A similar statement holds for an update of $\mathbf{y}$ (using $\mathbf{c}$ instead of $\mathbf{r}$ in the relative entropy).

When $\delta = 0$, the inequality becomes an equality which is well-known, see e.g. [2] or [20]. The lemma shows that updating the scaling vectors with additive precision δ suffices to make progress in minimizing the potential function f, as long as we are still $\Omega(\delta)$ away from the desired marginals (in relative entropy distance).

We thus wish to store the entries of $\mathbf{x}$ and $\mathbf{y}$ with additive precision $\delta > 0$. We want to do so using a (b_1, b_2) fixed-point format, so we need $b_2 \geq \lceil \log_2(1/\delta) \rceil$. The guarantees of `ApproxScalingFactor` and `TestScaling` assert that this choice of b_2 is also sufficient. Lemma 10 shows how large we need to take b_1 to ensure the requirements of `ApproxScalingFactor` and `TestScaling` are satisfied in every iteration. The algorithm returns as soon as `TestScaling` returns **True**, or after T iterations. However, to simplify the analysis, we always assume that $\mathbf{x}^{(t)}$ and $\mathbf{y}^{(t)}$ are defined for $t = 0, \ldots, T$.

▶ **Lemma 10** (Bounding the scalings). *Let $\mathbf{A} \in [0, 1]^{n \times n}$ with $\|\mathbf{A}\|_1 \leq 1$ and non-zero entries at least $\mu > 0$. Let $T \geq 1$ and $\delta \in [0, 1]$. Denote $\sigma = \max(|\ln r_{\min}|, |\ln c_{\min}|)$. Let $b_2 = \lceil \log_2(1/\delta) \rceil$ and choose $b_1 = \lceil \log_2(T) + \log_2(\ln(\frac{1}{\mu}) + 1 + \sigma) \rceil$. If for all $t \in [T]$ the subroutine `ApproxScalingFactor` succeeds, then for all $t \in [T]$ and $\ell \in [n]$ we have*

$$\left| \ln \left(\frac{r_\ell}{\sum_{j=1}^n A_{\ell j} e^{y_j^{(t)}}} \right) \right| \leq 2^{b_1}, \quad \left| \ln \left(\frac{c_\ell}{\sum_{i=1}^n A_{i \ell} e^{x_i^{(t)}}} \right) \right| \leq 2^{b_1}$$

and $\|(\mathbf{x}^{(t)}, \mathbf{y}^{(t)})\|_\infty \leq t \left(\ln \left(\frac{1}{\mu} \right) + \delta + \sigma \right) \leq t \left(\ln \left(\frac{1}{\mu} \right) + 1 + \sigma \right)$.

To formally analyze the expected progress it is convenient to define the following events.

▶ **Definition 11** (Important events). *For $t = 1, \ldots, T$, we define the following events:*

- *Let S_t be the event that all n calls to `ApproxScalingFactor` succeed in the t-th iteration.*
- *Define S to be the intersection of the events S_t, i.e., $S = \cap_{t=1}^T S_t$.*

To give some intuition, we note below that the event S is the "good" event where a row-update makes the relative entropy between $\mathbf{r}$ and the updated row-marginals at most δ (and similarly for the columns). We only use Lemma 12 in [9, App. C].

▶ **Lemma 12.** *If S holds and $\delta \leq 1$, then the following holds for all $t \in [T]$:*

- *If t is odd, then $D(\mathbf{r} \| \mathbf{r}(\mathbf{A}(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}))) \leq \delta$.*
- *If t is even, then $D(\mathbf{c} \| \mathbf{c}(\mathbf{A}(\mathbf{x}^{(t)}, \mathbf{y}^{(t)}))) \leq \delta$.*

We can combine Lemmas 8 and 9 to show Algorithm 1 returns, with high probability, an ε-relative-entropy-scaling to $(\mathbf{r}, \mathbf{c})$ by choosing $\delta = O(\varepsilon)$.

▶ **Proposition 13.** *Let $\mathbf{A} \in [0,1]^{n\times n}$ with $\|\mathbf{A}\|_1 \leq 1$ and non-zero entries at least $\mu > 0$ and rational, and let $\mathbf{r}, \mathbf{c} \in (0,1]^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$. Assume $\mathbf{A}$ is asymptotically scalable to $(\mathbf{r}, \mathbf{c})$. For $\varepsilon \in (0,1]$, choose $T = \left\lceil \frac{8}{\varepsilon} \ln\left(\frac{1}{\mu}\right) \right\rceil + 1$, $\delta = \frac{\varepsilon}{16}$, $\delta' = \frac{\varepsilon}{2}$, $\eta = \frac{1}{3(n+1)T}$, $b_2 = \lceil \log_2(\frac{1}{\delta}) \rceil$, and $b_1 = \lceil \log_2(T) + \log_2(\ln(\frac{1}{\mu}) + \sigma + 1) \rceil$, where $\sigma = \max(|\ln r_{\min}|, |\ln c_{\min}|)$. Then, Algorithm 1 returns $(\mathbf{x}, \mathbf{y})$ s.t. $D(\mathbf{r} \| \mathbf{r}(\mathbf{A}(\mathbf{x}, \mathbf{y}))) \leq \varepsilon$ and $D(\mathbf{c} \| \mathbf{c}(\mathbf{A}(\mathbf{x}, \mathbf{y}))) \leq \varepsilon$ with probability $\geq 2/3$.*

3.2 Quantum approximate summing

`ApproxScalingFactor` and `TestScaling` both rely on the computation of additive approximations to numbers of the form $\ln(\sum_{i=1}^n a_i e^{y_i})$. Here we sketch our approach and mention some complications; see [9, Sec. 4] for details. If we assume the numbers $b_i = a_i e^{y_i}$ can be queried at unit cost, then we can efficiently compute $\ln(\sum_{i=1}^n b_i)$ up to additive error δ using amplitude estimation, as follows. After pre-processing (using *quantum maximum finding* [24]) one may assume that $b_i \in [0,1]$ and $\max_i b_i \geq 1/2$. With 2 queries to the b_is and a small number of other gates we prepare $\frac{1}{\sqrt{n}} \sum_{i=1}^n |i\rangle \left(\sqrt{b_i}\,|0\rangle + \sqrt{1-b_i}\,|1\rangle\right)$. The squared norm of the part ending in $|0\rangle$ equals $p = \frac{1}{n}\sum_{i=1}^n b_i \in [1/2n, 1]$. Let $\delta \in (0, 1/2]$ be an error parameter that we instantiate later. Using amplitude amplification we estimate p up to multiplicative error $1 \pm \delta$ using $O(\frac{1}{\delta}\sqrt{1/p}) = O(\frac{1}{\delta}\sqrt{n})$ queries to the b_is, and $\widetilde{O}(\frac{1}{\delta}\sqrt{n})$ gates, with error probability $\leq 1/3$ [15, Theorem 12]. We can reduce the error probability to a small $\eta > 0$, by running this $O(\log(1/\eta))$ times and outputting the median outcome. Naturally, multiplicative approximation of $\sum_{i=1}^n b_i$ yields additive approximation of $\ln(\sum_{i=1}^n b_i) = \ln(\sum_{i=1}^n a_i e^{y_i})$.

One obstacle to efficiently implementing the above is that one cannot simply compute all numbers to sufficient precision. For `ApproxScalingFactor` for instance, we aim to compute a number $\ln(r/\sum_{j=1}^n a_j e^{y_j})$ where the y_j can (and typically do) grow linearly with n, so we cannot compute e^{y_j} with sufficiently high precision in time sublinear in n. Instead we compute additive approximations of relative quantities such as $e^{y_i - y_j} \leq 1$ for $i, j \in [n]$ with $y_j \geq y_i$, and use properties of the log to relate this to the original desired quantity. This approach is widely used in practice, e.g., [4]. Note that these issues concern both the classical and quantum setting, but are particularly important for the latter, since we aim for a better dependence on m and n for the time complexity. We implement everything such that the fixed-point format (b_1, b_2) for both the input and output of the oracles is the same, avoiding the need to change the encoding format in every Sinkhorn or Osborne iteration.

3.3 Time complexity

Combining the above, we prove one of our main results (already stated earlier), bounding the time complexity of computing an ε-relative-entropy-scaling of $\mathbf{A}$ to marginals $(\mathbf{r}, \mathbf{c})$.

▶ **Theorem 4.** *Let $\mathbf{A} \in [0,1]^{n\times n}$ be a matrix with $\|\mathbf{A}\|_1 \leq 1$ and m non-zero entries, each rational and at least $\mu > 0$, let $\mathbf{r}, \mathbf{c} \in (0,1]^n$ with $\|\mathbf{r}\|_1 = \|\mathbf{c}\|_1 = 1$, and let $\varepsilon \in (0,1]$. Assume $\mathbf{A}$ is asymptotically scalable to $(\mathbf{r}, \mathbf{c})$. Then there exists a quantum algorithm that, given sparse oracle access to $\mathbf{A}$, with probability $\geq 2/3$, computes $(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^n \times \mathbb{R}^n$ such that $\mathbf{A}(\mathbf{x}, \mathbf{y})$ is ε-relative-entropy-scaled to $(\mathbf{r}, \mathbf{c})$, for a total time complexity of $\widetilde{O}(\sqrt{mn}/\varepsilon^2)$.*

Proof. We show that Algorithm 1 with the parameters chosen as in Proposition 13 has the stated time complexity. Note that the cost of computing these parameters from the input will be dominated by the runtime of the algorithm. Proposition 13 shows that Algorithm 1 runs for at most $O(\ln(1/\mu)/\varepsilon)$ iterations. Next we show the time complexity per iteration is $\widetilde{O}(\sqrt{mn}/\varepsilon)$, which implies the claimed total time complexity of $\widetilde{O}(\sqrt{mn}/\varepsilon^2)$.

Theorem 4.5 in [9] formalizes the discussion of Section 3.2: using `ApproxScalingFactor` with precision $\delta = \Theta(\varepsilon)$ on a row containing s potentially non-zero entries incurs a cost $\widetilde{O}(\sqrt{s}/\varepsilon)$, where we suppress a polylogarithmic dependence on n. One iteration of Algorithm 1 applies `ApproxScalingFactor` once to each row or once to each column, so by Cauchy–Schwarz the total cost of the calls to `ApproxScalingFactor` in one iteration is

$$\widetilde{O}\Big(\sum_{i=1}^{n}\sqrt{s_i^r}/\varepsilon + \sum_{j=1}^{n}\sqrt{s_j^c}/\varepsilon\Big) \subseteq \widetilde{O}(\sqrt{mn}/\varepsilon),$$

where we recall that s_i^r and s_j^c are the numbers of potentially non-zero entries in the i-th row and j-th column of $\mathbf{A}$, respectively, and m is the total number of potentially non-zero entries in $\mathbf{A}$ (i.e., $\sum_{i=1}^n s_i^r = m = \sum_{j=1}^n s_j^c$). Similarly, [9, Thm. 4.7] shows invoking `TestScaling` with precision $\delta' = \Theta(\varepsilon)$ incurs a cost of order $\widetilde{O}(\sqrt{mn}/\varepsilon)$. Finally we observe that compiling the quantum circuits (and preparing their inputs) for the calls to `ApproxScalingFactor` and `TestScaling` can be done with at most a polylogarithmic overhead. ◀

Note that the dependency on $\ln(1/\mu)$ is suppressed by the $\widetilde{O}$, since we assume the numerator and denominators of the rational inputs are bounded by a polynomial in n.

3.4 Complications in Osborne's algorithm

For the matrix balancing problem one can use a similar approach as for the matrix scaling problem. The idea is to fix the requirement of being ε-ℓ_1-balanced for individual coordinates, one at a time. More precisely, given an index $\ell \in [n]$, the update is given by $\mathbf{x}' = \mathbf{x} + \Delta_\ell \mathbf{e}_\ell$, where Δ_ℓ is chosen such that $r_\ell(\mathbf{A}(\mathbf{x}')) = c_\ell(\mathbf{A}(\mathbf{x}'))$. Expanding this and using $A_{\ell\ell} = 0$ yields $e^{\Delta_\ell} \cdot r_\ell(\mathbf{A}(\mathbf{x})) = e^{-\Delta_\ell} \cdot c_\ell(\mathbf{A}(\mathbf{x}))$. Since we assume every row and column contains at least one non-zero entry, the above equation has a unique solution, given by

$$\Delta_\ell = \ln\left(\sqrt{c_\ell(\mathbf{A}(\mathbf{x}))/r_\ell(\mathbf{A}(\mathbf{x}))}\right). \tag{3.3}$$

Note that the updates of multiple coordinates *cannot* be done simultaneously, since each coordinate can potentially affect all row and column marginals. This is in contrast with the Sinkhorn algorithm for matrix scaling, where all rows or all columns can be updated at the same time. This provides a significant challenge in the analysis of the algorithm since we can no longer test whether we have found an ε-balancing in between each iteration. We give a novel analysis of Osborne's algorithm [9, Sec. 6] and of a randomized version of Sinkhorn's algorithm [9, Sec. 5] that shows a uniformly random iterate provides an ε-balancing/scaling with high probability. For matrix balancing this yields the following.

▶ **Theorem 14.** *Let $\mathbf{A} \in [0,1]^{n\times n}$ be a matrix whose non-zero entries are rational, at least $\mu > 0$, with zeroes on the diagonal, each row and column having at least one non-zero element, and let $\varepsilon \in (0,1]$. Assume $\mathbf{A}$ is asymptotically balanceable. Then there exists a quantum algorithm that, given sparse oracle access to $\mathbf{A}$, returns with probability $\geq 2/3$ a vector $\mathbf{x} \in \mathbb{R}^n$ such that $\mathbf{A}(\mathbf{x})$ is ε-ℓ_1-balanced, with expected time complexity $\widetilde{O}(\sqrt{mn}/\varepsilon^4)$.*

4 Matching lower bound for matrix scaling with constant ε

We show that our algorithm for matrix scaling is in fact optimal with respect to the dependence on n and m, for constant $\varepsilon > 0$. We prove an $\Omega(\sqrt{mn})$ lower bound on the query complexity of quantum algorithms for $\Theta(1)$-ℓ_1-scaling to the uniform marginals $(\mathbf{1}/n, \mathbf{1}/n)$. Here we sketch the case $m = n^2$; Section 7 in [9] gives the full proof also for the sparse case.

We consider the problem of learning a permutation "modulo two" in the following sense.[4]

▶ **Definition 15** (Single-bit descriptor). *Let $\sigma \in S_n$ be a permutation. The* single-bit descriptor *of σ is the bit string $z \in \{0,1\}^n$ with entries $z_i \equiv \sigma(i) \bmod 2$.*

We first use the adversary method [5] to prove an $\Omega(n\sqrt{n})$ bound for recovering the single-bit descriptor, given (dense) oracle access to the permutation matrix. This is tight, since one can use Grover on each column to fully recover the permutation matrix. We follow a similar proof structure as in the $\Omega(\sqrt{n})$-query lower bound given in [5] for finding $\sigma^{-1}(1)$, and the $\Omega(n\sqrt{n})$-query lower bound for graph connectivity [23].

▶ **Lemma 16.** *Let n be a positive multiple of 4. Given an $n \times n$ permutation matrix $\mathbf{P}$ corresponding to a permutation σ (i.e., $P_{ij} = \delta_{i,\sigma(j)}$ for $i, j \in [n]$), recovering the single-bit descriptor z of σ, with success probability at least $2/3$, requires $\Omega(n\sqrt{n})$ quantum queries to a dense matrix oracle for $\mathbf{P}$.*

One can then boost this lower bound to show that even learning a (certain) constant fraction of the entries of the single-bit descriptor of a permutation requires $\Omega(n\sqrt{n})$ quantum queries. (The precise constant depends on those in Lemma 16 and in Grover search.) We then reduce the problem of learning the single-bit descriptor to the scaling problem, by replacing each 1-entry of the permutation matrix by one of two 2×2 gadget matrices (and each 0-entry by the 2×2 all-0 matrix). These gadgets are such that we can determine (most of) the single-bit descriptor from the column-scaling vectors $\mathbf{y}$ of an $\Theta(1)$-ℓ_1-scaling to uniform marginals. Explicitly, the gadget matrices are as follows:

$$\mathbf{B}_0 = \begin{bmatrix} \frac{2}{9} & \frac{4}{9} \\ \frac{1}{9} & \frac{2}{9} \end{bmatrix}, \qquad \mathbf{B}_1 = \begin{bmatrix} \frac{4}{9} & \frac{2}{9} \\ \frac{2}{9} & \frac{1}{9} \end{bmatrix},$$

Note that the two matrices have the same columns, but in reverse order. We show in the next lemma that from an approximate scaling of $\mathbf{B}_i$ to uniform marginals, one can recover the bit i.

▶ **Lemma 17.** *The matrices $\mathbf{B}_0, \mathbf{B}_1 \in \{\frac{1}{9}, \frac{2}{9}, \frac{4}{9}\}^{2\times 2}$ are entrywise positive, with entries summing to one, and they are exactly scalable to uniform marginals. For $i \in \{0,1\}$, let $(\mathbf{x}, \mathbf{y})$ be $\frac{1}{8}$-ℓ_1-scaling vectors for $\mathbf{B}_i$ to uniform marginals. If $i = 0$ then $y_1 - y_2 > 0.18$, while if $i = 1$ then $y_1 - y_2 < -0.18$. Moreover, $(\mathbf{x}, (y_2, y_1))$ are $\frac{1}{8}$-ℓ_1-scaling vectors for $\mathbf{B}_{1-i}$ to uniform marginals.*

In other words, the matrices can be distinguished just by learning the column-scaling vectors, but they have the same set of possible row-scaling vectors.

[4] Alternatively, one could consider the problem of learning an entire permutation, which would simplify the notation and proofs slightly. However, for the reduction to matrix scaling, this seems to require gadget matrices of size roughly $\log_2 n \times \log_2 n$, leading to a slightly weaker lower bound.

Proof. Since one matrix is obtained by swapping the columns of the other, the last claim is immediately clear, and it suffices to prove the remaining claims for $\mathbf{B}_0$.

First, we note that $\mathbf{B}_0$ is exactly scalable, since

$$\begin{bmatrix} \frac{3}{4} & 0 \\ 0 & \frac{3}{2} \end{bmatrix} \begin{bmatrix} \frac{2}{9} & \frac{4}{9} \\ \frac{1}{9} & \frac{2}{9} \end{bmatrix} \begin{bmatrix} \frac{3}{2} & 0 \\ 0 & \frac{3}{4} \end{bmatrix} = \begin{bmatrix} \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} \end{bmatrix}$$

has uniform marginals. Now suppose that $(\mathbf{x}, \mathbf{y})$ is an $\frac{1}{8}$-ℓ_1-scaling of $\mathbf{B}_0$ to uniform marginals. By the requirement on the column marginals, we have

$$\left(\frac{2}{9}e^{x_1} + \frac{1}{9}e^{x_2}\right) e^{y_1} \geq \frac{1}{2} - \frac{1}{8} \quad \text{and} \quad \left(\frac{4}{9}e^{x_1} + \frac{2}{9}e^{x_2}\right) e^{y_2} \leq \frac{1}{2} + \frac{1}{8}.$$

By dividing the first inequality by the second one we get

$$\frac{1}{2} \cdot \frac{e^{y_1}}{e^{y_2}} \geq \frac{3}{5},$$

and so $y_1 - y_2 \geq \ln \frac{6}{5} > 0.18$. ◀

Together with Lemma 16 this leads to the following lower bound.

▶ **Theorem 18.** *There exists a constant $\varepsilon \in (0, 1)$ such that any quantum algorithm which, given a sparse oracle for an $n \times n$-matrix that is exactly scalable to uniform marginals and has m potentially non-zero entries which sum to 1, returns an ε-ℓ_1-scaling with probability $\geq 2/3$, requires $\Omega(\sqrt{mn})$ quantum queries to the oracle.*

Fourier Conjectures, Correlation Bounds, and Majority

Emanuele Viola
Khoury College of Computer Sciences, Northeastern University, Boston, MA, USA

Abstract

Recently several conjectures were made regarding the Fourier spectrum of low-degree polynomials. We show that these conjectures imply new correlation bounds for functions related to Majority. Then we prove several new results on correlation bounds which aim to, but don't, resolve the conjectures. In particular, we prove several new results on Majority which are of independent interest and complement Smolensky's classic result.

Acknowledgements This paper includes the results in [28].
I am grateful to Chin Ho Lee for pointing out the work [5] to me, and to an anonymous reviewer for suggesting the use of hypercontractivity to bound $\mathbb{E}|g_k(x)|$ in the proof of Theorem 1 (alternatively one can reason along the lines of the proof of Theorem 4).
A preliminary version of this paper had Theorem 7 only for $d \geq \Omega(n^{1/3})$, and the degree bound was $O(d\sqrt{\log n})$. Jarosław Błasiok pointed out to us how to improve the proof to obtain Theorem 7. The proof in the preliminary version was similar, but rather than performing a case analysis, detected the two cases explicitly with an auxiliary polynomial, which led to $d \geq \Omega(n^{1/3})$. It also used the polynomials for Maj with polynomially-small error, as opposed to constant, which led to the extra $\sqrt{\log n}$ factor. Following these ideas, we also improved the results on the coin problem and h_2. We are very grateful to Jarosław Błasiok for letting us include the improved results!

1 Introduction and our results

The recent "polarizing random walks" paradigm [6, 8, 7, 5] constructs new pseudorandom generators against classes of functions with "bounded Fourier tails." For a function $f : \{0,1\}^n \to \{-1,1\}$ define

$$L_k(f) := \sum_{S \subseteq \{1,2,\ldots,n\} : |S|=k} \left|\hat{f}(S)\right|,$$
$$M_k(f) := \sum_{S \subseteq \{1,2,\ldots,n\} : |S|=k} \hat{f}(S),$$

where $\hat{f}(S) := \mathbb{E}_x f(x)\chi_S(x)$ for $\chi_S(x) := (-1)^{\sum_{i \in S} x_i}$ is the Fourier transform of f [16]. These papers construct pseudorandom generators for functions with small L_k or M_k for several settings of parameters.

In an effort to use this framework to improve the state of pseudorandom generators against *low-degree polynomials* over $\mathbb{F}_2 = \{0,1\}$ [3, 14, 26, 10], several conjectures have been put forth about polynomials. Let p be a degree-d polynomial over $\mathbb{F}_2$ in n variables. For $f := (-1)^p$ it has been conjectured (see [6, 8, 5]):

$$L_k(f) \leq 2^{O(dk)} \qquad \forall k. \tag{1}$$

$$L_2(f) \leq O(d^2), \tag{2}$$

$$M_k(f) \leq 2^{o(dk)+O(k \log\log n)} \qquad \forall k \leq O(\log n). \tag{3}$$

Conjecture (1) would not imply new pseudorandom generators, but would come close to matching the state-of-the-art using this framework – something which was eventually achieved in [5]. But conjectures (2) and (3) would imply new generators, improving on long-standing open problems. One interesting feature of this approach is that, unlike the influential approach by Nisan [15], it is not based on *correlation bounds*. In particular, Conjecture (2) is not known to imply such bounds. Still, correlation bounds where shown to be *sufficient* for this approach in [7].

We show that in fact correlation bounds are also *necessary*. That is, we show that this approach requires proving new correlation bounds for polynomials. This is new information about Conjecture (2). Conjecture (3) was shown in [5] to imply new pseudorandom generators with good dependence on the error, and the latter are known to imply new correlation bounds for a function in NP [26]. We give a direct proof of this implication which yields a function in P (and other parameter improvements). In fact, we show that even weaker versions of the conjectures, such as $M_2 \leq o(\sqrt{n})$ for polynomials of degree $\log_2 n$, already imply new correlation bounds.

Correlation bounds

We say that a function $f : \{0,1\}^n \to \{-1,1\}$ has *δ-advantage (or $(1-\delta)$-error) (probabilistic) degree d* if there is a distribution P on polynomials $p : \{0,1\}^n \to \{0,1\}$ over $\mathbb{F}_2$ of degree d such that for every input x we have $\mathbb{P}[(-1)^{P(x)} = f(x)] \geq \delta$. By Yao's min-max argument [30], a function f has δ-advantage degree d iff for every distribution D on $\{0,1\}^n$ it has δ-advantage degree d under D, meaning there exists a polynomial p over $\mathbb{F}_2$ of degree d such that $\mathbb{P}[(-1)^{p(D)} = f(D)] \geq \delta$. If f has range $\{0,1\}$ instead of $\{-1,1\}$ we use the same notation except $(-1)^{P(x)}$ is replaced simply by $P(x)$.

For two functions f and g from $\{0,1\}^n$ to $\{-1,1\}$ we define their *correlation* under a distribution D by $\mathbb{E}[f(D)g(D)]$, which we note equals $2(\mathbb{P}[f(D) = g(D)] - 1/2)$ and so it is (twice) the distance of $1/2$ from the advantage.

Since the classical works by Razborov and Smolensky [17, 19] the best-available explicit probabilistic-degree lower bound for degree $d \geq \log_2 n$ gives error at best

$$1/2 - \Omega(d/\sqrt{n}) \tag{4}$$

which holds for the Majority function on n bits. In particular, it is consistent with our knowledge that every explicit function has $(1/2 + 1/\sqrt{n})$-advantage degree $\log_2 n$ (while non-constructively there exist functions which do not even have advantage exponentially close to $1/2$ for polynomial degree). For recent progress on functions computable in exponential-time classes see [29].

Proving correlation bounds is a fundamental open problem whose solution stands in the way of progress on a striking variety of fronts, including: circuit lower bounds, multiparty communication complexity, and matrix rigidity. For more on this long-standing challenge and a discussion of the just-mentioned implications, we refer the reader to [25, 27, 29].

The conjectures imply new correlation bounds

We show that bounds on M_k imply new probabilistic-degree lower bounds for an explicit function h_k. We now define h_k and state our results.

Let $g_k : \{0,1\}^n \to \mathbb{Z}$ and $h_k : \{0,1\}^n \to \{-1,1\}$ be defined as

$$g_k(x) := \sum_{S:|S|=k} \chi_S(x),$$

$$h_k(x) := \mathrm{Sign}(g_k(x)),$$

where $\mathrm{Sign}(i) = 1$ if $i > 0$ and -1 otherwise (the value on $i = 0$ is arbitrary).

▶ **Theorem 1.** *Let F be a distribution on functions from $\{0,1\}^n$ to $\{-1,1\}$ such that $\mathbb{P}[F(x) = h_k(x)] \geq 1/2 + \epsilon$ for every x. Then there is an outcome f of F such that $M_k(f) \geq 2\epsilon \cdot e^{-k}\sqrt{\binom{n}{k}}$.*

To illustrate the theorem, consider first $k = 2$, in which case the conclusion becomes $M_2(f) \geq \Omega(\epsilon n)$. This means that showing even just $M_2(p) \leq o(\sqrt{n})$ for every degree-d polynomial requires showing that h_2 does not have $(1/2 + \Omega(1/\sqrt{n}))$-advantage degree d. This would improve the tradeoff (4) mentioned above when $d \geq \log_2 n$. Conjecture (2) implies the stronger bound $M_2(p) \leq O(d^2)$ for every degree-d polynomial p. This would mean that h_2 does not even have $(1/2 + cd^2/n)$-advantage degree d for a constant c, a quadratic improvement on the tradeoff (4). Consider now the case of larger k. Assuming that h_k has $(1/2+\epsilon)$-advantage degree d, and assuming Conjecture (3) and using the bound $\binom{n}{k} \geq (n/k)^k$ we obtain

$$2\epsilon \cdot e^{-k}\left(\frac{n}{k}\right)^{k/2} \leq 2\epsilon \cdot e^{-k}\sqrt{\binom{n}{k}} \leq 2^{o(dk)+O(k\log\log n)}.$$

This implies $\epsilon \leq 2^{k(o(d)+O(\log\log n)-0.5\log_2(n/k))}$. For $k = \log_2 n$ this yields new correlation bounds. Indeed, let $d := \log_2 n$. Then because $o(d)$, $\log\log n$, and $\log(k)$ are all $o(\log n)$ we obtain

$$\epsilon \leq 2^{-\Omega(k\log n)} = 2^{-\Omega(\log^2 n)}$$

which improves on the tradeoff (4).

Proof. Note that for any function f, by linearity of expectation, we have

$$M_k(f) = \mathbb{E}_x f(x)g_k(x).$$

Fix any x and let $\mathbb{P}[F(x) = h_k(x)]$ be equal to $1/2 + \epsilon_x \geq 1/2 + \epsilon$. We can write

$$\mathbb{E}_F[F(x)g_k(x)] = (1/2 + \epsilon_x) \cdot \mathrm{Sign}(g_k(x)) \cdot g_k(x) + (1/2 - \epsilon_x) \cdot (-\mathrm{Sign}(g_k(x))) \cdot g_k(x),$$

holding even if $g_k(x) = 0$. Note that $\mathrm{Sign}(g_k(x)) \cdot g_k(x) = |g_k(x)|$. Hence

$$\mathbb{E}_F[F(x)g_k(x)] = (1/2 + \epsilon_x)|g_k(x)| + (1/2 - \epsilon_x)(-|g_k(x)|) = 2\epsilon_x|g_k(x)| \geq 2\epsilon|g_k(x)|.$$

This gives $\mathbb{E}_{x,F}F(x)g_k(x) \geq \mathbb{E}_x 2\epsilon|g_k(x)|$. In particular, there exists an outcome f such that

$$\mathbb{E}_x f(x)g_k(x) \geq 2\epsilon\mathbb{E}_x|g_k(x)|.$$

There remains to bound $\mathbb{E}_x|g_k(x)|$. We make use of *hypercontractivity* from the analysis of Boolean functions. Because g_k is a polynomial of degree k, by Theorem 9.22 in [16] we have

$$\mathbb{E}_x|g_k(x)| \geq e^{-k}\sqrt{\mathbb{E}_x|g_k(x)|^2}.$$

Now observe that

$$\mathbb{E}_x|g_k(x)|^2 = \mathbb{E}_x \sum_{S,T:|S|=|T|=k} \chi_S(x)\chi_T(x) = \mathbb{E}_x \sum_{S,T:|S|=|T|=k} \chi_{S\oplus T}(x) = \binom{n}{k},$$

where $\oplus$ is symmetric difference. The last equality holds because the terms where $S \neq T$ have expectation zero, and the others have expectation one. The result follows. ◀

A natural question is whether Theorem 1 holds even for functions that correlate with h_k under the uniform distribution. We show that it does not.

▶ **Theorem 2.** *Let n be a power of 2. For any integer s between 0 and $\sqrt{n}/2$ there is a function $f : \{0,1\}^n \to \{-1,1\}$ such that $\mathbb{P}[f(x) = h_2(x)] \geq 1/2 + \Omega(s/\sqrt{n})$ but $M_2(f) \leq O(s^2)$.*

To get a sense of the parameters let $\mathbb{P}[f(x) = h_2(x)] = 1/2 + \epsilon$. Then $M_2(f)$ is only $O(\epsilon^2 n)$ as opposed to $\Omega(\epsilon n)$ in Theorem 1. In particular, if $s = O(1)$ and $\epsilon = \Theta(1/\sqrt{n})$ we get $M_2(f) = O(1)$ as opposed to $\Omega(\sqrt{n})$ in Theorem 1.

We have shown that understanding the probabilistic degree of the functions h_k is also important for the feasibility of recent approaches to pseudorandom generators against polynomials. We obtain new bounds on the probabilistic degree of the functions h_k which however fall short of resolving whether the correlation bounds in the conclusion of Theorem 1 hold or not. We begin with studying h_1 which is essentially the majority function Maj. The results are of independent interest, and a natural step to tackle h_k for larger k. Indeed, below we use techniques developed for Maj to give new results on h_2.

We point out that the probabilistic degree tradeoff of Majority is not known. Given the tremendous interest in this function, this may come as a surprise. One might be tempted to think that Smolensky's tradeoff (4) is tight. We can show that it is indeed tight *under the uniform distribution.*

▶ **Theorem 3.** *Majority has $(1/2 + \Omega(d/\sqrt{n}))$-advantage degree d under the uniform distribution.*

Recall this means that there are degree-d polynomials p over $\mathbb{F}_2$ such that $\mathbb{P}_x[p(x) = \mathrm{Maj}(x)] \geq 1/2 + \Omega(d/\sqrt{n})$, where x is uniform in $\{0,1\}^n$. Such a result was only known for $d = O(1)$ or $d = \Omega(\sqrt{n})$, see [25].

However, there are harder distributions. We beat Smolensky's bound for degree one. While such polynomials are simple, in light of Theorem 3 this result already requires a non-uniform distribution.

▶ **Theorem 4.** *Majority does not have $(1/2 + c/n)$-advantage degree one, for some constant c. This bound is tight up to the value of c.*

We now turn to constructions of probabilistic polynomials for majority. This problem is related to the so-called *coin problem,* defined next.

▶ **Definition 5.** *For $\delta \in [0,1]$ we denote by N_δ^t the distribution over $\{0,1\}^t$ where the bits are i.i.d. and each comes up 1 with probability δ. We say that a distribution F on boolean functions on t bits $(1/2+\alpha)$*-solves the δ-coin problem with advantage α *if the following is true:*
(1) $\mathbb{P}[F(N_\delta^t) = 1] \geq 1/2 + \alpha$; *and*
(2) $\mathbb{P}[F(N_{1-\delta}^t) = 0] \geq 1/2 + \alpha$.

The study of the coin problem for low-degree polynomials goes back to [18] (see also the thesis [24]) and has been the subject of several recent works including [13, 11, 21]. This problem has also been studied in a variety of other models; the terminology "coin problem" was coined in [4].

However, these works consider large advantage $\alpha = \Omega(1)$. By contrast, we are interested in the setting where α is close to 0. We give tight bounds in this setting, showing that with degree d the best we can do is to boost the bias by d.

▶ **Theorem 6.** *There is a distribution on polynomials of degree $O(d)$ that $(1/2 + d\epsilon)$-solves the $(1/2+\epsilon)$-coin problem, whenever $d\epsilon < c$ for an absolute constant c. Moreover, this is tight up to the constant in the $O(.)$.*

Computing Majority on n bits for odd n can be randomly reduced to solving the $(1/2+1/n)$-coin problem, simply by selecting uniform bits from the input. Hence, Theorem 6 shows that Majority has $(1/2+d/n)$-advantage degree $\leq O(d)$. We improve the advantage to $\Omega(d^2/n)$, and conjecture that this is tight.

▶ **Theorem 7.** *Majority on n bits, for odd n, has $(1/2 + d^2/n)$-advantage degree $\leq O(d)$.*

▶ **Conjecture 8.** *Theorem 7 is tight. A "hard" distribution can be uniform on the inputs of Hamming weights $n/2 + 2^{\ell-1}$ and $n/2 - 2^{\ell-1}$ where $d < 2^\ell$.*

To understand the choice of the hard distribution, recall that *symmetric* polynomials of degree $d < 2^\ell$ only depend on the weight of the input modulo 2^ℓ (see Lemma 11). For example, for $\ell = 1$ symmetric polynomials of degree $1 < 2$ only depend on the input weight modulo 2. The two Hamming weights in the conjecture are congruent modulo 2^ℓ; hence any symmetric polynomial of degree $< 2^\ell$ has correlation zero.

Finally, we turn to h_2. One can reduce h_2 to a majority on $\binom{n}{2}$ bits, and then apply Theorem 7 to obtain advantage $1/2 + \Omega(d^2/n^2)$. We improve this to $1/2 + \Omega(d^2/n^{3/2})$, under a condition on n.

▶ **Theorem 9.** *Let ℓ be the smallest integer such that $d \leq 2^\ell$. Suppose that the remainder of $\sqrt{n}$ divided by $2^{\ell+100}$ is not in $[0, 2d] \cup [2^{\ell+100} - 2d, 2^{\ell+100}]$.*
Then h_2 has $(1/2 + d^2/n^{3/2})$-advantage degree $O(d)$.

This result is not strong enough to disprove Conjecture (2). For that we require advantage $1/2 + \omega(d^2/n)$.

The rest of the paper is organized as follows. After some preliminaries in Section 2 we prove the statements in the same order in which we discussed them, except that the proof of Theorem 2 is in Section 8.

2 Preliminaries

In this section we collect several results which are used in later proofs.

The following lemma shows that the majority of several i.i.d. Bernoulli random variables increases their bias, even in the regime where the bias is very small to start with.

▶ **Lemma 10.** $\mathbb{P}[\mathrm{Maj}(N^t_{1/2+\alpha}) = 1] \geq 1/2 + \Omega(\alpha\sqrt{t})$, *whenever* $\sqrt{t}\alpha < c$ *for an absolute constant* c.

We are not aware of a source from which this result can be easily extracted, so we provide a proof. But Jarosław Błasiok let us know that this lemma appears as Lemma 8 in [23].

Proof. We prove $\mathbb{P}[\mathrm{Maj}(N^t_{1/2+\alpha}) = 1] - \mathbb{P}[\mathrm{Maj}(N^t_{1/2+\alpha}) = 0] \geq \Omega(\alpha\sqrt{t})$. The former difference can be written as

$$\sum_{i=1/2}^{t/2} \binom{t}{t/2+i} \left((1/2+\alpha)^{t/2+i}(1/2-\alpha)^{t/2-i} - (1/2-\alpha)^{t/2+i}(1/2+\alpha)^{t/2-i}\right),$$

where the sum is for $i = 1/2, 1+1/2, 2+1/2, \ldots, t/2$.

Collecting a 2^t factor and writing z for 2α this equals

$$2^{-t} \sum_{i=1/2}^{t/2} \binom{t}{t/2+i} \left((1+z)^{t/2+i}(1-z)^{t/2-i} - (1-z)^{t/2+i}(1+z)^{t/2-i}\right).$$

Further collecting $(1-z)^{t/2}(1+z)^{t/2} = (1-z^2)^{t/2}$ we rewrite it as

$$2^{-t}(1-z^2)^{t/2} \sum_{i=1/2}^{t/2} \binom{t}{t/2+i} \left(\left(\frac{1+z}{1-z}\right)^i - \left(\frac{1-z}{1+z}\right)^i\right).$$

Note that $\left(\frac{1+z}{1-z}\right) > 1$ and so $\left(\frac{1+z}{1-z}\right)^i - \left(\frac{1-z}{1+z}\right)^i$ is positive and increasing with i. Hence for any s we can bound below the expression by

$$2^{-t}(1-z^2)^{t/2} \sum_{i=s}^{t/2} \binom{t}{t/2+i} \left(\left(\frac{1+z}{1-z}\right)^s - \left(\frac{1-z}{1+z}\right)^s\right).$$

Moreover, let us write

$$\left(\frac{1+z}{1-z}\right)^s - \left(\frac{1-z}{1+z}\right)^s = (1+x)^s - (1-y)^s$$

where $x = 2z/(1-z)$ and $y = 2z/(1+z)$. We bound below the right-hand side by

$$1 + xs - e^{-ys} \geq 1 + xs - (1 - ys + (ys)^2) = s(x+y) - y^2s^2.$$

We pick $s = \sqrt{t}/100 + 1/2$. The above expression is $\Omega(\sqrt{t}\alpha)$ as long as $\sqrt{t}\alpha = \Theta(st)$ is sufficiently small. Moreover, we have

$$2^{-t}(1-z^2)^{t/2} \sum_{i=s}^{t/2} \binom{t}{t/2+i} \geq \Omega(1).$$

This holds because $(1-z^2)^{t/2} \geq \Omega(1)$ and the sum of binomial coefficients is also $\Omega(2^{-t})$ using Stirling's approximation to the binomial coefficient. ◀

We use the following characterization of symmetric polynomials which is Theorem 2.4 in [2] and follows from Lucas' theorem.

▶ **Lemma 11.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a symmetric function that only depends on the input Hamming weight modulo 2^ℓ. Then f is computable by a symmetric $\mathbb{F}_2$ polynomial of degree $< 2^\ell$. Conversely, any function $f : \{0,1\}^n \to \{0,1\}$ computable by a symmetric $\mathbb{F}_2$ polynomial of degree $< 2^\ell$ only depends on the input Hamming weight modulo 2^ℓ.*

Then we need constructions of probabilistic polynomials for symmetric functions, obtained in [1]. The bounds in the earlier paper [20] would also suffice for the main points in this paper. See also [22] for a recent characterization.

▶ **Lemma 12** ([1])**.** *Let $f : \{0,1\}^n \to \{0,1\}$ be symmetric. Then f has $(1-\epsilon)$-advantage degree $O(\sqrt{n \log(1/\epsilon)})$, for any ϵ.*

3 Proof of Theorem 3

The main proof is for odd n. If n is even we can use the polynomial $p'(x_0, x_1, \ldots, x_{n-1}) := p(x_0, x_1, \ldots, x_{n-2})(1 - x_{n-1})$ where p is the polynomial with the highest correlation γ with majority on input length $n-1$. The correlation of p' with majority is $> \gamma/2$.

We now proceed with the main proof. We can assume without loss of generality that d is a power of 2 and $\leq 0.1\sqrt{n}$. The polynomial witnessing the correlation will be *symmetric.* For a symmetric function $f : \{0,1\}^n \to \{0,1\}$ write $f_w : \{0,1,\ldots,n\} \to \{0,1\}$ for $f(x) = f_w(|x|)$ where $|x|$ is the Hamming weight of x. The correlation between a symmetric polynomial p and $(-1)^{\mathrm{Maj}}$ can be written as

$$2^{-n} \sum_{i=0}^{n} \binom{n}{i} (-1)^{p_w(i)} (-1)^{Maj_w(i)}.$$

To construct p we use Lemma 11 for $\ell = \log_2(2d)$. That shows that for any $f_w : \{0,1,\ldots,n\} \to \{0,1\}$ that depends only on the input modulo 2^ℓ there is a symmetric polynomial $p : \{0,1\}^n \to \{0,1\}$ of degree 2^ℓ such that $p_w = f_w$.

The definition of f_w and hence p is as follows. Define Block i to be the $2d$ integers $2di + 0, 2di + 1, \ldots, 2di + 2d - 1$. Let i^* be the smallest i such that Block i contains an integer larger than $n/2$. Let t be the number of integers less than $n/2$ in Block i^*. (If $n+1$ is a power of 2 we have $t = 0$, and below there is no residual chunk.) Define f_w to be 1 on the smallest t inputs, 0 on the next t, 0 on the next $d - t$, and finally 1 on the next $d - t$. Here's an example for $n = 17, d = 2, t = 1, i^* = 2$; the last row shows the division in blocks:

weight	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
	-	-	-	-	-	-	-	-	-	+	+	+	+	+	+	+	+	+
$(-1)^{p_w}$	-	+	+	-	-	+	+	-	-	+	+	-	-	+	+	-	-	+

Note that p_w is by construction anti-symmetric in the sense, different from above, that: $p_w(i) = 1 - p_w(n-i)$. The same is true for Maj_w. Therefore $g(i) := (-1)^{p_w(i)}(-1)^{Maj_w(i)}$ is symmetric, that is $g(i) = g(n-i)$. Hence we only need to consider the bigger half of the Hamming weights. Majority is always 1, and so we can rewrite the correlation as

$$2^{-n} \cdot 2 \cdot \sum_{i=0}^{(n-1)/2} \binom{n}{(n+1)/2+i} (-1)^{p_w((n+1)/2+i)}.$$

Enumerate the above binomial coefficients starting from the biggest one for $i = 0$. The term $(-1)^{p_w((n+1)/2+i)}$ will be $+1$ on the first $t + (d-t) = d$, then -1 on the next d, then again $+1$ on the next d, and so on. We group the coefficients in chunks of length $2d$; in each chunk

the term is $+1$ for the first half and -1 for the second half. The number of coefficients is $(n+1)/2$. Hence we have $\lfloor (n+1)/4d \rfloor$ chunks, plus a residual truncated chunk of length $\ell < 2d$.

Hence we can write the correlation as follows.

$$2^{-n} \cdot 2 \cdot \sum_{i=0}^{\lfloor (n+1)/4d \rfloor - 1} \sum_{j=0}^{d-1} \left(\binom{n}{(n+1)/2 + 2di + j} - \binom{n}{(n+1)/2 + 2di + j + d} \right) + 2^{-n} \cdot 2 \cdot \sum_{i=0}^{\ell-1} \binom{n}{n-i} (-1)^{p_w((n+1)/2+i)}.$$

By, say, a Chernoff bound the absolute value of the latter summand $+2^{-n} \cdots$ is at most $2^{-\Omega(n)}$, using that $\ell < 2d = O(\sqrt{n})$. Now consider the first summand. Because the binomials are decreasing in size, each difference is positive. Hence we obtain a lower bound if we reduce the range of i. We reduce it to $\lfloor \sqrt{n}/d \rfloor$. So the correlation is at least

$$2^{-n} \cdot 2 \cdot \sum_{i=0}^{\lfloor \sqrt{n}/d \rfloor} \sum_{j=0}^{d-1} \left(\binom{n}{(n+1)/2 + 2di + j} - \binom{n}{(n+1)/2 + 2di + j + d} \right) - 2^{-\Omega(n)}.$$

The next lemma bounds below the difference of two such binomial coefficients.

▶ **Lemma 13.** *For $s \leq 4\sqrt{n}$ and $d \leq 0.1\sqrt{n}$ we have: $2^{-n} \left(\binom{n}{n/2+s} - \binom{n}{n/2+s+d} \right) \geq \Omega(sd/n^{3/2})$.*

We apply the lemma with $s = 1/2 + 2di + j$ which note is $\leq 1/2 + 2\sqrt{n} + 0.1\sqrt{n} \leq 3\sqrt{n}$. The correlation is at least

$$\sum_{i=0}^{\lfloor \sqrt{n}/d \rfloor} \sum_{j=0}^{d-1} \Omega((1/2 + 2di + j)d/n^{3/2}) - 2^{-\Omega(n)} \geq \sum_{k=0}^{\Omega(\sqrt{n})} \Omega(kd/n^{3/2}) - 2^{-\Omega(n)} \geq \Omega(d/\sqrt{n}).$$

To justify the first inequality we use $1/2 + 2di + j \geq di + j$ and then do the change of variable $k = di + j$. For the second we use that the sum of all k up to $\Omega(\sqrt{n})$ is $\Omega(n)$. This concludes the proof except for the lemma.

Proof of lemma

We have

$$\begin{aligned} &\binom{n}{n/2+s} - \binom{n}{n/2+s+d} \\ =&\frac{n!}{(n/2+s)!(n/2-s)!} - \frac{n!}{(n/2+s+d)!(n/2-s-d)!} \\ =&\frac{n!}{(n/2+s)!(n/2-s)!} \left[1 - \frac{(n/2-s)(n/2-s-1)\cdots(n/2-s-d+1)}{(n/2+s+d)(n/2+s+d-1)\cdots(n/2+s+1)} \right]. \end{aligned}$$

The ratio inside the square bracket is at most

$$\frac{(n/2-s)^d}{(n/2)^d} = (1-2s/n)^d \leq e^{-2sd/n} \leq 1 - sd/n,$$

where the last inequality holds because $2sd/n \leq 1$.

The binomial coefficient outside of the square bracket is

$$\binom{n}{n/2+s} \geq \frac{2^{nh(1/2+s/n)}}{\sqrt{8n(1/2+s/n)(1/2-sn)}} \geq \Omega\left(\frac{2^{n(1-O(s^2/n^2))}}{\sqrt{n}}\right) \geq \Omega\left(\frac{2^n}{\sqrt{n}}\right).$$

Here h is the binary entropy function, and the first inequality can be found as Lemma 17.5.1 in [9]. The second and third inequalities follow from the approximation $h(1/2+x) \geq 1-4x^2$, valid for every x, and $s = O(\sqrt{n})$.

The lemma follows by combining the two bounds.

4 Proof of Theorem 4

First let us discuss tightness. To show tightness for odd n we simply output a uniformly selected bit. For even n this works for all inputs except those of Hamming weight $= n/2$. To fix this, we modify the distribution on polynomials to equal 1 with probability $1/n$. On input of weight $= n/2$ we get the right value with probability $1/n + (1-1/n)(1/2) \geq 1/2+\Omega(1/n)$. On inputs of Hamming weight $\neq n/2$ we also get the right value with probability $(1-1/n)(1/2+1/n) \geq 1/2+\Omega(1/n)$.

We now move to negative results. First we note that we can reduce the case of even n to that of odd n: simply append a bit whose value is that of majority on balanced inputs. This does not change the value of majority, and has negligible effect on the advantage. Hence it suffices to prove a negative result for even n, and we do so in the rest of this section.

We select as the hard distribution the distribution D which is uniform on inputs of Hamming weight $n/2+1$ and $n/2-1$. Our goal is to show that for every fixed degree-one polynomial f we have $\mathbb{P}[f(D) = \mathrm{Maj}(D)] \leq 1/2 + O(1/n)$. Using *generating functions* we obtain a proof which is nearly calculation-free, requiring only elementary bounds on binomials. Let $m = n/2$ and $f = x_1 + x_2 + \cdots + x_k$ for a parameter k. Let

$$b(n,m,k) = \sum_{i=0}^{k} (-1)^i \binom{m}{i}\binom{n-m}{k-i}.$$

Note that $b(n,m,k)/\binom{n}{k}$ is the probability that a uniform set of size k has odd intersection with a fixed set of size m, minus the probability that it has even intersection. By the definition of D and f one obtains that $|\mathbb{P}[f(D) = \mathrm{Maj}(D)] - 1/2|$ is at most big-Oh of

$$\alpha(n, n/2-1, k) := \left|\frac{1}{\binom{n}{k}}(b(n,n/2-1,k) - b(n,n/2+1,k))\right|.$$

Note that we can assume that f has no constant term because we are taking absolute values in the expression $|\mathbb{P}[f(D) = \mathrm{Maj}(D)] - 1/2|$.

First we use generating functions to obtain a closed form for $b(n,m,k)$. Recall the generating functions (see e.g. [12] for background on this technique)

$$(1+z)^n = \sum_{i\geq 0}\binom{n}{i} z^i,$$

$$(1-z)^n = \sum_{i\geq 0}\binom{n}{i}(-1)^i z^i.$$

We have

$$(1-z)^m(1+z)^{n-m} = \sum_{i\geq 0, j\geq 0}\binom{m}{i}\binom{n-m}{j}(-1)^i z^{i+j} = \sum_{k\geq 0} b(n,m,k) z^k.$$

If $m = n/2 - t$ the left-hand side can be written as

$$\begin{aligned}&(1-z)^{n/2-t}(1+z)^{n/2-t}(1+z)^{2t}\\ =&(1-z^2)^{n/2-t}(1+z)^{2t}\\ =&\sum_{i\geq 0}(-1)^i\binom{n/2-t}{i}z^{2i}(1+z)^{2t}.\end{aligned}$$

Similarly, if $m = n/2 + t$ then it can be written as

$$\begin{aligned}&(1-z)^{n/2-t}(1+z)^{n/2-t}(1-z)^{2t}\\ =&\sum_{i\geq 0}(-1)^i\binom{n/2-t}{i}z^{2i}(1-z)^{2t}.\end{aligned}$$

Specializing to $t = 1$ we obtain

$$\begin{aligned}&\sum_{k\geq 0}(b(n,n/2-1,k)-b(n,n/2+1,k))z^k\\ =&\sum_{i\geq 0}(-1)^i\binom{n/2-1}{i}z^{2i}\left((1+z)^2-(1-z)^2\right)\\ =&\sum_{i\geq 0}(-1)^i\binom{n/2-1}{i}z^{2i}\cdot 4z\\ =&4\sum_{i\geq 0}(-1)^i\binom{n/2-1}{i}z^{2i+1}.\end{aligned}$$

Equating coefficients of z^k yields

$$b(n,n/2-1,k)-b(n,n/2+1,k) = 4(-1)^{(k-1)/2}\binom{n/2-1}{(k-1)/2}$$

if k is odd, otherwise the left-hand side is zero.

Hence we get

$$\alpha = 4\binom{n/2-1}{(k-1)/2}\Big/\binom{n}{k}$$

if k is odd, and $\alpha = 0$ if k is even.

There remains to bound the right-hand side. First, we can assume that $k \leq n/2$ because replacing k with $n-k$ does not change the value of α. If $k = 0, 1$ we readily have $\alpha = O(1/n)$, using that n is even. Otherwise we can use the bounds

$$(n/k)^k \leq \binom{n}{k} \leq (en/k)^k$$

to again show $\alpha = O(1/n)$. We have

$$\alpha \leq 4\left(\frac{n}{(k-1)}\right)^{(k-1)/2}\left(\frac{k}{n}\right)^k = 4\sqrt{\frac{k}{n}}\left(\sqrt{\frac{1}{k-1}}\cdot\frac{k}{\sqrt{n}}\right)^k.$$

We can conclude by noticing that if $k \leq 100\log_2 n$ then this is at most $\operatorname{poly}\log n/n^{1.5} \leq O(1/n)$, using $k \geq 2$; while if $k \geq 100\log_2 n$ using that $k \leq n/2$ and $k - 1 \geq 0.99k$ we have

$$\alpha \leq O(1)\cdot\left(\frac{\sqrt{k}}{\sqrt{0.99n}}\right)^k \leq O(1)(\sqrt{0.5/0.99})^k \leq O(1)(3/4)^k \leq 1/n.$$

5 Proof of Theorem 6

The theorem follows immediately from the following more general lemma, which we will also use later.

▶ **Lemma 14.** *There is a distribution P on polynomials on $s = O(d^2)$ bits of degree $O(d)$ such that for every $\epsilon \in [-1/2, 1/2]$, $\epsilon \leq 1/d$, we have $\mathbb{P}[P(N^s_{1/2+\epsilon}) = \mathrm{Sign}(\epsilon)] \geq 1/2 + \Omega(d\epsilon)$.*

Proof. Let $P'' : \{0,1\}^s \to \{0,1\}$ be the probabilistic polynomial of degree $O(d)$ from Theorem 12 which computes Maj on every input with probability 0.99, with input length $s = O(d^2)$ which is assumed to be odd without loss of generality.

We modify P'' so that the probability that it makes a mistake on input x only depends on $||x| - n/2|$. That is, it is the same on every two inputs of weights $n/2 + i$ and $n/2 - i$. First, let P' pick a random permutation of the input bits, and then apply P''. The probability that P' makes a mistake only depends on $|x|$. Second, define P that on input x tosses a coin, and if it is heads it outputs $P'(x)$, and if it is tails it complements x to obtain $\neg x$, runs $P'(\neg x)$, and flips the answer. Because $\mathrm{Maj}(x) = 1 - \mathrm{Maj}(\neg x)$ on inputs of odd length, the probability that it makes a mistake on input x only depends on $||x| - n/2|$

For an input y of Hamming weight i, denote

$$m_i := \mathbb{P}[P(y) \neq \mathrm{Maj}(y)].$$

We conclude the proof assuming $\epsilon \geq 0$. This will cover the case $\epsilon < 0$ as well, since $\mathbb{P}[P(N^s_{1/2-\epsilon}) = 0] = \mathbb{P}[P(N^s_{1/2+\epsilon}) = 1]$.

Let $p_i := \mathbb{P}[|N^s_{1/2+\epsilon}| = i]$. We can write

$$\begin{aligned}
\mathbb{P}[P(N^s_{1/2+\epsilon}) = 1] &= \sum_{i>s/2} p_i \cdot (1 - m_i) + \sum_{i<s/2} p_i \cdot m_i \\
&= \sum_{i>s/2} (p_i \cdot (1 - m_i) + p_{s-i} \cdot m_{s-i}) \\
&= \sum_{i>s/2} (p_i - m_i(p_i - p_{s-i}))\,.
\end{aligned}$$

Where the last equality holds because by construction $m_i = m_{n-i}$ for every i.

Because $\epsilon \geq 0$ and $i > s/2$, the factor $(p_i - p_{s-i})$ is positive. Hence we bound the sum below if we replace m_i with its maximum value 0.01, obtaining

$$\sum_{i>s/2} (p_i - 0.01(p_i - p_{s-i})) = \mathbb{P}[\mathrm{Maj}(N^s_{1/2+\epsilon}) = 1](1 - 0.01) + 0.01 \cdot \mathbb{P}[\mathrm{Maj}(N^s_{1/2+\epsilon}) = 0].$$

Writing $\mathbb{P}[\mathrm{Maj}(N^s_{1/2+\epsilon}) = 0] = 1 - \mathbb{P}[\mathrm{Maj}(N^s_{1/2+\epsilon}) = 1]$ this becomes

$$\mathbb{P}[\mathrm{Maj}(N^s_{1/2+\epsilon}) = 1](1 - 2 \cdot 0.01) + 0.01.$$

By Lemma 10, $\mathbb{P}[\mathrm{Maj}(N^s_{1/2+\epsilon}) = 1] \geq 1/2 + \Omega(d\epsilon)$. Hence we conclude

$$\mathbb{P}[P(N^s_{1/2+\epsilon}) = 1] \geq (1/2 + \Omega(d\epsilon))(1 - 2 \cdot 0.01) + 0.01 = 1/2 + \Omega(d\epsilon).$$ ◀

At first sight, it may seem suspicious that we can tolerate constant error in the polynomials for majority. Some intuition why this might be OK follows. If $\mathbb{P}[P(N^s_{1/2+\epsilon}) = 1]$ is close to 1, constant error won't bother us, since we are only aiming for advantage close to 1/2.

On the other hand, if that probability is close to 1/2, the loss will recouped thanks to the symmetrization. That is, mistakes will be made on $N^s_{1/2-\epsilon}$ with the same probability, boosting the correctness.

To prove that this result is tight, suppose there is a distribution on degree-d polynomials that solves the $(1/2+\epsilon)$-coin problem with advantage $1/2+\alpha$. If we sample $O(1/\alpha)^2$ times independently these polynomials, and compute the majority, a Chernoff bound shows that we obtain advantage 0.99. By Lemma 12 the majority computation can be done with error 1/100 by a probabilistic polynomial of degree $O(1/\alpha)$. Composing this with the degree-d polynomial we obtain a probabilistic polynomial of degree $O(d/\alpha)$ which solves the $(1/2+\epsilon)$-coin problem with advantage 0.98. By averaging we can fix the polynomial and still maintain advantage 0.96. Now we can appeal to a result proved in [13] which shows that any such polynomial has degree $\Omega(1/\epsilon)$. Hence, $d/\alpha \geq \Omega(1/\epsilon)$. In other words, $\alpha \leq O(d\epsilon)$, as desired.

6 Proof of Theorem 7

By Yao's argument mentioned in the introduction, it suffices to show that for every distribution Z on $\{0,1\}^n$ there exists a polynomial which computes Maj correctly with probability $1/2+\Omega(d^2/n)$ over Z. By averaging, it suffices to give, for any Z, a distribution $P=P(Z)$ on polynomials that computes Maj correctly with the same probability over both the input drawn from Z and P. Our polynomials will depend only on the Hamming weight $|Z|$ of Z.

Case: $\mathbb{P}[||\boldsymbol{Z}| - \boldsymbol{n/2}| \geq \boldsymbol{d}] \geq \mathbf{0.01}$

Let $M : \{0,1\}^{O(d^2)} \to \{0,1\}$ be the probabilistic polynomial of degree $O(d)$ from Lemma 14. Define $P(x)$ to compute M on an odd number $s := O(d^2)$ bits y selected uniformly at random from x. We first analyze the performance of this polynomial on any fixed input x of Hamming weight $w = n(1/2+\epsilon)$. Note that y has the distribution $N^s_{1/2+\epsilon}$

We have

$$\mathbb{P}[P(x) = \mathrm{Maj}(x)] = \mathbb{P}[M(N^s_{1/2+\epsilon}) = \mathrm{Sign}(\epsilon)] \geq 1/2 + \Omega(d\epsilon),$$

By Lemma 14.

Now we use the assumption on Z. With probability $\Omega(1)$, we have $|\epsilon| \geq d/n$, in which case the probability is $\geq 1/2+\Omega(d^2/n)$. In every other case, the probability is at least 1/2. Overall, $\mathbb{P}[P(Z) = \mathrm{Maj}(Z)] \geq 1/2+\Omega(d^2/n)$, concluding this case.

Case: $\mathbb{P}[||\boldsymbol{Z}| - \boldsymbol{n/2}| \leq \boldsymbol{d}] \geq \mathbf{0.99}$

Let P be the polynomial of degree $O(d)$ from Lemma 11 that computes Maj on every input whose Hamming weight w has distance $\leq d$ from $n/2$. In this case, we have $\mathbb{P}[P(Z) = \mathrm{Maj}(Z)] \geq \mathbb{P}[||Z| - n/2| \leq d] \geq 0.99$.

7 Proof of Theorem 9

As in the proof of Theorem 7, it suffices to show that for every distribution Z on $\{0,1\}^n$ there exists a distribution on polynomials which computes h_2 well over Z. Our polynomials will again depend only on the Hamming weight $|Z|$ of Z.

From the definition of g_2 we have that on inputs x with $n/2+t$ zeroes and $n/2-t$ ones we have

$$g_2(x) = 2t^2 - n/2.$$

As a function of t, this is a parabola which roots at $t = \pm\sqrt{n/4} = \pm n \cdot r$ where $r := 1/\sqrt{4n}$. Let $L := [-nr-d, -nr+d] \bigcap \mathbb{Z}$ and $R := [nr-d, nr+d] \bigcap \mathbb{Z}$ be the integers at distance $\leq d$ from either root.

Case: $\mathbb{P}[|Z| - n/2 \in L \bigcup R|] \geq 0.99$

In this case we use polynomials of degree $O(d)$ from Lemma 11 to compute h_2 correctly on $L \bigcup R$. This definition is possible if the elements in L and R are not congruent modulo $2^{\ell+100}$. That is, we require that for every x, y of absolute value at most d the values $-nr+x$ and $nr+y$ are not congruent modulo $2^{\ell+100}$. For this it suffices that the remainder of $2nr = \sqrt{n}$ divided by $2^{\ell+100}$ is not in $[0, 2d] \cup [2^{\ell+100} - 2d, 2^{\ell+100}]$, given by assumption.

Case: $\mathbb{P}[|Z| - n/2 \in L \bigcup R|] < 0.01$

Consider the following process. With probability $1/(1+4r^2)$ pick two uniform elements from the input and output their XOR; otherwise output zero. On any input with weight $1/2+\alpha$ the probability the process outputs 1 is

$$1/2 + \epsilon := \frac{1/2 + 2\alpha^2}{1+4r^2} = \frac{1/2 + 2(r+\alpha-r)^2}{1+4r^2} = 1/2 + \frac{2\left(\alpha^2 - r^2\right)}{1+4r^2}.$$

Note $\epsilon = 0$ exactly when $\alpha = \pm r$, and $\epsilon < 0$ exactly when α is between these two roots.

Now repeat the process s times to generate $N^s_{1/2+\epsilon}$, and run the polynomial from Lemma 14 on them.

On any input, we compute correctly with probability $\geq 1/2$.

Assume now the input weight is not in $L \bigcup R$. Let $c := 2/(1+4r^2)$.

If $|\alpha| \geq r + d/n$ then $\epsilon \geq c(d^2/n^2 + 2rd/n) = \Omega(rd/n)$.

If $|\alpha| \leq r - d/n$ then $\epsilon \leq c(d^2/n^2 - 2rd/n) = -\Omega(rd/n)$.

In either case, by Lemma 14 we compute h_2 correctly with probability $1/2 + d \cdot \Omega(rd/n) = 1/2 + \Omega(d^2/n^{3/2})$.

8 Proof of Theorem 2

We essentially define f to have correlation zero with h_2 on every Hamming weight, except for s Hamming weights where the value of g_2 is as small as possible. Let $M := \{n/2 + \sqrt{n}/2, n/2 + \sqrt{n}/2 - 1, \ldots, n/2 + \sqrt{n}/2 - s + 1\}$ and let Z_i be the inputs with i zeroes. For $x \in Z_i$ and $i \in M$ let $f(x) = h_2(x) = -1$. For $x \in Z_0$ let, say, $f(x) = 1$ and for $x \in Z_n$ let $f(x) = -1$. For any other Z_i, divide the inputs in Z_i in two equals parts, which is possible by Lucas' theorem because n is a power of 2. Let f be 1 on one part and -1 on the other.

Consider $\mathbb{E}_x[f(x)h_2(x)]$. We have $\mathbb{E}_x[f(x)h_2(x)|x \in Z_0 \cup Z_n] = 0$, and $\mathbb{E}_x[f(x)h_2(x)|x \in Z_i] = 0$ if $i \notin M$ and $i \neq 0$ and $i \neq n$, by definition. Otherwise the expectation is 1. Hence $\mathbb{E}_x[f(x)h(x)]$ is the probability that $x \in Z_i$ for some $i \in M$. Assuming $s \leq \sqrt{n}/2$ this probability is $\geq \Omega(s) \cdot \mathbb{P}[x \in Z_{n/2+\sqrt{n}/2}]$. The latter probability is $\Omega(1/\sqrt{n})$ using the standard bound $\binom{n}{n/2+\sqrt{n}/2} = \Theta(2^n/\sqrt{n})$ which can be verified using Stirling's approximation. Hence $\mathbb{E}_x[f(x)h_2(x)] \geq \Omega(s/\sqrt{n})$, and so $\mathbb{P}[f(x) = h_2(x)] \geq 1/2 + \Omega(s/\sqrt{n})$.

Now consider $\mathbb{E}_x[f(x)g_2(x)]$. Again, this is zero unless the number of zeroes of x lies in M. Note that $g_2(x) = 2t^2 - n/2$ on inputs in $Z_{n/2+t}$. The maximum value of $|g_2(x)|$ for inputs with weights in M is for $t = \sqrt{n}/2 - s + 1$ which yields value $|2(\sqrt{n}/2 - s + 1)^2 - n/2| = |2(-s+1)^2 + (-s+1)\sqrt{n}| \leq O(s^2 + s\sqrt{n})$. For $s \leq \sqrt{n}/2$ the latter is $O(s\sqrt{n})$. The chance that the number of zeroes of x lies in M is $\Theta(s/\sqrt{n})$ as noted before. Hence we get $M_2(f) \leq O(s\sqrt{n} \cdot s/\sqrt{n}) \leq O(s^2)$.

Separations for Estimating Large Frequency Moments on Data Streams

Abstract

We study the classical problem of moment estimation of an underlying vector whose n coordinates are implicitly defined through a series of updates in a data stream. We show that if the updates to the vector arrive in the random-order insertion-only model, then there exist space efficient algorithms with improved dependencies on the approximation parameter ε. In particular, for any real $p > 2$, we first obtain an algorithm for F_p moment estimation using $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$ bits of memory. Our techniques also give algorithms for F_p moment estimation with $p > 2$ on arbitrary order insertion-only and turnstile streams, using $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$ bits of space and two passes, which is the first optimal multi-pass F_p estimation algorithm up to $\log n$ factors. Finally, we give an improved lower bound of $\Omega\left(\frac{1}{\varepsilon^2} \cdot n^{1-2/p}\right)$ for one-pass insertion-only streams. Our results separate the complexity of this problem both between random and non-random orders, as well as one-pass and multi-pass streams.

1 Introduction

The efficient computation of statistics has emerged as an increasingly important goal for large databases storing information generated from financial markets, internet traffic, IoT sensors, scientific observations, etc. The one-pass streaming model formally defines an implicit and underlying dataset through sequential updates that arrive one at a time and describe the evolution of the dataset over time. The goal is to aggregate or approximate some statistic of the input data using space that is sublinear in the size of the input.

The frequency moment estimation problem is fundamental to data streams. Since the celebrated paper of Alon, Matias, and Szegedy [1], the frequency moment estimation problem has been a central problem in the streaming model; more than two decades of research [1, 14, 4, 33, 24, 23, 29, 27, 26, 17, 10, 9, 6, 11, 19, 35] has studied the space or time complexity of this problem. We first consider the *insertion-only* model, where updates take the form $u_1, \ldots, u_m$ in a stream of length m and each update u_t is in $[n] = \{1, 2, \ldots, n\}$ for $t \in [m]$. We assume for simplicity that $m \leq \text{poly}(n)$. The updates implicitly define a frequency vector $f \in \mathbb{R}^n$ so that each update effectively increases a coordinate of f in the sense that $f_i = |\{t : u_t = i\}|$ for each $i \in [n]$. Given $p, \varepsilon > 0$, the F_p moment estimation problem is to approximate $F_p = \sum_{i \in [n]} (f_i)^p$ within a $(1 \pm \varepsilon)$ factor. The complexity of

this problem differs greatly for the range of p. For $p > 2$, [4, 14] showed that even for the streaming model, the space usage for F_p-estimation requires polynomial factors in n and m, whereas polylogarithmic factors are achievable for $p \leq 2$ [1, 23, 29, 27, 26, 6].

We initially focus on the frequency moment estimation problem in the *random-order* model, where the set of stream updates to the underlying frequency vector is worst case, but the order of their arrival is uniformly random. As usual, the algorithms we initially consider are only permitted a single pass over the stream, though we later relax this constraint to permit adversarial ordering of updates, as well as both positive and negative integer updates (with magnitude bounded by $\text{poly}(n)$) to the coordinates of the frequency vector in the *turnstile* model. Random-order streams have been shown to be a natural assumption for problems of sorting and selecting in limited space [32] and many other real-world applications [21, 22, 16, 13]. Interestingly, there has sometimes been a significant qualitative difference between random-order streams and adversarial (or arbitrary) order streams [28, 9, 11]. In particular for F_p-moment estimation, the best known lower bound is $\Omega\left(\frac{1}{\varepsilon^2}\right)$ [12]. While the best known upper bound for $p \in (0, 2]$ on arbitrary order insertion-only streams is $\mathcal{O}\left(\frac{1}{\varepsilon^2}\log n\right)$ [1, 27, 26], Braverman *et. al.* [11] gave an algorithm for $p \in (0, 2)$ on random-order streams that only used $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^2} + \log n\right)$ space, where for a function $g(n, \varepsilon)$, we use $\tilde{\mathcal{O}}\left(g(n, \varepsilon)\right)$ to denote a function bounded by $g(n, \varepsilon) \cdot \text{polylog}(g(n, \varepsilon))$. They also gave an algorithm for F_2-moment estimation that only uses $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^2} + \log n\right)$ space, but requires the assumption that $F_2 \geq F_1 \cdot \log n$, i.e., the second moment must be a logarithmic factor larger than the length of the stream.

The above works raise a number of important questions. A tantalizing open question, studied extensively in [25], and dating back to the original work of Alon, Matias, and Szegedy [1], is the exact space complexity of F_p-moment estimation in insertion-only streams. For $p > 2$, the best known upper bound for F_p-moment estimation on arbitrary order insertion-only streams is the minimum of $\mathcal{O}\left(\frac{n^{1-2/p}}{\varepsilon^{20}}\right)$ [9] and $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^2} \cdot n^{1-2/p}\right)$ [17, 19]. For insertion-only streams, the best known lower bound is $\tilde{\Omega}\left(\frac{n^{1-2/p}}{\varepsilon^2 \log n}\right)$ [18]. We summarize these results in Figure 1. There are also major gaps in our understanding for F_p-moment estimation

for $p > 2$ in random order streams. The best known[1] lower bound is $\Omega(n^{1-2.5/p} + \varepsilon^{-2})$ [12], while no upper bounds that do better in random order streams than in arbitrary insertion streams are known.

1.1 Our Results

In this paper, we show a separation not only between random-order and arbitrary insertion-only streams for the F_p moment estimation problem, but also one-pass and multi-pass streams. We first show improved bounds for the F_p moment estimation problem for every $p > 2$ in the random-order insertion-only streaming model.

▶ **Theorem 1.1.** *For $p > 2$, there exists an algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment of a random-order insertion-only stream with probability at least $\frac{2}{3}$, while using total space (in bits) $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$.*

Theorem 1.1 utilizes the random-order model to improve the algorithm on arbitrary-order insertion-only streams using $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^2} \cdot n^{1-2/p}\right)$ space [17, 19], in terms of the dependence on $\frac{1}{\varepsilon}$. We then give an algorithm that uses roughly the same bounds even for the two-pass streaming model, even if the order of the updates is adversarial.

▶ **Theorem 1.2.** *For $p > 2$, there exists a two-pass streaming algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment with probability at least $\frac{2}{3}$.*

- *If the stream is insertion-only, the algorithm uses $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$ bits of space (see Theorem 3.6).*
- *If the steam has turnstile updates, the algorithm uses $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$ bits of space (see Theorem 3.5).*

Theorem 1.2 is the first algorithm to match the lower bound of $\tilde{\Omega}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$ for multi-pass frequency moment estimation [34] up to $\log n$ factors.

By contrast, we give a lower bound for F_p estimation in the one-pass insertion-only streaming model when the order of the updates is adversarial.

▶ **Theorem 1.3.** *For any constant $p > 2$ and parameter $\varepsilon = \Omega\left(\frac{1}{n^{1/p}}\right)$, any one-pass insertion-only streaming algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment of an underlying frequency vector with probability at least $\frac{9}{10}$ requires $\Omega\left(\frac{1}{\varepsilon^2} \cdot n^{1-2/p}\right)$ bits of space.*

Theorem 1.3 improves the lower bound of $\Omega\left(\frac{1}{\varepsilon^2 \log n} \cdot n^{1-2/p}\right)$ for general insertion-only streams for $p > 2$ by [17]. Together, Theorem 1.1 and Theorem 1.3 for small enough $\varepsilon > 0$ show a somewhat surprising result that random-order streams are strictly easier than arbitrary insertion-only streams. Similarly, Theorem 1.2 and Theorem 1.3 together show that multiple passes are strictly easier than a single pass on arbitrary insertion-only streams.

1.2 Our Techniques

We first describe our random-order insertion-only algorithm. At a high level, our algorithm interleaves the recent heavy-hitters algorithm of [7] with a subsampling procedure to estimate the contributions of various level sets toward the frequency moment.

[1] After discussion with the authors, there appears to be an error in [20], which claims a stronger lower bound.

Approximate frequencies of heavy-hitters. The heavy-hitters algorithm of [7] partitions the updates of a random-order stream into blocks of updates. It then randomly chooses a number of coordinates from the universe $[n]$ to test in each block. The heavy-hitters will pass the test and subsequently be tracked across a number of following blocks before estimates for their frequencies are output. Due to the uniformity properties of the random-order stream, the heavy-hitters are sufficiently "spread out", so the algorithm crucially outputs a $(1+\varepsilon)$-approximation to the frequency of each heavy-hitter; algorithms with the same guarantee and space complexity for arbitrary-order streams do not exist [18].

Using level sets to estimate frequency moments. Given the subroutine for finding $(1+\varepsilon)$-approximations to the frequencies of heavy-hitters, we now build upon a standard subsampling approach to estimate the frequency moment. Informally, we conceptually define the level sets so that level set Λ_i contains the coordinates $k \in [n]$ such that $f_k^p \in \left[\frac{F_p}{2^i}, \frac{2F_p}{2^i}\right]$. Since the level sets partition the universe, it is easy to see that if we define the contribution C_i of a level set Λ_i by the sum of the contributions of all their coordinates, $C_i := \sum_{k\in\Lambda_i} f_k^p$, then F_p is just the sum of all the contributions of the level sets, $F_p = \sum_i C_i$.

[24] showed that the contributions of each "significant" level set can be estimated by subsampling at exponentially smaller rates and considering the approximate frequencies of the heavy-hitters in each of the subsamples. For example, a single item with contribution F_p will be detected at the top level, while n items with contribution 1 will be detected at a subsampling level where there are roughly $\Theta\left(\frac{1}{\varepsilon^p}\right)$ survivors in expectation. Crucially, $(1+\varepsilon)$-approximations to the contribution of the surviving heavy-hitters in each subsampling level can then be rescaled by the sampling rate to obtain "good" approximations to the contributions of each significant level set; these very good estimates are not available in standard subsampling schemes for arbitrary order streams.

We adapt this approach for $p > 2$ to obtain Theorem 1.1. The first observation is that an item i with $f_i^p \geq \varepsilon^2 F_p$ should be identified to control the variance but also satisfies $f_i^2 \geq \varepsilon^{4/p}/n^{1-2/p} \cdot F_2$, so we can identify these items using the heavy-hitter algorithm of [7] with the corresponding threshold; this induces the overall $n^{1-2/p}/\varepsilon^{4/p}$ dependency. Moreover as we subsample, the space of the universe decreases in expectation from n to $n/2$ to $n/4$ and so forth. Thus determining the L_p-heavy hitters at lower subsampling rates can be done using significantly less space. We can take advantage of this by requiring that our heavy-hitter algorithm aggressively seeks heavy-hitters with lower thresholds at lower subsampling rates. We can thus achieve a geometric series and avoid an additional $\mathcal{O}(\log n)$ factor in our space.

From random-order to two-pass arbitrary order. As stated, our algorithm necessitates the random-order model so that the heavy-hitter subroutine can output $(1+\varepsilon)$-approximations to the frequencies of heavy-hitters across different subsampling levels; these approximations are then used to obtain $(1+\varepsilon)$-approximations to the contributions of each level set. The state-of-the-art heavy-hitter algorithms in insertion-only [8] or turnstile [15] streams with arbitrary arrival order do not give a $(1+\varepsilon)$-approximation to the frequency of each heavy-hitter while still using space dependency $\frac{1}{\varepsilon^2}$. Fortunately, our approach can be remedied in two-passes over the data stream by first using a pass to identify each of the heavy-hitters across the different subsampling levels and then using the second pass to exactly count their frequencies; note that since $n^{1-2/p}/\varepsilon^{4/p} \geq \frac{1}{\varepsilon^2}$ for $n \geq \frac{1}{\varepsilon^2}$, we are still permitted space to track the frequencies of $\min\left(n, \frac{1}{\varepsilon^2}\right)$ items. We can then obtain $(1+\varepsilon)$-approximations to the contributions of each significant level set, thus obtaining a $(1+\varepsilon)$-approximation to the F_p frequency moment.

Source of the separation. In summary, our improved upper bounds in both the random-order and multi-pass models exploit each model to obtain $(1+\varepsilon)$-approximate frequencies of the heavy-hitters in each subsampling level. Due to the uniformity of heavy-hitters across the stream in the random-order model, we are able to obtain $(1+\varepsilon)$-approximate frequencies by simply tracking the frequency of the heavy-hitters within a small block of the stream and then scaling by the entire length of the stream. For multi-pass models, we are able to identify heavy-hitters in the first pass and exactly track their frequencies in the second pass. By contrast, obtaining $(1+\varepsilon)$-approximate frequencies in adversarially ordered insertion-only streams with the same space guarantees in a single pass cannot be done [18].

Lower bound. To prove our improved lower bound, we first recall the standard approach for showing F_p moment estimation lower bounds in insertion-only streams for $p > 2$ that uses the multiplayer set disjointness problem, e.g., [4, 18]. In this problem, t players have binary vectors of length n and the promise is that the largest coordinate in the sum of all vectors is either (1) at most 1 or (2) exactly t. For $t = \varepsilon^{1/p} n^{1/p}$, the F_p frequency moment of the sum of the binary vectors differs by a factor of $(1+\varepsilon)$ between the two cases, so that a $(1+\varepsilon)$-approximation to F_p solves the multiplayer set disjointness problem. The total communication complexity of the multiplayer set disjointness problem is $\Omega\left(\frac{n}{t}\right)$ so one of the t players communicates $\Omega\left(\frac{n}{t^2}\right)$ bits, and thus a lower bound of $\Omega\left(\frac{1}{\varepsilon^{2/p}} \cdot n^{1-2/p}\right)$ follows.

To improve the ε dependency in the lower bound to $\frac{1}{\varepsilon^2}$, we define the (t, ε, n)-player set disjointness estimation problem so that there are $t+1$ players $P_1, \ldots, P_{t+1}$ with private coins in the standard blackboard model. The first t players each receive a vector $\mathbf{v}_s \in \{0,1\}^n$ for $s \in [t]$, while player P_{t+1} receives an index $j \in [n]$ and a bit $c \in \{0,1\}$. For $\mathbf{u} = \sum_{s\in[t]} \mathbf{v}_s$, the inputs are promised to satisfy $u_i \leq 1$ for each $i \neq j$ and either $u_j = 1$ or $u_j = t$, similar to the multiparty set disjointness problem. With probability at least $\frac{9}{10}$, P_{t+1} must differentiate between the three possible input cases (1) $u_j + \frac{ct}{\varepsilon} \leq t$, (2) $u_j + \frac{ct}{\varepsilon} \in \left\{\frac{t}{\varepsilon}, \frac{t}{\varepsilon}+1\right\}$, or (3) $u_j + \frac{ct}{\varepsilon} = (1+\varepsilon)\frac{t}{\varepsilon}$, where $\varepsilon \in (0,1)$. We call coordinate $j \in [n]$ the *spike* location and show that the (t, ε, n)-player set disjointness estimation problem requires $\Omega\left(\frac{n}{t}\right)$ total communication by using a direct sum embedding to decompose the conditional information complexity into a sum of n single coordinate problems. The intuition is that the first t players do not know the spike location, so they must effectively solve the problem on each coordinate. We then bound the conditional information complexity of each single coordinate problem by the Hellinger distances between inputs for which the outputs differ. We thus apply the same reduction and set $t = \Theta\left(\frac{1}{\varepsilon} \cdot n^{1/p}\right)$ to obtain the desired lower bound.

We remark that the (t, ε, n)-player set disjointness estimation problem can be seen as a generalization of the augmented L_∞ promise problem introduced by [30]. In the augmented L_∞ promise problem, there are only three players, but each coordinate in the first two players' input vectors can be as large as εk for some fixed parameter k. [30] used the augmented L_∞ promise problem to give a lower bound of $\Omega\left(\frac{\log n}{\varepsilon^2} \cdot n^{1-2/p}\right)$ for F_p moment estimation on turnstile streams. However, since their reduction crucially allows players to use turnstile updates, we cannot adapt their techniques to obtain a reduction for insertion-only streams.

1.3 Preliminaries

For a positive integer n, we use the notation $[n]$ to denote the set of integers $\{1, 2, \ldots, n\}$. For a frequency vector f with dimension n and $p \geq 2$, we define the F_p moment function by $F_p(f) := \sum_{k\in[n]} |f_k|^p$ and the L_p norm of f by $L_p(f) = (F_p(f))^{1/p}$. When f is defined through the updates of a insertion-only data stream, we simply use F_p to denote $F_p(f)$.

Thus for a subset $I \subseteq [n]$, the notation $F_p(I)$ is understood to mean $\sum_{k \in I} f_k^p$. We also use the notation $\|f\|_p$ to denote the L_p norm of f. The F_p moment estimation problem and the norm estimation problem are often used interchangeably, as a $(1+\varepsilon)$-approximation algorithm to one of these problems can be modified to output a $(1+\varepsilon)$-approximation to the other using a rescaling of ε, for constant $p > 0$.

We use log and ln to denote the base two logarithm and natural logarithms, respectively. We use $\text{poly}(n)$ to denote a fixed constant degree polynomial in n and $\frac{1}{\text{poly}(n)}$ to denote some arbitrary degree polynomial in n corresponding to the choice of constants in the algorithms. We use $\text{polylog}(n)$ to denote polylogarithmic factors of n.

The L_p-heavy hitters problem is to output all coordinates i such that $f_i \geq \varepsilon \cdot L_p$; such a coordinate is called a *heavy-hitter*. The problem allows coordinates j with $f_j \leq \varepsilon \cdot L_p$ to be output, provided that $f_j \geq \frac{\varepsilon}{2} \cdot L_p$. Moreover, each coordinate output by the algorithm must also have a frequency estimation with additive error at most $\frac{\varepsilon}{2} \cdot L_p$.

2 F_p Estimation for $p > 2$ in Random-Order Streams

In this section, we give our F_p estimation algorithm for $p > 2$. We first introduce an algorithm CountHH on random-order insertion-only streams that outputs an approximate frequency for each L_2 heavy-hitter.

▶ **Theorem 2.1** (Theorem 28 in [7]). *There exists a one-pass algorithm CountHH on random-order insertion-only streams that outputs a list H of ordered pairs $(j, \widehat{f_j})$ such that $\widehat{f_j} = (1 \pm 2\varepsilon) f_j$, for each $j \in H$, where f is the underlying frequency vector. Moreover, we have that $j \in H$ for each $j \in [n]$ with $f_j^2 \geq \varepsilon^2 \cdot F_2$ and $j \notin H$ for each j with $f_j^2 \leq \frac{\varepsilon^2}{2} \cdot F_2$. The algorithm uses $\mathcal{O}\left(\frac{1}{\varepsilon^2}\left(\log^2 \frac{1}{\varepsilon} + \log^2 \log m + \log n\right) + \log m\right)$ bits of space and succeeds with probability at least $38/39$.*

A standard heavy-hitter algorithm such as CountSketch [15] or BPTree [8] outputs each $j \in [n]$ with $f_j^2 \geq \frac{\varepsilon^2}{2} \cdot F_2$ but only finds a constant-factor approximation to the frequency of each heavy-hitter. By comparison, CountHH crucially uses the random-order stream to output a $(1+\varepsilon)$-approximation to the frequency of each heavy-hitter; we defer the full details of the algorithm to the full version of the paper [36]. We use CountHH in a subsampling approach to approximate the contributions of each of the level sets, defined as follows:

▶ **Definition 2.2** (Level sets and contribution). *Given $\widehat{F_p}$ such that $\widehat{F_p} \leq F_p \leq 1.01 \cdot \widehat{F_p}$ and a uniformly random $\zeta \in [1, 2]$, we define the* level set Λ_i *for each $i \in [\log 4n]$ so that*

$$\Lambda_i := \left\{ k \,|\, f_k^p \in \left[\frac{\zeta \cdot \widehat{F_p}}{2^i}, \frac{2\zeta \cdot \widehat{F_p}}{2^i} \right] \right\}.$$

Then we define the contribution C_i *of level set Λ_i to be $C_i := \sum_{k \in \Lambda_i} f_k^p$. We define the* fractional contribution ϕ_i *of level set Λ_i to be the ratio $\phi_i := \frac{C_i}{\zeta \widehat{F_p}}$, so that $\phi_i \in [0, 1.01]$.*

For a stream of length $m = \text{poly}(n)$, let α be an integer such that $2^\alpha > m^p$. We say a level set Λ_i is significant *if its fractional contribution ϕ_i is at least $\frac{\varepsilon}{2\alpha \log n}$. Otherwise, we say the level set is* insignificant.

Observe that it suffices to obtain a multiplicative $\left(1 + \frac{\varepsilon}{2}\right)$-approximation to the contribution of each significant level set and estimate the contributions of the insignificant level sets to be zero, since there are at most $\alpha \log n$ level sets and thus the total additive error from the insignificant level sets is at most $\frac{\varepsilon}{2\alpha \log n} \cdot F_p \cdot \alpha \log n = \frac{\varepsilon}{2} \cdot F_p$.

To estimate the contribution of each level set, we use a combination of CountHH and subsampling to approximate the frequencies of a number of heavy-hitters. The main idea is that subsampling induces a separate substream with a frequency vector with a smaller F_p. Thus the items in the level sets Λ_i with small i will be heavy-hitters of the frequency vector while the items in the level sets Λ_i with larger i will be heavy-hitters of the substreams with smaller sampling rates (if the items are subsampled), due to the lower F_p of the substreams. We can then use a $(1+\varepsilon)$-approximation to the frequency of each sampled heavy-hitter to estimate a $(1+\varepsilon)$-approximation to the contribution of the level set, due to uniformity properties of random-order streams. Note that this is where we crucially use CountHH over other possible heavy-hitter algorithms, due to its advantage of providing $(1+\varepsilon)$-approximate frequencies in the random-order model. We describe our algorithm for F_p estimation with $p > 2$ for random-order insertion-only streams in Algorithm 1.

Algorithm 1 F_p Estimation in the Random-Order Insertion-Only Model, $p > 2$.

Input: Accuracy parameter $\varepsilon \in (0,1)$, $\widehat{F_p} \le F_p \le 1.01 \cdot \widehat{F_p}$
Output: $(1+\varepsilon)$-approximation to F_p.

1: Let $\zeta \in [1,2]$ be chosen uniformly at random and α be a positive integer such that $2^\alpha > m^p$.
2: Let $\eta > \sum_{j \ge 0} 2^{-j(p/16-1/8)}$ be a sufficiently large constant.
3: $\gamma \leftarrow 2^{11}$, $n_i \leftarrow \min\left(\left(\frac{16\alpha p \log n}{\varepsilon^{1-2/p}}\right)^{(2p)/(p-2)}, \frac{10\gamma n}{2^i}\right)$, $\varepsilon_i = \frac{\varepsilon}{16\eta \cdot 2^{i(p/16-1/8)} \log \frac{1}{\varepsilon^2}}$
4: Let I_i^r be a (nested) subset of $[n]$ subsampled at rate $p_i := \min(1, 2^{-i}\gamma)$.
5: Let H_i^r be the output of CountHH with threshold parameter $\frac{(\varepsilon_i)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_i}\right)^{1/2-1/p}$ on the substream induced by I_i^r.
6: **for** $i \in [\alpha \log n]$, $r \le \mathcal{O}(\log \log n)$ **do**
7: $\quad \ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$
8: $\quad$ Let S_i^r be the set of ordered pairs $(j, \widehat{f_j})$ in $H_{\ell_i}^r$ with $\left(\widehat{f_j}\right)^p \in \left[\frac{\zeta \widehat{F_p}}{2^i}, \frac{2\zeta \widehat{F_p}}{2^i}\right]$.
9: $\quad \widehat{C_i} \leftarrow \text{median}_r \frac{1}{p_{\ell_i}} \cdot \left(\sum_{(j,\widehat{f_j}) \in S_i^r} \left(\widehat{f_j}\right)^p\right)$
10: **return** $\tilde{F_p} := \sum_i \widehat{C_i}$

▶ Remark 2.3. We remark that Algorithm 1 is written requiring an input $\widehat{F_p}$ such that $\widehat{F_p} \le F_p \le 1.01 \cdot \widehat{F_p}$ in order to correctly index the level sets defined by Definition 2.2. Algorithm 1 can be rewritten by setting $X = (F_1)^p$ to be an upper bound on F_p and redefining the level sets in Definition 2.2 so that $\Lambda_i := \left\{k \,|\, f_k^p \in \left[\frac{\zeta \cdot X}{2^i}, \frac{2\zeta \cdot X}{2^i}\right]\right\}$. Then we again have $F_p = \sum_i C_i$ across the contributions of all the level sets.

We first show that there exists a subsampling rate such that items in each level set will be reported as a heavy-hitter if they are successfully subsampled. Moreover, each item reported as a heavy-hitter will also be reported with an "accurate" estimate of its frequency.

▶ **Lemma 2.4.** *Let $\varepsilon \in (0,1)$, Λ_i be a fixed level set, and let $\ell := \ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$. For a fixed r, let $\mathcal{E}_1$ be the event that $|I_\ell^r| \le \frac{10\gamma n}{2^\ell}$ and let $\mathcal{E}_2$ be the event that $F_p(I_\ell^r) \le \frac{10\gamma F_p}{2^\ell}$. Conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$, there exists a $(j, \widehat{f_j})$ in S_i^r for each $j \in \Lambda_i \cap I_\ell^r$ such that with probability at least $\frac{7}{8}$,*

$$\left(1 - \frac{\varepsilon}{8\alpha \log n}\right) \cdot f_j^p \le \left(\widehat{f_j}\right)^p \le \left(1 + \frac{\varepsilon}{8\alpha \log n}\right) \cdot f_j^p.$$

Proof. Recall that Algorithm 1 considers H_ℓ^r across $r \le \mathcal{O}(\log\log n)$ independent subsamples of $[n]$, to construct $\widehat{C_i}$ by subsampling at rate $p_\ell := \min(1, 2^{-\ell}\gamma)$.

Suppose $2^i \cdot \varepsilon^2 < \gamma$, so that $\ell := \ell_i = \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\} \le \log\gamma$ since $\varepsilon_k \le \varepsilon$ for all k. Then $p_\ell = \min(1, 2^{-\ell}\gamma) = 1$ and all items are subsampled, i.e., $H_\ell^r = [n]$. By Definition 2.2 of the level sets, each item $j \in \Lambda_i$ satisfies $f_j^p \in \left[\frac{\zeta\cdot\widehat{F_p}}{2^i}, \frac{2\zeta\cdot\widehat{F_p}}{2^i}\right]$. Since $\varepsilon^2 \ge \frac{1}{2^i}$, then we have $f_j^p \ge \varepsilon^2 \cdot \widehat{F_p}$. We also have $\widehat{F_p} \le F_p \le 1.01 \cdot \widehat{F_p}$ and $n^{1/2-1/p} \cdot F_p^{1/p} \ge F_2^{1/2}$. Thus, each item in $j \in \Lambda_i$ satisfies

$$f_j \ge \frac{\varepsilon^{2/p}}{1.01^{1/p}} \cdot F_p^{1/p} \ge \frac{\varepsilon^{2/p}}{1.01^{1/p} n^{1/2-1/p}} \cdot F_2^{1/2},$$

so that $f_j^2 \ge \frac{\varepsilon^{4/p}}{1.01 n^{1-2/p}} F_2$. Then by Theorem 2.1, each item $j \in \Lambda_i$ corresponds to some estimate $\left(\widehat{f_j}\right)^2$ reported by H_ℓ^r output by CountHH with threshold $\frac{(\varepsilon_\ell)^{2/p}}{80\gamma}$, as $\varepsilon_\ell \le \varepsilon$ and $n_\ell = n$. Hence, $\widehat{f_j^p}$ is a $\left(1 + \frac{\varepsilon}{8\alpha\log n}\right)$-approximation to f_j^p. Furthermore, CountHH rounds the estimate of the frequency of each heavy-hitter to the nearest power of $\left(1 + \frac{\varepsilon}{16p\alpha\log n}\right)$. Hence, $\widehat{f_j^p}$ is a $\left(1 + \frac{\varepsilon}{8\alpha\log n}\right)$-approximation to f_j^p.

Now suppose $2^i \cdot \varepsilon^2 \ge \gamma$, so that $\ell := \ell_i = \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\} \ge \log\gamma$ and $p_\ell := \min(1, 2^{-\ell}\gamma) \ge \frac{\gamma}{2\cdot 2^i \varepsilon_\ell^2}$. Again by Definition 2.2 of the level sets, each item $j \in \Lambda_i$ satisfies $f_j^p \in \left[\frac{\zeta\cdot\widehat{F_p}}{2^i}, \frac{2\zeta\cdot\widehat{F_p}}{2^i}\right]$. Now if $j \notin I_\ell^r$, then it will not be reported by CountHH. Thus we assume that $j \in I_\ell^r$.

Conditioning on the event $\mathcal{E}_2$, we have that

$$F_p(I_\ell^r) \le \frac{10\gamma F_p}{2^\ell} \le \frac{20\gamma F_p}{2^i\varepsilon^2}.$$

Since $\widehat{F_p} \le F_p \le 1.01 \cdot \widehat{F_p}$, then we have that $f_j^p \ge \frac{\varepsilon^2}{80\gamma} \cdot F_p(I_\ell^r)$ and thus

$$f_j \ge \frac{\varepsilon^{2/p}}{(80\gamma)^{1/p}} \cdot F_p^{1/p}(I_\ell^r).$$

Instead of applying the inequality $n^{1/2-1/p} \cdot F_p^{1/p} \ge F_2^{1/2}$, we note that conditioning on the event $\mathcal{E}_1$, we have that $|I_\ell^r| \le n_\ell = \frac{10\gamma n}{2^\ell}$. Hence, the frequency vector defined by the substream I_ℓ^r potentially has much smaller support size than n. Thus we have

$$f_j \ge \frac{\varepsilon^{2/p}}{(80\gamma)^{1/p}} \cdot \left(\frac{1}{n_\ell}\right)^{1/2-1/p} \cdot F_2^{1/2}(I_\ell^r).$$

By Theorem 2.1, each item $j \in \Lambda_i \cap I_\ell^r$ corresponds to some estimate $\widehat{f_j}$ reported by H_ℓ^r output by CountHH with threshold $\frac{(\varepsilon_\ell)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_\ell}\right)^{1/2-1/p}$, since $\varepsilon_\ell \le \varepsilon$. Moreover, the estimate of the frequency of each heavy-hitter reported by CountHH is within a factor of $\left(1 + \frac{\varepsilon}{16p\alpha\log n}\right)$ of the true frequency, since $n_i \ge \left(\frac{16\alpha p\log n}{\varepsilon^{1-2/p}}\right)^{(2p)/(p-2)}$ implies that the threshold is at most $\frac{\varepsilon}{16p\alpha\log n}$. Hence for sufficiently small ε, $\left(\widehat{f_j}\right)^p$ is a $\left(1 + \frac{\varepsilon}{8\alpha\log n}\right)$-approximation to f_j^p. ◀

In summary, an item $k \in \Lambda_i$ may not always be sampled by I_ℓ^r, but CountHH outputs a quantity $\widehat{f_k}$ such that $\left(\widehat{f_k}\right)^p$ is a $\left(1 + \frac{\varepsilon}{8\alpha\log n}\right)$-approximation to f_k^p if $k \in I_\ell^r$.

These approximations allow us to recover a $(1+\varepsilon)$-approximation to the F_p moment through Lemma 2.5, which is our main correctness statement and which we now show. Lemma 2.5 claims that the output $\tilde{F}_p$ of our algorithm serves as a $(1+\varepsilon)$-approximation to the F_p moment of the underlying frequency vector. The proof of Lemma 2.5 first considers an idealized process and shows that we obtain "good" approximations to the contributions of each significant level set. Since the contributions of the insignificant level sets can be ignored, we thereby obtain a $(1+\varepsilon)$-approximation to the F_p moment. We then show that when the process is not idealized, the estimate $\tilde{F}_p$ only occurs a small error and thus still guarantees a $(1+\varepsilon)$-approximation to the F_p moment.

▶ **Lemma 2.5.** *With probability at least $\frac{2}{3}$, we have that $|\tilde{F}_p - F_p| \leq \varepsilon \cdot F_p$.*

Proof. Let Λ_i be a fixed level set and let $\ell := \ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$. Let $k \in \Lambda_i \cap S_\ell^r$, so that $f_k^p \in \left[\frac{\zeta \cdot \widehat{F_p}}{2^i}, \frac{2\zeta \cdot \widehat{F_p}}{2^i}\right]$ and k is subsampled at the level in which its estimated frequency $\left(\widehat{f_k}\right)^p$ is used to estimate the contribution C_i of level set Λ_i. Then Lemma 2.4 shows that we obtain an estimate $\left(\widehat{f_k}\right)^p$ such that

$$\left(1 - \frac{\varepsilon}{8\alpha \log n}\right) \cdot f_k^p \leq \left(\widehat{f_k}\right)^p \leq \left(1 + \frac{\varepsilon}{8\alpha \log n}\right) \cdot f_k^p,$$

with constant probability. In an idealized process, we would have

$$\frac{\zeta \cdot \widehat{F_p}}{2^i} \leq \left(\widehat{f_k}\right)^p \leq \frac{2\zeta \cdot \widehat{F_p}}{2^i},$$

so that the estimate $\left(\widehat{f_k}\right)^p$ is used toward the estimation $\widehat{C_i}$ of contribution C_i of level set Λ_i. However, this may not always be the case because the value of f_k^p may be near the boundary of the interval $\left[\frac{\zeta \cdot \widehat{F_p}}{2^i}, \frac{2\zeta \cdot \widehat{F_p}}{2^i}\right]$ and the value of the estimate $\left(\widehat{f_k}\right)^p$ may lie outside of the interval, so that the estimate $\left(\widehat{f_k}\right)^p$ is used toward the estimation of some other level set $\Lambda_{i'}$. We first analyze an idealized process, so that $\left(\widehat{f_k}\right)^p$ is correctly classified for all k across all level sets, and show that the output is a $(1+\mathcal{O}(\varepsilon))$-approximation to F_p. We then argue that because we randomize the boundaries of each interval due to the selection of ζ, the overall guarantee is only slightly worsened but remains a $(1+\varepsilon)$-approximation to F_p.

Idealized process. We first show that for an idealized process where $\left(\widehat{f_k}\right)^p$ is correctly classified for all k across all level sets, then for a fixed level set i, we have $|\widehat{C_i} - C_i| \leq \frac{\varepsilon_\ell}{2} \cdot F_p$ with probability at least $1 - \frac{1}{\text{polylog}(n)}$. Let $\mathcal{E}_1$ be the event that $|I_\ell^r| \leq \frac{10\gamma n}{2^\ell}$ and let $\mathcal{E}_2$ be the event that $F_p(I_\ell^r) \leq \frac{10\gamma F_p}{2^\ell}$. Lemma 2.4 shows that conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$, then CountHH outputs a $\left(1 + \frac{\varepsilon}{8\alpha \log n}\right)$-approximation to f_k^p if $k \in I_\ell^r$. We thus analyze the approximation $\widehat{C_i^r}$ to C_i for a given set of subsamples, where we define

$$\widehat{C_i^r} := \frac{1}{p_{\ell_i}} \cdot \sum_{(k, \widehat{f_k}) \in S_i^r} \left(\widehat{f_k}\right)^p,$$

so that $\widehat{C_i} = \text{median}_r \widehat{C_i^r}$. Conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$, we note that $\widehat{C_i^r}$ is a $\left(1 + \frac{\varepsilon}{8\alpha \log n}\right)$-approximation to

$$D_i^r := \frac{1}{p_{\ell_i}} \cdot \sum_{k \in S_i^r \cap \Lambda_i} f_k^p.$$

We thus analyze the expectation and variance of D_i^r.

We first analyze the expectation of D_i^r. Note that

$$\mathbb{E}\left[D_i^r\right] = \frac{1}{p_\ell} \cdot \sum_{k \in \Lambda_i} p_\ell \cdot f_k^p = C_i.$$

We next analyze the variance of D_i^r, which results from whether items $k \in \Lambda_i$ are sampled by I_ℓ^r. Since $p_\ell \geq \frac{\gamma}{2 \cdot 2^i \varepsilon_\ell^2}$, we have

$$\text{Var}(D_i^r) = \frac{1}{p_\ell^2} \cdot \sum_{k \in \Lambda_i} p_\ell f_k^{2p} \leq \sum_{k \in \Lambda_i} \frac{2 \cdot 2^i \varepsilon_\ell^2}{\gamma} \cdot f_k^{2p}.$$

Observe that for each $k \in \Lambda_i$, we have $f_k^{2p} \leq \frac{16(F_p)^2}{2^{2i}}$ and $\frac{|\Lambda_i|}{2^i} \leq \phi_i \leq 1$. Thus for $\gamma = 2^{11}$,

$$\text{Var}(D_i^r) \leq |\Lambda_i| \cdot \frac{2 \cdot 2^i \varepsilon_\ell^2}{\gamma} \cdot \frac{16(F_p)^2}{2^{2i}} \leq \phi_i \varepsilon_\ell^2 (F_p)^2 \leq \frac{\varepsilon_\ell^2}{64}(F_p)^2.$$

Hence, by Chebyshev's inequality, we have that

$$\mathbf{Pr}\left[|D_i^r - C_i| \geq \frac{\varepsilon_\ell}{2} \cdot F_p\right] \leq \frac{1}{16}.$$

Since $C_i \leq F_p$ and $\widehat{C_i^r}$ is a $\left(1 + \frac{\varepsilon}{8\alpha \log n}\right)$-approximation to D_i^r, then $\widehat{C_i^r}$ gives an approximation to C_i with additive error at most $\left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_\ell\right) \cdot F_p$ with probability at least $\frac{15}{16}$, conditioned on the events $\mathcal{E}_1$ and $\mathcal{E}_2$, and the correctness of the subroutine CountHH. By Theorem 2.1, the correctness of CountHH occurs with probability at least $\frac{38}{39}$. By a union bound, we have that conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$, then

$$\mathbf{Pr}\left[|\widehat{C_i^r} - C_i| \leq \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_\ell\right) \cdot F_p\right] \geq \frac{7}{8}.$$

For a fixed r, let $\mathcal{E}_1$ be the event that $|I_\ell^r| \leq \frac{10\gamma n}{2^\ell}$ and let $\mathcal{E}_2$ be the event that $F_p(I_\ell^r) \leq \frac{10\gamma F_p}{2^\ell}$. Recall that I_ℓ^r is a nested subset of $[n]$ subsampled at rate $p_\ell := \min(1, 2^{-\ell}\gamma)$. Thus we have $\mathbb{E}\left[|I_\ell^r|\right] \leq \frac{\gamma n}{2^\ell}$, so that by Markov's inequality, we have that $\mathbf{Pr}\left[\mathcal{E}_1\right] \geq \frac{9}{10}$. Similarly, we have $\mathbb{E}\left[F_p(I_\ell^r)\right] \leq \frac{\gamma F_p}{2^\ell}$, so that by Markov's inequality, we have that $\mathbf{Pr}\left[\mathcal{E}_2\right] \geq \frac{9}{10}$. Hence by a union bound, $\mathbf{Pr}\left[\mathcal{E}_1 \wedge \mathcal{E}_2\right] \geq \frac{8}{10}$.

By Lemma 2.4, conditioned on the events $\mathcal{E}_1$ and $\mathcal{E}_2$, we have that $|\widehat{C_i^r} - C_i| \leq \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_\ell\right) \cdot F_p$ for a fixed r, with probability at least $\frac{7}{8}$. Thus by a union bound, we have that $|\widehat{C_i^r} - C_i| \leq \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_\ell\right) \cdot F_p$ for a fixed r, with probability at least $\frac{5}{8}$. Since $\widehat{C_i} = \text{median}_r \widehat{C_i^r}$ across $r \leq \mathcal{O}\left(\log \log n\right)$ iterations, then we have that $|\widehat{C_i} - C_i| \leq \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_\ell\right) \cdot F_p$ with probability at least $1 - \frac{1}{\text{polylog}(n)}$.

By a union bound over the $\alpha \log n$ level sets, then with probability at least $1 - \frac{1}{\text{polylog}(n)}$, we have that $|\widehat{C_i} - C_i| \leq \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_{\ell_i}\right) \cdot F_p$ simultaneously for all $i \in [\alpha \log n]$, where $\ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$. We form our estimate $\tilde{F}_p$ to F_p by setting $\tilde{F}_p := \sum_i \widehat{C_i}$ and we have $F_p = \sum_i C_i$. Since $i \in [\alpha \log n]$, $\ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$, and $\varepsilon_{\ell_i} = \frac{\varepsilon}{16\eta \cdot 2^{\ell_i(p/16-1/8)} \log \frac{1}{\varepsilon^2}}$, then

$$
\begin{aligned}
|\tilde{F}_p - F_p| &= \left|\sum_i \widehat{C_i} - \sum_i C_i\right| \leq \sum_i |\widehat{C_i} - C_i| \leq \sum_i \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_{\ell_i}\right) \cdot F_p \\
&\leq \sum_{i \in [\alpha \log n]} \frac{\varepsilon}{4\alpha \log n} \cdot F_p + \sum_{i : \ell_i \leq \log \frac{1}{\varepsilon^2}} \varepsilon_{\ell_i} \cdot F_p + \sum_{i : \ell_i > \log \frac{1}{\varepsilon^2}} \varepsilon_{\ell_i} \cdot F_p \\
&\leq \frac{\varepsilon}{4} \cdot F_p + \log \frac{1}{\varepsilon^2} \cdot \frac{\varepsilon}{16 \log \frac{1}{\varepsilon^2}} \cdot F_p + \frac{\varepsilon}{16} \cdot F_p,
\end{aligned}
$$

where the last bound on the last term follows from $\eta > \sum_{j \geq 0} 2^{-j(p/16-1/8)}$. Thus we have that $|\tilde{F}_p - F_p| \leq \frac{\varepsilon}{2} \cdot F_p$ with probability at least $1 - \frac{1}{\text{polylog}(n)}$ in an idealized process.

Effects of randomized boundaries. We say that for a fixed r, an item $k \in [n]$ is *misclassified* if there exists a level set Λ_i such that

$$\frac{\zeta \cdot F_p}{2^i} \leq f_k^p \leq \frac{2\zeta \cdot F_p}{2^i},$$

but for an estimate $\left(\widehat{f_k}\right)^p$ output by CountHH on the set $S_{\ell_i}^r$, we have

$$\frac{\zeta \cdot F_p}{2^i} \leq \left(\widehat{f_k}\right)^p \leq \frac{2\zeta \cdot F_p}{2^i}.$$

Recall that by Lemma 2.4, we have for any fixed value of ζ that

$$\left(1 - \frac{\varepsilon}{8\alpha \log n}\right) \cdot f_k^p \leq \left(\widehat{f_k}\right)^p \leq \left(1 + \frac{\varepsilon}{8\alpha \log n}\right) \cdot f_k^p.$$

Since $\zeta \in [1, 2]$, then the probability that item $k \in [n]$ is misclassified is at most $\frac{\varepsilon}{2\alpha \log n}$. Moreover, in the event that item $k \in \Lambda_i$ is misclassified, it can only be misclassified into either level set Λ_{i+1} or level set Λ_{i-1}, since $\left(\widehat{f_k}\right)^p$ is a $\left(1 \pm \frac{\varepsilon}{8\alpha \log n}\right)$ multiplicative approximation to f_k^p.

Thus in the event that item $k \in [n]$ is misclassified, then $\left(\widehat{f_k}\right)^p$ will be rescaled by an incorrect probability, but only by at most a factor of two. Hence the error in the computation of the contribution of f_k^p to some level set Λ_i is at most $2f_k^p$. Then in expectation across all $k \in [n]$, the error due to the misclassification is at most $2F_p \cdot \frac{\varepsilon}{2\alpha \log n} = \frac{\varepsilon}{\alpha \log n} \cdot F_p$. Hence by Markov's inequality for sufficiently large n, the misclassification error is at most an additive $\frac{\varepsilon}{2} \cdot F_p$ with probability at least $\frac{3}{4}$. Therefore in total, we have that $|\tilde{F}_p - F_p| \leq \varepsilon \cdot F_p$ with probability at least $\frac{2}{3}$. ◀

It remains to analyze the space complexity of the algorithm as well as remove some additional unnecessary assumptions.

▶ **Theorem 1.1.** *For $p > 2$, there exists an algorithm that outputs a $(1 + \varepsilon)$-approximation to the F_p moment of a random-order insertion-only stream with probability at least $\frac{2}{3}$, while using total space (in bits) $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$.*

Proof. We first observe that we only require a 1.01-approximation $\widehat{F_p}$ to F_p as the input of Algorithm 1 to create the level sets and analyze accordingly. However, we can instead define the level sets using any upper bound X on $\widehat{F_p}$ by setting level set Λ_i to be the indices $k \in [n]$ for which $f_k^p \in \left[\frac{\zeta X}{2^i}, \frac{2\zeta X}{2^i}\right]$, rather than $\left[\frac{\zeta \widehat{F_p}}{2^i}, \frac{2\zeta \widehat{F_p}}{2^i}\right]$, and the same analysis will follow (see Remark 2.3). Intuitively, the fluidity of the definition of the level sets can be seen from the fact that we randomize the boundaries by going through a multiplicative ζ chosen randomly from $[1, 2]$ anyway, and additional empty level sets will not change the approximation guarantee. Thus by Lemma 2.5, there exists an algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment.

