LIPIcs – Leibniz International Proceedings in Informatics

LIPIcs is a series of high-quality conference proceedings across all fields in informatics. LIPIcs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

Editorial Board

- Luca Aceto (*Chair*, Reykjavik University, IS and Gran Sasso Science Institute, IT)
- Christel Baier (TU Dresden, DE)
- Mikolaj Bojanczyk (University of Warsaw, PL)
- Roberto Di Cosmo (Inria and Université de Paris, FR)
- Faith Ellen (University of Toronto, CA)
- Javier Esparza (TU München, DE)
- Daniel Král' (Masaryk University - Brno, CZ)
- Meena Mahajan (Institute of Mathematical Sciences, Chennai, IN)
- Anca Muscholl (University of Bordeaux, FR)
- Chih-Hao Luke Ong (University of Oxford, GB)
- Phillip Rogaway (University of California, Davis, US)
- Eva Rotenberg (Technical University of Denmark, Lyngby, DK)
- Raimund Seidel (Universität des Saarlandes, Saarbrücken, DE and Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Wadern, DE)

Organization
..... 0:xvii

List of Authors
..... 0:xxvii

Invited Talks

From Verification to Causality-Based Explications
Christel Baier, Clemens Dubslaff, Florian Funke, Simon Jantsch, Rupak Majumdar, Jakob Piribauer, and Robin Ziemek 1:1–1:20

Symmetries and Complexity
Andrei A. Bulatov 2:1–2:17

Distributed Subgraph Finding: Progress and Challenges
Keren Censor-Hillel 3:1–3:14

Error Resilient Space Partitioning
Orr Dunkelman, Zeev Geyzel, Chaya Keller, Nathan Keller, Eyal Ronen, Adi Shamir, and Ran J. Tessler 4:1–4:22

Algebraic Proof Systems
Toniann Pitassi 5:1–5:1

A Very Sketchy Talk
David P. Woodruff 6:1–6:8

Track A: Algorithms, Complexity and Games

Fine-Grained Hardness for Edit Distance to a Fixed Sequence
Amir Abboud and Virginia Vassilevska Williams 7:1–7:14

Local Approximations of the Independent Set Polynomial
Dimitris Achlioptas and Kostas Zampetakis 8:1–8:16

Almost-Linear-Time Weighted ℓ_p-Norm Solvers in Slightly Dense Graphs via Sparsification
Deeksha Adil, Brian Bullins, Rasmus Kyng, and Sushant Sachdeva 9:1–9:15

An Output-Sensitive Algorithm for Computing the Union of Cubes and Fat Boxes in 3D
Pankaj K. Agarwal and Alex Steiger 10:1–10:20

Dynamic Enumeration of Similarity Joins
Pankaj K. Agarwal, Xiao Hu, Stavros Sintos, and Jun Yang 11:1–11:19

Faster Algorithms for Bounded Tree Edit Distance
Shyan Akmal and Ce Jin 12:1–12:15

Improved Approximation for Longest Common Subsequence over Small Alphabets
Shyan Akmal and Virginia Vassilevska Williams 13:1–13:18

Efficient Splitting of Necklaces
Noga Alon and Andrei Graur 14:1–14:17

Comparative Design-Choice Analysis of Color Refinement Algorithms Beyond the Worst Case
Markus Anders, Pascal Schweitzer, and Florian Wetzels 15:1–15:15

Search Problems in Trees with Symmetries: Near Optimal Traversal Strategies for Individualization-Refinement Algorithms
Markus Anders and Pascal Schweitzer 16:1–16:21

Breaking the Barrier Of 2 for the Competitiveness of Longest Queue Drop
Antonios Antoniadis, Matthias Englert, Nicolaos Matsakis, and Pavel Veselý 17:1–17:20

Relaxed Locally Correctable Codes with Improved Parameters
Vahid R. Asadi and Igor Shinkar 18:1–18:12

Beating Two-Thirds For Random-Order Streaming Matching
Sepehr Assadi and Soheil Behnezhad 19:1–19:13

Optimal Fine-Grained Hardness of Approximation of Linear Equations
Mitali Bafna and Nikhil Vyas 20:1–20:19

Revisiting Priority k-Center: Fairness and Outliers
Tanvi Bajpai, Deeparnab Chakrabarty, Chandra Chekuri, and Maryam Negahbani 21:1–21:20

The Submodular Santa Claus Problem in the Restricted Assignment Case
Etienne Bamas, Paritosh Garg, and Lars Rohwedder 22:1–22:18

On Coresets for Fair Clustering in Metric and Euclidean Spaces and Their Applications
Sayan Bandyapadhyay, Fedor V. Fomin, and Kirill Simonov 23:1–23:15

Strong Approximate Consensus Halving and the Borsuk-Ulam Theorem
Eleni Batziou, Kristoffer Arnsfelt Hansen, and Kasper Høgh 24:1–24:20

How to Send a Real Number Using a Single Bit (And Some Shared Randomness)
Ran Ben Basat, Michael Mitzenmacher, and Shay Vargaftik 25:1–25:20

Using a Geometric Lens to Find k Disjoint Shortest Paths
Matthias Bentert, André Nichterlein, Malte Renken, and Philipp Zschoche 26:1–26:14

Deterministic Rounding of Dynamic Fractional Matchings
Sayan Bhattacharya and Peter Kiss 27:1–27:14

Traveling Repairperson, Unrelated Machines, and Other Stories About Average Completion Times
Marcin Bienkowski, Artur Kraska, and Hsiang-Hsuan Liu 28:1–28:20

Counting Short Vector Pairs by Inner Product and Relations to the Permanent
Andreas Björklund and Petteri Kaski 29:1–29:21

Learning Stochastic Decision Trees
Guy Blanc, Jane Lange, and Li-Yang Tan 30:1–30:16

Breaking $O(nr)$ for Matroid Intersection
Joakim Blikstad 31:1–31:17

Graph Similarity and Homomorphism Densities
Jan Böker 32:1–32:17

Direct Sum and Partitionability Testing over General Groups
Andrej Bogdanov and Gautam Prakriya 33:1–33:19

4 vs 7 Sparse Undirected Unweighted Diameter is SETH-Hard at Time $n^{4/3}$
Édouard Bonnet 34:1–34:15

Twin-width III: Max Independent Set, Min Dominating Set, and Coloring
Édouard Bonnet, Colin Geniet, Eun Jung Kim, Stéphan Thomassé, and Rémi Watrigant 35:1–35:20

Almost-Optimal Deterministic Treasure Hunt in Arbitrary Graphs
Sébastien Bouchard, Yoann Dieudonné, Arnaud Labourel, and Andrzej Pelc 36:1–36:20

Conditional Dichotomy of Boolean Ordered Promise CSPs
Joshua Brakensiek, Venkatesan Guruswami, and Sai Sandeep 37:1–37:15

Parameterized Applications of Symbolic Differentiation of (Totally) Multilinear Polynomials
Cornelius Brand and Kevin Pratt 38:1–38:19

A Linear-Time $n^{0.4}$-Approximation for Longest Common Subsequence
Karl Bringmann and Debarati Das 39:1–39:20

Current Algorithms for Detecting Subgraphs of Bounded Treewidth Are Probably Optimal
Karl Bringmann and Jasper Slusallek 40:1–40:16

Fast n-Fold Boolean Convolution via Additive Combinatorics
Karl Bringmann and Vasileios Nakos 41:1–41:17

Additive Approximation Schemes for Load Balancing Problems
Moritz Buchem, Lars Rohwedder, Tjark Vredeveld, and Andreas Wiese 42:1–42:17

Genome Assembly, from Practice to Theory: Safe, Complete and Linear-Time
Massimo Cairo, Romeo Rizzi, Alexandru I. Tomescu, and Elia C. Zirondelli 43:1–43:18

Lifting for Constant-Depth Circuits and Applications to MCSP
Marco Carmosino, Kenneth Hoover, Russell Impagliazzo, Valentine Kabanets, and Antonina Kolokolova 44:1–44:20

Sparsification of Directed Graphs via Cut Balance
Ruoxu Cen, Yu Cheng, Debmalya Panigrahi, and Kevin Sun 45:1–45:21

Fault Tolerant Max-Cut
Keren Censor-Hillel, Noa Marelly, Roy Schwartz, and Tigran Tonoyan 46:1–46:20

Algorithms, Reductions and Equivalences for Small Weight Variants of All-Pairs Shortest Paths
Timothy M. Chan, Virginia Vassilevska Williams, and Yinzhan Xu 47:1–47:21

An Almost Optimal Edit Distance Oracle
Panagiotis Charalampopoulos, Paweł Gawrychowski, Shay Mozes, and Oren Weimann 48:1–48:20

Faster Algorithms for Rooted Connectivity in Directed Graphs
Chandra Chekuri and Kent Quanrud 49:1–49:16

Isolating Cuts, (Bi-)Submodularity, and Faster Algorithms for Connectivity
Chandra Chekuri and Kent Quanrud 50:1–50:20

Majority vs. Approximate Linear Sum and Average-Case Complexity Below NC^1
Lijie Chen, Zhenjian Lu, Xin Lyu, and Igor C. Oliveira 51:1–51:20

Near-Optimal Two-Pass Streaming Algorithm for Sampling Random Walks over Directed Graphs
Lijie Chen, Gillat Kol, Dmitry Paramonov, Raghuvansh R. Saxena, Zhao Song, and Huacheng Yu 52:1–52:19

Sublinear Time Hypergraph Sparsification via Cut and Edge Sampling Queries
Yu Chen, Sanjeev Khanna, and Ansh Nagda 53:1–53:21

Streaming and Small Space Approximation Algorithms for Edit Distance and Longest Common Subsequence
Kuan Cheng, Alireza Farhadi, MohammadTaghi Hajiaghayi, Zhengzhong Jin, Xin Li, Aviad Rubinstein, Saeed Seddighin, and Yu Zheng 54:1–54:20

Quantum Query Complexity with Matrix-Vector Products
Andrew M. Childs, Shih-Han Hung, and Tongyang Li 55:1–55:19

Truthful Allocation in Graphs and Hypergraphs
George Christodoulou, Elias Koutsoupias, and Annamária Kovács 56:1–56:20

Towards the k-Server Conjecture: A Unifying Potential, Pushing the Frontier to the Circle
Christian Coester and Elias Koutsoupias 57:1–57:20

Haystack Hunting Hints and Locker Room Communication
Artur Czumaj, George Kontogeorgiou, and Mike Paterson 58:1–58:20

Improved Approximation Factor for Adaptive Influence Maximization via Simple Greedy Strategies
Gianlorenzo D'Angelo, Debashmita Poddar, and Cosimo Vinci 59:1–59:19

Approximation Algorithms for Min-Distance Problems in DAGs
Mina Dalirrooyfard and Jenny Kaufmann 60:1–60:17

On Greedily Packing Anchored Rectangles
Christoph Damerius, Dominik Kaaser, Peter Kling, and Florian Schneider 61:1–61:20

Approximately Counting Independent Sets of a Given Size in Bounded-Degree Graphs
Ewan Davies and Will Perkins 62:1–62:18

Linear Time Runs Over General Ordered Alphabets
Jonas Ellert and Johannes Fischer 63:1–63:16

Decremental APSP in Unweighted Digraphs Versus an Adaptive Adversary
Jacob Evald, Viktor Fredslund-Hansen, Maximilian Probst Gutenberg, and Christian Wulff-Nilsen 64:1–64:20

On the Approximability of Multistage Min-Sum Set Cover
Dimitris Fotakis, Panagiotis Kostopanagiotis, Vasileios Nakos, Georgios Piliouras, and Stratis Skoulakis 65:1–65:19

A Spectral Independence View on Hard Spheres via Block Dynamics
Tobias Friedrich, Andreas Göbel, Martin S. Krejca, and Marcus Pappik 66:1–66:15

Constant-Factor Approximation to Deadline TSP and Related Problems in (Almost) Quasi-Polytime
Zachary Friggstad and Chaitanya Swamy 67:1–67:21

Random Order Vertex Arrival Contention Resolution Schemes for Matching, with Applications
Hu Fu, Zhihao Gavin Tang, Hongxun Wu, Jinzhao Wu, and Qianfan Zhang 68:1–68:20

A Subexponential Algorithm for ARRIVAL
Bernd Gärtner, Sebastian Haslebacher, and Hung P. Hoang 69:1–69:14

Universal Algorithms for Clustering Problems
Arun Ganesh, Bruce M. Maggs, and Debmalya Panigrahi 70:1–70:20

LF Successor: Compact Space Indexing for Order-Isomorphic Pattern Matching
Arnab Ganguly, Dhrumil Patel, Rahul Shah, and Sharma V. Thankachan 71:1–71:19

Crossing-Optimal Extension of Simple Drawings
Robert Ganian, Thekla Hamm, Fabian Klute, Irene Parada, and Birgit Vogtenhuber 72:1–72:17

Quantum Logspace Algorithm for Powering Matrices with Bounded Norm
Uma Girish, Ran Raz, and Wei Zhan 73:1–73:20

Online Stochastic Matching with Edge Arrivals
Nick Gravin, Zhihao Gavin Tang, and Kangning Wang 74:1–74:20

Faster Monotone Min-Plus Product, Range Mode, and Single Source Replacement Paths
Yuzhou Gu, Adam Polak, Virginia Vassilevska Williams, and Yinzhan Xu 75:1–75:20

Constructing a Distance Sensitivity Oracle in $O(n^{2.5794}M)$ Time
Yong Gu and Hanlin Ren 76:1–76:20

Structural Iterative Rounding for Generalized k-Median Problems
Anupam Gupta, Benjamin Moseley, and Rudy Zhou 77:1–77:18

Near-Optimal Schedules for Simultaneous Multicasts
Bernhard Haeupler, D. Ellis Hershkowitz, and David Wajc 78:1–78:19

Analysis of Smooth Heaps and Slim Heaps
Maria Hartmann, László Kozma, Corwin Sinnamon, and Robert E. Tarjan 79:1–79:20

Approximating Maximum Integral Multiflows on Bounded Genus Graphs
Chien-Chung Huang, Mathieu Mari, Claire Mathieu, and Jens Vygen 80:1–80:18

Minimum-Norm Load Balancing Is (Almost) as Easy as Minimizing Makespan
Sharat Ibrahimpur and Chaitanya Swamy 81:1–81:20

Quasi-Polynomial Time Algorithms for Free Quantum Games in Bounded Dimension
Hyejung H. Jee, Carlo Sparaciari, Omar Fawzi, and Mario Berta 82:1–82:20

Fully Dynamic Algorithms for Minimum Weight Cycle and Related Problems
Adam Karczmarz 83:1–83:20

Coboundary and Cosystolic Expansion from Strong Symmetry
Tali Kaufman and Izhar Oppenheim 84:1–84:16

Maximum Matchings and Popularity
Telikepalli Kavitha 85:1–85:21

Automorphisms and Isomorphisms of Maps in Linear Time
Ken-ichi Kawarabayashi, Bojan Mohar, Roman Nedela, and Peter Zeman 86:1–86:15

Lower Bounds on Dynamic Programming for Maximum Weight Independent Set
Tuukka Korhonen 87:1–87:14

Sorting Short Integers
Michal Koucký and Karel Král 88:1–88:17

Improving Gebauer's Construction of 3-Chromatic Hypergraphs with Few Edges
Jakub Kozik 89:1–89:9

SoS Certification for Symmetric Quadratic Functions and Its Connection to Constrained Boolean Hypercube Optimization
Adam Kurpisz, Aaron Potechin, and Elias Samuel Wirth 90:1–90:20

On Counting (Quantum-)Graph Homomorphisms in Finite Fields of Prime Order
J. A. Gregor Lagodzinski, Andreas Göbel, Katrin Casel, and Tobias Friedrich 91:1–91:15

Minimum Stable Cut and Treewidth
Michael Lampis 92:1–92:16

Testing Triangle Freeness in the General Model in Graphs with Arboricity $O(\sqrt{n})$
Reut Levi 93:1–93:13

An Efficient Coding Theorem via Probabilistic Representations and Its Applications
Zhenjian Lu and Igor C. Oliveira 94:1–94:20

Degrees and Gaps: Tight Complexity Results of General Factor Problems Parameterized by Treewidth and Cutwidth
Dániel Marx, Govind S. Sankar, and Philipp Schepper 95:1–95:20

High-Girth Near-Ramanujan Graphs with Lossy Vertex Expansion
Theo McKenzie and Sidhanth Mohanty 96:1–96:15

Relational Algorithms for k-Means Clustering
Benjamin Moseley, Kirk Pruhs, Alireza Samadian, and Yuyan Wang 97:1–97:21

Testing Dynamic Environments: Back to Basics
Yonatan Nakar and Dana Ron 98:1–98:20

Decision Problems for Second-Order Holonomic Recurrences
Eike Neumann, Joël Ouaknine, and James Worrell 99:1–99:20

New Sublinear Algorithms and Lower Bounds for LIS Estimation
Ilan Newman and Nithin Varma 100:1–100:20

Optimal-Time Queries on BWT-Runs Compressed Indexes
Takaaki Nishimoto and Yasuo Tabei 101:1–101:15

Application of the Level-2 Quantum Lasserre Hierarchy in Quantum Approximation Algorithms
Ojas Parekh and Kevin Thompson 102:1–102:20

Matching on the Line Admits No $o(\sqrt{\log n})$-Competitive Algorithm
Enoch Peserico and Michele Scquizzato 103:1–103:3

Non-Mergeable Sketching for Cardinality Estimation
Seth Pettie, Dingyu Wang, and Longhui Yin 104:1–104:20

The Structure of Minimum Vertex Cuts
Seth Pettie and Longhui Yin 105:1–105:20

Knapsack and Subset Sum with Small Items
Adam Polak, Lars Rohwedder, and Karol Węgrzycki 106:1–106:19

Multiple Random Walks on Graphs: Mixing Few to Cover Many
Nicolás Rivera, Thomas Sauerwald, and John Sylvester 107:1–107:16

Detecting and Counting Small Subgraphs, and Evaluating a Parameterized Tutte Polynomial: Lower Bounds via Toroidal Grids and Cayley Graph Expanders
Marc Roth, Johannes Schmitt, and Philip Wellnitz 108:1–108:16

The Greedy Algorithm Is *not* Optimal for On-Line Edge Coloring
Amin Saberi and David Wajc 109:1–109:18

Quantum Algorithms for Matrix Scaling and Matrix Balancing
Joran van Apeldoorn, Sander Gribling, Yinan Li, Harold Nieuwboer, Michael Walter, and Ronald de Wolf 110:1–110:17

Fourier Conjectures, Correlation Bounds, and Majority
Emanuele Viola 111:1–111:15

Separations for Estimating Large Frequency Moments on Data Streams
David P. Woodruff and Samson Zhou 112:1–112:21

Breaking the 2^n Barrier for 5-Coloring and 6-Coloring
Or Zamir 113:1–113:20

Deterministic Maximum Flows in Simple Graphs
Tianyi Zhang 114:1–114:16

Track B: Automata, Logic, Semantics, and Theory of Programming

Arboreal Categories and Resources
Samson Abramsky and Luca Reggio 115:1–115:20

Dynamic Membership for Regular Languages
Antoine Amarilli, Louis Jachiet, and Charles Paperman 116:1–116:17

A Rice's Theorem for Abstract Semantics
Paolo Baldan, Francesco Ranzato, and Linpeng Zhang 117:1–117:19

Optimal Spectral-Norm Approximate Minimization of Weighted Finite Automata
Borja Balle, Clara Lacroce, Prakash Panangaden, Doina Precup, and Guillaume Rabusseau 118:1–118:20

Property Testing of Regular Languages with Applications to Streaming Property Testing of Visibly Pushdown Languages
Gabriel Bathie and Tatiana Starikovskaya 119:1–119:17

Datalog-Expressibility for Monadic and Guarded Second-Order Logic
Manuel Bodirsky, Simon Knäuer, and Sebastian Rudolph 120:1–120:17

Beyond PCSP(1-in-3, NAE)
Alex Brandts and Stanislav Živný 121:1–121:14

Computational Characterization of Surface Entropies for $\mathbb{Z}^2$ Subshifts of Finite Type
Antonin Callard and Pascal Vanier 122:1–122:20

Optimal Transformations of Games and Automata Using Muller Conditions
Antonio Casares, Thomas Colcombet, and Nathanaël Fijalkow 123:1–123:14

Faster Algorithms for Bounded Liveness in Graphs and Game Graphs
Krishnendu Chatterjee, Monika Henzinger, Sagar Sudhir Kale, and Alexander Svozil 124:1–124:21

Inference Systems with Corules for Fair Subtyping and Liveness Properties of Binary Session Types
Luca Ciccone and Luca Padovani 125:1–125:16

Deterministic and Game Separability for Regular Languages of Infinite Trees
Lorenzo Clemente and Michał Skrzypczak 126:1–126:15

A Complexity Approach to Tree Algebras: the Bounded Case
Thomas Colcombet and Arthur Jaquard 127:1–127:13

Improved Lower Bounds for Reachability in Vector Addition Systems
Wojciech Czerwiński, Sławomir Lasota, and Łukasz Orlikowski 128:1–128:15

New Techniques for Universality in Unambiguous Register Automata
Wojciech Czerwiński, Antoine Mottet, and Karin Quaas 129:1–129:16

The Theory of Concatenation over Finite Models
Dominik D. Freydenberger and Liat Peterfreund 130:1–130:17

Uniform Elgot Iteration in Foundations
Sergey Goncharov 131:1–131:16

Powerset-Like Monads Weakly Distribute over Themselves in Toposes and Compact Hausdorff Spaces
Alexandre Goy, Daniela Petrişan, and Marc Aiguier 132:1–132:14

Elementary Equivalence Versus Isomorphism in Semiring Semantics
Erich Grädel and Lovro Mrkonjić 133:1–133:20

Logarithmic Weisfeiler-Leman Identifies All Planar Graphs
Martin Grohe and Sandra Kiefer 134:1–134:20

Kernelization, Proof Complexity and Social Choice
Gabriel Istrate, Cosmin Bonchiş, and Adrian Crăciun 135:1–135:21

Quantum Relational Hoare Logic with Expectations
Yangjia Li and Dominique Unruh 136:1–136:20

Playing Stochastically in Weighted Timed Games to Emulate Memory
Benjamin Monmege, Julie Parreaux, and Pierre-Alain Reynier 137:1–137:17

Smooth Approximations and Relational Width Collapses
Antoine Mottet, Tomáš Nagy, Michael Pinsker, and Michał Wrona 138:1–138:20

Comparison-Free Polyregular Functions
Lê Thành Dũng (Tito) Nguyễn, Camille Noûs, and Cécilia Pradic 139:1–139:20

Higher-Order Model Checking Step by Step
Paweł Parys 140:1–140:16

Fluted Logic with Counting
Ian Pratt-Hartmann 141:1–141:17

Guarded Kleene Algebra with Tests: Coequations, Coinduction, and Completeness
Todd Schmid, Tobias Kappé, Dexter Kozen, and Alexandra Silva 142:1–142:14

Analytical Differential Calculus with Integration
Han Xu and Zhenjiang Hu 143:1–143:20

Preface

This volume contains the papers presented at the *48th International Colloquium on Automata, Languages and Programming (**ICALP 2021**)*, held *virtually*, hosted by the University of Glasgow, UK, during July 12–16, 2021. ICALP is a series of annual conferences of the *European Association for Theoretical Computer Science (EATCS)*, which first took place in 1972.

This year, the ICALP program consisted of two tracks:

- Track A: Algorithms, Complexity, and Games
- Track B: Automata, Logic, Semantics, and Theory of Programming

In response to the call for papers, a total of 362 submissions were received: 261 for Track A and 101 for Track B. Each submission was assigned to at least three Program Committee members, aided by 761 external subreviewers. The committees decided to accept 137 papers for inclusion in the scientific program: 108 papers for Track A and 29 for Track B. The selection was made by the Program Committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high indeed, and many deserving papers could not be selected.

The EATCS sponsored awards for both a best paper and a best student paper in each of the two tracks, selected by the Program Committees.

The **best paper awards** were given to the following papers:

Track A: Sayan Bhattacharya and Peter Kiss. *Deterministic Rounding of Dynamic Fractional Matchings.*

Track B: Antoine Amarilli, Louis Jachiet and Charles Paperman. *Dynamic Membership for Regular Languages.*

The **best student paper awards**, for papers that are solely authored by students, were given to the following paper:

Track A: Or Zamir. *Breaking the 2^n barrier for 5-coloring and 6-coloring.*

Track B: *none.*

Apart from the contributed talks, ICALP 2021 included invited presentations by Christel Baier (Technical University of Dresden), Andrei Bulatov (Simon Fraser University, Canada), Keren Censor-Hillel (Technion, Israel), Toniann Pitassi (University of Toronto, Canada), Adi Shamir (Weizmann Institute of Science, Israel), David Woodruff (Carnegie Mellon University, USA).

This volume contains all the contributed papers presented at the conference, papers that accompany the invited talks of Christel Baier, Andrei Bulatov, Keren Censor-Hillel, Adi Shamir, David Woodruff, and an abstract of the invited presentation of Toniann Pitassi.

The program of ICALP 2021 also included presentations of the EATCS Award 2021 to Toniann Pitassi, the Presburger Award 2021 to Shayan Oveis Gharan, the EATCS Distinguished Dissertation Awards to Talya Eden, Marie Fortin, Vera Traub, and the induction of new EATCS Fellows Luca Aceto, Rajeev Alur, Samir Khuller, David Peleg, Davide Sangiorgi, Saket Saurabh.

The following workshops were held as satellite events of ICALP 2021 on July 12, 2021:

- Algorithmic Aspects of Temporal Graphs IV (AATG)
- Verification of Session Types (VEST)
- Programming Research in Mainstream Languages (PRiML)

48th International Colloquium on Automata, Languages, and Programming (ICALP 2021).
Editors: Nikhil Bansal, Emanuela Merelli, and James Worrell
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- Graph Width Parameters: from Structure to Algorithms (GWP)
- Combinatorial Reconfiguration
- Formal methods education on-line: Tips, Tricks and Tools
- Flavours of Uncertainty in Verification, Planning and Optimization (FUNCTION)

We wish to thank all authors who submitted extended abstracts for consideration, the Program Committees for their scholarly effort, and all the referees who assisted the Program Committees in the evaluation process.

We are also grateful to the Conference General Chair, Simon Gay, and his colleagues from the School of Computing Science, University of Glasgow, for organizing ICALP 2021, and to the Scottish Informatics and Computer Science Alliance (SICSA) for sponsoring participation by PhD students from Scotland.

We would like to thank Anca Muscholl, the Chair of the ICALP Steering Committee, for her continuous support and Artur Czumaj, the president of EATCS, for his generous advice on the organization of the conference.

Track A

Nikhil Bansal	CWI Amsterdam, Netherlands, Chair
Yossi Azar	Tel Aviv University, Israel
Luca Becchetti	Sapienza University of Rome, Italy
Alexander Belov	University of Latvia, Latvia
Eric Blais	University of Waterloo, Canada
Niv Buchbinder	Tel Aviv University, Israel
Kevin Buchin	TU Eindhoven, Netherlands
Parinya Chalermsook	Aalto University, Finland
Vincent Cohen-Addad	Google Research, Switzerland
Shahar Dobzinski	Weizmann Institute, Israel
Ran Duan	Tsinghua University, China
Vida Dujmovic	University of Ottawa, Canada
Yuval Filmus	Technion, Israel
Samuel Fiorini	Université libre de Bruxelles, Belgium
Andreas Galanis	University of Oxford, UK
Mika Göös	EPFL, Switzerland
Inge Li Gørtz	TU Denmark, Denmark
Heng Guo	University of Edinburgh, UK
Prahladh Harsha	TIFR, Mumbai, India
Sungjin Im	UC Merced, USA
Stacey Jeffery	CWI Amsterdam, Netherlands
Michael Kapralov	EPFL, Switzerland
Iordanis Kerenidis	CNRS – Université Paris Diderot, France
Stefan Kratsch	HU Berlin, Germany
Ravi Kumar	Google Research, USA
Silvio Lattanzi	Google Research, Switzerland
Shi Li	SUNY Buffalo, USA
Konstantin Makarychev	Northwestern University, USA
Marcin Mucha	University of Warsaw, Poland
Wolfgang Mulzer	FU Berlin, Germany
Jesper Nederlof	Utrecht University, Netherlands
Aleksandar Nikolov	University of Toronto, Canada
Neil Olver	LSE, UK
Rasmus Pagh	IT University of Copenhagen, Denmark
Merav Parter	Weizmann Institute, Israel
Alexandros Psomas	Purdue University, USA
Barna Saha	UC Berkeley, USA
Thatchaphol Saranurak	University of Michigan, USA
Rahul Savani	University of Liverpool, UK
Mohit Singh	Georgia Tech, USA
Sahil Singla	IAS/Princeton, USA
Noah Stephens-Davidowitz	Cornell University, USA
László Végh	LSE, UK
Meirav Zehavi	Ben-Gurion University, Israel

Track B

James Worrell	University of Oxford, UK, Chair
Parosh Aziz Abdulla	Uppsala University, Sweden
S. Akshay	Indian Institute of Technology Bombay, India
Nathalie Bertrand	Inria Rennes, France
Michael Blondin	Université de Sherbrooke, Canada
Olivier Carton	IRIF, Université de Paris, France
Corina Cîrstea	University of Southampton, UK
Ugo Dal Lago	University of Bologna and Inria, Italy
Dana Fisman	Ben Gurion University, Israel
Paul Gastin	LSV, ENS Paris-Saclay, France
Stefan Göller	University of Kassel, Germany
Radha Jagadeesan	DePaul University Chicago, USA
Bakhadyr Khoussainov	University of Auckland, New Zealand
Emanuel Kieronski	Wroclaw University, Poland
Bartek Klin	Warsaw University, Poland
Barbara König	University of Duisburg-Essen, Germany
Laura Kovacs	Vienna University of Technology, Austria
Christoph Löding	RWTH Aachen University, Germany
Sebastian Maneth	University of Bremen, Germany
Richard Mayr	University of Edinburgh, UK
Annabelle McIver	Macquarie University, Australia
Madhavan Mukund	Chennai Mathematical Institute, India
Sophie Pinchinat	IRISA, Université de Rennes, France
Cristian Riveros	Pontificia Universidad Católica de Chile, Chile
Davide Sangiorgi	University of Bologna and Inria, Italy
Lijun Zhang	Institute of Software, Chinese Academy of Sciences, China

Organizing Committee

Simon Gay	University of Glasgow, Chair
Oana Andrei	University of Glasgow
Ornela Dardha	University of Glasgow
Jessica Enright	University of Glasgow
David Manlove	University of Glasgow
Ciaran McCreesh	University of Glasgow
Kitty Meeks	University of Glasgow
Alice Miller	University of Glasgow
Gethin Norman	University of Glasgow
Sofiat Olaosebikan	University of Glasgow
Michele Sevegnani	University of Glasgow

Steering Committee

Anca Muscholl	Bordeaux University, France, Chair
Christel Baier	TU Dresden, Germany
Javier Esparza	TUM Munich, Germany
Paola Flocchini	University of Ottawa, Canada
Leslie Ann Goldberg	Oxford University, United Kingdom
Thore Husfeldt	Lund University, Sweden and
	IT University of Copenhagen, Denmark
Giuseppe Italiano	Università di Roma Tor Vergata, Italy
Stefano Leonardi	Sapienza University of Rome, Italy
Emanuela Merelli	University of Camerino, Italy
Luke Ong	Oxford University, United Kingdom
Paul Spirakis	University of Liverpool, United Kingdom and
	University of Patras, Greece
Christos Zaroliagis	University of Patras and CTI, Greece

Financial Sponsors

University of Glasgow
Scottish Informatics and Computer Science Alliance (SICSA)

List of Authors

Amir Abboud (7)
Weizmann Institute of Science, Rehovot, Israel

Samson Abramsky (115)
Department of Computer Science,
University of Oxford, UK

Dimitris Achlioptas (8)
Department of Informatics &
Telecommunications, University of Athens,
Greece

Deeksha Adil (9)
University of Toronto, Canada

Pankaj K. Agarwal (10, 11)
Department of Computer Science,
Duke University, Durham, NC, USA

Marc Aiguier (132)
Université Paris-Saclay, CentraleSupélec,
MICS, France

Shyan Akmal (12, 13)
MIT, EECS and CSAIL, Cambridge, MA, USA

Noga Alon (14)
Department of Mathematics,
Princeton University, NJ, USA;
Schools of Mathematics and Computer Science,
Tel Aviv University, Israel

Antoine Amarilli (116)
LTCI, Télécom Paris, Institut Polytechnique de
Paris, France

Markus Anders (15, 16)
TU Kaiserslautern, Germany;
TU Darmstadt, Germany

Antonios Antoniadis (17)
University of Twente, The Netherlands

Vahid R. Asadi (18)
Simon Fraser University, Burnaby, Canada

Sepehr Assadi (19)
Department of Computer Science,
Rutgers University, Piscataway, NJ, USA

Mitali Bafna (20)
Harvard University, Cambridge, MA, USA

Christel Baier (1)
Technische Universität Dresden, Germany

Tanvi Bajpai (21)
University of Illinois, Urbana-Champaign,
Urbana, IL, USA

Paolo Baldan (117)
Dipartimento di Matematica,
University of Padova, Italy

Borja Balle (118)
DeepMind, London, UK

Etienne Bamas (22)
EPFL, Lausanne, Switzerland

Sayan Bandyapadhyay (23)
Department of Informatics,
University of Bergen, Norway

Gabriel Bathie (119)
École normale supérieure de Lyon, France

Eleni Batziou (24)
Technical University of Munich, Germany

Soheil Behnezhad (19)
Department of Computer Science,
University of Maryland, College Park, MD, USA

Ran Ben Basat (25)
University College London, UK

Matthias Bentert (26)
Faculty IV, Algorithmics and Computational
Complexity, Technische Universität Berlin,
Germany

Mario Berta (82)
Department of Computing,
Imperial College London, UK;
IQIM, California Institute of Technology,
Pasadena, CA, USA;
AWS Center for Quantum Computing,
Pasadena, CA, USA

Sayan Bhattacharya (27)
Department of Computer Science,
University of Warwick, Coventry, UK

Marcin Bienkowski (28)
Institute of Computer Science,
University of Wrocław, Poland

Andreas Björklund (29)
Lund, Sweden

Guy Blanc (30)
Stanford University, CA, USA

48th International Colloquium on Automata, Languages, and Programming (ICALP 2021).
Editors: Nikhil Bansal, Emanuela Merelli, and James Worrell
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Joakim Blikstad (31)
KTH Royal Institute of Technology, Stockholm, Sweden

Manuel Bodirsky (120)
Institut für Algebra, TU Dresden, Germany

Andrej Bogdanov (33)
Department of Computer Science and Engineering and Institute of Theoretical Computer Science and Communications, Chinese University of Hong Kong, China

Cosmin Bonchiş (135)
West University of Timişoara, Romania

Édouard Bonnet (34, 35)
Univ Lyon, CNRS, ENS de Lyon, Université Claude Bernard Lyon 1, LIP UMR5668, France

Sébastien Bouchard (36)
Univ. Bordeaux, Bordeaux INP, CNRS, LaBRI, UMR5800, F-33400 Talence, France

Joshua Brakensiek (37)
Computer Science Department, Stanford University, CA, USA

Cornelius Brand (38)
Charles University, Prague, Czech Republic

Alex Brandts (121)
Department of Computer Science, University of Oxford, UK

Karl Bringmann (39, 40, 41)
Saarland University, Saarland Informatics Campus, Saarbrücken, Germany; Max-Planck-Institute for Informatics, Saarland Informatics Campus, Saarbrücken, Germany

Moritz Buchem (42)
Maastricht University, Maastricht, The Netherlands

Andrei A. Bulatov (2)
School of Computing Science, Simon Fraser University, Burnaby, Canada

Brian Bullins (9)
Toyota Technological Institute at Chicago, IL, USA

Jan Böker (32)
RWTH Aachen University, Germany

Massimo Cairo (43)
Department of Computer Science, University of Helsinki, Finland

Antonin Callard (122)
Université Paris-Saclay, ENS Paris-Saclay, Département Informatique, 91190 Gif-sur-Yvette, France

Marco Carmosino (44)
Department of Computer Science, Boston University, MA, USA

Antonio Casares (123)
LaBRI, Université de Bordeaux, France

Katrin Casel (91)
Hasso Plattner Institute, University of Potsdam, Germany

Ruoxu Cen (45)
Duke University, Durham, NC, USA

Keren Censor-Hillel (3, 46)
Department of Computer Science, Technion, Haifa, Israel

Deeparnab Chakrabarty (21)
Dartmouth College, Hanover, NH, USA

Timothy M. Chan (47)
University of Illinois at Urbana-Champaign, IL, USA

Panagiotis Charalampopoulos (48)
The Interdisciplinary Center Herzliya, Israel

Krishnendu Chatterjee (124)
IST Austria, Klosterneuburg, Austria

Chandra Chekuri (21, 49, 50)
University of Illinois, Urbana-Champaign, Urbana, IL, USA

Lijie Chen (51, 52)
MIT, Cambridge, MA, USA

Yu Chen (53)
Department of Computer and Information Science, University of Pennsylvania, Philadelphia, PA, USA

Kuan Cheng (54)
Peking University, Beijing, China

Yu Cheng (45)
University of Illinois at Chicago, IL, USA

Andrew M. Childs (55)
Joint Center for Quantum Information and Computer Science, Department of Computer Science, and Institute for Advanced Computer Studies, University of Maryland, College Park, MD, USA

George Christodoulou (56)
University of Liverpool, UK

Luca Ciccone (125)
University of Torino, Italy

CWI, Amsterdam, The Netherlands

Thomas Colcombet (123, 127)
CNRS, IRIF, Université de Paris, France

Adrian Crăciun (135)
West University of Timişoara, Romania

Wojciech Czerwiński (128, 129)
University of Warsaw, Poland

Artur Czumaj (58)
Department of Computer Science and DIMAP,
University of Warwick, Coventry, UK

Gianlorenzo D'Angelo (59)
Gran Sasso Science Institute, L'Aquila, Italy

Mina Dalirrooyfard (60)
MIT, Cambridge, MA, USA

Christoph Damerius (61)
University of Hamburg, Germany

Debarati Das (39)
Basic Algorithm Research Copenhagen (BARC),
University of Copenhagen, Denmark

Ewan Davies (62)
Department of Computer Science,
University of Colorado, Boulder, CO, USA

Ronald de Wolf (110)
QuSoft, CWI, Amsterdam, The Netherlands;
University of Amsterdam, The Netherlands

Yoann Dieudonné (36)
MIS Lab., Université de Picardie Jules Verne,
Amiens, France

Clemens Dubslaff (1)
Technische Universität Dresden, Germany

Orr Dunkelman (4)
Computer Science Department,
University of Haifa, Israel

Jonas Ellert (63)
Department of Computer Science,
Technical University of Dortmund, Germany

Matthias Englert (17)
University of Warwick, Coventry, UK

Jacob Evald (64)
BARC, University of Copenhagen, Denmark

Alireza Farhadi (54)
University of Maryland, College Park, MD, USA

Omar Fawzi (82)
Univ Lyon, ENS Lyon, UCBL, CNRS, Inria,
LIP, F-69342, Lyon Cedex 07, France

Nathanaël Fijalkow (123)
CNRS, LaBRI, Université de Bordeaux, France;
The Alan Turing Institute of Data Science,
London, UK

Johannes Fischer (63)
Department of Computer Science,
Technical University of Dortmund, Germany

Fedor V. Fomin (23)
Department of Informatics,
University of Bergen, Norway

Dimitris Fotakis (65)
National Technical University of Athens, Greece

Viktor Fredslund-Hansen (64)

Abstract

In view of the growing complexity of modern software architectures, formal models are increasingly used to understand *why* a system works the way it does, opposed to simply verifying *that* it behaves as intended. This paper surveys approaches to formally explicate the observable behavior of reactive systems. We describe how Halpern and Pearl's notion of actual causation inspired verification-oriented studies of cause-effect relationships in the evolution of a system. A second focus lies on applications of the Shapley value to responsibility ascriptions, aimed to measure the influence of an event on an observable effect. Finally, formal approaches to probabilistic causation are collected and connected, and their relevance to the understanding of probabilistic systems is discussed.

2012 ACM Subject Classification Theory of computation → Logic and verification

Keywords and phrases Model Checking, Causality, Responsibility, Counterfactuals, Shapley value

Funding This work was funded by DFG grant 389792660 as part of TRR 248 – CPEC (see `https://perspicuous-computing.science`), the Cluster of Excellence EXC 2050/1 (CeTI, project ID 390696704, as part of Germany's Excellence Strategy), DFG-projects BA-1679/11-1 and BA-1679/12-1, and the European Research Council under the Grant Agreement 610150 (`http://www.impact-erc.eu/`) (ERC Synergy Grant ImPACT).

1 Introduction

Modern software systems are increasingly complex and even small changes to a system or its environment may lead to unforeseen and disastrous behaviors. As software controls more aspects of our lives everyday, it is desirable – and for widespread acceptance in societal decisions, eventually inevitable – to have comprehensive and powerful techniques available to understand what a system does.

The field of formal methods has developed a portfolio of tools that provide confidence in the working of complex software systems. In formal methods, one builds a formal model of a system and specifies its desired behavior in an appropriate (temporal) logical formalism. Algorithmic techniques such as model checking [12, 31] can answer the question whether the model satisfies the specification, or in other words, whether the system behaves as intended, often in a "push button" way. Moreover, an important aspect of these algorithms is that they can produce independently verifiable justifications of their outcome, such as *counterexamples* or *certificates* to justify the violation or correctness of a property, respectively. Since the earliest successes of model checking, the availability of counterexample traces was stated as a major advantage for the method over deductive verification [30]. As model checkers became

© Christel Baier, Clemens Dubslaff, Florian Funke, Simon Jantsch, Rupak Majumdar, Jakob Piribauer, and Robin Ziemek;
licensed under Creative Commons License CC-BY 4.0

more complex, concerns about their correct implementation led to research on producing certificates for correctness. Examples are inductive invariants or derivations in a deductive system [62, 64, 44, 70] that can be checked independently from the verification process.

While certificates and counterexample traces can provide a useful explication about the behavior of a system, they only provide rudimentary understanding of *why* a system works the way it does. In epistemic terms, the outcome of model checking applied to a system and a specification provides *knowledge that* a system satisfies a specification or not in terms of an assertion (whether the system satisfies the specification) and a justification (certificate or counterexample) to increase the belief in the result. However, model checking usually does not provide *understanding* on *why* a system behaves in a certain way. Such an understanding can be obtained by causal links between possible events and their observed outcome.[1]

The need to better understand why a system is correct or incorrect has led to a broad research program on models and reasoning methods that aim to provide such knowledge of causes (see, e.g., [97, 98]). The goal of this survey is to summarize research on causal reasoning in the field of verification and highlight the challenges that lie ahead.

The first step in understanding knowledge of causes is the mathematical formulation and study of *causality*. Grasping the intuitive concept of cause-effect relationships in a formal model has proved notoriously difficult. Centuries of philosophical reasoning on the subject have distilled the *counterfactuality principle* [67, 68, 88] as a central feature of what constitutes an actual cause: if the cause had not occurred, then the effect would not have happened. While the counterfactuality principle was generally agreed upon, a rigorous mathematical formulation was developed only recently, through the seminal work of Halpern and Pearl and their coworkers [95, 45, 46, 55]. In a nutshell, they model causal systems using *structural equation models*, and provide a set of axioms to characterize when an event is an actual cause of another. We provide a summary of the foundations of causality and some of their applications in verification in Section 2.

While causality is a qualitative concept, in that an event is an actual cause of another or is not, more recent work considers *quantitative* measures of *responsibility*. Responsibility measures the relative importance that an event had in causing another event. In other words, the responsibility of an acting agent gauges what fraction of an observable effect can be attributed to that agent's behavior. Here, an agent could be, e.g., an individual, a coalition, a software component, or device in a computer network. Chockler and Halpern [23] define the *degree of responsibility* of an actual cause in the Halpern-Pearl sense based on the cardinality of the smallest witness change that makes an event a cause of another. A more recent strand for formalizing responsibility is based on the *Shapley value* [106]. In cooperative game theory, the Shapley value measures the influence of an agent on the outcome jointly brought about by the agents and is classically used to find a fair division of a cost or a surplus among them. The appeal of the Shapley value stems on the one hand from its uniqueness with respect to a relatively simple set of axioms, and on the other hand from its seemingly universal applicability. Research on employing Shapley-like values for the explication of machine-learning predictions [117, 35, 91, 1, 110] and the behavior of formal models [119, 11, 93, 10] is currently very active. A summary of applications of Shapley values in the verification context is provided in Section 3.

[1] Epistemologists since Gettier [47] will recognize that justified true belief does not constitute a comprehensive theory of knowledge. For the same reason, a theory of understanding as knowledge of causes is a matter of vigorous debate, with Gettier-like counterexamples [52, 100, 101]. These subtle epistemic issues are orthogonal to our work.

From a systematic viewpoint, causality and responsibility can be understood in either a *backward* or a *forward* manner [113]. In the backward or *ex post* setting, an effect has already transpired, and the goal is to describe its causes and determine their relative influence in producing the effect. The actual causation framework by Halpern and Pearl follows this paradigm, and therefore also most approaches presented in Section 2. In the forward or *ex ante* setting, a reasoning model includes possible contingencies and the goal is to characterize the global power of agents and events in affecting the outcome. The forward responsibility in game structures (see Section 3.1) and the importance value for temporal logics (see Section 3.2) pursue this pattern. There are also attempts to express forward-looking causality notions by structural equations in the context of *accountability* [73]. Seen from an operational angle, the distinction between backward and forward notions loosely relates to when the causal analysis is executed. Backward notions tend to be applicable at inspection time, e.g., to guide the debugging process in post mortem analyses. Forward notions are prone to be used at design time of the system, laying out general phenomena of its inner workings.

Finally, we consider causality in the setting of probabilistic models. Unlike the deterministic setting, mathematical notions of causality and responsibility are less understood. There is widespread agreement in the philosophy literature that a quintessential characteristic of causes in the probabilistic setting is the *probability-raising property* [111, 21, 107, 39]: an occurrence of the cause should increase the probability of subsequently observing the effect. Nevertheless, it has also been observed that simply taking probabilities often leads to counterintuitive phenomena owing to mutual dependencies and latent correlations with other events [104, 21, 107]. Section 4 discusses attempts to formulate probability-raising approaches to causation for operational probabilistic models. These approaches tend to produce forward notions since probabilities inherently refer to a collection of evolutions in which an event happened. There are numerous philosophical accounts on actual probabilistic causation [89, 84, 42]. In terms of formal models, Pearl's early notion of actual causality in terms of *causal beams* [96, 97] entailed probabilistic flavor, and the *causal probabilistic logic* of [115, 14] describes a language for reasoning about probabilistic causation. Nonetheless, we are aware of only a few works that study a probabilistic version of causality in operational models (see, e.g., [75, 2, 37, 9]). Along these lines, we point out open directions for research that focus on the operational point of view.

2 Counterfactual Notions of Causality

An important starting point for the study of causality in formal methods is the influential work by Halpern and Pearl [58, 59, 60, 56, 57] on *actual causality*, henceforth abbreviated *HP causality*. We provide a brief and informal overview of their definition.

Halpern and Pearl use *structural equation systems* as a modeling language for causal models. A causal model relies on exogeneous variables U and endogeneous variables V, representing external or independent factors and internal factors, respectively. The value of each endogeneous variable $x \in V$ is specified by a deterministic function f_x that may depend on exogeneous variables and on endogeneous variables that are preceding x with respect to a fixed order on V. Intuitively, a causal model can be thought of as an arithmetic circuit whose primary inputs are the exogeneous variables and where some of whose internal nodes are labeled by the endogeneous variables. The circuit then specifies the functions defining the endogeneous variables as well as the dependencies between the variables.

More formally, let $M = (U, V, \{f_x\}_{x \in V})$ be a causal model. Given a formula φ over the exogeneous and endogeneous variables (in some appropriate logic), and a *context* $\vec{u}$ that assigns values to all variables in U, the goal of actual causality is to state whether an assignment of values $\vec{X} = \vec{x}$ to a subset $X \subseteq V$ is a cause of φ. Halpern and Pearl define $\vec{X} = \vec{x}$ to be a *cause* of a formula φ in $(M, \vec{u})$ if the following three axioms hold.

AC1 both the cause and the effect are true: the model $(M, \vec{u})$ satisfies $\vec{X} = \vec{x}$ as well as φ,
AC2 the principle of counterfactual dependence (discussed below), and
AC3 causes are minimal: no partial assignment of $\vec{X} = \vec{x}$ satisfies AC1 and AC2.

The key to AC2 is captured by the notion of *interventions*, describing a direct assignment of values to some endogeneous variables while disregarding their defining functions. Formally, $[\vec{Y} \leftarrow \vec{y}]$ stands for the intervention on variables $Y \subseteq V$ by assigning them values $\vec{y}$ and leaving all other values for variables $V \setminus Y$ to follow from their defining functions. Then, $[\vec{Y} \leftarrow \vec{y}]\psi$ describes the impact of an intervention on a formula ψ. An intervention thus can represent a counterfactual: *what if* variables in Y took values $\vec{y}$ instead of their actual values? Turning back to the definition of actual causes for φ, axiom AC2 now requires the existence of an intervention $[\vec{X} \leftarrow \vec{x}']$ on the variables in X such that the effect φ is not observable, i.e., $[\vec{X} \leftarrow \vec{x}']\neg\varphi$ holds in $(M, \vec{u})$. The precise definition of AC2 is, however, more involved and several variants exist for AC2 to account for different settings and applications.[2]

2.1 Instances of HP Causality in Verification

Principles of causality have been used, often implicitly, in formal verification for a long time. An early example is *program slicing* (see, e.g., [61]) where by following program dependencies one aims to identify approximations of an actual cause for reaching a program location. Causality is also a key concept in error localization, the problem of reducing a counterexample trace for ease of debugging [120, 13, 105, 53, 118, 72, 121]. A correspondence of causality in counterexample traces to finding minimal `UNSAT` cores has been identified in [16]. Early and influential work on causality in formal verification is exemplified by research on *vacuity* and *coverage*. Vacuity [17, 81, 102] explicates whether a positive verification result originates from an unintended trivial behavior. Coverage [65, 25, 27, 26] is dual to vacuity, and explicates whether certain parts of the system were not relevant for the successful result. While for determining vacuity one considers small changes to the specification and checks whether these change the result, coverage is obtained by perturbations to the system rather than the specification and is actually a particular instance of HP causality.

Temporal logics play a crucial role in the verification context to describe properties of and requirements on the system. Common temporal logics are, e.g., *computation tree logic* (CTL) [29] or *linear temporal logic* (LTL) [99]. In LTL, e.g., $\neg E \,\mathcal{U}\, C$ describes that an effect E does not occur before a cause C and $\Diamond E$ stands for the effect E to eventually occur.

From Coverage to HP Causality. Coverage itself is a concept with a manifold of incarnations and we focus here on the formalization by [24], where the connection of coverage to HP causality has been addressed. The operational model is provided by a Kripke structure K, i.e., a finite directed graph over states labeled by atomic propositions. Further, we are given an atomic proposition q and a specification ψ expressed in an appropriate (temporal)

[2] Halpern and Pearl's definition of causality underwent a considerable amount of development over the past 20 years, primarily varying AC2. One usually distinguishes the *original* version [58], the *updated* version [59, 60], and the *modified* version [56, 57] (alongside variations by other authors [54, 63]).

logic over the set of atomic propositions such that K satisfies ψ. Then, a state s of K is said to be *q-covered* if changing the truth value of q in s leads to a structure that does not satisfy ψ. Considering the hypothetical mutant system in which q takes the opposite value in s corresponds to a counterfactual notion from the causality literature. Yet, coverage only allows simple counterfactuals containing *individual* changes to the system. As pointed out in [24], it is for this reason that coverage at times fails to express deeper dependencies involved in the satisfaction of ψ.

To define a *cause* in this setting, one can consider the following simple causal model: for each state s, there is one endogeneous variable v_s, which specifies whether the value of q in s is swapped in contrast to the original structure K, or not. One first refers to a context where all variables v_s are set to `false` and then considers possible swap operations. From K and ψ one can derive a Boolean function φ over the endogeneous variables V such that an instantiation $I\colon V \to \{\texttt{true}, \texttt{false}\}$ satisfies φ if and only if swapping the truth value of q exactly in states s with $I(v_s) = \texttt{true}$ leads to a structure satisfying ψ. Now s is a *cause of ψ with respect to q* [24, Definition 3.2] if there exists a set of variables Y such that $[Y \leftarrow \texttt{true}]\varphi$ and $[Y \cup \{v_s\} \leftarrow \texttt{true}]\neg\varphi$ hold. In other words, s is a cause if there exists a set of states S' (corresponding to variables Y) such that swapping q in S' leads to a structure satisfying ψ[3], but swapping the value of q in S' and s gives a structure falsifying ψ. These two conditions postulate precisely the axiom AC2, which takes a simpler form than usual thanks to the lack of higher-order dependencies among the variables in this causal model. In the presented causal model, axiom AC1 holds by the assumption that K satisfies ψ, and the minimality axiom AC3 is trivially fulfilled as only single states are considered as potential causes.

While this causal model is very simple, in particular it does not include any dependencies in between variables, the work in [24] shows that even such restricted models are useful.

Fault Localization. The causality interpretation of coverage presented above takes a forward-looking perspective in that changes to the system are globally tested against the given specification. In [16], a similar approach is applied to the backward-oriented setting of fault localization, i.e., the problem of pointing out those parts of a (finite) counterexample trace π that are most relevant for violation of a given linear-time specification φ. In this incarnation of HP causality, the endogeneous variables V contain a variable $v_{(s,q)}$ for each pair consisting of a state s and atomic proposition q of the Kripke structure. These variables can take values $\{\texttt{true}, \texttt{false}\}$ and the interpretation is exactly as before, namely $v_{(s,q)} = \texttt{true}$ means that the truth value of q in state s is changed in contrast to the initial context. Moreover, the axiom AC2 takes the same form as in the previous case. Specifically, it expresses that there is a set of variables $Y \subseteq V$ such that changing the truth value for the corresponding state-proposition pairs lets π still violate φ, while additionally swapping q in s leads to π satisfying φ (interpreted over a weak semantics of LTL on finite paths).

Counterfactual Reasoning for Configurable Systems. Nowadays, almost every practical software system is configurable, let it be using `#ifdef` constraints or through *features* [5]. Features inherently have a designated meaning, usually expressed by their name, e.g., a "verbose" feature indicates that the software will expose additional information during runtime. Debugging configurable systems is challenging, as the number of possible systems suffers from an exponential blowup in the number of features. While there are specifically tailored methods for analyzing configurable systems [112], e.g., through model checking [32, 38],

[3] The updated version of HP causality [59, 60] would require this condition also for all subsets of S'.

research on identifying root causes in configurable systems on the abstraction level of features is still in its infancy. Such a causal analysis can provide useful insights for debugging: developers can focus on the parts implementing the features identified to be responsible for the bug, and users can obtain suggestions to reconfigure the system to not expose the bug. First ideas to explicate which feature activations and deactivations cause an effect in configurable systems were described in [6]. There, the set of feature configurations with observable effect is obtained by configurable systems analysis, e.g., through family-based verification [32, 112, 38, 28]. Exploiting the Boolean case of HP causality [40, 69], those partial feature configurations can be determined where the corresponding systems all show the effect (see AC1), for which there is a reconfiguration that does not exhibit the effect (AC2), and that are minimal (AC3).

2.2 Further Approaches Inspired by HP Causality

The work [34] presents a formal definition of actual causes in the setting of concurrent interacting programs. Originating from logs written by the concurrent system, the goal is to localize causes in those *program actions* that are most relevant for the violation of a desirable property. The approach is investigated in detail for the prominent class of safety properties, with a view towards legal accountability in security-critical systems.

In [78], a causality-based approach to explain *timed diagnostic traces* has been presented, which are used as counterexamples for model-checking results in timed systems. Such traces represent a set of violating executions and the goal of [78] is to compute the parts that can be considered causal for violating the property.

A different definition inspired by HP causality was used in [86]. There, causes for reachability properties are formulas of a temporal logic called *event order logic*, used to describe temporal relations between events. Algorithms to compute causes in this sense were also studied in [15, 77], and the approach was extended to handle general LTL formulas as effects rather than just reachability in [20].

In [49, 50] the authors argue that the HP causality, which is propositional in nature, is not the ideal starting point for a framework of causality in formal verification. They present a formalism which is based on counterfactual reasoning, uses system traces as first-class objects and is designed to work for compositional systems. In [51] the formalism is further generalized by defining abstract *counterfactual builders*, which specify what alternative scenarios should be considered for counterfactual reasoning. Further, [51] also considers hyperproperties as specifications. While hyperproperties are useful to specifying system properties, it was observed in [33] that they can also be used to formalize causality. Similar observations have been made for probabilistic causation [2, 37].

3 Responsibility and Shapley-like Ascriptions

While the previous section defined and applied qualitative concepts of causation, this section shifts the focus towards quantitative approaches of *responsibility*. Loosely speaking, responsibility refers to a numerical value designed to measure how much weight an event had in producing an effect, relative to concurring or competing events linked to the same effect. There is widespread agreement that a necessary condition for assuming responsibility is causal relevance of the event in question to the effect [41, 18]. As a consequence, the term *responsibility* usually builds directly or indirectly on concepts of causality. While the specific numerical value in a notion of responsibility may not have a semantic content, it can order the events in terms of their causal relevance.

Chockler and Halpern [23] introduced the notion of *degree of responsibility*, which is attributed to actual causes in causal models of HP causality. This degree measures how many changes to the evolution of events are necessary until counterfactual values for the actual cause change the observable effect. In [24] this notion is combined with the study of mutant coverage to build a degree of responsibility in CTL model checking assigned to state-proposition pairs (see also Section 2.1).

The degree of responsibility measures the influence of an event by looking at how many further counterfactual changes are (minimally) required to swap the effect, but is does not take into account how many such minimal sets of changes exist. One can argue that a cause is individually more influential if it admits *many* such sets since this means less dependencies on other events. This rationale has generated an active strand in formalization of responsibility based on the *Shapley value* [106]. The Shapley value is a central solution concept from theoretical economics and was originally designed to find a fair distribution of a financial surplus that was brought about cooperatively by a number of producers.

Formally, a *cooperative game* with n players is a mapping $g\colon 2^{[n]} \to \mathbb{R}$ such that $g(\emptyset) = 0$, where $[n] = \{1, \ldots, n\}$. The value $g(C)$ is meant to represent the surplus (or, depending on the specific situation, the cost) that the coalition $C \subseteq [n]$ can ensure upon acting collaboratively. The Shapley value of player i is then defined as

$$\mathrm{Sh}(i) \;=\; \frac{1}{n!} \cdot \sum_{\pi \in S_n} g(\pi_{\geq i}) - g(\pi_{\geq i} \setminus \{i\}) \tag{1}$$

where S_n denotes the set of self-bijections $[n] \to [n]$ and where $\pi_{\geq i} = \{j \in [n] \mid \pi(j) \geq \pi(i)\}$ for a given $\pi \in S_n$. Intuitively, $g(\pi_{\geq i}) - g(\pi_{\geq i} \setminus \{i\})$ describes the marginal contribution of player i to the coalition $\pi_{\geq i}$. The Shapley value takes the average of all such marginal contributions. Thus, $\mathrm{Sh}(i)$ is a measure for the overall influence of player i in the game g.

The general setup of cooperative games as real-valued functions on the power set of $[n]$ makes the Shapley value amenable to measuring the influence of abstract players in formalized situations of collaborative interaction. This rationale has recently been invoked for the interpretation of machine learning models [117, 35, 91, 1, 110]. In this case, the players are the input parameters to a machine learning model, and the Shapley value has the goal to measure the influence of each parameter on the output of the model.

This section outlines three approaches that employ the Shapley value as a means to distribute an overall effect into individual responsibilities. In Section 3.1 the general setting of an *extensive form game* is chosen and responsibilities are attributed to its players with respect to producing a certain outcome. Section 3.2 discusses a notion of importance of states for the satisfaction of an LTL property in a Kripke structure. Section 3.3 finally presents an extension of the Shapley value that can be used to define responsibilities in a setting of continuously varying parameters.

3.1 Responsibility in Game Structures

As summarized in Section 2, causal models are by now a fundamental building block for notions of actual causation in the verification domain. However, in complex scenarios that involve cooperative interaction, non-cooperative competition, and imperfect information, they fall short of modeling various natural features such as temporal sequentiality, knowledge, and agency. The work [10] presents an approach to establish notions of responsibility in these strategic settings by passing to *extensive form games* [116, 80]. These provide a popular formalism for studying the dynamics that underlie strategic interaction in the presence of

competing objectives. In a nutshell, an extensive form game is an explicit presentation of the strategic scenario in terms of a tree structure whose edges describe the transitions between states when actions are taken, certain states may be indistinguishable for the players given their knowledge, and each path from the root to a leaf is associated with an outcome. Apart from being a highly expressive model, a century of research on the subject has generated a rich set of solution concepts on which a study of responsibility can build, primarily following economic rationales.

In [10] three responsibility notions are defined with respect to an event E that is encoded by a binary labelling on the leaves of the game tree, i.e., E took place on a play or not. All three notions follow the common two-step process consisting of first defining (qualitatively) what it means for a coalition C to be responsible and then extracting (quantitatively) an individual responsibility value through an application of the Shapley value on coalition responsibilities. That is, one takes the cooperative game g to take binary values $\{0, 1\}$ depending on whether or not a coalition is responsible. They also share the counterfactual paradigm in that a necessary condition for being responsible for the occurrence of E is the power to preclude E. While the notions can be ordered according to their logical strength, they are perhaps best explained along two lines of distinction given by the *temporal perspective* and *epistemic state*.

The temporal perspective can be either *forward-looking* or *backward-looking* [113]. For forward-looking notions one attains a prospective, *ex ante* viewpoint that studies the preclusive power for the game as a whole. The forward-looking notion put forth in [10] is called *forward responsibility* and requires the coalition to possess a strategy that globally avoids E. In contrast, backward-looking notions consider a specific play from a retrospective, *ex post* viewpoint and study who was responsible for E as the play evolved.

Depending on how the epistemic state is taken into account, [10] distinguishes *strategic* backward responsibility and *causal* backward responsibility. In order for a coalition to be strategically backward responsible, it must have had the power to avoid E at some point on the play and it must have been aware of this fact *given its epistemic knowledge*. In situations of imperfect information, this latter condition is crucial for arriving at a *responsibility-as-capacity* notion [113] in a strategic sense that goes beyond a mere counterfactuality check: when one does not know all relevant information, one can even bring about E inadvertently or unintendedly. Causal backward responsibility essentially drops the latter requirement in that the coalition is able to avoid E from some point on, everything else held fixed. This corresponds to the *responsibility-as-cause* from the classification presented in [113].

There is a translation of a causal model into an extensive form game under which causal backward responsibility corresponds exactly to but-for causes [10]. It can therefore happen that a player is causally backward responsible without belonging to an actual cause in the HP causality sense [59] and, therefore, with degree of responsibility 0 in the sense of [23]. In the prototypical example in which Suzy and Billy both throw rocks at a bottle and Suzy's stone hits first, Billy's degree of responsibility is 0, while both are attributed causal backward responsibility 1/2. Since both players acted in exactly the same way based on the same information, there is reason to favor the latter symmetric notion, and avoid actual causation *en route* to accurately model intuitive responsibility concepts. A detailed comparison to causal models, other notions of responsibility in strategic games of imperfect information [119], and proof-theoretic approaches to formalize responsibility [19, 94] is given in [10].

3.2 The Importance Value for Temporal Logics

The paradigm of passing from binary coalitional responsibilities to quantitative individual responsibilities by virtue of the Shapley value is also applied in [93] to model check Kripke structures against temporal logic specifications. The resulting notion is called the *importance value* and measures the influence of a state in a system for the satisfaction of a given specification. Intuitively, a state is important in this framework if the way that the nondeterministic choices of the state are resolved has a large impact on whether the given specification is met.

Formally, let K be a Kripke structure with states S and a dedicated initial state, and φ be an LTL formula. Then one defines the cooperative game $g\colon 2^S \to \{0,1\}$ using an induced two-player game as follows. For a set of states $C \subseteq S$ we let $\mathcal{G}_C$ be the two-player game over the arena K where player `SAT` controls the states in C, player `UNSAT` controls the states in $S \backslash C$ and the winning condition is φ. Then, $g(C) = 1$ if player `SAT` wins $\mathcal{G}_C$, and $g(C) = 0$ otherwise. With this definition, the importance value $\mathcal{I}(s)$ of a state $s \in S$ with respect to K and φ is defined to be the Shapley value of player s in g (see Equation (1)). The notion can be straightforwardly extended to define the importance of a set of states $P_i \subseteq S$, where $S = P_1 \dot\cup \ldots \dot\cup P_n$ is a given partition of the state space. This generalization is intended to take an existing compositional structure of the system appropriately into account.

The work [93] studies the associated computational problems of deciding whether $\mathcal{I}(s) > 0$ (called the *usefulness problem*) and deciding whether $\mathcal{I}(s) > \eta$ for a rational threshold η. The intrinsic complexity of solving two-player LTL-games (the decision problem is 2EXPTIME-complete) carries over to these problems. This computational intractability of the importance value motivates further studying the complexity when restricted to fragments of LTL, and tight complexity results were shown in [93] for a wide range of specifications.

In [93], the presented framework is also applied to CTL model checking of *modal transition systems* (MTS) [85]. MTSs have two levels of nondeterminism: the standard nondeterminism of the underlying graph and additionally a choice on which of the transitions in a state are actually included in the system. The latter kind of nondeterminism is used to design a two-player game where one player tries to satisfy the CTL specification and the other player tries to violate it. However, since the semantics of CTL relies on infinite trees and the order in which the branches are evolving has a strong impact on which player wins, there does not appear to be a natural candidate game that proceeds in a turn-by-turn fashion. Hence [93] considers *one-shot games* in which the players commit to a valid set of transitions in the states under their control once at the beginning of their play. This determines once more a binary cooperative game g that induces importance values in the same way as for LTL.

There is a straightforward generalization of the importance value to a $2\frac{1}{2}$-player game $\mathcal{G}$ in which the actions taken by the players are associated with probability distributions over the states. In this formalism, the players each make non-deterministic choices among its available actions, but the actual successor state then depends on a random choice according to the associated distribution. Given an LTL specification, the goal of `SAT` is to maximize the probability that the resulting path satisfies the specification, while `UNSAT` tries to minimize it. These $2\frac{1}{2}$-player games are *determined* in a quantitative sense [92]: the maximal probability that can be enforced by `SAT` against all strategies of `UNSAT` is 1 minus the minimal probability that can be enforced by `UNSAT` against all strategies of `SAT`. This probability is called the *value* $\mathrm{val}(\mathcal{G})$ of the game (see also the survey [22]). Let $S = S_{\texttt{SAT}} \dot\cup S_{\texttt{UNSAT}}$ be the partition of the states of $\mathcal{G}$ into those under control of `SAT` and `UNSAT`, respectively. For a subset $C \subseteq S_{\texttt{SAT}}$ the value $g(C)$ is then defined as $\mathrm{val}(\mathcal{G}_C)$, where $\mathcal{G}_C$ is the $2\frac{1}{2}$-player game obtained from $\mathcal{G}$ by putting the states in $S \backslash C$ under the control of player `UNSAT`. Taking Shapley values as above then induces the importance value of a state in $S_{\texttt{SAT}}$.

3.3 Attributing Responsibility in Continuous Models

The Shapley value [106] is an inherently discrete solution concept. On the other hand, realistic formal models of reactive systems often entail continuous features such as timing [4, 36, 90], physical phenomena [3, 108], or parametric dependencies [71, 48, 79]. Notions of responsibility for these models therefore tend to require new mathematical approaches if the continuous nature is to be taken into account appropriately.

The continuous scenario seen from an economic angle generalizes (discrete) cooperative games: rather than just participating in a coalition, the n players of a game each pick a value v_i from a continuous domain $D_i \subseteq \mathbb{R}$ including 0 and the (generalized) game then determines a collective surplus or cost based on this input. This is formally described by a continuously differentiable function $g\colon D_1 \times \ldots \times D_n \to \mathbb{R}$ such that $g(0, \ldots, 0) = 0$. Economists usually take the domains to be of the form $D_i = [0, m_i)$ for some maximal input $m_i \in \mathbb{R}$, and further assume g to be non-decreasing with non-negative range. The *Aumann-Shapley value* [7] is a generalization of the Shapley value designed to provide a solution to the question how the value $g(v_1, \ldots, v_n)$ should be "fairly" distributed among the players. It is one instance of what is called a *cost-sharing scheme* and admits an axiomatization in the spirit of its discrete predecessor [43, 110].

Inspired by this model, the work [11] presents an approach to measure the relative importance of the parameters on the behavior of *parametric Markov chains* for a wide range of properties, including ω-regular specifications, specifications in probabilistic CTL, and on expected rewards. Here, a parametric Markov chain is a directed graph where each edge is assigned a probability that may depend on a set of parameters such that for each instantiation of the parameters the probabilities outgoing from a state sum up to 1. A parametric Markov chain instantiated with fixed values for the parameters then coincides with a *discrete-time Markov chain* (DTMC). For this purpose the aforementioned assumptions on g must be relaxed: the continuously differentiable function $g\colon D \to \mathbb{R}$ has arbitrary domain $D \subseteq \mathbb{R}^n$ and is not subject to monotonicity and non-negativity restrictions. This also means that the canonical baseline value 0 for v_i is not always available anymore. The responsibility problem in this generalized setting then reads as follows: given g and two parameter choices $v, v' \in D$, how *responsible* is the i-th parameter for the observable change $g(v') - g(v)$? In this slightly generalized form, the Aumann-Shapley value of the i-th parameter is defined as

$$\mathrm{AS}_i(g, v, v') = (v'_i - v_i) \cdot \int_0^1 \partial_i g\left(v + \alpha(v' - v)\right) d\alpha. \tag{2}$$

The integrand involves the i-th partial derivative of g and intuitively measures the marginal contribution of the i-th parameter at the points lying between v and v'. The integral then takes the average of these contributions along the straight line from v to v'. While taking the straight line is desirable in an economic context to meet the *average cost for homogeneous goods axiom* [43], this axiom is often void of meaning when applied to formal systems. When one replaces the straight line in Equation (2) with an arbitrary (monotonic) path from v to v', then one speaks of *path attribution schemes* [109]. Of course, taking different paths induces different attributions, and which ones should be considered worthwhile depends on the specific scenario. This could for instance be due to potential restrictions on the way that changes on the parameters can be implemented in practice. The work [11] applies these path attribution schemes to the function induced by ω-regular or probabilistic CTL specifications on a parametric Markov chain. The set of axioms presented there is adjusted to this particular situation and justifies why one can conceive the value $\mathrm{AS}_i(g, v, v')$ as the fraction of the observable effect $g(v') - g(v)$ that is produced by the i-th parameter.

It is noteworthy, however, that the approach put forth in [11] is by no means specific to the context of parametric Markov chains. Any scenario in which continuously varying parameters determine a value can in principle be handled similarly. Of course, which path attribution schemes should be regarded as meaningful needs to be checked case-by-case, and corresponding axiomatizations should be chosen with care. But it is no accident that the main decidability result in [11] is formulated in terms of path attribution schemes on functions in n independent variables – a generality that makes the approach potentially applicable for a range of similar problems.

4 Probabilistic Causation

As seen in the preceding sections, notions of causality and responsibility have been widely explored in the non-probabilistic setting. In contrast, there have been far less attempts at defining a suitable notion of causes for probabilistic operational systems such as Markov chains. However, probabilistic theories of causation have been considered in various philosophical accounts [111, 21, 107, 39]. One central idea behind these theories is the *probability-raising principle*, which goes back to Reichenbach [103, 104]. It states that causes should raise the probability of their effects. After observing a cause C, the probability of an effect E is higher than after observing that the cause has not occurred. Formulated with conditional probabilities, this can be written as

$$\Pr(E \mid C) > \Pr(E \mid \neg C), \qquad \text{or equivalently} \qquad \Pr(E \mid C) > \Pr(E).$$

For the conditional probabilities to be well-defined, it is necessary that $\Pr(C) > 0$ and $\Pr(\neg C) > 0$. Later on, we will make sure that the events conditioned on have positive probability. Note that if $\Pr(C) > 0$ and $\Pr(E \mid C) > \Pr(E)$, it already follows that $\Pr(\neg C) > 0$. Defining $p \stackrel{\text{def}}{=} \Pr(C)$, the equivalence of the two inequalities follows from the equation $\Pr(E) = p \cdot \Pr(E \mid C) + (1-p) \cdot \Pr(E \mid \neg C)$, which implies

$$\Pr(E \mid C) - \Pr(E) = (1-p)(\Pr(E \mid C) - \Pr(E \mid \neg C)).$$

The probability-raising principle alone, however, cannot distinguish between cause and effect as it holds if and only if $\Pr(C \mid E) > \Pr(C \mid \neg E)$ as well. For this reason, additional conditions have to be imposed for causal reasoning. One key condition is temporal priority, which prescribes that a cause has to occur *before* the effect.

This section formalizes both the probability-raising principle as well as the requirement of temporal priority for probabilistic operational models. We draw connections between different ideas from the literature to provide an overview over basic probabilistic notions of causality in the context of formal verification. For this, we assume to have given a DTMC $\mathcal{M}$ with a probability distribution over initial states. This way, the sets Π_φ of paths starting in initial states and fulfilling an LTL property φ are measurable [114] and have a well-defined probability value $\Pr_{\mathcal{M}}(\Pi_\varphi)$, which we also denote by $\Pr_{\mathcal{M}}(\varphi)$. Applying the probability-raising principle and expressing the temporal priority using LTL leads to the following first definition of causality in DTMCs for reachability properties.

▶ **Definition 1** (reachability-cause). *Let $\mathcal{M}$ be a DTMC with state space S and let $C, E \subseteq S$ be two disjoint sets of states. Then C is a* reachability-cause *of E if $\Pr_{\mathcal{M}}(\neg E \,\mathcal{U}\, C) > 0$ and*

$$\Pr_{\mathcal{M}}(\Diamond E \mid \neg E \,\mathcal{U}\, C) > \Pr_{\mathcal{M}}(\Diamond E). \tag{3}$$

Note that Equation (3) implies that $\Pr_{\mathcal{M}}\big(\neg(\neg E \,\mathcal{U}\, C)\big) > 0$. This ensures that also $\Pr_{\mathcal{M}}\big(\Diamond E \mid \neg(\neg E \,\mathcal{U}\, C)\big)$ is well-defined and so Equation (3) is equivalent to $\Pr_{\mathcal{M}}(\Diamond E \mid \neg E \,\mathcal{U}\, C) > \Pr_{\mathcal{M}}\big(\Diamond E \mid \neg(\neg E \,\mathcal{U}\, C)\big)$. If there are no paths first reaching the effect E and afterwards the cause C, e.g., because the states in the effect E are absorbing, Equation (3) simplifies to $\Pr_{\mathcal{M}}(\Diamond E \mid \Diamond C) > \Pr_{\mathcal{M}}(\Diamond E)$.

In this treatment of reachability properties, a cause C specifies the set of finite executions ending in C that cause the subsequent extension to an infinite execution to satisfy $\Diamond E$. This idea can be lifted to the treatment of causes of arbitrary events in $\mathcal{M}$ specified by a measurable set of infinite paths $\mathcal{L} \subseteq S^\omega$. A cause is then a set of finite paths $\Gamma \subseteq S^+$. Besides the probability-raising property, the temporal priority condition needs to be included. For path properties this needs extra consideration. While for a cause $\Gamma \subseteq S^+$ it is clear that the cause is observed once a finite path in Γ is generated in a DTMC, this is not the case for the effect $\mathcal{L} \subseteq S^\omega$ as it consists of infinite executions. However, it seems natural to say that the effect occurred on a finite path δ whenever $\Pr_{\mathcal{M}}(\mathcal{L} \mid \delta) = 1$, i.e., if a generated finite path ensures that almost all infinite extensions belong to $\mathcal{L}$. Here, we used δ to also denote the event of all infinite paths having δ as a prefix. Analogously, for a set of finite paths Γ, we denote by Γ also the event of all infinite paths with a prefix in Γ. Consequently, $\neg\Gamma$ denotes the event of all infinite paths that have no prefix in Γ. The discussed treatment of temporal priority is now used in the following definition of a cause in a DTMC.

▶ **Definition 2** (global PR-cause). *Let $\mathcal{M}$ be a DTMC with state space S, let $\Gamma \subseteq S^+$ be a non-empty set of finite paths, and let $\mathcal{L} \subseteq S^\omega$ be a measurable set of paths. Then, Γ is a* global probability-raising cause (global PR-cause) *for $\mathcal{L}$ if the following two conditions hold:*
PAC1: $\Pr_{\mathcal{M}}(\mathcal{L} \mid \Gamma) > \Pr_{\mathcal{M}}(\mathcal{L})$, *and*
PAC2: *for all $\gamma \in \Gamma$, no proper prefix γ' of γ satisfies $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma') = 1$.*
As Γ is a set of finite paths in $\mathcal{M}$, the cylinder set spanned by each $\gamma' \in \Gamma$ has positive probability. So, the conditional probabilities $\Pr_{\mathcal{M}}(\mathcal{L} \mid \Gamma)$ and $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma')$ in Definition 2 are well-defined.

Axiom PAC1 expresses the probability-raising principle. It implies that $\Pr_{\mathcal{M}}(\neg\Gamma) > 0$. As this ensures that all necessary conditional probabilities are well-defined, PAC1 is equivalent to the probability-raising condition $\Pr_{\mathcal{M}}(\mathcal{L} \mid \Gamma) > \Pr_{\mathcal{M}}(\mathcal{L} \mid \neg\Gamma)$. Axiom PAC2 captures that the effect must not occur before the cause.

The requirement on the cause in the provided definition is of *global* nature: the cause Γ as a whole has to guarantee the probability-raising property with respect to the effect. Single elements $\gamma \in \Gamma$, however, do not necessarily guarantee that the probability of the effect has been raised. Furthermore, under mild assumptions, the definition subsumes the treatment of reachability properties above:

▶ **Proposition 3.** *Let $\mathcal{M}$ be a DTMC with state space S and let $C, E \subseteq S$ be disjoint. Assume that no state in $s \in S \setminus E$ satisfies $\Pr_{\mathcal{M},s}(\Diamond E) = 1$. Then the following are equivalent:*
1. *C is a reachability-cause for E.*
2. *The set Γ of finite paths in $(S \setminus (C \cup E))^* C$ is a global PR-cause for the set $\mathcal{L}$ of paths satisfying $\Diamond E$.*

In the proposition above, $\Pr_{\mathcal{M},s}$ denotes the probability measure induced by $\mathcal{M}$ with assuming s as the unique initial state. A related notion of causality based on probability-raising in DTMCs has been introduced by Kleinberg et al. in a series of papers [75, 76, 74, 66, 122]. Here, probabilistic CTL is used to describe the cause C and the effect E via state formulas. We can describe both events also directly as sets of states in the DTMC by considering exactly those states that fulfil the corresponding probabilistic CTL formula. For reachability

properties, the set C is then said to be a cause of E if $\Pr_{\mathcal{M},c}(\Diamond E) > \Pr_{\mathcal{M}}(\Diamond E)$ for all $c \in C$. So, the requirement for this notion of causality is *local*: reaching any state $c \in C$ has to ensure that the probability of reaching E afterwards is raised. In case $C = \{c\}$ is a singleton disjoint from E, this notion agrees with Definition 1.

Adapting PAC1 to sets of paths and including the temporal priority requirement that the effect does not occur before the cause (PAC2 as before), we obtain the following definition of causality:

▶ **Definition 4** (local PR-cause). *Let $\mathcal{M}$ be a DTMC with state space S, $\Gamma \subseteq S^+$ a set of finite paths, and let $\mathcal{L} \subseteq S^\omega$ be a measurable set of paths. Then Γ is a* local probability-raising cause *(local PR-cause) for $\mathcal{L}$ if*
PAC1$^{\text{loc}}$: *for all $\gamma \in \Gamma$ we have $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma) > \Pr_{\mathcal{M}}(\mathcal{L})$, and*
PAC2: *for all $\gamma \in \Gamma$ no proper prefix γ' of γ satisfies $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma') = 1$.*

Axiom PAC1$^{\text{loc}}$ can be seen as the local version of PAC1. Clearly, PAC1$^{\text{loc}}$ implies PAC1. Furthermore, PAC1$^{\text{loc}}$ implies that $\Pr_{\mathcal{M}}(\neg\gamma) > 0$ for all $\gamma \in \Gamma$. Hence, we could equivalently reformulate PAC1$^{\text{loc}}$ as $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma) > \Pr_{\mathcal{M}}(\mathcal{L} \mid \neg\gamma)$ for all $\gamma \in \Gamma$.

The work by Kleinberg et al. proceeds relative to an explicit probability value $p > \Pr_{\mathcal{M}}(\mathcal{L})$ such that $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma) \geqslant p$ for all γ in a cause Γ. The higher this value p lies above $\Pr_{\mathcal{M}}(\mathcal{L})$, the greater is the amount by which all elements of Γ are guaranteed to raise the probability of the effect $\mathcal{L}$.

Such a reference to a specific threshold value p has also been incorporated into a notion of *p-causes* in [9]. Motivated by monitoring applications (see, e.g., [87]), the underlying idea is that notions of causality could be used to foresee undesirable behavior. If a cause for an erroneous execution is observed, countermeasures can be taken before the error actually occurs. Here it is particularly useful to specify a sensitivity p that expresses how likely an error is after observing the cause. In addition, the occurrence of an erroneous execution should not stay undetected. Therefore, an additional condition is imposed on p-causes: almost all executions that exhibit the error should have a prefix in the cause. Together with the temporal priority of the cause (PAC2) as before, these requirements lead to the following definition:

▶ **Definition 5** (p-cause). *Let $\mathcal{M}$ be a DTMC with state space S and $p \in (0, 1]$. A non-empty set $\Gamma \subseteq S^+$ is a* p-cause *for a measurable set $\mathcal{L} \subseteq S^\omega$ if*
PAC1$^{\text{p}}$: *for all $\gamma \in \Gamma$ we have $\Pr_{\mathcal{M},s_0}(\mathcal{L} \mid \gamma) \geqslant p$,*
PAC2: *for all $\gamma \in \Gamma$ no proper prefix γ' of γ satisfies $\Pr_{\mathcal{M}}(\mathcal{L} \mid \gamma') = 1$, and*
PAC3: $\Pr_{\mathcal{M}}(\Gamma \mid \mathcal{L}) = 1$.

Besides the practicality in monitoring applications, condition PAC3 also adds the counterfactual idea to the definition. Since almost all executions in $\mathcal{L}$ have a prefix in Γ, the effect occurs with probability 0 if the cause was not observed. Condition PAC1$^{\text{p}}$ is a third variant of the probability-raising requirement that compares the probability of the effect after observing an element of the cause to a specific threshold value p rather than the overall probability $\Pr_{\mathcal{M}}(\mathcal{L})$. In case $p > \Pr_{\mathcal{M}}(\mathcal{L})$, this variant implies PAC1 and PAC1$^{\text{loc}}$.

For ω-regular $\mathcal{L}$ there always exist p-causes for any $p \in (0, 1]$. The reason is that then almost all paths in $\mathcal{L}$ have a prefix π with $\Pr_{\mathcal{M}}(\mathcal{L} \mid \pi) = 1$. Choosing the shortest of such prefixes in accordance with condition PAC2 yields a 1-cause and hence a p-cause for any p. For $p < 1$, there are multiple p-causes in general. In [9], the problem to find cost-optimal p-causes with respect to a variety of cost measures is addressed.

The relationship between the different notions of causes is summarized in the following proposition. It is a direct consequence of the implications between the axioms used in the definitions that have been discussed so far.

▶ **Proposition 6.** *Let $\mathcal{M}$ be a DTMC with state space S, $\Gamma \subseteq S^+$, and let $\mathcal{L} \subseteq S^\omega$ be a measurable set of paths. Then the following statements hold:*

1. *If Γ is a p-cause for $\mathcal{L}$ for some $p > \Pr_{\mathcal{M}}(\mathcal{L})$, then Γ is also a local PR-cause for $\mathcal{L}$.*
2. *If Γ is a local PR-cause for $\mathcal{L}$, then Γ is also a global PR-cause for $\mathcal{L}$.*
3. *If Γ is a singleton, then Γ is a local PR-cause for $\mathcal{L}$ iff Γ is a global PR-cause for $\mathcal{L}$.*

The probabilistic notions of causality discussed in this section naturally constitute forward-looking notions: the probability-raising principle inherently addresses the behavior of a system across multiple executions, and causes are prone to exhibiting a predictive character. These notions can be useful in inferring causal dependencies in data series [75, 74, 66] and predicting undesirable behavior of reactive systems through runtime monitoring [9]. Nevertheless, as far as formal probabilistic models are concerned, a comprehensive study of cause-effect relationships is still at the beginning.

5 Concluding Remarks

This article gave an overview of recent trends in causality-based reasoning in the verification context. The focus of this article was on concepts that aim to explicate *why* a system exhibits a specific observable behavior and to which degree individual agents of a system can be held *responsible* for it. For non-probabilistic formal models, concepts of causation have been introduced in multiple facets and examined for manifold applications. To increase the power of causal inferences, a more systematic study relating forward and backward notions of causality would be highly beneficial.

Compared to the non-probabilistic setting, research on probabilistic causation in stochastic operational models is still in its infancy. While the techniques presented here are limited to purely probabilistic models (Markov chains), an examination of causality in probabilistic models with nondeterminism (Markov decision processes) is largely open. A first step in this direction is a formalization of action causes as a hyperproperty in Markov decision processes [37]. Another important future direction is to reason about cause-effect relationships in hidden Markovian models where states (and events) are not fully observable.

Another research strand not covered in this article are causality-based verification techniques (see, e.g., [82, 83]) that rely on the successive identification of cause-effect relationships between events to generate a causality-based proof for the satisfaction or violation of a system property. Along these lines, the work [8] presents a causality-based technique for solving symbolically expressed, infinite-state two-player reachability games. Applying this paradigm also in a probabilistic setting is a promising direction of study.

Symmetries and Complexity

Andrei A. Bulatov
School of Computing Science, Simon Fraser University, Burnaby, Canada

Abstract

The Constraint Satisfaction Problem (CSP) and a number of problems related to it have seen major advances during the past three decades. In many cases the leading driving force that made these advances possible has been the so-called algebraic approach that uses symmetries of constraint problems and tools from algebra to determine the complexity of problems and design solution algorithms. In this presentation we give a high level overview of the main ideas behind the algebraic approach illustrated by examples ranging from the regular CSP, to counting problems, to optimization and promise problems, to graph isomorphism.

As Jeavons et al. [39] discovered in the mid 90s, symmetries or lack thereof of combinatorial structures in many cases determine the complexity of the corresponding computational problems. This was the starting point of the so-called algebraic approach that has been initially developed for certain kinds of Constraint Satisfaction Problems (CSPs), and over the course of 20 years has been instrumental in resolving a number of long standing open problems, most important of which is the CSP Dichotomy Conjecture by Feder and Vardi [31]. These techniques also spread out and found applications in multiple areas somewhat related to the CSP. The types of research problems the algebraic approach has been most useful include complexity classifications and design of algorithms. It clearly does not apply to every single kind of CSP-related problems, but whenever the algebraic approach is possible, it has led to a significant progress in the area.

In this presentation we take a bird's-eye view on the main ideas behind the algebraic approach. We do not go into deep technical details, although we give links that can be used by an interested reader, but give a collection of simple examples showing how algebraic techniques can be used in various types of computational problems. In the first part of the presentation, Sections 1,2 we introduce several common types of constraint problems and lay out the basics of the algebraic approach. Then in Sections 3,4 we show how these ideas apply to the CSP Dichotomy Conjecture, and also briefly outline how the algebraic approach works for Counting, Promise, and Valued CSPs. We also mention a somewhat unexpected use of the method in Graph Isomorphism. Although there has been developed a rich and beautiful theory of CSPs on infinite domains [6, 7], we only focus here on finite domains. Also, we leave out many areas were the approach has been successfully used: Quantified CSPs [45], homomorphism lower bounds [41], robust approximation [3], proof complexity [1], global cardinality constraints [20, 21], Subalgebra [12] and Ideal Membership Problems [46, 22], solvability of equations [42], learnability [27], property testing [26], and many others.

1 Constraint Problems

1.1 The problem

There are multiple ways to define the CSP. For our purpose here we give two equivalent definitions [39, 43]. We use the terms *predicate* and *relation* interchangeably.

The first one, we refer to it as the *logic* definition, goes as follows. Fix a set A (always finite in this paper), a *domain*. The input of the CSP is a collection $\mathcal{I}$ of constraints, $R(x_1, \ldots, x_k)$, expressed as predicates over A, where the variables x_i are from some finite set X of variables. The goal is to decide whether a *solution* exists, that is, a mapping $\varphi : X \to A$ that satisfies all the constraints. Alternatively, the input can be thought of as the conjunction of all the constraints, and we want to know whether this formula is satisfiable.

The second definition of the CSP, which we will refer to as the *homomorphic* definition, is given in terms of relational structures. Recall that a relational *signature* is a collection of *relational symbols*, that is, names of relations we are going to use, each symbol R is assigned a natural number k_R, the *arity* of R. For instance, the relational signature of a graph or digraph is $\{E\}$, only one relational symbol, whose arity is 2. For a signature σ a *relational structure* $\mathcal{A}$ with signature σ is a set A along with a predicate $R^{\mathcal{A}} \subseteq A^{k_R}$ for each $R \in \sigma$, called an *interpretation* of R. The set A is called the *base set* of $\mathcal{A}$. Structures with signature σ are often referred to as *σ-structures* and structures with the same signature are called *similar*. Let $\mathcal{A}, \mathcal{B}$ be two σ-structures with base sets A, B, respectively. A *homomorphism* from $\mathcal{A}$ to $\mathcal{B}$ is a mapping $\varphi : A \to B$ such that $R^{\mathcal{B}}(\varphi(a_1), \ldots, \varphi(a_{k_R})) = 1$ for every $R \in \sigma$ and any $a_1, \ldots, a_{k_R} \in A$ with $R^{\mathcal{A}}(a_1, \ldots, a_{k_R}) = 1$. If there is a homomorphism from $\mathcal{A}$ to $\mathcal{B}$, we write $\mathcal{A} \to \mathcal{B}$.

In the homomorphic version of the CSP the input is a pair of similar relational structures $\mathcal{A}, \mathcal{B}$ (always finite in this paper). The question is to decide whether there exists a homomorphism from $\mathcal{A}$ to $\mathcal{B}$. A translation between the two versions of the CSP is straightforward, it will be illustrated in Example 2 below.

▶ **Example 1.** In the 3-SAT problem the question is to decide the satisfiability of a 3-CNF. 3-SAT is readily a CSP in the logic form, it is a conjunction of clauses, each of which represents a ternary predicate on $\{0, 1\}$.

▶ **Example 2.** In the 3-Coloring problem we need to decide the existence of a proper 3-coloring of a given graph G. It can be stated as a CSP by treating the vertices of G as variables that need to be assigned one of the three colors, and edges of G as constraints requiring that if $uv \in E(G)$ then the values of u, v satisfy the predicate $\neq_3$ (u, v), which is the disequality relation on the set of colors.

Note that 3-Coloring can also be naturally represented in the homomorphic form: Any proper 3-coloring of G is a homomorphism from G to K_3. Using this approach one can generalize 3-Coloring to H-Coloring, where H is a fixed graph. The goal in this problem is to decide the existence of a homomorphism from a given graph G to H.

This transition between the two forms of the CSP can be extended to more general case: The structure $\mathcal{A}$ in the homomorphic form encodes the interaction between constraints, while the structure $\mathcal{B}$ encodes the constraints themselves.

▶ **Example 3.** A system of linear (as well as any other type of equations) naturally provides a conjunction of constraints, in which every constraint is represented by an equation.

▶ **Example 4.** The Clique problem, in which we are given a number k and a graph G, asks whether or not G contains a clique of size at least k. This problem can be reformulated as the question about the existence of a homomorphism from K_k to G, that is, a CSP in the homomorphic form.

▶ **Example 5.** The Perfect Matching problem asks whether a graph G has a perfect matching It is representable as a CSP in the logic form, although in a slightly more sophisticated way. The edges of G represent the variables of our CSP instance $\mathcal{I}(G)$ that take values 1 or 0 (in a matching or not), and the vertices correspond to constraints. For each $v \in V(G)$ of degree d we introduce a constraint of the form $R_{1\text{-in-}d}(x_1, \dots, x_d)$, where $x_1, \dots, x_d$ are the edges incident to v, which is true if and only if exactly one of $x_1, \dots, x_d$ equals 1 and the rest equal 0. As is easily seen, any solution of $\mathcal{I}(G)$ corresponds to a perfect matching in G and vice versa.

In order to capture specific computational problems the general CSP is often restricted in a certain way. It can be easily done for the homomorphic version of the CSP [43]. Let $\mathfrak{A}, \mathfrak{B}$ be classes of similar structures with signature σ. Then $\mathrm{CSP}(\mathfrak{A}, \mathfrak{B})$ denotes the class of CSP instances $\mathcal{A}, \mathcal{B}$, in which $\mathcal{A} \in \mathfrak{A}$ and $\mathcal{B} \in \mathfrak{B}$. If $\mathfrak{A}$ or $\mathfrak{B}$ is the class of all σ-structures, we use $\mathrm{CSP}(-, \mathfrak{B})$ and $\mathrm{CSP}(\mathfrak{A}, -)$, respectively. If one of the classes contains only one structure, we write $\mathrm{CSP}(-, \mathcal{B}), \mathrm{CSP}(\mathcal{A}, -)$ instead of $\mathrm{CSP}(-, \{\mathcal{B}\}), \mathrm{CSP}(\{\mathcal{A}\}, -)$. The general CSP is NP-complete as the examples above show, and assuming the Exponential Time Hypothesis it cannot be solved faster than $|\mathcal{B}|^{O(|\mathcal{A}|)}$ [33]. However, restricted problems may have much lower complexity, and this is the drive to understand the complexity of restricted problems that has been guiding the study of the CSP.

▶ **Example 6.** All the problems from Examples 1–5 can be viewed as $\mathrm{CSP}(\mathfrak{A}, \mathfrak{B})$ for appropriate classes $\mathfrak{A}, \mathfrak{B}$.

- 3-SAT is the problem $\mathrm{CSP}(-, \mathcal{B}_{3\text{-SAT}})$ where $\mathcal{B}_{3-SAT}$ is the relational structure with base set $\{0, 1\}$ and 8 predicates that are defined by the 8 possible 3-clauses.
- 3-Coloring is the problem $\mathrm{CSP}(-, K_3)$. More generally, the H-Coloring problem for a graph or digraph H can be represented as $\mathrm{CSP}(-, H)$.
- Representing Linear Equations requires a relational structure with an infinite signature: a predicate symbol for each possible linear equation. It is therefore a common practice to first observe that every system of linear equations is equivalent to one in which every equation contains at most 3 variables; it may require introducing new variables. Then in the case of a finite field $\mathbb{F}$ such a problem is the same as $\mathrm{CSP}(-, \mathcal{B}_{3\text{-Lin}})$, where $\mathcal{B}_{3\text{-Lin}}$ is the relational structure with the base set $\mathbb{F}$ whose predicates are given by all the possible linear equations over $\mathbb{F}$ containing at most 3 variables.
- The Clique problem is $\mathrm{CSP}(\mathfrak{K}, -)$, where $\mathfrak{K}$ is the class of all cliques.
- The Perfect Matching problem is a bit more difficult to represent. Let σ be an (infinite) signature that contains one symbol $R_{1\text{-in-}d}$ for every natural d. Then Perfect Matching is equivalent to $\mathrm{CSP}(\mathfrak{A}_2, \mathcal{B}_{1\text{-in}})$, where $\mathfrak{A}_2$ is the class of σ-structures $\mathcal{A}$ in which every element of the base set appears in exactly two tuples from the predicates of $\mathcal{A}$. Then $\mathcal{B}_{1\text{-in}}$ is the σ-structure with the base set $\{0, 1\}$ and whose predicates are interpreted as in Example 5. Note that the Perfect Matching problem can be expressed more naturally as a *holant* problem [24].

In this paper we focus on the problems of the form $\mathrm{CSP}(-, \mathcal{B})$, which are often referred to as *nonuniform* CSPs. We will shorten the notation to $\mathrm{CSP}(\mathcal{B})$. In this case it is often convenient to replace the structure $\mathcal{B}$ with a *constraint language*, the set of relations given by the predicates of $\mathcal{B}$. For any collection Γ of relations over a set A such a problem is denoted by $\mathrm{CSP}(\Gamma)$. The base set of $\mathcal{B}$ or the set on which Γ is defined on will be called the *domain* of $\mathrm{CSP}(\mathcal{B})$ or $\mathrm{CSP}(\Gamma)$.

1.2 Friends of the CSP

The CSP is not limited to just the decision problem from the previous section. It can also be modified to include other types of problems, some of which we will consider next. Most of the variations below were considered in [28] in the case of a 2-element domain.

Quantified CSP

The CSP in the logic form can also be thought of as checking the validity of an existentially quantified sentence $\exists x_1, \ldots, x_n(R_1 \wedge \cdots \wedge R_k)$. The problem that allows for an arbitrary quantifier prefix is known as the Quantified CSP or QCSP for short. Examples of QCSPs are the Quantified Satisfiability problem (QSAT) as well as a number of standard problems in PSPACE. For a structure $\mathcal{B}$ or a constraint language Γ, $\mathrm{QCSP}(\mathcal{B}), \mathrm{QCSP}(\Gamma)$ denote the Quantified CSPs restricted in the same way as the regular CSP [28, 45].

Counting CSPs

In the Counting CSP, or #CSP, the goal is to find the number of solutions of a CSP instance. In general, such problems belong to the class #P and many of them are #P-complete. Counting CSPs restricted by specifying a relational structure or a constraint language are denoted by $\#\mathrm{CSP}(\mathcal{B}), \#\mathrm{CSP}(\Gamma)$.

Optimization problems

There are several ways to convert a CSP into an optimization problem, see [28] for some examples. The most natural one is, given a CSP instance that may have no solution, find an assignment of variables that maximizes the number of satisfied constraints. This optimization problem is called the Max-CSP. Clearly, even when $\mathrm{CSP}(\Gamma)$ can be solved efficiently, the optimization problem may be hard. Linear Equations provides a well known example of such problem. More examples will be mentioned in Section 4.2 and can be found in [28]. The book [28] also presents the range of possible complexities of Max-CSPs on the domain $\{0, 1\}$.

Another way to optimize a CSP instance is to look for a solution that assigns a specific value to a maximal number of variables. For instance, Max-Ones is the version of SAT that seeks for an assignment in which as many propositional variables as possible are assigned 1.

Valued CSPs

The Valued CSP, or the VCSPs for short, is a generalization of optimization constraint problems such as Max-CSP and Max-Ones. In order to introduce them we need to replace predicates in the regular CSP with more general functions. Let A be a domain and $\mathbb{K}$ an ordered semiring, e.g. the ring of natural, integer, rational, or real numbers. Instead of predicates we now consider functions $R : A^k \to \mathbb{K}$ for some k. An instance of the Valued CSP consists of a set X of variables and a collection $\mathcal{C}$ of *function applications* of the form $R(x_1, \ldots, x_k)$, where each R is as above. For a mapping $\varphi : X \to A$ define its *weight* to be $w(\varphi) = \sum_{R(x_1,\ldots,x_k)\in\mathcal{C}} R(\varphi(x_1), \ldots, \varphi(x_k))$. The goal now is to find a mapping φ that yields the maximal (or minimal) weight possible. Similar to regular CSPs, VCSPs can also be parametrized by a constraint language, which in this case is a set of functions that are allowed in VCSP instances.

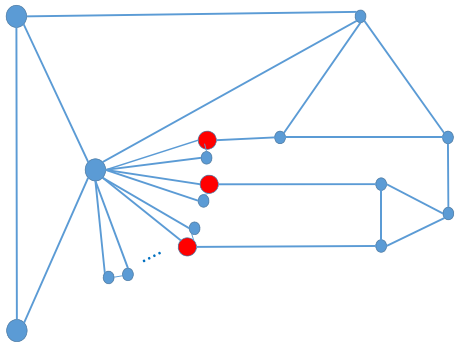

Figure 1 The gadget used to reduce 3-SAT to 3-Coloring.

▶ **Example 7** (Max-CSP as a VCSP)**.** Let Γ be a constraint language, that is, a set of predicates on some set A. We view the predicates from Γ as functions from Cartesian powers of A to $\mathbb{N}$. They take values $0, 1$. This way every instance of CSP(Γ) is treated as an instance of VCSP(Γ). As is easily seen, a mapping that maximizes the number of satisfied constraints in a CSP instance also has the maximal weight in the corresponding instance of the VCSP.

▶ **Example 8** (Max-Ones as a VCSP)**.** Transforming the Max-Ones problem into a VCSP is less straightforward, because we need to make sure that optimization is only happening over solutions of a Max-Ones instance. This is achieved by adding the *infinity* elements $-\infty, \infty$ to $\mathbb{N}$. In terms of order and arithmetic operations they relate to other elements of $\mathbb{N}$ in the natural way. Let Γ be a constraint language on $\{0,1\}$, and let $\Gamma' = \{R' \mid R \in \Gamma\} \cup \{O\}$, where $O : \{0,1\} \to \mathbb{N}$ with $O(0) = 0, O(1) = 1$, and $R'(a_1, \dots, a_k) = 1$ when $R(a_1, \dots, a_k) = 1$, $a_1, \dots, a_k \in \{0,1\}$, and $R'(a_1, \dots, a_k) = -\infty$ otherwise. Take an instance $\mathcal{I}$ of Max-Ones(Γ), replace every predicate $R(x_1, \dots, x_k)$ with a function application $R'(x_1, \dots, x_k)$, and for each variable $x \in X$ of $\mathcal{I}$ add the function application $O(x)$. Denote the resulting instance by $\mathcal{I}'$, it is an instance of VCSP(Γ'). The weight of a mapping $\varphi : X \to \{0,1\}$ in $\mathcal{I}'$ is not negative infinite if and only if φ is a solution of $\mathcal{I}$. Moreover, if w is a solution of $\mathcal{I}$ we have $w(\varphi) = m + \ell$, where m is the number of constraints in $\mathcal{I}$ that does not depend on φ, and ℓ is the number of variables that are assigned 1 by φ. Thus φ maximizes the number of ones if and only if it maximizes the weight in $\mathcal{I}'$.

2 Reductions and symmetries

In this section we look at the formalism that includes primitive-positive definitions and interpretations, and that captures one of the oldest tools in complexity theory, gadget reductions. We then introduce higher level symmetries of problems, polymorphisms, that set boundaries of what can be done using gadget reductions. Finally, we give some examples showing that polymorphisms can also be useful when designing solution algorithms. A more detailed and technical exposition can be found in [4].

2.1 Gadget reductions and primitive-positive definitions

A usual gadget reduction known from a basic course in complexity looks somewhat like what is shown in Fig. 1. They may be complicated and often difficult to come up with. Can we make the process of constructing such gadgets more orderly?

Let Γ be a set of relations (predicates) over a set A. A predicate R over A is said to be *primitive-positive (pp-) definable* in Γ if $R(\mathbf{x}) = \exists \mathbf{y}\ \Phi(\mathbf{x}, \mathbf{y})$, where Φ is a conjunction that involves predicates from Γ and equality relations. The formula above is then called a *pp-definition* of R in Γ. A constraint language Δ is pp-definable in Γ if so is every relation from Δ. In a similar way pp-definability can be introduced for relational structures.

▶ **Example 9.** Let $K_3 = (\{0, 1, 2\}, E)$ be a 3-element complete graph. Its edge relation is the binary disequality relation $\neq_3$ on $\{0, 1, 2\}$. Then the pp-formula

$$\begin{aligned} Q(x, y, z) \quad = \quad & \exists t, u, v, w (E(t, x) \wedge E(t, y) \wedge E(t, z) \wedge E(u, v) \wedge E(v, w) \\ & \wedge E(w, u) \wedge E(u, x) \wedge E(v, y) \wedge E(w, z)) \end{aligned}$$

defines the predicate Q that is true on all triples containing exactly 2 different elements from $\{0, 1, 2\}$.

A link between pp-definitions and reducibility of nonuniform CSPs was first observed in [39].

▶ **Theorem 10** ([39]). *Let Γ and Δ be constraint languages and Δ finite. If Δ is pp-definable in Γ then* $\mathrm{CSP}(\Delta)$ *is polynomial time reducible*[1] *to* $\mathrm{CSP}(\Gamma)$.

The gadget in Fig. 1 can be represented by a pp-formula, in which every variable corresponds to a vertex in the graph, the large red vertices are the free variables, and the edges are the constraints $\neq_3$. In general it seems plausible that pp-definitions and pp-interpretations discussed later capture what we think of "gadgets" and "gadget reductions".

2.2 Polymorphisms

While pp-definitions is a convenient and uniform way of representing gadgets, it is polymorphisms that are at the core of the algebraic approach.

Primitive positive definability can be concisely characterized using polymorphisms. An operation $f : A^k \to A$ is said to be a *polymorphism* of a relation $R \subseteq A^n$ if for any $\mathbf{a}_1, \ldots, \mathbf{a}_k \in R$, $\mathbf{a}_i = (a_{i1}, \ldots, a_{in})$, the tuple $f(\mathbf{a}_1, \ldots, \mathbf{a}_k)$ also belongs to R, where $f(\mathbf{a}_1, \ldots, \mathbf{a}_k)$ stands for $(f(a_{11}, \ldots, a_{k1}), \ldots, f(a_{1n}, \ldots, a_{kn}))$. The parameter k above is called the *arity* of f. Relation R is said to be *invariant* under f. Operation f is a polymorphism of a constraint language Γ if it is a polymorphism of every relation from Γ. Similarly, operation f is a polymorphism of a relational structure $\mathcal{B}$ if it is a polymorphism of every relation of $\mathcal{B}$. The set of all polymorphisms of language Γ or relational structure $\mathcal{B}$ is denoted by $\mathsf{Pol}(\Gamma)$, $\mathsf{Pol}(\mathcal{B})$, respectively.

▶ **Example 11.** Let R be an affine relation, that is, R is the solution space of a system of linear equations over a field $\mathbb{F}$. Then the operation $f(x, y, z) = x - y + z$, where $+, -$ are operations of $\mathbb{F}$, is a polymorphism of R. Indeed, let $A \cdot \mathbf{x} = \mathbf{b}$ be the system defining R, and $\mathbf{x}, \mathbf{y}, \mathbf{z} \in R$. Then

$$A \cdot f(\mathbf{x}, \mathbf{y}, \mathbf{z}) = A \cdot (\mathbf{x} - \mathbf{y} + \mathbf{z}) = A \cdot \mathbf{x} - A \cdot \mathbf{y} + A \cdot \mathbf{z} = \mathbf{b}.$$

In fact, the converse can also be shown: if R is invariant under f, where f is defined in a certain finite field $\mathbb{F}$, then R is the solution space of some system of linear equations over $\mathbb{F}$.

[1] In fact, due to the result of [47] this reduction can be made log-space.

Polymorphisms can be viewed as a generalization of homomorphisms of relational structures. We use $[k]$ to denote the set $\{1,\dots,k\}$. For a structure $\mathcal{B}$ with signature σ and $k \geq 1$, let $\mathcal{B}^k$ denote the following relational structure. The base set of $\mathcal{B}^k$ is B^k, where B is the base set of $\mathcal{B}$. For every symbol $R \in \sigma$, say, ℓ-ary, the predicate $R^{\mathcal{B}^k}$ is given by $(\mathbf{a}_1,\dots,\mathbf{a}_\ell) \in R^{\mathcal{B}^k}$ if and only if $(a_{1i},\dots,a_{\ell i}) \in R^{\mathcal{B}}$ for each $i \in [k]$, where $\mathbf{a}_j = (a_{j1},\dots,a_{jk})$. Then a mapping $f : B^k \to B$ is a polymorphism of $\mathcal{B}$ if and only if f is a homomorphism of $\mathcal{B}^k$ to $\mathcal{B}$.

A link between polymorphisms and pp-definability of relations is given by *Galois connection*.

▶ **Theorem 12** (Galois connection, [8, 34]). *Let Γ be a constraint language on A, and let $R \subseteq A^n$ be a non-empty relation. Then R is preserved by all polymorphisms of Γ if and only if R is pp-definable in Γ.*

Every relation on a set A has projections as polymorphisms. A *projection* is an operation f, say, k-ary, such that for some $i \in [k]$, $f(x_1,\dots,x_k) = x_i$. Theorem 12 means, in particular, that if a constraint language Γ on A does not have polymorphisms other than the projections, every relation is pp-definable in Γ.

The following statement is what makes the algebraic approach possible.

▶ **Corollary 13.** *Let Γ and Δ be constraint languages and Δ finite. If $\mathsf{Pol}(\Gamma) \subseteq \mathsf{Pol}(\Delta)$ then $\mathrm{CSP}(\Delta)$ is polynomial time reducible to $\mathrm{CSP}(\Gamma)$.*

For our next example we need another more technical result.

▶ **Proposition 14** ([19]). *Let Γ be a constraint language on a set A. Then either*

1. *there is a non-injective unary polymorphism f of Γ and $\mathrm{CSP}(\Gamma)$ is polynomial time interreducible with $\mathrm{CSP}(f(\Gamma))$, where $f(\Gamma) = \{f(R) \mid R \in \Gamma\}$, $f(R) = \{f(\mathbf{a}) \mid \mathbf{a} \in R\}$; or*
2. *all unary polymorphisms of Γ are injective and $\mathrm{CSP}(\Gamma)$ is polynomial time interreducible with $\mathrm{CSP}(\Gamma^*)$, where $\Gamma^* = \Gamma \cup \{R_a \mid a \in A\}$, $R_a = \{(a)\}$ is a* constant *relation, i.e. a unary relation that contains only one tuple.*

Constraint languages that contain all the constant relations are called *idempotent*.

▶ **Example 15.** We revisit the reducibility of 3-SAT to 3-Coloring. Let $\Gamma = \{\neq_3\}$ be the constraint language consisting of just the disequality relation $\neq_3$ on the 3-element set $\{0,1,2\}$. As we noted in Example 2, $\mathrm{CSP}(\Gamma)$ is equivalent to 3-Coloring. Let also Γ_{3-SAT} denote the constraint language consisting of the 8 ternary relations represented by 3-clauses. Then $\mathrm{CSP}(\Gamma_{3-SAT})$ is equivalent to 3-SAT. We show that Γ_{3-SAT} is pp-definable in Γ^*. By Theorem 10 and Proposition 14 it implies that 3-SAT is reducible to 3-Coloring.

First, we prove that every polymorphism of $\neq_3$ has only one *essential variable*, that is, a variable such that the value of the function can be changed by changing the value of this variable only. Suppose there is $f \in \mathsf{Pol}(\neq_3)$ that has at least two essential variables. To save on notation we assume that $f(x,y)$ is binary. Assume first that for some $a,a',b,b' \in \{0,1,2\}$ we have $f(a,b) \neq f(a',b), f(a,b) \neq f(a,b')$. Without loss of generality, let $a = b = 0, a' = b' = 1$. Then since $(0,1),(1,0) \in \neq_3$ and f is a polymorphism of $\neq_3$, we also have $f(0,1) \neq f(1,0)$. For a similar reason $f(2,2)$ is not equal to any of $f(0,0), f(0,1), f(1,0)$, which is impossible. Next, as y is an essential variable in $f(x,y)$ there are $a,b,b' \in \{0,1,2\}$ such that $f(a,b) \neq f(a,b')$. Again, let us assume $a = b = 0, b' = 1$. If $f(0,0) \neq f(1,0)$, or $f(0,0) \neq f(2,0)$, or $f(0,1) \neq f(1,1)$, or $f(0,1) \neq f(2,1)$, we have the previous case. Otherwise $f(0,2) \neq f(1,0) = f(0,0), f(0,2) \neq f(1,1) = f(0,1)$, because $(0,1),(2,0),(2,1) \in \neq_3$ and f is a polymorphism of $\neq_3$. By the same argument, either we have the previous case, or $f(0,2) = f(1,2) = f(2,2)$ implying that x is not essential variable in $f(x,y)$, a contradiction.

Second, if $f \in \mathsf{Pol}(\neq_3)$ has only one essential variable, we have $f(x_1, \dots, x_k) = g(x_i)$ for some operation g. Since f is a polymorphism of each constant relation R_a we get $g(a) = f(a, \dots, a) = a$, that is, f is a projection. Thus, the only polymorphisms of Γ^* are projections. By Theorem 12 every relation on $\{0, 1, 2\}$ is pp-definable in Γ^*. This includes the relations from Γ_{3-SAT}. By Theorem 10 $\mathrm{CSP}(\Gamma_{3-SAT})$ is polynomial time reducible to $\mathrm{CSP}(\Gamma)$.

Example 15 gives a reduction and a hardness proof only in one very special case. However, we shall see soon that together with pp-interpretability introduced next this technique gives a hardness proof for all NP-complete CSPs of the form $\mathrm{CSP}(\Gamma)$.

Let Γ, Δ be constraint languages over sets A, B, respectively. We say that Γ *pp-interprets* Δ if there exists a natural number ℓ, a set $F \subseteq A^\ell$, and an onto mapping $\pi : F \to B$ such that Γ pp-defines the following relations

1. the relation F,
2. the π-preimage of the equality relation on B, and
3. the π-preimage of every relation in Δ,

where by the π-preimage of a k-ary relation R on B we mean the ℓk-ary relation $\pi^{-1}(R)$ on A defined by

$$\pi^{-1}(R)(x_{11}, \dots, x_{1k}, x_{21}, \dots, x_{2k}, \dots, x_{\ell 1}, \dots, x_{\ell k}) \qquad \text{is true}$$

if and only if

$$R(\pi(x_{11}, \dots, x_{\ell 1}), \dots, \pi(x_{1k}, \dots, x_{\ell k})) \qquad \text{is true.}$$

If $\ell = 1$ in this definition, we say that Γ *1-pp-interprets* Δ.

▶ **Theorem 16** ([19, 4]). *Let Γ and Δ be constraint languages and Δ finite. If Δ is pp-interpretable in Γ then $\mathrm{CSP}(\Delta)$ is polynomial time reducible to $\mathrm{CSP}(\Gamma)$.*

▶ **Example 17.** We demonstrate how to use pp-interpretability in a small special case of the H-Coloring problem, see Example 2. Consider graph H on the left hand side of Fig. 2, we show that H-Coloring for this graph is NP-complete. In order to do that we will 1-pp-interpret $\neq_3$ in the constraint language $\Gamma = \{E = E(H)\}$. In the definition of pp-interpretation above we set $F = A = \{0, 0', 1, 2\}$, $B = \{0, 1, 2\}$, $\Delta = \{\neq_3\}$, $\ell = 1$, and $\pi : A \to B$ as shown in Fig. 2. The only thing we need to check is that $\pi^{-1}(B)$, $\pi^{-1}(=)$, and $\pi^{-1}(\neq_3)$ are pp-definable in H^2. The first and the last requirements are straightforward, because $\pi^{-1}(B) = A$ and $\pi^{-1}(\neq_3) = E$. For the preimage of the equality relation, the relation $\pi^{-1}(=)$ is the equivalence relation on A with classes $\{0, 0'\}, \{1\}, \{2\}$. This relation is defined by the pp-formula

$$\exists u, w(E(u, w) \wedge E(x, u) \wedge E(x, w) \wedge E(y, v) \wedge E(y, w)).$$

[2] Note that although π is a homomorphism from H to K_3, this does not yet give rise to a reduction from H-Coloring to 3-Coloring. Indeed, any graph is a homomorphic image of a collection of disconnected edges. Homomorphism π is a very special kind of homomorphism that gets along pp-definitions well.

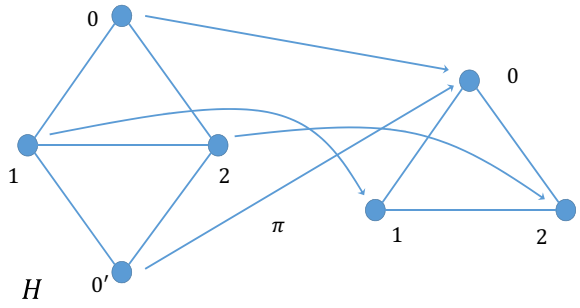

Figure 2 Pp-interpretations of 3-Coloring.

2.3 Polymorphisms and algorithms

So far we have only seen applications of polymorphisms and pp-interpretations for discovering polynomial time reductions between CSPs. In this section we mention two examples when polymorphisms also help developing efficient solution algorithms.

▶ **Example 18.** As we saw in Example 11, a relation can be represented as the set of solutions of a system of linear equations over a finite field $\mathbb{F}$ if and only if it is invariant under the affine operation $f(x, y, z) = x - y + z$, where $+, -$ are the operations of the same field $\mathbb{F}$. This means that if a constraint language Γ is invariant with respect to f then any instance of CSP(Γ) can be thought of as a system of linear equations over $\mathbb{F}$ and so can be solved by Gaussian elimination. In particular, it is possible not only to decide the existence of a solution in polynomial time, but also to construct a concise representation of the set of all solutions – a basis of the solution space.

Affine operations are a special kind of more general Maltsev operations. A ternary operation f is said to be *Maltsev* if it satisfies the equations $f(x, y, y) = f(y, y, x) = x$. The affine operation clearly satisfies them. It was shown in [16] that if a constraint language Γ has a Maltsev operation as a polymorphism, there is a polynomial time algorithm that constructs a concise representation of the set of solutions of any instance of CSP(Γ). Note that when applied to systems of linear equations this algorithm provides an alternative to Gaussian elimination. This result was further generalized in [38].

▶ **Example 19.** For this example it will be convenient to use infix notation for binary operations, that is, to write $x \cdot y$ rather than $f(x, y)$. A binary operation $\cdot$ on a set A is said to be *semilattice* if it is idempotent ($x \cdot x = x$), commutative ($x \cdot y = y \cdot x$), and associative ($x \cdot (y \cdot z) = (x \cdot y) \cdot z$), where the equations hold for all $x, y, z \in A$. A semilattice operation defines a partial order on A: $a \leq b$ if and only if $b = a \cdot b$.

Let $R \subseteq A^k$ be a relation invariant with respect to $\cdot$. Let also $R_i \subseteq A$ denote its *ith projection*, the set $R_i = \{a_i \mid (a_1, \dots, a_k) \in R\}$. As is easily seen, R_i is invariant under $\cdot$, that is, $a \cdot b \in R_i$ for any $a, b \in R_i$. Every set R_i has a greatest element in terms of the order $\leq$, it is the product of all the elements of R_i. Let us denote this element by m_i. Now, if $\mathbf{a}_1, \dots, \mathbf{a}_r$ is a list of all tuples from R_i, we have $\mathbf{a}_1 \cdot \mathbf{a}_2 \cdot \dots \cdot \mathbf{a}_r = (m_1, \dots, m_k)$. In other words, the tuple, whose entries are the greatest elements of the corresponding projections, belongs to R.

The following algorithm known as the *arc-consistency* algorithm [40] uses the discussed above properties of relations invariant under $\cdot$ to solve CSP(Γ) where Γ is any constraint language invariant under $\cdot$. Let $\mathcal{I}$ be an instance of CSP(Γ) with the set of variables X. The algorithm works in rounds until the instance cannot be further improved. Suppose that two constraints $R^1(x, \mathbf{y})$ and $R^2(x, \mathbf{z})$ from $\mathcal{I}$ share a variable. Here $\mathbf{y}, \mathbf{z}$ stand for some variables involved in R^1, R^2, and clearly x does not have to be in the same position in R^1, R^2. Let $R_1 = R^1_1 \cap R^2_1$. If $R_1 \neq R^1_1$, we remove from R^1 all tuples $(a, \mathbf{b})$ such that $a \notin R_1$. Then we repeat the procedure for R^2. After the process converges, every variable $x \in X$ has a domain $A_x \subseteq A$ such that the projection of every constraint containing x on the corresponding coordinate position equals A_x. Finally, that $\cdot$ is a polymorphism of Γ implies that the mapping $\varphi : X \to A$, $\varphi(x) = m_x$, where m_x is the greatest element of A_x is a solution of $\mathcal{I}$.

3 Dichotomies

3.1 The CSP dichotomy

The first attempt for a broad classification of problems of the form CSP(Γ) was made in [48]. When translated into the language of polymorphisms, the main result is

▶ **Theorem 20** ([48]). *Let Γ be a constraint language over $\{0, 1\}$. Then* CSP(Γ) *is solvable in polynomial time if and only if Γ has one of the following polymorphisms: a constant operation, the affine operation $x - y + z \pmod 2$, one of the semilattice operations $x \vee y$ or $x \wedge y$, or the* majority *operation $(x \wedge y) \vee (y \wedge z) \vee (z \wedge x)$. Otherwise it is NP-complete.*

The hardness part of the theorem follows by an argument similar to that in Example 15. The tractability part follows from Proposition 14 and Examples 18 and 19. The case of the majority operation can be solved as 2-SAT or by a slightly stronger consistency algorithm, see [40].

An important feature of Theorem 20 is that it leaves no room for CSPs of intermediate complexity: every CSP(Γ) is either solvable in polynomial time or is NP-complete. Results of this kind are also known as *complexity dichotomies*, and believed to be true for the majority of "natural" problems, even though problems of intermediate complexity provably exist provided P≠NP, [44].

A dichotomy for CSPs over arbitrary finite sets was conjectured in [31, 32]. This conjecture has been referred to as the CSP Dichotomy Conjecture. The conjecture was refined by providing a specific criterion of polynomial time solvability in [19], and settled in [14, 15, 51].

We now state the Dichotomy Theorem from [14, 15, 51]. Let Γ, Δ be constraint languages on sets A, B respectively and such that Γ 1-pp-interprets Δ. Suppose $F \subseteq A$ and $\pi : F \to B$ are the parameters of the pp-interpretation, and θ the equivalence relation on F that is the π-preimage of the equality relation on B, or the kernel of π. For $a \in F$ let $a/_\theta$ denote the θ-class containing a. Take a polymorphism $f(x_1, \dots, x_k)$ of Γ. By $f_{F,\pi}$ we denote the k-ary operation on B given by $f_{F,\pi}(x_1, \dots, x_k) = \pi(f(\pi^{-1}(x_1), \dots, \pi^{-1}(x_k)))$. Since θ is invariant under f, the operation $f_{F,\pi}(x_1, \dots, x_k)$ is properly defined, that is, its value does not depend on the choices of preimages $\pi^{-1}(x_i)$. It is straightforward to verify that $f_{F,\pi}$ is a polymorphism of Δ. Note that in order to define $f_{F,\pi}$ we do not need to specify constraint language Δ, we only need F and π.

Also, by Proposition 14 it suffices to consider idempotent constraint languages.

▶ **Theorem 21** ([14, 15, 51]). *Let Γ be an idempotent constraint language on a finite set A. Then* $\mathrm{CSP}(\Gamma)$ *is NP-complete if and only if there is a pp-interpretation with parameters F, π such that $f_{F,\pi}$ is a projection for any $f \in \mathsf{Pol}(\Gamma)$.*

The criterion in Theorem 21 can be elevated to a higher level of abstraction that involves considering sets of polymorphisms as a new algebraic structure and using the properties of mappings between these structures, *clone homomorphisms*. We touch upon such approach in Section 4.1.

3.2 Counting CSPs and polymorphisms

In this section we give some examples that hint at how a dichotomy result can be obtained for the counting version of the CSP of the form $\#\mathrm{CSP}(\Gamma)$.

We first remark that the algebraic approach works for counting CSPs as well as for decision CSPs. Recall that Γ^* for a constraint language Γ denotes Γ with added constant relations.

▶ **Theorem 22** ([17]). *Let Γ be a constraint language on a finite set A.*

1. $\#\mathrm{CSP}(\Gamma)$ *and* $\#\mathrm{CSP}(\Gamma^*)$ *are polynomial time interreducible.*
2. *For any constraint language Δ on A such that* $\mathsf{Pol}(\Gamma) \subseteq \mathsf{Pol}(\Delta)$ *the problem* $\#\mathrm{CSP}(\Delta)$ *is polynomial time reducible to* $\mathrm{CSP}(\Gamma)$.
3. *For any constraint language Δ, if Γ pp-interprets Δ then* $\#\mathrm{CSP}(\Delta)$ *is polynomial time reducible to* $\#\mathrm{CSP}(\Gamma)$.

Next we use the algebraic approach to prove a dichotomy theorem for $\#H$-Coloring, the counting version of H-Coloring, first proved in [29].

▶ **Example 23.** It was proved in [29] that $\#H$-Coloring is #P-complete, unless every connected component of H is either an isolated vertex, or a complete graph with all loops present, or a complete bipartite graph. That $\#H$-Coloring can be solved in polynomial time for graphs of this kind is straightforward. We show how to prove the hardness part through the algebraic approach in 3 easy steps.

First, using some algebraic machinery ([36] or Theorem 9.13 from [37]) it can be shown that if a constraint language Γ does not have a Maltsev polymorphism, Γ pp-interprets a binary reflexive but not symmetric relation R. Second, using the standard interpolation technique (see e.g. [50]) [17] proves that $\#\mathrm{CSP}(R)$ is #P-complete. This shows that $\#\mathrm{CSP}(\Gamma)$, not only $\#H$-Coloring, is #P-complete for any Γ without a Maltsev polymorphism.

Finally, if a connected graph H is not a single vertex, a complete graph with all loops present, or a complete bipartite graph, it contains the N-graph shown in Fig. 3 as an induced subgraph (some of a, b, c, d may be equal). It remains to observe that no Maltsev operation can be a polymorphism of such graph. Indeed, if f is a Maltsev operation on H then

$$f\left(\binom{a}{c}, \binom{a}{d}, \binom{b}{d}\right) = \binom{b}{c} \notin E(H).$$

It turns out that a generalized version of avoiding N-graphs is key in the case of general counting CSPs, $\#\mathrm{CSP}(\Gamma)$. A constraint language is said to be *singular* if for any pp-interpretable equivalence relations θ, η a certain condition holds on the number of elements in θ- and η-classes. For more details, see [18, 13, 30].

▶ **Theorem 24** ([13, 30]). *For a constraint language Γ on a finite set,* $\#\mathrm{CSP}(\Gamma)$ *is solvable in polynomial time if and only if Γ has a Maltsev polymorphism and is singular. Otherwise it is #P-complete.*

Theorem 24 has been generalized to the weighted version of the CSP in [25].

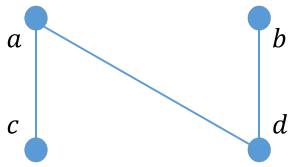

Figure 3 The N-graph.

4 Beyond CSP

In this section we consider several examples in which some sort of algebraic approach is used, although it requires significant modifications. In the first two examples, the Promise CSP and the optimization version, the Valued CSP, while preserving the main motifs of the algebraic approach, that is, rich families of polymorphisms give rise to easy problems, and poor ones give rise to hard problems, new types of "polymorphism-like" objects need to be introduced. In the third case, Graph Isomorphism, the algebraic approach does not (probably) provide a general technique, but is useful in some special cases.

4.1 Promise CSP

Unlike the regular CSP that is often parametrized by a single relational structure, $\mathrm{CSP}(\mathcal{B})$, a Promise CSP or PCSP for short is parametrized by a pair of similar relational structures, $\mathrm{PCSP}(\mathcal{A},\mathcal{B})$, such that $\mathcal{A}\to\mathcal{B}$. An instance of $\mathrm{PCSP}(\mathcal{A},\mathcal{B})$ is a relational structure $\mathcal{C}$ similar to $\mathcal{A},\mathcal{B}$, and the question is whether $\mathcal{C}\to\mathcal{A}$ or $\mathcal{C}\not\to\mathcal{B}$; no specific answer is required if $\mathcal{C}\not\to\mathcal{A}$ but $\mathcal{C}\to\mathcal{B}$. It is also often formulated in a slightly different way: the input is a structure $\mathcal{C}$ such that $\mathcal{C}\to\mathcal{A}$, and the goal is to find a homomorphism from $\mathcal{C}$ to $\mathcal{B}$, which explains the "promise" in the name of the problem, [10, 23].

▶ **Example 25.** The Approximate Graph Coloring problem is parametrized by two numbers k,c, $k\le c$, and the goal is to find a c-coloring of a given k-colorable graph. As is easily seen, this problem is equivalent to $\mathrm{PCSP}(K_k,K_c)$.

Polymorphisms of a single relational structure $\mathcal{A}$ were defined as homomorphisms from $\mathcal{A}^k$ to $\mathcal{A}$. In the case of PCSPs such mappings do not make much sense. Instead, a polymorphism of a pair $\mathcal{A},\mathcal{B}$ is a homomorphism from $\mathcal{A}^k$ to $\mathcal{B}$. Let $\mathsf{Pol}(\mathcal{A},\mathcal{B})$ denote the set of all such homomorphisms for all natural k. Note that as there is a homomorphism $\varphi:\mathcal{A}\to\mathcal{B}$, there also exist some homomorphisms in $\mathsf{Pol}(\mathcal{A},\mathcal{B})$: Fix $i\in[k]$ the mapping $\varphi_i:\mathcal{A}^k\to\mathcal{B}$ given by $\varphi_i(a_1,\dots,a_k)=\varphi(a_i)$ is a homomorphism. Homomorphisms φ_i are analogous to projections in the realm of polymorphisms of a single structure.

We describe the algebraic approach to the PCSP at a higher level of abstraction than that for the CSP. An operation $f:A^n\to B$ is a *minor* of operation $g:A^m\to B$ if there is a mapping $\pi:[m]\to[n]$ such that $f(x_1,\dots,x_n)=g(x_{\pi(1)},\dots,x_{\pi(m)})$. In other words, f is obtained from g by permuting and identifying variables. For example, $f(x_1,x_2,x_3)=g(x_2,x_3,x_2,x_1,x_1,x_3)$ is a minor of $g(x_1,x_2,x_3,x_4,x_5,x_6)$. Let $\mathcal{A}_1,\mathcal{B}_1$, and $\mathcal{A}_2,\mathcal{B}_2$, $\mathcal{A}_1\to\mathcal{B}_1$, $\mathcal{A}_2\to\mathcal{B}_2$, be two pairs of relational structures such that $\mathcal{A}_1,\mathcal{B}_1$ are similar and so are $\mathcal{A}_2,\mathcal{B}_2$. A mapping $\Psi:\mathsf{Pol}(\mathcal{A}_1,\mathcal{B}_1)\to\mathsf{Pol}(\mathcal{A}_2,\mathcal{B}_2)$ (i.e., polymorphisms are mapped to polymorphisms) is called a *minion homomorphism* if the following two conditions hold.

1. Ψ preserves arity, that is, for an operation $f : A_1^k \to B_1$, it holds $\Psi f : A_2^k \to B_2$.
2. Ψ preserves minors, that is, for any m-ary $g \in \mathsf{Pol}(\mathcal{A}_1, \mathcal{B}_1)$ and any $\pi : [m] \to [n]$, if $f(x_1, \dots, x_n) = g(x_{\pi(1)}, \dots, x_{\pi(m)})$ is a minor of g then $\Psi f(x_1, \dots, x_n) = \Psi g(x_{\pi(1)}, \dots, x_{\pi(m)})$.

The core of the algebraic approach to the PCSP is the following

▶ **Theorem 26** ([23]). *Let* $\mathrm{PCSP}(\mathcal{A}_1, \mathcal{B}_1), \mathrm{PCSP}(\mathcal{A}_2, \mathcal{B}_2)$ *be two Promise CSPs such that there is a minion homomorphism from* $\mathsf{Pol}(\mathcal{A}_1, \mathcal{B}_1)$ *to* $\mathsf{Pol}(\mathcal{A}_2, \mathcal{B}_2)$*. Then* $\mathrm{PCSP}(\mathcal{A}_2, \mathcal{B}_2)$ *is polynomial time reducible to* $\mathrm{PCSP}(\mathcal{A}_1, \mathcal{B}_1)$*.*

Note that by setting $\mathcal{A}_1 = \mathcal{B}_1$ and $\mathcal{A}_2 = \mathcal{B}_2$ Theorem 26 specializes to a statement about sets of polymorphisms of a single relational structure. Thus, Theorem 26 is a generalized and more abstract version of the combination of Corollary 13, Proposition 14, and Theorem 16.

▶ **Example 27** ([23]). In this example we use Theorem 26 to prove that $\mathrm{PCSP}(K_3, K_4)$ is NP-complete. In other words we outline a proof that given a 3-colorable graph it is in general NP-hard to find its 4-coloring. In order to do this we present a minion homomorphism from $\mathsf{Pol}(K_3, K_4)$ to $\mathsf{Pol}(\mathcal{A}, \mathcal{A})$, where $\mathcal{A}$ is any 2-element relational structure that only has projections as polymorphisms. Note that $\mathsf{Pol}(\mathcal{A}, \mathcal{A}) = \mathsf{Pol}(\mathcal{A})$, and by Corollary 13 what specific structure we choose is completely irrelevant. For instance, the structure with the base set $\{0, 1\}$ and the only predicate, which is $R_{1\text{-in-}3}$, see Example 6, fits this purpose. Since $\mathrm{CSP}(\mathcal{A}) = \mathrm{PCSP}(\mathcal{A}, \mathcal{A})$ is NP-complete in this case, it implies the result.

The structure of polymorphisms from $\mathsf{Pol}(K_3, K_4)$ is described in [23, 9]. For each (say, k-ary) $f \in \mathsf{Pol}(K_3, K_4)$, there exist $t \in K_4$, $i \in [k]$, and a mapping $\varphi : K_3 \to K_4$ such that $f(a_1, \dots, a_k) \in \{t, \varphi(a_i)\}$ for all $a_1, \dots, a_n \in K_3$. In other words, if the value of f is not t, it depends only on x_i. A mapping $\Psi : \mathsf{Pol}(K_3, K_4) \to \mathsf{Pol}(\mathcal{A}, \mathcal{A})$ is defined as follows: For every k-ary $f \in \mathsf{Pol}(K_3, K_4)$, Ψf is the k-ary projection $p(x_1, \dots, x_k) = x_i$, where i is the parameter associated with f. It is straightforward to verify that Ψ is a minion homomorphism.

4.2 Valued CSP, optimization

The VCSP and optimization problems admit some sort of algebraic approach, however the concept of a polymorphism is substantially different. In this section we briefly outline how the approach works when we want to find the exact optimum of a VCSP [49], and also for approximation algorithms [11]. The functions we consider here are real-valued.

To introduce the notion of polymorphisms needed for VCSPs, we need to take into account all the operations of certain arity on a set, rather than a single operation. Let $\mathcal{O}_A^{(k)}$ denote the set of all k-ary operations on a set A. Let $R : A^m \to \mathbb{R}$ be a function on A. A k-ary *fractional polymorphism* of R is a probability distribution μ on $\mathcal{O}_A^{(k)}$ that for any $\mathbf{a}_1, \dots, \mathbf{a}_k \in A^m$, $\mathbf{a}_i = (a_{i1}, \dots, a_{im})$ satisfies (in the case of minimization problems) the following condition

$$\mathbb{E}_{f \sim \mu}[R(f(\mathbf{a}_1, \dots, \mathbf{a}_k))] \le \mathsf{avg}(R(\mathbf{a}_1), \dots, R(\mathbf{a}_k)),$$

where $f(\mathbf{a}_1, \dots, \mathbf{a}_k) = (f(a_{11}, \dots, a_{k1}), \dots, f(a_{1m}, \dots, a_{km}))$. In the case of maximization problems the inequality should be reversed. Distribution μ is a fractional polymorphism of a valued constraint language Γ if it is a fractional polymorphism of every function from Γ.

▶ **Example 28.** Let $A = \{0, 1\}$, and let μ be the distribution on $\mathcal{O}_A^{(2)}$ that assigns probability $1/2$ to $\vee$ (disjunction) and $\wedge$ (conjunction), which are binary operations on $\{0, 1\}$, and probability 0 to all other operations. For a binary function R the inequality above is transformed into

$$\frac{1}{2}(R(x_1 \vee x_2, y_1 \vee y_2) + R(x_1 \wedge x_2, y_1 \wedge y_2) \le \frac{1}{2}(R(x_1, y_1) + R(x_2, y_2)),$$

which is the well known condition of submodularity.

A binary fractional polymorphism μ (i.e., a distribution on $\mathcal{O}_A^{(2)}$) is said to be *symmetric* if it assigns nonzero probabilities only to operations $f(x,y)$ satisfying $f(x,y) = f(y,x)$.

▶ **Theorem 29** ([49]). *For a valued constraint language* Γ *with real values the problem* VCSP(Γ) *is solvable in polynomial time if and only if* Γ *has a binary symmetric fractional polymorphism.*

Observe that the condition of submodularity is an example of a symmetric fractional polymorphism.

Many VCSPs that cannot be solved exactly can be approximated within a constant factor. Assuming the Unique Games Conjecture (UGC) [11] determines the best approximation factor, so-called *approximation threshold*, for arbitrary VCSPs. The main tool in this result is a variation of fractional polymorphisms. For a set A we again consider probability distributions over $\mathcal{O}_A^{(k)}$. Let $\alpha \in [0,1]$. Distribution μ is said to be an *α-approximation polymorphism* of $R : A^m \to \mathbb{R}$ if for any $\mathbf{a}_1, \dots, \mathbf{a}_k \in A^m$ it satisfies the following condition

$$\alpha \cdot \mathbb{E}_{f\sim\mu}[R(f(\mathbf{a}_1, \dots, \mathbf{a}_k))] \geq \mathsf{avg}(R(\mathbf{a}_1), \dots, R(\mathbf{a}_k)).$$

For a definition of pseudorandom approximation polymorphisms the reader is referred to [11].

▶ **Theorem 30** ([11]). *Let* Γ *be a valued constraint language, and let* α_Γ *be the greatest constant such that there is a pseudorandom* α_Γ*-approximation polymorphism of* Γ*. Then (assuming the UGC)* α_Γ *is the approximation threshold for* VCSP(Γ).

4.3 Graph Isomorphism: bounded color classes

A somewhat surprising application of the algebraic approach in the Graph Isomorphism problem was observed in [5]. In the Graph Isomorphism problem [35] the question is to decide whether two given graphs are isomorphic. The equivalent formulation we use here asks to find a generating set for the *automorphism group* $\mathsf{Aut}(G)$ of G. Often considering the structure of G, e.g. the degrees of its vertices, it is possible to identify some restrictions on the *orbits* of $\mathsf{Aut}(G)$, that is, which vertices can be mapped to each other by automorphisms. For instance, a vertex can only be mapped to a vertex of the same degree. Usually such restrictions are a result of some sort of *color refinement* process, but this is not important here. Suppose that we can identify a partition of $V(G)$ into classes $V_1, \dots, V_k$ such that any automorphism φ maps V_i to V_i. Assume also that the sizes of the V_is are bounded by $\ell \in \mathbb{N}$. Let us further assume for simplicity that $|V_i| = \ell$ for all $i \in [k]$. Then any $\varphi \in \mathsf{Aut}(G)$ is a union of permutations φ_i of V_i, $i \in [k]$, and the question is which combinations of such local permutations give rise to an automorphism of G.

We describe how this problem can be reduced to CSP(Γ) where Γ is a constraint language with a Maltsev polymorphism, see Example 18. Let $V_i = \{v_i^1, \dots, v_i^\ell\}$ be some enumeration of V_i, and let the symmetric group S_ℓ of permutations of $[\ell]$ acts on V_i as follows: for $\pi \in S_\ell$, $\pi(v_i^j) = v_i^{\pi(j)}$. The domain for our CSP is S_ℓ, and the variables are $V_1, \dots, V_k$. For every pair V_i, V_j we introduce a constraint $R_{ij}(V_i, V_j)$ as follows. Suppose $v_i^s v_j^r$ is an edge of G. Then if φ_i, φ_j are a part of an automorphism of G, $\varphi_i(v_i^s)\varphi_j(v_j^r) \in E(G)$. Permutations φ_i, φ_j correspond to some $\pi_i, \pi_j \in S_\ell$. Thus, we define R_{ij} to be $\{(\pi_i, \pi_j) \mid$ for any $v_i^s v_j^r \in E(G)$, $v_i^{\pi_i(s)} v_j^{\pi_j(r)} \in E(G)\}$. Let $\Gamma = \{R_{ij} \mid i, j \in [k]\}$. Observe that R_{ij} is invariant under composition, i.e. if $(\pi_i, \pi_j), (\tau_i, \tau_j) \in R_{ij}$ then $(\pi_i \circ \tau_i, \pi_j \circ \tau_j) \in R_{ij}$. In particular, it is invariant under the operation $x \circ y^{-1} \circ z$ of S_ℓ, which is a Maltsev operation on S_ℓ.

The algorithm from [16] finds a concise representation of the set of solutions of the CSP above, which then can be used to construct a generating set for $\mathsf{Aut}(G)$. The running time of this algorithm is polynomial in k and $|S_\ell| = \ell!$.

5 Conclusion

As we have seen, algebraic methods in CSPs have found their applications in numerous areas of computer science. In some of those areas such as decision, counting, and valued CSPs comprehensive and broad results have been obtained. In some other areas active research is ongoing. In particular the algebraic structure of the Promise CSP and CSPs over infinite domains have received much attention recently, although major questions remain open. There have been attempts to introduce the algebraic approach to the study of the holant problem [2] and certain proof systems suitable for approximation (such as Sum-of-Squares) [22], but these studies are in their infancy. Finally, from our perspective one of the most interesting areas where the algebraic approach is yet to be developed is approximate counting. Apart from the CSP itself it also has strong connections to other fields such as statistical physics, and it would be very interesting to see what kind of algebraic structure is possible here.

Distributed Subgraph Finding: Progress and Challenges

Keren Censor-Hillel
Department of Computer Science, Technion, Haifa, Israel

Abstract

This is a survey of the exciting recent progress made in understanding the complexity of distributed subgraph finding problems. It overviews the results and techniques for assorted variants of subgraph finding problems in various models of distributed computing, and states intriguing open questions.

2012 ACM Subject Classification Networks → Network algorithms; Theory of computation → Distributed algorithms

Keywords and phrases distributed algorithms, subgraph finding, limited bandwidth

Digital Object Identifier 10.4230/LIPIcs.ICALP.2021.3

Category Invited Talk

Funding This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement no. 755839.

Acknowledgements The author thanks Francois Le Gall for clarifications and Dean Leitersdorf for useful feedback on a preliminary version of this survey.

1 Introduction

Distributed subgraph finding is motivated by considering a user in a network whose connections are unknown to its users. Typical examples could be friends or followers in social networks, or computing devices in large networks. A prime question is what is the local structure of the network, e.g., do two connected users share common connections, or are they part of a slightly larger cycle or clique? While some social networks provide the user with information about common connections they have with their connections, the general fundamental question that arises is that of finding small subgraphs in such distributed settings. This type of questions also emerges when processing huge graphs by distributed systems. For example, Hirvonen, Rybicki, Schmid, and Suomela [33] study distributed algorithms for finding large cuts in triangle-free graphs, and Pettie and Su [46] study coloring in triangle-free graphs.

This article surveys the state-of-the-art in distributed subgraph finding. We focus on synchronous settings, in which the main complexity measure is the number of communication rounds that is required in order to find a subgraph H. We will elaborate on the computational models and on the possible interpretations of what it means to *find* a subgraph, but let us start with a warm-up.

Warm-up: locality. The first simple observation is that in a synchronous network with no additional restrictions, the round complexity of finding a subgraph H by the devices in the network is $\Theta(k)$, where k is the diameter of H. The reason for this is that in a single round of communication, all nodes of the network can learn the neighbors of their neighbors,[1] and by induction, within t rounds each node can learn the topology within its t-neighborhood.

[1] This assumes that all nodes begin with knowledge of their neighbors. Removing this assumption incurs another round of communication to this argument.

© Keren Censor-Hillel;
licensed under Creative Commons License CC-BY 4.0

To be more precise, what we get is that within $O(k)$ rounds, each node is able to *list* all the instances of H to which it belongs. This is the most powerful variant of subgraph finding.

The clear drawback of the above example is that it sweeps the under the carpet the complexity of sending potentially very large messages in a single round. Therefore, while the above classic LOCAL model [42] is suitable for studying many other tasks, it misrepresents the complexity of subgraph finding. We will thus focus mainly on two distributed settings that capture limited bandwidth, and in which the complexity of some subgraph finding problems is related. Additional settings will be discussed towards the end of the survey.

Computational models. The standard model that imposes restrictions on the bandwidth over the above setting is the CONGEST model [45]. This is a synchronous model, in which each of n nodes can send a message to each of its neighbors in every round, where the size of messages is bounded by $O(\log n)$ bits. This choice of this bound on the size of messages allows sending a node identifier within a single message. Typically, the graph that is processed is the graph that underlies the communication network.

Another important model is the CONGESTED CLIQUE model [43], which we will abbreviate as the CLIQUE model in this document, in which the n nodes are part of a fully connected network, with the same message bound of $O(\log n)$ bits as in the CONGEST model. Here, the input graph is an arbitrary graph G on n nodes, which is typically assigned through a bijection to the nodes of the CLIQUE, such that each node receives as input the edges in G that are adjacent to its assigned node.

Subgraph finding. The extreme case mentioned above, where each node in the system lists all instances of H to which it belongs is referred to as *membership listing* (or sometimes *local listing* or *local enumeration*). In settings with bounded bandwidth, this is typically a difficult variant that is known to require many rounds of computation for many subgraphs (see, e.g., discussion about triangle finding in Section 2). A weaker variant is that of *listing* or *enumeration*, in which it is required that every instance of the subgraph H is output by some node, but not necessarily a node which belongs to that instance.

Apart from these two listing variants, it is in many cases important to merely *detect* whether the input contains a copy of H or not. The standard formalization of distributed detection is that if there is no copy of H then all nodes output `false`, and otherwise at least one node outputs `true`. The reason for not demanding a unanimous output is to avoid incurring an overhead just for propagating the information of existence of H, for example if a graph contains a single copy of H and has many nodes that are very far from that instance.

Similarly to the case of listing, the detection problem also has a membership variant, which requires each node to output `true` or `false` based on whether it is a part of a copy of H or not.

Outline. Section 2 overviews the case in which H is a triangle. It covers both the CLIQUE and the CONGEST models. Sections 3 and 4 address larger cliques and larger cycles in both models, respectively. Finally, Section 5 briefly mentions additional subgraphs and additional settings.

2 Triangle Finding

A naïve simulation of the warm-up algorithm for membership listing in the CONGEST or CLIQUE models, in which all neighbors are sent to each other neighbor one by one, gives a trivial $O(\Delta)$-round algorithm for triangle membership listing, where Δ is the maximum degree in the graph. However, it is possible to do better, as we overview in this section.

2.1 Triangle Finding in the CLIQUE Model

We begin with the CLIQUE model.

Triangle listing in the CLIQUE model. The first non-trivial algorithm for triangle finding is due to Dolev, Lenzen, and Peled [19]. This is a deterministic triangle listing algorithm for the CLIQUE model, which has a complexity of $O(n^{1/3}/\log n)$ rounds. The simplicity of this algorithm turned out to be a huge advantage for later additional results, as we will see. The algorithm works as follows: The vertices of the graph are partitioned into $n^{1/3}$ subsets $S_1, \ldots, S_{n^{1/3}}$, each of $n^{2/3}$ nodes. Each of the n nodes receives a different tuple of three of these subsets. A node that receives $S_{i_1}, S_{i_2}, S_{i_3}$ for indices $1 \leq i_1, i_2, i_3 \leq n^{1/3}$ (that are not necessarily different) collects all edges with one endpoint in one of the three subsets and one endpoint in another, that is, this node collects all edges in $E(S_{i_1}, S_{i_2}) \cup E(S_{i_1}, S_{i_3}) \cup E(S_{i_2}, S_{i_3})$, and reports all triangles that it finds. It is straightforward to see that all triangles are listed by this algorithm since the number of 3-tuples of subsets is n and so each is handled by some node.

The round complexity of the algorithm follows by proving that each node needs to send and receive $O(n^{4/3})$ edges in total, which are to and from locations that are known to all nodes (we will discuss this knowledge property later), since the partition to subsets is hardcoded and so it is known to all nodes. Sending: Take a node v and assume that it is in the subset S_i. There can be at most $n^{2/3}$ edges between v and nodes in S_j and these edges need to be sent to all nodes that have S_i and S_j in their 3-tuple. Since there are $n^{1/3}$ such 3-tuples, these $n^{2/3}$ edges need to be sent to $n^{1/3}$ nodes. Repeating this for all $n^{1/3}$ possibilities for j gives a total of $n^{2/3+1/3+1/3} = n^{4/3}$ edges that v has to send. Receiving: Each node needs to learn 3 subsets of edges, each containing at most $n^{2/3} \cdot n^{2/3} = n^{4/3}$ edges. To conclude the complexity analysis, one can use the simple claim that [19] proves, which states that a routing task in which each node needs to send and receive n messages in a known pattern can be done in 2 rounds. This means that the $O(n^{4/3})$ sent and received messages per node are divided by n, yielding a complexity of $O(n^{1/3})$ rounds. Noticing that the partition and routing are fixed, one can refrain from sending actual edge identifiers and replace them with a bit mask, which saves a logarithmic factor and results in a complexity of $O(n^{1/3}/\log n)$ rounds.

This complexity turns out to be optimal. The first lower bound for this task was of $\Omega(n^{1/3}/\log^3 n)$ rounds given by Pandurangan, Robinson and Scquizzato [44], and it was followed by a tight lower bound of $\Omega(n^{1/3}/\log n)$ rounds given by Izumi and Le Gall [36]. The lower bound is proven using an information-theoretic argument, which bounds by $\Omega(n^{4/3})$ the entropy of the transcript that a certain node sees on a random graph in which each edge appears independently at random with probability 1/2. As the entropy of the transcript is a lower bound on its length, and since each node can receive at most $O(n \log n)$ bits per round, the lower bound on the round complexity follows. This approach also allowed [36] to obtain a lower bound of $\Omega(n/\log n)$ rounds for *local* listing of triangles, in which each node needs to output a list of all the triangles which include it.

In addition to the aforementioned algorithm, [19] also gives a triangle-listing algorithm whose complexity improves upon the above in the case that the graph contains *many* triangles. Specifically, they provide a randomized algorithm that completes in $O(n^{1/3}/(t^{2/3}+1)+1)$ rounds in expectation, where t is the number of triangles in the graph, and in $O(\min\{n^{1/3}\log^{2/3} n/(t^{2/3}+1), n^{1/3}\})$ rounds with high probability.

Triangle detection in the CLIQUE model. The approach of [19] inherently lists all triangles. A natural question is whether the decision problem of triangle detection is easier than listing, for which the answer turns out to be affirmative. Censor-Hillel, Kaski, Korhonen, Lenzen, Paz, and Suomela [12] show how to perform matrix multiplication over a ring in the CLIQUE model within $O(n^{0.158})$ rounds. More precisely, the complexity is $O(n^{1-2/\omega})$ rounds, where ω is the matrix multiplication exponent, currently known to be bounded by 2.3728596 due to Alman and Vassilevska-Williams [2]. Ring matrix multiplication directly carries over to triangle detection with the same complexity. The main approach of [12] is to simulate matrix multiplication algorithms for parallel settings in the CLIQUE model. This includes the so-called parallel 3D matrix multiplication, as well as bilinear Strassen-like algorithms.

Elaborating upon the matrix multiplication algorithms is beyond the scope of this survey. Yet, we must mention a crucial component that underlies these CLIQUE algorithms, as well as numerous additional CLIQUE algorithms for various tasks, which is the ingenious routing technique of Lenzen [41]. In a nutshell, this technique provides a way to route in $O(1)$ rounds any set of messages in which each node needs to send and receive at most n messages.

The above complexity of $O(n^{0.158})$ rounds for triangle detection in the CLIQUE model is the current state-of-the-art. For reasons that will be explained shortly, unlike the $\Omega(n^{1/3})$ lower bound for triangle listing in this model, there is no known lower bound for triangle detection. We thus have the following major open problem in distributed triangle finding.

▶ **Open Problem 2.1.** *What is the complexity of triangle detection in the* CLIQUE *model? In particular, is there an algorithm that is faster than $O(n^{0.158})$ rounds? Can any lower bound be proven?*

The second part of the above question which asks for a lower bound for triangle detection in the CLIQUE model is considered hard: Very roughly speaking, Drucker, Kuhn, and Oshman [20] show that the CLIQUE model is strong enough to simulate certain circuits, which implies that for a wide range of problems, any super-constant lower bound in the CLIQUE model would result in a major breakthrough in circuit complexity. It is noteworthy that the problem of triangle listing does not fall into this category of problems due to its large outputs, which explains why this does not contradict the aforementioned lower bound of $\Omega(n^{1/3})$ rounds for triangle listing.

For the broadcast version of this model, a.k.a. the BROADCAST CONGESTED CLIQUE model, in which the messages sent by a node in a certain round must all be identical, an $\Omega(n/e^{O(\sqrt{\log n})} \log n)$-round lower bound on deterministic triangle detection is given by [20], through a reduction from 3-party number-on-forehead set disjointness.

Triangle listing in sparse graphs in the CLIQUE model. The first algorithms for triangle finding in sparse graphs were given by Dolev, Lenzen, and Peled [19]. One algorithm has a round complexity of $O(\Delta^2/n + 1)$ and another has a round complexity of $O(A^2/n + \log_{2+n/A^2} n)$, where A is the arboricity of the graph.[2] The latter implies a round complexity of $O(m^2/n^3)$, in terms of the number of edges, m.

Pandurangan, Robinson, and Scquizzato [44] give a randomized triangle listing algorithm that completes within $\tilde{O}(m/n^{5/3} + 1)$ rounds, w.h.p. At the heart of the algorithm lies the partitioning approach of [19], but more is needed in order to exploit sparsity. In [44], the

[2] The arboricity of a graph is the minimal number of forests that contain all of its edges. While bounded by the maximum degree Δ, the arboricity can in some cases be much smaller, e.g., a star has a linear maximum degree but its arboricity is 1.

partition is random, and the routing of edges to the nodes to which they are assigned is done in a randomized load balanced manner. This approach is what handles load balancing of the information that needs to be routed in the system in a way which is sensitive to the sparsity of the graph, rather than optimizing only for the worst case. Moreover, the aforementioned $\tilde{\Omega}(n^{1/3})$ lower bound of [44] for triangle listing in general graphs follows from a $\tilde{\Omega}(m/n^{5/3})$ lower bound for graphs with m edges.[3]

Censor-Hillel, Leitersdorf, and Turner [14] obtained an algorithm for sparse graphs, with a complexity of $O(m/n^{5/3}+1)$ which is similar to, but slightly improves upon, the complexity of the algorithm of [44], by polylogarithmic factors. The algorithm of [14] is deterministic and is based on an algorithm for sparse matrix multiplication, which completes in $O((\rho_S\rho_T n)^{1/3}+1)$ rounds, where S and T are the input matrices and ρ_A is the average number of non-zero elements per row of a matrix A (i.e., it is the number of non-zero elements of A, divided by n).[4] While the aforementioned semi-ring matrix multiplication algorithm of [12] assigns the n^3 element-wise multiplication to the nodes in an optimal manner, it applies to the worst case. The general approach used by [14] for sparse matrix multiplication is to assign the element-wise multiplications to nodes in a way which is optimal given the input sparsity. The way this is done is by load balancing the number of non-zero elements that each node needs to send and receive in order for all element-wise multiplications to be computed.

Notes on matrix multiplication in the CLIQUE model. The first algorithm for matrix multiplication in this model is due to Drucker, Kuhn, and Oshman [20], who showed a randomized complexity of $O(n^{\omega-2}) \approx O(n^{0.373})$ rounds with high probability, for semirings. A deterministic $O(n^{1/3})$-round algorithm for matrix multiplication over a semiring is given in [12].

Censor-Hillel, Dory, Korhonen, and Leitersdorf [8] provide two additional sparse matrix multiplication algorithms, used for distance computations. Compared to [14], these algorithms also benefit from sparsity of the output matrix $P = ST$. More concretely, their first algorithm completes in $O((\rho_S\rho_T\rho_P)^{1/3}/n^{2/3}+1)$ rounds. This matches the complexity algorithm of [14] for a general P, but improves upon it for sparse output matrices (recall that the multiplication of two sparse matrices need not be sparse in general). The second algorithm of [8] pays an additive $\log n$ over the first one, i.e., has a round complexity of $O((\rho_S\rho_T\rho)^{1/3}/n^{2/3} + \log n)$, but here ρ_P is replaced by ρ, which stands for the number of elements per row that are needed. That is, there is no need to compute any element in the output matrix P that is not among the ρ smallest ones in its row (given an appropriate definition of the total order on matrix elements). In other words, the complexity of this algorithm does not depend on the sparsity of $P = ST$, but on some sparsity parameter that is given as input.

Additional algebraic algorithms in the CLIQUE model with important applications were given by Le Gall [27]. These include fast algorithms for rectangular matrix multiplications, as well as for multiple instances of matrix multiplication.

As explained earlier, we do not expect a lower bound for matrix multiplication in the CLIQUE model. However, it is shown in [12] that a near-linear number of rounds is required in the BROADCAST CONGESTED CLIQUE model.

Finally, we mention that matrix multiplication based algorithms also give results for *counting* for some small subgraphs [12, 14].

[3] In fact, the results of [44] hold for the k-machine model (see Klauck, Nanongkai, Pandurangan, and Robinson [39]), which is similar to the CLIQUE model, but has k nodes rather than n. For a general k, the complexity of the algorithm is $\tilde{O}(m/n^{5/3} + n/k^{4/3})$, and the lower bound is $\tilde{\Omega}(m/k^{5/3})$.

[4] The sparse matrix multiplication algorithm of [14] can also be converted to the k-machine model, in which it has a complexity of $O(n^{4/3}(\rho_S\rho_T)^{1/3}/k^{5/3} + 1)$ rounds.

2.2 Triangle Finding in the CONGEST Model

We now move to triangle finding problems in the CONGEST model.

The first breakthroughs in this model are the first non-trivial (sublinears) algorithms due to Izumi and Le Gall [36]. These are randomized algorithms for triangle listing and detection in $O(n^{3/4}\log n)$ and $O(n^{2/3}\log^{2/3} n)$ rounds w.h.p., respectively. The approach of these algorithms is to split the task of finding triangles into two parts: one which looks for triangles that are ϵ-heavy and another which looks for other triangles, where an ϵ-heavy triangle is one in which at least one of its edges appears in at least n^ϵ triangles. Very roughly speaking, heavy triangles can be detected within $O(n^{1-\epsilon})$ rounds by randomly sampling which edges to send, and can be listed in $O(n^{1-\epsilon/2})$ rounds by randomly hashing the edges sent to different neighbors. A more involved argument shows that non-heavy triangles can be listed in $O(n^{1-\epsilon} + n^{(1+\epsilon)/2}\log n)$ rounds, w.h.p. Carefully plugging in the right values of $n^\epsilon = \tilde{O}(n^{1/3})$ and $n^\epsilon = \tilde{O}(n^{1/2})$ then gives the round complexities for triangle detection and listing.

The breakthrough that came after [36] is due to Chang, Pettie, and Zhang [15], who showed triangle listing (and thus also detection) in the CONGEST model in $\tilde{O}(n^{1/2})$ rounds, w.h.p. In a nutshell, the main methodology of this algorithm has two elements: One element is an algorithm for decomposing the graph into well-connected components which could behave somewhat similarly to the CLIQUE model. The second element is to have the nodes of each component search for triangles that have an edge in the component.

In more detail, [15] showed how to compute the following expander decomposition in $O(n^{1/2})$ rounds. This decomposition is a partition of the set of edges of the graph into three sets. In the first set E_m, each connected component has minimum degree $n^{1/2}$ and conductance $\Omega(1/\operatorname{polylog} n)$. The graph induced by the edges in the second set, E_s, is such that its arboricity is at most $n^{1/2}$. The third set of remaining edges, E_r is at most a constant fraction of the total number of edges, and the triangle listing algorithm which we discuss in what follows recurses over this remaining set of edges. The algorithm for the decomposition itself is beyond the scope of this survey, and here we only mention that it is rather far from being merely a distributed implementation of its centralized counterpart.[5]

The triangle listing algorithm over the two first sets above then works as follows. Since the arboricity in E_s is bounded by $n^{1/2}$, triangles with at least one edge in this set are listed in a straightforward manner, using an orientation that is deduced by the decomposition algorithm. Then, triangles with an edge in any high-conductance component (i.e., in E_m) are listed by having the nodes of each component mimic a variant of the triangle listing algorithm in the CLIQUE model of Dolev, Lenzen, and Peleg [19]. This mimicking has three aspects. First, it replaces the deterministic partition of [19] with a randomized partition, in order to have a good probability for a good balance of information within the component. Second, the fact that a component has large conductance indeed implies that it has a small mixing time, but this alone is insufficient for efficiently exchanging large amounts of information within the component. To this end, the algorithm makes use of the random-walk based routing techniques of Ghaffari, Kuhn, and Su [28] and Ghaffari and Li [29], whose complexities improve as the mixing time decreases. Finally, even with these ingredients, some nodes of a component may have too many edges that touch them that are not inside the component, preventing them from efficiently using their inner-component edges for routing this large amount of information. Thus, some additional edges are added to the set E_r of remaining edges that the decomposition left for recursing over.

[5] The actual decomposition result is more general, with a parameter δ which is tuned here to be $\delta = 1/2$ in order to optimize the running time of the triangle listing algorithm that uses it.

The decomposition approach was refined by Chang and Saranurak [16], allowing the complexity of triangle listing to drop to $\tilde{O}(n^{1/3})$ rounds, w.h.p. Since the $\tilde{\Omega}(n^{1/3})$ lower bound for triangle listing in the CLIQUE model directly applies also in CONGEST, this complexity is near-optimal (up to polylog n factors). At a high level, the decomposition obtained in [16] improves upon the one in [15] in that it does not have E_s at all (the bounded arboricity part) and in the complexity of obtaining it. In addition, a somewhat modified version of the routing algorithms of [28, 29] is introduced, for the triangle listing usage of the decomposition.

Chang and Saranurak [17] then show deterministic algorithms for expander decomposition and for expander routing. These yield round complexities of $O(n^{0.58})$ and $n^{2/3} + o(1)$ for deterministic triangle detection and triangle listing, respectively.

An additional algorithm for deterministic triangle listing is given by Huang, Pettie, Zhang, and Zhang [34]. The complexity of this algorithm, given in terms of the maximum degree Δ, is $O(\Delta/\log n + \log\log\Delta)$ rounds, w.h.p. For $\Delta = \tilde{O}(n^{1/3})$, this is faster compared with the algorithm of [17], while the latter is faster for the larger range of Δ.

Since the complexities of both [17] and [34] do not reach yet the lower bound of $\tilde{\Omega}(n^{1/3})$ rounds, we note the following open question.

▶ **Open Problem 2.2.** *What is the complexity of deterministic triangle listing in the* CONGEST *model? Does randomization help for this problem?*

The above are triangle listing algorithms so they clearly also solve the detection variant. However, as opposed to triangle listing, for triangle detection we currently do not have good lower bounds. What we do know is the following. Abboud, Censor-Hillel, Khoury, and Lenzen [1] showed that triangle detection cannot be solved in the CONGEST model within a single round by a deterministic algorithm. Specifically, they showed that any single-round algorithm requires a bandwidth of $\Delta \log n$ bits. Fischer, Gonen, Kuhn, and Oshman [24] showed that this also holds for randomized algorithms, by showing that randomized single-round algorithms require a bandwidth of Δ bits. Both works also addressed the round complexity of 1-bit bandwidth algorithms, with a lower bound of $\Omega(\log^* n)$ rounds given in [1], which was improved to $\Omega(\log n)$ rounds in [24].[6]

We will later (Section 4) describe some lower bounds for finding other subgraphs in the CONGEST model which are based on reductions from 2-party communication complexity problems, and there we will see why these techniques do not give any meaningful lower bound for triangles. Moreover, in the spirit of the aforementioned argument of Drucker, Kuhn, and Oshman [20], Eden, Fiat, Fischer, Kuhn, and Oshman [21] showed that a lower bound of $\omega(\log n)$ for triangle detection in CONGEST would imply major breakthroughs in circuit complexity. This leaves us with another curious gap in our knowledge of triangle finding in this model.

▶ **Open Problem 2.3.** *What is the complexity of triangle detection in the* CONGEST *model (randomized and deterministic)?*

3 Finding Larger Cliques

The CLIQUE model. The deterministic triangle listing algorithm of [19] for the CLIQUE model can be easily generalized to list larger cliques. To find cliques of size p for some integer $p \geq 3$, the set of nodes is partitioned into $n^{1/p}$ sets. Each node is assigned a p-tuple of sets

[6] The function $\log^* n$ counts the number of times the logarithm function needs to be applied starting from n until the value drops to at most 1.

and learns all edges between any two of its sets. A similar argument to that of triangles shows that indeed all p-cliques are listed by this algorithm, and that its round complexity is $O(n^{1-2/p}/\log n)$. In fact, it is easy to see that this algorithm lists all instances of any subgraph H of p nodes.

This complexity is optimal, due to a lower bound of $\tilde{\Omega}(n^{1-2/p})$ rounds by Fischer, Gonen, Kuhn, and Oshman [24], which generalizes the aforementioned lower bound for triangle listing of [44] and [36], using additional machinery. In the BROADCAST CONGESTED CLIQUE model, Drucker, Kuhn, and Oshman [20] show that $\Omega(n/\log n)$ rounds are needed for p-cliques, even for the stronger detection variant, for almost all values of $p \geq 4$ (as long as $p \leq (1-\epsilon)n$ for some constant $\epsilon > 0$).

For sparse graphs, Censor-Hillel, Le Gall, and Leitersdorf [11] show that listing can be complete within $\tilde{O}(m/n^{1+2/p}+1)$ rounds, for $p \geq 3$. This follows from their CONGEST approach which is discussed below, and is tight up to polylogarithmic factors using the lower bound technique of [24, 36, 44].

As opposed to the listing variant, for p-clique detection the aforementioned hardness of obtaining lower bounds in the CLIQUE model by [20] kicks in, and we do not know any non-constant lower bound (or any larger than 1 lower bound, for that matter), leaving the complexity of p-clique detection open for $p > 4$.

▶ **Open Problem 3.1.** *What is the complexity of p-clique detection in the* CLIQUE *model (randomized and deterministic), for $p \geq 4$?*

The CONGEST model. Algorithms for finding larger cliques in the CONGEST model, as in the case of triangles, are also based on the conductance decomposition algorithms of Chang, Pettie, and Zhang [15] and of Chang and Saranurak [16]. The first sublinear algorithms for larger cliques in CONGEST are due to Eden, Fiat, Fischer, Kuhn, and Oshman [21]. They show that 4-cliques can be listed in $\tilde{O}(n^{5/6+o(1)})$ rounds and that 5-cliques can be listed in $\tilde{O}(n^{21/22+o(1)})$ rounds, w.h.p. These listing algorithms are more involved compared with the triangle listing algorithm, due to the need to handle, for example, a 4-clique with one edge within a certain component and another edge within a different component, which imposes a complex challenge that becomes even worse as p grows.

Following [21], the work of Censor-Hillel, Le Gall, and Leitersdorf [11] provided algorithms for listing p-cliques in $\tilde{O}(n^{p/(p+2)})$ rounds, w.h.p., for all $p \geq 4$ except for $p = 5$. For $p = 5$, this work gave an algorithm which completes in $\tilde{O}(n^{3/4+o(1)})$ rounds, w.h.p. The main approach of these algorithms is iterating over the decomposition in a way that balances the minimum degree and the arboricity thresholds. Within each cluster, sparsity-aware listing helps speeding up the computation. While these algorithms improved upon the state-of-the-art for $p = 4, 5$ and were the first sublinear algorithms for $p \geq 6$, they fell short of the [24] lower bound of $\tilde{\Omega}(n^{1-2/p})$ rounds. The question of whether clique listing in the CONGEST model is as easy as, or harder than, its CLIQUE counterpart, was recently answered by Censor-Hillel, Chang, Le Gall, and Leitersdorf [7], using the newer conductance decomposition of Chang and Saranurak [16] and additional mechanisms for optimal sparsity-aware listing and for efficient transmission of edges in the clutsers.

For $p = 4$, the tight listing of [7] also implies that 4-clique detection is not easier than its listing counterpart in the CONGEST model. This is due to a lower bound of $\tilde{\Omega}(n^{1/2})$ for 4-clique detection in CONGEST, by Czumaj and Konrad [18]. The lower bound of [18] is more general, and says that detecting p-cliques in the CONGEST model requires $\tilde{\Omega}(n^{1/2}/p)$ rounds for $p \leq n^{1/2}$, and $\tilde{\Omega}(n/p)$ rounds for $p \geq n^{1/2}$. Thus, for values of p larger than 4, there is still a gap between detection and listing.

▶ **Open Problem 3.2.** *What is the complexity of p-clique detection in the* CONGEST *model (randomized and deterministic), for $p > 4$?*

The lower bound of [18] uses a reduction from 2-party set disjointness. The same work also shows that listing can be done sufficiently fast by the two parties, which shows that if the detection problems are harder, a different lower bound technique must be used.

4 Finding Larger Cycles

The CLIQUE model. Since the algorithm of [19] easily lists any subgraph of p nodes, we have that, in particular, p-cycles can be listed in the CLIQUE model within $O(n^{1-2/p})$ rounds (deterministically).

The detection variant was then addressed by Censor-Hillel, Kaski, Korhonen, Lenzen, Paz, and Suomela [12], who show a deterministic constant-round algorithm for detecting 4-cycles. In addition, they show an $O(n^{0.158})$-round algorithm for detecting p-cycles, for any constant p. More accurately, the complexity is $2^{O(p)}n^{0.158}$ rounds. This is a randomized algorithm that relies on the color coding technique of Alon, Yuster, and Zwick [3], in order to avoid too much congestion that would be caused by collecting all possible candidates for cycle nodes. More recently, Censor-Hillel, Fischer, Gonen, Le Gall, Leitersdorf, and Oshman [10] showed that $2p$-cycles can be detected in $O(1)$ rounds for any p, using a technique which also allows fast girth approximation. This is, notably, a deterministic algorithm. For odd values of p, it is still not known whether there is a constant-round p-cycle detection algorithm.

▶ **Open Problem 4.1.** *What is the complexity of p-cycle detection in the* CLIQUE *model (randomized and deterministic), for odd values of p?*

The CONGEST model. For 4-cycle detection, Drucker, Kuhn, and Oshman [20] provide a tight complexity of $\tilde{\Theta}(n^{1/2})$, by providing both an algorithm and a lower bound. They also show that for any odd value of p, detecting p-cycles requires $\tilde{\Omega}(n)$ rounds. The upper bound is obtained by setting a threshold of $T = 2n^{1/2}$, and defining heavy nodes as nodes with at least T neighbors. First, all non-heavy nodes send all their neighbors to all their neighbors, in T rounds. This detects 4-cycles which have at least 2 non-neighboring non-heavy nodes. Then, a heavy node v with more than T heavy neighbors reports that there exists a 4-cycle. Finally, a heavy node v with at most T heavy neighbors sends its heavy neighbors to all of its neighbors, again in T rounds. The reason for which too many heavy neighbors imply a 4-cycle is because this means that the total number of neighbors of heavy neighbors is at least T^2, which is more than $2n$, and so there must be a node other than v which is connected to two of the neighbors of v, and hence we have a 4-cycle. Otherwise, if v sends its heavy neighbors to all of its neighbors, then any 4-cycle with two neighboring nodes that are heavy is detected by one of its nodes (by a simple case analysis).

The matching lower bound for 4-cycles is a good point of reference for understanding lower bounds for the CONGEST model that rely on reductions from 2-party communication complexity. It relies on the fact that there is a 4-cycle-free graph G on n nodes with $\Theta(n^{3/2})$ edges, due to Erdös [22], whose work implies that this is the Turán Number of 4-cycles [48]. The setting is as follows. Each of two players, Alice and Bob, has an input string of k bits, $x = (x_1, \ldots, x_k)$ and $y = (y_1, \ldots, y_k)$, respectively. By communicating with each other, the players need to compute the set disjointness function $Disj(x, y)$, whose value is 1 if and only if the input strings represent disjoint subsets of the set $\{1, \ldots, k\}$, that is, if and only if there is no index $1 \leq i \leq k$ such that $x_i = y_i = 1$. The 2-party set disjointness problem is known

to require exchanging $\Omega(k)$ bits, even by randomized protocols, due to Kalyanasundaram and Schnitger [38], Razborov [47], and Bar-Yossef, Jayram, Kumar, and Sivakumar [4]. The reduction to distributed detection of 4-cycles is as follows. Each of the two players takes a subgraph of the 4-cycle free graph G according to their respective input. That is, the edges of G are mapped to the set $\{1, \ldots, k\}$, with a value of n for which $k = \Theta(n^{3/2})$. Each player imagines a subgraph of G that has an edge for any index in which their input is 1. The players then imagine that their two subgraphs are connect by a perfect matching: each node in Alice's subgraph is connected to the respective node in Bob's subgraph (the nodes of both subgraphs are the nodes of G). Now, it is easy to see that the combined graph contains a 4-cycle if and only if the input strings x, y are disjoint, as the only 4-cycles that can occur are those that have two edges from the perfect matching, and two edges that represent the same index in the bit strings of the players. Thus, if Alice and Bob can simulate a distributed algorithm for 4-cycle detection, they solve set disjointness. They simulate a given algorithm as follows. Any message that the algorithm sends between two nodes that are in the same subgraph (either that of Alice of that of Bob) can be internally simulated by the respective player. The only messages that need to be explicitly sent between the two players are those that are sent along the edges of the perfect matching. There are n such edges, and so simulating a round of the detection algorithms costs $O(n \log(n))$ bits of communication between the two players. Since $\Omega(k) = \Omega(n^{3/2})$ is a lower bound on the total number of bits that need to be exchanged for solving set disjointness, we get that the distributed 4-cycle detection algorithm must consist of at least $\Omega(k/n \log(n)) = \Omega(n^{3/2}/n \log(n)) = \tilde{\Omega}(n^{1/2})$ rounds.

A remark on triangle detection. While this approach for reductions which imply CONGEST lower bounds is heavily used in the literature, it is doomed to fail for triangle detection. The reason is that any triangle in a graph has at least one player which knows at least two of its nodes and thus all of its edges, which nullifies any attempt for a lower bound constructions, regardless of the 2-party problem or the graph construction.

Korhonen and Rybicki [40] then showed that the $\tilde{\Omega}(n^{1/2})$ lower bound for 4-cycles can be extended and applies to p-cycles for all even values of p. Notably, in the spirit of the results of [20], it is shown in Censor-Hillel, Fischer, Gonen, Oshman, Le Gall, and Leitersdorf [10] that going above this lower bound for $p = 6$ would imply new lower bounds in circuit complexity, which are considered hard to obtain. The reason that this barrier for lower bounds works in the CONGEST model is because it is shown that it is sufficient to consider high-conductance clusters, and that these can simulate circuits in a similar manner to the CLIQUE model.

On the upper bound side, Korhonen and Rybicki [40] showed that p-cycle detection for any constant p can be done in a linear in n number of rounds. For odd values of p, this is optimal due to the above lower bound. They also showed that this can be done faster for degenerate graphs. Fischer, Gonen, Kuhn, and Oshman [24] showed how to detect $2p$-cycles within $O(n^{1-1/p(p-1)})$ rounds, for $p \geq 2$. This was subsequently improved by Eden, Fiat, Fischer, Kuhn, and Oshman [21], who showed how to detect $2p$-cycles in $\tilde{O}_p(n^{1-2/(p^2-p+2)})$ rounds for odd $p \geq 3$, and in $\tilde{O}_p(n^{1-2/(p^2-2p+4)})$ rounds for even $p \geq 4$. They also show that as opposed to the case of 4-cliques, the listing variant of 4-cycles is harder than its detection counterpart, requiring $\tilde{\Omega}(n)$ rounds. For $p = 3, 4, 5$, Censor-Hillel, Fischer, Gonen, Oshman, Le Gall, and Leitersdorf [10] then showed improved algorithms (randomized) for detecting $2p$-cycles, which completes within $\tilde{O}(n^{1-1/p})$ rounds. Still, the upper bounds here are above the respective $\tilde{\Omega}(n^{1/2})$ lower bound.

▶ **Open Problem 4.2.** *What is the complexity of p-cycle detection in the* CONGEST *model (randomized and deterministic), for even value of $p \geq 6$?*

5 Additional Variants of Distributed Subgraph Finding

Finding Other Subgraphs. The literature has also been studying additional subgraphs, apart from cliques and cycles.

Drucker, Kuhn, and Oshman [20] study the complexity of finding trees and complete bipartite subgraphs in the BROADCAST CONGESTED CLIQUE model. Korhonen and Rybicki [40] show that trees can be detected in $O(1)$ rounds in the BROADCAST CONGEST model.

On the lower bound front, Gonen and Oshman [31] showed lower bounds for finding subgraphs that are created from smaller ones using certain allowed operations. Fischer, Gonen, Kuhn, and Oshman [24] showed that for any $p \geq 4$, there exists a subgraph H of size p such that H detection requires $\tilde{\Omega}(n^{2-\Theta(1/p)})$ rounds. Eden, Fiat, Fischer, Kuhn, and Oshman [21] showed that this complexity is roughly the right one, by providing an upper bound of $\tilde{O}(n^{2-2/(3p+1)} + o(1))$ rounds. In particular, their result shows that there does not exist a constant-sized subgraph for which detection requires a truly quadratic number of rounds.

Subgraph Freeness Testing. The variant of testing for H-freeness has also been studied in the distributed setting, initially introduced by Brakerski and Patt-Shamir [6].

The definition of distributed testing for H-freeness requires that if there is no instance of H in the graph then all the nodes output `true`, but instead of requiring at least one node to output `false` in case there is an instance of H as would be an analog to the detection problem, testing only requires at least one node to output `false` in case the graph is far from being H-free. Here, being ϵ-far from having a property is the same as its standard definition by Goldreich, Goldwasser, and Ron [30], and means that no matter which ϵ-fraction of the graph is changed (removed, in the case of H-freeness), the resulting graph must still have a copy of H. For triangles and other small subgraphs, this typically means that there are many instances of H in a graph that is far from being H-free.

For testing triangle-freeness, Censor-Hillel, Fischer, Schwartzman, and Vasudev [9] showed a $O(1/\epsilon^2)$-round algorithm. This was later improved by Even, Fischer, Fraigniaud, Gonen, Levi, Medina, Montealegre, Olivetti, Oshman, Rapaport, and Todinca [23] and Fraigniaud and Olivetti [25] to a complexity of $O(1/\epsilon)$ rounds. These, along with the work of Fraigniaud, Rapaport, Salo, and Todinca [26] also show fast testing for larger cliques, cycles, and additional subgraphs.

Subgraph Finding in Dynamic Networks. Subgraph finding has also been studied from the perspective of dynamic networks. Bonne and Censor-Hillel [5] characterize the bandwidth that is required for various clique finding problems by algorithms that work in a dynamic setting and must produce the correct answer immediately at the end of the round in which a topology change occurs.

Subgraph finding in a harsh dynamic setting in which the number of topology changes per round is unlimited, was studied by Censor-Hillel, Kolobov, and Schwartzman [13], who showed upper and lower bounds for small subgraphs.

Subgraph Finding in Quantum Networks. Izumi, Le Gall, and Magniez [37] have shown that in a quantum CONGEST model, triangle detection can be solved within $\tilde{O}(n^{1/4})$ rounds, using a distributed version developed by Izumi and Le Gall in [35] of a *Grover Search* [32]. We note that the listing variant for triangles cannot be improved using quantum tools, since it is obtained through information theoretic arguments, which apply to this setting as well.

Abstract

In this paper we consider a new type of space partitioning which bridges the gap between continuous and discrete spaces in an *error resilient* way. It is motivated by the problem of rounding noisy measurements from some continuous space such as $\mathbb{R}^d$ to a discrete subset of representative values, in which each tile in the partition is defined as the preimage of one of the output points. Standard rounding schemes seem to be inherently discontinuous across tile boundaries, but in this paper we show how to make it perfectly consistent (with *error resilience* ϵ) by guaranteeing that any pair of consecutive measurements X_1 and X_2 whose L_2 distance is bounded by ϵ will be rounded to the same nearby representative point in the discrete output space. We achieve this resilience by allowing a few bits of information about the first measurement X_1 to be unidirectionally communicated to and used by the rounding process of the second measurement X_2. Minimizing this revealed information can be particularly important in privacy-sensitive applications such as COVID-19 contact tracing, in which we want to find out all the cases in which two persons were at roughly the same place at roughly the same time, by comparing cryptographically hashed versions of their itineraries in an error resilient way.

The main problem we study in this paper is characterizing the achievable tradeoffs between the amount of information provided and the error resilience for various dimensions. We analyze the problem by considering the possible colored tilings of the space with k available colors, and use the color of the tile in which X_1 resides as the side information. We obtain our upper and lower bounds with a variety of techniques including isoperimetric inequalities, the Brunn-Minkowski theorem, sphere packing bounds, Sperner's lemma, and Čech cohomology. In particular, we show that when $X_i \in \mathbb{R}^d$, communicating $\log_2(d+1)$ bits of information is both sufficient and necessary (in the worst case) to achieve positive resilience, and when d=3 we obtain a tight upper and lower asymptotic bound of $(0.561\ldots)k^{1/3}$ on the achievable error resilience when we provide $\log_2(k)$ bits of information about X_1's color.

1 Introduction

Studying various types of space partitioning of a continuous space such as $\mathbb{R}^d$ is a central topic in computational geometry (see, e.g., [11, Chapters 6,12] and the references therein), and each type of partition has different properties and applications within computer science, electrical engineering, and applied mathematics. For example, in *error-correcting codes* (which are extensively used in data communication) we try to squeeze the largest possible number of equal sized disjoint balls into the input space, while in *vector quantization* [16] (which is used extensively in data compression) we try to completely cover the input space with a small number of tiles whose volumes are as similar as possible. In this paper we investigate a new variant which can be viewed as "continuous error correction over the reals". Our main motivation is the problem of rounding noisy analog measurements in $\mathbb{R}^d$, in order to digitally process or store them (see, e.g., [2, 10]). This rounding process seems to be inherently discontinuous across tile boundaries, and this problem is compounded by the fact that for large d almost all input vectors are near boundaries. One natural solution to this discontinuity problem is to try to minimize the fraction of pairs X_1, X_2 with $distance(X_1, X_2) < \epsilon$ which are rounded differently by considering *foam tilings* that minimize the total surface area of unit volume tiles (such a tiling is called "foam" since it emerges in physical collections of soap bubbles). In a beautiful FOCS paper [22] (which was highlighted at CACM [23]), Kindler et al. introduced a clever new construction of such tiles which they called *spherical cubes*. What makes these tiles special is that they have the $O(\sqrt{d})$ surface area of a ball and yet they can tile the whole $\mathbb{R}^d$ space without gaps, which solved an open problem posed by Lord Kelvin in 1887.

In this paper we consider the more ambitious goal of achieving *error resilience* which completely eliminates all the discontinuities in the rounding process rather than reducing their fraction. We call such a rounding scheme *consistent rounding*[1], and make it possible by thinking about X_1 and X_2 as two consecutive noisy measurements of the same X. When the first measurement X_1 is rounded, we allow it to produce a few bits of side information about how it was rounded, and to provide them as an auxiliary input to the process that decides how to round X_2. Note that both X_1 and X_2 are assumed to be real valued vectors which require an infinite number of bits to fully specify them.

To demonstrate the basic idea, consider the one dimensional case in which X_1 and X_2 are real values which have to be consistently rounded to the same nearby integer whenever they are close enough. X_1 is always rounded to the nearest integer, and it produces a single bit of side information which is whether it was rounded to an even or an odd integer P. When X_2 is measured, it is rounded to the nearest integer which has the same parity as P. To demonstrate this process, consider the problematic inputs $X_1 = 0.4999$ and $X_2 = 0.5001$: X_1 is rounded to 0, and X_2 is also rounded to 0 since it is the closest even integer. In fact, X_2 could be anywhere between -1 and 1 and still be consistently rounded to 0, and thus the rounding scheme is resilient to additive errors of up to 0.5. In fact (see Sec. 4.1), this is the highest possible error resilience of any one dimensional consistent rounding scheme; other natural schemes (such as providing one bit of side information about whether X_1 was rounded up or down) provide lower resilience.

The way we think about the problem is to consider a colored tiling of the real line with two colors: All the values in $[-0.5, 0.5)$, $[1.5, 2.5)$, etc. are colored by 1, and all the values in $[0.5, 1.5)$, $[2.5, 3.5)$, etc. are colored by 2. The side information provided about X_1 is the

[1] We note that in statistics, the term "consistent rounding" is used to denote a rounding that is consistent with some external constraints; see [26, p. 237].

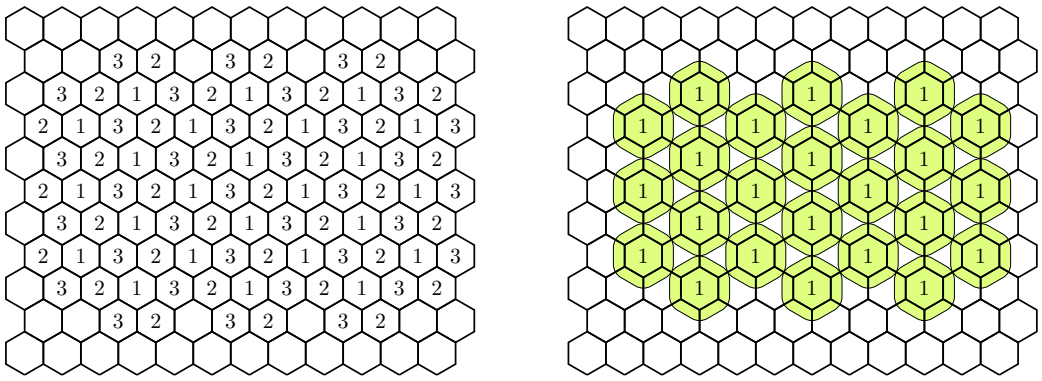

Figure 1 A 3-colored hexagonal tiling of the plane, and a maximal non-intersecting inflation of the tiles colored 1.

color of the tile in which it is located, and the way we process X_2 is to round it to the center of the closest tile which has the same color as that of X_1. The essential property of our partition is that the minimum distance between any two tiles with the same color is 1, and thus we can "inflate" all the tiles of any particular color to their outer parallel body in order to include any erroneously measured value X_2 up to a distance of 0.5 away from the original tile, and still get nonoverlapping tiles which make it possible to uniquely associate such points with original tiles.

To make this perspective clearer, consider the two dimensional plane. In the obvious checkerboard tiling by unit squares, we need at least 4 colors (and thus 2 bits of side information) to color the tiles if we do not allow equi-colored tiles to touch. We can reduce the number of colors to 3 (and thus, provide only $\log_2(3) = 1.58$ bits of side information) by considering the hexagonal partition of the plane depicted in the left part of Figure 1. Given a two dimensional point X_1, we always round it to the center of the hexagon in which it is located, and given X_2 we round it to the center of the nearest hexagon which has X_1's color. To determine the error resilience of this scheme, we inflate all the hexagonal tiles of a particular color by the same amount until they touch each other, as depicted in the right part of Figure 1. As it turns out, this natural scheme is not optimal since the inflated hexagons' corners touch prematurely, leaving large gaps between them. A 3-colored tiling with a higher error resilience will be described in Section 5.1.1, and an asymptotically optimal tiling for a large number of colors will be described in Section 5.2.1.

For inputs $X \in \mathbb{R}^d$, we can provide one bit of side information about each one of its d entries separately, but for large d this is very inefficient. In our colored tiling formulation, it suffices to reveal the color of X_1 in order to consistently round X_2, and thus if we can tile the space with k colors, we need only $\log_2(k)$ bits to specify this color. This naturally leads to the question of what is the minimum number of colors needed to tile $\mathbb{R}^d$ by bounded sized tiles so that no two tiles of the same color will touch (even at a corner). Surprisingly, we could not find any reference to this natural question. As we show in Section 3, there can be no such colored tiling with d colors, and as we show in Section 5.3, $d+1$ colors are sufficient. Consequently, $\log_2(d+1)$ bits of side information about X_1 are necessary and sufficient (in the worst case) to obtain a consistent rounding scheme with positive error resilience. To prove the negative result, we use techniques borrowed from algebraic topology (namely, either a generalization of Sperner's lemma or the Čech cohomology and other cohomology theories), and to prove the positive result we provide an explicit construction of such a colored tiling.

Table 1 Summary of our lower and upper bounds on the error resilience, for different d and k.

Scenario	Lower Bound (LB) on ER	Upper Bound (UB) on ER	Techniques	Source
3 colors in $\mathbb{R}^2$	0.354	0.413	Brunn-Minkowski ineq. (UB), Brick wall tiling (LB)	Sec. 4.1 (UB), Sec. 5.1.1 (LB)
4 colors in $\mathbb{R}^2$	0.5	0.564	Brunn-Minkowski ineq. (UB), Brick wall tiling (LB)	Sec. 4.1 (UB), Sec. 5.1.1 (LB)
k colors in $\mathbb{R}^2$	$0.537\sqrt{k} - O(1)$	$0.537\sqrt{k}$	Circle packing (UB), HCR tiling (LB)	Sec. 4.2 (UB), Sec. 5.2.1 (LB)
4 colors in $\mathbb{R}^3$	0.25	0.365	Brunn-Minkowski ineq. (UB), 3-dim Brick wall (LB)	Sec. 4.1 (UB), Sec. 5.1.2 (LB)
k colors in $\mathbb{R}^3$	$(0.561 - o(1))k^{1/3}$	$0.561k^{1/3}$	Sphere packing (UB), CPB tiling (LB)	Sec. 4.2 (UB), Sec. 5.2.2 (LB)
k colors in $\mathbb{R}^8$	$(0.707 - o(1))k^{1/8}$	$0.707k^{1/8}$	Sphere packing (UB), CPB tiling (LB)	Sec. 4.2 (UB), Sec. 5.2.2 (LB)
k colors in $\mathbb{R}^{24}$	$(1 - o(1))k^{1/24}$	$k^{1/24}$	Sphere packing (UB), CPB tiling (LB)	Sec. 4.2 (UB), Sec. 5.2.2 (LB)
$d+1$ colors in $\mathbb{R}^d$	$\Omega(1/d)$	$O(\log d/\sqrt{d})$	Brunn-Minkowski ineq. (UB), Dimension reducing tiling (LB)	Sec. 4.1 (UB), Sec. 5.3 (LB)

ER – error resilience, LB – lower bound, UB – upper bound,
HCR – honeycomb of rectangles, CPB – close packing of boxes

In addition to minimizing the amount of side information, we study the question of maximizing the error resilience for a given d and k. In the negative direction, in Section 4 we obtain several upper bounds on the achievable error resilience, using different techniques from geometry and analysis (including isoperimetry, the Brunn-Minkowski inequality and results on the sphere packing problem). In the positive direction, we construct in Section 5 a variety of tiling schemes. In particular, while for $d = 2$ and $k = 3$ the hexagonal tiling scheme described above is resilient to additive errors of up to 0.31, we present a tiling with resilience of 0.354, and show that no 3-color tiling can have resilience higher than 0.413. We also show that the maximal resilience achieved by a $(d+1)$-coloring of $\mathbb{R}^d$ is between $\Omega(1/d)$ and $O(\log d/\sqrt{d})$, and use the recent breakthrough results on sphere packing [6, 18, 25] to obtain tight asymptotic lower and upper bounds on the resilience in dimensions $2, 3, 8$, and 24. Our bounds are summarized in Table 1.

Applications. The problem of "continuous error correction over the reals" has numerous applications. For example, in biometric identification, multiple measurements of the same fingerprint are similar but not identical. It would be very helpful if all these slight variants could be represented by the same rounded point P, and we can achieve this by storing a small amount of side information in the biometric database during the initial registration of a new employee.

Another example is the problem of developing a contact tracing app for the COVID-19 pandemic, where we want to record all the cases in which two smart phones were at roughly the same place at roughly the same time. We can do this by measuring in each phone the GPS location, the local time, and perhaps other parameters such as the ambient noise level (in order to rule out the case of people living in different apartments which are separated by a common wall). When someone tests positive for COVID-19, the health authority wants

to reveal a list of his measurements, but in order to keep the patient's privacy, it wants to cryptographically hash each measurement before publishing it. Since the measurements are likely to be slightly different for the infected and exposed persons, the health authority can publish the small amount of side information along with the consistently rounded and then hashed measurements.

Finally, the problem may also be relevant to the construction of quantum error correction codes, since the state of a quantum computer is a complex-valued vector in a Hilbert space with exponentially many dimensions which can be perturbed by external noise. Note that the logarithmic number of side information bits we need for error correction can be stored and processed classically. However, describing such potential applications is beyond the scope of this paper.

Related work. A line of study that seems related to our work is *fuzzy* constructions that were widely studied in the cryptographic literature, such as the *fuzzy commitment scheme* of Juels and Wattenberg [20]). Dodis et al. [12] introduced the notions of *fuzzy extractors* and *secure sketches*, which enable two parties to secretly reach a consensus value from multiple noisy measurements of some high entropy source (a recent survey of such techniques can be found in [14]). However, such schemes concentrate on the aspects of cryptographic security (which we do not consider), and produce sketches whose size depends on the number of possible inputs (which is meaningless for real valued inputs). In this sense our consistent rounding scheme can be viewed as an exceptionally efficient reconciliation process, since it can produce for each million entry vector of arbitrarily large real numbers a 20 bit "sketch" (in the form of its color side information), and process this information with trivial point location algorithms.

Open problems. While we fully solved the question of minimizing the amount of side information required for error resilience, several questions remain open regarding the maximal resilience rate that can be achieved for a given amount of side information. In particular, for dimensions $2, 3, 8, 24$ we determined the exact asymptotic resilience when $\log_2 k$ bits of information are allowed, using a connection to the *densest sphere packing* problem. When only very few bits of information are allowed, the situation is much less clear. For example, we do not even know whether the brick wall constructions we present in Section 5.1.1 have the highest error resilience among rounding schemes in $\mathbb{R}^2$ with $\log_2 3$ and $\log_2 4$ bits of side information. It will be interesting to obtain new upper bounds via different techniques or new lower bound constructions.

2 Our Setting

In this section we present the basic setting that will be assumed throughout the paper.

Colored tiling. We study tilings of $\mathbb{R}^d$, where each tile is *connected*, *closed* and *bounded*, and the tiles intersect only in their boundaries. In some of the results we make additional assumptions on the tiles or drop some of the assumptions; such changes are stated explicitly. Each tile is colored in one of k colors.

Error resilience and inflation. In order to compute the error resilience of a given tiling (with respect to the L_2 distance), we consider all tiles of the same color and inflate them (i.e., replace the tile T by the set $T' = \{y : \exists x \in T, |x - y| < r\}$ for some $r > 0$) until they touch each other. Clearly, the error resilience is the maximal r for which such a non-intersecting

inflation is possible. We note that in convex geometry, such an inflation T' is called *the outer parallel body of radius r* of T (see [15, p. 943]). The minimal distance between two same-colored points in different tiles is denoted by t, and so, the error resilience is $t/2$.

Breaking ties. A fine point about consistent rounding schemes is how to break ties, and here we deal differently with X_1 and X_2. We want to be able to deal with any X_1, and thus we think about the tiles as being closed sets which include their boundaries. Therefore, points X_1 which are on the boundary between tiles can have more than one possible color. We allow such ties to be broken arbitrarily in the sense that X_1 can be rounded to the center of any one of the tiles that it belong to. However, when we think about X_2 we allow it to be at a distance of strictly less than some bound, and thus the inflated tiles (that contain all the possible X_2's we are interested in) are open sets which have no intersections. Consequently, each X_2 can belong to at most one inflated tile, and is rounded to the center of that tile with no possible ties.

Normalization. The d-dimensional volume of a figure $T \subset \mathbb{R}^d$ is denoted by $\lambda(T)$. We normalize the tiling by assuming that *the volume of each tile is bounded by* 1 (like in the 1-dimensional case presented in the introduction, where all tiles are segments of length 1). We make the natural assumption that any inflated tile T' satisfies $\lambda(\bar{T}') = \lambda(T')$, where $\bar{T}'$ is the topological closure of T'. Normalization with respect to other natural metrics, as well as alternative distance metrics, are discussed in the full version of the paper.

3 The Minimal Number of Colors Required for Error Resilience

In this section we prove that the minimal number of colors required for achieving any positive error resilience in a tiling of $\mathbb{R}^d$ is $d+1$. We provide two proofs, under different additional natural assumptions on the tiles. The first assumes that all tiles are uniformly bounded and relies on a generalization of Sperner's lemma. The second proof assumes that the tiles and their non-empty intersections are contractible (while not having to be uniformly bounded) and uses a more advanced algebraic-topologic argument. The lower bound $d+1$ on the number of required colors is tight; a matching construction for any d is presented in Section 5.3.

3.1 Lower bound for bounded tiles, using Sperner's Lemma

The main result of this subsection is the following.

▶ **Proposition 1.** *For any $m > 0$, the following holds. Let $T_1, T_2, \ldots$ be a colored tiling of $\mathbb{R}^d$ in $d+1$ colors, in which each tile is contained in a box with side length m. If the error resilience of the tiling is $\delta > 0$, then there exist tiles in all $d+1$ colors that intersect at a point.*
Consequently, any tiling with positive error resilience uses at least $d+1$ colors.

We use a generalization of the classical Sperner's lemma [24], called *Bapat's connector-free lemma*. As Bapat's lemma was originally proved only in $\mathbb{R}^2$ and in a discrete setting, we first provide a proof of a continuous version in $\mathbb{R}^d$, and then derive Proposition 1 from it.

3.1.1 Bapat's connector-free lemma – continuous version

Let Δ be a d-simplex in a Euclidean space, i.e., the convex hull of $d+1$ points $x_0, \ldots, x_d$ which do not lie in a d-space. The i'th face of Δ is the span of $\{x_j\}_{j \neq i}$. A *connector* in a d-simplex is a connected set which intersects all its $(d-1)$-dimensional faces.

Bapat's connector-free lemma asserts the following:

▶ **Theorem 2.** *Let $C_0, \ldots, C_d$ be a cover of a d-simplex Δ by closed sets such that the minimal distance between two connected components of the same set is $\delta > 0$. Suppose that the interiors of the sets are disjoint and that no C_i contains a connector. Then $\bigcap_{i=0}^{d} C_i \neq \emptyset$.*

In order to prove the theorem we will reduce it to an analogous discrete claim. The reduction is simple, but requires some more terminology.

A *triangulation* T of a simplex $\Delta \subset \mathbb{R}^d$ is a cover of it by simplices whose interiors are disjoint, such that the intersection of any set of simplices is either empty or the convex hull of some vertices. Note that the vertices of Δ are, in particular, vertices of the triangulation, and that the faces of Δ are endowed by an induced triangulation. The *diameter* of T is the supremum of distances between vertices which share an edge. The 1-*skeleton* of T is the graph formed by the vertices and the edges. A *discrete connector* is a connected subset of the 1-skeleton of T which contains vertices from each facet of Δ. We can now state the discrete version of Theorem 2 (which is the actual statement proved by Bapat, for $d = 2$).

▶ **Theorem 3** (Bapat). *Suppose that the vertices of T are partitioned into disjoint sets $A_0, A_1, \ldots, A_d$ such that no A_i contains a discrete connector. Then there exists a simplex in T whose $d+1$ vertices belong to different sets A_i.*

Proof of Theorem 2, assuming Theorem 3. Assume towards contradiction that there exist sets $C_0, \ldots, C_d$ which cover Δ, such that no C_i contains a connector, but $\bigcap_{i=0}^{d} C_i = \emptyset$. Define the function $f : C_0 \times C_1 \cdots \times C_d \to \mathbb{R}_+$ by setting $f(p_0, \ldots, p_d)$ to be the diameter of the convex hull of $(p_0, \ldots, p_d)$, which is the maximal distance between two p_i's. The domain of the function f compact (here we use the assumption that the minimal distance between two connected components of the same C_i is at least δ) and its range is $\mathbb{R}_+$ (since we assumed $\bigcap_{i=0}^{d} C_i = \emptyset$). Hence, f attains a minimum $\epsilon > 0$.

Let $\eta = \min(\delta, \epsilon)/3$. Let $\tilde{C}_i$ be the η-thickening of C_i in Δ, i.e., $\tilde{C}_i = \{p \in \Delta : \operatorname{dist}(p, C_i) < \eta\}$. Then $\tilde{C}_i$ is an open cover of Δ. By the choice of η, neither $\tilde{C}_i$ contains a connector,[2] and $\bigcap_{i \in \{0,\ldots,d\}} \tilde{C}_i = \emptyset$.

Let T be a triangulation of Δ whose diameter is less than η and all whose vertices lie in the interiors of the sets C_i. (Clearly, such a triangulation exists.) Define A_i as the subset of vertices which lie in $\operatorname{int}(C_i)$. These sets are well defined since the interiors of the different C_i's are disjoint. Since the triangulation is of diameter less than η, each edge between two vertices which belong to the same A_i lies in $\tilde{C}_i$. Indeed, its endpoints are in C_i and any point on the edge is of distance less than η to any endpoint, hence it is in $\tilde{C}_i$. Thus, since $\tilde{C}_i$ contains no connector, A_i contains no discrete connector.

We can now apply Theorem 3 to deduce that there exists a simplex $t = \{v_0, \ldots, v_d\} \in T$ such that $\forall i : v_i \in A_i$. But since $v_i \in C_i$ for all i, this implies $f(v_0, \ldots, v_d) < \eta < \epsilon$, a contradiction to the definition of ϵ. This completes the proof. ◀

[2] To be precise, this relies on the slightly stronger assumption that each connected component of C_i is at least δ-far from one of the facets of Δ. While this extra assumption can be avoided in the proof, it clearly holds in our setting so we make it for simplicity.

To prove Theorem 3, we use the classical Sperner's lemma [24]. To present it, a few more definitions are due.

A *(d+1)-labelling* of a triangulation T is of the simplex $\Delta = \text{conv}(e_0, \ldots, e_d)$ is a function $\ell : V(T) \to \{0, 1, \ldots, d\}$, that is, an assignment of one of $d+1$ colors to each vertex of the triangulation. A $(d+1)$-labelling ℓ is called *proper* if $\ell(e_i) = i$, and for each $v \in T$ that belongs to a lower-dimensional face $\text{conv}(e_{i_1}, \ldots, e_{i_r})$, we have $\ell(v) \in \{i_1, \ldots, i_r\}$.

▶ **Theorem 4** (Sperner's lemma)**.** *For any triangulation T of Δ, any proper labelling of T contains a simplex all whose vertices have different labels.*

Proof of Theorem 3. We define, using the sets $A_0, \ldots, A_d$, a proper labelling ℓ of T. For any j and any $v \in A_j$, $\ell(v)$ is defined as the minimal $i \in \{0, \ldots, d\}$ such that the connected component of v in A_j does not intersect the i'th face of Δ. Note that ℓ is well-defined, since each v belongs to a single A_j and no A_j contains a connector. Clearly, $\ell(v) \neq i$, whenever v belongs to the i'th face of Δ. Furthermore, this implies that if $v \in \text{conv}(e_{i_1}, \ldots, e_{i_r})$, then $\ell(v) \in \{i_1, \ldots, i_r\}$ (as all other colors are forbidden). Hence, ℓ is proper.

By Sperner's lemma, applied to the labelling ℓ, there exists a simplex $\{v_0, \ldots, v_d\} \in T$ all whose vertices have different labels. Assume w.l.o.g. that $\ell(v_i) = i$. We want to show that each v_i belongs to a different A_j, which will complete the proof. Assume towards contradiction $v_i, v_k \in A_j$ for $i \neq k$. On the one hand, $\ell(v_i) = i \neq k = \ell(v_k)$. On the other hand, $v_i,\ v_k$ belong to the same connected component in A_j, hence, by the definition of ℓ they must map to the same value. A contradiction, and Theorem 3 follows. ◀

3.1.2 Proof of Proposition 1

We are now ready to prove Proposition 1.

Let $T_1, T_2, \ldots$ be a tiling of $\mathbb{R}^d$ that satisfies the assumptions of the proposition. Consider the restriction of the tiling to a large simplex Δ (say, of side length $100m$).

For $i = 0, \ldots, d$, denote by $C_i \subset \Delta$ the union of all tiles colored i, restricted to Δ. Clearly, C_i is a closed set and the distance between any two connected components of C_i is at least 2δ. (Indeed, each tile is connected, and as the error resilience of the tiling is δ, the distance betwen two same-colored tiles is at least 2δ).

We claim that no C_i contains a connector. Indeed, a connector cannot include points from different tiles. A single tile is included in a box with side length m, and thus, cannot touch all facets of a simplex with side length $100m$. Hence, there is no single-colored connector.

Therefore, we can apply Theorem 2 to deduce that $\bigcap_{i=0}^{d} C_i \neq \emptyset$, which is exactly the assertion of Proposition 1.

3.2 Lower bound for contractible tiles, using Čech cohomology

Recall that a set in $\mathbb{R}^d$ is called *contractible* if it can be continuously shrunk to a point within the set. (The formal definition is that the identity is homotopic to a constant map.)

Informally, in this section we prove that if the tiles and their non-empty intersections are finite unions of contractible sets (that do not have to be uniformly bounded), then at least $d+1$ colors are required for error resilience. We note that the proof uses a somewhat heavier algebraic-topologic machinery, and so, a reader might prefer to skip it in first reading.
Due to the possibility of pathologies, the formal statement is a bit more cumbersome:

▶ **Proposition 5.** *Let $T_1, T_2, \ldots$ be a colored tiling of $\mathbb{R}^d$ with positive error resilience, in which the tiles and all their non-empty intersections are disjoint unions of finitely many closed contractible sets. Assume that the tiling is locally finite (meaning that the number*

of tiles that intersect any bounded ball $B(0,r)$ is finite) and that all T_i's are bounded (not necessarily uniformly). In addition, assume that each T_i has an open neighborhood U_i such that for any I,

$$\bigcap_{i\in I} U_i \neq \emptyset \Leftrightarrow \bigcap_{i\in I} T_i \neq \emptyset,$$

and the U_i's and their non-empty intersections are disjoint unions of finitely many contractibles. Then the number of colors is at least $d+1$.

A similar method proves an analogous statement for colored tilings of the sphere $\mathbb{S}^d$ (i.e., the unit sphere in $\mathbb{R}^{d+1}$):

▶ **Proposition 6.** *Let $T_1, T_2, \ldots, T_N$ be a colored tiling of $\mathbb{S}^d$ with positive error resilience, in which the tiles and all their non-empty intersections are disjoint unions of finitely many closed contractible sets. Assume that each T_i has an open neighborhood U_i such that for any set of indices I,*

$$\bigcap_{i\in I} U_i \neq \emptyset \Leftrightarrow \bigcap_{i\in I} T_i \neq \emptyset,$$

and the U_i's and their non-empty intersections are disjoint unions of finitely many contractibles. Then the number of colors is at least $d+1$.

▶ Remark 7. We stress that for most natural tilings the additional assumption on the existence of the neighborhoods U_i follows from the existence of T_i's with the corresponding properties. However, there are topological pathologies in which this is not the case.

The proof of Propositions 5 and 6 uses the notion of Čech cohomology and classical results regarding its properties. For the ease of reading, we begin with an intuitive explanation of the proof ideas, and then present the formal proof.

Intuitive proof. The d'th (singular) cohomology group is a topological invariant of a manifold which roughly counts "non trivial holes" of dimension d. A classical result asserts that the d'th cohomology group of a d-dimensional compact oriented manifold like $\mathbb{S}^d$ is $\mathbb{R}$. (This corresponds to the intuitive understanding that $\mathbb{S}^d$ has one d-dimensional hole.) The de-Rham cohomology and the Čech cohomology are analytic and algebro-geometric/combinatorial invariants, that in many cases agree with their topological cousin. In particular, the d'th de-Rham and Čech cohomologies of $\mathbb{S}^d$ are equal to $\mathbb{R}$ as well.

The d'th Čech cohomology with respect to an open cover of the manifold depends on properties of intersections of $d+1$ sets in that cover. In general, it depends on the sets which form the cover, however, it is known that if these sets and their non-empty intersections are finite disjoint unions of contractibles, then the cohomology groups remain the same, independently of the cover. In particular, if the d'th Čech cohomology with respect to such a cover is non trivial, then there must be $d+1$ sets with a non-empty intersection.

Hence, for our cover $U_1, U_2, \ldots$, we know that its d'th Čech cohomology is $\mathbb{R}$. This readily completes the proof of the proposition for $\mathbb{S}^d$, as this implies that there must be a point that belongs to at least $d+1$ of the U_i's. The proof in $\mathbb{R}^d$ works in essentially the same way, with cohomology groups replaced by cohomology groups with compact support.

Formal proof. For the proof we recall the notion of Čech cohomology with values in the constant sheaf $\underline{\mathbb{R}}$, and describe the slightly less standard concept of Čech cohomology with compact support.

Definitions. Let S be either $\mathbb{R}^d$ or a compact manifold such as $\mathbb{S}^d$. Let $\mathcal{U} = \{U_1, U_2, \ldots\}$ be an open cover of S. If S is compact, we assume the collection to be finite. If S is $\mathbb{R}^d$, we assume it to be locally finite and assume in addition that each U_i is bounded.

- A $q-$*simplex* $\sigma = (U_{i_0}, \ldots, U_{i_q})$ of $\mathcal{U}$ is an ordered collection of $q+1$ different sets chosen from $\mathcal{U}$, such that
$$\bigcap_{k=0}^{q} U_{i_k} \neq \emptyset.$$
- For a $q-$simplex $\sigma = (U_{i_k})_{k\in\{0,\ldots,q\}}$, the j'th *partial boundary* is the $(q-1)$-simplex
$$\partial_j \sigma := (U_{i_k})_{k\in\{0,\ldots,q\}\setminus\{j\}},$$
obtained by removing the j'th set from σ.
- A $q-$*cochain* of $\mathcal{U}$ is a function which associates to any $q-$simplex a real number. The $q-$cochains form a vector space denoted by $C^q(\mathcal{U}, \underline{\mathbb{R}})$, with operations
$$(\lambda f + \mu g)(\sigma) = \lambda f(\sigma) + \mu g(\sigma), \quad \text{where} \quad \lambda, \mu \in \mathbb{R},\ f, g \in C^q(\mathcal{U}, \underline{\mathbb{R}}),\ \sigma \text{ is a } q-\text{simplex}.$$
Similarly, we define $C^q_c(\mathcal{U}, \underline{\mathbb{R}})$, as the vector space of $q-$cochains *with compact support*, meaning those cochains which assign 0 to all $q-$simplices, except for finitely many.
- There is a *differential map* $\delta_q : C^q(\mathcal{U}, \underline{\mathbb{R}}) \to C^{q+1}(\mathcal{U}, \underline{\mathbb{R}})$ whose application to $f \in C^q(\mathcal{U}, \underline{\mathbb{R}})$ is the $(q+1)-$cochain $\delta_q(f)$ whose value at a $(q+1)-$simplex σ is
$$(\delta_q f)(\sigma) = \sum_{j=0}^{q+1} (-1)^j f(\partial_j \sigma).$$
The restriction of δ_q to $C^q_c(\mathcal{U}, \underline{\mathbb{R}})$ maps it to $C^{q+1}_c(\mathcal{U}, \underline{\mathbb{R}})$.
- It can be easily seen that $\delta_{q+1} \circ \delta_q = 0$.
- The *q'th Čech cohomology group (with compact support)* of S with respect to the cover $\mathcal{U}$ and values in $\underline{\mathbb{R}}$ is
$$\check{H}^q(\mathcal{U}, \underline{\mathbb{R}}) := \mathrm{Ker}(\delta_q)/\mathrm{Image}(\delta_{q-1}),$$
$$\check{H}^q_c(\mathcal{U}, \underline{\mathbb{R}}) := \mathrm{Ker}(\delta_q|_{C^q_c(\mathcal{U},\underline{\mathbb{R}})})/\mathrm{Image}(\delta_{q-1}|_{C^{q-1}_c(\mathcal{U},\underline{\mathbb{R}})}).$$
- A cover (by open sets) is *good* if all its sets as well as their multiple intersections are either empty or contractible. It is *almost good* if all non empty intersections are unions of finitely many disjoint contractible components.

Classical results we use. The first result we use is the following:

▶ **Theorem 8.** *If S is a compact smooth orientable manifold (such as $\mathbb{S}^d$), and $\mathcal{U}$ is a good or an almost good finite cover, then*
$$\check{H}^i(\mathcal{U}, \underline{\mathbb{R}}) \simeq H^i_{dR}(S),$$
where the right hand side is the standard de-Rham cohomology group.
Similarly, if $S = \mathbb{R}^d$ and $\mathcal{U}$ is a locally finite good or almost good cover whose sets are bounded, then
$$\check{H}^i_c(\mathcal{U}, \underline{\mathbb{R}}) \simeq H^i_{dR,c}(S),$$
where the right hand side is the i'th de-Rham cohomology group with compact support.

For further reading about de-Rham cohomology, with or without compact support, we refer the reader to [4, Sec. 1]. For further reading about the Čech cohomology, we refer to [4, Sec. 8]. In particular, Theorem 8, for the compact case and good covers is Theorem 8.9 there. The passage to almost good covers is straightforward: In the paragraph which precedes the proof, it is explained that the obstructions to the isomorphism between Čech and de-Rham cohomologies are given by products of the i'th de-Rham cohomology groups, for $i \geq 1$, of the different intersections $\bigcap_{k=0}^{q} U_{i_k}$. Since those intersections are disjoint unions of contractibles, their higher cohomology groups vanish, hence there is no obstruction to the isomorphism.

Regarding the case $S = \mathbb{R}^d$, the proof in [4, Sec. 8] requires a few small changes: In the statement of Proposition 8.5 there, one needs to replace the de-Rham complex of the manifold with the de-Rham complex with compact support, and the direct product with direct sum. The maps r, δ which appear there will still be well defined by our local finiteness assumption on the cover, and the assumption that U_i's are bounded. The proof requires no change. Then, the double complex in the definition of Proposition 8.8 should also be defined using direct sum rather than direct product, but again there is no change in the proof. Given these changes in definitions, the proof of Theorem 8.9 (also for the almost good case) is unchanged.

The second standard result, which is a consequence of Poincaré duality, is the following:

▶ **Theorem 9.** *For a compact smooth oriented manifold S of dimension d (such as $\mathbb{S}^d$),*

$$H^d_{dR}(S) \simeq \mathbb{R}.$$

Similarly, for $S = \mathbb{R}^d$, we have $H^d_{dR,c}(\mathbb{R}^d) \simeq \mathbb{R}$.

See, for example, [4, Sec. 7] for the compact case, and [4, Sec. 4] for $\mathbb{R}^d$.

Theorems 8 and 9 yield:

▶ **Corollary 10.** *If S is a compact smooth orientable manifold (such as $\mathbb{S}^d$), and $\mathcal{U}$ is a good or an almost good finite cover, then*

$$\check{H}^d(\mathcal{U}, \underline{\mathbb{R}}) = \mathbb{R}.$$

Similarly, if $S = \mathbb{R}^d$ and $\mathcal{U}$ is a locally finite good or almost good cover whose sets are bounded, then $\check{H}^d_c(\mathcal{U}, \underline{\mathbb{R}}) = \mathbb{R}$.

Proof of Propositions 5 and 6. We show that there must exist $d+1$ T_i's whose intersection is non-empty. This clearly implies that for achieving any positive error resilience, at least $d+1$ colors are needed.

Assume on the contrary that any $(d+1)$-intersection of the T_i's is empty. Let U_i be as in the statement of the Propositions. Then by definition, they form an almost good cover. All intersections of at least $d+1$ U_i's are empty by our assumptions. Therefore, there are no $d-$simplices, and so $C^d(\mathcal{U}, \underline{\mathbb{R}}) = 0$. Thus, in the compact case, $\check{H}^d(\mathcal{U}, \underline{\mathbb{R}}) = 0$. But on the other hand, by Corollary 10,

$$\check{H}^d(\mathcal{U}, \underline{\mathbb{R}}) \simeq \mathbb{R},$$

a contradiction. For $\mathbb{R}^d$ the same argument works, with $\check{H}^d_c(\mathcal{U}, \underline{\mathbb{R}})$ in place of $\check{H}^d(\mathcal{U}, \underline{\mathbb{R}})$.

4 Upper Bounds on the Error Resilience

In this section we consider tilings of $\mathbb{R}^d$ by tiles $T_1, T_2, \ldots$ of volume at most 1. Each point in $\mathbb{R}^d$ is colored in one of $k \geq d+1$ colors, and our goal is to maximize the minimal distance t between two points of the same color that belong to different tiles. (The maximum is taken over all possible tilings that satisfy the mild regularity conditions stated in Section 2 and over all possible colorings.) Clearly, the error resilience of a rounding scheme based on such a colored tiling is $t/2$.

We present two upper bounds on t, using the Brunn-Minkowski inequality and results on sphere packing. Another bound, using the Minkowski-Steiner formula, is presented in the full version of the paper (see [13]).

The basic idea behind our upper bound proofs is as follows. Assume we have a colored tiling of $\mathbb{R}^d$, with minimal distance t. Pick a single color – say, black – and consider all black tiles inside a large cube S. We obtain a new collection of tiles $T'_1, T'_2, \ldots, T'_m$ that covers part of S. The assumption that the minimal distance between two same-colored points in different tiles is t implies that if we inflate each black tile T'_i into its open parallel outer body of radius $t/2$,

$$T''_i = \{x : \exists y \in T'_i, |x-y| < t/2\}, \tag{1}$$

then the inflations T''_i are pairwise disjoint. Hence, the sum of their volumes essentially cannot exceed the volume of the large cube, and this allows bounding t from above.

4.1 An upper bound using the Brunn-Minkowski inequality

The inflations T''_i can be represented in terms of the *Minkowski sum* of sets in $\mathbb{R}^d$.

▶ **Definition 11.** *For $A, B \subset \mathbb{R}^d$, the Minkowski sum of A, B is $A+B = \{a+b : a \in A, b \in B\}$.*

In terms of this definition, we have

$$T''_i = T'_i + B(0, t/2), \tag{2}$$

where $B(0, t/2)$ is an open ball of radius $t/2$ around the origin. This allows us to lower bound the volume of each T''_i, using the classical Brunn-Minkowski (BM) inequality (see, e.g., [5]). Recall the inequality asserts the following.

▶ **Theorem 12** (Brunn-Minkowski)**.** *Let A, B be compact sets in $\mathbb{R}^d$. Then*

$$\lambda(A+B)^{1/d} \geq \lambda(A)^{1/d} + \lambda(B)^{1/d},$$

where $\lambda(X)$ is the volume of X (formally, the d-dimensional Lebesgue measure of X).

▶ **Proposition 13.** *Let $T_1, T_2, \ldots$ be a k-colored tiling of $\mathbb{R}^d$, with tiles of volume ≤ 1 and minimal distance t. Then*

$$t \leq \left(\frac{2\Gamma(d/2+1)^{1/d}}{\sqrt{\pi}} \right) \cdot (k^{1/d} - 1),$$

where $\Gamma(\cdot)$ is the Gamma function.

Proof. Consider a cube S such that $\lambda(S) = n^d$ (for some "large" n). By the pigeonhole principle, there exists a color (say, black) that covers at least n^d/k of the volume of S. Look at the black tiles whose intersection with S is non-empty, and denote their intersections with S by $T'_1, T'_2, \ldots, T'_m$. Hence, we have m "black" subsets of S, each of volume at most 1, whose total volume is at least n^d/k.

For each T'_i, define $T''_i = T'_i + B(0, t/2)$. By assumption, the regions T''_i are disjoint. Furthermore, they are included in $S + B(0, t/2)$ whose volume is less than $(n+t)^d$. Hence,

$$\sum_i \lambda(T''_i) \leq (n+t)^d. \tag{3}$$

By the Brunn-Minkowski inequality, we have

$$\forall i : \lambda(T''_i)^{1/d} \geq \lambda(T'_i)^{1/d} + (b_{t/2})^{1/d},$$

where $b_{t/2}$ is the volume of the d-dimensional ball $B(0, t/2)$. Thus,

$$\forall i : \lambda(T''_i) \geq \sum_{j=0}^{d} \binom{d}{j} \lambda(T'_i)^{j/d} (b_{t/2})^{1-j/d}.$$

Summing over i and using (3), we get

$$(n+t)^d \geq \sum_{i=1}^{m} \sum_{j=0}^{d} \binom{d}{j} \lambda(T'_i)^{j/d} (b_{t/2})^{1-j/d}. \tag{4}$$

As $0 \leq \lambda(T'_i) \leq 1$, for any $0 \leq j \leq d$ we have $\sum_i \lambda(T'_i)^{j/d} \geq \sum_i \lambda(T'_i) \geq n^d/k$, and hence we obtain

$$(n+t)^d \geq \frac{n^d}{k} \cdot \left(1 + b_{t/2}^{1/d}\right)^d.$$

This implies

$$(1 + \frac{t}{n}) k^{1/d} - 1 \geq b_{t/2}^{1/d} = \frac{\pi^{1/2}}{\Gamma(d/2+1)^{1/d}} \cdot \frac{t}{2}.$$

Letting $n \to \infty$ and rearranging, we obtain

$$t \leq \left(\frac{2\Gamma(d/2+1)^{1/d}}{\sqrt{\pi}} \right) \cdot (k^{1/d} - 1),$$

as asserted. ◀

Asymptotic upper bound. For a large number $k \gg d$ of colors, Proposition 13 gives the upper bound

$$t \leq (\sqrt{\frac{2}{\pi e}} + o_d(1)) \sqrt{d} k^{1/d},$$

as follows from (5). This bound is not far from being tight. Indeed, its dependence on k is correct, as it can be easily matched by a periodic cubic tiling, in which each tile is a cube with side length 1 and the basic unit is a large cube with side length $k^{1/d}$ that contains each color in exactly one tile (in the same order). Moreover, even regarding the "coefficient" of $k^{1/d}$, the optimal asymptotic upper bounds for $d = 3, 8, 24$ which we obtain below via the sphere packing problem, improve over this bound by only a small factor.

Upper bound for $k = d + 1$ colors. To estimate the upper bound we obtain in this case, note that

$$(d+1)^{1/d} - 1 = (1 + o_d(1))\frac{\ln(d)}{d}, \qquad \text{and} \qquad \Gamma(d/2+1)^{1/d} = \left(\frac{1}{\sqrt{2e}} + o_d(1)\right)\sqrt{d}. \quad (5)$$

Therefore, the bound we obtain in this case is

$$t \leq \left(\sqrt{\frac{2}{\pi e}} + o_d(1)\right)\frac{\ln d}{\sqrt{d}},$$

which implies that the error resilience decreases to zero as d tends to infinity. For comparison, the lower bound we obtain in Section 5.3 is $t \geq \Omega(1/d)$.

Upper bounds for small values of d, k. For $d = 3, k = 4$, the bound is

$$t \leq \frac{2\Gamma(2.5)^{1/3}}{\sqrt{\pi}} \cdot (4^{1/3} - 1) \approx 0.729.$$

For $d = 2$ and $k = 3, 4$, the upper bounds we obtain are $t \leq 0.826$ and $t \leq 1.128$, respectively. For comparison, the best constructions we have in these settings satisfy $t = 0.5$, $t = 1/\sqrt{2}$, and $t = 1$, respectively.

Discussion. The upper bound given by Proposition 13 is loose in two ways. One source of loss is the application of the Brunn-Minkowski inequality. Here, the inequality is tight if the tiles are *balls*, and the farther they are from balls, the larger is the loss. Another source of loss is the space left between the inflations, that is not taken into account in the proof.

Interestingly, there is a dichotomy between these two sources of loss. As follows from the sphere packing problem, when the tiles are balls (and so, there is no loss in the BM inequality), the space between the inflations (and so, the loss of the second type) is relatively large. The space between the inflations can be made smaller if the tiles are taken to be polytopes with a few vertices. However, this comes at the expense of increased loss in the BM inequality, as is demonstrated in the full version of the paper.

Optimality of our 1-dimensional rounding scheme. The argument described above gives an easy proof of the optimality of the 1-dimensional rounding scheme presented in the introduction. Indeed, consider a 2-colored tiling of the line and look at the segment $I = [-n, n]$ for some large n. By the pigeonhole principle, we may assume that black tiles cover at least half of I. By the 1-dimensional Brunn-Minkowski inequality, for each black tile $T'_i \subset I$ and the corresponding inflation $T''_i = T'_i + (-t/2, t/2)$, we have $\lambda(T''_i) \geq \lambda(T'_i) + t$. As $\forall i : \lambda(T'_i) \leq 1$, there are at least n tiles. Since the T''_i's are pairwise disjoint and included in $[-n-1, n+1]$, we obtain

$$2n + 2 \geq \sum_i \lambda(T''_i) \geq \sum_i \lambda(T'_i) + \sum_i t \geq n + nt,$$

and thus, $t \leq (n+2)/n$. By letting n tend to infinity, we obtain $t \leq 1$, implying that the error resilience of any two-colored tiling of the line is at most $1/2$.

4.2 An upper bound using the Sphere Packing problem

Our second upper bound uses reduction to the classical *sphere packing* problem, which asks for the maximal possible *density* of a set of non-intersecting congruent spheres in $\mathbb{R}^d$.

▶ **Definition 14.** *The density of a sphere packing (i.e., collection of pairwise disjoint congruent spheres) $P = \cup P_i$ in $\mathbb{R}^d$ is*

$$\limsup_{r\to\infty} \frac{\lambda\left(B(0,r) \cap \bigcup P\right)}{\lambda(B(0,r))}.$$

Intuitively, this measures the fraction of the volume of a large ball covered by the packing.

▶ **Notation 15.** *Denote the maximal density of a sphere packing in $\mathbb{R}^d$ by δ_d, and the volume of the unit ball $B(0,1) \subset \mathbb{R}^d$ by $v_d = \pi^{d/2}/\Gamma(d/2+1)$.*

▶ **Proposition 16.** *Let $T_1, T_2, \ldots$ be a tiling of $\mathbb{R}^d$ in k colors, with tiles of volume ≤ 1 and minimal distance t. Then*

$$t \leq \left(2(\delta_d/v_d)^{1/d}\right) \cdot k^{1/d} = \left(\frac{2\Gamma(d/2+1)^{1/d} \cdot \delta_d^{1/d}}{\sqrt{\pi}}\right) \cdot k^{1/d}.$$

Note that the asymptotic upper bound of Proposition 16 is stronger than the asymptotic upper bound that follows from Proposition 13 by the constant factor $(\delta_d)^{1/d}$. For small values of k, the upper bound given by Proposition 13 is stronger.

Proof. Let T be a k-colored tiling of $\mathbb{R}^d$ that satisfies the assumptions of the proposition, and consider the sequence of balls $\{B(0,n)\}_{n=1,2,3,\ldots}$. By the pigeonhole principle, there exists a color (say, black) such that for each n_ℓ in an infinite subsequence $\{n_\ell\}_{\ell=1,2,\ldots}$, the intersection of the black tiles with the ball $B(0,n_\ell)$ has volume of at least

$$\lambda(B(0,n_\ell))/k = \frac{n_\ell^d \cdot v_d}{k}.$$

As the volume of each tile is at most 1, we know that for each n_ℓ, the number of black tiles that intersect $B(0,n_\ell)$ is at least $n_\ell^d v_d/k$.
Pick some value n_ℓ, denote the intersections of black tiles with $B(0,n_\ell)$ by $T_1', T_2', \ldots$, and take one point x_i from each tile T_i'. As the minimal distance between two black points in different tiles is t, balls of radius $t/2$ around the points x_i are pairwise disjoint. Hence, their total volume is at least

$$\frac{n_\ell^d \cdot v_d}{k} \cdot (t/2)^d \cdot v_d.$$

On the other hand, each such ball is contained in the ball $B(0,(n_\ell+t))$ (since its radius is $t/2$, and it contains a point in $B(0,n_\ell)$). This implies that for any $\epsilon > 0$ and for a sufficiently large $\ell = \ell(\epsilon)$, the total volume of these balls must be smaller than $(1+\epsilon)\delta_d \cdot \lambda(B(0,n_\ell+t))$, as otherwise, the infinite collection of the balls $B(x_i,t/2)$ (where for each ball $B(0,n_\ell)$ we select x_i's in the way described above, respecting the x_i's selected for smaller values of n_ℓ) would be a sphere packing of $\mathbb{R}^d$ whose density is larger than δ_d. Therefore, for a sufficiently large n_ℓ, we have

$$\frac{n_\ell^d \cdot v_d}{k} \cdot (t/2)^d \cdot v_d \leq (1+\epsilon)(1+\frac{t}{n_\ell})^d \delta_d \cdot n_\ell^d v_d,$$

and letting $\epsilon \to 0$ and $n_\ell \to \infty$, we obtain $t \leq 2(\delta_d/v_d)^{1/d} \cdot k^{1/d}$, as asserted. ◀

Discussion. In the two last decades, there has been a tremendous progress in the research of the sphere packing problem. In 2005, Hales ([18], see also [17]) solved the problem for $d = 3$, proving a 17'th century conjecture of Kepler. Three years ago, in a beautiful short paper, Viazovska [25] solved the problem for $d = 8$, and shortly after, Cohn, Kumar, Miller, Radchenko, and Viazovska [6] used Viazovska's method along with other tools to solve the problem for $d = 24$. For other dimensions, the problem is still open. We can use the results of [6, 18, 25], along with the value of δ_2 that was obtained already by Lagrange, to obtain tight upper bounds on t in dimensions $2, 3, 8$, and 24.

- For $d = 2$, Lagrange (1773) showed that $\delta_2 = \frac{\pi}{2\sqrt{3}} \approx 0.907$. Hence, we obtain the bound $t \leq \frac{2^{1/2}}{3^{1/4}} \cdot k^{1/2} \approx 1.074k^{1/2}$.
- For $d = 3$, Hales [18, 17] showed that $\delta_3 = \frac{\pi}{3\sqrt{2}} \approx 0.740$. Hence, we obtain the bound $t \leq 2^{1/6} \cdot k^{1/3} \approx 1.122k^{1/3}$.
- For $d = 8$, Viazovska [25] showed that $\delta_8 = \frac{\pi^4}{2^4 4!} \approx 0.254$. Hence, we obtain the bound $t \leq \sqrt{2}k^{1/8} \approx 1.414k^{1/8}$.
- For $d = 24$, Cohn et al. [6] showed that $\delta_{24} = \frac{\pi^{12}}{12!} \approx 0.0019$. Hence, we obtain the bound $t \leq 2k^{1/24}$.

As we show in Section 5, all these bounds are asymptotically tight.

Using the same method, we can leverage any upper bound for the sphere packing problem (namely, upper bound on δ_d) into an upper bound on the error resilience of a rounding scheme in the corresponding dimension. The best currently known bound on δ_d for a large d is by Cohn and Zhao [7], who obtained a constant-factor improvement over the classical Kabatiansky-Levenshtein [21] bound $\delta_d \leq 2^{-(0.5990+o(1))d}$. A list of conjectured bounds for $d \leq 10$ can be found in [8].

5 Lower Bounds on the Error Resilience

In this section (like in Section 4), we consider tilings of $\mathbb{R}^d$ by tiles $T_1, T_2, \ldots$ of volume at most 1. Each point in $\mathbb{R}^d$ is colored in one of $k \geq d + 1$ colors, and our goal is to maximize the minimal distance t between two points of the same color that belong to different tiles.

We obtain lower bounds on t for various values of d, k, by constructing explicit tilings. First, we present *brick-wall* tilings, which provide lower bounds for small values of d, k. Then we present tilings based on *close sphere packing*, which show the tightness of our asymptotic bounds for $d = 2, 3, 8, 24$. Finally, we inductively construct a *dimension-reducing* tiling which shows that for any dimension d, positive error resilience can be obtained with $d + 1$ colors.

5.1 Brick-wall tilings

We begin with a tiling of the plane, and then use it to construct a tiling of $\mathbb{R}^3$.

5.1.1 2-dimensional brick wall

In the 2-dimensional brick wall tiling with k colors, demonstrated in Figure 2, each tile is a rectangle with side lengths $\sqrt{(k-2)/2}$ and $\sqrt{2/(k-2)}$ (and so, the area of each tile is 1). The tiling is periodic, where the basic unit is two rows of adjacent rectangles, colored in a round robin fashion. For an even k, the second row is placed exactly below the first row, and the sequence of colors is shifted by $k/2$. For an odd k, the second row is indented by half a brick (making the tiling look like a brick wall), and the sequence is shifted by $(k + 1)/2$.

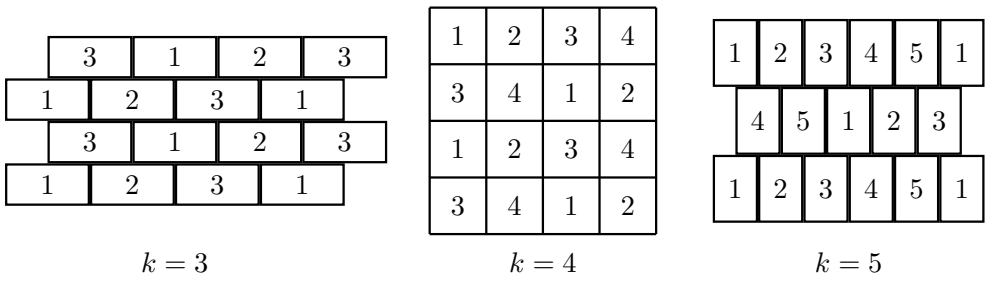

Figure 2 The 2-dimensional brick wall tiling for $k = 3, 4, 5$ colors. The ratio between the width and the height of each tile is $2 : k - 2$.

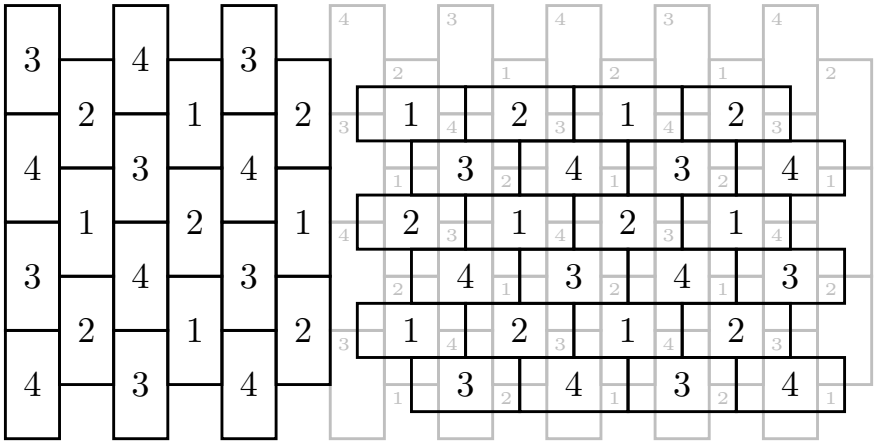

Figure 3 The 3-dimensional brick wall tiling.

It is easy to see that the minimal distance between two same-colored points in different tiles is $\sqrt{(k-2)/2}$. (This distance is attained both in the vertical and in the horizontal directions. Having the same minimal distance in both directions is the optimization that dictates the side lengths of the bricks.) In particular, we obtain the lower bounds $t \geq 1/\sqrt{2}$ for 3 colors, $t \geq 1$ for 4 colors, and $t \geq \sqrt{3/2}$ for 5 colors.

5.1.2 3-dimensional brick wall

The 3-dimensional brick wall (3BW) tiling, demonstrated in Figure 3, is a periodic tiling of $\mathbb{R}^3$, colored in 4 colors. In order to present the tiling, we need an auxiliary notation.

Notation. Consider the slab $D = \mathbb{R} \times \mathbb{R} \times [z_1, z_2] \subset \mathbb{R}^3$. We say that a tiling $T_1, T_2, \ldots$ of D is a *fattened plane tiling* if there exists a tiling $T'_1, T'_2, \ldots$ of the plane such that $\forall i : T_i = T'_i \times [z_1, z_2]$.

The structure of 3BW. The 3BW tiling is periodic, where the basic unit consists of two brick wall layers, placed one on top of the other in the way presented in Figure 3. Each brick wall layer is a fattening of a brick wall tiling of the plane. The underlying plane tiling is a

15	16	13	14	15	16	13	14
1	2	3	4	1	2	3	4

15	16	13	14	15	16	13	14
1	2	3	4	1	2	3	4

Figure 4 The honeycomb of rectangles tiling for $d = 2$ and $k = 16$ colors. The boundaries of the basic "large rectangles" are depicted in bold. The placement of the tiles in each single color corresponds to the honeycomb lattice.

periodic tiling, in which the basic unit consists of four columns of adjacent rectangles, where the even columns are indented by half a brick, making the tiling look like a brick wall. In the lower layer, in odd columns, the colors 1,2 are used alternately, and in even columns, the colors 3,4 are used alternately. Furthermore, the colors in the third and fourth columns are shifted by one, see Figure 3. In the upper layer columns are replaced by rows. Note that once the layers are placed, the coloring of one layer fully determines the coloring of the other.

Analysis given in the full version of the paper shows that by taking $a = 1$ and fixing the height of each layer to be $1/2$, we obtain $t = 1/2$, and thus, error resilience of 0.25.

5.2 Tilings based on close sphere packing

We present the tiling in the case of $\mathbb{R}^2$, where it is easier to describe and analyze, and then we generalize it to higher dimensions.

5.2.1 Honeycomb of rectangles

In the honeycomb of rectangles tiling of the plane with $k = m^2$ colors, each tile is a rectangle with side lengths a and $1/a$, where

$$a = \left(\frac{m^2 - 2m + 1}{\frac{3}{4}m^2 - m}\right)^{1/4} \geq \left(\frac{4}{3} - \frac{8}{3m}\right)^{1/4}. \tag{6}$$

The tiling is periodic, where the basic unit is composed as follows. First, we construct a basic "large rectangle", which is an m-by-m square block of tiles, using all the $k = m^2$ colors (in arbitrary order). Then, the basic unit of the tiling is two "fat rows" of adjacent large rectangles, where the second row is indented by half a large rectangle. The coloring of each large rectangle is the same. The tiling, for $k = 16$, is demonstrated in Figure 4. Note that the tiles colored in some single color form the shape of a honeycomb lattice (including the centers of the hexagons). This is why we call the tiling "honeycomb of rectangles".

It is easy to see that the minimal horizontal and diagonal distances between two same-colored tiles are

$$(m-1)a \qquad \text{and} \qquad \sqrt{\left(\frac{m-1}{a}\right)^2 + \left(\left(\frac{m}{2}-1\right)a\right)^2},$$

respectively. By choosing a such that the two distances are equal, we obtain (6), and the asymptotic lower bound

$$t \geq \left(\frac{4}{3} - \frac{8}{3m}\right)^{1/4} \cdot (m-1) \geq (4/3)^{1/4} \cdot \sqrt{k} - O(1) \approx 1.074\sqrt{k} - O(1),$$

that matches the upper bound obtained above up to an additive $O(1)$ term.

5.2.2 Close packing of boxes

Motivation. This construction, a k-colored tiling of $\mathbb{R}^3$ where $k \gg 3$, is a natural generalization to $\mathbb{R}^3$ of the "honeycomb of rectangles" tiling presented in Section 5.2.1. The idea behind the construction is to choose an optimal sphere packing in $\mathbb{R}^3$, and construct a fattened plane tiling in which the tiles in each color are placed at the centers of the spheres of the packing. (Recall that as the number of colors is large, the size of each tile is negligible with respect to the size of its inflation, and hence, we can treat the tiles as single points.)

We use the classical HCP lattice (one of the most common *closed packings*, see [9]), which corresponds to a periodic sphere packing in which the basic unit is two hexagonal layers of spheres, where in the top layer, each sphere is placed on top in the hollow between three spheres in the bottom layer. The coordinates of the centers of these spheres are:

$$(r,r,r), (3r,r,r), (5r,r,r), \ldots, (2r, r+\sqrt{3}r, r), (4r, r+\sqrt{3}r, r), (6r, r+\sqrt{3}r, r), \ldots$$

for the bottom layer, and

$$(2r, r+\frac{\sqrt{3}}{3}r, r+\frac{2\sqrt{6}}{3}r), (4r, r+\frac{\sqrt{3}}{3}r, r+\frac{2\sqrt{6}}{3}r), \ldots, (r, r+\frac{4\sqrt{3}}{3}r, r+\frac{2\sqrt{6}}{3}r), (3r, r+\frac{4\sqrt{3}}{3}r, r+\frac{2\sqrt{6}}{3}r), \ldots$$

for the top layer.

The structure of the tiling. Assume that the number of colors is $k = m^3$. Each tile is a box with side lengths (a, b, c) to be determined below, and the basic unit is a "large box", which is an $m \times m \times m$ cubic block of tiles, using all the $k = m^3$ colors (in arbitrary order). Then, the basic unit of the tiling is a two-layer fattened plane tiling, in which each layer is a fattened copy of the "honeycomb of rectangles" tiling. The upper layer is shifted by $\frac{m}{2}a$ in the x-coordinate and by $\frac{\sqrt{3}m}{6}a$ in the y-coordinate, so that the corners of the large boxes lie in the coordinates of the sphere centers described above (for $r = \frac{m}{2}a$). A quick calculation shows that in order to make this possible, the proportion $(a : b : c)$ should be *approximately* $(2 : \sqrt{3} : 2\sqrt{6}/3)$ (where we neglect the size of each tile with respect to the size of the inflation, which can be absorbed in an $1 - o(1)$ multiplicative factor in the final value of t). The volume of each tile is clearly abc. In order to make the volumes of all tiles equal to 1, we need

$$a \cdot \frac{\sqrt{3}}{2}a \cdot \frac{\sqrt{6}}{3}a = 1,$$

and thus, $a = (6/\sqrt{18})^{1/3} = 2^{1/6} \approx 1.122$. Hence, the side lengths of each tile are

$$(2^{1/6}, 3^{1/2}/2^{5/6}, 2^{2/3}/3^{1/2}) \approx (1.122, 0.972, 0.916),$$

and the minimal distance between two same-colored points in different tiles is

$$(m-1)a = (2^{1/6} - o(1))k^{1/d},$$

which matches the upper bound proved in Section 4.1.

Generalization to higher dimensions. A similar tiling can be constructed to match any *lattice sphere packing*, assuming the number of colors k is sufficiently large with respect to d. Hence, any dense lattice sphere packing can be translated into a lower bound on the asymptotic error resilience of rounding schemes in the corresponding dimension. In particular, as the E_8 *lattice* and the *Leech lattice* which attain the maximal possible density of sphere packings in dimension 8 and 24 (respectively) are lattice packings, they can be translated to box tilings showing that the asymptotic upper bounds on the error resilience in $\mathbb{R}^8$ and $\mathbb{R}^{24}$ proved in Section 4.1 are tight.

5.3 The dimension reducing tiling

We exemplify the tiling in $\mathbb{R}^3$, but it will be apparent how to generalize it to higher dimensions.

Informal description of the tiling. Informally, the tiling is constructed as follows.

Step 1: We begin with dividing $\mathbb{R}^3$ into basic cubes with side length a (to be determined below), depicted in Figure 5(a). Then, we make the "interior" of each basic cube into a tile and give all these tiles the color 1. In order to keep a minimal distance of t between two points colored 1 in different tiles, we must leave a neighborhood of width $t/2$ in each side of each facet of the basic cube. Hence, we are left with "fattened" walls of total width t. The part of such a wall included in a basic cube is shown in Figure 5(b).

Step 2: We make the "interior" of each wall (i.e., fattened facet) into a tile and give all these tiles the color 2, as is demonstrated in Figure 5(b). (Note that each tile contains points from two adjacent basic cubes.) In order to keep a minimal distance of t between two points colored 2 in different tiles, we must leave a neighborhood of $t/\sqrt{2}$ near each edge (i.e., intersection of facets), as is shown in Figure 5(c). Hence, we are left with a "fattened skeleton".

Step 3: We make the "interior" of each edge of the skeleton into a tile and give all these tiles the color 3, as is shown in Figure 5(d). (Note that each tile contains points from four adjacent basic cubes.) In order to keep a minimal distance of t between two points colored 3 in different tiles, we must leave an additional neighborhood of $t/\sqrt{2}$ near each vertex (i.e., intersection of edges), as is demonstrated in Figure 5(d). Hence, we are left with neighborhoods of the corners (a.k.a. vertices).

Step 4: We make the neighborhoods of the corners into tiles and give them the color 4. (Note that each tile contains points from 8 adjacent basic cubes.) We have to make sure that the distance between each two such "fattened corners" is at least t, and this requirement dictates the choice of t.

The analysis of the tiling (including its formal definition and explanation of the choice of parameters) is presented in the full version of the paper. It is clear that the resulting 4-colored tiling can be generalized into a $(d+1)$-colored tiling of $\mathbb{R}^d$.

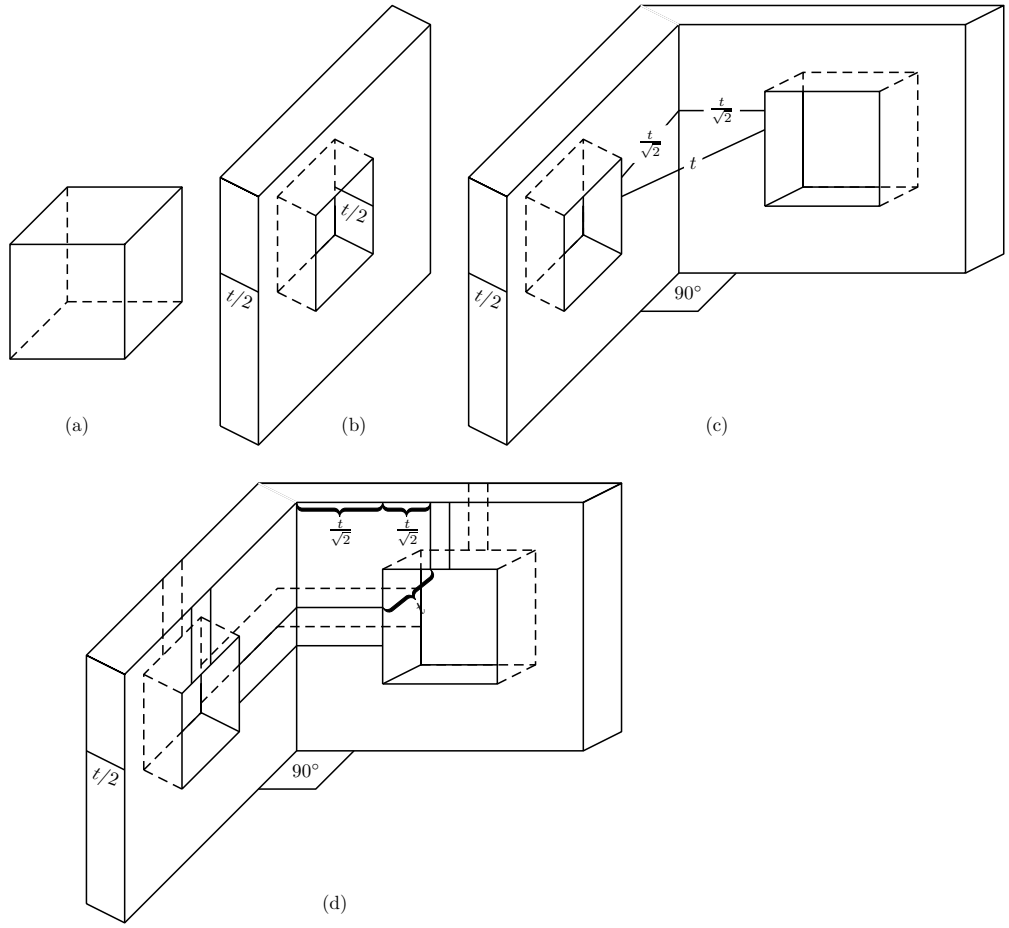

Figure 5 The dimension reducing tiling. Part (a) shows the basic cubes we start with. Part (b) shows a fattened wall of width $t/2$, and its interior that gets the color 2. Part (c) shows where the minimal distance between two tiles colored 2 is attained. Part (d) presents (in full lines) the interiors of the fattened edges that get the color 3 and shows where the minimal distance between two such tiles is attained.

Algebraic Proof Systems

Toniann Pitassi ✉
University of Toronto, Canada

Abstract

Given a set of polynomial equations over a field F, how hard is it to prove that they are simultaneously unsolvable? In the last twenty years, algebraic proof systems for refuting such systems of equations have been extensively studied, revealing close connections to both upper bounds (connections between short refutations and efficient approximation algorithms) and lower bounds (connections to fundamental questions in circuit complexity.)

The Ideal Proof System (IPS) is a simple yet powerful algebraic proof system, with very close connections to circuit lower bounds: [2] proved that lower bounds for IPS imply $VNP \neq VP$, and very recently connections in the other direction have been made, showing that circuit lower bounds imply IPS lower bounds [3, 1].

In this talk I will survey the landscape of algebraic proof systems, focusing on their connections to complexity theory, derandomization, and standard proposional proof complexity. I will discuss the state-of-the-art lower bounds, as well as the relationship between algebraic systems and textbook style propositional proof systems. Finally we end with open problems, and some recent progress towards proving superpolynomial lower bounds for bounded-depth Frege systems with modular gates (a major open problem in propositional proof complexity).

A Very Sketchy Talk

David P. Woodruff ✉
Carnegie Mellon University, Pittsburgh, PA, USA

Abstract

We give an overview of dimensionality reduction methods, or sketching, for a number of problems in optimization, first surveying work using these methods for classical problems, which gives near optimal algorithms for regression, low rank approximation, and natural variants. We then survey recent work applying sketching to column subset selection, kernel methods, sublinear algorithms for structured matrices, tensors, trace estimation, and so on. The focus is on fast algorithms. This is a short survey accompanying an invited talk at ICALP, 2021.

1 Introduction

Sketching, or data dimensionality reduction, is a popular tool for speeding up algorithms in machine learning, optimization, and randomized numerical linear algebra.

In the overconstrained least squares regression problem one is given an $n \times d$ matrix A, $n > d$, together with an $n \times 1$ vector b, and one is tasked with finding an $x \in \mathbb{R}^d$ for which $\|Ax - b\|_2^2 = \sum_{i=1}^n (\langle A_i, x\rangle - b_i)^2$ is as small as possible, where A_i is the i-th row of A, b_i is the i-th entry of b, and $\langle A_i, x\rangle$ denotes the inner product between A_i and x. Geometrically, in $\mathbb{R}^n$ one can view this as finding the vector Ax which is closest to b in the column span of A (which is a d-dimensional subspace) in terms of Euclidean distance, that is, Ax is just the projection of b onto the column span of A. Alternatively, in $\mathbb{R}^{d+1}$ one can think of having n points, the i-th of which is (A_i, b_i), and one is trying to find a hyperplane defined by x so as to minimize the sum of squares of distances between the points $(A_i, \langle A_i, x\rangle)$ and the points (A_i, b_i). There is a closed-form solution to this problem of the form $x = A^- b$, where A^- is the Moore-Penrose pseudoinverse of A, and the optimal x can be computed in $O(nd^2)$ time by computing the singular value decomposition (SVD) [1] of A. While this is an exact solution, the $O(nd^2)$ running time is prohibitive for large values of n and moderate values of d.

The sketch-and-solve paradigm instead solves this problem by first choosing a random matrix $S \in \mathbb{R}^{k \times n}$, where $k \ll n$. One then computes $S \cdot A$, which is a small $k \times n$ matrix, as well as $S \cdot b$, which is a small $k \times 1$ vector. One then solves the much smaller regression problem $\min_x \|SAx - Sb\|_2$ by computing its minimizer $x' = (SA)^- Sb$, and the hope is that $\|Ax' - b\|_2^2 \leq (1+\epsilon)\|Ax^* - b\|_2$, where $x^* = A^- b$ is the minimizer of $\|Ax - b\|_2^2$.

[1] This can be sped up using theoretical algorithms for fast matrix multiplication, giving $O(n \cdot d^{\omega-1})$ time, where $\omega \approx 2.376$ is the exponent of fast matrix multiplication.

A natural question is how to choose the sketching matrix S. One could choose S to be a $k \times n$ matrix of independent and identically distributed $N(0, 1/k)$ random variables (normal with mean 0 and variance $1/k$), where $k = O(d/\epsilon^2)$, which turns out to work (see, e.g., discussion in [39]), but then computing $S \cdot A$ would take at least nd^2 time naïvely, which although it can be sped up with fast matrix multiplication, is slower than just computing the exact solution $x^* = A^- b$. Sárlos [32] pioneered the sketch-and-solve paradigm and observed that one could instead choose S to be a so-called Subsampled Randomized Hadamard Transform, that is, $S = P \cdot H \cdot D$, where D is an $n \times n$ diagonal matrix with independent diagonal entries each chosen uniformly in $\{-1, 1\}$, H is the $n \times n$ Hadamard matrix (assuming n is a power of 2), and P uniformly samples $d \operatorname{poly}(\log d)/\epsilon^2$ entries of whichever vector it is applied to (see [20] for optimizations to the logarithmic factors). Then $S \cdot A$ and $S \cdot b$ can now be computed in $O(nd \log n)$ time; indeed, this follows since D and P can be applied to a vector in $O(n)$ time, and using the recursive structure defining H the matrix H can be applied to a vector in $O(n \log n)$ time. Consequently, $SA = PHDA$ can be computed in $O(nd \log n)$ time. One can then solve $\min_x \|SAx - Sb\|_2$ in $d^3 \operatorname{poly}(\log d)/\epsilon^2$ time, and the solution x' can be shown to, with large probability, satisfy $\|SAx' - Sb\|_2 \leq (1+\epsilon)\|Ax^* - b\|_2$. This gives a runtime of $\tilde{O}(nd \log n + d^3/\epsilon^2)$, where the notation $\tilde{O}(f)$ denotes $f \cdot \operatorname{poly}(\log f)$. The additive d^3/ϵ^2 term can be further improved using fast matrix multiplication algorithms.

This was later improved by Clarkson and Woodruff [14] who showed that one could instead choose the so-called CountSketch matrix S [12] as one's sketching matrix; the analysis was later simplified and improved in [24, 27, 8, 17]. Here S is $k \times n$, where $k = O(d^2/\epsilon^2)$ is again independent of the large dimension n. The key property is that S has a single randomly chosen non-zero entry per column, which is chosen at a uniformly random position and is uniform in $\{-1, 1\}$, and chosen independently across the columns. The key property is that now SA and Sb can be computed in $\operatorname{nnz}(A)$ time, where $\operatorname{nnz}(A)$ denotes the number of non-zero entries of A, and that the solution x' to $\min_x \|SAx - Sb\|_2$ is such that $\|Ax' - b\|_2 \leq (1+\epsilon)\|Ax^* - b\|_2$. The proof in [14] departed from previous proofs which first argued that any fixed vector y has its norm preserved up to a $(1 \pm \epsilon)$-multiplicative factor with probability $1 - 2^{-O(d)}$; after this, a standard net argument could then be used. In fact CountSketch does not have this property and [14] instead observed that the $2^{O(d)}$ vectors one is interested in preserving the norms of, all live in a low-dimensional subspace, and consequently, the number of "heavy coordinates" as one ranges over all vectors in the subspace is a small subset of all possible n coordinates. This then enables CountSketch to work in the sketch-and-solve paradigm, and gives an overall algorithm for solving regression in $\operatorname{nnz}(A) + \operatorname{poly}(d/\epsilon)$ time.

While we have the property that $\|Ax' - b\|_2^2 \leq (1+\epsilon)\|Ax^* - b\|_2^2$, this guarantee is often not sufficient in machine learning and optimization tasks, and one would instead like to bound $\|x^* - x'\|_2^2$. Indeed, one could hope x' is close to a "ground truth" hyperplane and therefore give good generalization error. To do so, note that

$$\begin{aligned}
\|x^* - x'\|_2^2 &\leq \frac{\|Ax^* - Ax'\|_2^2}{\sigma_{min}^2(A)} \\
&\leq \frac{\|Ax' - b\|_2^2 - \|Ax^* - b\|_2^2}{\sigma_{min}^2(A)} \\
&\leq \frac{((1+\epsilon)^2 - 1)\|Ax^* - b\|_2^2}{\sigma_{min}^2(A)} \\
&\leq \frac{O(\epsilon)\|Ax^* - b\|_2^2}{\sigma_{min}^2(A)},
\end{aligned}$$

where the first inequality follows from the definition of the minimum singular value, the second inequality follows since $Ax^* - b$ and $Ax^* - Ax'$ are orthogonal, and the third inequality follows from the objective function guarantee discussed above. We note that this simple guarantee was significantly improved in [30], where the authors bounded $\|x^* - x\|_\infty^2$, i.e., the difference on every single coordinate; this improved analysis holds for the Subsampled Randomized Hadamard Transform as well as Gaussian sketches, but not CountSketch.

Another unsatisfactory aspect of the above is that the dependence on the approximation factor ϵ is polynomial, rather than polylogarithmic. To achieve the latter, one can combine sketching and optimization techniques in a somewhat different way. One can first run the sketch-and-solve paradigm with CountSketch with a constant $\epsilon_0 = 1/2$ to find an x' with $\|Ax' - b\|_2^2 \leq 3/2 \cdot \|Ax^* - b\|_2^2$. This step takes $\text{poly}(d)$ time independent of the value of ϵ. Let $x_0 = x'$. In parallel, one could compute $S \cdot A$ for a CountSketch matrix S with $\epsilon_0 = 1/2$. Then write $SA = QR$, where Q is a matrix with orthonormal columns; one could find QR by letting $SA = U\Sigma V^T$ be its SVD and setting $Q = U$. This step takes $\text{poly}(d)$ time independent of the value of ϵ. Let

$$\kappa(AR^{-1}) = \frac{\sigma_{max}^2(AR^{-1})}{\sigma_{min}^2(AR^{-1})}.$$

It is not hard to see that $\kappa(AR^{-1}) \leq 3$. Indeed, by the so-called subspace embedding property of S, we have for all x:

$$\frac{1}{2}\|Ax\|_2^2 \leq \|SAx\|_2^2 \leq \frac{3}{2}\|Ax\|_2^2.$$

This means for all unit vectors x, $\|AR^{-1}x\|_2^2 \leq (3/2)\|SAR^{-1}x\|_2^2 = 3/2$, and similarly for all unit vectors x, $\|AR^{-1}x\|_2^2 \geq (1/2)\|SAR^{-1}x\|_2^2 = 1/2$. Here the equalities follow from the fact that $SAR^{-1} = Q$, which has orthonormal columns, so $\|Qx\|_2^2 = 1$ for all unit vectors x. Using that $\sigma_{max}(B) = \sup_{\text{unit } x} \|Bx\|_2$ and $\sigma_{min}(B) = \inf_{\text{unit } x} \|Bx\|_2$ for a matrix B with more rows than columns, we have:

$$\sigma_{max}^2(AR^{-1}) \leq \frac{3}{2} \cdot \sigma_{max}^2(SAR^{-1}) = \frac{3}{2} \cdot 1 = \frac{3}{2}.$$

Here the equality follows from the fact that $SAR^{-1} = Q$, and Q has orthonormal columns, and thus $\sigma_{max}(Q) = \sigma_{min}(Q) = 1$. Similarly,

$$\sigma_{min}^2(AR^{-1}) \geq \frac{1}{2} \cdot \sigma_{min}^2(SAR^{-1}) = \frac{1}{2}.$$

Consequently, $\kappa(AR^{-1}) \leq 3$. At this point, one can simply run gradient descent on the function $f(x) = \frac{1}{2}\|AR^{-1}x - b\|_2^2$ with initial solution Rx_0. By standard arguments, the number of iterations required to get ϵ error is $O(\kappa \log(1/\epsilon)) = O(\log(1/\epsilon))$. Moreover, one never needs to explicitly compute $A \cdot R^{-1}$. Indeed, given an iterate x_t in some iteration t, one can compute $R^{-1}x_t$ and then $AR^{-1}x_t$, in $O(d^2 + \text{nnz}(A))$ time per iteration, and thus $O((\text{nnz}(A) + d^2)\log(1/\epsilon))$ time overall. This, together with the additive $O(\text{nnz}(A) + \text{poly}(d))$ time needed to find R^{-1} and x_0, gives an overall running time of $O((\text{nnz}(A) + d^2)\log(1/\epsilon) + \text{poly}(d))$. We refer the reader to [14] for further details.

2 Extensions

There are many related problems to regression (and other problems!) for which sketching can be applied, and we outline only a few here.

2.1 Ridge Regression

There are regularized variants of regression, such as ridge regression, where one instead seeks to minimize $\|Ax-b\|_2^2+\lambda\|x\|_2^2$, for a parameter $\lambda>0$. Here the $\lambda\|x\|_2^2$ term is known as the ridge or regularization, and encourages low-norm solutions. This formulation is useful both when $n>d$ as well as when $n<d$; in the latter case A is underconstrained, i.e., has more columns than rows, and without the regularization there are multiple solutions possible and one is often interested in a low-norm solution. We remark that low-norm solutions often have better properties for applications, e.g., may not overfit the data as much, and by setting λ to be large one encourages low norm solutions. For ridge regression, one can sketch A with a dimension that depends on the so-called statistical dimension $sd_\lambda(A)=\sum_i \frac{\sigma_i^2}{\lambda+\sigma_i^2}$, which is always bounded by the rank of A though can be much smaller if a few values σ_i are very large and λ is set appropriately. Sketching is thus immediately useful in the overconstrained case when $n>d$, since $sd_\lambda(A)$ may be much less than d, and so the sketching dimension is much smaller. In the underconstrained case, one often instead *sketches on the right*, setting up the problem $\min_y\|ARy-b\|_2^2+\lambda\|Ry\|_2^2$, for a sketching matrix R. In this case sketching ultimately allows for solving the problem in $\mathrm{nnz}(A)+\mathrm{poly}(sd_\lambda\sigma_1(A)/(\epsilon\lambda))$ time, which although depends on $\sigma_1(A)$, can still be useful. We note that one can combine sketching on both the left and the right for ridge regression; we refer the reader to [2, 3] and the references therein for further details and the history of sketching as applied to this problem.

2.2 Kernel Regression

Another application is kernel regression. In the kernel setting one is given n points $x^1,\ldots,x^n\in\mathbb{R}^d$ and one would like to apply an often non-linear mapping ϕ to "lift" them to a feature space. A notable example is the polynomial kernel of degree q, where $\phi:\mathbb{R}^d\to\mathbb{R}^{d^q}$ where $\phi(x)_{i_1,i_2,\ldots,i_q}=x_{i_1}\cdot x_{i_2}\cdots x_{i_q}$. One reason the polynomial kernel is so important is that one can often Taylor-expand other kernels, such as the Gaussian kernel, and approximate them by a polynomial kernel of large enough degree. Define the $d^q\times n$ matrix A with i-th column equal to $\phi(x^i)$. One would never want to compute this matrix, as the number d^q of rows is prohibitively large. Nevertheless, one would like to be able to solve optimization problems with respect to this matrix.

In particular, in the kernel ridge regression problem one seeks to find a vector $y\in\mathbb{R}^d$ so as to minimize $\|A^TAy-b\|_2^2+\lambda\|y\|_2^2$. Initial work [28] showed how, given vectors $x^1,\ldots,x^q$, each in $\mathbb{R}^d$, to compute a sketch $S(x^1\otimes x^2\otimes\cdots\otimes x^q)$ without first having to compute the tensor product $x^1\otimes x^2\otimes\cdots\otimes x^q$, which would require an unreasonable d^q amount of time. The rough idea is to apply separate sketches $S^1,\ldots,S^q$ to each of the q "modes", obtaining $S^1x^1,S^2x^2,\ldots,S^qx^q$, where each S^i is a CountSketch matrix. If S^i has k rows, then the coordinates of each S^ix^i are associated with the coefficients of a degree-$(k-1)$ polynomial in a formal variable z. One then multiplies these polynomial modulo z^k-1 using the Fast Fourier Transform to improve efficiency. Interestingly, one can show this corresponds to applying another CountSketch S (which is a function of $S^1,\ldots,S^q$) to the vector $x^1\otimes x^2\otimes\cdots\otimes x^q$, with certain structural properties (so S is not a truly random CountSketch matrix, but nevertheless is good enough). Applying this to each column of A separately, which has the form $(x^i)^{\otimes q}$, one can then solve the sketched kernel regression problem:

$$\min_y\|A^TS^TSAy-b\|_2^2+\lambda\|Ay\|_2^2,$$

where now one has SA without ever having to materialize the matrix A.

While the initial work was well-suited for low degree polynomial kernels (small q), their dependence on the sketching dimension is exponential in q, making them less suitable for tasks such as approximating the Gaussian kernel, where q is chosen to be at least logarithmic in n. In recent work [1], a binary tree scheme was used, together with additional sketching at each internal node, to design a linear and oblivious (not dependent on the input) sketch which reduces the dependence on the degree q to polynomial. This was then successfully applied to sketching the Gaussian kernel.

2.3 Structured Matrix Regression

In a number of real-world instances of regression, the design matrix A is structured, e.g., it might be a Hankel, Toeplitz, Vandermonde, or more generally a low-displacement rank matrix. Such matrices A come with fast matrix multiplication algorithms, meaning one can compute $A \cdot x$ in $O(n \log n)$ or $n \cdot \text{polylog}(n)$ time, which is often significantly faster than the nd time needed to multiply an arbitrary $n \times d$ matrix A with a vector x. Notice that the running time is sublinear in the time to write down the matrix A and this leads to the quest for obtaining sublinear time algorithms for a number of optimization problems. Using dimensionality reduction-based methods [19, 33], if $T(A)$ is the time to multiply a given matrix A by an arbitrary vector x, it is possible to $(1+\epsilon)$-approximate least squares regression in $T(A) \log n + \text{poly}(d \log n/\epsilon)$ time, yielding sublinear time (in nd) for a number of structured regression problem.

3 Wrapping Up

While our focus in this short survey was on variants of regression, there is also a large body of work on applying sketching to other optimization problems. A very small set of examples includes the following:

- low rank approximation [14], where one seeks to approximate an $n \times d$ matrix A by a product of an $n \times k$ matrix L and a $k \times d$ matrix R, where $k \ll \min(n, d)$, and thus one can store A with only $(n + d)k$ parameters as opposed to nd parameters
- CUR decomposition [9], which is a special kind of low rank approximation where one seeks to approximate A by CUR, where C is an $n \times c$ matrix and consists of an actual subset of columns of A, R is an $r \times d$ matrix and consists of an actual subset of rows of A, and U is a small $c \times r$ arbitrary matrix. Here the hope is that r, c are small and that this provides a more "interpretable" low rank approximation
- clustering, for which low-rank approximation can quickly provide an initial dimensionality reduction, which can then be used to create a coreset for problems such as k-means [18], or k-median [35, 21]
- distributed, sliding window, and streaming computation (see, e.g., [13, 10, 11], and references therein): since sketches provide a form of compression and can be easily updated due to their linearity, they are naturally useful for providing communication-efficient distributed algorithms as well as space-efficient algorithms in the sliding window and streaming models
- optimization, where sketching can be used for example to compress gradients in first order optimization [23], as well as inside of each iteration in second order methods [29], which often involve solving a least squares regression problem
- finding a latent simplex is an important problem in topic models and community detection, for which one is given n data points that are formed by randomly perturbing some points that come from a latent simplex. Sketching was recently used to obtain truly input sparsity time algorithms in [4]

- trace estimation, where one is given an $n \times n$ positive semidefinite matrix A and would like to estimate $\sum_{i=1}^{n} A_{i,i}$ up to a multiplicative factor of $1+\epsilon$. Recently, fast sketching algorithms for low rank approximation were used in part to do this with constant probability using $O(1/\epsilon)$ matrix-vector products [25], improving the long-standing Hutchinson's algorithm which uses $\Omega(1/\epsilon^2)$ matrix-vector products.
- tensor low rank approximation [37] and weighted low rank approximation [31, 7], where one is given a tensor and would like to find a low rank approximation in some norm; such problems are often NP-hard and bicriteria algorithms, as well as fixed parameter tractable algorithms, have been proposed to obtain provable guarantees.
- robust variants of regression and low rank approximation, where the standard sum of squares error measure is replaced with more robust loss functions such as sum of absolute values [34, 15, 16, 36, 38]
- sublinear time low rank approximation, where one uses the structure of the input matrix to devise algorithms that achieve relative error low rank approximation in sublinear time, e.g., for positive semidefinite matrices [26, 5] or distance matrices [6, 22].

Sketching and dimensionality reduction are rapidly expanding areas. Some of these topics are covered in my older monograph [39]. See also the course notes for the "Algorithms for Big Data" class I teach at CMU, which contains much of this material[2]. I would like to thank the ICALP program committee for giving me the opportunity to write this, and my apologies for only covering a small part of the vast body of work on sketching and for focusing on work that I am most familiar with, and even unfortunately omitting many of those references as well. Hopefully though, if the reader has not seen sketching before, this document can serve as a short and simple introduction to the area.

Fine-Grained Hardness for Edit Distance to a Fixed Sequence

Abstract

Nearly all quadratic lower bounds conditioned on the Strong Exponential Time Hypothesis (SETH) start by reducing k-SAT to the Orthogonal Vectors (OV) problem: Given two sets A,B of n binary vectors, decide if there is an orthogonal pair $a \in A, b \in B$. In this paper, we give an alternative reduction in which the set A does not depend on the input to k-SAT; thus, the quadratic lower bound for OV holds even if one of the sets is fixed in advance.

Using the reductions in the literature from OV to other problems such as computing similarity measures on strings, we get hardness results of a stronger kind: there is a family of sequences $\{S_n\}_{n=1}^{\infty}$, $|S_n| = n$ such that computing the Edit Distance between an input sequence X of length n and the (fixed) sequence S_n requires $n^{2-o(1)}$ time under SETH.

1 Introduction

The first step in nearly all hardness proofs for polynomial time problems, that are conditioned on the Strong Exponential Time Hypothesis (SETH), is a seminal reduction of Williams [42] from k-SAT to the Orthogonal Vectors problem.

▶ **Definition 1** (The OV Problem). *Given two sets $A, B \subseteq \{0,1\}^{d(n)}$ of n binary vectors of dimension $d(n)$, decide if there is a pair $a \in A, b \in B$ that are orthogonal, i.e. $\forall i \in [d(n)]$: $a[i] = 0 \vee b[i] = 0$.*

The SETH states that k-SAT cannot be solved in $(2-\varepsilon)^n$ time, where $\varepsilon > 0$ is independent of k. The aforementioned reduction takes such a k-CNF formula on n variables and produces two sets of $N = 2^{n/2}$ binary vectors in $d(N) = O(\log N)$ dimensions. Thus, a subquadratic $O(N^{2-\varepsilon})$ algorithm for OV gives a $(2-\varepsilon')^n$ algorithm for k-SAT and refutes SETH. The current best algorithms for OV are mildly subquadratic $O(N^2/f(N))$ where $f(N) = N^{o(1)}$ [11, 25].

It turns out that OV is at the core of so many other problems, making their complexity quadratic. Dozens of fine-grained reductions from OV to various important problems from diverse fields have been designed in the last decade, resulting in a long list of quadratic SETH-based lower bounds [40]. For example, to prove their $n^{2-o(1)}$ lower bound for the Edit

Distance problem, Backurs and Indyk [14] encode each set of vectors A, B with a sequence S_A, S_B of length $O(nd(n))$, such that the edit distance between them reveals the existence of an orthogonal pair.

1.1 Results

In this paper we revisit the simple reduction of Williams from k-SAT to OV, that has been presented in countless lectures on fine-grained complexity, and expose a surprising room for improvement: there is an alternative reduction (with vectors of a mildly larger dimension) that encodes the k-CNF formula with *only one* of the sets. That is, the set of vectors A is *fixed* in all the instances produced by the new reduction. The implications for the SETH-hard problems may sound bizarre: it takes n^2 time to compute the Edit Distance even if one of the two sequences is always the same (for all inputs of length n). Before discussing the implications further, let us try to clarify the result with a high level technical overview.

1.1.1 Main idea

The difference between the two reductions is simple to explain. Assume we are given a k-CNF formula ϕ on n variables $x_1, \ldots, x_n$ and m clauses $C_1, \ldots, C_m$ such that $\phi = (C_1 \wedge \cdots \wedge C_m)$. In both reductions, we enumerate all partial assignments $\alpha \in \{\texttt{false}, \texttt{true}\}^{n/2}$ to the first half of the variables $x_1, \ldots, x_{n/2}$, and also all partial assignments $\beta \in \{\texttt{false}, \texttt{true}\}^{n/2}$ to the other half of the variables $x_{n/2+1}, \ldots, x_n$, and the goal is to find a satisfying pair, i.e. a pair α, β that when put together make a full satisfying assignment $(\alpha\beta)$.

To do this, Williams encodes each partial assignment, α or β, with a binary vector in m dimensions that has a 0 at the j^{th} coordinate if the partial assignment satisfies the clause C_j and 1 otherwise; it follows that a pair of vectors is orthogonal iff $(\alpha\beta)$ is a satisfying assignment. The vectors corresponding to the α's (the partial assignment to the first half of variables) go to the set A and the vectors corresponding to the β's go to the set B; notice that the vectors in both sets depend on the clauses of ϕ.

In the new reduction, the vectors corresponding to the α's are defined *as if ϕ has all possible clauses of size k*, i.e. as if ϕ is the complete k-CNF formula. The j^{th} coordinate depends on whether α satisfies the j^{th} clause in a certain canonical ordering of all k-CNF clauses over n variables. Thus, the set A does not depend on the (real) input formula ϕ. Then, the definition of the vectors for the β's is similar but with an extra condition: the j^{th} coordinate is automatically set to 0 if the j^{th} clause in the canonical ordering does not exist in ϕ, regardless of whether β satisfies it or not. As a result, all clauses that do not appear in ϕ cannot affect the orthogonality of any pair in $A \times B$, and the correctness of the reduction is maintained.

The only downside of the new reduction is that the size of the vectors grows from $m = O(n)$ (because of the sparsification lemma) to $O(n^{2k})$. That is, from $O(\log N)$ to $\log^{O(1)} N$. However, the dimension is still $N^{o(1)}$ and this is sufficient to deduce many $n^{2-o(1)}$ SETH-based lower bounds. Indeed, as often observed, these lower bounds can be based on the (safer than SETH) hypothesis that OV is hard when the dimension is $N^{o(1)}$.[1] Some exceptions, where the reductions crucially rely on the dimension being logarithmic, are [7, 27, 31].

To formalize the new result as a theorem, in Section 2 we introduce the $\mathrm{OV}_{\mathcal{A}}$ problem in which we are given as input only one set B of n vectors and are asked if there is an orthogonal pair in $A_n \times B$ where A_n is the n^{th} set in an (efficiently producible) family of sets $\mathcal{A} = \{A_n\}_{n=1}^{\infty}$.

[1] Recent works [33, 5] have shown that refuting this "moderate dimension OV" hypothesis has consequences that are potentially more remarkable than refuting SETH.

1.1.2 Implications for other problems

Combining the new reduction with the existing reductions from OV in a black-box way leads to some interesting consequences. For example, the reductions from OV to the computation of certain distance measures on pairs of sequences, curves, or time-series, such as Edit Distance [14], Longest Common Subsequence [3, 22, 19], Local Alignment [9], Fréchet Distance [20], and Dynamic Time Warping Distance [22, 3], all proceed by encoding each of the sets A, B *independently* with a sequence S_A, S_B. Therefore, the quadratic $n^{2-o(1)}$ lower bounds implied by SETH hold even if only one sequence S_B is given as input, while S_A only depends on $n = |S_B|$. Another example is the regular expression matching problem [15, 21] of deciding whether a string x can be generated from a regular expression y. Again, the new reduction shows a quadratic lower bound even if the string (or the expression) are fixed. We find it surprising that such severe-looking restrictions of the problems do not reduce the complexity.

The corollaries go beyond sequence problems. The lower bounds for Bichromatic Closest Pair [12, 28] now also hold when one of the two sets is fixed; note that this is incomparable to the recent lower bound for Monochromatic Closest Pair [30]. In the Subtree Isomorphism problem we are given two rooted, unordered, unlabelled trees and are asked if one is contained in the other (a pattern and a host). The quadratic lower bound [2] can now be shown even for a fixed pattern or a fixed host. The implications are less clear-cut for many other graph problems; for example, the basic reduction from OV to diameter in sparse graphs [39] may now produce slightly simpler graphs but it is hard to characterize in what way. It is likely that a white-box usage of the new reduction will lead to interesting results; we leave this for future work.

1.1.3 Generalizing to k-OV

The SETH lower bound for OV generalizes to an $n^{k-o(1)}$ lower bound, for all $k \geq 2$, for the k-OV problem: given k sets of binary vectors $A_1, \ldots, A_k$ in d dimensions, decide if there are k vectors $a_i \in A_i$ that are orthogonal in the sense that $\forall j \in [d] : (a_1[j] \wedge \cdots \wedge a_k[j]) = 0$. The hardness of k-OV has been used to prove the hardness of several other problems (where a reduction from 2-OV is not known) [8, 10, 33, 38, 1, 16, 32, 29, 23]; e.g. an $n^{k-o(1)}$ lower bound for k-LCS, the problem of computing the longest common subsequence of k strings.

The reduction to OV extends to k-OV in the same way: instead of partitioning the variables into two sets of size $n/2$, we split them into k sets of n/k, resulting in k sets of $N = 2^{n/k}$ vectors. Applying the new idea, in Section 3, we get a reduction to instances where the first $k-1$ sets are fixed, and only one set is given as input. Consequently, the k-LCS problem has an $n^{k-o(1)}$ lower bound even if $k-1$ of the sequences are fixed.

1.1.4 Hardness for compressible instances

A surprising feature of SETH-based hardness results for problems in P is that they are proved for highly compressible instances. The reductions produce OV instances of size $N = 2^{n/2}$ that are fully determined by a k-CNF formula of size $O(n^k)$ and can therefore be losslessly encoded with $O(\log N)$ bits. This is surprising because a priori one might expect the worst case instances to require $\Omega(N)$ bits to specify. The reductions can even be adapted (with major modifications) [1] to prove the hardness for instances where the data is compressible with standard grammar-compression schemes such as the Lempel-Ziv family. The new results go a step further: the hardness holds even if one of the inputs is fully determined.

The preprocessing model

A few recent papers study the complexity of the central problems of fine-grained complexity in models with preprocessing [17, 24, 35, 36, 34]. For instance, it was shown that if we can preprocess one of the strings of an Edit Distance instance in near-linear time, then we can obtain a better approximation in sublinear time [34].

It is not difficult to get strong lower bounds for OV (and Edit Distance) in these models by combining the old reduction with a partitioning trick (similar to [41]): an algorithm that solves OV in subquadratic time $n^{2-\varepsilon}$ after preprocessing each set (separately) in arbitrary polynomial time, say n^{100}, also refutes SETH, because we can split A and B into $n^{2-1/200}$ sets of size $n^{1/200}$, preprocess each in a total of $n^{1-1/200} \cdot n^{100/200} < n^{1.5}$ and then solve OV for each pair of parts in a total of $n^{2(1-1/200)} \cdot n^{1/200(2-\varepsilon)} = n^{2-\varepsilon'}$.

The new reduction gives even more power since it implies the hardness with a fixed set, that intuitively, can be preprocessed indefinitely; formally, we get conditional lower bounds even against algorithms with preprocessing using arbitrary polynomial *space*, rather than time (see Section 5).[2] This also has implications for dynamic algorithms where a preprocessing phase is often allowed [8, 37], strengthening the lower bounds from polynomial time to space. Observe that if we relax the requirements further to allow exponential space, a linear time algorithm becomes possible: using $2^{O(n)}$ space we can construct a look-up table storing the answers to all possible inputs.

1.1.5 Generalization to Formula-SAT

Hansen, Williams, and the authors [6] have observed that Edit Distance and other problems in P are even harder than OV; if we solve them in subqadratic time, not only do we solve SAT faster on CNF formulas (the simplest kind of formulas), but we also solve it on arbitrary formulas, small depth circuits, and branching programs. Thus, the quadratic lower bounds for Edit Distance and LCS (but not OV) can be based on the safer Formula-SETH (or BP-SETH or NC-SETH): the hypothesis that SAT on arbitrary formulas of size $2^{o(n)}$ cannot be solved in $(2-\varepsilon)^n$ time [6, 4, 26]. These reductions start by reducing Formula-SAT to a problem similar in spirit to OV, called Formula-Satisfying-Pair, that can then be reduced to Edit Distance. It turns out that the new idea of encoding the formula only in one set can be applied in this case as well (see Section 6), and so all the Formula-SETH lower bounds still hold if one of the sequences is fixed.

1.1.6 Roadmap and preliminaries

We start with the new reduction from k-SAT to OV in Section 2. Then, in Section 3, we generalize it to OV on $k \geq 2$ sets. In Section 4 we explain the implication for Edit Distance. Then, we discuss conditional lower bounds for the preprocessing model in Section 5. And finally, in Section 6 we extend the new reduction to formulas beyond CNF's.

We use the notation $[n] = \{1, \ldots, n\}$ and `false`, `true` for boolean truth values.

[2] These results were mentioned in [34] and credited to this work as a personal communication.

2 The new reduction: k-SAT to OV with a fixed set

In this section we give the main result of the paper: a reduction from k-SAT to the Orthogonal Vectors problem (Definition 1) where one of the two sets is fixed for all inputs of size n.

To formalize this, we define the $\text{OV}_{\mathcal{A}}$ problem, which is the same as OV but where the input set A is not given as input. Instead, if the input set B has size n, then we will always choose A to be the set $A_n \in \mathcal{A}$ where $\mathcal{A} = \{A_n\}_{n=1}^{\infty}$ is a family of vector sets, containing one set of each size n. The formal definition below also incorporates the dimension of the vectors $d(n)$ which is taken to be a function of the number of vectors n, as is standard when studying OV.

▶ **Definition 2** (The $\text{OV}_{\mathcal{A}}$ Problem). *For a family $\mathcal{A} = \{A_n\}_{n=1}^{\infty}$ of vector-sets, such that $A_n \subseteq \{0,1\}^{d(n)}$ is a set of n binary vectors of dimension $d(n)$, we define the $OV_{\mathcal{A}}$ problem as: Given a set B of n binary vectors of dimension $d(n)$ decide if there is a pair $a \in A_n, b \in B$ that are orthogonal, i.e. $\forall i \in [d(n)] : a[i] = 0 \vee b[i] = 0$.*

We can now give the main theorem of this paper, giving a quadratic lower bound for $\text{OV}_{\mathcal{A}}$ under SETH. The family $\mathcal{A}$ for which the result holds will be clarified in the proof; we remark that it is quite natural and that is easy to produce each set A_n algorithmically in linear time.

▶ **Theorem 3** (Main). *For any function $d(n) = \log^{\omega(1)} n$, there is a family of vector-sets $\mathcal{A} = \{A_n\}_{n=1}^{\infty}$ of dimension $d(n)$ such that the $OV_{\mathcal{A}}$ problem requires $n^{2-o(1)}$ under SETH. Moreover, each set A_n can be produced in $O(n \cdot d(n))$ time and log space.*

Proof. Fix integers $n, k \geq 1$, and let $\mathcal{C}_{n,k}$ be the set of width k clauses over n variables,

$$\mathcal{C}_{n,k} = \{(\ell_1 \vee \cdots \vee \ell_k) \mid \forall i \in [k] : \ell_i \in \{x_1, \ldots, x_n\} \cup \{x_1, \ldots, x_n\}\},$$

and pick an arbitrary ordering over the clauses such that $\mathcal{C}_{n,k} = \{C_1, \ldots, C_M\}$ where $M = \binom{2n}{k} = O(n^{2k})$.

We now define the set $A_N \in \mathcal{A}$ for $N = 2^{n/2}$ as follows.[3] For each truth assignment α to the variables $x_1, \ldots, x_{n/2}$, i.e. a partial assignment, we create a vector v_α. That is, $\forall \alpha \in \{\texttt{false}, \texttt{true}\}^{n/2}$ representing the assignment $x_1 = \alpha(1), \ldots, x_{n/2} = \alpha(n/2)$, we define the vector v_α as follows:

$$\forall j \in [M] : v_\alpha[j] = \begin{cases} 0, & \text{if } \alpha \text{ satisfies the clause } C_j \\ 1, & \text{otherwise.} \end{cases}$$

That is, to set the j^{th} coordinate of v_α we check if the partial assignment α already satisfies the clause C_j (the j^{th} clause in $\mathcal{C}$) and choose 0 if so, and 1 otherwise.

Notice that the dimension of the vectors is $O(n^{2k}) = \log^{O(1)} N$ and it is asymptotically dominated by $d(N) = \log^{\omega(1)} N$. Moreover, A_N can be produced in $2^{n/2} \cdot n^{2k} = O(Nd(N))$ time, and $O(n + k \log n) = O(\log N)$ space.

We are now ready to reduce k-SAT to the $\text{OV}_{\mathcal{A}}$ problem. Given a k-CNF formula ϕ on n variables $x_1, \ldots, x_n$ as input, we define a set B of $N = 2^{n/2}$ vectors as follows. For each truth assignment $\beta \in \{\texttt{false}, \texttt{true}\}^{n/2}$ to the variables $x_{n/2+1}, \ldots, x_n$, i.e. a partial assignment to the second half of the variables, we create a vector v_β such that:

$$\forall j \in [M] : v_\beta[j] = \begin{cases} 0, & \text{if either } \beta \text{ satisfies the clause } C_j, \text{ or } C_j \notin \phi \\ 1, & \text{otherwise, i.e. } \mathcal{C}_j \in \phi \text{ but } \beta \text{ does not satisfy it.} \end{cases}$$

[3] While this only defines A_N for values of N that are equal to $2^{n/2}$ with integer n, it is easy to extend these A_N's into a family $\mathcal{A}$, e.g. by padding with dummy vectors that are all 1.

Thus, while v_α considered all clauses $C_j \in \mathcal{C}$ similarly, the vectors $v_\beta \in B$ depend on the input formula ϕ and automatically set to 0 all coordinates corresponding to clauses that do not appear in ϕ.

Finally, we claim that B is a "yes" $\text{OV}_{\mathcal{A}}$ instance iff ϕ is satisfiable, and therefore if $\text{OV}_{\mathcal{A}}$ can be solved in truly subquadratic time then for all k, k-SAT can be solved in $(2^{n/2})^{2-\varepsilon} = 2^{(1-\varepsilon/2)n}$ for some $\varepsilon > 0$, refuting SETH. The correctness follows from the following claim proved below.

▷ Claim 4. There is an orthogonal pair $a \in A_N, b \in B$ iff ϕ is satisfiable.

There exist a pair $a \in A_N, b \in B$ that are orthogonal iff there are partial assignments α, β to the first and second half of the variables, respectively, such that $v_\alpha \in A_N$ and $v_\beta \in B$ are orthogonal, meaning that for all $j \in [M]$ either $v_\alpha[j] = 0$ or $v_\beta = 0$, i.e. either α satisfies C_j or β satisfies C_j or C_j is not a clause in ϕ at all. The latter is equivalent to saying that the truth assignment $(\alpha\beta)$ composed of α and β satisfies all clauses that are in ϕ, and we conclude that there is an orthogonal pair iff ϕ has a satisfying assignment. ◀

3 Extension to k-OV

In this section we extend the result of Section 2 to the k-OV problem.

▶ **Definition 5** (The k-OV Problem). *Given k sets $A_1, \ldots, A_k \subseteq \{0,1\}^{d(n)}$ of n binary vectors of dimension $d(n)$, decide if there are k vectors $a_i \in A_i$ that are orthogonal, i.e. $\forall j \in [d(n)] : a_1[j] = 0 \vee \cdots \vee a_k[j] = 0$.*

As before, we define a version of the problem in which only one of the sets is given as input and the other $k-1$ are fixed.

▶ **Definition 6** (The k-$\text{OV}_{\mathcal{A}_1,\ldots,\mathcal{A}_k}$ Problem). *For any $k-1$ families $\mathcal{A}_i = \{A_{i,n}\}_{n=1}^{\infty}, i \in [k-1]$ of vector-sets, such that $\forall i \in [k-1] : A_{i,n} \subseteq \{0,1\}^{d(n)}$ is a set of n binary vectors of dimension $d(n)$, we define the k-$OV_{\mathcal{A}_1,\ldots,\mathcal{A}_k}$ problem as: Given a set A_k of n binary vectors of dimension $d(n)$ decide if there are k vectors $\forall i \in [k-1] : a_i \in A_{i,n}$ and $a_k \in A_k$ that are orthogonal, i.e. $\forall j \in [d(n)] : a_1[j] = 0 \vee \cdots \vee a_k[j] = 0$.*

We are now ready to extend Theorem 3.

▶ **Theorem 7.** *For all $k \geq 2$ and any function $d(n) = \log^{\omega(1)} n$, there exist $k-1$ families of vector-sets $\mathcal{A}_i = \{A_{i,n}\}_{n=1}^{\infty}, i \in [k-1]$ of dimension $d(n)$ such that the k-$OV_{\mathcal{A}_1,\ldots,\mathcal{A}_k}$ problem requires $n^{k-o(1)}$ under SETH. Moreover, each set $A_{i,n}$ can be produced in $O(n \cdot d(n))$ time and log space.*

Proof. Recall from the proof of Theorem 3, the definition of $\mathcal{C}_{n,w}$ the set of all width w clauses over n variables.[4]

For all $i \in [k-1]$, we define the set $A_{i,N} \in \mathcal{A}_i$, where $N = 2^{n/k}$ as follows. For each partial assignment $\alpha^{(i)}$ to the variables $x_{(i-1)\cdot n/k+1}, \ldots, x_{i\cdot(n/k)}$, we create a vector $v_{\alpha^{(i)}}$ and add it to $A_{i,N}$. Let C_j denote the j^{th} clause in a canonical ordering of the clauses in $\mathcal{C}_{n,w}$ and define $v_{\alpha^{(i)}}$ as:

[4] Note that we changed the notation of the clause size from k to w to avoid conflict with k the number of sets. That is, we are now reducing w-SAT to k-OV.

$$\forall j \in [|\mathcal{C}_{n,w}|] : v_{\alpha^{(i)}}[j] = \begin{cases} 0, & \text{if } \alpha^{(i)} \text{ satisfies the clause } C_j \\ 1, & \text{otherwise.} \end{cases}$$

Notice that the dimension of the vectors is $O(n^{2w}) = \log^{O(1)} N$ and it is asymptotically dominated by $d(N) = \log^{\omega(1)} N$. Moreover, $A_{i,N}$ can be produced in $2^{n/k} \cdot n^{2k} = O(Nd(N))$ time, and $O(n + w \log n) = O(\log N)$ space.

We are now ready to reduce w-SAT to the k-OV$_{\mathcal{A}_1,\ldots,\mathcal{A}_k}$ problem. Given a w-CNF formula ϕ on n variables $x_1, \ldots, x_n$ as input, we define a set A_k of $N = 2^{n/k}$ vectors as follows. For each partial assignment $\alpha^{(k)}$ to the variables $x_{(k-1)\cdot n/k+1}, \ldots, x_n$, we create a vector $v_{\alpha^{(k)}}$ such that:

$$\forall j \in [|\mathcal{C}_{n,w}|] : v_{\alpha^{(i)}}[j] = \begin{cases} 0, & \text{if either } \alpha^{(k)} \text{ satisfies the clause } C_j, \text{ or } C_j \notin \phi \\ 1, & \text{otherwise, i.e. } \mathcal{C}_j \in \phi \text{ but } \alpha^{(k)} \text{ does not satisfy it.} \end{cases}$$

Thus, while $v_{\alpha^{(i)}} \in A_{i,N}$ for $i \in [k-1]$ considered all clauses $C_j \in \mathcal{C}_{n,w}$ similarly, the vectors $v_{\alpha^{(k)}} \in A_k$ depend on the input formula ϕ and automatically set to 0 all coordinates corresponding to clauses that do not appear in ϕ.

Finally, we claim that A_k is a "yes" k-OV$_{\mathcal{A}_1,\ldots,\mathcal{A}_k}$ instance iff ϕ is satisfiable, and therefore if k-OV$_{\mathcal{A}_1,\ldots,\mathcal{A}_k}$ can be solved faster than $n^{k-o(1)}$ time then for all w, w-SAT can be solved in $(2^{n/k})^{k-\varepsilon} = 2^{(1-\varepsilon/k)n}$ for some $\varepsilon > 0$, refuting SETH. The correctness follows from the following claim, which can be proved similarly to Claim 4.

▷ Claim 8. There exist k-orthogonal vectors $a_i \in A_{i,N}$ for $i \in [k-1]$ and $a_k \in A_k$ iff ϕ is satisfiable. ◀

4 Corollaries for Edit Distance and other problems

The hardness of OV$_{\mathcal{A}}$ has immediate consequences to all the many OV-hard problems, establishing their hardness even in restricted settings. Let us formalize the implication for Edit Distance, and briefly remark on how it applies to the other problems.

▶ **Definition 9** (The Edit Distance Problem). *Given two sequences X, Y of length n, return the minimum number operations that can transform X into Y. The allowed edit-operations are insertions, deletions, and substitutions of single characters.*

In a similar way to our definition of OV$_{\mathcal{A}}$ in Section 2, we formalize a restricted problem where only one of the two sequences is given as input.

▶ **Definition 10** (The ED$_{\mathcal{X}}$ Problem). *For a family $\mathcal{X} = \{X_n\}_{n=1}^{\infty}$ of sequences, such that X_n is a sequence of length n, we define the ED$_{\mathcal{X}}$ problem as: Given a sequence Y of length n, return the minimum number edit-operations that can transform X_n into Y.*

We can now prove the statement in the title of the paper, showing a quadratic SETH lower bound for ED$_{\mathcal{X}}$.

▶ **Theorem 11.** *There is a family of sequences $\mathcal{X} = \{X_n\}_{n=1}^{\infty}, |X_n| = n$ such that the ED$_{\mathcal{X}}$ problem requires $n^{2-o(1)}$ under SETH. Moreover, each sequence X_n can be produced in $O(n)$ time and log space.*

Proof. By Theorem 3 it is enough to reduce the $\mathrm{OV}_{\mathcal{A}}$ problem to $\mathrm{ED}_{\mathcal{X}}$. To do that, we start with an $\mathrm{OV}_{\mathcal{A}}$ instance B of size n and dimension $d(n) = n^{o(1)}$, for the family $\mathcal{A}$ constructed by Theorem 3, and we apply the reduction of Backurs and Indyk [14] (or the later one which uses a smaller alphabet [22]) to B and A_n. We get two sequences $X = S_X(A_n)$ and $Y = S_Y(B)$ of length $N = f(n) = O(n \cdot d(n))$, for some specific function $f : \mathbb{N} \to \mathbb{N}$, such that the Edit Distance between X and Y is less than a certain value τ_n iff A, B contains an orthogonal pair. Moreover, the encodings S_X and S_Y have the property that they take linear time and log space to compute, and most importantly, that S_X only depends on A_n and n but not on B. Therefore, we can construct the family of sequences $\mathcal{X}$ by setting $X_N = S_X(A_n)$ where $N = f(n)$. We get that solving $\mathrm{ED}_{\mathcal{X}}$ in $O(N^{2-\varepsilon})$ time, for some $\varepsilon > 0$, leads to an $O(n^{2-\varepsilon'})$ time algorithm for solving $\mathrm{OV}_{\mathcal{A}}$, for some $\varepsilon' > 0$, refuting SETH. ◀

To get the corollaries for LCS, k-LCS, Subtree Isomorphism, and the other problems mentioned in Section 1.1, the same arguments work: we simply have to check that the reductions from OV operate on each set separately.

5 Lower bounds for the Preprocessing model

In this section we present the implications of the new reductions for the limitations of preprocessing. As discussed in Section 1.1, any quadratic lower bound for OV already implies a quadratic lower bound even if the algorithm is allowed to preprocess one of the sets in arbitrary polynomial time. However, having a reduction from k-SAT to OV with a fixed set leads to stronger conditional lower bounds that address algorithms with arbitrary polynomial *space* preprocessing. These lower bounds are no longer based on SETH but on a plausible strengthening of it to *nonuniform* algorithms.

Recall [13] that $TIME[T(n)]/A(n)$ is the class of problems that can be solved by an $O(T(n))$ time algorithm that is given an advice string X_n of length $O(A(n))$ for all inputs of size n.

▶ **Hypothesis 12** (Nonuniform-SETH). *There is no $\varepsilon > 0$ such that for all $k \geq 3$ the k-SAT problem is in $TIME[(2-\varepsilon)^n]/2^{(1+o(1))\cdot n/2}$.*

This is a strong hypothesis, but it is not at all clear how the nonuniformity can help in solving SAT faster, and therefore it might be as plausible as SETH. Moreover, even the extreme version of this hypothesis, where the size of the advice is increased from $2^{n/2\cdot(1+o(1))}$ all the way to $2^{n\cdot(1-\varepsilon)}$ remains plausible. In fact, for our conditional lower bound below, we can weaken the hardness hypothesis to allow significantly smaller advice length: $O(2^{\varepsilon n})$ for any constant $\varepsilon > 0$, and the same conclusion for OV would follow. To obtain this stronger result it suffices to give a modification to Theorem 3 so that it reduces to *asymmetric* $\mathrm{OV}_{\mathcal{A}}$ where the sets A and B have different sizes; the details of this standard modification are omitted from this paper. In any case, the main message of the following theorem is to highlight a connection between algorithms in the preprocessing model and a breakthrough in the nonuniform complexity of SAT.

▶ **Theorem 13.** *Suppose there is an algorithm that, given two sets A, B of n binary vectors in $d(n) = \log^{\omega(1)} n$ dimensions, can preprocess the set A using $S(n) = O(n^c)$ bits of space, and subsequently solve OV on A, B in $O(n^{2-\varepsilon})$ time, for some $\varepsilon > 0, c \geq 1$. Then, Nonuniform-SETH is false.*

Proof. Fix $\varepsilon > 0, c \geq 1$ and suppose that an algorithm ALG can solve OV in subquadratic $O(n^{2-\varepsilon})$ time after preprocessing the set A using $S(n) = n^c$ space. We start by reducing k-SAT on N variables to $\mathrm{OV}_{\mathcal{A}}$ on sets of size $n = 2^{N/2}$ using Theorem 3. Then, to solve

$\mathrm{OV}_{\mathcal{A}}$ instances of size n using ALG we can take the set A_n and split it into $n^{1-1/tc}$ instances of size $n^{1/tc}$ each, for some $t \geq 2$ to be specified later. We use ALG to preprocess each of these parts in an unknown amount of time but only $O((n^{1/tc})^c)$ space; the total space that it uses for all the parts is $s_n = n^{1-1/tc} \cdot O(n^{c/tc}) = O(n^{1+1/t-1/tc})$. Let X_n be the bit-string of length s_n that encodes the state of the memory after the algorithm is done preprocessing these sets, i.e. the concatenation of the $n^{1-1/tc}$ memory tapes. Observe, crucially, that the string X_n only depends on n, even though generating it might have take an unknown amount of time. We will choose it to be the advice string for our algorithm for all inputs of size n. Then, using the string X_n our algorithm can solve any $\mathrm{OV}_{\mathcal{A}}$ instance B of size n in truly subquadratic time: we split B into $n^{1-1/tc}$ parts of size $n^{1/tc}$ each, and then solve each pair of parts using ALG and the string X_n in subquadratic $(n^{1/tc})^{2-\varepsilon}$ time, giving a total of $(n^{1-1/tc})^2 \cdot (n^{1/tc})^{2-\varepsilon} = n^{2-\varepsilon'}$ time, for $\varepsilon' = \varepsilon/tc > 0$. Going back to k-SAT, our algorithm runs in time $2^{N/2\cdot(2-\varepsilon')}$ time and has used $O(n^{1+1/t}) = O(2^{N/2\cdot(1+1/t)}) = 2^{N/2\cdot(1+o(1))}$ bits of advice, where the latter equality holds because we can choose t to be arbitrarily large, refuting Nonuniform-SETH. ◀

6 Extension to Formula-SAT and Formula-Satisfying-Pair

In this section, we extend the results of Section 2 so that the starting point is Formula-SAT rather than CNF-SAT, and the end problem is Formula-Satisfying-Pair (with a fixed formula and set A) rather than OV (with a fixed set A). Throughout, we consider deMorgan formulas that have AND/OR gates of fan-in two, and we assume that all the NOT gates are at the bottom, meaning that the leaves of each formula are either variables or their negation. The size of a formula is the total number of gates and the depth is the maximum number of levels from root to leaf.

▶ **Definition 14** (Formula-SAT). *Given a formula F over n variables, decide if it is satisfiable.*

Notice that CNF formulas are a special kind of depth 2 formulas. The following hypothesis is a more believable version of SETH.

▶ **Hypothesis 15** (Formula-SETH [6]). *There is no $\varepsilon > 0$ such that Formula-SAT on formulas of size $2^{o(n)}$ can be solved in $O((2-\varepsilon)^n)$ time.*

This hypothesis is sometimes referred to as Branching-Program-SETH (BP-SETH) since it is equivalent to a hypothesis about SAT on branching programs, or as NC-SETH which is a similar assumption about SAT on polylog depth circuits, which are equivalent to formulas of $2^{\mathrm{poly}\log n}$ size.

Just like the SETH-based lower bounds go via the OV problem, the Formula-SETH lower bounds often go via a problem such as the Formula-Satisfying-Pair problem.

▶ **Definition 16** (Formula-Satisfying-Pair [4]). *Given a formula $F = F(x_1, \ldots, x_m, y_1, \ldots, y_m)$ of size $2m$ where each variable is used exactly once, and two sets $A, B \subseteq \{0,1\}^m$ of size n, decide whether there is a pair $a \in A, b \in B$ such that $F(a_1, \ldots, a_m, b_1, \ldots, b_m) =$ `true`.*

A simple reduction, similar to the one by Williams [42], shows an $n^{2-o(1)}$ lower bound for Formula-Satisfying-Pair with $m = n^{o(1)}$ under the Formula-SETH. And with intricate gadgetry, Formula-Satisfying-Pair can be reduced to Edit Distance, LCS, Fréchet, and other problems establishing Formula-SETH lower bounds for them as well [6, 4]. The main result of this section is to prove a Formula-SETH lower bound for Formula-Satisfying-Pair with a fixed formula F and a fixed set A. As a result, the Formula-SETH lower bounds for Edit Distance and the other problems also hold when one sequence is fixed.

▶ **Definition 17** ($\mathsf{FSP}_{\mathcal{F},\mathcal{A}}$). *For a family $\mathcal{A} = \{A_n\}_{n=1}^{\infty}$ of vector-sets, such that $A_n \subseteq \{0,1\}^{d(n)}$ is a set of n binary vectors of dimension $d(n)$, and a family $\mathcal{F} = \{F_n\}_{n=1}^{\infty}$ of formulas, such that F_n is over $d(n)$ variables and has size $2d(n)$ we define the $FSP_{\mathcal{F},\mathcal{A}}$ problem as: Given a set B of n binary vectors of dimension $d(n)$ decide if there is a pair $a \in A_n, b \in B$ such that $F_n(a,b) =$ `true`.*

After formalizing the problem with fixed formula and set A we are ready to state the theorem. The rest of this section is dedicated to the proof.

▶ **Theorem 18.** *There is a family of vector-sets $\mathcal{A} = \{A_n\}_{n=1}^{\infty}$ of dimension $d(n) = n^{o(1)}$ and a family of formulas $\mathcal{F} = \{F_n\}_{n=1}^{\infty}$ over $d(n)$ variables and of size $2d(n)$ such that the $FSP_{\mathcal{F},\mathcal{A}}$ problem requires $n^{2-o(1)}$ under Formula-SETH. Moreover, each set A_n and formula F_n can be produced in $O(n \cdot d(n))$ time.*

Our approach is to imitate the main idea in the proof of Theorem 2. There, we looked at the set of all clauses, which is similar to thinking about the super-set of all k-CNF formulas. Now, we are faced with arbitrary formulas, and it is not so clear what the corresponding super-set would be: the set of all gates does not make much sense. To make this work, we go through the following intermediate problem, which is similar to Formula-SAT but has a structure that is easier to work with when constructing a fixed formula for $\mathrm{FSP}_{\mathcal{F},\mathcal{A}}$.

For a depth bound $depth(n)$ we define the *Canonical-Depth-$d(n)$* formula to be the formula over n variables defined by a full binary tree in which all the gates are (?) indicating a gate that could either be AND or OR. Moreover, each leaf pointing to a variable x_i is also labelled with a (?) indicating that it could either be x_i or $\bar{x_i}$. We also fix a canonical numbering of the $s(n) = 2^{d(n)}$ gates of this formula. To get a "real" formula, we must specify $s(n)$ bits indicating for each (?) gate whether it is AND, OR, or if it is a leaf whether it is a negation or not. A natural way to make the specification is to make the j^{th} gate AND if the j^{th} bit is 1 and OR otherwise, and to make a leaf-gate a negation iff the corresponding bit is 1.

▶ **Definition 19** (Canonical-Formula-SAT)**.** *Given $s(n)$ bits for specifying the gates of a canonical-depth-$d(n)$ formula over n variables, decide if the resulting formula is satisfiable.*

The reduction has two steps, described in Sections 6.1 and 6.2.

6.1 From Formula-SAT to Canonical-Formula-SAT

This step is not immediate only because an arbitrary $s(n)$-sized formula could have a structure that is very far from a full-binary tree. Nonetheless, we can transform it into such using standard techniques without blowing up the size by more than polynomial factors. And since our interest is in $s(n) = 2^{o(n)}$, polynomial blowups do not matter.

Given a formula F of size $s(n)$ we begin by applying the depth-reduction of Bonet-Buss [18] to get an equivalent formula F' of depth $depth(n) = O(\log s(n))$. Then, we enforce that all paths from root to leaves have length exactly $d(n)$: if a leaf is higher, we add an equivalent subtree, e.g. by replacing x_i with $(x_i \wedge \mathtt{true}) \wedge (\mathtt{true} \wedge \mathtt{true})$ and so on. The total size of the final formula F'' is $2^{depth(n)} = s^{O(1)}$.

Then, to complete the reduction, we simply go over the gates of F'' and generate a string g of $s(n)$ bits that encodes it with the above natural representation. Thus, g is a "yes" instance for Canonical-Formula-SAT iff F is satisfiable.

6.2 From Canonical-Formula-SAT to $\text{FSP}_{\mathcal{F},\mathcal{A}}$

The next idea is to transform the canonical formula $F^{(?)}$ that is full of (?) gates along with a bit-string g specifying the gates, into a formula F with real gates that takes the bits of g as inputs. In more details, we take the j^{th} gate in $F^{(?)}$, that takes input from the two gates G_1 and G_2 and we replace it with the following subformula (a similar but different formula is used for leaf-gates):

$$G_j = (g_j \wedge (G_1 \wedge G_2)) \vee (\bar{g_j} \wedge (G_1 \vee G_2))$$

This subformula encodes our natural representation where $g_j = 1$ iff the gate is AND. After these transformations, the size of the formula blows up by $2^{depth(n)}$ since we have to make two copies of each subformula at every level, but this is still $s^{O(1)}$. Notice that the formula F is now fixed, and the formula we started from is only encoded with the g_j's which can be thought of as inputs to F (note that, as opposed to the x_i's these inputs are not free, and so they do not increase the complexity of SAT).

We are now ready to define the $\text{FSP}_{\mathcal{F},\mathcal{A}}$ instances that encode the satisfiability of F. Let $N = 2^{n/2}$. We define the formula F_N, i.e. the N^{th} member of the family of formulas $\mathcal{F}$, to be equal to F after we duplicate each variable so that it is used once in the formula. The vectors $a \in A_N$ have dimension $O(s(n)) = N^{o(1)}$ and are defined as follows. For each partial assignment $\alpha \in \{\texttt{true}, \texttt{false}\}^{n/2}$ to the variables $x_1, \ldots, x_{n/2}$ we define the vector a such that for all $j \in [s(n)]$ a_j is set to 1 iff the j^{th} gate in F is a leaf gate marked with a literal x_h or $\bar{x_h}$ and α makes this literal true. Note that the vectors in A do not depend on the g_j's at all.

Finally, the vectors $b \in B$ do depend on the g_j's. For each partial assignment β to the variables $x_{n/2+1}, \ldots, x_n$, we construct a vector b. For all $j \in [s(n)]$ we set b_j as follows. If the j^{th} gate in F is a leaf gate marked with a literal x_h or $\bar{x_h}$ and β makes this literal true, then we set $b_j = 1$. If the j^{th} gate is a leaf gate marked with a variable g_h (or its negation) then we set $b_j = g_h$ (or its negation). Notice that the g's affect all vectors in B in the same way (as is the case in the proof of Theorem 3).

To conclude the correctness of this reduction, observe that an evaluation of F_N on a pair of vectors a, b is equivalent to the evaluation of F on the corresponding partial assignments α, β and the given g.

Local Approximations of the Independent Set Polynomial

Abstract

The independent set polynomial of a graph has one variable for each vertex and one monomial for each independent set, comprising the product of the corresponding variables. Given a graph G on n vertices and a vector $\boldsymbol{p} \in [0,1)^n$, a central problem in statistical mechanics is determining whether the independent set polynomial of G is non-vanishing in the polydisk of $\boldsymbol{p}$, i.e., whether $|Z_G(\boldsymbol{x})| > 0$ for every $\boldsymbol{x} \in \mathbb{C}^n$ such that $|x_i| \leq p_i$. Remarkably, when this holds, $Z_G(-\boldsymbol{p})$ is a lower bound for the avoidance probability when G is a dependency graph for n events whose probabilities form vector $\boldsymbol{p}$. A *local* sufficient condition for $|Z_G| > 0$ in the polydisk of $\boldsymbol{p}$ is the Lovász Local Lemma (LLL).

In this work we derive several new results on the efficient evaluation and bounding of Z_G. Our starting point is a monotone mapping from subgraphs of G to truncations of the tree of self-avoiding walks of G. Using this mapping our first result is a local *upper* bound for $Z(-\boldsymbol{p})$, similar in spirit to the local lower bound for $Z(-\boldsymbol{p})$ provided by the LLL. Next, using this mapping, we show that when G is chordal, Z_G can be computed exactly and in linear time on the entire complex plane, implying *perfect* sampling for the hard-core model on chordal graphs. We also revisit the task of bounding $Z(-\boldsymbol{p})$ from below, i.e., the LLL setting, and derive four new lower bounds of increasing sophistication. Already our simplest (and weakest) bound yields a strict improvement of the famous asymmetric LLL, i.e., a strict relaxation of the inequalities of the asymmetric LLL without any further assumptions. This new asymmetric local lemma is sharp enough to recover Shearer's *optimal* bound in terms of the maximum degree $\Delta(G)$. We also apply our more sophisticated bounds to estimate the zero-free region of the hard-core model on the triangular lattice (hard hexagons model).

Acknowledgements We are deeply grateful to the anonymous reviewers for their extremely thorough review of our submission and for an abundance of insightful comments and suggestions that greatly clarified the presentation and motivated the improvement of some of the results.

1 The Independent Set Polynomial

We write $[n]$ to denote the set $\{1, 2, \ldots, n\}$, with the convention $[0] = \emptyset$. Throughout, G is a graph on $[n]$ and $\mathrm{Ind}(G)$ denotes the set of all independent sets of G.

▶ **Definition 1.** *The* independent set polynomial *of a graph G with variables $x_1, \ldots, x_n$ is*

$$Z_G(\boldsymbol{x}) = Z(\boldsymbol{x}) := \sum_{\substack{I \subseteq S \\ I \in \mathrm{Ind}(G)}} \prod_{i \in I} x_i \ . \tag{1}$$

For arbitrary $S \subseteq [n]$ we denote the independent set polynomial of the subgraph of G induced by S by $Z_G(\boldsymbol{x}; S) = Z(S)$, the latter notation relying on $\boldsymbol{x}$ being clear from context.

▶ Remark 2. We will often refer to the components of the variable vector $\boldsymbol{x}$ as *activities*.

▶ **Definition 3.** *The* polydisk *of* $\boldsymbol{p} \in [0,\infty)^n$ *is the set* $\{\boldsymbol{x} \in \mathbb{C}^n : |x_i| \le p_i \text{ for all } i \in [n]\}$.

The complexity of computing and approximating the independent set polynomial is an extensively studied subject. This is because there are important instantiations of the polynomial when the activities are positive reals, negative reals, and even complex numbers.

1.1 Positive Reals: The Hard-Core Model

In many natural computational problems in combinatorics, statistics, and statistical physics we are given as input a graph G that defines a set $\Omega = \Omega(G)$ of objects (configurations) of interest, e.g., matchings in G. A weight function $w : \Omega \to (0, +\infty)$ assigns a positive weight to each element $\sigma \in \Omega$, giving rise to a probability distribution $\pi(\sigma) = w(\sigma)/Z$, where the normalizing factor $Z := \sum_{\sigma\in\Omega} w(\sigma)$ is called the *partition function*. When $\Omega = \mathrm{Ind}(G)$ and each $I \in \mathrm{Ind}(G)$ has weight $w(I) = \prod_{i\in I} x_i$, where $\boldsymbol{x} \in (0,+\infty)^n$, the distribution is the *hard-core* model of statistical physics, and the independent set polynomial when $S = [n]$ equals its partition function. Observe that in the *univariate* case where all vertex activities equal $x > 0$, i.e., $\boldsymbol{x} = x\mathbf{1}$, as $x \to \infty$ the polynomial is increasingly dominated by the contribution of the largest independent sets, readily suggesting the intractability of evaluating the polynomial for arbitrarily large values of x. A celebrated achievement in this area is the characterization of the computational tractability of approximating the univariate partition function. Let $\Delta = \Delta(G)$ denote the maximum degree of G, let $\boldsymbol{x} = x\mathbf{1}$, and let

$$x_c = x_c(\Delta) := \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^{\Delta}} \searrow \frac{\mathrm{e}}{\Delta} \ ,$$

where $\searrow$ denotes convergence from above. Weitz [22] proved the partition function can be approximated arbitrary well (FPTAS) for $x < x_c$, while Sly and Sun [19] proved that approximating the partition function is NP-hard for $x > x_c$.

1.2 Complex Numbers: Phase Transitions

The study of partition functions when the arguments of the corresponding polynomial are complex numbers dates back to the 1952 work of Lee and Yang [23] who established a connection between the location of zeros of the partition function on the complex plane and the presence of phase transitions on the real axis. The high-level idea is that since we identify phase transitions as discontinuities in the derivatives of free energy, i.e., of $\log Z$, such a transition can only occur at a point of the complex plane if there is at least one nearby zero of the partition function. Specifically, in the follow-up paper [12], Lee and Yang instantiated this connection for the ferromagnetic Ising model by proving that the zeros of the partition function always lie on the unit circle in the complex plane, and used this fact to conclude that the ferromagnetic Ising model can have at most one phase transition. The Lee-Yang approach has since become a cornerstone of the study of phase transitions, and has been used extensively in the statistical physics literature: see, e.g., [2, 9, 13, 21] for specific examples, and Ruelle's book [16] for background. There have also been attempts to relate the Lee-Yang program to the Riemann hypothesis [14].

Zeros of partition functions when the variables take complex values have also been studied in a purely combinatorial setting without reference to the physical interpretation: see, for example, Choe et al. [6]. Another important example is the work of Chudnovsky and Seymour [7], who show that the zeros of the univariate independent set polynomial of

claw-free graphs lie on the real line. Finally, in a seminal work, Scott and Sokal [17] proved that the independent set polynomial is non-zero in the polydisk of $\boldsymbol{p} \in [0,1)^n$, if and only if $Z_G(-\lambda \boldsymbol{p}) > 0$ for every $\lambda \in [0,1]$.

1.3 The Probabilistic Method and the Lovász Local Lemma

The *Probabilistic Method* [1] amounts to establishing the existence of mathematical objects with a property of interest by demonstrating a probability distribution under which they have positive probability. The power of the method stems from the fact that if the probability of the objects under the distribution is indeed positive, then *any* multiplicative underestimation of it is enough to imply existence. Typically, the property of interest, $\mathcal{P}$, is the intersection of the complements of several simpler properties, each property expressing some particular "flaw," so that $\mathcal{P}$ coincides with flawlessness. Thus, if we endow a universe of candidate objects Ω, where sets $\{F_i\}_{i=1}^n \subseteq \Omega$ correspond to the different flaws, with a probability measure μ, the goal is to prove that the *avoidance probability*, $\mu(\bigcap_{i\in[n]} \overline{F}_i)$, is strictly positive.

Given only the marginals $p_i := \mu(F_i)$, the best lower bound we can give for the avoidance probability is $1 - \sum_i p_i$ since, for all we know, the flaws could be disjoint. To improve upon the union bound, we need to constrain the flaw overlaps. A natural and extremely successful way to do this is in terms of a graph G on $[n]$. Concretely, let $\Gamma_i(G) = \Gamma_i$ denote the neighborhood of vertex i in G and let $\Gamma_i^+ = \Gamma_i \cup \{i\}$. We say that G is a *dependency graph* for $\{F_i\}_{i=1}^n$ with respect to μ if for every $i \in [n]$ and every set $\{j_1, j_2, \ldots\} \subseteq [n] \setminus \Gamma_i^+$,

$$\mu(F_i \mid \overline{F_{j_1}} \cap \overline{F_{j_2}} \cap \cdots) = \mu(F_i) = p_i \ . \tag{2}$$

Note that the presence of an edge in G does not prescribe any specific kind of dependency between its two corresponding events, only a lack of constraint thereof. Thus, a complete dependency graph (clique) conveys no information at all about how the n events overlap, while an empty dependency graph implies that the n events are mutually independent.

In applications, given the measure μ and the sets of flaws $\{F_i\}_{i=1}^n$ it is typically difficult to derive much more than a vector $\boldsymbol{p} = (p_1, p_2, \ldots, p_n)$ of (upper bounds for) the flaw probabilities and a (possibly pessimistic) dependency graph G. As a result, it is desirable to have sufficient conditions for a pair $\boldsymbol{p}, G$ to have the property that *every* probability measure compatible with it has strictly positive avoidance probability. Remarkably, Shearer [18] gave a sufficient *and necessary* condition for a pair to have this property.

▶ **Definition 4.** *Given a graph G, let $\mathcal{S}(G) = \{\boldsymbol{p} \in [0,1)^n : Z_G(-\boldsymbol{p}; S) > 0$, for all $S \subseteq [n]\}$.*

Shearer showed that membership in $\mathcal{S}(G)$ characterizes the vectors $\boldsymbol{p}$ for which every probability measure compatible with $\boldsymbol{p}, G$ has strictly positive avoidance probability. For this he showed that given $\boldsymbol{p}, G$, in order to minimize the avoidance probability, one should try to realize the (unique) measure μ^* under which events adjacent in G are disjoint. He then showed that if $Z(-\boldsymbol{p}; S) \leq 0$ for some $S \subseteq [n]$, then μ^* can not be realized and the avoidance probability is 0, while, otherwise, $\mu^*(\bigcap_{i\in S} \overline{F}_i) = Z(-\boldsymbol{p}; S) \geq 0$ for every $S \subseteq [n]$ and, therefore, the avoidance probability is at least $Z(-\boldsymbol{p}; [n])$, i.e., the value of the independent set polynomial of G at $-\boldsymbol{p}$. Unfortunately, performing this evaluation is generally intractable, as it involves a summation over $\mathrm{Ind}(G)$.

The Lovász Local Lemma is a *sufficient* condition for membership in $\mathcal{S}(G)$, along with a lower bound for $Z(-\boldsymbol{p})$. Below is a general formulation (the so-called *asymmetric*).

▶ **Theorem 5** (Lovász [20]). *Let μ be a probability measure on set Ω and let G be a dependency graph for $\{F_i\}_{i\in[n]} \subseteq \Omega$. If there exist $r_1, r_2, \ldots, r_n \in [0,1)$ such that for every $i \in [n]$,*

$$p_i \leq r_i \prod_{j\in\Gamma_i} (1-r_j) \ , \tag{3}$$

then $\mu\left(\bigcap_{i=1}^{n} \overline{F_i}\right) \geq \prod_{i\in[n]} (1-r_i) > 0.$

▶ Remark 6. Theorem 5 holds (and is known as the "Lopsided LLL" of Erdős and Spencer [8]) if condition (2) holds with "$\leq$" instead of "$=$". All our results also hold in that setting.

2 Our Results

2.1 An Improved General / Asymmetric LLL

We strictly improve the asymmetric LLL, and thus all its applications, as follows.

▶ **Theorem 7.** *Theorem 5 holds if* (3) *is replaced by*

$$p_i \leq r_i \prod_{j\in\Gamma_i} \frac{1-r_j}{1-r_i r_j} \ . \tag{4}$$

While our Theorem 7 retains all the flexibility of the asymmetric LLL to adjust to events with different degrees and probabilities, it is sharp enough to recover the *optimal* bound in terms of the maximum degree $\Delta(G)$ (attained as a limit by Δ-regular trees as depth goes to infinity). Specifically, if every event has probability at most p and is mutually independent of all but $\Delta \geq 2$ other events, Theorem 7 implies the optimal condition $p < \frac{(\Delta-1)^{(\Delta-1)}}{\Delta^\Delta}$ originally proven by Shearer [18], whereas the asymmetric LLL requires $p < \frac{\Delta^\Delta}{(\Delta+1)^{(\Delta+1)}}$.

A fairly recent improvement of Theorem 5 is the so-called *cluster expansion* LLL by Bissacot et al. [5], wherein the presence of edges in the neighborhood of a vertex, i.e., the presence of triangles, allow one to relax the condition corresponding to that vertex. While our Theorem 7 is, in general, incomparable with the cluster expansion LLL, the overall trend is that the former wins when neighborhoods are sparse, while the latter when they are dense.

In Sections 2.4, 2.5 we will see four significant improvements of Theorem 7. The weakest of these is already *exact* on *arbitrary* trees (uniform trees being the worst case for given Δ).

2.2 An Upper Bound for the Partition Function on the Negative Reals

Recall that given a vector $\boldsymbol{p}$, the central problem is determining whether $|Z_G| > 0$ on the *polydisk* of $\boldsymbol{p}$, i.e., for every $\boldsymbol{x} \in \mathbb{C}^n$ such that $|x_i| \leq p_i$ for all $i \in [n]$. Since $Z_G(\mathbf{0}) = 1 > 0$, if $\boldsymbol{p} \notin \mathcal{S}(G)$, continuity implies $|Z_G(\lambda \boldsymbol{p}_S)| = 0$ for some $S \subseteq [n]$ and $\lambda \in (0,1]$, where $\boldsymbol{p}_S$ is the vector that results by setting to 0 all coordinates of $\boldsymbol{p}$ outside S. On the other hand, Scott and Sokal [17] showed that for $\boldsymbol{p} \in \mathcal{S}(G)$ and every $\lambda \in [0,1]$, the magnitude of Z_G over the polydisk of $\lambda\boldsymbol{p}$ is minimized at $-\lambda\boldsymbol{p}$. Thus, membership in $\mathcal{S}(G)$ is equivalent to $Z(-\lambda\boldsymbol{p}) > 0$ for every $\lambda \in [0,1]$ and characterizes the vectors on whose polydisks Z_G does not vanish.

The LLL is a local sufficient condition for $\boldsymbol{p} \in \mathcal{S}(G)$, providing a strictly positive lower bound for $Z_G(-\boldsymbol{p})$ for such $\boldsymbol{p}$ (and, thus, for $|Z_G|$ on the polydisk of $\boldsymbol{p}$). We show that $Z_G(-\boldsymbol{p})$ can also be bounded *from above* for $\boldsymbol{p} \in \mathcal{S}(G)$.

▶ **Definition 8.** *Given a permutation π of $[n]$, let $\overleftarrow{\Gamma_i} = \overleftarrow{\Gamma_i}(\pi) = \Gamma_i \cap \{j \in [n] : \pi(j) < \pi(i)\}$ and let $\overrightarrow{\Gamma_i} = \overrightarrow{\Gamma_i}(\pi) = \Gamma_i \cap \{j \in [n] : \pi(j) > \pi(i)\}$.*

▶ **Theorem 9** (Upper Bound). *Given $\boldsymbol{p}, G$ and a permutation π of $[n]$, define $\boldsymbol{r} = \boldsymbol{r}(\pi)$ by*

$$p_i = r_i \prod_{j \in \overleftarrow{\Gamma}_i(\pi)} (1 - r_j) \ , \quad \text{for every } i \in [n] \ . \tag{5}$$

(Note that $\boldsymbol{r}$ is well-defined as $r_1 = p_1$, while for $i > 1$, r_i is determined by $p_i, r_1, \ldots, r_{i-1}$.) If $\boldsymbol{p} \in \mathcal{S}(G)$, then $Z(-\boldsymbol{p}; S) \leq \prod_{j \in S}(1 - r_j)$, for every $S \subseteq [n]$.

▶ Remark 10. If $\boldsymbol{r'}$ satisfies (3) and $\boldsymbol{r}$ is defined by (5), then $1 - r'_i \leq 1 - r_i$ for every $i \in [n]$.

2.3 Exact Partition Function Computation for Chordal Graphs

Recall that a graph is *chordal* if all its induced cycles have length three. We prove that the independent set polynomial of a chordal graph can be evaluated *anywhere* on the complex plane in *linear* time. We conjecture that chordality is closely related to the exact solvability of the hard-core model for certain highly transitive graphs, e.g., triangular lattice (hard hexagons model [3]), and that the hard-core model is not the only statistical mechanics model for which chordality relates to exact solvability. We leave this as future work.

▶ **Fact 11.** *A graph G on $[n]$ is chordal iff it has a* perfect elimination ordering*, i.e., a permutation π of $[n]$ such that $\overrightarrow{\Gamma}_i(\pi)$ is a clique for every $i \in [n]$. If the identity permutation is a perfect elimination ordering for G, we say that G is chordally presented.*

▶ **Theorem 12.** *If G is chordally presented, then $Z_G(\boldsymbol{x}) = \prod_{i \in [n]} (1 + r_i)$, where*

$$x_i = r_i \prod_{j \in \overleftarrow{\Gamma}_i} (1 + r_j) \ , \quad \text{for every } i \in [n] \ . \tag{6}$$

(Note that $\boldsymbol{r}$ is well-defined as $r_1 = x_1$, while for $i > 1$, r_i is determined by $x_i, r_1, \ldots, r_{i-1}$.)

▶ **Corollary 13.** *The independent set polynomial of a chordal graph can be evaluated anywhere on the complex plane in linear time. A perfect sample from the hard-core distribution on a chordal graph can be obtained in linear time.*

Proof. A chordal presentation of chordal graph $G = (V, E)$ can be found in time $O(|V| + |E|)$. Computing each r_i given $r_1, \ldots, r_{i-1}$ requires $O(|\Gamma_i|)$ steps. Thus, $Z_G(\boldsymbol{x}, [n])$ can be evaluated in $O(|V| + |E|)$ steps. Regarding sampling we observe that chordal graphs are closed with respect to vertex deletions. Thus, given $Z_G(\boldsymbol{x}, S)$ for arbitrary $S \subseteq [n]$ and $\{r_i\}_{i \in S}$, computing $Z_G(\boldsymbol{x}, T)$ for $T \subseteq S$ can be done by $O(|S| - |T|)$ divisions. Since $\{r_i\}_{i \in [n]}$ can be computed in $O(|V| + |E|)$ steps via (6), the claim follows. ◀

The previous best result on the independent set polynomial of chordal graphs is due to Okamoto, Uno, and Uehara [15] who showed that it can be evaluated exactly in linear time at $\boldsymbol{x} = \mathbf{1}$, i.e., that the number of independent sets can be counted. Since their algorithm is also capable of counting the number of independent sets of any given size $k = 1, \ldots, n$ in linear time, evaluating the univariate independent set polynomial can be done in polynomial time. However, our algorithm is significantly simpler, runs in linear time, and works also on the multivariate setting. A very recent related work by Heinrich and Müller [10] showed that the independent set polynomial can be evaluated exactly for $\boldsymbol{x} \in \mathbb{R}^n$, when G is strongly orderable. These form a subclass of weakly chordal graphs that contains chordal bipartite graphs. Finally, in terms of (arbitrarily good, randomized) approximate evaluation of the independent set polynomial, Bezakova and Sun [4] showed that a natural Markov chain for the hard core model with positive fugacities, i.e., for the case $\boldsymbol{x} \in \mathbb{R}^n$, mixes in polynomial time on chordal graphs with separators of *bounded* size.

2.4 Local Lemmata on Unordered Vertices (Simpler)

In this section we present four local lemmata providing sufficient conditions for $\boldsymbol{p} \in \mathcal{S}(G)$. As we will see in Section 3.2, determining $Z_G(-\boldsymbol{p})$ exactly amounts to understanding the set of all possible walks on G obeying certain ordering and self-avoidance constraints.

Dropping the ordering restriction and replacing self-avoidance by non-repetitiveness within distance 1 gives Theorem 14. Extending the scope of non-repetitiveness to distance 2 gives Theorem 15. Enforcing the ordering restriction while replacing self-avoidance by non-repetitiveness within distance 1 and 2, yields Theorems 17 and 18, respectively.

2.4.1 Incorporating All Paths of Length at most One

▶ **Theorem 14.** *Given $\boldsymbol{p} \in [0,1)^n$ and G, assume that for every path (i) of length 0 and every path (i,j) of length 1, there exist $r_i, r_{i,j} \in [0,1)$, respectively, such that*

$$p_i \leq r_i \prod_{j \in \Gamma_i} (1 - r_{i,j}) \tag{7}$$

$$p_j \leq r_{i,j} \prod_{k \in \Gamma_j \setminus \{i\}} (1 - r_{j,k}) \ . \tag{8}$$

Then, $Z(-\boldsymbol{p}) \geq \prod_{i \in [n]} (1 - r_i)$.

Theorem 7 follows from Theorem 14, as we show in Section 4.3: given $\{r'_i\}_{i \in [n]}$ satisfying (4) we can compute $r_{i,j}$ for every oriented edge (i,j) to satisfy (7), (8) (with $r_i = r'_i$).

2.4.2 Incorporating All Paths of Length at most Two

▶ **Theorem 15.** *Given $\boldsymbol{p} \in [0,1)^n$ and G, assume that for every path (i) of length 0, every path (i,j) of length 1, and every path (i,j,k) of length 2 such that $i \in \Gamma_k$, there exist $r_i, r_{i,j}, r_{i,j,k} \in [0,1)$, respectively, such that*

$$p_i \leq r_i \prod_{j \in \Gamma_i} (1 - r_{i,j}) \tag{9}$$

$$p_j \leq r_{i,j} \prod_{\substack{k \in \Gamma_j \setminus \{i\} \\ i \notin \Gamma_k}} (1 - r_{j,k}) \prod_{\substack{k \in \Gamma_j \setminus \{i\} \\ i \in \Gamma_k}} (1 - r_{i,j,k}) \tag{10}$$

$$p_k \leq r_{i,j,k} \prod_{\substack{\ell \in \Gamma_k \setminus \{i,j\} \\ j \notin \Gamma_\ell}} (1 - r_{k,\ell}) \prod_{\substack{\ell \in \Gamma_k \setminus \{i,j\} \\ j \in \Gamma_\ell}} (1 - r_{j,k,\ell}) \ . \tag{11}$$

Then, $Z(-\boldsymbol{p}) \geq \prod_{i \in [n]} (1 - r_i)$.

2.5 Local Lemmata on Ordered Vertices (Sharper)

A *walk* starting at vertex i is a sequence of vertices $(v_0, v_1, \ldots, v_\ell)$, such that $v_0 = i$ and for all $k \in [\ell]$, vertex v_{k-1} is adjacent to vertex v_k.

▶ **Definition 16.** *Given a walk $w = (v_0, v_1, \ldots, v_\ell)$, let $\mathcal{F}(v_0) = \emptyset$, while for $k \in [\ell]$ let*

$$\mathcal{F}(v_0, \ldots, v_k) = \mathcal{F}(v_0, \ldots, v_{k-1}) \cup \{v_{k-1}\} \cup \{u \in \Gamma_{v_{k-1}} : u \geq v_k\} \ . \tag{12}$$

Let $\mathcal{N}(v_0, \ldots, v_\ell) = \Gamma_{v_\ell} \cap \mathcal{F}(v_0, \ldots, v_\ell)$.

2.5.1 Incorporating All Paths of Length at most One

▶ **Theorem 17.** *Given $\boldsymbol{p} \in [0,1)^n$ and G, assume that for every vertex $i \in [n]$ and every oriented edge (i,j) there exist $r_i, r_{i,j} \in [0,1)$, respectively, such that*

$$p_i \le r_i \prod_{j \in \Gamma_i} (1 - r_{i,j}) \tag{13}$$

$$p_j \le r_{i,j} \prod_{k \in \Gamma_j \setminus \mathcal{N}(i,j)} (1 - r_{j,k}) \ . \tag{14}$$

Then, $Z(-\boldsymbol{p}) \ge \prod_{i \in [n]} (1 - r_i)$.

Theorem 17 implies Theorem 14, since $\{i\} \subseteq \mathcal{N}(i,j)$ implying that any collection of numbers satisfying (8) also satisfies (14).

2.5.2 Incorporating All Paths of Length at most Two

▶ **Theorem 18.** *Given $\boldsymbol{p} \in [0,1)^n$ and G assume that for every path (i) of length 0, every path (i,j) of length 1, and every path (i,j,k) of length 2 for which $\mathcal{N}(i,j,k) \neq \mathcal{N}(j,k)$, there exist $r_i, r_{i,j}, r_{i,j,k} \in [0,1)$, respectively, such that*

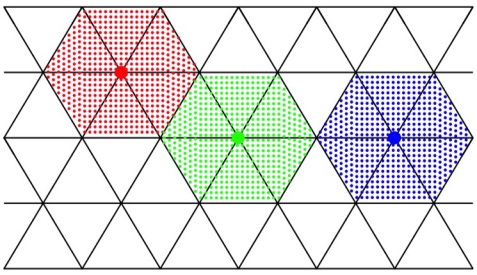
$$p_i \le r_i \prod_{j \in \Gamma_i} (1 - r_{i,j}) \tag{15}$$

$$p_j \le r_{i,j} \prod_{\substack{k \in \Gamma_j \setminus \mathcal{N}(i,j) \\ \mathcal{N}(i,j,k) = \mathcal{N}(j,k)}} (1 - r_{j,k}) \prod_{\substack{k \in \Gamma_j \setminus \mathcal{N}(i,j) \\ \mathcal{N}(i,j,k) \neq \mathcal{N}(j,k)}} (1 - r_{i,j,k}) \tag{16}$$

$$p_k \le r_{i,j,k} \prod_{\substack{\ell \in \Gamma_k \setminus \mathcal{N}(i,j,k) \\ \mathcal{N}(j,k,\ell) = \mathcal{N}(k,\ell)}} (1 - r_{k,\ell}) \prod_{\substack{\ell \in \Gamma_k \setminus \mathcal{N}(i,j,k) \\ \mathcal{N}(j,k,\ell) \neq \mathcal{N}(k,\ell)}} (1 - r_{j,k,\ell}) \ . \tag{17}$$

Then, $Z(-\boldsymbol{p}) \ge \prod_{i \in [n]} (1 - r_i)$.

Theorem 18 implies Theorem 15, since $\{i\} \subseteq \mathcal{N}(i,j)$ and $\Gamma_k \cap \{i,j\} \subseteq \mathcal{N}(i,j,k)$, implying that any collection of numbers satisfying (10), (11) also satisfy (16), (17).



Theorem 18 also yields Theorem 17, by replacing the set $\mathcal{N}(i,j,k)$ in inequality (17) with its subset $\mathcal{N}(i,j)$ and imposing the additional equality constraints $r_{i,j,k} = r_{j,k}$. These modifications increase the number of (shrinking) factors in both (16) and (17), and together with the additional equality constraints make the resulting system of inequalities stricter.

Thus, to prove Theorems 14–18 it suffices to prove Theorem 18, which we do in Section 4.4.

2.6 Benchmarking: the Radii of $\mathcal{S}(G)$

As mentioned earlier, determining the set of activities for which the partition function is non-vanishing in the corresponding polydisk is a central problem in statistical mechanics. This is primarily motivated by the Lee-Yang [23] approach to studying phase transitions. Since phase transitions (non-analyticies of [one or more derivatives of] the log-partition function) can occur only in infinite-size systems, to study them on a locally-finite countable graph G_∞ (typically a regular lattice), we consider an increasing sequence of subgraphs $(G_n)_{n \ge 1}$ converging to G_∞ and study the limiting free energy per vertex $f_{G_\infty} = \lim_{n \to \infty} n^{-1} \log Z_{G_n}(\boldsymbol{x})$. Nonanalyticities of f_{G_∞} for real $\boldsymbol{x}$, arise from singularities of $\log Z_{G_n}(\boldsymbol{x})$ for complex $\boldsymbol{x}$ that approach the real axis in the limit $n \to \infty$. But the singularities of $\log Z_{G_n}(\boldsymbol{x})$ are precisely the zeros of $Z_{G_n}(\boldsymbol{x})$, hence the desire to determine the set $\mathcal{S}(G)$. Of particular interest is the so-called *uniform*, i.e., univariate, case $\boldsymbol{x} = x\mathbf{1}$, where all the activities are the same.

To benchmark our methods, we consider one of the very few exactly solved cases of the hard-core model, namely the case where G_∞ is the triangular lattice. This is known as the "hard hegaxons" model, since its valid configurations amount to placements of (centers of) hexagons in a triangular lattice so that no two hexagons overlap, i.e., to selecting an independent set of the triangular lattice to serve as the set of hexagon centers.

For this model it is known that the critical value is $x_c = \frac{5\sqrt{5}-11}{2} = 0.09016...$ Applying the asymmetric LLL, which only exploits that $\Delta(G_n) = 6$, gives $x_c \geq \Delta^\Delta/(\Delta+1)^{\Delta+1} = 6^6/7^7 = 0.0566$. Our improved asymmetric LLL (Theorem 7), improving the dependence on Δ, yields $x_c \geq (\Delta-1)^{\Delta-1}/\Delta^\Delta = 5^5/6^6 = 0.0669$.

Kolipaka, Szegedy, and Xu [11], introduced a family of sufficient conditions for the avoidance probability to be positive that range between the asymmetric LLL and the exact result of Shearer [18]. To apply their so-called "clique LLL" we color the triangular faces in a chess board pattern and decompose the triangular lattice using the white triangles as the parts of the clique-decomposition. Optimizing the resulting parameters yields $x_c \geq 0.07407$.

Finally, the cluster expansion LLL of Bissacot et al. [5], exploiting the presence of 6 triangles in the neighborhood of each vertex, yields $x_c \geq 0.0776$.

2.6.1 Simpler Bound: $x_c \geq 0.08115$

To apply Theorem 17 in the triangular lattice we order the neighbors of each vertex by taking the eastern neighbor to be the greatest, and then descending counter-clockwise. The translation symmetry of the lattice allows us to capture all possible paths of length up to one using only seven variables. Specifically, r_0 corresponds to vertices (paths of length 0), r_1 corresponds to arcs (paths of length 1) heading east, r_2 to arcs heading northeast, etc. Thus, inequalities (13) and (14) require x to be simultaneously less than all of the following:

$$
\begin{aligned}
&r_0 \cdot (1-r_1)\cdot(1-r_2)\cdot(1-r_3)\cdot(1-r_4)\cdot(1-r_5)\cdot(1-r_6)\\
&r_1 \cdot (1-r_1)\cdot(1-r_2)\cdot(1-r_3)\cdot(1-r_5)\cdot(1-r_6)\\
&r_2 \cdot (1-r_1)\cdot(1-r_2)\cdot(1-r_3)\cdot(1-r_4)\\
&r_3 \cdot (1-r_2)\cdot(1-r_3)\cdot(1-r_4)\cdot(1-r_5)\\
&r_4 \cdot (1-r_3)\cdot(1-r_4)\cdot(1-r_5)\cdot(1-r_6)\\
&r_5 \cdot (1-r_1)\cdot(1-r_4)\cdot(1-r_5)\cdot(1-r_6)\\
&r_5 \cdot (1-r_1)\cdot(1-r_5)\cdot(1-r_6)
\end{aligned}
$$

Taking $r_0 = 0.3055479560$, $r_1 = 0.2499747372$, $r_2 = 0.2063465756$, $r_3 = 0.1924531372$, $r_4 = 0.1818805124$, $r_5 = 0.1958294533$, $r_6 = 0.1602118920$, this is achieved for $x \leq 0.08115$.

2.6.2 Sharper Bound: $x_c \geq 0.08636$

To apply Theorem 18 we need to also consider paths of length 2. To do this we introduce a set of 6 additional variables $r_{1,3}, r_{2,1}, r_{2,4}, r_{3,5}, r_{5,1}, r_{6,1}$ (while, a priori, there are 6^2 "types" of paths of length 2, many of them are infeasible, while for others the type of the first arc implies the type of the second). Specifically, $r_{1,3}$ corresponds to a path first heading east and then heading northwest, $r_{2,1}$ corresponds to a path first heading northeast and then heading east, etc. The resulting 13 inequalities are satisfied for $x \leq 0.08636$ and $r_0 = 0.3939972440$, $r_1 = 0.2956228200$, $r_2 = 0.2271540263$, $r_3 = 0.2187337137$, $r_4 = 0.2144822763$, $r_5 = 0.2060776445$, $r_6 = 0.1736041642$, $r_{1,3} = 0.1820809928$, $r_{2,1} = 0.2347015656$, $r_{2,4} = 0.1772472600$, $r_{3,5} = 0.1675677715$, $r_{5,1} = 0.1868706968$, $r_{6,1} = 0.2417955235$.

3 Relating the Independent Set Polynomial to Walk Trees

3.1 Main Recurrence, Occupation Ratios, and Trees

For $i \in [n]$ and $S \subseteq [n] \setminus \{i\}$, given input $\boldsymbol{x}$, we define

$$Z(\boldsymbol{x}; i \mid S) := \frac{Z(\boldsymbol{x}; S \cup \{i\})}{Z(\boldsymbol{x}; S)} = Z(i \mid S) \ .$$

Trivially, $Z = Z([n]) = \prod_{i \in [n]} Z(i \mid [i-1])$, since $Z(\emptyset) = 1$. To estimate $Z(i \mid S)$ observe that the contribution to $Z(S \cup \{i\})$ of the sets including vertex i equals x_i times the contribution of the sets not including $\Gamma^+(i)$. Therefore,

$$Z(S \cup \{i\}) = Z(S) + x_i Z(S \setminus \Gamma_i) \ . \tag{18}$$

With the above in mind, let $j_1 \geq \ldots \geq j_d$ be the descending ordering of $\Gamma_i \cap S$, and for $\ell \in [d]$ write $S_\ell = S \setminus \{j_1, \ldots, j_\ell\}$. Dividing (18) by $Z(S)$ and writing the ratio $Z(S \setminus \Gamma_i)/Z(S)$ in telescopic form yields

$$Z(i \mid S) = 1 + x_i \frac{1}{\frac{Z(S)}{Z(S \setminus \Gamma_i)}} = 1 + x_i \frac{1}{\prod_{\ell=1}^{d} \frac{Z(S \setminus \{j_1, \ldots, j_{\ell-1}\})}{Z(S \setminus \{j_1, \ldots, j_\ell\})}} = 1 + x_i \prod_{\ell=1}^{d} \frac{1}{Z(j_\ell \mid S_\ell)} \ . \tag{19}$$

It is convenient to introduce the quantity $\text{ratio}_G(\boldsymbol{x}; (i, S)) := Z(i \mid S) - 1 = \text{ratio}(i, S)$ and rewrite (19) as

$$\text{ratio}(i, S) = x_i \prod_{\ell=1}^{d} \frac{1}{1 + \text{ratio}(j_\ell, S_\ell)} \ . \tag{20}$$

Thus,

$$Z = Z([n]) = \prod_{i \in [n]} Z(i \mid [i-1]) = \prod_{i \in [n]} (1 + \text{ratio}(i, [i-1])) \ . \tag{21}$$

We can now characterize the set $\mathcal{S}(G)$ as follows.

▶ **Lemma 19.** *The following are equivalent:*

1. *For every $S \subseteq [n]$, $Z(-\boldsymbol{p}; S) > 0$.*
2. *For every $i \in [n]$, and $S \subseteq [n] \setminus \{i\}$, $\text{ratio}(-\boldsymbol{p}; (i, S)) > -1$.*
3. *For every $i \in [n]$, and $S \subseteq [i-1]$, $\text{ratio}(-\boldsymbol{p}; (i, S)) > -1$.*

Proof.
$(1 \implies 2)$ If $Z(S), Z(S \cup \{i\}) > 0$, then $1 + \mathrm{ratio}(i, S) = Z(S \cup \{i\})/Z(S) > 0$.
$(2 \implies 3)$ Trivial.
$(3 \implies 1)$ For any $S \subseteq [n]$ and $j \in S$, write $S_j = \{k \in S : k < j\}$. By telescoping, $Z(S) = \prod_{j \in S} Z(j|S_j) = \prod_{j \in S} (1 + \mathrm{ratio}(j, S_j))$. Since $S_j \subseteq [i-1]$, the last product is positive. ◀

Say that $S, T \subseteq [n]$ are *separate* if they are disjoint and no edge has one endpoint in each. Clearly, if S, T are separate, then $Z(S \cup T) = Z(S)Z(T)$. Moreover, if $T \subseteq [n]$ is separate from $S \cup \{i\}$, then

$$\begin{aligned} \mathrm{ratio}(i, S \cup T) &= x_i \frac{Z((S \cup T) \setminus \Gamma_i)}{Z(S \cup T)} \\ &= x_i \frac{Z((S \setminus \Gamma_i) \cup T)}{Z(S \cup T)} \\ &= x_i \frac{Z(S \setminus \Gamma_i)Z(T)}{Z(S)Z(T)} = \mathrm{ratio}(i, S) \ . \end{aligned} \tag{22}$$

▶ **Definition 20.** *For a vertex v of a rooted tree T, we use $\widehat{\mathrm{ratio}}_T(v)$ to denote the quantity $\mathrm{ratio}_T(v, T(v))$, where $T(v)$ is the set of vertices other than v in the subtree rooted at v.*

Using (22) we observe that for a rooted tree T, recurrence (20) can be rewritten as

$$\widehat{\mathrm{ratio}}_T(v) = x_v \prod_{\ell=1}^{d} \frac{1}{1 + \widehat{\mathrm{ratio}}_T(v_\ell)} \ , \tag{23}$$

where $\{v_1, \ldots, v_d\}$ are the children of v in T.

3.2 Relating Arbitrary Graphs to Walk-Trees

Let $w = (v_0, v_1, \ldots, v_\ell)$ be an arbitrary walk of length ℓ.

▶ **Definition 21.** *w is* self-avoiding *if its vertices are* distinct.

▶ **Definition 22.** *w is* descending *if $v_k < v_{k-1}$ for all $k \in [\ell]$.*

Recall that, per Definition 16, for a walk $w = (v_0, v_1, \ldots, v_\ell)$, we let $\mathcal{F}(v_0) = \emptyset$, while for $k \in [\ell]$ we let $\mathcal{F}(v_0, \ldots, v_k) = \mathcal{F}(v_0, \ldots, v_{k-1}) \cup \{v_{k-1}\} \cup \{u \in \Gamma_{v_{k-1}} : u \geq v_k\}$.

▶ **Definition 23.** *$w = (v_0, v_1, \ldots, v_\ell)$ is* self-bounding *if $v_{k+1} \notin \mathcal{F}(v_0, \ldots, v_k)$ for all $k \in [\ell]$.*

▶ Remark 24. Self-bounding walks were defined in [17] as "truncated self-avoiding walks." The idea is that the next vertex in a self-bounding walk is subject to the additional requirement, relative to a self-avoiding walk, that it can also not be connected to certain neighbors of previously visited vertices. While a descending walk is self-bounding, the converse need not hold. For instance, in $G = ([4], \{\{1,2\}, \{2,3\}, \{3,4\}, \{4,1\}\})$, the walk $(4, 1, 2)$ is self-bounding but not descending.

For $S \subseteq [n]$, we write G_S for the subgraph of G induced by S.

▶ **Definition 25.** *Let $\mathcal{W}$ be a set of walks on G all starting at i, such that if $w \in \mathcal{W}$, then the same is true for every prefix of w. The* walk-tree *corresponding to the set of walks $\mathcal{W}$ has as its root the walk (i) of length 0, while the children of each vertex (walk) are its extensions by one step. The* activity *of vertex $(i, v_1, \ldots, v_\ell)$ of the walk-tree is x_{v_ℓ}.*

We use $\mathcal{L}_i := \mathcal{L}_i(G)$ to denote the walk-tree of self-bounding walks on $G_{[i]}$ starting at i.

The following theorem reduces the computation of ratios of an arbitrary graph G, to that of the tree ratios of $\mathcal{L}_i(G)$.

▶ **Theorem 26.** *For every vertex $i \in [n]$ and every walk $w = (v_0, v_1, \ldots, v_\ell)$ in $\mathcal{L}_i$,*

$$\widehat{\text{ratio}}_{\mathcal{L}_i}(w) = \text{ratio}_G\left(v_\ell, [i-1] \setminus \mathcal{F}(v_0, \ldots, v_\ell)\right) \quad . \tag{24}$$

In particular, $\widehat{\text{ratio}}_{\mathcal{L}_i}((i)) = \text{ratio}_G\left(i, [i-1]\right)$.

Proof. We proceed by induction on the size of the subtree rooted at w.

If w is a leaf in $\mathcal{L}_i$ then, trivially, $\text{ratio}_{\mathcal{L}_i}(w) = x_{v_\ell}$ and $\mathcal{F}(v_0, \ldots, v_\ell) \supseteq \Gamma_{v_\ell}$, for otherwise w could be extended. Thus, $[i-1] \setminus \mathcal{F}(v_0, \ldots, v_\ell)$ is separate from v_ℓ, which per (22) implies that $\text{ratio}_G\left(v_\ell, [i-1] \setminus \mathcal{F}(v_0, \ldots, v_\ell)\right) = \text{ratio}_G(v_\ell, \emptyset) = x_{v_\ell}$.

If w is not a leaf in $\mathcal{L}_i$, assume the theorem holds for its descendants. Let $\{j_1, \ldots, j_d\} = \Gamma_{v_\ell} \cap ([i-1] \setminus \mathcal{F}(v_0, \ldots, v_\ell))$, with $j_1 \geq \ldots \geq j_d$, and for $t \in [d]$ write $w_t = (v_0, v_1, \ldots, v_\ell, j_t)$. The first equality below follows from (23), the second from the inductive hypothesis, the third from the definition of $\mathcal{F}$, and the last from (20):

$$\widehat{\text{ratio}}_{\mathcal{L}_i}(w) = x_{v_\ell} \prod_{t=1}^{d} \frac{1}{1 + \widehat{\text{ratio}}_{\mathcal{L}_i}(w_t)} \tag{25}$$

$$= x_{v_\ell} \prod_{t=1}^{d} \frac{1}{1 + \text{ratio}_G\left(j_t, [i-1] \setminus \mathcal{F}\left(v_0, \ldots, v_\ell, j_t\right)\right)} \tag{26}$$

$$= x_{v_\ell} \prod_{t=1}^{d} \frac{1}{1 + \text{ratio}_G\left(j_t, ([i-1] \setminus \mathcal{F}\left(v_0, \ldots, v_\ell\right)) \setminus \{j_1, \ldots, j_t\}\right)} \tag{27}$$

$$= \text{ratio}_G\left(v_\ell, [i-1] \setminus \mathcal{F}\left(v_0, \ldots, v_\ell\right)\right) \quad . \tag{28}$$

◀

3.3 Tree Monotonicity

▶ **Definition 27.** *Let T be a tree with root r. The set of* prefixes *of T comprises T itself, and every tree with root r that can be derived by removing a leaf from a prefix of T.*

▶ **Lemma 28.** *Let T be a tree with root r and assume that $\boldsymbol{p}$ is such that $\widehat{\text{ratio}}_T(-\boldsymbol{p}; v) > -1$ for every vertex $v \neq r$ of T. Then the function $f : \boldsymbol{x} \mapsto \widehat{\text{ratio}}_T\left(-\boldsymbol{x}; r\right)$ is smooth and strictly decreasing in each coordinate inside $P = \{(x_1, \ldots, x_n) : 0 \leq x_i \leq p_i\}$. In particular, if T' is a prefix of T, then $\widehat{\text{ratio}}_T\left(-\boldsymbol{p}; r\right) \leq \widehat{\text{ratio}}_{T'}\left(-\boldsymbol{p}; r\right)$.*

Proof. We use induction on the size of T. If T consists of just $\{r\}$, then $\widehat{\text{ratio}}_T\left(-\boldsymbol{x}; r\right) = -x_r$, satisfying the claim trivially. Let now T be a tree of size n, and assume that the lemma holds for every tree of size strictly less than n. If $\Gamma_i = \{j_1, \ldots, j_d\}$, then per (23),

$$\widehat{\text{ratio}}_T\left(-\boldsymbol{x}; r\right) = -x_r \prod_{\ell=1}^{d} \frac{1}{1 + \widehat{\text{ratio}}_T\left(-\boldsymbol{x}; j_\ell\right)} \quad . \tag{29}$$

Since each subtree rooted at j_ℓ has size strictly less than n, the inductive hypothesis implies that $\widehat{\text{ratio}}_T\left(-\boldsymbol{x}; j_\ell\right)$ is strictly decreasing inside P. Therefore, the lemma hypothesis that $\widehat{\text{ratio}}_T\left(-\boldsymbol{p}; j_\ell\right) > -1$ implies that $\widehat{\text{ratio}}_T\left(-\boldsymbol{x}; j_\ell\right) > -1$. Since the function $1/(1+x)$ is smooth and strictly decreasing for $x > -1$, the claim follows by the smoothness and monotonicity of the d factors in (29) implied by the inductive hypothesis.

To see the claim regarding prefixes of T, observe that $\widehat{\text{ratio}}_{T'}\left(-\boldsymbol{p}; r\right) = \widehat{\text{ratio}}_T\left(-\boldsymbol{p'}; r\right)$, where $\boldsymbol{p'}$ is derived by setting to 0 all coordinates of $\boldsymbol{p}$ corresponding to vertices not in T'. ◀

▶ **Theorem 29.** *$\boldsymbol{p} \in \mathcal{S}(G)$ iff $\widehat{\text{ratio}}_{\mathcal{L}_i}(-\boldsymbol{p}; w) > -1$, for all $i \in [n]$ and $w \in \mathcal{L}_i$.*

Proof. If $\boldsymbol{p} \in \mathcal{S}(G)$, then, by Lemma 19, $\text{ratio}_G(i, S) > -1$, for every $i \in [n]$ and $S \subseteq [n] \setminus \{i\}$. Thus, per Theorem 26, $\widehat{\text{ratio}}_{\mathcal{L}_i}(-\boldsymbol{p}; w) = \text{ratio}_G(v_\ell, [i-1] \setminus \mathcal{F}(v_0, \ldots, v_\ell)) > -1$.

For the converse, we will show that if $\widehat{\text{ratio}}_{\mathcal{L}_i}(-\boldsymbol{p}; w) > -1$ for all $i \in [n]$ and $w \in \mathcal{L}_i$, then $\text{ratio}(i, S) > -1$ for every $i \in [n]$ and $S \subseteq [i-1]$, which, by Lemma 19, implies $\boldsymbol{p} \in \mathcal{S}(G)$. Let $i \in [n]$ and $S \subseteq [i-1]$ be arbitrary, write $S^+ := S \cup \{i\}$, and let $\widetilde{\mathcal{L}}_i$ be the prefix of $\mathcal{L}_i$ obtained by deleting all walks intersecting the complement of S^+. It is easy to check that $\widetilde{\mathcal{L}}_i$ coincides with the tree of self-bounding walks starting at i on the subgraph of $G_{[i]}$ induced by S^+, i.e., $\widetilde{\mathcal{L}}_i(G) = \mathcal{L}_i(G_{S^+})$. Thus, Theorem 26 gives the second equality below, while the monotonicity of tree prefixes, per Lemma 28, gives the first inequality:

$$\text{ratio}_G(-\boldsymbol{p}; (i, S)) = \text{ratio}_{G_{S^+}}(-\boldsymbol{p}; (i, S)) = \widehat{\text{ratio}}_{\widetilde{\mathcal{L}}_i}(-\boldsymbol{p}; (i)) \geq \widehat{\text{ratio}}_{\mathcal{L}_i}(-\boldsymbol{p}; (i)) > -1 \ . \quad \blacktriangleleft$$

4 Proofs of Results

4.1 Upper Bound (Theorem 9)

Let $\mathcal{D}_i := \mathcal{D}_i(G)$ denote the tree of descending walks on G starting at i. Due to its highly recursive structure, if two vertices in $\mathcal{D}_i$ correspond to walks that end on the same vertex, then their ratios are equal. As a result, the different root ratios satisfy the following simple system of equations.

▶ **Theorem 30.** *Given $\boldsymbol{x} \in \mathbb{C}^n$, for $i = 1, 2, \ldots, n$ let*

$$r_i = x_i \prod_{j \in \overleftarrow{\Gamma}_i} \frac{1}{1 + r_j} \ . \tag{30}$$

Then, $\widehat{\text{ratio}}_{\mathcal{D}_i}(\boldsymbol{x}; (i)) = r_i$, for every $i \in [n]$.

Proof. We use induction on i. For $i = 1$, trivially, $\widehat{\text{ratio}}_{\mathcal{D}_1}(\boldsymbol{x}; (1)) = x_1 = r_1$. Assume now that (30) holds for all $i < k$. Clearly, the root walk (k) can only be extended by taking a step to a neighbor smaller than k. If $\{j_1, \ldots, j_d\} = \overleftarrow{\Gamma}_k$, then (23) yields (31). For the first equality in (32), note that appending k as a prefix to every vertex of $\mathcal{D}_{j_\ell}$ yields the subtree of $\mathcal{D}_k$ rooted at (k, j_ℓ), while the inductive hypothesis yields the second equality in (32).

$$\widehat{\text{ratio}}_{\mathcal{D}_k}(\boldsymbol{x}; (k)) = x_k \prod_{\ell=1}^{d} \frac{1}{1 + \widehat{\text{ratio}}_{\mathcal{D}_k}(\boldsymbol{x}; (k, j_\ell))} \tag{31}$$

$$= x_k \prod_{\ell=1}^{d} \frac{1}{1 + \widehat{\text{ratio}}_{\mathcal{D}_{j_\ell}}(\boldsymbol{x}; (j_\ell))} = x_i \prod_{j \in \overleftarrow{\Gamma}_i} \frac{1}{1 + r_j} = r_k \ . \tag{32}$$

$\blacktriangleleft$

Proof of Theorem 9. Without loss of generality, we assume that π is the identity. Equation (21) yields (33), while (34) follows from Theorem 26. Recalling that descending walks are self-bounding shows that $\mathcal{D}_i$ is a prefix of $\mathcal{L}_i$ and, thus, per Lemma 28, $\widehat{\text{ratio}}_{\mathcal{D}_i}(-\boldsymbol{p}; (i)) \geq \widehat{\text{ratio}}_{\mathcal{L}_i}(-\boldsymbol{p}; (i))$, yielding (35). Finally, our hypothesis is equivalent to $-r_i$ satisfying (30) for $\boldsymbol{x} = -\boldsymbol{p}$ so that Theorem 30, implies $\widehat{\text{ratio}}_{\mathcal{D}_i}(-\boldsymbol{p}; (i)) = -r_i$ and, thus, (36).

$$Z(-\boldsymbol{p}; S) = \prod_{i\in[n]} (1 + \mathrm{ratio}_G(-\boldsymbol{p}; (i, [i-1]))) \tag{33}$$

$$= \prod_{i\in[n]} \left(1 + \widehat{\mathrm{ratio}}_{\mathcal{L}_i}(-\boldsymbol{p}; (i))\right) \tag{34}$$

$$\leq \prod_{i\in[n]} \left(1 + \widehat{\mathrm{ratio}}_{\mathcal{D}_i}(-\boldsymbol{p}; (i))\right) \tag{35}$$

$$= (1 - r_i) \ . \tag{36}$$

◀

4.2 Chordal Graphs (Theorem 12)

We claim that a graph on $[n]$ is chordally presented iff its set of descending walks equals its set of self-bounding walks. Given this claim, Theorem 12 follows from Theorem 30. Since descending walks are self-bounding, the following suffices to prove our claim.

▶ **Theorem 31.** *G is not chordally presented iff there is a vertex i and a self-bounding walk on $G_{[i]}$ starting at i that is not descending.*

Proof. Let $(i =: v_0, v_1, \ldots, v_\ell)$ be a self-bounding walk on $G_{[i]}$ that is not descending and let $2 \leq k \leq \ell$ be the minimum index such that $v_{k-1} < v_k$. The minimality of k implies $v_{k-1} < v_{k-2}$ and, hence, that $v_k, v_{k-2} \in \overrightarrow{\Gamma}_{v_{k-1}}$. Since the walk is self-bounding, $v_k \notin \Gamma_{v_{k-2}}$, i.e., there is no edge between v_{k-2} and v_k, implying that G is not chordally presented.

If G is not chordally presented, there must be vertices $a < b < c$ such that a is connected to b and c, but b is not connected to c. Clearly, the walk (c, a, b) on $G_{[c]}$ is self-bounding but not descending. ◀

4.3 Proof of Theorem 7 given Theorem 14

Proof. Given $\{r'_i\}_{i\in[n]}$, let $r_i = r'_i$ and $r_{i,j} = r'_i \frac{1-r'_j}{1-r'_i r'_j}$. We show that if (4) is satisfied, then (7) and (8) are satisfied. Indeed,

$$r_i \prod_{j\in\Gamma_i} (1 - r_{j,i}) = r'_i \prod_{j\in\Gamma_i} \left(1 - r'_j \frac{1-r'_i}{1-r'_j r'_i}\right) = r'_i \prod_{j\in\Gamma_i} \left(\frac{1-r'_j}{1-r'_j r'_i}\right) \geq p_i \ ,$$

and

$$r_{i,j} \prod_{k\in\Gamma_i\setminus\{j\}} (1 - r_{k,i}) = r'_i \frac{1-r'_j}{1-r'_i r'_j} \prod_{k\in\Gamma_i\setminus\{j\}} \left(1 - r'_k \frac{1-r'_i}{1-r'_k r'_i}\right) = r'_i \prod_{j\in\Gamma_i} \left(\frac{1-r'_j}{1-r'_j r'_i}\right) \geq p_i.$$

◀

4.4 Proof of Theorem 18

Proof. We claim that (15)–(17) imply $\mathrm{ratio}(-\boldsymbol{p}; (i, S)) \geq -r_i$ for all $i \in [n]$ and $S \subseteq [n] \setminus \{i\}$. This suffices since $Z([n]) = \prod_{i=1}^n Z(i|[i-1]) = \prod_{i=1}^n (1 + \mathrm{ratio}(i, [i-1])) \geq \prod_{i=1}^n (1 - r_i)$.

To prove the claim we prove that if (15)–(17) hold, then (a),(b),(c) below hold (our claim is equivalent to (a); we only prove (b), (c) as aids for proving (a)):

(a) $\text{ratio}(-\boldsymbol{p}; (i, S)) \geq -r_i$, for every (empty) path (i) and every $S \subseteq [n] \setminus \{i\}$.

(b) $\text{ratio}(-\boldsymbol{p}; (j, S)) \geq -r_{i,j}$, for every path (i, j) and every $S \subseteq [n] \setminus \mathcal{N}(i, j)$.

(c) $\text{ratio}(-\boldsymbol{p}; (k, S)) \geq -r_{i,j,k}$, for every path (i, j, k) such that $\mathcal{N}(i, j, k) \neq \mathcal{N}(j, k)$ and every $S \subseteq [n] \setminus \mathcal{N}(i, j, k)$.

To prove (a),(b),(c) we proceed by induction on $|S|$. For $S = \emptyset$, we see that (15)–(17) imply $-p_i \geq \max\{-r_{k,j,i}, -r_{j,i}, -r_i\}$, for any $i, j, k \in [n]$, while $\text{ratio}(-\boldsymbol{p}; (i, S)) = -p_i$.

For $S \neq \emptyset$, assume that (a),(b),(c) hold for all sets of size strictly less than $|S|$.

(a) For any path (i) and any set $S \subseteq [n] \setminus \{i\}$, equation (20) implies the first equality below, while the inductive hypothesis yields the first inequality (since $\mathcal{N}(i, j)$ is non-empty):

$$\begin{aligned}
\text{ratio}(i, S) &= -p_i \prod_{j \in S \cap \Gamma_i} \frac{1}{1 + \text{ratio}(j, S \setminus \mathcal{N}(i, j))} \\
&\geq -p_i \prod_{j \in S \cap \Gamma_i} \frac{1}{1 - r_{i,j}} \\
&\geq -p_i \prod_{j \in \Gamma_i} \frac{1}{1 - r_{i,j}} \ .
\end{aligned}$$

Assumption (15) concludes the argument.

(b) For any path (i, j) and any set $S \subseteq [n] \setminus \mathcal{N}(i, j)$, equation (20) implies the first equality below, the second equality holds since S is devoid of vertices from $\mathcal{N}(i, j)$, while the third equality follows easily from the definition of $\mathcal{N}$:

$$\begin{aligned}
\text{ratio}(j, S) &= -p_j \prod_{k \in S \cap \Gamma_j} \frac{1}{1 + \text{ratio}(k, S \setminus \mathcal{N}(j, k))} \\
&= -p_j \prod_{k \in S \cap \Gamma_j} \frac{1}{1 + \text{ratio}(k, S \setminus (\mathcal{N}(i, j) \cup \mathcal{N}(j, k)))} \\
&= -p_j \prod_{k \in S \cap \Gamma_j} \frac{1}{1 + \text{ratio}(k, S \setminus \mathcal{N}(i, j, k))} \qquad (37)
\end{aligned}$$

Decomposing the product in (37) into two groups of factors yields (38) and invoking the inductive hypothesis yields (39):

$$\prod_{\substack{k \in S \cap \Gamma_j \\ \mathcal{N}(i,j,k) = \mathcal{N}(j,k)}} \left(\frac{1}{1 + \text{ratio}(k, S \setminus \mathcal{N}(j, k))} \right) \prod_{\substack{k \in S \cap \Gamma_j \\ \mathcal{N}(i,j,k) \neq \mathcal{N}(j,k)}} \left(\frac{1}{1 + \text{ratio}(k, S \setminus \mathcal{N}(i, j, k))} \right) \qquad (38)$$

$$\leq \prod_{\substack{k \in S \cap \Gamma_j \\ \mathcal{N}(i,j,k) = \mathcal{N}(j,k)}} \left(\frac{1}{1 - r_{j,k}} \right) \prod_{\substack{k \in S \cap \Gamma_j \\ \mathcal{N}(i,j,k) \neq \mathcal{N}(j,k)}} \left(\frac{1}{1 - r_{i,j,k}} \right) \qquad (39)$$

$$\leq \prod_{\substack{k \in \Gamma_j \setminus \mathcal{N}(i,j) \\ \mathcal{N}(i,j,k) = \mathcal{N}(j,k)}} \left(\frac{1}{1 - r_{j,k}} \right) \prod_{\substack{k \in \Gamma_j \setminus \mathcal{N}(i,j) \\ \mathcal{N}(i,j,k) \neq \mathcal{N}(j,k)}} \left(\frac{1}{1 - r_{i,j,k}} \right) \ .$$

Assumption (16) concludes the argument.

(c) For any path (i,j,k) such that $\mathcal{N}(i,j,k) \neq \mathcal{N}(j,k)$ and any set $S \subseteq [n] \setminus \mathcal{N}(i,j,k)$, equation (20) implies the first equality below, the second equality holds since S is devoid of vertices from $\mathcal{N}(j,k)$, while the third equality follows easily from the definition of $\mathcal{N}$:

$$\begin{aligned}\text{ratio}(k,S) &= -p_k \prod_{\ell \in S \cap \Gamma_k} \frac{1}{1+\text{ratio}(\ell, S \setminus \mathcal{N}(k,\ell))} \\ &= -p_k \prod_{\ell \in S \cap \Gamma_k} \frac{1}{1+\text{ratio}(\ell, S \setminus (\mathcal{N}(j,k) \cup \mathcal{N}(k,\ell)))} \\ &= -p_k \prod_{\ell \in S \cap \Gamma_k} \frac{1}{1+\text{ratio}(\ell, S \setminus \mathcal{N}(j,k,\ell))} \ . \end{aligned} \tag{40}$$

Decomposing the product in (40) into two groups of factors yields (41) and invoking the inductive hypothesis yields (42):

$$\prod_{\substack{\ell \in S \cap \Gamma_k \\ \mathcal{N}(j,k,\ell) = \mathcal{N}(k,\ell)}} \left(\frac{1}{1+\text{ratio}(\ell, S \setminus \mathcal{N}(k,\ell))} \right) \prod_{\substack{\ell \in S \cap \Gamma_j \\ \mathcal{N}(j,k,\ell) \neq \mathcal{N}(k,\ell)}} \left(\frac{1}{1+\text{ratio}(\ell, S \setminus \mathcal{N}(j,k,\ell))} \right) \tag{41}$$

$$\leq \prod_{\substack{\ell \in S \cap \Gamma_k \\ \mathcal{N}(j,k,\ell) = \mathcal{N}(k,\ell)}} \left(\frac{1}{1-r_{k,\ell}} \right) \prod_{\substack{\ell \in S \cap \Gamma_k \\ \mathcal{N}(j,k,\ell) \neq \mathcal{N}(k,\ell)}} \left(\frac{1}{1-r_{j,k,\ell}} \right) \tag{42}$$

$$\leq \prod_{\substack{\ell \in \Gamma_k \setminus \mathcal{N}(i,j,k) \\ \mathcal{N}(j,k,\ell) = \mathcal{N}(k,\ell)}} \left(\frac{1}{1-r_{k,\ell}} \right) \prod_{\substack{\ell \in \Gamma_k \setminus \mathcal{N}(i,j,k) \\ \mathcal{N}(j,k,\ell) \neq \mathcal{N}(k,\ell)}} \left(\frac{1}{1-r_{j,k,\ell}} \right) \ .$$

Assumption (17) concludes the argument. ◀

Almost-Linear-Time Weighted ℓ_p-Norm Solvers in Slightly Dense Graphs via Sparsification

Abstract

We give almost-linear-time algorithms for constructing sparsifiers with $n\,\mathrm{poly}(\log n)$ edges that approximately preserve weighted $(\ell_2^2 + \ell_p^p)$ flow or voltage objectives on graphs. For flow objectives, this is the first sparsifier construction for such mixed objectives beyond unit ℓ_p weights, and is based on expander decompositions. For voltage objectives, we give the first sparsifier construction for these objectives, which we build using graph spanners and leverage score sampling. Together with the iterative refinement framework of [Adil et al, SODA 2019], and a new multiplicative-weights based constant-approximation algorithm for mixed-objective flows or voltages, we show how to find $(1 + 2^{-\mathrm{poly}(\log n)})$ approximations for weighted ℓ_p-norm minimizing flows or voltages in $p(m^{1+o(1)} + n^{4/3+o(1)})$ time for $p = \omega(1)$, which is almost-linear for graphs that are slightly dense $(m \geq n^{4/3+o(1)})$.

1 Introduction

Network flow problems are some of the most extensively studied problems in optimization (e.g. see [4, 37, 20]). A general network flow problem on a graph $G(V, E)$ with n vertices and m edges can be formulated as

$$\min_{\boldsymbol{B}^\top \boldsymbol{f} = \boldsymbol{d}} \mathtt{cost}(\boldsymbol{f}),$$

where $\boldsymbol{f} \in \mathbb{R}^E$ is a flow vector on edges satisfying net vertex demands $\boldsymbol{d} \in \mathbb{R}^V$, $\boldsymbol{B} \in \mathbb{R}^{E \times V}$ is the signed edge-vertex incidence matrix of the graph, and $\mathtt{cost}(\boldsymbol{f})$ is a cost measure on flows. The weighted ℓ_∞-minimizing flow problem, i.e., $\mathtt{cost}(\boldsymbol{f}) = \|\boldsymbol{S}^{-1}\boldsymbol{f}\|_\infty$, captures

© Deeksha Adil, Brian Bullins, Rasmus Kyng, and Sushant Sachdeva;
licensed under Creative Commons License CC-BY 4.0

the celebrated maximum-flow problem with capacities $\boldsymbol{S}$; the weighted ℓ_1-minimizing flow problem, $\texttt{cost}(\boldsymbol{f}) = \|\boldsymbol{Sf}\|_1$ captures the transshipment problem generalizing shortest paths with lengths $\boldsymbol{S}$; and $\texttt{cost}(\boldsymbol{f}) = \boldsymbol{f}^\top \boldsymbol{Rf} = \|\boldsymbol{R}^{\frac{1}{2}}\boldsymbol{f}\|_2^2$ captures the electrical flow problem [42].

Dual to flow problems are voltage problems, which can be formulated as

$$\min_{\boldsymbol{d}^\top \boldsymbol{v}=1} \texttt{cost}'(\boldsymbol{Bv}),$$

Analogous to the flow problems, picking $\texttt{cost}'(\boldsymbol{Bv}) = \|\boldsymbol{SBv}\|_1$ captures the capacitated min-cut problem, $\texttt{cost}'(\boldsymbol{Bv}) = \|\boldsymbol{S}^{-1}\boldsymbol{Bv}\|_\infty$ captures vertex-labeling [26], and $\texttt{cost}'(\boldsymbol{Bv}) = (\boldsymbol{Bv})^\top \boldsymbol{R}^{-1}\boldsymbol{Bv} = \|\boldsymbol{R}^{-\frac{1}{2}}\boldsymbol{Bv}\|_2^2$ captures the electrical voltages problem.

The seminal work of Spielman and Teng [42] gave the first nearly-linear-time algorithm for computing $(1 + 1/\operatorname{poly}(n))$-approximate solutions to electrical (weighted ℓ_2-minimizing) flow/voltage problems. This work spurred the "Laplacian Paradigm" for designing faster algorithms for several classic graph optimization problems including maximum flow [11, 38, 22], multi-commodity flow [22], bipartite matching [29], transshipment [39], and graph partitioning [32]; culminating in almost-linear-time or nearly-linear-time low-accuracy algorithms (i.e. $1+\varepsilon$ approximations with $\operatorname{poly}(\frac{1}{\varepsilon})$ running time dependence) for many of these problems.

Progress on high-accuracy algorithms (i.e. algorithms that return $(1 + 1/\operatorname{poly}(n))$-approximate solutions with only a $\operatorname{poly}(\log n)$ factor overhead in time) for solving these problems has been harder to come by, and for many flow problems has been based on interior point methods [18]. E.g. the best running time for maximum flow stands at $\widetilde{O}(\min(m\sqrt{n}, n^\omega + n^{2+1/6}))$ [27, 15] and $\widetilde{O}(m^{4/3})$ for unit-capacity graphs [29, 28, 21]. Other results making progress in this direction include works on shortest paths with small range negative weights [16], and matrix-scaling [13, 5]. Recently, there has been progress on the dense case. In [44], the authors developed an algorithm for weighted bipartite matching and transshipment running in $\widetilde{O}(m + n^{3/2})$ time. This is a nearly-linear-time algorithm in moderately dense graphs.

Bubeck et al. [9] restarted the study of faster high-accuracy algorithms for the weighted ℓ_p-norm objective, $\texttt{cost}(\boldsymbol{f}) = \|\boldsymbol{Sf}\|_p$, a natural intermediate objective between ℓ_2 and ℓ_∞. This result improved the running time significantly over classical interior point methods [31] for p close to 2. Adil et al. [1] gave a high-accuracy algorithm for computing ℓ_p-norm minimizing flows in time $\min\{m^{\frac{4}{3}+o(1)}, n^\omega\}$ for $p \in (2, \sqrt{\log n}]$. Building on their work, Kyng et al. [25] gave an almost-linear-time high-accuracy algorithm for *unit-weight* ℓ_p-norm minimizing flows $\texttt{cost}(\boldsymbol{f}) = \|\boldsymbol{f}\|_p^p$ for large $p \in (\omega(1), \sqrt{\log n}]$. More generally, they give an almost-linear time-high-accuracy algorithm for *mixed* $\ell_2^2 + \ell_p^p$ objectives as long as the ℓ_p^p-norm is unit-weight, i.e.,

$$\texttt{cost}(\boldsymbol{f}) = \|\boldsymbol{R}^{\frac{1}{2}}\boldsymbol{f}\|_2^2 + \|\boldsymbol{f}\|_p^p.$$

Their algorithm for $(\ell_2^2 + \ell_p^p)$-minimizing flows was subsequently used as a key ingredient in recent results improving the running time for high-accuracy/exact maximum flow on unit-capacity graphs to $m^{4/3+o(1)}$ [28, 21].

In this paper, we obtain a nearly-linear running time for weighted $\ell_2^2 + \ell_p^p$ flow/voltage problems on graphs. Our algorithm requires $p(m^{1+o(1)} + n^{4/3+o(1)})$ time for $p = \omega(1)$ which is almost-linear-time for $p \le m^{o(1)}$ in slightly dense graphs, $(m \ge n^{4/3+o(1)})$.

Our running time $m^{1+o(1)} + n^{4/3+o(1)}$ is even better than the $\widetilde{O}(m + n^{3/2})$ time obtained for bipartite matching in [44]. Our result beats the $\Omega(n^{3/2})$ barrier that arises in [44] from the use of interior point methods that maintain a vertex dual solution using dense updates across $\sqrt{n}$ iterations. The progress on bipartite matching relies on highly technical

graph-based inverse maintenance techniques that are tightly interwoven with interior point method analysis. In constrast, our sparsification methods provide a clean interface to iterative refinement, which makes our analysis much more simple and compact.

Graph Sparsification. Various notions of graph sparsification – replacing a dense graph with a sparse one, while approximately preserving some key properties of the dense graph – have been key ingredients in faster low-accuracy algorithms. Benczúr and Karger [8] defined cut-sparsifiers that approximately preserve all cuts, and used them to give faster low-accuracy approximation algorithms for maximum-flow. Since then, several notions of sparsification have been studied extensively and utilized for designing faster algorithms [33, 41, 35, 40, 30, 38, 22, 36, 17, 24, 19, 12].

Sparsification has had a smaller direct impact on the design of faster high-accuracy algorithms for graph problems, limited mostly to the design of linear system solvers [42, 23, 34, 24]. Kyng et al. [25] constructed sparsifiers for weighted ℓ_2^2 + unweighted ℓ_p^p-norm objectives for flows. In this paper, we develop almost-linear time algorithms for building sparsifiers for weighted $\ell_2^2 + \ell_p^p$ norm objectives for flows and voltages,

$$\texttt{cost}(\boldsymbol{f}) = \|\boldsymbol{R}^{\frac{1}{2}}\boldsymbol{f}\|_2^2 + \|\boldsymbol{S}\boldsymbol{f}\|_p^p, \text{ and } \texttt{cost}'(\boldsymbol{B}\boldsymbol{v}) = \|\boldsymbol{W}^{\frac{1}{2}}\boldsymbol{B}\boldsymbol{v}\|_2^2 + \|\boldsymbol{U}\boldsymbol{B}\boldsymbol{v}\|_p^p,$$

and utilize them as key ingredients in our faster high-accuracy algorithms for optimizing such objectives on graphs. Our construction of sparsifiers for flow objectives builds on the machinery from [25], and our construction of sparsifiers for voltage objectives builds on graph spanners [6, 33, 7].

2 Our Results

Our main results concern flow and voltage problems for mixed $(\ell_2^2 + \ell_p^p)$-objectives for $p \geq 2$. Since our algorithms work best for large p, we restrict our attention to $p = \omega(1)$ in this overview. Section 3 provides detailed running times for all $p \geq 2$. We emphasize that by setting the quadratic term to zero in our mixed $(\ell_2^2 + \ell_p^p)$-objectives, we get new state of the art algorithms for ℓ_p-norm miniziming flows and voltages.

Mixed ℓ_2-ℓ_p-norm minimizing flow. Consider a graph $G = (V, E)$ along with non-negative diagonal matrices $\boldsymbol{R}, \boldsymbol{S} \in \mathbb{R}^{E\times E}$, and a gradient vector $\boldsymbol{g} \in \mathbb{R}^E$, as well as demands $\boldsymbol{d} \in \mathbb{R}^V$. We refer to the diagonal entries of $\boldsymbol{R}$ and $\boldsymbol{S}$ as ℓ_2-weights and ℓ_p-weights respectively. Let $\boldsymbol{B}$ denote the signed edge-vertex incidence of G (see Appendix in full version). We wish to solve the following minimization problem with the objective $\mathcal{E}(\boldsymbol{f}) = \boldsymbol{g}^\top\boldsymbol{f} + \|\boldsymbol{R}^{1/2}\boldsymbol{f}\|_2^2 + \|\boldsymbol{S}\boldsymbol{f}\|_p^p$

$$\min_{\boldsymbol{B}^\top\boldsymbol{f}=\boldsymbol{d}} \mathcal{E}(\boldsymbol{f}) \tag{1}$$

We require $\boldsymbol{g} \perp \{\ker(\boldsymbol{R}) \cap \ker(\boldsymbol{S}) \cap \ker(\boldsymbol{B})\}$ so that the problem has bounded minimum value, and $\boldsymbol{d} \perp \boldsymbol{1}$ so a feasible solution exists. These conditions can be checked in linear time and have a simple combinatorial interpretation. Note that the choice of graph edge directions in $\boldsymbol{B}$ matters for the value of $\boldsymbol{g}^\top\boldsymbol{f}$,. The flow on an edge is allowed to be both positive or negative.

Mixed ℓ_2-ℓ_p-norm minimizing voltages. Consider a graph $G = (V, E)$ along with non-negative diagonal matrices $\boldsymbol{W} \in \mathbb{R}^{E\times E}$ and $\boldsymbol{U} \in \mathbb{R}^{E\times E}$, and demands $\boldsymbol{d} \in \mathbb{R}^V$. We refer to the diagonal entries of $\boldsymbol{W}$ and $\boldsymbol{U}$ as ℓ_2-conductances and ℓ_p-conductances respectively.

In this case, we want to minimize the objective $\mathcal{E}(\boldsymbol{v}) = \boldsymbol{d}^\top \boldsymbol{v} + \|\boldsymbol{W}^{1/2}\boldsymbol{B}\boldsymbol{v}\|_2^2 + \|\boldsymbol{U}\boldsymbol{v}\|_p^p$ in minimization problem

$$\min_{\boldsymbol{v}} \mathcal{E}(\boldsymbol{v}) \tag{2}$$

In the voltage setting, we only require $\boldsymbol{d} \perp \mathbf{1}$ so the problem has bounded minimum value.

Obtaining good solutions. For both these problems, we study high accuracy approximation algorithms that provide feasible solutions $\boldsymbol{x}$ (a flow or a voltage respectively), that approximately minimize the objective function from some starting point $\boldsymbol{x}^{(0)}$, i.e., for some small $\varepsilon > 0$, we have

$$\mathcal{E}(\boldsymbol{x}) - \mathcal{E}(\boldsymbol{x}^\star) \leq \varepsilon(\mathcal{E}(\boldsymbol{x}^{(0)}) - \mathcal{E}(\boldsymbol{x}^\star))$$

wher $\boldsymbol{x}^\star$ denotes an optimal feasible solution. Our algorithms apply to problems with quasipolynomially bounded parameters, including quasipolynomial bounds on non-zero singular values of matrices we work with. Below we state our main algorithmic results.

▶ **Theorem 1** (Flow Algorithmic Result)**.** *Consider a graph G with n vertices and m edges, equipped with non-negative ℓ_2 and ℓ_p-weights, as well as a gradient and demands, all with quasi-polynomially bounded entries. For $p = \omega(1)$, in $p(m^{1+o(1)} + n^{4/3+o(1)}) \log^2 1/\varepsilon$ time we can compute an ε-approximately optimal flow solution to Problem* (1) *with high probability.*

This improves upon [1, 2, 3] which culminated in a $pm^{4/3+o(1)} \log^2 1/\varepsilon$ time algorithm.

▶ **Theorem 2** (Voltage Algorithmic Result)**.** *Consider a graph G with n vertices and m edges, equipped with non-negative ℓ_2 and ℓ_p-conductances, as well as demands, all with quasi-polynomially bounded entries. For $p = \omega(1)$, in $p(m^{1+o(1)} + n^{4/3+o(1)}) \log^2 1/\varepsilon$ time we can compute an ε-approximately optimal voltage solution to Problem* (2) *with high probability.*

Background: Iterative Refinement for Mixed ℓ_2-ℓ_p-norm Flow Objectives. Adil et al. [1] developed a notion of iterative refinement for mixed $(\ell_2^2 + \ell_p^p)$-objectives which in the flow setting, i.e. Problem (1), corresponds to approximating $\mathcal{E}'(\boldsymbol{\delta}) = \mathcal{E}(\boldsymbol{f} + \boldsymbol{\delta})$ using another $(\ell_2^2 + \ell_p^p)$-objective which roughly speaking corresponds to the 2nd degree Taylor series approximation of $\mathcal{E}'(\boldsymbol{\delta})$ combined with an ℓ_p-norm term $\|\boldsymbol{S}\boldsymbol{\delta}\|_p^p$, while ensuring feasibility of $\boldsymbol{f} + \boldsymbol{\delta}$ through a constraint $\boldsymbol{B}\boldsymbol{\delta} = \mathbf{0}$. We call the resulting problem a *residual* problem. Adil et al. [1] showed that obtaining a constant-factor approximate solution to the residual problem in δ is sufficient to ensure that $\mathcal{E}(\boldsymbol{f} + \boldsymbol{\delta})$ is closer to the optimal solution by a multiplicative factor depending only on p. In [2], this result was sharpened to show that such an approximate solution for the residual problem can be used to make $(1 - \Omega(1/p))$ multiplicative progress to the optimum, so that $O(p \log(m/\varepsilon))$ iterations suffice to produce an ε-accurate solution.

In order to solve the residual problem to a constant approximation, Adil et al. [1] developed an accelerated multiplicative weights method for $(\ell_2^2 + \ell_p^p)$-flow objectives, or more generally, for mixed $(\ell_2^2 + \ell_p^p)$-regression in an underconstrained setting.

Sparsification results. Our central technical results in this paper concern sparsification of residual flow and voltage problems, in the sense outlined in the previous paragraph. Concretely, in nearly-linear time, we can take a residual problem on a dense graph and produce a residual problem on a sparse graph with $\widetilde{O}(n)$ edges, with the property that constant factor solutions to the sparse residual problem still make $(1 - \Omega(m^{-\frac{2}{p-1}} p))$ multiplicative

progress on the original problem. This leads to an iterative refinement that converges in $O(pm^{\frac{2}{p-1}}\log(m/\varepsilon))$ steps. However, the accelerated multiplicative weights algorithm that we use for each residual problem now only requires $\widetilde{O}(n^{4/3})$ time to compute a crude solution.

Flow residual problem sparsification. In the flow setting, we show the following:

▶ **Theorem 3** (Informal Flow Sparsification Result). *Consider a graph G with n vertices and m edges, equipped with non-negative ℓ_2 and ℓ_p-weights, as well as a gradient. In $\widetilde{O}(m)$ time, we can compute a graph H with n vertices and $\widetilde{O}(n)$ edges, equipped with non-negative ℓ_2 and ℓ_p-weights, as well as a gradient, such that a constant factor approximation to the flow residual problem on H, when scaled by $m^{\frac{-1}{p-1}}$ results in an $\widetilde{O}(m^{\frac{2}{p-1}})$ approximate solution to the flow residual problem on G. The algorithm works for all $p \geq 2$ and succeeds with high probability.*

Our sparsification techniques build on [25], require a new bucketing scheme to deal with non-uniform ℓ_p-weights, as well as a prepreprocessing step to handle cycles with zero ℓ_2-weight and ℓ_p-weight. This preprocessing scheme in turn necessitates a more careful analysis of additive errors introduced by gradient rounding, and we provide a more powerful framework for this than [25].

Voltage residual problem sparsification. In the voltage setting, we show the following.

▶ **Theorem 4** (Voltage Sparsification Result (Informal)). *Consider a graph G with n vertices and m edges, equipped with non-negative ℓ_2 and ℓ_p-conductances. In $\widetilde{O}(m)$ time, we can compute a graph H with n vertices and $\widetilde{O}(n)$ edges, equipped with non-negative ℓ_2 and ℓ_p-conductances, such that constant factor approximation to the voltage residual problem on H, when scaled by $m^{\frac{-1}{p-1}}$ results in an $\widetilde{O}(m^{\frac{1}{p-1}})$ approximate solution to the voltage residual problem on G. The algorithm works for all $p \geq 2$ and succeeds with high probability.*

Note that our voltage sparsification is slightly stronger than our flow sparsification, as the former loses only a factor $\widetilde{O}(m^{\frac{1}{p-1}})$ in the approximation while the latter loses a factor $\widetilde{O}(m^{\frac{2}{p-1}})$. Our voltage sparsification uses a few key observations: In voltage space, surprisingly, we can treat treat the ℓ_2 and ℓ_p costs separately. This behavior is very different than the flow case, and arises becase in voltage space, every edge provides an "obstacle", i.e. adding an edge increases cost, whereas in flow space, every edge provides an "opportunity", i.e. adding an edge decreases cost. This means that in voltage space, we can separately account for the energy costs created by our ℓ_2 and ℓ_p terms, whereas in flow space, the ℓ_2 and ℓ_p weights must be highly correlated in a sparsifier. Armed with this decoupling observation, we preserve ℓ_2 cost using standard tools for spectral graph sparsification, and we preserve ℓ_p cost approximately by a reduction to graph distance preservation, which we in turn achieve using weighted undirected graph spanners.

Voltage space accelerated multiplicative weights solver. The algorithm from [1] for constant approximate solutions to the residual problem works in the flow setting. Using iterative refinement, the algorithm could be used to compute high-accuracy solutions. Because we can use high-accuracy flow solutions to extract high-accuracy solutions to the dual voltage problem, [1] were also able to produce solutions to ℓ_q-norm minimizing voltage problems (where ℓ_q for $q = p/(p-1)$ is the dual norm to ℓ_p). Hence, by solving ℓ_p-flow problems for all $p \in (2, \infty)$, [1] were able to solve ℓ_q-norm minimizing voltage problems for all $q \in (1, 2)$.

Our sparsification of flow and voltage problems works only for $p \geq 2$. Thus, in order to solve for q-norm minimizing voltages for $q > 2$, we require a solver that works directly in voltage space for mixed $(\ell_2^2 + \ell_p^p)$-voltage objectives.

We develop an accelerated multiplicative weights algorithm along the lines of [11, 10, 1] that works directly in voltage space for mixed $(\ell_2^2 + \ell_p^p)$-objectives, or more generally for overconstrained mixed $(\ell_2^2 + \ell_p^p)$-objective regression. Concretely, this directly gives an algorithm for computing crude solutions to the residual problems that arise from applying [1] iterative refinement to Problem (2). Our solver produces an improved $O(1)$-approximation to the residual problem rather than a $p^{O(p)}$-approximation from [1]. This gives an $\widetilde{O}(m^{4/3})$ high-accuracy algorithm for mixed $(\ell_2^2 + \ell_p^p)$-objective voltage problems for $p > 2$, unlike [1], which could only solve pure $p > 2$ voltage problems. We then speed this up to a $p(m^{1+o(1)} + n^{4/3+o(1)})$ time algorithm for $p = \omega(1)$ by developing a sparsification procedure that applies directly to mixed $(\ell_2^2 + \ell_p^p)$-voltage problems for $p > 2$.

Mixed ℓ_2-ℓ_p-norm regression. Our framework can also be applied outside of a graph setting, where our new accelerated multiplicative weights algorithm for overconstrained mixed $(\ell_2^2 + \ell_p^p)$-regression gives new state-of-the-art results in some regimes when combined with new sparsification results. In this setting we develop sparsification techniques based on the Lewis weights sampling from the work of Cohen and Peng [17]. We focus on the case $2 < p < 4$, where [17] provided fast algorithms for Lewis weight sampling.

▶ **Theorem 5** (General Matrices Sparsification Result). *Let $p \in [2, 4)$, let $\boldsymbol{M} \in \mathbb{R}^{m_1 \times n}, \boldsymbol{N} \in \mathbb{R}^{m_2 \times n}$ be matrices, $m_1, m_2 \geq n$, and let $LSS(\boldsymbol{B})$ denote the time to solve a linear system in $\boldsymbol{B}^\top \boldsymbol{B}$. Then, we may compute $\widetilde{\boldsymbol{M}}, \widetilde{\boldsymbol{N}} \in \mathbb{R}^{O(n^{p/2}\log(n)) \times n}$ such that with probability at least $1 - \frac{1}{n^{\Omega(1)}}$, for all $\Delta \in \mathbb{R}^n$,*

$$\|\widetilde{\boldsymbol{M}}\Delta\|_2^2 + \|\widetilde{\boldsymbol{N}}\Delta\|_p^p \approx_{O(1)} \|\boldsymbol{M}\Delta\|_2^2 + \|\boldsymbol{N}\Delta\|_p^p,$$

in time $\tilde{O}\Big(\mathrm{nnz}(\boldsymbol{M}) + \mathrm{nnz}(\boldsymbol{N}) + LSS(\widehat{\boldsymbol{M}}) + LSS(\widehat{\boldsymbol{N}})\Big)$, for some $\widehat{\boldsymbol{M}}$ and $\widehat{\boldsymbol{N}}$ each containing $O(n\log(n))$ rescaled rows of $\boldsymbol{M}$ and $\boldsymbol{N}$, respectively.

▶ **Theorem 6** (General Matrices Algorithmic Result). *For $p \in [2, 4)$, with high probability we can find an ε-approximate solution to (3) in time*

$$\widetilde{O}\Big(\Big(\mathrm{nnz}(\boldsymbol{M}) + \mathrm{nnz}(\boldsymbol{N}) + \Big(LSS(\widetilde{\boldsymbol{M}}) + LSS(\widetilde{\boldsymbol{N}})\Big)n^{\frac{p(p-2)}{6p-4}}\Big)\log^2(1/\varepsilon)\Big),$$

for some $\widetilde{\boldsymbol{M}}$ and $\widetilde{\boldsymbol{N}}$ each containing $O(n^{p/2}\log(n))$ rescaled rows of $\boldsymbol{M}$ and $\boldsymbol{N}$, respectively, where $LSS(\boldsymbol{A})$ is the time required to solve a linear equation in $\boldsymbol{A}^\top \boldsymbol{A}$ to quasipolynomial accuracy.

Note that for all $p \in (2, 4)$, we have that the exponent $\frac{p(p-2)}{6p-4} \leq 0.4$.

▶ Remark 7. By [14], a linear equation in $\boldsymbol{A}^\top \boldsymbol{A}$, where $\boldsymbol{A} \in \mathbb{R}^{m \times n}$ can be solved to quasipolynomial accuracy in time $\widetilde{O}(\mathrm{nnz}(\boldsymbol{A}) + n^\omega)$.

Using the above result for solving the required linear systems, we get a running time of $\widetilde{O}(\mathrm{nnz}(\boldsymbol{M}) + \mathrm{nnz}(\boldsymbol{N}) + (n^{p/2} + n^\omega)n^{\frac{p(p-2)}{6p-4}})$, matching an earlier input sparsity result by Bubeck et al. [9] that achieves $\widetilde{O}((\mathrm{nnz}(\boldsymbol{M}) + \mathrm{nnz}(\boldsymbol{N}))(1 + n^{\frac{1}{2}}m^{-\frac{1}{p}}) + m^{\frac{1}{2}-\frac{1}{p}}n^2 + n^\omega)$, where $\boldsymbol{M} \in \mathbb{R}^{m_1 \times n}, \boldsymbol{N} \in \mathbb{R}^{m_2 \times n}$ and $m = \max\{m_1, m_2\}$.

3 Main Algorithm

In this section, we prove Theorems 1, 2, and 6. We first design an algorithm to solve the following general problem:

▶ **Definition 8.** *For matrices* $\boldsymbol{M} \in \mathbb{R}^{m_1 \times n}$, $\boldsymbol{N} \in \mathbb{R}^{m_2 \times n}$ *and* $\boldsymbol{A} \in \mathbb{R}^{d \times n}$, $m_1, m_2 \geq n, d \leq n$, *and vectors* $\boldsymbol{b} \perp \{\ker(\boldsymbol{M}) \cap \ker(\boldsymbol{N}) \cap \ker(\boldsymbol{A})\}$ *and* $\boldsymbol{c} \in im(\boldsymbol{A})$, *we want to solve*

$$\begin{aligned} \min_{\boldsymbol{x}} \quad & \boldsymbol{b}^\top \boldsymbol{x} + \|\boldsymbol{M}\boldsymbol{x}\|_2^2 + \|\boldsymbol{N}\boldsymbol{x}\|_p^p \\ s.t. \quad & \boldsymbol{A}\boldsymbol{x} = \boldsymbol{c}. \end{aligned} \tag{3}$$

In order to solve the above problem, we use the iterative refinement framework from [2] to obtain a residual problem which is defined as follows.

▶ **Definition 9.** *For any* $p \geq 2$, *we define the residual problem* $res(\Delta)$, *for* (3) *at a feasible* $\boldsymbol{x}$ *as,*

$$\max_{\boldsymbol{A}\Delta=0} \quad res(\Delta) \stackrel{\text{def}}{=} \boldsymbol{g}^\top \Delta - \Delta^\top \boldsymbol{R} \Delta - \|\boldsymbol{N}\Delta\|_p^p, \text{ where,}$$

$$\boldsymbol{g} = \frac{1}{p}\boldsymbol{b} + \frac{2}{p}\boldsymbol{M}^\top \boldsymbol{M}\boldsymbol{x} + |\boldsymbol{N}\boldsymbol{x}|^{p-2}\boldsymbol{N}\boldsymbol{x} \quad \text{and} \quad \boldsymbol{R} = \frac{2}{p^2}\boldsymbol{M}^\top \boldsymbol{M} + 2\boldsymbol{N}^\top Diag(|\boldsymbol{N}\boldsymbol{x}|^{p-2})\boldsymbol{N}.$$

This residual problem can further be reduced by moving the term linear in $\boldsymbol{x}$ to the constraints via a binary search. This leaves us with a problem of the form,

$$\begin{aligned} \min_{\Delta} \quad & \Delta^\top \boldsymbol{R}\Delta + \|\boldsymbol{N}\Delta\|_p^p \\ \text{s.t.} \quad & \boldsymbol{g}^\top \Delta = a, \boldsymbol{A}\Delta = 0, \end{aligned}$$

for some constant a.

In order to solve the above problem with $\ell_2^2 + \ell_p^p$ objective, we reduce the instance size via a sparsification routine, and then solve the smaller problem by a multiplicative weights algorithm. We adapt the multiplicative-weights algorithm from [1] to work in the voltage space while improving the p dependence of the runtime from $p^{O(p)}$ to p, and the approximation quality from $p^{O(p)}$ to $O(1)$. The precise sparsification routines are described in later sections.

For large p, i.e., $p > \log m$, in order to get a linear dependence on the running time on p, we need to reduce the residual problem in ℓ_p-norm to a residual problem in $\log m$-norm by using the framework from [3].

The entire meta-algorithm is described formally in Algorithm 1, and its guarantees are described by the next theorem. Most proof details are deferred to the full version.

▶ **Theorem 10.** *For an instance of Problem* (3), *suppose we are given a starting solution* $\boldsymbol{x}^{(0)}$ *that satisfies* $\boldsymbol{A}\boldsymbol{x}^{(0)} = \boldsymbol{c}$ *and is a* κ *approximate solution to the optimum. Consider an iteration of the while loop, line 8 of Algorithm 1 for the* ℓ_p*-norm residual problem at* $\boldsymbol{x}^{(t)}$. *We can define* μ_1 *and* κ_1 *such that if* $\bar{\Delta}$ *is a* β *approximate solution to a corresponding* p'*-norm residual problem, then* $\mu_1\bar{\Delta}$ *is a* κ_1*-approximate solution to the* p*-residual problem. Further, suppose we have the following procedures,*

1. SPARSIFY*: Runs in time* K, *takes as input any matrices* $\boldsymbol{R}, \boldsymbol{N}$ *and vector* $\boldsymbol{g}$ *and returns* $\widetilde{\boldsymbol{R}}, \widetilde{\boldsymbol{N}}, \widetilde{\boldsymbol{g}}$ *having sizes at most* $\tilde{n} \times n$ *for the matrices , such that if* $\widetilde{\Delta}$ *is a* β *approximate solution to,*

$$\max_{\boldsymbol{A}\Delta=0} \quad \widetilde{\boldsymbol{g}}^\top \Delta - \|\widetilde{\boldsymbol{R}}\Delta\|_2^2 - \|\widetilde{\boldsymbol{N}}\Delta\|_{p'}^{p'},$$

for any $p' \geq 2$, *then* $\mu_2\widetilde{\Delta}$, *for a computable* μ_2 *is a* $\kappa_2\beta$*-approximate solution for,*

$$\max_{\boldsymbol{A}\Delta=0} \quad res(\Delta) \stackrel{\text{def}}{=} \boldsymbol{g}^\top \Delta - \|\boldsymbol{R}^{1/2}\Delta\|_2^2 - \|\boldsymbol{N}\Delta\|_{p'}^{p'}.$$

2. SOLVER*: Approximately solves* (4) *to return* $\bar{\Delta}$ *such that* $\|\widetilde{\boldsymbol{R}}\bar{\Delta}\|_2^2 \le \kappa_3\nu$ *and* $\|\widetilde{\boldsymbol{N}}\Delta\|_p^p \le \kappa_4\nu$ *in time* $\tilde{K}(\tilde{n})$ *for instances of size at most* $\tilde{n}$*.*

Algorithm 1 finds an ε*-approximate solution for Problem* (3) *in time*

$$\widetilde{O}\left(p\kappa_4^{1/(p-1)}\kappa_3\kappa_2\kappa_1(K+\tilde{K}(\tilde{n}))\log\left(\frac{\kappa p}{\varepsilon}\right)^2\right).$$

3.1 Algorithms for ℓ_p-norm Problems

The problems discussed in Section 2 are special cases of Problem (3), which means we can use Algorithm 1. To prove our results, we will utilize Theorem 10, with the respective sparsification procedures and the following multiplicative-weights based algorithm for solving problems of the form,

$$\min_{\Delta} \quad \Delta^\top\boldsymbol{M}^\top\boldsymbol{M}\Delta + \|\boldsymbol{N}\Delta\|_p^p \quad \text{s.t.} \quad \boldsymbol{A}\Delta = \boldsymbol{c}. \tag{5}$$

We describe our solver formally and prove the following theorem about its guarantees in the full version.

▶ **Theorem 11.** *Let $p \geq 2$. Consider an instance of Problem (5) described by matrices $\boldsymbol{A} \in \mathbb{R}^{d\times n}, \boldsymbol{N} \in \mathbb{R}^{m_1\times n}, \boldsymbol{M} \in \mathbb{R}^{m_2\times n}$, $d \leq n \leq m_1, m_2$, and vector $\boldsymbol{c} \in \mathbb{R}^d$. If the optimum of this problem is at most ν, Procedure* Residual-Solver *returns an $\boldsymbol{x}$ such that $\boldsymbol{A}\boldsymbol{x} = \boldsymbol{c}$, and $\boldsymbol{x}^\top \boldsymbol{M}^\top \boldsymbol{M}\boldsymbol{x} \leq O(1)\nu$ and $\|\boldsymbol{N}\boldsymbol{x}\|_p^p \leq O(3^p)\nu$. The algorithm makes $O\left(pm_1^{\frac{p-2}{(3p-2)}}\right)$ calls to a linear system solver.*

We utilize Procedure Residual-Solver as the Procedure Solver in Algorithm Sparsified-p-Problems. The algorithm uses the procedure only for solving problems instances with $p \leq \log m$. Thus, its running time is $\tilde{K}(\tilde{n}) = \widetilde{O}\left(\tilde{n}^{\frac{p-2}{3p-2}} \cdot \mathrm{LSS}(\tilde{n})\right) \leq \widetilde{O}\left(\tilde{n}^{1/3} \cdot \mathrm{LSS}(\tilde{n})\right)$, where $\mathrm{LSS}(\tilde{n})$ denotes the time required to solve a linear system in matrices of size $\tilde{n}$. We also have, $\kappa_3 = O(1), \kappa_4^{1/(p-1)} = O(1)$.

We next estimate the values of κ_1 and μ_1. If $p \leq \log m$, we have $\mu_1 = 1$ and $\kappa_1 = 1$. Otherwise, $\mu_1 = \widetilde{O}(1)$ and $\kappa_1 = O(m^{o(1)})$ (Refer to the full version).

In order to obtain an initial solution, we usually solve an ℓ_2-norm problem. This gives an $m^{p/2}$ approximate initial solution which results in a factor of p^2 in the running time. To avoid this, we can do a homotopy on p similar to [3], i.e., start with an ℓ_2 solution and solve the ℓ_{2^2} problem to a constant approximation, followed by $\ell_{2^3}, ..\ell_p$. We note that a constant approximate solution to the $\ell_{p/2}$-norm problem gives an $O(m)$ approximation to the ℓ_p problem and thus, we can solve $\log p$ problems where we can assume $\kappa = O(m)$.

We now complete the proof of our various algorithmic results by utilizing sparsification procedures specific to each problem.

ℓ_p Flows

We will prove Theorem 1 (Flow Algorithmic Result), with explicit p dependencies.

Proof. From Theorem 3, we obtain a sparse graph in $K = \widetilde{O}(m)$ time with $\tilde{n} = \widetilde{O}(n)$ edges. A constant factor approximation to the flow residual problem on this sparse graph when scaled by $\mu_2 = m^{-\frac{1}{p-1}}$ gives a $\kappa_2 = \widetilde{O}\left(m^{\frac{2}{p-1}}\right)$-approximate solution to the flow residual problem on the original graph. We can solve linear systems on the sparse graph in $\widetilde{O}(\tilde{n}) = \widetilde{O}(n)$ time using fast Laplacian solvers. Using all these values in Theorem 10, we get the final runtime to be $pm^{\frac{2}{p-1}+o(1)}\left(m + n^{1+\frac{p-2}{3p-2}}\right)\log^2\left(\frac{pm}{\varepsilon}\right)$ as claimed. We prove Theorem 3 in the full version. ◀

ℓ_p Voltages

We will prove Theorem 2 (Voltage Algorithmic Result), with explicit p dependencies.

Proof. From Theorem 4, we obtain a sparse graph in $K = \widetilde{O}(m)$ time with $\tilde{n} = \widetilde{O}(n)$ edges. A constant factor approximation to the voltage residual problem on this sparse graph when scaled by $\mu_2 = m^{-\frac{1}{p-1}}$ gives a $\kappa_2 = \widetilde{O}\left(m^{\frac{1}{p-1}}\right)$-approximate solution to the voltage residual problem on the original graph. We can solve linear systems on the sparse graph in $\widetilde{O}(\tilde{n}) = \widetilde{O}(n)$ time using fast Laplacian solvers. Using these values in Theorem 10, we get the final runtime to be $pm^{\frac{1}{p-1}+o(1)}\left(m + n^{1+\frac{p-2}{3p-2}}\right)\log^2\left(\frac{pm}{\varepsilon}\right)$ as claimed. We prove Theorem 4 in Section 4. ◀

General Matrices

We will now prove Theorem 6.

Proof. We assume Theorem 5, which we prove in Appendix (refer to full version). From the theorem, we have $\kappa_2 = O(1)$ and $\mu_2 = O(1)$. Note that $K = \mathrm{LSS}(\widehat{\boldsymbol{M}}) + \mathrm{LSS}(\widehat{\boldsymbol{N}})$ for some $\widehat{\boldsymbol{M}}, \widehat{\boldsymbol{N}} \in \mathbb{R}^{O(n\log(n))\times n}$, which is the time required to solve linear systems in $\widehat{\boldsymbol{M}}^\top \widehat{\boldsymbol{M}}$ and $\widehat{\boldsymbol{N}}^\top \widehat{\boldsymbol{N}}$, respectively. Since, by Theorem 5, the size of $\widetilde{\boldsymbol{M}}$ and $\widetilde{\boldsymbol{N}}$ is $\tilde{n} = O(n^{p/2}\log(n))$, the cost from the solver in Theorem 11 is $\tilde{O}_p\Big(\Big(\mathrm{LSS}(\widetilde{\boldsymbol{M}}) + \mathrm{LSS}(\widetilde{\boldsymbol{N}})\Big)n^{\frac{p(p-2)}{6p-4}}\Big)$. ◀

4 Construction of Sparsifiers for $\ell_2^2 + \ell_p^p$ Voltages

In this section, we prove a formal version of the voltage sparsification result (Theorem 4):

▶ **Theorem 12.** *Consider a graph $G = (V, E)$ with non-negative 2-weights $\boldsymbol{w} \in \mathbb{R}^E$ and non-negative p-weights $\boldsymbol{s} \in \mathbb{R}^E$, with m and n vertices. We can produce a graph $H = (V, F)$ with edges $F \subseteq E$, ℓ_2-weights $\boldsymbol{u} \in \mathbb{R}^F$, and ℓ_p-weights $\boldsymbol{t} \in \mathbb{R}^F$, such that with probability at least $1 - \delta$ the graph H has $O(n\log(n/\varepsilon))$ edges and*

$$\frac{1}{1.5}\|\boldsymbol{W}\boldsymbol{B}_G\boldsymbol{x}\|_2 \le \|\boldsymbol{U}\boldsymbol{B}_H\boldsymbol{x}\|_2 \le 1.5\|\boldsymbol{W}\boldsymbol{B}_G\boldsymbol{x}\|_2 \tag{6}$$

and for any $p \in [1, \infty]$

$$\frac{1}{m^{1/p}\log(n)}\|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_p \le \|\boldsymbol{T}\boldsymbol{B}_H\boldsymbol{x}\|_p \le \|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_p \tag{7}$$

where $\boldsymbol{W} = \textsc{Diag}(\boldsymbol{w})$, $\boldsymbol{U} = \textsc{Diag}(\boldsymbol{u})$, $\boldsymbol{S} = \textsc{Diag}(\boldsymbol{s})$, $\boldsymbol{T} = \textsc{Diag}(\boldsymbol{t})$. We denote the routine computing H and $\boldsymbol{u}, \boldsymbol{t}$ by SpannerSparsify, so that $(H, \boldsymbol{u}, \boldsymbol{t}) = \textsc{SpannerSparsify}(G, \boldsymbol{w}, \boldsymbol{s})$. This algorithm runs in $\widetilde{O}(m\log(1/\delta))$ time.

We will first define some terms required for our result. Given a undirected graph $G = (V, E)$, with edge lengths $\boldsymbol{l} \in \mathbb{R}^E$, and $u, v \in V$, we let $d_G(u, v)$ denote the shortest path distance in G w.r.t $\boldsymbol{l}$, so that if P is the shortest path w.r.t $\boldsymbol{l}$ then

$$d_{G,\boldsymbol{l}}(u, v) = \sum_{e\in P} \boldsymbol{l}(e)$$

▶ **Definition 13.** *Given a undirected graph $G = (V, E)$ with edge lengths $\boldsymbol{l} \in \mathbb{R}^E$, a K-spanner is a subgraph H of G with the same edge lengths s.t. $d_H(u, v) \le K d_G(u, v)$.*

Baswana and Sen showed the following result on spanners [7].

▶ **Theorem 14.** *Given an undirected graph $G = (V, E, \boldsymbol{l})$ with m edges and n vertices, and an integer $k > 1$, we can compute a $(2k-1)$-spanner H of G with $O(n^{1+1/k})$ edges in expected time $O(km)$.*

▶ **Lemma 15.** *Given an undirected graph $G = (V, E)$ with positive edge lengths $\boldsymbol{l} \in \mathbb{R}^E$, and a K-spanner $H = (V, F)$ of G, for all $\boldsymbol{x} \in \mathbb{R}^V$ we have*

$$\max_{(u,v)\in F} \frac{1}{\boldsymbol{l}(u,v)}|\boldsymbol{x}(u) - \boldsymbol{x}(v)| \le \max_{(u,v)\in E} \frac{1}{\boldsymbol{l}(u,v)}|\boldsymbol{x}(u) - \boldsymbol{x}(v)| \le K \max_{(u,v)\in F} \frac{1}{\boldsymbol{l}(u,v)}|\boldsymbol{x}(u) - \boldsymbol{x}(v)|$$

Proof. The inequality $\max_{(u,v)\in F} \frac{1}{\boldsymbol{l}(u,v)}|\boldsymbol{x}(u)-\boldsymbol{x}(v)| \leq \max_{(u,v)\in E} \frac{1}{\boldsymbol{l}(u,v)}|\boldsymbol{x}(u)-\boldsymbol{x}(v)|$ is immediate from $F \subseteq E$.

To prove the second inequality, we note that if $(u,v) \in E$ has shortest path P in H then

$$\frac{1}{\boldsymbol{l}(u,v)}|\boldsymbol{x}(u)-\boldsymbol{x}(v)| \leq \frac{K}{\sum_{(z,y)\in P}\boldsymbol{l}(z,y)}\left|\sum_{(z,y)\in P}\boldsymbol{x}(z)-\boldsymbol{x}(y)\right| \leq \max_{(z,y)\in P}\frac{K}{\boldsymbol{l}(z,y)}|\boldsymbol{x}(z)-\boldsymbol{x}(y)|.$$

◀

▶ **Definition 16.** *Given a undirected graph $G=(V,E)$ with m edges and n vertices with positive edge ℓ_2-weights $\boldsymbol{w} \in \mathbb{R}^E$, a spectral ε-approximation of G is a graph $H=(V,F)$ with $F \subseteq E$ with positive edge ℓ_2-weights $\boldsymbol{u} \in \mathbb{R}^F$ s.t.*

$$\frac{1}{1+\varepsilon}\|\boldsymbol{W}\boldsymbol{B}_G\boldsymbol{x}\|_2 \leq \|\boldsymbol{U}\boldsymbol{B}_H\boldsymbol{x}\|_2 \leq (1+\varepsilon)\|\boldsymbol{W}\boldsymbol{B}_G\boldsymbol{x}\|_2$$

where $\boldsymbol{W} = \textsc{Diag}(\boldsymbol{w})$ and $\boldsymbol{U} = \textsc{Diag}(\boldsymbol{u})$.

The following result on spectral sparsifiers was shown by Spielman and Srivastava [40] (see also [43]).

▶ **Theorem 17.** *Given a graph $G=(V,E)$ with positive ℓ_2-weights $\boldsymbol{w} \in \mathbb{R}^E$ with m edges and n vertices, for any $\varepsilon \in (0,1/2]$, we can produce a graph $H=(V,F)$ with edges $F \subseteq E$ and ℓ_2-weights $\boldsymbol{u} \in \mathbb{R}^F$ such that H has $O(n\varepsilon^{-2}\log(n/\delta))$ edges and with probability at least $1-\delta$ we have that $(H,\boldsymbol{u})$ is a spectral ε-approximation of $(G,\boldsymbol{w})$. We denote the routine computing H and $\boldsymbol{u}$ by SpectralSparsify, so that $(H,\boldsymbol{u}) = \textsc{SpectralSparsify}(G,\boldsymbol{s},\varepsilon,\delta)$. This algorithm runs in $\widetilde{O}(m)$ time. Furthermore, if the weights $\boldsymbol{w}$ are quasipolynomially bounded, then so are the weights of $\boldsymbol{u}$.*

We can now prove our main result.

Proof of Theorem 12. We consider a graph $G=(V,E)$ with m edges and n vertices, and with non-negative ℓ_p-weights $\boldsymbol{r} \in \mathbb{R}^E$, non-negative ℓ_2-weights $\boldsymbol{s} \in \mathbb{R}^E$. We define $\hat{E} \subseteq E$ to be the edges s.t. $\boldsymbol{s}(e) > 0$, and then let $\boldsymbol{l} \in \mathbb{R}^{\hat{E}}$ by $\boldsymbol{l}(e) = 1/\boldsymbol{s}(e)$, and $\hat{G} = (V,\hat{E})$. We then apply Theorem 14 to $\hat{G}$ with $\boldsymbol{l}$ as edge lengths, and with $k = \log(n)$. We turn the algorithm of Theorem 14 into running time $\widetilde{O}(m\log(1/\delta))$, instead of expected time $\widetilde{O}(m)$, by applying the standard Las Vegas to Monte-Carlo reduction. With probability $1-\delta/2$, this gives us a $\log n$-spanner H_1 of $\hat{G}$, and we define $\boldsymbol{t}$ by restricting $\boldsymbol{s}$ to the edges of H_1. By Lemma 15, we then have

$$\|\boldsymbol{T}\boldsymbol{B}_{H_1}\boldsymbol{x}\|_\infty \leq \|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_\infty \leq \log(n)\|\boldsymbol{T}\boldsymbol{B}_{H_1}\boldsymbol{x}\|_\infty$$

Because $\boldsymbol{T}\boldsymbol{B}_{H_1}\boldsymbol{x}$ is a restriction of $\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}$ to a subset of the coordinates, we always have for any $p \geq 1$ that $\|\boldsymbol{T}\boldsymbol{B}_{H_1}\boldsymbol{x}\|_p \leq \|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_p$.

At the same time, we also have

$$\|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_p \leq m^{1/p}\|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_\infty \leq m^{1/p}\log(n)\|\boldsymbol{T}\boldsymbol{B}_{H_1}\boldsymbol{x}\|_\infty \leq m^{1/p}\log(n)\|\boldsymbol{T}\boldsymbol{B}_{H_1}\boldsymbol{x}\|_p$$

We define $\tilde{E} \subseteq E$ to be the edges s.t. $\boldsymbol{r}(e) > 0$, and the let $\tilde{G} = (V,\tilde{E})$. Now, appealing to Theorem 17, we let $(H_2,\boldsymbol{u}) = \textsc{SpectralSparsify}(\tilde{G},\boldsymbol{r},1/2,\varepsilon/2)$.

Finally, we form H by taking the union of the edge sets of H_1 and H_2 and extending $\boldsymbol{u}$ and $\boldsymbol{t}$ to the new edge set by adding zero entries as needed. By a union bound, the approximation guarantees of Equations (6) and (7) simultaneously hold with probability at least $1-\delta$.

The edge set remains bounded in size by $O(n\log n)$. ◀

To see Theorem 4, note that from Theorem 12, we get,

$$m^{-\frac{1}{p-1}}\left(m^{-\frac{1}{p-1}}\|\boldsymbol{W}\boldsymbol{B}_G\boldsymbol{x}\|_2^2+m^{-1}\|\boldsymbol{S}\boldsymbol{B}_G\boldsymbol{x}\|_p^p\right)\leq m^{-\frac{1}{p-1}}\left(\|\boldsymbol{U}\boldsymbol{B}_H\boldsymbol{x}\|_2^2+\|\boldsymbol{T}\boldsymbol{B}_H\boldsymbol{x}\|_p^p\right)$$

The other direction is easy to see.

5 Extensions of Our Results and Open Problems

Solving dual problems: q-norm minimizing flows and voltages for $q < 2$

When the mixed $(\ell_2^2+\ell_p^p)$-objective flow problem (Problem (1)) is restricted to the case $\boldsymbol{g}=\boldsymbol{0}$ and $\boldsymbol{R}=\boldsymbol{0}$, it becomes a pure ℓ_p-norm minimizing flow problem, and its dual problem can be slightly rearranged to give

$$\min_{\boldsymbol{v}}\boldsymbol{d}^\top\boldsymbol{v}+\left\|\boldsymbol{S}^{-1}\boldsymbol{B}\boldsymbol{v}\right\|_q^q \tag{8}$$

where $q=p/(p-1)=1+1/(p-1)$. We refer to the diagonal entries of $\boldsymbol{S}^{-1}$ as ℓ_q-conductances. Because we can solve Problem (1) to high-accuracy in near-linear time for $p=\omega(1)$, this allows us to solve Problem (8), the dual voltage ℓ_q-norm minimization, in time $p(m^{1+o(1)}+n^{4/3+o(1)})\log^2 1/\varepsilon$ (see [1, Section 7] for the reduction). We summarize this in the theorem below.

▶ **Theorem 18** (Voltage Algorithmic Result, $q<2$ (Informal)). *Consider a graph G with n vertices and m edges, equipped with positive ℓ_q-conductances, as well as a demand vector. For $1<q<2$, when $q=1+o(1)$, in $\mathrm{poly}\left(\frac{1}{q-1}\right)(m^{1+o(1)}+n^{4/3+o(1)})\log^2 1/\varepsilon$ time, we can compute an ε-approximately optimal voltage solution to Problem (8) with high probability.*

Similarly, we can solve ℓ_q-norm minimizing flows for $q<2$ as dual to the ℓ_p-voltage problem, a special case of the mixed $(\ell_2^2+\ell_p^p)$-voltage problem. Picking $\boldsymbol{W}=\boldsymbol{0}$ in Problem (2), we obtain a pure ℓ_p-norm minimizing voltage problem, and its dual problem can be slightly rearranged to give

$$\min_{\boldsymbol{B}^\top\boldsymbol{f}=\boldsymbol{d}}\left\|\boldsymbol{U}^{-1}\boldsymbol{f}\right\|_q^q \tag{9}$$

where $q=p/(p-1)=1+1/(p-1)$. We refer to the diagonal entries of $\boldsymbol{U}^{-1}$ as q-weights. Again, because we can solve Problem (2) to high-accuracy in near-linear time for $p=\omega(1)$, this allows us to solve Problem (9), the dual flow ℓ_q-norm minimization, in time $p(m^{1+o(1)}+n^{4/3+o(1)})\log^2 1/\varepsilon$.

▶ **Theorem 19** (Flow Algorithmic Result, $q<2$ (Informal)). *Consider a graph G with n vertices and m edges, equipped with positive q-weights, as well as a demand vector. For $1<q<2$, when $q=1+o(1)$, in $\mathrm{poly}\left(\frac{1}{q-1}\right)(m^{1+o(1)}+n^{4/3+o(1)})\log^2 1/\varepsilon$ time, we can compute an ε-approximately optimal flow solution to Problem (9) with high probability.*

Open Questions

Mixed ℓ_2,ℓ_q problems for small $q<2$. In this work, we provided new state-of-the-art algorithms for weighted mixed ℓ_2,ℓ_p-norm minimizing flow and voltage problems for $p>>2$, and for pure ℓ_q-norm minimizing flow and voltage problems for q near 1.

A reasonable definition of mixed ℓ_2,ℓ_q-norm problems for $q<2$ is based on gamma-functions as introduced in [9] and used in [1]. We believe that with minor adjustments to our multiplicative weights solver, these objectives could be handled too, by solving their dual ℓ_2,ℓ_p-gamma function problem for $p>2$.

Directly sparsifying mixed ℓ_2, ℓ_q problems for $q < 2$. A second approach to developing a fast ℓ_2, ℓ_q-gamma function solver for $q < 2$ would be to directly develop sparsification in this setting. We believe this might be possible, and in the general matrix setting might provide better algorithms than alternative approaches.

Removing the $m^{\frac{O(1)}{p-1}}$ loss in sparsification. Our current approaches to graph mixed ℓ_2, ℓ_p-sparsification lose a factor $m^{\frac{O(1)}{p-1}}$ in their quality of approximation, which leads to a $m^{\frac{O(1)}{p-1}}$ factor slowdown in running time, and makes our algorithms less useful for small p. We believe a more sophisticated graph sparsification routine could remove this loss and result in significantly faster algorithms for p close to 2.

Using mixed ℓ_2, ℓ_p-objectives as oracles for ℓ_∞ regression. The current state-of-the-art algorithm for computing maximum flow in unit capacity graphs runs in $\widetilde{O}(m^{4/3})$ time [21], and uses the almost-linear-time algorithm from [25] for solving *unweighted* $\ell_2^2 + \ell_p^p$ instances as a key ingredient.

An Output-Sensitive Algorithm for Computing the Union of Cubes and Fat Boxes in 3D

Pankaj K. Agarwal
Department of Computer Science, Duke University, Durham, NC, USA

Alex Steiger
Department of Computer Science, Duke University, Durham, NC, USA

Abstract

Let $\mathcal{C}$ be a set of n axis-aligned cubes of arbitrary sizes in $\mathbb{R}^3$. Let $\mathcal{U}$ be their union, and let κ be the number of vertices on $\partial\mathcal{U}$; κ can vary between $O(1)$ and $O(n^2)$. We show that $\mathcal{U}$ can be computed in $O(n\log^3 n+\kappa)$ time if $\mathcal{C}$ is in general position. The algorithm also computes the union of a set of fat boxes (i.e., boxes with bounded aspect ratio) within the same time bound. If the cubes in $\mathcal{C}$ are congruent or have bounded depth, the running time improves to $O(n\log^2 n)$, and if both conditions hold, the running time improves to $O(n\log n)$.

1 Introduction

Let $\mathcal{C}$ be a set of n axis-aligned cubes of arbitrary sizes in $\mathbb{R}^3$. Let $\mathcal{U}:=\mathcal{U}(\mathcal{C})$ be their union, and let κ be the number of vertices on $\partial\mathcal{U}$. It is known that $\kappa=\Theta(n^2)$ in the worst case, though it is linear or near-linear in many special cases. For example, $\kappa=O(n)$ if the cubes in $\mathcal{C}$ have roughly the same size [6] or if they have bounded depth (i.e., any point in $\mathbb{R}^3$ lies in $O(1)$ cubes) [14]. If their sizes are drawn independently from an arbitrary distribution, the expected complexity of their union is $O(n\log^2 n)$ [3]. A natural problem is to develop an algorithm for computing $\partial\mathcal{U}$, by which we mean compute its vertices, edges, and faces. Although $\mathcal{U}$ can be computed in $O(n^2\log n)$ time by computing $\partial\mathcal{U}$ on each face of every cube of $\mathcal{C}$, an output-sensitive algorithm with $O(n\log n+\kappa)$ running time has remained elusive. In this paper we present an algorithm that almost matches this running time.

Related work. Motivated by VLSI design and other applications, the problem of computing the union of a set of axis-aligned rectangles in $\mathbb{R}^2$ and its variants have been studied since the 1970's; see [17]. An optimal $O(n\log n+\kappa)$-time algorithm was presented by Güting [12].

A closely related problem, which also has been studied extensively, is the so-called *Klee's measure problem*, which asks to compute the *volume* of the union of axis-aligned boxes in $\mathbb{R}^d$. For $d=2$, Bentley presented an $O(n\log n)$-time algorithm for this problem, which extends to higher dimensions and computes the volume in $O(n^{d-1}\log n)$ time. For $d\geq 3$, Overmars and Yap [16] gave an $O(n^{d/2}\log n)$-time algorithm. The running time was improved to $O(n^{d/2})$ by Chan [8]. It was an open question whether a faster algorithm exists if the input boxes are hypercubes or fat. Agarwal *et al.* [2] described an $O(n^{4/3}\log n)$-time algorithm for cubes in 3D, which was subsequently improved to $O(n\log^4 n)$ in [1]. Bringmann [7] presented an $O(n^{(d+2)/3})$-time algorithm for fat boxes in $\mathbb{R}^d$, which was later improved to $O(n^{(d+1)/3}\,\mathrm{polylog}(n))$ in [8]; see also [19].

Despite extensive work on Klee's measure problem, relatively less is known about computing the union boundary. For example, no $O(n \log n)$-time algorithm is known even for computing the union of unit cubes in $\mathbb{R}^3$. For $d = 3$, the Overmars-Yap algorithm can be adapted to compute the boundary of the union of boxes in $O((n^{3/2} + \kappa) \log n)$ time, where κ is the output size. But it is not obvious whether the algorithm in [1] can be adapted to compute the union of axis-aligned cubes in $O((n + \kappa)\,\mathrm{polylog}(n))$ time. Agarwal *et al.* [4] have presented a randomized algorithm that computes the union of congruent cubes in $\mathbb{R}^3$ in $O(n^{1+\varepsilon})$ expected time, for any constant $\varepsilon > 0$.

A related line of work is to partition the union (or its complement) into few axis-aligned boxes. Chew *et al.* [9] describe an algorithm to compute a partition of the union of n congruent cubes into $O(n)$ axis-aligned boxes in $O(n \log n)$ time, assuming that the union has already been computed[1]. For a special case of orthants in $\mathbb{R}^d$, Kaplan *et al.* [15] describe an algorithm to partition the union of n such orthants into $O(\kappa)$ axis-aligned (semiunbounded) boxes in $O((n + \kappa) \log^{d-1} n)$ time, for any $d \geq 1$, where κ is the union complexity.

Our results. The main result of the paper is an output-sensitive algorithm to compute $\mathcal{U}$. That is, our algorithm computes the vertices, edges, and 2D faces of $\partial\mathcal{U}$. For each 2D face f, it computes the components of ∂f. We say that $\mathcal{C}$ is in *general position* if any plane contains the boundary face of at most one cube in $\mathcal{C}$. Our algorithm assumes $\mathcal{C}$ to be in general position. Although it can be extended to degenerate configurations using symbolic perturbation techniques (e.g., [10]), the running time depends on the union complexity of the perturbed configuration.

▶ **Theorem 1.** *Given a set $\mathcal{C}$ of n axis-aligned cubes in $\mathbb{R}^3$, $\mathcal{U}(\mathcal{C})$ can be computed in $O(n \log^3 n + \kappa)$ time if $\mathcal{C}$ is in general position. If $\mathcal{C}$ is not in general position, the running time is $O(n \log^3 n + \widehat{k})$, where $\widehat{k}$ is the maximum complexity of $\mathcal{U}(\mathcal{C})$ under an infinitesmal perturbation.*

A 3D box is *fat* if its aspect ratio (i.e., the ratio of its longest side length and its shortest side length) is bounded by a constant. A fat box can be decomposed into $O(1)$ (possibly intersecting) cubes. Replacing fat boxes in general position with $O(1)$ such cubes then perturbing them into general position increases the union complexity at most by a constant factor. From Theorem 1, we have the following:

▶ **Corollary 2.** *Given a set $\mathcal{B}$ of n axis-aligned fat boxes in $\mathbb{R}^3$, where the aspect ratio of each box is bounded by a constant, $\mathcal{U}(\mathcal{B})$ can be computed in $O(n \log^3 n + \kappa)$ time, assuming $\mathcal{B}$ is in general position. If $\mathcal{B}$ is not in general position, the running time is $O(n \log^3 n + \widehat{k})$, where $\widehat{k}$ is the maximum complexity of $\mathcal{U}(\mathcal{B})$ under an infinitesmal perturbation.*

For some special cases, simpler algorithms compute the union slightly more efficiently: when all cubes in $\mathcal{C}$ are congruent or when they have bounded *depth* (i.e., any point in $\mathbb{R}^3$ is contained in at most c cubes of $\mathcal{C}$, for a constant $c > 0$). In both cases, $\kappa = O(n)$. Since the output size is always linear after perturbing the cubes to be in general position, we do not need the general-position assumption here.

▶ **Theorem 3.** *Let $\mathcal{C}$ be a set of n axis-aligned cubes in $\mathbb{R}^3$. If all cubes in $\mathcal{C}$ are congruent or they have bounded depth, then $\mathcal{U}(\mathcal{C})$ can be computed in $O(n \log^2 n)$ time. If the cubes in $\mathcal{C}$ are congruent and have bounded depth, then $\mathcal{U}(\mathcal{C})$ can be computed in $O(n \log n)$ time.*

---

[1] Theorem 1 in [9] suggests that the union $\mathcal{U}(\mathcal{C})$ of n unit axis-aligned cubes $\mathcal{C}$ in $\mathbb{R}^3$ can be computed in $O(n \log n)$, but no such algorithm is presented in the paper. It shows that given $\mathcal{U}(\mathcal{C})$, it can be decomposed into $O(n)$ boxes in $O(n \log n)$ time [11].