It remains to analyze the space complexity. By Theorem 2.1, CountHH with threshold ε requires $\mathcal{O}\left(\frac{1}{\varepsilon^2}\left(\log^2\frac{1}{\varepsilon} + \log^2\log m + \log n\right) + \log m\right)$ bits of space. Algorithm 1 runs a separate instance of CountHH with threshold $\frac{(\varepsilon_i)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_i}\right)^{1/2-1/p}$ to output a set H_i^r for $r \le \mathcal{O}(\log\log n)$, where γ is a sufficiently large constant. Thus the total space for the CountHH instances across all i for a fixed r is at most

$$C_1 \log n + \left(C_1^2 \log n\right) \cdot \sum_{i \in [\alpha \log n]} \frac{C_1 (n_i)^{1-2/p}}{(\varepsilon_i)^{4/p}},$$

for some positive constants $C_1, \alpha > 0$. In particular, we have $\varepsilon_i = \frac{\varepsilon}{16\eta \cdot 2^{i(p/16-1/8)} \log\frac{1}{\varepsilon^2}}$ and $n_i = \min\left(\left(\frac{16\alpha p \log n}{\varepsilon^{1-2/p}}\right)^{(2p)/(p-2)}, \frac{10\gamma n}{2^i}\right)$ for a sufficiently large constant η. Then the total space for the CountHH instances across all i for a fixed r is at most

$$C_1 \log n + \left(C_1 \log^2 n\right) \cdot \sum_{i=1}^{\alpha \log n} \left(\frac{C_2 n^{1-2/p}}{\varepsilon^{4/p}} \cdot \frac{2^{i(1/4-1/(2p))}}{2^{i(1-2/p)}} \log^2\frac{1}{\varepsilon} + \frac{C_2 \log^2 n}{\varepsilon^2}\right),$$

for some positive constants $C_1, C_2 > 0$. Observe that $\sum_{i=1}^{\infty} \frac{2^{i(1/4-1/(2p))}}{2^{i(1-2/p)}} = \sum_{i=1}^{\infty} \frac{1}{2^{3i(1-2/p)/4}}$ is a geometric series that is upper bounded by an absolute constant. Hence, the total space across all i for a fixed r is at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n \log^2\frac{1}{\varepsilon} + \frac{1}{\varepsilon^2}\log^5 n\right)$ and the total space across all $r \le \mathcal{O}(\log\log n)$ is

$$\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n \log^2\frac{1}{\varepsilon} \log\log n + \frac{1}{\varepsilon^2}\log^5 n \log\log n\right),$$

which is $\tilde{\mathcal{O}}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p}\right)$ space in total, since $n \ge \frac{1}{\varepsilon^2}$ implies $\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \ge \frac{1}{\varepsilon^2}$. ◀

3 F_p Estimation for $p > 2$ in Two-Pass Streams

In this section, we consider two-pass algorithms for F_p estimation, with $p > 2$. For turnstile streams, we require the guarantees of the well-known CountSketch algorithm for finding heavy-hitters.

▶ **Theorem 3.1** ([15]). *There exists an algorithm CountSketch that reports all items $i \in [n]$ such that $f_i \ge \varepsilon L_2$ and no items $j \in [n]$ such that $f_j \le \frac{\varepsilon}{2} \cdot L_2$ in the turnstile streaming algorithm. The algorithm uses $\mathcal{O}\left(\frac{1}{\varepsilon^2}\log^2 n\right)$ bits of space and succeeds with probability $1 - \frac{1}{\mathrm{poly}(n)}$.*

For insertion-only streams, we use the more space-efficient BPTree algorithm for finding heavy-hitters.

▶ **Theorem 3.2** ([8]). *There exists an algorithm BPTree that reports all items $i \in [n]$ such that $f_i \geq \varepsilon L_2$ and no items $j \in [n]$ such that $f_j \leq \frac{\varepsilon}{2} \cdot L_2$ in the turnstile streaming algorithm. The algorithm uses $\mathcal{O}\left(\frac{1}{\varepsilon^2} \log n\right)$ bits of space and succeeds with probability 0.99.*

Recall that the main idea of our one-pass algorithm in the random-order insertion-only streaming model was to subsample at different rates and find $(1+\varepsilon)$-approximations to the frequencies of the heavy-hitters in each subsampling rate, which are then used to form estimates of the contributions of each level set and ultimately estimate of the frequency moment. The random-order setting crucially allowed us to obtain $(1+\varepsilon)$-approximations to the frequencies of the heavy-hitters. By contrast, in an adversarial-order setting, by the time a possible heavy-hitter is detected, a significant fraction of its frequency may have already appeared in the stream if we use a heavy-hitter algorithm with space dependency $\frac{1}{\varepsilon^2}$. Fortunately, in a two-pass setting, we can use the first pass to identify possible heavy-hitters and the second pass to find their frequencies. We give the full details in Algorithm 2, where the subroutine HeavyHitters denotes the algorithm CountSketch of Theorem 3.1 for turnstile streams and BPTree of Theorem 3.2 for insertion-only streams.

Algorithm 2 F_p Estimation on Two-Pass Streams, $p > 2$.

Input: Accuracy parameter $\varepsilon \in (0,1)$, $\widehat{F_p} \leq F_p \leq 1.01 \cdot \widehat{F_p}$
Output: $(1+\varepsilon)$-approximation to F_p

Let $\eta > \sum_{j \geq 0} 2^{-j(p/16-1/8)}$ be a sufficiently large constant.
$\gamma \leftarrow 2^{11}$, $n_i \leftarrow \frac{10\gamma n}{2^i}$, $\varepsilon_i = \frac{\varepsilon}{16\eta \cdot 2^{i(p/16-1/8)} \log \frac{1}{\varepsilon^2}}$
Let I_i^r be a (nested) subset of $[n]$ subsampled at rate $p_i := \min(1, 2^{-i}\gamma)$.
for first pass $i \in [\alpha \log n]$, $r \leq \mathcal{O}(\log \log n)$: **do**
    Let H_i^r be the output of HeavyHitters with threshold parameter $\frac{(\varepsilon_i)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_i}\right)^{1/2-1/p}$ on the substream induced by I_i^r.
for second pass do
    Track the frequency f_k for any coordinate $k \in \cup H_i^r$.
    Let S_i^r be the items $k \in [n]$ with $f_k^p \in \left[\frac{\widehat{F_p}}{2^i}, \frac{2\widehat{F_p}}{2^i}\right]$.
    $\ell_i \leftarrow \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$
    $D_i^r \leftarrow \frac{1}{p_{\ell_i}} \cdot \left(\sum_{k \in S_i^r} f_k^p\right)$
    $\widehat{C_i} \leftarrow \text{median}_r\, D_i^r$
return $\tilde{F}_p := \sum_i \widehat{C_i}$

Using CountSketch as the subroutine for HeavyHitters on two-pass turnstile streams and BPTree as the subroutine for HeavyHitters on two-pass insertion-only streams, we obtain the following guarantees for Algorithm 2. We first show that there exists a subsampling rate such that items in each level set will be reported as a heavy-hitter. The proof is similar to the proof of Lemma 2.4, but we no longer require each reported item to also be reported with a $(1+\varepsilon)$-approximation to their frequency. In fact, this cannot be done in a single pass; we will instead track their frequencies in the second pass.

▶ **Lemma 3.3.** *Let $\varepsilon \in (0,1)$, Λ_i be a fixed level set, and let $\ell := \ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$. For a fixed r, let $\mathcal{E}_1$ be the event that $|I_\ell^r| \leq \frac{10\gamma n}{2^\ell}$ and let $\mathcal{E}_2$ be the event that $F_p(I_\ell^r) \leq \frac{10\gamma F_p}{2^\ell}$. Conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$, then HeavyHitters reports $j \in S_i^r$ for each $j \in \Lambda_i \cap I_\ell^r$ with probability at least $1 - \frac{1}{\text{poly}(n)}$.*

Proof. We consider casework on the value of i. First suppose $2^i \cdot \varepsilon^2 < \gamma$, so that $\ell := \ell_i = \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\} \leq \log \gamma$ since $\varepsilon_k \leq \varepsilon$ for all k. By Definition 2.2 of the level sets, each item $j \in \Lambda_i$ satisfies $f_j^p \in \left[\frac{\zeta \cdot \widehat{F_p}}{2^i}, \frac{2\zeta \cdot \widehat{F_p}}{2^i}\right]$. We also have $\widehat{F_p} \leq F_p \leq 1.01 \cdot \widehat{F_p}$ and $n^{1/2-1/p} \cdot F_p^{1/p} \geq F_2^{1/2}$. Thus, each item in $j \in \Lambda_i$ satisfies

$$f_j \geq \frac{\varepsilon^{2/p}}{1.01^{1/p}} \cdot F_p^{1/p} \geq \frac{\varepsilon^{2/p}}{1.01^{1/p} n^{1/2-1/p}} \cdot F_2^{1/2},$$

so that $f_j^2 \geq \frac{\varepsilon^{4/p}}{1.01 n^{1/2-1/p}} F_2$. Then by Theorem 3.1 or Theorem 3.2, each item $j \in \Lambda_i$ is reported by CountSketch or BPTree with threshold $\frac{(\varepsilon_\ell)^{2/p}}{80\gamma}$, as $\varepsilon_\ell \leq \varepsilon$ and $n_\ell = n$.

Otherwise, suppose $2^i \cdot \varepsilon^2 \geq \gamma$, so that $\ell := \ell_i = \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\} \geq \log \gamma$ and $p_\ell := \min(1, 2^{-\ell}\gamma) \geq \frac{\gamma}{2 \cdot 2^i \varepsilon_\ell^2}$. Again by Definition 2.2 of the level sets, each item $j \in \Lambda_i$ satisfies $f_j^p \in \left[\frac{\zeta \cdot \widehat{F_p}}{2^i}, \frac{2\zeta \cdot \widehat{F_p}}{2^i}\right]$. If $j \notin I_\ell^r$, then j certainly will not be reported by HeavyHitters (regardless of whether HeavyHitters is CountSketch or BPTree). Hence, we assume that $j \in I_\ell^r$.

Conditioning on the event $\mathcal{E}_2$,

$$F_p(I_\ell^r) \leq \frac{10\gamma F_p}{2^\ell} \leq \frac{20\gamma F_p}{2^i \varepsilon^2}.$$

Given $\widehat{F_p} \leq F_p \leq 1.01 \cdot \widehat{F_p}$, then $f_j^p \geq \frac{\varepsilon^2}{80\gamma} \cdot F_p(I_\ell^r)$. Therefore,

$$f_j \geq \frac{\varepsilon^{2/p}}{(80\gamma)^{1/p}} \cdot F_p^{1/p}(I_\ell^r).$$

Rather than applying the inequality $n^{1/2-1/p} \cdot F_p^{1/p} \geq F_2^{1/2}$, we observe that conditioning on the event $\mathcal{E}_1$, it follows that $|I_\ell^r| \leq n_\ell = \frac{10\gamma n}{2^\ell}$. Thus, the frequency vector defined by the substream I_ℓ^r has significantly smaller support size than n, which we can leverage to use a heavy-hitter algorithm with a lower threshold. We have

$$f_j \geq \frac{\varepsilon^{2/p}}{(80\gamma)^{1/p}} \cdot \left(\frac{1}{n_\ell}\right)^{1/2-1/p} \cdot F_2^{1/2}(I_\ell^r).$$

Therefore by Theorem 3.1 or Theorem 3.2, each item $j \in \Lambda_i \cap I_\ell^r$ will be reported by H_ℓ^r output by HeavyHitters with threshold $\frac{(\varepsilon_\ell)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_\ell}\right)^{1/2-1/p}$, since $\varepsilon_\ell \leq \varepsilon$. ◀

We now show our main correctness statement for our two-pass algorithms. Lemma 3.4 proves that the output $\tilde{F}_p$ of our algorithm gives a $(1+\varepsilon)$-approximation to the F_p moment of the underlying frequency vector. Although the guarantees of Lemma 3.4 are similar to the guarantees of Lemma 2.5 are similar, the proof of Lemma 3.4 is much simpler. We show that we obtain $(1+\varepsilon)$-approximations to the contributions of each significant level set, thus obtaining a $(1+\varepsilon)$-approximation to the F_p moment, since the contributions of the insignificant level sets can be ignored. Unlike Lemma 2.5, we need not concern about an idealized process since the frequency of each heavy-hitter is exactly tracked in the second pass of the algorithm over the data stream, so no heavy-hitters can be accidentally misclassified into an incorrect level set.

▶ **Lemma 3.4.** *With probability at least $\frac{2}{3}$, we have that $|\tilde{F}_p - F_p| \leq \varepsilon \cdot F_p$.*

Proof. Let Λ_i be a fixed level set and $\ell := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$. Let $\mathcal{E}_1$ be the event that $|I_\ell^r| \leq \frac{10\gamma n}{2^\ell}$ and let $\mathcal{E}_2$ be the event that $F_p(I_\ell^r) \leq \frac{10\gamma F_p}{2^\ell}$. By Lemma 3.3, CountSketch returns each $k \in \Lambda_i \cap I_\ell^r$ in S_i^r, conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$. Thus in the second pass, Algorithm 2 tracks the contribution f_k^p explicitly, by tracking f_k. We first analyze the approximation $\widehat{C_i^r}$ to C_i for a given set of subsamples, where we define

$$D_i^r := \frac{1}{p_\ell} \cdot \sum_{k \in \Lambda_i \cap I_\ell^r} f_k^p.$$

so that $\widehat{C_i} = \text{median}_r\, D_i^r$. Conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$, we note that

$$\mathbb{E}\left[D_i^r\right] = \frac{1}{p_\ell} \cdot \sum_{k \in \Lambda_i} p_\ell \cdot f_k^p = C_i.$$

We also have

$$\text{Var}(D_i^r) = \frac{1}{p_\ell^2} \cdot \sum_{k \in \Lambda_i} p_\ell f_k^{2p} \leq \sum_{k \in \Lambda_i} \frac{2 \cdot 2^i \varepsilon_\ell^2}{\gamma} \cdot f_k^{2p},$$

since $p_\ell \geq \frac{\gamma}{2 \cdot 2^i \varepsilon_\ell^2}$. Observe that for each $k \in \Lambda_i$, we have $f_k^{2p} \leq \frac{16(F_p)^2}{2^{2i}}$ and $\frac{|\Lambda_i|}{2^i} \leq \phi_i \leq 1$. Thus for $\gamma = 2^{11}$,

$$\text{Var}(D_i^r) \leq |\Lambda_i| \cdot \frac{2 \cdot 2^i \varepsilon_\ell^2}{\gamma} \cdot \frac{16(F_p)^2}{2^{2i}} \leq \phi_i \varepsilon_\ell^2 (F_p)^2 \leq \frac{\varepsilon_\ell^2}{64}(F_p)^2.$$

Hence, by Chebyshev's inequality, we have that

$$\mathbf{Pr}\left[|D_i^r - C_i| \geq \frac{\varepsilon_\ell}{2} \cdot F_p\right] \leq \frac{1}{16}.$$

In summary, D_i^r gives an approximation to C_i with additive error at most $\frac{\varepsilon_\ell}{2} \cdot F_p$ with probability at least $\frac{15}{16}$, conditioned on the events $\mathcal{E}_1$ and $\mathcal{E}_2$, and the correctness of the subroutine CountSketch. Since CountSketch fails with probability at most $1 - \frac{1}{\text{poly}(n)}$ by Theorem 3.1, then by a union bound, we have that conditioned on $\mathcal{E}_1$ and $\mathcal{E}_2$,

$$\mathbf{Pr}\left[|D_i^r - C_i| \leq \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_\ell\right) \cdot F_p\right] \geq \frac{7}{8}.$$

For a fixed r, let $\mathcal{E}_1$ be the event that $|I_\ell^r| \leq \frac{10\gamma n}{2^\ell}$ and let $\mathcal{E}_2$ be the event that $F_p(I_\ell^r) \leq \frac{10\gamma F_p}{2^\ell}$. Recall that I_ℓ^r is a nested subset of $[n]$ subsampled at rate $p_\ell := \min(1, 2^{-\ell}\gamma)$, so that $\mathbb{E}\left[|I_\ell^r|\right] \leq \frac{\gamma n}{2^\ell}$. Thus by Markov's inequality, $\mathbf{Pr}\left[\mathcal{E}_1\right] \geq \frac{9}{10}$. Similarly, $\mathbb{E}\left[F_p(I_\ell^r)\right] \leq \frac{\gamma F_p}{2^\ell}$. Thus by Markov's inequality, $\mathbf{Pr}\left[\mathcal{E}_2\right] \geq \frac{9}{10}$. By a union bound, we first have $\mathbf{Pr}\left[\mathcal{E}_1 \wedge \mathcal{E}_2\right] \geq \frac{8}{10}$. Applying another union bound, we have that $|D_i^r - C_i| \leq \frac{\varepsilon_\ell}{2} \cdot F_p$ for a fixed r, with probability at least $\frac{5}{8}$. Since $\widehat{C_i} = \text{median}_r\, D_i^r$ across $r \leq \mathcal{O}\left(\log \log n\right)$ iterations, then we have that $|\widehat{C_i} - C_i| \leq \frac{\varepsilon_\ell}{2} \cdot F_p$ with probability at least $1 - \frac{1}{\text{polylog}(n)}$.

By a union bound over the indices $i \in [\alpha \log n]$, corresponding to the $\alpha \log n$ level sets, then with probability at least $1 - \frac{1}{\text{polylog}(n)}$, we have that $|\widehat{C_i} - C_i| \leq \frac{\varepsilon_\ell}{2} \cdot F_p$ simultaneously for all $i \in [\alpha \log n]$, where $\ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$. We form our estimate $\tilde{F}_p$ to F_p by setting $\tilde{F}_p := \sum_i \widehat{C_i}$ and we have $F_p = \sum_i C_i$. Since $i \in [\alpha \log n]$, $\ell_i := \min\{k : 2^k > 2^i \cdot \varepsilon_k^2\}$, and $\varepsilon_{\ell_i} = \frac{\varepsilon}{16\eta \cdot 2^{\ell_i(p/16 - 1/8)} \log \frac{1}{\varepsilon^2}}$, then

$$|\tilde{F}_p - F_p| = \left|\sum_i \widehat{C_i} - \sum_i C_i\right| \le \sum_i |\widehat{C_i} - C_i| \le \sum_i \left(\frac{\varepsilon}{4\alpha \log n} + \varepsilon_{\ell_i}\right) \cdot F_p$$
$$\le \sum_{i \in [\alpha \log n]} \frac{\varepsilon}{4\alpha \log n} \cdot F_p + \sum_{i:\ell_i \le \log \frac{1}{\varepsilon^2}} \varepsilon_{\ell_i} \cdot F_p + \sum_{i:\ell_i > \log \frac{1}{\varepsilon^2}} \varepsilon_{\ell_i} \cdot F_p$$
$$\le \frac{\varepsilon}{4} \cdot F_p + \log \frac{1}{\varepsilon^2} \cdot \frac{\varepsilon}{16 \log \frac{1}{\varepsilon^2}} \cdot F_p + \frac{\varepsilon}{16} \cdot F_p,$$

where the last bound on the last term follows from $\eta > \sum_{j \ge 0} 2^{-j(p/16 - 1/8)}$. Therefore with probability at least $1 - \frac{1}{\text{polylog}(n)}$, we have that $|\tilde{F}_p - F_p| \le \frac{\varepsilon}{2} \cdot F_p$. ◀

We now justify the full guarantees claimed by Theorem 1.2. We first handle two passes over a turnstile stream.

▶ **Theorem 3.5.** *For $p > 2$, there exists a two-pass turnstile streaming algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment with probability at least $\frac{2}{3}$, while using $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n \log\log n\right)$ bits of space.*

Proof. Our analysis is similar to the proof of Theorem 1.1. We again observe that by redefining the level sets according to any upper bound on F_p, we do not require a 1.01-approximation $\widehat{F_p}$ to F_p as the input of Algorithm 2. Thus by Lemma 3.4, there exists an algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment on two pass turnstile streams and it remains to analyze the space complexity. By Theorem 3.1, CountSketch with threshold ε requires $\mathcal{O}\left(\frac{1}{\varepsilon^2} \log^2 n\right)$ bits of space to output the indices of the heavy-hitters. Algorithm 2 runs a separate instance of CountSketch with threshold $\frac{(\varepsilon_i)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_i}\right)^{1/2-1/p}$ to output a set H_i^r for $r \le \mathcal{O}(\log\log n)$, where γ is a sufficiently large constant. Thus the total space in the first pass across all indices i for a fixed r is at most

$$\left(C_1 \log^2 n\right) \cdot \sum_{i \in [\alpha \log n]} \frac{(n_i)^{1-2/p}}{(\varepsilon_i)^{4/p}},$$

for some positive constants $C_1, \alpha > 0$. In particular, we have $n_i = \frac{10\gamma n}{2^i}$ and $\varepsilon_i = \frac{\varepsilon}{16\eta \cdot 2^{i(p/16-1/8)} \log \frac{1}{\varepsilon^2}}$ for a sufficiently large constant η. Then the total space in the first pass across all indices i for a fixed r is at most

$$\left(C_1 \log^2 n\right) \cdot \sum_{i=1}^{\infty} \frac{C_2 n^{1-2/p}}{\varepsilon^{4/p}} \cdot \frac{2^{i(1/4-1/(2p))}}{2^{i(1-2/p)}},$$

for some positive constants $C_1, C_2 > 0$. Since $\sum_{i=1}^{\infty} \frac{2^{i(1/4-1/(2p))}}{2^{i(1-2/p)}} = \sum_{i=1}^{\infty} \frac{1}{2^{3i(1-2/p)/4}}$ is a geometric series that is upper bounded by a fixed constant, the total space in the first pass across all i for a fixed r is $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n\right)$. Because $r \in \mathcal{O}(\log\log n)$, then the total space is $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n \log\log n\right)$.

In the second pass, we track the frequencies of each item reported by some instance of CountSketch. Since at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log\log n\right)$ indices can be reported across all instances of CountSketch and $\mathcal{O}(\log n)$ bits of space can be used to track the frequency of each reported index, then the total space for the second pass is at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n \log\log n\right)$. Thus, the total space is $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n \log\log n\right)$. ◀

Finally, we note that to report at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log\log n\right)$ indices of possible heavy-hitters in turnstile streams, CountSketch uses at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log^2 n \log\log n\right)$ space. By the same reasoning, we use space $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n \log\log n\right)$ in insertion-only streams by using the more space efficient BPTree.

▶ **Theorem 3.6.** *For $p > 2$, there exists a two-pass insertion-only streaming algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment with probability at least $\frac{2}{3}$, while using $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n \log\log n\right)$ bits of space.*

Proof. The proof of correctness is exactly the same as that of Theorem 3.5 since using BPTree as the subroutine for HeavyHitters rather than CountSketch offers the same guarantee for insertion-only streams. By Theorem 3.2, BPTree with threshold ε requires $\mathcal{O}\left(\frac{1}{\varepsilon^2} \log n\right)$ bits of space to output the indices of the heavy-hitters. To analyze the space complexity, note that Algorithm 2 runs a separate instance of BPTree with threshold $\frac{(\varepsilon_i)^{2/p}}{80\gamma} \cdot \left(\frac{1}{n_i}\right)^{1/2-1/p}$ to output a set H_i^r for $r \leq \mathcal{O}(\log\log n)$, where γ is a sufficiently large constant. Hence, the first pass across all indices i for a fixed r uses space at most

$$(C_1 \log n) \cdot \sum_{i \in [\alpha \log n]} \frac{(n_i)^{1-2/p}}{(\varepsilon_i)^{4/p}},$$

for some absolute constants $C_1, \alpha > 0$. Since $n_i = \frac{10\gamma n}{2^i}$ and $\varepsilon_i = \frac{\varepsilon}{16\eta \cdot 2^{i(p/16-1/8)} \log \frac{1}{\varepsilon^2}}$ for a sufficiently large constant η, the first pass uses space at most

$$(C_1 \log n) \cdot \sum_{i=1}^{\infty} \frac{C_2 n^{1-2/p}}{\varepsilon^{4/p}} \cdot \frac{2^{i(1/4-1/(2p))}}{2^{i(1-2/p)}},$$

for some absolute constants $C_1, C_2 > 0$, across all indices i for a fixed r. As $\sum_{i=1}^{\infty} \frac{2^{i(1/4-1/(2p))}}{2^{i(1-2/p)}} = \sum_{i=1}^{\infty} \frac{1}{2^{3i(1-2/p)/4}}$ is a geometric series that is upper bounded by some constant, then the total space in the first pass is $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n\right)$ across all indices i for a fixed r. Since $r \leq \mathcal{O}(\log\log n)$, then the total space in the first pass is $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n \log\log n\right)$.

The second pass tracks the frequencies of each item reported by some instance of BPTree. Since at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log\log n\right)$ indices can be reported across all instances of BPTree and $\mathcal{O}(\log n)$ bits of space can be used to track the frequency of each reported index, then the total space for the second pass is at most $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n \log\log n\right)$. Thus, the total space is $\mathcal{O}\left(\frac{1}{\varepsilon^{4/p}} \cdot n^{1-2/p} \log n \log\log n\right)$. ◀

4 Lower Bounds

In this section, we first consider the standard *blackboard* communication model, where a number of players each have a local input and the goal is to solve some predetermined communication problem by sending messages to a shared medium. Each player is assumed to have access to an unlimited amount of private randomness. The sequence of messages on the shared blackboard is called the *transcript* and the maximum length of the transcript over all inputs is the *communication cost* of a given protocol. The communication complexity of f, denoted by $R_\delta(f)$, is the minimal communication cost of all protocols that succeed with probability at least $1-\delta$ for all legal inputs to f.

▶ **Definition 4.1.** *In the (t, ε, n)-player set disjointness estimation problem (t, ε, n) − DisjInfty, there are $t+1$ players $P_1, \ldots, P_{t+1}$ with private coins in the standard blackboard model. For $s \in [t]$, each player P_s receives a vector $\mathbf{v}_s \in \{0,1\}^n$ and player P_{t+1} receives both an index $j \in [n]$ and a bit $c \in \{0,1\}$. For $\mathbf{u} = \sum_{s\in[t]} \mathbf{v}_s$, the inputs are promised to satisfy $u_i \leq 1$ for each $i \neq j$ and either $u_j = 1$ or $u_j = t$. With probability at least $\frac{9}{10}$, P_{t+1} must differentiate between the three possible input cases:*
(1) $u_j + \frac{ct}{\varepsilon} \leq t$
(2) $u_j + \frac{ct}{\varepsilon} \in \left\{\frac{t}{\varepsilon}, \frac{t}{\varepsilon} + 1\right\}$
(3) $u_j + \frac{ct}{\varepsilon} = (1+\varepsilon)\frac{t}{\varepsilon}$,
where $\varepsilon \in (0,1)$. We call coordinate $j \in [n]$ the spike *location.*

Direct sum embedding. We use the direct sum technique by showing that even in the case where $u_i \leq 1$ for all $i \in [n]$, the information cost of the players is sufficiently high. We describe the embedding performed by each player to sample coordinates independently conditioned on the auxiliary variable D. We define the auxiliary variable $D = (D_1, \ldots, D_n)$ by first defining a distribution μ for D_i and $v_{s,i}$, for each fixed coordinate $i \in [n]$ and across all players $s \in [t]$:
(1) $D_i \sim [t]$ uniformly at random, so that D_i determines a player whose input bit will be randomized while the remaining players have input bit zero.
(2) Conditioned on $D_i = s$, then each player P_r with $r \neq s$ sets $v_{r,i} = 0$ while player P_s independently and uniformly sets $v_{s,i} \in \{0,1\}$.
We define the distribution $\zeta := \mu^n$ so that the auxiliary random variable $D = (D_1, \ldots, D_n)$ is the vector whose i-th coordinate determines the player P_{D_i} whose i-th bit $v_{D_i,i}$ in their input vector will vary, while the other players P_s have i-th bit $v_{s,i}$ zero in their vectors, for $s \neq D_i$. Observe that under the distribution ζ, we indeed have $u_i \leq 1$ for each coordinate $i \in [n]$ of $\mathbf{u} = \sum_{s\in[t]} \mathbf{v}_s$. Finally, we fix the input $c = 0$ to player P_{t+1} and pick $j \in [n]$ according to any arbitrary distribution.

▶ **Theorem 4.2.** *The total communication complexity for the (t, ε, n)-player set disjointness estimation problem is $\Omega\left(\frac{n}{t}\right)$.*

We remark that the communication complexity of Theorem 4.2 matches the communication complexity of t-player set disjointness. However, since the problem requires correctness on all inputs, then we can distinguish between the possible input cases by focusing on the specific coordinate j given to player P_{t+1}. By contrast, the reduction of [18] from t-player set disjointness requires an algorithm to "test" all coordinates $i \in [n]$ for the spike location. Thus the reduction requires that an F_p moment estimation algorithm succeeds with probability $1 - \frac{1}{\mathrm{poly}(n)}$, thereby losing a multiplicative $\mathcal{O}(\log n)$ factor and achieving $\Omega\left(\frac{n^{1-2/p}}{\varepsilon^2 \log n}\right)$ in the space lower bound for F_p moment estimation. Since our communication problem gives the specific spike location as input, our reduction only requires an F_p moment estimation algorithm that succeeds with constant probability. We remark that a similar technique was used in [30] for the L_∞ promise problem.

Reduction. Let $t = \Theta\left(\frac{1}{\varepsilon} \cdot n^{1/p}\right)$. We reduce $(1+\varepsilon)$-approximate F_p moment estimation to an instance of (t, ε) − DisjInfty as follows. Let $\mathcal{A}$ be any fixed randomized one-pass insertion-only streaming algorithm that outputs a $\left(1 + \frac{\varepsilon}{3}\right)$-approximation to the F_p moment of the underlying frequency vector with probability at least $\frac{2}{3}$. Recall that the first t players each receive a vector $\mathbf{v}_s$ with $s \in [t]$ and player P_{t+1} receives both a special index $j \in [n]$ and a bit $c \in \{0,1\}$.

- For each $s \in [t]$, player P_s takes the state of the algorithm $\mathcal{A}$, inserts the coordinates of vector $\mathbf{v}_s$, and passes the state of the algorithm to player P_{s+1}.
- Player P_{t+1} takes the state of $\mathcal{A}$, adds the vector $\frac{ct}{\varepsilon} \cdot \mathbf{e}_j$, where $\mathbf{e}_j$ is the elementary vector with a one in position j and zeros elsewhere, and then queries the state of $\mathcal{A}$ to obtain a $\left(1+\frac{\varepsilon}{3}\right)$-approximation to the F_p moment of underlying frequency vector.

▶ **Theorem 4.3.** *For any constant $p > 2$ and parameter $\varepsilon = \Omega\left(\frac{1}{n^{1/p}}\right)$, any one-pass insertion-only streaming algorithm that outputs a $(1+\varepsilon)$-approximation to the F_p moment of an underlying frequency vector with probability at least $\frac{9}{10}$ requires $\Omega\left(\frac{1}{\varepsilon^2} \cdot n^{1-2/p}\right)$ bits of space.*

Proof. Player P_{t+1} receives the state of $\mathcal{A}$ on the input $\mathbf{u} = \sum_{s\in[t]} \mathbf{v}_s$ and induces a frequency vector $\mathbf{x} := \mathbf{u} + \frac{ct}{\varepsilon} \cdot \mathbf{e}_j$. Recall that the inputs are promised to satisfy $u_i \leq 1$ for each $i \neq j$ and either $u_j = 1$ or $u_j = t$. If $c = 0$, then $\mathbf{x} = \mathbf{u}$ so that for a constant $C > 0$ and $t = \frac{C}{\varepsilon} \cdot n^{1/p}$,

$$\|\mathbf{x}\|_p^p \leq F_0 + t^p \leq n + \frac{C^p}{\varepsilon^p} \cdot n.$$

If $c = 1$ and $u_j \leq 1$, then for $t = \frac{C}{\varepsilon} \cdot n^{1/p}$, we have $\|\mathbf{x}\|_p^p \geq \left(\frac{t}{\varepsilon}\right)^p = \frac{C^p}{\varepsilon^{2p}} \cdot n$ and thus

$$\|\mathbf{x}\|_p^p \leq F_0 + \left(1+\frac{t}{\varepsilon}\right)^p \leq n + p + \frac{p \cdot C^p}{\varepsilon^{2p}} \cdot n.$$

Finally, if $c = 1$ and $u_j = t$, then

$$\|\mathbf{x}\|_p^p \geq \left(t+\frac{t}{\varepsilon}\right)^p = \left(1+\frac{1}{\varepsilon}\right)^p \cdot \frac{C^p}{\varepsilon^{2p}} \cdot n.$$

For sufficiently small $\varepsilon \in (0,1)$ with $\varepsilon = \Omega\left(\frac{1}{n^{1/p}}\right)$ and constant $p > 2$, there exists a constant $C > 0$ such that these three cases are separated by a multiplicative $(1+\varepsilon)$. Since $\mathcal{A}$ outputs a $\left(1+\frac{\varepsilon}{3}\right)$-approximation to the F_p moment of the underlying frequency vector, then player P_{t+1} obtains a $\left(1+\frac{\varepsilon}{3}\right)$-approximation to $\|\mathbf{x}\|_p^p$ and can differentiate between the three cases, thus solving $(t,\varepsilon) - \textsc{DisjInfty}$ with probability at least $\frac{9}{10}$. By Theorem 4.2, $\mathcal{A}$ uses $\Omega\left(\frac{n}{t}\right)$ total communication across the $t+1$ players. Therefore, the space complexity of $\mathcal{A}$ is $\Omega\left(\frac{n}{t^2}\right) = \Omega\left(\frac{1}{\varepsilon^2} \cdot n^{1-2/p}\right)$ for $t = \Theta\left(\frac{1}{\varepsilon} \cdot n^{1/p}\right)$. The result then follows from rescaling ε. ◀

Breaking the 2^n Barrier for 5-Coloring and 6-Coloring

Or Zamir ✉
Blavatnik School of Computer Science, Tel Aviv University, Israel

Abstract

The coloring problem (i.e., computing the chromatic number of a graph) can be solved in $O^*(2^n)$ time, as shown by Björklund, Husfeldt and Koivisto in 2009. For $k = 3, 4$, better algorithms are known for the k-coloring problem. 3-coloring can be solved in $O(1.33^n)$ time (Beigel and Eppstein, 2005) and 4-coloring can be solved in $O(1.73^n)$ time (Fomin, Gaspers and Saurabh, 2007). Surprisingly, for $k > 4$ no improvements over the general $O^*(2^n)$ are known. We show that both 5-coloring and 6-coloring can also be solved in $O\left((2-\varepsilon)^n\right)$ time for some $\varepsilon > 0$. As a crucial step, we obtain an exponential improvement for computing the chromatic number of a very large family of graphs. In particular, for any constants $\Delta, \alpha > 0$, the chromatic number of graphs with at least $\alpha \cdot n$ vertices of degree at most Δ can be computed in $O\left((2-\varepsilon)^n\right)$ time, for some $\varepsilon = \varepsilon_{\Delta,\alpha} > 0$. This statement generalizes previous results for bounded-degree graphs (Björklund, Husfeldt, Kaski, and Koivisto, 2010) and graphs with bounded average degree (Golovnev, Kulikov and Mihajlin, 2016). We generalize the aforementioned statement to List Coloring, for which no previous improvements are known even for the case of bounded-degree graphs.

1 Introduction

The problem of k-coloring a graph, or determining the *chromatic number* of a graph (i.e., finding the smallest k for which the graph is k-colorable) is one of the most classic and well studied NP-Complete problems. Computing the chromatic number is listed as one of the first NP-Complete problems in Karp's paper from 1972 [17]. In a similar fashion to k-SAT, the problem of 2-coloring is polynomial, yet k-coloring is NP-complete for every $k \geqslant 3$ (proven independently by Lovász [22] and Stockmeyer [30]). An algorithm solving 3-coloring in sub-exponential time would imply, via the mentioned reductions, that 3-SAT can also be solved in sub-exponential time. It is strongly believed that this is not possible (as stated in a widely believed conjecture called *The Exponential Time Hypothesis* [15]), and thus it is believed that exact algorithms solving k-coloring must be exponential.

There is a substantial and ever-growing body of work exploring exponential-time worst-case algorithms for NP-Complete problems. A 2003 survey of Woeginger [31] covers and refers to dozens of papers exploring such algorithms for many problems including satisfiability,

graph coloring, knapsack, TSP, maximum independent sets and more. Subsequent review article of Fomin and Kaski [10] and book of Fomin and Kratsch [11] further cover the topic of exact exponential-time algorithms.

For satisfiability (commonly abbreviated as SAT), the running time of the trivial algorithm enumerating over all possible assignments is $O^*(2^n)$. No algorithms solving SAT in time $O^*\left((2-\varepsilon)^n\right)$ for any $\varepsilon > 0$ are known, and a popular conjecture called The *Strong* Exponential Time Hypothesis [5] states that no such algorithm exists. On the other hand, it is known that for every fixed k there exists a constant $\varepsilon_k > 0$ such that k-SAT can be solved in $O^*\left((2-\varepsilon_k)^n\right)$ time. A result of this type was first published by Monien and Speckenmeyer in 1985 [23]. A long list of improvements for the values of ε_k were published since, including the celebrated 1998 PPSZ algorithm of Paturi, Pudlák, Saks and Zane [25] and the recent improvement over it by Hansen, Kaplan, Zamir and Zwick [13].

For coloring, on the other hand, the situation is less understood. The trivial algorithm solving k-coloring by enumerating over all possible colorings takes $O^*(k^n)$ time. Thus, it is not even immediately clear that computing the chromatic number of a graph can be done in $O^*(c^n)$ time for a constant c independent of k. In 1976, Lawler [21] introduced the idea of using dynamic-programming to find the minimal number of independent sets covering the graph. The trivial implementation of this idea results in an $O^*(3^n)$ algorithm. More sophisticated bounds on the number of maximal independent sets in a graph and fast algorithms to enumerate over them (Moon and Moser [24], Paull and Unger [26]) resulted in an $O^*(2.4422^n)$ algorithm. This was improved several times (including Eppstein [8] and Byskov [4]), until finally an algorithm computing the chromatic number in $O^*(2^n)$ time was devised by Björklund, Husfeldt and Koivisto in 2009 [3]. This settled an open problem of Woeginger [31]. A relatively recent survey of Husfeldt [14] covers the progress on graph coloring algorithms.

For $k = 3, 4$, better algorithms are known for the k-coloring problem. Schiermeyer [28] showed that 3-coloring can be solved in $O^*(1.415^n)$ time. Beigel and Eppstein [1] gave algorithms solving 3-coloring in $O^*(1.3289^n)$ time and 4-coloring in $O^*(1.8072^n)$ time in 2005. Fomin, Gaspers and Saurabh [9] have improved the running time of 4-coloring to $O^*(1.7272^n)$ in 2007. Unlike the situation in k-SAT, for every $k > 4$ the best known running time for k-coloring is $O^*(2^n)$, the same as computing the chromatic number. Thus, a very fundamental question was left wide open.

▶ **Open Problem 1.** *Can 5-coloring be solved in $O^*\left((2-\varepsilon)^n\right)$ time, for some $\varepsilon > 0$?*

More generally,

▶ **Open Problem 2.** *Can k-coloring be solved in $O^*\left((2-\varepsilon_k)^n\right)$ time, for some $\varepsilon_k > 0$, for every k?*

In our work, we answer Problem 1 affirmatively, the answer extends to 6-coloring as well. We also make steps towards settling Problem 2.

The main technical theorem of our paper follows.

▶ **Definition 3.** *For $0 \leqslant \alpha \leqslant 1$ and $\Delta > 0$ we say that a graph $G = (V(G), E(G))$ is* (α, Δ)-bounded *if it contains at least $\alpha \cdot |V(G)|$ vertices of degree at most Δ.*

▶ **Theorem 4.** *For every $\Delta, \alpha > 0$ there exists $\varepsilon_{\Delta,\alpha} > 0$ such that we can compute the chromatic number of (α, Δ)-bounded graphs in $O\left((2-\varepsilon_{\Delta,\alpha})^n\right)$ time.*

In other words, we can answer Problem 2 affirmatively unless the graph has almost only vertices of super-constant degrees. This theorem generalizes a few previous results. A similar statement for the restricted case of bounded degree graphs was obtained by Björklund et

al. in [2]. Golovnev, Kulikov and Mihajlin [12] used a variant of FFT to get an algorithmic improvement for computing the chromatic number of graphs with bounded average degree. Prior to that, Cygan and Pilipczuk [7] obtained an improvement for the running time required for the Traveling Salesman Problem for graphs with bounded average degree.

It is important to stress that Theorem 4 is much more general than the mentioned results. In particular, (α, Δ)-bounded graphs may have $\Omega(n^2)$ edges (and in turn average degree $\Omega(n)$). The techniques used for graphs with bounded average degree do not extend to this case. Another important difference is that our algorithms extend to finding a coloring of the graph while the mentioned ones solve the decision problem, as later discussed in Section 2.2. Moreover, the generality of Theorem 4 is crucial for our derivation of the reductions resulting in the improvements for 5 and 6 coloring.

In the List Coloring problem (defined formally in Section 2), we are given a graph and lists C_v of colors for each vertex v, and are asked to find a valid coloring of the graph such that each vertex v is colored by some color appearing in its list C_v. In the k-list-coloring problem each list C_v is of size at most k.

List Coloring can also be solved in $O^*(2^n)$ time [3], yet no improvements were known even for the bounded-degree case. We extend Theorem 4 to k-list-coloring, for any constant k, as follows.

▶ **Theorem 5.** *For every $k, \Delta, \alpha > 0$ there exists $\varepsilon_{k,\Delta,\alpha} > 0$ such that we can solve k-list-coloring for (α, Δ)-bounded graphs in $O\left((2 - \varepsilon_{k,\Delta,\alpha})^n\right)$ time, regardless of the size of the universe of colors.*

Using Theorem 4 as a crucial component, we devise the following reductions and corollaries.

▶ **Theorem 6.** *Given an algorithm solving $(k-1)$-list-coloring in time $O\left((2-\varepsilon)^n\right)$ for some constant $\varepsilon > 0$, we can construct an algorithm solving k-coloring in time $O\left((2-\varepsilon')^n\right)$ for some (other) constant $\varepsilon' > 0$. Furthermore, the reduction is deterministic.*

▶ **Theorem 7.** *Given an algorithm solving $(k-2)$-list-coloring in time $O\left((2-\varepsilon)^n\right)$ for some constant $\varepsilon > 0$, we can construct an algorithm solving k-coloring with high probability in time $O\left((2-\varepsilon')^n\right)$ for some (other) constant $\varepsilon' > 0$.*

From which we finally conclude the following, answering Problem 1 affirmatively.

▶ **Theorem 8.** *5-coloring can be solved in time $O\left((2-\varepsilon)^n\right)$ for some constant $\varepsilon > 0$.*

▶ **Theorem 9.** *6-coloring can be solved with high probability in time $O\left((2-\varepsilon)^n\right)$ for some constant $\varepsilon > 0$.*

We note that our 5-coloring algorithm is deterministic, while our 6-coloring algorithm is randomized with an exponentially small one-sided error probability.

As part of our work, we develop a new removal lemma for small subsets. This could be of independent interest. Very roughly, it states that every collection of small sets must have a large sub-collection that can be made pairwise-disjoint by the removal of a small subset of the universe. The exact statement follows.

▶ **Theorem 10.** *Let $\mathcal{F}$ be a collection of subsets of a universe U such that every set $F \in \mathcal{F}$ is of size $|F| \leqslant \Delta$. Let $C > 0$ be any constant. Then, there exist subsets $\mathcal{F}' \subseteq \mathcal{F}$ and $U' \subseteq U$, such that*

- *$|\mathcal{F}'| > \rho(\Delta, C) \cdot |\mathcal{F}| + C \cdot |U'|$, where $\rho(\Delta, C) > 0$ depends only on Δ, C.*
- *The sets in $\mathcal{F}'$ are disjoint when restricted to $U \backslash U'$, i.e., for every $F_1, F_2 \in \mathcal{F}'$ we have $F_1 \cap F_2 \subseteq U'$.*

In the full version of the paper we present an upper bound for the function ρ appearing in Theorem 10. This upper bound implies that the constant ε we can obtain using our technique must be very small.

2 Preliminaries

The terminology used throughout the paper is standard. For a graph G we denote by $V(G)$ and $E(G)$ its vertex-set and edge-set, respectively. Throughout the paper, n is used to denote $|V(G)|$. For a subset $V' \subseteq V(G)$ we denote by $G[V']$ the sub-graph of G induced by V'. For $v \in V$ we denote by $\deg(v)$ the degree of v in G, by $N(v)$ the set of neighbours of v, and by $N[v] := N(V) \cup \{v\}$.

For $0 \leqslant \alpha \leqslant 1$ and $\Delta > 0$ we say that a graph $G = (V(G), E(G))$ is (α, Δ)-*bounded* if it contains at least $\alpha \cdot |V(G)|$ vertices of degree at most Δ. Note that if $\alpha = 1$ this definition coincides with the standard definition of a bounded degree graph.

In the *k-coloring problem*, we are given a graph G and need to decide whether there exists a k-coloring $c : V(G) \to [k]$ of G, such that for every $(u, v) \in E(G)$ we have $c(u) \neq c(v)$. If a graph has a k-coloring, we say that it is k-colorable. In the *chromatic number problem*, we are given a graph G and need to compute $\chi(G)$, the minimal integer k for which G is k-colorable.

In the *k-list-coloring problem*, we are given a graph G and a set $C_v \subseteq U$ of size $|C_v| \leqslant k$ for every $v \in V(G)$, where U is some arbitrary universe. We need to decide whether there exists a coloring $c : V(G) \to U$ such that for every $v \in V(G)$ we have $c(v) \in C_v$ and for every $(u, v) \in E(G)$ we have $c(u) \neq c(v)$.

In a general (a, b)-CSP (Constraint Satisfaction Problem, see [20] or [29] for a complete definition and discussions) we are given a list of *constraints*[1] on the values of subsets of size b of n a-ary variables, and need to decide whether there exists an assignment of values to the variables for which all constraints are satisfied. k-coloring and k-list-coloring are examples of $(k, 2)$-CSP problems. k-SAT is an example of a $(2, k)$-CSP problem.

2.1 Inverse Möbius Transform

Let U be an n-element set. The *Inverse Möbius* transform (sometimes also called the *Zeta* transform) [27] maps a function $f : P(U) \to \mathbb{R}$ from the power-set of U into another function $\hat{f} : P(U) \to \mathbb{R}$ defined as

$$\hat{f}(X) = \sum_{Y \subseteq X} f(Y).$$

Naively, $\hat{f}(X)$ is computed using $2^{|X|}$ additions. Thus, we can compute all values of $\hat{f}$ in a straightforward manner with $O(3^n)$ operations. Yates' method from 1937 ([19, 32]) improves on the above and computes all values of $\hat{f}$ using just $O(n2^n)$ operations. The resulting algorithm is usually called *the fast möbius transform* or *the fast zeta transform* ([3, 18]). The authors of [2] and [3] use the fast Inverse Möbius Transform to devise algorithms for combinatorial optimization problems such as computing the chromatic and the domatic numbers of a graph. The algorithm of [3] is summarized in Section 3.

A description of Yates' method follows.

---

[1] A general constraint on a set $x_1, \ldots, x_b$ of a-ary variables is a subset T of the a^b possible assignments in $\{x_1, \ldots x_b\} \to [a]$. The constraint is satisfied by an assignment c, possibly on more variables, if $c|_{\{x_1, \ldots x_b\}} \in T$.

▶ **Lemma 11.** *The Inverse Möbius Tranform $\hat{f}$ for some function $f : P(U) \to \mathbb{R}$ can be computed in $O(n2^n)$ time, where $n := |U|$.*

Proof. Denote by $U = \{u_1, \ldots, u_n\}$ some enumeration of U's elements. Denote by $f_0 := f$. We preform n iterations for $i = 1, \ldots, n$, in which we compute all values of the function $f_i : P(U) \to \mathbb{R}$ defined using f_{i-1} as follows.

$$f_i(X) = \begin{cases} f_{i-1}(X) + f_{i-1}(X \backslash \{u_i\}) & \text{if } u_i \in X \\ f_{i-1}(X) & \text{otherwise} \end{cases}$$

Namely, in the i-th iteration we add the values the function gets in the sub-cube defined by $u_i = 0$ to the corresponding values in the sub-cube defined by $u_i = 1$.

A simple induction on i shows that $f_i(X) = \sum_{Y \in S_i(X)} f(Y)$ where $S_i(X)$ is the set of all subsets $Y \subseteq X$ such that

$$\{u_j \in Y \mid j > i\} = \{u_j \in X \mid j > i\}$$

In particular, by the end of the algorithm $f_n = \hat{f}$. ◀

2.2 Decision versus Search

The k-coloring problem can be stated in two natural ways. In the first, given a graph G decide whether it can be colored using k colors. The second, given a graph G return a k-coloring for it if one exists, or say that no such coloring exists. A few folklore reductions show that the two problems have the same running time up to polynomial factors. We state one for completeness. Others appear in the survey of [14].

▶ **Lemma 12.** *Let $\mathcal{A}$ be an algorithm deciding whether a graph is k-colorable in $O(T(n))$ time. Then, there exists an algorithm $\mathcal{A}'$ that finds a k-coloring for G, if one exists, in $O^*(T(n))$ time.*

Proof. We describe $\mathcal{A}'$. First, use $\mathcal{A}(G)$ to decide whether G is k-colorable, if it returns *False* we return that no k-coloring exists. Otherwise, repeat the following iterative process. For every pair of distinct vertices $(u, v) \notin E(G)$ that is not an edge of G, use $\mathcal{A}\left(G' := (V(G), E(G) \cup \{(u, v)\})\right)$ to check whether G stays k-colorable after adding (u, v) as an edge. If it does, add (u, v) to $E(G)$. We stop when no such pair (u, v) exists.

The reader can verify that the resulting graph must be a complement of k disjoint cliques, and thus we can easily construct a k-coloring. ◀

A problem comes up while trying to use this type of reductions in the settings of this paper. The aforementioned reduction adds edges to the graph, and therefore increases the degrees of vertices. In particular, we cannot use it (or other similar reductions) in a black-box manner for statements like Theorem 4. The algorithm of [2] solves the decision version of k-coloring for bounded degree graphs, and cannot be trivially converted into an algorithm that finds a coloring. The algorithms presented in this paper, on the other hand, can be easily converted into algorithms that find a k-coloring. This is briefly discussed later in Section 4.4.

3 Overview of the $O^*(2^n)$ algorithm

In this section we present a summary of Björklund, Husfeldt and Koivisto's algorithm from [3]. We present a concise variant of their work that applies specifically to the coloring problem. The original paper covers a larger variety of set partitioning problems and thus the description in this section is simpler.

We begin by making the following very simple observation, yielding an equivalent phrasing of the coloring problem.

▶ **Observation 13.** *A graph G is k-colorable if and only if its vertex set $V(G)$ can be* covered *by k independent sets.*

A short outline of the algorithm follows, complete details appear below. We need to decide whether $V(G)$ can be covered by k independent sets. In order to do so, we compute the number of independent sets in every induced sub-graph and then use a simple inclusion-exclusion argument in order to compute the number of (ordered) covers of $V(G)$ by k independent sets. We are interested in whether this number is positive.

▶ **Definition 14.** *For a subset $V' \subseteq V(G)$ of vertices, let $i(G[V'])$ denote the number of independent sets in the induced sub-graph $G[V']$.*

We next show that using dynamic programming, we can quickly compute these values.

▶ **Lemma 15.** *We can compute the values of $i(G[V'])$ for all $V' \subseteq V$ in $O^*(2^n)$ time.*

Proof. Let $v \in V'$ be an arbitrary vertex contained in V'. The number of independent sets in V' that do not contain v is exactly $i(G[V' \backslash \{v\}])$. On the other hand, the number of independent sets in V' that do contain v is exactly $i(G[V' \backslash N[v]])$. Thus, we have

$$i(G[V']) = i(G[V' \backslash \{v\}]) + i(G[V' \backslash N[v]]).$$

We note that both $V' \backslash \{v\}$ and $V' \backslash N[v]$ are of size strictly less than $|V'|$. Thus, we can compute all 2^n values of $i(G[\cdot])$ using dynamic programming processing the sets in non-decreasing order of size. ◀

Consider the expression

$$F(G) = \sum_{V' \subseteq V(G)} (-1)^{|V(G)|-|V'|} \cdot i(G[V'])^k.$$

Using the values of $i(G[\cdot])$ computed in Lemma 15, we can easily compute the value of $F(G)$ by directly evaluating the above expression in $O^*(2^n)$ time.

▶ **Lemma 16.** *Let $S_1 \subseteq S_2$ be sets. It holds that*

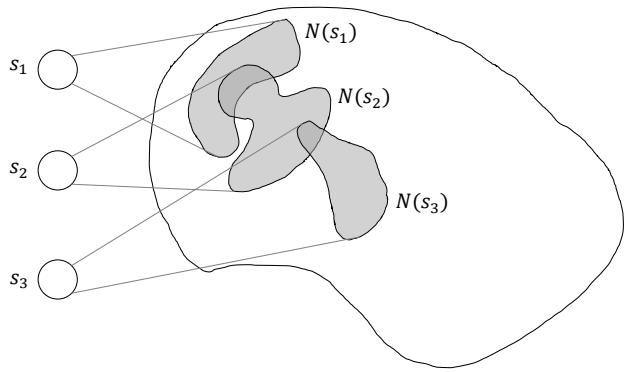
$$\sum_{S_1 \subseteq S \subseteq S_2} (-1)^{|S|} = \begin{cases} 0 & \text{if } S_1 \neq S_2 \\ (-1)^{|S_2|} & \text{if } S_1 = S_2 \end{cases}$$

Proof. If $S_1 \subsetneq S_2$ then there exists a vertex $v \in S_2 \backslash S_1$. We can pair each set $S_1 \subseteq S \subseteq S_2$ with $S \triangle \{v\}$, its symmetric difference with $\{v\}$. Clearly, in each pair of sets one is of odd size and one is of even size, and thus their signs cancel each other. Therefore, the sum is zero. In the second case, the claim is straightforward. ◀

▶ **Lemma 17.** *$F(G)$ equals the number of k-tuples $(I_0, \ldots, I_{k-1})$ of independent sets in G such that $V(G) = I_0 \cup \ldots \cup I_{k-1}$.*

Proof. As $i(G[V'])$ counts the number of independent sets in $G[V']$, raising it to the k-th power (namely, $i(G[V'])^k$) counts the number of k-tuples of independent sets in $G[V']$.

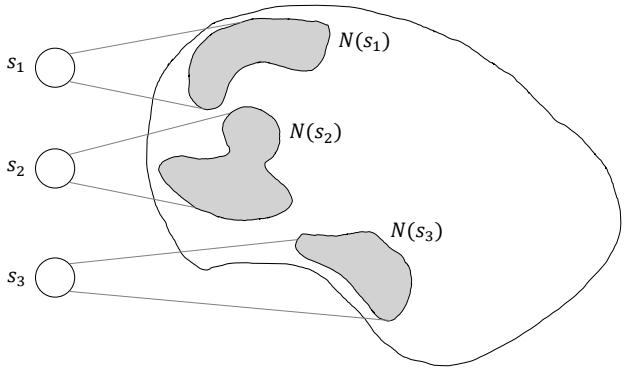
Let $(I_0, \ldots, I_{k-1})$ be a k-tuple of independent sets in G. It appears exactly in terms of the sum corresponding to sets V' such that $I_0 \cup \ldots \cup I_{k-1} \subseteq V' \subseteq V(G)$. Each time this k-tuple is counted, it is counted with a sign determined by the parity of V'. By Lemma 16, the sum of the signs corresponding to sets $I_0 \cup \ldots \cup I_{k-1} \subseteq V' \subseteq V(G)$ is zero if $I_0 \cup \ldots \cup I_{k-1} \neq V(G)$ and one if $I_0 \cup \ldots \cup I_{k-1} = V(G)$. ◀



We conclude with

▶ **Corollary 18.** *$F(G)$ can be computed in time $O^*(2^n)$, and G is k-colorable if and only if $F(G) > 0$.*

4 Faster Coloring Algorithms for (α, Δ)-bounded Graphs



The main purpose of this section is proving Theorem 4.

We first outline our approach. Let G be a graph with a constant chromatic number $\chi(G) \leqslant k$. It is well known that G must contain a large independent set. Let S be an independent set in G. We think of $|S|$ as a constant fraction of $|V(G)|$, when we consider k as a constant. Let $c : (V(G) \backslash S) \to [k]$ be a k-coloring of the induced sub-graph $G[V(G) \backslash S]$. We say that c can be *extended* to a k-coloring of G if there exists a proper k-coloring $c' : V(G) \to [k]$ such that $c'|_{V(G)\backslash S} = c$. For a subset $V' \subseteq V(G) \backslash S$ of vertices, we say that *c does not use the full palette on V'* if $|c(V')| < k$, namely, if c does not use all k colors on the vertices of V'. Clearly, a proper k-coloring c of $V(G) \backslash S$ can be extended to a proper k-coloring of G if and only if $|c(N(s))| < k$ for every $s \in S$. Our approach, on a high-level, is to construct an algorithm that finds an extendable k-coloring of $V(G) \backslash S$. We aim to do so in $O\left(2^{|V(G)\backslash S|} (2 - \varepsilon)^{|S|}\right)$ time.

In Section 4.1 we consider a restricted version of the problem in which the independent set S has the following two additional properties. First, we assume that every vertex $s \in S$ is of degree $\deg(s) \leqslant \Delta$, where Δ is some constant. Second, we assume that no pair of vertices $s_1, s_2 \in S$ share a neighbor in G. Equivalently, the neighborhoods $N(s)$ for every $s \in S$ are all

disjoint. Under these conditions, we present an algorithm that runs in $O\left(2^{|V(G)\setminus S|}\left(2-\varepsilon\right)^{|S|}\right)$ time, where ε depends only on Δ. As ε does not depend on k, we can in fact compute the chromatic number of G exponentially faster than $O^*(2^n)$ if G contains an independent set S with these properties. We also observe that if G is of maximum degree Δ then it contains a large such independent set S. Our algorithm is based on methods that generalize Section 3, and on a simple approach to implicitly compute values of the Inverse Möbius Transform.

In Section 4.2 we modify the algorithm of Section 4.1 and remove the second assumption on S. Namely, we now only assume that S is an independent set and that for every $s \in S$ we have $\deg(s) \leqslant \Delta$. Our algorithm still runs in $O\left(2^{|V(G)\setminus S|}\left(2-\varepsilon\right)^{|S|}\right)$ time. A main ingredient in the modification is a new removal lemma for small subsets. The proof of this combinatorial lemma is given in the full version of the paper and its statement is used in a black-box manner in this section.

In Section 4.3 we extend the result to List Coloring.

4.1 k-coloring bounded-degree graphs

In this subsection we begin illustrating the ideas leading towards proving Theorem 4. We also prove the following (much) weaker statement.

▶ **Theorem 19.** *For every k, Δ there exists $\varepsilon_{k,\Delta} > 0$ such that we can solve k-coloring for graphs with maximum degree Δ in $O\left((2-\varepsilon_{k,\Delta})^n\right)$ time.*

In fact, as a graph G with maximum degree Δ has chromatic number $\chi(G) \leqslant \Delta + 1$, we can compute the chromatic number of a graph with degrees bounded by Δ in time $O\left((2-\varepsilon_{\Delta+1,\Delta})^n\right)$.

As outlined in the beginning of this section, our approach begins by finding a large independent set with some additional properties. We show that a graph with bounded degrees must contain a very large independent set S such that the distance between each pair of vertices in S is at least three. In other words, S is an independent set, and no pair of vertices in S share a neighbor. In particular, the neighborhoods $N(s)$ for $s \in S$ are all disjoint. The core theorem of this subsection is

▶ **Theorem 20.** *Let G be a graph and $S \subseteq V(G)$ a set of vertices such that the distance between each two vertices in S is at least three and the degree of each vertex in S is at most Δ. For any k, we can solve k-coloring for G in $O^*\left(2^{|V(G)|-|S|} \cdot (2-2^{-\Delta})^{|S|}\right)$ time.*

It is important to note that the existence of such a set S is our sole use of the bound on the graph degrees. Note that the bound of Theorem 20 does not depend on k. Thus, we get an exponential improvement for computing the chromatic number of a graph G that contains a large enough set S with the stated properties.

Before proving Theorem 20, we describe a simple algorithm for finding a set S with the required properties in bounded-degree graphs.

▶ **Lemma 21.** *Let G be a graph with maximum degree at most Δ. There exists a set $S \subseteq V(G)$ of at least $\frac{1}{1+\Delta^2} \cdot |V(G)|$ vertices such that the distance between every distinct pair $s_1, s_2 \in S$ is at least three. Furthermore, we can find such S efficiently.*

Proof. We construct S in a greedy manner. We begin with $S = \varnothing$ and $V' = V(G)$. As long as V' is not empty we pick an arbitrary vertex $v \in V'$ and add it to S. We then remove from V' the vertex v and every vertex of distance at most two from it.

By construction, the minimum distance between a pair of vertices in S is at least three. The size of the 2-neighborhood of a vertex is bounded by $1 + \Delta + \Delta \cdot (\Delta - 1) = 1 + \Delta^2$ and thus we get the desired lower bound on the size of S. ◀

Theorem 19 now follows from Lemma 21 and Theorem 20.

Proof of Theorem 19. Let G be a graph of maximum degree at most Δ and let k be an integer. By Lemma 21, we can construct a set S of size $|S| \geqslant \frac{1}{1+\Delta^2} \cdot |V(G)|$ satisfying the conditions of Theorem 20. Thus, by Theorem 20, we can solve k-coloring for G in time

$$O^*\left(2^{n-\frac{1}{1+\Delta^2}\,n} \cdot (2-2^{-\Delta})^{\frac{1}{1+\Delta^2}\,n}\right) = O^*\left(\left(2 \cdot \left(1-2^{-(\Delta+1)}\right)^{\frac{1}{1+\Delta^2}}\right)^n\right).$$ ◀

In the rest of the subsection we prove Theorem 20.

▶ **Definition 22.** *For subsets $V' \subseteq V(G)\backslash S$ and $S' \subseteq S$ denote by $\beta(V', S')$ the number of independent sets I in $G[V']$ that intersect every neighborhood $N(s)$ of $s \in S'$, that is, $I \cap N(s) \neq \varnothing$ for every $s \in S'$.*

Consider, for a subset $S' \subseteq S$, the following sum

$$h(G, S') := \sum_{V' \subseteq V(G)\backslash S} (-1)^{|V(G)|-|V'|}\, \beta\left(V', S'\right)^k.$$

The following proof is almost identical to the proof of Lemma 17 in Section 3.

▶ **Lemma 23.** *$h(G, S')$ is the number of covers of $V(G)\backslash S$ by k-tuples $(I_0, \ldots, I_{k-1})$ of independent sets in $G[V(G)\backslash S]$ such that $I_i \cap N(s) \neq \varnothing$ for every $s \in S'$ and every $0 \leqslant i \leqslant k-1$.*

Proof. Each value of $\beta(V', S')$ counts independent sets in $G[V']$ that intersect every neighborhood $N(s)$ for $s \in S'$.

Each k-tuple $(I_0, \ldots, I_{k-1})$ of that type is counted in terms corresponding to sets V' such that

$$I_0 \cup \ldots \cup I_{k-1} \subseteq V' \subseteq V(G)\backslash S.$$

By Lemma 16 the multiplicity with which such k-tuple is counted is one if

$$I_0 \cup \ldots \cup I_{k-1} = V(G)\backslash S.$$

and zero otherwise. ◀

Consider the following expression.

$$H(G,S) := \sum_{S' \subseteq S} (-1)^{|S'|}\, h(G,S')$$

$H(G,S)$ is the number of covers of $V(G)\backslash S$ by k-tuples of independent sets that *do not use the full palette* on any neighborhood $N(s)$ for $s \in S$. The precise claim follows.

▶ **Lemma 24.** *$H(G,S)$ is the number of covers of $V(G)\backslash S$ by k-tuples $(I_0,\ldots,I_{k-1})$ of independent sets in $G[V(G)\backslash S]$ such that for every $s \in S$ there exists $0 \leqslant i \leqslant k-1$ such that $I_i \cap N(s) = \varnothing$.*

Proof. In Lemma 23 we showed that $h(G,S')$ counts the number of covers of $V(G)\backslash S$ by k-tuples $(I_0,\ldots,I_{k-1})$ of independent sets in $G[V(G)\backslash S]$ such that for every $s \in S'$ and for every $0 \leqslant i \leqslant k-1$ we have $I_i \cap N(s) \neq \varnothing$.

A covering k-tuple of independent sets $(I_0,\ldots,I_{k-1})$ is counted exactly in terms corresponding to subsets S' such that for every $0 \leqslant i \leqslant k-1$ and every $s \in S'$, the independent set I_i intersects the neighborhood $N(s)$. These are exactly the subsets S' such that

$$S' \subseteq \{s \in S \mid \forall 0 \leqslant i \leqslant k-1,\ I_i \cap N(s) \neq \varnothing\}.$$

Using Lemma 16 with $S_1 = \varnothing$ and $S_2 = \{s \in S \mid \forall 0 \leqslant i \leqslant k-1,\ I_i \cap N(s) \neq \varnothing\}$ we deduce that the multiplicity with which the k-tuple is counted is one if

$$\{s \in S \mid \forall 0 \leqslant i \leqslant k-1,\ I_i \cap N(s) \neq \varnothing\} = \varnothing$$

and zero otherwise. ◀

As outlined at the beginning of the section, we now claim that $H(G,S)$ is positive if and only if G is k-colorable. Note that for the correctness of this lemma we still did not use the disjointness of the neighborhoods $N(s)$. We will need this property to improve the computation time.

▶ **Lemma 25.** *Let G be a graph and S an independent set in it. Then, $H(G,S) > 0$ if and only if G is k-colorable.*

Proof. Assume that there exists a k-coloring $c : V(G) \to [k]$ of G. For $0 \leqslant i \leqslant k-1$ denote by

$$I_i := \{v \in V(G)\backslash S \mid c(v) = i\}$$

the subset of $V(G)\backslash S$ colored by i. Each I_i is an independent set as c is a proper coloring of G. Furthermore, for each $s \in S$, the neighborhood $N(s)$ does not intersect $I_{c(s)}$. Thus, $(I_0,\ldots,I_{k-1})$ is a cover of $V(G)\backslash S$ by k independent sets that do not all intersect any neighborhood $N(s)$ of $s \in S$. By Lemma 24, $H(G,S) \geqslant 1$.

On the other hand, if $H(G,S) > 0$ then by Lemma 24 there exists a cover by independent sets and in particular a k-coloring $c : V(G)\backslash S \to [k]$ of $G[V(G)\backslash S]$ such that the full palette is not used on any neighborhood $N(s)$ for $s \in S$. Thus, we may extend c to a k-coloring $c' : V(G) \to [k]$ of the entire graph by coloring each $s \in S$ with a color that does not appear in $c(N(s))$. As S is an independent set, this coloring is proper. ◀

Up to this point, we have formalized the outline from the beginning of this section, reducing k-coloring to a problem of k-coloring with some restrictions the smaller graph $G[V(G)\backslash S]$ and then to the computation of $H(G,S)$.

Unfortunately, $H(G,S)$ is a sum of $2^{|S|}$ terms, each of the form $h(G,S')$ which is a sum of $2^{|V(G)|-|S|}$ terms by itself. Evidently, there are 2^n different terms of the form $\beta(V',S')$ that are used in the definition of $H(G,S)$. Thus, we cannot hope to compute $H(G,S)$ in less than 2^n steps if we need to explicitly examine 2^n terms of the form $\beta(\cdot,\cdot)$. Moreover, it is also not clear how quickly we can compute the values of $\beta(\cdot,\cdot)$.

We begin by explaining how values of $\beta(\cdot)$ can be computed efficiently. The term $h(G,S')$ is a weighted sum of the values $\beta\left(V',S'\right)$ for all $V' \subseteq V(G)\backslash S$. Denote by $\beta_\mu\left(V',S'\right)$ the indicator function that gets the value 1 if V' is an independent set in $G[V(G)\backslash S]$ and for every $s \in S'$ we have $V' \cap N(s) \neq \varnothing$, and 0 otherwise. We can efficiently compute the value of β_μ for a specific input in a straightforward manner (i.e., checking whether it is an independent set that intersects the relevant sets). We observe that

$$\beta\left(V',S'\right) = \sum_{V''\subseteq V'} \beta_\mu\left(V'',S'\right),$$

thus, $\beta = \hat{\beta_\mu}$ as functions of V', and we can compute the values of $\beta\left(V',S'\right)$ for all $V' \subseteq V(G)\backslash S$ in $O^*(2^{|V(G)|-|S|})$ time using the Inverse Möbius Transform presented in Section 2.1.

An improvement to the running time comes from noticing that for many inputs (V',S') the value of $\beta\left(V',S'\right)$ is zero. In particular, if $V' \cap N(s) = \varnothing$, for some $s \in S'$, then $\beta\left(V',S'\right) = 0$ as no subset (and in particular no independent set) in V' intersects $N(s)$. In the computation of $h(G,S')$ we only need to consider terms corresponding to subsets $V' \subseteq V(G)\backslash S$ in which for every $s \in S'$ the intersection $V' \cap N(s)$ is non-empty, as the values of other terms are all zero. We present a variant of the Inverse Möbius Transform that computes only the non-zero values by implicitly setting the others to zero. We then show that for most subsets $S' \subseteq S$ the number of non-zero entries is exponentially smaller than $2^{|V(G)|-|S|}$.

▶ **Definition 26.** *For any $S' \subseteq S$ denote by $B(S') := \{V' \subseteq V(G)\backslash S \mid \forall s \in S'.\ V' \cap N(s) \neq \varnothing\}$ the set of all subsets of $V(G)\backslash S$ intersecting all neighborhoods of S'.*

As we observed above, for every $V' \notin B(S')$ we have $\beta\left(V',S'\right) = 0$. We conclude that

▶ **Observation 27.** *For every S' we have*

$$h(G,S') = \sum_{V'\in B(S')} (-1)^{|V(G)|-|V'|}\, \beta\left(V',S'\right)^k.$$

▶ **Lemma 28.** *If the neighborhoods $N(s)$ are disjoint for all $s \in S'$, then we can compute $h(G,S')$ in $O^*(|B(S')|)$ time.*

Proof. It suffices to compute $\beta\left(V',S'\right)$ for every $V' \in B(S')$ and then use Observation 27. We do so by introducing a variant of the Inverse Möbius Transform that implicitly sets the value of $\beta\left(V',S'\right)$ to zero for every $V' \notin B(S')$.

We first note that

$$B(S') \cong P\left(V(G)\backslash\left(S \cup \bigcup_{s\in S'} N(s)\right)\right) \times \bigtimes_{s\in S'} \left(P(N(s))\backslash\{\varnothing\}\right).$$

Thus, we can efficiently construct a simple bijection between $[|B(S')|]$ and $B(S')$ as a Cartesian product. We can also efficiently check if a set V' belongs to $B(S')$. Let $index : B(S') \to [|B(S')|]$ be a map from $B(S')$ to indices of $[|B(S')|]$. If $V' \notin B(S')$ we define

$index(V') = -1$. By the observation above, we can define *index* in way for which *index* and $index^{-1}$ are efficiently computable. We also arbitrarily order the vertices of $V(G)\backslash S$ as $v_1, v_2, \ldots, v_{|V(G)\backslash S|}$.

We describe the algorithm in pseudo-code.

        f(ℓ) ← 1 ;
    else
        f(ℓ) ← 0 ;
for i in [|V(G)\S|] do
    for ℓ in [|B(S')|] do
        V' ← index^{-1}(ℓ) ;
        if v_i ∈ V' and index(V'\{v_i}) ≠ −1 then
            f(ℓ) ← f(ℓ) + f(index(V'\{v_i}));
```

We view f throughout the algorithm as function $f : B(S') \to \mathbb{N}$. Denote the function represented by f at the end of the first *for* loop by f_0. By definition, $f_0(V') = \beta_\mu(V', S')$ for every $V' \in B(S')$. Denote by f_i the function represented by f at the end of the i-th iteration of the second (outer) *for* loop.

We observe that f_i is defined using f_{i-1} as

$$f_i(V') = \begin{cases} f_{i-1}(V') + f_{i-1}(V'\backslash\{v_i\}) & \text{if } v_i \in V' \\ f_{i-1}(V') & \text{otherwise} \end{cases}$$

where $f_{i-1}(V'\backslash\{v_i\})$ is implicitly defined to be zero if $V'\backslash\{v_i\} \notin B(S')$.

By induction on i, similar to this of Section 2.1, we can show that

$$f_i(V') = \sum_{\substack{V'' \subseteq V' \\ V''\backslash\{v_1,\ldots,v_i\} = V'\backslash\{v_1,\ldots,v_i\}}} f(V'').$$

In particular, by the end of the algorithm $f = \hat{f}_0 = \hat{\beta}_\mu = \beta$ for the entire domain $B(S')$. ◀

After computing $h(G, S')$ for every $S' \subseteq S$ we can compute $H(G, S)$ in $O^*(2^{|S|})$ time. We thus finish the proof of Theorem 20 with the following counting lemma.

▶ **Lemma 29.** *Assume that the neighborhoods $N(s)$ are disjoint for all $s \in S$ and that each neighborhood is of size $|N(s)| \leqslant \Delta$. Then, $\sum_{S' \subseteq S} |B(S')| = O^*\left(2^{|V(G)\backslash S|} \cdot (2 - 2^{-\Delta})^{|S|}\right)$.*

Proof. Denote $n(s) := |N(s)|$. Also denote by $N = \bigcup_{s \in S} N(s)$ all neighbors of vertices of S and by $N^c = (V(G)\backslash S)\backslash N$ their complement in $V(G)\backslash S$. We have

$$\begin{aligned} |B(S')| &= 2^{|N^c|} \cdot \prod_{s \in S'} \left(2^{n(s)} - 1\right) \cdot \prod_{s \in S\backslash S'} 2^{n(s)} \\ &= 2^{|N^c|} \cdot \prod_{s \in S'} \left(1 - 2^{-n(s)}\right) \cdot \prod_{s \in S} 2^{n(s)} \\ &= 2^{|N^c|} \cdot \prod_{s \in S'} \left(1 - 2^{-n(s)}\right) \cdot 2^{|N|} \\ &= 2^{|V(G)\backslash S|} \cdot \prod_{s \in S'} \left(1 - 2^{-n(s)}\right). \end{aligned}$$

For every $s \in S$ we have $n(s) \leqslant \Delta$ and thus $\left(1-2^{-n(s)}\right) \leqslant \left(1-2^{-\Delta}\right)$. Hence,

$$\begin{aligned}|B(S')| &\leqslant 2^{|V(G)\setminus S|} \cdot \prod_{s\in S'} \left(1-2^{-\Delta}\right) \\ &= 2^{|V(G)\setminus S|} \cdot \left(1-2^{-\Delta}\right)^{|S'|}.\end{aligned}$$

Therefore we have

$$\begin{aligned}\sum_{S'\subseteq S} |B(S')| &\leqslant \sum_{S'\subseteq S} 2^{|V(G)\setminus S|} \cdot \left(1-2^{-\Delta}\right)^{|S'|} \\ &= 2^{|V(G)\setminus S|} \cdot \sum_{i=0}^{|S|} \binom{|S|}{i} \left(1-2^{-\Delta}\right)^{i} \\ &= 2^{|V(G)\setminus S|} \cdot \left(2-2^{-\Delta}\right)^{|S|}.\end{aligned}$$

◀

4.2 From bounded-degree graphs to (α, Δ)-bounded graphs

In this section we prove the main technical theorem of the paper.

▶ **Theorem 4.** *For every $\Delta, \alpha > 0$ there exists $\varepsilon_{\Delta,\alpha} > 0$ such that we can compute the chromatic number of (α, Δ)-bounded graphs in $O\left(\left(2-\varepsilon_{\Delta,\alpha}\right)^n\right)$ time.*

We prove the following seemingly weaker statement.

▶ **Theorem 30.** *For every $k, \Delta, \alpha > 0$ there exists $\varepsilon_{k,\Delta,\alpha} > 0$ such that we can solve k-coloring for (α, Δ)-bounded graphs in $O\left(\left(2-\varepsilon_{k,\Delta,\alpha}\right)^n\right)$ time.*

We then note that Theorem 30 in fact implies Theorem 4. Let G be a (α, Δ)-bounded graph. We use Theorem 30 for every $1 \leqslant k \leqslant \Delta$. If we did not find a valid coloring of G, then $\chi(G) \geqslant \Delta + 1$ and we may use a standard argument (fully presented in the full version of the paper) to show that removing all vertices of degree at most Δ does not change $\chi(G)$. By definition of (α, Δ)-bounded graphs, removing these vertices leaves a graph with at most $(1-\alpha)n$ vertices and thus the standard chromatic number algorithm runs in $O^*(2^{(1-\alpha)n})$ time.

As in Section 4.1, we deduce Theorem 30 from the following theorem.

▶ **Theorem 31.** *Let G be a graph and $S \subseteq V(G)$ an independent set in G. Assume that the degree of each vertex in S is at most Δ. Then, we can solve k-coloring for G in $O^*\left(2^{|V(G)|} \cdot (1-\varepsilon_{k,\Delta})^{|S|}\right)$ time, for some constant $\varepsilon_{k,\Delta} > 0$.*

Let G be a graph with a subset $U \subseteq V(G)$ of vertices such that for every $v \in U$ we have $\deg(v) \leqslant \Delta$. In a similar fashion to Lemma 21 of the previous subsection (and even slightly simpler), we can greedily construct a subset $S \subseteq U$ of size $|S| \geqslant \frac{1}{1+\Delta} \cdot |U|$ which is an independent set. Thus, Theorem 31 immediately implies Theorem 4. Unlike the case of Section 4.1, this time the neighborhoods $N(s)$ for $s \in S$ are not necessarily disjoint. Thus, statements comparable to Lemma 29 are not true. Our solution for this problem is surprisingly general. In the full version of the paper we prove Theorem 10. Plugging $\mathcal{F} = \{N(s)\}_{s\in S}$, we get a small set $U' \subseteq V(G)\setminus S$ of graph vertices, and a large subset $S' \subseteq S$ of the independent set, such that the neighborhoods $N(s)$ of $s \in S'$ become pairwise disjoint if we remove the vertices of U' from G. As we want to preserve the correctness of the algorithm, we do not actually remove U' from G, but *enumerate* over the colors they receive in a proper k-coloring, if one exists. The main technical gap is adjusting the algorithm and proofs of Section 4.1 to the case in which some of the graph vertices have fixed colors.

▶ **Theorem 32.** *Let G be a graph, $V_0 \subseteq V(G)$ a subset of its vertices and $c : V_0 \to [k]$ a proper k-coloring of $G[V_0]$. Denote by $V := V(G) \backslash V_0$. Let $S \subseteq V$ be an independent set in G such that the distance in $G[V]$ between each two vertices of S is at least three and the degree in $G[V]$ of each vertex in S is at most Δ. For any k, we can decide whether c can be extended to a k-coloring of the entire graph G in $O^*\left(2^{|V|-|S|} \cdot (2-2^{-\Delta})^{|S|}\right)$ time.*

Throughout the rest of the section, it is important to carefully distinguish $V(G)$ from V. Note that V does not include the vertices of V_0, as their colors are already fixed. For $j \in [k]$, denote by $V_0^j := c^{-1}(j)$ the subset of V_0 colored by j color. Note that $V_0 = \bigcup_{j=1}^{k} V_0^j$. We begin adapting the algorithm by redefining the $\beta(\cdot,\cdot)$ function.

▶ **Definition 33.** *For subsets $V' \subseteq V \backslash S$, $S' \subseteq S$, and a color $j \in [k]$, we denote by $\beta_j(V', S')$ the number of sets $I \subseteq V'$ such that $I \cup V_0^j$ is an independent set in G and that $I \cup V_0^j$ intersects $N(s)$ for every $s \in S'$, that is, for every $s \in S'$ we have $\left(I \cup V_0^j\right) \cap N(s) \neq \varnothing$.*

We also revise the definition of

$$h(G, S') := \sum_{V' \subseteq V \backslash S} (-1)^{|V|-|V'|} \prod_{j=0}^{k-1} \beta_j\left(V', S'\right).$$

The proof of Lemma 23 can be easily revised to show the following.

▶ **Lemma 34.** *$h(G, S')$ is the number of covers of $V \backslash S$ by k-tuples of sets $I_0, \ldots, I_{k-1}$ such that for every $j \in [k]$, $I_j \cup V_0^j$ is an independent set in G and that for every $s \in S'$ and every $j \in [k]$ the set $I_j \cup V_0^j$ intersects the neighborhood $N(s)$.*

Without revising the definition of $H(G, S)$, the proof of Lemma 24 now shows that

▶ **Lemma 35.** *$H(G, S)$ is the number of covers of $V \backslash S$ by k-tuples of sets $I_0, \ldots, I_{k-1}$ such that for every $j \in [k]$, $I_j \cup V_0^j$ is an independent set in G and that for every $s \in S$ the neighborhood $N(s)$ is not intersected by at least one of the k independent sets $\left(I_j \cup V_0^j\right)$ for $j \in [k]$.*

Therefore, we have

▶ **Lemma 36.** *Let G be a graph, $V_0 \subseteq V(G)$ a subset of its vertices and $c : V_0 \to [k]$ a proper k-coloring of $G[V_0]$. Denote by $V := V(G) \backslash V_0$. Let $S \subseteq V$ be an independent set in G. Then, $H(G, S) > 0$ if and only if c can be extended to a k-coloring of G.*

The non-trivial part of the revision and the heart of this subsection, is adjusting the algorithm for computing the values of $h(G, S')$ without increasing the running time.

For $j \in [k]$, denote by

$$S_j := \{s \in S \mid N(s) \cap V_0^j \neq \varnothing\}$$

the set of vertices in S whose neighborhood intersects V_0^j. The key observation of this subsection follows.

▶ **Lemma 37.** *For any $j \in [k]$, $S' \subseteq S$, $V' \subseteq V$, we have*

$$\beta_j\left(V', S'\right) = \beta_j\left(V', S' \cup S_j\right)$$

Proof. For any set $I \subseteq V'$ the set $I \cup V_0^j$ intersects every set in $\{N(s)\}_{s \in S_j}$. In particular, an independent set $I \subseteq V'$ intersects all of $\{N(s)\}_{s \in S'}$ if and only if it intersects all of $\{N(s)\}_{s \in (S' \cup S_j)}$. ◀

Lemma 37 implies that it is enough to compute $\beta_j(V', S')$ only for sets $S' \subseteq S \backslash S_j$, as its other values can be deduced from these as $\beta_j(V', S') = \beta_j(V', S' \backslash S_j)$.

For any $S' \subseteq S$ we again denote by $B(S') := \{V' \subseteq V \backslash S \mid \forall s \in S'.\ V' \cap N(s) \neq \varnothing\}$ the set of all subsets of $V \backslash S$ intersecting all neighborhoods of S'. Note the slight difference from Section 4.1 of considering subsets of $V \backslash S$ and not of $V(G) \backslash S$.

As for every $s \in S \backslash S_j$, $N(s) \cap V_0^j = \varnothing$, we still have that for every $V' \notin B(S')$ the value of $\beta_j(V', S')$ is zero. In particular, we can still use the implicit Inverse Möbius Transform of Lemma 28 and get

▶ **Lemma 38.** *Assume $S' \subseteq S \backslash S_j$. We can compute $\beta_j(V', S')$ for every $V' \in B(S')$ in $O^*(|B(S')|)$ time.*

By Lemma 29 we get

$$\sum_{S' \subseteq S \backslash S_j} |B(S')| = O^*\left(2^{|V \backslash S|} \cdot (2 - 2^{-\Delta})^{|S \backslash S_j|}\right).$$

We can thus compute $\beta_j(V', S')$ for every $S' \subseteq S \backslash S_j$ and every $V' \in B(S')$ in $O^*\left(2^{|V \backslash S|} \cdot (2 - 2^{-\Delta})^{|S \backslash S_j|}\right)$ time. This is the time to emphasise a crucial point. Note that if we would consider every $S' \subseteq S$ instead of $S' \subseteq S \backslash S_j$, then the running time would be $O^*\left(2^{|V \backslash S|} \cdot (2 - 2^{-\Delta})^{|S \backslash S_j|} \cdot 2^{|S_j|}\right)$, as the neighborhoods corresponding to S_j are intersected by V_0^j. This is why we compute every β_j separately, and do so for *all* relevant sets S' before computing even a single value $h(G, S')$. As it always holds that $|S \backslash S_j| \leqslant |S|$, we conclude that

▶ **Corollary 39.** *We can compute $\beta_j(V', S')$ for all $j \in [k]$, $S' \subseteq S \backslash S_j$ and $V' \in B(S')$ in $O^*\left(2^{|V \backslash S|} \cdot (2 - 2^{-\Delta})^{|S|}\right)$ time.*

Note that $k = O^*(1)$.

We are now ready to compute the values of $h(G, S')$. We start by making the following observation.

▶ **Observation 40.** *If $\bigcap_{j=0}^{k-1} S_j \neq \varnothing$ then c cannot be extended to a coloring of G.*

This holds as if some $s \in S$ has neighbors colored in each of the k colors then it cannot be properly colored. We are thus dealing with the case where $\bigcap_{j=0}^{k-1} S_j = \varnothing$.

▶ **Lemma 41.** *For any $S' \subseteq S$ and $V' \subseteq V \backslash S$ such that $V' \notin B(S')$ we have*

$$\prod_{j=0}^{k-1} \beta_j(V', S') = 0.$$

Proof. As $V' \notin B(S')$ there exists some $s \in S$ such that $V' \cap N(s) = \varnothing$. As $\bigcap_{j=0}^{k-1} S_j = \varnothing$, there exists a $j \in [k]$ for which $s \notin S_j$. Thus, $V_0^j \cap N(s) = \varnothing$ as well. We conclude that $\beta_j(V', S') = 0$. ◀

From Lemma 37 and Lemma 41 we conclude that

$$h(G, S') := \sum_{V' \in B(S')} (-1)^{|V| - |V'|} \prod_{j=0}^{k-1} \beta_j\left(V', S' \backslash S_j\right).$$

Thus, we can compute $h(G, S')$ in $O^*(|B(S')|)$ time using the values computed in Corollary 39. Using Lemma 29 once again, we get that

$$\sum_{S' \subseteq S} |B(S')| = O^*\left(2^{|V \setminus S|} \cdot (2 - 2^{-\Delta})^{|S|}\right)$$

which completes the proof of Theorem 32.

We can now prove Theorem 31.

Proof. We apply the removal lemma of Theorem 10 to $\mathcal{F} = \{N(s)\}_{s \in S}$ with C to be chosen later. We thus get a sub-collection $S' \subseteq S$ and a subset of vertices $V_0 \subseteq V(G) \setminus S$ such that $|S'| > \rho(\Delta, C) \cdot |S| + C \cdot |V_0|$ and that for every $s_1, s_2 \in S'$ it holds that $N(s_1) \cap N(s_2) \subseteq V_0$. Denote by $V = V(G) \setminus (S' \cup V_0)$. We enumerate over all k-colorings $c : V_0 \to [k]$. For each coloring c, we check if it is a proper k-coloring of $G[V_0]$ and if so we apply Theorem 32 on G with V_0, c, S'. If any of the applications of Theorem 32 returned that there exists a valid extension of c to a coloring of G, we return that G is k-colorable, and otherwise that it is not.

The running time of the entire algorithm, up to polynomial factors, is

$$\begin{aligned} k^{|V_0|} \cdot \left(2^{|V \setminus S'|} \cdot (2 - 2^{-\Delta})^{|S'|}\right) &= 2^{|V|} \cdot k^{|V_0|} \cdot (1 - 2^{-(\Delta+1)})^{|S'|} \\ &\leqslant 2^{|V|} \cdot k^{|V_0|} \cdot (1 - 2^{-(\Delta+1)})^{\rho(\Delta,C) \cdot |S| + C \cdot |V_0|}. \end{aligned}$$

By picking $C = \frac{\log k}{-\log\left(1 - 2^{-(\Delta+1)}\right)} > 0$ we have

$$k^{|V_0|} \cdot (1 - 2^{-(\Delta+1)})^{C \cdot |V_0|} = 1$$

and thus the running time is bound by

$$2^{|V|} \cdot (1 - 2^{-(\Delta+1)})^{\rho(\Delta,C) \cdot |S|}.$$ ◀

4.3 Generalization to List Coloring

In this Section we deduce Theorem 5.

Proof. Let $G = (V, E)$ be a (α, Δ)-bounded graph with color lists C_v of size at most k for each $v \in V$. Denote by $U = \bigcup_{v \in V} C_v$ the color universe. Note that $|U|$ might be as large as kn, where $n = |V|$. We construct a new graph G' on the set of vertices $V \cup U$ by adding $|U|$ isolated vertices to the graph G and then connecting each node $v \in V$ to every node $u \in U$ such that $u \notin C_v$. If we color each $u \in U$ by the color u, then there is an extension of this coloring to a (regular) $|U|$-coloring for all of G' if and only if G is list-colorable.

We now follow the proof of Theorem 31. We can again find a subset $S \subset V$ of size $|S| \geqslant \frac{\alpha}{1+\Delta} n$ which is an independent set in G that contains only vertices of degree at most Δ. We then apply the removal lemma of Theorem 10 to $\mathcal{F} = \{N(s)\}_{s \in S}$ where the neighbourhoods are within G and C is to be chosen later. Define S' and V_0 as in the proof of Theorem 31. Since every color-list C_v is of size at most k, there are only $k^{|V_0|}$ possible colorings $c : V_0 \to U$. We enumerate over these colorings and for each one which is a proper coloring of $G[V_0]$ we apply Theorem 32 on G' where $U \cup V_0$ are already colored (by their corresponding colors and by c, respectively). The crucial point here is that in Theorem 32 the running time depends on $|V|$, the number of uncolored vertices, and is independent of the number of colored vertices. In particular, the total runtime is thus

$$\begin{aligned} k^{|V_0|} \cdot \left(2^{|V \setminus (S' \cup V_0)|} \cdot (2 - 2^{-\Delta})^{|S'|}\right) &\leqslant 2^{|V|} \cdot k^{|V_0|} \cdot (1 - 2^{-(\Delta+1)})^{|S'|} \\ &\leqslant 2^{|V|} \cdot k^{|V_0|} \cdot (1 - 2^{-(\Delta+1)})^{\rho(\Delta,C) \cdot |S| + C \cdot |V_0|}. \end{aligned}$$

We can thus again pick $C = \frac{\log k}{-\log\left(1-2^{-(\Delta+1)}\right)} > 0$ to have

$$k^{|V_0|} \cdot (1-2^{-(\Delta+1)})^{C\cdot|V_0|} = 1$$

which results in a running time bounded by

$$2^{|V|} \cdot (1-2^{-(\Delta+1)})^{\rho(\Delta,C)\cdot|S|}.$$ ◀

4.4 On finding a coloring

In both previous subsections, we used the bounds on the degrees only in order to construct a *good* independent set S. After doing so, we may apply the self-reduction of Section 2.2 to the graph $G[V(G)\backslash S]$, in which we no longer care about the number of edges nor the degrees. This would result in finding a k-coloring of $G[V(G)\backslash S]$. Such coloring can be extended to a k-coloring of G by the constructive proof of Lemma 25. The exact claim follows.

▶ **Lemma 42.** *In the conditions of Theorem 20 or Theorem 31 we can also* find *a k-coloring of G.*

Proof. Consider the reduction between the decision and search versions of k-coloring of Lemma 12. Since adding edges to vertices whose both endpoints are in $V(G)\backslash S$ does not violate the conditions of the theorems, we may apply the reduction of Lemma 12 to $G[V(G)\backslash S]$. By the end of the reduction, we have a k-coloring of $G[V(G)\backslash S]$ that is a restriction of some k-coloring of G. We can extend this k-coloring to a k-coloring of G using the algorithm of Lemma 25. ◀

As a corollary, in the conditions of Theorem 4 we can also *find* a k-coloring of G.

5 Summary of the full version of this paper

Due to length limitation, several main components of the paper appear only in the full version of the paper. The full version is available on-line.

5.1 Removal Lemma For Small Sets

We show that any collection of small sets must contain a *large* sub-collection of *almost* pairwise-disjoint sets. The precise statement follows.

▶ **Theorem 10.** *Let $\mathcal{F}$ be a collection of subsets of a universe U such that every set $F \in \mathcal{F}$ is of size $|F| \leqslant \Delta$. Let $C > 0$ be any constant. Then, there exist subsets $\mathcal{F}' \subseteq \mathcal{F}$ and $U' \subseteq U$, such that*

- *$|\mathcal{F}'| > \rho(\Delta, C) \cdot |\mathcal{F}| + C \cdot |U'|$, where $\rho(\Delta, C) > 0$ depends only on Δ, C.*
- *The sets in $\mathcal{F}'$ are disjoint when restricted to $U\backslash U'$, i.e., for every $F_1, F_2 \in \mathcal{F}'$ we have $F_1 \cap F_2 \subseteq U'$.*

We should think of the statement of Theorem 10 in the following manner. We interpret an *almost* pairwise-disjoint sub-collection as a sub-collection that would become pairwise-disjoint after the removal of a *small* number of elements of the universe. If Δ is a constant, then the precise meaning of *small* and *large* is that on the one hand, the size of the sub-collection is at least a constant fraction of the size of the entire collection, and on the other hand, its size is arbitrarily larger than the number of removed universe elements. The constant C represents the exact meaning of *arbitrarily larger*.

We also discuss the optimality of Theorem 10. In particular, we show that in the settings of Theorem 10 we must have $\rho(\Delta, C) \leqslant (C+1)^{-\Delta}$.

5.2 Reducing k-coloring to $(k-1)$-list-coloring

We prove the following reduction.

▶ **Theorem 6.** *Given an algorithm solving $(k-1)$-list-coloring in time $O\left((2-\varepsilon)^n\right)$ for some constant $\varepsilon > 0$, we can construct an algorithm solving k-coloring in time $O\left((2-\varepsilon')^n\right)$ for some (other) constant $\varepsilon' > 0$. Furthermore, the reduction is deterministic.*

Beigel and Eppstein [1] show that 4-list-coloring (as a special case of a $(4,2)$-CSP) can be solved in time $O(1.81^n)$. Therefore we conclude the proof of Theorem 8 regarding 5-coloring.

We include a short intuitive description of the reduction. By Theorem 4, it suffices to solve k-coloring for graphs in which most vertices have high degrees. We show that in this case, the graph has a small *dominating set*, this is a subset R of vertices such that every vertex not in R is adjacent to at least one vertex of R. Given a k-coloring of the dominating set, the problem of extending the coloring to a k-coloring of the entire graph becomes a problem of $(k-1)$-list-coloring the rest of the graph. This is because each vertex not in the dominating set has a neighbor in it, and thus has at least one of the k colors which it cannot use. Assuming the dominating set is small enough, we can enumerate over the k-colorings of vertices in it, and then solve the remaining $(k-1)$-list-coloring problem. The complete details appear in the full version.

5.3 Reducing k-coloring to $(k-2)$-list-coloring

We then prove the following much more complicated reduction.

▶ **Theorem 7.** *Given an algorithm solving $(k-2)$-list-coloring in time $O\left((2-\varepsilon)^n\right)$ for some constant $\varepsilon > 0$, we can construct an algorithm solving k-coloring with high probability in time $O\left((2-\varepsilon')^n\right)$ for some (other) constant $\varepsilon' > 0$.*

Once again, we use the 4-list-coloring algorithm of Beigel and Eppstein [1] to conclude the proof of Theorem 9 regarding 6-coloring.

The problem with generalizing the idea used in the proof of Theorem 6 is that even if R contains several neighbors of every graph vertex, it could be that in the correct k-coloring all of these neighbors are colored by the same color. In that case, the size of the list of possible colors would not get smaller than $(k-1)$. Thus, more involved algorithmic ideas are necessary for proving Theorem 7.

6 Conclusions and Open Problems

The main algorithmic contribution of the paper is Theorem 4. We use it in order to answer a few fundamental questions regarding the running time of k-coloring algorithms. In particular, we present the first $O\left((2-\varepsilon)^n\right)$ algorithms solving 5-coloring and 6-coloring, for some $\varepsilon > 0$. While the ε we can get using our tools is very small, this serves as the first proof that 5-coloring can be solved faster than we can currently compute the chromatic number in general. The upper bound on ρ in the full version shows that the magnitude of ε is a necessary consequence of using the removal lemma.

The main open problem that we leave unsettled is

▶ **Open Problem 43.** *Can we solve k-coloring in $O^*\left((2-\varepsilon_k)^n\right)$ time for some $\varepsilon_k > 0$, for every k?*

Theorem 4 makes some progress towards answering it, by giving some additional conditions on the input graph under which the answer is affirmative. In particular, we show that it holds for every graph that does not contain almost only vertices of super-constant degrees. In [12] very different techniques (using modifications of the FFT algorithm) were used to get a statement similar to Theorem 4 for graphs with bounded average degree. It seems like their methods do not extend to the case of (α, Δ)-bounded graphs, nevertheless, it is intriguing to find out whether a combination of their techniques with these presented in this paper can lead to further improvements.

While it is believed that $O^*(2^n)$ is the right bound for computing the chromatic number, we have no strong evidence to support this. There are reductions from popular problems and conjectures (like SETH) to other partitioning problems [6] or other parameterizations of the coloring problem [16]. It is interesting whether it can be showed that an $O^*\left((2-\varepsilon)^n\right)$ algorithm for computing the chromatic number would refute any other popular conjecture. This question was raised several times, including in the book of Fomin and Kratsch [11].

Another technical contribution of the paper is Theorem 10. We believe that the presented removal lemma could serve as a tool in the design of other exponential time algorithms. It would be interesting to find more problems for which it can be used.

Deterministic Maximum Flows in Simple Graphs

Tianyi Zhang ✉
Tsinghua University, Beijing, China

Abstract

In this paper we are interested in deterministically computing maximum flows in undirected simple graphs where edges have unit capacities. When the input graph has n vertices and m edges, and the maximum flow is known to be upper bounded by τ as prior knowledge, our algorithm has running time [1]$\tilde{O}(m + n^{5/3}\tau^{1/2})$; in the extreme case where $\tau = \Theta(n)$, our algorithm has running time $\tilde{O}(n^{2.17})$. This always improves upon the previous best deterministic upper bound $\tilde{O}(n^{9/4}\tau^{1/8})$ by [Duan, 2013]. Furthermore, when $\tau \geq n^{0.67}$ our algorithm is faster than a classical upper bound of $O(m + n\tau^{3/2})$ by [Karger and Levin, 1998].

1 Introduction

Let $G = (V, E)$ be an undirected simple graph on n vertices and m edges, where each edge has unit capacity. Fix two special vertices $s, t \in V$ and we are interested in deterministic algorithms that compute an exact maximum flow from s to t in graph G. There has been a long line of literature on the study of maximum flows since the 60's. As one of the pioneering works, Ford and Fulkerson [5] introduced the idea of augmenting paths and proposed an algorithm that runs in time $O(m\tau)$; here τ is an upper bound on the maximum flow value. Subsequent improvements came along in [3, 7], which are known as the blocking flow algorithm and the push-relabel algorithm. For several decades, the best running time was $\tilde{O}(m \min\{m^{1/2}, n^{2/3}\} \log U)$ (U being the largest integer capacity) by [6]. Recently, a new line of developments [17, 14, 18, 16, 15, 13, 19] based on the interior point method surpassed the blocking flow barrier; for large capacities, the best running time is $\tilde{O}((m + n^{1/2}) \log U)$ [19], while for small capacities, the best running time so far is $O(m^{4/3+o(1)}U^{1/3})$ [15, 13].

Another branch of literature focuses on a special case when the maximum flow is known to be small as a prior knowledge. Let τ be a known upper bound on the maximum flow value. Karger proposed the first such kind of upper bound in [10], which is a randomized algorithm running in time $\tilde{O}(m^{2/3}n^{1/3}\tau)$ for simple graphs. This was improved later in [11] to randomized upper bounds of $\tilde{O}(m + n\tau^{5/4})$ and $\tilde{O}(m + n^{11/9}\tau)$ and deterministic upper bound $O(m + n\tau^{3/2})$. This line of works culminated in [12] as a randomized upper bound $\tilde{O}(m + n\tau)$. In a very recent work [1], the authors obtained a deterministic upper bound of $\tilde{O}(m\tau^{2/3})$ time which is even faster when τ is small.

A gap between randomized and deterministic algorithms has remained so far. For many years, the best deterministic algorithm has running time $\tilde{O}(m + n\tau^{3/2})$ [11], so in simple graphs this upper bound could be as large as $\Omega(n^{2.5})$. The basic idea of this algorithm is

[1] $\tilde{O}$ hides poly-logarithmic factors.

to sparsify the residual graph so that it always has $O(n\tau^{1/2})$ directed edges, and it uses connectivity structures to handle undirected edges, and in this way each flow augmentation takes time only proportional to the number of directed edges, yielding a total running time of $O(m + n\tau^{3/2})$. It was explicitly asked by the authors in [11] whether one could achieve a full sparsification of $O(n\tau^{1/2})$ edges so that running the blocking flow algorithm of [6] on the sparsified graph would take time $\tilde{O}(m + n^{5/3}\tau^{1/2})$.

To break through the 2.5 exponent even in simple graphs when $\tau = \Theta(n)$, the author of [4] managed to combine the original approach of [11] with the blocking flow technique and achieved a better running time $\tilde{O}(n^{9/4}\tau^{1/8})$ in simple graphs; this upper bound is always at most $\tilde{O}(n^{2.375})$ so it beats the 2.5 exponent in the worst case when $\tau = \Theta(n)$.

1.1 Our result

In this chapter, we answer the question from [11] in the affirmative for simple graphs.

▶ **Theorem 1.** *Assume $\tau \geq n^{2/3}$ is an upper bound on the value of the maximum s-t flow, then there is a deterministic algorithm that computes s-t maximum flows in undirected simple graphs in $\tilde{O}(n^{5/3}\tau^{1/2})$ running time.*

Our algorithm is always faster than [4] for any choice of $1 \leq \tau < n$ in simple graphs; in the extreme case where $\tau = \Omega(n)$, we have a running time of $O(n^{2.17})$. For a moderately large $\tau \geq n^{0.67}$, our result is also better than the classical algorithm from [11] which has $O(m + n\tau^{3/2})$ running time.

1.2 Technical overview

Generalizing the blocking flows. Our algorithm will be based on [4], so let us first try to summarize the benchmark. Throughout iterations, it maintains a set of disjoint connected components $\mathcal{V}$ in the residual graph, and define a binary edge weight function $\mu : E \to \{0, 1\}$, where inter-component edges have weight 1, and intra-component edges have weight 0. In each iteration, the algorithm searches for a blocking flow whose augmentation would increase the s-t distance in the residual graph under edge weight μ. To search for a blocking flow in the current residual graph, the algorithm performs a depth-first search only on inter-component edges, and use a connectivity data structure to route flows within components. Therefore, in general their algorithm needs to keep the total number of inter-component edges small.

The first obstacle of this approach is that the total number of directed edges would grow during augmentations. As all directed edges are inter-component ones, this immediately affects the time of finding blocking flows. To work around this issue, the algorithm of [4] was to perform a decycle operation between every pair of consecutive levels in terms of distances from s. Although this could keep the number of directed edges small, it merely translates directed edges to inter-component undirected edges, so the total number of inter-component edges remains large. To handle this large number of inter-component edges, their algorithm builds a decremental clustering structure between each pair of consecutive levels that comprises a collection of disjoint clusters and a sparse graph. More specifically, their data structure accepts an integer parameter h and decrementally maintains a set of disjoint star subgraphs, each of size $> h$, such that the number of edges incident tn unclustered vertices is bounded by $O(nh)$. The key motivation of using star subgraphs is that it ensures each flow augmentation uses at most $O(n/h)$ inter-component edges, so that the number of inter-component edges grows slowly.

A better clustering approach. One downside of [4]'s decremental clustering algorithm is that each edge deletion could add $O(n)$ more edges incident on unclustered vertices. This substantially limits the usage of the decremental data structure since it needs frequently rebuilding as the number of edges incident on unclustered vertices increases fast. Our new data structure does not need any rebuilding, and furthermore, this advantage allows us to apply it to maintain the set of disjoint components $\mathcal{V}$ directly, instead of maintaining inter-component edges between consecutive levels. In this way, we can directly upper bound the length of each flow, and so we do not need any decycling step, which simplifies the blocking flow approach of [4] as well.

Comparison with layered core decompositions. Our new decremental clustering data structure is actually inspired by the layered core decompositions devised in a recent paper [2], but ours is much simpler and weaker in some sense. The total update time of our algorithm is at least quadratic, and it also depends on the pattern of updates, while the layered core decomposition has almost linear total update time in the worst case. Furthermore, in our clustering scheme, each cluster is simply a star subgraph, where in the layered core decomposition each cluster is an expander.

One reason we do not directly apply the layered core decomposition in the maximum flow computations is that it is a heavy tool and may probably make an overkill. When computing maximum flows, edge updates to the clustering scheme always have some benign properties, and so even though star graphs are far less robust than expanders, the clustering scheme does not have to work against strong adversaries. Furthermore, a more technical reason is that paths within the same core may have sub-polynomial lengths, while each star only has diameter 2, which contributes to the length of augmenting paths. Therefore, using the layered core decompositions might induce an extra sub-polynomial factor in the running time of max-flows.

2 Preliminaries

Let $G = (V, E)$ be an undirected simple graph with unit-capacities, and let $s, t \in V$ be a source and a sink. For the rest, G will be the input graph where we compute max-flows.

For any graph $H = (X, F)$ and vertex subset $S \subseteq H$, let $H[S]$ be the induced subgraph of H on S. An edge orientation on the edge set is represented as $\mathcal{O} : V \times V \to \{-1, 0, 1\}$, such that for each edge $(u, v) \in E$, $\mathcal{O}(u, v)$ is equal to 1 if the edge (u, v) is oriented from u to v, and -1 if it is from v to u, and 0 if it is not oriented. For each $u \in V$, define $\deg_H(u)$ to be the number of neighbors of u in H. If an orientation $\mathcal{O} : F \to \{-1, 0, -1\}$ of edges is imposed on F, then let $\deg^+_{H,\mathcal{O}}(u), \deg^-_{H,\mathcal{O}}(u)$ be the out/in-degree of u in G. Usually, when H and $\mathcal{O}$ are known from context, we would ignore the subscripts.

For any s-t flow f in G, let $|f|$ denote the value of the flow, and E_f the set of edges carrying the flow. The residual graph of G with respect to f is denoted by G_f, which is defined as following.

▶ **Definition 2** (residual graph). *Given a flow f in G, a residual graph G_f is defined as following: for each edge $(u, v) \in E$ such that $f(u, v) = 1$, there is a directed edge from v to u with capacity 2.*

Here we emphasize that the orientation of edges have nothing to do with the direction of edges in the residual graph.

Next, we state some lemmas regarding flows from previous works.

▶ **Lemma 3** ([11]). *An acyclic flow f in a graph with integer capacities and no parallel edges uses at most $2n\sqrt{|f|}$ edges.*

▶ **Lemma 4** ([11]). *In a simple undirected graph, it is possible to take a flow f and find an acyclic flow f' of the same value in time $\tilde{O}(|E_f|)$.*

▶ **Lemma 5** ([11]). *Given an acyclic flow f, finding k augmenting paths takes $\tilde{O}(m + kn(k + |f|)^{1/2})$ deterministic time.*

We will also be using a dynamic maximum spanning forest algorithm with fast amortized update time.

▶ **Lemma 6** ([8, 9]). *Given an undirected weighted graph on n vertices undergoing edge insertions and deletions, there is a deterministic dynamic algorithm that maintains a maximum spanning forest with $O(\log^4 n)$ amortized update time.*

3 Decremental layered clustering

In this section, let $H = (V, F)$ be an arbitrary undirected simple graph on n vertices that undergoes a sequence of edge deletions.

▶ **Definition 7.** *For any undirected simple graph $H = (X, F)$, a subset $A \subseteq X$ is called **d-pruned** with respect to graph H, if all edges incident on A could be oriented under an orientation $\mathcal{O}$ of F such that*
(1) *All edges between A and $X \setminus A$ are directed outward from A.*
(2) *Out-degree of every vertex in A is less than d.*

▶ **Lemma 8.** *For any simple graph $H = (X, F)$, there exists a d-pruned set A, such that for any $u \in X \setminus A$, $\deg_{H[X\setminus A]}(u) \geq d$; plus such A can be computed in linear time.*

Proof. The set A is constructed in the greedy manner: starting with $A \leftarrow \emptyset$, repeatedly check if there is a vertex $u \in X \setminus A$ such that $\deg_{H[X\setminus A]} < d$; if so, orient all edges incident on u in $H[X \setminus A]$ away from u, and move u to A. So, in this way, the out-degree is small $\deg^+_H(u) < d$. Clearly, the algorithm can be implemented in linear time. By the stopping condition, all vertices in the induced subgraph $H[X \setminus A]$ have degree at least d. ◀

Now, let us define a layering scheme of H.

▶ **Definition 9** (layering). *Let $h > 0$ be an integer parameter. A partition $(A_0, A_1, \cdots, A_{\lceil \log(n/h) \rceil})$ of V, together with an orientation $\mathcal{O}$ of all edges in E, is called a layering scheme of H, if the following requirements are satisfied.*
(1) *$(u, v) \in E$ such that $u \in A_i, v \in A_j, i < j$, this edge is oriented from u to v, namely $\mathcal{O}(u, v) = 1$.*
(2) *For each index $b \geq 0$, $u \in A_b$, we have $\deg^+_{H,\mathcal{O}}(u) < 2^{b+1}h$.*

To initialize a layering of H, consider the following procedure: initialize $X = V$, and for $i = 0, 1, 2, \cdots, \lceil \log(n/h) \rceil - 1$, apply Lemma 8 on $H[X]$ with parameter $d = 2^i h$ to compute a set A_i, and then update $X \leftarrow X \setminus A_i$. After all iterations, define $A_{\lceil \log(n/h) \rceil} = X$ and orient edges in $E \cap (A_{\lceil \log(n/h) \rceil} \times A_{\lceil \log(n/h) \rceil})$ arbitrarily. By construction, for each $u \in A_b$, all its out-neighbors are in $\bigcup_{i \geq b} A_i$, and $\deg^+_{H,\mathcal{O}}(u) \leq 2^b h < 2^{b+1}h$.

On top of the layering scheme, we need to define a clustering scheme of vertices.

▶ **Definition 10** (clustering). *Given a layering* $(A_0, A_1, \cdots, A_{\lceil \log(n/h) \rceil})$ *of* H*, a set of tuples* $\{(\mathcal{C}_b, Y_b, Z_b)\}_{b \geq 1}$ *is called a* cluster structure *on layer* $(A_0, A_1, \cdots)$*, where each layer* $A_b, b \geq 1$ *can be divided into two parts* $A_b = Y_b \cup Z_b$*, if the following properties hold.*

(1) *Y_b is partitioned into a collection of clusters $\mathcal{C}_b = \{C_1, C_2, \cdots\}$ of subsets, where each C_i has size $\geq 2^{b-1}h + 1$ and is spanned by a star subgraph of H. For each C_i, its center is defined to be the center of a star subgraph that spans C_i.*

(2) *Each vertex $z \in Z_b$ is adjacent to some vertices in $Y_b \cup \bigcup_{i>b} A_i$.*

Besides, define edge weight function ω associated with this cluster structure as follows.

(a) *All edges of star graphs in $\mathcal{C}_b$ have weight $2b$.*

(b) *All non-star edges incident on Y_b in $H[A_b]$, and edges between A_b and $\bigcup_{i>b} A_i$ have weight $2b - 1$.*

(c) *All edges in $H[Z_b]$ have weight $2b - 2$.*

▶ **Lemma 11.** *Given any layering* $(A_0, A_1, \cdots, A_{\lceil \log(n/h) \rceil})$ *of* H*, a cluster structure* $\{(\mathcal{C}_b, Y_b, Z_b)\}_{b \geq 1}$ *can be computed in* $\tilde{O}(n^2)$ *time.*

Proof. For each $b \geq 1$, construct Y_b in the greedy manner: starting with an empty set $Y_b = \emptyset$, whenever there exists a vertex $c \in A_b \setminus Y_b$ with $\deg_{H[A_b \setminus Y_b]}(u) \geq 2^b h$, take an arbitrary set of $2^b h$ neighbors $u_1, u_2, \cdots, u_{2^b h} \in A_b \setminus Y_b$ and add this cluster $\{c, u_1, u_2, \cdots, u_{2^b h}\}$ to Y_b, with c being its center. In the end when the above procedure stops, define $Z_b = A_b \setminus Y_b$. Clearly this procedure takes $O(|F|) = O(n^2)$ time.

To verify property (2), by construction of the layering scheme, for each $z \in Z_b$, $\deg_{H[\cup_{i \geq b} A_i]}(z) \geq 2^b h$. So if z was not added to Y_b as a star center, then z must be adjacent to some vertices from $Y_b \cup \bigcup_{i>b} A_i$. ◀

Next, we try to maintain the layering $(A_0, A_1, \cdots)$ together with a clustering structure when edges are being deleted from G. During the execution of our decremental algorithm, we need to ensure a basic requirement.

▶ **Invariant 12.** *During the decremental algorithm, vertices could only move from layers A_{b+1} to A_b, $\forall b \geq 0$; in other words, vertices only move from upper layers to lower layers.*

The rest of the section would be devoted to the following statement.

▶ **Lemma 13.** *Suppose H undergoes a sequence of edge deletions. Then a clustering structure $\{(\mathcal{C}_b, Y_b, Z_b)\}_{b \geq 1}$ together with an induced edge weight ω in Definition 10 can be explicitly maintained using total update time $\tilde{O}(\sum_{b=1}^{\lceil \log(n/h) \rceil} 2^b D_b h + n^2)$, plus that the dynamic algorithm meets Invariant 12; here D_b is an upper bound on the number of edges which are incident on layer A_b right when they get deleted.*

3.1 Maintaining clusters under edge deletions

In this subsection we describe the algorithm behind Lemma 13. Let us first focus on a fixed layer A_b. Assume the updates to $H[A_b]$ are either edge deletions or vertex transfers from A_{b+1} to A_b; if $b = \lceil \log(n/h) \rceil$ then A_{b+1} is always empty. Initialize an arbitrary clustering $(\mathcal{C}_b, Y_b, Z_b)$ as in Lemma 11. We will be maintaining all adjacency lists in the induced subgraph $H[\bigcup_{i \geq b} A_i]$, and more importantly, the following auxiliary data structure based on edge orientation $\mathcal{O}$.

Auxiliary data structures based on edge orientation $\mathcal{O}$

- **(i)** For each $u \in A_b$, a list of all out-neighbors in H. By Invariant 12, these out-neighbors are all in $\bigcup_{i \geq b} A_i$.
- **(ii)** For each $u \in A_b$, a list of neighbors $Z^-(u) = \{z \mid (u,z) \in E, \mathcal{O}(u,z) = -1, z \in Z_b\}$.
- **(iii)** For each $u \in Z_b$, a list of neighbors $Z^+(u) = \{z \mid (u,z) \in E, \mathcal{O}(u,z) = 1, z \in Z_b\}$.
- **(iv)** A priority queue on all vertices in Z_b, which are ordered by degrees $\deg_{H[Z_b]}(u) = |Z^-(u)| + |Z^+(u)|, \forall u \in Z_b$ in the induced subgraph $H[Z_b]$.

In other words, for each vertex in Z_b, it knows both its out-neighbors and in-neighbors in $H[Z_b]$, while for each vertex in Y_b, it only knows its in-neighbors in Z_b. Plus, all vertices in Z_b are ordered by their degrees in the induced subgraph $H[Z_b]$.

Vertex insertions. Assume a new vertex u has moved to A_b from upper layer A_{b+1}. First, for each edge (u,v) where $v \in \bigcup_{i>b} A_i$, we need to adjust the orientation of $\mathcal{O}(u,v) = 1$, reassign edge weights for all edges $\omega(u,v) = 2b-1$.

By definition of layering, before u came downward from A_{b+1}, all its edges incident on A_b were directed inward. So when it joins A_b, $Z^+(u)$ should be empty. After insertion of u, we add u to Z_b, and initialize $Z^-(u)$ by scanning u's adjacency list in H, and initialize $Z^+(u) = \emptyset$. Then, for each $v \in A_b$ adjacent to u, add u to the list $Z^+(v)$. Next, update the keys of u and its neighbors in Z_b in the priority queue. Finally, if $v \in Y_b$, stay with $\omega(u,v) = 2b-1$, and otherwise reassign $\omega(u,v) = 2b-2$.

After that, repeat the following greedy procedure (1)(2)(3) to form star subgraphs out of $H[Z_b]$. For a more concise description of this procedure, check pseudo-code GreedyCluster.

- **(1)** If there exists $c \in Z_b$ such that $\deg_{H[Z_b]}(c) = |Z^-(c)| + |Z^+(c)| \geq 2^b h$, pick an arbitrary such vertex c; if there is none, then halt.
- **(2)** Find all of c's neighbors $u_1, u_2, \cdots, u_k \in Z_b$ by scanning $Z^-(c) \cup Z^+(c)$. Then move all vertices $c, u_1, u_2, \cdots, u_k$ from Z_b to Y_b, and add the star subgraph around all u_i's centered at c as a cluster to $\mathcal{C}_b$.
- **(3)** Lastly, we need to maintain all lists $Z^+(\cdot), Z^-(\cdot)$ and edge weights. To maintain lists and edge weights, for every vertex $x \in \{c, u_1, u_2, \cdots, u_k\}$, do the following steps.
  - **(a)** For each $z \in Z^-(x)$, remove x from $Z^+(z)$; for each $z \in Z^+(x)$, remove x from $Z^-(z)$. Then, for each such edge (x,z), reassign $\omega(x,z) = 2b-1$, and for all star edges $(c,u_i), 1 \leq i \leq k$, assign $\omega(c,u_i) = 2b$.
  - **(b)** Scan the out-neighborhood of x, then for each (x,y) such that $\mathcal{O}(x,y) = 1$ and $y \in Y_b$, remove x from $Z^-(y)$.

Non-star edge deletions. Now assume an edge deletion (u,v) occurs in subgraph $H[\bigcup_{i \geq b} A_i]$, and $u \in A_b$. Let us first study the simpler case where (u,v) is not a star edge in any cluster of $\mathcal{C}_b$.

A preliminary step is updating these four lists $Z^+(u), Z^-(u), Z^+(v), Z^-(v)$ due to (u,v)'s deletion. After this, some vertex $z \in Z_b$ might have a small degree in subgraph $H[\bigcup_{i \geq b} A_i]$, and in this case we would have to move it to A_{b-1} to ensure each $z \in Z_b$ is adjacent to some vertices in $Y_b \cup \bigcup_{i>b} A_i$. More specifically, while some vertices in $z \in Z_b$ have degree less than $2^b h$ in subgraph $H[\bigcup_{i \geq b} A_i]$, move z from Z_b to A_{b-1}, do the following steps to restore our data structures.

Algorithm 1 GreedyCluster.

while $\exists c \in Z_b$ *such that* $\deg_{H[Z_b]}(c) \geq 2^b h$ **do**
  list all neighbors of c in $H[Z_b]$ as $u_1, u_2, \cdots, u_k$;
  form a star subgraph around $u_1, u_2, \cdots, u_k$ centering at c, and add this as a cluster to $\mathcal{C}_b$;
  for each $x \in \{c, u_1, u_2, \cdots, u_k\}$, scan $Z^-(x), Z^+(x)$ to maintain all other affected lists $Z^-(z), Z^+(z), z \in Z_b$, and update the induced edge weights ω;
  for each $x \in \{c, u_1, u_2, \cdots, u_k\}$, scan its out-neighbors in $H[A_b]$ to update all $Z^-(y), \forall y \in Y_b$;

(1) Scan z's adjacency list, and for each of its neighbor $y \in A_b$, remove z from $Z^+(y), Z^-(y)$, and update the orientation $\mathcal{O}(z, y) = 1$ if necessary. Finally, remove z from the priority queue on Z_b.
(2) Besides, for each of z's neighbor x in $H[\bigcup_{i \geq b} A_i]$, reassign $\omega(z, x) = 2b - 3$.

The pseudo-code of the above procedure is presented below as GreedyPrune.

Algorithm 2 GreedyPrune.

while $\exists z \in Z_b$ *such that* $\deg_{H[\bigcup_{i \geq b} A_i]}(z) < 2^b h$ **do**
  move z from Z_b to A_{b-1}, and scan its adjacency list to update all affected lists $Z^+(\cdot), Z^-(\cdot)$, and update ω and $\mathcal{O}$ properly;

Star edge deletions. Now consider the harder case where the deleted edge is a star edge of a cluster in $\mathcal{C}_b$. In this case, let (c, u) be the deleted edge and c be the cluster center. After the edge deletion, one or more vertices in the cluster centered at c might have to leave Y_b. The two possibilities are the following.

- Excluding u, if the star subgraph now has at most $2^{b-1}h$ vertices, the whole cluster should be destroyed and removed from Y_b back to Z_b.
- Otherwise, only u needs to join Z_b.

Let vertex subset S be the set of all vertices in this cluster that might join Z_b shortly, so S is either a singleton $\{u\}$ or the whole star cluster. For each vertex $v \in S \setminus \{c\}$, a preliminary step is reweighing $\omega(c, v) = 2b - 1$ as (c, v) is no longer a star edge.

Go over all vertices $v \in S$ in an arbitrary order and do the following. Scan the list of all out-neighbors of v to find the set S_v of its out-neighbors in Z_b; remember that currently we do not maintain $Z^+(v)$ as $v \notin Z_b$, so instead of directly retrieving $S_v = Z^+(v)$, we have to scan all of v's out-neighbors. Now, as we have already maintained $Z^-(v)$, we can now decide whether v has at least $2^b h$ (undirected) neighbors in Z_b by checking if $|S_v| + |Z^-(v)| \geq 2^b h$. We need to study both possibilities.

- $|S_v| + |Z^-(v)| < 2^b h$. In this case, set $Z^+(v) = S_v$. Move v from Y_b to Z_b. To restore orientation-based data structures, first, for each $z \in Z^-(v)$ add v to $Z^+(z)$, and for every $z \in S_v$ add v to $Z^-(z)$; second, scan the out-neighbors of v, and for every (v, y) such that $y \in Y_b$, add v to $Z^-(y)$.
  Finally, to restore edge weights, for each of $z \in S_v \cup Z^-(v)$, change the edge weight $\omega(v, z)$ from $2b - 1$ to $2b - 2$.

- $|S_v| + |Z^-(v)| \geq 2^b h$. In this case, we would directly collect a star cluster around v using $S_v \cup Z^-(v)$. Namely, move all vertices in $S_v \cup Z^-(v)$ from Z_b to Y_b, and add the star subgraph centered at v as a cluster to $\mathcal{C}_b$. To restore the auxiliary data structures and edge weights, go over all vertices $x \in S_v \cup Z^-(v)$ and follow the same steps (3)(a) and (3)(b) when handling vertex insertions.

After we have iterated over all vertices from S, each $v \in S$ either has entered Z_b or formed a new cluster in $\mathcal{C}_b$. Subgraph $H[Z_b]$ could still contain vertices whose degree is at least $2^b h$, so we perform another round of GreedyCluster to exhaustively collect new clusters out of Z_b. Finally, to ensure property (2) in Definition 10, we invoke GreedyPrune on Z_b to remove vertices with small degrees.

Stacking all layers. In order to maintain the entire clustering structures $\{(\mathcal{C}_b, Y_b, Z_b)\}_{b\geq 1}$ across all layers $(A_0, A_1, \cdots)$ against edge deletions to H, we simply apply the above algorithm for each layer $A_b, b \geq 1$. When vertices move from upper layers to lower layers, it is equivalent to vertex insertions to lower layers, which can be handled by the algorithm.

3.2 Proof of correctness

The proof of correctness of our algorithm is divided into several lemmas.

▶ **Lemma 14.** *Invariant 12 is preserved by the algorithm, and $(A_0, A_1, \cdots)$ is always a layering satisfying the requirements in Definition 9.*

Proof. During the algorithm, vertices never move from lower levels A_b to higher levels A_{b+1}, so Invariant 12 is satisfied.

Now let us turn to verify properties of Definition 9. For property (1), when vertices move across different layers, our algorithm always adjusts $\mathcal{O}$ to ensure this requirement, so this property holds. As for property (2), by the algorithm description, whenever a vertex $z \in Z_b$ moves from A_b to A_{b-1}, it must be the case that $\deg_{H[\bigcup_{i\geq b} A_i]}(z) < 2^b h$. In the near future, as long as z stays in A_{b-1}, its out-neighbors under orientation $\mathcal{O}$ should always be a subset of its current neighbors in $\bigcup_{i\geq b} A_i$, and so the number of its out-neighbors is always bounded by $2^b h$, and thus property (2) holds. ◀

▶ **Lemma 15.** *During edge deletions, the algorithm correctly maintains the auxiliary data structures based on the edge orientation $\mathcal{O}$.*

Proof. Maintaining part (i)(iv) is straightforward, so we only focus on part (ii)(iii).

- **Vertex insertions.** Z_b could only change during GreedyCluster. Consider any new cluster $c, u_1, \cdots, u_k$ centered at c. To move them from Z_b to Y_b, for each $x \in \{c, u_1, \cdots, u_k\}$, on the one hand, we need to go over all of its neighbors in $H[Z_b]$ to fix lists $Z^-(z), Z^+(z)$ for all $z \in Z_b$; on the other hand, we only need to scan x's out-neighbors to fix lists $Z^-(y)$ for all $y \in Y_b$, since we do not require $Z^+(\cdot)$ for vertices in Y_b, which is a key point behind the design of the auxiliary data structures.
- **Non-star edge deletions.** In this case, some vertices might move from Z_b downward to A_{b-1}. As the maintenance of the auxiliary data structures is done in the straightforward manner, so correctness should follow easily.
- **Star edge deletions.** This case involves two rounds of vertex transfers between Y_b and Z_b. The first round is when it enumerates all vertices $v \in S$ and check if $|S_v| + |Z^-(v)| < 2^b h$. In this case, we have discussed two possibilities.

- If $|S_v| + |Z^-(v)| < 2^b h$, then the algorithm moves v from Y_b to Z_b. To restore part (ii)(iii), it suffices to scan $Z^-(v)$ and all out-neighbors of v, which is what the algorithm does.
- Otherwise if $|S_v| + |Z^-(v)| \geq 2^b h$, the algorithm would collect a star cluster around v with $S_v \cup Z^-(v)$. To move $S_v \cup Z^-(v)$ to Y_b, we would use a similar procedure as steps (3)(a)(b) of vertex insertions, and so the auxiliary data structures should be maintained correctly as well.

The second round is when it invokes GreedyCluster to further remove vertices $z \in Z_b$ such that $\deg_{H[Z_b]}(z) \geq 2^b h$. After that, the algorithm calls GreedyPrune to remove vertices $z \in Z_b$ such that $\deg_{H[\bigcup_{i \geq b} A_i]}(z) < 2^b h$. Using the same analysis as before, we know the algorithm always correctly maintains the auxiliary data structures. ◀

▶ **Lemma 16.** *A cluster structure $\{(\mathcal{C}_b, Y_b, Z_b)\}_{b \geq 1}$ from Definition 10 is correctly maintained by our algorithm.*

Proof. It is straightforward to verify that our algorithm correctly maintains the edge weight ω. So let us only focus on properties (1)(2).

Property (1) is automatically guaranteed by the algorithm, since the algorithm only collects star clusters of size $\geq 2^b h$, and whenever a star cluster becomes smaller than $2^{b-1} h$ after losing too many of its leaves due to edge deletions, the algorithm would try to move it back to Z_b. Now, let us turn to property (2).

▷ Claim 17. After every update, it holds that for each vertex $z \in Z_b$, $\deg_{H[\bigcup_{i \geq b} A_i]}(z) \geq 2^b h$, $\deg_{H[Z_b]}(z) < 2^b h$.

Proof of claim. When the cluster structure has just been initialized, this claim holds by construction of the layers $(A_0, A_1, \cdots)$. Next, consider vertex insertions and edge deletions separately.

- **Vertex insertions.** After a vertex insertion from upper layers, the degrees of vertices in Z_b in subgraph $H[\bigcup_{i \geq b} A_i]$ remains unchanged. By the GreedyCluster procedure, all vertices in Z_b should have degree less than $2^b h$ in $H[Z_b]$ afterwards.
- **Edge deletions.** After an edge deletion, by the end of the algorithm, it performs one round of GreedyCluster and then GreedyPrune, which first moves vertices in Z_b whose degree in $H[Z_b]$ is at least $2^b h$ to Y_b, and then moves vertices whose degree in $H[\bigcup_{i \geq b} A_i]$ is less than $2^b h$ downward to A_{b-1}. So the claim should hold when it finishes. ◀

By this claim, for any vertex $z \in Z_b$, on the one hand we know $\deg_{H[\bigcup_{i \geq b} A_i]}(z) \geq 2^b h$, and on the other hand $\deg_{H[Z_b]}(z) < 2^b h$, so there exists $y \in \bigcup_{i \geq b} A_i \setminus Z_b = Y_b \bigcup_{i > b} A_i$ adjacent to z, which is property (2). ◀

3.3 Running time analysis

▶ **Lemma 18.** *The total time of the algorithm for handling layer A_b is bounded by $O(2^b D_b h + n^2)$.*

Proof. Let us first analyze the total time of GreedyPrune throughout edge deletions. During this subroutine, the algorithm repeatedly picks $z \in Z_b$ such that $\deg_{H[\bigcup_{i \geq b} A_i]}(z) < 2^b h$ and move it to A_{b-1}. This requires scanning the adjacency list of z. Since each z can transfer from A_b to A_{b-1} for at most once, the total time is bounded by $O(|F|) = O(n^2)$.

For each cluster $C \in \mathcal{C}_b$, define $\mathsf{del}(C)$ to be the current number of star edges that have been deleted since C joined $\mathcal{C}_b$. Define a potential function, where K is a large constant:

$$\Phi = |F \cap (Z_b \times Z_b)| + 2^b h|Z_b| + K \cdot 2^b h \sum_{C \in \mathcal{C}_b} \mathsf{del}(C) = O(K \cdot 2^b D_b h + n^2)$$

▷ Claim 19. The total time of GreedyCluster across all updates is bounded by $O(2^b h D_b + n^2)$.

Proof of claim. In the while-loop, locating a $c \in Z_b$ such that $\deg_{H[Z_b]}(c) = |Z^-(c)| + |Z^+(c)| \geq 2^b h$ takes $O(\log n)$ time using the priority queue. By the algorithm, forming a cluster around c requires scanning all neighbors in $H[Z_b]$ for each $x \in \{c, u_1, u_2, \cdots, u_k\}$, plus x's out-neighbors in $H[\bigcup_{i \geq b} A_i]$. Suppose the total number of edges in $H[Z_b]$ incident on $\{c, u_1, u_2, \cdots, u_k\}$ is m_0. Then, on the one hand, the time cost would be $O(m_0 + 2^b h(k+1))$, as each x has out-neighbors at most $2^{b+1}h$ by Definition 9; on the other hand, the potential decrease of Φ is exactly $m_0 + 2^b h(k+1)$ as well, which cancels out the time cost. Hence, the total time of GreedyCluster across all updates is bounded by $O(2^b h D_b + n^2)$. ◁

A dominant part of the overall running time is handling star edge deletions, where we need to iterate over the set S. Let C be the star cluster centered at c. For any $v \in S$, computing the number of v's neighbors in Z_b takes time at most $2^{b+1}h$ as out-degree is bounded $\deg^+_{H,\mathcal{O}}(v) \leq 2^{b+1}h$ and $Z^-(v)$ is accessible as a list. Now consider two possibilities.

- $|S_v \cup Z^-(v)| < 2^b h$. In this case, the algorithm moves v back to Z_b by scanning $S_v \cup Z^-(v)$ plus all out-neighbors, and the running time is bounded by $O(2^b h)$. As for potential change, moving v to Z_b increases Φ by $|S_v \cup Z^-(v)| + 2^b h \leq 2^{b+1}h$, so the amortized cost is bounded by $O(2^b h)$.
- $|S_v \cup Z^-(v)| \geq 2^b h$. In this case, we would collect a new cluster around v. Similar to the analysis of GreedyCluster, the amortized cost of this part is zero.

If $S = \{v\}$, then this part of the amortized cost incurred by a star edge deletion is bounded by $O(2^b h)$. Plus that $\mathsf{del}(C)$ increases by 1, the amortized cost would be $K 2^b h$.

Otherwise, if S is the entire cluster centered at c, then on the one hand, summing up the above two cases, the amortized cost of iterating over S is $O(2^b h|S|)$; on the other hand, since the star C centered at c is canceled from $\mathcal{C}_b$, the potential decrease would be $K \cdot 2^b h \cdot \mathsf{del}(C)$. So the amortized cost of handling S would be $O(2^b h|S|) - K \cdot 2^b h \cdot \mathsf{del}(C)$.

A key point is that, by the algorithm, when C joined $\mathcal{C}_b$ it had at least $2^b h$ leaves by then, but now when C leaves it has $2^{b-1}h$ leaves. Therefore, $\mathsf{del}(C) \geq |S|$. Hence, if we choose K to be a sufficiently large constant, the amortized cost $O(2^b h|S|) - K \cdot 2^b h \cdot \mathsf{del}(C)$ would be negative.

To summarize, we have proved that each star edge deletion has amortized cost at most $K 2^b h$, plus that other costs are bounded by $O(2^b h D_b + n^2)$. So the total update time is $O(2^b h D_b + n^2)$. ◀

4 The main algorithm

Initialization. Let f be an empty flow, and we will keep augmenting f throughout $O(n^{2/3})$ iterations. Apply Lemma 13 on G to initialize a layering $(A_0, A_1, \cdots)$ as well as a clustering $\{(\mathcal{C}_b, Y_b, Z_b)\}_{b \geq 1}$ together with edge weights ω, where $h = \lceil \tau^{1/2} \rceil$; we can enforce $s, t \in A_0$ at the beginning since this would only increase $O(n)$ edges incident on A_0. We maintain two disjoint edge sets F_0 and F_1, where initially F_0 includes all edges in $G[V \setminus A_0]$, and let F_1 be the rest. So initially F_1 contains at most $O(nh)$ edges.

Throughout the iterations, $(V, F_0 \cup F_1)$ will be the residual graph G_f, and F_0 will be the set of all undirected edges used by the clustering structure, and F_1 could contain both undirected and directed edges in the residual graph G_f.

Iterations. In each iteration, we try to find a blocking flow with respect to f with increasing path (unweighted) length. Denote by G_f the residual graph with respect to f.

For each edge $(u, v) \in F_0 \cup F_1$, associate it with a binary weight μ such that $\mu(u, v) = 0$ if $(u, v) \in F_0$, and $\mu(u, v) = 1$ otherwise. To keep track of all connected components of (V, F_0), maintain a fully dynamic maximum weight spanning forest MSF on (V, F_0) according to weights ω using standard approach [8], and for each $u \in V$, let $\mathsf{mst}(u)$ denote the maximum weight spanning tree in MSF containing u (if $u \in A_0$, then $\mathsf{mst}(u)$ refers to u itself).

The following invariant regarding the s-t distance in G_f under edge weight μ will be guaranteed by our algorithm.

▶ **Invariant 20.** *At the beginning of the l-th iteration, the s-t distance in G_f is at least l.*

At the beginning of each iteration, perform Dijkstra's algorithm on $G_f = (V, F_0 \cup F_1, \mu)$ from s, and so each vertex $u \in V$ has a distance label $\mathsf{level}(u)$ which is set to the distance from s to u under edge weight μ. Since all edges in F_0 are undirected and have zero μ-weight, for shortest paths computations we could contract all edges in F_0, and so Dijkstra's algorithm takes time $O(|F_1| + n \log n)$; plus, vertices in any tree component in MSF can share the same label.

Later on when we search for augmenting paths, more edge weights $\mu(\cdot)$ would turn from 0 to 1 as edges are deleted from F_0. However, during this iteration, we will keep the labels $\mathsf{level}(\cdot)$ unchanged and ensure the following property.

▶ **Invariant 21.** *For any vertex $u \in V$, the distance from s to u in the residual graph G_f under edge weight μ is always at least $\mathsf{level}(u)$.*

Depth first search. Next, let focus on a single iteration. Each vertex in V has two phases: active or inactive. At the beginning of the search, activate all vertices whose label is $< l$ as well as terminal t. Starting with source vertex $u = s$. Assume inductively that we have found a sequence of vertices $s = u_0, u_1, \cdots, u_k$. As long as $k < l$ and s is active, repeat the following steps.

(1) Enumerate all vertices in $v \in \mathsf{mst}(u_k)$. For each v, try to find an edge (v, w) in G_f such that:
  (a) w is active, and $\mathsf{level}(w) = \mathsf{level}(v) + 1$.
  (b) Either the edge (v, w) is undirected or it is from v to w.
  If such an edge (v, w) is found, then assign $u_{k+1} \leftarrow w, k \leftarrow k + 1$.

(2) If no such edge (v, w) can be found, then deactivate all vertices in $\mathsf{mst}(u_k)$ and $k \leftarrow k - 1$.

Now, suppose at some point $k = l$. Since u_k is active, we know $u_k = t$. Then we try to send flows from s to t in G_f on an augmenting path of length l under edge weights μ. Recalling the way we found all of $u_0, u_1, \cdots, u_l$, each $\mathsf{mst}(u_i)$ and $\mathsf{mst}(u_{i+1})$ are connected by an edge (v_{i-1}, u_i) with positive capacity in G_f, and each pair of u_i, v_i are in the same tree component of (V, F_0), so we can route one unit of flow from s to t going through $u_0, u_1, \cdots, u_l$.

Let the augmenting path be $s = p_0, p_1, \cdots, p_e = t$, and augment f by sending one unit of flow along this path. After that, we need to update the residual graph G_f, the subgraph H on which the layered clustering is maintained, the maximum spanning forest MSF. Go over all $0 \le i < e$, and consider the following two cases.

- If (p_i, p_{i+1}) is an undirected edge in F_0, then delete it from F_0, and add a directed edge (p_{i+1}, p_i) to F_1 with residual capacity 2.
- If (p_i, p_{i+1}) is an undirected edge in F_1, then it is connecting two vertices with consecutive labels. In this case, add a directed edge (p_{i+1}, p_i) to F_1 with residual capacity 2, and delete the old edge from F_1.
- If (p_i, p_{i+1}) is a directed edge in F_1, then remove it from F_1 and add an undirected edge (p_i, p_{i+1}) with unit capacity to F_1.

After G_f is updated, we should reset $k \leftarrow 0$, and update the layered clustering structure, the maximum spanning forest accordingly.

The whole blocking flow computation is summarized as pseudo-code BlockingFlow.

Algorithm 3 BlockingFlow(f, l).