Analogous to Corollary 2, we obtain the following:

▶ **Corollary 4.** *Given a set $\mathcal{B}$ of n axis-aligned fat boxes in $\mathbb{R}^3$. If the ratio of the largest to the smallest size box is bounded by a constant or they have bounded depth, then $\mathcal{U}(\mathcal{B})$ can be computed in $O(n \log^2 n)$ time. If both conditions hold, then the running time is $O(n \log n)$.*

At a high level, the general approach of our algorithm is similar to Agarwal's [1] to compute the volume of the union of 3D cubes, but ours is considerably simpler and more efficient. We reduce the problem to maintaining the union of a set of squares in the plane under insertions and deletions, which are the xy-projections of the faces of cubes in $\mathcal{C}$. At the core of the data structure in [1] is a hierarchical decomposition of the plane using a variant of a kd-tree. In constrast, our data structure is a variant of a quadtree whose regions are squares. Using this property – having square regions – we crucially circumvent much of the intracacies in [1] and attain a simpler algorithm. We use a sweep-line algorithm to compute the changes in the union-boundary of squares and rely on auxiliary data structures, which are also somewhat simpler than in [1] to perform this sweep efficiently. Finally, we are also able to simplify and improve the algorithm because we can charge time to the $O(\kappa)$ vertices reported.

Roadmap of the paper. As a warm-up, we first present in Section 2 an algorithm for a special case where the spread of the xy-projections of the vertices of the cubes in $\mathcal{C}$ (regarded as a 2D point set) is (polynomially) bounded, i.e., the ratio of the distance between the farthest and closest pairs of such points in $\mathbb{R}^2$ is bounded by n^c, for some constant $c > 0$. In Section 3 we describe how to remove this assumption to obtain our main result (Theorem 1). Finally, we describe the more efficient algorithms for congruent cubes and cubes with bounded depth (Theorem 3) in Section 4.

2 Algorithm for the Bounded Spread Case

Let $\mathcal{C} := \{C_1, \ldots, C_n\}$ be a set of n axis-aligned cubes in $\mathbb{R}^3$ in general position. We assume that the spread of the xy-projections of the vertices of $\mathcal{C}$ is polynomially bounded. For any set A of objects (e.g. segments in $\mathbb{R}$, squares in $\mathbb{R}^2$, or cubes in $\mathbb{R}^3$), let $\mathcal{U}(A)$ denote the union of the objects in A, and let $V(A)$ be the vertices of $\mathcal{U}(A)$. Set $\mathcal{U} := \mathcal{U}(\mathcal{C})$. For any 3D object a, let $a^{\downarrow}$ be the xy-projection of a.

In this section, we describe an algorithm to compute the boundary of $\mathcal{U}$, denoted by $\partial\mathcal{U}$, namely its vertices, edges, and faces. Once the vertices of $\partial\mathcal{U}$ have been computed, the edges and faces can be computed using standard techniques, so we first focus only on computing the vertices and remark at the end of the section how to extend it to compute edges and faces of $\partial\mathcal{U}$.

2.1 Overview of the algorithm

We first introduce some notation. For a cube $C_i \in \mathcal{C}$, let $S_i := C_i^{\downarrow}$ be the xy-projection of C_i, which is an axis-aligned square in $\mathbb{R}^2$. Let $z_1 < \ldots < z_{2n}$ be the z-coordinates of the vertices of cubes in $\mathcal{C}$, sorted in decreasing order. For all i with $1 \le i \le 2n$, let $\mathcal{C}_i \subseteq \mathcal{C}$ be the set of cubes whose z-spans cover the interval (z_i, z_{i+1}), and let $\mathcal{S}_i = \{S_j \mid C_j \in \mathcal{C}_i\}$. Let V_i denote the set of vertices of $\mathcal{U}(\mathcal{S}_i)$.

Note that every vertex of $\mathcal{U}$ is the intersection of three orthogonal faces of cubes in $\mathcal{C}$ – in particular, every vertex lies on a xy-face of some cube, i.e., the z-coordinate of every vertex is one of the z_i's, and is incident to a z-edge of $\mathcal{U}$. Therefore, our high-level approach is to

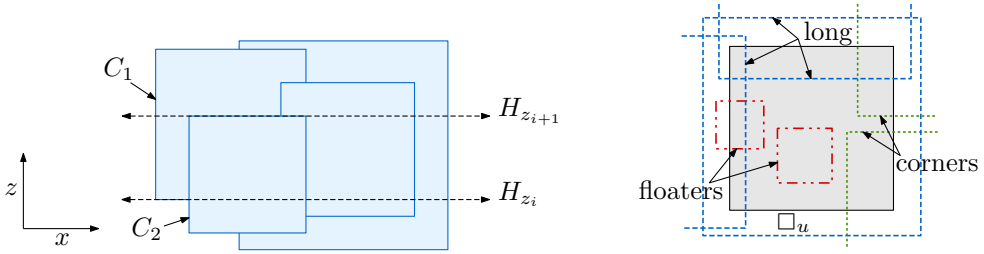

Figure 1 (left) A 2D view of $\mathcal{C}$. The bottom (resp. top) face of cube C_1 (resp. C_2) lies on the xy-plane $H_{z_i} : z = z_i$ (resp. $H_{z_{i+1}} : z = z_{i+1}$). (right) Various long and short squares at node u.

sweep a horizontal plane H in the $(+z)$-direction, from z_1 to z_{2n}, and maintain $H \cap \mathcal{U}$ in the process. We stop the sweep at each z_i and report the vertices of $\mathcal{U}$ that are incident on the face of the cube of $\mathcal{C}$ lying in the plane H_{z_i}.

For any value $a \in (z_i, z_{i+1})$, let $\mathcal{U}_a := \mathcal{U} \cap H_a$. Then we have

$$\mathcal{U}_a = \mathcal{U}\big(\{H_a \cap C \mid C \in \mathcal{C}_i\}\big) = \mathcal{U}(\{S_i \times \{a\} \mid S_i \in \mathcal{S}_i\}) = \mathcal{U}(\mathcal{S}_i) \times \{a\}$$

so the combinatorial structure of $\mathcal{U}$, and $\mathcal{U}(\mathcal{S}_i) = \mathcal{U}_a^{\downarrow}$, does not change in $[z_i, z_{i+1})$. See Figure 1. Furthermore, each vertex (x_0, y_0, a) of $\mathcal{U}_a$ is the intersection point of a z-edge e of $\mathcal{U}$ with H_a and $(x_0, y_0) \in V_i$. Let p^- (resp. p^+) be the lower (resp. upper) endpoint of e. Let $z_i := z(p^-)$ and $z_j := z(p^+)$, where $i < j$. Then $(p^-)^{\downarrow} \in V_i \setminus V_{i-1}$, and $(p^+)^{\downarrow} \in V_{j-1} \setminus V_j$. Conversely, for any i with $1 \le i \le 2n$, every vertex of $\Delta V_i := V_i \oplus V_{i-1}$ is the projection of an endpoint of a z-edge of $\mathcal{U}$ and thus a vertex of $\mathcal{U}$, where $\oplus$ is symmetric difference. (So that ΔV_1 is well-defined, set $\Delta V_0 := \varnothing$.) Thus, to compute the vertices of $\mathcal{U}$, we report ΔV_i when the plane H stops at z_i, for all i, $1 \le i \le 2n$.

We report the vertices of ΔV_i using a data structure $\mathbb{T}$ that stores $\mathcal{S}_i$ and implicitly maintains $\mathcal{U}(\mathcal{S}_i)$ as we sweep H. A square S_j is inserted into $\mathcal{S}_i$ when H reaches the bottom face of C_j, and it is deleted from $\mathcal{S}_i$ when H reaches the top face of C_j. Let $|A|$ denote the length of the longest side length of A, where A is a box or rectangle. Since C_j's are cubes, the sequence of updates satisfies the following property:

(P1): Let $C_u, C_v \in \mathcal{C}$ be two cubes such that $|C_u| < |C_v|$ and S_u is inserted before S_v. Then S_u is also deleted before S_v.

When the sweep stops at z_i, the insertion or deletion of a square to $\mathcal{S}_{i-1}$ (to obtain $\mathcal{S}_i$) into $\mathbb{T}$ is performed in $O(\log^3 n)$ amortized time, and ΔV_i is reported in $O(\log^3 n + |\Delta V_i|)$ amortized time. Thus, the sweep takes $O(\sum_{i=1}^{2n} \log^3 n + \sum \Delta V_i) = O(n \log^3 n + \kappa)$ time. With $O(n \log n)$ additional preprocessing to initialize $\mathbb{T}$ before the sweep, and $O(n \log n + \kappa)$ postprocessing to compute the edges and faces of $\mathcal{U}$ using the vertices reported during the sweep, the algorithm takes $O(n \log^3 n + \kappa)$ overall time, proving Theorem 1 for the bounded-spread case.

2.2 Reporting ΔV_i

Next, we describe our dynamic data structure $\mathbb{T}$ that stores a set $\mathcal{S}$ of squares in $\mathbb{R}^2$ and implicitly maintains $\mathcal{U}(\mathcal{S})$. After each update – an insertion or deletion of a square – it reports $\Delta V := V(\mathcal{S}^{\text{new}}) \oplus V(\mathcal{S}^{\text{old}})$, where $\mathcal{S}^{\text{old}}$ (resp. $\mathcal{S}^{\text{new}}$) is $\mathcal{S}$ before (resp. after) the update operation. Let $\mathsf{X} \subset \mathbb{R}^2$ be the set of points corresponding to the xy-projections of vertices of cubes in $\mathcal{C}$. Recall that the spread of X is polynomially bounded. Let $\square_0$ be a square

containing X. $\mathbb{T}$ is a quadtree built on X with $\square_0$ being the square associated with the root node of $\mathbb{T}$. Without loss of generality, we assume that no point of X lies on the boundary of a square $\square_u$ for any node $u \in \mathbb{T}$.

Each node $u \in \mathbb{T}$ is associated with a square $\square_u$. For the root node r, $\square_r = \square_0 \supset \mathsf{X}$. If $|\mathsf{X} \cap \square_u| \leq 1$, u is a leaf, otherwise $\square_u$ is partitioned into four congruent squares, each associated with a child of u. Set $\mathsf{X}_u \coloneqq \mathsf{X} \cap \square_u$. The height of $\mathbb{T}$ is $O(\log n)$. A square S that intersects the region $\square_u$, for a node $u \in \mathbb{T}$, is *long* at u if no vertex of S lies in $\square_u$, and S is *short* at u otherwise. A short square S at node u is called a *floater square* if at least two vertices of S lie in $\operatorname{int}(\square_u)$, and a *corner square* otherwise. A corner square S contains exactly one vertex of $\square_u$. See Figure 1 (right). For each node $u \in \mathbb{T}$, let $\mathcal{L}_u \subseteq \mathcal{S}$ (resp. $\mathcal{S}_u \subseteq \mathcal{S}$) be the set of long (resp. short) squares at u, and let $\mathcal{L}^*_u \coloneqq \mathcal{L}_u \setminus \mathcal{L}_{p(u)} = \mathcal{L}_u \cap \mathcal{S}_{p(u)}$, where $p(u)$ is the parent node of u in $\mathbb{T}$; $\mathcal{L}_{\text{root}} \coloneqq \varnothing$. Let $\mathcal{F}_u \subseteq \mathcal{S}_u$ (resp. $\mathcal{R}_u \subseteq \mathcal{S}_u$) denote the set of floater (resp. corner) squares at u. Note that any square $S \in \mathcal{S}$ is short at no more than four nodes in any level of $\mathbb{T}$. Hence S is short at $O(\log n)$ nodes of $\mathbb{T}$.

At each node $u \in \mathbb{T}$, we maintain $\mathcal{L}^*_u$ and $\mathcal{S}_u$. A long square $S \in \mathcal{L}^*_u$ contains at least one edge of $\square_u$; it may contain all four edges of $\square_u$ if $\square_u \subseteq S$. We partition $\mathcal{L}^*_u$ into four sets: for each edge $e \in \square_u$, let $\mathcal{L}^*_{u,e} \subseteq \mathcal{L}^*_u$ be the set of squares that contain e. If $\square_u \subseteq S$, then S is assigned only to the set associated with the top edge of $\square_u$. Suppose e is the top edge of $\square_u$. Then the bottom edges of squares in $\mathcal{L}^*_{u,e}$ intersect $\square_u$ or lie below $\square_u$. We store $\mathcal{L}^*_{u,e}$ in a red-black tree, sorted in increasing order of the distances of their bottom edges from e (i.e., in decreasing order of their y-coordinates). We similarly store $\mathcal{L}^*_{u,e}$ for the other three edges e of $\square_u$. Let $\mathcal{E}^x_u$ (resp. $\mathcal{E}^y_u$) be the sequences of x-edges (resp. y-edges) of $\mathcal{F}_u$ in increasing order of their y-coordinates (resp. x-coordinates). We maintain $\mathcal{E}^x_u, \mathcal{E}^y_u$ using red-black trees.

For each edge e of $\square_u$, we store a value ℓ_e that maintains the position of a sweep-line L_e associated with the edge e. The roles of ℓ_e and L_e will become clear in the insertion and deletion procedures. The value of ℓ_e (and the sweep-line) changes dynamically. Initially, for each x-edge (resp. y-edge) e of $\square_u$, ℓ_e is the y-coordinate (resp. x-coordinate) of e, and it always lies in the y-span (resp. x-span) of $\square_u$. If e is an x-edge (resp. y-edge), then let $\mathcal{I}_e$ be the set of x-projections (resp. y-projections) of the floater squares in $\mathcal{F}_u$ whose y-spans (resp. x-spans) contain ℓ_e. $\mathcal{I}_e$ changes dynamically with ℓ_e.

We also maintain two secondary structures for each edge e of $\square_u$:

- *Wall data structure* $\mathbb{W}_e(\mathcal{I}_e)$: It supports the following two operations:
  - Insert/Delete(I): Insert or delete an interval I to $\mathcal{I}_e$.
  - Report-Holes(ζ): For a query interval ζ, return the endpoints of $\zeta \setminus \operatorname{int}(\mathcal{U}(\mathcal{I}_e))$. If an endpoint x of ζ does not lie in $\operatorname{int}(\mathcal{U}(\mathcal{I}_e))$, x is also returned.

  The Insert, Delete, and Membership operations take $O(\log n)$ time and Report-Holes takes $O(\log n + \kappa)$ time, where κ is the number of points reported.

- *Corner data structure* $\mathbb{C}_e(\mathcal{R}_u, \mathcal{I}_e)$: It supports the following four operations:
  - Insert/Delete(R): Insert or delete a corner square R to $\mathcal{R}_u$.
  - Insert/Delete(I): Insert or delete an interval I to $\mathcal{I}_e$.
  - Report-Hole(σ): Given a query axis-aligned segment $\sigma \subset \square_u$, return the (at most one) interval of $\sigma \setminus \operatorname{int}(\mathcal{U}(\mathcal{R}_u))$.
  - Report-Vertices(ρ): Given a query rectangle $\rho \subseteq \square_u$, return $V(\mathcal{R}_u \cup \mathcal{W}_e) \cap \rho$, where $\mathcal{W}_e \coloneqq \{I \times \mathbb{R} \mid I \in \mathcal{I}_e\}$ if e is an x-edge and $\mathcal{W}_e \coloneqq \{\mathbb{R} \times I \mid I \in \mathcal{I}_e\}$ if e is a y-edge. Namely, the vertices of $\mathcal{U}(\mathcal{R}_u)$ that do not lie in $\mathcal{U}(\mathcal{W}_e)$ or the intersection points of the edges of $\mathcal{U}(\mathcal{R}_u)$ and $\mathcal{U}(\mathcal{W}_e)$ that lie in ρ are reported.

  An Insert/Delete takes $O(\log^2 n)$ time, Report-Hole takes $O(\log n)$ time, and Report-Vertices takes $O(\log n + \kappa)$ time, where κ is the number of vertices reported.

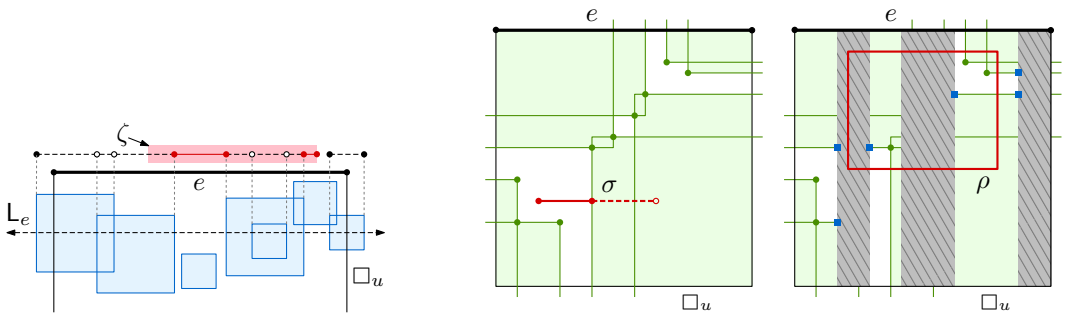

Figure 2 (left) An illustration of call Report-Hole(ζ) to $\mathbb{W}_e$. The x-projections of floater squares intersecting L_e that compose $\mathcal{I}_e$. The intervals of $\mathcal{U}(\mathcal{I}_e)$ are dashed. The solid red intervals in ζ are the answer to the query. (right) Illustrations of calls Report-Hole(σ) and Report-Vertices(ρ) to $\mathbb{C}_e$. The vertices of $\mathcal{U}(\mathcal{R}_u)$ are shown as green circles, and the vertices of $\mathcal{U}(\mathcal{R}_u \cup \mathcal{W}_e)$ that are the intersection points of a "strip" in $\mathcal{W}_e$ (gray hatched) and an edge of $\mathcal{U}(\mathcal{R}_u)$ are shown as blue squares. The solid portion of σ is the answer to Report-Hole(σ), and the two blue vertices and three green vertices (inside ρ) are the answer to Report-Vertices(ρ).

See Figure 2. We describe these data structures in Section 2.4. For now, we assume that, for all four edges of $\square_u$ and for all nodes $u \in \mathbb{T}$, $\mathbb{W}_e$, and $\mathbb{C}_e$ are at our disposal.

For each square $S \in \mathcal{S}$, let $\Lambda(S) := \{u \in \mathbb{T} \mid S \in \mathcal{L}^*_u\}$ and $\Sigma(S) := \{u \in \mathbb{T} \mid S \in \mathcal{S}_u\}$. Any square $S \in \mathcal{S}$ is short at no more than four nodes of any fixed level of $\mathbb{T}$. The nodes in $\Sigma(S)$ lie along at most four root-to-leaf paths to the leaves whose squares contain the vertices of S, and the nodes in $\Lambda(S)$ are those children u of nodes in $\Sigma(S)$ for which $S \cap \square_u \neq \varnothing$ and S is not short at u. Since the height of $\mathbb{T}$ is $O(\log n)$, $|\Lambda(S)|, |\Sigma(S)| = O(\log n)$. Finally, let $\Xi(S)$ be $\Lambda(S)$ and the four leaves of $\Sigma(S)$, and set $\Pi(S) := \{S \cap \square_u \mid \square_u \in \Xi(S)\}$. See Figure 3 (left). The following lemma is straightforward.

▶ **Lemma 5.** *For any square S, $\Pi(S)$ is a partition of S into $O(\log n)$ rectangles.*

When we insert or delete a square S, every vertex of ΔV lies in S. Thus, to report ΔV, we report $\Delta V_u := \Delta V \cap \square_u$ for each node $u \in \Xi(S)$. We now describe how to update $\mathbb{T}$ and compute ΔV_u at each node $u \in \Xi(S)$.

Insertion of S. There are four main steps:

(1) At each node $u \in \Lambda(S) \cup \Sigma(S)$, we compute $\rho_u := \mathrm{cl}(\square_u \setminus \mathcal{U}(\mathcal{L}_u))$, as described below.

(2) At each node $u \in \Xi(S)$, we report ΔV_u, which is also described below.

(3) For each node $u \in \Lambda(S)$, we insert S to $\mathcal{L}^*_u$. In particular, if S contains the edge e of $\square_u$, S is inserted into $\mathcal{L}^*_{u,e}$; recall that if $\square_u \subseteq S$, then S is associated with the top edge of $\square_u$.

(4) For each $u \in \Sigma(S)$, we update $\mathcal{S}_u$ and its secondary structures, as follows. If S is a corner square at u, we insert S into all four corner data structures $\mathbb{C}_e$ stored at u for each edge of $\square_u$. If S is a floater, we first insert the x-edges (resp. y-edges) of S which intersect $\square_u$ into $\mathcal{E}^*_u$ (resp. $\mathcal{E}^y_u$). Then, for each x-edge (resp. y-edge) e of $\square_u$ such that ℓ_e lies in the y-span (resp. x-span) of S, we insert the x-projection (resp. y-projection) of S to $\mathbb{W}_e$ and $\mathbb{C}_e$.

We now describe the first two steps in more detail. We compute ρ_u at each node $u \in \Lambda(S) \cup \Sigma(S)$, as follows. Observe that $\rho_u \subseteq \square_u$ is a (possibly empty) rectangle. Similarly, $\mathrm{cl}(\square_u \setminus \mathcal{U}(\mathcal{L}^*_u))$ is a rectangle $\rho^*_u \subseteq \square_u$. By definition, $\rho_u = \mathrm{cl}(\square_u \setminus (\mathcal{U}(\mathcal{L}_{p(u)}) \cup \mathcal{U}(\mathcal{L}^*_u))) =$

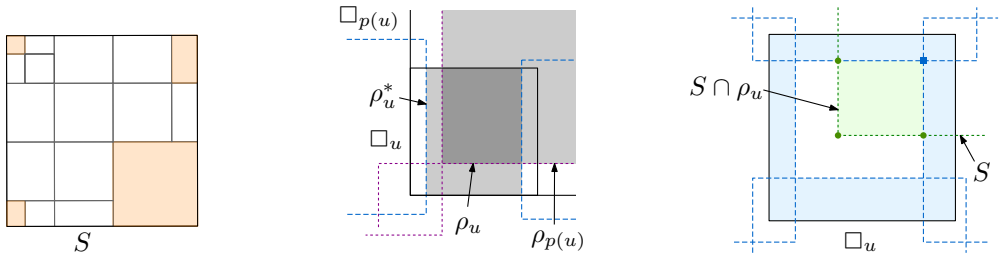

Figure 3 (left) The rectangles of $\Pi(S)$. The shaded (resp. empty) rectangles lie in squares $\square_u$ of nodes u in $\Sigma(S)$ (resp. $\Lambda(S)$). (middle) Computing ρ_u using ρ_u^* and $\rho_{p(u)}$. The squares at the ends of the sequences $\mathcal{L}^*_{u,e}$ for each edge e of $\square_u$ are dashed and the squares of $\mathcal{L}_{p(u)}$ that contribute to $\mathcal{U}(\mathcal{L}_{p(u)})$ are dotted. (right) An example of a square S being inserted at $u \in \Sigma(S)$. The four vertices of ΔV_u are shown, where the blue vertex is old and the rest are new.

$\rho_{p(u)} \cap \rho_u^*$. See Figure 3 (middle). Furthermore, for each edge e_i, $1 \le i \le 4$, let S_i be the last square in the sequence $\mathcal{L}^*_{u,e_i}$, and let h_i be the halfplane bounded by the line supporting the edge of S_i that intersects $\square_u$ and does not contain S_i (if $S_i \supseteq \square_u$, then choose the halfplane bounded by the edge of $\square_u$ opposite e_i and not containing $\square_u$). Then $\rho_u^* = \bigcap_{i=1}^4 h_i \cap \square_u$. Hence, ρ_u^* can be computed in $O(1)$ time. Also, with $\rho_{p(u)}$ at our disposal $\rho_u = \rho_{p(u)} \cap \rho_u^*$ can be computed in $O(1)$ time. Thus, using a top-down traversal of $\mathbb{T}$, starting at the root node r (with $\mathcal{L}_r = \varnothing$) and ending at the nodes of $\Xi(S)$, we compute ρ_u at each visited node; $O(\log n)$ nodes are visited in this process, so the step takes $O(\log n)$ time overall. This completes step (1).

Next, let u be a node of $\Xi(S)$. We report ΔV_u as follows. If $u \in \Sigma(S)$, then $\mathcal{S}_u = \varnothing$ (before the insertion of S) and hence ΔV_u can be reported in $O(1)$ time; see Figure 3 (right). We now focus on reporting ΔV_u when $u \in \Lambda(S)$. For sake of concreteness, suppose S contains the top edge of $\square_u$. Let S_u^{exp} be the rectangle $S \cap \rho_u = \mathrm{cl}((S \cap \square_u) \setminus \mathcal{U}(\mathcal{L}_u)))$, i.e., the portion of $S \cap \square_u$ that is left "exposed" by the squares of $\mathcal{L}_u$. All vertices of ΔV_u lie in S_u^{exp}. Note that S_u^{exp} may be empty, e.g., if $\square_u \subseteq \mathcal{U}(\mathcal{L}_u)$ or $S \cap \rho_u = \varnothing$, in which case $\Delta V_u = \varnothing$ and there is nothing to do; see Figure 4 (middle). If $S_u^{\mathsf{exp}} \neq \varnothing$, we sweep a line L_e in the $(-y)$-direction from the top edge of S_u^{exp} (defined by $\mathcal{U}(\mathcal{L}_u)$ or $\square_u$) to its bottom edge (defined by S, $\square_u$, or $\mathcal{U}(\mathcal{L}_u)$), and report all vertices of ΔV_u in the process by using the secondary data structures as described in Section 2.3. Recall that ℓ_e keeps track of the position of L_e.

Deletion of S. Intuitively, the deletion is "undoing" the insertion of S.

(1) At each node $u \in \Lambda(S) \cup \Sigma(S)$, we compute $\rho_u := \mathrm{cl}(\square_u \setminus \mathcal{U}(\mathcal{L}_u \setminus \{S\}))$ as in the insertion case.

(2) At each node $u \in \Xi(S)$, we report ΔV_u, as described below.

(3) For each node $u \in \Lambda(S)$, we delete S from $\mathcal{L}_u^*$.

(4) For each node $u \in \Sigma(S)$, we update $\mathcal{S}_u$ and its secondary structures, as follows. If S is a corner square at u, we delete S from all four corner data structures $\mathbb{C}_e$ stored at u for each edge e of $\square_u$. If S is a floater, we first delete the x-edges (resp. y-edges) of S which intersect $\square_u$ from $\mathcal{E}_u^*$ (resp. $\mathcal{E}_u^y$). Then, for each x-edge (resp. y-edge) e of $\square_u$, we delete the x-projection (resp. y-projection) of S from $\mathbb{W}_e$ and $\mathbb{C}_e$ if ℓ_e lies in the y-span (resp. x-span) of S.

Let S_u^{exp} be the rectangle $S \cap \rho_u = \mathrm{cl}(S \cap \square_u) \setminus \mathcal{U}(\mathcal{L}_u \setminus \{S\}))$ i.e., the portion of $S \cap \square_u$ that is left "exposed" by the other squares of $\mathcal{L}_u$. Again, all vertices of ΔV_u lie in S_u^{exp}. We note that S_u^{exp} may be empty because ρ_u is empty or the bottom edge of S lies above the

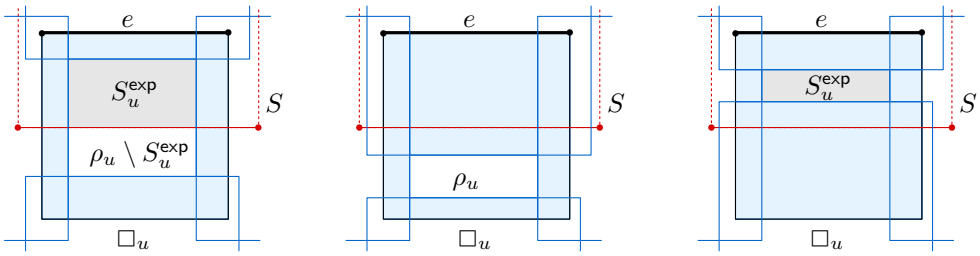

Figure 4 Various cases for S_u^{exp} when $\rho_u \neq \varnothing$: (left) $S_u^{\mathsf{exp}} \subset \rho_u$. (middle) $S_u^{\mathsf{exp}} = \varnothing$. (right) $S_u^{\mathsf{exp}} = \rho_u$.

top edge of S_u^{exp}. If $S_u^{\mathsf{exp}} = \varnothing$, $\Delta V_u = \varnothing$ and there is nothing to do. So assume $S_u^{\mathsf{exp}} \neq \varnothing$. We report ΔV_u by sweeping a line L_e in the $(+y)$-direction from the bottom edge of S_u^{exp} (defined by S, $\square_u$, or $\mathcal{U}(\mathcal{L}_u)$), to its top edge (which is the top edge of ρ_u).

Runtime analysis. We now analyze the amortized running time of inserting or deleting a square. Let c be a sufficiently large constant. For each node $u \in \mathbb{T}$, we assign $4c \log^2 n$ credits to each of the four edges of every floater in $\mathcal{F}_u$. These credits will be used to pay part of the cost of reporting ΔV_u (see Lemma 8). Note that S is a floater at $O(\log n)$ nodes. Therefore $O(\log^3 n)$ credits are assigned to a square S. This cost is charged to the insertion of S.

Suppose a square S is being inserted. The total time spent in computing ρ_u at all nodes $u \in \Lambda(S) \cup \Sigma(S)$ is $O(\log n)$. By Lemma 8, which is given in Section 2.3, the amortized cost of reporting ΔV_u and updating the secondary structures at all nodes in $\Xi(S)$ is $O(\log^2 n + |\Delta V_u|)$. Summing at all nodes of $\Xi(S)$, the total amortized time spent in reporting ΔV is $O(\log^3 n + |\Delta V|)$. Finally, we spend $O(\log n)$ time at each node $u \in \Lambda(S)$ to insert S into $\mathcal{L}_u^*$ and $O(\log^2 n)$ time to insert S into the secondary structures at each node in $\Sigma(S)$. Summing this cost over all nodes in $\Lambda(S) \cup \Sigma(S)$ and adding the cost of credits assigned to S, the total amortized time spent in inserting S is $O(\log^3 n + |\Delta V|)$ time. A similar analysis shows that the amortized time spent in deleting a square is $O(\log^3 n + |\Delta V|)$. Hence, we obtain the following:

▶ **Lemma 6.** *The amortized cost of inserting or deleting a square in $\mathbb{T}$ and reporting ΔV is $O(\log^3 n + |\Delta V|)$.*

2.3 Reporting ΔV_u via Sweep-Line

We describe the sweep-line procedure for the insertion of a square S; the deletion case is symmetric. Without loss of generality, assume that S contains the top edge of $\square_u$; the procedures for the other cases are similar. Let $\rho_u := \mathrm{cl}(\square_u \setminus \mathcal{U}(\mathcal{L}_u))$ and $S_u^{\mathsf{exp}} := S \cap \rho_u$ as defined above. If $S_u^{\mathsf{exp}} = \varnothing$, there is nothing to do. So assume $S_u^{\mathsf{exp}} \neq \varnothing$. Suppose S_u^{exp} is of the form $\gamma \times [a^-, a^+]$, where γ is the x-span of S_u^{exp} and $a^- < a^+$ are the y-coordinates of the bottom and top edges of S_u^{exp}; the bottom edge of S_u^{exp} is the bottom edge of S, ρ_u, or $\square_u$.

Let $V_u^{\mathrm{new}} \subseteq \Delta V_u$ be the set of vertices that are created by the insertion of S (which appear on ∂S) and let $V_u^{\mathrm{old}} \subseteq \Delta V_u$ be the set of vertices that no longer appear on $\mathcal{U}$ after the insertion of S (which lie in $\mathrm{int}(S)$). The vertices of V_u^{new} lie on $S_u^{\mathsf{exp}} \cap \partial S$, i.e., on the bottom edge of S_u^{exp} if it is contained in the bottom edge of S, and $V_u^{\mathrm{new}} = \varnothing$ if the bottom edge of $\square_u$ is not contained in that of S. Next, a vertex v of V_u^{old} can be classified into the following categories depending on the types of the two (not necessarily distinct) squares S_1, S_2 whose edges contain v: v is a *long-long* (LL) vertex if both S_1 and S_2 are long, in which case v

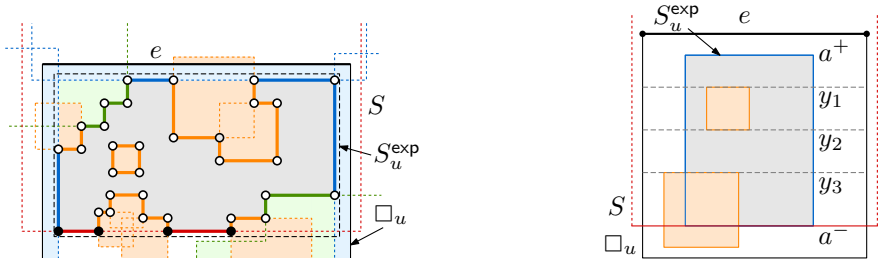

Figure 5 (left) A zoomed-in example of $S_u^{\exp}$ (slightly enlarged for visibility) and the vertices of ΔV where the bottom edge of $S_u^{\exp}$ lies on the bottom edge of the inserted square S. $\mathcal{U}(\mathcal{L}_u)$ is blue, $\mathcal{U}(\mathcal{F}_u) \setminus \mathcal{U}(\mathcal{L}_u)$ is orange, $\mathcal{U}(\mathcal{R}_u) \setminus \mathcal{U}(\mathcal{L}_u \cup \mathcal{F}_u)$ is green, and the edges of S are red. The edges of $\mathcal{U} \cap S_u^{\exp}$ are thick, the old vertices covered by S are hollow, and the new vertices on ∂S are solid. (right) Dashed lines supporting floater edges (orange) with y-coordinates in (a^-, a^+) partition $S_u^{\exp}$ (blue) into rectangles.

is a vertex of $S_u^{\exp}$ not contained in $\mathcal{U}(\mathcal{S}_u)$, a *long-short* (LS) vertex if S_1 is long and S_2 is short, in which case v is an intersection point of an edge of $\mathcal{U}(\mathcal{S}_u)$ with an edge of $S_u^{\exp}$, and a *short-short* (SS) vertex if both S_1 and S_2 are short, in which case v is a vertex of $\mathcal{U}(\mathcal{S}_u)$ that lies in $\operatorname{int}(S_u^{\exp})$. SS vertices are further classified into three categories, CC, CF, or FF, depending on whether S_1 and S_2 are corners (C) or floaters (F). See Figure 5 (left).

With this characterization of ΔV_u at hand, we report ΔV_u by sweeping downward ($(-y)$-direction) with a horizontal line L_e from $y = a^+$ to $y = a^-$. Let $\mathsf{Y} = \langle y_0 = a^+, y_1, y_2, \ldots, y_t = a^- \rangle$ where $y_1, \ldots, y_{t-1}$ are the y-coordinates of edges of floaters $F \in \mathcal{F}_u$ in the interval (a^-, a^+), sorted in decreasing order. Y can be constructed from $\mathcal{E}_u^y$. The lines $y = y_i$, $0 < i < t$, partition $S_u^{\exp}$ into rectangles. See Figure 5 (right).

The sweep line starts at $y = y_0$ and stops at every y_i, for $0 \le i \le t$. At each y_i, we perform two steps:

(i) Report all vertices of ΔV_u that lie on the line $\mathsf{L}_i : y = y_i$.

(ii) For $i \ge 1$, we report the vertices of ΔV_u that lie in the semi-open rectangle $\sigma_i := \gamma \times (y_i, y_{i-1})$, i.e., all vertices that lie in σ_i but not on its x-edges, using the secondary structures.

We now describe the details of the sweep-line algorithm. As we sweep L_e from a^+ to a^-, we vary ℓ_e, the value associated with the top edge e, to the current position of the sweep-line, so we update the set $\mathcal{I}_e$ (and the secondary structures $\mathbb{W}_e$ and $\mathbb{C}_e$ that store it) as ℓ_e changes. We note that $\mathcal{I}_e$ does not change in the interval (y_i, y_{i-1}). However, when we initialize L_e to y_0, we need to reset ℓ_e to y_0 and update $\mathcal{I}_e$, $\mathbb{W}_e$, and $\mathbb{C}_e$. We will describe this initialization step later and for now assume that $\mathcal{I}_e, \mathbb{W}_e$, and $\mathbb{C}_e$ are consistent with $\ell_e = y_0$. At each y_i, we perform steps (i) and (ii) follows.

Performing step (i). For $i = 0, t$, we set $\delta := \gamma \times \{y_i\}$ to be the top (or bottom) edge of $S_u^{\exp}$. By definition $\delta \cap \operatorname{int}(\mathcal{U}(\mathcal{L}_u)) = \varnothing$. Next, by calling Report-Hole(δ), we compute $\delta_0 := \delta \setminus \operatorname{int}(\mathcal{U}(\mathcal{R}_u)) = \delta \setminus \operatorname{int}(\mathcal{U}(\mathcal{L}_u \cup \mathcal{R}_u))$. Finally, set $\delta_0^{\downarrow}$ to be the x-projection of δ_0. By querying the wall data structure $\mathbb{W}_e$ for edge e with Report-Holes($\delta_0^{\downarrow}$), we compute the intervals of $\delta_0^{\downarrow} \setminus \mathcal{U}(\mathcal{I}_e)$. Let $x_0, \ldots, x_s$ be the endpoints of these intervals. Then, for $0 < j < s$, (x_j, y_i) is a LS vertex. If (x_0, y_i),(x_s, y_i) are endpoints of δ then they are LL vertices, otherwise they are LS vertices.

For $0 < i < t$, L_i contains an x-edge η of a floater $F \in \mathcal{F}_u$. Let $\delta := \eta \cap S_u^{\exp}$. As above, by calling Report-Hole(δ) on the corner data structure $\mathbb{C}_e$ for edge e, we compute $\delta_0 := \delta \setminus \operatorname{int}(\mathcal{U}(\mathcal{L}_u \cup \mathcal{R}_u))$. If η is the bottom edge of F then we first delete the interval $\eta^{\downarrow}$,

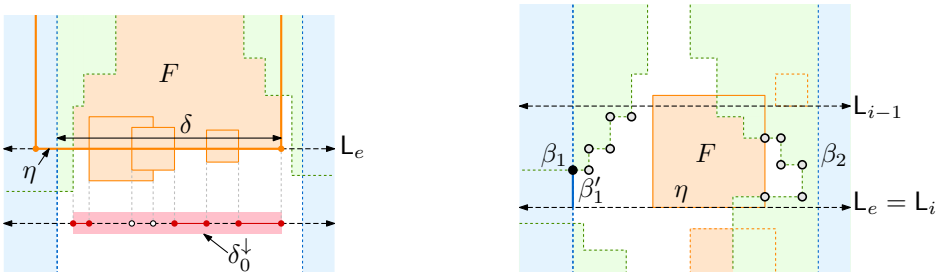

Figure 6 Zoomed-in illustrations of steps (i) and (ii) where the sweep-line L_e reaches the bottom edge η of floater F. Floaters are shown in orange, $\mathcal{U}(\mathcal{L}_u)$ is shown in blue, and $\mathcal{U}(\mathcal{R}_u) \setminus \mathcal{U}(\mathcal{L}_u)$ is shown in green. (left) Step i: The endpoints of the solid intervals in $\delta_0^{\downarrow}$ are the x-projections of the vertices of $\Delta V_u \cap \mathsf{L}_e$. (right) Step ii: The SS vertices in σ_i are hollow, and the lone LS vertex is solid. β_2, the right edge of σ_i, is contained in $\mathcal{U}(\mathcal{R}_u)$ so $\beta_2' = \varnothing$ and it contains no LS vertices.

the x-projection of η, from $\mathbb{W}_e$. Next, we query $\mathbb{W}_e$ with REPORT-HOLES($\delta_0^{\downarrow}$) to report the endpoints of the intervals of $\delta_0^{\downarrow} \setminus \text{int}(\mathcal{U}(\mathcal{I}_e))$. If $x_0, \ldots, x_s$ are these endpoints then (x_j, y_i), for $0 \le j \le s$, are vertices of ΔV_u lying on L_i: If x_0 or x_s lies on $\partial S_u^{\mathsf{exp}}$ then it is an LS vertex, and if it lies on an edge of a square in $\mathcal{R}_u$, (i.e., an endpoint of δ_0 lying inside S_u^{exp}), it is a CF vertex. All other vertices are FF vertices. See Figure 6 (left).

Performing step (ii). Our goal is to report all vertices of $V_u \cap \int(\sigma_i)$. A vertex of ΔV_u not lying on L_{i-1} or L_i lies on an x-edge of a corner square. Since no x-edge of any floater square lies in the interval (y_i, y_{i-1}), the set $\mathcal{I}_e$, and thus $\mathcal{W}_e$, remains the same for all y-values in this interval. Furthermore, $V(\mathcal{R}_u \cup \mathcal{F}_u) \cap \sigma_i = V(\mathcal{R}_u \cap \mathcal{W}_e) \cap \sigma_i$. We can thus report all CF and CC vertices lying in σ_i by querying $\mathcal{R}_e$ with REPORT-VERTICES(σ_i). The $O(1)$ LS vertices in σ_i are defined by a long square, namely a long square that defines a y-edge of σ_i, and a corner square. For each y-edge β_j of σ_i, we call $\mathbb{W}_e$ with REPORT-HOLE($\beta_j^{\downarrow}$). If $\beta_j^{\downarrow}$ is returned, then β_j is not contained in $\mathcal{U}(\mathcal{W}_e) \cap \sigma_i = \mathcal{U}(\mathcal{F}_u) \cap \sigma_i$ and we call $\mathbb{C}_e$ with REPORT-HOLE(β_j); let $\beta_j' \subseteq \beta_j$ be the returned (possibly empty) interval. The endpoints of β_j^* that lie in int(β_j), if any, are the LS vertices on β_j. See Figure 6 (right). Finally, for $i < t$, if η is the top edge of F, we insert $\eta^{\downarrow}$ into $\mathbb{W}_e$ and $\mathbb{C}_e$, otherwise η is the bottom edge of F and we delete $\eta^{\downarrow}$ from $\mathbb{C}_e$. (In the latter case, $\eta^{\downarrow}$ was already deleted from $\mathbb{W}_e$ in the previous step.) Note that if η is an edge of a floater F, then $\eta^{\downarrow}$ is accordingly inserted or deleted to $\mathbb{W}_e$ and $\mathbb{C}_e$ by the end of these two steps, and hence they are made consistent with ℓ_e.

When the sweep procedure ends, we set $\ell_e := a^-$. Note that now $\mathcal{I}_e$ consists of the x-projections of floaters that intersect the line $y = a^-$, as desired. Therefore the secondary structures $\mathbb{W}_e$ and $\mathbb{C}_e$ are consistent with the new value of ℓ_e.

Initializing the sweep line. At the beginning of the procedure, the value of ℓ_e is the value at which the sweep procedure stopped after inserting or deleting a long square at u that contained the top edge of $\square_u$. To initialize the sweep line at $y = a^+$, the top edge of S_u^{exp}, and to initialize $\mathbb{W}_e$ and $\mathbb{C}_e$ correctly for $y = a^+$, we again perform a line sweep from the current value of ℓ_e to a^+ by a horizontal line L_e as above, except that no reporting of vertices occurs. That is, as we sweep, we stop at each encountered x-edge η of a floater square, and insert or delete the interval $\eta^{\downarrow}$ in $\mathbb{W}_e$ and $\mathbb{C}_e$ without (querying for and) reporting any vertices.

Runtime analysis. Let κ_u be the number of vertices in ΔV_u, and let a_{pr} be the value of ℓ_e before the sweep line is initialized. For the insertion of a square S, let φ_u be the number of y-coordinates of floater edges in the intervals $[a^-, a^+]$ and $[\ell_e, a^+]$ (resp. $[a^+, a_{pr}]$) if $a_{pr} \leq a^+$ (resp. $a_{pr} > a^+$). For the deletion of a square S, let φ_u be the number of y-coordinates of floater edges in the intervals $[a^-, a^+]$ and $[\ell_e, a^-]$ (resp. $[a^-, a_{pr}]$) if $a_{pr} \leq a^-$ (resp. $a_{pr} > a^-$). (Some y-coordinates may be counted twice by φ_u.) Thus, the total time spent for the insertion or deletion of S at each node $u \in \Xi(S)$ is $(1 + \varphi_u) \cdot O(\log^2 n) + O(\kappa_u)$.

We charge $O(\log^2 n)$ units of time to each of the φ_u floater edges that are parallel to the sweep line and that were crossed by the two sweep-line procedures – one in the initialization step and one for reporting the vertices. This charging pays for the $\varphi_u \log^2 n$ term in the running time. The amortized cost of reporting ΔV_u at u is $O(\log^2 n + \kappa_u)$, provided that each floater at u had enough credits to pay for the costs charged to it. The following lemma proves that the floater is not charged too many times.

▶ **Lemma 7.** *Let f be an edge of a floater F at a node $u \in \mathbb{T}$. Then f is charged by the sweeps at $\square_u$ at most six times during the entire algorithm.*

Proof. Without loss of generality assume that f is an x-edge. Then f is charged by the *top* and *bottom* sweeps, i.e., sweeps performed when a square $S \in \mathcal{L}^*_u$ containing the top or the bottom edge of $\square_u$ is inserted or deleted. We claim that f is charged at most three times by the top sweep – a similar argument holds for the bottom sweep. Let e denote the top edge of $\square_u$. Recall that f is charged whenever the horizontal sweep-line L_e crosses f – either in the initialization step or in the reporting step. Furthermore L_e will cross f from opposite directions, i.e., when L_e is sweeping *downward* ($(-y)$-direction) or *upward* ($(+y)$-direction), in any two consecutive crossings. We claim that L_e crosses f in at most three top sweeps.

Recall that during the insertion or deletion of a square S, either $S_u^{\mathsf{exp}} = \varnothing$ and no sweeps occur, otherwise $S_u^{\mathsf{exp}} \neq \varnothing$ and two sweeps occur (one in the initialization step and one in the reporting step). We classify downward (resp. upward) sweeps that occur during an insertion of a square as DI (resp. UI) sweeps, and classify downward (resp. upward) sweeps that occur during a deletion of a square as DD (resp. UD) sweeps. Consider the sequence of sweeps that cross f while $F \in \mathcal{F}_u$, i.e., after the insertion of F and before the deletion of F at node u. We claim the sequence satisfies the following two constraints:

(i) No sweeps can occur after a DI sweep.

(ii) No sweeps can occur before a DD sweep.

Clearly the longest valid sequences of sweeps are of the form "DD, UD, DI" or "DD, UI, DI," and hence f is crossed by L_e in at most three top sweeps. (It can be shown that the latter sequence is not possible, but this fact is not needed in order to prove the lemma.) It remains to prove the constraints above.

Proof of claim (i). Suppose L_e crosses f in a DI sweep, and let $S \in \mathcal{L}^*_{u,e}$ be the square being inserted. We argue that if the bottom edge of g of S lies above f then f could not have been crossed in this sweep, either during the initialization step or during the reporting step, as follows. $S_u^{\mathsf{exp}} \neq \varnothing$, so the bottom edge of $S_u^{\mathsf{exp}} = S \cap \rho_u$ is either contained in g or lies above it. A downward sweep in the initialization step sweeps to the top edge of S_u^{exp}, and a downward sweep in the reporting step sweeps from the top edge of S_u^{exp} to the bottom edge of S_u^{exp}; in either case, the sweeps stop above g and hence above f, so f is not crossed. So we assume that g lies below f; see Figure 7. Note that an upward sweep, either in the initialization step of the insertion of a square or in the reporting step of the deletion of a square, always stops at the top edge of ρ_u. After S has been inserted into $\mathcal{L}^*_{u,e}$ and until

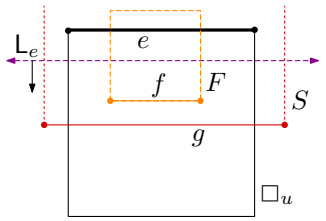

Figure 7 An illustration of the proof of Lemma 7: Sweep-line L_e is swept downward toward edge f of floater F during the insertion or deletion of S at node u.

it is deleted from $\mathcal{L}^*_{u,e}$, the top edge of ρ_u is contained in g or lies below it, which implies that no upward sweep will cross g until after S is deleted. Let $|B|$ denote the length of the longest side of any rectangle B. Since F is a floater at u and S contains an edge of $\square_u$ (as S is long at u), $|F| < |\square_u| < |S|$. Then, since S is inserted after F, S will be deleted after F has been deleted by property (P1), which implies that after L_e crosses f during the insertion of S, f will not be crossed by L_e in any subsequent sweeps. This proves claim (i).

Proof of claim (ii). Suppose L_e crosses f in a DD sweep, where $S \in \mathcal{L}^*_{u,e}$ is the square being deleted. This sweep occurs in the initialization step of the deletion of S as L_e moves from some position above f to the bottom edge of S^{exp}_u, which must be below f. The latter edge lies above the bottom edge g of S. See Figure 7 again. As noted above, in an upward sweep, either in the initialization step of the insertion of a square or in the reporting step of the deletion of a square, always stops at the top edge of ρ_u. While S is present, the top edge of ρ_u is contained in g or lies below it, which implies that no upward sweep can cross g until after S is deleted. Again, we have that $|F| < |\square_u| < |S|$, and hence property (P1) implies S is inserted before F since f is present during the deletion of S. Since g is below f, no upward sweeps preceding the deletion of S can cross f, proving claim (ii). ◀

Lemma 7 implies that each floater edge in $\mathcal{F}_u$ has sufficient credits to pay for the cost charged to it. Hence, we obtain the following:

▶ **Lemma 8.** *The amortized cost of inserting/deleting a square S at a node $u \in \Xi(S)$ is $O(\log^2 n + |\Delta V_u|)$ and at a node $u \in \Sigma(S) \setminus \Xi(S)$ is $O(\log^2 n)$.*

▶ Remark 9. The sweep-line algorithm and secondary data structures can be extended so that not only they compute ΔV_u, but also compute (the xy-projection of) $\partial\mathcal{U}$ within $S \cap \square_u$ in the same time bound. Hence, we can compute $\partial\mathcal{U}$ within each rectangle of $\Pi(S)$. By merging these pieces together over all rectangles of $\Pi(S)$, we can compute (the xy-projection of) $\partial\mathcal{U}$ within S. We thus compute $\partial\mathcal{U}$ on each horizontal face of the cubes in $\mathcal{C}$ in time $O(n \log^3 n + \kappa)$. By performing the plane-sweep in the x-direction and y-direction, we can compute $\partial\mathcal{U}$ on the other faces of cubes in $\mathcal{C}$ as well. These sweeps will be simpler because we already have computed the vertices of $\mathcal{U}$. We omit the details from this version.

2.4 Secondary structures

In this section, we describe the details of the wall and corner data structures at every node $u \in \mathbb{T}$ and edge e of $\square_u$.

Wall data structure. For $\mathbb{W}_e$, we use the data structure described by Wood [18], which is a standard segment tree augmented with additional information stored at each of its nodes. It supports our desired operations, Insert, Delete, Membership, and Report-Holes

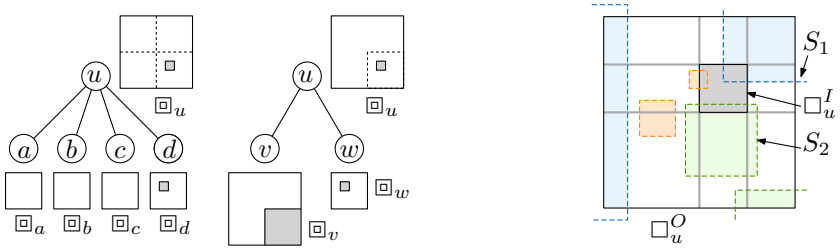

Figure 8 (left) Two examples of internal nodes in $\mathbb{T}$ with identical regions $\boxdot_u$. On the left, the outer square of $\boxdot_u$ is partitioned into four congruent squares, and on the right, $\boxdot_u$ is partitioned by a quadrant of its outer box. (right) Examples of long (blue), floater (orange), and corner (green) squares at rectangles of ∇_u. S_1 (resp. S_2) is a long (resp. corner) square for each rectangle of ∇_u that it intersects (even though S_1 is not a long square for $\square_u^O$).

in the time mentioned earlier. Its size is $O(|\mathsf{X}_u|)$ and is constructed in $O(|\mathsf{X}_u|)$ time at the preprocessing stage of the algorithm. Every point $p \in \mathsf{X}$ is contained in region $\square_u$ of exactly one node u in each level of $\mathbb{T}$. $\mathbb{T}$ has $O(\log n)$ levels, so constructing all wall data structures takes $O(\sum_u |\mathsf{X}_u|) = O(n \log n)$ time.

Corner data structure. For each edge e of $\square_u$, we construct the data structure of Agarwal [1, Lemma 5]. Although it was originally described to support *area* queries (report the area of $\rho \cap \mathcal{U}(\mathcal{R}_u) \setminus \mathcal{U}(\mathcal{W}_e)$ for a given query rectangle ρ), it is straightforward to extend the data structure to support our required operations, Report-Hole and Report-Vertices. In particular, to answer the area queries, it maintains the x-edges (resp. y-edges) of $\mathcal{U}(\mathcal{R}_u \cup \mathcal{W}_e)$ that lie on x-edges (resp. y-edges) of corner squares sorted by their y-coordinates (resp. x-coordinates), which is sufficient to answer our desired operations by searching over these lists of edges. Like $\mathbb{W}_e$, it is constructed in $O(|\mathsf{X}_u|)$ time at the preprocessing stage of the algorithm, so constructing all corner data structures takes $O(\sum_u |\mathsf{X}_u|) = O(n \log n)$ time.

3 Algorithm for the Unbounded-Spread Case

In this section, we extend the algorithm of Section 2 to the case when the spread of X, the xy-projections of the vertices of $\mathcal{C}$, is arbitrary. The algorithm is largely the same. The main challenge is that we cannot use a standard quadtree for our dynamic data structure $\mathbb{T}$, as it may have $\Omega(n)$ depth even if we use a compressed quadtree. Instead, $\mathbb{T}$ is a compressed quadtree with fingers[2] [13]. Its height is $O(\log n)$ regardless of the spread of X, its size is $O(n)$, and it can be constructed in $O(n \log n)$ time.

The properties of $\mathbb{T}$ are as follows. Every node $u \in \mathbb{T}$ is associated with a region $\boxdot_u$ that is a square or the difference of two nested squares $\square_u^O \setminus \square_u^I$, where $\square_u^O \supset \square_u^I$. For nodes u at which $\boxdot_u$ is a square, we say $\square_u^O = \boxdot_u$ and $\square_u^I = \varnothing$ so that $\square_u^O, \square_u^I$ are well-defined for all nodes of $\mathbb{T}$. For the root node r, $\boxdot_r \supset \mathsf{X}$. If $|\mathsf{X} \cap \boxdot_u| \leq 1$, u is a leaf; otherwise u is an internal node and $\boxdot_u$ is partitioned either into four regions with congruent outer squares, or it is partitioned into $\boxdot_u \setminus \square_u^S$ and $\square_u^S$ by a square $\square_u^S$ such that $\square_u^O \supset \square_u^S \supset \square_u^I$. In either

[2] The regions associated with the nodes of a compressed quadtree with fingers as described in [13] may have multiple holes, whereas the *BBD trees* proposed in [5] have at most one hole per node but rectangular regions (which may not be squares). By combining some of the ideas from the construction of BBD trees in [5] to ensure each region has at most one hole, our tree $\mathbb{T}$ can be constructed with all stated properties.

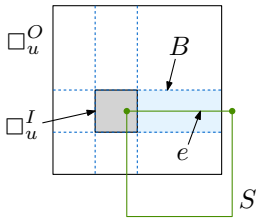

Figure 9 An illustration of the proof of Lemma 10: An edge e of a long square (green) intersecting rectangle $B \in \nabla_u$.

case, the regions in the partition of $\boxdot_u$ are associated with a child of u, and hence u has either two or four children. See Figure 8 (left). Recall that $|\rho|$ denotes the length of the longest side length of any rectangle ρ. Any nodes where $\square_u^I \neq \varnothing$, $\mathbb{T}$ has the property that $\square_u^I$ is *sticky*; that is, the distance between the top (resp. right, bottom, left) edge of $\square_u^O$ and the top (resp. right, bottom, left) edge of $\square_u^I$ is either 0, in which case the former contains the latter, or at least $|\square_u^I|$. For example, if $[o_1, o_2]$ (resp. $[i_1, i_2]$) is the x-projection of $\square_u^O$ (resp. $\square_i^I$), then for $j = 1, 2$ we have that $|o_j - i_j|$ is 0 or at least $|i_1 - i_2|$.

For a node u, we define long and short squares and the sets $\mathcal{S}_u$, $\mathcal{L}_u$, and $\mathcal{L}_u^*$ as earlier. Note that a vertex of a square $S \in \mathcal{L}_u$ may lie in the inner square $\square_u^I$ of $\boxdot_u$ (in fact, at most one vertex of S); see Figure 8 (right). For a square S, let $\Lambda(S)$, $\Sigma(S)$, $\Xi(S)$, and $\Pi(S)$ be the same as before. We report $\Delta V_u \coloneqq \Delta V \cap \square_u$ for each node $u \in \Xi(S)$. However, because $\boxdot_u$ may have a hole, reporting ΔV_u at u is more involved than a single sweep through $\boxdot_u$. We describe what we store at each node u, then how we update $\mathbb{T}$ and ultimately report ΔV_u at each node $u \in \Xi(S)$ due to the insertion or deletion of a square S at u.

The information at node u. We avoid all issues involving the inner square $\square_u^I$ by further partitioning $\boxdot_u$ into rectangles, then using essentially the same algorithm. In particular, the lines supporting the inner square $\square_u^I$ (if it exists) induce a partition of $\square_u$ into a set ∇_u of $m \leq 8$ non-empty rectangles $\{B_u^1, \ldots, B_u^m\}$; if $\square_u^I = \varnothing$, set $\nabla_u \coloneqq \{\boxdot_u\}$. See Figure 8 (right). For a rectangle $B \in \nabla_u$, let $\mathcal{L}_B$ (resp. $\mathcal{S}_B$) be the set of long (resp. short) squares at u that intersect B, and let $\mathcal{L}_B^* \coloneqq \mathcal{L}_B \cap \mathcal{L}_u^*$. Let $\mathcal{F}_B$ be the subset of short squares with at least two vertices in $\text{int}(B)$, and let $\mathcal{R}_B \coloneqq \mathcal{S}_B \setminus \mathcal{F}_B$ be the set of short squares with at most one vertex in $\text{int}(B)$. The following lemma will be crucial for our runtime analysis.

▶ **Lemma 10.** *For any node u of $\mathbb{T}$, rectangle $B \in \nabla$, and square $S \in \mathcal{L}_B$, $|S| > |B|$ and hence S contains an edge of B.*

Proof. Let S be a square in $\mathcal{L}_B$. S intersects $\text{int}(\boxdot_u)$ but no vertex of S lies in $\text{int}(\boxdot_u)$, so its vertices either lie in $\text{int}(\square_u^I)$ or outside $\square_u^O$. There are two cases. First, suppose all vertices of S lie outside $\square_u^O$. Then $|S| > |\square_u^O| > |B|$, as desired.

Next, suppose a vertex v_1 of S lies in $\text{int}(\square_u^I)$. If $S \supset B$, we are done, so suppose otherwise. No vertices of S lie in $\text{int}(B)$, so an edge $e \coloneqq v_1v_2$ of S spans B where v_2 is a vertex of S that lies outside $\square_u^O$. (If all vertices of S lie inside $\text{int}(\square_u^I)$ then S does not intersect B.) See Figure 9. By construction of ∇_u, the edges of B perpendicular to e have length $|\square_u^I|$ (in particular, one is an edge of $\square_u^I$ and the other is a portion of an edge of $\square_u^O$). By the sticky property of $\square_u^I$, the edges of B parallel to e has length at least $|\square_u^I|$, and thus at least as long as the former ones. Since e is longer than the edges of B parallel to it, $|S| > |B|$. ◀

To be consistent with the previous algorithm, we refer to the squares in $\mathcal{F}_B$ as *floater squares* and the squares in $\mathcal{R}_B$ as *corner squares*, even though a square $S \in \mathcal{R}_B$ may not have any vertices in $\text{int}(B)$ and may even contain B. For such a corner square $S \in \mathcal{R}_B$, we associate S with the top-left vertex v_1 of B if $v_1 \in S$, otherwise we associate S with the bottom-right vertex v_2 of B (in which case $v_2 \in S$).

We maintain $\mathcal{L}^*_B$ and $\mathcal{S}_B$ for each $B \in \nabla_u$ in the same fashion as $\mathcal{L}^*_u, \mathcal{S}_u$ were stored at nodes u of the quadtree in the previous algorithm. Note that by Lemma 10, we have the property that any square $S \in \mathcal{L}_B$ contains an edge of B as before. For each edge e of B, we store the long squares that contain e, $\mathcal{L}^*_{B,e}$, in red-black trees as before. We similarly store the x-edges (resp. y-edges) of floater squares in $\mathcal{F}_B$ sorted by their y-coordinates (resp. x-coordinates), which we call $\mathcal{E}^x_B$ (resp. $\mathcal{E}^y_B$).

For each edge e of a rectangle $B \in \nabla_u$, we maintain a value ℓ_e that is the position of the sweep-line L_e associated with edge e, a wall data structure $\mathbb{W}_e(\mathcal{I}_e)$ and corner data structure $\mathbb{C}_e(\mathcal{R}_B, \mathcal{I}_e)$, where $\mathcal{I}_e$ are the x-projections (resp. y-projections) of squares in $\mathcal{F}_B$ intersected by L_e if e is an x-edge (resp. y-edge). Recall their descriptions from Section 2.2.

Reporting ΔV_u. To report ΔV_u when we insert (or delete) a square S, we report $\Delta V_B := B \cap \Delta V_u$ for each rectangle $B \in \nabla_u$ intersected by S (there are no vertices of ΔV_B if $S \cap B = \varnothing$). The insertion and deletion procedures are largely the same as before. In particular, we employ the sweep-line approach from the previous algorithm and essentially treat B as if it was $\square_u$ to report ΔV_B, as follows.

3.1 Reporting ΔV

We describe the procedure to report ΔV and update the data structures for the insertion of a square S; the procedure for the deletion of S is a similar extension of the deletion procedure described in Section 2.2 for bounded spread. There are four main steps:

(1) At each node $u \in \Lambda(S) \cup \Sigma(S)$, we compute $\rho_B := \text{cl}(B \setminus \mathcal{U}(\mathcal{L}_B))$ for all rectangles $B \in \nabla_u$ using a top-down traversal of $\mathbb{T}$ and the sequences of $\mathcal{L}^*_B$, as described below.

(2) At each node $u \in \Xi(S)$, we report ΔV_B for all rectangles $B \in \nabla_u$ by sweeping a line from an edge of rectangle $S^{\text{exp}}_B := S \cap \rho_B$, i.e., the portion of $S \cap B$ that is left "exposed" by the squares of $\mathcal{L}_B$.

(3) For each node $u \in \Lambda(S)$, we insert S to $\mathcal{L}^*_B$ for each rectangle $B \in \nabla_u$ that S intersects. In particular, if S contains the edge e of B, S is inserted into $\mathcal{L}^*_{B,e}$; recall that if $B \subseteq S$, then S is associated with the top edge of B.

(4) For each rectangle $B \in \nabla_u$ at node $u \in \Sigma(S)$, we update $\mathcal{S}_B$ and its secondary structures, as follows. If $S \cap B = \varnothing$, there is nothing to do, so suppose otherwise. If S is a corner square for B, we insert S into all four corner data structures $\mathbb{C}_e$ stored at B for each of its edges. Otherwise, S is a floater square, and we first insert the x-edges (resp. y-edges) of S which intersect B into $\mathcal{E}^x_B$ (resp. $\mathcal{E}^y_B$). Then, for each x-edge (resp. y-edge) e of B such that ℓ_e lies in the y-span (resp. x-span) of S, we insert the x-projection (resp. y-projection) of S to $\mathbb{W}_e$ and $\mathbb{C}_e$.

We now describe the first two steps in more detail. Consider a node $u \in \Lambda(S) \cup \Sigma(S)$, and assume that the rectangle ρ_D has been computed for all $D \in \nabla_{p(u)}$. Let $\rho^*_B := B \setminus \mathcal{U}(\mathcal{L}^*_B)$, which can be computed in $O(1)$ time using the sequences of $\mathcal{L}^*_B$. Then ρ_B can be computed in $O(1)$ time using ρ^*_B and the rectangles ρ_D for each $D \in \nabla_{p(u)}$, using the fact that

$$\begin{aligned}\rho_B &= B \setminus \mathcal{U}(\mathcal{L}_B) = B \setminus \mathcal{U}(\mathcal{L}^*_B \cup \mathcal{L}_{p(u)}) = (B \setminus \mathcal{U}(\mathcal{L}^*_B)) \cap (B \setminus \mathcal{U}(\mathcal{L}_{p(u)})\\ &= \rho^*_B \cap (\boxdot_{p(u)} \setminus \mathcal{U}(\mathcal{L}_{p(u)})) = \rho^*_B \cap \Big(\bigcup_{D \in \nabla_{p(u)}} B_D \setminus \mathcal{U}(\mathcal{L}_D)\Big)\\ &= \rho^*_B \cap \Big(\bigcup_{D \in \nabla_{p(u)}} \rho_D\Big) = \bigcup_{D \in \nabla_{p(u)}} (\rho^*_B \cap \rho_D).\end{aligned}$$

That is, ρ_B is the union of at most eight interior-disjoint rectangles, each of which is of the intersection of rectangles ρ^*_B and ρ_D for a rectangle $D \in \nabla_{p(u)}$, which we assume have been precomputed. Hence, ρ_B can be computed in $O(1)$ time. This completes step (1).

Let B be a rectangle of ∇_u for a node $u \in \Xi(S)$. Note that S^{exp}_B and ρ_B are indeed rectangles, since any square in $\mathcal{L}_u$ contains an edge of B by Lemma 10 and B is a rectangle. The main idea is that even though the sweep-line procedure to report ΔV_u in Section 2.3 was described for a square, the correctness is invariant of whether it is a square or a rectangle as in this scenario. We report ΔV_B in the same way as before: If $u \in \Sigma(S)$, then ΔV_B is the set of $O(1)$ vertices of $S \cap \rho_B$ that lie in $\mathrm{int}(S \cap B)$ and hence can be computed in $O(1)$ time. Otherwise, $u \in \Lambda(S)$. Suppose S contains the top edge e of B. If $S^{\mathsf{exp}}_B = \varnothing$, $\Delta V_B = \varnothing$, and there is nothing to. So assume $S^{\mathsf{exp}}_B \neq \varnothing$. We first initialize the sweep line L_e to be at the top edge of rectangle S^{exp}_B, then we sweep it to its bottom edge and report all vertices of ΔV_B using $\mathbb{W}_e$ and $\mathbb{C}_e$ in the process. The details of the sweep-line procedure are the same as in the bounded spread case; see Section 2.3.

Runtime analysis. Most of the runtime analysis of the previous algorithm easily extends to this algorithm. Let S be a square being inserted or deleted. Since $|\nabla_u| \leq 8$ for each node $u \in \mathbb{T}$, inserting S to the secondary structures at each rectangle $B \in \nabla_u$ of a node u in $\Lambda(S)$ (resp. $\Sigma(S)$) still takes $O(\log n)$ (resp. $O(\log^2 n)$) time. To extend the amortized time to report ΔV_B for a rectangle $B \in \nabla_u$ of a node $u \in \Xi(S)$, we again charge $O(\log^2 n)$ time to the edges of floaters encountered during the sweep-line procedure at B. Then, as in Lemma 7, it can be shown that each such edge is charged at most six times by the sweeps at B during the entire algorithm. However, there is a subtle issue when extending the proof of the lemma to this setting: the proof used the inequalities $|S| > |B| > |F|$ for any floater $F \in \mathcal{F}_B$ in order to conclude $|S| > |F|$ and apply property (P1), but our justification for those inequalities relied on B being a square in that setting. We instead use Lemma 10 to conclude $|S| > |F|$, which crucially relies on the sticky property of $\mathbb{T}$.

The remainder of the analysis follows as before: it follows that the amortized runtime to perform the at most eight sweeps (at most one per rectangle of ∇_u) at node $u \in \Xi(S)$ is $O(\log^2 n + |\Delta V_u|)$, and hence inserting or deleting S to $\mathbb{T}$ and reporting ΔV takes $O(\log^3 n + |\Delta V|)$ time. Thus, the entire algorithm takes $O(n \log^3 n + \kappa)$ time, where κ is the number of vertices of $\mathcal{U}$, proving Theorem 1.

4 Algorithms for Special Cases

In this section, we simplify the algorithm for two special cases in which $\mathcal{C} := \{C_1, \ldots, C_n\}$ is a set of n axis-aligned cubes in $\mathbb{R}^3$ in general position that:

1. have bounded *depth*, i.e., the maximum number of cubes in $\mathcal{C}$ that contain any point $p \in \mathbb{R}^3$ is bounded by a constant $c > 0$, or
2. are all congruent.

4.1 Cubes with Bounded Depth

We assume that the depth of the cubes in $\mathcal{C}$ is bounded by a constant. For simplicity, we also assume that the cubes in $\mathcal{C}$ have bounded spread; it is straightforward but slightly more tedious to extend the following techniques to the unbounded spread case. In this case, we employ the same algorithm as described in Section 2, except that we no longer need the corner data structures and can perform their operations in $O(1)$ time, as explained below. As a result, the amortized runtime to report ΔV due to the insertion or deletion of a square in $\mathcal{S}$ improves to $O(\log^2 n + |\Delta V|)$, as follows.

Fix a rectangle $B \in \nabla_u$ for a node $u \in \mathbb{T}$, and let $v \coloneqq (x_i, y_i)$ be one of the four vertices of B. For any $a \in \mathbb{R}$, $O(1)$ cubes of $\mathcal{C}$ contain (x_i, y_i, a), and hence $O(1)$ squares in $\mathcal{S}$ contain v at any point during the plane-sweep. In particular, $O(1)$ squares contain any of the four vertices of B. Any square in $\mathcal{R}_B$ contains a vertex of B, and hence $|\mathcal{R}_B| = O(1)$. Then $\mathcal{U}(\mathcal{R}_B)$, and thus $\mathcal{U}(\mathcal{R}_B) \cap \square_u$, has constant complexity, so the latter can be maintained explicitly in $O(1)$ time per insertion or deletion to $\mathcal{R}_u$ (at worst, it takes $O(1)$ time to recompute it from scratch any time that it is needed). Furthermore, given any query segment $\sigma \supset B$, $\sigma \setminus \operatorname{int}(\mathcal{U}(\mathcal{R}_u))$ can be computed in $O(1)$ time, which replaces the need for the Report-Hole(σ) operation of the corner data structures.

Lastly, we need to implement the Report-Vertices(ρ) operation of the corner data structures for each edge e of B using $\mathcal{U}(\mathcal{R}_u) \cap \square_u$ and $\mathbb{W}_e$, where $\rho \subset \square_u$ is a query rectangle. Suppose e is an x-edge of B. We first compute $\mathcal{U}_\rho \coloneqq \mathcal{U}(\mathcal{R}_u) \cap \rho$ in $O(1)$ time, and then, for each edge σ of $\mathcal{U}_\rho$, we compute the endpoints of the intervals of $\sigma^\downarrow \setminus \operatorname{int}(\mathcal{U}(\mathcal{I}_e))$ in $O(\log n + \kappa_\sigma)$ time, where $\sigma^\downarrow$ is the x-projection of σ and κ_σ is the number of endpoints reported. These 1D vertices correspond to the 2D vertices of $\mathcal{U}(\mathcal{S})$ on σ, and any vertex is reported at most twice. Thus, the overall runtime for this operation is $O(\log n + \kappa)$, where κ is the total number of vertices reported.

Plugging these improved bounds for the corresponding operations of the corner data structures in the analysis of the sweep-line procedure, we have that the amortized time to report ΔV for the insertion or deletion of a square S to $\mathcal{S}$ is $O(\log^2 n + |\Delta V|)$. Given that κ, the total number of vertices of $\mathcal{U}$, is $O(n)$ in this case, the overall runtime is $O(n \log^2 n)$, as claimed in Theorem 3.

4.2 Congruent Cubes

Without loss of generality, assume that all cubes in $\mathcal{C}$ are unit cubes. In this case, $\mathcal{S}$ is now a set of unit squares in $\mathbb{R}^2$. Whenever the sweeping plane reaches the top or bottom face of a cube in $\mathcal{C}$, we neither need a tree data structure nor do we need a 2D sweep-line procedure to report ΔV. Instead we only need a 2D grid and a simpler version of the corner data structure, as described below.

The data structure. Let $\mathcal{G}$ be the 2-dimensional integer grid. Without loss of generality, no point of X lies in on the grid lines of $\mathbb{R}^2$. For $i, j \in \mathbb{Z}$, let $\square_{i,j}$ denote the grid cell $[i, i+1] \times [j, j+1]$. For all $i, j \in \mathbb{Z}$, let $\mathsf{X}_{i,j} \coloneqq \mathsf{X} \cap \square_{i,j}$, and let $\mathcal{G}^*$ be the non-empty grid cells of $\mathcal{G}$, i.e., $\mathcal{G}^* = \{\square_{i,j} \in \mathcal{G} \mid |\mathsf{X}_{i,j}| > 0\}$.

For any square $S \in \mathcal{S}$, any grid cell $\square \in \mathcal{G}^*$ intersected by S contains exactly one vertex of S; that is, S is a *corner square* for $\square$. For any grid cell $\square \in \mathcal{G}^*$, let $\mathcal{S}_\square$ be the set of squares in $\mathcal{S}$ that intersect $\square$. Since there are no long or floater squares at any grid cell $\square \in \mathcal{G}^*$, there are no (projections of) floaters to maintain, nor any vertices of ΔV defined by such squares to report, which accounts for much of the intricacies of the previous algorithms.

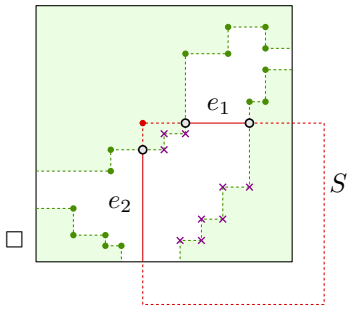

Figure 10 An illustration of a square S (red) being inserted at a grid cell $\square \in \Sigma(S)$ (black). The solid portions of edges e_1,e_2 of S are the portions of the edges returned by the calls to Report-Hole. The vertices of $V^{\text{new}} \cap \square$ are marked as hollow and lie on e_1 and e_2, and the vertices of $V^{\text{old}} \cap \square$ are marked as crosses and lie in $\text{int}(S) \cap \square$.

For each $\square \in \mathcal{G}^*$, we build one *corner data structure* $\mathbb{C}_\square$, that maintains $\mathcal{S}_\square$ and supports the following operations:

- Insert/Delete(S): Insert or delete a corner square S to $\mathcal{R}_\square$.
- Report-Hole(σ): Given a query axis-aligned segment $\sigma \subset \square$, return the (at most one) interval of $\sigma \setminus \text{int}(\mathcal{U}(\mathcal{S}_\square))$.
- Report-Vertices(ρ): Let $\rho \subseteq \square$ be a corner rectangle, i.e., one of its vertices is a vertex of $\square$. Return $V(\mathcal{S}_\square) \cap \rho$.

As in Section 2.1, we implement $\mathbb{C}_\square$ using the data structure of Agarwal [1, Lemma 5], which supports the operations above without modification. An Insert/Delete takes $O(\log^2 n)$ time, Report-Hole takes $O(\log n)$ time, and Report-Vertices takes $O(\log n + \kappa)$ time, where κ is the number of vertices reported. Note that, in contrast with the corner data structures used in the previous two algorithms, we build only one for each cell $\square$ instead of one per edge of $\square$, and this data structure does not maintain a set of intervals in addition to the set of corner squares $\mathcal{S}_\square$. Using the fact that there are no intervals and the query rectangle is a corner rectangle, the corner data structure in [1] can be simplified, but we skip the details here.

Reporting ΔV. We describe the procedure to report ΔV and update the data structures for the insertion of a square S; the procedure for the deletion of S is a similar extension of the deletion procedure described in Section 2.2 for bounded spread. Let $\Sigma(S)$ be the four grid cells that S intersects. The grid cells in $\Sigma(S)$ partition S. We report $\Delta V_\square := \Delta V \cap \square$ for each grid cell $\square \in \Sigma(S)$.

Let $V^{\text{new}} \subseteq \Delta V$ be the set of vertices that are created by the insertion of S (which appear on ∂S), and let V^{old} be the set of vertices that no longer appear on $\mathcal{U}$ after the insertion of S (which lie in $\text{int}(S)$).

Fix a grid cell $\square \in \Sigma(S)$. Let e_1, e_2 be the edges incident to the vertex of S in $\text{int}(\square)$. The vertices of $V^{\text{new}} \cap \square$ that lie on e_1 (resp. e_2) are the endpoints of $e_1 \setminus \text{int}(\mathcal{U}(\mathcal{S}_\square))$ (resp. $e_2 \setminus \text{int}(\mathcal{U}(\mathcal{S}_\square))$ that lie in $\text{int}(\square)$. See Figure 10. There are at most two such vertices lying on each edge e_i, and they are computed by calling $\mathbb{C}_\square$ with Report-Hole($e_i \cap \square$)). Then we report $V^{\text{old}} \cap \square$, i.e., the vertices of $\mathcal{U}(\mathcal{S}_\square) \cap \square$, by calling $\mathbb{C}_\square$ with Report-Vertices($S \cap \square$). The vertices reported account for all vertices of ΔV. Finally, we insert S to $\mathcal{S}_\square$ by calling $\mathbb{C}_\square$ with Insert(S). Repeating this step for all four cells in $\Sigma(S)$, we report ΔV.

The eight Report-Hole calls take $O(\log n)$ time overall, the four Report-Vertices calls take $O(\log n + |\Delta V|)$ time, and the four Insert calls take $O(\log^2 n)$ time. Hence, the total time spent for the insertion of S is $O(\log^2 n + |\Delta V|)$. Similarly, the deletion of a square takes $O(\log^2 n + |\Delta V|)$ time.

Runtime analysis. $\mathcal{G}^*$ and $\Sigma(S)$ for all squares S can be computed in $O(n \log n)$ time. At the beginning of the algorithm, no cubes intersect the sweeping plane and hence $\mathcal{S}_\square = \varnothing$, so building $\mathbb{C}_\square$ for $\square \in \mathcal{G}^*$ takes $O(n)$ time overall. Given that κ, the total number of vertices of $\mathcal{U}$, is $O(n)$ in this case, the overall runtime is $O(n \log^2 n)$, as claimed in Theorem 3.

Unit cubes with bounded depth. Suppose the cubes of $\mathcal{C}$ are unit cubes with bounded depth. Let $\mathcal{G}$ be the 3D integer grid, which partitions $\mathbb{R}^3$ into unit cubes, and let $\mathcal{G}^* \subset \mathcal{G}$ be the grid cells intersected by at least one cube in $\mathcal{C}$; $|\mathcal{G}^*| \leq 8n$. Let $\mathcal{C}_G \subseteq \mathcal{C} := \{C \cap G \neq \varnothing \mid C \in \mathcal{C}\}$ for each grid cell $G \in \mathcal{G}^*$; $\sum_{G \in \mathcal{G}^*} |\mathcal{C}_G| \leq 8n$. For any grid cell $G \in \mathcal{G}^*$, any cube in $\mathcal{C}_G$ contains a vertex of G, which implies that $|\mathcal{C}_G|$ is bounded by a constant since the cubes of $\mathcal{C}$ have bounded depth. Therefore $\mathcal{U}(\mathcal{C}_G) \cap G = \mathcal{U} \cap G$ can be computed in $O(1)$ time. Then $\mathcal{U}$ can be computed by merging the portions within each grid cell of $\mathcal{G}^*$ in $O(n + \kappa) = O(n)$ time, where κ is the number of vertices on $\mathcal{U}$, which is bounded by $O(n)$ in this case. Computing $\mathcal{C}_G$ for all grid cells $G \in \mathcal{G}^*$ takes $O(n \log n)$ time, so the running time of the entire algorithm is $O(n \log n)$. Note that if the maximum distance between any two centers of cubes in $\mathcal{C}$ is polynomially bounded (i.e., is at most n^c for a constant $c > 0$) and $\lfloor x \rfloor$ can be computed in constant time for any $x \in \mathbb{R}$, computing the $\mathcal{C}_G$'s can be done in $O(n)$ time, which improves the overall running time to $O(n)$.

5 Conclusion

We have described algorithms to compute (the boundary of) the union of axis-aligned 3D cubes (or fat boxes) in general position in an output-sensitive manner. In particular, if the cubes have different sizes the union can be computed in $O(n \log^3 n + \kappa)$ time, where κ is the number of union vertices. If all cubes have the same size or they have bounded depth, then the union can be computed in $O(n \log^2 n)$ time, and if both conditions hold then the running time improves to $O(n \log n)$. We conclude by mentioning two open problems:

- **(i)** Can the running time be improved to $O(n \log n + \kappa)$?
- **(ii)** Can the union of a set of n cubes in $\mathbb{R}^d$ be computed in $O(n^{\lfloor d/2 \rfloor} + \kappa)$ time? In particular, can the union of n hypercubes in $\mathbb{R}^4$ be computed in $O(n \operatorname{polylog}(n) + \kappa)$ time? Kaplan *et al.* [15] have shown that for a special case of orthants in $\mathbb{R}^d$, the union of n such orthants can be computed in $O(n + \kappa) \log^{d-1} n)$ time, but their algorithm does not extend to hypercubes.

Abstract

This paper considers enumerating answers to *similarity-join* queries under dynamic updates: Given two sets of n points A, B in $\mathbb{R}^d$, a metric $\phi(\cdot)$, and a distance threshold $r > 0$, report all pairs of points $(a, b) \in A \times B$ with $\phi(a, b) \leq r$. Our goal is to store A, B into a dynamic data structure that, whenever asked, can enumerate all result pairs with worst-case *delay* guarantee, i.e., the time between enumerating two consecutive pairs is bounded. Furthermore, the data structure can be efficiently updated when a point is inserted into or deleted from A or B.

We propose several efficient data structures for answering similarity-join queries in low dimension. For exact enumeration of similarity join, we present near-linear-size data structures for ℓ_1, ℓ_∞ metrics with $\log^{O(1)} n$ update time and delay. We show that such a data structure is not feasible for the ℓ_2 metric for $d \geq 4$. For *approximate* enumeration of similarity join, where the distance threshold is a soft constraint, we obtain a unified linear-size data structure for ℓ_p metric, with $\log^{O(1)} n$ delay and update time. In high dimensions, we present an efficient data structure with worst-case delay-guarantee using *locality sensitive hashing* (LSH).

1 Introduction

There has been extensive work in many areas including theoretical computer science, computational geometry, and database systems on designing efficient dynamic data structures to store a set $\mathscr{O}$ of objects so that certain queries on $\mathscr{O}$ can be answered quickly and objects can be inserted into or deleted from $\mathscr{O}$ dynamically. A query $\mathscr{Q}$ is specified by a set of constraints and the goal is to report the subset $\mathscr{Q}(\mathscr{O}) \subseteq \mathscr{O}$ of objects that satisfy the constraints, the so-called *reporting* or *enumeration* queries. More generally, $\mathscr{Q}$ may be specified on k-tuples of objects in $\mathscr{O}$, and we return the subset of $\mathscr{O}^k$ that satisfy $\mathscr{Q}$. One may also ask to return certain statistics on $\mathscr{Q}(\mathscr{O})$ instead of $\mathscr{Q}(\mathscr{O})$ itself, but here we focus on enumeration queries. As an example, $\mathscr{O}$ is set of points in $\mathbb{R}^d$ and a query $\mathscr{Q}$ specifies a simple geometric region Δ (e.g., box, ball, simplex) and asks to return $\mathscr{O} \cap \Delta$, the so-called *range-reporting* problem. As another example, $\mathscr{O}$ is again a set of points in $\mathbb{R}^d$, and $\mathscr{Q}$ now specifies a value $r \geq 0$ and asks to return all pairs $(p, q) \in \mathscr{O} \times \mathscr{O}$ with $\|p - q\| \leq r$. Traditionally, the performance of a

data structure has been measured by its size, the time needed to update the data structure when an object is inserted or deleted, and the *total time* spent in reporting $\mathscr{Q}(\mathscr{O})$. In some applications, especially in exploratory or interactive data analysis of large datasets, it is desirable to report $\mathscr{Q}(\mathscr{O})$ incrementally one result at a time so that users can start exploiting the first answers while waiting for the remaining ones. To offer guarantees on the regularity during the enumeration process, we consider an important complexity measure of such data structures as the maximum *delay* between the enumeration of two consecutive objects [11]. Formally speaking, δ-*delay enumeration* requires that the time between the start of the enumeration process to the first result, the time between any consecutive pair of results, and the time between the last result and the termination of the enumeration process should all be at most δ.

In this paper, we are interested in dynamic data structures for *(binary) similarity join* queries, which have numerous applications in data cleaning, data integration, collaborative filtering, etc. Given two sets of points A and B in $\mathbb{R}^d$, a metric $\phi(\cdot)$, and a distance threshold $r > 0$, the similarity join asks to report all pairs of $(a, b) \in A \times B$ with $\phi(a, b) \leq r$. Similarity joins have been studied extensively in the database and data mining literature [19, 33, 40, 43, 45], but it is still unclear how to enumerate similarity join results efficiently when the underlying data is updated. Our goal is to design a dynamic data structure that can be efficiently updated when an input point is inserted or deleted; and whenever an enumeration query is issued, all join results can be enumerated from it with *worst-case delay* guarantee.

1.1 Previous results

We briefly review the previous work on similarity join and related problems. See surveys [8, 10, 44] for more results.

Enumeration for Conjunctive Queries. Conjunctive queries are built upon natural join ($\bowtie$), which is a special case of similarity join with $r = 0$, i.e., two tuples can be joined if and only if they have the same value on the join attributes. Enumeration for conjunctive queries has been extensively studied in the static settings [11, 42, 16] for a long time. In 2017, two papers [14, 31] started to study dynamic enumeration for conjunctive query. Both obtained a dichotomy. First, a linear-size data structure that can be updated in $O(1)$ time while supporting $O(1)$-delay enumeration exists for a conjunctive query if and only if it is *q-hierarchical* (e.g., the degenerated natural join over two tables is q-hierarchical). However, for non-q-hierarchical queries with input size n, they showed a lower bound $\Omega(n^{\frac{1}{2}-\varepsilon})$ on the update time for any small constant $\varepsilon > 0$, if aiming at $O(1)$ delay. This result is very negative since q-hierarchical queries are a very restricted class; for example, the matrix multiplication query $\pi_{X,Z} R_1(X, Y) \bowtie R_2(Y, Z)$, where $\pi_{X,Y}$ denotes the projection on attributes X, Y, and the triangle join $R_1(X, Y) \bowtie R_2(Y, Z) \bowtie R_3(Z, X)$ are already non-q-hierarchical. Later, Kara et al. [34] designed optimal data structures supporting $O(\sqrt{n})$-time maintenance for some selected non-q-hierarchical queries such as the triangle queries. However, it is still unclear if a data structure of $O(\sqrt{n})$-time maintenance exists for a large class of queries. Some additional trade-off results have been obtained in [35, 46].

Range search. A widely studied problem related to similarity join is *range searching* [2, 3, 13, 47]: Preprocess a set A of points in $\mathbb{R}^d$ with a data structure so that for a query range γ (e.g., rectangle, ball, simplex), all points of $A \cap \gamma$ can be reported quickly. A particular instance of range searching, the so-called *fixed-radius-neighbor* searching, in which the range is a ball of fixed radius centered at query point is particularly relevant for similarity joins.

Table 1 Summary of Results: n is the input size; r is the distance threshold; d is the dimension of input points; $\rho \leq \frac{1}{(1+\varepsilon)^2} + o(1)$ is the quality of LSH family for the ℓ_2 metric. For ℓ_1, Hamming $\rho \leq \frac{1}{1+\varepsilon}$. $\widetilde{O}$ notation hides a $\log^{O(1)} n$-factor; for the results where d is constant the $O(1)$ exponent is at most linear on d, while for the high dimensional case the exponent is at most 3.

Enumeration	Metric	Properties	Data Structures		
			Space	Update	Delay
Exact	ℓ_1/ℓ_∞	r is fixed	$\widetilde{O}(n)$	$\widetilde{O}(1)$	$\widetilde{O}(1)$
	ℓ_2	r is fixed	$\widetilde{O}(n)$	$\widetilde{O}(n^{1-\frac{1}{d+1}})$	$\widetilde{O}(n^{1-\frac{1}{d+1}})$
ϵ-Approximate	ℓ_p	r is fixed	$O(n)$	$\widetilde{O}(\epsilon^{-d})$	$\widetilde{O}(\epsilon^{-d})$
		r is variable spread is poly(n)	$O(\varepsilon^{-d}n)$	$\widetilde{O}(\varepsilon^{-d})$	$O(1)$
	ℓ_1, ℓ_2, hamming	r is fixed high dimension	$\widetilde{O}(dn + n^{1+\rho})$	$\widetilde{O}(dn^{2\rho})$	$\widetilde{O}(dn^{2\rho})$

For a given metric ϕ, let $\mathscr{B}_\phi(x, r)$ be the ball of radius r centered at x. A similarity join between two sets A, B can be answered by querying A with ranges $\mathscr{B}_\phi(b, r)$ for all $b \in B$. Notwithstanding this close relationship between range searching and similarity join, the data structures for the former cannot be used for the latter: It is too expensive to query A with $\mathscr{B}_\phi(b, r)$ for every $b \in B$ whenever an enumeration query is issued, especially since many such range queries may return empty set, and it is not clear how to maintain the query results as the input set A changes dynamically.

Reporting neighbors. The problem of reporting neighbors is identical to our problem in the offline setting. In particular, given a set P of n points in $\mathbb{R}^d$ and a parameter r, the goal is to report all pairs of P within distance r. The algorithm proposed in [36] can be modified to solve the problem of reporting neighbors under the ℓ_∞ metric in $O(n + k)$ time, where k is the output size. Aiger et al. [7] proposed randomized algorithms for reporting neighbors using the ℓ_2 metric in $O((n + k) \log n)$ time, for constant d.

Scalable continuous query processing. There has been some work on scalable *continuous query* processing, especially in the context of data streams [21, 18, 49] and publish/subscribe [25], where the queries are standing queries and whenever a new data item arrives, the goal is to report all queries that are affected by the new item [6, 5]. In the context of similarity join, one can view A as the data stream and $\mathscr{B}_\phi(b, r)$ as standing queries, and we update the results of queries as new points in A arrive. There are, however, significant differences with similarity joins – arbitrary deletions are not handled; continuous queries do not need to return previously produced results; basing enumeration queries on a solution for continuous queries would require accessing previous results, which can be prohibitive if stored explicitly.

1.2 Our results

We present several dynamic data structures for enumerating similarity joins under different metrics. Table 1 summarizes our main results. It turns out that dynamic similarity join is hard for some metrics, e.g., ℓ_2. Therefore we also consider *approximate similarity join* where the distance threshold r is a soft constraint. Formally, given parameter $r, \varepsilon > 0$, the *ε-approximate similarity join* relaxes the distance threshold: (1) all pairs of $(a, b) \in A \times B$ with $\phi(a, b) \leq r$ should be returned; (2) no pair of $(a, b) \in A \times B$ with $\phi(a, b) > (1 + \varepsilon)r$ is returned; (3) some pairs of $(a, b) \in A \times B$ with $r < \phi(a, b) \leq (1 + \varepsilon)r$ may be returned. We classify our results in four broad categories:

Exact similarity join. Here we assume that d is constant and the distance threshold is fixed. Our first result (Section 2.1) is an $\widetilde{O}(1)$-size data structure for similarity join under the ℓ_1/ℓ_∞ metrics that can be updated in $\widetilde{O}(1)$ time whenever A or B is updated, and ensures $\widetilde{O}(1)$ delay during enumeration. Based on range trees [12, 23], the data structure stores the similarity join pairs *implicitly* so that they can be enumerated without probing every input point. We extend these ideas to construct a data structure for similarity join under the ℓ_2 metric (in Section 2.3) with $\widetilde{O}(n^{1-1/d})$ amortized update time while supporting $\widetilde{O}(n^{1-1/d})$-delay enumeration. Lower bounds on ball range searching [1, 20] rule out the possibility of a linear-size data structure with $\widetilde{O}(1)$ delay.

Approximate similarity join in low dimensions. Due to the negative result for ℓ_2 metric, we shift our attention to ε-approximate similarity join. We now allow the distance threshold to be part of the query, but the value of ε, the error parameter, is fixed. We present a simple linear-size data structure based on quad trees and the notion of well-separated pair decomposition, with $O(\epsilon^{-d})$ update time and $O(1)$ delay. If we fix the distance threshold, then the data structure can be further simplified and somewhat improved by replacing the quad tree with a simple uniform grid.

Approximate similarity join in high dimensions. So far we assumed d to be constant and the big O notation in some of the previous bounds hides a constant that is exponential in d. Our final result is an LSH-based [27] data structure for similarity joins in high dimensions. Two technical issues arise when enumerating join results from LSH: one is to ensure bounded delay because we do not want to enumerate false positive results identified by the hash functions, and the other is to remove duplicated results as one join result could be identified by multiple hash functions. For the ℓ_2 metric (the results can also be extended to ℓ_1 and Hamming metrics) we propose a data structure of $\widetilde{O}(nd + n^{1+\rho})$ size and $\widetilde{O}(dn^{2\rho})$ amortized update time that supports $(1 + 2\varepsilon)$-approximate enumeration with $\widetilde{O}(dn^{2\rho})$ delay with high probability, where $\rho \leq \frac{1}{(1+\varepsilon)^2} + o(1)$ is the quality of the LSH family. Alternatively, we present a data structure with $\widetilde{O}(dn^{\rho})$ amortized update time and $\widetilde{O}(dn^{3\rho})$ delay. Our data structure can be extended to the case when the distance threshold r is variable. If we allow worse approximation error we can improve the results for the Hamming distance. Finally, we show a lower bound by relating similarity join to the *approximate nearest neighbor* query.

We also consider similarity join beyond binary joins.

Triangle similarity join in low dimensions. Given three sets of points A, B, S in $\mathbb{R}^d$, a metric $\phi(\cdot)$, and a distance threshold $r > 0$, the *triangle similarity join* asks to report the set of all triples of $(a, b, s) \in A \times B \times S$ with $\phi(a, b) \leq r, \phi(a, s) \leq r, \phi(b, s) \leq r$. The *$\varepsilon$-approximate triangle similarity join* can be defined similarly by taking the distance threshold r as a soft constraint. In the full version [4], we extend our data structures to approximate *triangle similarity join* by paying an extra factor of $\log^{O(1)} n$ in the performance.

High-level framework. All our data structures rely on the following common framework. We model the (binary) similarity join as a bipartite graph $G' = (A \cup B, E)$, where an edge $(a, b) \in E$ if and only if $\phi(a, b) \leq r$. A naive solution by maintaining all edges of G' explicitly leads to a data structure of $\Theta(n^2)$ size that can be updated in $\Theta(n)$ time while supporting $O(1)$-delay enumeration. To obtain a data structure with poly-logarithmic update time and delay enumeration, we find a compact representation of G' with a set $\mathscr{F} = \{(A_1, B_1), (A_2, B_2), \ldots, (A_u, B_u)\}$ of edge-disjoint bi-cliques such that (i) $A_i \subseteq A$,

$B_i \subseteq B$ for any i, (ii) $E = \bigcup_{i=1}^{u} A_i \times B_i$, and (iii) $(A_i \times B_i) \cap (A_j \times B_j) = \emptyset$ for any $i \neq j$. We represent $\mathscr{F}$ using a tripartite graph $\mathscr{G} = (A \cup B \cup C, E_1 \cup E_2)$ where $C = \{c_1, \ldots, c_u\}$ has a node for each bi-clique in $\mathscr{F}$ and for every $i \leq u$, we have the edges $(a_j, c_i) \in E_1$ for all $a_j \in A_i$ and $(b_k, c_i) \in E_1$ for all $b_k \in B_i$. We *cannot* afford to maintain E_1 and E_2 explicitly. Instead, we store some auxiliary information for each c_i and use geometric data structures to recover the edges incident to a vertex $c_i \in C$. We also use data structures to maintain the set C and the auxiliary information dynamically as A and B are being updated. We will not refer to this framework explicitly but it provides the intuition behind all our data structures. Section 2 describes the data structures to support this framework for exact similarity join, and Section 3 presents simpler, faster data structures for approximate similarity join. Both Sections 2 and 3 assume d to be constant. Section 4 describes the data structure for approximate similarity join when d is not constant.

2 Exact Similarity Join

In this section, we describe the data structure for exact similarity joins under the $\ell_\infty, \ell_1, \ell_2$ metrics, assuming d is constant. We first describe the data structure for the ℓ_∞ metric. We show that similarity join under the ℓ_1 metric in $\mathbb{R}^d$ can be reduced to that under the ℓ_∞ metric in $\mathbb{R}^{d+1}$. Finally, we describe the data structure for the ℓ_2 metric. Throughout this section, the threshold r is fixed, which is assumed to be 1 without loss of generality.

2.1 Similarity join under ℓ_∞ metric

Let A and B be two point sets in $\mathbb{R}^d$ with $|A| + |B| = n$. For a point $p \in \mathbb{R}^d$, let $\mathscr{B}(p) = \{x \in \mathbb{R}^d \mid \|p - x\|_\infty \leq 1\}$ be the hypercube of side length 2. We wish to enumerate pairs $(a, b) \in A \times B$ such that $a \in \mathscr{B}(b)$.

Data structure. We build a d-dimensional dynamic range tree $\mathscr{T}$ on the points in A. For $d = 1$, the range tree on A is a balanced binary search tree $\mathscr{T}$ of $O(\log n)$ height. The points of A are stored at the leaves of $\mathscr{T}$ in increasing order, while each internal node v stores the smallest and the largest values, α_v^- and α_v^+, respectively, contained in its subtree. The node v is associated with an interval $I_v = [\alpha_v^-, \alpha_v^+]$ and the subset $A_v = I_v \cap A$. For $d > 1$, $\mathscr{T}$ is constructed recursively: We build a 1D range tree $\mathscr{T}_d$ on the x_d-coordinates of points in A. Next, for each node $v \in \mathscr{T}_d$, we recursively construct a $(d-1)$-dimensional range tree $\mathscr{T}_v$ on A_v^*, which is defined as the projection of A_v onto the hyperplane $x_d = 0$, and attach $\mathscr{T}_v$ to v as its secondary tree. The size of $\mathscr{T}$ in $\mathbb{R}^d$ is $O(n \log^{d-1} n)$ and it can be constructed in $O(n \log^d n)$ time. See [23] for details.

For a node v at a level-i tree, let $p(v)$ denote its parents in that tree. If v is the root of that tree, $p(v)$ is undefined. For each node u of the d-th level of $\mathscr{T}$, we associate a d-tuple $\pi(u) = \langle u_1, u_2, \ldots, u_d = u \rangle$, where u_i is the node at the i-th level tree of $\mathscr{T}$ to which the level-$(i+1)$ tree containing u_{i+1} is connected. We associate the rectangle $\square_u = \prod_{j=1}^{d} I_{u_j}$ with the node u. For a rectangle $\rho = \prod_{i=1}^{d} \delta_i$, a d-level node u is called a *canonical node* if for every $i \in [1, d]$, $I_{u_i} \subseteq \delta_i$ and $I_{p(u_i)} \not\subseteq \delta_i$. For any rectangle ρ, there are $O(\log^d n)$ canonical nodes in $\mathscr{T}$, denoted by $\mathscr{N}(\rho)$, and they can be computed in $O(\log^d n)$ time [23]. $\mathscr{T}$ can be maintained dynamically, as points are inserted into A or deleted from A using the standard partial-reconstruction method, which periodically reconstructs various bottom subtrees. The amortized time is $O(\log^d n)$; see [39] for details.

We query $\mathscr{T}$ with $\mathscr{B}(b)$ for all $b \in B$ and compute $\mathscr{N}(b) := \mathscr{N}(\mathscr{B}(b))$ the sets of its canonical nodes. For each level-d tree node u of $\mathscr{T}$, let $B_u = \{b \in B \mid u \in \mathscr{N}(b)\}$. We have $\sum_u |B_u| = O(n \log^d n)$. By construction, for all pairs $(a, b) \in A_u \times B_u$, $\|a - b\|_\infty \leq 1$, so

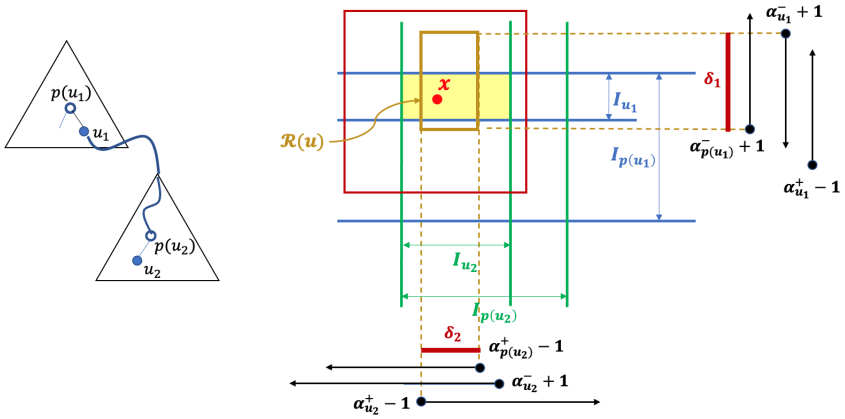

Figure 1 Left: Two levels of the range tree. Right: Definition of $\mathscr{R}(u)$.

(A_u, B_u) is a bi-clique of join results. We call u *active* if both $A_u, B_u \neq \emptyset$. A naive approach for reporting join results is to maintain A_u, B_u for every d-level node u of $\mathscr{T}$ as well as the set $\mathscr{C}$ of all active nodes. Whenever an enumerate query is issued, we traverse $\mathscr{C}$ and return $A_u \times B_u$ for all $u \in \mathscr{C}$ (referring to the tripartite-graph framework mentioned in Introduction, C is the set of all level-d nodes of $\mathscr{T}$). The difficulty with this approach is that when A changes and $\mathscr{T}$ is updated, some d-level nodes change and we have to construct B_u for each new level-d node $u \in \mathscr{T}$. It is too expensive to scan the entire B at each update. Furthermore, although the average size of B_u is small, it can be very large for a particular u and this node may appear and disappear several times. So we need a different approach. The following lemma is the key observation.

▶ **Lemma 1.** *Let u be a level-d node, and let $\pi(u) = \langle u_1, \ldots, u_d = u\rangle$. Then there is a d-dimensional rectangle $\mathscr{R}(u) = \prod_{i=1}^{d} \delta_i$, where the endpoints of δ_i, for $i \in [1, d]$, are defined by the endpoints of I_{u_i} and $I_{p(u_i)}$, such that for any $x \in \mathbb{R}^d$, $u \in \mathscr{N}(x)$ if and only if $x \in \mathscr{R}(u)$. Given u_i's and $p(u_i)$'s, $\mathscr{R}(u)$ can be constructed in $O(1)$ time.*

Proof. Notice that $\mathscr{B}(x)$ is the hypercube of side length 2 and center x. Let $I_{u_i} = [\alpha^-_{u_i}, \alpha^+_{u_i}]$ for any u_i and $i \in [1, d]$. Recall that $u \in \mathscr{N}(x)$ if and only if for each $i \in [1, d]$,

$$I_{u_i} \subseteq [x_i - 1, x_i + 1] \text{ and } I_{p(u_i)} \not\subseteq [x_i - 1, x_i + 1], \quad (*)$$

Fix a value of i. From the construction of a range tree either $\alpha^-_{u_i} = \alpha^-_{p(u_i)}$ or $\alpha^+_{u_i} = \alpha^+_{p(u_i)}$. Without loss of generality, assume $\alpha^-_{u_i} = \alpha^-_{p(u_i)}$; the other case is symmetric. Then $(*)$ can be written as: $x_i \leq \alpha^-_{u_i} + 1$ and $\alpha^+_{u_i} - 1 \leq x_i < \alpha^+_{p(u_i)} - 1$. Therefore x_i has to satisfy three 1D linear constraints. The feasible region of these constraints is an interval δ_i and $x_i \in \delta_i$ (see also Figure 1). Hence, u is a canonical node of $\mathscr{B}(x)$ if and only if for all $i \in [1, d]$, $x_i \in \delta_i$. In other words, $x = (x_1, \ldots, x_d) \in \prod_{i=1}^{d} \delta_i := \mathscr{R}(u)$. The endpoints of δ_i are the endpoints of I_{u_i} or $I_{p(u_i)}$. In order to construct $\mathscr{R}(u)$, we only need the intervals I_{u_i} and $I_{p(u_i)}$ for each $i \in [1, d]$, so it can be constructed in $O(d) = O(1)$ time. ◀

In view of Lemma 1, we proceed as follows. We build a dynamic range tree $\mathscr{Z}$ on B. Furthermore, we augment the range tree $\mathscr{T}$ on A as follows. For each level-d node $u \in \mathscr{T}$, we compute and store $\mathscr{R}(u)$ and $\beta_u = |B_u|$. By construction, $|A_u| \geq 1$ for all u. We also store a pointer at u to the leftmost leaf of the subtree of $\mathscr{T}$ rooted at u, and we thread all the leaves

of a d-level tree so that for a node u, A_u can be reported in $O(|A_u|)$ time. Updating these pointers as $\mathscr{T}$ is updated is straightforward. Whenever a new node u of $\mathscr{T}$ is constructed, we query $\mathscr{Z}$ with $\mathscr{R}(u)$ to compute β_u. Finally, we store $\mathscr{C}$, the set of all active nodes of $\mathscr{T}$, in a red-black tree so that a node can be inserted or deleted in $O(\log n)$ time. The total size of the data structure is $O(n \log^{d-1} n)$, and it can be constructed in $O(n \log^d n)$ time.

Update and Enumerate. Updating A is straightforward. We update $\mathscr{T}$, query $\mathscr{Z}$ with $\mathscr{R}(u)$, for all newly created d-level nodes u in $\mathscr{T}$ to compute β_u, and update $\mathscr{C}$ to delete all active nodes that are no longer in $\mathscr{T}$ and to insert new active nodes. Since the amortized time to update $\mathscr{T}$ as a point is inserted or deleted is $O(\log^d n)$, the amortized update time of a point in A is $O(\log^{2d} n)$ – we spend $O(\log^d n)$ time to compute β_u for each of the $O(\log^d n)$ newly created nodes. If a point b is inserted (resp. deleted) in B, we update $\mathscr{Z}$ and query $\mathscr{T}$ with $\mathscr{B}(b)$. For all canonical nodes u in $\mathscr{N}(b)$, we increment (resp. decrement) b_u. If u becomes active (resp. inactive), we insert (resp. delete) u in $\mathscr{C}$ in $O(\log n)$ time. The amortized update time for b is $O(\log^{d+1} n)$.

Finally, to enumerate the pairs in join results, we traverse the active nodes $\mathscr{C}$ and for each $u \in \mathscr{C}$, we first query $\mathscr{Z}$ with $\mathscr{R}(u)$ to recover B_u. Recall that B_u is reported as a set of $O(\log^d n)$ canonical nodes of $\mathscr{Z}$ whose leaves contain the points of B_u. We simultaneously traverse the leaves of the subtree of $\mathscr{T}$ rooted at u to compute A_u and report $A_u \times B_u$. The traversals can be performed in $O(\log^d n)$ maximum delay. Putting everything together, we obtain:

▶ **Theorem 2.** *Let A, B be two sets of points in $\mathbb{R}^d$, where $d \geq 1$ is a constant, with $|A| + |B| = n$. A data structure of $\widetilde{O}(n)$ size can be built in $\widetilde{O}(n)$ time and updated in $\widetilde{O}(1)$ amortized time, while supporting $\widetilde{O}(1)$-delay enumeration of similarity join under ℓ_∞ metric.*

2.2 Similarity join under ℓ_1 metric

For $d \leq 2$ it is straightforward to reduce similarity join under ℓ_1 metric to ℓ_∞ metric. For $d = 1$, ℓ_1 metric is obviously equivalent to the ℓ_∞ metric. For $d = 2$, notice that the ℓ_1 ball is a diamond, while the ℓ_∞ ball is a square. Hence, given an instance of the similarity join under the ℓ_1 metric we can rotate $A \cup B$ by 45 degrees to create an equivalent instance of the similarity join problem under the ℓ_∞ metric.

Next, we focus on $d \geq 3$. The data structure we proposed in Section 2.1 for the ℓ_∞ norm can be straightforwardly extended to the *rectangle-containment* problem in which for each $b \in B$, $\mathscr{B}(b)$ is an arbitrary axis-aligned hyper-rectangle with center b, and the goal is to report all $(a, b) \in A \times B$ such that $a \in \mathscr{B}(b)$. Lemma 1 can be extended so that $\mathscr{R}(u)$ is a $2d$-dimensional rectangle. Overall, Theorem 2 remains the same assuming $\mathscr{B}(b)$ are hyper-rectangles (and not hypercubes).

Given an instance of similarity join under ℓ_1 metric in $\mathbb{R}^d$, we next show how to reduce it to 2^d $(d+1)$-dimensional rectangle-containment problems. As above, assume $r = 1$, so our goal is to report all pairs $a = (a_1, \ldots, a_d) \in A$, $b = (b_1, \ldots, b_d) \in B$ such that $\sum_{i=1}^d |a_i - b_i| \leq 1$.

Let $E = \{-1, +1\}^d$ be the set of all 2^d vectors in $\mathbb{R}^d$ with coordinates either 1 or -1. For each vector $e \in E$, we construct an instance of the rectangle-containment problem. For each $e = (e_1, \ldots, e_d) \in E$, we map each point $a = (a_1, \ldots, a_d) \in A$ to a point $\bar{a}_e = (a_1, \ldots, a_d, \sum_{i=1}^d e_i a_i) \in \mathbb{R}^{d+1}$. Let $\bar{A}_e = \{\bar{a}_e \mid a \in A\}$. For each point $b = (b_1, \ldots, b_d) \in B$, we construct the axis-align rectangle $\bar{b}_e = \prod_{i=1}^{d+1} b_e^{(i)}$ in $\mathbb{R}^{d+1}$, where $b_e^{(i)}$ is the interval $[b_i, \infty)$ if $e_i = 1$ and $(-\infty, b_i]$ if $e_i = -1$ for each $i = 1, \ldots, d$, and $b_e^{(d+1)} = (-\infty, 1 + \sum_{i=1}^d e_i b_i]$. Let $\bar{B}_e = \{\bar{b}_e \mid b \in B\}$. See Figure 2.

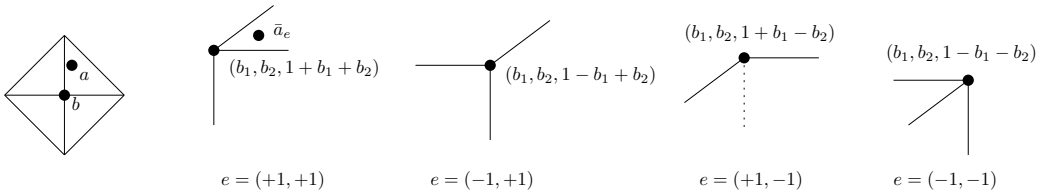

Figure 2 An illustration of mapping each b to rectangles.

For each $e \in E$, we construct the dynamic data structure for $\bar{A}_e, \bar{B}_e$. Whenever A or B is updated, we update all 2^d rectangle-containment data structures. A similarity join enumeration query on A, B is answered by enumerating containment pairs $(\bar{A}_e, \bar{B}_e)$ for $e \in E$. If a pair $(\bar{a}_e, \bar{b}_e)$ is reported, we report (a, b). The update time and delay are $\widetilde{O}(1)$. The correctness of the algorithm follows from the following lemma. Let $\mathrm{sgn}(x) = +1$ if $x \geq 0$ and -1 otherwise.

▶ **Lemma 3.** *Let $a = (a_1, \ldots, a_d) \in A$, $b = (b_1, \ldots, b_d) \in B$ be an arbitrary pair of points. Let $e^* = (e_1^*, \ldots, e_d^*)$ where $e_i^* = \mathrm{sgn}(a_i - b_i)$ for $1 \leq i \leq d$. Then $\bar{a}_e \notin \bar{b}_e$ for all $e \in E \setminus \{e^*\}$. Furthermore, $\bar{a}_{e^*} \in \bar{b}_{e^*}$ if and only if $\|a - b\|_1 \leq 1$.*

Proof. First, we note that for any $e \in E \setminus \{e^*\}$, there must exist some i such that $e_i \neq e_i^*$. Without loss of generality, assume $e_j = 1$ when $a_j < b_j$. By the definition of $\bar{a}_e, \bar{b}_e$, $a_j \notin [b_j, \infty)$, thus $\bar{a}_e \notin \bar{b}_e$. Next, we show that $\bar{a}_{e^*} \in \bar{b}_{e^*}$ if and only if $\|a - b\|_1 \leq 1$. On one hand, we assume $\bar{a}_{e^*} \in \bar{b}_{e^*}$. By definition, $\sum_{i=1}^d e_i^* a_i$ lies in the interval associated with $b_{e^*}^{d+1}$, i.e., $\sum_{i=1}^d e_i^* a_i \leq 1 + \sum_{i=1}^d e_i^* b_i$, or $\sum_{i=1}^d e_i^* (a_i - b_i) \leq 1$. Implied by the fact that $\|a - b\|_1 = \sum_{i=1}^d e_i^* (a_i - b_i)$, we have $\|a - b\|_1 \leq 1$. On the other hand, assume $\|a - b\|_1 \leq 1$. Similarly, we have $\|a - b\|_1 = \sum_{i=1}^d e_i^* (a_i - b_i) \leq 1 \Leftrightarrow \sum_{i=1}^d e_i^* a_i \leq 1 + \sum_{i=1}^d e_i^* b_i$, or $\sum_{i=1}^d e_i^* a_i \in (-\infty, 1 + \sum_{i=1}^d e_i^* b_i]$. Moreover, for any $i \in \{1, \ldots, d\}$, we have: (1) if $e_i^* = 1$, $a_i \geq b_i$, i.e., $a_i \in [b_i, \infty)$; (2) if $e_i^* = -1$, $a_i \leq b_i$, i.e., $a_i \in (-\infty, b_i]$. Hence, $\bar{a}_{e^*} \in \bar{b}_{e^*}$. ◀

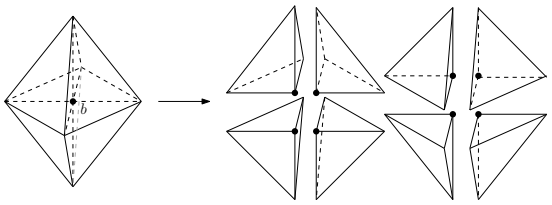

Figure 3 An illustration of ℓ_1 ball in $\mathbb{R}^3$. It is decomposed to $2^d = 8$ types of simplices.

▶ Remark. Roughly speaking, we partition the ℓ_1-ball centered at 0 into 2^d simplices $\Delta_1, \ldots, \Delta_{2^d}$ (see Figure 3) and build a separate data structure for each simplex Δ_i. Namely, let $\mathscr{B}_i = \{b + \Delta_i \mid b \in B\}$ and we report all pairs $(a, b) \in A \times B$ such that $a \in b + \Delta_i$. If $\|a - b\|_1 \leq 1$ then a lies in exactly one simplex $b \in \Delta_i$. We map each simplex to a rectangle in $\mathbb{R}^{d+1}$ and use the previous data structure.

Using Theorem 2, we obtain:

▶ **Theorem 4.** *Let A, B be two sets of points in $\mathbb{R}^d$, where $d \geq 1$ is a constant, with $|A| + |B| = n$. A data structure of $\widetilde{O}(n)$ size can be built in $\widetilde{O}(n)$ time and updated in $\widetilde{O}(1)$ amortized time, while supporting $\widetilde{O}(1)$-delay enumeration of similarity join under ℓ_1 metric.*

2.3 Similarity join under ℓ_2 metric

In this section, we consider the similarity join between two point sets A and B in $\mathbb{R}^d$ under the ℓ_2 metric.

Reduction to halfspace containment. We use the *lifting transformation* [23] to convert an instance of the similarity join problem under ℓ_2 metric to the halfspace-containment problem in $\mathbb{R}^{d+1}$. For any two points $a = (a_1, \ldots, a_d) \in A$ and $b = (b_1, \ldots, b_d) \in B$, $\|a - b\|_2 \leq 1$ if and only if $(a_1 - b_1)^2 + \ldots + (a_d - b_d)^2 \leq 1$, or a lies in the unit sphere centered at b. The above condition can be rewritten as

$$a_1^2 + b_1^2 + \cdots + a_d^2 + b_d^2 - 2a_1b_1 - \cdots - 2a_db_d - 1 \geq 0.$$

We map the point a to a point $a' = (a_1, \ldots, a_d, a_1^2 + \cdots + a_d^2)$ in $\mathbb{R}^{d+1}$ and the point b to a halfspace b' in $\mathbb{R}^{d+1}$ defined as

$$b' : -2b_1z_1 - \cdots - 2b_dz_d + z_{d+1} + b_1^2 + \cdots + b_d^2 - 1 \geq 0.$$

Note that $\|a - b\|_2 \leq 1$ if and only if $a' \in b'$. Set $A' = \{a' \mid a \in A\}$ and $B' = \{b' \mid b \in B\}$. Thus, in the following, we study the halfspace-containment problem, where given a set of points A' and a set of halfspaces B' we construct a dynamic data structure that reports all pairs $(a \in A', b \in B')$, such that a belongs in the halfspace b, with delay guarantee.

Partition tree. A partition tree on a set P of points in $\mathbb{R}^d$ [17, 37, 48] is a tree data structure formed by recursively partitioning a set into subsets. Each point is stored in exactly one leaf and each leaf usually contains a constant number of points. Each node u of the tree is associated with a simplex Δ_u and the subset $P_u = P \cap \Delta_u$; the subtree rooted at u is a partition tree of P_u. We assume that the simplices associated with the children of a node u are pairwise disjoint and lie inside Δ_u, as in [17]. In general, the degree of a node is allowed to be non-constant. Given a query simplex Δ, a partition tree finds a set of $O(n^{1-1/d})$ *canonical* nodes whose cells contain the points of $P \cap \Delta$. Roughly speaking, a node u is a canonical node for Δ if $\Delta_u \subset \Delta$ and $\Delta_{p(u)} \not\subseteq \Delta$. A simplex counting (resp. reporting) query can be answered in $O(n^{1-1/d})$ (resp. $O(n^{1-1/d} + k)$) time using a partition tree. Chan [17] proposed a randomized algorithm for constructing a linear size partition tree with constant degree, that runs in $O(n \log n)$ time and it has $O(n^{1-1/d})$ query time with high probability.

Data structure. For simplicity, with slight abuse of notation, let A be a set of points in $\mathbb{R}^d$ and B a set of halfspaces in $\mathbb{R}^d$ each lying below the hyperplane bounding it, and our goal is to build a dynamic data structure for halfspace-containment join on A, B. The overall structure of the data structure is the same as for rectangle containment described in Section 2.1, so we simply highlight the difference.

Instead of constructing a range tree, we construct a dynamic partition tree $\mathscr{T}_A$ for A so that the points of A lying in a halfspace can be represented as the union of $O(n^{1-1/d})$ canonical subsets. For a halfplane bounding a halfspace $b \in B$, let $\bar{b}$ denote its dual point in $\mathbb{R}^d$ (see [23] for the definition of duality transform). Note that a point a lies in b if and only if the dual point $\bar{b}$ lies in the halfspace lying below the hyperplane dual to a. Set $\bar{B} = \{\bar{b} \mid b \in B\}$. We construct a multi-level dynamic partition tree on $\bar{B}$, so that for a pair of simplices Δ_1 and Δ_2, it returns the number of halfspaces of B that satisfy the following two conditions: (i) $\Delta_1 \subseteq b$ and (ii) $\Delta_2 \cap \partial b \neq \emptyset$, where ∂b is the hyperplane boundary defined by the halfspace b. This data structure uses $O(n)$ space, can be constructed in $\widetilde{O}(n)$ time, and answers a query in $\widetilde{O}(n^{1-1/d})$ time.

For each node $u \in \mathscr{T}_A$, we issue a counting query to $\mathscr{T}_B$ and get the number of halfspaces in B that have u as a canonical node. Hence, $\mathscr{T}_A$ can be built in $\widetilde{O}(n^{2-1/d})$ time. For a node u, $\mu_A(u)$ can be computed in $O(1)$ time by storing A_u at each node $u \in \mathscr{T}_A$. Recall that $\mu_B(u)$ is the number of halfspaces b of B for which u is a canonical node, i.e., $\Delta_u \subseteq b$ and $\Delta_{p(u)} \cap \partial b \neq \emptyset$, where $p(u)$ is the parent of u. Using $\mathscr{T}_B$, $\mu_B(u)$ can be computed in $\widetilde{O}(n^{1-1/d})$ time.

Update and enumeration. The update procedure is the same that in Section 2.1, however the query time now on $\mathscr{T}_A$ or $\mathscr{T}_B$ is $\widetilde{O}(n^{1-\frac{1}{d}})$ so the amortized update time is $\widetilde{O}(n^{1-\frac{1}{d}})$. The enumeration query is also the same as in Section 2.1 but a reporting query in $\mathscr{T}_B$ takes $\widetilde{O}(n^{1-\frac{1}{d}}+k)$ time (and it has delay at most $\widetilde{O}(n^{1-\frac{1}{d}})$), so the overall delay is $\widetilde{O}(n^{1-\frac{1}{d}})$.

▶ **Theorem 5.** *Let A be a set of points and B be a set of half-spaces in $\mathbb{R}^d$ with $|A|+|B| = n$. A data structure of $\widetilde{O}(n)$ size can be built in $\widetilde{O}(n^{2-\frac{1}{d}})$ time and updated in $\widetilde{O}(n^{1-\frac{1}{d}})$ amortized time while supporting $\widetilde{O}(n^{1-\frac{1}{d}})$-delay enumeration of halfspace-containment query.*

Using Theorem 5 and the lifting transformation described at the beginning of this section we conclude with Corollary 6.

▶ **Corollary 6.** *Let A, B be two sets of points in $\mathbb{R}^d$, where $d \geq 1$ is a constant, with $|A| + |B| = n$. A data structure of $\widetilde{O}(n)$ size can be constructed in $\widetilde{O}(n^{2-\frac{1}{d+1}})$ time and updated in $\widetilde{O}(n^{1-\frac{1}{d+1}})$ amortized time, while supporting $\widetilde{O}(n^{1-\frac{1}{d+1}})$-delay enumeration of similarity join under the ℓ_2 metric.*

Lower bound. We show a lower bound for the similarity join in the pointer-machine model under the ℓ_2 metric based on the hardness of unit sphere reporting problem. Let P be a set of n points in $\mathbb{R}^d$ for $d > 3$. The unit-sphere reporting problem asks for a data structure on the points in P, such that given any unit-sphere b report all points of $P \cap b$. If the space is $\widetilde{O}(n)$, it is not possible to get a data structure for answering unit-sphere reporting queries in $\widetilde{O}(k+1)$ time in the pointer-machine model, where k is the output size for $d \geq 4$ [1].

For any instance of sphere reporting problem, we construct an instance of similarity join over two sets, with $A = \emptyset$, $B = P$, and $r = 1$. Given a query unit-sphere of center q, we insert point q in A, issue an enumeration query, and then remove q from A. All results enumerated (if any) are the results of the sphere reporting problem. If there exists a data structure for enumerating similarity join under ℓ_2 metric using $\widetilde{O}(n)$ space, with $\widetilde{O}(1)$ update time and $\widetilde{O}(1)$ delay, we would break the barrier.

▶ **Theorem 7.** *Let A, B be two sets of points in $\mathbb{R}^d$ for $d > 3$, with $|A| + |B| = n$. If using $\widetilde{O}(n)$ space, there is no data structure under the pointer-machine model that can be updated in $\widetilde{O}(1)$ time, while supporting $\widetilde{O}(1)$-delay enumeration of similarity join under the ℓ_2 metric.*

3 Approximate Enumeration

In this section we propose a dynamic data structure for answering approximate similarity-join queries under any ℓ_p metric. For simplicity, we use the ℓ_2 norm to illustrate the main idea and assume $\phi(a,b) = ||a-b||_2$. Recall that all pairs of $(a,b) \in A \times B$ with $\phi(a,b) \leq r$ must be reported, along with (potentially) some pairs of (a',b') with $\phi(a',b') \leq (1+\varepsilon)r$, but no pair (a,b) with $\phi(a,b) > (1+\varepsilon)r$ is reported.

We will start with the setting where the distance threshold r is not fixed and specified as part of a query, and then move to a simpler scenario where r is fixed.

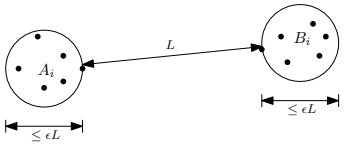

Figure 4 An example pair of ε-WSPD.

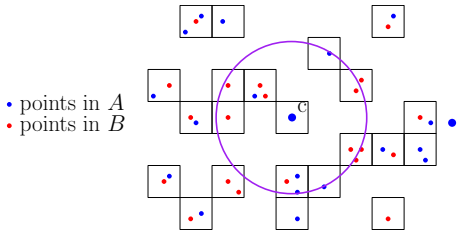

Figure 5 An example of active cell c in the grid.

3.1 Variable Similarity Threshold

We describe the data structure when r is part of the query. In this subsection we assume that the spread of $A \cup B$ is polynomially bounded, i.e., $sp(A \cup B) = \frac{\max_{p,q \in A \cup B} \phi(p,q)}{\min_{p \neq q \in A \cup B} \phi(p,q)} = n^{O(1)}$. We use a quad tree and well-separated pair decomposition (WSPD) for our data structure. We describe them briefly here and refer the reader to [28, 41] for details.

Quad tree and WSPD. A d-dimensional quad tree over a point set P is a tree data structure $\mathscr{T}$ in which each node u is associated with a hypercube $\square_u$ in $\mathbb{R}^d$, called a *cell*, and each internal node has 2^d children. The root is associated with a hypercube containing P. For a node u, let $P_u = P \cap \square_u$. A node u is a leaf if $|P_u| \leq 1$. The tree recursively subdivides the space into 2^d congruent hypercubes until a box contains at most one point from P. If $sp(P) = n^{O(1)}$, the height of $\mathscr{T}$ is $O(\log n)$.

Given two point sets $A, B \subset \mathbb{R}^d$, with $|A| + |B| = n$, and a parameter $0 < \varepsilon < \frac{1}{2}$, a family of pairs $\mathscr{W} = \{(A_1, B_1), (A_2, B_2), \cdots, (A_s, B_s)\}$ is an ε-WSPD if the following conditions hold: (1) for any $i \leq s$, $A_i \subseteq A$, $B_i \subseteq B$ (2) for each pair of points $(a, b) \in A \times B$, there exists a unique pair $(A_j, B_j) \in \mathscr{W}$ such that $a \in A_j$ and $b \in B_j$ (3) for any $i \leq s$, $\max\{\text{diam}(A_i), \text{diam}(B_i)\} \leq \varepsilon \cdot \phi(A_i, B_i)$, where $\text{diam}(X) = \max_{x,y \in X} \phi(x, y)$ and $\phi(X, Y) = \min_{x \in X, y \in Y} \phi(x, y)$ (see Figure 4). As shown in [28, 30] if $sp(A \cup B) = n^{O(1)}$, a quad tree T on $A \cup B$ can be used to construct, in time $O(n \log n + \varepsilon^{-d} n)$, a WSPD $\mathscr{W}$ of size $O(\varepsilon^{-d} n)$ such that each pair $(A_i, B_i) \in \mathscr{W}$ is associated with pair of cells $(\square_i, \boxplus_i)$ in $\mathscr{T}$ where $A_i = A \cap \square_i$ and $B_i = B \cap \boxplus_i$. It is also known that for each pair $(A_i, B_i) \in \mathscr{W}$ (i) $\square_i \cap \boxplus_i = \emptyset$, (ii) $\max\{\text{diam}(\square_i), \text{diam}(\boxplus_i)\} \leq \varepsilon \phi(\square_i, \boxplus_i)$, and each cell appears in $O(\varepsilon^{-d} \log n)$ cells (see Figure 4). We will use $\mathscr{W} = \{(\square_1, \boxplus_i), \ldots, (\square_s, \boxplus_s)\}$ to denote the WSPD, with A_i, B_i being implicitly defined from the cells. Using the techniques in [15, 26], the quad tree $\mathscr{T}$ and the WSPD $\mathscr{W}$ can be maintained under insertions and deletions of points in $\widetilde{O}(\varepsilon^{-d})$ time.

Data structure. We construct a quad tree $\mathscr{T}$ on $A \cup B$. For each node $u \in \mathscr{T}$, we store a pointer A_u (and B_u) to the leftmost leaf of subtree $\mathscr{T}_u$ that contains a point from A (and B). Furthermore, we store sorted lists L_A and L_B of the leaves that contain points from A and B, respectively. We use these pointers and lists to report points in $\square_u$ with $O(1)$ delay. Using $\mathscr{T}$, we can construct a WSPD $\mathscr{W} = \{(\square_1, \boxplus_1), \ldots, (\square_s, \boxplus_s)\}$, $s = O(\varepsilon^{-d})$. For each i, let $\Delta_i = \min_{p \in \square_i, q \in \boxplus_i} \phi(p, q)$. We store all pairs $(\square_i, \boxplus_i)$ in a red-black tree $\mathscr{Z}$ using Δ_i as the key. The data structure has $O(\varepsilon^{-d} n)$ size and $O(\varepsilon^{-d} n \log n)$ construction time.

Update. After inserting or deleting an input point, the quad tree $\mathscr{T}$ and W can be updated in $\widetilde{O}(\varepsilon^{-d})$ time, following the standard techniques in [15, 26]. As there are at most $\widetilde{O}(\varepsilon^{-d})$ pairs changed, we can update the tree $\mathscr{Z}$ in $\widetilde{O}(\varepsilon^{-d})$ time. Furthermore, we note that there are only $O(1)$ changes in the structure of quad tree $\mathscr{T}$ and the height of $\mathscr{T}$ is $O(\log n)$, so we can update all necessary pointers A_u, B_u and sorted lists L_A, L_B in $O(\log n)$ time.

Enumeration. Let r be the threshold parameter specified as part of a query. We traverse the tree $\mathscr{Z}$ in order and report pairs of cells until we reach a pair $(\square_j, \boxplus_j)$ with $\Delta_j > r$. For each pair $(\square_i, \boxplus_i)$ reported, we traverse we enumerate $(a, b) \in (A \cap \square_i) \times (B \cap \boxplus_i)$ using the stored pointers and the sorted lists L_A, L_B. The delay guarantee is $O(1)$.

Let $(a, b) \in A \times B$ be a pair with $\phi(a, b) \leq r$. Implied by the definition, there exists a unique pair $(A_i, B_i) \in \mathscr{W}$ such that $a \in A_i$ and $b \in B_i$. Notice that $\phi(\square_i, \boxplus_i) \leq \phi(a, b) \leq r$. Thus, all results of $A_i \times B_i$ will be reported, including (a, b). Next, let $(\square_i, \boxplus_i)$ be a pair that is reported by the enumeration procedure in $\mathscr{Z}$, with $\phi(\square_i, \boxplus_i) \leq r$. For any pair of points $x \in \square_i, y \in \boxplus_i$, we have $\phi(x, y) \leq \phi(\square_i, \boxplus_i) + \operatorname{diam}(\square_i) + \operatorname{diam}(\boxplus_i) \leq (1 + 2 \cdot \frac{\varepsilon}{2}) \cdot \phi(\square_i, \boxplus_i) \leq (1 + \varepsilon)r$, thus $\phi(a, b) \leq (1 + \varepsilon)r$ for any pair $(a, b) \in A_i \times B_i$.

▶ **Theorem 8.** *Let A, B be two sets of points in $\mathbb{R}^d$ for constant d, with $O(n^{O(1)})$ spread and $|A| + |B| = n$. A data structure of $O(\varepsilon^{-d} n)$ space can be built in $\widetilde{O}(\varepsilon^{-d} n)$ time and updated in $\widetilde{O}(\varepsilon^{-d})$ time, while supporting ε-approximate enumeration for similarity join under any ℓ_p metric with $O(1)$ delay, for any query similarity threshold r.*

3.2 Fixed distance threshold

Without loss of generality we assume that $r = 1$. We use a grid-based data structure for enumerating similarity join with fixed distance threshold r.

Data structure. Let $\mathscr{G}$ be an infinite uniform grid[1] in $\mathbb{R}^d$, where the size of each grid cell is $\frac{\varepsilon}{2\sqrt{d}}$ and the diameter is $\frac{\varepsilon}{2}$. For a pair of cells $c, c' \in$, define $\phi(c, c') = \min_{p \in c, q \in c'} \phi(p, q)$. Each grid cell $c \in \mathscr{G}$ is associated with (1) $A_c = A \cap c$; (2) $B_c = B \cap c$; (3) $m_c = \sum_{c' : \phi(c, c') \leq 1} |B_{c'}|$ as the number of points in B that lie in a cell c' within distance 1 from cell c. Let $\mathscr{C}_{NE} \subseteq \mathscr{G}$ be the set of all non-empty cells, $\mathscr{C}_{NE} = \{c \in \mathscr{G} \mid A_c \cup B_c \neq \emptyset\}$. A grid cell $c \in \mathscr{C}_{NE}$ is *active* if and only if $A_c \neq \emptyset$ and $m_c > 0$ (see Figure 5 for an example). Let $\mathscr{C} \subseteq \mathscr{C}_{NE}$ be the set of active grid cells (Figure 5). Notice that a grid cell is stored when there is at least one point from A or B lying inside it, so $|\mathscr{C}_{NE}| \leq n$. Finally, we build a balanced search tree on $\mathscr{C}$ so that whether a cell c is stored in $\mathscr{C}$ can be answered in $O(\log n)$ time. Similarly, we build another balanced search tree to store the set of non-empty cells $\mathscr{C}_{NE}$.

Update. Assume point $a \in A$ is inserted into cell $c \in \mathscr{G}$. If c is already in $\mathscr{C}_{NE}$, simply add a to A_c. Otherwise, we add c to $\mathscr{C}_{NE}$ with $A_c = \{a\}$ and update m_c as follows. We visit each cell $c' \in \mathscr{C}_{NE}$ with $\phi(c, c') \leq 1$, and add $|B_{c'}|$ to m_c. A point of A is deleted in a similar manner. Assume point $b \in B$ is inserted into cell $c \in \mathscr{G}$. If $c \notin \mathscr{C}_{NE}$, we add it to $\mathscr{C}_{NE}$. In any case, we first insert b into B_c and for every cell $c' \in \mathscr{C}_{NE}$ with $\phi(c, c') \leq 1$, we increase $m_{c'}$ by 1 and add c' to $\mathscr{C}$ if c' turns from inactive to active. A point from B is deleted in a similar manner. As there are $O(\varepsilon^{-d})$ cells within distance 1 from c, this procedure takes $\widetilde{O}(\varepsilon^{-d})$ time.

Enumeration. For each active cell $c \in \mathscr{C}$, we visit each cell $c' \in \mathscr{C}_{NE}$ within distance 1. If $B_{c'} \neq \emptyset$, we report all pairs of points in $A_c \times B_{c'}$. It is obvious that each pair of points is enumerated at most once. For an active cell c, there must exists a pair $(a \in A_c, b \in B_{c'})$ for some cell $c' \in \mathscr{C}_{NE}$ such that $\phi(a, b) \leq \phi(c, c') + \operatorname{diam}(c) + \operatorname{diam}(c') \leq 1 + \varepsilon$. So it takes at most $O(\varepsilon^{-d} \log n)$ time before finding at least one result for c; thus, the delay is $O(\varepsilon^{-d} \log n)$.

[1] When extending it to any ℓ_p norm, the size of each grid cell is $\varepsilon/(2d^{1/p})$ and the diameter is $\frac{\epsilon}{2}$.

Furthermore, consider every pair of points a, b with $\phi(a, b) \leq 1$. Assume $a \in c$ and $b \in c'$. By definition, c must be an active grid cell. Thus, (a, b) will definitely be enumerated in this procedure, thus guaranteeing the correctness of ε-enumeration.

▶ **Theorem 9.** *Let A, B be two sets of points in $\mathbb{R}^d$ for some constant d, with $|A| + |B| = n$. A data structure of $O(n)$ size can be constructed in $O(n\varepsilon^{-d} \log n)$ time and updated in $O(\varepsilon^{-d} \log n)$ time, while supporting ε-approximate enumeration of similarity join under any ℓ_p metric with $O(\varepsilon^{-d} \log n)$ delay.*

Note that if for each active cell $c \in \mathscr{C}$, we store the cells within distance 1 that contain at least a point from B, i.e., $\{c' \in C \mid \phi(c, c') \leq 1, B_c \neq \emptyset\}$, then the delay can be further reduced to $O(1)$ but the space becomes $O(\varepsilon^{-d} n)$.

4 Similarity Join in High Dimensions

So far, we have treated the dimension d as a constant. In this section we describe a data structure for approximate similarity join using the *locality sensitive hashing* (LSH) technique, so that the dependency on d is a small polynomial. For simplicity, we assume that r is fixed, however our results can be extended to the case in which r is part of the enumeration query.

For $\varepsilon > 0$, $0 < p_2 < p_1 \leq 1$, a family $\mathscr{H}$ of hash functions is $(r, (1+\varepsilon)r, p_1, p_2)$-sensitive, if for any uniformly chosen hash function $h \in H$ and any two points x, y:

- $\Pr[h(x) = h(y)] \geq p_1$ if $\phi(x, y) \leq r$;
- $\Pr[h(x) = h(y)] \leq p_2$ if $\phi(x, y) \geq (1+\varepsilon)r$.

The quality of $\mathscr{H}$ is measured by $\rho = \frac{\ln p_1}{\ln p_2} < 1$, which is upper bounded by a number that depends only on ε; and $\rho = \frac{1}{1+\varepsilon}$ for many common distance functions [27, 22, 29]. For ℓ_2 the best result is $\rho \leq \frac{1}{(1+\varepsilon)^2} + o(1)$ [9].

The essence of LSH is to hash "similar" points into the same buckets with high probability. A simple approach based on LSH is to (i) hash points into buckets; (ii) probe each bucket and check for each pair of points $(a, b) \in A \times B$ inside the same bucket whether $\phi(a, b) \leq r$; and (iii) report (a, b) if the inequalities holds. However, two challenges arise for enumeration. First, without any knowledge of false positive results inside each bucket, checking every pair of points could lead to a huge delay. Our key insight is that after checking a small number (to be determined later) of pairs of points in one bucket, we can safely skip the bucket since any pair of result missed in this bucket will be found in another one with high probability. Second, one pair of points may collide under multiple hash functions, so an additional step is necessary in the enumeration to remove duplicates. If we wish to keep the size of data structure to be near-linear and if we are not allowed to store the reported pairs (so that the size remains near linear), detecting duplicates requires care.

Since we do not define new hash functions, our results hold for any metric for which LSH works, in particular for Hamming, ℓ_2, ℓ_1 metrics.

Data structure. We fix an LSH family $\mathscr{H}$. Let ρ be its quality parameter. To ensure high-probability guarantee, we maintain $O(\log n)$ copies of the whole data structure below.

We randomly choose $\tau = O(n^\rho)$ hash functions. Each possible value in the range of hash functions defines a bucket. We maintain some extra statistics for all buckets. We choose a parameter $M = O(n^\rho)$. For a bucket $\square$, let $A_\square = A \cap \square$ and $B_\square = B \cap \square$. We choose two arbitrary subsets $\bar{A}_\square, \bar{B}_\square$ of $A_\square, B_\square$, respectively, of M points each. For each point $a \in \bar{A}_\square$, we maintain a counter $\beta_a = |\{b \in \bar{B}_\square \mid \phi(a, b) \leq 2(1+\varepsilon)r\}|$, i.e., the number of points in $\bar{B}_\square$ with distance at most $2(1+\varepsilon)r$ from a. We store $\bar{A}_\square$ in an increasing order of their

β values. If there exists some positive counter $\beta_a > 0$, we denote bucket $\square$ as *active* and store an arbitrary pair $(a, b) \in \bar{A}_\square \times \bar{B}_\square$ with $\phi(a, b) \leq 2(1+\varepsilon)r$ as its *representative* pair, denoted as $(a_\square, b_\square)$. Let $\mathscr{C}$ denote the set of active buckets.

Before diving into the details of update and enumeration, we give some intuition about active buckets. Given a set P of points and a distance threshold r, let $\overline{\mathscr{B}}(q, P, r) = \{p \in P \mid \phi(p, q) > r\}$. For any pair of points $(a, b) \in A \times B$ and a hashing bucket $\square$, we refer to $\square$ as the *proxy bucket* for (a, b) if (i) $a \in A_\square, b \in B_\square$; (ii) $|\bar{\mathscr{B}}(a, A_\square \cup B_\square, (1+\varepsilon)r)| \leq M$. A crucial property of proxy bucket is captured by Lemma 10. Moreover, it can be shown that with high probability each close pair of points has a proxy bucket in Lemma 11 (more details are given in the full version [4]). In this way, it is safe to skip a bucket after we have seen up to M^2 faraway pairs of points inside, since the close pairs of points in this bucket will be captured by other buckets. In this way, we only need to report pairs from active buckets.

▶ **Lemma 10.** *For any bucket $\square$, if there exist M points from $A_\square$ and $B_\square$ each, such that none of the M^2 pairs has its distance within $2(1+\varepsilon)r$, $\square$ is not a proxy bucket for any pair $(a, b) \in A_\square \times B_\square$ with $\phi(a, b) \leq r$.*

Proof of Lemma 10. Let A', B' be two sets of M points from $A_\square, B_\square$ respectively. We assume that all pairs of points in $A' \times B'$ have their distances larger than $2(1+\varepsilon)r$. Observe that $\square$ is not a proxy bucket for any pair $(a \in A', b \in B')$. It remains to show that $\square$ is not a proxy bucket for any pair $(a \in A_\square \setminus A', b \in B_\square)$. Assume $b \in B_\square \setminus B'$ (the case is similar if $b \in B'$). If $A' \subseteq \bar{\mathscr{B}}(a, A, (1+\varepsilon)r)$ or $B' \subseteq \bar{\mathscr{B}}(a, B, (1+\varepsilon)r)$, $\square$ is not a proxy bucket for (a, b). Otherwise, there must exist at least one point $a' \in A'$ as well as $b' \in B'$ such that $\phi(a, a') \leq (1+\varepsilon)r$ and $\phi(a, b') \leq (1+\varepsilon)r$, so $\phi(a', b') \leq \phi(a, a') + \phi(a, b') \leq 2(1+\varepsilon)r$. Thus, $(a', b') \in A' \times B'$ is a pair within distance $2(1+\varepsilon)r$, coming to a contradiction. ◀

▶ **Lemma 11** ([27, 28, 32])**.** *For $M = O(n^\rho)$, with probability $1 - 1/n$, every pair of points (a, b) with $\phi(a, b) \leq r$ has a proxy bucket.*

Update. Assume a point $a \in A$ is being inserted. We visit every bucket $\square$ into which a is hashed and insert a to $A_\square$. If $|\bar{A}_\square| \geq M$, we do nothing. Otherwise, we insert a to $\bar{A}_\square$ and compute its counter β_a. If $\beta_a > 0$ and $\square \notin \mathscr{C}$, we add $\square$ to $\mathscr{C}$ and store an arbitrary pair (a, b) for some $b \in \bar{B}_\square$ with $\phi(a, b) \leq 2(1+\varepsilon)r$, as the representative pair of $\square$. Notice that there always exists such a point b since $\beta_a > 0$.

Assume a point $a \in A$ is being deleted. We visit every bucket $\square$ into which a is hashed and delete a from $A_\square$. If $a \in \bar{A}_\square$, we delete it from $\bar{A}_\square$ and insert an arbitrary point (if any) from $A_\square \setminus \bar{A}_\square$ into $\bar{A}_\square$. If $a = a_\square$, i.e., a participates in the representative pair of $\square$, we find a new representative pair by considering an arbitrary point $a' \in \bar{A}_\square$ with $\beta_{a'} > 0$. If no such point exists, we remove $\square$ from $\mathscr{C}$.

The case when point $b \in B$ is inserted or deleted is similar but with slight differences. Assume a point $b \in B$ is being inserted. We visit every bucket $\square$ into which b is hashed and inserted b to $B_\square$. If $|\bar{B}_\square| \geq M$, we do nothing. Otherwise, we insert b to $\bar{B}_\square$ and increment counter β_a for every point $a \in \bar{A}_\square$ with $\phi(a, b) \leq 2(1+\epsilon)r$. Moreover, if $\square \notin \mathscr{C}$ and there exists some point $a \in \bar{A}_\square$ with $\beta_a > 0$ after update, say a', we store (a', b) as the representative pair of $\square$ and add $\square$ to $\mathscr{C}$.

Assume a point $b \in B$ is being deleted. We visit every bucket $\square$ into which b is hashed and delete b from $B_\square$. If $b \in \bar{B}_\square$, we delete it from $\bar{B}_\square$ and insert an arbitrary point (if any) from $B_\square \setminus \bar{B}_\square$ into $\bar{B}_\square$. Moreover, we need to update counter β_a for every point $a \in \bar{A}_\square$. If

$b = b_\square$, i.e., b participates in the representative pair of $\square$, we find a new representative pair by considering an arbitrary point $a \in \bar{A}_\square$ with $\beta_a > 0$. If no such pair exists, we remove $\square$ from $\mathscr{C}$.

After performing $n/2$ updates, we reconstruct the entire data structure from scratch.

Enumeration. Let $\mathscr{R}$ be the set of representative pairs. As mentioned, the high-level idea is to enumerate representative pairs from active buckets. More specifically, we start with an arbitrary representative pair $(a, b) \in \mathscr{R}$, and enumerate all pairs involving point a from $\mathscr{C}(a)$, where $\mathscr{C}(a) \subseteq \mathscr{C}$ is the set of active buckets containing a. Then, we remove a from each bucket $\square \in \mathscr{C}(a)$. If $a \in \bar{A}_\square$, we remove a from $\bar{A}_\square$; moreover, we add a point $a' \in \bar{A} - \bar{A}_\square$ to $\bar{A}_\square$ to ensure $|\bar{A}_\square| = M$ if $|A_\square| \geq M$ and compute $\beta_{a'}$. If $a = a_\square$, we compute a new representative pair $(a_\square, b_\square)$ of $\square$. If no such new representative pair exists, we just remove $\square$ from the set of active buckets; otherwise, we add the new pair $(a_\square, b_\square)$ to $\mathscr{R}$. We repeat this process until $\mathscr{R}$ becomes empty. The whole procedure is described in Algorithm 1.

Algorithm 1 ENUMERATE.

```
1  R ← {(a□, b□) : □ ∈ C};
2  while R ≠ ∅ do
3      (a, b) ← R;
4      C(a) ← {□ ∈ C : a ∈ A□};
5      REPORT(a, C(a));
6      foreach □ ∈ C(a) do
7          A□ ← A□ − {a};
8          if a ∈ Ā□ then
9              Ā□ ← Ā□ − {a};
10             if |A□| ≥ M then
11                 Pick arbitrary point a' ∈ A□ − Ā□;
12                 Ā□ ← Ā□ ∪ {a'};
13         if a = a□ then
14             R ← R − {(a□, b□)};
15             Recompute (a□, b□) for □;
16             if (a□, b□) = ∅ then
17                 C ← C − {□};
18             else
19                 R ← R ∪ {(a□, b□)};
```

In line 5 of Algorithm 1, we report all pairs including point a is described in Algorithm 2. For a bucket $\square \in \mathscr{C}(a)$, whenever we report a pair (a, b), we *mark* b with a. If b was already marked by some other point a' because (a', b) was reported, we overwrite a' with a. Let $X(\square, a) \subseteq B_\square$ be the set of points in $B_\square$ marked with a. We visit every bucket $\square \in \mathscr{C}(a)$ and check the distances between a and points in $B_\square \setminus X(\square, a)$. Each time a pair (a, b) with $\phi(a, b) \leq 2(1 + \varepsilon)r$ is found, we report it and mark b with a to ensure that we will not report (a, b) again. More specifically, we go over each active bucket $\square \in \mathscr{C}(a)$ into which b is also hashed, and put a marker on b with respect to a. Implied by line 3 of Algorithm 2, we only

consider points not marked by $X(\square, a)$, thus avoiding repeated enumeration.[2] Whenever more than M points from $B_\square$ have been checked without finding a pair with distance less than $2(1+\varepsilon)r$ (or if all points in $B_\square$ have been considered), we just skip this bucket.

Algorithm 2 REPORT$(a, \mathscr{C}(a))$.

```
1  foreach □ ∈ C(a) do
2  |  i ← 0;
3  |  foreach b ∈ B_□ − X(□, a) do
4  |  |  if φ(a, b) ≤ 2(1 + ε)r then
5  |  |  |  Report (a, b);
6  |  |  |  foreach □′ ∈ C(a) with b ∈ B_□′ do
7  |  |  |  |  X(□′, a) ← X(□′, a) ∪ {b};
8  |  |  else
9  |  |  |  i ← i + 1;
10 |  |  |  if i > M then break;
```

Correctness analysis. The report procedure guarantees that each pair of points is enumerated at most once. It remains to show that $(1+2\varepsilon)$-approximate enumeration is supported.

We show that $(1+2\varepsilon)$-approximate enumeration is supported with probability $1-1/n$. It can be easily checked that any pair of points farther than $2(1+\varepsilon)r$ will not be enumerated. Hence, it suffices to show that all pairs within distance r are enumerated with high probability. From Lemma 11, with high probability every pair within distance 1 has a proxy bucket. Let $\square$ be a proxy bucket for pair (a, b). Implied by Lemma 10, there exist no M points from $A_\square$ (for example $\bar{A}_\square$) and M points from $B_\square$ (for example $\bar{B}_\square$) such that all M^2 pairs have their distance larger than $2(1+\varepsilon)r$, so $\square$ is active. Moreover, from the definition of M and the proof of Lemma 10 (check [4] the complete proof) there exist no M points from $B_\square$ such that all of them have distance more than $2(1+\varepsilon)r$ from a, so Algorithm 2 will report (a, b).

Complexity analysis. Recall that $\tau, M = O(n^\rho)$. The data structure uses $O(dn + n\tau \log n)$ space since we only use linear space with respect to the points in each bucket. The update time is $\widetilde{O}(dM \cdot \tau)$ as there are $\widetilde{O}(\tau)$ buckets to be investigated and it takes $\widetilde{O}(dM)$ time to update the representative pair. After $n/2$ updates we re-build the data structure so the update time is amortized. The delay is $\widetilde{O}(dM \cdot \tau)$. In order to replace a with an arbitrary point $a' \in A_\square - \bar{A}_\square$ in line 8 of Algorithm 1 we need $O(dM)$ time and there are $\widetilde{O}(\tau)$ buckets that we need to visit. In total, this step takes $\widetilde{O}(dM\tau)$ time. In Algorithm 2, we spend $\widetilde{O}(dM\tau)$ time to report a pair of results and $\widetilde{O}(\tau)$ time to mark point b over all buckets.

We conclude with the following result:

▶ **Theorem 12.** *Let A and B be two sets of points in $\mathbb{R}^d$, where $|A| + |B| = n$ and let ε, r be positive parameters. For $\rho = \frac{1}{(1+\varepsilon)^2} + o(1)$, a data structure of $\widetilde{O}(dn + n^{1+\rho})$ size can be constructed in $\widetilde{O}(dn^{1+2\rho})$ time, and updated in $\widetilde{O}(dn^{2\rho})$ amortized time, while supporting $(1+2\varepsilon)$-approximate enumeration for similarity join under the ℓ_2 metric with $\widetilde{O}(dn^{2\rho})$ delay.*

[2] To avoid conflicts with the markers made by different enumeration queries, we can generate them randomly and delete old values by lazy updates [24, 38, 39] after finding new pairs to report.

▶ Remark. Alternatively, we can insert or delete points from $A \cup B$ without maintaining the sets $\bar{A}_\square, \bar{B}_\square$ for every bucket $\square$. In the enumeration phase, given a bucket $\square$, we can visit M arbitrary points from $A_\square$ and M arbitrary points from $B_\square$ and compute their pairwise distances. If there is no pair $(a \in A_\square, b \in B_\square)$ with $\phi(a,b) \leq 2(1+\varepsilon)r$, we just skip this bucket. Otherwise, we report the pair (a,b) and invoke Algorithm 2 for point a. In this case, the update time decreases to $\widetilde{O}(dn^\rho)$ but the delay will increases to $\widetilde{O}(dn^{3\rho})$.

The same result holds for Hamming and ℓ_1 metrics with $\rho = \frac{1}{1+\varepsilon}$. Using [32], for the Hamming metric and $\varepsilon > 1$ we can get $M = O(1)$. Skipping the details, we have:

▶ **Theorem 13.** *Let A and B be two sets of points in $\mathbb{H}^d$, where $|A| + B| = n$ and let ε, r be positive parameters. For $\rho = \frac{1}{1+\varepsilon}$, a data structure of $\widetilde{O}(dn + n^{1+\rho})$ size can be built in $\widetilde{O}(dn^{1+\rho})$ time, and updated in $\widetilde{O}(dn^\rho)$ amortized time, while supporting $(3+2\varepsilon)$-approximate enumeration for similarity join under the Hamming metric with $\widetilde{O}(dn^\rho)$ delay.*

In the full version [4], we show that our results can be extended to the case where r is part of the enumeration procedure, and we also prove a lower bound relating similarity join to the approximate nearest neighbor query.

5 Conclusion

In this paper, we presented dynamic data structures for enumerating similarity join queries with delay guarantees. We present several efficient data structures for dynamic enumeration of similarity joins in constant or higher dimensions over various metrics.

Note that our data structures provide worst-case delay guarantee for arbitrary input data and arbitrary updates. In practice, most real-world update sequences are "nice", nowhere near these worst-case scenarios; and input points from two sets might be dependent, or follow certain parameterized distributions. A more fine-grained analysis on the intrinsic difficulty of update sequences in dynamic enumeration of similarity joins is quite interesting but still open. Similar instance-dependent analysis has been considered in [46].

Another interesting direction is to investigate other variants of similarity join queries under more general metrics, such as doubling metric space, and more complicated distance functions, such as the cosine distance.

Faster Algorithms for Bounded Tree Edit Distance

Shyan Akmal

MIT, EECS and CSAIL, Cambridge, MA, USA

Abstract

Tree edit distance is a well-studied measure of dissimilarity between rooted trees with node labels. It can be computed in $O(n^3)$ time [Demaine, Mozes, Rossman, and Weimann, ICALP 2007], and fine-grained hardness results suggest that the weighted version of this problem cannot be solved in truly subcubic time unless the APSP conjecture is false [Bringmann, Gawrychowski, Mozes, and Weimann, SODA 2018].

We consider the *unweighted* version of tree edit distance, where every insertion, deletion, or relabeling operation has unit cost. Given a parameter k as an upper bound on the distance, the previous fastest algorithm for this problem runs in $O(nk^3)$ time [Touzet, CPM 2005], which improves upon the cubic-time algorithm for $k \ll n^{2/3}$. In this paper, we give a faster algorithm taking $O(nk^2 \log n)$ time, improving both of the previous results for almost the full range of $\log n \ll k \ll n/\sqrt{\log n}$.

1 Introduction

Many tasks involve measuring the similarity between two sets of data. When the data is naturally represented as a string of characters, one of the most popular and well-studied ways of measuring similarity is via the (string) edit distance, defined to be the minimum number of characters that must be deleted, inserted, and substituted to turn one string into the other. Although edit distance is a fundamental problem in computer science and has been employed to great effect in many other areas, it can be less useful for applications where we are interested in comparing data that is not just linearly ordered, but has some hierarchical organization. When the data admits a tree structure, a natural measure of similarity is the *tree edit distance*, first introduced by Tai [34] as a generalization of the string edit distance problem [38]. Computing this metric has a wide variety of applications in a diverse array of fields including computational biology [22, 32, 23, 39], structured data analysis [14, 16, 21], and image processing [7, 26, 25, 31].

Given two *rooted ordered* trees with node labels, the tree edit distance is the minimum number of node deletions, insertions, and relabelings needed to turn one tree into the other. When we delete a node, its children become children of the parent of the deleted node. Beyond this widely studied definition, there are many other variants of the tree edit distance problem, including those defined for unrooted trees or unordered trees, or parameterized by the depth or the number of leaves, which we do not consider in this paper. We refer interested readers to the survey by Bille [8] for a comprehensive review.

We now recount the development of exact algorithms for tree edit distance. In 1979, Tai [34] gave the first algorithm that computes the tree edit distance between two node-labeled rooted trees on n nodes in $O(n^6)$ time. The time complexity was improved to $O(n^4)$ by Zhang and Shasha [40] using a dynamic programming approach. Later, Klein [24] applied the heavy-light decomposition technique to obtain an $O(n^3 \log n)$ time algorithm. Finally, Demaine, Mozes, Rossman, and Weimann [17] improved the running time by a log-factor to $O(n^3)$, and further showed that this running time is optimal among a certain class of dynamic programming algorithms termed *decomposition strategy algorithms* by Dulucq and Touzet [19, 20]. When the two input trees have different sizes $m \leq n$, their algorithm runs in $O\left(nm^2(1 + \log \frac{n}{m})\right)$ time.

All algorithms mentioned above actually compute tree edit distance in the general *weighted* setting where the cost of deleting, inserting, or relabeling is a function of the labels (so that deleting nodes with certain labels might be cheaper than deleting other nodes with different labels). In this setting, Bringmann, Gawrychowski, Mozes, and Weimann [13] showed conditional hardness results for the tree edit distance problem: a truly subcubic time algorithm for this problem would imply a truly subcubic time algorithm for the All-Pairs Shortest Paths (APSP) problem (assuming alphabet of size $\Theta(n)$), and an $O(n^{k(1-\varepsilon)})$ time algorithm for the Max-weight k-clique problem (assuming a sufficiently large constant-size alphabet). However, the instances produced by their fine-grained reduction have non-unit edit costs, and it is not clear yet how to prove a conditional hardness result for the *unweighted* tree edit distance problem with unit edit costs. In contrast, the quadratic-time fine-grained lower bound for the *string* edit distance problem (based on the Strong Exponential Time Hypothesis) holds for unit-cost operations [6, 1].

Therefore, it is natural to consider the unweighted unit-cost setting, where every elementary operation has cost 1, independent of the labels. In this case, the distance between two trees of sizes n and m cannot be larger than $n + m$, and is arguably even smaller in practical scenarios. In 2005, Touzet [35, 36] gave an algorithm in this context that computes the unweighted tree edit distance in $O(nk^3)$ time, assuming the distance is at most k. When $k = \Theta(n)$, Touzet's algorithm has the same performance as the $O(n^4)$ time algorithm by Zhang and Shasha [40]. However, the running time significantly improves if the upper bound k is much smaller than n. We remark that similar progress was shown earlier for the string edit distance problem: although the best known running time for the general case is $O(n^2/\log^2 n)$ [29, 9], when the distance is at most k, Ukkonen [37] gave an $O(nk)$ time algorithm, which was later improved to $\widetilde{O}(n + k^2)$ time[1] by Myers [30], Landau and Vishkin [28] using suffix trees.

Although we focus on exact algorithms in this work, approximation algorithms for the tree edit distance problem have also been studied [2, 11]. Boroujeni, Ghodsi, Hajiaghayi, and Seddighin [11] showed an algorithm that computes a $(1 + \varepsilon)$-approximation of the tree edit distance in $\widetilde{O}(\varepsilon^{-3}n^2)$ time. If an upper bound k on the distance is known, the running time can be improved to $\widetilde{O}(\varepsilon^{-3}nk)$. For the easier problem of approximating string edit distance, there is a longer line of research [5, 3, 10, 15, 12, 27] culminating in a near-linear time constant-factor approximation algorithm [4].

[1] In this paper, $\widetilde{O}(f)$ stands for $f \cdot (\log f)^{O(1)}$.

1.1 Our contribution

We present a faster algorithm for exactly computing the unweighted tree edit distance (where every elementary operation has unit cost), with a parameter $k \leq O(n)$ given as an upper bound on the distance.

▶ **Theorem 1.** *Given two node-labeled rooted trees T_1, T_2 each of size at most n, we can compute the unweighted tree edit distance between T_1 and T_2 exactly in $O(nk^2 \log n)$ time, assuming the distance is at most k.*

When the distance parameter k is constant our algorithm runs in quasilinear time, and as k reaches its upper bound $O(n)$ we recover the $O(n^3 \log n)$ time algorithm by Klein [24]. Our algorithm outperforms the $O(n^3)$ time algorithms of Demaine et al. [17] when $k = o(n/\sqrt{\log n})$. As mentioned earlier, the previous best algorithm for bounded tree edit distance by Touzet [36] takes $O(nk^3)$ time. The time complexity of our algorithm improves upon this prior work whenever $k = \omega(\log n)$.

1.2 High-level Overview

Touzet's $O(nk^3)$-time algorithm is based on Zhang and Shasha's $O(n^4)$-time dynamic programming algorithm [40]. The improvement was achieved by pruning unuseful DP states, and only considering $O(nk^3)$ many states instead of $O(n^4)$. This pruning technique was inspired by an idea used in the previous $O(nk)$-time algorithm for string edit distance [37]: for input strings whose edit distance is at most k, when building the dynamic programming table for computing the edit distance, it suffices to only compute entries of the table corresponding to prefixes whose lengths differ by at most k. Touzet's improvement for tree edit distance employs a similar technique and relies on measuring the "distance" between two DP states with respect to the preorder tree traversal, which is compatible with the DP transitions of Zhang and Shasha.

We modify Klein's $O(n^3 \log n)$ time algorithm by further reducing the number of useful states, similar in spirit to the algorithm by Touzet [36]. The main difficulty in adapting this idea is that unlike the algorithm of Zhang and Sasha, Klein's DP algorithm does not follow the same preorder traversal of the nodes. Hence we need completely new arguments to bound the number of useful DP states. Beyond considering the sizes of the subproblems generated, our proofs examine how various subforests are generated by different transition rules and employ some combinatorial arguments about how the subgraphs of deleted nodes can be structured when the edit distance is known to be bounded.

1.3 Paper Organization

In Section 2 we formally define the tree edit distance problem and introduce the notation used throughout the rest of the paper. Next, in Section 3, we review Klein's algorithm [24] which our algorithm builds off of. Then, in Section 4, we present our improved algorithm. Finally, we conclude by mentioning several open questions relevant to our work in Section 5.

2 Preliminaries

In this paper, we consider rooted trees that are *ordered*, meaning that the order between siblings is significant. We also consider *forests* consisting of disjoint rooted trees, where the order between these trees is also significant. It is convenient to treat the tree roots of a forest as the children of a virtual root node. Let $\mathsf{par}(v)$ denote the parent node of v, or the virtual root node if v is a tree root in the forest.

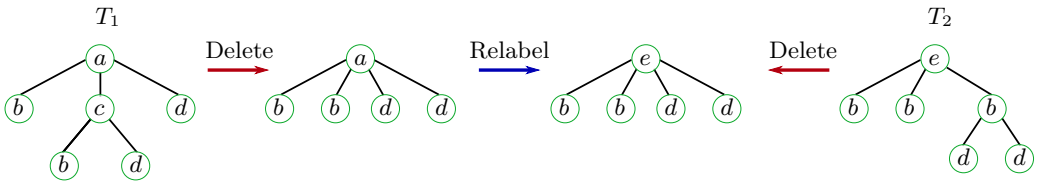

Figure 1 To turn T_1 and T_2 into the same tree with a minimum number of operations, we can delete a node from each and relabel a node in T_1. So in this example $\mathsf{ed}(T_1, T_2) = 3$.

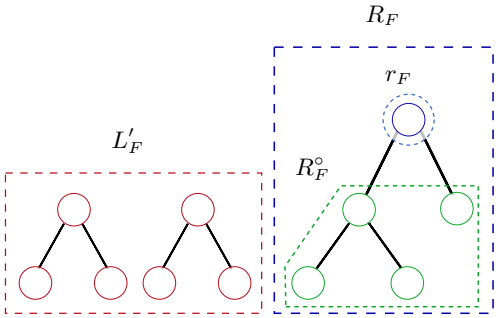

Figure 2 The example forest F above is partitioned into L'_F, r_F, and R°_F.

We define the *node removal operation* in the following natural way: after removing a node v from the forest F, the children of v become children of $\mathsf{par}(v)$, preserving the same relative order. We use $F - v$ to denote the forest obtained by removing v from F.

We now formally define the *tree edit distance* as a metric on ordered rooted trees with node labels.

▶ **Definition 2** ((Unweighted) Tree Edit Distance). *Let T_1 and T_2 be two ordered rooted trees whose nodes are labeled with symbols from some alphabet Σ. There are two types of allowed operations:*

- *Relabeling: change the label of a node from one symbol in Σ to another.*
- *Deletion: remove a node.*

Then the tree edit distance between T_1 and T_2, denoted by $\mathsf{ed}(T_1, T_2)$, is the minimum number of operations that must be performed on T_1 and T_2 to obtain two identical forests.

Figure 1 provides an example of these operations in action.

▶ Remark 3. An alternative definition of tree edit distance is the minimum number of insertions, deletions, and relabeling needed to turn one tree into the other. It is easy to see that these two definitions are equivalent.

Since the operations of relabeling and deletion also apply to labeled forests, the above definition naturally extends to measure the edit distance between two *forests* F_1 and F_2, and for the rest of the paper we write $\mathsf{ed}(F_1, F_2)$ to denote this edit distance as well.

Given a forest F, we write L_F (or R_F) to denote the leftmost (or rightmost) tree in F, and write ℓ_F (or r_F) to denote the root of L_F (or R_F). For convenience, let L'_F denote $F - R_F$, and let R°_F denote $R_F - r_F$ (similarly, $R'_F = F - L_F$ and $L^\circ_F = L_F - \ell_F$). Hence, the nodes of a nonempty forest F can be partitioned into three parts: L'_F, r_F, and R°_F (an example is given in Figure 2). Finally, $\mathsf{size}(F)$ or $|F|$ denote the number of nodes in F (where F can also be any subset of nodes).

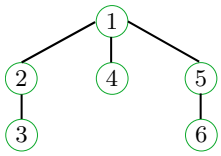

Figure 3 The subforests of this rooted tree are: $\{1,2,3,4,5,6\}, \{2,3,4,5,6\}, \{3,4,5,6\}, \{4,5,6\}, \{5,6\}, \{6\}, \emptyset, \{2,3,4,6\}, \{3,4,6\}, \{4,6\}, \{2,3,4\}, \{3,4\}, \{4\}, \{2,3\}, \{3\}$. For example, the subforest $\{3,4,6\}$ can be obtained by first removing the leftmost root 1, then removing the rightmost root 5, and finally removing the leftmost root 2.

▶ **Definition 4** (Subforest). *Given a rooted tree T, we say F is a* subforest *of T if we can obtain F from T by repeatedly deleting the leftmost or rightmost root.*

An example illustrating the definition of subforests is given in Figure 3.

▶ **Proposition 5.** *A rooted tree T of n nodes has at most $O(n^2)$ subforests.*

Proof. Although a subforest may result from interleaving operations of removing the leftmost root and removing the rightmost root, it is not hard to see that every such subforest F can also be obtained from T by first removing the leftmost root a times, and then removing the rightmost root b times, for some nonnegative integer a, b with $a+b \le n$. Specifically, let u be the node in F with the smallest index $\mathsf{pre}(u)$ in the *preorder traversal* of T ($1 \le \mathsf{pre}(u) \le n$), and we can set $a = \mathsf{pre}(u) - 1$ and $b = n - a - \mathsf{size}(F)$. The claim then follows from the number of choices of (a, b). ◀

For a subforest F of T, define $\mathsf{LCA}_T(F)$ as the lowest common ancestor in T of all nodes in F. When the identity T is clear from context, we may write $\mathsf{LCA}(F)$ and leave the underlying tree implicit. Observe that $\mathsf{LCA}(F)$ is in F precisely when F is a subtree of T.

Throughout, we use T_1, T_2 to denote the input trees (or T if we do not specify which one of the two) we want to compute the edit distance between.

3 Review of Klein's Algorithm

We briefly review Klein's algorithm [24] in the context of computing the unweighted tree edit distance $\mathsf{ed}(T_1, T_2)$ (see [17, 8, 18] for other overviews of this algorithm).

The algorithm uses dynamic programming (DP) over pairs (F_1, F_2), where F_1, F_2 are subforests of T_1, T_2, respectively. Let the node relabeling cost $\delta(x, y) = 1$ if nodes x, y have different labels, and $\delta(x, y) = 0$ otherwise. Then $\mathsf{ed}(F_1, F_2)$ can be computed recursively as follows [40]:

- The base case is where either of F_1, F_2 is empty (denoted as $\emptyset$), and we have

$$\mathsf{ed}(F_1, \emptyset) = \mathsf{size}(F_1), \mathsf{ed}(\emptyset, F_2) = \mathsf{size}(F_2). \tag{1}$$

- When both F_1, F_2 are nonempty, if $\mathsf{size}(L_{F_1}) > \mathsf{size}(R_{F_1})$, then we recurse with

$$\mathsf{ed}(F_1, F_2) = \min \begin{cases} \mathsf{ed}(F_1 - r_{F_1}, F_2) + 1 \\ \mathsf{ed}(F_1, F_2 - r_{F_2}) + 1 \\ \mathsf{ed}(R^\circ_{F_1}, R^\circ_{F_2}) + \mathsf{ed}(L'_{F_1}, L'_{F_2}) + \delta(r_{F_1}, r_{F_2}). \end{cases} \tag{2}$$

- Otherwise, $\mathsf{size}(L_{F_1}) \leq \mathsf{size}(R_{F_1})$, and we recurse with

$$\mathsf{ed}(F_1, F_2) = \min \begin{cases} \mathsf{ed}(F_1 - \ell_{F_1}, F_2) + 1 \\ \mathsf{ed}(F_1, F_2 - \ell_{F_2}) + 1 \\ \mathsf{ed}(L^\circ_{F_1}, L^\circ_{F_2}) + \mathsf{ed}(R'_{F_1}, R'_{F_2}) + \delta(\ell_{F_1}, \ell_{F_2}). \end{cases} \tag{3}$$

Taking Equation (2) as an example, the recursion considers three options concerning the rightmost roots of F_1, F_2: (1) r_{F_1} is removed. (2) r_{F_2} is removed. (3) The two roots are matched to each other, generating two subproblems of matching their subtrees $R^\circ_{F_1}, R^\circ_{F_2}$, and matching the remaining parts L'_{F_1}, L'_{F_2}. The other recursion rule in Equation (3) is symmetric and considers the leftmost roots.

We can easily verify that, if we compute $\mathsf{ed}(T_1, T_2)$ using this recursion, the DP states visited by the recursion are indeed pairs of subforests of T_1 and T_2. We call a subforest F_1 or F_2 which appears in the above dynamic programming procedure a *relevant* subforest. Klein showed the following bound on the number of relevant subforests F_1 of T_1 generated by the DP procedure.

▶ **Lemma 6** (Lemma 3 of [24]). *If we use top-down dynamic programming to compute* $\mathsf{ed}(T_1, T_2)$ *with respect to the recursion defined in Equations* (1)–(3)*, we only ever need to compute* $\mathsf{ed}(F_1, F_2)$ *for* $O(|T_1| \log |T_1|)$ *distinct subforests* F_1 *of* T_1*.*

The proof of this lemma uses a heavy-light decomposition argument, which crucially relies on choosing the "direction" of recursion (Equations (2) and (3)) based on the sizes of the leftmost and rightmost trees in F_1. This improves upon the previous DP algorithm by Zhang and Shasha [40], which always recurses on the rightmost roots and could only give an $O(|T_1|^2)$ bound instead of $O(|T_1| \log |T_1|)$.

Since there are only $O(|T_2|^2)$ possible subforests F_2 of T_2 (Proposition 5), Lemma 6 shows that we can compute $\mathsf{ed}(T_1, T_2)$ in $O(|T_1||T_2|^2 \log |T_1|)$ time. In the next section, we show how to use the assumption that $\mathsf{ed}(T_1, T_2) \leq k$ to bound the number of relevant F_2 as well, and through this get a faster algorithm.

4 Improved Algorithm

4.1 DP state transition graph

Our algorithm builds on Klein's DP algorithm described in Section 3. For the sake of analysis, it is helpful to consider the DP state transition graph, which is a directed acyclic graph with vertices representing the DP states (F_1, F_2) and edges representing DP transitions. Each edge is associated with a proxy cost that lower bounds the true incurred cost when using this transition in the actual DP. These will be based off the trivial lower bound

$$\mathsf{ed}(F_1, F_2) \geq |\mathsf{size}(F_1) - \mathsf{size}(F_2)|, \tag{4}$$

which holds because each operation changes the size of a tree by at most 1, and at the end of applying $\mathsf{ed}(F_1, F_2)$ operations the trees must have the same size.

To define the DP state transition graph, we distinguish three types of DP transition that can occur from following the recursion of Klein's algorithm described in Equations (2) and (3). The first type corresponds to the first two cases of Equations (2) and (3) where we delete the rightmost or leftmost root of the forest. The second and third types of transition capture the two subproblems generated from the third case of Equations (2) and (3) where we match nodes in the trees. Hence, the edges in the DP state transition graph and their proxy costs are defined as follows:

Type 1 (Node Removal) We delete the rightmost (or leftmost) root of F_1 (or F_2).
For example, we can transition $(F_1, F_2) \to (F_1 - r_{F_1}, F_2)$. This transition has cost 1.

Type 2 (Subtree Removal) We remove the rightmost (or leftmost) subtrees of F_1 and F_2.
For example, we can transition $(F_1, F_2) \to (L'_{F_1}, L'_{F_2})$. This transition costs at least $|\mathsf{size}(R_{F_1}) - \mathsf{size}(R_{F_2})|$ by Equation (4) and the last case of Equation (2).

Type 3 (Subtree Selection) We focus on the subtrees below the rightmost (or leftmost) roots of F_1 and F_2.
For example, we can transition $(F_1, F_2) \to (R^\circ_{F_1}, R^\circ_{F_2})$. This transition costs at least $|\mathsf{size}(L'_{F_1}) - \mathsf{size}(L'_{F_2})|$ by Equation (4) and the last case of Equation (2).

4.2 Pruning DP states

Each pair of subforests (F_1, F_2) is a potential state in the DP table. We say a state (F_1, F_2) is "not useful" or *useless* if we do not need to evaluate $\mathsf{ed}(F_1, F_2)$ to compute the overall tree edit distance $\mathsf{ed}(T_1, T_2)$. Having defined the DP state transition graph, we use the following simple observation to label some states as useless.

▶ **Proposition 7** (DP State Pruning Rule 1). *Suppose input trees T_1, T_2 satisfy $\mathsf{ed}(T_1, T_2) \le k$. Then if a state cannot be reached from (T_1, T_2) by traversing a sequence of edges with total cost at most k in the DP state transition graph, that state is useless.*

We will also make use of the following pruning rule, which is a direct application of Equation (4).

▶ **Proposition 8** (DP State Pruning Rule 2). *Suppose input trees T_1, T_2 satisfy $\mathsf{ed}(T_1, T_2) \le k$. If $|\mathsf{size}(F_1) - \mathsf{size}(F_2)| > k$, then the DP state (F_1, F_2) is useless.*

The two pruning rules will enable us to prove the following core result, which shows that when the tree edit distance is bounded, each relevant subforest cannot occur in too many useful states.

▶ **Lemma 9** (Number of useful DP states). *Suppose input trees T_1, T_2 satisfy $\mathsf{ed}(T_1, T_2) \le k$. For each relevant subforest F_1 of T_1, there are at most $O(k^2)$ subforests F_2 of T_2 such that (F_1, F_2) is a useful DP state.*

Lemma 9 together with Lemma 6 immediately shows an $O(nk^2 \log n)$ bound on the number of useful DP states, which will suffice to prove Theorem 1, so in the remainder of this section, we setup the proof of this lemma.

▶ **Definition 10** (Upper parts). *Given a subforest F of T, we partition the nodes of $T \setminus F$ into three disjoint upper parts MU_F, LU_F, and RU_F as follows.*

- *The middle upper part MU_F contains the nodes on the path from the root of T to $\mathsf{LCA}(F)$ (excluding $\mathsf{LCA}(F)$ if $\mathsf{LCA}(F) \in F$).*
- *The left upper part is defined as $LU_F := \{u \in T \setminus MU_F \mid \mathsf{pre}(u) < \mathsf{pre}(v) \text{ for all } v \in F\}$, where $\mathsf{pre}(u)$ denote the index of u in the preorder traversal of T ($1 \le \mathsf{pre}(u) \le |T|$). The right upper part RU_F is defined symmetrically using the postorder traversal of T. Intuitively, LU_F consists of the nodes to the left of the path MU_F, and RU_F consists of the nodes to the right of this path.*

See Figure 4 for some examples.

If a DP state (G_1, G_2) can be reached from (T_1, T_2) in the DP state transition graph, it means that we obtain G_1 and G_2 by removing some nodes in T_1 and T_2 respectively, following the DP transition rules. We classify the removed nodes in $T_1 \setminus G_1$ according to which of

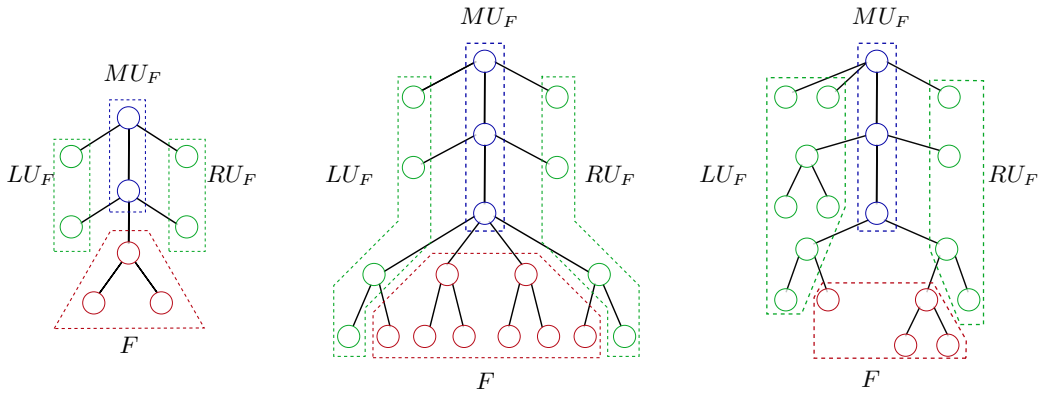

Figure 4 Three examples of subforests F in different underlying trees, with upper parts labeled.

the three upper parts they belong to. For node $v \in T_1 \setminus G_1$, if $v \in LU_{G_1}$ (or $v \in RU_{G_1}$, $v \in MU_{G_1}$), then we say v is *left-removed* (or *right-removed*, *middle-removed*) with respect to subforest G_1. If during a DP transition $(F_1, F_2) \to (G_1, G_2)$, a node $v \in F_1 \setminus G_1$ is left-removed (or right-removed, middle-removed) with respect to not only G_1, but also all subforests $G_1' \subseteq G_1$ (which may be reached by later DP transitions), then we simply say v is left-removed (or right-removed, middle-removed) during this DP transition, without specifying the subforest G_1. The above discussion also similarly applies to the second input tree T_2 and its subforests.

By inspecting the DP transition rules described in Section 4.1, we immediately have the following simple but useful observation.

▶ **Lemma 11.** *Let (F_1, F_2) be a DP state. The following hold:*

- *A type 2 transition from this state either right-removes $\mathsf{size}(R_{F_1})$ nodes, or left-removes $\mathsf{size}(L_{F_1})$ nodes from F_1, depending on whether the right or left subtree were removed.*
- *A type 3 transition from this state either left-removes $\mathsf{size}(F_1 - R_{F_1})$ nodes and middle-removes one node, or right-removes $\mathsf{size}(F_1 - L_{F_1})$ nodes and middle-removes one node from F_1, depending on whether the transition zoomed in on the right or left subtree.*

Similar statements hold for removals in F_2.

Note that in the case of type 1 transitions, we cannot tell whether the node being removed was a left, middle, or right-removal. However, we observe that a type 1 transition always has cost 1. Combining this observation with Lemma 11 and the pruning rule in Proposition 7, we obtain the following property of useful DP states (G_1, G_2):

▶ **Lemma 12.** *If DP state (G_1, G_2) survives the pruning rule in Proposition 7, then*

$$|\mathsf{size}(LU_{G_1}) - \mathsf{size}(LU_{G_2})| \leq k,$$

and

$$|\mathsf{size}(RU_{G_1}) - \mathsf{size}(RU_{G_2})| \leq k.$$

Proof. Consider the sets LU_{G_1} and LU_{G_2} of left-removed nodes in G_1 and G_2. Suppose k_1 nodes of LU_{G_1} and k_2 nodes of LU_{G_2} were removed by type 1 transitions, incurring a total cost of $k_1 + k_2$. The remaining $\mathsf{size}(LU_{G_1}) - k_1$ nodes in LU_{G_1} and $\mathsf{size}(LU_{G_2}) - k_2$ nodes in LU_{G_2} must be the result of type 2 and 3 transitions.

From Lemma 11 and the discussion in Section 4.1, we know that when a type 2 or 3 transition t left-removes $c_1^{(t)}$ nodes from T_1 and $c_2^{(t)}$ nodes from T_2, the incurred cost is at least $|c_1^{(t)} - c_2^{(t)}|$. Then by triangle inequality, the total cost from all type 2 and 3 transitions is at least

$$\sum_t \left|c_1^{(t)} - c_2^{(t)}\right| \geq \left|\sum_t c_1^{(t)} - \sum_t c_2^{(t)}\right| = \left|(\mathsf{size}(LU_{G_1}) - k_1) - (\mathsf{size}(LU_{G_2}) - k_2)\right|,$$

where the sum is over all type 2 and 3 transitions t leading from state (T_1, T_2) to state (G_1, G_2). Then, by applying triangle inequality once more, the total cost from all transitions is at least

$$k_1 + k_2 + \left|(\mathsf{size}(LU_{G_1}) - k_1) - (\mathsf{size}(LU_{G_2}) - k_2)\right| \geq \left|\mathsf{size}(LU_{G_1}) - \mathsf{size}(LU_{G_2})\right|.$$

This proves the first inequality. The second inequality follows from identical reasoning, applied to the right-removed instead of the left-removed nodes of G_1 and G_2. ◀

We have just derived the useful Lemma 12 from the first pruning rule in Proposition 7. To prove Lemma 9, we still need to apply the second pruning rule in Proposition 8 as well. We will use the following lemma.

▶ **Lemma 13.** *Given three integers a, b, c, the number of subforests F of a tree T which simultaneously satisfy $|\mathsf{size}(LU_F) - a| \leq k$, $|\mathsf{size}(RU_F) - b| \leq k$, and $|\mathsf{size}(F) - c| \leq k$ is at most $O(k^2)$.*

Before proving Lemma 13, we show that it implies the desired upper bound on the number of useful DP states that survive both pruning rules in Proposition 7 and Proposition 8.

Proof of Lemma 9 given Lemma 13. We are given a relevant subforest F_1 of T_1, and want to bound the number of subforests F_2 of T_2 such that (F_1, F_2) is a useful state. By Lemma 12, the state (F_1, F_2) is useful only if

$$\left|\mathsf{size}(LU_{F_2}) - a\right|, \left|\mathsf{size}(RU_{F_2}) - b\right| \leq k$$

for $a = \mathsf{size}(LU_{F_1})$ and $b = \mathsf{size}(RU_{F_1})$. Moreover, by Proposition 8 if the state is useful then

$$\left|\mathsf{size}(F_2) - c\right| \leq k$$

for $c = \mathsf{size}(F_1)$. Hence, applying Lemma 13 with $T = T_2$ immediately implies that there are $O(k^2)$ possibilities for F_2, which proves the desired result. ◀

4.3 Proof of Lemma 13

Suppose $\mathsf{size}(LU_F) = \ell$ and $\mathsf{size}(RU_F) = r$ for some integers ℓ and r within k of a and b respectively. Then we claim the following algorithm outputs all possible subforests F satisfying the hypotheses of the lemma:

1. Initialize $F = T$ as the given tree.
2. While $\ell \neq 0$ or $r \neq 0$:
   a. If F has only root remaining, delete this root (middle-removal) from F
   b. Otherwise, F has more than one root remaining:
      i. If $\mathsf{size}(L_F) \leq \ell$: remove the leftmost tree and update $\ell \leftarrow \ell - \mathsf{size}(L_F)$
      ii. Else if $\mathsf{size}(R_F) \leq r$: remove the rightmost tree and update $r \leftarrow r - \mathsf{size}(R_F)$
      iii. Otherwise remove the leftmost root ℓ times, remove the rightmost root r times, and return F *(unique solution case)*

3. If F has one root remaining: repeatedly remove the only root (middle-removal) until we no longer have a single root. Return all the forests encountered during this procedure as possible solutions of F *(multiple solutions case)*
4. Otherwise, F has more than one root remaining: return F *(unique solution case)*

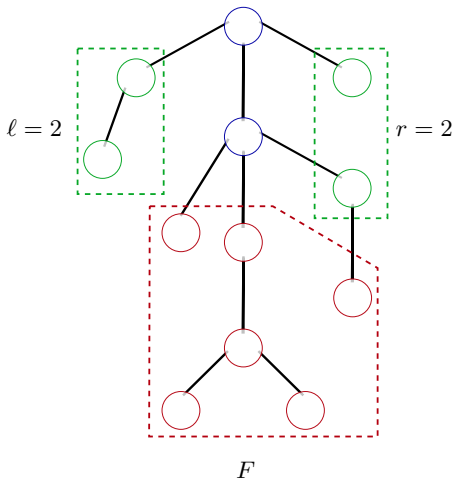

Figure 5 An example of the unique solution case, where $\ell = 2$ and $r = 2$.

At each step of the algorithm, we are either at a state with multiple roots or at a state with one root. In the former case, we have to left-remove or right-remove which we do (unless we have already left-removed ℓ times and right-removed r times, in which case we halt). In the latter case, if we still have not left-removed or right-removed the full number of times, we must keep middle-removing until we can make left or right removals. Terminating in one of these states corresponds to the *unique solution* cases of the algorithm (at step 2(b)iii or step 4). An example is given in Figure 5.

In these situations, the algorithm halts on the unique subforest F of T with $\mathsf{size}(LU_F) = \ell$ and $\mathsf{size}(RU_F) = r$. Since there are $O(k)$ possible values for ℓ and r individually, we get that there are at most $O(k^2)$ distinct subforests F which can be outputted as a "unique solution" in the above procedure.

The only other possibility is that we find ourselves in step 3 of the algorithm at a point where we have already left-removed ℓ times and right-removed r times, and there is only one root u remaining. In this case F might not be uniquely determined: we can continue to middle-remove the remaining root for some number of times and then return a possible solution of F. Formally, let w be the deepest descendant of the remaining root u, such that for every node v on the path from w to u, v has no siblings. Then, for every such node v, the subtree rooted at v (denoted T_v) and $T_v - v$ can be a valid solution for F. This describes the *multiple solutions case* annotated in step 3 of the above procedure. An example of the multiple solutions case is given in Figure 6.

By the above discussion, a subforest F from the multiple solutions case can be determined uniquely by the identity of the lowest common ancestor $v = \mathsf{LCA}(F)$, and the choice of whether v is in F or not. We now prove that, over all choices of valid ℓ and r, there are only $O(k)$ many possibilities for the node v. Combined with the unique solution case, this will immediately finish the proof of the lemma.

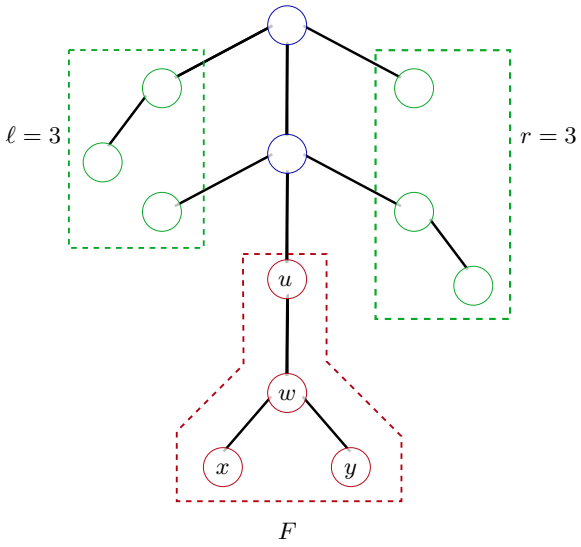

Figure 6 An example of the multiple solutions case, where $l = 3, r = 3$. Before executing step 3 of the algorithm, the remaining F consists of $\{u, w, x, y\}$. Then the algorithm returns three possible solutions: $\{u, w, x, y\}, \{w, x, y\}$, and $\{x, y\}$.

We first consider the case where, among all possible node choices for v, there are two such that neither is an ancestor of the other. Then pick the leftmost (with respect to post-order traversal) and the rightmost (with respect to preorder traversal) of such possibilities for v, denoted v_1 and v_2 respectively. Let G_1 and G_2 be the subtrees in T rooted at v_1 and v_2, respectively. Then by the assumptions on F we necessarily have

$$|\mathsf{size}(RU_{G_1}) - b|, |\mathsf{size}(RU_{G_2}) - b| \leq k.$$

Note that $RU_{G_2} \subseteq RU_{G_1}$. Write $D = RU_{G_1} \setminus RU_{G_2}$ for the difference of the right upper part of G_1 and the right upper part G_2. Thus, by triangle inequality, we get that

$$\mathsf{size}(D) = \mathsf{size}(RU_{G_1}) - \mathsf{size}(RU_{G_2}) \leq 2k.$$

By our choice of v_1 and v_2, we know that any possible choice for v is either a node in D or an ancestor of v_1. For the former case, we have already shown that there are at most $O(k)$ nodes in D. In the latter case, each distinct v which is an ancestor of v_1 determines a subforest F of a different size. Then because we are assuming that $|\mathsf{size}(F) - c| \leq k$, there are only $O(k)$ possibilities for the choices of v which are ancestors of v_1.

The previous argument applies whenever there are two choices for v, neither of which is an ancestor of the other. If there do not exist such options for v, then all possible choices of v lie on the a single root-to-leaf path of T. By the same reasoning as before, the number of possible cases for v here is again at most $O(k)$, because each v would determine a different-sized subforest and $\mathsf{size}(F)$ is allowed to take on $O(k)$ distinct values.

This completes the proof of Lemma 13. As noted earlier, this implies Lemma 9. We conclude by tying these results back to our main theorem.

Proof of Theorem 1. Set up a table which can be indexed by pairs of subforests (F_1, F_2) of T_1 and T_2. Begin using Klein's dynamic programming approach outlined in Section 3 and Lemma 6 but avoid generating subproblems according to the pruning rules described

in Proposition 7 and Proposition 8, and store solutions $\mathsf{ed}(F_1, F_2)$ produced. In particular, when Klein's algorithm would normally generate a subproblem, we first check if the produced subproblem would be a useful state according to our previous definitions. Proposition 8 and the proof of Lemma 13 make it clear that we can quickly check if a state is useful provided we know the sizes of $F_1, F_2, LU_{F_1}, RU_{F_1}, LU_{F_2}$, and RU_{F_2}, and this information can be kept track of easily simply by updating the sizes according to the type of transition we follow in the table.

So, we can compute $\mathsf{ed}(T_1, T_2)$ while only computing $\mathsf{ed}(F_1, F_2)$ for useful states. By Lemma 6 there are $O(n \log n)$ possibilities for F_1 and by Lemma 9 there are $O(k^2)$ choices for F_2 for each F_1. So overall we only fill in at most $O(nk^2 \log n)$ entries of the DP table. Since we do a constant amount of work to get the value at each entry of the table, our algorithm has the desired running time. ◀

5 Open problems

For trees of bounded edit distance $k = O(1)$ our algorithm runs in linear time. However, for larger tree edit distances $k = \Theta(n)$ our algorithm requires $O(n^3 \log n)$ time, which is slower than the fastest known algorithm [17] for general tree edit distance by a logarithmic factor. This motivates the question: can we solve the bounded tree edit distance problem in $O(nk^2)$ time instead of $O(nk^2 \log n)$?

The easier problem of *string* edit distance can be solved in $\widetilde{O}(n + k^2)$ time [30, 28], which is quasilinear even for super constant distance parameter $k = O(\sqrt{n})$. This motivates the question of whether it is possible to get similar speedups for tree edit distance. It would be especially interesting to see if the bounded tree edit distance problem can be solved in $\widetilde{O}(n + k^3)$ time. Perhaps the suffix tree techniques used in [33] (and discussed in [11, Appendix]) could prove useful in showing such a result.

Regarding variants of tree edit distance, it remains an open question to get faster algorithms for the harder problem of *unrooted* tree edit distance [24, 18] (where the elementary operations are edge contraction, insertion, and relabeling) when the distance is bounded by k. The best known algorithm for unrooted tree edit distance was recently given by Dudek and Gawrychowski [18] and runs in $O(n^3)$ time. The previous $O(n^3 \log n)$ time algorithm by Klein [24] also applies to the unrooted setting. Although we extended Klein's algorithm to tackle the rooted tree edit distance problem in $O(nk^2 \log n)$ time, it is not obvious how to extend their approach to the unrooted bounded distance setting. This is because Klein solves the unrooted version of the problem by dynamic programming over the subproblems generated by all possible rootings of T_2. This is fine for computing general edit distance because the number of subforests over all possible rootings is $O(n^2)$ just like the number of subforests for a fixed rooted tree on n nodes. However, when the tree edit distance is bounded, the number of possible relevant subproblems over all possible rootings can be $\Omega(n)$ even when k is small. Although our algorithm can be used to recover a near quadratic time algorithm for unrooted tree edit distance when $k = O(1)$ is constant, it remains open whether we can obtain a quasilinear time algorithm in this setting.

Finally, although general tree edit distance with *arbitrary weights* cannot be solved in truly subcubic time unless certain popular conjectures are false [13], analogous fine-grained hardness results rule out truly subquadratic time algorithms for string edit distance even when deletions and insertions have unit cost [6]. Can we show conditional hardness for tree edit distance with unit costs, or can we find a subcubic time algorithm for this problem?

Improved Approximation for Longest Common Subsequence over Small Alphabets

Abstract

This paper investigates the approximability of the Longest Common Subsequence (LCS) problem. The fastest algorithm for solving the LCS problem exactly runs in essentially quadratic time in the length of the input, and it is known that under the Strong Exponential Time Hypothesis the quadratic running time cannot be beaten. There are no such limitations for the approximate computation of the LCS however, except in some limited scenarios. There is also a scarcity of approximation algorithms. When the two given strings are over an alphabet of size k, returning the subsequence formed by the most frequent symbol occurring in both strings achieves a $1/k$ approximation for the LCS. It is an open problem whether a better than $1/k$ approximation can be achieved in truly subquadratic time ($O(n^{2-\delta})$ time for constant $\delta > 0$).

A recent result [Rubinstein and Song SODA'2020] showed that a $1/2 + \epsilon$ approximation for the LCS over a binary alphabet is possible in truly subquadratic time, provided the input strings have the same length. In this paper we show that if a $1/2 + \epsilon$ approximation (for $\epsilon > 0$) is achievable for binary LCS in truly subquadratic time when the input strings can be unequal, then for every constant k, there is a truly subquadratic time algorithm that achieves a $1/k + \delta$ approximation for k-ary alphabet LCS for some $\delta > 0$. Thus the binary case is the hardest. We also show that for every constant k, if one is given two strings of *equal* length over a k-ary alphabet, one can obtain a $1/k + \epsilon$ approximation for some constant $\epsilon > 0$ in truly subquadratic time, thus extending the Rubinstein and Song result to all alphabets of constant size.

1 Introduction

In a large variety of applications, from spell-checkers to DNA sequence alignment, one seeks to compute how similar two given sequences of letters are. Arguably the most popular measures of sequence similarity are the *longest common subsequence (LCS)* and the *edit distance*. The LCS of two given sequences A and B (as the name suggests) measures the maximum length of a sequence whose symbols appear in both A and B in the same order. The edit distance, on the other hand, measures how far apart two strings are by counting the minimum number of insertions, deletions and substitutions of characters that must be performed on one string to transform it into the other. These two measures are related: the complement of the LCS is the version of edit distance in which one minimizes only the

licensed under Creative Commons License CC-BY 4.0

number of insertions and deletions (in fact, both versions of edit distance are the same up to a factor of 2, so with respect to constant factor approximation algorithms they are equivalent). Both the LCS and the edit distance of two length n strings can be computed in $O(n^2)$ time using a classic dynamic programming approach. The fastest algorithm for both problems is the $O(n^2/(\log n)^2)$ time algorithm of Masek and Paterson [20].

Hardness results from fine-grained complexity have shown that truly subquadratic time algorithms (those running in time $O(n^{2-\delta})$ for some constant $\delta > 0$) for LCS and edit distance cannot exist under the Strong Exponential Time Hypothesis [2, 9, 14] and other even more believable hypotheses [3, 16]. Consequently, much of the recent interest around LCS and edit distance has concerned approximation algorithms for the problems. A long chain of progress on edit distance approximation (e.g. [19, 11, 19, 10, 8, 6, 12]) has culminated in the breakthrough constant-factor approximation algorithm of [15] running in truly subquadratic time. Several improvements followed this breakthrough including [5, 18, 13], with the most recent result being a constant factor approximation algorithm running in near linear time [7].

In contrast, much less is known about how well LCS can be approximated in truly subquadratic time. For inputs over non-constant size alphabets, some fine-grained hardness results [1, 4, 16] and nontrivial super-constant approximations [17] are known. When the input strings come from a fixed alphabet of constant size k, there is a trivial $1/k$-approximation algorithm that returns in linear time the longest common *unary* subsequence of two inputs. Despite the simplicity of this algorithm, until recently no better constant-factor approximation algorithm was known for *any* constant size alphabet. There are also no existing hardness results that rule out better approximation algorithms.

Recently, for the case of *binary* strings of *equal* length, Rubinstein and Song [21] were able to improve upon the simple 1/2-approximation algorithm described above, obtaining for some constants $\epsilon, \delta > 0$ an $O(n^{2-\delta})$ time algorithm that returns a $(1/2 + \epsilon)$-approximation. It is still open, however, whether one can obtain such an algorithm for binary strings of unequal length, and whether one can extend the result to achieve a truly subquadratic time algorithm achieving a better than k-approximation for strings over an alphabet of size k, for every constant k.

Our results

In this paper we present two results. The first result shows that if one can obtain a truly subquadratic time, better than 2-approximation algorithm for the LCS of binary strings of possibly unequal lengths, then one can use this algorithm to obtain a truly subquadratic time, better than k-approximation algorithm for the LCS of strings over a k-ary alphabet, for any constant k.

▶ **Theorem 1.** *For any fixed integer $k \geq 2$ there is an $O(n)$ time algorithm that given an instance of LCS for strings of length at most n over an alphabet of size k, reduces it to $O(k^2)$ instances of LCS over* binary *strings of length at most n, so that $(1/2 + \epsilon)$-approximate solutions (for $\epsilon > 0$) for these LCS instances can be translated in $O(n)$ time into a $(1/k + \epsilon_k)$ approximation of the k-ary alphabet LCS instance, where $\epsilon_k > 0$ is a constant only depending on ϵ and k.*

In other words, in order to beat the longstanding $1/k$-approximation algorithm for LCS, one merely needs to obtain a better than 1/2 approximation for the binary case, i.e. to extend the Rubinstein and Song result to strings of possibly unequal length.

Our second result generalizes the Rubinstein-Song result by proving that one can beat the simple $1/k$-approximation algorithm for every constant k, as long as the input strings have equal length.

▶ **Theorem 2.** *Given two strings A and B of length n over an arbitrary alphabet of size k, there exist positive constants ϵ and δ such that we can compute a $1/k + \epsilon$ approximation for the longest common subsequence of A and B in $O(n^{2-\delta})$ time.*

In fact, our algorithm can actually $(1/k + \epsilon)$-approximate the LCS in near-linear time. Note that our result applies only to strings with equal input lengths. The relevance of this restriction is discussed in Section 2, which also contains the proof of Theorem 1. We present the proof of Theorem 2 in Section 3.

Preliminaries

We write approximation ratios as constants less than 1, so that for example a $1/2 + \epsilon$ approximation algorithm for the LCS of A and B is an algorithm that returns a common subsequence of A and B with length at least $(1/2 + \epsilon) \cdot \text{LCS}(A, B)$.

When we discuss edit distance in the rest of the paper we mean the version of edit distance that does not allow symbol substitutions but only measures the number of insertions and deletions. For constant factor approximation algorithms, this version of the problem is equivalent to the original.

2 Reduction to Binary Alphabets & Input Length Conditions

We begin by showing how to reduce nontrivial constant factor approximations of LCS over large alphabets to better than 1/2 approximations of LCS over binary alphabets. Although we do not directly apply this reduction in our proof of Theorem 2, the reduction is elegant and motivates the approach we end up using. Moreover, the reduction works even for strings of non-equal lengths, thus showing that one merely needs to extend the Rubinstein-Song result to non-equal length strings in order to truly improve upon the trivial alphabet-size approximation algorithm. We will need the following definition.

▶ **Definition 3** (Restrictions). *Given an alphabet Σ, we call a subset $\Sigma' \subseteq \Sigma$ a* subalphabet. *Given a string A from alphabet Σ the* restriction *of A to a subalphabet Σ' is the maximum subsequence of A whose characters are all in Σ'.*

▶ **Theorem 4.** *Fix integers s and ℓ with $s > \ell \geq 2$. Suppose that there is a $T(n, \ell)$ time algorithm that achieves an $1/(\ell - \epsilon)$-approximation of the LCS of two strings of length at most n from an alphabet of size ℓ. Then, there is also a $O((n + T(n, \ell))\binom{s}{\ell})$ time algorithm that achieves an $1/(s(1 - \epsilon/\ell))$-approximation of the LCS of two strings of length at most n from an alphabet of size s.*

Proof. We will show how to reduce the LCS for two strings of length at most n over a s-ary alphabet, to the LCS for two strings of length at most n over an ℓ-ary alphabet for any $\ell < s$. The reduction runs in $O(n\binom{s}{\ell})$ time and produces $\binom{s}{\ell}$ instances of ℓ-ary alphabet LCS.

Let A and B two strings of length at most n over an alphabet Σ of size s. Let C be the longest common subsequence of A and B (we do not know C). For the sake of argument, sort the alphabet symbols according to their number of occurrences in C.

Let x be the collection of the ℓ most frequent alphabet symbols in C. Let C_x be the subsequence of C obtained by restricting C to the subalphabet of Σ that contains the symbols of x. Since x has the ℓ most frequent symbols in C, C_x contains at least an ℓ/s fraction of C.

Now, let us describe our algorithm. Given A and B, we consider all subsets of the alphabet consisting of precisely ℓ symbols (one of these subsets will be x.) For each such collection y, consider the sub-instance of the LCS instance restricted to the symbols of y. Let $\text{OPT}(y)$ be the optimal LCS for this instance.

We know that $|\operatorname{OPT}(x)| \geq |C_x| \geq (\ell/s)|C|$. So when we consider $y = x$, if we can efficiently obtain an $1/(\ell - \epsilon)$ approximation for $\operatorname{OPT}(x)$, we will get a common subsequence of A and B of length at least

$$\frac{|\operatorname{OPT}(x)|}{\ell - \epsilon} \geq \frac{|C|}{s(1 - \epsilon/\ell)},$$

and thus yields the desired approximation for the LCS of A and B. The running time is multiplied by $\binom{s}{\ell}$ which is a constant, as long as s is. ◀

By setting $\epsilon = \ell\delta s/(1+\delta s)$ in the above Theorem statement, we obtain a linear time reduction from obtaining a $1/s+\delta$-approximation for s-ary strings to a $1/\ell+(\delta s)/\ell$-approximation for ℓ-ary strings. We obtain Theorem 1 as a corollary:

▶ **Corollary 5.** *Fix an integer $s \geq 3$ and a constant $\delta > 0$. The problem of obtaining a $1/s + \delta$ approximation for the LCS of two strings from an alphabet of size s can be reduced in linear time to the problem of obtaining a $1/2 + (\delta s)/2$ approximation for the LCS of two strings binary strings (i.e. strings from an alphabet of size two).*

Proof. This follows from Theorem 4 by taking $\ell = 2$. The reduction has $O(s^2)$ overhead. ◀

The reason we cannot prove Theorem 2 by combining Corollary 5 with the result of [21] is that the latter gives a better than $1/2$ approximation for strings from an alphabet of size 2 only when the input strings have *equal length*. Note that in the reduction from the proof of Theorem 4, the subsequences obtained from restrictions to subalphabets may be of different lengths even if the original strings have equal lengths.

Although at first it may seem that extending the Rubinstein-Song result to strings of differing length should not be too hard, generalizing the result does not appear straightforward. In the following we will discuss why this not simple. The main hurdles come from the lemma and algorithm used in [21] stated below.

▶ **Lemma 6** (LCS and Edit Distance Connection). *For any strings X and Y of length n and m respectively, we have*

$$2 \cdot \operatorname{LCS}(X, Y) + \operatorname{ED}(X, Y) = n + m.$$

For the sake of completeness, we include a proof of the above lemma.

Proof. Consider an optimal alignment between X and Y, which matches the maximum possible number of characters of X with identical characters of Y while respecting the order in which the characters appear in each string. The characters that are matched in X and Y correspond to a longest common subsequence. This is because if there were a longer common subsequence, we could get a larger alignment by matching the characters of the subsequence in X and Y, but this would contradict the optimality of X and Y.

Similarly, the unmatched characters correspond to a minimum set of symbols that need to be deleted from X and inserted from Y to turn X into Y. If there were a smaller edit distance computation, then all the characters which were not deleted or inserted could be paired up to form a larger alignment, again contradicting optimality.

Thus there are exactly $2 \cdot \operatorname{LCS}(X, Y)$ characters paired up in the alignment and $\operatorname{ED}(X, Y)$ unmatched characters. These encompass all the characters in X and Y, and thus account for $n + m$ symbols. ◀

▶ **Definition 7** (Approximating LCS through Edit Distance). *Given strings A and B of length n, the algorithm* ApproxED(A, B) *approximates the edit-distance between A and B and then returns the lower bound on the LCS implied by this. More precisely, the algorithm computes an approximate edit distance* $\widetilde{\text{ED}}(A, B)$ *and then returns*

$$n - \frac{1}{2} \cdot \widetilde{\text{ED}}(A, B). \tag{1}$$

As stated ApproxED can use any edit distance approximation $\widetilde{\text{ED}}$ as a black box. For concreteness, we will take $\widetilde{\text{ED}}$ to be the edit distance algorithm from [5] which can achieve an approximation ratio of c for any constant $c > 3$ and runs in truly subquadratic time.

In [21], the authors use the ApproxED algorithm to handle the case of binary strings with large LCS. In this case, they notice that if the LCS is large then the edit distance must be small. Then constant factor approximations to edit distance will give good lower bounds on the LCS because in the calculation from Equation (1) we are subtracting off a small quantity from the maximum possible LCS value of n.

However, if we tried extending this algorithm to the case where the inputs X and Y have lengths n and m with $n = 100m$ (for example) by using the identity from Lemma 6, then even when the LCS is large (say of length $(1 - \epsilon)m$ for some small positive ϵ) the edit distance will still be very large compared to the length of the smaller string (at least $(99 + \epsilon)m$). So even a 3-approximation to edit-distance would incur massive error when trying to approximate LCS by computing

$$\frac{1}{2} \cdot \left(n + m - \widetilde{\text{ED}}(X, Y)\right)$$

and the result would not give any nontrivial lower bound for the LCS. In other words, when the input strings have very different lengths it is not clear how to use approximate edit distance in general to obtain good approximations for LCS. This is essentially why the algorithm from [21] and Theorem 2 both require equal length inputs.

3 Extending Alphabet Size

This section proves Theorem 8 which restates Theorem 2 from the introduction slightly.

▶ **Theorem 8.** *Given two strings A and B of length n over an arbitrary alphabet Σ of size s, there exist a positive constant ϵ such that we can compute a $1/s + \epsilon$ approximation for the longest common subsequence* LCS(A, B) *of A and B in truly subquadratic time.*

Throughout the rest of this section, we assume A and B refer to strings satisfying the conditions of Theorem 8 and that $s \geq 3$. We begin by establishing lemmas corresponding to easy instances of the problem. The following definition is useful for identifying these easy cases.

▶ **Definition 9** (Balanced Strings). *Given a string A of length n from an alphabet of size s and a parameter $\rho > 0$, we say a string is* ρ-balanced *if all its character frequencies are within ρn of n/s.*

▶ **Lemma 10** (Balanced Inputs, adapted from Lemma 3.2 of [21]). *For all sufficiently small $\rho > 0$, if either A or B is ρ-balanced, we can $(1/s + \gamma)$-approximate* LCS(A, B) *in truly subquadratic time, where γ is some positive constant depending on ρ.*

Proof. We reduce the problem to approximating the edit distance between A and B.

Without loss of generality assume A is ρ-balanced. This means that all of its character frequencies are at least $(1/s - \rho)n$. So there exists a unary common subsequence of A and B of at least this length. If this is a $(1/s + \gamma)$ approximation we are done. Otherwise the LCS must be quite large:

$$\mathrm{LCS}(A, B) > s(1/s - \rho)n - s\gamma n = (1 - s(\rho + \gamma))n.$$

Recall from Lemma 6 that

$$\mathrm{ED}(A, B) + 2 \cdot \mathrm{LCS}(A, B) = 2n,$$

where $\mathrm{ED}(A, B)$ denotes the (no substitutions) edit distance of A and B. Using the ED approximation of [5] with some approximation ratio $c > 3$ we recover an LCS approximation of length at least

$$n - c\,(n - \mathrm{LCS}(A, B)) > n\,(1 - cs(\rho + \gamma))$$

so as long as we have $1 - cs(\rho + \gamma) \geq 1/s + \gamma$, this approximation is strong enough. This inequality holds when

$$\gamma \leq \frac{s - 1 - cs^2\rho}{s(1 + cs)}.$$

We can ensure it does by picking ρ small enough that the numerator of the right hand side above is positive and then taking γ smaller than the right hand side. Note that smaller values of ρ correspond to larger values of γ. ◀

▶ **Lemma 11** (Balanced LCS). *If the LCS of A and B is not ρ-balanced, then in linear time we can $(1/s + \rho/(s-1))$-approximate* $\mathrm{LCS}(A, B)$.

Proof. Returning the longest common unary subsequence gives the desired approximation. To see this, let $\sigma_{\max}$ and $\sigma_{\min}$ be the most frequent and least frequent characters in the LCS respectively. Since the LCS is not balanced, either $\sigma_{\max}$ makes up more than a $(1/s + \rho)$ fraction of all symbols in the LCS, or $\sigma_{\min}$ makes up fewer than a $(1/s - \rho)$ fraction of the symbols in the LCS.

In the latter case, the $s - 1$ members of the alphabet besides $\sigma_{\min}$ must account for at least an $((s-1)/s + \rho)$ fraction of characters in the LCS. Among these, $\sigma_{\max}$ appears the most often, which means by averaging that $\sigma_{\max}$ accounts for at least a

$$\frac{1}{s} + \frac{\rho}{s - 1}$$

fraction of all symbols in the LCS.

In either case, $\sigma_{\max}$ makes up at least a $(1/s + \rho/(s-1))$ fraction of the symbols in the LCS. Then the string consisting of $\sigma_{\max}$ repeated $\min(\sigma_{\max}(A), \sigma_{\max}(B))$ times is a common subsequence of A and B which has at least as many instances of $\sigma_{\max}$ as the LCS does, and thus yields the desired approximation. ◀

After handling these easy cases, our approach is to restrict A and B to binary strings and invoke the frequency arguments from previous work. As we noted before, we cannot directly use the reduction in Corollary 5 because the better than 1/2 approximation of [21] only applies when the inputs have the same length. It turns out however, that the arguments

of [21] *do* hold for strings of differing length as long as the inputs satisfy a nice frequency condition. The following lemma demonstrates how by careful choice of subalphabets we can find restrictions meeting this condition. To describe this condition, we introduce some new notation: given a string A from an alphabet Σ, for any symbol $\sigma \in \Sigma$ we let $\sigma(A)$ denote the number of times σ appears in A.

▶ **Lemma 12** (Binary Restriction). *Suppose neither A nor B are ρ-balanced. Then there exists $\Sigma' \subseteq \Sigma$ with $|\Sigma'| = 2$ such that the restrictions of A and B to Σ' are not ρ/s-balanced.*

Proof. Let $\alpha_1 \leq \cdots \leq \alpha_s$ be the number of times the distinct symbols $\sigma_1, \ldots, \sigma_s$ of Σ appear respectively in A, so that σ_s is the most frequent symbol of A and σ_1 is the least common character in A. By averaging we know that $\alpha_s \geq n/s \geq \alpha_1$. Since A is not ρ-balanced we deduce that

$$\alpha_s - \alpha_1 > \rho n.$$

We can decompose the left hand side of the above equation to

$$\alpha_s - \alpha_1 = \sum_{i=2}^{s} (\alpha_i - \alpha_{i-1}).$$

Since all the summands on the right hand side are positive, there exists some index j with

$$\alpha_j - \alpha_{j-1} > (\rho/s)n. \tag{2}$$

Note that we can find such a j in linear time by scanning through A and B and keeping counts of all the characters that appear. Now, consider the $(s-1)$ two-element sets

$$\{\sigma_s, \sigma_{j-1}\}, \{\sigma_{s-1}, \sigma_{j-1}\}, \ldots, \{\sigma_j, \sigma_{j-1}\}, \{\sigma_j, \sigma_{j-2}\}, \ldots, \{\sigma_j, \sigma_1\}. \tag{3}$$

We claim that one of these sets satisfies the properties of Σ' from the lemma statement. First, note that Equation (2) ensures that the restriction of A to any of the above sets is not ρ/s-balanced, so it suffices to verify that the restriction of B will not be balanced for one of these sets. Suppose to the contrary that none of the sets from Equation (3) satisfies the desired conditions. We will use a triangle-inequality argument on the character frequencies of B to derive a contradiction. Let M and m be indices such that σ_M is the most frequent character of B and σ_m is the least frequent. Since B is not ρ-balanced, we know that $M \neq m$. If $M \geq j > m$ we may write

$$|\sigma_M(B) - \sigma_m(B)| \leq |\sigma_M(B) - \sigma_{j-1}(B)| + |\sigma_{j-1}(B) - \sigma_j(B)| + |\sigma_j(B) - \sigma_m(B)|.$$

By assumption, the restrictions of B to the sets $\{\sigma_M, \sigma_{j-1}\}$, $\{\sigma_j, \sigma_{j-1}\}$, and $\{\sigma_j, \sigma_m\}$ are (ρ/s)-balanced. Thus, each addend on the right hand side of the above inequality is bounded above by $(\rho/s)n$. It follows that

$$|\sigma_M(B) - \sigma_m(B)| \leq (3\rho/s)n.$$

By similar reasoning, if $m = j$ and $M \geq j$ then we have

$$|\sigma_M(B) - \sigma_m(B)| = |\sigma_M(B) - \sigma_j(B)| \leq |\sigma_M(B) - \sigma_{j-1}(B)| + |\sigma_{j-1}(B) - \sigma_j(B)| \leq (2\rho/s)n.$$

If instead $M, m > j$ we know that

$$|\sigma_M(B) - \sigma_m(B)| \leq |\sigma_M(B) - \sigma_{j-1}(B)| + |\sigma_{j-1}(B) - \sigma_m(B)| \leq (2\rho/s)n$$

since now the subalphabets $\{\sigma_M, \sigma_{j-1}\}$ and $\{\sigma_m, \sigma_{j-1}\}$ both occur in Equation (3). Similar reasoning on the remaining cases of the values of M and m relative to j to establishes the inequality

$$\sigma_M(B) - \sigma_m(B) \leq (3\rho/s)n.$$

We have dropped absolute value signs because the left hand side of the above equation is positive by definition of M and m. Since $s \geq 3$ this contradicts the assumption that B is not ρ-balanced, and the desired result follows. Note that we can find which of subalphabets from Equation (3) satisfies the conditions of the lemma in $O(n + s)$ time by scanning through B to get the counts of each of its characters and trying out all the restrictions. ◀

In our proof of Theorem 2, we will require a stronger form of the result from Section 4 of [21]. This variant of their theorem is useful because it applies to strings of different length.