```
maintain layered clustering {(C_b, Y_b, Z_b)}_{b≥1}, maximum spanning forest MSF;
compute distance labels level(·);
activate all vertices whose label is < l as well as terminal t;
u_0 ← s, k ← 0;
while s is active do
    if k < l then
        if exists (v, w) such that w is active, v ∈ mst(u_k), level(w) = level(v) + 1 then
            u_{k+1} ← w and k ← k + 1;
        else
            deactivate the entire mst(u_k) and backtrack k ← k − 1;
    else
        send one unit of s-t flow;
        reset k ← 0, update residual graph, layered clustering, maximum spanning
         forest;
```

Now we can summarize our main algorithm as a piece of pseudo-code MaxFlow below.

Algorithm 4 MaxFlow(G, τ).

```
initialize empty flow f;
initialize a layered clustering structure on G parameterized by h = ⌈τ^{1/2}⌉;
for l = 1, 2, ··· , ⌈2n^{2/3}⌉ do
    call BlockingFlow(f, l);
decycle f using Lemma 4;
apply Lemma 5 on f exhaustively;
return f;
```

4.1 Proof of correctness

▶ **Lemma 22.** *Invariant 21 is preserved after G_f is updated.*

Proof. When a connected component in MSF is split due to edge deletions in F_0, the current distances in G_f cannot increase. If vertices move from $V \setminus A_0$ to A_0 due to degree losses, some inter-component edges would be inserted to G_f. However, such kind of edge insertions can never decrease distances, as they were connecting vertices with the same label value level$(\cdot)$. ◀

After the depth-first search is completed, we need to prove that the distance from s to t in the contracted graph G_f is at least $l+1$, namely preserving Invariant 20 for the next iteration.

▶ **Lemma 23.** *After the depth-first search which augments f, the distance from s to t in the residual graph G_f under edge weights μ is at least $l+1$.*

Proof. Suppose after all the augmentations by a blocking flow, there still exists an s-t flow with length at most l under edge weights μ. So there exists a path $s = p_0, p_1, \cdots, p_e = t$ in G_f such that $e \leq l$. Consider two possibilities.

- $\mathsf{level}(p_i) = i, \forall 0 \leq i \leq e$. Then it must be $e = l$. For any edge (p_i, p_{i+1}), the capacity from p_i to p_{i+1} should always be positive throughout the depth-first search, since the algorithm never pushes flows from level $i+1$ to i. Hence, the depth-first search could not have terminated, which is a contradiction.
- There exists $0 \leq i < e$ such that $\mathsf{level}(p_{i+1}) > \mathsf{level}(p_i) + 1$. By the algorithm, the depth-first search never adds flows directly across nonconsecutive levels, so the capacity from p_i to p_{i+1} should be positive at the beginning as well. Then, by the shortest paths computation, $\mathsf{level}(p_{i+1})$ should be at most $\mathsf{level}(p_i) + 1$, which makes a contradiction as well. ◀

By the above lemma together with Lemma 4.6 from [4], we have the following corollary.

▶ **Corollary 24** ([4]). *After $2n^{2/3}$ iterations, the residual flow of f (namely, maximum flow in G_f) becomes at most $n^{2/3}$.*

Proof. By the pigeon-hole principle, there exists a pair of consecutive levels in the residual graph G_f whose union contains at most $n^{1/3}$ vertices. Therefore, the capacity of the cut between these two levels is at most $2 \cdot (\frac{n^{1/3}}{2})^2 < n^{2/3}$. ◀

4.2 Running time analysis

Finally, let us analyze the running time of our max flow algorithm. To analyze the total time of maintaining the layered clusters, first we need some properties regarding the maximum spanning forest MSF.

▶ **Lemma 25.** *For each index b, all star edges in $\mathcal{C}_b$ are tree edges in the maximum spanning forest. Plus, for each vertex $z \in Z_b$, there exists $y \in Y_b \cup \bigcup_{i>b} A_i$ such that (y, z) is also a tree edge.*

Proof. Consider any star edge (c, u) with c being the center. If (c, u) is not a tree edge, then the tree path between u, c connects u to another vertex $v \neq c$. By definition of ω, $\omega(u, v) \leq 2b - 1$, so switching (c, u) for (u, v) in the spanning forest gives a strictly larger total weight, which makes a contradiction.

Now consider the second half of the statement. By property (2) of the clustering structure, there exists $y \in Y_b \cup \bigcup_{i>b} A_i$ adjacent to z, and so $\omega(y, z) = 2b-1$. If (y, z) is not a tree edge, then there exists a tree path that connects z to y. Consider the first edge (z, w) on this path. As the spanning forest has maximum total weight, it must be $\omega(z, w) \geq \omega(z, y) = 2b - 1$. As $z \notin Y_b$, it can only be the case that $\omega(z, w) = 2b - 1$, and so w cannot be in Z_b or $\bigcup_{i<b} A_i$. Hence, $w \in Y_b \bigcup_{i>b} A_i$, which completes the proof. ◀

▶ **Corollary 26.** *For each $u \in A_b$, there exists a tree path of at most $\log n$ edges connecting u to a star center in $\bigcup_{i \geq b} Y_i$.*

▶ **Lemma 27.** *For each index b, and for each spanning tree $T \in \mathsf{MSF}$, suppose it contains k centers in $\bigcup_{i \geq b} Y_i$, then any tree path of T contains at most $O(k \log n)$ vertices in A_b.*

Proof. Suppose otherwise a tree path contains $20k \log n$ vertices in A_b, then there exists a sub-sequence of this tree path $u_1, u_2, \cdots, u_{2k}$ vertices in A_b, such that for each $1 \leq j < 2k$, the tree path from u_j to u_{j+1} has at least $9 \log n$ tree edges. By Corollary 26, there exists a center $v_j \in \bigcup_{i \geq b} Y_i$ such that u_j, v_j are connected by a tree path of length at most $\log n$ in MSF. By the pigeon-hole principle, there exists distinct indices $j_1 < j_2$ such that $v_{j_1} = v_{j_2}$, which means u_{j_1}, u_{j_2} are connected by a tree path of at most $2 \log n$ edges, contradiction. ◀

▶ **Lemma 28.** *The overall running time throughout all iterations of maintaining the layered clusters*

$$\{(\mathcal{C}_b, Y_b, Z_b)\}_{b \geq 1}$$

together with its induced edge weight ω is bounded by $\tilde{O}(n^2 + n\tau)$. Also, the total update time of maintaining the maximum spanning forest MSF is also bounded by $\tilde{O}(n^2 + n\tau)$.

Proof. Consider any unit flow that we send from s to t during this round. Focus on the part within the same component of MSF. By the routing scheme, the flow always uses the tree edges of the maximum spanning tree. By Lemma 27, the length of the tree path is at most proportional to the number of centers. Therefore, for the b-th layer, the number of vertices in A_b on the unit flow is bounded by $O(\frac{n}{2^b h} \log n)$. Since the augmenting path is a simple path, the number of edge deletions incident on A_b is at most $O(\frac{n}{2^b h} \log n)$ as well. Summing over at most τ augmentations, the total edge deletions incident on A_b is at most $\tilde{O}(\frac{n\tau}{2^b h})$. By Lemma 13, the total update time of maintaining the layered clustering is $\tilde{O}(n^2 + n\tau)$.

As for the dynamic maximum spanning forest MSF, the number of changes to G_f and ω is always upper bounded by the time to maintain the layered clustering, so the total time of maintaining MSF is bounded similarly. ◀

Next we bound the total number of new inter-component edges added to F_1 throughout all $2n^{2/3}$ iterations for a single round.

▶ **Lemma 29.** *During the for-loop of MaxFlow, the total number of edges in F_1 is bounded by $O(n\tau^{1/2} \log n)$.*

Proof. Similar to the previous lemma, we can prove that each augmentation turns at most $O(n/h \log n)$ undirected edges from F_0 to be directed edges in F_1. Since F_1 contains at most $O(nh)$ initially before the first iteration, the overall edges to F_1 is bounded by $O(nh + \frac{n\tau \log n}{h}) = O(n\tau^{1/2} \log n)$. ◀

The above lemma helps us bounding the total time of computing blocking flows through all iterations.

▶ **Lemma 30.** *The running time of a single iteration takes time $\tilde{O}(n\tau^{1/2})$.*

Proof. First, invoking Dijkstra's algorithm takes time $O(|F_1| + n \log n) = \tilde{O}(n\tau^{1/2})$. Next, we need to argue that in each iteration, the blocking flow procedure takes time $\tilde{O}(|F_1| + n)$ as well. In fact, we claim that each edge $(v, w) \in F_1$ can be visited by at most twice during the depth-first search. If $\mathsf{level}(w) \neq \mathsf{level}(v) + 1$, then the algorithm does to need to consider it when searching for augmenting paths, as $\mathsf{level}(\cdot)$ does not change within this iteration. Now let us assume $\mathsf{level}(w) = \mathsf{level}(v) + 1$. If (v, w) is a directed edge, then after two augmentations it would be a directed edge from w to v, and so it would never be visited again; if (v, w) is an undirected edge, then after one augmentation it would be a directed one from w to v as well.

Finally, we efficiently enumerate edges incident on any tree in MSF under edge deletions, we could arrange all vertices in this tree according to the Euler-tour which supports fast link and cut operations on trees. ◀

By the above lemmas, the total time of for-loop is bounded by $\tilde{O}(n^2 + n\tau + n^{5/3}\tau^{1/2}) = \tilde{O}(n^{5/3}\tau^{1/2})$. After the while-loop, the total residual flow is bounded by $O(n^{2/3})$, so by Lemma 5 the rest takes time $\tilde{O}(n^{5/3}\tau^{1/2})$ as well.

Arboreal Categories and Resources

Abstract

We introduce *arboreal categories*, which have an intrinsic process structure, allowing dynamic notions such as bisimulation and back-and-forth games, and resource notions such as number of rounds of a game, to be defined. These are related to extensional or "static" structures via *arboreal covers*, which are resource-indexed comonadic adjunctions. These ideas are developed in a very general, axiomatic setting, and applied to relational structures, where the comonadic constructions for pebbling, Ehrenfeucht-Fraïssé and modal bisimulation games recently introduced in [1, 5, 6] are recovered, showing that many of the fundamental notions of finite model theory and descriptive complexity arise from instances of arboreal covers.

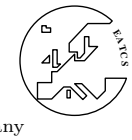
1 Introduction



In previous work ([1, 5, 6]), it has been shown how a range of model comparison games which play a central role in finite model theory, including Ehrenfeucht-Fraïssé, pebbling, and bisimulation games, can be captured in terms of resource-indexed comonads on the category of relational structures and homomorphisms. This was done for k-pebble games in [1], and extended to Ehrenfeucht-Fraïssé games, and bisimulation games for the modal fragment, in [5]. In subsequent work, this has been further extended to games for generalized quantifiers [9], and for guarded fragments of first-order logic [3]. An important feature of this comonadic analysis is that it leads to novel characterisations of important combinatorial parameters such as tree-width and tree-depth. The coalgebras for each of these comonads correspond to certain forms of tree decompositions of structures, with the resource index matching the corresponding combinatorial parameter.

This leads to the question motivating the present paper:

> Can we capture the significant common elements of these constructions?

Our aim is to develop an elegant axiomatic account, based on clear conceptual principles, which will yield all these examples and more, and allow a deeper and more general understanding of resources.

Conceptually, a key ingredient is the assignment of a process structure – an intensional description – to an extensional object, such as a function, a set, or a relational structure. It is this process structure, unfolding in space and time, to which a resource parameter can be applied, which can then be transferred to the extensional object. At the basic level of computability, this happens when we assign a Turing machine description or a Gödel number to a recursive function. It is then meaningful to assign a complexity measure to the function. The same phenomenon arises in semantics: for example, the notion of *sequentiality* is applicable to a *process* computing a higher-order function. Reifying these processes in the form of *game semantics* led to a resolution of the famous full abstraction problem for PCF [2, 11], and to a wealth of subsequent results [20].

It is now becoming clear that this phenomenon is at play in the game comonads described in [1, 5, 6, 9, 3]. They build tree-structured covers of a given, purely extensional relational structure. Such a tree cover will in general not have the full properties of the original structure, but be a "best approximation" in some resource-restricted setting. More precisely, this means that we have an adjunction, yielding the corresponding comonad. The objects of the category where the approximations live have an intrinsic tree structure, which can be captured axiomatically. The tree encodes a process for generating (parts of) the relational structure, to which resource notions can be applied.

In this paper, we make this intuition precise. We introduce a notion of *arboreal category*, and show how all the examples of game comonads considered to date arise from *arboreal covers*, i.e. adjunctions between extensional categories of relational structures, and arboreal categories. Importantly, these adjunctions are comonadic, and the categories of coalgebras provide a setting for a general notion of bisimulation, which yields a wide range of logical equivalences in the examples. This notion refines the open maps formulation of bisimulation [13, 12] with the condition that the maps are *pathwise embeddings*, generalizing the ideas introduced in [6]. This allows a much wider range of logical equivalences to be captured.

After some preliminaries, we shall develop the axiomatization of paths, open pathwise embeddings and bisimulations, and arboreal categories. Then we establish the correspondence between bisimulations and back-and-forth equivalences in the setting of arboreal categories. Next, we show how many of the fundamental notions of finite model theory and descriptive complexity arise from instances of arboreal covers. We shall use the concrete constructions in finite model theory as running examples throughout.

We conclude this introduction by observing that the notion of *extendability*, a key ingredient for Rossman-type preservation theorems [19], can be defined in this general setting (more details are provided in the expanded version [4]).

2 Preliminaries

We shall assume familiarity with standard notions in category theory. All needed background can be found in [7, 16]. All categories under consideration are assumed to be locally small and *well-powered*, i.e. every object has a set of subobjects (as opposed to a proper class).

▶ **Example 1.** The extensional categories of primary interest in this paper are categories of relational structures. A relational vocabulary σ is a set of relation symbols R, each with a specified positive integer arity. A σ-structure $\mathcal{A}$ is given by a set A, the universe of the structure, and for each R in σ with arity n, a relation $R^{\mathcal{A}} \subseteq A^n$. A homomorphism

$h\colon \mathcal{A} \to \mathcal{B}$ is a function $h\colon A \to B$ such that, for each relation symbol R of arity n in σ, for all $a_1, \dots, a_n$ in A, $R^{\mathcal{A}}(a_1, \dots, a_n) \Rightarrow R^{\mathcal{B}}(h(a_1), \dots, h(a_n))$. We write $\mathsf{Struct}(\sigma)$ for the category of σ-structures and homomorphisms. The Gaifman graph of a structure $\mathcal{A}$ is a graph with vertices A, such that two distinct elements are adjacent if they both occur in some tuple $\vec{a} \in R^{\mathcal{A}}$ for some relation symbol R in σ.

2.1 Proper factorisation systems

We recall the notion of weak factorisation system in a category $\mathcal{C}$. Given arrows e and m in $\mathcal{C}$, we say that e has the *left lifting property* with respect to m, or that m has the *right lifting property* with respect to e, if for every commutative square as on the left-hand side below

there exists a (not necessarily unique) *diagonal filler*, i.e. an arrow d such that the right-hand diagram above commutes. If this is the case, we write $e \pitchfork m$. For any class $\mathcal{H}$ of morphisms in $\mathcal{C}$, let ${}^{\pitchfork}\mathcal{H}$ (respectively $\mathcal{H}^{\pitchfork}$) be the class of morphisms having the left (respectively right) lifting property with respect to every morphism in $\mathcal{H}$.

▶ **Definition 2.** *A pair of classes of morphisms $(\mathcal{Q}, \mathcal{M})$ in a category $\mathcal{C}$ is a* weak factorisation system *provided it satisfies the following conditions:*

(i) *every morphism f in $\mathcal{C}$ can be written as $f = m \circ e$ with $e \in \mathcal{Q}$ and $m \in \mathcal{M}$;*

(ii) $\mathcal{Q} = {}^{\pitchfork}\mathcal{M}$ *and* $\mathcal{M} = \mathcal{Q}^{\pitchfork}$.

A proper factorisation system *is a weak factorisation system $(\mathcal{Q}, \mathcal{M})$ such that $\mathcal{Q} \subseteq \{\text{epis}\}$ and $\mathcal{M} \subseteq \{\text{monos}\}$. A proper factorisation system is* stable *if, for any $e \in \mathcal{Q}$ and $m \in \mathcal{M}$ with common codomain, the pullback of e along m exists and belongs to $\mathcal{Q}$.*[1]

▶ Remark 3. Any proper factorisation system is an *orthogonal* factorisation system, i.e. the diagonal fillers are unique. In particular, factorisations are unique up to (unique) isomorphism.

▶ **Example 4.** If $\mathcal{A}$ is a relational structure, then for any $S \subseteq A$, there is an induced substructure with universe S. The inclusion map $S \hookrightarrow A$ is an *embedding*, i.e. an injective homomorphism which reflects as well as preserves relations. Any embedding $m\colon \mathcal{A} \to \mathcal{B}$ factors as $\mathcal{A} \cong \mathsf{Im}(m) \hookrightarrow \mathcal{B}$. Taking $\mathcal{Q}$ to be the surjective homomorphisms and $\mathcal{M}$ to be the embeddings gives a proper factorisation system on $\mathsf{Struct}(\sigma)$. This factorisation system is stable because pullbacks in $\mathsf{Struct}(\sigma)$ are computed in the category of sets and functions, where (surjections, injections) is a stable proper factorisation system.

Next, we state some well known properties of weak factorisation systems (cf. [10] or [18]):

▶ **Lemma 5.** *Let $(\mathcal{Q}, \mathcal{M})$ be a weak factorisation system in $\mathcal{C}$. The following hold:*

(a) *$\mathcal{Q}$ and $\mathcal{M}$ are closed under compositions.*

(b) $\mathcal{Q} \cap \mathcal{M} = \{\textit{isomorphisms}\}$.

(c) *The pullback in $\mathcal{C}$ of an $\mathcal{M}$-morphism along any morphism, if it exists, is again in $\mathcal{M}$.*

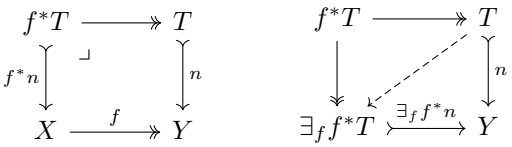
Moreover, if $(\mathcal{Q}, \mathcal{M})$ is proper, then the following hold:

(d) *$g \circ f \in \mathcal{Q}$ implies $g \in \mathcal{Q}$.*

(e) *$g \circ f \in \mathcal{M}$ implies $f \in \mathcal{M}$.*

[1] In the literature, the adjective *stable* is usually reserved for the stronger property stating that, for every $e \in \mathcal{Q}$, the pullback of e along any morphism exists and belongs to $\mathcal{Q}$.

Throughout this paper, we will refer to $\mathcal{M}$-morphisms as *embeddings* and denote them by $\rightarrowtail$. $\mathcal{Q}$-morphisms will be referred to as *quotients* and denoted by $\twoheadrightarrow$.



Assume $\mathcal{C}$ is a category admitting a proper factorisation system $(\mathcal{Q}, \mathcal{M})$. In the same way that one usually defines the poset of subobjects of a given object $X \in \mathcal{C}$, we can define the poset of $\mathcal{M}$-subobjects of X. Given embeddings $m\colon S \rightarrowtail X$ and $n\colon T \rightarrowtail X$, let us say that $m \trianglelefteq n$ provided there is a morphism $i\colon S \to T$ such that $m = n \circ i$ (note that i is necessarily an embedding). This yields a preorder on the class of all embeddings with codomain X. The symmetrization $\sim$ of $\trianglelefteq$ can be characterised as follows: $m \sim n$ if, and only if, there exists an isomorphism $i\colon S \to T$ such that $m = n \circ i$. Let $\mathbb{S}\,X$ be the class of $\sim$-equivalence classes of embeddings with codomain X, equipped with the natural partial order $\leq$ induced by $\trianglelefteq$. We shall systematically represent a $\sim$-equivalence class by any of its representatives. Because $\mathcal{C}$ is well-powered and $\mathcal{M} \subseteq \{\text{monos}\}$, we see that $\mathbb{S}\,X$ is a set.

For any morphism $f\colon X \to Y$ and embedding $m\colon S \rightarrowtail X$, we can consider the $(\mathcal{Q}, \mathcal{M})$-factorisation $S \twoheadrightarrow \exists_f S \rightarrowtail Y$ of $f \circ m$. This yields a monotone map $\exists_f\colon \mathbb{S}\,X \to \mathbb{S}\,Y$ sending m to the embedding $\exists_f S \rightarrowtail Y$. (Note that the map $\exists_f$ is well-defined because factorisations are unique up to isomorphism.) Further, if $(\mathcal{Q}, \mathcal{M})$ is stable and f is a quotient, we let $f^*\colon \mathbb{S}\,Y \to \mathbb{S}\,X$ be the monotone map sending $n\colon T \rightarrowtail Y$ to its pullback along f. It is not difficult to see that f^* is right adjoint to $\exists_f$.

▶ **Lemma 6.** *Let $\mathcal{C}$ be any category equipped with a stable proper factorisation system, and let $f\colon X \to Y$ be any morphism in $\mathcal{C}$. The following statements hold:*
(a) *If f is an embedding, then $\exists_f\colon \mathbb{S}\,X \to \mathbb{S}\,Y$ is an order-embedding.*
(b) *If f is a quotient, then $f^*\colon \mathbb{S}\,Y \to \mathbb{S}\,X$ is an order-embedding.*

Proof. For item (a) note that, as $f\colon X \to Y$ is an embedding, $\exists_f\colon \mathbb{S}\,X \to \mathbb{S}\,Y$ sends m to $f \circ m$. Let $m_1\colon S_1 \rightarrowtail X$ and $m_2\colon S_2 \rightarrowtail X$ be embeddings such that $f \circ m_1 \leq f \circ m_2$. Then there exists $k\colon S_1 \to S_2$ such that $f \circ m_1 = f \circ m_2 \circ k$. Because f is a monomorphism, it follows that $m_1 = m_2 \circ k$, i.e. $m_1 \leq m_2$. Hence, $\exists_f$ is an order-embedding.

For item (b), it is enough to prove that $\exists_f f^* n = n$ for any $n\colon T \rightarrowtail Y$, for then $f^* n_1 \leq f^* n_2$ implies $n_1 = \exists_f f^* n_1 \leq \exists_f f^* n_2 = n_2$. Consider the pullback of f along n, as displayed on the left-hand side below.

Since the square on the right-hand side above commutes, there exists a diagonal filler $T \to \exists_f f^* T$. Note that this diagonal filler must be both a quotient and an embedding, hence an isomorphism. Therefore, $\exists_f f^* n = n$ in $\mathbb{S}\,Y$. ◀

3 Path Categories

3.1 Paths

Throughout this section, we fix a category $\mathcal{C}$ equipped a stable proper factorisation system.

If $(P, \leq)$ is a poset, then $C \subseteq P$ is a *chain* if it is linearly ordered. $(P, \leq)$ is a *forest* if, for all $x \in P$, the set $\downarrow x := \{y \in P \mid y \leq x\}$ is a finite chain. The *height* of a forest is the supremum of the cardinalities of its chains. The *covering relation* $\prec$ associated with a partial order $\leq$ is defined by $u \prec v$ if and only if $u < v$ and there is no w such that $u < w < v$. It is

convenient to allow the empty forest. The *roots* of a forest are the minimal elements. A *tree* is a forest with at most one root. Morphisms of forests are maps which preserve roots and the covering relation. Equivalently, a monotone map $\varphi\colon U \to V$ between forests is a forest morphism if, for all $u \in U$, the restriction of φ yields a bijection between $\downarrow u$ and $\downarrow \varphi(u)$. The category of forests is denoted by $\mathcal{F}$, and the full subcategory of trees by $\mathcal{T}$. We equip these categories with the factorisation system (surjective morphisms, injective morphisms).

▶ **Definition 7.** *An object X of $\mathcal{C}$ is called a* path *provided the poset $\mathbb{S}\,X$ is a finite chain. Paths will be denoted by $P, Q, R, \ldots$.*

▶ **Example 8.** The paths in $\mathcal{F}$ and $\mathcal{T}$ are the finite chains, i.e. the trees consisting of a single branch.

▶ **Example 9.** We define a *forest-ordered σ-structure* $(\mathcal{A}, \leq)$ to be a σ-structure $\mathcal{A}$ with a forest order $\leq$ on A. A morphism of forest-ordered σ-structures $f\colon (\mathcal{A}, \leq) \to (\mathcal{B}, \leq')$ is a σ-homomorphism $f\colon \mathcal{A} \to \mathcal{B}$ that is also a forest morphism. This determines a category $\mathcal{R}(\sigma)$. We equip $\mathcal{R}(\sigma)$ with the factorisation system given by (surjective morphisms, embeddings), where an embedding is a morphism which is an embedding *qua* σ-homomorphism.

In [6], it is shown that the categories of coalgebras for the various comonads studied there are given, up to isomorphism, by subcategories of $\mathcal{R}(\sigma)$ (or minor variants thereof):

- For the Ehrenfeucht-Fraïssé comonad, this is the full subcategory $\mathcal{R}^E(\sigma)$ determined by those objects satisfying the condition (E): adjacent elements of the Gaifman graph of $\mathcal{A}$ are comparable in the forest order. For each $k > 0$, $\mathcal{R}^E_k(\sigma)$ is the full subcategory of $\mathcal{R}^E(\sigma)$ of those forest orders of height $\leq k$. The objects $(\mathcal{A}, \leq)$ of $\mathcal{R}^E_k(\sigma)$ are forest covers of $\mathcal{A}$ witnessing that its tree-depth is $\leq k$ [17].
- For the pebbling comonad, for each $k > 0$ this is the category $\mathcal{R}^P_k$ whose objects have the form $(\mathcal{A}, \leq, p)$, where $(\mathcal{A}, \leq)$ is a forest-ordered σ-structure, and $p\colon A \to [k]$ is a pebbling function. In addition to condition (E), these structures have to satisfy the condition (P): if a is adjacent to b in the Gaifman graph of $\mathcal{A}$, and $a < b$ in the forest order, then for all x such that $a < x \leq b$, $p(a) \neq p(x)$. It is shown in [6] that these structures are equivalent to the more familiar form of tree decomposition used to define tree-width [14]. Morphisms have to preserve the pebbling function.
- For the modal comonad, the category $\mathcal{R}^M_k$ has as objects the tree-ordered σ-structures of height $\leq k$ satisfying the condition (M): for $x, y \in A$, $x \prec y$ if and only if for some unique binary relation R_α in σ ("transition relation"), $R^{\mathcal{A}}_\alpha(x, y)$.

The paths in each of these categories are those structures in which the order is a finite chain. These are our key motivating examples for paths. Note that in the (multi-)modal case, ignoring propositional variables, these correspond to synchronization trees consisting of a single branch, i.e. traces.

The following fact is an immediate consequence of Lemma 6:

▶ **Lemma 10.** *Let $f\colon X \to Y$ be any morphism in $\mathcal{C}$. The following statements hold:*

(a) *If Y is a path and f is an embedding, then X is a path.*

(b) *If X is path and f is a quotient, then Y is a path.*

A *path embedding* is an embedding $P \rightarrowtail X$ whose domain is a path. Given any object X of $\mathcal{C}$, we let $\mathbb{P}\,X$ be the sub-poset of $\mathbb{S}\,X$ consisting of the path embeddings. By Lemma 10(b), for any arrow $f\colon X \to Y$, the monotone map $\exists_f\colon \mathbb{S}\,X \to \mathbb{S}\,Y$ restricts to a monotone map

$$\mathbb{P}\,f\colon \mathbb{P}\,X \to \mathbb{P}\,Y, \quad (m\colon P \rightarrowtail X) \mapsto (\exists_f m\colon \exists_f P \rightarrowtail Y).$$

By the uniqueness up to isomorphism of factorisations, this assignment is functorial.

3.2 Path categories

▶ **Definition 11.** *A* path category *is a category $\mathcal{C}$ satisfying the following conditions:*

(i) *$\mathcal{C}$ has a stable proper factorisation system;*

(ii) *$\mathcal{C}$ has all coproducts of small families of paths;*

(iii) *for any paths P, Q, R, if a composite $P \to Q \to R$ is a quotient, then so is $P \to Q$.*

▶ Remark 12. Item (iii) above is equivalent to the following condition: For any paths P, Q, R and morphisms $f\colon P \to Q$ and $g\colon Q \to R$, if any two of f, g, and $g \circ f$ are quotients, then so is the third. Thus, we shall refer to (iii) as the *2-out-of-3 condition*.

Any path category has an initial object, obtained as the coproduct of the empty family.

▶ **Example 13.** $\mathcal{F}$ and $\mathcal{T}$ are path categories. Coproducts of forests are given by disjoint union. For trees, coproducts are given by smash sum, with the bottom elements identified. Since forest morphisms preserve height, we see that $\mathcal{F}$ and $\mathcal{T}$ satisfy the 2-out-of-3 condition. Similarly, it is not difficult to see that $\mathcal{R}(\sigma)$ and its subcategories mentioned in Example 9 are all path categories ($\mathcal{R}(\sigma)$ has an initial object because we allow empty σ-structures).

▶ **Theorem 14.** *Let $\mathcal{C}$ be a path category. Then the assignment $X \mapsto \mathbb{P}\,X$ induces a functor $\mathbb{P}\colon \mathcal{C} \to \mathcal{T}$ into the category of trees.*

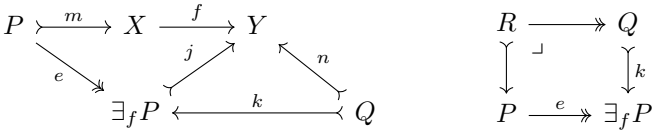
To prove this theorem, we start by showing that each poset $\mathbb{P}\,X$ is a tree.

▶ **Lemma 15.** *Let $\mathcal{C}$ be a path category. For any object X of $\mathcal{C}$, $\mathbb{P}\,X$ is a non-empty tree.*

Proof. Using Lemma 6(a), it is not difficult to see that the sub-poset of $\mathbb{P}\,X$ consisting of those elements that are below a given $P \in \mathbb{P}\,X$ is isomorphic to $\mathbb{P}\,P$. In turn, $\mathbb{P}\,P \cong \mathbb{S}\,P$ by Lemma 10(a). Since $\mathbb{S}\,P$ is a finite chain, we see that $\mathbb{P}\,X$ is a forest. Now, let $\mathbf{0} \twoheadrightarrow \widetilde{\mathbf{0}} \overset{m}{\rightarrowtail} X$ be the (quotient, embedding) factorisation of the unique morphism $\mathbf{0} \to X$ from the initial object. We claim that $m\colon \widetilde{\mathbf{0}} \rightarrowtail X$ is the unique root of $\mathbb{P}\,X$.

Note that $\mathbf{0}$ is a path: just observe that any embedding $S \rightarrowtail \mathbf{0}$ admits the unique morphism $\mathbf{0} \to S$ as a right inverse, and thus is a retraction. It follows that $S \cong \mathbf{0}$, i.e., $\mathbb{S}\,\mathbf{0}$ is the one-element poset. In particular, $\mathbf{0}$ is a path. Thus, $\widetilde{\mathbf{0}}$ is a path by Lemma 10(b). We show that $m\colon \widetilde{\mathbf{0}} \rightarrowtail X$ is the least element of $\mathbb{P}\,X$. If $m'\colon P \rightarrowtail X$ is any path embedding, we have a commutative square as follows.

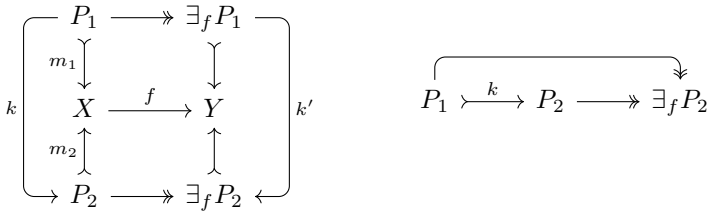
$$\begin{array}{ccc} \mathbf{0} & \twoheadrightarrow & \widetilde{\mathbf{0}} \\ \downarrow & & \downarrow{\scriptstyle m} \\ P & \overset{m'}{\rightarrowtail} & X \end{array}$$



Hence there exists a diagonal filler $d\colon \widetilde{\mathbf{0}} \to P$, and so $m \leq m'$ in $\mathbb{P}\,X$. ◀

We next show that the functor $\mathbb{P}$ sends morphisms in a path category to tree morphisms, thus completing the proof of Theorem 14.

▶ **Proposition 16.** *Let $\mathcal{C}$ be a path category. For any arrow f in $\mathcal{C}$, $\mathbb{P}\,f$ is a tree morphism.*



Proof. It is enough to show that, for any path embedding $m\colon P \rightarrowtail X$, the induced map $\mathbb{P}\,f\colon {\downarrow}m \to {\downarrow}\mathbb{P}\,f(m)$ is a bijection.

We start by establishing surjectivity, i.e. $\downarrow \mathbb{P}\, f(m) \subseteq \mathbb{P}\, f(\downarrow m)$. Let (e, j) be the (quotient, embedding) factorisation of $f \circ m$. If $n \colon Q \rightarrowtail Y$ is a path embedding such that $n \leq \mathbb{P}\, f(m)$ in $\mathbb{P}\, Y$, there exists an embedding $k \colon Q \rightarrowtail \exists_f P$ such that the left-hand diagram below commutes. Consider the pullback of k along e, as displayed in the right-hand diagram below.

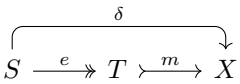
Then R is a path by Lemmas 5(c) and 10(a), and the composite $i \colon R \rightarrowtail P \rightarrowtail X$ is a path embedding which is below m in the poset $\mathbb{P}\, P$. Further, the top horizontal arrow in the pullback square is a quotient and so, by the uniqueness up to isomorphism of factorisations, the (quotient, embedding) factorisation of $f \circ i$ is $R \twoheadrightarrow Q \overset{n}{\rightarrowtail} Y$, i.e., $\mathbb{P}\, f(i) = n$.

For injectivity, let $m_1 \colon P_1 \rightarrowtail X$ and $m_2 \colon P_2 \rightarrowtail X$ be path embeddings in $\downarrow m$. Since P is a path, m_1 and m_2 are comparable in the order of $\mathbb{P}\, X$. Assume without loss of generality that $m_1 \leq m_2$, i.e., there exists an embedding $k \colon P_1 \rightarrowtail P_2$ such that $m_1 = m_2 \circ k$. If $\mathbb{P}\, f(m_1) = \mathbb{P}\, f(m_2)$, there exists an isomorphism $k' \colon \exists_f P_1 \to \exists_f P_2$ making the left-hand diagram below commute.

In particular, the diagram on the right-hand side above commutes, where the top horizontal arrow is the composition of $P_1 \twoheadrightarrow \exists_f P_1$ with the isomorphism $k' \colon \exists_f P_1 \to \exists_f P_2$. By the 2-out-of-3 condition, k is an isomorphism, and so $m_1 = m_2$ in $\mathbb{P}\, X$. ◀

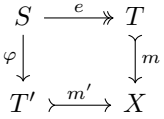
We conclude this section with the following useful observation:

▶ **Lemma 17.** *The following statements hold for any object X of a path category $\mathcal{C}$:*



(a) *Any subset $\mathcal{U} \subseteq \mathbb{P}\, X$ admits a supremum $\bigvee \mathcal{U}$ in $\mathbb{S}\, X$.*

(b) *For any path embedding $m \in \mathbb{P}\, X$ and non-empty set $\mathcal{S} \subseteq \mathbb{S}\, X$, if $m = \bigvee \mathcal{S}$ then $m \in \mathcal{S}$.*



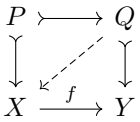
Proof. For item (a), consider a set of path embeddings

$$\mathcal{U} = \{m_i \colon P_i \rightarrowtail X \mid i \in I\} \subseteq \mathbb{P}\, X.$$

Let $S \coloneqq \coprod_{i \in I} P_i$ be the coproduct in $\mathcal{C}$ of the paths P_i and consider the (quotient, embedding) factorisation of the canonical morphism $\delta \colon S \to X$ whose component at P_i is m_i:

Each path embedding $m_i \in \mathcal{U}$ factors through m, thus m is an upper bound for $\mathcal{U}$. We claim that m is the least upper bound, i.e., $m = \bigvee \mathcal{U}$ in $\mathbb{S}\, X$. Suppose that all path embeddings in $\mathcal{U}$ factor through some embedding $m' \colon T' \rightarrowtail X$. By the universal property of S, we get a morphism $\varphi \colon S \to T'$. Further, using again the universal property of S, it is not difficult to see that $m' \circ \varphi$ coincides with δ, and so the following square commutes.

Therefore, there exists a diagonal filler $T \to T'$. In particular, the commutativity of the lower triangle entails that $m \leq m'$, as was to be proved.



For item (b), let $m\colon P \rightarrowtail X$ be a path embedding and $\mathcal{S} \subseteq \mathbb{S}\,X$ a non-empty set such that $m = \bigvee \mathcal{S}$. Then $n \leq m$ for each $n \in \mathcal{S}$. Since P is a path, $\downarrow m$ is a finite chain in $\mathbb{S}\,X$ and so $\mathcal{S}$ must be a finite set whose largest element coincides with m. In particular, $m \in \mathcal{S}$. ◀

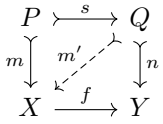
4 Pathwise Embeddings, Open Maps, and Bisimulations

Throughout this section, we fix a category $\mathcal{C}$ equipped with a stable proper factorisation system.

Pathwise embeddings and open maps

Following [6], let us say that a morphism $f\colon X \to Y$ in $\mathcal{C}$ is a *pathwise embedding* if, for all path embeddings $m\colon P \rightarrowtail X$, the composite $f \circ m$ is a path embedding. Hence, $\mathbb{P}\,f(m) = f \circ m$ for all $m \in \mathbb{P}\,X$. Following again [6], we introduce a notion of open map – inspired by [13] – that, combined with the concept of pathwise embedding, will allow us to define an appropriate notion of bisimulation. A morphism $f\colon X \to Y$ in $\mathcal{C}$ is said to be *open* if it satisfies the following path-lifting property: Given any commutative square

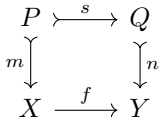
with P, Q paths, there exists a diagonal filler $Q \to X$ (i.e., an arrow $Q \to X$ making the two triangles commute). Note that, if it exists, such a diagonal filler must be an embedding.



▶ Remark 18. The previous definition of open map differs from the one given in [13] because we require that, in the square above, the top horizontal morphism and the vertical ones be embeddings. However, a pathwise embedding is open in $\mathcal{C}$ (according to the definition above) if, and only if, it is open (in the sense of [13]) in the subcategory $\mathcal{C}_*$ of $\mathcal{C}$ having the same objects as $\mathcal{C}$ and morphisms the pathwise embeddings.

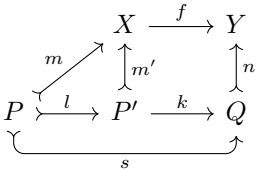
For pathwise embeddings $f\colon X \to Y$, openness can be characterised in terms of the corresponding monotone map $\mathbb{P}\,f\colon \mathbb{P}\,X \to \mathbb{P}\,Y$:

▶ **Proposition 19.** *The following are equivalent for any pathwise embedding $f\colon X \to Y$:*



1. *f is open.*
2. *$\mathbb{P}\,f$ is a p-morphism, i.e. $\mathbb{P}\,f(\uparrow m) = \uparrow \mathbb{P}\,f(m)$ for all $m \in \mathbb{P}\,X$.*

Proof. (1) ⇒ (2). Suppose f is open, and let $m\colon P \rightarrowtail X$ be an arbitrary element of $\mathbb{P}\,X$. The inclusion $\mathbb{P}\,f(\uparrow m) \subseteq \uparrow \mathbb{P}\,f(m)$ follows at once from monotonicity of $\mathbb{P}\,f$. For the converse inclusion, assume that $n\colon Q \rightarrowtail Y$ is an element of $\mathbb{P}\,Y$ above $\mathbb{P}\,f(m) = f \circ m$. Then, the composite $f \circ m$ must factor through n, say $f \circ m = n \circ s$ for some embedding $s\colon P \rightarrowtail Q$. Hence, we have a commutative square as displayed below.



Since f is open, there exists a diagonal filler $m' \colon Q \rightarrowtail X$. The commutativity of the upper triangle entails that $m' \in \uparrow m$, while the commutativity of the lower triangle implies that $\mathbb{P}\, f(m') = n$. Therefore, $\uparrow \mathbb{P}\, f(m) \subseteq \mathbb{P}\, f(\uparrow m)$.

(2) $\Rightarrow$ (1). Assume $\mathbb{P}\, f$ is a p-morphism, and consider a commutative square as follows,

where P and Q are paths. We have $\mathbb{P}\, f(m) \leq n$ in $\mathbb{P}\, Y$, and thus there exists a path embedding $m' \colon P' \rightarrowtail X$ satisfying $m \leq m'$ and $\mathbb{P}\, f(m') = n$. The inequality $m \leq m'$ amounts to saying that $m = m' \circ l$ for some embedding $l \colon P \rightarrowtail P'$, while the equality $\mathbb{P}\, f(m') = n$ means that $f \circ m' = n \circ k$ for some isomorphism $k \colon P' \to Q$. We have a commutative diagram as displayed below.

We claim that $m' \circ k^{-1} \colon Q \to X$ satisfies $m' \circ k^{-1} \circ s = m$ and $f \circ m' \circ k^{-1} = n$, thus showing that f is open. To start with, note that $k \circ l = s$. Just observe that

$$n \circ k \circ l = f \circ m' \circ l = f \circ m = n \circ s,$$

and so $k \circ l = s$ because n is a monomorphism. Now, by diagram chasing we see that

$$m' \circ k^{-1} \circ s = m' \circ k^{-1} \circ k \circ l = m' \circ l = m$$

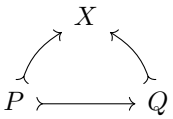
and $f \circ m' \circ k^{-1} = n \circ k \circ k^{-1} = n$. This concludes the proof. ◀

Bisimulations

A *bisimulation* between objects X, Y of $\mathcal{C}$ is a span of open pathwise embeddings $X \leftarrow Z \rightarrow Y$ in $\mathcal{C}$. If such a bisimulation exists, we say that X and Y are *bisimilar*.

▶ **Example 20.** This definition directly generalizes that in [6], and the notions of bisimulation given there for the Ehrenfeucht-Fraïssé, pebbling and modal comonads are the special cases arising in the categories $\mathcal{R}_k^E(\sigma)$, $\mathcal{R}_k^P(\sigma)$ and $\mathcal{R}_k^M(\sigma)$ respectively, as described in Example 9.

▶ Remark 21. Let $\mathcal{C}$ be a path category. If we regard trees as Kripke models where the accessibility relation is the tree order, then it follows from Theorem 14 and Proposition 19 that a span of pathwise embeddings $X \xleftarrow{f} Z \xrightarrow{g} Y$ in $\mathcal{C}$ is a bisimulation if, and only if, $\mathbb{P}\, X \xleftarrow{\mathbb{P}\, f} \mathbb{P}\, Z \xrightarrow{\mathbb{P}\, g} \mathbb{P}\, Y$ is a bisimulation of Kripke models in the usual sense.



Given a bisimulation $X \leftarrow Z \rightarrow Y$, we would like to think of Z as providing a winning strategy for Duplicator in an appropriate game played "between X and Y". To substantiate this idea, in the next two sections we introduce *arboreal categories* – a refinement of the concept of path category – and show that, in these categories, bisimilarity is captured by back-and forth systems which model the dynamic nature of games.

5 Arboreal Categories

By Theorem 14, any path category $\mathcal{C}$ admits a functor $\mathbb{P}\colon \mathcal{C} \to \mathcal{T}$ into the category of trees. In general, the tree $\mathbb{P}\,X$ may retain little information about X. We are interested in the case where X is determined by $\mathbb{P}\,X$. This leads us to the notion of path-generated object.

Path-generated objects

Let $\mathcal{C}$ be a path category. For any object X of $\mathcal{C}$, we have a diagram with vertex X consisting of all path embeddings with codomain X:

The morphisms between paths are those which make the obvious triangles commute. Choosing representatives in an appropriate way, this can be seen as a cocone over the small diagram $\mathbb{P}\,X$. We say that X is *path-generated* provided this is a colimit cocone in $\mathcal{C}$. Intuitively, an object is path-generated if it is the colimit of its paths.

Let $\mathcal{C}_p$ be the full subcategory of $\mathcal{C}$ defined by the paths and recall that a functor $J\colon \mathcal{A} \to \mathcal{B}$ is *dense* if every $b \in \mathcal{B}$ is the colimit of the diagram $J{\downarrow}b \xrightarrow{\pi} \mathcal{A} \xrightarrow{J} \mathcal{B}$, where $J{\downarrow}b$ is the comma category and π is the natural forgetful functor.

▶ **Lemma 22.** *The following statements are equivalent for any path category $\mathcal{C}$:*
1. *Every object of $\mathcal{C}$ is path-generated.*
2. *The inclusion $\mathcal{C}_p \hookrightarrow \mathcal{C}$ is dense.*

Arboreal categories

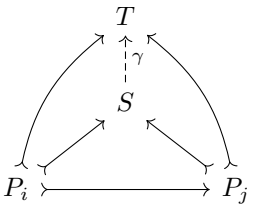
We now state the axioms for an arboreal category. To this end, let us say that an object X of a path category $\mathcal{C}$ is *connected* if, for all small families of paths $\{P_i \mid i \in I\}$ in $\mathcal{C}$, any morphism $X \to \coprod_{i\in I} P_i$ factors through some coproduct injection $P_j \to \coprod_{i\in I} P_i$.

▶ **Definition 23.** *An* arboreal category *is a path category $\mathcal{C}$ satisfying the following conditions:*
- **(i)** *every object of $\mathcal{C}$ is path-generated;*
- **(ii)** *every path in $\mathcal{C}$ is connected.*

▶ **Example 24.** The category $\mathcal{T}$ of trees is arboreal; this is essentially the observation that (i) every tree is the colimit of the diagram given by its branches and the embeddings between them, and (ii) finite chains are connected in $\mathcal{T}$. Similarly, $\mathcal{F}$ is arboreal. Our key examples of the categories $\mathcal{R}_k^E(\sigma)$, $\mathcal{R}_k^P(\sigma)$ and $\mathcal{R}_k^M(\sigma)$ from Example 9 are also arboreal.

Note that, in view of Theorem 14, any arboreal category $\mathcal{C}$ admits a functor $\mathbb{P}\colon \mathcal{C} \to \mathcal{T}$ into the category of trees. This crucial fact is what will allow us, given an arboreal cover (cf. Section 7), to regard process structures as tree-like objects.

We collect some useful consequences of the axioms above.



▶ **Lemma 25.** *Let $\mathcal{C}$ be an arboreal category. The following statements hold:*
(a) *Between any two paths there is at most one embedding.*
(b) *For any object X of $\mathcal{C}$ and any $m \in \mathbb{S}\,X$, $m = \bigvee \{p \in \mathbb{P}\,X \mid p \leq m\}$.*
(c) *If f is a quotient in $\mathcal{C}$, then $\mathbb{P}\,f$ is a surjection.*

Proof. For item (a), since there is at most on tree morphism between any two finite chains, it suffices to show that $\mathbb{P}\colon \mathcal{C} \to \mathcal{T}$ is faithful on embeddings between paths. That is, whenever $f, g\colon P \rightrightarrows Q$ are embeddings between paths, $\mathbb{P}\,f = \mathbb{P}\,g$ implies $f = g$. We show that, in fact, $\mathbb{P}$ is faithful on all pathwise embeddings in $\mathcal{C}$. Suppose $f, g\colon X \rightrightarrows Y$ are pathwise embeddings. If $\mathbb{P}\,f = \mathbb{P}\,g$ then, for all path embeddings $m\colon P \rightarrowtail X$,

$$f \circ m = \mathbb{P}\,f(m) = \mathbb{P}\,g(m) = g \circ m.$$

As X is path-generated, it follows that $f = g$.

For item (b), let $m\colon S \rightarrowtail X$ be an arbitrary embedding. Clearly, $\bigvee \{p \in \mathbb{P}\,X \mid p \leq m\} \leq m$. For the converse direction, assume that $n\colon T \rightarrowtail X$ is an upper bound for $\{p \in \mathbb{P}\,X \mid p \leq m\}$. This means that each path embedding $P \rightarrowtail X$ that factors through m must factor through n. We then have a commutative diagram as displayed below.

Because S is path-generated, the cocone with vertex S is a colimit cocone. Therefore, there exists a unique mediating arrow $\gamma\colon S \to T$ making the diagram commute. Using the universal property of S, it is not difficult to see that the composite $S \xrightarrow{\gamma} T \overset{n}{\rightarrowtail} X$ coincides with m, and so $m \leq n$.

For item (c), suppose that $f\colon X \twoheadrightarrow Y$ is a quotient in $\mathcal{C}$. We first assume that $Y = P$ is a path, and then settle the general case. To show that $\mathbb{P}\,f$ is a surjection, it suffices to prove that $\mathrm{id}_P \in \mathbb{P}\,f(\mathbb{P}\,X)$, where $\mathrm{id}_P\colon P \to P$ is the identity. We have

$$\begin{aligned} f^*\mathrm{id}_P &= \bigvee \{p \in \mathbb{P}\,X \mid p \leq f^*\mathrm{id}_P\} && \text{by item (b)} \\ &= \bigvee \{p \in \mathbb{P}\,X \mid \exists_f p \leq \mathrm{id}_P\} && \text{since } \exists_f \dashv f^* \\ &= \bigvee \mathbb{P}\,X, \end{aligned}$$

and so (using the fact that left adjoints preserve suprema)

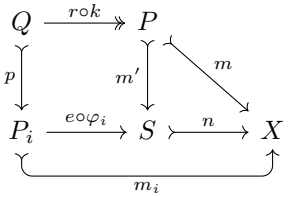
$$\mathrm{id}_P = \exists_f f^*\mathrm{id}_P = \bigvee \mathbb{P}\,f(\mathbb{P}\,X),$$

where the first step follows from the fact that $\exists_f \circ f^*$ is the identity of $\mathbb{S}\,P$ (cf. the proof of Lemma 6(b)). Hence, $\mathrm{id}_P \in \mathbb{P}\,f(\mathbb{P}\,X)$ by Lemma 17(b).

For the general case, let $m\colon P \rightarrowtail Y$ be an arbitrary path embedding and consider the following pullback square in $\mathcal{C}$.

$$\begin{array}{ccc} f^*P & \xrightarrow{g} & P \\ {\scriptstyle f^*m}\downarrow & \lrcorner & \downarrow{\scriptstyle m} \\ X & \xrightarrow{f} & Y \end{array}$$

By the argument above, there is a path embedding $n\colon Q \rightarrowtail f^*P$ such that $\mathbb{P}\,g(n) = \mathrm{id}_P$. It follows easily that $\mathbb{P}\,f(f^*m \circ n) = m$. ◀



The next proposition will allow us to construct an object from a prescribed set of path embeddings, without adding any new paths in the process.

▶ **Proposition 26.** *Let $\mathcal{C}$ be an arboreal category, X an object of $\mathcal{C}$, and $\mathcal{U} \subseteq \mathbb{P}X$. A path embedding $m \in \mathbb{P}X$ is below $\bigvee \mathcal{U}$ if, and only if, it is below some element of $\mathcal{U}$.*

Proof. Fix an arbitrary object X of $\mathcal{C}$ and a set of path embeddings $\mathcal{U} = \{m_i \colon P_i \rightarrowtail X \mid i \in I\}$. Let $m \colon P \rightarrowtail X$ be an arbitrary path embedding. If m is below some element of $\mathcal{U}$, then clearly $m \leq \bigvee \mathcal{U}$. For the converse direction, suppose that $m \leq \bigvee \mathcal{U}$. Recall from the proof of Lemma 17(a) that the supremum of $\mathcal{U}$ is obtained by taking the (quotient, embedding) factorisation $\coprod_{i \in I} P_i \overset{e}{\twoheadrightarrow} S \overset{n}{\rightarrowtail} X$ of the canonical morphism $\coprod_{i \in I} P_i \to X$. With this notation, $\bigvee \mathcal{U} = n$. Since $m \leq \bigvee \mathcal{U}$, there exists an embedding $m' \colon P \rightarrowtail S$ such that $m = n \circ m'$. Consider the pullback of m' along e:

$$\begin{array}{ccc} T & \xrightarrow{r} & P \\ {\scriptstyle j}\downarrow & \lrcorner & \downarrow{\scriptstyle m'} \\ \coprod_{i \in I} P_i & \xrightarrow{e} & S \end{array}$$

Applying Lemma 25(c) to the quotient r, we see that there exists a path embedding $k \colon Q \rightarrowtail T$ such that $r \circ k$ is a quotient. Because Q is connected, $j \circ k \colon Q \rightarrowtail \coprod_{i \in I} P_i$ must factor through some coproduct injection $\varphi_i \colon P_i \to \coprod_{i \in I} P_i$, i.e., $j \circ k = \varphi_i \circ p$ for some path embedding $p \colon Q \rightarrowtail P$. We then have a commutative diagram as follows.

As $m \circ r \circ k = m_i \circ p$ and the right-hand side of the equation is an embedding, $r \circ k$ is an isomorphism. So $m \leq m_i \in \mathcal{U}$, thus concluding the proof. ◀

6 Back-and-Forth Systems and Games

Throughout this section, we work in a fixed arboreal category $\mathcal{C}$. First, we introduce back-and-forth systems in $\mathcal{C}$ and show that they capture precisely the bisimilarity relation defined in Section 4 in terms of spans of open pathwise embeddings. Then, we show that back-and-forth systems can be equivalently seen as appropriate back-and-forth games.

Back-and-forth systems

Given objects X and Y of $\mathcal{C}$, we consider spans of (equivalence classes of) path embeddings of the form $X \overset{m}{\hookleftarrow} P \overset{n}{\rightarrowtail} Y$. Such a span can be thought of as a partial isomorphism "of shape P" between X and Y. A back-and-forth system between X and Y is a collection of such spans containing an "initial element" and satisfying an appropriate extension property.

Let X, Y be any two objects of $\mathcal{C}$. Given $m \in \mathbb{P}X$ and $n \in \mathbb{P}Y$, we write $[\![m, n]\!]$ to denote that $\mathrm{dom}(m) \cong \mathrm{dom}(n)$. Observe that (i) any two embeddings in the same $\sim$-equivalence class have isomorphic domains, and (ii) given $[\![m, n]\!]$, there exist path embeddings $m' \sim m$ and $n' \sim n$ such that $\mathrm{dom}(m') = \mathrm{dom}(n')$. Hence, the pairs of the form $[\![m, n]\!]$ capture the partial isomorphisms $X \overset{m}{\hookleftarrow} P \overset{n}{\rightarrowtail} Y$ "of shape P".

▶ **Definition 27.** *A* back-and-forth system *between objects X, Y of $\mathcal{C}$ is a set $\mathcal{B} = \{[\![m_i, n_i]\!] \mid m_i \in \mathbb{P}\,X,\ n_i \in \mathbb{P}\,Y,\ i \in I\}$ satisfying the following conditions:*

- **(i)** *$[\![\bot_X, \bot_Y]\!] \in \mathcal{B}$, where $\bot_X$ and $\bot_Y$ are the least elements of $\mathbb{P}\,X$ and $\mathbb{P}\,Y$, respectively;*
- **(ii)** *if $[\![m, n]\!] \in \mathcal{B}$ and $m' \in \mathbb{P}\,X$ are such that $m \prec m'$, there exists $n' \in \mathbb{P}\,Y$ satisfying $n \prec n'$ and $[\![m', n']\!] \in \mathcal{B}$;*
- **(iii)** *if $[\![m, n]\!] \in \mathcal{B}$ and $n' \in \mathbb{P}\,Y$ are such that $n \prec n'$, there exists $m' \in \mathbb{P}\,X$ satisfying $m \prec m'$ and $[\![m', n']\!] \in \mathcal{B}$.*

A back-and-forth system $\mathcal{B}$ is strong *if, for all $[\![m, n]\!] \in \mathcal{B}$ and all $m' \in \mathbb{P}\,X$, $n' \in \mathbb{P}\,Y$, if $m' \prec m$ and $n' \prec n$ then $[\![m', n']\!] \in \mathcal{B}$.*

Two objects X and Y of $\mathcal{C}$ are said to be *(strong) back-and-forth equivalent* if there exists a (strong) back-and-forth system between them.

▶ Remark 28. The definition of (strong) back-and-forth system given above is a variant of the notion of *(strong) path bisimulation* from [12]. The nomenclature adopted here is motivated by the analogy with back-and-forth systems of partial isomorphisms from model theory [15].

The aim of this section is to prove the following result:

▶ **Theorem 29.** *In an arboreal category with binary products, any two objects are bisimilar if, and only if, they are strong back-and-forth equivalent.*

In all our key examples of arboreal categories, binary products exist:

▶ **Example 30.** The category $\mathcal{T}$ has binary products. These are computed as "synchronous products" consisting of the pairs (x, y) of elements having the same height, with the componentwise order. Similarly, $\mathcal{F}$ has binary products, and so does the category $\mathcal{R}(\sigma)$ if the relations in the synchronous product are interpreted componentwise. As synchronous products do not increase the height of forests, we see that the category $\mathcal{R}_k^E(\sigma)$ from Example 9 has binary products. Finally, binary products exist in $\mathcal{R}_k^P(\sigma)$ and $\mathcal{R}_k^M(\sigma)$ and can be described again as variants of synchronous products.

▶ Remark 31. Direct inspection of the relevant proofs shows that Theorem 29 can be slightly generalized to the effect that, for any two objects X and Y of an arboreal category, if the product $X \times Y$ exists, then X and Y are bisimilar precisely when they are strong back-and-forth equivalent.

We start by establishing the easy direction of Theorem 29.

▶ **Proposition 32.** *Any two bisimilar objects of an arboreal category are strong back-and-forth equivalent.*

Proof. Suppose that $X \xleftarrow{f} Z \xrightarrow{g} Y$ is a span of open pathwise embeddings in an arboreal category $\mathcal{C}$. We claim that

$$\mathcal{B} \coloneqq \{[\![\mathbb{P}\,f(m), \mathbb{P}\,g(m)]\!] \mid m \in \mathbb{P}\,Z\}$$

is a strong back-and-forth system between X and Y. We show that items (i), (ii), and (iii) in Definition 27 are satisfied.

For item (i), let $\bot_Z$ be the least element of $\mathbb{P}\,Z$. Then $\mathbb{P}\,f(\bot_Z) = \bot_X$ and $\mathbb{P}\,g(\bot_Z) = \bot_Y$ because tree morphisms preserve roots, and so $[\![\bot_X, \bot_Y]\!] \in \mathcal{B}$. For item (ii), let $[\![\mathbb{P}\,f(m), \mathbb{P}\,g(m)]\!] \in \mathcal{B}$ and $m' \in \mathbb{P}\,X$ be such that $\mathbb{P}\,f(m) \prec m'$. Let us denote $P \coloneqq \mathrm{dom}(m)$ and $P' \coloneqq \mathrm{dom}(m')$. As $f \circ m \leq m'$ in $\mathbb{P}\,X$, there exists $k \colon P \rightarrowtail P'$ such that $f \circ m = m' \circ k$ in $\mathcal{C}$. Therefore, we have a commutative square as follows.

$$\begin{array}{ccc} P & \xrightarrow{k} & P' \\ {\scriptstyle m}\downarrow & & \downarrow{\scriptstyle m'} \\ Z & \xrightarrow{f} & X \end{array}$$

Since f is open, there exists a diagonal filler $n\colon P' \rightarrowtail Z$. Thus, $m' = \mathbb{P}\, f(n)$ and $[\![m', \mathbb{P}\, g(n)]\!] \in \mathcal{B}$. It remains to show that $\mathbb{P}\, g(m) \prec \mathbb{P}\, g(n)$. Note that $m \leq n$ and $\mathbb{P}\, f(m) \prec \mathbb{P}\, f(n)$ entail $m \prec n$, and so $\mathbb{P}\, g(m) \prec \mathbb{P}\, g(n)$ because $\mathbb{P}\, g$ preserves the covering relation.

The proof of item (iii) is the same, mutatis mutandis, as for (ii). Finally, observe that the back-and-forth system $\mathcal{B}$ is strong. To see this, suppose that $[\![\mathbb{P}\, f(m), \mathbb{P}\, g(m)]\!] \in \mathcal{B}$, and let $p_1 \in \mathbb{P}\, X$ and $p_2 \in \mathbb{P}\, Y$ satisfy $p_1 \prec \mathbb{P}\, f(m)$ and $p_2 \prec \mathbb{P}\, g(m)$. As $\mathbb{P}\, f$ is a tree morphism, there exists $m' \in \mathbb{P}\, Z$ such that $m' \prec m$ and $\mathbb{P}\, f(m') = p_1$. But then $\mathbb{P}\, g(m') \prec \mathbb{P}\, g(m)$ implies $\mathbb{P}\, g(m') = p_2$, and therefore $[\![p_1, p_2]\!] \in \mathcal{B}$. ◀

To establish the other direction of Theorem 29, we start by considering a strong back-and-forth system $\mathcal{B} = \{[\![m_i, n_i]\!] \mid i \in I\}$ between X and Y, and attempt to construct an object Z and a span of open pathwise embeddings $X \leftarrow Z \rightarrow Y$. Intuitively, Z is obtained by gluing together the paths $P_i \coloneqq \mathrm{dom}(m_i)$, for $i \in I$, by taking a colimit in $\mathcal{C}$. This colimit can be equivalently described as the supremum of a set of path embeddings as we now explain.

Consider an arbitrary $[\![m_i, n_i]\!] \in \mathcal{B}$ and assume without loss of generality that $\mathrm{dom}(m_i) = P_i = \mathrm{dom}(n_i)$ for some path P_i. Then the product arrow $\langle m_i, n_i \rangle\colon P_i \to X \times Y$ is an embedding. In fact, it suffices that m_i be an embedding (or, symmetrically, that n_i be an embedding), for then $m_i = \pi_X \circ \langle m_i, n_i \rangle$ entails that $\langle m_i, n_i \rangle$ is an embedding, where $\pi_X\colon X \times Y \to X$ is the projection. Therefore, we can identify each $[\![m_i, n_i]\!] \in \mathcal{B}$ with a path embedding $\langle m_i, n_i \rangle \in \mathbb{P}\,(X \times Y)$ and compute the supremum $m\colon Z \rightarrowtail X \times Y$ in $\mathbb{S}\,(X \times Y)$ of all these path embeddings. (It is not difficult to see that the assignment $[\![m_i, n_i]\!] \mapsto \langle m_i, n_i \rangle \in \mathbb{P}\,(X \times Y)$ does not depend on the choice of the representatives in the equivalence classes of m_i and n_i.) We note in passing the following immediate fact:

▶ **Lemma 33.** *Let $\mathcal{B} = \{[\![m_i, n_i]\!] \mid i \in I\}$ be a back-and-forth system between X and Y. If $\mathcal{B}$ is strong, then $\{\langle m_i, n_i \rangle \in \mathbb{P}\,(X \times Y) \mid i \in I\}$ is downwards closed in $\mathbb{S}\,(X \times Y)$.*

To show that the span $X \xleftarrow{\pi_X \circ m} Z \xrightarrow{\pi_Y \circ m} Y$ is a bisimulation, we exploit the fact that Z does not admit more path embeddings than those prescribed (cf. Proposition 26). The following proposition then completes the proof of Theorem 29:

▶ **Proposition 34.** *In an arboreal category with binary products, any two strong back-and-forth equivalent objects are bisimilar.*

Proof. Let $\mathcal{C}$ be an arboreal category with binary products, and let X, Y be any two objects of $\mathcal{C}$. Assume that there is a strong back-and-forth system $\mathcal{B} = \{[\![m_i, n_i]\!] \mid i \in I\}$ between X and Y, and consider the set

$$\mathcal{U} \coloneqq \{\langle m_i, n_i \rangle \in \mathbb{P}\,(X \times Y) \mid i \in I\}.$$

Let $m\colon Z \rightarrowtail X \times Y$ be the supremum of $\mathcal{U}$ in $\mathbb{S}\,(X \times Y)$. We claim that

$$X \xleftarrow{\pi_X \circ m} Z \xrightarrow{\pi_Y \circ m} Y$$

is a bisimulation between X and Y.

To see that this is a span of pathwise embeddings, consider an arbitrary path embedding $n\colon P \rightarrowtail Z$. In view of Proposition 26 and Lemma 33, $m \circ n \in \mathcal{U}$. That is, $m \circ n = \langle m_i, n_i \rangle$ in $\mathbb{P}(X \times Y)$ for some $[\![m_i, n_i]\!] \in \mathcal{B}$. It follows that $m \circ n = \langle m_i, n_i \rangle \circ \varphi$ in $\mathcal{C}$ for some isomorphism φ, and so $\pi_X \circ m \circ n$ and $\pi_Y \circ m \circ n$ are embeddings because $\pi_X \circ m \circ n = m_i \circ \varphi$ and $\pi_Y \circ m \circ n = n_i \circ \varphi$.

It remains to show that $\pi_X \circ m$ and $\pi_Y \circ m$ are open. We prove that $\pi_X \circ m$ is open; the proof for $\pi_Y \circ m$ follows by symmetry. Consider a commutative square in $\mathcal{C}$ as displayed below, where P and Q are paths.

$$\begin{array}{ccc} P & \overset{k}{\rightarrowtail} & Q \\ {\scriptstyle n}\downarrow & & \downarrow{\scriptstyle m_j} \\ Z & \xrightarrow{\pi_X \circ m} & X \end{array}$$

Reasoning as above, we see that $m \circ n = \langle m_i, n_i \rangle$ in $\mathbb{P}(X \times Y)$ for some $[\![m_i, n_i]\!] \in \mathcal{B}$. Therefore, in $\mathbb{P}X$, we have $m_i = \pi_X \circ m \circ n \leq m_j$. Applying item (ii) in Definition 27 (possibly finitely many times), it follows that there exists $n_j \in \mathbb{P}Y$ such that $n_i \leq n_j$ and $[\![m_j, n_j]\!] \in \mathcal{B}$. Suppose without loss of generality that $\mathrm{dom}(m_j) = \mathrm{dom}(n_j)$. Then, $\langle m_j, n_j \rangle \in \mathcal{U}$ and so $\langle m_j, n_j \rangle\colon Q \rightarrowtail X \times Y$ factors through the supremum $m\colon Z \rightarrowtail X \times Y$ of $\mathcal{U}$. That is, $\langle m_j, n_j \rangle = m \circ h$ in $\mathcal{C}$ for some morphism $h\colon Q \to Z$. We claim that the following diagram commutes, thus establishing that $\pi_X \circ m$ is open.

$$\begin{array}{ccc} P & \overset{k}{\rightarrowtail} & Q \\ {\scriptstyle n}\downarrow & \overset{h}{\swarrow} & \downarrow{\scriptstyle m_j} \\ Z & \xrightarrow{\pi_X \circ m} & X \end{array}$$

For the commutativity of the lower triangle, just observe that

$$\pi_X \circ m \circ h = \pi_X \circ \langle m_j, n_j \rangle = m_j.$$

Now, assume without loss of generality that $\mathrm{dom}(m_i) = R = \mathrm{dom}(n_i)$ for some path R. As already observed above, $m \circ n = \langle m_i, n_i \rangle$ in $\mathbb{P}(X \times Y)$ implies that $m \circ n = \langle m_i, n_i \rangle \circ \varphi$ in $\mathcal{C}$ for some isomorphism $\varphi\colon P \to R$. Thus, for the upper triangle, we have

$$\begin{aligned} n = h \circ k &\Leftrightarrow m \circ n = m \circ h \circ k \\ &\Leftrightarrow \langle m_i, n_i \rangle \circ \varphi = \langle m_j, n_j \rangle \circ k \\ &\Leftrightarrow \begin{cases} m_i \circ \varphi = m_j \circ k \\ n_i \circ \varphi = n_j \circ k \end{cases} \end{aligned}$$

where in the first step we used the fact that m is a monomorphism. In turn, the inequalities $m_i \leq m_j$ and $n_i \leq n_j$ entail the existence of embeddings $k_1, k_2\colon R \rightrightarrows Q$ such that $m_i = m_j \circ k_1$ and $n_i = n_j \circ k_2$. By Lemma 25(a) we have $k_1 \circ \varphi = k = k_2 \circ \varphi$. It follows that $m_i \circ \varphi = m_j \circ k$ and $n_i \circ \varphi = n_j \circ k$, and so $n = h \circ k$. ◀

Back-and-forth games

Let $\mathcal{C}$ be an arboreal category and let X, Y be any two objects of $\mathcal{C}$. We define a back-and-forth game $\mathcal{G}(X, Y)$ played by Spoiler and Duplicator on X and Y as follows. Positions in the game are pairs of (equivalence classes of) path embeddings $(m, n) \in \mathbb{P}X \times \mathbb{P}Y$. The winning relation $\mathcal{W}(X, Y) \subseteq \mathbb{P}X \times \mathbb{P}Y$ consists of the pairs (m, n) such that $\mathrm{dom}(m) \cong \mathrm{dom}(n)$.

Let $\bot_X : P \rightarrowtail X$ and $\bot_Y : Q \rightarrowtail Y$ be the roots of $\mathbb{P}\,X$ and $\mathbb{P}\,Y$, respectively. If $P \ncong Q$, then Duplicator loses the game. Otherwise, the initial position is $(\bot_X, \bot_Y)$. At the start of each round, the position is specified by a pair $(m, n) \in \mathbb{P}\,X \times \mathbb{P}\,Y$, and the round proceeds as follows: Either Spoiler chooses some $m' \succ m$ and Duplicator must respond with some $n' \succ n$, or Spoiler chooses some $n'' \succ n$ and Duplicator must respond with $m'' \succ m$. Duplicator wins the round if they are able to respond and the new position is in $\mathcal{W}(X, Y)$. Duplicator wins the game if they have a strategy which is winning after t rounds, for all $t \geq 0$.

▶ Remark 35. It is shown in [6] that the abstract game $\mathcal{G}(X, Y)$ restricts, in the case of the arboreal categories $\mathcal{R}_k^E(\sigma)$, $\mathcal{R}_k^P(\sigma)$ and $\mathcal{R}_k^M(\sigma)$, to the usual k-round Ehrenfeucht-Fraïssé, k-pebble and k-round bisimulation games, respectively.

The following straightforward observation makes precise the translation between strong back-and-forth systems and back-and-forth games.

▶ **Lemma 36.** *Two objects X, Y of an arboreal category $\mathcal{C}$ are strong back-and-forth equivalent if, and only if, Duplicator has a winning strategy in the game $\mathcal{G}(X, Y)$.*

Proof. Clearly, if $\mathcal{B} = \{[\![m_i, n_i]\!] \mid i \in I\}$ is a strong back-and-forth system between X and Y, then the plays in the set

$$\{(m_i, n_i) \mid i \in I\} \subseteq \mathbb{P}\,X \times \mathbb{P}\,Y$$

yield a winning strategy for Duplicator in the game $\mathcal{G}(X, Y)$.

Conversely, a winning strategy for Duplicator in the game $\mathcal{G}(X, Y)$ determines a set $W \subseteq \mathcal{W}(X, Y)$ of the plays following this strategy, and

$$\mathcal{B} \coloneqq \{[\![m, n]\!] \mid (m, n) \in W\}$$

is a back-and-forth system. It is not difficult to see that $\mathcal{B}$ is strong. ◀

The previous lemma, combined with Theorem 29, yields at once the following result:

▶ **Theorem 37.** *Let $\mathcal{C}$ be an arboreal category with binary products. Any two objects X, Y of $\mathcal{C}$ are bisimilar if, and only if, Duplicator has a winning strategy in the game $\mathcal{G}(X, Y)$.*

7 Arboreal Covers

We return to the underlying motivation for the axiomatic development in this paper. Arboreal categories have a rich intrinsic process structure, which allows "dynamic" notions such as bisimulation and back-and-forth games, and resource notions such as the height of a tree, to be defined. A key idea is to relate these process notions to extensional, or "static" structures. In particular, much of finite model theory and descriptive complexity can be seen in this way.

In the general setting, we have an arboreal category $\mathcal{C}$, and another category $\mathcal{E}$, which we think of as the extensional category.

▶ **Definition 38.** *An* arboreal cover *of $\mathcal{E}$ by $\mathcal{C}$ is given by a comonadic adjunction*

$$\mathcal{C} \underset{R}{\overset{L}{\rightleftarrows}} \mathcal{E}\,.$$

As for any adjunction, this induces a comonad on $\mathcal{E}$. The comonad is (G, ε, δ), where $G \coloneqq LR$, ε is the counit of the adjunction, and $\delta_a : LRa \to LRLRa$ is given by $\delta_a \coloneqq L(\eta_{Ra})$, with η the unit of the adjunction. The comonadicity condition states that the Eilenberg-Moore

category of coalgebras for this comonad is isomorphic to $\mathcal{C}$. The idea is then that we can use the arboreal category $\mathcal{C}$, with its rich process structure and all the associated notions, to study the extensional category $\mathcal{E}$ via the adjunction. Both the co-Kleisli category of the comonad, and the full Eilenberg-Moore category, are useful in this regard.

We now bring resources into the picture.

▶ **Definition 39.** *Let $\mathcal{C}$ be an arboreal category, with full subcategory of paths $\mathcal{C}_p$. We say that $\mathcal{C}$ is* resource-indexed *by a resource parameter k if for all $k \geq 0$, there is a full subcategory $\mathcal{C}_p^k$ of $\mathcal{C}_p$ closed under embeddings*[2] *with*

$$\mathcal{C}_p^0 \hookrightarrow \mathcal{C}_p^1 \hookrightarrow \mathcal{C}_p^2 \hookrightarrow \cdots$$

This induces a corresponding tower of full subcategories $\mathcal{C}_k$ of $\mathcal{C}$, with the objects of $\mathcal{C}_k$ those whose cocone of path embeddings with domain in $\mathcal{C}_p^k$ is a colimit cocone in $\mathcal{C}$.

▶ **Example 40.** One resource parameter which is always available is to take $\mathcal{C}_p^k$ to be given by those paths in $\mathcal{C}$ whose chain of subobjects is of length $\leq k$. In the case of $\mathcal{F}$ and $\mathcal{T}$, the corresponding categories $\mathcal{F}_k$ and $\mathcal{T}_k$ are the forests and trees of height $\leq k$. We can think of this as a temporal parameter, restricting the number of sequential steps, or the number of rounds in a game. For the Ehrenfeucht-Fraïssé and modal comonads, we recover $\mathcal{R}_k^E$ and $\mathcal{R}_k^M$ as described in Example 9, corresponding to k-round versions of the Ehrenfeucht-Fraïssé and modal bisimulation games respectively [6]. However, note that for the pebbling comonad, the relevant resource index is the number of pebbles, which is a memory restriction along a computation or play of a game. This leads to $\mathcal{R}_k^P$ as described in Example 9.

In Proposition 42 below we shall see that, given a resource-indexed arboreal category $\{\mathcal{C}_k\}$, each category $\mathcal{C}_k$ is arboreal. This allows us to exploit the ideas developed in this paper for any choice of the resource parameter k. We start by proving the following fact:

▶ **Lemma 41.** *Let $\{\mathcal{C}_k\}$ be a resource-indexed arboreal category and suppose that $X \rightarrowtail Y$ is an embedding in $\mathcal{C}$. For any k, if $Y \in \mathcal{C}_k$ then also $X \in \mathcal{C}_k$.*

Proof. We start by showing that, for any path embedding $P \rightarrowtail Y$ in $\mathcal{C}$, if $Y \in \mathcal{C}_k$ then $P \in \mathcal{C}_p^k$. Consider the set

$$\mathcal{U} \coloneqq \{p \in \mathbb{P}Y \mid \mathrm{dom}(p) \in \mathcal{C}_p^k\}.$$

(Note that $\mathcal{U}$ is well-defined because any two representatives in the equivalence class of p have isomorphic domains, and $\mathcal{C}_p^k$ is closed under isomorphisms.) As Y is the colimit in $\mathcal{C}$ of the subdiagram of $\mathbb{P}Y$ consisting of those path embeddings whose domain is in $\mathcal{C}_p^k$, it follows that $\bigvee \mathcal{U} = \mathrm{id}_Y$ in $\mathbb{S}Y$. If there exists a path embedding $m \colon P \rightarrowtail Y$, then $m \leq \bigvee \mathcal{U}$ in $\mathbb{P}Y$ and so, by Proposition 26, m factors through some $p \in \mathcal{U}$. In particular, there exists an embedding $P \rightarrowtail \mathrm{dom}(p)$. Because $\mathrm{dom}(p) \in \mathcal{C}_p^k$, we see that $P \in \mathcal{C}_p^k$.

Now, suppose that $j \colon X \rightarrowtail Y$ is an embedding in $\mathcal{C}$ and $Y \in \mathcal{C}_k$. Since X is path-generated, it is the colimit in $\mathcal{C}$ of the small diagram $\mathbb{P}X$. We show that, for any path embedding $P \rightarrowtail X$, the path P must belong to $\mathcal{C}_p^k$. It then follows immediately that $X \in \mathcal{C}_k$. Let $m \colon P \rightarrowtail X$ be an arbitrary path embedding. The composite $j \circ m \colon P \rightarrowtail Y$ is also a path embedding, and so $P \in \mathcal{C}_p^k$ by the argument above. ◀

[2] That is, for any embedding $P \rightarrowtail Q$ in $\mathcal{C}$ with P, Q paths, if $Q \in \mathcal{C}_p^k$ then also $P \in \mathcal{C}_p^k$.

▶ **Proposition 42.** *Let $\{\mathcal{C}_k\}$ be a resource-indexed arboreal category. Then $\mathcal{C}_k$ is an arboreal category for each k.*

Proof. If $\mathcal{C}$ is equipped with the stable proper factorisation system $(\mathcal{Q}, \mathcal{M})$, consider the classes of morphisms $\mathcal{Q}' \coloneqq \mathcal{Q} \cap \mathcal{C}_k$ and $\mathcal{M}' \coloneqq \mathcal{M} \cap \mathcal{C}_k$. It is not difficult to see that $(\mathcal{Q}', \mathcal{M}')$ is a proper factorisation system in $\mathcal{C}_k$. Just observe that, whenever $W \to Z$ is a morphism in $\mathcal{C}_k$ and

$$W \twoheadrightarrow X \rightarrowtail Y$$

is its (quotient, embedding) factorisation in $\mathcal{C}$, then $X \in \mathcal{C}_k$ by Lemma 41. Using again Lemma 41, along with the fact that embeddings are stable under pullbacks, it follows at once that $(\mathcal{Q}', \mathcal{M}')$ is stable (and, in fact, pullbacks of $\mathcal{Q}'$-morphisms along $\mathcal{M}'$-morphisms are computed in $\mathcal{C}$). With respect to this factorisation system, it is not difficult to see that the paths in $\mathcal{C}_k$ are precisely the objects of $\mathcal{C}_p^k$.

Moreover, $\mathcal{C}_k$ has all coproducts of small families of paths, and they are computed in $\mathcal{C}$. To see this, consider a set of paths $\{P_i \in \mathcal{C}_p^k \mid i \in I\}$ and let $\coprod_{i\in I} P_i$ be the coproduct in $\mathcal{C}$. If $m\colon P \rightarrowtail \coprod_{i\in I} P_i$ is any path embedding in $\mathcal{C}$ then, because P is connected, m must factor through some coproduct injection. In particular, there exist $i \in I$ and an embedding $P \rightarrowtail P_i$. Since $P_i \in \mathcal{C}_p^k$, we get $P \in \mathcal{C}_p^k$. As $\coprod_{i\in I} P_i$ is path-generated in $\mathcal{C}$, it follows at once that $\coprod_{i\in I} P_i \in \mathcal{C}_k$. Hence, $\coprod_{i\in I} P_i$ coincides with the coproduct of the family $\{P_i \in \mathcal{C}_p^k \mid i \in I\}$ in $\mathcal{C}_k$.

We conclude that $\mathcal{C}_k$ is a path category. Further, every object of $\mathcal{C}_k$ is path-generated by definition, and paths in $\mathcal{C}_k$ are connected because any path in $\mathcal{C}_k$ is also a path in $\mathcal{C}$ and, as observed above, coproducts of paths in $\mathcal{C}_k$ are computed in $\mathcal{C}$. Therefore, $\mathcal{C}_k$ is arboreal. ◀

▶ **Definition 43.** *Let $\{\mathcal{C}_k\}$ be a resource-indexed arboreal category. A* resource-indexed arboreal cover *of $\mathcal{E}$ by $\mathcal{C}$ is an indexed family of comonadic adjunctions*

$$\mathcal{C}_k \underset{R_k}{\overset{L_k}{\rightleftarrows}} \mathcal{E}$$

with corresponding comonads G_k on $\mathcal{E}$.

▶ **Example 44.** Our key examples arise by taking the extensional category $\mathcal{E}$ to be $\mathsf{Struct}(\sigma)$. For each $k \geq 0$, there are evident forgetful functors

$$L_k^E\colon \mathcal{R}_k^E \to \mathsf{Struct}(\sigma), \quad L_k^P\colon \mathcal{R}_k^P \to \mathsf{Struct}(\sigma), \quad L_k^M\colon \mathcal{R}_k^M \to \mathsf{Struct}(\sigma)$$

which forget the forest order, and in the case of $\mathcal{R}_k^P$, also the pebbling function. These functors are all comonadic over $\mathsf{Struct}(\sigma)$. (To be precise, in the modal logic case the category $\mathcal{E}$ consists of *pointed* structures, cf. [6].) The right adjoints build a forest over a structure $\mathcal{A}$ by forming sequences of elements over the universe A, suitably labelled and with the σ-relations interpreted so as to satisfy the conditions (E), (P) and (M) respectively. This yields the comonads described concretely in [1, 6]. The sequences correspond to plays in the Ehrenfeucht-Fraïssé, pebbling and modal bisimulation games respectively.

We now show how resource-indexed arboreal covers can be used to define important notions on the extensional category. For a resource-indexed arboreal cover of $\mathcal{E}$ by $\mathcal{C}$, with adjunctions L_k, R_k and comonads G_k, we define three resource-indexed equivalence relations on objects of $\mathcal{E}$. The first two use the co-Kleisli category of G_k, while the third uses the Eilenberg-Moore category.

▶ **Definition 45.** *Consider a resource-indexed arboreal cover of $\mathcal{E}$ by $\mathcal{C}$, and objects $a, b \in \mathcal{E}$.*
1. *We define $a \rightleftarrows_k^{\mathcal{C}} b$ iff there are co-Kleisli morphisms $G_k a \to b$ and $G_k b \to a$.*
2. *We define $a \cong_k^{\mathcal{C}} b$ iff a and b are isomorphic in the co-Kleisli category of G_k.*
3. *We define $a \leftrightarrow_k^{\mathcal{C}} b$ iff there is a bisimulation between $R_k a$ and $R_k b$ in $\mathcal{C}_k$.*

▶ **Proposition 46.** *Assume $\mathcal{E}$ has binary products. For objects a and b of $\mathcal{E}$, $a \leftrightarrow_k^{\mathcal{C}} b$ iff $R_k a$ and $R_k b$ are strong back-and-forth equivalent, iff Duplicator has a winning strategy in the game $\mathcal{G}(R_k a, R_k b)$.*

Proof. This follows directly from Theorems 29 and 37, and Proposition 42 (cf. also Remark 31). Just observe that, since right adjoints preserve limits, the product of $R_k a$ and $R_k b$ in $\mathcal{C}_k$ exists and can be identified with $R_k(a \times b)$. ◀

What do these notions mean in Example 44? For each of our three types of model comparison game, there are corresponding fragments $\mathcal{L}_k$ of first-order logic [15, 8]:
- For Ehrenfeucht-Fraïssé games, $\mathcal{L}_k$ is the fragment of quantifier-rank $\leq k$.
- For pebble games, $\mathcal{L}_k$ is the k-variable fragment.
- For bisimulation games, $\mathcal{L}_k$ is the modal fragment with modal depth $\leq k$.

In each case, we write $\exists\mathcal{L}_k$ for the existential positive fragment of $\mathcal{L}_k$, and $\mathcal{L}_k(\#)$ for the extension of $\mathcal{L}_k$ with counting quantifiers [15]. For each logic $\mathcal{L}$, there is the usual equivalence on σ-structures: $\mathcal{A} \equiv^{\mathcal{L}} \mathcal{B}$ iff for all φ in $\mathcal{L}$, $\mathcal{A} \models \varphi \iff \mathcal{B} \models \varphi$.

We now have the following result from [6]:

▶ **Theorem 47.** *For σ-structures $\mathcal{A}$ and $\mathcal{B}$:*
1. $\mathcal{A} \equiv^{\exists\mathcal{L}_k} \mathcal{B} \iff \mathcal{A} \rightleftarrows_k^{\mathcal{C}} \mathcal{B}$.
2. $\mathcal{A} \equiv^{\mathcal{L}_k} \mathcal{B} \iff \mathcal{A} \leftrightarrow_k^{\mathcal{C}} \mathcal{B}$.
3. $\mathcal{A} \equiv^{\mathcal{L}_k(\#)} \mathcal{B} \iff \mathcal{A} \cong_k^{\mathcal{C}} \mathcal{B}$.

Note that this is really a family of three theorems, one for each type of game arising from a resource-indexed arboreal cover $\mathcal{C}$ as in Example 44. Thus in each case, we capture the salient logical equivalences in syntax-free, categorical form.

We return to the general setting. Given a resource-indexed arboreal cover of $\mathcal{E}$ by $\mathcal{C}$, we know by comonadicity that for each k, $\mathcal{C}_k$ is isomorphic to the Eilenberg-Moore category for the comonad G_k. For each $a \in \mathcal{E}$, we can ask if it carries a G_k-coalgebra structure; that is, whether there is a morphism $\alpha\colon a \to G_k a$ satisfying the G_k coalgebra conditions. Moreover, we can ask for the *least* k such that this is the case. We call this the *coalgebra number* of a.

The intuition behind this, as explained in [1, 6], is that the resource parameter is bounding access to the structure, making it more difficult to have a morphism in $\mathcal{E}$ with codomain $G_k a$. So the least k for which this *is* possible is a significant invariant of the structure. This intuition is born out by the following result from [1, 6].

▶ **Theorem 48.**
1. *For the Ehrenfeucht-Fraïssé comonad, the coalgebra number of $\mathcal{A}$ corresponds precisely to the* tree-depth *of $\mathcal{A}$.*
2. *For the pebbling comonad, the coalgebra number of $\mathcal{A}$ corresponds precisely to the* tree-width *of $\mathcal{A}$.*
3. *For the modal comonad, the coalgebra number of $\mathcal{A}$ corresponds precisely to the* modal unfolding depth *of $\mathcal{A}$.*

What underlies these results is the comonadicity of the arboreal covers, which means that the coalgebras are witnesses for the various forms of tree decompositions of structures in $\mathcal{E}$ corresponding to these combinatorial invariants.

As a further illustration of the use of our axiomatic setting, we note that it is possible to give an account of the key notion of *extendability*, used by Rossman in his seminal results on homomorphism preservation [19], at this level of generality. For more details, see [4].

Abstract

We study the *dynamic membership problem* for regular languages: fix a language L, read a word w, build in time $O(|w|)$ a data structure indicating if w is in L, and maintain this structure efficiently under letter substitutions on w. We consider this problem on the unit cost RAM model with logarithmic word length, where the problem always has a solution in $O(\log|w| / \log\log|w|)$ per operation.

We show that the problem is in $O(\log\log|w|)$ for languages in an algebraically-defined, decidable class **QSG**, and that it is in $O(1)$ for another such class **QLZG**. We show that languages not in **QSG** admit a reduction from the prefix problem for a cyclic group, so that they require $\Omega(\log|w| / \log\log|w|)$ operations in the worst case; and that **QSG** languages not in **QLZG** admit a reduction from the prefix problem for the multiplicative monoid $U_1 = \{0, 1\}$, which we conjecture cannot be maintained in $O(1)$. This yields a conditional trichotomy. We also investigate intermediate cases between $O(1)$ and $O(\log\log|w|)$.

Our results are shown via the dynamic word problem for monoids and semigroups, for which we also give a classification. We thus solve open problems of the paper of Skovbjerg Frandsen, Miltersen, and Skyum [29] on the dynamic word problem, and additionally cover regular languages.

1 Introduction

This paper studies how to handle letter substitution updates on a word while maintaining the information of whether the word belongs to a regular language. Specifically, we fix a regular language L – for instance $L = a^*b^*$. We are then given an input word w, e.g., $w = aaaa$. We first preprocess w in linear time to build a data structure, which we can use in particular to test if $w \in L$. Now, w is edited by letter substitutions, and we want to update w and keep track at each step of whether $w \in L$. For instance, an update can replace the third letter of w by a b, so that $w = aaba$, which is no longer in L. Then another update can replace, e.g., the fourth letter of w by a b, so that $w = aabb$, and now we have $w \in L$ again. Our problem, called *dynamic membership*, is to devise a data structure to handle such update

operations and determine whether $w \in L$, as efficiently as possible. We study this task from a theoretical angle, but it can also be useful in practice to maintain a Boolean condition (expressed as a regular language) on a user-edited word.

Dynamic membership was studied for various update operations, e.g., append operations for streaming algorithms or the sliding window model [14, 13, 15], letter substitutions for the dynamic word problem for monoids [29], or concatenations and splits [22]. It was also studied in the case of *pattern matching*, where we check if the word contains some target pattern [9], which is also assumed to be editable. It is also connected to the incremental validation problem, which has been studied for strings and for XML documents [5]. The problem was also studied from the angle of *dynamic complexity*, which does not restrict the running time but the logical language used to handle updates [16]; and very recently refined to a study of the amount of *parallel work* required [28].

Our focus in this work is to identify classes of fixed regular languages for which dynamic membership can be solved extremely efficiently, e.g., in constant time or sublogarithmic time. Our update language only allows letter substitutions to the input word, in particular the length of the input word can never be changed by updates. We make this choice because insertions and deletions already make it challenging to efficiently maintain the word itself (see Section 7). We work within the computational model of the unit-cost RAM, with logarithmic cell size.

Dynamic word problem for monoids [29]. Our problem closely relates to the work by Skovbjerg Frandsen, Miltersen, and Skyum on the *dynamic word problem for monoids* [29]: fix a finite monoid, read a *word* which is a sequence of monoid elements, and maintain under substitution updates the composition of these elements according to the monoid's internal law. Indeed, the dynamic membership problem for a language L reduces to the dynamic word problem for any monoid that recognizes L; but the converse is not true. Hence, studying the dynamic word problem for monoids is coarser than studying the dynamic membership problem for languages, although it is a natural first step and is already very challenging.

In the context of monoids, Skovbjerg Frandsen et al. [29] propose a general algorithm for the dynamic word problem that can handle each operation in time $O(\log n / \log\log n)$, for n the length of the word. This is a refinement of the elementary $O(\log n)$ algorithm that decomposes the word as a balanced binary tree whose nodes are annotated with the monoid image of the corresponding infix. They show that the $O(\log n / \log\log n)$ bound is tight for some monoids, namely noncommutative groups, and a generalization of them defined via an equation. This is obtained by a reduction from the so-called *prefix-$\mathbb{Z}_d$ problem*, for which an $\Omega(\log n / \log\log n)$ lower bound [12] is known in the cell probe model [17]. We will reuse this lower bound in our work.

They also show that the problem is easier for some monoids. For instance, commutative monoids can be maintained in $O(1)$, simply by maintaining the number of element occurrences. They also show a trickier $O(\log\log n)$ upper bound for *group-free monoids*: this is based on a so-called Krohn-Rhodes decomposition [27] and uses a predecessor data structure implemented as a van Emde Boas tree [34]. However, there are non-commutative monoids for which the problem is in $O(1)$ (as we will show), and there is still a gap between group-free monoids (with an upper bound in $O(\log\log n)$) and the monoids for which the $\Omega(\log n / \log\log n)$ lower bound applies. This was claimed as open in [29] and not addressed afterwards. While there is a more recent study by Pătraşcu and Tarniţă [23], it focuses on single-bit memory cells.

Our contributions. In this paper, we attack these problems using algebraic monoid theory. This unlocks new results: first on the dynamic word problem for monoids, where we extend the results of [29], and then on the dynamic membership problem for regular languages.

We start with our results on the dynamic word problem for monoids, which are summarized in Figure 1 along with a table of the main classes in Table 1. First, in Section 3, we show how a more elaborate $O(\log \log n)$ algorithm can cover all monoids to which the $\Omega(\log n / \log \log n)$ lower bound of [29] does not apply: we dub this class **SG** and characterize it by the equation $x^{\omega+1}yx^{\omega} = x^{\omega}yx^{\omega+1}$, for any elements x and y, where ω denotes the idempotent power. Our algorithm shares some ideas with the $O(\log \log n)$ algorithm of [29], in particular it uses van Emde Boas trees, but it faces significant new challenges. For instance, we can no longer use a Krohn-Rhodes decomposition, and proceed instead by a rather technical induction on the $\mathcal{J}$-classes of the monoid. Thus, we have an unconditional dichotomy between monoids in **SG**, which are in $O(\log \log n)$, and monoids outside of **SG**, which are in $\Theta(\log n / \log \log n)$.

Second, in Section 4, we generalize the $O(1)$ result on commutative monoids to the monoid class **ZG** [4]. This class is defined via the equation $x^{\omega+1}y = yx^{\omega+1}$, i.e., only the elements that are part of a group are required to commute with all other elements. We show that the dynamic word problem for these monoids is in $O(1)$: we use an algebraic characterization to reduce them to commutative monoids and to monoids obtained from nilpotent semigroups, for which we design a simple but somewhat surprising algorithm. We also show a conditional lower bound: for any monoid M not in **ZG**, we can reduce the *prefix-U_1* problem to the dynamic word problem for M. This is the problem of maintaining a binary word under letter substitution updates while answering queries asking if a prefix contains a 0. It can be seen as a priority queue (slightly weakened), so we conjecture that no $O(1)$ data structure for this problem exists in the RAM model. If this conjecture holds, **ZG** is exactly the class of monoids having a dynamic word problem in $O(1)$.

We then extend our results in Section 5 from monoids to the dynamic word problem for semigroups. Our results for **SG** extend directly: the upper bound on **SG** also applies to semigroups in **SG**, and semigroups not in **SG** must contain a submonoid not in **SG** so covered by the lower bound. For **ZG**, there are major complications, and we must study the class **LZG** of semigroups where all submonoids are in **ZG**. Semigroups not in **LZG** are covered by our conditional lower bound on prefix-U_1, but it is very tricky to show the converse, i.e., that imposing the condition on **LZG** suffices to ensure tractability. We do so by showing tractability for $\mathbf{ZG} * \mathbf{D}$, the semigroups generated by *semidirect products* of **ZG** semigroups and so-called *definite semigroups*, and by showing in [3] that $\mathbf{ZG} * \mathbf{D} = \mathbf{LZG}$, a *locality result* of possible independent interest.

Next, we extend our results in Section 6 from semigroups to languages. This is done using the notion of *stable semigroup* [6, 7], denoted as the **Q** operator; and specifically the class **QSG** of regular languages where the stable semigroup of the syntactic morphism in is **SG**, and the class **QLZG** where all local monoids of the stable semigroup of the syntactic morphism are in **ZG**. We obtain:

▶ **Theorem 1.1.** *Let L be a regular language, and consider the dynamic membership problem for L on the unit-cost RAM with logarithmic word length under letter substitution updates:*

- *If L is in the class* **QLZG***, then the problem is in $O(1)$.*
- *If L is not in the class* **QLZG** *but is in the class* **QSG***, then the dynamic membership problem is in $O(\log \log n)$ with n the length of the word. Further, solving it in $O(1)$ time gives an $O(1)$ implementation of a structure for the prefix-U_1 problem.*
- *If L is not in the class* **QSG***, then the dynamic membership problem is in $\Theta(\log n / \log \log n)$.*

We last present in Section 7 some extensions and questions for future work: preliminary observations on the precise complexity of languages in **QSG** $\setminus$ **QLZG** (as the $O(\log \log n)$ bound is not shown to be tight), the complexity of deciding which case of the theorem applies, the support for insertion and deletion updates, and the support for infix queries. Because of space constraints, the complete proofs of results are deferred to the full version [2].

2 Preliminaries and Problem Statement

Computation model. We work in the RAM model with unit cost, i.e., each cell can store integers of value at most polynomial in $O(|w|)$ where $|w|$ is the length of the input, and arithmetic operations (addition, successor, modulo, etc.) on two cells take unit time. As the integers have at most polynomial value, the memory usage is also polynomially bounded.

We consider *dynamic problems* where we are given an input word, preprocess it in linear time to build a data structure, and must then handle *update operations* on the word (by reflecting them in the data structure), and *query operations* on the current state of the word (using the data structure). The *complexity* of the problem is the worst-case complexity of handling an update or answering a query.

Like in [29], the lower bounds that we show actually hold in the coarser *cell probe* model, which only considers the number of memory cells accessed during a computation. Furthermore, they hold even without the assumption that the preprocessing is linear.

Given two dynamic problems A and B, we say that A has a *(constant-time) reduction* to B if we can implement a data structure for problem A having constant-time complexity when using as oracle constantly many data structures for problem B (built during the preprocessing). In other words, queries and updates on the structure for A can perform constant-time computations using its own memory, but they can also use the data structures for B as an oracle, i.e., perform a constant number of queries and updates on them, which are considered to run in $O(1)$. We similarly talk of a dynamic problem having a *(constant-time) reduction* to multiple problems, meaning we can use all of them as oracle. If problem A reduces to problems $B_1, \ldots, B_n$, then any complexity upper bound that holds on all problems $B_1, \ldots, B_n$ also holds for A, and any complexity lower bound on A extends to at least one of the B_i.

Problem statement. Our problems require some algebraic prerequisites. We refer the reader to the book of Pin [25] and his lecture notes [26] for more details. A *semigroup* is a set S equipped with an associative composition law (written multiplicatively), and a *monoid* is a semigroup M with a *neutral element*, i.e., an element 1 such that $1x = x1 = x$ for all $x \in M$; the neutral element is then unique. One example of a monoid is the *free monoid* Σ^* defined for a finite alphabet Σ and consisting of all words with letters in Σ (including the empty word), with concatenation as its law. Except for the free monoid, all semigroups and monoids considered are finite.

A semigroup element $x \in S$ is *idempotent* if $xx = x$. For $x \in S$, we denote by ω the idempotent power of x, i.e., the least positive integer such that x^ω is idempotent. A *zero* for S is an element $0 \in S$ such that $0x = x0 = 0$ for all $x \in S$: if it exists, it is unique. Given a semigroup S, we write S^1 for the monoid obtained by adding a fresh neutral element to S if it does not already have one.

A *morphism* from a semigroup S to a semigroup S' is a map $\mu \colon S \to S'$ such that for any $x, y \in S$, we have $\mu(xy) = \mu(x)\mu(y)$. A *morphism* from a monoid M to a monoid M' must additionally verify that $\mu(1) = 1'$, for 1 and $1'$ the neutral elements of M and M' respectively.

The *direct product* of two monoids M_1 and M_2 is $M_1 \times M_2$ with componentwise composition; it is also a monoid. A *quotient* of a monoid M is a monoid M' such that there is a surjective morphism from M to M'. A *submonoid* is a subset of a monoid which is also a monoid. The analogous notions for semigroups are defined in the expected way. A *pseudovariety* of monoids (resp., semigroups) is a class of monoids (resp., semigroups) closed under direct product, quotient and submonoid (resp., subsemigroup). The pseudovariety of monoids (resp., semigroups) *generated* by a class $\mathbf{V}$ of monoids (resp., of semigroups) is the least pseudovariety closed under these operations and containing $\mathbf{V}$. As we are working with finite semigroups and monoids, we refer to pseudovarieties simply as varieties.

We consider dynamic problems where we maintain a word w on a finite alphabet Σ, every letter being stored in a cell. We allow *letter substitution* updates of the form (i, a) for $1 \leq i \leq |w|$ and $a \in \Sigma$. The letter substitution update (i, a) replaces the i-th letter of w by a; the size $|w|$ of the word never changes. Given the input word w, we first preprocess it in time $O(|w|)$ to build a data structure. The data structure must then support update operations for letter substitution updates, and some query operations (to be defined below). The complexity that we measure is the worst-case complexity of an update operation or query operation, as a function of $|w|$. Our definition does not limit the memory used. However, all our upper complexity bounds actually have memory usage in $O(|w|)$. Further, all our lower bounds hold even when no assumption is made on the memory usage.

We focus on three related dynamic problems, allowing different query operations. The first is the *dynamic word problem for monoids*: fix a monoid M, the alphabet Σ is M, and the query returns the *evaluation* of the current word w, i.e., the product of the elements of w (it is an element of M). This is the problem studied in [29]. The second is the *dynamic word problem for semigroups*, which is the same but with a semigroup, and assuming that $|w| > 0$. The third is the *dynamic membership problem for regular languages*: we fix a regular language L on the alphabet Σ, and the query checks whether the current word belongs to L.

We study the data complexity of these problems in the rest of this paper, i.e., the complexity expressed as a function of w, with the monoid, semigroup, or language being fixed. Let us first observe that, for monoids and more generally for semigroups, the usual algebraic operators of quotient, subsemigroup, and direct product, do not increase the complexity of the problem:

▶ **Proposition 2.1.** *Let S and T be finite semigroups. The dynamic word problem of subsemigroups or quotients of S reduces to the same problem for S, and the dynamic word problem of $S \times T$ reduces to the same problem for S and T.*

Hard problems. All our lower bounds are obtained by reducing from the problem *prefix-M*, for M a fixed monoid. In this problem, we maintain a word of M^* under letter substitution updates, and handle *prefix queries*: given a prefix length, return the evaluation of the prefix of that length.

In particular, for $d \geq 2$, we consider the problem *prefix-$\mathbb{Z}_d$* for $\mathbb{Z}_d$ the cyclic group of order d, i.e., $\mathbb{Z}_d = \{0, \ldots, d-1\}$ with addition modulo d, where the evaluation of prefix is the sum of its elements modulo d. The following lower bound is known already in the cell probe model:

▶ **Theorem 2.2** ([12, 29])**.** *For any fixed $d \geq 2$, any structure for prefix-$\mathbb{Z}_d$ on a word of length n has complexity $\Omega(\log n / \log \log n)$.*

We also consider the problem *prefix-U_1*, where $U_1 = \{0, 1\}$ is the multiplicative monoid whose composition is the logical AND, i.e., prefix queries check if the prefix contains an occurrence of 0. Equivalently, we must maintain a subset S of a universe $\{1, \ldots, n\}$ (intuitively

n is the length of the word) under insertions and deletions, and support *threshold queries* that ask, given $0 \leq i \leq n$, whether S contains some element which is $\leq i$ (i.e., if some position before i has a 0). The prefix-U_1 problem can be solved in $O(\log \log n)$ [33] with a priority queue data structure, or even in expected $O(\sqrt{\log \log n})$ if we allow randomization [18]. Note that prefix-U_1 is slightly weaker than a priority queue as we can only *compare* the minimal value to a value given as input. We do not know of lower bounds on prefix-U_1, but conjecture [20] that it cannot be solved in $O(1)$:

▶ **Conjecture 2.3.** *There is no structure for prefix-U_1 with complexity $O(1)$.*

Note that the best algorithm for prefix-U_1 works by sorting small sets of large integers. This takes linear time in the cell probe model, so does not rule out the existence of an $O(1)$ priority queue [33]. Hence, a lower bound for prefix-U_1 would need to apply to the RAM model specifically, which would require new techniques.

Our last hard problem is prefix-U_2 where U_2 is the monoid $\{1, a, b\}$ with composition law $xy = y$ for $x, y \in \{a, b\}$, i.e., queries check if the last non-neutral element is a or b (or nothing). By adapting known results on the *colored predecessor problem* [24], we have:

▶ **Theorem 2.4** (Adapted from [24])**.** *Any structure for prefix-U_2 on a word of length n must be in $\Omega(\log \log n)$.*

General algorithms. Of course, the "hard" prefix problems, and the three problems that we study, can all be solved in $O(|w|)$ by re-reading the whole word at each update. We can improve this to $O(\log |w|)$ by maintaining a balanced binary tree on the letters of the word, with each node of the tree carrying the evaluation in the monoid of the letters reachable from that node. Any letter substitution update on the word can be propagated up to the root in logarithmic time, and the annotation of the root is the evaluation of the word. This algorithm has been implemented in practice [22]. A finer bound is given in [29] using a folklore technique of working with $(\log n)$-ary trees rather than binary trees, and using the power of the RAM model. We recall it here for monoids (but it applies to all three problems):

▶ **Theorem 2.5** ([29])**.** *For any fixed monoid M, the dynamic word problem and prefix problem for M are in $O(\log n / \log \log n)$.*

Our goal in this paper is to solve the dynamic word problem and dynamic membership problem more efficiently for specific classes of monoids, semigroups, and languages. We start our study with monoids in the next two sections, by studying the varieties **SG** and **ZG**.

3 Dynamic Word Problem for Monoids in SG

We define the class **SG** of monoids by the equation $x^{\omega+1}yx^{\omega} = x^{\omega}yx^{\omega+1}$ for all x, y. It incidentally occurs in [10, Theorem 3.1], but to our knowledge was not otherwise studied. The name **SG** means *swappable groups*. Intuitively, a monoid M is in **SG** iff, for any two elements $r, t \in M$ belonging to the same subgroup of M, we can *swap* them, i.e., $rst = tsr$ for all $s \in M$. We first recall the lower bound from [29] on the dynamic word problem for monoids *not in* **SG**, and then show an upper bound for monoids in **SG**.

Lower bound. The monoids not in **SG** are in fact those covered by the lower bound of [29]. Namely, we have the following, implying the $\Omega(\log n / \log \log n)$ lower bound by Theorem 2.2:

▶ **Theorem 3.1** ([29], Theorem 2.5.1)**.** *For any monoid M not in* **SG***, there exists $d \geq 2$ such that the prefix-$\mathbb{Z}_d$ problem reduces to the dynamic word problem for M.*

Upper bound. The rest of this section presents our upper bound on monoids in **SG**. In fact, we show a more general claim on the dynamic word problem for *semigroups* in **SG**, i.e., those satisfying the equation of **SG**. This covers in particular the monoids of **SG**:

▶ **Theorem 3.2.** *The dynamic word problem for any semigroup in* **SG** *is in* $O(\log \log n)$.

This result extends the result of [29] on group-free monoids, because **SG** contains all aperiodic monoids and all commutative monoids. Indeed, an aperiodic monoid satisfies the equation $x^{\omega+1} = x^\omega$, and then $x^{\omega+1}yx^\omega = x^\omega yx^\omega = x^\omega yx^{\omega+1}$. Besides, commutative monoids clearly satisfy the equation. Of course, **SG** captures monoids not covered by [29], e.g., products of a commutative monoid and an aperiodic monoid.

The result of [29] uses van Emde Boas trees [34], which we extend to store values in an alphabet Σ. Fixing an alphabet Σ, a *vEB tree* (or *vEB*) is a data structure parametrized by an integer n called its *span*, which stores a set $X \subseteq \{1, \ldots, n\}$ and a mapping $\mu\colon X \to \Sigma$, and supports the following operations: *inserting* an integer $x \in \{1, \ldots, n\} \setminus X$ with a label $\mu(x) := a$; *retrieving* the label of $x \in \{1, \ldots, n\}$ if $x \in X$ (or a special value if $x \notin X$); *removing* an integer $x \in X$ and its label; *finding the next integer* of X that follows an input $x \in \{1, \ldots, n\}$ (or a special value if none exists); and *finding the previous integer*.

We can implement vEBs so that these five operations run in $O(\log \log n)$ time in the worst case, and so that a vEB can be constructed in linear time from an ordered list.

We use vEBs in our inductive proof to represent words with "gaps": a vEB represents the word obtained by concatenating the labels of the elements of X in order. For a semigroup S and span $n \in \mathbb{N}$, the *dynamic word problem on vEBs* for S is to maintain a vEB T of span n on alphabet S under insertions and deletions, and to answer queries asking the evaluation in S of the word currently represented by T. As before, the complexity is the worst-case complexity of an insertion, deletion, or query, measured as a function of the span n (which never changes). The data structure for this problem must be initialized during a preprocessing phase on the initial vEB T, which must run in $O(n)$. Note that when T is empty then its evaluation is not expressible in the semigroup S: we then return a special value.

It is then clear that Theorem 3.2 follows from its generalization to vEBs, as a word in the usual sense can be converted in linear time to a vEB where $X = \{1, \ldots, n\}$:

▶ **Theorem 3.3.** *Let S be a semigroup in* **SG**. *The dynamic word problem for S on a vEB of span n is in* $O(\log \log n)$.

We show this result in the rest of the section. We assume without loss of generality that S has a zero, as otherwise we can simply add one. We first introduce some algebraic preliminaries, and then present the proof, which is an induction on $\mathcal{J}$-classes of the semigroup.

Preliminaries and proof structure. The *$\mathcal{J}$-order* of S is the preorder $\leq_\mathcal{J}$ on S defined by $s \leq_\mathcal{J} s'$ if $S^1 s S^1 \subseteq S^1 s' S^1$, recalling that S^1 is the monoid where we add a neutral element to S if it does not already have one. The equivalence classes of the symmetric closure of this preorder are called *$\mathcal{J}$-classes*. We lift the $\mathcal{J}$-order to $\mathcal{J}$-classes C, C' by writing $C \leq_\mathcal{J} C'$ if $u \leq_\mathcal{J} v$ for all $u \in C$ and $u' \in C'$. A $\mathcal{J}$-class is *maximal* if it is maximal for this order.

We show Theorem 3.3 by induction on the number of $\mathcal{J}$-classes of the semigroup. More precisely, at every step, we consider a maximal $\mathcal{J}$-class C, and remove it by reducing to the semigroup $S \setminus C$. Remember that the number of classes only depends on the fixed semigroup S, so it is constant. Thus, as the constant number of operations on vEBs at each class each take time $O(\log \log n)$, the overall bound is indeed in $O(\log \log n)$.

The base case of the induction is that of a semigroup with a single $\mathcal{J}$-class; from our assumption that the semigroup has a zero, that $\mathcal{J}$-class must then consist of the zero, i.e., we have the trivial monoid $\{0\}$, and the image is always 0 (or undefined if the word is empty).

We now show the induction step of Theorem 3.3. Take a semigroup S with more than one $\mathcal{J}$-class, and fix a maximal $\mathcal{J}$-class C of S: we know that $S \setminus C$ is not empty. What is more:

▷ Claim 3.4. For any x, y of S with $xy \in C$, then $x \in C$ and $y \in C$.

Thus, whenever a combination of elements "falls" outside of the maximal class C, then it remains in $S \setminus C$; and we can see $S \setminus C$ as a semigroup, which still has a zero, and has strictly less $\mathcal{J}$-classes. So we will study how to reduce to $S \setminus C$. We now make a case disjunction depending on whether C is *regular*, i.e., whether it contains an idempotent element.

Non-regular maximal classes. This case is easy, because products of two or more elements of C are never in C. To formalize this property, for a maximal $\mathcal{J}$-class C of S, we call a word w on S^* *pair-collapsing* for C if the product of any two adjacent letters of w is in $S \setminus C$. We show:

▶ **Lemma 3.5.** *Let C be a maximal $\mathcal{J}$-class. If C is non-regular, then any word is pair-collapsing: for any $x, y \in C$, we have $xy \in S \setminus C$.*

We can then show the following, which we will reuse for regular maximal classes:

▶ **Lemma 3.6.** *Let S be a semigroup and let C be a maximal $\mathcal{J}$-class of S. Consider the dynamic word problem for S on vEBs of some span n where we assume that, at every step, the represented word is pair-collapsing for C. Then that problem reduces to the dynamic word problem for $S \setminus C$ on vEBs of span n.*

Thanks to Lemma 3.5, this allows us to settle the case of a non-regular maximal $\mathcal{J}$-class, using the induction hypothesis to maintain the problem on $S \setminus C$.

Case of a regular maximal class. We now consider a maximal $\mathcal{J}$-class C that is regular. Consider the semigroup $C^0 := C \cup \{0\}$ for a fresh zero 0, i.e., the multiplication is that of C except that $x0 = 0x = 0$ for all $x \in C^0$, and that $xy = 0$ in C^0 for all $x, y \in C$ for which the product xy in S is not an element of C. Note that 0 is unrelated to the zero which S was assumed to have; intuitively, the 0 of C^0 stands for combinations of elements that are not in C. Another way to see C^0 is as the quotient of S by the ideal $S \setminus C$, i.e., we identify all elements of $S \setminus C$ to 0. By Prop. 4.35 of Chapter V of [26], we know that C^0 is a so-called *0-simple semigroup*. By the Rees-Sushkevich theorem (Theorem 3.33 of [26]), S is isomorphic to some *Rees matrix semigroup with 0*. This is a semigroup $M^0(G, I, J, P)$ with I and J two non-empty sets, G a group called the *structuring group*, and P a matrix indexed by $J \times I$ having values in G^0. The elements of the semigroup are the elements of $I \times G \times J$ and the element 0, with $x0 = 0x = 0$ for any element $x \in I \times G \times J$, and for (i, g, j) and (i', g', j') two elements of $I \times G \times J$, their product is 0 if $p_{j,i'} = 0$, and $(i, gp_{j,i'}g', j')$ otherwise.

With this representation, the idea is to collapse together the maximal runs of consecutive elements of C^0 whose product is not 0, i.e., does not "fall" outside of C. Once this is done, the product of two elements always falls in $S \setminus C$, so we can conclude using Lemma 3.6.

However, we cannot do this in a naive fashion. For instance, if we insert a letter in the vEB in the middle of such a maximal run, we cannot hope to split the run and know the exact group annotation of the two new runs – this could amount to solving a prefix-$\mathbb{Z}_d$ problem. Instead, we must now use the fact that S is in **SG**, and derive the consequences

of the equation in terms of the Rees-Sushkevich representation. Intuitively, the equation ensures that the structuring group G is commutative, and that annotations in G can "move around" relative to other elements in S without changing the evaluation. Formally:

▷ Claim 3.7. The structuring group G is commutative.

▷ Claim 3.8. Let $r, s, t \in S^*$ and $(i, g, j), (i', g', j') \in I \times G \times J$. Write $w = r(i, g, j)s(i', g', j')t$ and $w' = r(i, gg', j)s(i', 1, j')t$ where 1 is the neutral element of G. Then $\mathrm{eval}(w) = \mathrm{eval}(w')$.

This allows us to reduce the dynamic word problem on S to the same problem where we assume that the word is always pair-collapsing:

▷ Claim 3.9. The dynamic word problem for S on vEBs (of some span n) reduces to the same problem on vEBs of span n where we additionally require that, at every step, the represented word is pair-collapsing for the maximal $\mathcal{J}$-class C.

Proof sketch. We maintain a mapping where all maximal runs of word elements evaluating to C are collapsed to a single element, which we can evaluate following the Rees-Sushkevich representation. The tricky case is whenever an update breaks a maximal run into two parts: we cannot recover the G-component of the annotation of each part, but we use Claim 3.8 to argue that we can simply put it on the left part without altering the evaluation in S. ◁

This claim together with Lemma 3.6 implies that the dynamic word problem for S reduces to the same problem for $S \setminus C$, for which we use the induction hypothesis. This establishes the induction step and concludes the proof of Theorem 3.2.

4 Dynamic Word Problem for Monoids in ZG

We pursue our study of the dynamic word problem for monoids with the class **ZG**, introduced in [4] and defined by the equation $x^{\omega+1}y = yx^{\omega+1}$ for all x, y. This asserts that elements of the form $x^{\omega+1}$, which are the ones belonging to a *subgroup* of the monoid, are *central*, i.e., commute with all other elements. By the equations, and recalling that $x^{\omega+1} = x^\omega x^{\omega+1}$, clearly **ZG** $\subseteq$ **SG**. In this section, we show an $O(1)$ upper bound on the dynamic word problem for monoids in **ZG**, and a conditional lower bound for any monoid not in **ZG**.

Upper bound. Recall the result on commutative monoids from [29]:

▶ **Theorem 4.1** ([29]). *The dynamic word problem for any commutative monoid is in* $O(1)$.

Our goal is to generalize it to the following result:

▶ **Theorem 4.2.** *The dynamic word problem for any monoid in* **ZG** *is in* $O(1)$.

This generalizes Theorem 4.1 (as commutative monoids are clearly in **ZG**) and covers other monoids, e.g., the monoid $M = \{1, a, b, ab, 0\}$ with $a^2 = b^2 = ba = 0$, where it intuitively suffices to track the position of a's and b's and compare them if there is only one of each.

We now prove Theorem 4.2. A semigroup S is *nilpotent* if it has a zero and there exists $k > 0$ such that $S^k = \{0\}$, i.e., all products of k elements are equal to 0. Alternatively [26, Chapter X, Section 4], S is nilpotent iff it satisfies the equation $x^\omega y = yx^\omega = x^\omega$. We then consider the monoids of the form S^1 where S is nilpotent – an example of this is the monoid M described above. The variety generated by such monoids is called **MNil** and was studied by Straubing [30]. We can show:

▶ **Proposition 4.3.** *For any nilpotent S, the dynamic word problem for S^1 is in $O(1)$.*

Proof sketch. We maintain a (non-sorted) doubly-linked list L of the positions of the word w that contain a non-neutral element. As S is nilpotent, the evaluation of w is 0 unless constantly many non-neutral letters remain, which we can then find in $O(1)$ with L. ◀

In [3] we show that **ZG** is generated by such monoids S^1 and by commutative monoids:

▶ **Proposition 4.4** (Corollary 3.6 of [3]). *The variety* **ZG** *is generated by commutative monoids and monoids of the form S^1 for S a nilpotent semigroup.*

In view of Theorem 4.1 and Proposition 4.3, the dynamic word problem is in $O(1)$ for the semigroups that generate the variety **ZG** (Proposition 4.4). Theorem 4.2 then follows from Proposition 2.1.

Lower bound. We now show a conditional lower bound on the dynamic word problem for monoids outside of **ZG**. To do this, we will reduce from the prefix-U_1 problem:

▶ **Theorem 4.5.** *For any monoid M in $\mathbf{SG} \setminus \mathbf{ZG}$, the prefix-$U_1$ problem reduces to the dynamic word problem for M.*

Proof sketch. We consider the variety **ZE** [1] of monoids whose idempotents are central, i.e., the variety defined by the equation $x^\omega y = yx^\omega$. We show that $\mathbf{ZG} = \mathbf{SG} \cap \mathbf{ZE}$. We then show that, for any monoid not in **ZE**, we can reduce from the prefix-U_1 problem by encoding the elements 0 and 1 of U_1 using carefully chosen elements of the monoid. ◀

Using Conjecture 2.3, and together with Theorem 3.1 for the monoids not in **SG**, this implies a conditional super-constant lower bound for monoids outside **ZG**.

5 Dynamic Word Problem for Semigroups

We have classified the complexity of the dynamic word problem for monoids: it is in $O(\log \log n)$ for monoids in **SG**, in $O(1)$ for monoids in **ZG**, in $\Omega(\log n / \log \log n)$ for monoids not in **SG**, and non-constant for monoids not in **ZG** conditionally to Conjecture 2.3. In this section, we extend our results from monoids to *semigroups*.

Submonoids and local monoids. A *submonoid* of a semigroup S is a subset of the semigroup which is stable under its composition law and is a monoid. We first notice via Proposition 2.1 that a semigroup that contains a hard submonoid is also hard:

▷ Claim 5.1. The dynamic word problem for any submonoid of a semigroup S reduces to the same problem for S.

We will investigate if studying the submonoids of a semigroup suffices to understand the complexity of its dynamic word problem. To do so, we focus on a certain kind of submonoids: the *local monoids*. A submonoid N of S is a *local monoid* if there exists an idempotent element e of S such that $N = eSe$, i.e., N is the set of elements that can be written as ese for some $s \in S$. The point of local monoids is that they are maximal in the sense that every submonoid T of S is a submonoid of a local monoid: indeed, taking 1 the neutral element of T, all elements of T can be written as $1T1 \subseteq 1S1$ and $1S1$ is a local monoid. For **V** a variety of monoids, we denote by **LV** the variety of semigroups such that all local monoids are in **V**. As we explained, this is equivalent to imposing that all submonoids are in **V** (since varieties are closed under the submonoid operation).

Case of SG. We now revisit our results on monoids to extend them to semigroups, starting with **SG**. We denote by **LSG** the variety of semigroups whose local monoids are in **SG**. We show that a semigroup where all local monoids are in **SG** must itself be in **SG**:

▷ Claim 5.2. We have **LSG** = **SG** as varieties of semigroups.

Semigroups in **SG** are already covered by our upper bound (Theorem 3.2), and semigroups not in **LSG** have a submonoid not in **SG**, so we can use Claim 5.1 and Theorem 3.1. Hence:

▶ **Corollary 5.3.** *Let S be a semigroup. If S is in* **SG***, then the dynamic word problem for S is in $O(\log\log n)$. Otherwise, the dynamic word problem for S is in $\Omega(\log n/\log\log n)$.*

Case of ZG. The variety **ZG** is not equal to **LZG**. For instance, let S be the syntactic semigroup of a^*b^*, that is the semigroup $\{a, b, ab, 0\}$ defined with $a^2 = a$, $b^2 = b$ and $ba = 0$. It is not in **ZG**, since a and b are idempotents that do not commute. However, its local monoids are either trivial or U_1, so they are all in **ZG**, showing that this semigroup is in **LZG**. Still, we can extend our characterization from monoids to semigroups up to studying **LZG**:

▶ **Theorem 5.4.** *Let S be a semigroup. If S is in* **LZG***, then the dynamic word problem for S is in $O(1)$. Otherwise, unless prefix-U_1 is in $O(1)$, the dynamic word problem for S is not in $O(1)$.*

The second part of the claim is by Claim 5.1 and Theorem 3.1, but the first part is much trickier. We use a characterization of **LZG** as a *semidirect product* **ZG** $*$ **D**, which follows from a very technical *locality result* on **ZG** [3], and then design an algorithm for the dynamic word problem for semigroups in **ZG** $*$ **D**. We prove Theorem 5.4 in the rest of this section.

Given two semigroups S and T, a *semigroup action* of S on T is defined by a map $\mathrm{act} : S \times T \to T$ such that $\mathrm{act}(s_1, \mathrm{act}(s_2, t)) = \mathrm{act}(s_1 s_2, t)$ and $\mathrm{act}(s, t_1 t_2) = \mathrm{act}(s, t_1)\mathrm{act}(s, t_2)$. We then define the product $\circ_{\mathrm{act}}$ on the set $T \times S$ as follows: for all s_1, s_2 in S and t_1, t_2 in T, we have: $(t_1, s_1) \circ_{\mathrm{act}} (t_2, s_2) := (t_1 \mathrm{act}(s_1, t_2), s_1 s_2)$. The set $T \times S$ equipped with the product $\circ_{\mathrm{act}}$ is a semigroup called the *semidirect product* of S by T, denoted $T \circ_{\mathrm{act}} S$.

We say that a semigroup D is *definite* if there exists an integer $k \in \mathbb{N}$ such that for all $y, x_1, \ldots, x_k$ in D, we have $yx_1 \cdots x_k = x_1 \cdots x_k$. Alternatively, a semigroup is definite iff it satisfies the equation $yx^\omega = x^\omega$ [31, Proposition 2.2] for all x, y in D. In particular, every nilpotent semigroup is definite. We write **D** for the variety of definite semigroups.

Our alternative definition of **LZG** will be the variety of semigroups **ZG** $*$ **D** generated by semigroups that are the semidirect product of a **ZG** monoid by a definite semigroup.

The variety **ZG** $*$ **D** of semigroups is not immediately related to the variety **LZG** defined above. One can easily show that **ZG** $*$ **D** $\subseteq$ **LZG**, but the other direction is much more challenging to establish. We show this as a so-called *locality theorem*, which we defer to a separate paper [3] because it uses different tools and is of possible independent interest:

▶ **Theorem 5.5** ([3], Theorem 1.1)**.** *We have:* **ZG** $*$ **D** = **LZG**.

To conclude the proof of Theorem 5.4, by the locality theorem above, it suffices to solve the dynamic word problem for semigroups in **ZG** $*$ **D**. By Proposition 2.1, it suffices to consider the semigroups that generate the variety. We do this below, establishing Theorem 5.4:

▶ **Proposition 5.6.** *Let S be a definite semigroup, let T be a semigroup of* **ZG***, and let* act *be a semigroup action of S on T. The dynamic word problem for the semigroup $T \circ_{\mathrm{act}} S$ reduces to the same problem for T.*

Proof sketch. We express the direct product of the letters of the input word as a product involving elements of T and prefix sums of elements of S, which we can maintain in $O(1)$. ◀

6 Dynamic Word Problem for Languages

We now turn to the dynamic membership problem for regular languages, and show Theorem 1.1 using the three previous sections and some extra algebraic results.

Connection to the dynamic word problem. A regular language L is *recognized* by a finite monoid if there exists a morphism $\eta\colon \Sigma^* \to M$ such that $L = \eta^{-1}(\eta(L))$. The *syntactic congruence* of L is the equivalence relation on Σ^* where $u, v \in \Sigma^*$ are equivalent iff, for each $r, t \in \Sigma^*$, either $rut \in L$ and $rvt \in L$, or $rut \notin L$ and $rvt \notin L$. The *syntactic monoid* M of L is the quotient of Σ^* by the syntactic congruence of L, and the *syntactic morphism* is the morphism mapping Σ^* to M; the syntactic morphism witnesses that the syntactic monoid recognizes L.

The dynamic membership problem for a language clearly reduces to the dynamic word problem for its syntactic monoid. However, the converse is not true: the language $L := (aa)^*ba^*$ has a syntactic monoid M that can be shown to be outside of **SG**, but we can solve dynamic membership for L in $O(1)$ by counting the b's at even and odd positions. Intuitively, M has a neutral element 1 so that the dynamic word problem for M has a reduction from prefix-$\mathbb{Z}_2$, but 1 is not achieved by a letter of the alphabet so dynamic membership for L is easier.

We extend our results to languages using the notion of *stable semigroup* [6, 7]. This allows us to remove the neutral element (as it is a semigroup not a monoid) and ensures that all semigroup elements can be achieved by subwords of some constant length (the *stability index*).

Formally, let L be a regular language and $\eta\colon \Sigma^* \to M$ its syntactic morphism. The *powerset* of M is the monoid whose elements are subsets of M and for $E, F \subseteq M$, the product EF is $\{xy \mid x \in E, y \in F\}$. The *stability index* of L is the idempotent power s of $\eta(\Sigma)$ in the powerset monoid. Intuitively, this choice of s ensures that, for any two words $w_1, w_2 \in \Sigma^s$, the value $\eta(w_1w_2)$ of their concatenation in the monoid can be achieved by another word of Σ^s, i.e., $\eta(w_1w_2) = \eta(w)$ for some $w \in \Sigma^s$. Then $\eta(\Sigma^s)$ is a subsemigroup of M, because $(\eta(\Sigma^s))^2 = \eta(\Sigma^s)$: we call it the *stable semigroup* of L. For any class of semigroups $\mathbf{V}$, we denote by $\mathbf{QV}$ the class of languages whose stable semigroup is in $\mathbf{V}$.

Upper bounds. We first show that the dynamic membership problem for a regular language reduces more specifically to the dynamic word problem for its *stable semigroup*:

▶ **Proposition 6.1.** *Let L be a regular language. The dynamic membership problem for L reduces to the dynamic word problem for the stable semigroup of L.*

Proof sketch. We partition the word of L into chunks of size s (plus one of size $\leq s$) for s the stability index, and feed them to the data structure for the stable semigroup of L. ◀

By Corollary 5.3 and Theorem 5.4, this implies that languages in **QSG** (resp., in **QLZG**) have a dynamic membership problem in $O(\log \log n)$ (resp., in $O(1)$).

Lower bounds. We now show that languages whose stable semigroup is not in **LV** admit a reduction from the dynamic word problem of a monoid of **V**.

▶ **Proposition 6.2.** *Let $\mathbf{V}$ be a variety of monoids and let L be a regular language not in $\mathbf{QLV}$. There is a monoid not in $\mathbf{V}$ whose dynamic word problem reduces to the dynamic membership problem for L.*

Proof sketch. If L is not in **QLV**, then its stable semigroup contains a submonoid M not in **V**, and all elements can be achieved by a block of s letters for s the stability index. ◀

Again by Corollary 5.3 and Theorem 5.4, we deduce that languages outside of **QSG** have complexity at least $\Omega(\log n/\log\log n)$. Further, assuming Conjecture 2.3, and languages outside of **QLZG** do not have complexity $O(1)$.

7 Extensions, Problem Variants, and Future Work

We have presented our results on the dynamic word problem for monoids and semigroups, and on the dynamic membership problem for regular languages. We conclude the paper by a discussion of problems for further study. We first discuss the question of *intermediate complexities* between $O(1)$ and $O(\log\log n)$. We then study the complexity of *deciding which case applies* as a function of the target language, semigroup, or monoid. We last explore the issue of *handling insertions and deletions* on the input word, and of supporting *infix queries*.

Intermediate complexities. Our $O(\log\log n)$ upper bound in Theorem 3.2 and its variants may not be tight. Still, we can identify a language L_{U_2} in $\mathbf{QSG} \setminus \mathbf{QLZG}$ for which we show that the dynamic membership problem is in $\Theta(\log\log n)$ (even allowing randomization and allowing a probably correct answer), because the prefix-U_2 problem reduces to it.

We can also identify a language of $\mathbf{QSG} \setminus \mathbf{QLZG}$ that reduces to prefix-U_1 and so can be solved in expected $O(\sqrt{\log\log n})$. This shows that languages in $\mathbf{QSG} \setminus \mathbf{QLZG}$ have different complexity regimes, at least when allowing randomization.

▶ **Proposition 7.1.** *There is a language L_{U_2} in $\mathbf{QSG} \setminus \mathbf{QLZG}$ which is equivalent to prefix-U_2 under constant-time reductions, and a language L_{U_1} in $\mathbf{QSG} \setminus \mathbf{QLZG}$ which is equivalent to prefix-U_1 under constant-time reductions.*

Deciding which case applies. A natural question about our results is the question of efficiently identifying, given a regular language, which of the cases of Theorem 1.1 applies, or in particular of determining, given an input monoid or semigroup, if it is in **SG**, or in **ZG**. This depends on how the input is represented. If we are given a monoid explicitly (as a table of its operations), then the equations of **ZG** and of **SG** can be checked in polynomial time. If the monoid is represented more concisely as the transition monoid of some automaton, then the verification can be performed in PSPACE. We do not know if the problems are PSPACE-hard, though this seems likely at least for **SG** because of its proximity to aperiodic monoids [8]. We leave open the precise complexities of this task, in particular for the **L** and **Q** operators.

Handling insertions and deletions. Another natural question is to handle insertion and deletion updates, i.e., *inserting* letter a at position k transforms the word $w_1 \cdots w_{k-1} w_k \cdots w_n$ into $w_1 \cdots w_{k-1} a w_k \cdots w_n$, and *deleting* at position k does the opposite. Any regular language can be maintained under such updates in $O(\log n)$ using a Fenwick tree, but it makes the problem much harder for most languages. For example, if the alphabet has two letters a and b, just testing if the word that we maintain contains an a requires $\Omega(\log n/\log\log n)$ by [21]. This is why we do not study such updates in this work. Interestingly, notice that our algorithm in Theorem 3.3 supports insertions and deletions on words represented as vEBs, but the semantics are different (they use explicit positions in a fixed range).

Infix queries. A natural extension of dynamic membership for a regular language L is the *dynamic infix membership problem*, where we can query any *infix* of the word (identified by its endpoints) to ask whether it is in L. The $O(\log n/\log\log n)$ algorithm of Theorem 2.5 supports this, and so can the $O(\log\log n)$ algorithm of [29] for group-free monoids. However, the infix problem can be harder. Consider for instance the language L_2 on $\{a, b\}$ of words with an even number of a's. Dynamic membership has complexity $O(1)$ because L_2 is commutative, but infix queries (or even prefix queries) require $\Omega(\log n/\log\log n)$ as prefix-$\mathbb{Z}_2$ reduces to it.

We leave open the study of the complexity of the infix problem. We note, however, that this problem for a language L can be studied as the dynamic membership problem for a regular language defined from L. So our results cover the infix problem via this transformation; we leave to future work a characterization of the resulting classes.

▷ Claim 7.2. For any fixed regular language L, the dynamic infix membership problem is equivalent up to constant-time reductions to the dynamic membership problem for the language $\Sigma^* x L x \Sigma^*$ where x is a fresh letter.

Other open questions. A natural question for future work would be to study the complexity of our problems in weaker models, e.g., pointer machines [32], or machines with counters. One could also extend our study to languages that are not regular, e.g., generalizing bounds on maintaining the language of well-parenthesized strings ([19, Proposition 1] and [11]).

Appendix

Table 1 Summary of the main classes of monoids and semigroups used in the paper.

Class	Description	Equation	References
ZE	Monoids/semigroups with central idempotents	$x^\omega y = yx^\omega$	[1]
ZG	Monoids/semigroups with central groups	$x^{\omega+1}y = yx^{\omega+1}$	[4]
SG	Monoids/semigroups with swappable groups	$x^{\omega+1}yx^\omega = x^\omega yx^{\omega+1}$	[10, 29]
A	Aperiodic semigroups/monoids	$x^{\omega+1} = x^\omega$	[26]
Com	Commutative semigroups/monoids	$xy = yx$	[26]
Nil	Nilpotent semigroups	$x^\omega y = yx^\omega$	[26]
MNil	Monoids dividing a nilpotent semigroup		[30]
D	Definite semigroups	$yx^\omega = x^\omega$	[31]

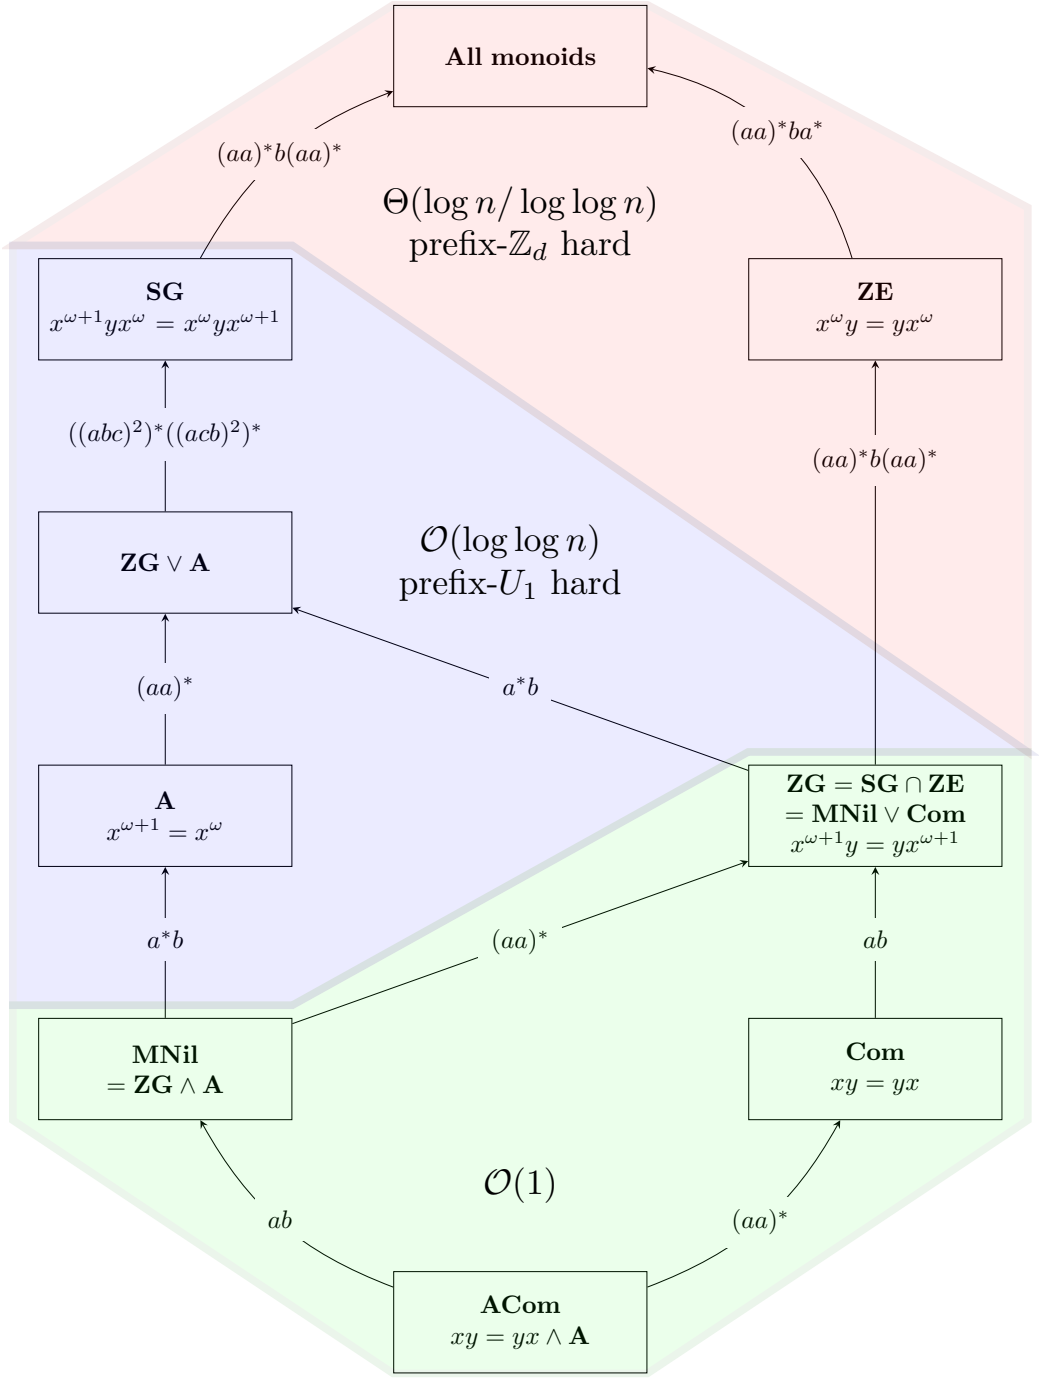

Figure 1 Complexity of the dynamic word problem for common classes of monoids. Arrows denote inclusion and are labeled with languages (with an implicit neutral letter e) whose syntactic monoids separate the classes. The classes **ZG** and **SG** are maximal for the $O(1)$ region and $O(\log\log n)$ region respectively.

A Rice's Theorem for Abstract Semantics

Abstract

Classical results in computability theory, notably Rice's theorem, focus on the extensional content of programs, namely, on the partial recursive functions that programs compute. Later and more recent work investigated intensional generalisations of such results that take into account the way in which functions are computed, thus affected by the specific programs computing them. In this paper, we single out a novel class of program semantics based on abstract domains of program properties that are able to capture nonextensional aspects of program computations, such as their asymptotic complexity or logical invariants, and allow us to generalise some foundational computability results such as Rice's Theorem and Kleene's Second Recursion Theorem to these semantics. In particular, it turns out that for this class of abstract program semantics, any nontrivial abstract property is undecidable and every decidable overapproximation necessarily includes an infinite set of false positives which covers all values of the semantic abstract domain.

1 Introduction

Most classical results in computability theory focus on the so-called *extensional* properties of programs, i.e., on the properties of the partial functions they compute. Notably, the renowned Rice's Theorem [25] states that any nontrivial extensional property of programs is undecidable. Despite being very general, Rice's Theorem and similar results in computability theory, due to the requirement of extensionality, leave out several *intensional* properties which are of utmost importance in the practice of programming. Essential intensional properties of programs include their asymptotic complexity of computation, their logical invariants (e.g., relations between variables at program points), or any event that might happen during program computation while not affecting the program output.

State-of-the-Art

A generalisation of well-established results of computability theory to the realm of program complexity has been put forward by Asperti [1]. A first observation is that Blum's complexity classes [2], i.e., sets of recursive functions (rather than sets of programs) with some given (lower or upper) bound on their (space and/or time) complexity, are not adequate for investigating the decidability aspects of program complexity: in fact, viewed as program properties they are trivially extensional. Thus, a key idea in [1] is to focus on the so-called *complexity cliques*, namely, sets of programs (i.e., program indices) closed with respect to their extensional input/output behaviour and their asymptotic complexity. Asperti [1] showed how this approach enables intensional versions of Rice's theorem, Rice-Shapiro theorem, and Kleene's second recursion theorem ([8, 28] are standard references for these foundational results) for complexity cliques.

More recently, a different approach has been considered by Moyen and Simonsen in [19], where the classical definition of extensionality has been weakened to a notion of *partial extensionality*. Roughly, a given set of programs is partially extensional if it includes the set of all programs computing a given partial recursive function. It is shown in [19] that if a set of programs and its complement are partially extensional, then they cannot be both recursive. Interestingly, this result can be further generalised by replacing the extensionality with an equivalence relation on programs satisfying some suitable structural conditions, notably, the existence of a so-called intricated switching family. Moyen and Simonsen [19] show how to derive within their framework intensional versions of Rice's Theorem – generalising Asperti's result [1] – and Rice-Shapiro Theorem.

Main Contributions

Along the lines traced by Asperti [1], we investigate whether and how some fundamental extensional results of computability theory can be systematically generalised to intensional aspects of computation, but rather than focussing on specific intensional properties we deal with generic *abstract program semantics*. More in detail, we distill two fundamental properties of abstract program semantics in our approach: the *strong smn property* and the existence of a *universal fair program*, roughly, an interpreter that preserves the abstract semantics. We show that for abstract semantics satisfying the strong smn property and admitting a universal fair program, a generalisation of Kleene's second recursion theorem can be proved. This, in turn, leads to a generalisation of Rice's theorem. Besides relying on a general abstract program semantics, inspired by Moyen and Simonsen's approach [19], we also relax the extensionality condition to partial extensionality. This weakening provides stronger impossibility results as it allows us to show that it is undecidable whether a given program *can* have a particular semantics, i.e., even nontrivial overapproximations of such properties are undecidable. On a different route, we establish a precise connection with Moyen and Simonsen's work [19] by showing that for any abstract program semantics satisfying the strong smn property and a structural *branching* condition (roughly, expressing some form of conditional choice), we can prove the existence of an intricated switching family, which turns out to be the crucial hypothesis in [19] for deriving an intensional version of Rice's theorem.

Therefore, on the one hand, we generalise the results in [1], going beyond complexity cliques, and, on the other hand, we provide an explicit characterisation of a class of program semantics that admit intricated switching families so that the results in [19] can be applied.

Finally, we show some applications of our intensional Rice's theorem that generalise some undecidability results for intensional properties used in static program analysis. In particular, we focus on program analysis in Karr's abstract domain of affine relations between program

variables [13]. By exploiting an acute reduction to the undecidable Post correspondence problem, Müller-Olm and Seidl [20] prove that for affine programs with positive affine guards it is undecidable whether a given nontrivial affine relation holds at a given program point or not. Here, we first show that this class of affine programs with positive affine guards, modeled as control flow graphs, turns out to be Turing complete since, by selecting a suitable program semantics, these programs can simulate a URM. Then, this allows us to derive the undecidability result in [20] as a consequence of our results.

The rest of the paper is structured as follows. In Section 2, we provide some background and our basic notions. In Section 3, we introduce the strong smn property, fair universal programs, and the branching condition that will play a fundamental role in our results. In Section 4, we provide our generalisation of Kleene's second recursion theorem and use it to derive our intensional Rice's theorem. We also establish an explicit connection with the notion of intricated switching family given in [19]. Section 5 provides some applications of our results to the analysis of affine programs. Section 6 discusses in detail the relation with some of Asperti's results [1] and with Rogers' systems of indices [27, 28]. Finally, Section 7 concludes and outlines some directions of future work.

2 Basic Notions

Given an n-ary partial function $f : \mathbb{N}^n \to \mathbb{N}$, we denote by $\mathrm{dom}(f)$ the domain of f and by $\mathrm{rng}(f) \triangleq \{f(\vec{x}) : \vec{x} \in \mathrm{dom}(f)\}$ its range. We write $f(\vec{x})\downarrow$ if $\vec{x} \in \mathrm{dom}(f)$ and $f(\vec{x})\uparrow$ if $\vec{x} \notin \mathrm{dom}(f)$. Moreover, $\lambda\vec{x}.\uparrow$ denotes the always undefined function. We denote by $\mathcal{F}_n \triangleq \mathbb{N}^n \to \mathbb{N}$ the class of all n-ary (possibly partial) functions and by $\mathcal{F} \triangleq \bigcup_n \mathcal{F}_n$ the class of all such functions. Additionally, $\mathcal{C}_n \subseteq \mathcal{F}_n$ denotes the subset of n-ary partial recursive functions ($\mathcal{C}$ stands for computable) and $\mathcal{C} \triangleq \bigcup_n \mathcal{C}_n$ the set of all partial recursive functions.