▶ **Lemma 13.** *Let X and Y be binary strings of length n and m respectively, where $m \leq n$. Suppose the frequencies $0(Y)$ and $1(X)$ are both at most $(1/2-\rho)m$ for some positive constant ρ. Then there exist positive constants δ and ϵ such that if $0(Y)$ and $1(X)$ are within δm of each other, we can compute a $(1/2+\epsilon)$ approximation of $\mathrm{LCS}(X, Y)$ in subquadratic time.*

Although the realization that this type of result holds for strings of differing length is novel, the proof of Lemma 13 itself is conceptually identical to the frequency analysis used in [21], requiring only minor changes to make the argument go through. For completeness we include the detailed casework proof of this result in Section 4.

Finally we apply a lemma that provides some frequency information about the strings.

▶ **Lemma 14** (Lemma 3.1 from [21])**.** *For any $\delta > 0$ if*

$$\min(0(X), 0(Y)) > (1+\delta)\min(1(X), 1(Y))$$

or

$$\min(1(X), 1(Y)) > (1+\delta)\min(0(X), 0(Y))$$

then there is a unary $(1+\delta)/(2+\delta)$ approximation for $\mathrm{LCS}(X, Y)$.

Proof. Observe that for any binary strings X and Y we have

$$\mathrm{LCS}(X, Y) \leq \min(0(X), 0(Y)) + \min(1(X), 1(Y)). \tag{4}$$

This equation holds because the LCS is a subsequence of X and Y, and thus cannot contain more zeros or ones than either of the strings X or Y individually have.

Suppose by symmetry that $\min(0(X), 0(Y))$ is the larger of the two addends on the right. Then the we can return the all zeros string of this length. By the first inequality we get

$$\min(0(X), 0(Y)) > (1+\delta)(\mathrm{LCS}(X, Y) - \min(0(X), 0(Y)))$$

and then rearranging proves the claim. ◀

We now combine these results to improve LCS approximation on all alphabets.

Proof of Theorem 8. Let ρ and ρ' be positive parameters whose values will be specified later. If either of the strings A or B are ρs-balanced, we are done by Lemma 10 (by taking ρ to be small enough so that the lemma applies). If the LCS of A and B is not ρ'-balanced we are done by Lemma 11. So, we may assume that neither A nor B are ρs-balanced and that their LCS is ρ'-balanced.

By Lemma 12 we can find binary alphabet restrictions X and Y of A and B respectively with the property that neither X nor Y are ρ-balanced. Informally, since the LCS of A and B is balanced, a better than $1/2$ approximation for the LCS of X and Y acts as a better than $1/s$ approximation for $\text{LCS}(A, B)$. More precisely, since $\text{LCS}(A, B)$ is ρ'-balanced, each of its characters occurs at least $(1/s - \rho')\,\text{LCS}(A, B)$ times in the LCS. By construction, we also know that $\text{LCS}(X, Y)$ is at least as large as a binary alphabet restriction of $\text{LCS}(A, B)$. Thus, it follows that given a positive constant ϵ', a $1/2 + \epsilon'$ approximation of $\text{LCS}(X, Y)$ has length at least

$$(1/2 + \epsilon') \cdot 2\,(1/s - \rho')\,\text{LCS}(A, B) = (1/s + 2\epsilon'/s - \rho' - 2\epsilon'\rho')\,\text{LCS}(A, B).$$

By setting $\epsilon = \epsilon'/s$ (for example) and ρ' sufficiently small in terms of ϵ', the above calculation shows that a $1/2 + \epsilon'$ approximation for the LCS of X and Y acts as a $1/s + \epsilon$ approximation for $\text{LCS}(A, B)$. Hence to complete the proof, it suffices to get a better than $1/2$ approximation for $\text{LCS}(X, Y)$. We may assume that

$$\min(0(X), 0(Y)) \leq (1 + \delta)\min(1(X), 1(Y)) \tag{5}$$

and

$$\min(1(X), 1(Y)) \leq (1 + \delta)\min(0(X), 0(Y)) \tag{6}$$

for some constant δ since otherwise Lemma 14 yields a better than $1/2$ approximation.

As mentioned previously, [21] gives a better than $1/2$ approximation for the LCS when X and Y have equal length. If X and Y have different lengths, without loss of generality we assume that $|X| > |Y|$ and $0(Y) \leq 1(Y)$. We do casework on frequencies in X, relative to the frequencies in Y.

Since X is longer than Y, we cannot have both $1(X) \leq 1(Y)$ and $0(X) \leq 0(Y)$.

If $1(X) > 1(Y)$ and $0(X) > 0(Y)$ simultaneously, then Equation (6) implies that

$$1(Y) \leq (1 + \delta) \cdot 0(Y)$$

which contradicts the fact that Y is not ρ-balanced as long as we take $\delta \leq 2\rho$.

If instead $1(X) \leq 1(Y)$ and $0(X) \leq 0(Y)$, by Equation (6) we similarly have

$$0(X) \leq 0(Y) \leq 1(Y) \leq (1 + \delta) \cdot 0(X)$$

which again contradicts the fact that Y is not ρ-balanced for the same choice of δ.

Thus, the only possibility is that $1(X) \leq 1(Y)$ and $0(X) > 0(Y)$. Let $m = |Y|$ be the length of string Y. Then Equation (5) implies that

$$0(Y) \leq (1 + \delta) \cdot 1(X) \leq 1(X) + \delta m$$

while Equation (6) implies that

$$1(X) \leq (1 + \delta) \cdot 0(Y) \leq 0(Y) + \delta m.$$

Consequently, $0(Y)$ and $1(X)$ are within δm of each other. Then by Lemma 13, as long as we take δ small enough in terms of ρ we get a subquadratic $1/2 + \epsilon'$ approximation for $\text{LCS}(X, Y)$. As noted earlier, this then yields the desired $1/s + \epsilon$ approximation for $\text{LCS}(A, B)$ in truly subquadratic time. In fact, because we only ever use subroutines that run in linear time or constant factor approximations to edit distance which take near-linear time, the overall algorithm takes near-linear time. ◀

4 Proof of Lemma 13

This section is devoted to proving Lemma 13. We do this working through the individual arguments in the case analysis of [21] and verifying that the arguments still hold in the case where the strings have different lengths, as long as they satisfy the frequency requirements included in the hypotheses of the lemma. Throughout this section we fix the binary alphabet $\Sigma = \{0, 1\}$ and assume that all strings come from this alphabet.

We carry over the following subroutines from [21].

▶ **Definition 15.** *Given strings A and B and a symbol σ, the algorithm* $\mathrm{Match}(A, B, \sigma)$ *returns the largest subsequence of A and B consisting entirely of copies of σ.*

▶ **Definition 16.** *Given strings A and B, the algorithm* $\mathrm{BestMatch}(A, B)$ *returns the longer of the strings*

$$\mathrm{Match}(A, B, 0) \quad \textit{and} \quad \mathrm{Match}(A, B, 1).$$

In other words, the algorithm returns the largest common unary subsequence.

Note that BestMatch is a $1/2$ approximation algorithm for LCS.

▶ **Definition 17.** *Given strings A_1, A_2, and B, the algorithm* $\mathrm{Greedy}(A_1, A_2, B)$ *returns*

$$\max_{B=B_1 \sqcup B_2} \mathrm{BestMatch}(A_1, B_1) + \mathrm{BestMatch}(A_2, B_2)$$

taken over all possible splits of B into two contiguous left and right substrings B_1 and B_2.

These algorithms can all be implemented to run in linear time by scanning through the counting how many 0s and 1s appear in each string. The final procedure we will invoke utilizes an approximation algorithm for computing the edit distance of two strings as a black-box. Although any fast enough constant factor approximation for edit distance will work, for concreteness we assume that it leverages the algorithm $\widetilde{\mathrm{ED}}$ from [5], which runs in subquadratic time and can approximate the edit distance to a $c = 3 + \epsilon'$ factor for any fixed positive constant ϵ'. Note that this algorithm can also return a common subsequence achieving the given length.

Proof of Lemma 13. Let $1(X) = \alpha m$ for some $\alpha \in [0, 1]$. By assumption, we know that $\alpha < 1/2$ is bounded away from $1/2$ by some constant amount. We can also assume that $0(Y)$ is within δm of $1(X)$ for some positive parameter $\delta < 0$ to be picked later on. We will end up setting δ to be some sufficiently small constant depending on α. We will use the notation $\approx$ to denote quantities that are within δm of each other. For example $1(X) \approx 0(Y)$. This lets us avoid having to stick in $\pm\delta m$ symbols in all the inequalities and helps make the arguments cleaner without affecting the correctness (since we just care about getting a $1/2 + \epsilon$ approximation for *some* constant $\epsilon > 0$).

Note that by Equation (4) the LCS of the input strings

$$\mathrm{LCS}(X, Y) \leq (2\alpha + \delta)m \tag{7}$$

cannot be too large, because the LCS contain at most αm 1s from X and $\approx \alpha m$ 0s from Y.

Let R_X and R_Y denote the substrings of X and Y consisting of their rightmost αm characters respectively. Similarly define L_X and L_Y as the substrings of X and Y consisting of the leftmost αm characters. Set $M_X = X \setminus (L_X \cup R_X)$ and $M_Y = Y \setminus (L_Y \cup R_Y)$ to be the middle substrings of X and Y that remain when these left and right ends are chopped off.

We now follow the casework of [21], explaining at each step why the arguments still hold in our more general setting. These cases are based off the frequencies of 0s and 1s in the left and right ends of the inputs, and consider separately the situation where these substrings are pseudorandom (balanced) or structured (imbalanced). In the former case we can appeal to edit distance as in the proof of Lemma 10, and in the latter situation we can exploit the imbalance in the strings to use the simpler unary algorithms described in definitions 15, 16, and 17. Intuitively, we succeed in using edit distance approximation arguments (and overcome the barrier described the end of Section 2) in this particular case because even though X and Y may have different size, we identify right and left substrings which all have equal length and only employ edit distance approximation around these areas.

Recall that we assumed that $\alpha < 1/2 - \rho$ for some constant ρ. Take a parameter $\beta < \rho/20$ to represent deviation from the balanced case. By choosing δ sufficiently small in terms of β we may additionally assume that

$$1(X), 0(Y) < (1/2 - 10\beta)\, m \tag{8}$$

since in the hypothesis of the lemma we supposed that $1(X) < (1/2 - \rho)m$ and that $0(Y) \approx 1(X)$. Finally, as one last piece of notation, we write $|A|$ to denote length of an arbitrary string A. We now begin the casework, maintaining consistency with [21].

Case 1(a): $1(R_Y), 0(R_X) \in [(\alpha/2 - 4\beta)\, m, (\alpha/2 + 4\beta)\, m]$

In this case both right ends of the strings are balanced. We will give a good approximation for the LCS by splitting these strings at the right ends and using the aforementioned algorithms.

Consider an optimal alignment between X and Y (i.e. a maximum partial matching of identical characters in X and Y, corresponding to the LCS of X and Y). Let $\widehat{R_Y}$ be the minimal suffix (from the right end) of the string Y with the property that every character from R_X which is matched in the alignment is paired up with some character in $\widehat{R_Y}$.

Without loss of generality, we may assume that $\widehat{R_Y}$ is a substring of R_Y. This is because if $\widehat{R_Y}$ was not contained in R_Y, we could define an analogous substring of $\widehat{R_X}$ of X satisfying $\widehat{R_X} \subseteq R_X$ and then use a symmetric argument to get the desired approximation. Let $\widehat{L_Y} = Y \setminus \widehat{R_Y}$ be the left substring of Y that remains after chopping of $\widehat{R_Y}$.

Optimality of the alignment implies that

$$\mathrm{LCS}(X, Y) = \mathrm{LCS}(X \setminus R_X, \widehat{L_Y}) + \mathrm{LCS}(R_X, \widehat{R_Y}). \tag{9}$$

Define the quantities

$$f_L = \min(1(X \setminus R_X), 1(\widehat{L_Y})) + \min(0(X \setminus R_X), 0(\widehat{L_Y}))$$

and

$$f_R = \min(1(R_X), 1(\widehat{R_Y})) + \min(0(R_X), 0(\widehat{R_Y}))$$

which represent frequency-based upper bounds for the LCS terms from the right hand side of Equation (9). They are useful because Equation (4) together with Equation (9) implies that

$$\mathrm{LCS}(X, Y) \leq f_L + f_R. \tag{10}$$

We also introduce the quantity

$$Z = \max\left(\min(1(X \setminus R_X), 1(\widehat{L_Y})), \min(0(X \setminus R_X), 0(\widehat{L_Y}))\right)$$

which is the larger of the two addends defining f_L, and equal to the length of the string returned by

$$\mathrm{BestMatch}(X \setminus R_X, \widehat{L_Y}).$$

We further subdivide into cases based off the size of Z.

Case 1(a)(i): $Z > (\alpha/2 + 10\beta)\, m$

When Z is large we can combine two unary subsequences to get a good enough LCS approximation. We first show that Z is bigger than $f_L/2$ by a constant fraction of m.

By definition we have

$$f_L - Z = \min\left(\min(1(X \setminus R_X), 1(\widehat{L_Y})), \min(0(X \setminus R_X), 0(\widehat{L_Y}))\right) \leq 1(X \setminus R_X).$$

Since X has αm ones and R_X has length αm we get that

$$1(X \setminus R_X) = \alpha m - 1(R_X) = \alpha m - (\alpha m - 0(R_X)) = 0(R_X).$$

Then using the case assumptions we have

$$0(R_X) \leq (\alpha/2 + 4\beta)\, m < Z - 6\beta m.$$

Chaining these inequalities together and rearranging we deduce that

$$Z > f_L/2 + 3\beta m.$$

Now if we make a single call to the Greedy routine we obtain a string of length

$$\text{Greedy}(X \setminus R_X, R_X, Y) \geq \text{BestMatch}(X \setminus R_X, \widehat{L_Y}) + \text{BestMatch}(R_X, \widehat{R_Y}). \tag{11}$$

From our earlier discussion we have

$$\text{BestMatch}(X \setminus R_X, \widehat{L_Y}) \geq Z > f_L/2 + 3\beta m.$$

Moreover

$$\text{BestMatch}(R_X, \widehat{R_Y}) = \max(\min(1(R_X), 1(\widehat{R_Y})), \min(0(R_X), 0(\widehat{R_Y}))) \geq f_R/2$$

since we are taking the maximum over two addends that sum to f_R.

Finally, if we substitute the above inequalities into Equation (11) and apply Equation (10) we get that

$$\begin{aligned}\text{Greedy}(X \setminus R_X, R_X, Y) &\geq (f_L + f_R)/2 + 3\beta m \geq \text{LCS}(X, Y)/2 + 3\beta m \\ &\geq (1/2 + 3\beta)\, \text{LCS}(X, Y).\end{aligned}$$

Thus running Greedy gives us a better than $1/2$ approximation in this case.

Case 1(a)(ii): $Z \leq (\alpha/2 + 10\beta)\, m$

Intuitively, in this case Z is too small for us to ensure a good approximation using frequency guarantees alone. However, because Z is so small, the LCS also cannot be too large. Because of this, we will be able to get a good approximation by combining a common subsequence of the (balanced) right ends of the strings with a common subsequence of the strings with the right ends removed.

More concretely, we leverage the ApproxED algorithm from Definition 7. From our previous observation we have $f_L \leq 2Z \leq (\alpha + 20\beta)\, m$. So via Equation (9) we can bound the LCS by

$$\text{LCS}(X, Y) \leq f_L + \text{LCS}(R_X, \widehat{R_Y}) \leq (\alpha + 20\beta)\, m + \text{LCS}(R_X, R_Y) \tag{12}$$

where in the last step we also used the fact that $\widehat{R_Y} \subseteq R_Y$.

We will get an approximation by returning a unary subsequence from the left parts of the strings, and using edit distance approximation on the right ends. First, we can make a call to BestMatch and get a common subsequence of length at least

$$\text{BestMatch}(X \setminus R_X, Y \setminus R_Y) \geq \text{Match}(X \setminus R_X, Y \setminus R_Y, 0) \geq (\alpha/2 - 4\beta)\, m.$$

This last inequality above follows from combining the case 1 assumptions about the frequencies of characters in $0(R_X)$ and $1(R_Y)$, together with the facts that $0(Y) \approx 1(X) = \alpha m$ and $|R_X| = |R_Y| = \alpha m$.

Now, since R_X and R_Y are $(4\beta/\alpha)$-balanced we can apply Lemma 10 with $n = \alpha m$ as long as we take β sufficiently small in terms of α. Note that for fixed alphabet size and ρ, the parameter β remains $\Omega(1)$. This ensures that in subquadratic time we can compute a common subsequence of R_X and R_Y with length at least

$$(1/2 + \gamma)\, \text{LCS}(R_X, R_Y)$$

where $\gamma < 1$ is the constant from Lemma 10, which is larger for smaller values of β. By the frequency assumptions on R_X and R_Y, we know that

$$\text{LCS}(R_X, R_Y) \geq (\alpha/2 - 4\beta)\, m$$

so in fact the subsequence of R_X and R_Y returned by Lemma 10 has length at least

$$(1/2 + \gamma)\, \text{LCS}(R_X, R_Y) \geq \text{LCS}(R_X, R_Y)/2 + \gamma(\alpha/2 - 4\beta)m.$$

Now if we combine these two subsequences together, we get a common subsequence of X and Y of length at least

$$\text{LCS}(R_X, R_Y)/2 + (\alpha/2 - 4\beta)\, m + \gamma(\alpha/2 - 4\beta)m$$

which can be written in the form

$$((\alpha + 20\beta)m + \text{LCS}(R_X, R_Y))\,/2 + (\gamma\alpha/2 - 14\beta - 4\gamma\beta)\, m.$$

By applying Equation (12) and the fact that $\gamma < 1$ we see that this is at least

$$\text{LCS}(X, Y)/2 + (\gamma\alpha/2 - 18\beta)\, m.$$

Finally, by picking β small enough this expression is at least

$$\text{LCS}(X, Y)/2 + (\gamma\alpha/3)\, m \geq (1/2 + \gamma/6)\, \text{LCS}(X, Y)$$

where in the last step we have used Equation (4) together with $1(X) = \alpha m$ and $0(Y) \approx \alpha m$. This proves that we can attain a better than 1/2 approximation for the LCS as claimed.

Case 1(b): $1(R_Y) < (\alpha/2 - 4\beta)\, m$ and $0(R_X) \leq (\alpha/2 + 2\beta)\, m$

In this case the right ends of X and Y each do not contain too much their respective strings' most common characters. We show that this implies the LCS of both strings must be so small that simply returning a unary string yields a better than 1/2 approximation.

As in case 1(a), consider an optimal alignment between X and Y. Now define the substring $\widehat{R_Y}$ to be the minimal suffix of Y which contains all characters of Y that R_X is aligned to. Let $\widehat{L_Y} = Y \setminus \widehat{R_Y}$ be what remains of Y after R_Y is removed. Since the alignment is optimal, Equation (9) holds.

We now subdivide into further case based off how the right ends of strings are aligned.

Case 1(b)(i): every character of R_X is matched to some character of R_Y in the alignment

In this case $\widehat{R_Y}$ is a substring of R_Y. From Equation (4) and the case assumptions we get that

$$\mathrm{LCS}(X \setminus R_X, \widehat{L_Y}) \leq 1(X \setminus R_X) + 0(\widehat{L_Y}) \leq (\alpha/2 + 2\beta)\, m + 0(\widehat{L_Y})$$

and

$$\mathrm{LCS}(R_X, \widehat{R_Y}) \leq 1(\widehat{R_Y}) + 0(\widehat{R_Y}) \leq (\alpha/2 - 4\beta)\, m + 0(\widehat{R_Y}).$$

Note that in this second inequality we are using the inequality $1(\widehat{R_Y}) \leq 1(R_Y)$ which follows from the earlier observation that $\widehat{R_Y} \subseteq R_Y$. By adding these inequalities together and substituting the result into Equation (9) we deduce that

$$\mathrm{LCS}(X, Y) \leq (\alpha - 2\beta)\, m + \left(0(\widehat{L_Y}) + 0(\widehat{R_Y})\right) \leq (\alpha - 2\beta)\, m + \alpha m = (2\alpha - 2\beta)\, m$$

where we have used the fact that 0 occurs in $Y \approx \alpha m$ times.

Case 1(b)(ii): some character of R_X is matched outside R_Y in the alignment

In this case R_Y is a substring of $\widehat{R_Y}$.

Using Equation (4) again we find that

$$\mathrm{LCS}(X \setminus R_X, \widehat{L_Y}) \leq 1(X \setminus R_X) + 0(\widehat{L_Y}) \tag{13}$$

From $0(R_X) \leq (\alpha/2 + 2\beta)\, m$ we know that $1(R_X) \geq (\alpha/2 - 2\beta)\, m$ since R_X has length αm. It follows that

$$1(X \setminus R_X) = 1(X) - 1(R_X) \leq (\alpha/2 + 2\beta)\, m$$

since $1(X) = \alpha m$.

Similarly, since $1(R_Y) \leq (\alpha/2 - 4\beta)\, m$ and R_Y has length αm we know that $0(R_Y) > (\alpha/2 + 4\beta)\, m$. Since $R_Y \subseteq \widehat{R_Y}$ it must be the case that $0(\widehat{R_Y}) > (\alpha/2 + 4\beta)\, m$ which means that

$$0(\widehat{L_Y}) = 0(Y) - 0(\widehat{R_Y}) \approx \alpha m - 0(\widehat{R_Y}) < (\alpha/2 - 4\beta)\, m.$$

Adding these two inequalities and substituting into Equation (13) proves that

$$\mathrm{LCS}(X \setminus R_X, \widehat{L_Y}) \leq (\alpha - 2\beta)\, m.$$

Then applying Equation (9) and using the fact that R_X has length αm proves that

$$\mathrm{LCS}(X, Y) = \mathrm{LCS}(X \setminus R_X, \widehat{L_Y}) + \mathrm{LCS}(R_X, \widehat{R_Y}) \leq (\alpha - 2\beta)m + \alpha m = (2\alpha - 2\beta)\, m.$$

Thus in both this subcase and the previous one, the LCS is at most $(2\alpha - 2\beta)\, m$. Hence, returning the string of $\approx \alpha m$ zeros obtained by calling $\mathrm{Match}(X, Y, 0)$ gives a better than $1/2$ approximation as desired.

Case 1(c): $1(R_Y) \leq (\alpha/2 + 2\beta)\, m$ and $0(R_X) < (\alpha/2 - 4\beta)\, m$

This case is symmetric to case 1(b) and similar reasoning handles it.

Case 2: $1(L_Y), 0(L_X) \leq (\alpha/2 + 2\beta)\, m$
Combining cases 1(a), 1(b), and 1(c) resolves the situation where

$$1(R_Y), 0(R_X) \leq \alpha/2 + 2\beta.$$

Consequently, case 2 is symmetric to case 1. In particular, we can flip the strings (by replacing X with the string X' which consists of the symbols of X read in reverse from right to left, and replacing Y with its analogous reverse string Y') and apply the arguments from case 1 to handle this case.

Case 3: $1(L_Y), 1(R_Y) \leq (\alpha/2 + \beta)\, m$ and $0(L_X), 0(R_X) > (\alpha/2 + 2\beta)\, m$
In this case both ends of the inputs have many 0s, so repeated calls to Match will be enough to guarantee a better than 1/2 approximation.

Since L_Y has length αm and at most $(\alpha/2 + \beta)\, m$ instances of 1, it must have at least

$$0(L_Y) \geq \alpha m - (\alpha/2 + \beta)m = (\alpha/2 - \beta)m$$

occurrences of 0. Since $1(R_Y) \leq (\alpha/2 + \beta)\, m$ the same reasoning shows that

$$0(R_Y) \geq (\alpha/2 - \beta)\, m.$$

Consequently we can get common subsequences of the left and right ends of the strings consisting entirely of 0s with lengths

$$\text{Match}(L_X, L_Y, 0) = \min(0(L_X), 0(L_Y)) \geq (\alpha/2 - \beta)\, m$$

and

$$\text{Match}(R_X, R_Y, 0) = \min(0(R_X), 0(R_Y)) \geq (\alpha/2 - \beta)\, m.$$

Since the ends have many 0s, we expect the middle substrings to have many 1s. Indeed, since the left end of X

$$1(L_X) = |L_X| - 0(L_X) < \alpha m - (\alpha/2 + 2\beta)m = (\alpha/2 - 2\beta)\, m$$

does not have many 1s and similar reasoning shows that

$$1(R_X) < (\alpha/2 - 2\beta)\, m$$

this holds for the right end as well, the middle of X has only

$$1(M_X) = 1(X) - 1(L_X) - 1(R_X) > \alpha m - 2(\alpha/2 - 2\beta)m = 4\beta m$$

appearances of 1.

To argue that M_Y has enough 1s we will need to appeal to the fact that Y is not balanced. From Equation (8) we know that

$$1(Y) = m - 0(Y) > m - (1/2 - 10\beta)m = (1/2 + 10\beta)\, m.$$

We can use the case assumptions together $\alpha < 1/2$ to then deduce

$$1(M_Y) = 1(Y) - 1(L_Y) - 1(R_Y) > (\alpha + 10\beta)m - 2(\alpha/2 + \beta)m = 8\beta m.$$

Consequently the largest all 1s subsequence between the middle substrings has length at least

$$\text{Match}(M_X, M_Y, 1) = \min(1(M_X), 1(M_Y)) \geq 4\beta m.$$

Thus, by combining these three subsequences from three calls to match we can recover in linear time a common subsequence of size

$$\text{Match}(L_X, L_Y, 0) + \text{Match}(M_X, M_Y, 1) + \text{Match}(R_X, R_Y, 0) > 2(\alpha/2 - \beta)m + 4\beta m = (\alpha + 2\beta)m.$$

By Equation (7) the true LCS has length at most $\approx 2\alpha m$, so a string of length $(\alpha + 2\beta)\, m$ is a $1/2 + \epsilon$ approximation for some constant $\epsilon < 2\beta/\alpha$ as desired.

Case 4: $0(L_X), 0(R_X) \leq (\alpha/2 + \beta)\, m$ and $1(L_Y), 1(R_Y) > (\alpha/2 + 2\beta)\, m$

This case is symmetric to case 3 and similar reasoning handles it.

Case 5: $0(L_X), 1(R_Y) > (\alpha/2 + \beta)\, m$

In this case, the ends of the strings have unusually large instances of either 0 or 1. This will enable us to combine two calls to Match to get the desired approximation.

We can check that the right end of Y does not have many 0s

$$0(R_Y) = |R_Y| - 1(R_Y) < \alpha m - (\alpha/2 + \beta)m = (\alpha/2 - \beta)\, m.$$

It follows that the remainder of the string $Y \setminus R_Y = L_Y \cup M_Y$ has many zeros

$$0(Y \setminus R_Y) = 0(Y) - 0(R_Y) \approx \alpha m - 0(R_Y) > (\alpha/2 + \beta)\, m.$$

Similar reasoning shows that

$$1(L_X) = \alpha m - 0(L_X) < (\alpha/2 - \beta)\, m$$

so that the remaining portion of X has many ones

$$1(X \setminus L_X) = 1(X) - 1(L_X) = \alpha m - 1(L_X) > (\alpha/2 + \beta)\, m.$$

It follows that

$$\text{Match}(L_X, Y \setminus R_Y, 0) + \text{Match}(X \setminus L_X, R_Y, 1) > (\alpha + 2\beta)\, m$$

yields a better than $1/2$ approximation since by Equation (7) the LCS is at most $\approx 2\alpha m$.

Case 6: $1(L_Y), 0(R_X) > (\alpha/2 + \beta)\, m$

This is symmetric to case 5 and a similar argument proves the result holds in this situation.

By inspection or by referring to Table 1 of [21], we can verify that these cases handle all possible input strings satisfying the conditions of the lemma. Since in every case we obtain a better than $1/2$ approximation for the LCS in subquadratic time, we have proven the claim. ◀

5 Open Problems

Theorem 2 of our work shows how to obtain better than $1/|\Sigma|$ approximations for the longest common subsequence of *equal-length strings* over an alphabet Σ. It remains an open problem to get such approximations in the setting where the input strings have different length (and by Corollary 5, to solve this problem it suffices to obtain an improvement in the setting of binary alphabets, where $|\Sigma| = 2$).

Additionally, although our algorithm beats the longstanding trivial approximation ratio for LCS, it does so only by a modest amount. It would be interesting to get better approximation ratios, both in terms of their concrete value for small $|\Sigma|$ and in terms of their growth as a function of the alphabet size.

Efficient Splitting of Necklaces

Abstract

We provide efficient approximation algorithms for the Necklace Splitting problem. The input consists of a sequence of beads of n types and an integer k. The objective is to split the necklace, with a small number of cuts made between consecutive beads, and distribute the resulting intervals into k collections so that the discrepancy between the shares of any two collections, according to each type, is at most 1. We also consider an approximate version where each collection should contain at least a $(1-\varepsilon)/k$ and at most a $(1+\varepsilon)/k$ fraction of the beads of each type. It is known that there is always a solution making at most $n(k-1)$ cuts, and this number of cuts is optimal in general. The proof is topological and provides no efficient procedure for finding these cuts. It is also known that for $k=2$, and some fixed positive ε, finding a solution with n cuts is PPAD-hard.

We describe an efficient algorithm that produces an ε-approximate solution for $k=2$ making $n(2+\log(1/\varepsilon))$ cuts. This is an exponential improvement of a $(1/\varepsilon)^{O(n)}$ bound of Bhatt and Leighton from the 80s. We also present an online algorithm for the problem (in its natural online model), in which the number of cuts made to produce discrepancy at most 1 on each type is $\tilde{O}(m^{2/3}n)$, where m is the maximum number of beads of any type. Lastly, we establish a lower bound showing that for the online setup this is tight up to logarithmic factors. Similar results are obtained for $k>2$.

1 Introduction

1.1 The problems

The Necklace Splitting problem deals with a fair partition of a necklace with beads of n colors among k agents. The objective is to cut the necklace into intervals and distribute them to the agents in an equitable way. Before adding more on the background, we give the formal definition of the problem.

▶ **Definition 1** (Necklace Splitting). *An instance of Necklace Splitting for n colors and k agents consists of a set of beads ordered along a line, where each bead is colored by a color $i \in [n] = \{1, 2, \ldots, n\}$. The goal is to split the necklace, via at most $n(k-1)$ cuts made between consecutive beads, into intervals and distribute them to the k agents so that for each color i, every agent gets either $\lceil \frac{m_i}{k} \rceil$ or $\lfloor \frac{m_i}{k} \rfloor$ beads of color i, where m_i is the number of beads of color i.*

licensed under Creative Commons License CC-BY 4.0

Note that this definition is slightly broader than the one given in [1], where it is assumed that m_i is divisible by k for all $i \in [n]$. However, as shown in [4], these two forms of the Necklace Splitting problem are equivalent. We call the special case $k = 2$ of two agents the Necklace Halving problem. A related problem is the ε-Consensus Splitting problem. Its formal definition is the following:

▶ **Definition 2** (ε-Consensus Splitting)**.** *An instance $I_{n,k}$ of ε-Consensus Splitting with n measures and k agents consists of n non-atomic probability measures on the interval $[0, 1]$, which we denote by μ_i, for $i \in [n] = \{1, 2, , \ldots, n\}$. The goal is to split the interval, via at most $n(k-1)$ cuts, into subintervals and distribute them to the k agents so that for every two agents $a, b \in [k]$ and every measure $i \in [n]$, we have $|\mu_i(U_a) - \mu_i(U_b)| \leq \frac{2\varepsilon}{k}$, where U_a, U_b are the unions of all intervals a, b receive, respectively.*

The ε-Consensus Splitting problem can be viewed as a continuous variant of the Necklace Splitting problem. Furthermore, as will be shown in the proofs of our results, every instance of Necklace Splitting can be converted into an instance of ε-Consensus Splitting. We also consider the **ε-approximate version of Necklace Splitting**, where the goal is to split the necklace so that the difference between the shares of any two agents, according to each type i, is at most $2\varepsilon m_i/k$.

The existence of a solution for the Necklace Splitting problem using at most $n(k-1)$ cuts, a bound which is tight in general, was proved, using topological arguments, first for $k = 2$ agents in [19] (see also [5] for a short proof and [20] for an earlier continuous version), and then for the general case of k agents in [1]. A more recent proof of this existence result appears in [21]. However, the proofs are non-constructive. The Necklace Halving problem is first discussed in [10]. The problem of finding an efficient algorithmic proof of Necklace Splitting is mentioned in [2].

Recently, there have been several results regarding the hardness of the Necklace Halving problem. These are discussed in the next subsection. These suggest pursuing the challenge of finding efficient approximation algorithms, as well as that of proving non-conditional hardness in restricted models.

1.2 Hardness and Approximation

PPA and PPAD are two complexity classes introduced in the seminal paper of Papadimitriou, [22]. Both of these are contained in the class TFNP, which is the complexity class of *total search* problems, consisting of all problems in NP where a solution exists for every instance. A problem is PPA-complete if and only if it is polynomially equivalent to the canonical problem LEAF, described in [22]. Similarly, a problem is PPAD-complete if and only if it is polynomially equivalent to the problem END-OF-THE-LINE. A problem is PPA-hard or PPAD-hard if the respective canonical problem is polynomially reducible to it. A number of important problems, such as several versions of Nash Equilibrium [14] and Market Equilibrium [13], have been proved to be PPAD-complete. It is known that PPAD $\subseteq$ PPA. Hence, PPA-hardness implies PPAD-hardness. Filos-Ratsikas and Goldberg showed that the Necklace Halving problem, as well as the ε-Consensus Halving problem, is PPA-hard [16], see also [17], [15]. Additionally, in [18] it is shown that for a fixed constant $\delta > 0$, and ε inversely polynomial in n, obtaining a solution to the ε-Consensus Halving with fewer than $n + n^{1-\delta}$ is PPA-hard. Our main objective here is to find efficient approximation algorithms for the problems. Although not directly related to our results, it is worth mentioning that in [11] it is proved that for $k = 2$ agents it is NP-hard to minimize the number of cuts for instances where the optimal number is less than n, even with 2 beads of each type.

1.3 Our contribution

We consider approximation algorithms for two versions of the problem, namely the online and the offline versions. We allow the algorithms to make more than n cuts, and expect either a *proper* solution or an ε-approximate one. A *proper* solution is a finite set of cuts and a distribution of the resulting intervals to the k agents so that the absolute discrepancy is at most 1. The absolute discrepancy here and in what follows is the maximum discrepancy, over all types, between the shares of beads of this type allocated to any two agents. An ε-approximate solution is a relaxation in which the discrepancy in any type is at most a fraction $2\varepsilon/k$ of the number of beads of this type. The objective is to minimize the number of cuts the algorithm makes. This problem for the ε-approximate version has been considered earlier in [9] and [12].

In addition to approximation, we also consider hardness in the online model, discussed in the next subsection. In the online model, the hardness is measured by the minimum number of cuts needed to produce a proper solution. Lower bounds on the number of cuts needed in this model provide a barrier for what online algorithms can achieve.

Some of our ideas for finding deterministic approximation algorithms are inspired by papers in Discrepancy Minimization, such as [3], [7], [6] and [8]. In [3], the terminology refers to the **Balancer** as the entity with the designated task of minimizing the absolute discrepancy between agents. We adopt the same terminology here. Thus, the Balancer has the role of an algorithm that makes cuts and assigns the resulting intervals to agents in order to achieve a proper solution for Necklace Splitting.

Our main algorithmic results are summarized in the theorems below. The upper and lower bounds for the number of cuts obtained for the online model appear in the table at the end of this subsection. Throughout the paper, for Necklace Halving, we use the notation $m = \max_{i\in[n]} m_i$ where m_i is the number of beads of color i, and n is the number of types (=colors).

▶ **Theorem 1.** *There exists an efficient, deterministic, offline algorithm that provides a proper solution to the Necklace Halving problem, making at most* $n(\log m + O(1))$ *cuts.*

Here and in what follows an efficient algorithm means an algorithm whose running time is polynomial in the length of the input necklace.

In [9] and [12] the authors describe offline algorithms for the ε-approximate version of Necklace Halving, making $O((\frac{1}{\varepsilon})^{\Theta(n)})$ cuts. Our techniques here provide an algorithm that requires only $n(\log(1/\varepsilon) + O(1))$ cuts for the problem, yielding an exponential improvement for the number of cuts.

▶ **Theorem 2.** *There exists an efficient, deterministic, online algorithm that provides a proper solution to the Necklace Halving problem, making at most* $O(m^{2/3} \cdot n(\log n)^{1/3})$ *cuts.*

The algorithmic results in the online model, and the nearly matching lower bounds we establish appear in the table below. Note that the algorithms are optimal up to constant factors for any fixed constant $n \geq 3$. In the lower bounds for Online Necklace Halving, we always assume that $m_i = m$ for all $i \in [n]$.

Problem	$n = 2$ colors	$n \geq 3$, $n = O(1)$ colors	n colors (general case)
Upper bound	$O(m^{2/3})$	$O(m^{2/3})$	$O(m^{2/3} \cdot n(\log n)^{1/3})$
Lower bound	$\Omega(\sqrt{m})$	$\Omega(m^{2/3})$	$\Omega(n \cdot m^{2/3})$

1.4 Computational model and online version

The offline computational model considered here is natural. The input for Necklace Splitting, for an instance with k agents and n colors, consists of a series of indices, each one taking a value in $[n]$, which represents the color of the respective bead. The runtime is, as usual, the number of basic operations the algorithm makes to provide a solution.

Next, we describe the online model. The parameters k, n and m_i for $i \in [n]$ are given in advance. We refer to *time* t, $0 \leq t \leq \sum_{i\in[n]} m_i - 1$ as the state after the first t beads were revealed and decisions about cutting before any of these have already been made. The beads are revealed one by one in the following way: for integral $t, 0 \leq t \leq \sum_{i\in[n]} m_i - 1$, at time t the Balancer receives the color of bead number $t+1$ and is given the opportunity to make a cut between beads t and $t+1$, where this decision is irreversible. If a cut is made, and J is the newly created interval, the Balancer also has to choose immediately the agent that gets J, before advancing to time $t+1$.

1.5 Techniques

The proofs in the paper combine combinatorial and probabilistic ideas with linear algebra and geometric tools. Theorem 1 is proved by converting the instance of Necklace Halving into a continuous instance, which can be considered an instance of ε-Consensus Halving, where the $[0,1]$ interval is colored by n colors. We reason about finding a solution to this ε-Consensus Halving instance, for a suitable ε, and then adapt the algorithm to obtain a valid solution for the discrete Necklace Halving instance. The algorithm for the continuous instance is based on Carathéodory's Theorem for cones, and involves linear algebra manipulations. To obtain a solution for the discrete instance from the solution to the continuous instance, we describe how to shift cuts at the end to ensure they are not made in the interior of (intervals corresponding to) beads.

The online algorithm discussed in Theorem 2 is inspired by known techniques used in online algorithms for discrepancy minimization. The idea here is to cut the necklace into pieces, each having a sufficiently small number of beads of each color. The problem then becomes an online discrepancy problem, where one can use a derandomization of a natural randomized algorithm that proceeds by using an appropriate potential function motivated by the method of conditional expectations. Obtaining discrepancy ≤ 1 at the end of the necklace traversal requires a modification to the potential function technique, that handles beads of certain colors in a more careful manner once the remaining beads of these colors become scarce. The lower bound showing that the online algorithm is optimal up to logarithmic factors is proved in two steps. The first one is an argument showing that if anytime during the process the discrepancy between the shares allocated so far to the two agents according to one of the colors is relatively large, while according to another color both shares are 0, then a large number of cuts is required to ensure an appropriate solution at the end. In the second step, it is proved that in order to keep the discrepancy according to each color sufficiently small during the process, a large number of cuts is needed. This is shown by introducing and analyzing appropriate potential functions, where the challenge here is to define functions that enable the adversary to ensure they will keep growing for any choice of a place to cut, and any allocation of the resulting interval, provided that the interval created is not too short. One of the lemmas in the proof here is based on the fact that a certain matrix is totally unimodular. The full details appear in the following sections.

1.6 Structure

The structure of the rest of the paper is as follows: in Section 2 we present the approximation algorithm for the offline version of the problem. Section 3 contains the algorithm for the online version. Section 4 contains the lower bounds for the online model. The final Section 5 contains several extensions and open problems. To simplify the presentation we omit all floor and ceiling signs throughout the paper whenever these are not crucial. All logarithms are in base 2, unless otherwise specified.

2 An offline algorithm

Proof of Theorem 1

Proof. Given a necklace with m_i beads of color i for $1 \leq i \leq n$, where $m = \max m_i$, construct an instance of ε-Consensus Halving as follows. Replace each bead of color i by an interval of i-measure $1/m_i$ and j-measure 0 for all $j \neq i$. These intervals are placed next to each other according to the order in the necklace, and their lengths are chosen so that altogether they cover $[0,1]$. We first give a marking procedure that splits the continuous necklace so that the absolute discrepancy is at most ε, with $\varepsilon = \frac{1}{2m}$. Then, we show how to modify the solution from the continuous instance to the discrete necklace so that the cuts are made between consecutive beads and we obtain a proper solution.

Given n non-atomic measures μ_i on the interval $[0,1]$ we describe an efficient algorithm that cuts the interval in at most $n(2 + \lceil \log_2 \frac{1}{\varepsilon} \rceil)$ places and splits the resulting intervals into two collections C_0, C_1 so that $\mu_i(C_j) \in [\frac{1}{2} - \frac{\varepsilon}{2}, \frac{1}{2} + \frac{\varepsilon}{2}]$ for all $i \in [n], 0 \leq j \leq 1$. Note, first, that if the collection C_1 has the right amount according to each of the measures μ_i, so does the collection C_0. For each interval $I \subset [0,1]$ denote $\mu(I) = \mu_1(I) + \ldots + \mu_n(I)$. Thus $\mu([0,1]) = n$. Using $2n-1$ cuts split $[0,1]$ into $2n$ intervals $I_1, I_2, \ldots, I_{2n}$ so that $\mu(I_r) = 1/2$ for all r. Note that it is easy to find these cuts efficiently, since each measure μ_i is uniform on its support.

For each interval I_r let v_r denote the n-dimensional vector $(\mu_1(I_r), \mu_2(I_r), \ldots, \mu_n(I_r))$.

By a simple linear algebra argument, which is a standard fact about the properties of basic solutions for Linear Programming problems, one can write the vector $(1/2, 1/2, \ldots, 1/2)$ as a linear combination of the vectors v_r with coefficients in $[0,1]$, where at most n of them are not in $\{0,1\}$. This follows from Carathédory's Theorem for cones. For completeness, we include the proof, which also shows that one can find coefficients as above efficiently. Start with all coefficients being $1/2$. Call a coefficient which is not in $\{0,1\}$ *floating* and one in $\{0,1\}$ *fixed*. Thus at the beginning all $2n$ coefficients are floating. As long as there are more than n floating coefficients, find a nontrivial linear dependence among the corresponding vectors and subtract a scalar multiple of it which keeps all floating coefficients in the closed interval $[0,1]$ shifting at least one of them to the boundary $\{0,1\}$, thus fixing it.

This process clearly ends with at most n floating coefficients. The intervals with fixed coefficients with value 1 are now assigned to the collection C_1 and those with coefficient 0 to C_0. The rest of the intervals remain. Split each of the remaining intervals into two intervals, each with μ-value $1/4$. We get a collection $J_1, J_2, \ldots, J_m$ of $m \leq 2n$ intervals, each of them has the coefficient it inherits from its original interval. Each such interval defines an n-vector as before, and the sum of these vectors with the corresponding coefficients (in $(0,1)$) is exactly what the collection C_1 should still get to have its total vector of measures being $(1/2, \ldots, 1/2)$.

As before, we can shift the coefficients until at most n of them are floating, assign the intervals with $\{0,1\}$ coefficients to the collections C_0, C_1 and keep at most n intervals with floating coefficients. Split each of those into two intervals of μ-value $1/8$ each and proceed as before, until we get at most n intervals with floating coefficients, where the μ-value of each of them is at most $\varepsilon/2$. This happens after at most $\lceil \log_2(1/\varepsilon) \rceil$ rounds. In the first one, we have made $2n-1$ cuts and in each additional round at most n cuts. Thus the total number of cuts is at most $n(2+\lceil \log_2(1/\varepsilon) \rceil)-1$.

From now on we add no additional cuts, and show how to allocate the remaining intervals to C_0, C_1. Let $\mathcal{I}$ denote the collection of intervals with floating coefficients. Then $|\mathcal{I}| \leq n$ and $\mu(I) \leq \varepsilon/2$ for each $I \in \mathcal{I}$. This means that

$$\sum_{i=1}^{n} \sum_{I \in \mathcal{I}} \mu_i(I) \leq n\varepsilon/2$$

It follows that there is at least one measure μ_i so that

$$\sum_{I \in \mathcal{I}} \mu_i(I) \leq \varepsilon/2.$$

We can think of the remaining floating coefficients as the fraction of each corresponding interval that agent 1 owns. Observe that for any assignment of the intervals $I \in \mathcal{I}$ to the two collections C_0, C_1, the total μ_i measure of C_1 (and hence also of C_0) lies in $[1/2-\varepsilon/2, 1/2+\varepsilon/2]$, as this measure with the floating coefficients is exactly $1/2$ and any allocation of the intervals with the floating coefficients changes this value by at most $\varepsilon/2$. We can thus ignore this measure, for ease of notation assume it is measure number n, and replace each measure vector of the members in $\mathcal{I}$ by a vector of length $n-1$ corresponding to the other $n-1$ measures. If $|\mathcal{I}| > n-1$ (that is, if $|\mathcal{I}| = n$), then it is now possible to shift the floating coefficients as before until at least one of them reaches the boundary, fix it assigning its interval to C_1 or C_0 as needed, and omit the corresponding interval from $\mathcal{I}$ ensuring its size is at most $n-1$. This means that for the modified $\mathcal{I}$ the sum

$$\sum_{i=1}^{n-1} \sum_{I \in \mathcal{I}} \mu_i(I) \leq (n-1)\varepsilon/2.$$

Hence there is again a measure i, $1 \leq i \leq n-1$ so that

$$\sum_{I \in \mathcal{I}} \mu_i(I) \leq \varepsilon/2.$$

Again, we may assume that $i = n-1$, observe that measure $n-1$ will stay in its desired range for any future allocation of the remaining intervals, and replace the measure vectors by ones of length $n-2$. This process ends with an allocation of all intervals to C_1 and C_0, ensuring that at the end $\mu_i(C_j) \in [1/2-\varepsilon/2, 1/2+\varepsilon/2]$ for all $1 \leq i \leq n$, $0 \leq j \leq 1$. These are the desired collections. It is clear that the procedure for generating them is efficient, requiring only basic linear algebra operations.

The intervals separated by the marks are partitioned by the algorithm into two collections forming a solution of the continuous problem. Note that the continuous solution would give discrepancy at most $\max_{i \in [n]} m_i \cdot \varepsilon \leq 1/2$ in terms of beads if we were allowed to cut at the marked points. The only subtle point is that some of the marks may be in the interior of small intervals corresponding to beads, and we wish to cut only between beads.

Call a mark between two consecutive beads *fixed* and call the other marks *floating*. We first show how to shift each of the floating marks so that the absolute discrepancy does not increase beyond $1/2$ and all but at most one mark for each color are made between two consecutive beads. To do so, if there exists a floating mark between two intervals assigned to the same agent eliminate it and merge the two intervals. If there is no such mark and there are at least two floating marks in the interior of intervals corresponding to color i, we shift both of them by the same amount in the appropriate way until at least one of them becomes fixed. If during this simultaneous shift one of the two marks arrives in a spot occupied by a different mark, we stop the shift and discard one of the duplicate marks. Note that the quantities the two agents receive do not change.

This procedure reduces the number of floating marks until there is at most one floating mark for each color. If there is such a floating mark, round it to the closest boundary between beads noting that this can increase the absolute discrepancy by at most 1. Therefore, once all marks are fixed, the absolute discrepancy is $\leq 3/2$. Since all the cuts are between consecutive beads, this discrepancy has to be an integer, and thus it is at most 1, as desired. The number of cuts made is $\leq n(2 + \lceil \log_2 \frac{1}{\varepsilon} \rceil) = n(3 + \lceil \log_2 m \rceil) = n(\log m + O(1))$. ◀

▶ Remarks.

- The argument can be extended to splitting into k nearly fair collections of intervals. See section 5 for more details.
- The ε-approximate Necklace Halving problem can be solved with $n(\log(\frac{1}{\varepsilon}) + O(1))$ cuts by using the above algorithm for the continuous instance with the required value of ε.
- The proof can be adapted to obtain a solution with $n(\log(\frac{1}{\varepsilon}) + O(1))$ cuts to the ε-Consensus Halving problem, with the appropriate natural assumptions about the way the measures are presented.
- In [18] the authors give an efficient algorithm for solving a special case of the ε-Consensus Halving problem that works for probability measures each of which is uniform on a single interval. The algorithm provides a solution making at most n cuts for this special case.

3 An online algorithm

Proof of Theorem 2

Proof. We describe an efficient online algorithm that achieves absolute discrepancy at most 1. The algorithm makes $O(m^{2/3}n(\log n)^{1/3})$ cuts. It is worth mentioning that the main part of the algorithm is a derandomization of a simple randomized algorithm which cuts the necklace into pieces each of which has a sufficiently small number of beads of each color and then assigns them randomly and uniformly to the two agents.

Note first that if, say, $\log n > m/1000$, the result is trivial, as less than nm cuts suffice to split the necklace into single beads, hence we may and will assume that $m \geq 1000 \log n$. Throughout the algorithm we call the beads that have not yet been revealed the *remaining beads*. This definition makes sense as in the online model the beads of the necklace are revealed one by one. We provide a cutting rule and a distribution rule. During the algorithm, we call a color i *critical* if the number of remaining beads of this color is smaller than $20\frac{m_i}{m^{1/3}}(\log n)^{1/3}$, otherwise it is *normal*. When encountering a bead of a critical color i while traversing the necklace, the algorithm makes a cut before and after it, allocating that bead to the agent with a smaller number of beads of this type, where ties are broken arbitrarily. We call such cuts that are made right before or after beads of a critical color *forced*.

In addition to the rule about forced cuts, we provide a rule determining when to stop traversing the necklace and make a cut when no beads of a critical color are seen. Define $g = \frac{100}{8m^{2/3}(\log n)^{1/3}}$, and for every $i \in [n]$, $g_i = m_i g = \frac{100m_i}{8m^{2/3}(\log n)^{1/3}}$. Whenever after the last cut made after bead number x we reach a bead number y so that $[x, y]$ (the interval containing beads $x+1, x+2, ..., y$) contains at most g_i beads of color i for every i that is normal at that time and exactly g_j beads of some normal color j, we make a cut. As explained above, the exception to this rule is when we encounter a bead of a color i that is critical before the portion following the last cut has enough beads of some normal color. If $g_i \leq 1$ for some color i, then we cut before and after each bead of color i, essentially treating color i as critical from the beginning.

To decide about the allocation of the intervals created we define, for each color $i \in [n]$, a potential function $\phi_i(t)$, and a function $\psi_i(t)$ that is an upper bound of ϕ_i and is computable efficiently. The variable t here will denote, throughout the algorithm, the index of the last cut made.

The functions ϕ_i, ψ_i are defined by considering an appropriate probabilistic process. For each $i \in [n]$, let X_i be the random variable whose value is the difference between the number of beads of color i belonging to agent 1 and that belonging to agent 2 if after each cut the interval created is assigned to a uniform random agent. Let ε_k be 1 if the k'th interval is assigned to agent 1 and -1 otherwise. Therefore $X_i = \sum_{j=1}^{p} \varepsilon_j a_j$, where $p-1$ is the total number of cuts made and a_j the number of beads of color i on interval I_j, the j'th created interval. The distribution defining X_i is the one where each ε_j is 1 or -1 randomly, uniformly and independently. The function $\phi_i(t)$ is defined as follows

$$\phi_i(t) = \mathbb{E}\left[\frac{e^{\lambda X_i/m_i} + e^{-\lambda X_i/m_i}}{2} | \varepsilon_1, \varepsilon_2, ..., \varepsilon_t\right]$$

This is a conditional expectation, where the conditioning is on the allocation of the first t intervals represented by $\varepsilon_1, \ldots, \varepsilon_t$, and where $\lambda = \frac{4m^{1/3}(\log n)^{2/3}}{10}$. (This choice of λ will become clear later). The purpose of the division by m_i is to normalize the exponent of the potential functions to ensure maintaining a relatively small discrepancy for all colors i simultaneously. Since $X_i = \sum_j \varepsilon_j a_j$, where a_j is the number of beads on the j'th interval of color i, we have that

$$\phi_i(t) = \mathbb{E}\left[\frac{e^{\lambda \sum_j \varepsilon_j a_j/m_i} + e^{-\lambda \sum_j \varepsilon_j a_j/m_i}}{2} | \varepsilon_1, \varepsilon_2, ..., \varepsilon_t\right]$$

The function $\psi_i(t)$ is defined in a way ensuring it upper bounds the function $\phi_i(t)$. It is convenient to split each $\phi_i(t)$ into

$$\frac{1}{2}\mathbb{E}\left[e^{\lambda \sum_j \varepsilon_j a_j/m_i} | \varepsilon_1, .., \varepsilon_t\right] + \frac{1}{2}\mathbb{E}\left[e^{-\lambda \sum_j \varepsilon_j a_j/m_i} | \varepsilon_1, .., \varepsilon_t\right].$$

For simplicity, denote the first term ϕ_i' and the second term ϕ_i''. Therefore

$$\phi_i'(t) = \frac{1}{2}\mathbb{E}\left[e^{\lambda \sum_j \varepsilon_j a_j/m_i} | \varepsilon_1, .., \varepsilon_t\right] = \frac{1}{2} e^{\lambda \sum_{j=1}^{t} \varepsilon_j a_j/m_i} \cdot \prod_{j \geq t+1} \left(\frac{e^{\lambda a_j/m_i} + e^{-\lambda a_j/m_i}}{2}\right)$$

$$= \frac{1}{2} e^{\lambda \sum_{j=1}^{t} \varepsilon_j a_j/m_i} \cdot \prod_{j \geq t+1} \cosh(\lambda a_j/m_i)$$

A similar expression exists for ϕ_i''. Define $s_t = \sum_{j=1}^{t} a_j/m_i$ and $u_t = \sum_{j=1}^{t} \varepsilon_j a_j/m_i$. By the discussion above

$$\phi_i(t) = \frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} \prod_{j \geq t+1} \cosh(\lambda a_j/m_i).$$

Using the well-known inequality that $\cosh(x) \leq e^{x^2/2}$, it follows that

$$\phi_i(t) \leq \frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} e^{\lambda^2 \sum_{j \geq t+1} (a_j/m_i)^2/2}.$$

By the way the cuts are produced $a_j \leq g_i$ for all j, and hence

$$\sum_{j=t+1} (a_j/m_i)^2 \leq \max_{j \geq t+1} (|a_j/m_i|) \cdot (\sum_{j \geq t+1} a_j/m_i) \leq g \cdot (\sum_{j \geq t+1} a_j/m_i) = g(1 - s_t).$$

Therefore

$$\phi_i(t) \leq \frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} e^{\lambda^2 g(1-s_t)/2}.$$

Define $\psi_i(t)$ to be the above upper bound for $\phi_i(t)$, that is

$$\psi_i(t) = \frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} e^{\lambda^2 g(1-s_t)/2}.$$

Note that $\psi_i(t)$ can be easily computed efficiently at time t, since s_t and u_t (as well as g and λ) are known at this point.

Having defined the potential functions ϕ_i and their upper bounds ψ_i, we are now ready to describe the allocation rule following cuts that create intervals with no beads of any critical color. (The rule for allocating intervals consisting of a single bead of a critical color has already been described). Initialize $\phi(0) = \sum_{i \in [n]} \phi_i(0), \psi(0) = \sum_{i \in [n]} \psi_i(0)$, where by convention $\psi_i(0) = e^{g\lambda^2/2}$. After each cut t during the process, we define $\phi(t) = \sum_{i \text{ normal}} \phi_i(t)$ and $\psi(t) = \sum_{i \text{ normal}} \psi_i(t)$. In other words, once a color i becomes critical, the terms ϕ_i and ψ_i are dropped from the respective expressions.

Having allocated the first t intervals, at cut $t+1$, we choose ε_{t+1}, which corresponds to a choice of the agent who gets the interval, in order to minimize $\psi(t+1)$. To show that this algorithm produces a proper solution, where the absolute discrepancy at the end is at most 1, we prove the following two claims:

▷ Claim 1. The upper bound $\psi(t)$ is (weakly) decreasing in the variable t.

▷ Claim 2. For each i, after each cut made before the color becomes critical, the discrepancy in color i is at most $10\frac{m_i}{m^{1/3}}(\log n)^{1/3}$ (in absolute value).

Claim 2 implies that after the first cut that causes color i to become critical, the discrepancy on i is at most $10\frac{m_i}{m^{1/3}}(\log n)^{1/3} + g_i < 20\frac{m_i}{m^{1/3}}(\log n)^{1/3} - g_i$. Hence, it follows from the way the algorithm deals with subsequent beads of color i, that the process will end with a balanced partition of the beads of each color i between the agents, allocating to each of them either $\lfloor m_i/2 \rfloor$ or $\lceil m_i/2 \rceil$ of these beads. As this argument works for every color, the algorithm produces a proper solution. Next, we prove the claims.

Proof of Claim 1. Note that whenever some color i becomes critical, the term ψ_i that we drop from ψ is positive. Hence, it is enough to prove that $\psi(t) \geq \frac{\psi(t+1|\varepsilon_{t+1}=1)+\psi(t+1|\varepsilon_{t+1}=-1)}{2}$, where $\psi(t+1|\varepsilon_{t+1} = \chi)$ denotes the value of $\psi(t+1)$ if we choose $\varepsilon_{t+1} = \chi \in \{-1, 1\}$. It suffices to show that for every i, $\psi_i(t) \geq \frac{1}{2}[\psi_i(t+1|\varepsilon_{t+1} = 1] + \frac{1}{2}[\psi_i(t+1|\varepsilon_{t+1} = -1]$.

We proceed with the proof of this inequality. To do so, note that

$$\psi_i(t+1|\varepsilon_{t+1}=1) = \frac{e^{\lambda(u_t+a_{t+1}/m_i)} + e^{-\lambda(u_t+a_{t+1}/m_i)}}{2} e^{\lambda^2 g(1-s_t-a_{t+1}/m_i)/2},$$

and

$$\psi_i(t+1|\varepsilon_{t+1}=-1) = \frac{e^{\lambda(u_t-a_{t+1}/m_i)} + e^{-\lambda(u_t-a_{t+1}/m_i)}}{2} e^{\lambda^2 g(1-s_t-a_{t+1}/m_i)/2}.$$

Therefore

$$\frac{\psi_i(t+1|\varepsilon_{t+1}=1) + \psi_i(t+1|\varepsilon_{t+1}=-1)}{2} =$$

$$\frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} \cdot \frac{e^{\lambda a_{t+1}/m_i} + e^{-\lambda a_{t+1}/m_i}}{2} e^{\lambda^2 g(1-s_t-a_{t+1}/m_i)/2}$$

$$\leq \frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} \cdot e^{\lambda^2 g(a_{t+1}/m_i)/2} e^{\lambda^2 g(1-s_t-a_{t+1}/m_i)/2} = \frac{e^{\lambda u_t} + e^{-\lambda u_t}}{2} \cdot e^{\lambda^2 g(1-s_t)/2} = \psi_i(t),$$

as needed. ◁

Proof of Claim 2. Let t be a cut made while color i is normal. To prove that the discrepancy on color i in absolute value is at most $10\frac{m_i}{m^{1/3}}(\log n)^{1/3}$, it suffices to prove $\psi_i(t) \leq \frac{1}{2} e^{\lambda \cdot 10(\frac{\log n}{m})^{1/3}} e^{\lambda^2 g(1-s_t)} = \frac{1}{2} e^{2\log n} e^{\lambda^2 g(1-s_t)}$. By Claim 1, $\psi(t) \leq \psi(0) = ne^{g\lambda^2/2}$. Hence, it is enough to prove that $ne^{g\lambda^2/2} \leq \frac{1}{2} e^{2\log n} e^{\lambda^2 g(1-s_t)}$. This is equivalent to $\lambda^2 g s_t/2 + \log 2 \leq 4\log n$. Since $s_t \leq 1$, we get $\lambda^2 g s_t/2 + \log 2 \leq \log n + \log 2 \leq 2\log n$, as needed. ◁

Lastly, we prove that the total number of cuts is $O(n(\log n)^{1/3} \cdot m^{2/3})$. The number of forced cuts cannot exceed $2n \cdot 20\frac{m_i}{m^{1/3}}(\log n)^{1/3} = O(m^{2/3} n (\log n)^{1/3})$. To bound the number of non-forced cuts, note that whenever we make such a cut, there is a color j such that the number of beads of this color on the interval created is exactly g_j. We call the cut j-tight for that respective color. It is easy to see that for every color i there are most $O(m^{2/3}(\log n)^{1/3})$ i-tight cuts. Hence, the total number of non-forced cuts is at most $O(m^{2/3} n (\log n)^{1/3})$. This completes the proof. ◀

4 Lower bounds

In this section we present the lower bounds for Necklace Halving in the online model.

4.1 A preliminary bound

We provide a $\Omega(\sqrt{m})$ lower bound for the number of cuts required in any online algorithm when the number of colors is $n = 2$ and there are m beads of each color. We need the following simple lemma, which is a special case of a more general elegant result of Tijdeman [23]. Since this special case is much simpler, we include its proof, for completeness.

▶ **Lemma 1.** *For every real $\gamma \in [0,1]$ there is an infinite binary sequence $a_1, a_2, a_3, \ldots$ so that in every prefix of it $a_1, a_2, \ldots, a_j$ the number of elements a_i which are 1 deviates from γj by less than 1.*

Proof. By compactness it suffices to prove the existence of such a sequence of any finite length r. Consider the following system of linear inequalities in the variables $x_1, x_2, \ldots, x_r$: $0 \leq x_i \leq 1$ for all $1 \leq i \leq r$, and for every $j \leq r$, $\lfloor \gamma j \rfloor \leq \sum_{i=1}^{j} x_i \leq \lceil \gamma j \rceil$. This system has a real solution $x_i = \gamma$ for every i and the matrix of coefficients of the constraints is totally unimodular. Hence there is an integral solution $x_i = a_i \in \{0, 1\}$ providing the required sequence. ◀

We use the following notation. During the algorithm let t denote the number of beads revealed so far. If a cut is made at this point, let x_t be the difference between the number of beads of color 1 allocated to agent 1 and the number of beads of color 1 allocated to agent 2. Define y_t similarly for beads of color 2. Let α_t, β_t denote the number of remaining beads of colors 1 and 2, respectively.

▶ **Lemma 2.** *Let Δ be a positive integer. Suppose that a cut is made at point t and $|x_t| = \Delta$ and assume that no bead of color 2 appeared so far. Then there exists an adversarial input that forces the Balancer to make at least $\Delta/4 = \Omega(\Delta)$ cuts.*

Proof. Without loss of generality assume that $x_t = \Delta > 0$. Note that by assumption $\beta_t = m$ and $\alpha_t < m$. Put $\gamma = \frac{m}{\alpha_t + m}$ and note that $\gamma > 1/2$. By Lemma 1 it is possible to choose an ordering of the remaining $\alpha_t + m$ beads of the necklace so that in every prefix of it of any length j, the number of beads of color 2 deviates from γj by less than 1. Since our online model allows the Balancer to see the next bead before the decision to make a cut preceding it we may have to change the first bead in this ordering, this still ensures that in any interval of length ℓ in the remainder of the necklace, the number of beads of color 2 deviates from $\gamma\ell$ by at most 2.

Suppose the Balancer cuts the remainder of the necklace and allocates the resulting intervals $R_1, ..., R_u$ to agent 1 and $T_1, ..., T_v$ to agent 2 to obtain a balanced allocation. For each one of these intervals I let $\ell(I)$ denote its length. By assumption at time t agent 1 has exactly Δ more beads than agent 2. Since at the end each agent has half of the beads (for simplicity we assume that m is even), $\sum_{i=1}^{v} \ell(T_i) - \sum_{j=1}^{u} \ell(R_j) = \Delta$.

By construction, the total number of beads of color 2 in all intervals T_i deviates from $\gamma \sum_{i=1}^{v} \ell(T_i)$ by at most $2v$. Similarly, the total number of beads of color 2 in all intervals R_j deviates from $\gamma \sum_{j=1}^{u} \ell(R_j)$ by at most $2u$. As these two numbers should be equal it follows that

$$\gamma\Delta = \gamma\left(\sum_{i=1}^{v} \ell(T_i) - \sum_{j=1}^{u} \ell(R_j)\right) \leq 2u + 2v$$

This implies that $2(u + v) \geq \gamma\Delta > \Delta/2$ and as the number of cuts is at least $u + v$ the desired result follows. ◀

The last lemma easily implies the following.

▶ **Theorem 3.** *There exists an adversarial input that forces any deterministic algorithm for Online Necklace Halving with $n = 2$ colors to make $\Omega(\sqrt{m})$ cuts in order to obtain a proper solution.*

Proof. Put $\Delta = \sqrt{m}$ and proceed by revealing only beads of color 1. By Lemma 2, if after a cut at some t, $|x_t| > \sqrt{m}$, the desired result follows. Otherwise it is clear the number of beads between any two consecutive cuts is less than $2\sqrt{m}$, implying that the total number of cuts made by the Balancer is $\Omega(\sqrt{m})$. ◀

4.2 A nearly tight bound

▶ **Theorem 4.** *An adversary can force any deterministic algorithm for Online Necklace Halving with $n = 3$ colors and m beads of each color to make $\Omega(m^{2/3})$ cuts.*

Proof. As in the previous subsection, let x_t denote the discrepancy between the number of beads of color 1 allocated to agent 1 and that allocated to agent 2 after cut t, and let y_t denote the corresponding discrepancy for color 2, where color 3 will be kept as a potential threat. We proceed by revealing only beads of the first two colors. By Lemma 2 with $\Delta = m^{2/3}$ the Balancer needs to maintain $|x_t|, |y_t| \leq m^{2/3}$, since otherwise the adversary can force $\Omega(m^{2/3})$ cuts, using beads of the third color. Hence, we assume that during the process of revealing the initial $m + 4m^{2/3}$ beads of the necklace x_t, y_t stay in the above range after each cut.

Define a potential function

$$M(x, y) = x^2 + y^2 + 5m^{2/3}(x - y)$$

After a cut with $v_t = (x_t, y_t) = (x, y)$ define $\gamma = \frac{10m^{2/3} - 4y}{20m^{2/3} + 4(x-y)}$. Note that $0 < \gamma < 1$, as $|x|, |y| \leq m^{2/3}$. By Lemma 1 it is possible to order the remaining part of the first $m + 4m^{2/3}$ beads of the necklace so that in each prefix of any length j of this remaining part the number of beads of color 1 deviates from γj by less than 1 and the number of beads of color 2 deviates by less than 1 from $(1 - \gamma)j$. As the first bead of this remaining part has been observed already by the Balancer we may need to change one bead in this ordering, getting a deviation of less than 2 in each prefix. This means that if the next cut will be made after some j additional beads, the vector $p = (p_1, p_2)$ of additional beads of colors 1 and 2, respectively, can be written as a sum of the vector $p' = (\gamma j, (1 - \gamma)j)$ and an error vector $\delta = (\delta_1, \delta_2)$ of ℓ_∞-norm smaller than 2. We get that

$$M(v_t + p') - M(v) = p_1'^2 + p_2'^2 + 2xp_1' + 2yp_2' + 5m^{2/3}p_1' - 5m^{2/3}p_2' =$$

$$= p_1'^2 + p_2'^2 + \frac{1}{2}[p_1' \cdot (10m^{2/3} + 4x) - p_2' \cdot (10m^{2/3} - 4y)] = p_1'^2 + p_2'^2 \geq \frac{1}{2}j^2$$

and similarly,

$$M(v - p') - M(v) = p_1'^2 + p_2'^2 + \frac{1}{2}[-p_1' \cdot (10m^{2/3} + 4x) + p_2' \cdot (10m^{2/3} - 4y)] = p_1'^2 + p_2'^2 \geq \frac{1}{2}j^2$$

A simple computation using the fact that $|x|, |y| \leq m^{2/3}$ and that a similar bound holds after adding or subtracting the vector p' shows that adding or subtracting the vector δ can decrease the value of M by less than $15m^{2/3}$. Therefore, we get

$$M(v_t \pm p) - M(v_t) \geq j^2/2 - 15m^{2/3}$$

which implies $M(v_{t+1}) - M(v_t) \geq j^2/2 - 15m^{2/3}$, with a cut of j beads.

Suppose that we have r cuts among the first $m + 4m^{2/3}$ beads of the necklace, and the lengths of the resulting intervals are $j_1, j_2, \ldots, j_r$. Since throughout the process $|x_t|, |y_t| \leq m^{2/3}$, it follows that $M(x_t, y_t) \leq 12m^{2/3}$. On the other hand by the above discussion the value of M at the end is at least $\sum_{i=1}^{r} \frac{j_i^2}{2} - 15m^{2/3}r$. Since $\sum_{i=1}^{r} j_i \geq m$ (as we cannot have $4m^{2/3}$ consecutive beads with no cut among them), it follows, by Cauchy-Schwartz, that $\sum j_i^2 \geq \frac{m^2}{r}$. This implies that

$$\frac{1}{2}\frac{m^2}{r} - 15rm^{2/3} \leq 12m^{4/3}$$

showing that $r = \Omega(m^{2/3})$, as needed. ◀

▶ Remark. For $n > 3$ colors with m beads of each color one can consider a necklace consisting of $\lfloor n/3 \rfloor$ segments with at least 3 colors in each of them. The above argument shows that it is possible to force $\Omega(m^{2/3})$ cuts in each segment, implying an $\Omega(nm^{2/3})$ lower bound. Thus, for n colors, the gap between our lower and upper bounds for the number of cuts required is only a factor of $\Theta((\log n)^{1/3})$.

5 Extensions and open problems

We conclude with some generalizations of the algorithms presented and the lower bounds obtained, and with comments on some of the questions that remain open.

5.1 Generalizations

In this section, we present our online and offline results for the general case of k agents.

▶ **Theorem 5.** *There exists an efficient, deterministic, offline algorithm that provides a proper solution to the Necklace Splitting problem, making at most* $n(k-1)\lceil 4 + \log_2(3km)\rceil$ *cuts.*

Proof. As in the proof of Theorem 1, we first convert the Necklace Splitting instance into a continuous instance J, and obtain a solution with absolute discrepancy at most $\frac{\varepsilon}{2k} = \frac{1}{2km}$, possibly making some floating cuts. Then, to obtain a proper solution for the discrete instance, we shift the floating cuts by solving a network flow problem.

To obtain the solution to the continuous instance J, we recursively apply a modified version of the algorithm that makes cuts on the continuous necklace from Theorem 1. Define $\varepsilon' = \varepsilon/3k = \frac{1}{3km}$, and divide the k players into two disjoint groups A, B, with $\lfloor k/2 \rfloor$ agents and $\lceil k/2 \rceil$ agents respectively. Think of A, B as two agents and split the continuous necklace among them. By following the algorithm in the proof of Theorem 1, one can make $\leq n(2+\lceil \log_2 \frac{1}{\varepsilon'} \rceil)$ cuts and split the interval so that A gets $\frac{\lfloor k/2 \rfloor}{k} \pm \varepsilon'/2$ of each measure i. We can do so by starting with all floating coefficients equal to $\frac{\lfloor k/2 \rfloor}{k}$ instead of $\frac{1}{2}$ and by following the proof of Theorem 1. Repeat the same procedure for the groups A and B recursively, splitting the share of A among its $|A|$ members and doing the same for B. In the end, the error can be bounded by $\varepsilon' + \frac{2}{3}\varepsilon' + \frac{2}{3} \cdot \frac{4}{7}\varepsilon' + \ldots < 3\varepsilon'$. If we denote by $T(k)$ the number of cuts made to obtain absolute discrepancy $\leq \varepsilon'$ for a continuous instance with n types and k agents, then $T(2) = n[\log_2 \frac{1}{\varepsilon'} + 2]$, and $T(k) = T(\lfloor k/2 \rfloor) + T(\lceil k/2 \rceil) + n[\log_2 \frac{1}{\varepsilon'} + 2]$, which gives that the number of cuts made for this split is $T(k) = n(k-1)\lceil 2 + \log_2(3km)\rceil)$.

Hence, we have obtained a proper solution for the continuous instance J, making $n(k-1)\lceil 2 + \log_2(3km)\rceil)$ cuts, yet we have to handle floating cuts. We categorize each floating cut by the color of the interval in whose interior it lies. For each color i, we handle the corresponding floating cuts. First, note that if $k > m_i$, we can shift each floating cut on color i to one of the ends of the i-interval in such a way that no agent gets more than one bead of color i and this will provide discrepancy at most 1 on color i without creating any additional cuts. Hence, we may assume $m_i \geq k$.

We use a network flow algorithm to decide, for each bead of color i that does not fully belong to one agent, to whom it should be allocated. Define a directed graph G_i, with vertices s, the source, t, the sink, V_i, representing the set of beads of color i, and H, the set of vertices representing the agents. Let E be the set of edges with

$$E = \{(s, v), v \in V_i\} \cup \{(h, t), h \in H\} \cup \{(v, h), \text{agent h owns a share of bead v}\}$$

All edges $\{(s,v), v \in V_i\}$ have capacity 1 and lower bound 1. Each edge (v,h) has capacity 1 and lower bound 0. Finally, for each edge (h,t), set the capacity to be $\lceil x_h \rceil$ and the lower bound to be $\lfloor x_h \rfloor$, where x_h is the quantity of type i allocated to agent h in the solution to the continuous instance. Now, if we assign each edge (v,h) a value equal to the share of bead v allocated to agent h in the continuous solution and each edge (h,t) the value x_h, this is a legal flow. Hence, there exists an integral legal flow in the network, and it is well known that one can find such a flow efficiently. Note that an integral flow corresponds to a distribution of the beads of color i where no additional cut is made and the absolute discrepancy is at most 1 if $k \nmid a_i$ and at most 2 if $k|a_i$. Thus, the integral flow determines which agent gets each of the contested beads of color i, corresponding to a shift of each floating cut to one of the ends of the bead it crosses.

If $k|a_i$, the continuous solution could give some agent a a share of $x_a = a_i/k - \varepsilon_1$ and some agent b a share $x_b = a_i/k + \varepsilon_2$, for small positive values $\varepsilon_1, \varepsilon_2$. In this case, the integral network flow solution could give agent a $a_i/k - 1$ beads and agent b $a_i/k + 1$ beads of color i. As a_i/k is an integer, the number of agents receiving $a_i/k + 1$ beads is the same as the number of agents receiving $a_i/k - 1$. Hence, we can make at most $2k$ cuts after the shift is done to obtain discrepancy 0. We perform the shifting procedure for every color i, and obtain a proper solution with at most $nk + n(k-1)\lceil 2 + \log_2(3km) \rceil < n(k-1)\lceil 4 + \log_2(3km) \rceil$, as needed. This completes the proof. The network flow argument follows the approach in [4]. ◀

▶ **Theorem 6.** *There exists an efficient, deterministic, online algorithm that provides a proper solution for the Necklace Splitting problem, making at most $\tilde{O}(nk^{1/3} \cdot m^{2/3})$ cuts.*

Proof. Note that the result is trivial for $k > m$. For $k \leq m$, we again use the idea of defining a potential function ϕ and a function ψ that is an upper bound for ϕ and is computable efficiently. Instead of having one pair of functions ϕ_i, ψ_i for each color i, we now have $\binom{k}{2}$ such functions, one for each pair of agents. For each color i and agents $p \neq q$, define $\phi_i^{p,q} = \mathbb{E}\left[\frac{e^{\lambda X_{p,q,i}/m_i} + e^{-\lambda X_{p,q,i}/m_i}}{2}\right]$, where $X_{p,q,i}$ is the random variable of the difference between the number of beads of color i given to agent p and that of agent q. The relevant random distribution here assigns every newly created interval to one of the k agents with equal probability which is $1/k$. The quantity $g = g(n,k,m)$ is defined here as $g = \frac{1}{m^{2/3}k(\log(nk))^{1/3}}$, and each g_i, the maximum number of beads of color i allowed between two consecutive cuts as $g_i = m_i g$. We say color i is *critical* when the number of remaining beads of this color is at most $20k^{1/3}m^{2/3}$.

The function $\psi_i^{p,q}$ is defined by

$$\psi_i^{p,q}(t) = \frac{e^{\lambda x_{t,i}^{p,q}} + e^{-\lambda x_{t,i}^{p,q}}}{2} \cdot e^{2\lambda^2 g(1-s_t)/k}$$

where s_t is, as before, the proportion of beads of color i allocated already, and $x_{t,i}^{p,q}$ is the discrepancy between p and q on color i after cut t divided by m_i.

The main difference required here is the replacement of the inequality $\cosh(\lambda a) \leq e^{\lambda^2 a^2/2}$ by the following inequality which holds whenever, say, $\lambda a \leq 1$:

$$\frac{k-2}{k}e^{\lambda \cdot 0} + \frac{1}{k}e^{\lambda a} + \frac{1}{k}e^{-\lambda a} = 1 + \frac{2}{k}(\cosh(\lambda a) - 1)$$

$$\leq 1 + \frac{2}{k}(e^{\lambda^2 a^2/2} - 1) \leq 1 + \frac{2}{k}\frac{2\lambda^2 a^2}{2} = 1 + \frac{2\lambda^2 a^2}{k} \leq e^{2\lambda^2 a^2/k}.$$

Each $\phi_i^{p,q}$ is bounded using the fact that each of the intervals created has at most $g_i = m_i g$ beads of color i for every i. By the inequality applied with $a \leq g$ and $\lambda = \frac{(k/m)^{1/3}}{4g}$ (ensuring that indeed $\lambda a \leq \frac{(k/m)^{1/3}}{4} < 1/2$), it follows that if every interval generated is allocated to an agent in order to minimize $\psi = \sum_{p,q\in[k],\ p\neq q,\ i\in[n]} \psi_i^{p,q}$, then the function ψ never increases during the algorithm. As

$$\psi(0) < nk^2 e^{2\lambda^2 g/k} = nk^2 e^{\varepsilon^2/8gk} < \frac{e^{\lambda\varepsilon/k}}{2}$$

the computation shows that at the end the absolute discrepancy is $\leq \varepsilon/k$. We omit the details. ◀

Next, we present two simple special cases where we obtain proper solutions efficiently with the optimal number of cuts, $n(k-1)$. In the first case, the number of beads of each color is equal to k, the number of agents. In the second case, we set the number of colors to be $n = 2$.

▶ **Proposition 1.** *There exists an efficient algorithm that solves any instance of Necklace Splitting for n colors and k agents where there are exactly k beads of each color, making at most $n(k-1)$ cuts.*

Proof. Traverse the necklace once bead by bead and cut between any pair of consecutive beads unless the second one is the first appearance of a bead of color i for some $i \in [n]$. After each cut made, if S is the set of colors present in the newly created interval J, we allocate J to an agent that has not received up to that point any beads of any color in S. To show that after each cut such an agent exists, first note that by the description above, no agent receives two beads of the same color. If J contains only one bead and its color is i, there must exist an agent who has not received any bead of color i up to that point, as there are as many agents as beads of color i. If J has $p \geq 2$ beads, of colors $c_1, ..., c_p \in [n]$ appearing in this order, we can still give it to an agent that has not received any bead of color c_1, since each of the other beads in J has a color that has not appeared before.

It thus follows that with this allocation rule each agent gets exactly 1 bead of each color. To prove the upper bound on the number of cuts, note that for each $i \in [n]$, we never cut right before the first bead of color i that appears on the necklace. Hence, there are exactly $n-1$ beads (besides the very first one) with no cut right before them. Since there are $kn-1$ points between consecutive beads the algorithm makes exactly $kn - 1 - (n-1) = n(k-1)$ cuts. ◀

▶ **Proposition 2.** *There exists an efficient algorithm that solves any instance of Necklace Splitting for $n = 2$ colors and k agents, making at most $2(k-1)$ cuts.*

Proof. We first consider the case when k divides both m_1, m_2, where m_i is the number of beads of color i. Given a necklace with m_1 beads of color 1 and m_2 beads of color 2 consider it as a circular necklace. By the discrete intermediate value theorem there is a circular arc of $(m_1 + m_2)/k$ beads containing exactly m_1/k beads of color 1 (and hence also exactly m_2/k beads of color 2). Cut in the ends of this circular arc, assign it to the first agent, and continue inductively. Clearly, every agent gets the same number of beads of each color.

To extend the proof for general m_1, m_2, write $m_1 = kp + r$ and $m_2 = kq + s$. We look for a circular arc of $\lceil \frac{m_1}{k} \rceil + \lceil \frac{m_2}{k} \rceil$ beads containing exactly $\lceil \frac{m_1}{k} \rceil$ beads of color 1 (and hence also exactly $\lceil \frac{m_2}{k} \rceil$ beads of color 2). If $r \neq 0$, the agent to whom we distribute the arc gets $p+1$ beads of color 1. Similarly, if $s \neq 0$, the agent gets $q+1$ beads of color 2. Hence, by

inductively finding a suitable arc and cutting it from the necklace, at the end of the process, the first r agents will get $p+1$ beads of color 1 and the rest p. Similarly, the first s agents will get $q+1$ beads of color 2 and the rest q. ◀

5.2 Connections to ε-Consensus Splitting

Our results easily extend to the ε-Consensus Splitting problem with non-atomic probability measures whose density functions are piecewise linear. This is stated in the next two theorems whose detailed proofs are provided in the full version.

▶ **Theorem 7.** *There exists an efficient, deterministic, offline algorithm that provides a solution to the ε-Consensus Splitting problem, making at most $n(k-1)\lceil 4+\log_2(3km)\rceil$ cuts, provided that the density functions of the probability measures are piecewise linear.*

▶ **Theorem 8.** *There exists an efficient, deterministic, online algorithm that provides a solution for the ε-Consensus Splitting problem, making at most $O(\frac{kn\log(nk)}{\varepsilon^2})$ cuts, provided that the density functions of the probability measures are piecewise linear.*

Note that for $k=2$ agents, the number of cuts resulting from the algorithm corresponding to Theorem 8 is $O(\frac{n\log n}{\varepsilon^2})$. The proof of Theorem 2 relies on using this algorithm for $k=2$ agents with $\varepsilon=\Theta((\frac{\log n}{m})^{1/3})$.

5.3 Open questions

Theorem 1 provides a proper solution to the offline version for $k=2$ agents by making a number of cuts that depends logarithmically on m, the maximum number of beads of a color. It would be interesting to see if this dependency can be improved asymptotically.

Another open question arises in the context of the Online Necklace Halving problem for $n=2$ colors, where the lower bound for the number of cuts is only $\Omega(\sqrt{m})$, whereas the upper bound for the number of cuts produced by our algorithm is $O(m^{2/3})$. Lastly, for the general case of n colors for the online version of Necklace Halving there is a $\Theta((\log n)^{1/3})$ gap between the lower bound and the algorithm we provided. It will be interesting to close these gaps.

Abstract

Color refinement is a crucial subroutine in symmetry detection in theory as well as practice. It has further applications in machine learning and in computational problems from linear algebra.

While tight lower bounds for the worst case complexity are known [Berkholz, Bonsma, Grohe, ESA2013] no comparative analysis of design choices for color refinement algorithms is available.

We devise two models within which we can compare color refinement algorithms using formal methods, an online model and an approximation model. We use these to show that no online algorithm is competitive beyond a logarithmic factor and no algorithm can approximate the optimal color refinement splitting scheme beyond a logarithmic factor.

We also directly compare strategies used in practice showing that, on some graphs, queue based strategies outperform stack based ones by a logarithmic factor and vice versa. Similar results hold for strategies based on priority queues.

1 Introduction

Color refinement, also known as 1-dimensional Weisfeiler-Leman algorithm, is a crucial cornerstone of symmetry detection in theory as well as practice. It emerged as a subroutine for algorithms solving the graph isomorphism problem and its efficiency remains to date one of the determining factors for the running time of practical isomorphism solvers. Modern, highly efficient implementations are based on Hopcroft's algorithm for automata minimization [8], which was first adapted to color refinement by McKay in his widely used tool NAUTY [11]. A more recent but also in the meantime large application area of color refinement can be found in machine learning. Specifically, color refinement is used in the Weisfeiler-Leman Kernel for graph classifications as a measure for similarity [15] and as the foundation of graph neural networks [13]. The algorithm can also be applied to effectively reduce the size of linear equation systems [7].

Given a graph, color refinement iteratively recolors the vertices producing increasingly fine partitions of vertices into color classes. Starting with an initial, usually monochromatic coloring, in each iteration the colors of the vertices are chosen to depend on the colors of the neighbors and their multiplicities. If vertices differ in the number of neighbors they have in some color class, the algorithm *splits* up the vertices accordingly by assigning them distinct colors. This is done exhaustively until no further splits are possible.

The applications mentioned above depend on highly engineered implementations of the algorithm. This is the reason why modern implementations meticulously optimize the color refinement subroutine treating many special cases with tailored code [1, 9, 12]. Especially in machine learning applications it is crucial to achieve scalability for big data inputs [15]. Overall, demand for fast implementations of color refinement is high. Since color refinement has a quasilinear worst case running time, even small logarithmic or constant factors can have a crucial impact.

Indeed, the best known implementation of color refinement runs in time $\mathcal{O}(m \log(n))$ (see [4, 10]). Remarkably, within a model with modest assumptions, a tight lower bound construction matching this upper bound was given in 2015 [4]. This result tells us that there are graphs for which color refinement, no matter how it is implemented, runs in $\Omega(m \log(n))$. However, the result does not make any comparative statements between various ways to implement color refinement. In fact, there are dramatic differences in the various implementations of color refinement. While all color refinement algorithms depend on performing the aforementioned splits, there is a lot of freedom as to which order we perform the splits in. A *worklist* is usually employed to determine in what order these splits are performed. Common choices include a stack, queue, priority queue or combinations of these.

So far however, there has been no rigorous analysis as to whether one worklist choice is superior over another – or how significant the order of splits actually is. Going one step further, a natural question is whether there are efficient optimal solutions. If not the case, maybe there are at least solutions that are competitive with all other methods.

Contribution. This paper performs an in-depth comparative analysis of design choices for color refinement algorithms. The first challenge is to actually find a model within which we can compare color refinement algorithms with formal methods. We employ a two-pronged approach. We distinguish (1) algorithms that may only use information realistically collected during the color refinement process itself, and (2) algorithms that are allowed to compute additional information about the underlying graph. Remarkably, our results in the two orthogonal models concur in their conclusion. Namely, that there is no design choice that is competitive beyond a logarithmic factor.

More specifically, in (1) we model algorithms that may only access information explored during the color refinement process itself. For this we define a formal online model within which, in fact, all practical algorithms operate. In this model, the algorithmic decisions of when to refine with respect to what may solely depend on this information. We prove that this information does not suffice to make optimal or even competitive choices, no matter the amount of computational power used. Specifically, we show no online algorithm is within a logarithmic factor of the offline optimum. We also investigate the direct relationship between practical (online) color refinement strategies. Each of the strategies stack, queue, and priority queue, is outperformed by another of the strategies by a logarithmic factor on some graphs.

For (2), we define an "offline" version of the problem, which is essentially to compute an optimal split order for a given graph. Through a reduction from the set cover problem we prove an approximation hardness result. Specifically, unless $\mathsf{P} = \mathsf{NP}$, no approximation factor

Algorithm 1 A typical rendition of color refinement.

```
1  function ColorRefinement(G, π)
       Input  : graph G, coloring π
       Output : refined coloring π
2      initialize empty worklist W;
3      put all cells of π into W;
4      while W is non-empty do
5          take a cell C from W;
6          for each cell X containing a neighbor of a vertex in C do
7              for each vertex in X count its neighbors in C ;
8              split X into X_1, ..., X_k in π, according to neighbor counts;
9              let X_i be one of the largest cells of X_1, ..., X_k;
10             put all sets X_1, ..., X_k except X_i into W;
11             if X ∈ W then replace X in W with X_i;
12     return π
```

in $o(\log(n))$ can be achieved by polynomial-time algorithms. This proves that unless $\mathsf{P} = \mathsf{NP}$, even when collecting more information about the underlying graph than current algorithms actually do, computing a competitive let alone optimal order of splits is intractable.

Overall, our results demonstrate that while the choice of worklist can indeed make a crucial difference, there is no clear optimal color refinement strategy. We conclude that users need to adapt color refinement algorithms to the specific type of graphs encountered in the algorithmic application area in mind.

2 Color Refinement

All graphs in this paper are finite, simple, undirected graphs, unless stated otherwise. The neighborhood of a vertex v is denoted $N(v)$. For a set of vertices $V' \subseteq V(G)$ the *neighborhood* is the set $N[V'] \coloneqq (\cup_{v \in V'} N(v)) \setminus V'$. A *coloring* of a graph G is a map $\pi \colon V(G) \to \mathcal{C}$ from the vertices to some set of colors. A (color) *class* is a set $\pi^{-1}(c)$ of vertices of the same color.

We begin with a discussion of the color refinement algorithm itself. Algorithm 1 describes a typical rendition of color refinement. The basic idea is as follows. If two vertices in some class X have a different number of neighbors in some class C then X can be split by partitioning it according to neighbor counts in C. Whenever we split up a class X according to its connections to another class C in such a fashion (see Line 7 and Line 8) we say that we *refine X with respect to C*. Specifically this means that after the split, two vertices have the same color precisely if they had the same color before the split and they have the same number of neighbors in C. We repeatedly split classes with respect to other classes until no further splits are possible. A partition not admitting further splits is called *equitable*.

Algorithm 1 maintains the classes with respect to which refinements still have to be performed in a worklist W. Note that the algorithm does not fully specify the internals of the worklist. Specifically, it does not state in Line 5 which cell is extracted from the worklist next. We should emphasize that the final partition into color classes is independent of the choices of cells that are extracted, however the overall running time may depend on it. Typical implementations use a stack, queue, priority queue or a similar data structure. All of these choices result in the same worst case running time of $\Theta((n+m)(\log n))$ (see [4]). To achieve this running time it is crucial to prevent one largest cell (Line 9) from being added to the worklist. Splits with respect to this class are already covered by the other classes.

Overall, the main design choice of the algorithm is the choice of when to split which class with respect to which other class. To describe a general framework for the possible strategies of what to split when, we first need to understand what information is available to the algorithm for making its decision.

2.1 Partial Quotient Graphs

For an equitable partition, quotient graphs capture the information of how many neighbors vertices from one class have in another class. They are used in individualization refinement algorithms as pruning invariants (see [12]). Typically, the quotient graph is computed on the fly during the execution of a color refinement algorithm.

We now introduce the concept of *partial quotient graphs*. These graphs are a tool to formalize the information gathered up to a certain point during the execution of color refinement algorithms. As we cannot precisely say which information an algorithm collects, the quotient graphs give an overapproximation of the available information and model all information that could have possibly been gathered. For the purpose of our lower bounds, overapproximating can only strengthen the conclusions.

The partial quotient graph of a colored graph (G, π) is denoted by $P(G, \pi)$. Quotient graphs are directed and contain self-loops. They include vertex labels l_V as well as edge labels l_E. The vertex set of $P(G, \pi)$ is the set of all sets of colors of (G, π), i.e., $V(P(G, \pi)) := 2^{\pi(V(G))}$. A set of colors also represents the union of the respective color classes.

Vertices of the partial quotient graph are labeled with the size of their corresponding set of vertices in G, i.e., for all sets of colors $c \in 2^{\pi(V(G))}$ we define $l_V(P(G, \pi))(c) := |\pi^{-1}(c)|$, where by $\pi^{-1}(c)$ we denote the vertices whose color is in c. The edge set contains all connections between (unions of) color classes that would not cause a split. Thus there is an edge from c_1 to c_2 if $\pi^{-1}(c_2)$ does not split $\pi^{-1}(c_1)$. Formally, this means

$$E(P(G, \pi)) := \{(c_1, c_2) \mid c_1, c_2 \in 2^{\pi(V(G))}, \forall v, w \in \pi^{-1}(c_1) : \ d_{\pi^{-1}(c_2)}(v) = d_{\pi^{-1}(c_2)}(w)\}.$$

Edges only exist whenever the connection between unions of color classes are regular on one side, so we can label each edge with the corresponding degree, i.e., $l_E(P(G, \pi))((c_1, c_2)) := d_{\pi^{-1}(c_2)}(v)$, where $v \in \pi^{-1}(c_1)$ is arbitrary.

Let us justify the definition with an example. Suppose we split in a monochromatic graph the class of all vertices with itself. Then the new coloring partitions the vertices precisely by degree. That is, classes contain vertices of the same degree. An algorithm would know this degree, since it has counted the edges incident with each vertex, but it would not know how many neighbors a vertex has within a current color class. In the partial quotient graph, there is an edge from each new color classes to the union of all color classes.

The definition of partial quotient graphs contains many more vertices and edges and information on these than would truly be available while executing color refinement. In fact, partial quotient graphs grow exponentially in size, since all possible unions of color classes are considered. Common color refinement algorithms clearly gather much less information. Firstly, only connections of classes that are involved in a refinement are actually considered. Secondly, only information about unions of colors that occurred as a color class in a previous step of the refinement is known. Thus, usually color refinement algorithms only uncover a small, polynomial-sized portion of the partial quotient graphs defined above.

However, for our lower bounds, we assume that algorithms have access to the entire partial quotient graphs. We show that even if we generously allow such access, the information is not sufficient to derive a strategy with constant competitive ratio. For upper bounds, we only use information of the aforementioned polynomial-sized portion of partial quotient graphs. In fact, the upper bounds are based on a stack-based approach akin to Algorithm 1.

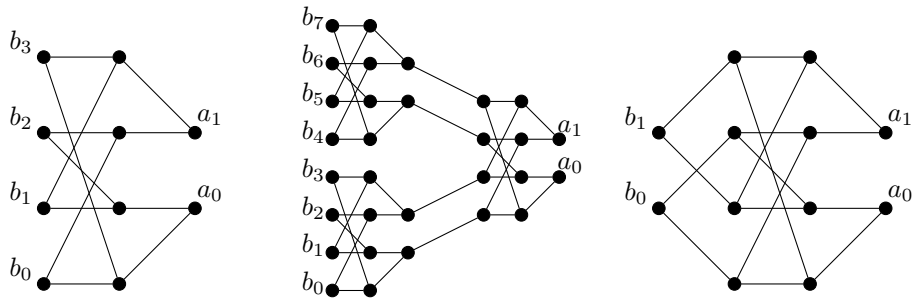
Algorithm 2 Corresponding color refinement for a strategy W.

```
1 function ColorRefinement(G, π)
    Input  : graph G, coloring π
    Output : refined coloring π
2   create list S containing P(G, π);
3   while π is not equitable do
4     (C, X) := W(S);
5     for each vertex in X count its neighbors in C;
6     split X into X_1, ..., X_k in π, according to neighbor counts;
7     append P(G, π) to S;
8   return π
```

2.2 Online Model

We now define a model that bases the choice of which color classes to use for the next refinement solely on the information available through partial quotient graphs. Practical implementations such as a queue or a stack are naturally captured by this, but the model even allows for much more powerful choices. The goal is then to prove that no strategy based solely on information of partial quotient graphs is sufficient to make optimal choices.

Let us start by defining the concept of a *strategy* $W : \mathcal{P}^* \to (2^{\mathbb{N}})^2$. A strategy is a function mapping a sequence of quotient graphs $P = P_1 \cdots P_k \in \mathcal{P}^*$ to two vertices of the last quotient graph $(C, X) \in V(P_k)^2$, that is, two unions of color classes. The sequence of graphs P denotes all partial quotient graphs observed during execution of the algorithm up to step k. The pair (C, X) denotes the choice of colors with which the algorithm continues in the next step: in step $k+1$, the algorithm refines X with respect to C.



For a strategy W we now define a *corresponding color refinement implementation*. Assume we are working on G and have already refined up to a coloring π_k within k steps. Furthermore, let $P_1, \ldots, P_k$ denote the partial quotient graphs corresponding to the execution. Next, we compute $(C, X) = W(P_1 \cdots P_k)$ and refine X with respect to C. The algorithm terminates whenever π_k is equitable. A formal definition is given in Algorithm 2. We call W a *valid* strategy if the corresponding color refinement implementation is correct, i.e., if it terminates with an equitable partition in finite time on all finite graphs.

Throughout this paper, we measure the *cost* of the strategy W, denoted $\mathrm{cost}(W, G)$, in terms of the number of edges that need to be considered to execute the refinements. Specifically, when refining X with respect to C, we charge the algorithm the number of edges connecting X with C. This is the same model as used in [4] reflecting the actual running time of practical implementations (see [11, 12]). We use the terms cost and time interchangeably.

3 Graph Gadgets

Throughout the paper we construct graphs that cause color refinement to behave in particular manners. These graphs are mostly built using three types of graph gadgets, described next.

And gadgets. Let us first discuss the AND_i gadgets as used by Berkholz et al. [4]. There is set B of 2^i in-vertices that come in pairs and 2 out-vertices. The goal of the gadget is that whenever all pairs of *in-vertices* have been split, a split of two *out-vertices* a_0 and a_1 is induced, but not before.

(a) An AND_2 gadget. **(b)** An AND_3 gadget. **(c)** The unidirectional gadget.

Figure 1 Basic gadget constructions as used throughout the paper. Vertices labeled with b_i always denote in-vertices, while a_i denotes out-vertices.

The AND_2 gadget (see Figure 1) is the well known CFI-gadget [5], where two gates form the in-vertices B and the third one the out-vertices a_0, a_1.

The AND_i gadget is constructed recursively using AND_2 gadgets. For $i > 2$, the AND_i gadget is constructed by taking the union of two AND_{i-1} and one AND_2 gadget. The four out-vertices of the AND_{i-1} gadgets are then connected to the four in-vertices of the AND_2 gadget. Figure 1 shows how the AND_3 gadget can be constructed using three AND_2 gadgets.

The important property is that in an AND_i gadget, all pairs b_{2j}, b_{2j+1} with $j \in \{0, ..., 2^{i-1}\}$ need to be distinguished to induce a split of a_0 and a_1. We should also record a property for the opposite direction: if a_0 and a_1 are distinguished, no split on B should be induced.

Unidirectional gadgets. We now describe the *undirectional gadget*. As the name suggests, it blocks the continuation of a split of pairs in one direction but allows it in the opposite direction. Figure 1 illustrates the gadget.

The gadget behaves as follows. Consider in-vertices b_0, b_1 and out-vertices a_0 and a_1. Distinguishing b_0 and b_1 should induce a split of a_0 and a_1. However, distinguishing a_0 and a_1 should *not* cause a split of b_0 and b_1. The gadget is obtained through a modification of the AND_2 gadget. We use the fact that a split of out-vertices in AND_2 does not cause a split of the pairs of in-vertices. Therefore, by connecting the in-vertices to new vertices a_0 and a_1, such that the AND_2 gadget is activated by any of the two singletons, we get the desired property.

Interestingly, the unidirectional gadget has also been used as a crucial building block in [3] and [6] to study the complexity of various problems closely related to color refinement.

Concealer gadgets. We conclude our discussion of gadgets with the *concealer gadgets*. Similar to the AND_i gadget, a concealer gadget C_i of level i has 2^i in-vertices B and 2 out-vertices a_0, a_1. Whereas in the AND gadget, *all* input pairs need to be distinguished, the concealer gadget only includes *one* specific pair that causes a split of the out-vertices. We call the pair causing the split of out-vertices the *correct pair*, while all other pairs not causing the split are called *dead end pairs*.

The idea is that the correct pair can not be located easily by color refinement algorithms. Hence, the gadget *conceals* where refinement can be continued.

To achieve this behavior, the gadget consists of 2^{i-1} unidirectional gadgets and the out-vertices a_0, a_1. We modify all but one of the unidirectional gadgets so that the connection of the in-gate agrees with the one of the out-gate. This causes these gadgets to become dead

ends – activating any of these gadgets has no effect on the out-vertices. The last, unmodified unidirectional gadget is the only one that can actually split the out-vertices and is therefore the only correct gadget.

The out-vertices of the entire concealer gadget are then connected to the out-vertices of all the unidirectional gadgets so that activating the correct pair causes a split of the out-vertices. Figure 2 shows a concealer gadget C_3.

Since we did not specify which of the pairs is the correct pair, there are several concealer gadgets for each $i \in \mathbb{N}$. Abusing notation we denote all of them by C_i. The concealer gadgets have two crucial properties. First, as long as the correct pair has not been split (and the neighbors of a correct pair have not been split) the partial quotient graphs of two concealer gadgets on the same size are isomorphic. Second, the correct pair can only be split from outside the gadget. We formalize these properties in the following.

Consider two colored concealer gadgets $(C_i, \pi), (C_i', \pi')$ of the same order. Suppose $\{b_s, b_{s+1}\}$ is the correct pair in (C_i, π) and $\{b_t, b_{t+1}\}$ is the correct pair in (C_i', π'). We say the two graphs still *concur* if the colors for the vertices agree (note that the two graphs have the same vertex set) and in both graphs neither the correct pairs nor their neighbors have been split. Specifically, we require that

- the vertex colorings agree, (i.e., $\pi(v) = \pi'(v)$ for every $v \in V(C_i) = V(C_i')$),
- the correct pairs have not been distinguished (i.e., $\pi(b_s) = \pi(b_{s+1})$ and $\pi'(b_t) = \pi'(b_{t+1})$),
- the neighbors of the correct pairs have not been distinguished (i.e., $\pi(v) = \pi(v')$ for all $v, v' \in N_{C_i}(b_s) \cup N_{C_i}(b_{s+1})$ and $\pi(v) = \pi(v')$ for all $v, v' \in N_{C_i'}(b_t) \cup N_{C_i'}(b_{t+1})$).

▶ **Lemma 1.** *Suppose (C_i, π) and (C_i', π') are colored concealer gadgets that concur. Then the graphs have the same partial quotient graphs, i.e., $P(C_i, \pi) = P(C_i', \pi')$.*

Proof. Suppose for a vertex v we want to count the number of neighbors that v has in a union of color classes X. We claim that this number is the same in C_i and C_i'. Indeed, we only need to consider edges incident with v that have one endpoint in $M = \{b_s, b_{s+1}, b_t, b_{t+1}\}$ and one endpoint in $N[M]$ (the neighborhood of M). Let E' be the set of these edges and let E_v' be the set of these edges incident with v.

Note that for each of the four sets $\{b_s, b_{s+1}\}$, $\{b_t, b_{t+1}\}$, $N[\{b_s, b_{s+1}\}]$, and $N[\{b_t, b_{t+1}\}]$ either X contains the set entirely or not at all.

If v is in M then either all edges of E_v' have an endpoint in X or no such edge does.

Likewise if v is in $N[M]$ then either all edges of E_v' have an endpoint in X or no such edge does.

Moreover, in either case, whether all such edges are or no such edge is contained does not depend on whether we consider C_i or C_i'.

This implies that the number of edges counted in the refinement (i.e., those incident with v and having an endpoint in X) is the same in C_i and C_i'. ◀

▶ **Lemma 2.** *For concealer gadgets (C_i, π) and (C_i', π') suppose $\pi = \pi'$ so that*

- *vertices in an input pair that is correct in one of the graphs have the same color and*
- *all vertices that are not in an input pair have the same color.*

Then (C_i, π) and (C_i', π') concur. After an arbitrary sequence of splits to both graphs the resulting graphs still concur and neither correct input pairs nor the out pair are split.

Proof. This follows by induction on the number of steps observing that the functionality of the unidirectional gadget ensures that the output pair is never split, and thus vertices inside correct gadgets are never split. ◀

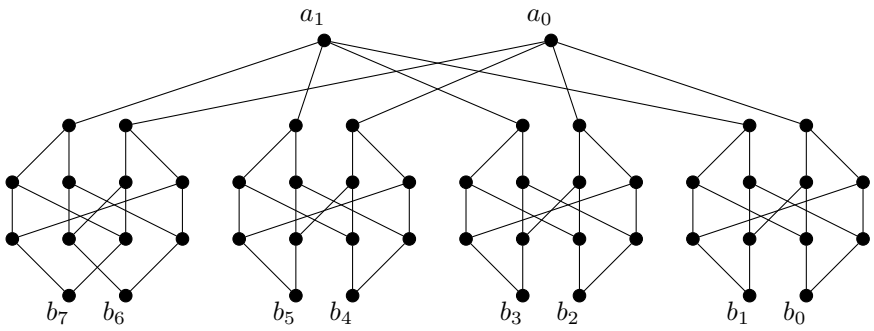


Figure 2 A concealer gadget C_3. Vertices b_6, b_7 form the correct pair; other pairs are dead ends.

The two lemmas show that unless a correct pair is split, the gadgets always concur and an algorithm in the online model will have to perform splits consistently on both graphs. Moreover, the output pair is never split.

Intuitively this means that in the online model, an algorithm can only guess which pair is the correct pair. Therefore, when faced with a concealer gadget, the algorithm potentially has to try all input pairs.

4 Competitive Ratio

We prove the non-existence of a c-competitive strategy in the online model. In particular, in this section, we prove the following theorem:

▶ **Theorem 3.** *For every strategy W of the online model, there is an infinite family of graphs G_k ($k \in \mathbb{N}$) such that* $\text{cost}(W, G_k) \in \Omega(\text{opt}(G_k) \cdot \log(\text{opt}(G_k)))$*, where* $\text{opt}(G_k) \in \Theta(|G_k|)$ *is the minimal cost of a strategy on G_k.*

The theorem implies that the information provided by partial quotient graphs is not sufficient to make competitive let alone optimal choices in color refinement algorithms.

Towards this goal, we first define the class of *concealer graphs*, which we denote with $\mathcal{G}_k$ ($k \in \mathbb{N}$). Concealer graphs resemble the graphs of the lower bound construction in [4] closely. Essentially, we swap out AND_i gadgets in the original construction for concealer gadgets C_i. A concealer graph of $\mathcal{G}_4$ is illustrated in Figure 3.

The main idea is that we can then speed-up or slow-down particular strategies by changing the position of the correct pairs within the concealer gadgets. This forces one strategy to extensively search for the correct pairs, while another strategy finds them immediately.

In the rest of this section we provide formal arguments for the above claims. We start with a precise description of concealer graphs. Then, we show that for every concealer graph there exists a fast strategy. Contrarily, we then provide a slow concealer graph for every strategy. Together these two statements prove Theorem 3.

4.1 Concealer Graphs

The first ingredient for the concealer graphs is a "splitting scheme" that results in the worst case running time of $\Omega(m \log(n))$. Consider a vertex set of size $n = 2^k$, on which the following refinements are performed. First, we split the set in halves, then quarters, then eighths and so on, until all vertices have their own distinct color. This gives us $\log(n)$ rounds of refinements, each with a cost of $\Omega(n)$. This results in total costs of $\Omega(n \log(n))$. By ensuring that sufficiently many edges are involved, the running time can be increased to $\Omega(m \log(n))$.

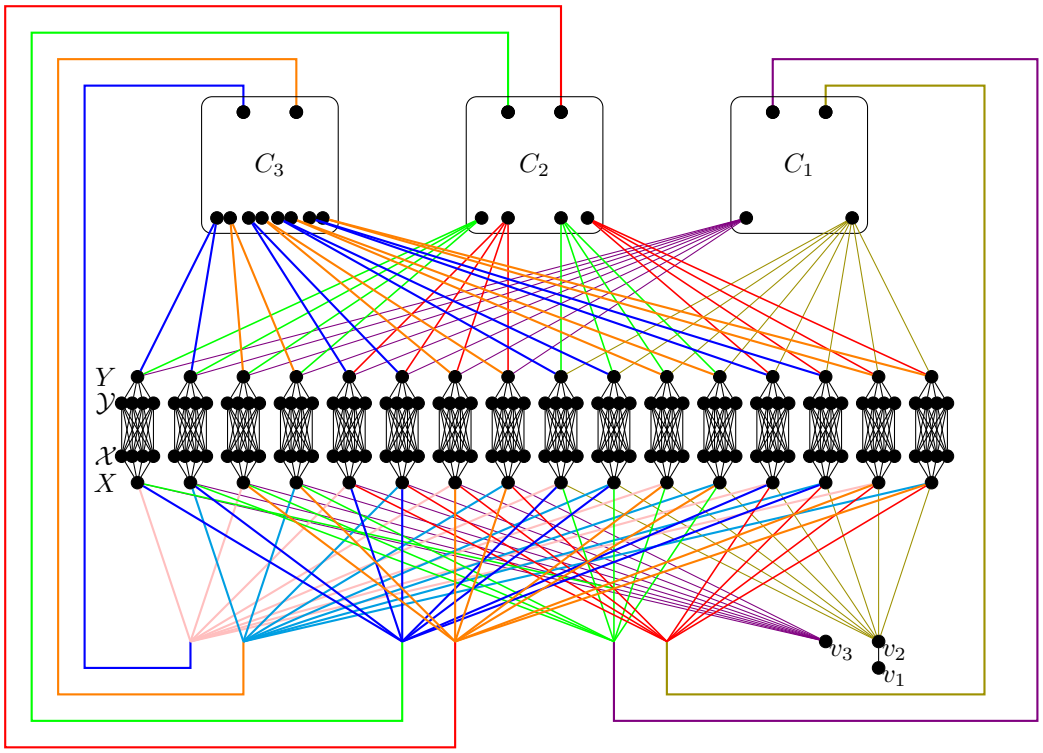

Figure 3 A concealer graph from the class $\mathcal{G}_4$.

Concealer graphs can be used to cause the splitting scheme just described. The graphs contain *middle layers* $(X, \mathcal{X}, \mathcal{Y}, Y)$ (see Figure 3) in which the splitting scheme can be forced. The graph is constructed in a way such that splitting Y into halves, quarters, eighths and so on, causes the next halving refinement on X. The edge colors in Figure 3 indicate the splitting scheme. While the halves (yellow and purple) of Y lead to a split of X into quarters (red and green), the quarters of Y lead to eighths (blue and orange) of X and so on. By initially splitting X in halves, any color refinement algorithm needs to cycle through these layers until X is fully discrete.

The core idea of the general lower bound construction in [4] is that the AND_i gadget enforces refinements with respect to *every* block of level i, which in turn ensures costs of $2^k \cdot k^2 \in \Omega(m)$ for every level.

We modify the construction to suit our purposes as follows. In the concealer graphs, we swap for each i the AND_i gadget for a concealer gadget C_i. On a particular graph, the worst case behavior is therefore not enforced for all refinement strategies anymore. However, a deterministic online algorithm cannot choose for *all* possible concealer gadgets the correct pair in level i to allow it to continue with level $i+1$. Hence, an adversary can construct a graph that makes a specific color refinement slow, while keeping a "shortcut" for other algorithms that choose the correct pair directly.

We now formally define the class $\mathcal{G}_k$ of concealer graphs. Note that for every $k \in \mathbb{N}$, we define a set of graphs $\mathcal{G}_k$. Essentially, we describe a graph $G_k \in \mathcal{G}_k$ based on concealer gadgets, and the set $\mathcal{G}_k$ then simply consists of all possible instantiations (i.e., positions of the correct pairs) for the included concealer gadgets.

At its core, a graph $G_k \in \mathcal{G}_k$ consists of the four middle layers of vertices $(X, \mathcal{X}, \mathcal{Y}, Y)$, that are interconnected using additional gadgets. Formally, the vertex set of G_k includes $X = \{x_0, ..., x_{2^k-1}\}$, $\mathcal{X} = \{x_i^j \mid 0 \leq i < 2^k, 0 \leq j < k\}$, $\mathcal{Y} = \{y_i^j \mid 0 \leq i < 2^k, 0 \leq j < k\}$,

$Y = \{y_0, ..., y_{2^k-1}\}$, a simple starting gadget induced by only three vertices v_1, v_2, v_3 and $k-1$ concealer gadgets. For $0 \leq l \leq k$ and $0 \leq q \leq 2^l - 1$ let $\mathcal{B}_q^l = \{q2^{k-l}, ..., (q+1)2^{k-l} - 1\}$ be the q-th binary block of level l. We use this notation on all sets of size 2^k for some $k \in \mathbb{N}$.

Every x_i is connected to a corresponding y_i via a complete bipartite graph of size k consisting of vertices in $\mathcal{X}$ and $\mathcal{Y}$ (see Figure 3). Formally, each x_i is connected to all x_i^j, y_i to all y_i^j and x_i^j to all $y_i^{j'}$. For each level $l \in \{1, ..., k-1\}$, the i-th binary block of level l is connected to the i-th in-vertex of the l-th concealer gadget. Furthermore, for each gadget C_l, we connect a_0 to all X_i^l with i even and a_1 to all X_i^l with i odd. The starting construction splits X into the blocks X_0^0 and X_1^0. We refer to the i-th in-vertex of the l-th concealer gadget as b_i^l and to the i-th out-vertex as a_i^l.

Let us generally consider how a refinement strategy has to operate on G_k. The algorithm starts with the monochromatic coloring of G_k. The first refinement always distinguishes vertices by their degree, meaning we get the individualized starting gadget $\{v_1\}, \{v_2\}, \{v_3\}$, the distinct layers in the middle $X, \mathcal{X} \cup \mathcal{Y}, Y$, the in- and out-vertices of the concealer gadgets $\bigcup_{l \in \{1,...,k-1\}} \{b_i^l, a_j^l \mid i \in \{0, ..., 2^l\}, j \in \{0, 1\}\}$, and the union of the inner vertices of the concealer gadgets. Next the middle layers are split in half. From this point onwards the splits that are possible depend on finding the correct pair in the gadgets. This can lead to fast or slow refinements, as discussed next.

4.2 A Fast Strategy for Every Concealer Graph

We now show that for every *fixed* concealer graph $G_k \in \mathcal{G}_k$ we can define a linear time strategy. We show this by providing an appropriate sequence of refinements.

For each concealer gadget C_l in G_k, let $b_{i_l}^l, b_{i_l+1}^l$ be the correct pair. Now consider an online refinement strategy on such a graph. After the first (and fixed) refinement, we refine X with respect to $\{v_2\}$ or $\{v_3\}$. We choose one half of $X_{i_1}^1$ for the next refinement and then $\mathcal{X}_{i_1}^1$, $\mathcal{Y}_{i_1}^1$ and $Y_{i_1}^1$ while propagating the split through the middle layers. The important property is that $Y_{i_1}^1$ always splits the correct pair of the next concealer gadget. The concealer gadget then in turn splits X into quarters. Now, we continue with the quarters $X_{i_2}^2$, $\mathcal{X}_{i_2}^2$, $\mathcal{Y}_{i_2}^2$ and $Y_{i_2}^2$, such that the second concealer gadget is activated. This splits X in eighths.

We now repeat this scheme, such that for each level we only propagate the blocks corresponding to correct pairs through the layers and immediately continue with the next level after activating the concealer gadget. When X is discrete, we get the equitable coloring by refining with respect to each level k block of X, $\mathcal{X}$, $\mathcal{Y}$ and Y.

Now consider the cost of this strategy. While cycling through the layers, the most expensive refinements are those with respect to the blocks of $\mathcal{X}$ and $\mathcal{Y}$. On level l, they have cost $2^{k-l} \cdot k^2$, which means the total cost for all levels is $2^k \cdot k^2 = \Theta(m)$. Once X is discrete the cost of the final refinements of $\mathcal{X}$, $\mathcal{Y}$ and Y is also in $\Theta(m)$.

Overall, the cost for an optimal solution for G_k is linear, i.e., $\text{opt}(G_k) \in \Theta(m)$. Note that since refinement is always continued with color classes that have just been created, the scheme actually follows a depth-first approach and can be implemented using a stack.

4.3 A Slow Concealer Graph for Every Strategy

For a *fixed* strategy W, we now provide an infinite family of concealer graphs G_k on which this strategy is slow, i.e., incurs super-linear cost. The family is constructed by choosing for every $k \in \mathbb{N}$ one specific concealer graph $G_k \in \mathcal{G}_k$.

We start with an arbitrary graph $G_k \in \mathcal{G}_k$. We run W on G_k and observe which color classes are split within the concealer gadgets. Say we are looking at concealer gadget C_i. If W distinguishes the correct pair in G_k, but there are still dead ends that have not been

distinguished, then we replace G_k by the graph $G'_k \in \mathcal{G}_k$ obtained from G_k by replacing the gadget C_i with another one so that a dead end not yet investigated becomes the correct pair. Due to Lemma 1 and Lemma 2 we know that up until the point where W finds the correct pair in C_i for graph G_k, the strategy W performs the same sequence of splits when executed on G'_k as on G_k. Thus, by doing these transformations exhaustively, we ensure W distinguishes all correct pairs in all the concealer gadgets last. This causes $2^k \cdot k^2$ cost per level and hence $2^k \cdot k^3 = \Theta(m \log(n))$ total cost.

Since the optimal solution for fixed G_k only has linear cost (see Section 4.2), we in turn get that $\text{cost}(W, G_k) \in \Omega(\text{opt}(G_k) \cdot \log(\text{opt}(G_k)))$. This in turn proves Theorem 3. Further details and a more formal reasoning can be found in the full version [2].

5 Comparison of Practical Worklists

We now compare specific, practical worklist data structures. First, we compare stacks with queues. We show that either of the two can asymptotically outperform the other. We can also show the same result for priority queues (see the full version [2]).

5.1 Stack Advantage over Queue

To see how a stack worklist might outperform a queue, recall the fast strategies for concealer graphs of Section 4. The specific, fast split scheme discussed there is realized by a worklist maintained as a stack. Indeed, whenever possible we continue with a "newest" class.

We conclude from Theorem 3 that there is a class of graphs on which a stack based worklist asymptotically outperforms a queue based worklist by a logarithmic factor.

We should remark that it is possible to prove the same result with a simpler construction that does not rely on concealer gadgets. We should also remark that the construction does not apply to all stack based worklists. However, it is possible to modify the construction such that a particular stack based worklist is optimal. For example this can be done for the worklist that choses smallest color classes first (see the full version [2]).

5.2 Queue Advantage over Stack

Now, we construct a graph class, called the *queue graphs*, for which a queue based worklist outperforms a stack based one by a logarithmic factor. This complements the result of the previous section. The construction is also based on the graph class of Berkholz et al. [4]. It is an extension of these graphs, which allows queue worklists to finish quickly but maintains the slow behavior for stacks. We provide an intuitive description. A formal definition and a detailed analysis is given in the full version [2].

The starting gadget. We use a starting gadget (see Figure 4) that forces a stack worklist to perform certain splits before others, while a queue worklist behaves differently.

Consider the gadget together with the coloring indicated in the figure. Any color refinement eventually splits the pairs $\{p_1^{1,3}, p_1^{2,3}\}$, $\{p_2^{1,3}, p_2^{2,3}\}$ and $\{a_0, a_1\}$. However, a stack based worklist splits $\{p_1^{1,3}, p_1^{2,3}\}$ or $\{p_2^{1,3}, p_2^{2,3}\}$ *before* $\{a_0, a_1\}$, while a queue based one splits $\{a_0, a_1\}$ before the other two pairs.

Graph class construction. We start with the graphs from [4] as a main building block. Recall that these graphs are the graphs from Section 4 where the concealer gadgets are replaced by AND gadgets. As argued in [4] a worst case behavior is enforced for every refinement strategy: any refinement on these graphs has a cost of $\Omega(2^k \cdot k^3) = \Omega(m \log(n))$.

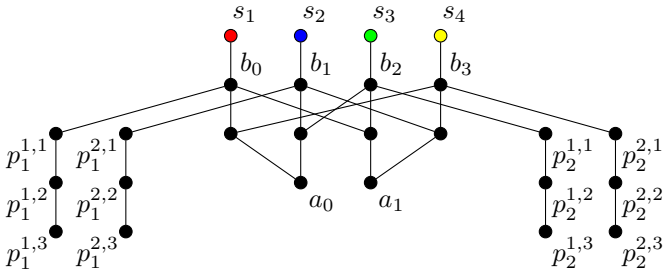

Figure 4 An extension of AND_2 gadget, which will be used as the starting gadget of the new construction. The starting vertices $s_1, ..., s_4$ have been individualized.

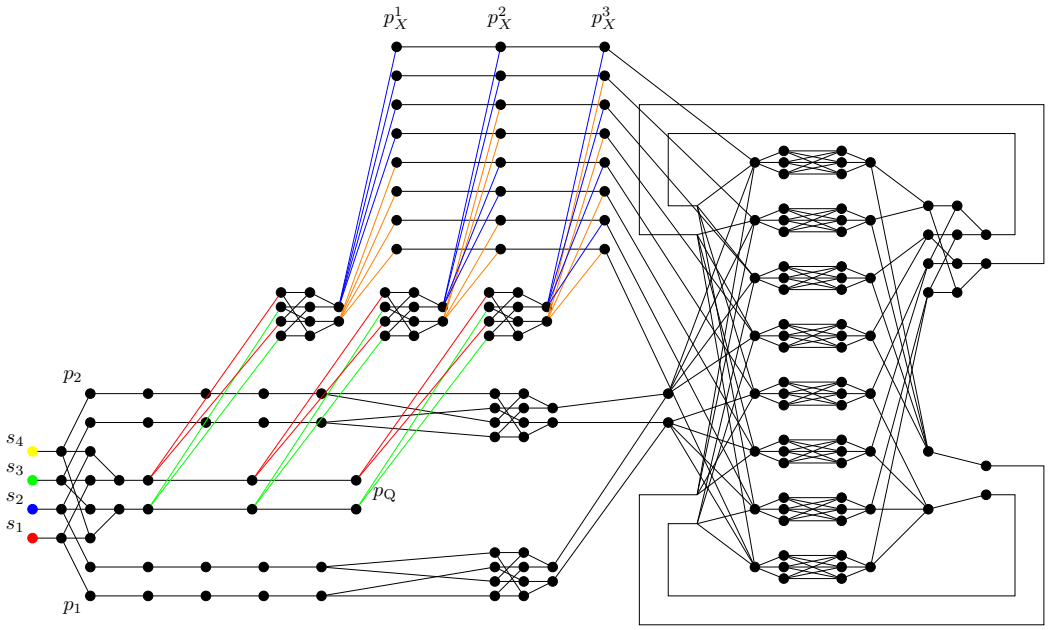

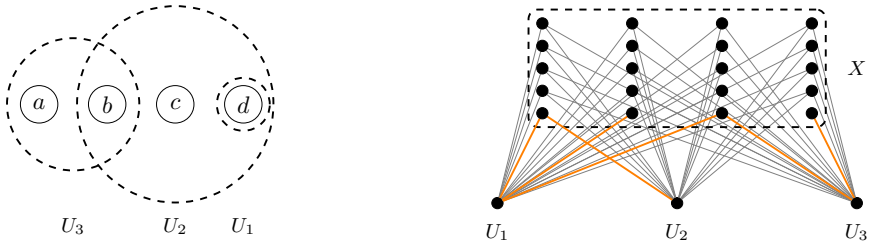

Figure 5 The graph G_3^{Q} for the queue advantage.

We now add "shortcuts" that allow queue based algorithms to bypass the construction. The core idea is to ensure the queue algorithm refines the set X into a discrete set within a single level of its breadth first behavior. This causes $\mathcal{X}$, $\mathcal{Y}$ and Y to completely split in subsequent rounds, thereby preventing the cycling behavior that causes superlinear cost. Indeed, if $\mathcal{X}$ and $\mathcal{Y}$ are handled only once, then the total cost is in $\mathcal{O}(2^k \cdot k^2) = \mathcal{O}(m)$.

Simultaneously we force the stack into the typical cycling behavior. We do so by forcing it to make the same splits of X as the simple starting gadget from Section 4 would.

We apply the following changes to define queue graphs G_k^{Q} (see Figure 5): we connect each vertex in X to a path of length k. We add the new starting gadget described above. We extend the paths p_1 and p_2 to a length of $k+2$ and connect the ends to the old starting vertices through unidirectional gadgets. We also attach a third path p_{Q} of length k to a_0 and a_1 and connect the i-th pair to the level-i blocks of the i-th vertices of the X-paths, again through unidirectional gadgets. Note that the graph has still a size of $\mathcal{O}(2^k \cdot k^2)$.

(a) Set cover instance. **(b)** Result of the reduction.

Figure 6 Reduction of the set cover instance $S = \{a, b, c, d\}$ and $\mathcal{U} = \{\{d\}, \{b, c, d\}, \{a, b\}\}$. Orange lines indicate connections to elements of S, all other edges are connections to dummy elements.

Queue Behavior. Consider a queue based color refinement. It splits the pairs within the paths p_1, p_2, p_Q layer by layer. The splits of the i-th pair of p_Q induce a split of the i-th vertices of the X-paths into the binary blocks of level i. After $k + 7$ many rounds, this leads to a split of X into the blocks of level k. Note that at the same time $\{p^0_{\text{end}}\}$ or $\{p^1_{\text{end}}\}$ will be able to split X. Therefore, we know that X will be fully discrete before any subset of $\mathcal{X}$ can be considered by the worklist.

Stack Behavior. Any stack based color refinement running on G^Q_k splits one of the paths p_1, p_2 in the starting gadget before splitting the path p_Q. This induces the worst case cycling behavior of the construction from [4]. The unidirectional gadgets and depth first strategy hinder the algorithm from distinguishing anything else in the starting gadget before the rest of the graph has been distinguished. Therefore, no "shortcut" can be applied and a stack based color refinement on G^Q_k has costs of at least $\Omega(m \log(n))$.

6 Approximation Hardness

Complementing our previous results, we now provide an approximation hardness result for computing optimal color refinement strategies. We begin by defining the optimal refinement worklist problem:

▶ **Problem** (Refinement Worklist Problem). *Given a colored graph (G, π), compute a minimal cost sequence of pairs of color classes $W = (C_1, X_1), \ldots, (C_t, X_t)$ such that:*

1. *Refining with respect to W results in the stable coloring π^∞.*
2. *For all prefixes $(C_1, X_1), \ldots, (C_s, X_s)$, the partial quotient graph obtained after refining C_i w.r.t. X_i for $i = 1, \ldots, s-1$ contains C_s and X_s (as unions of color classes).*

The cost of a sequence W is the sum of the costs for refining with respect to all $(C_i, X_i) \in W$.

The approximation hardness result is based on a reduction from the set cover problem. The set cover problem takes a finite universe S and a set of subsets of S, i.e., $\mathcal{U} \subseteq 2^S$. The decision variant then asks whether there exists a selection of k subsets in $\mathcal{U}$ whose union equals S. For simplicity, we assume $\bigcup_{U \in \mathcal{U}} U = S$. Set cover is well-known to be NP-complete.

The optimization variant requires a minimal selection of subsets that cover S, i.e., a solution that minimizes k. This problem is known to be NP-hard. More specifically, it is known that unless P = NP, polynomial-time algorithm can only reach an approximation factor of $\Omega(\log(n))$ [14].

▶ **Theorem 4.** *Unless* P = NP*, polynomial-time algorithms may only reach an approximation factor of* $\Omega(\log(n))$ *for the refinement worklist problem.*

Proof. We reduce the optimization variant of the set cover problem to the refinement worklist problem. More specifically, we reduce it in a manner which allows control of the parameters, so that the approximation hardness result of set cover immediately transfers to refinement worklists. The reduction is illustrated in Figure 6.

Given a set cover instance $(S,\mathcal{U})$ we define a related colored graph (G,π). We create one large color class X containing all elements of the universe S, as well as n^2 *dummy elements* (where n is the size of the set cover instance). Hence, the size of X is $n^2+|S|$.

We add a singleton color class for each subset $U \in \mathcal{U}$, i.e., we add vertex U with color U. We connect the vertex U with all vertices of X *except* for the elements that are contained in U. Formally, we define the edges $E(G) := \{\{U,x\} \mid x \in X \wedge x \notin U\}$. Note that U has $n^2+|S|-|U|$ connections to X.

In the constructed graph, all elements of the universe are eventually distinguished from the dummy elements in X. Refining X with respect to X is not productive, since there are no edges present and no splits occur. The only way to distinguish elements of X is to refine X with respect to an element of $\mathcal{U}$. Doing so always distinguishes all the elements contained in $U \in \mathcal{U}$ from the dummy elements and other remaining elements of X. Overall, we need to refine X with a subset of $\mathcal{U}$ that forms a set cover of S.

After that, assuming all elements of S have been distinguished from the dummy elements, it might be possible to split the resulting classes further through their connections to $\mathcal{U}$. However, the total cost for these further refinements is bounded by $c \cdot n^2$ for some fixed constant c.

The cost for refining X with respect to U is n^2+m, where m is the number of remaining elements of S in X *after* the elements of U have been removed. Since we need to choose at most $|S|$ subsets in a reasonable solution (otherwise we could remove redundant elements from the solution), and each time X gets smaller by at least one element, the cost incurred by m over all subsets is at most $|S|^2 \leq n^2$. Ignoring the cost of m, we get that each subset incurs additional cost of n^2 through the dummy elements.

Hence, the final cost is upper bounded by $c \cdot n^2 + (N_U+1) \cdot n^2 = (N_U+c+1)n^2$ and lower bounded by $N_U n^2$, where N_U is the number of chosen subsets.

We finish our arguments with a proof by contradiction. Assume there is a polynomial-time algorithm with an approximation factor in $o(\log(n))$. Given a set cover instance $(S,\mathcal{U})$, we apply the polynomial-time reduction stated above. Assume now we get an approximate solution with cost $x \cdot n^2$. We know that this implies a set cover solution with cost at most x.

The optimal set cover solution with cost x' would imply a worklist solution with cost at most $(x'+c)n^2$ (for a fixed c). Hence, we know that the worklist solution also approximates the optimal solution of the original set cover instance with a factor in $o(\log(n))$.

The set cover instance has a size in the 3rd root of the size of the refinement worklist problem. But since $o(\log(n)) = o(\log(\sqrt[3]{n}))$, we get a contradiction to the approximation hardness result of set cover. ◀

Search Problems in Trees with Symmetries: Near Optimal Traversal Strategies for Individualization-Refinement Algorithms

Abstract

We define a search problem on trees that closely captures the backtracking behavior of all current practical graph isomorphism algorithms. Given two trees with colored leaves, the goal is to find two leaves of matching color, one in each of the trees. The trees are subject to an invariance property which promises that for every pair of leaves of equal color there must be a symmetry (or an isomorphism) that maps one leaf to the other.

We describe a randomized algorithm with errors for which the number of visited nodes is quasilinear in the square root of the size of the smaller of the two trees. For inputs of bounded degree, we develop a Las Vegas algorithm with a similar running time.

We prove that these results are optimal up to logarithmic factors. For this, we show a lower bound for randomized algorithms on inputs of bounded degree that is the square root of the tree sizes. For inputs of unbounded degree, we show a linear lower bound for Las Vegas algorithms. For deterministic algorithms we can prove a linear bound even for inputs of bounded degree. This shows why randomized algorithms outperform deterministic ones.

Our results explain why the randomized "breadth-first with intermixed experimental path" search strategy of the isomorphism tool Traces (Piperno 2008) is often superior to the depth-first search strategy of other tools such as nauty (McKay 1977) or bliss (Junttila, Kaski 2007). However, our algorithm also provides a new traversal strategy, which is theoretically near optimal and which has better worst case behavior than traversal strategies that have previously been used.

1 Introduction

We define a new search problem involving trees with symmetries. In this problem, two unknown trees are given as input and they can be gradually explored. The leaves of the trees are colored and the task is to find a pair of leaves, one in each tree, with matching colors or determine that such a pair does not exist. The crucial element that distinguishes our model from standard exploration tasks is that the color of the leaves allows us to draw conclusions about the local surroundings of the leaf. More precisely, there is an invariance

axiom guaranteed to always hold. It says that if two leaves are of the same color then there is a symmetry (an automorphism or an isomorphism depending on the leaves being in the same tree or not) that maps one leaf to the other.

The invariance property guarantees that the local neighborhood around the leaf is structurally the same as the neighborhood around other leaves of the same color. This allows us to discard unexplored parts of the search tree thereby opening the possibility of having algorithms that explore only a sublinear number of the nodes of the trees.

Our motivation behind the model lies in the desire for a theoretical analysis of practical solvers for the graph isomorphism problem, automorphism group computations, and graph canonization. While the best theoretical algorithms, such as Babai's quasipolynomial time algorithm [2], are based on algorithmic group theory, practical solvers [4, 6, 7, 11, 15] exclusively follow the individualization-refinement (IR) paradigm. First introduced into the realm of practical isomorphism testing and canonization by McKay in 1977 [10], the basic principle has remained unchanged to date. Indeed, all algorithms in this paradigm perform some form of backtracking, implicitly creating a recursion tree for each input graph. The tools solve the graph isomorphism problem by finding two leaves in this recursion tree that correspond to each other. The number of nodes in the recursion tree that are actually called during the execution is closely linked to the running time of the overall algorithm. Despite being simple, our search problem and the exploration model capture precisely the task needed to be solved and assess correctly the running times of solutions.

Traditionally, IR tools have followed a depth-first search approach to traverse the search tree. However, in 2008, Piperno [15] introduced his tool Traces, which broke away from this principle, performing a form of breadth-first search that is intermixed with random traversal of the tree (so-called experimental paths). The traversal strategy is at the very heart of the underlying algorithm. Significantly outperforming all the other tools on most practical inputs [12], Traces revealed that the traversal strategy is arguably the most important design choice in IR algorithms. This immediately raises the question whether there are theoretical, structural reasons why this traversal strategy is favorable. Going one step further, we can ask for optimal traversal strategies.

However, so far there has been no rigorous justification as to why one traversal strategy should be superior and in particular there is no research into optimal traversal strategies.

Contribution. The introduction of our particular search problem in trees with symmetry allows us to strip away all the other design choices that have to be made in the creation of an IR algorithm and isolates the core issue of the traversal strategy in the search tree. The ultimate goal is twofold. Firstly, to provide a more rigorous, theoretical foundation for the design of practical graph isomorphism tools. Secondly, to design novel, near optimal strategies to be adopted in future generations of practical solvers.

An input consists of two trees without vertices that only have one child. Let n denote the size of the smaller one of the two trees and N the size of the larger one. The cost of our algorithms is measured in the number of nodes that are explored. For our algorithms, the terms "running time" or "complexity" refer to this cost measure.

Regarding *upper bounds*, we provide a simple randomized Monte Carlo algorithm with an upper bound of $\mathcal{O}(\sqrt{n}\log n)$ explored nodes. For trees of bounded degree we design a more complicated algorithm achieving an upper bound of $\mathcal{O}(\sqrt{n}\log N)$ for Las Vegas algorithms (i.e., randomized algorithms without errors).

Table 1 This table summarizes lower and upper bounds for the isomorphism problem implied by the results of this paper. Here $n = \min\{n_1, n_2\}$ and $N = \max\{n_1, n_2\}$, where the sizes of the trees are n_1, n_2 and d gives the maximum degree of the two input trees. We state separate lower bounds for trees with bounded (d-adic) and unbounded degree.

Setting	Lower Bound	Lower Bound (d-adic)	Upper Bound
Monte Carlo	$\Omega(\sqrt{n})$	$\Omega(\sqrt{n})$	$\mathcal{O}(\log(n)\sqrt{n})$
Las Vegas	$\Omega(n)$	$\Omega(\sqrt{n})$	$\mathcal{O}(d\log(N)\sqrt{n})$
Deterministic	$\Omega(n)$	$\Omega(n)$	$\mathcal{O}(n)$

These algorithms are accompanied by nearly matching *lower bounds*, showing that $\Omega(\sqrt{n})$ nodes need to be explored for randomized Monte Carlo algorithms even on bounded degree trees and that for unbounded degree inputs, Las Vegas algorithms need to visit $\Omega(n)$ nodes in expectation. For deterministic algorithms we get a lower bound of $\Omega(n)$ even for inputs of bounded degree. Table 1 gives an overview of the lower and upper bounds we prove.

Overall this shows that the new traversal strategies are optimal up to logarithmic factors. However, it also shows that randomized traversal strategies, even those without error, asymptotically outperform deterministic ones.

The algorithms for proving the upper bounds immediately imply IR algorithms with the same runtimes (up to almost linear factors in the graph order for non-recursive work). We should emphasize that our new upper bounds asymptotically outperform the traversal strategies that are currently being used in practice in the worst case. In fact, we implemented the Monte Carlo algorithm in a new graph isomorphism solver DEJAVU which runs significantly faster than existing tools on most graphs [1].

2 A Model for Tree Exploration with Symmetries

This section presents the exploration model that is used throughout this paper. The model enables us to perform a focused analysis of the traversal strategies used in the search trees of IR algorithms. We state the model independent of any discussion regarding IR.

2.1 Black Box Search Trees

In our search problems the input consists of one or two hidden trees of which certain information is to be discovered. We first explain how the trees can be explored.

Exploration Model. We consider rooted trees in which there is a priori no bound on the degree of the vertices. However, we require that no vertex has exactly one child. Furthermore, the leaves of the tree are colored.

Our exploration model for the trees restricts access of algorithms to the trees themselves and how they can be explored. We think of new information as being provided by an oracle to the exploration algorithm. During execution, a node of the tree is either *explored* or *unexplored*. Whenever a new node is explored, the algorithm learns the number of children of the node. In particular the algorithm knows whether the node is a leaf or not. Furthermore, in case the node is a leaf, it learns its color. At the beginning of an execution, everything except the root is deemed unexplored. The algorithm can only ever access previously explored nodes. The degree (i.e., the number of children) of an explored node v, which we denote by $\deg(v)$, is always known. To explore further nodes, the algorithm can explore a child

Figure 1 Example exploration in the black box search tree model. Starting from the root, the algorithm only ever knows explored nodes and their degrees. Through the use of an oracle, random children of explored nodes may then be queried.

of a previously explored node. Specifically, the algorithm can request the i-th child of v with $i \in \{1, \dots, d(v)\}$, which thereby becomes explored. For this, the input has an arbitrary but fixed ordering for the children of each vertex.

The *cost* of the exploration is measured in the number of oracle accesses, i.e., the number of nodes that are ever visited by the algorithm. (In particular there is no cost for traversing previously explored parts of the tree.)

Figure 1 illustrates such an exploration of a tree. Note that while the algorithm always knows the degree of explored nodes, it is essentially unable to chose a new specific child to explore since in another input the ordering of the children may be different.

More formally, a black box search tree $T = (V, E, \mathrm{col})$ consists of a rooted tree with colored leaves and for each node an ordering of the children. We omit the orderings from the notation. Of course all choices of orderings lead to proper search trees. The function $\mathrm{col}\colon L(T) \to \mathbb{N}$ maps the *leaves of the tree* $L(T)$ to natural numbers, referred to as colors.

In our algorithms, we use the procedure `NewChild`$\colon V \to V \cup \{\bot\}$ to explore the tree, which agrees with the previous description as follows. For an explored vertex v the algorithm chooses the smallest index of a previously unexplored child of v and queries the oracle for that child. If no unexplored child exists, the function returns $\bot$.

In the description of randomized algorithms, we also use the function `RandomChild`$\colon V \to V \cup \{\bot\}$, which returns a child chosen uniformly at random among all children of v, which means that it can in particular return previously explored children.

Isomorphism Invariance. So far we are lacking the crucial part of the model, namely symmetries. The core property of our trees is that the presence of leaves with equal colors implies the existence of symmetries of the trees. More specifically, they imply *color-preserving isomorphisms*, defined as follows. An isomorphism φ between two trees T_1 and T_2 is a bijection on vertices $\varphi\colon V(T_1) \to V(T_2)$, such that v is a child of v' if and only if $\varphi(v)$ is a child of $\varphi(v')$. A color-preserving isomorphism furthermore requires that $\mathrm{col}(l) = \mathrm{col}(\varphi(l))$ holds for all leaves $l \in L(V_1)$. This implies that leaves of a color can only be mapped to leaves of that same color. If $T_1 = T_2$ we also call φ an *automorphism* or a symmetry.

The crucial property that we require for all black box search trees is that whenever two leaves have the same color, we can derive an isomorphism:

▶ **Axiom** (Complete Isomorphism Invariance). *If $l_1 \in T_1, l_2 \in T_2$ and $\mathrm{col}(l_1) = \mathrm{col}(l_2)$, then there exists a color-preserving isomorphism $\varphi\colon V(T_1) \to V(T_2)$ such that $\varphi(l_1) = l_2$.*

We should highlight that the axiom in particular has to hold for the case $T_1 = T_2$, yielding automorphisms (possibly the identity if $l_1 = l_2$).

The crucial consequence of the axiom is that it allows us to draw conclusions about the structure of unexplored parts of the search tree. For example, applying this knowledge enables us to conclude that the last remaining node of Figure 1 is blue.

Throughout the paper, we assume that all inputs, may they consist of one or two trees, adhere to this axiom. Also, all exploration algorithms operate in our exploration model.

Algorithm 1 Random Walk of the Search Tree.

```
1 function RandomWalk(v)
    Input  : vertex v of a black box search tree
    Output : a random leaf of the search tree rooted at v
2   while deg(v) ≠ 0 do  v := RandomChild(v) ;
3   return v;
```

Isomorphism Exploration Problem. We are now ready to state our problem of interest for black box search trees: the isomorphism exploration problem.

▶ **Problem** (Isomorphism Exploration). *Given two search trees T_1 and T_2, compute leaves $l_1 \in T_1$ and $l_2 \in T_2$ with $\mathrm{col}(l_1) = \mathrm{col}(l_2)$, if they exist and return $\perp$ otherwise.*

For simplicity we will always assume that the trees are disjoint, that is $V(T_1) \cap V(T_2) = \varnothing$. This way we do not need to specify for oracle queries what tree they relate to.

There are other interesting problems, such as finding two leaves of the same color within one tree, that can be defined within the model. These and their relationship are discussed in Section 5.

While the tree model and the exploration problem can be defined it their own right, we have a concrete motivation behind the definitions. Indeed, the motivation behind the specifics of our model lies in so-called *individualization-refinement* algorithms, the prevailing method to solve the graph isomorphism problem in practice. In fact, the isomorphism exploration problem captures very closely the runtime of these algorithms. A more detailed explanation of this is deferred to the end of the paper in Section 5.

However, let us briefly remark that in our context the requirement that inner nodes may not have exactly one child is not only natural for our intended application but also crucial. If we drop this requirement the nature of the problem changes dramatically and ray searching as well as doubling techniques become relevant (see [3] for further pointers).

3 Upper Bounds

We provide upper bounds for the isomorphism exploration problem by developing appropriate algorithms. Of course by querying the oracle for the input trees alternatingly, there is a simple deterministic algorithm with a complexity of $\mathcal{O}(\min\{|T_1|, |T_2|\})$. For randomized algorithms, we start with a Monte Carlo algorithm. Subsequently we argue that there is also a Las Vegas algorithm, (i.e., an algorithm that always answers correctly) which still has a good expected runtime if there is a modest bound on the maximum degree of the tree.

3.1 Probabilistic Bidirectional Search

The central idea of the probabilistic isomorphism test discussed in this section is to perform *random root to leaf walks* in the black box search trees. The recursive procedure for such walks is described in Algorithm 1 and simply works as follows: a random walk is performed by starting in the root node and repeatedly choosing uniformly at random a child of the current node, until a leaf is reached.

Repeatedly executing random walks, the probabilistic isomorphism test exploits the following observation: assume we have two isomorphic trees T_1, T_2. Further assume we fix some leaf $l \in T_1$. We call all leaves l' with $\mathrm{col}(l) = \mathrm{col}(l')$ *occurrences* of l. The algorithm tries to find occurrences of l through random walks of the trees. Towards finding l, we

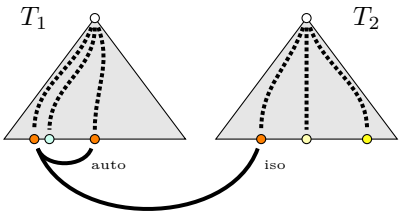

Figure 2 The probabilistic bidirectional search algorithm simultaneously samples leaves in both trees using random walks. It then tests for automorphisms within a tree and isomorphisms across trees to perform the probabilistic test.

always perform two random walks, one in T_1 and one in T_2. Since we assumed the trees *are isomorphic*, we are *equally likely* to find an occurrence of l in T_1 or in T_2. But if the trees *are not isomorphic*, we can find occurrences of l *only* in T_1 (otherwise, due to the isomorphism invariance axiom, T_1 and T_2 would be isomorphic).

Algorithm 2 describes a procedure based on this observation. Instead of using just a single leaf l however, it uses two sets of leaves L_1 and L_2 for comparison. Whenever an entirely new leaf is found (that is not an occurrence of a previously found leaf), it is added to the respective set of leaves and used for subsequent testing.

If a leaf is an occurrence of a previously discovered leaf, it either reveals an isomorphism between the trees or an automorphism (possibly the identity) of one of the trees. This is again a consequence of the isomorphism invariance axiom. If an isomorphism[1] is discovered, the algorithm has found two equally colored leaves in both trees and terminates. Otherwise, after a certain number of automorphisms have been found (the number depends on the desired error bound), the algorithm concludes that the trees are probably non-isomorphic within the given error bound. If the trees are isomorphic, we find automorphisms and isomorphisms with equal probability. Hence, we are highly unlikely to discover many automorphisms without also discovering an isomorphism. Figure 2 illustrates this key concept underlying the algorithm. The following lemma provides a correctness and running time analysis.

▶ **Lemma 1.** *Given black box search trees T_1, T_2 of heights h_1, h_2 and a desired error probability ϵ, Algorithm 2 solves the isomorphism exploration problem with probability at least $1-\epsilon$ with an expected worst-case runtime bounded by $\mathcal{O}\left(\lceil \log_2(\frac{1}{\epsilon})\rceil \cdot \max(h_1, h_2) \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}\right)$.*

Proof. *(Correctness.)* First, observe that whenever a pair of leaves is returned their color is checked for equality. This ensures that if the algorithm returns a pair of leaves, the answer is always correct. The algorithm can therefore only fail to produce the correct output by not finding a suitable pair of equally colored leaves despite the fact that they exist. In particular, this implies that if the trees are non-isomorphic, the algorithm cannot err.

To bound the error probability, we view the computation as a sequence of *tests*. A test repeatedly performs random walks of the search trees until one automorphism (possibly the identity) or one isomorphism is found. Hence, each test can be described as a sequence of j iterations. In each iteration $j' < j$, neither l_1 nor l_2 produced an isomorphism or automorphism. During a test, the algorithm neither terminates, nor is c incremented. In

[1] Slightly abusing terminology we often use the term isomorphism to mean an isomorphism between the two trees rather than an isomorphism that is an automorphism of one tree.

Algorithm 2 Probabilistic Bidirectional Search.

```
1  function Isomorphism(T_1, T_2, ε)
       Input  : black box search trees T_1, T_2 and probability ε
       Output : two leaves l_1 ∈ T_1, l_2 ∈ T_2 such that col(l_1) = col(l_2) with probability
                at least 1 − ε if such leaves exist, ⊥ otherwise
2      c := 0;
3      L_1 := L_2 := ∅;
4      while c ≤ ⌈−log_2(ε)⌉ do
5          f_(aut,1) := f_(aut,2) := false;   // f_(aut,i) signals automorphism found in
            T_i
6          l_1 := RandomWalk(root of T_1) ;
7          l_2 := RandomWalk(root of T_2) ;
8          if col(l_1) = col(l_2) then return (l_1, l_2);
9          for i ∈ {1, 2} do
10             for l' ∈ L_(3−i) do
11                 if col(l_i) = col(l') then return (l_i, l') ;
12                 if col(l_{3−i}) = col(l') then f_(aut,(3−i)) := true ;
13         if ¬f_(aut,1) then L_1 := L_1 ∪ {l_1};
14         if ¬f_(aut,2) then L_2 := L_2 ∪ {l_2};
15         if f_(aut,1) ∨ f_(aut,2) then c := c + 1;
16     return ⊥;
```

iteration j of the test, an automorphism or isomorphism is found. Now, note that when T_1 and T_2 are isomorphic, leaves contained in L_i can equally likely be found in T_1 or T_2. Hence, finding an automorphism or isomorphism in a test is equally likely. In particular, the probability is $\frac{1}{2}$ for finding an isomorphism for each $i \in \{1, 2\}$ rather than an automorphism. Anytime we find an automorphism but no isomorphism, we increment c by 1. We terminate when c reaches $e := \lceil -\log_2(\epsilon) \rceil$. Assuming the trees are isomorphic, the probability of this outcome is therefore bounded by $(\frac{1}{2})^e$.

(Runtime.) We will calculate the expected number of leaves explored before termination. We may consider the number of leaves instead of nodes by adding the multiplicative factor $\max(h_1, h_2)$ for the maximum length of a root to leaf walk in the search trees to our runtime. (We explain subsequently how to improve this factor.)

We may assume that the input trees are non-isomorphic and thus that the algorithm terminates because the condition $c > e = \lceil -\log_2(\epsilon) \rceil$ was met. This suffices to give an upper bound since earlier termination due to the discovery of isomorphisms clearly only leads to a smaller expected running time.

Consider running $2\sqrt{|T_i|}$ iterations of the algorithm. We may assume that in the j-th iteration L_1 and L_2 each contain at least j leaves: otherwise, some previous iteration already discovered an automorphism or an isomorphism. Furthermore, we may assume that the probability to find a leaf is uniform across all leaves: if probabilities are non-uniform, the chance for finding some leaves repeatedly only increases (see [13]). The probability of finding an automorphism in L_i (with $i \in \{1, 2\}$) within j iterations is therefore at least $\frac{j}{|T_i|}$. After $\sqrt{|T_i|}$ iterations, the probability for finding an automorphism in T_i is then at least $\frac{\sqrt{|T_i|}}{|T_i|} = \frac{1}{\sqrt{|T_i|}}$. Hence, the probability of finding no automorphism after $2\sqrt{|T_i|}$ many steps is at most

$$\left(\frac{\sqrt{|T_i|}-1}{\sqrt{|T_i|}}\right)^{\sqrt{|T_i|}} \leq \frac{1}{\mathbf{e}} < \frac{1}{2}, \quad \text{where } \mathbf{e} \text{ is the Euler constant.}$$

We view the computation as a series of batches consisting of $2\sqrt{|T_i|}$ iterations each. For each of them, the probability for finding an automorphism is at least $1/2$. For termination, we need to find e many automorphisms. The expected number of batches is thus in $\mathcal{O}(e)$, which shows that the overall number of iterations is in $\mathcal{O}(e \cdot 2\sqrt{|T_i|})$. ◀

We can improve the bound on the running time replacing the factor $\max\{h_1, h_2\}$ with the factor $\log_2(\min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$. To do so we alter the algorithm to take into account that the trees may be of very different sizes and also the trees may be quite unbalanced. To compensate for this we employ a doubling technique. However, we first need a bound for the expected length of the random root to leaf walks used in our algorithm.

▶ **Lemma 2.** *In an n-node black box search tree the expected length of a random root to leaf walk (i.e., the running time of Algorithm 1) is in $\mathcal{O}(\log n)$.*

Proof. Let $g(T)$ be the expected length of a random root to leaf walk in tree T. Note that the number of leaves t of a black box search tree is in $\Theta(n)$ for an n-node tree. We will argue that among the trees T with t leaves the value $g(T)$ is maximal if T is a binary tree in which all leaves are located on two consecutive levels. Since in such a tree even the maximum root to leaf distance is $\mathcal{O}(\log n)$, this proves the theorem.

First let T be a tree which has a vertex v with more than two children $u_1, \ldots, u_j$. Let T_i be the subtree of T rooted at u_i and assume without loss of generality that $g(T_i) < g(T_j)$ for $i < j$. Alter the tree T into a new tree T' by inserting a new node w as a child of v and then relocating the trees T_1 and T_2 so that their roots are now children of w instead of v. Then, conditional on the event that the random walk reaches v, the expected length of the walk has increased. Thus $g(T') > g(T)$. Since there are only finitely many trees with t leaves, by induction it suffices now to consider binary trees.

Let T be a binary tree and suppose there are leaves ℓ_1 and ℓ_2 whose height differs by more than 1. Say ℓ_1 is on the level furthest from the root. There must be another leaf ℓ_3 whose parent p is also the parent of ℓ_1. Alter the tree to obtain a new tree T' by assigning ℓ_2 as the new parent of ℓ_3 and ℓ_2. Note that p is further away from the root than ℓ_2. Thus, the tree being binary, the probability of a random walk reaching ℓ_2 is larger than that of reaching p. Therefore $g(T') > g(T)$. By induction this proves the theorem. ◀

▶ **Theorem 3.** *There is an algorithm that solves the isomorphism exploration problem with probability at least $1 - \epsilon$ and expected worst-case runtime bounded by*
$\mathcal{O}\left(\lceil \log_2(\frac{1}{\epsilon}) \rceil \cdot \log_2(\min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}) \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}\right)$.

Proof. Set $n = \min\{|T_1|, |T_2|\}$. For an integer s, we run the algorithm with a budget $2s$ that limits the number of walks that can be performed in each tree to s. Furthermore, we limit the length of the random walks by $h = c \log_2(s)$ for some suitable constant determined later. Whenever a random walk exceeds the length h, we abort the walk and ignore it. If the algorithm does not terminate within the alloted budget then we double s and restart. This guarantees that the number of queries does not exceed $\mathcal{O}(s \log s)$ when we run it with integer s.

At least in the smaller of the two trees, automorphisms are found with high probability whenever s exceeds $\sqrt{n}$. Indeed, by Lemma 2 the average length of a random walk in the smaller tree is in $\mathcal{O}(\log n) = \mathcal{O}(\log \sqrt{n})$. Thus, by Markov's bound with probability $1/2$, the

random walks end in a leaf of height at most $\mathcal{O}(\log n)$. Thus, by the Chernoff bound, for sufficiently large s, with probability $1/2$ at least $1/4$ of the random walks end in a leaf of height at most $\mathcal{O}(\log n)$. We choose c so that this height is at most $c \log_2(n)$.

In case the graphs are isomorphic, automorphisms and isomorphisms are still found with equal probability. Thus our arguments for the probabilities remain in place since we essentially perform the same algorithm in pruned subtrees. Regarding the running time, note that the probability that the algorithm does not terminate with budget s decreases exponentially with s. That is, the probability is in $\mathcal{O}(a^{s/\min\{\sqrt{|T_1|},\sqrt{|T_2|}\}})$ for some constant $a < 1$ once $s > 2\min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. ◀

We should remark that the collision problem was previously exploited in the context of the group isomorphism problem [16], but in that context structural information on the corresponding trees is known. Also the idea of sampling with random walks was used for the isomorphism algorithm in [17], but that algorithm only uses a single leaf in the search tree and thus cannot achieve sublinear running time guarantees.

3.2 Las Vegas Bidirectional Search

The major drawback of the probabilistic bidirectional search algorithm is that it makes errors. Considering trees of height 1 it is not difficult to see that a non-erring algorithm, even a randomized one, needs to query a linear fraction of the leaves to distinguish non-isomorphic trees. However, if the degree of the input graphs is restricted, we can beat this bound.

To do this, we basically strive to choose a specific set of nodes in both trees that ensures a "collision" of leaves. This guarantees that we find equally colored leaves, if they exist.

We refer to the maximum degree among the considered trees as d. Our main new idea is to split search trees in a balanced manner, followed by techniques to exploit isomorphism invariance. We want to note that the techniques for exploiting isomorphism invariance are inspired by techniques described in [12, 18], which essentially also perform splits. However, rather than heuristically applying them, here we perform them in a balanced and systematic way. Towards this goal we need the notion of a *split* (v, h), which is a node $v \in T_i$ at level h in one of the input trees. We define the *cost* of a split as a pair of numbers (s_1, s_2) as follows: s_1 is the size of the tree T_{3-i} truncated at level h (i.e., the ball of radius h around the root). If the tree T_i truncated at level h is non-isomorphic to the tree T_{3-i} truncated at level h then $s_2 := s_1$, *otherwise* s_2 is the size of the subtree rooted in $v \in T_i$ at level h.

The intuition for our exploration strategy is that s_1 bounds the size of the subtree to be explored in T_{3-i}, while s_2 bounds the size of the subtree to be explored in T_i (up to logarithmic factors). While the special treatment of the case when the trees disagree on the first h levels may seem cumbersome at first, the idea is that if trees already differ in the first h levels, we can decide non-isomorphism by exploring all nodes in the subtree of T_i consisting of the first h levels and then at most as many vertices within the first h levels of T_{3-i}.

We call a split (v, h) a *balanced split* whenever its cost (s_1, s_2) satisfies $\max\{s_1, s_2\} \leq 4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. Note that slightly abusing terminology in a balanced split the subtree with root v can be unproportionally large, as long as the two trees truncated at level h are non-isomorphic and s_1 is sufficiently small.

At this point it might neither be clear how to find a balanced split nor that a balanced split always exists. However, assume for now that we are given a balanced split. In that case we can efficiently solve isomorphism (even deterministically) as follows. We perform breadth-first search up to level h in both trees T_1 and T_2, visiting all nodes $N_1 \subseteq V(T_1)$ and $N_2 \subseteq V(T_2)$ up to and including level h. We can conclude non-isomorphism immediately

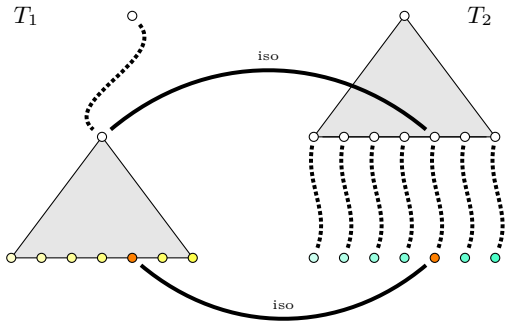

Figure 3 State of the search trees after termination of Algorithm 4. If trees are isomorphic, a node v_1 in T_1 at some level h must be mapped to some node v_2 in T_2 at level h by an isomorphism. But if that is the case, then a leaf below v_2 is isomorphic to some leaf below v_1.

whenever the breadth-first search has finished level h and the two trees truncated at level h are non-isomorphic. We can thus assume now that these trees are isomorphic. By exploring all nodes up to level h (which is the level containing v), we surely explore the node v in one of the trees. Without loss of generality assume in the following that $v \in V(T_1)$.

In T_1, we explore *all* leaves L_v of the subtree rooted at *one* fixed node, namely v from the balanced split. Let $N_2' \subseteq N_2$ denote the set of nodes at level h in T_2. Then, we explore for each node v' in N_2' *one* arbitrary leaf $l_{v'}$ in the subtree rooted at v'. If the trees are isomorphic, there must exist some $v' \in N_2'$ that can be mapped to v with an isomorphism. Since we explored all leaves of v, the leaf $l_{v'}$ with ancestor v' must be isomorphic (equally colored) to one of the leaves in L_v. Figure 3 illustrates how the collision of leaves is enforced through the exploration strategy.

The procedure for exploring, within our model, the first h levels of the subtree rooted at a particular node v is described in Algorithm 3. Starting from a given node v, it performs breadth-first traversal until only leaves are left, or h levels have been explored. The algorithm is also given a cost limit s and the algorithm aborts if this limit is reached.

Using Algorithm 3 as a subroutine, Algorithm 4 gives an implementation in the exploration model of the entire algorithm just described.

Let us argue an upper bound for the runtime of Algorithm 4 (still assuming that we are given a balanced split). From the definition of a balanced split, we can conclude that $|L_v|$ and $|N_2|$ are bounded by $\mathcal{O}(d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$. Since exploration up to level h in T_1 (Line 3) may only explore as many nodes as the exploration in T_2, we ensure that $|N_1| \leq |N_2|$ holds. Now, the last phase probes at most $\mathcal{O}(d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$ many paths, giving an overall upper bound of $\mathcal{O}\left(d \cdot h(T_2) \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}\right)$.

However, note that the factor $h(T_2)$ can be excessively large because the paths from level h to the leaves can be of length $\Theta(|T_2|)$. To prevent this, we alter the algorithm as follows. In T_2 we allocate a total budget of $c'\sqrt{|T_2|}\log(|T_2|)$ for some constant c' for all the level-h-to-leaves paths. By Lemma 2 the expected length of one such path is in $\mathcal{O}(\log|T_2|)$. Thus, by linearity of expectation, the expected total cost for the paths is $\mathcal{O}(\sqrt{|T_2|}\log|T_2|)$. By Markov's inequality for a suitable choice of c', with probability $1/2$ the total cost is in $\mathcal{O}(\sqrt{|T_2|}\log|T_2|)$. If the total cost exceeds this bound we simply restart the process.

Overall we can replace the factor $h(T_2)$ by $\mathcal{O}(\log(|T_2|))$, giving $\mathcal{O}(d \cdot \log_2(\max\{|T_1|, |T_2|\}) \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$. More generally, it is easy to see that given a split of cost (s_1, s_2), the modification of Algorithm 4 runs in $\mathcal{O}(\log_2(\max\{|T_1|, |T_2|\}) \cdot \max\{s_1, s_2\})$. There is an interesting analogy to the runtime of the probabilistic bidirectional search algorithm. A main difference is that the runtime directly depends on the maximum degree of the trees.

Algorithm 3 Breadth-first Search: Computing a Subtree of the Search Tree.

```
1  function Subtree(v, h, s)
       Input  : start node v, height limit h, cost limit s
       Output : (L, s') where L is the set of leaves of the subtree under v up to level h
                and s' is the number of explored nodes, or (⊥, ⊥) if cost limit did not
                suffice
2      if h = 0 then return {v};
3      N := {(v, 0)};
4      L := {};
5      s' := 0;
6      while N ≠ ∅ do
7          (v, h') := Some(N) ;                    // pick arbitrary element of N
8          N := N ∖ {(v, h')};
9          h' := h' + 1;
10         c := NewChild(v);
11         while c ≠ ⊥ do
12             s' := s' + 1;
13             if s' > s then return (⊥, ⊥) ;
14             if h' = h ∨ deg(c) = 0 then L := L ∪ {c} ;
15             else N := N ∪ {(c, h')} ;
16             c := NewChild(v);
17     return (L, s');
```

The crucial question remains whether balanced splits always exist and whether they can be found efficiently. We first address the question of existence of balanced splits.

▶ **Lemma 4.** *Let T_1, T_2 be black box search trees with maximum degree d. Then there exists a balanced split for search trees T_1 and T_2.*

Moreover, if h' is the maximal level for which the tree T_1 truncated at level h' is smaller than $4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$, the two subtrees up to level h' are isomorphic, and there are no leaves up to level h', then at least $\frac{3}{4}$ of the nodes at level h' in the smaller tree constitute balanced splits with cost $s_2 \leq 2\min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$.

Proof. We can assume w.l.o.g. that $|T_1| \leq |T_2|$. Let h' be the maximal level of T_2 where the size of the subtree up to level h' is smaller than or equal to $4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$.

If the subtrees up to level h' in T_1 and T_2 differ, we have found a balanced split. Furthermore, if there are leaves in the trees up to level h', we have found a balanced split as well. Hence, we assume that subtrees are isomorphic and no leaves are present.

We now argue that at least $\frac{3}{4}$ of the nodes at level h' in T_1 constitute balanced splits. Consider level h' of T_1 and T_2. Let $s_{h'} \leq 4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$ be the size of the subtree up to and including level h' in T_1. By assumption, the respective subtree of T_2 is of equal size. Furthermore, by assumption there are no leaves up to level h', implying that the tree contains at least $n_{h'} \geq \frac{1}{2} \cdot s_{h'}$ nodes at level h'.

Towards a contradiction, we assume that $s_{h'} \leq 4 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. But then we can increment h': since $s_{h'} \leq 4 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$, it holds that $s_{h'+1} \leq 4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. This is a contradiction to the assumption that h' is maximal. Hence, we know $4 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\} < s_{h'} \leq 4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$.

Algorithm 4 Bidirectional Search.

```
1  function Isomorphism(T_1, T_2, v, h)
       Input  : black box search trees T_1, T_2 and a split v, h with v ∈ V(T_1)
       Output : two leaves l_1 ∈ T_1, l_2 ∈ T_2 such that col(l_1) = col(l_2) if they exist, ⊥
                otherwise
2      (N_2, s) := Subtree(root of T_2, h, ∞) ;
3      (N_1, _) := Subtree(root of T_1, h, s) ;                    // explores v
4      if N_1 = ⊥ or T_1 and T_2 up to level h non-isomorphic then
5          return ⊥;
6      (L_v, _) := Subtree(v, ∞, ∞);
7      for n ∈ N_2 do
8          l := RandomWalk(n);      // can be an arbitrary, even determinsitic
9          for l' ∈ L_v do
10             if col(l) = col(l') then return (l, l') ;
11     return ⊥;
```

We can immediately conclude $n_{h'} \geq 2 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. Naturally, there can be at most $\frac{1}{2} \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$ corresponding subtrees which have a size greater than $2 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$ with roots at level h' in T_1 (since $|T_1| \leq |T_2|$). Consequently, there must be at least $n_{h'} - \frac{1}{2} \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\} \geq \frac{3}{4} n_{h'}$ subtrees rooted at level h' with a size smaller than $2 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. This concludes the proof for both claims of the lemma. ◀

Thus, for all search trees there exist balanced splits. We now explain how to find balanced splits efficiently. As shown by the lower bound in the next section, it is impossible to do this deterministically in an adequate running time. We thus need a randomized procedure for finding balanced splits. We will show that the following method is suitable. Rather than pseudocode we give a high level description in Algorithm 5.

It turns out that when the cost limit is sufficiently high the algorithm finds balanced splits with good probability. The intuition behind this is based on Lemma 4: once the algorithm reaches a sufficiently high level of the tree with breadth-first search, the majority of nodes constitute balanced splits.

From the description of the algorithm, the following corollary follows readily:

▶ **Corollary 5.** *If Algorithm 5 chooses in some iteration an element v at some level h in Step 3 so that (v, h) constitutes a split with cost (s_1, s_2) and at this point $s \geq s_2$, then the algorithm terminates after this iteration and returns a split with cost (s'_1, s'_2) where $s'_1 = s_1, s'_2 \leq s_2$.*

Proof. By assumption, (v, h) constitutes a split with cost (s_1, s_2). This implies that the entire subtree below v is smaller than s_2. Consequently, since s is large enough, Algorithm 5 explores the entire subtree below v in Step 4, unless probing the other way in parallel terminates first: this only contradicts our claim if it results in a more expensive split. However, since a more costly split necessitates more steps to explore its respective subtree, running the search in parallel ensures that the cheaper split is found first. Note that $s_1 = s'_1$ holds for all nodes at level h, concluding the proof. ◀

Using this, we can prove that Algorithm 5 terminates with a balanced split with good probability, giving what we need for our isomorphism test:

▶ **Lemma 6.** *Lemma If Algorithm 5 terminates with a split, it constitutes a balanced split with a probability of at least $\frac{3}{4}$.*

Algorithm 5 Las Vegas Balanced Splits.

function `SplitOrNotIsomorphic`(T_1, T_2)

Input : Black box search trees T_1 and T_2.

Output : Split (v, h) or conclude T_1 and T_2 are non-isomorphic

Step 1. Set cost limit $s \leftarrow 1$.

Step 2. Perform breadth-first search in T_1 and T_2, limiting the size of the traversed subtree to s nodes (each). If after any level the breadth-first search trees for T_1 and T_2 are non-isomorphic, terminate concluding non-isomorphism. Let h denote the level reached so far. If breadth-first search discovers a leaf v at or below level h, the algorithm terminates with the split (v, h).

Step 3. For each $i \in \{1, 2\}$, uniformly and independently at random choose a node v_i at level h in both trees. Compute breadth-first search starting from the node v_i in T_i, until one of the following conditions is met: (1) Breadth-first search finishes exploring the entire subtree of v_i, constituting the split (v_i, h). (2) Breadth-first search explored s nodes. This step is performed in parallel for both $i \in \{1, 2\}$ (i.e., each step alternates between the two), until one method succeeds in finding a split or both finish unsuccessfully. If at any point a split is found, the algorithm terminates immediately returning the split.

Step 4. Set $s \leftarrow 2s$ and jump to Step 2.

Proof. We can assume w.l.o.g. that $|T_1| \leq |T_2|$. Let h' be the maximal level of T_2 where the size of the subtree up to level h' is smaller than or equal to $4d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$.

First, we observe that we may always assume that the breadth-first trees explored in T_1 and T_2 up to level h' are isomorphic, since otherwise Algorithm 5 terminates immediately with no split (Step 2). Furthermore, since Algorithm 5 terminates when discovering leaves within the first h' levels in the breadth-first exploration (Step 2) and this result in balanced splits, we may assume that Algorithm 5 explores no leaves in the breadth-first search. We note that if Algorithm 5 finds no leaves, each doubling of s can only increase the level h reached by breadth-first search by at most 1.

Consider now Step 3 in the algorithm once level h' is reached. The algorithm picks a node of level h' uniformly at random. We now argue that with probability at least $\frac{3}{4}$ a node that is the root of a *small subtree* is chosen, i.e., a subtree that is smaller than $2 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$. This however follows readily from Lemma 4: since all subtrees at level h' are chosen for exploration with uniform probability, we can conclude that choosing a node that is the root of such a small subtree in T_1 has a probability of at least $\frac{3}{4}$. From the maximality of h' we can conclude that $s \geq 4 \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\}$ (see proof of Lemma 4). Hence, Corollary 5 ensures that the algorithm terminates with a balanced split when choosing a node that is the root of a small subtree.

Furthermore, note that before level h' is reached, it is not possible for Algorithm 5 to return a split that is not a balanced split since the cost of probing is smaller than the bound for balanced splits. ◀

At level h' Algorithm 5 terminates with probability $\frac{3}{4}$. Careful inspection of the proof of Lemma 4 and Lemma 6 reveals that Algorithm 5 also terminates with probability at least $\frac{3}{4}$ after every consecutive doubling of s. While the cost (and therefore runtime) doubles, the probability of not terminating quarters, which defines a geometric series: this results in an expected runtime of Algorithm 5 bounded by $\mathcal{O}(d \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$.

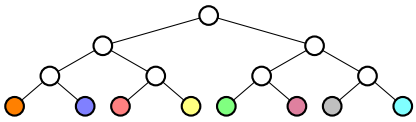

Figure 4 A search tree from the class $\mathcal{M}_3$.

We now run Algorithm 5 and Algorithm 4 in series, which results in the desired algorithm: if Algorithm 5 terminates with non-isomorphism we are done and otherwise Algorithm 4 tests isomorphism with the provided split. We observe that whenever Algorithm 5 terminates with a split, the costs of the split are also bounded by s: the execution time cannot be larger than the cost of the returned split. Running the previously described modification of Algorithm 4 with a split of cost s incurs expected cost bounded by $\mathcal{O}(\log_2(\max\{\sqrt{|T_1|}, \sqrt{|T_2|}\}) \cdot s)$. Using this, the following theorem follows.

▶ **Theorem 7.** *Let T_1, T_2 be black box search trees with maximum degree d. There exists an algorithm for the isomorphism exploration problem with no error that has an expected worst-case runtime bounded by $\mathcal{O}(d \cdot \log_2(\max\{\sqrt{|T_1|}, \sqrt{|T_2|}\}) \cdot \min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$.*

4 Lower Bounds

We prove lower bounds within the confines of the model. Easy lower bounds can be obtained by considering input trees of height 1, however, we are interested in bounds that also apply to trees of bounded degree. We utilize the search tree family $\mathcal{M}_h$ for this purpose (see Figure 4). A tree is in $\mathcal{M}_h$, if it is a complete binary tree of height h such that leaves have pair-wise distinct colors, i.e., for all $(l_1, l_2) \in L(V(\mathcal{M}_h))^2$ with $l_1 \neq l_2$ it holds that $\text{col}(l_1) \neq \text{col}(l_2)$.

We remark that shrunken multipedes (see [14]) are graphs that produce search trees very similar to those in $\mathcal{M}_h$ when used as input for IR algorithms.

Generally, due to their uniformity, trees from $\mathcal{M}_h$ can only be distinguished or proven isomorphic by considering leaves. A traversal strategy must either conclude – with good probability $(\frac{1}{2})$– that the set of leaves of the trees are entirely disjoint or equal. In the case when trees are isomorphic, the traversal strategy must provide two leaves with equal colors.

4.1 Randomized Lower Bound

We prove lower bounds for the isomorphism problem for randomized algorithms that err.

We will use a particular type of exploration algorithm for our purposes. We call an algorithm *unadaptive* on a class of inputs, if on each input from the class, the number of queries is always the same (in particular independent of randomness involved in the algorithm) and the queries performed by the algorithms on inputs from the class are independent of the answers given by the oracle. (The queries may still depend on the randomness involved in the algorithm.) This means in particular that even when matching leaves have been found, the algorithm will simply continue to run, possibly making further queries, and at some later point make a decision about the output.

▶ **Lemma 8.** *If some (possibly randomized) algorithm A solves the isomorphism exploration problem with expected run-time $f(n)$ and error-probability ϵ then for each $h \in \mathbb{Z}$ there is a randomized algorithm B that is unadaptive on the class of inputs $\mathcal{M}_h$ with a run-time in $\mathcal{O}(f(n))$ and error-probability ϵ.*

Proof. If an algorithm A solving the problem with expected run-time $f(n)$ and error probability ϵ is given, then by repeating the algorithm and using Markov's inequality we can design an algorithm A' with a run-time bounded by $\mathcal{O}(f(n))$ (not just in expectation) that still has an error probability of ϵ. For this note that even if the trees have been partially explored, it is possible to simulate the algorithm from scratch by pretending that explored nodes of the tree are unexplored.

To obtain the algorithm B we alter algorithm A' by simply pretending all discovered leaves have a randomly chosen previously unused color. More precisely, when a leaf is discovered, we pretend it has a color in $\{1, \ldots, 2^h\}$ drawn independently and uniformly at random from the colors that have not been used yet. We continue the simulation until A' halts. We then claim the input to be a yes instance if we found matching leaves and a no instance otherwise. This can only decrease the error probability in comparison to A'. ◀

For our lower bound we define a combinatorial problem of trees. Let M_h be the complete binary tree of height h, so that trees in $\mathcal{M}_h$ are colored versions of M_h. For two rooted trees U, S let $\mathrm{Inj}(U, S)$ be the set of root respecting injective homomorphisms from U to S. That is, the set contains the injective maps from $V(U)$ to $V(S)$ that map the root of U to the root of S and that map an edge of U to an edge of S.

From now on fix a height h and consider the tree M_h. Let $\mathcal{U}_h$ be the set of trees U for which $\mathrm{Inj}(U, M_h)$ is non-empty. This set contains exactly the trees isomorphic to a subtree of M_h. For two trees $U_1, U_2 \in \mathcal{U}_h$ we let $P(h, U_1, U_2)$ be the probability that for uniformly chosen $\alpha_1 \in \mathrm{Inj}(U_1, M_h)$ and independently, uniformly chosen $\alpha_2 \in \mathrm{Inj}(U_2, M_h)$ the set $L(M_h) \cap \alpha_1(V(U_1)) \cap \alpha_2(V(U_2))$ is non-empty. For integers a, b define

$$P(h, a, b) = \max \{P(U_1, U_2) \mid |L(U_1)| = a \wedge |L(U_2)| = b\}.$$

Let $P(h, m) = \max\{P(h, a, b) \mid a + b \leq m\}$. We will argue that $P(h, m)$ constitutes an upper bound on the probability of success for a randomized algorithm for isomorphism exploration that queries at most m nodes.

▶ **Lemma 9.** *Let B be an algorithm that is unadaptive on the class of inputs from $\mathcal{M}_h$. Suppose on inputs from $\mathcal{M}_h$ algorithm B makes m queries and has error probability ϵ. Then $1 - \epsilon \leq P(h, m)$.*

Proof. Consider the behavior of algorithm B on inputs from $\mathcal{M}_h$ with the colors $\{1, \ldots, 2^h\}$ being randomly assigned bijectively to the leaves. The algorithm B explores subtrees T_1' and T_2', one in each of the input trees. Since the algorithm makes m queries, together these trees can have at most m leaves. Our argument groups the possibilities in which B can query the oracle according to the topology of the two subtrees.

For two trees U_1 and U_2 consider the event E_{U_1,U_2} that T_1' is isomorphic to U_1 and T_2' is isomorphic to U_2. The event can of course only occur if $|U_1| + |U_2| \leq m$. Recall that algorithm B, being unadaptive, does not use the information on colors of the leaves provided by the oracle until the very end. Thus, the probability that B finds matching leaves on isomorphic inputs conditional to event E_{U_1,U_2} is $P(h, U_1, U_2)$.

We conclude that the probability that B finds matching leaves[2] is at most $P(h, m)$. ◀

We show that the trees need to have sufficiently many leaves for $P(h, T_1, T_2)$ to be large.

[2] In our problem definition the algorithm has to find two leaves of the same color. If the task only asked to decide whether the graphs are isomorphic, the algorithm could still guess, which would incur another factor of 1/2.

▶ **Lemma 10.** $P(h,a,b) \leq \frac{ab}{2^h}$.

Proof. For two trees T_1 and T_2 let $E(T_1,T_2)$ be the expected number of elements contained in the set $L(\mathcal{M}_h) \cap \alpha_1(V(T_1)) \cap \alpha_2(V(T_2))$, where α_1 and α_2 are taken independently and uniformly from $\mathrm{Inj}(T_1,\mathcal{M}_h)$ and $\mathrm{Inj}(T_2,\mathcal{M}_h)$, respectively. We define $E(h,a,b)$ in analogy to $P(h,a,b)$ as the maximum $E(T_1,T_2)$ over all choices of T_1 and T_2 with $|L(T_1)| = a$ and $|L(T_2)| = b$. By the Markov inequality it suffices to show that $E(h,a,b) \leq \frac{ab}{2^h}$.

Only vertices that are of distance h from the root in T_i can be mapped to a vertex in $L(\mathcal{M}_h)$. The automorphism group of $\mathcal{M}_h$ can map each leaf to every other leaf (i.e., acts transitively on the leaves). The graph $\mathcal{M}_h$ has 2^h leaves. Thus, for vertices $v_1 \in T_1$ and $v_2 \in T_2$ both of distance h from the root, the probability that $\alpha(v_1) = \alpha(v_2)$ is at most $\frac{1}{2^h}$.

By linearity of expectation the expected number of pairs (v_1,v_2) for which $\alpha(v_1) = \alpha(v_2) \in L(\mathcal{M}_h)$ is at most $\frac{1}{2^h} \cdot a \cdot b$. ◀

▶ **Theorem 11** (randomized lower bound)**.** *In the black box search tree model, a (possibly randomized making errors) traversal strategy runs in* $\Omega(\min\{\sqrt{|T_1|}, \sqrt{|T_2|}\})$ *worst-case cost for the isomorphism exploration problem, even on binary trees.*

Proof. By Lemma 8, it suffices to show the statement for an unadaptive algorithm B on $\mathcal{M}_h$. By Lemma 10, if B queries less than $\frac{1}{2}\sqrt{|\mathcal{M}_h|}$ nodes then both trees T_1 and T_2 uncovered by B have at most $\frac{1}{2}\sqrt{|\mathcal{M}_h|}$ leaves. But by the previous lemma we know that $P(h, \frac{1}{2}\sqrt{|\mathcal{M}_h|}, \frac{1}{2}\sqrt{|\mathcal{M}_h|}) \leq \frac{1}{4}$, which shows that the probability that B finds matching leaves in the two trees is at most $\frac{1}{4}$. This shows that B cannot find matching leaves with probability $\frac{1}{2}$. ◀

4.2 Deterministic Lower Bound

We exploit the randomized lower bound to obtain a strengthened deterministic one.

▶ **Theorem 12** (deterministic lower bound)**.** *In the black box search tree model, a deterministic traversal strategy runs in* $\Omega(\min\{|T_1|, |T_2|\})$ *worst-case cost for the isomorphism exploration problem, even on binary trees.*

Proof. Consider a deterministic algorithm on inputs from $\mathcal{M}_{2h}$, where $h = \log(n)$ and n is a power of 2. By Theorem 11 there are instances consisting of pairs of trees T_1, T_2 on which the algorithm makes $\Theta(\sqrt{2^{2\log(n)}}) = \Theta(n)$ queries in total. We know from the proof that the trees T_i can be chosen from $\mathcal{M}_{2h}$. For each $i \in \{1,2\}$, remove from T_i all non-root vertices whose parents have not been explored (and thus who have not been explored either). Let T_i' be the resulting tree, respectively for each i. On the input pair (T_1',T_2') the algorithm behaves exactly the same as on (T_1,T_2) and thus also makes $\Theta(n)$ queries in total, however T_i' has at most $\mathcal{O}(n)$ vertices. This shows that on (T_1',T_2') the algorithm makes $\Omega(\min\{|T_1'|, |T_2'|\})$ queries. ◀

Note that balanced splits for the trees of $\mathcal{M}_h$ can be found almost trivially: after finding out the height h through a single walk, an arbitrary node at level $\frac{h}{2}$ will induce a balanced split. This shows that while $\mathcal{M}_h$ constitutes worst-case examples for probabilistic algorithms, this is not true for deterministic algorithms. And indeed, our deterministic lower bound applies to subtrees of trees in $\mathcal{M}_h$ which have leaves on different levels.

5 Motivation Behind the Model

The motivation behind the specifics of our model lies in so-called *individualization-refinement* (IR) algorithms, the prevailing method to solve the graph isomorphism problem in practice. We explain that and why the isomorphism exploration problem captures the runtime of these algorithms, but refer to [11, 12] for a formal definition of IR algorithms.

Currently all practical state-of-the-art tools are based on the IR paradigm. Invariably, these algorithms perform a type of backtracking procedure to explore the structure of input graphs. Naturally, this leads to a *search tree*. While work is performed by the algorithms in each node of the search tree, the dominating factor for the running time is the size of the tree itself. Specifically, the running time per node is almost linear. However, the size of the search tree is exponential in the worst case [14].

When solving for isomorphisms of two graphs we get two search trees, one for each of the graphs. The leaves of the search trees correspond to complete invariants (described in more detail below), i.e., colors in our terminology. The task of finding isomorphisms in the graphs translates to finding pairs of leaves of equal color in the trees.

As mentioned earlier, nowadays there are various software packages implementing the paradigm in different flavors. These packages differ in many details (see below), of which the most crucial aspect is the traversal strategy through the tree.

The Search Tree. While the problem definition, algorithms, and lower bounds in this paper do not require further knowledge on how IR algorithms operate, we want to give some intuition about the composition of the search tree and in particular where the axiom regarding complete isomorphism invariance comes from.

The IR search tree is the recursion tree of a backtracking procedure whose goal it is to analyze the structure of an input graph (two input graphs in case of the isomorphism problem). Initially, forming the root of the tree, the algorithm distinguishes the vertices of the input graph using readily computed invariants. For example the vertices are easily distinguished by their degree, but other information is also used. The algorithm typically used for this is the *color refinement algorithm* (also known as vertex classification or 1-dimensional Weisfeiler-Leman algorithm). In case all vertices are distinguished from another, isomorphism can easily be checked, and no recursion is needed. Otherwise the algorithm starts to pick a class of indistinguishable vertices and for each vertex in this class, one at a time, artificially alters the vertex to make it distinguishable. This process is called *individualization* (hence the name individualization-refinement algorithm). Each individualization causes a recursive call, which corresponds to a child of the current node in the search tree. In the recursion, the refinement algorithm is called again to check if new information propagates through the graph and can be used to distinguish vertices further. As the entire procedure proceeds recursively it allows us to distinguish more and more vertices from each other. Recursion continues until all vertices have been distinguished from one another, i.e., the partition of the vertices into different types is *discrete*. The leaves of the IR search tree therefore correspond to discrete partitions. To the leaves, because all vertices have been distinguished, we can associate an invariant that completely describes the structure. We call this a complete invariant. This invariant corresponds to the color of the leaf in our exploration model.

The defining property of these algorithms is that all computations are made in an isomorphism-invariant fashion. This is precisely what leads to our invariance axiom. Indeed, checking isomorphism between two leaves l_1, l_2 in the backtracking tree then becomes trivial since in each leaf all vertices have been distinguished from one another. In particular there

can be only one possible isomorphism, which would have to map vertices of the same type to each other. If an isomorphism exists this implies that the individualization choices made to get to l_1 can be mapped to the choices made to get to l_2. The isomorphism-invariance of the entire procedure guarantees that for matching leaves there is an automorphism (isomorphism when considering trees from different graphs) mapping one leaf to the other.

While, depending on the input, the backtracking trees can come in many shapes and sizes, we want to record several properties. For starters internal vertices cannot have only one child since there is no reason to individualize vertices in singleton classes. Furthermore the number of children a node in the search tree can have is certainly bounded by the number of vertices of the input graph. However, in practice most nodes have significantly fewer children.

The size of the search tree is the dominating factor of the running time. In fact, for most implementations the non-recursive work can be polynomially bounded. Thus, up to a polynomial factor, the running time agrees with the number of vertices of the search tree that are traversed (see for example [17, Theorem 9] and [15]).

Practical Heuristics. A closer look at the practical tools reveals that for most graphs they do not traverse the entire tree. Two main heuristics are commonly applied to prune the search tree, called *invariant pruning* and *automorphism pruning*. The reader familiar with IR tools may worry that our model omits these two crucial aspects. However, in the following, we explain why both of these pruning techniques are captured by the model.

First of all, by using *invariant pruning*, IR algorithms are sometimes able to cut off parts of the search tree at inner nodes. This is done using invariants which yield different values at different parts of the tree. In principle this process could be emulated in the model by adding colors to the inner nodes. When doing so, it is crucial that the invariance axiom does not apply to the inner nodes, since only for leaves the associated invariants are complete. We could extend all results from this paper to the adapted model. In any case, it turns out that to some extent this kind of mechanism is already captured in our model since it allows inner vertices to have different degrees. Degrees of vertices can serve to distinguish inner nodes exactly in the same fashion as invariants do.

Second of all, by using discovered automorphisms of the graph, *automorphism pruning* is a method to skip branches that we already know are symmetric. Another way of seeing this is that automorphisms allow us to form quotients of the search tree. In our setting, we can simply define the trees to be the quotients of the original search trees. This simulates perfect automorphism pruning. It does not explain how to find one or all automorphisms in one of the trees, but these kinds of problems are closely linked to finding isomorphisms and can also be expressed in our search tree model (see below).

In summary, both types of heuristics are captured by our model.

Traversal Strategies in Practical Tools. There are only two main traversal strategies used by competitive practical tools. In fact, with the exception discussed below, all competitive tools essentially traverse the search tree using depth-first search [5, 6, 8, 12].

However, the practical solver Traces introduced a radically different strategy, which turns out to be much more effective in most practical cases: breadth-first traversal is combined with random walks of the search trees [12, 15]. The idea is that breadth-first traversal maximizes applicability of pruning rules, while random walks are used to discover automorphisms for pruning. While crucially exploiting randomization, the tool does not make errors.

Related Problems. Practical algorithms mostly do not decide the graph isomorphism problem, but rather solve one of two strongly related types of problems. In the following, we discuss these related problems and how they can be modeled using black box search trees.

The *automorphism group problem* requires computation of the entire automorphism group of a graph. This problem is closely related to the graph isomorphism problem and there are polynomial-time Turing reductions from each problem to the other [9]. Regarding IR search trees, in our model the problem corresponds to finding all leaves of an arbitrary color.

Alternatively, we can solve the *asymmetry problem* or equivalently the problem of searching for a *non-trivial graph automorphism*. In our model this translates to finding two distinct leaves of the same color if they exist. In IR algorithms, it suffices to solve the asymmetry problem. When non-trivial automorphisms are discovered, a wrapper algorithm may then remove the symmetry from the search tree and repeat the task on a quotient of the search tree. Such a wrapper algorithm has to repeat the problem at most a number of times that is quasi-linear in the order of the graph (repetitions are directly tied to the length of the longest subgroup series). Overall, our results on traversal strategies immediately carry over to the various tasks regarding automorphism group computations.

Another important problem in practice is *canonization*. The goal here is essentially to find a normal form for graphs by finding a canonical ordering of the vertices. This way isomorphism testing reduces to equality testing of the normal forms. Hence, graph isomorphism reduces to canonization in polynomial-time, but we currently do not know whether graph isomorphism and canonization are polynomial-time equivalent.

In IR algorithms, this problem can be modeled as follows. The solvers are now executed on a single graph, yielding a single search tree. The goal is to return a particular leaf in the given input trees. The requirement is that the output has to be consistent across different but isomorphic inputs. It is not clear to us whether any of the techniques for sublinear exploration developed in this paper can be transferred to the canonization problem.

6 Conclusion and Future Work

We designed an abstract model that captures the backtracking behavior of IR algorithms and proved bounds for various scenarios. We want to stress the fact that the class of trees $\mathcal{M}_h$ used throughout the paper for lower bound constructions models actual recursion trees of the IR algorithms. In fact the trees closely resemble those arising form so-called shrunken multipede graphs of [14], which form worst case inputs for all IR algorithms. These recursion trees are in particular of degree at most 4 and have exponential size. In other words, our worst case lower bounds apply to instances stemming from true inputs to IR algorithms.

Using our new insights we can explain why some of the strategies used by the currently fastest practical solver Traces turn out to be highly efficient. As discussed previously, Traces uses breadth-first search intertwined with random walks of the search tree. In particular, this is often done in a cost balancing manner, such that the number of random walks is proportional to the cost of breadth-first search. This in turn often leads to the automorphism group being found in time proportional to the square root of the search tree size. For sophisticated pieces of software such as Traces, the traversal strategy is of course not the only deciding factor when it comes to running time. However, generally, the experimental paths often enable Traces to discover automorphisms much earlier than solvers solely utilizing depth-first traversal. Hence automorphisms are available more quickly for pruning. Overall, in some sense, Traces emulates some of the techniques described in our Monte Carlo algorithm.

Interestingly, Traces also sometimes uses some techniques of the Las Vegas algorithm we describe. Specifically it performs splits in its "special traversal" strategy for automorphism groups (see [12]). When Traces detects a leaf on level h with parent v, in our terminology it executes the split $(v, h-1)$. Since many graphs in the benchmark suite of [12] have search trees of height 2 or 3, Traces in practice turns out to frequently perform splits that are fairly balanced. This results in significant speedups over other solvers (e.g., see runtime on combinatorial graphs with switched edges in [12]).

In subsequent work, we were able to show that an implementation of the Monte Carlo approach indeed outperforms state-of-the-art solutions for isomorphism testing in practice. Interestingly, besides superior worst-case guarantees, the approach has further practical advantages that simplify its implementation over state-of-the-art tools [1].

Regarding future work, a theoretical question that remains is whether sublinear traversal strategies for the graph canonization problem are possible. Furthermore, the challenge remains to close the gap of logarithmic factors between our upper and lower bounds. Also one might want to address the fact that the size of the larger tree rather than the size of the smaller tree appears in the upper bound of the Las Vegas algorithm.

Abstract

We consider the problem of managing the buffer of a shared-memory switch that transmits packets of unit value. A shared-memory switch consists of an input port, a number of output ports, and a buffer with a specific capacity. In each time step, an arbitrary number of packets arrive at the input port, each packet designated for one output port. Each packet is added to the queue of the respective output port. If the total number of packets exceeds the capacity of the buffer, some packets have to be irrevocably rejected. At the end of each time step, each output port transmits a packet in its queue and the goal is to maximize the number of transmitted packets.

The Longest Queue Drop (LQD) online algorithm accepts any arriving packet to the buffer. However, if this results in the buffer exceeding its memory capacity, then LQD drops a packet from the back of whichever queue is currently the longest, breaking ties arbitrarily. The LQD algorithm was first introduced in 1991, and is known to be 2-competitive since 2001. Although LQD remains the best known online algorithm for the problem and is of practical interest, determining its true competitiveness is a long-standing open problem. We show that LQD is 1.707-competitive, establishing the first $(2-\varepsilon)$ upper bound for the competitive ratio of LQD, for a constant $\varepsilon > 0$.

1 Introduction

The fact that communication networks are omnipresent highlights the significance of improving their performance. A natural way to achieve such performance improvements is to develop better algorithms for buffer management of shared-memory switches which form the lower levels of network communication. We study a fundamental model of such switches.

Consider a shared-memory network switch consisting of a buffer of size $M \in \mathbb{N}$, an input port, and $N \in \mathbb{N}$ output ports. Furthermore, consider a slotted time model. In each time step, an arbitrary number of unit-valued packets arrive to the input port. Each packet comes with a label specifying the output port that it has to be forwarded to. A buffer management algorithm has to make a decision for each packet: either irrevocably reject it, or accept it while ensuring that the buffer capacity M is respected, which may mean that a previously accepted packet has to be evicted. At the end of the time step, each output port with at least one packet in the buffer destined to it transmits a packet. The goal of the buffer management algorithm is to accept/reject incoming packets or evict already accepted packets, so as to maximize the throughput, i.e., the total number of transmitted packets, while ensuring that at most M packets in total are stored for all output ports at any time.

Given the inherently online nature of buffer management problems, a standard approach is to design online algorithms for them and evaluate the algorithm's performance using its competitive ratio. More specifically, an online algorithm ALG is c-competitive (where $c \geq 1$), if the number of packets transmitted by an optimal offline algorithm OPT (that has full knowledge of the incoming packet sequence a priori) is at most c times the number of packets transmitted by ALG. There exists an extensive body of research dedicated to designing competitive online algorithms with the aim of improving the performance of networking devices that incorporate buffers (see e.g. [20, 32]).

Since packets have unit value, we can assume without loss of generality that the packets destined to a specific output port are transmitted in an earliest-arrival (FIFO) fashion and thus, it is helpful to associate each output port with a queue.

Intuitively speaking, to maximize throughput, one would like to maintain a flow of packet transmissions for as many queues in parallel as possible. It is therefore desirable to prioritize accepting packets for queues that do not have many incoming packets in the near future. Unfortunately, an online algorithm does not know which queues these are, and in order to be insured against an adversarial input it seems reasonable to try to keep the queue lengths as balanced as possible in every step. This is exactly the idea behind the online algorithm *Longest Queue Drop (LQD)*, introduced in 1991 by Wei, Coyle, and Hsiao [35]: The incoming packet is always accepted and if this causes the buffer to exceed its capacity then one packet from the longest queue, breaking ties arbitrarily, is evicted (this could be the incoming packet).[1]

The LQD algorithm, apart from being a natural online algorithm to derive, remains the only known competitive algorithm for this problem. Since the algorithm is simple and can be used, for instance, to achieve a fair distribution of the bandwidth, it is of some practical interest; see e.g. [10, 11, 12, 13, 31, 33].

Previous Results

Hahne, Kesselman, and Mansour [21] provided the first formal analysis of LQD, showing that it is 2-competitive (see also Aiello, Kesselman, and Mansour [1]). The proof follows from a simple procedure that charges the extra profit of OPT to the profit of LQD. Furthermore, they demonstrate that LQD is at least $\sqrt{2}$-competitive, and also showed a general lower bound of 4/3 for the competitive ratio of any deterministic online algorithm.

[1] Wei, Coyle, and Hsiao proposed the LQD algorithm for the problem of shared-memory switches, consisting of N input ports and N output ports. Rather than assuming N input ports, each of which may receive at most one packet per time step, we more generally assume that there is a single input port of infinite capacity. Furthermore, we do not put any restrictions on the number of output ports, i.e., we allow N to be arbitrarily large. Again, this only makes the problem more general.

The analysis of LQD in [1, 21] was then refined by Kobayashi, Miyazaki, and Okabe [28] who showed that the LQD competitive ratio is at most $2 - \min_{k=1,\dots,N}(\lfloor M/k \rfloor + k - 1)/M$. However, for $N > \sqrt{M}$, this bound becomes $2 - O(1/\sqrt{M})$ and therefore does not establish a $2 - \varepsilon$ upper bound for a constant $\varepsilon > 0$ in general. Additionally, for the case of $N = 2$ output ports, LQD is exactly $\frac{4M-4}{3M-2}$-competitive [28] (we note that although this result holds for an even buffer size, the argument unfortunately breaks down when the buffer size is odd). For the case of $N = 3$ output ports, Matsakis shows that LQD is 1.5-competitive [30].

More recently, Bochkov, Davydow, Gaevoy, and Nikolenko [9] improved the lower bound on the competitiveness of LQD from $\sqrt{2}$ to approximately 1.44 (using a direct simulation of LQD and also independently, by solving a linear program). Moreover, they show that any deterministic online algorithm is at least $\sqrt{2}$-competitive, using a construction inspired by the LQD specific lower bound from [1, 21]. To the best of our knowledge, so far, no randomized algorithms for this problem have been studied.

Our Contribution

Although LQD is the best known online algorithm for buffer management in shared-memory switches, determining its true competitiveness remains an elusive problem and has been described as a significant open problem in buffer management [20, 32]. After the initial analysis which showed that LQD is 2-competitive and not better than $\sqrt{2}$-competitive [1, 21] progress on the upper bound has been limited to special cases (e.g., with restrictions on the number of output ports or memory size) [28, 30]. In this paper, we make the first major progress in almost twenty years on upper bounding the competitive ratio of LQD. Namely, we prove the first $(2 - \varepsilon)$ upper bound for a constant $\varepsilon > 0$ without restrictions on the number of ports or the size of the buffer:

▶ **Theorem 1.** *LQD is* 1.707*-competitive.*

We remark that Theorem 1 applies to LQD with any tie-breaking rule, even if tie-breaking is under control of the adversary, and that our upper bound is strictly smaller than $1 + 1/\sqrt{2}$.

Our Techniques

The proof of 2-competitiveness of LQD in [1, 21] uses the following general approach. If an optimal offline algorithm OPT currently stores more packets for a queue than LQD does, these excess packets present potential extra profit for OPT. Each such potential extra packet p in OPT is then matched to a packet that is transmitted by LQD at some point before packet p can be transmitted by OPT.

Our approach is different in that we (for the most part) do not match specific packets to one another. Instead, the idea is to take the total profit of LQD in each step and distribute it evenly among all potential extra packets that exist at the time. As such, the scheme is less discrete than the previous one. We then carefully calculate that, for each queue, *on average* each potential extra packet in that queue receives a profit strictly larger than one.

As described here, this approach does not quite work yet. Two additional types of charging concepts have to be combined with this first idea: One involves not splitting the LQD profit completely evenly and instead slightly favoring queues with relatively few potential extra packets, and the other involves matching some of the potential extra packets of OPT to extra packets that LQD transmits. Another difficulty is that the lengths of two queues, from which packets are rejected or evicted in the same time step, may differ by one packet. This makes our proof more intricate. To deal with this, we introduce a potential function that

will amortize the LQD profit in a suitable way. Then, the main challenge is to obtain useful lower bounds on the profit assigned to each queue, for which we introduce a novel scheme that relates the buffers of LQD and of OPT.

Further Related Work

We refer the reader to the survey by Goldwasser [20] for an overview of online algorithms for buffer management problems. Additionally, the survey of Nikolenko and Kogan [32] incorporates some more recent work. In the following, we discuss some of the results related to online buffer management for switches. In general, buffer management algorithms can be partitioned into *preemptive* ones, i.e., algorithms that allow for the eviction of already accepted packets from the buffer (eviction is also referred to as preemption), and *non-preemptive* ones that never evict a packet after it has been accepted.

Kesselman and Mansour [25] study buffer management in shared-memory switches in the non-preemptive setting in which a packet has to be transmitted once it is stored in the buffer and can no longer be evicted. They introduce the Harmonic online algorithm, which tries to maintain the length of the i^{th} longest queue as roughly proportional to a $1/i$ fraction of the memory. They show that this algorithm is $(\ln(N) + 2)$-competitive and give a general lower bound of $\Omega(\log N / \log\log N)$ for the performance of any deterministic non-preemptive online algorithm. Considering the non-constant lower bound that they establish, it follows that preemption provides a significant advantage.

Eugster, Kogan, Nikolenko, and Sirotkin [19] generalize the same problem in the following two ways: First, they study unit-valued packets labeled with an output port and a processing requirement (in our case, we have a unit processing cycle per packet). Packets accepted to the same queue have the same processing requirement. They introduce the preemptive Longest-Work-Drop algorithm: If the buffer is not full, the incoming packet is accepted; otherwise, a packet is preempted from a queue that has the largest total processing requirement. They show that this algorithm is 2-competitive and at least $\sqrt{2}$-competitive and that the competitive ratio of LQD for this more general problem is at least $(\sqrt{k} - o(\sqrt{k}))$, where k is the maximum processing time of any packet. Second, they address the problem of different packet values when all packets have unit processing requirements. They show that LQD is at least $(\sqrt[3]{k} - o(\sqrt[3]{k}))$-competitive in this case, where k is the maximum packet value. They also introduce a new algorithm which they conjecture to have a constant competitive ratio.

Azar and Richter [6] study switches with multiple input queues. More specifically, they consider one output port and N input ports and assume that each input port has an independent buffer of size M. At each time step, one packet can be sent from a single input port to the output port. For $M = 1$, they prove a lower bound of $1.46 - \Theta(1/N)$ for the competitive ratio of any randomized online algorithm and a lower bound of $2 - 1/N$ for deterministic online algorithms. They also give a randomized $\frac{e}{e-1} \approx 1.582$-competitive algorithm for $M > \log N$. For $M > 1$, Albers and Schmidt [3] design a deterministic 1.889-competitive algorithm for this problem and show a deterministic lower bound of $\frac{e}{e-1} \approx 1.582$ when $N \gg M$. Azar and Litichevskey [5] give a deterministic online algorithm matching this bound for large M.

A lot of research has been dedicated to the natural single input and single output port model. The model is trivial for unit packet values, but challenging if packets can have different values and the goal is to maximize the total value of transmitted packets. There exists a single queue for the accepted packets and one of the most studied versions of this problem requires packet transmission in the FIFO order. Kesselman, Lotker, Mansour, Patt-Shamir, Schieber, and Sviridenko [24] show that a simple greedy algorithm is exactly

$(2-1/(M+1))$-competitive when preemption is allowed. A series of works gradually improved the analysis of a better online algorithm from 1.983 [26], over 7/4 [7], to $\sqrt{3}$ [17]. Kesselman, Mansour, and van Stee [26] also show a general lower bound of 1.419 for the competitive ratio of any preemptive deterministic online algorithm.

The authors of [24] introduce the bounded-delay model of single output port switches. In this model, the buffer has unlimited size and allows for packets to be transmitted in any order, however, each packet has a deadline after which it needs to be dropped from the buffer. Once again, the problem is only interesting if packets can have different values. Any deterministic online algorithm is at least $\phi \approx 1.618$-competitive [4, 15, 22, 36], and after a sequence of gradual improvements [16, 18, 29], Veselý, Chrobak, Jeż, and Sgall [34] recently gave a ϕ-competitive algorithm. The competitive ratio of randomized algorithms is still open, with the best upper bound of $\frac{e}{e-1} \approx 1.582$ [8, 14, 23] (that holds even against the adaptive adversary), while the lower bounds are 1.25 against the oblivious adversary [8] and 4/3 against the adaptive adversary [15].

Lastly, we mention the model of Combined Input and Output Queued (CIOQ) Switches, in which the switch has N input ports and N output ports. Each input and output port has its own buffer and each input port can transfer a packet to any output port; however, at most one packet can be sent from any input port and at most one packet can be accepted by any output port, during one transfer cycle of the switch. A parameter S called *speedup* equals the number of transfer cycles of the switch taking place per one time step. For the unit-value case, Kesselman and Rosén [27] provide a 2-competitive non-preemptive online algorithm for $S = 1$, which becomes 3-competitive for any S. A faster algorithm with the same competitive ratio is given by Al-Bawani, Englert, and Westermann [2].

2 Setup of the Analysis

We fix an arbitrary instance I. Let OPT and LQD be the optimal offline algorithm and the Longest Queue Drop algorithm, respectively. In a slight abuse of notation, we also denote the profit that the optimal offline algorithm gains on input instance I as OPT and the profit that the Longest Queue Drop algorithm gains as LQD. Our goal is to give an upper bound on $\mathsf{OPT}/\mathsf{LQD}$.

For a time step t and a queue q, we say that OPT transmits an OPT-extra packet from q if OPT transmits a packet from q in step t but LQD does not. Equivalently, queue q is non-empty in OPT's buffer but empty in LQD's buffer at t. Similarly, we say that LQD transmits an LQD-extra packet from a queue q in step t if LQD transmits a packet from q at t but OPT does not.

Let $\mathsf{OPT}_{\mathsf{EXTRA}}$ and $\mathsf{LQD}_{\mathsf{EXTRA}}$ be the total number of transmitted OPT-extra and LQD-extra packets, respectively, over all time steps and queues. Then $\mathsf{OPT} - \mathsf{OPT}_{\mathsf{EXTRA}} = \mathsf{LQD} - \mathsf{LQD}_{\mathsf{EXTRA}}$ and hence $\frac{\mathsf{OPT}}{\mathsf{LQD}} = 1 + \frac{\mathsf{OPT}_{\mathsf{EXTRA}} - \mathsf{LQD}_{\mathsf{EXTRA}}}{\mathsf{LQD}}$. Therefore, if we show that $\varrho \cdot (\mathsf{OPT}_{\mathsf{EXTRA}} - \mathsf{LQD}_{\mathsf{EXTRA}}) \leq \mathsf{LQD}$ for some $\varrho > 1$, it will imply a competitive ratio of $1 + 1/\varrho < 2$ for the Longest Queue Drop algorithm.

Let e_q denote the total number of transmitted OPT-extra packets from queue q over all time steps. Then we have $\mathsf{OPT}_{\mathsf{EXTRA}} = \sum_q e_q$ and we will show

$$\varrho \cdot \left(\sum_q e_q - \mathsf{LQD}_{\mathsf{EXTRA}} \right) \leq \mathsf{LQD} \ . \tag{1}$$

We now give a high-level overview of the proof of Equation (1), which consists of two parts: (i) splitting the LQD profit among queues q with $e_q > 0$, and (ii) mapping transmitted LQD-extra packets to queues q with $e_q > 0$.

For (ii), we use the term $\mathsf{LQD}_{\mathsf{EXTRA}}$ in (1) to "cancel out" some transmitted OPT-extra packets. To this end, we will define how each transmitted LQD-extra packet p is mapped to a queue q (which is different from the one p is transmitted from). Let m_q be the number of transmitted LQD-extra packets which are mapped to q. The mapping will be such that $\sum_q m_q \leq \mathsf{LQD}_{\mathsf{EXTRA}}$ and that $m_q \leq e_q$. Define $\hat{e}_q = e_q - m_q \geq 0$ as the number of OPT-extra packets transmitted from queue q which are not canceled out.

We have $\left(\sum_q e_q - \mathsf{LQD}_{\mathsf{EXTRA}}\right) \leq \sum_q (e_q - m_q) = \sum_q \hat{e}_q$. Hence, it is sufficient for each q to receive a profit of at least $\varrho \cdot \hat{e}_q$, from which it follows that $\varrho \cdot \sum_q \hat{e}_q \leq \mathsf{LQD}$, implying (1).

We describe splitting the LQD profit, enhanced with a suitable potential, in Section 3 and introduce useful quantities for bounding the profit assigned to a particular queue in Section 4. Then, in Section 5, we introduce the mapping of transmitted LQD-extra packets to queues and derive a relation between the buffers of LQD and of OPT. Finally, we put the bounds together and optimize the value of ϱ in Section 6, which will yield our upper bound on the LQD competitive ratio.

3 Splitting the LQD Profit

In this section, we explain how the LQD profit is split. Before we proceed, we introduce some notation and terminology and define a key time step for a queue. When we refer to the state of a queue at time step t under some algorithm, we refer to the state after all new packets of step t have arrived and after all possible rejections/preemptions of packets by the algorithm, but before any packet is transmitted by the algorithm at the end of step t. (Note that by preemption we mean an eviction of an already accepted packet.) We use the following notation:

$s^t_{\mathsf{OPT}}(q)$: the number of packets in queue q in the OPT buffer in step t,
$s^t_{\mathsf{LQD}}(q)$: the number of packets in queue q in the LQD buffer in step t,
$s^t_{\max} = \max_q s^t_{\mathsf{LQD}}(q)$: the maximal size of a queue in the LQD buffer in step t.

We say that a queue q is *active* in a time step t if $s^t_{\mathsf{OPT}}(q) \geq 1$ or $s^t_{\mathsf{LQD}}(q) \geq 1$. Otherwise, if q is empty in both buffers at t, we say that q is *inactive* at t. See Figure 1 for an illustration.

Assumptions on the Instance

First, we assume without loss of generality (w.l.o.g.) that the longest queue in LQD's buffer has at least two packets in every step before the last step when packets are transmitted by LQD.

(A1) We assume that once $s^t_{\max} \leq 1$, no packet arrives to any queue in any step $t' > t$. Consequently, $s^t_{\max} \geq 2$ for any step t starting from the step in which the first packets are stored in the buffer and before the last step when the LQD buffer is not empty.

To see that this assumption is w.l.o.g., note that if $s^t_{\max} \leq 1$ then after packets are transmitted in step t, the LQD buffer is empty. Hence, LQD's processing of possible packets arriving after t is essentially independent of its behavior up to step t, and the adversary may postpone the arrival of future packets by an arbitrary number of steps, which may only help to increase the throughput of OPT but does not change the throughput of LQD.

We also make the following assumption w.l.o.g., which will greatly reduce the additional notation required.

(A2) For any queue q and step t, we assume that if $s^t_{\mathsf{LQD}}(q) \leq 1$ but at least one packet arrived to q at or before time step t, then no packet arrives to queue q after step t. (If $s^t_{\mathsf{LQD}}(q) = 1$ then the last packet is transmitted from q in step t.)

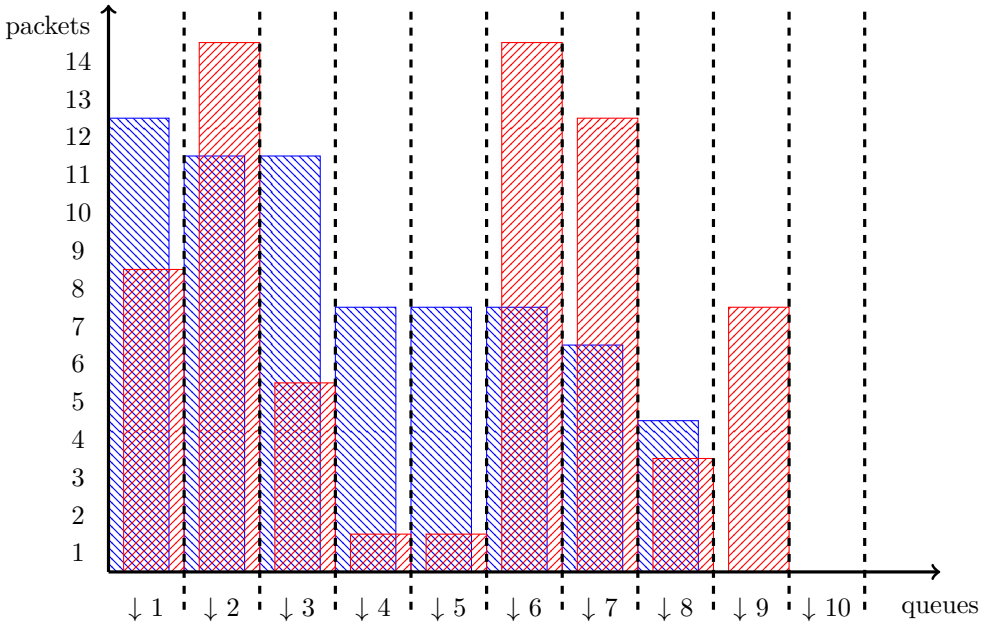

Figure 1 An example of the buffer configuration for LQD and OPT at some time step t. The blue, north-west shaded areas (aligned to the left) correspond to the packets in queues of LQD and the red, north-east shaded areas (aligned to the right) to the queues of OPT. For instance, we have $s^t_{\mathsf{OPT}}(6) = 14$, and $s^t_{\mathsf{LQD}}(6) = 7$. Furthermore, $s^t_{\max} = 12$ is the maximal size of a queue for LQD. Note that an OPT-extra packet is going to be transmitted from queue 9 in step t, and as queue 9 is empty for LQD, no further packet arrives to this queue by assumption (A2). All the queues with an index ≥ 10 are inactive (i.e., empty in both buffers). According to Definition 2, queues $1, 2$, and 3 overflow. As an example, assume that further 3 packets arrive into queue 8. Then LQD would first preempt a packet from queue 1 and then select two of the queues 1, 2 or 3, dropping one packet from each selected queue.

To see that this assumption is w.l.o.g., we iteratively modify the instance under consideration as follows: Let q be any queue q that does not satisfy this assumption and let t be the first time step such that $s^t_{\mathsf{LQD}}(q) \leq 1$ and there is a packet arriving to q at t or before. As q does not satisfy the assumption, there is a packet arriving to q after step t; let p be the first such packet. In the modified instance, p and all later packets for queue q are instead sent to a new queue which is not used in the instance otherwise. Observe that the profit of LQD does not change after redirecting these packets to a new queue, while the profit of OPT cannot decrease when we make this change. We remark that the new queue is always available as the number of output ports N is not restricted and can be arbitrarily large. Note that we only make this assumption to simplify our notation and it does not affect the generality of our analysis. Indeed, if the number of output ports used in the original instance is bounded by N_0, then after applying this transformation, there are always at most N_0 queues non-empty for LQD at any one time.

For instance, under assumption (A2), if an OPT-extra packet is transmitted from a queue q in some step t (as q is empty for LQD), then no packet arrives to q in any step $t' > t$.

Overflowing Queues

Intuitively, if a packet destined to q is rejected or preempted by LQD at t, then we say that q *overflows*. Furthermore, in such a case, the LQD buffer is full in step t and q has $s^t_{\max} - 1$ or $s^t_{\max}$ packets at t (see the example in Figure 1). This possible difference of 1 in the lengths

of two different overflowing queues makes our analysis substantially more involved.[2] For technical reasons, we also call a queue q' containing at least $s^t_{\max} - 1$ packets at t overflowing, provided that the LQD buffer is full and $s^t_{\mathsf{LQD}}(q') \geq 1$, even though there may be no packet for q' that is rejected or preempted at time t (it may even happen that no packet destined to any queue gets rejected or preempted at t but there are still some overflowing queues).

▶ **Definition 2.** *We say that a queue q* overflows *in step t if the LQD buffer is full in step t, $s^t_{LQD}(q) \geq s^t_{\max} - 1$, and $s^t_{LQD}(q) \geq 1$.*

Assumption (A2) also implies that once $s^t_{\mathsf{LQD}}(q) \leq 1$, then queue q does not overflow after t (as after step t, it is empty in the LQD buffer).

Key Time Step

Based on assumption (A2), we give a definition of a key time step t_q for queue q. For each queue q, we define:

t_q: the last time step in which queue q overflows; if q does not overflow in any step, we define $t_q = -1$ (we index time steps starting from 0).