▶ **Assumption 2.1** (Turing completeness)**.** Throughout the paper, we assume a fixed Turing complete model and we denote by $\mathcal{P}$ the corresponding set of programs. Moreover, we consider a fixed Gödel numbering for the programs in $\mathcal{P}$ and, given an index $a \in \mathbb{N}$, we write P_a for the a-th program in $\mathcal{P}$. A program can take a varying number n of inputs and we denote by $\phi_a^{(n)} \in \mathcal{C}_n$ the n-ary partial function computed by P_a. Therefore, by Turing completeness, $\{\phi_a^{(n)} \mid a, n \in \mathbb{N}\} = \mathcal{C}$ must hold. ⌟

The binary relation between programs that compute the same n-ary function is called *Rice's equivalence* and denoted by $\sim_R^n$, i.e.,

$$a \sim_R^n b \overset{\triangle}{\iff} \phi_a^{(n)} = \phi_b^{(n)}.$$

Classical Rice's theorem [25] compares the extension of programs, i.e., the functions they compute, and shows that unions of equivalence classes of programs computing the same function are undecidable. In Asperti's work [1], by relying on the notion of complexity clique, the asymptotic program complexity can be taken into account. The idea here is to further generalise the approach in [1] by considering generic program semantics rather than asymptotic program complexity. Additionally, an equivalence relation on program semantics allows us to further abstract and identify programs with different extensional semantics. More precisely, such an equivalence relation allows us to reason on semantic program properties that may not hold with functional equivalence.

▶ **Definition 2.2** (Abstract semantics)**.** An *abstract semantics* is a pair $\langle \pi, \equiv_\pi \rangle$ where:

(1) $\pi : \mathbb{N}^2 \to \mathcal{F}$ associates a program index a and arity n with an n-ary function $\pi_a^{(n)} \in \mathcal{F}_n$, called *semantics* of a;

(2) $\equiv_\pi \subseteq \mathcal{F} \times \mathcal{F}$ is an equivalence relation between functions.

Given $n \in \mathbb{N}$, the *n-ary program equivalence* induced by an abstract semantics $\langle \pi, \equiv_\pi \rangle$ is the equivalence $\sim_\pi^n \subseteq \mathbb{N} \times \mathbb{N}$ defined as follows: for all $a, b \in \mathbb{N}$,

$$a \sim_\pi^n b \overset{\triangle}{\iff} \pi_a^{(n)} \equiv_\pi \pi_b^{(n)}.$$ ⌟

The notation for the case of arity $n = 1$ will be simplified by omitting the arity, e.g., ϕ_a instead of $\phi_a^{(1)}$ and $\sim_\pi$ in place of $\sim_\pi^1$. Abstract semantics can be viewed as a generalisation of the notion of system of indices (or numbering), as found in standard reference textbooks [22, 28] and discussed in detail later in Section 6.2. Let us now show how the standard extensional interpretation of programs, complexity and complexity cliques can be cast into our setting.

▶ **Example 2.3** (Concrete semantics)**.** The concrete input/output semantics can be trivially seen as an abstract semantics $\langle \phi, = \rangle$ where $\phi_a^{(n)}$ is the n-ary function computed by P_a and $=$ is the equality between functions. Observe that this concrete semantics induces an n-ary program equivalence which is Rice's equivalence $\sim_R^n$. ⌟

▶ **Example 2.4** (Domain semantics)**.** For a given set of inputs $S \subseteq \mathbb{N}$, consider $\langle \phi, \equiv_S \rangle$ where $\phi_a^{(n)}$ is the n-ary function computed by P_a and for $f, g : \mathbb{N}^n \to \mathbb{N}$, their equivalence is defined by $f \equiv_S g \overset{\triangle}{\iff} \mathrm{dom}(f) \cap S = \mathrm{dom}(g) \cap S$. ⌟

▶ **Example 2.5** (Blum complexity)**.** Let $\Phi : \mathbb{N}^2 \to \mathcal{C}$ be a Blum complexity [2], i.e., for all $a \in \mathbb{N}$ and $\vec{x} \in \mathbb{N}^n$, (1) $\Phi_a^{(n)}(\vec{x}) \downarrow \Leftrightarrow \phi_a^{(n)}(\vec{x}) \downarrow$ holds, and (2) for all $m \in \mathbb{N}$, the predicate $\Phi_a^{(n)}(\vec{x}) = m$ is decidable. Letting $\Theta(f)$ to denote the standard Big Theta complexity class of a function f, the pair $\langle \Phi, \equiv_\Phi \rangle$ defined by

$$\Phi_a^{(n)} \equiv_\Phi \Phi_b^{(n)} \overset{\triangle}{\iff} \Phi_a^{(n)} \in \Theta(\Phi_b^{(n)})$$

is an abstract semantics. ⌟

▶ **Example 2.6** (Complexity clique)**.** *Complexity cliques* as defined by Asperti in [1] can be viewed as an abstract semantics $\langle \pi, \equiv_\pi \rangle$, that we will refer to as the complexity clique semantics. For each arity n and program index a let us define:

$$\pi_a^{(n)} \triangleq \lambda \vec{y}. \langle\!\langle \phi_a^{(n)}(\vec{y}), \Phi_a^{(n)}(\vec{y}) \rangle\!\rangle$$

where $\langle\!\langle _, _ \rangle\!\rangle : \mathbb{N}^2 \to \mathbb{N}$ is an effective bijective encoding for pairs and $\Phi : \mathbb{N}^2 \to \mathcal{C}$ is a Blum complexity. The equivalence $\equiv_\pi$ is defined as follows: for all $a, b, n \in \mathbb{N}$,

$$\pi_a^{(n)} \equiv_\pi \pi_b^{(n)} \overset{\triangle}{\iff} \phi_a^{(n)} = \phi_b^{(n)} \wedge \Phi_a^{(n)} \equiv_\Phi \Phi_b^{(n)}.$$ ⌟

Classical Rice's theorem states the undecidabilty of extensional program properties. Following [19], we parameterise extensional sets by means of a generic equivalence relation.

▶ **Definition 2.7** (∼-extensional set)**.** Let $\sim \subseteq \mathbb{N} \times \mathbb{N}$ be an equivalence relation between programs whose equivalence classes are denoted by $[a]_\sim$. A set of indices $A \subseteq \mathbb{N}$ is called:

- *∼-extensional* when for all $a, b \in \mathbb{N}$, if $a \in A$ and $a \sim b$ then $b \in A$;
- *partially ∼-extensional* when there exists $a \in \mathbb{N}$ such that $[a]_\sim \subseteq A$;
- *universally ∼-extensional* when for all $a \in \mathbb{N}$, $[a]_\sim \cap A \neq \varnothing$. ⌟

In words, a set A is $\sim$-extensional if A is a union of $\sim$-equivalence classes, partially $\sim$-extensional if A contains at least a whole $\sim$-equivalence class, and universally $\sim$-extensional if A contains at least an element from each $\sim$-equivalence class, i.e., its complement $\mathbb{N} \setminus A$ is not partially $\sim$-extensional. Notice that if A is not trivial (i.e., $A \neq \varnothing$ and $A \neq \mathbb{N}$) and $\sim$-extensional then A is partially $\sim$-extensional and not universally $\sim$-extensional. Let us observe that $\sim_R$-extensionality is the standard notion of extensionality so that classical Rice's theorem [25] states that if A is $\sim_R$-extensional and not trivial then A is not recursive.[1]

3 Fair and Strong smn Semantics

In this section, we identify some fundamental properties of abstract semantics that will be later used in our intensional computability results. A first basic property stems from the fundamental smn theorem and intuitively amounts to requiring that the operation of fixing some parameters of a program is effective and preserves its abstract semantics.

▶ **Definition 3.1** (Strong smn semantics). An abstract semantics $\langle \pi, \equiv_\pi \rangle$ has the *strong smn* (*ssmn*) *property* if, given $m, n \geq 1$, there exists a total computable function $s : \mathbb{N}^{m+2} \to \mathbb{N}$ such that for all $a, b \in \mathbb{N}$, $\vec{x} \in \mathbb{N}^m$:

$$\lambda \vec{y}.\pi_a^{(n+1)}(\phi_b^{(m)}(\vec{x}), \vec{y}) \equiv_\pi \pi^{(n)}_{s(a,b,\vec{x})}. \tag{1}$$

In such a case, the abstract semantics $\langle \pi, \equiv_\pi \rangle$ is called *strong smn*. ⌟

The above definition requires the property (1) which is slightly stronger than one would expect. The natural generalisation of the standard smn property, in the style, e.g., of [1], would amount to asking that, given $m, n \geq 1$, there exists a total computable function $s : \mathbb{N}^{m+1} \to \mathbb{N}$ such that for any program index $a \in \mathbb{N}$ and input $\vec{x} \in \mathbb{N}^m$, it holds $\lambda \vec{y}.\pi_a^{(m+n)}(\vec{x}, \vec{y}) \equiv_\pi \pi^{(n)}_{s(a,\vec{x})}$. The concrete semantics $\langle \phi, = \rangle$ of Example 2.3 clearly satisfies this ssmn property. In fact, the function $\lambda a, b, \vec{y}.\pi_a^{(n+1)}(\phi_b^{(m)}(\vec{x}), \vec{y})$ is computable (by composition, relying on the existence of universal functions), hence the existence of a total computable $s : \mathbb{N}^{m+2} \to \mathbb{N}$ such that $\lambda \vec{y}.\pi_a^{(n+1)}(\phi_b^{(m)}(\vec{x}), \vec{y}) \equiv_\pi \pi^{(n)}_{s(a,b,\vec{x})}$ holds, as prescribed by Definition 3.1, follows by the standard smn theorem. It is easily seen that the same applies to the domain semantics of Example 2.4.

The reason for the stronger requirement (1) in Definition 3.1 is that, to deal with generic abstract semantics, thus going beyond asymptotic complexity, a suitable smn definition needs to embody a condition on program composition (of a and b in Definition 3.1). Indeed, if we consider the semantics based on program complexity (i.e., Examples 2.5 and 2.6), it turns out that whenever they enjoy the smn property in [1, Definition 11] and, additionally, they satisfy the linear time composition hypothesis in [1, Section 4] relating the asymptotic complexities of a program composition to those of its components, then they are ssmn semantics according to Definition 3.1. More details on the relationship with Asperti's approach [1] will be given later in Section 6.1.

Note that for an ssmn abstract semantics $\langle \pi, \equiv_\pi \rangle$, there always exists a program whose denotation is equivalent to the always undefined function, namely,

$$\text{for any arity } n \in \mathbb{N} \text{ there exists a program index } e_0 \in \mathbb{N} \text{ such that } \pi^{(n)}_{e_0} \equiv_\pi \lambda \vec{y}.\uparrow. \tag{2}$$

[1] In [19], the term "extensional" is replaced by "compatible" when one refers to generic equivalence relations $\sim$.

In fact, if b is a program index for the always undefined function $\lambda\vec{y}.\uparrow$ then, by (1), we have that $\lambda\vec{y}.\pi_0^{(n+1)}(\phi_b(0),\vec{y}) = \lambda\vec{y}.\uparrow \equiv_\pi \pi^{(n)}_{s(0,b,0)}$, so that we can pick $e_0 \triangleq s(0,b,0)$.

It is also worth exhibiting an example of abstract semantics which is not ssmn. Let $\pi_a(\vec{x})$ be defined as the number of different variables accessed in a computation of the program a on the input $\vec{x}$. Then, let us observe that the mere fact that π_a is always a total function trivially makes the abstract semantics $\langle \pi, = \rangle$ non-ssmn.

To generalise Kleene's second recursion theorem, besides the ssmn property, we need to postulate the existence of so-called *fair universal programs*, namely, programs that can simulate every other program w.r.t. a given abstract semantics. This generalises the analogous notion in [1, Definition 26], where this simulation is specific to complexity cliques and must preserve both the computed function and its asymptotic complexity.

▶ **Definition 3.2** (Fair semantics). An index $u \in \mathbb{N}$ is a *fair universal program* for an abstract semantics $\langle \pi, \equiv_\pi \rangle$ and an arity $n \in \mathbb{N}$ if for all $a \in \mathbb{N}$:

$$\pi_a^{(n)} \equiv_\pi \lambda\vec{y}.\pi_u^{(n+1)}(a,\vec{y}).$$

An abstract semantics is *fair* if it admits a fair universal program for every arity. ⌟

Clearly, the concrete (Example 2.3) and domain (Example 2.4) semantics are fair. In general, as noted in [1], the existence of a fair universal program may not only depend on the reference abstract semantics, but also on the underlying computational model. For instance, when considering program complexity, as argued by Asperti [1, Section 6] by relying on some remarks by Blum [3], multi-tape Turing machines seem not to admit fair universal programs. By contrast, single tape Turing machines do have fair universal programs, despite the fact that this is commonly considered a folklore fact and cannot be properly quoted. Hereafter, when referring to the complexity-based semantics of Examples 2.5 and 2.6, we will implicitly use that they are ssmn and fair semantics.

4 Kleene's Second Recursion Theorem and Rice's Theorem

In this section, we show how some foundational results of computability theory can be extended to a general abstract semantics. The first approach relies on a generalisation of Kleene's second recursion theorem, which is then used to derive a corresponding Rice's theorem. A second approach consists in identifying conditions that ensure the existence of an intricated switching family in the sense of [19], from which Rice's theorem also follows.

4.1 Kleene's Second Recursion Theorem

We show that Kleene's second recursion theorem holds for any fair ssmn abstract semantics. This generalises the analogous result proved by Asperti [1, Section 5] for complexity cliques.

▶ **Theorem 4.1** (Intensional Second Recursion Theorem). *Let $\langle \pi, \equiv_\pi \rangle$ be a fair ssmn abstract semantics. For any total computable function $h : \mathbb{N} \to \mathbb{N}$ and arity $n \in \mathbb{N}$, there exists an index $a \in \mathbb{N}$ such that $a \sim^n_\pi h(a)$.*

As an example, this result, instantiated to the complexity semantics of Example 2.5, entails the impossibility of designing a program transform that modifies the asymptotic complexity of every program, even without preserving its input-output behavior.

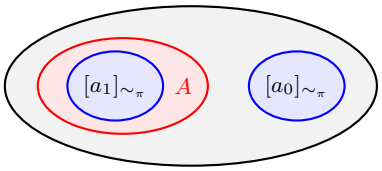

Figure 1 A graphical representation of Theorem 4.3.

▶ **Example 4.2** (Fixpoints of Blum complexity semantics)**.** Let $\langle \Phi, \equiv_\Phi \rangle$ be the Blum complexity semantics of Example 2.5. A program transform $h : \mathbb{N} \to \mathbb{N}$ is a total computable function which maps indices of programs into indices of transformed programs. By applying Theorem 4.1, for any arity $n \in \mathbb{N}$, we know that there exists an index of a program a such that $a \sim_\pi^n h(a)$ holds, so that the program transform h necessarily does not alter the asymptotic complexity of, at least, the program a. ⌟

This second recursion theorem allows us to obtain an intensional version of Rice's theorem for fair and ssmn abstract semantics. Inspired by [19], we generalise the statement to cover partially extensional properties.

▶ **Theorem 4.3** (Rice by fair and ssmn semantics)**.** *Let $\langle \pi, \equiv_\pi \rangle$ be a fair and ssmn semantics. If $A \subseteq \mathbb{N}$ is partially $\sim_\pi^n$-extensional and not universally $\sim_\pi^n$-extensional, for some arity $n \in \mathbb{N}$, then A is not recursive.*

Fig. 1 provides a graphical representation of this result: if we can find two program indices $a_0, a_1 \in \mathbb{N}$ such that A overapproximates the $\equiv_\pi$-equivalence class $[a_1]_{\sim_\pi}$ and A does not intersect $[a_0]_{\sim_\pi}$, then A cannot be recursive. For example, as observed in Section 3, the asymptotic complexity on a suitable computational model such as single tape Turing machines is a fair ssmn semantics, so that Theorem 4.3 applies. Let us illustrate some further applications of Theorem 4.3.

▶ **Example 4.4** (Halting set)**.** Let $\langle \phi, \equiv_\mathbb{N} \rangle$ be the domain semantics of Example 2.4 with $S = \mathbb{N}$, hence $f \equiv_\mathbb{N} g$ when $\mathrm{dom}(f) = \mathrm{dom}(g)$. The halting set $K \triangleq \{a \in \mathbb{N} \mid \phi_a(a)\!\downarrow\}$ can be proved to be non-recursive by resorting to Theorem 4.3 for $\langle \phi, \equiv_\mathbb{N} \rangle$. Let $e_0, e_1 \in \mathbb{N}$ be such that $\phi_{e_0} = \lambda x.\uparrow$ and $\phi_{e_1} = \lambda x.1$. Since $[e_1]_{\equiv_\mathbb{N}}$ is the set of programs that compute total functions, we have that $[e_1]_{\equiv_\mathbb{N}} \subseteq K$. Moreover, $[e_0]_{\equiv_\mathbb{N}}$ is the set of nonterminating programs for any input, so that $[e_0]_{\equiv_\mathbb{N}} \cap K = \varnothing$. This means that $\langle \phi, \equiv_\mathbb{N} \rangle$ satisfies the hypotheses of Theorem 4.3, thus entailing that K is not recursive. ⌟

▶ **Example 4.5** (Complexity sets)**.** Let $\langle \phi, = \rangle$, $\langle \Phi, \equiv_\Phi \rangle$ be, resp., the semantics of Examples 2.3 and 2.5. Let $sort : \mathbb{N} \to \mathbb{N}$ be a total function that takes as input an encoded sequence of numbers and outputs the encoding of the corresponding sorted sequence. It turns out that by applying Theorem 4.3, the following sets can be proved to be non-recursive:
(1) $A \triangleq \{a \mid \Phi_a \in \Theta(n \log n) \wedge \phi_a = sort\}$,
(2) $B \triangleq \{a \mid \Phi_a \in \mathcal{O}(n \log n)\}$,
(3) $C \triangleq \{a \mid \Phi_a \in \Omega(n \log n)\}$.
Let *is*, *ms* be different implementations of *sort*, i.e., $\phi_{is} = \phi_{ms} = sort$, such that $\Phi_{is} \in \Theta(n^2)$ and $\Phi_{ms} \in \Theta(n \log n)$ – *is* and *ms* could be, resp., insertion and merge sort. Recall that $\sim_R$ denotes the Rice equivalence induced by $\langle \phi, = \rangle$ (i.e., $a \sim_R b \Leftrightarrow \phi_a = \phi_b$), and, in turn, let $\sim_{\Phi R} = \sim_\Phi \cap \sim_R$ be the equivalence induced by the complexity clique semantics of Example 2.6, which is a fair ssmn semantics. Then, we have that:

(1) since $[is]_{\sim_{\Phi R}} \cap A = \varnothing$ and $[ms]_{\sim_{\Phi R}} \subseteq A$, by Theorem 4.3 A is non-recursive;
(2) since $[is]_{\sim_{\Phi}} \cap B = \varnothing$ and $[ms]_{\sim_{\Phi}} \subseteq B$, by Theorem 4.3 B is non-recursive;
(3) let e be any program index such that $\Phi_e \in \Theta(1)$. Since $[e]_{\sim_{\Phi}} \cap C = \varnothing$ and $[is]_{\sim_{\Phi}} \subseteq C$, by Theorem 4.3, the set C is non-recursive. ⌟

It is worth remarking that in Example 4.5, $n \log n$ could be replaced by any function, thus showing the undecidability of the asymptotic complexities "big O" (case (2)) and "big Omega" (case (3)). Let us also point out that Example 4.4 shows how easily the halting set K can be proved to be non-recursive by applying Theorem 4.3.

4.2 Branching Semantics

Let us investigate the connection between our results and the key notion of intricated switching family used by Moyen and Simonsen [19] for proving their intensional version of Rice's theorem. Firstly, we argue that every ssmn abstract semantics admits an intricated switching family whenever it is able to express a suitable form of *conditional branching*. This allows us to derive an intensional Rice's theorem. Moreover, we show that for fair and ssmn semantics, the identity can always play the role of intricated switching family.

▶ **Definition 4.6** (Branching and discharging semantics)**.** An abstract semantics $\langle \pi, \equiv_\pi \rangle$ is *branching* if, given $n \geq 1$, there exists a total computable function $r : \mathbb{N}^4 \to \mathbb{N}$ such that $\forall a, b, c_1, c_2, x \in \mathbb{N}$ such that $c_1 \neq c_2$:

$$\lambda \vec{y}.\pi^{(n)}_{r(a,b,c_1,c_2)}(x, \vec{y}) \equiv_\pi \begin{cases} \lambda \vec{y}.\pi^{(n)}_a(x, \vec{y}) & \text{if } x = c_1 \\ \lambda \vec{y}.\pi^{(n)}_b(x, \vec{y}) & \text{if } x = c_2 \\ \lambda \vec{y}.\uparrow & \text{otherwise} \end{cases}$$

Moreover, $\langle \pi, \equiv_\pi \rangle$ is (variable) *discharging* if, for all $n \geq 1$, there exists a total computable function $t : \mathbb{N} \to \mathbb{N}$ such that for all $a, x \in \mathbb{N}$:

$$\pi^{(n)}_a \equiv_\pi \lambda \vec{y}.\pi^{(n+1)}_{t(a)}(x, \vec{y}).$$ ⌟

Hence, intuitively, an abstract semantics is branching when it is able to model the branching structure of conditional statements with multiple positive guards, while the property of being variable discharging holds when one can freely add fresh and unused variables without altering the abstract semantics. Let us recall the notion of intricated switching family from [19, Definition 5].[2]

▶ **Definition 4.7** (Intricated switching family [19, Definition 5])**.** Let $\sim \subseteq \mathbb{N} \times \mathbb{N}$ be an equivalence relation on program indices. An *intricated switching family* (ISF) w.r.t. $\sim$ is an indexed set of total computable functions $\{\sigma_{a,b}\}_{a,b \in \mathbb{N}}$, with $\sigma_{a,b} : \mathbb{N} \to \mathbb{N}$, such that for all $a, b \in \mathbb{N}$, the sets $A_{a,b} = \{x \in \mathbb{N} \mid \sigma_{a,b}(x) \sim a\}$ and $B_{a,b} = \{x \in \mathbb{N} \mid \sigma_{a,b}(x) \sim b\}$ are recursively inseparable (i.e., no recursive C exists such that $A_{a,b} \subseteq C$ and $C \cap B_{a,b} = \varnothing$). ⌟

Moyen and Simonsen [19, Theorem 3] show that if an equivalence $\sim$ admits an ISF, then every partially $\sim$-extensional and not universally $\sim$-extensional set is not recursive. A simplified version of their intensional result, tailored for our setting, can be stated as follows.

[2] For the sake of simplicity, [19, Definition 5] is here instantiated to the case of recursive sets.

▶ **Theorem 4.8** ([19, Theorem 3]). *Let $\sim \subseteq \mathbb{N} \times \mathbb{N}$ be an equivalence relation. If $A \subseteq \mathbb{N}$ is partially $\sim$-extensional, not universally $\sim$-extensional and there exists an ISF w.r.t. $\sim$ then A is not recursive.*

Branching semantics allow us to derive the following intensional version of Rice's Theorem.

▶ **Theorem 4.9** (Rice by branching, discharging and ssmn semantics). *Let $\langle \pi, \equiv_\pi \rangle$ be a branching, discharging and ssmn semantics. If $A \subseteq \mathbb{N}$ is partially $\sim_\pi^n$-extensional and not universally $\sim_\pi^n$-extensional for some arity $n \in \mathbb{N}$, then A is not recursive.*

Let us discuss more in detail the relationship with the approach in [19]. Firstly, it turns out that a fair ssmn semantics always admits a canonical ISF, namely, the identity $\textsc{Id} \triangleq \{(\lambda x.x)_{a,b}\}_{a,b\in\mathbb{N}}$.

▶ **Proposition 4.10.** *Let $\langle \pi, \equiv_\pi \rangle$ be a fair and ssmn semantics. Then, the identity* Id *is an ISF w.r.t. $\sim_\pi^n$, for all $n \geq 1$.*

Let us point out that the identity function has not been exploited in [19], that instead focuses on the standard switching family. It turns out that the identity function plays a key role as ISF.

▶ **Proposition 4.11.** *Let $\sim \subseteq \mathbb{N} \times \mathbb{N}$ be an equivalence relation. The following statements are equivalent:*

(1) *Every set $A \subseteq \mathbb{N}$ partially $\sim$-extensional and not universally $\sim$-extensional is non-recursive.*

(2) *The identity* Id *is an ISF w.r.t. $\sim$.*

(3) *There exists an ISF w.r.t. $\sim$.*

Therefore, the above result roughly states that the identity function is the "canonical" ISF, meaning that if an ISF exists, then Id is an ISF as well. Moreover, the intensional Rice's Theorem 4.8 of [19] provides a sufficient condition (i.e., the existence of an ISF) for a partially and not universally extensional set to be undecidable. Proposition 4.11 enhances Theorem 4.8 by showing that such a sufficient condition is necessary as well, or, equivalently, that a partially and not universally extensional set is undecidable iff there exists an ISF.

We conclude this section by discussing an alternative notion of branching, which requires the preservation of a full conditional statement with positive and negative guards. This is an adaptation to our framework of a property that would be needed to exploit a so-called standard switching family as defined in [19, Example 1].

▶ **Definition 4.12** (Strongly branching semantics). An abstract semantics $\langle \pi, \equiv_\pi \rangle$ is *strongly branching* if, given $n \geq 1$, there exists a total computable function $r : \mathbb{N}^3 \to \mathbb{N}$ such that for all $a, b, c, x \in \mathbb{N}$:

$$\lambda\vec{y}.\pi^{(n)}_{r(a,b,c)}(x,\vec{y}) \equiv_\pi \begin{cases} \lambda\vec{y}.\pi^{(n)}_a(x,\vec{y}) & \text{if } x = c \\ \lambda\vec{y}.\pi^{(n)}_b(x,\vec{y}) & \text{otherwise} \end{cases}$$ ⌟

Despite appearing to be more natural, the preservation of conditionals with positive and negative conditions is a stronger requirement than the one we considered in Definition 4.6. Indeed, it turns out that every ssmn and strongly branching semantics is a branching semantics.

▶ **Proposition 4.13** (Strongly branching implies branching). *If $\langle \pi, \equiv_\pi \rangle$ is an ssmn and strongly branching semantics, then $\langle \pi, \equiv_\pi \rangle$ is branching.*

4.3 An Application to Static Program Verifiers

We adapt the general definition of static program verifier of Cousot et al. [7, Definition 4.3] to our framework. Given a program property $P \subseteq \mathbb{N}$ to check, a static program verifier is a total recursive function $\mathcal{V} : \mathbb{N} \to \{0, 1\}$, which is *sound* when for all $p \in \mathbb{N}$, $\mathcal{V}(p) = 1 \Rightarrow p \in P$, while $\mathcal{V}$ is *precise* if the reverse implication also holds, i.e., when $\mathcal{V}(p) = 1 \Leftrightarrow p \in P$ holds. Informally, soundness guarantees that only false negatives are allowed, i.e., $\mathbb{N} \setminus P$ is merely a subset of $\{p \in \mathbb{N} : \mathcal{V}(p) = 0\}$, while precise verifiers output true positives and true negatives only (i.e., they decide P).

Classical Rice's theorem clearly entails the impossibility of designing a precise verifier for a nontrivial extensional property. However, one may wonder whether there exist sound verifiers with "few" false negatives. By applying our intensional Theorem 4.3, we are able to show that sound but imprecise verifiers necessarily have at least one false negative for each equivalence class of programs, even for intensional properties.

▶ **Example 4.14** (Constant value verifier)**.** Assume we are interested in checking if a program can output a given constant value, for instance, zero with the aim of statically detecting division-by-zero bugs. Let $\mathcal{V}$ be a sound static verifier for the set $P_{=0} \triangleq \{p \in \mathbb{N} \mid 0 \in \mathrm{rng}(\phi_p)\}$ of programs that output zero for some input. The set $N \triangleq \{p \in \mathbb{N} \mid \mathcal{V}(p) = 0\}$ is recursive since $\mathcal{V}$ is assumed to be a total computable function. By soundness of $\mathcal{V}$, we have that $\mathbb{N} \setminus P_{=0} \subseteq N$, so that N includes, for example, the programs computing the constant function $\lambda x.1$. Therefore, N is partially extensional, and, by Theorem 4.3, N has to be universally extensional. This means that for any computable function $f \in \mathcal{C}$ there exists a program $p \in \mathbb{N}$ that computes f such that $\mathcal{V}(p) = 0$. Thus, when $0 \in \mathrm{rng}(f)$ holds (e.g., for $f = \lambda x.0$), $\mathcal{V}$ necessarily outputs a false negative for p. Hence, $\mathcal{V}$ outputs infinitely many false negatives. ⌟

▶ **Example 4.15** (Complexity verifier)**.** Consider a speculative sound static verifier $\mathcal{V}$ for recognizing programs that meet some lower bound, for instance, programs having a cubic lower bound $P_{\Omega(n^3)} \triangleq \{p \in \mathbb{N} \mid \Phi_p = \Omega(n^3)\}$. Thus, $N \triangleq \{p \in \mathbb{N} \mid \mathcal{V}(p) = 0\}$ has to be recursive and if $\sim_\Phi$ is the program equivalence induced by the Blum complexity semantics $\langle \Phi, \equiv_\Phi \rangle$ of Example 2.5 then, by soundness of $\mathcal{V}$, we have, for example, $\{p \in \mathbb{N} \mid \Phi_p = \Theta(1)\} \subseteq N$. This means that N is partially $\sim_\Phi$-extensional and, by Theorem 4.3, N is universally extensional, namely, $\mathcal{V}$ will output 0 for at least a program in each Blum complexity class. For instance, even some programs with an exponential lower bound will be wrongly classified by $\mathcal{V}$ as programs that do not meet a cubic lower bound. ⌟

As shown by Cousot et al. [7, Theorem 5.4], precise static verifiers cannot be designed (unless for trivial program properties). The examples above prove that, additionally, we cannot have any certain information on an input program p whenever the output of a sound (and imprecise) verifier for p is 0. In fact, when this happens, p could compute any partial function (cf. Example 4.14) or have any complexity (cf. Example 4.15).

5 On the Decidability of Affine Program Invariants

Karr's abstract domain [13] consisting of affine equalities between program variables, such as $2x - 3y = 1$, is well known and widely used in static program analysis [18, 26]. Karr [13] put forward an algorithm that infers for each program point q of a control flow graph modelling an affine program P (i.e., an unguarded program with non-deterministic branching and affine assignments) a set of affine equalities that hold among the variables of P when the control reaches q, namely, an *affine invariant* for P. Müller-Olm and Seidl [20] show that

Karr's algorithm actually computes the strongest affine invariant for affine programs (this result has been extended to a slightly larger class of affine programs in [23, Theorem 5.1]). Moreover, they design a more efficient algorithm implementing this static analysis and they extend in [21] the algorithm for computing bounded polynomial invariants, i.e., the strongest polynomial equalities of degree at most a given $d \in \mathbb{N}$. Later, Hrushovski et al. [11] put forward a sophisticated algorithm for computing the strongest unbounded polynomial invariants of affine programs, by relying on the Zariski closure of semigroups.

On the impossibility side, Müller-Olm and Seidl [20, Section 7] prove that for affine programs allowing positive affine guards it is undecidable whether a given nontrivial affine equality holds at a given program point or not. In practical applications, static analyses on Karr's domain of guarded affine programs ignore non-affine Boolean guards, while for an affine guard b, the current affine invariant i is propagated through the positive branch of b by the intersection $i \cap b$, that remains an affine subspace. By the aforementioned undecidability result [20, Section 7], this latter analysis algorithm for guarded affine programs turns out to be sound but necessarily imprecise, thus inferring affine invariants which are not the strongest ones.

Müller-Olm and Seidl [20, Section 7] prove their undecidability result by exploiting an acute reduction to the undecidable Post correspondence problem, inspired by early reductions explored in data flow analysis [9, 12]. In this section, we show that our Theorem 4.9 allows us to derive and extend this undecidability result by exploiting an orthogonal intensional approach. More precisely, we prove that any nontrivial (and not necessarily affine) relation on the states of control flow graphs of programs allowing: (1) zero, variable and successor assignments, resp., $x := 0$, $x := y$ and $x := y + 1$, and (2) positive equality guards $x = y?$ and $x = v?$, turns out to be undecidable. Since these control flow graphs form a subclass of affine programs with positive affine guards, the undecidability result of Müller-Olm and Seidl [20, Section 7] is retrieved as a consequence.

We consider control flow graphs that consist of program points connected by edges labeled by assignments and guards. Variables are denoted by x_i, with $i \in \mathbb{N}$, and store values ranging in $\mathbb{N}$, while Karr's abstract domain is designed for variables assuming values in $\mathbb{Q}$. Clearly, from a computability perspective, this is not a restriction simply by considering a computable bijection between $\mathbb{N}$ and $\mathbb{Q}$.

▶ **Definition 5.1** (Basic affine control flow graph)**.** A *basic affine control flow graph* (BACFG) is a tuple $G = (N, E, s, e)$, where N is a finite set of nodes, $s, e \in N$ are the start and end nodes, and $E \subseteq N \times \mathrm{Com} \times N$ is a set of labelled edges, where the set Com of commands consists of assignments of type $x_n := 0$, $x_n := x_m$, $x_n := x_m + 1$, and equality guards of type $x_n = x_m?$, $x_n = v?$, with $v \in \mathbb{N}$. ⌟

Let us remark that BACFGs only include basic affine assignments and positive affine guards, in particular inequality checks such as $x_n \neq x_m?$ and $x_n \neq v?$ are not allowed. Thus, BACFGs are a subclass of affine programs with positive affine guards.

As in dataflow analysis and abstract interpretation [6, 9, 26], BACFGs have a *collecting semantics* where, given a set of input states In, each program point is associated with the set of states that occur in some program execution from some state in In. A finite number of variables may occur in a BACFG, so that a state of a BACFG G is a tuple $(x_1, \ldots, x_k) \in \mathbb{N}^k$, where k is the maximum variable index occuring in G and $k = 0$ is a degenerate case for trivial BACFGs with $\mathbb{N}^0 = \{\bullet\}$. The *collecting transfer function* $f_{(\cdot)}(\cdot) : \mathrm{Com} \to \wp(\mathbb{N}^k) \to \wp(\mathbb{N}^k)$ for $k \in \mathbb{N}$ variables and with $n, m \in [1, k]$ is defined as follows:

$$
\begin{aligned}
f_{x_n:=0}(S) &\triangleq \{(x_1,\ldots,x_{n-1},0,x_{n+1},\ldots,x_k) \mid \vec{x} \in S\},\\
f_{x_n:=x_m}(S) &\triangleq \{(x_1,\ldots,x_{n-1},x_m,x_{n+1},\ldots,x_k) \mid \vec{x} \in S\},\\
f_{x_n:=x_m+1}(S) &\triangleq \{(x_1,\ldots,x_{n-1},x_m+1,x_{n+1},\ldots,x_k) \mid \vec{x} \in S\},\\
f_{x_n=v?}(S) &\triangleq \{\vec{x} \in S \mid x_n = v\},\\
f_{x_n=x_m?}(S) &\triangleq \{\vec{x} \in S \mid x_n = x_m\}.
\end{aligned}
$$

A no-op ϵ command is a syntactic sugar for $x_1 := x_1$, i.e., $f_\epsilon \triangleq f_{x_1:=x_1} = \lambda S.S$. Given $k, k' \in \mathbb{N}$ and $S \in \wp(\mathbb{N}^{k'})$, the projection $S\restriction_k \in \wp(\mathbb{N}^k)$ is defined as follows:

$$
S\restriction_k \triangleq \begin{cases} S \times \mathbb{N}^{k-k'} & \text{if } 0 \leq k' < k \\ S & \text{if } k' = k \\ \{(x_1,\ldots,x_k) \mid \vec{x} \in S\} & \text{if } k < k' \end{cases}
$$

▶ **Definition 5.2** (Collecting semantics of BACFGs)**.** Given a BACFG $G = (N, E, s, e)$ with $k \in \mathbb{N}$ variables and a set of input states $S \subseteq \mathbb{N}^{k'}$, with $k' \leq k$, the *collecting semantics* $[\![G]\!]_S : N \to \wp(\mathbb{N}^k)$ is the least, w.r.t. pointwise set inclusion, solution in $\wp(\mathbb{N}^k)^{|N|}$ of the following system of constraints:

$$
\begin{cases} [\![G]\!]_S[s] \supseteq S\restriction_k & \text{for the start node } s \\ [\![G]\!]_S[v] \supseteq f_c([\![G]\!]_S[u]) & \text{for each edge } (u,c,v) \in E \end{cases}
$$

⌟

Let us observe that, since the collecting transfer functions f_c are additive on the complete lattice $\langle \wp(\mathbb{N}^k), \subseteq \rangle$, by Knaster-Tarski fixpoint theorem, $[\![G]\!]_S$ is well defined. For $\vec{x} \in \mathbb{N}^{k'}$, we write $[\![G]\!]_{\vec{x}}$ instead of $[\![G]\!]_{\{\vec{x}\}}$. Notice that $[\![G]\!]_{(\cdot)}$ is an additive function, so that, for any program point $u \in N$, $[\![G]\!]_S[u] = \bigcup_{\vec{x} \in S} [\![G]\!]_{\vec{x}}[u]$ holds.

5.1 Turing Completeness of BACFGs

Let us recall that an ssmn abstract semantics needs an underlying Turing complete concrete semantics of programs (cf. Assumption 2.1). A crucial observation is that any URM (Unlimited Register Machine[3]) program, provided with suitable operational semantics, can be simulated by a BACFG, that is, BACFGs turn out to be Turing complete despite not including full (both positive and negative) Boolean tests.

▶ **Theorem 5.3** (Turing completeness of BACFGs)**.** BACFGs *are a Turing complete computational model.*

It is worth providing an intuition of the proof of Theorem 5.3. First, we point out that all four types of instructions of URMs, namely, using the definition and notation of [8],

- $z(n)$: sets register r_n to 0 ($r_n \leftarrow 0$) and transfers the control to the next instruction;
- $s(n)$: increments register r_n by 1 ($r_n \leftarrow r_n + 1$) and transfers the control to the next instruction;
- $t(m,n)$: sets register r_n to r_m ($r_n \leftarrow r_m$) and transfers the control to the next instruction;
- $j(m,n,p)$: if $r_m = r_n$ and I_p is a proper instruction, then it jumps to the instruction I_p; otherwise, it skips to the next instruction;

[3] Recall that URMs are a Turing complete computational model [8].

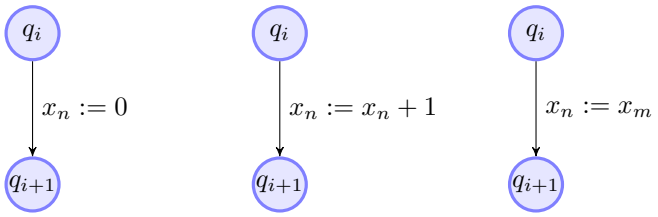

Figure 2 BACFGs simulating: $z(n)$ (left), $s(n)$ (center), $t(m, n)$ (right).

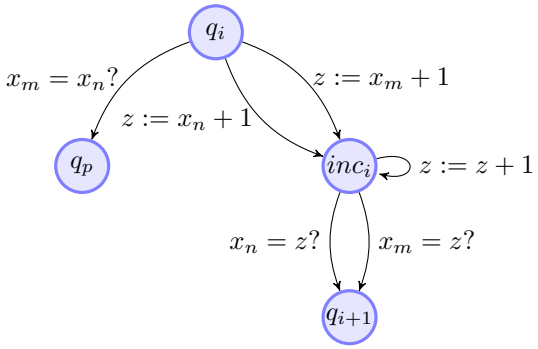

Figure 3 BACFG simulating a jump instruction $j(m, n, p)$.

can be simulated by the BACFGs depicted in Figures 2 and 3. While the BACFGs in Figure 2 are trivial, let us describe more in detail how to simulate a jump instruction by the BACFG in Figure 3. Intuitively, a difficulty arises for simulating the negative branch $x_n \neq x_m?$. Here, the BACFG at node q_i initialises a fresh unused variable z with both $x_n + 1$ and $x_m + 1$ and transfers the control to a node inc_i where z is incremented infinitely many times. Thus, in the least fixpoint solution, at node inc_i the variable z stores any value $v > \min(x_m, x_n)$, including $z = \max(x_m, x_n)$. Suppose now that $x_n > x_m$ holds: in this case, the guard $x_n = z?$ between nodes inc_i and q_{i+1} eventually will be made true and at the node q_{i+1} the store will retain the original values of all variables (x_m and x_n included), except for the new variable z which will be ignored by the remaining nodes. The case $x_m > x_n$ is analogous. Therefore, it turns out that the node q_{i+1} will be reached if and only if $x_m \neq x_n$ holds, while q_p will be reached if and only if $x_m = x_n$ holds, thus providing a simulation for the jump instruction $j(m, n, p)$.

5.2 Concrete and Abstract Semantics

One key insight is that the concrete semantics is defined on the URM programs that satisfy the Assumption 2.1 of Turing completeness, while the abstract semantics is defined on BACFGs. Let us consider two Gödel numberings for BACFGs and URMs, so that for an index $a \in \mathbb{N}$, G_a and RM_a denote, resp., the a-th BACFG and URM programs. The concrete semantics $\langle \phi, = \rangle$ of URMs, for an index $a \in \mathbb{N}$ and an arity $n \in \mathbb{N}$, is defined as follows: for all $\vec{x} \in \mathbb{N}^n$,

$$\phi_a^{(n)}(\vec{x}) \triangleq \begin{cases} y & \text{if } RM_a \text{ on input } \vec{x} \text{ halts with value } y \text{ on its first register,} \\ \uparrow & \text{otherwise.} \end{cases}$$

On the other hand, the abstract semantics of BACFGs is as follows.

▶ **Definition 5.4** (State semantics of BACFGs)**.** Let $Q \subseteq \wp(\mathbb{N}^t)$ be a predicate on sets of states with $t \in \mathbb{N}$ variables. The *state semantics* $\langle Q, = \rangle$ of BACFGs, for any index $a \in \mathbb{N}$ and arity $n \in \mathbb{N}$, is given by the function $Q_a^{(n)} : \mathbb{N}^n \to \{0, 1\}$ defined as follows: for all $\vec{x} \in \mathbb{N}^n$,

$$Q_a^{(n)}(\vec{x}) \triangleq \begin{cases} 1 & \text{if } [\![G_a]\!]_{\vec{x}}[e_a] \neq \varnothing \wedge [\![G_a]\!]_{\vec{x}}[e_a] \restriction_t \in Q \\ 0 & \text{if } [\![G_a]\!]_{\vec{x}}[e_a] \neq \varnothing \wedge [\![G_a]\!]_{\vec{x}}[e_a] \restriction_t \notin Q \\ \uparrow & \text{if } [\![G_a]\!]_{\vec{x}}[e_a] = \varnothing \end{cases}$$

where e_a is the end node of the a-th BACFG G_a. ⌟

Predicates of type $Q \subseteq \wp(\mathbb{N}^t)$ are also known as hyperproperties [5] and the state semantics of Definition 5.4 models the validity of a given predicate Q at the end node of a BACFG. Note that it is not restrictive to consider the end node, since this can be arbitrarily chosen in a BACFG.

▶ **Theorem 5.5.** *The state semantics of Definition 5.4 is ssmn, branching and discharging.*

Let us now consider a state semantics $\langle Q, = \rangle$ for some predicate $Q \subseteq \wp(\mathbb{N}^t)$. For all $n \geq 1$, let us define two sets $A^{\forall Q}$ and $A^{\exists Q}$, by distinguishing two cases depending on whether Q includes the empty set, that models nontermination, or not:

(1) if $\varnothing \notin Q$ then $A^{\forall Q} \triangleq \{a \in \mathbb{N} \mid \forall \vec{y}.\, Q_a^{(n)}(\vec{y}) = 1\}$ and $A^{\exists Q} \triangleq \{a \in \mathbb{N} \mid \exists \vec{y}.\, Q_a^{(n)}(\vec{y}) = 1\}$;
(2) if $\varnothing \in Q$ then $A^{\forall Q} \triangleq \{a \in \mathbb{N} \mid \forall \vec{y}.\, Q_a^{(n)}(\vec{y}) \in \{1, \uparrow\}\}$ and $A^{\exists Q} \triangleq \{a \in \mathbb{N} \mid \exists \vec{y}.\, Q_a^{(n)}(\vec{y}) \in \{1, \uparrow\}\}$.

Hence, $A^{\forall Q}$ ($A^{\exists Q}$) is the set of BACFGs such that Q holds at e_a for any (some) input state. It turns out that if $A^{\forall Q}$ is nontrivial then it is not recursive. Indeed, observe that $A^{\forall Q}$ is $\sim_Q$-extensional, so that Theorem 5.5 enables applying Theorem 4.9 to $\langle Q, = \rangle$. The same argument applies to the existential version $A^{\exists Q}$. We have therefore the following consequence.

▶ **Corollary 5.6.** *If Q is not trivial then $A^{\forall Q}$ and $A^{\exists Q}$ are not recursive.*

Corollary 5.6 means that we cannot decide if a nontrivial predicate Q holds at a given program point of a BACFG for all input states, neither whether there exists an input state that will make Q true. It is worth remarking that the predicates Q are arbitrary and include, but are not limited to, relational predicates between program variables such as affine equalities of Karr's abstract domain. Let us define some noteworthy examples of predicates:

(1) Given a set of affine equalities $\mathit{aff} = \{\vec{a_j} \cdot \vec{x} = b_j\}_{j=1}^m$, with $\vec{a_j} \in \mathbb{Z}^t$ and $b_j \in \mathbb{Z}$, $Q_{\mathit{aff}} \triangleq \{S \in \wp(\mathbb{N}^t) \mid \forall \vec{v} \in S. \forall j \in [1, m].\, \vec{a_j} \cdot \vec{v} = b_j\}$;
(2) Given $i \in [1, t]$ and $c \in \mathbb{N}$, $Q_{=c} \triangleq \{S \in \wp(\mathbb{N}^t) \mid \exists \vec{v} \in S.\ v_i = c\}$;
(3) Given a size $k \in \mathbb{N}$, $Q_{\mathrm{fin}_k} \triangleq \{S \in \wp(\mathbb{N}^t) \mid |S| = k\}$ and $Q_{\mathrm{fin}} \triangleq \cup_{k \in \mathbb{N}} Q_{\mathrm{fin}_k}$.

Therefore, Corollary 5.6 for $A^{\forall Q_{\mathit{aff}}}$ entails the undecidability result of Müller-Olm and Seidl [20, Section 7] discussed above. The predicate $Q_{=c}$ can be used to derive the undecidability of checking if some variable x_i may store a given constant c for affine programs with positive affine guards, e.g., for $c = 0$ this amounts to the undecidability of detecting division-by-zero bugs. Finally, with Q_{fin_0} we obtain the undecidability of dead code elimination, Q_{fin_1} entails the well-known undecidability of constant detection [9, 24], while the existential predicate Q_{fin} encodes whether some program point may only have finitely many different states.

6 Discussion of Related Work

In this section we discuss in detail the relation with some of Asperti's results [1] and with Rogers' systems of indices [27, 28].

6.1 Relation with Asperti's Approach

We show that our ssmn property in Definition 3.1 is a generalisation of the smn property in Asperti's approach [1], in a way that the Kleene's second recursion theorem and Rice's theorem for complexity cliques in [1] arise as instances of the corresponding results in our approach. Let us first recall and elaborate on the axioms for the complexity of function composition studied by Lischke [15, 16, 17] and assumed in [1, Section 4].

▶ **Definition 6.1** (Linear time and space complexity composition)**.** Consider a given concrete semantics ϕ and a Blum complexity Φ. The pair $\langle \phi, \Phi \rangle$ has the *linear time composition* property if there exists a total computable function $h : \mathbb{N}^2 \to \mathbb{N}$ such that for all $i, j \in \mathbb{N}$:
(1) $\phi_{h(i,j)} = \phi_i \circ \phi_j$,
(2) $\Phi_{h(i,j)} \in \Theta(\Phi_i \circ \phi_j + \Phi_j)$.
If (2) is replaced by
(2′) $\Phi_{h(i,j)} \in \Theta(\max\{\Phi_i \circ \phi_j, \Phi_j\})$
then $\langle \phi, \Phi \rangle$ has the *linear space composition* property. ⌟

Roughly speaking, the linear time composition property states that there exists a program $h(i, j)$ which computes the composition $\phi_i(\phi_j(x))$ in an amount of time which is asymptotically equivalent to the sum of the time needed for computing P_i on input $\phi_j(x)$ and the time to compute P_j on input x. On the other hand, the linear space composition property aims at modeling the needed space, so that rather than adding the complexities of P_i and P_j, their maximum is considered, since this intuitively is the maximum amount of space needed for computing a composition of programs.

By observing that $\Theta(\max\{\Phi_i \circ \phi_j, \Phi_j\}) = \Theta(\Phi_i \circ \phi_j + \Phi_j)$ we can merge the linear time and space properties of Definition 6.1 and extend them for n-ary compositions as follows.

▶ **Definition 6.2** (Linear complexity composition)**.** Given a concrete semantics ϕ and a Blum complexity Φ, the pair $\langle \phi, \Phi \rangle$ has the *linear complexity composition* property if, given $n, m \geq 1$, there exists a total computable function $h : \mathbb{N}^2 \to \mathbb{N}$ such that for all $i, j \in \mathbb{N}$:

$$\phi^{(m+n)}_{h(i,j)} = \lambda\vec{x}\lambda\vec{y}.\ \phi^{(n+1)}_i(\phi^{(m)}_j(\vec{x}), \vec{y}),$$
$$\Phi^{(m+n)}_{h(i,j)} \in \Theta(\lambda\vec{x}\lambda\vec{y}.\ (\Phi^{(n+1)}_i(\phi^{(m)}_j(\vec{x}), \vec{y})) + \Phi^{(m)}_j(\vec{x}))).$$ ⌟

We can now recall the smn property as defined in [1, Definition 11].

▶ **Definition 6.3** (Asperti's smn property)**.** Given a concrete semantics ϕ, a Blum complexity Φ and $m, n \geq 1$, the pair $\langle \phi, \Phi \rangle$ has the *Asperti's smn* property if there exists a total computable function $s : \mathbb{N}^{m+1} \to \mathbb{N}$ such that $\forall e \in \mathbb{N}, \vec{x} \in \mathbb{N}^m$:

$$\lambda\vec{y}.\phi^{(m+n)}_e(\vec{x}, \vec{y}) = \phi^{(n)}_{s(e,\vec{x})},$$
$$\lambda\vec{y}.\Phi^{(m+n)}_e(\vec{x}, \vec{y}) \in \Theta(\lambda\vec{y}.\Phi^{(n)}_{s(e,\vec{x})}(\vec{y})).$$ ⌟

Informally, the smn property of Definition 6.3 states that the operation of fixing parameters preserves both the concrete semantics and the asymptotic complexity. Under these assumptions, we can show that Asperti's complexity clique semantics satisfies our ssmn property.

▶ **Lemma 6.4.** *Let $\langle \pi, \equiv_\pi \rangle$ be the complexity clique semantics of Example 2.6. If $\langle \pi, \equiv_\pi \rangle$ satisfies Asperti's smn and linear complexity composition properties then $\langle \pi, \equiv_\pi \rangle$ is ssmn.*

This result, together with the observation that the notion of fairness (Definition 3.2) instantiated to the complexity clique semantics is exactly that of [1, Definition 26], allows us to retrieve Kleene's second recursion theorem and Rice's theorem for complexity cliques in [1] as instances of our corresponding results given in Section 4.1.

6.2 Relation with Systems of Indices

As mentioned in Section 2, our definition of abstract semantics resembles the acceptable systems of indices [22, Definition II.5.1] or numberings [28, Exercise 2-10], firstly studied by Rogers [27]. In this section we discuss how such notions compare.

▶ **Definition 6.5** (System of indices [22, Definition II.5.1])**.** A *system of indices* is a family of functions $\{\psi^n\}_{n\in\mathbb{N}}$ such that each $\psi^n : \mathbb{N} \to \mathcal{C}_n$ is a surjective map that associates program indices to n-ary partial recursive functions.

- $\{\psi^n\}_{n\in\mathbb{N}}$ has the *parametrization* (or smn) property if for every $m, n \in \mathbb{N}$ there is a total computable function $s : \mathbb{N}^{m+1} \to \mathbb{N}$ such that $\forall e \in \mathbb{N}, \vec{x} \in \mathbb{N}^m$:

$$\lambda \vec{y}.\psi_e^{m+n}(\vec{x}, \vec{y}) = \psi^n_{s(e,\vec{x})}.$$

- $\{\psi^n\}_{n\in\mathbb{N}}$ has the *enumeration* property if for every $n \in \mathbb{N}$ there exists $u \in \mathbb{N}$ such that for all and $e \in \mathbb{N}$ and $\vec{y} \in \mathbb{N}^n$:

$$\psi_e^n = \lambda \vec{y}.\psi_u^{n+1}(e, \vec{y}).$$ ⌟

Any standard Gödel numbering associating a program with the function it computes is a system of indices with the parametrization and enumeration properties. Moreover, exactly as we did in Example 2.3, any system of indices $\{\psi^n\}_{n\in\mathbb{N}}$ can be viewed as an abstract semantics $\langle \pi, = \rangle$ with $\pi_n^a \triangleq \psi_a^n$. In this context, the enumeration and parametrization properties correspond to our fairness and ssmn conditions: fairness is exactly enumeration while ssmn follows from parametrization and enumeration, as discussed in Section 3 for the concrete semantics (cf. Example 2.3).

A system of indices is defined to be *acceptable* if it allows to get back and forth with a given system of indices satisfying the parametrization and enumeration properties through a pair of total computable functions.

▶ **Definition 6.6** (Acceptable system of indices [27, Definition 4])**.** Let $\{\varphi^n\}_{n\in\mathbb{N}}$ be a given system of indices with the parametrization and enumeration properties. A system of indices $\{\psi^n\}_{n\in\mathbb{N}}$ is *acceptable* if there exist two total computable functions $f, g : \mathbb{N} \to \mathbb{N}$ such that for all $a, n \in \mathbb{N}$:

$$\psi_a^n = \varphi^n_{f(a)} \quad \text{and} \quad \varphi_a^n = \psi^n_{g(a)}.$$ ⌟

As shown in [22, Proposition II.5.3], it turns out that a system of indices is acceptable if and only if it satisfies both enumeration and parametrization (a proof of this characterization was first given by Rogers [27, Section 2]). Consequently, an acceptable system of indices $\{\psi^n\}_{n\in\mathbb{N}}$ can be viewed as an abstract semantic $\langle \pi, = \rangle$, where $\pi_a^n = \psi_a^n$, which, by this characterization of acceptability, is ssmn and fair, and therefore, by Theorem 4.1 it enjoys Kleene's second recursion theorem, as already known from [22, Corollary II.5.4]. Under this

perspective, a generic abstract semantics according to Definition 2.2 can be viewed as a proper generalisation of the notion of acceptable system of indices, which merely encodes a change of program numbering and does not allow to take into account an actual abstraction of the concrete input/output behaviour of programs.

7 Conclusion and Future Work

This work generalises some traditional extensional results of computability theory, notably Kleene's second recursion theorem and Rice's theorem, to intensional abstract program semantics that include the complexity cliques investigated by Asperti [1]. Our approach was also inspired by Moyen and Simonsen [19] and relies on weakening the classical definition of extensional program property to a notion of partial extensionality w.r.t. abstract program semantics that satisfy some structural conditions. As an application, we strengthened and generalised a result by Müller-Olm and Seidl [20] proving that for affine programs with positive affine guards it is undecidable whether an affine relation holds at a given program point. Our results also shed further light on the claim that these undecidability results hinge on the Turing completeness of the underlying computational model, as argued in [19].

As future work, a natural question would be to investigate intensional extensions of Rice-Shapiro's theorem that fit our framework based on abstract semantics. This appears to be a nontrivial challenge. Generalisations of Rice-Shapiro's theorem have been given in [1, Section 5] and [19, Section 5.1]. A generalisation in the vein of the approach in [1] seems to be viable, but would require structural assumptions on abstract program semantics that, while natural in [1] whose focus is on complexity properties, would be artificial for abstract program semantics and would limit a general applicability. A further stimulating research topic is to apply our approach to abstract semantics as defined by abstract interpretation of programs, in particular for investigating the relationship with the notion of abstract extensionality studied by Bruni et al. [4]. Finally, while our framework relies on the assumption of an underlying Turing complete computational model, in a different direction, one could try to consider intensional properties for classes of programs indexing subrecursive functions (e.g., primitive recursive functions), whose extensional properties have been already studied (see, e.g., [10, 14]). Despite the fact that we suppose that our approach will fall short on these program classes, as one cannot expect to have a universal program inside the class itself or the validity of Kleene's second recursion theorem, we think that this represents an intriguing research challenge.

Abstract

We address the approximate minimization problem for weighted finite automata (WFAs) with weights in $\mathbb{R}$, over a one-letter alphabet: to compute the best possible approximation of a WFA given a bound on the number of states. This work is grounded in Adamyan-Arov-Krein approximation theory, a remarkable collection of results on the approximation of Hankel operators. In addition to its intrinsic mathematical relevance, this theory has proven to be very effective for model reduction. We adapt these results to the framework of weighted automata over a one-letter alphabet. We provide theoretical guarantees and bounds on the quality of the approximation in the spectral and ℓ^2 norm. We develop an algorithm that, based on the properties of Hankel operators, returns the optimal approximation in the spectral norm.

1 Introduction

Weighted finite automata (WFAs) are an expressive class of models representing functions defined over sequences. The *approximate minimization problem* is concerned with finding an automaton that approximates the behaviour of a given minimal WFA, while being smaller in size. This second automaton recognizes a different language, and the objective is to minimize the approximation error [11, 12]. Approximate minimization becomes particularly useful in the context of spectral learning algorithms [5, 7, 9, 23]. When applied to a learning task, such algorithms can be viewed as working in two steps. First, they compute a minimal WFA that explains the training data exactly. Then, they obtain a model that generalizes to the unseen data by producing a smaller approximation to the minimal WFA. It is not just a question of saving space by having a smaller state space; the exact machine will *overfit* the data and generalize poorly. To obtain accurate results it is crucial to guess correctly the size of the minimal WFA, in particular when the data is generated by this type of machine.

The minimization task is greatly shaped by the way we decide to measure the approximation error. It is thus natural to wonder if there are norms that are preferable to others. We believe that the chosen norm should be computationally reasonable to minimize. For instance, the distance between WFAs can be computed using a metric based on bisimulation [8]. While this approach could still be interesting, the fact that this metric is hard to compute makes it unsuitable for our purposes. Moreover, this metric is specifically designed for WFAs, so it is not directly applicable to other models dealing with sequential data. We think that being transferable is a second important feature for a norm. In fact, being able to compare different classes of models is desirable for future applications of this method. For example, one can think of the burgeoning literature on approximating Recurrent Neural Networks (RNNs) using WFAs, where the objective is to extract from a trained RNN an automaton that accurately mimics its behaviour [37, 41, 32, 4, 19]. With this in mind, we think that it is preferable to consider a norm defined on the input-output function – or the Hankel matrix – rather than the parameters of the specific model considered. Finally, it is important to choose a norm that can be computed accurately. The spectral norm seems to be a good candidate for the task. In particular, it allows us to exploit the work of Adamyan, Arov and Krein which has come to be known as AAK theory [1]: a series of results connecting the theory of complex functions on the unit circle to Hankel matrices, a mathematical object representing functions defined over sequences. The core of this theory provides us with theoretical guarantees for the exact computation of the spectral norm of the error, and a method to construct the optimal approximation. We summarize our main contributions:

- We use AAK theory to study the approximate minimization problem of WFAs. To connect those areas, we establish a correspondence between the parameters of a WFA and the coefficients of a complex function on the unit circle. To the best of our knowledge, this paper represents the first attempt to apply AAK theory to WFAs.
- We present a theoretical analysis of the optimal spectral-norm approximate minimization problem for WFAs, based on their connection with finite-rank infinite Hankel matrices. We provide a closed form solution for real weighted automata $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ over a one-letter alphabet, under the assumption $\rho(\mathbf{A}) < 1$ on the spectral radius. We bound the approximation error, both in terms of spectral and ℓ^2 norm.
- We propose a self-contained algorithm that returns the unique optimal spectral-norm approximation of a given size.
- We tighten the connection, made in [12], between WFAs and discrete dynamical systems, by adapting some of the control theory concepts, *e.g.* the *allpass system*.

2 Background

2.1 Preliminaries

We denote with $\mathbb{N}$, $\mathbb{Z}$ and $\mathbb{R}$ the set of natural, integers and real numbers, respectively. We use bold letters for vectors and matrices; all vectors considered are column vectors. We denote with $\mathbf{1}$ the identity matrix, specifying its dimension only when not clear from the context. We refer to the i-th row and the j-th column of $\mathbf{M}$ by $\mathbf{M}(i,:)$ and $\mathbf{M}(:,j)$. Given a matrix $\mathbf{M} \in \mathbb{R}^{p\times q}$ of rank n, a *rank factorization* is a factorization $\mathbf{M} = \mathbf{PQ}$, where $\mathbf{P} \in \mathbb{R}^{p\times n}$, $\mathbf{Q} \in \mathbb{R}^{n\times q}$ and $\text{rank}(\mathbf{P}) = \text{rank}(\mathbf{Q}) = n$. Let $\mathbf{M} \in \mathbb{R}^{p\times q}$ of rank n, the compact *singular value decomposition* SVD of $\mathbf{M}$ is the factorization $\mathbf{M} = \mathbf{UDV}^\top$, where $\mathbf{U} \in \mathbb{R}^{p\times n}$, $\mathbf{D} \in \mathbb{R}^{n\times n}$, $\mathbf{V} \in \mathbb{R}^{q\times n}$ are such that $\mathbf{U}^\top\mathbf{U} = \mathbf{V}^\top\mathbf{V} = \mathbf{1}$, and $\mathbf{D}$ is a diagonal matrix. The columns of $\mathbf{U}$ and $\mathbf{V}$ are called left and right *singular vectors*, while the entries of $\mathbf{D}$ are the *singular values*. The *Moore-Penrose pseudo-inverse* $\mathbf{M}^+$ of $\mathbf{M}$ is the unique matrix such that $\mathbf{MM}^+\mathbf{M} = \mathbf{M}$, $\mathbf{M}^+\mathbf{MM}^+ = \mathbf{M}^+$, with $\mathbf{M}^+\mathbf{M}$ and $\mathbf{MM}^+$ Hermitian [43]. The *spectral radius* $\rho(\mathbf{M})$ of a matrix $\mathbf{M}$ is the largest modulus among its eigenvalues.

A *Hilbert space* is a complete normed vector space where the norm arises from an inner product. A linear operator $T : X \to Y$ between Hilbert spaces is *bounded* if it has finite operator norm, *i.e.* $\|T\|_{op} = \sup_{\|g\|_X \leq 1} \|Tg\|_Y < \infty$. We denote by $\mathbf{T}$ the (infinite) matrix associated with T by some (canonical) orthonormal basis on H. An operator is *compact* if the image of the unit ball in X is relatively compact. Let $T : X \to Y$ be a compact operator between Hilbert spaces, the *adjoint operator* T^* is the linear operator $T^* : Y \to X$ such that $\langle Tx, y\rangle_Y = \langle x, T^*y\rangle_X$, with $x \in X$, $y \in Y$ and $\langle\cdot,\cdot\rangle$ denotes the inner product of the corresponding Hilbert space. The *singular numbers* $\{\sigma_n\}_{n\geq 0}$ of T are the square roots of the non-negative eigenvalues of the self-adjoint operator T^*T, arranged in decreasing order. A *σ-Schmidt pair* $\{\boldsymbol{\xi}, \boldsymbol{\eta}\}$ for T is a couple of norm 1 vectors such that: $\mathbf{T}\boldsymbol{\xi} = \sigma\boldsymbol{\eta}$ and $\mathbf{T}^*\boldsymbol{\eta} = \sigma\boldsymbol{\xi}$. The Hilbert-Schmidt decomposition provides a generalization of the compact SVD for the infinite matrix of a compact operator T using singular numbers and orthonormal Schmidt pairs: $\mathbf{Tx} = \sum_{n\geq 0} \sigma_n \langle \mathbf{x}, \boldsymbol{\xi}_n\rangle \boldsymbol{\eta}_k$ [43]. The *spectral norm* $\|\mathbf{T}\|$ of the matrix representing the operator T is the largest singular number of T. Note that the spectral norm of $\mathbf{T}$ corresponds to the operator norm of T.

Let ℓ^2 be the Hilbert space of square-summable sequences over Σ^*, with norm $\|f\|_2^2 = \sum_{x\in\Sigma^*} |f(x)|^2$ and inner product $\langle f, g\rangle = \sum_{x\in\Sigma^*} f(x)g(x)$ for $f, g \in \mathbb{R}^{\Sigma^*}$. Let $\mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ be the complex unit circle, $\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\}$ the (open) complex unit disc. Let $1 < p < \infty$, $\mathcal{L}^p(\mathbb{T})$ be the space of measurable functions on $\mathbb{T}$ for which the p-th power of the absolute value is Lebesgue integrable. For $p = \infty$, we denote with $\mathcal{L}^\infty(\mathbb{T})$ the space of measurable functions that are bounded, with norm $\|f\|_\infty = \sup\{|f(x)| : x \in \mathbb{T}\}$.

2.2 Weighted Finite Automata

Let Σ be a fixed finite alphabet, Σ^* the set of all finite strings with symbols in Σ. We use ε to denote the empty string. Given $p, s \in \Sigma$, we denote with ps their concatenation.

A *weighted finite automaton* (WFA) of n states over Σ is a tuple $A = \langle \boldsymbol{\alpha}, \{\mathbf{A}_a\}, \boldsymbol{\beta}\rangle$, where $\boldsymbol{\alpha}$, $\boldsymbol{\beta} \in \mathbb{R}^n$ are the vector of initial and final weights, respectively, and $\mathbf{A}_a \in \mathbb{R}^{n\times n}$ is the matrix containing the transition weights associated with each symbol a. Every WFA A with real weights realizes a function $f_A : \Sigma^* \to \mathbb{R}$, *i.e.* given a string $x = x_1 \cdots x_t \in \Sigma^*$, it returns $f_A(x) = \boldsymbol{\alpha}^\top \mathbf{A}_{x_1} \cdots \mathbf{A}_{x_t} \boldsymbol{\beta} = \boldsymbol{\alpha}^\top \mathbf{A}_x \boldsymbol{\beta}$. A function $f : \Sigma^* \to \mathbb{R}$ is called *rational* if there exists a WFA A that realizes it. The *rank* of the function is the size of the smallest WFA realizing f. Given $f : \Sigma^* \to \mathbb{R}$, we can consider a matrix $\mathbf{H}_f \in \mathbb{R}^{\Sigma^*\times\Sigma^*}$ having rows and columns indexed by strings and defined by $\mathbf{H}_f(p, s) = f(ps)$ for $p, s \in \Sigma^*$.

▶ **Definition 1.** *A (bi-infinite) matrix* $\mathbf{H} \in \mathbb{R}^{\Sigma^* \times \Sigma^*}$ *is* ***Hankel*** *if for all* $p, p', s, s' \in \Sigma^*$ *such that* $ps = p's'$*, we have* $\mathbf{H}(p,s) = \mathbf{H}(p',s')$*. Given a Hankel matrix* $\mathbf{H} \in \mathbb{R}^{\Sigma^* \times \Sigma^*}$*, there exists a unique function* $f : \Sigma^* \to \mathbb{R}$ *such that* $\mathbf{H}_f = \mathbf{H}$*.*

▶ **Theorem 2** ([16, 20])**.** *A function* $f : \Sigma^* \to \mathbb{R}$ *is realized by a WFA* A *if and only if* $\mathbf{H}_f$ *has finite rank* n*. In that case,* n *is the minimal number of states of any* A *such that* $f = f_A$*.*

Given a WFA $A = \langle \boldsymbol{\alpha}, \{\mathbf{A}_a\}, \boldsymbol{\beta} \rangle$, the *forward matrix* of A is the infinite matrix $\mathbf{F}_A \in \mathbb{R}^{\Sigma^* \times n}$ given by $\mathbf{F}_A(p,:) = \boldsymbol{\alpha}^\top \mathbf{A}_p$ for any $p \in \Sigma^*$, while the *backward matrix* of A is $\mathbf{B}_A \in \mathbb{R}^{\Sigma^* \times n}$, given by $\mathbf{B}_A(s,:) = (\mathbf{A}_s \boldsymbol{\beta})^\top$ for any $s \in \Sigma^*$. Let $\mathbf{H}_f$ be the Hankel matrix of f, its forward-backward (FB) factorization is: $\mathbf{H}_f = \mathbf{F}\mathbf{B}^\top$. A WFA with n states is *reachable* if $\operatorname{rank}(\mathbf{F}_A) = n$, while it is *observable* if $\operatorname{rank}(\mathbf{B}_A) = n$. A WFA is *minimal* if it is reachable and observable. If A is minimal, the FB factorization is a rank factorization [7].

We recall the definition of the singular value automaton, a canonical form for WFAs [11].

▶ **Definition 3.** *Let* $f : \Sigma^* \to \mathbb{R}$ *be a rational function and suppose* $\mathbf{H}_f$ *admits an SVD,* $\mathbf{H}_f = \mathbf{U}\mathbf{D}\mathbf{V}^\top$*. A* ***singular value automaton*** *(SVA) for* f *is the minimal WFA* A *realizing* f *such that* $\mathbf{F}_A = \mathbf{U}\mathbf{D}^{1/2}$ *and* $\mathbf{B}_A = \mathbf{V}\mathbf{D}^{1/2}$*.*

The SVA can be computed with an efficient algorithm relying on the following matrices [12].

▶ **Definition 4.** *Let* $f : \Sigma^* \to \mathbb{R}$ *be a rational function,* $\mathbf{H}_f = \mathbf{F}\mathbf{B}^\top$ *a FB factorization. If the matrices* $\mathbf{P} = \mathbf{F}^\top\mathbf{F}$ *and* $\mathbf{Q} = \mathbf{B}^\top\mathbf{B}$ *are well defined, we call* $\mathbf{P}$ *the* ***reachability Gramian*** *and* $\mathbf{Q}$ *the* ***observability Gramian****.*

Note that if A is an SVA, then the Gramians associated with its FB factorization satisfy $\mathbf{P}_A = \mathbf{Q}_A = \mathbf{D}$, where $\mathbf{D}$ is the matrix of singular values of its Hankel matrix. The Gramians can alternatively be characterized (and computed [12]) using fixed point equations, corresponding to Lyapunov equations when $|\Sigma| = 1$ [28].

▶ **Theorem 5.** *Let* $|\Sigma| = 1$*,* $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ *a WFA with* n *states and well-defined Gramians* $\mathbf{P}$*,* $\mathbf{Q}$*. Then* $X = \mathbf{P}$ *and* $Y = \mathbf{Q}$ *solve the equations* $X - \mathbf{A}X\mathbf{A}^\top = \boldsymbol{\beta}\boldsymbol{\beta}^\top$ *and* $Y - \mathbf{A}^\top Y \mathbf{A} = \boldsymbol{\alpha}\boldsymbol{\alpha}^\top$*.*

Finally, we recall the definition of *generative probabilistic automata* (GPA). A WFA $A = \langle \boldsymbol{\alpha}, \{\mathbf{A}_a\}, \boldsymbol{\beta} \rangle$ is a GPA if $f_A(x) \geq 0$ for every x and $\sum_{x \in \Sigma^*} f_A(x) = 1$, *i.e.* if f_A computes a probability distribution over Σ^*.

▶ **Example 6.** Let $|\Sigma| = 1$, $\Sigma = \{x\}$. The WFA A: $\mathbf{A} = \begin{pmatrix} 0 & \frac{1}{2} \\ \frac{1}{2} & 0 \end{pmatrix}$, $\boldsymbol{\alpha} = \boldsymbol{\beta} = \begin{pmatrix} \frac{\sqrt{3}}{2} \\ 0 \end{pmatrix}$, is a GPA. Ideed, $f_A(x) \geq 0$ and $\sum_{x \in \Sigma^*} f_A(x) = 1$, since the rational function is:

$$f_A(x \cdots x) = f_A(k) = \boldsymbol{\alpha}^\top \mathbf{A}^k \boldsymbol{\beta} = \begin{cases} 0 & \text{if } k \text{ is odd} \\ \frac{3}{4} 2^{-k} & \text{if } k \text{ is even} \end{cases}$$

where k corresponds to the string where x is repeated k-times. We remark that A is minimal and in its SVA form, with Gramians $\mathbf{P} = \mathbf{Q} = \begin{pmatrix} \frac{4}{5} & 0 \\ 0 & \frac{1}{5} \end{pmatrix}$, and f_A has rank 2. Finally, the corresponding Hankel matrix, also of rank 2, is:

$$\mathbf{H} = \begin{pmatrix} f_A(0) & f_A(1) & f_A(2) & \cdots \\ f_A(1) & f_A(2) & f_A(3) & \cdots \\ f_A(2) & f_A(3) & f_A(4) & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} = \begin{pmatrix} \frac{3}{4} & 0 & \frac{3}{16} & \cdots \\ 0 & \frac{3}{16} & 0 & \cdots \\ \frac{3}{16} & 0 & \frac{3}{64} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix}. \tag{1}$$

2.3 AAK Theory

Theorem 2 provides us with a way to associate a minimal WFA A with n states to a Hankel matrix $\mathbf{H}$ of rank n. The approach we propose to approximate A is to find the WFA corresponding to the matrix that minimizes $\mathbf{H}$ in the spectral norm. We recall the fundamental result of Schmidt, Eckart, Young and Mirsky [18].

▶ **Theorem 7** ([18]). *Let $\mathbf{H}$ be a Hankel matrix corresponding to a compact Hankel operator of rank n, and σ_m, with $0 \leq m < n$ and $\sigma_0 \geq \cdots \geq \sigma_{n-1} > 0$, its singular numbers. Then, if $\mathbf{R}$ is a matrix of rank k, we have: $\|\mathbf{H} - \mathbf{R}\| \geq \sigma_k$. The equality is attained when $\mathbf{R}$ corresponds to the truncated SVD of $\mathbf{H}$.*

Note that a low-rank approximation obtained by truncating the SVD is not in general a Hankel matrix. This is problematic, since $\mathbf{G}$ needs to be Hankel in order to be the matrix of a WFA. Surprisingly, we can obtain a result comparable to the one of Theorem 7 while preserving the Hankel property. This is the possible thanks to AAK theory [1], a theory of optimal approximation. To apply this theory, we will need to rewrite the approximation problem in functional analysis terms. First, we will associate a linear operator to the Hankel matrix. Then, we will use Fourier analysis to reformulate the problem in a function space. A comprehensive presentation of the concepts recalled in this section can be found in [31, 34, 29].

Let $f : \Sigma^* \to \mathbb{R}$ be a rational function, we interpret the corresponding Hankel matrix $\mathbf{H}_f$ as the expression of a linear (Hankel) operator $H_f : \ell^2 \to \ell^2$ in terms of the canonical basis. We recall that a Hankel operator H_f is bounded if and only if $f \in \ell^2$ [12]. This property, together with the fact that we only consider finite rank operators (corresponding to the Hankel matrices of WFAs), is sufficient to guarantee compactness.

To introduce AAK theory, we need to consider a second realization of Hankel operators on complex spaces. Since in this paper we work with two classes of functions – functions over sequences and complex functions – to avoid any confusion we will make explicit the dependence on the complex variable $z = e^{it}$. We start by recalling a few fundamental definitions from the theory of complex functions. Note that a function $\phi(z) \in \mathcal{L}^2(\mathbb{T})$ can be represented, using the orthonormal basis $\{z^n\}_{n\in\mathbb{Z}}$, by means of its Fourier series: $\phi(z) = \sum_{n\in\mathbb{Z}} \widehat{\phi}(n) z^n$, with Fourier coefficients $\widehat{\phi}(n) = \int_{\mathbb{T}} \phi(z)\bar{z}^n dz$, $n \in \mathbb{Z}$. This establishes an isomorphism between the function $\phi(z)$ and the sequence of the corresponding Fourier coefficients $\widehat{\phi}$. Thus, we can partition the function space $\mathcal{L}^2(\mathbb{T})$ into two subspaces.

▶ **Definition 8.** *For $0 < p \leq \infty$, the **Hardy space** $\mathcal{H}^p$ and the **negative Hardy space** $\mathcal{H}^p_-$ on $\mathbb{T}$ are the subspaces of $\mathcal{L}^p(\mathbb{T})$ defined as:*

$$\mathcal{H}^p = \{\phi(z) \in \mathcal{L}^p(\mathbb{T}) : \widehat{\phi}(n) = 0, n < 0\}, \qquad \mathcal{H}^p_- = \{\phi(z) \in \mathcal{L}^p(\mathbb{T}) : \widehat{\phi}(n) = 0, n \geq 0\}.$$

Interestingly, the elements of the Hardy space can be canonically identified with the set of functions analytic in $\mathbb{D}$, with the property that the p-th power of their absolute value is integrable on $\mathbb{T}$ (a proof can be found in [31]). Thus, we will make no difference between these functions in the unit disc and their boundary value on the circle.

We can now embed the sequence space ℓ^2 into $\ell^2(\mathbb{Z})$ by "duplicating" each vector, *i.e.* by associating $\boldsymbol{\mu} = (\mu_0, \mu_1, \dots) \in \ell^2$ to $\boldsymbol{\mu}^{(2)} = (\dots, \mu_1, \mu_0, \mu_1, \dots) \in \ell^2(\mathbb{Z})$. Then, we can use the Fourier isomorphism to map the vector $\boldsymbol{\mu}^{(2)} \in \ell^2(\mathbb{Z})$ to the function space $\mathcal{L}^2(\mathbb{T})$. In this way each vector $\boldsymbol{\mu} \in \ell^2$ corresponds to two functions in the Hardy spaces:

$$\mu^-(z) = \sum_{j=0}^{\infty} \boldsymbol{\mu}_j z^{-j-1} \in \mathcal{H}^2_-, \qquad \mu^+(z) = \sum_{j=0}^{\infty} \boldsymbol{\mu}_j z^j \in \mathcal{H}^2. \tag{2}$$

This leads to an alternative characterization of Hankel operators in Hardy spaces.

▶ **Definition 9.** *Let $\phi(z)$ be a function in the space $\mathcal{L}^2(\mathbb{T})$. A **Hankel operator** is an operator $H_\phi : \mathcal{H}^2 \to \mathcal{H}^2_-$ defined by $H_\phi f(z) = \mathbb{P}_- \phi f(z)$, where $\mathbb{P}_-$ is the orthogonal projection from $\mathcal{L}^2(\mathbb{T})$ onto $\mathcal{H}^2_-$. The function $\phi(z)$ is called a **symbol** of the Hankel operator H_ϕ.*

We briefly recall the following theorem, due to Nehari [30], characterizing bounded Hankel operators.

▶ **Theorem 10** ([30])**.** *Let $\phi \in \mathcal{L}^2(\mathbb{T})$ be a symbol of the Hankel operator on Hardy spaces $H_\phi : \mathcal{H}^2 \to \mathcal{H}^2_-$. Then, H_ϕ is bounded on $\mathcal{H}^2$ if and only if there exists $\psi \in \mathcal{L}^\infty(\mathbb{T})$ such that $\widehat{\psi}(m) = \widehat{\phi}(m)$ for all $m < 0$. If the conditions above are satisfied, then:*

$$\|H_\phi\| = \inf\{\|\psi\|_\infty : \widehat{\psi}(m) = \widehat{\phi}(m),\, m < 0\}. \tag{3}$$

As a consequence of Theorem 10, if H_ϕ is a bounded operator, we can consider without loss of generality $\phi(z) \in \mathcal{L}^\infty(\mathbb{T})$. We remark that a Hankel operator has infinitely many different symbols, since $H_\phi = H_{\phi+\psi}$ for $\psi(z) \in \mathcal{H}^\infty$.

▶ Remark 11. Note that, in the standard orthonormal bases $\{z^k\}_{k\geq 0}$ of $\mathcal{H}^2$ and $\{z^{-(j+1)}\}_{j\geq 0}$ of $\mathcal{H}^2_-$, H_ϕ has Hankel matrix $\mathbf{H}(j,k) = \widehat{\phi}(-j-k-1)$ for $j,k \geq 0$.

▶ **Example 12.** In the case of the Hankel matrix in Example 6, we have that $\mathbf{H}(j,k) = 0$ if $j+k$ is odd, and $\mathbf{H}(j,k) = \frac{3}{4}2^{-(j+k)}$ if $j+k$ is even. Since $\mathbf{H}(j,k) = \widehat{\phi}(-j-k-1)$, we can recover the corresponding symbol: $\mathbb{P}_-\phi = \sum_{n\geq 0} \widehat{\phi}(-n-1)z^{-n-1} = \sum_{n\geq 0} \frac{3}{4}2^{-2n}z^{-2n-1} = \frac{3z}{4z^2-1}$.

▶ **Definition 13.** *The complex function $\phi(z)$ is **rational** if $\phi(z) = p(z)/q(z)$, with $p(z)$ and $q(z)$ polynomials. The rank of $\phi(z)$ is the maximum between the degrees of $p(z)$ and $q(z)$. A rational function is **strictly proper** if the degree of $p(z)$ is strictly smaller than that of $q(z)$.*

We remark that the poles of a complex function $\phi(z)$ correspond to the zeros of $1/\phi(z)$. The following result of Kronecker relates finite-rank infinite Hankel matrices to rational functions.

▶ **Theorem 14** ([25])**.** *Let H_ϕ be a bounded Hankel operator with matrix $\mathbf{H}$. Then $\mathbf{H}$ has finite rank if and only if $\mathbb{P}_-\phi$ is a strictly proper rational function. Moreover the rank of $\mathbf{H}$ is equal to the number of poles (with multiplicities) of $\mathbb{P}_-\phi$ inside the unit disc.*

▶ **Example 15.** The function in Example 12 is rational with degree 2 and has two poles inside the unit disc at $z = \pm\frac{1}{2}$. Thus, the Hankel matrix associated has rank 2.

We state as remark an important takeaway from this section.

▶ Remark 16. Given a rank n Hankel matrix $\mathbf{H}$, we can look at it in two alternative ways. On the one hand we can consider the Hankel operator over sequences $H_f : \ell^2 \to \ell^2$, associated to a function $f : \Sigma^* \to \mathbb{R}$. In this case $\mathbf{H}(i,j) = f(i+j)$ for $i,j \geq 0$, and f is rational in the sense that it is realized by a WFA of size n. On the other hand, we can consider the Hankel operator over complex (Hardy) spaces $H_\phi : \mathcal{H}^2 \to \mathcal{H}^2_-$, associated to a function $\phi(z) \in \mathcal{L}^2(\mathbb{T})$, the symbol. In this case $\mathbf{H}(j,k) = \widehat{\phi}(-j-k-1)$ for $j,k \geq 0$, and $\mathbb{P}_-\phi = \widehat{\phi}(-j-k-1)$ is rational of rank n in the sense of Definition 13.

We can introduce now the main result of Adamyan, Arov and Krein [1]. The theorem, stated for Hankel operators over Hardy spaces, shows that for infinite dimensional Hankel matrices the constraint of preserving the Hankel property does not affect the achievable approximation error.

▶ **Theorem 17** (AAK-1[1]). *Let H_ϕ be a compact Hankel operator of rank n and singular numbers σ_m, with $0 \leq m < n$ and $\sigma_0 \geq \cdots \geq \sigma_{n-1} > 0$. Then there exists a unique Hankel operator G of rank $k < n$ such that:*

$$\|\mathbf{H} - \mathbf{G}\| = \sigma_k. \tag{4}$$

We can reformulate the theorem in terms of symbols. Let $\mathcal{R}_k \subset \mathcal{H}^\infty_-$ be the set of strictly proper rational functions of rank k, and $\mathcal{H}^\infty_k = \{\psi \in \mathcal{L}^\infty(\mathbb{T}) : \ \exists g \in \mathcal{R}_k, \exists l \in \mathcal{H}^\infty, \ \psi = g + l\}$.

▶ **Theorem 18** (AAK-2 [1]). *Let $\phi(z) \in \mathcal{L}^\infty(\mathbb{T})$. Then, there exists $\psi(z) \in \mathcal{H}^\infty_k$ such that:*

$$\|\phi(z) - \psi(z)\|_\infty = \sigma_k(H_\phi). \tag{5}$$

The solutions of Theorem 17 and 18 are strictly related.

▶ **Corollary 19.** *Let $\psi(z) = g(z) + l(z) \in \mathcal{H}^\infty_k$, with $g(z) \in \mathcal{R}_k$, $l(z) \in \mathcal{H}^\infty$. If $\psi(z)$ solves Equation 5, then $G = H_g$ is the unique Hankel operator from Theorem 17.*

Proof of Corollary 19. Let H_ϕ be a Hankel operator with symbol $\phi(z) \in \mathcal{L}^\infty(\mathbb{T})$ and matrix $\mathbf{H}$. Let $\psi(z) = g(z) + l(z) \in \mathcal{H}^\infty_k$ be the solution of Equation 5. We have:

$$\begin{aligned} \|H_\phi - H_\psi\| &= \|H_{\phi-\psi}\| && (6)\\ &= \|H_{\sigma_k \eta_k^-(z)/\xi_k^+(z)}\| && (7)\\ &\leq \sigma_k \|\eta_k^-(z)/\xi_k^+(z)\|_\infty = \sigma_k && (8) \end{aligned}$$

where first we used Corollary 20 and then we applied Theorem 10. Now, using the definition of Hankel operator, we have:

$$\|H_\phi - H_\psi\| = \|H_\phi - H_g\| = \|\mathbf{H} - \mathbf{G}\| \leq \sigma_k. \tag{9}$$

Since $\|\mathbf{H} - \mathbf{G}\| \geq \sigma_k$ (from Eckart-Young theorem [18]), it follows that $\|\mathbf{H} - \mathbf{G}\| = \sigma_k$. Note that $\mathbf{G}$ has rank k, as required, because $g \in \mathcal{R}_k$(Theorem 14). ◀

We state as corollary the key point of the proof of AAK Theorem, that provides us with a practical way to find the best approximating symbol.

▶ **Corollary 20.** *Let $\phi(z)$ and $\{\boldsymbol{\xi}_k, \boldsymbol{\eta}_k\}$ be a symbol and a σ_k-Schmidt pair for H_ϕ. A function $\psi(z) \in \mathcal{L}^\infty$ is the best AAK approximation according to Theorem 18, if and only if:*

$$(\phi(z) - \psi(z))\xi_k^+(z) = \sigma_k \eta_k^-(z). \tag{10}$$

Moreover, the function $\psi(z)$ does not depend on the particular choice of the pair $\{\boldsymbol{\xi}_k, \boldsymbol{\eta}_k\}$.

3 Approximate Minimization

3.1 Assumptions

To apply AAK theory to the approximate minimization problem, we consider only automata with real weights, defined over a one-letter alphabet. In this case, the free monoid generated by the single letter can be identified with $\mathbb{N}$, and canonically embedded into $\mathbb{Z}$. This passage is fundamental to use Fourier analysis and the isomorphism that leads to Theorem 17 and 18. Unfortunately, this idea cannot be directly generalized to bigger alphabets, since in this case we would obtain a free non-abelian monoid (not identifiable with $\mathbb{Z}$).

Theorem 17 requires the Hankel operator H to be bounded. To ensure that a minimal WFA $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ satisfies this condition, we assume $\rho(\mathbf{A}) < 1$, where ρ is the spectral radius of $\mathbf{A}$ [12]. As a matter of fact, to guarantee the boundness of the Hankel operator it is enough that the considered WFA computes a function $f \in \ell^2$ [12]. However, the stricter assumption on the spectral radius is needed when computing the symbol associated to a WFA. This condition directly implies the existence of the SVA, and of the Gramian matrices $\mathbf{P}$ and $\mathbf{Q}$, with $\mathbf{P} = \mathbf{Q}$ and diagonal [12]. We assume $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ is in SVA form. In this case, given the size of the alphabet, the Hankel matrix $\mathbf{H}$ is symmetric, so $\mathbf{A} = \mathbf{A}^\top$. Moreover, if we denote with λ_i the i-th non-zero eigenvalue of $\mathbf{H}$, and we consider the coordinates of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$, we have that $\boldsymbol{\alpha}_i = \operatorname{sgn}(\lambda_i)\boldsymbol{\beta}_i$, where $\operatorname{sgn}(\lambda_i) = \lambda_i/|\lambda_i|$.

For example, we note that a minimal GPA computes a function $f \in \ell^1$, so the condition on $\rho(\mathbf{A})$ is automatically satisfied by this class of WFAs [12]. Possible relaxations of the spectral radius assumption are discussed in Section 5, together with an alternative method to find the optimal spectral-norm approximation of a Hankel matrix without extracting a WFA.

Finally, in this paper we consider only automata with weights in $\mathbb{R}$, though results remain true for complex numbers. The method we present can be easily extended to vector-valued automata [36], but the solution to the optimal approximation problem will not be unique [34].

3.2 Problem Formulation

Let $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ be a minimal WFA with n states in SVA form, defined over a one-letter alphabet. Let $\mathbf{H}$ be the Hankel matrix of A, we denote with σ_i, for $0 \leq i < n$, the singular numbers. Given a target number of states $k < n$, we say that a WFA $\widehat{A}_k$ with k states solves the *optimal spectral-norm approximate minimization* problem if the Hankel matrix $\mathbf{G}$ of $\widehat{A}_k$ satisfies $\|\mathbf{H} - \mathbf{G}\| = \sigma_k(\mathbf{H})$. Note that the content of the "optimal spectral-norm approximate minimization" is equivalent to the problem solved by Theorem 17, with the exception that here we insist on representing the inputs and outputs of the problem effectively by means of WFAs. Based on the AAK theory sketched in Section 2.3, we draw the following steps:

1. *Compute a symbol $\phi(z)$ for H using Remark 16.* We obtain the negative Fourier coefficients of $\phi(z)$ and derive its Fourier series.
2. *Compute the optimal symbol $\psi(z)$ using Corollary 20.* The main challenge here is to find a suitable representation for the functions $\psi(z)$ and $e(z) = \phi(z) - \psi(z)$. We define them in terms of two auxiliary WFAs. The key point is to select constraints on their parameters to leverage the properties of weighted automata, while still keeping the formulation general.
3. *Extracting the rational component by solving for $g(z)$ in Corollary 19.* This step is arguably the most conceptually challenging, as it requires to identify the position of the function's poles. In fact, we know from Theorem 14 that $g(z)$ has k poles, all inside the unit disc.
4. *Find a WFA representation for $g(z)$.* Since in Step 2 we parametrized the functions using WFAs, the expression of $g(z)$ directly reveals the WFA $\widehat{A}_k$.

3.3 Spectral-Norm Approximate Minimization

In the following sections we will consider a minimal WFA $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ with n states in SVA form, defined over a one-letter alphabet $\Sigma = \{a\}$, its Hankel matrix $\mathbf{H}$, corresponding to the bounded operator H, and the singular numbers σ_i, for $0 \leq i < n$. Let $f : \Sigma^* \to \mathbb{R}$ be the function realized by A. We denote by x the string where a is repeated x times, so we have $f(x) = \boldsymbol{\alpha}^\top \mathbf{A}^x \boldsymbol{\beta}$.

3.3.1 Computation of a Symbol for A

To determine the symbol $\phi(z)$ of H, we recall that each entry of the Hankel matrix corresponds simultaneously to the values of f and to the negative Fourier coefficients of $\phi(z)$. In fact, as seen in Remark 16, we have:

$$\mathbf{H} = \begin{pmatrix} f_A(0) & f_A(1) & \dots \\ f_A(1) & f_A(2) & \dots \\ \vdots & \vdots & \ddots \end{pmatrix} = \begin{pmatrix} \widehat{\phi}(-1) & \widehat{\phi}(-2) & \dots \\ \widehat{\phi}(-2) & \widehat{\phi}(-3) & \dots \\ \vdots & \vdots & \ddots \end{pmatrix}. \tag{11}$$

We obtain:

$$\mathbb{P}_-\phi(z) = \sum_{k\geq 0} f(k) z^{-k-1} = \sum_{k\geq 0} \boldsymbol{\alpha}^\top \mathbf{A}^k \boldsymbol{\beta} z^{-k-1} = \boldsymbol{\alpha}^\top (z\mathbf{1} - \mathbf{A})^{-1} \boldsymbol{\beta} \tag{12}$$

where we use the fact that $\rho(A) < 1$ for the last equality. Since the function obtained is already bounded, we can directly consider $\phi(z) = \boldsymbol{\alpha}^\top (z\mathbf{1} - \mathbf{A})^{-1}\boldsymbol{\beta}$ as a symbol for H.

▶ **Example 21.** If we apply the formula in Equation 12 to the GPA in Example 6, we recover the rational function $\phi(z) = \frac{3z}{4z^2-1}$ found in Example 12.

3.3.2 Computation of the Optimal Symbol

We consider two auxiliary WFAs. Let $\widehat{A} = \langle \widehat{\boldsymbol{\alpha}}, \widehat{\mathbf{A}}, \widehat{\boldsymbol{\beta}} \rangle$ be a WFA with $j \geq k$ states, satisfying the following properties:

1. 1 is not an eigenvalue of $\widehat{\mathbf{A}}$
2. the automaton $E = \langle \boldsymbol{\alpha}_e, \mathbf{A}_e, \boldsymbol{\beta}_e \rangle$ is minimal, with

$$\mathbf{A}_e = \begin{pmatrix} \mathbf{A} & \mathbf{0} \\ \mathbf{0} & \widehat{\mathbf{A}} \end{pmatrix}, \quad \boldsymbol{\alpha}_e = \begin{pmatrix} \boldsymbol{\alpha} \\ -\widehat{\boldsymbol{\alpha}} \end{pmatrix}, \quad \boldsymbol{\beta}_e = \begin{pmatrix} \boldsymbol{\beta} \\ \widehat{\boldsymbol{\beta}} \end{pmatrix}. \tag{13}$$

Using the parameters of the automaton $\widehat{A}$ and a constant C, we define a function $\psi(z) = \widehat{\boldsymbol{\alpha}}^\top (z\mathbf{1} - \widehat{\mathbf{A}})^{-1}\widehat{\boldsymbol{\beta}} + C$. We remark that the poles of $\psi(z)$ correspond to the eigenvalues of $\widehat{\mathbf{A}}$, counted with their multiplicities. By assumption, 1 is not an eigenvalue of $\widehat{A}$, so $\psi(z)$ does not have any poles on the unit circle, and therefore $\psi(z) \in \mathcal{L}^\infty(\mathbb{T})$. Analogously, the function $e(z) = \phi(z) - \psi(z) = \boldsymbol{\alpha}_e^\top (z\mathbf{1} - \mathbf{A}_e)^{-1}\boldsymbol{\beta}_e - C$ is also bounded on the circle.

Our objective is to compute the parameters of $\widehat{A} = \langle \widehat{\boldsymbol{\alpha}}, \widehat{\mathbf{A}}, \widehat{\boldsymbol{\beta}} \rangle$ that make $\psi(z)$ the best approximation of $\phi(z)$ according to Theorem 18. In particular, we will use Corollary 20 to find the triple $\widehat{\boldsymbol{\alpha}}, \widehat{\mathbf{A}}, \widehat{\boldsymbol{\beta}}$ such that $\psi(z)$ satisfies Equation 10. Note that, with this purpose, the constant term $C \in H^\infty$ becomes necessary to characterize $\psi(z)$. In fact, while the H^∞-component of the symbol does not affect the Hankel norm, it plays a role in the computation of the $\mathcal{L}^\infty$-norm (in Equation 5) according to Theorem 10, so it cannot be dismissed.

The following theorem provides us with an explicit expression for the functions in the Hardy space corresponding to a σ_k-Schmidt pair.

▶ **Theorem 22.** *Let σ_k be a singular number of the Hankel operator H. The singular functions associated with the σ_k-Schmidt pair $\{\boldsymbol{\xi}_k, \boldsymbol{\eta}_k\}$ of H are:*

$$\xi_k^+(z) = \sigma_k^{-1/2} \boldsymbol{\alpha}^\top (\mathbf{1} - z\mathbf{A})^{-1} \mathbf{e}_k \tag{14}$$

$$\eta_k^-(z) = \sigma_k^{-1/2} \boldsymbol{\beta}^\top (z\mathbf{1} - \mathbf{A})^{-1} \mathbf{e}_k. \tag{15}$$

*If $\psi(z)$ is the best approximation to the symbol, then $\sigma_k^{-1} e(z)$ has modulus 1 almost everywhere on the unit circle (*i.e. *it is unimodular).*

Proof. Let $\mathbf{F}$ and $\mathbf{B}$ be the forward and backward matrices, respectively, with $\mathbf{H} = \mathbf{F}\mathbf{B}^\top$, $\mathbf{P} = \mathbf{F}^\top\mathbf{F}, \mathbf{Q} = \mathbf{B}^\top\mathbf{B}$. We consider the σ_k-Schmidt pair $\{\boldsymbol{\xi}_k, \boldsymbol{\eta}_k\}$. By definition, we have $\mathbf{H}^\top\mathbf{H}\boldsymbol{\xi}_k = \sigma_k^2\boldsymbol{\xi}_k$. Rewriting in terms of the FB factorization, we obtain:

$$\mathbf{H}^\top\mathbf{H}\boldsymbol{\xi}_k = \sigma_k^2\boldsymbol{\xi}_k \tag{16}$$
$$\mathbf{B}\mathbf{F}^\top\mathbf{F}\mathbf{B}^\top\boldsymbol{\xi}_k = \sigma_k^2\boldsymbol{\xi}_k \tag{17}$$
$$\mathbf{B}\mathbf{P}\mathbf{B}^\top\boldsymbol{\xi}_k = \sigma_k^2\boldsymbol{\xi}_k \tag{18}$$
$$\mathbf{B}\mathbf{P}\mathbf{e}_k = \sigma_k^2\boldsymbol{\xi}_k \tag{19}$$

where in the last step we set $\mathbf{e}_k = \mathbf{B}^\top\boldsymbol{\xi}_k$, to reduce the SVD problem of $\mathbf{H}$ to the one of $\mathbf{Q}\mathbf{P}$. Note that, since $\mathbf{P}$ and $\mathbf{Q}$ are diagonal, $\mathbf{e}_k$ is the k-th coordinate vector $(0, \dots, 0, 1, 0, \dots, 0)^\top$. Since $\mathbf{e}_k$ is an eigenvector of $\mathbf{Q}\mathbf{P}$ for σ_k^2, we get:

$$\mathbf{B}\mathbf{Q}^{-1}\mathbf{Q}\mathbf{P}\mathbf{e}_k = \sigma_k^2\boldsymbol{\xi}_k \tag{20}$$
$$\mathbf{B}\mathbf{Q}^{-1}\mathbf{e}_k = \boldsymbol{\xi}_k. \tag{21}$$

Moreover, $\mathbf{H}$ is symmetric, so we have that the singular vectors $\boldsymbol{\eta}_k$ and $\boldsymbol{\xi}_k$ have the same coordinates up to the sign of the corresponding eigenvalues. We obtain:

$$\xi_k^+(z) = \sum_{j=0}^{\infty} \sigma_k^{-1/2}\boldsymbol{\alpha}^\top\mathbf{A}^j\mathbf{e}_k z^j = \sigma_k^{-1/2}\boldsymbol{\alpha}^\top(\mathbf{1} - z\mathbf{A})^{-1}\boldsymbol{e}_k \tag{22}$$

$$\eta_k^-(z) = \sum_{j=0}^{\infty} \sigma_k^{-1/2}\boldsymbol{\beta}^\top\mathbf{A}^j\mathbf{e}_k z^{-j-1} = \sigma_k^{-1/2}\boldsymbol{\beta}^\top(z\mathbf{1} - \mathbf{A})^{-1}\boldsymbol{e}_k \tag{23}$$

where the singular functions have been computed following Equation 2. If r is the multiplicity of σ_k, from Corollary 20 we get the following fundamental equation:

$$(\phi(z) - \psi(z))\boldsymbol{\alpha}^\top(\mathbf{1} - z\mathbf{A})^{-1}\mathbf{V} = \sigma_k\boldsymbol{\beta}^\top(z\mathbf{1} - \mathbf{A})^{-1}\mathbf{V}$$

where $\mathbf{V} = \begin{pmatrix}\mathbf{0} & \mathbf{1}_r\end{pmatrix}^\top$ is a $n \times r$ matrix. Consequently, we obtain the unimodular function:

$$\sigma_k^{-1}e(z) = \frac{\boldsymbol{\beta}^\top(z\mathbf{1} - \mathbf{A})^{-1}\mathbf{V}}{\boldsymbol{\alpha}^\top(\mathbf{1} - z\mathbf{A})^{-1}\mathbf{V}}$$

which is unimodular, since $\boldsymbol{\alpha}_i = \operatorname{sgn}(\lambda_i)\boldsymbol{\beta}_i$. ◀

It is reasonable to wonder how the fact that $\sigma_k^{-1}e(z)$ is unimodular reflects on the structure of the WFA $E = \langle \boldsymbol{\alpha}_e, \mathbf{A}_e, \boldsymbol{\beta}_e \rangle$ associated with it. We remark that, *a priori*, the controllability and observability Gramians of E might not be well defined. The following theorem provides us with two matrices $\mathbf{P}_e$ and $\mathbf{Q}_e$ satisfying properties similar to those of the Gramians. This theorem is the analogous of a control theory result [17], rephrased in terms of WFAs. The proof, that relies on the minimality of the WFA E [39], can be found in [17].

▶ **Theorem 23** ([17]). *Consider the function $e(z) = \boldsymbol{\alpha}_e^\top(z\mathbf{1} - \mathbf{A}_e)^{-1}\boldsymbol{\beta}_e - C$ and the corresponding minimal WFA $E = \langle \boldsymbol{\alpha}_e, \mathbf{A}_e, \boldsymbol{\beta}_e \rangle$ associated with it. If $\sigma_k^{-1}e(z)$ is unimodular, then there exists a unique pair of symmetric invertible matrices $\mathbf{P}_e$ and $\mathbf{Q}_e$ satisfying:*

(a) $\mathbf{P}_e - \mathbf{A}_e\mathbf{P}_e\mathbf{A}_e^\top = \boldsymbol{\beta}_e\boldsymbol{\beta}_e^\top$
(b) $\mathbf{Q}_e - \mathbf{A}_e^\top\mathbf{Q}_e\mathbf{A}_e = \boldsymbol{\alpha}_e\boldsymbol{\alpha}_e^\top$
(c) $\mathbf{P}_e\mathbf{Q}_e = \sigma_k^2\mathbf{1}$

We can now derive the parameters of the WFA $\widehat{A} = \langle \widehat{\boldsymbol{\alpha}}, \widehat{\mathbf{A}}, \widehat{\boldsymbol{\beta}} \rangle$.

▶ **Theorem 24.** *Let $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ be a minimal WFA with n states in its SVA form, and let $\phi(z) = \boldsymbol{\alpha}^\top (z\mathbf{1} - \mathbf{A})^{-1}\boldsymbol{\beta}$ be a symbol for its Hankel operator H. Let σ_k be a singular number of multiplicity r for H, with $\sigma_0 \geq \cdots > \sigma_k = \cdots = \sigma_{k+r-1} > \sigma_{k+r} \geq \cdots \geq \sigma_{n-1} > 0$. We can partition the Gramian matrices $\mathbf{P}$, $\mathbf{Q}$ and, conformally to them, $\mathbf{A}$, $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$, as follows:*

$$\mathbf{P} = \mathbf{Q} = \begin{pmatrix} \boldsymbol{\Sigma} & \mathbf{0} \\ \mathbf{0} & \sigma_k \mathbf{1}_r \end{pmatrix}, \quad \mathbf{A} = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{12}^\top & \mathbf{A}_{22} \end{pmatrix}, \quad \boldsymbol{\alpha} = \begin{pmatrix} \boldsymbol{\alpha}_1 \\ \boldsymbol{\alpha}_2 \end{pmatrix}, \quad \boldsymbol{\beta} = \begin{pmatrix} \boldsymbol{\beta}_1 \\ \boldsymbol{\beta}_2 \end{pmatrix}. \tag{24}$$

where $\boldsymbol{\Sigma} \in \mathbb{R}^{(n-r)\times(n-r)}$ is the diagonal matrix containing the remaining singular numbers. Let $\mathbf{R} = \sigma_k^2 \mathbf{1}_{n-r} - \boldsymbol{\Sigma}^2$, we denote by $(\cdot)^+$ the Moore-Penrose pseudo-inverse. If the function $\psi(z) = \widehat{\boldsymbol{\alpha}}^\top (z\mathbf{1} - \widehat{\mathbf{A}})^{-1}\widehat{\boldsymbol{\beta}} + C$ is the best approximation of $\phi(z)$, then:

- *If $\boldsymbol{\alpha}_2 \neq \mathbf{0}$:*

$$\begin{cases} \widehat{\boldsymbol{\beta}} = -\widehat{\mathbf{A}}\mathbf{A}_{12}(\boldsymbol{\beta}_2^\top)^+ \\ \widehat{\boldsymbol{\alpha}} = \widehat{\mathbf{A}}^\top \mathbf{R}\mathbf{A}_{12}(\boldsymbol{\alpha}_2^\top)^+ \\ \widehat{\mathbf{A}}(\mathbf{A}_{11} - \mathbf{A}_{12}(\boldsymbol{\beta}_2^\top)^+\boldsymbol{\beta}_1^\top) = \mathbf{1} \end{cases} \tag{25}$$

- *If $\boldsymbol{\alpha}_2 = \mathbf{0}$:*

$$\begin{cases} \widehat{\boldsymbol{\beta}} = (\mathbf{1} - \widehat{\mathbf{A}}\mathbf{A}_{11})(\boldsymbol{\beta}_1^\top)^+ \\ \widehat{\boldsymbol{\alpha}} = -(\mathbf{R} - \widehat{\mathbf{A}}^\top \mathbf{R}\mathbf{A}_{11})(\boldsymbol{\alpha}_1^\top)^+ \\ \widehat{\mathbf{A}}\mathbf{A}_{12} = \mathbf{0} \end{cases} \tag{26}$$

Proof. Since $\sigma^{-1}e(z) = \phi(z) - \psi(z)$ is unimodular, from Theorem 23 there exist two symmetric nonsingular matrices $\mathbf{P}_e$, $\mathbf{Q}_e$ satisfying the fixed point equations:

$$\mathbf{P}_e - \mathbf{A}_e \mathbf{P}_e \mathbf{A}_e^\top = \boldsymbol{\beta}_e \boldsymbol{\beta}_e^\top \tag{27}$$

$$\mathbf{Q}_e - \mathbf{A}_e^\top \mathbf{Q}_e \mathbf{A}_e = \boldsymbol{\alpha}_e \boldsymbol{\alpha}_e^\top \tag{28}$$

and such that $\mathbf{P}_e\mathbf{Q}_e = \sigma_k^2\mathbf{1}$. We can partition $\mathbf{P}_e$ and $\mathbf{Q}_e$ according to the definition of $\mathbf{A}_e$ (see Eq. 13):

$$\mathbf{P}_e = \begin{pmatrix} \mathbf{P}_{11} & \mathbf{P}_{12} \\ \mathbf{P}_{12}^\top & \mathbf{P}_{22} \end{pmatrix}, \quad \mathbf{Q}_e = \begin{pmatrix} \mathbf{Q}_{11} & \mathbf{Q}_{12} \\ \mathbf{Q}_{12}^\top & \mathbf{Q}_{22} \end{pmatrix}.$$

From Equation 27 and 28, we note that $\mathbf{P}_{11}$ and $\mathbf{Q}_{11}$ corresponds to the controllability and observability Gramians of A:

$$\mathbf{P}_{11} = \mathbf{Q}_{11} = \mathbf{P} = \begin{pmatrix} \boldsymbol{\Sigma} & \mathbf{0} \\ \mathbf{0} & \sigma_k \mathbf{1} \end{pmatrix}.$$

Moreover, since $\mathbf{P}_e\mathbf{Q}_e = \sigma_k^2\mathbf{1}$, we get $\mathbf{P}_{12}\mathbf{Q}_{12}^\top = \sigma_k^2\mathbf{1} - \mathbf{P}^2$. It follows that $\mathbf{P}_{12}\mathbf{Q}_{12}^\top$ has rank $n - r$. Without loss of generality we can set $\dim \widehat{\mathbf{A}} = j = n - r$, and choose an appropriate basis for the state space such that $\mathbf{P}_{12} = \begin{pmatrix} \mathbf{1} & \mathbf{0} \end{pmatrix}^\top$ and $\mathbf{Q}_{12} = \begin{pmatrix} \mathbf{R} & \mathbf{0} \end{pmatrix}^\top$, with $\mathbf{R} = \sigma_k^2\mathbf{1} - \boldsymbol{\Sigma}^2$. Once $\mathbf{P}_{12}$ and $\mathbf{Q}_{12}$ are fixed, the values of $\mathbf{P}_{22}$ and $\mathbf{Q}_{22}$ are automatically determined. We obtain:

$$\mathbf{P}_e = \begin{pmatrix} \boldsymbol{\Sigma} & \mathbf{0} & \mathbf{1} \\ \mathbf{0} & \sigma_k\mathbf{1} & \mathbf{0} \\ \mathbf{1} & \mathbf{0} & -\boldsymbol{\Sigma}\mathbf{R}^{-1} \end{pmatrix}, \quad \mathbf{Q}_e = \begin{pmatrix} \boldsymbol{\Sigma} & \mathbf{0} & \mathbf{R} \\ \mathbf{0} & \sigma_k\mathbf{1} & \mathbf{0} \\ \mathbf{R} & \mathbf{0} & -\boldsymbol{\Sigma}\mathbf{R} \end{pmatrix}. \tag{29}$$

Now that we have an expression for the matrices $\mathbf{P}_e$ and $\mathbf{Q}_e$ of Theorem 23, we can rewrite the fixed point equations to derive the parameters $\widehat{\boldsymbol{\alpha}}$, $\widehat{\mathbf{A}}$ and $\widehat{\boldsymbol{\beta}}$. We obtain the following systems:

$$\begin{cases} \mathbf{P} - \mathbf{A}\mathbf{P}\mathbf{A} = \boldsymbol{\beta}\boldsymbol{\beta}^\top \\ \mathbf{N} - \mathbf{A}\mathbf{N}\widehat{\mathbf{A}}^\top = \boldsymbol{\beta}\widehat{\boldsymbol{\beta}}^\top \\ -\boldsymbol{\Sigma}\mathbf{R}^{-1} + \widehat{\mathbf{A}}\boldsymbol{\Sigma}\mathbf{R}^{-1}\widehat{\mathbf{A}}^\top = \widehat{\boldsymbol{\beta}}\widehat{\boldsymbol{\beta}}^\top \end{cases} \qquad \begin{cases} \mathbf{P} - \mathbf{A}\mathbf{P}\mathbf{A} = \boldsymbol{\alpha}\boldsymbol{\alpha}^\top \\ \mathbf{M} - \mathbf{A}^\top\mathbf{M}\widehat{\mathbf{A}} = -\boldsymbol{\alpha}\widehat{\boldsymbol{\alpha}}^\top \\ -\boldsymbol{\Sigma}\mathbf{R} + \widehat{\mathbf{A}}^\top\boldsymbol{\Sigma}\mathbf{R}\widehat{\mathbf{A}} = \widehat{\boldsymbol{\alpha}}\widehat{\boldsymbol{\alpha}}^\top \end{cases} \tag{30}$$

where $\mathbf{N} = \begin{pmatrix} \mathbf{1} \\ \mathbf{0} \end{pmatrix}$ and $\mathbf{M} = \begin{pmatrix} \mathbf{R} \\ \mathbf{0} \end{pmatrix}$. We can rewrite the second equation of each system as follows:

$$\begin{cases} \mathbf{1} - \mathbf{A}_{11}\widehat{\mathbf{A}}^\top = \boldsymbol{\beta}_1\widehat{\boldsymbol{\beta}}^\top \\ -\mathbf{A}_{12}^\top\widehat{\mathbf{A}}^\top = \boldsymbol{\beta}_2\widehat{\boldsymbol{\beta}}^\top \end{cases} \qquad \begin{cases} \mathbf{R} - \mathbf{A}_{11}\mathbf{R}\widehat{\mathbf{A}} = -\boldsymbol{\alpha}_1\widehat{\boldsymbol{\alpha}}^\top \\ \widehat{\mathbf{A}}^\top\mathbf{R}\mathbf{A}_{12} = \widehat{\boldsymbol{\alpha}}\boldsymbol{\alpha}_2^\top \end{cases} \tag{31}$$

If $\boldsymbol{\alpha}_2 \neq \mathbf{0}$, then also $\boldsymbol{\beta}_2 \neq \mathbf{0}$ (recall that $\boldsymbol{\alpha}_i = \operatorname{sgn}(\lambda_i)\boldsymbol{\beta}_i$), and we have:

$$\begin{cases} \widehat{\boldsymbol{\beta}} = -\widehat{\mathbf{A}}\mathbf{A}_{12}(\boldsymbol{\beta}_2^\top)^+ \\ \widehat{\boldsymbol{\alpha}} = \widehat{\mathbf{A}}^\top\mathbf{R}\mathbf{A}_{12}(\boldsymbol{\alpha}_2^\top)^+ \\ \widehat{\mathbf{A}}(\mathbf{A}_{11} - \mathbf{A}_{12}(\boldsymbol{\beta}_2^\top)^+\boldsymbol{\beta}_1^\top) = \mathbf{1} \end{cases} \tag{32}$$

with $(\boldsymbol{\alpha}_2^\top)^+ = \frac{\boldsymbol{\alpha}_2}{\boldsymbol{\alpha}_2^\top\boldsymbol{\alpha}_2}$ and $(\boldsymbol{\beta}_2^\top)^+ = \frac{\boldsymbol{\beta}_2}{\boldsymbol{\beta}_2^\top\boldsymbol{\beta}_2}$.

If $\boldsymbol{\alpha}_2 = \mathbf{0}$, we have $\widehat{\mathbf{A}}\mathbf{A}_{12} = \mathbf{0}$. We remark that $\widehat{\mathbf{A}}$ has size $(n-r)\times(n-r)$, while $\mathbf{A}_{12}$ is $(n-r)\times r$, so the system of equations corresponding to $\widehat{\mathbf{A}}\mathbf{A}_{12} = \mathbf{0}$ is underdetermined if $r < \frac{n}{2}$, in which case we can find an alternative set of solutions:

$$\begin{cases} \widehat{\boldsymbol{\beta}} = (\mathbf{1} - \widehat{\mathbf{A}}\mathbf{A}_{11})(\boldsymbol{\beta}_1^\top)^+ \\ \widehat{\boldsymbol{\alpha}} = -(\mathbf{R} - \widehat{\mathbf{A}}^\top\mathbf{R}\mathbf{A}_{11})(\boldsymbol{\alpha}_1^\top)^+ \\ \widehat{\mathbf{A}}\mathbf{A}_{12} = \mathbf{0} \end{cases} \tag{33}$$

with $\widehat{\mathbf{A}} \neq \mathbf{0}$. On the other hand, if $r \geq \frac{n}{2}$, *i.e.* if the multiplicity of the singular number σ_k is more than half the size of the original WFA, the system might not have any solution unless $\widehat{\mathbf{A}} = \mathbf{0}$ (or unless $\mathbf{A}_{12}$ was zero to begin with). In this setting, the method proposed returns $\widehat{\mathbf{A}} = \mathbf{0}$. An alternative in this case is to search for an approximation of size $k-1$ or $k+1$, so that $r < \frac{n}{2}$, and the system in Equation 33 is underdetermined. ◀

3.3.3 Extraction of the Rational Component

The function $\psi(z) = \widehat{\boldsymbol{\alpha}}^\top(z\mathbf{1} - \widehat{\mathbf{A}})^{-1}\widehat{\boldsymbol{\beta}} + C$ found in Theorem 24 corresponds to the solution of Theorem 18. To find the solution to the approximation problem we only need to "isolate" the function $g(z) \in \mathcal{R}_k$, *i.e.* the *rational component*. To do this, we study the position of the poles of $\psi(z)$, since the poles of a strictly proper rational function lie in the unit disc (Theorem 14). As noted before, we parametrized $\psi(z)$ so that its poles correspond to the eigenvalues of $\widehat{A}$. After a change of basis (detailed in Paragraph 3.3.3), we can rewrite $\widehat{\mathbf{A}}$ in block-diagonal form:

$$\widehat{\mathbf{A}} = \begin{pmatrix} \widehat{\mathbf{A}}_+ & \mathbf{0} \\ \mathbf{0} & \widehat{\mathbf{A}}_- \end{pmatrix} \tag{34}$$

where the modulus of the eigenvalues of $\widehat{\mathbf{A}}_+$ (resp. $\widehat{\mathbf{A}}_-$) is smaller (resp. greater) than one. We apply the same change of coordinates on $\widehat{\boldsymbol{\alpha}}$ and $\widehat{\boldsymbol{\beta}}$.

To conclude the study of the eigenvalues of $\widehat{\mathbf{A}}$, we need the following auxiliary result from Ostrowski [33]. A proof of this theorem can be found in [42].

▶ **Theorem 25** ([33]). *Let $|\Sigma| = 1$, and let $\mathbf{P}$ be a solution to the fixed point equation $X - \mathbf{A}X\mathbf{A}^\top = \boldsymbol{\beta}\boldsymbol{\beta}^\top$ for the WFA $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$. If A is reachable, then:*

- *The number of eigenvalues λ of $\mathbf{A}$ such that $|\lambda| < 1$ is equal to the number of positive eigenvalues of $\mathbf{P}$.*
- *The number of eigenvalues λ of $\mathbf{A}$ such that $|\lambda| > 1$ is equal to the number of negative eigenvalues of $\mathbf{P}$.*

We can finally find the rational component of the function $\psi(z)$, *i.e.* the function $g(z)$ from Corollary 19 necessary to solve that approximate minimization problem.

▶ **Theorem 26.** *Let $\widehat{\mathbf{A}}_+, \widehat{\boldsymbol{\alpha}}_+, \widehat{\boldsymbol{\beta}}_+$ be as in Theorem 24. The rational component of $\psi(z)$ is the function $g(z) = \widehat{\boldsymbol{\alpha}}_+^\top (z\mathbf{1} - \widehat{\mathbf{A}}_+)^{-1} \widehat{\boldsymbol{\beta}}_+$.*

Proof. Clearly $\psi(z) = g(z) + l(z)$, with $l(z) = \widehat{\boldsymbol{\alpha}}_-^\top (z\mathbf{1} - \widehat{\mathbf{A}}_-)^{-1} \widehat{\boldsymbol{\beta}}_-$, $l \in \mathcal{H}^\infty$. To conclude the proof we need to show that $g(z)$ has k poles inside the unit disc, and therefore has rank k. We do this by studying the position of the eigenvalues of $\widehat{\mathbf{A}}_+$.

Since $\widehat{A}$ is reachable (follows from the minimality of E), we can use Theorem 25 and solve the problem by directly examining the eigenvalues of $-\boldsymbol{\Sigma}\mathbf{R}$. From the proof of Theorem 24 we have $-\boldsymbol{\Sigma}\mathbf{R} = \boldsymbol{\Sigma}(\boldsymbol{\Sigma}^2 - \sigma_k^2 \mathbf{1})$, where $\boldsymbol{\Sigma}$ is the diagonal matrix having as elements the singular numbers of H different from σ_k. It follows that $-\boldsymbol{\Sigma}\mathbf{R}$ has only k strictly positive eigenvalues, and $\widehat{\mathbf{A}}$ has k eigenvalues with modulus smaller than 1. Thus, $\widehat{\mathbf{A}}_+$ has k eigenvalues, corresponding to the poles of $g(z)$. ◀

Block Diagonalization

In this paragraph we detail the technical steps necessary to rewrite $\widehat{\mathbf{A}}$ in block-diagonal form. The problem of computing the Jordan form of a matrix is ill-conditioned, hence it is not suitable for our algorithmic purposes [40]. Instead, we compute the Schur decomposition, *i.e.* we find an orthogonal matrix $\mathbf{U}$ such that $\mathbf{U}^\top \widehat{\mathbf{A}} \mathbf{U}$ is upper triangular, with the eigenvalues of $\widehat{\mathbf{A}}$ on the diagonal. We obtain:

$$\mathbf{T} = \mathbf{U}^\top \widehat{\mathbf{A}} \mathbf{U} = \begin{pmatrix} \widehat{\mathbf{A}}_+ & \widehat{\mathbf{A}}_{12} \\ \mathbf{0} & \widehat{\mathbf{A}}_- \end{pmatrix} \tag{35}$$

where the eigenvalues are arranged in increasing order of modulus, and the modulus of those in $\widehat{\mathbf{A}}_+$ (resp. $\widehat{\mathbf{A}}_-$) is smaller (resp. greater) than one. To transform this upper triangular matrix into a block-diagonal one, we use the following result.

▶ **Theorem 27** ([38]). *The matrix $\mathbf{X}$ is a solution of the equation $\widehat{\mathbf{A}}_+\mathbf{X} - \mathbf{X}\widehat{\mathbf{A}}_- + \widehat{\mathbf{A}}_{12} = \mathbf{0}$ if and only if $\mathbf{M} = \begin{pmatrix} \mathbf{1} & \mathbf{X} \\ \mathbf{0} & \mathbf{1} \end{pmatrix}$ and $\mathbf{M}^{-1} = \begin{pmatrix} \mathbf{1} & -\mathbf{X} \\ \mathbf{0} & \mathbf{1} \end{pmatrix}$ satisfy $\mathbf{M}^{-1}\mathbf{T}\mathbf{M} = \begin{pmatrix} \widehat{\mathbf{A}}_+ & \mathbf{0} \\ \mathbf{0} & \widehat{\mathbf{A}}_- \end{pmatrix}$, where $\mathbf{T}$ is the matrix defined in Equation 35.*

Setting $\boldsymbol{\Gamma} = \begin{pmatrix} \mathbf{1}_k & \mathbf{0} \end{pmatrix}$ we can now derive the rational component of the WFA:

$$\widehat{\mathbf{A}}_+ = \boldsymbol{\Gamma}\mathbf{M}^{-1}\mathbf{U}^\top \widehat{\mathbf{A}} \mathbf{U}\mathbf{M}\boldsymbol{\Gamma}^\top, \quad \widehat{\boldsymbol{\alpha}}_+ = \boldsymbol{\Gamma}\mathbf{M}^\top \mathbf{U}^\top \widehat{\boldsymbol{\alpha}}, \quad \widehat{\boldsymbol{\beta}}_+ = \boldsymbol{\Gamma}\mathbf{M}^{-1}\mathbf{U}^\top \widehat{\boldsymbol{\beta}}. \tag{36}$$

3.3.4 Solution to the Approximation Problem

In the previous sections, we have derived the rational function $g(z)$ corresponding to the symbol of G, the operator that solves Theorem 17. To find the solution to the approximation problem we only need to find the parameters of $\widehat{A}_k$, the optimal approximating WFA. These are directly revealed by the expression of $g(z)$, thanks to the way we parametrized the functions.

▶ **Theorem 28.** *Let $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$ be a minimal WFA with n states over a one-letter alphabet. Let A be in its SVA form. The optimal spectral-norm approximation of rank k is given by the WFA $\widehat{A}_k = \langle \widehat{\boldsymbol{\alpha}}_+, \widehat{\mathbf{A}}_+, \widehat{\boldsymbol{\beta}}_+ \rangle$.*

Proof. From Corollary 19 we know that $g(z)$ is the rational function associated with the Hankel matrix of the best approximation. Given the correspondence between the Fourier coefficients of $g(z)$ and the entries of the matrix (Remark 16), we have:

$$g(z) = \widehat{\boldsymbol{\alpha}}_+^\top (z\mathbf{1} - \widehat{\mathbf{A}}_+)^{-1} \widehat{\boldsymbol{\beta}}_+ = \sum_{k \geq 0} \widehat{\boldsymbol{\alpha}}_+^\top \widehat{\mathbf{A}}_+^k \widehat{\boldsymbol{\beta}}_+ z^{-k-1} = \sum_{k \geq 0} \bar{f}(k) z^{-k-1} \tag{37}$$

where $\bar{f} : \Sigma^* \to \mathbb{R}$ is the function computed by $\widehat{A}_k$, and $\widehat{\boldsymbol{\alpha}}_+, \widehat{\mathbf{A}}_+, \widehat{\boldsymbol{\beta}}_+$ are the parameters. ◀

3.4 Error Analysis

The theoretical foundations of AAK theory guarantee that the construction detailed in Section 3.3 produces the rank k optimal spectral-norm approximation of a WFA satisfying our assumptions, and the singular number σ_k provides the exact error.

Similarly to the case of SVA truncation [12], due to the ordering of the singular numbers, the error decreases when k increases, meaning that allowing $\widehat{A}_k$ to have more states guarantees a better approximation of A. We remark that, while the solution we propose is optimal in the spectral norm, the same is not necessarily true in other norms. Nonetheless, we have the following bound between ℓ^2-norm and spectral-norm.

▶ **Theorem 29.** *Let A be a minimal WFA computing $f : \Sigma^* \to \mathbb{R}$, with matrix $\mathbf{H}$. Let $\widehat{A}_k$ be its optimal spectral-norm approximation, computing $g : \Sigma^* \to \mathbb{R}$, with matrix $\mathbf{G}$. Then:*

$$\|f - g\|_{\ell^2} \leq \|\mathbf{H} - \mathbf{G}\| = \sigma_k. \tag{38}$$

Proof. Let $\mathbf{e}_0 = \begin{pmatrix} 1 & 0 & \cdots \end{pmatrix}^\top$, $f : \Sigma^* \to \mathbb{R}$, $g : \Sigma^* \to \mathbb{R}$ with Hankel matrices $\mathbf{H}$ and $\mathbf{G}$, respectively. We have:

$$\|f-g\|_{\ell^2} = \left(\sum_{n=0}^{\infty} |f_n - g_n|^2 \right)^{1/2} = \|(\mathbf{H}-\mathbf{G})\mathbf{e}_0\|_{\ell^2} \leq \sup_{\|\mathbf{x}\|_{\ell^2}=1} \|(\mathbf{H}-\mathbf{G})\mathbf{x}\|_{\ell^2} = \|\mathbf{H}-\mathbf{G}\| = \sigma_k$$

where the second equation follows by definition and by observing that matrix difference is computed entry-wise. ◀

4 Algorithm

In this section we describe the algorithm for spectral-norm approximate minimization. The algorithm takes as input a target number of states $k < n$, a minimal WFA A with $\rho(\mathbf{A}) < 1$, $\boldsymbol{\alpha}_2 \neq 0$, n states and in SVA form, and its Gramian $\mathbf{P}$. Note that, in the case of $\boldsymbol{\alpha}_2 = 0$, it is

Algorithm 1 `AAKapproximation`.

input : A minimal WFA A, with $\boldsymbol{\alpha}_2 \neq 0$, n states and in SVA form, its Gramian $\mathbf{P}$, a target number of states $k < n$
output : A WFA $\widehat{A}_k$ with k states

Let $\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \mathbf{A}_{11}, \mathbf{A}_{12}, \mathbf{A}_{22}, \boldsymbol{\Sigma}$ be the blocks defined in Eq. 24
Let $(\boldsymbol{\alpha}_2^\top)^+ = \frac{\boldsymbol{\alpha}_2}{\boldsymbol{\alpha}_2^\top \boldsymbol{\alpha}_2}$, $(\boldsymbol{\beta}_2^\top)^+ = \frac{\boldsymbol{\beta}_2}{\boldsymbol{\beta}_2^\top \boldsymbol{\beta}_2}$
Let $\mathbf{R} = \sigma_k^2 \mathbf{1} - \boldsymbol{\Sigma}^2$
Let $\widehat{\mathbf{A}} = (\mathbf{A}_{11} - \mathbf{A}_{12}(\boldsymbol{\beta}_2^\top)^+ \boldsymbol{\beta}_1^\top)^{-1}$
Let $\widehat{\boldsymbol{\alpha}} = \widehat{\mathbf{A}}^\top \mathbf{R} \mathbf{A}_{12} (\boldsymbol{\alpha}_2^\top)^+$
Let $\widehat{\boldsymbol{\beta}} = -\widehat{\mathbf{A}} \mathbf{A}_{12} (\boldsymbol{\beta}_2^\top)^+$
Let $\widehat{A} = \langle \widehat{\boldsymbol{\alpha}}, \widehat{\mathbf{A}}, \widehat{\boldsymbol{\beta}} \rangle$
Let $\widehat{A}_k \leftarrow$ `BlockDiagonalize`$(\widehat{A})$
return $\widehat{A}_k$

Algorithm 2 `BlockDiagonalize`.

input : A WFA $\widehat{A}$
output : A WFA $\widehat{A}_k$ wit $\rho < 1$

Compute the Schur decomposition of $\widehat{\mathbf{A}} = \mathbf{U}\mathbf{T}\mathbf{U}^\top$, where $|T_{11}| \leq |T_{22}| \leq \dots$
Solve $\widehat{\mathbf{A}}_{11}\mathbf{X} - \mathbf{X}\widehat{\mathbf{A}}_{22} + \widehat{\mathbf{A}}_{12} = \mathbf{0}$ for $\mathbf{X}$
Let $\mathbf{M} = \begin{pmatrix} \mathbf{1} & \mathbf{X} \\ \mathbf{0} & \mathbf{1} \end{pmatrix}$ and $\mathbf{M}^{-1} = \begin{pmatrix} \mathbf{1} & -\mathbf{X} \\ \mathbf{0} & \mathbf{1} \end{pmatrix}$
Let $\boldsymbol{\Gamma} = \begin{pmatrix} \mathbf{1}_k & \mathbf{0} \end{pmatrix}$
Let $\widehat{\mathbf{A}}_+ = \boldsymbol{\Gamma}\mathbf{M}^{-1}\mathbf{U}^\top \widehat{\mathbf{A}} \mathbf{U} \mathbf{M} \boldsymbol{\Gamma}^\top$
Let $\widehat{\boldsymbol{\alpha}}_+ = \boldsymbol{\Gamma}\mathbf{M}^\top \mathbf{U}^\top \widehat{\boldsymbol{\alpha}}$
Let $\widehat{\boldsymbol{\beta}}_+ = \boldsymbol{\Gamma}\mathbf{M}^{-1}\mathbf{U}^\top \widehat{\boldsymbol{\beta}}$
Let $\widehat{A}_k = \langle \widehat{\boldsymbol{\alpha}}_+, \widehat{\mathbf{A}}_+, \widehat{\boldsymbol{\beta}}_+ \rangle$
return $\widehat{A}_k$

enough to substitute the Steps $4, 5, 6$ with the analogous from Equation 26. The constraints on the WFA A to be minimal and in SVA form are non essential. In fact a WFA with n states can be minimized in time $O(n^3)$ [15], and the SVA computed in $O(n^3)$ [12].

Using the results of Theorem 24, we outline in Algorithm 1, `AAKapproximation`, the steps necessary to extract the best spectral-norm approximation of a WFA.

The algorithm involves a call to Algorithm 2, `BlockDiagonalize`. This corresponds to the steps, outlined in Paragraph 3.3.3, necessary to derive the WFA $\widehat{A}_k$ corresponding to the rational function $g(z)$. We remark that Step 2 in `BlockDiagonalize` can be performed using the Bartels-Stewart algorithm [14].

To compute the computational cost we recall the following facts [40]:

- The product of two $n \times n$ matrices can be computed in time $O(n^3)$ using a standard iterative algorithm, but can be reduced to $O(n^\omega)$ with $\omega < 2.4$.
- The inversion of a $n \times n$ matrix can be computed in time $O(n^3)$ using Gauss-Jordan elimination, but can be reduced to $O(n^\omega)$ with $\omega < 2.4$.
- The computation of the Schur decomposition of a $n \times n$ matrix can be done with a two-step algorithm, where each step takes $O(n^3)$, using the Hessenberg form of the matrix.
- The Bartels-Stewart algorithm applied to upper triangular matrices to find a matrix $m \times n$ takes $O(mn^2 + nm^2)$.

The running time of `BlockDiagonalize` with input a WFA $\widehat{A}$ with $(n-r)$ states is thus in $O((n-r)^3)$, where r is the multiplicity of the singular value considered. The running time of `AAKapproximation` for an input WFA $\widehat{A}$ with n states is in $O((n-r)^3)$.

5 Possible Extensions

5.1 Relaxing the Spectral Radius Assumption

It is possible to extend part of our method to WFAs over a one-letter alphabet with $\rho(\mathbf{A}) \neq 1$, but the approximation recovered is not optimal in the spectral norm.

Let $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$, with $\rho(\mathbf{A}) \neq 1$, be a WFA with n states that we want to minimize. The idea is to block-diagonalize $\mathbf{A}$ like we did in Section 3.3.3, and tackle each component separately. The case of $A_+ = \langle \boldsymbol{\alpha}_+, \mathbf{A}_+, \boldsymbol{\beta}_+ \rangle$, the component having $\rho(\mathbf{A}) < 1$, can be dealt with in the way presented in the previous sections. This means that we can find an optimal spectral-norm approximation of the desired size for A_+. Now we can consider the second component, $A_- = \langle \boldsymbol{\alpha}_-, \mathbf{A}_-, \boldsymbol{\beta}_- \rangle$. The key idea is to apply the transformation $z^{j-1} \mapsto z^{-j}$ for $j \geq 1$ to the function $\phi''(z)$ associated to A_-. Then, the function

$$\phi''(z^{-1}) = \sum_{k \geq 0} \boldsymbol{\alpha}_-^\top \mathbf{A}_-^k z^k \boldsymbol{\beta}_- = \boldsymbol{\alpha}_-^\top (\mathbf{1} - z\mathbf{A}_-)^{-1} \boldsymbol{\beta}_- \tag{39}$$

is well defined, as the series converges for z with small enough modulus. Using this transformation we obtain a function with poles inside the unit disc and we can apply the method presented in the paper. An important choice to make is the size of the approximation of A_-, as it can influence the quality of the approximation. Analyzing the effects of this parameter on the approximation error constitutes an interesting direction for future work, both in the theoretical and experimental side. We refer the reader to the control theory literature [21], where some theoretical work has been done to study an analogous approach for continuous time systems and their approximation error.

5.2 Polynomial method

We remark that Equation 10 from Corollary 20 can be rewritten as

$$\psi(z) = \phi(z) - \frac{H\xi_k^+(z)}{\xi_k^+(z)}, \tag{40}$$

where $\xi_k^+(z)$ is the function in $\mathcal{H}^2$ associated to the vector $\boldsymbol{\xi}_k \in \mathrm{Ker}(\mathbf{H}^*\mathbf{H} - \sigma_k^2 \mathbf{1})$ (and $\psi(z)$ does not depend on the choice of the specific $\boldsymbol{\xi}_k$). There is an alternative way to find the best approximation, particularly useful when the objective is to approximate a finite-rank infinite Hankel matrix with another Hankel matrix, without necessarily extract a WFA. We can consider the adjoint operator H^* and its matrix $\mathbf{H}^*$. The singular numbers and singular vectors of H correspond to the eigenvalues and eigenvectors of $\mathbf{R} = (\mathbf{H}^*\mathbf{H})^{1/2}$. Hence, it is possible to compute σ_k and a corresponding singular vector $\boldsymbol{\xi}_k$. The function $\xi_k^+(z)$ is then obtained following Equation 2. Then, the Hankel matrix $\mathbf{G}$ that best approximates $\mathbf{H}$ is given by $\mathbf{G} = \mathbf{H} - \mathbf{M}$, where $\mathbf{M}$ is the Hankel matrix having $\frac{H\xi_k^+(z)}{\xi_k^+(z)}$ as symbol.

6 Related Work

The study of approximate minimization for WFAs is very recent, and only a few works have been published on the subject. In [11, 12] the authors present an approximate minimization technique using a canonical expression for WFAs, and provide bounds on the error in the

ℓ^2 norm. The result is supported by strong theoretical guarantees, but it is not optimal in any norm. An extension of this method to the case of Weighted Tree Automata can be found in [13]. A similar problem is addressed in [26], with less general results. In [27], the authors connect spectral learning to the approximate minimization problem of a small class of Hidden Markov models, bounding the error in terms of the total variation distance.

The control theory community has largely studied approximate minimization in the context of linear time-invariant systems [3]. A parallel with those results can be drown by noting that the impulse response of a discrete Single-Input-Single-Output SISO system can be parametrized as a WFA over a one-letter alphabet. In [21] Glover presents a state-space solution for the case of continuous Multi-Input-Multi-Output MIMO systems. His method led to a widespread application of these results, thanks to its computational and theoretical simplicity. This stems from the structure of the continuous Lyapunov equations. For discrete systems, though, the quadratic nature of the Lyapunov equations does not allow for a simple closed form formula for the state space solution [17]. Thus, most of the results for the discrete case work with a suboptimal version of the problem [6, 2, 24]. A solution for the SISO case can be found using a polynomial approach, but it does not provide an explicit representation of the state space nor it generalizes to the MIMO setting. The first to actually extend Glover results is Gu, who provides an elegant solution for the MIMO discrete problem [22]. Glover and Gu's solutions rely on building an *all-pass system*, equivalent to the WFA E in our case. Part of our contribution is the adaptation of some of the control theory tools to WFAs.

7 Conclusion

In this paper we applied the AAK theory for Hankel operators and complex functions to the framework of WFAs in order to construct the best possible approximation to an automaton given a bound on the size. We provide an algorithm to find the parameters of the best WFA approximation in the spectral norm, and bounds on the error. Our method applies to real WFAs $A = \langle \boldsymbol{\alpha}, \mathbf{A}, \boldsymbol{\beta} \rangle$, defined over a one-letter alphabet, with $\rho(\mathbf{A}) < 1$. While this setting is certainly restricted, we believe that this work constitutes a first fundamental step towards optimal approximation. Furthermore, the use of AAK techniques has proven to be very fruitful in related areas like control theory; we think that automata theory can also benefit from it. The use of such methods can help deepen the understanding of the behaviour of rational functions. This paper highlights and strengthens the interesting connections between functional analysis, automata theory and control theory, unifying tools from different domains in one formalism.

A compelling direction for future work is to extend our results to the multi-letter case. The work of Adamyan, Arov and Krein provides us with a powerful theory connecting sequences to the study of complex functions. We note that, unfortunately, this approach cannot be directly generalized to the multi-letter case because of the non-commutative nature of the monoid considered. Extending this work would require adapting standard harmonic analysis results to the non-abelian case. A recent line of work in functional analysis is centered around extending this theory to the case of non-commutative operators, and in [35] a non-commutative version of the AAK theorem is presented. However, those results are non-constructive, making this direction, already challenging, even harder to pursue.

Abstract

In this work, we revisit the problem of testing membership in regular languages, first studied by Alon et al. [1]. We develop a one-sided error property tester for regular languages under weighted edit distance that makes $\mathcal{O}(\varepsilon^{-1}\log(1/\varepsilon))$ non-adaptive queries, assuming that the language is described by an automaton of constant size. Moreover, we show a matching lower bound, essentially closing the problem for the edit distance. As an application, we improve the space bound of the current best streaming property testing algorithm for visibly pushdown languages from $\mathcal{O}(\varepsilon^{-4}\log^6 n)$ to $\mathcal{O}(\varepsilon^{-3}\log^5 n \log\log n)$, where n is the size of the input. Finally, we provide a $\bar{\Omega}(\max(\varepsilon^{-1}, \log n))$ lower bound on the memory necessary to test visibly pushdown languages in the streaming model, significantly narrowing the gap between the known bounds.

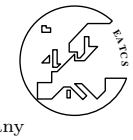
1 Introduction



A one-sided error ε-property tester for a language L is a randomised algorithm that accepts an input u of length n if $u \in L$ with probability one, and rejects if the distance from u to L is at least εn with probability $\geq 2/3$. In the property testing setting, we do not have access to the whole input u, but instead must take the decision by querying as few symbols of the input as possible. The number of queried symbols is called the query complexity of the tester.

The study of property testing of formal languages was initiated in the seminal paper of Alon et al. [1], who showed a property tester for regular languages as well as lower bounds for context-free languages. Property testing of regular languages has been also studied in [6, 17, 19, 20]. Apart from regular languages, there is a series of work that studied the question of testing membership in $\textsc{Dyck}(s)$, the language of well-parenthesized expressions with s types of parentheses [1, 4, 21]. When the distance allows sufficient modifications of the input, such as moves of arbitrarily large factors, it was shown that any context-free language is testable with a constant number of queries [3].

In this work, we revisit the problem of property testing of regular languages. Recall that the Hamming distance is the number of mismatches between two equal-length strings, and the edit distance between two strings is the smallest number of insertions, deletions, and substitutions required to convert one string into another. The weighted edit distance is a

generalisation of the edit distance for weighted words (see Section 2 for a definition). Fix a regular language specified by an automaton with m states and k connected components. The first property tester for regular languages was given by Alon et al. [1]. The tester of Alon et al. is for the Hamming distance, it queries $\mathcal{O}(k^2 m \cdot \varepsilon^{-1} \log^3(m/\varepsilon))$ symbols of the input, and its runtime is exponential in the size of the automaton that defines the regular language. Alon et al. [1] also showed a $\bar{\Omega}(1/\varepsilon)$ lower bound for such testers[1]. Magniez and De Rougemont [17] built upon [1] to show a property tester for regular languages under the edit distance with moves. The query complexity of their algorithm is $\mathcal{O}(m^3 \cdot \varepsilon^{-1} \log^2(m/\varepsilon))$ and its running time exponential. Later, Fischer et al. [3] improved the query complexity to remove the dependency on m. Ndione et al. [19, 20] continued this line of work with a goal of devising property testers that run in polynomial time, both for the Hamming distance and the edit distance. Their tester for the Hamming distance has query complexity $\mathcal{O}(k^2 m^4 \cdot \varepsilon^{-1} \log^3(km^4/\varepsilon))$ and runtime $\mathcal{O}(k^2 m^{10} \cdot \varepsilon^{-1} \log^3(km^4/\varepsilon))$. Unfortunately, their tester for the edit distance, which is of more interest to us, contains a fatal error in one of the key lemmas, which is why we do not give its complexities here[2]. Finally, François et al. [5, 6] gave a tester for regular languages under the weighted edit distance with query complexity $\mathcal{O}(m^3 \cdot \varepsilon^{-2})$ and $\mathcal{O}(km^5 \cdot \varepsilon^{-2})$ running time.

Table 1 Summary of property testing algorithms for regular languages, assuming that a regular language is described by an automaton on a constant-size alphabet Σ with m states and k strongly connected components.

	Queries	**Time**	**Distance**
Alon et al. [1]	$\mathcal{O}(k^2 m \cdot \varepsilon^{-1} \log^3(m/\varepsilon))$	$\mathcal{O}(2^{m^2} + \varepsilon^{-k})$	Hamming
Magniez et De Rougemont [17]	$\mathcal{O}(m^3 \cdot \varepsilon^{-1} \log^2(m/\varepsilon))$	$\mathcal{O}(2^m m^5 \cdot \varepsilon^{-1} \log^2(m/\varepsilon))$	edit w. moves
Fischer et al. [3]	$\mathcal{O}(\frac{\Sigma^{2/\varepsilon} \log \lvert\Sigma\rvert}{\varepsilon^4})$	$m^{\lvert\Sigma\rvert^{\mathcal{O}(1/\varepsilon)}}$	edit w. moves
Ndione et al. [19, 20]	$\mathcal{O}(k^2 m^4 \cdot \varepsilon^{-1} \log^3(km^4/\varepsilon))$	$\mathcal{O}(k^2 m^{10} \cdot \varepsilon^{-1} \log^3(km^4/\varepsilon))$	Hamming
François et al. [6]	$\mathcal{O}(m^3 \cdot \varepsilon^{-2})$	$\mathcal{O}(km^5 \cdot \varepsilon^{-2})$	weight. edit
This work	$\mathcal{O}(km \cdot \varepsilon^{-1} \log(m/\varepsilon))$	$\mathcal{O}(km^3 \cdot \varepsilon^{-1} \log(m/\varepsilon))$	weight. edit

Our main contribution is a tight bound on query complexity of property testing of regular languages under the weighted edit distance. First, we show a new property tester with query complexity $\mathcal{O}(km \cdot \varepsilon^{-1} \log(m/\varepsilon))$ and time complexity $\mathcal{O}(km^3 \cdot \varepsilon^{-1} \log(m/\varepsilon))$(Theorem 5). Essentially, our tester is very simple: it samples a set of short factors of the input string u, and checks whether the factors can be complemented to a word that belongs to the given regular language L. The analysis is much more involved. Our inspiration originates from the ideas from [5, 19, 20], which we extend in a non-trivial way to show a better (and correct) bound. In Theorem 15, we complement the upper bound with a matching lower bound. As the Hamming distance is always larger than the edit distance, the bound also holds for the Hamming distance, improving the lower bound by Alon et al. [1]. See Table 1 for a summary of previously known results and comparison with our work.

[1] We use the following asymptotic notation: For functions $f, g : \mathbb{N} \to \mathbb{R}_{\geq 0}$, $f(n) = \bar{\Omega}(g(n))$ holds if $f(n) \geq c \cdot g(n)$ for some $c > 0$ and infinitely many $n \in \mathbb{N}$.

[2] The error is in [19, Lemma 12], namely, the value l' chosen in the last two sentences of the proof does not necessarily exist (confirmed via personal communication with the authors).

As an almost straightforward application of our result, in Section 4 we plug our property tester into the algorithm of François et al. [5] to show an improved space bound for streaming property testing for the class of visibly pushdown languages (VPL) (that, in particular, contains regular languages and $\textsc{Dyck}(s)$). Informally, a streaming property tester for a language L is an algorithm that receives an input word u of length n as a stream, one symbol at a time, and must accept if $u \in L$ with probability one and reject if the distance from u to L is at least εn with probability at least $2/3$. Assuming that the automaton that specifies a VPL L is of constant size, the streaming property tester of François et al. [6] requires $\mathcal{O}(\varepsilon^{-4}\log^6 n)$ bits of space. Our result improves this bound to $\mathcal{O}(\varepsilon^{-3}\log^5 n \log\log n)$ (Corollary 22). François et al. [5] showed that for $\varepsilon = 0$, a streaming property tester for visibly pushdown languages must use $\Omega(n)$ bits, even when randomisation is allowed. As our final contribution, we show a space lower bound of $\tilde{\Omega}(\max(\varepsilon^{-1}, \log n))$ bits (Theorem 23), thus narrowing the gap between the best existing bounds by $\log^2 n/\log\log n$.

Apart from VPL, the problem of testing membership in formal languages in the streaming setting has been studied for $\textsc{Dyck}(s)$ [14, 16, 18], and for DLIN and $\mathsf{LL}(k)$ [2]. A variant of the streaming setting, called the sliding window model, where one must decide the membership for the n-length suffix of the stream after each symbol arrival, has been considered for regular languages [9, 10, 11, 12], VPL [8], and context-free languages [13].

2 Preliminaries

An alphabet Σ is a finite set the elements of which are called symbols. The length of a word u, denoted $|u|$, is the number of symbols in u. For $1 \le i \le j \le |u|$, we let $u[i]$ denote the i-th symbol in u, and $v = u[i,j]$ the word $u[i]\dots u[j]$, which we call a *factor* of u. A factor of length l is called an *l-factor*. If $i = 1$, then v is called a *prefix* of u, and if $j = n$, a *suffix*. We let Σ^n denote the set of all n-length words over Σ and $\Sigma^* = \bigcup_{n\in\mathbb{N}} \Sigma^n \cup \epsilon$, where ϵ is the empty word. Any subset of Σ^* is called a *language*.

The *edit distance* between two words u and v, $\mathsf{ed}(u,v)$, is defined as the minimum number of deletions, insertions, and substitutions of symbols required to transform u into v. The *indel distance* between two words u, v, $\delta(u,v)$, is defined as the smallest number of insertions and deletions needed to convert u into v.

We say that a word $u \in \Sigma^*$ is *weighted* if each position i of u has a non-zero integer weight that we denote by $\mathsf{weight}(u[i])$. We define the weight of u, $\mathsf{weight}(u)$, as the sum of the weights of its positions. The *weighted edit distance* between a weighted word u and a (non-weighted) word v, $\mathsf{wed}(u,v)$, is defined as the minimum cost of deletions and insertions of symbols that we must apply to u to obtain v. The cost of deletion or insertion of a symbol is equal to its weight. (Substitutions are not allowed.) For example, if $u = abb$ and the weights of the positions are $3, 2, 2$, and $v = abc$ then $\mathsf{wed}(u,v) = 3$: we delete $u[2] = b$ with weight 2, and insert c with weight 1.

▶ **Observation 1.** *Consider two words u, v, and assume that the weight of any position in u equals 1. We then have $\mathsf{ed}(u,v) \le \mathsf{wed}(u,v) \le 2\mathsf{ed}(u,v)$.*

▶ **Definition 2.** *The* weight distribution *over a word $u \in \Sigma^n$ is the probability distribution over $\{1,\dots n\}$ where the probability to sample a position i is equal to $\mathsf{weight}(u[i])/\mathsf{weight}(u)$.*

▶ **Definition 3.** *A* non-deterministic finite automaton (NFA) *is defined as a tuple $A = (\Sigma, Q, Q_{in}, Q_f, \Delta)$, where:*

- *Σ is a finite input alphabet,*
- *Q is a finite set of states $Q_{in} \subseteq Q$ of initial states, and $Q_f \subseteq Q$ of final states,*
- *$\Delta \subseteq Q \times \Sigma \times Q$ is the transition relation. For $(p,a,q) \in \Delta$, we write $p \xrightarrow{a}_\Delta q$.*

For a word $u = u[1] \dots u[n]$ and states $p, q \in Q$, we write $p \xrightarrow{u}_\Delta q$ if there exists a sequence of states $p = q_0, \dots, q_n = q$ such that $\forall i = 1, \dots, n \;\; q_{i-1} \xrightarrow{u[i]}_\Delta q_i$. The sequence $q_0, \dots, q_n$ is called a *run* labelled by u. A word u is recognized by A if there exists $(q_{in}, q_f) \in Q_{in} \times Q_f$ such that $q_{in} \xrightarrow{u}_\Delta q_f$. We write $L(A)$ for the set of all words recognized by A. A language $L \subseteq \Sigma^*$ is *regular* if there exists an NFA A such that $L = L(A)$.

Property testing model

For a given distance function d on Σ^*, we define the distance from a word $u \in \Sigma^*$ to L, $d(u, L) = \min_{w \in L} d(u, w)$. If a word u is weighted, we say that it is *ε-far* from L if $d(u, L) \geq \varepsilon \cdot \mathsf{weight}(u)$. In the unweighted case, if $d(u, L) \geq \varepsilon \cdot |u|$.

In the property testing model, we assume that we can query any symbol of the input according to the weight distribution over it in constant time. In the unweighted case, this is equivalent to constant-time random access.

▶ **Definition 4** (Property tester). *An ε-*property tester *for a language L for a distance d is a randomised algorithm that:*

- *accepts if $u \in L$ with probability 1,*
- *rejects with probability at least $2/3$ if u is ε-far from L under d,*
- *accepts or rejects otherwise.*

In addition to standard complexity measures, we are interested in so-called *query complexity* which is defined to be the number of symbols of u that a tester queries. The time complexity is defined as usual, and the space complexity of a tester is defined as space used beyond the space required to store the input.

Property testers can be *non-adaptive* (the symbols to query are selected offline) and *adaptive* (the position of the i-th queried symbol depends on the first $i - 1$ queried symbols). In this work, we focus on non-adaptive testers.

3 Property testing of regular languages

In this section, we show an improved upper bound and a matching lower bound on the query complexity of property testing of regular languages under weighted edit distance.

3.1 Upper bound

We start by showing the following theorem:

▶ **Theorem 5.** *Let $A = (\Sigma, Q, Q_{in}, Q_f, \Delta)$ be an NFA, $m = |Q|$, and k be the number of strongly connected components in the underlying graph. There exists an ε-property tester for membership of a weighted word u in the regular language $L = L(A)$ under the weighted edit distance. The query complexity of the tester is $\mathcal{O}(km \cdot \varepsilon^{-1} \log(m/\varepsilon))$ and the time complexity is $\mathcal{O}(km^3 \cdot \varepsilon^{-1} \log(m/\varepsilon))$, assuming constant-size alphabet.*

3.1.1 Combinatorics of blocking factors and fragments

▶ **Definition 6** (Blocking factor). *Consider a strongly connected component C of A. We say that a factor v of a word u is a C-*blocking *factor if for any two states p, q of C we have $p \overset{v}{\nrightarrow}_\Delta q$.*

We say that a sequence of components $P = (C_1, \dots, C_j)$ is a *component path* of A if for any $1 \le i \le j-1$ there is $p \in C_i, q \in C_{i+1}$ such that $p \xrightarrow{a}_\Delta q$ for some symbol $a \in \Sigma$. Note that $j \le k \le m$.

▶ **Definition 7** (P-partition, β-saturation). *Let $u \in \Sigma^*, \beta > 0$ and $P = (C_1, \dots, C_j)$ be a component path. We build the* P-partition *of u recursively. We start with $i = 1$. Let $u = vxu'$, where $v \in \Sigma^*$, $x \in \Sigma$, and vx is the shortest C_i-blocking prefix of u. If $\mathsf{weight}(x) > \beta \cdot \mathsf{weight}(u)$, we say that x is* heavy*, and otherwise we call it* light*. Consider three cases:*

- *If x is not C_i-blocking, add vx to the set $B_i(P)$;*
- *If x is C_i-blocking and heavy, add it to the set $H_i(P)$;*
- *If x is C_i-blocking and light, add it to the set $L_i(P)$.*

Recurse for $u = u'$ and the value of i computed as follows:

$$i = \begin{cases} \min_{i'}(\{i' \mid i' > i, \exists p \in C_{i'-1} \cup C_{i'}, q \in C_{i'}, p \xrightarrow{x}_\Delta q\} \cup \{j+1\}), & \text{if } x \text{ is heavy;} \\ i+1, & \text{if } x \text{ is light and } \big(|B_i(P)| \ge \beta \cdot \mathsf{weight}(u) \text{ or } \mathsf{weight}(L_i(P)) \ge \beta \cdot \mathsf{weight}(u)\big); \\ i, & \text{otherwise.} \end{cases}$$

Stop if $i = j+1$, if u is empty, or if there is no C_i-blocking factor in u. If we reach $i = j+1$, we say that u β-saturates *P. The sets $B_i(P), H_i(P), L_i(P), i \le j$ form the P-partition of u.*

We show that if a word is ε-far from L, then it β-saturates P for $\beta = \varepsilon/(6m)$. The proof is by contradiction: we show that if a word does not β-saturate P, then we can obtain a word in L by deleting the factors in $\cup_i L_i(P)$ and then inserting a small number of factors of length and weight at most m.

▶ **Lemma 8.** *Let $u \in \Sigma^*$ be such that $\mathsf{weight}(u) \ge 6km/\varepsilon$ and $P = (C_1, \dots, C_j)$ be a component path of A. Let $\beta = \varepsilon/(6m)$. If u is ε-far from L, then u β-saturates P.*

Proof. By contrapositive: assume that u does not β-saturate P, in other words, the algorithm that built the P-partition of u reached the end of u but $i \ne j+1$. We will show that there is a word $u' \in L$ such that the weighted edit distance between u and u' is at most $\varepsilon \cdot \mathsf{weight}(u)$. We first delete all the elements in $L_i(P)$, for all i. Note that $\mathsf{weight}(L_i(P)) \le 2\beta \cdot \mathsf{weight}(u)$ for any i, so the total weight of the deleted factors is at most $2k\beta \cdot \mathsf{weight}(u) = \varepsilon \cdot \mathsf{weight}(u)k/(3m)$. Next, we edit the elements of $B_i(P)$ as follows: let $v \in B_i(P)$, $v = v'x$ where $v' \in \Sigma^*, x \in \Sigma$. Since v is a minimal blocking prefix, v' is not C_i-blocking, and there exist $p, q \in C_i$ such that $p \xrightarrow{v'}_\Delta q$. Similarly, as $v \in B_i(P)$, x is not C_i-blocking and labels a run within C_i, from p' to q'. Therefore, we can edit v into $v'' = v'wx$, where $q \xrightarrow{w}_\Delta p'$ and $|w| \le |C_i|$. Since C_i is strongly connected, we can similarly insert factors of length at most $|C_i|$ between the elements of $B_i(P)$ to obtain a word w_i that labels a run within C_i. Note that we can choose the weights of the inserted symbols arbitrarily, and we put them equal to one. Hence, the cost of this step is at most $|B_i(P)| \cdot |C_i|$ for each i. Finally, we insert factors of length at most m in between the words w_i and the heavy blocking 1-factors in $H_i(P)$, as well as before and after the last factor, so that the resulting word u' belongs to L. Again, we put the weights of the symbols of the inserted factors equal to one, and hence the cost of this step is at most $2km$. We have the following bound on the weighted edit distance of u to L:

$$\begin{aligned} d(u, L) \le d(u, u') &\le \varepsilon \cdot \mathsf{weight}(u)k/(3m) + 2km + \sum_{i=1}^{j} 2 \cdot |B_i(P)| \cdot |C_i| \\ &\le \varepsilon(\mathsf{weight}(u)/3 + \mathsf{weight}(u)k/(3m)) + 2km \le \varepsilon \cdot \mathsf{weight}(u) \end{aligned}$$

A contradiction. ◀

Suppose that u β-saturates a component path $P = (C_1, \dots C_j)$, in other words, the algorithm that built the P-partition reached $i = j + 1$. For every $1 \leq i \leq j$, let $S_i(P) = B_i(P) \cup L_i(P) \cup H_i(P)$. We define indices $0 = a_0 \leq \cdots \leq a_j$ so that for each i either $S_i(P)$ is empty (because C_i was skipped by the algorithm of Definition 7 due to a heavy factor), or all the factors in it are the factors of $u[a_{i-1} + 1, a_i]$. For $i = 0$, we let $a_0 = 0$, and then for all i, $a_i = a_{i-1}$ if $S_i(P) = \emptyset$ and the largest index of a symbol in $S_i(P)$ otherwise. If $S_i(P) \neq \emptyset$, then by Definition 7, one of the following holds:

- The total weight of C_i-blocking 1-factors in $H_i(P) \cup L_i(P)$ is at least $\beta \cdot \mathsf{weight}(u)$;
- $|B_i(P)| \geq \beta \cdot \mathsf{weight}(u)$.

Blocking factors are witnesses of the fact that $u \notin L$. If there are many short blocking factors, as in the first case, we can sample them with a few queries. However, in the second case, the factors can be arbitrarily long. To develop an efficient tester, we must give a more accurate bound.

▶ **Corollary 9.** *Let $\gamma = \lceil 2/\beta \rceil = \lceil 12m/\varepsilon \rceil$. If $|B_i(P)| \geq \beta \cdot \mathsf{weight}(u)$, then $B_i(P)$ contains at least $\mathsf{weight}(u)/\gamma$ disjoint C_i-blocking factors of length at most γ.*

Proof. Since the factors in $B_i(P)$ are disjoint and their total weight is bounded by $\mathsf{weight}(u)$, at most $\mathsf{weight}(u)/\gamma$ of them can have weight (and length) larger than γ. Consequently, $B_i(P)$ contains at least $\beta \cdot \mathsf{weight}(u) - \mathsf{weight}(u)/\gamma \geq \mathsf{weight}(u)/\gamma$ factors of length $\leq \gamma$. ◀

Let us now introduce the notion of a fragment that will allow us to test the sampled factors efficiently.

▶ **Definition 10** (Fragment)**.** *Given a set of factors $u[i_r, j_r]$, $1 \leq r \leq t$, consider the decomposition of the set $S = \bigcup_{1 \leq r \leq t} [i_r, j_r]$ into maximal disjoint intervals, that is, $S = \sqcup_{1 \leq r \leq t'} [i'_r, j'_r]$, where $i'_1 \leq j'_1 < i'_2 \leq j'_2 < \dots i'_{t'} \leq j'_{t'}$. The* fragment F *formed by the factors is the word $F = * \, u[i'_1, j'_1] * u[i'_2, j'_2] * \cdots * u[i'_{t'}, j'_{t'}] \, *$, where "$*$" is a special symbol not in Σ. A word v* contains F as a fragment *if there exist words $w_1, \dots w_{t'+1} \in \Sigma^*$ such that by replacing the i-th symbol "$*$" with w_i in F, we obtain v.*

For example, for $u = abbabbab$ the fragment formed by factors $u[1, 2]$, $u[2, 3]$, $u[4, 4]$, and $u[6, 8]$, is $F = * \, u[1, 4] * u[6, 8] * = * \, abba * bab *$. The word $cabbadebabcde$ contains F.

▶ **Definition 11** (Blocking fragment)**.** *A fragment F is* A-blocking *if none of the words that contain F as a fragment belongs to $L(A)$.*

The following lemma relates C_i-blocking factors and A-blocking fragments and is crucial for correctness of our tester. To show it, we prove by induction that any run that starts in C_1 and is labelled by the prefix of the fragment containing the factors in $\cup_{1 \leq i \leq t} H_i(P)$ and at least one C_i-blocking factor from each $S_i \neq \emptyset$, $1 \leq i \leq t$, must end at a state in $\cup_{i \geq t+1} C_i$.

▶ **Lemma 12.** *If for any component path $P = (C_1, \dots, C_j)$ and i, the fragment F contains all factors in $\bigcup_i H_i(P)$, and a C_i-blocking factor from $u[a_{i-1} + 1, a_i]$ for each i such that $H_i(P) = \emptyset$ and $L_i(P) \cup B_i(P) \neq \emptyset$, then F is A-blocking.*

Proof. By contradiction, suppose that there is a word $w \in L(A)$ that contains F as a fragment. Since $w \in A$, there is a run in A labelled by w that goes through the connected components $C_1, \dots, C_j$. Consider the path $P = (C_1, \dots, C_j)$ and let $0 \leq a_0 \leq a_1 \cdots \leq a_j$ be the indices such that for each i either $S_i(P)$ is empty (because C_i was skipped by the algorithm of Definition 7 due to a heavy factor), or all the factors in it are the factors of $u[a_{i-1} + 1, a_i]$. Let w_t be the shortest prefix of w that contains the blocking factors from each

of the non-empty intervals $u[a_{i-1}+1, a_i]$, $1 \leq i \leq t$, as well as all factors in $\bigcup_{1\leq i\leq t} H_i(P)$. We show by induction on t that every run that starts at a state in C_1 and is labelled by w_t ends after C_t, i.e. in a state of $\bigcup_{t'>t} C_{t'}$.

As w_1 contains a C_1-blocking factor, any run labelled by w_1 that starts in C_1 exits C_1 and therefore ends after C_1. Suppose that the induction hypothesis holds for some $t' < j$. We show that there is no run labelled by $w_{t'+1}$ from C_1 to $C_{t'+1}$. There are two possibilities. First, $C_{t'+1}$ was skipped because of a heavy C_t-blocking factor, for some $t \leq t'$, which is therefore included in $w_{t'+1}$, and ends after $C_{t'+1}$. The other possibility is that $w_{t'+1}$ is $w_{t'}$ with an additional $C_{t'+1}$-blocking factor. If any run labelled by $w_{t'}$ ends after $C_{t'+1}$, so does the run labelled by $w_{t'+1}$, and we are done. If some of these runs end in $C_{t'+1}$, the $C_{t'+1}$-blocking factor that appears in $w_{t'+1}$ but not in $w_{t'}$ ensures that the run labelled by $w_{t'+1}$ ends after $C_{t'+1}$.

Adding symbols to w_j to obtain w, we get that there is no run labelled by w that starts in C_1 and ends in C_j, a contradiction. ◀

3.1.2 Tester

Our tester is as stated in Algorithm 1. We define the *l-factor sampling* over u as the distribution over factors v of u that have length at most l, where a position i is selected according to the weight distribution over u, and $v = u[i, \min(i+l-1, |u|)]$.

Algorithm 1 ε-property tester for regular languages.

$\beta \leftarrow \varepsilon/(6m)$, $\gamma \leftarrow 2/\beta$
if $\mathsf{weight}(u) \leq 6km/\varepsilon$ **then**
    Query all symbols of u and run the automaton A on it
    Reject if A rejects, else accept
else
    Query $\tau = \lceil 2\ln(9k \cdot 2^k)/\beta \rceil$ 1-factors of u
    for $t = 0$ to $T = \lceil \log(2\gamma) \rceil$ **do**
        $\ell_t \leftarrow 2^t, r_t \leftarrow \lceil 2\ln(9k \cdot 2^k)\gamma/\ell_t \rceil$
        Query $u[1, 2\ell_t]$
        Query r_t factors of u according to the $2\ell_t$-factor distribution
    Reject if the fragment formed by the sampled factors is A-blocking, else accept

If $\mathsf{weight}(u) \leq 6km/\varepsilon$, the length of u is at most $6km/\varepsilon$ as well, and hence Algorithm 1 queries $\mathcal{O}(6km/\varepsilon)$ symbols. Otherwise, Algorithm 1 first makes $\mathcal{O}(2\ln(9k \cdot 2^k)/\beta) = \mathcal{O}(km \cdot \varepsilon^{-1})$ queries to sample 1-factors, and then for each $t = 0, \ldots, T$, another $2^{t+1} \cdot (r_t + 1) = \mathcal{O}(4\ln(9k2^k)\gamma) = \mathcal{O}(km \cdot \varepsilon^{-1})$ queries. Hence, it has query complexity $O(km \cdot \varepsilon^{-1} \log(m/\varepsilon))$. To estimate the time complexity, we must explain how we check if the sampled fragment F is A-blocking. Given a fragment F and $S \subseteq Q$, let $\mathsf{reach}(F, S)$ denote the set of states that can be reached from a state of S when following a run labelled by some word v that contains F as a fragment, i.e.

$$\mathsf{reach}(F, S) = \{q \in Q \mid \exists p \in S, v \in \Sigma^* \ : \ p \xrightarrow{v}_{\Delta} q \text{ and } v \text{ contains the fragment } F\}$$

By definition, F is A-blocking if and only if $\mathsf{reach}(F, Q_{in}) \cap Q_f = \emptyset$.

▶ **Lemma 13.** *For any F, S, $\mathsf{reach}(F, S)$ can be computed in time $\mathcal{O}(|F| \cdot m^2)$.*

Proof. Recall that a constant-size alphabet is assumed. If $|F| = 1$, $\mathsf{reach}(F, S)$ can be computed in time and space $\mathcal{O}(m^2)$. If $F = a \in \Sigma$, $\mathsf{reach}(a, S) = \{q \in Q \mid \exists p \in S, p \xrightarrow{a}_\Delta q\}$. In this case, we can compute $\mathsf{reach}(a, S)$ by following every transition that is labelled by a and starts at a state $p \in S$. If $F = *$, $\mathsf{reach}(*, S)$ is the set of states q such that there exists a path from a state $p \in S$ to q. It can therefore be computed using a breadth-first traversal of the graph induced by the automaton, initialized at every $p \in S$. For any F, $|F| > 1$, we have $\mathsf{reach}(F, S) = \mathsf{reach}(F[2, |F|], \mathsf{reach}(F[1], S))$. Therefore, we can compute $\mathsf{reach}(F, S)$ in a recursive manner: let $S_0 = S$, and for every $1 \leq i \leq |F|$, $S_i = \mathsf{reach}(F[i], S_{i-1})$. By induction, we have $S_{|F|} = \mathsf{reach}(F, S)$. The algorithm makes $|F|$ calls to the reach function on a single symbol, which requires $\mathcal{O}(|F| \cdot m^2)$ time. ◀

The fragment F constructed in Algorithm 1 has size $\mathcal{O}(km \cdot \varepsilon^{-1} \log(m/\varepsilon))$, and therefore the time complexity of the tester is $\mathcal{O}(km^3 \cdot \varepsilon^{-1} \log(m/\varepsilon))$.

3.1.3 Correctness of the tester

In what follows, let $W := \mathsf{weight}(u)$. If $W \leq 6km/\varepsilon$, we query all symbols of u and run the automaton on u, the answer is correct with probability 1. Below we assume that $W > 6km/\varepsilon$.

If $u \in L$, there is no A-blocking fragment in u, and therefore the tester accepts with probability 1. We must now show that if u is ε-far from L, then the tester accepts with probability at most $1/3$, or in other words, the probability that F is not blocking is at most $1/3$. By Lemma 12, the probability that F is not blocking is smaller than the probability that there exist a component path $P = (C_1, \ldots, C_j)$ and an index $i, 1 \leq i \leq j$ such that F contains neither the factor from $H_i(P)$ (if $H_i(P) \neq \emptyset$), nor a factor from $L_i(P) \cup B_i(P)$ (if $H_i(P) = \emptyset$). Fix a path P and an index i. If $\mathsf{weight}(H_i(P)) \geq \beta \cdot W$ or $\mathsf{weight}(L_i(P)) \geq \beta \cdot W$, then by sampling independently $\ln(9k \cdot 2^k)/\beta$ factors of length 1 w.r.t. the 1-factor distribution, we miss such a factor with probability at most $1/(9k \cdot 2^k)$. Otherwise, if $S_i \neq \emptyset$, we have $|B_i(P)| \geq \beta \cdot W$.

▶ **Lemma 14.** *Assume $W > 6km/\varepsilon$ and $|B_i(P)| \geq \beta \cdot W$. Algorithm 1 fails to sample a C_i-blocking factor with probability at most $1/(9k2^k)$.*

Proof. Consider a fixed $t \in [0, T]$. If $u[1, 2\ell_t]$ contains a factor from $B_i(P)$, $u[1, 2\ell_t]$ is C_i-blocking and we are done. Assume that this is not the case.

We estimate the number of $2\ell_t$-factors that contain a factor from $B_i(P)$. For brevity, let $B' = \{v \in B_i(P) : |v| \leq \gamma\}$. Let $v_1, v_2, \ldots, v_{f_t}$ be the factors in B' of length at most ℓ_t, in the order of appearance in u. For all $j > 1$, the number of $2\ell_t$-factors such that v_j is the first factor appearing in them is equal to $\min(2\ell_t - |v_j| + 1, \mathsf{dist}(v_{j-1}, v_j))$, where $\mathsf{dist}(v_{j-1}, v_j)$ is the difference between the starting positions of v_{j-1} and v_j. Since $|v_j| \leq \ell_t$, we have $2\ell_t - |v_j| \geq \ell_t$. We also have $\mathsf{dist}(v_{j-1}, v_j) \geq |v_{j-1}|$, since the factors v_j and v_{j-1} are disjoint. Therefore, for all $j > 1$, $\min(2\ell_t - |v_j| + 1, \mathsf{dist}(v_{j-1}, v_j)) \geq \min(\ell_t, |v_{j-1}|) = |v_{j-1}|$. The first term corresponds to the case where there is no interval of length $2\ell_t$ that contains both v_{j-1} and v_j: if v_j starts at a position p in u, it ends at position $p + |v_j| - 1$, and the interval can start at any position p' such that $p' \leq p$ and $p' + 2\ell_t - 1 \geq p + |v_j| - 1$, i.e. $p - (2\ell_t - |v_j|) \leq p'$. The second term is equal to the number of positions between the start of v_{j-1} and the start of v_j in u: if an interval that contains v_j also contains v_{j-1}, then it does not contain v_j as its first blocking factor, and therefore it is associated with v_{j-1}. By summing over all j, we obtain that the number of $2\ell_t$-factors containing a factor from B' is at least

$$2\ell_t - |v_1| + \sum_{j=1}^{f_t} |v_{j-1}| \geq \ell_t + \sum_{j=0}^{f_t-1} |v_j| \geq l_{v_{f_t}} + \sum_{j=0}^{f_t-1} |v_j| \geq \sum_{j=0}^{f_t} |v_j|.$$

Let p_t be the probability that a factor of length $2\ell_t = 2^{t+1}$ sampled according to the $2\ell_t$-factor distribution is C_i-blocking. As any factor containing a factor from B' is C_i-blocking, from above we obtain that $p_t \geq \frac{1}{W}\sum_{j=0}^{f_t} |v_j| \geq \frac{1}{W}\sum_{v\in B':|v|\leq \ell_t} |v|$.

Consequently, for a fixed t, the probability that none of the r_t factors is C_i-blocking is at most $(1-p_t)^{r_t} \leq e^{-p_t r_t}$. By independence, the probability p that the algorithm failed to sample a C_i-blocking factor for every t satisfies:

$$p \leq \prod_{t=0}^{T} \exp(-p_t r_t) \leq \exp\left(\sum_{t=0}^{T} -p_t r_t\right) \leq \exp\left(-\sum_{t=0}^{T} \frac{2\ln(9k\cdot 2^k)\gamma 2^{-t}}{W} \sum_{v\in B':|v|\leq \ell_t} |v|\right).$$

We now show that $\sum_{t=0}^{T} 2^{-t} \sum_{v\in B':|v|\leq \ell_t} |v| \geq W/(2\gamma)$, which implies that $p \leq e^{-\ln(9k\cdot 2^k)} = 1/(9k2^k)$. We have:

$$\sum_{t=0}^{T} 2^{-t} \sum_{v\in B':|v|\leq \ell_t} |v| = \sum_{v\in B'} |v| \sum_{t=\lceil \log(|v|)\rceil}^{T} 2^{-t} = \sum_{v\in B'} |v| \frac{1}{2^{\lceil \log|v|\rceil}} \frac{1-2^{-(T-\lceil \log|v|\rceil+1)}}{1-1/2}$$
$$\geq \sum_{v\in B'} \left(1-2^{-(T-\lceil \log|v|\rceil+1)}\right) \geq \sum_{v\in B'} 1 - \frac{|v|}{2\gamma} \geq \sum_{v\in B'} 1/2 \geq W/(2\gamma),$$

where the last inequality holds because of Corollary 9. ◀

Hence, for fixed P and i, the probability that the fragment F built by Algorithm 1 contains neither the factor from $H_i(P)$ (if $H_i(P) \neq \emptyset$) nor a factor from $L_i(P) \cup B_i(P)$ (if $H_i(P) = \emptyset$) is bounded from above by $\left(\frac{1}{9k2^k} + \frac{1}{9k2^k} + \frac{1}{9k2^k}\right) \leq \frac{1}{3k2^k}$. By the union bound over all P and all k, and since there are at most 2^k component paths in A, we obtain that $\Pr[F \text{ is not blocking}] \leq \frac{1}{3}$. This concludes the proof of Theorem 5.

3.2 Lower bound

In this section we show that the query complexity of Theorem 5 is tight. Note that the indel distance is the weighted edit distance when all weights are equal to one, and hence it suffices to show the lower bound for the former.

▶ **Theorem 15.** *There exists a regular language L and constants $\varepsilon_0, C > 0$ such that on an input of length n and for any $1/n^{1/3} < \varepsilon < \varepsilon_0$, a non-adaptive ε-property tester for L under the indel distance has query complexity $\geq C\varepsilon^{-1}\log(1/\varepsilon)$.*

Note that by running a property tester twice, the error probability can be reduced from 1/3 to 1/9, while increasing the query complexity by a factor of two. From that and by Yao's minimax principle [23], it suffices to find a distribution $\mathcal{D}$ on $\{a,b,c,d\}^*$ and a constant $C > 0$ such that any *deterministic* algorithm A that makes at most $C\varepsilon^{-1}\log(1/\varepsilon)$ queries and accepts all inputs in L, errors with probability $> 1/9$.

Let n be the length of the input. Below, we fix arbitrarily a precision parameter $1/n^{1/3} \leq \varepsilon < 1/2^{-48}$. Consider regular languages $L_0 = \{u \in \{a,c\}^* : u \text{ contains an even number of } c\}$ and $L = (a \mid bL_0d)^*$. Define the distribution $\mathcal{D}$ as follows. Let r be a fair coin. For $\ell = \lceil 5/\varepsilon \rceil$,

divide $[1,n]$ into $z=\lfloor n/\ell \rfloor \geq 1$ intervals of size ℓ each, except for the last one that can be longer. Let $[a_j,b_j]$ be the j-th interval. We associate with it a random variable τ_j, distributed as follows:

$$\tau_j = \begin{cases} t, & \text{with probability } p_t = 12\varepsilon 2^t/\log(1/\varepsilon) \text{ for } t=1,2,\ldots,\lceil \log(1/\varepsilon)\rceil; \\ 0, & \text{with probability } p_0 = 1-\sum_{t=1}^{\lceil \log(1/\varepsilon)\rceil} p_t. \end{cases}$$

For any $\varepsilon < 2^{-48}$, we have $p_0 = 1-\sum_{t=1}^{\lceil \log(1/\varepsilon)\rceil} p_t > 0$, and hence the distribution is well-defined. The variable τ_j characterizes the length of the instances of L_0 that we will put in the j-th interval. If $\tau_j=0$, we put no instances at all: set $u[a_j,b_j]=aa\ldots a$. If $\tau_j=t>0$, set $u[a_j,b_j]=(bw_jd)^{\lceil 2^{-t}/\varepsilon\rceil}aa\ldots a$, where w_j is a word of length 2^t chosen uniformly at random from L_0 if $r=0$ and from $\{a,c\}^*\setminus L_0$ otherwise.

Notice that $\mathcal{D}$ produces a positive instance with probability at least $1/2$, since whenever $r=0$, $u\in L$. We prove in the following lemma that $\mathcal{D}$ also produces a word ε-far from L with constant probability.

▶ **Lemma 16.** *Let u be a word of length n sampled w.r.t. $\mathcal{D}$. With probability at least $1/4$, $\delta(u,L)\geq \varepsilon n$.*

Proof. Assume $r=1$ and let $\xi_j=\lceil 2^{-\tau_j}/\varepsilon\rceil$ if $\tau_j>0$, and 0 otherwise (ξ_j is the number of instances of L_0 in the j-th interval). The variables ξ_j are independent, and for every j, we have $1\leq \xi_j\leq 1/\varepsilon$. Let $\xi=\left(\sum_{j=1}^{z}\xi_j\right)/z$. We have:

$$\mathbb{E}[\xi]=\mathbb{E}[\xi_j]=\sum_{t>0}p_t\cdot\lceil 2^{-t}/\varepsilon\rceil=\sum_{t>0}\frac{12\varepsilon 2^t}{\log(1/\varepsilon)}\cdot\lceil 2^{-t}/\varepsilon\rceil\geq\sum_{t>0}\frac{12}{\log(1/\varepsilon)}\geq 12.$$

By Hoeffding's inequality, we have $\Pr[\xi\geq 6]\geq 1-e^{-\frac{72z^2}{z/\varepsilon^2}}=1-e^{-72\varepsilon^2 z}\geq 1/2$ and $z=\lfloor n/\lceil 5/\varepsilon\rceil\rfloor\geq \varepsilon n/6$, as $1/n^{1/3}\leq\varepsilon<2^{-48}$. Hence, $\Pr\left[\sum_j\xi_j\geq\varepsilon n\right]\geq\Pr[\xi\geq 6]\geq 1/2$.

It remains to show that conditioned on $r=1$, the indel distance between u and L is at least $\sum_j\xi_j$. As each word of form bw_jd, where $w_j\in\{a,c\}^*\setminus L_0$ requires at least one insertion or deletion to become a factor of a word in L, the bound follows by construction. Hence, $\Pr[\delta(u,L)\geq\varepsilon n]\geq\Pr[r=1]\cdot\Pr\left[\sum_j\xi_j\geq\varepsilon n\right]\geq 1/4$. ◀

▶ **Lemma 17.** *Let q_j be the number of symbols queried by A in the j-th interval $[a_j,b_j]$. Consider an input u sampled w.r.t. $\mathcal{D}$. If for all j such that $\tau_j>0$ we have $q_j<2^{\tau_j}$, then A must accept u.*

Proof. Assume that A rejects u. If $u\in L$, we immediately get a contradiction. If u is a negative instance, then for all j such that $\tau_j>0$ we have $u[a_j,b_j]=(bw_jd)^{\lceil 2^{-\tau_j}/\varepsilon\rceil}aa\ldots a$, where w_j is a word of length 2^{τ_j} not in L_0. Since A queries less than 2^{τ_j} symbols in $u[a_j,b_j]$, there is a symbol of w_j that A does not query. Hence, there is a word in L_0 that we denote by w'_j that has length 2^{τ_j} and does not differ from w_j on the queried symbols. We replace all copies of w_j by w'_j. Let u' denote the resulting word. Notice that $u'\in L$, and all the symbols for u and u' in the queried positions are equal and therefore A rejects it as well. The probability of u' under the distribution $\mathcal{D}$ is non-zero, and therefore there is a non-zero probability that A rejects a positive instance, a contradiction. ◀

Proof of Theorem 15. We finally derive that if A queries $\sum_j q_j < 1/(3\cdot 192\varepsilon)\log(1/\varepsilon)$ symbols, then it errs with probability $>1/9$, which implies the theorem.

Consider an input u of length n generated according to the distribution $\mathcal{D}$. Let $A(u)$ denote the output of A on u: 1 for accepting, 0 for rejecting. Let F denote the event "$\delta(u, L) \geq \varepsilon n$". The probability that A rejects inputs that are far from L is given by:

$$\begin{aligned}
\Pr[A(u) = 0 \mid F] &= \Pr[A(u) = 0 \wedge F] / \Pr[F] \leq \Pr[A(u) = 0] / \Pr[F] \\
&\leq 4 \cdot \Pr[A(u) = 0] \text{ (Lemma 16)} \\
&\leq 4 \cdot \Pr[\exists j : q_j \geq 2^{\tau_j} \wedge \tau_j > 0] \text{ (Lemma 17)} \\
&\leq 4 \cdot \sum_j \Pr[q_j \geq 2^{\tau_j} \wedge \tau_j > 0] \text{ (union bound)} \\
&\leq 4 \cdot \sum_j \sum_{t=1}^{\lceil \log q_j \rceil} p_t \leq 4 \sum_j \frac{12\varepsilon}{\log(1/\varepsilon)} \sum_{t=1}^{\lceil \log q_j \rceil} 2^t \leq \frac{192\varepsilon}{\log(1/\varepsilon)} \sum_j q_j < 1/3.
\end{aligned}$$

The probability that A gives an incorrect answer is at least the probability that it accepts a word that is ε-far. In other words, this probability is equal to $\Pr[A(u) = 1 \wedge F] = \Pr[A(u) = 1 \mid F] \cdot \Pr[F] > (2/3) \cdot (1/4) > 1/9$, concluding the proof. ◀

4 Streaming property testing of VPLs

Let us start by reminding the formal definitions of visibly pushdown languages and streaming property testers. Let $\Sigma = \Sigma_+ \sqcup \Sigma_= \sqcup \Sigma_-$. We refer to the symbols in Σ_+ as *push* symbols, and the symbols in Σ_- as *pop* symbols.

▶ **Definition 18** (Visibly pushdown automaton). *A visibly pushdown automaton (VPA) $\mathcal{A}$ over Σ is a tuple $(\Sigma, \Gamma, Q, Q_{in}, Q_f, \Delta)$, where*

- *Γ is a finite set of stack symbols,*
- *Q is a finite set of states, $Q_{in} \subseteq Q$ of initial states, $Q_f \subseteq Q$ of final states,*
- *$\Delta \subseteq (Q \times \Sigma_+ \times Q \times \Gamma) \cup (Q \times \Sigma_= \times Q) \cup (Q \times \Sigma_- \times \Gamma \times Q)$ is the transition relation.*

When running the automaton on a word $u \in \Sigma^n$, we maintain a stack. Let $\perp \notin \Gamma$ be a special symbol to denote the bottom of the stack. A configuration of a VPA $\mathcal{A}$ is a tuple $(\sigma, q) \in (\perp \cdot \Gamma^*) \times Q$. For $a \in \Sigma$, there is a transition from a configuration (σ, q) to (σ', q'), denoted $(\sigma, q) \xrightarrow{a}_\Delta (\sigma', q')$, in the following cases:

- *if $a \in \Sigma_+, \sigma' = \sigma \cdot \gamma, \gamma \in \Gamma$ and $(q, a, q', \gamma) \in \Delta$ (we write $q \xrightarrow{a}_\Delta (q', push(\gamma))$),*
- *if $a \in \Sigma_-, \sigma = \sigma' \cdot \gamma, \gamma \in \Gamma$ and $(q, a, \gamma, q') \in \Delta$ (we write $(q, pop(\gamma)) \xrightarrow{a}_\Delta q'$),*
- *if $a \in \Sigma_=$ and $(q, a, q') \in \Delta$ (we write $q \xrightarrow{a}_\Delta q'$).*

For a word $u \in \Sigma^n$, if for all $1 \leq i \leq n, (\sigma_{i-1}, q_{i-1}) \xrightarrow{u[i]}_\Delta (\sigma_i, q_i)$, we write $(\sigma_0, q_0) \xrightarrow{u}_\Delta (\sigma_n, q_n)$. A word u is accepted by an automaton $\mathcal{A}$ if there exists a initial state $q_{in} \in Q_{in}$ and a final state $q_f \in Q_f$ such that $(\perp, q_{in}) \xrightarrow{u}_\Delta (\perp, q_f)$. We denote the language of all words accepted by $L(\mathcal{A})$. A language $L \subseteq \Sigma^*$ is a visibly pushdown language *(VPL) if $L = L(\mathcal{A})$ for some VPA $\mathcal{A}$.*

▶ **Definition 19** (Streaming property testing algorithm). *A **streaming ε-property testing algorithm** for a language L under distance d is an algorithm that given streaming access to a word u:*

- *accepts if $u \in L$ with probability 1,*
- *rejects with probability at least p if u is ε-far from L w.r.t. d,*
- *accepts or rejects otherwise.*

If $p = 1$, we say that a streaming ε-property testing algorithm is deterministic. *If $p = 2/3$, we say that it is randomised. The* space complexity *of the algorithm is defined to be the total space used (in bits)* including *the space needed to store any information about the input.*

4.1 Upper bound

François et al. [5] showed that streaming property testing of visibly pushdown languages can be reduced to the problem of (approximately) encoding words as relationships in finite automata[3]. Consider a (non-deterministic) finite automaton $A = (\widehat{\Sigma}, \widehat{Q}, \widehat{Q}_{in}, \widehat{Q}_f, \widehat{\Delta})$. For $\widehat{\Sigma}' \subseteq \widehat{\Sigma}$, define a distance function $\mathsf{wed}_{\widehat{\Sigma}'}$ as the weighted edit distance where the insertions are restricted to symbols in $\widehat{\Sigma}'$. For a word u, let $R_u = \{(p,q) \mid p,q \in \widehat{Q}, p \xrightarrow{u}_{\widehat{\Delta}} q\}$.

▶ **Definition 20** (ξ-approximation). *A relation $R \subseteq Q^2$ is an (ξ, Σ')-approximation of R_u if the following two conditions are satisfied:*

- *For all p, q such that $p \xrightarrow{u}_{\widehat{\Delta}} q$, $(p,q) \in R$,*
- *If $(p,q) \in R$, then there exists a word v such that $\mathsf{wed}_{\widehat{\Sigma}'}(u,v) \leq \xi \cdot \mathsf{weight}(u)$ and $p \xrightarrow{v}_{\widehat{\Delta}} q$.*

We call A *$\widehat{\Sigma}'$-closed* if $p \xrightarrow{u}_{\widehat{Q}} q$ for some $u \in (\widehat{\Sigma})^*$ iff $p \xrightarrow{u'}_{\widehat{Q}} q$ for some $u' \in (\widehat{\Sigma}')^*$. The *$\widehat{\Sigma}'$-diameter* of A, denoted by d, is the maximum over all pairs of states p, q of $\min\{|u| : u \in (\widehat{\Sigma}')^*, p \xrightarrow{u}_{\widehat{\Delta}} q\}$, whenever this minimum is not over the empty set. Finally, for a fragment F and $S \subseteq \widehat{Q}$, let $\mathsf{reach}_{\widehat{\Sigma}'}(F, S)$ denote the set of states that can be reached from a state of S when following a run labelled by some word v that contains F as a fragment and such that all symbols in $v \setminus F$ belong to $\widehat{\Sigma}'$. By extending our property tester for regular languages, we obtain:

▶ **Lemma 21.** *Let A be $\widehat{\Sigma}'$-closed. Given a query access to a word u, Algorithm 2 computes a $(\xi, \widehat{\Sigma}')$-approximation of $R_u = \{(p,q) \mid p,q \in \widehat{Q}, p \xrightarrow{u}_{\widehat{Q}} q\}$ correctly with probability $\geq 1 - \mu$.*

Proof. For every $p, q \in \widehat{Q}$ and every fragment F of u, if $p \xrightarrow{u}_{\widehat{Q}} q$, then $q \in \mathsf{reach}_{\widehat{\Sigma}'}(F, \{p\})$. Therefore, the algorithm can err only if there exist $p, q \in \widehat{Q}$ such that $(p,q) \in R$ and for every word w such that $p \xrightarrow{w}_{\widehat{Q}} q$ there is $\mathsf{wed}_{\widehat{\Sigma}'}(w,u) \geq \xi \cdot \mathsf{weight}(u)$. This is equivalent to saying that $\mathsf{wed}_{\widehat{\Sigma}'}(u, L(A_{p,q})) \geq \xi \cdot \mathsf{weight}(u)$, where $A_{p,q}$ is the finite automaton A with a unique initial state p and a unique final state q. As A is $\widehat{\Sigma}'$-closed, an argument analogous to Theorem 5 shows that the algorithm errs for p, q with probability at most μ/m^2. The claim follows by the union bound. ◀

By plugging this result into the framework of François et al. [5], we obtain:

▶ **Corollary 22.** *Let $\varepsilon > 0$ be a constant, $\mathcal{A} = (Q, \Sigma, \Gamma, Q_{in}, Q_f, \Delta)$ be a VPA of constant size over $\Sigma = \Sigma_+ \sqcup \Sigma_= \sqcup \Sigma_-$, and $L = L(\mathcal{A})$. There is a randomised streaming property tester for L that uses $\mathcal{O}(\varepsilon^{-3} \log^5 n \log\log n)$ space.*

Proof. François et al. showed that property testing of visibly pushdown languages can be solved by running $\mathcal{O}(\varepsilon^{-1} \log^2 n)$ instances of the approximation algorithm of Lemma 21 with $\xi = \varepsilon/(6 \log n)$ and $\mu = 2/3n$, on an NFA of constant size [5, Theorem 5.4]. Furthermore, sampling factors of the input strings according to the ℓ-factor distribution can be imitated in streaming at an expense of $\mathcal{O}(\ell \cdot (\ell + \log n))$ space per sample [5, Fact 4.6]. We implement $\mathsf{reach}_{\widehat{\Sigma}'}$ similar to Lemma 13 using constant extra space. Therefore, an instance of the approximation algorithm of Lemma 21 requires space

$$\mathcal{O}(\xi^{-1} \log(1/\mu) + \sum_t r_t \ell_t \cdot (\ell_t + \log n)) =$$

$$= \mathcal{O}(\xi^{-2} \log^2(1/\mu) + \xi^{-1} \ln(1/\mu) \log(\xi^{-1} \ln(1/\mu)) \log n) = \mathcal{O}(\varepsilon^{-2} \log^3 n \log\log n).$$

The bound follows. ◀

[3] In this section, we refer to a more complete arXiv version of the paper.

Algorithm 2 Building an $(\xi, \widehat{\Sigma}')$-approximation R of R_u. Here k is the number of strongly connected components of A, and $m = |\widehat{Q}|$.

return R

4.2 Lower bound

▶ **Theorem 23.** *There exist a VPL L and a constant ε_0 such that for any $1/n \leq \varepsilon < \varepsilon_0$ any deterministic streaming ε-property tester for L under the edit distance uses space $\tilde{\Omega}(n(1 - 16\varepsilon\log(1/\varepsilon)))$. Any randomised streaming ε-property tester for VPLs under the edit distance uses space $\tilde{\Omega}(\max(\varepsilon^{-1}, \log n))$.*

Proof of Theorem 23. We first prove the deterministic bound, and then use it to derive the randomised one. Let L_{mirror} be a VPL over $\Sigma = \{0, 1, \bar{0}, \bar{1}\}$ defined as $L_{mirror} = \{w\bar{w}, w \in \{0,1\}\}$, where $\bar{w} = \overline{w[n]} \dots \overline{w[1]}$. For example, if $w = 1101$ then $\bar{w} = \bar{1}\bar{0}\bar{1}\bar{1}$. Recall that the indel distance $\delta(u, v)$ between two words u, v is equal to the minimum number of insertions and deletions needed to transform u into v and that a lower bound for the indel distance gives an asymptotically equal lower bound for the edit distance.

▶ **Lemma 24.** *Assume n is even. Let $u, v \in \Sigma^{n/2}$. If $\delta(u, v) > 2\varepsilon n$, then $\delta(u\bar{v}, L_{mirror}) > \varepsilon n$.*

Proof. We prove the claim by contrapositive. We assume that $\delta(u\bar{v}, L_{mirror}) \leq \varepsilon n$ and show that $\delta(u, v) \leq 2\varepsilon n$. Let $w\bar{w}$ be a word of L_{mirror} such that $\delta(u\bar{v}, L_{mirror}) = \delta(u\bar{v}, w\bar{w})$. By the triangle inequality, we have $\delta(u, v) \leq \delta(u, w) + \delta(w, v) = \delta(u, w) + \delta(\bar{w}, \bar{v})$.

Let us start with an auxiliary claim. Consider $y \in \Sigma^k, z \in \Sigma^l$. Let y_1 (resp. y_2) denote $y[1, \lceil k/2 \rceil]$ (resp. $y[\lceil k/2 \rceil + 1, k]$), and similarly for z. We show that if $\delta(y, z) = 2$, then $\delta(y_1, z_1) + \delta(y_2, z_2) \leq 4$.

We have either $k = l$ or $|k - l| = 2$. If $k = l$, then $|y_1| = |z_1|$, $|y_2| = |z_2|$, and the two edits are one insertion and one deletion. If the two edits occur in y_1, we have $\delta(y_1, z_1) \leq 2$ and $\delta(y_2, z_2) = 0$. The case when the two edits occur in y_2 is symmetric. If one edit occurs in y_1 and the other in y_2, then y_1 is transformed into a prefix of z of length $|y_1| - 1$ or $|y_1| + 1$, and y_2 into a suffix of z of length $|y_2| + 1$ or $|y_2| + 1$, respectively. Therefore, $\delta(y_1, z_1) \leq 2$ and $\delta(y_2, z_2) \leq 2$. Assume now $|k - l| = 2$. W.l.o.g., $k = l + 2$, and the two edit operations are deletions. Since $k = l + 2$, we have $|y_1| = |z_1| + 1$, $|y_2| = |z_2| + 1$. Consider two cases:

- One deletion occurs in y_1, and one deletion occurs in y_2. In this case, y_1 is transformed into z_1, and y_2 into z_2. Hence, $\delta(y_1, z_1) + \delta(y_2, z_2) = 2$.
- The two deletions occur in y_1 (the proof for y_2 is symmetrical). In this case, y_1 is transformed into a prefix of v of length $|y_1| - 2 = |z_1| - 1$, and y_2 is equal to the suffix of v of length $|y_2|$. Therefore, $\delta(y_1, z_1) \leq 3$ and $\delta(y_2, z_2) = 1$, and the claim follows.

For simplicity, let $T = \delta(u\bar{v}, w\bar{w})$. Note that T is even, as both words have even length. For every $0 \leq t \leq T$, let x_t be the word obtained by applying the first t edit operations to $u\bar{v}$ in the sequence that transforms $u\bar{v}$ into $w\bar{w}$, and let $x_1^t = x^t[1, \lceil |x^t|/2 \rceil]$ and $x_2^t = x_t[\lceil |x^t|/2 \rceil + 1, |x^t|]$. For all $t \leq T-2$, $\delta(x^t, x^{t+2}) = 2$, and therefore $\delta(x_1^t, x_1^{t+2}) + \delta(x_2^t, x_2^{t+2}) \leq 4$. Finally, we obtain

$$\begin{aligned}\delta(u,w) + \delta(\bar{v},\bar{w}) = \delta(x_1^0, x_1^T) + \delta(x_2^0, x_2^T) &\leq \sum_{t=0}^{T/2} \delta(x_1^{2t}, x_1^{2t+2}) + \sum_{t=0}^{T/2} \delta(x_2^{2t}, x_2^{2t+2}) \\ &\leq \sum_{t=0}^{T/2} \left(\delta(x_2^{2t}, x_2^{2t+2}) + \delta(x_2^{2t}, x_2^{2t+2})\right) \leq 4T/2 \leq 2\varepsilon n\end{aligned}$$

In short, we have $\delta(u,w) + \delta(\bar{v},\bar{w}) \leq 2\varepsilon n$, which completes the proof. ◀

▷ Claim 25. Let $u \in \{0,1\}^n$ and $B(u,k,n) = \{v \in \{0,1\}^n | \, \delta(u,v) \leq k\}$. For all $2/n \leq \alpha < 1$, we have $|B(u, \alpha n, n)| \leq 2^{\alpha n(1+2\log 8e/\alpha)/2}$.

Proof. Let $2t$ be the largest even number smaller or equal to αn. Let $v \in B(u,k,n)$. Since $|u| = |v| = n$, we can obtain v from u using t insertions and t deletions. (If $\delta(u,v) < 2t$, we can insert a symbol $(2t - \delta(u,v))/2$ times, and then delete it $(2t - \delta(u,v))/2$ times.)

W.l.o.g., assume that the insertions occur before the deletions. After t insertions, we obtain a word of size $n+t$. The number of possible ways to delete t symbols in this word is therefore $\binom{n+t}{t}$. We give an upper bound on the number of words that can be reached with t insertions from a word of length n the following way: in a word of length $n+t$, there are t symbols that have been inserted, and there are two options for each symbol. Therefore, there are at most $2^t\binom{n+t}{t}$ such words. The number of words in $B(u,k,n)$ is at most the number of words reached after a sequence of t insertions, multiplied by the number of sequences of t deletions. Overall, we obtain:

$$\begin{aligned}|B(u,\alpha n,n)| &\leq 2^t \binom{n+t}{t}^2 \leq 2^t \left(\frac{e(n+t)}{t}\right)^{2t} \leq 2^{(1+2\log e)t}(\frac{n}{t}+1)^{2t} \\ &\leq 2^{(1+2\log e)t}(8/\alpha)^{2t} \leq 2^{\alpha n(1+2\log e + 2\log(8/\alpha))/2} \\ &\leq 2^{\alpha n(1+2\log(8e/\alpha))/2}\end{aligned}$$

◁

▶ **Corollary 26.** *There exists a constant ε_0 such that for any $1/n \leq \varepsilon < \varepsilon_0$, any deterministic streaming ε-property tester for L_{mirror} under the indel distance uses space $\bar{\Omega}(n(1 - 16\varepsilon\log(1/\varepsilon)))$.*

Proof. Assume n is even. Consider the memory state of a tester after reading two words $u, v \in \{0,1\}^{n/2}$. Suppose that they give the same memory state. We can then continue the streams with $\bar{u}$, and since the algorithm must accept $u\bar{u} \in L_{mirror}$, it must also accept $v\bar{u}$. By the definition of a streaming ε-property tester and Lemma 24, we have $\delta(u,v) \leq 2\varepsilon n$. Therefore, the number of distinct memory states of the tester after reading $n/2$ symbols is at least $2^{n/2}/|B(u, 2\varepsilon n, n/2)|$. The space $s(n)$ used by the tester is at least the logarithm of the number of memory states. Therefore,

$$\begin{aligned}s(n) &\geq \log(2^{n/2}/|B(u,2\varepsilon n, n/2)|) \\ &\geq \log(2^{n/2}/2^{\varepsilon n(1+2\log(2e/\varepsilon))}) \text{ (applying Claim 25 for } \alpha = 4\varepsilon \text{ and size } n/2) \\ &\geq n/2 - \varepsilon n(1+2\log(2e/\varepsilon)) \geq \frac{n}{2}(1 - 16\varepsilon\log(1/\varepsilon))\end{aligned}$$

◀

The deterministic bound for the edit distance follows immediately. We now derive the randomised lower bound. We show $\bar{\Omega}(\log n)$ and $\bar{\Omega}(1/\varepsilon)$ space lower bounds separately, and then combine them to yield the theorem.

▶ **Corollary 27.** *Any randomised streaming ε-property tester for L_{mirror} under the edit distance uses space $\bar{\Omega}(\log n)$.*

Proof. A streaming ε-property tester for a VPL L with an input of length n can be viewed as an automaton A_n whose states are the memory states of the algorithm. Deterministic algorithms are deterministic automata, and randomised algorithms are probabilistic automata (see Rabin [22] for definitions).

Consider a randomised streaming ε-property testing algorithm A_n for L_{mirror} on inputs of length n. Let $L(A_n) = \{u \in \{0,1,\bar{0},\bar{1}\}^n \mid A_n \text{ accepts } u \text{ with probability } \geq 2/3\}$. By definition, a deterministic streaming algorithm that recognizes $L(A_n)$ is a streaming ε-property tester for L_{mirror}. By [7, Lemma 6.4], the space complexity of A_n is at least the logarithm of the space complexity of the deterministic one, that is $\bar{\Omega}(\log(n(1-16\varepsilon\log(1/\varepsilon)))) = \bar{\Omega}(\log n)$. ◀

We now show the $\bar{\Omega}(1/\varepsilon)$ bound. Consider a VPL $L_{disj} = \{x\bar{y} \mid x,y \in \{0,1\}^n \text{ and } \forall 1 \leq i \leq n, x[i]\cdot y[i] = 0\}$.

▷ Claim 28. Let $\alpha = \lfloor 1/\varepsilon \rfloor$ and assume that n is a multiple of α. Define a morphism $\phi : \Sigma^* \to \Sigma^*$ such that for any $a \in \Sigma$ we have $\phi(a) = a^{6n/\alpha}$. Consider a word $u = x\bar{y}$, where $x,y \in \Sigma^\alpha$. If $u \in L_{disj}$, then $\mathsf{ed}(\phi(u), L_{disj}) = 0$, and otherwise $\mathsf{ed}(\phi(u), L_{disj}) > \varepsilon n$.

Proof. The first part of the claim is obvious. The rest of the proof is devoted to the case $u \notin L_{disj}$. Assume by contradiction that $\mathsf{ed}(\phi(u), L_{disj}) \leq \varepsilon n$, in other words, that there exists a sequence of at most εn edits such that when applied to $\phi(u)$, we obtain a word in L_{disj}. W.l.o.g. assume that the edits are applied only to the first half of $\phi(u)$, i.e. to $\phi(x)$. Since $u \notin L_{disj}$, there exists i such that $x[i]\cdot y[i] = 1$. Consider the middle part of $\phi(x[i])$, i.e. the factor $w = \phi(u)[(i-1)\cdot(6n/\alpha) + 2n/\alpha + 1, (i-1)\cdot(6n/\alpha) + 4n/\alpha]$. After we apply the at most $\varepsilon n \leq n/\alpha$ edits to $\phi(x)$, there is at least one symbol of w that does not change and therefore is equal to 1, let it be $w[j]$. Moreover, the index of this symbol in the resulting word is between $(i-1)\cdot(6n/\alpha) + n/\alpha + 1$ and $(i-1)\cdot(6n/\alpha) + 5n/\alpha$. On the other hand, $\phi(y[i])$ can be shifted by at most εn positions to the left or to the right. Therefore, $w[j]$ will be aligned with a symbol in $\phi(y[i])$ equal to 1 as well, a contradiction. ◁

The $\bar{\Omega}(1/\varepsilon)$ bound follows immediately from the linear space lower bound for randomised streaming 0-property testing algorithms for L_{disj} [5, 15]. ◀

Datalog-Expressibility for Monadic and Guarded Second-Order Logic

Abstract

We characterise the sentences in Monadic Second-order Logic (MSO) that are over finite structures equivalent to a Datalog program, in terms of an existential pebble game. We also show that for every class $\mathcal{C}$ of finite structures that can be expressed in MSO and is closed under homomorphisms, and for all $\ell, k \in \mathbb{N}$, there exists a *canonical* Datalog program Π of width (ℓ, k), that is, a Datalog program of width (ℓ, k) which is sound for $\mathcal{C}$ (i.e., Π only derives the goal predicate on a finite structure $\mathfrak{A}$ if $\mathfrak{A} \in \mathcal{C}$) and with the property that Π derives the goal predicate whenever *some* Datalog program of width (ℓ, k) which is sound for $\mathcal{C}$ derives the goal predicate. The same characterisations also hold for Guarded Second-order Logic (GSO), which properly extends MSO. To prove our results, we show that every class $\mathcal{C}$ in GSO whose complement is closed under homomorphisms is a finite union of constraint satisfaction problems (CSPs) of ω-categorical structures.

1 Introduction

Monadic Second-order Logic (MSO) is an important logic in theoretical computer science. By Büchi's theorem, a formal language can be defined in MSO if and only if it is regular (see, e.g., [24]). MSO sentences can be evaluated in polynomial time on classes of structures whose treewidth is bounded by a constant; this is known as Courcelle's theorem [16]. The latter result even holds for the more expressive logic of *Guarded Second-order Logic (GSO)* [21, 18], which extends First-order Logic by second-order quantifiers over *guarded relations*. Guarded Second-order Logic contains *Guarded First-order Logic* (which itself captures many description logics [20]).

Another fundamental formalism in theoretical computer science, which is heavily studied in database theory, is *Datalog* (see, e.g., [24]). Every Datalog program can be evaluated on finite structures in polynomial time. Like MSO, Datalog strikes a good balance between expressivity and good mathematical and computational properties. Two important parameters of a Datalog program Π are the maximal arity ℓ of its auxiliary predicates (IDBs), and the maximal number k of variables per rule in Π. We then say that Π has *width* (ℓ, k), following the terminology of Feder and Vardi [19]. These parameters are important both in theory and in practice: ℓ closely corresponds to the exponent of the size of the memory space and k to the exponent of the number of computation steps needed when evaluating Π on a given structure (see, e.g., [4]).

In some scenarios we are interested in having the good computational properties of expressibility in Datalog *and* having the good computational properties of expressibility in MSO. A wide variety of popular query formalisms (among them (unions of) conjunctive queries, (2-way conjunctive) regular path queries, monadic Datalog, guarded Datalog, monadically defined queries, or nested monadically defined queries) are known to be both in Datalog and GSO [25]. Also, all these formalisms have favourable properties when it comes to static analysis, most notably decidable query containment [25]. Note that on the contrary, query containment in unrestricted Datalog is undecidable, as is query containment in unrestricted MSO / GSO. So it is really the interplay of the restrictions imposed by both formalisms that is required to ensure decidability of a central task in databases and that makes this fragment interesting and worthwhile investigating.

In this paper we investigate two questions that (perhaps surprisingly) turn out to be closely related:

1. Which classes of finite structures are simultaneously expressible in MSO and in Datalog?
2. Which *constraint satisfaction problems (CSPs)* can be expressed in MSO, or, more generally, in GSO?

For a structure $\mathfrak{B}$ with a finite relational signature τ, the *constraint satisfaction problem for* $\mathfrak{B}$ is the class of all finite τ-structures that homomorphically map to $\mathfrak{B}$. Every finite-domain constraint satisfaction problem can already be expressed in monotone monadic SNP (MMSNP; [19]), which is a small fragment of MSO. On the other hand, the constraint satisfaction problem for $(\mathbb{Q}; <)$, which is the class of all finite acyclic digraphs $(V; E)$, cannot be expressed in MMSNP [6], but can be expressed in MSO by the sentence

$$\forall X \neq \emptyset \; \exists x \in X \; \forall y \in X \colon \neg E(x, y).$$

The class of CSPs of arbitrary infinite structures $\mathfrak{B}$ is quite large; it is easy to see that a class $\mathcal{D}$ of finite structures with a finite relational signature τ is a CSP of a countably infinite structure if and only if

- it is closed under disjoint unions, and
- $\mathfrak{A} \in \mathcal{D}$ for any $\mathfrak{A}$ that maps homomorphically to some $\mathfrak{A}' \in \mathcal{D}$.

The second item can equivalently be rephrased as the *complement* of $\mathcal{D}$ (meant within the class of all finite τ-structures; this comment applies throughout and will be omitted in the following) being *closed under homomorphisms*: a class $\mathcal{C}$ is closed under homomorphisms if for any structure $\mathfrak{A} \in \mathcal{C}$ that maps homomorphically to some $\mathfrak{C}$ we have $\mathfrak{C} \in \mathcal{C}$. Examples of classes of structures that are closed under homomorphisms naturally arise from Datalog. We say that a class $\mathcal{C}$ of finite τ-structures *is definable in Datalog*[1] if there exists a Datalog

[1] Warning: Feder and Vardi [19] say that a CSP is in Datalog if its *complement* in the class of all finite τ-structures is in Datalog.

program Π with a distinguished predicate nullary goal such that Π derives goal on a finite τ-structure if and only if the structure is in $\mathcal{C}$; in this case, we write $[\![\Pi]\!]$ for $\mathcal{C}$. Every class of τ-structures in Datalog is closed under homomorphisms. However, not every class of finite structures in Datalog describes the complement of a CSP: consider for example, for unary predicates R and B, the class $\mathcal{C}_{R,B}$ of finite $\{R,B\}$-structures $\mathfrak{A}$ such that $R^{\mathfrak{A}}$ is empty or $B^{\mathfrak{A}}$ is empty. Clearly, $\mathcal{C}_{R,B}$ is not closed under disjoint unions. However, a finite structure is in $\mathcal{C}_{R,B}$ if and only if the Datalog program that consists of just one rule

$$\mathsf{goal} :- R(x), B(y)$$

does not derive goal on that structure.

An important class of CSPs is the class of CSPs for structures $\mathfrak{B}$ that are countably infinite and *ω-categorical*. A structure $\mathfrak{B}$ is *ω-categorical* if all countable models of the first-order theory of $\mathfrak{B}$ are isomorphic. A well-known example of an ω-categorical structure is $(\mathbb{Q};<)$, which is a result due to Cantor [15]. Constraint satisfaction problems of ω-categorical structures can be evaluated in polynomial time on classes of treewidth bounded by some constant $k \in \mathbb{N}$, by a result of Bodirsky and Dalmau [7]. The polynomial-time algorithm presented by Bodirsky and Dalmau is in fact a Datalog program of width $(k-1,k)$. A Datalog program Π is called *sound* for a class of τ-structures $\mathcal{C}$ if $[\![\Pi]\!] \subseteq \mathcal{C}$. Bodirsky and Dalmau showed that if $\mathcal{C}$ is the complement of the CSP of an ω-categorical τ-structure $\mathfrak{B}$ then there exists for all $\ell, k \in \mathbb{N}$ a *canonical Datalog program of width (ℓ,k) for $\mathcal{C}$*, i.e., a Datalog program Π of width (ℓ,k) such that

- Π is sound for $\mathcal{C}$, and
- $[\![\Pi']\!] \subseteq [\![\Pi]\!]$ for every Datalog program Π' of width (ℓ,k) which is sound for $\mathcal{C}$.

Moreover, whether the canonical Datalog program of width (ℓ,k) for $\mathcal{C}$ derives goal on a given τ-structure $\mathfrak{A}$ can be characterised in terms of the existential pebble game from finite model theory, played on $(\mathfrak{A},\mathfrak{B})$ [7]. The *existential ℓ,k pebble game* is played by two players, called *Spoiler* and *Duplicator* (see, e.g., [17, 19, 23]). Spoiler starts by placing k pebbles on elements $a_1,\dots,a_k$ of $\mathfrak{A}$, and Duplicator responds by placing k pebbles $b_1,\dots,b_k$ on $\mathfrak{B}$. If the map that sends $a_1,\dots,a_k$ to $b_1,\dots,b_k$ is not a partial homomorphism from $\mathfrak{A}$ to $\mathfrak{B}$, then the game is over and Spoiler wins. Otherwise, Spoiler removes all but at most ℓ pebbles from $\mathfrak{A}$, and Duplicator has to respond by removing the corresponding pebbles from $\mathfrak{B}$. Then Spoiler can again place all his pebbles on $\mathfrak{A}$, and Duplicator must again respond by placing her pebbles on $\mathfrak{B}$. If the game continues forever, then Duplicator wins. If $\mathfrak{B}$ is a finite, or more generally a countable ω-categorical structure then Spoiler has a winning strategy for the existential ℓ,k pebble game on $(\mathfrak{A},\mathfrak{B})$ if and only if the canonical Datalog program for $\mathrm{CSP}(\mathfrak{B})$ derives goal on $\mathfrak{A}$ (Theorem 19). This connection played an essential role in proving Datalog inexpressibility results, for example for the class of finite-domain CSPs [2] (leading to a complete classification of those finite structures $\mathfrak{B}$ such that the complement of $\mathrm{CSP}(\mathfrak{B})$ can be expressed in Datalog [3]).

Results and Consequences

We present a characterisation of those GSO sentences Φ that are over finite structures equivalent to a Datalog program. Our characterisation involves a variant of the existential pebble game from finite model theory, which we call the *(ℓ,k)-game*. This game is defined for a homomorphism-closed class $\mathcal{C}$ of finite τ-structures, and it is played by the two players Spoiler and Duplicator on a finite τ-structure $\mathfrak{A}$ as follows.

- Duplicator picks a countable τ-structure $\mathfrak{B}$ such that $\mathrm{CSP}(\mathfrak{B}) \cap \mathcal{C} = \emptyset$.
- The game then continues as the existential (ℓ,k) pebble game played by Spoiler and Duplicator on $(\mathfrak{A},\mathfrak{B})$.

In Section 4 we show that a GSO sentence Φ is over finite structures equivalent to a Datalog program of width (ℓ, k) if and only if

- $[\![\Phi]\!]$ is closed under homomorphisms, and
- Spoiler wins the existential (ℓ, k)-game for $[\![\Phi]\!]$ on $\mathfrak{A}$ if and only if $\mathfrak{A} \models \Phi$.

We also show that for every GSO sentence Φ whose class of finite models $\mathcal{C}$ is closed under homomorphisms and for all $\ell, k \in \mathbb{N}$ there exists a canonical Datalog program Π of width (ℓ, k) for $\mathcal{C}$ (Theorem 22). To prove these results, we first show that every class of finite structures in GSO whose complement is closed under homomorphisms is a finite union of CSPs that can also be expressed in GSO (Lemma 16; an analogous statement holds for MSO). Moreover, every CSP in GSO is the CSP of a countable ω-categorical structure (Corollary 10); this allows us to use results from [7] to make the link to existential pebble games. We also present an example of such a CSP which is even expressible in MSO and coNP-complete, and hence not the CSP of a reduct of a finitely bounded homogeneous structure, unless NP=coNP (Proposition 23). Note that our results imply that every class of finite structures that can be expressed both in in GSO and in Datalog is a finite intersection of the complements of CSPs for ω-categorical structures. In general, it is not true that a Datalog program describes a finite intersection of complements of CSPs (we present a counterexample in Example 18).

2 Preliminaries

In the entire text, τ denotes a finite signature containing relation symbols and sometimes also constant symbols. If $R \in \tau$ is a relation symbol, we write $ar(R)$ for its arity. If $\mathfrak{A}$ is a τ-structure we use the corresponding capital roman A letter to denote the domain of $\mathfrak{A}$; the domains of structures are assumed to be non-empty. If $R \in \tau$, then $R^{\mathfrak{A}} \subseteq A^{ar(R)}$ denotes the corresponding relation of $\mathfrak{A}$.

A *primitive positive τ-formula* (in database theory also *conjunctive query*) is a first-order τ-formula without disjunction, negation, and universal quantification. Every primitive positive formula is equivalent to a formula of the form

$$\exists x_1, \dots, x_n (\psi_1 \wedge \cdots \wedge \psi_m)$$

where $\psi_1, \dots, \psi_m$ are atomic τ-formulas, i.e., formulas built from relation symbols in τ or equality. An *existential positive τ-formula* is a first-order τ-formula without negation and universal quantification. We write $\psi(x_1 \dots, x_n)$ if the free variables of ψ are from $x_1, \dots, x_n$. If $\mathfrak{A}$ is a τ-structure and $\psi(x_1, \dots, x_n)$ is a τ-formula, then the relation

$$R := \{(a_1, \dots, a_n) \mid \mathfrak{A} \models \psi(a_1, \dots, a_n)\}$$

is called the relation *defined by ψ over $\mathfrak{A}$*; if ψ can be chosen to be primitive positive (or existential positive) then R is called *primitively positively definable* (or *existentially positively definable*, respectively).

For all logics over the signature τ considered in this text, we say that two formulas $\Phi(x_1, \dots, x_n)$ and $\Psi(x_1, \dots, x_n)$ are *equivalent (over finite structures)* if for all (finite) τ-structures $\mathfrak{A}$ and all $a_1, \dots, a_n \in A$ we have

$$\mathfrak{A} \models \Phi(a_1, \dots, a_n) \Leftrightarrow \mathfrak{A} \models \Psi(a_1, \dots, a_n).$$

It is easy to see that every existential positive τ-formula is a disjunction of primitive positive τ-formulas (and hence referred to as a *union of conjunctive queries* in database theory). Formulas without free variables are called *sentences*; in database theory, formulas are often called *queries* and sentences are often called *Boolean queries*. If Φ is a sentence, we write $[\![\Phi]\!]$ for the class of all finite models of Φ.

A *reduct* of a relational structure $\mathfrak{A}$ is a structure $\mathfrak{A}'$ obtained from $\mathfrak{A}$ by dropping some of the relations, and $\mathfrak{A}$ is called an *expansion* of $\mathfrak{A}'$.

2.1 Datalog

In this section we refer to the finite set of relation and constant symbols τ as *EDBs* (for *extensional database predicates*). Let ρ be a finite set of new relation symbols, called the *IDBs* (for *intensional database predicates*). A Datalog program is a set of rules of the form

$$\psi_0 :- \psi_1, \ldots, \psi_n$$

where ψ_0 is an atomic ρ-formula and $\psi_1, \ldots, \psi_n$ are atomic $(\rho \cup \tau)$-formulas; we also assume that every variable that appears in the head also appears in the body. If $\mathfrak{A}$ is a τ-structure, and Π is a Datalog program with EDBs τ and IDBs ρ, then a $(\tau \cup \rho)$-expansion $\mathfrak{A}'$ of $\mathfrak{A}$ is called a *fixed point of* Π *on* $\mathfrak{A}$ if $\mathfrak{A}'$ satisfies the sentence

$$\forall \bar{x}(\psi_0 \vee \neg\psi_1 \vee \cdots \vee \neg\psi_n)$$

for each rule $\psi_0 :- \psi_1, \ldots, \psi_n$. If $\mathfrak{A}_1$ and $\mathfrak{A}_2$ are two $(\rho \cup \tau)$-structures with the same domain A, then $\mathfrak{A}_1 \cap \mathfrak{A}_2$ denotes the $(\rho \cup \tau)$-structure with domain A such that $R^{\mathfrak{A}_1 \cap \mathfrak{A}_2} := R^{\mathfrak{A}_1} \cap R^{\mathfrak{A}_2}$. Note that if $\mathfrak{A}_1$ and $\mathfrak{A}_2$ are two fixed points of Π on $\mathfrak{A}$, then $\mathfrak{A}_1 \cap \mathfrak{A}_2$ is a fixed point of Π on $\mathfrak{A}$, too. Hence, there exists a unique smallest (with respect to inclusion) fixed point of Π on $\mathfrak{A}$, which we denote by $\Pi(\mathfrak{A})$. It is well-known that if $\mathfrak{A}$ is a finite structure then $\Pi(\mathfrak{A})$ can be computed in polynomial time in the size of $\mathfrak{A}$ [24]. If $R \in \rho$, we also say that Π *defines* $R^{\Pi(\mathfrak{A})}$ *on* $\mathfrak{A}$. A Datalog program together with a distinguished predicate $R \in \rho$ may also be viewed as a formula, which we also call a *Datalog query*, and which over a given τ-structure $\mathfrak{A}$ denotes the relation $R^{\Pi(\mathfrak{A})}$. If the distinguished predicate has arity 0, we often call it the *goal predicate*; we say that Π *derives* goal *on* $\mathfrak{A}$ if $\mathsf{goal}^{\Pi(\mathfrak{A})} = \{()\}$. The class $\mathcal{C}$ of finite τ-structures $\mathfrak{A}$ such that Π derives goal on $\mathfrak{A}$ is called *the class of finite τ-structures defined by* Π, and denoted by $[\![\Pi]\!]$. Note that this class $\mathcal{C}$ is definable in universal second-order logic (we have to express that in every expansion of the input by relations for the IDBs that satisfies all the rules of the Datalog program the goal predicate is non-empty).

2.2 Second-Order Logic

Second-order logic is the extension of first-order logic which additionally allows existential and universal quantification over relations; that is, if R is a relation symbol and ϕ is a second-order $\tau \cup \{R\}$-formula, then $\exists R\colon \phi$ and $\forall R\colon \phi$ are second-order τ-formulas. If $\mathfrak{A}$ is a τ-structure and Φ is a second-order τ-sentence, we write $\mathfrak{A} \models \Phi$ (and say that $\mathfrak{A}$ is a model of Φ) if $\mathfrak{A}$ satisfies Φ, which is defined in the usual Tarskian style. We write $[\![\Phi]\!]$ for the class of all finite models of Φ. A second-order formula is called *monadic* if all second-order variables are unary. We use syntactic sugar and also write $\forall x \in X\colon \psi$ instead of $\forall x(X(x) \Rightarrow \psi)$ and $\exists x \in X\colon \psi$ instead of $\exists x(X(x) \wedge \psi)$.

2.3 Guarded Second-Order Logic

Guarded Second-order Logic (GSO), introduced by Grädel, Hirsch, and Otto [21], is the extension of *guarded first-order logic* by second-order quantifiers. Guarded (first-order) τ-formulas are defined inductively by the following rules [1]:

1. all atomic τ-formulas are guarded τ-formulas;
2. if ϕ and ψ are guarded τ-formulas, then so are $\phi \wedge \psi$, $\phi \vee \psi$, and $\neg\phi$.
3. if $\psi(\bar{x}, \bar{y})$ is a guarded τ-formula and $\alpha(\bar{x}, \bar{y})$ is an atomic τ-formula such that all free variables of ψ occur in α then $\exists\bar{y}\big(\alpha(\bar{x}, \bar{y}) \wedge \psi(\bar{x}, \bar{y})\big)$ and $\forall\bar{y}\big(\alpha(\bar{x}, \bar{y}) \Rightarrow \psi(\bar{x}, \bar{y})\big)$ are guarded τ-formulas.

Guarded second-order formulas are defined similarly, but we additionally allow (unrestricted) second-order quantification; GSO generalises Courcelle's logic MSO_2 from graphs to general relational structures.

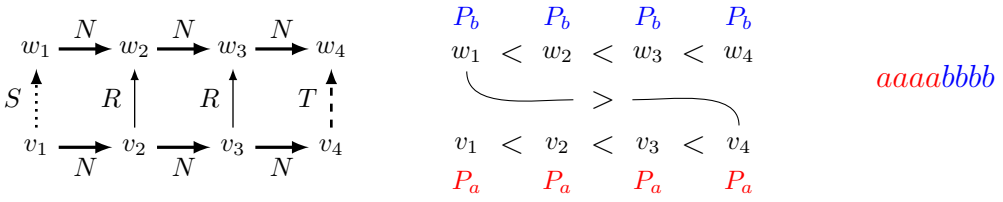
▶ **Definition 1.** *A second-order τ-formula is called* guarded *if it is defined inductively by the rules (1)–(3) for guarded first-order logic and additionally by second-order quantification.*

There are many semantically equivalent ways of introducing GSO [21]. Let $\mathfrak{B}$ be a τ-structure. Then $(t_1, \ldots, t_n) \in B^n$ is called *guarded in* $\mathfrak{B}$ if there exists an atomic τ-formula ϕ and $b_1, \ldots, b_k$ such that $\mathfrak{B} \models \phi(b_1, \ldots, b_k)$ and $\{t_1, \ldots, t_n\} \subseteq \{b_1, \ldots, b_k\}$. Note that (for $n = 1$) every element of B is guarded (because of the atomic formula $x = x$). A relation $R \subseteq B^n$ is called *guarded* if all tuples in R are guarded. Note that all unary relations are guarded. If Ψ is an arbitrary second-order sentence, we say that a finite structure $\mathfrak{A}$ *satisfies* Ψ *with guarded semantics*, in symbols $\mathfrak{A} \models_g \Phi$, if all second-order quantifiers in Ψ are evaluated over guarded relations only. Note that for MSO sentences, the usual semantics and the guarded semantics coincide.

▶ **Proposition 2** (see [21])**.** *Guarded Second-order Logic and full Second-order Logic with guarded semantics are equally expressive.*

It follows that GSO is at least as expressive as MSO. There are Datalog programs that are equivalent to a GSO sentence, but not to an MSO sentence. The proof is based on a variant of an example of a Datalog query in GSO given in [13] (Example 2).

▶ **Proposition 3.** *There is a Datalog query that can be expressed in GSO but not in MSO.*



Proof. Let τ be the signature consisting of the binary relation symbols S, T, R, N, and let $\mathcal{C}$ be the class of finite τ-structures such that the following Datalog program with one binary IDB U derives goal.

$$
\begin{aligned}
U(x, y) &:\!- S(x, y) \\
U(x', y') &:\!- U(x, y), N(x, x'), N(y, y'), R(x', y') \\
\mathsf{goal} &:\!- U(x, y), T(x, y)
\end{aligned}
$$

◀

On the left of Figure 1 one can find an example of a $\{S, T, R, N\}$-structure $\mathfrak{B}$ where the given Datalog program derives goal. To show that $\mathcal{C}$ is not MSO definable, suppose for contradiction that there exists an MSO sentence Φ such that $[\![\Phi]\!] = \mathcal{C}$. We use Φ to construct an MSO sentence Ψ which holds on a finite word $w \in \{a, b\}^*$ (represented as a structure with signature $P_a, P_b, <$ in the usual way [24]) if and only if $w \in \{a^n b^n \mid n \geq 1\}$; this contradicts the theorem of Büchi-Elgot-Trakhtenbrot (see, e.g., [24]). Let Φ' be the MSO sentence obtained from Φ by replacing all subformulas of Φ of the form

- $S(x, y)$ by a formula $\phi_S(x, y)$ that states that x is the smallest element with respect to $<$, that $P_b(y)$, and that there is no $z < y$ in P_b;
- $T(x, y)$ by a formula $\phi_T(x, y)$ that states that $P_a(x)$, that there is no $z > x$ in P_a, and that y is the largest element with respect to $<$;
- $R(x, y)$ by the formula $\phi_R(x, y)$ given by $x < y$;
- $N(x, y)$ by a formula $\phi_N(x, y)$ stating that y is the next element after x with respect to $<$.

(a) Structure $\mathfrak{B}$ **(b)** Structure $\mathfrak{A}$ **(c)** Word $w_{\mathfrak{A}}$

Figure 1 An example of an $\{S, T, R, N\}$-structure $\mathfrak{B}$ in the class $\mathcal{C}$ of Proposition 3.

The resulting MSO sentence Ψ_1 has the signature $\{P_a, P_b, <\}$; let Ψ be the conjunction of Ψ_1 with the sentence Ψ_2 which states that for all $x, y \in A$, if $x < y$ and $P_a(y)$ then $P_a(x)$. We first show that if $\mathfrak{A}$ is a $\{<, P_a, P_b\}$-structure that represents a word $w_{\mathfrak{A}} \in \{a, b\}^*$, then $\mathfrak{A} \models \Psi$ if and only if $w_{\mathfrak{A}}$ is of the form $a^n b^n$ for some $n \geq 1$. Let $\mathfrak{B}$ be the $\{S, T, R, N\}$-structure such that for $X \in \{S, T, R, N\}$ we have $X^{\mathfrak{B}} := \{(x, y) \mid \mathfrak{A} \models \phi_X(x, y)\}$. See Figure 1 for an example of a structure $\mathfrak{A}$ such that $w_{\mathfrak{A}} = a^4 b^4$ and the corresponding $\{S, T, R, N\}$-structure $\mathfrak{B}$.

If $w_{\mathfrak{A}}$ is of the form $a^n b^n$ for some $n \geq 1$, then $\mathfrak{A}$ clearly satisfies Ψ_2. To show that it also satisfies Ψ_1, let $v_1, \ldots, v_n, w_1, \ldots, w_n \in A$ be such that $\{v_1, \ldots, v_n\} = P_a^{\mathfrak{A}}$ and $\{w_1, \ldots, w_n\} = P_b^{\mathfrak{A}}$ such that for all $i, j \in \{1, \ldots, n\}$, if $i < j$ then $v_i <^{\mathfrak{A}} v_j$ and $w_i <^{\mathfrak{A}} w_j$. Then

$$\begin{aligned} &(v_1, w_1) \in S^{\mathfrak{B}}, \qquad (v_n, w_n) \in T^{\mathfrak{B}}, \\ &(v_i, w_i) \in R^{\mathfrak{B}} \text{ for all } i \in \{2, \ldots, n-1\}, \\ &(v_i, v_{i+1}), (w_i, w_{i+1}) \in N^{\mathfrak{B}} \text{ for all } i \in \{1, \ldots, n-1\}. \end{aligned} \tag{1}$$

It follows that $\mathfrak{B}$ satisfies Φ and therefore $\mathfrak{A} \models \Psi$.

For the converse direction, suppose that $\mathfrak{A} \models \Psi$. Clearly, $w_{\mathfrak{A}} \in a^* b^*$ because $\mathfrak{A} \models \Psi_2$. Moreover, since $\mathfrak{A} \models \Psi_1$ we have that $\mathfrak{B} \models \Phi$, and hence there exist $n \in \mathbb{N}$ and elements $v_1, \ldots, v_n, w_1, \ldots, w_n \in A$ such that $\mathfrak{B}$ satisfies (1). We first prove that $P_a^{\mathfrak{A}} = \{v_1, \ldots, v_n\}$ and $|P_a^{\mathfrak{A}}| = n$. Since $(v_n, w_n) \in T^{\mathfrak{B}}$ we have $\phi_T(v_n, w_n)$ and hence $v_n \in P_a^{\mathfrak{A}}$. Since $\mathfrak{B} \models N(v_1, v_2), \ldots, N(v_{n-1}, v_n)$ we have that $v_1 < v_2 < \cdots < v_{n-1} < v_n$ holds in $\mathfrak{A}$ and it also follows that $|P_a^{\mathfrak{A}}| = n$. Then for every $i \in n$ we have that $v_i \in P_a^{\mathfrak{A}}$ because $v_i \leq v_n$, $v_n \in P_a^{\mathfrak{A}}$, and $w_{\mathfrak{A}} \in a^* b^*$. Now suppose for contradiction that there exists $x \in P_a^{\mathfrak{A}} \setminus \{v_1, \ldots, v_n\}$; choose x largest with respect to $<^{\mathfrak{A}}$. Since $(v_n, w_n) \in T^{\mathfrak{B}}$ and $x \in P_a^{\mathfrak{A}}$ we must have $x \leq v_n$, and hence $x < v_n$ since $x \notin \{v_1, \ldots, v_n\}$. Then there exists $y \in A$ such that $\phi_N(x, y)$ holds in $\mathfrak{A}$. Since $y \leq v_n$, $v_n \in P_a^{\mathfrak{A}}$, and $w_{\mathfrak{A}} \in a^* b^*$, we must have $P_a^{\mathfrak{A}}$. By the maximal choice of x we get that $y = v_i$ for some $i \in \{1, \ldots, n\}$. But then $\phi_N(x, v_i)$ implies that $x \in \{v_1, \ldots, v_{n-1}\}$, a contradiction. Similarly, one can prove that $P_b^{\mathfrak{A}} = \{w_1, \ldots, w_n\}$ and that $|P_b^{\mathfrak{A}}| = n$. This implies that $w_{\mathfrak{A}} = a^n b^n$.

We finally have to prove that $\mathcal{C}$ is in GSO. Let Φ be the GSO $\{S, T, R, N\}$ sentence with existentially quantified unary relations V, W, and existentially quntified binary relations $R' \subseteq R$ and $N' \subseteq N$, which states that

- there are elements $v_1, v_n \in V$ and $w_1, w_n \in W$ such that $S(v_1, w_1)$ and $T(v_n, w_n)$ hold;
- for every $x \in V \setminus \{v_1\}$ there exists a unique element $y \in V \setminus \{v_n\}$ such that $N'(y, x)$ holds;
- for every $x \in V \setminus \{v_n\}$ there exists a unique element $y \in V \setminus \{v_1\}$ such that $N'(x, y)$ holds;

- for every $x \in W \setminus \{w_1\}$ there exists a unique element $y \in W \setminus \{w_n\}$ such that $N'(y, x)$ holds;
- for every $x \in W \setminus \{w_n\}$ there exists a unique element $y \in W \setminus \{w_1\}$ such that $N'(x, y)$ holds;
- for all $v \in V$ and $w \in W$ we have that $N'(v_1, v) \wedge N'(w_1, w)$ implies $R'(v, w)$.
- for all $v, v' \in V \setminus \{v_1, v_n\}$ and $w, w' \in W \setminus \{w_1, w_n\}$ we have that $R'(v, w) \wedge N'(v, v') \wedge N'(w, w')$ implies $R'(v, w)$.
- For all $v \in V$ and $w \in W$ we have that $N'(v, v_n) \wedge N'(w, w_n)$ implies $R'(v, w)$.

Then Φ holds on a finite $\{S, T, R, N\}$-structure $\mathfrak{B}$ if and only if B has elements $v_1, \ldots, v_n, w_1, \ldots, w_n$ satisfying (1), which is the case if and only if $\mathfrak{B} \in \mathcal{C}$.

Sometimes, we will also use the term GSO (MSO, Datalog) to denote all problems (i.e., all classes of structures) that can be expressed in the formalism. In particular, this justifies to say that a certain CSP is *in* GSO (MSO, Datalog).

3 Homomorphism-Closed GSO

We prove that the class of finite models of a GSO sentence is a finite union of CSPs of ω-categorical structures whenever its complement is closed under homomorphisms. In particular, every CSP in GSO (and therefore every CSP in MSO) is the CSP of an ω-categorical structure. CSPs that can be formulated as the CSP of an ω-categorical structure have been characterised [10]; this characterisation will be recalled in the next section.

3.1 CSPs for Countably Categorical Structures

By the theorem of Ryll-Nardzewski, a countable structure $\mathfrak{B}$ is ω-categorical if and only if for every $n \in \mathbb{N}$ there are finitely many orbits of the componentwise action of the automorphism group of $\mathfrak{B}$ on B^n (see, e.g., [22]). We now present a condition that characterises classes of structures that are CSPs of ω-categorical structures. Let $\mathcal{C}$ be a class of finite τ-structures. Let Λ_n be the class of primitive positive τ-formulas with free variables $x_1, \ldots, x_n$ whose canonical database is in $\mathcal{C}$. We define $\sim_n^{\mathcal{C}}$ to be the equivalence relation on Λ_n such that $\phi_1 \sim_n^{\mathcal{C}} \phi_2$ holds if for all primitive positive τ-formulas $\psi(x_1, \ldots, x_n)$ we have that $\phi_1(x_1, \ldots, x_n) \wedge \psi(x_1, \ldots, x_n)$ is satisfiable in a structure from $\mathcal{C}$ if and only if $\phi_2(x_1, \ldots, x_n) \wedge \psi(x_1, \ldots, x_n)$ is satisfiable in a structure from $\mathcal{C}$. The *index* of an equivalence relation is the number of its equivalence classes.

▶ **Theorem 4** (Bodirsky, Hils, Martin [10], Theorem 4.27). *Let $\mathcal{C}$ be a constraint satisfaction problem. Then there is an ω-categorical structure $\mathfrak{B}$ such that $\mathcal{C} = \mathrm{CSP}(\mathfrak{B})$ iff $\sim_n^{\mathcal{C}}$ has finite index for all n. Moreover, the structure $\mathfrak{B}$ can be chosen so that for all $n \in \mathbb{N}$ the orbits of the componentwise action of the automorphism group of $\mathfrak{B}$ on B^n are primitively positively definable in $\mathfrak{B}$.*

▶ **Example 5.** The structure $\mathfrak{B}_1 := (\mathbb{Z}; <)$ is not ω-categorical. However, $\sim_n^{\mathrm{CSP}(\mathfrak{B}_1)}$ has finite index for all n, and indeed $\mathrm{CSP}(\mathbb{Z}; <) = \mathrm{CSP}(\mathbb{Q}; <)$ and $(\mathbb{Q}; <)$ is ω-categorical. On the other hand, for $\mathfrak{B}_2 := (\mathbb{Z}; \mathrm{Succ})$ we have that the index $\sim_2^{\mathrm{CSP}(\mathfrak{B}_2)}$ is infinite, and it follows that there is no ω-categorical structure $\mathfrak{B}$ such that $\mathrm{CSP}(\mathfrak{B}_2) = \mathrm{CSP}(\mathfrak{B})$; see [6].

A rich source of examples of ω-categorical structures are structures with finite relational signature that are *homogeneous*, i.e., every isomorphism between finite substructures can be extended to an automorphism. There are uncountably many countable homogeneous

digraphs with pairwise distinct CSP, and it follows that there are homogeneous digraphs with undecidable CSPs. A structure $\mathfrak{B}$ is called *finitely bounded* if there exists a finite set $\mathcal{F}$ of finite structures such that a finite structure $\mathfrak{A}$ embeds into $\mathfrak{B}$ if and only if no structure in $\mathcal{F}$ embeds into $\mathfrak{A}$.

It is well-known that if a structure is ω-categorical, then all of its *reducts* are ω-categorical as well [22]. Moreover, it is easy to see that the CSP of reducts of finitely bounded structures is in NP. It has been conjectured that the CSP of reducts of finitely bounded homogeneous structures is in P or NP-complete [12]; this conjecture generalises the finite-domain complexity dichotomy that was conjectured by Feder and Vardi [19] and proved by Bulatov [14] and by Zhuk [26].

3.2 Quantifier Rank

In order to construct ω-categorial structures for a given CSP in GSO, we need to verify the condition given in Theorem 4; in this context, it will be convenient to work with signatures that also contain constant symbols. The *quantifier rank* of a second-order τ-formula Φ is the maximal number of nested (first-order or second-order) quantifiers in Φ; for this definition, we view Φ as a second-order sentence with guarded semantics, just as in [5]. If $\mathfrak{A}$ and $\mathfrak{B}$ are τ-structures and $q \in \mathbb{N}$ we write $\mathfrak{A} \equiv_q^{\mathrm{GSO}} \mathfrak{B}$ if $\mathfrak{A}$ and $\mathfrak{B}$ satisfy the same GSO τ-sentences of quantifier rank at most q.

▶ **Lemma 6** (Proposition 3.3 in [5]). *Let $q \in \mathbb{N}$ and τ be a finite signature with relation and constant symbols. Then $\equiv_q^{\mathrm{GSO}}$ is an equivalence relation with finite index on the class of all finite τ-structures. Moreover, every class of $\equiv_q^{\mathrm{GSO}}$ can be defined by a single GSO sentence with quantifier rank q. The analogous statements hold for MSO as well.*

If $\mathfrak{A}$ is a τ-structure and $\bar{a}$ is a k-tuple of elements of A, then we write $(\mathfrak{A}, \bar{a})$ for a $\tau \cup \{c_1, \dots, c_k\}$-structure expanding $\mathfrak{A}$ where $c_1, \dots, c_k$ denote fresh constant symbols being mapped to the corresponding entries of $\bar{a}$. If $\mathfrak{A}$ and $\mathfrak{B}$ are τ-structures and $\bar{a} \in A^k$, $\bar{b} \in B^k$, and when writing $(\mathfrak{A}, \bar{a}) \equiv_q^{\mathrm{GSO}} (\mathfrak{B}, \bar{b})$ we implicitly assume that we have chosen the same constant symbols for $\bar{a}$ and for $\bar{b}$.

▶ **Lemma 7** (Proposition 3.4 in [5]). *Let $q \in \mathbb{N}$ and let $\mathfrak{A}$ and $\mathfrak{B}$ be τ-structures. Then $\mathfrak{A} \equiv_{q+1}^{\mathrm{GSO}} \mathfrak{B}$ if and only if the following properties hold:*

- *(first-order forth) For every $a \in A$, there exists $b \in B$ such that $(\mathfrak{A}, a) \equiv_q^{\mathrm{GSO}} (\mathfrak{B}, b)$.*
- *(first-order back) For every $b \in B$, there exists $a \in A$ such that $(\mathfrak{A}, a) \equiv_q^{\mathrm{GSO}} (\mathfrak{B}, b)$.*
- *(second-order forth) For every expansion $\mathfrak{A}'$ of $\mathfrak{A}$ by a guarded relation, there exists an expansion $\mathfrak{B}'$ of $\mathfrak{B}$ by a guarded relation such that $\mathfrak{A}' \equiv_q^{\mathrm{GSO}} \mathfrak{B}'$.*
- *(second-order back) For every expansion $\mathfrak{B}'$ of $\mathfrak{B}$ by a guarded relation, there exists an expansion $\mathfrak{A}'$ of $\mathfrak{A}$ by a guarded relation such that $\mathfrak{A}' \equiv_q^{\mathrm{GSO}} \mathfrak{B}'$.*

In the following, τ denotes a finite relational signature.

▶ **Definition 8.** *Let $\rho := \{c_1, \dots, c_n\}$ be a finite set of constant symbols. Then $\mathcal{D}_n$ is defined to be the set of all pairs $(\mathfrak{A}, \mathfrak{B})$ of finite $(\tau \cup \rho)$-structures such that*

- *$c^{\mathfrak{A}} = c^{\mathfrak{B}}$ for all constant symbols $c \in \rho$;*
- *$\{c_1^{\mathfrak{A}}, \dots, c_n^{\mathfrak{A}}\} = A \cap B = \{c_1^{\mathfrak{B}}, \dots, c_n^{\mathfrak{B}}\}$.*

We write $\mathfrak{A} \uplus \mathfrak{B}$ for the structure with domain $A \cup B$ such that $R^{\mathfrak{A} \uplus \mathfrak{B}} := R^{\mathfrak{A}} \cup R^{\mathfrak{B}}$ for each relation symbol $R \in \tau$ and $c^{\mathfrak{A} \uplus \mathfrak{B}} = c^{\mathfrak{A}} = c^{\mathfrak{B}}$ for each constant symbol $c \in \rho$.

The following theorem in the special case of $n = 0$ is Proposition 4.1 in [5].

▶ **Theorem 9.** *Let $q, n, r, s \in \mathbb{N}$, let $(\mathfrak{A}_1, \mathfrak{B}_1), (\mathfrak{A}_2, \mathfrak{B}_2) \in \mathcal{D}_n$, and let $\bar{a}_1 \in (A_1)^r$, $\bar{a}_2 \in (A_2)^r$, $\bar{b}_1 \in (B_1)^s$, $\bar{b}_2 \in (B_2)^s$ be such that $(\mathfrak{A}_1, \bar{a}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{A}_2, \bar{a}_2)$ and $(\mathfrak{B}_1, \bar{b}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{B}_2, \bar{b}_2)$. Then*

$$(\mathfrak{A}_1 \uplus \mathfrak{B}_1, \bar{a}_1, \bar{b}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{A}_2 \uplus \mathfrak{B}_2, \bar{a}_2, \bar{b}_2).$$

Proof. Our proof is by induction on q. Every quantifier-free formula is a Boolean combination of atomic formulas, so for $q = 0$ it suffices to consider atomic formulas ϕ. By symmetry, it suffices to show that if $(\mathfrak{A}_1 \uplus \mathfrak{B}_1, \bar{a}_1, \bar{b}_1) \models \phi$ then $(\mathfrak{A}_2 \uplus \mathfrak{B}_2, \bar{a}_2, \bar{b}_2) \models \phi$. Then ϕ is built using a relation symbol $R \in \tau$, and the tuple that witnesses the truth of ϕ in $\mathfrak{A}_1 \uplus \mathfrak{B}_1$ must be from $R^{\mathfrak{A}_1}$ or from $R^{\mathfrak{B}_1}$, by the definition of $\mathfrak{A}_1 \uplus \mathfrak{B}_1$. We first consider the former case; the latter case can be treated similarly. If a constant that appears in ϕ is from $A_1 \cap B_1$, then by the definition of $\mathcal{D}_n$ this element is denoted by a constant symbol $c \in \rho$, and therefore we may assume without loss of generality that ϕ is a formula over the signature of $(\mathfrak{A}_1, \bar{a}_1)$. Hence, $(\mathfrak{A}_1, \bar{a}_1) \models \phi$ and by assumption $(\mathfrak{A}_2, \bar{a}_2) \models \phi$. This in turn implies that $(\mathfrak{A}_2 \uplus \mathfrak{B}_2, \bar{a}_2, \bar{b}_2) \models \phi$.

For the inductive step, suppose that the claim holds for q, and that $(\mathfrak{A}_1, \bar{a}_1) \equiv_{q+1}^{\mathrm{GSO}} (\mathfrak{A}_2, \bar{a}_2)$ and $(\mathfrak{B}_1, \bar{b}_1) \equiv_{q+1}^{\mathrm{GSO}} (\mathfrak{B}_2, \bar{b}_2)$. By symmetry and Lemma 7 it suffices to verify the properties (first-order forth) and (second-order forth). Let $c_1 \in A_1 \cup B_1$. We may assume that $c_1 \in A_1$; the case that $c_1 \in B_1$ can be shown similarly. By Lemma 7, there exists $c_2 \in A_2$ such that $(\mathfrak{A}_1, \bar{a}_1, c_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{A}_2, \bar{a}_2, c_2)$. By the inductive assumption, this implies that

$$(\mathfrak{A}_1 \uplus \mathfrak{B}_1, \bar{a}_1, c_1, \bar{b}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{A}_2 \uplus \mathfrak{B}_2, \bar{a}_2, c_2, \bar{b}_2)$$

and concludes the proof of (first-order forth).

Now let R be a guarded relation of $\mathfrak{A}_1 \uplus \mathfrak{B}_1$ of arity k. Let $\mathfrak{A}_1'$ be the expansion of $\mathfrak{A}_1$ by the guarded relation $R \cap A_1^k$, and $\mathfrak{B}_1'$ be the expansion of $\mathfrak{B}_1$ by the guarded relation $R \cap B_1^k$. By Lemma 7 there are expansions $\mathfrak{A}_2'$ of $\mathfrak{A}$ and $\mathfrak{B}_2'$ of $\mathfrak{B}_2$ by guarded relations such that $(\mathfrak{A}_1', \bar{a}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{A}_2', \bar{a}_2)$ and $(\mathfrak{B}_1', \bar{b}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{B}_2', \bar{b}_2)$. By the inductive assumption, this implies that $(\mathfrak{A}_1' \uplus \mathfrak{B}_1', \bar{a}_1, \bar{b}_1) \equiv_q^{\mathrm{GSO}} (\mathfrak{A}_2' \uplus \mathfrak{B}_2', \bar{a}_2, \bar{b}_2)$, which completes the proof of (second-order forth). ◀

▶ **Corollary 10.** *Let $\mathcal{C}$ be a CSP that can be expressed in GSO. Then there exists a countable ω-categorical structure $\mathfrak{B}$ such that $\mathcal{C} = \mathrm{CSP}(\mathfrak{B})$.*

Proof. Let τ be the signature of $\mathcal{C}$, and let Φ be a GSO τ-formula with quantifierrank q such that $\mathcal{C} = [\![\Phi]\!]$. By Theorem 4 it suffices to show that the equivalence relation $\sim_n^{\mathcal{C}}$ has finite index for every $n \in \mathbb{N}$. Let $\rho := \{c_1, \ldots, c_n\}$ be a set of new constant symbols. By Lemma 6, there exists an $m \in \mathbb{N}$ such that $\equiv_q^{\mathrm{GSO}}$ has m equivalence classes on $(\tau \cup \rho)$-structures. If $\phi(x_1, \ldots, x_n)$ is a primitive positive τ-formula, then define $\mathfrak{S}_\phi$ to be the $(\tau \cup \rho)$-structure whose elements are the equivalence classes of the smallest equivalence relation on the variables of ϕ that contains all pairs x, y such that ϕ contains the conjunct $x = y$, and such that $(C_1, \ldots, C_n) \in R^{\mathfrak{S}}$ for $R \in \tau$ if and only if there are $y_1 \in C_1, \ldots, y_n \in C_2$ such that $R(y_1, \ldots, y_n)$ is a conjunct of ϕ; finally, we set $c_i^{\mathfrak{S}_\phi} := [x_i]$ for all $i \in \{1, \ldots, n\}$.

We claim that if $\mathfrak{S}_\phi \equiv_q^{\mathrm{GSO}} \mathfrak{S}_\psi$, then $\phi \sim_n^{\mathcal{C}} \psi$. Let $\theta(x_1, \ldots, x_n)$ be a primitive positive τ-formula; we may assume that the existentially quantified variables of θ are disjoint from the existentially quantified variables of ϕ and of ψ, so that $(\mathfrak{S}_\phi, \mathfrak{S}_\theta), (\mathfrak{S}_\psi, \mathfrak{S}_\theta) \in \mathcal{D}_n$. Since $\mathfrak{S}_\phi \equiv_q^{\mathrm{GSO}} \mathfrak{S}_\psi$ and $\mathfrak{S}_\theta \equiv_q^{\mathrm{GSO}} \mathfrak{S}_\theta$, we have $\mathfrak{S}_\phi \uplus \mathfrak{S}_\theta \equiv_q^{\mathrm{GSO}} \mathfrak{S}_\psi \uplus \mathfrak{S}_\theta$ by Theorem 9. Now suppose that $\phi \wedge \theta$ is satisfiable in a model of Φ. This is the case if and only if $\mathfrak{S}_\phi \uplus \mathfrak{S}_\theta$ satisfies Φ, which in turn implies that $\mathfrak{S}_\psi \uplus \mathfrak{S}_\theta$ satisfies Φ since Φ has quantifierrank q. This in turn is the case if and only if $\psi \wedge \theta$ is satisfiable in a model of Φ, which proves the claim.

The claim implies that $\sim_n^{\mathcal{C}}$ has at most m equivalence classes, concluding the proof. ◀

▶ **Example 11.** Let Φ be the following MSO sentence.

$$\forall X \big(\exists x\colon X(x) \Rightarrow \exists x, y \in X\ \forall z \in X(\neg E(x,z) \vee \neg E(y,z))\big)$$

It is easy to see that $[\![\Phi]\!]$ is closed under disjoint unions and that its complement is closed under homomorphisms. Corollary 10 implies that there exists a countable ω-categorical structure with $\mathrm{CSP}(\mathfrak{B}) = [\![\Phi]\!]$.

3.3 Finite Unions of CSPs

In this section we prove that every class in GSO whose complement is closed under homomorphisms is a finite union of CSPs (Lemma 16); the statement announced at the beginning of Section 3 then follows (Corollary 17). Throughout this section, let $\mathcal{C}$ be a non-empty class of finite τ-structures whose complement is closed under homomorphisms. In particular, $\mathcal{C}$ contains the structure $\mathfrak{I}$ with only one element where all relations are empty.

Let $\sim$ be the equivalence relation defined on $\mathcal{C}$ by letting $\mathfrak{A} \sim \mathfrak{B}$ if for every $\mathfrak{C} \in \mathcal{C}$ we have $\mathfrak{A} \uplus \mathfrak{C} \in \mathcal{C}$ if and only if $\mathfrak{B} \uplus \mathfrak{C} \in \mathcal{C}$; here $\uplus$ denotes the usual disjoint union of structures, which is a special case of Definition 8 for $n = 0$. Note that the equivalence classes of $\sim$ are in one-to-one correspondence to the equivalence classes of $\sim_0^{\mathcal{C}}$. Also note that $\mathcal{C}$ is closed under disjoint unions if and only if $\sim$ has only one equivalence class.

If $\mathfrak{A} \in \mathcal{C}$, then we write $[\mathfrak{A}]$ for the equivalence class of $\mathfrak{A}$ with respect to $\sim$. The following observations are immediate consequences from the definitions:

1. each $\sim$-equivalence class is closed under homomorphic equivalence.
2. each $\sim$-equivalence class is closed under disjoint unions.
3. $\mathfrak{A} \in [\mathfrak{I}]$ if and only if $\mathfrak{A} \uplus \mathfrak{B} \in \mathcal{C}$ for all $\mathfrak{B} \in \mathcal{C}$.

▶ **Lemma 12.** *Let $\mathfrak{A} \in \mathcal{C}$ and let $\mathcal{D}$ be the smallest subclass of $\mathcal{C}$ that contains $[\mathfrak{A}]$ and whose complement is closed under homomorphisms. Then*

1. *$\mathcal{D}$ is a union of equivalence classes of $\sim$, and*
2. *if $\sim$ has more than one equivalence class, then $\mathcal{C} \setminus \mathcal{D}$ is non-empty.*

Proof. Let $\mathfrak{C} \in [\mathfrak{A}]$, let $\mathfrak{B}$ be a finite structure with a homomorphism to $\mathfrak{C}$, and let $\mathfrak{B}' \in [\mathfrak{B}]$. Since $\mathfrak{B} \uplus \mathfrak{C}$ and $\mathfrak{C}$ are homomorphically equivalent, we have that $\mathfrak{B} \uplus \mathfrak{C} \sim \mathfrak{C}$. We claim that $\mathfrak{B}' \uplus \mathfrak{C} \sim \mathfrak{C}$. To see this, let $\mathfrak{D} \in \mathcal{C}$. Then

$$\begin{aligned}
\mathfrak{C} \uplus \mathfrak{D} \in \mathcal{C} &\Leftrightarrow (\mathfrak{B} \uplus \mathfrak{C}) \uplus \mathfrak{D} \in \mathcal{C} && \text{(since } \mathfrak{B} \uplus \mathfrak{C} \sim \mathfrak{C}\text{)} \\
&\Leftrightarrow \mathfrak{B} \uplus (\mathfrak{C} \uplus \mathfrak{D}) \in \mathcal{C} \\
&\Leftrightarrow \mathfrak{B}' \uplus (\mathfrak{C} \uplus \mathfrak{D}) \in \mathcal{C} && \text{(since } \mathfrak{B} \sim \mathfrak{B}'\text{)} \\
&\Leftrightarrow (\mathfrak{B}' \uplus \mathfrak{C}) \uplus \mathfrak{D} \in \mathcal{C}
\end{aligned}$$

which shows the claim. So $\mathfrak{B}' \uplus \mathfrak{C} \in [\mathfrak{C}] = [\mathfrak{A}]$. Since $\mathfrak{B}'$ has a homomorphism to $\mathfrak{B}' \uplus \mathfrak{C}$ we obtain that $\mathfrak{B}' \in \mathcal{D}$; this proves the first statement.

To prove the second statement, first observe that the statement is clear if $\mathfrak{A} \in [\mathfrak{I}]$, since the complement of $[\mathfrak{I}]$ is closed under homomorphisms. The statement therefore follows from the assumption that $\sim$ has more than one equivalence class. Otherwise, if $\mathfrak{A} \notin [\mathfrak{I}]$, then there exists a structure $\mathfrak{B} \in \mathcal{C}$ such that $\mathfrak{A} \uplus \mathfrak{B} \notin \mathcal{C}$. Then $\mathfrak{B} \in \mathcal{C} \setminus \mathcal{D}$ can be shown indirectly as follows: otherwise $\mathfrak{B}$ would have a homomorphism to a structure $\mathfrak{A}' \in [\mathfrak{A}]$. Since $\mathfrak{B} \uplus \mathfrak{A}'$ is homomorphically equivalent to $\mathfrak{A}'$, we have $\mathfrak{B} \uplus \mathfrak{A}' \sim \mathfrak{A}' \sim \mathfrak{A}$ and in particular $\mathfrak{B} \uplus \mathfrak{A}' \in \mathcal{C}$. But $\mathfrak{B} \uplus \mathfrak{A}' \in \mathcal{C}$ if and only if $\mathfrak{B} \uplus \mathfrak{A} \in \mathcal{C}$ since $\mathfrak{A} \sim \mathfrak{A}'$. This is in contradiction to our assumption on $\mathfrak{B}$. ◀

▶ **Example 13.** We consider a signature $\tau := \{R_1, R_2, R_3\}$ of unary relation symbols. Define for every $i \in \{1,2,3\}$ the τ-structure $\mathfrak{S}_i$ to be a one-element structure where R_i is non-empty and R_j, for $j \neq i$, is empty. Let

$$\mathcal{C} := \mathrm{CSP}(\mathfrak{S}_1 \uplus \mathfrak{S}_2) \cup \mathrm{CSP}(\mathfrak{S}_2 \uplus \mathfrak{S}_3) \cup \mathrm{CSP}(\mathfrak{S}_3 \uplus \mathfrak{S}_1).$$

Clearly, the complement of $\mathcal{C}$ is closed under homomorphisms. The equivalence classes of $\sim$ can be described as follows. For distinct $i, j \in \{1,2,3\}$,

$$\begin{aligned}[\mathfrak{S}_i \uplus \mathfrak{S}_j] &= \mathrm{CSP}(\mathfrak{S}_i \uplus \mathfrak{S}_j) \setminus (\mathrm{CSP}(\mathfrak{S}_i) \cup \mathrm{CSP}(\mathfrak{S}_j)) \\ [\mathfrak{S}_i] &= \mathrm{CSP}(\mathfrak{S}_i) \setminus [\mathfrak{I}] \\ [\mathfrak{I}] &= \mathrm{CSP}(\mathfrak{I}).\end{aligned}$$

For the remainder of the section we fix a GSO τ-sentence Φ of quantifier rank q. Recall that Lemma 6 asserts that the equivalence relation $\equiv_q^{\mathrm{GSO}}$ on the class of finite τ-structures has finitely many equivalence classes $\mathcal{C}_1, \ldots, \mathcal{C}_m$, and that each of the equivalence classes $\mathcal{C}_i$ can be defined by a single GSO τ-sentence Ψ_i with quantifier rank q; we write $T_q^\tau := \{\Psi_1, \ldots, \Psi_m\}$ for this set of GSO sentences. Let $J \subseteq \{1, \ldots, m\}$ be such that $\{\Psi_j \in T_q^\tau \mid j \in J\}$ is exactly the set of all sentences in T_q^τ that imply Φ. Then $|J|$ is called the *degree* of Φ. It is easy to see that the degree of Φ is exactly the index of $\equiv_q^{\mathrm{GSO}}$ restricted to $[\![\Phi]\!]$. Let $\sim$ be the equivalence relation defined in the beginning of this section for the class $\mathcal{C} := [\![\Phi]\!]$.

▶ **Lemma 14.** *For every $\sim$-class $\mathcal{D}$ there exists $I \subseteq \{1, \ldots, m\}$ such that $\mathcal{D} = \bigcup_{i \in I} [\![\Psi_i]\!]$.*

Proof. As in the proof of Corollary 10 one can use Theorem 9 to show for all finite τ-structures $\mathfrak{A}, \mathfrak{B}$ that if $\mathfrak{A} \equiv_q^{\mathrm{GSO}} \mathfrak{B}$, then $\mathfrak{A} \sim \mathfrak{B}$. This means that $\mathcal{D}$ is a union of $\equiv_q^{\mathrm{GSO}}$-classes and therefore there exists $I \subseteq J \subseteq \{1, \ldots, m\}$ such that $\mathcal{D} = \bigcup_{i \in I} [\![\Psi_i]\!]$. ◀

▶ **Corollary 15.** *The index of $\sim$ is smaller than or equal to the degree of Φ.*

▶ **Lemma 16.** *If the complement of $[\![\Phi]\!]$ is closed under homomorphisms, then there are GSO τ-sentences $\Phi_1, \ldots, \Phi_t$ each of which describes a CSP such that Φ is equivalent to $\Phi_1 \vee \cdots \vee \Phi_t$. If Φ is an MSO sentence, then $\Phi_1, \ldots, \Phi_t$ can be be chosen to be MSO sentences as well.*

Proof. We prove the statement by induction on the degree n of Φ. By Lemma 15 the equivalence relation $\sim$ has at most n equivalence classes on τ-structures. Hence, if $n = 1$, then $[\![\Phi]\!]$ is closed under disjoint unions, and we are done.

Let $\mathfrak{A}_1, \ldots, \mathfrak{A}_s$ be τ-structures such that $\{[\mathfrak{A}_1], \ldots, [\mathfrak{A}_s]\}$ is the set of all equivalence classes of $\sim$ that are distinct from $[\mathfrak{I}]$. Let $\mathcal{D}_i$ be the smallest subclass of $[\![\Phi]\!]$ that contains $[\mathfrak{A}_i]$ and whose complement is closed under homomorphisms. Note that $[\![\Phi]\!] = \bigcup_{i \leq s} \mathcal{D}_i$ since $[\mathfrak{I}]$ is contained in $\mathcal{D}_i$ for all $i \leq s$. By Lemma 12 (1), each $\mathcal{D}_i$ is a union of $\sim$-classes which are themselves a union of $\equiv_q^{\mathrm{GSO}}$-classes by Lemma 14. It follows that there exists $I_i \subseteq \{1, \ldots, m\}$ such that $\mathcal{D}_i = \bigcup_{j \in I_i} [\![\Psi_j]\!]$. We define $\Phi_i := \bigvee_{j \in I_i} \Psi_j$. Note that the GSO sentence Φ_i is of quantifier rank q such that $\mathcal{D}_i = [\![\Phi_i]\!]$. Hence, Φ is equivalent to $\bigvee_{i \leq s} \Phi_i$. Lemma 12 (2) asserts that $[\![\Phi]\!] \setminus \mathcal{D}_i$ is non-empty, and hence the degree of Φ_i must be strictly smaller than n for all $i \in \{1, \ldots, s\}$. The statement now follows from the inductive assumption. The same argument applies to MSO as well. ◀

Lemma 16 together with Corollary 10 implies the following.

▶ **Corollary 17.** *Every GSO sentence which is closed under homomorphisms is equivalent to a finite conjunction of GSO sentences each of which describes the complement of a CSP of a countable ω-categorical structure. The analogous statement holds for MSO.*

Not every homomorphism-closed class of structures that can be expressed in Second-order Logic is a finite intersection of complements of CSPs. We even have an example of a class of finite τ-structures that can be expressed in Datalog but cannot be written in this form.

▶ **Example 18.** Let S and T be unary, and let R be a binary relation symbol. Let $\mathcal{C}$ be the class of all finite $\{S,T,R\}$-structures $\mathfrak{A}$ such that the following Datalog program Π with the binary IDB E derives goal on $\mathfrak{A}$.

$$\begin{aligned} E(x,y) &:\!- S(x), S(y) \\ E(x,y) &:\!- E(x',y'), R(x',x), R(y',y) \\ \mathsf{goal} &:\!- T(x), E(x,x'), R(x',y) \end{aligned}$$

For $n \in \mathbb{N}$, let $\mathfrak{P}_n$ be the $\{S,T,R\}$-structure on the domain $\{1,\dots,n\}$ with

$$S^{\mathfrak{P}_n} := \{1\} \qquad T^{\mathfrak{P}_n} := \{n\} \qquad R^{\mathfrak{P}_n} := \big\{(i,i+1) \mid i \in \{1,\dots,n-1\}\big\}.$$

It is easy to see that each of the structures in $\{\mathfrak{P}_n \mid n \geq 1\}$ is not contained in $\mathcal{C}$, and that the disjoint union of $\mathfrak{P}_i$ and $\mathfrak{P}_j$, for $i \neq j$, is contained in $\mathcal{C}$. It follows that $\mathcal{C}$ is not a finite intersection of complements of CSPs (and, by Corollary 17, cannot be expressed in GSO).

4 Canonical Datalog Programs

A remarkable fact about the expressive power of Datalog for constraint satisfaction problems over finite domains is the existence of *canonical Datalog programs* [19]; this has been generalised to CSPs for ω-categorical structures.

▶ **Theorem 19** (Bodirsky and Dalmau [7])**.** *Let $\mathfrak{B}$ be a countable ω-categorical τ-structure. Then for all $\ell, k \in \mathbb{N}$ there exists a canonical Datalog program Π of width (ℓ,k) for the complement of* CSP($\mathfrak{B}$)*. Moreover, for every finite τ-structure $\mathfrak{A}$ the following are equivalent:*

- *Π derives* goal *on $\mathfrak{A}$;*
- *Spoiler has a winning strategy for the existential (ℓ,k)-pebble game on $(\mathfrak{A},\mathfrak{B})$.*

We later need the following well-known fact.

▶ **Lemma 20.** *If $\mathcal{C}_1$ and $\mathcal{C}_2$ are in Datalog, then so are $\mathcal{C}_1 \cup \mathcal{C}_2$ and $\mathcal{C}_1 \cap \mathcal{C}_2$. If Π_1 and Π_2 are Datalog programs of width (ℓ,k), then there is a Datalog program Π of width (ℓ,k) for $[\![\Pi_1]\!] \cup [\![\Pi_2]\!]$ and for $[\![\Pi_1]\!] \cap [\![\Pi_2]\!]$.*

Proof. For union, let Π be obtained by taking the union of the rules of Π_1 and of Π_2, possibly after renaming IDB predicate names to make them disjoint except for goal. For intersection, we proceed similarly, but we first rename the symbol goal in Π_1 to goal_1 and the symbol goal in Π_2 to goal_2. Finally we add the new rule $\mathsf{goal} :\!- \mathsf{goal}_1, \mathsf{goal}_2$ to the union of Π_1 and Π_2. It is clear that these constructions preserve the width. ◀

▶ **Theorem 21.** *Let Φ be a GSO sentence such that $[\![\Phi]\!]$ is closed under homomorphisms. Let $\ell, k \in \mathbb{N}$. Then there exists a canonical Datalog program Π of width (ℓ,k) for $[\![\Phi]\!]$.*

Proof. By Corollary 17 there are GSO sentences $\Phi_1, \dots, \Phi_m$ and ω-categorical structures $\mathfrak{B}_1, \dots, \mathfrak{B}_m$ such that Φ is equivalent to $\Phi_1 \wedge \dots \wedge \Phi_m$ and $[\![\neg\Phi_i]\!] = \mathrm{CSP}(\mathfrak{B}_i)$. Let Π_i be the canonical Datalog program for $\mathrm{CSP}(\mathfrak{B}_i)$ which exists by Theorem 19. Then Lemma 20 implies that there exists a Datalog program Π such that $[\![\Pi]\!] = [\![\Pi_1]\!] \cap \dots \cap [\![\Pi_m]\!]$. It is clear that Π is sound for $[\![\Phi]\!]$. To see that Π is a canonical Datalog program for $[\![\Phi]\!]$, suppose that $\mathfrak{A}$ is such that some Datalog program Π' of width (ℓ, k) which is sound for $[\![\Phi]\!]$ derives goal on $\mathfrak{A}$. Since, for every $i \in \{1, \dots, m\}$, the program Π' is also sound for $[\![\Phi_i]\!]$, and Π_i is a canonical Datalog program for $[\![\Phi_i]\!]$, the program Π_i derives goal on $\mathfrak{A}$. Hence, $\mathfrak{A} \in [\![\Pi]\!] = [\![\Pi_1]\!] \cap \dots \cap [\![\Pi_m]\!]$. ◀

▶ **Theorem 22.** *Let Φ be a GSO sentence. Then $[\![\Phi]\!]$ can be defined in Datalog if and only if*

1. *$[\![\Phi]\!]$ is closed under homomorphisms, and*
2. *there exist $\ell, k \in \mathbb{N}$ such that for all finite structures $\mathfrak{A}$, Spoiler wins the (ℓ, k)-game for $[\![\Phi]\!]$ on $\mathfrak{A}$ if and only if $\mathfrak{A} \models \Phi$.*

Proof. First suppose that $[\![\Phi]\!]$ is in Datalog. That is, there exists $\ell, k \in \mathbb{N}$ and a Datalog program Π of width (ℓ, k) such that $[\![\Phi]\!] = [\![\Pi]\!]$. Then clearly $[\![\Phi]\!]$ is closed under homomorphisms, and by Lemma 16, there are GSO sentences $\Phi_1, \dots, \Phi_m$ such that Φ is equivalent to $\Phi_1 \wedge \dots \wedge \Phi_m$ and $[\![\Phi_i]\!]$ is the complement of a CSP, for each $i \in \{1, \dots, m\}$. Corollary 10 implies that there exists an ω-categorical structure $\mathfrak{B}_i$ such that $\mathrm{CSP}(\mathfrak{B}_i) = [\![\neg\Phi_i]\!]$. Now suppose that $\mathfrak{A}$ is a finite τ-structure such that $\mathfrak{A} \models \Phi$. Then Spoiler wins the (ℓ, k)-game as follows. Suppose that Duplicator plays the countable structure $\mathfrak{B}$ such that $\mathrm{CSP}(\mathfrak{B}) \cap [\![\Phi]\!] = \emptyset$. Then $\mathrm{CSP}(\mathfrak{B}) \cap [\![\Phi_i]\!] = \emptyset$ for some $i \in \{1, \dots, m\}$; otherwise, if there is a structure $\mathfrak{A}_i \in \mathrm{CSP}(\mathfrak{B}) \cap [\![\Phi_i]\!]$ for every $i \in \{1, \dots, m\}$, then the disjoint union of $\mathfrak{A}_1, \dots, \mathfrak{A}_m$ satisfies Φ_i since Φ_i is closed under homomorphisms, and is in $\mathrm{CSP}(\mathfrak{B})$ since $\mathrm{CSP}(\mathfrak{B})$ is closed under disjoint unions; but this is in contradiction to our assumption that $\mathrm{CSP}(\mathfrak{B}) \cap [\![\Phi]\!] = \emptyset$. Hence, $\mathrm{CSP}(\mathfrak{B}) \subseteq \mathrm{CSP}(\mathfrak{B}_i)$ and hence there is a homomorphism h from $\mathfrak{B}$ to $\mathfrak{B}_i$ (see [7]). Note that Π is sound for $\mathrm{CSP}(\mathfrak{B}_i)$, and Π derives goal on $\mathfrak{A}$, and hence Theorem 19 implies that Spoiler wins the existential (ℓ, k)-pebble game on $(\mathfrak{A}, \mathfrak{B}_i)$. But since $\mathfrak{B}$ homomorphically maps to $\mathfrak{B}_i$, this implies that Spoiler wins the existential (ℓ, k)-pebble game on $(\mathfrak{A}, \mathfrak{B}_i)$. Now suppose that $\mathfrak{A} \models \neg\Phi$. Hence, there exists $i \in \{1, \dots, m\}$ such that $\mathfrak{A} \models \neg\Phi_i$. Then Duplicator wins the (ℓ, k)-game as follows. She starts by playing $\mathfrak{B}_i$. Then $\mathfrak{A}$ homomorphically maps to $\mathfrak{B}_i$, and Duplicator can win the existential (ℓ, k) pebble game on $(\mathfrak{A}, \mathfrak{B}_i)$ by always playing along the homomorphism.

For the converse implication, suppose that 1. and 2. hold. Since $[\![\Phi]\!]$ is closed under homomorphisms, Corollary 17 implies that there are GSO sentences $\Phi_1, \dots, \Phi_m$ and ω-categorical structures $\mathfrak{B}_1, \dots, \mathfrak{B}_m$ such that Φ is equivalent to $\Phi_1 \wedge \dots \wedge \Phi_m$ and $[\![\neg\Phi_i]\!] = \mathrm{CSP}(\mathfrak{B}_i)$. By Theorem 19, for every $i \in \{1, \dots, m\}$ there exists a canonical Datalog program Π_i of width (ℓ, k) for $[\![\Phi_i]\!]$. Then Lemma 20 implies that there exists a Datalog program Π such that $[\![\Pi]\!] = [\![\Pi_1]\!] \cap \dots \cap [\![\Pi_m]\!]$. Since each Π_i is sound for $[\![\Phi_i]\!]$, it follows that Π is sound for $[\![\Phi]\!]$. Hence, it suffices to show that if $\mathfrak{A}$ is a finite τ-structure such that $\mathfrak{A} \models \Phi$, then Π derives goal on $\mathfrak{A}$. Since $\mathfrak{A} \models \Phi_i$ for all $i \in \{1, \dots, m\}$, the assumption implies that Spoiler wins the existential (ℓ, k) pebble game on $(\mathfrak{A}, \mathfrak{B}_i)$. By Theorem 19, it follows that Π_i derives goal on $\mathfrak{A}$. Hence, Π derives goal on $\mathfrak{A}$. ◀

5 A coNP-complete CSP in MSO

In this section we show that the class of CSPs in MSO is (under complexity-theoretic assumptions) larger than the class of CSPs for reducts of finitely bounded structures (see Section 3.1). Let $\mathcal{T} = \{\mathfrak{T}_2, \mathfrak{T}_3, \dots\}$ be the set of *Henson tournaments*: the tournament $\mathfrak{T}_n$, for $n \geq 2$, has vertices $0, 1, \dots, n+1$ and the following edges:

- $(i, i+1)$ for $i \in \{0, \dots, n\}$;
- $(0, n+1)$;
- (j, i) for $i+1 < j$ and $(i, j) \neq (0, n+1)$.

The class $\mathcal{C}$ of all finite loopless digraphs that do not embed any of the digraphs from $\mathcal{T}$ is an amalgamation class, and hence there exists a homogenous structure $\mathfrak{H}$ with age $\mathcal{C}$. It has been shown in [9] that CSP($\mathfrak{H}$) is coNP-complete.

▶ **Proposition 23.** CSP($\mathfrak{H}$) *can be expressed in MSO.*

Proof. We have to find an MSO sentence that holds on a given digraph $(V; E)$ if and only if $(V; E)$ does not embed any of the tournaments from $\mathcal{T}$. We specify an MSO $\{X, E\}$-sentence Φ, for a unary relation symbol X, that is true on a finite $\{X, E\}$-structure $\mathfrak{S}$ if and only if $(X^{\mathfrak{S}}; E^{\mathfrak{S}})$ is isomorphic to $\mathfrak{T}_n$, for some $n \geq 2$. In ϕ we existentially quantify over

- two vertices $s, t \in X$ (that stand for the vertex 0 and the vertex $n+1$ in $\mathfrak{T}_n$).
- a partition of $X \setminus \{s\}$ into two sets A and B (they stand for the set of even and the set of odd numbers in $\{1, \dots, n+1\}$).

The formula Φ has the following conjuncts:

1. a first-order formula that states that E defines a tournament on X;
2. a first-order formula that expresses that E is a linear order on A with maximal element a;
3. a first-order formula that expresses that E is a linear order on B with maximal element b;
4. $E(s, t)$, $E(s, a)$, $E(a, b)$, and $E(x, s)$ for all $x \in X \setminus \{a, t\}$;
5. a first-order formula that states that if there is an edge from an element $x \in A$ to an element $y \in B$ then there is precisely one element $z \in A$ such that $(y, z), (z, x) \in E$, unless $y = t$;
6. a first-order formula that states that if there is an edge from an element $x \in B$ to an element $y \in A$ then there is precisely one element $z \in B$ such that $(y, z), (z, x) \in E$, unless $y = t$.

We claim that the MSO sentence $\forall x \colon \neg E(x, x) \wedge \forall X \colon \neg\Phi$ holds on a finite digraph if and only if the digraph is loopless and does not embed $\mathfrak{T}_n$, for all $n \geq 3$. The forwards implication easily follows from the observation that if $(X; T)$ is isomorphic to $\mathfrak{T}_n$, for some $n \geq 2$, then ϕ holds; this is straightforward from the construction of Φ (and the explanations above given in brackets). Conversely, suppose that Φ holds. Then $(X; T)$ is a tournament. We construct an isomorphism f from $(X; T)$ to $\mathfrak{T}_{|X|-1}$ as follows. Define $f(s) := 0$, $f(a) := 1$, and $f(b) = 2$. Since $E(a, b)$, by item 5 there exists exactly one $a' \in A$ such that $E(b, a')$ and $E(a', a)$. Define $f(a') := 3$. If $a' = t$ then we have found an isomorphism with $\mathfrak{T}_2$. Otherwise, the partial map f defined so far is an embedding into $\mathfrak{T}_n$ for some $n \geq 3$. Item 6 and $E(b, a')$ imply that there exists exactly one $b' \in B$ such that $E(a', b')$ and $E(b', b)$, and we define $f(b') := 4$. Continuing in this manner, we eventually define f on all of X and find an isomorphism with $\mathfrak{T}_{|X|-1}$. ◀

This shows that CSP($\mathfrak{H}$) cannot be expressed, unless NP = coNP, as CSP($\mathfrak{B}$) for some reduct of a finitely bounded structure and such CSPs are in NP. We do not know how to show this statement without complexity-theoretic assumptions, even if we just want to rule out that CSP($\mathfrak{H}$) can be expressed as CSP($\mathfrak{B}$) for some reduct of a finitely bounded *homogeneous* structure.

6 Conclusion and Open Problems

We provided a game-theoretic characterisation of those problems in Guarded Second-order Logic that are equivalent to a Datalog program. We also proved the existence of canonical Datalog programs for GSO sentences whose models are closed under homomorphisms. To

prove these results, we showed that every class of finite τ-structures in GSO whose complement is closed under homomorphisms is a finite union of CSPs. We also showed that every CSP in GSO can be formulated as a CSP of an ω-categorical structure. These results also imply that the so-called universal-algebraic approach, which has eventually led to the classification of finite-domain CSPs in Datalog [3], can be applied to study problems that are simultaneously in Datalog and in GSO (also see [11]). Our results might also pave the way towards a syntactic characterisation of Datalog $\cap$ GSO. We close with two open problems.

1. *Nested monadically defined queries (Nemodeq)* have been introduced by Rudolph and Krötzsch [25]; they prove that Nemodeq is contained both in MSO and in Datalog. We ask wether conversely, every problem in MSO $\cap$ Datalog is expressible as a Nemodeq.
2. Is every CSP of a reduct of a finitely bounded homogeneous structure in GSO?

We are also confident that our results will advance the understanding of CSPs (the complements of) which are obtained as the homomorphism-closure of the set of some theory's finite models. For example, the homomorphism-closures of the model sets of guarded- and guarded-negation-theories have recently been found to be GSO-expressible [8] so, by virtue of our results, we immediately know they must be (complements of) ω-categorical CSPs.

Abstract

The promise constraint satisfaction problem (PCSP) is a recently introduced vast generalisation of the constraint satisfaction problem (CSP) that captures approximability of satisfiable instances. A PCSP instance comes with two forms of each constraint: a strict one and a weak one. Given the promise that a solution exists using the strict constraints, the task is to find a solution using the weak constraints. While there are by now several dichotomy results for fragments of PCSPs, they all consider (in some way) symmetric PCSPs.

1-in-3-SAT and Not-All-Equal-3-SAT are classic examples of Boolean symmetric (non-promise) CSPs. While both problems are NP-hard, Brakensiek and Guruswami showed [SODA'18] that given a satisfiable instance of 1-in-3-SAT one can find a solution to the corresponding instance of (weaker) Not-All-Equal-3-SAT. In other words, the PCSP template (**1-in-3**, **NAE**) is tractable.

We focus on *non-symmetric* PCSPs. In particular, we study PCSP templates obtained from the Boolean template (**t-in-k**, **NAE**) by either adding tuples to **t-in-k** or removing tuples from **NAE**. For the former, we classify all templates as either tractable or not solvable by the currently strongest known algorithm for PCSPs, the combined basic LP and affine IP relaxation of Brakensiek and Guruswami [SODA'20]. For the latter, we classify all templates as either tractable or NP-hard.

1 Introduction

How hard is it to find a 6-colouring of a graph if it is promised to be 3-colourable? We do not know but believe it to be NP-hard. Despite sustained effort, this so-called *approximate graph colouring* problem has been elusive since it was considered by Garey and Johnson almost 50 years ago [22]. The current state of the art, established in 2019, is NP-hardness of finding a 5-colouring of a 3-colourable graph [17]. Approximate graph colouring is an example of the very general promise constraint satisfaction problem, which is the focus of this paper. We start with (non-promise) constraint satisfaction problems to set the stage.

Constraint satisfaction. While deciding whether a graph is 2-colourable is solvable in polynomial time, deciding 3-colourability is NP-complete [26]. The *constraint satisfaction problem* (CSP) is a general framework that captures graph colourings and many other

fundamental computational problems. Feder and Vardi initiated a systematic study of so-called fixed-template decision CSPs. Let $\mathbf{A}$ be a fixed finite relational structure, called the *template* or constraint language; i.e., $\mathbf{A}$ consists of a finite universe A and finitely many relations on A, each of possibly different arity. The fixed-template CSP over $\mathbf{A}$, denoted by $\mathrm{CSP}(\mathbf{A})$, is the class of CSPs in which all constraint relations come from $\mathbf{A}$. In more detail, $\mathrm{CSP}(\mathbf{A})$ denotes the following computational problem: Given a structure $\mathbf{X}$ over the same signature as $\mathbf{A}$, is there a homomorphism from $\mathbf{X}$ to $\mathbf{A}$, denoted by $\mathbf{X} \to \mathbf{A}$? (Formal definitions can be found in Section 2.) If $\mathbf{A} = K_3$ is a clique on 3 vertices then $\mathrm{CSP}(\mathbf{A})$ is precisely the standard graph 3-colouring problem.

A classic result of Schaefer shows that, for any $\mathbf{A}$ on a 2-element set, $\mathrm{CSP}(\mathbf{A})$ is either solvable in polynomial time or NP-complete. The non-trivial tractable cases from Schaefer's classification are taught in undergraduate algorithms courses: 2-SAT, (dual) Horn-SAT, and linear equations over $\{0,1\}$. Two concrete CSPs that are NP-hard by Schaefer's result are the (positive) 1-in-3-SAT and (positive) Not-All-Equal-3-SAT. For both problems, the instance is a list of triples of variables. In 1-in-3-SAT, the task is to find a mapping from the variables to $\{0,1\}$ so that in each triple exactly one variable is set to 1. Formally, 1-in-3-SAT is $\mathrm{CSP}(\mathbf{A})$, where $\mathbf{A} = (\{0,1\}; \{(1,0,0),(0,1,0),(0,0,1)\})$. In Not-All-Equal-3-SAT, the task is to find a mapping from the variables to $\{0,1\}$ so that in each triple not all variables are assigned the same value. Formally, Not-All-Equal-3-SAT is $\mathrm{CSP}(\mathbf{A})$, where $\mathbf{A} = (\{0,1\}; \{0,1\}^3 \setminus \{(0,0,0),(1,1,1)\})$.

If $\mathbf{A}$ is a graph (i.e., a single symmetric binary relation) then, as shown by Hell and Nešetřil [24], $\mathrm{CSP}(\mathbf{A})$ is either solvable in polynomial time or NP-complete. In this case, essentially the only non-trivial tractable case is graph 2-colouring.

Based on these two examples and a connection to logic, Feder and Vardi famously conjectured [20] that, for any finite $\mathbf{A}$, $\mathrm{CSP}(\mathbf{A})$ is either solvable in polynomial time or NP-complete. Bulatov [16], and independently Zhuk [31], proved the conjecture in the affirmative, both relying on the algebraic approach to CSPs [25, 15, 6]. In this case, the tractable cases are complicated and hard to describe in an elementary way.

Promise constraint satisfaction. Austrin, Guruswami, and Håstad [2] and Brakensiek and Guruswami [8, 9] initiated the investigation of the *promise constraint satisfaction problem* (PCSP), which is a vast generalisation of the CSP. Let $\mathbf{A}$ and $\mathbf{B}$ be two relational structures such that $\mathbf{A} \to \mathbf{B}$. The fixed-template PCSP over $\mathbf{A}$ and $\mathbf{B}$, denoted by $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$, is the following computational problem: Given $\mathbf{X}$ such that $\mathbf{X} \to \mathbf{A}$, find a homomorphism from $\mathbf{X}$ to $\mathbf{B}$ (which exists by the composition of the promised homomorphism from $\mathbf{X}$ to $\mathbf{A}$ and the homomorphism from $\mathbf{A}$ to $\mathbf{B}$). If we take $\mathbf{A} = K_3$ to be a clique on 3 vertices and $\mathbf{B} = K_6$ to be a clique on 6 vertices, then $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$ is an instance of the approximate graph colouring problem mentioned at the beginning of this article. Actually, what we described is the *search* version of the PCSP. The *decision* version is as follows: Given $\mathbf{X}$, return YES if $\mathbf{X} \to \mathbf{A}$ and return NO if $\mathbf{X} \not\to \mathbf{B}$. (The promise in the decision version is that it does not happen that $\mathbf{X} \not\to \mathbf{A}$ but $\mathbf{X} \to \mathbf{B}$.) It is well known that the decision version reduces to the search version but it is not known whether there is a reduction the other way [5]. In most results (including ours), hardness is established for the decision version and tractability for the search version.

If $\mathbf{A} = \mathbf{B}$ then $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$ is the same as $\mathrm{CSP}(\mathbf{A})$ and thus PCSPs indeed generalise CSPs. For CSPs, the decision and search versions are known to be equivalent [15].

Building on the result of Barto, Opršal, and Pinsker [7] that the complexity of $\mathrm{CSP}(\mathbf{A})$ is captured by certain types of identities of higher-order symmetries (called polymorphisms) of $\mathbf{A}$, Barto, Bulín, Krokhin, and Opršal showed that the basics of the algebraic approach developed for CSPs [7] can be generalised to PCSPs [17, 5], thus introducing a general methodology for investigating the computational complexity of PCSPs.

Related work. Motivated by the goal to understand the computational complexity of all fixed-template PCSPs, a recent line of research has focused on restricted classes of templates, with the main directions being Boolean templates (i.e., templates on a two-element set) and symmetric templates (i.e., all relations in the template satisfy that if a tuple belongs to a relation then so do all of its permutations).

Austrin, Guruswami, and Håstad [2] considered the $(1, g, k)$-SAT problem: Given an instance of k-SAT with the promise that there is an assignment satisfying at least g literals in each clause, find an assignment that satisfies at least one literal in each clause. They showed that this problem is NP-hard if $\frac{g}{k} < \frac{1}{2}$, and polynomial-time solvable otherwise. $(1, g, k)$-SAT is a Boolean PCSP with a (symmetric) template that includes the binary disequality relation and a relation containing all tuples of particular Hamming weights. The NP-hardness in [2] was proved via reduction from the label cover problem using the idea of polymorphisms lifted from CSPs to PCSPs. Building on the algebraic theory from [17, 5], Brandts, Wrochna, and Živný [13] extended the classification of $(1, g, k)$-SAT to arbitrary finite domains.

Brakensiek and Guruswami [9] managed to classify all PCSPs over symmetric Boolean templates with the disequality relation as NP-hard or solvable in polynomial time. Ficak, Kozik, Olšák, and Stankiewicz [21] extended this result to all symmetric Boolean templates.

In very recent work, Barto, Battistelli, and Berg [4] explored symmetric PCSPs on three- and four-element domains.

While the approximate graph colouring problem remains open, hardness was proved under stronger assumptions (namely Khot's 2-to-1 Conjecture [27] for k-colourings with $k \geq 4$ and its non-standard variant for 3-colourings) by Dinur, Mossel, and Regev [18]. Guruswami and Sandeep [23] recently established this result under a weaker assumption, the so-called d-to-1 conjecture for any fixed $d \geq 2$. For approximate *hypergraph* colouring, another important PCSP, NP-hardness was established by Dinur, Regev, and Smyth [19]. There has been some recent progress on approximate graph colourings [30] and related PCSPs, e.g. approximate graph homomorphism problems [28, 30], and rainbow vs. normal hypergraph colourings [1].

Unlike most previous works, which focused on symmetric PCSPs, we investigate non-symmetric PCSPs. Our first motivation is that a classification of more concrete PCSP templates is needed to improve and extend the general algebraic theory from [17, 5]. At the moment, even an analogue of Schaefer's result, i.e., classifying all Boolean PCSPs, seems out of reach. Our second motivation is the pure beauty of the template $(\mathbf{1\text{-}in\text{-}3}, \mathbf{NAE})$. While PCSP$(\mathbf{1\text{-}in\text{-}3}, \mathbf{NAE})$ admits a polynomial-time algorithm [9, 10], Barto showed [3, 5] that this tractability result cannot be obtained via an algebraic reduction to tractable finite-domain CSPs.

Contributions. Consider the Boolean PCSP$(\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE})$, which is a natural generalisation of PCSP$(\mathbf{1\text{-}in\text{-}3}, \mathbf{NAE})$. This is a symmetric, tractable PCSP. When can we add tuples to **t-in-k** to keep the PCSP tractable? When can we remove tuples from **NAE** to keep the PCSP tractable? Note that these changes generally do not give symmetric templates.

For the second question, we give a complete answer in Theorem 11: If t is odd, k is even, and tuples of only even Hamming weight are removed from **NAE**, the resulting PCSP is solvable in polynomial time. In all other cases, the resulting PCSP is NP-hard.

For the first question, we give a second-best possible answer in Theorem 10: If t is odd, k is even, and tuples of only odd Hamming weight are added to **t-in-k**, the resulting PCSP is tractable. In all other cases, the resulting PCSP is not solved by the combined basic LP and affine IP relaxation of Brakensiek and Guruswami [11], the currently strongest known algorithm for PCSPs. The power of this relaxation has recently been characterised by Brakensiek, Guruswami, Wrochna, and Živný [12].

2 Preliminaries

We denote by $[n]$ the set $\{1, 2, \ldots, n\}$. For a k-tuple $\mathbf{x}$, we write $\mathbf{x} = (x_1, \ldots, x_k)$. We denote by $\leq_p$ a polynomial-time many-one reduction.

A *relational structure* is a tuple $\mathbf{A} = (A; R_1, \ldots, R_p)$, where A is a finite set called the *domain* of $\mathbf{A}$, and each R_i is a relation of arity $\mathrm{ar}(R_i) \geq 1$, that is, R_i is a non-empty subset of $A^{\mathrm{ar}(R_i)}$. A relational structure is *symmetric* if each relation in it is invariant under any permutation of coordinates. Two relational structures $\mathbf{A} = (A; R_1, \ldots, R_p)$ and $\mathbf{B} = (B; S_1, \ldots, S_q)$ have the same *signature* if $p = q$ and $\mathrm{ar}(R_i) = \mathrm{ar}(S_i)$ for every $i \in [p]$. In this case, a mapping $\phi : A \to B$ is called a *homomorphism* from $\mathbf{A}$ to $\mathbf{B}$, denoted by $\phi : \mathbf{A} \to \mathbf{B}$, if ϕ preserves all relations; that is, for every $i \in [p]$ and every tuple $\mathbf{x} \in R_i$, we have $\phi(\mathbf{x}) \in S_i$, where ϕ is applied component-wise. The existence of a homomorphism from $\mathbf{A}$ to $\mathbf{B}$ is denoted by $\mathbf{A} \to \mathbf{B}$. A PCSP *template* is a pair $(\mathbf{A}, \mathbf{B})$ of relational structures over the same signature such that $\mathbf{A} \to \mathbf{B}$.

▶ **Definition 1.** *Let $(\mathbf{A}, \mathbf{B})$ be a PCSP template. The* decision version *of* $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ *is the following problem: Given as input a relational structure $\mathbf{X}$ over the same signature as $\mathbf{A}$ and $\mathbf{B}$, output* Yes *if $\mathbf{X} \to \mathbf{A}$ and* No *if $\mathbf{X} \not\to \mathbf{B}$. The* search version *of* $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ *is the following problem: Given as input a relational structure $\mathbf{X}$ over the same signature as $\mathbf{A}$ and $\mathbf{B}$ such that $\mathbf{X} \to \mathbf{A}$, find a homomorphism from $\mathbf{X}$ to $\mathbf{B}$.*

We call $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ *tractable* if any instance of $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ can be solved in polynomial time in the size of the input structure $\mathbf{X}$. It is easy to show that the decision version reduces to the search version [5]. Our hardness results will be for the decision version and our tractability results for the search version. For a relational structure $\mathbf{A}$, the constraint satisfaction problem with the template $\mathbf{A}$, denoted by $\mathrm{CSP}(\mathbf{A})$, is $\mathrm{PCSP}(\mathbf{A}, \mathbf{A})$.

The following notion of polymorphisms is at the heart of the algebraic approach to (P)CSPs. Intuitively, an arity m polymorphism of a PCSP template $(\mathbf{A}, \mathbf{B})$ is a homomorphism from the m-th Cartesian power of $\mathbf{A}$ to $\mathbf{B}$.

▶ **Definition 2.** *Let $(\mathbf{A}, \mathbf{B})$ be a PCSP template. A function $f : A^m \to B$ is a* polymorphism *of arity m of $(\mathbf{A}, \mathbf{B})$ if for each pair of corresponding relations R_i and S_i from $\mathbf{A}$ and $\mathbf{B}$, respectively, the following holds: For any $(k \times m)$ matrix M whose columns are tuples in R_i, the application of f to rows of M gives a tuple in S_i. We denote by* $\mathrm{Pol}(\mathbf{A}, \mathbf{B})$ *the set of all polymorphisms of $(\mathbf{A}, \mathbf{B})$.*

In a PCSP template $(\mathbf{A}, \mathbf{B})$ we view tuples from $\mathbf{A}$ and $\mathbf{B}$ as columns. When writing tuples in text we may write them as rows to simplify notation but they should still be understood as columns. For a k-ary relation R on the set $[t]$, we denote by $R^c = [t]^k \setminus R$ the complement of R. For a relational structure $\mathbf{A}$, we denote by $\mathbf{A}^c$ the structure with relations R^c for each relation R in $\mathbf{A}$. Most of our relational structures will be on the Boolean domain $\{0, 1\}$ and contain a single relation of arity k. The (Hamming) weight of a tuple $\mathbf{x} \in \{0, 1\}^k$, denoted throughout by d, is the number of 1's in $\mathbf{x}$. For $1 \leq t < k$, the Boolean relational structure **t-in-k** consists (of one relation consisting) of all k-tuples with weight t. The Boolean relational structure **NAE** contains all k-tuples except 0^k and 1^k.

We need a definition and some notation to state existing results on Boolean (P)CSPs.

▶ **Definition 3.** *A function $f : \{0, 1\}^m \to \{0, 1\}$ is*

- *an OR_m (AND_m) if it returns the logical OR (respectively logical AND) of its arguments;*
- *an alternating threshold AT_m if $m \geq 1$ is odd and*

$$f(x_1, \ldots, x_m) = \mathbb{1}[x_1 - x_2 + x_3 - \cdots + x_m] > 0;$$

- *a parity function* XOR_m *if* $f(x_1,\dots,x_m) = x_1 + \cdots + x_m \mod 2$*;*
- *a q-threshold* $\mathrm{THR}_{q,m}$ *(for* q *a rational between 0 and 1 and* mq *not an integer) if* $f(x_1,\dots,x_m) = 0$ *if* $\sum_{i=1}^{m} x_i < mq$ *and* 1 *otherwise;*
- *a majority* MAJ_m *if* f *is a* $\frac{1}{2}$*-threshold.*

We denote by OR *and* AND *the set of all* OR_m *and* AND_m *functions, respectively, for* $m \geq 2$*. We denote by* AT *and* XOR *the set of all* AT_m *and* XOR_m *functions, respectively, for odd* $m \geq 1$*. Finally,* THR_q *denotes the set of all* $\mathrm{THR}_{q,m}$ *functions for* $qm \notin \mathbb{Z}$*.*

Define $\overline{f}$*, the* inversion of f*, as the function* $x \mapsto 1 - f(x)$*, and for a family of functions* F*, define the* inversion of F *by* $\overline{F} = \{\overline{f} | f \in F\}$*.*

Schaefer's celebrated dichotomy theorem classified all Boolean CSP templates.

▶ **Theorem 4** ([29])**.** *Let* $\mathbf{B}$ *be a Boolean CSP template. If* $\mathrm{Pol}(\mathbf{B})$ *contains a constant,* AND_2*,* OR_2*,* MAJ_3*, or* XOR_3*, then* $\mathrm{CSP}(\mathbf{B})$ *is tractable. Otherwise,* $\mathrm{CSP}(\mathbf{B})$ *is NP-hard.*

Ficak et al. classified all symmetric Boolean PCSP templates [21].

▶ **Theorem 5** ([21])**.** *Let* $(\mathbf{A},\mathbf{B})$ *be a symmetric Boolean PCSP template. If* $\mathrm{Pol}(\mathbf{A},\mathbf{B})$ *contains a constant or at least one of* OR*,* AND*,* XOR*,* AT*,* THR_q *(for some* q*) or their inversions, then* $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$ *is tractable. Otherwise,* $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$ *is NP-hard.*

The only possibly unresolved promise templates are those with NP-hard CSP templates.

▶ **Proposition 6.** *Let* $(\mathbf{A},\mathbf{B})$ *be a promise template such that at least one of* $\mathrm{CSP}(\mathbf{A})$*,* $\mathrm{CSP}(\mathbf{B})$ *is tractable. Then* $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$ *is tractable.*

Theorem 4 established NP-hardness of two natural CSPs: $\mathrm{CSP}(\mathbf{1\text{-}in\text{-}3})$ and $\mathrm{CSP}(\mathbf{NAE})$. Interestingly, $\mathrm{PCSP}(\mathbf{1\text{-}in\text{-}3},\mathbf{NAE})$ is solvable in polynomial-time, as first shown by Brakensiek and Guruswami [9]. (Note that this shows that the converse of Proposition 6 is false.) A natural generalisation of **1-in-3** is **t-in-k**. Theorem 4 implies that $\mathrm{CSP}(\mathbf{t\text{-}in\text{-}k})$ is NP-hard. Theorem 5 implies that the tractability of $\mathrm{PCSP}(\mathbf{1\text{-}in\text{-}3},\mathbf{NAE})$ also holds for $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k},\mathbf{NAE})$; both observations are proved in the full version [14].

▶ **Proposition 7.** *For* $k \geq 3$ *and* $1 \leq t < k$*,* $\mathrm{CSP}(\mathbf{t\text{-}}\boldsymbol{in}\mathbf{\text{-}k})$ *is NP-hard.*

▶ **Proposition 8.** *For* $k \geq 2$ *and* $1 \leq t < k$*,* $\mathrm{PCSP}(\mathbf{t\text{-}}\boldsymbol{in}\mathbf{\text{-}k},\mathbf{NAE})$ *is tractable.*

We now give a characterisation of the power of a certain convex relaxation useful for tractability of (the decision version of) PCSPs. The relaxation is called the *combined basic LP and affine IP relaxation* (BLP+AIP) and was introduced in [11]; see also [10]. All known tractable PCSPs are solvable by either BLP+AIP or a reduction to a tractable CSP.

A $(2m+1)$-ary function f is called 2-block-symmetric if its $2m+1$ coordinates of f can be partitioned into two blocks of size $m+1$ and m in such a way that the value of f is invariant under any permutation of coordinates within each block. Without loss of generality, we will assume that the two blocks are the odd and even coordinates of f.

▶ **Theorem 9** ([12, Theorem 5.1])**.** *Let* $(\mathbf{A},\mathbf{B})$ *be a PCSP template. Then (the decision version of)* $\mathrm{PCSP}(\mathbf{A},\mathbf{B})$ *is tractable via BLP+AIP if and only if* $\mathrm{Pol}(\mathbf{A},\mathbf{B})$ *contains 2-block-symmetric functions of all odd arities.*

In the proof of one of our results (Theorem 10) we will use Theorem 9 to rule out solvability by BLP+AIP. However, for our tractability results, we will only need a characterisation result (in terms of polymorphisms) of a weaker relaxation, namely the affine IP relaxation (AIP) [5], which also works for the search version of PCSPs; details can be found in [14].

3 Our results

Our results are concerned with templates that arise from $(\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE})$ by either adding tuples to $\mathbf{t\text{-}in\text{-}k}$ or removing tuples from $\mathbf{NAE}$. For a set of tuples $S \subseteq \{0,1\}^k$, we write $\mathbf{t\text{-}in\text{-}k} \cup \mathbf{S}$ for the relational structure whose (only) relation contains all k-tuples of weight t and the tuples from S, and similarly for $\mathbf{NAE} \setminus \mathbf{S}$.

▶ **Theorem 10** (Main #1). *Let $k \geq 3$ and $\emptyset \neq S \subseteq (\mathbf{t\text{-}in\text{-}k})^c \cap \mathbf{NAE}$. If t is odd, k is even, and S contains tuples of only odd weight, then* $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k} \cup \mathbf{S}, \mathbf{NAE})$ *is tractable. Otherwise,* $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k} \cup \mathbf{S}, \mathbf{NAE})$ *is not solved by BLP+AIP.*

The tractability part of Theorem 10 follows easily from existing work, cf. [14]. Our contribution is ruling out the applicability of BLP+AIP from [11]. Using Theorem 9, we prove the second part of Theorem 10 for $t = 1$ in Section 4 and for general t in [14].

▶ **Theorem 11** (Main #2). *Let $k \geq 3$ and $\emptyset \neq S \subseteq (\mathbf{t\text{-}in\text{-}k})^c \cap \mathbf{NAE}$. If t is odd, k is even, and S contains tuples of only even weight, then* $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE} \setminus \mathbf{S})$ *is tractable. Otherwise,* $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE} \setminus \mathbf{S})$ *is NP-hard.*

Again, the tractability part of Theorem 11 follows easily from existing work. Our contribution is establishing the hardness. It essentially follows from the following result.

▶ **Theorem 12.** *Let $k \geq 3$ and let $\mathbf{T} \subseteq \{0,1\}^k$ be a relation such that* $\mathrm{CSP}(\mathbf{T})$ *is NP-hard. Then* $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k}, \mathbf{T})$ *is tractable if and only if $\mathbf{T} = \mathbf{NAE}$.*

Theorem 12 is proved in Section 5 and relies on Theorem 5, as well as a symmetrisation trick (Proposition 14, observed independently in [4]) and the following simple observation.

▶ **Proposition 13.** *Let $t, t' \geq 1$ and let R be a symmetric relation on $[t]$. For any function $f : [t] \to [t']$, the component-wise image of R under f, denoted $f(R)$, is also symmetric.*

Proof. Suppose that $\mathbf{y} \in f(R)$, so $\mathbf{y} = f(\mathbf{x})$ for some $\mathbf{x} \in R$. We must show that $\pi(\mathbf{y}) \in f(R)$ for an arbitrary permutation π. But since R is symmetric, we have $\pi(\mathbf{x}) \in R$, and so $f(\pi(\mathbf{x})) = \pi(\mathbf{y})$ since f is applied component-wise. ◀

▶ **Proposition 14.** *Let $(\mathbf{A}, \mathbf{B})$ be a PCSP template with $\mathbf{A}$ symmetric. For each relation $R \in \mathbf{B}$, let R' be the largest symmetric relation contained in R. Let $\mathbf{B}'$ be the relational structure with the same domain as $\mathbf{B}$ but with relations R' instead of R. Then* $\mathrm{PCSP}(\mathbf{A}, \mathbf{B})$ *is polynomial-time equivalent to* $\mathrm{PCSP}(\mathbf{A}, \mathbf{B}')$.

Proof. We must first check that $(\mathbf{A}, \mathbf{B}')$ is a valid PCSP template, i.e., that there is a homomorphism $\mathbf{A} \to \mathbf{B}'$. Let ϕ be a homomorphism from $\mathbf{A}$ to $\mathbf{B}$. By Proposition 13, $\phi(\mathbf{A})$ is symmetric, and since $\mathbf{B}'$ is the largest symmetric relational structure contained in $\mathbf{B}$, we have $\phi(\mathbf{A}) \subseteq \mathbf{B}'$. Therefore $(\mathbf{A}, \mathbf{B}')$ is a valid PCSP template.

The reduction $\mathrm{PCSP}(\mathbf{A}, \mathbf{B}) \leq_p \mathrm{PCSP}(\mathbf{A}, \mathbf{B}')$ is trivial since $\mathbf{B}' \subseteq \mathbf{B}$.

To see that $\mathrm{PCSP}(\mathbf{A}, \mathbf{B}') \leq_p \mathrm{PCSP}(\mathbf{A}, \mathbf{B})$, suppose that a relation $R \in \mathbf{B}$ gives rise to the symmetric relation $R' \in \mathbf{B}'$ as described above. For each constraint $C = R'(x_1, ..., x_k)$ of the symmetrised instance of $\mathrm{PCSP}(\mathbf{A}, \mathbf{B}')$, we create $k!$ constraints by taking all coordinate permutations of C. Homomorphisms to $\mathbf{A}$ are preserved since $\mathbf{A}$ is symmetric. Conversely, suppose that we have a homomorphism ψ from the created instance to $\mathbf{B}$ and suppose that the tuple $\mathbf{x}$ was removed from R to create R'. Then no constraint is assigned $\mathbf{x}$ under ψ, since by our construction this would force all permutations of $\mathbf{x}$ to appear in constraints, violating membership in the relation R. Therefore, for any removed tuple $\mathbf{x}$, applying ψ does not produce $\mathbf{x}$ in any constraint, so ψ is a homomorphism from the original input to $\mathbf{B}'$. To complete the reduction, we repeat this construction for each $R \in \mathbf{B}$. ◀

4 Adding tuples for $t = 1$

We will rule out 2-block-symmetric polymorphisms of certain odd arities for PCSP templates of the form $(\mathbf{1\text{-}in\text{-}k} \cup \{\mathbf{x}\}, \mathbf{NAE})$ such that the weight of $\mathbf{x}$ is even if k is even. This implies the second part of Theorem 10 with $t = 1$. The more general case stated in Theorem 10, for any $t \geq 1$, can be found in [14].

Any 2-block-symmetric function $f : \{0,1\}^{2m+1} \to \{0,1\}$ of odd arity $2m+1$ is determined by the values on the $(m+2)(m+1)$ possible combinations of weights of the two blocks. Thus we will represent f by $f(x,y)$, where x and y are the number of 1's on the odd and even coordinates, respectively.

▶ **Proposition 15.** *Let $k \geq 3$ and $2 \leq d \leq \frac{k+1}{2}$ be such that if k is even then so is d. Let $\mathbf{x}$ be a tuple of weight d. Then,* $\mathrm{Pol}(\mathbf{1\text{-}in\text{-}k} \cup \{\mathbf{x}\}, \mathbf{NAE})$ *has no 2-block-symmetric function of arity $2(k-d+1)+1$.*

Proof. Since **NAE** is symmetric, permuting the rows of a matrix of inputs to a polymorphism permutes the values of the output tuple and does not affect membership in **NAE**. Hence we will assume that $\mathbf{x} = 1^d 0^{k-d}$. Let f be a 2-block-symmetric function of arity $2(k-d+1)+1$. Thus the odd block is of size $k-d+2$ and the even block is of size $k-d+1$. We exhibit a set of tableaux such that for any f, one of these tableaux prevents f from being a polymorphism of $(\mathbf{1\text{-}in\text{-}k} \cup \{\mathbf{x}\}, \mathbf{NAE})$. Each tableau in this set contains the same construction on its even coordinates: the tuple $\mathbf{x}$ as its first column, followed by the $(k-d) \times (k-d)$ identity matrix below and to the right of $\mathbf{x}$, so that every row has exactly one 1. An illustration is given in Figure (1a).

$$\begin{pmatrix} 1&0&0&0&0&0\\ 1&0&0&0&0&0\\ 1&0&0&0&0&0\\ 1&0&0&0&0&0\\ 0&1&0&0&0&0\\ 0&0&1&0&0&0\\ 0&0&0&1&0&0\\ 0&0&0&0&1&0\\ 0&0&0&0&0&1 \end{pmatrix} \qquad \begin{pmatrix} 1&0&0&0&0&0&0\\ 0&1&0&0&0&0&0\\ 0&0&1&0&0&0&0\\ 0&0&0&1&0&0&0\\ 0&0&0&0&1&0&0\\ 0&0&0&0&0&1&0\\ 0&0&0&0&0&0&1\\ 0&0&0&0&0&0&0\\ 0&0&0&0&0&0&0 \end{pmatrix}$$

(a) Even block. **(b)** Odd block if $f(0,1) = f(1,1)$.

Figure 1 Example with $k = 9$ and $d = 4$.

It remains to give only the description of each tableau's odd coordinates.

If $f(0,1) = f(1,1)$, then the block of odd coordinates consists of the $(k-d+2) \times (k-d+2)$ identity matrix on top of $d-2$ rows of zeros. Since $2 \leq d < k$, the dimensions of the identity matrix are between 3 and k. An illustration is given in Figure (1b).

If $f(1,1) = f(2,1)$, then we obtain the block of odd coordinates by adding any tuple of weight 1 to the block of even coordinates.

Otherwise we have $f(0,1) \neq f(1,1) \neq f(2,1)$, so $f(0,1) = f(2,1)$.

If the number of odd coordinates $k-d+2$ is even, then we place two copies of the $\frac{k-d+2}{2} \times \frac{k-d+2}{2}$ identity matrix in the first $\frac{k-d+2}{2}$ rows, followed by zeros in the remaining rows. There are always enough rows to accommodate these matrices since $\frac{k-d+2}{2} \leq k \Leftrightarrow k+d \geq 2$. An illustration is given in Figure (2a).

$$\begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

(a) Odd block with $d = 5$ and $k - d + 2 = 6$ even.

$$\begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

(b) Odd block with $d = 4$ and $k - d + 2 = 7$ odd.

Figure 2 Example with $k = 9$ and $f(0,1) = f(2,1)$.

If $k - d + 2$ is odd then so is $k - d$. By the assumption "even k implies even d", we must have k odd and d even. The construction consists of the tuple $\mathbf{x}$ with the $d \times d$ identity matrix to its right. To fill the remaining $k - 2d + 1$ columns (assuming $d \leq \frac{k+1}{2}$), we place two copies of the $\frac{k-2d+1}{2} \times \frac{k-2d+1}{2}$ identity matrix starting from row $d+1$ and column $d+2$, and fill any remaining rows with zeros. There are always enough rows to accommodate the identity matrices since $\frac{k-2d+1}{2} \leq k - d$. An illustration is given in Figure (2b). ◀

▶ **Proposition 16.** *Let $k \geq 3$ and $\frac{k+1}{2} < d < k$ be such that if k is even then so is d. Let $\mathbf{x}$ be a tuple of weight d. Then,* $\mathrm{Pol}(\mathbf{1\text{-}in\text{-}k} \cup \{\mathbf{x}\}, \mathbf{NAE})$ *has no 2-block-symmetric function of arity $2k + 1$.*

Proof. Without loss of generality let $\mathbf{x} = 1^d 0^{k-d}$. The proof is similar to the proof of Proposition 15: We will again exhibit a set of tableaux such that for any f, one of these tableaux prevents f from being a polymorphism of $(\mathbf{1\text{-}in\text{-}k} \cup \{\mathbf{x}\}, \mathbf{NAE})$. Each tableau in this set has the $k \times k$ identity matrix as its even coordinates, so it remains only to give a description of each tableau's odd coordinates. Consider the values $f(1,1)$, $f(2,1)$, and $f(3,1)$: At least two of these must be equal since f takes only the values 0 and 1.

If $f(1,1) = f(2,1)$, then taking the odd coordinates to be the $k \times k$ identity matrix along with any other tuple of weight 1 prevents f from being a polymorphism.

If $f(1,1) = f(3,1)$, the odd coordinates are as follows: the first column is the tuple $\mathbf{x}$, followed immediately below and to the right by the $(k-d) \times (k-d)$ identity matrix, and then by two copies of the $\frac{d}{2} \times \frac{d}{2}$ identity matrix in the upper-right corner. The tuple $\mathbf{x}$ and the $(k-d) \times (k-d)$ matrix occupy $k - d + 1$ columns, leaving d columns to be filled by the two $\frac{d}{2} \times \frac{d}{2}$ identity matrices, and since d is even, $\frac{d}{2}$ is always an integer. An illustration is given in Figure (3a).

Finally, if $f(2,1) = f(3,1)$, the odd coordinates are as follows: two columns of $\mathbf{x}$, followed immediately below and to the right by two copies of the $(k-d) \times (k-d)$ identity matrix, and then by the $(2d-k-1) \times (2d-k-1)$ identity matrix in the upper-right corner. This fills all the columns. To place the two $(k-d) \times (k-d)$ identity matrices requires $2(k-d)$ columns after the $\mathbf{x}$'s. This is always possible since $2(k-d) \leq k-1 \Leftrightarrow d \geq \frac{k+1}{2}$. After placing these, there remain $2d - k - 1$ columns for the final identity matrix, and since $(2d-k-1) \leq k \Leftrightarrow d \leq k + \frac{1}{2}$, the number of available rows is never exceeded. An illustration is given in Figure (3b). ◀

$$\begin{pmatrix} 1&0&0&0&1&0&0&1&0&0\\ 1&0&0&0&0&1&0&0&1&0\\ 1&0&0&0&0&0&1&0&0&1\\ 1&0&0&0&0&0&0&0&0&0\\ 1&0&0&0&0&0&0&0&0&0\\ 1&0&0&0&0&0&0&0&0&0\\ 0&1&0&0&0&0&0&0&0&0\\ 0&0&1&0&0&0&0&0&0&0\\ 0&0&0&1&0&0&0&0&0&0 \end{pmatrix}$$

(a) Odd block with $f(1,1) = f(3,1)$.

$$\begin{pmatrix} 1&1&0&0&0&0&0&0&1&0\\ 1&1&0&0&0&0&0&0&0&1\\ 1&1&0&0&0&0&0&0&0&0\\ 1&1&0&0&0&0&0&0&0&0\\ 1&1&0&0&0&0&0&0&0&0\\ 1&1&0&0&0&0&0&0&0&0\\ 0&0&1&0&0&1&0&0&0&0\\ 0&0&0&1&0&0&1&0&0&0\\ 0&0&0&0&1&0&0&1&0&0 \end{pmatrix}$$

(b) Odd block with $f(2,1) = f(3,1)$.

Figure 3 Example with $k = 9$ and $d = 6$.

5 Removing tuples

In this section, we will prove Theorem 12 and show how it implies Theorem 11.

▶ **Theorem** (Theorem 12 restated). *Let $k \geq 3$ and let $\mathbf{T} \subseteq \{0,1\}^k$ be a relation such that* CSP($\mathbf{T}$) *is NP-hard. Then* PCSP(**t-*in*-k**, $\mathbf{T}$) *is tractable if and only if* $\mathbf{T} = \mathbf{NAE}$.

Proof. By Proposition 14, we can assume that $\mathbf{T}$ is symmetric. If $\mathbf{T} = \mathbf{NAE}$ then PCSP(**t-in-k**, $\mathbf{T}$) is tractable by Proposition 8. Otherwise, we show that Pol(**t-in-k**, $\mathbf{T}$) does not contain any of the tractable polymorphism families identified in the symmetric Boolean PCSP dichotomy (Theorem 5), and therefore PCSP(**t-in-k**, $\mathbf{T}$) is NP-hard.

The families are constants, OR, AND, XOR, AT, and THR_q for $q \in \mathbb{Q}$, as well as their inversions. We deal first with the non-inverted families. Since $0^k \notin \mathbf{T}$ and $1^k \notin \mathbf{T}$, Pol(**t-in-k**, $\mathbf{T}$) does not contain constants. Let C_k^t be the $k \times k$ matrix containing the k cyclic shifts of the column 1^t0^{k-t}. Then C_k^t prevents the polymorphism families OR, AND, XOR (if k is odd), and THR_q for all $q \neq \frac{t}{k}$. For all k, it remains to show that Pol(**t-in-k**, $\mathbf{T}$) contains neither $\mathrm{THR}_{\frac{t}{k}}$ nor AT. For even k it remains to show that Pol(**t-in-k**, $\mathbf{T}$) excludes XOR when t is even, and likewise when t is odd and $\mathbf{T}$ is missing a tuple of odd weight.