Some important properties follow directly from the definition of t_q: No packet is ever preempted by LQD from q after t_q and no packet arriving to q after t_q is rejected by LQD, since a preemption or rejection in some step t implies that the queue overflows at t. We remark that we define $t_q = -1$ for queues q that do not overflow in any step in order to have the property that for such queues, $t_q < t$ for all time steps t.

We would like to keep track of how many OPT-extra packets are yet to be transmitted from a queue, for which the following notation is useful.

e^t_q: the number of OPT-extra packets transmitted from q in step t or later.

$\hat{e}^t_q = \max\{e^t_q - m_q, 0\}$: that is, e^t_q adjusted for the packets that are canceled out by transmitted LQD-extra packets. Note that m_q will be specified in Section 5.

Note that $e_q = e^0_q = e^{t_q}_q$ as no OPT-extra packet is transmitted before time t_q by assumption (A2). Thus, e^t_q is constant up to time t_q. After that, it further remains constant until q becomes empty for LQD, and then it decreases by one in each step until it becomes equal to zero. The same property holds for $\hat{e}^t_q$. The definition of t_q gives us a useful observation:

▶ **Observation 3.** *For any step t and queue q with $t \geq t_q$ (i.e., that does not overflow after t), it holds that* $\max\left\{s^t_{OPT}(q) - s^t_{LQD}(q), 0\right\} \geq e^t_q$.

Phases

It will be convenient in certain parts of the analysis to consider time phases instead of time steps. More specifically, let $\tau_1 < \tau_2 < ... < \tau_\ell$ be the time steps in which at least one queue overflows for the last time, i.e., for each $1 \leq i \leq \ell$ there is a queue q such that $\tau_i = t_q \geq 0$. Note that it has to be $\ell > 0$ so that OPT gains extra profit (equivalently, $\ell = 0$ only if $\mathsf{OPT}_{\mathsf{EXTRA}} = 0$). We call the time interval $[\tau_i, \tau_{i+1})$ the *i-th phase*; for $i = \ell$, we define $\tau_{\ell+1} = \infty$. We remark that time steps before τ_1 do not belong to any phase, because there

[2] A less sophisticated version of our proof, which deals with this scenario in a less careful way, only gives an upper bound of about 1.906 on the competitive ratio. Nevertheless, this analysis still requires the majority of concepts, lemmas, and calculations developed in the paper.

are no OPT-extra packets transmitted before step τ_1. Finally, observe that for any queue q that overflows at least once (i.e., $t_q \geq 0$), there has to exist an i such that $t_q = \tau_i$ as this queue overflows at t_q for the last time.

In the remainder of the paper, our focus will be mainly on steps $\tau_1, \ldots, \tau_\ell$. For simplicity and to avoid double indexing, we shall write $s^i_{\mathsf{LQD}}(q)$ instead of $s^{\tau_i}_{\mathsf{LQD}}(q)$, and similarly, we use index i instead of τ_i in other notations. Throughout the paper, i will be used solely to index phases and time steps $\tau_1, \ldots, \tau_\ell$.

Intuition for Splitting the LQD Profit

The key ingredient of our analysis is the splitting of the LQD profit such that we assign a profit of at least $\varrho \cdot \hat{e}_q$ to each q. To keep track of how much profit we assigned to a queue q, we use counter Φ_q. In particular, $\Delta^i \Phi_q$ will be the LQD profit assigned to q in phase i and $\Phi_q = \sum_{i=1}^{\ell} \Delta^i \Phi_q$ will be the LQD profit assigned to q over all phases. We will ensure that $\mathsf{LQD} \geq \sum_q \Phi_q$. The crucial part will be to show that $\Phi_q \geq \varrho \cdot \hat{e}_q$, which, together with $\sum_q (e_q - \hat{e}_q) = \sum_q m_q \leq \mathsf{LQD}_{\mathsf{EXTRA}}$, implies (1) using

$$\mathsf{LQD} \geq \sum_q \Phi_q \geq \sum_q \varrho \cdot \hat{e}_q \geq \varrho \cdot \left(\sum_q e_q - \mathsf{LQD}_{\mathsf{EXTRA}} \right) .$$

Let LQD^i be the profit of LQD in phase i, i.e., the total number of packets transmitted by LQD in all time steps in $[\tau_i, \tau_{i+1})$. A first idea is to split LQD^i among queues q satisfying $t_q \leq \tau_i$ proportionally to $\hat{e}^i_q$, meaning that we assign a profit of $\mathsf{LQD}^i \cdot \hat{e}^i_q / \hat{e}^i$ to a queue q with $\tau_i \geq t_q$, where $\hat{e}^i = \sum_{q:\tau_i \geq t_q} \hat{e}^i_q$. Such a scheme is useful because we can relate $\hat{e}^i$ to a certain fraction of the LQD profit; this is elaborated in Section 5.

Unfortunately, this simple idea fails for "short" queues, by which we mean queues for which $\hat{e}_q$ is relatively small compared to the number of packets that LQD transmits from q starting from time t_q. In particular, the total profit assigned to such a short queue q may be very close to $\hat{e}_q$, which would only be sufficient for $\varrho = 1$, thus proving 2-competitiveness.

To give a higher profit to a short queue q, we choose a parameter $\alpha \in (0, 1)$ and directly assign to q a $(1 - \alpha)$-fraction of the profit LQD gains by transmitting packets from q itself starting at time step t_q, whereas the remaining α-fraction of these packets is split proportionally to $\hat{e}^i_q$. The parameter $\alpha \approx 0.58$ is chosen at the very end of the analysis, so as to minimize the competitive ratio upper bound.

Potential

Before describing how exactly we split the LQD profit, we introduce a potential that will help us to deal with the fact that some queues overflowing in step t may only have $s^t_{\max} - 1$ packets and not $s^t_{\max}$ packets. On an intuitive level, this potential amortizes the profit assignment by moving some profit from phases with a slack to phases in which our lower bounds on the profit assigned are tight; we develop these bounds in the subsequent sections.

Namely, at any phase i, let $\mathcal{A}^i$ be the set of queues q that are active in step τ_i and satisfy $t_q > \tau_i$ (i.e., will overflow after the beginning of phase i). Thus, for any such queue q we have $t_q = \tau_j$ for some $j > i$ and consequently, q is non-empty for LQD in every step during phase i by assumption (A2) (as otherwise, q would not overflow at τ_j).

Then, using the aforementioned parameter α, we define potential $\Psi^i := \alpha \cdot |\mathcal{A}^i|$. Note that the potential at the beginning is $\Psi^1 \leq \alpha \cdot M$ and after the last packet of the input instance is transmitted, the potential equals $\Psi^{\ell+1} = 0$. We define two quantities which express the change of this potential in phase i:

u^i = the number of queues active in step τ_{i+1} that were inactive in step τ_i and will overflow after τ_{i+1}, i.e., the number of "new" active queues that will overflow after τ_{i+1}; and
v^i = the number of queues that are active in step τ_i and overflow at τ_{i+1} for the last time, i.e., $\tau_{i+1} = t_q$ for any such queue q.

Let $\Delta^i\Psi := \Psi^{i+1} - \Psi^i$ be the change of the potential in phase i; observe that $\Delta^i\Psi = \alpha \cdot (u^i - v^i)$.

Splitting the LQD Profit

We now formally define our scheme of splitting the LQD profit. Consider phase i. Let o^i be the number of packets that LQD transmits in the i-th phase from queues q with $\tau_i \geq t_q$ and $e_q > 0$, and let n^i be the number of packets transmitted by LQD in phase i from all other queues. Note that $\mathsf{LQD}^i = o^i + n^i$.

Apart from parameter $\alpha \in (0,1)$, we use another parameter $\beta \in (0,1)$ such that $\alpha + \beta < 1$; namely we will set $\beta = \alpha^2/(8 \cdot (1-\alpha))$ (we will require that α is not too close to 1 so that $\alpha + \beta < 1$). Given the two parameters, in each phase i, we assign an LQD profit of

$$\Delta^i\Phi_q := \underbrace{\frac{\hat{e}^i_q}{\hat{e}^i} \cdot (n^i + \alpha \cdot o^i - \Delta^i\Psi) + \beta \cdot o^i_q}_{\text{L-increase}} + \underbrace{(1-\alpha-\beta) \cdot o^i_q}_{\text{S-increase}} \tag{2}$$

to each queue q with $\tau_i \geq t_q$ and $\hat{e}^i_q > 0$, where o^i_q is the number of packets that LQD transmits from q during the i-th phase.

We call the first two terms in Equation (2) (i.e., $(\hat{e}^i_q/\hat{e}^i) \cdot (n^i + \alpha \cdot o^i - \Delta^i\Psi) + \beta \cdot o^i_q$) the *L-increase* for q as they will be mainly useful for "long" queues (with relatively high $\hat{e}_q$). We call the last term, $(1-\alpha-\beta) \cdot o^i_q$, the *S-increase* for q as it works well for "short" queues. Note that we only assign profit to queues that already have overflown for the last time. Furthermore, once a queue q with $\tau_i \geq t_q$ is empty in both the LQD and OPT buffers at the start of a phase, it does not get any profit as $\hat{e}^i_q \leq e^i_q = 0$ and $o^i_q = 0$.

To ensure feasibility of our scheme, we show that in total over all queues q with $\tau_i \geq t_q$ and $\hat{e}^i_q > 0$ we assign a profit of at most $\mathsf{LQD}^i - \Delta^i\Psi$. Indeed, using $\hat{e}^i = \sum_{q:\tau_i \geq t_q} \hat{e}^i_q$ and $\sum_{q:\tau_i \geq t_q \text{ and } \hat{e}^i_q > 0} o^i_q \leq o^i$, we have

$$\begin{aligned}
\sum_{q:\tau_i \geq t_q \text{ and } \hat{e}^i_q > 0} \Delta^i\Phi_q &= \sum_{q:\tau_i \geq t_q \text{ and } \hat{e}^i_q > 0} \left(\frac{\hat{e}^i_q}{\hat{e}^i} \cdot (n^i + \alpha \cdot o^i - \Delta^i\Psi) + \beta \cdot o^i_q + (1-\alpha-\beta) \cdot o^i_q \right) \\
&\leq n^i + \alpha \cdot o^i - \Delta^i\Psi + \beta \cdot o^i + (1-\alpha-\beta) \cdot o^i \\
&= n^i + o^i - \Delta^i\Psi = \mathsf{LQD}^i - \Delta^i\Psi\,.
\end{aligned}$$

While the scheme to split the LQD profit is relatively simple to define, showing $\Phi_q \geq \varrho \cdot \hat{e}_q$ brings technical challenges, namely, in obtaining suitable lower bounds on the profits assigned proportionally to $\hat{e}^i_q$ and in summing up these lower bounds over all phases. We get our lower bound based on a novel scheme that relates the buffers of LQD and of OPT, which is introduced in the next two sections.

4 Live and Let Die

Analyzing the S-increases is relatively easy. Most of the remainder of the proof is focused on analyzing the L-increases. We start by deriving a helpful lower bound on $n^i + \alpha \cdot o^i - \Delta^i\Psi$. For this, we first introduce the notion of live and dying queues, which are defined with respect to a fixed queue q with $t_q \leq \tau_i$ and $\hat{e}_q > 0$. For this fixed queue, we need to define live and

dying queues up until the first phase that comes after OPT transmits the last packet from q not canceled out by an LQD-extra packet. Let $j_q := \min\{j : \hat{e}_q^j = 0\}$ be the index j of the earliest step τ_j in which all remaining OPT-extra packets to be transmitted from q are canceled out.

▶ **Definition 4.** *Fix a queue q with $\hat{e}_q > 0$, and consider a phase i with $t_q \leq \tau_i$ and $i \leq j_q$. Let q' be a queue for which LQD stores at least one packet at time step τ_i. Queue q' is called* live *with respect to (w.r.t.) queue q at time step τ_i if*

(i) *$\tau_i < t_{q'}$, i.e., q' overflows at some time step after the i-th phase, or*

(ii) *$e_{q'} = 0$ and $s_{LQD}^{j_q}(q') \geq 1$,*

or both. Otherwise, q' is called dying *with respect to queue q at time τ_i.*

Note that step τ_{j_q} referred to in $s_{\mathsf{LQD}}^{j_q}(q')$ is after t_q, since $\hat{e}_q^t = \hat{e}_q > 0$ in any step t before the first OPT-extra packet is transmitted from q. Furthermore, $e_{q'} > 0$ implies that q' becomes empty in the LQD buffer before it becomes empty in the OPT buffer, by Observation 3. Intuitively, and assuming that $\hat{e}_q = e_q$, at time step τ_i, a queue q' is dying with respect to q if (i) it no longer overflows and (ii) either LQD runs out of packets to send from q' before the time OPT does or LQD runs out of packets to send from q' before the beginning of phase j_q.

The definition of live and dying queues implies the following property about transitions between these two types. This follows since the only property in Definition 4 (for a fixed q) that may change with increasing i is whether or not $\tau_i < t_{q'}$.

▶ **Observation 5.** *If a queue q' is dying (w.r.t. queue q) in time step τ_i, it will never be live (w.r.t. queue q) in step τ_j for any $j > i$. If q' is live (w.r.t. queue q) at τ_i, it can become dying (w.r.t. queue q) in time step τ_{i+1} only if it overflows in time step τ_{i+1} for the last time.*

For any phase i, we denote the set of queues that are live in step τ_i w.r.t. q as $\mathcal{L}_q^i$ and the set of queues dying in step τ_i w.r.t. q as $\mathcal{D}_q^i$. For a fixed phase i and queue q, the sets $\mathcal{L}_q^i$ and $\mathcal{D}_q^i$ partition all queues in which LQD stores packets at time τ_i. Let d_q^i be the number of packets transmitted from queues in $\mathcal{D}_q^i$ during phase i. We now relate $n^i + \alpha \cdot o^i$ to $|\mathcal{L}_q^i|$ and d_q^i.

▶ **Observation 6.** *It holds that $n^i \geq |\mathcal{L}_q^i| \cdot (\tau_{i+1} - \tau_i)$ and also $n^i + \alpha \cdot o^i \geq |\mathcal{L}_q^i| \cdot (\tau_{i+1} - \tau_i) + \alpha \cdot d_q^i$.*

Proof. Recall that o^i is the number of packets that LQD transmits in phase i from queues q' satisfying $\tau_i \geq t_{q'}$ and $e_{q'} > 0$, and that $n^i = \mathsf{LQD}^i - o^i$ (i.e., n^i is the number of packets that LQD sends in the i-th phase from queues q' that will overflow after τ_i or that satisfy $e_{q'} = 0$). As packets sent from queues that are live in step τ_i are accounted for in n^i, it holds that $n^i \geq |\mathcal{L}_q^i| \cdot (\tau_{i+1} - \tau_i)$, which proves the first claim.

Since every queue q' with $\tau_i \geq t_{q'}$ and $e_{q'} > 0$ is dying w.r.t. queue q at time step τ_i, we have that $o^i \leq d_q^i$. It holds that $|\mathcal{L}_q^i| \cdot (\tau_{i+1} - \tau_i) + d_q^i \leq \mathsf{LQD}^i = n^i + o^i$, and this inequality implies the second claim by using $o^i \leq d_q^i$ and $\alpha \leq 1$. ◀

Fix a queue q. We would like to lower bound the number d_q^i of packets transmitted from dying queues during the i-th phase in some way. Note that the LQD buffer is full at times τ_i and τ_{i+1}. Suppose for a moment that the set of live queues (w.r.t. queue q) does not change between step τ_i and step τ_{i+1}, i.e., $\mathcal{L}_q^{i+1} = \mathcal{L}_q^i$. Now, if the number of packets that LQD stores in live queues $\mathcal{L}_q^i$ increases by m between step τ_i and step τ_{i+1}, then we know that $d_q^i \geq m$. This is because the buffer is full, so if the live queues gain m packets, then dying queues must have lost at least m packets (possibly more if there are new dying queues in step τ_{i+1}). Since dying queues do not overflow, the only possible way to reduce the number of packets stored by LQD in dying queues is to transmit them.

We now formalize this intuition and handle cases where the set of live queues changes from one phase to the next. For the fixed queue q and each phase i such that $\tau_i \geq t_q$ and $i \leq j_q$, we define

$$\sigma_q^i = \begin{cases} \left(\sum_{q' \in \mathcal{L}_q^i} s_{\mathsf{LQD}}^i(q')\right) / |\mathcal{L}_q^i| & \text{if } |\mathcal{L}_q^i| \geq 1, \\ 1 & \text{otherwise}. \end{cases} \tag{3}$$

In words, σ_q^i equals the average number of LQD packets in live queues (w.r.t. queue q) in step τ_i, provided that there is at least one such queue. Later, in Lemma 13, we show that $\hat{e}_q^i > 0$ implies $|\mathcal{L}_q^i| \geq 1$ for any phase i (i.e., that there is at least one live queue w.r.t. queue q) and in most cases, we will only need σ_q^i in phases i with $\hat{e}_q^i > 0$. Since live queues are non-empty for LQD, it holds that $\sigma_q^i \geq 1$. Furthermore, as the average is at most the maximum and as the maximum is an integer, this gives us the following observation.

▶ **Observation 7.** *In any phase i such that $\tau_i \geq t_q$ and $i \leq j_q$, it holds that $\lceil \sigma_q^i \rceil \leq s_{\max}^i$.*

The following lower bound on σ_q^i is useful for making β as small as possible.

▶ **Observation 8.** *Assuming $|\mathcal{L}_q^i| \geq 1$, it holds that $\sigma_q^i \geq 2$ for any i with $\tau_i \geq t_q$ and $i < j_q$.*

Proof. We show that any live queue q' (w.r.t. queue q) has at least two packets in the LQD buffer in any step $\tau_i \geq t_q$ with $i < j_q$, which is sufficient as σ_q^i is the average size of live queues, provided that $|\mathcal{L}_q^i| \geq 1$. For a live queue q', consider two cases (as in Definition 4): First, if $\tau_i < t_{q'}$ then indeed $s_{\mathsf{LQD}}^i(q') \geq 2$ by assumption (A2) (if we had $s_{\mathsf{LQD}}^i(q') \leq 1$, then q' would be empty at $t_{q'}$ and would not overflow in that step). Second, if $e_{q'} = 0$ and $s_{\mathsf{LQD}}^{j_q}(q') \geq 1$, where $j_q = \min\{j : \hat{e}_q^j = 0\}$, then we have that $s_{\mathsf{LQD}}^i(q') \geq 2$, using assumption (A2) again together with $i < j_q$. ◀

Packets Transmitted from Dying Queues

We can now formally state our lower bound on the number of packets transmitted from dying queues, taking into account the change of the potential as well. As a byproduct (by rearranging the bound on d_q^i below), we obtain an upper bound on u^i, the number of "new" active queues that will overflow after τ_{i+1}, which captures the increase of the potential. Recall that v^i equals the number of queues that are active in step τ_i and overflow at τ_{i+1} for the last time.

▶ **Lemma 9.** *Consider any queue q with $\hat{e}_q > 0$. For each phase i with $\tau_i \geq t_q$ and $\hat{e}_q^i > 0$, $d_q^i \geq (\sigma_q^{i+1} - \sigma_q^i) \cdot |\mathcal{L}_q^i| + \sigma_q^{i+1} \cdot u^i - v^i$.*

Proof. As q is fixed, we consider live and dying queues w.r.t. queue q only. For simplicity, let $\tau = \tau_i$ and $\tau' = \tau_{i+1}$, thus the i-th phase is $[\tau, \tau')$. By the definition of σ_q^i, live queues contain $\sigma_q^i \cdot |\mathcal{L}_q^i|$ packets in the LQD buffer in step τ and thus, dying queues $\mathcal{D}_q^i$ have $M - \sigma_q^i \cdot |\mathcal{L}_q^i|$ packets in total in step τ, since the LQD buffer is full in step τ. As dying queues do not overflow in any step after τ, it is sufficient to show that queues $\mathcal{D}_q^i$ altogether contain at most $M - \sigma_q^i \cdot |\mathcal{L}_q^i| - (\sigma_q^{i+1} - \sigma_q^i) \cdot |\mathcal{L}_q^i| - \sigma_q^{i+1} \cdot u^i + v^i = M - \sigma_q^{i+1} \cdot |\mathcal{L}_q^i| - \sigma_q^{i+1} \cdot u^i + v^i$ packets in LQD's buffer in step τ'. Let x be the number of LQD packets in queues $\mathcal{D}_q^i$ in step τ', so our goal is to show

$$x \leq M - \sigma_q^{i+1} \cdot |\mathcal{L}_q^i| - \sigma_q^{i+1} \cdot u^i + v^i \,. \tag{4}$$

To this end, we analyze the LQD buffer in step τ'. By Observation 5, any live queue in $\mathcal{L}_q^i$ is also live in step τ' or overflows in step τ' (possibly both). Let $\mathcal{L}' = \mathcal{L}_q^i \cup \mathcal{L}_q^{i+1}$ be

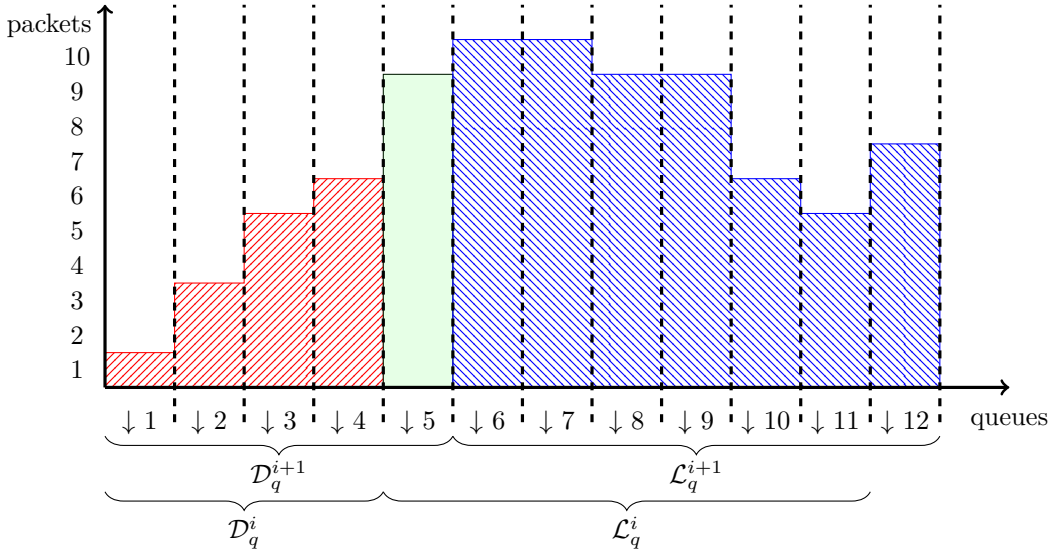

Figure 2 An example of the LQD buffer in step $\tau' = \tau_{i+1}$ for illustrating the proof of Lemma 9. Note that $s_{\max}^{i+1} = 10$ and that queues $5-9$ overflow. However, only queue 5 becomes dying as it overflows for the last time at τ', i.e., $t_5 = \tau'$. Moreover, queue 12 was empty in step τ_i and queue 1 will become empty for LQD just after packets are transmitted in step τ' (note that no further packets will arrive to queue 1 after step τ' by assumption (A2)). We have that $\mathcal{L}' = \{5, 6, \ldots, 12\}$. Finally, $\sigma_q^{i+1} = 56/7 = 8$, since there are 56 packets in 7 live queues $\mathcal{L}_q^{i+1}$.

the set of queues that are live in step τ or in step τ'. Observe that $\mathcal{L}' \cap \mathcal{D}_q^i = \emptyset$, since by Observation 5 dying queues may only become empty in LQD's buffer but not live. It follows that queues in $\mathcal{L}' \setminus \mathcal{L}_q^i$ must be inactive in step τ. Next, no queue that is live in step τ is empty for LQD in step $\tau' = \tau_{i+1}$ by Definition 4, using $i < j_q$, which follows from $\hat{e}_q^i > 0$. Finally, note that $\mathcal{L}'$ may contain some dying queues in $\mathcal{D}_q^{i+1}$, but all of them must overflow at τ', and that $\mathcal{L}' \setminus \mathcal{L}_q^{i+1} \subseteq \mathcal{D}_q^{i+1} \setminus \mathcal{D}_q^i$ (however, equality is not necessarily true). Concluding, set $\mathcal{L}'$ consists of three disjoint types of queues:

- **(i)** live queues in step τ that remain live in step τ',
- **(ii)** live queues in step τ that become dying in step τ' – these are queues in $\mathcal{L}' \setminus \mathcal{L}_q^{i+1}$ and we have that $|\mathcal{L}' \setminus \mathcal{L}_q^{i+1}| = v^i$, which follows from Observation 5 and from the definition of v^i, and
- **(iii)** queues inactive in step τ that are live in step τ' – these are queues in $\mathcal{L}' \setminus \mathcal{L}_q^i$ and there are at least u^i many of them (some live queues may not overflow in any step, so they are not accounted for in u^i).

See Figure 2 for an illustration.

Any queue in $\mathcal{L}' \setminus \mathcal{L}_q^{i+1}$ must overflow at τ', so it has at least $s_{\max}^{i+1} - 1 \geq \sigma_q^{i+1} - 1$ LQD packets at τ', where we use $\sigma_q^{i+1} \leq s_{\max}^{i+1}$ by Observation 7. It follows that queues in $\mathcal{D}_q^{i+1}$ have at least $x + |\mathcal{L}' \setminus \mathcal{L}_q^{i+1}| \cdot (\sigma_q^{i+1} - 1)$ packets in total in step τ'. By the definition of σ_q^{i+1} and since LQD's buffer is full at τ', queues in $\mathcal{D}_q^{i+1}$ contain $M - |\mathcal{L}_q^{i+1}| \cdot \sigma_q^{i+1}$ packets and thus $x + |\mathcal{L}' \setminus \mathcal{L}_q^{i+1}| \cdot (\sigma_q^{i+1} - 1) \leq M - |\mathcal{L}_q^{i+1}| \cdot \sigma_q^{i+1}$. Rearranging and using $|\mathcal{L}' \setminus \mathcal{L}_q^{i+1}| = v^i$, we get $x \leq M - |\mathcal{L}'| \cdot \sigma_q^{i+1} + v^i$. Using $|\mathcal{L}'| = |\mathcal{L}_q^i| + |\mathcal{L}' \setminus \mathcal{L}_q^i| \geq |\mathcal{L}_q^i| + u^i$, we obtain $x \leq M - (|\mathcal{L}_q^i| + u^i) \cdot \sigma_q^{i+1} + v^i$, implying (4). This concludes the proof as explained above. ◀

We now give two more upper bounds on u^i, the number of "new" active queues that will overflow after τ_{i+1}. The advantage of the following bound over the one from Lemma 9 is that it does not use σ_q^{i+1}.

▶ **Lemma 10.** *Consider any queue q with $\hat{e}_q > 0$. For each phase i with $\tau_i \geq t_q$ and $\hat{e}_q^i > 0$, $u^i \leq \frac{1}{2} \cdot \left(|\mathcal{L}_q^i| \cdot (\sigma_q^i - 1) + d_q^i\right)$.*

Proof. As q is fixed, we consider live and dying queues w.r.t. queue q only. Let x be the number of LQD packets in queues $\mathcal{D}_q^i$ in step τ_{i+1}. Similarly as in the proof of Lemma 9, we show that

$$x \leq M - |\mathcal{L}_q^i| - 2 \cdot u^i \,. \tag{5}$$

This equation implies the lemma, since dying queues $\mathcal{D}_q^i$ have $M - \sigma_q^i \cdot |\mathcal{L}_q^i|$ packets in total in step τ_i and thus, $d_q^i = M - \sigma_q^i \cdot |\mathcal{L}_q^i| - x \geq M - \sigma_q^i \cdot |\mathcal{L}_q^i| - (M - |\mathcal{L}_q^i| - 2 \cdot u^i) = 2 \cdot u^i - (\sigma_q^i - 1) \cdot |\mathcal{L}_q^i|$ by (5), from which the lemma follows by rearranging. To justify (5), queues accounted for in u^i are empty for LQD at τ_i and overflow after τ_{i+1}, so LQD must store at least two packets in each of them in step τ_{i+1} by assumption (A2). Moreover, no queue that is live in step τ_i is empty for LQD in step τ_{i+1} by Definition 4, using $i < j_q$, which follows from $\hat{e}_q^i > 0$. Hence, there can be at most $M - |\mathcal{L}_q^i| - 2 \cdot u^i$ LQD packets in queues $\mathcal{D}_q^i$ in step τ_{i+1}. ◀

Finally, we give a third upper bound on u^i that is incomparable to those in Lemmas 9 and 10 and is useful for phases with a relatively small number of steps.

▶ **Lemma 11.** *For any phase i with $\tau_{i+1} - \tau_i \leq \lceil \sigma_q^i \rceil - 2$, it holds that $u^i \leq \frac{1}{2} \cdot (n^i + o^i)$.*

Proof. Recall that the new active queues accounted for in u^i are empty in both buffers in step τ_i and will overflow after τ_{i+1}; let $\mathcal{U}$ be the set of these u^i queues. We show that the number of packets in queues $\mathcal{U}$ in step τ_{i+1} is at most $n^i + o^i$, i.e., the number of packets LQD transmits during the i-th phase. This is sufficient, since any queue in $\mathcal{U}$ has at least two LQD packets at τ_{i+1} (otherwise, if there was a queue in $\mathcal{U}$ with at most one LQD packet in step τ_{i+1}, no packets would arrive after τ_{i+1} to this queue by assumption (A2), so it would not overflow after τ_{i+1}).

Since the LQD buffer is full in step τ_i, it is sufficient to observe that any queue q' has at least $s_{\mathsf{LQD}}^i(q') - (\tau_{i+1} - \tau_i)$ packets in step τ_{i+1} in the LQD buffer; in other words, that packets present in q' at τ_i are not preempted till step τ_{i+1}. Suppose for a contradiction that $s_{\mathsf{LQD}}^{i+1}(q') \leq s_{\mathsf{LQD}}^i(q') - (\tau_{i+1} - \tau_i) - 1$. Thus, there must be a step $t \in (\tau_i, \tau_{i+1}]$ such that a packet is preempted from q' and $s_{\mathsf{LQD}}^t(q') \leq s_{\mathsf{LQD}}^i(q') - (t - \tau_i) - 1$. As $s_{\mathsf{LQD}}^i(q') \leq s_{\max}^i$, it holds that

$$s_{\mathsf{LQD}}^t(q') \leq s_{\max}^i - (t - \tau_i) - 1 \,. \tag{6}$$

Recall that there is a queue $\bar{q}$ with $\tau_i = t_{\bar{q}}$, i.e., which overflows for the last time at τ_i. At τ_i, queue $\bar{q}$ has at least $s_{\max}^i - 1$ packets and thus,

$$s_{\mathsf{LQD}}^t(\bar{q}) \geq s_{\max}^i - 1 - (t - \tau_i) \,. \tag{7}$$

Combining this with (6), we obtain $s_{\mathsf{LQD}}^t(\bar{q}) \geq s_{\mathsf{LQD}}^t(q')$. It holds that $t - \tau_i \leq \tau_{i+1} - \tau_i \leq \lceil \sigma_q^i \rceil - 2 \leq s_{\max}^i - 2$, where the second inequality is by the assumption of the lemma and the third inequality by Observation 7. Plugging this into (7), we obtain $s_{\mathsf{LQD}}^t(\bar{q}) \geq 1$. As a packet is preempted from q' at t, queue q' overflows at t, i.e., it has at least $s_{\max}^t - 1$ LQD packets. Thus, $s_{\mathsf{LQD}}^t(\bar{q}) \geq s_{\max}^t - 1$ and by Definition 2, $\bar{q}$ overflows at t (here, we also use that the

LQD buffer is full at t as q' overflows and that $s^t_{\mathsf{LQD}}(\bar{q}) \geq 1$). However, this contradicts $t_{\bar{q}} = \tau_i < t$. Hence, any queue q' has at least $s^i_{\mathsf{LQD}}(q') - (\tau_{i+1} - \tau_i)$ LQD packets in step τ_{i+1} and the number of LQD packets in queues $\mathcal{U}$ in step τ_{i+1} is at most $n^i + o^i$, which concludes the proof. ◀

5 Mapping Transmitted LQD-extra Packets

So far we derived a lower bound on $n^i + \alpha \cdot o^i$ for a phase i which depends, among other things, on the number of queues $|\mathcal{L}^i_q|$ which are live w.r.t. a queue q at time τ_i. To make this bound useful, we now would like to relate $|\mathcal{L}^i_q|$ to $\hat{e}^i$.

The underlying idea behind establishing a relationship between $|\mathcal{L}^i_q|$ and $e^i = \sum_{q':\tau_i \geq t_{q'}} e^i_{q'}$ is simple. By Observation 3, quantity e^i is bounded by the number of packets that are stored in OPT's buffer, but not in LQD's buffer at time τ_i. Recall that the LQD buffer is full in step τ_i. Intuitively, for each packet that OPT has in its buffer but LQD has not, there must be a packet that LQD has in its buffer but OPT has not. Suppose for a moment that the latter packets are all located in queues in $\mathcal{L}^i_q$. Then there can be no more than $\sigma^i_q \cdot |\mathcal{L}^i_q|$ of them and so, we would have $e^i \leq \sigma^i_q \cdot |\mathcal{L}^i_q|$. Unfortunately, things are more complicated because not all packets of the latter type may be located in live queues. We address this problem by introducing the earlier mentioned careful mapping of transmitted LQD-extra packets to cancel out some of the packets counted in e^i. The following notation will be useful for brevity:

- $\mathcal{Q}^i$: the set of queues q with $\tau_i \geq t_q$ and $e^i_q > 0$. In words, $\mathcal{Q}^i$ is the set of queues that have overflowed for the last time by step τ_i and there are still some OPT-extra packets to be transmitted from them in phase i or later.

To describe our specific mapping, we apply the procedure specified in Algorithm 1 on the solutions of LQD and OPT on the fixed instance I. Our values m_q are given as the final values of m'_q after the procedure has been run.

Algorithm 1 Mapping Procedure.

foreach *queue* q **do**
  Initialize $m'_q := 0$ `// counter for packets assigned to` q
foreach *phase* i **do**
  foreach *LQD-extra packet* p *transmitted in phase* i **do**
    if *there is a queue* $q \in \mathcal{Q}^i$ *with* $m'_q < e^i_q$ **then**
      $q' := \operatorname{arg\,min}_{q:q\in\mathcal{Q}^i \text{ and } m'_q < e^i_q} \{t_q\}$ `// breaking ties arbitrarily`
      $m'_{q'} := m'_{q'} + 1$ `// assign packet` p `to queue` q'
    `// Otherwise, packet` p `is not assigned`
foreach *queue* q **do**
  $m_q := m'_q$ `// the final value of` m'_q

We now show a lower bound on the $m_{q'}$ values for a phase i. The bound is specific to a particular queue $q \in \mathcal{Q}^i$ with $m_q < e_q$; in the following, live and dying queues are w.r.t. queue q. For technical reasons, we prove a lower bound on the following quantity: Let $\overline{m}^i_{q'}$ be the number of LQD-extra packets transmitted in a phase $j \geq i$ that are mapped to q'. The point is that the constraint $m'_{q'} < e^i_{q'}$ for assigning an LQD-extra packet to q' in Algorithm 1 implies that $e^i_{q'} \geq \overline{m}^i_{q'}$, even though it may happen that $e^i_{q'} < m_{q'}$.

For simplicity, let $z_q^i := \sum_{q' \in \mathcal{L}_q^i} [s_{\mathsf{OPT}}^i(q') > 0]$ be the number of live queues $\mathcal{L}_q^i$ that are non-empty in OPT. In words, the first term of the bound in Lemma 12 below, i.e., $\sum_{q' \in \mathcal{D}_q^i} \max\left\{s_{\mathsf{LQD}}^i(q') - s_{\mathsf{OPT}}^i(q'), 0\right\}$, equals the number of packets that LQD stores in excess of OPT in dying queues $q' \in \mathcal{D}_q^i$ with $s_{\mathsf{LQD}}^i(q') > s_{\mathsf{OPT}}^i(q')$ in step τ_i, while the second term, i.e., $|\mathcal{L}_q^i| - z_q^i$, equals the number of live queues $\mathcal{L}_q^i$ that are empty in the OPT buffer in step τ_i.

▶ **Lemma 12.** *For any phase i and queue $q \in \mathcal{Q}^i$ with $m_q < e_q^i$ (i.e., with $\hat{e}_q^i > 0$) we have* $\sum_{q' \in \mathcal{Q}^i} \overline{m}_{q'}^i \geq \sum_{q' \in \mathcal{D}_q^i} \max\left\{s_{LQD}^i(q') - s_{OPT}^i(q'), 0\right\} + \left(|\mathcal{L}_q^i| - z_q^i\right)$.

Proof. Recall from Definition 4 that $j_q = \min\{j : \hat{e}_q^j = 0\}$ is the index j of the earliest step τ_j in which all remaining OPT-extra packets to be transmitted from q are canceled out. Note that $i < j_q$ by the assumption of the lemma and that $m_q < e_q^j$ and $q \in \mathcal{Q}^j$ for any $j \in [i, j_q)$.

Consider a dying queue $q' \in \mathcal{D}_q^i$ with $s_{\mathsf{LQD}}^i(q') - s_{\mathsf{OPT}}^i(q') > 0$. It holds that $e_{q'} = 0$ by Observation 3. By Definition 4, q' will be empty for LQD in step τ_{j_q}. Since q' does not overflow after time τ_i (and hence LQD will accept all packets which may arrive to q' after time τ_i), at least $s_{\mathsf{LQD}}^i(q') - s_{\mathsf{OPT}}^i(q')$ LQD-extra packets are transmitted from q' from time τ_i until time $\tau_{j_q} - 1$, i.e., in phases $j \in [i, j_q)$. Using $m_q < e_q^j$ and $q \in \mathcal{Q}^j$ for any $j \in [i, j_q)$, all these LQD-extra packets are allocated to queues $\overline{q}$ that satisfy $t_{\overline{q}} \leq t_q \leq \tau_i$ and $e_{\overline{q}}^i > 0$; the second property holds as $t_{\overline{q}} \leq t_q \leq \tau_i$ and as $\overline{q} \in \mathcal{Q}^j$ for a phase $i \leq j < j_q$ in which the LQD-extra packet assigned to it is transmitted, by Algorithm 1. Thus, such queues $\overline{q}$ are part of the set $\mathcal{Q}^i$.

In addition, there are $|\mathcal{L}_q^i| - z_q^i$ live queues in step τ_i that are empty in the OPT buffer. Hence, LQD transmits $|\mathcal{L}_q^i| - z_q^i$ LQD-extra packets in step τ_i from such queues, and these packets are assigned to queues $\overline{q} \in \mathcal{Q}^i$ by Algorithm 1, using again that $m_q < e_q^i$. ◀

Finally, we bound the number of OPT-extra packets which are not canceled out by LQD-extra packets. Equivalently, for a queue q, we show a lower bound on $|\mathcal{L}_q^i|$ in terms of $\hat{e}^i$. The lemma below in particular implies that if $\hat{e}_q^i > 0$ then also $|\mathcal{L}_q^i| \geq 1$, i.e., there is at least one live queue w.r.t. queue q.

▶ **Lemma 13.** *For any phase i and queue $q \in \mathcal{Q}^i$ with $\hat{e}_q^i > 0$, we have that $\hat{e}^i \leq (\sigma_q^i - 1) \cdot |\mathcal{L}_q^i|$.*

Proof. First note that

$$\hat{e}^i = \sum_{q' \in \mathcal{Q}^i} \hat{e}_{q'}^i = \sum_{q' \in \mathcal{Q}^i} \max\{e_{q'}^i - m_{q'}, 0\} \leq \sum_{q' \in \mathcal{Q}^i} \max\{e_{q'}^i - \overline{m}_{q'}^i, 0\} = \sum_{q' \in \mathcal{Q}^i} (e_{q'}^i - \overline{m}_{q'}^i) \,,$$

where the inequality holds by $\overline{m}_{q'}^i \leq m_{q'}$ and the last step follows from $e_{q'}^i \geq \overline{m}_{q'}^i$, by the definition of $\overline{m}_{q'}^i$ and Algorithm 1. Using Lemma 12, we obtain

$$\hat{e}^i \leq \sum_{q' \in \mathcal{Q}^i} (e_{q'}^i) - \sum_{q' \in \mathcal{D}_q^i} \max\left\{s_{\mathsf{LQD}}^i(q') - s_{\mathsf{OPT}}^i(q'), 0\right\} - \left(|\mathcal{L}_q^i| - z_q^i\right) \tag{8}$$

By the definition of σ_q^i in (3) and since the LQD buffer is full in step τ_i, we have

$$M = \sigma_q^i \cdot |\mathcal{L}_q^i| + \sum_{q' \in \mathcal{D}_q^i} s_{\mathsf{LQD}}^i(q') \,. \tag{9}$$

Regarding the OPT buffer, we have

$$\begin{aligned} M \geq \sum_{q'} s^i_{\mathsf{OPT}}(q') &\geq \sum_{q' \in \mathcal{Q}^i} \max\left\{s^i_{\mathsf{OPT}}(q') - s^i_{\mathsf{LQD}}(q'), 0\right\} + \sum_{q'} \min\{s^i_{\mathsf{LQD}}(q'), s^i_{\mathsf{OPT}}(q')\} \\ &\geq \sum_{q' \in \mathcal{Q}^i} \left(e^i_{q'}\right) + \sum_{q'} \min\{s^i_{\mathsf{LQD}}(q'), s^i_{\mathsf{OPT}}(q')\} \\ &\geq \sum_{q' \in \mathcal{Q}^i} \left(e^i_{q'}\right) + \sum_{q' \in \mathcal{D}^i_q} \min\{s^i_{\mathsf{LQD}}(q'), s^i_{\mathsf{OPT}}(q')\} + z^i_q\,, \end{aligned} \tag{10}$$

where the third inequality uses Observation 3. Combining (9) and (10), we obtain

$$\sum_{q' \in \mathcal{Q}^i} \left(e^i_{q'}\right) + \sum_{q' \in \mathcal{D}^i_q} \min\{s^i_{\mathsf{LQD}}(q'), s^i_{\mathsf{OPT}}(q')\} + z^i_q \leq \sigma^i_q \cdot |\mathcal{L}^i_q| + \sum_{q' \in \mathcal{D}^i_q} s^i_{\mathsf{LQD}}(q')$$

After rearranging, we get

$$\sum_{q' \in \mathcal{Q}^i} \left(e^i_{q'}\right) - \sum_{q' \in \mathcal{D}^i_q} \max\left\{s^i_{\mathsf{LQD}}(q') - s^i_{\mathsf{OPT}}(q'), 0\right\} + z^i_q \leq \sigma^i_q \cdot |\mathcal{L}^i_q|\,. \tag{11}$$

Finally, plugging (11) into Equation (8), we get $\hat{e}^i \leq \sigma^i_q \cdot |\mathcal{L}^i_q| - |\mathcal{L}^i_q|$, as desired. ◀

6 Putting It All Together

In this section, we complete the proof of 1.707-competitiveness for LQD. First, we use the lemmas developed in previous sections to show a lower bound on the L-increase in phase i for a queue q. This will be divided into two cases, according to whether the value of σ^i_q decreases or not (w.r.t. variable i). Next, we sum these lower bounds over all phases and derive a lower bound for this sum. Finally, we optimize the parameters α and β to maximize ϱ (and thus, minimize the competitive ratio upper bound) subject to $\Phi_q \geq \varrho \cdot \hat{e}_q$ for any queue q.

6.1 Lower Bounds on the L-Increase

In this section, for a queue q, we show lower bounds on the L-increase for a phase i with $\tau_i \geq t_q$ and $\hat{e}^i_q > 0$. In such a phase, Lemma 13 implies that $\hat{e}^i \leq (\sigma^i_q - 1) \cdot |\mathcal{L}^i_q|$. We consider two main cases, depending on whether or not σ_q decreases. We first deal with the case $\sigma^{i+1}_q \geq \sigma^i_q$.

▶ **Lemma 14.** *Consider any phase i and queue q with $\tau_i \geq t_q$, $\hat{e}^i_q > 0$, and $\sigma^{i+1}_q \geq \sigma^i_q$. Then the L-increase in phase i for queue q satisfies*

$$\frac{\hat{e}^i_q}{\hat{e}^i} \cdot (n^i + \alpha \cdot o^i - \Delta^i \Psi) + \beta \cdot o^i_q \geq \hat{e}^i_q \cdot \frac{\alpha \cdot \left(\sigma^{i+1}_q - \sigma^i_q\right) + (\tau_{i+1} - \tau_i)}{\sigma^i_q - 1}\,. \tag{12}$$

Proof. Recall that d^i_q is the number of packets transmitted from queues in $\mathcal{D}^i_q$ during phase i. Using Lemma 9 and $\sigma^{i+1}_q \geq 1$, we get

$$d^i_q \geq (\sigma^{i+1}_q - \sigma^i_q) \cdot |\mathcal{L}^i_q| + \sigma^{i+1}_q \cdot u^i - v^i \geq (\sigma^{i+1}_q - \sigma^i_q) \cdot |\mathcal{L}^i_q| + u^i - v^i\,. \tag{13}$$

Multiplying (13) by $\alpha \in (0, 1)$, adding $(\tau_{i+1} - \tau_i) \cdot |\mathcal{L}^i_q|$ to both sides, and rearranging, we obtain

$$(\tau_{i+1} - \tau_i) \cdot |\mathcal{L}^i_q| + \alpha \cdot d^i_q - \alpha \cdot (u^i - v^i) \geq \left(\alpha \cdot \left(\sigma^{i+1}_q - \sigma^i_q\right) + (\tau_{i+1} - \tau_i)\right) \cdot |\mathcal{L}^i_q|.$$

Using $n^i + \alpha \cdot o^i \geq (\tau_{i+1} - \tau_i) \cdot |\mathcal{L}_q^i| + \alpha \cdot d_q^i$ by Observation 6 and $|\mathcal{L}_q^i| \geq \hat{e}^i/(\sigma_q^i - 1)$ by Lemma 13, we get $n^i + \alpha \cdot o^i - \Delta^i\Psi \geq \dfrac{\alpha \cdot \left(\sigma_q^{i+1} - \sigma_q^i\right) + (\tau_{i+1} - \tau_i)}{\sigma_q^i - 1} \cdot \hat{e}^i$, and multiplying this by $\hat{e}_q^i/\hat{e}^i$ proves (12). ◀

Next, we deal with the (most involved) case when $\sigma_q^{i+1} < \sigma_q^i$. The following technical lemma also captures the case of the last phase $i = j_q - 1$ in which we assign some LQD profit to queue q (in this phase, we have $\hat{e}_q^{i+1} = 0$). We omit its proof due to space constraints.

▶ **Lemma 15.** *Consider any phase i and queue q with $\tau_i \geq t_q$, $\hat{e}_q^i > 0$, and $\sigma_q^{i+1} < \sigma_q^i$. Then, for $\beta = \alpha^2/(8 \cdot (1-\alpha))$ and any $0 < \alpha \leq 8/9$, it holds that*

$$\frac{\hat{e}_q^i}{\hat{e}^i} \cdot (n^i + \alpha \cdot o^i - \Delta^i\Psi) + \beta \cdot o_q^i \geq \sum_{t=\tau_i}^{\tau_{i+1}-1} \left(\frac{\hat{e}_q^t}{\sigma_q^i - 1}\right) - \frac{g_q^i}{2(\sigma_q^i - 1)} - \hat{e}_q^{i+1} \cdot \left(\frac{1}{\sigma_q^{i+1} - 1} - \frac{1}{\sigma_q^i - 1}\right), \tag{14}$$

where g_q^i is the number of steps $t \in [\tau_i, \tau_{i+1})$ with $\hat{e}_q^t > 0$ and $s_{LQD}^t(q) = 0$.

6.2 Total LQD Profit Assigned to a Queue

Fix a queue q with $\hat{e}_q > 0$, i.e., with transmitted OPT-extra packets that are not canceled out by transmitted LQD-extra packets. We now show a lower bound on $\sum_i \Delta^i\Phi_q$. Recall that $\Delta^i\Phi_q > 0$ only for phases i with $\tau_i \geq t_q$ and $\hat{e}_q^i > 0$.

First, we bound the sum of S-increases. Note that as q overflows at t_q, LQD stores for this queue at least $s_{\max}^{t_q} - 1$ packets in step t_q, and since it does not overflow after t_q, LQD transmits at least $s_{\max}^{t_q} - 1 \geq \left\lceil \sigma_q^{t_q} \right\rceil - 1$ packets from q at or after t_q, where the inequality is from Observation 7 (recall that $t_q = \tau_i$ for some phase i). Thus, the sum of S-increases is at least $(1 - \alpha - \beta) \cdot \left(\left\lceil \sigma_q^{t_q} \right\rceil - 1\right)$. The next lemma shows a bound on the total L-increase assigned to queue q (its proof is omitted due to space constraints).

▶ **Lemma 16.** *Assuming $\alpha \leq 0.6$ and using $b_0 = \left\lceil \sigma_q^{t_q} \right\rceil - 1$ for simplicity, the sum of L-increases assigned to a queue q with $\hat{e}_q > 0$ over all phases is at least*

$$\alpha \cdot \hat{e}_q \cdot \left(1 + \frac{b_0}{\hat{e}_q}\right) \cdot \ln\left(1 + \frac{\hat{e}_q}{b_0}\right) + \alpha \cdot \hat{e}_q \cdot \ln\left(\frac{1}{\alpha}\right).$$

Summing up the lower bound on the total S-increase with the lower bound on the total L-increase from Lemma 16, we obtain the following lower bound (where $b_0 = \left\lceil \sigma_q^{t_q} \right\rceil - 1$):

$$\sum_i \Delta^i\Phi_q \geq (1 - \alpha - \beta) \cdot b_0 + \alpha \cdot \hat{e}_q \cdot \left(1 + \frac{b_0}{\hat{e}_q}\right) \cdot \ln\left(1 + \frac{\hat{e}_q}{b_0}\right) + \alpha \cdot \hat{e}_q \cdot \ln\left(\frac{1}{\alpha}\right). \tag{15}$$

6.3 Calculation of the Competitive Ratio Upper Bound

According to the following lemma, we can have $\varrho = 1.41478$ in (1), which implies that the competitive ratio of LQD is at most $1 + 1/\varrho < 1.707$, according to the discussion in Section 2. Thus, the following lemma concludes the proof of Theorem 1.

▶ **Lemma 17.** *Consider a queue q with $\hat{e}_q > 0$. For any values of $\sigma_q^{t_q}$ and $\hat{e}_q$, it holds that $\sum_i \Delta^i\Phi_q \geq \varrho \cdot \hat{e}_q$ for $\varrho = 1.41478$.*

Proof sketch. As before, let $b_0 = \left\lceil \sigma_q^{t_q} \right\rceil - 1$. Using inequality (15) as a lower bound on $\sum_i \Delta^i \Phi_q$, it is sufficient to show

$$(1-\alpha-\beta)\cdot b_0 + \alpha\cdot\hat{e}_q\cdot\left(1+\frac{b_0}{\hat{e}_q}\right)\cdot\ln\left(1+\frac{\hat{e}_q}{b_0}\right)+\alpha\cdot\hat{e}_q\cdot\ln\left(\frac{1}{\alpha}\right)\geq\varrho\cdot\hat{e}_q\,.$$

Dividing by $\hat{e}_q$ and defining $x=\frac{\hat{e}_q}{b_0}$ gives us that the optimal choice of ϱ satisfies,

$$\varrho := \sup_{0<\alpha<0.6}\inf_{x>0}\left((1-\alpha-\beta)\cdot\frac{1}{x}+\alpha\cdot\left(1+\frac{1}{x}\right)\cdot\ln(1+x)+\alpha\cdot\ln\left(\frac{1}{\alpha}\right)\right)\,. \tag{16}$$

(Here, we also take into account that we require $\alpha < 0.6$ in the analysis.) Using routine calculations and optimizing through mathematical software, we get that the optimal choice for α is approximately 0.57635 for which $\varrho \geq 1.41478$ and therefore, the competitive ratio of LQD is at most $1 + 1/\varrho \leq 1.70683$. ◀

Relaxed Locally Correctable Codes with Improved Parameters

Vahid R. Asadi

Abstract

Locally decodable codes (LDCs) are error-correcting codes $C\colon \Sigma^k \to \Sigma^n$ that admit a local decoding algorithm that recovers each individual bit of the message by querying only a few bits from a noisy codeword. An important question in this line of research is to understand the optimal trade-off between the query complexity of LDCs and their block length. Despite importance of these objects, the best known constructions of constant query LDCs have super-polynomial length, and there is a significant gap between the best constructions and the known lower bounds in terms of the block length.

For many applications it suffices to consider the weaker notion of *relaxed LDCs (RLDCs)*, which allows the local decoding algorithm to abort if by querying a few bits it detects that the input is not a codeword. This relaxation turned out to allow decoding algorithms with constant query complexity for codes with *almost linear* length. Specifically, [2] constructed a q-query RLDC that encodes a message of length k using a codeword of block length $n = O_q(k^{1+O(1/\sqrt{q})})$ for any sufficiently large q, where $O_q(\cdot)$ hides some constant that depends only on q.

In this work we improve the parameters of [2] by constructing a q-query RLDC that encodes a message of length k using a codeword of block length $O_q(k^{1+O(1/q)})$ for any sufficiently large q. This construction matches (up to a multiplicative constant factor) the lower bounds of [14, 23] for constant query *LDCs*, thus making progress toward understanding the gap between LDCs and RLDCs in the constant query regime.

In fact, our construction extends to the stronger notion of relaxed locally *correctable* codes (RLCCs), introduced in [13], where given a noisy codeword the correcting algorithm either recovers each individual bit of the codeword by only reading a small part of the input, or aborts if the input is detected to be corrupt.

1 Introduction

Locally decodable codes (LDCs) are error-correcting codes that admit a decoding algorithm that recovers each specific symbol of the message by reading a small number of locations in a possibly corrupted codeword. More precisely, a locally decodable code $C\colon \mathbb{F}^k \to \mathbb{F}^n$ with local decoding radius $\tau \in [0, 1]$ is an error-correcting code that admits a local decoding

algorithm $\mathcal{D}_C$, such that given an index $i \in [k]$ and a corrupted word $w \in \mathbb{F}^n$ which is τ-close to an encoding of some message $C(M)$, reads a small number of symbols from w, and outputs M_i with high probability. Similarly, we have the notion of *locally correctable codes (LCCs)*, which are error-correcting codes that not only admit a local algorithm that decodes each symbol of the message, but are also required to correct an arbitrary symbol from the entire codeword. Indeed, note that for systematic codes the notion of LCC is strengthening of LDC. Locally decodable and locally correctable codes have many applications in different areas of theoretical computer science, such as complexity theory, coding theory, property testing, cryptography, and construction of probabilistically checkable proof systems. For details, see the surveys [26, 18] and the references within.

Despite the importance of LDCs and LCCs, and the extensive amount of research studying these objects, the best known construction of constant query LDCs has super-polynomial length $n = \exp(\exp(\log^{\Omega(1)}(k)))$, which is achieved by the highly non-trivial constructions of [25] and [9]. For constant query LCCs, the best known constructions are of exponential length, which can be achieved by some parameterization of Reed-Muller codes. It is important to note that there is a huge gap between the best known lower bounds for the length of constant query LDCs and the length of best known constructions. Currently, the best known lower bound on the length of LDCs says that for $q \geq 3$ it must be at least $k^{1+\Omega(1/q)}$, where q stands for the query complexity of the local decoder. See [14, 17, 23] for the best general lower bounds for constant query LDCs.

Motivated by applications to probabilistically checkable proofs (PCPs), Ben-Sasson, Goldreich, Harsha, Sudan, and Vadhan introduced in [2] the notion of *relaxed locally decodable codes (RLDCs)*. Informally speaking, a relaxed locally decodable code is an error-correcting code which allows the local decoding algorithm to abort if the input codeword is corrupt, but does not allow it to err with high probability. In particular, the decoding algorithm should always output the correct symbol, if the given word is not corrupted. Formally, a code $C\colon \mathbb{F}^k \to \mathbb{F}^n$ is an RLDC with decoding radius $\tau \in [0, 1]$ if it admits a relaxed local decoding algorithm $\mathcal{D}_C$ which given an index $i \in [k]$ and a possibly corrupted codeword $w \in \mathbb{F}^n$, makes a small number of queries to w, and satisfies the following properties.

Completeness: If $w = C(M)$ for some $M \in \mathbb{F}^k$, then $\mathcal{D}_C^w(i)$ should output M_i.

Relaxed decoding: If w is τ-close to some codeword $C(M)$, then $\mathcal{D}_C^w(i)$ should output either M_i or a special *abort* symbol with probability at least $2/3$.

This relaxation turns out to be very helpful in terms of constructing RLDCs with better block length. Indeed, [2] constructed of a q-query RLDC with block length $n = k^{1+O(1/\sqrt{q})}$.

The notion of *relaxed LCCs (RLCCs)*, recently introduced in [13], naturally extends the notion of RLDCs. These are error-correcting codes that admit a correcting algorithm that is required to correct every symbol of the codeword, but is allowed to abort if noticing that the given word is corrupt. More formally, the local correcting algorithm gets an index $i \in [n]$, and a (possibly corrupted) word $w \in \mathbb{F}^n$, makes a small number of queries to w, and satisfies the following properties.

Completeness: If $w \in C$, then $\mathcal{D}_C^w(i)$ should output w_i.

Relaxed correcting: If w is τ-close to some codeword $c^* \in C$, then $\mathcal{D}_C^w(i)$ should output either c_i^* or a special *abort* symbol with probability at least $2/3$.

Note that if the code C is systematic, i.e., the encoding of any message $M \in \mathbb{F}^k$ contains M in its first k symbols, then the notion of RLCC is stronger than RLDC.

Recently, building on the ideas from [13], [3] constructed RLCCs whose block length matches the RLDC construction of [2]. For the lower bounds, the only result we are aware of is the work of Gur and Lachish [12], who proved that for any RLDC the block length must be at least $n = k^{1+\Omega(1/q^2)}$.

Given the gap between the best constructions and the known lower bounds, it is natural to ask the following question:

> What is the best possible trade-off between the query complexity and the block length of an RLDC and RLCC?

In particular, [2] asked whether it is possible to obtain a q-query RLDC whose block length is strictly smaller than the best known lower bound on the length of LDCs. A positive answer to their question would show a separation between the two notions, thus proving that the relaxation is *strict*. See paragraph *Open Problem* in the end of Section 4.2 of [2].

In this work we make progress on this problem by constructing a relaxed locally decodable code $C\colon \mathbb{F}^K \to \mathbb{F}^N$ with query complexity $O(q)$ and block length $K^{1+O(1/q)}$. In fact, our construction gives the stronger notion of a relaxed locally correctable code.

▶ **Theorem 1** (Main Theorem). *For every sufficiently large $q \in \mathbb{N}$ there exists an q-query relaxed locally correctable code $C\colon \{0,1\}^K \to \{0,1\}^N$ with constant relative distance and constant decoding radius, such that the block length of C is*

$$N = q^{O(q^2)} \cdot K^{1+O(1/q)} \ .$$

Furthermore, the code C is linear and systematic.

Therefore, our construction improves the parameters of the q-query RLDC construction of [2] with block length $N = K^{1+O(\sqrt{1/q})}$, and matches (up to a multiplicative factor in q) the lower bound of $\Omega(K^{1+\frac{1}{\lceil q/2 \rceil - 1}})$ for the block length of q-query LDCs [14, 23].

▶ Remark 2. In this paper we prove Theorem 1 for a code $C\colon \mathbb{F}^K \to \mathbb{F}^N$ over a large alphabet. Specifically, we show a code $C\colon \mathbb{F}^K \to \mathbb{F}^N$ satisfying Theorem 1, for a finite field $\mathbb{F}$ satisfying $|\mathbb{F}| \geq c_q \cdot K^{1/q}$, for some $c_q \in \mathbb{N}$ that depends only on q.

Using the techniques from [3] it is not difficult to obtain an RLCC over the binary alphabet with almost the same block length. Indeed, this can be done by concatenating our code over large alphabet with an arbitrary binary code with constant rate and constant relative distance. The concatenation we use slightly differs from how it is usually applied, as we apply it on the CTRW level, and not on each symbol of the large alphabet separately. See Section 3 for details.

1.1 Related works

RLDC and RLCC constructions. Relaxed locally decodable codes, were first introduced by [2], motivated by applications to constructing short PCPs. Their construction has a block length equal to $N = K^{1+O(1/\sqrt{q})}$. Since that work, there were no constructions with better block length, in the constant query complexity regime . Recently, [13] introduced the related notion of relaxed locally correctable codes (RLCCs), and has found applications in efficient interactive protocols, in particular, in interactive oracle proofs [21].

The work of [13] showed a construction of a q-query RLCCs with block length $N = \text{poly}(K)$. Then, [3] constructed relaxed locally correctable codes with block length matching that of [2] (up to a multiplicative constant factor that only depends on q). The construction of [3] had two main components, that we also use in the current work.

Consistency test using random walk (CTRW): Informally, given a word w, and a coordinate i we wish to correct, CTRW samples a sequence of constraints $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_t$ on w, such that the domains of $\mathcal{C}_i$ and $\mathcal{C}_{i+1}$ intersect, with the guarantee that if w is close

to some codeword $c^* \in C$, but $w_i \neq c^*_i$, then with high probability w will be far from satisfying at least one of the constraints. In other words, CTRW performs a random walk on the constraints graph and checks if w is consistent with c^* in the i'th coordinate. We introduce this notion in detail in Section 2.1.

Correctable canonical PCPPs (ccPCPP): These are PCPP systems for some specified language L satisfying the following properties:

- **(i)** for each $w \in L$ there is a unique proof $\pi(w)$ that satisfies the verifier with probability 1,
- **(ii)** the verifier accepts with high probability only pairs (x, π) that are close to some $(w, \pi(w))$ for some $w \in L$, i.e., only the pairs where x is close to some $w \in L$, and π is close to $\pi(w)$, and
- **(iii)** the set $\{w \circ \pi_w : w \in L\}$ is an RLCC.

Canonical proofs of proximity have been introduced in [11] and have been studied in [7, 13, 20].

Lower bounds. For lower bounds, the only bound we are aware of is that of [12], who proved that any q-query relaxed locally decodable code must have a block length $N \geq K^{1+\Omega(\frac{1}{q^2})}$.

For the strict notion of locally decodable codes, it is known by [14, 23] that for $q \geq 3$ any q-query LDC must have block length $N \geq \Omega(K^{1+\frac{1}{\lceil q/2-1 \rceil}}/\log(K))$. For $q = 3$ a slightly stronger bound of $N \geq \Omega(K^2/\log\log(K))$ is known for *linear* LDCs [23]. For $q = 2$ [17] proved an exponential lower bound of $N \geq \exp(\Omega(K))$. See also [4, 10, 19, 22, 24] for more related work on lower bounds for LDCs.

2 Proof overview

In this section we informally describe our code construction. Roughly speaking, our construction consists of two parts:

The Reed-Muller encoding: Given a message $M \in \mathbb{F}^K$, its Reed-Muller encoding is the evaluation of an m-variate polynomial of degree at most d over $\mathbb{F}$, whose coefficients are determined by the message we wish to encode.

Proofs of proximity: The second part of the encoding consists of the concatenation of PCPPs, each claiming that a certain restriction of the first part agrees with some Reed-Muller codeword.

Specifically, given a message $M \in \mathbb{F}^K$, we first encode it using the Reed-Muller encoding $\mathsf{RM}_{\mathbb{F}}(m, d)$, where m roughly corresponds to the query complexity of our RLDC, and the field is large enough so that the distance of the Reed-Muller code, which is equal to $1 - \frac{d}{|\mathbb{F}|}$, is some constant, say $3/4$. That is, the first part of the encoding corresponds to an evaluation of some polynomial $f \colon \mathbb{F}^m \to \mathbb{F}$ of degree at most d. The second part of the encoding consists of a sequence of PCPPs claiming that the restrictions of the Reed-Muller part to some carefully chosen planes in $\mathbb{F}^m$ are evaluations of some low-degree polynomial.

The planes we choose are of the form $\mathcal{P}_{\vec{a},\vec{h},\vec{h}'} = \{\vec{a} + t \cdot \vec{h} + s \cdot \vec{h}' : t, s \in \mathbb{F}\}$, where $\vec{a} \in \mathbb{F}^m$, and $\vec{h}, \vec{h}' \in \mathbb{H}^m$ for some $\mathbb{H}$ subfield of $\mathbb{F}$. We will call such planes $\mathbb{H}$-*planes*. In order to obtain the RLDC with the desired parameters, we choose the field $\mathbb{H}$ so that $\mathbb{F}$ is the extension of $\mathbb{H}$ of degree $[\mathbb{F} : \mathbb{H}] = m$. It will be convenient to think of $\mathbb{H}$ as a field and think of $\mathbb{F}$ as a vector space of $\mathbb{H}$ of dimension m (augmented with the multiplicative structure on $\mathbb{F}$). Indeed, the saving in the block length of the RLDC we obtain crucially relies on the fact that we ask for PCPPs for only a small collection of planes, and not all planes in $\mathbb{F}^m$. The actual constraints required to be certified by the PCPPs are slightly more complicated, and we describe them next.

The constraints of the first type correspond to $\mathbb{H}$-planes $\mathcal{P}$ and points $\vec{x} \in \mathcal{P}$. For each such pair $(\mathcal{P}, \vec{x})$ the code will contain a PCPP certifying that

(i) the restriction of the Reed-Muller part to $\mathcal{P}$ is close to an evaluation of some polynomial of total degree at most d,

(ii) and furthermore, this polynomial agrees with the value of the Reed-Muller part on $\vec{x}$.

In order to define it formally, we introduce the following notation.

▶ **Notation 3.** *Let $\mathbb{F}$ be a finite field of size n. Fix $f\colon \mathbb{F}^m \to \mathbb{F}$, a plane $\mathcal{P}$ in $\mathbb{F}^m$, and a point $\vec{x} \in \mathcal{P}$. Denote $f_{|\mathcal{P}}^{(\vec{x})} = f_{|\mathcal{P}} \circ (f(\vec{x}))^{n^2}$. That is, the length of $f_{|\mathcal{P}}^{(\vec{x})}$ is $2 \cdot n^2$, and it consists of $f_{|\mathcal{P}}$ concatenated with n^2 repetitions of $f(\vec{x})$.*

Given the notation above, if f is the first part of the codeword, corresponding to the Reed-Muller encoding of the message, then the PCPP for the pair $(\mathcal{P}, \vec{x})$ is expected to be the proof of proximity claiming that $f_{|\mathcal{P}}^{(\vec{x})}$ is close to the language

$$\mathsf{RM}_{|\mathcal{P}}^{(\vec{x})} = \{Q \circ (Q(\vec{x}))^{(n^2)} : Q \text{ is the evaluation of a degree-}d \text{ polynomial on } \mathcal{P}\} \subseteq \mathbb{F}^{2n^2} \quad . \quad (1)$$

Note that by repeating the symbol $Q(\vec{x})$ for n^2 times, the definition indeed puts weight $1/2$ on the constraint that the input $f_{|\mathcal{P}}$ is close to some low-degree polynomial Q, and puts weight $1/2$ on the constraint $f(\vec{x}) = Q(\vec{x})$. In particular, if $f_{|\mathcal{P}}$ is δ-close to some bivariate low degree polynomial Q for some small $\delta > 0$, but $f(\vec{x}) \neq Q(\vec{x})$, then $f_{|\mathcal{P}}^{(\vec{x})}$ is at least $(1 - \frac{d}{|\mathbb{F}|} - \delta)/2$-far from any bivariate low degree polynomial on $\mathcal{P}$.

The constraints of second type correspond to $\mathbb{H}$-planes $\mathcal{P}$ and lines $\ell \subseteq \mathcal{P}$. For each such pair $(\mathcal{P}, \ell)$ the code will contain a PCPP certifying that

(i) the restriction of the Reed-Muller part to $\mathcal{P}$ is close to an evaluation of some polynomial of total degree at most d,

(ii) and furthermore, the restriction of this polynomial to ℓ is close to $f_{|\ell}$.

(In particular, this implies that $f_{|\ell}$ is close to some low-degree polynomial.)

Next, we introduce the notation analogous to Notation 3 replacing the points with lines.

▶ **Notation 4.** *Let $\mathbb{F}$ be a finite field of size n. Fix $f\colon \mathbb{F}^m \to \mathbb{F}$, a plane $\mathcal{P}$ in $\mathbb{F}^m$, and a line $\ell \subseteq \mathcal{P}$. Denote by $f_{|\mathcal{P}}^{(\ell)} = f_{|\mathcal{P}} \circ (f_{|\ell})^n$. That is, the length of $f_{|\mathcal{P}}^{(\ell)}$ is $2 \cdot n^2$, and it consists of $f_{|\mathcal{P}}$ concatenated with n repetitions of $f_{|\ell}$.*

If f is the Reed-Muller part of the codeword, corresponding to the Reed-Muller encoding of the message, then the PCPP for the pair $(\mathcal{P}, \ell)$ is expected to be the proof of proximity claiming that $f_{|\mathcal{P}}^{(\ell)}$ is close to the language

$$\mathsf{RM}_{|\mathcal{P}}^{(\ell)} = \{Q \circ (Q_{|\ell})^n : Q \text{ is the evaluation of some degree-}d \text{ polynomial on } \mathcal{P}\} \subseteq \mathbb{F}^{2n^2} \quad . \quad (2)$$

Again, similarly to the first part, repeating the evaluation of $Q_{|\ell}$ for n times puts weight $1/2$ on the constraint that the input $f_{|\mathcal{P}}$ is a close to some low-degree polynomial Q, and puts weight $1/2$ of the constraint $f_{|\ell}$ is close to $Q_{|\ell}$.

With the proofs specified above, we now sketch the local correcting algorithm for the code. Below we only focus on correcting symbols from the Reed-Muller part. Correcting the symbols from the PCPP part follows a rather straightforward adaptation of the techniques from [3], and we omit them from the overview.

Given a word $w \in \mathbb{F}^N$ and an index $i \in [N]$ of w corresponding to the Reed-Muller part of the codeword, let $f\colon \mathbb{F}^m \to \mathbb{F}$ be the Reed-Muller part of w, and let $\vec{x} \in \mathbb{F}^m$ be the input to f corresponding to the index i. The local decoder works in two steps.

Consistency test using random walk: In the first step the correcting algorithm invokes a procedure we call *consistency test using a random walk (*CTRW*)* for the Reed-Muller code. This step creates a sequence of $\mathbb{H}$-planes of length $(m+1)$, where each plane defines a constraint checking that the restriction of w to the plane is low-degree. Hence, we get $m+1$ constraints, each depending on n^2 symbols.

Composition using proofs of proximity: Then, instead of reading the entire plane for each constraint, we use the PCPPs from the second part of the codeword to reduce the arity of each constraint to $O(1)$, thus reducing the total query complexity of the correcting algorithm to $q = O(m)$. That is, for each constraint we invoke the corresponding PCPP verifier to check that the restrictions of f to each of these planes is (close to) a low-degree polynomial. If at least one of the verifiers rejects, then the word f must be corrupt, and hence the correcting algorithm returns $\perp$. Otherwise, if all the PCPP verifiers accept, the correcting algorithm returns $f(\vec{x})$.

In particular, if f is a correct Reed-Muller encoding, then the algorithm will always return $f(\vec{x})$, and the main part of the analysis is to show that if f is close to some $Q^* \in \mathsf{RM}_{\mathbb{F}}(m,d)$, but $f(\vec{x}) \neq Q^*(\vec{x})$, then the correcting algorithm catches an inconsistency, and returns $\perp$ with some constant probability.

The key step in the analysis says that if f is close to some codeword $Q^* \in \mathsf{RM}$ but $f(\vec{x}) \neq Q^*(\vec{x})$, then with high probability f will be far from a low degree polynomial on at least one of these planes, where "far" corresponds to the notion of distances defined by the languages $\mathsf{RM}^{(\vec{x})}_{|\mathcal{P}}$ and $\mathsf{RM}^{(\ell)}_{|\mathcal{P}}$. In particular, if on one of the planes f is far from the corresponding language, then the PCPP verifier will catch this with constant probability, thus causing the correcting algorithm to return $\perp$. We discuss this part in detail below.

It is important to emphasize that the main focus of this work is constructing a correcting algorithm for the Reed-Muller part. Using the techniques developed in [3], it is rather straightforward to design the algorithm for correcting symbols from the PCPPs part of the code. See the full version for details.

2.1 CTRW on Reed-Muller codes

Below we define the notion of *consistency test using random walk (*CTRW*)* for the Reed-Muller code. This notion is a slight modification of the notion originally defined in [3] for general codes. In this paper we define it only for the Reed-Muller code. Given a word $f\colon \mathbb{F}^m \to \mathbb{F}$ and some $\vec{x} \in \mathbb{F}^m$, the goal of the test is to make sure that $f(\vec{x})$ is consistent with the codeword of Reed-Muller code closest to f. [3] describe a CTRW for the tensor power $C^{\otimes m}$ of an arbitrary codes C with good distance (e.g., Reed-Solomon). The CTRW they describe works by starting from the point we wish to correct, and choosing an axis-parallel line ℓ_1 containing the starting point. The test continues by choosing a sequence of random axis-parallel lines $\ell_2, \ell_3, \ldots \ell_t$, such that each ℓ_i intersects the previous one, ℓ_{i-1}, until reaching a uniformly random coordinate of the tensor code. That is, the length of the sequence t denotes the *mixing time of the corresponding random walk*. The predicates are defined in the natural way; namely, the test expects to see a codeword of C on each line it reads.

In this work, we present a CTRW for the Reed-Muller code, which is a variant of the CTRW described above. The main differences compared to the description above are that

(i) the test chooses a sequence of planes $\mathcal{P}_1, \mathcal{P}_3, \ldots \mathcal{P}_t$ (and not lines),

(ii) and every two planes intersect on a line (and not on a point).

Roughly speaking, the algorithm works as follows.

1. Given a point $\vec{x} \in \mathbb{F}^m$ the test picks a uniformly random $\mathbb{H}$-plane $\mathcal{P}_0$ containing $\vec{x}$.
2. Given $\mathcal{P}_0$, the test chooses a random line $\ell_1 \subseteq \mathcal{P}_0$, and then chooses another random $\mathbb{H}$-plane $\mathcal{P}_1 \subseteq \mathbb{F}^m$ containing ℓ_1.
3. Given $\mathcal{P}_1$, the test chooses a random line $\ell_2 \subseteq \mathcal{P}_1$, and then chooses another random $\mathbb{H}$-plane $\mathcal{P}_2 \subseteq \mathbb{F}^m$ containing ℓ_2.
4. The algorithm continues for some predefined number of iterations, choosing $\mathcal{P}_0, \mathcal{P}_1, \mathcal{P}_2, \ldots \mathcal{P}_t$. Roughly speaking, the number of iterations is equal to the mixing time of the corresponding Markov chain. More specifically, the process continues until a uniformly random point in $\mathcal{P}_t$ is close to a uniform point in $\mathbb{F}^m$.
5. The constraints defined for each $\mathcal{P}_i$ are the natural constraints; namely checking that the restriction of f to the entire plane $\mathcal{P}_i$ is a polynomial of degree at most d.

One of the important parameters, directly affecting the query complexity of our construction is the mixing time of the random walk. Indeed, as explained above, the query complexity of our RLDC is proportional to the mixing time of the random walk. We prove that if $[\mathbb{F} : \mathbb{H}] = m$, then the mixing time is upper bounded by m. In order to prove this we use the following claim, saying that if $\mathbb{F}$ is the field extension of $\mathbb{H}$ of degree m, and $\vec{h}_1, \ldots, \vec{h}_m \in \mathbb{H}^m$ and $t_1, \ldots, t_m \in \mathbb{F}$ are sampled uniformly, independently from each other, then $\sum_{i=1}^{m} t_i \cdot \vec{h}_i$ is close to a uniformly random point in $\mathbb{F}^m$. See the full version for the exact statement.

As explained above, the key step of the analysis is to prove that if f is close to some codeword $Q^* \in \mathsf{RM}$ but $f(\vec{x}) \neq Q^*(\vec{x})$, then with high probability at least one of the predicates defined will be violated. Specifically, we prove that with high probability the violation will be in the following strong sense.

▶ **Theorem 5** (informal, see the full version [1]). *If f is close to some codeword $Q^* \in \mathsf{RM}$ but $f(\vec{x}) \neq Q^*(\vec{x})$, then with high probability*
1. *either $f^{(\vec{x})}_{|\mathcal{P}_0}$ is $\Omega(1)$-far from $\mathsf{RM}^{(\vec{x})}_{|\mathcal{P}_0}$,*
2. *or $f^{(\ell_i)}_{|\mathcal{P}_i}$ is $\Omega(1)$-far from $\mathsf{RM}^{(\ell_i)}_{|\mathcal{P}_i}$ for some $i \in [m]$.*

Indeed, this strong notion of violation allows us to use the proofs of proximity in order to reduce the query complexity to $O(1)$ queries for each $i \in [m]$. We discuss proofs of proximity next.

2.2 PCPs of proximity and composition

The second building block we use in this work is the notion of *probabilistic checkable proofs of proximity (PCPPs)*. PCPPs were first introduced in [2] and [8]. Informally speaking, a PCPP verifier for a language L, gets an oracle access to an input x and a proof π claiming that x is close to some element of L. The verifier queries x and π in some small number of (random) locations, and decides whether to accept or reject. The completeness and soundness properties of a PCPP are as follows.

Completeness: If $x \in L$, then there exists a proof causing the verifier accept with probability 1.

Soundness: If x is far from L, then no proof can make the verifier accept with probability more than $1/2$.

In fact, we will use the slightly stronger notion of *canonical PCPP (cPCPP) systems*. These are PCPP systems satisfying the following completeness and soundness properties. For completeness, we demand that for each w in the language there is a unique *canonical* proof

$\pi(w)$ that causes the verifier to accept with probability 1. For soundness, the demand is that the only pairs (x, π) that are accepted by the verifier with high probability are those where x is close to some $w \in L$ and π is close to $\pi(w)$. Such proof system have been studied in [7, 20], who proved that such proof systems exist for every language in $\mathcal{P}$.

Furthermore, for our purposes we will demand a stronger notion of correctable canonical PCPP systems (ccPCPP). These are canonical PCPP systems where the set $\{w \circ \pi^*(w) : w \in L\}$ is a q-query RLCC for some parameter q, with $\pi^*(w)$ denoting the canonical proof for $w \in L$. It was shown in [3] how to construct ccPCPP by combining a cPCPP system with *any* systematic RLCC. Informally speaking, for every $w \in L$, and its canonical proof $\pi(w)$, we define $\pi^*(w)$ by encoding $w \circ \pi(w)$ using a systematic RLCC. The verifier for the new proof system is defined in a straightforward manner. See [3] for details.

The PCPPs we use throughout this work, are the proofs of two types, certifying that

1. $f^{(\vec{x})}_{|\mathcal{P}}$ is close to $\mathsf{RM}^{(\vec{x})}_{|\mathcal{P}}$ for some plane $\mathcal{P}$ and some $\vec{x} \in \mathcal{P}$, and
2. $f^{(\ell)}_{|\mathcal{P}}$ is close to $\mathsf{RM}^{(\ell)}_{|\mathcal{P}}$ for some plane $\mathcal{P}$ and some line $\ell \subseteq \mathcal{P}$.

Indeed, it is easy to see that the first type of proofs checks that

- **(i)** the restriction of f to $\mathcal{P}$ is close to an evaluation of some polynomial Q^* of total degree at most d,
- **(ii)** and $f(\vec{x}) = Q^*(\vec{x})$.

Similarly, the second type proof certifies that

- **(i)** the restriction of f to $\mathcal{P}$ is close to an evaluation of some polynomial Q^* of total degree at most d,
- **(ii)** and $f_{|\ell}$ is close to $Q^*_{|\ell}$.

These notions of distance go together well with the guarantees we have for CTRW in Theorem 5. This allows us to *compose* CTRW with the PCPPs to obtain a correcting algorithm with query complexity $q = O(m)$. Informally speaking, the composition theorem works as follows. We first run the CTRW to obtain a collection of $m + 1$ constraints on the planes $\mathcal{P}_0, \mathcal{P}_1, \ldots, \mathcal{P}_m$. By Theorem 5, we have the guarantee that with high probability either $f^{(\vec{x})}_{|\mathcal{P}_0}$ is $\Omega(1)$-far from $\mathsf{RM}^{(\vec{x})}_{|\mathcal{P}_0}$, or $f^{(\ell_i)}_{|\mathcal{P}_i}$ is $\Omega(1)$-far from $\mathsf{RM}^{(\ell_i)}_{|\mathcal{P}_i}$ for some $i \in [m]$. Then, instead of actually reading the values of f on all these planes, we run the PCPP verifier on $f^{(\vec{x})}_{|\mathcal{P}_0}$ to check that it is close to $\mathsf{RM}^{(\vec{x})}_{|\mathcal{P}_0}$, and running the PCPP verifier on each of the $f^{(\ell_i)}_{|\mathcal{P}_i}$ to check that they are close to $\mathsf{RM}^{(\ell_i)}_{|\mathcal{P}_i}$. Each execution of the PCPP verifier makes $O(1)$ queries to f and to the proof, and thus the total query complexity will be indeed $O(m)$. As for soundness, if $f^{(\vec{x})}_{|\mathcal{P}_0}$ is $\Omega(1)$-far from $\mathsf{RM}^{(\vec{x})}_{|\mathcal{P}_0}$, or $f^{(\ell_i)}_{|\mathcal{P}_i}$ is $\Omega(1)$-far from $\mathsf{RM}^{(\ell_i)}_{|\mathcal{P}_i}$ for some $i \in [m]$, then the corresponding verifier will notice an inconsistency with constant probability, causing the decoder to output $\perp$.

A detailed discussion of proofs of proximity and the composition is available in the full version of this work [1].

2.3 Putting it all together

Below we discuss the block length and query complexity of our code.

Query complexity: For the query complexity, the mixing time of the CTRW is upper bounded by m, and for each step of the random walk, we read $O(1)$ queries from the PCPP part. Therefore, the total query complexity is bounded by $O(m)$.

Block length: As for the block length of the code, the encoding takes a message of length K and encodes it first using the Reed-Muller code of degree d over the field $\mathbb{F}$ of size $|\mathbb{F}| = n = O(d)$, where $O(\cdot)$ depends on m, so that $K = \binom{m+d}{m} > \left(\frac{d}{m}\right)^m$. In particular, the length of the Reed-Muller part is $n^m \leq O(K)$, where, again, $O(\cdot)$ hides a constant that depends on m.

The total number of predicates (of both types) defined for the CTRW is upper bounded by $B \leq 2n^m \cdot |\mathbb{H}|^{2m} \cdot n^2 = 2n^{m+4}$, as $[\mathbb{F} : \mathbb{H}] = m$, and hence $|\mathbb{H}| = n^{1/m}$. For each such predicate, we have a PCPP part of length $\text{poly}(|\mathbb{F}|) = \text{poly}(n)$.
Therefore, the total length of our code N is upper bounded by

$$N = n^m + B \cdot \text{poly}(n) = n^{m+O(1)} \ .$$

A straightforward computation reveals that this is upper bounded by $C_m \cdot K^{1+O(1/m)}$, where C_m is a constant that depends on m (but is independent of all other parameters). See the full version for the exact computation.

2.4 Comparison to the previous work

Despite the high level similarity of our work with [3], we contribute several new and crucial ideas required in order to improve the parameters of RLCCs. To demonstrate the contribution of this work, we recall the previous best-known construction of RLCCs, due to [3]. The construction in [3] consists of two parts. First, they take a message M and encode it using tensor power of Reed–Solomon code which we denote by $C^{\otimes m}$. Then, for each axis-parallel line in $C^{\otimes m}$, they append a PCPP proof asserting that restriction of the codeword to the corresponding line is (close to) a Reed-Solomon code C. The relaxed local decoding procedure for a word f and a point $\vec{x} \in C^{\otimes m}$ works by running a CTRW as follows. First, the algorithm starts by choosing an axis-parallel line ℓ_1 that passes through $\vec{x}$, and invokes a PCPP verifier on the proof for ℓ_1 to check that $f_{|\ell_1}$ is (close to) a Reed–Solomon codeword. The algorithm continues by choosing another line ℓ_2 that intersects the ℓ_1, and checks that $f_{|\ell_2}$ is (close to) a Reed–Solomon codeword. The procedure is repeated m times by sampling $\ell_3, \ell_4, \ldots, \ell_m$, where a ℓ_{i+1} intersect ℓ_i on a uniformly random point on the line. The length of the walk m is chosen so that a uniformly random point in ℓ_m is a uniform point in the tensor code. In particular, with high probability the line ℓ_m is close to the closest global codeword.

Informally, the main idea of the analysis boils down to the following. Suppose that the line ℓ_1 is far from the closest global codeword $Q^* \in C^{\otimes m}$. That is, either (1) $f_{|\ell_1}$ is far from the Reed-Solomon code or (2) it is close to some Reed-Solomon codeword but is inconsistent with the closest global codeword $Q^*_{|\ell_1}$. In particular, using the fact that Reed-Solomon code has good distance, it follows that $\text{dist}(f_{|\ell_1}, Q^*_{|\ell_1}) = \Omega(1)$. Since after m random steps we reach a line ℓ_m that is close to the closest global codeword, i.e., $\text{dist}(f_{|\ell_1}, Q^*_{|\ell_1}) = o(1)$, then it must be the case that one of the lines $\ell_1, \ell_2, \ldots, \ell_{m-1}$ is far from a Reed-Solomon, and thus the PCPP verifier rejects with high probability.

The main barrier in improving the parameters of [3] comes from the fact that ℓ_{i+1} and ℓ_i only intersect in a single point, and since we only check that the restrictions to ℓ_i's are $\Theta(1)$-close to the Reed-Solomon code, each random step chooses a non-corrupted point with some constant probability, which causes the algorithm to fail.

A natural idea to overcome this difficulty is to replace the lines $\ell_1, \ell_2, \ldots, \ell_m$ in [3] with the planes $\mathcal{P}_1, \mathcal{P}_2, \ldots, \mathcal{P}_m$, such that two consecutive planes intersect on a line. Indeed, using the fact that a random line is a good sampler it will follow that corruption in $\mathcal{P}_1$ will propagate with high probability to $\mathcal{P}_m$.

The key difficulty in implementing this idea is deciding on the collection of the planes for which we require the PCPPs. For example, if we ask for a PCPP for *all* planes in $\mathbb{F}^m$, then the block length becomes at least $\mathbb{F}^{4m}$, which is a lot more than we can afford. On the other hand, if we ask for a PCPP for all *axis-parallel* planes, then we will not be able to sample a uniformly random line in each step of the random walk, as a uniformly random line will not be axis-parallel with high probability.

We overcome this difficulty by requiring PCPPs for all $\mathbb{H}$-planes, where $\mathbb{H}$ is a carefully chosen subfield of $\mathbb{F}$, and an $\mathbb{H}$-plane is a plane of the form $\mathcal{P}_{\vec{a},\vec{h},\vec{h}'} = \{\vec{a}+t\cdot\vec{h}+s\cdot\vec{h}' : t,s \in \mathbb{F}\}$, where $\vec{a} \in \mathbb{F}^m$, and $\vec{h},\vec{h}' \in \mathbb{H}^m$ for some $\mathbb{H}$ subfield of $\mathbb{F}$.

Specifically, we choose the subfield $\mathbb{H}$ to satisfy the following properties:

1. $\mathbb{H}$ is sufficiently small, so that the total number of planes is small, which in turn reduces the block length of the code.
2. Mixing time for CTRW on the planes converges rapidly.

Note that the two requirements are conflicting, as fast mixing implies that the collection of the planes must be somewhat large. We show a subfield $\mathbb{H}$ of $\mathbb{F}$ satisfying both of these properties, thus finding a pseudo-random collection of planes which allows us to improve the parameters of the entire construction, thus obtaining the main goal of this paper. See the full version for details.

3 Concluding remarks and open problems

In this section, we first briefly discuss how to obtain a binary RLDC using the code concatenation technique. Then, we conclude the section by reviewing some open problem which we leave for future research.

3.1 Code concatenation for binary alphabet

In this paper we constructed an $O(q)$-query RLDC $C\colon \mathbb{F}^K \to \mathbb{F}^N$ with block length $N = q^{O(q^2)} \cdot K^{1+O(1/q)}$, assuming that the field is large enough, namely, assuming that $|\mathbb{F}| \geq c_q \cdot K^{1/q}$. Using standard techniques it is possible to obtain a binary RLDC with similar parameters. This can be done by concatenating our code with an arbitrary binary code with constant rate and constant relative distance. Indeed, this transformation appears in [3, Appendix A], who showed how concatenating CTRW-based RLDC over large alphabet with a good binary code gives a binary RLDC that essentially inherits the block length and the query complexity of the RLDC over large alphabet. Below we provide the proof sketch, explaining how the concatenation works.

Proof sketch. Suppose that we want to construct a short binary RLCC. Let $C_{RLCC} : \mathbb{F}^K \to \mathbb{F}^N$ be the RLCC over some field $\mathbb{F}$ with the desired block length, and let $C_{bin} : \{0,1\}^{K'} \to \{0,1\}^{N'}$ be an error-correcting code with constant rate and constant distance. We also assume that field $\mathbb{F}$ is chosen so that $|\mathbb{F}| = 2^{K'}$. (To satisfy this condition, one can simply set $\mathbb{H}$ to be a field of characteristic 2.) This assumption will allow us to have a bijection between each symbol of $\mathbb{F}$ and binary string of length K'.

We construct the binary concatenated code $C_{concat} : \{0,1\}^{K\cdot K'} \to \{0,1\}^{N\cdot N'}$ as follows. Given a message $M \in \{0,1\}^{K\cdot K'}$, we first convert it to an string in $M' \in \mathbb{F}^K$ in the natural way. Then, we encode M' using C_{RLCC} to obtain a codeword $c^* \in C_{RLCC}$. Finally, we encode each symbol of c^* using C_{bin} to get the final codeword $c \in \{0,1\}^{N\cdot N'}$.

To prove that the concatenated code is an RLCC, Chiesa, Gur, and Shinkar proved in [3, Theorem A.4] that if C_{RLCC} admits an r-steps CTRW with some soundness guarantees, then C_{concat} admits an r-steps CTRW with related soundness guarantees. The CTRW on the concatenated code C_{concat} emulates the CTRW on C_{RLCC} by sampling planes for the CTRW on the Reed-Muller code, and instead of reading the symbols from $\mathbb{F}$, it reads the binary encodings of all symbols belonging to these planes.

Indeed, it is not difficult to see that if C_{RLCC} admits an r-steps CTRW with some soundness guarantees, then so does the concatenated code. We omit the details, and refer the interested reader to Appendix A in [3]. ◀

3.2 Open problems

We conclude the paper with several open problems we leave for future research.

1. The most fundamental open problem regarding RLDCs/RLCCs is to understand the optimal trade-off between the query complexity of LDCs and their block length in the constant query regime. It is plausible that the lower bound of [12] can be improved to $K^{1+\Omega(1/q)}$, although we do not have any evidence for this.
2. As discussed in the intoduction, [2] asked whether it is possible to prove a separation between LDCs and RLDCs. Understanding the trade-off between the query complexity and the block length is one possible way to show such separation.
3. Another interesting open problem is to construct an RLDC/RLCC with constant rate and small query complexity. In particular, it is plausible that there exist polylog(N)-query RLDCs with $N = O(K)$. It should be noted that [13] constructed constant-rate RLCCs (in fact with a rate approaching 1) and query complexity $\log(N)^{O(\log\log(N))}$.
4. Also, it would be interesting to construct RLDCs/RLCCs using high-dimensional expanders [15, 6, 5, 16]. Since there are several definitions of high-dimensional expanders, it would be interesting to state the sufficient properties of high-dimensional expanders required for RLDCs. We believe this approach can be useful in constructing constant rate RLDCs with small query complexity.

Beating Two-Thirds For Random-Order Streaming Matching

Department of Computer Science, University of Maryland, College Park, MD, USA

Abstract

We study the maximum matching problem in the *random-order* semi-streaming setting. In this problem, the edges of an arbitrary n-vertex graph $G = (V, E)$ arrive in a stream one by one and in a random order. The goal is to have a single pass over the stream, use $O(n \cdot \text{polylog}(n))$ space, and output a large matching of G.

We prove that for an absolute constant $\varepsilon_0 > 0$, one can find a $(2/3 + \varepsilon_0)$-approximate maximum matching of G using $O(n \log n)$ space with high probability. This breaks the natural boundary of $2/3$ for this problem prevalent in the prior work and resolves an open problem of Bernstein [ICALP'20] on whether a $(2/3 + \Omega(1))$-approximation is achievable.

1 Introduction

A matching in a graph $G = (V, E)$ is any collection of vertex-disjoint edges and in the maximum matching problem, we are interested in finding a matching of largest size in G. This problem has been a cornerstone of algorithmic research and its study has led to numerous breakthrough results in theoretical computer science. In this paper, we study the maximum matching problem in the *semi-streaming* model of computation [9] defined as follows.

▶ **Definition 1.** *Given a graph $G = (V, E)$ with n vertices $V = \{1, \ldots, n\}$ and m edges in E presented in a stream $S = \langle e_1, \ldots, e_m \rangle$, a semi-streaming algorithm makes a single pass over the stream of edges S and uses $O(n \cdot \text{polylog}(n))$ space, measured in words of size $\Theta(\log n)$ bits, and at the end outputs an approximate maximum matching of G.*

The greedy algorithm for maximal matching gives a simple $1/2$-approximation algorithm to this problem in $O(n)$ space. When the stream of edges is adversarially ordered, this is simply the best result known for this problem, while it is also known that a better than

$\frac{1}{1+\ln 2} \sim 0.59$-approximation is not possible [14] (see also [11,13]). Closing the gap between these upper and lower bounds is among the most longstanding open problems in the graph streaming literature.

Going beyond this "doubly worst case" scenario, namely, an adversarially-chosen graph and an adversarially-ordered stream, there has been an extensive interest in recent years in studying this problem on **random order streams**. This line of work was pioneered in [16] who showed that the $1/2$-approximation of greedy can be broken in this case and obtained an algorithm with approximation ratio $(1/2 + 0.003)$ for this problem. Since [16], there has been two main lines of attack on this problem. Firstly, [8,10,15] followed up on the approach of [16] and improved the approximation ratio all the way to $6/11$ [8]. In parallel, [1] built on the sparsification approach of [6,7] in dynamic graphs to achieve an (almost) $2/3$-approximation but at the cost of $\widetilde{O}(n^{1.5})$ space, which is no longer semi-streaming. A beautiful work of [5] then obtained a semi-streaming (almost) $2/3$-approximation by showing how a generalization of the sparsification approach in [1] can be found in $\widetilde{O}(n)$ space.

The $2/3$-approximation ratio of the algorithm of [5] is the best possible among all prior techniques for this problem: the first line of attack in [8, 10, 15, 16] is based on finding length-3 augmenting paths and even finding *all* these paths does not lead to a better-than-$2/3$-approximation[1]. The second line in [1, 5] is based on finding an edge-degree constrained subgraph (EDCS) which hits the same exact barrier as there are graphs whose EDCS does not provide a better than $2/3$-approximation (see [6]). Finally, even for an algorithmically easier variant of this problem, the one-way communication problem, which roughly corresponds to only measuring the space of the algorithm when crossing the midpoint of the stream, the best known approximation ratio is still $2/3$ which is known to be tight for adversarial orders/partitions [11].

Given this state-of-affairs, the $2/3$-approximation ratio for random-order streaming matching has emerged as natural barrier [5,15]. In particular, [5] posed obtaining a $(2/3 + \Omega(1))$-approximation to this problem as an important open question. We resolve this question in the affirmative in our work.

1.1 Our Contributions

Our main result is a semi-streaming algorithm for maximum matching in random-order streams with approximation ratio strictly-better-than-$2/3$.

▶ **Theorem 2** (Main Result). *Let G be an n-vertex graph whose edges arrive in a random-order stream. For an absolute constant $\varepsilon_0 > 0$, there is a single-pass streaming algorithm that obtains a $(\frac{2}{3} + \varepsilon_0)$-approximate maximum matching of G using $O(n \log n)$ space w.h.p.*

Theorem 2 breaks the $2/3$-barrier of all prior work in [1, 5, 8, 10, 15, 16]. Moreover, even though the improvement over $2/3$ is minuscule in this theorem (while we did not optimize for constants, the bound on ε_0 is only $\sim 10^{-14}$ at this point), it still proves that $(2/3)$-approximation is not the "right" answer to this problem. This is in contrast to some other problems of similar flavor such as one-way communication complexity of matching (on adversarial partitions) [3,11] or the fault-tolerant matching problem [3] which are both solved using similar techniques (see the unifying framework of [3] based on EDCS) and for both $2/3$-approximation is provably best possible.

[1] The work of [8] also considers length-5 augmenting paths. However, these paths are used *instead of* length-3 paths "missed" by the algorithm *not in addition to* length-3 paths and thus the same shortcoming persists.

Beyond (2/3)-approximation. Breaking this 2/3-barrier naturally raises the question on what is the right bound on the approximation ratio of random-order streaming matching. In particular, is $(1-\varepsilon)$-approximation possible? We make progress toward settling this question as well by showing that no "completely" space-efficient algorithm exists for this latter problem: there is provably no semi-streaming algorithm for the matching problem even on bipartite graphs that can achieve a $(1-\varepsilon)$-approximation in $O(2^{(1/\varepsilon)^{0.99}} \cdot n \cdot \text{polylog}n)$ space; in other words, if one hopes for achieving a $(1-\varepsilon)$-approximation, an exponential dependence on $(1/\varepsilon)$ in the space is unavoidable. As the main focus of our work is on the algorithm in Theorem 2, we provide the details of the lower bound only in the full version [2].

1.2 Overview of Techniques

Prior work. As stated earlier, there has been two main lines of attacks on the streaming matching problem in random-order streams. The first approach aims to find a *large* matching of the graph G early on in the stream, and then spends the rest of the stream *augmenting* this matching. For instance, [16] showed that in order for the greedy algorithm to fail to find a better-than-1/2-approximation, the algorithm should necessarily pick many "wrong" edges early on in the stream. As such, in instances where greedy is not beating the 1/2-approximation itself, we already have an almost 1/2-approximation by the *middle* of the stream, and we can thus focus on augmenting this matching in the remainder half to beat 1/2-approximation. The work of [15] then improved this result further by showing that a modified greedy algorithm, when unsuccessful in obtaining a large matching itself, finds an almost 1/2-approximation when only $o(1)$-fraction of the stream has passed (as opposed to middle), which gives us more room for augmentation. Finally, [8] built on this approach and further improved the augmentation phase.

The second approach to this problem was based on obtaining an EDCS, a subgraph defined by [6, 7] and studied further in [3], that acts as a "matching sparsifier". On a high level, an EDCS is a sparse subgraph satisfying the following two constraints: (i) edge-degree of edges in the EDCS cannot be "high", while (ii) edge-degree of missing edges cannot be "low". These constraints ensure that an EDCS always contains an almost 2/3-approximate matching of the graph and has additional robustness properties. For instance, [1] proved that union of several EDCS computed on different parts of a random stream, is itself an EDCS for the entire stream. This allowed them to compute an EDCS of the input in $\widetilde{O}(n^{1.5})$ space and directly obtain their almost 2/3-approximation. Finally, [5] gave an elegant proof that weakening the requirement of EDCS allows one to still preserve the almost 2/3-approximation but now recover this subgraph in only $O(n \log n)$ space. More specifically, the algorithm of [5] first finds a subgraph only satisfying property (i) of the EDCS in the first $o(m)$ edges of the stream, and then picks *all* (potentially) necessary edges for satisfying property (ii) in the remainder; the proof then shows that this set of potentially necessary edges is of size only $O(n \log n)$.

Our work. Our approach can be seen as a natural combination of these two mostly disjoint lines of work. The first part comes from a better understanding of EDCS. We present a rough characterization of when an EDCS cannot beat the 2/3-approximation, which shows that in these instances, we can effectively ignore the second constraint of EDCS. As a result, we obtain that the only way for the algorithm of [5] to fail to achieve a better-than-2/3-approximation, is if it already picks an almost 2/3-approximation in the first $o(m)$ edges. Note that this is conceptually similar to the first line of work on random-order streaming matching, but the techniques are entirely disjoint. In particular, our proof is a deterministic property of EDCS not a randomized property of a greedy algorithm on a particular ordering.

We are now in the familiar territory of having a large matching very early on in the stream, and we can spend the remainder of the stream augmenting it. The main difference however is that starting from an almost $2/3$-approximation matching, there is essentially no length-3 paths for us to augment and we instead need to handle length-5 augmenting paths. The key challenge is to find the middle edge of these length-5 augmenting paths. Indeed, we note that the $2/3$-approximation lower bound of [11] for *adversarial* order streams gives away a $2/3$-approximate matching early on for free, yet it is provably impossible to augment it in the remainder of the stream using $\widetilde{O}(n)$ space. To get around this, we crucially use the random arrival assumption again. Particularly, we regard any length-5 augmenting path whose middle edge arrives after its two endpoint edges as a "discoverable" path and then find a constant fraction of such paths. Since the edges arrive in a random order, a constant fraction of length-5 augmenting will be discoverable and thus we are able to beat $2/3$-approximation in our setting.

2 Notation and Preliminaries

General notation. For a graph $G = (V, E)$ and $v \in V$, we use $\deg_G(v)$ to denote the degree of v in G and $N_G(v)$ to denote the neighborset of v (when clear from the context, we may drop the subscript G). For any edge $e = (u, v) \in E$, we define the edge-degree of e in G as $\deg(u) + \deg(v)$. We use $\mu(G)$ to denote the *size* (i.e., the number of edges) of the maximum matching in G.

For integer $k \geq 1$ and $p \in [0, 1]$, we use $\mathcal{B}(k, p)$ to denote the *binomial distribution* with parameters k and p. That is, $\mathcal{B}(k, p)$ is the discrete probability distribution of the number of successful experiments out of k independent experiments each with probability p of success.

Random-order streams. We consider the random-order streaming setting where the edges of G arrive one by one in an order chosen uniformly at random from all possible orderings. Let e_i be the i-th edge that arrives in the stream. For any two parameters a, b satisfying $1 \leq a < b \leq m$ we use $G[a, b]$ to denote the subgraph of G on vertex-set V and edge-set $\{e_a, \ldots, e_b\}$. We may also use $G_{<a}$ and $G_{\geq a}$ respectively for $G[1, a-1]$ and $G[a, m]$.

For the input graph G defined by the stream, we can assume w.l.o.g. that $\mu(G) \geq c \log n$ for any desirably large constant c. The reason is that any graph can be easily shown to have at most $2n \cdot \mu(G)$ edges and if $\mu(G) = O(\log n)$ then we can store the whole input in the memory and report an optimal solution using $O(n \log n)$ space. We further assume throughout the paper that the number of edges m is known by the algorithm in advance. This is a common assumption in the literature and can be removed via standard techniques by guessing m in geometrically increasing values at the expense of multiplying the space by an $O(\log n)$ factor.

2.1 Preliminaries

Hall's theorem. We use the following standard extension of the Hall's marriage theorem for characterizing maximum matching size in bipartite graphs.

▶ **Fact 3** (Extended Hall's Theorem [12]). *Let $G = (L, R, E)$ be a bipartite graph with $|L| = |R| = n$. Then, $\max\Big(|A| - |N(A)|\Big) = n - \mu(G)$, where A ranges over L or R, separately. We refer to such set A as a* ***witness set****.*

Fact 3 follows from Tutte-Berge formula for matching size in general graphs [4, 17] or a simple extension of the proof of Hall's marriage theorem itself.[2]

Alternating and augmenting paths. Given a matching M, an *alternating path* P for M is a path whose edges alternatively belong to M and do not belong to M. An *augmenting path* for M is an alternative path that starts and ends with edges that do not belong to M. Given an augmenting path P for M, we use notation $M \oplus P := (M \setminus P) \cup (P \setminus M)$ to denote the matching obtained by flipping the containment of edges of P in M. Given two matchings M and M', their *symmetric difference* $M \Delta M'$ is a graph including only the edges that belong to exactly one of M and M'.

2.2 Bernstein's Algorithm

We briefly review the parameters and guarantees of the algorithm of Bernstein [5] that we need. In the following, we slightly increase the constants in the parameters which is needed for our results.

▶ **Definition 4 (Parameters).** *For some small $\varepsilon \in (0, \frac{1}{2})$ to be determined later, let*

$$\lambda := \frac{\varepsilon}{128}, \qquad \beta_+ := 64 \cdot \lambda^{-2} \log(1/\lambda), \qquad \beta_- = (1-\lambda) \cdot \beta_+.$$

A high level overview of the algorithm of [5] is as follows:

Algorithm 1 Bernstein's Algorithm [5].

The algorithm of [5] proceeds in two phases as follows:

- Phase I terminates within the first εm edges of the stream. At the end of Phase I, the algorithm constructs a subgraph $H \subseteq G_{<\varepsilon m}$ (using the algorithm of Lemma 5) that in particular guarantees that for all $(u, v) \in H$, $\deg_H(u) + \deg_H(v) \leq \beta_+$. Also let U be the set of *all* edges in $G_{\geq \varepsilon m}$ such that $\deg_H(u) + \deg_H(v) < \beta_-$.
- In Phase II, the algorithm simply stores U in the memory and at the end of the stream returns a maximum matching of $H \cup U$.

The following lemma is all we need from [5] in our paper.

▶ **Lemma 5** (See Lemma 4.1 of [5]). *There is a way of constructing the subgraph H of $G_{<\varepsilon m}$ such that with probability at least $1 - n^{-3}$, $|H \cup U| = O(n \log(n) \cdot \text{poly}(1/\varepsilon))$.*

3 Finding an Almost (2/3)-Approximation Early On

We start by characterizing the tight instances of the algorithm of [5] (Algorithm 1). Roughly speaking, we show that the only way for Algorithm 1 to end up with a (2/3)-approximation is if in its Phase I it computes a subgraph H that already has an almost (2/3)-approximate matching. This will then be used by our algorithm in the next section to obtain a strictly better-than-(2/3)-approximation by augmenting this already-large matching. We start by presenting and proving this result for bipartite graphs which is the main part of the proof; we then extend the result to general graphs (with no considerable loss of parameters for our purpose) using the probabilistic method approach of [3] for the original EDCS.

[2] Simply add $n - \mu(G)$ vertices to each side of the graph and connect them to all the original vertices; then apply original's Hall's theorem for perfect matching to this graph as this graph now has one.

3.1 Bipartite Graphs

In this section we prove the following structural result:

▶ **Theorem 6.** *Let $\lambda \in (0, 1/2)$ and $\beta_- \leq \beta_+$ be such that $\beta_+ \geq \frac{10}{\lambda}$ and $\beta_- \geq (1-\lambda)\beta_+$. Suppose $G = (L, R, E)$ is any bipartite graph and:*

(i) *H is a subgraph of G where for all $(u, v) \in H$: $\deg_H(u) + \deg_H(v) \leq \beta_+$; and*

(ii) *U is the set of all edges (u, v) in $G \setminus H$ such that $\deg_H(u) + \deg_H(v) < \beta_-$.*

Then, for any parameter $\delta \in (0, 1)$, either:

$$\mu(H) \geq (1-4\lambda) \cdot \left(\frac{2}{3} - \delta\right) \cdot \mu(G) \quad \text{or} \quad \mu(H \cup U) \geq (1-2\lambda) \cdot \left(\frac{2}{3} + \frac{\delta^2}{18}\right) \cdot \mu(G).$$

Let us define the following (see Figure 1 for an illustration):

- Let M^* be a maximum matching of G and define $M^*_U := M^* \cap U$ and $M^*_{\bar{U}} := M^* \setminus U$.
- A is a Hall's theorem witness set in $H \cup M^*_U$ (as in Fact 3) and $B := N_{H \cup M^*_U}(A)$. Without loss of generality we assume $A \subseteq L$ and define $\bar{A} := L \setminus A$ and $\bar{B} := R \setminus B$.

We start with the following simple claim that follows easily from Fact 3. See the full version of the paper for details [2].

▷ Claim 7. For the witness set A:

(i) $|\bar{A}| + |B| \leq \mu(H \cup U)$.

(ii) There is a matching $\bar{M} \subseteq M^*_{\bar{U}}$ between A and $\bar{B}$ in G with size $|\bar{M}| = \mu(G) - \mu(H \cup M^*_U)$.

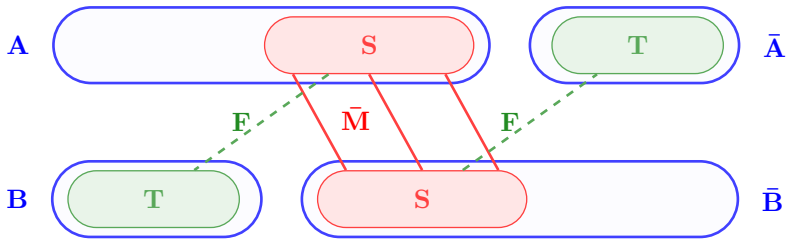

Figure 1 An illustration of the Hall's witness set and our notation in the proof of Theorem 6. Note that there are no edges between A and $\bar{B}$ in $H \cup M^*_U$, and matching $\bar{M}$ belongs entirely to $M^*_{\bar{U}}$.

Consider any edge $(u, v) \in \bar{M}$ defined in Claim 7. As $\bar{M} \subseteq M^*_{\bar{U}}$, by property (ii) of the statement of Theorem 6, we have, $\deg_H(u) + \deg_H(v) \geq \beta_-$. We arbitrarily remove the edges on u and v until the above inequality becomes tight for every edge. We let F be the remaining edges. Note that any edge in F is incident on exactly one vertex of $\bar{M}$ as there are no edges in $H \cup M^*_U$ between the endpoints of $\bar{M}$. We record these properties as follows:

$$\forall (u, v) \in \bar{M} : \ \deg_F(u) + \deg_F(v) = \beta_- \quad \text{and} \quad |F| = |\bar{M}| \cdot \beta_-. \tag{1}$$

We refer the reader to the full version of the paper [2] for illustrative examples that highlight the ideas for proving Theorem 6. Here for space constraints, we only provide the formal proof.

In Lemma 8, we prove a lower bound on $\mu(H)$. This lemma can then be used as follows: if the degrees of most edges in $\bar{M}$ are "balanced", i.e., both endpoints have degree $\approx \beta_-/2$, then $\mu(H)$ will already be of size $2 \cdot |\bar{M}|$ which is sufficient for the first condition of Theorem 6.

▶ **Lemma 8** (matching of H is large). *We have* $\mu(H) \geq \frac{\beta_-}{1+4\lambda} \cdot \sum_{(u,v)\in \bar{M}} \frac{1}{\max\{\deg_F(u)\,,\,\deg_F(v)\}}$.

Proof. For every edge $(u,v) \in \bar{M}$, define $F(u,v)$ as set of edges in F that are incident on u or v. We define the following fractional matching $x \in \mathbb{R}^F$ on edges of F:

- for any edge $e \in F(u,v)$: set $x_e := \frac{1}{1+4\lambda} \cdot \frac{1}{\max\{\deg_F(u)\,,\,\deg_F(v)\}}$.

Let us now prove this is indeed a valid fractional matching. For any vertex w matched by $\bar{M}$,

$$x_w := \sum_{e \ni w} x_e \leq \deg_F(w) \cdot \frac{1}{1+4\lambda} \cdot \frac{1}{\deg_F(w)} < 1,$$

thus satisfying the fractional matching constraint.

Now fix a vertex w not matched by $\bar{M}$. Let $u_1, \ldots, u_{\deg_F(w)}$ denote the neighbors of w in F. By definition, all these vertices are matched by $\bar{M}$. Let $v_1, \ldots, v_{\deg_F(w)}$ be the matched pairs of these vertices. We need the following simple claim proved in the full version.

▷ Claim 9. For every $i \in [\deg_F(w)]$, $\deg_F(w) \leq (1+4\lambda) \cdot \max\{\deg_F(u_i)\,,\,\deg_F(v_i)\}$.

To finalize Lemma 8, for any vertex w not matched by $\bar{M}$, we have,

$$x_w := \sum_{e=(w,u_i)} x_e = \sum_{u_i} \frac{1}{1+4\lambda} \cdot \frac{1}{\max\{\deg_F(u_i)\,,\,\deg_F(v_i)\}} \underset{\text{Claim 9}}{\leq} \sum_{u_i} \frac{1}{\deg_F(w)} = 1,$$

thus satisfying the fractional matching constraint. This implies that x is a valid fractional matching. Finally, the value of this fractional matching is:

$$\begin{aligned}\sum_{e\in F} x_e &= \sum_{(u,v)\in N} \sum_{e\in F(u,v)} x_e = \sum_{(u,v)\in N} \frac{\deg_F(u) + \deg_F(v)}{(1+4\lambda)\cdot \max\{\deg_F(u)\,,\,\deg_F(v)\}} \\ &= \frac{\beta_-}{1+4\lambda} \cdot \sum_{(u,v)\in N} \frac{1}{\max\{\deg_F(u)\,,\,\deg_F(v)\}},\end{aligned}$$

where the last equation is by Eq (1). As the integrality gap of the matching polytope on bipartite graphs is one, we obtain the desired lower bound on $\mu(H)$. ◀

We now prove that if on the other hand most edges of $\bar{M}$ are "unbalanced", then $\mu(H \cup U)$ should be sufficiently large. To continue, we need a quick definition. Let S denote the endpoints of the matching $\bar{M}$ and T be the neighborset of these vertices in F. Recall that by Eq (1), S and T are disjoint (see Figure 1).

▶ **Lemma 10** (matching of $\mu(H \cup U)$ is large). *We have* $\mu(H \cup U) \geq \frac{|\bar{M}|^2 \cdot {\beta_-}^2}{|\bar{M}| \cdot \beta_- \cdot \beta_+ - \sum_{s\in S} (\deg_F(s))^2}$.

Proof. Since $F \subseteq H$, by property (i) of Theorem 6, we have that

$$|F| \cdot \beta_+ \geq \sum_{(u,v)\in F} \deg_F(u) + \deg_F(v) = \sum_{s\in S} (\deg_F(s))^2 + \sum_{t\in T} (\deg_F(t))^2. \tag{2}$$

We can lower bound the second term of the RHS as follows. Recall that sum of quadratics is minimized over all-equal terms. As $\sum_{t\in T} \deg_F(t) = |F|$, this implies that,

$$\sum_{t\in T} (\deg_F(t))^2 \geq \sum_{t\in T} \left(\frac{|F|}{|T|}\right)^2 = |T| \cdot \left(\frac{|F|}{|T|}\right)^2 = \frac{|F|^2}{|T|}.$$

By plugging in this bound in Eq (2) and moving the terms around, we have that

$$|T| \geq \frac{|F|^2}{|F| \cdot \beta_+ - \sum_s (\deg_F(s))^2} = \frac{|\bar{M}|^2 \cdot {\beta_-}^2}{|\bar{M}| \cdot \beta_- \cdot \beta_+ - \sum_s (\deg_F(s))^2}. \qquad \text{(as } |F| = |\bar{M}| \cdot \beta_- \text{ by Eq (1))}$$

Finally, $T \subseteq \bar{A} \cup B$ (as there are no edges between A and $\bar{B}$) and thus by Claim 7, $|T| \leq \mu(H \cup U)$ which finalizes the proof. ◀

Lemma 10 can be used as follows: when degree of most edges in $\bar{M}$ are "balanced", the quantity $\sum_s (\deg_F(s))^2$ will be close to $|\bar{M}| \cdot (\beta_-)^2/2$ which implies that $\mu(H \cup U)$ will be almost $2 \cdot |\bar{M}|$; however, when degrees of edges in $\bar{M}$ are "unbalanced", the quantity $\sum_s (\deg_F(s))^2$ *cannot* decrease all the way to $|\bar{M}| \cdot (\beta_-)^2/2$ and thus we can get a higher lower bound on the value of $\mu(H \cup U)$ which breaks the (2/3)-approximation.

To finalize the proof of Theorem 6, we need the following claim for lower bounding $\sum_{s \in S} (\deg_F(s))^2$ in the RHS of Lemma 10, in the cases where RHS of Lemma 8 is small.

▷ Claim 11. Suppose $\sum_{(u,v) \in \bar{M}} \frac{\beta_-}{\max\{\deg_F(u), \deg_F(v)\}} = (2-\gamma) \cdot |\bar{M}|$ for some $\gamma \in [0,1)$; then $\sum_s (\deg_F(s))^2 \geq |\bar{M}| \cdot \left(\frac{(2+\gamma^2-2\gamma) \cdot {\beta_-}^2}{4+\gamma^2-4\gamma}\right)$.

The proof of Claim 11 is given in the full version [2]. We are now ready to prove Theorem 6.

Proof of Theorem 6. Let us pick $\gamma \in [0,1)$ such that $\sum_{(u,v) \in \bar{M}} \frac{\beta_-}{\max\{\deg_F(u), \deg_F(v)\}} = (2-\gamma) \cdot |\bar{M}|$ (as the max-term is at least $\beta_-/2$, such a γ always exist). By plugging in the bound of Claim 11 in Lemma 10, we have that,

$$\begin{aligned}
\mu(H \cup U) &\geq \frac{|\bar{M}|^2 \cdot {\beta_-}^2}{|\bar{M}| \cdot \beta_- \cdot \beta_+ - |\bar{M}| \cdot \left(\frac{(2+\gamma^2-2\gamma) \cdot {\beta_-}^2}{4+\gamma^2-4\gamma}\right)} \\
&\geq (1-2\lambda) \cdot |\bar{M}| \cdot \frac{1}{1 - \left(\frac{(2+\gamma^2-2\gamma)}{4+\gamma^2-4\gamma}\right)} && \text{(as } \beta_- \geq (1-\lambda)\beta_+\text{)} \\
&= (1-2\lambda) \cdot |\bar{M}| \cdot \frac{4+\gamma^2-4\gamma}{2-2\gamma} = (1-2\lambda) \cdot |\bar{M}| \cdot (2 + \frac{\gamma^2}{2-2\gamma}).
\end{aligned}$$

Considering $|\bar{M}| \geq \mu(G) - \mu(H \cup U)$ by Claim 7, we obtain that

$$\mu(H \cup U) \geq (1-2\lambda) \cdot \mu(G) \cdot \left(\frac{2}{3} + \frac{\gamma^2}{18 - 18\gamma + 3\gamma^2}\right) \geq (1-2\lambda) \cdot \mu(G) \cdot \left(\frac{2}{3} + \frac{\gamma^2}{18}\right).$$

Now if for the parameter δ in Theorem 6, we already have $\gamma \geq \delta$, we will obtain the second condition. Further, without loss of generality, we can assume that $|\bar{M}| \geq (\frac{1}{3} - \frac{\delta}{3}) \cdot \mu(G)$ as otherwise $\mu(H \cup M^*_U) \geq (\frac{2}{3} + \delta) \cdot \mu(G)$ by Claim 7 which is stronger than the second condition of Theorem 6.

Suppose $\gamma < \delta$ and $|\bar{M}| \geq (\frac{1}{3} - \frac{\delta}{3}) \cdot \mu(G)$ then. In this case, by the definition of γ and Lemma 8,

$$\begin{aligned}
\mu(H) &\geq \frac{1}{1+4\lambda} \cdot (2-\gamma) \cdot |\bar{M}| \geq \frac{1}{1+4\lambda} \cdot (2-\delta) \cdot \left(\frac{1}{3} - \frac{\delta}{3}\right) \cdot \mu(G) \\
&\geq (1-4\lambda) \cdot \left(\frac{2}{3} - \delta\right) \cdot \mu(G),
\end{aligned}$$

thus satisfying the first condition. This concludes the proof. ◀

We can also extend the guarantee of Theorem 6 to general (non-bipartite) graphs following the probabilistic method technique of [3] (see the full version [2] for the exact guarantee) without incurring any loss to the guarantees up to constants.

4 An Improved Algorithm via Augmentation

In this section, we show that the maximum matching of the subgraph H constructed in the early part of the stream of Algorithm 1 can be augmented well via the remaining edges. Combined with our guarantee of Section 3, we complete in this section the proof of Theorem 2. Namely, we show that for some parameter $\varepsilon_0 > 0$, there is a single-pass random-order streaming algorithm (formalized as Algorithm 2) that obtains a $(\frac{2}{3} + \varepsilon_0)$-approximate maximum matching of G using $O(n \log n)$ space with high probability of $1 - 1/\text{poly}(n)$.

4.1 The Algorithm

Our starting point is Algorithm 1. Recall that this algorithm stores two subgraphs H and U of G of size $O(n \log n)$. Subgraph H is constructed early on, after merely observing εm edges of the stream. In addition to H and U, here we store an additional subset of edges that we use to augment a matching of H with. Particularly, let M_H be an arbitrary maximum matching of H. Having matching M_H early on, in our algorithm we augment M_H using the edges that arrive in the rest of the stream (i.e., Phase II) in parallel to storing U. The augmenting paths that we find may be of size up to *five*. This is crucial since we may not have enough augmenting paths of length smaller than five to go beyond (2/3)-approximation. Now by plugging our bound of Section 3, it can be shown that either $H \cup U$ includes our desired approximation of strictly better that 2/3, or M_H is almost a (2/3)-approximate matching which coupled with the augmenting paths that we find for it in Phase II leads to our better-than-(2/3)-approximation.

To find these augmenting paths, we divide the $(1-\varepsilon)m$ edges of Phase II into Phase II.A and Phase II.B. To do this, we first draw a random variable $\tau \sim \mathcal{B}((1-\varepsilon)m, \gamma)$. Phase II.A will then proceed on the edges that arrive up to the τ-th edge of Phase II and Phase II.B proceeds on the rest of the edges. Drawing random variable τ (instead of having a fixed threshold) is particularly useful in the analysis: Conditioned on the edges that are to arrive in Phase II (but not their ordering), each edge now belongs to Phase II.A *independently* with probability γ and to Phase II.B otherwise. Note that with a fixed threshold, we do not get this independence.

For Phase II.A, let us define G_H to be the subgraph of G whose edges arrive in Phase II.A and have exactly one endpoint matched by M_H. Note that G_H is bipartite (even though G may not be) with one partition corresponding to vertices $V(M_H)$ and another to $V \setminus V(M_H)$. In Phase II.A, we only consider the edges of G_H and greedily construct a maximal $(2, b)$-matching T of G_H (for some constant $b \geq 2$). It is the vertices in part $V(M_H)$ of G_H that have maximum degree 2 in T and those in the other partition can have degree up to b. In our analysis, we show that the edges of T can be used as the two endpoint edges of many augmenting paths of length three or five for M_H (see Figure 2).

In Phase II.B, we first let $M \leftarrow M_H$ and upon arrival of each edge e, we iteratively augment M via length-up-to-five augmenting paths using the edges in $T \cup \{e\}$ until no such path is left. In our analysis, we use the edges of Phase II.B either as the middle edge of length-five augmenting paths or as the single edge of the length-one augmenting paths the algorithm may find (see Figure 2).

At the end of the stream, we return a maximum matching of $M \cup H \cup U$. The algorithm outlined above is formalized as Algorithm 2.

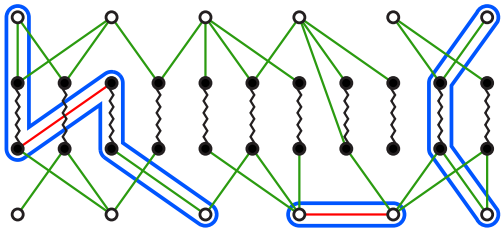

Figure 2 An example of an execution of Algorithm 2. Here the black zig-zagged edges denote M_H which is fixed by the end of Phase I and we would like to augment it. The black nodes are those matched by M_H and the white ones are those left unmatched by M_H. The edges between white and black nodes (colored green) are the edges in T. Each black node has at most two edges in T and the green nodes can have up to b. The red edges are those that arrive in Phase II.B. Three augmenting paths of length one, three, and five that are discoverable by the algorithm are highlighted by blue.

Algorithm 2 Our final random-order streaming matching algorithm with approximation ratio strictly-better-than-$2/3$.

Parameters: $\gamma = 2/3$, $b = 500$, and a sufficiently small constant $\varepsilon < 0.01$ to be fixed later.

(1) In Phase I of the algorithm, which consists of the first εm edges of the stream, we construct a subgraph H of G as in Phase I of Algorithm 1. At the end of Phase I, we fix an arbitrary maximum matching M_H of H.

(2) In Phase II, which includes all the edges that arrive after Phase II, we store subgraph U using Phase II of Algorithm 1. In addition, we store another subset of edges that we use to augment M_H. These edges are constructed in two sub-phases Phase II.A and Phase II.B.

(3) Draw random variable τ from the Binomial distribution $\mathcal{B}((1-\varepsilon)m, \gamma)$. Note that this can be done in $O(m)$ time and $O(1)$ space as we only need to count the successes.

(4) Phase II.A starts after Phase I and ends upon arrival of the τ'th edge of Phase II.

- **a.** Let $G_H(V_H, U_H, E_H)$ be a bipartite subgraph of G where $V_H := V(M_H)$ is the set of vertices matched in M_H, $U_H := V \setminus V(M_H)$ is the set of vertices left unmatched in M_H, and E_H is the edges of G between V_H and U_H that arrive in Phase II.A.
- **b.** We initialize $T \leftarrow \emptyset$ and upon arrival of an edge $e = (u, v)$ of G_H with $u \in U_H$ and $v \in V_H$, if $\deg_T(v) < 2$ and $\deg_T(u) < b$ we add e to T. That is, T is a maximal $(2, b)$-matching of G_H which requires $O(nb)$ space to store.

(5) Phase II.B starts after Phase II.A and continues to the end of the stream:

- **a.** $M \leftarrow M_H$. Upon arrival of each edge e in Phase II.B, we iteratively take an arbitrary augmenting path P for M of length up to five using the edges in $M \cup T \cup \{e\}$ and let $M \leftarrow M \oplus P$. We repeat this process until no more augmenting paths of length up to five exist in $M \cup T \cup \{e\}$; we then continue to the next edge of the stream in Phase II.B.

(6) Finally, we return a maximum matching of $M \cup H \cup U$.

Analysis of Algorithm 2

It is straightforward to verify that Algorithm 2 uses $O(|H| + |U| + nb)$ space which by Lemma 5 is $O(n \log n)$ w.h.p. Here we analyze the approximation ratio of the algorithm.

Let $M^\star$ be an arbitrary maximum matching of $G_{\geq \varepsilon m}$. Fixing an arbitrary maximum matching of G, each of its edges appears in $G_{\geq \varepsilon m}$ with probability $(1-\varepsilon)$, thus $\mathbf{E}|M^\star| \geq (1-\varepsilon)\mu(G)$. Now so long as $\mu(G) \geq 20\log(n)\varepsilon^{-2}$ and $\varepsilon < 1/2$ (which we can assume to hold as discussed in Section 2.1), we can prove a high probability lower bound on the size of $M^\star$ via a Chernoff bound on negatively associated random variables. See, e.g., [5, Lemma 2.2] for the proof of the following:

▶ **Observation 12.** *If $\mu(G) \geq 20\log(n)\varepsilon^{-2}$ and $\varepsilon < 1/2$, $\mathbf{Pr}[|M^\star| \geq (1-2\varepsilon)\mu(G)] \geq 1 - n^{-5}$.*

From now on, we condition on $G_{<\varepsilon m}$ which fixes subgraph H and matching $M^\star$. We only assume that $G_{<\varepsilon m}$ is chosen such that the high probability event of Observation 12 holds.

▶ **Assumption 13.** $|M^\star| \geq (1-2\varepsilon)\mu(G)$.

Other than Assumption 13, we do not need any other assumption on how $G_{<\varepsilon m}$ is chosen for the rest of the analysis of the approximation ratio.[3] By conditioning on the outcome of Phase I, the only randomization that will be left, is the order with which the edges of $G_{\geq \varepsilon m}$ arrive in the stream. For brevity, we do not explicitly write the conditioning on $G_{<\varepsilon m}$ for the rest of the section, but it should be noted that **all random statements are conditioned on the outcome of Phase I**.

Let $\mathcal{P}$ be the set of all augmenting paths of M_H in $S := M^\star \Delta M_H$ with length at most five. Note that since we regard H (and thus M_H) as given, the set $\mathcal{P}$ is deterministic (as it only depends on M_H and $M^\star$ and not on the order of edges in $G_{\geq \varepsilon m}$).

▶ **Observation 14.** *We have $|\mathcal{P}| \geq |M^\star| - \frac{4}{3} \cdot \mu(H)$.*

We use $G_{\text{II.A}}$ to denote the subgraph of G that arrives in Phase II.A and use $G_{\text{II.B}}$ to denote the subgraph of G that arrives in Phase II.B.

▶ **Definition 15.** *We say an augmenting path $P \in \mathcal{P}$ is "lucky" if the following holds:*

1. *If $P = \langle e_1 \rangle$ then $e_1 \in G_{II.B}$.*
2. *If $P = \langle e_1, e_2, e_3 \rangle$ then $e_1, e_3 \in G_{II.A}$.*
3. *If $P = \langle e_1, e_2, e_3, e_4, e_5 \rangle$ then $e_1, e_5 \in G_{II.A}$ and $e_3 \in G_{II.B}$.*

We denote the set of lucky augmenting paths in $\mathcal{P}$ by $\mathcal{P}_L$.

Note that the subset $\mathcal{P}_L$ of $\mathcal{P}$ is now random since it depends on the order of edges in $G_{\geq \varepsilon m}$. Lemma 16 below proves that a relatively large fraction of augmenting paths in $\mathcal{P}$ will turn out to be lucky with high probability. The proof is straightforward; see [2].

▶ **Lemma 16.** *It holds that* $\mathbf{Pr}\left(|\mathcal{P}_L| \leq \gamma^2(1-\gamma)|\mathcal{P}| - \sqrt{15\mu(G)\ln n}\right) \leq 2n^{-5}$.

Next, observe that in Phase II.B of Algorithm 2 where we iteratively discover augmenting paths, we do not have the whole subgraph $G_{\text{II.A}}$ and have stored only a subgraph T of $G_{\text{II.A}}$ in the memory. In addition, when finding augmenting paths we use only the current edge e of $G_{\text{II.B}}$ in Algorithm 2. Therefore, not all lucky paths are actually discoverable by Algorithm 2. This motivates our next definition for "discoverable paths".

[3] We note, however, that the randomization in $G_{<\varepsilon m}$ is crucial for arguing that the algorithm uses $O(n \log n)$ space. Here, however, we are only analyzing the approximation ratio.

▶ **Definition 17.** *We say an augmenting path P (not necessarily in $\mathcal{P}$) for M_H is "discoverable" if $|P| \leq 5$, all edges of P are in $M_H \cup T \cup G_{II.B}$, and P has ≤ 1 edge in $G_{II.B}$.*

The next lemma proves there are many vertex-disjoint discoverable augmenting paths, by relating them to the number of lucky augmenting paths $|\mathcal{P}_L|$.

▶ **Lemma 18.** *There is a set $\mathcal{Q}$ of vertex-disjoint discoverable augmenting paths of M_H with*

$$|\mathcal{Q}| \geq \frac{1}{2b+3}\left(|\mathcal{P}_L| - \frac{4}{b}\cdot\mu(H)\right).$$

Observe that $\mathcal{Q}$ is only a set of vertex-disjoint discoverable augmenting paths. However, since Algorithm 2 applies augmenting paths greedily and in an arbitrary order, the set of applied augmenting paths may be very different from $\mathcal{Q}$. The next claim shows that we can nonetheless relate the number of augmenting paths that Algorithm 2 applies to the size of $\mathcal{Q}$.

▷ Claim 19. Let $\mathcal{Q}$ be as in Lemma 18. Algorithm 2 applies at least $|\mathcal{Q}|/6$ augmenting paths in Phase II.B. In other words, $|M| \geq \mu(H) + \frac{1}{6}|\mathcal{Q}|$.

Next, we show that the output of Algorithm 2 is strictly larger than $\mu(H)$.

▶ **Lemma 20.** *There is an absolute constant $\varepsilon_0' > 0$ such that for any $\varepsilon < 0.01$, if $\mu(H) \leq 0.68\mu(G)$ then with probability $1 - 1/\text{poly}(n)$, we have $|M| \geq \mu(H) + \varepsilon_0' \cdot \mu(G)$.*

Proof. We have

$$|M| \overset{\text{Claim 19}}{\geq} \mu(H) + \frac{1}{6}|\mathcal{Q}| \overset{\text{Lemma 18}}{\geq} \mu(H) + \frac{|\mathcal{P}_L| - \frac{4}{b}\mu(H)}{6(2b+3)}. \tag{3}$$

On the other hand, by Lemma 16 we know that with $1 - 1/\text{poly}(n)$ probability,

$$\begin{aligned}
|\mathcal{P}_L| &> \gamma^2(1-\gamma)|\mathcal{P}| - \sqrt{15\mu(G)\ln n} && \text{(By Lemma 16)}\\
&= \frac{4}{27}|\mathcal{P}| - \sqrt{15\mu(G)\ln n} && \text{(Since } \gamma = 2/3\text{)}\\
&\geq \frac{4}{27}\left(|M^\star| - \frac{4}{3}\mu(H)\right) - \sqrt{15\mu(G)\ln n} && \text{(By Observation 14)}\\
&\geq \frac{4}{27}\left((1-2\varepsilon)\mu(G) - \frac{4}{3}\mu(H)\right) - \sqrt{15\mu(G)\ln n} && \text{(By Assumption 13)}\\
&> 0.0108\mu(G) - \sqrt{15\mu(G)\ln n} && (\varepsilon < 0.01 \text{ and } \mu(H) \leq 0.68\mu(G))\\
&> 0.01\mu(G). && \text{(Since } \mu(G) > c\log n \text{ for any desirably large constant } c.\text{)}
\end{aligned}$$

Replacing this high probability lower bound for $|\mathcal{P}_L|$ into (3) we get that w.h.p.,

$$\begin{aligned}
|M| &\geq \mu(H) + \frac{0.01\mu(G) - \frac{4}{b}\mu(H)}{6(2b+3)}\\
&> \mu(H) + 10^{-7}\mu(G). && \text{(Replacing } b = 500 \text{ and noting } \mu(H) \leq 0.68\mu(G)\text{.)}
\end{aligned}$$

This completes the proof. ◀

Lemma 20 states that the output of Algorithm 2 is strictly larger than $\mu(H)$. Moreover, the guarantee of Section 3 implies that $\mu(H)$ must be at least (almost) $\frac{2}{3}\mu(G)$ (or otherwise $\mu(H \cup U)$ is strictly larger than $2/3\mu(G)$). The combination of these implies the output of Algorithm 2 is at least $(2/3 + \Omega(1))\mu(G)$ proving Theorem 2.

Optimal Fine-Grained Hardness of Approximation of Linear Equations

Abstract

The problem of solving linear systems is one of the most fundamental problems in computer science, where given a satisfiable linear system (A, b), for $A \in \mathbb{R}^{n \times n}$ and $b \in \mathbb{R}^n$, we wish to find a vector $x \in \mathbb{R}^n$ such that $Ax = b$. The current best algorithms for solving dense linear systems reduce the problem to matrix multiplication, and run in time $O(n^\omega)$. We consider the problem of finding ε-approximate solutions to linear systems with respect to the L_2-norm, that is, given a satisfiable linear system $(A \in \mathbb{R}^{n \times n}, b \in \mathbb{R}^n)$, find an $x \in \mathbb{R}^n$ such that $||Ax - b||_2 \leq \varepsilon ||b||_2$. Our main result is a fine-grained reduction from computing the rank of a matrix to finding ε-approximate solutions to linear systems. In particular, if the best known $\tilde{O}(n^\omega)$ time algorithm for computing the rank of $n \times O(n)$ matrices is optimal (which we conjecture is true), then finding an ε-approximate solution to a dense linear system also requires $\tilde{\Omega}(n^\omega)$ time, even for ε as large as $(1 - 1/\text{poly}(n))$. We also prove (under some modified conjectures for the rank-finding problem) optimal hardness of approximation for sparse linear systems, linear systems over positive semidefinite matrices and well-conditioned linear systems. At the heart of our results is a novel reduction from the rank problem to a decision version of the approximate linear systems problem. This reduction preserves properties such as matrix sparsity and bit complexity.

1 Introduction

Algorithms for solving linear equations are one of the most fundamental primitives in computer science. Formally this is the problem where, given a linear system (A, b), where $A \in \mathbb{R}^{m \times n}$ is a real matrix and $b \in \mathbb{R}^m$ is a vector in the column space of A, we need to find a vector $x \in \mathbb{R}^n$ such that $Ax = b$. Gaussian elimination running in time[1] $O(n^3)$ was one of the first algorithms for this problem. Hopcraft and Bunch [9] reduced solving linear equations to fast matrix multiplication of two $n \times n$ matrices [35, 14, 34, 37, 17, 3] which can be done in $m(n) = n^\omega$, where ω is the matrix multiplication constant. The current best known upper bound on ω is approximately 2.372.. [3]. The best known algorithms for solving linear systems reduce the problem to matrix multiplication, but there is no known reduction in the other direction. We study the complexity of finding approximate solutions to linear systems (defined more precisely later) under the following conjecture:

[1] Here we are discussing algorithms and hardness over the Real RAM, unless stated otherwise. We discuss the Word RAM in more detail in Section 1.3.

▶ **Conjecture 1.1** (Rank-Finding Conjecture over RealRAM). *Finding the rank of a matrix $A \in \mathbb{R}^{m\times n}$ with $m = O(n)$ in RealRAM is $\Omega(n^\omega)$-hard.*

The problem of finding the rank of a matrix is a central problem in linear algebra. It is known that this problem can be reduced to fast matrix multiplication [9, 20], hence there exist algorithms for the rank-finding algorithm that run in time $O(n^\omega)$. There are known faster algorithms for restricted classes of matrices. For sparse matrices we know of $O(n^2)$ algorithms [36] and for low-rank matrices the $O(n^2+\text{rank}(A)^\omega)$-time algorithms of [21, 15, 11] run in time $n^{\omega-\Omega(1)}$ when $\text{rank}(A) = n^{1-\Omega(1)}$. No improvement over the $O(n^\omega)$-runtime is known for general matrices though. We conjecture that this run time is in fact *optimal* for general matrices. The rank-finding problem is equivalent to checking whether the determinant of a matrix is 0. We get some evidence towards the truth of our conjecture by considering the computational model of arithmetic circuits[2]: In a seminal work Baur and Strassen [7] linearly reduced the the problem of matrix multiplication to the problem of computing the determinant, thus showing that the latter problem requires arithmetic circuits of size as large as those required for matrix multiplication. Furthermore, this is a central conjecture because falsifying it (getting faster algorithms for the rank-finding problem) would yield better algorithms for important problems like finding the size of a maximum matching in a graph [26, 27]. [3] For some direct evidence: there has been a line of work by Musco et al [28] that gives algorithms to approximate the Schatten p-norms in time better that $O(n^\omega)$ when $p > 0$. But at $p = 0$, the problem of finding the Schatten p-norm is the same as finding the rank of the matrix, and their algorithms run in time $\Omega(n^\omega)$. Hence they are not able to beat the runtime of $O(n^\omega)$ to approximate the rank of a matrix, let alone determine it exactly.

Conjecture 1.1 allows us to study the hardness of linear system solving and related linear algebraic problems in the style of fine-grained complexity [38]. We show that the conjecture directly implies $\tilde{\Omega}(n^\omega)$-hardness of finding exact solutions to linear systems. One could hope to get faster algorithms though when allowed to find an approximate solution to the linear system. In this paper, we consider the problem of finding approximate solutions to linear systems. Specifically, we consider the following notion of approximation:

▶ **Definition 1.2** ($\varepsilon(n)$-Approximate Linear Search). *For a function $\varepsilon : \mathbb{N} \to [0, 1]$, the ε-Approximate Linear Search problem is defined as, given a satisfiable[4] linear system $(A \in \mathbb{R}^{O(n)\times n}, b)$, find an $x \in \mathbb{R}^n$ such that $||Ax - b||_2 \leq \varepsilon(n)||b||_2$.*

Note that the all 0's vector $x = 0^n$ is a 1-approximate solution to any linear system as $||A0^n - b|| = ||b||_2$. Our main result shows that doing barely better than the trivial approximation is hard: $(1 - 1/n^{100})$-Approximate Linear Search i.e. finding an x such that $||Ax - b||_2 \leq (1 - 1/n^{100})||b||_2$. is $\tilde{\Omega}(n^\omega)$ hard under Conjecture 1.1.

Spielman and Teng [32] gave nearly linear-time algorithms ($O(n^2 \log(1/\varepsilon(n)))$-time) for finding $\varepsilon(n)$-approximate solutions to Laplacian linear-systems and this result was built upon by many works [23, 12] to give such algorithms for other restricted classes of linear systems. Our result shows that under the hardness of the rank-finding problem, these algorithms cannot be extended to general linear systems. As mentioned above, we conditionally rule out $\tilde{O}(n^2)$-time algorithms for finding $\varepsilon(n)$-approximate solutions to general linear systems even for $\varepsilon(n) = 1 - 1/n^{100}$.

---

[2] Such a reduction is unknown in the RealRAM model.

[3] This is because maximum matching algorithms has a randomized reduction to the rank-finding problem.

[4] Keeping with the convention of promise problems, we will assume that when given an unsatisfiable instance the algorithm is allowed to output an arbitrary vector.

We also extend our results to give optimal conditional hardness of approximation (under analogous conjectures for the rank-finding problem) for restricted classes of linear systems: sparse linear systems, linear systems over positive-semidefinite matrices, and well-conditioned linear systems.

Recently there has been a lot of progress in relating the exact time-complexities of various problems that have polynomial running times. Although there has been success in a variety of graph-theoretic, geometric and string problems [31, 2, 6], there are very few fine grained reductions from the assumptions therein to linear algebraic problems, an example being, the work of Musco et al [28] that showed conditional lower bounds for spectrum approximation.

The theory of probabilistically checkable proofs [5, 18] was instrumental in proving a host of NP-hardness of approximation results. Though this theory was very successful in settling the time-complexity for approximation problems in NP, there are inherent limitations to extend these techniques to problems in P. Towards this, there has been recent progress for establishing hardness of approximation results for problems in P [1, 10, 22]. Our paper makes further progress in this direction.

1.1 Our results

The table below gives a summary of our hardness results over the RealRAM.

Table 1 ε-ALS refers to ε-Approximate Linear Search Problem. Our hardness results are under different conjectures, see statements for more details. All hardness results are for $\varepsilon = 1 - 1/n^{100}$, while all algorithms are for the much (apriori) harder exact search problem. For small values of condition number better algorithms are known [19] but for our regime of either unbounded or poly(n) condition number the above algorithms are the best known.

Problem	Hardness	Algorithm
ε-ALS	$\tilde{\Omega}(n^\omega)$ (Corollary 4.2)	$O(n^\omega)$ ([9])
Sparse ε-ALS	$\tilde{\Omega}(n^2)$ (Corollary 4.4)	$O(n^2)$([19])
Well-conditioned ε-ALS (Definition 4.13)	$\tilde{\Omega}(n^\omega)$ (Corollary 4.17)	$O(n^\omega)$ ([9])
ε-ALS with PSD matrix	$\tilde{\Omega}(n^\omega)$ (Corollary 4.10)	

We consider the question: Can one get fast approximate linear system solvers for general linear systems that run in time $\tilde{o}(n^\omega)$? We answer this question in the negative, under Conjecture 1.1. In this section we discuss the hardness result for solving general linear systems approximately (first row of Table 1). We discuss the other results of the table in Section 1.2.

We refer to the decision version of the ε-approximate linear search problem as Approximate Linear Decision problem (formally defined in Definition 1.4). We prove all our hardness results by showing a reduction from the rank-finding problem to the Approximate Linear Decision problem. We now state the lemma that proves our main reduction:

▶ **Theorem 1.3** (Main reduction: Informal). *There exists a randomized Turing reduction from the rank-finding problem on $A \in \mathbb{R}^{m\times n}$ to the $(1 - 1/n^{100})$-Approximate linear decision problem*[5] *on square matrices with sparsity $\tilde{O}(nnz(A))$ and dimension $O(\max(m, n))$. The reduction runs in time $\tilde{O}(nnz(A))$ and works with high probability.*

[5] The constant 100 here is arbitrary and in fact our reduction works for all constants.

Our reduction

At the heart of our results lies an "exact to approximate" reduction for *deciding* the satisfiability of linear systems. For showing hardness of finding approximate solutions, we are able to use this philosophy of "increasing the gap" between the YES and NO instances. We consider the following natural decision analogue of the ε-approximate search problem:

▶ **Definition 1.4** ($\varepsilon(n)$-Approximate Linear Decision problem [25]). *For a function $\varepsilon : \mathbb{N} \to [0, 1]$, given a linear system $(A \in \mathbb{R}^{m\times n}, b \in \mathbb{R}^m)$, with $m = O(n)$ and the promise that it falls into one of the following two sets of instances:*
1. *YES instance: There exists an $x \in \mathbb{R}^n$ such that $Ax = b$.*
2. *NO instances: For all $x \in \mathbb{R}^n$, $||Ax - b||_2 > \varepsilon(n)||b||_2$,*

decide whether (A, b) is a YES instance or a NO instance. We will refer to $\varepsilon(n)$ as the "gap" of the instance.

We show that the rank-finding problem reduces to the $(1 - 1/n^{100})$-approximate linear decision problem described above. We also show that the rank-finding problem is equivalent to the *exact* linear decision problem i.e. the problem of deciding satisfiability of linear systems. Hence our reduction can be interpreted as increasing the gap between the YES/NO cases from almost 0 (can be arbitrarily small as we are working over the RealRAM) to $1 - 1/n^{100}$. We increase this gap in two stages, first to $\varepsilon(n) = 1/n^{O(1)}$ and then to $1 - 1/n^{100}$. This gives conditional $\tilde{\Omega}(n^\omega)$-hardness of the $(1 - 1/n^{100})$-approximate linear decision problem.

Even though the main reduction discussed here is from the rank-finding problem, we are also able to give a search to search reduction from the $1/n^{O(1)}$-approximate linear search problem to the $(1 - 1/n^{100})$-approximate linear search (see Corollary 1.6).

We will now discuss the corollaries of the main reduction outlined above. Given Theorem 1.3, we perform a standard decision to search reduction (Lemma 4.1) to get optimal hardness of approximation for the $(1-1/n^{100})$-approximate *search* problem, under Conjecture 1.1. Thus under the rank finding conjecture, this reduction rules out all $(1-1/n^{100})$-approximation algorithms that run in time $\tilde{o}(n^\omega)$.

▶ **Corollary 1.5** (Informal). *Under Conjecture 1.1, for all constants $c > 0$, the $(1 - 1/n^{100})$-approximate linear search problem is $\tilde{\Omega}(n^\omega)$-hard in the RealRAM model of computation.*

The second step of our reduction can also be used to increase the gap of the $1/n^{O(1)}$-Approximate Linear *Search* problem from $1/n^{O(1)}$ to $1 - 1/n^{100}$. This gives us the following corollary:

▶ **Corollary 1.6** (Search to Search reduction: Informal). *If for any constant a there exists an $\tilde{O}(n^a)$-time algorithm for $(1 - 1/n^{100})$-approximate linear search problem then there exists an $\tilde{O}(n^a)$-time algorithm for the $1/n^{100}$-approximate linear search problem.*

Our hardness result is tight because there exist algorithms which solve the $(1 - 1/n^c)$-Approximate Linear Search problem in $O(n^\omega)$ over the RealRAM. In fact, one can solve the more general problem of linear regression, i.e. given a (possibly unsatisfiable) linear system (A, b), find an x that minimizes $||Ax - b||_2$, in time $O(n^\omega)$.

1.2 Extensions

We prove several extensions of our main theorem using the reduction discussed above. We can modify our main reduction so that it preserves the sparsity and condition number of the original instance to get the results for sparse and well-conditioned linear systems. To get hardness for PSD linear systems we need additional ideas beyond this reduction. We get the following results:

Sparse Linear Systems

Linear equation solving has also been studied in the case of sparse linear systems. We know of $O(\text{nnz}(A)n)$ time algorithms for solving a linear system $(A \in \mathbb{R}^{O(n)\times n}, b)$ where $\text{nnz}(A)$ denotes the number of non-zero entries of A, that use Conjugate Gradient Descent [19], so that when the sparsity of A is $\tilde{O}(n)$, these algorithms run in time $\tilde{O}(n^2)$. Our reduction (discussed above), preserves the sparsity of the original matrix A and thus reduces the exact problem over sparse linear systems to the approximate problem over sparse ones. We start with an analogous conjecture to Conjecture 1.1 for finding the rank of a sparse matrix:

▶ **Conjecture 1.7** (Rank-finding Conjecture for Sparse matrices over RealRAM)**.** *Finding the rank of a matrix $A \in \mathbb{R}^{m\times n}$ with $m = O(n)$ and $nnz(A) = \tilde{O}(n)$ in RealRAM is $\Omega(n^2)$-hard.*

Under the above conjecture we show (see Corollary 4.4) that solving $(1 - 1/n^{100})$-Approximate Linear Search problems on sparse linear systems is $\tilde{\Omega}(n^2)$-hard, which is optimal up to poly-logarithmic factors.

Positive Semi-Definite Linear systems

We give optimal hardness for the $(1 - 1/n^{100})$-approximate linear search problem when the matrix A is restricted to be positive semidefinite (see Corollary 4.10). Recently there has been a lot of work for getting nearly linear-time approximation algorithms for restricted classes of matrices. For a slightly more restricted class of linear systems than PSD ones, called Strongly Diagonally Dominant (SDD) systems, Spielman and Teng gave near-linear time approximate solvers [32], leaving near-linear time approximation algorithms for PSD linear systems as the next open problem. In fact, resolving the time-complexity for PSD linear systems was in mentioned as an open problem in [4], where they gave unconditional hardness for PSD linear systems for sublinear-time algorithms. Interestingly, we show that under Conjecture 4.6, such solvers are not possible for PSD linear systems, thus giving a conditional separation of the time complexity required for approximately solving SDD linear systems versus PSD ones.

Well-conditioned linear systems

We now turn our attention to the problem of solving well-conditioned (polynomially bounded condition number) linear systems approximately. In Section 4.4, we give optimal conditional hardness of approximation for linear systems over matrices with polynomially bounded condition number under the $\tilde{\Omega}(n^\omega)$-hardness of the well-conditioned rank-finding problem.

We also prove the following analogue of Corollary 1.6 which amplifies the gap for the *search* problem on well-conditioned matrices:

▶ **Corollary 1.8.** *If there exists as $\tilde{O}(n^a)$ time algorithm for Well-conditioned $(1 - 1/n)$-Approximate Linear Search then there exists a $\tilde{O}(n^a)$-time algorithm for Well-conditioned $(1/n)$-Approximate Linear Search problem.*

1.3 Reductions over the WordRAM

Our main reduction can be modified to preserve the bit-complexity of the original matrix. In Section 5, we show analogous results for all the problems considered above over the WordRAM. We show that under analogous conjectures for the rank-finding problem over

the WordRAM, the problem of finding $(1 - 1/n^{100})$-approximate solutions to linear systems with bit-complexity $O(\log n)$ is $\tilde{\Omega}(n^\omega)$-hard over the WordRAM. Our hardness result is tight up to polylogarithmic factors because there exist $\tilde{O}(n^\omega)$-time algorithms for exactly solving linear systems on the WordRAM [33, 29, 8].

1.4 Further applications and related work

Recently, there has been a lot of progress on the algorithmic front for finding approximate solutions to restricted classes of linear systems (A, b). In a breakthrough work, Spielman and Teng [32] obtained $\tilde{O}(\text{nnz}(A)\log(1/\varepsilon(n)))$-time algorithms for finding $\varepsilon(n)$-approximate solution to Laplacian systems and Strongly Diagonally Dominant (SDD) systems. This result was followed up by algorithms for more general classes of linear systems such as Connection Laplacians [23] and Directed Laplacian systems [13]. This raised the hope that such approximation algorithms could be obtained for more general classes of matrices such as truss stiffness matrices and total variation matrices. Kyng and Zhang [25] showed that such algorithms for these slightly more general classes would imply approximation algorithms for general linear systems. Therefore, by composing our reduction with theirs, one immediate corollary we get is that solving approximately for these classes of restricted linear systems is as hard as the rank-finding problem.

In [24] the authors prove conditional hardness for the problems of Packing/Covering Linear Programs based on the hardness of approximately solving general linear equations. Prior to our work there was no evidence of hardness for approximately solving linear equations. Our results therefore imply hardness for these problems under the rank-finding problem, which is a more well-studied problem in our opinion.

Organization

In section 2 we introduce notation and basic definitions that will be used throughout the paper. In Section 3 we give a proof of our main reduction (Theorem 3.1). In Section 4, we show conditional hardness for finding approximate solutions to linear systems over the Real RAM. We then extend these conditional hardness results to restricted classes of linear systems: Section 4.2 considers sparse linear systems, Section 4.3 considers positive semidefinite linear systems, and finally Sec 4.4 considers well-conditioned linear systems. In Section 5 we show the analogues of these results over the WordRAM model of computation.

All the proofs are deferred to the full version of the paper.

2 Preliminaries

Below is some notation that will be used throughout:

Notation

We will use $\text{nnz}(A)$ for to denote the sparsity of a matrix A and we will assume that $\text{nnz}(A) \geq \max(n, m)$ for $A \in \mathbb{R}^{m\times n}$. We will call a matrix $A \in \mathbb{R}^{m\times n}$ sparse if $\text{nnz}(A) = \tilde{O}(\max(m, n))$. We will use $\kappa(A)$ to denote the condition number of a matrix A. By bit complexity of A or $\mathcal{B}(A)$ we will refer to maximum bit complexity of any entry in the matrix/vector A. We will use $\leq_T$ to denote Turing reductions. Most of our Turing reductions run in quasi-time linear in the input size. We say $\langle a, b\rangle$ to denote the inner product of a and b i.e. $\sum_i a_i b_i$. We denote $W^\perp$ to denote the subspace orthogonal to the subspace W. By $P_W(b)$ we denote the projection of b on the vector space W. For a matrix M we denote its column space by

colspace(M). By $A^\dagger$ we mean the pseudoinverse of a matrix A. For a matrix $A \in \mathbb{R}^{m\times n}$ by $\Pi_A = A(AA^T)^\dagger A^T$ we mean the linear operator such that for all $x \in \mathbb{R}^m$, $\Pi_A(x)$ is the projection of x on colspace(A). By $g = \tilde{O}(f)$ we mean $g = O(f \cdot \text{polylog}(f))$. By $g = \tilde{\Omega}(f)$ we mean $g = \Omega(f/\text{polylog}(f))$. Whenever not specified by algorithms we mean randomized algorithms. We use w.h.p. to denote a probability of $1 - 1/n^{\log n}$, where n is the input size under consideration.

We refer to the exact version of the $\varepsilon(n)$-Approximate Linear Search problem as the Linear Search Problem. Similarly we refer to the exact version of the $\varepsilon(n)$-Approximate Linear Decision problem as the Linear Decision problem.

3 Proof of Main Reduction (Theorem 1.3)

In this section we will prove the reduction from the rank-finding problem to the approximate version of the linear decision problem. For simplicity, throughout this section we work on the RealRAM model of computation and wherever we do not state it we assume that this is the case, so we *do not* discuss the bit complexity of the reductions. Our reduction can be modified to work on the WordRAM which we do in Section 5.

▶ **Theorem 3.1** (Restatement of Theorem 1.3). *For all constants $c > 0$, there exists a randomized Turing reduction in the RealRAM model of computation, from the rank-finding problem on $A \in \mathbb{R}^{m\times n}$ to the $(1 - 1/n^c)$-Approximate linear decision problem on $(A' \in \mathbb{R}^{n'\times n'}, \mathbf{1}^{n'})$, with dimension $n' = O(\max(m, n))$ and sparsity $\tilde{O}(nnz(A))$, where in the YES case we have the additional property that the matrices produced have full rank. The reduction runs in time $\tilde{O}(nnz(A))$, produces polylog(mn) instances of the approximate linear decision problem and works with high probability.*

We will prove this reduction in three steps:

1. Lemma 3.3: Rank-Finding Problem $\leq_T$ Full Rank problem (see Definition 3.2)
2. Lemma 3.4: Full Rank problem $\leq_T$ $(1/n^{O(1)})$-Approximate linear decision problem
3. Lemma 3.5: $1/n^{O(1)}$-Approximate linear decision problem $\leq$ $(1 - 1/n^c)$-Approximate linear decision problem

Given the lemmas, it will be straightforward to combine these reductions to get that the linear decision problem reduces to the $(1 - 1/n^c)$-Approximate linear decision problem. Let us now show each of the steps stated above. We will prove the first reduction from the rank-finding problem to the full-rank problem. This is similar to a reduction by Wiedemann [36] for finite fields. Let us formally introduce the Full rank problem.

▶ **Definition 3.2** (Full Rank Problem.). *Given a matrix $A \in \mathbb{R}^{n\times n}$, is rank$(A) = n$?*

The intuition behind the following reduction from the rank-finding problem to the full-rank problem is the following: For a matrix $A \in \mathbb{R}^{m\times n}$ with $m > n$ and rank$(A) = k < n$, adding t "random" columns will give a full column rank matrix if and only if $t \geq n - k$. Hence we can binary search for the first value of t which gives us a full column rank matrix, yielding k.

▶ **Lemma 3.3.** *There exists a randomized Turing reduction which works w.h.p. from the Rank-Finding problem on $A \in \mathbb{R}^{m\times n}$ to the Full rank problem, that runs in time $\tilde{O}(nnz(A))$ and produces $O(\log m)$ instances of the Full rank problem, such that all instances of the matrices produced have dimension $O(\max(m, n)) \times O(\max(m, n))$ and sparsity $\tilde{O}(nnz(A))$.*

We will now prove that the full rank problem reduces to the $(1/n^{O(1)})$-Approximate linear decision problem. The idea behind the proof is that for a full-rank square matrix $A \in \mathbb{R}^{n\times n}$ every vector $b \in \mathbb{R}^n$ belongs in the column space of A and hence the linear system (A, b) is satisfiable. On the other hand if $\text{rank}(A) < n$ we expect a random vector b to be outside the column space of A and hence we expect the linear system (A, b) to be unsatisfiable. We show a strengthened version of the previous statement by proving that w.h.p. for a random Gaussian vector b, it holds that for all x, $||Ax - b|| \geq \varepsilon(n)||b||$ for some $\varepsilon(n) = 1/n^{O(1)}$. We also show that we can rescale the rows of the linear system (A, b) to get the system $(A', \mathbf{1}^n)$ while maintaining the property that $||A'x - \mathbf{1}^n|| \geq \varepsilon(n)||\mathbf{1}^n||$. We perform the rescaling to obtain $b = \mathbf{1}^n$ as that will simplify our later reductions.

▶ **Lemma 3.4.** *Consider a matrix $M \in \mathbb{R}^{n\times n}$. There exists a randomized Turing reduction from the problem of checking whether M has full rank to the Linear Decision $(1/n^{O(1)})$-Approximation problem. The reduction runs in time $\tilde{O}(nnz(M))$, produces polylog(n) instances of the form $(M' \in \mathbb{R}^{n\times n}, \mathbf{1}^n)$ where in the YES case M' is a full rank matrix, and works w.h.p.*

We will now show that one can amplify the error in the NO case from $1/n^{O(1)}$ to $1 - 1/n^c$ for all constants c.

The following lemma works for all $\varepsilon(n), \delta(n)$, but we only state it for $\varepsilon(n) = 1/n^{O(1)}, \delta(n) = 1/n^c$ to maintain consistency with the later sections in which we will work over WordRAM.

▶ **Lemma 3.5.** *For all constants c and $\varepsilon(n) = 1/n^{O(1)}, \delta(n) = 1/n^c$, there exists a deterministic many-one reduction from the $\varepsilon(n)$-Approximate linear search problem on the linear system $(A \in \mathbb{R}^{n\times n}, \mathbf{1}^n)$ to the $(1 - \delta(n))$-Approximate linear search problem on the linear system $(A' \in \mathbb{R}^{n\times n}, \mathbf{1}^n)$, with $nnz(A') = O(nnz(A))$. The reduction runs in time $\tilde{O}(nnz(A))$. Additionally if A is full rank then the matrix A' produced is also full rank.*

As this is a deterministic many-one reduction we also get a gap-amplifying reduction for the $\varepsilon(n)$-Approximate linear decision problem with the same parameters.

We can now combine all the lemmas above to get the proof of Theorem 3.1.

Proof of Theorem 3.1. We have proved the following sequence of reductions which preserve sparsity:

1. Lemma 3.3: Linear decision problem $\leq_T$ Full rank problem
2. Lemma 3.4: Full rank problem $\leq_T$ $1/n^{O(1)}$-Approximate linear decision problem
3. Lemma 3.5: $1/n^{O(1)}$-Approximate decision problem $\leq_T$ $(1 - 1/n^c)$-Approximate linear decision problem.

Note that in the YES case of Full-Rank problem we have a square full rank matrix, and this is propagated through Lemma 3.4 and Lemma 3.5 hence the final instance we produce has a full rank matrix in the YES case. Since each of these reductions work whp, one can compose them to get the theorem statement. ◀

4 Hardness of finding L_2-Approximate solutions on Real RAM

In this section, we elaborate on the implications of our main reduction from the previous section (Theorem 3.1). Below is the map of reductions we showed in the previous sections. We will introduce conjectures for the Rank-finding problem in this section and given the reductions, the conjectures will imply conditional hardness of the approximate linear search problem.

All the results in this section are for the RealRAM but can be obtained over the WordRAM too. In Section 5, we prove the conditional hardness of the approximate linear search problem over general matrices in the WordRAM model.

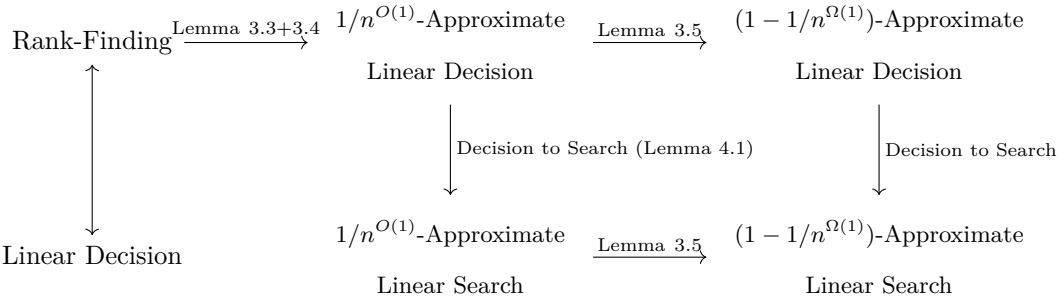

Figure 1 Reductions on RealRAM preserving sparsity (up to polylog(n) factors) and dimension (up to constant factors).

Note that all the lemmas pointed out here (except for the decision to search reduction) were shown in the previous section. The decision to search reduction is straightforward to carry out in the RealRAM and we formally prove it in Lemma 4.1.

In the sections below we discuss the hardness of the approximate linear search problem over general matrices, and then the case of restricted classes of linear systems - sparse linear systems and linear systems given by positive-semidefinite matrices. Our results give tight conditional hardness for all the problems considered.

4.1 General linear systems

We base the hardness result for the approximate linear search problem under the following conjecture for the rank-finding problem:

We now prove the search to decision reduction.

▶ **Reminder of Conjecture 1.1** *Finding the rank of a matrix $A \in \mathbb{R}^{m\times n}$ with $m = O(n)$ in the RealRAM model of computation is $\tilde{\Omega}(n^{\omega})$-hard.*

▶ **Lemma 4.1.** *If there exists a $O(t(n))$ time algorithm to solve ε-Approximate linear search problem for a linear system with sparsity s then there exists a $O(t(n) + sn)$ time algorithm to solve ε-Approximate linear decision problem for linear system with sparsity s.*

Proof. We will follow the standard decision to search reductions which proceed by solving and then confirming. Suppose we are given a linear system (A, b) with $\text{nnz}(A) = s$ for which we want to solve ε-Approximate linear decision problem.

Suppose it is a YES instance i.e. there exists an exact solution, then by the assumed algorithm for ε-Approximate linear search problem we can find an x' such that $||Ax' - b||_2 \leq \varepsilon||b||_2$. This can be done in $O(t(n))$ time.

Suppose instead we were in the NO case i.e. for all x', $||Ax' - b||_2 > \varepsilon||b||_2$ i.e. there exists no x' such that $||Ax' - b||_2 \leq \varepsilon||b||_2$.

Hence checking whether $||Ax' - b||_2 \leq \varepsilon||b||_2$ is true of not for the x' returned by the assumed algorithm for ε-Approximate linear search problem will let us solve the ε-Approximate linear decision problem. We can check if $||Ax' - b||_2 \leq \varepsilon||b||_2$ in time $O(sn)$. Hence the total running time is $O(t(n) + sn)$. ◀

Combining the main reduction (Theorem 3.1) with a decision to search reduction (Lemma 4.1) we get optimal conditional hardness for the $(1-1/n^c)$-approximate linear search problem under Conjecture 1.1:

▶ **Corollary 4.2** (Corollary 1.5 restated). *Under Conjecture 1.1, for all constants $c > 0$, the $(1-1/n^c)$-approximate linear search problem is $\tilde{\Omega}(n^\omega)$ hard in the RealRAM model of computation. Moreover, this remains true even when the matrix A in the given linear system (A, b) is square and has full rank.*

This conditional hardness result is tight as the best algorithms for (exactly) solving general linear systems run in time $\tilde{O}(n^\omega)$ [9].

The next corollary is a search to search reduction between the approximate linear search problem with small gap to one with a larger gap. This is a direct consequence of Lemma 3.5. Recall that in the proof of Lemma 3.1 we used Lemma 3.5 to amplify the gap of the approximate linear *decision* problem. Lemma 3.5 is in fact more general and can amplify the gap of the approximate linear *search* problem too (as noted in the lemma statement):

▶ **Corollary 4.3** (Corollary 1.6 restated). *If for any constant $c > 0$ and a there exists an $\tilde{O}(n^a)$-time algorithm for $(1-1/n^c)$-Approximate Linear Search problem then for all constants d there exists a $\tilde{O}(n^a)$-time algorithms for $1/n^d$-Approximate Linear Search problem.*

Even though this is stated as a reduction, one could potentially use the above corollary to get better algorithms for the $1/n^{O(1)}$-approximate linear search problem.

4.2 Sparse linear systems

In this section, we give analogous results for sparse linear systems. Here we use the fact that our main reduction (Theorem 3.1) preserves the sparsity of the original matrix. Hence if we assume the hardness of the rank-finding problem over sparse matrices, we get conditional hardness for approximately solving sparse linear systems.

▶ **Reminder of Conjecture 1.7** *Finding the rank of a matrix $A \in \mathbb{R}^{m\times n}$, where $m = O(n)$ and $nnz(A) = \tilde{O}(n)$, in the RealRAM model of computation, is $\tilde{\Omega}(n^2)$-hard.*

Combining the main reduction (Theorem 3.1) with a decision to search reduction we get optimal conditional hardness for the $(1-1/n^c)$-approximate linear search problem on sparse matrices, under Conjecture 1.7:

▶ **Corollary 4.4.** *Under Conjecture 1.7, for all constants $c > 0$, the $(1-1/n^c)$-approximate linear search problem (A, b) with $nnz(A) = \tilde{O}(n)$ is $\tilde{\Omega}(n^2)$ hard, in the RealRAM model of computation. Moreover, this remains true even when the matrix A is square and has full rank.*

Note that here we crucially used the fact that the main reduction preserves the sparsity of the original matrix. This conditional hardness result is tight as the best algorithms for (exactly) solving linear equations run in time $\tilde{O}(\text{nnz}(A)\cdot n)$ [19] which is equal to $\tilde{O}(n^2)$ for sparse matrices.

Now we state the search to search reduction for the approximate linear search problem over sparse matrices which follows from Lemma 3.5. This reduction amplifies a small gap to a large gap.

▶ **Corollary 4.5.** *If for any constant $c > 0$ and a there exists an $\tilde{O}(n^a)$-time algorithm for the $(1-1/n^c)$-Approximate Linear Search problem over (A, b) then for all constants d there exists an $\tilde{O}(n^a)$-time algorithm for the $1/n^d$-Approximate Linear Search problem over (A', b) where $nnz(A') = nnz(A)$.*

4.3 Positive semidefinite linear systems

In this section, we show hardness for dense linear systems over PSD matrices. To do so, we need some additional ideas beyond our main reduction and also a conjecture for solving linear systems on matrices with intermediate sparsities. This conjecture also allows us to show optimal conditional hardness of approximately solving linear systems (A, b) for any sparsity.

▶ **Conjecture 4.6** (Rank-finding conjecture for all sparsities)**.** *Finding the rank of a matrix $A \in \mathbb{R}^{m\times n}$, where $m = O(n)$, is $\min(\tilde{\Omega}(nnz(A)\cdot n), \tilde{\Omega}(n^\omega))$ hard in the RealRAM model of computation.*

The current best known algorithms for the Rank-Finding problem ($A \in \mathbb{R}^{O(n)\times O(n)}$) runs in time $\min(\text{nnz}(A)n, n^\omega)$. The above conjecture assumes that this is optimal. We can prove the following theorem directly by combining Conjecture 4.6 and Lemma 5.5.

▶ **Corollary 4.7.** *Under Conjecture 4.6, for all constants $c > 0$, $(1 - 1/n^c)$-approximate linear search problem (A, b), is $\min(\tilde{\Omega}(nnz(A)\cdot n), \tilde{\Omega}(n^\omega))$ hard in the RealRAM model of computation. Moreover, this remains true even when the matrix A in the given linear system (A, b) has full rank.*

The next lemma reduces the approximate linear search problem for intermediate sparsities to approximate linear search problem on dense PSD matrices. It's proof exploits the fact that the algorithm of Yuster and Zwick [39] does matrix multiplication of two matrices A, A' in $O(\min(n^\omega, z^{.7}n^{1.2} + n^2))$ time where $z \geq \text{nnz}(A)$ and $z > \text{nnz}(A')$. This is faster than the best algorithm for solving linear systems (A, b) which runs in $O(\min(n^\omega, zn))$ where $z = \text{nnz}(A)$ for certain sparsities. Specifically we will use the following result from Yuster and Zwick [39]:

▶ **Theorem 4.8** (Yuster and Zwick [39], See Theorem 3.1 and discussion)**.** *Assuming $\omega > 2$ there exists constants $.1 \geq \gamma, \gamma' > 0$ such that for two matrices $A, B \in \mathbb{R}^{O(n)\times O(n)}$ which satisfy $nnz(A), nnz(B) \leq n^{\frac{\omega+1}{2}-\gamma}$ can be multiplied in time $O(n^{\omega-\gamma'})$.*

This allows to do the following reduction:

▶ **Lemma 4.9.** *Assuming $\omega > 2$, there exists constants $.1 \geq \gamma, \gamma' > 0$ and a reduction running in time $O(\max(n^{\omega-\gamma'}, n^{\omega-\gamma}))$ from $(1 - \delta(n))$-approximate linear search problem $(V \in \mathbb{R}^{n\times n}, b)$ with $nnz(V) \leq n^{\frac{\omega+1}{2}-\gamma}$ to $(1 - \delta(n))$-approximate linear search problem (V', b) such that the matrix V' is PSD.*

We now compose the above reduction with Conjecture 4.6 to get the following tight conditional hardness.

▶ **Corollary 4.10.** *Under Conjecture 4.6, for all constants $c > 0$ $(1 - 1/n^c)$-approximate linear search problem (A, b) where A is restricted to be a PSD matrix, is $\tilde{\Omega}(n^\omega)$ hard in the RealRAM model of computation. Moreover, this remains true even when the matrix A in the given linear system (A, b) has full rank.*

4.4 Well-Conditioned Linear Systems

In this section, we show conditional hardness of approximately solving well-conditioned linear systems. The condition number of a full-rank square matrix is the ratio of its maximum and minimum singular values. If the entries of a matrix are all $O(\log n)$-bits then the condition

number of this matrix is at most exponential in n (this is true even for rectangular full column-rank matrices). Therefore linear systems over matrices with polynomially-bounded condition number could be significantly easier to solve than general linear systems.

For the case of certain restricted classes of matrices such as directed Laplacians, the algorithm of Cohen et al [12] for the $\varepsilon(n)$-approximate linear search problem runs in time $\tilde{O}(\text{nnz}(A)\log(\kappa(A)/\varepsilon(n)))$ which is a near-linear time algorithm for $\kappa(A) = \text{poly}(n)$. This is a significant improvement over algorithms for directed Laplacian systems with no bound on the condition number (which run in time $\tilde{O}(n^{\omega})$).

But for general systems no such improvement is known! Conjugate gradient [19] runs in time $\tilde{O}(\text{nnz}(A))$, when $\kappa(A) = \text{poly}\log n$, whereas when $\kappa(A) = \text{poly}(n)$ this algorithm gives *no improvement* over the algorithm for general matrices.

We show that if we assume that the rank-finding problem is hard over well-conditioned matrices ($\kappa(A) = \text{poly}(n)$), then the approximate linear search problem is hard to solve over well-conditioned linear systems. The proof goes along the same lines as that for general matrices: we show in Lemmas 4.15 and 4.16 that our main reduction (Theorem 3.1) in fact preserves the condition number of our original matrix. Then as a corollary we obtain the conditional hardness for approximately solving well-conditioned linear systems. Note that we show all the results here over the RealRAM but they can be easily modified to work on the WordRAM too.

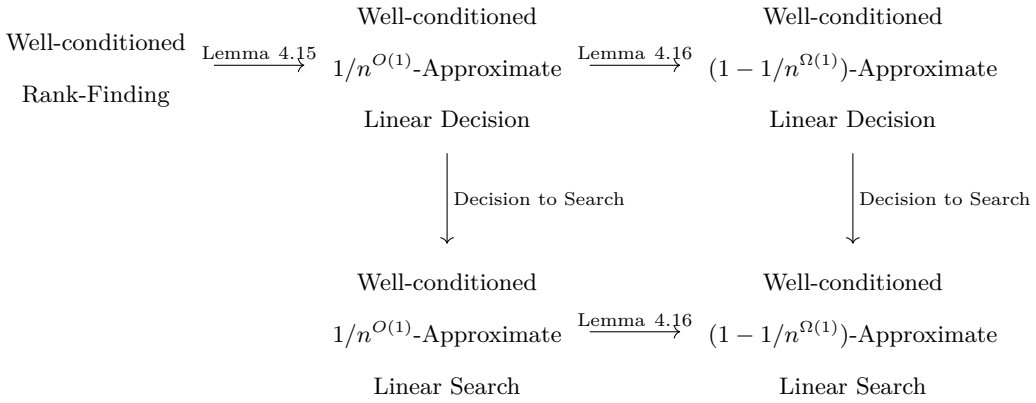

Figure 2 Reductions on the RealRAM preserving sparsity (up to polylog(n) factors), dimension (up to constant factors) and condition-number (upto poly(n) factors). One difference from the results from the previous sections is that we no longer have the equivalence for the Rank-Finding Problem and the Linear Decision problem for Well-conditioned matrices.

Before diving into the reduction, we will formally define all the problems used in the reduction-map above. As discussed in the definition of the condition-number, the condition-number is bounded only when the matrix has full column-rank, therefore in all the definitions below the matrices considered have dimension $m \times n$ with $n \leq m$.

▶ **Definition 4.11** (Well-conditioned Rank-Finding Problem)**.** *Given a matrix $A \in \mathbb{R}^{m\times n}$ where $n \leq m \leq O(n)$, with the promise that it falls into one of the following two sets of instances:*

1. *YES instances: $rank(A) = n$ and $\kappa(A) \leq poly(n)$.*
2. *NO instances: $rank(A) < n$*

decide whether A is a YES instance or a NO instance.

▶ **Definition 4.12** (Well-conditioned Full Column-Rank Problem). *Given a square matrix $A \in \mathbb{R}^{m \times n}$, where $n \leq m$, with the promise that it falls into one of the following two sets of instances:*

1. *YES instances: col-rank$(A) = n$ and $\kappa(A) \leq poly(n)$.*
2. *NO instances: col-rank$(A) < n$*

decide whether A is a YES instance or a NO instance.

Note that the Well-conditioned Rank-finding problem easily reduces to the Well-conditioned Full Column-rank problem. This is because the YES instances of the former always have full column-rank by definition. In fact, we can also reduce the well-conditioned rank-finding problem to the well-conditioned *full-rank* problem on *square* matrices, by adding random columns, since this operation preserves the condition-number [16]. For simplicity of presentation we do not perform this operation and continue to work with full column-rank and (possibly) rectangular matrices throughout.

Next we formally introduce the search and decision problems on well-conditioned linear systems:

▶ **Definition 4.13** (Well-conditioned $\varepsilon(n)$-Approximate Linear Search Problem). *For a function $\varepsilon : \mathbb{N} \to [0, 1]$, given a satisfiable linear system (A, b) with $A \in \mathbb{Z}^{m \times n}$ for $n \leq m$ and $\kappa(A) = poly(n)$ find an assignment x such that $||Ax - b|| \leq \varepsilon(n)||b||$*

▶ **Definition 4.14** (Well-Conditioned $\varepsilon(n)$-Approximate Linear Decision problem). *For a function $\varepsilon : \mathbb{N} \to [0, 1]$, given a linear system $(A \in \mathbb{Z}^{m \times n}, b \in \mathbb{Z}^n)$ for $n \leq m$, with the promise that it falls into one of the following two sets of instances:*

1. *YES instance: There exists an $x \in \mathbb{Q}^n$ such that $Ax = b$ and A is well-conditioned.*
2. *NO instances: For all $x \in \mathbb{R}^n$, $||Ax - b||_2 > \varepsilon(n)||b||_2$,*

decide whether (A, b) is a YES instance or a NO instance.

We will now show our main reduction from the Well-conditioned Rank-finding problem to the Well-conditioned $(1 - 1/n^c)$-approximate linear decision problem. As noted above the Well-conditioned Rank-finding problem reduces to the Well-conditioned Full Column-Rank problem, so we will show a reduction from the latter to the approximate linear decision problem. To do so, we will show that the proofs in Section 3 preserve the condition-number of the original matrix.

Let us start with showing that "well-conditioned" property is preserved in the reduction in Lemma 3.4.

▶ **Lemma 4.15.** *There exists a randomized Turing reduction from the Well-conditioned Full Column-Rank Problem on $M \in \mathbb{Z}^{m \times n}$ to the Well-conditioned $(1/n^{O(1)})$-Approximate Linear Decision problem. The reduction produces polylog(n) instances of the form $(M', \mathbf{1}^n)$ where $M' \in \mathbb{Z}^{m \times n}$ and $\kappa(M') = poly(n)$, runs in time $\tilde{O}(nnz(M))$, and works w.h.p.*

Next let us show that the "well-conditioned" property is preserved in the reduction in Lemma 3.5.

▶ **Lemma 4.16.** *For all constants $c, d > 0$, there exists a deterministic many-one reduction from the Well-conditioned $1/n^d$-Approximate linear search problem on the linear system $(A \in \mathbb{Z}^{m \times n}, \mathbf{1}^n)$ to the Well-conditioned $(1 - 1/n^c)$-Approximate linear search problem on the linear system $(A' \in \mathbb{Z}^{n \times n}, \mathbf{1}^n)$, with $nnz(A') = O(nnz(A))$ and $\kappa(A') = poly(n)$.*

As this is a deterministic many-one reduction we also get a gap-amplifying reduction for the $\varepsilon(n)$-Approximate linear decision problem with the same parameters.

Combining the two lemmas above we get the well-conditioned analogue of the main reduction from the Rank-finding problem to the $(1 - 1/n^c)$-approximate linear decision problem. We can now apply a decision to search reduction to get conditional hardness for approximately solving linear systems over well-conditioned matrices:

▶ **Corollary 4.17.** *For all constants c, assuming $\tilde{\Omega}(n^\omega)$ hardness of the well-conditioned rank-finding problem we get that the well-conditioned $(1 - 1/n^c)$-approximate linear search problem is $\tilde{\Omega}(n^\omega)$-hard.*

We also state the following search to search reduction which follows directly from Lemma 4.16:

▶ **Corollary 4.18.** *For all constants $a, c, d > 0$, if there exists an $\tilde{O}(n^a)$ time algorithm for well-conditioned $(1 - 1/n^c)$-approximate linear search then there exists an $\tilde{O}(n^a)$-time algorithm for the well-conditioned $(1/n^d)$-approximate linear search problem.*

5 Hardness of finding L_2-Approximate solutions on Word RAM

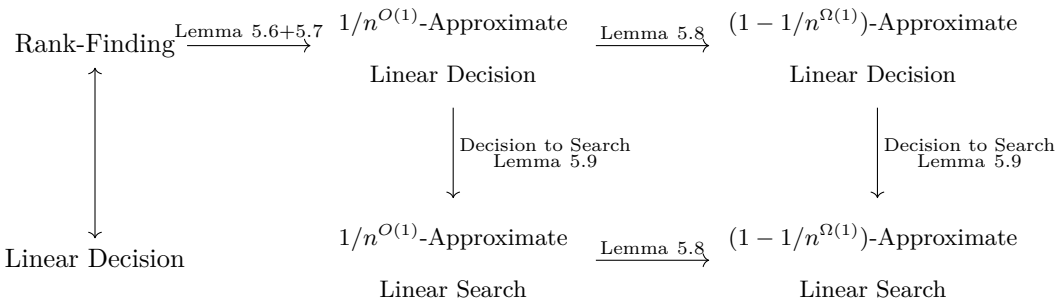

Figure 3 Reductions on WordRAM preserving sparsity (up to polylog(n) factors), dimension (up to constant factors) and bit complexity of entries (up to constant factors).

In Section 4 we gave conditional hardness for solving linear equations in RealRAM. In this section we will give hardness for WordRAM through some modifications of the reduction for RealRAM. We will assume that for a matrix/vector of dimension $m \times n$ in this section that all input entries are from $\mathbb{Z}$ and have $O(\log mn)$ bits in.

The reduction in RealRAM does not directly work for WordRAM as:

1. As we are in WordRAM we need to argue that the final problem instance has bounded bit complexity if the starting problem has bounded bit complexity. To verify this we show that this is true for all the steps of the reduction.
2. We sampled a random gaussian vector in the reduction (Lemma 3.4), this is not possible in the WordRAM. We will get around this issue (in Lemma 5.7) by sampling a random vector whose each entry is a random integer from a predefined range.
3. The decision to search reduction for RealRAM (Lemma 4.1) was nearly trivial. This is not the case for WordRAM as the solution can have large bit complexity and hence given a solution directly substituting to check if it is a good solution or not may require too much time. We give an alternative decision to search reduction in WordRAM in Lemma 5.9.

We start by defining the Linear Decision Problem over Word-RAM:

▶ **Definition 5.1** (Linear Decision Problem over Word-RAM). *Given a linear system (A, b) with $A \in \mathbb{Q}^{m\times n}$ with $\mathcal{B}(A) = O(\log mn)$, distinguish between the following two sets of instances:*

- *YES instances: There exists an x such that $Ax = b$.*
- *NO instances: For all x, $Ax \neq b$.*

We will consider the following conjecture (analogous to Conjecture 1.1) for the Word RAM:

▶ **Conjecture 5.2** (Rank-Finding Conjecture on WordRAM). *There exists no $\tilde{o}(n^\omega)$-time randomized algorithm for finding the rank of a matrix $A \in \mathbb{Z}^{m\times n}$ with $m = O(n)$ and $\mathcal{B}(A) = O(\log n)$, in the WordRAM model of computation.*

The conjecture is tight as using an easy randomized reduction [33] Rank over integers with $O(\log n)$ bit complexity can be reduced to rank over finite fields GF(poly(n)) which gives a $\tilde{O}(n^\omega)$ time randomized algorithm on WordRAM.

We will prove the following main theorem:

▶ **Corollary 5.3** (Hardness of solving linear equation on WordRAM). *For all constant $c > 0$, under Conjecture 1.1, there does not exist a $\tilde{o}(n^\omega)$ time randomized algorithm for the $(1 - 1/n^c)$-approximate linear search problem (A, b) with $\mathcal{B}(A) = O((c + 1)\log n)$ in the WordRAM model of computation. Moreover, this remains true even when the matrix A in the given linear system (A, b) has full rank.*

The conditional hardness in the above theorem is tight as there exists $O(n^\omega)$ time algorithms for exactly solving linear equations over $\mathbb{Z}$ in WordRAM [33, 29, 8].

We are also able to establish the following corollary of one of the intermediate steps in our reduction (Lemma 5.8) which reduces approximately solving linear systems with low error to approximately solving linear systems with barely non-trivial error.

▶ **Corollary 5.4.** *For all constant $c, d > 0$, if over WordRAM there exists as $\tilde{O}(n^a)$ time algorithm for $(1-1/n^c)$-Approximate Linear Search then there exists a $\tilde{O}(n^a)$-time algorithms for $(1/n^d)$-Approximate Linear Search problem.*

Analogous to Theorem 3.1 we will prove a reduction from the rank finding problem to approximate linear decision problem from which Corollary 5.3 will follow by a decision to search reduction (Lemma 5.9). Formally,

▶ **Lemma 5.5** (Reduction from exact to approximate). *For all constant c, there exists a randomized Turing reduction from the rank-finding problem on $A \in \mathbb{Z}^{m\times n}$ to the $(1 - 1/n^c)$-Approximate linear decision problem on $n' \times n'$-square matrices with bit complexity $\mathcal{B}(A) = O((c + 1)\log(n))$, with $n' = O(\max(m, n))$, where in the YES case we have the additional property that the matrices produced have full rank. The reduction runs in time $\tilde{O}(c \cdot nnz(A))$, produces polylog$(mn)$ instances of the approximate linear decision problem and works w.h.p..*

To prove the above Lemma, we will go through each of the steps in the proof of Theorem 1.3 and see that all of them work for WordRAM with small modifications. We start with the reduction the Rank-Finding Problem to the Full rank problem for WordRAM (analogous to Lemma 3.3 for RealRAM).

▶ **Lemma 5.6.** *There exists a randomized Turing reduction which works w.h.p. from the Rank-Finding problem on $A \in \mathbb{Z}^{m\times n}$ with $m = O(n)$ and $\mathcal{B}(A) = O(\log n)$, to the Full rank problem, that runs in time $\tilde{O}(nnz(A))$ and produces $O(\log m)$ instances of the Full rank problem, such that all instances of the matrices produced have dimension $O(\max(m, n)) \times O(\max(m, n))$, sparsity $\tilde{O}(nnz(A))$ and bit complexity $O(\log n)$.*

Analogous to Lemma 3.4, we now reduce the Full-Rank Problem to the $(1/n^{O(1)})$-Linear Decision Approximation problem on WordRAM.

▶ **Lemma 5.7.** *Consider a matrix $M \in \mathbb{Z}^{n\times n}$. There exists a randomized Turing reduction from the problem of checking whether M has full rank to the $(1/n^{12})$-Linear Decision Approximation problem. The reduction runs in time $\tilde{O}(nnz(M))$, produces polylog(n) instances of the form $(M', \mathbf{1}^n)$ where $M' \in \mathbb{Z}^{n\times n}, \mathcal{B}(M') = O(\mathcal{B}(M) + (\log n))$, in the YES case M' is a full rank matrix, and works w.h.p..*

Finally we reduce the $(1/n^{O(1)})$-Linear Decision Approximation problem to the $(1-1/n^c)$-Linear Decision Approximation problem over WordRAM. This is straightforward to work out from the analogous Lemma 3.5 in Section 4.

▶ **Lemma 5.8.** *For all constants c and $\varepsilon(n) = 1/n^{O(1)}, \delta(n) = 1/n^c$, there exists a deterministic many-one reduction from the $\varepsilon(n)$-Approximate linear search problem on the linear system $(A \in \mathbb{R}^{n\times n}, \mathbf{1}^n)$ to the $(1-\delta(n))$-Approximate linear search problem on the linear system $(A' \in \mathbb{R}^{n\times n}, \mathbf{1}^n)$, with $nnz(A') = O(nnz(A))$. The reduction runs in time $\tilde{O}(nnz(A))$. Additionally if A is full rank then the matrix A' produced is also full rank.*

As this is a deterministic many-one reduction we also get a gap-amplifying reduction for the $\varepsilon(n)$-Approximate linear decision problem with the same parameters.

Now we are ready to prove Lemma 5.5.

Proof of Lemma 5.5. Similar to the proof of Theorem 1.3, The proof follows by composing Lemma 5.6, Lemma 5.7 and Lemma 5.8 (for $\varepsilon(n) = 1/n^{O(1)}$ and $\delta(n) = 1/n^c$). The bit complexity of the final matrix is $O(\log n) + O(\log(n/(\varepsilon(n)\delta(n)))) = O((c+1)(\log n))$ and the running time is $\tilde{O}(c \cdot \text{nnz}(A))$ ◀

To prove Corollary 5.3 we need the following decision to search reduction:

▶ **Lemma 5.9.** *Let $\varepsilon(n) = 1/n^{O(1)}$, given an $A \in \mathbb{Z}^{m\times n}, x, b$ where $m = O(n), \mathcal{B}(A), \mathcal{B}(b) =$ polylog$(n), \mathcal{B}(x) = \tilde{O}(n)$ we can distinguish between:*
1. $||Ax - b|| \le \varepsilon(n)||b||/2$.
2. $||Ax - b|| \ge \varepsilon(n)||b||$.

w.h.p. in time $\tilde{O}(nnz(A)n)$.

Combining Lemma 5.5 and Lemma 5.9 give us Corollary 5.3:

Proof of Corollary 5.3. For all constants c, Composing Conjecture 5.2 and Lemma 5.5 gives us $\tilde{\Omega}(n^\omega)$ hardness of $(1-1/n^c)$-Approximate linear decision problem $(A \in \mathbb{Z}^{n\times n}, b)$ with bit complexity $O((c+1)\log(n))$ where in the YES case we have the additional property that A has full rank. The hardness of $(1-1/n^c)$-Approximate linear search problem with the same properties follows from the decision to search reduction from Lemma 5.9. ◀

We now prove Corollary 5.4:

Proof of Corollary 5.4. Note that the input size is $\tilde{O}(n^2)$ and hence $a \ge 2$. The corollary directly follows from noting that Lemma 5.8 applied for $\varepsilon(n) = 1/n^d$ and $\delta(n) = 1/n^c$ reduces $(1/n^d)$-Approximate Linear Search problem to $(1-1/n^d)$-Approximate Linear Search problem in time $\tilde{O}(n^2) = \tilde{O}(n^a)$. ◀

5.1 Sparse Matrices

Starting from the WordRAM version of Conjecture 1.7 and using Lemma 5.5 we can establish that there does not exist a $\tilde{o}(n^2)$ algorithm for $(1 - 1/\text{poly}(n))$-Approximate linear decision problem on sparse matrices in the WordRAM model. By the decision to search reduction in Lemma 5.9 we get that there does not exist a $\tilde{o}(n^2)$ algorithm for $(1 - 1/\text{poly}(n))$-Approximate linear decision search on sparse matrices in the WordRAM model. Note though that this hardness is trivial to obtain since there exist sparse linear systems such that every $(1 - 1/\text{poly}(n))$-approximate solution to the system requires $\Omega(n^2)$ bits to represent.

On the algorithmic side no improvement over the dense case algorithmic runtime of $O(n^\omega)$ was known until the recent result of Peng and Vempala [30] who gave an asymptotically faster algorithm for the $1/\text{poly}(n)$-approximate linear search problem.

Abstract

In the *Priority k-Center* problem, the input consists of a metric space (X, d), an integer k and for each point $v \in X$ a priority radius $r(v)$. The goal is to choose k-centers $S \subseteq X$ to *minimize* $\max_{v \in X} \frac{1}{r(v)} d(v, S)$. If all $r(v)$'s were uniform, one obtains the classical k-center problem. Plesník [32] introduced this problem and gave a 2-approximation algorithm matching the best possible algorithm for vanilla k-center. We show how the Priority k-Center problem is related to two different notions of *fair* clustering [23, 28]. Motivated by these developments we revisit the problem and, in our main technical contribution, develop a framework that yields constant factor approximation algorithms for Priority k-Center with *outliers*. Our framework extends to generalizations of Priority k-Center to matroid and knapsack constraints, and as a corollary, also yields algorithms with fairness guarantees in the lottery model of Harris et al.

1 Introduction

Clustering is a basic task in a variety of areas, and clustering problems are ubiquitous in practice, and are well-studied in algorithms and discrete optimization. Recently *fairness* has become an important concern as automated data analysis and decision making have become increasingly prevalent in society. This has motivated several problems in fair clustering and associated algorithmic challenges. In this paper, we show that two different fairness views are inherently connected with a previously studied clustering problem called the *Priority k-Center* problem.

The input to Priority k-Center is a metric space (X, d) and a priority radius $r(v)$ for each $v \in X$. The objective is to choose k-centers $S \subseteq X$ such that $\max_{v \in X} \frac{d(v,S)}{r(v)}$ is minimized. If one imagines clients located at each point in X, and $r(v)$ is the "speed" of a client at point v, then the objective is to open k-centers so that every client can reach an open center as quickly as possible. When all the $r(v)$'s are the same, then one obtains the classic

k-center problem [26]. Plesník [32] introduced this problem and showed how to generalize Hochbaum and Shmoys' [26] 2-approximation algorithm for the k-center problem, to obtain a 2-approximation for Priority k-Center. This approximation ratio is tight since $(2-\varepsilon)$-factor approximation is ruled out even for the classic k-center problem under the assumption that $P \neq NP$ [19, 25].

Connections to Fair Clustering. Our motivation to revisit Priority k-Center came from two recent papers that considered fair variants in clustering, without explicitly realizing the connection to Priority k-Center. One of them is the paper of Jung, Kannan and Lutz [28] who defined a version of fair clustering as follows. Given (X, d) representing clients/people in a geographic area, and an integer k, for each $v \in X$ let $r_\ell(v)$ denote the smallest radius r such that there are at least ℓ points of X inside a ball of radius r around v. They suggested a notion of fair k-clustering as one in which each point $v \in X$ should be served by a center not farther than $r(v) = r_{n/k}(v)$ since the average size of a cluster in a k-clustering is n/k. [28] describe an algorithm that finds k centers such that each point v is served by a center at most distance $\leq 2r_{n/k}(v)$ away from v. Once the radii are fixed for the points, then one obtains an instance of Priority k-Center, and the result essentially[1] follows from the algorithm in [32]; indeed, the algorithm in [28] is the same.

Another notion of fairness related to the Priority k-Center is the *lottery model* introduced by Harris et al. [22]. In this model, every client $v \in X$ has a "probability demand" $p(v)$ and a "distance demand" $r(v)$. The objective is to find a *distribution* $\mathcal{S}$ over k-center locations such that for every client $v \in X$, $\Pr_{S\sim\mathcal{S}}[d(v, S) \leq r(v)] \geq p(v)$. One needs to either prove such a solution is not possible, or provide a distribution where the distance to S can be relaxed to $\alpha r(v)$. Using a by now almost standard reduction via the ellipsoid method [6, 1], this boils down to the *outlier* version of Priority k-Center, where some points in X are allowed to be discarded. The outlier version of Priority k-Center had not been explicitly studied before.

Our Contributions. Motivated by these connections to fairness, we study the natural generalizations of Priority k-Center that have been studied for the classical k-center problem. The main generalization is the *outlier* version of Priority k-Center: the algorithm is allowed to discard a certain number of points when evaluating the quality of the centers chosen. First, the outlier version arises in the lottery model of fairness. Second, in many situations it is useful and important to discard outliers to obtain a better solution. Finally, it is also interesting from a technical point of view. We also consider the situation when the constraint on where centers can be opened is more general than the cardinality constraint. In particular, we study the matroid priority center problem where the set of centers must be an independent set of a given matroid, and the knapsack priority center problem where the total weight of centers opened is at most a certain amount. Our main contribution is an algorithmic framework to study the outlier problems in all these variations. Our results also imply interesting generalizations for fair clustering.

1.1 Statement of Results

We briefly describe some variants of Priority k-Center. In the supplier version, the metric space is partitioned into facilities F and clients C, and goal is to select k facilities $S \subseteq F$ to minimize $\max_{v\in C} d(v, S)/r(v)$. In the Priority Matroid Supplier problem, the subset of

[1] One needs to observe that Plesník's analysis [32] can be made with respect to a natural LP which has a feasible solution with $r(v) := r_{n/k}(v)$.

facilities need to be an independent set of matroid on F. In the Priority Knapsack Supplier problem, the subset of facilities must have weight at most a certain amount. All these generalizations have a 3-approximation [26, 14] in the vanilla version where all $r(v)$'s are the same. Our first observation is that these extend to Priority k-Center in a simple fashion. This result also implicitly relates the approximation ratio to the integrality gap of the natural LP relaxation. This allows us to rederive and extend the algorithmic results in [28] we give details in Section 6.

▶ **Result 1.** *There is a* 3*-approximation for Priority* k*-Supplier and Priority Matroid Supplier and Priority Knapsack Supplier.*

Our second, and the main technical contribution, is a general framework to handle *outliers*. Given an instance of Priority k-Center and an integer $m \leq n$, the outlier version that we refer to as PkCO, is to find k centers S and a set C' of at least an m points from C such that $\max_{v \in C'} \frac{1}{r(v)} d(v, S)$ is minimized. While the k-Center with outliers admits a clever, yet relatively simple, greedy 3-approximation due to Charikar et al. [10], a similar approach seems difficult to adapt for Priority k-Center. Instead, we take a more general and powerful LP-based approach from [7, 8] to develop a framework to handle PkCO, and also the outlier version of Matroid Center (PMCO), where the opened centers must be an independent set, and Knapsack Center (PKnapCO), where the total weight of the open centers must fit in a budget. We obtain the following results.

▶ **Result 2.** *There is a* 9*-approximation for P*k*CO and PMCO and a* 14*-approximation for PKnapCO. Moreover the approximation ratio for P*k*CO and PMCO are based on a natural LP relaxation.*

At this point we remark that a result in Harris et al. [22] (Theorem 2.8 in the arXiv version) also indirectly gives a 9-approximation for PkCO. We believe that our framework is more general and can handle PMCO and PKnapCO easily. The [22] paper do not consider these versions, and indeed for the PKnapCO problem their framework cannot give a constant factor approximation for they (in essence) use a weak LP relaxation.

Furthermore, our framework yields *better* approximation factors when either the number of distinct priorities are small, or they are in different scales. In practice, one indeed expects this to be the case. In particular, when there are only two distinct types of radii, then we get a 3-approximation which is tight; it is not too hard to show that it is NP-hard to obtain a better than 3-approximation for PkCO with two types[2] of priorities. We get improved factors (5 and 7) when the number of radii are three and four as well. On the other hand, if all the different priorities are powers of b (for some parameter $b > 1$), then we get a $\frac{3b-1}{b-1}$-approximation. Thus, if all the priorities are in vastly different scales ($b \to \infty$), then our approximation factor approaches 3.

▶ **Result 3.** *Suppose there are only two distinct priority radii among the clients. Then there is a* 3*-approximation for P*k*CO, PMCO and PKnapCO. With* t *distinct types of priorities, the approximation factor for P*k*CO and PMCO is* $2t - 1$*. If all distinct types are powers of* b*, the approximation factor for P*k*CO and PMCO becomes* $(3b - 1)/(b - 1)$*.*

It is possible that the PkCO problem has a 3-approximation in general, and even the natural LP-relaxation may suffice; we have not been able to obtain a worse than 3 integrality gap example. As we explain in Section 1.2 below, many approaches to the k-center type problems

[2] Interestingly, when there is a single priority, the vanilla k-center with outliers has a 2-approximation [7] showing a gap between the two problems.

begin with a Hochbaum-Shmoys [26] style partition of the points X to representatives. We could show examples where such an *approach* has a gap worse than 3, though not showing an integrality gap instance. Resolving the integrality gap of the natural LP-relaxation and/or obtaiting improved approximation ratios are interesting open questions highlighted by our work.

1.2 Technical Discussion

Almost all clustering algorithms for the k-center objective proceeds via a partitioning subroutine due to Hochbaum and Shmoys [26] (HS, henceforth). This procedure returns a partition Π of X along with a representative for each part such that all vertices of a part "piggy-back" on the representative. More precisely, if the representative is assigned to a center $f \in X$, then so are all other vertices in that part. To ensure a good algorithm in vanilla k-center, it suffices to ensure the radius of each part is small.

For the Priority k-Center objective, one needs to be more careful : to use the above idea, one needs to make sure that if vertex v is piggybacking on vertex u, then $r(v)$ better be more than $r(u)$. Indeed, this can be ensured by running the HS procedure in a particular order, namely by allowing vertices with smaller $r(v)$ to form the parts first. This precisely gives Plesník's algorithm [32]. In fact, this idea easily gives a 3-approximation for the matroid and supplier versions as well.

Outliers are challenging in the setting of Priority k-Center. We start with the approach of Chakrabarty et al. [7] for k-center. First, they construct an LP where $\mathsf{cov}(v)$ denotes the fractional coverage (amount to which one is *not* an outlier) of any point, and then write a natural LP for it. They show that if the HS algorithm is run according to the $\mathsf{cov}(v)$ order (higher coverage vertices first), then the resulting partition can be used to obtain a 2-approximation for the k-center with outliers problem.

When one moves to the priority k-center with outliers, one sees the obvious trouble: what if the $r(v)$ order and the $\mathsf{cov}(v)$ order are at loggerheads? Our approach out of this is a simple bucketing idea. We first write a natural LP with fractional coverages $\mathsf{cov}(v)$ for every point. Then, we partition vertices into classes: all vertices v with $r(v)$ between 2^i and 2^{i+1} are in the same class. We then use the HS partitioning algorithm in the decreasing $\mathsf{cov}(v)$ order separately on each class. The issue now is to handle the interaction across classes. To handle this, we define a directed acyclic graph across these various partitions where representative u has an edge to representative v iff $d(u, v)$ is small ($\leq r(u) + r(v)$). It is a DAG because we point edges from higher $r(u)$ to the lower $r(v)$. Our main observation is that if we can peel out k paths with "large value" (each representative's value is how many points piggyback on it), then we can get a 9-approximation for the priority k-center with outlier problem. We can show that a *fractional* solution of large value does exist using the fact that the DAG was constructed in a greedy fashion. Also, since the graph is a DAG, this LP is an integral min-cost max-flow LP. The factor 9 arises out of a geometric series and bucketing. Indeed, when the radii are exact powers of 2, we get a 5-approximation, and when there are only two type of radii, we get a 3 approximation which is tight.

The above framework can handle the outlier versions for the matroid and knapsack version. For the matroid version, the flow problem is no longer a min-cost max-flow problem, but rather it reduces to a *submodular flow* problem which is solvable in polynomial time. Modulo this, the above framework gives a 9-approximation. For the knapsack version, there are two issues. One is that the flow problem involves non-uniform numbers and is no longer integral and solving the underlying optimization problem is likely to be NP-hard (we did not attempt a formal proof). Nevertheless, our framework has sufficient flexibility that by

increasing the approximation factor from 9 to 14, the DAG can in fact be made into a rooted forest. In this rooted forest, we can employ dynamic programming to solve the problem of finding the desired paths. The second issue is that a fractional LP solution of the natural LP does not suffice when using the DP based algorithm on the forest; indeed the natural LP has an unbounded gap. Here we need to use the round-or-cut framework from [8]; either the DP on the rooted forest succeeds or we find a violated inequality for the large implicit LP that we use.

1.3 Other Related Works

There is a huge literature on clustering, and instead of summarizing the landscape, we mention a few works relevant to our paper. Gørtz and Wirth [20] study the priorty k-center problem in the asymmetric metric case, and prove that it is NP-hard to obtain any non-trivial approximation. A related problem to priority k-clustering is the *non-uniform* k-center problem by Chakrabarty et al. [7] where instead of clients having radii bounds, the objective is to figure out centers of balls for different types of radii. Another related problem [21] is the local k-median problem where clients need to connect to facilities within a certain radius, but the objective is the sum instead of the max.

Fairness in clustering has also seen a lot of works recently. Apart from the two notions of fairness described above, which can be thought of as "individual fairness" guarantees, Chierichetti et al. [16] introduce the "group fairness" notion where points have color classes, and each cluster needs to contain similar proportion of colors as in the universe. Their results were generalized by a series of follow ups [33, 5, 4]. A similar concept for outliers led to the study of *fair colorful k-center*. In this problem, the objective is to find k centers which covers at least a prescribed number of points from each color class. This was introduced by Bandapadhyay et al. [3], and recently true approximation algorithms were concurrently obtained by Jia et al. [27] and Anegg et al. [1].

Another notion of fairness is introduced by Chen et al. [15] in which a solution is called fair if there is no facility and a group of at least n/k clients, such that opening that facility lowers the cost of all members of the group. They give a $(1+\sqrt{2})$-approximation for L_1, L_2, and L_∞ norm distances for the setting where facilities can be places anywhere in the real space. Recently Micha and Shah [31] showed that a modification of the same approach can give a close to 2-approximation for L_2 case and proved $(1+\sqrt{2})$ factor is tight for L_1 and L_∞.

Coming back to the model of Jung et al. [28], the local notion of neighborhood radius is also present in the metric embedding works of [9, 11] and were recently used by Mahabadi and Vakilian [30] to extend the results in [28] to other objectives such as k-median and k-means. We leave the outlier versions of these problems as an open direction of study.

2 Preliminaries

We provide some formal definitions and describe a clustering routine from [26].

▶ **Definition 1** (Priority $k-$Center). *The input is a metric space (X,d) and radius function $r: X \to \mathbb{R}^+$, and integer k. The goal is to find $S \subseteq X$ of size at most k to minimize α such that for all $v \in X$, $d(v,S) \leq \alpha \cdot r(v)$*

▶ **Definition 2** (Priority $\mathscr{F}$-supplier). *(Generalization from [8]). The input is a metric space (X,d) where $X = F \cup C$, C is the set of points, and F the set of facilities. We are also given a radius function $r: C \to \mathbb{R}^+$. The goal is to find $S \subseteq F$ to minimize α such that for all*

$v \in C$, $d(v, S) \leq \alpha \cdot r(v)$. The constraint on F is that it must be selected from a down-ward closed family $\mathscr{F}$. Different families lead to different problems. We get the priority k-supplier problem if $\mathscr{F} = \{F : |F| \leq k\}$. We get the priority matroid supplier problem when $(F, \mathscr{F})$ is a matroid. We get the priority knapsack supplier problem when there is a weight function $w : F \to \mathbb{R}_{\geq 0}$ and $\mathscr{F} = \{F : w(F) \leq B\}$ for some budget B.

For the remainder of this manuscript, we focus on the *feasibility* version of the problem. More precisely, given an instance of the problem, we either want to show there is no solution with $\alpha = 1$, or find a solution with $\alpha \leq \rho$. If we succeed, then via binary search we get a ρ-approximation.

Plesník [32] obtained a 2-approximation for Priority k-Center. Algorithm 1 is a slight generalization of his algorithm; in addition to the radius function and the metric, we take as input a function $\phi : X \to R_{\geq 0}$ which encodes an ordering over the points (we can think of the points as being ordered from largest to smallest ϕ values). The algorithm is a similar procedure to that of Hochbaum and Shmoys from [26], but while [26] picks points arbitrarily, points get picked in the order mandated by ϕ.

▶ **Fact 1.** *The following is true for the output of HS: (a) $\forall u, v \in S, d(u, v) > r_u + r_v$, (b) The set $\{D(u) : u \in S\}$ partitions X, (c) $\forall u \in S, \forall v \in D(u), \phi(u) \geq \phi(v)$, and (d) $\forall u \in S, \forall v \in D(u), d(u, v) \leq r_u + r_v$.*

Algorithm 1 HS.

Input: Metric (X, d), radius function $r : X \to \mathbb{R}_{>0}$, and ordering $\phi : X \to \mathbb{R}_{\geq 0}$

$U \leftarrow X$ ▷ The set of uncovered points
$S \leftarrow \emptyset$ ▷ The set of "representatives"
while $U \neq \emptyset$ **do**
  $u \leftarrow \arg\max_{v \in U} \phi(v)$ ▷ The first point in U in non-increasing ϕ order
  $S \leftarrow S \cup u$
  $D(u) \leftarrow \{v \in U : d(u, v) \leq r_u + r_v\}$ ▷ Note: $D(u)$ includes u itself
  $U \leftarrow U \backslash D(u)$
end while

Output: S, $\{D(u) : u \in S\}$

▶ **Theorem 3** ([32]). *There is a 2-approximation for Priority k-Center.*

Proof. (For completeness and later use.) We claim that S, the output of Algorithm 1 for $\phi := 1/r$, is a 2-approximate solution; this follows from the observations in Fact 1. For any $v \in X$ there is some $u \in S$ for which $v \in D(u)$. By our choice of ϕ, $r_u \leq r_v$. Since $d(u, v) \leq r_u + r_v$, we have $d(u, v) \leq 2r_v$. To see why $|S| \leq k$, recall that for any $u, v \in S$, by Fact 1, $d(u, v) > r_u + r_v$ so no two points in S can be covered by the same center. Thus any feasible solution needs at least $|S|$ many points to cover all of S. ◀

In fact, the algorithm almost immediately gives a 3-approximation for Priority $\mathscr{F}$-Supplier for many families via the framework in [8].

One needs to check if given any partition Π of F, whether the following *partition feasibility* problem is solvable: does there exist $A \in \mathscr{F}$ such that $|A \cap P| = 1$ for all $P \in \Pi$? We ask this for the partition returned by Algorithm 1, that is, $\Pi = \{\{f \in F : d(f, u) \leq r_u\} : u \in S\}$. If no such A exists, then the instance is infeasible since the centers S of the parts cannot be covered. If such an A exists, then by construction every $v \in X$ in part $D(u)$ satisfies

$d(v, A) \leq d(u, v) + d(u, A) \leq 2r_u + r_v \leq 3r_v$ since $r_u \leq r_v$. It is easy to see for the supplier, knapsack, and matroid center versions, the partition feasibility problem is solvable in polynomial time. This leads to the following theorem.

▶ **Theorem 4.** *There is a 3-approximation for Priority k-Supplier, Priority Knapsack Center, and the Priority Matroid Center problem.*

3 Priority k-Center with Outliers

In this section we describe our framework for handling priorities and outliers and give a 9-approximation algorithm for the following problem.

▶ **Definition 5** (Priority $k-$Center with Outliers (PkCO))**.** *The input is a metric space (X, d), a radius function $r : X \to \mathbb{R}_{>0}$, and parameters $k, m \in \mathbb{N}$. The goal is to find $S \subseteq X$ of size at most k to minimize α such that for at least m points $v \in X$, $d(v, S) \leq \alpha \cdot r(v)$.*

▶ **Theorem 6.** *There is a 9-approximation for PkCO.*

The following is the natural LP relaxation for the feasibility version of PkCO. For each point $v \in X$, there is a variable $0 \leq x_v \leq 1$ that denotes the (fractional) amount by which v is opened as a center. We use $\mathsf{cov}(v)$ to indicate the amount by which v is *covered* by itself or other open facilities. To be precise, $\mathsf{cov}(v)$ is the sum of x_u over all $u \in X$ at distance at most r_v from v. Note that $\mathsf{cov}(v)$ is an auxiliary variable. We want to ensure that at least m units of coverage are assigned using at most k centers (hence the first two constraints).

$$\sum_{v \in X} \mathsf{cov}(v) \geq m \qquad \text{(P}k\text{CO LP)}$$

$$\sum_{v \in X} x_v \leq k$$

$$\mathsf{cov}(v) := \sum_{\substack{u \in X: \\ d(u,v) \leq r_v}} x_u \leq 1 \qquad \forall v \in X$$

$$0 \leq x_v \leq 1 \qquad \forall v \in X.$$

Next, we define another problem called Weighted k-Path Packing (WkPP) on a DAG. Our approach is to do an LP-aware reduction from PkCO to WkPP. To be precise, we use a fractional solution of the PkCO LP to reduce to a WkPP instance $\mathcal{J}$. We show that a good integral solution for $\mathcal{J}$ translates to a 9-approximate solution for the PkCO instance. We prove that $\mathcal{J}$ has a good integral solution by constructing a feasible fractional solution for an LP relaxation of WkPP; this LP relaxation is integral. Henceforth, $\mathcal{P}(G)$ denotes the set of all the paths in G where each path is an ordered subset of the edges in G.

▶ **Definition 7** (Weighted k-Path Packing (WkPP))**.** *The input is $\mathcal{J} = (G = (V, E), \lambda, k)$ where G is a DAG, $\lambda : V \to \{0, 1, \ldots, n\}$ for some integer n. The goal is to find a set of k* vertex *disjoint paths $P \subseteq \mathcal{P}(G)$ that maximizes:*

$$\mathit{val}(P) := \sum_{p \in P} \sum_{v \in p} \lambda(v).$$

Even though this problem is NP-hard on general graphs[3], it can be easily solved if G is a DAG by reducing to Min-Cost Max-Flow (MCMF). To build the corresponding flow network,

[3] $k = 1$ and unit λ is the longest path problem which is known to be NP-hard [18].

we augment G to a new DAG $G' = (V', E')$ with source and sink nodes s, t. $V' = V \cup \{s, t\}$. Each node $v \in V$ has unit capacity and cost equal to $-\lambda(v)$. s and t have zero cost with capacities ∞ and k respectively. As for the arcs, E' includes the entirety of E, plus arcs (s, v) and (v, t) for all $v \in V$. All the arcs have unit capacity and zero cost. One can now write the MCMF LP for WkPP which is known to be integral. We use $\delta^+(v)$ and $\delta^-(v)$ to denote the set of outgoing and incoming edges of a vertex v respectively. The LP has a variable y_e for each arc $e \in E'$ to denote the amount of (fractional) flow passing through it. Similarly, the amount of flow entering a vertex is denoted by $\mathsf{flow}(v) := \sum_{e \in \delta^-(v)} y_e$. The objective is to minimize the cost of the flow which is equivalent to maximizing the negation of the costs.

$$\max \sum_{v \in V} \mathsf{flow}(v)\lambda(v) \qquad \text{(W}k\text{PP LP)}$$

$$\mathsf{flow}(v) := \sum_{e \in \delta^-(v)} y_e = \sum_{e \in \delta^+(v)} y_e \qquad \forall v \in V$$

$$\mathsf{flow}(t) \leq k$$

$$\mathsf{flow}(v) \leq 1 \quad \forall v \in V, \qquad 0 \leq y_e \leq 1 \quad \forall e \in E'.$$

▷ Claim 8. WkPP is equivalent to solving MCMF on G'.

Proof. Observe that any solution P for the WkPP instance translates to a valid flow of cost $-\mathsf{val}(P)$ for the flow problem. For any path $p \in P$ with start vertex u and sink vertex v, send one unit of flow from s to u, through p to v and then to t. Since the paths in P are vertex disjoint and there are at most k of them, the edge and vertex capacity constraints in the network are satisfied.

Now we argue that any solution to the MCMF instance with cost $-m$ translates to a solution P for the original WkPP instance with $\mathsf{val}(P) = m$. To see this, note that the MCMF solution consists of at most k many s, t paths that are vertex disjoint with respect to V. This is because of our choice of vertex capacities. Let P be those paths modulo vertices s and t. For a $v \in V$, $-\lambda(v)$ is counted towards the MCMF cost iff v has a flow passing through it which means v is included in some path in P. Thus $\mathsf{val}(P) = m$. ◁

3.1 Reduction to WkPP

Using a fractional solution of the PkCO LP we construct a WkPP instance. In particular, we use the cov assignment generated by the LP solution. Without loss of generality, by scaling the distances, we assume that the smallest neighborhood radius is 1. Let $t := \lceil \log_2 r_{max} \rceil$, where r_{max} is the largest value of r (after scaling). We use $[t]$ to denote $\{1, 2, \ldots, t\}$. Partition X according to each point's radius into $C_1, \ldots, C_t$, where $C_i := \{v \in X : 2^{i-1} \leq r_v < 2^i\}$ for $i \in [t]$. Note that some sets may be empty if no radius falls within its range.