$\mathrm{THR}_{\frac{t}{k}}$: Suppose that $\mathbf{T}$ does not contain the tuple $\mathbf{x} = 1^d0^{k-d}$ of weight d where $1 \leq d < k$. Note that we cannot have $d = t$ as this would violate **t-in-k** $\to \mathbf{T}$, so either $t < d$ or $t > d$.

If $t < d$, then the $k \times d$ matrix M formed by placing C_d^t on top of the $(k-d) \times d$ zero matrix returns the forbidden tuple $\mathbf{x}$ when $\mathrm{THR}_{\frac{t}{k},d}$ is applied. An illustration is given in Figure (4a).

We must check that $\mathrm{THR}_{\frac{t}{k},d}$ is indeed in $\mathrm{THR}_{\frac{t}{k}}$, which requires that $d \times \frac{t}{k} \notin \mathbb{Z}$. This is equivalent to $dt \not\equiv 0 \pmod{k}$. However this is not always true, for example when $t = 2$, $k = 6$ and $d = 3$. When $dt \equiv 0 \pmod{k}$, we take instead $\mathrm{THR}_{\frac{t}{k},2d+1}$ and the $k \times (2d+1)$ input matrix M' consisting of two side-by-side copies of M and any extra column from M. In the first d rows of M, t of the d entries are 1's, so $\mathrm{THR}_{\frac{t}{k},d}$ returns 1 since $\frac{t}{d} > \frac{t}{k}$. Alternatively, in the first d rows of M', at least $2t$ of the $2d+1$ entries are 1's, so $\mathrm{THR}_{\frac{t}{k},2d+1}$ returns 1 since $\frac{2t}{2d+1} > \frac{t}{k}$. Both $\mathrm{THR}_{\frac{t}{k},d}$ and $\mathrm{THR}_{\frac{t}{k},2d+1}$ return 0 when applied to any of the last $k-d$ rows of M and M', respectively, since these rows contain only 0's. This completes the case $t < d$.

If $t > d$, let M be the $d \times (k-d)$ 1's matrix on top of C_{k-d}^{t-d}. Then applying $\mathrm{THR}_{\frac{t}{k},k-d}$ $\mathrm{THR}_{\frac{t}{k}}$ to M returns the forbidden tuple $\mathbf{x}$. An illustration is given in Figure (4b).

$$\mathrm{THR}_{\frac{3}{7},5}\left(\begin{array}{ccccc}1&0&0&1&1\\1&1&0&0&1\\1&1&1&0&0\\0&1&1&1&0\\0&0&1&1&1\\\hline 0&0&0&0&0\\0&0&0&0&0\end{array}\right)=\begin{array}{c}1\\1\\1\\1\\1\\\hline 0\\0\end{array}$$

(a) $t = 3$ and $d = 5$.

$$\mathrm{THR}_{\frac{4}{7},5}\left(\begin{array}{ccccc}1&1&1&1&1\\1&1&1&1&1\\\hline 1&0&0&0&1\\1&1&0&0&0\\0&1&1&0&0\\0&0&1&1&0\\0&0&0&1&1\end{array}\right)=\begin{array}{c}1\\1\\\hline 0\\0\\0\\0\\0\end{array}$$

(b) $t = 4$ and $d = 2$.

Figure 4 Example with $k = 7$.

Again we have to check that $(k-d)\times\frac{t}{k}\notin\mathbb{Z}$, or equivalently, that $(k-d)t\not\equiv 0 \pmod k$. If $(k-d)t\equiv 0 \pmod k$, then $d\neq 1$, and we use instead $\mathrm{THR}_{\frac{t}{k},k-d+1}$ and the input matrix M' which is equal to M but with any one column repeated. Both $\mathrm{THR}_{\frac{t}{k},k-d}$ and $\mathrm{THR}_{\frac{t}{k},k-d+1}$ return 1 when applied to the first d rows of M and M', respectively. In the last $k-d$ rows of M, $t-d$ of the $k-d$ entries are 1's, so $\mathrm{THR}_{\frac{t}{k},k-d}$ returns 0 as $\frac{t-d}{k-d}<\frac{t}{k}$. In the last $k-d+1$ rows of M', at most $t-d+1$ of the $k-d+1$ entries are 1's, so $\mathrm{THR}_{\frac{t}{k},k-d+1}$ returns 0 since $\frac{t-d+1}{k-d+1}<\frac{t}{k}$ (note that $d>1$ in this case). This completes the proof for $t>d$, and thus we conclude that $\mathrm{THR}_{\frac{t}{k}}\not\subseteq \mathrm{Pol}(\textbf{t-in-k},\mathbf{T})$.

AT: Again we split into the cases $t < d$ and $t > d$.

Let $t < d$ and suppose that T does not contain the tuple $\mathbf{x} = 1^d0^{k-d}$ of weight d where $1\leq d<k$. We construct an input that returns $\mathbf{x}$ when a specific AT function is applied. This is done in two stages. First, we construct a matrix M such that for some AT function f, $f(M)$ agrees with $\mathbf{x}$ on all coordinates but one. Next we pad the input M with a matrix P such that for another AT function f', we have $f'(M|P|\cdots|P)=\mathbf{x}$.

To ease readability, we will separate the odd and even columns into two contiguous blocks, with the odd columns appearing first in the matrices. We take $f=\mathrm{AT}_{2d-1}$ and define M to be the following $k\times(2d-1)$ matrix. In the d odd columns, we fill the first d rows with the matrix C_d^t. We fill the remaining $k-d$ rows with 0's. In the $d-1$ even columns, we place on top a row of 1's, followed by $d-1$ rows of 0's, then $t-1$ rows of 1's, and finally $k-d-t+1$ rows of 0's. An illustration is given in Figure (5a).

$$\mathrm{AT}_9\left(\begin{array}{ccccc|cccc}1&0&0&1&1&1&1&1&1\\1&1&0&0&1&0&0&0&0\\1&1&1&0&0&0&0&0&0\\0&1&1&1&0&0&0&0&0\\0&0&1&1&1&0&0&0&0\\\hline 0&0&0&0&0&1&1&1&1\\0&0&0&0&0&1&1&1&1\\\hline 0&0&0&0&0&0&0&0&0\end{array}\right)=\begin{array}{c}0\\1\\1\\1\\1\\\hline 0\\0\\\hline 0\end{array}$$

(a) AT_9.

$$P=\left(\begin{array}{ccc|ccc}1&1&1&1&1&0\\1&1&1&1&0&1\\1&1&1&0&1&1\\\hline 0&0&0&0&0&0\\0&0&0&0&0&0\\0&0&0&0&0&0\\0&0&0&0&0&0\\\hline 0&0&0&1&1&1\end{array}\right)$$

(b) P.

Figure 5 $t = 3$, $k = 8$, and $d = 5$.

Notice that $\mathrm{AT}_{2d-1}(M)$ agrees with $\mathbf{x}$ everywhere except the first coordinate. This happens because the first row of M has too many 1's in the even columns; we would require at least $(d-1)-t+1 = d-t$ more 1's in the odd columns for f to output 1 on the first row. We can achieve this by padding M with a matrix P that increases the proportion of 1's in the odd coordinates of the first row but does not affect the output of AT functions on the other rows.

Take $f' = \mathrm{AT}_{2d-1+2t(d-t)}$ and define the $k \times 2t$ matrix P as follows. In the t odd columns of P, we place t rows of 1's followed by $k-t$ rows of 0's. In the even columns of P, we place C_t^{t-1} in the first t rows, followed by $k-t-1$ rows of 0's, and then by a final row of 1's. An illustration is given in Figure (5b).

By padding M with copies of P, we increase the proportion of 1's in odd columns in the first $t < d$ rows, and in particular in the first row. The 0's in rows $t+1, \ldots, k-1$ do not affect the output, and the 1's in the last row do not affect the output since they are in even columns and the last coordinate of x is always zero since $d < k$. Therefore $f'(M|P|\cdots|P) = \mathbf{x}$, where P appears $d-t$ times. This completes the case $t < d$.

Now let $t > d$ and again suppose that T does not contain the tuple $\mathbf{x} = 1^d 0^{k-d}$ of weight d. Define the $k \times (2d-1)$ input matrix M to AT_{2d-1} as follows. In the d odd columns of M, we first place d rows of 1's. Then in next $t-d+1$ rows, we place side-by-side as many copies of C_{t-d+1}^{t-d} as we can, removing columns of the last copy if necessary. We fill the remaining rows with 0's. In the $d-1$ even columns, we place a row of 0's, then t rows of 1's, and then fill the remaining rows with 0's. An illustration is given in Figure (6).

$$\mathrm{AT}_7 \left(\begin{array}{cccc|ccc} 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ \hline 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ \hline 1 & 1 & 0 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 1 & 1 & 1 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{array}\right) = \begin{array}{c} 1 \\ 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{array}$$

Figure 6 $t = 6$, $k = 8$, and $d = 4$.

We have $\mathrm{AT}_{2d-1}(M) = x$, which concludes the case $t > d$. Therefore $\mathrm{AT} \not\subseteq \mathrm{Pol}(\textbf{t-in-k}, \mathbf{T})$.

XOR: Let t and k be even. Applying XOR_k to the matrix C_k^t returns the tuple 0^k, so applying XOR_{k-1} to the first $k-1$ columns of C_k^t returns the last column $1^{t-1}0^{k-t}1$. We can "fill in" the 0's in the output by swapping 0-1 pairs of values in the input matrix. In particular, in the columns $k-1, k-3, \ldots, t+1$, we swap the entries in the pairs of rows $(k-1, k-2), (k-3, k-4), \ldots, (t+1, t)$, respectively. The resulting $k \times (k-1)$ matrix M then satisfies $\mathrm{XOR}_{k-1}(M) = 1^k$ and the arity $k-1$ is odd as required. An example with swapped values in bold is illustrated in Figure (7a).

Now let t be odd, k be even, and suppose that T does not contain the tuple $\mathbf{x} = 1^d 0^{k-d}$ of odd weight d. If $t < d$, then XOR_d applied to the input matrix C_d^t padded with $k-d$ rows of 0's returns $\mathbf{x}$. If $t > d$, let M be the $k \times (t-d+1)$ matrix with d rows of 1's followed by the matrix C_{t-d+1}^{t-d}. Fill any extra rows with 0's. Then $\mathrm{XOR}_{t-d+1}(M) = \mathbf{x}$. An illustration is given in Figure (7b). Therefore $\mathrm{XOR} \not\subseteq \mathrm{Pol}(\textbf{t-in-k}, \mathbf{T})$.

$$\mathrm{XOR}_7 \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & \mathbf{1} & 0 & 0 \\ 0 & 1 & 1 & 1 & \mathbf{0} & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & \mathbf{1} \\ 0 & 0 & 0 & 1 & 1 & 1 & \mathbf{0} \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix} = \begin{matrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{matrix}$$

(a) $t = 4$ and $k = 8$.

$$\mathrm{XOR}_3 \left(\begin{array}{ccc} 1 & 1 & 1 \\ \hline 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \\ \hline 0 & 0 & 0 \\ 0 & 0 & 0 \end{array}\right) = \begin{matrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{matrix}$$

(b) $t = 3$, $k = 6$, and $d = 1$.

Figure 7 XOR.

Inversions: Let F be a family of functions. We reduce the task of showing $\overline{F} \not\subseteq \mathrm{Pol}(\mathbf{t\text{-}in\text{-}k}, \mathbf{T})$ to the already completed task of showing $F \not\subseteq \mathrm{Pol}(\mathbf{t\text{-}in\text{-}k}, \mathbf{T})$. Let $\mathbf{x} \in \{0,1\}^k \setminus \mathbf{T}$, let $f \in F$ be a function of arity m, and let M be a $k \times m$ matrix of inputs to f whose columns are **t-in-k** tuples. We established $F \not\subseteq \mathrm{Pol}(\mathbf{t\text{-}in\text{-}k}, \mathbf{T})$ by finding f and M with $f(M) = \mathbf{x}$, and in the remaining cases we must find $\overline{f} \in \overline{F}$ and M such that $\overline{f}(M) = \mathbf{x}$. But since $\overline{f}(M) = \mathbf{x} \Leftrightarrow f(M) = \overline{\mathbf{x}}$, it suffices to find $f \in F$ such that $f(M) = \overline{\mathbf{x}}$, where $\overline{\mathbf{x}} = (1 - x_1, \ldots, 1 - x_k)$ if $\mathbf{x} = (x_1, \ldots, x_k)$.

The families $\overline{\mathrm{AND}}$, $\overline{\mathrm{OR}}$, and $\overline{\mathrm{XOR}}$ (except when t is odd and k is even) are excluded from $\mathrm{Pol}(\mathbf{t\text{-}in\text{-}k}, \mathbf{T})$ in the same way as AND, OR, and XOR, with the same matrices serving as counterexamples. To see that $\overline{\mathrm{AT}}$ and $\overline{\mathrm{THR}_{\frac{t}{k}}}$ are also excluded, let $\mathbf{x} \notin \mathbf{T}$ be a tuple of weight $d, d \neq t, 1 \leq d < k$. Then the tuple $\overline{\mathbf{x}}$ of weight $k - d$ can be returned by an AT function and a $\mathrm{THR}_{\frac{t}{k}}$ function by the arguments above. If $k - d = t$, then the AT and $\mathrm{THR}_{\frac{t}{k}}$ functions of arity 1 output $\overline{\mathbf{x}}$ on input $\overline{\mathbf{x}}$.

Finally, when t is odd and k is even, and $\mathbf{T}$ does not contain the tuple $\mathbf{x}$ of odd weight d, the XOR argument above applies since $\overline{\mathbf{x}}$ also has odd weight $k - d$. Again, if $k - d = t$, then the XOR function of arity 1 outputs $\overline{\mathbf{x}}$ on input $\overline{\mathbf{x}}$. ◀

Schaefer's dichotomy theorem (Theorem 4) allows us to obtain a simple description of all $\mathbf{T}$ with $\mathrm{CSP}(\mathbf{T})$ tractable and $\mathbf{t\text{-}in\text{-}k} \to \mathbf{T}$; a proof can be found in [14].

▶ **Proposition 17.** *Let $k \geq 3$, $1 \leq t < k$, and suppose that $\mathbf{t\text{-}in\text{-}k} \to \mathbf{T}$. Then $\mathrm{CSP}(\mathbf{T})$ is tractable if and only if*

1. *$0^k \in \mathbf{T}$ or $1^k \in \mathbf{T}$, or*
2. *t is odd, k is even, and $\mathbf{T}$ contains all tuples of odd weight.*

Observe that Proposition 17 in particular implies Proposition 7, NP-hardness of $\mathrm{CSP}(\mathbf{t\text{-}in\text{-}k})$.

With Proposition 17 in hand, we can prove Theorem 11.

▶ **Theorem** (Theorem 11 restated). *Let $k \geq 3$ and $\emptyset \neq S \subseteq (\mathbf{t\text{-}in\text{-}k})^c \cap \mathbf{NAE}$. If t is odd, k is even, and S contains tuples of only even weight, then $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE} \setminus \mathbf{S})$ is tractable. Otherwise, $\mathrm{PCSP}(\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE} \setminus \mathbf{S})$ is NP-hard.*

Proof. The tractability in the first statement of the theorem is proved in [14]. Otherwise, t is even, or k is odd, or S contains a tuple of odd weight. Take $\mathbf{T} = \mathbf{NAE} \setminus \mathbf{S}$. Observe that case (1) of Proposition 17 does not apply as neither 0^k nor 1^k is part of the template. Moreover,

case (2) of Proposition 17 does not apply either: If t is odd and k is even then S contains a tuple of odd weight and hence $\mathbf{NAE} \setminus \mathbf{S}$ cannot have all odd weight tuples. Thus, by Proposition 17, CSP($\mathbf{T}$) is NP-hard. Then, by Theorem 12, PCSP($\mathbf{t\text{-}in\text{-}k}, \mathbf{T}$) = PCSP($\mathbf{t\text{-}in\text{-}k}, \mathbf{NAE} \setminus \mathbf{S}$) is NP-hard. ◀

Abstract

Subshifts of finite type (SFTs) are sets of colorings of the plane that avoid a finite family of forbidden patterns. In this article, we are interested in the behavior of the growth of the number of valid patterns in SFTs. While entropy h corresponds to growths that are squared exponential 2^{hn^2}, surface entropy (introduced in Pace's thesis in 2018) corresponds to the eventual linear term in exponential growths. We give here a characterization of the possible surface entropies of SFTs as the Π_3 real numbers of $[0, +\infty]$.

1 Introduction

For a finite alphabet of colors, a two dimensional subshift is the set of all colorings of the plane $\mathbb{Z}^2$ that respect some local constraints. These constraints are usually given as a family of forbidden patterns. The most studied class of subshift are *Subshifts of Finite Type* (SFTs), subshifts that can be defined by a finite family of forbidden patterns. A famous special case is defined by Wang tilesets (unit squares with colored edges that may be placed side by side only when the colors on the edges match) are a famous special: the set of all tilings by some Wang tileset is always an SFT.

Subshifts were introduced in order to discretize continuous dynamical systems and are themselves dynamical systems. While it has long been known that most problems concerning Wang tiles (and thus subshifts) are undecidable [2, 5, 6], the role of computability has since shifted from an obstacle to a major tool in the study of SFTs and other related classes of subshifts. An aperiodic subshift has for instance been constructed [4] based on Kleene's *fixed-point theorem* [11], a classical theorem of computability theory. Many conjugacy invariants have been characterized using computability or complexity classes. The first such characterization was for *topological entropy*, which measures the exponential growth of the number of valid colorings of finite patterns. For a subshift X, its (topological) entropy is defined by:

© Antonin Callard and Pascal Vanier;
licensed under Creative Commons License CC-BY 4.0

$$h(X) = \lim \frac{\log N_X(n)}{n^2}$$

where $N_X(n)$ denotes the number of $n \times n$ patterns appearing in colorings of X. Having entropy h corresponds to having $N_X = 2^{hn^2+o(n^2)}$. It turns out that the possible entropies for $\mathbb{Z}^2$ are exactly the upper semi-computable [8] real numbers. Another invariant related to growth, called *entropy dimension*, was then characterized using the arithmetical hierarchy of real numbers [13]. Many other invariants have since been linked to computability: for instance, there is a relationship between periodic colorings and computational complexity classes [10], subactions [7, 1, 3] can be characterized through recursively enumerable forbidden patterns, and many more.

We focus here on the notion of *surface entropy*, a notion which was introduced in Dennis Pace's thesis [14] in order to quantify the linear term inside exponential growth functions. Indeed, topological entropy cannot distinguish between the two following behaviors of the complexity function:

$$N_X(n) \approx 2^{hn^2} \qquad \text{and} \qquad N_X(n) \approx 2^{hn^2+2sn}.$$

Surface entropy corresponds roughly to the s term in the second behavior and will be introduced more formally in Subsection 2.2. In his thesis, Pace realizes Π_1 and Σ_1 numbers of the arithmetical hierarchy of real numbers and conjectures that surface entropies are exactly the Π_3 numbers. This is exactly what we prove here:

▶ **Theorem 1.** *The class of surface entropies of $\mathbb{Z}^2$ SFTs is $[0, +\infty] \cap \Pi_3$.*

In fact, surface entropies still cover the whole class of Π_3 real numbers for sofic subshifts, which are the letter-by-letter projections of SFTs, and for effective subshifts, which are the subshifts that can be defined with a recursively enumerable family of forbidden patterns:

▶ **Theorem 2.** *The class of surface entropies of $\mathbb{Z}^2$ sofic subshifts, and of $\mathbb{Z}^2$ effective subshifts, is $[0, +\infty] \cap \Pi_3$.*

The paper is organized as follows. The next section recalls some background and useful definitions. Section 3 and Section 4 focus on the proof of Theorem 1, and provide in particular a construction which creates $\mathbb{Z}^2$ SFTs with arbitrary Π_3 surface entropies. Some open questions are then discussed in Section 5.

2 Preliminaries

2.1 Subshifts

This subsection introduces some standard definitions and facts about subshifts. The reader may consult [12] for more details.

Let Σ be a finite alphabet of colors. A $\mathbb{Z}^d$ *configuration* (in this paper, $d = 1$ or $d = 2$) is a coloring $x : \mathbb{Z}^d \mapsto \Sigma$, and the value of x at position z is noted x_z. A *(d-dimensional) pattern* is a coloring $p : D \mapsto \Sigma$, with $D \subseteq \mathbb{Z}^d$ a finite domain. For a configuration x, we say that a pattern p appears in x (noted $p \sqsubseteq x$) if there exists some position $t \in \mathbb{Z}^d$ such that for all $z \in D$, $p_z = x_{t+z}$. A *subshift* is a set of colorings/configurations defined by some family of forbidden patterns. Each family of forbidden patterns $\mathcal{F}$ defines a subshift, possibly empty:

$$X_{\mathcal{F}} = \{(x : \mathbb{Z}^d \mapsto \Sigma) : \forall p \in \mathcal{F}, p \not\sqsubseteq x\}.$$

A subshift is *effective* if it can be defined by a recursively enumerable family of forbidden patterns. A subshift is *of finite type* (SFT) if it can be defined by a finite family of forbidden patterns. A subshift Y on Σ is *sofic* if there exists an SFT X on an alphabet Σ' and a letter-by-letter projection $\pi : \Sigma' \mapsto \Sigma$ that sends X on Y.

Finally, for any $\mathbb{Z}$ subshift X_1, the $\mathbb{Z}^2$ *lift of* X_1 is the subshift Y_2 whose configurations are vertically repeated configurations of X_1:

$$Y_2 = \{(y : \mathbb{Z}^2 \mapsto \Sigma) : \exists x \in X_1, \forall i, j \in \mathbb{Z}, y_{(i,j)} = x_i\}.$$

2.2 Complexity function of $\mathbb{Z}^2$ subshifts

Given a $\mathbb{Z}^2$ subshift X, its *complexity function* $N_X(m, n)$ (for $m, n \in \mathbb{N}$) is the number of different patterns that appear in a rectangle of size $m \times n$ in the configurations of X:

$$N_X(m, n) = \left|\left\{p \in \Sigma^{m\times n} : \exists x \in X, p \sqsubseteq x\right\}\right|.$$

This complexity function can be used to define the (topological) entropy $h(X)$:

$$h(X) = \lim_{n\to+\infty} \frac{\log N_X(n, n)}{n^2}.$$

This led Dennis Pace to introduce in [14] the notion of *surface entropy*, which corresponds to the "linear term" of the complexity function. Here, we define *surface entropy with eccentricity* α as:

$$h_s(X, \alpha) = \limsup_{n\to+\infty} \frac{\log N_X(pn, qn) - pqn^2 h(X)}{(p + q)n} \qquad \text{with } \alpha = \frac{p}{q} \in \mathbb{Q}^+,$$

where p, q are relatively prime integers. This definition slightly differs from the one of [14]; this will be further discussed in Section 5.

Note that in the definition of the topological entropy, only square patterns are used. In fact, any rectangular patterns would generate the same value. Interestingly, this is no longer the case with surface entropy: the *eccentricity* (ratio of the patterns' widths to heights) affects the value of the calculations. This explains why h_s is a function of both a subshift X and a rational parameter $\alpha = p/q$. The study in [14] focuses on both the realizability of specific surface entropies, and the behavior of surface entropies as functions of their eccentricities.

While surface entropy is not a conjugacy invariant, it was proved in [14] that the finiteness of surface entropy is invariant under conjugacy. For more details or examples about surface entropies, one may refer to [14, Section 3.2].

Links with other growth-type invariants

Links with (topological) entropy. If X_1 is a $\mathbb{Z}$ subshift, and Y_2 its $\mathbb{Z}^2$ lift (ie. the subshift whose configuration are vertically repeated configurations of X_1), then $h_s(Y_2, \alpha) = \frac{\alpha}{1+\alpha} h(X_1)$.

Links with entropy dimension. In [13], a growth-type invariant called *entropy dimension* was introduced as $h_d(X) = \limsup_{n\to+\infty}(\log\log N_X(n))/\log n$. It roughly represents the exponent α if $\log N_X(n) \simeq n^\alpha$. For any $\mathbb{Z}^2$ subshift X, $0 \leq h_d(X) \leq 2$.

Entropy dimension and surface entropies are linked as follows:

- If $h_d(X) = 2$, then $h_s(X)$ can be either finite or infinite (similarly to $h_d(X) = 1$);
- If $1 < h_d(X) < 2$, then $h_s(X) = +\infty$;
- If $h_d(X) = 1$, $h_s(X)$ can either be finite (if $\log N_X(n) = O(n)$, see [14, Example 3.2.14]) or infinite (for example, if $\log N_X(n) \simeq n \log n$, see [14, Example 3.2.4]);
- If $0 \leq h_d(X) < 1$, then $h_s(X) = 0$.

2.3 Arithmetical hierarchy of real numbers

In order to state our main result, this section recalls from [15] the arithmetical hierarchy of real numbers, which classifies elements of the real line according to their computational properties. Denote by $\Gamma_{\mathbb{Q}}$ the set of total computable functions $f : \mathbb{N}^k \mapsto \mathbb{Q}$ for any k. For $n \geq 1$, the classes of real numbers Σ_n, Π_n and Δ_n are defined as follows:

$$\Sigma_n = \{ \sup_{i_1} \inf_{i_2} \sup_{i_3} \dots f(i_1, \dots, i_n) \mid f \in \Gamma_{\mathbb{Q}} \}$$

$$\Pi_n = \{ \inf_{i_1} \sup_{i_2} \inf_{i_3} \dots f(i_1, \dots, i_n) \mid f \in \Gamma_{\mathbb{Q}} \}$$

$$\Delta_n = \Sigma_n \cap \Pi_n.$$

It is known that for any $n \geq 1$, the inclusions $\Pi_n \subset \Sigma_{n+1}$ and $\Sigma_n \subset \Pi_{n+1}$ are proper. One may refer to [15] for more details.

In this paper, we will be interested in the third level of the hierarchy, and one of its equivalent characterization proved in [15]:

$x \in \Pi_3$ iff there exists $f \in \Gamma_{\mathbb{Q}}$ such that $x = \limsup_i \inf_j f(i, j)$.

3 Arithmetical restrictions of surface entropies

In this section, we prove the first and easiest direction of Theorem 1:

▶ **Theorem 3.** *For any $\mathbb{Z}^2$ SFT X and $\alpha \in \mathbb{Q}^+$:*

$$h_s(X, \alpha) \in [0, +\infty] \cap \Pi_3$$

Proof. Let X be a $\mathbb{Z}^2$ an SFT. We prove that $N_X(m, n)$ is a Π_1 real number (it is not computable in X: indeed, $N_X(m, n) = 0$ if and only if $X = \emptyset$; the latter is well-known for being undecidable). A pattern is said to be *admissible* if it does not contain a pattern which is forbidden: any valid pattern of X is admissible, but the converse is false. For $j \geq m, n$, define $N_X^{(j)}(m, n)$ as the number of $m \times n$ patterns that appear at the center of admissible patterns of size $j \times j$ (ie. the squares of size $j \times j$ in which none of the forbidden patterns of X appear).

By compactness, if a pattern is not valid in X, there exists some j such that it does not appear in any admissible pattern bigger than $j \times j$: this proves $N_X(m, n) = \inf_{j \geq m,n} N_X^{(j)}(m, n)$. In particular, this implies that $\log N_X(m, n)$ is a Π_1 real number.

It follows that $h(X)$ is a Π_1 real number (as proved in [8]). As the difference of two Π_1 real numbers is a Δ_2 real number, this proves that for any $\alpha = p/q \in \mathbb{Q}^+$, and for every $n \in \mathbb{N}$, the following is a Δ_2 real number:

$$\frac{\log N_X(pn, qn) - pqn^2 h(X)}{(p + q)n}$$

which then leads to $h_s(X, \alpha) \in \Pi_3$. Finally, by sub-additivity $h_s(X, \alpha) \geq 0$ (see [14]). ◀

A very similar reasoning proves that this is still the case for sofic or effective subshifts:

▶ Remark 4. For any $\mathbb{Z}^2$ sofic or effective subshift X and $\alpha \in \mathbb{Q}^+$, $h_s(X, \alpha) \in [0, +\infty] \cap \Pi_3$.

Proof. As sofic subshifts are effective, we can focus on the latter. For X an effective subshift, we slightly alter the definition of $N_X^{(j)}(m,n)$: it will now count the number of patterns of size $m \times n$ which appear in the squares of size $j \times j$ in which *none of the first j enumerated forbidden patterns* of X appear. Then we still have $N_X(m,n) = \inf_{j \geq m,n} N_X^{(j)}(m,n)$, and this still leads to $\log N_X(m,n) \in \Pi_1$ and $h(X) \in \Pi_1$.

After this, the end of the proof is the same. ◀

4 Realization of Π_3 real numbers as surface entropies

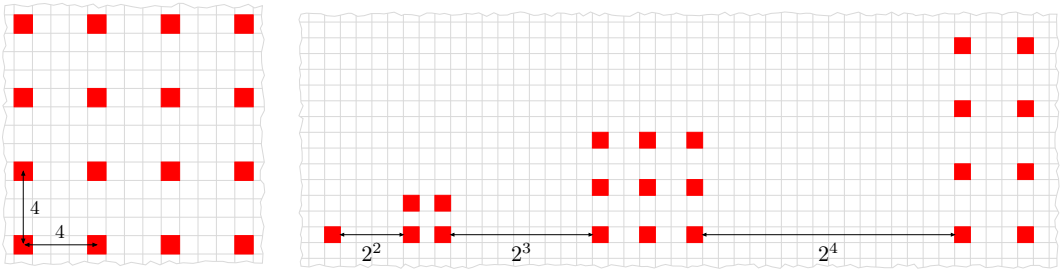
In this section, we prove the other (and harder) direction of Theorem 1. Because [14] provides examples of SFTs with infinite surface entropy, we now prove:

▶ **Theorem 5.** *For any $x \in [0, +\infty) \cap \Pi_3$, there exists an SFT X with surface entropy:*

$$\forall \alpha \in \mathbb{Q}^+, \qquad h_s(X, \alpha) = \frac{\min(\alpha, 1)}{1+\alpha} \cdot x.$$

Theorem 1 and 2 are consequences of the previous section together with this statement.

A naive construction could consist in lifting $\mathbb{Z}$ subshifts to obtain $\mathbb{Z}^2$ SFTs with specific surface entropies. However, as the topological entropy of a $\mathbb{Z}$ effective subshift is a Π_1 real number (by ideas similar to Section 3), lifts can only have Π_1 surface entropies (cf. the link between $\mathbb{Z}$ entropies and $\mathbb{Z}^2$ surface entropies in Section 2.2).



Any method to overcome this limitation would need some creative spatial distribution. Hence the *sparse squares* we develop below.

Proof. Let $x \in [0, +\infty) \cap \Pi_3$ be a Π_3 real number.

Let $e \in \mathbb{N}$ and $x' \in [0, 1)$ be such that $x = e + x'$. Because x' is also a Π_3 real number, there exists a computable function $f : \mathbb{N}^2 \mapsto \mathbb{Q}$ such that $x' = \limsup_k \inf_l f(k,l)$ (see the characterization in Subsection 2.3). We can assume that f only takes values in $[0, 1)$.

In the following subsections, we create an SFT X which verifies the property of Theorem 5. The proof is organized as follows:

1. Subsection 4.1 introduces our "sparse squares" construction, which aims at creating a set of colorings of the plane with controlled surface entropy. All the following sections focus on implementing this geometrical construction into an actual SFT X.
2. Subsection 4.2 recalls the Toeplitz sequences, which are sequences of uniform densities. They will be used in the sparse square layout to control the density of each square.
3. In Subsection 4.3, we create a $\mathbb{Z}$ effective subshift X_1. Effectiveness gives us a lot of room to control its patterns, and we will use X_1 as the foundation of X.
4. We use the *fixed-point* construction of [3] to create a $\mathbb{Z}^2$ SFT which simulates X_1. Subsection 4.4 provides an intermediary lemma about the entropy and the surface entropy of this construction: in our case, it proves that the intermediary construction has surface entropy zero.
5. In Subsection 4.5, we then create the desired SFT X, which arranges the sparse squares on the plane (with the help of the previous points).
6. Finally, in Subsection 4.6 and Subsection 4.7 we create and compute the surface entropy of X. This proves that X is a valid example for Theorem 5.

(a) 4^{th} sparse square. **(b)** (Portion of) the sparse square layout.

Figure 1 Presentation of the sparse square layout.

4.1 The sparse squares and the sparse square layout

To understand the idea behind this construction, consider the *full shift* over $\mathbb{Z}^2$ on the alphabet $\{0,1\}$. Configurations are full grids of *free bits*, ie. bits that are allowed to vary freely in $\{0,1\}$. It is not difficult to see that for the full shift, $\log N_{\text{full}}(n,n) = n^2$. In particular, its complexity function is quadratic in n, and its entropy is 1.

To realize specific surface entropies, we first need to figure out a way to contribute *linearly* to $\log N_X$, instead of quadratically. To do this, we create a sequence of *sparse squares*. A sparse square is, roughly, a finite piece taken from the full shift, but whose points are moved apart from one another: the square is *sparsified*.

More precisely, the *sparse square of index* k (see Figure 1a) is a set of positions that form a finite grid. Any position not in this set of points is blank. In the grid, there are k columns (the distance between two columns is also k), and in each column there are k points (the distance between two points in a column is also k).

The *sparse square layout* (see Figure 1b) makes the sparse squares sit next to one another on a single line, according to their indices. We set the distance between the square of index $k-1$ and the square of index k to 2^k.

The key feature of this geometrical layout lies in its linearity: the k^{th} square has edges of size $k(k-1)+1$: thus it has an area which is roughly $\left(k^2\right)^2$, while it also contains k^2 points. In addition, as the distance between two points increases as one considers squares of greater indices, compactness will only lead to degenerate configurations that contain at most one point. As such, they will not contribute significantly to the complexity function.

For now, the set of positions in the sparse square layout is not very interesting. In order to increase the complexity function, we will allow free bits to vary at each position inside a sparse square. Additionally, to create a surface entropy related to x, the density of free bits in each square will be related to x.

More precisely, define $x'_k = \inf_l f(k,l)$ (recall that $x = e + x'$, and $x' = \limsup_k \inf_l f(k,l)$). For each k, let t_k be a word of size k over the alphabet $\{\text{On}, \text{Off}\}$, whose density of On is x'_k. Then, define the subshift X' as (the closure of) the following configurations (see Figure 2):

- These configurations follow the sparse square layout.
- Each position not marked in the sparse square layout is blank (ie. marked with $\square$).
- The word t_k is written in each row of the k^{th} square.

On the positions marked by On, we then allow free bits to vary. On every position of the sparse square, we also allow free letters to vary in $\{1,\dots,2^e\}$. With this, the square of index k contributes to $\log N_{X'}$ with a term $k^2(x'_k + e)$. More precisely:

▶ **Lemma 6.** *The k^{th} sparse square contributes to $\log N_{X'}$ more than $k^2(e + x'_k) + O(k)$.*

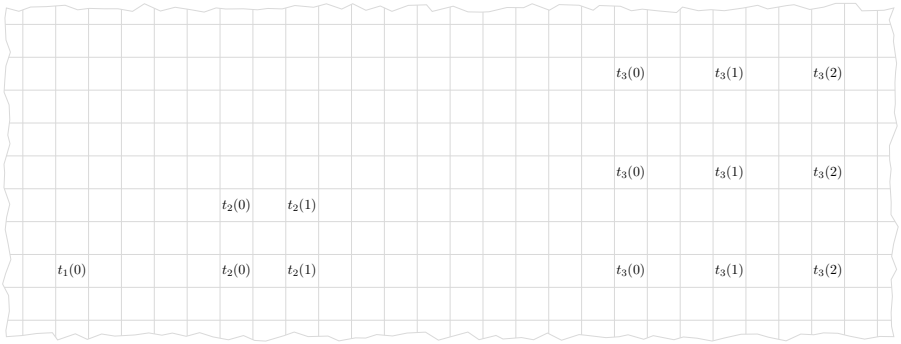


Figure 2 A sequence of words (t_k) written in (a finite piece of) the sparse square layout.

Proof. As this is a lower bound, consider the position of the k^{th} sparse square fixed, and only look at the contribution induced by its "free bits" and "free letters".

Free bits: (For now, we assume the "free letters" are fixed). A word t_k of density x'_k is written in this square, and the square contains $k|t_k|_{\text{ON}}$ free bits: indeed, there are k identical lines, and in each line there are $|t_k|_{\text{ON}}$ positions marked with ON. Additionally, one has $|t_k|_{\text{ON}} = kx'_k + O(1)$ (because the density is x'_k). This implies that all the free bits of the k^{th} sparse square (fixed at this position), when marked with t_k, contribute to the complexity function with a term $\exp_2(k|t_k|_{\text{ON}}) = \exp_2(k^2x'_k + O(k))$.

Free letters: Recall that free letters vary in the alphabet $\{1, \dots, 2^e\}$ at each point in the k^{th} sparse squares. There are k^2 points in this square, so the previous contribution is multiplied by $\exp_2(k^2e)$. This concludes the proof. ◀

This provides a lower bound for the complexity function: for a given size of pattern, we only count the biggest square that fits in it. If the squares do not interfere too much, one should expect the surface entropy to "converge" towards $\limsup_k x'_k + e = x' + e = x$.

The previous paragraphs were a draft of a geometrical construction. Below, we create an actual $\mathbb{Z}^2$ SFT X which implements this subshift (with some additional construction lines). Then, we formally prove that X has the desired surface entropy.

4.2 Effective $\mathbb{Z}$ upper-density Toeplitz subshifts

In order to create specific densities of letters in a subshift, we recall the useful Toeplitz sequences from [9]. Let $0 \leq y = \sum_{i=1}^{+\infty} y_i 2^{-i} \leq 1$ be a real number. A *Toeplitz sequence* associated to y is a bi-infinite sequence $b \in \{0,1\}^{\mathbb{Z}}$ such that:

$$\forall k \geq 1, \exists j_k \notin \left(\sum_{i=1}^{k-1} j_i + 2^i \mathbb{Z} \right), \ b_{j_k + 2^k \mathbb{Z}} = y_k$$

i.e. one bit in two is y_1; on the remaining bits, one bit in two is y_2; etc...

For any $y \in [0,1)$, we define the *upper-density Toeplitz subshift* $\mathcal{T}(y)$ *associated to* y:

$$\mathcal{T}(y) = \{(b) \in \{0,1\}^{\mathbb{Z}} : \exists 0 \leq y' \leq y, (b) \text{ is a Toeplitz sequence associated to } y'\}.$$

In the following subsection, we will use subwords of Toeplitz sequences on the alphabet $\{\text{ON}, \text{OFF}\}$ (rather than $\{1,0\}$). They have high regularity and tightly controlled densities. Indeed, assume that t_n is a factor of length n which appears in $\mathcal{T}(y)$. Then the number of letters ON in t_n is bounded by $0 \leq |t_n|_{\text{ON}} \leq ny + O(1)$.

We will use these subshits in the context of Π_1 real numbers. Indeed:

▶ **Lemma 7.** *If $y \in \Pi_1 \cap [0,1)$, then $\mathcal{T}(y)$ is an effective $\mathbb{Z}$ subshift.*

Proof. If $y \in \Pi_1$, there exists a computable total function $f : \mathbb{N} \mapsto \mathbb{Q}$ such that $y = \inf_n f(n)$. It is possible to recursively enumerate the different values of f, to computably forbid patterns of $\mathcal{T}(y)$ which do not respect the structure of Toeplitz sequences, and to computably forbid patterns of $\mathcal{T}(y)$ that respect the structure of Toeplitz sequences but whose density is too high. ◀

4.3 Building the base line

Consider the line on which all the sparse squares sit in the previous layout. We call it the *base line*. In this section, we create a $\mathbb{Z}$ effective subshift X_1 on the alphabet $\Sigma = \{\#, S, E, B, \text{On}, \text{Off}\}$ which implements the base line: its configurations will be all the possible values for this base line.

Base of the k^{th} sparse square. The base of the k^{th} sparse square is composed of k points, each separated by $k-1$ blanks (in X_1, these blanks will be marked by B). In each point, a letter On or Off is written, and the word t_k composed by these k letters is a Toeplitz subword of $\mathcal{T}(x'_k)$, where $x'_k = \inf_l f(k,l)$.

This naturally leads to defining the set of all possible bases for the k^{th} sparse square:

$$\mathcal{W}_k = \{t_k(1)\ B^{k-1}\ t_k(2)\ B^{k-1}\ \dots\ B^{k-1}\ t_k(k) \mid t_k \text{ is a toeplitz subword in } \mathcal{T}(x'_k)\}.$$

Prefixes for the squares. In order to implement the sparse square layout, we will build the sparse squares on top of the base line. In order to build the squares properly, we set a specific prefix before the base of each square. These prefixes have no meaning in terms of surface entropy, and can be considered as construction lines.

In the layout, the positions of these prefixes were blank; in the implementation, they are marked with letters S, B and E, which will have different roles when building other construction lines in Subsection 4.5.

These prefixes are $s_1 = S$, and for $k \geq 2$, $s_k = SB^{k-2}E$.

The whole subshift. We now create a whole base line with these considerations: for any k, the base of the k^{th} sparse square is a word of $\mathcal{W}_k$; before the base of the k^{th} sparse square, we add the word s_k; and the other positions are marked with blanks $\#$.

For the rest of the paper, we denote X_1 as the closure of the following configurations:

$$X_1 = \text{cl}\{\#^\infty s_1 w_1\ \#^{2^2-2}\ s_2 w_2\ \dots\ s_{k-1} w_{k-1}\ \#^{2^k-k}\ s_k w_k\ \cdots \mid \forall k, w_k \in \mathcal{W}_k\}$$

(for ease of understanding, we highlight the base of each sparse square in red).

The construction below relies on the fact that X_1 (ie. the set of all possible base lines) is a $\mathbb{Z}$ effective subshift. Indeed, it is possible to computably enumerate all the patterns in which at least two letters of the set $\{\text{On}, \text{Off}\}$ appear, and to forbid each of these patterns that do not respect the structure of the configurations above. Furthermore, by definition each $x'_k = \inf_l f(k,l)$ is a Π_1 real number, and its upper-density Toeplitz subshift $\mathcal{T}(x'_k)$ is effective. We conclude that X_1 is an effective $\mathbb{Z}$ subshift.

4.4 Entropy of the fixed-point realization of effective $\mathbb{Z}$ subshifts as subactions of $\mathbb{Z}^2$ SFTs

We now have a $\mathbb{Z}$ subshift X_1 which can be used as a foundation in order to implement the whole sparse square layout into an actual SFT. In this section, we recall a particular method (from [3]) which transforms $\mathbb{Z}$ effective subshifts into $\mathbb{Z}^2$ SFTs. Additionally, we compute how much this method impacts the surface entropy.

The construction of *fixpoint-based tile sets* was originally introduced in [4]. One particular application of this construction, explained in [3], is the following theorem: for any $\mathbb{Z}$ effective subshift X_1, the $\mathbb{Z}^2$ lift Y_2 of X_1 (ie. the subshift whose configurations are the configurations of X_1 repeated vertically) is sofic.

It was also proved in [1] with a different method. These constructions improve the original construction of [7], which realized $\mathbb{Z}$ effective subshifts as $\mathbb{Z}^3$ sofic subshifts. We use the construction of [3] in order to prove:

▶ **Lemma 8.** *Let X_1 be a $\mathbb{Z}$ effective subshift. There exists a $\mathbb{Z}^2$ SFT X_2 composed of two superimposed layers of tilings such that:*

1. *The projection of X_2 on its first layer is the $\mathbb{Z}^2$ lift Y_2 of X_1, whose configurations are the configurations of X_1 repeated vertically.*
2. *The second layer of X_2 is composed of tilings of a fixpoint based tile set.*
3. (New) *For any p, q relatively prime,*

$$h(X_2) = h(Y_2) = 0 \qquad \text{and} \qquad h_s(X_2, \alpha) = h_s(Y_2, \alpha) = \frac{\alpha}{1+\alpha} h(X_1).$$

Proof. Points 1 and 2 of this lemma come directly from the construction of Theorem 1 in [3]. We prove point 3, and use notations from [3]. The reader should feel free to skip this proof and go directly to the next section if they are more interested in the geometrical construction.

Let X_1 be some $\mathbb{Z}$ effective subshift, and X_2 (resp. Y_2) be the SFT (resp. the sofic subshift) given by the first two points of Lemma 8. Below, we compute the entropies and the surface entropies of X_2 and Y_2.

First, we prove that $\log N_{X_2}(pn, qn) = pnh(X_1) + o(n)$.

By definition of $\mathbb{Z}$ entropy, $\log N_{X_1}(n) = nh(X_1) + o(n)$. As any configuration of Y_2 is entirely determined by a single line, one has $\log N_{Y_2}(pn, qn) = \log N_{X_1}(pn) = pnh(X_1) + o(n)$. The complexity function of X_2 is at least the contribution of its first layer, which leads to $\log N_{X_2}(pn, qn) \geq \log N_{Y_2}(pn, qn) = pnh(X_1) + o(n)$.

On the other hand, one can find an upper bound of $\log N_{X_2}(pn, qn)$ by considering the contributions of the two layers independently. As the contribution of the first layer is the contribution of Y_2, we now focus on the contribution of all the tilings obtained from the fixpoint-based tile set. Here, we use notions and notations of [3].

In the basic construction of a self-simulating tile set, each macro-tile of level i (ie. of size N_i) is entirely determined by its four macro-colors, which fit in $O(\log N_i)$ bits. In the construction used in [3] to transform $\mathbb{Z}$ effective subshifts into $\mathbb{Z}^2$ SFTs, these macro-colors contain additional data: the level of the macro-tile ($\log N_i$ bits), one segment of l_i and three segments of l_{i+1} letters from configurations of X_1, and the position in the grand-father macro-tile ($\log N_{i+2}$ bits). By taking (as in [3]) $N_i = 2^{C2^i}$ with C being a constant, $L_i = \prod_{j=0}^{i-1} N_i$ and $l_i = \log \log L_i$, we obtain that these macro-colors still fit in $O(\log N_i)$ bits.

For any n big enough, there exists i verifying $L_i \leq pn \leq L_{i+1}$ and $qn \leq L_{i+2}$ (indeed, $\lim_{i \to +\infty} L_{i+2}/L_{i+1} = +\infty$). In this context, a pattern of size $pn \times qn$ can partially cover at most four macro-tiles of level $i+2$. These macro-tiles are entirely determined by their

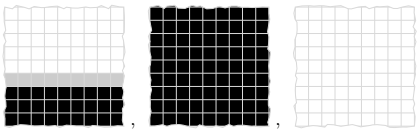
four macro-colors; each macro-tile of level $i+1$ entirely determines the macro-tiles of inferior levels that compose it; and by the previous paragraph each macro-color fits on $O(\log N_{i+2})$ bits (and the constant in the O does not depend on i): all these considerations imply that the number of patterns of size $pn \times qn$ on the second layer is at most polynomial in N_{i+2}.

Considering now the contribution of the two layers independently, one obtains that $\log N_{X_2}(pn, qn) \leq \log N_{Y_2} + \log poly(N_{i+2})$. We have just proved:

$$\log N_{X_2}(pn, qn) = pn\ h(X_1) + o(n) \qquad \text{and} \qquad \log N_{Y_2}(pn, qn) = pn\ h(X_1) + o(n).$$

This immediately leads to:

$$h(X_2) = \lim_{n \to +\infty} \frac{nh(X_1) + o(n)}{n^2} = 0 = h(Y_2)$$
$$h_s(X_2, p/q) = \limsup_{n \to +\infty} \frac{pnh(X_1) + o(n)}{(p+q)n} = \frac{p}{p+q} h(X_1) = h_s(Y_2, p/q). \qquad \blacktriangleleft$$

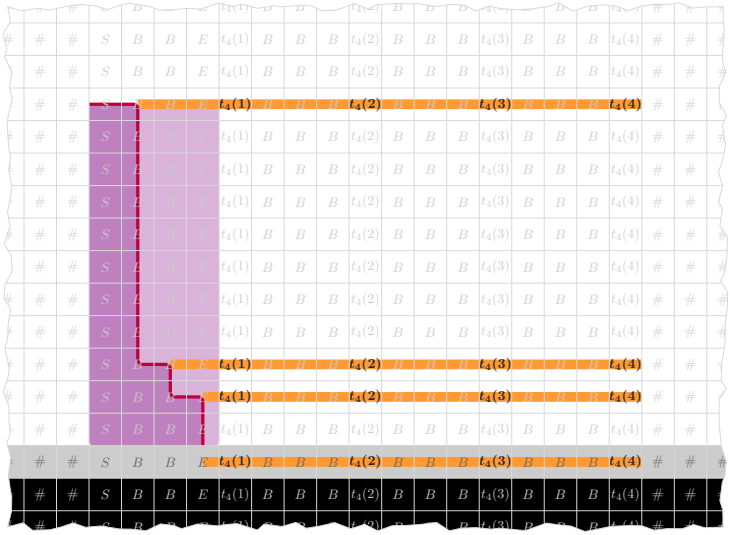


4.5 Building the sparse square layout

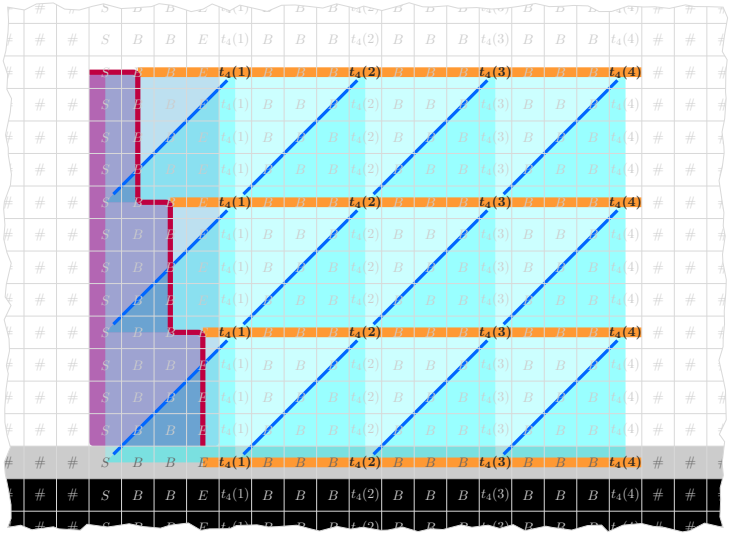
In this section, we use the $\mathbb{Z}$ subshift X_1 to build the whole sparse square layout.

First, apply Lemma 8 from the previous section: there exists a $\mathbb{Z}^2$ SFT X_2 with two superimposed layers, such that its first layer (**Base Layer 1**) contains all the vertical replications of configurations of X_1, and the second layer (**Computation Layer 2**) contains some embedded computations. We then create a $\mathbb{Z}^2$ SFT X_3 by superimposing a third layer to X_2, which we describe below.

This third layer (**Square Layer 3**) is itself a superimposition of several sub-layers:



1. First, one must choose a line to be the base line on *Base Layer 1.* It is composed of the same line repeated vertically: we choose one. To do so, we add a [Layer 3a] with three colors (black, white and gray) whose only type of configurations are the following three:



The base line will appear in gray (if it exists).

▶ **Important.** *The other markings of the Square Layer 3 (Layers 3b to 3d) will only be applied on white and gray areas. Additionally, they are not applied on areas marked by # on Base Layer 1.*

2. Add [Layer 3b] with purple construction lines (see Figure 3a). Any E marked in gray (on [Layer 3a]) starts a line at its top, and this line goes up.
   Purple lines have the ability to "start" an orange line (on [Layer 3c]). Each time they start an orange line, they move to their left (it ensures that there are at most k orange lines in the k^{th} sparse square).
   Purple lines can only end on an S.
   Because compactness might lead to surprising results (like infinitely many purple lines behaving erratically), we add colored areas below and above these lines. In these areas of color, we forbid any other purple line to exist: this ensures that there are exactly one purple line per square.
3. Add [Layer 3c] with orange construction lines (see Figure 3a). *These lines will highlight the rows of the sparse squares.* They can only be started by the purple line at their left, and end just before a # on the right. Additionally, an E colored in gray (on [Layer 3a]) must start an orange line.

(a) Base Layer 1 and 3a–3c. Layer 3b ensures there are at most 4 orange lines on Layer 3c.

(b) Base Layer 1 and 3a–3d. Layer 3d enforces the positions of the orange lines.

Figure 3 Behavior of the construction for a pattern which contains the 4^{th} sparse square. These figures highlight the effect of each layer. (Positions of the sparse square are highlighted for the convenience of the reader).

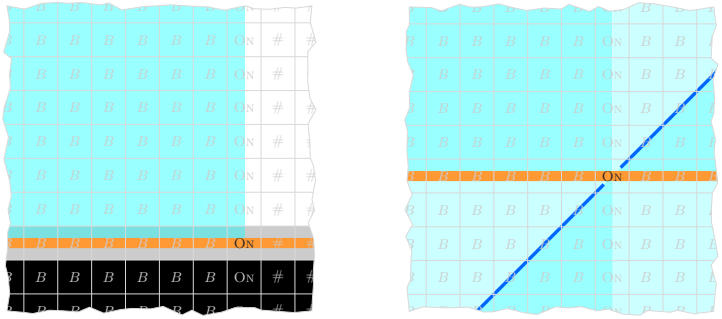


Figure 4 Two examples of degenerate configurations.

(In the figure, we highlight in bold the $t_k(i)$ marked by an orange line. These lines mark the future rows of the sparse squares, and these letters On, Off marked by an orange line will be at the exact non-blank positions of the sparse squares layout.)

4. Add [Layer 3d] with blue construction lines (see Figure 3b). These lines are diagonals. Each $t_k(i)$ colored in orange (on [Layer 3c]) and not in gray (on [Layer 3a]) should start a line that goes diagonally down and left. Additionally, these lines should end either on a letter S (colored in purple on [Layer 3b]), or on the next column marked with $t_k(i-1)$ at a position which is colored in orange (on [Layer 3c]).
   We also impose with colored areas that at each horizontal position, there can be only one blue line between two orange lines. These blue lines ensure the structure of the sparse squares, and constrain the behavior of degenerate configurations (see Figure 4 for examples of these degenerate configurations).

4.6 Contributing to the entropy

The subshift X_3 reflects the sparse square layout in the following way: by considering letters $t_k(i)$ marked in orange on [Layer 3c], we obtain a set of positions that respects the layout.

The final step of the construction consists in adding a fourth layer (**Entropy Layer 4**) to X_3 with *free letters* (ie. letters in the alphabet $1, \dots, 2^e$) and *free bits* (ie. bits in $\{0,1\}$) to obtain an SFT X with the right surface entropy. More precisely:

- *Free letters.* At each site in the sparse square layout (ie. for each position marked by On or Off on *Base Layer 1*, and which is marked in orange on [Layer 3c], we add a free letter which varies in $\{1, \dots, 2^e\}$.
- *Free bits.* At each activated position in the sparse square layout (ie. for each position marked by On on *Base Layer 1*, and which is marked in orange on [Layer 3c]), we add a free bit which varies in $\{0,1\}$.

Let X be the SFT composed of these four superimposed layers. We prove in Subsection 4.7:

▶ **Lemma 9.** *For any $\alpha = p/q \in \mathbb{Q}^+$ (for p and q relatively prime), and for any $n \in \mathbb{N}$, if k is the integer such that $k(k-1)+1 \leq \min(p,q)n < (k+1)k+1$, then the complexity function of the SFT X (defined in Section 4) behaves as follows:*

$$\min(p,q)n\,(e + x'_k) + o(n) \leq \log N_X(pn, qn) \leq \min(p,q)n \left(e + \sup_{\log n \leq i} x'_i\right) + o(n).$$

In particular, this first implies that $h(X) = 0$, then that:

$$h_s(X, \alpha) = \limsup_{n \to +\infty} \frac{\log N_X(pn, qn)}{(p+q)n} = \frac{\min(p,q)}{p+q}\left(e + \limsup_{n \to +\infty} x'_n\right) = \frac{\min(p,q)}{p+q} x$$

which concludes the proof of Theorem 5. ◀

4.7 Computation of the complexity function

This section solely proves Lemma 9. The reader not interested in the precise computation of the complexity function N_X should feel free to skip these pages.

Let $\alpha = p/q$ (for p and q relatively prime) be a positive rational number. In this section, we compute the complexity function $N_X(pn, qn)$ of the SFT X introduced in the previous section. We recall that $x = e + x'$ is a Π_3 real number with $x' \in \Pi_3 \cap [0,1)$, given by $x' = \limsup_i \inf_l f(i,l)$, and that we defined $x'_i = \inf_l f(i,l)$.

We now prove Lemma 9. In this statement, the value $k(k-1)+1$ corresponds to the length of the edges of the k^{th} sparse square.

Proof. As we already proved the lower bound (see Lemma 6), we focus on the upper bound. Here is the structure of the proof:

1. We first consider the contribution of "degenerate configurations" (ie. configurations that do not respect the structure of the sparse square layout: these are obtained when defining X_1 as a closure) to $\log N_X(pn, qn)$, and prove that they contribute only as $o(n)$ (subsection 4.7.1).
2. Then, we consider how many sparse squares can appear simultaneously in a pattern of size $pn \times qn$ (subsection 4.7.2), and:
   a. We provide an upper bound for the sparse square that appear simultaneously in a pattern of size $pn \times qn$ (subsection 4.7.3). As these squares have very low indices, they only contribute as $o(n)$.
   b. We provide an upper bound for the sparse squares that appear alone (subsection 4.7.4; they contribute with the significant term of the upper bound). To obtain it, we bound the number of positions that can appear simultaneously (in a pattern of size $pn \times qn$) of such a sparse square.

Before we begin, in the whole proof we denote by k the integer such that $k(k-1)+1 \leq \min(p, q)n < (k+1)k+1$. (As mentioned above, $k(k-1)+1$ is the length of the edges of the k^{th} sparse square). In the rest of the proof, we look for an upper bound of $\log N_X(pn, qn)$.

4.7.1 Contribution of degenerate configurations

We call *degenerate* the configurations that do not respect the structure of the sparse square layout. There are two possible sources for these configurations: some were obtained when X_1 was defined as a closure (first kind); and some are obtained if *Base Layer 1* respects the structure of a line in the sparse square layout, but [Layer 3a] does not choose a base line for the squares to sit on (second kind).

▷ Claim 10. The contribution of these configurations to $\log N_X(pn, qn)$ is $o(n)$.

Proof. First, we consider the case of a degenerate configurations of the first kind: *Base Layer 1* is not a base line. The number of such patterns only depends on the position of the gray line on [Layer 3a] (if it exists at all), of the position of the letter On or Off in the pattern, etc... There exists at most one varying bit in this pattern (there can be at most one letter On or Off colored in orange in such a degenerate configuration, because of the colored areas of the blue line on [Layer 3d]), which only multiplies the number of patterns by two.

All these patterns depend on finitely many parameters that range from 0 to $\max(p, q)n$. These configurations contribute polynomially in n to $N_X(pn, qn)$, so they contribute $O(\log n)$ to $\log N_X(pn, qn)$.

Consider then the case of degenerate configurations of the second kind: [Layer 3a] does not have a gray line (ie. it does not choose a line for the squares to sit on). If [Layer 3a] is a full black configuration, there are no markings at all on *Square Layer 3* or *Entropy Layer 4*, and the number of patterns depends only on *Base Layer 1*. If [Layer 3a] is a full white configuration, then purple lines on [Layer 3b] can only go up, and never go left: if they did, there would be an orange line on [Layer 3c], which is impossible because of the blue areas of color on [Layer 3d]. This implies that the number of patterns again only depends on *Base Layer 1* (and by Lemma 8, it contributes $o(n)$ to $\log N_X(pn, qn)$).

All in all, degenerate configurations contribute $o(n)$ to $\log N_X(pn, qn)$. ◁

In the rest of the proof, we assume that we consider non-degenerate configurations, ie. configurations that respect the sparse square layout.

We also assume that the gray line of [Layer 3a] is fixed at the bottom of the pattern of size $pn \times qn$ that we consider: this maximizes the number of free bits/free letters in the pattern. Furthermore, we will happily forget to count the different horizontal positions of the squares in the patterns.

Indeed, all these other patterns can be taken into account by translating the figure/varying some parameters which range between 0 and $\max(p,q)n$: these considerations only multiply the complexity function by a polynomial in n, or in other words only add a $o(n)$ to $\log N_X(pn, qn)$.

We also define the following set of words for any $l \in \mathbb{N}$ and $y \in [0,1)$ (usually $\mathcal{T}(y)$ is defined on the alphabet $\{0,1\}$ rather than $\{\text{On}, \text{Off}\}$; otherwise, there is no difference):

$$\mathcal{T}_l(y) = \{t_l \in \{\text{On}, \text{Off}\}^l : \ t_l \text{ is a subword of } \mathcal{T}(y)\}.$$

As we are looking at non-degenerate configurations, [Layers 3b–3d] (construction layers) are fixed by the line chosen by [Layer 3a]. This means that we can now focus the different Toeplitz words written on *Base Layer 1*, and on the contribution from the free bits and free letters that appear on *Entropy Layer 4*. To count these patterns, we mainly have to compute how many free bits/letters can fit in a pattern at the same time.

4.7.2 Which sparse squares can only appear alone in a pattern?

To find an upper bound of the complexity function, we ask the following question: how many sparse squares can fit in a pattern of size $pn \times qn$?

▷ Claim 11. For $n \geq p$, if at least two different sparse squares appear (maybe partially) in a pattern of size $pn \times qn$, then their indices are below $2 \log n$.

Proof. Assume that a range of squares from i to j, with $i < j$, appear (maybe partially) in a pattern of size $pn \times qn$. Then the horizontal space before the square of index j is entirely contained in the pattern, ie $2^j < pn$. Then for any $n \geq p$, one has $j \leq 2 \log n$. ◁

Reciprocally,

▷ Claim 12. If a sparse square can only appear alone in a pattern of size $pn \times qn$, then its index is greater than $\log n$.

Proof. Assume that a square of index j can "only" appear alone in a pattern of size $pn \times qn$. This means that the space before the sparse square, and the space after the sparse square, are bigger than the horizontal size of the pattern pn. In other words, $2^j \geq pn$, which becomes $j \geq \log n + \log p \geq \log n$. ◁

4.7.3 Contribution of simultaneously appearing sparse squares

▷ Claim 13. The sparse squares that can appear grouped with others contribute as $M_1 = o(n)$ to $\log N_X(pn, qn)$.

Proof. Assume that a range (between i and j, $i < j$) of sparse squares appear (partially) in a pattern of size $pn \times qn$. For n big enough, one has $j \leq 2 \log n$ by Claim 11. Additionally, because we are interested in an upper bound of $\log N_X(pn, qn)$, we can freely assume that all the free bits of the sparse squares of index i and j appear in this pattern.

If $C_{i,j}$ denotes the contribution to $N_X(pn, qn)$ of this slice of squares between i and j, then an upper bound on $C_{i,j}$ is (we count all the Toeplitz subwords written in the squares on *Base Layer 1*, and then their free bits and free letters on *Entropy Layer 4*):

$$\begin{aligned}
C_{i,j} &\leq \sum_{t_i \in \mathcal{T}_i(x'_i), \dots, t_j \in \mathcal{T}_j(x'_j)} \exp_2\left(\sum_{r=i}^{j} r|t_r|_{\text{ON}} + e\sum_{t=i}^{j} r^2\right) \\
&\leq \sum_{t_i \in \mathcal{T}_i(x'_i), \dots, t_j \in \mathcal{T}_j(x'_j)} \exp_2\left(\sum_{r=1}^{j} (r|t_r|_{\text{ON}} + er^2)\right) \\
&\leq \sum_{t_i \in \mathcal{T}_i(x'_i), \dots, t_j \in \mathcal{T}_j(x'_j)} \exp_2(j^3(1+e)) \\
&\leq \sum_{t_1, \dots, t_j \in \{\text{ON},\text{OFF}\}^{1+\dots+j}} \exp_2((2\log n)^3(1+e)) \\
&\leq \exp_2(j^2 + o(j^2)) \exp_2((2\log n)^3(1+e)) \\
&\leq \exp_2(O((\log n)^3)).
\end{aligned}$$

As there are less than $(2\log n)^2$ different tuples of $i, j \leq 2\log n$, the contribution M_1 of these sparse squares to $\log N_X(pn, qn)$ verifies:

$$\begin{aligned}
M_1 \leq \log\left(\sum_{i<j\leq 2\log n} C_{i,j}\right) &\leq \log\left[(4(\log n)^2)\exp_2(O((\log n)^3))\right] \\
&\leq \log \exp_2(O((\log n)^3))) \\
&\leq o(n).
\end{aligned}$$

◁

4.7.4 Contribution of the other sparse squares

The other sparse squares can only appear alone (maybe partially) in a pattern of size $pn \times qn$. We distinguish two cases for them:

- The sparse squares of indices $i \leq k$. As they can fit entirely in a pattern of size $pn \times qn$ (recall that $k(k+1) - 1 \leq \min(p, q)n \leq (k+1)k + 1$), we assume they do (this maximizes the number of free bits that appear simultaneously).
- The sparse squares of indices $i > k$. They can only fit partially in a pattern of size $pn \times qn$, and we need to "count" the number of their free bits/letters that can appear simultaneously.

Contribution of the sparse squares of index $i \leq k$.

▷ Claim 14. The sparse squares that can only appear alone in a pattern of size $pn \times qn$, and of indices $i \leq k$, contribute to $\log N_X(pn, qn)$ with a term:

$$M_2 \leq \min(p, q)n\left(e + \max_{\log n \leq i \leq k} x'_i\right) + o(n).$$

Proof. As $\#\mathcal{T}_i(x'_i) \leq 2^i$, each of these squares contribute with a term (again, we count the words of $\mathcal{T}_i(x'_i)$ on *Base Layer 1*, and free letters and free bits on *Entropy Layer 4*):

$$\begin{aligned} C_i &\leq (2^e)^{i^2} \times \sum_{t_i \in \mathcal{T}_i(x'_i)} \exp_2(i|t_i|_{\text{ON}}) \\ &\leq \exp_2(ei^2) \times \exp_2(i) \exp_2(i^2 x'_i + O(i)) \\ &\leq \exp_2(i^2(e + x'_i) + O(i)). \end{aligned}$$

By Claim 12, such a square must be of index $\geq \log n$. This implies that all these squares contribute to $\log N_X(pn, qn)$ with a term:

$$\begin{aligned} M_2 &\leq \log \left(\sum_{i=\log n}^{k} C_i \right) \\ &\leq \log \left(\sum_{i=\log n}^{k} \exp_2(i^2(e + x'_i) + O(i)) \right) \\ &\leq \log \left(k \exp_2 \left(k^2 \left(e + \max_{\log n \leq i \leq k} x'_i \right) + O(k) \right) \right) \\ &\leq \log \exp_2 \left(k^2 \left(e + \max_{\log n \leq i \leq k} x'_i \right) + O(k) \right) \\ &\leq k^2 \left(e + \max_{\log n \leq i \leq k} x'_i \right) + O(k) \\ &\leq \min(p, q) n \left(e + \max_{\log n \leq i \leq k} x'_i \right) + o(n). \end{aligned}$$

◁

Contribution of the sparse squares of index $i \geq k$. Finally, we consider the sparse squares of indices $i \geq k$: these square only appear partially in a pattern of size $pn \times qn$. They contribute significantly to $\log N_X(pn, qn)$, as explained in the following claim:

▷ Claim 15. The sparse squares of indices $i \geq k$ contribute to $\log N_X(pn, qn)$ with a term:

$$M_3 \leq \min(p, q) n \left(e + \max_{k \leq i \leq \max(p,q)(k+1)^2} x'_i \right) + o(n).$$

Proof. This proof is organized as follows:

1. We provide an upper bound on the contribution C_i of the i^{th} sparse square to $N_X(pn, qn)$, for $i \geq k$, according to the number of free bits/free letters of these squares that can appear simultaneously in a pattern of size $pn \times qn$.
2. Then, we provide an upper bound on the contribution M_3 of all these sparse squares of indices $i \geq k$ to $\log N_X(pn, qn)$.
3. By studying the variations of two functions $h : \mathbb{N} \mapsto \mathbb{N}$ and $v : \mathbb{N} \mapsto \mathbb{N}$ we prove that for any $i \geq k$ the number of simultaneously appearing free bits/free letters of the i^{th} sparse square is $h(i)v(i) \leq \min(p, q)n + o(n)$. This will conclude the proof.

Contribution C_i of the sparse square of index i. First, we need to answer the following question: how many bits can appear simultaneously in a pattern of size $pn \times qn$? Recall that there are exactly i bits in the square of index i per row (and per column). If $h(i)$ denotes the number of horizontal bits that can appear simultaneously in a slice of width pn (and height 1), and $v(i)$ the number of vertical bits in a slice of height qn (and width 1), then:

$$h(i) = \min\left(i, \left\lfloor \frac{pn-1}{i} \right\rfloor + 1\right) \qquad v(i) = \min\left(i, \left\lfloor \frac{qn-1}{i} \right\rfloor + 1\right).$$

h and v are eventually decreasing, and $\lim_{i\to+\infty} h(i) = \lim_{i\to+\infty} v(i) = 1$. There exists an integer $J_k \leq \max(p,q)(k+1)^2$ such that for any $i \geq J_k$, one has $v(i) = h(i) = 1$.

We now count free letters and free bits to compute an upper bound on the contribution C_i of a square of index $i \geq k$. As opposed to the previous cases, in which the squares appeared entirely in the pattern of size $pn \times qn$, here we can only see at once $h(i)$ different column: but thanks to the use of Toeplitz sequences, which have a very uniform distribution, the density of a Toeplitz subword of size $h(i)$ is still less than or equal to $h(i)x'_i + O(1)$:

$$\begin{aligned} C_i &\leq \sum_{t_i \in \mathcal{T}(x'_i)h(i)} \exp_2\left[h(i)v(i)e + v(i)|t_i|_{0N})\right] \\ &\leq \exp_2\left[h(i)v(i)(e+x'_i) + O(v(i))\right]. \end{aligned}$$

Additionally, as $v(i) \leq \frac{qn-1}{i} + 1$, $i \geq k$ and $k = \Theta(\sqrt{n})$, one has $O(v(i)) = O(\sqrt{n})$.

Contribution M_3 of the sparse square of index $i \geq k$. This implies that the contribution M_3 of all these squares of indices $i \geq k$ is:

$$\begin{aligned} M_3 &\leq \log\left(\sum_{i=k}^{J_k} \exp_2[h(i)v(i)(e+x'_i) + o(h(i)v(i))]\right) \\ &\leq \log\left(J_k \exp_2\left(\left[\max_{k\leq i\leq J_k} h(i)v(i) + o(h(i)v(i))\right] \times \left[e + \max_{k\leq i\leq J_k} x'_i\right]\right)\right) \\ &\leq \left[\max_{k\leq i\leq J_k} h(i)v(i) + o(h(i)v(i))\right] \times \left[e + \max_{k\leq i\leq J_k} x'_i\right] + o(n). \end{aligned}$$

Study of the product $h(i)v(i)$ for $k \geq i \geq J_k$. We now have to study the product $h(i)v(i)$ for $k \leq i \leq J_k$. Below, we will prove that $\forall k \leq i \leq J_k, h(i)v(i) \leq \min(p,q)n + O(\sqrt{n})$.

Without any loss of generality, assume $q \geq p$. We prove that:

$$h(i)v(i) \leq pn + O(\sqrt{n}), \qquad \text{i.e.} \qquad M_3 \leq pn\left(e + \max_{k\leq i\leq \max(p,q)(k+1)^2} x'_i\right) + o(n).$$

As $p = \min(p,q)$, one has $h(i) = \left\lfloor \frac{pn-1}{i} \right\rfloor + 1$ and $v(i) = \min\left(i, \left\lfloor \frac{qn-1}{i} \right\rfloor + 1\right)$. For the first values of i, h is an increasing function, and it then decreases for i large enough: below, we study these variations and conclude about the product $h(i)v(i)$.

- For any $i \leq \lfloor\sqrt{qn-1}\rfloor$, one has $\left\lfloor \frac{qn-1}{i} \right\rfloor + 1 \geq i$ (which implies $v(i) = i$). Indeed,
$$\begin{aligned} \left\lfloor \frac{qn-1}{i} \right\rfloor + 1 &\geq \left\lfloor \sqrt{qn-1} \right\rfloor + 1 \\ &\geq i. \end{aligned}$$
- For any $k \leq i \leq \lfloor\sqrt{qn-1}\rfloor$, one has $h(i)v(i) \leq pn + O(\sqrt{n})$. Indeed,
$$\begin{aligned} h(i)v(i) = h(i)i &\leq \left(\left\lfloor \frac{pn-1}{i} \right\rfloor + 1\right) i \\ &\leq i\left\lfloor \frac{pn-1}{i} \right\rfloor + i \\ &\leq pn - 1 + i \\ &\leq pn + O(\sqrt{n}). \end{aligned}$$

- For any $i \geq \lfloor \sqrt{qn-1} \rfloor + 1$, one has $i \geq \left\lfloor \frac{qn-1}{i} \right\rfloor + 1$ (which implies $v(i) = \left\lfloor \frac{qn-1}{i} \right\rfloor + 1$). Indeed,
$$\begin{aligned}\left\lfloor \frac{qn-1}{i} \right\rfloor + 1 &\leq \left\lfloor \frac{qn-1}{\sqrt{qn-1}} \right\rfloor + 1 \\ &\leq \left\lfloor \sqrt{qn-1} \right\rfloor + 1 \\ &\leq i.\end{aligned}$$
- For any $\lfloor \sqrt{qn-1} \rfloor + 1 \leq i \leq J_k$, one has $h(i)v(i) \leq pn + O(\sqrt{n})$. Indeed,
$$\begin{aligned}h(i)v(i) = h(i)\left(\left\lfloor \frac{qn-1}{i} \right\rfloor + 1\right) &= \left\lfloor \frac{pn-1}{i} + 1 \right\rfloor \left\lfloor \frac{qn-1}{i} + 1 \right\rfloor \\ &\leq \left\lfloor \frac{pn-1}{\sqrt{qn-1}} + 1 \right\rfloor \left\lfloor \frac{qn-1}{\sqrt{qn-1}} + 1 \right\rfloor \\ &\leq \left\lfloor \frac{pn-1}{\sqrt{qn-1}} + 1 \right\rfloor \left(\sqrt{qn-1} + 1\right) \\ &\leq pn + O(\sqrt{n}).\end{aligned}$$
With all of these computations, we conclude that
$$\max_{k \leq i \leq J_k} h(i)v(i) \leq pn + o(n).$$
In the case $p \geq q$, the computations are completely symmetric and one obtains:
$$\max_{k \leq i \leq J_k} h(i)v(i) \leq qn + O(\sqrt{n}).$$ ◁

4.7.5 End of the proof

We can now conclude the proof of Lemma 9 about the bounds of $\log N_X(pn, qn)$:

$$\min(p,q)n\,(e + x'_k) + o(n) \leq \log N_X(pn, qn) \leq \min(p,q)n\left(e + \sup_{\log n \leq i} x'_i\right) + o(n).$$

The lower bound comes from Lemma 6. Indeed, if $k(k-1)+1 \leq \min(p,q)n \leq k(k+1)+1$, then $k^2 = \min(p,q)n + o(n)$, which leads to the desired lower bound. In order to compute the upper bound, we can count the contributions of the different layers independently.

Base Layer 1 and *Computation Layer 2* (the 1D subshift composed of the base line repeated vertically, and the tilings obtained with self-simulating tile sets) do not contribute to the surface entropy by Lemma 8. Indeed, the 1D entropy of the base line is $h(X_1) = 0$. In other words, these two layers add $o(n)$ to $\log N_X(pn, qn)$.

Degenerate configurations, *Square Layer 3*, along with considerations on the different shifts of the configurations, also contribute as $o(n)$ to $\log N_X(pn, qn)$ (they indeed contribute polynomially in n to $N_X(pn, qn)$, see the remark at the end of "Contribution of degenerate configurations"). Finally, in the previous sections, we provided 3 quantities M_1, M_2, M_3 whose sum is greater than the contribution of *Entropy Layer 4* (and which take into account the different written words on non-degenerate configurations of *Base Layer 1*).

With these considerations, we conclude that:

$$\begin{aligned}\log N_X(pn, qn) &\leq o(n) + M_1 + M_2 + M_3 \\ &\leq o(n) + o(n) + \min(p,q)n\left(e + \max_{\log n \leq i \leq \max(p,q)(k+1)^2} x'_i\right) + o(n) \\ &\leq \min(p,q)n\left(e + \max_{\log n \leq i \leq \max(p,q)(k+1)^2} x'_i\right) + o(n).\end{aligned}$$ ◀

5 Conclusive remarks and open questions

Many questions remain open about the notion of surface entropy.

Computational behavior of the definition in [14]. The definition of *surface entropy* used in this paper differs from the original notion of surface entropy in Pace's thesis [14], which was: for any eccentricity $\alpha \in \mathbb{R}^+$,

$$h_s(X,\alpha) = \sup_{\substack{(x_n,y_n)\in(\mathbb{N}^2)^{\mathbb{N}}:\\ x_n,y_n\to+\infty,\ \frac{x_n}{y_n}\to\alpha}} \limsup_{n\to+\infty} \frac{\log N_X(x_n,y_n) - x_n y_n h(X)}{x_n+y_n}.$$

This definition was chosen in [14] because it provides a unified approach for rational (ie. $\alpha \in \mathbb{Q}^+$) and irrational eccentricities. However, we are currently unsure of how the supremum over all sequences impacts the computational characterization of surface entropies. Our construction still realizes any Π_3 surface entropy with the definition of [14], but surface entropies may not be Π_3 real numbers anymore. For all we know, they may not be at any level of the arithmetical hierarchy.

Equivalence between the two definitions. Furthermore, as we modified [14]'s definition of surface entropy, a natural question is whether our new definition coincides with it in the case of rational eccentricities. In other words, can the supremum over all sequences be removed when the eccentricity is a rational number. We are not sure of the answer at the time of writing.

Arbitrary topological entropy with an arbitrary surface entropy. Finally, in the main section of this paper, we created SFTs with zero topological entropy and any Π_3 surface entropy. It was proved in [8] that the class of entropies of $\mathbb{Z}^2$ SFTs is exactly the class of Π_1 real numbers. This led us to wonder whether we could create a family of $\mathbb{Z}^2$ SFTs with arbitrary Π_1 entropy and arbitrary Π_3 surface entropy.
As we do not know the surface entropies of the main constructions of Π_1 entropies, we could not answer this problem with the straightforward solution (ie. a Cartesian product of our construction with one for Π_1 entropies).

Abstract

We consider the following question: given an automaton or a game with a Muller condition, how can we efficiently construct an equivalent one with a parity condition? There are several examples of such transformations in the literature, including in the determinisation of Büchi automata.

We define a new transformation called the alternating cycle decomposition, inspired and extending Zielonka's construction. Our transformation operates on transition systems, encompassing both automata and games, and preserves semantic properties through the existence of a locally bijective morphism. We show a strong optimality result: the obtained parity transition system is minimal both in number of states and number of priorities with respect to locally bijective morphisms.

We give two applications: the first is related to the determinisation of Büchi automata, and the second is to give crisp characterisations on the possibility of relabelling automata with different acceptance conditions.

1 Introduction

Games and automata form the theoretical basis for the verification and synthesis of reactive systems; we refer to the recent Handbook [5] for a broad exposition of this research area, in particular Chapters 2 and 27. A milestone objective is the synthesis of reactive systems specified in *Linear Temporal Logic* (LTL). The original approach of Pnueli and Rosner [24] using automata and games devised more than four decades ago is today at the heart of the state of the art synthesis tools [8, 16, 20, 21]. The bottleneck is the determinisation of Büchi automata: given a non-deterministic Büchi automaton, construct an equivalent parity automaton. This problem has a long history; it was originally solved by McNaughton [18], and the first asymptotically optimal construction is due to Safra [25], see also [15] for a recent

exposition. Most of the recent theoretical and practical solutions of this problem are based on the construction of Piterman [23]. Schewe's [26] enlightening perspective on this construction is to decompose it into two steps: first construct a deterministic Muller automaton, and then transform it into an equivalent deterministic parity automaton. Piterman and Schewe's determinisation procedure is one of many examples of constructions using as an intermediate step (subclasses of) Muller conditions before transforming them into parity conditions, either working with automata models or games models.

The objective of this work is to focus on this particular step and study transformations from Muller to parity. We work with general transition systems to seamlessly encompass both automata and games models.

There are several existing constructions transforming subclasses of Muller conditions to parity. The first is the Latest Appearance Record (LAR) [9], which applies to all Muller conditions. It was proved to be optimal in the worst case [17]: *there exists* a family of Muller automata for which the obtained parity automata are minimal. Many refinements of the LAR have been constructed for subclasses of Muller conditions, *e.g.* [17, 13].

The starting point of our work is the notion of a Zielonka tree of a Muller condition, which was introduced in [30] and shown to capture the exact memory requirements of Muller games [7]. In the long version of [7], it implicitly appears that the Zielonka tree of a Muller condition can be used to construct a parity automaton recognising this Muller condition. Our first observation is to show a *strong* optimality result: *for all* Muller conditions, the parity automaton obtained from the Zielonka tree of a Muller condition is minimal both in the number of states and in the number of priorities. This result has also been obtained in the independent unpublished work [19]. This optimality result is much stronger than the worst case optimality result of the LAR transformation; in essence, it shows that the Zielonka tree of a Muller condition precisely captures the properties of the Muller condition, whereas for instance the LAR only depends on the number of colours.

Our first insight is to note that all existing constructions, including the one based on Zielonka trees, only consider the Muller condition but do not take into account the structure of the underlying transition system. In other words, all transformations work at the level of conditions: they transform a Muller condition into a parity condition, and ignore the interplay between the condition and the transition structure.

Our main contribution is to construct a new transformation called the alternating cycle decomposition (ACD) which captures this interplay: the ACD transforms a Muller transition system $\mathcal{T}$ into a parity transition system $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$, extending Zielonka trees by considering the alternation of accepting and rejecting cycles in $\mathcal{T}$.

Our second insight is to introduce the notion of locally bijective morphisms to capture the notion of a "transformation", preserving many natural semantic properties (such as language equivalence, being deterministic, unambiguous, or good for game in the context of automata, and the winner for games). We use this notion to state and prove a strong optimality result for the ACD transformation: $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ is minimal both in the number of states and in the number of priorities amongst parity transition systems admitting a locally bijective morphism into $\mathcal{T}$.

We present two applications. The first is an improvement in the determinisation of Büchi automata: the second step of the Piterman and Schewe construction is a locally bijective transformation of some deterministic Muller automaton into a deterministic parity automaton; we show that our ACD transformation yields in all cases smaller (and in some sense minimal) automata, and in many cases strictly smaller. The second application is a set of crisp characterisations for relabelling transition systems with different classes of

acceptance conditions: for instance, given a transition system with a Rabin condition, does there exist a parity condition on the same structure yielding an equivalent transition system? This unifies and extends results from [1, 30].

The outline of the paper follows the narration of this introduction. We show in Section 3 how the Zielonka tree yields a parity automaton recognising the Muller condition, inducing a transformation at the level of conditions. We then lift this transformation from conditions to transition systems: we introduce the alternating cycle decomposition and its transformation in Section 4. Our two applications are discussed in Section 5.

2 Notations and definitions

The symbol ω denotes the ordered set of non-negative integers. For $i, j \in \omega$, $i \leq j$, the notation $[i, j]$ stands for $\{i, i+1, \dots, j-1, j\}$. For a set Σ, a *word* over Σ is a sequence of elements from Σ. The length of a word u is $|u|$. The set of words of finite length (resp. of length ω) over Σ will be written Σ^* (resp. Σ^ω). We let $\Sigma^\infty = \Sigma^* \cup \Sigma^\omega$. For a word $u \in \Sigma^\infty$ we write u_i to represent the i-th letter of u. If $u = v \cdot w$ for $v \in \Sigma^*, u, w \in \Sigma^\infty$, we say that v is a *prefix* of u and we write $v \sqsubseteq u$ (it induces a partial order on Σ^*). For a finite word $u \in \Sigma^*$ we write $\mathit{First}(u) = u_1$ and $\mathit{Last}(u) = u_{|u|}$. For a word $u \in \Sigma^\infty$, we let $\mathit{Inf}(u) = \{a \in \Sigma \ : \ u_i = a \text{ for infinitely many } i \in \omega\}$ and $\mathit{Occ}(u) = \{a \in \Sigma \ : \ \exists i \in \omega \text{ such that } u_i = a\}$. Given a map $\alpha : A \to B$, we implicitly extend α to words component-wise, i.e., $\alpha : A^\infty \to B^\infty$ will be defined as $\alpha(a_1 a_2 \dots) = \alpha(a_1)\alpha(a_2)\dots$. A *directed graph* is a tuple $(V, E, \mathit{Source}, \mathit{Target})$ where V is a set of vertices, E a set of edges and $\mathit{Source}, \mathit{Target} : E \to V$ are maps indicating the source and target for each edge. A *path* is a word $\varrho \in E^*$ such that $\mathit{Source}(\varrho_{i+1}) = \mathit{Target}(\varrho_i)$ for $i < |\varrho|$. A graph is *strongly connected* if there is a path connecting each pair of vertices. A *subgraph* of $(V, E, \mathit{Source}, \mathit{Target})$ is a graph $(V', E', \mathit{Source}', \mathit{Target}')$ such that $V' \subseteq V$, $E' \subseteq E$ and Source' and Target' are the restriction to E' of Source and Target, respectively. A *strongly connected component* is a maximal strongly connected subgraph. For a subset of vertices $A \subseteq V$ we write: $\mathit{In}(A) = \{e \in E \ : \ \mathit{Target}(e) \in A\}$ and $\mathit{Out}(A) = \{e \in E \ : \ \mathit{Source}(e) \in A\}$.

Transition systems. A *transition system graph* $\mathcal{T}_G = (V, E, \mathit{Source}, \mathit{Target}, I_0)$ is a directed graph with a non-empty set of initial vertices $I_0 \subseteq V$. We will also refer to vertices and edges as *states* and *transitions*, respectively. We will suppose that every vertex has at least one outgoing edge. A *transition system* $\mathcal{T}$ is obtained from a transition system graph $\mathcal{T}_G$ by adding:

- A function $\gamma : E \to \Gamma$. The set Γ will be called a *set of colours* and the function γ a *colouring function*.
- An *acceptance condition* $\mathit{Acc} \subseteq \Gamma^\omega$.

For technical convenience we use transition-labelled systems: acceptance conditions are defined over edges instead of over states. These can be easily transformed into state-labelled systems. We will usually take $\Gamma = E$ and γ the identity function. In that case we will omit γ in the description of $\mathcal{T}$. We let $|\mathcal{T}|$ denote $|V|$, for V the set of vertices.

A (finite or infinite) *run* from $q \in V$ on a transition system graph $\mathcal{T}$ is a path $\varrho = e_1 e_2 \dots \in E^\infty$ starting at q. For $A \subseteq V$ we let $\mathcal{R}un_{\mathcal{T},A}$ denote the set of runs on $\mathcal{T}$ starting from some $q \in A$, and $\mathcal{R}un_{\mathcal{T}} = \mathcal{R}un_{\mathcal{T},I_0}$ the set of runs starting from some initial vertex. A run $\varrho \in \mathcal{R}un_{\mathcal{T}}$ is *accepting* if $\gamma(\varrho) \in \mathit{Acc}$, and rejecting otherwise. In this work we suppose that only infinite runs can be accepted.

We say that a vertex $v \in V$ is *accessible* if there exists a finite run $\varrho \in \mathcal{R}un_{\mathcal{T}}$ ending in v. A set of vertices $B \subseteq V$ is accessible if every vertex $v \in B$ is accessible. The *accessible part* of a transition system is the set of accessible vertices.

We might want to add additional information to a transition system (as illustrated in the following paragraphs). For this purpose we introduce labelled transition system: a *vertex-labelled* (resp. edge-labelled) transition system is a transition system $\mathcal{T}$ with a labelling function $l_V : V \to L_V$ (resp. $l_E : E \to L_E$) from vertices (resp. edges) into a set of labels.

Automata as transition systems. An *automaton* is an edge-labelled transition system $\mathcal{A} = (V, E, \mathit{Source}, \mathit{Target}, I_0, \mathit{Acc}, l_E)$ where $l_E : E \to \Sigma$, for Σ a finite set called the *input alphabet* (we say that $\mathcal{A}$ is an automaton over Σ). Given a word $w \in \Sigma^\omega$, a *run over* w is an infinite run $\varrho \in \mathcal{R}un_{\mathcal{T}}$ such that $l_E(\varrho_i) = w_i$ for every $i > 0$. The word $w \in \Sigma^\omega$ is accepted by the automaton $\mathcal{A}$ if there exists an accepting run over w in $\mathcal{A}$. The *language accepted* by an automaton $\mathcal{A}$ is the set $\mathcal{L}(\mathcal{A}) := \{u \in \Sigma^\omega \ : \ u \text{ is accepted by } \mathcal{A}\}$.

We say that an automaton $\mathcal{A}$ is *deterministic* if $|I_0| = 1$ and for every $q \in V$ and every $a \in \Sigma$ there is exactly one edge $e \in \mathit{Out}(v)$ such that $l_E(e) = a$. In this case, we write $\delta(q, a)$ for the only state reachable from q taking the transition labelled with a. We extend the function $\delta(q, -)$ to finite words in the natural way. If $\mathcal{A}$ is deterministic then there is a single run over w for each $w \in \Sigma^\omega$, written $\mathcal{A}(w)$.

Games as transition systems. A *game* $\mathcal{G}_{v_0} = (V, E, \mathit{Source}, \mathit{Target}, v_0, \mathit{Acc}, l_V)$ is a vertex-labelled transition system with a single initial vertex v_0 and vertices labelled by a function $l_V : V \to \{\mathit{Eve}, \mathit{Adam}\}$ that induces a partition of V into vertices controlled by two different players. A *play* is an infinite run produced by moving a token along edges: the player controlling the current vertex chooses what transition to take. It is *winning* for Eve if it is accepting, and winning for Adam otherwise. We say that player $P \in \{\mathit{Eve}, \mathit{Adam}\}$ *wins* the game $\mathcal{G}_{v_0}$ if P can force to always produce a winning play. The *winning region* for player P is the set of vertices $v \in V$ such that P wins the game $\mathcal{G}_v$ obtained by setting the initial vertex to v.

Classes of acceptance conditions. We present the main classes of *ω-regular conditions*. Let Γ be a finite set of *colours*, it will usually be the set of edges of a transition system.

Büchi A *Büchi condition* Acc_B is represented by a subset $B \subseteq \Gamma$. An infinite word $u \in \Gamma^\omega$ belongs to Acc_B if some colour from B appears infinitely often in u.

Rabin A *Rabin condition* Acc_R is represented by a family of *Rabin pairs*, $R = \{(E_1, F_1), \ldots, (E_r, F_r)\}$, where $E_i, F_i \subseteq \Gamma$. A word $u \in \Gamma^\omega$ belongs to Acc_R if $\mathit{Inf}(u) \cap E_i \neq \emptyset$ and $\mathit{Inf}(u) \cap F_i = \emptyset$ for some index $i \in \{1, \ldots, r\}$.

Streett A word $u \in \Gamma^\omega$ belongs to the *Streett condition* Acc_S associated to the family $S = \{(E_1, F_1), \ldots, (E_r, F_r)\}$, $E_i, F_i \subseteq \Gamma$ if $\mathit{Inf}(u) \cap E_i \neq \emptyset \ \rightarrow \ \mathit{Inf}(u) \cap F_i \neq \emptyset$ for every $i \in \{1, \ldots, r\}$.

Parity To define a *parity condition* we suppose that Γ is a finite subset of $\mathbb{N}$. A word $u \in \Gamma^\omega$ belongs to the condition Acc_P if $\min \mathit{Inf}(u)$ is even. The elements of Γ are called *priorities* in this case. We associate to a parity condition the interval $[\mu, \eta]$, where $\mu = \min \Gamma$ and $\eta = \max \Gamma$.

Muller A *Muller condition* $\mathit{Acc}_{\mathcal{F}}$ is given by a family $\mathcal{F} \subseteq \mathcal{P}(\Gamma)$. A word $u \in \Gamma^\omega$ is accepted if the colours appearing infinitely often in u form a set of the family $\mathcal{F}$.

Equivalent conditions. Two different acceptance conditions over a set Γ are *equivalent* if they define the same set $Acc \subseteq \Gamma^\omega$. Given a transition system graph $\mathcal{T}_G$, two representations $\mathcal{R}_1, \mathcal{R}_2$ of acceptance conditions are equivalent over $\mathcal{T}_G$ if they define the same accepting subset of runs of $\mathcal{R}un_T$. We write $(\mathcal{T}_G, \mathcal{R}_1) \simeq (\mathcal{T}_G, \mathcal{R}_2)$ in that case.

If $\mathcal{A}$ is the transition system graph of an automaton and $\mathcal{R}_1, \mathcal{R}_2$ are two representations of acceptance conditions such that $(\mathcal{A}, \mathcal{R}_1) \simeq (\mathcal{A}, \mathcal{R}_2)$, then they recognise the same language: $\mathcal{L}(\mathcal{A}, \mathcal{R}_1) = \mathcal{L}(\mathcal{A}, \mathcal{R}_2)$. However, the converse only holds for deterministic automata.

▶ **Proposition 2.1.** *Let $\mathcal{A}$ be the the transition system graph of a deterministic automaton over the alphabet Σ and let $\mathcal{R}_1, \mathcal{R}_2$ be two representations of acceptance conditions such that $\mathcal{L}(\mathcal{A}, \mathcal{R}_1) = \mathcal{L}(\mathcal{A}, \mathcal{R}_2)$. Then, both conditions are equivalent over $\mathcal{A}$, $(\mathcal{A}, \mathcal{R}_1) \simeq (\mathcal{A}, \mathcal{R}_2)$.*

▶ Remark. A parity condition given by $\Gamma \subseteq \mathbb{N}$ is equivalent to Rabin and Streett conditions over Γ. Any of the previous conditions over a set Γ is equivalent to a Muller condition.

Trees. A *tree* is a set of sequences of non-negative integers $T \subseteq \omega^*$ that is prefix-closed: if $\tau \cdot i \in T$, for $\tau \in \omega^*, i \in \omega$, then $\tau \in T$. In this paper we will only consider finite trees.

The elements of T are called *nodes*. A *subtree* of T is a tree $T' \subseteq T$. The empty sequence ε belongs to every non-empty tree and it is called the *root* of the tree. A node of the form $\tau \cdot i$, $i \in \omega$, is called a *child* of τ, and τ is called its *parent*. We let $Children(\tau)$ denote the set of children of a node τ. Two different children σ_1, σ_2 of τ are called *siblings*, and we say that σ_1 is *older* than σ_2 if $Last(\sigma_1) < Last(\sigma_2)$. If two nodes τ, σ verify $\tau \sqsubseteq \sigma$, then τ is called an *ancestor* of σ, and σ a *descendant* of τ (we add the adjective "strict" if in addition they are not equal). A node is called a *leaf* of T if it is a maximal sequence of T. A *branch* of T is the set of prefixes of a leaf. The set of branches of T is denoted $Branch(T)$. We order the set of branches from left to right.

For a node $\tau \in T$ we define $Subtree_T(\tau)$ as the subtree consisting on the set of nodes that appear below τ, or above it in the same branch: $Subtree_T(\tau) = \{\sigma \in T \ : \ \sigma \sqsubseteq \tau \text{ or } \tau \sqsubseteq \sigma\}$.

Given a node τ of a tree T, the *depth* of τ in T is defined as the length of τ, $Depth(\tau) = |\tau|$. The *height of a tree* T, written $Height(T)$, is defined as the maximal depth of a leaf of T plus 1. The *height of the node* $\tau \in T$ is $Height(T) - Depth(\tau)$.

A *labelled tree* is a pair (T, ν), where T is a tree and $\nu : T \to \Lambda$ is a labelling function into a set of labels Λ.

3 An optimal transformation of Muller into parity conditions

In this section we show how to use the Zielonka tree of a Muller condition to construct a deterministic parity automaton recognising the Muller condition. This can be seen as an extension of the existing constructions transforming Muller conditions into parity conditions such as the LAR [9] or the Index Appearance Record (IAR) [13, 17]. We prove that for all Muller conditions, the parity automaton has a minimal number of states (Theorem 3.7) and a minimal number of priorities (Proposition 3.6).

3.1 The Zielonka tree automaton

▶ **Definition 3.1** (Zielonka tree of a Muller condition [30]). *Let Γ be a finite set of colours and $\mathcal{F} \subseteq \mathcal{P}(\Gamma)$ a Muller condition over Γ. The* Zielonka tree *of $\mathcal{F}$, written $T_\mathcal{F}$, is a tree labelled with subsets of Γ via the labelling $\nu : T_\mathcal{F} \to \mathcal{P}(\Gamma)$, defined inductively as:*

- $\nu(\varepsilon) = \Gamma$
- *If τ is a node already constructed labelled with $S = \nu(\tau)$, we let $S_1, \dots, S_k$ be the maximal subsets of S verifying the property $S_i \in \mathcal{F} \ \Leftrightarrow \ S \notin \mathcal{F}$, for $i \in \{1, \dots, k\}$. For each $i \in \{1, \dots, k\}$ we add a child to τ labelled with S_i.*

We say that the condition $\mathcal{F}$ and the tree $T_{\mathcal{F}}$ are *even* (resp. *odd*) if $\Gamma \in \mathcal{F}$ (resp. $\Gamma \notin \mathcal{F}$). To each node τ of the Zielonka tree we associate the priority $p_Z(\tau) = Depth(\tau)$, and we add 1 to it if $T_{\mathcal{F}}$ is odd.

This way, $p_Z(\tau)$ is even if and only if $\nu(\tau) \in \mathcal{F}$. We represent nodes $\tau \in T_{\mathcal{F}}$ such that $p_Z(\tau)$ is even as a *circle* (*round nodes*), and those for which $p_Z(\tau)$ is odd as a *square*.

▶ **Example 3.2.** Let $\Gamma_1 = \{a, b, c\}$ and $\mathcal{F}_1 = \{\{a\}, \{b\}\}$. The Zielonka tree $T_{\mathcal{F}_1}$ is shown in Figure 1. It is odd.

Let $\Gamma_2 = \{a, b, c, d\}$ and $\mathcal{F}_2 = \{\{a, b, c, d\}, \{a, b, d\}, \{a, c, d\}, \{b, c, d\}, \{a, b\}, \{a, d\}, \{b, c\}, \{b, d\}, \{a\}, \{b\}, \{d\}\}$. The Zielonka tree $T_{\mathcal{F}_2}$ is even and it is shown on Figure 2.

On the right of each tree there are the priorities assigned to the nodes of the corresponding level. We have named the branches of the Zielonka trees with greek letters and we indicate the names of the nodes in violet.

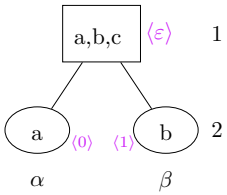

Figure 1 Zielonka tree $T_{\mathcal{F}_1}$.

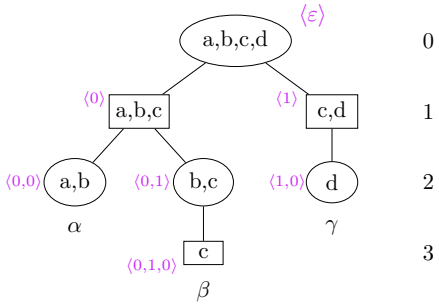

Figure 2 Zielonka tree $T_{\mathcal{F}_2}$.

We show next how to use the Zielonka tree of $\mathcal{F}$ to build a deterministic automaton recognizing the Muller condition $\mathcal{F}$. This automaton can be implicitly found in [7].

For a branch $\beta \in Branch(T_{\mathcal{F}})$ and a colour $a \in \Gamma$ we define $Supp(\beta, a) = \tau$ as the deepest node (maximal for $\sqsubseteq$) in β such that $a \in \nu(\tau)$.

Given a node $\tau \in \beta$, if τ is not a leaf then it has a unique child σ_β such that $\sigma_\beta \in \beta$. In this case, we let $Nextchild(\beta, \tau)$ be the next sibling of σ_β on its right, or the smallest child of τ if σ_β is the biggest one.

We define $Nextbranch(\beta, \tau)$ as the leftmost branch in T below $Nextchild(\beta, \tau)$, if τ is not a leaf, and we let $Nextbranch(\beta, \tau) = \beta$ if τ is a leaf of T.

▶ **Definition 3.3** (Zielonka tree automaton). *Given a Muller condition $\mathcal{F}$ over Γ with Zielonka tree $T_{\mathcal{F}}$, we define the* Zielonka tree automaton *$\mathcal{Z}_{\mathcal{F}}$ as a deterministic automaton over Γ using a parity acceptance condition given by $p : E \to [\mu, \eta]$, where*

- *$Q = Branch(T_{\mathcal{F}})$, the set of states is the set of branches of $T_{\mathcal{F}}$.*
- *The initial state q_0 is irrelevant, we pick the leftmost branch of $T_{\mathcal{F}}$.*
- *The transitions are: $\delta(\beta, a) = Nextbranch(\beta, Supp(\beta, a))$, for $\beta \in Branch(T_{\mathcal{F}})$ and $a \in \Gamma$.*
- *$\mu = 0$, $\eta = Height(T_{\mathcal{F}}) - 1$ if $\mathcal{F}$ is even; $\mu = 1$, $\eta = Height(T_{\mathcal{F}})$ if $\mathcal{F}$ is odd.*
- *$p(\beta, a) = p_Z(Supp(\beta, a))$.*

The transitions of the automaton are determined as follows: if we are in a branch β and we read a colour a, then we move up in the branch β until we reach a node τ that contains the colour a in its label. Then we pick the child of τ just on the right of the branch β (in a cyclic way) and we move to the leftmost branch below it. We produce the priority corresponding to the depth of τ.

▶ **Example 3.4.** Let us consider the conditions of Example 3.2. The Zielonka tree automaton for the Muller condition $\mathcal{F}_1$ is shown in Figure 3, and that for $\mathcal{F}_2$ in Figure 4.

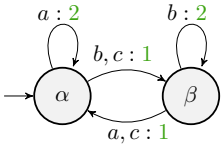

Figure 3 The Zielonka tree automaton $\mathcal{Z}_{\mathcal{F}_1}$.

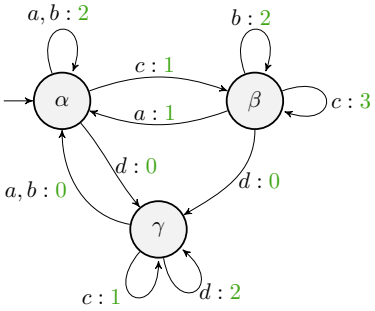

Figure 4 The Zielonka tree automaton $\mathcal{Z}_{\mathcal{F}_2}$.

▶ **Proposition 3.5** (Correctness). *Let $\mathcal{F} \subseteq \mathcal{P}(\Gamma)$ be a Muller condition over Γ. Then, a word $u \in \Gamma^\omega$ verifies $Inf(u) \in \mathcal{F}$ if and only if u is accepted by $\mathcal{Z}_{\mathcal{F}}$.*

3.2 Optimality of the Zielonka tree automaton

We prove in this section the strong optimality of the Zielonka tree automaton, both for the number of priorities (Proposition 3.6) and for the size (Theorem 3.7). These results have been obtained independently in a recent unpublished work by Meyer and Sickert [19].

▶ **Proposition 3.6** (Optimal number of priorities, independently proved in [19]). *The Zielonka tree $\mathcal{Z}_{\mathcal{F}}$ uses the optimal number of priorities for recognizing a Muller condition $\mathcal{F}$. More precisely, if $[\mu, \eta]$ are the priorities used by $\mathcal{Z}_{\mathcal{F}}$ and $\mathcal{P}$ is another parity automaton recognizing $\mathcal{F}$, then $\mathcal{P}$ uses at least $\eta - \mu + 1$ priorities, and in case of equality, its smallest priority has the same parity as μ.*

▶ **Theorem 3.7** (Optimal size of the Zielonka tree automaton, independently proved in [19]). *Every deterministic parity automaton $\mathcal{P}$ accepting a Muller condition $\mathcal{F}$ over Γ verifies $|\mathcal{Z}_{\mathcal{F}}| \leq |\mathcal{P}|$.*

The proof of both results appear in the full version of this paper [4], and Proposition 3.6 can also be deduced from the results of [22]. We sketch the proof of Theorem 3.7: for a set of letters $X \subseteq \Sigma$ we define an X-SCC of an automaton $\mathcal{A}$ over Σ as a strongly connected component of the graph obtained restricting the transitions of $\mathcal{A}$ to those labelled with letters from X. We prove that if A and B are the labels of two siblings in the Zielonka tree $T_{\mathcal{F}}$, and $\mathcal{P}$ is a parity automaton recognising the Muller condition $\mathcal{F}$, then A-SCCs and B-SCCs of $\mathcal{P}$ must be disjoint. Finding such disjoints X-SCC for the children of the nodes of the Zielonka tree allows us to conclude the proof by induction.

4 An optimal transformation of Muller into parity transition systems

In the previous section we have shown how the Zielonka tree yields a transformation of a Muller condition into a parity condition, through the construction of a deterministic parity automaton. This can be naturally lifted to transition systems by composing the automaton with the transition system. However this approach is oblivious to the transition system, meaning it does not consider the possibly fruitful interplay between the transition structure and the condition. All existing transformations follow this approach.

In this section we present our main contribution: an optimal transformation of Muller transition systems into parity transition systems. The key novelty is that it precisely captures the way the transition structure interacts with the condition. In the seminal work [28], Wagner introduces the *alternating chains of loops* of an automaton. This idea has been successfully applied to determine the complexity of computing the Rabin index of different types of ω-automata [2, 14, 22, 29]. Inspired by the notion of Zielonka trees and Wagner's alternating chains, we define a data structure called the alternating cycle decomposition (ACD) analysing the alternating chains of accepting and rejecting cycles of the transition system. We arrange this information in a collection of Zielonka trees obtaining a data structure, the alternating cycle decomposition, that subsumes all the structural information of the transition system necessary to determine whether a run is accepted or not.

We start in Subsection 4.1 by defining the notion of "transformations" using locally bijective morphisms. This will allow us to state the strong optimality result of Proposition 4.8 and Theorem 4.10: for all Muller transition system $\mathcal{T}$, the parity transition system $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ is minimal both in number of states and number of priorities amongst parity transition systems admitting a locally bijective morphism into $\mathcal{T}$.

4.1 Locally bijective morphisms as witnesses of transformations

▶ **Definition 4.1.** *Let $\mathcal{T} = (V, E, Source, Target, I_0, Acc)$, $\mathcal{T}' = (V', E', Source', Target', I_0', Acc')$ be two transition systems. A* morphism of transition systems, *written $\varphi : \mathcal{T} \to \mathcal{T}'$, is a pair of maps $(\varphi_V : V \to V', \varphi_E : E \to E')$ such that:*

- *$\varphi_V(v_0) \in I_0'$ for every $v_0 \in I_0$ (initial states are preserved).*
- *$Source'(\varphi_E(e)) = \varphi_V(Source(e))$ for every $e \in E$ (origins of edges are preserved).*
- *$Target'(\varphi_E(e)) = \varphi_V(Target(e))$ for every $e \in E$ (targets of edges are preserved).*
- *For every run $\varrho \in \mathcal{R}un_{\mathcal{T}}$, $\varrho \in Acc \Leftrightarrow \varphi_E(\varrho) \in Acc'$ (acceptance condition is preserved).*

For labelled transition systems, we say that φ is a morphism of labelled transition systems *if it also preserves the labels.*

We will denote both maps by φ whenever no confusion arises.

▶ **Definition 4.2.** *Given two transition systems $\mathcal{T}$ and $\mathcal{T}'$, a morphism of transition systems $\varphi : \mathcal{T} \to \mathcal{T}'$ is called* locally bijective *if for every $v \in V$ the restriction of φ_E (resp. φ_V) to $Out(v)$ (resp. I_0) is a bijection into $Out(\varphi(v))$ (resp. I_0').*

This is a very similar concept to the usual notion of bisimulation. The main difference is that locally bijective morphisms treat the acceptance of a run as a whole, allowing us to compare transition systems using different classes of acceptance conditions.

▶ **Observation 4.3.** *If $\varphi : \mathcal{T} \to \mathcal{T}'$ is a locally bijective morphism, then φ induces a bijection between the runs in $\mathcal{R}un_{\mathcal{T}}$ and $\mathcal{R}un_{\mathcal{T}'}$ that preserves their acceptance.*

Intuitively, if we transform a transition system $\mathcal{T}_1$ into $\mathcal{T}_2$ "without adding non-determinism", we will have a locally bijective morphism $\varphi : \mathcal{T}_2 \to \mathcal{T}_1$. In particular, if we take the product $\mathcal{T}_2 = \mathcal{T}_1 \times \mathcal{B}$ of $\mathcal{T}_1$ by some deterministic automaton $\mathcal{B}$, the projection over $\mathcal{T}_1$ yields a locally bijective morphism.

The existence of a locally bijective morphism is a witness of the fact that two systems share the same semantic properties: languages recognised by automata are preserved, as well as winning regions of games. Moreover, other important semantic properties of automata, such as being *unambiguous* or *good for games* (notions studied, respectively, in [3] and [10]) are preserved too. We refer to the full version for details [4].

4.2 The alternating cycle decomposition

In the following we will consider Muller transition systems $\mathcal{T} = (V, E, Source, Target, I_0, \mathcal{F})$ with the Muller acceptance condition using edges as colours. We can always suppose this, however, the size of the representation of the condition $\mathcal{F}$ might change. Making this assumption corresponds to considering what are called *explicit Muller conditions*. In particular, solving Muller games with explicit Muller conditions is in PTIME [11], while solving general Muller games is PSPACE-complete [12].

▶ **Example 4.4.** We will use the transition system $\mathcal{T}$ in Figure 5 as a running example. Its Muller condition is given by $\mathcal{F} = \{\{c, d, e\}, \{e\}, \{g, h, i\}, \{l\}, \{h, i, j, k\}, \{j, k\}\}$.

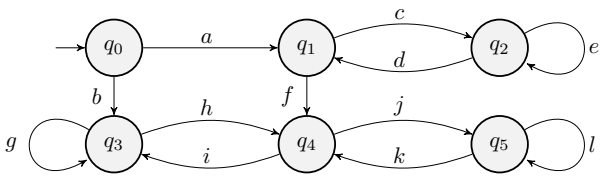

Figure 5 Transition system $\mathcal{T}$.

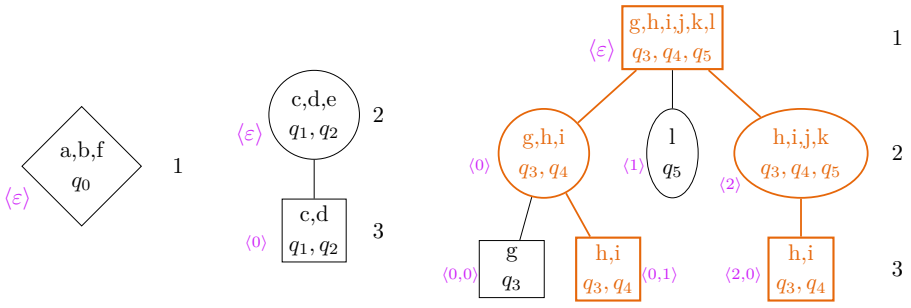
Given a transition system $\mathcal{T}$, a *loop* is a subset of edges $l \subseteq E$ such that exists $v \in V$ and a finite run $\varrho \in \mathcal{R}un_{T,v}$ starting and ending in v and $Occ(\varrho) = l$. The set of loops of $\mathcal{T}$ is denoted $\mathcal{L}oop(\mathcal{T})$. For a loop $l \in \mathcal{L}oop(\mathcal{T})$ we write $States(l) := \{v \in V \ : \ \exists e \in l, \ Source(e) = v\}$.

There is a natural partial order in the set $\mathcal{L}oop(\mathcal{T})$ given by set inclusion. The maximal loops of $\mathcal{L}oop(\mathcal{T})$ are disjoint and in one-to-one correspondence with the strongly connected components of $\mathcal{T}$.

In the system $\mathcal{T}$ in Figure 5, examples of loops are $l_1 = \{c, d, e\}$ or $l_2 = \{j, k\}$, with $States(l_1) = \{q_1, q_2\}$ and $States(l_2) = \{q_4, q_5\}$. The loop l_1 is maximal.

▶ **Definition 4.5** (Alternating cycle decomposition)**.** *Let $\mathcal{T}$ be a Muller transition system with acceptance condition given by $\mathcal{F} \subseteq \mathcal{P}(E)$. The* alternating cycle decomposition *of $\mathcal{T}$, noted $\mathcal{ACD}(\mathcal{T})$, is a family of labelled trees $(t_1, \nu_1), \dots, (t_r, \nu_r)$ with nodes labelled by loops in $\mathcal{L}oop(\mathcal{T})$, $\nu_i : t_i \to \mathcal{L}oop(\mathcal{T})$. We define it inductively as follows:*



- *Let $\{l_1, \dots, l_r\}$ be the set of maximal loops of $\mathcal{L}oop(\mathcal{T})$. For each $i \in \{1, \dots, r\}$ we consider a tree t_i and define $\nu_i(\varepsilon) = l_i$.*
- *Given an already defined node τ of a tree t_i we consider the maximal loops of the set $\{l \subseteq \nu_i(\tau) \ : \ l \in \mathcal{L}oop(\mathcal{T})$ and $l \in \mathcal{F} \Leftrightarrow \nu_i(\tau) \notin \mathcal{F}\}$ and for each of these loops l we add a child to τ in t_i labelled by l.*

For notational convenience we add a special tree (t_0, ν_0) with a single node ε labelled with the edges not appearing in any other tree of the forest, i.e., $\nu_0(\varepsilon) = E \setminus \bigcup_{i=1}^{r} l_i$. We define $States(\nu_0(\varepsilon)) := V \setminus \bigcup_{i=1}^{r} States(l_i)$.

We call the trees $t_1, \dots, t_r$ the proper trees *of the alternating cycle decomposition of $\mathcal{T}$. Given a node τ of t_i, we note $States_i(\tau) := States(\nu_i(\tau))$.*

The ACD of $\mathcal{T}$ is shown in Figure 6. It consists of two proper trees, t_1 and t_2, corresponding to the strongly connected components of $\mathcal{T}$ and the tree t_0 that corresponds to the edges not appearing in the strongly connected components.

▶ Remark. The Zielonka tree for a Muller condition $\mathcal{F}$ can be seen as a special case of this construction, for an automaton with a single state.

Tree t_0. Tree t_1. Tree t_2. In bold orange, the subtree t_{q_4}.

Figure 6 Alternating cycle decomposition of $\mathcal{T}$. The priority assigned to the nodes of each level of the trees is indicated on the right. Nodes with an even priority are drawn as circles and those with an odd priority as rectangles (excepting the special node forming the root of t_0). Each node τ is labelled with $\nu_i(\tau)$ and with $States_i(\tau)$. In violet the names of the nodes.

Since each state and edge of $\mathcal{T}$ appears in exactly one of the trees of $\mathcal{ACD}(\mathcal{T})$, we can define the *index* of a state $q \in V$ (resp. of an edge $e \in E$) in $\mathcal{ACD}(\mathcal{T})$ as the only number $j \in \{0, 1, \ldots, r\}$ such that $q \in States_j(\varepsilon)$ (resp. $e \in \nu_j(\varepsilon)$).

For each state $q \in V$ of index j we define the *subtree associated to the state* q as the subtree t_q of t_j consisting in the set of nodes $\{\tau \in t_j \ : \ q \in States_j(\tau)\}$.

In Figure 6, state q_4 has index 2, and the subtree associated to q_4 is shown in bold orange.

For each proper tree t_i of $\mathcal{ACD}(\mathcal{T})$ we say that t_i is *even* if $\nu_i(\varepsilon) \in \mathcal{F}$ and that it is *odd* if $\nu_i(\varepsilon) \notin \mathcal{F}$. We say that $\mathcal{ACD}(\mathcal{T})$ is *odd* if all the trees of maximal height of $\mathcal{ACD}(\mathcal{T})$ are odd.

For each $\tau \in t_i$, $i = 1, \ldots, r$, we define the *priority* of τ in t_i as $p_i(\tau) = Depth(\tau)$, adding 1 if t_i is odd. In the case where $\mathcal{ACD}(\mathcal{T})$ is odd we add 2 to nodes on even trees in order to use an optimal number of priorities. We assign to $p_0(\varepsilon)$ the minimal priority appearing in other trees (0 or 1).

We proceed to show how to use the alternating cycle decomposition of a Muller transition system to obtain a parity one.

▶ **Definition 4.6** (ACD-transformation). *Let $\mathcal{T}$ be a Muller transition system with alternating cycle decomposition $\mathcal{ACD}(\mathcal{T}) = \{(t_0, \nu_0), (t_1, \nu_1), \ldots, (t_r, \nu_r)\}$. We define its* ACD-transformation *$\mathcal{P}_{\mathcal{ACD}(\mathcal{T})} = (V_P, E_P, Source_P, Target_P, I'_0, p : E_P \to \mathbb{N})$ as follows:*

For each state $q \in \mathcal{T}$ we consider the subtree t_q consisting of the nodes with q in its label, and we add a state for each branch of this subtree. For each initial state in $\mathcal{T}$, we choose one of its corresponding states in $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ and we set it as initial (the leftmost branch of t_q).

To define transitions in $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ we move simultaneously in $\mathcal{T}$ and in $\mathcal{ACD}(\mathcal{T})$. When we take a transition e in $\mathcal{T}$ that goes from q to q', while being in a branch β, we climb the branch β searching the lowest node τ with e and q' in its label (the support*). We produce the priority corresponding to the level reached. If no such node exists in the branch β, we jump to the root of the tree containing q', producing the priority assigned to this root. After having reached the support τ, we move to the next child of τ on the right of β in the tree $t_{q'}$, and we pick the leftmost branch under it in $t_{q'}$. If we had jumped to the root of $t_{q'}$ from a different tree, we just pick the leftmost branch of $t_{q'}$.*

For a formal definition we refer the reader to the full version of this paper [4].

In Figure 7 we show the ACD-transformation $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ of $\mathcal{T}$. States are labelled with the corresponding state q_j in $\mathcal{T}$, the tree of its index and a node $\tau \in t_i$ that is a leaf in t_{q_j}.

We have tagged the edges of $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ with names of edges from $\mathcal{T}$, in order to indicate the image of the edges by the morphism $\varphi : \mathcal{P}_{\mathcal{ACD}(\mathcal{T})} \to \mathcal{T}$.

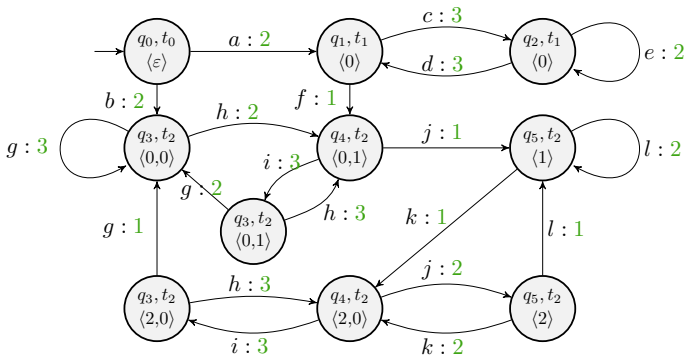


Figure 7 Transition system $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$.

▶ **Proposition 4.7** (Correctness). *Let $\mathcal{T}$ be a (possibly labelled) Muller transition system and $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ its ACD-transformation. Then, there exists a locally bijective morphism (of labelled transition systems) $\varphi : \mathcal{P}_{\mathcal{ACD}(\mathcal{T})} \to \mathcal{T}$.*

4.3 Optimality of the alternating cycle decomposition transformation

▶ **Proposition 4.8** (Optimality of the number of priorities). *Let $\mathcal{T}$ be a Muller transition system and let $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ be its ACD-transition system. If $\mathcal{P}$ is another parity transition system such that there is a locally bijective morphism $\varphi : \mathcal{P} \to \mathcal{T}$, then $\mathcal{P}$ uses at least the same number of priorities than $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$.*

In the case of deterministic automata, the results from [22] imply this proposition:

▶ **Proposition 4.9.** *If $\mathcal{A}$ is a deterministic Muller automaton, then $\mathcal{P}_{\mathcal{ACD}(\mathcal{A})}$ uses the optimal number of priorities to recognize $\mathcal{L}(\mathcal{A})$.*

Finally, we state the optimality of $\mathcal{P}_{\mathcal{ACD}(\mathcal{A})}$ for size.

▶ **Theorem 4.10** (Optimality of the number of states). *Let $\mathcal{T}$ be a Muller transition system and let $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ be its ACD-transition system. If $\mathcal{P}$ is another parity transition system such that there is a locally bijective morphism $\varphi : \mathcal{P} \to \mathcal{T}$, then $|\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}| \leq |\mathcal{P}|$.*

The proof of Theorem 4.10 follows the same lines as for Theorem 3.7, we refer to the full version of this paper [4]. We note that from the hypothesis of Theorem 4.10 we cannot deduce that there is a morphism from $\mathcal{P}$ to $\mathcal{P}_{\mathcal{ACD}(\mathcal{T})}$ or vice-versa.

5 Applications

Determinisation of Büchi automata

The best theoretical bounds for the determinisation of Büchi automata are achieved by Piterman's construction [23]. In [26], Schewe revisits this construction and presents it as two consecutive steps: a first one producing a deterministic Rabin automaton $\mathcal{R}_{\mathcal{B}}$, and a second one transforming $\mathcal{R}_{\mathcal{B}}$ into a parity automaton $\mathcal{P}_{\mathcal{B}}$. This second step induces a locally

bijective morphism from $\mathcal{P}_{\mathcal{B}}$ to $\mathcal{R}_{\mathcal{B}}$, therefore, thanks to Theorem 4.10 it is guaranteed that the ACD-transformation $\mathcal{P}_{\mathcal{ACD}(\mathcal{R}_{\mathcal{B}})}$ always yields a smaller deterministic parity automaton that uses less priorities. In particular, by Proposition 4.9 the number of priorities used by $\mathcal{P}_{\mathcal{ACD}(\mathcal{R}_{\mathcal{B}})}$ are the optimal one for recognising $\mathcal{L}(\mathcal{B})$ (that is, $\mathcal{ACD}(\mathcal{R}_{\mathcal{B}})$ gives the *parity index* of the language).

In many cases, the gain in both size and number of priorities is strict (we refer to the full version for one example [4]). However, both steps of Piterman Schewe's construction are already optimal in the worst case [6, 27], and applying the ACD-transformation in this worst-case example would generate the same parity automaton.

Relabelling of transition systems by acceptance conditions

We use the information provided by the alternating cycle decomposition to obtain results about the possibility of relabelling Muller transition systems with parity, Rabin and Streett conditions. The results presented here lift the seminal results of [30, Section 5] from conditions to transition systems.

Given a Zielonka tree $T_{\mathcal{F}}$, we say that it has *Rabin shape* (resp. *parity shape*) if every node with an even (reps. even or odd) priority assigned has at most one child. Given a Muller transition system $\mathcal{T}$, we say that its alternating cycle decomposition $\mathcal{ACD}(\mathcal{T})$ is a *Rabin ACD* (resp. *parity ACD*) if for every state $q \in V$, the tree t_q has Rabin shape (resp. parity shape).

▶ **Theorem 5.1.** *Let $\mathcal{T}$ be a Muller transition system. The following conditions are equivalent:*

1. *We can define a Rabin (resp. parity) condition that is equivalent to $\mathcal{F}$ over $\mathcal{T}$.*
2. *For every pair of loops $l_1, l_2 \in \mathcal{L}oop(\mathcal{T})$, if $l_1 \notin \mathcal{F}$ and $l_2 \notin \mathcal{F}$ (resp. l_1 and l_2 are both in $\mathcal{F}$ or both in $\mathcal{P}(\Gamma) \setminus \mathcal{F}$), then $l_1 \cup l_2 \notin \mathcal{F}$ (resp. $l_1 \cup l_2 \in \mathcal{F} \Leftrightarrow l_1 \in \mathcal{F}$).*
3. *$\mathcal{ACD}(\mathcal{T})$ is a Rabin ACD (resp. parity ACD).*

By duality, a symmetric result of the Rabin case holds for Streett conditions.

Similar results can be obtained for weak automata, see the full version for details [4].

▶ **Corollary 5.2.** *Given a transition system graph $\mathcal{T}_G$ and a Muller condition $\mathcal{F} \subseteq \mathcal{P}(E)$, we can define a parity condition $p : E \to \mathbb{N}$ equivalent to $\mathcal{F}$ over $\mathcal{T}_G$ if and only if we can define both Rabin and Streett conditions over $\mathcal{T}_G$, R and S, such that $(\mathcal{T}_G, \mathcal{F}) \simeq (\mathcal{T}_G, R) \simeq (\mathcal{T}_G, S)$.*

The previous results are stated for non-labelled transition systems. We must be careful when translating these results to non-deterministic automata [1, Section 4]. However, Proposition 2.1 allows us to obtain analogous results for deterministic automata.

▶ **Corollary 5.3** (First proven in [1, Theorem 7])**.** *Let $\mathcal{A}$ be a deterministic automaton such that there are a Rabin condition R and a Streett condition S over $\mathcal{A}$ such that $\mathcal{L}(\mathcal{A}, R) = \mathcal{L}(\mathcal{A}, S)$. Then, there exists a parity condition p over $\mathcal{A}$ such that $\mathcal{L}(\mathcal{A}, p) = \mathcal{L}(\mathcal{A}, R) = \mathcal{L}(\mathcal{A}, S)$.*

6 Discussions

In this work we have introduced the alternating cycle decomposition of a transition system, uncovering the interplay between a transition system and its acceptance condition. In order to formalise the notion of a "transformation" we have introduced locally bijective morphisms, which open new lines of research concerning questions such as the complexity of minimising automata with respect to these morphisms. We formulate the following conjecture, which implies that lower bounds established for Muller, Rabin or Streett automata [6] yield lower bounds for parity automata.

▶ **Conjecture 6.1.** *If $\mathcal{A}$ is a minimal deterministic Muller (resp. Rabin) automaton recognising $\mathcal{L}(\mathcal{A})$, then $\mathcal{P}_{\mathcal{ACD}(\mathcal{A})}$ is a minimal deterministic parity automaton recognising $\mathcal{L}(\mathcal{A})$.*

Abstract

Graphs and games on graphs are fundamental models for the analysis of reactive systems, in particular, for model-checking and the synthesis of reactive systems. The class of ω-regular languages provides a robust specification formalism for the desired properties of reactive systems. In the classical infinitary formulation of the liveness part of an ω-regular specification, a "good" event must happen eventually without any bound between the good events. A stronger notion of liveness is bounded liveness, which requires that good events happen within d transitions. Given a graph or a game graph with n vertices, m edges, and a bounded liveness objective, the previous best-known algorithmic bounds are as follows: (i) $O(dm)$ for graphs, which in the worst-case is $O(n^3)$; and (ii) $O(n^2d^2)$ for games on graphs. Our main contributions improve these long-standing algorithmic bounds. For graphs we present: (i) a randomized algorithm with one-sided error with running time $O(n^{2.5}\log n)$ for the bounded liveness objectives; and (ii) a deterministic linear-time algorithm for the complement of bounded liveness objectives. For games on graphs, we present an $O(n^2d)$ time algorithm for the bounded liveness objectives.

1 Introduction

Graphs and games on graphs. Graphs and two-player games played on graphs provide a general mathematical framework for a wide range of problems in computer science: in particular, for the analysis of reactive systems, where the vertices of the graph represent the states of a reactive system and the edges represent the transitions between the states. The classical synthesis problem (the problem of Church) asks for the construction of a winning strategy in a game played on the graph [13, 21, 20] and the fundamental model-checking problem is an algorithmic graph problem [14].

Omega-regular specifications: strength and weakness. In the analysis of reactive systems, the desired temporal properties that the system should satisfy constitute the specification. The class of ω-regular languages provides a robust specification formalism [18, 20]. Every ω-regular objective can be decomposed into a safety part and a liveness part [3]. The safety part ensures that the system will not do anything "bad" (such as violating an invariant) within any finite number of transitions. The liveness part ensures that the system will do something "good" (such as proceed or respond) in the long-run. Liveness can be violated only in the limit, by infinite sequences of transitions, as no bound is specified on when a "good" event must happen. This infinitary formulation has several strengths, such as robustness and simplicity [18, 23]. However, there is also a weakness of the classical definition of liveness: it can be satisfied by systems that are unsatisfactory because no bound can be put between the occurrence of desired events.

Stronger notion of liveness. For the weakness of the infinitary formulation of liveness, alternative and stronger formulations of liveness have been proposed. The first formulation is *bounded liveness* which ensures, given a bound d, that eventually, good events happen within d transitions. The second formulation is *finitary liveness* which requires the existence of a bound such that eventually good events happen within the bound. Finitary liveness was proposed in [4] and has been widely studied; e.g., games on graphs with finitary ω-regular objectives [12], and logics such as PromptLTL based on finitary liveness [17]. The notion of bounded liveness has also been investigated in many contexts, such as MSO with bounding quantifiers [7], bounded model-checking [6], and "bounded until" in logics such as RTCTL [15].

Algorithmic questions for bounded liveness. In this work, we consider graphs and games on graphs with bounded liveness objectives. Consider a graph with n vertices, m edges, and a bounded liveness objective with bound d. A basic algorithmic approach is to reduce the bounded liveness objective to a liveness objective on a larger graph (that we call the auxiliary graph) that explicitly keeps track of the number of transitions since the last good event. This basic approach yields the following bounds: (a) an $O(dm)$-time algorithm for graphs (applying the linear-time algorithm for liveness objectives on graphs), and (b) an $O(n^2d^2)$-time algorithm for games on graphs (applying the current best-known $O(n^2)$-time algorithm for games on graphs with liveness objectives [11]). A fundamental algorithmic question is whether the above bounds can be improved.

Our contributions. In this work, our main contributions are improved algorithmic bounds for bounded liveness on graphs and games on graphs.

- In graphs, there are two relevant semantics: (a) an existential semantic that asks whether there exists a path to satisfy the objective, and (b) a universal semantic that asks whether all paths satisfy the objective. The answer to the universal semantics with bounded liveness is "Yes" if and only if the answer is "No" for existential semantics with the complementary bounded coliveness objective. We consider graphs with the existential semantics and bounded liveness and bounded coliveness objectives. For bounded liveness objectives, all previous algorithmic approaches yield an $O(n^3)$ worst-case time-bound (where $d = O(n)$) and we present a randomized algorithm with one-sided error whose worst-case time-bound is $O(n^{2.5} \log n)$. For bounded coliveness objectives, we present a deterministic linear-time algorithm.
- For games on graphs with bounded liveness objectives, we present an $O(n^2d)$-time algorithm that improves the previous $O(n^2d^2)$-time algorithm.

Significance of the contributions. On the technical front, it is threefold.

1. To break the $O(n^3)$-time barrier for graphs, we exploit randomization to estimate for all pairs of good events how far they are from each other. Using this information along with a suitably modified auxiliary graph results in the faster $O(n^{2.5} \log n)$-time algorithm.

To get the improved time bound of $O(n^2 d)$ for game graphs:

2. we construct an auxiliary game graph (similar to the graph case) and make a crucial observation that this game graph after each iteration has a lot of structure, a property we call *induced symmetry*;
3. we strategically introduce as many "layover" vertices as there are good events; in combination with induced symmetry, this enables us to prove that a significant chunk of the auxiliary game graph is deleted after each iteration.

Furthermore, there are several important implications of our contributions. First, for graphs with bounded liveness objectives, the previous worst-case time-bound is $O(n^3)$. In recent years, many such algorithmic problems with $O(n^3)$ bound have been shown to be conditionally optimal with a reduction from classical problems such as BMM (boolean matrix multiplication) [1, 2, 8, 9, 10, 24]. Our new algorithm breaks the $O(n^3)$ barrier and shows that such conditional lower bound approaches do not apply for bounded liveness in graphs. Second, for graphs with bounded coliveness objectives our linear-time bound shows that there is a very efficient algorithm for the complement of the bounded liveness objectives. Finally, we show that the basic algorithmic approach for games on graphs can also be improved. Given our results improve the bounds for graphs and games on graphs with bounded liveness objectives, there are several interesting questions for future work. Whether the bounds can be further improved or a deterministic sub-cubic time algorithm can be obtained for graphs with bounded liveness objectives are the most interesting algorithmic open questions.

2 Preliminaries

Since the notation and definitions are standard, we base this section on the definitions section by Chatterjee and Henzinger [11].

Game graphs and graphs. A game graph $\Gamma = ((V, E), \langle V_1, V_2 \rangle)$ is a directed graph, where V is a finite set of vertices, E is a finite set of edges, and $\langle V_1, V_2 \rangle$ is a partition of V into player-1 vertices V_1 and the adversarial player-2 vertices V_2. Graphs are a special case of game graphs with $V_2 = \emptyset$. Define $Out(v) = \{u \in V \mid (v, u) \in E\}$ to be the set of vertices to which v has an outgoing edge and $In(v) = \{u \in V \mid (u, v) \in E\}$ to be the set of vertices from which v has an incoming edge. As is standard, we assume that there are no self-loops and that every vertex has an outgoing edge. Let $n = |V|$ be the number of vertices and $m = |E|$ be the number of edges.

Plays. A *play* $\langle v_0, v_1, v_2, \ldots \rangle$ is an infinite sequence of vertices in Γ such that each $(v_{i-1}, v_i) \in E$ for all $i \geqslant 1$. We denote by Ω the set of all plays. A *finite play* V^* is a prefix of a play.

Strategies. A player-ρ strategy tells which edge to follow next given a finite play that ends in a player-ρ vertex. More formally, a player-1 *strategy* is a function $\sigma : V^* \cdot V_1 \mapsto V$ such that for $\omega \in V^* \cdot V_1$ and v being the last vertex, $(v, \sigma(\omega)) \in E$. A player-2 strategy is defined in the same way. We denote by Σ the set of all player-1 strategies and by Π the set of all player-2 strategies.

Outcome of strategies. Given a starting vertex v and the strategies $\sigma \in \Sigma$ and $\pi \in \Pi$, there is a unique play $\omega(v, \sigma, \pi) = \langle v_0, v_1, v_2, \ldots \rangle$, which is defined as follows: $v_0 = v$; for all $i > 0$ if $v_i \in V_1$ then $\sigma(\langle v_0, \ldots, v_i \rangle) = v_{i+1}$, and if $v_i \in V_2$, then $\pi(\langle v_0, \ldots, v_i \rangle) = v_{i+1}$.

Objectives. An objective $\Phi \subseteq \Omega$ is a set of "winning" plays. The main objectives of this paper are the bounded Büchi objective for player 1 and the complementary bounded coBüchi objective for player 2. For a play ω, we define by $Inf(\omega)$ the set of vertices that occur infinitely often in ω. More formally, if $\omega = \langle v_0, v_1, v_2, \ldots \rangle \in \Omega$, then $Inf(\omega) = \{v \in V \mid \forall i \geqslant 0 \exists j > i : v_j = v\}$. We also need the reachability, safety, Büchi and the coBüchi objectives for the analyses. In the following definitions, assume that we are given a game graph Γ.

1. *Reachability and Safety objectives.* For $T \subseteq V$, the reachability objective states that *at least one* vertex in T be visited, and dually, the safety objective states that *only* vertices in C be visited. Formally, $\text{Reach}(T, \Gamma) = \{\langle v_0, v_1, v_2, \ldots \rangle \in \Omega \mid \exists k \geqslant 0 : v_k \in T\}$ and $\text{Safety}(C, \Gamma) = \{\langle v_0, v_1, v_2, \ldots \rangle \in \Omega \mid \forall k \geqslant 0 : v_k \in C\}$. The two objectives are dual, i.e., $\text{Reach}(T, \Gamma) = \Omega \setminus \text{Safety}(V \setminus T, \Gamma)$.
2. *Büchi and coBüchi objectives.* Given a set of *Büchi* vertices, the Büchi objective states that some Büchi vertex be visited infinitely often, and dually, the coBüchi objective states that only vertices in a given set C be visited infinitely often. Formally, given $B \subseteq V$, define $\text{Büchi}(B, \Gamma) = \{\omega \in \Omega \mid Inf(\omega) \cap B \neq \emptyset\}$ and given $C \subseteq V$, define $\text{coBüchi}(C, \Gamma) = \{\omega \in \Omega \mid Inf(\omega) \subseteq C\}$. The two objectives are dual, i.e., $\text{Büchi}(B, \Gamma) = \Omega \setminus \text{coBüchi}(V \setminus B, \Gamma)$.
3. *Bounded Büchi and bounded coBüchi objectives.* Given a set of Büchi vertices and an integer $d \geqslant 0$, the bounded Büchi objective states that from some point on, the distance between any two consecutive Büchi vertices is at most d. Dually, given $C \subseteq V$, the bounded coBüchi objective requires that there are at least d consecutive vertices in C infinitely often. Formally, the sets of winning plays are $\text{boundedBüchi}(B, d, \Gamma) = \{\omega \in \Omega \mid \exists i \geqslant 0 \forall j \geqslant i : \{v_j, v_{j+1}, \ldots, v_{j+d-1}\} \cap B \neq \emptyset\}$ and $\text{boundedcoBüchi}(C, d, \Gamma) = \{\omega \in \Omega \mid \forall i \geqslant 0 \ \exists j \geqslant i \text{ s.t. } \{v_j, v_{j+1}, \ldots, v_{j+d-1}\} \subseteq C\}$. These are also dual, i.e., $\text{boundedBüchi}(B, d, \Gamma) = \Omega \setminus \text{boundedcoBüchi}(V \setminus B, d, \Gamma)$.

When studying bounded Büchi (and bounded coBüchi) objectives, one can assume without loss of generality that $d \leqslant n$, because otherwise they are equivalent to Büchi objectives. We omit Γ from the definition of the objectives if it is obvious on which game graph the objectives are defined.

For an objective Φ, a strategy $\sigma \in \Sigma$ is a *winning strategy* for player 1 from vertex v if for all player-2 strategies $\pi \in \Pi$ the resulting play $\omega(v, \sigma, \pi) \in \Phi$, and the *set of winning vertices for player 1* is $W_1(\Phi) = \{v \in V \mid \exists \sigma \in \Sigma \text{ s.t. } \forall \pi \in \Pi : \omega(v, \sigma, \pi) \in \Phi\}$. Player-2 winning strategies and winning vertices are defined in the same way.

Remark about determinacy. The following theorem shows that every vertex in V either belongs to the winning set of bounded Büchi objectives of player 1 or to the winning set of bounded coBüchi objectives for player 2. The same holds for Büchi and coBüchi objectives. We say that a vertex is either *winning for player 1* or *winning for player 2*.

▶ **Theorem 1** (Determinancy [19]). *For all game graphs Γ, all (bounded) Büchi objectives Φ for player 1 and the complementary (bounded) coBüchi objectives $\Psi = \Omega \setminus \Phi$ for player 2 we have $W_1(\Phi) = V \setminus W_2(\Psi)$.*

Observe that for (bounded) Büchi objectives Φ for player 1 and the (bounded) coBüchi objectives $\Psi = \Omega \setminus \Phi$, by definition, we have $V \setminus W_2(\Psi) = \{v \in V \mid \forall \pi \in \Pi \ \exists \sigma \in \Sigma \text{ s.t. } \omega(v, \sigma, \pi) \in \Phi\}$. Theorem 1 allows to change existential and universal quantifiers, i.e.,

$V \setminus W_2(\Psi) = \{v \in V \mid \exists \sigma \in \Sigma \text{ s.t. } \forall \pi \in \Pi\ \omega(v, \sigma, \pi) \in \Phi\} = W_1(\Phi)$. If for every strategy π of player 2, there exists a strategy σ for player 1 that wins from vertex v, then there exists a (unique) strategy σ for player 1 that wins against every strategy π of player 2.

The computational problem. Given a game graph with bounded Büchi objective Φ the goal is to compute the set $W_1(\Phi)$. The focus of this paper is on bounded Büchi and bounded coBüchi objectives, and when we mention winning vertices or winning strategies, we mean winning for bounded Büchi objectives, unless stated otherwise.

Closed Sets. A set $U \subseteq V$ of vertices is a closed set for player 1 if $\forall u \in (U \cap V_1) : Out(u) \subseteq U$ and $\forall u \in (U \cap V_2) : Out(u) \cap V_2 \neq \emptyset$. We define player-2 closed sets analogously. Observe that every closed set U induces a subgame graph denoted $G \restriction U$.

A connection between closed sets, winning for safety, reachability and coBüchi objectives in the following proposition.

▶ **Proposition 2** ([11, Proposition 2.2]). *Consider a game graph Γ, and a closed set U for player 1. Then, the following assertions hold:*

1. *Player 2 has a winning strategy for the objective Safety(U) for all vertices in U, that is, player 2 can ensure that if the play starts in U, then the play never leaves the set U.*
2. *If $U \cap B = \emptyset$ (i.e., there is no Büchi vertex in U), then every vertex in U is winning for player 2 for the coBüchi objective.*

Attractors. For a set of "target" vertices $T \subseteq V$, the set of vertices from which player ρ can reach T against all strategies of the other player, is called the *player-ρ attractor* of T; formally [25, 23], $attr_\rho(T, \Gamma) = W_\rho(\text{Reach}(T, \Gamma))$. An attractor $A = attr_\rho(T, \Gamma)$ can be computed in $O(m)$ time [5, 16].

The following observation stipulates the connection between closed sets and attractors.

▶ **Observation 3** ([11]). *For all game graphs Γ, all players $\rho \in \{1, 2\}$, and all sets $U \subseteq V$ we have the following: The set $V \setminus attr_\rho(U, \Gamma)$ is a closed set for player ρ, i.e., no player-ρ vertex in $V \setminus attr_\rho(U, \Gamma)$ has an edge to $attr_\rho(U, \Gamma)$ and every vertex of the other player in $V \setminus attr_\rho(U, \Gamma)$ has an edge in $V \setminus attr_\rho(U, \Gamma)$.*

3 Algorithms for Graphs

Graphs are a special case of game graphs with $V_2 = \emptyset$. Hereon, we will call this "the graph case" as opposed to "the game graph case" (where $V_1 \neq \emptyset$ and $V_2 \neq \emptyset$). The objectives we consider are *prefix independent*, i.e., if $\omega \in \Omega$, then any play obtained by adding or removing a finite prefix to or from ω is also in Ω. Hence, with respect to computing winning vertices, it is enough to focus on strongly connected graphs. The reasoning is as follows.

In the input graph, we call a strongly connected component (SCC) S *good* if the graph restricted to S has a winning vertex. Due to prefix independence, all vertices in a good SCC and those from which you can reach a good SCC are winning. We will prove that such vertices are exactly the winning vertices, and that this set can be computed by the following procedure:

- Compute the SCCs of the input graph (can be done in linear time [22]).
- Determine for each SCC if it is good (this step depends on the objective).
- Consider the set of all vertices belonging to a good SCC. Perform reachability to this set. (This can also be done in linear time.)

▶ **Lemma 4.** *A vertex v is a winning vertex if and only if it there is path from v to some vertex in a good SCC.*

Proof. As mentioned before, due to prefix independence, if v has a path to some vertex in a good SCC, then it is winning. Next, we show the converse.

If v is winning, then there is a winning play ω starting at v. Since SCCs themselves form a directed acyclic graph (DAG), ω must eventually enter an SCC S and stay there. Again, due to prefix independence, the vertices visited by ω in S are also winning, i.e., S is a good SCC. ◀

By Lemma 4 and the procedure described above it, the problem of computing the winning vertices is reduced to determining, given a strongly-connected graph, whether there is a winning vertex or not. More formally, we get the following lemma.

▶ **Lemma 5.** *Let $S_1, S_2, \ldots$ be SCCs of the graph $G = (V, E)$. When $V_2 = \emptyset$, i.e., in the graph case, for a prefix independent objective, the set of winning vertices can be computed in time $O(m + \sum_i t(S_i))$ time, where $m = |E|$ and $t(S_i)$ is the time required to compute whether S_i is a good SCC or not.*

In this paper, we consider bounded Büchi and bounded coBüchi objectives.

3.1 The Bounded Büchi Objective

We are given a graph $G = (V, E)$, a set B of Büchi vertices, and a positive integer d. A cyclic-walk in G is a walk $(v_1, v_2, \ldots, v_\ell)$ such that $v_1 = v_\ell$. We say that a cyclic-walk C is *feasible* if it has at least one Büchi vertex and the number of edges in C between any two consecutive Büchi vertices is at most d. We assume that G is strongly connected, and our goal is to determine if there is a winning vertex in G. Then, using Lemma 5, we generalize the result to a graph that might not be strongly connected. The following lemma reduces this problem to finding a feasible cyclic-walk in G.

▶ **Lemma 6.** *The strongly-connected input graph G has a winning vertex with respect to the bounded Büchi objective if and only if it has a feasible cyclic-walk.*

Proof. If G has a winning vertex, say v, then there is a winning play ω that starts at v. Let $\omega = \langle v_0 = v, v_1, v_2, \ldots \rangle$; so by the definition of winning play, $\exists i \geqslant 1$ such that $\forall j \geqslant i : \{v_j, v_{j+1}, \ldots, v_{j+d-1}\} \cap B \neq \emptyset$. Consider the set $Inf(\omega)$ of vertices that appear infinitely often in ω. Since ω is winning, $Inf(\omega) \cap B \neq \emptyset$. Thus, we can choose a $j' \geqslant i$ such that $v_{j'} \in Inf(\omega) \cap B$. Since $v_{j'}$ appears infinitely often, for some $j'' > j'$, we have that $v_{j''} = v_{j'}$. Thus $(v_{j'}, v_{j'+1}, \ldots, v_{j''} = v_{j'})$ is a feasible cyclic-walk because $j' \geqslant i$ and, as mentioned earlier, $\forall j \geqslant i : \{v_j, v_{j+1}, \ldots, v_{j+d-1}\} \cap B \neq \emptyset$.

In the other direction, if G has a feasible cyclic-walk, then we can keep traversing it to construct a winning play, which means G has a winning vertex. ◀

An $O(dm)$-time algorithm for bounded Büchi

Next, we recall the basic $O(dm)$-time algorithm to determine if there is a feasible cyclic-walk. This algorithm tries to trace a feasible cycle by maintaining a counter with each possible non-Büchi vertex denoting how far away we are from the last visit to a Büchi vertex. We construct a $(d+1)$-layered auxiliary graph $G^* = (V^*, E^*)$, where $V^* = (B \times \{0\}) \cup ((V \setminus B) \times \{1, \ldots, d\})$. We define a more general graph here that we also use in Section 4. We illustrate an example in Figure 1. So, for $(v, \ell) \in V^*$, the integer ℓ corresponds to the aforementioned counter. We

call the vertices in $B \times \{0\}$ Büchi vertices and the vertices in $(V \setminus B) \times \{1, \ldots, d\}$ non-Büchi vertices. The edge set E^* is constructed by Algorithm 1. The last layer of the auxiliary graph is actually not needed for the graph case but is needed for the game graph case later. Observe that the auxiliary graph is also a game graph. (The ownership of the vertices will be defined later in a natural way.)

Algorithm 1 Construction of the auxiliary graph G^* from G, B, and d. It is easy to see that the running time of this algorithm is $O(dm)$ and G^* has at most dm edges.

procedure ConstructAuxiliaryGraph($G = (V, E), B \subseteq V$, d)
  $V^* \leftarrow (B \times \{0\}) \cup ((V \setminus B) \times \{1, \ldots, d\})$ and $E^* \leftarrow \emptyset$.
  for $(u, v) \in E$ such that $v \notin B$ (add counter-incrementing edges) **do**
    if $u \notin B$ **then**
      for $i \in \{1, \ldots, d-1\}$ **do**
        Add $((u, i), (v, i+1))$ to E^*.
      Add $((u, d), (v, d))$ to E^* (edges in the last layer to $V \setminus B$ stay in the last layer).
    else Add $((u, 0), (v, 1))$ to E^*.
  for $(u, v) \in E$ such that $v \in B$ (add counter-resetting edges) **do**
    if $u \notin B$ **then**
      for $i \in \{1, \ldots, d\}$ **do**
        Add $((u, i), (v, 0))$ to E^*.
    else Add $((u, 0), (v, 0))$ to E^*.
  return $G^* = (V^*, E^*)$
procedure AuxiliaryGraph-d-Layers($G = (V, E), B \subseteq V$, d)
  $G^* \leftarrow$ ConstructAuxiliaryGraph($G = (V, E), B \subseteq V, d$)
  Return the graph resulted by removing layer-d from G^*, called $G' = (V', E')$.

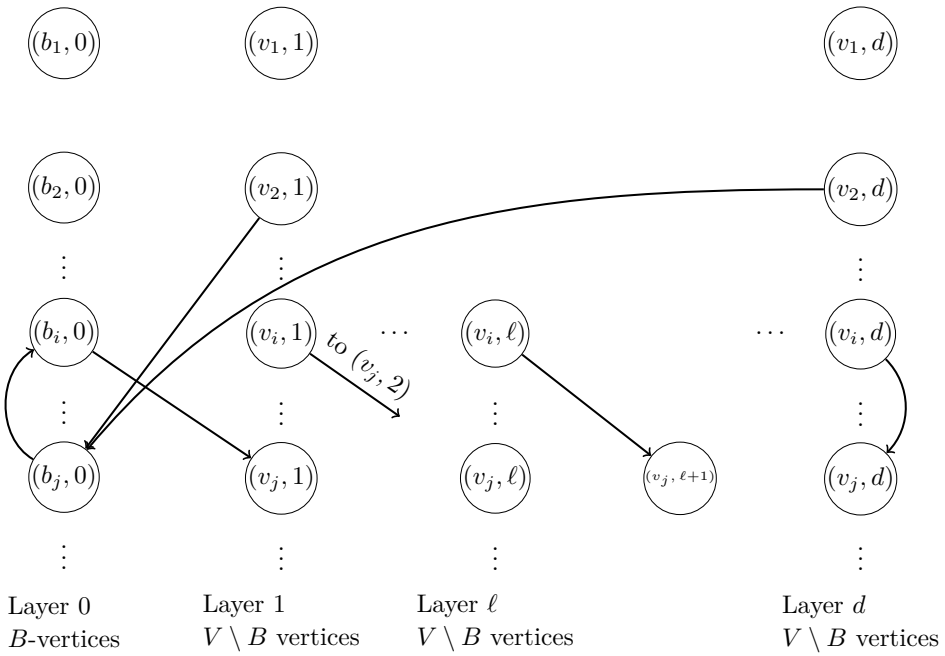

Figure 1 An illustration of how the auxiliary layered graph is constructed. If G contains the edges (b_j, b_i), (b_i, v_j), (v_2, b_j), and (v_i, v_j), then the auxiliary layered graph G^* will have shown edges.

▶ **Lemma 7.** *The running time of the procedures* ConstructAuxiliaryGraph *and* AuxiliaryGraph-d-Layers *in Algorithm 1 is* $O(dm)$.

Proof. In ConstructAuxiliaryGraph, each of the outer for loop runs for at most m iterations, and each of the inner for loops runs for at most d iterations. AuxiliaryGraph-d-Layers just calls ConstructAuxiliaryGraph and removes the last layer, which takes $O(dm)$ time. ◀

For the graph case, we are interested in G^* induced on layers-$\{0, 1, \ldots, d-1\}$. Let G' denote this graph.

▶ **Lemma 8.** *The strongly-connected input graph G has a feasible cyclic-walk if and only if G' has a cycle.*

Proof. Let $C = (b_1, v_{1,1}, \ldots, v_{1,\ell_1}, b_2, v_{2,1}, \ldots, v_{2,\ell_2}, b_3, \ldots, b_1)$, where each $b_i \in B$, each $v_{i,j} \in V \setminus B$, and each $\ell_i \leqslant d-1$, be a feasible cyclic-walk in G. There is a corresponding cyclic-walk C' in G':

- for each $(b_i, v_{i,1}) \in C$, the edge $((b_i, 0), (v_{i,1}, 1)) \in E'$,
- for each $(v_{i,j}, v_{i,j+1}) \in C$, the edge $((v_{i,j}, j), (v_{i,j+1}, j{+}1)) \in E'$,
- for each $(v_{i,\ell_j}, b_{i+1}) \in C$, the edge $((v_{i,\ell_j}, \ell_j), (b_{i+1}, 0)) \in E'$, and
- for the final edge $(v_{i,\ell_j}, b_1) \in C$, the edge $((v_{i,\ell_j}, \ell_j), (b_1, 0)) \in E'$.

If C' consists of union of cycles can be short-cut to get a cycle in G'.

In the other direction, consider a cycle in G'. A projection of this cycle on the first coordinate of the vertices, by construction, gives a feasible cyclic-walk in G, because the number of edges between consecutive Büchi vertices is at most d. ◀

Thus, by Lemmas 6 and 8, we get Algorithm 2.

Algorithm 2 This algorithm determines if the strongly-connected input graph has a winning vertex with respect to the bounded Büchi objective.