Algorithm 2 shows the PkCO to WkPP reduction. The algorithm constructs a DAG called contact DAG (see Definition 9) as a part of the WkPP instance definition. We first run Algorithm 1 on each C_i to produce a set of representatives R_i and their respective clusters $\{D(u) : u \in R_i\}$. The λ function is constructed using the $D(v)$'s. Each R_i defines a *row* of the contact DAG starting with R_t at the top. Arcs in the contact DAG exist only between points in different rows, and only when they share a point in X that can cover them both within their desired radii. We always have arcs pointing downwards, that is, from points in R_i to points in R_j where $i > j$. See Figure 1 for an example on how a contact DAG looks like.

Algorithm 2 Reduction to WkPP.

Input: PkCO instance $\mathcal{I} = ((X, d), r, k, m)$ and assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in X\}$
1: $R_i, \{D(u) : u \in R_i\} \leftarrow \mathsf{HS}((C_i, d), r, \mathsf{cov})$ for all $i \in [t]$
2: Construct contact DAG $G = (V, E)$ per Definition 9
3: $\lambda(v) \leftarrow |D(v)|$ for all $v \in V$
Output: WkPP instance $\mathcal{J} = (G = (V, E), \lambda, k)$

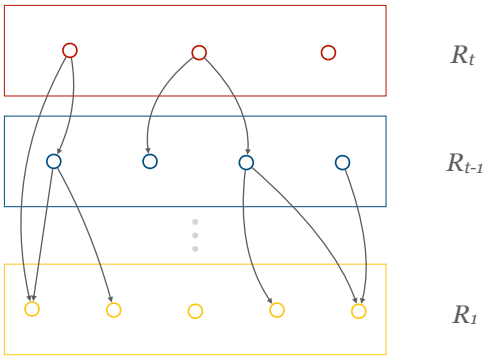

Figure 1 A contact DAG.

▶ **Definition 9** (contact DAG). *Let $R_i \subseteq C_i$, $i \in [t]$ be the set of representatives acquired after running HS on C_i according to Line 1 of Algorithm 2. contact DAG $G = (V, E)$ is a DAG on vertex set $V = \bigcup_i R_i$ where the arcs are constructed by the following rule:*

For $u \in R_i$ and $v \in R_j$ where $i > j$, $(u, v) \in E$
$\iff \exists f \in X : d(u, f) \leq r_u$ and $d(v, f) \leq r_v$.

Our first observation is that the WkPP instance has a good fractional solution and since the LP is integral, it also has a good integral solution.

▶ **Lemma 10.** *There is a valid solution to WkPP LP of value $\geq m$ for the WkPP instance $\mathcal{J}$. Since WkPP LP is integral, this implies $\mathcal{J}$ has an integral solution of value $\geq m$.*

The proof of this lemma can be found in [2]. Theorem 6 now follows from the following lemma.

▶ **Lemma 11.** *Any solution with value at least m for the WkPP instance $\mathcal{J}$ given by Algorithm 2 translates to a 9-approximation for the PkCO instance $\mathcal{I}$.*

Proof. We begin with a few observations. Per definition of contact DAG we have the following property. Note that the converse is not necessarily true.

▶ **Fact 2.** *If $u \in R_i$, $v \in R_j$, and (u, v) is an arc in contact DAG, $d(u, v) \leq r_u + r_v$.*

▶ **Fact 3.** *$\{D(v), v \in V\}$ as constructed in Algorithm 2 partitions X.*

Proof. $\{C_i\}_{i \in [t]}$ partitions X and HS further partitions each C_i according to Fact 1. ◀

▷ Claim 12. For any $u \in R_i$, $v \in R_j$ reachable from u in a contact DAG, $d(u, v) < 3 \cdot 2^i$.

Proof. Observe that by definition of contact DAG, $i > j$. A path from u to v may contain a vertex from any level of the DAG between i and j. In the worst case, the path has a vertex w_k from every level R_k for $j < k < i$:

$$\begin{aligned} d(u,v) &\le d(u,w_{i-1}) + d(w_{i-1},w_{i-2}) + \ldots + d(w_{j+1},v) \\ &\le (r_u + r_{w_{i-1}}) + (r_{w_{i-1}} + r_{w_{i-2}}) + \ldots + (r_{w_{j+1}} + r_v) && \text{(by Fact 2)} \\ &= r_u + 2\sum_{k=j+1}^{i-1} r_{w_k} + r_v < r_u + 2\sum_{k=1}^{i-1} 2^k \\ &= r_u + 2\cdot(2^i - 2) < 3\cdot 2^i. && (r_u < 2^i) \end{aligned}$$ ◁

Now we are armed with all the facts we need to prove Lemma 11. We are assuming the constructed WkPP instance has a solution of value at least m, which means there exists a set of k disjoint paths $P \subseteq \mathcal{P}(G)$ in the contact DAG such that $\mathsf{val}(P) \ge m$. For any path $p \in P$, let $\mathsf{sink}(p)$ denote the last node in this path (i.e. $\mathsf{sink}(p) = \arg\min_{u \in p} r_u$). Our final solution would be $S := \{\mathsf{sink}(p) : p \in P\}$. We argue that this S is a 9-approximate solution for the initial PkCO instance. Since P has at most k many paths, $|S| \le k$.

Now we show any $w \in D(u)$ where $u \in p \in P$, can be covered by $v = \mathsf{sink}(p)$ with dilation at most 9. Assume $u \in R_i$ for some $i \in [t]$.

$$\begin{aligned} d(w,v) &\le d(w,u) + d(u,v) < r_w + r_u + 3\cdot 2^i && \text{(by Fact 1 and above claim)} \\ &< r_w + 4\cdot 2^i \le 9 r_w. && (r_u < 2^i \text{ and } 2^{i-1} \le r_w) \end{aligned}$$

The last piece is to argue at least m points will be covered by S. The set of points that are covered by S within 9 times their radius is precisely the set $D_{\mathsf{total}} := \bigcup_{p\in P}\bigcup_{u\in p} D(v)$. So we need to show $|D_{\mathsf{total}}| \ge m$. By Fact 3 we have:

$$|D_{\mathsf{total}}| = |\bigcup_{p\in P}\bigcup_{v\in p} D(v)| = \sum_{p\in P}\sum_{v\in p} |D(v)| = \mathsf{val}(P),$$

where the last equality is by the definition of $\lambda(v), v \in V$ (in Line 3 of Algorithm 2) and definition of $\mathsf{val}(P)$. By assumption $\mathsf{val}(P) \ge m$ thus D_{total} contains at least m points. ◀

In the special case where there are 2 types of radii we can slightly modify our approach to get a 3-approximation algorithm. This result is tight. To see this consider PkCO instances where clients having priority radii in $\{0, 1\}$ with n_0 of the former type and n_1 of the latter, and the number of outliers allowed is $n_0 - k$. Clients with priority radii 0 either need to have a facility opened at that same point, or need to be an outlier. Since only $n_0 - k$ outliers and k centers are allowed, all the outliers and centers are on these n_0 points. Thus, the n_0 points act as facilities in the k-supplier problem which is hard to approximate with a factor better than 3. This shows a gap with the vanilla k-center with outliers has a 2-approximation [7].

In general, our framework yields improved approximation factors when the number of distinct priorities are less than 5 (see Theorem 13). In the special case when all radii are powers of 2, our algorithm is actually a 5-approximation. This factor improves if the radii are powers of some $b > 2$ and approaches 3 as b goes to infinity (see Theorem 14).

▶ **Theorem 13.** *There is a $(2t-1)$-approximation for PkCO instances where there are only t types of radii.*

Proof. Given PkCO instance $\mathcal{I}$ obtain fractional solution x by solving the PkCO LP. Partition X according to each point's radius into $C_1, \ldots, C_t$, where C_i is points of radius type i for $i \in [t]$. Run Algorithm 2 with input cov corresponding to x and take resulting WkPP instance

$\mathcal{J}$. Assuming the WkPP instance has a solution with value at least m, we can show how to obtain a $(2t-1)$-approximate solution as follows. Let P be the WkPP solution. Take any $p \in P$. If p is a single vertex, simply add it to solution S. Otherwise, instead of adding $v' = \mathsf{sink}(p)$ to S, if v is the vertex before v' in p, add a point $f \in X$ that covers both the endpoints v and v' (f exists by Definition 9).

Take any $w \in D(u)$ where $u \in p$ and assume $u \in R_i$ for some $i \in [t]$. Similar to the proof of Claim 12 one can show $d(u,v) < 2(i-2)r_u$ by bounding the radius of any vertex in between them by r_u and noting that v is in level 2 or higher (remember p ends at v' and (v,v') is an edge). Since $d(w,f) \le d(w,u) + d(u,v) + d(v,f)$ and $d(w,u) \le r_w + r_u$ (Fact 1), plus $d(v,f) < r_v \le r_u$ we have $d(w,f) < r_w + 2(i-1)r_u$. But $r_w = r_u$ by definition of C_i so w is covered by f with dilation at most $2i-1 \le 2t-1$. The part to argue at least m points will be covered by S, is done similar to the proof of Lemma 11.

The remainder of this proof, i.e. showing that $\mathcal{J}$ does indeed have a solution of value at least m that can be determined in polynomial time using an MCMF algorithm, is identical to the proof of Theorem 6. ◀

▶ **Theorem 14.** *There is a $((3b-1)/(b-1))$-approximation for PkCO instances where the radii are powers of $b \ge 2$.*

Proof. Given PkCO instance $\mathcal{I}$ obtain fractional solution x by solving the PkCO LP. Partition X according to each point's radius into $C_1, \ldots, C_t$, where $t := \lceil \log_b r_{max} \rceil$ and $C_i := \{v \in X : r_v = b^{i-1}\}$ for $i \in [t]$. Run Algorithm 2 with input cov corresponding to x and take resulting WkPP instance $\mathcal{J}$. Assume the WkPP instance has a solution P with value at least m. For any $p \in P$ add $v = \mathsf{sink}(p)$ to solution S. Consider arbitrary $w \in D(u)$ where $u \in p \in P$ and assume $u \in R_i$ for some $i \in [t]$. Similar to the proof of Claim 12 one can show $d(u,v) < ((b+1)/(b-1)) \times b^{i-1}$. By Fact 1 $d(w,u) \le r_w + r_u = 2b^{i-1}$. Thus any w is covered by dilation $(3b-1)/(b-1)$ as $d(w,v) \le d(w,u) + d(u,v) < 2b^{i-1} + ((b+1)/(b-1)) \times b^{i-1} = (3b-1)/(b-1)r_w$. To argue at least m points will be covered by S, see the proof of Lemma 11. Showing that $\mathcal{J}$ does indeed have a solution of value at least m that can be determined in polynomial time using an MCMF algorithm, is identical to the proof of Theorem 6 as well. ◀

4 Priority Matroid-Center with Outliers

In this section, we show how to generalize the results from the previous section for the case of Priority Matroid-Center with Outliers (PMCO).

▶ **Definition 15** (Priority Matroid-Center with Outliers (PMCO))**.** *The input is a metric space (X,d), parameter $m \in \mathbb{N}$, radius function $r : X \to \mathbb{R}_{>0}$, and $\mathscr{F} \subseteq 2^X$ a family of independent sets of a matroid. The goal is to find $S \in \mathscr{F}$ to minimize α such that for at least m points $v \in X$, $d(v,S) \le \alpha \cdot r(v)$.*

▶ **Theorem 16.** *There is a 9-approximation for PMCO.*

As in the previous section, we assume $\alpha = 1$ and consider the feasibility version of the problem. For any $S \subseteq V$, let $\mathsf{rank}_{\mathscr{F}}(S)$ be the rank of S in the given matroid. The natural LP relaxation for this problem is very similar to that of PkCO LP except that we replace the cardinality constraints with *rank constraints* $x(S) \le \mathsf{rank}_{\mathscr{F}}(S)$ for all $S \subseteq V$. This is because for any $S \in \mathscr{F}$, $|S| = \mathsf{rank}_{\mathscr{F}}(S)$.

$$\sum_{v \in X} \mathsf{cov}(v) \geq m \qquad \text{(PMCO LP)}$$

$$\sum_{v \in S} x_v \leq \mathsf{rank}_{\mathscr{F}}(S) \qquad \forall S \subseteq V$$

$$\mathsf{cov}(v) := \sum_{\substack{u \in X: \\ d(u,v) \leq r_v}} x_u \leq 1 \qquad \forall v \in X$$

$$0 \leq x_v \leq 1 \qquad \forall v \in X.$$

Similar to WkPP, we have the path packing version of PMCO defined below. Recall from the last section, that after reducing from PkCO to WkPP we returned a set of k vertices in DAG G as our final solution. Now that we have matroid constraints, we must instead return a set S of vertices such that $S \in \mathscr{F}$. Doing so is not as straightforward, since our reduction does not guarantee that such a subset of vertices actually exists and covers enough points in their corresponding vertex disjoint paths. Instead, we show there is an $S \in \mathscr{F}$ such that each member of this S is *close* to some vertex of G. These close points in G will correspond to a set of vertex disjoint paths that will cover enough points.

▶ **Definition 17** (Weighted $\mathscr{F}$-Path Packing (WMatPP))**.** *The input is $G = (V, E)$ and λ same as in WkPP, plus a finite set X, $\mathcal{Y} = \{Y_v \subseteq X : v \in V\}$, and $\mathscr{F} \subseteq 2^X$ a family of independent sets of a matroid. The goal is to find a set of disjoint paths $P \in \mathcal{P}(G)$ with maximum $\mathsf{val}(P)$ for which there exists $S \in \mathscr{F}$ such that $\forall p \subseteq P$, $S \cap Y_{\mathsf{sink}(p)} \neq \emptyset$.*

Observe that the reduction procedure in Algorithm 2 and all of our subsequent observations in Section 3.1 do not rely on how we define a feasible set of centers. Hence, the main obstacle in proving Theorem 16 lies in our reduction to MCMF. Luckily, the result of [13] helps us address this by giving LP integrality results similar to MCMF using the following formulation on directed *polymatroidal flows* [17, 24, 29]: For a network $G' = (V', E')$, for all $v \in V'$, we are given polymatroids[4] ρ_v^- and ρ_v^+ on $\delta^-(v)$ and $\delta^+(v)$ respectively. For every arc $e \in E'$ there is a variable $0 \leq y_e \leq 1$. The capacity constraints for each $v \in V'$ are defined as:

$$\sum_{e \in U} y_e \leq \rho_v^-(U) \qquad \forall U \subseteq \delta^-(v)$$

$$\sum_{e \in U} y_e \leq \rho_v^+(U) \qquad \forall U \subseteq \delta^+(v).$$

We augment the DAG G given in WMatPP to construct a polymatroidal flow network G'. In this new network, $V' = V \cup X \cup \{s, t\}$ where each node $v \in V$ has cost $-\lambda(v)$. **Note:** Even though a vertex $v \in V$ might correspond to a point in X, in V' we make a distinction between the two copies. E' includes all of E, plus arcs (s, v) for all $v \in V$. Finally, instead of adding arcs (v, t), we add arcs (v, f) and (f, t) for all $f \in Y_v$.

The polymatroids for this instance are constructed as follows: for any $v \in V \cup X$, $\rho_v^-(U) = 1$ for all non-empty $U \subseteq \delta^-(v)$ and ρ_v^+ is defined similarly on $\delta^+(v)$. For s, we only have outgoing edges where $\rho_s^+(U) = |U|$ for all $U \subseteq \delta^+(s)$. Finally, we enforce the matroid constraints of $\mathscr{F}$ on t. For any $U \subseteq \delta^-(t)$, let $T \subseteq X$ be the set of starting nodes in U. That is, $U = \{(f, t) : f \in T\}$. Set $\rho_t^-(U) = \mathsf{rank}_{\mathscr{F}}(T)$. Since $\delta^-(t) \subseteq X$, these capacity constraints on t are equivalent to the following set of constraints:

$$\sum_{f \in T} y_{(f,t)} \leq \mathsf{rank}_{\mathscr{F}}(T) \qquad \forall T \subseteq X : \{(f, t) : f \in T\} \subseteq \delta^-(t).$$

[4] Monotone integer-valued submodular functions.

Now, we prove a claim analogous to that of Claim 8.

▷ Claim 18. WMatPP is equivalent to solving the polymatroidal flow on network G'.

Proof. Any solution P for the WMatPP instance translates to a valid flow of cost $-\mathsf{val}(P)$ for the flow problem. Let $S \in \mathscr{F}$ be the independent set that intersects $Y_{\mathsf{sink}(p)}$ for all $p \in P$. For any path $p \in P$ with start vertex u and sink vertex v, take arbitrary $f \in S \cap Y_v$. Send one unit of flow from s to u, through p to v and then to f and t. All the polymatroidal constraints in WMatPP LP are satisfied.

Now we argue that any solution to the flow instance with cost $-m$ translates to a solution P for WMatPP with $\mathsf{val}(P) = m$. To see this, note that the flow solution consists of s,t paths that are vertex disjoint with respect to $V \cup X$. This is due to our choice of $V \cup X$ polymatroids. Each path passes through one $v \in V$, then immediately to $f \in Y_v$ and then ends in t. By polymatroidal constraints on t, the subset of X that has a flow going through it will be an independent set of $\mathscr{F}$.

Let P be the described paths induced on V. For a $v \in V$, $-\lambda(v)$ is counted towards the MCMF cost iff v has a flow passing through it. This means v is included in some path in P. Thus $\mathsf{val}(P) = m$. ◁

The polymatroidal LP for this particular construction is as follows (recall $\mathsf{flow}(v) := \sum_{e \in \delta^-(v)} y_e$):

$$\max \sum_{v \in V} \mathsf{flow}(v)\lambda(v) \qquad \text{(WMatPP LP)}$$

$$\mathsf{flow}(v) := \sum_{e \in \delta^-(v)} y_e = \sum_{e \in \delta^+(v)} y_e \qquad \forall v \in V \cup X$$

$$\sum_{f \in T} y_{(f,t)} \leq \mathsf{rank}_{\mathscr{F}}(T) \qquad \forall T \subseteq X : \{(f,t) : f \in T\} \subseteq \delta^-(t)$$

$$\mathsf{flow}(v) \leq 1 \qquad \forall v \in V \cup X$$

$$0 \leq y_e \leq 1 \qquad \forall e \in E'$$

By [13], WMatPP LP is integral and there are polynomial time algorithms to solve it.

As for reducing PMCO to WMatPP, most of the notation and results can be recycled from Section 3.1. Specially, the reduction itself (Algorithm 3) is just Algorithm 2 with Line 4 added. **Note:** By definition of an arc in contact DAG, for two nodes $u, v \in V$, (u,v) is an arc iff Y_v intersects Y_u.

Algorithm 3 Reduction to WMatPP.

Input: PMCO instance $\mathcal{I} = ((X,d), r, \mathscr{F}, m)$ and assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in X\}$

1: $R_i, \{D(u) : u \in R_i\} \leftarrow \mathsf{HS}((C_i, d), r, \mathsf{cov})$ for all $i \in [t]$
2: Construct contact DAG $G = (V, E)$ per Definition 9
3: $\lambda(v) \leftarrow |D(v)|$ for all $v \in V$
4: $Y_v \leftarrow \{u \in X : d(u,v) \leq r_v\}$ for all $v \in V$

Output: WMatPP instance $(G = (V,E), \lambda, X, \mathcal{Y}, \mathscr{F})$

Before we start to prove our 9-approximation result for PMCO, we need to slightly modify Claim 12 to account for the fact that a vertex covered by v (the sink of some path) has to travel slightly farther than v to reach an $f \in Y_v$. Fortunately, the proof of Claim 12 has a slight slack that allows us to derive the same distance guarantees even with this extra step.

▷ Claim 19. For any $u \in R_i$ and $v \in R_j$ reachable from u in contact DAG G, and any $f \in Y_v$, $d(u, f) < 3 \cdot 2^i$.

Proof. By definition of G it must be the case that $i > j$. Also for all $f \in Y_v$, $d(f, v) \leq r_v$. If v is reachable from u, a path between u and v may contain a vertex w_k from every level R_k for $j < k < i$:

$$\begin{aligned} d(u,f) &\leq d(u,v) + d(v,f) \leq d(u,v) + r_v \\ &\leq (r_u + r_{w_{i-1}}) + (r_{w_{i-1}} + r_{w_{i-2}}) + \ldots + (r_{w_{j+1}} + r_v) + r_v && \text{(by Fact 2)} \\ &\leq r_u + 2\sum_{k=1}^{i-1} 2^k && \text{(by definition of } C_k\text{)} \\ &= r_u + 2 \cdot (2^i - 2) < 3 \cdot 2^i. && (u \in C_i,\ r_u < 2^i) \end{aligned}$$

◁

Since the previous claim has the same guarantee as Claim 12, Lemma 11 easily translates to the following:

▶ **Lemma 20.** *Any solution with value at least m for the output of Algorithm 3 translates to a 9-approximation for the input $\mathcal{I}$.*

Proof. Let $P \in \mathcal{P}(G)$ be the promised WMatPP solution. Let $S \in \mathscr{F}$ be the independent set that intersects $Y_{\mathsf{sink}(p)}$ for all $p \in P$. By Claim 19, S covers all the vertices $v \in V$ that are included in P by dilation 3. Proof of Lemma 11 shows that for any such $v \in V$ covered by P and any $w \in D(v)$, $d(w, S) \leq 9r_w$. This holds for at least m points. ◀

We can now prove our 9-approximation result for PMCO.

Proof of Theorem 16. The algorithm is very similar to that of Theorem 6: Given PMCO instance $\mathcal{I} = ((X, d), r, \mathscr{F}, m)$, solve the PMCO LP and use the solution in the procedure of Algorithm 3 to reduce to WMatPP instance $\mathcal{J} = (G = (V, E), \lambda, X, \mathcal{Y}, \mathscr{F})$. Let $P \in \mathcal{P}(G)$ be the solution to this instance and $S \in \mathscr{F}$ be the independent set that intersects $Y_{\mathsf{sink}(p)}$ for all $p \in P$. If $\mathsf{val}(P) \geq m$, S is a 9-approximate solution for $\mathcal{I}$ via Lemma 20. So we prove such solution P exists by constructing a feasible (possibly fractional) WMatPP LP solution.

Take the contact DAG of Algorithm 3 $G = (V, E)$ and recall that each $v \in V$ is also a point in X. For any $f \in X$ let $A_f := \{v \in V : d(f, v) \leq r_v\}$ be the set of points $v \in V$ for which x_f contributes to $\mathsf{cov}(v)$. By definition of an edge in contact DAG, for any $u, v \in A_f$, we have $(u, v) \in E$. Define p_f to be the s, t path that passes through A_f in the order of decreasing neighborhood radii. Formally, let $(u_1, \ldots, u_l)$ be A_f sorted in decreasing order of neighborhood radii. Then, $p_f = ((s, u_1), (u_1, u_2), \ldots (u_l, f), (f, t))$. Similar to the proof of Theorem 6 we define $H_e := \{f \in X : e \in p_f\}$ and set y as follows:

$$y_e := \sum_{f \in H_e} x_f.$$

Now, we argue that y is a feasible solution for WMatPP LP with objective value at least m. The flow is conserved for each vertex $v \in V \cup X$ since for any $f \in X$, we add the same amount x_f to y_e of all $e \in p_f$. Observe that $\mathsf{flow}(v) = \mathsf{cov}(v)$ thus the constraint $\mathsf{cov}(v) \leq 1$ in PkCO LP implies $\mathsf{flow}(v) \leq 1$. To see why the rank constraints are satisfied, the key observation is that any $e \in \delta^-(t)$ must be of the form (f, t) for some $f \in X$, and by our construction $y_e = x_f$. So according to constraint $\sum_{f \in T} x_f \leq \mathsf{rank}_{\mathscr{F}}(T)$ in PMCO LP we have $\sum_{f \in T} y_{(f,t)} \leq \mathsf{rank}_{\mathscr{F}}(T)$. Lastly, the WMatPP LP objective for this solution is at least m. The proof is identical to what we had for Theorem 6. ◀

5 Priority Knapsack-Center with Outliers

In this section, we show how to generalize the results from the previous section for the case of Priority Knapsack-Center with Outliers (PKnapCO).

▶ **Definition 21** (Priority Knapsack-Center with Outliers (PKnapCO)). *The input is a metric space (X, d), a radius function $r : X \to \mathbb{R}_{>0}$, a weight function $\mathsf{w} : X \to \mathbb{R}_{\geq 0}$, parameters $B > 0$ and $m \in \mathbb{N}$. The goal is to find $S \subseteq X$ with $\mathsf{w}(S) \leq B$ to minimize α such that for at least m points $v \in X$, $d(v, S) \leq \alpha \cdot r(v)$.*

▶ **Theorem 22.** *There is a 14-approximation for PKnapCO.*

As in PkCO and PMCO, we reduce to the following path packing problem.

▶ **Definition 23** (Weighted Knapsack-Path Packing (WNapPP)). *The input is $G = (V, E)$ and λ same as in WkPP, plus X a finite set, $\mathsf{w} : X \to \mathbb{R}_{\geq 0}$, $\mathcal{Y} = \{Y_v \subseteq X : v \in V\}$, and parameter $B > 0$. The goal is to find a set of disjoint paths $P \in \mathcal{P}(G)$ with maximum $\mathsf{val}(M)$ for which there exists $S \subseteq X$ with $w(S) \leq B$ such that $\forall p \in P$, $S \cap Y_{\mathsf{sink}(p)} \neq \emptyset$.*

There are two main issues in generalizing our techniques from Section 3 and Section 4. First, the WNapPP problem seems hard on a general DAG. To circumvent this, we make two changes to the LP-aware PKnapCO to WNapPP reduction (given in Algorithm 4). First, we modify Algorithm 1 so that a representative captures points at *larger* distances. To be precise, for a representative u, Algorithm 1 is modified to: $D(u) \leftarrow \{v \in U : d(u, v) \leq r_u + 2r_v\}$. Second, the partition induced by C_i's in Algorithm 2 is done via powers of 4 instead of 2. This is what bumps our approximation factor from 9 to 14. However it helps, as the resulting contact DAG is in fact a directed out-forest. It is not too hard to solve WNapPP when G is a directed-out forest using dynamic programming.

Algorithm 4 Reduction to WNapPP.

Input: PKnapCO instance $\mathcal{I} = ((X, d), r, \mathsf{w}, B, m)$ and assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in X\}$

1: $R_i, \{D(u) : u \in R_i\} \leftarrow \mathsf{ModHS}((C_i, d), r, \mathsf{cov})$ for all $i \in [t]$
2: Construct contact forest $G = (V, E)$ per Definition 24
3: $\lambda(v) \leftarrow |D(v)|$ for all $v \in V$
4: $Y_v \leftarrow \{u \in X : d(u, v) \leq r_v\}$ for all $v \in V$

Output: WNapPP instance $(G = (V, E), \lambda, X, \mathcal{Y}, \mathsf{w}, B)$

▶ **Definition 24** (contact forest). *Let $R_i \subseteq C_i$, $i \in [t]$ be the set of representatives acquired after running ModHS procedure on C_i according to Line 2 of Algorithm 4. contact forest $G = (V, E)$ is a directed forest on vertex set $V = \bigcup_i R_i$ where the arcs are constructed by the as follows: For $u \in R_i$ and $v \in R_j$ where $i > j$, add the arc $(u, v) \in E$ if there exists $f \in X$ such that $d(u, f) \leq r_u$ and $d(v, f) \leq 2r_v$. Next, remove all the forward edges*[5].

The second issue is more difficult to handle. In PkCO and PMCO, we used the fact that WkPP and WMatPP LPs are integral to show that the instances constructed by the reduction have large value. This is not true any more as the WNapPP LP is not integral even when G is a forest. Indeed, the natural LP relaxation for PKnapCO has unbounded integrality gap even without priorities [14].

[5] In a DAG, edge (u, v) is a forward edge if there is a path of length two or more in the graph that connects u to v.

We circumvent this by using the round and cut framework of [8]. Instead of using the PKnapCO LP, we would use cov in the convex hull of the integral solutions (call it $\mathscr{P}_{\mathsf{cov}}$). Of course, we do not know the integral solutions and there may indeed be exponentially such solutions. So, we have to employ the ellipsoid algorithm. In each iteration of ellipsoid, we get some cov that may or may not be in $\mathscr{P}_{\mathsf{cov}}$. In any case, if we manage to get a good path packing solution using this cov, we get an approximate PKnapCO solution and we are done. Otherwise, we are able to give ellipsoid a linear constraint that should be satisfied by any point in $\mathscr{P}_{\mathsf{cov}}$ but is violated by the current cov. Ultimately, either we find an approximate solution for PKnapCO along the way, or ellipsoid prompts that $\mathscr{P}_{\mathsf{cov}}$ is empty, indicating that the problem is infeasible.

From here on, let $\mathscr{F}$ be the set of all possible centers that fit in the budget. That is, $\mathscr{F} := \{S \subseteq X : \mathsf{w}(S) \leq B\}$. The following is the convex hull of the integral solutions for PKnapCO.

$$\mathscr{P}_{\mathsf{cov}} = \{(\mathsf{cov}(v) : v \in X) : \sum_{v \in X} \mathsf{cov}(v) \geq m \qquad (\mathscr{P}_{\mathsf{cov}}.1)$$

$$\forall v \in X, \quad \mathsf{cov}(v) := \sum_{\substack{S \in \mathscr{F}: \\ d(v,S) \leq r_v}} z_S \qquad (\mathscr{P}_{\mathsf{cov}}.2)$$

$$\sum_{S \in \mathscr{F}} z_S = 1 \qquad (\mathscr{P}_{\mathsf{cov}}.3)$$

$$\forall S \in \mathscr{F}, \quad z_S \geq 0\} \qquad (\mathscr{P}_{\mathsf{cov}}.4)$$

We show if $\mathsf{cov}(v) \in \mathscr{P}_{\mathsf{cov}}$, then indeed the WNapPP instance obtained is "valuable", that is, has value $\geq m$. More importantly, we show that if the instance is *not* valuable, then we can find a hyperplane separating cov from $\mathscr{P}_{\mathsf{cov}}$. One can now use the ellipsoid method to get the 14-approximation: given cov, we either get a valuable WNapPP instance leading to a 14 approximation, or we find a separating hyperplane which can be fed to the ellipsoid method to obtain a new cov vector. The details are omitted in this version due to space restrictions and can be found in [2].

6 Connections to Fair Clustering

In this section, we show how our results imply results in the two fairness notions as defined by [28] and [22].

6.1 "A Center in your Neighborhood" notion of [28]

Jung et al. [28] argue that fairness in clustering should take into account population densities and geography. For every $v \in X$, they define a *neighborhood radius* $\mathrm{NR}(v)$ to be the distance to its $(\lceil n/k \rceil - 1)$th nearest neighbor. A solution is fair, they argue, if every v is served within their $\mathrm{NR}(v)$. They also observe that this may not always be possible, and therefore they wish to find a placement $S \subseteq X$ minimizing $\max_v \frac{d(v,S)}{\mathrm{NR}(v)}$. As an optimization problem, the problem is precisely an instantiation of Priority k-Center. Thus, one can easily obtain a 2-approximation once $r(v) = \mathrm{NR}(v)$ is fixed.

[28] in fact show that it is always possible to find S such that $d(v, S) \leq 2\mathrm{NR}(v)$. They do so by looking at the centers obtained from running their algorithm which is the same as that of Plesník. Note that a 2-approximation to the instance of Priority k-Center defined by

$r(v) = \mathrm{NR}(v)$ does not necessarily imply this additional property. Here we show why it is not a coincidence by considering the natural LP relaxation for Priority k-Center. Given an instance of Priority k-Center one can obtain a lower bound on the optimum value by finding the smallest α such that the following LP is feasible.

$$\mathrm{PkCFeasLP}(\alpha) \;:=\; \{(y_u \geq 0 \;:\; u \in X) : \quad \sum_{u \in X} y_u \leq k; \quad \forall v \in X : \sum_{u : d(u,v) \leq \alpha r(v)} y_u \geq 1\} \quad (1)$$

▷ Claim 25. Suppose $\mathrm{PkCFeasLP}(\alpha)$ has a feasible solution, then Algorithm 1 run with $\phi(v) = \frac{1}{r(v)}$ finds at most k centers that cover each point v within distance $2\alpha r(v)$.

Proof. The proof is similar to that of Theorem 3. Without loss of generality we can assume $\alpha = 1$, otherwise we can scale all the radii by $1/\alpha$. We need to argue $|S| \leq k$. For any $u \in S$, we have $\sum_{v \in D(u)} y_v \geq 1$ since $B(u, r(u)) \subseteq D(u)$. Since $D(u)$'s are disjoint and $\sum_{u \in X} y_u \leq k$, the claim follows. ◁

The preceding discussion and the claim show the utility of viewing the clustering problem of [28] as a special case of Priority k-Center. One can then bring to bear all the positive algorithmic results on Priority k-Center (such as Theorem 4) to fine-tune the fair clustering model. Below we list a few high-level speculative ideas on how the Priority k-Center view can help.

- The LP relaxation could be useful in obtaining better empirical solutions. For example, it has been shown that for k-center, the LP relaxation is integral under notions of stability [12].
- The model of [28] allows $\mathrm{NR}(v)$ to be very large for points v which may not be near many points. However, one may want to put an upper bound M on the radius that is independent of $\mathrm{NR}(v)$. The same algorithm works to give a 2-approximation but one may no longer have the property that all points are covered within twice $\mathrm{NR}(v)$.
- In many scenarios it makes sense to work with the supplier version since centers cannot necessarily be placed at all locations in X. Second, there could be several additional constraints on the set of centers that can be chosen. Theorem 4 shows that more general constraints than cardinality can be handled.
- Related to the first point above, far away points in less dense regions (outliers) can be harmed by setting $\mathrm{NR}(v)$ to be a large number. Alternatively, one can skew the choice of centers if one tries to set a small radius for these points. In this situation it is useful to have algorithms that can handle outliers such that one can find a good solution for vast majority of points and help the outliers via other techniques.

6.2 The Lottery Model of Harris et al. [22]

Harris et al. [22] define a lottery model of fairness where every client $v \in X$ has a "distance demand" $r(v)$ and a "probability demand" $p(v)$. They deem a lottery or a distribution over feasible solutions fair if every client is connected to a facility within their distance demand with probability at least the probability demand. The computational question is to figure out if this is (approximately) feasible. We show a connection to the outlier version of the priority k-center problem, and then generalize their results. We start with a definition.

▶ **Definition 26** (Lottery Priority $\mathscr{F}$-Center (LP$\mathscr{F}$C)). *The input is a metric space (X, d) where each point v has a distance demand $r(v) > 0$ and probability demand $\mathsf{prob}(v)$. The input also (implicitly) specifies a family $\mathscr{F} \subseteq 2^X$ of allowed locations where centers can be opened. A distribution over $\mathscr{F}$ is α-approximate if*

$$\forall v \in X : \quad \Pr_{S \sim \mathscr{F}}[d(v, S) \leq \alpha \cdot r(v)] \geq \mathsf{prob}(v).$$

An α-approximation algorithm in the lottery model either asserts the instance infeasible in that an 1-approximate distribution doesn't exist, or returns an α-approximate distribution.

Harris et al. [22] show that for the case when $\mathscr{F}$ is simply $\{S : |S| \leq k\}$, there is a 9-approximate distribution. Using our results described before, and the by now standard framework using the ellipsoid method (as in [6, 1]), we can get the following results.

▶ **Theorem 27.** *There is a 9-approximation for LP$\mathscr{F}$C where $\mathscr{F}$ is the independent set of a matroid.*

▶ **Theorem 28.** *There is a 14-approximation for LP$\mathscr{F}$C on points X where $\mathscr{F} = \{S \subseteq X : \mathsf{w}(S) \leq B\}$ for a poly-bounded weight function $\mathsf{w} : X \to \mathbb{R}_{\geq 0}$ and parameter $B > 0$.*

We first describe the reduction. For this, we need to define the Fractional Priority $\mathscr{F}$-Center where each point comes with a (possibly fractional) weight μ_v and given $m \geq 0$, the goal is to find a set $S \in \mathscr{F}$ that covers a total weight of more than m with minimum dilation of neighborhood radii.

▶ **Definition 29** (Fractional Priority $\mathscr{F}$-Center (FP$\mathscr{F}$C)). *The input is a metric space (X, d) where each point v has a radius $r_v > 0$ and a weight $\mu_v \geq 0$. Given parameter $m \geq 0$ and a family of subsets of points $\mathscr{F} \subseteq 2^X$, the goal is to find $S \in \mathscr{F}$ to minimize α such that $\mu(\{v \in X : d(v, S) \leq \alpha \cdot r_v\}) > m$.*

An instance of FP$\mathscr{F}$C is specified by the tuple $((X, d), r, \mu, \mathscr{F}, m)$. The following theorem states the reduction from LP$\mathscr{F}$C to FP$\mathscr{F}$C using the ellipsoid method. The proof of this theorem can be found in [2].

▶ **Theorem 30.** *Given LP$\mathscr{F}$C instance $\mathcal{I}$ and a black-box α-approximate algorithm $\mathcal{A}$ for FP$\mathscr{F}$C that runs in time $T(\mathcal{A})$, one can get an α-approximate solution for $\mathcal{I}$ in time poly$(|\mathcal{I}|)T(\mathcal{A})$.*

Now we discuss how our results generalize to solve FP$\mathscr{F}$C for matroid and knapsack constraints.

Proof of Theorem 27. According to Theorem 30 we only need to prove that we can find a 9-approximate solution for any given FP$\mathscr{F}$C instance $\mathcal{I} = ((X, d), r, \mu, \mathscr{F}, m)$. First, observe that the LP for $\mathcal{I}$ is the same as PMCO LP with a minor modification: The constraint $\sum_{v \in X} \mathsf{cov}(v) \geq m$ is changed to $\sum_{v \in X} \mu_v \mathsf{cov}(v) > m$. Solve the LP for $\mathcal{I}$ and use the obtained cov to run the reduction in Algorithm 3; but with a change in Line 3): instead of setting $\lambda(v) \leftarrow |D(v)|$ for all $v \in V$, we will have $\lambda(v) \leftarrow \mu(D(v))$. This results in a WMatPP instance $\mathcal{J}$ with fractional λ. The procedure in [13] can handle fractional λ's so we can still compute the solution for $\mathcal{J}$ in polynomial time. If this solution has value less than or equal to m, we know that $\mathcal{I}$ is infeasible. Otherwise, Lemma 20 tells us that this solution for $\mathcal{J}$ translates to a 9-approximation for $\mathcal{I}$ and we are done. ◀

Proof of Theorem 28. We follow a procedure similar to the proof of Theorem 27. Per Theorem 30 we only need to prove there is a 14-approximation for the FP$\mathscr{F}$C instance where $\mathscr{F}$ is a set of feasible knapsack solutions with poly-bounded weights $\mathsf{w} : X \to \mathbb{R}_{\geq 0}$ and budget $B > 0$. Change the constraint $\mathscr{P}_{\mathsf{cov}}.1$ in $\mathscr{P}_{\mathsf{cov}}$ to $\sum_{v \in X} \mu_v \mathsf{cov}(v) > m$ and modify Line 3 of Algorithm 4 to $\lambda(v) \leftarrow \mu(D(v))$ then follow the round-or-cut procedure in the proof of Theorem 22. The only challenge here is to prove the WNapPP problem can be solved in polynomial time. The dynamic program (which can be found in [2]) depends on the assumption that λ's are poly-bounded. But here, our λ's are real numbers so instead, we assume that our weights $\mathsf{w} : X \to \mathbb{R}_{\geq 0}$ are poly-bounded so we can still solve the problem via dynamic programming. ◀

The Submodular Santa Claus Problem in the Restricted Assignment Case

Abstract

The submodular Santa Claus problem was introduced in a seminal work by Goemans, Harvey, Iwata, and Mirrokni (SODA'09) as an application of their structural result. In the mentioned problem n unsplittable resources have to be assigned to m players, each with a monotone submodular utility function f_i. The goal is to maximize $\min_i f_i(S_i)$ where $S_1, \dots, S_m$ is a partition of the resources. The result by Goemans et al. implies a polynomial time $O(n^{1/2+\varepsilon})$-approximation algorithm.

Since then progress on this problem was limited to the linear case, that is, all f_i are linear functions. In particular, a line of research has shown that there is a polynomial time constant approximation algorithm for linear valuation functions in the restricted assignment case. This is the special case where each player is given a set of desired resources Γ_i and the individual valuation functions are defined as $f_i(S) = f(S \cap \Gamma_i)$ for a global linear function f. This can also be interpreted as maximizing $\min_i f(S_i)$ with additional assignment restrictions, i.e., resources can only be assigned to certain players.

In this paper we make comparable progress for the submodular variant: If f is a monotone submodular function, we can in polynomial time compute an $O(\log\log(n))$-approximate solution.

1 Introduction

In the Santa Claus problem (sometimes referred to as Max-Min Fair Allocation) we are given a set of n players P and a set of m indivisible resources R. In its full generality, each player $i \in P$ has a utility function $f_i : 2^R \mapsto \mathbb{R}_{\geq 0}$, where $f_i(S)$ measures the happiness of player i if he is assigned the resource set S. The goal is to find a partition of the resources that maximizes the happiness of the least happy player. Formally, we want to find a partition $\{S_i\}_{i \in P}$ of the resources that maximizes $\min_{i \in P} f_i(S_i)$.

With such an objective function one seeks to find the fairest solution as opposed to for example the best average happiness. Most of the recent literature on this problem focuses on cases where f_i is a linear function for all players i. If we assume all valuation functions are linear, the best approximation algorithm known for this problem, designed by Chakrabarty, Chuzhoy, and Khanna [4], has an approximation rate of n^ϵ and runs in time $n^{O(1/\epsilon)}$ for $\epsilon \in \Omega(\log\log(n)/\log(n))$. On the negative side, it is only known that computing

a $(2-\delta)$-approximation is NP-hard [13]. Apart from this there has been significant attention on the so-called *restricted assignment case*. Here the utility functions are defined by one linear function f and a set of resources Γ_i for each player i. Intuitively, player i is interested in the resources Γ_i, whereas the other resources are worthless for him. The individual utility functions are then implicitly defined by $f_i(S) = f(S \cap \Gamma_i)$. In a seminal work, Bansal and Srividenko [3] provide a $O(\log\log(m)/\log\log\log(m))$-approximation algorithm for this case. This was improved by Feige [8] to an $O(1)$-approximation. Further progress on the constant or the running time was made since then, see e.g. [1, 7, 6, 5, 10, 2, 15].

Let us now move to the non-linear case. Indeed, the problem becomes hopelessly difficult without any restrictions on the utility functions. Consider the following reduction from set packing. There are sets of resources $\{S_1, \ldots, S_k\}$ and all utility functions are equal and defined by $f_i(S) = 1$ if $S_j \subseteq S$ for some j and $f_i(S) = 0$ otherwise. Deciding whether there are m disjoint sets in $S_1, \ldots, S_k$ (a classical NP-hard problem) is equivalent to deciding whether the optimum of the Santa Claus problem is non-zero. In particular, obtaining any bounded approximation ratio for Santa Claus in this case is NP-hard.

Two naturally arising properties of utility functions are monotonicity and submodularity, see for example the related submodular welfare problem [12, 16] where the goal is to maximize $\sum_i f_i(S_i)$. A function f is monotone, if $f(S) \leq f(T)$ for all $S \subseteq T$. It is submodular, if $f(S \cup \{a\}) - f(S) \geq f(T \cup \{a\}) - f(T)$ for all $S \subseteq T$ and $a \notin T$. The latter is also known as the *diminishing returns* property in economics. A standard assumption on monotone submodular functions (used throughout this work) is that the value on the empty set is zero, i.e., $f(\emptyset) = 0$. Goemans, Harvey, Iwata, and Mirrokni [9] first considered the Santa Claus problem with monotone submodular utility functions as an application of their fundamental result on submodular functions. Together with the algorithm of [4] it implies an $O(n^{1/2+\epsilon})$-approximation in time $n^{O(1/\epsilon)}$. In the case that the valuation functions are all equal, that is, $f_i(S) = f(S)$ for a monotone submodular function f, Krause, Rajagopal, Gupta, and Guestrin gave a constant approximation [11]. We also refer to their work for an application of this problem in sensor placement.

In this paper we investigate the restricted assignment case with a monotone submodular utility function. That is, all utility functions are defined by $f_i(S) = f(S \cap \Gamma_i)$, where f is a monotone submodular function and Γ_i is a subset of resources for each players i. Before our work, the state-of-the-art for this problem was the $O(n^{1/2+\epsilon})$-approximation algorithm mentioned above, since none of the previous results for the restricted assignment case with a linear utility function apply when the utility function becomes monotone submodular.

1.1 Overview of results and techniques

Our main result is an approximation algorithm for the submodular Santa Claus problem in the restricted assignment case.

▶ **Theorem 1.** *There is a randomized polynomial time $O(\log\log(n))$-approximation algorithm for the restricted assignment case with a monotone submodular utility function.*

Our way to this result is organised as follows. In Section 2, we first reduce our problem to a hypergraph matching problem (see next paragraph for a formal definition). We then solve this problem using Lovasz Local Lemma (LLL) in Section 3. In [3] the authors also reduce to a hypergraph matching problem which they then solve using LLL, although both parts are substantially simpler. The higher generality of our utility functions is reflected in the more general hypergraph matching problem. Namely, our problem is precisely the weighted variant of the (unweighted) problem in [3]. We will elaborate later in this section why the previous techniques do not easily extend to the weighted variant.

The hypergraph matching problem. After the reduction in Section 2 we arrive at the following problem. There is a hypergraph $\mathcal{H} = (P \cup R, \mathcal{C})$ with hyperedges $\mathcal{C}$ over the vertices P and R. We write $m = |P|$ and $n = |R|$. We will refer to hyperedges as configurations, the vertices in P as players and R as resources[1]. Moreover, a hypergraph is said to be regular if all vertices in P and R have the same degree, that is, they are contained in the same number of configurations. The hypergraph may contain multiple copies of the same configuration. Each configuration $C \in \mathcal{C}$ contains exactly one vertex in P, that is, $|C \cap P| = 1$. Additionally, for each configuration $C \in \mathcal{C}$ the resources $j \in C$ have weights $w_{j,C} \geq 0$. We emphasize that the same resource j can be given different weights in two different configurations, that is, we may have $w_{j,C} \neq w_{j,C'}$ for two different configurations C, C'.

We require to select for each player $i \in P$ one configuration C that contains i. For each configuration C that was selected we require to assign a subset of the resources in C which has a total weight of at least $(1/\alpha) \cdot \sum_{j \in C} w_{j,C}$ to the player in C. A resource can only be assigned to one player. We call such a solution an α-relaxed perfect matching. One seeks to minimize α.

We show that every regular hypergraph has an α-relaxed perfect matching for some $\alpha = O(\log \log(n))$ assuming that $w_{j,C} \leq (1/\alpha) \cdot \sum_{j' \in C} w_{j',C}$ for all j, C, that is, all weights are small compared to the total weight of the configuration. Moreover, we can find such a matching in randomized polynomial time. In the reduction we use this result to round a certain LP relaxation and α essentially translates to the approximation rate. This result generalizes that of Bansal and Srividenko on hypergraph matching in the following way. They proved the same result for unit weights and uniform hyperedges, that is, $w_{j,C} = 1$ for all j, C and all hyperedges have the same number of resources[2]. In the next paragraph we briefly go over the techniques to prove our result for the hypergraph matching problem.

Our techniques. Already the extension from uniform to non-uniform hypergraphs (assuming unit weights) is highly non-trivial and captures the core difficulty of our result. Indeed, we show with a (perhaps surprising) reduction, that we can reduce our weighted hypergraph matching problem to the unweighted (but non-uniform) version by introducing some bounded dependencies between the choices of the different players. For sake of brevity we therefore focus in this section on the unweighted non-uniform variant, that is, we need to assign to each player a configuration C and at least $|C|/\alpha$ resources in C. We show that for any regular hypergraph there exists such a matching for $\alpha = O(\log \log(n))$ assuming that all configurations contain at least α resources and we can find it in randomized polynomial time. Without the assumption of uniformity the problem becomes significantly more challenging. To see this, we lay out the techniques of Bansal and Srividenko that allowed them to solve the problem in the uniform case. We note that for $\alpha = O(\log(n))$ the statement is easy to prove: We select for each player i one of the configurations containing i uniformly at random. Then by standard concentration bounds each resource is contained in at most $O(\log(n))$ of the selected configurations with high probability. This implies that there is a fractional assignment of resources to configurations such that each of the selected configurations C receives $\lfloor |C|/O(\log(n)) \rfloor$ of the resources in C. By integrality of the bipartite matching polytope, there is also an integral assignment with this property.

To improve to $\alpha = O(\log \log(n))$ in the uniform case, Bansal and Srividenko proceed as follows. Let k be the size of each configuration. First they reduce the degree of each player and resource to $O(\log(n))$ using the argument above, but taking $O(\log(n))$ configurations for

[1] We note that these do not have to be the same players and resources as in the Santa Claus problem we reduced from, but n and m do not increase.

[2] In fact they get a slightly better ratio of $\alpha = O(\log \log(m)/ \log \log \log(m))$.

each player. Then they sample uniformly at random $O(n \log(n)/k)$ resources and drop all others. This is sensible, because they manage to prove the (perhaps surprising) fact that an α-relaxed perfect matching with respect to the smaller set of resources is still an $O(\alpha)$-relaxed perfect matching with respect to all resources with high probability (when assigning the dropped resources to the selected configurations appropriately). Indeed, the smaller instance is easier to solve: With high probability all configurations have size $O(\log(n))$ and this greatly reduces the dependencies between the bad events of the random experiment above (the event that a resource is contained in too many selected configurations). This allows them to apply Lovász Local Lemma (LLL) in order to show that with positive probability the experiment succeeds for $\alpha = O(\log \log(n))$.

It is not obvious how to extend this approach to non-uniform hypergraphs: Sampling a fixed fraction of the resources will either make the small configurations empty – which makes it impossible to retain guarantees for the original instance – or it leaves the big configurations big – which fails to reduce the dependencies enough to apply LLL. Hence it requires new sophisticated ideas for non-uniform hypergraphs, which we describe next.

Suppose we are able to find a set $\mathcal{K} \subseteq \mathcal{C}$ of configurations (one for each player) such that for each $K \in \mathcal{K}$ the sum of intersections $|K \cap K'|$ with smaller configurations $K' \in \mathcal{K}$ is very small, say at most $|K|/2$. Then it is easy to derive a 2-relaxed perfect matching: We iterate over all $K \in \mathcal{K}$ from large to small and reassign all resources to K (possibly stealing them from the configuration that previously had them). In this process every configuration gets stolen at most $|K|/2$ of its resources, in particular, it keeps the other half. However, it is non-trivial to obtain a property like the one mentioned above. If we take a random configuration for each player, the dependencies of the intersections are too complex. To avoid this we invoke an advanced variant of the sampling approach where we construct not only one set of resources, but a hierarchy of resource sets $R_0 \supseteq \cdots \supseteq R_d$ by repeatedly dropping a fraction of resources from the previous set. We then formulate bad events based on the intersections of a configuration C with smaller configurations C', but we write it only considering a resource set R_k of convenient granularity (chosen based on the size of C'). In this way we formulate a number of bad events using various sets R_k. This succeeds in reducing the dependencies enough to apply LLL. Unfortunately, even with this new way of defining bad events, the guarantee that for each $K \in \mathcal{K}$ the sum of intersections $|K \cap K'|$ with smaller configurations $K' \in \mathcal{K}$ is at most $|K|/2$ is still too much to ask. We can only prove some weaker property which makes it more difficult to reconstruct a good solution from it. The reconstruction still starts from the biggest configurations and iterates to finish by including the smallest configurations but it requires a delicate induction where at each step, both the resource set expands and some new small configurations that were not considered before come into play.

Additional implications of non-uniform hypergraph matchings to the Santa Claus problem. We believe this hypergraph matching problem is interesting in its own right. Our last contribution is to show that finding good matchings in unweighted hypergraphs with fewer assumptions than ours would have important applications for the Santa Claus problem with linear utility functions. We recall that here, each player i has its own utility function f_i that can be any linear function. In this case, the best approximation algorithm is due to Chakrabarty, Chuzhoy, and Khanna [4] who gave a $O(n^\epsilon)$-approximation running in time $O(n^{1/\epsilon})$. In particular, no sub-polynomial approximation running in polynomial time is known. Consider as before $\mathcal{H} = (P \cup R, \mathcal{C})$ a non-uniform hypergraph with unit weights ($w_{j,C} = 1$ for all j, C such that $j \in C$). Finding the smallest α (or an approximation of it) such that there exists an α-relaxed perfect matching in $\mathcal{H}$ is already a very non-trivial question to solve in polynomial time.

We show, via a reduction, that a c-approximation for this problem would yield a $O((c\log^*(n))^2)$-approximation for the Santa Claus problem with arbitrary linear utility functions. In particular, any sub-polynomial approximation for this problem would significantly improve the state-of-the-art[3]. Details of this last result can be found in the full version of the paper.

A remark on local search techniques. We focus here on an extension of the LLL technique of Bansal and Srividenko. However, another technique proved itself very successful for the Santa Claus problem in the restricted assignment case with a linear utility function. This is a local search technique discovered by Asadpour, Feige, and Saberi [2] who used it to give a non-constructive proof that the integrality gap of the configuration LP of Bansal and Srividenko is at most 4. One may wonder if this technique could also be extended to the submodular case as we did with LLL. Unfortunately, this seems problematic as the local search arguments heavily rely on amortizing different volumes of configurations (i.e., the sum of their resources' weights or the number of resources in the unweighted case). Amortizing the volumes of configurations works well, if each configuration has the same volume, which is the case for the problem derived from linear valuation functions, but not the one derived from submodular functions. If the volumes differ then the amortization arguments break and the authors of this paper believe this is a fundamental problem for this approach.

2 Reduction to hypergraph matching problem

In this section we give a reduction of the restricted submodular Santa Claus problem to the hypergraph matching problem. As a starting point we solve the configuration LP, a linear programming relaxation of our problem. The LP is constructed using a parameter T which denotes the value of its solution. The goal is to find the maximal T such that the LP is feasible. In the LP we have a variable $x_{i,C}$ for every player $i \in P$ and every configuration $C \in \mathcal{C}(i,T)$. The configurations $\mathcal{C}(i,T)$ are defined as the sets of resources $C \subseteq \Gamma_i$ such that $f(C) \geq T$. We require every player $i \in P$ to have at least one configuration and every resource $j \in R$ to be contained in at most one configuration.

$$\sum_{C \in \mathcal{C}(i,T)} x_{i,C} \geq 1 \quad \text{for all } i \in P$$

$$\sum_{i \in P} \sum_{C \in \mathcal{C}(i,T): j \in C} x_{i,C} \leq 1 \quad \text{for all } j \in R$$

$$x_{i,C} \geq 0 \quad \text{for all } i \in P, C \in \mathcal{C}(i,T)$$

Since this linear program has exponentially many variables, we cannot directly solve it in polynomial time. We will give a polynomial time constant approximation for it via its dual. This is similar to the linear variant in [3], but requires some more work. In their case they can reduce the problem to one where the separation problem of the dual can be solved in polynomial time. In our case even the separation problem can only be approximated. Nevertheless, this is sufficient to approximate the linear program in polynomial time.

▶ **Theorem 2.** *The configuration LP of the restricted submodular Santa Claus problem can be approximated within a factor of* $(1-1/e)/2$ *in polynomial time.*

[3] We mention that our result on relaxed matchings in Section 3 does not imply an $O(\log\log(n))$-approximation for this problem since we make additional assumptions on the regularity of the hypergraph or the size of hyperedges.

We defer the proof of this theorem to the full version of the paper. Given a solution x^* of the configuration LP we want to arrive at the hypergraph matching problem from the introduction such that an α-relaxed perfect matching of that problem corresponds to an $O(\alpha)$-approximate solution of the restricted submodular Santa Claus problem. Let T^* denote the value of the solution x^*. We will define a resource $j \in R$ as *fat* if $f(\{j\}) \geq T^*/(100\alpha)$.

Resources that are not fat are called *thin*. We call a configuration $C \in \mathcal{C}(i,T)$ thin, if it contains only thin resources and denote by $\mathcal{C}_t(i,T) \subseteq \mathcal{C}(i,T)$ the set of thin configurations. Intuitively in order to obtain an $O(\alpha)$-approximate solution, it suffices to give each player i either one fat resource $j \in \Gamma_i$ or a thin configuration $C \in \mathcal{C}_t(i, T^*/O(\alpha))$. For our next step towards the hypergraph problem we use a technique borrowed from Bansal and Srividenko [3]. This technique allows us to simplify the structure of the problem significantly using the solution of the configuration LP. Namely, one can find a partition of the players into clusters such that we only need to cover one player from each cluster with thin resources. All other players can then be covered by fat resources. Informally speaking, the following lemma is proved by sampling configurations randomly according to a distribution derived in a non-trivial way from the configuration LP.

▶ **Lemma 3.** *Let $\ell \geq 12\log(n)$. Given a solution of value T^* for the configuration LP in randomized polynomial time we can find a partition of the players into clusters $K_1 \cup \cdots \cup K_k \cup Q = P$ and multisets of configurations $\mathcal{C}_h \subseteq \bigcup_{i \in K_h} \mathcal{C}_t(i, T^*/5)$, $h = 1, \ldots, k$, such that*

1. *$|\mathcal{C}_h| = \ell$ for all $h = 1, \ldots, k$ and*
2. *Each small resource appears in at most ℓ configurations of $\bigcup_h \mathcal{C}_h$.*
3. *given any $i_1 \in K_1, i_2 \in K_2, \ldots, i_k \in K_k$ there is a matching of fat resources to players $P \setminus \{i_1, \ldots, i_k\}$ such that each of these players i gets a unique fat resource $j \in \Gamma_i$.*

The role of the players Q in the lemma above is that each one of them gets a fat resource for certain. The proof follows closely that in [3]. For completeness we include it in the full version of the paper. We are now ready to define the hypergraph matching instance. The vertices of our hypergraph are the clusters $K_1, \ldots, K_k$ and the thin resources. Let $\mathcal{C}_1, \ldots, \mathcal{C}_k$ be the multisets of configurations as in Lemma 3. For each K_h and $C \in \mathcal{C}_h$ there is a hyperedge containing K_h and all resources in C. Let $\{j_1, \ldots, j_m\} = C$ ordered arbitrarily, but consistently. Then we define the weights as normalized marginal gains of resources if they are taken in this order, that is,

$$w_{j_i,C} = \frac{5}{T^*} f(\{j_i\} \mid \{j_1, \ldots, j_{i-1}\}) = \frac{5}{T^*}(f(\{j_1, \ldots, j_{i-1}, j_i\}) - f(\{j_1, \ldots, j_{i-1}\})).$$

This implies that $\sum_{j \in C} w_{j,C} \geq 5f(C)/T^* \geq 1$ for each $C \in \mathcal{C}_h$, $h = 1, \ldots, k$.

▶ **Lemma 4.** *Given an α-relaxed perfect matching to the instance as described by the reduction, one can find in polynomial time an $O(\alpha)$-approximation to the instance of restricted submodular Santa Claus.*

Proof. The α-relaxed perfect matching implies that each cluster K_h gets some small resources C' where $C' \subseteq C$ for some $C \in \mathcal{C}_h$ and $\sum_{j \in C'} w_{j,C} \geq 1/\alpha$. By submodularity we have that $f(C') \geq T^*/(5\alpha)$. Therefore we can satisfy one player in each cluster using thin resources and by Lemma 3 all others using fat resources. ◀

The proof above is the most critical place in the paper where we make use of the submodularity of the valuation function f. We note that since all resources considered are thin resources we have, by submodularity of f, the assumption that

$$w_{j,C} \leq \frac{5}{T^*} f(\{j\}) \leq \frac{5}{T^*} \frac{T^*}{100\alpha} \leq \frac{5}{100\alpha} \sum_{j \in C} w_{j,C}$$

for all j, C such that $j \in C$. This means that the weights are all small enough, as promised in introduction. From now on, we will assume that $\sum_{j \in C} w_{j,C} = 1$ for all configurations C. This is without loss of generality, since we can just rescale the weights inside each configuration. This does not hurt the property that all weights are small enough.

2.1 Reduction to unweighted hypergraph matching

Before proceeding to the solution of this hypergraph matching problem, we first give a reduction to an unweighted variant of the problem. We will then solve this unweighted variant in the next section. First, we note that we can assume that all the weights $w_{j,C}$ are powers of 2 by standard rounding arguments. This only loses a constant factor in the approximation rate. Second, we can assume that inside each configuration C, each resource has a weight that is at least a $1/(2n)$. Formally, we can assume that $\min_{j \in C} w_{j,C} \geq 1/(2n)$ for all $C \in \mathcal{C}$. If this is not the case for some $C \in \mathcal{C}$, simply delete from C all the resources that have a weight less than $1/(2n)$. By doing this, the total weight of C is only decreased by a factor $1/2$ since it looses in total at most a weight of $n \cdot (1/2n) = 1/2$. (Recall that we rescaled the weights so that $\sum_{j \in C} w_{j,C} = 1$).

Hence after these two operations, an α-relaxed perfect matching in the new hypergraph is still an $O(\alpha)$-relaxed perfect matching in the original hypergraph. From there we reduce to an unweighted variant of the matching problem. Note that each configuration contains resources of at most $\log(n)$ different possible weights (powers of 2 from $1/(2n)$ to $1/\alpha$). We create the following new unweighted hypergraph $\mathcal{H}' = (P' \cup R, \mathcal{C}')$. The resource set R remains unchanged. For each player $i \in P$, we create $\log(n)$ players, which later correspond each to a distinct weight. We will say that the players obtained from duplicating the original player form a *group*. For every configuration C containing player i in the hypergraph $\mathcal{H}$, we add a set $\mathcal{S}_C = \{C_1, \ldots, C_s, \ldots, C_{\log(n)}\}$ of configurations in $\mathcal{H}'$. C_s contains player i_s and all resources that are given a weight $2^{-(s+1)}$ in C. In this new hypergraph, the resources are not weighted. Note that if the hypergraph $\mathcal{H}$ is regular then $\mathcal{H}'$ is regular as well.

Additionally, for a group of player and a set of $\log(n)$ configurations (one for each player in the group), we say that this set of configurations is *consistent* if all the configurations selected are obtained from the same configuration in the original hypergraph $\mathcal{H}$ (i.e. the selected configurations all belong to $\mathcal{S}_C$ for some C in $\mathcal{H}$).

Formally, we focus of the following problem. Given the regular hypergraph $\mathcal{H}'$, we want to select, for each group of $\log(n)$ players, a consistent set of configurations $C_1, \ldots, C_s, \ldots, C_{\log(n)}$ and assign to each player i_s a subset of the resources in the corresponding configuration C_s so that i_s is assigned at least $\lfloor |C_s|/\alpha \rfloor$ resources. No resource can be assigned to more than one player. We refer to this assignment as a consistent α-relaxed perfect matching. Note that in the case where $|C_s|$ is small (e.g. of constant size) we are not required to assign any resource to player i_s.

▶ **Lemma 5.** *A consistent α-relaxed matching in $\mathcal{H}'$ induces a $O(\alpha)$-relaxed matching in $\mathcal{H}$.*

Due to space constraint, the proof of this lemma is moved to the full version of the paper.

3 Matchings in regular hypergraphs

In this section we solve the hypergraph matching problem we arrived to in the previous section. For convenience, we give a self contained definition of the problem before formulating and proving our result.

Input. We are given $\mathcal{H} = (P \cup R, \mathcal{C})$ a hypergraph with hyperedges $\mathcal{C}$ over the vertices P (players) and R (resources) with $m = |P|$ and $n = |R|$. As in previous sections, we will refer to hyperedges as configurations. Each configuration $C \in \mathcal{C}$ contains exactly one vertex in P, that is, $|C \cap P| = 1$. The set of players is partitioned into groups of size at most $\log(n)$, we will use A to denote a group. These groups are disjoint and contain all players. Finally there exists an integer ℓ such that for each group A there are ℓ consistent sets of configurations. A consistent set of configurations for a group A is a set of $|A|$ configurations such that all players in the group appear in exactly one of these configurations. We will denote by $\mathcal{S}_A$ such a set and for a player $i \in A$, we will denote by $\mathcal{S}_A^{(i)}$ the unique configuration in $\mathcal{S}_A$ containing i. Finally, no resource appears in more than ℓ configurations. We say that the hypergraph is regular (although some resources may appear in less than ℓ configurations).

Output. We wish to select a matching that covers all players in P. More precisely, for each group A we want to select a consistent set of configurations (denoted by $\{\mathcal{S}_A^{(i)}\}_{i \in A}$). Then for each player $i \in A$, we wish to assign a subset of the resources in $\mathcal{S}_A^{(i)}$ to the player i such that:

1. No resource is assigned to more than one player in total.
2. For any group A and any player $i \in A$, player i is assigned at least $\lfloor |\mathcal{S}_A^{(i)}|/\alpha \rfloor$ resources from $\mathcal{S}_A^{(i)}$.

We call this a consistent α-relaxed perfect matching. Our goal in this section will be to prove the following theorem.

▶ **Theorem 6.** *Let $\mathcal{H} = (P \cup R, \mathcal{C})$ be a regular (non-uniform) hypergraph where the set of players is partitioned into groups of size at most $\log(n)$. Then we can, in randomized polynomial time, compute a consistent α-relaxed perfect matching for $\alpha = O(\log\log(n))$.*

We note that Theorem 6 together with the reduction from the previous section will prove our main result (Theorem 1) stated in introduction.

3.1 Overview and notations

To prove Theorem 6, we introduce the following notations. Let $\ell \in \mathbb{N}$ be the regularity parameter as described in the problem input (i.e. each group has ℓ consistent sets and each resource appears in no more than ℓ configurations). As we proved in Lemma 3 we can assume with standard sampling arguments that $\ell = 300.000 \log^3(n)$ at a constant loss. If this is not the case because we might want to solve the hypergraph matching problem by itself (i.e. not obtained by the reduction in Section 2), the proof of Lemma 3 can be repeated in a very similar way here.

For a configuration C, its size will be defined as $|C \cap R|$ (i.e. its cardinality over the resource set). For each player i, we denote by $\mathcal{C}_i$ the set of configurations that contain i. We now group the configurations in $\mathcal{C}_i$ by size: We denote by $\mathcal{C}_i^{(0)}$ the configurations of size in $[0, \ell^4)$ and for $k \geq 1$ we write $\mathcal{C}_i^{(k)}$ for the configurations of size in $[\ell^{k+3}, \ell^{k+4})$. Moreover, define $\mathcal{C}^{(k)} = \bigcup_i \mathcal{C}_i^{(k)}$ and $\mathcal{C}^{(\geq k)} = \bigcup_{h \geq k} \mathcal{C}^{(h)}$. Let d be the smallest number such that $\mathcal{C}^{(\geq d)}$ is empty. Note that $d \leq \log(n)/\log(\ell)$. Now consider the following random process.

▶ **Random Experiment 7.** *We construct a nested sequence of resource sets $R = R_0 \supseteq R_1 \supseteq \ldots \supseteq R_d$ as follows. Each R_k is obtained from R_{k-1} by deleting every resource in R_{k-1} independently with probability $(\ell - 1)/\ell$.*

In expectation only a $1/\ell$ fraction of resources in R_{k-1} survives in R_k. Also notice that for $C \in \mathcal{C}^{(k)}$ we have that $\mathbb{E}[|R_k \cap C|] = \text{poly}(\ell)$.

The proof of Theorem 6 is organized as follows. In Section 3.2, we give some properties of the resource sets constructed by Random Experiment 7 that hold with high probability. Then in Section 3.3, we show that we can find a single consistent set of configurations for each group of players such that for each configuration selected, its intersection with smaller selected configurations is bounded if we restrict the resource set to an appropriate R_k. Restricting the resource set is important to bound the dependencies of bad events in order to apply Lovasz Local Lemma. Finally in Section 3.4, we demonstrate how these configurations allow us to reconstruct a consistent α-relaxed perfect matching for an appropriate assignment of resources to configurations.

3.2 Properties of resource sets

In this subsection, we give a precise statement of the key properties that we need from Random Experiment 7. The first two lemmas have a straight-forward proof. The last one is a generalization of an argument used by Bansal and Srividenko [3]. Since the proof is more technical and tedious, we also defer it to the full version of the paper along with the proof of the first two statements.

We start with the first property which bounds the size of the configurations when restricted to some R_k. This property is useful to reduce the dependencies while applying LLL later.

▶ **Lemma 8.** *Consider Random Experiment 7 with $\ell \geq 300.000 \log^3(n)$. For any $k \geq 0$ and any $C \in \mathcal{C}^{(\geq k)}$ we have*

$$\frac{1}{2}\ell^{-k}|C| \leq |R_k \cap C| \leq \frac{3}{2}\ell^{-k}|C|$$

with probability at least $1 - 1/n^{10}$.

The next property expresses that for any configuration the sum of intersections with configurations of a particular size does not deviate much from its expectation. In particular, for any configuration C, the sum of it's intersections with other configurations is at most $|C|\ell$ as each resource is in at most ℓ configurations. By the lemma stated below, we recover this up to a multiplicative constant factor when we consider the appropriately weighted sum of the intersection of C with other configurations C' of smaller sizes where each configuration $C' \in \mathcal{C}^{(k)}$ is restricted to the resource set R_k.

▶ **Lemma 9.** *Consider Random Experiment 7 with $\ell \geq 300.000 \log^3(n)$. For any $k \geq 0$ and any $C \in \mathcal{C}^{(\geq k)}$ we have*

$$\sum_{C' \in \mathcal{C}^{(k)}} |C' \cap C \cap R_k| \leq \frac{10}{\ell^k}\left(|C| + \sum_{C' \in \mathcal{C}^{(k)}} |C' \cap C|\right)$$

with probability at least $1 - 1/n^{10}$.

We now define the notion of *good* solutions which is helpful in stating our last property. Let $\mathcal{F}$ be a set of configurations, $\alpha : \mathcal{F} \to \mathbb{N}$, $\gamma \in \mathbb{N}$, and $R' \subseteq R$. We say that an assignment of R' to $\mathcal{F}$ is (α, γ)-good if every configuration $C \in \mathcal{F}$ receives at least $\alpha(C)$ resources of $C \cap R'$ and if no resource in R' is assigned more than γ times in total.

Below we obtain that given a (α, γ)-good solution with respect to resource set R_{k+1}, one can construct an almost $(\ell \cdot \alpha, \gamma)$-good solution with respect to the bigger resource set R_k. Informally, starting from a good solution with respect to the final resource set and iteratively applying this lemma would give us a good solution with respect to our complete set of resources.

▶ **Lemma 10.** *Consider Random Experiment 7 with $\ell \geq 300.000 \log^3(n)$. Fix $k \geq 0$. Conditioned on the event that the bounds in Lemma 8 hold for k, then with probability at least $1 - 1/n^{10}$ the following holds for all $\mathcal{F} \subseteq \mathcal{C}^{(\geq k+1)}$, $\alpha : \mathcal{F} \to \mathbb{N}$, and $\gamma \in \mathbb{N}$ such that $\ell^3/1000 \leq \alpha(C) \leq n$ for all $C \in \mathcal{F}$ and $\gamma \in \{1, \ldots, \ell\}$: If there is a (α, γ)-good assignment of R_{k+1} to $\mathcal{F}$, then there is a (α', γ)-good assignment of R_k to $\mathcal{F}$ where*

$$\alpha'(C) \geq \ell \left(1 - \frac{1}{\log(n)}\right) \alpha(C)$$

for all $C \in \mathcal{F}$. Moreover, this assignment can be found in polynomial time.

Given the lemmata above, by a simple union bound one gets that all the properties of resource sets hold.

3.3 Selection of configurations

In this subsection, we give a random process that selects one consistent set of configurations for each group of players such that the intersection of the selected configurations with smaller configurations is bounded when considered on appropriate sets R_k. We will denote $\mathcal{S}_A$ the selected consistent set for group A and for ease of notation we will denote $K_i = \mathcal{S}_A^{(i)}$ the selected configuration for player $i \in A$. For any integer k, we write $\mathcal{K}_i^{(k)} = \{K_i\}$ if $K_i \in \mathcal{C}_i^{(k)}$ and $\mathcal{K}_i^{(k)} = \emptyset$ otherwise. As for the configuration set, we will also denote $\mathcal{K}^{(k)} = \bigcup_i \mathcal{K}_i^{(k)}$ and $\mathcal{K} = \bigcup_k \mathcal{K}^{(k)}$. The following lemma describes what are the properties we want to have while selecting the configurations. For better clarity we also recall what the properties of the sets $R_0, \ldots, R_d$ that we need are. These hold with high probability by the lemmata of the previous section.

▶ **Lemma 11.** *Let $R = R_0 \supseteq \ldots \supseteq R_d$ be sets of fewer and fewer resources. Assume that for each k and $C \in \mathcal{C}_i^{(k)}$ we have*

$$1/2 \cdot \ell^{k-h} \leq |C \cap R_h| \leq 3/2 \cdot \ell^{-h}|C| < 3/2 \cdot \ell^{k-h+4}$$

for all $h = 0, \ldots, k$. Then there exists a selection of one consistent set $\mathcal{S}_A$ for each group A such for all $k = 0, \ldots, d$, $C \in \mathcal{C}^{(k)}$ and $j = 0, \ldots, k$ then we have

$$\sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^h |K \cap C \cap R_h| \leq \frac{1}{\ell} \sum_{j \leq h \leq k} \sum_{C' \in \mathcal{C}^{(h)}} \ell^h |C' \cap C \cap R_h| + 1000 \frac{d+\ell}{\ell} \log(\ell)|C|.$$

Moreover, this selection of consistent sets can be found in polynomial time.

Before we prove this lemma, we give an intuition of the statement. Consider the sets $R_1, \ldots, R_d$ constructed as in Random Experiment 7. Then for $C' \in \mathcal{C}^{(h)}$ we have $\mathbb{E}[\ell^h |C' \cap C \cap R_h|] = |C' \cap C|$. Hence

$$\sum_{h \leq k} \sum_{K \in \mathcal{K}^{(h)}} |K \cap C| = \mathbb{E}[\sum_{h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^h |K \cap C \cap R_h|].$$

Similarly for the right-hand side we have

$$\mathbb{E}[\frac{1}{\ell} \sum_{j \leq h \leq k} \sum_{C' \in \mathcal{C}^{(h)}} \ell^h |C' \cap C \cap R_h| + O(\frac{d+\ell}{\ell} \log(\ell)|C|)]$$
$$= \frac{1}{\ell} \underbrace{\sum_{j \leq h \leq k} \sum_{C' \in \mathcal{C}^{(h)}} |C' \cap C|}_{\leq \ell |C|} + O\left(\frac{d+\ell}{\ell} \log(\ell)|C|\right) = O\left(\frac{d+\ell}{\ell} \log(\ell)|C|\right).$$

Hence, the lemma says that each resource in C is roughly covered $O((d+\ell)/\ell \cdot \log(\ell))$ times by smaller configurations.

We now proceed to the proof of Lemma 11.

Proof. We perform the following random experiment and show with LLL that there is a positive probability of success.

▶ **Random Experiment 12.** *For each group A, select one consistent set $\mathcal{S}_A$ uniformly at random. Then for each player $i \in A$ set $K_i = \mathcal{S}_A^{(i)}$.*

Given this experiment we can define the following random variables. For all $h = 0, \dots, d$ and $i \in P$ we define

$$X_{i,C}^{(h)} = \sum_{K \in \mathcal{K}_i^{(h)}} |K \cap C \cap R_h| \leq \min\{3/2 \cdot \ell^4, |C \cap R_h|\}.$$

Let $X_C^{(h)} = \sum_{i=1}^m X_{i,C}^{(h)}$. Then

$$\mathbb{E}[X_C^{(h)}] \leq \frac{1}{\ell} \sum_{C' \in \mathcal{C}^{(h)}} |C' \cap C \cap R_h| \leq |C \cap R_h|.$$

We are now ready to define the bad events on which we will apply the Lovasz Local Lemma. As we will show later, if none of them occur, Lemma 11 will hold. For each k, $C \in \mathcal{C}^{(k)}$, and $h \leq k$ let $B_C^{(h)}$ be the event that

$$X_C^{(h)} \geq \begin{cases} \mathbb{E}[X_C^{(h)}] + 63|C \cap R_h| \log(\ell) & \text{if } k-5 \leq h \leq k, \\ \mathbb{E}[X_C^{(h)}] + 135|C \cap R_h| \log(\ell) \cdot \ell^{-1} & \text{if } h \leq k-6. \end{cases}$$

The intuitive reason as to why we define these two different bad events can be summarized as follows. In the case $h \leq k-6$, we are counting how many times C is intersected by configurations that are much smaller than C. Hence the size of this intersection can be written as a sum of independent random variables of value at most $O(\ell^4)$ which is much smaller than the total size of the configuration $|C \cap R_h|$. Since the random variables are in a much smaller range, Chernoff bounds give much better concentration guarantees and we can afford a very small deviation from the expectation. In the other case, we do not have this property hence we need a bigger deviation to maintain a sufficiently low probability of failure. However, this does not hurt the statement of Lemma 11 since we sum this bigger deviation only a constant number of times. One key idea to be able to apply Lovasz Local Lemma here is also to consider intersection of C with smaller configurations but restricted to a set R_h of convenient granularity. One can notice that $|C' \cap R_h| = \text{poly}(\ell)$ if $C' \in \mathcal{C}^{(h)}$ (by the assumption made in Lemma 11). This allows to reduce significantly the dependencies between bad events which is crucial to make any use of LLL here.

With this in mind, we claim that the probability of each bad event happening is small.

▷ Claim 13. For each k, $C \in \mathcal{C}^{(k)}$, and $h \leq k$ we have

$$\mathbb{P}[B_C^{(h)}] \leq \exp\left(-2\frac{|C \cap R_h|}{\ell^9} - 18\log(\ell)\right).$$

Proof. Consider first the case that $h \geq k-5$. By a Chernoff bound (see full version for the precise formulation) with

$$\delta = 63\frac{|C \cap R_h| \log(\ell)}{\mathbb{E}[X_C^{(h)}]} \geq 1$$

we get

$$\mathbb{P}[B_C^{(h)}] \leq \exp\left(-\frac{\delta\mathbb{E}[X_C^{(h)}]}{3|C\cap R_h|}\right) \leq \exp(-21\log(\ell))) \leq \exp\Bigg(-2\underbrace{\frac{|C\cap R_h|}{\ell^9}}_{\leq 3/2} - 18\log(\ell)\Bigg).$$

Now consider $h \leq k-6$. We apply again a Chernoff bound with

$$\delta = 135\frac{|C\cap R_h|\log(\ell)}{\ell\mathbb{E}[X_C^{(h)}]} \geq \frac{1}{\ell}.$$

This implies

$$\begin{aligned}\mathbb{P}[B_C^{(h)}] \leq \exp\left(-\frac{\min\{\delta,\delta^2\}\mathbb{E}[X_C^{(h)}]}{3\cdot 3/2\cdot \ell^4}\right) &\leq \exp\left(-30\frac{|C\cap R_h|\log(\ell)}{\ell^6}\right)\\ &\leq \exp\left(-2\frac{|C\cap R_h|}{\ell^9} - 18\log(\ell)\right).\end{aligned}$$ ◁

We can now state Lovasz Local Lemma and use it in our setting.

▶ **Proposition 14** (Lovasz Local Lemma (LLL)). *Let $B_1,\dots,B_t$ be bad events, and let $G=(\{B_1,\dots,B_t\},E)$ be a dependency graph for them, in which for every i, event B_i is mutually independent of all events B_j for which $(B_i,B_j)\notin E$. Let x_i for $1\leq i\leq t$ be such that $0<x(B_i)<1$ and $\mathbb{P}[B_i]\leq x(B_i)\prod_{(B_i,B_j)\in E}(1-x(B_j))$. Then with positive probability no event B_i holds.*

Let $k\in\{0,\dots,d\}$, $C\in\mathcal{C}^{(k)}$ and $h\leq k$. For event $B_C^{(h)}$ we set

$$x(B_C^{(h)}) = \exp(-|C\cap R_h|/\ell^9 - 18\log(\ell)).$$

We now analyze the dependencies of $B_C^{(h)}$. The event depends only on random variables $\mathcal{S}_A$ for groups A that contain at least one player i that has a configuration in $\mathcal{C}_i^{(h)}$ which overlaps with $C\cap R_h$. The number of such configurations (in particular, of such groups) is at most $\ell|C\cap R_h|$ since the hypergraph is regular.

In each of these groups, we count at most $\log(n)$ players, each having ℓ configurations hence in total at most $\ell\cdot\log(n)$ configurations.

Each configuration $C'\in\mathcal{C}^{(h')}$ can only influence those events $B_{C''}^{(h')}$ where $C'\cap C''\cap R_{h'}\neq\emptyset$. Since $|C'\cap R_{h'}|\leq 3/2\cdot\ell^4$ and since each resource appears in at most ℓ configurations, we see that each configuration can influence at most $3/2\cdot\ell^5$ events.

Putting everything together, we see that the bad event $B_C^{(h)}$ is independent of all but at most

$$(\ell|C\cap R_h|)\cdot(\ell\cdot\log(n))\cdot(3/2\cdot\ell^5) = 3/2\cdot\ell^7\cdot\log(n)|C\cap R_h| \leq |C\cap R_h|\ell^8$$

other bad events.

We can now verify the condition for Proposition 14 by calculating

$$\begin{aligned}x(B_C^{(h)}) &\prod_{(B_C^{(h)},B_{C'}^{(h')})\in E}(1-x(B_{C'}^{(h')}))\\ &\geq \exp(-|C\cap R_h|/\ell^9 - 18\log(\ell))\cdot(1-\ell^{-18})^{|C\cap R_h|\ell^8}\\ &\geq \exp(-|C\cap R_h|/\ell^9 - 18\log(\ell))\cdot\exp(-|C\cap R_h|/\ell^9)\\ &\geq \exp(-2|C\cap R_h|/\ell^9 - 18\log(\ell)) \geq \mathbb{P}[B_C^{(h)}].\end{aligned}$$

By LLL we have that with positive probability none of the bad events happen. Let $k \in \{0, \dots, d\}$ and $C \in \mathcal{C}^{(k)}$. Then for $k - 5 \leq h \leq k$ we have

$$\ell^h X_C^{(h)} \leq \ell^h \mathbb{E}[X_C^{(h)}] + 63\ell^h |C \cap R_h| \log(\ell) \leq \ell^h \mathbb{E}[X_C^{(h)}] + 95|C| \log(\ell).$$

Moreover, for $h \leq k - 6$ it holds that

$$\ell^h X_C^{(h)} \leq \ell^h \mathbb{E}[X_C^{(h)}] + 135\ell^{h-1} |C \cap R_h| \log(\ell) \leq \ell^h \mathbb{E}[X_C^{(h)}] + 203|C| \log(\ell) \cdot \ell^{-1}.$$

We conclude that, for any $0 \leq j \leq k$,

$$\begin{aligned}\sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^h |K \cap C \cap R_h| &\leq \sum_{j \leq h \leq k} \ell^h \mathbb{E}[X_C^{(h)}] + 1000 \frac{(k-j+1)+\ell}{\ell} |C| \log(\ell) \\ &\leq \frac{1}{\ell} \sum_{j \leq h \leq k} \ell^h \sum_{C' \in \mathcal{C}^{(h)}} |C' \cap C \cap R_h| + 1000 \frac{d+\ell}{\ell} |C| \log(\ell).\end{aligned}$$

This proves Lemma 11. ◀

▶ Remark 15. Since there are at most $\text{poly}(n, m, \ell)$ bad events and each bad event B has $\frac{x(B)}{1-x(B)} \leq 1/2$ (because $x(B) \leq \ell^{-18}$), the constructive variant of LLL by Moser and Tardos [14] can be applied to find a selection of configurations such that no bad events occur in randomized polynomial time.

3.4 Assignment of resources to configurations

In this subsection, we show how all the previously established properties allow us to find, in polynomial time, a good assignment of resources to the configurations $\mathcal{K}$ chosen as in the previous subsection. We will denote as in the previous subsection $\mathcal{K}_i^{(k)} = \{K_i\}$ if $K_i \in \mathcal{C}_i^{(k)}$ and $\mathcal{K}_i^{(k)} = \emptyset$ otherwise. We also define $\mathcal{K}^{(k)} = \bigcup_i \mathcal{K}_i^{(k)}$ and $\mathcal{K}^{(\geq k)} = \bigcup_{h \geq k} \mathcal{K}^{(k)}$. Finally we define the parameter

$$\gamma = 100.000 \frac{d+\ell}{\ell} \log(\ell),$$

which will define how many times each resource can be assigned to configurations in an intermediate solution. Note that $d \leq \log(n)/\log(\ell)$. By our choice of $\ell = 300.000 \log^3(n)$, we have that $\gamma \leq 310.000 \log\log(n)$. Lemma 11 implies the following bound.

▷ Claim 16. For any $k \geq 0$, any $0 \leq j \leq k$, and any $C \in \mathcal{K}^{(k)}$

$$\sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^h |K \cap C \cap R_h| \leq 2000 \frac{d+\ell}{\ell} \log(\ell) |C|$$

Proof. By Lemma 11 we have that

$$\sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^h |K \cap C \cap R_h| \leq \frac{1}{\ell} \sum_{j \leq h \leq k} \sum_{C' \in \mathcal{C}^{(h)}} \ell^h |C' \cap C \cap R_h| + 1000 \frac{d+\ell}{\ell} \log(\ell) |C|.$$

Furthermore, by Lemma 9, we get

$$\sum_{C' \in \mathcal{C}^{(h)}} \ell^h |C' \cap C \cap R_h| \leq \ell^h \frac{10}{\ell^h} \left(|C| + \sum_{C' \in \mathcal{C}^{(h)}} |C' \cap C| \right).$$

Finally note that each resource appears in at most ℓ configurations, hence

$$\sum_{j\le h\le k}\sum_{C'\in\mathcal{C}^{(h)}}|C'\cap C|\le \ell|C|.$$

Putting everything together we conclude

$$\begin{aligned}\sum_{j\le h\le k}\sum_{K\in\mathcal{K}^{(h)}}\ell^h|K\cap C\cap R_h| &\le \frac{1}{\ell}\sum_{j\le h\le k}\sum_{C'\in\mathcal{C}^{(h)}}\ell^h|C'\cap C\cap R_h| + 1000\frac{d+\ell}{\ell}\log(\ell)|C|\\ &\le \frac{1}{\ell}\sum_{j\le h\le k}10\left(|C|+\sum_{C'\in\mathcal{C}^{(h)}}|C'\cap C|\right)+1000\frac{d+\ell}{\ell}\log(\ell)|C|\\ &\le \frac{k-j}{\ell}10|C|+10|C|+1000\frac{d+\ell}{\ell}\log(\ell)|C|\\ &\le 20|C|+1000\frac{d+\ell}{\ell}\log(\ell)|C|\\ &\le 2000\frac{d+\ell}{\ell}\log(\ell)|C|.\end{aligned}$$ ◁

We can now proceed to the main technical part of this section which is the following lemma proved by induction.

▶ **Lemma 17.** *For any $j\ge 0$, there exists an assignment of resources of R_j to configurations in $\mathcal{K}^{(\ge j)}$ such that no resource is taken more than γ times and each configuration $C\in\mathcal{K}^{(k)}$ $(k\ge j)$ receives at least*

$$\left(1-\frac{1}{\log(n)}\right)^{2(k-j)}\ell^{k-j}|C\cap R_k| - \frac{3}{\gamma}\sum_{j\le h\le k}\sum_{K\in\mathcal{K}^{(h)}}\ell^{h-j}|K\cap C\cap R_h|$$

resources from R_k.

Before going through the proof, we give here the intuition of why this is what we want to prove. Note that the term $\ell^{k-j}|C\cap R_k|$ is roughly equal to $\ell^{-j}|C|$ by the properties of the resource sets (precisely Lemma 8). The second term

$$\sum_{j\le h\le k}\sum_{K\in\mathcal{K}^{(h)}}\ell^{h-j}|K\cap C\cap R_h|$$

can be shown to be

$$O\left(\ell^{-j}\frac{d+\ell}{\ell}\log(\ell)|C|\right)=O(\ell^{-j}\log\log(n)|C|)$$

by Claim 16. Hence by choosing γ to be $\Theta(\log\log(n))$ we get that the bound in Lemma 17 will be $\Theta(\ell^{-j}|C|)$. At the end of the induction, we have $j=0$ which indeed implies that we have an assignment in which configurations receive

$$\Theta(\ell^{-0}|C|)=\Theta(|C|)$$

resources and such that each resource is assigned to at most $O(\log\log(n))$ configurations. With this in mind, we give the formal proof of Lemma 17.

Proof. We start from the biggest configurations and then iteratively reconstruct a good solution for smaller and smaller configurations. Recall d is the smallest integer such that $\mathcal{K}^{(\ge d)}$ is empty. Our base case for these configurations in $\mathcal{K}^{(\ge d)}$ is vacuously satisfied.

Now assume that we have a solution at level j, i.e. an assignment of resources to configurations in $\mathcal{K}^{(\geq j)}$ such that no resource is taken more than γ times and each configuration $C \in \mathcal{K}^{(k)}$ such that $k \geq j$ receives at least

$$\left(1 - \frac{1}{\log(n)}\right)^{2(k-j)} \ell^{k-j}|C \cap R_k| - \frac{3}{\gamma} \sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-j}|K \cap C \cap R_h|$$

resources from R_j. We show that this implies a solution at level $j-1$ in the following way. First by Lemma 10, this implies an assignment of resources of R_{j-1} to configurations in $\mathcal{K}^{(\geq j)}$ such that each $C \in \mathcal{K}^{(k)}$ receives at least

$$\begin{aligned}
&\left(1 - \frac{1}{\log(n)}\right) \ell \left(\ell^{k-j} \left(1 - \frac{1}{\log(n)}\right)^{2(k-j)} |C \cap R_k| - \frac{3}{\gamma} \sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-j}|K \cap C \cap R_h| \right) \\
&= \left(1 - \frac{1}{\log(n)}\right)^{2(k-(j-1))-1} \ell^{k-(j-1)}|C \cap R_k| - \frac{3}{\gamma} \left(1 - \frac{1}{\log(n)}\right) \sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-(j-1)}|K \cap C \cap R_h| \\
&\geq \left(1 - \frac{1}{\log(n)}\right)^{2(k-(j-1))-1} \ell^{k-(j-1)}|C \cap R_k| - \frac{3}{\gamma} \sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-(j-1)}|K \cap C \cap R_h|
\end{aligned}$$

resources and no resource of R_{j-1} is taken more than γ times. Note that we can apply Lemma 10 since we have by Claim 16 and Lemma 8

$$\begin{aligned}
&\left(1 - \frac{1}{\log(n)}\right)^{2(k-j)} \ell^{k-j}|C \cap R_k| - \frac{3}{\gamma} \sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-j}|K \cap C \cap R_h| \\
&\geq \frac{\ell^{k-j}}{e^2}|C \cap R_k| - \frac{3}{\gamma} 2000 \ell^{-j} \frac{d+\ell}{\ell} \log(\ell)|C| \\
&\geq \ell^{-j}|C| \left(\frac{1}{2e^2} - \frac{6000}{\gamma} \frac{d+\ell}{\ell} \log(\ell) \right) \\
&\geq \frac{\ell^{-j}|C|}{3e^2} > \frac{\ell^3}{1000}
\end{aligned}$$

Now consider configurations in $\mathcal{K}^{(j-1)}$ and proceed for them as follows. Give to each $C \in \mathcal{K}^{(j-1)}$ all the resources in $C \cap R_{j-1}$ except all the resources that appear in more than γ configurations in $\mathcal{K}^{(j-1)}$. Since each deleted resource is counted at least γ times in the sum $\sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1}|$, we have that each configuration C in $\mathcal{K}^{(j-1)}$ receives at least

$$|C \cap R_{j-1}| - \frac{1}{\gamma} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1}|$$

resources and no resource is taken more than γ times by configurations in $\mathcal{K}^{(j-1)}$. Notice that now every resource is taken no more than γ times by configurations in $\mathcal{K}^{(\geq j)}$ and no more than γ times by configurations in $\mathcal{K}^{(j-1)}$ which in total can sum up to 2γ times.

Therefore to finish the proof consider an resource $i \in R_{j-1}$. This resource is taken b_i times by configurations in $\mathcal{K}^{(\geq j)}$ and a_i times by configurations in $\mathcal{K}^{(j-1)}$. If $a_i + b_i \leq \gamma$, nothing needs to be done. Otherwise, denote by O the set of problematic resources (i.e. resources i such that $a_i + b_i > \gamma$). For every $i \in O$, select uniformly at random $a_i + b_i - \gamma$ configurations in $\mathcal{K}^{(\geq j)}$ that currently contain resource i and delete the resource from these configurations. When this happens, each configuration in $C \in \mathcal{K}^{(\geq j)}$ that contains i has a probability of $(a_i + b_i - \gamma)/b_i$ to be selected to loose this resource. Hence the expected number of resources that C looses with such a process is

$$\mu = \sum_{i \in O \cap C} \frac{a_i + b_i - \gamma}{b_i}$$

It is not difficult to prove the following claim.

▷ Claim 18. For any $C \in \mathcal{K}^{(\geq j)}$,

$$\frac{1}{\gamma^2} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O| \leq \mu \leq \frac{2}{\gamma} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O|$$

Proof. Note that we can write

$$\mu = \sum_{i \in O \cap C} \frac{a_i + b_i - \gamma}{b_i} \leq \max_{i \in O \cap C} \left\{ \frac{a_i + b_i - \gamma}{a_i b_i} \right\} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O|.$$

The reason for this is that each resource i accounts for an expected loss of $(a_i + b_i - \gamma)/b_i$ while it is counted a_i times in the sum

$$\sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O|.$$

Similarly,

$$\mu = \sum_{i \in O \cap C} \frac{a_i + b_i - \gamma}{b_i} \geq \min_{i \in O \cap C} \left\{ \frac{a_i + b_i - \gamma}{a_i b_i} \right\} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O|.$$

Note that by assumption we have that $a_i + b_i > \gamma$. This implies that either a_i or b_i is greater than $\gamma/2$. Assume w.l.o.g. that $a_i \geq \gamma/2$. Since by assumption $a_i \leq \gamma$ we have that

$$\frac{a_i + b_i - \gamma}{a_i b_i} \leq \frac{b_i}{a_i b_i} = \frac{1}{a_i} \leq \frac{2}{\gamma}.$$

In the same manner, since $a_i + b_i > \gamma$ and that $a_i, b_i \leq \gamma$, we can write

$$\frac{a_i + b_i - \gamma}{a_i b_i} \geq \frac{1}{a_i b_i} \geq \frac{1}{\gamma^2}.$$

We therefore get the following bounds

$$\frac{1}{\gamma^2} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O| \leq \mu \leq \frac{2}{\gamma} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O|,$$

which is what we wanted to prove. ◁

Assume then that $\mu \leq \frac{|C \cap R_k|}{10^{12} \log^3(n)}$. Note that C cannot loose more than $\sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O|$ resources in any case. Therefore, by assumption on μ, and since

$$\mu \geq \frac{1}{\gamma^2} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O| \ ,$$

we have that

$$\sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O| \leq \frac{\gamma^2}{10^{12} \log^3(n)} |C \cap R_k| \leq \frac{10^{11} \log^2 \log(n)}{10^{12} \log^3(n)} |C \cap R_k| \leq \frac{1}{\log(n)} |C \cap R_k| \ .$$

Therefore C looses at most $|C \cap R_k| / \log(n)$ resources. Otherwise we have that

$$\mu > \frac{|C \cap R_k|}{10^{12} \log^2(n)} \geq \frac{\ell^3}{10^{12} \log^3(n)} \geq 200 \log(n)$$

by Lemma 8. Hence noting X the number of deleted resources in C we have that

$$\mathbb{P}\left(X \geq \frac{3}{2}\mu\right) \leq \exp\left(-\frac{\mu}{12}\right) \leq \frac{1}{n^{10}}.$$

With high probability no configuration looses more than

$$\frac{3}{2}\mu \leq \frac{3}{\gamma} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1} \cap O| \leq \frac{3}{\gamma} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1}|$$

resources. Hence each configuration $C \in \mathcal{K}^{(\geq j)}$ ends with at least

$$\begin{aligned}
&\left(1 - \frac{1}{\log(n)}\right)^{2(k-(j-1))-1} \ell^{k-(j-1)}|C \cap R_k| - \frac{3}{\gamma} \sum_{j \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-(j-1)}|K \cap C \cap R_h| \\
&- \frac{1}{\log(n)}\left(1 - \frac{1}{\log(n)}\right)^{2(k-(j-1))-1} \ell^{k-(j-1)}|C \cap R_k| - \frac{3}{\gamma} \sum_{K \in \mathcal{K}^{(j-1)}} |K \cap C \cap R_{j-1}| \\
&\geq \left(1 - \frac{1}{\log(n)}\right)^{2(k-(j-1))} \ell^{k-(j-1)}|C \cap R_k| - \frac{3}{\gamma} \sum_{j-1 \leq h \leq k} \sum_{K \in \mathcal{K}^{(h)}} \ell^{h-(j-1)}|K \cap C \cap R_h|
\end{aligned}$$

resources which concludes the proof of Lemma 17. ◀

Given Lemma 17 and the intuition below it, it is straightforward to prove the following corollary which will complete the proof of Theorem 6.

▶ **Corollary 19.** *There exists an assignment of resources R to $\mathcal{K}$ such that each configuration $C \in \mathcal{K}$ receives at least $\lfloor |C|/(100\gamma) \rfloor$ resources. Moreover, this assignment can be found in polynomial time.*

Proof. Lemma 17 with $k = 0$ and Claim 16 together imply that we can assign at least

$$\frac{|C|}{2e^2} - \frac{6000}{100.000}|C| \geq \frac{|C|}{100}$$

resources to every $C \in \mathcal{K}$ such that no resource in R is assigned more than γ times. In particular, we can fractionally assign at least $|C|/(100\gamma)$ resources to each $C \in \mathcal{K}$ such that no resource is assigned more than once. By integrality of the bipartite matching polytope, the corollary follows. ◀

Abstract

Fair clustering is a variant of constrained clustering where the goal is to partition a set of colored points. The fraction of points of each color in every cluster should be more or less equal to the fraction of points of this color in the dataset. This variant was recently introduced by Chierichetti et al. [NeurIPS 2017] and became widely popular. This paper proposes a new construction of coresets for fair k-means and k-median clustering for Euclidean and general metrics based on random sampling. For the Euclidean space $\mathbb{R}^d$, we provide the first coresets whose size does not depend exponentially on the dimension d. The question of whether such constructions exist was asked by Schmidt, Schwiegelshohn, and Sohler [WAOA 2019] and Huang, Jiang, and Vishnoi [NeurIPS 2019]. For general metric, our construction provides the first coreset for fair k-means and k-median.

New coresets appear to be a handy tool for designing better approximation and streaming algorithms for fair and other constrained clustering variants. In particular, we obtain

- the first fixed-parameter tractable (FPT) PTAS for fair k-means and k-median clustering in $\mathbb{R}^d$. The near-linear time of our PTAS improves over the previous scheme of Böhm, Fazzone, Leonardi, and Schwiegelshohn [ArXiv 2020] with running time $n^{\mathrm{poly}(k/\epsilon)}$;
- FPT "true" constant-approximation for metric fair clustering. All previous algorithms for fair k-means and k-median in general metric are bicriteria and violate the fairness constraints;
- FPT 3-approximation for lower-bounded k-median improving the best-known 3.736 factor of Bera, Chakrabarty, and Negahbani [ArXiv 2019];
- the first FPT constant-approximations for metric chromatic clustering and ℓ-Diversity clustering;
- near linear-time (in n) PTAS for capacitated and lower-bounded clustering improving over PTAS of Bhattacharya, Jaiswal, and Kumar [TOCS 2018] with super-quadratic running time;
- a streaming $(1+\epsilon)$-approximation for fair k-means and k-median of space complexity polynomial in k, d, ϵ and $\log n$ (the previous algorithms have exponential space complexity on either d or k).

1 Introduction

Given a set of n data points in a metric space and an integer k, *clustering* is the task of partitioning the points into k groups or clusters so that the points in each cluster are similar. In this paper, we consider clustering problems with *fairness* constraints. While there are many competing notions of fairness in the literature, here we consider clustering with fairness constraints or fair clustering as introduced by Chierichetti et al. [16] in their seminal work. The notion became widely popular within a short period triggering a large body of new work [38, 7, 9, 28, 4, 11, 15, 1, 32]. The idea of fair clustering is to enforce additional (fairness) constraints to remove the inherent bias or discrimination from vanilla (unconstrained) clustering. For example, suppose we have a sensitive feature (e.g, race or gender). We want to find a clustering where the fraction of points from a traditionally underrepresented group in every cluster is more or less equal to the fraction of points from this group in the dataset. Indeed, the work of Chierichetti et al. [16] shows that clustering computed by classical vanilla algorithms can lead to widely varied ratios for a particular group, especially when the number of clusters is large enough.

In this work, we consider the fair clustering model independently formulated by Bercea et al. [9] and Bera et al. [7]. In this model, we are given ℓ groups $P_1, \ldots, P_\ell$ of points in a metric space and balance parameters $\alpha_i, \beta_i \in [0, 1]$ for each group $1 \leq i \leq \ell$. A clustering is *fair* if the fraction of points from group i in every cluster is at least β_i and at most α_i. Additionally, in [7], the groups are allowed to overlap, i.e, a point can belong to multiple protected classes. We refer to the fair clustering problem with overlapping groups as (α, β)-*fair clustering*. We note that this is the most general version of fair clustering considered in the literature, and this is the notion of fairness we adapt in this paper. Both [9] and [7] obtain polynomial time $O(1)$-approximation for this problem that violates the fairness constraints by at most small additive factors.

We denote by Γ the maximum number of distinct collections of groups to which a point belongs. If all the groups are disjoint, then $\Gamma = \ell$. Note that if every point belongs to at most Λ groups, then Γ is at most ℓ^Λ. As noted in [7, 28], while Λ can very well be more than 1, it is usually a constant in most of the applications. Thus, in this case, $\Gamma = \ell^{O(1)}$, which is expected to be much smaller compared to n, the total number of points in the union of the groups.

Several works related to fair clustering were devoted to scalability [28, 38, 11, 4]. Along this line, in a beautiful work, Schmidt et al. [38] defined coresets for fair clustering. Note that a coreset for a center-based vanilla clustering problem is roughly a summary of the data that for every set C of k centers approximately (within $(1 \pm \epsilon)$ factor) preserves the optimal clustering cost. Over the years, researchers have paid increasing attention to the design of coreset construction algorithms to optimize the coreset size. Indeed, finding smaller coresets continues to be an active research area in the context of vanilla k-median and k-means clustering. For general metric spaces, the best-known upper bound on coreset size is $O((k \log n)/\epsilon^2)$ [21] and the lower bound is known to be $\Omega((k \log n)/\epsilon)$ [5]. For Euclidean spaces of dimension d, it is possible to construct coresets, based on random sampling, of size $(k/\epsilon)^{O(1)}$ [22, 39, 29, 13], which in particular does not depend on n and d.

In the vanilla version of a clustering problem, given the cluster centers, clusters are formed by assigning each point to its nearest center. In contrast, in a constrained version, such an assignment might not lead to a clustering that satisfies the constraints. Hence, for fair clustering, we need a stronger definition of coreset. Accordingly, Schmidt et al. [38] initiated the study of fair coresets. Schmidt et al. [38] and subsequently Huang et al. [28]

designed deterministic algorithms in $\mathbb{R}^d$ that construct fair coresets whose sizes exponentially depend on d. To remove this exponential dependency on d, Schmidt et al. [38] proposed an interesting open question whether it is possible to use random sampling for construction of fair coresets. Huang et al. [28] also suggested the same open question. Besides, Huang et al. asked whether it is possible to achieve a similar size bound as in the vanilla setting.

1.1 Our Results and Contributions

We study fair clustering under the k-median and k-means objectives. Our first main result is the following theorem.

▶ **Theorem 1.** *There is an $O(n(k+\ell))$ time randomized algorithm that w.p. at least $1-1/n$, computes a coreset of size $O(\Gamma(k\log n)^2/\epsilon^3)$ for (α,β)-fair k-median and $O(\Gamma(k\log n)^7/\epsilon^5)$ for (α,β)-fair k-means, where Γ is the number of distinct collections of groups to which a point may belong. If the groups are disjoint, the algorithm runs in $O(nk)$ time. Moreover, in $\mathbb{R}^d$, the coreset sizes are $O\left(\frac{\Gamma}{\epsilon^3}\cdot k^2\log n(\log n + d\log(1/\epsilon))\right)$ for (α,β)-fair k-median[1] and $O\left(\frac{\Gamma}{\epsilon^5}\cdot k^7(\log n)^6(\log n + d\log(1/\epsilon))\right)$ for (α,β)-fair k-means.*

Theorem 1 provides the first coreset construction for fair clustering problem in general metric spaces. Note that if the number of groups is just 1, we obtain coresets of size $O_\epsilon(\text{poly}(k\log n))$, which is somewhat comparable to the best-known bound of $O_\epsilon(k\log n)$ [21] in the vanilla case. We also note that this is the first sampling based coreset construction scheme for fair clustering, and in $\mathbb{R}^d$, the first coreset construction scheme where the size of the coreset does not depend exponentially on the dimension d (see Table 1). In fact, the dependency on d is only linear. Specifically, our result improves the bound (for k-median) in [28] by a factor of $\Theta\left(\frac{\epsilon^{-d+3}}{\log n(\log n+d)}\right)$ (see Table 1). Thus, if d is sufficiently large, our coreset size is much smaller compared to theirs. In fact, the dependency of the previous coreset size on n can be super-polylogarithmic (or super-polynomial) when d is large, whereas ours is only polylogarithmic in the worst case. In the light of the above discussion, our result solves the open question proposed in [38] and partly solves the open question proposed in [28].

Table 1 Previous and current coreset results in $\mathbb{R}^d$.

	k-median		k-means	
	size	construction time	size	construction time
[38]			$O(\Gamma k\epsilon^{-d-2}\log n)$	$O(k\epsilon^{-d-2}n\log n)$
[28]	$O(\Gamma k^2\epsilon^{-d})$	$O(k\epsilon^{-d+1}n)$	$O(\Gamma k^3\epsilon^{-d-1})$	$O(k\epsilon^{-d+1}n)$
This	$O(\frac{\Gamma}{\epsilon^3}\cdot k^2\log n(\log n+ d\log(1/\epsilon)))$	$O(nd(k+\ell))$	$O(\frac{\Gamma}{\epsilon^5}\cdot k^7(\log n)^6(\log n+ d\log(1/\epsilon)))$	$O(nd(k+\ell))$

Actually, our coreset construction scheme, similar to [38, 28], is much more general in the following sense. The coreset can preserve not only the cost of optimal fair clustering, but also the cost of any optimal clustering with group-cardinality constraints. In particular, for

[1] The Euclidean version is not a special case of the general metrics case, as here the set of potential centers is infinite.

any clustering problem with constraints that can be expressed in terms of the number of elements that go from each group to each cluster (formally defined in Section 2), we obtain a small size coreset. This gives rise to new coresets for a wide range of clustering problems including lower-bounded clustering [40, 2, 8].

We further exploit the new coreset construction to design clustering algorithms in various settings. In general metrics, we obtain the first fixed-parameter tractable (FPT) constant-factor approximation for (α, β)-fair clustering with parameters k and Γ. That is, the running time of our algorithm is exponential only in the values k and Γ while polynomial in the size of the input. All previous constant-approximation algorithms were bicriteria and violated the fairness constraints by some additive factors. Hence, the study of FPT approximation is well-motivated. Our approximation factors are reasonably small and improve the best-known approximation factors of the existing bicriteria algorithms (see Table 2). Moreover, our coreset leads to improved constant FPT approximations for many other clustering problems. For example, we obtain an improved ≈ 3-approximation algorithm for lower-bounded k-median [40, 2, 8] that is FPT parameterized by k. Previously, the best-known factor for FPT approximation for this problem was 3.736 [8].

Based on our coreset, we also obtain the first FPT $(1+\epsilon)$-approximation for (α, β)-fair clustering in $\mathbb{R}^d$ with parameters k and Γ. For constant Γ, the running time of our algorithm is near-linear and up to $\log n$, matches the time of the algorithm of Kumar, Sabharwal, and Sen for vanilla clustering [34]. A comparison with the running time of the previous $(1+\epsilon)$-approximation algorithms can be found in Table 3. We also obtain FPT $(1+\epsilon)$-approximations with parameter k for the Euclidean version of several other problems including capacitated clustering [19, 17] and lower-bounded clustering. We note that these are the first $(1+\epsilon)$-approximations for these problems with near-linear dependency on n. For Euclidean capacitated clustering, quadratic time FPT algorithms follow due to [20, 10] (see Table 4). Also, the $(1+\epsilon)$-approximation for Euclidean capacitated clustering in [19] and [17] have running time $(k\epsilon^{-1})^{k\epsilon^{-O(1)}} n^{O(1)}$ and at least $n^{\epsilon^{-O(1)}}$ (see Table 4).

Table 2 Approximation results for (α, β)-fair clustering in general metrics. "multi" denotes if the algorithm can handle overlapping groups. In "approx." columns, the first (resp. second) value in a tuple is the approximation factor (resp. violation). [7] does not explicitly compute the $O(1)$ factor, but it is $> 3+\epsilon$ (resp. $> 9+\epsilon$) for k-median (resp. k-means), where ϵ is a sufficiently large constant.

	multi	k-median		k-means	
		approx.	time	approx.	time
[9]		$(4.675, 1)$	$\text{poly}(n)$	$(62.856, 1)$	$\text{poly}(n)$
[7]	✓	$(O(1), 4\Lambda + 3)$	$\text{poly}(n)$	$(O(1), 4\Lambda + 3)$	$\text{poly}(n)$
This		≈ 3	$(k\ell)^{O(k\ell)} n \log n$	≈ 9	$(k\ell)^{O(k\ell)} n \log n$
This	✓	≈ 3	$(k\Gamma)^{O(k\Gamma)} n \log n$	≈ 9	$(k\Gamma)^{O(k\Gamma)} n \log n$

Our coreset also leads to small space $(1+\epsilon)$-approximation in streaming setting for (α, β)-fair clustering in $\mathbb{R}^d$ when the groups are disjoint. We show how to maintain an $O(d^2 \ell \cdot \text{poly}(k \log n)/\epsilon^4)$ size coreset in each step. One can apply our $(1+\epsilon)$-approximation algorithm on the coreset to compute a near-optimal clustering. In the previous streaming algorithms [38], the space complexity depended exponentially on either d or k.

Our coreset construction scheme is based on the algorithm for the vanilla case due to Chen [14]. Chen showed that a small number of points can be chosen randomly from a metric space (in a clever way) that form a coreset for vanilla clustering. Our construction first divides the input points into a number of subsets, and for each subset, applies Chen's algorithm to compute a coreset for that subset. Our final coreset is the union of all these computed coresets. Surprisingly, our algorithm for fair clustering is as simple as that. Our main technical contribution is the analysis of this algorithm, which shows that the returned weighted subset of the points is a coreset for fair clustering with high probability.

Table 3 Running time of the $(1+\epsilon)$-approximations for fair clustering in $\mathbb{R}^d$.

	running time	version
[38]	$n^{O(k/\epsilon)}$	2-color, $(1,k)$-fair clustering
[11]	$n^{\text{poly}(k/\epsilon)}$	ℓ-color, $(1,k)$-fair clustering
This	$2^{\tilde{O}(k/\epsilon^{O(1)})}(k\Gamma)^{O(k\Gamma)}nd\log n$	(α,β)-fair clustering

Although our algorithm follows the framework of Chen's, the proof that the algorithm correctly computes a fair coreset is much more complicated. Our analysis is strongly inspired by the analysis of Cohen-Addad and Li [19] of Chen's algorithm in the context of capacitated clustering. However, there are two major difficulties of applying the analysis technique of [19] directly to our problem. Firstly, in our case input points belong to groups which can overlap, and secondly, fairness constraints are much more general compared to capacity constraints. The novelty of our work lies in overcoming the two above-mentioned hurdles. To overcome the first hurdle, we divide the input points into equivalence classes based on their group membership and using a probabilistic argument prove that it is possible to consider these classes separately. To overcome the second hurdle, we prove that fairness constraints can be treated as a collection of independent constraints each of which is similar to a capacity constraint. All these ideas together help us generalize the approach of [19] to fair clustering.

Table 4 Running time of the $(1+\epsilon)$-approximations for capacitated clustering in $\mathbb{R}^d$.

	running time
[20]	$2^{\text{poly}(k/\epsilon)}n^2(\log n)^{k+2}d$
[10]	$2^{\tilde{O}(k/\epsilon^{O(1)})}\cdot n^2(\log n)^2 d$
[19]	$(k\epsilon^{-1})^{k\epsilon^{-O(1)}}n^{O(1)}$
[17]	$n^{\epsilon^{-O(1)}}(d=2)$ $n^{(\log n/\epsilon)^{O(d)}}(d\geq 3)$
This	$2^{\tilde{O}(k/\epsilon^{O(1)})}nd^{O(1)}+nk^2\epsilon^{-O(1)}\log n$

Apart from the coreset construction, the novelty of our work lies in the design of an algorithm for computing the minimum cost fair assignment to given centers, based on mixed-integer linear programming. This is the heart of all our approximation algorithms.

1.2 Related Work

Schmidt et al. [38] defined the concept of fair coresets and gave coreset of size $O(\ell k \epsilon^{-d-2} \log n)$ for the disjoint group case of Euclidean (α, β)-fair k-means. They also gave an $n^{O(k/\epsilon)}$ time $(1+\epsilon)$-approximation for the two-color version of the problem. Using the framework in [25], Huang et al. [28] improved the coreset size bound of [38] by a factor of $\Theta\left(\frac{\log n}{\epsilon k^2}\right)$ and gave the first coreset for Euclidean (α, β)-fair k-median of size $O(\Gamma k^2 \epsilon^{-d})$. Böhm et al. [11] obtained near-linear time constant-approximation in a restricted setting. They also obtained an $n^{\text{poly}(k/\epsilon)}$ time $(1+\epsilon)$-approximation for the Euclidean version in the same setting.

Chierichetti et al. [16] gave a polynomial time $\Theta(t)$-approximation for a special version of (α, β)-fair k-median with two groups, where t is a balance parameter. Bera et al. [7] obtained polynomial time $O(1)$-approximation for (α, β)-fair clustering that violates the fairness constraints by at most an additive factor of $4\Lambda + 3$. For the disjoint group case, their violation factor is only 3. Independently, Bercea et al. [9] obtained algorithms with the same approximation guarantees as in [7] for the disjoint version, but with at most 1 additive factor violation. For other related works on fair clustering, see [4, 16, 37, 9, 7, 1, 15, 32, 33]. For related works on coresets, see [27, 26, 23, 35, 21, 22, 39, 6, 12, 29].

2 Preliminaries

In all the clustering problems we study in this paper, we are given a set P of points in a metric space $(\mathcal{X}, d(\cdot,\cdot))$, that we have to cluster. We are also given a set F of cluster centers in the same metric space. We note that P and F are not-necessarily disjoint, and in fact, P may be equal to F. We assume that the distance function $d(\cdot,\cdot)$ is provided by an oracle that for any given $x, y \in \mathcal{X}$ in constant time returns $d(x,y)$. In the Euclidean version of a clustering problem, $P \subseteq \mathbb{R}^d$, $F = \mathbb{R}^d$ and $d(\cdot,\cdot)$ is the Euclidean metric.[2] In the metric version, we assume that F is finite. Thus, strictly speaking, the Euclidean version is not a special case of the metric version. In the metric version, we denote $|P \cup F|$ by n and in the Euclidean version, $|P|$ by n. For any set S and a point p, $d(p,S) := \min_{q \in S} d(p,q)$. Also, for any integer $t \geq 1$, we denote the set $\{1, 2, \ldots, t\}$ by $[t]$.

In the k-median problem, given an additional parameter k, the goal is to select a set of at most k centers $C \subset F$ such that the quantity $\sum_{p \in P} d(p,C)$ is minimized. k-means is identical to k-median, except here we would like to minimize $\sum_{p \in P} (d(p,C))^2$.

Next, we define our notion of fair clustering following the definition in [7].

▶ **Definition 2** (Definition 1, [7]). *In the fair version of a clustering problem (k-median or k-means), one is additionally given ℓ many (not necessarily disjoint)* groups *of P, namely P_1, P_2, …, P_ℓ. One is also given two* fairness vectors *$\alpha, \beta \in [0,1]^\ell$, $\alpha = (\alpha_1, \ldots, \alpha_\ell)$, $\beta = (\beta_1, \ldots, \beta_\ell)$. The objective is to select a set of at most k centers $C \subset F$ and an assignment $\varphi : P \to C$ such that φ satisfies the following* fairness constraints*:*

$$|\{x \in P_i : \varphi(x) = c\}| \leq \alpha_i \cdot |\{x \in P : \varphi(x) = c\}|, \quad \forall c \in C, \forall i \in [\ell],$$
$$|\{x \in P_i : \varphi(x) = c\}| \geq \beta_i \cdot |\{x \in P : \varphi(x) = c\}|, \quad \forall c \in C, \forall i \in [\ell],$$

and $\text{cost}(\varphi)$ *is minimized among all such assignments.*

In the (α, β)-Fair k-median problem, $\text{cost}(\varphi) := \sum_{x \in P} d(x, \varphi(x))$, and in the (α, β)-Fair k-means problem, $\text{cost}(\varphi) := \sum_{x \in P} d(x, \varphi(x))^2$. To refer to these two problems together, we will use the term (α, β)-Fair Clustering. We call φ that satisfies the fairness constraints *a*

[2] Due to the lack of better notations, we denote the dimension by d and distance function by $d(\cdot,\cdot)$.

fair assignment. We denote the minimum cost of a fair assignment of a set of points P to a set of k centers C by faircost(P, C), and faircost(P) denotes the minimum of faircost(P, C') over all possible sets of k centers C'.

Next, we state our notion of coresets. We follow the definitions in [38, 28]. For a clustering problem with k centers and ℓ groups $P_1, \ldots, P_\ell$, a *coloring constraint* is a $k \times \ell$ matrix M having non-negative integer entries. The entry of M corresponding to row i and column j is denoted by M_{ij}. Next, we have the following observation, which was also noted in [38, 28].

▶ **Proposition 3.** *Given a set C of k centers, the assignment restriction required for (α, β)-Fair Clustering can be expressed as a collection of coloring constraints.*

In our definition, a coreset is required to preserve the optimal clustering cost w.r.t. all coloring constraints, and hence it also preserves the optimal fair clustering cost. Next, we formally define the cost of a clustering w.r.t. a set of centers and a coloring constraint.

First, consider the k-median objective. Suppose we are given a weight function $w : P \to \mathbb{R}_{\geq 0}$ (non-negative reals). Let $W \subseteq P \times \mathbb{R}$ be the set of pairs $\{(p, w(p)) \mid p \in P \text{ and } w(p) > 0\}$. For a set of centers $C = \{c_1, \ldots, c_k\}$ and a coloring constraint M, wcost(W, M, C) is the minimum value $\sum_{p \in P, c_i \in C} \psi(p, c_i) \cdot d(p, c_i)$ over all assignments $\psi : P \times C \to \mathbb{R}_{\geq 0}$ such that

1. For each $p \in P$, $\sum_{c_i \in C} \psi(p, c_i) = w(p)$.
2. For each $c_i \in C$ and group $1 \leq j \leq \ell$, $\sum_{p \in P_j} \psi(p, c_i) = M_{ij}$.

For k-means, wcost(W, M, C) is defined in the same way except it is the minimum value $\sum_{p \in P, c_i \in C} \psi(p, c_i) \cdot d(p, c_i)^2$. If there is no such assignment ψ, wcost$(W, M, C) = \infty$. When $w(p) = 1$ for all $p \in P$, we simply denote W by P and wcost(W, M, C) by cost(P, M, C). Now we define a coreset. We call it universal coreset, as it is required to preserve optimal clustering cost w.r.t. all coloring constraints.

▶ **Definition 4** (Universal coreset)**.** *For a given unweighted point set P and a clustering objective, a universal coreset is a set of weighted points $W \subseteq P \times \mathbb{R}$ such that for every set of centers C of size k and any coloring constraint M,*

$$(1 - \epsilon) \cdot cost(P, M, C) \leq wcost(W, M, C) \leq (1 + \epsilon) \cdot cost(P, M, C).$$

3 Our Techniques

Here, we describe the techniques and key ideas used to obtain the new results of the paper. The detailed version of our results and formal proofs appear in the attached full version. For simplicity, we limit our discussion to k-median clustering. We start with the coreset results.

3.1 Universal Coreset Construction

Our coreset construction algorithms are based on random sampling and we will prove that our algorithms produce universal coresets with high probability (w.h.p.). At a first glance, it is not easy to see how to sample points in the overlapping group case, as the decision has an effect on multiple groups. For simplicity, first we discuss the disjoint group case.

The Disjoint Group Case

Our coreset construction algorithm is built upon the coreset construction algorithm for vanilla clustering due to Chen [14]. In our case, we have points from ℓ disjoint color classes. So, we apply Chen's algorithm for each color class independently. Note that Chen's algorithm

was used to show that for any given set of centers C, the constructed coreset approximately preserves the optimal clustering cost. However, we would like to show that for any given set of centers C, the constructed coreset approximately preserves the optimal clustering cost corresponding to any given constraint M. At this stage, it is not clear why Chen's algorithm should work in such a generic setting. Our main technical contribution is to show that sampling based approaches like Chen's algorithm can be used even for such a stronger notion of universal coreset. We will try to give some intuition after describing our algorithm. Our algorithm is as follows.

Given the set of points P, first we apply the algorithm of Indyk [30] for computing a vanilla k-median clustering of P. This is a bicriteria approximation algorithm that uses $O(k)$ centers and runs in $O(nk)$ time. Let C^* be the set of computed centers, ν be the constant approximation factor and Π be the cost of the clustering. Also, let $\mu = \Pi/(\nu n)$ be a lower bound on the average cost of the points in any optimal k-median clustering. Note that for any point p, $d(p, C^*) \leq \Pi = \nu n \cdot \mu$.

For each center $c_i^* \in C^*$, let $P_i^* \subseteq P$ be the corresponding cluster of points assigned to c_i^*. We consider the ball $B_{i,j}$ centered at c_i^* and having radius $2^j\mu$ for $0 \leq j \leq N$, where $N = \lceil \log(\nu n) \rceil$. We note that any point at a distance $2^N\mu \geq \nu n \cdot \mu$ from c_i^* is in $B_{i,N}$, and thus all the points in P_i^* are also in $B_{i,N}$. Let $B'_{i,0} = B_{i,0}$ and $B'_{i,j} = B_{i,j} \setminus B_{i,j-1}$ for $1 \leq j \leq N$. We refer to each such $B'_{i,j}$ as a ring for $1 \leq i \leq k, 0 \leq j \leq N$. For each $0 \leq j \leq N$ and color $1 \leq t \leq \ell$, let $P'_{i,j,t}$ be the set of points in $B'_{i,j}$ of color t, and $P_{i,j} = \cup_{t=1}^{\ell} P'_{i,j,t}$. Let $s = \Theta(k \log n/\epsilon^3)$ for a sufficiently large constant hidden in $\Theta(.)$.

For each center $c_i^* \in C^*$, we perform the following steps.

Random Sampling. For each color $1 \leq t \leq \ell$ and ring index $0 \leq j \leq N$, do the following. If $|P'_{i,j,t}| \leq s$, add all the points of $P'_{i,j,t}$ to $W_{i,j}$ and set the weight of each such point to 1. Otherwise, select s points from $P'_{i,j,t}$ independently and randomly (without replacement) and add them to $W_{i,j}$. Set the weight of each such point to $|P'_{i,j,t}|/s$.

The set $W = \cup_{i,j} W_{i,j}$ is the desired universal coreset. As the number of rings is $O(k \log n)$, the size of W is $O(\ell(k \log n)^2/\epsilon^3)$. From [14], it follows that for each color, the coreset points can be computed in time linear in the number of points of that color times $O(k)$. Thus, our coreset construction algorithm runs in $O(nk)$ time. Next, we show that W is indeed a universal coreset w.h.p.

Note that we need to show that for any set of centers C, the optimal clustering cost is approximately preserved w.r.t. all possible combinations of cluster sizes as defined by the constraint matrices. In Chen's analysis, it was sufficient to argue that for any set of centers C, the optimal clustering cost needs to be preserved. This seems much easier compared to our case. (Obviously, the details are much more complicated even in the vanilla case.) For example, in the vanilla case, let $p \in P$ be a point that is assigned to a center $c \in C$ in an optimal clustering. Note that c must be a closest center to p. For simplicity, suppose p has a unique closest center. Now, if p is chosen in the coreset, then the total weight of p must also be assigned to c in any optimal assignment w.r.t. C. Thus, the assignment function for original and coreset points remains same in the vanilla case. This fact is in the heart of their analysis. Note that this is not necessarily true in our case. We cannot just use the nearest neighbor assignment scheme, as in our case cluster sizes are predefined through M. Indeed, in our case we might very well need to assign the weight of a coreset point to multiple centers to satisfy M. In general, this is the main hurdle one faces while analyzing a sampling based approach for fair coreset construction.

For analyzing our algorithm, we follow an approach similar to the one by Cohen-Addad and Li in [19]. They considered the capacitated clustering problem, where for each center c a capacity value U_c is given, and if the center c is chosen, at most U_c points can be assigned to c. They analyzed Chen's algorithm and showed that for any center C, the coreset approximately preserves the optimal capacitated clustering cost. One crucial idea they use in their proof is representation of assignments through network flow. Suppose we are given a fixed set of centers and weighted input points, and we would like to compute a minimum cost assignment of the points to the centers such that the capacities are not violated. This problem can be modeled as a minimum cost network flow problem.

The first hurdle to adapt the approach in [19] is that it is not possible to represent the assignment problem for fair clustering as a simple flow computation problem. Thus it is not clear how to directly use their approach for fair clustering. Nonetheless, we show that for a fixed constraint M, the assignment problem can be modeled in the desired way. Thus, we can get high probability bound w.r.t. a fixed constraint M. However, to obtain a coreset for fair clustering we need to show this w.r.t. all such constraints (and this leads us towards a universal coreset). The number of such constraints can be as large as $n^{\Omega(k\ell)}$. Hence, to obtain the h.p. bound over all M, we need to show that for a fixed M the error probability is at most $1/n^{\Omega(k\ell)}$. However, it is not clear how to show such a strong bound ($1/n^{\Omega(k)}$ bound can be shown). Nevertheless, we show that it is not necessary to consider all those choices of the constraints together – one can focus on a single color and the constraints w.r.t. that color only. Indeed, this is the reason that we apply Chen's algorithm to different color classes independently. Unfortunately, we pay a heavy toll for this: the coreset size is proportional to ℓ, unlike the vanilla coreset size, and it is not clear how to avoid this dependency. Anyway, this solves our problem, as now we have only $n^{\Omega(k)}$ constraints. It follows that, for a fixed color and a fixed constraint matrix, one can apply an approach similar to the one in [19] (the details are slightly different). This allows us to adapt the ideas from [19] and [14] to construct coresets for much more general clustering problems. Next, we describe the details. We will prove the following lemma.

▶ **Lemma 5.** *For any fixed set C of k centers and for all $k \times \ell$ matrices M, w.p. at least $1 - 1/n^{k+2}$, $|\mathrm{cost}(P, M, C) - \mathrm{wcost}(W, M, C)| \leq \sum_{(i,j)} \epsilon |P_{i,j}| \cdot 2^j \mu$.*

Now, consider all the rings $B'_{i,j}$ with $j = 0$. Then,

$$\sum_{(i,j):j=0} \epsilon |P_{i,j}| \cdot 2^j \mu \leq \epsilon n \cdot \mu \leq \epsilon \cdot \mathrm{OPT}_v \leq \epsilon \cdot \mathrm{cost}(P, M, C).$$

Here, OPT_v is the optimal cost of vanilla k-median clustering. The last inequality follows, as the optimal cost of vanilla clustering is at most the cost of any constrained clustering. On the other hand, for any ring $B'_{i,j}$ with $j \geq 1$ and any point p in the ring, $d(p, c^*_i) \geq 2^{j-1}\mu$. Thus,

$$\sum_{(i,j):j\geq 1} \epsilon |P_{i,j}| \cdot 2^j \mu \leq \epsilon \sum_{p \in P} 2 \cdot d(p, c^*_{i_p}) \leq 2\epsilon \cdot \mathrm{OPT}_v \leq 2\epsilon \cdot \mathrm{cost}(P, M, C),$$

where for a point $p \in P$ by i_p we denote the index of a center such that p belongs to $B'_{i_p,j}$ for some j.

Taking union bound over all C and scaling down ϵ by 3 factor, we get the desired result.

▶ **Lemma 6.** *For every set C of k centers and every $k \times \ell$ matrices M, w.p. at least $1 - 1/n$, $|\mathrm{cost}(P, M, C) - \mathrm{wcost}(W, M, C)| \leq \epsilon \cdot \mathrm{cost}(P, M, C)$.*

3.2 Proof of Lemma 5

Let P_τ be the points in P of color τ. Also, let W_τ be the chosen samples of color τ. For $1 \leq t \leq \ell - 1$, let $W^t = (\cup_{\tau=1}^{t} W_\tau) \cup (\cup_{\tau=t+1}^{\ell} P_\tau)$. Also, let $W^\ell = \cup_{\tau=1}^{\ell} W_\tau$ be the coreset points of all colors. Recall that for any ring $B'_{i,j}$, $P'_{i,j,\tau}$ is the points of color τ in the ring. Also, $P_{i,j} = \cup_{\tau=1}^{\ell} P'_{i,j,\tau}$.

Note that in the above, W^t contains the sampled points for color 1 to t and original points of color $t+1$ to ℓ. We will prove the following lemma that gives a bound when the coreset contains sampled points of a fixed color t and original points of the other colors.

▶ **Lemma 7.** *Consider any color $1 \leq t \leq \ell$. For any fixed set C of k centers and for all $k \times \ell$ matrices M, w.p. at least $1 - 1/n^{k+4}$, $|\text{cost}(P, M, C) - \text{wcost}(W_t \cup (P \setminus P_t), M, C)| \leq \sum_{(i,j)} \epsilon |P'_{i,j,t}| \cdot 2^j \mu$.*

Note that for a particular color class, if we select all original points in the coreset, there is no error corresponding to those coreset points. This is true, as one can use the corresponding optimal assignment for these points. Assuming that the above lemma holds, now we prove Lemma 5. Consider the coreset W^1. From the above lemma, we readily obtain the following.

▶ **Corollary 8.** *For any fixed set C of k centers and for all $k \times \ell$ matrices M, w.p. at least $1 - 1/n^{k+4}$, $|\text{cost}(P, M, C) - \text{wcost}(W^1, M, C)| \leq \sum_{(i,j)} \epsilon |P'_{i,j,1}| \cdot 2^j \mu$.*

Now, in W^1 consider replacing the points of P_2 by the samples in W_2. We obtain the coreset W^2. Note that the samples in W_1 and W_2 are chosen independent of each other. Thus, by taking union bound over colors 1 and 2, from Lemma 7 we obtain, for all M, w.p. $\geq 1 - 2/n^{k+4}$, $|\text{cost}(P, M, C) - \text{wcost}(W^2, M, C)| \leq \sum_{(i,j)} \epsilon (|P'_{i,j,1}| + |P'_{i,j,2}|) \cdot 2^j \mu$. Similarly, by taking union bound over all $\ell \leq n$ colors and noting that $W^\ell = W$, Lemma 5 follows.

3.3 Proof of Lemma 7

Recall that P_t is the set of points of color t, and W_t is the coreset points of color t. C is the given set of centers. For any matrix M, let M^t be the t^{th} column of M. We have the following observation that implies that it is sufficient to consider the points only in P_t to give the error bound.

▶ **Observation 9.** *Suppose w.p. at least $1 - 1/n^{k+4}$, for all column matrices M', $|\text{cost}(P_t, M', C) - \text{wcost}(W_t, M', C)| \leq \sum_{(i,j)} \epsilon |P'_{i,j,t}| \cdot 2^j \mu$. Then, with the same probability, for all $k \times \ell$ matrices M, $|\text{cost}(P, M, C) - \text{wcost}(W_t \cup (P \setminus P_t), M, C)| \leq \sum_{(i,j)} \epsilon |P'_{i,j,t}| \cdot 2^j \mu$.*

Proof. Consider any $k \times \ell$ matrix M. Then,

$$\text{cost}(P, M, C) = \sum_{\tau=1}^{\ell} \text{cost}(P_\tau, M^\tau, C), \text{ and}$$

$$\text{wcost}(W_t \cup (P \setminus P_t), M, C) = \text{wcost}(W_t, M^t, C) + \sum_{\tau \in [\ell] \setminus \{t\}} \text{cost}(P_\tau, M^\tau, C)$$

It follows that,

$$|\text{cost}(P, M, C) - \text{wcost}(W_t \cup (P \setminus P_t), M, C)| = |\text{cost}(P_t, M^t, C) - \text{wcost}(W_t, M^t, C)|$$

Now, by our assumption, it follows that the probability of the event: for all M, $|\text{cost}(P_t, M^t, C) - \text{wcost}(W_t, M^t, C)|$ exceeds $\sum_{(i,j)} \epsilon |P'_{i,j,t}| \cdot 2^j \mu$ is at most $1/n^{k+4}$. Hence, the observation follows. ◀

By the above observation, it is sufficient to prove that w.p. at least $1 - 1/n^{k+4}$, for all column matrices M, $|\text{cost}(P_t, M, C) - \text{wcost}(W_t, M, C)| \leq \sum_{(i,j)} \epsilon |P'_{i,j,t}| \cdot 2^j \mu$. The proof of this claim is similar to the analysis in [19] and appears in Section 4 of the full version.

The Overlapping Group Case

We are given ℓ groups of points $P_1, \ldots, P_\ell$ such that a point can potentially belong to multiple groups. Note that the algorithm in the disjoint case does not work here. This is because we sample points from each group separately and independently, and thus it is not clear how to assign the weight of a point that belongs to multiple groups. One might think of the following trivial modification of this algorithm. Assign each point to a single group to which it belongs. Based on this assignment, now we have disjoint groups, and we can apply our previous algorithm. But, the new algorithm can have a very large error bound. For example, suppose a point p belongs to two groups i and j, and it is assigned to group i. Also, suppose p was not chosen in the sampling process. Note that the weight of p is represented by some other chosen point p', which was also assigned to group i. However, now we have lost the information that this weight of p was also contributing towards fairness of group j. Thus, the constructed coreset might not preserve any optimal fair clustering with a small error. In the overlapping case, it is not clear how to obtain a coreset whose size depends linearly in ℓ – we design a new coreset construction algorithm where the size depends linearly on Γ. Recall that Γ is the maximum number of distinct collections of groups to which a point belongs.

The main idea of our algorithm is to divide the points into equivalence classes based on their group membership and sample points from each equivalence class. Let $P = \cup_{i=1}^{\ell} P_i$. For each point $p \in P$, let $J_p \subseteq [\ell]$ be the set of indexes of the groups to which p belongs. Let I be the distinct collection of these sets $\{J_p \mid p \in P\}$ and $|I| = \Gamma$. In particular, let $I_1, \ldots, I_\Gamma$ be the distinct sets in I. Now, we partition the points in P based on these sets. For $1 \leq i \leq \Gamma$, let $P^i = \{p \in P \mid I_i = J_p\}$. Thus, $\{P^i \mid 1 \leq i \leq \Gamma\}$ defines equivalence classes for P such that two points $p, p' \in P$ belong to the same equivalence class if they are in exactly the same set of groups. Now we apply our algorithm in the disjoint case on the disjoint sets of points $P^1, \ldots, P^\Gamma$. Let W be the constructed coreset.

Note that here we have Γ disjoint classes, and thus the coreset size is $O(\Gamma(k \log n)^2/\epsilon^3)$. As our coreset size is at least Γ, we assume that $\Gamma < n$. Note that the equivalence classes can be computed in $O(n\ell)$ time, and thus the algorithm runs in time $O(n\ell) + O(nk) = O(n(k+\ell))$. The proof that W is indeed a universal coreset w.h.p. follows the same line as of the disjoint-group case. Again, the idea here is to reduce the analysis to the one class case. However, this is not as straightforward as in the disjoint case. Note that although the classes $P^1, \ldots, P^\Gamma$ are disjoint, two classes can contain points from the same group. Moreover, the constraints are defined w.r.t. the groups, not w.r.t. the classes. Thus, two classes need to interact to satisfy the constraints. Nevertheless, we use the independence of the samples from different classes and exploit the structure of a special class of matrices to complete the proof, which appears in Section 5 of the full version.

The algorithm in the Euclidean case is the same as for general metrics, except we set s to $\Theta(k \log(nb)/\epsilon^3)$, where $b = \Theta(k \log(n/\epsilon)/\epsilon^d)$. Here the main challenge is that it is not possible to take union bound over all possible sets of k centers. Nevertheless, we show that for every set $C \subseteq \mathbb{R}^d$ of k centers and constraint M, the optimal cost is preserved approximately w.h.p. Our main contribution in this part is to devise a discretization technique for obtaining a finite set of centers, so that if instead we draw centers from this set, the cost of any clustering is preserved approximately. The details appear in Section 6 of the full version.

3.4 Approximation Algorithms Based on Universal Coresets

All the algorithms that we design follow one general strategy: first, compute a universal coreset, then, enumerate a small family of sets of possible k centers, such that at least one of them is guaranteed to provide a good approximation, and finally pick the best set of centers by finding the optimal assignment from the coreset to each of the center sets. Throughout this section, we limit our discussion to fair clustering. One major difficulty in the case of fair clustering is solving the assignment problem, for which we devise a novel FPT algorithm.

Solving the Assignment Problem

The fair assignment problem is the following: given an instance of (α, β)-Fair Clustering and a set of k centers C, compute a minimum-cost fair assignment to the centers of C. For fair clustering, the assignment problem is one of the features that makes it harder than other constrained clustering problems. While often the optimal assignment can be found with the help of network flow, e.g. for capacitated clustering, there was no previously known algorithms to compute an optimal or approximate fair assignment without violating the constraints. Moreover, it was observed by Bera et al. [7] that the fair assignment problem is NP-hard, so there is no hope to have a polynomial time assignment algorithm.

We design a fair assignment algorithm with running time $(k\Gamma)^{O(k\Gamma)}n^{O(1)}$. The general idea is to reduce to a linear programming instance. The unknown optimal assignment can be naturally expressed in terms of linear inequalities by introducing a variable f_{ij} for the i-th point and the j-th center, denoting which fraction of the point is assigned to each center, and constraints $f_{ij} \geq 0$ for all i, j, and $\sum_{j=1}^{k} f_{ij} = 1$. Clearly this generalizes a discrete assignment, which corresponds to exactly one of $\{f_{ij}\}_{j=1}^{k}$ being equal to 1, for each $i \in [n]$. Moreover, the fairness of the assignment can also be expressed as linear constraints on $\{f_{ij}\}$.

The main obstacle is that in general the optimal solution to this linear program is not integral, and the integrality gap could be arbitrarily large. Thus, an optimal fractional solution does not yield the desired assignment, and this is not surprising since the fair assignment problem is NP-hard. One possible solution could be restricting the variables to be integral, solving an integer linear program (ILP) instead. But the number of variables is too large for an FPT algorithm. Instead, we introduce the integral variables $\{g_{tj}\}$ denoting how many points from the t-th point equivalence class gets to the j-th center, while leaving the $\{f_{ij}\}$ variables to be fractional. Thus, we obtain an instance of mixed-integer linear programming (MILP) with $k\Gamma$ integer variables and nk fractional variables. By using the celebrated result of Lenstra [36] with subsequent improvements by Kannan [31], and Frank and Tardos [24], we obtain an optimal solution to the MILP instance in time $(k\Gamma)^{O(k\Gamma)}n^{O(1)}$.

Now we explain that after constraining the $\{g_{tj}\}$ variables to be integral, we can assume that all the other variables $\{f_{ij}\}$ are integral too, thus we actually obtain an optimal discrete assignment of the same cost. Consider a particular point equivalence class P^t, and the integral values $\{g_{tj}\}_{j=1}^{k}$ from the optimal solution to the MILP. When these values are fixed, the problem boils down to finding an assignment from P^t to C such that exactly g_{tj} points are assigned to the j-th center. This problem can be solved by a minimum-cost maximum flow in the network where each point has supply one, the j-th center has demand of g_{tj}, and the costs are the distances between the respective points. Moreover, the values $\{f_{ij}\}$ from the MILP correspond exactly to the flow values on the respective edges. Since there is an optimal integral flow in this network, this flow is also an optimal integral solution for $\{f_{ij}\}$.

The downside of the above algorithm is that the time complexity is roughly n^5, and we cannot use it directly to obtain a near-linear time algorithm. So, we also show how to obtain a $(1+\epsilon)$-approximate fair assignment in near-linear time with the help of the coreset. For

this, we compute a universal coreset, and then compute the optimal fair assignment from the coreset to the centers C. However, this does not yet give us a fair assignment of the original points to the centers. To construct this assignment, we take the values $\{g_{tj}\}$ computed by the assignment algorithm on the coreset, and then, for each point equivalence class P^t, we solve the simple assignment problem from P^t to C that assigns exactly g_{tj} points to the j-th center. As mentioned above, this can be done by a network flow algorithm. Since the network is bipartite and one of the parts is small (k), this problem can be solved in near-linear time by the specialized flow algorithm in [3]. By the property of the universal coreset, the resulting assignment achieves a $(1+\epsilon)$-approximation (see Section 8 of the full version).

$(1+\epsilon)$-Approximation in $\mathbb{R}^d$. Besides our coreset construction and assignment algorithm, the key ingredient to obtain a $(1+\epsilon)$-approximation is the generic clustering algorithm of Bhattacharya et al. [10]. Their algorithm outputs a list of $2^{\tilde{O}(k/\epsilon^{O(1)})}$ candidate sets of k centers, such that for any clustering of the points there exists a set of centers C in this list that is slightly worse than the optimal set of centers for this clustering. Together with our assignment algorithm this provides a $(1+\epsilon)$-approximation algorithm with the running time of $2^{\tilde{O}(k/\epsilon^{O(1)})}(k\Gamma)^{O(k\Gamma)}nd\log n$. We describe this algorithm in Section 9 of the full version.

$(3+\epsilon)$-Approximation in General Metric. With the help of our universal coreset, the strategy to obtain $(3+\epsilon)$-approximation for (α,β)-Fair k-median is essentially same as that used in [18, 19]: from each of the clusters in an optimal solution on the coreset we guess the closest point to the center, called a *leader* of that cluster. We also guess a suitably discretized distance from each leader to the center of the corresponding cluster. Finally, selecting any center that has roughly the guessed distance to the leader provides us with a $(3+\epsilon)$-approximation. In this way we obtain a list of $|W|^k(\log n/\epsilon)^{O(k)}$ candidate sets of k centers. Afterwards, our algorithm proceeds similarly to the Euclidean case above, resulting in the running time of $(k\Gamma)^{O(k\Gamma)}/\epsilon^{O(k)}\cdot n\log n$ (see Section 10 of the full version).

Kasper Høgh
Aarhus University, Denmark

Abstract

In the consensus halving problem we are given n agents with valuations over the interval $[0, 1]$. The goal is to divide the interval into at most $n + 1$ pieces (by placing at most n cuts), which may be combined to give a partition of $[0, 1]$ into two sets valued equally by all agents. The existence of a solution may be established by the Borsuk-Ulam theorem. We consider the task of computing an approximation of an exact solution of the consensus halving problem, where the valuations are given by distribution functions computed by algebraic circuits. Here approximation refers to computing a point that is ε-close to an exact solution, also called *strong* approximation. We show that this task is polynomial time equivalent to computing an approximation to an exact solution of the Borsuk-Ulam search problem defined by a continuous function that is computed by an algebraic circuit.

The Borsuk-Ulam search problem is the defining problem of the complexity class BU. We introduce a new complexity class BBU to also capture an alternative formulation of the Borsuk-Ulam theorem from a computational point of view. We investigate their relationship and prove several structural results for these classes as well as for the complexity class FIXP.

1 Introduction

Many computational problems, e.g. linear and semidefinite programming, are most naturally expressed using real numbers. When the model of computation is discrete, these problems must be recast as discrete problems. In the case of linear programming this causes no problems. Namely, when the input is given as rational numbers and an optimal solution exists, a rational valued optimal solution exists and may be computed in polynomial time. For semidefinite programming however, it may be the case that all optimal solutions are irrational. For dealing with such cases we may instead consider the *weak optimization* problem as defined by Grötschel, Lovász and Schrijver [18]: Given $\varepsilon > 0$, the task is to compute a rational-valued vector x that is ε-close to the set of feasible solutions and has objective value ε-close to optimal. Assuming we are also given, as an additional input, a strictly feasible

solution and a bound on the magnitude of the coordinates of an optimal solution, the weak optimization problem may be solved in polynomial time using the ellipsoid algorithm [18]. Let us note however that without additional assumptions, even the complexity of the basic *existence problem* of semidefinite feasibility is unknown. In fact, the problem is likely to be computationally very hard [23]. More precisely, it is hard for the problem PosSLP, which is the fundamental problem of deciding whether an integer given by a division free arithmetic circuit is positive [2].

In this paper we consider real valued search problems, where existence of a solution is guaranteed by topological existence theorems such as the Brouwer fixed point theorem and the Borsuk-Ulam theorem. This means that the search problems are *total*, thereby fundamentally differentiating them from general search problems where, as described above, even the existence problem may be computationally hard. We are mainly interested in the *approximation* problem: given $\varepsilon > 0$, the task is to compute a rational-valued vector x that is ε-close to the set of solutions.

Recall that the Brouwer fixed point theorem states that every continuous function $f : B^n \to B^n$, where B^n is the unit n-ball, has a fixed point, i.e. there is $x \in B^n$ such that $f(x) = x$ [6]. The Borsuk-Ulam theorem states that every continuous function $f \colon S^n \to \mathbb{R}^n$, where S^n is the unit n-sphere in $\mathbb{R}^{n+1}$, maps a pair of antipodal points of S^n to the same point in $\mathbb{R}^n$, i.e. there is $x \in S^n$ such that $f(x) = f(-x)$ [5]. The Brouwer fixed point theorem is of course not restricted to apply to the domain B^n, but applies to any domain that is homeomorphic to B^n. Similarly the Borsuk-Ulam theorem applies to any domain homeomorphic to S^n by an antipode-preserving homeomorphism. It is well-known that the Borsuk-Ulam theorem generalizes the Brouwer fixed point theorem, in the sense that the Brouwer fixed point theorem is easy to prove using the Borsuk-Ulam theorem [22, 24].

The Brouwer fixed point theorem and the Borsuk-Ulam theorem naturally define corresponding real valued search problems, and thereby also corresponding approximation problems. In addition, the statements of the theorems naturally lead to another notion of approximation. For the case of the Brouwer fixed point theorem we may look for an *almost* fixed point, i.e. $x \in B^n$ such that $f(x)$ is ε-close to x, and for the case of the Borsuk-Ulam theorem we look for a pair of antipodal points that *almost* map to the same point, i.e. $x \in S^n$ such that $f(x)$ and $f(-x)$ are ε-close. Following [12], we shall refer to this notion of approximation as *weak* approximation and to make the distinction clear we refer to the former (and general) notion of approximation as *strong* approximation. In the setting of weak approximation in relation to the Borsuk-Ulam theorem we assume that f has domain B^n.

In their seminal work, Etessami and Yannakakis [12] introduced the complexity class FIXP to capture the computational complexity of the real-valued search problems associated with the Brouwer fixed point theorem, and proved that the problem of finding a Nash equilibrium in a given 3-player game in strategic form is FIXP-complete. In order to have a notion of completeness, the class FIXP is defined to be closed under reductions. The type of reductions chosen by Etessami and Yannakakis, SL-reductions, consists of mapping between sets of solutions by a composition of a *projection* reduction followed by individual affine transformations applied to each coordinate.

Etessami and Yannakakis considered different ways to cast real valued search problems as discrete search problems. In addition to the approximation problem, these are the *partial computation* problem where the task is to compute a solution to a given number of bits of precision and *decision* problems, where the task is to evaluate a sign condition of the set of solutions given the promise that either all solutions satisfy the condition or none of them do. Of these we shall only consider the approximation problem. The class FIXP_a denotes the class of discrete search problems corresponding to strong approximation of Brouwer

fixed points and is defined to be closed under polynomial time reductions. Etessami and Yannakakis also prove that the problem PosSLP reduces to the problem of approximating a Nash equilibrium, thereby showing that FIXP_a likely contains search problems that are computationally very hard.

While the notion of SL-reductions is very restricted, it is sufficient for proving completeness of the problem of finding a Nash equilibrium. Likewise, SL-reductions are sufficient for showing that FIXP is robust with respect to the choice of domain for the Brouwer function.

Another important reason for using SL-reductions is that they immediately imply polynomial time reductions between the corresponding decision and approximation problems (the partial computation problem is more fragile and requires additional assumptions, cf. [12]). As we are mainly interested in the approximation problem more expressive notions of reducibility can be considered, while maintaining the property that reducibility implies polynomial time reducibility between the corresponding approximation problems. A sufficient condition for this is that the mapping of solutions is *polynomially continuous* and polynomial time computable.

1.1 The Borsuk-Ulam Theorem

Deligkas, Fearnley, Melissourgos, and Spirakis [11] recently introduced the complexity class BU to capture, in an analogy to FIXP, the computational complexity of the real-valued search problems associated with the Borsuk-Ulam theorem.

The Borsuk-Ulam theorem has a number of equivalent statements that are also easy to derive from each other. A function f defined on the unit sphere S^n is *odd* if $f(x) = -f(-x)$ for all $x \in S^n$. Note that the boundary ∂B^n of the unit n-ball B^n is identical to S^{n-1}. We thus say that a function f defined on B^n is odd on ∂B^n if f is odd when restricted to S^{n-1}. We present the simple proof of the known fact that the different formulations can be derived from each other, for the purpose of discussing equivalence from a computational point of view.

▶ **Theorem 1** (Borsuk-Ulam). *The following statements hold:*
(1) *If $f\colon S^n \to \mathbb{R}^n$ is continuous there exists $x \in S^n$ such that $f(x) = f(-x)$.*
(2) *If $g\colon S^n \to \mathbb{R}^n$ is continuous and odd there exists $x \in S^n$ such that $g(x) = 0$.*
(3) *If $h\colon B^n \to \mathbb{R}^n$ is continuous and odd on ∂B^n there exists $x \in B^n$ such that $h(x) = 0$.*

Proof of equivalence. Given f we may define $g(x) = f(x) - f(-x)$. Clearly g is odd and we have $g(x) = 0$ if and only if $f(x) = f(-x)$, which shows that (2) implies (1). Conversely, given g we simply let $f = g$. If $f(x) = f(-x)$, then since g is odd we have $f(x) = g(x) = -g(-x) = -f(-x) = -f(x)$ and hence $g(x) = f(x) = 0$, which therefore shows that (1) implies (2).

We may view S^n as two hemispheres, each homeomorphic to B^n, which are glued together along their equators. Let $\pi\colon S^n \to B^n$ be the orthogonal projection defined by $\pi(x_1, \ldots, x_{n+1}) = (x_1, \ldots, x_n)$. Then given h we may define $g(x) = h(\pi(x))$ for $x_{n+1} \geq 0$ and $g(x) = -h(-\pi(x))$ for $x_{n+1} \leq 0$. The assumption that h is odd on ∂B^n makes g a well-defined continuous odd function. We have $g(x) = 0$ if and only if $h(x) = 0$, which shows that (2) implies (3). Conversely, given g we define h by $h(x) = g\left(x, (1 - \|x\|_2^2)^{\frac{1}{2}}\right)$. Then h is continuous and odd on ∂B^n, since $x \in \partial B^n$ if and only if $\|x\|_2^2 = 1$. Clearly if $h(x) = 0$ we may let $y = (x, (1 - \|x\|_2^2)^{\frac{1}{2}})$ and have $g(y) = 0$. On the other hand, when $g(y) = 0$ we may define $x = (y_1, \ldots, y_n)$ if $y_{n+1} \geq 0$ and $x = (-y_1, \ldots, -y_n)$ if $y_{n+1} < 0$, and we have $h(x) = 0$. Together this shows that (3) implies (2). ◀

The class BU defined in [11] corresponds to the first formulation of the above theorem. We may clearly consider the second formulation equivalent to the first also from a computational point of view. In particular, when translating between formulations, the set of solutions is unchanged. Note that this set of solutions has the property that all solutions come in pairs: when x is a solution then $-x$ is a solution as well. For the third formulation of the theorem this property only holds for solutions on the boundary ∂B^n.

In contrast, while the mapping of solutions of the third formulation to the second (and first) formulation given above is continuous this is not the case in the other direction. More precisely, consider $y \in S^n$ such that $g(y) = 0$. For a solution strictly contained in the upper hemisphere, the orthogonal projection to the first n coordinates produces $x \in B^n$ such that $h(x) = 0$. For a solution y strictly contained in the lower hemisphere, the projection is instead applied to the antipodal solution $-y$.

To clarify this issue from a computational point of view we introduce a new class BBU of real valued search problems corresponding to the third formulation of Theorem 1, and it will follow from definitions that BU $\subseteq$ BBU. In the context of strong approximation however, the corresponding classes of discrete search problems BU_a and BBU_a will be shown to coincide. The idea is that given an approximation to $y \in S^n$, where $g(y) = 0$, that is sufficiently close to the equator of S^n, there is no harm in *incorrectly* deciding to which hemisphere y belongs, since solutions $x \in \partial B^n$ for which $h(x) = 0$ also come in pairs.

For the class BU, the notion of SL-reductions is clearly too restrictive to allow a reasonable comparison to FIXP. Closing the class BU by SL-reductions, the solutions would still come in pairs, thereby imposing strong conditions on the set of solutions. On the other hand the reductions should also not be *too* strong. In particular it would be desirable that FIXP would still be closed under the chosen notion of reductions. This issue is not discussed in [11]. We shall therefore propose a suitable notion of reductions for both BU and BBU.

1.2 Consensus Halving

The Consensus halving problem is a classical problem of *fair division* [21]. We are given a set of n bounded and continuous measures $\mu_1, \ldots, \mu_n$ defined on the interval $A = [0, 1]$. The goal is to partition the interval A into at most $n + 1$ intervals, i.e. by placing at most n *cuts*, such that unions of these intervals form another partition $A = A^+ \cup A^-$ of A satisfying $\mu_i(A^+) = \mu_i(A^-)$ for every i. We may think of the intervals being assigned a *label* from the set $\{+, -\}$, and A^+ is precisely the union of the intervals labeled by $+$. Such a partition is also known as a consensus halving. Using the Borsuk-Ulam theorem, Simmons and Su [21] proved that a consensus halving using at most n cuts always exists. Simmons and Su represent a division of A as a point x on the unit n-sphere S_1^n with respect to the ℓ_1-norm. The point x is viewed as representing a division into *precisely* $n + 1$ intervals, where some intervals are possibly empty. More precisely, the i-th interval has length $|x_i|$, and intervals of length 0 may simply be discarded. The intervals of positive length are then labeled according to $\operatorname{sgn}(x_i)$. Note that for any x, the antipode $-x$ represents the division where the sets A^+ and A^- are exchanged. This naturally leads to a formulation using the Borsuk-Ulam theorem [21]. Namely we may consider the function $F\colon S_1^n \to \mathbb{R}^n$ given by $F(x)_i = \mu_i(A^+)$, and note that any $x \in S_1^n$ for which $F(x) = F(-x)$ represent a consensus halving.

We are interesting in the simple setting of additive measures, where we have corresponding density functions $f_1, \ldots, f_n$ such that $\mu_i(B) = \int_B f_i(x)\,dx$. To cast the consensus halving problem as a real valued search problem we follow [11] and assume that the measures $\mu_1, \ldots, \mu_n$ are given by the distribution functions $F_1, \ldots, F_n$ defined by $F_i(x) = \int_0^x f_i(t)\,dt$. An instance of the consensus halving problem is then given as a list of algebraic circuits computing these distribution functions.

1.3 Strong versus Weak Approximation

The difference between weak and strong approximation was studied in detail in the general context of the Brouwer fixed point theorem by Etessami and Yannakakis. A central example is the problem of finding a Nash equilibrium (NE). An important notion of approximation of a NE is the notion of an ε-NE. Computing an ε-NE of a given strategic form game Γ is polynomial time equivalent to computing a weak ε'-approximation to a fixed point the Nash's Brouwer function F_Γ associated to Γ [12, Proposition 2.3]. In turn, computing a weak ε'-approximation to a fixed point of F_Γ polynomial time reduces to computing a strong ε''-approximation to a fixed point of F_Γ [12, Proposition 2.2], since the function F_Γ is polynomially continuous and polynomial time computable. In general however an ε-NE might be far from any actual NE, unless ε is inverse doubly exponentially small as a function of the size of the game [12, Corollary 3.8].

For the problem of consensus halving we can illustrate the difference between weak and strong approximation by a simple example. We shall refer to a weak ε-approximation of a consensus halving as simply an ε-consensus halving. Consider a single agent whose measure μ on the interval $[0,1]$ is given by the following density

$$f(x) = \begin{cases} (1+\varepsilon)/\varepsilon & \text{if } 0 \leq x < \varepsilon/2 \\ 0 & \text{if } \varepsilon/2 \leq x < 1-\varepsilon/2 \\ (1-\varepsilon)/\varepsilon & \text{if } 1-\varepsilon/2 \leq x \leq 1 \end{cases}$$

We have $\mu([0,1]) = 1$ and since μ is a step function, the corresponding distribution function F is piecewise linear. The unique consensus halving is obtained by placing a cut at the point $\varepsilon/2 - \varepsilon^2/(2+2\varepsilon)$. Placing a cut at any point $t \in [\varepsilon/2 - \varepsilon^2/(1+\varepsilon), 1-\varepsilon/2]$ results in an ε-consensus halving, i.e. such that $\left|\mu([0,t]) - \mu([t,1])\right| \leq \varepsilon$. Thus an ε-consensus halving might be very far from an actual consensus halving. Note also that placing a cut at any point $t \in [0, 3\varepsilon/2 - \varepsilon^2/(2+2\varepsilon)]$ is a strong ε-approximation, which illustrates that a strong approximation is not necessarily a weak approximation. On the other hand, a strong $(\varepsilon^2/2)$-approximation is also an ε-consensus halving.

The Brouwer fixed point theorem and the Borsuk-Ulam theorem can both be proved starting from combinatorial analogues of the two theorems, namely from Sperner's lemma and Tucker's lemma, respectively. The proofs of these two lemmas are constructive, but using them to derive the Brouwer fixed point theorem and the Borsuk-Ulam theorem involve a nonconstructive limit argument. Let us note in passing that while Sperner's lemma, like the Borsuk-Ulam theorem, has several different formulations, it is usually formulated as the combinatorial analogue of the third formulation of Theorem 1.

Sperner's and Tucker's lemma give rise to total NP search problems. These turn out to be complete for the complexity classes PPAD and PPA introduced in the seminal work by Papadimitriou [19]. Papadimitriou proved PPAD-completeness of the problem given by Sperner's lemma as well as membership in PPA of the problem given by Tucker's lemma, while PPA-completeness of the latter problem was proved recently by Aisenberg, Bonet, and Buss [1]. These results also imply that the classes PPAD and PPA correspond to the problems of computing weak approximations to Brouwer fixed points and to Borsuk-Ulam points.

The computational complexity of the problems of computing an ε-NE and of computing an ε-consensus halving was settled in breakthroughs of two lines of research. Computing an ε-NE was shown to be PPAD-complete by Daskalakis, Goldberg and Papadimitriou [9] and Cheng and Deng [8]. Computing an ε-consensus halving was shown to be PPA-complete by Filos-Ratsikas and Goldberg [14, 15].

1.4 Our Results

Our main result is that the problem of strong approximation of consensus halving is equivalent to strong approximation of the Borsuk-Ulam theorem.

▶ **Theorem 2.** *The strong approximation problem for* CH *is* BU_a*-complete.*

As described, we view the consensus halving problem as the real valued search problem with its domain being either the unit sphere or the unit ball with respect to the ℓ_1-norm. The theorem is proved by reduction from the real valued search problem associated with the Borsuk-Ulam theorem on the domain being the unit ball with respect to the ℓ_∞-norm, i.e. from a defining problem of the class BBU.

It is of general interest to study the relationship between search problems given by the Borsuk-Ulam theorem on different domains from a computational point of view. The reduction establishing the proof of Theorem 2 gives additional motivation for this. The domains we consider are unit spheres S_p^n and unit balls B_p^n with respect to the ℓ_p-norm for $p \geq 1$ or $p = \infty$. It is of course straightforward to construct homeomorphisms between unit spheres or unit balls with respect to different norms, and these could be used to define reductions between the different problems. We would however like that the mapping of solutions is simple, and in particular we would like to avoid divisions and root operations. We prove that one may in fact reduce between domains using SL-reductions.

Deligkas et al. gave a reduction from the FIXP-complete problem of finding a Nash equilibrium to CH. Combined with membership of CH in BU, this gives the inclusion $\mathrm{FIXP} \subseteq \mathrm{BU}$. We observe that a proof due to Volovikov [24] of the Brouwer fixed point theorem from the Borsuk-Ulam theorem may be adapted to give a simple proof of the inclusion $\mathrm{FIXP} \subseteq \mathrm{BU}$.

For the class FIXP we prove two interesting structural properties that do not appear to have been observed earlier. While FIXP is defined using SL-reductions, we show that FIXP is closed under polynomial time reductions where the mapping of solutions is expressed by *general* algebraic circuits. This in particular supports that one may reasonably define the classes BU and BBU using less restrictive notions of reductions than SL-reductions. We propose to have the mapping of solutions be computed by algebraic circuits involving the operations of addition, multiplication by scalars, as well as maximization. This means that the mapping of solutions is a piecewise linear function, and we refer to these as PL-reductions. The second structural result for FIXP is a characterization of the class by very simple Brouwer functions. These are defined on the unit-hypercube domain $[0,1]^n$ and each coordinate function is simply one of the operations $\{+, -, *, \max, \min\}$, modified to have the output truncated to the interval $[0,1]$.

For the classes BU and BBU we prove that they are also closed under reductions where the mapping of solutions is computed by general algebraic circuits, but with the additional requirement that this function must be odd.

For the class FIXP, an interesting consequence of the proof that finding a Nash equilibrium is complete, is that the class may be characterized by Brouwer functions computed by algebraic circuits without the division operation. The proof also shows that the class FIXP is unchanged even when allowing root operations as basic operations. We prove by a simple transformation that the classes BU and BBU may be characterized using algebraic circuits without the division operation. Furthermore, as a consequence of Theorem 2 the class of strong approximation problems $\mathrm{BU}_a = \mathrm{BBU}_a$ is unchanged even when allowing root operations as basic operations.

1.5 Comparison to previous work

As a precursor to the proof of PPA-completeness of computing an ε-consensus halving, Filos-Ratsikas, Frederiksen, Goldberg and Zhang [13] proved the problem to be PPAD-hard. Deligkas et al. [11] uses ideas from this proof together with additional new ideas to obtain their proof of FIXP-hardness for computing an exact consensus halving.

While PPAD $\subseteq$ PPA, the PPAD-hardness result of [13] is not implied by the recent proofs of PPA-completeness. In particular, the work [13] proves PPAD-hardness even for *constant* ε, while the work of [15] only proves PPA-hardness for ε being inverse polynomially small. In the same way, while FIXP $\subseteq$ BU, FIXP-hardness of computing an exact consensus halving is not implied by our reduction, since Theorem 2 establishes BU_a-hardness rather than BU-hardness. Recently a considerably simpler proof of PPA-hardness for computing an ε-consensus halving was given by Filos-Ratsikas, Hollender, Sotiraki and Zampetakis [16], and our reduction is inspired by this work.

All reductions described above are similar in the sense that one or more evaluations of a circuit are expressed in the consensus halving instance. The full interval A is partitioned into subintervals, cuts within these subintervals encode values in various ways, and agents implement the gates of the circuit by placing cuts. A main difference between the reductions establishing PPAD-hardness and FIXP-hardness to those establishing PPA-hardness is that in the former reductions, all cuts are constrained to be placed in distinct subintervals. The reason this is possible is that the objective is to find a fixed point of the circuit, which means that inputs and outputs may be identified.

In the setting of PPA and BBU the objective is to find a "zero" of the circuit. More precisely, for the setting of PPA the objective is to find two adjacent points of a given Tucker labeling that receive complementary labels, i.e. labels of different sign but same absolute value. For the setting of BBU the objective is to find an actual zero point of the circuit. All of the reductions establishing PPA-hardness of computing an ε-consensus halving have the property that cuts encoding the input of the circuit are *free* cuts, meaning that they can in principle be placed anywhere, and as a result also interfere with the evaluations of the circuit. This is also the case for our reduction, and this invariably limits its applicability to the approximation problem.

In the reduction of [16], the interval A is structured into different regions, a coordinate-encoding region, a constant-creation region, several circuit-simulation regions, and finally a feedback region. Our reduction also has a coordinate-encoding region and several circuit simulation regions, but the functions performed by the constant-creation region and feedback regions in [16] are in our reduction integrated into the individual circuit simulation regions and done differently.

A novelty of the reduction of [16] compared to previous reductions is in how values are encoded by cuts in subintervals. In previous reductions, values are encoded by what we will call *position encoding*. In that encoding it is required that there is exactly one cut in the subinterval, and the value encoded is determined by the distance between the cut position and the left endpoint of the interval. In [16] values are encoded by what we will call *label encoding*. Here there is no requirement on the number of cuts in the subinterval, and the value encoded is simply the difference between the Lebesgue measures of the subsets of the interval receiving label $+$ and label $-$. We shall employ a hybrid approach where the coordinate-encoding region uses label encoding while the circuit-simulation regions uses position encoding. The first step performed in a circuit-simulation region is thus to copy the input from the coordinate-encoding region. Switching to position encoding allows us in particular to implement a multiplication gate, similarly to [11]. Here the multiplication xy is

computed via the identity $xy = ((x+y)^2 - x^2 - y^2)/2$. In [11] where values range over $[0,1]$, the squaring operation may be implemented directly by agents. In our case values range over the interval $[-1,1]$, and the squaring operation is decomposed further, having agents compute it separately over the intervals $[-1,0]$ and $[0,1]$.

In analogy to [16] we have feedback agents that ensures that the circuit evaluates to 0 on the encoded input. The criteria that the agents check is however different, and for our purposes it is crucial that we have the same sign pattern in the position encoding of the output of the circuit as the copy of the input made by the circuit-simulation region. The actual detection of an output of 0 is performed by using approximations of the Dirac delta function. For computing the distribution functions of the feedback agents, we make use of the fact that these are computed by algebraic circuits, which enable us to make a strong approximation of the Dirac delta function via repeated squaring.

1.6 Organization of Paper

We introduce required terminology in Section 2. We refer to the full version of this paper for our structural results for the classes FIXP, BU, and BBU as well as the simple proof of the inclusion FIXP $\subseteq$ BU. The proof of our main result, Theorem 2, is given in Section 3.

2 Preliminaries

2.1 Algebraic Circuits

Central to our work are algebraic circuits computing real valued functions. Let B be a finite set of real valued functions, for example $B = \{+, -, *, \div, \max, \min\}$. An *algebraic circuit* C with n inputs and m outputs over the *basis* B is given by an acyclic graph $G = (V, A)$ as follows. The *size* of C is equal to the number of nodes of G, which are also referred to as *gates*. The *depth* of C is equal to the length of the longest path of G. Every node of indegree 0 is either an *input gate* labeled by a variable from the set $\{x_1, \ldots, x_n\}$ or a *constant gate* labeled by a real valued constant. Every other node is labeled by an element of B called the *gate function*. If a node v is labeled by a gate function $g\colon A \to \mathbb{R}$ with $A \subset \mathbb{R}^k$ we require that g has exactly k ingoing arcs with a linear order specifying the order of arguments to g. The output of C is specified by an ordered list of m (not necessarily distinct) nodes of G. The computation of C on a given input $x \in \mathbb{R}^n$ is defined in the natural way. Computation may fail in case a gate of C labeled by a function $g\colon A \to \mathbb{R}$ receives an input outside A, and in this case the output of C is undefined. Otherwise we say that the output is well defined and denote its value by $C(x)$. If $D \subseteq \mathbb{R}^n$ we say that C computes a function $f\colon D \to \mathbb{R}^m$ if $C(x)$ is well defined for all $x \in D$.

We shall in this paper just consider algebraic circuits where the basis consists only of continuous functions. This means in particular that any algebraic circuits computes a continous function as well. We shall also only consider consider constant gates labeled with rational numbers. In this case we are also interested in the *bitsize* of the encoding of the constants, which is the maximum bitsize of the numerator or denominator.

By using multiplication with the constant -1, the functions $-$ and min may be simulated using $+$ and max, respectively. In this way we may convert a circuit over the full basis $\{+, -, *, \div, \max, \min\}$ into an equivalent $\{+, *, \div, \max\}$-circuit. We shall also consider circuits where use of the multiplication operator $*$ is *restricted* to having one of the arguments being a constant gate. We denote this by the symbol $*\zeta$ and use it in particular for defining $\{+, *\zeta, \max\}$-circuits.

2.2 Search problems

A general search problem Π is defined by specifying to each input instance I a *search space* (or *domain*) D_I and a set $\mathrm{Sol}(I) \subseteq D_I$ of *solutions*. We distinguish between *discrete* and *real-valued* search problems. For discrete search problems we assume that $D_I \subseteq \{0,1\}^{d_I}$ for an integer d_I depending on I. Analogously, for real-valued search problems we assume that $D_I \subseteq \mathbb{R}^{d_I}$ for an integer d_I depending on I. One could likewise distinguish between search problems with discrete input and real-valued input. We are however mostly interested in problems where the input is discrete. That is, we assume that instances I are encoded as strings over a given finite alphabet Σ (e.g. $\Sigma = \{0,1\}$).

Many natural search problems are however defined with a continous search space. Not all of these may adequately be recast as discrete search problems, but are more naturally viewed as real-valued search problems. One approach for studying such problems would be to switch to the Blum-Shub-Smale model of computation [4]. A BSS machine resembles a Turing machine, but operates with real numbers instead of symbols from a finite alphabet. In particular is the input real-valued, and input instances are therefore encoded as real-valued vectors. All basic arithmetic operations and comparisons are unit-cost operations. One may then define real-valued analogues of Turing machine based classes. In particular, Blum, Shub and Smale defined and studied the real-valued analogues $\mathrm{P}_{\mathbb{R}}$ and $\mathrm{NP}_{\mathbb{R}}$ of P and NP. A BSS machine may in general make use of real-valued *machine constants*. If a BSS machine only uses rational valued machine constants we shall call it *constant-free*.

For the classes $\mathrm{P}_{\mathbb{R}}$ and $\mathrm{NP}_{\mathbb{R}}$, if we simply restrict the input to be discrete and consider only constant-free BSS machines this results in complexity classes, denoted by $\mathrm{BP}(\mathrm{P}^0_{\mathbb{R}})$ and $\mathrm{BP}(\mathrm{NP}^0_{\mathbb{R}})$, that may directly be compared to Turing machine based complexity classes. Indeed, it was proved by Allender, Bürgisser, Kjeldgaard-Pedersen and Miltersen [2, Proposition 1.1] that $\mathrm{BP}(\mathrm{P}^0_{\mathbb{R}}) = \mathrm{P}^{\mathrm{PosSLP}}$, where PosSLP is the problem of deciding whether an integer given by a division free arithmetic circuit (i.e. a $\{+,-,*\}$-circuit using just the constant 1) is positive. While the precise complexity of PosSLP is not known, Allender et al. proved that it is contained in the *counting hierarchy* CH (not to be confused with the consensus halving problem whose abbreviation coincides). The class $\mathrm{BP}(\mathrm{NP}^0_{\mathbb{R}})$ is equal to the class $\exists\mathbb{R}$ that was defined by Schaefer and Štefankovič [20] to capture the complexity of the existential theory of the reals ETR. It is known that $\mathrm{NP} \subseteq \exists\mathbb{R} \subseteq \mathrm{PSPACE}$, where the latter inclusion follows from the decision procedure for ETR due to Canny [7].

We define the class of $\exists\mathbb{R}$ search problems as the following subclass of all real valued search problems. Instaces I are encoded as string over a given finite alphabet Σ and we assume there is a polynomial time algorithm that given I computes d_I, where $D_I \subseteq \mathbb{R}^{d_I}$. We next assume that there are polynomial time constant free *BSS machines* that given I and $x \in \mathbb{R}^{d_I}$ checks whether $x \in D_I$, and given I and $x \in D_I$ checks whether $x \in \mathrm{Sol}(I)$. The corresponding language in $\exists\mathbb{R}$ is then $L = \{I \mid \mathrm{Sol}(I) \neq \emptyset\}$.

2.3 Solving real-valued search problems

Let Π be a $\exists\mathbb{R}$ search problem. In analogy with the case of NP search problems, one could consider the task of solving Π to be that of giving as output some member y of $\mathrm{Sol}(I)$ in case $\mathrm{Sol}(I) \neq \emptyset$. In general each member of $\mathrm{Sol}(I)$ may be irrational valued which precludes a Turing machine to compute a solution explicitly. This is in general also the case for a BSS machine, even when allowing machine constants. Regardless, we shall restrict our attention to Turing machines below.

On the other hand, when $\mathrm{Sol}(I) \neq \emptyset$ a solution is guaranteed to exist with coordinates being algebraic numbers, since a member of $\mathrm{Sol}(I)$ may be defined by an existential first-order formula over the reals with only rational-valued coefficients. This means that one could instead compute an indirect description of the coordinates of a solution, for instance by describing isolated roots of univariate polynomials. If such a description could be computed in polynomial time in $|I|$ we could consider that to be a polynomial time solution of Π.

Etessami and Yannakakis [12] suggest several other computational problems one may alternatively consider in place of solving a search problems Π explicitly or exactly. Our main interest is in the problem of *approximation*. We shall assume for simplicity that $D_I \subseteq [-1,1]^{d_I}$. Together with an instance I of Π we are now given as an auxiliary input a rational number $\varepsilon > 0$, and the task is to compute $x \in \mathbb{Q}^{d_I}$ such that there exist $x^* \in \mathrm{Sol}(I)$ with $\|x^* - x\|_\infty \leq \varepsilon$. We shall turn this into a *discrete* search problem by encoding the coordinates of x as binary strings. More precisely, to Π we shall associate a discrete search problem Π_a where instances are of the form (I,k), where I is an instance of Π and k is a positive integer. We define $\varepsilon = 2^{-k}$ and let the domain of (I,k) be $D_{I,k} = \{0,1\}^{d_I(k+3)}$, thereby allowing the specification of a point $x \in D_I$ with coordinates of the form $x_i = a_i 2^{-k+1}$, where $a_i \in \{-2^{k+1}, \ldots, 2^{k+1}\}$. The solution set $\mathrm{Sol}(I,k)$ is defined from $\mathrm{Sol}(I)$ by approximating each coordinate. That is, we define $\mathrm{Sol}(I,k) = \{x \in D_{I,k} \mid \exists x^* \in \mathrm{Sol}(I) : \|x^* - x\|_\infty \leq \varepsilon\}$. Note that if we had defined $\mathrm{Sol}(I,k)$ by instead truncating the coordinates of solutions $x^* \in \mathrm{Sol}(I)$ to k bits of precision, we would have obtained the possibly harder problem of *partial computation* which was also considered by Etessami and Yannakakis [12].

We say that Π can be approximated in polynomial time if the approximation problem Π_a can be solved in time polynomial in $|I|$ and k.

2.4 Reductions between search problems

Let Π and Γ be search problems. A *many-one reduction* from Π to Γ consists of a pair of functions (f,g). The function f is called the instance mapping and the function g the solution mapping. The instance mapping f maps any instance I of Π to an instance $f(I)$ of Γ and for any solution $y \in \mathrm{Sol}(f(I))$ of Γ the solution mapping g maps the pair (I,y) to a solution $x = g(I,y) \in \mathrm{Sol}(I)$ of Π. It is required that $\mathrm{Sol}(f(I)) \neq \emptyset$ whenever $\mathrm{Sol}(I) \neq \emptyset$. We will only consider many-one reductions, and will refer to these simply as *reductions*.

If Π_1 and Π_2 are discrete search problems a reduction (f,g) between Π_1 and Π_2 is a *polynomial time reduction* if both functions f and g are computable in polynomial time. If Π_1 and Π_2 are real-valued search problems it is less obvious which notion of reduction is most appropriate and we shall consider several different types of reductions. For all these we assume that f is computable in polynomial time. The reduction (f,g) is a *real polynomial time reduction* if g is computable in polynomial time by a constant free BSS machine. We shall generally consider this notion of reduction too powerful. In particular the definition does not guarantee that the function g is a continuous function in its second argument y. For this reason we instead consider reductions defined by algebraic circuits over a given basis B of real-valued basis functions.

We say that the reduction (f,g) is a *polynomial time B-circuit reduction* if there is a function computable in polynomial time thats maps an instance I to a B-circuit C_I in such a way that C_I computes a function $C_I \colon D_{f(I)} \to D_I$ where $g(I,y) = C_I(y)$ for all $y \in \mathrm{Sol}(f(I))$. Note in particular that the size of C_I and the bitsize of all constant gates are bounded by a polynomial in $|I|$. If in addition there exists a constant h such that the depth of C_I is bounded by h for all I we say that the reduction (f,g) is a *polynomial time constant depth B-circuit reduction*. Etessami and Yannakakis [12] defined the even weaker notion where the function

f is a *separable linear* transformation. The reduction (f, g) is an SL-reduction if there is a function $\pi\colon \{1,\dots,d_I\} \to \{1,\dots,d_{f(I)}\}$ and rational constants a_i, b_i, for $i = 1,\dots,d_I$, all computable in polynomial time from I, such that for all $y \in \mathrm{Sol}(f(I))$ it holds that $x_i = a_i y_{\pi(i)} + b_i$, where $x = g(I, y)$. Thus an SL-reduction is simply a *projection reduction* together with an individual affine transformation of each coordinate of the solution.

Functions computed by algebraic circuits over the basis $\{+, *\zeta, \max\}$ are piecewise linear. We shall thus call polynomial time $\{+, *\zeta, \max\}$-circuit reductions for polynomial time piecewise linear reductions, or simply PL-reductions.

It is easy to see that all notions of reductions defined above are transitive, i.e. if Π reduces to Γ and Γ reduces to Λ, then Π reduces to Λ as well.

A desirable property of PL-reductions is that the solution mapping g is *polynomially continuous*. By this we mean that for all rational $\varepsilon > 0$ there is a rational $\delta > 0$ such that for all points x and y of the domain, $\|x - y\|_\infty \leq \delta$ implies $\left\|g(x) - g(y)\right\|_\infty \leq \varepsilon$, and the bitsize of δ is bounded by a polynomial in the bitsize of ε and of $|I|$.

2.5 Total real-valued search problems

Like in the case of TFNP where interesting classes of total NP search problems may be defined in terms of existence theorems for finite structures [19, 17], we may define classes of total real valued $\exists\mathbb{R}$ search problems based on existence theorems concerning domains $D_I \subseteq \mathbb{R}^n$. Typical examples of such domains D_I are spheres and balls. Suppose p is either a real number $p \geq 1$ or $p = \infty$. By S_p^n and B_p^n we denote the unit n-sphere and unit n-ball with respect to the ℓ_p-norm defined as $S_p^n = \{x \in \mathbb{R}^{n+1} \mid \|x\|_p = 1\}$ and $B_p^n = \{x \in \mathbb{R}^n \mid \|x\|_p \leq 1\}$, respectively. If p is not specified, we simply assume $p = 2$.

2.5.1 The Brouwer fixed point theorem and FIXP

We recall here the definition of the class FIXP by Etessami and Yannakis [12]. The class FIXP is defined by starting with $\exists\mathbb{R}$ search problems given by the Brouwer fixed point theorem, and afterwards closing the class with respect to SL-reductions. We shall refer to these defining problems as *basic* FIXP problems.

▶ **Definition 3.** *An $\exists\mathbb{R}$ search problem Π is a* basic FIXP *problem if every instance I describes a nonempty compact convex domain D_I and a continuous function $F_I\colon D_I \to D_I$, computed by an algebraic circuit C_I, and these descriptions must be computable in polynomial time. The solution set is* $\mathrm{Sol}(I) = \{x \in D_I \mid F_I(x) = x\}$.

The Brouwer fixed point theorem guarantees that every basic FIXP problem is a total $\exists\mathbb{R}$ search problem. To define the class FIXP, Etessami and Yannakis restrict attention to a concrete class of basic FIXP problems.

▶ **Definition 4.** *The class* FIXP *consists of all* total $\exists\mathbb{R}$ *search problems that are SL-reducible to a basic* FIXP *problem for which each domain D_I is a convex polytope described by a set of linear inequalities with rational coefficients and the function F_I is defined by a $\{+, -, *, \div, \max, \min\}$-circuit C_I.*

The class FIXP_a is the class of strong approximation problems corresponding to FIXP. More precisely, FIXP_a consist of all discrete search problems polynomial time reducible to the problem Π_a for $\Pi \in \mathrm{FIXP}$.

The definition of FIXP is quite robust with respect to the choice of domain and set of basis functions allowed by circuits in the basic FIXP problems. Etessami and Yannakis proved that basic FIXP problems defined by $\{+, -, *, \div, \max, \min, \sqrt[k]{\ }\}$-circuits are still in

the class FIXP. Likewise, basic FIXP-problems where D_I is a ball with rational-valued center and diameter, or more generally an ellipsoid given by a rational center-point and a positive-definite matrix with rational entries, are still in the class FIXP [12, Lemma 4.1]. The same argument allows for using as domain the ball B_p^d with respect to the ℓ_p norm for any rational $p \geq 1$ or $p = \infty$, with the coordinates possibly transformed by individual affine functions.

2.5.2 The Borsuk-Ulam theorem, BU, and BBU

A new class BU of total $\exists\mathbb{R}$ search problems based on the Borsuk Ulam theorem was recently introduced by Deligkas et al. [11]. The definition of BU is meant to capture the Borsuk-Ulam theorem as stated in formulation (1) of Theorem 1. Following the definition of FIXP by Etessami and Yannakakis, Deligkas et al. first consider a set of basic search problems and then close the class under reductions. For defining BU, Deligkas et al. restrict their attention to spheres with respect to the ℓ_1-norm as domains and functions computed by $\{+, -, *, \max, \min\}$-circuits. Compared to the definition of FIXP, division gates are thus excluded. Having thus fixed the set of basic BU search problems what remains in order to define BU is to settle on a notion of reductions. In their journal paper, Deligkas et al. [11] suggest using reductions computable by general algebraic circuits including non-continuous comparison gates, whereas in the preceeding conference paper [10] they did not precisely define a choice of reductions.

We propose defininining BU using a different notion of reduction below. We additionally define a class BBU based on the Borsuk-Ulam theorem corresponding to formulation (3) of Theorem 1. We start by defining basic BU and basic BBU problems. We shall restrict our attention to domains being the unit n-sphere and unit n-ball, but with regards to any ℓ_p-norm for $p \geq 1$ or $p = \infty$.

▶ **Definition 5.**

1. *An $\exists\mathbb{R}$ search problem Π is a basic ℓ_p-*BU *problem if for every instance I we have $D_I = S_p^{d_I}$ and I describes a continuous function $F_I \colon D_I \to \mathbb{R}^{d_I - 1}$, computed by an algebraic circuit C_I whose description is computable in polynomial time. The solution set is* $\mathrm{Sol}(I) = \{x \in D_I \mid F_I(x) = F_I(-x)\}$.
2. *An $\exists\mathbb{R}$ search problem Π is a basic ℓ_p-*BBU *problem if for every instance I we have $D_I = B_p^{d_I}$ and I describes a continuous function $F_I \colon D_I \to \mathbb{R}^{d_I}$, which is odd on the boundary $\partial B_p^{d_I}$. The function F_I must be computed by an algebraic circuit C_I whose description is computable in polynomial time. The solution set is* $\mathrm{Sol}(I) = \{x \in D_I \mid F_I(x) = 0\}$.

The condition that the function F_I is odd on $\partial B_p^{d_I}$ for basic ℓ_p-BBU problems is a semantic condition. However, typically the function F_I would be defined from a basic ℓ_p-BU problem by a transformation done in a similar way as in the proof of Theorem 1, and thereby F_I would satisfy the condition automatically.

To define the classes BU and BBU, we restrict our attention to domains with respect to the ℓ_∞-norm.

▶ **Definition 6.** *The class* BU *(respectively,* BBU*) consists of all* total $\exists\mathbb{R}$ *search problems that are PL-reducible to a basic ℓ_∞-*BU *problem (respectively, basic ℓ_∞-*BBU *problem) for which the function F_I is defined by a $\{+, -, *, \div, \max, \min\}$-circuit C_I.*

While the definition of BU in [11] was using as domain the unit sphere with respect to the ℓ_1-norm and not allowing for division gates, we show in the full version of this paper that these changes do not change the class. We propose choosing PL-reductions for closing the

class under reductions. PL-reductions are sufficient for obtaining all of our results and they are polynomially continuous. Another reason for this choice is that if we restrict the circuits defining the classes FIXP and BU to also be piecewise linear, i.e. be $\{+, *\zeta, \max\}$-circuits, we obtain the classes LinearFIXP and LinearBU, that when closed under polynomial-time reductions are equal to PPAD and PPA, respectively [12, 11].

2.6 Consensus Halving

We give here a formal definition of consensus halving with additive measures as real valued search problems.

▶ **Definition 7.** *The problem* CH *is defined as follows. An instance I consists of a list of $\{+, -, *, \div, \max, \min\}$-circuits $C_1, \ldots, C_n$ computing distribution functions $F_1, \ldots, F_n$ defined on the interval $A = [0, 1]$. The domain is $D_I = S_1^n$ and* $\mathrm{Sol}(I)$ *constists of all x for which*

$$\sum_{j:x_j>0} F_i(t_j) - F_i(t_{j-1}) = \sum_{j:x_j<0} F_i(t_j) - F(t_{j-1}) \ , \tag{1}$$

where $t_0 = 0$ and $t_j = \sum_{k\leq j}|x_k|$, for $j = 1, \ldots, n+1$.

Given $\{+, -, *, \div, \max, \min\}$-circuits computing the distribution functions F_i, the function F computing the left-hand-side of equation (1) may now clearly be computed by $\{+, -, *, \div, \max, \min\}$-circuits as well. The result of Deligkas et al. that CH is contained in BU follows.

The existence proof of a consensus halving by Simmons and Su as well the formulation as an $\exists\mathbb{R}$ search problem by Deligkas et al. match the Borsuk-Ulam theorem as stated in formulation (1) of Theorem 1.

3 Consensus Halving

In this section we present the proof of our main result Theorem 2. This result enables an additional structural result about the class of strong approximation problems $\mathrm{BU}_a = \mathrm{BBU}_a$, showing that the class is unchanged even when allowing root operations as basic operations. We refer to the full version of this paper for details of this.

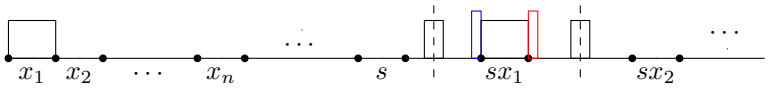
Suppose we are given a basic $\ell_\infty - \mathrm{BBU}_a$ problem Π_a with circuits over the basis $\{+, -, *, \max, \min\}$. Let (I, k) denote an instance of Π_a and put $\varepsilon = 2^{-k}$. We may in polynomial time compute a circuit C defining a function $F\colon B_\infty^n \to \mathbb{R}^n$ that is odd on the boundary S_∞^{n-1} such that $\mathrm{Sol}(I) = \{x \in B_\infty^n \mid F(x) = 0\}$. We now provide a reduction from Π_a to a CH_a-problem. In the reduction we will make use of the "almost implies near" paradigm as expressed in the following lemma. The simple proof is given in the full version of this paper.

▶ **Lemma 8.** *Let $F\colon B_\infty^n \to \mathbb{R}^n$ be a continuous map. For any $\varepsilon > 0$ there is a $\delta > 0$ such that if $\left\|F(x)\right\|_\infty \leq \delta$ then there is an $x^* \in B_\infty^n$ such that $\|x - x^*\|_\infty \leq \varepsilon$ and $F(x^*) = 0$.*

The lemma says that for any $\varepsilon > 0$, if $\left\|F(x)\right\|_\infty$ is sufficiently close to being zero, then x is ε-close to a real zero of F. When F is computed by an algebraic circuit of polynomial size, it follows by using tools from real algebraic complexity [3] that there exists some fixed polynomial q with integer coefficients such that the above lemma holds true for some $\delta \geq \varepsilon^{2^{q(|I|)}}$. We refer to the full version of this paper for details. The lemma then holds

true for $\delta = \varepsilon^{2^{q(|I|)}}$, and we may construct this number using a circuit of polynomial size by repeatedly squaring the number ε exactly $q(|I|)$ times. This number will be used by the feedback agents in our CH_a instance in order to ensure that any solution gives a solution to the $\ell_\infty - \mathrm{BBU}_a$ instance.

3.1 Overview of the Reduction



Overview. As in previous works, we describe a consensus halving instance on an interval $A = [0, M]$, where M is bounded by a polynomial in $|I|$, rather than the interval $[0, 1]$. This instance may then be translated to an instance on the interval $[0, 1]$ by simple scaling. Like [16], in the leftmost end of the instance we place the *Coordinate-Encoding* region consisting of n intervals. In a solution these intervals will encode a value $x \in [-1, 1]^n$. A *circuit simulator* C will simulate the circuit of F on this value x. The circuit simulators will consist of a number of agents each implementing one gate of the circuit. However, such a circuit simulator may fail in simulating F properly, so we will use a polynomial number of circuit simulators $C_1, \ldots, C_{p(n)}$. Each of these circuit simulators will output n values $[C_j(x)]_1, \ldots, [C_j(x)]_n$ into intervals $I_{1j}, \ldots, I_{nj}$ immediately after the simulation. Finally, we introduce the so-called *feedback agents* $f_1, \ldots, f_n$. The agent f_i will have some very thin *Dirac blocks* centered in each of the intervals I_{ij} where $j \in [p(n)]$. These agents will ensure that if z is an exact solution to the CH instance, then the encoded value x satisfies that $\left\|F(x)\right\|_\infty$ is sufficiently small that we may conclude that x is ε-close to a zero x^* of F.

Label Encoding. For a unit interval I we let $I^\pm$ denote the subsets of I assigned the corresponding label. We define the *label encoding* of I to be a value in $[-1, 1]$ given by the formula $v_l(I) := \mu(I^+) - \mu(I^-)$. This makes sense as $I^\pm$ is measurable, because it is the union of a finite number of intervals.

Coordinate-Encoding Region. The interval $[0, n]$ is called the *Coordinate-Encoding* region. For every $i \in [n]$, the subinterval $[i-1, i]$ of the Coordinate-Encoding region encodes a value $x_i := v_l([i-1, i])$ via the label encoding.

Position Encoding. For an an interval I which contains only a single cut, thus dividing I into two subintervals $I = I_a \cup I_b$, where I_a is the subinterval at the left of the cut and I_b the subinterval at the right of the cut, we define the *position encoding* of I to be the value $v_p(I) := \mu(I_a) - \mu(I_b)$. We note that $v_p(I) = v_l(I)$ if the labeling sequence is $+/-$, and $v_p(I) = -v_l(I)$ in the case the labeling sequence is $-/+$.

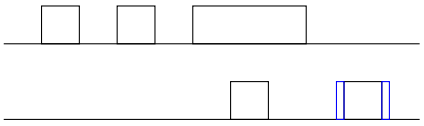
From Label to Position. Before a circuit simulator there is a *sign detection* interval I_s which detects the labeling sequence. Unless it contains a stray cut, this interval will encode a sign $s = \pm 1$ (to be precise 1 if the label is $+$ and -1 is the label is $-$). By placing agents that flip the label as indicated in the figure below, we may now obtain position encodings of the values $sx_1, \ldots, sx_n$. These values will be read-in as inputs to the subsequent circuit simulator.

Circuit Simulators. As mentioned above, each circuit simulator C_j will read-in the values $s_j x_1, \ldots, s_j x_n$ and simulate the circuit computing F on this input. They then output their values into n intervals immediately after the simulation.

Feedback Agents. By the discussion after the statement of Lemma 8 we may by repeated squaring construct a circuit of polynomial size in $|I|$ computing a tiny number $\delta > 0$ such that if $\left\|F(x)\right\|_\infty \leq \delta$ then x is $(\varepsilon/2)$-close to a zero of F. Now fix $i \in [n]$ and let c_{ij} denote the centre of the feedback interval I_{ij} that outputs the value $[C_j(s_j \cdot x)]_i$. We then define the ith feedback agent to have constant density $1/\delta$ in the intervals $[c_{ij} - \delta/2, c_{ij} + \delta/2]$.

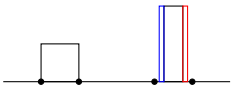
The reason for having the feedback agents have these very narrow Dirac blocks is that if $F_i(x) > \delta$ for some i, then in any of the "uncorrupted" circuits (i.e. circuits outputting the correct values) all the density of the ith agent will contribute to the same label. Moreover, we will show using the boundary condition of F that the contribution is to the same label in all the uncorrupted circuit simulators. This will contradict that the feedback agents should value I^+ and I^- equally. That is, the feedback agents ensure that $\left\|F(x)\right\|_\infty \leq \delta$ if x is the value encoded by an exact solution to the consensus halving instance we construct.

Stray Cuts. Any of the agents implementing one of the gates in a circuit simulator will force a cut to be placed in an interval in that same circuit simulator. The only agents whose cuts we have no control over are the n feedback agents. The expectation is that these agents should make cuts in the Coordinate-Encoding region that flip the label. If they do not do this we will call it a *stray cut*. If a circuit simulator contains a stray cut, we will say nothing about its value.



▶ **Observation 9.** *If it is not the case that every unit interval encoding a coordinate x_i in the Coordinate-Encoding region contains a cut that flips the label, then the encoded point $x \in B^n_\infty$ will lie on the boundary S^n_∞. With this in mind we may ensure that $x \in S^n_\infty$ or $s_1 = s_2 = \cdots = s_{p(n)} = \pm 1$ where the sign is the same as the label of the first interval. This can be done by, if necessary, placing one single-block agent after the Coordinate-Encoding region and each of the circuit simulators (if placing such an agent is necessary depends on, respectively, the number of variables n and the size of the circuits).*

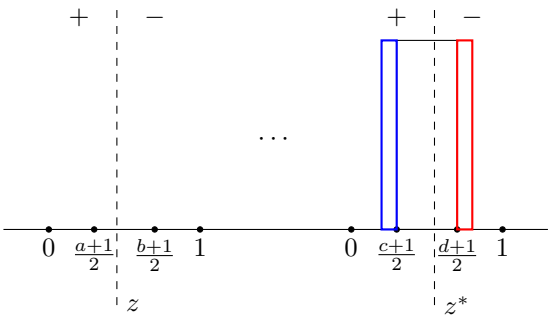
3.2 Construction of Gates



In this section we describe how to construct Consensus-Halving agents implementing the required gates $\{+, -, *, \max, \min\}$ for building the circuit simulators. By placing single-block agents between intervals, we may assume that the labeling sequence is the same in all the intervals of a circuit simulator. First, we show that we may transform the given circuit such that all gates only take values in the interval $[-1, 1]$ on input from B^n_∞.

Transforming the Circuit. By propagating every gate to the top of the circuit we may assume that the circuit is layered. Let C' denote the resulting circuit. By repeated squaring we may maintain a gate with value $1/2^{2^d}$ in the dth layer. Suppose $g = \alpha(g_1, g_2)$ is a gate with inputs g_1, g_2 in layer d. We modify the gates as follows: if $\alpha \in \{+, -, \max, \min\}$ then we multiply g_i by $1/2^{2^d}$ before applying α; if $\alpha = *$, then we multiply the input by 1 before applying α. Finally, we transform C' into the circuit C'' as follows: on input x, the circuit C'' multiplies the input by $1/2$ and then evaluates C' on input $x/2$. Inductively, one may show that if g is a gate in layer d in the circuit C', then the corresponding gate in in the circuit C'' has value $g/2^{2^d}$. As all the gates are among $\{+, -, *, \max, \min\}$, this ensures that all the gates in C'' take values in $[-1, 1]$.

Addition Gate [G_+]. We may construct an addition gate using two agents. The first agent has two unit input intervals that we assume contain one cut each. This then forces a cut in the long output interval that has length 3. The second agent then truncates this value (a cut is forced by the adjacent narrow rectangles).



Constant Gate [G_ζ]. Let $\zeta \in [-1,1] \cap \mathbb{Q}$ be a rational constant. The agent will have a block of unit height in the sign interval and a block of width $\zeta/2$ and height $2/\zeta$ centered in another interval.

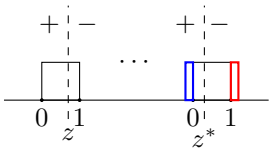
Before proceeding with the remaining gates, we construct a general function gate, an agent that implements any decreasing function.

Function Gate [G_h]. Let $-1 \leq a < b \leq 1$ and $-1 \leq c < d \leq 1$ be rational numbers and consider a continuously differentiable map $h\colon [a,b] \to [c,d]$ satisfying $h(a) = d$ and $h(c) = c$. Let $\overline{h}$ denote the extension of h that is constant on $[-1,a]$ and $[b,1]$. We now construct an agent with input interval I and output interval O computing this map, that is the agent should force a cut in the output interval such that $\overline{h}(v_p(I)) = v_p(O)$.

The agent that we construct has a block of height $2/(d-c)$ in the sub-interval $[(c+1)/2, (d+1)/2]$ of the output interval and density $f(z) := -2h'(2z-1)/(d-c)$ in the sub-interval $((a+1)/2, (b+1)/2)$ of the input interval. We note that f is positive in this interval as h is assumed to be a decreasing map, so it makes sense for the agent to have density f. One may verify that the agent values the input interval and output interval equally. We further add two narrow rectangles adjacent to the output interval. These will ensure that if the cut in the input interval is placed at $z \leq (a+1)/2$ such that $v_p(I) \leq a$, then the cut in the output interval must be placed at $z^* = (d+1)/2$, meaning that $v_p(O) = d$. Similarly, if $v_p(I) \geq b$ then $v_p(O) = c$.

Suppose cuts are placed in z in the input interval and in z^* in the output interval. As the agent must value the parts with positive and negative label equally, we get the equality

$$1 = \int_{(a+1)/2}^{z} \frac{-2h'(2t-1)}{d-c}\,dt + \left(z^* - \tfrac{c+1}{2}\right)\tfrac{2}{d-c}$$



From this we obtain that

$$d - c = -\int_a^{2z-1} h'(u)\,du + 2z^* - c - 1 = -h(2z-1) + d + 2z^* - c - 1$$

where we use that $h(a) = d$ by assumption. We conclude that $h(2z-1) = 2z^* - 1$, that is we obtain the equality $h(v_p(I)) = v_p(O)$.

Using this general function gate, we may now build up the remaining gates required by the circuit.

Multiplication By -1 Gate [$G_{-(\cdot)}$]. In order to realise this gate, we consider the function $h\colon [-1,1] \to [-1,1]$ given by $x \mapsto -x$. The agent's density function in the input interval is then given by $f(z) = 1$.

Subtraction Gate [G_-]. We may build this using the gates $G_{-(\cdot)}$ and G_+.

Multiplication by $\zeta \in [-1,1]$ [$G_{\cdot\zeta}$]. If $\zeta < 0$ we mahy construct $G_{\cdot\zeta}$ as a function gate using the function $h\colon [-1,1] \to [\zeta, -\zeta]$. If $\zeta > 0$ we construct using $-\zeta$ and a minus gate, i.e. $G_{\cdot\zeta} = -G_{\cdot(-\zeta)}$.

Maximum Gate [$G_{\max}$]. First we show how to construct a gate computing the absolute value of the input. We may construct gates G_1, G_2 such that $G_1(x) = -\max(x, 0)$ and $G_2(x) = \max(-x, 0)$ as function gates by using the functions $h_1\colon [0,1] \to [-1,0]$ given by $x \mapsto -x$ and $h_2\colon [-1,0] \to [0,1]$ given by $x \mapsto -x$. Now, we may constrcuct the absolute value gate as $G_{|\cdot|} = -G_1 + G_2$. We may now construct $G_{\max}$ by using the formula $\max(x,y) = (x + y + |x - y|)/2$.

Minimum Gate [$G_{\min}$]. We may build this using $\min(x,y) = x + y - \max(x,y)$.

Multiplication Gate [G_*]. We start off by constructing a gate squaring the input. First we construct G_1 and G_2 as function gates with respect to $h_1\colon [-1,0] \to [0,1]$ given by $x \mapsto x^2$ and $h_2\colon [0,1] \to [-1,0]$ given by $x \mapsto -x^2$. Then we may construct the squaring gate as $G_{(\cdot)^2} = G_1 - G_2$. Now we may use the previously constructed gates to make a multiplication gate via the identity $xy = ((x+y)^2 - x^2 - y^2)/2$.

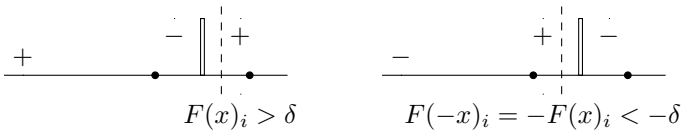
3.3 Describing valuation functions as circuits

In the description above, we described the valuations of the agents by providing formulas for their densities. However, an instance of CH actually consists of a list of algebraic circuits computing the distribution functions of the agents. In order to construct gates, it is sufficient for agents to have densities that are piece-wise polynomial. Therefore, consider an agent with polynomial densities f_i in the intervals $[a_i, b_i)$ for $i = 1, \ldots, s$, and let F_i denote the indefinite integral of f_i. We note that F_i is a polynomial so it may be computed by an algebraic circuit. Now we claim that the distribution function of this agent may be computed by an algebraic circuit via the formula $F(x) = \sum_{i=1}^{s} [F_i(\max(a_i, \min(x, b_i))) - F_i(a_i)]$.

This is the case, because the summands will be equal to $F_i(a_i) - F_i(a_i) = 0$ if $x < a_i$, to $F_i(x) - F_i(a)$ if $a_i \leq x \leq b_i$ and to $F_i(b) - F_i(a)$ if $x > b_i$, meaning that this formula does indeed calculate the valuation of the agent in the interval $[0, x]$.

3.4 Reduction and Correctness

Recall that we are given an instance (F, ε) of the BBU_a problem and that we have to construct an instance of the CH_a problem. The reduction now outputs an instance of the CH_a problem where the consensus halving instance is constructed as above with $p(n) = 2n + 1$ circuit simulators and the approximation parameter is given by $\varepsilon' = \varepsilon/(4n)$. Let z denote a solution to this CH_a instance. By definition, there exists an exact solution z^* to the consensus-halving problem such that $\|z - z^*\|_\infty \leq \varepsilon'$.



Let x and x^* denote the values encoded by respectively z and z^* in the Coordinate-Encoding region. Suppose, generally, we are given an interval I with a number of cut points $t_1, \ldots, t_s$. Moving a cut point by a distance $\leq \varepsilon'$ we create a new interval I'. This changes the label encoding by at most $2\varepsilon'$, that is $|v_l(I) - v_l(I')| \leq 2\varepsilon'$. Succesively, if we move all the cuts by a distance $\leq \varepsilon'$, then we get an interval I^* such that $|v_l(I) - v_l(I^*)| \leq 2s\varepsilon'$. As $\|z - z^*\|_\infty \leq \varepsilon'$ and any of the subintervals in the Coordinate-encoding region can contain at most n cuts, we conclude that $\|x - x^*\|_\infty \leq 2n\varepsilon' = 2n(\varepsilon/(4n)) = \varepsilon/2$. In order to show that x is ε-close to a zero of F, it now suffices by the triangle inequality to show that x^* is $(\varepsilon/2)$-close to a zero of F. This will follow from the two following lemmas.

▶ **Lemma 10.** *If there are no stray cuts in the exact solution z^*, then the associated value x^* encoded in the Coordinate-encoding region satisfies $F(x^*) = 0$.*

Proof. We recall that if the solution z^* contain no stray cuts, then the signs of all the circuit simulators are equal $s_1 = \cdots = s_{2n+1} = s$ where $s = \pm 1$. Furthermore, all the circuit simulators will output the same values $F_1(sx^*), \ldots, F_n(sx^*)$ into the feedback intervals. Thus, there can be no cancellation, so in order for the feedback agents to value the positive and negative part equally it must be the case that $F(sx^*) = 0$. ◀

▶ **Lemma 11.** *If there is a stray cut in the exact solution z^*, then the associated value x^* encoded in the Encoding-region satisfies the inequality $\left\|F(x^*)\right\|_\infty \leq \delta$.*

Proof. Suppose toward contradiction that $|F(x^*)_i| > \delta$ for some i. Without loss of generality we assume that $F(x^*)_i > \delta$. As there is a stray cut, the Coordinate-Encoding region can contain at most $n - 1$ cuts. Thus, at least one of the coordinates x_i^* must be ± 1 showing that $x^* \in S^{n-1}$. From this and the boundary condition we conclude that $F(x^*) = -F(-x^*)$. Furthermore, there is at most n stray cuts, so at most n circuit simulators can become corrupted. This means that $n + 1$ circuit simulators work correctly. Now suppose that the circuit simulator C_j is uncorrupted. If the label is $s_j = +1$, then C_j will output $F(x^*)$ into the feedback region and the labeling sequence will be $+/-$; if the label is $s_j = -1$ then C_j will output $F(-x^*) = -F(x^*)$ into the feedback region and the labeling sequence will be $-/+$. This is indicated below:

From this we conclude that the $n+1$ uncorrupted circuit simulators altogether contribute $(n+1)\delta$ to the part with negative label. However, the n corrupted circuit simulators can contribute at most $n\delta$ to the part with positive label. This implies that f_i cannot value the negative and positive part equally. This contradicts the assumption that z^* is an exact consensus-halving. We conclude that $\left\|F(x^*)\right\|_\infty \leq \delta$. ◀

By the two lemmas above, it follows that the value x^* encoded by the exact consensus-halving z^* satisfies the inequality $\left\|F(x^*)\right\|_\infty \leq \delta$. By choice of δ, this implies that there exists some x^{**} such that $\|x^* - x^{**}\|_\infty \leq \varepsilon/2$ and $F(x^{**}) = 0$. From the discussion before the two lemmas, it follows that x is ε-close to a zero of F and is thus a solution to the BBU_a instance (F, ε).

Mapping back a Solution. What remains is to show that we may recover a solution x to the BBU_a instance from the solution z to the CH_a instance. Recall that in a solution $z = (z_1, \ldots, z_N)$ to the consensus-halving problem $|z_i|$ and $\mathrm{sgn}(z_i)$ represents the length and label of the ith interval. For $i \leq n$ and $j \leq n+1$ we let $t_j = \sum_{k=1}^{j-1} |z_k|$ and define

$$x_{ij}^+ = \max(0, \min(t_{j-1} + z_j, i) - \max(t_{j-1}, i-1)) \quad \text{and}$$
$$x_{ij}^- = \max(0, \min(t_{j-1} - z_j, i) - \max(t_{j-1}, i-1))$$

These numbers may be computed efficiently by a circuit over the basis $\{+, -, \max, \min\}$. We notice that if $z_j > 0$ then $x_{ij}^- = 0$ (and if $z_j < 0$ then $x_{ij}^+ = 0$). Furthermore, by checking a couple of cases, one finds that if $z_j > 0$ (respectively $z_j < 0$) then x_{ij}^+ (respectively x_{ij}^-) is the length of the jth interval that is contained in $[i-1, i]$. As the coordinate-encoding region can contain at most n cuts (corresponding to at most $n+1$ intervals), we deduce from the above that the values encoded can be computed as $x_i = \sum_{j=1}^{n+1} x_{ij}^+ - x_{ij}^-$, for every $i \leq n$. If there is a stray cut then both x and $-x$ are valid solutions by the boundary condition of F. If there is no stray cut, then $s_1 = s_2 = \cdots = s_{p(n)} = s = \mathrm{sgn}(z_1)$ by Observation 9 and in this case we may recover a solution as sx.

How to Send a Real Number Using a Single Bit (And Some Shared Randomness)

Abstract

We consider the fundamental problem of communicating an estimate of a real number $x \in [0, 1]$ using a single bit. A sender that knows x chooses a value $X \in \{0, 1\}$ to transmit. In turn, a receiver estimates x based on the value of X. The goal is to minimize the cost, defined as the worst-case (over the choice of x) expected squared error.

We first overview common biased and unbiased estimation approaches and prove their optimality when no shared randomness is allowed. We then show how a small amount of shared randomness, which can be as low as a single bit, reduces the cost in both cases. Specifically, we derive lower bounds on the cost attainable by any algorithm with unrestricted use of shared randomness and propose optimal and near-optimal solutions that use a small number of shared random bits. Finally, we discuss open problems and future directions.

1 Introduction

We consider the fundamental problem of communicating an estimate of a real number $x \in [0, 1]$ using a single bit. A sender, that we call *Buffy*, knows x, and chooses a value $X \in \{0, 1\}$ to transmit. In turn, a receiver, that we call *Angel*, estimates x based on the value of X.

This problem naturally appears in distributed computations where multiple machines perform parallel tasks and transmit their results/state to an aggregator. If the bandwidth to the aggregator is limited, the machines must compress the data before sending it. Bandwidth optimization is fundamental in many domains, including network measurements [3, 11] and telemetry [5], load balancing [16, 22], and satellite communication [25]. We are especially motivated by recent work addressing the communication bottleneck in distributed and federated machine learning [13]. There, *clients* compute a local gradient and send it to a

parameter server that computes the global gradient and updates the model [15]. For the typical large-scale federated learning problems over edge devices (e.g., mobile phones), the devices may only be able to communicate a small number of bits per gradient coordinate. In fact, solutions such as 1-Bit SGD [20] and signSGD [6], have recently been studied as appealing low-communication solutions that use a single bit per coordinate. Another common communication-efficient solution is TernGrad [23] that quantizes each coordinate to $\{-1, 0, 1\}$ instead of $\{-1, 1\}$ as commonly done by the 1-bit algorithms.

It is often desirable that each estimate be an *unbiased* random variable with a mean equal to corresponding x. For example, this provides that the estimates' average is an unbiased estimate of the average value. Alternatively, there are cases where it is beneficial to allow *biased* estimates if it reduces the error for that setting (e.g., see EF-signSGD [14]).

In this work, we consider several variations of the above problem. For algorithms that provide unbiased estimates for every value x, we use the *worst-case* (over all values of x) variance as the cost function to be minimized. For biased estimates, we consider the worst-case *expected squared error* as the cost, as it coincides with variance for unbiased algorithms. That is, the worst-case is over the value of x, and the expectation of the cost is over the random choices used by the algorithm. Note that any lower bound for biased algorithms with these costs also applies to unbiased algorithms, and an upper bound for unbiased algorithms also applies to biased algorithms. We are interested in both lower and upper bounds in our work.

Beyond unbiased and biased variations, we also consider settings where Buffy and Angel have access to *shared randomness*. Shared randomness (often also referred to as public or common randomness) has been intensively studied in the field of communication complexity (e.g., see [17]). In our context, such shared randomness can arise naturally by having Buffy and Angel share a common seed for a pseudo-random number generator, for example. Here, we model the shared randomness as "perfectly random," leaving issues related to pseudo-randomness aside. Nevertheless, we consider solutions using limited amounts of shared randomness, including the case of just one bit of shared randomness. Such solutions may be easier and cheaper to implement, including with pseudo-random generators.

We remark that there are known approaches to this problem. These include (deterministic) rounding, randomized rounding (also called stochastic quantization), and subtractive dithering [18]. For a detailed survey of such techniques, we refer the reader to [9]. We discuss these methods and compare our results with them in context throughout the paper.

Our contribution. In this paper, we study how to minimize the cost (i.e., the worst-case variance or worst-case expected squared error) for various settings. First, we consider the setting where there is no shared randomness. In this setting, we show that randomized rounding is the optimal unbiased algorithm and that deterministic rounding is optimal when biased estimations are allowed. While these algorithms are widely used in practice, the optimality proofs under these cost models have not appeared elsewhere to the best of our knowledge.

Next, we explore how to reduce the cost if Buffy and Angel have access to shared randomness. We prove upper and lower bounds on the attainable variance for unbiased algorithms and expected squared error for biased ones. For our upper bounds, we assume that Buffy and Angel have access to ℓ shared random bits, for some $\ell \in \mathbb{N}$. We also consider the *limiting algorithms* where ℓ is not restricted. Our work addresses several extensions for cases where unbounded private randomness is allowed and when it is not. Finally, we consider the special case where x is known to be in $\{0, 1/2, 1\}$, a setting that is of high interest, for example, for the sign-based federated learning algorithms (e.g., [6, 14]) and particularly for TernGrad [23] that uses 3-level quantization. We provide an improved algorithm and a matching lower bound for this setting, thus proving its optimality. A summary of our results appears in Table 1.

Table 1 A summary of our results.

Scenario	Unbiased (Variance)	Biased (Exp. Squared Error)
No shared randomness	$1/4 = 0.25$ (randomized rounding) Optimal (Section 3.1)	$1/16 = 0.0625$ (deterministic rounding) Optimal (Section 3.2)
ℓ-bit shared randomness Unbounded private randomness	$\ell = 1 : \frac{1}{8} = 0.125$ $\ell = 8 : \frac{1}{12} + \frac{1}{393216} \approx 0.08334$ In general: $1/6 \cdot (1/2 + 4^{-\ell})$ (Section 5)	Open
ℓ-bit shared randomness No private randomness	Impossible (Section 6)	$\ell = 1 : \frac{1}{20} = 0.05$ $\ell = 8 : \approx 0.04599$ (Section 6.2.4)
Lower Bounds for $x \in [0, 1]$ Unbounded shared randomness	$1/16 = 0.0625$ (Section 4.2)	≈ 0.0459 (Section 4.1.2)
$x \in \{0, 1/2, 1\}$ 1-bit shared randomness No private randomness	$1/16 = 0.0625$ (Section 5)	$3/4 - 1/\sqrt{2} \approx 0.04289$ (Section 6.1)
Lower Bounds for $x \in \{0, 1/2, 1\}$ Unbounded shared randomness	$1/16 = 0.0625$ (Section 4.2)	$3/4 - 1/\sqrt{2} \approx 0.04289$ (Section 4)

2 Preliminaries

We start with some notation. We use $[n]$ to denote $\{0, 1, \ldots, n-1\}$, and $\Delta(S)$ to denote all possible probability distributions over the set S. (An element of $\Delta(S)$ will be expressed as a density function when S is uncountable, e.g., if $S = [0, 1]$.) We also use, for a binary predicate B, $\mathbb{1}_B$ as an indicator such that $\mathbb{1}_B = 1$ if B is true and 0 otherwise. Lastly, $\phi = (1 + \sqrt{5})/2$ denotes the Golden Ratio, which naturally comes up in some of our results.