```
procedure BoundedBüchi(G = (V, E), B ⊆ V, d)
  G' ← AuxiliaryGraph-d-Layers(G, B, d)
  Run depth-first search on G' to determine if it has a cycle.
  if G' has a cycle then
    return "G has a winning vertex."
  else
    return "G does not have a winning vertex."
```

▶ **Lemma 9.** *Algorithm 2 determines if the strongly-connected input graph G has a winning vertex with respect to the bounded Büchi objective in $O(dm)$ time.*

Proof. By Lemmas 6 and 8, G has a winning vertex if and only if G' has a cycle. Since a depth-first search finds if there is a cycle in G', the correctness of the algorithm is established. By Lemma 7, AuxiliaryGraph-d-Layers takes $O(dm)$ time, and a depth-first search on G' takes time $O(dm)$, because the number of edges in G' is $O(dm)$. ◀

Thus, by Lemma 5, we get the following theorem.

▶ **Theorem 10.** *The set of winning vertices for the bounded Büchi objective in the graph case can be computed in time $O(dm)$.*

Proof. Let $S_1, S_2, \ldots$ be SCCs of the input graph $G = (V, E)$. Let $m_1, m_2, \ldots$ be the number of edges in the SCCs $S_1, S_2, \ldots$. Then, by Lemma 9, for $i = 1, 2, \ldots$, we can determine in time $O(dm_i)$ whether S_i is good. Since $m \geqslant \sum_i m_i$, the proof is complete by Lemma 5. ◀

An $O(|B|m)$-time algorithm for bounded Büchi

Now, we briefly discuss an $O(|B|m)$-time algorithm for bounded Büchi. Given $G = (V, E)$ and B, consider the graph $G' = (B, E')$ such that $(b, b') \in E'$ if the distance from b to b' in G is at most d. We allow self loops in G'. It is easy to see that G has a feasible-cyclic walk if and only if G' has a cycle. To construct G', we perform $|B|$ breadth-first searches, one starting from each vertex in B. This takes time $O(|B|m)$. Then, by a similar argument as in the proof of Theorem 10, we get the following theorem.

▶ **Theorem 11.** *The set of winning vertices for the bounded Büchi objective in the graph case can be computed in time $O(|B|m)$.*

▶ Remark 12. Note that both algorithms that we have seen so far can take $\Theta(n^3)$ time if $m = \Theta(n^2)$ and B and d are $\Theta(n)$. The next algorithm we see is combinatorial and has running time $O(n^{2.5} \log n)$ for the worst setting of the parameters and breaks the cubic barrier. This also rules out any conditional lower bound approaches to get an $\Omega(n^3)$ lower bound for combinatorial algorithms.

An $O((m + |B|^2)\sqrt{n} \log n)$-time algorithm for bounded Büchi

In this section, we present an $O((m+|B|^2)\sqrt{n} \log n)$-time algorithm for bounded Büchi in the graph case. This is one of our main contributions. Here, we give a procedure that computes distances between all pairs of Büchi vertices if the distance is at least $\sqrt{N}$, where $N \geqslant |V|$ is a parameter that we will fix later. This information can be used to reduce the number of layers in the auxiliary graph to $\sqrt{N}$. By dist, we denote the distance function with respect to G. For any $u, v \in V$, if $u \neq v$, then $\text{dist}(u, v)$ denotes the length of a shortest path from u to v, and for any $u \in V$, $\text{dist}(u, u)$ denotes the length of a shortest cycle through u.

Algorithm 3 This algorithm determines if the strongly-connected input graph has a winning vertex with respect to the bounded Büchi objective.

procedure RandBoundedBüchi($G = (V, E), B \subseteq V$, d, N)
  if $d < \sqrt{N}$ **then**
    return BoundedBüchi($G = (V, E), B \subseteq V$, d)
  Sample $4\sqrt{N} \ln N$ vertices uniformly at random, independently, and with replacement.
  $S \leftarrow$ the set of sampled vertices.
  for $s \in S$ **do**
    Perform incoming and outgoing breadth-first search (BFS) to and from s.
    Compute distances $\text{dist}(b, s)$ and $\text{dist}(s, b)$ for each $b \in B$ during the BFSs.
  $G' \leftarrow$ AuxiliaryGraph-d-Layers($G, B, \sqrt{N} - 1$)
  for $b \in B$ **do**
    for $b' \in B$ **do**
      $\text{dist}^S(b, b') \leftarrow \infty$
      for $s \in S$ **do**
        $\text{dist}^S(b, b') \leftarrow \min\{\text{dist}^S(b, b'), \text{dist}(b, s) + \text{dist}(s, b')\}$
      if $\text{dist}^S(b, b') \leqslant d$ **then**
        Add $((b, 0), (b', 0))$ to E' (this would be a self-loop if $b = b'$).
  Run depth-first search on G' to determine if it has a cycle.
  if G' has a cycle **then**
    return "G has a winning vertex."
  else
    return "G does not have a winning vertex."

▶ **Lemma 13.** *Let $N \geqslant |V|$. Algorithm 3 determines with probability at least $1 - 1/N^2$ if the strongly-connected input graph G has a winning vertex with respect to the bounded Büchi objective in $O((m + |B|^2)\sqrt{N} \log N)$ time. It never returns a* false positive*, i.e., if it outputs that G has a winning vertex, then it is correct with probability* 1*. Its running time is $O((m + |B|^2)\sqrt{N} \log N)$.*

Proof. If $d < \sqrt{N}$, then we are done by Lemma 9. Thus, we assume for the rest of the proof that $d \geqslant \sqrt{N}$.

For any $b, b' \in B$, by $T(b, b')$, we denote a fixed shortest cycle through b if $b = b'$ or a fixed shortest path from b to b' otherwise. Let the event that a vertex $v(b, b') \in T(b, b')$ is sampled into S be denoted by $\mathcal{E}(b, b')$. Since $v(b, b') \in T(b, b')$, we have that $\mathrm{dist}(b, b') = \mathrm{dist}(b, v(b, b')) + \mathrm{dist}(v(b, b'), b')$. This implies that if $\mathcal{E}(b, b')$ occurs, then $\mathrm{dist}(b, v(b, b'))$ and $\mathrm{dist}(v(b, b'), b')$ are computed by the algorithm using the incoming and outgoing BFS at $v(b, b')$, and hence $\mathrm{dist}^S(b, b') = \mathrm{dist}(b, b')$. Let $\mathcal{E}^c(b, b')$ be the complement of $\mathcal{E}(b, b')$. Now, $\Pr[\mathcal{E}^c(b, b')] = (1 - \mathrm{dist}(b, b')/|V|)^{4\sqrt{N} \ln N}$, because $1 - \mathrm{dist}(b, b')/|V|$ is the probability that a fixed sample does not contain a vertex of $T(b, b')$ and we draw $4\sqrt{N} \ln N$ independent samples.

For any $b, b' \in B$, where $\mathrm{dist}(b, b') \geqslant \sqrt{N}$, we denote the event that $\mathrm{dist}^S(b, b') = \mathrm{dist}(b, b')$ by $\mathcal{E}'(b, b')$. As noted earlier, $\mathrm{dist}^S(b, b') = \mathrm{dist}(b, b')$ if $\mathcal{E}(b, b')$ occurs, hence:

$$
\begin{aligned}
\Pr[\mathcal{E}'(b, b')] &\geqslant \Pr[\mathcal{E}(b, b')] = 1 - \Pr[\mathcal{E}^c(b, b')] && \mathcal{E}(b, b') \text{ is a subevent of } \mathcal{E}'(b, b'),\\
&= 1 - \left(1 - \frac{\mathrm{dist}(b, b')}{|V|}\right)^{4\sqrt{N} \ln N} && \text{by the argument earlier,}\\
&\geqslant 1 - \left(1 - \frac{1}{\sqrt{N}}\right)^{4\sqrt{N} \ln N} && \text{because } \mathrm{dist}(b, b')/|V| \geqslant 1/\sqrt{N},\\
&\geqslant 1 - \frac{1}{N^4} && \text{by well-known fact } (1 - 1/x)^x \leqslant 1/e.
\end{aligned}
$$

Since $N \geqslant |B|$, by the union bound and because the $\mathcal{E}'(b, b')$ are independent, we have $\Pr[\forall (b, b') \in B \times B : \mathcal{E}'(b, b')] \geqslant 1 - 1/N^2$. Let us condition on the event that for all $(b, b') \in B \times B : \mathcal{E}'(b, b')$, and let G' be the auxiliary graph constructed by the algorithm.

Suppose G has a winning vertex. By Lemma 6, there is a feasible cyclic-walk C in G. Then for any consecutive Büchi vertices b and b' in C, either $\mathrm{dist}(b, b') \geqslant \sqrt{N}$, in which case there is an edge $((b, 0), (b', 0))$ or $\mathrm{dist}(b, b') < \sqrt{N}$, in which case there exists a cycle $((b, 0), (u_1, 1), (u_2, 2), \ldots, (u_\ell, \ell), (b', 0))$ in G', where $\ell < \sqrt{N} - 1$. Thus, C induces a cycle in G'.

On the other hand, if there is a cycle C' in G', then a projection of C' on the first coordinate of the vertices, by construction of G', gives a feasible cyclic-walk in G after replacing all edges in C' of the form $((b, 0), (b', 0))$ by corresponding paths of length at most d that certify $\mathrm{dist}^S(b, b')$. By Lemma 6, G has a winning vertex.

Also, if the algorithm does return that G has a winning vertex, then G' has a cycle, and existence of a feasible cyclic-walk in G can be shown in the same way as above. This shows that the algorithm never returns a false positive.

Running time. Incoming and outgoing BFSs from the vertices in S take time $O(m\sqrt{N} \log N)$. Auxiliary-Graph-d-Layers takes $O(m\sqrt{N})$ time. Computing dist^S takes time $O(|B|^2\sqrt{N} \log N)$. DFS on G' takes time $O(|B|^2 + m\sqrt{N})$. In total, Algorithm 3 has running time $O((m + |B|^2)\sqrt{N} \log N)$. ◀

Finally, we use Lemma 5 to generalize the above to a graph that may not be strongly connected. Fix N to be n in Algorithm 3 when running it for each SCC. Then, by a similar argument as in the proof of Theorem 10, we get the following theorem.

▶ **Theorem 14.** *The set of winning vertices for the bounded Büchi objective can be computed with probability at least* $1-1/n$ *in time* $O((m+|B|^2)\sqrt{n}\log n)$ *which is* $O(n^{2.5}\log n)$*. Moreover, the algorithm never returns a* false positive*, i.e., each vertex in the set it outputs is a winning vertex with probability* 1*.*

Proof. Let $S_1, S_2, \ldots$ be SCCs of the input graph $G = (V, E)$. Let $m_1, m_2, \ldots$ be the number of edges and by $\beta_1, \beta_2, \ldots,$ be the number of Büchi vertices in the SCCs $S_1, S_2, \ldots$, respectively. Then, by Lemma 13, for $i = 1, 2, \ldots$, the algorithm outputs in time $O((m_i + \beta_i^2)\sqrt{n}\log n)$ whether S_i is good. Since $m \geqslant \sum_i m_i$ and $|B|^2 = (\sum_i \beta_i)^2 \geqslant \sum_i \beta_i^2$, the running time bound is proved.

The probability bound is obtained by a union bound over at most n SCCs. Moreover, the algorithm never returns a *false positive* by Lemma 13. ◀

3.2 The Bounded coBüchi Objective

Given a graph $G = (V, E)$, a set C of vertices, and a positive integer d, a walk W is called a *feasible* walk if $W \subseteq C$ and the number of vertices in W is at least d. Let $G[C]$ be the graph induced by C. The bounded coBüchi problem reduces to finding a feasible walk, which further reduces to finding whether there is a cycle in $G[C]$ (can be done in linear time), and if not $G[C]$ is a directed acyclic graph (DAG), so it reduces to determining whether the length of a longest path in the DAG $G[C]$ is at least d (also can be done in linear time). This gives us the following theorem.

▶ **Theorem 15.** *The set of winning vertices for the bounded coBüchi objective in the graph case can be computed in time* $O(m)$*.*

4 Algorithms for Game Graphs

In this section, we present algorithms for the bounded Büchi objective in game graphs. We first introduce the auxiliary *game graph* similar to the auxiliary graph defined earlier. We then show that we can compute in $O(n^2d^2)$ time the winning set of a given bounded Büchi objective on game graphs by computing the winning set of a coBüchi objective on the auxiliary game graph. Finally, we show how to improve the running time to $O(n^2d)$ by using structural properties of the auxiliary game graph and adapting a known technique for solving Büchi Games [11].

The Auxiliary Game Graph. Given a game graph $\Gamma = (V, E, \langle V_1, V_2\rangle)$ with n vertices, m edges and a bounded Büchi objective boundedBüchi(B, d), we first construct the auxiliary graph by calling ConstructAuxiliaryGraph$((V, E), B, d)$ in Algorithm 1 and additionally partition the vertices of the auxiliary graph V^* into player-1 vertices V_1^* and player-2 vertices V_2^*, i.e., for each $(v, \ell) \in V^*$ we get $(v, \ell) \in V_1^*$ if $v \in V_1$ and $(v, \ell) \in V_2^*$ if $v \in V_2$. The auxiliary game graph has $O(nd) = O(n^2)$ vertices and $O(md) = O(mn)$ edges. We say that a vertex $(v, \ell) \in V^*$ is a *layer-ℓ vertex* and v is its *first component*.

For any play λ, we denote by λ_k the kth vertex of the play. If a play has a superscript, it denotes the starting vertex of the play, e.g λ^v means that the play λ starts at v. By λ_k^v we refer to the kth vertex of the play λ^v which starts at v. Given a finite feasible play

$\lambda^{(w,\ell)}$ in Γ^* starting at (w,ℓ), we define $\mathrm{Proj}(\lambda^{(w,\ell)})$ to be the projection of $\lambda^{(w,\ell)}$ on the first component of the vertices in it; by definition, this finite play starts at w and is feasible in Γ. Analogously, given a finite feasible play λ^w in Γ, we define $\mathrm{Lift}(\lambda^w,\ell)$ to be the unique finite feasible play in Γ^* starting at (w,ℓ) such that the first component of $\mathrm{Lift}(\lambda^w,\ell)_k$ is the same as λ^w_k. For (u,v) in E such that $(u,j)\in V^*$ define (the appropriate next layer number if you followed the copy of (u,v) starting in layer j)

$$\mathrm{NxtLyr}(u,v,j)=\begin{cases} j+1 \text{ if } j<d \text{ and } v\notin B\\ d \text{ if } j=d \text{ and } v\notin B\\ 0 \text{ if } v\in B\,. \end{cases}$$

Now, define $\mathrm{Lift}(\lambda^w,\ell)_1=(w,\ell)$, and for $k>1$, given $\mathrm{Lift}(\lambda^w,\ell)_{k-1}=(\lambda^w_{k-1},j)$ define $\mathrm{Lift}(\lambda^w,\ell)_k=(\lambda^w_k,\mathrm{NxtLyr}(\lambda^w_{k-1},\lambda^w_k,j))$. Similarly, given the finite feasible play $\lambda^{(w,\ell)}$ in Γ^*, we define $\mathrm{Shift}(\lambda^{(w,\ell)},\ell')$ to be the finite play that starts at (w,ℓ') in Γ^* such that, for any k, the first components of $\lambda^{(w,\ell)}_k$ and $\mathrm{Shift}(\lambda^{(w,\ell)},\ell')_k$ are the same. By construction of Γ^* the finite play $\mathrm{Shift}(\lambda^{(w,\ell)},\ell')$ is well-defined because (1) edges going from layer-i vertices to layer-$(i+1)$ vertices ($1\leqslant i\leqslant d-1$) exist in all layers with the same respective first components except in layer-d where these edges go again to layer-d, (2) edges going to layer-0 vertices exist in all layers ($1\leqslant i\leqslant d$) and (3) because edges originating from layer-0 vertices implies that both plays are currently visiting the same layer-0 vertex.

In comparison, the goal of the two operations $\mathrm{Proj}(\cdot)$ and $\mathrm{Lift}(\cdot)$ is to map finite plays between Γ^* and Γ such that the finite play in Γ^* has, for all vertices, the same first component as the corresponding finite play in Γ and vice versa. In contrast, $\mathrm{Shift}(\lambda^{(w,\ell)},\ell')$ maps a finite play in Γ^* to a finite play also in Γ^* which has the same first component but a "shifted" starting vertex.

4.1 An $O(n^2d^2)$-time Algorithm for Bounded Büchi in Games

In this section, we show that we can compute the winning set of a given *bounded Büchi objective* on game graphs by computing the winning set of a *coBüchi objective* on the auxiliary game graph. Then we apply the best-known algorithm for computing the winning set of a Büchi objective on the auxiliary game graph to get the desired result.

In the following lemma, we prove that computing $W_1(\mathrm{boundedBüchi}(B,d,\Gamma))$ is the same as computing $W_1(\mathrm{coBüchi}(C^*,\Gamma^*))$ where C^* are the vertices in layers-$\{0,1,\ldots,d-1\}$. Intuitively, when a play ϕ in $\mathrm{coBüchi}(C^*,\Gamma^*)$ stays in layers-$\{0,1,\ldots,d-1\}$, it reaches a vertex in layer 0 every at most d steps by construction of Γ^*. The layer-0 vertices correspond to the vertices in B which means that a play ϕ' in Γ defined as the projection on the first component of the vertices in ϕ visits a vertex in B every at most d steps which implies that $\phi'\in\mathrm{boundedBüchi}(B,d,\Gamma)$. On the other hand, when player 1 has a strategy in Γ to visit a vertex in B every at most d steps, a similar strategy which visits the same vertices in the first component in Γ^* allows player 1 to stay in the first d layers of the auxiliary graph.

▶ **Lemma 16.** *Let $\Gamma=(V,E,\langle V_1,V_2\rangle)$ be a game graph with bounded Büchi objective boundedBüchi(B,d), let $\Gamma^*=(V^*,E^*,\langle V_1^*,V_2^*\rangle)$ be the corresponding auxiliary game graph, and let C^* be the vertices in the first d layers of the auxiliary graph, i.e., $C^*=\{(v,i)\in V^*\mid 0\leqslant i\leqslant d-1\}$. Then $\{w\mid (w,i)\in W_1(\mathit{coBüchi}(C^*,\Gamma^*)),\ \mathit{for\ some}\ 0\leqslant i\leqslant d\}=W_1(\mathit{boundedBüchi}(B,d,\Gamma))$.*

Proof. We first prove that $\{w \mid (w,i) \in W_1(\text{coBüchi}(C^*, \Gamma^*)), \text{ for some } 0 \leqslant i \leqslant d\} \subseteq W_1(\text{boundedBüchi}(B,d,\Gamma))$. Let $(w,i) \in W_1(\text{coBüchi}(C^*,\Gamma^*))$. Then player 1 has a winning strategy σ^* in Γ^* such that for all player-2 strategies π^*, we have that $\omega((w,i),\sigma^*,\pi^*) \in \text{coBüchi}(C^*,\Gamma^*)$.

Whenever player 1 makes a move in Γ^*, we define the corresponding move in Γ as follows: For any finite play λ^w in Γ that ends in a player-1 vertex, define $\sigma(\lambda^w)$ to be the first component of $\sigma^*(\text{Lift}(\lambda^w, i))$. (It does not matter how we define σ for plays that do not start at w.)

Next, we argue why σ is a winning player-1 strategy for $\text{boundedBüchi}(B,d,\Gamma)$ starting at w. Let π be an arbitrary player-2 strategy in Γ. We define a corresponding player-2 strategy π^* in Γ^*: for $\lambda^{(w,i)}$ that ends in a player-2 vertex (u,j), let $v = \pi(\text{Proj}(\lambda^{(w,i)}))$ and define $\pi^*(\lambda^{(w,i)}) = (v, \text{NxtLyr}(u,v,j))$.

Now, it is straightforward to show that the first component of $\omega((w,i),\sigma^*,\pi^*)_k$ is equal to $\omega(w,\sigma,\pi)_k$ by induction on k.

Since the play $\omega((w,i),\sigma^*,\pi^*) \in \text{coBüchi}(C^*,\Gamma^*)$, it stays in C^* after a finite number of steps. Note that to stay in C^* means to visit a layer-0 vertex after every at most d steps because there are only d layers in C^* and each step that does not go to a layer-0 vertex increases the layer counter. Since the first component of each layer-0 vertex is in B, the play $\omega(w,\sigma,\pi)$ visits a vertex in B every at most d steps after a finite number of steps and is in $\text{boundedBüchi}(B,d,\Gamma)$.

The other direction, $W_1(\text{boundedBüchi}(B,d,\Gamma)) \subseteq \{w \mid (w,i) \in W_1(\text{coBüchi}(C^*,\Gamma^*)), \text{for some } 0 \leqslant i \leqslant d\}$ can be shown with a similar argument. ◀

To compute $W_1(\text{coBüchi}(C^*))$ in Γ^*, we observe that, by Theorem 1, $W_1(\text{coBüchi}(C^*)) = V^* \setminus W_2(\text{Büchi}(V^* \setminus C^*)) = V^* \setminus W_2(\text{Büchi}(\{(v,d) \in V^*\}))$. Since, traditionally, we always compute the player-1 winning set of a given objective, we swap player-1 and player-2 vertices in Γ^*. Then we compute $W = W_1(\text{Büchi}(\{(v,d) \in V^*\}))$ using the algorithm of Chatterjee and Henzinger [11], which is the fastest algorithm for Büchi games known, and project $V^* \setminus W$ on the first coordinate. We illustrate the details in Algorithm 4.

Algorithm 4 Determine $W_1(\text{boundedBüchi}(B,d))$, given a game graph Γ.