Problem statement. Given a real number $x \in [0, 1]$, Buffy compresses it to a single bit value $X \in \{0, 1\}$ that is sent to Angel, who derives an estimate $\widehat{x}$. We also consider the special case where x is known to be in $\{0, 1/2, 1\}$. Our objective is to minimize the *cost* that is defined as the *worst-case expected squared error*, i.e., $\max_{x \in [0,1]} \mathbb{E}[(\widehat{x} - x)^2]$. Note that the worst-case is taken over the value of x and the expectation is over the randomness of the algorithm. In the *unbiased* setting, we additionally require $\mathbb{E}[\widehat{x}] = x$, in which case the cost becomes $\mathrm{Var}[\widehat{x}]$, i.e., the estimation variance. In some cases, we allow the parties to use ℓ bits of *shared randomness*. That is, we assume that they have access to a random value $h \in [2^\ell]$, known to both Buffy and Angel. When applicable, we use $r \in [0, 1]$ to denote the private randomness of Buffy.

3 Algorithms without Shared Randomness

We recap the performance of two standard algorithms – randomized and deterministic rounding. Interestingly, we show that when no shared randomness is allowed, randomized rounding is an optimal unbiased algorithm, and deterministic rounding is an optimal biased algorithm.

3.1 Randomized Rounding

In randomized rounding, Buffy uses private randomness to generate $X \sim \mathrm{Bernoulli}(x)$ which is sent using a single bit. In turn, Angel estimates $\widehat{x} = X$. Clearly, we have that $\mathbb{E}[\widehat{x}] = \mathbb{E}[X] = x$, and thus the algorithm is unbiased. The variance of the algorithm is $\mathrm{Var}[\widehat{x}] = \mathrm{Var}[X] = x(1 - x)$, and thus the worst-case is reached at $x = 1/2$, which gives a cost of $1/4$. The following theorem, whose proof is deferred to full version [4],

shows that randomized rounding is optimal, in the sense that no unbiased algorithm without shared randomness can have a worst-case variance lower than 1/4. Intuitively, requiring the estimate to be unbiased forces the algorithm to send 1 with a probability that is linear in x, maximizing its cost for $x = 1/2$. The proof also establishes the intuitive idea that it is not possible to benefit from randomness used solely by Angel.

▶ **Theorem 1.** *Any unbiased algorithm without shared randomness must have a worst-case variance of at least* 1/4.

3.2 Deterministic Rounding

With deterministic rounding, Buffy sends $X = 1$ when $x \geq 1/2$. Angel then estimates $\widehat{x} = X/2 + 1/4$. Deterministic rounding has an (absolute) error of at most 1/4, which is achieved for $x \in \{0, 1/2, 1\}$. Therefore, its cost is 1/16. The next theorem, whose proof appears in Supplement 9.1, shows that deterministic rounding is optimal, as no algorithm that does not use shared randomness can have a lower cost (even with unrestricted private randomness). We show that any such algorithm must have an expected squared error of at least 1/16 on at least one of $\{0, 1/2, 1\}$.

▶ **Theorem 2.** *Any algorithm without shared randomness must have a worst-case expected squared error of at least* 1/16.

4 Lower Bounds

We next explore lower bounds for algorithms with shared randomness. We use Yao's minimax principle [24] to prove a lower bound on the cost of any biased shared randomness protocol. Then, we show a stronger lower bound for unbiased algorithms using a different approach.

4.1 Lower Bound for Biased Algorithms

We place Yao's general formulation in the context of our specific problem.

▶ **Theorem 3** ([24])**.** *Consider our estimation problem over the inputs $x \in [0, 1]$, and let $\mathcal{A}$ be the set of all possible* deterministic *algorithms. For a (deterministic) algorithm $a \in \mathcal{A}$ and input $x \in [0, 1]$, let the function $c(a, x) = (a(x) - x)^2$ be its squared error.*
Then for any randomized *algorithm A and input distribution $q \in \Delta([0, 1])$ such that $X \sim q$:*

$$\max_{x\in[0,1]} \mathbb{E}\left[c(A, x)\right] \geq \min_{a\in\mathcal{A}} \mathbb{E}\left[c(a, X)\right] \ .$$

That is, the expected *squared error (over the choice of x from distribution q) of the* best *deterministic algorithm (for q) lower bounds the* expected *squared error of any randomized (potentially biased) algorithm A for the* worst-case *x (i.e., its cost). Further, the inequality holds as an equality for the optimal distribution q and algorithm A, i.e.,*

$$\min_{A} \max_{x\in[0,1]} \mathbb{E}\left[c(A, x)\right] = \max_{q} \min_{a\in\mathcal{A}} \mathbb{E}\left[c(a, X)\right] \ .$$

We proceed by selecting distributions q to lower bound $\min_{a\in\mathcal{A}} \mathbb{E}\left[c(a, X)\right]$. Notice that a deterministic algorithm can be defined using two values $v_0, v_1 \in [0, 1]$, such that if $|x-v_0| \leq |x-v_1|$ then Buffy sends 0 and Angel estimates x as v_0. Similarly, if $|x-v_0| > |x-v_1|$ then Buffy sends 1 and Angel estimates x as v_1.[1] In general, the above framework asserts that the cost, for the worst-case input, of any randomized algorithm is

[1] Other deterministic algorithms, e.g., that send 0 despite having $|x - v_0| > |x - v_1|$, can trivially be improved by an algorithm with the above form.

$$\max_{q\in\Delta([0,1])}\min_{v_0,v_1\in[0,1]}\int_0^1 \min\left\{(x-v_0)^2,(x-v_1)^2\right\}q(x)dx\ . \tag{1}$$

Our framework lower bounds the cost for any (biased or unbiased) algorithm that may use any amount of (shared or private) randomness. We now consider distributions q to lower bound the cost and later discuss the limitations of this approach.

4.1.1 The $\{0, 1/2, 1\}$ case

First, consider a discrete probability distribution q over $\{0, 1/2, 1\}$, and assume without loss of generality that $q(0) \le q(1)$. Any deterministic algorithm cannot estimate all values exactly, and it must map at least two of the points to a single value, thus allowing us to lower bound its cost. In Supplement 9.2, we prove the following.

▶ **Lemma 4.** *Any deterministic algorithm must incur a cost of at least* $\frac{q(0)\cdot q(1/2)}{4(q(0)+q(1/2))}$.

For $q(0) = q(1) = (2-\sqrt{2})/2$ and $q(1/2) = \sqrt{2}-1$, this lemma yields a lower bound of $3/4 - 1/\sqrt{2} \approx 0.04289$. In Section 6.1, we show that this is *an optimal* lower bound when x is known to be in $\{0, 1/2, 1\}$, by giving an algorithm with a matching cost.

4.1.2 The $[0, 1]$ case

In the general case, where x can take on any value in $[0, 1]$, we can get a tighter bound by looking at mixed distributions. Specifically, for parameters $a, w \in [0, 1/2]$, we consider the distribution where:

$$q(x) = \begin{cases} 0 & \text{with probability } w \\ 1 & \text{with probability } w \\ \text{uniform on } [a, 1-a] & \text{otherwise} \end{cases}\ .$$

Directly analyzing the optimal deterministic algorithm for this distribution proves complex. Instead, we first *hypothesize* that there exists an optimal deterministic algorithm for which either (1) $v_1 = 1 - v_0$ or (2) $v_1 = 1$. We emphasize that the lower bound holds even if the hypothesis is false. We then analyze what values of a, w maximize the cost of the best deterministic algorithm with the above form. Finally, we verify that the lower bound for the resulting distribution (with the specific a, w values) holds *for all deterministic algorithms.*

For case (1), we can express the cost as $2\cdot\left(wv_0^2 + \frac{1/2-w}{1/2-a}\int_a^{1/2}(x-v_0)^2dx\right)$. Similarly, for case (2), we get a cost of $wv_0^2 + \frac{1-2w}{1-2a}\cdot\left(\int_a^{\min\{1-a,(v_0+1)/2\}}(x-v_0)^2dx + \int_{(v_0+1)/2}^{1-a}(x-1)^2dx\right)$. Therefore, the cost of the optimal algorithm from the above family is given as:

$$\min\left\{2\cdot\left(wv_0^2 + \frac{1/2-w}{1/2-a}\int_a^{1/2}(x-v_0)^2dx\right),\right.$$
$$\left. wv_0^2 + \frac{1-2w}{1-2a}\cdot\left(\int_a^{\min\{1-a,(v_0+1)/2\}}(x-v_0)^2dx + \int_{(v_0+1)/2}^{1-a}(x-1)^2dx\right)\right\}\ .$$

This cost is maximized for $a = \frac{-2w^2+w-2\sqrt{w(1-w)}+1}{4w^2-6w+2}$, where the value of w satisfies

$$32w^3 - 56w^2 + \sqrt{w(1-w)}\cdot(8w^4 - 24w^3 + 38w^2 - 8w - 7) + 24w = 0.$$

The resulting bound is slightly larger than 0.0459. Next, we verify that for these a, w values, no deterministic algorithm can achieve a lower cost. Specifically, instead of using $q(x)$ as described above, we generate a finite discrete distribution. For a parameter $n \in \mathbb{N}$, we define:

$$q_n(x) = \begin{cases} \frac{\lfloor n \cdot w \rfloor}{n} & \text{if } x \in \{0,1\} \\ \frac{1}{n} & \text{if } x \in \left\{ a + \frac{1-2a}{2(n-2\lfloor n \cdot w \rfloor))} + i \cdot \frac{1-2a}{n-2\lfloor n \cdot w \rfloor} \mid i \in [n - 2\lfloor n \cdot w \rfloor] \right\} \\ 0 & \text{otherwise} \end{cases} .$$

Note that $\lim_{n\to\infty} q_n(x) = q(x)$. We then find the optimal deterministic solution for this distribution by using a deterministic k-means clustering algorithm (for $k = 2$), that is guaranteed to converge, e.g., using [10]. The code that we used to obtain this result is available at [2]. The optimal deterministic algorithm for $q_n(x)$ tends to have either $v_1 = 1 - v_0$ or $v_1 = 1$ as hypothesized. Finally, for $n = 10^6$ we get a cost higher than 0.0459 which we use as a lower bound.

We do not believe that this bound is tight. Nonetheless, as we show in Section 6.2.4, our bound is within 0.2% of the optimum.

4.2 Lower Bound for Unbiased Algorithms - Beyond MiniMax

We now consider lower bounds for unbiased algorithms. Utilizing Yao's lemma does not appear to provide means to obtain sharper bounds when requiring the algorithm to be unbiased. We consider the case where $x \in \{0, 1/2, 1\}$ and directly prove that any unbiased algorithm must have a worst-case variance of at least $1/16$. This lower bound then also holds for $x \in [0, 1]$, although an improved bound of $\pi^2/64 - 1/12 \approx 0.07$ for this case, based on an average-case analysis, is presented in [7].

Assume that we have $h \in [0, 1]$. Buffy sends $X(x, h)$ to Angel, which determines an estimate $\widehat{x}(X(x, h), h)$. For $x', x'' \in \{0, 1/2, 1\}$, let $p_{x',x''} = \Pr[X(x', h) = X(x'', h)]$ denote the probability (with respect to h) that the same bit is sent for x', x''. Since we send a single bit, we have that $p_{0,1/2} + p_{1/2,1} + p_{0,1} \geq 1$. For all $x', x'' \in \{0, 1/2, 1\}$, we define $H_{x',x''} = \{h \in [0, 1] : X(x', h) = X(x'', h)\}$ to be the set of shared-randomness values that would lead Buffy to send the same bit for both x' and x''. Next, denote by $G_{x',x''} = \mathbb{E}[\widehat{x} | h \in H_{x',x''}, x \in \{x', x''\}]$ the expected estimate value, conditioned on the shared randomness being in $H_{x',x''}$. We have that:

$$\begin{aligned} \mathrm{Var}[\widehat{x}|x = 0] &\geq p_{0,1/2} \cdot (G_{0,1/2} - 0)^2 + p_{0,1} \cdot (G_{0,1} - 0)^2 + p_{1/2,1} \cdot (\mathbb{E}[\widehat{x}|h \in H_{1/2,1}, x = 0] - 0)^2 \\ \mathrm{Var}[\widehat{x}|x = 1/2] &\geq p_{0,1/2} \cdot (G_{0,1/2} - 1/2)^2 + p_{0,1} \cdot (\mathbb{E}[\widehat{x}|h \in H_{0,1}, x = 1/2] - 1/2)^2 \\ &\qquad + p_{1/2,1} \cdot (G_{1/2,1} - 1/2)^2 \\ \mathrm{Var}[\widehat{x}|x = 1] &\geq p_{0,1/2} \cdot (\mathbb{E}[\widehat{x}|h \in H_{0,1/2}, x = 1] - 1)^2 + p_{0,1} \cdot (G_{0,1} - 1)^2 + p_{1/2,1} \cdot (G_{1/2,1} - 1)^2. \end{aligned}$$

To proceed, we require the algorithm to be unbiased:

$$\begin{aligned} &G_{0,1/2}p_{0,1/2} + G_{0,1}p_{0,1} + \mathbb{E}[\widehat{x}|h \in H_{1/2,1}, x = 0]p_{1/2,1} = 0 \\ &G_{0,1/2}p_{0,1/2} + \mathbb{E}[\widehat{x}|h \in H_{0,1}, x = 1/2]p_{0,1} + G_{1/2,1}p_{1/2,1} = 1/2 \\ &\mathbb{E}[\widehat{x}|h \in H_{0,1/2}, x = 1]p_{0,1/2} + G_{0,1}p_{0,1} + G_{1/2,1}p_{1/2,1} = 1. \end{aligned}$$

This allows us to express the expectations $\{E[\widehat{x}|h \in H_{x',x''}, x = x'''] | x', x'', x''' \in \{0, 1/2, 1\}\}$ using $p_{x',x''}, G_{x',x''}$ and obtain a set of three inequalities with six variables. Our full analysis, given in the full version [4], proceeds with a case analysis based on the value of $p_{0,1}$, the probability that the sender would send the same bit for $0, 1$. We show that there exists an optimal algorithm in which $p_{0,1/2} + p_{1/2,1} + p_{0,1} = 1$, $p_{0,1/2} = p_{1/2,1}$, and $G_{1/2,1} = 1 - G_{0,1/2}$. This reduces the number of variables to three, allowing us to optimize the expression and show a lower bound of $1/16$ on any unbiased algorithm.

5 Algorithms with Unbounded Private Randomness

Here, we consider the case where the shared randomness is limited to ℓ bits, i.e., $h \in [2^\ell]$, but Buffy may use unbounded private randomness $r \sim U[0,1]$ (that is independent of h).

We present the following algorithm: Buffy sends X to Angel, where

$$X \triangleq \begin{cases} 1 & \text{if } x \geq (r+h)2^{-\ell} \\ 0 & \text{otherwise} \end{cases}.$$

Angel then estimates $\widehat{x} = X + (h - 0.5(2^\ell - 1)) \cdot 2^{-\ell}$.

We first show that our protocol is unbiased. It holds that $\mathbb{E}[h] = 0.5(2^\ell - 1)$ and $(r+h) \sim U[0, 2^\ell]$ (i.e., $(r+h)2^{-\ell} \sim U[0,1]$), and thus $\mathbb{E}[\widehat{x}] = \mathbb{E}[X] = x$.
We state theorem, whose proof appears in the full version [4], that bounds the variance:

▶ **Theorem 5.** *$Var[\widehat{x}] \leq 1/12 \cdot (1 - 4^{-\ell}) + 1/4 \cdot 4^{-\ell} = 1/6 \cdot (1/2 + 4^{-\ell})$.*

In Supplement 9.3, we describe a simple generalization of this algorithm, together with a lower bound, for sending $k > 1$ bits. We now explain the connection to subtractive dithering and explore the applicability of the algorithm for the $x \in \{0, 1/2, 1\}$ special case.

Connection to subtractive dithering. First invented for improving the visibility of quantized pictures [18], subtractive dithering aims to alleviate potential distortions that originate from quantization. Subtractive dithering was later extended for other domains such as speech [8], distributed deep learning [1], and federated learning [21].

In our setting, subtractive dithering corresponds to using shared randomness to add *noise* ς to x before applying a deterministic quantization and subtracting ς from the estimation. Specifically, let $\mathcal{Q} : [0,1] \to \{0,1\}$ be a two-level deterministic quantizer such that $\mathcal{Q}(g) = 1$ if $g \geq 1/2$ and 0 otherwise. Then, in subtractive dithering Buffy sends $X = \mathcal{Q}(x + \varsigma)$ and Angel estimates $\widehat{x} = X - \varsigma$.

There are several noise classes that ς can be drawn from, as classified in [19], that yield $\widehat{x} \sim U[x - 1/2, x + 1/2]$. For example, ς can be distributed uniformly on $[-1/2, 1/2]$.

Consider our algorithm of this section without restricting the number of random bits (i.e., $\ell \to \infty$, and rescale so $h \in U[0,1]$). This would yield the following algorithm:

$$X \triangleq \begin{cases} 1 & \text{if } x \geq h \\ 0 & \text{otherwise} \end{cases}$$

and $\widehat{x} = X + h - 0.5$. Similarly to subtractive dithering, we get that $\widehat{x} \sim U[x - 1/2, x + 1/2]$, as we prove in the full version [4] for completeness. To see that the two algorithms are equivalent (for $\varsigma \sim U[-1/2, 1/2]$), denote $h' = 1/2 - h$ (i.e., $h' \sim U[-1/2, 1/2]$). Then $X = 1$ if $x + h' \geq 1/2$ and $\widehat{x} = X - h'$.

Therefore, we conclude that our algorithm provides a spectrum between randomized rounding ($\ell = 0$) and a form of subtractive dithering ($\ell \to \infty$). In practice, this means that a small number of shared random bits yields a variance that is close to that of subtractive dithering ($\text{Var}[\widehat{x}] = 1/12$). For example, with a single shared random byte (i.e., $\ell = 8$), our algorithm has a worst-case variance that is within 0.02% of 1/12.

The $x \in \{0, 1/2, 1\}$ case. Notice that if x is known to be in $\{0, 1/2, 1\}$, then our ($\ell = 1$) algorithm gives $\text{Var}[\widehat{x}] = 1/16$, as evident from Theorem 5. Further, in this case, we do not require the private randomness as we can rewrite Buffy's algorithm as:

$$X \triangleq \begin{cases} 0 & \text{if } x = 0 \\ 1-h & \text{if } x = 1/2 \\ 1 & \text{if } x = 1 \end{cases}$$

while Angel estimates $\widehat{x} = X + (h - 0.5)/2$. This algorithm considerably improves over randomized rounding (which is optimal when no shared randomness is allowed, as shown in the full version [4]), that has a variance of $1/4$ for $x = 1/2$; i.e., a single shared random bit reduces the worst-case variance by a factor of 4. Further, it also improves over subtractive dithering, reducing the variance by a $4/3$ factor. Finally, this result is optimal according to the Section 4.2 lower bound, even if unbounded shared randomness is allowed.

6 Algorithms without Private Randomness

In some cases, generating random bits may be expensive, e.g., when running on power-constrained devices. This is particularly acute when the device operates in an energy harvesting mode [26]. Past works have even considered how to "recycle" random bits (e.g., [12]). Therefore, it is important to study how to design algorithms that use just a few random bits. To address this need, we consider scenarios where Buffy and Angel have access to a shared ℓ-bit random value h, but no private randomness.

One thing to notice is that Angel can produce at most $2^{\ell+1}$ different values since Angel is deterministic after obtaining the $\ell + 1$ bits of h and X. In particular, this means there is no unbiased protocol for general $x \in [0, 1]$. Therefore, we focus on biased algorithms and study how shared randomness allows improving over deterministic rounding (which is optimal without shared randomness, as we show in Section 3.2).

We start by proposing an optimal algorithm for the case where x is known to be in $\{0, 1/2, 1\}$. Then, we present adaptations of the subtractive dithering estimation method for the biased $x \in [0, 1]$ setting. These improve over both (unbiased) subtractive dithering and deterministic rounding. To the best of our knowledge, these adaptations are novel. Next, we show how Buffy can further reduce the cost while, among other changes, using a small number of shared random bits. We conclude by giving design principles for numerically approximating the optimal algorithm and give realizations for small number of shared random bits.

6.1 The $x \in \{0, 1/2, 1\}$ Case

We now consider the scenario where x is guaranteed to be in $\{0, 1/2, 1\}$ using a single shared randomness bit $h \in \{0, 1\}$. For some $\alpha \in [0, 1]$, Buffy sends

$$X = \begin{cases} 1 & \text{if } x = 1 \vee (x = 1/2 \wedge h = 0) \\ 0 & \text{otherwise} \end{cases}$$

while Angel estimates $\widehat{x} = \alpha \cdot h + (1 - \alpha) \cdot X$.

For example, this means that if $x = 0$, the squared error is 0 if $h = 0$ and α^2 otherwise. That is, the expected squared error is $\alpha^2/2$. We optimize over the α value to minimize the cost

$$\min_{\alpha \in [0,1]} \max \left\{ \alpha^2/2, (1 - (1 - \alpha))^2/2, \mathbb{E}\left[(1/2 - (\alpha \cdot h + (1 - \alpha) \cdot (1 - h)))^2 \right] \right\}.$$

This is optimized for $\alpha = 1 - 1/\sqrt{2}$, yielding a cost of $3/4 - 1/\sqrt{2} \approx 0.04289$, which is *optimal* according to our Section 4 lower bound, even if unbounded shared randomness is allowed.

6.2 The $x \in [0,1]$ Case

An important observation regarding optimal biased algorithms is that they, without loss of generality, can be expressed as a pair of monotone increasing functions $T, Z_0 : [0,1] \to [0,1]$ as follows. Here T is a threshold function that determines whether 0 or 1 is sent, Z_0 is the estimator when 0 is received, and $Z_1 : [0,1] \to [0,1]$, given by $Z_1(h) = 1 - Z_0(1-h)$, is the estimator when 1 is received. That is, Buffy sends

$$X = \begin{cases} 1 & \text{if } x \geq T(h) \\ 0 & \text{otherwise} \end{cases}.$$

In turn, Angel estimates $\widehat{x} = Z_X(h)$. We further explain this representation in Supplement 9.4. Based on this observation, we next lay out a sequence of algorithmic improvements over deterministic rounding that leverage the shared randomness to reduce the cost. We visualize the algorithms resulting from each improvement in Figure 1.

6.2.1 Subtractive dithering adaptations

As subtractive dithering provides the lowest cost (albeit using unbounded shared randomness) of the previously mentioned unbiased algorithms, one may wonder if it is possible to adapt it to the biased scenario. Accordingly, we first briefly overview two natural adjustments that use unbounded shared randomness and improve over the $1/16$ cost of deterministic rounding. We then propose improved protocols that reduce the cost further despite using only a small number (e.g., $\ell = 3$) of random bits.

Intuitively, subtractive dithering may produce estimates that are outside the $[0,1]$ range. Therefore, by *truncating* the estimates to $[0,1]$ one may only reduce the expected squared error for any $x \neq 1/2$. However, it does not reduce the expected squared error for $x = 1/2$, and thus the cost would remain $1/12$.

To reduce the cost, one may further truncate the estimates to $[z, 1-z]$ for some $z \in [0, 1/2]$. Indeed, we show in the full version [4] that this truncation reduces the cost to ≈ 0.0602, for z satisfying $1/24 + z^2/2 + (2z^3)/3 = 0$ ($z \approx 0.17349$).

A better adaptation strategy is obtained by changing the estimation to a linear combination of X and h. Specifically, consider the protocol where Buffy sends (for a shared $h \sim U[0,1]$)

$$X = \begin{cases} 1 & \text{if } x \geq h \\ 0 & \text{otherwise} \end{cases}$$

and Angel estimates, for some $\alpha \in [0,1]$, $\alpha \cdot h + (1-\alpha) \cdot X$. Optimizing the parameters, we show in the full version [4] that this algorithm achieves a cost of $5/3 - \phi \approx 0.04863$, which is obtained for $\alpha = 2 - \phi \approx 0.382$. Interestingly, this cost is achieved for *all* $x \in [0,1]$.

In Figure 1, we illustrate this algorithm. As shown, the subtractive dithering adaption has $T(h) = h$ and $Z_0(h) = \alpha \cdot h$. This means that Buffy sends $X = 1$ if $x \geq h$ and Angel estimates $\widehat{x} = \alpha \cdot h$ if $X = 0$ and $\widehat{x} = (1 - \alpha \cdot (1-h)) = (1-\alpha) + \alpha \cdot h$ otherwise.

6.2.2 Deterministically rounding extreme values

We now show how to leverage a finite number of shared random bits ℓ to design improved algorithms. As we show, it is possible to benefit from *deterministically* rounding values that are "close" to 0 or 1 and use the shared randomness otherwise.

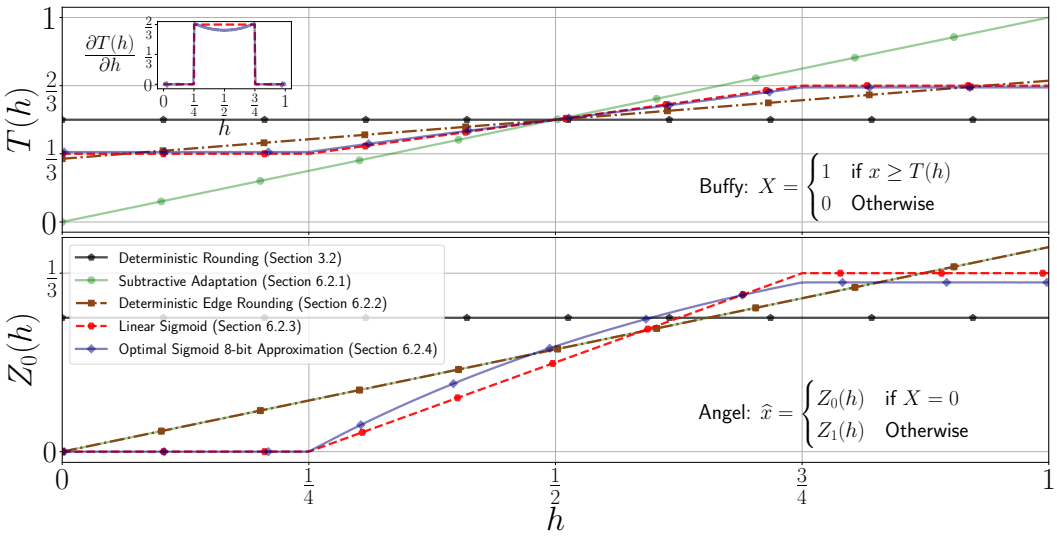

Figure 1 Illustration of the different biased algorithms. While deterministic rounding does not use the shared randomness and is thus constant, the other algorithms have both the threshold and estimation be monotone functions of h.

Similarly to the subtractive dithering adaptation above, Angel estimates x using a linear combination of h (with weight α) and X (with a weight of $1-\alpha$), where $\alpha \in [0,1]$ is chosen later. For all $i \in [2^\ell - 1]$, define the interval

$$\mathcal{I}_i = \left[(1-\alpha)/2 + i \cdot \frac{\alpha}{2^\ell - 1},\ (1-\alpha)/2 + (i+1) \cdot \frac{\alpha}{2^\ell - 1} \right). \tag{2}$$

In our algorithm, Buffy sends

$$X = \begin{cases} 0 & \text{if } x < (1-\alpha)/2 \\ \mathbb{1}_{h \leq i} & \text{if } x \in \mathcal{I}_i,\ i \in [2^\ell - 1] \\ 1 & \text{if } x \geq (1+\alpha)/2 \end{cases},$$

and Angel estimates: $\widehat{x} = \alpha \cdot h/(2^\ell - 1) + (1-\alpha) \cdot X$.

Note that we deterministically partition the range $[(1-\alpha)/2, (1+\alpha)/2]$ into $2^\ell - 1$ equally spaced intervals. Intuitively, the chosen intervals are designed to make the expected squared error a continuous function of x, as our analysis, given in the full version [4], indicates.

As we show, minimizing $cost = \min_\alpha \max_x \mathbb{E}[(\widehat{x} - x)^2]$ yields cumbersome expressions. For example, we get that with one shared random bit ($\ell = 1$), our algorithm has a cost of $1/18 \approx 0.05556$ (obtained for $\alpha = 1/3$, different than the α value used for the $x \in \{0, 1/2, 1\}$ case), lower than that of deterministic rounding (i.e., $1/16$). For $\ell = 2$, we obtain a cost of $\frac{259-140\sqrt{3}}{338} \approx 0.04885$ (reached for $\alpha = \frac{15-6\sqrt{3}}{13}$), and $\ell = 3$ bits further reduces the cost to $35/722 \approx 0.04848$ (when $\alpha = 7/19$). Additionally, with $\ell = 3$ bits, this improves over the subtractive dithering adaptions (that use unbounded shared randomness) for all $x \in [0,1]$. Notice that these costs are ≈21%, ≈6.4%, and ≈5.6% from the ≈ 0.0459 lower bound (see Section 4.1.2), and thus from the optimal algorithm. For completeness, we give the limiting algorithm (as $\ell \to \infty$) in the full version [4]. For intuition, we illustrate the limiting algorithm ($h \in [0,1]$) in Figure 1. As shown, we have $T(h) = \frac{1-\alpha}{2} + \alpha \cdot h$ (where $\alpha = 2 - \phi \approx 0.38$) and $Z_0(h) = \alpha \cdot h$. Observe that Angel uses the same estimation function as in Section 6.2.1,

but Buffy's threshold function is different. Intuitively, the new threshold function ensures that each x is mapped to the closest estimate value. For example, if $x = 0.1$ and $h = 0$, the subtractive adaptation would have $X = 1$ and thus $\widehat{x} = 1 - \alpha \approx 0.62$ while here we get $X = 0$ and $\widehat{x} = 0$.

Interestingly, the cost slightly and monotonically *increases* when increasing the number of bits ℓ beyond 3. This phenomenon suggests that we need more complex algorithms to leverage additional available random bits. We explore several approaches; in the full version [4], we show that by probabilistically selecting between the above algorithm (for $\ell \to \infty$) and the $\{0, 1/2, 1\}$ algorithm from Section 6.1, we can reduce the error to $\frac{6\sqrt{10}+11\sqrt{5}-18\sqrt{2}-17}{24} \approx 0.04644$. Intuitively, Buffy and Angel can implicitly agree on the chosen algorithm using the shared randomness. Here, we proceed by analyzing the potential benefits of non-uniform partitioning of the h values, which reduces the error further.

6.2.3 Non-uniform partitioning

Intuitively, the above algorithms have a threshold function that is linear in h; i.e., it takes the form $T(h) = a \cdot h + b$. We now show that this can be improved by looking at *sigmoid*-like functions. For ease of exposition, in this section, we consider $h \in [0, 1]$ to represent unbounded shared randomness, although the algorithm can be discretized given sufficient random bits. Recall from Section 6.2 that an algorithm can be expressed as a pair of functions $T, Z_0 : [0, 1] \to [0, 1]$ such that Buffy sends 1 if $x \geq T(h)$ while Angel estimates $Z_0(h)$ when receiving $X = 0$ and $Z_1(h) = 1 - Z_0(1 - h)$ otherwise. Here, we consider a *linear sigmoid* function (also illustrated in Figure 1), which, for some $h_0 \in [0, 1/2]$, is defined as

$$T(h) = \begin{cases} \alpha & \text{if } h < h_0 \\ \alpha + \frac{(1-2\alpha)(h-h_0)}{1-2h_0} & \text{if } h \in [h_0, 1-h_0] \\ 1 - \alpha & \text{otherwise} \end{cases}, \quad Z_0(h) = \begin{cases} 0 & \text{if } h < h_0 \\ \frac{(1-2\alpha)(h-h_0)}{1-2h_0} & \text{if } h \in [h_0, 1-h_0] \\ 1 - 2\alpha & \text{otherwise} \end{cases}.$$

Notice that in this algorithm we have $Z_0(h) = T(h) - \alpha$.

Our analysis, given in Supplement 9.5, shows that the cost is minimized for $h_0 = 1/4, \alpha = 1/3$, where the error is:

$$\mathbb{E}[(\widehat{x} - x)^2] = \mathbb{E}[(\widehat{x})^2] - 2x\mathbb{E}[\widehat{x}] + x^2 = \begin{cases} 5/108 - x/3 + x^2 & \text{if } x < 1/3 \\ 5/108 & \text{if } x \in [1/3, 2/3] \\ 77/108 - 5x/3 + x^2 & \text{otherwise} \end{cases}.$$

Therefore, the cost is $5/108 \approx 0.0463$, which is less than 0.9% higher than the 0.0459 lower bound (Section 4.1.2). The algorithm has two interesting properties. First, its expected squared error is constant for all $x \in \{0, 1\} \cup [1/3, 2/3]$ and, second, its expectation is not continuous as a function of x, as shown in Figure 2.

6.2.4 Towards the optimal algorithm

We now consider more general algorithms that have arbitrary estimate function Z_0. To that end, we use a numerical solver that approximates the optimal solution. Clearly, to define the input problem, we need to limit the number of variables and constraints. We achieve this using several observations:

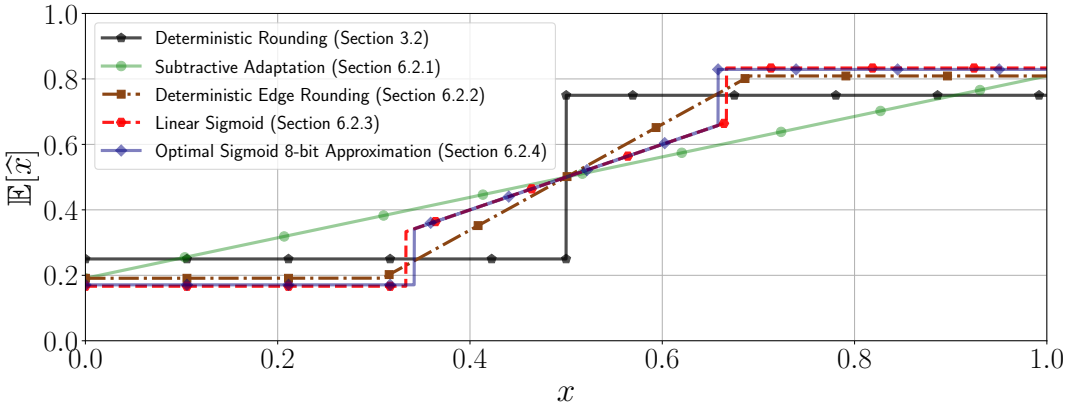

Figure 2 Illustration of the expectation of the different biased algorithms. Deterministic rounding does not use randomization and is therefore a step function, while others increase gradually in x. Notice that the expectations of the linear sigmoid and optimal approximation are not continuous.

- We consider bounded shared randomness $h \in [2^\ell]$ for $\ell \in \mathbb{N}$ bits. In fact, bounded shared randomness is precisely what allows us to develop this numerical approach.
- We use the observation that an optimal algorithm's T and Z_0 functions are not independent and satisfy $\forall h \in [0,1] : T(h) = \frac{Z_0(h)+Z_1(h)}{2} = \frac{Z_0(h)+(1-Z_0(1-h))}{2}$; this is because, that way, every $x \in [0,1]$ is estimated using the value closer to it between $Z_0(h)$ and $Z_1(h) = 1 - Z_0(1-h)$. In fact, the algorithms in sections 6.2.2-6.2.3 follow this rule, while the subtractive adaptation (Section 6.2.1) does not. As a result, we can define the variables $\{z_h | h \in [2^\ell]\}$ and derive the thresholds from the solver's output by $Z_0(h) = z_h$.
- For computing the maximal error for any $x \in [0,1]$, it is enough to look at a discrete set of points. This is because the number of possible estimates is $2^{\ell+1}$. Therefore, given two estimates $z_h, 1 - z_{2^\ell-1-h}$ that correspond to the values Angel uses given h and $X = 0$ or $X = 1$, the worst expected squared error (for this h) is obtained for $y_h \triangleq \frac{z_h+1-z_{2^\ell-1-h}}{2}$. Therefore, by checking all $x \in \{y_h \mid h \in [2^\ell]\}$, we can compute the cost.

Using these observations, we formulate the input as:

$$\begin{aligned} \underset{\{z_h|h\in[2^\ell]\}}{\text{minimize}} \quad & C \\ \text{subject to} \quad & C \geq \sum_{j=0}^{h} \left(y_h - (1 - z_{2^\ell-1-h})\right)^2 + \sum_{j=h+1}^{2^\ell-1} \left(y_h - z_h\right)^2, \quad h = 0, \ldots, 2^\ell - 1 \\ & y_h = \frac{z_h+1-z_{2^\ell-1-h}}{2}, \qquad z_h \in [0,1] \qquad\qquad h = 0, \ldots, 2^\ell - 1 \end{aligned}$$

In the above, we express the expected squared error at y_h by considering the h values for which $x \geq T(h)$ ($j \in [h]$) and those that $x < T(h)$. The output for the above problem does not seem to follow a compact representation. However, it is still possible to implement using a simple lookup table. For example, if $\ell = 8$, we can store all z_h when implementing Buffy and Angel. This algorithm's cost is lower than that of the linear sigmoid (that uses unbounded randomness) when using $\ell \geq 4$ bits. Specifically, using 4 shared random bits, the cost is ≈ 0.04611, while using 8 bits, it further reduces to ≈ 0.04599. Notice that these are less than 0.5% and 0.2% higher than the lower bound of Section 4.1.2. We note that this approach yields improvement even for a small number of shared random bits; for example, using $\ell = 1$ bit ($h \in \{0,1\}$), we get a cost of $1/20$ for $z_0 = 0.1, z_1 = 0.3$ which is equivalent to the following algorithm:

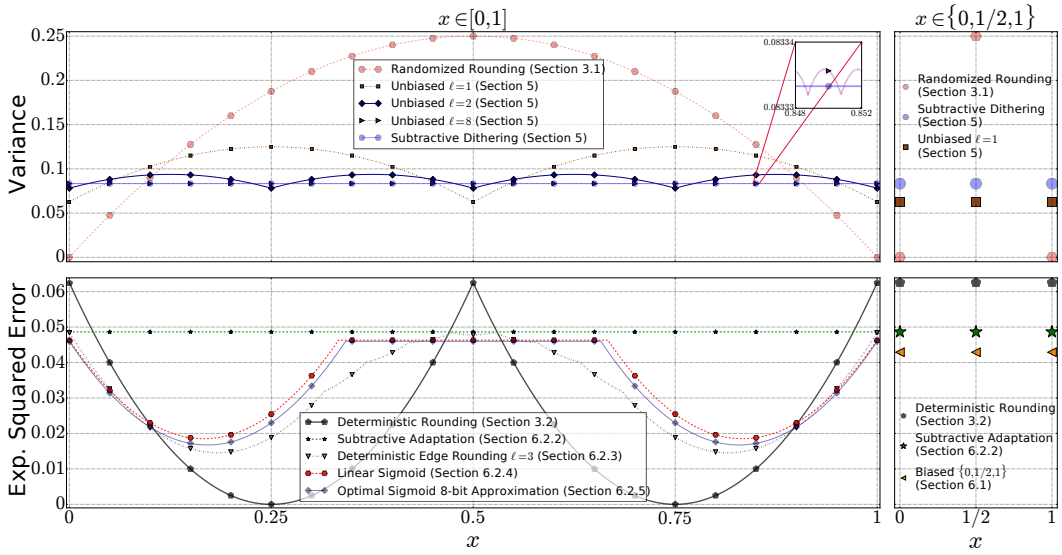

Figure 3 An illustration of the variance and expected squared error of the different algorithms. As shown, our unbiased algorithm is competitive with subtractive dithering despite using a single shared random byte, while our single-bit algorithm improves over subtractive on $\{0, 1/2, 1\}$. For the biased case, in addition to improving the $\{0, 1/2, 1\}$ case, our optimal sigmoid approximation algorithm achieves the lowest cost (less than 0.2% of the optimum!) while using a single shared random byte.

$$X = \begin{cases} 1 & \text{if } x \geq 0.4 + 0.2h \\ 0 & \text{otherwise} \end{cases}, \qquad \widehat{x} = 0.1 + 0.2h + 0.6X \ .$$

We visualize the resulting algorithm, for $\ell = 8$, in Figures 1 and 2. Notice that while the algorithm looks almost similar to our linear sigmoid, looking that the derivative $\frac{\partial T(h)}{\partial h}$ (Figure 1) shows that this optimal solution is not piece-wise linear.

7 Visual Comparison of the Algorithm Costs

We illustrate the various algorithms in Figure 3. In the unbiased case, notice how a single ($\ell = 1$) shared random bit significantly improves over randomized rounding (which is optimal when Buffy and Angel are restricted to private randomness). This further improves for larger ℓ values, where for $\ell = 8$ we have a cost that is only 0.02% higher than that of subtractive dithering, which uses unbounded shared randomness (the difference shown in zoom). When x is known to be in $\{0, 1/2, 1\}$ (right-hand side of the figure), it is evident how our unbiased $\ell = 1$ algorithm improves over both randomized rounding and subtractive dithering.

In the biased case, our adaptation to the subtractive dithering estimation (termed Subtractive Adaptation) improves over the cost of deterministic rounding. This is further improved by the algorithm of Section 6.2.2, termed Deterministic Edge Rounding, which is depicted using $\ell = 3$ bits as it minimizes its cost. Next, the Linear sigmoid (Section 6.2.3) shows how to lower the cost (using unbounded shared randomness) by non-uniform partitioning of the h values. Additionally, we show the optimal 8-bit algorithm (Section 6.2.4) that gets within 0.2% from the lower bound while using a single shared random byte. Finally, if x is known to be in $\{0, 1/2, 1\}$, our (optimal) biased $\{0, 1/2, 1\}$ algorithm improves over all other solutions while using only a single shared random bit.

8 Discussion

In this paper, we studied upper and lower bounds for the problem of sending a real number using a single bit. The goal is to minimize the cost, which is the worst-case variance for unbiased algorithms, or the worst-case expected squared error for biased ones. For all cases, we demonstrated how shared randomness helps to reduce the cost. Motivated by real-world applications, we derived algorithms with a bounded number of random bits that can be as low as a single shared bit. For example, in the unbiased case, using just one shared random bit reduces the variance two-fold compared to randomized rounding (which is optimal when no shared randomness is available). Further, using a single byte of shared randomness, our algorithm's variance is within 0.02% from the state of the art, which uses unbounded shared randomness. Our results are also near-optimal in the biased case, with a gap lower than 0.2% between the upper and lower bounds with a single shared random byte. Our upper bound is presented as a sequence of algorithms, each generalizing the previous while reducing the cost further.

For the special case where x is known to be in $\{0, 1/2, 1\}$, we give optimal unbiased and biased algorithms, together with matching lower bounds. Our algorithms use a single shared random bit, and the lower bounds show that the cost cannot be improved even when unbounded shared randomness is allowed.

We conclude by identifying directions for future research, beyond settling the correct bounds. First, our lower bounds apply for algorithms that use unbounded shared randomness, and new techniques for developing sharper bounds for other cases are of interest. Another direction is looking into optimizing the cost when sending k bits, for some $k > 1$. We make a first small step in Supplement 9.3, where we provide simple generalizations of our unbiased algorithm and lower bound to sending k bits. Finally, we are unclear on whether private randomness can help improve biased algorithms (see Table 1).

9 Supplementary Material

9.1 Optimality of Deterministic Rounding

We show that without shared randomness, deterministic rounding is an optimal biased solution. Notice that, in such a case, any protocol is defined by the probability of sending 1, denoted $Y(x)$, and the reconstruction distributions $V_0, V_1 \in \Delta([0,1])$.

Let us examine $\mathbb{E}[V_0]$ and $\mathbb{E}[V_1]$. We assume, without lost of generality, that $\mathbb{E}[V_0] \leq \mathbb{E}[V_1]$.

We have that:

$$\mathbb{E}[\widehat{x}] = Y(x)\mathbb{E}[V_1] + (1 - Y(x))\mathbb{E}[V_0].$$

That is, we have that *for any* $x \in [0,1]$: $\mathbb{E}[V_0] \leq \mathbb{E}[\widehat{x}] \leq \mathbb{E}[V_1]$. Next, we have that the cost, $\mathbb{E}[(\widehat{x} - x)^2]$, is bounded as

$$\mathbb{E}[(\widehat{x} - x)^2] \geq (\mathbb{E}[(\widehat{x} - x)])^2 .$$

In particular, for $x = 0$, we get that

$$\mathbb{E}[(\widehat{x} - x)^2 | x = 0] \geq (\mathbb{E}[\widehat{x} | x = 0])^2 \geq (\mathbb{E}[V_0])^2 .$$

Similarly, for $x = 1$, we have

$$\mathbb{E}[(\widehat{x} - x)^2 | x = 1] \geq (\mathbb{E}[(\widehat{x}) | x = 1] - 1)^2 \geq (1 - \mathbb{E}[V_1])^2 .$$

Notice that if $\mathbb{E}[V_0] \geq 0.25$ then $\mathbb{E}[(\widehat{x}-x)^2|x=0] \geq 1/16$, and similarly, if $\mathbb{E}[V_1] \leq 0.75$ then $\mathbb{E}[(\widehat{x}-x)^2|x=1] \geq 1/16$. Assume to the contrary that there exists an algorithm with a with a worst-case expected squared error lower than $1/16$, then we have $\mathbb{E}[V_0] \leq 0.25$ and $\mathbb{E}[V_1] \geq 0.75$. However, we have that $x = 0.5$ gives:

$$\begin{aligned}
\mathbb{E}[(\widehat{x}-x)^2|x=0.5] &= \mathbb{E}[\widehat{x}^2|x=0.5] - 2x\mathbb{E}[\widehat{x}|x=0.5] + 0.25 \\
&= Y(0.5)\mathbb{E}[V_1^2] + (1-Y(0.5))\mathbb{E}[V_0^2] - (Y(0.5)\mathbb{E}[V_1] + (1-Y(0.5))\mathbb{E}[V_0]) + 0.25 \\
&\geq Y(0.5)(\mathbb{E}[V_1])^2 + (1-Y(0.5))(\mathbb{E}[V_0])^2 - (Y(0.5)\mathbb{E}[V_1] + (1-Y(0.5))\mathbb{E}[V_0]) + 0.25 \\
&= Y(0.5)\cdot\mathbb{E}[V_1]\cdot(\mathbb{E}[V_1]-1) + (1-Y(0.5))\cdot\mathbb{E}[V_0]\cdot(\mathbb{E}[V_0]-1) + 0.25 \\
&\geq Y(0.5)\cdot 0.75\cdot(-0.25) + (1-Y(0.5))\cdot 0.25\cdot(-0.75) + 0.25 = 0.25 - 3/16 = 1/16.
\end{aligned}$$

In the first inequality, we used that fact that for any random variable V: $\mathbb{E}[V^2] \geq (\mathbb{E}[V])^2$, and in the second we used $\mathbb{E}[V_0] \leq 0.25$ and $\mathbb{E}[V_1] \geq 0.75$. This concludes the proof and establishes the optimality of deterministic rounding when no shared randomness is used.

9.2 Proof of the Biased $\{0, 1/2, 1\}$ Lower Bound

We recall Lemma 4:

▶ **Lemma 4.** *Any deterministic algorithm must incur a cost of at least* $\frac{q(0)\cdot q(1/2)}{4(q(0)+q(1/2))}$.

Proof. We denote by X_0 the set of values in $\{0, 1/2, 1\}$ that are closer to v_0 than to v_1. We assume without loss of generality that $v_0 \leq v_1$ and $q(0) \leq q(1)$ and prove that an optimal algorithm would set $v_0 = \frac{q(1/2)}{2(q(0)+q(1/2))}, v_1 = 1$, which incurs a cost of $\frac{q(0)\cdot q(1/2)}{4(q(0)+q(1/2))}$. Indeed, for this choice of v_0, v_1 we have that $X_0 = \{0, 1/2\}$, and we get a cost of

$$\begin{aligned}
q(0)\left(\frac{q(1/2)}{2(q(0)+q(1/2))}\right)^2 + q(1/2)\left(\frac{1}{2} - \frac{q(1/2)}{2(q(0)+q(1/2))}\right)^2 &= q(0)\left(\frac{q(1/2)}{2(q(0)+q(1/2))}\right)^2 \\
+ q(1/2)\left(\frac{q(0)}{2(q(0)+q(1/2))}\right)^2 &= \frac{q(0)q(1/2)^2 + q(1/2)q(0)^2}{4\left(q(0)+q(1/2)\right)^2} = \frac{q(0)\cdot q(1/2)}{4\left(q(0)+q(1/2)\right)}.
\end{aligned}$$

We now bound the performance of the optimal algorithm. We first notice that an optimal algorithm should have $0 \in X_0$ and $1 \notin X_0$. Next, notice that v_0 should be at most $1/2$ and v_1 should be at least $1/2$. Otherwise, one can improve the error for $x = 0$ or $x = 1$, respectively, without increasing the error at $1/2$. Further, observe that an optimal algorithm must have $v_0 = 0$ or $v_1 = 1$. That is because if $1/2 \in X_0$, we can reduce the error for $x = 1$ by setting $v_1 = 1$. Similarly, when $1/2 \notin X_0$, choosing $v_0 = 0$ decreases the error for $x = 0$. Now, we claim that there exists an optimal algorithm for which $v_1 = 1$. Consider some solution, and set $v_0' = 1 - v_1$ and $v_1' = 1$. This does not affect the error of $x = 1/2$, and does not increase the cost as $q(0) \leq q(1)$. We are left with choosing v_0; let us denote by $c(v_0) = q(0)v_0^2 + q(1/2)(1/2 - v_0)^2$ the resulting cost. This function has a minimum at $v_0 = \frac{q(1/2)}{2(q(0)+q(1/2))}$, which gives a cost of $\frac{q(0)\cdot q(1/2)}{4(q(0)+q(1/2))}$. ◀

This cost is maximized for $q(1/2) = \sqrt{2} - 1$ and $q(0) = q(1) = \frac{2-\sqrt{2}}{2}$, giving a lower bound of $3/4 - 1/\sqrt{2} \approx 0.04289$. In fact, one can verify that this is the best attainable lower bound for *any* discrete distribution on three points. Further, in Section 6.1, we show that this is *an optimal* lower bound when x is known to be in $\{0, 1/2, 1\}$, by giving an algorithm with a matching cost.

9.3 Generalization to k Bits

9.3.1 General Quantized Algorithm

We use a hash function h such that $h \in \{0,1\}^\ell$ is uniformly distributed. Let $A \sim U[0,1]$ be independent of h.

$$C = \lfloor (2^k - 1) \cdot x \rfloor$$

$$p = (2^k - 1) \cdot x - \lfloor (2^k - 1) \cdot x \rfloor$$

$$R = 2^k - 1$$

We then set

$$X \triangleq \begin{cases} C+1 & \text{if } p \geq (A+h)2^{-\ell} \\ C & \text{otherwise} \end{cases}$$

We send X to Angel which estimates

$$\widehat{x} = \frac{X + (h - 0.5(2^\ell - 1)) \cdot 2^{-\ell}}{R}.$$

To show that our protocol is unbiased, notice that: $\mathbb{E}[X] = R \cdot x$ and that $\mathbb{E}[h] = 0.5(2^\ell - 1)$.

9.3.2 Lower Bounds

Similarly to the 1-bit case, we consider the discrete distribution over

$$\left\{ i \cdot \left(\frac{1}{3 \cdot 2^{k-1} - 1} \right) \mid i \in \left\{0, 1, \ldots, 3 \cdot 2^{k-1} - 1\right\} \right\}.$$

We set $a_{1/2} = \frac{\sqrt{2}-1}{2^{k-1}}$ and $a_0 = a_1 = \frac{1 - a_{1/2}}{2^k}$ and

$$\forall i : q\left(i \cdot \left(\frac{1}{3 \cdot 2^{k-1} - 1} \right) \right) = a_{(i \mod 3)/2}.$$

When each consecutive set of three points has the same probability, one can derive an optimal algorithm with precisely two values between each such triplet. The optimal choice of locations of the values in each triplet is similar to our single-bit analysis of the previous subsection, i.e., one should have a values at

$$\left\{ \frac{\sqrt{2} - 1 + i}{2^{k-1}} \;\middle|\; i \in \left\{0, 1, \ldots, 2^{k-1} - 1\right\} \right\} \bigcup \left\{ \frac{i}{2^{k-1}} \middle|\; i \in \left\{1, \ldots, 2^{k-1}\right\} \right\}.$$

We turn into calculating the cost. Notice that every triplet has a width of $\frac{2}{3 \cdot 2^{k-1} - 1}$. Therefore, the cost now reduces, compared to the 1-bit analysis, by a factor of $\left(\frac{2}{3 \cdot 2^{k-1} - 1} \right)^2$. That is, we get a lower bound of $\frac{3 - 2\sqrt{2}}{(3 \cdot 2^{k-1} - 1)^2} = \frac{3 - 2\sqrt{2}}{2.25(2^k - 2/3)^2}$. We note that, for large k and ℓ values, our variance is within 10% of the lower bound, as

$$\lim_{k,\ell \to \infty} \frac{\frac{1}{12(2^k - 1)^2}}{\frac{3 - 2\sqrt{2}}{2.25(2^k - 2/3)^2}} = \frac{9 + 6\sqrt{2}}{16} \approx 1.093.$$

9.4 Reducing Algorithms to Monotone T, Z_0 Functions

We now show how an algorithm can be represented as described in Section 6.2. Fixing the shared randomness value h, Angel estimates $\widehat{x}$ solely based on the sent bit X; denote these values by $A_X(h)$. Without loss of generality, assume that $\forall h : A_1(h) \geq A_0(h)$.[2] This means that, in an optimal algorithm, Buffy should send $X = 1$ if $x \geq \frac{A_0(h)+A_1(h)}{2}$, as otherwise the error would be suboptimal for any x not satisfying the condition. In particular, this means that we can express Buffy's algorithm using a threshold function T.

Next, we claim that the threshold function can be considered monotone, without increasing the cost. To that end, we first consider a finite shared randomness $h \in [2^\ell]$. In such a case, if there exists some $h_1 > h_2 \in [2^\ell]$ such that $T(h_1) < T(h_2)$, we can modify the algorithm as follows: For all $h \notin \{h_1, h_2\}$, no modification is made. If $h = h_1$, then the modified algorithm works as if $h = h_2$, and vice versa. Following this process, we can sort T until it becomes monotone. A similar argument can be made for the continuous ($h \in [0, 1]$) case (possibly with an additional ϵ discretization cost).

We proceed with showing that there exists an optimal algorithm in which $Z_1(h) = 1 - Z_0(1 - h)$. This is achieved using a symmetry observation. Specifically, if an algorithm does not satisfy the above, consider its "dual algorithm": instead of sending x using $T(h)$, we send $x' = 1 - x$ using $T'(h) = 1 - T(1 - h)$; similarly, Angel estimates $\widehat{x}' = 1 - \widehat{x}$. Then, if both Buffy and Angel use the shared randomness to implicitly agree on whether to run the original or dual algorithms, each with probability half, the cost can only decrease. Additional details are given in the full version [4].

9.5 Analysis of the Linear Sigmoid (Section 6.2.3)

First, we have (see Section 6.2) that the estimate function for $X = 1$ is:

$$Z_1(h) = 1 - Z_0(1 - h) = \begin{cases} 2\alpha & \text{if } h < h_0 \\ 2\alpha + (1 - 2\alpha) \cdot \frac{h - h_0}{1 - 2h_0} & \text{if } h \in [h_0, 1 - h_0] \\ 1 & \text{otherwise} \end{cases}.$$

For $x \in [\alpha, 1 - \alpha]$, denote by $T^{-1}(x) = \frac{(1-2h_0)(x-\alpha)}{1-2\alpha} + h_0$ the value such that $T(T^{-1}(x)) = x$. We proceed with computing the expectation:

$$\mathbb{E}[\widehat{x}|x < \alpha](\implies X = 0) = h_0 \cdot (1 - 2\alpha) + \int_{h_0}^{1-h_0} \left((1 - 2\alpha) \cdot \frac{h - h_0}{1 - 2h_0} \right) dh = 1/2 - \alpha$$

$$\begin{aligned} \mathbb{E}[\widehat{x}|x > 1 - \alpha](\implies X = 1) &= h_0 \cdot (1 + 2\alpha) + \int_{h_0}^{1-h_0} \left(2\alpha + (1 - 2\alpha) \cdot \frac{h - h_0}{1 - 2h_0} \right) dh \\ &= 1/2 + \alpha \end{aligned}$$

[2] If for some h, $A_0(h) > A_1(h)$, there exists an equivalent algorithm that replaces the role of $X = 0$ and $X = 1$ for this specific h.

$$\begin{aligned}\mathbb{E}[\widehat{x}|x\in[\alpha,1-\alpha]] &= h_0\cdot(2\alpha)+h_0(1-2\alpha)\\ &\quad+\int_{h_0}^{T^{-1}(x)}\left(2\alpha+(1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)dh\\ &\quad+\int_{T^{-1}(x)}^{1-h_0}\left((1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)dh\\ &= h_0+2\alpha(T^{-1}(x)-h_0)+\int_{h_0}^{1-h_0}\left((1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)dh\\ &= 1/2+(-1+2h_0)\alpha+2\alpha(T^{-1}(x)-h_0)=1/2-\alpha+2\alpha T^{-1}(x)\end{aligned}$$

Therefore, we have:

$$\mathbb{E}[\widehat{x}]=\begin{cases}1/2-\alpha & \text{if } x<\alpha\\ 1/2-\alpha+2\alpha\left(\frac{(1-2h_0)(x-\alpha)}{1-2\alpha}+h_0\right) & \text{if } x\in[\alpha,1-\alpha]\\ 1/2+\alpha & \text{otherwise}\end{cases}.$$

Next, we calculate the second moment of the estimate:

$$\begin{aligned}\mathbb{E}[(\widehat{x})^2|x<\alpha](\implies X=0) &= h_0\cdot(1-2\alpha)^2+\int_{h_0}^{1-h_0}\left((1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)^2dh\\ &= 1/3+h_0/3-4\alpha/3-4h_0\alpha/3+4\alpha^2/3+4h_0\alpha^2/3\end{aligned}$$

$$\begin{aligned}\mathbb{E}[(\widehat{x})^2|x>1-\alpha](\implies X=1) &= h_0\cdot(1+(2\alpha)^2)\\ &\quad+\int_{h_0}^{1-h_0}\left(2\alpha+(1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)^2dh\\ &= 1/3+h_0/3+2\alpha/3-4h_0\alpha/3+4\alpha^2/3+4h_0\alpha^2/3\end{aligned}$$

$$\begin{aligned}\mathbb{E}[(\widehat{x})^2|x\in[\alpha,1-\alpha]] &= h_0\cdot((1-2\alpha)^2+(2\alpha)^2)\\ &\quad+\int_{h_0}^{T^{-1}(x)}\left(2\alpha+(1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)^2dh+\int_{T^{-1}(x)}^{1-h_0}\left((1-2\alpha)\cdot\frac{h-h_0}{1-2h_0}\right)^2dh\\ &= h_0\cdot((1-2\alpha)^2+(2\alpha)^2)+\frac{(1-2h_0)(x-\alpha)(x^2+4x\alpha+7\alpha^2)}{3-6\alpha}\\ &\quad+\frac{(2h_0-1)(-1+x+\alpha)(1+x+x^2-4x\alpha+\alpha(-5+7\alpha))}{3-6\alpha}\\ &= \frac{1-6\alpha-6\alpha x^2(-1+2h_0)+12\alpha^2-14\alpha^3+h_0(1-6\alpha+24\alpha^2-20\alpha^3)}{3-6\alpha}\end{aligned}$$

Putting it together, we get:

$$\mathbb{E}[\widehat{x}^2]=\begin{cases}1/3+h_0/3-4\alpha/3-4h_0\alpha/3+4\alpha^2/3+4h_0\alpha^2/3 & \text{if } x<\alpha\\ \frac{1-6\alpha-6\alpha x^2(-1+2h_0)+12\alpha^2-14\alpha^3+h_0(1-6\alpha+24\alpha^2-20\alpha^3)}{3-6\alpha} & \text{if } x\in[\alpha,1-\alpha]\\ 1/3+h_0/3+2\alpha/3-4h_0\alpha/3+4\alpha^2/3+4h_0\alpha^2/3 & \text{otherwise}\end{cases}.$$

By solving

$$\min_{h_0\in[0,1/2],\alpha\in[0,1/2]}\max_{x\in[0,1]}\mathbb{E}[(\widehat{x}-x)^2]=\min_{h_0\in[0,1/2],\alpha\in[0,1/2]}\max_{x\in[0,1]}\mathbb{E}[\widehat{x}^2]-2x\mathbb{E}[\widehat{x}]+x^2,$$

we get that the algorithm is optimized for $\alpha=1/3$ and $h_0=1/4$, where the resulting cost is:

$$\mathbb{E}[(\widehat{x}-x)^2] = \mathbb{E}[(\widehat{x})^2] - 2x\mathbb{E}[\widehat{x}] + x^2$$
$$= \begin{cases} 5/108 - x/3 + x^2 & \text{if } x < 1/3 \\ 5/108 & \text{if } x \in [1/3, 2/3] \\ 77/108 - 5x/3 + x^2 & \text{otherwise} \end{cases}.$$

Therefore, the cost is $5/108 \approx 0.0463$, which is less than 0.9% higher than the 0.0459 lower bound (Section 4.1.2).

Abstract

Given an undirected n-vertex graph and k pairs of terminal vertices $(s_1, t_1), \ldots, (s_k, t_k)$, the k-Disjoint Shortest Paths (k-DSP) problem asks whether there are k pairwise vertex-disjoint paths $P_1, \ldots, P_k$ such that P_i is a shortest s_i-t_i-path for each $i \in [k]$. Recently, Lochet [SODA '21] provided an algorithm that solves k-DSP in $n^{O\left(k^{5^k}\right)}$ time, answering a 20-year old question about the computational complexity of k-DSP for constant k. On the one hand, we present an improved $O(kn^{16k \cdot k! + k + 1})$-time algorithm based on a novel geometric view on this problem. For the special case $k = 2$, we show that the running time can be further reduced to $O(nm)$ by small modifications of the algorithm and a further refined analysis. On the other hand, we show that k-DSP is W[1]-hard with respect to k, showing that the dependency of the degree of the polynomial running time on the parameter k is presumably unavoidable.

1 Introduction

The k-Disjoint Paths problem is a fundamental and well-studied combinatorial problem. Given an undirected graph G and k terminal pairs $(s_i, t_i)_{i \in [k]}$, the question is whether there are pairwise disjoint [1] s_i-t_i-paths P_i for each $i \in [k]$. The problem was shown to be NP-hard by Karp [9] when k is part of the input. On the positive side, Robertson and Seymour [13] provided an algorithm running in $O(n^3)$ time for any constant k. Later, Kawarabayashi et al. [10] improved the running time to $O(n^2)$, again for fixed k. On directed graphs, in contrast, the problem is NP-hard even for $k = 2$ [7]. However, on directed acyclic graphs, the problem becomes again polynomial-time solvable for constant k [7] and linear-time solvable for $k = 2$ [14].

[1] We only consider the vertex-disjoint setting to which the edge-disjoint version can be reduced.

Focusing on the undirected case, we study the problem variant where all paths in the solution have to be shortest paths. This variant was introduced by Eilam-Tzoreff [5].

k Disjoint Shortest Paths (k-DSP)

Input: A graph $G = (V, E)$ and $k \in \mathbb{N}$ pairs $(s_i, t_i)_{i \in [k]}$ of vertices.

Task: Find k disjoint paths P_i such that P_i is a shortest s_i-t_i-path for each $i \in [k]$.

Throughout the whole paper, we assume that the input graph is connected. Eilam-Tzoreff [5] showed the NP-hardness of k-DSP when k is part of the input. Moreover, Eilam-Tzoreff provided a dynamic-programming based $O(n^8)$-time algorithm for 2-DSP. This algorithm for 2-DSP works also for positive edge lengths. Recently, Gottschau et al. [8] and Kobayashi and Sako [11] independently extended this result by providing polynomial-time algorithms for the case that the edge lengths are non-negative. As for directed graphs, Berczi and Kobayashi [2] provided a polynomial-time algorithm for strictly positive edge length. Very recently, Akhmedov [1] presented an algorithm solving 2-DSP in $O(n^6)$ time for unweighted graphs and in $O(n^7)$ for strictly positive edge lengths. Note that allowing zero-length edges generalizes 2-Disjoint Path on directed graphs, which is NP-hard [7]. Extending the problem to finding two disjoint s_i-t_i-paths of minimal total length (in undirected graphs), Björklund and Husfeldt [4] provided a randomized algorithm with running time $O(n^{11})$.

The existing algorithms for 2-DSP are based on dynamic programming with tedious case distinctions. We provide a new algorithm using a simple and elegant geometric perspective:

▶ **Theorem 1.** *2-DSP can be solved in $O(nm)$ time.*

Whether or not k-DSP for constant $k \geq 3$ is polynomial-time solvable was posed as a research challenge [6, open problem 4.6]. Recently, Lochet [12] settled this long standing open question by showing that k-DSP can be solved in $n^{O(k^{5^k})}$ time. Using our geometric approach, we provide an improved $O(k \cdot n^{16k \cdot k! + k + 1})$-time algorithm.

▶ **Theorem 2.** *k-DSP can be solved in $O(k \cdot n^{16k \cdot k! + k + 1})$ time.*

We describe the basic idea of our algorithms and the new geometric tools in Section 2. In Section 3, we formalize these geometric tools for two paths and prove Theorem 1. In Section 4, we lift these arguments to $k > 2$ paths. In Section 5, we present our algorithm for Theorem 2 and prove its correctness.

Finally, we show that k-DSP is W[1]-hard with respect to k. Hence, under standard assumptions from parameterized complexity, there is no algorithm with running time $f(k)n^{O(1)}$ for any function f. Thus, polynomial-time algorithms where k does not appear in the exponent (as the $O(n^2)$-time algorithm for k-Disjoint Path for any constant k [13, 10]) are unlikely to exist for k-DSP. Furthermore, under the Exponential-Time Hypothesis (ETH), we show that there is no algorithm with running time $f(k) \cdot n^{o(k)}$ for any computable function f.

▶ **Proposition 3** ($\star$[2])**.** *k-DSP is W[1]-hard with respect to k. Moreover, assuming ETH, there is no $f(k) \cdot n^{o(k)}$-time algorithm for k-DSP.*

Preliminaries. We set $\mathbb{N} := \{0, 1, 2, \dots, \}$ and $[n] := \{1, 2, \dots, n\}$. We always denote by $G = (V, E)$ a graph (undirected and connected unless said otherwise) and by n and m the number of vertices and edges in G, respectively. A *path* of length $\ell \geq 0$ in a graph G is a

[2] Some proofs (marked with a $\star$) are deferred to a full version.

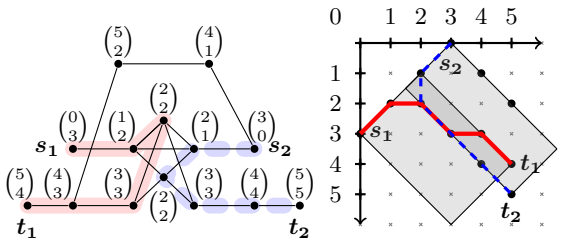

Figure 1 *Left side:* A graph with distinguished vertices s_1, s_2, t_1, t_2; vertex coordinates written next to the vertices. Two shortest paths are highlighted. *Right side:* The 2D-arrangement of the vertices. The two gray rectangles spanned by s_1 and t_1 and by s_2 and t_2 contain the two shortest paths s_1-t_1 (solid red path) and s_2-t_2 (dashed blue path).

sequence of distinct vertices $v_0v_1 \dots v_\ell$ such that each pair v_{i-1}, v_i is connected by an edge in G. The first and last vertex v_0 and v_ℓ are called the *end vertices* or *ends* of P and are denoted by s_P and t_P. We also say that P is a path *from* v_0 *to* v_ℓ, a path *between* v_0 and v_ℓ, or a v_0-v_ℓ-path. When no ambiguity arises, we do not distinguish between a path and its set of vertices. For $v, w \in P$, we denote by $P[v, w]$ the subpath of P with end vertices v and w. For two vertices v, w, we denote the length of a shortest v-w-path in G by $\mathrm{dist}_G(v, w)$ or $\mathrm{dist}(v, w)$ if the graph G is clear from the context. If for all $i \in [k]$ there is a path P_i that is a shortest s_i-t_i-path and disjoint with P_j for all $j \in [k] \setminus \{i\}$, then we say that the paths $(P_i)_{i\in[k]}$ are a solution for an instance $(G, (s_i, t_i)_{i\in[k]})$ of k-DSP.

2 The Key Concepts behind our Polynomial-Time Algorithm

In this section, we describe our approach to solve k-DSP in polynomial-time for any fixed k. As a warm-up, we start with sketching an algorithm for 2-DSP based on the same approach.

Solving 2-DSP in the plane. Before describing the algorithm, we show the central geometric idea behind it. Recall that we want to find two shortest paths P_1 and P_2 from s_1 to t_1 and from s_2 to t_2, respectively. We now arrange the vertices on a 2-dimensional grid where the first coordinate of each vertex is the distance to s_1 and the second coordinate the distance to s_2; see left side of Figure 1 for an example graph with the corresponding coordinates and the right side for an arrangement of the vertices in a grid with a continuous drawing of the paths (drawing straight lines between points occurring in the paths). Clearly, with two breadth-first searches from s_1 and s_2 we can compute the coordinates of all vertices in linear time. Note that there might be multiple vertices with the same coordinates. However, at most one vertex per coordinate can be part of a shortest s_1-t_1- or s_2-t_2-path.

This arrangement of the vertices allows the following simple geometric observation: The drawing of each shortest s_1-t_1-path has to be within a rectangle with angles of 45° to the coordinate axes and with corner points s_1 and t_1 (see gray rectangles in right side of Figure 1). As a consequence, shortest paths that have to stay within two disjoint such rectangles cannot intersect. We use this argument extensively in the subsequently sketched algorithm.

We assume that the drawings of P_1 and P_2 cross as displayed in the right side of Figure 1 (the non-crossing case is easier to deal with). Our algorithm solving 2-DSP in this case is as follows: We distinguish whether the intersection of the drawings of P_1 and P_2 contain a point with integer coordinates (that is, our algorithm tries both possibilities).

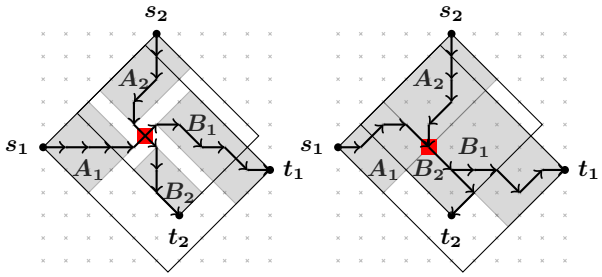

Figure 2 An illustration of the directed acyclic graph used for Theorem 1. The first point p in the intersection of the drawing of P_1 and P_2 is marked by a red square. *Left side:* Straigh-line drawings of P_1 and P_2 intersect, but not in points with integer coordinates. *Right side:* Both P_1 and P_2 use vertices with same coordinates.

If the intersection does not have a point with integer coordinates, then it is easy to see that the intersection of the drawing of P_1 and P_2 has to be a single point p (with non-integer coordinates). We guess[3] the four coordinate pairs $(x, y), (x, y+1), (x+1, y)$, and $(x+1, y+1)$, $x, y \in \mathbb{N}$, surrounding the intersection point of the drawings of P_1 and P_2. Note that this can be done in $O(n)$ time by guessing the vertex on the coordinate pair (x, y). The goal is now to turn the input graph G into a directed acyclic graph D such that each shortest s_i-t_i-path in G corresponds to an s_i-t_i-path in D. To this end, we partition the grid into four areas A_1, B_1, A_2, B_2 (each area is defined by one of the guessed points and the closer endpoint of the path going through the point) and orient each edge according to the area it lies in (see left side of Figure 2 for an illustration). An edge $\{v, w\}$ in the area A_i or B_i, $i \in [2]$, is oriented towards the vertex w with the larger i coordinate. Edges between A_i and B_i are oriented towards the vertex in B_i. All remaining (unoriented) edges are removed. Note that this results in a directed acyclic graph. Furthermore, a shortest s_i-t_i-path in G induces an s_i-t_i-path in D and each s_i-t_i-path in D is a shortest path in G because it is strictly monotone increasing in the i-coordinate and all strictly monotone increasing paths have the same length as each path contains one vertex for each integer i-coordinate between the i-coordinates of s_i and t_i. Observe that in this case the two paths cannot intersect as P_1 can only reach vertices with coordinates in A_1 and B_1 and P_2 can only use vertices with coordinates in A_2 and B_2. Hence, one can find P_1 and P_2 in linear time. Altogether, this gives a running time of $O(nm)$ in this case.

Assume now that there is a point with integer coordinates in this intersection; this case requires more work. We assume that if there are two points (x_1, y_1) and (x_2, y_2) in the intersection of the drawings of P_1 and P_2, then we have $x_1 < x_2 \Leftrightarrow y_1 < y_2$. If this is not the case, then repeat the algorithm below with swapped s_2 and t_2. We guess the first point p in the intersection (note that it has integer coordinates). This can be done in $O(n)$ time by guessing a vertex on p. Now we arrange the areas slightly different. The areas are defined by p and one coordinate of s_1, t_1, s_2, t_2; see the right side of Figure 2 for an illustration. Edges in the area $A_i \setminus B_j$ or $B_i \setminus A_j$ are oriented towards the vertex with the larger i-coordinate. Note that edges on the line in $A_i \cap B_j, i \neq j$, could either be used by P_1 or P_2 (but not both), meaning that we have to direct the edges towards the vertex with either the larger 1- or 2-coordinate. Since there are only two possibilities for orienting the edges in $A_1 \cap B_2$, there are only four different possibilities to orient the edges on $A_1 \cap B_2$ and $A_2 \cap B_1$. We try

[3] Whenever we pretend to guess something, the algorithm actually exhaustively tests all possible choices.

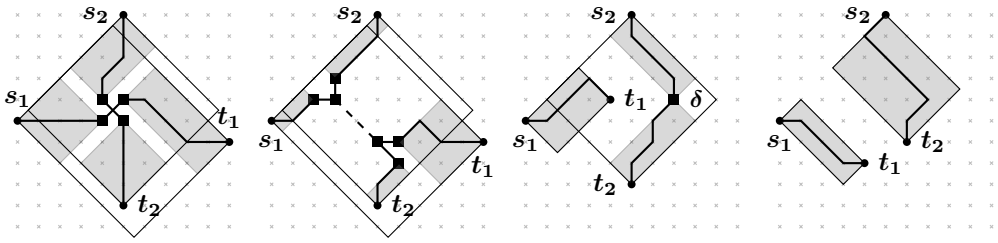

Figure 3 The four cases for the projection of two paths P_1 and P_2 in the two-dimensional grid. From left to right: (1) The projection of the paths cross in one point with non-integer coordinates. (2) The projection of the paths cross in at least one point with integer coordinates. (3) The rectangles defined by the endpoints of P_1 and P_2 intersect, but the projections of P_1 and P_2 do not intersect. (4) The rectangles defined by the endpoints of P_1 and P_2 do not intersect. For each of the two paths our algorithm guesses the vertices on the positions marked by squares.

all four possible orientations and if at least one of them yields a solution, then we know that there is a solution. All other (unorientated) edge are removed – a shortest s_i-t_i-path cannot use it. Note that this results for each of the four described cases in a directed acyclic graph. Furthermore, again a shortest s_i-t_i-path in G induces a s_i-t_i-path in D and each s_i-t_i-path in D is an shortest path in G.

Finally, we use a $O(n+m)$-time algorithm of Tholey [14] for 2-Disjoint Paths on a DAG to find P_1 and P_2. Since there are $O(n)$ possibilities for the point p and 4 possibilities for directing the edges between A_i and B_j, $i \neq j$, we call $O(n)$ instances of the algorithm of Tholey [14]. Thus, we obtain Theorem 1 which is formally proven in Section 3.

Generalizing to k-DSP. We now discuss how to generalize the ideas from above to k-DSP, where $k > 2$. One central idea for $k = 2$ is that the subpaths within the areas A_1, A_2, B_1, B_2 (see Figure 2) can hardly overlap. The only overlap is possible along the borders. In our approach for $k > 2$, we simplify this even further by guessing the vertices on each path before and after the intersection (thus incurring a higher running time). This results in four cases; see Figure 3 for an overview of the cases and the guessed vertices (marked by black squares). It is easy to see in Figure 3 that in each case no subpath within one gray area can possibly intersect with a subpath within another gray area. As can be seen in Figure 3, there is only one case where subpaths of P_1 and P_2 have to be computed carefully due to possible intersections: Both paths use the dashed line in the second case from the left. However, this is the part where both paths are strictly monotone in both coordinates. This is what allowed us for $k = 2$ to transform the graph into a DAG while preserving the solutions (both paths being strictly monotone in at least one coordinate is actually sufficient for this transformation).

Considering k paths, we associate with each vertex $v \in V$ a position in the k-dimensional Euclidean vector space. For brevity, we say that a path has color i if it is strictly monotone in its i-coordinate. Thus, each path P_j has color j. The problem k-Disjoint Paths on a DAG is solvable in polynomial time for constant k [7]. Thus, if we want to find k subpaths from u_i to v_i, $i \in [k]$, that all have the same color (i. e. for each $i \in [k]$ we have that the difference of the i-th coordinate of u_i and v_i is $\text{dist}(u_i, v_i)$), then we can use the algorithm of Fortune et al. [7]. For completeness, we provide a dynamic program with a precise running time analysis as Fortune et al. [7] only state "polynomial time". The general approach to solve the given k-DSP instance is thus as follows: Split the paths $P_1, \ldots, P_k$ into $f(k)$ subpaths (i. e. guess the endpoints of the subpaths) and find a partition of the subpaths such that

(i) subpaths in the same part of the partition share a common color and hence can be computed by the algorithm of Fortune et al. [7] or our dynamic program, and

(ii) subpaths in different parts of the partition cannot intersect.

We remark that this is essentially the same general approach used by Lochet [12]. However, he does not use the geometric view of the paths (as we do). As a result, even for $k = 2$ he only bounds the number of created subpaths by 9^{91} (cf. Lochet [12, Lemma 4.2]). While this constant is certainly not optimized, one can easily see in Figure 3 that our approach splits the two paths in at most five parts (in the second case). Moreover, our geometric view allows us to use a more efficient way of splitting the paths for general k, which we describe below.

Recall that for $k = 2$ the two paths P_1 and P_2 have at most one intersection (point or straight line); see Figure 3. However, in three dimensions $k > 2$ this is no longer true as neither P_1 nor P_2 needs to be monotone in a third dimension. Thus, to exploit the properties shown in Figure 3 for two paths P_i and P_j, we need to project into two dimensions using the i and j coordinate. Hence, we need to be careful with using proper projections to 2D; see Section 3 for details on the geometric arguments. However, whenever two paths P_i and P_j intersect, then we know that the two subpaths in the intersection have both colors i and j. Thus, we can use for these subpaths the two-dimensional observations behind Figure 3 with new projections. We store for each subpath P' of P_i the set Φ of all indices of paths P' intersects, that is, Φ is a subset of all colors that P' has. Now, if P' and P_j intersect, then there is a subpath of P_j that has colors $\Phi \cup \{i\}$. Hence this set Φ of colors can be seen as a "tower of colors" that is transferred to other paths. Our algorithm transfers these towers from one path to another as long as possible. These towers will be defined over permutations of subsets of $[k]$ that encode how these color-towers are produced; see Section 4. As there are at most $k \cdot k!$ such permutations, this explains the exponent of our algorithm. In the end, we arrive at Theorem 2, see Section 5 for details.

3 The Geometry of Two Shortest Paths

In this section, we formalize and generalize the idea behind the geometric view (visualized in Figures 1–3). We start by introducing our notation for projections. For any $\emptyset \subset I \subseteq [k]$ and any vector $x \in \mathbb{R}^k$ we denote with $x^I \in \mathbb{R}^{|I|}$ the orthogonal projection of x to the coordinates in I. That is, x^I is the $|I|$-dimensional vector obtained by deleting all dimensions in x that are not in I. We usually drop the brackets in the exponent, thus writing e.g., $(5,6,7,8,9)^{1,3,4} = (5,7,8)$ or $(5,6,7)^2 = 6$. Similarly, for $R \subseteq \mathbb{R}^k$ we define $R^I := \{x^I \mid x \in R\} \subseteq \mathbb{R}^{|I|}$.

We associate with each vertex $v \in V$ a position in the k-dimensional Euclidean vector space. Formally, $\vec{v} := (\vec{v}^i)_{i\in[k]} := (\mathrm{dist}(s_i, v))_{i\in[k]} \in \mathbb{N}^k$ and for $U \subseteq V$ we use $\vec{U} := \{\vec{u} \mid u \in U\}$. For the k-DSP-instance at hand, one can compute the positions of each vertex in $O(km)$ using simple breadth-first-search from each vertex s_i.

In the following, we will use the following notations for any index set $\emptyset \subset I \subseteq [k]$:
$v \circ^I w \Leftrightarrow \forall a \in I\colon \vec{v}^a \circ \vec{w}^a$, for any $\circ \in \{<, \leq, =, \geq, >\}$ and vertices v, w.
$V \circ^I W \Leftrightarrow \{\vec{v}^I \mid v \in V\} \circ \{\vec{w}^I \mid w \in W\}$, for any $\circ \in \{\subset, \subseteq, =, \supseteq, \supset\}$ and vertex sets V, W.
We further write $x \in^I X$ if there is a vertex $x' \in X$ with $x' =^I x$ and $x \notin^I X$ otherwise.

▶ **Lemma 4.** *For any pair of vertices $v, w \in V$, we have $\|\vec{v} - \vec{w}\|_\infty \leq \mathrm{dist}(v, w)$.*

Proof. Let P be a shortest v-w-path with edge set E_P. Each edge $\{p, q\}$ of P has $\|\vec{p} - \vec{q}\|_\infty = 1$ and thus by the triangle inequality $\|\vec{v} - \vec{w}\|_\infty \leq \sum_{e\in E_P} 1 = \mathrm{dist}(v, w)$. ◀

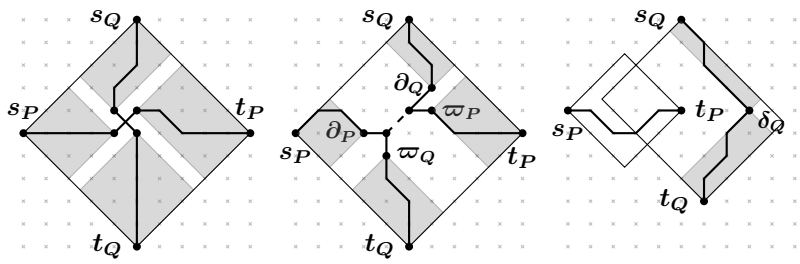

Figure 4 Picture of the a, b-projection of an a-colored path P and a b-colored path Q. The labels are abbreviated as $\partial_Q = \partial_Q^{a,b}(P)$, $\Delta = \Delta^{a,b}(P, Q)$, etc. *Left side:* The case that the two paths a, b-cross but do not share vertices with common a, b-coordinates (thus $\alpha_P(Q) = \omega_P(Q) = \bot$, see Definition 8). *Middle:* Illustration of Lemma 10. The dashed black edge is the a, b-crossing of P and Q. The rectangle areas $\overrightarrow{s_P} \diamond \overrightarrow{\partial_P}$, $\overrightarrow{\varpi_P} \diamond \overrightarrow{t_P}$, $\overrightarrow{s_Q} \diamond \overrightarrow{\partial_Q}$, and $\overrightarrow{\varpi_Q} \diamond \overrightarrow{t_Q}$ are highlighted in gray. These areas are pairwise disjoint. *Right side:* Illustration of Lemma 14. If P and Q are a, b-noncrossing and $\delta_Q \neq \bot$, then the two shaded areas are disjoint from $\overrightarrow{s_P} \diamond \overrightarrow{t_P}$.

For two vertices $u, w \in V$, define $u \diamond w := \{v \in V \mid \mathrm{dist}(u, v) + \mathrm{dist}(v, w) = \mathrm{dist}(u, w)\}$ to be the set of all vertices that lie on a shortest u-w-path. Similarly, for any $x, y \in \mathbb{N}^k$ define $x \diamond y := \{z \in \mathbb{R}^k \mid \|x - z\|_\infty + \|z - y\|_\infty = \|x - y\|_\infty\}$ which is a rectangle whose sides form an angle of 45° with the coordinate axes (see right side of Figure 1).

▶ **Definition 5.** *Let $s, t \in V$ with $\mathrm{dist}(s, t) = \|\vec{s} - \vec{t}\|_\infty$ and P be any shortest s-t-path. We then call the pair (s, t) and the path P* colored*. Furthermore, we define $C(P) := C(s, t) := \{a \in [k] \mid |\vec{s}^a - \vec{t}^a| = \|\vec{s} - \vec{t}\|_\infty\}$ and call (s, t) and P a-*colored *if $a \in C(s, t)$.*

Note that, if P is an a-colored path, then P is strictly monotone in its a-coordinate. Note that for arbitrary $u, w \in V$ we do *not* always have $\overrightarrow{u \diamond w} \subseteq \vec{u} \diamond \vec{w}$, that is the coordinates of all vertices on shortest u-w-paths are not necessarily contained in the set of coordinates "spanned" by $\vec{u}$ and $\vec{w}$. However, this inclusion holds for colored vertex pairs as shown next:

▶ **Lemma 6** (⋆). *Let $v, w \in V$ be an a-colored pair for any color a. Then, $\overrightarrow{v \diamond w} \subseteq \vec{v} \diamond \vec{w}$.*

We will usually be concerned with the projection of $\vec{v} \diamond \vec{w}$ to some set of coordinates $I \subseteq [k]$. Note in this context that $(\vec{v} \diamond \vec{w})^I = \vec{v}^I \diamond \vec{w}^I$.

For some $a \neq b$, consider the projections of an a-colored path P_a and a b-colored path P_b to the $\{a, b\}$-plane, that is, the coordinates of the vertices of the paths are projected to their a- and b-coordinate and edges are drawn as straight lines between the projected vertices. To this end, for any path P we define $\zeta(P) \subset \mathbb{R}^k$ as the piecewise linear curve connecting the points of $\vec{P}$ in the order given by P. It is not hard to see (e.g. in Figure 1 (right) and Figure 3 case (2)), that the intersection of P_a and P_b in the a, b-projection is also a straight line segment with an angle of 45° to the coordinate axes.

▶ **Lemma 7** (⋆). *Let P be an a-colored path and Q be a b-colored path. Then $\zeta(P)^{a,b} \cap \zeta(Q)^{a,b}$ is a (possibly empty) straight line segment.*

Note that even if $\zeta(P)^{a,b} \cap \zeta(Q)^{a,b}$ is non-empty, it needs not contain points from $\mathbb{N}^2$ as can be seen in the left side of Figure 4. In the following, we define the first and last vertices of P and Q on their crossing as well as the coordinates of the vertices before and after their crossing.

▶ **Definition 8.** *Let P be an a-colored path and Q be a b-colored path. We say P and Q are a,b-*crossing *if the intersection $X := \zeta(P)^{a,b} \cap \zeta(Q)^{a,b}$ is non-empty. If $X = \emptyset$, they are called a,b-noncrossing.*

If $\overrightarrow{P}^{a,b} \cap X \neq \emptyset$, then we define $\alpha_P^{a,b}(Q)$ (resp. $\omega_P^{a,b}(Q)$) as the first (resp. last) vertex v of P with $v^{a,b} \in X$. In all other cases set $\alpha_P^{a,b}(Q) := \omega_P^{a,b}(Q) := \perp$.

If P and Q are a,b-crossing, we further define $\partial_P^{a,b}(Q)$ (resp. $\varpi_P^{a,b}(Q)$) as the last (resp. first) vertex of P before (resp. after) that intersection. If no such vertex exists, we set $\partial_P^{a,b}(Q) := \perp$ (resp. $\varpi_P^{a,b}(Q) := \perp$). In all these notations we will omit a, b, and Q if it is clear from context.

▶ **Observation 9.** *If P, Q are two paths with $\alpha_P^{a,b}(Q) \neq \perp$, then $P[\alpha_P^{a,b}(Q), \omega_P^{a,b}(Q)] =^{a,b} Q[\alpha_Q^{a,b}(P), \omega_Q^{a,b}(P)]$. In particular, both of these subpaths are a,b-colored.*

If P and Q are a,b-crossing, then Observation 9 characterizes the behavior of the "crossing subpaths". Let us now consider the remaining path segments before and after the crossing. By Lemma 6 these segments have to lie in the rectangle areas $\overrightarrow{s_P} \diamond \overrightarrow{\partial_P^{a,b}(Q)}$, $\overrightarrow{\varpi_P^{a,b}(Q)} \diamond \overrightarrow{t_P}$, $\overrightarrow{s_Q} \diamond \overrightarrow{\partial_Q^{a,b}(P)}$, and $\overrightarrow{\varpi_Q^{a,b}(P)} \diamond \overrightarrow{t_Q}$ which are displayed in Figure 4 (left and middle). We can show that these areas are indeed pairwise disjoint.

▶ **Lemma 10** (⋆). *Let P and Q be two a,b-crossing paths. Then the sets $\left(\overrightarrow{s_P} \diamond \overrightarrow{\partial_P^{a,b}(Q)}\right)^{a,b}$, $\left(\overrightarrow{\varpi_P^{a,b}(Q)} \diamond \overrightarrow{t_P}\right)^{a,b}$, $\left(\overrightarrow{s_Q} \diamond \overrightarrow{\partial_Q^{a,b}(P)}\right)^{a,b}$, and $\left(\overrightarrow{\varpi_Q^{a,b}(P)} \diamond \overrightarrow{t_Q}\right)^{a,b}$ are pairwise disjoint (or undefined).*

Unfortunately, when P and Q are a,b-noncrossing, then $s_P \diamond t_P$ and $s_Q \diamond t_Q$ are not disjoint in general, see for example Figure 4 (right). To deal with this case, we show that when splitting one path into two subpaths at the vertex δ_Q (see Figure 4 (right)), then we get the desired properties that the respective rectangles do not intersect.

▶ **Definition 11.** *Let P, Q be two colored paths and $a, b \in [k]$. The* common a,b-area *of P and Q is $\Delta^{a,b}(P,Q) := (\overrightarrow{s_P} \diamond \overrightarrow{t_P})^{a,b} \cap (\overrightarrow{s_Q} \diamond \overrightarrow{t_Q})^{a,b}$.*

▶ **Definition 12.** *Let P be an a-colored path and Q a b-colored path where (without loss of generality) $s_P <^a t_P$. Define $B := \{v \in V \mid v =^b s_P \wedge v <^a s_P\} \cup \{v \in V \mid v =^b t_P \wedge v >^a t_P\}$. Define $\delta_Q^{b,a}(P)$ as the unique vertex in $Q \cap B$ or as $\perp$ if that intersection is empty.*

▶ **Lemma 13** (⋆). *If P, Q are a,b-noncrossing paths with $\Delta^{a,b}(P,Q) \neq \emptyset$, then $\delta_P^{a,b}(Q) \neq \perp$ or $\delta_Q^{a,b}(P) \neq \perp$.*

The next lemma shows that if P and Q are not crossing but have a common area $\Delta_{a,b}$, then the path whose end vertex lies not in the common area $\Delta_{a,b}$ does not enter $\Delta_{a,b}$ at all.

▶ **Lemma 14** (⋆). *If P is an a-colored path and Q a b-colored path with $\delta_P^{a,b}(Q) \neq \perp$, then $\left(\overrightarrow{s_Q} \diamond \overrightarrow{t_Q}\right)^{a,b}$ is disjoint from $\left(\overrightarrow{s_P} \diamond \overrightarrow{\delta_P^{a,b}(Q)}\right)^{a,b} \cup \left(\overrightarrow{\delta_P^{a,b}(Q)} \diamond \overrightarrow{t_P}\right)^{a,b}$.*

▶ **Definition 15.** *Let P be an a-colored s_P-t_P-path and Q a b-colored s_Q-t_Q-path. We then define $\mathcal{C}_P^{a,b}(Q) := \{s_P, t_P, \mu_P^{a,b}(Q) \mid \mu \in \{\alpha, \omega, \partial, \varpi, \delta\}\} \setminus \{\perp\}$.*

The next proposition shows the sets $\mathcal{C}_P^{a,b}(Q)$ and $\mathcal{C}_Q^{a,b}(P)$ "characterize" the crossing of P and Q in the sense that any two shortest paths using these vertices have exactly the same vertex coordinates in the crossing.

▶ **Proposition 16** (⋆). *Let P and P' be a-colored s_P-t_P-paths, and let Q and Q' be b-colored s_Q-t_Q-paths. If $\mathcal{C}_P^{a,b}(Q) \subseteq P'$ and $\mathcal{C}_Q^{a,b}(P) \subseteq Q'$, then $\{v \in P' \mid v \in^{a,b} Q'\} =^{a,b} \{v \in P \mid v \in^{a,b} Q\}$.*

We now have all ingredients for the proof of Theorem 1.

Proof of Theorem 1. Let $I := (G = (V, E), k, ((s_1, t_1), (s_2, t_2))$ be an instance of 2-DSP. Compute $\vec{v}$ for all $v \in V$ via two breadth-first searches in $O(n + m)$ time. We assume without loss of generality that G is connected. To ensure that we report I being a *yes*-instance only if I is indeed a *yes*-instance, we perform a sanity-check in the very end to verify that our guesses were correct. Hence, we only need to show that we find in $O(nm)$ time a solution to I if there is one. To this end, assume there are disjoint shortest s_i-t_i-paths P_i for $i \in [2]$. By Lemma 7 we have three cases.

(Case 1): $\zeta(P_1) \cap \zeta(P_2)$ is empty. If $\Delta^{1,2}(P_1, P_2) = \emptyset$, then, by Lemma 6, a solution can easily be found by two independent breadth-first-searches. Otherwise, we guess in $O(n)$ time the vertex $\delta_{P_1}^{1,2}(P_2)$ on P_1 or $\delta_{P_2}^{2,1}(P_1)$ on P_2 from Definition 12. By Lemma 13, at least one of them exists (assume without loss of generality that $\delta_{P_1}^{1,2}(P_2)$ exists). By Lemma 14, $\delta_{P_1}^{1,2}(P_2) \neq \perp$ and any shortest s_1-$\delta_{P_1}^{1,2}(P_2)$-path ($\delta_{P_1}^{1,2}(P_2)$-t_1-path) is vertex disjoint from any shortest s_2-t_2-path. Hence, we now can check in $O(m)$ time whether I is a *yes*-instance.

(Case 2): $\zeta(P_1) \cap \zeta(P_2)$ has no point with integer coordinates. Then, we guess the four points surrounding $\zeta(P_1) \cap \zeta(P_2)$ in $O(n)$ time. This can be done in $O(n)$ time by guessing the vertex $\partial_{P_1}^{1,2}(P_2)$ and branch into two cases. Let p_{s_i} and p_{t_i} be the guessed points used by P_i such that $p_{s_i}^i + 1 = p_{t_i}^i$, for $i \in [2]$. Now we construct a directed graph D on the vertices V such that there is an arc (v, w) if $\{v, w\} \in E$, $\vec{v}^i + 1 = \vec{w}^i$, and $\overrightarrow{\{v, w\}} \subseteq \vec{s_i} \diamond p_{s_i} \cup p_{t_i} \diamond \vec{t_i}$ for some $i \in [2]$. Note that D is acyclic and that each s_i-t_i-path in D corresponds (same set of vertices) to a shortest s_i-t_i-path in G, and has an arc (v, w) such that $\vec{v} = p_{s_i}$ and $\vec{w} = p_{t_i}$. Hence, by Lemma 10 we can simply use two breadth-first-searches from s_1 and s_2 to find a solution.

(Case 3): $\zeta(P_1) \cap \zeta(P_2)$ has at least one point with integer coordinates. Without loss of generality, we assume that $\overrightarrow{\alpha_{P_1}^{1,2}(P_2)} = \overrightarrow{\alpha_{P_2}^{1,2}(P_1)}$, otherwise we swap the terminal pairs in the input instance. We guess in $O(n)$ time the discrete point $p \in \zeta(P_1)^{1,2} \cap \zeta(P_2)^{1,2}$ such that $\vec{p}^1$ is minimized. Let $A_i := \vec{s_i} \diamond \vec{p}$ and $B_i := \vec{p} \diamond \vec{t_i}$, for all $i \in [2]$. Now we construct a directed acyclic graph D on the vertices V such that there is an arc (v, w) if for some $i \in [2]$ we have (1) $\{v, w\} \in E$, (2) $\vec{v}^i + 1 = \vec{w}^i$, and (3) (a) $\vec{v} \in A_i \setminus B_i$ and $\vec{w} \in A_i$ or (b) $\vec{v} \in B_i$ and $\vec{w} \in B_i \setminus A_i$.

To add the edges with coordinates in $A_1 \cap B_2, A_2 \cap B_1$ to D, we observe that our assumption implies that $\zeta(P_1) \cap \zeta(P_2) \subseteq B_1 \cap B_2$. Hence, all edges where the vertices have coordinates in $A_i \cap B_j$ can only be used by either P_1 or P_2, for each $\{i, j\} = [2]$. Thus, we branch in four cases and add the edges accordingly. Note that D is acyclic and that each s_i-t_i-path in D corresponds to a shortest s_i-t_i-path in G going through point p. Hence, by Lemma 10 I is *yes*-instance if and only if there are disjoint s_i-t_i-path in D, for all $i \in [2]$. Thus, we apply an $O(n+m)$-time algorithm of Tholey [14] for 2-Disjoint Paths on a DAG. This yields a total running time of $O(nm)$. ◀

4 The Geometry of Many Shortest Paths

In the previous section, we looked at two shortest paths P and Q from s_P to t_P and s_Q and t_Q respectively. We showed that selecting at most six vertices from P and Q (three per path; see Definition 15) is sufficient to ensure that each pair of shortest s_P-t_P- and s_Q-t_Q-paths

that also contain the vertices $\mathcal{C}_P^{a,b}(Q)$ and $\mathcal{C}_Q^{a,b}(P)$, respectively, "behave" like P and Q in the sense of using the same coordinates or not (see Proposition 16). In this section, we define a set $\mathcal{C}$, $|\mathcal{C}| \in O(k \cdot k!)$, that basically ensures the same properties for k paths. To formalize our goal in this section, we introduce the concept of *avoiding* paths.

▶ **Definition 17** (I-avoiding). *Let $\emptyset \subset I \subseteq [k]$. We say that two paths P and Q are* I-avoiding *if $p \notin^I Q$ holds for every internal vertex p of P and $q \notin^I P$ for every internal vertex q of Q.*

We further call two vertex pairs (s_p, t_p) and (s_q, t_q) I-avoiding, if $(\vec{s_p}^I \diamond \vec{t_p}^I) \cap (\vec{s_q}^I \diamond \vec{t_q}^I) \subseteq \{\vec{s_p}^I, \vec{t_p}^I\} \cap \{\vec{s_q}^I, \vec{t_q}^I\}$.

Note that being I-avoiding implies being I'-avoiding for all $I' \supseteq I$. We use *avoiding* as a shorthand for $[k]$-avoiding. The reason for defining *avoiding* in such a way that the endpoints of the paths play a special role is as follows: When partitioning a colored path $P = v_1 \dots v_\ell$ into two subpaths $P' = v_1 \dots v_j$ and $P'' = v_j v_{j+1} \dots v_n$, then these two subpaths obviously share exactly one vertex, namely v_j. However, we still want to call the pairs $(\vec{v_1}, \vec{v_j})$ and $(\vec{v_j}, \vec{v_\ell})$ avoiding since these two subpaths cannot have any other intersection besides $\vec{v_j}$.

Two paths P_1 and P_2 are internally disjoint if neither of them contains an internal vertex of the other path. Avoiding paths are clearly internally disjoint.

▶ **Observation 18.** *Let P, Q be two avoiding paths. Then P is internally disjoint from Q.*

Moreover, avoiding vertex pairs (s, t) and (u, w) ensure that the corresponding shortest s-t- and u-v-paths are internally disjoint.

▶ **Lemma 19** ($\star$). *Let (s, t) and (u, w) be two colored pairs of vertices. If (s, t) and (u, w) are avoiding, then each shortest s-t-path is internally disjoint from each shortest u-w-path.*

With the notation of avoiding pairs, we can formulate our goal for this section. To this end, fix a solution $\mathcal{P} = (P_i)_{i \in [k]}$ for the k-DSP instance $(G, (s_i, t_i)_{i \in [k]})$, that is, P_i is the s_i-t_i-path in this solution. Essentially, we want to partition the paths in $\mathcal{P}$ into subpaths and assign labels (subsets of $[k]$) to each subpath such that the following holds:

(1.) Let P be a subpath with labels $\Phi \subseteq [k]$. For each $a \in \Phi$, P is a-colored.

(2.) Let P and Q be subpaths from s_P to t_P and s_Q and t_Q with labels $\Phi_P, \Phi_Q \subseteq [k]$ respectively. If $\Phi_P \neq \Phi_Q$, then (s_P, t_P) and (s_Q, t_Q) are avoiding.

Note that (2.) will be the central argument in our algorithm for k-DSP. The algorithm guesses the endpoints of these subpaths and based on (2.), the algorithm can compute the interior points of subpaths with different label sets independently of each other.

Note that for $k = 2$ the partition of P_1 and P_2 along the sets $\mathcal{C}_{P_1}^{1,2}(P_2)$ and $\mathcal{C}_{P_2}^{1,2}(P_1)$, respectively, satisfies the above two points: Each subpath of P_i, $i \in [2]$, has label i. Moreover, the subpaths between the α and ω-vertices have both labels 1 and 2. Hence, (1.) above is satisfied. Furthermore, (2.) essentially follows from Proposition 16.

We now give some intuition on how to lift this to arbitrary fixed k leading to Definition 20, a generalization of Definition 15. Initially, each path P_i has label i. Whenever two paths P_i and P_j in the solution intersect in the (i, j)-projection (that is, we have α and ω vertices), then the subpaths in the intersection gets both labels i and j. If a third path P' also intersects with the subpath of P_j that intersects with P_i, then we try to use the intersections to move the label i via path P_j to some subpath of P'. Generalizing this, we consider for each sequence $\sigma = (\ell_1, \dots, \ell_h)$ whether label ℓ_1 could be "transported" from P_{ℓ_1} to P_{ℓ_2}, from P_{ℓ_2} to P_{ℓ_3}, ..., and from $P_{\ell_{h-1}}$ to P_{ℓ_h}. The reason for doing it this way is that we will have for each such sequence $\sigma = (\ell_1, \dots, \ell_h)$ at most one consecutive subpath on P_{ℓ_h} that has label ℓ_1 transported via σ. While the idea of transporting labels would also work with triplets (transport label a via path P_b to path P_c), we do not have any bound on the number of resulting subpaths (as for each triplets there might be many such subpaths).

In order to formalize this idea and define the *crossing set* $\mathcal{C}$ of these paths (Definition 20), we need some notation. Let $\sigma = (\ell_1, \dots, \ell_h)$ be a sequence. We define $\text{set}(\sigma) := \{\ell_1, \dots, \ell_h\}$ to be the set with all entries of σ. For a path $P = v_0 \dots v_h$ and $1 \leq i < j \leq h$ let $P[v_i, v_j] := v_i \dots v_j$ be the subpath of P with endpoints v_i and v_j. The set $\mathcal{C}$ for each permutation σ of each $\Phi \subseteq [k]$ is recursively defined as follows. Therein, $\mathcal{T}$ describes the first and last vertex on the respective subpath having exactly the set of labels in Φ.

▶ **Definition 20.** *For each $\Phi \subseteq [k]$ and each permutation $\sigma = (\ell_1, \dots, \ell_h)$ of Φ set:*

- *If $h = 1$ with $\sigma = (i)$, then set $\mathcal{C}^\sigma := \mathcal{T}(\sigma) := \{s_i, t_i\}$.*
- *If $h = 2$ with $\sigma = (i, j)$, then set $\mathcal{T}(\sigma) := \{\alpha^{i,j}_{P_j}(P_i), \omega^{i,j}_{P_j}(P_i)\}$, and $\mathcal{C}^\sigma := \mathcal{C}^{i,j}_{P_j}(P_i)$.*
- *If $h \geq 3$, then let $\sigma_{start} := (\ell_1, \dots, \ell_{h-1})$, $\sigma_{end} := (\ell_2, \dots, \ell_h)$. If $\mathcal{T}(\sigma_{start}) = \{\perp\}$ or $\mathcal{T}(\sigma_{end}) = \{\perp\}$ or $Q := P_{\ell_{h-1}}[\mathcal{T}(\sigma_{start})] \cap P_{\ell_{h-1}}[\mathcal{T}((\ell_h, \ell_{h-1}))] = \emptyset$, then set $\mathcal{T}(\sigma) := \mathcal{C}^\sigma := \{\perp\}$. Otherwise, let $P := P_{\ell_h}[\mathcal{T}(\sigma_{end})]$. Then set $\mathcal{T}(\sigma) := \{\alpha^{\ell_1,\ell_h}_P(Q), \omega^{\ell_1,\ell_h}_P(Q)\}$. Moreover, set $\mathcal{C}^\sigma := \mathcal{C}^{\ell_1,\ell_h}_P(Q) \cup \mathcal{C}^{\ell_1,\ell_h}_Q(P)$.*

The set $\mathcal{C} := \bigcup_\sigma \mathcal{C}^\sigma$ is the crossing set *of $\mathcal{P}$.*

As subsequently shown, when transporting the labels via a sequence $\sigma = (\ell_1, \dots, \ell_h)$, the intersecting subpath in the target path P_{ℓ_h} agrees in all coordinates in $\text{set}(\sigma)$ with the subpath of $P_{\ell_{h-1}}$ where the label is transported from.

▶ **Lemma 21 (⋆).** *Let $\sigma := (\ell_1, \dots, \ell_h)$ be any permutation of any $\Phi \subseteq [k]$ with $|\Phi| = h \geq 2$. If $\mathcal{T}(\sigma) \neq \{\perp\}$, then $P_{\ell_h}[\mathcal{T}(\sigma)] =^\Phi Q'$ for some subpath Q' of $Q := P_{\ell_{h-1}}[\mathcal{T}(\sigma_{start})] \cap P_{\ell_{h-1}}[\mathcal{T}((\ell_h, \ell_{h-1}))]$ where $\sigma_{start} := (\ell_1, \dots, \ell_{h-1})$.*

We next formalize the notions used in the context of the intersection of $\mathcal{C}$ with the paths $\mathcal{P}$.

▶ **Definition 22.** *An* i-marble path *T is a set of vertices such that $\{s_i, t_i\} \subseteq T$ and for each $u, v \in T$ the pair (u, v) is i-colored. A* segment *S of a i-marble path T is a subset of T containing two vertices denoted* $\text{start}(S)$ *and* $\text{end}(S)$ *and all vertices $v \in T$ with* $\text{start}(S) <^i v <^i \text{end}(S)$*. A segment is minimal if it contains exactly two vertices.*

We say a segment is i-colored, if $(\text{start}(S), \text{end}(S))$ is i-colored. We say two segments S and S' are avoiding if the minimal subsegments of S and S' are pairwise avoiding.

We say a path P follows *S if it is i-colored, has end vertices* $\text{start}(S)$ *and* $\text{end}(S)$*, and $S \subseteq V(P)$.*

To prove the central statement of this section, we need to formalize the labels of a segment. To this end, let S_i be a segment of P_i. Then set

$$\mathit{labels}[S_i] := \{a \mid \exists \sigma = (a = \ell_1, \dots, \ell_h = i), h \geq 1 \colon S_i \subseteq P_i[\mathcal{T}(\sigma)]\}.$$

▶ **Proposition 23 (⋆).** *For $i, j \in [k]$ let $S_i \subseteq V(P_i) \cap \mathcal{C}$ and $S_j \subseteq V(P_j) \cap \mathcal{C}$ be two minimal segments. If $\mathit{labels}[S_i] \neq \mathit{labels}[S_j]$, then S_i and S_j are avoiding.*

5 The Algorithm: Utilizing the Geometry

In this section, we finally present the algorithm behind Theorem 2. Pseudo-code for this algorithm is listed in Algorithm 1. In a nutshell, we first guess all marble paths T_i and the map $\mathcal{T}$ corresponding to the crossing set $\mathcal{C}$ of some solution (if one exists). Then, we find all minimal segments of each marble path T_i and partition them such that (1) all minimal segments in the same part of the partition are strictly monotone in the same set of

Algorithm 1 Our algorithm for k-DSP.

```
1  function solve(G, (s_i, t_i)_{i∈[k]})
2      foreach guess (T_i)_{i∈[k]}, Ends of the crossing set do
           /* We assume now that the guess is correct, that is, for a
              solution P = (P_i)_{i∈[k]} we have T_i = C ∩ P_i, i ∈ [k], & Ends = T   */
3          P_i = ∅, for all i ∈ [k]
4          foreach minimal segment S of some T_i, i ∈ [k] do
5              marks[S] ← ∅
6              foreach sequence σ = (ℓ_1, ℓ_2, ..., i) with S ⊆ Ends(σ) do
7                  marks[S] ← marks[S] ∪ set(σ)
8              j ← min marks[S]
9              x ← arg min{ v⃗^j | v ∈ {start(S), end(S)} }
10             y ← arg max{ v⃗^j | v ∈ {start(S), end(S)} }
11             P_j = P_j ∪ {(x, y)}
12         foreach j ∈ [k] do Order P_j = ((x_1, y_1), (x_2, y_2), ...) so that x⃗_1^j ≤ x⃗_2^j ≤ ...
13         if all instances (D(G, i), P_i), i ∈ [k] of |P_i|-Disjoint Paths on i-layered
            DAGs are yes-instances and the combined solutions form a solution of
            k-DSP then return yes
14     return no
```

coordinates, and (2) two minimal segments in distinct parts of the partition are avoiding. The crucial improvement over the algorithm of Lochet [12] is that our partition is much smaller. Afterwards, we find shortest disjoint paths for each part of our partition separately via dynamic programming.

To this end, we introduce *c-layered DAGs* and the p-Disjoint Paths on DAGs problem. For a graph G with coordinates $\vec{v}$ (as defined in Section 3) for all $v \in V$, the c-layered DAG $D(G, c)$ of G is the directed graph $(V(G), A)$, where $(x, y) \in A$ if and only if $\{x, y\} \in E(G)$ and $\vec{y}^c - \vec{x}^c = 1$. Crucial here is the following simple observation.

▶ **Observation 24.** *A path P in G is c-colored if and only if $(V(P), \{(u, v) \mid \{u, v\} \in E(P), \vec{v}^c - \vec{u}^c = 1\})$ is a path in the c-layered DAG of G.*

In p-Disjoint Paths on DAGs we are given a directed acyclic graph D and a list $(s_i, t_i)_{i\in[p]}$ of (possibly intersecting) terminal pairs, and ask whether there are pairwise internally disjoint s_i-t_i-path in D, for each $i \in [p]$. Fortune et al. [7] showed a $n^{O(p)}$-time algorithm for p-Disjoint Path on DAGs. A straight-forward dynamic program yields a more specific running time of $O(n^{p+1})$.

▶ **Lemma 25** (⋆). *An instance of p-Disjoint Paths on DAGs on a graph with n vertices can be solved in $O(n^{p+1})$ time.*

▶ **Lemma 26** (⋆). *Algorithm 1 runs in $O(k \cdot n^{16k \cdot k! + k + 1})$ time.*

For the correctness of Algorithm 1, we need to show that each part of the partition of minimal segments can be solved independently. This follows from Proposition 23 together with the fact that Algorithm 1 exhaustively tries all possibilities for the crossing set $\mathcal{C}$. Together with Lemma 26, this implies Theorem 2.

6 Conclusion

We provided an improved polynomial-time for k-DSP. However, while the running time of our algorithm can certainly be slightly improved by some case distinctions and a more careful analysis, the algorithm is still far from being practical. Reducing the factor in the exponent to a polynomial in k is a clear challenge for future work. Considering the fine-grained complexity of 2-DSP, it would be interesting to know whether there are running time barriers based on e. g. the Strong Exponential Time Hypothesis.

Concerning generalizations of k-DSP, we believe that we can modify our algorithm in a straight-forward way to work with positive edge-lengths. However, the case of non-negative edge-lengths seems much more difficult. Our basic geometric observations made in Section 3 crucially depend on the fact that we are looking for shortest paths. Thus, if there are no k disjoint shortest paths, then computing k disjoint paths minimizing their total length in polynomial time is still an open problem for $k \geq 3$ (for $k = 2$ Björklund and Husfeldt [4] provided a randomized $O(n^{11})$ time algorithm and moreover proved that this problem is contained in NC if the graph is planar and cubic [3]).

Deterministic Rounding of Dynamic Fractional Matchings

Sayan Bhattacharya
Department of Computer Science, University of Warwick, Coventry, UK

Peter Kiss
Department of Computer Science, University of Warwick, Coventry, UK

Abstract

We present a framework for *deterministically* rounding a dynamic fractional matching. Applying our framework in a black-box manner on top of existing fractional matching algorithms, we derive the following new results: (1) The first deterministic algorithm for maintaining a $(2-\delta)$-approximate maximum matching in a fully dynamic bipartite graph, in arbitrarily small polynomial update time. (2) The first deterministic algorithm for maintaining a $(1+\delta)$-approximate maximum matching in a decremental bipartite graph, in polylogarithmic update time. (3) The first deterministic algorithm for maintaining a $(2+\delta)$-approximate maximum matching in a fully dynamic general graph, in *small* polylogarithmic (specifically, $O(\log^4 n)$) update time. These results are respectively obtained by applying our framework on top of the fractional matching algorithms of Bhattacharya et al. [STOC'16], Bernstein et al. [FOCS'20], and Bhattacharya and Kulkarni [SODA'19].

Previously, there were two known general-purpose rounding schemes for dynamic fractional matchings. Both these schemes, by Arar et al. [ICALP'18] and Wajc [STOC'20], were randomized.

Our rounding scheme works by maintaining a good *matching-sparsifier* with bounded arboricity, and then applying the algorithm of Peleg and Solomon [SODA'16] to maintain a near-optimal matching in this low arboricity graph. To the best of our knowledge, this is the first dynamic matching algorithm that works on general graphs by using an algorithm for low-arboricity graphs as a black-box subroutine. This feature of our rounding scheme might be of independent interest.

1 Introduction

The central question in the area of *dynamic algorithms* is to understand how can we efficiently maintain a good solution to a computational problem, when the underlying input changes over time [26, 28]. In the past decade, an extensive body of work in this area has been devoted to the study of *dynamic matching* [1, 5, 6, 7, 8, 10, 11, 17, 22, 24, 34, 35, 38, 39].

A matching $M \subseteq E$ in G is a set of edges that do not share any common endpoint. In the dynamic matching problem, the input is a graph $G = (V, E)$ that keeps getting updated via edge insertions/deletions, and the goal is to maintain an approximately *maximum matching* in G with small (preferably polylogarithmic) update time, where the phrase "update time" refers to the time it takes to handle an "update" (edge insertion/deletion) in G.[1] From the current landscape of dynamic matching, we can identify a common template that underpins a number of existing algorithms for this problem. This template consists of three steps.

[1] An algorithm has an "amortized" update time of $O(\tau)$ iff starting from an empty graph, it can handle any sequence of κ edges insertions/deletions in $O(\tau \cdot \kappa)$ total time.

Step (I). Design an efficient dynamic algorithm that maintains an approximately maximum *fractional matching*[2] $w : E \to [0, 1]$ in the input graph $G = (V, E)$. All the known algorithms for this first step are deterministic [9, 12, 13, 15, 14, 16, 23].

Step (II). Maintain a *sparse* (bounded-degree) subgraph $S = (V, E_S)$ of the input graph, with $E_S \subseteq E$, that approximately preserves the size of maximum matching [3, 40]. In a bit more details, the subgraph S should have the property that $\mu(S)$ is very close to $size(w)$, where $\mu(S)$ denotes the size of maximum (integral) matching in S, and $size(w) = \sum_{e \in E} w(e)$ denotes the size of the fractional matching w from the previous step. Such a subgraph S is often referred to as a *matching-sparsifier* of G [4]. There are two known algorithms for this second step and both of them are randomized, in sharp contrast to Step (I). Specifically, Arar et al. [3] designed a randomized rounding scheme for sparsifying a dynamic fractional matching. Their algorithm works only in the *oblivious adversary* setting, where the future updates cannot depend on the past actions taken by the algorithm. This result was very recently improved upon by Wajc [40], who presented an elegant dynamic rounding scheme for Step (II) that, although randomized, works in a much more general *adaptive adversary* setting, where the future updates to the algorithm can depend on all its past random bits.

Step (III). Maintain a near-optimal matching in the (bounded-degree) sparsifier S from the previous step, using a known algorithm by Gupta et al. [25], which has $O(\Delta)$ update time on dynamic graphs with maximum degree $\leq \Delta$. Since S has bounded degree, the third step incurs only a small overhead in the update time. The algorithm in [25] is also deterministic.

A natural question arises from the preceding discussion. Can we design an efficient *deterministic* dynamic algorithm for Step (II)? Since Step (I) and Step (III) are already deterministic, an efficient deterministic algorithm for Step (II) will allow us to derandomize multiple existing results in the literature on dynamic matching. We resolve this question in the affirmative. Specifically, our main result is summarized in the theorem below.

▶ **Theorem 1.** *Fix any small constant $\delta > 0$. Consider a dynamic graph $G = (V, E)$ on n nodes and a (dynamic) fractional matching w in G. In this setting, an update either inserts/deletes an edge in $G = (V, E)$ or changes the weight $w(e)$ of an existing edge $e \in E$. We can deterministically maintain a subgraph $S = (V, E_S)$ of G, with $E_S \subseteq E$, such that:*

1. *There exists a fractional matching $h' : E_S \to [0, 1]$ in S with $size(w) \leq (1 + \delta) \cdot size(h')$.*
2. *If w is a (δ, δ)-approximate maximal matching in G, then $\mu(G) \leq (2 + \delta) \cdot \mu(S)$.*
3. *The arboricity of S is $O(\log^2 n)$.*
4. *Every update in G or w, on average, leads to $O(\log^2 n)$ updates in S.*
5. *Our dynamic algorithm for maintaining S has $O(\log^2 n)$ amortized update time.*

Bounded arboricity matching-sparsifiers. We will shortly explain part-(2) of Theorem 1, which uses the notion of a (δ, δ)-*approximate maximal matching* that has not been defined yet. For now, we focus on an intriguing feature of Theorem 1, namely, that it only maintains a subgraph S with bounded *arboricity*.[3] This is in sharp contrast to all previous work on dynamic matching-sparsifiers: they satisfy the strictly stronger requirement of bounded

[2] A fractional matching w in G assigns a weight $w(e) \in [0, 1]$ to every edge $e \in E$, ensuring that the total weight assigned to all the edges incident on any given node is ≤ 1.

[3] Informally, an undirected graph $G' = (V', E')$ has arboricity κ if we can assign a direction to each of its edges $e \in E'$ in such a way that every node $v \in V'$ gets an out-degree of at most $O(\kappa)$. If a graph has maximum degree at most κ, then its arboricity is also $O(\kappa)$, but not vice versa.

maximum degree [3, 40]. Our algorithm exploits this feature in a crucial manner, allowing certain nodes to have large degrees in S while ensuring that the arboricity of S remains at most $O(\log^2 n)$. This does not cause any problem in the overall scheme of things, however, because Peleg and Solomon [37] have shown how to deterministically maintain a $(1+\delta)$-approximate maximum matching in $O(\Delta)$ update time in a dynamic graph with arboricity $\leq \Delta$. Their algorithm allows us to efficiently maintain a near-optimal matching in S.

To summarize, there is an existing line of work on dynamic matching which deal with the special class of low-arboricity graphs [29, 34, 37]. Theorem 1 shows that if we have a good dynamic matching algorithm for low-arboricity graphs, then we can use it in a black-box manner to design better dynamic matching algorithms for *general graphs* as well.

Implications of Theorem 1. We start by focussing on bipartite graphs. If a graph G is bipartite, then the size of a maximum fractional matching in G is equal to $\mu(G)$. Accordingly, part-(1) of Theorem 1 implies that if the input graph G is bipartite, then our dynamic algorithm maintains a sparsifier $S = (V, E_S)$ such that $size(w) \leq (1+\delta) \cdot \mu(S)$. We can now run the dynamic algorithm from [37] on S, which has small arboricity, to efficiently maintain a near-optimal (integral) matching $M \subseteq E_S$ with $size(w) \leq (1+\delta) \cdot |M|$.

Bhattacharya et al. [14] gave a deterministic algorithm for maintaining $(2-\epsilon)$-approximate maximum *fractional* matchings in bipartite graphs with arbitrarily small polynomial update time. Applying our dynamic rounding framework on top of this result from [14], we get the *first deterministic* algorithm for dynamic (integral) matchings in bipartite graphs with the same approximation ratio and similar update time, as summarized in the theorem below.

▶ **Theorem 2.** *For every constant $k \geq 10$, there exists a $\beta_k \in (1,2)$, and a* deterministic *dynamic algorithm that maintains a β_k-approximate maximum matching in an n-node bipartite graph with $O(n^{1/k} \cdot \log^4 n)$ amortized update time.*

Next, very recently Bernstein et al. [9] showed how to maintain a $(1+\delta)$-approximate maximum *fractional* matching in a bipartite graph with $O(\log^3 n)$ amortized update time in the *decremental* setting, where the input graph only undergoes edge-deletions. Applying our dynamic rounding framework on top of their result, we get the *first deterministic* algorithm for maximum (integral) matching in an analogous decremental setting, with the same approximation ratio and similar update time. This is stated in the theorem below.

▶ **Theorem 3.** *We can* deterministically *maintain a $(1+\delta)$-approximate maximum matching in a decremental bipartite graph on n nodes with $O(\log^7 n)$ amortized update time.*

Moving on to general graphs, we note that if a graph $G = (V, E)$ is non-bipartite, then the size of a maximum fractional matching can be as large as $(3/2) \cdot \mu(G)$. Thus, if we are to naively apply our dynamic rounding framework based on the guarantee given to us by part-(1) of Theorem 1, then we will lose out on a factor of $3/2$ in the approximation ratio. This is where part-(2) of Theorem 1 comes in handy. Specifically, as in [3, 40], we invoke the notion of an (α, β)-*approximate maximal matching* (see Definition 6).

To see why this notion is useful for us, consider the result of Bhattacharya and Kulkarni [16], who designed a deterministic dynamic algorithm for $(2+\delta)$-approximate maximum *fractional* matching, for small constant $\delta > 0$, in general graphs with $O(1)$ amortized update time. Furthermore, the fractional matching maintained by [16] is (δ, δ)-approximately maximal. Thus, applying Theorem 1 on top of this result from [16], we can deterministically maintain a sparsifier $S = (V, E_S)$ of the input graph G with $\mu(G) \leq (2+\delta) \cdot \mu(S)$. We can now maintain a near-optimal maximum matching $M \subseteq E_S$ in S, using the algorithm of [37]. Since $\mu(G) \leq (2+\delta) \cdot \mu(S)$, M will be a $(2+\delta)$-approximate maximum (integral) matching in G. Putting everything together, we get the result summarized in the theorem below.

▶ **Theorem 4.** *We can* deterministically *maintain a* $(2+\delta)$*-approximate maximum matching in an* n*-node dynamic graph with* $O(\log^4 n)$ *amortized update time, for small constant* $\delta > 0$.

Prior to our work, the only *deterministic* dynamic algorithm for $(2+\delta)$-approximate maximum matching in general graphs with polylogarithmic update time was due to Bhattacharya et al. [14]. The exact polylogarithmic factor in the update time of [14] was huge (more than $\log^{20} n$), and the algorithm of [14] was significantly more complicated than ours.

Perspective. Existing techniques for proving update-time lower bounds for dynamic problems cannot distinguish between deterministic and randomized algorithms [2, 27, 30, 31, 36]. Thus, understanding the power of randomization in the dynamic setting is an important research agenda, which comprises of two separate strands of work. (1) Studying the power of the *oblivious adversary* assumption while designing a randomized algorithm for a given dynamic problem. (2) Studying the separation between randomized algorithms that work against *adaptive adversaries* on the one hand, and deterministic algorithms on the other. Our work falls under the second category. A recent breakthrough result under this category has been a deterministic algorithm for dynamic minimum spanning forest with worst-case subpolynomial update time [18, 21]. This improves upon earlier work which achieved the same update time guarantee for dynamic minimum spanning forest, but using a randomized algorithm that works against adaptive adversary [32]. There are other well-studied dynamic problems where currently we have polynomial gaps between the update times of the best-known deterministic algorithm and the best-known randomized algorithm against adaptive adversary [19, 20]. Bridging these gaps remain challenging open questions.

Our Techniques. The key ingredient in our rounding scheme is a simple *degree-split* procedure. Given any graph $G' = (V', E')$ as input, this procedure runs in linear time and outputs a subgraph $G'' = (V', E'')$ where the degree of every node $v \in V'$ drops by a factor of $(1/2) \cdot (1 \pm \epsilon)$, provided the initial degree of v in G' was larger than $(1/\epsilon)$. See Algorithm 3.

Using this degree-split procedure, we first design a simple *static* algorithm for sparsifying a *uniform* fractional matching w (which assigns the same weight to every edge) in an input graph $G = (V, E)$. This works in rounds. In each round, we start by repeatedly removing the nodes with degree at most $(1/\epsilon)$, until we are left with a graph $G' = (V', E')$ where every remaining node has degree larger than $(1/\epsilon)$. We now apply the degree-split procedure on $G' = (V', E')$ to obtain a subset of edges $E'' \subseteq E'$, double the weight of every edge $e \in E''$, and discard the edges $e \in E'' \setminus E'$ from the support of the fractional matching. Since the degree-split procedure reduces the degree of every node in V' by (approximately) a factor of $1/2$, it follows that we (approximately) preserve the total weight received by every node while implementing a given round. We can show that if we continue with this process for (roughly) logarithmic many rounds, then we end up with a bounded-arboricity subgraph of the input graph G that approximately preserves the size of the fractional matching w. In the dynamic setting, we try to mimic this static algorithm in a natural lazy manner.

When the input is a dynamic graph G and a (not necessarily uniform) fractional matching w, then, roughly speaking, we first discretize w and then decompose it into $O(\log n)$ many uniform fractional matchings, defined on mutually edge-disjoint subgraphs of G. We run a dynamic algorithm for sparsifying a uniform fractional matching on each of these subgraphs, and we maintain the union of the outputs of all these $O(\log n)$ many dynamic sparsifiers.

2 Notations and Preliminaries

Throughout this paper, we let $G = (V, E)$ denote the input graph, and $n = |V|$ will be the number of nodes in G. For any $v \in V$, $E' \subseteq E$ and $V' \subseteq V$, we let $E'(v, V') = \{(u, v) \in E' : u \in V'\}$ denote the set of edges in E' that are incident on v and have their other endpoints in V'. To ease notations, we define $E'(v) := E'(v, V)$. We also define $\deg_{E'}(v, V') := |E'(v, V')|$ and $\deg_{E'}(v) := |E'(v)|$. Furthermore, given any subset of edges $E' \subseteq E$, we let $V(E') = \bigcup_{(u,v)\in E'} \{u, v\}$ denote the set of endpoints of the edges in E'. Throughout the rest of this paper, we will consider δ to be some small constant, and we will fix two more parameters β and ϵ as stated below.

$$10^{-3} \geq \delta = 20 \cdot \beta = 5000 \cdot \epsilon \cdot \log n > 0. \tag{1}$$

Given any subset of edges $E' \subseteq E$, a *weight-function* $w' : E' \to [0, 1]$ assigns a (possibly fractional) weight $0 \leq w'(e) \leq 1$ to every edge $e \in E'$. We say that E' is the *support* of w' and write $\textsc{Support}(w') := E'$. The *size* of the weight-function w' is defined as $size(w') := \sum_{e\in E'} w'(e)$. For any node $v \in V$, let $w'(v) := \sum_{(u,v)\in E'} w'(u, v)$ denote the total weight received by v from all its incident edges under the weight-function w'. We say that w' is a *fractional matching* in the graph $G' := (V, E')$ iff $w'(v) \leq 1$ for all $v \in V$. Since $E' \subseteq E$, we often abuse notation to say that such a weight-function w' is a fractional matching in $G = (V, E)$ as well. For any $0 \leq \lambda \leq 1$, we say that w' is a λ-*uniform* weight-function (or, fractional matching, if $w'(v) \leq 1$ for all $v \in V$) iff $w'(e) = \lambda$ for all edges $e \in E'$.

Let $\mu(G')$ and $\mu_f(G')$ respectively denote the size of maximum matching and the size of maximum fractional matching in a graph G'. We will use the following well-known theorem.

▶ **Theorem 5.** *Consider any graph G'. If G' is bipartite, then $\mu(G') = \mu_f(G')$. Otherwise, we have $\mu(G) \leq \mu_f(G') \leq (3/2) \cdot \mu(G)$.*

We will use the notion of an *approximately maximal* matching as in Arar et al. [3].

▶ **Definition 6.** *Consider any graph $G' = (V', E')$ and a fractional matching w' in G'. We say that w' is a (α, β)-approximately maximal matching in G' iff the following holds. For every edge $(u, v) \in E'$, either (1) $\{w'(u, v) \geq \beta\}$, or (2) $\{$there is at least one endpoint $x \in \{u, v\}$ such that $w'(x) \geq 1 - \alpha$ and $w'(x, y) < \beta$ for all edges $(x, y) \in E'$ incident on $x\}$.*

An *orientation* of a graph $G' = (V', E')$ assigns a direction to every edge $(u, v) \in E'$. For the rest of this paper, whenever we say that a graph G' has *arboricity* $O(\kappa)$, we mean that G' admits an orientation of its edges where the maximum out-degree of a node is $O(\kappa)$ [33].

3 A Static Algorithm for Sparsifying a Uniform Fractional Matching

In this section, we present a simple static algorithm for sparsifying a uniform fractional matching. This will form the basis of our dynamic algorithm in Section 4 and Section 5.

As input, we receive a graph $G = (V, E)$ and a λ-uniform fractional matching $w : E \to [0, 1]$ in G, for some $\lambda \in [\delta/n^2, \beta)$. Define $L = L(\lambda)$ to be the largest integer k such that $\beta/2 \leq 2^k\lambda < \beta$. Since δ is a constant and $\delta/n^2 \leq \lambda < \beta$, from (1) we infer that $L = O(\log n)$.

The algorithm proceeds in *rounds* $i \in \{0, \ldots, L - 1\}$. Before the start of round $i = 0$, we initialize $E^{(\geq 0)} := E$, $V^{(\geq 0)} := V$, $G^{(\geq 0)} := \left(V^{(\geq 0)}, E^{(\geq 0)}\right)$ and $\gamma^{(0)} := w$. Thus, $\gamma^{(0)}$ is a λ-uniform fractional matching in G. In each round i, we identify a subset of edges $F^{(i)} \subseteq E^{(\geq i)}$ that get *frozen*, in the sense that they are *not* considered in subsequent rounds. Define $\mathcal{F}^{(i)} := E^{(\geq i)} \bigcup_{j=0}^{i-1} F^{(j)}$ and $\mathcal{H}^{(i)} := (V, \mathcal{F}^{(i)})$ for all $i \in [0, L]$. The following invariant will be satisfied in the beginning of each round $i \in [0, L]$. The weight-function $\gamma^{(i)} : \mathcal{F}^{(i)} \to [0, 1]$ ensures that $\gamma^{(i)}(v) \simeq w(v)$ for all $v \in V$. Clearly, this invariant holds for $i = 0$.

Implementing a given round $i \in [0, L-1]$. Initialize $G' = (V', E') := G^{(\geq i)}$. There are two distinct *steps* in this round. During the first step, we keep iteratively removing the nodes with degree $\leq (1/\epsilon)$ from G'. Let $V^{(i)} \subseteq V^{(\geq i)}$ be the collection of nodes that get removed from G' in this manner, and let $F^{(i)} \subseteq E^{(\geq i)}$ denote the set of edges incident on $V^{(i)}$. Define $V^{(\geq i+1)} := V^{(\geq i)} \setminus V^{(i)}$. At the end of this first step, the status of $G' = (V', E')$ is as follows: $V' = V^{(\geq i+1)}$ and $E' = E^{(\geq i)} \setminus F^{(i)}$. Intuitively, we can afford to remove the nodes $V^{(\geq i)}$ from G' because the edges in $F^{(i)}$ admit an orientation with maximum out-degree $(1/\epsilon)$. At the end of this first step every node in G' has degree $\geq (1/\epsilon)$.

In the second step, we call a subroutine Degree-Split(E'), which returns a subset of edges $E'' \subseteq E'$ with the following property: $\deg_{E''}(v) \simeq (1/2) \cdot \deg_{E'}(v)$ for all nodes $v \in V'$. We will shortly see how to implement this Degree-Split subroutine. For now, we move ahead with the description of round i. We set $E^{(\geq i+1)} := E''$ and $G^{(\geq i+1)} := \big(V^{(\geq i+1)}, E^{(\geq i+1)}\big)$. Next, we discard the edges in $E' \setminus E^{(\geq i+1)}$ from the support of γ and double the weights on the remaining edges in $E^{(\geq i+1)}$. This leads us to a new weight-function $\gamma^{(i+1)} : \mathcal{F}^{(i+1)} \to [0, 1]$ in $\mathcal{H}^{(i+1)} = (V, \mathcal{F}^{(i+1)})$ which is defined as follows. For every edge $e \in \mathcal{F}^{(\geq i+1)}$, we have:

$$\gamma^{(i+1)}(e) = \begin{cases} 2 \cdot \gamma^{(i)}(e) & \text{if } e \in E^{(\geq i+1)}; \\ \gamma^{(i)}(e) & \text{else if } e \in \bigcup_{j=0}^{i} F^{(j)}. \end{cases} \tag{2}$$

At this point, if $i < L-1$, then we are ready to proceed to the next round $i+1$. Otherwise, if $i = L-1$, then we terminate the algorithm after setting $F^{(L)} := E^{(\geq L)}$ and $V^{(L)} := V^{(\geq L)}$.

Define $F := \bigcup_{i=0}^{L} F^{(i)}$, $H := (V, F)$, and $h := \gamma^{(L)}$. We will show that $H = (V, F)$ is a good matching-sparsifier for the λ-uniform matching w in the input graph $G = (V, E)$. The relevant pseudocodes are summarized in Algorithm 1, Algorithm 2 and Algorithm 3. For clarity of exposition, in some of these pseudocodes we use one additional notation $h^{(i)}$, which is basically a weight-function $h^{(i)} : F^{(i)} \to [0, 1]$ such that $h^{(i)}(e) = 2^i \lambda$ for all $e \in F^{(i)}$.

Implementing the Degree-Split(E')subroutine. Consider any graph $G^* = (V^*, E^*)$. A *walk* W in G^* is a set of distinct edges $\{(u_0, v_0), \ldots, (u_k, v_k)\} \subseteq E^*$ such that $v_i = u_{i+1}$ for all $i \in [0, k-1]$. Let $W^{(even)} = \{(u_{2i}, v_{2i}) : i \in [0, \lfloor k/2 \rfloor]\}$ denote the collection of even numbered edges from this walk W. The walk W is said to be *maximal* in G^* iff $\deg_{E^* \setminus W}(u_0) = \deg_{E^* \setminus W}(u_k) = 0$. When we call Degree-Split(E'), it first partitions the edge-set E' into a collection of walks $\mathcal{W}$ as specified in Algorithm 3. It then returns the set $E'' \subseteq E'$, which consists of all the even numbered edges from all the walks $W \in \mathcal{W}$.

▷ Claim 7. The subroutine Degree-Split(E') runs in $O(|E'|)$ time.

Proof. We can compute a maximal walk W in a given graph $G^* = (V^*, E^*)$ in $O(|W|)$ time. Hence, the total running time of Algorithm 3 is given by $\sum_{W \in \mathcal{W}} O(|W|) = O(|E'|)$. ◁

▷ Claim 8. In Algorithm 3, $\deg_{E''}(v) \in \left[\frac{\deg_{E'}(v)}{2} - 1, \frac{\deg_{E'}(v)}{2} + 1\right]$ for all nodes $v \in V(E')$.

Proof. Consider any graph $G^* = (V^*, E^*)$ and a walk $W = \{(u_0, v_0), \ldots, (u_k, v_k)\}$ in G^*. Let End$(W) = \{u_0, v_k\}$ denote the endpoints of this walk W, and let $V(W) = \bigcup_{i=0}^{k} \{u_i\} \bigcup_{i=0}^{k} \{v_i\}$ denote the set of all nodes touched by W. Note that $\deg_{W^{(even)}}(v) = (1/2) \cdot \deg_W(v)$ for all nodes $v \in V(W) \setminus$ End(W), and $\deg_{W^{(even)}}(v) \in [(1/2) \cdot \deg_W(v) - 1, (1/2) \cdot \deg_W(v) + 1]$ for all nodes $v \in$ End(W). Now, fix any node $v \in V(E')$, and observe that:

1. $\deg_{E''}(v) = \sum_{W \in \mathcal{W}} \deg_{W^{(even)}}(v)$ and $\deg_{E'}(v) = \sum_{W \in \mathcal{W}} \deg_W(v)$.
2. The definition of a maximal walk implies that $v \in$ End(W) for at most one $W \in \mathcal{W}$.

These observations, taken together, imply the claim. ◁

Algorithm 1 STATIC-UNIFORM-SPARSIFY($G = (V, E), \lambda$), where $\delta/n^2 \leq \lambda < \beta$.

Let $w : E \to [0, 1]$ be a λ-uniform fractional matching in G.
Initialize $V^{(\geq 0)} := V$ and $E^{(\geq 0)} := E$.
Initialize a weight-function $h^{(0)} : E^{(\geq 0)} \to [0, 1]$ so that $h^{(0)}(e) := \lambda$ for all $e \in E^{(\geq 0)}$.
Let $L := L(\lambda)$ be the unique nonnegative integer k such that $\beta/2 \leq 2^k\lambda < \beta$.
Call the subroutine REBUILD$(0, \lambda)$. (see Algorithm 2)
Define $F := \bigcup_{i=0}^{L} F^{(i)}$, and $H := (V, F)$.
Define $h : F \to [0, 1]$ such that for all $i \in [0, L]$ and $e \in F^{(i)}$ we have $h(e) := h^{(i)}(e)$.

Algorithm 2 REBUILD(i', λ).

for $i = i'$ to $(L - 1)$ **do**:
  $V^{(i)} \leftarrow \emptyset$.
  while there is some node $v \in V^{(\geq i)} \setminus V^{(i)}$ with $\deg_{E^{(\geq i)}}\left(v, V^{(\geq i)} \setminus V^{(i)}\right) \leq (1/\epsilon)$ **do**:
    $V^{(i)} \leftarrow V^{(i)} \cup \{v\}$.
  $V^{(\geq i+1)} \leftarrow V^{(\geq i)} \setminus V^{(i)}$.
  $F^{(i)} \leftarrow \{(u, v) \in E^{(\geq i)} : \text{ either } u \in V^{(i)} \text{ or } v \in V^{(i)}\}$.
  $E^{(\geq i+1)} \leftarrow$ DEGREE-SPLIT$(E^{(\geq i)} \setminus F^{(i)})$.
  for all edges $e \in E^{(\geq i+1)}$ **do**:
    $h^{(i+1)}(e) \leftarrow 2 \cdot h^{(i)}(e)$.
$F^{(L)} \leftarrow E^{(\geq L)}$.
$V^{(L)} \leftarrow V^{(\geq L)}$.

Algorithm 3 DEGREE-SPLIT(E').

Initialize $E^* \leftarrow E'$ and $\mathcal{W} \leftarrow \emptyset$.
while $E^* \neq \emptyset$ **do**
  Let $G^* := (V(E^*), E^*)$, where $V(E^*)$ is the set of endpoints of the edges in E^*.
  Compute a *maximal* walk W in G^*.
  Set $\mathcal{W} \leftarrow \mathcal{W} \cup \{W\}$, and $E^* \leftarrow E^* \setminus W$.
Return the set of edges $E'' := \bigcup_{W \in \mathcal{W}} W^{(even)}$.

Note that $h^{(i)}$ and $F^{(i)}$ represent global variables in the pseudocodes above.

▶ **Lemma 9.** *Algorithm 1 runs in $O(|E|)$ time.*

Proof. The runtime of Algorithm 1 is dominated by the call to REBUILD$(0, \lambda)$. Accordingly, focus on any given iteration $i \in [0, L - 1]$ of the outer FOR loop in Algorithm 2. During this iteration, using appropriate data structures the inner WHILE loop takes $O(|F^{(i)}|)$ time, the call to DEGREE-SPLIT$(E^{(\geq i)} \setminus F^{(i)})$ takes $O(|E^{(\geq i)} \setminus F^{(i)}|)$ time as per Claim 7, and the inner FOR loop takes $O(|E^{(\geq i+1)}|)$ time. Hence, the total time taken to implement iteration i of the outer FOR loop is at most $O(|E^{(\geq i)}|) + O(|E^{(\geq i)} \setminus F^{(i)}|) + O(|E^{(\geq i+1)}|) = O(|E^{(\geq i)}|)$.

Summing over all $i \in [0, L - 1]$, we derive that:

$$\text{The total runtime of Algorithm 1 is at most } \sum_{i=0}^{L-1} O\left(|E^{(\geq i)}|\right). \tag{3}$$

Next, fix an iteration i of the outer For loop in Algorithm 2, and focus on the call to Degree-Split($E^{(\geq i)} \setminus F^{(i)}$). The inner While loop ensures that $\deg_{E^{(\geq i)} \setminus F^{(i)}}(v) > (1/\epsilon)$ for all $v \in V^{(\geq i+1)}$. By Claim 8, the degree of every concerned node is (roughly) halved by a call to Degree-Split(.). Hence, $|E^{(\geq i+1)}| = O\left((1/2) \cdot |E^{(\geq i)}|\right)$ for all $i \in [0, L-1]$. Plugging this back into (3), the lemma follows since $\sum_{i=0}^{L-1} O\left(|E^{(\geq i)}|\right) = O\left(|E^{(\geq 0)}|\right) = O(|E|)$. ◀

We will next show that the subgraph $H = (V, F)$ returned by our algorithm is a good matching-sparsifier.Towards this end, we first derive the following important claim.

▷ Claim 10 (Informal). For all $v \in V$ and $i \in [0, L-1]$, we have $\gamma^{(i+1)}(v) \simeq (1+\epsilon) \cdot \gamma^{(i)}(v)$.

Proof. Let us track how starting from $\gamma^{(i)}$, the weight-function $\gamma^{(i+1)}$ is constructed during round i. Recall that Support $\left(\gamma^{(i)}\right) := E^{(\geq i)} \bigcup_{j=0}^{i-1} F^{(j)}$. During round i, we first identify the subset $F^{(i)} \subseteq E^{(\geq i)}$, and then identify another subset $E^{(\geq i+1)} \subseteq E^{(\geq i)} \setminus F^{(i)}$. As we switch from $\gamma^{(i)}$ to $\gamma^{(i+1)}$, the following three events occur: (1) The weights of the edges $e \in F^{(i)} \bigcup_{j=0}^{i-1} F^{(j)}$ do not change. (2) The edges $e \in \left(E^{(\geq i)} \setminus F^{(i)}\right) \setminus E^{(\geq i+1)}$ get discarded from the support of $\gamma^{(i+1)}$. (3) The weights of the remaining edges $e \in E^{(\geq i+1)}$ get doubled.

Now, fix any node $v \in V$. The claim follows from our analysis of the two cases below.

Case 1: $v \in V^{(\geq i+1)}$. In this case, the inner While loop in Algorithm 2 ensures that $\deg_{E^{(\geq i)} \setminus F^{(i)}}(v) > (1/\epsilon)$. Hence, applying Claim 8, we get: $\deg_{E^{(\geq i+1)}}(v) \simeq (1 \pm \epsilon) \cdot (1/2) \cdot \deg_{E^{(\geq i)} \setminus F^{(i)}}(v)$. To summarize, (about) half the edges in $E^{(\geq i)} \setminus F^{(i)}$ that are incident on v get discarded from the support of $\gamma^{(i+1)}$, while the remaining edges in $E^{(\geq i)} \setminus F^{(i)}$ double their weights. In contrast, the edges in $F^{(i)} \bigcup_{j=0}^{i-1} F^{(j)}$ that are incident on v do not change their weights at all. This implies that $\gamma^{(i+1)}(v) \simeq (1 \pm \epsilon) \cdot \gamma^{(i)}(v)$.

Case 2: $v \notin V^{(\geq i+1)}$. In this case, every edge $(u, v) \in$ Support $\left(\gamma^{(i)}\right)$ continues to remain in the support of $\gamma^{(i+1)}$ with the same weight. Hence, we get: $\gamma^{(i+1)}(v) = \gamma^{(i)}(v)$. ◁

▶ **Lemma 11** (Informal). *The weight-function $h : F \to [0, 1]$ satisfies three properties:*

1. *$h(e) < \beta$ for all edges $e \in F$.*
2. *$w(v) \simeq (1 \pm \epsilon L) \cdot h(v)$ for all nodes $v \in V$.*
3. *$size(w) \simeq (1 \pm \epsilon L) \cdot size(h)$.*

Proof. Before the start of round 0, we have $\gamma^{(0)}(e) = \lambda$ for all edges $e \in E^{(\geq 0)}$. Subsequently, in each round $i \in [0, L-1]$, the weight of each edge $e \in E^{(\geq i+1)}$ gets doubled. Hence, we have $h(e) = \gamma^{(L)}(e) \leq 2^L \lambda < \beta$ for all $e \in F$. This proves part-(1) of the lemma.

Next, fix any node $v \in V$. Before the start of round 0, we have $\gamma^{(0)} = w$ and hence $\gamma^{(0)}(v) = w(v)$. Subsequently, after each round $i \in [0, L-1]$, Claim 10 guarantees that $\gamma^{(i+1)}(v) \simeq (1 \pm \epsilon) \cdot \gamma^{(i)}(v)$. This gives us: $h(v) = \gamma^{(L)}(v) \simeq (1 \pm \epsilon)^L \cdot \gamma^{(0)}(v) \simeq (1 \pm \epsilon L) \cdot \gamma^{(0)}(v) \simeq (1 \pm \epsilon L) \cdot w(v)$. Finally, summing this (approximate) equality over all nodes $v \in V$, we get: $size(w) \simeq (1 \pm \epsilon L) \cdot size(h)$. This proves part-(2) and part-(3) of the lemma. ◀

Levels of nodes and edges. The *level* of a node $v \in V$ is defined as $\ell(v) := \max\{i \in [0, L] : v \in V^{(\geq i)}\}$. Similarly, the *level* of an edge $e \in E$ is defined as $\ell(e) := \max\{i \in [0, L] : e \in E^{(\geq i)}\}$. Since $V^{(i)} = V^{(\geq i)} \setminus V^{(\geq i+1)}$ for all $i \in [0, L]$, it follows that $\ell(v) = i$ iff $v \in V^{(i)}$.

▶ **Observation 12.** *For all $(u, v) \in F$, we have $\ell(u, v) = \min(\ell(u), \ell(v))$ and $(u, v) \in F^{(\ell(u,v))}$.*

Proof. Consider any edge $(u,v) \in F = \bigcup_{i=0}^{L} F^{(i)}$. W.l.o.g., suppose that $(u,v) \in F^{(j)}$ for some $j \in [0,L]$. Before the start of round 0, we have $(u,v) \in E^{(\geq 0)}$. During each round $i \in [0, j-1]$, the edge (u,v) gets included in the set $E^{(\geq i+1)}$, and both its endpoints u, v get included in the set $V^{(\geq i+1)}$. At round j, one of its endpoints (say, u) gets included in $V^{(j)}$, and the edge (u,v) also gets included in $F^{(j)}$. Since $F^{(j)} \subseteq E^{(\geq j+1)} \setminus E^{(\geq j)}$, we infer that $\ell(u) = j$, $\ell(v) \geq j$, and $\ell(u,v) = \max\left\{i \in [0,L] : (u,v) \in E^{(\geq i)}\right\} = j = \min(\ell(u), \ell(v))$. ◀

▶ **Observation 13.** *For every edge $(u,v) \in F$, we have $h(u,v) = 2^{\ell(u,v)} \cdot \lambda$.*

Proof. Suppose that $\ell(u,v) = i \in [0,L]$, and hence $(u,v) \in F^{(i)}$. Before the start of round 0, we have $(u,v) \in E^{(\geq 0)}$ and $\gamma^{(0)}(u,v) = \lambda$. During each round $j \in [0, i-1]$, the edge (u,v) gets included in $E^{(\geq j+1)}$ and we double its weight, i.e., we set $\gamma^{(j+1)}(u,v) := 2 \cdot \gamma^{(j)}(u,v)$. Thus, at the start of round i, we have $(u,v) \in E^{(\geq i)}$ and $\gamma^{(i)}(u,v) = 2^i \cdot \lambda$. During round i, the edge (u,v) gets included in the set $F^{(i)}$ and its weight is frozen for the subsequent rounds, so that we get: $2^i \cdot \lambda = \gamma^{(i)}(u,v) = \gamma^{(i+1)}(u,v) = \cdots = \gamma^{(L)}(u,v) = h(u,v)$. ◀

▶ **Lemma 14.** *The graph $H = (V,F)$ has arboricity at most $O\left(\epsilon^{-1} + \beta^{-1}\right) = O(\log n)$.*

Proof. For any nodes $u, v \in V$ with $\ell(u) = \ell(v) = i < L$, we say that u was assigned its level *before* v iff we had $u \in V^{(i)}$ just before the iteration of the inner WHILE loop in Algorithm 2 which adds v to $V^{(i)}$. We now define the following orientation of the graph $H = (V,F)$:

- Consider any edge $(u,v) \in F$. W.l.o.g. suppose that $\ell(u) \leq \ell(v)$. If $\ell(u) < \ell(v)$, then the edge is orientated *from u towards v*. Otherwise, if $\ell(u) = \ell(v) = L$, then the edge is oriented in any arbitrary direction. Finally, if $\ell(u) = \ell(v) < L$ and (say) the node u was assigned its level before the node v, then the edge is oriented *from u towards v*.

Fix any node $x \in V$. Define $\text{Out}_F(x) := \{(x,y) \in F :$ the edge (x,y) is oriented away from $x\}$. We will show that $|\text{Out}_F(x)| \leq O\left(\epsilon^{-1} + \beta^{-1}\right)$. The lemma will then follow from (1).

Case 1: $\ell(x) = i < L$. Let $X^- \subseteq V^{(\geq i)}$ be the set of nodes in $V^{(\geq i)}$ that are assigned the level i *before* the node x. In words, the symbol X^- denotes the status of the set $V^{(i)}$ just before x gets added to $V^{(i)}$ in Algorithm 2. For every edge $(x,y) \in \text{Out}_F(x)$, we have $y \in V^{\geq i} \setminus X^-$ and $(x,y) \in E^{(\geq i)}$. Hence, it follows that $|\text{Out}_F(x)| \leq \deg_{E^{(\geq i)}}(x, V^{(\geq i)} \setminus X^-) \leq \epsilon^{-1}$.

Case 2: $\ell(x) = L$. Consider any edge $(x,y) \in \text{Out}_F(x)$. Clearly, this implies that $\ell(y) = L$, and hence $\ell(x,y) = L$ by Observation 12. Thus, by Observation 13 we have $h(x,y) = 2^L \cdot \lambda \geq \beta/2$. In other words, $h(x,y) \geq \beta/2$ for all $(x,y) \in \text{Out}_F(x)$. Now, part-(2) of Lemma 11 implies that: $w(x) = \Omega(h(x)) = \Omega\left(\sum_{(x,y) \in \text{Out}_F(x)} h(x,y)\right) = \Omega\left(|\text{Out}_F(x)| \cdot (\beta/2)\right)$. Accordingly, we get: $w(x) = \Omega\left(|\text{Out}_F(x)| \cdot \beta\right)$, and hence: $|\text{Out}_F(x)| = O\left(\beta^{-1} \cdot w(x)\right) = O(\beta^{-1})$. The last inequality holds since $w(x) \leq 1$. ◀

To summarize, our static algorithm runs in linear time (Lemma 9), returns a subgraph $H = (V,F)$ with bounded arboricity (Lemma 14), and this subgraph H admits a fractional matching that closely approximates the input λ-uniform matching w in G (Lemma 11).

4 Dynamically Sparsifying a Uniform Fractional Matching

In this section, we will present a dynamic algorithm for sparsifying a uniform fractional matching, which will be referred to as DYNAMIC-UNIFORM-SPARSIFY$(G = (V,E), \lambda)$. The input to this algorithm is a dynamic graph $G = (V,E)$ that keeps changing via a sequence of updates (edge insertions/deletions), and a fixed parameter $\delta/n^2 \leq \lambda < \beta$. Throughout this

sequence of updates, it is guaranteed that the graph G admits a valid λ-uniform fractional matching w. We will show how to maintain a subgraph $H_{(a)} = (V, F_{(a)})$ of this dynamic graph $G = (V, E)$, with $F_{(a)} \subseteq E$, that is a good matching-sparsifier of G with respect to w.

Our dynamic algorithm will be heavily based on the static algorithm from Section 3. We now introduce a couple of (informal) terms that relate to various aspects of this static algorithm. These terms will be very useful in the ensuing discussion. First, for each $i \in [0, L]$, the term *level-i-structure* will refer to the following sets: $E^{(\geq i)}, V^{(\geq i)}, V^{(i)}$ and $F^{(i)}$. Second, the term *hierarchy* will refer to the union of the level-i-structures over all $i \in [0, L]$.

We will maintain a partition of the edge-set E into two subsets: $E_{(a)}$ and $E_{(p)}$. The edges in $E_{(a)}$ (resp., $E_{(p)}$) will be called *active* (resp., *passive*). We will let $G_{(a)} := (V, E_{(a)})$ and $G_{(p)} := (V, E_{(p)})$ respectively denote the active and passive subgraphs of the input graph $G = (V, E)$. Our dynamic algorithm will make a *lazy attempt* at mimicking the static algorithm from Section 3, when the latter receives the active subgraph $G_{(a)}$ as input.

Preprocessing. At preprocessing, we set $E_{(p)} := \emptyset$ and $E_{(a)} := E$, and then call Static-Uniform-Sparsify$(G_{(a)} = (V, E_{(a)}), \lambda)$, as described in Algorithm 1. It returns the hierarchy, where for each $i \in [0, L]$ the level-i-structure consists of $E^{(\geq i)}, V^{(\geq i)}, F^{(i)}, V^{(i)}$. Finally, for each $i \in [0, L]$, we initialize a set $D^{(\geq i)} := \emptyset$. This concludes the preprocessing step.

Handling an edge-insertion. When an edge e gets inserted into the input graph $G = (V, E)$, we call the subroutine Handle-Insertion(e, λ), as described in Algorithm 4. This classifies the edge e as passive, and sets $E_{(p)} \leftarrow E_{(p)} \cup \{e\}$. If the previous step does not violate Invariant 1, then we are done. Otherwise, if Invariant 1 gets violated, then we throw away the existing hierarchy and all its associated structures (such as the sets $D^{(\geq i)}$), and perform the preprocessing step again on the current input graph G.

▶ **Invariant 1.** $|E_{(p)}| \leq \epsilon \cdot |E_{(a)}|$.

Handling an edge-deletion. When an edge e gets deleted from G, we call the subroutine Handle-Deletion(e, λ), as described in Algorithm 6. If e was already passive, then it simply gets removed from the set $E_{(p)}$, and we are done. Henceforth, we assume that e was active, and at level $\ell(e) = k$, just before getting deleted.[4]

First, we remove e from the set $E_{(a)}$, because the edge is no longer present in G. Next, for every $i \in [0, k]$, we insert e into the set $D^{(\geq i)}$. From now on, we will refer to e as a *dead edge*. Intuitively, the edge e, even after getting deleted, continues to be present in the level-i-structure for each $i \in [0, k]$. Thus, up until this point, the hierarchy does not change.

Next, we check if the previous steps lead to a violation of Invariant 2. If Invariant 2 continues to remain satisfied, then we are done. Otherwise, we find the minimum index $j \in [0, L]$ such that $\left|D^{(\geq j)}\right| > \epsilon \cdot |E^{(\geq j)}|$, and then perform the following operations: (1) For every $i \in [j, L]$, we delete the dead edges $D^{(\geq i)}$ from the level-i-structure and reset $D^{(\geq i)} \leftarrow \emptyset$. (2) Finally, we call the subroutine Rebuild(j, λ) as described in Algorithm 2.

▶ **Invariant 2.** $\left|D^{(\geq i)}\right| \leq \epsilon \cdot \left|E^{(\geq i)}\right|$ *for all* $i \in [0, L]$.

[4] See the paragraph just before Observation 12 for the definition of the level of an edge.

Algorithm 4 HANDLE-INSERTION(e, λ).

$E_{(p)} \leftarrow E_{(p)} \cup \{e\}$.
if $\left|E_{(p)}\right| > \epsilon \cdot \left|E_{(a)}\right|$ **then**
  Call the subroutine CLEAN-UP$(0, \lambda)$.
  $E_{(a)} \leftarrow E_{(a)} \cup E_{(p)}$.
  $E_{(p)} \leftarrow \emptyset$.
  Call the subroutine STATIC-UNIFORM-SPARSIFY$\big(G_{(a)} := (V, E_{(a)}), \lambda\big)$.

Algorithm 5 CLEAN-UP(j, λ).

for all $i = j$ to L **do**
  $E^{(\geq i)} \leftarrow E^{(\geq i)} \setminus D^{(\geq i)}$.
  $F^{(i)} \leftarrow F^{(i)} \setminus D^{(\geq i)}$.
  $D^{(\geq i)} \leftarrow \emptyset$.

Algorithm 6 HANDLE-DELETION(e, λ).

if $e \in E_{(p)}$ **then**
  $E_{(p)} \leftarrow E_{(p)} \setminus \{e\}$.
else
  $k \leftarrow \ell(e) := \max\left\{i \in [0, L] : e \in E^{(\geq i)}\right\}$.
  $E_{(a)} \leftarrow E_{(a)} \setminus \{e\}$.
  for $i = 0$ to k **do**
    $D^{(\geq i)} \leftarrow D^{(\geq i)} \cup \{e\}$.
  if $\left|D^{(\geq i)}\right| > \epsilon \cdot \left|E^{(\geq i)}\right|$ for some index $i \in [0, L]$ **then**
    Let j be the minimum index $i \in [0, L]$ for which $\left|D^{(\geq i)}\right| > \epsilon \cdot \left|E^{(\geq i)}\right|$.
    Call the subroutine CLEAN-UP(j, λ).
    Call the subroutine REBUILD(j, λ).

Note that $E_{(p)}, E_{(a)}, E^{(\geq i)}, D^{(\geq i)}, F^{(i)}$ represent global variables in these pseudocodes.

To summarize, we satisfy Invariant 1 and Invariant 2, and handle the updates to G in a lazy manner. Newly inserted edges are classified as passive, and they are completely ignored in the hierarchy unless their number becomes sufficiently large compared to the total number of active edges, at which point we rebuild everything from scratch. In contrast, when an active edge gets deleted from some level $i \in [0, L]$, it is classified as dead and it continues to be present in the level-j-structure for all $j \in [0, i]$. Finally, if we notice that for some $k \in [0, L]$ the level-k-structure has too many dead edges $D^{(\geq k)}$, then we remove all the dead edges from every level-j-structure with $j \in [k, L]$, and rebuild these structures from scratch.

From Section 3, recall that $F := \bigcup_{i=0}^{L} F^{(i)}$. For any set of edges E', we will use the notation $E'_{(a)} := E' \cap E_{(a)}$ to denote the subset of edges in E' that are active in the current input graph $G = (V, E)$. Accordingly, we define $F_{(a)} := F \cap E_{(a)}$ and $H_{(a)} := (V, F_{(a)})$.

Lemma 15 and Lemma 16 below should respectively be seen as analogues of Lemma 14 and Lemma 11 from Section 3. They show that the subgraph $H_{(a)} = (V, F_{(a)})$ is a good matching sparsifier of the input dynamic graph $G = (V, E)$. Intuitively, Lemma 15 and Lemma 16 hold because Invariant 1 and Invariant 2 ensure that throughout the sequence of updates, the hierarchy maintained by our dynamic algorithm is *very close* to the hierarchy

constructed by the algorithm from Section 3 when it receives the current graph $G = (V, E)$ as input. Due to space constraints, the proofs of these two lemmas are deferred to the full version.

▶ **Lemma 15.** *The graph $H_{(a)} = (V, F_{(a)})$ has arboricity at most $O(\epsilon^{-1} + \beta^{-1}) = O(\log n)$.*

▶ **Lemma 16.** *The graph $H_{(a)}$ admits a fractional matching $h' : F_{(a)} \to [0, 1]$ such that:*
1. *For every edge $e \in F_{(a)}$, we have $h'(e) < \beta$.*
2. *For every node $v \in V$, we have $h'(v) \leq w(v)$.*
3. *We have $size(w) \leq (1 + 60\epsilon \cdot \log(\beta/\lambda)) \cdot size(h')$.*

▶ **Lemma 17.** *The dynamic algorithm* Dynamic-Uniform-Sparsify(G, λ) *has an amortized update time of $O\left(\epsilon^{-1} \cdot \log(\beta/\lambda)\right) = O(\log^2 n)$.*

Proof. Define a potential function $\Phi := |E_{(p)}| + \sum_{i=0}^{L} \left|D^{(\geq i)}\right|$. Insertion of an edge increases the potential Φ by at most one unit, as the newly inserted edge gets classified as passive. On the other hand, deletion of an edge e increases the potential Φ by at most $L+1$ units, since e gets added to each of the sets $D^{(\geq 0)}, \ldots, D^{(\geq \ell(e))}$, and $\ell(e) \leq L$. To summarize, each update in G creates at most $O(L)$ units of new potential. We will show that whenever our dynamic algorithm spends T units of time, the potential Φ drops by at least $\Omega(\epsilon \cdot T)$. Since Φ is always ≥ 0, this implies the desired amortized update time of $O(\epsilon^{-1} \cdot L) = O\left(\epsilon^{-1} \cdot \log(\beta/\lambda)\right)$.

Consider the insertion of an edge e into $G = (V, E)$, and suppose that we call Static-Uniform-Sparsify$(G_{(a)}, \lambda)$ while handling this insertion. Let $m_{(a)} := |E_{(a)}|$, $m_{(p)} := |E_{(p)}|$, $m_{(d)} := |D^{(\geq 0)}|$ and $m := |E|$, just before e gets inserted. Invariant 1 and Invariant 2 respectively ensure that $m_{(p)} = \epsilon \cdot m$ and $m_{(d)} \leq \epsilon \cdot m$. By Lemma 9, the call to Static-Uniform-Sparsify$(G_{(a)}, \lambda)$ takes $O(m)$ time. Thus, the total time to handle this edge insertion is given by $T := O(m + m_d) = O(m)$. On the other hand, when our algorithm finishes handling this edge insertion, we have $E_{(p)} = \emptyset$, and hence the potential Φ decreases by at least $m_{(p)} = \epsilon \cdot m$ units. In other words, the drop in the potential Φ is at least $\Omega(\epsilon \cdot T)$.

Next, consider the deletion of an edge e from $G = (V, E)$, and suppose that while handling this deletion we call the subroutine Rebuild(k, λ) for some $k \in [0, L]$. Just before e gets deleted, let $m_{(d)}^{(\geq k)} := \left|D^{(\geq k)}\right|$ and $m^{(\geq k)} := E^{(\geq k)}$. Invariant 2 ensures that $m_{(d)}^{(\geq k)} = \epsilon \cdot m^{(\geq k)}$. By Lemma 9, the call to Rebuild(k, λ) takes $O\left(m^{(\geq k)}\right)$ time. Hence, excluding the time it takes to identify the level k, which is $O(L) = O(\log(\beta/\lambda)) = O(\log n)$ in the worst-case, our dynamic algorithm spends $T = O\left(m^{(\geq k)}\right)$ time to handle this edge deletion. On the other hand, this decreases the potential Φ by at least $m_{(d)}^{(\geq k)} = \epsilon \cdot m^{(\geq k)}$, since once we are done processing this edge deletion, we have $D^{(\geq k)} = \emptyset$. So the potential Φ drops by $\Omega(\epsilon \cdot T)$. ◀

5 Dynamically Sparsifying an Arbitrary Fractional Matching

In this section, we briefly sketch our dynamic algorithm for maintaining a matching-sparsifier as specified by Theorem 1.

The input is a dynamic graph $G = (V, E)$ with n nodes, and a (*not* necessarily uniform) fractional matching $w : E \to [0, 1]$ in G. An "update" either inserts/deletes an edge in G or changes the weight $w(e)$ of an existing edge e in G. Our algorithm works in three steps.

Step I (Discretizing w). For every integer $j \geq 0$, define $\lambda_j := (\beta/n^2) \cdot (1 + \beta)^j$. Let K be the largest integer j such that $\lambda_j < \beta$. We now discretize w to get a new fractional matching $\hat{w} : E \to [0, 1]$, which is defined as follows. Consider any edge $e \in E$. If $w(e) < \lambda_0$, then $\hat{w}(e) := 0$. Else if $\lambda_0 \leq w(e) < \beta$, then $\hat{w}(e) := \lambda_i$ where i is the unique integer such that $\lambda_i \leq w(e) < \lambda_{i+1}$. Otherwise, if $w(e) \geq \beta$, then $\hat{w}(e) := w(e)$.

For each $i \in [0, K]$, let E_i denote the subset of edges $e \in E$ with $\hat{w}(e) = \lambda_i$, let $G_i := (V, E_i)$, and let $w_i : E_i \to [0, 1]$ be the restriction of the fractional matching $\hat{w}$ onto the set E_i (i.e., w_i is a λ_i-uniform fractional matching in G_i). Finally, define the subset of edges $E_{\geq\beta} := \{e \in E : \hat{w}(e) = w(e) \geq \beta\}$, and let $G_{\geq\beta} := (V, E_{\geq\beta})$. In the dynamic setting, we can easily maintain the subgraphs $G_0, \ldots, G_K, G_{\geq\beta}$ of the input graph G *on the fly*.

Step II (Sparsifying each G_i). For each $i \in [0, K]$, we maintain a sparsifier of G_i with respect to w_i, with the help of the dynamic algorithm from Section 4. Specifically, let $H_i = (V, F_i)$ denote the sparsifier $H_{(a)} = (V, F_{(a)})$ maintained by the algorithm Dynamic-Uniform-Sparsify(G_i, λ_i) from Section 4 (thus, we have $F_i \subseteq E_i$).

Step III (Putting everything together). Let $E_S := \bigcup_{i=0}^{K} F_i \bigcup E_{\geq\beta}$. In the full version of the paper, we show that the subgraph $S := (V, E_S)$ of G satisfies all the five conditions stated in Theorem 1.

Abstract

We present a unified framework for minimizing average completion time for many seemingly disparate *online* scheduling problems, such as the traveling repairperson problems (TRP), dial-a-ride problems (DARP), and scheduling on unrelated machines.

We construct a simple algorithm that handles all these scheduling problems, by computing and later executing auxiliary schedules, each optimizing a certain function on already seen prefix of the input. The optimized function resembles a prize-collecting variant of the original scheduling problem. By a careful analysis of the interplay between these auxiliary schedules, and later employing the resulting inequalities in a factor-revealing linear program, we obtain improved bounds on the competitive ratio for all these scheduling problems.

In particular, our techniques yield a 4-competitive deterministic algorithm for all previously studied variants of online TRP and DARP, and a 3-competitive one for the scheduling on unrelated machines (also with precedence constraints). This improves over currently best ratios for these problems that are 5.14 and 4, respectively. We also show how to use randomization to further reduce the competitive ratios to $1 + 2/\ln 3 < 2.821$ and $1 + 1/\ln 2 < 2.443$, respectively. The randomized bounds also substantially improve the current state of the art. Our upper bound for DARP contradicts the lower bound of 3 given by Fink et al. (Inf. Process. Lett. 2009); we pinpoint a flaw in their proof.

1 Introduction

In the traveling repairperson problem (TRP) [37], requests arrive in time at points of a metric space and they need to be eventually serviced. In the same metric, there is a mobile server, that can move at a constant speed. The server starts at a distinguished point called the origin. A request is considered serviced once the server reaches its location; we call such time its *completion time*. The goal is to minimize the sum (or equivalently the average) of all completion times. We focus on a weighted variant, where all requests have non-negative weights and the goal is to minimize the weighted sum of completion times.

A natural and well-studied extension of the TRP problem is a so-called *dial-a-ride problem* (DARP) [20], where each request has a source and a destination and the goal is to transport an object between these two points. There, the server may have a fixed capacity limiting

© Marcin Bienkowski, Artur Kraska, and Hsiang-Hsuan Liu;

the number of objects it may carry simultaneously; this capacity may be also infinite. For the finite-capacity case, one can also distinguish between preemptive variant, where objects can be unloaded at some points of the metric space (different than their destination) and non-preemptive variant, where such unloading is not allowed.

A seemingly disparate problem is scheduling on m unrelated machines [23]. There, weighted jobs arrive in time, each with a vector of size m describing execution times of the job when assigned to a given machine. A single machine can execute at most one job at a time. The goal is to assign each job (at or after its arrival) to one of the machines to minimize the weighted sum of completion times. This problem comes in two flavors: in the preemptive one, job execution may be interrupted and picked up later, while in the non-preemptive one, such interruption is not possible. As an extension, each job may have precedence constraints, i.e., can be executed only once some other jobs are completed.

Online Algorithms. Our focus is on natural *online* scenarios of TRP, DARP [21], and machine scheduling [24]. There, an online algorithm ALG, at time t, knows only requests/jobs that arrived before or at time t. The number of requests/jobs is also not known by an algorithm a priori. We say that an online algorithm ALG is c-competitive if for any request/job sequence $\mathcal{I}$ it holds that $\text{COST}_{\text{ALG}}(\mathcal{I}) \leq c \cdot \text{COST}_{\text{OPT}}(\mathcal{I})$, where OPT is a cost-optimal *offline* solution for $\mathcal{I}$. For a randomized algorithm ALG, we replace its cost by its expectation. The competitive ratio of ALG is the infimum over all values c such that ALG is c-competitive [15].

In this paper, we present a unified framework for handling such online scheduling problems where the cost is the weighted sum of completion times. We present an algorithm MIMIC that yields substantially improved competitive ratios for all the problems described above.

1.1 Previous Work

The currently best algorithms for the TRP, the DARP, and machine scheduling on unrelated machines share a common framework. Namely, each of these algorithms works in phases of geometrically increasing lengths. In each phase, it computes and executes an auxiliary schedule for the requests presented so far. (In the case of the TRP and DARP, the server additionally returns to the origin afterward.) The auxiliary schedule optimizes a certain function, such as maximizing the weight of served requests [8,16,24,28,32,33] or minimizing the sum of completion times with an additional penalty for non-served requests [27].[1] Moreover, known randomized algorithms are also based on a common idea: they delay the execution of the deterministic algorithm by a random offset [16, 27, 32, 33]. We call these approaches *phase based*. The currently best results are gathered in Table 1.

Traveling Repairperson and Dial-a-Ride Problems. The online variant of the TRP has been first investigated by Feuerstein and Stougie [21]. By adapting an algorithm for the cow-path problem problem [7], they gave a 9-competitive solution for line metrics. The result has been improved by Krumke et al. [32], who gave a phase-based deterministic algorithm INTERVAL attaining competitive ratio of $3 + 2\sqrt{2} < 5.829$ for an arbitrary metric space. A slightly different algorithm with the same competitive ratio was given by Jaillet and Wagner [28]. Bienkowski and Liu [8] applied postprocessing to auxiliary schedules, serving heavier requests

[1] Computing such auxiliary schedule usually involves optimally solving an NP-hard task. This is typical for the area of online algorithms, where the focus is on information-theoretic aspects and not on computational complexity. Algorithms presented in this paper also aim at minimizing the achievable competitive ratio rather than minimizing the running time.

earlier, and improved the ratio to 5.429 on line metrics. Finally, Hwang and Jaillet proposed a phase-based algorithm Plan-And-Commit [27]. They give a computer-based upper bound of 5.14 for the competitive ratio and an analytical upper bound of 5.572.

Randomized counterparts of algorithms Interval and Plan-And-Commit achieve ratios of 3.874 [32, 33] and 3.641 [27], respectively. Interestingly, the latter bound is not a direct randomization of the deterministic algorithm, but uses a different parameterization, putting more emphasis on penalizing requests not served by auxiliary schedules.

The phase-based algorithm Interval extends in a straightforward fashion to the DARP problem with an arbitrary assumption on the server capacity, both for the preemptive and non-preemptive variants: all the details of the solved problem are encapsulated in the computations of auxiliary schedules [32]. In the same manner, Interval can be enhanced to handle k-TRP and k-DARP variants, where an algorithm has k servers at its disposal (also for any k, any server capacities, and any preemptiveness assumptions) [14]. Although this was not explicitly stated in [27], the algorithm Plan-And-Commit can be extended in the same way.

From the impossibility side, Feuerstein and Stougie [21] gave a lower bound for the TRP (that also holds already for a line) of $1 + \sqrt{2} > 2.414$, while the bound of 7/3 for randomized algorithms was presented by Krumke et al. [32]. For the variant of the TRP with multiple servers, the deterministic lower bound is only 2 [14] (it holds for any number of servers). Clearly, all these lower bounds hold also for any variant of DARP. For the DARP with a single server of capacity 1, the deterministic lower bound can be improved to 3 [21] and the randomized one to 2.410 [32].

The authors of [22] claimed a lower bound of 3 for randomized k-DARP (for any k). This contradicts the upper bound we present in this paper. In Section 7, we pinpoint a flaw in their argument.

TRP and DARP: Related Results. Both online TRP and DARP problems were considered under different objectives, such as minimizing the total makespan (when the TRP becomes online TSP) [3–6, 9–11, 13, 18, 29, 30, 35] or maximum flow time [25, 31, 34].

The offline variants of TRP and DARP have been extensively studied both from the computational hardness (see, e.g., [20, 37]) and approximation algorithms perspectives. In particular, the TRP, also known as the *minimum latency problem* problem, is NP-hard already on weighted trees [40] (where the closely related traveling salesperson problem [12] becomes trivial) and the best known approximation factor in general graphs is 3.59 [17]. For some metrics (Euclidean plane, planar graphs or weighted trees) the TRP admits a PTAS [2, 42].

Machine Scheduling on Unrelated Machines. The first online algorithm for the scheduling on unrelated machines ($R|r_j|\sum w_jC_j$ in the Graham et al. notation [23]) was given by Hall et al. [24]. They gave 8-competitive polynomial-time algorithm, which would be 4-competitive if the polynomial-time requirement was lifted. Chakrabarti et al. showed how to randomize this algorithm, achieving the ratio of $2/\ln 2 < 2.886$ [16]. They also observe that both algorithms can handle precedence constraints. The currently best deterministic lower of 1.309 is due to Vestjens [45], and the best randomized one of 1.157 is due to Seiden [39].

Machine Scheduling: Related Results. While for unrelated machines, the results have not been beaten for the last 25 years, the competitive ratios for simpler models were improved substantially. For example, for parallel identical machines, a sequence of papers lowered the ratio to 1.791 [19, 36, 38, 41].

Table 1 Previous and current bounds on the competitive ratios for the TRP and the DARP problems. Asterisked results were not given in the referenced papers, but they are immediate consequences of the arguments therein. All upper bounds for the TRP/DARP variants hold for any number k of servers, any server capacities, both in the preemptive and the non-preemptive case. Upper bounds for scheduling hold also in the presence of precedence constraints. Bounds proven in the current paper are given in boldface.

	deterministic		randomized	
	lower	upper	lower	upper
TRP	2.414 [21]	5.14 [27]	2.333 [32]	3.641 [27]
DARP	3 [21]	5.14* [27]	2.410 [32]	3.641* [27]
k-TRP	2 [14]	5.14* [27]	2 [14]	3.641* [27]
k-DARP	2 [14]	5.14* [27]	2 [14]	3.641* [27]
k-TRP, k-DARP (all variants)		**4**		**2.821**
scheduling on unrelated machines	1.309 [45]	4 [24] **3**	1.157 [39]	2.886 [16] **2.443**

The problem has also been studied intensively in the offline regime. Both weighted preemptive and non-preemptive variants were shown to be APX-hard [26, 43]. On the positive side, a 1.698-approximation for the preemptive case was given by Sitters [43], and a 1.5-approximation for the non-preemptive case by Skutella [44]. A PTAS for a constant number of machines is due to Afrati et al. [1].

1.2 Resettable Scheduling

The phase-based algorithms for DARP variants and machine scheduling on unrelated machines both execute auxiliary schedules, but the ones for the DARP variants need to bring the server back to the origin between schedules. We call the latter action *resetting*. To provide a single algorithm for all these scheduling variants, we define a class of *resettable scheduling* problems.

We assume that jobs are handled by an *executor*, which has a set of possible states. And at time 0, it is in a distinguished *initial state*. An input to the problem consists of a sequence of jobs $\mathcal{I}$ released over time. Each job r is characterized by its arrival time $a(r)$, its weight $w(r)$, and possibly other parameters that determine its execution time. The executor cannot start executing job r before its arrival time $a(r)$. We will slightly abuse the notation and use $\mathcal{I}$ to also denote the *set* of all jobs from the input sequence. There is a problem-specific way of executing jobs and we use $s_{\text{ALG}}(r)$ to denote the *completion time* of a job by an algorithm ALG. The cost of an algorithm is defined as the weighted sum of job completion times, $\text{COST}_{\text{ALG}}(\mathcal{I}) = \sum_{r\in\mathcal{I}} w(r) \cdot s_{\text{ALG}}(r)$.

For any time τ, let $\mathcal{I}_\tau$ be the set of jobs that appear till τ. An *auxiliary τ-schedule* is a problem-specific way of feasibly executing a subset of jobs from $\mathcal{I}_\tau$. Such schedule starts at time 0, terminates at time τ, and leaves no job partially executed. We require that the following properties hold for any resettable scheduling problem.

Delayed execution. At any time t, if the executor is in the initial state, it can execute an arbitrary auxiliary τ-schedule (for $\tau \le t$). Such action takes place in time interval $[t, t+\tau)$. Any job r that would be completed at time $z \in [0, \tau)$ by the τ-schedule started at time 0 is now completed exactly at time $t + z$ (unless it has been already executed before).

Resetting executor. Assume that at time t, the executor was in the initial state, and then executed a τ-schedule, ending at time $t+\tau$. Then, it is possible to *reset* the executor using extra $\gamma \cdot \tau$ time, where γ is a parameter characteristic to the problem. That is, at time $t + (1+\gamma) \cdot \tau$, the executor is again in its initial state.

Learning minimum. We define $\min(\mathcal{I})$ to be the earliest time at which Opt may complete some job. We require that the value of $\min(\mathcal{I})$ is learned by an online algorithm at or before time $\min(\mathcal{I})$ and that $\min(\mathcal{I}) > 0$.

We call scheduling problems that obey these restrictions γ-resettable.

Example 1: Machine Scheduling is 0-Resettable. For the machine scheduling problem, the executor is always in the initial state, and no resetting is necessary. As we may assume that processing of any job takes positive time, $\min(\mathcal{I}) > 0$ holds for any input $\mathcal{I}$.

Example 2: DARP Problems are 1-Resettable. For the DARP variants, the executor state is the position of the algorithm server, with the origin used as the initial state.[2] Jobs are requests for transporting objects and an auxiliary τ-schedule is a fixed path of length τ starting at the origin, augmented with actions of picking up and dropping particular objects.[3] It is feasible to execute a τ-schedule starting at any time t when the server is at the origin. In such case, jobs are completed with an extra delay of t. Furthermore, right after serving the τ-schedule, the distance between the server and the origin is at most τ. Thus, it is possible to reset the executor to the initial state within extra time $1 \cdot \tau$.

Finally, as we may assume that there are no requests that arrive at time 0 with both start and destination at the origin, $\min(\mathcal{I}) > 0$ for any input $\mathcal{I}$.

1.3 Our Contribution

In this paper, we provide a deterministic routine Mimic and its randomized version that solves any γ-resettable scheduling problem. It achieves a deterministic ratio of $3+\gamma$ and a randomized one of $1 + (1+\gamma)/\ln(2+\gamma)$.

That is, for 1-resettable scheduling problems (the DARP variants with arbitrary server capacity, an arbitrary number of servers, and both in the preemptive and non-preemptive setting, or the TRP problem with an arbitrary number of servers), this gives solutions whose ratios are at most 4 and $1+2/\ln 3 < 2.821$, respectively. For 0-resettable scheduling problems (that include scheduling on unrelated machines with or without precedence constraints), the ratios of our solutions are 3 and $1 + 1/\ln 2 < 2.443$.

In both cases, our results constitute a substantial improvement over currently best ratios as illustrated in Table 1. Our result for the scheduling on unrelated machines is the first improvement in the last 25 years for this problem.

Challenges and Techniques. Mimic works in phases of geometrically increasing lengths. At the beginning of each phase, at time τ, it computes an auxiliary τ-schedule that optimizes the total completion time of jobs seen so far with an additional penalty for non-completed jobs: they are penalized as if they were completed at time τ. Then, within the phase it executes this schedule and afterward it resets the executor. We obtain a randomized variant by delaying the start of Mimic by an offset randomly chosen from a *continuous* distribution.

[2] In the variants with k servers, the executor state is a k-tuple describing the positions of all servers.
[3] In the preemptive variants, preemption is allowed *inside* an auxiliary schedule, provided that after a τ-schedule terminates, each job is either completed or untouched.

Admittedly, this idea is not new, and in fact, when we apply MIMIC to the TRP problem, it becomes a slightly modified variant of PLAN-AND-COMMIT [27]. Hence, the main technical contribution of our paper is a careful and exact analysis of such an approach. The crux here is to observe several structural properties and relations among schedules produced by MIMIC in consecutive phases, carefully tracking the overlaps of the job sets completed by them. On this basis, and for a fixed number Q of phases, we construct a maximization linear program (LP), whose optimal value upper-bounds the competitive ratio of MIMIC. Roughly speaking, the LP encodes, in a sparse manner, an adversarially created input. To upper bound its value, we explicitly construct a solution to its dual (minimization) program and show that its value is at most 4 for any number of phases Q.

Bounding the competitive ratio for the randomized version of MIMIC is substantially more complicated as we need to combine the discrete world of an LP with uncountably many random choices of the algorithm. To tackle this issue, we consider an intermediate solution DISC which approximates the random choice of MIMIC to a given precision, choosing an offset randomly from a discrete set of M values. This way, we upper-bound the ratio of MIMIC by $1 + (1/M) \cdot \sum_{j=1}^{M} (2+\gamma)^{j/M}$. This bound holds for an arbitrary value of M, and thus by taking the limit, we obtain the desired bound on the competitive ratio. Interestingly, we use the same LP for analyzing both the deterministic and the randomized solution.

2 Deterministic and Randomized Algorithms: Routine MIMIC

To describe our approach for γ-resettable scheduling, we start with defining auxiliary schedules used by our routine MIMIC. The parameter γ will be used to define partitioning of time into phases. Both our deterministic and randomized solutions will run MIMIC, however, the randomized one will execute it for a random choice of parameters.

Auxiliary Schedules. As introduced already in Subsection 1.2, an (auxiliary) τ-schedule A describes a sequence of job executions, has the total duration τ, and may be executed whenever the executor is in the initial state. For the preemptive variants, we assume that once such a schedule terminates, each job is processed either completely or not at all.

For a fixed input $\mathcal{I}$, and a τ-schedule A, we use $R(A)$ to denote the set of jobs that would be served by A if it was executed from time 0, i.e., in the interval $[0, \tau)$. For any set of jobs $R \subseteq R(A)$, let

$$w(R) = \sum_{r \in R} w(r) \qquad \text{and} \qquad \textsc{cost}_A(R) = \sum_{r \in R} w(r) \cdot s_A(r). \tag{1}$$

Note that if a schedule A serves all jobs from the input ($R(A) = \mathcal{I}$), then $\textsc{cost}_A(R(A))$ coincides with the cost of an algorithm that executes schedule A at time 0.

Recall that $\mathcal{I}_\tau \subseteq \mathcal{I}$ denotes the set of jobs that arrive till time τ. For any τ-schedule A, we define its value as

$$\textsc{val}_\tau(A) = \textsc{cost}_A(R(A)) + \tau \cdot w\left(\mathcal{I}_\tau \setminus R(A)\right). \tag{2}$$

The value corresponds to the actual cost of completing jobs from $\mathcal{I}_\tau$ by schedule A in interval $[0, \tau)$, but we charge A for unprocessed jobs as if they were completed at time τ.

▶ **Definition 1.** *For any $\tau \geq 0$, let S_τ be the τ-schedule minimizing function $\textsc{val}_\tau$. Ties are broken arbitrarily, but in a deterministic fashion.*

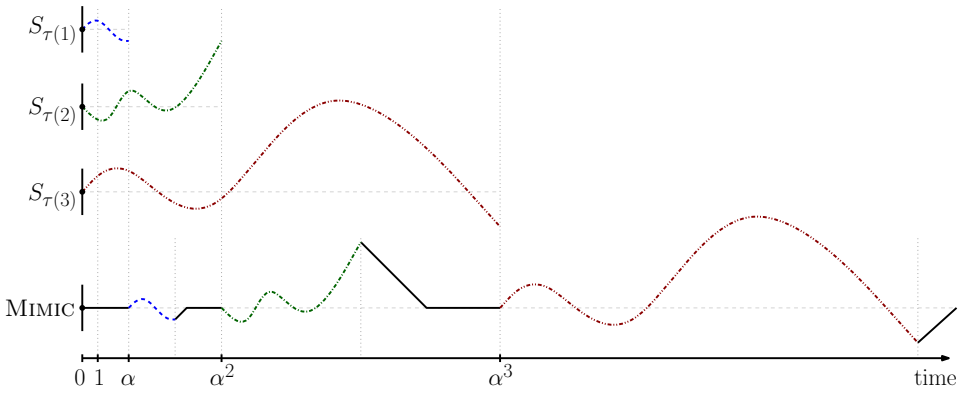

Figure 1 An example execution of algorithm MIMIC$(1,0)$ applied for the TRP problem (i.e., we use $\alpha = 3$). We assume that $\min(\mathcal{I}) = 1$. Within time interval $[\tau(k) = \alpha^k, 2 \cdot \alpha^k)$ of phase $k+1$, MIMIC executes a $\tau(k)$-schedule $S_{\tau(k)}$ that optimizes function $\text{VAL}_{\tau(k)}$. Afterwards within time interval $[2 \cdot \alpha^k, \tau(k+1) = 3 \cdot \alpha^k)$, MIMIC resets its state to the initial one (the server of TRP returns to the origin).

Routine MIMIC. For solving the γ-resettable scheduling problem, we define routine MIMIC(γ, ω), where $\omega \in (-1, 0]$ is an additional parameter that controls the initial delay.

- Our deterministic algorithm is simply MIMIC$(\gamma, 0)$.
- Our randomized algorithm first chooses a value ω uniformly at random from the range $(-1, 0]$. Then, it executes MIMIC(γ, ω).

Internally, MIMIC(γ, ω) uses a parameter $\alpha = 2 + \gamma$. It splits time into phases in the following way. For any k, let $\tau_k = \tau(k) = \min(\mathcal{I}) \cdot \alpha^{k+\omega}$. The k-th phase (for $k \geq 1$) starts at time $\tau_{k-1} = \min(\mathcal{I}) \cdot \alpha^{k-1+\omega}$ and ends at time $\tau_k = \min(\mathcal{I}) \cdot \alpha^{k+\omega}$. The time interval $[0, \tau_0) = [0, \alpha^\omega \cdot \min(\mathcal{I}))$ does not belong to any phase. As $\alpha^\omega \cdot \min(\mathcal{I}) \leq \min(\mathcal{I})$, no jobs can be completed within this interval, by the definition of $\min(\mathcal{I})$ (see Subsection 1.2).

MIMIC does nothing till the end of phase 1 (till time $\tau_1 = \alpha^{1+\omega} \cdot \min(\mathcal{I})$). Since $\omega \geq -1$, we have $\tau_1 \geq \min(\mathcal{I})$. As MIMIC learns the value of $\min(\mathcal{I})$ latest at time $\min(\mathcal{I})$, it can thus correctly identify the value of τ_1 before or at time τ_1.

For a phase $k+1$, where $k \geq 1$, MIMIC behaves in the following way. We ensure that at time τ_k, at the beginning of phase $k+1$, MIMIC is in its initial state. At this time, MIMIC computes the τ_k-schedule $S_{\tau(k)}$ (see Definition 1), executes it within time interval $[\tau_k, 2 \cdot \tau_k)$ and afterwards, it resets its state to the initial one. The execution of $S_{\tau(k)}$ will not be interrupted or modified when new jobs arrive within phase $k+1$. Furthermore, MIMIC serves only those requests from $S_{\tau(k)}$ it has not yet served earlier. The resetting part takes time $\gamma \cdot \tau_k$, and is thus finished at time $(2+\gamma) \cdot \tau_k = \alpha \cdot \tau_k = \tau_{k+1}$ when the next phase starts. An illustration is given in Figure 1.

3 Intermediate Algorithm DISC

As mentioned in the introduction, we introduce an additional intermediate algorithm DISC, whose analysis will allow us to bound the competitive ratios of both our deterministic and randomized solution. For an integer ℓ, we use $[\ell]$ to denote the set $\{0, \ldots, \ell - 1\}$.

DISC(γ, M, β) solves the γ-resettable scheduling problem, and is additionally parameterized by a positive integer M, and a real number $\beta \in (0, 1/M]$. DISC(γ, M, β) first chooses a random integer $m \in [M]$. Then, it executes MIMIC$(\gamma, \omega = -1 + m/M + \beta)$. The main result of this paper is the following bound, whose proof is will be given in the next two sections.

▶ **Theorem 2.** *For any γ, any positive integer M, and any $\beta \in (0, 1/M]$, the competitive ratio of $\textsc{Disc}(\gamma, M, \beta)$ for the γ-resettable scheduling is at most $1 + (1/M) \cdot \sum_{j=1}^{M} (2+\gamma)^{j/M}$.*

▶ **Corollary 3.** *For any γ, the competitive ratio of our Mimic-based deterministic solution is at most $3 + \gamma$ and the ratio of randomized one at most $1 + (1+\gamma)/\ln(2+\gamma)$.*

Proof. Let $\xi_M = 1 + (1/M) \cdot \sum_{j=1}^{M} \alpha^{j/M}$. First, we note that $\textsc{Disc}(\gamma, M = 1, \beta = 1)$ chooses deterministically $m = 0$ and executes $\textsc{Mimic}(\gamma, \omega = -1 + 0 + 1 = 0)$, i.e., is equivalent to our deterministic algorithm. Hence, by Theorem 2, the corresponding competitive ratio is at most $\xi_1 = 3 + \gamma$.

For analyzing our randomized algorithm, we observe that instead of choosing a random $\omega \in (-1, 0]$, we may choose a random integer $m \in [M]$ and a random real $\beta \in (0, 1/M]$ and set $\omega = -1 + m/M + \beta$. Thus, for any fixed integer M, our randomized algorithm is equivalent to choosing random $\beta \in (0, 1/M]$ and running $\textsc{Disc}(\gamma, M, \beta)$.

Fix any input $\mathcal{I}$. By Theorem 2, $\mathbf{E}_m[\textsc{cost}_{\textsc{Disc}(\gamma,M,\beta)}(\mathcal{I})] \le \xi_M \cdot \textsc{cost}_{\textsc{Opt}}(\mathcal{I})$ holds for any $\beta \in (0, 1/M]$, where the expected value is taken over random choice of m. Clearly, this relation holds also when β is chosen randomly, i.e., $\mathbf{E}_\omega[\textsc{cost}_{\textsc{Mimic}(\gamma,\omega)}] = \mathbf{E}_\gamma \mathbf{E}_m[\textsc{cost}_{\textsc{Disc}(\gamma,M,\beta)}(\mathcal{I})] \le \xi_M \cdot \textsc{cost}_{\textsc{Opt}}(\mathcal{I})$. As the bound is valid for any M, and the competitive ratio of our randomized algorithm is at most $\inf_{M \in \mathbb{N}}\{\xi_M\} = \lim_{M\to\infty} \xi_M = 1 + (1+\gamma)/\ln(2+\gamma)$. ◀

4 Structural Properties of DISC

In this section, we build relations useful for analyzing the performance of $\textsc{Disc}(\gamma, M, \beta)$ on any instance $\mathcal{I}$ of the γ-resettable scheduling problem.

We start by presenting structural properties of schedules S_τ. We note that even if there exists a τ-schedule A that completes all jobs from $\mathcal{I}$, S_τ may leave some jobs untouched. However, a sufficiently long schedule S_τ completes all jobs.

▶ **Lemma 4.** *Fix any input $\mathcal{I}$. There exists a value $T_\mathcal{I}$, such that for any $\tau \ge T_\mathcal{I}$, S_τ completes all jobs of $\mathcal{I}$ and is an optimal (cost-minimal) solution for $\mathcal{I}$.*

Proof. Let $\textsc{Opt}$ be a cost-optimal schedule for $\mathcal{I}$ and let t be its length. Let w be the weight of the lightest job from $\mathcal{I}$. We fix $T_\mathcal{I} = \max\{t, (\textsc{val}_t(\textsc{Opt}) + 1)/w\}$. Now, we pick any $\tau \ge T_\mathcal{I}$, and investigate properties of S_τ.

As $\tau \ge T_\mathcal{I} \ge t$, the schedule of $\textsc{Opt}$ can be trivially extended to a τ-schedule A that does nothing in its suffix of length $\tau - t$. Both A and $\textsc{Opt}$ complete all jobs, and thus $\textsc{val}_\tau(A) = \textsc{val}_t(\textsc{Opt})$. Moreover, as S_τ minimizes function $\textsc{val}_\tau$, $\textsc{val}_\tau(S_\tau) \le \textsc{val}_\tau(A) = \textsc{val}_t(\textsc{Opt}) < T_\mathcal{I} \cdot w \le \tau \cdot w$, and thus S_τ completes all jobs (as otherwise $\textsc{val}_\tau$ would include a penalty of at least $\tau \cdot w$). As S_τ and $\textsc{Opt}$ complete all jobs, $\textsc{cost}_{S_\tau}(\mathcal{I}) = \textsc{val}_\tau(S_\tau) \le \textsc{val}_t(\textsc{Opt}) = \textsc{cost}_{\textsc{Opt}}(\mathcal{I})$, i.e., S_τ is an optimal solution for $\mathcal{I}$. ◀

Sub-phases. Recall that the algorithm $\textsc{Disc}(\gamma, M, \beta)$ chooses a random integer $m \in [M]$, and executes $\textsc{Mimic}(\gamma, \omega = -1 + m/M + \beta)$. To compare $\textsc{Disc}$ executions for different random choices, we introduce sub-phases. Recall that $\alpha = 2 + \gamma$; let $\delta = \alpha^{1/M}$.

Recall that the k-th phase of $\textsc{Mimic}$ starts at time τ_{k-1} and ends at time τ_k, where $\tau_k = \min(\mathcal{I}) \cdot \alpha^{k-1+m/M+\beta} = \min(\mathcal{I}) \cdot \alpha^{\beta-1} \cdot \delta^{m+k\cdot M}$. For any q, we define

$$\eta_q = \eta(q) = \min(\mathcal{I}) \cdot \alpha^{\beta-1} \cdot \delta^q. \tag{3}$$

In these terms, $\tau_k = \eta_{m+k\cdot M}$. We define the q-th sub-phase (for $q \ge 0$) as the time interval starting at time η_{q-1} and ending at time η_q. Then, phase k of $\textsc{Disc}(\gamma, M, \beta)$ consists of exactly M sub-phases, numbered from $(k-1) \cdot M + m + 1$ to $k \cdot M + m$. An example of

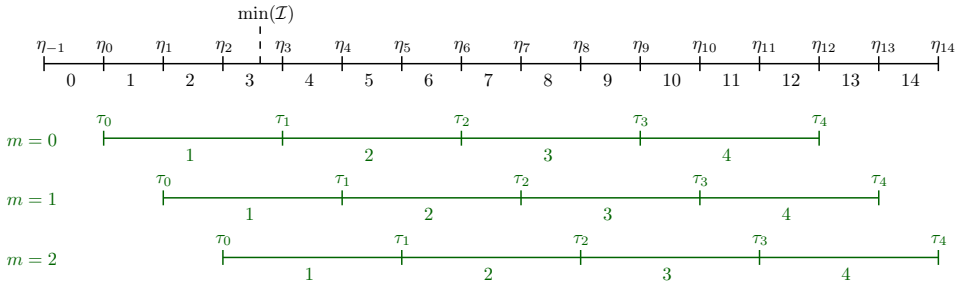

Figure 2 Example of phases (green) and sub-phases (black) of algorithm Disc$(\gamma, M = 3, \beta)$ for all possible choices of m. The time interval lengths are in logarithmic scale. The starts and ends of sub-phases are deterministic functions of γ, M, and β, but the start of a phase depends additionally on the integer $m \in [M]$ chosen randomly by Disc. Sub-phase 0 is not contained in any phase, but will be used in our analysis.

phases and sub-phases is given in Figure 2. We emphasize that the start and the end of a sub-phase is a deterministic function of the parameters of Disc, while the start and end of a phase depend additionally on the value $m \in [M]$ that Disc chooses randomly.

Recall that our deterministic algorithm is equivalent to Mimic$(\gamma, 0) \equiv$ Disc$(\gamma, 1, 1)$. In this case $m = 0$, and thus $\eta_q = \tau_q$ for any q, i.e., each phase consists of one sub-phase, and their indexes coincide.

Sub-phases vs Auxiliary Schedules. We now identify the times when auxiliary schedules are computed by Disc(γ, M, β). Recall that at the beginning of any phase $k+1$ (where $k \geq 1$), i.e., at time $\tau_k = \eta_{m+k \cdot M}$, Disc computes and executes schedule $S_{\eta(m+k \cdot M)}$. Let $T_{\mathcal{I}}$ be the threshold guaranteed by Lemma 4 and we define $K_{\mathcal{I}}$ as the smallest integer satisfying $\eta(K_{\mathcal{I}} \cdot M) \geq T_{\mathcal{I}}$. Note that $K_{\mathcal{I}}$ is a deterministic function of input $\mathcal{I}$.

For any choice of $m \in [M]$, the schedule $S_{\eta(m+K_{\mathcal{I}} \cdot M)}$ completes all jobs. This schedule is executed by Disc in phase $K_{\mathcal{I}} + 1$, and thus Disc terminates latest in phase $K_{\mathcal{I}} + 1$. Summing up, Disc(γ, M, β) executes schedules $S_{\eta(m+M)}, S_{\eta(m+2M)}, \ldots, S_{\eta(m+K_{\mathcal{I}} \cdot M)}$. At the beginning of the first phase, Disc does nothing, but for notational ease, we assume that in the first phase, it also computes and executes a dummy schedule $S_{\eta(m)}$, which does not complete any job. For succinctness, we use $A_q = S_{\eta(q)}$. In these terms, Disc(γ, M, β) executes schedules $A_{m+k \cdot M}$ for $k \in [K_{\mathcal{I}} + 1]$.

Let $Q = K_{\mathcal{I}} \cdot M + (M - 1)$: possible schedule indexes used by Disc range from 0 to Q. For any schedule A_q, we define the set of indexes of *preceding schedules* $P(q) = \{q', q' + M, \ldots, q - M\}$, where $q' = q \mod M$.

Fresh and Stale Requests. We assume that no jobs are completed by the online algorithm while it is resetting the executor, and we assume that the execution of schedule A_q may complete only jobs from set $R(A_q)$. It is however important to note that $R(A_q)$ and $R(A_{q-M})$ may overlap significantly, in which case the execution of schedule A_q serves only these jobs from $R(A_q)$ that have not been served already. To further quantify this effect, for $q \in [Q+1]$, we define the set of *fresh* jobs of schedule A_q as

$$R^{\mathrm{F}}(A_q) = R(A_q) \setminus \bigcup_{\ell \in P(q)} R(A_\ell). \tag{4}$$

The remaining jobs from $R(A_q)$ are called *stale* and are denoted $R^{\mathrm{S}}(A_q) = R(A_q) \setminus R^{\mathrm{F}}(A_q)$. For succinctness, we define the following shorthand notations for their weights:

$$w_q^{\mathrm{F}} = w(R^{\mathrm{F}}(A_q)), \qquad w_q^{\mathrm{S}} = w(R^{\mathrm{S}}(A_q)), \qquad w_q = w(R(A_q)) = w_q^{\mathrm{F}} + w_q^{\mathrm{S}}. \tag{5}$$

▶ **Lemma 5.** *For any $q \in [Q+1]$, it holds that $w_q^{\mathrm{S}} \le \sum_{\ell \in P(q)} w_\ell^{\mathrm{F}}$. This relation becomes equality for $q \ge K_{\mathcal{I}} \cdot M$.*

Proof. By a simple induction, it can be shown that $\biguplus_{\ell \in P(q)} R^{\mathrm{F}}(A_\ell) = \bigcup_{\ell \in P(q)} R(A_\ell)$ for any $q \in [Q+1]$. Then, using the definition of stale jobs, $R^{\mathrm{S}}(A_q) \subseteq \bigcup_{\ell \in P(q)} R(A_\ell) = \biguplus_{\ell \in P(q)} R^{\mathrm{F}}(A_\ell)$. Applying weight to both sides yields $w_q^{\mathrm{S}} \le \sum_{\ell \in P(q)} w_\ell^{\mathrm{F}}$.

Next, we show that this relation can be reversed for $q \ge K_{\mathcal{I}} \cdot M$ (i.e., for the schedule executed in the last phase of Disc). For such q, A_q completes all jobs, and thus $\bigcup_{\ell \in P(q)} R(A_\ell) \subseteq R(A_q) = R^{\mathrm{F}}(A_q) \uplus R^{\mathrm{S}}(A_q)$. By the definition of fresh jobs, $R^{\mathrm{F}}(A_q)$ does not contain any job from $\bigcup_{\ell \in P(q)} R(A_\ell)$, and thus $\bigcup_{\ell \in P(q)} R(A_\ell) \subseteq R^{\mathrm{S}}(A_q)$. This implies that $\biguplus_{\ell \in P(q)} R^{\mathrm{F}}(A_\ell) = \bigcup_{\ell \in P(q)} R(A_\ell) \subseteq R^{\mathrm{S}}(A_q)$. After applying weights to both sides, we obtain $w_q^{\mathrm{S}} \ge \sum_{\ell \in P(q)} w_\ell^{\mathrm{F}}$ as desired. ◀

Jobs Completed in Sub-phases. For further analysis, we refine our notions when a job is completed. For a η_q-schedule A_q, let $R_j(A_q)$ be the set of jobs completed in sub-phase $j \le q$, i.e., within interval $[\eta_{j-1}, \eta_j)$. As $\eta_{-1} \le \eta_{m-1} \le \min(\mathcal{I})$ (cf. (3)), no job can be completed within the interval $[0, \eta_{-1})$ (before sub-phase 0). Hence, $R(A_q) = \biguplus_{j=0}^{q} R_j(A_q)$.

We partition sets $R^{\mathrm{F}}(A_q)$ and $R^{\mathrm{S}}(A_q)$ analogously, defining sets $R_j^{\mathrm{F}}(A_q)$ and $R_j^{\mathrm{S}}(A_q)$ (for $0 \le j \le q$), such that $R^{\mathrm{F}}(A_q) = \biguplus_{j=0}^{q} R_j^{\mathrm{F}}(A_q)$ and $R^{\mathrm{S}}(A_q) = \biguplus_{j=0}^{q} R_j^{\mathrm{S}}(A_q)$. For succinctness, for $0 \le j \le q$, we introduce the following shorthand notations:

- $w_{qj}^{\mathrm{F}} = w(R_j^{\mathrm{F}}(A_q))$, $w_{qj}^{\mathrm{S}} = w(R_j^{\mathrm{S}}(A_q))$, and $w_{qj} = w(R_j(A_q)) = w_{qj}^{\mathrm{F}} + w_{qj}^{\mathrm{S}}$;
- $g_{qj}^{\mathrm{F}} = \textsc{cost}_{A_q}(R_j^{\mathrm{F}}(A_q))$, $g_{qj}^{\mathrm{S}} = \textsc{cost}_{A_q}(R_j^{\mathrm{S}}(A_q))$, and $g_{qj} = \textsc{cost}_{A_q}(R_j(A_q)) = g_{qj}^{\mathrm{F}} + g_{qj}^{\mathrm{S}}$.

▶ **Lemma 6.** *For any $0 \le q < \ell \le Q$, it holds that $\sum_{j=0}^{q}(g_{qj} - g_{\ell j}) + \sum_{j=0}^{q} \eta_q \cdot (w_{\ell j} - w_{qj}) \le 0$.*

Proof. For any η_q-schedule B, it holds that

$$\begin{aligned}\textsc{val}_{\eta(q)}(B) &= \textsc{cost}_B(R(B)) + \eta_q \cdot w\left(\mathcal{I}_{\eta(q)} \setminus R(B)\right) \\ &= \textstyle\sum_{j=0}^{q} \textsc{cost}_B(R_j(B)) + \eta_q \cdot w(\mathcal{I}_{\eta(q)}) - \eta_q \cdot \sum_{j=0}^{q} w(R_j(B)).\end{aligned}$$

Fix any $\ell \le Q$ and let A_ℓ^q be the η_q-schedule consisting of the first q sub-phases of η_ℓ-schedule A_ℓ. Since A_q is a minimizer of $\textsc{val}_{\eta(q)}$, it holds that $\textsc{val}_{\eta(q)}(A_q) \le \textsc{val}_{\eta(q)}(A_\ell^q)$. Thus, $\sum_{j=0}^{q} g_{qj} - \eta_q \cdot \sum_{j=0}^{q} w_{qj} \le \sum_{j=0}^{q} g_{\ell j} - \eta_q \cdot \sum_{j=0}^{q} w_{\ell j}$. ◀

Costs of DISC and OPT. Finally, we can express costs of Disc and Opt using the newly introduced notions.

▶ **Lemma 7.** *For any input $\mathcal{I}$, parameters M and $\beta \in (0, 1/M]$, it holds that $\mathbf{E}[\mathit{COST}_{\textsc{Disc}}(\mathcal{I})] = (1/M) \cdot \sum_{q=0}^{Q} \sum_{j=0}^{q} \left(\eta_q \cdot w_{qj}^{\mathrm{F}} + g_{qj}^{\mathrm{F}}\right)$.*

Proof. Recall that Disc chooses random $m \in [M]$ and then at time η_q it executes schedule A_q, for all $q \in \{m, m+M, \ldots, m+K_{\mathcal{I}} \cdot M\}$. When Disc executes A_q, it completes jobs from $R^{\mathrm{F}}(A_q)$. By the delayed execution property of the resettable scheduling (cf. Subsection 1.2), each job $r \in R^{\mathrm{F}}(A_q)$ is completed at time $\eta_q + s_{A_q}(r)$. Thus, the cost of executing A_q by Disc is equal to

$$\sum_{r\in R^{\mathrm{F}}(A_q)} w(r)\cdot(\eta_q + s_{A_q}(r)) = \eta_q \cdot w(R^{\mathrm{F}}(A_q)) + \textsc{cost}_{A_q}(R^{\mathrm{F}}(A_q))$$
$$= \eta_q \cdot w_q^{\mathrm{F}} + \sum_{j=0}^{q} g_{qj}^{\mathrm{F}} = \sum_{j=0}^{q} \left(\eta_q \cdot w_{qj}^{\mathrm{F}} + g_{qj}^{\mathrm{F}}\right).$$

For any $q \in [Q+1]$, the probability that Disc executes A_q is equal to $1/M$, and thus the lemma follows. ◀

▶ **Lemma 8.** *For any input $\mathcal{I}$ and any $q \in \{Q-M+1, Q-M+2, \ldots, Q\}$, it holds that $\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) = \sum_{j=0}^{q} g_{qj}$.*

Proof. Recall that for such choice of q, schedules A_q serve all jobs of $\mathcal{I}$ achieving optimal cost. Therefore, $\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) = \textsc{cost}_{A_q}(R(A_q)) = \sum_{j=0}^{q} \textsc{cost}_{A_q}(R_j(A_q)) = \sum_{j=0}^{q} g_{qj}$. ◀

5 Factor-Revealing Linear Program

Now we show that the Disc-to-Opt cost ratio on an arbitrary input $\mathcal{I}$ can be upper-bounded by a value of a linear (maximization) program.

Assume we fixed γ and any input $\mathcal{I}$ to the γ-resettable scheduling problem. We also fix parameters of Disc: an integer M and $\beta \in (0, 1/M]$. These choices imply the values of Q and η_q for any q. This allows us to define the linear program $\mathcal{P}_{\gamma,\mathcal{I},M,\beta}$ whose goal is to maximize

$$\sum_{q=0}^{Q} \sum_{j=0}^{q} \eta_q \cdot w_{qj}^{\mathrm{F}} + g_{qj}^{\mathrm{F}} \tag{6}$$

subject to the following constraints:

$$\sum_{j=0}^{q} g_{qj} \le 1 \qquad \text{for all } Q-M+1 \le q \le Q \tag{7}$$
$$\sum_{j=0}^{q} w_{qj}^{\mathrm{S}} - \sum_{\ell\in P(q)} \sum_{j=0}^{\ell} w_{\ell j}^{\mathrm{F}} \le 0 \qquad \text{for all } 0 \le q \le Q-M \tag{8}$$
$$\sum_{\ell\in P(q)} \sum_{j=0}^{\ell} w_{\ell j}^{\mathrm{F}} - \sum_{j=0}^{q} w_{qj}^{\mathrm{S}} \le 0 \qquad \text{for all } Q-M+1 \le q \le Q \tag{9}$$
$$\sum_{j=0}^{q} (g_{qj} - g_{\ell j}) + \sum_{j=0}^{q} \eta_q \cdot (w_{\ell j} - w_{qj}) \le 0 \qquad \text{for all } 0 \le q < \ell \le Q \tag{10}$$
$$\eta_{j-1} \cdot w_{qj}^{\mathrm{S}} - g_{qj}^{\mathrm{S}} \le 0 \qquad \text{for all } 0 \le j \le q \le Q \tag{11}$$
$$g_{qj}^{\mathrm{F}} - \eta_j \cdot w_{qj}^{\mathrm{F}} \le 0 \qquad \text{for all } 0 \le j \le q \le Q \tag{12}$$
$$\eta_{j-1} \cdot w_{qj}^{\mathrm{F}} - g_{qj}^{\mathrm{F}} \le 0 \qquad \text{for all } 0 \le j \le q \le Q \tag{13}$$

and non-negativity of all variables. In (10), we treat w_{qj} and g_{qj} not as variables, but as shorthand notations for $w_{qj}^{\mathrm{F}} + w_{qj}^{\mathrm{S}}$ and $g_{qj}^{\mathrm{F}} + g_{qj}^{\mathrm{S}}$, respectively.

The intuition behind this LP formulation is that instead of creating the whole input $\mathcal{I}$, the adversary only chooses the values of variables w_{qj}^{F}, w_{qj}^{S}, g_{qj}^{F} and g_{qj}^{S} that satisfy some subset of inequalities (inequalities that have to be satisfied if these variables were created on the basis of actual input $\mathcal{I}$). This intuition is formalized below.

▶ **Lemma 9.** *Fix any γ, any input $\mathcal{I}$ for γ-resettable scheduling, and parameters of Disc: integer M and $\beta \in (0, 1/M]$. Then, $\mathbf{E}[\textsc{cost}_{\textsc{Disc}}(\mathcal{I})]/\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) \le P^*_{\gamma,\mathcal{I},M,\beta}/M$, where $P^*_{\gamma,\mathcal{I},M,\beta}$ is the value of the optimal solution to $\mathcal{P}_{\gamma,\mathcal{I},M,\beta}$.*

Proof. By scaling all variables by the same value, $\mathcal{P}_{\gamma,\mathcal{I},M,\beta}$ is equivalent to the (non-linear) optimization program $\mathcal{P}'_{\gamma,\mathcal{I},M,\beta}$, whose objective is to maximize $(\sum_{q=0}^{Q} \sum_{j=0}^{q} \eta_q \cdot w_{qj}^{\mathrm{F}} + g_{qj}^{\mathrm{F}}) / \max_{Q-M+1\le q\le Q} \sum_{j=0}^{q} g_{qj}$, subject to constraints (8)–(13). In particular, the optimal values of these programs, $P^*_{\gamma,\mathcal{I},M,\beta}$ and $P'^*_{\gamma,\mathcal{I},M,\beta}$ are equal.

Next, we set the values of variables w^{F}_{qj}, w^{S}_{qj}, g^{F}_{qj} and g^{S}_{qj} on the basis of input $\mathcal{I}$, and parameters M and β. (Note that the variables depend on these parameters, but not on the random choices of Disc.) We now show that they satisfy the constraints of $\mathcal{P}'^{*}_{\gamma,\mathcal{I},M,\beta}$ and we relate $\mathbf{E}[\textsc{cost}_{\textsc{Disc}}(\mathcal{I})]/\textsc{cost}_{\textsc{Opt}}(\mathcal{I})$ to $P^{*}_{\gamma,\mathcal{I},M,\beta}$.

By Lemma 5 and the relations $w^{\mathrm{F}}_{q} = \sum_{j=0}^{q} w^{\mathrm{F}}_{qj}$ and $w^{\mathrm{S}}_{q} = \sum_{j=0}^{q} w^{\mathrm{S}}_{qj}$, the variables satisfy (8) and (9). Next, Lemma 6 implies (10). Inequalities (11), (12) and (13) follow directly by the definition of costs and weights. Finally, by Lemma 7 and Lemma 8, for any $q \in \{Q-M+1,\ldots,Q\}$, it holds that $\mathbf{E}[\textsc{cost}_{\textsc{Disc}}(\mathcal{I})]/\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) = (1/M)\cdot(\sum_{q=0}^{Q}\sum_{j=0}^{q}\eta_q\cdot w^{\mathrm{F}}_{qj} + g^{\mathrm{F}}_{qj})/(\sum_{j=0}^{q} g_{qj})$, and thus $\mathbf{E}[\textsc{cost}_{\textsc{Disc}}(\mathcal{I})]/\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) \le P'^{*}_{\gamma,\mathcal{I},M,\beta}/M = P^{*}_{\gamma,\mathcal{I},M,\beta}/M$. ◀

5.1 Dual Program and Competitive Ratio

By Lemma 9, the optimal value of $\mathcal{P}_{\gamma,\mathcal{I},M,\beta}$ is an upper bound on the competitive ratio of Disc. By weak duality, an upper-bound is given by any feasible solution to the dual program $\mathcal{D}_{\gamma,\mathcal{I},M,\beta}$ that we present below.

$\mathcal{D}_{\gamma,\mathcal{I},M,\beta}$ uses variables $\xi_q, B_q, C_q, D_{\ell q}, F_{qj}, G_{qj}$, and H_{qj}, corresponding to inequalities (7)–(13) from $\mathcal{P}_{\gamma,\mathcal{I},M,\beta}$, respectively. In the formulas below, we use $L_q = M\cdot K + (q \mod M)$ and $S(q) = \{q+M, q+2\cdot M, \ldots, L_q - M\}$. For succinctness of the description, we introduce two auxiliary variables for any $0 \le j \le q \le Q$:

$$U_{qj} = \sum_{\ell=q+1}^{Q} D_{\ell q} - \sum_{\ell=j}^{q-1} D_{q\ell} \quad \text{and} \quad V_{qj} = \sum_{\ell=j}^{q-1} \eta_\ell \cdot D_{q\ell} - \sum_{\ell=q+1}^{Q} \eta_q \cdot D_{\ell q}. \tag{14}$$

The goal of $\mathcal{D}_{\gamma,\mathcal{I},M,\beta}$ is to minimize

$$\sum_{q=Q-M+1}^{Q} \xi_q \tag{15}$$

subject to the following constraints (in all of them, we omitted the statement that they hold for all $j \in \{0,\ldots,q\}$):

$$U_{qj} + G_{qj} - H_{qj} \ge 1 \qquad \text{for all } 0 \le q \le Q-M \tag{16}$$
$$U_{qj} - F_{qj} \ge 0 \qquad \text{for all } 0 \le q \le Q-M \tag{17}$$
$$U_{qj} + G_{qj} - H_{qj} + \xi_q \ge 1 \qquad \text{for all } Q-M+1 \le q \le Q \tag{18}$$
$$U_{qj} - F_{qj} + \xi_q \ge 0 \qquad \text{for all } Q-M+1 \le q \le Q \tag{19}$$
$$V_{qj} + \eta_{j-1}\cdot H_{qj} - \eta_j \cdot G_{qj} + C_{L_q} - \textstyle\sum_{\ell\in S(q)} B_\ell \ge \eta_q \qquad \text{for all } 0 \le q \le Q-M \tag{20}$$
$$V_{qj} + \eta_{j-1}\cdot F_{qj} + B_q \ge 0 \qquad \text{for all } 0 \le q \le Q-M \tag{21}$$
$$V_{qj} - \eta_j \cdot G_{qj} + \eta_{j-1}\cdot H_{qj} \ge \eta_q \qquad \text{for all } Q-M+1 \le q \le Q \tag{22}$$
$$V_{qj} + \eta_{j-1}\cdot F_{qj} - C_q \ge 0 \qquad \text{for all } Q-M+1 \le q \le Q \tag{23}$$

and non-negativity of all variables.