```
1: procedure BoundedBüchiGames(Γ = (V, E, ⟨V1, V2⟩), B, d)
2:     (V*, E*) ← ConstructAuxiliaryGraph((V, E))
3:     V1* ← {(v,i) ∈ V* | v ∈ V1}, V2* ← {(v,i) ∈ V* | v ∈ V2}
4:     Γ* ← (V*, E*, V1*, V2*); B* ← {(v,d) ∈ V* | v ∈ V \ B}
5:     W ← BüchiGamesFast(Γ* = (V*, E*, ⟨V2*, V1*⟩), B*) ([11], Algorithm 5)
6:     return {x | (x,i) ∈ V* \ W for some 0 ⩽ i ⩽ d}
```

The correctness of Algorithm 4 is due to the correctness of the fast Büchi games algorithm [11, Theorem 2.14], the argument above, and Lemma 16. The argument for the running time of Algorithm 4 is as follows. We first construct Γ^* in $O(md)$ time and then compute the winning set of $\text{coBüchi}(C^*)$ in time $O(|V^*|^2)$ [11, Theorem 2.14]. As $|V^*| = O(nd)$ and $d = O(n)$, we get the following theorem.

▶ **Theorem 17.** *The set of winning vertices for the bounded Büchi objectives in games can be computed in time $O(n^2d^2) = O(n^4)$.*

4.2 An $O(n^2d)$-time Algorithm for Bounded Büchi in Games

In this section, we give a refined running time analysis of Algorithm 4 giving us an $O(n^2d)$-time algorithm for bounded Büchi games. We first describe the fastest algorithm for Büchi Games [11] for completeness. Then, we identify key ideas of the refined running time analysis when the input is an auxiliary game graph and prove the improved running time formally.

4.2.1 The Büchi Games Algorithm of [11]

Given a game graph $\Gamma = (V, E, \langle V_1, V_2\rangle)$ and a set B of Büchi vertices[1], we fix an order on the edges. In this fixed order, the edges (u, v) where u is a non-Büchi player-2 vertex, i.e., $u \in (V_2 \setminus B)$, come before all other edges. We call them priority-1 edges. All the other edges are priority-0 edges.

▶ **Definition 18.** *Given a game graph $\Gamma = (V, E, \langle V_1, V_2\rangle)$, let $\Gamma_i = (V, E_i, \langle V_1, V_2\rangle)$ for $1 \leqslant i \leqslant \log n$ be a subgraph of Γ which we define as follows: For all $u \in V$, the set E_i contains the following edges:*

1. *If the outdegree of u in E is at most 2^i, E_i contains all edges of the form (u, v), i.e., if $|Out(u)| \leqslant 2^i$ then the set $\{(u, v) \mid v \in Out(u)\} \subseteq E_i$.*
2. *If the edge (v, u) belongs to the first 2^i inedges of vertex u in E, we have $(v, u) \in E_i$ ("first" means with respect to the fixed order we specified above).*

Note that $E_{i-1} \subseteq E_i$ since the order of the edges is fixed. We form a partition of V in Γ_i by giving each vertex a color:

- Blue*: A player-1 vertex v in Γ_i is blue if the outdegree of v is greater than 2^i.*
- Red*: A player-2 vertex u in Γ_i is red if it has no outedge in E_i.*[2]
- *All other vertices are* white*.*

Thus, if a player-1 vertex is white then all its outedges are in E_i, and if a player-2 vertex is white then it has at least one outgoing edge in E_i.

Algorithm description. The input of Algorithm 5 is a game graph Γ and a set of Büchi vertices B. Recall that every vertex in a player-1 closed set S without Büchi vertices cannot be in the player-1 winning set of the given Büchi objective $W_1(\text{Büchi}(B))$ (Proposition 2 (2)). We repeatedly find such a set S by removing from V the player-1 attractor of the set B (Proposition 3) and forming S from all the remaining vertices. Then we remove the player-2 attractor of S. In the algorithm, we identify such a set S_j at Line 11 and remove the attractor at Line 15. Note that a naive algorithm would take $O(nm)$ time, as the attractor of S could always be of size 1 and computing the attractor is in $O(m)$ time. To obtain a quadratic-time (in the number of vertices) algorithm, the improved algorithm of Chatterjee and Henzinger constructs, for $i = 1, \ldots, \log n$, the graph Γ_i which has at most 2^i edges. Due to the properties of Γ_i, it can be shown that the set S_j has size of at least 2^{i-1}. In this way, the attractor computation take time proportional to the removed vertices. Since player-1 vertices with missing outgoing edges or player-2 vertices with no outgoing edge in Γ^i, i.e., non-white vertices might still be able to reach a vertex in B, we compute the player-1 attractor of the non-white vertices combined with the vertices in B. We illustrate the details in Algorithm 5.