▶ **Lemma 10.** *For any γ, any input $\mathcal{I}$ for γ-resettable scheduling, any positive integer M, and any $\beta \in (0, 1/M]$, there exists a feasible solution to $\mathcal{D}_{\gamma,\mathcal{I},M,\beta}$ of value at most $M + \sum_{j=1}^{M}(2+\gamma)^{j/M}$.*

We defer the proof to the next subsection, first arguing how it implies the main theorem of the paper (the competitive ratio of Disc).

Proof of Theorem 2. Fix any γ, and consider algorithm $\textsc{Disc}(\gamma, M, \beta)$ for any positive integer M, and any $\beta \in (0, 1/M]$. Fix any input $\mathcal{I}$ to the γ-resettable scheduling problem. Let $P^{*}_{\gamma,\mathcal{I},M,\beta}$ be the value of an optimal solution to $\mathcal{P}_{\gamma,\mathcal{I},M,\beta}$. By weak duality and Lemma 10, $P_{\gamma,\mathcal{I},M,\beta} \le M + \sum_{j=1}^{M}(2+\gamma)^{j/M}$. Hence, by Lemma 9, $\mathbf{E}[\textsc{cost}_{\textsc{Disc}}(\mathcal{I})]/\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) \le P^{*}_{\gamma,\mathcal{I},M,\beta}/M \le 1 + (1/M)\cdot\sum_{j=1}^{M}(2+\gamma)^{j/M}$, as desired. ◀

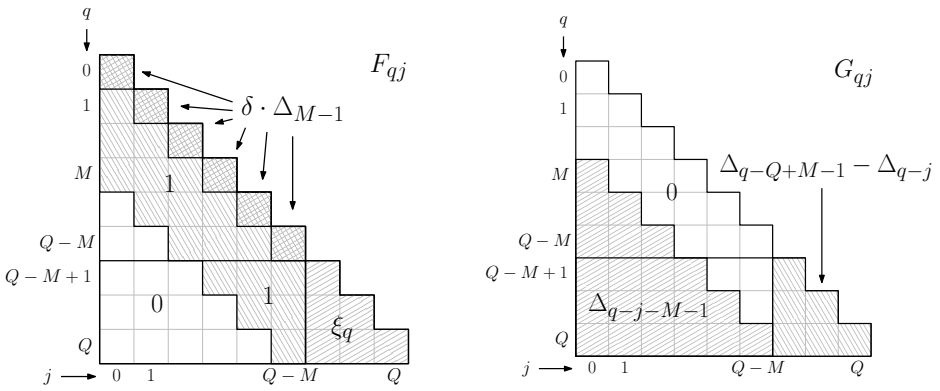

Figure 3 Visual presentation of values assigned to dual variables F_{qj} (left) and G_{qj} (right) for $M = 3$ and $Q = 8$.

5.2 Proof of Lemma 10

Let

$$\Delta_k = \sum_{i=0}^{k} \delta^i = \left(\delta^{k+1} - 1\right) / \left(\delta - 1\right).$$

In particular $\Delta_{-1} = 0$. We choose the following values of the dual variables:

$$\xi_q = 1 + \delta^{q-Q+M} \quad \text{for } Q - M + 1 \le q \le Q,$$

$$F_{qj} = \begin{cases} \xi_q & \text{for } Q - M + 1 \le j \le q \le Q, \\ \delta \cdot \Delta_{M-1} & \text{for } 0 \le j \le Q - M \text{ and } q = j, \\ 1 & \text{for } 0 \le j \le Q - M \text{ and } q \in \{j+1, \ldots, j+M\}, \\ 0 & \text{otherwise,} \end{cases}$$

$$G_{qj} = \begin{cases} \Delta_{q-Q+M-1} - \Delta_{q-j} & \text{for } Q - M + 1 \le j \le q \le Q, \\ \Delta_{q-j-M-1} & \text{for } j \le q - M \\ 0 & \text{otherwise,} \end{cases}$$

$$\begin{aligned} B_q &= \eta_{q-M-1} \cdot \left(\delta^{M+1} + 1\right) \cdot \left(\delta^M - 1\right) && \text{for } 0 \le q \le Q - M, \\ C_q &= \eta_{q-M-1} \cdot \left(\delta^{M+1} + 1\right) && \text{for } Q - M + 1 \le q \le Q, \\ D_{qj} &= F_{q,j+1} - F_{qj} && \text{for } 0 \le j < q \le Q, \\ H_{qj} &= F_{qj} + G_{qj} - 1 && \text{for } 0 \le j \le q \le Q. \end{aligned}$$

The values of F_{qj} and G_{qj} (for $0 \le j \le q \le Q$) are depicted in Figure 3 for an easier reference. We will extensively use the property that $\eta_i \cdot \delta^j = \eta_{i+j}$ for any i and j.

Objective Value. With the above assignment of dual variables the objective value of $\mathcal{D}_{\gamma,\mathcal{I},M,\beta}$ is equal to $\sum_{q=Q-M+1}^{Q} \xi_q = M + \sum_{j=1}^{M} \delta^j = M + \sum_{j=1}^{M} (2+\gamma)^{j/M}$ as desired.

Non-negativity of Variables. Variables ξ_q, C_q, B_q, F_{qj} and G_{qj} are trivially non-negative (for those q and j for which they are defined). The non-negativity of $D_{qj} = F_{q,j+1} - F_{qj}$ follows as F_{qj} is a non-decreasing function of its second argument (cf. Figure 3).

Finally, for showing non-negativity of variable H_{qj}, we consider two cases. If $j \geq q - M$, then $F_{qj} \geq 1$. Otherwise, $j \leq q - M - 1$, and then $G_{qj} = \Delta_{q-j-M-1} \geq 1$. Thus, in either case $H_{qj} = F_{qj} + G_{qj} - 1 \geq 0$.

Helper Bounds. It remains to show that the given values of dual variables satisfy all constraints (16)–(23) of the dual program $\mathcal{D}_{\gamma,\mathcal{I},M,\beta}$. We define a few helper notions and identities that are used throughout the proof of dual feasibility. For any $q \in [Q+1]$, let

$$R_q = \textstyle\sum_{\ell=q+1}^{Q} D_{\ell q} = \sum_{\ell=q+1}^{Q} (F_{\ell,q+1} - F_{\ell q})\,.$$

▶ **Lemma 11.** *$R_q = \delta \cdot \Delta_{M-1}$ for $q \leq Q - M$ and $R_q = 0$ otherwise.*

Proof. We consider three cases.

1. $q \in \{0, \ldots, Q - M - 1\}$. Then, $R_q = F_{q+1,q+1} + \sum_{\ell=q+1}^{Q} (F_{\ell+2,\ell+1} - F_{\ell+1,\ell}) - F_{Qq} = \delta \cdot \Delta_{M-1} + \sum_{\ell=q+1}^{Q} 0 - 0 = \delta \cdot \Delta_{M-1}$.
2. $q = Q - M$. Then, $R_q = \sum_{\ell=Q-M+1}^{Q} (\xi_\ell - 1) = \sum_{j=1}^{M} \delta^j = \delta \cdot \Delta_{M-1}$.
3. $q \in \{Q - M + 1, \ldots, Q\}$. Then, $R_q = \sum_{\ell=q+1}^{Q} (\xi_\ell - \xi_\ell) = 0$. ◀

Next, we investigate the values of V_{qj} for different q and j. Using its definition (cf. (14)),

$$V_{qj} = \textstyle\sum_{\ell=j}^{q-1} \eta_\ell \cdot D_{q\ell} - \sum_{\ell=q+1}^{Q} \eta_q \cdot D_{\ell q} = \sum_{\ell=j}^{q-1} \eta_\ell \cdot (F_{q,\ell+1} - F_{q\ell}) - \eta_q \cdot R_q. \tag{24}$$

Additionally, using $H_{qj} = F_{qj} + G_{qj} - 1$, we obtain

$$\eta_j \cdot G_{qj} - \eta_{j-1} \cdot H_{qj} = (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1} - \eta_{j-1} \cdot F_{qj}. \tag{25}$$

Using the chosen values of G_{qj}, we observe that

$$(\eta_j - \eta_{j-1}) \cdot G_{qj} = \begin{cases} \eta_{q+j-Q+M-1} - \eta_q & \text{for } Q - M + 1 \leq j \leq q, \\ \eta_{q-M-1} - \eta_{j-1} & \text{for } j \leq q - M - 1, \\ 0 & \text{otherwise.} \end{cases} \tag{26}$$

Furthermore, in all the cases, it can be verified that

$$(\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1} - \eta_{q-M-1} \geq 0. \tag{27}$$

5.2.1 Showing inequalities (16)–(19)

We prove that relations (16)–(19) hold with equality. In fact, it suffices to show (17) and (19): inequalities (16) and (18) follow immediately as we chose $H_{qj} = F_{qj} + G_{qj} - 1$. Using the definition of U_{qj} (cf. (14)), we obtain

$$U_{qj} = \textstyle\sum_{\ell=q+1}^{Q} D_{\ell q} - \sum_{\ell=j}^{q-1} D_{q\ell} = R_q - \sum_{\ell=j}^{q-1} (F_{q,\ell+1} - F_{q\ell}) = R_q - F_{qq} + F_{qj}.$$

Now, we observe that for $q \leq Q - M$, it holds that $R_q - F_{qq} = \delta \cdot \Delta_{M-1} - \delta \cdot \Delta_{M-1} = 0$, and thus $U_{qj} - F_{qj} = 0$, which implies (17). On the other hand, for $q > Q - M$, it holds that $R_q - F_{qq} = 0 - \xi_q$, and hence $U_{qj} - F_{qj} + \xi_q = 0$, which implies (19).

5.2.2 Showing inequalities (20)–(21)

Within this part, we assume $q \le Q - M$. We start with evaluating some terms that are present in (20) and (21). First, we observe that

$$B_q = \eta_{q-M-1} \cdot \left(\delta^{M+1} + 1\right) \cdot \left(\delta^M - 1\right) = \eta_{q+M} - \eta_q + \eta_{q-1} - \eta_{q-M-1}. \tag{28}$$

Second, we compute the term $C_{L_q} - \sum_{\ell \in S(q)} B_\ell$. Recall that $S(q) = \{q+M, q+2\cdot M, \ldots, L_q - M\}$. Thus,

$$\begin{aligned} C_{L_q} - \textstyle\sum_{\ell \in S(q)} B_\ell &= \left(\delta^{M+1} + 1\right) \cdot \left[\eta(L_q - M - 1) - (\delta^M - 1) \cdot \eta(-M-1) \cdot \textstyle\sum_{\ell \in S(q)} \delta^\ell\right] \\ &= (\delta^{M+1} + 1) \cdot \left[\eta(L_q - M - 1) - \eta(-M-1) \cdot \left(\delta^{L_q} - \delta^{q+M}\right)\right] \\ &= (\delta^{M+1} + 1) \cdot \eta_{q-1} = \eta_{q+M} + \eta_{q-1}. \end{aligned} \tag{29}$$

▶ **Lemma 12.** *Fix any $0 \le j \le q \le Q - M$. Then,*

$$V_{qj} = \eta_q - \eta_{q-1} - \eta_{q+M} - \eta_{j-1} \cdot F_{qj} + (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1}.$$

Proof. By the definition, $\Delta_{M-1} = \sum_{i=0}^{M-1} \delta^i$, and therefore $(\eta_{q-1} - \eta_q) \cdot \delta \cdot \Delta_{M-1} = \eta_q - \eta_{q+M}$. Thus, it suffices to show the following relation

$$V_{qj} = \eta_{q-1} \cdot (\delta \cdot \Delta_{M-1} - 1) - \eta_q \cdot \delta \cdot \Delta_{M-1} - \eta_{j-1} \cdot F_{qj} + (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1}.$$

To evaluate V_{qj} using (24), it is useful to trace values $F_{qj}, F_{q,j+1}, \ldots, F_{qq}$ (cf. Figure 3), noting that only the increases of these values contribute to V_{qj}. We also note that for $q \le Q - M$, possible increases are from 0 to 1 (between $F_{q,q-M-1}$ and $F_{q,q-M}$) and from 1 to $\delta \cdot \Delta_{M-1}$ (between $F_{q,q-1}$ and F_{qq}). We consider three cases, using $R_q = \delta \cdot \Delta_{M-1}$ below.

1. $j \le q - M - 1$. Then, $F_{qj} = 0$ and

$$\begin{aligned} V_{qj} &= \eta_{q-1} \cdot (F_{qq} - F_{q,q-1}) + \eta_{q-M-1} \cdot (F_{q,q-M} - F_{q,q-M-1}) - \eta_q \cdot R_q \\ &= \eta_{q-1} \cdot (\delta \cdot \Delta_{M-1} - 1) - \eta_q \cdot \delta \cdot \Delta_{M-1} + \eta_{q-M-1} - \eta_{j-1} + \eta_{j-1} - \eta_{j-1} \cdot F_{qj}. \end{aligned}$$

   The lemma follows as $(\eta_j - \eta_{j-1}) \cdot G_{qj} = \eta_{q-M-1} - \eta_{j-1}$ (see (26)).
2. $j \in \{q - M, \ldots, q - 1\}$. Then $F_{qj} = 1$, and

$$\begin{aligned} V_{qj} &= \eta_{q-1} \cdot (F_{qq} - F_{q,q-1}) - \eta_q \cdot R_q \\ &= \eta_{q-1} \cdot (\delta \cdot \Delta_{M-1} - 1) - \eta_q \cdot \delta \cdot \Delta_{M-1} \\ &= \eta_{q-1} \cdot (\delta \cdot \Delta_{M-1} - 1) - \eta_q \cdot \delta \cdot \Delta_{M-1} - \eta_{j-1} \cdot F_{qj} + \eta_{j-1}. \end{aligned}$$

   The lemma follows as $(\eta_j - \eta_{j-1}) \cdot G_{qj} = 0$ (see (26)).
3. $j = q$. Then $F_{qj} = \delta \cdot \Delta_{M-1}$, and thus

$$\begin{aligned} V_{qj} &= -\eta_q \cdot R_q \\ &= \eta_{q-1} \cdot \delta \cdot \Delta_{M-1} - \eta_q \cdot \delta \cdot \Delta_{M-1} - \eta_{j-1} \cdot F_{qj} \\ &= \eta_{q-1} \cdot (\delta \cdot \Delta_{M-1} - 1) - \eta_q \cdot \delta \cdot \Delta_{M-1} - \eta_{j-1} \cdot F_{qj} + \eta_{j-1}. \end{aligned}$$

   As in the previous case, the lemma follows as $(\eta_j - \eta_{j-1}) \cdot G_{qj} = 0$. ◀

Showing Inequality (20). We show that (20) holds with equality. Using Lemma 12, (29), and (25) yields

$$\begin{aligned} &V_{qj} + \eta_{j-1} \cdot H_{qj} - \eta_j \cdot G_{qj} + C_{L_q} - \textstyle\sum_{\ell \in S(q)} B_\ell \\ &\quad = \eta_q - \eta_{q-1} - \eta_{q+M} - \eta_{j-1} \cdot F_{qj} + (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1} \\ &\qquad - (\eta_j - \eta_{j-1}) \cdot G_{qj} - \eta_{j-1} + \eta_{j-1} \cdot F_{qj} + \eta_{q+M} + \eta_{q-1} = \eta_q. \end{aligned}$$

Showing Inequality (21). Using Lemma 12, (29), and (25) yields

$$\begin{aligned} &V_{qj} + \eta_{j-1} \cdot F_{qj} + B_q \\ &\quad = \eta_q - \eta_{q-1} - \eta_{q+M} - \eta_{j-1} \cdot F_{qj} + (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1} \\ &\qquad + \eta_{j-1} \cdot F_{qj} + \eta_{q+M} - \eta_q + \eta_{q-1} - \eta_{q-M-1} \\ &\quad = (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1} - \eta_{q-M-1} \geq 0. \end{aligned}$$

where the last inequality follows by (27).

5.2.3 Showing inequalities (22)–(23)

Within this part, we assume that $q \geq Q - M + 1$.

▶ **Lemma 13.** *Fix any $q \geq Q - M + 1$ and $0 \leq j \leq q$. Then,*

$$V_{qj} = \eta_q + (\eta_j - \eta_{j-1}) \cdot G_{qj} - \eta_{j-1} \cdot F_{qj} + \eta_{j-1}.$$

Proof. As $g \geq Q - M + 1$, it holds that $R_q = 0$, and thus (24) reduces to

$$V_{qj} = \textstyle\sum_{\ell=j}^{q-1} \eta_\ell \cdot (F_{q,\ell+1} - F_{q\ell}) .$$

As in the proof of Lemma 12, to further evaluate V_{qj}, it is useful to trace values $F_{qj}, F_{q,j+1}, \ldots, F_{qq}$ (cf. Figure 3), where the increases of these values contribute to V_{qj}. We also note that for $q \geq Q - M + 1$, the possible increases are from 0 to 1 (between $F_{q,q-M-1}$ and $F_{q,q-M}$) and from 1 to ξ_q (between $F_{q,Q-M}$ and $F_{q,Q-M+1}$). We consider three cases.

1. $j \leq q - M - 1$. Then $F_{qj} = 0$, and

$$\begin{aligned} V_{qj} &= \eta_{Q-M} \cdot (F_{qq} - F_{q,q-1}) + \eta_{q-M-1} \cdot (F_{q,q-M} - F_{q,q-M-1}) \\ &= \eta_{Q-M} \cdot (\xi_q - 1) + \eta_{q-M-1} \\ &= \eta_q + \eta_{q-M-1} - \eta_{j-1} + \eta_{j-1} - \eta_{j-1} \cdot F_{qj}. \end{aligned}$$

   The lemma follows as $(\eta_j - \eta_{j-1}) \cdot G_{qj} = \eta_{q-M-1} - \eta_{j-1}$ (see (26)).
2. $j \in \{q - M, \ldots, Q - M\}$. Then $F_{qj} = 1$, and

$$\begin{aligned} V_{qj} &= \eta_{Q-M} \cdot (F_{qq} - F_{q,q-1}) \\ &= \eta_{Q-M} \cdot (\xi_q - 1) \\ &= \eta_q - \eta_{j-1} \cdot F_{qj} + \eta_{j-1}. \end{aligned}$$

   The lemma follows as $(\eta_j - \eta_{j-1}) \cdot G_{qj} = 0$ (see (26)).
3. $j \in \{q - M, \ldots, Q - M\}$. Then $F_{qj} = \xi_q = 1 + \delta^{q-Q+M}$, and

$$\begin{aligned} V_{qj} = 0 &= \eta_q + \eta_{q+j-Q+M-1} - \eta_q - \eta_{j-1} \cdot (1 + \delta^{q-Q+M}) + \eta_{j-1} \\ &= \eta_q + \eta_{q+j-Q+M-1} - \eta_q - \eta_{j-1} \cdot F_{qj} + \eta_{j-1}. \end{aligned}$$

   The lemma follows as $(\eta_j - \eta_{j-1}) \cdot G_{qj} = \eta_{q+j-Q+M-1} - \eta_q$ (see (26)). ◀

Showing Inequality (22). We show that (22) holds with equality. Using Lemma 13 and (25), we obtain

$$\begin{aligned} &V_{qj} + \eta_{j-1} \cdot H_{qj} - \eta_j \cdot G_{qj} \\ &\quad = \eta_q + (\eta_j - \eta_{j-1}) \cdot G_{qj} - \eta_{j-1} \cdot F_{qj} + \eta_{j-1} - (\eta_j - \eta_{j-1}) \cdot G_{qj} - \eta_{j-1} + \eta_{j-1} \cdot F_{qj} \\ &\quad = \eta_q. \end{aligned}$$

Showing Inequality (23). Using Lemma 13, (25), and the definition of C_q, we obtain

$$\begin{aligned} &V_{qj} + \eta_{j-1} \cdot F_{qj} - C_q \\ &\quad = \eta_q + (\eta_j - \eta_{j-1}) \cdot G_{qj} - \eta_{j-1} \cdot F_{qj} + \eta_{j-1} + \eta_{j-1} \cdot F_{qj} - \eta_q - \eta_{q-M-1} \\ &\quad = (\eta_j - \eta_{j-1}) \cdot G_{qj} + \eta_{j-1} - \eta_{q-M-1} \geq 0. \end{aligned}$$

where the last inequality follows by (27).

6 Tightness of the Analysis

The analysis of our algorithms is tight as proven below. For the deterministic one, we additionally show that choosing ω different from 0 does not help.

▶ **Theorem 14.** *For any γ, there are γ-resettable scheduling problems, such that for any $\omega \in (-1, 0]$, the competitive ratio of* Mimic(γ, ω) *is at least $3 + \gamma$.*

Proof. We fix a small $\varepsilon > 0$ and let $\alpha = 2 + \gamma$. The input $\mathcal{I}$ contains two jobs: the first one of weight ε that arrives at time 1, and second one of weight 1 that arrives at time $\alpha^{1+\omega} + \varepsilon$. We assume that there exists a schedule S_1 that serves the first job at the time of its arrival and a schedule S_2 that serves both jobs at the times of their arrivals. Therefore, $\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) = \varepsilon \cdot 1 + 1 \cdot (\alpha^{1+\omega} + \varepsilon) = \alpha^{1+\omega} + 2 \cdot \varepsilon$.

For analyzing the cost of Mimic, note that at at time 1, Mimic observes the first job and learns the value of $\min(\mathcal{I}) = 1$. This is the sole purpose of the first job: setting $\min(\mathcal{I}) = 1$ makes the algorithm miss the opportunity to serve the second job early. At time $\tau_1 = \alpha^{1+\omega}$, Mimic executes the τ_1-schedule S'_1, which is schedule S_1 prolonged trivially to length τ_1. Next, at time $\tau_2 = \alpha^{2+\omega}$, Mimic executes the τ_2-schedule S'_2, which is schedule S_2 prolonged trivially to length τ_2. This way it completes the second job at time $\tau_2 + (\alpha^{1+\omega} + \varepsilon)$, and thus $\textsc{cost}_{\textsc{Mimic}}(\mathcal{I}) \geq \tau_2 + \alpha^{1+\omega} + \varepsilon = \alpha^{1+\omega} \cdot (1 + \alpha) + \varepsilon$. By taking appropriately small $\varepsilon > 0$, the ratio between $\textsc{cost}_{\textsc{Mimic}}(\mathcal{I})$ and $\textsc{cost}_{\textsc{Opt}}(\mathcal{I})$ becomes arbitrarily close to $1 + \alpha = 3 + \gamma$. ◀

▶ **Theorem 15.** *For any γ, there are γ-resettable scheduling problems, such that the competitive ratio of a randomized algorithm that runs* Mimic(γ, ω) *with a random $\omega \in (-1, 0]$ is at least $1 + (1 + \gamma)/\ln(2 + \gamma)$.*

Proof. Let $\alpha = 2 + \gamma$. The input $\mathcal{I}$ contains a single job of weight 1 arriving at time 1. We also assume that for any $\tau \geq 1$, there exists a τ-schedule S_τ that completes this job at time 1. Clearly, $\textsc{cost}_{\textsc{Opt}}(\mathcal{I}) = 1 \cdot 1 = 1$.

At time 1, Mimic observes the only job of $\mathcal{I}$ and learns that $\min(\mathcal{I}) = 1$. Its sets $\tau_1 = \alpha^{1+\omega}$ and at time τ_1 it executes schedule S_{τ_1}, thus completing the job at time $\tau_1 + 1$. Therefore, $\textsc{cost}_{\textsc{Mimic}}(\mathcal{I}) = \int_{-1}^{0} \tau_1 + 1 \, d\omega = \int_{-1}^{0} \alpha^{1+\omega} + 1 \, d\omega = 1 + (\alpha - 1)/\ln \alpha = 1 + (1 + \gamma)/\ln(2 + \gamma)$. This implies the desired lower bound. ◀

7 Flaw in the Randomized Lower Bound for DARP

The authors of [22] claim a lower bound of 3 for randomized k-DARP (for any $k \geq 1$), see Theorem 4 of [22]. Below we show a flaw in their argument.

The construction given in the proof of their Theorem 4 uses Yao min-max principle and is parameterized with a few variables, in particular with an integer m and with a real number $v \in [0, 1]$. Towards the end of the proof, they show that the competitive ratio of any randomized algorithm for the k-DARP problem is at least

$$L_{m,v} = \frac{3m - 4km - 4km^2 + v^{\frac{m+1}{2-m}} \cdot (3 + (4km^2 + 4km + 6m + 6) \cdot v)}{-4 - m - 2km - 2km^2 + v^{\frac{m+1}{2-m}} \cdot (3 + (2km^2 + 2km + 4m + 4) \cdot v)}$$

and they claim that there exists v, such that $L_{m,v} = 3$ when m tends to infinity. However, for any fixed k and any v (also being a function of m), by dividing numerator and denominator by m^2, we obtain that

$$\lim_{m\to\infty} L_{m,v} = \frac{-4k + v^{\frac{m+1}{2-m}} \cdot 4k \cdot v}{-2k + v^{\frac{m+1}{2-m}} \cdot 2k \cdot v} = 2.$$

That is, the proven lower bound is 2 instead of 3.

Abstract

Given as input two n-element sets $\mathcal{A}, \mathcal{B} \subseteq \{0,1\}^d$ with $d = c \log n \leq (\log n)^2/(\log\log n)^4$ and a target $t \in \{0,1,\ldots,d\}$, we show how to count the number of pairs $(x,y) \in \mathcal{A} \times \mathcal{B}$ with integer inner product $\langle x,y\rangle = t$ deterministically, in $n^2/2^{\Omega\left(\sqrt{\log n \log\log n/(c\log^2 c)}\right)}$ time. This demonstrates that one can solve this problem in deterministic subquadratic time almost up to $\log^2 n$ dimensions, nearly matching the dimension bound of a subquadratic randomized detection algorithm of Alman and Williams [FOCS 2015]. We also show how to modify their randomized algorithm to count the pairs w.h.p., to obtain a fast randomized algorithm.

Our deterministic algorithm builds on a novel technique of reconstructing a function from sum-aggregates by prime residues, or *modular tomography*, which can be seen as an additive analog of the Chinese Remainder Theorem.

As our second contribution, we relate the fine-grained complexity of the task of counting of vector pairs by inner product to the task of computing a zero-one matrix permanent over the integers.

1 Introduction

The Inner Product and the Size of Preimages. The inner product map $\langle x,y\rangle = \sum_{i=1}^{d} x_i y_i$ of two d-dimensional vectors $x = (x_1, x_2, \ldots, x_d)$ and $y = (y_1, y_2, \ldots, y_d)$ is one of the cornerstones of linear algebra and its applications. For example, when x and y are vectors of observations normalized to zero mean and unit standard deviation, $\langle x,y\rangle$ is the Pearson correlation between x and y. As such, it is a fundamental computational and data-analytical task to efficiently gain information about the *preimages* of the inner product map; for example, to highlight pairs of similar or dissimilar observables between two families of n observables.

The protagonist of this paper is the following counting problem (#InnerProduct):

Given as input a target $t \in \{0, 1, \ldots, d\}$ and two n-element sets $\mathcal{A} \subseteq \{0,1\}^d$ and $\mathcal{B} \subseteq \{0,1\}^d$, count the number of vector pairs $(x, y) \in \mathcal{A} \times \mathcal{B}$ with integer inner product $\langle x, y \rangle = t$.

From a complexity-theoretic standpoint, this problem generalizes many conjectured-hard problems in the study of fine-grained complexity – such as the $t = 0$ special case, the *orthogonal vector counting* (#OV) problem – as well as generalizing fundamental application settings, such as similarity search in Hamming spaces. While it is immediate that subquadratic scalability in n is obtainable when $d = o(\log n)$, our interest in this paper is to obtain an improved understanding of the fine-grained complexity landscape for *moderately short* vectors, specifically for d at most poly-logarithmic in n.

Subquadratic Scaling for Moderately Short Vectors. Our main positive result establishes deterministic subquadratic scalability for #InnerProduct up to d growing essentially as the square of the logarithm of n:

▶ **Theorem 1** (Main; Subquadratic Scaling for #InnerProduct)**.** *There exists a deterministic algorithm that, given as input a target $t \in \{0, 1, \ldots, c \log n\}$ and two n-element sets $\mathcal{A}, \mathcal{B} \subseteq \{0,1\}^{c \log n}$ with $4 \leq c \leq \frac{\log n}{(\log \log n)^4}$, outputs the number of pairs $(x, y) \in \mathcal{A} \times \mathcal{B}$ with $\langle x, y \rangle = t$ in time*

$$n^2 / 2^{\Omega\left(\sqrt{\frac{\log n \log \log n}{c \log^2 c}}\right)}. \tag{1}$$

The algorithm in Theorem 1 is based on a novel technique of reconstructing a function from its sum-aggregates by prime residue, which can be seen as an *additive* analog of the Chinese Remainder Theorem and may be of independent interest (cf. Sect. 2).

We also show how a randomized algorithm for the decision problem of checking for a pair of vectors whose Hamming distance is less than a target by Alman and Williams [6], can with a small modification be turned into an algorithm for #InnerProduct.

▶ **Theorem 2** (Randomized Subquadratic Scaling for #InnerProduct)**.** *There exists a randomized algorithm that w.h.p., given as input a target $t \in \{0, 1, \ldots, c \log n\}$ and two n-element sets $\mathcal{A}, \mathcal{B} \subseteq \{0,1\}^{c \log n}$ with $4 \leq c \leq \frac{\log n}{(\log \log n)^3}$, outputs the number of pairs $(x, y) \in \mathcal{A} \times \mathcal{B}$ with $\langle x, y \rangle = t$ in time*

$$n^2 / 2^{\Omega\left(\frac{\log n}{c \log^2 c}\right)}. \tag{2}$$

While the randomized algorithm in Theorem 2 is faster than the deterministic one in Theorem 1, we stress that as far as we know no deterministic algorithm in subquadratic time was previously known for #InnerProduct, even for $O(\log n)$ dimensions. In particular, derandomizing Theorem 2 while retaining subquadratic time seems challenging, even though some progress on the amount of randomness needed in the algorithm has been made, cf. Theorem 1.1 in [3].

Our further objective is to understand the fine-grained complexity of #InnerProduct in relation to that of #OV and other counting problems. For $d = O(\log n)$, it is known that these problems are truly-subquadratically related; indeed, Chen and Williams [15] give a parsimonious reduction for the detection variants of these two problems. That is, if #OV can be solved in $n^{2-\omega(1)}$ time, then so can #InnerProduct. However, while

there is a subquadratic time algorithm for #OV whose running time scales as good as $n^{2-\Omega(1/\log c)}$ [14], the reduction of Chen and Williams [15] does not immediately give a non-trivial algorithm for #InnerProduct. Indeed, the fastest known algorithm for the decision version InnerProduct utilizes probabilistic polynomials for symmetric Boolean functions with optimal dependence on the degree and error [6], and does not go via fast OV algorithms and the reduction above. In Theorem 2, we show how a simple modification to the algorithm in Alman and Williams [6] can turn their algorithm into a counting one. We note that while Alman, Chan, and Williams [3] later presented a deterministic algorithm based on Chebyshev polynomials over the reals for minimum/maximum Hamming weight pair, with the same running time as the randomized one in [6], that deterministic algorithm, or the even faster randomized one they presented, can not be turned into one for #InnerProduct by our suggested modification alone.

Lower Bounds via the Permanent. The running times (1) and (2) would, at least at first, appear to leave room for improvement. Indeed, the running time (2) is considerably worse than the running time $n^{2-\Omega(1/\log c)}$ obtained by Chan and Williams [14] for #OV. We proceed to show that this intuition might be misleading, since such scalability would imply the existence of considerably faster algorithms for a canonical hard problem in exponential-time complexity. Accordingly, to gain insight into the complexity of #InnerProduct and #OV when $d = \omega(\log n)$, we introduce our second protagonist (R-Permanent):

> Given as input an $n \times n$ matrix M with entries m_{ij} in a ring R for $i, j \in [n]$, compute the *permanent*
>
> $$\operatorname{per} M = \sum_{\sigma \in S_n} \prod_{i \in [n]} m_{i,\sigma(i)} \,,$$
>
> where S_n is the group of all permutations of $[n] = \{1, 2, \ldots, n\}$.

Ryser's algorithm from 1963 computes the permanent with $O(n2^n)$ arithmetic operations in R [22]. It is a major open problem whether this can be improved to $O(c^n)$ for some constant $c < 2$. Even improving the running time to less than 2^n operations has been noted as a challenge by Knuth in the *Art of Computer Programming* [19, Exercise 4.6.4.11]. Valiant in 1979 famously proved that the permanent is #P-complete even when restricted to $m_{ij} \in \{0, 1\}$ and evaluated over the ring of integers [24]; this version of the problem can be interpreted as counting the perfect matchings in a balanced bipartite graph having the matrix as its biadjacency matrix. For zero-one inputs over the integers, *somewhat* faster algorithms are known (cf. related work below); to the best of our knowledge, the current champion for zero-one matrices computes the permanent in $2^{n-\Omega\left(\sqrt{n/\log\log n}\right)}$ time [12].

As our second contribution, we relate the fine-grained scalability of #InnerProduct and #OV to the task of computing the permanent of a zero-one matrix over the integers. In particular, our first result shows that if we could solve #InnerProduct as fast as the fastest currently known algorithms for #OV [14], then we would immediately obtain a much faster algorithm for the zero-one matrix permanent:

▶ **Theorem 3** (Lower Bound for #InnerProduct via Integer Permanent). *If there exists an algorithm for solving #InnerProduct for N vectors from $\{0,1\}^{c \log N}$ in time $N^{2-\Omega(1/\log c)}$, then there exists an algorithm solving the permanent of an $n \times n$ zero-one matrix over the integers in time $2^{n-\Omega(n/\log n)}$.*

Thus, despite the true-subquadratic equivalence for $d = O(\log n)$ [15], it would appear that #InnerProduct and #OV have different complexity characteristics when $d = \omega(\log n)$.

Our next result shows that a modest improvement in fine-grained scalability of #OV would likewise imply much faster algorithms for the permanent.

▶ **Theorem 4** (Lower Bound for #OV via Integer Permanent)**.** *If there exists an algorithm for solving #OV for N vectors from $\{0,1\}^{c \log N}$ in time $N^{2-\Omega(1/\log^{1-\epsilon} c)}$ for some $\epsilon > 0$, then there exists an algorithm solving the permanent of an $n \times n$ zero-one matrix over the integers in time $2^{n-\Omega(n/\log^{2/\epsilon-2} n)}$.*

We note that such fast algorithms for #OV would already disprove the so-called Super Strong ETH, that k-CNFSAT on n variables has no $2^{n-n/o(k)}$-time algorithm, by the reduction to OV by Williams [26] after sparsification [17]. The present result merely adds to the list of consequences of faster algorithms for #OV.

Methodology and Organization of the Paper. The key methodological contribution underlying our main algorithmic result (Theorem 1) is a novel additive analog of the Chinese Remainder Theorem (Lemma 5 developed in Sect. 2 independently of the application), which enables us to recover the number of pairs $(x, y) \in \mathcal{A} \times \mathcal{B}$ with $\langle x, y \rangle = t$ from counts of pairs (x, y) satisfying $\langle x, y \rangle \equiv r \pmod{p}$ for multiple small primes p and residues $r \in \{0, 1, \ldots, p-1\}$. In particular, the crux of the algorithmic speedup lies in the observation that to recover the count associated with a target $0 \leq t \leq d$, primes up to roughly $\sqrt{d}$ suffice by Lemma 5. To obtain the counts of pairs in each residue class r modulo p, we employ the polynomial method with modulus-amplifying polynomials of Beigel and Tarui [9] to accommodate the counts under a prime-power modulus, with fast rectangular matrix multiplication of Coppersmith [16] as the key subroutine implementing the count; this latter part of the algorithm design developed in Sect. 3 follows well-known techniques in fine-grained algorithm design (e.g. [3]). Similarly, the randomized algorithm design in Theorem 2 follows by a minor adaptation of the probabilistic-polynomial techniques of Alman and Williams [6] to a counting context; a proof is relegated to Sect. 4.

Our two lower-bound reductions, Theorem 3 and Theorem 4, rely on reducing an $m \times m$ integer permanent first via the Chinese Remainder Theorem into permanents modulo multiple primes p with $p \leq m \ln m$, and then using algebraic splitting via Ryser's formula [22] to obtain short-vector instances of #InnerProduct and #OV, respectively. For #InnerProduct and Theorem 3, the split employs a novel discrete-logarithm version of Ryser's formula modulo p to arrive at two collections of vectors whose counts of pairs with specific inner products enable recovery of the permanent modulo p; the proof is presented in Sect. 5. For #OV and Theorem 4, the split analogously employs Ryser's formula modulo p but with a more intricate vector-coding of group residues modulo p to obtain the desired correspondence with counts of pairs of orthogonal vectors; we relegate the proof to Sect. 6.

Related Work and Further Applications. As regards exact and approximate inner products, Abboud, Williams, and Yu [1] used the polynomial method to construct a randomized subquadratic time algorithm for OV. Chan and Williams [14] derandomized the algorithm and showed that it could also solve the counting problem #OV. The first result that addressed an inner product different from zero, was the randomized algorithm for minimum Hamming weight pair by Alman and Williams [6]. Subsequently, Alman, Chan, and Williams [3] found an even faster randomized as well as a deterministic subquadratic algorithm matching [6].

A number of studies address approximate versions of inner-product counting in subquadratic time, such as the detection of outlier correlations and offline computation of approximate nearest neighbors, including Valiant [23], Karppa, Kaski, and Kohonen [18], Alman [2], and Alman, Chan, and Williams [4]. All the algorithms use fast rectangular matrix multiplication.

As regards permanents, Bax and Franklin presented a randomised $2^{n-\Omega(n^{1/3}/\log n)}$ expected time algorithm for the 0/1-matrix permanent [8]. Björklund [10] derived a faster and deterministic $2^{n-\Omega(\sqrt{n/\log n})}$ time algorithm. The algorithm was subsequently improved to a deterministic $2^{n-\Omega(\sqrt{n/\log\log n})}$ time algorithm by Björklund, Kaski, and Williams [12].

For the computation of an integer matrix permanent modulo a prime power $p^{\lambda n/p}$ for any constant $\lambda < 1$, Björklund, Husfeldt, and Lyckberg [11] derived a $2^{n-\Omega(n/(p\log p))}$ time algorithm. For the computation of a matrix permanent over an arbitrary ring R on r elements, Björklund and Williams [13] gave a deterministic $2^{n-\Omega(\frac{n}{r})}$ time algorithm.

The problem #InnerProduct has various applications in combinatorial algorithms. For example, it can be used to count the satisfying assignments to a Sym∘And formula (cf. Sect. 7), or compute the weight enumerator polynomial of a linear code (cf. Sect. 7). We would also like to highlight a recent application of deterministic algorithms for #OV [14] in efficient construction of rigid matrices [5].

2 Reconstruction from Sum-Aggregates by Prime Residue

This section develops the main methodological contribution of this work. Namely, we show that a complex-valued function $f : D \to \mathbb{C}$ can be reconstructed from its sum-aggregates by prime residue when the domain D is a prefix of the set of nonnegative integers. In essence, reconstruction of a function from its sum-aggregates can be viewed as an *additive* analog of the Chinese Remainder Theorem; that is, we obtain reconstruction up to the *sum* of the prime moduli – in the precise sense of (3) below – whereas the Chinese Remainder Theorem enables reconstruction up to the product of the moduli.[2]

In our application of counting pairs of vectors by inner product, we let f be a counting function such that $f(\ell)$ counts the number of pairs $(x, y) \in \mathcal{A} \times \mathcal{B}$ with $\langle x, y\rangle = \ell$. Reconstruction from sum-aggregates then enables us to recover f by counting the number of pairs (x, y) with $\langle x, y\rangle \equiv r \pmod p$ for small primes p and residues $r \in \{0, 1, \ldots, p-1\}$; we postpone the details of this application to Sect. 3 and first proceed to study reconstructibility.

Sum-Aggregation by Prime Residue. Let $p_1, p_2, \ldots, p_m$ be distinct prime numbers and let

$$D \subseteq \{0, 1, \ldots, s_m - 1\} \qquad \text{where} \qquad s_m = 1 + \sum_{b=1}^{m} (p_b - 1)\,. \tag{3}$$

Letting f_ℓ be shorthand for $f(\ell)$, we show that we can recover f from the sequence of its *sum-aggregates*

$$F_{br} = \sum_{\substack{\ell \in D \\ \ell \equiv r \pmod{p_b}}} f_\ell \quad \text{for each residue } r \in \{0, 1, \ldots, p_b - 1\} \text{ and each } b \in \{1, 2, \ldots, m\}. \tag{4}$$

[2] Here it should be noted that the scope of the classical Chinese Remainder Theorem is also somewhat more restricted than our present setting; indeed, the Chinese Remainder Theorem does not enable the reconstruction of an arbitrary function f but rather is restricted to reconstruction in the case when f is known to vanish in all but one point of D. We also note that the present additive setting can be captured algebraically through generalized Chinese remaindering in polynomial rings; here we refer to the alternative proof of Lemma 5 at the end of this section.

To start with, we observe that this sequence is linearly dependent. Indeed, define

$$F_{01} = \sum_{\ell \in D} f_\ell \tag{5}$$

and observe that for each $b \in \{1, 2, \ldots, m\}$ we have the linear relation $F_{01} = \sum_{r=0}^{p_b - 1} F_{br}$.

To obtain an equivalent and – as we will shortly show – linearly independent sequence, take the sequence formed by the sum F_{01} followed by F_{br} for each *nonzero* residue $r \in \{1, 2, \ldots, p_b - 1\}$ and each $b \in \{1, 2, \ldots, m\}$. Let us write F for this sequence of length s_m. By extending the domain of the function f with zero-values $f_\ell = 0$ as needed, we can also assume that $D = \{0, 1, \ldots, s_m - 1\}$ in what follows.

Sum-Aggregation as a Linear System – Modular Tomography. Let us now study reconstruction of f from F. From (4) and (5) we observe that to reconstruct f from F it suffices to solve the linear system

$$F = Af\,, \tag{6}$$

where A is the $s_m \times s_m$ *nonzero residue aggregation matrix* whose entries are defined for all $b \in \{0, 1, 2, \ldots, m\}$, $i \in \{1, 2, \ldots, p_b - 1\}$, and $\ell \in \{0, 1, \ldots, s_m - 1\}$ by the rule

$$A_{bi,\ell} = \begin{cases} 1 & \text{if } b = 0; \\ 1 & \text{if } b \geq 1 \text{ and } i \equiv \ell \pmod{p_b}; \\ 0 & \text{if } b \geq 1 \text{ and } i \not\equiv \ell \pmod{p_b}, \end{cases} \tag{7}$$

where we have assumed for convenience that $p_0 = 2$. Indeed, we readily verify from (4), (5), and (7) that

$$F_{bi} = \sum_{\ell=0}^{s_m - 1} A_{bi,\ell} f_\ell$$

holds for each $b \in \{0, 1, \ldots, m\}$ and $i \in \{0, 1, \ldots, p_b - 1\}$. When we want to stress the m selected primes, we write $A^{p_1, p_2, \ldots, p_m}$ for the matrix A.

The row-banded structure given by (7) is perhaps easiest illustrated with a small example. Below we display the matrix A for the primes $p_1 = 2$, $p_2 = 3$, and $p_3 = 5$:

$$A^{2,3,5} = \left[\begin{array}{cccccccc} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ \hline 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ \hline 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ \hline 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \end{array}\right]. \tag{8}$$

Observe in particular that the first band $b = 0$ corresponds to the sum (5) and the subsequent bands $b \in \{1, 2, \ldots, m\}$ each correspond to one of the primes $p_1, p_2, \ldots, p_m$ so that the $p_b - 1$ rows inside each band correspond to the sum-aggregates (4) of the $p_b - 1$ *nonzero* residue classes modulo p_b.

Our main technical lemma establishes that the matrix A is invertible, thus enabling reconstruction of f from F. Or, what is the same, we can recover f by *modular tomography* from the sequence F of *tomographs*; indeed, from a tomographic standpoint we can by (7) and (8) view each $b \in \{1, 2, \ldots, m\}$ as corresponding to a bundle of pairwise disjoint parallel lines aggregating the data f, with $i \in \{1, 2, \ldots, p_b - 1\}$ indexing the lines in a bundle.

▶ **Lemma 5** (Reconstruction from Sum-Aggregates by Prime Residue). *The nonzero residue aggregation matrix $A^{p_1,p_2,\ldots,p_m}$ is invertible whenever $p_1, p_2, \ldots, p_m$ are distinct primes.*

The key idea in the proof is to decompose $A^{p_1,p_2,\ldots,p_m}$ over the complex numbers into the product of a near-block-diagonal matrix with near-Vandermonde blocks and a Vandermonde matrix, both of which are then shown to have nonzero determinant. We will also present an alternative proof using elementary commutative algebra.

Proof of the Reconstruction Lemma. We now prove Lemma 5. We show that for distinct primes $p_1, p_2, \ldots, p_m$ the matrix $A = A^{p_1,p_2,\ldots,p_m}$ is invertible over rational numbers. Our strategy is to show that $A = UV$ for two complex matrices U and V that both have nonzero determinant. Indeed, the near-cyclic banded structure of A suggests that one should pursue a decomposition in terms of block-structured near-Vandermonde matrices. Let us first define the matrices U and V, then present a small example, and then complete the proof.

We will use the following standard facts about complex roots of unity. For a positive integer N, let us write $\omega_N = \exp\left(\frac{2\pi\mathfrak{i}}{N}\right)$, where $\mathfrak{i} = \sqrt{-1}$ is the imaginary unit. For all $m \in \mathbb{Z}$ we have

$$\frac{1}{N}\sum_{j=0}^{N-1} \omega_N^{km} = \begin{cases} 1 & \text{if } k \equiv 0 \pmod{N}; \\ 0 & \text{if } k \not\equiv 0 \pmod{N}. \end{cases} \tag{9}$$

The matrix U will use a $(m+1) \times (m+1)$ block structure that is similar to the $(m+1)$-band structure of A, but now the structure is used both for rows and columns. Again for convenience we assume $p_0 = 2$. The matrix U is defined for all $b \in \{0, 1, 2, \ldots, m\}$, $i \in \{1, 2, \ldots, p_b - 1\}$, $d \in \{0, 1, \ldots, m\}$, and $k \in \{1, 2, \ldots, p_d - 1\}$ by the rule

$$U_{bi,dk} = \begin{cases} 1 & \text{if } d = 0 \text{ and } b = 0; \\ \frac{1}{p_b} & \text{if } d = 0 \text{ and } b \geq 1; \\ 0 & \text{if } d \geq 1 \text{ and } b \neq d; \\ \frac{1}{p_b}\omega_{p_b}^{-ik} & \text{if } d \geq 1 \text{ and } b = d. \end{cases} \tag{10}$$

The matrix V is a Vandermonde matrix with $(m+1)$-banded structure defined for all $d \in \{0, 1, \ldots, m\}$, $k \in \{1, 2, \ldots, p_d - 1\}$, and $\ell \in \{0, 1, \ldots, s_m - 1\}$ by the rule

$$V_{dk,\ell} = \begin{cases} 1 & \text{if } d = 0; \\ \omega_{p_d}^{k\ell} & \text{if } d \geq 1\,. \end{cases} \tag{11}$$

Before proceeding with the proof that $A = UV$, let us present an example for the primes $p_1 = 2$, $p_2 = 3$, and $p_3 = 5$; recall (8). We have

$$\left[\begin{array}{cccccccc} 1&1&1&1&1&1&1&1\\ \hline 0&1&0&1&0&1&0&1\\ \hline 0&1&0&0&1&0&0&1\\ 0&0&1&0&0&1&0&0\\ \hline 0&1&0&0&0&0&1&0\\ 0&0&1&0&0&0&0&1\\ 0&0&0&1&0&0&0&0\\ 0&0&0&0&1&0&0&0 \end{array}\right]_{A^{2,3,5}} =$$

$$= \left[\begin{array}{c|c|cc|cccc} 1&0&0&0&0&0&0&0\\ \hline \frac{1}{2}&\frac{1}{2}\omega_2^{-1\cdot 1}&0&0&0&0&0&0\\ \hline \frac{1}{3}&0&\frac{1}{3}\omega_3^{-1\cdot 1}&\frac{1}{3}\omega_3^{-1\cdot 2}&0&0&0&0\\ \frac{1}{3}&0&\frac{1}{3}\omega_3^{-2\cdot 1}&\frac{1}{3}\omega_3^{-2\cdot 2}&0&0&0&0\\ \hline \frac{1}{5}&0&0&0&\frac{1}{5}\omega_5^{-1\cdot 1}&\frac{1}{5}\omega_5^{-1\cdot 2}&\frac{1}{5}\omega_5^{-1\cdot 3}&\frac{1}{5}\omega_5^{-1\cdot 4}\\ \frac{1}{5}&0&0&0&\frac{1}{5}\omega_5^{-2\cdot 1}&\frac{1}{5}\omega_5^{-2\cdot 2}&\frac{1}{5}\omega_5^{-2\cdot 3}&\frac{1}{5}\omega_5^{-2\cdot 4}\\ \frac{1}{5}&0&0&0&\frac{1}{5}\omega_5^{-3\cdot 1}&\frac{1}{5}\omega_5^{-3\cdot 2}&\frac{1}{5}\omega_5^{-3\cdot 3}&\frac{1}{5}\omega_5^{-3\cdot 4}\\ \frac{1}{5}&0&0&0&\frac{1}{5}\omega_5^{-4\cdot 1}&\frac{1}{5}\omega_5^{-4\cdot 2}&\frac{1}{5}\omega_5^{-4\cdot 3}&\frac{1}{5}\omega_5^{-4\cdot 4} \end{array}\right]_{U^{2,3,5}} \cdot$$

$$\cdot \left[\begin{array}{cccccccc} 1&1&1&1&1&1&1&1\\ \hline \omega_2^{1\cdot 0}&\omega_2^{1\cdot 1}&\omega_2^{1\cdot 2}&\omega_2^{1\cdot 3}&\omega_2^{1\cdot 4}&\omega_2^{1\cdot 5}&\omega_2^{1\cdot 6}&\omega_2^{1\cdot 7}\\ \hline \omega_3^{1\cdot 0}&\omega_3^{1\cdot 1}&\omega_3^{1\cdot 2}&\omega_3^{1\cdot 3}&\omega_3^{1\cdot 4}&\omega_3^{1\cdot 5}&\omega_3^{1\cdot 6}&\omega_3^{1\cdot 7}\\ \omega_3^{2\cdot 0}&\omega_3^{2\cdot 1}&\omega_3^{2\cdot 2}&\omega_3^{2\cdot 3}&\omega_3^{2\cdot 4}&\omega_3^{2\cdot 5}&\omega_3^{2\cdot 6}&\omega_3^{2\cdot 7}\\ \hline \omega_5^{1\cdot 0}&\omega_5^{1\cdot 1}&\omega_5^{1\cdot 2}&\omega_5^{1\cdot 3}&\omega_5^{1\cdot 4}&\omega_5^{1\cdot 5}&\omega_5^{1\cdot 6}&\omega_5^{1\cdot 7}\\ \omega_5^{2\cdot 0}&\omega_5^{2\cdot 1}&\omega_5^{2\cdot 2}&\omega_5^{2\cdot 3}&\omega_5^{2\cdot 4}&\omega_5^{2\cdot 5}&\omega_5^{2\cdot 6}&\omega_5^{2\cdot 7}\\ \omega_5^{3\cdot 0}&\omega_5^{3\cdot 1}&\omega_5^{3\cdot 2}&\omega_5^{3\cdot 3}&\omega_5^{3\cdot 4}&\omega_5^{3\cdot 5}&\omega_5^{3\cdot 6}&\omega_5^{3\cdot 7}\\ \omega_5^{4\cdot 0}&\omega_5^{4\cdot 1}&\omega_5^{4\cdot 2}&\omega_5^{4\cdot 3}&\omega_5^{4\cdot 4}&\omega_5^{4\cdot 5}&\omega_5^{4\cdot 6}&\omega_5^{4\cdot 7} \end{array}\right]_{V^{2,3,5}} . \tag{12}$$

The main technical aspect of the proof that $A = UV$ is to partition the index $\ell \in \{0, 1, \ldots, s_m - 1\}$ to the $m + 1$ bands. Towards this end, define for each $c \in \{0, 1, \ldots, m\}$ the prefix-sum

$$\underline{s}_c = \begin{cases} 0 & \text{if } c = 0; \\ 1 + \sum_{\ell=1}^{c-1} \big(p_c - 1\big) & \text{if } c \geq 1. \end{cases}$$

In particular, for every $\ell \in \{0, 1, \ldots, s_m - 1\}$, we observe that there exist unique $c \in \{0, 1, \ldots, m\}$ and $j \in \{1, 2, \ldots, p_c - 1\}$ such that

$$\ell = j - 1 + \underline{s}_c \,. \tag{13}$$

We are now ready to show that $A = UV$. Let $b \in \{0, 1, \ldots, m\}$, $i \in \{0, 1, \ldots, p_b - 1\}$, and $\ell \in \{0, 1, \ldots, s_k - 1\}$ be arbitrary. Let $c \in \{0, 1, \ldots, m\}$ and $j \in \{1, 2, \ldots, p_c - 1\}$ be uniquely determined from ℓ by (13). From (10), (11), (9), and (7) we observe that

$$\sum_{d=0}^{m} \sum_{k=0}^{p_d - 1} U_{bi,dk} V_{dk,\ell} =$$

$$= \begin{cases} 1 & \text{if } b = 0; \\ \frac{1}{p_b}\big(1 + \sum_{k=1}^{p_b-1} \omega_{p_b}^{-ik+k(j-1+\underline{s}_b)}\big) & \\ \qquad = \frac{1}{p_b} \sum_{k=0}^{p_b-1} \omega_{p_b}^{k(j-i-1+\underline{s}_b)} = 1 & \text{if } b \geq 1 \text{ and } i \equiv j - 1 + \underline{s}_b = \ell \pmod{p_b}; \\ \frac{1}{p_b}\big(1 + \sum_{k=1}^{p_b-1} \omega_{p_b}^{-ik+k(j-1+\underline{s}_b)}\big) & \\ \qquad = \frac{1}{p_b} \sum_{k=0}^{p_b-1} \omega_{p_b}^{k(j-i-1+\underline{s}_b)} = 0 & \text{if } b \geq 1 \text{ and } i \not\equiv j - 1 + \underline{s}_b = \ell \pmod{p_b}. \end{cases}$$

$$= A_{bi,\ell} \,.$$

Thus, $A = UV$ holds. It remains to show that both matrices U and V have nonzero determinant over the complex numbers. Starting with the Vandermonde matrix V, let $\nu_0 = 1$ and $\nu_\ell = \omega_{p_c}^j$ for $\ell \in \{1, 2, \ldots, s_m - 1\}$, where $c \in \{0, 1, \ldots, m\}$ and $j \in \{1, 2, \ldots, p_c - 1\}$ are uniquely determined from ℓ by (13). In particular, we observe that V is a Vandermonde matrix with $D = s_m - 1$ and $V = \big[\nu_i^j\big]_{i=0,1,\ldots,D}^{j=0,1,\ldots,D}$. The Vandermonde determinant formula

thus gives $\det V = \sum_{0 \le k < \ell \le D} (\nu_\ell - \nu_k)$. Furthermore, this determinant is nonzero because $p_1, p_2, \ldots, p_m$ are distinct primes and thus $\nu_0, \nu_1, \ldots, \nu_D$ are distinct. Next, let us consider the matrix U defined by (10). At this point it may be useful to revisit the structure of U via the example (12). We observe that the block-diagonal of U with $b = c \ge 1$ consists of matrices that each decompose into the product of a $(p_b - 1) \times (p_b - 1)$ diagonal matrix with diagonal entries $\frac{1}{p_b}\omega_{p_b}^{-i}$ for $i \in \{1, 2, \ldots, p_b - 1\}$ and a $(p_b - 1) \times (p_b - 1)$ Vandermonde matrix with a nonzero determinant since $\omega_{p_b}^{-i}$ for $i \in \{1, 2, \ldots, p_b - 1\}$ are distinct. Thus, since the determinant of U is the product of the determinants of the block-matrices on the diagonal, each of which is nonzero, the determinant of U is nonzero. It follows that A is invertible and thus given F we can solve for f via (6). This completes the proof of Lemma 5. ◀

An Alternative Proof. Let us sketch an alternative algebraic proof for Lemma 5. Let us view $f = \sum_{\ell=0}^{s_m - 1} f_\ell x^\ell \in \mathbb{C}[x]$ as a univariate polynomial in the indeterminate x over the complex numbers. For each $b \in \{1, 2, \ldots, m\}$, we observe that the polynomial remainder of f divided by $x^{p_b} - 1$ satisfies $f \operatorname{rem} (x^{p_b} - 1) = \sum_{i=0}^{p_b - 1} F_{bi} x^i \in \mathbb{C}[x]$. Furthermore, for distinct $b, c \in \{1, 2, \ldots, m\}$ we have that the sets of complex roots of $x^{p_b} - 1$ and $x^{p_c} - 1$ are disjoint apart from the common root $x = 1$; that is, $(x^{p_b} - 1)/(x - 1)$ and $(x^{p_c} - 1)/(x - 1)$ are coprime polynomials. Thus, by (3) and the Chinese Remainder Theorem in $\mathbb{C}[x]$, we can recover f from the sequence of remainders $f \operatorname{rem} (x^{p_b} - 1)$ for $b \in \{1, 2, \ldots, m\}$; cf. von zur Gathen and Gerhard [25] for the algebraic background and associated near-linear-time algorithmic toolbox. ◀

3 Counting Pairs of Zero-One Vectors by Inner Product

This section documents our main algorithm and proves Theorem 1. Let κ be a parameter that satisfies, with foresight,

$$4 \le \kappa \le \frac{\log n}{(\log \log n)^4}\,. \tag{14}$$

Let $a^{(1)}, a^{(2)}, \ldots, a^{(n)} \in \{0,1\}^d$ and $b^{(1)}, b^{(2)}, \ldots, b^{(n)} \in \{0,1\}^d$ be given as input with $d \le \kappa \log n$. We want to compute for each $t \in \{0, 1, \ldots, d\}$ the count

$$f_t = |\{(i,j) \in \{1,2,\ldots,n\}^2 : \langle a^{(i)}, b^{(j)} \rangle = t\}|\,.$$

Our high-level approach will be to use Lemma 5 and (6) to solve for the counts $f_0, f_1, \ldots, f_d$ using as input counts that have been sum-aggregated by prime residue. More precisely, we will work with prime moduli $p_1, p_2, \ldots, p_m$ and develop an algorithm that computes, for given further input $p \in \{p_1, p_2, \ldots, p_m\}$ and $r \in \{0, 1, \ldots, p-1\}$, the sum-aggregated count

$$F_{pr} = |\{(i,j) \in \{1,2,\ldots,n\}^2 : \langle a^{(i)}, b^{(j)} \rangle \equiv r \pmod p\}|\,.$$

The detailed choices for m and the primes $p_1, p_2, \ldots, p_m$ will be presented later.

The Residue-Indicator Polynomial. Assume p and r have been given. We will rely on the polynomial method, and accordingly we first build a standard polynomial that indicates the residue r modulo p in a pair of vectors.

Let $x = (x_1, x_2, \ldots, x_d)$ and $y = (y_1, y_2, \ldots, y_d)$ be two vectors of indeterminates. By Fermat's little theorem, the $2d$-indeterminate polynomial

$$G_{p,r}(x,y) = 1 - \left(\sum_{k=1}^{d} x_k y_k - r\right)^{p-1} \tag{15}$$

satisfies for all $i, j \in \{1, 2, \ldots, n\}$ the indicator property

$$G_{p,r}\big(a^{(i)}, b^{(j)}\big) \equiv \begin{cases} 1 \pmod p & \text{if } \langle a^{(i)}, b^{(j)} \rangle \equiv r \pmod p; \\ 0 \pmod p & \text{if } \langle a^{(i)}, b^{(j)} \rangle \not\equiv r \pmod p. \end{cases} \tag{16}$$

We observe that $G_{p,r}$ has degree $2p - 2$.

Modulus Amplification for Zero-One Residues. To enable taking the sum of a large number of indicators, we make use of the *modulus amplifying polynomials* of Beigel and Tarui [9].

▶ **Theorem 6** (Modulus amplification; Beigel and Tarui [9]). *For $h \in \mathbb{Z}_{\geq 1}$, define the polynomial*

$$A_h(z) = 1 - (1 - z)^h \sum_{j=0}^{h-1} \binom{h + j - 1}{j} z^j \,. \tag{17}$$

Then, for all $m \in \mathbb{Z}_{\geq 2}$ and $s \in \mathbb{Z}$, we have

(i) *$s \equiv 0 \pmod m$ implies $A_h(s) \equiv 0 \pmod{m^h}$, and*

(ii) *$s \equiv 1 \pmod m$ implies $A_h(s) \equiv 1 \pmod{m^h}$.*

We observe that A_h has degree $2h - 1$. Composing (17) and (15), we obtain the amplified residue-indicator polynomial

$$G^h_{p,r}(x, y) = A_h\big(G_{p,r}(x, y)\big) \,. \tag{18}$$

From (16) and Theorem 6, we observe the amplified indicator property

$$G^h_{p,r}\big(a^{(i)}, b^{(j)}\big) \equiv \begin{cases} 1 \pmod{p^h} & \text{if } \langle a^{(i)}, b^{(j)} \rangle \equiv r \pmod p; \\ 0 \pmod{p^h} & \text{if } \langle a^{(i)}, b^{(j)} \rangle \not\equiv r \pmod p. \end{cases} \tag{19}$$

Furthermore, we observe that $G^h_{p,r}$ has degree $(2h - 1)(2p - 2)$.

Multilinear Reduct and Bounding the Number of Monomials. For a nonnegative integer e, define $\underline{e} = 0$ if $e = 0$ and $\underline{e} = 1$ if $e \geq 1$. For a monomial $x_1^{e_1} x_2^{e_2} \cdots x_d^{e_d} y_1^{f_1} y_2^{f_2} \cdots y_d^{f_d}$, define the *multilinear reduct* by

$$\underline{x_1^{e_1} x_2^{e_2} \cdots x_d^{e_d} y_1^{f_1} y_2^{f_2} \cdots y_d^{f_d}} = x_1^{\underline{e}_1} x_2^{\underline{e}_2} \cdots x_d^{\underline{e}_d} y_1^{\underline{f}_1} y_2^{\underline{f}_2} \cdots y_d^{\underline{f}_d} \,.$$

For a polynomial $Q(x, y)$, define the multilinear reduct $\underline{Q}(x, y)$ by taking the multilinear reduct of each monomial $Q(x, y)$ and simplifying. Since $a^{(i)}$ and $b^{(j)}$ are $\{0, 1\}$-valued vectors, over the integers we have

$$Q\big(a^{(i)}, b^{(j)}\big) = \underline{Q}\big(a^{(i)}, b^{(j)}\big) \,. \tag{20}$$

Furthermore, if Q has degree D, then $\underline{Q}$ has at most $\sum_{j=0}^{D} \binom{2d}{j}$ monomials. In particular, we observe that $\underline{G}^h_{p,r}$ has at most $\sum_{j=0}^{4hp} \binom{2d}{j}$ monomials.

Split-Monomial Form of the Multilinear Reduct. Suppose that the multilinear reduct $\underline{G}^h_{p,r}(x,y)$ has exactly M monomials with the representation

$$\underline{G}^h_{p,r}(x,y) = \sum_{k=1}^{M} \gamma^{(k)}\, x_1^{e_1^{(k)}} x_2^{e_2^{(k)}} \cdots x_d^{e_d^{(k)}} y_1^{f_1^{(k)}} y_2^{f_2^{(k)}} \cdots y_d^{f_d^{(k)}}\,. \tag{21}$$

For $I, J \subseteq \{1,2,\ldots,n\}$ and $k \in \{1,2,\ldots,M\}$, define

$$L_{I,k} = \sum_{i\in I} \big(a_1^{(i)}\big)^{e_1^{(k)}} \big(a_2^{(i)}\big)^{e_2^{(k)}} \cdots \big(a_d^{(i)}\big)^{e_d^{(k)}} \gamma^{(k)}\,,\ R_{J,k} = \sum_{j\in J} \big(b_1^{(j)}\big)^{f_1^{(k)}} \big(b_2^{(j)}\big)^{f_2^{(k)}} \cdots \big(b_d^{(j)}\big)^{f_d^{(k)}}\,. \tag{22}$$

From (22), (21), (20), and (19), we have

$$\begin{aligned}\sum_{k=1}^{M} L_{I,k} R_{J,k} &= \sum_{i\in I}\sum_{j\in J} \underline{G}^h_{p,r}\big(a^{(i)}, b^{(j)}\big) \\ &\equiv \big|\big\{(i,j) \in I\times J : \langle a^{(i)}, b^{(j)}\rangle \equiv r \pmod p\big\}\big| \pmod{p^h}\,.\end{aligned} \tag{23}$$

In particular, assuming that $|I||J| \leq p^h - 1$, from (23) it follows that $\sum_{k=1}^{M} L_{I,k}R_{J,k}$ computed modulo p^h recovers the number of pairs $(i,j) \in I \times J$ with $\langle a^{(i)}, b^{(j)}\rangle \equiv r \pmod p$.

We now move from deriving the polynomial and its properties to describing the algorithm.

Algorithm for the Prime-Residue Count. The algorithm will rely on (23) via fast rectangular matrix multiplication to count the number of pairs $(i,j) \in \{1,2,\ldots,n\}^2$ that satisfy $\langle a^{(i)}, b^{(j)}\rangle \equiv r \pmod p$.

The algorithm first computes the explicit M-monomial representation of the polynomial $\underline{G}^h_{p,r}$ in (21). More precisely, the algorithm evaluates (15), (17), and (18) in explicit monomial representation, taking multilinear reducts with respect to the variables $x_1, x_2, \ldots, x_d, y_1, y_2, \ldots, y_d$ whenever possible. This results in the set

$$\{(k, \gamma^{(k)}, e_1^{(k)}, e_2^{(k)}, \ldots, e_d^{(k)}, f_1^{(k)}, f_2^{(k)}, \ldots, f_d^{(k)}) : k \in \{1,2,\ldots,M\}\}\,. \tag{24}$$

Next, the algorithm constructs two rectangular matrices S and T, with the objective of making use of the following algorithm of Coppersmith [16].

▶ **Theorem 7** (Coppersmith [16]). *Given an $N \times \lfloor N^{0.17}\rfloor$ matrix S and an $\lfloor N^{0.17}\rfloor \times N$ matrix T as input, the matrix product ST over the integers can be computed in $O(N^2 \log^2 N)$ arithmetic operations.*

Towards this end, let g be a positive integer whose value we will fix later. Introduce two set partitions of $\{1,2,\ldots,n\}$ with cells

$$I_1, I_2, \ldots, I_{\lceil n/g\rceil} \subseteq \{1,2,\ldots,n\} \qquad \text{and} \qquad J_1, J_2, \ldots, J_{\lceil n/g\rceil} \subseteq \{1,2,\ldots,n\}\,,$$

respectively, so that $|I_u| = g$ and $|I_v| = g$ for $u, v \in \{1,2,\ldots,\lfloor n/g\rfloor\}$. Indeed, we thus have $|I_u||J_v| \leq g^2$ for all $u, v \in \{1,2,\ldots,\lceil n/g\rceil\}$, so (23) applied to I_u and J_v modulo p^h recovers the number of pairs $(i,j) \in I_u \times J_v$ with $\langle a^{(i)}, b^{(j)}\rangle \equiv r \pmod p$, assuming that $g^2 \leq p^h - 1$, which will be justified by our eventual choice of g.

Now let $N = \lceil n/g\rceil$ and define the $N \times M$ and $M \times N$ matrices S and T by setting $S_{uk} = L_{I_u,k}$ and $T_{kv} = R_{I_v,k}$ for $u, v \in \{1,2,\ldots,\lceil n/g\rceil\}$ and $k \in \{1,2,\ldots,M\}$. Concretely, the algorithm computes S and T from the given input one entry at a time using the computed monomial list (24) and the formulas (22) for $I = I_u$ and $J = J_v$ for each $u, v \in \{1,2,\ldots,\lceil n/g\rceil\}$ and $k = 1,2,\ldots,M$. The algorithm then multiplies S and T to obtain the product matrix ST modulo p^h, where we assume that each entry of ST is reduced to $\{0,1,\ldots,p^h-1\}$. Finally, the algorithm outputs the sum $F_{pr} = \sum_{u=1}^{\lceil n/g\rceil}\sum_{v=1}^{\lceil n/g\rceil} (ST)_{uv}$.

Parameterizing the Algorithm. Let us now fix precise values for the parameters g, h, and p that were left open. First, to apply the algorithm in Theorem 7 to the matrices S and T, we need $M \leq N^{0.17} = \lceil n/g \rceil^{0.17}$. Subject to the assumption $g \leq n^{0.1}$ – to be justified later – it will be sufficient to show that $M \leq n^{0.15}$. We recall that $M \leq \sum_{j=0}^{4hp} \binom{2d}{j}$ and $d \leq \kappa \log n$. With foresight, let us set

$$\beta_\kappa = \frac{K}{\log \kappa}\,, \tag{25}$$

where $K > 0$ is a small constant that will be fixed later. In particular, since $\kappa \geq 4$, we have the upper bound

$$\beta_\kappa \log \frac{\kappa}{\beta_\kappa} = K - \frac{K \log K}{\kappa} + \frac{K \log \log \kappa}{\kappa} \leq \frac{5K}{4} \tag{26}$$

which we can make an arbitrarily small and positive by choosing a small enough K. Let us assume – to be justified later – that $p = o(\beta_\kappa \log n)$. Taking

$$h = \left\lfloor \beta_\kappa \frac{\log n}{p} \right\rfloor \tag{27}$$

we have, for all large enough n,

$$\begin{aligned} M &\leq \sum_{j=0}^{4hp} \binom{2d}{j} \leq 4hp \binom{2d}{4hp} \leq 4hp \left(\frac{2ed}{4hp}\right)^{4hp} \\ &\leq 4\left(\beta_\kappa \frac{\log n}{p} + 1\right) p \left(\frac{2e\kappa \log n}{4\big(\beta_\kappa \frac{\log n}{p} - 1\big)p}\right)^{4\left(\beta_\kappa \frac{\log n}{p} + 1\right)p} \\ &= 4\big(\beta_\kappa \log n + p\big) \left(\frac{2e\kappa \log n}{4\big(\beta_\kappa \log n - p\big)}\right)^{4(\beta_\kappa \log n + p)} \\ &\leq \big(5\beta_\kappa \log n\big) \left(\frac{2e\kappa}{3\beta_\kappa}\right)^{5\beta_\kappa \log n} \leq n^{0.15}\,, \end{aligned} \tag{28}$$

where the last inequality follows by (26) and choosing K small enough. Thus, Theorem 7 applies, subject to the assumptions $g \leq n^{0.1}$, $g^2 \leq p^h - 1$, and $p = o(\beta_\kappa \log n)$, which still need to be established. Before this, we digress to further preliminaries to enable reconstruction.

Preliminaries on Asymptotics of Primes. In what follows let us write p_j for the jth prime number with $j = 1, 2, \ldots$; that is, $p_1 = 2$, $p_2 = 3$, $p_3 = 5$, and so forth. Asymptotically, from the Prime Number Theorem we have $p_m \sim m \ln m$ (e.g. Rosser and Schoenfeld [21]), and the sum of the first m primes satisfies $\sum_{j=1}^{m} p_j \sim \frac{1}{2} m^2 \ln m$ (cf. Bach and Shallit [7]), where we write $f(m) \sim g(m)$ if $\lim_{m\to\infty} \frac{f(m)}{g(m)} = 1$.

When evaluated for the first m primes, the reconstruction parameter (3) thus satisfies

$$s_m = 1 + \sum_{j=1}^{m} (p_j - 1) \sim \frac{p_m^2}{2 \ln p_m}\,. \tag{29}$$

We are now ready to continue parameterization of the algorithm.

Further Parameterization of the Algorithm. Let m be a positive integer whose value will be fixed shortly. The algorithm will work with $p_1, p_2, \ldots, p_m$, the first m prime numbers. To reconstruct inner products of length-d zero-one vectors over the integers, we need $d+1 \leq s_m$, which for $d \leq \kappa \log n$ and (29) means

$$\frac{p_m^2}{2 \ln p_m} \sim \kappa \log n \,.$$

From Bertrand's postulate it thus follows that choosing the least m so that

$$2\sqrt{\kappa (\ln n) \ln \ln n} \leq p_m \leq 4\sqrt{\kappa (\ln n) \ln \ln n} \tag{30}$$

implies that we have $d+1 \leq s_m$ for all large enough n and thus reconstruction is feasible. The choice (30) also justifies our ealier assumption made in the context of (27) and (28) that $p_j = o(\beta_\kappa \log n)$ for all $j \in \{1, 2, \ldots, m\}$; indeed, from (14) and (25), we have

$$\beta_\kappa \log n = \frac{K \log n}{\log \kappa}$$

and thus from (14) and (30) we observe that

$$\frac{p_j}{\beta_\kappa \log n} \leq \frac{4\kappa^{1/2} (\log \kappa)(\ln n)^{1/2} (\ln \ln n)^{1/2}}{K \log n} = o(1) \,.$$

Let us next choose the parameter g. Using $p_j = o(\beta_\kappa \log n)$ again, we have

$$p_j^{h_j} = p_j^{\left\lfloor \beta_\kappa \frac{\log n}{p_j} \right\rfloor} \geq p_j^{\beta_\kappa \frac{\log n}{p_j} - 1} \geq p_j^{\beta_\kappa \frac{\log n}{2p_j}} = 2^{\beta_\kappa \frac{\log n}{2p_j} \log p_j} = n^{\beta_\kappa \frac{\log p_j}{2p_j}} \,.$$

Since $p_1 < p_2 < \cdots < p_m$, for $j \in \{1, 2, \ldots, m\}$ thus $p_j^{h_j} \geq n^{\beta_\kappa \frac{\log p_m}{2p_m}}$. It follows that choosing

$$g = \left\lfloor \sqrt{n^{\beta_\kappa \frac{\log p_m}{2p_m}} - 1} \right\rfloor \tag{31}$$

justifies our assumption $g^2 \leq p_j^{h_j} - 1$ for $j \in \{1, 2, \ldots, m\}$. The final assumption $g \leq n^{0.1}$ is justified by observing that $\frac{\log p_m}{2p_m}$ is a decreasing function of m and observing that $\beta_\kappa = o(1)$ by (14) and (25). The algorithm is now parameterized. Let us next analyse its running time.

Running Time Analysis. First, let us seek control on N as a function of n. From (30) and (31), we have

$$g \geq \sqrt{n^{\beta_\kappa \frac{2 \log 2 + \log \kappa + \log \ln n + \log \ln \ln n}{16 \sqrt{\kappa \ln n \ln \ln n}}} - 1} - 1 \,.$$

This together with (14) gives us the crude lower bound

$$g = \exp\left(\Omega\left(\beta_\kappa \sqrt{\frac{(\ln n) \ln \ln n}{\kappa}} \right) \right) .$$

We thus have

$$N^2 = \lceil n/g \rceil^2 = n^{2 - \Omega\left(\beta_\kappa \sqrt{\frac{\ln \ln n}{\kappa \ln n}}\right)} \,.$$

Recalling (28), we observe that the time to compute the M-monomial list (24) can be bounded by $n^{0.31}$ because the algorithm is careful to take multilinear reducts and thus at no stage of evaluating (15), (17), and (18) the number of monomials increases above $(n^{0.15})^2 = n^{0.30}$. Since $\log p_j^{h_j} = h_j \log p_j = \lfloor \beta_\kappa \frac{\log n}{p_j} \rfloor \log p_j = O(\log n)$, the arithmetic over the integers and modulo $p_j^{h_j}$ for each $j = 1, 2, \ldots, m$ runs in time polylogarithmic in n for each arithmetic operation executed by the algorithm. Because the algorithm in Theorem 7 runs in $O(N^2 \log^2 N)$ arithmetic operations, we observe that the polylogarithmic terms are subsumed by the asymptotic notation and the entire algorithm for computing F_{pr} for given $p \in \{p_1, p_2, \ldots, p_m\}$ and $r \in \{0, 1, \ldots, p-1\}$ runs in time

$$n^{2-\Omega\left(\beta_\kappa \sqrt{\frac{\log\log n}{\kappa \log n}}\right)} = n^{2-\Omega\left(\sqrt{\frac{\log\log n}{\kappa (\log \kappa)^2 \log n}}\right)}. \tag{32}$$

From (30) we observe that the required repeats for different p and r result in multiplicative polylogarithmic terms in n and are similarly subsumed to result in total running time of the form (32). This completes the proof of Theorem 1. ◀

4 A Faster Randomized Algorithm for #InnerProduct

This section sketches a proof for Theorem 2. We follow the algorithm outlined in Alman and Williams [6]. We note that by their Theorem 1.2, there are probabilistic polynomials over any field with error ϵ of degree $O(\sqrt{n \log(1/\epsilon)})$. In their Theorem 4.2, they have a probabilistic OR-construction that takes the disjunction of a random set of s^2 pairs of vector inner products as

$$q(x_1, y_1, x_2, y_2, \ldots, x_s, y_s) = 1 + \prod_{k=1}^{2} \left(1 + \sum_{(i,j) \in R_k} \left(1 + p(x_{i,1} + y_{i,1}, x_{i,2} + y_{j,2}, \ldots, x_{i,s} + y_{j,s})\right)\right),$$

where p is a probabilistic threshold polynomial over $\mathbb{F}_2$ of error $\epsilon = s^{-3}$, and $R_k \subseteq [s]^2$ for $k = 1, 2$ are sieve subsets drawn uniformly at random. This construction can be used to detect w.h.p. if there is a pair in the s^2-sized batch whose difference Hamming weight is less than the threshold. By repeated computations with new p's and R_k's, a majority vote for the batch can be chosen as the correct answer, again w.h.p. for all batches.

We implement the following change of q to get an #InnerProduct algorithm. We take p to be a probabilistic polynomial of error $\epsilon = s^{-3}$ for the symmetric function $[\![\sum_{i=1}^{n} z_i = t]\!]$, over a field of characteristic $> s^2$. We then construct q as

$$q(x_1, y_1, x_2, y_2, \ldots, x_s, y_s) = \sum_{(i,j) \in [s]^2} p(x_{i,1} y_{i,1}, x_{i,2} y_{j,2}, \ldots, x_{i,s} y_{j,s}). \tag{33}$$

Since the characteristic of the field is large enough, (33) is equal to the number of pairs in the s^2-sized batch that has inner product equal to t with probability at least $1 - s^2\epsilon \geq 1 - \frac{1}{s}$, a similar bound on the probability as in Theorem 4.2. Also, the degree of the polynomials is only a factor 2 larger. As with the original algorithm, if we repeat this enough times and take the majority in each batch, we get the correct number of pairs with t as inner product in all batches. By summing these final majority numbers over the integers, we obtain the output. We note that the parameters of the error and the degree has only changed by a constant, and hence that all calculations of the running time and the error bound of the original algorithm carries through also for our modification of the algorithm. This completes the proof sketch. ◀

5 A Lower Bound for #InnerProduct via Zero-One Permanents

This section proves Theorem 3; the proof of Theorem 4 is presented in Sect. 6.

Throughout this section we let M be an $n \times n$ matrix with entries $m_{ij} \in \{0,1\}$ for $i,j \in \{1,2,\ldots,n\}$. For convenience, let us write $[n] = \{1,2,\ldots,n\}$. Recalling Ryser's formula, we have

$$\operatorname{per} M = (-1)^n \sum_{S \subseteq [n]} (-1)^{|S|} \prod_{i \in [n]} \sum_{j \in S} m_{ij} \,. \tag{34}$$

First Reduction: Chinese Remaindering. Since it is immediate that $0 \leq \operatorname{per} M \leq n!$, it suffices to compute the permanent modulo small primes p and then assemble the result over the integers via the Chinese Remainder Theorem. Let us first state and prove a crude upper bound on the size of the primes needed. For a positive integer m, let us write $m\#$ for the product of all prime numbers at most m.

▶ **Lemma 8.** *For all sufficiently large n, we have $n! \leq (n \ln n)\#$.*

Proof. Recall that for a positive integer m we write write $m\#$ for the product of all prime numbers at most m. For $m \geq 563$, we have $\ln m\# > m\big(1 - \frac{1}{2 \ln m}\big)$; cf. Rosser and Schoenfeld [21]. For the factorial function, for $n \geq 1$, Robbins [20] shows that $n! = \sqrt{2\pi n}\big(\frac{n}{e}\big)^n e^{\alpha_n}$ with $\frac{1}{12n+1} < \alpha_n < \frac{1}{12n}$, which gives us the comparatively crude upper bound $\ln n! < \big(n + \frac{1}{2}\big) \ln n - n + 1$ for $n \geq 1$. We want $\ln n! < \ln m\#$. Accordingly, it suffices to have $m \geq 563$ and $\big(n + \frac{1}{2}\big) \ln n - n + 1 < m\big(1 - \frac{1}{2 \ln m}\big)$. It is immediate that $m \geq n \ln n$ suffices for $m \geq 563$, which completes the proof. ◀

Thus, it suffices to work with all primes p with $p \leq n \ln n$ in what follows.

A Reduction from Zero-One Permanent to #InnerProduct. This section starts our work towards Theorem 3 without yet parameterizing the reduction in detail. Let a prime $2 \leq p \leq n \ln n$ be given. We seek to compute $\operatorname{per} M$ modulo p. Fix a primitive root $g \in \{1,2,\ldots,p-1\}$ modulo p. For an integer a with $a \not\equiv 0 \pmod p$, let us write $\operatorname{dlog}_{p,g} a$ for the *discrete logarithm* of a relative to g modulo p. That is, $\operatorname{dlog}_{p,g} a$ is the unique integer in $\{0,1,\ldots,p-2\}$ that satisfies $g^{\operatorname{dlog}_{p,g} a} \equiv a \pmod p$. Working modulo p and collecting the outer sum in (34) by the sign $\sigma \in \{-1,1\}$ and the *nonzero* products by their discrete logarithm, we have

$$\operatorname{per} M \equiv (-1)^n \sum_{e=0}^{p-2} g^e \big(w_1^{(e)} - w_{-1}^{(e)}\big) \pmod p \,,$$

where

$$w_\sigma^{(e)} = \left| \left\{ S \subseteq [n] \,:\, (-1)^{|S|} = \sigma \text{ and } \operatorname{dlog}_{p,g} \prod_{i \in [n]} \sum_{j \in S} m_{ij} \equiv e \pmod{p-1} \right\} \right|$$

for $\sigma \in \{-1,1\}$ and $e \in \{0,1,\ldots,p-2\}$. Thus, to compute $\operatorname{per} M$ modulo p it suffices to compute the coefficients $w_\sigma^{(e)}$. Towards this end, suppose that $n \geq 4$ is even and let

$$L = \{1,2,\ldots,n/2\} \qquad \text{and} \qquad R = \{n/2, n/2+1, \ldots, n\} \,.$$

For $\sigma_L, \sigma_R \in \{1,-1\}$, let

$$w_{\sigma_L,\sigma_R}^{(e)} = \left| \left\{ S \subseteq [n] : (-1)^{|S \cap L|} = \sigma_L,\ (-1)^{|S \cap R|} = \sigma_R \text{ and } \operatorname{dlog}_{p,g} \prod_{i \in [n]} \sum_{j \in S} m_{ij} \equiv e \pmod{p-1} \right\} \right|$$

Clearly $w_\sigma^{(e)} = \sum_{\substack{\sigma_L,\sigma_R\in\{-1,1\}\\ \sigma_L\sigma_R=\sigma}} w_{\sigma_L,\sigma_R}^{(e)}$, so it suffices to focus on computing $w_{\sigma_L,\sigma_R}^{(e)}$ in what follows. Define the set families

$$\mathcal{L}_{\sigma_L} = \big\{A \subseteq L : (-1)^{|A|} = \sigma_L\big\} \qquad \text{and} \qquad \mathcal{R}_{\sigma_R} = \big\{B \subseteq R : (-1)^{|B|} = \sigma_R\big\}$$

with $|\mathcal{L}_{\sigma_L}| = |\mathcal{R}_{\sigma_R}| = 2^{n/2-1}$. Next we will define two families of length-d zero-one vectors whose pair counts by inner product will enable us to recover the coefficients $w_{\sigma_L,\sigma_R}^{(e)}$. The structure of the vectors will be slightly elaborate, so let us first define an index set D for indexing the $|D| = d$ dimensions. Let

$$D = \big\{(i,\ell,r,k) \in [n]\times\{0,1,\ldots,p-1\}\times\{0,1,\ldots,p-1\}\times[np] : \\ \ell + r \not\equiv 0 \pmod p \text{ implies } k \le \operatorname{dlog}_{p,g}\big(\ell+r\big)\big\}.$$

We have $d = n^2p^2 + np(p-1)(p-2)/2 < n^4(\ln n)^3$.

For $A \in \mathcal{L}_{\sigma_L}$ and $B \in \mathcal{R}_{\sigma_R}$, define the vectors $\lambda(A) \in \{0,1\}^D$ and $\rho(B) \in \{0,1\}^D$ for all $(i,\ell,r,k) \in D$ by the rules

$$\lambda(A)_{i\ell rk} = \begin{cases} 1 & \text{if } \ell \equiv \sum_{j\in A} m_{ij} \pmod p; \\ 0 & \text{otherwise;}\end{cases} \quad \text{and} \quad \rho(B)_{i\ell rk} = \begin{cases} 1 & \text{if } r \equiv \sum_{j\in B} m_{ij} \pmod p; \\ 0 & \text{otherwise.}\end{cases}$$

To study the inner product $\langle\lambda(A),\rho(B)\rangle$ it will be convenient to work with Iverson's bracket notation. Namely, for a logical proposition P, let

$$[\![P]\!] = \begin{cases} 1 & \text{if } P \text{ is true;} \\ 0 & \text{if } P \text{ is false.}\end{cases}$$

Over the integers, we now have

$$\begin{aligned}
\langle\lambda(A),\rho(B)\rangle &= \sum_{(i,\ell,r,k)\in D} \lambda(A)_{i\ell rk}\rho(B)_{i\ell rk} \\
&= \sum_{(i,\ell,r,k)\in D} [\![\ell \equiv \sum_{j\in A} m_{ij} \pmod p]\!][\![r \equiv \sum_{j\in B} m_{ij} \pmod p]\!] \\
&= \sum_{i\in[n]} \sum_{\substack{\ell,r=0\\ \ell+r\not\equiv 0 \pmod p}}^{p-1} [\![\ell \equiv \sum_{j\in A} m_{ij} \pmod p]\!][\![r \equiv \sum_{j\in B} m_{ij} \pmod p]\!] \operatorname{dlog}_{p,g}\big(\ell+r\big) \\
&\qquad + \sum_{i\in[n]} \sum_{\ell=0}^{p-1} [\![\ell \equiv \sum_{j\in A} m_{ij} \pmod p]\!][\![p-\ell \equiv \sum_{j\in B} m_{ij} \pmod p]\!] np \\
&= \begin{cases} \sum_{i\in[n]} \operatorname{dlog}_{p,g} \sum_{j\in A\cup B} m_{ij} & \text{if } \prod_{i\in[n]} \sum_{j\in A\cup B} m_{ij} \not\equiv 0 \pmod p; \\ \ge np & \text{if } \prod_{i\in[n]} \sum_{j\in A\cup B} m_{ij} \equiv 0 \pmod p.\end{cases}
\end{aligned} \tag{35}$$

In particular, letting $f_{\sigma_L,\sigma_R,t} = \big|\big\{(A,B) \in \mathcal{L}_{\sigma_L}\times\mathcal{R}_{\sigma_R} : \langle\lambda(A),\rho(B)\rangle = t\big\}\big|$, it follows immediately from (35) that we have $w_{\sigma_1,\sigma_2}^{(e)} = \sum_{t=0,\ t\equiv e \pmod{p-1}}^{n(p-2)} f_{\sigma_L,\sigma_R,t}$, which enables us to recover $\operatorname{per} M$ from the counts of pairs in $\mathcal{L}_{\sigma_L}\times\mathcal{R}_{\sigma_R}$ by inner product.

Completing the Proof of Theorem 3. Suppose we have an algorithm for #InnerProduct that runs in $N^{2-\Omega(1/\log c)}$ time when given an input of N vectors from $\{0,1\}^{c\log N}$. Take $N = 2^{n/2-1}$ and observe that $\log N = n/2 - 1$. The reduction from previous section has $d \le n^4(\ln n)^3$ and thus we can take $c = (n\ln n)^3$ and thus solve $n\times n$ zero-one permanent in time $N^{2-\Omega(1/\log c)} = 2^{n-\Omega(n/\log n)}$. This completes the proof of Theorem 3. ◀

6 A Lower Bound for #OV via Zero-One Permanents

A Reduction from Zero-One Permanent to #OV. This section starts our work towards Theorem 4 without yet parameterizing the reduction in detail. As in Sect. 5, it suffices to describe how to compute $\operatorname{per} M$ modulo a given prime p with $2 \leq p \leq n \ln n$.

Let g be a positive integer parameter, which we assume divides n. For $h \in [g]$, let $V_h = \{i \in [n] : (h-1)n/g + 1 \leq i \leq hn/g\}$ be a partition of the rows of M into g groups, each of size n/g. Again from Ryser's formula, we have

$$\operatorname{per} M = (-1)^n \sum_{S \subseteq [n]} (-1)^{|S|} \prod_{h \in [g]} \prod_{i \in V_h} \sum_{j \in S} m_{ij} \,.$$

Grouping by sign $\sigma \in \{-1, 1\}$ and per-group residues $r \in \{0, 1, \ldots, p-1\}^g$, we thus have

$$\operatorname{per} M \equiv (-1)^n \sum_{r \in \{0,1,\ldots,p-1\}^g} (t_{1,r} - t_{-1,r}) \prod_{h=1}^{g} r_h \pmod{p}\,, \tag{36}$$

where $t_{\sigma,r} = \left|\left\{S \subseteq [n] : (-1)^{|S|} = \sigma \text{ and } \prod_{i \in V_h} \sum_{j \in S} m_{ij} \equiv r_h \pmod{p} \text{ for each } h \in [g]\right\}\right|$. Observe that given all the counts $t_{\sigma,r}$, it takes $O(p^g g)$ operations modulo p to compute the permanent modulo p via (36), which is less than $2^n n$ when $g < n/\log p$. We continue to describe how to get the counts $t_{\sigma,r}$ via orthogonal-vector counting.

Assuming that $n \geq 4$ is even, introduce again the split

$$L = \{1, 2, \ldots, n/2\} \qquad \text{and} \qquad R = \{n/2, n/2+1, \ldots, n\}\,.$$

Let the residue vector $r \in \{0, 1, \ldots, p-1\}^g$ be fixed. For $\sigma_L, \sigma_R \in \{1, -1\}$, let

$$t_{\sigma_L,\sigma_R,r} = \Big|\Big\{S \subseteq [n] : (-1)^{|S\cap L|} = \sigma_L \;,\; (-1)^{|S\cap R|} = \sigma_R\,, \\ \text{and } \prod_{i \in V_h} \sum_{j \in S} m_{ij} \equiv r_h \pmod{p} \text{ for each } h \in [g]\Big\}\Big|\,.$$

Clearly $t_{\sigma,r} = \sum_{\substack{\sigma_L,\sigma_R \in \{-1,1\} \\ \sigma_L\sigma_R = \sigma}} t_{\sigma_L,\sigma_R,r}$, so it suffices to focus on computing $t_{\sigma_L,\sigma_R,r}$ in what follows. We again work with the set families

$$\mathcal{L}_{\sigma_L} = \left\{A \subseteq L : (-1)^{|A|} = \sigma_L\right\} \qquad \text{and} \qquad \mathcal{R}_{\sigma_R} = \left\{B \subseteq R : (-1)^{|B|} = \sigma_R\right\}.$$

Let $D = [g] \times \{0, 1, \ldots, p-1\}^{n/g}$. We have $d = |D| = gp^{n/g}$.

For $A \in \mathcal{L}_{\sigma_L}$ and $B \in \mathcal{R}_{\sigma_R}$, define the vectors $\lambda(A) \in \{0,1\}^D$ and $\rho(B) \in \{0,1\}^D$ for all $(h, u) \in D$ by the rules

$$\lambda(A)_{hu} = \begin{cases} 1 & \text{if we have } \sum_{j \in A} m_{ij} \equiv u_{i-(h-1)n/g} \pmod{p} \text{ for all } i \in V_h; \\ 0 & \text{otherwise} \end{cases}$$

and

$$\rho(B)_{hu} = \begin{cases} 0 & \text{if } \prod_{i \in V_h} \left(u_{i-(h-1)n/g} + \sum_{j \in B} m_{ij}\right) \equiv r_h \pmod{p}; \\ 1 & \text{otherwise.} \end{cases} \tag{37}$$

Over the integers, from (37) we now have

$$\begin{aligned}
\langle \lambda(A), \rho(B) \rangle &= \sum_{(h,u)\in D} \lambda(A)_{hu}\rho(B)_{hu} \\
&= \sum_{h\in[g]} \sum_{u\in\{0,1,\ldots,p-1\}^{n/g}} \prod_{i\in V_h} \left[\!\!\left[\sum_{j\in A} m_{ij} \equiv u_{i-(h-1)n/g} \pmod p \right]\!\!\right] \\
&\qquad\qquad \left[\!\!\left[\prod_{i\in V_h} \left(u_{i-(h-1)n/g} + \sum_{j\in B} m_{ij}\right) \not\equiv r_h \pmod p \right]\!\!\right] \\
&= \sum_{h\in[g]} \left[\!\!\left[\prod_{i\in V_h} \left(\sum_{j\in A} m_{ij} + \sum_{j\in B} m_{ij} \right) \not\equiv r_h \pmod p \right]\!\!\right] \\
&= \begin{cases} 0 & \text{if we have } \prod_{i\in V_h} \sum_{j\in A\cup B} m_{ij} \equiv r_h \pmod p \text{ for each } h\in[g]; \\ \geq 1 & \text{otherwise.} \end{cases} \qquad (38)
\end{aligned}$$

In particular, we have $t_{\sigma_L,\sigma_R,r} = \left|\left\{(A,B) \in \mathcal{L}_{\sigma_L} \times \mathcal{R}_{\sigma_R} : \langle \lambda(A), \rho(B)\rangle = 0\right\}\right|$, which enables us to recover $\operatorname{per} M$ from the counts of orthogonal pairs in $\mathcal{L}_{\sigma_L} \times \mathcal{R}_{\sigma_R}$.

Completing the Proof of Theorem 4. Suppose now that we have an algorithm for #OV that runs in $N^{2-\Omega(1/\log^{1-\epsilon} c)}$ time for some $0 < \epsilon < 1$ when given an input of N vectors from $\{0,1\}^{c\log N}$. Take $N = 2^{n/2-1}$ and observe that $\log N = n/2 - 1$.

Let $K > 1$ be a constant that will depend on ϵ and the constant hidden by the $\Omega(\cdot)$ notation in the running time of the #OV algorithm. Take $g = \lfloor K^{-1/\epsilon} n (\log p)^{1-2/\epsilon} \rfloor$ and recall that the prime p is in the range $2 \leq p \leq n \ln n$. To compute the parameters $t_{\sigma,r}$ using the reduction in the previous section, for each prime p we need $4p^g$ invocations of the #OV algorithm on an input of N vectors of dimension $d = gp^{n/g}$. Thus, for all large enough n, since $\frac{1}{2}K^{-1/\epsilon} n (\log p)^{1-2/\epsilon} \leq g$, we have $d = gp^{n/g} \leq n 2^{2K^{1/\epsilon}(\log p)^{2/\epsilon}}$. Since clearly $d = c\log N = c(n/2-1)$ and $2/\epsilon > 2$, for all large enough n, we have $\log c \leq 1 + 2K^{1/\epsilon}(\log p)^{2/\epsilon} \leq 3K^{1/\epsilon}(\log p)^{2/\epsilon}$, where the last inequality depends on choosing a large enough K so that the inequality is true for $p = 2$. Thus, $-(\log c)^{\epsilon-1} \leq -3^{\epsilon-1}K^{1-1/\epsilon}(\log p)^{2-2/\epsilon}$. One invocation of the #OV algorithm thus runs in $N^{2-\Omega(\log^{\epsilon-1} c)} = 2^{n-\Omega(n3^{\epsilon-1}K^{1-1/\epsilon}(\log p)^{2-2/\epsilon})}$ time. For each prime $2 \leq p \leq n \ln n$, we need $4p^g \leq 2^{2+K^{-1/\epsilon} n (\log p)^{2-2/\epsilon}}$ invocations of the #OV algorithm. Thus, the running time of all the invocations for the prime p is bounded by $4p^g N^{2-\Omega(\log^{\epsilon-1} c)} \leq 2^{n-\Omega(n3^{\epsilon-1}K^{1-1/\epsilon}(\log p)^{2-2/\epsilon})+2+K^{-1/\epsilon} n (\log p)^{2-2/\epsilon}}$. By choosing a large enough K to dominate the constant hidden by the $\Omega(\cdot)$ notation in the running time of the #OV algorithm, we thus have, for all large enough n,

$$\begin{aligned}
4p^g N^{2-\Omega(\log^{\epsilon-1} c)} &\leq 2^{n-\Omega(n3^{\epsilon-1}K^{-1/\epsilon}(\log p)^{2-2/\epsilon})} \\
&\leq 2^{n-\Omega(n3^{\epsilon-1}K^{-1/\epsilon}(\log n + \log\ln n)^{2-2/\epsilon})} \\
&\leq 2^{n-\Omega(n(\log n)^{2-2/\epsilon})}.
\end{aligned}$$

Since there are at most $n \ln n$ primes p to consider, the total running time to compute $\operatorname{per} M$ is bounded by $2^{n-\Omega(n/\log^{2/\epsilon-2} n)}$. This completes the proof of Theorem 4. ◀

7 Further Applications

Counting Satisfying Assignments to a Sym∘And circuit via #InnerProduct. We describe how to embed a Sym∘And circuit, i.e., a circuit of s And gates working on n Boolean inputs, connected by a top gate that is an arbitrary symmetric gate, in a #InnerProduct instance

of size $N = 2^{n/2}$ and $d = s$. Assuming n even, we divide the n inputs in two equal halves L and R. We let $\mathcal{A}$ have one vector u for each assignment to the inputs in L, with one coordinate in u for each AND gate, representing the truth value of that gate restricted to the inputs in L. Likewise, we let $\mathcal{B}$ have one vector v for each assignment to the inputs in R, with each coordinate set to the truth value of the represented gate restricted to the inputs in R. It is readily verified that $\langle u, v\rangle$ counts the number of AND gates that are satisfied by the assignment represented by (u, v). Hence, knowing the number of assignments that satisfy exactly t of the AND gates, for $t = 0, 1, \ldots, s$, which is what the solution to the #INNERPRODUCT gives us, we can count the total number of assignments that also satisfies the top symmetric gate.

Variations where the circuit instead is a SYM∘OR or a SYM∘XOR, are also possible.

Computing the Weight Enumerator Polynomial via #InnerProduct. A binary linear code of length n and rank k is a linear subspace C with dimension k of the vector space $\mathbb{F}_2^n$. The *weight enumerator polynomial* is $W(C; x, y) = \sum_{w=0}^{n} A_w x^w y^{n-w}$, where $A_w = |\{c \in C : \langle c, c\rangle = w\}|$ for $w = 0, 1, \ldots, n$ is the *weight distribution*; that is, A_w equals the number of codewords of C having exactly w ones.

We will reduce the computation of the weight distribution, and hence the weight enumerator polynomial, to $(k/2+1)^2$ instances of #INNERPRODUCT with $N \leq 2^{k/2}$ and $d = 2(n-k)$ when k is even.

Let the $k \times n$ matrix G be the generating matrix of the code; that is, the codewords of C are exactly the row-span of G. We can assume without loss of generality that the generator matrix has the standard form $G = [I_k|P]$, where I_k is the $k \times k$ identity matrix. For each $s_A = 0, 1, \cdots, k/2$ and $s_B = 0, 1, \ldots, k/2$, we make one instance of #INNERPRODUCT.

We let the set $\mathcal{A}$ have one vector u for each code c obtained as the linear combination of exactly s_A of the first $k/2$ rows. Each of the $n-k$ last coordinates in the code word c is described by a block of two coordinates in u. If $c_i = 0$ we encode this as 01 in u, and if $c_i = 1$ we encode this as 10 in u. We concatenate all $n-k$ encoded blocks to obtain u. Likewise, we let the set $\mathcal{B}$ have one vector v for each code c obtained as a linear combination of s_B of the last $k/2$ rows. Again, each of the $n-k$ last coordinates in the code word c is described by a block of two coordinates in v, but the encoding is opposite the one for $\mathcal{A}$: If $c_i = 0$ we encode this as 10 in v, and if $c_i = 1$ we encode this as 01 in v. We again concatenate all $n-k$ encoded blocks to obtain v. With this design, it is readily verified that for $(u, v) \in \mathcal{A} \times \mathcal{B}$, the inner product $\langle u, v\rangle$ is equal to the number of ones in the last $n-k$ coordinates in the code word obtained as the sum of the code word represented by u and the code word represented by v. Also, by design the number of ones in the first k coordinates equals $s_A + s_B$. Hence, by summing over all pairs that have the same inner product t, and aggregating over all s_A and s_B, we can compute the weight distribution.

Abstract

We give a quasipolynomial-time algorithm for learning *stochastic decision trees* that is optimally resilient to adversarial noise. Given an η-corrupted set of uniform random samples labeled by a size-s stochastic decision tree, our algorithm runs in time $n^{O(\log(s/\varepsilon)/\varepsilon^2)}$ and returns a hypothesis with error within an additive $2\eta+\varepsilon$ of the Bayes optimal. An additive 2η is the information-theoretic minimum.

Previously no non-trivial algorithm with a guarantee of $O(\eta)+\varepsilon$ was known, even for weaker noise models. Our algorithm is furthermore proper, returning a hypothesis that is itself a decision tree; previously no such algorithm was known even in the noiseless setting.

1 Introduction

Decision trees are a touchstone class in learning theory. There is by now a rich and vast literature on the problem of learning decision trees, spanning three decades and studying it in a variety of models and from a variety of perspectives [10, 32, 5, 16, 7, 27, 4, 17, 23, 30, 20, 31, 15, 28, 26, 22, 19, 9, 2, 3, 1, 6].

We consider the problem of learning *stochastic decision trees*, a generalization of standard deterministic decision trees that allows for stochastic nodes. This generalization broadens the expressive power of decision trees, enabling them to represent not just deterministic functions but also stochastic functions. Figure 1 depicts a stochastic decision tree with two stochastic nodes, labeled "$", one that branches on the outcome of a Bernoulli(0.8) random variable, and the other on the outcome of a Bernoulli(0.3) random variable.

Many real-world learning scenarios are inherently stochastic in nature, and relatedly, much of current research in learning theory focuses on the "probabilistic concept" generalization [24] of the standard PAC model of learning deterministic concepts (e.g. see [14, 13, 11, 12] for an ongoing line of work on learning neural networks in the probabilistic concept model). As discussed in [24], probabilistic concepts can also be viewed as latent variable models, where the uncertainty concerning latent variables is modeled as apparent probabilistic behavior.

Stochastic decision trees are a simple and natural way to represent stochastic functions. Despite compelling theoretical and practical motivations, there has thus far been considerably less attention on the problem learning stochastic decision trees as compared to deterministic decision trees. Many basic questions remain open; for example:

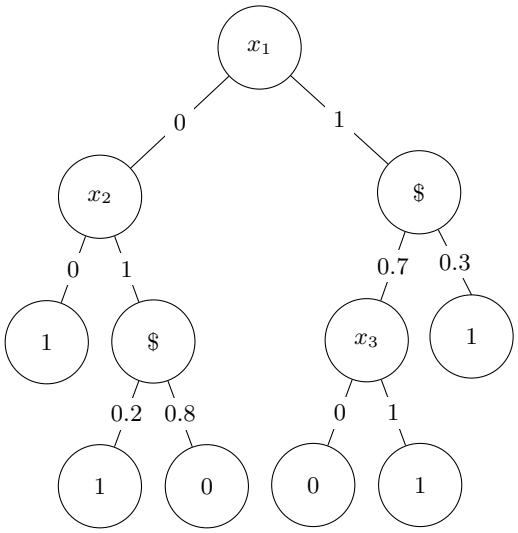

Figure 1 A stochastic decision tree with two stochastic nodes.

- Is there an algorithm for *properly* learning stochastic decision trees, one that returns a decision tree hypothesis?
- Is there an algorithm for learning stochastic decision trees that is resilient to *adversarial noise*?

These questions have been intensively studied in the case of deterministic decision trees, and the algorithms and techniques developed to answer them (e.g. [10, 21, 15]) have become foundational results in learning theory. A broad goal of our work is to help bring the state of our understanding of learning stochastic decision trees into closer alignment with that of deterministic decision trees.

1.1 Our results

We give new algorithms for learning stochastic decision trees under the uniform distribution. En route to our main result, we give the first algorithm for *properly* learning stochastic decision trees – our algorithm in fact returns a deterministic decision tree hypothesis:

▶ **Theorem 1** (Properly learning stochastic decision trees)**.** *There is an algorithm $\mathcal{A}$ with the following guarantee. For all $\varepsilon \in (0,1)$ and $s \in \mathbb{N}$, given access to labeled samples $(\boldsymbol{x}, \boldsymbol{T}(\boldsymbol{x}))$ where $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$ is a size-s stochastic decision tree and $\boldsymbol{x}$ is uniform random, $\mathcal{A}$ runs in $n^{O(\log(s/\varepsilon)/\varepsilon^2)}$ time and with high probability outputs a deterministic decision tree h such that $\Pr[h(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt} + \varepsilon$, where opt denotes the Bayes optimal error for $\boldsymbol{T}$.*

Theorem 1 is a special case of our main result, which gives a generalization of the algorithm $\mathcal{A}$ of Theorem 1 that is optimally resilient to adversarial noise.

▶ **Definition 2** (η-corrupted samples; "nasty noise" [8])**.** *Let $\boldsymbol{f} : \{0,1\}^n \to \{0,1\}$ be a stochastic function. We say that $\mathcal{S}$ is an η-corrupted set of uniform random samples labeled by $\boldsymbol{f}$ if it is formed in the following fashion: draw a set of labeled samples $(\boldsymbol{x}, \boldsymbol{f}(\boldsymbol{x}))$ where $\boldsymbol{x}$ is uniform random, and modify any η fraction to form $\mathcal{S}$.*

We allow for corruptions of both the example (i.e. changing $\boldsymbol{x}$ to a different $\boldsymbol{x}'$) and its label (i.e. flipping $\boldsymbol{f}(\boldsymbol{x})$), and note that the adversarial choice of which η fraction of samples to corrupt can be adaptive, depending arbitrarily on the original uncorrupted set of samples. This is regarded as the most challenging noise model for classification problems; weaker noise models include random classification noise, Massart noise, and agnostic noise.

Our main result is as follows:

▶ **Theorem 3** (Our main result: Properly learning stochastic decision trees in the presence of adversarial noise)**.** *There is an algorithm $\mathcal{A}$ with the following guarantee. For all $\varepsilon, \eta \in (0,1)$ and $s \in \mathbb{N}$, given access to a sufficiently large η-corrupted set $\mathcal{S}$ of uniform random samples labeled by a size-s stochastic decision tree $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$, $\mathcal{A}$ runs in $n^{O(\log(s/\varepsilon)/\varepsilon^2)}$ time and with high probability outputs a decision tree hypothesis h such that $\Pr[h(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt} + 2\eta + \varepsilon$, where opt denotes the Bayes optimal error for $\boldsymbol{T}$.*

An error of $\mathrm{opt} + 2\eta$ is the information-theoretic minimum (see e.g. [8]). Prior to our work there were (improper) algorithms that achieved either $\mathrm{opt} + O(\sqrt{\eta}) + \varepsilon$ or $2\mathrm{opt} + 2\eta + \varepsilon$, the low-degree algorithm of [29] and the L_1 polynomial regression algorithm of [21] respectively, but not the information-theoretically optimal $\mathrm{opt} + 2\eta + \varepsilon$. This was the case even for weaker noise models such as label-only noise (i.e. agnostic noise [18, 25]). In fact, the low-degree and L_1 polynomial regression algorithms are, in general, only known to be resilient to noise in the labels.

As our final contribution, we show that when applied in the context of decision tree learning, these algorithms are in fact resilient to noise in both the examples and their labels:

▶ **Theorem 4** (Noise-tolerant properties of the low-degree algorithm and L_1 polynomial regression)**.** *For all $\varepsilon, \eta \in (0,1)$ and $s \in \mathbb{N}$, given access to a sufficiently large η-corrupted set $\mathcal{S}$ of uniform random samples labeled by a size-s stochastic decision tree $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$,*

- *the low-degree algorithm runs in time $n^{O(\log(s/\varepsilon))}$ and with high probability outputs a hypothesis h satisfying $\Pr[h(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt} + O(\sqrt{\eta}) + \varepsilon$.*
- *the L_1 polynomial regression algorithm runs in time $n^{O(\log(s/\varepsilon))}$ and with high probability outputs a stochastic hypothesis $\boldsymbol{h}$ satisfying $\Pr[\boldsymbol{h}(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq 2\mathrm{opt} + 2\eta + \varepsilon$.*

1.1.1 Summary and comparison with existing algorithms

The low-degree algorithm of Linial, Mansour, and Nisan [29] and a recent algorithm of Chen and Moitra [9] for learning mixtures of subcubes can both be used to learn stochastic decision trees as a special case of their main results. The algorithm of [29] runs in time $n^{O(\log(s/\varepsilon))}$, whereas the algorithm of [9] runs in time $O_s(1) \cdot n^{O(\log s)} \cdot \mathrm{poly}(1/\varepsilon)$. However, neither of these algorithms returns a decision tree hypothesis, and hence both are improper when applied in this context. The classic algorithm of Ehrenfeucht and Haussler [10, 5] properly learns deterministic decision trees in time $n^{O(\log s)} \cdot \mathrm{poly}(1/\varepsilon)$. However, being an Occam algorithm, its analysis seems fundamentally unable to accommodate stochasticity of the target concept.

Table 1 summarizes our contributions and places them in the context of prior work.

1.2 Our techniques

Our approach to Theorems 1 and 3 is simple and has two main conceptual parts: a structural lemma concerning stochastic decision trees and a noise-tolerant algorithm for learning a special type of stochastic decision tree.

Table 1 Performance guarantees of our algorithm and existing algorithms for learning stochastic decision trees in the presence of adversarial noise. Among these algorithms, ours is the only one that returns a decision tree hypothesis. Prior to our work, the error guarantees for the low-degree algorithm and L_1 polynomial regression were only known for label noise; we show in the context of decision tree learning, these guarantees can be strengthened to allow for noise in both the examples and labels.

Reference	Technique	Running time	Error guarantee
[29]	Low-degree algorithm	$n^{O(\log(s/\varepsilon))}$	$\mathrm{opt} + O(\sqrt{\eta}) + \varepsilon$ (**This work**)
[21]	L_1 polynomial regression	$n^{O(\log(s/\varepsilon))}$	$2\mathrm{opt} + 2\eta + \varepsilon$ (**This work**)
[9]	Learning mixtures of subcubes	$O_s(1) \cdot n^{O(\log s)} \cdot \mathrm{poly}(\frac{1}{\varepsilon})$	$\mathrm{opt} + \varepsilon$ Noiseless setting ($\eta = 0$)
This work	Approximation by stochastic-leaf DTs; Noise-tolerant learning of stochastic-leaf DTs	$n^{O(\log(s/\varepsilon)/\varepsilon^2)}$	$\mathrm{opt} + 2\eta + \varepsilon$

- *Structural lemma:* We show that every size-s stochastic decision tree can be ε-approximated by a "stochastic-leaf decision tree" of size $s^{O(1/\varepsilon^2)}$. A stochastic-leaf decision tree is a very specific type of stochastic decision tree, one whose stochastic nodes only occur at its leaves.

This lemma reduces the task of learning stochastic decision trees to that of learning stochastic-leaf decision trees, with a catch: due to the approximation error incurred, the algorithm for learning stochastic-leaf decision trees has to be *noise-tolerant*.

- *Noise-tolerant learning stochastic-leaf decision trees:* Mehta and Raghavan [30] gave an algorithm for properly learning deterministic decision trees in the noiseless setting. We show that their algorithm can be generalized to handle stochastic-leaf decision trees, and furthermore, we show that our generalization is optimally resilient to adversarial noise. This stands in contrast to the algorithm of Ehrenfeucht and Haussler [10], which as mentioned above seems fundamentally unable to accommodate either stochasticity or noise.

We are hopeful that each of these two parts will see further utility in problems involving stochastic decision trees, beyond the learning-theoretic setting that is the focus of this work.

As for Theorem 4, the low-degree algorithm and L_1 polynomial regression are versatile and powerful "meta-algorithms" in learning, but they are not generally known to handle the challenging nasty noise. Our key observation here is that the mean functions of stochastic decision trees are well-approximated by low-degree polynomials *with bounded outputs*. We then show that when run on such polynomials, the low-degree algorithm and L_1 polynomial regression are in fact resilient to nasty noise. Given the broad applicability of both algorithms, we are similarly hopeful that this fact will be of independent interest beyond decision trees.

1.3 Preliminaries

Let $\boldsymbol{f} : \{0,1\}^n \to \{0,1\}$ be a stochastic function. We associate $\boldsymbol{f}$ with its *mean function* $\mu_{\boldsymbol{f}} : \{0,1\}^n \to [0,1]$, $\mu_{\boldsymbol{f}}(x) := \Pr_{\boldsymbol{f}}[\boldsymbol{f}(x) = 1]$. The *Bayes optimal classifier* for $\boldsymbol{f}$ is the (deterministic) function $x \mapsto \mathrm{round}(\mu_{\boldsymbol{f}}(x))$, where $\mathrm{round}(t) := \mathbb{1}[t \geq \frac{1}{2}]$. Given two stochastic functions $\boldsymbol{f}, \boldsymbol{h} : \{0,1\}^n \to \{0,1\}$, we define

$$\mathrm{error}_{\boldsymbol{f}}(\boldsymbol{h}) \coloneqq \mathop{\mathbb{E}}_{\boldsymbol{x}}\left[\Pr_{\boldsymbol{f},\boldsymbol{h}}[\boldsymbol{f}(\boldsymbol{x}) \neq \boldsymbol{h}(\boldsymbol{x})]\right],$$

where here and throughout this paper, $\boldsymbol{x}$ denotes a uniform random input from $\{0,1\}^n$. We define $\mathrm{opt}_{\boldsymbol{f}} \coloneqq \mathrm{error}_{\boldsymbol{f}}(\mathrm{round}(\mu_{\boldsymbol{f}}))$, and when $\boldsymbol{f}$ is clear from context, we simply write opt.

▶ **Fact 5** (Bayes optimal classifier minimizes classification error). *For all stochastic functions $\boldsymbol{f}, \boldsymbol{h} : \{0,1\}^n \to \{0,1\}$, we have $\mathrm{error}_{\boldsymbol{f}}(\boldsymbol{h}) \geq \mathrm{opt}_{\boldsymbol{f}}$.*

▶ **Fact 6** (L_1-error and Bayes optimality). *Let $\boldsymbol{f} : \{0,1\}^n \to \{0,1\}$ be a stochastic function. For any $h : \{0,1\}^n \to [0,1]$,*

$$\Pr[\mathrm{round}(h(\boldsymbol{x})) \neq \boldsymbol{f}(\boldsymbol{x})] \leq \mathrm{opt}_{\boldsymbol{f}} + 2\,\mathbb{E}[|\mu_{\boldsymbol{f}}(\boldsymbol{x}) - h(\boldsymbol{x})|].$$

Fact 6 states that if we have a function close to $\mu_{\boldsymbol{f}}$, we can convert it to a classifier with error close to $\mathrm{opt}_{\boldsymbol{f}}$.

Proof. We need to upper bound $\mathrm{error}_{\boldsymbol{f}}(\mathrm{round} \circ h) - \mathrm{opt}_{\boldsymbol{f}}$ at $2\,\mathbb{E}[|\mu_{\boldsymbol{f}}(\boldsymbol{x}) - h(\boldsymbol{x})|]$. We rewrite that quantity as

$$\begin{aligned}
\mathrm{error}_{\boldsymbol{f}}(\mathrm{round} \circ h) - \mathrm{opt}_{\boldsymbol{f}} &= \Pr_{\boldsymbol{x}\sim\{0,1\}^n}[\boldsymbol{f}(\boldsymbol{x}) \neq \mathrm{round}(h(\boldsymbol{x}))] - \Pr_{\boldsymbol{x}\sim\{0,1\}^n}[\boldsymbol{f}(x) \neq \mathrm{round}(\mu_{\boldsymbol{f}}(\boldsymbol{x}))] \\
&= \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}[|\,\mu_{\boldsymbol{f}}(\boldsymbol{x}) - \mathrm{round}(h(\boldsymbol{x}))\,| - |\,\mu_{\boldsymbol{f}}(\boldsymbol{x}) - \mathrm{round}(\mu_{\boldsymbol{f}}(\boldsymbol{x}))\,|] \\
&= \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}\left[\mathbb{1}(\mathrm{round}(h(\boldsymbol{x}))) \neq \mathrm{round}(\mu_{\boldsymbol{f}}(\boldsymbol{x}))) \cdot 2 \cdot \left|\,\mu_{\boldsymbol{f}}(\boldsymbol{x}) - \tfrac{1}{2}\,\right|\right]
\end{aligned}$$

It is only possible that $\mathrm{round}(h(x)) \neq \mathrm{round}(\mu_{\boldsymbol{f}}(x))$ if $|\,f(x) - \mu_{\boldsymbol{f}}(x)\,| \geq |\,\mu_{\boldsymbol{f}}(x) - \frac{1}{2}\,|$. Therefore,

$$\begin{aligned}
\mathrm{error}_{\boldsymbol{f}}(\mathrm{round} \circ h) - \mathrm{opt}_{\boldsymbol{f}} &\leq \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}\left[\mathbb{1}(|\,f(x) - \mu_{\boldsymbol{f}}(x)\,| \geq |\,\mu_{\boldsymbol{f}}(x) - \frac{1}{2}\,|) \cdot 2 \cdot \left|\,\mu_{\boldsymbol{f}}(\boldsymbol{x}) - \tfrac{1}{2}\,\right|\right] \\
&\leq 2 \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}[|\,f(x) - \mu_{\boldsymbol{f}}(x)\,|]\,. \qquad ◀
\end{aligned}$$

2 Approximating stochastic DTs with stochastic-leaf DTs

▶ **Definition 7** (Stochastic-leaf DT). *A stochastic-leaf DT is a stochastic DT for which all stochastic nodes have only leaves as their children.*

▶ **Lemma 8** (Approximating stochastic DTs with stochastic-leaf DTs). *Let $\boldsymbol{T}$ be a size-s stochastic DT. For every $\varepsilon \in (0, \frac{1}{2})$, there is a size-$S$* stochastic-leaf *DT $\overline{\boldsymbol{T}}$ such that $S \leq s^{O(1/\varepsilon^2)}$ and $\mathbb{E}_{\boldsymbol{x}}[|\mu_{\boldsymbol{T}}(\boldsymbol{x}) - \mu_{\overline{\boldsymbol{T}}}(\boldsymbol{x})|] \leq \varepsilon$.*

Proof. Let m denote the number of stochastic transitions in $\boldsymbol{T}$. For a fixed $r \in \{0,1\}^m$, let $\boldsymbol{T}(x, r)$ be the value of $\boldsymbol{T}$ evaluated on x with stochastic transitions determined by r. Suppose we pick random strings $\boldsymbol{r}_1, \ldots, \boldsymbol{r}_c \sim \{0,1\}^m$ independently and uniformly at random. For each $x \in \{0,1\}^n$, consider the following random variable:

$$\mathbf{est}(x) \coloneqq \mathop{\mathbb{E}}_{\boldsymbol{i}\in[c]}[\boldsymbol{T}(x, \boldsymbol{r_i})].$$

Note that

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{r}_1,\ldots,\boldsymbol{r}_c\in\{0,1\}^m}[\mathbf{est}(x)] = \mu_{\boldsymbol{T}}(x) &= \mathop{\mathbb{E}}_{\boldsymbol{r}\sim\{0,1\}^m}[\boldsymbol{T}(x, \boldsymbol{r})] \\
\mathrm{Var}[\mathbf{est}(x)] &= \tfrac{1}{c} \cdot \mathbf{Var}_{\boldsymbol{r}\sim\{0,1\}^m}[\boldsymbol{T}(x, \boldsymbol{r})],
\end{aligned}$$

where in both cases above, $\boldsymbol{r} \sim \{0,1\}^m$ on the RHS denotes $\boldsymbol{r}$ chosen uniformly at random from $\{0,1\}^m$. Since $\boldsymbol{T}$ is $\{0,1\}$-valued, it has variance at most $\frac{1}{4}$. Hence, the variance of $\mathbf{est}(x)$ is at most $\frac{1}{4c}$. If we take $c = 1/\varepsilon^2$, the following holds for any $x \in \{0,1\}^n$:

$$\mathop{\mathbb{E}}_{\boldsymbol{r}_1,\ldots,\boldsymbol{r}_c \sim \{0,1\}^m} \left[\left(\mathbf{est}(x) - \mu_{\boldsymbol{T}}(x) \right)^2 \right] \leq \frac{\varepsilon^2}{4}, \quad \text{and therefore} \quad \mathop{\mathbb{E}}_{\boldsymbol{r}_1,\ldots,\boldsymbol{r}_c \sim \{0,1\}^m} [|\mathbf{est}(x) - \mu_{\boldsymbol{T}}(x)|] \leq \frac{\varepsilon}{2}.$$

Averaging over $\boldsymbol{x} \sim \{0,1\}^n$ and swapping expectations, we get:

$$\mathop{\mathbb{E}}_{\boldsymbol{r}_1,\ldots,\boldsymbol{r}_c \sim \{0,1\}^m} \left[\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \{0,1\}^n} \left[|\mathbf{est}(x) - \mu_{\boldsymbol{T}}(x)| \right] \right] \leq \frac{\varepsilon}{2}.$$

Therefore, there must exist outcomes $r_1^\star, \ldots, r_c^\star \in \{0,1\}^m$ of $\boldsymbol{r}_1, \ldots, \boldsymbol{r}_c$ such that

$$\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \{0,1\}^n} \left[\left| \mathop{\mathbb{E}}_{\boldsymbol{i} \in [c]} [\boldsymbol{T}(\boldsymbol{x}, r_{\boldsymbol{i}^\star})] - \mu_{\boldsymbol{T}}(\boldsymbol{x}) \right| \right] \leq \frac{\varepsilon}{2}. \tag{1}$$

For each $i \in [c]$, we define a size-s DT by fixing the stochastic nodes of $\boldsymbol{T}$ according to $r_i^\star \in \{0,1\}^m$. We define our stochastic-leaf DT $\overline{\boldsymbol{T}}$ by stacking these c many size-s DTs on top of one another: for each $i < n$, we replace each leaf of the i_{th} DT with a copy of the $(i+1)_{th}$ DT. Then for each leaf ℓ of this stacked tree, let x_ℓ be an input that is consistent with the root-to-ℓ path in $\overline{\boldsymbol{T}}$. We replace ℓ with a stochastic node which transitions to a 1-leaf with probability $p_\ell := \mathbb{E}_{\boldsymbol{i} \in [c]}[\boldsymbol{T}(x_\ell, r_{\boldsymbol{i}}^\star)]$, and to a 0-leaf with probability $1 - p_\ell$. Note that for each $i \in [c]$, the tree $\boldsymbol{T}(\cdot, r_i^\star)$ gives the same classification for all inputs reaching leaf ℓ of $\overline{\boldsymbol{T}}$, so p_ℓ does not depend on the choice of x_ℓ.

$\overline{\boldsymbol{T}}$ is a stochastic-leaf DT that computes $x \mapsto \mathbb{E}_{\boldsymbol{i} \in [c]}[\boldsymbol{T}(\boldsymbol{x}, r_{\boldsymbol{i}}^\star)]$, which by Equation (1), has sufficiently small error. Since this DT has size $s^c = s^{O(1/\varepsilon^2)}$, the proof of Lemma 8 is complete. ◀

3 A simple backtracking algorithm for finding the optimal small-depth tree

The algorithmic core of Theorems 1 and 3 is a recursive backtracking procedure FIND shown in Algorithm 1, which takes a labeled set of samples X and finds a depth-d decision tree that achieves minimal classification error. This algorithm is inspired by and simplifies the FIND algorithm given by Mehta and Raghavan [30] for building a minimum-error decision tree from any "sat-countable representation" of a function.

▶ **Lemma 9** (Correctness of FIND). *Consider any sample set X of labeled examples (x, y) and depth budget d. The algorithm FIND(X, d) (see Algorithm 1) returns a depth-d DT $T^\star$ that minimizes $\Pr_{(\boldsymbol{x},\boldsymbol{y}) \sim X}[T^\star(\boldsymbol{x}) \neq \boldsymbol{y}]$ among all depth-d DTs.*

Proof. We proceed by induction on d. If $d = 0$, then FIND returns at Step 1 and is clearly correct. For the inductive step, suppose that $d \geq 1$. For any $i \in [n]$, we first claim that the tree T_i defined in Step 2 is a depth d DT that minimizes classification error with respect to X among those that query x_i at the root. Let $(T_i)_{\text{left}}$ and $(T_i)_{\text{right}}$ be its left and right subtrees respectively. By the inductive hypothesis, the left and right subtrees $(T_i)_{\text{left}}$ and $(T_i)_{\text{right}}$ are depth $d-1$ DTs that minimize error with respect to $X_{x_i=0}$ and $X_{x_i=1}$ respectively. Hence, T_i is a depth d DT that achieves minimal error with respect to X among those that query x_i at the root.

Since FIND returns the $T_{i^\star}$ that minimizes $\Pr_{(\boldsymbol{x},\boldsymbol{y}) \sim X}[T_i(\boldsymbol{x}) \neq \boldsymbol{y}]$ among all $i \in [n]$ in Step 3, and each T_i is a minimal-error depth-d DT among those that query x_i at the root, we conclude that FIND returns a tree of minimal error with respect to X. ◀

Algorithm 1 A recursive backtracking algorithm for finding a depth-d DT of minimal classification error.

FIND(X, d):

Input: Set X of labeled examples (x, y) and depth budget d.

Output: A depth-d DT $T^\star$ that minimizes $\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim X}[T^\star(\boldsymbol{x}) \neq \boldsymbol{y}]$ among all depth-d DTs.

1. If $d = 0$, return the constant $c \in \{0, 1\}$ that minimizes $\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim X}[c \neq \boldsymbol{y}]$.
2. For every $i \in [n]$, let T_i be the DT defined as follows:
   - T_i queries x_i at the root;
   - Has FIND$(X_{x_i=0}, d-1)$ as its left subtree;
   - Has FIND$(X_{x_i=1}, d-1)$ as its right subtree.

   Here $X_{x_i=b}$ denotes the subset of X containing only examples where x_i is set to b.
3. Return the tree $T_{i^\star}$ that minimizes $\Pr_{(\boldsymbol{x},\boldsymbol{y})\in X}[T_i(\boldsymbol{x}) \neq \boldsymbol{y}]$ among all $i \in [n]$.

▶ **Lemma 10** (Efficiency of FIND). *Consider any sample set X of labeled examples and depth budget d. The algorithm FIND(X, d) (see Algorithm 1) takes time $n^{O(d)} \cdot O(|X|)$.*

Proof. Let $T(d)$ denote the running time of FIND when run with depth budget d. If $d = 0$ then the algorithm only executes Step 1, which can be done in $O(|X|)$ time by computing round$(\mathbb{E}_{(\boldsymbol{x},\boldsymbol{y})\sim X}[\boldsymbol{y}])$.

Next we consider the case of $d \geq 1$. In step 2, FIND recurses $2n$ times, each with d decremented by one. Each time it also partitions X into $X_{x_i=0}$ and $X_{x_i=1}$. All of these recursive calls and partitioning takes total time $2n \cdot T(d-1) + n|X|$. In step 3, FIND must compute $\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim X}[T_i(\boldsymbol{x}) \neq \boldsymbol{y}]$ for up to n different coordinates i, where each T_i has depth at most d. This takes time $n \cdot d \cdot |X|$. We therefore have the recurrence relation:

$$T(d) \leq 2n \cdot T(d-1) + O(nd|X|).$$

Solving this recurrence relation gives us the bound $T(d) \leq (2n)^d \cdot O(nd|X|)$, which is $\leq n^{O(d)} \cdot O(|X|)$ as desired. ◀

4 Learning stochastic DTs: proofs of Theorems 1 and 3

4.1 Proof of Theorem 1

We recall Theorem 1, this time including the confidence parameter δ.

▶ **Theorem 1** (Properly learning stochastic decision trees). *There is an algorithm $\mathcal{A}$ with the following guarantee. For all $\varepsilon \in (0, 1)$ and $s \in \mathbb{N}$, given access to labeled samples $(\boldsymbol{x}, \boldsymbol{T}(\boldsymbol{x}))$ where $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$ is a size-s stochastic decision tree and $\boldsymbol{x}$ is uniform random, $\mathcal{A}$ runs in $n^{O(\log(s/\varepsilon)/\varepsilon^2)} \cdot \mathrm{poly}(\log(1/\delta))$ time and with probability $1 - \delta$ outputs a deterministic decision tree h such that $\Pr[h(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt} + \varepsilon$, where opt denotes the Bayes optimal error for $\boldsymbol{T}$.*

Let $\boldsymbol{T}$ be a size-s stochastic decision tree. By Lemma 8, there is a stochastic-leaf decision tree $\overline{\boldsymbol{T}}$ of size $S \leq s^{O(1/\varepsilon^2)}$ such that $\mathbb{E}_{\boldsymbol{x}}[|\mu_{\boldsymbol{T}}(\boldsymbol{x}) - \mu_{\overline{\boldsymbol{T}}}(\boldsymbol{x})|] \leq \varepsilon$. Consider the Bayes optimal classifier $x \mapsto \mathrm{round}(\mu_{\overline{\boldsymbol{T}}}(x))$ for $\overline{\boldsymbol{T}}$. Since $\overline{\boldsymbol{T}}$ is a *stochastic-leaf* decision tree, we have that this function is computed by a size-S (deterministic) decision tree $T^\star$: to obtain $T^\star$ from $\overline{\boldsymbol{T}}$,

simply replace every stochastic node in $\overline{\boldsymbol{T}}$, all of which occur at the leaves of $\overline{\boldsymbol{T}}$, with a 1-leaf if it branches on Bernoulli(p) where $p \geq \frac{1}{2}$, and a 0-leaf otherwise. Applying Fact 6, we get that

$$\Pr_{\boldsymbol{x},\boldsymbol{T}}[T^\star(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt}_{\boldsymbol{T}} + 2\varepsilon.$$

Next, consider the decision tree $T^\star_{\mathrm{trunc}}$ obtained by truncating $T^\star$ to depth $\log(S/\varepsilon)$ (and replacing all truncated branches with a leaf with an arbitrary value, say a 1-leaf). $T^\star_{\mathrm{trunc}}$ and $T^\star$ can only differ on inputs that reach a leaf in $T^\star$ of depth at least $\log(S/\varepsilon)$, and there are at most S such leaves. Therefore,

$$\Pr_{\boldsymbol{x}}[T^\star_{\mathrm{trunc}}(\boldsymbol{x}) \neq T^\star(\boldsymbol{x})] \leq 2^{-\log(S/\varepsilon)} \cdot S = \varepsilon.$$

Note that the depth of $T^\star_{\mathrm{trunc}}$ is $\leq \log(s/\varepsilon)/\varepsilon^2$. We have shown the following corollary of Lemma 8:

▶ **Corollary 11** (Approximating stochastic DTs with deterministic ones). *Let $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$ be a size-s stochastic DT. For every $\varepsilon \in (0, \frac{1}{2})$, there is a deterministic DT $T^\star_{\mathrm{trunc}} : \{0,1\}^n \to \{0,1\}$ such that*

1. $\mathrm{depth}(T^\star_{\mathrm{trunc}}) \leq \log(S/\varepsilon) \leq \log(s/\varepsilon)/\varepsilon^2$ *and*
2. $\Pr_{\boldsymbol{x},\boldsymbol{T}}[T^\star_{\mathrm{trunc}}(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon$.

To show that Find returns a tree of small error with respect to $\boldsymbol{T}$, we need the following generalization bound from [30]:

▶ **Lemma 12** (Generalization). *Let $\boldsymbol{T}$ be a stochastic tree of size s. For $S = s^{O(1/\varepsilon^2)}$ and a sample size of*

$$m \coloneqq \mathrm{poly}\left(n^{\log(S/\varepsilon)}, \frac{1}{\varepsilon}, \log\left(\frac{1}{\delta}\right)\right),$$

let X be a dataset of m i.i.d points of the form $(\boldsymbol{x}, \boldsymbol{T}(\boldsymbol{x}))$. Then $\textsc{Find}(X, \log(S/\varepsilon))$ outputs $T^\star$ such that

$$\Pr_{\text{draw of } \boldsymbol{X}}\left[\Pr_{\boldsymbol{x}\sim\{0,1\}^n}[T^\star(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon\right] \geq 1 - \delta.$$

Proof. The proof is given in the proof of Theorem 2 in [30]. Lemma 9 gives us that Find outputs a tree of minimal error with respect to X. They apply Chernoff bounds to bound the probability that a fixed tree T' of depth $\log(S/\varepsilon)$ and error $> \mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon$ with respect to $\boldsymbol{T}$ has smaller error with respect to X than $T^\star_{\mathrm{trunc}}$ as described in Corollary 11. More specifically, the probability over draws of X that $\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim X}[T^\star_{\mathrm{trunc}}(\boldsymbol{x}) \neq \boldsymbol{y}] > \mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon$ or $\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim X}[T'(\boldsymbol{x}) \neq \boldsymbol{y}] \leq \mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon$ is exponentially small in $|X|$. This is a bound on the probability that Find outputs a particular tree of error greater than $\mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon$; the lemma follows from a union bound over all trees of depth at most $\log(S/\varepsilon)$. ◀

Lemma 10 gives us that $\textsc{Find}(X, \log(S/\varepsilon))$ runs in time $n^{O(\log(S/\varepsilon))} \cdot O(|X|) = n^{O(\log(s/\varepsilon)/\varepsilon^2)} \cdot O(|X|)$. For confidence parameter δ, $|X|$ is polynomial in $n^{\log(S/\varepsilon)}$, $\log(1/\varepsilon)$, and $\log(1/\delta)$. Thus, the total runtime of Find is $n^{O(\log(s/\varepsilon)/\varepsilon^2)} \cdot \mathrm{poly}\log(1/\delta))$. The desired result holds by renaming $\varepsilon' = \varepsilon/3$. ◀

4.2 Proof of Theorem 3

We recall Theorem 3, this time including the confidence parameter δ.

▶ **Theorem 3** (Our main result). *There is an algorithm $\mathcal{A}$ with the following guarantee. For all $\varepsilon, \eta \in (0,1)$ and $s \in \mathbb{N}$, given access to a sufficiently large η-corrupted set $\mathcal{S}$ of uniform random samples labeled by a size-s stochastic decision tree $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$, $\mathcal{A}$ runs in $n^{O(\log(s/\varepsilon)/\varepsilon^2)} \cdot \mathrm{poly}(\log(1/\delta))$ time and with probability $1-\delta$ outputs a decision tree hypothesis h such that $\Pr[h(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] \leq \mathrm{opt} + 2\eta + \varepsilon$, where opt denotes the Bayes optimal error for $\boldsymbol{T}$.*

The proof requires the following fact.

▶ **Fact 13** (Error from sample corruption). *For any bounded function $p : \{0,1\}^n \to [0,1]$ and sample $\mathcal{S}^\circ$ of points $(x_1, y_1), \ldots, (x_m, y_m)$ with $0 \leq y_i \leq 1$. Let $\mathcal{S}$ be a corrupted sample formed by picking an arbitrary η-fraction of points $\mathcal{S}^\circ$ and replacing each with an arbitrary (also bounded) point. Then for any $\mathrm{err} : [0,1] \times [0,1] \to [0,1]$*

$$\left| \mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}^\circ} [\mathrm{err}(p(\boldsymbol{x}), \boldsymbol{y})] - \mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}} [\mathrm{err}(p(\boldsymbol{x}), \boldsymbol{y})] \right| < \eta.$$

Recall $T^\star_{\mathrm{trunc}}$ as described in Corollary 11, which has error $\leq \mathrm{opt}_{\boldsymbol{T}} + O(\varepsilon)$ with respect to $\boldsymbol{T}$. Let $\mathcal{S}^\circ$ be the uncorrupted set of examples of $\boldsymbol{T}$, and $\mathcal{S}$ be an η-corruption of $\mathcal{S}^\circ$. Then with probability $1-\delta$ over draws of $\mathcal{S}^\circ$,

$$\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}^\circ}[T^\star_{\mathrm{trunc}}(\boldsymbol{x}) \neq \boldsymbol{y}] \leq \mathrm{opt}_{\boldsymbol{T}} + 3\varepsilon \qquad \text{(Lemma 12)}$$

$$\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}}[T^\star_{\mathrm{trunc}}(\boldsymbol{x}) \neq \boldsymbol{y}] \leq \mathrm{opt}_{\boldsymbol{T}} + \eta + 3\varepsilon. \qquad \text{(Fact 13)}$$

Let $T^\star$ be the output of $\textsc{Find}(\mathcal{S}, \log(S/\varepsilon))$. Then,

$$\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}}[T^\star(\boldsymbol{x}) \neq \boldsymbol{y}] \leq \mathrm{opt}_{\boldsymbol{T}} + \eta + 3\varepsilon \qquad \text{(Lemma 9)}$$

$$\Pr_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}^\circ}[T^\star(\boldsymbol{x}) \neq \boldsymbol{y}] \leq \mathrm{opt}_{\boldsymbol{T}} + 2\eta + 3\varepsilon. \qquad \text{(Fact 13)}$$

$$\Pr_{\text{draw of } \mathcal{S}^\circ}\left[\Pr_{x\sim\{0,1\}^n}[T^\star(x) \neq \boldsymbol{T}(x)] \leq \mathrm{opt}_{\boldsymbol{T}} + 2\eta + 3\varepsilon \right] > 1-\delta \qquad \text{(Lemma 12)}$$

The desired result holds by renaming $\varepsilon' = \varepsilon/3$. ◀

5 Noise-tolerant properties of L_1 and L_2 regression

In this section, we prove Theorem 4, showing that the low-degree algorithm of [29] (also known as L_2 regression) and L_1 regression algorithm of [21] both learn stochastic-leaf DTs with adversarial corruption, albeit with worse parameters than our method. Throughout this section, we use the following function.

▶ **Definition 14** (The trunc function). *The function,* $\mathrm{trunc} : \mathbb{R} \to [0,1]$, *is defined as*

$$\mathrm{trunc}(x) = \begin{cases} 0 & \text{if } x < 0 \\ 1 & \text{if } x > 1 \\ x & \text{otherwise.} \end{cases}$$

The basis of the results in this section is Proposition 15, that if $\boldsymbol{T}$ is a size-s stochastic DT, there is a degree $\log(s/\varepsilon)$ bounded polynomial $p : \{0,1\}^n \to [0,1]$ which is ε close to $\mu_{\boldsymbol{T}}$:

▶ **Proposition 15** ($\mu_{\boldsymbol{T}}$ is morally low degree). *Let $\boldsymbol{T}$ be a size-s stochastic DT. There is a polynomial $p : \{0,1\}^n \to [0,1]$ such that $\Pr_{\boldsymbol{x}}[p(\boldsymbol{x}) \neq \mu_{\boldsymbol{T}}(\boldsymbol{x})] \leq \varepsilon$, where $\deg(p) \leq \log(s/\varepsilon)$.*

In order to handle our challenging noise model, it is important that we can guarantee the p in Proposition 15 is bounded. Without that guarantee, L_1 and L_2 regression are not known to handle noise in both the examples and the labels.

Proof. For any leaf ℓ of $\boldsymbol{T}$, let $\text{depth}(\ell)$ be the number of *deterministic* nodes on the root-to-leaf path to ℓ, not counting ℓ itself. The fraction of inputs in $\{0,1\}^n$ that have a nonzero chance of reaching ℓ is $2^{-\text{depth}(\ell)}$. Now, let $\boldsymbol{T}'$ be the stochastic decision tree that is nearly equivalent to $\boldsymbol{T}$ except if an input reaches a leaf with deterministic depth more than $\log(s/\varepsilon)$, $\boldsymbol{T}'$ returns 0. We claim that $p \coloneqq \mu_{\boldsymbol{T}'}$ satisfies Proposition 15. For that, we need to verify three things about $\mu_{\boldsymbol{T}'}$:

1. $\mu_{\boldsymbol{T}'}$ and $\mu_{\boldsymbol{T}}$ are close: $\Pr_{\boldsymbol{x}}[\mu_{\boldsymbol{T}}(\boldsymbol{x}) \neq \mu_{\boldsymbol{T}'}(\boldsymbol{x})] \leq \varepsilon$. This is true because $\boldsymbol{T}$ and $\boldsymbol{T}'$ can differ only on inputs which reach a leaf with deterministic depth at least $\log(s/\varepsilon)$. At most $2^{-\log(s/\varepsilon)} = \varepsilon/s$ fraction of inputs reach each such leaf, and there are at most s of them.
2. $\mu_{\boldsymbol{T}'}$ is a degree $\log(s/\varepsilon)$ polynomial. We can write $\mu_{\boldsymbol{T}'}(x)$ as

$$\begin{aligned}\mu_{\boldsymbol{T}'}(x) &= \sum_{\text{leaves } \ell \in \boldsymbol{T}'} \Pr[x \text{ reaches } \ell] \cdot (\text{label of } \ell) \\ &= \sum_{\text{leaves } \ell \in \boldsymbol{T}} \Pr[x \text{ reaches } \ell] \cdot \mathbb{1}[\text{depth}(\ell) \leq \log(s/\varepsilon)] \cdot (\text{label of } \ell).\end{aligned}$$

   The expression $\Pr[x \text{ reaches } \ell]$ is a degree $\text{depth}(\ell)$ polynomial. Therefore, $\mu_{\boldsymbol{T}'}(x)$ is a degree $\log(s/\varepsilon)$ polynomial.
3. The output of $\mu_{\boldsymbol{T}'}$ is bounded on $[0,1]$. This is true since $\boldsymbol{T}'$ always returns a value in $\{0,1\}$. ◀

5.1 L_2 Regression

Given corrupted samples from some stochastic DT $\boldsymbol{T}$, we will apply Lemma 16, given below, to show that L_2 regression can find a function f that is close to $\mu_{\boldsymbol{T}}$. Then, we will apply Fact 6 to generate a hypothesis with error close to the Bayes optimal error.

▶ **Lemma 16** (L_2 error to mean error). *Fix any stochastic DT $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$, degree $d \in \mathbb{N}$, and $\varepsilon, \delta > 0$. For a sample size of*

$$m \coloneqq \text{poly}\left(n^d, 1/\varepsilon, \log(1/\delta)\right),$$

let $\mathcal{S}^\circ$ be a dataset of m i.i.d points of the form $(\boldsymbol{x}, \boldsymbol{T}(\boldsymbol{x}))$. With probability at least $1-\delta$, there exists a constant $C \in \mathbb{R}$ for which the following holds for all degree d polynomials $p : \{0,1\}^n \to \mathbb{R}$.

$$\left| \mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y}) \sim \mathcal{S}^\circ} \left[(\text{trunc}(p(\boldsymbol{x})) - \boldsymbol{y})^2\right] - \left(\mathop{\mathbb{E}}_{\boldsymbol{x} \sim \{0,1\}^n} \left[(\text{trunc}(p(\boldsymbol{x})) - \mu_{\boldsymbol{T}}(\boldsymbol{x}))^2\right] + C \right) \right| \leq \varepsilon. \tag{2}$$

Proof. We prove Lemma 16 in two steps: First, we argue that there is a C for which Equation (2) holds for any fixed polynomial with extremely high probability. Then, we discretize the set of all truncated degree d polynomials into a finite set $\mathcal{P}$. By union bound, we can show that Equation (2) applies to all functions in $\mathcal{P}$, and since every truncated degree d polynomial is sufficiently close to a function in $\mathcal{P}$, this is enough to guarantee that Equation (2) applies to all degree d polynomials.

We use the following identity: For any constant $a \in \mathbb{R}$ and random variable $\boldsymbol{z} \in \mathbb{R}$,

$$\mathop{\mathbb{E}}_{\boldsymbol{z}}\left[(a-\boldsymbol{z})^2\right] = (a - \mathbb{E}[\boldsymbol{z}])^2 + \mathrm{Var}[\boldsymbol{z}].$$

Fix any $p : \{0,1\}^n \to \mathbb{R}$. For any $x \in \{0,1\}^n$, $\boldsymbol{T}(x)$ is a random variable with mean $\mu_{\boldsymbol{T}}(x)$. Therefore,

$$\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}\left[(\mathrm{trunc}(p(\boldsymbol{x})) - \boldsymbol{T}(x))^2\right] = \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}\left[(\mathrm{trunc}(p(\boldsymbol{x})) - \mu_{\boldsymbol{T}}(x))^2\right] + \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}\left[\mathrm{Var}[\boldsymbol{T}(x)]\right]$$

For $C = \mathbb{E}_{\boldsymbol{x}\sim\{0,1\}^n}\left[\mathrm{Var}[\boldsymbol{T}(x)]\right]$, Equation (2) holds in expectation over $\mathcal{S}$ with $\varepsilon = 0$. Since $(\mathrm{trunc}(p(x)) - y)^2$ is bounded on $[0,1]$, we can apply Hoeffdings inequality: For any fixed p, Equation (2) holds with probability at least $1 - 2\exp_e(-2m^2\varepsilon^2)$.

We next discretize the set of all truncated degree d polynomials. Let $\mathcal{P}$ be the following finite set of functions,

$$\mathcal{P} \coloneqq \{\mathrm{trunc} \circ p \mid p \text{ is degree-}d \text{ polynomial with coefficients that are all a multiple of } \varepsilon/n^d\}$$

Degree d polynomials have at most n^d coefficients. Therefore,

$$\log(|\mathcal{P}|) \le \log\left(\left(\frac{n^d}{\varepsilon}\right)^{n^d}\right) = \mathrm{poly}\left(n^{O(d)}, \log(1/\varepsilon)\right).$$

This means that for the sample size in Lemma 16, Equation (2) holds for all functions in $\mathcal{P}$ with probability at least $1-\delta$. We show that Equation (2) holding for function in $\mathcal{P}$ implies the desired result.

Every degree d truncated polynomial is *pointwise* close to a function in $\mathcal{P}$: Fix any degree d polynomial p. There is some $f \in \mathcal{P}$, for which

$$|\mathrm{trunc}(p(x)) - f(x)| < \varepsilon \quad \text{for all } x \in \{0,1\}^n.$$

This f is easy to specify: It's the truncation of p', where p' is p with all of its coefficients rounded to the nearest ε/n^d. In order to expand Equation (2) to p, we use the following inequality for all $a, \varepsilon \in [0,1]$:

$$|\,(a+\varepsilon)^2 - a^2\,| = |2a\varepsilon| + \varepsilon^2 \le 3|\varepsilon|.$$

Therefore,

$$\begin{aligned}\left|\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}}\left[(\mathrm{trunc}(p(\boldsymbol{x})) - \boldsymbol{y})^2\right] - \mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}}\left[f(\boldsymbol{x}) - \boldsymbol{y})^2\right]\right| &\le 3 \max_{x\in\{0,1\}^n} |\,\mathrm{trunc}(p(x)) - f(x)\,| \\ &\le 3\,\varepsilon.\end{aligned}$$

Similarly, $\mathbb{E}_{\boldsymbol{x}\sim\{0,1\}^n}\left[(\mathrm{trunc}(p(\boldsymbol{x})) - \mu_{\boldsymbol{T}}(\boldsymbol{x}))^2\right]$ and $\mathbb{E}_{\boldsymbol{x}\sim\{0,1\}^n}\left[(f(\boldsymbol{x}) - \mu_{\boldsymbol{T}}(\boldsymbol{x}))^2\right]$ are within 3ε of one another. Finally, by triangle inequality,

$$\left|\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}}\left[(\mathrm{trunc}(p(\boldsymbol{x})) - \boldsymbol{y})^2\right] - \left(\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}\left[(\mathrm{trunc}(p(\boldsymbol{x})) - \mu_{\boldsymbol{T}}(\boldsymbol{x}))^2\right] + C\right)\right| \le 7\varepsilon.$$

The desired result holds if we rename $\varepsilon' = \frac{\varepsilon}{7}$. ◀

We are now ready to prove the low-degree algorithm (i.e. L_2 regression) part of Theorem 4.

▶ **Lemma 17** (L_2 regression part of Theorem 4). *Choose any $\varepsilon, \eta, \delta \in (0,1)$, $s \in \mathbb{N}$, and size-s stochastic decision tree $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$. For a sample of size*

$$m \coloneqq \text{poly}\left(n^{O(d)}, \frac{1}{\varepsilon}, \log\left(\frac{1}{\delta}\right)\right),$$

let $\mathcal{S}$ be an η-corrupted set of m uniform random samples from $\boldsymbol{T}$. If

$$p^* = \underset{\text{Degree } \log(s/\varepsilon) \text{ polynomials } p}{\arg\min} \left(\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}} \left[(p(\boldsymbol{x}) - \boldsymbol{y})^2\right] \right),$$

and $h : \{0,1\}^n \to \{0,1\}$ is the hypothesis $h(x) = \text{round}(\text{trunc}(p^*(x)))$. Then with probability at least $1-\delta$ over the randomness of the sample,

$$\text{error}_{\boldsymbol{T}}(h) \le \text{opt} + O(\sqrt{\eta}) + \varepsilon.$$

Proof. Let $\mathcal{S}^\circ$ be the original uncorrupted (i.i.d) set of samples, from which $\mathcal{S}$ differs on at most η fraction of points. By Lemma 16, Equation (2) holds, with respect to $\mathcal{S}^\circ$, for all degree $\log(s/\varepsilon)$ polynomials with probability at least $1-\delta$. We show that if it holds, then $\text{error}_{\boldsymbol{T}}(h) \le \text{opt} + O(\sqrt{\eta}) + \varepsilon$.

Proposition 15 guarantees there exists $p : \{0,1\}^n \to [0,1]$, a degree $\log(s/\varepsilon)$ bounded polynomial, satisfying

$$\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n} \left[(p(\boldsymbol{x}) - \mu_{\boldsymbol{T}}(\boldsymbol{x}))^2\right] \le \varepsilon.$$

Fix C as in Lemma 16. Combining Equation (2) and Fact 13, we have that

$$\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}} \left[(p(\boldsymbol{x}) - \boldsymbol{y})^2\right] \le C + 2\varepsilon + \eta.$$

Since p^* has the minimum L_2 error of all degree $\log(s/\varepsilon)$ polynomials on $\mathcal{S}$,

$$\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}} \left[(p^*(\boldsymbol{x}) - \boldsymbol{y})^2\right] \le C + 2\varepsilon + \eta.$$

Truncating p^* can only decrease its L_2 error. Combining that with a second application of Fact 13,

$$\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}^\circ} \left[(\text{trunc}(p^*(\boldsymbol{x})) - \boldsymbol{y})^2\right] \le C + 2\varepsilon + 2\eta.$$

Then, by Equation (2),

$$\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n} \left[(\text{trunc}(p^*(\boldsymbol{x})) - \mu_{\boldsymbol{T}}(\boldsymbol{x}))^2\right] \le 3\varepsilon + 2\eta. \tag{3}$$

Finally,

$$\begin{aligned}
\text{error}_{\boldsymbol{T}}(h) &\le \text{opt}_{\boldsymbol{T}} + 2 \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n} [|\, \mu_{\boldsymbol{T}}(\boldsymbol{x}) - \text{trunc}(p^*(\boldsymbol{x}))\,|] && \text{Fact 6} \\
&\le \text{opt}_{\boldsymbol{T}} + 2\sqrt{\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n} [(\mu_{\boldsymbol{T}}(\boldsymbol{x}) - \text{trunc}(p^*(\boldsymbol{x})))^2]} && \text{Jensen's inequality} \\
&\le \text{opt}_{\boldsymbol{T}} + 2\sqrt{3\varepsilon + 2\eta} && \text{Equation (3)} \\
&\le \text{opt}_{\boldsymbol{T}} + O(\sqrt{\varepsilon}) + O(\sqrt{\eta}).
\end{aligned}$$

The desired result then holds by renaming $\varepsilon' = \Omega(\varepsilon^2)$. ◀

5.2 L_1 regression

We will need the following generalization bound:

▶ **Lemma 18** (L_1 error generalization). *Fix any stochastic DT* $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$*, degree* $d \in \mathbb{N}$*, and* $\varepsilon, \delta > 0$*. For a sample size of*

$$m := \text{poly}\left(n^{O(d)}, \frac{1}{\varepsilon}, \log\left(\frac{1}{\delta}\right)\right),$$

let $\mathcal{S}^\circ$ *be a dataset of* m *i.i.d points of the form* $(\boldsymbol{x}, \boldsymbol{T}(\boldsymbol{x}))$*. With probability at least* $1-\delta$*, the following holds for all degree* d *polynomials* $p : \{0,1\}^n \to \mathbb{R}$*.*

$$\left| \mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}^\circ} \left[|\text{trunc}(p(\boldsymbol{x})) - \boldsymbol{y}|^2 \right] - \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n, \boldsymbol{T}} \left[|\text{trunc}(p(\boldsymbol{x})) - \boldsymbol{T}(\boldsymbol{x})| \right] \right| \leq \varepsilon. \tag{4}$$

Lemma 18 can be proven using the same discretization argument as Lemma 16. We omit the proof for brevity.

▶ **Lemma 19** (L_1 regression part of Theorem 4). *Choose any* $\varepsilon, \eta, \delta \in (0,1)$*,* $s \in \mathbb{N}$*, and size-*s *stochastic decision tree* $\boldsymbol{T} : \{0,1\}^n \to \{0,1\}$*. For a sample of size*

$$m := \text{poly}\left(n^{O(d)}, \frac{1}{\varepsilon}, \log\left(\frac{1}{\delta}\right)\right),$$

let $\mathcal{S}$ *be an* η*-corrupted set of* m *uniform random samples from* $\boldsymbol{T}$*. If*

$$p^* = \mathop{\arg\min}_{\text{Degree } \log(s/\varepsilon) \text{ polynomials } p} \left(\mathop{\mathbb{E}}_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{S}} [|\, p(\boldsymbol{x}) - \boldsymbol{y})\,|] \right),$$

and $\boldsymbol{h} : \{0,1\}^n \to \{0,1\}$ *is the randomized hypothesis where* $\boldsymbol{h}(x)$ *is* 1 *with probability* $\text{trunc}(p^*(x))$ *and* 0 *otherwise. Then with probability at least* $1-\delta$ *over the randomness of the sample,*

$$\text{error}_{\boldsymbol{T}}(\boldsymbol{h}) \leq 2\text{opt} + 2\eta + \varepsilon.$$

Proof. Let $\mathcal{S}^\circ$ be the original uncorrupted (i.i.d) set of samples from which $\mathcal{S}$ differs on at most η fraction of points. By Lemma 18, Equation (4) holds, with respect to $\mathcal{S}^\circ$ for all degree $\log(s/\varepsilon)$ polynomials with probability at least $1-\delta$. We show that if it holds, then $\text{error}_{\boldsymbol{T}}(h) \leq 2\text{opt} + 2\eta + \varepsilon$.

Proposition 15 guarantees there exists $p : \{0,1\}^n \to [0,1]$, a degree $\log(s/\varepsilon)$ polynomial, satisfying

$$\mathop{\mathbb{E}}_{\boldsymbol{x}} [|p(\boldsymbol{x}) - \mu_{\boldsymbol{T}}(\boldsymbol{x})|] \leq \varepsilon.$$

We first bound the expected error of $\mu_{\boldsymbol{T}}(\boldsymbol{x})$ relative to $\boldsymbol{T}(\boldsymbol{x})$.

$$\begin{aligned}
\mathop{\mathbb{E}}_{\boldsymbol{x}} [|\mu_{\boldsymbol{T}}(\boldsymbol{x}) - \boldsymbol{T}(\boldsymbol{x})|] &= \mathop{\mathbb{E}}_{\boldsymbol{x}} [\Pr[\boldsymbol{T}(\boldsymbol{x}) = 1](1 - \mu_{\boldsymbol{T}}(\boldsymbol{x})) + \Pr[\boldsymbol{T}(\boldsymbol{x}) = 0](\mu_{\boldsymbol{T}}(\boldsymbol{x}))] \\
&= \mathop{\mathbb{E}}_{\boldsymbol{x}} [2\mu_{\boldsymbol{T}}(\boldsymbol{x})(1 - \mu_{\boldsymbol{T}}(\boldsymbol{x}))] \\
&\leq 2 \cdot \mathop{\mathbb{E}}_{\boldsymbol{x}} [\min(\mu_{\boldsymbol{T}}(\boldsymbol{x}), 1 - \mu_{\boldsymbol{T}}(\boldsymbol{x}))] \\
&= 2 \cdot \text{opt}_{\boldsymbol{T}}
\end{aligned}$$

By triangle inequality, we have that $\mathbb{E}_{\boldsymbol{x}}[|p(\boldsymbol{x}) - \boldsymbol{T}(\boldsymbol{x})|] \leq 2 \cdot \text{opt}_{\boldsymbol{T}} + \varepsilon$. By Equation (4)

$$\mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\sim\mathcal{S}^\circ}[|p(\boldsymbol{x}) - \boldsymbol{y}|] \leq 2 \cdot \text{opt}_{\boldsymbol{T}} + 2\varepsilon.$$

By Fact 13 initialized with $\text{err}(x, y) = |x - y|$,

$$\mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\sim\mathcal{S}}[|p(\boldsymbol{x}) - \boldsymbol{y}|] \leq 2 \cdot \text{opt}_{\boldsymbol{T}} + 2\varepsilon + \eta.$$

Since p^* has minimum L_1 error among all degree $\log(s/\varepsilon)$ polynomials,

$$\mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\sim\mathcal{S}}[|p^*(\boldsymbol{x}) - \boldsymbol{y}|] \leq 2 \cdot \text{opt}_{\boldsymbol{T}} + 2\varepsilon + \eta.$$

Reapplying Fact 13, combined with the fact that truncating p^* can only decrease its error,

$$\begin{aligned}\mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\sim\mathcal{S}^\circ}[|\text{trunc}(p^*(\boldsymbol{x})) - \boldsymbol{y}|] &\leq \mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\sim\mathcal{S}}[|\text{trunc}(p^*(\boldsymbol{x})) - \boldsymbol{y}|] + \eta \\ &\leq 2 \cdot \text{opt}_{\boldsymbol{T}} + 2\varepsilon + 2\eta.\end{aligned}$$

Applying Equation (4) again.

$$\begin{aligned}\mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}[|p(\boldsymbol{x}) - \boldsymbol{T}(\boldsymbol{x})|] &\leq \mathop{\mathbb{E}}_{\boldsymbol{x},\boldsymbol{y}\sim\mathcal{S}^\circ}[|p(\boldsymbol{x}) - \boldsymbol{T}(\boldsymbol{x})|] + \varepsilon \\ &\leq 2 \cdot \text{opt}_{\boldsymbol{T}} + 3\varepsilon + 2\eta.\end{aligned}$$

Finally, since $\boldsymbol{h}(x)$ returns 1 with probability $\text{trunc}(p^*(x))$, and $\boldsymbol{T}(x)$ is always in $\{0, 1\}$,

$$\begin{aligned}\Pr_{\boldsymbol{x},\boldsymbol{h},\boldsymbol{T}}[\boldsymbol{h}(\boldsymbol{x}) \neq \boldsymbol{T}(\boldsymbol{x})] &= \mathop{\mathbb{E}}_{\boldsymbol{x}\sim\{0,1\}^n}[|p(\boldsymbol{x}) - \boldsymbol{T}(\boldsymbol{x})|] \\ &\leq 2 \cdot \text{opt}_{\boldsymbol{T}} + 3\varepsilon + 2\eta.\end{aligned}$$

The desired result holds with the renaming $\varepsilon' = \frac{\varepsilon}{3}$. ◀

Breaking $O(nr)$ for Matroid Intersection

Joakim Blikstad ✉
KTH Royal Institute of Technology, Stockholm, Sweden

Abstract

We present algorithms that break the $\tilde{O}(nr)$-independence-query bound for the Matroid Intersection problem *for the full range of* r; where n is the size of the ground set and $r \leq n$ is the size of the largest common independent set. The $\tilde{O}(nr)$ bound was due to the efficient implementations [CLSSW FOCS'19; Nguyễn 2019] of the classic algorithm of Cunningham [SICOMP'86]. It was recently broken for large r ($r = \omega(\sqrt{n})$), first by the $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$-query $(1-\varepsilon)$-approximation algorithm of CLSSW [FOCS'19], and subsequently by the $\tilde{O}(n^{6/5}r^{3/5})$-query exact algorithm of BvdBMN [STOC'21]. No algorithm – even an approximation one – was known to break the $\tilde{O}(nr)$ bound for the full range of r. We present an $\tilde{O}(n\sqrt{r}/\varepsilon)$-query $(1-\varepsilon)$-approximation algorithm and an $\tilde{O}(nr^{3/4})$-query exact algorithm. Our algorithms improve the $\tilde{O}(nr)$ bound and also the bounds by CLSSW and BvdBMN for the full range of r.

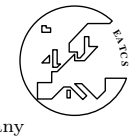
1 Introduction



Matroid Intersection is a fundamental problem in combinatorial optimization that has been studied for more than half a century. The classic version of this problem is as follows: *Given two matroids* $\mathcal{M}_1 = (V, \mathcal{I}_1)$ *and* $\mathcal{M}_2 = (V, \mathcal{I}_2)$ *over a common ground set* V *of* n *elements, find the largest common independent set* $S^* \in \mathcal{I}_1 \cap \mathcal{I}_2$ *by making independence oracle queries*[1] *of the form "Is* $S \in \mathcal{I}_1$*?" or "Is* $S \in \mathcal{I}_2$*?" for* $S \subseteq V$*.* The size of the largest common independent set is usually denoted by r.

Matroid intersection can be used to model many other combinatorial optimization problems, such as bipartite matching, arborescences, spanning tree packing, etc. As such, designing algorithms for matroid intersection is an interesting problem to study.

In this paper, we consider the task of finding a $(1-\varepsilon)$-approximate solution to the matroid intersection problem, that is finding some common independent set S of size at least $(1-\varepsilon)r$. We show an improvement of approximation algorithms for matroid intersection, and as a consequence also obtain an improvement for the *exact* matroid intersection problem.

[1] There are also other oracle models considered in the literature (e.g. rank-oracles), but in this paper we focus on the independence query model. Whenever we say *query* in this paper, we thus mean *independence query*.

Previous work. Polynomial algorithms for matroid intersection started with the work of Edmond's $O(n^2r)$-query algorithms [6, 7, 8] in the 1960s. Since then, there has been a long line of research e.g. [1, 2, 3, 4, 5, 9, 10]. Cunningham [5] designed a $O(nr^{1.5})$-query blocking-flow algorithm in 1986, similar to that of Hopcroft-Karp's bipartite-matching or Dinic's maximum-flow algorithms. Chekuri and Quanrud [4] pointed out that Cunningham's classic algorithm [5] from 1986 is already a $O(nr/\varepsilon)$-query $(1-\epsilon)$-approximation algorithm. Recently, Chakrabarty-Lee-Sidford-Singla-Wong [3] and Nguyễn [11] independently showed how to implement Cunningham's classic algorithm using only $\tilde{O}(nr)$ independence queries. This is akin to spending $\tilde{O}(n)$ queries to find each of the so-called *augmenting paths*. A fundamental question is whether several augmenting paths can be found simultaneously to break the $\tilde{O}(nr)$ bound.

This question has been answered for large r ($r = \omega(\sqrt{n})$), first by the $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$-query $(1-\epsilon)$-approximation algorithm of Chakrabarty-Lee-Sidford-Singla-Wong[2] [3], and very recently by the randomized $\tilde{O}(n^{6/5}r^{3/5})$-query exact algorithm of Blikstad-v.d.Brand-Mukhopadhyay-Nanongkai [2]. Whether we can break the $O(nr)$-query bound *for the full range of* r remained open *even for approximation algorithms.*

Our results. We break the $O(nr)$-query bound for both *approximation* and *exact* algorithms. We first state our results for approximate matroid intersection.[3]

▶ **Theorem 1** (Approximation algorithm)**.** *There is a deterministic algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ with $|S| \geq (1-\varepsilon)r$, using $O\left(\frac{n\sqrt{r \log r}}{\varepsilon}\right)$ independence queries.*

Plugging Theorem 1 in the framework of [2], we get an improved algorithm – more efficient than the previous state-of-the-art – for exact matroid intersection which we state next.

▶ **Theorem 2** (Exact algorithm)**.** *There is a randomized algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ of maximum cardinality r, and w.h.p.[4] uses $O(nr^{3/4} \log n)$ independence queries. There is also a deterministic exact algorithm using $O(nr^{5/6} \log n)$ queries.*

▶ Remark 3. Although we only focus on the query-complexity in this paper, we note that the time-complexity of the algorithms are dominated by query-oracle calls. That is, our approximation algorithm runs in $\tilde{O}(n\sqrt{r}\mathcal{T}_{\text{ind}}/\varepsilon)$ time, and the exact algorithms in $\tilde{O}(nr^{3/4}\mathcal{T}_{\text{ind}})$ (randomized) respectively $\tilde{O}(nr^{5/6}\mathcal{T}_{\text{ind}})$ time (deterministic), where $\mathcal{T}_{\text{ind}}$ denotes the time-complexity of the independence-oracle.

1.1 Technical Overview

Approximation algorithm. Our approximation algorithm (Theorem 1) is a modified version of Chakrabarty-Lee-Sidford-Singla-Wong's $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$-query approximation algorithm [3, Section 6]. The algorithm is based on the ideas of Cunningham's classic blocking-flow

[2] In the same paper they also show a $\tilde{O}(n^2r^{-1}\varepsilon^{-2} + r^{1.5}\varepsilon^{-4.5})$-query algorithm.

[3] The $\tilde{O}(n^2r^{-1}\varepsilon^{-2} + r^{1.5}\varepsilon^{-4.5})$-query algorithm of [3] is the only previous algorithm which is more efficient than our algorithm in some range of r and ε. Actually, since the $\tilde{O}(n^2r^{-1}\varepsilon^{-2} + r^{1.5}\varepsilon^{-4.5})$-query algorithm use the $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$ algorithm as a subroutine, we do get a slightly improved version by using our $\tilde{O}(n\sqrt{r}/\varepsilon)$ algorithm as the subroutine instead: $\tilde{O}(n^2r^{-1}\varepsilon^{-2} + r^{1.5}\varepsilon^{-4})$.

[4] *w.h.p. = with high probability* meaning with probability $1 - n^{-c}$ for some arbitrarily large constant c.

algorithm [5] and runs in $O(1/\varepsilon)$ phases, where in each phase the algorithm seeks to find a *maximal* set of *augmentations* in the *exchange graph*. Given a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$, the *exchange graph* $G(S)$ is a directed bipartite graph (with bipartition $(S + \{s, t\}, V \setminus S)$). Finding a shortest (s, t)-path, called an *augmenting path*, in $G(S)$ means one can increase the size of the common independent set S by 1. Since the exchange graph changes after each augmentation,[5] and we do not know how to find a single augmenting path faster than $\Omega(n)$ queries, the need to find several augmentations in parallel arises. [3, Section 6] introduces the notion of *augmenting sets*: a generalization of the classical *augmenting paths* but where one can perform many augmentations in parallel.

So the revised goal of the algorithm is to, in each phase, efficiently find a *maximal augmenting set* (akin to a *blocking-flow* in bipartite matching or flow algorithms). Towards this goal, the algorithm maintains a relaxed version of augmenting set – called a *partial* augmenting set – and keeps *refining* it to make it "better" (i.e. closer to a maximal augmenting set). Here we give two independent improvements on top of the algorithm of [3]:

1. The algorithm of [3] refines the partial augmenting set by a sequence of operations on two adjacent distance layers in the exchange graph. In our algorithm, we instead consider *three* consecutive layers for our basic refinement procedures. This lets us focus our analysis on what happens in S – the "left" side of the bipartite exchange graph – which contains at most r elements in total (in contrast to [3] where the performance analysis is dependent on all n elements). The number of times we need to run the refinement procedures thus depends on r, instead of n, which makes the algorithm faster when $r = o(n)$.
2. When the partial augmenting set is "close enough" to a maximal augmenting set, [3] falls back to finding the remaining augmenting paths one at a time. In our algorithm, we also change to a different procedure when the partial augmenting set is close enough to maximal. The difference is that, instead of finding arbitrary augmenting paths, we find a special type of *valid paths* with respect to the partial augmenting set, so that these paths can be used to further improve (refine) the partial augmenting set. The number of valid paths we need to find is less than the number of augmenting paths [3] needs to find. This decreases the dependency on ε in the final algorithm.

The first improvement (Item 1) replaces the $\sqrt{n}$ term with a $\sqrt{r}$ term in the query complexity of the algorithm. The second improvement (Item 2) shaves off a $1/\sqrt{\varepsilon}$ term from the query complexity. Together they thus bring down the query complexity from $\tilde{O}(\frac{n\sqrt{n}}{\varepsilon\sqrt{\varepsilon}})$ in [3] to $\tilde{O}(\frac{n\sqrt{r}}{\varepsilon})$ as in our Theorem 1. Note that these two improvements are independent of each other, and can be applied individually.

Exact algorithm. To obtain the exact algorithm (Theorem 2), we use the framework of Blikstad-v.d.Brand-Mukhopadhyay-Nanongkai's $\tilde{O}(n^{6/5}r^{3/5})$-query exact algorithm [2]. The main idea of this algorithm is to combine approximation algorithms – which can efficiently find a common independent set only εr away from the optimal – with a randomized $\tilde{O}(n\sqrt{r})$-query subroutine to find each of the remaining *few, very long* augmenting paths. The $\tilde{O}(n^{6/5}r^{3/5})$-query exact algorithm [2] currently uses Chakrabarty-Lee-Sidford-Singla-Wong's $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$ approximation algorithm [3] as a subroutine. Simply replacing it with our improved approximation algorithm (Theorem 1) yields our $\tilde{O}(nr^{3/4})$-query exact algorithm.

[5] Unlike what happens in augmenting path algorithms for flow and bipartite matching, where the underlying graphs remain the same.

2 Preliminaries

We use the standard definitions of *matroid* $\mathcal{M} = (V, \mathcal{I})$; *rank* $\text{rk}(X)$ for any $X \subseteq V$; *exchange graph* $G(S)$ for a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$; and *augmenting paths* in $G(S)$ throughout this paper. For completeness, we define them below. We also need the notions of *augmenting sets* introduced by [3], which we also define in later this section.

Matroids

▶ **Definition 4** (Matroid). A *matroid* is a tuple $\mathcal{M} = (V, \mathcal{I})$ of a *ground set* V of n elements, and non-empty family $\mathcal{I} \subseteq 2^V$ of *independent sets* satisfying
Downward closure: if $S \in \mathcal{I}$, then $S' \in \mathcal{I}$ for all $S' \subseteq S$.
Exchange property: if $S, S' \in \mathcal{I}$, $|S| > |S'|$, then there exists $x \in S \setminus S'$ such that $S' \cup \{x\} \in \mathcal{I}$.

▶ **Definition 5** (Set notation). We will use $A + x$ and $A - x$ to denote $A \cup \{x\}$ respectively $A \setminus \{x\}$, as is usual in matroid intersection literature. We will also use $\bar{A} := V \setminus A$, $A + B := A \cup B$, and $A - B := A \setminus B$.

▶ **Definition 6** (Matroid rank). The *rank* of $A \subseteq V$, denoted by $\text{rk}(A)$, is the size of the largest (or, equivalently, any maximal) independent set contained in A. It is well-known that the rank-function is submodular, i.e. $\text{rk}(A + x) - \text{rk}(A) \geq \text{rk}(B + x) - \text{rk}(B)$ whenever $A \subseteq B \subseteq V$ and $x \in V \setminus B$.[6] Note that $\text{rk}(A) = |A|$ if and only if $A \subseteq \mathcal{I}$.

▶ **Definition 7** (Matroid Intersection). Given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ over the same ground set V, a *common independent set* S is a set in $\mathcal{I}_1 \cap \mathcal{I}_2$. The *matroid intersection problem* asks us to find the largest common independent set – whose cardinality we denote by r. We use rk_1 and rk_2 to be the rank functions of the corresponding matroids.

The Exchange Graph

Many matroid intersection algorithms, e.g. those in [1, 2, 5, 7, 9, 11], are based on iteratively finding *augmenting paths* in the *exchange graph*.

▶ **Definition 8** (Exchange graph). Given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ over the same ground set, and a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$, the *exchange graph* $G(S)$ is a directed bipartite graph on vertex set $V \cup \{s, t\}$ with the following arcs (or directed edges):
1. (s, b) for $b \in \bar{S}$ when $S + b \in \mathcal{I}_1$.
2. (b, t) for $b \in \bar{S}$ when $S + b \in \mathcal{I}_2$.
3. (a, b) for $b \in \bar{S}, a \in S$ when $S + b - a \in \mathcal{I}_1$.
4. (b, a) for $b \in \bar{S}, a \in S$ when $S + b - a \in \mathcal{I}_2$.

We will denote the set of elements at distance k from s by the distance-layer D_k.

▶ **Definition 9** (Shortest augmenting path). A shortest (s, t)-path $p = (s, b_1, a_1, b_2, a_2, \ldots, a_\ell, b_{\ell+1}, t)$ (with $b_i \in \bar{S}$ and $a_i \in S$) in $G(S)$ is called a *shortest augmenting path*. We can *augment* S along the path p to obtain $S' = S \oplus p = S + b_1 - a_1 + b_2 - a_2 \ldots + b_{\ell+1}$, which is well-known to also be a common independent set (with $|S'| = |S| + 1$) [5]. Conversely, there must exist a shortest augmenting path whenever $|S| < r$.

The following lemma is very useful for $(1-\varepsilon)$-approximation algorithms since it essentially says that one needs only to consider paths up to length $O(\frac{1}{\varepsilon})$.

[6] Usually denoted as the *diminishing returns* property of submodular functions.

▶ **Lemma 10** (Cunningham [5]). *If the length of the shortest (s,t)-path in $G(S)$ is at least $2\ell+2$, then $|S| \geq (1-O(1/\ell))r$.*

▶ **Lemma 11** (Exchange discovery by binary search [3, 11]). *Suppose $\mathcal{M}=(V,\mathcal{I})$ is a matroid, $Y \subseteq X \in \mathcal{I}$, and $b \notin X$ such that $X+b \notin \mathcal{I}$. Then, using $O(\log|Y|)$ independence queries one can find some $a \in Y$ such that $X+b-a \in \mathcal{I}$ or determine that none exist.*[7]

Augmenting Sets

A generalization of the classical *augmenting paths* – called *augmenting sets* – play a key role in the approximation algorithm of [3], and therefore also in the modified version of this algorithm presented in this paper. In order to efficiently find "good" augmenting sets, the algorithm works with a relaxed form of them instead: *partial* augmenting sets. The following definitions and key properties of (partial) augmenting sets are copied from [3] where one can find the corresponding proofs.

▶ **Definition 12** (Augmenting Sets, from [3, Definition 24]). Let $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ and $G(S)$ be the corresponding exchange graph with shortest (s,t)-path of length $2(\ell+1)$ and distance layers $D_1, D_2, \ldots, D_{2\ell+1}$. A collection of sets $\Pi_\ell := (B_1, A_1, B_2, A_2, \ldots, A_\ell, B_{\ell+1})$ form an *augmenting set* (of *width* w) in $G(S)$ if the following conditions are satisfied:
(a) For $1 \leq k \leq \ell+1$, we have $A_k \subseteq D_{2k}$ and $B_k \subseteq D_{2k-1}$.
(b) $|B_1| = |A_1| = |B_2| = \cdots = |B_{\ell+1}| = w$
(c) $S + B_1 \in \mathcal{I}_1$
(d) $S + B_{\ell+1} \in \mathcal{I}_2$
(e) For all $1 \leq k \leq \ell$, we have $S - A_k + B_{k+1} \in \mathcal{I}_1$
(f) For all $1 \leq k \leq \ell$, we have $S - A_k + B_k \in \mathcal{I}_2$

▶ **Definition 13** (Partial Augmenting Sets, from [3, Definition 37]). We say that $\Phi_\ell := (B_1, A_1, B_2, A_2, \ldots, A_\ell, B_{\ell+1})$ forms a *partial augmenting set* if it satisfies the conditions (a), (c), (d), and (e) of an *augmenting set*, plus the following two relaxed conditions:
(b) $|B_1| \geq |A_1| \geq |B_2| \geq \cdots \geq |B_{\ell+1}|$.
(f) For all $1 \leq k \leq \ell$, we have $\mathrm{rk}_2(S - A_k + B_k) = \mathrm{rk}_2(S)$.

▶ **Theorem 14** (from [3, Theorem 25]). *Let $\Pi_\ell := (B_1, A_1, B_2, A_2, \cdots, B_\ell, A_\ell, B_{\ell+1})$ be the an augmenting set in the exchange graph $G(S)$. Then the set $S' := S \oplus \Pi_\ell := S + B_1 - A_1 + B_2 - \cdots + B_\ell - A_\ell + B_{\ell+1}$ is a common independent set.*[8]

We also need the notion of *maximal* augmenting sets, which naturally correspond to a maximal ordered collection of shortest augmenting paths, where, after augmentation, the (s,t)-distance must have increased. The following are due to [3].

▶ **Definition 15** (Maximal Augmenting Sets, from [3, Definition 35]). Let $\Pi_\ell = (B_1, A_1, B_2, \cdots, B_\ell, A_\ell, B_{\ell+1})$ and $\tilde{\Pi}_\ell = (\tilde{B}_1, \tilde{A}_1, \tilde{B}_2, \cdots, \tilde{B}_\ell, \tilde{A}_\ell, \tilde{B}_{\ell+1})$ be two augmenting sets in $G(S)$. We say $\tilde{\Pi}_\ell$ *contains* Π_ℓ if $B_k \subseteq \tilde{B}_k$ and $A_k \subseteq \tilde{A}_k$, for all k. An augmenting set Π_ℓ is called *maximal* if there exists no other augmenting set $\tilde{\Pi}_\ell$ containing Π_ℓ.

▶ **Theorem 16** (from [3, Theorem 36]). *An augmenting set Π_ℓ is maximal if and only if there is no augmenting path of length at most $2(\ell+1)$ in $G(S \oplus \Pi_\ell)$.*

[7] When $X = S$, we can use this to find edges of type 3 and 4 in the exchange graph.
[8] Note that $|S'| = |S| + w$, where w is the width of Π_ℓ. In particular, an augmenting set with width $w = 1$ is exactly an augmenting path.

3 Improved Approximation Algorithm

Our algorithm closely follows the algorithm of Chakrabarty-Lee-Sidford-Singla-Wong [3, Section 6]. The algorithm runs in phases, where in each phase the algorithm finds a maximal set of augmentations to perform, so that the (s,t)-distance in the exchange graph increases between phases. By Lemma 10, only $O(1/\varepsilon)$ phases are necessary.

In the beginning of a phase, the algorithm runs a breadth-first-search to compute the distance layers $D_1, D_2, \ldots D_{2\ell+1}$ in the exchange graph $G(S)$, where S is the current common independent set. The total number of independence queries, across all phases, for these BFS's can be bounded by $O(n\log(r)/\varepsilon)$. We refer to [3, Algorithm 4, Lemma 19, and Proof of Theorem 21] for how to implement such a BFS efficiently.

After the distance layers have been found, the search for a maximal augmenting set begins. We start by summarizing on a high level how the algorithm of [3] does this in two stages:

1. The first stage keeps track of a *partial* augmenting set which it keeps *refining* by a series of operations on adjacent distance layers in the exchange graph, to make it closer to a *maximal* augmenting set.
2. When we are "close enough" to a *maximum* augmenting set, the second stage handles the last few augmenting paths – for which the first stage slows down – by finding the remaining augmenting paths individually one at a time.

Here we give two independent improvements over the algorithm of [3], one for each stage. The first improvement is to replace the refine operations in the first stage by a new subroutine `RefineABA` (Section 3.1.2) working on *three* consecutive layers instead of two. This allows us to measure progress in terms of r instead of n. The second improvement is for the second stage where we, instead of finding arbitrary augmenting paths, work directly on top of the output of the first stage and find a specific type of *valid paths* with respect to the partial augmenting set, using a new a subroutine `RefinePath` (Section 3.2).

3.1 Implementing a Phase: Refining

The basic refining ideas and procedures in this section are the same as in [3]. The goal is to keep track of a partial augmenting set $\Phi_\ell = (B_1, A_1, B_2, \ldots, A_\ell, B_{\ell+1})$ which is iteratively made "better" through some *refine procedures*. Eventually, the partial augmenting set will become a maximal augmenting set, which concludes the phase. Towards this goal, we maintain three types of elements in each layer:

Selected. Denoted by A_k or B_k. These form the partial augmenting set $\Phi_\ell = (B_1, A_1, B_2, \ldots, A_\ell, B_{\ell+1})$.

Removed. Denoted by R_k. These elements are safe to disregard from further computation (i.e. deemed useless) when refining Φ_ℓ towards a maximal augmenting set.

Fresh. Denoted by F_k. These are the elements that are neither *selected* nor *removed*.

Elements can change their types from *fresh* $\to$ *selected* $\to$ *removed*, but never in the other direction. Initially, we start with all elements being fresh.[9] For convenience, we also define "imaginary" layers D_0 and $D_{2\ell+2}$ with $A_0 = R_0 = F_0 = D_0 = A_{\ell+1} = R_{2\ell+2} = F_{2\ell+2} = D_{2\ell+2} = \emptyset$. The algorithm maintains the following *phase invariants* (which are initially satisfied) during the refinement process:

[9] This differs slightly from [3], where the initially B_1 is greedily picked to be maximal so that $S + B_1 \in \mathcal{I}_1$, while the rest of the elements are fresh.

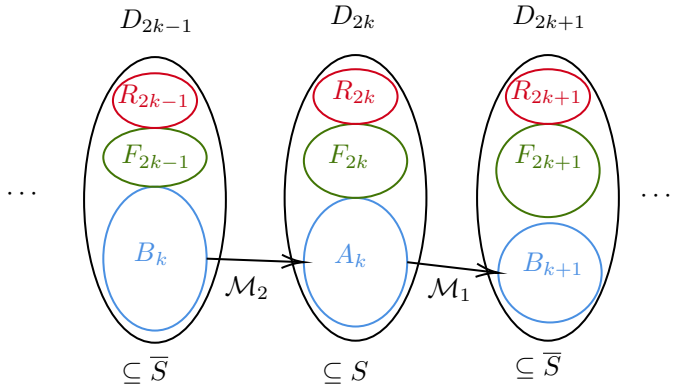

Figure 1 An illustration of a few neighboring layers. Note that $(B_k, R_{2k-1}, F_{2k-1})$ form a partition of odd layer $D_{2k-1} \subseteq \bar{S}$, and (A_k, R_{2k}, F_{2k}) form a partition of even layer $D_{2k} \subseteq S$.

▶ **Definition 17** (Phase Invariants, from [3, Section 6.3.2])**.** The *phase invariants* are:

(a-b) $\Phi_\ell = (B_1, A_1, B_2, \ldots, A_\ell, B_{\ell+1})$ forms a partial augmenting set.[10]

(c) For $1 \leq k \leq \ell$, for any $X \subseteq B_{k+1} + F_{2k+1} = D_{2k+1} - R_{2k+1}$, if $S - (A_k + R_{2k}) + X \in \mathcal{I}_1$ then $S - A_k + X \in \mathcal{I}_1$. [11]

(d) $\mathrm{rk}_2(W + R_{2k-1}) = \mathrm{rk}_2(W)$ where $W = S - (D_{2k} - R_{2k}) + B_k$.

▶ Remark 18. Invariant (c) essentially says that if R_{2k+1} is "useless", then so is R_{2k}. Similarly, Invariant (d) says that if R_{2k} is "useless", then so is R_{2k-1}. Together they imply that we can safely ignore all the removed elements.

▶ **Lemma 19.** *Suppose that (i) the phase invariants hold; (ii)* $|B_1| = |A_1| = \cdots = |B_{\ell+1}|$*; and (iii)* B_1 *is a maximal subset of* $D_1 \setminus R_1$ *satisfying* $S + B_1 \in \mathcal{I}_1$*. Then* $(B_1, A_1, \ldots, B_{\ell+1})$ *is a maximal augmenting set.*

Proof idea. (See [3, Proof of Lemma 44] for a complete proof). If it was not maximal, there exists an augmenting path $(b_1, a_1, \ldots, b_{\ell+1})$ in the exchange graph after augmenting along $(B_1, A_1, \ldots, B_{\ell+1})$. However, (iii) then says that b_1 must have been removed since it cannot be fresh. But if b_1 is removed, then so was a_1, then so was b_2 etc., by invariants (c) and (d) (this requires a technical, but straightforward, argument). However, $b_{\ell+1}$ cannot have been removed (by invariant (d)), which gives the desired contradiction. ◀

3.1.1 Refining Two Adjacent Layers

We now present the basic refinement procedures from [3], which are operations on neighboring layers. There is some asymmetry in how (odd, even) and (even, odd) layer-pairs are handled, arising from the inherent asymmetry of the independence query between S and $\bar{S}$, but the ideas are the same.

`RefineAB(`k`)` extends B_{k+1} as much as possible while respecting invariant (a-b) (Lines 1-2). Then a maximal collection of element in A_k which can be "matched" to B_{k+1} is found, and the others elements in A_k are removed (Lines 3-4).

[10] The naming of this invariant as (a-b) is to be consistent with [3] where this condition is split up into two separate items (a) and (b).

[11] An equivalent condition for (c) is: $\mathrm{rk}_1(W - R_{2k}) = \mathrm{rk}_1(W) - |R_{2k}|$, where $W = S - A_k + (D_{2k+1} - R_{2k+1})$.

`RefineBA(k)` finds a maximal subset B_k that can be "matched" to $A_k + F_{2k}$, and removes the other elements of B_k (Lines 1-2). Then A_k is extended with elements from F_{2k} which are the endpoints of the above "matching" (Lines 3-4).

Algorithm 1 `RefineAB`(k). (called `Refine1` in [3, Algorithm 9])

1: Find maximal $B \subseteq F_{2k+1}$ s.t. $S - A_k + B_{k+1} + B \in \mathcal{I}_1$
2: $B_{k+1} \longleftarrow B_{k+1} + B, F_{2k+1} \longleftarrow F_{2k+1} - B$
3: Find maximal $A \subseteq A_k$ s.t. $S - A_k + B_{k+1} + A \in \mathcal{I}_1$
4: $A_k \longleftarrow A_k - A, R_{2k} \longleftarrow R_{2k} + A$

Algorithm 2 `RefineBA`(k). (called `Refine2` in [3, Algorithm 10])

1: Find maximal $B \subseteq B_k$ s.t. $S - (D_{2k} - R_{2k}) + B \in \mathcal{I}_2$
2: $R_{2k-1} \longleftarrow R_{2k-1} + B_k \backslash B, B_k \longleftarrow B$
3: Find maximal $A \subseteq F_{2k}$ s.t. $S - (D_{2k} - R_{2k}) + B_k + A \in \mathcal{I}_2$
4: $A_k \longleftarrow A_k + F_{2k} \backslash A, F_{2k} \longleftarrow A$

The following properties of the `RefineAB` and `RefineBA` methods are proven in [3].

▶ **Lemma 20** (from [3, Lemmas 40-42]). *Both `RefineAB` and `RefineBA` preserve the invariants. Also: after `RefineAB`(k) is run, we have $|A_k| = |B_{k+1}|$ (unless $k = 0$). After `RefineBA`(k) is run, we have $|B_k| = |A_k|$ (unless $k = \ell + 1$).*

▶ **Lemma 21** (from [3, Lemma 45]). *`RefineAB` can be implemented with $O(|D_{2k}| + |D_{2k+1}|)$ queries. `RefineBA` can be implemented with $O(|D_{2k-1}| + |D_{2k}|)$ queries.*

▶ **Observation 22.** *Lemma 20 is particularly interesting. It says that at least $|A_k^{old}| - |B_{k+1}^{old}|$ (respectively $|B_k^{old}| - |A_k^{old}|$) elements change type when running `RefineAB` (respectively `RefineAB`).*

▶ Remark 23. Observation 22 is used in [3] to bound the number of times one needs to refine the partial augmenting set. Indeed, every element can only change its type a constant number of times. In a single refinement pass, procedures `RefineAB`(k) and `RefineBA`(k) are called for all k, and we obtain a telescoping sum guaranteeing us that $|B_1^{old}| - |B_{\ell+1}^{old}|$ elements have changed their types. Hence, after $O(\sqrt{n})$ refinement passes we have $|B_1| - |B_{\ell+1}| \leq \sqrt{n}$, and we are "close" to having a maximal augmenting set – only around $\sqrt{n}$ many augmenting paths away. This is essentially what lets [3] obtain their subquadratic $\tilde{O}(n^{1.5}/\text{poly}(\varepsilon))$ algorithm.

3.1.2 Refining Three Adjacent Layers

We are now ready to present the new `RefineABA` method (Algorithm 3), which is **not** present in [3]. This method works similarly to `RefineAB` and `RefineBA`, but on **three** (instead of two) consecutive layers $(D_{2k}, D_{2k+1}, D_{2k+2})$ with the corresponding sets (A_k, B_{k+1}, A_{k+1}).

The motivation for this new procedure is that we can get a stronger version of Observation 22: after running `RefineABA`(k) we want that at least $|A_k^{old}| - |A_{k+1}^{old}|$ element in **even** layers have changed types. Note that there are at most $|S| \leq r$ elements in the even layers (as opposed to n elements in total, which can be much larger), so this means we need to refine the partial augmenting set fewer times when using `RefineABA` compared to when just using `RefineAB` and `RefineBA`. In particular, we will get that after $O(\sqrt{r})$ refinement passes, $|B_1| - |B_{\ell+1}| \leq \sqrt{r}$.

▶ Remark 24. A natural question to ask is if it actually could be the case that only elements in odd layers (i.e. those in $\bar{S}$ which there are up to n many of) change their type (while elements in even layers do not) during the refinement passes in the algorithm of [3] (which only uses the two-layer refinement procedures)? That is, is the new three-layer refinement procedure necessary? The answer is yes. Consider for example the case with 5 layers $B_1 \subseteq D_1; A_1 \subseteq D_2; B_2 \subseteq D_3; A_2 \subseteq D_4; B_3 \subseteq D_5$ where $q := |B_1| = |A_1|$ and $|A_2| = |B_3| = 0$. Refining the consecutive pair (B_1, A_1) or (A_2, B_3) will not do anything. When refining (A_1, B_2) it could be the case that only B_2 increases (say any q-size subset in D_3 can be "matched" with A_1). Similarly, when refining (B_2, A_2) it could be the case that only B_2 decreases (say there is only a single element in D_3 which could be "matched" with anything in the next layer D_4, then it is unlikely that this specific element is already selected in B_2). In this case, we would need to run the two-layer refinement procedures around $|D_3|/q \approx n/q$ times before anything other than B_2 changes. In contrast, the new `RefineABA` method would, when run on (A_1, B_2, A_2), terminate with $|A_1| = |B_2| = |A_2|$ (that is it would have found the "special" element in D_3 the first time it is run).

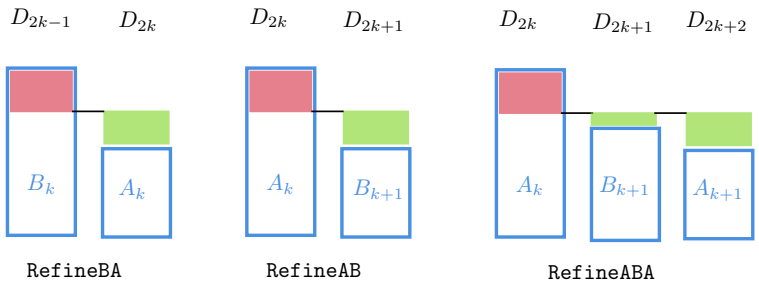

Figure 2 An illustration how the different refine methods change the partial augmenting sets. Newly selected elements are marked in green, while newly removed elements are marked in red.

To explain how `RefineABA` works, let us start with a simple case, namely when $S = \emptyset$, i.e. there is only one layer between s and t in the exchange graph. Here, finding a maximal augmenting set is the same as finding some maximal set B which is independent in both matroids. Running `RefineAB` would extend this B with elements as long as it is independent in the first matroid (ignoring the second matroid), while `RefineBA` would throw away elements from B until it is independent in the second matroid (now ignoring the first matroid). If we just alternate running `RefineAB` and `RefineBA` we would in the worst case need to do this up to n times (which is too expensive). Instead, there is a very simple greedy algorithm that efficiently finds a maximal set B independent in both of the matroids[12]: *for each element, include it in B if this does not break independence for either matroid.* This is akin to how our `RefineABA` method works: it looks at the constraints from both matroids simultaneously (both neighboring layers) and greedily selects B.

In the general case, `RefineABA` can be seen as running `RefineAB` and `RefineBA` simultaneously. The algorithm starts by asserting $|B_{k+1}| = |A_{k+1}|$ (so that $S + B_{k+1} - A_{k+1} \in \mathcal{I}_2$) by running `RefineBA`. So now we have both $S + B_{k+1} - A_k \in \mathcal{I}_1$ and $S + B_{k+1} - A_{k+1} \in \mathcal{I}_2$, and the algorithm proceeds to greedily extend B_{k+1} while it is still consistent with both the previous layer A_k and the next layer $A_{k+1} + F_{2k+2}$. Some care has to be taken here to also mark elements as removed to preserve the phase invariants. Finally, the algorithm decreases the size of A_k, respectively increases the size of A_{k+1}, to both match $|B_{k+1}|$.

[12] This algorithm on its own is a well-known $\frac{1}{2}$-approximation algorithm for matroid intersection.

Algorithm 3 `RefineABA`(k).

```
1: RefineBA(k + 1)
2: for x ∈ F_{2k+1} do
3:     if S − A_k + B_{k+1} + x ∈ I_1 then
4:         if S − A_{k+1} − F_{2k+2} + B_{k+1} + x ∈ I_2 then
5:             B_{k+1} ← B_{k+1} + x,   F_{2k+1} ← F_{2k+1} − x        ▷ Select x
6:         else
7:             R_{2k+1} ← R_{2k+1} + x,   F_{2k+1} ← F_{2k+1} − x      ▷ Remove x
8: RefineBA(k + 1)
9: RefineAB(k)
```

We now state some properties of `RefineABA`. These properties are relatively straightforward, although technical and notation-heavy, to prove.

▶ **Lemma 25.** *`RefineABA`(k) preserves the phase invariants.*

▶ **Lemma 26.** *After `RefineABA`(k) is run, we have $|A_k| = |B_{k+1}| = |A_{k+1}|$ (unless $k = 0$ or $k = \ell$, where the sets $A_0 = A_{\ell+1} = \emptyset$ are "imaginiary").*

▶ **Lemma 27.** *`RefineABA`(k) uses $O(|D_{2k}| + |D_{2k+1}| + |D_{2k+2}|)$ independence queries.*

Proof of Lemma 25. Intuitively, the only tricky part is showing that invariant (c) is preserved when some x is removed in line 7. We can pretend that we add x to B_{k+1} temporarily, and then run `RefineBA`$(k+1)$ in a way which would remove this x immediately (and thus removing x did indeed preserve the invariants). We present a formal proof below.

We already know that `RefineAB` and `RefineBA` preserve the invariants by Lemma 20, so it suffices to check that the for-loop starting in line 2 preserves the invariants. We verify that this is the case after processing each $x \in F_{2k+1}$ in the for-loop:

Invariant (a-b) holds by design: when x is added to B_{k+1} we know both that $S - A_k + B_{k+1} + x \in \mathcal{I}_1$ and $\mathrm{rk}_2(S - A_{k+1} + B_{k+1})$ cannot decrease. Note also that $\mathrm{rk}_2(S - A_{k+1} + B_{k+1}) \leq \mathrm{rk}_2(S)$ when $k + 1 \leq \ell$ too (so it cannot increase either), since otherwise there must exist some $b \in B_{k+1}$ so that $S + b \in \mathcal{I}_2$ (by the matroid exchange property) which is impossible since we are not in the last layer (the layer preceding t in $G(S)$).

Invariant (c) trivially holds, since the set $B_{k+1} + F_{2k+1}$ will only decrease, which only restricts the choice of $X \subseteq B_{k+1} + F_{2k+1}$.

Invariant (d) will also be preserved. We need to argue that this is the case when x is removed in line 7. Let $W := S - A_{k+1} - F_{2k+2} + B_{k+1} = S - (D_{2k+2} - R_{2k+2}) + B_{k+1}$, and R^{old}_{2k+1} be the set R_{2k+1} before x was added to it. First note that $W \in \mathcal{I}_2$, since this holds after the `RefineBA` call in line 1, (since $|A_{k+1}| = |B_{k+1}|$ after this call) and B_{k+1} is only extended with elements which preserve this property. This means that $\mathrm{rk}_2(W + x) = \mathrm{rk}_2(W) = |W|$, since $W + x = S - A_{k+1} - F_{2k+2} + B_{k+1} + x \notin \mathcal{I}_2$. Since the invariant held before, we also know that $\mathrm{rk}_2(W + R^{old}_{2k+1}) = \mathrm{rk}_2(W) = |W|$. Hence W is a maximal independent (in $\mathcal{M}_2$) subset of $W + R^{old}_{2k+1} + x$, as neither x nor elements from R^{old}_{2k+1} can be used to extend it. Hence $\mathrm{rk}_2(W + R^{old}_{2k+1} + x) = |W| = \mathrm{rk}_2(W)$; that is invariant (d) is preserved. ◀

Proof of Lemma 26. We focus our attention on the `RefineBA` and `RefineAB` calls in lines 8-9, and argue that they do not change B_{k+1}. This would prove the lemma, since by Lemma 20 we would then have $|A_k| = |B_{k+1}|$ and $|B_{k+1}| = |A_{k+1}|$.

Indeed, `RefineBA`$(k+1)$ finds a maximal $B \subseteq B_{k+1}$ such that $S-(D_{2k+2}-R_{2k+2})+B \subseteq \mathcal{I}_2$, and remove all elements not in B from B_{k+1}. Here, $B = B_{k+1}$ will be found, since $S-(D_{2k+2}-R_{2k+2})+B_{k+1} \in \mathcal{I}_2$ after the for-loop in line 2 of `RefineABA`.

Similarly, we see that `RefineAB`(k) finds a maximal $B \subseteq F_{2k+1}$ such that $S-A_k+B_{k+1}+B \in \mathcal{I}_1$, and extend B_{k+1} with this B. However, only $B = \emptyset$ works, since each $x \in F_{2k+1}$ for which $S-A_k+B_{k+1}+x \in \mathcal{I}_1$ was either selected or removed in lines 5 or 7. ◀

Proof of Lemma 27. `RefineAB`(k) uses $O(|D_{2k}|+|D_{2k+1}|)$ queries, and `RefineBA`$(k+1)$ uses $O(|D_{2k+1}|+|D_{2k+2}|)$ queries. The for-loop in line 2 will use $O(|D_{2k+1}|)$ queries. ◀

3.1.3 Refinement Pass

We can now present the full `Refine` method (Algorithm 4), which simply scans over the layers and calls `RefineABA` on them. Our `Refine` is a modified version of `Refine` from [3, Algorithm 11] using our new `RefineABA` method instead of just `RefineAB` and `RefineBA`. Just replacing the `Refine` method in the final algorithm of [3] with our modified `Refine` below leads to an $\tilde{O}(n\sqrt{r}/\varepsilon^{1.5})$-query algorithm (compared to their $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$), and concludes our first improvement (as discussed in Item 1 in Section 1.1).

Algorithm 4 `Refine`(k).

1: **for** $k = \ell,\ \ell-1,\ \ell-2,\ \ldots,\ 1,\ 0$ **do**
2: `RefineABA`(k)

The following Lemma 28 will be useful to bound the number of `Refine` calls needed in our final algorithm, and closely corresponds to [3, Corollary 43]. Our `Refine` implementation has the advantage that it only counts the elements in the **even** layers, of which there are at most r.

▶ **Lemma 28.** *Let $(B_1^{old}, A_1^{old}, \ldots)$ and $(B_1^{new}, A_1^{new}, \ldots)$ be the sets before and after `Refine` is run. Then at least $|B_1^{new}| - |B_{\ell+1}^{new}|$ elements in even layers have changed types.*

Proof. Note that whenever A_k changes, it is because some elements changed it types in D_{2k}. In particular, if the size of A_k increases (respectively decreases) by z, at least z elements will change types from fresh to selected (respectively from selected to removed) in D_{2k}.

After the first iteration $|A_\ell| = |B_{\ell+1}^{new}|$, so at least $|A_\ell^{old}| - |B_{\ell+1}^{new}|$ elements in $D_{2\ell}$ changed types. Similarly, after the iteration when $k = i$ (for $1 \le i \le \ell-1$), $|A_i| = |A_{i+1}|$, and hence at least $|A_i^{old}| - |A_i|$ elements in D_{2i} changed types plus at least $|A_{i+1}| - |A_{i+1}^{old}|$ elements in D_{2i+2} changed types.[13] Finally, after the last iteration $|A_1| = |B_1^{new}|$, and hence at least $|B_1^{new}| - |A_1^{old}|$ elements in D_2 changed types.

The above terms telescope, and we conclude that at least $|B_1^{new}| - |B_{\ell+1}^{new}|$ elements in the even layers changed its types when `Refine` was run. ◀

▶ **Lemma 29.** *`Refine` uses $O(n)$ independence queries.*

Proof. This follows directly by Lemma 27. ◀

[13] $|A_{i+1}| \le |A_{i+1}^{old}|$ just before the `RefineABA`(i) call, since earlier iterations can only have decreased the size of $|A_{i+1}|$.

3.2 Refining Along a Path

If we just run `Refine` until we get a maximal augment set (i.e. until $|B_1| = |B_{\ell+1}|$) we need to potentially run `Refine` as many as $\Theta(r)$ times, which needs too many independence queries. Lemma 28 tells us that `Refine` makes the most "progress" while $|B_1| - |B_{\ell+1}|$ is large: in fact, only $O(r/p)$ calls to `Refine` is needed until $|B_1| - |B_{\ell+1}| \leq p$. The idea in [3] is thus to stop refining when $|B_1| - |B_{\ell+1}|$ is small enough and fall back to finding augmenting paths one at a time (they prove that one needs to find at most $O((|B_1| - |B_{\ell+1}|)\ell)$ many). We use a similar idea in that we swap to a different procedure when $|B_1| - |B_{\ell+1}|$ is small enough, the difference being that we still work with the partial augmenting set. This will let us show that only $O(|B_1| - |B_{\ell+1}|)$ many "paths" need to be found, saving a factor $\ell \approx \frac{1}{\varepsilon}$ compared to [3].

This section thus describes the second improvement (as discussed in Item 2 in Section 1.1). Note that this improvement is independent of the first improvement (i.e. the three-layer refine). We aim to prove the following lemma.

▶ **Lemma 30.** *There exists a procedure (`RefinePath`, Algorithm 5), which uses $O(n \log r)$ independence queries, preserves the invariants, and either:*

(i) *Increases the size of $B_{\ell+1}$ by at least 1.*

(ii) *Terminates with $(B_1, A_1, \ldots, B_{\ell+1})$ being a maximal augmenting set.*

`RefinePath` attempts to find what we call a *valid path*. What we want is a sequence of elements which we can add to the partial augmenting set without violating the invariants and the properties of the partial augmenting set. It turns out (not very surprisingly) that such sequences of elements can be characterized by a notion of *paths* in something which resembles the *exchange graph with respect to our partial augmenting set*. This is what motivates the definition of *valid paths* below.

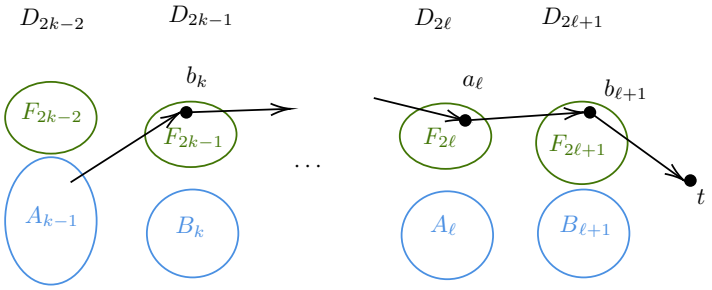

Figure 3 A valid path $(b_k, \ldots, a_\ell, b_{\ell+1}, t)$ "starting" from the partial augmenting set at A_{k-1}, so that we can use Lemma 33 and augment along it.

▶ **Definition 31** (Valid path)**.** A sequence $(b_i, a_i, b_{i+1}, \ldots, b_{\ell+1}, t)$ (or $(a_i, b_{i+1}, \ldots, b_{\ell+1}, t)$) is called a *valid path* (with respect to the partial augmenting set) if for all $k \geq i$:

(a) $a_k \in F_{2k}$ and $b_k \in F_{2k-1}$.

(b) $S + B_{\ell+1} + b_{\ell+1} \in \mathcal{I}_2$.

(c) $S - A_k + B_k - a_k + b_k \in \mathcal{I}_2$.

(d) $S - A_k + B_{k+1} - a_k + b_{k+1} \in \mathcal{I}_1$.

▶ Remark 32. Compare the properties of valid paths with the edges in the exchange graph from Definition 8. A valid path is essentially a path in the exchange graph *after* we have already augmented S by our partial augmenting set (even though this exchange graph is not exactly defined, since it is not guaranteed that S remains a common independent set when augmented by a *partial* augmenting set).

▶ **Lemma 33.** *If $p = (b_i, a_i, b_{i+1}, \ldots, b_{\ell+1}, t)$ is a valid path starting at b_i, such that $S - A_{i-1} + B_i + b_i \in \mathcal{I}_1$, then $(B_1, A_1, \ldots, B_{i-1}, A_{i-1}, B_i + b_i, A_i + a_i, \ldots, B_{\ell+1} + b_\ell)$ is a partial augmenting set satisfying the invariants.*

Proof. That it forms a partial augmenting set is true by the definition of valid paths, and the fact that $S - A_{i-1} + B_i + b_i \in \mathcal{I}_1$. Indeed, it cannot be the case that $|A_{i-1}| < |B_i + b_i|$ when $i > 1$, since then $\text{rk}_1(S - A_{i-1} + B_i + b_i) > |S| = \text{rk}_1(S)$ implies that some element $x \in (B_i + b_i)$ satisfies $S + x \in \mathcal{I}_1$ (i.e. it is in the first layer D_1) by the exchange property of matroids. Invariants (c) and (d) are trivially true since the sets A_k and B_k are only extended. ◀

The goal of `RefinePath` (Algorithm 5) is thus to find a valid path satisfying the conditions in Lemma 33. Towards this goal, `RefinePath` will start from the last layer $D_{2\ell+1}$ and "scan left" in a breadth-first-search manner while keeping track of valid paths starting at each fresh vertex x (the next element on such a path will be stored as $\texttt{next}[x]$). If at some point one valid path can "enter" the partial augmenting set in a layer, we are done and can use Lemma 33. We also show that it is safe (i.e. preserves the invariants) to remove all the fresh elements x for which we cannot find a valid path starting at x.

To efficiently find the "edges" during our breadth-first-search using only independence-queries, we use the binary-search trick from Lemma 11. However, this relies on the partial augmenting set being locally "flat" in the layers we are currently exploring, i.e. $|B_k| = |A_k|$ respectively $|B_k| = |A_{k+1}|$. We can ensure this by running `RefineAB` respectively `RefineBA` while performing the scan.

Now we are ready to present the pseudo-code of the `RefinePath` method (Algorithm 5). Due to the asymmetry between even/odd layers and independence queries, we need to handle moving from layer B to A and from A to B a bit differently, but the ideas are similar.

▶ **Lemma 34.** *`RefinePath` preserves the invariants.*

Proof. The proof is relatively straightforward, but technical. The only non-trivial part is showing that invariants (c) and (d) are preserved after we remove something in line 8 or line 20. Intuitively, if we remove b in line 8, we can instead think of temporarily adding b to B_k and running $\texttt{RefineBA}(k)$ in such a way so that b is immediately removed. A similar intuitive argument works for line 20. We next present a formal proof.

We know that `RefineAB` and `RefineBA` preserve the invariants, by Lemma 20. We also know by Lemma 33 that adding a valid path to the partial augmenting set also preserves the invariants. So what remains is to show that the invariants are preserved after:

Line 8. We only need to check invariant (d), the other ones trivially hold. Let $W = S - A_k - F_{2k} + B_k = S - (D_{2k} - R_{2k}) + B_k$ and R^{old}_{2k-1} be R_{2k-1} before b was added to it. Note that b is such that $W + b \notin \mathcal{I}_2$, and we know that $W \subseteq S - A_k + B_k \in \mathcal{I}_2$ and hence $\text{rk}_2(W + R^{old}_{2k-1}) = \text{rk}_2(W) = |W|$ and $\text{rk}_2(W + b) = \text{rk}_2(W) = |W|$. We thus need to show that $\text{rk}_2(W + R^{old}_{2k-1} + b) = |W|$ too, which is clear since W is a maximal independent subset of $W + R^{old}_{2k-1} + b$ (it can neither be extended with elements from R^{old}_{2k-1} nor with b).

Line 20. We only need to check invariant (c), the other ones trivially hold. We imagine we add the $a \in Q$ to R_{2k-2} one-by-one, and show that the invariant (c) is preserved after each such addition. So consider some $a \in Q$ which will be removed, and let R^{old}_{2k-2} be the set R_{2k-2} just before we added a to it. First note that $\text{rk}_1(S - A_{k-1} + B_k + F_{2k-1} - a) = \text{rk}_1(S - A_{k-1} + B_k + F_{2k-1}) - 1 = |S - A_{k-1} + B_k| - 1$, as otherwise there must exist some $b \in F_{2k-1}$ such that $S - A_{k-1} + B_k + b - a \in \mathcal{I}_1$ (by the matroid exchange property),

Algorithm 5 `RefinePath`.

1: **for** $k = \ell + 1,\ \ell,\ \ldots,\ 2,\ 1$ **do**
▷ Process (B_k, A_k)
2: `RefineBA`(k)
3: **if** some element a was added to A_k in the above refine-call **then**
4: Add the valid path starting at `next`$[a]$ to the partial augmenting set
5: **return**
6: **for** each element $b \in F_{2k-1}$ **do**
7: **if** $S - A_k - F_{2k} + B_k + b \notin \mathcal{I}_2$ **then**
8: Remove b, that is: $F_{2k-1} \leftarrow F_{2k-1} - b, \quad R_{2k-1} \leftarrow R_{2k-1} + b$
9: **else**
10: Find an $a \in F_{2k}$ such that $S - A_k + B_k + b - a \in \mathcal{I}_2$. Let `next`$[b] = a$.
11: (Or, if $k = \ell + 1$, just let `next[b]` $= t$)
▷ Process (A_{k-1}, B_k)
12: **if** some element $b \in F_{2k-1}$ satisfies $S - A_{k-1} + B_k + b \in \mathcal{I}_1$ **then**
13: Add the valid path starting at b to the partial augmenting set.
14: **return**
15: `RefineAB`$(k-1)$
16: $Q \leftarrow F_{2k-2}$.
17: **for** each element $b \in F_{2k-1}$ **do**
18: **while** can find $a \in Q$ such that $S - A_{k-1} + B_k + b - a \in \mathcal{I}_1$ **do**
19: $Q \leftarrow Q - a$. Let `next`$[a] = b$.
20: Remove all elements in Q, that is: $F_{2k-2} \leftarrow F_{2k-2} - Q, \quad R_{2k-2} \leftarrow R_{2k-2} + Q$.

21: If we reached here, $(B_1, A_1, \ldots, B_{\ell+1})$ is a maximal augmenting set.

and a would have been discovered in line 18 and therefore been removed from Q. So the "return" of adding a to $S - A_{k-1} + B_k + F_{2k-1} - a$ is increasing the rank by 1. Now consider some arbitrary $X \subseteq B_k + F_{2k-1}$ such that $S - A_{k-1} + X - R^{old}_{2k-2} - a \in \mathcal{I}_1$. We need to show that $S - A_{k-1} + X \in \mathcal{I}_1$. Note that $S - A_{k-1} + X - R^{old}_{2k-2} - a \subseteq S - A_{k-1} + B_k + F_{2k-1} - a$. Hence, by the diminishing returns (of adding a) we know $\mathrm{rk}_1(S - A_{k-1} + X - R^{old}_{2k-2}) \geq \mathrm{rk}_1(S - A_{k-1} + X - R^{old}_{2k-2} - a) + 1 = |S - A_{k-1} + X - R^{old}_{2k-2}|$, or equivalently that $S - A_{k-1} + X - R^{old}_{2k-2} \in \mathcal{I}_1$. Since the invariant held before, we conclude that $S - A_{k-1} + X \in \mathcal{I}_1$ too, which finishes the proof. ◀

Valid paths. The algorithm keeps track of a valid path starting at each fresh vertex it has processed. That is, after processing layer D_k, all elements in F_k must be the beginning of a valid path, else they were removed. In particular, the algorithm remembers the valid path starting at x as $(x, \texttt{next}[x], \texttt{next}[\texttt{next}[x]], \ldots)$. It is easy to verify that this sequence does indeed satisfy the conditions of *valid paths* by inspecting lines 10 and 18.

We also discuss what happens when the algorithm chooses to add a valid path to the partial augmenting set (i.e. in line 4 or 13). If we are in Line 13, we can directly apply Lemma 33. Say we instead are in Line 4, and some a which was previously fresh has been added to A_k. The `RefineBA` call can only have increased A_k (that is $A_k \supseteq A^{old}_k + a$), so $S - A_k + B_{k+1} + b \in \mathcal{I}_1$ will holds for $b = \texttt{next}[a]$ and we can apply Lemma 33 here too.

When no path is found. In the case when no valid path to add to the partial augmenting set is found, `RefinePath` must terminate with $|B_1| = |A_1| = \cdots = |B_{\ell+1}|$. This is because the `RefineAB` and `RefineBA` will never select any new elements. That is `RefineBA` will not change A_k (as otherwise we enter the if-statement at line 4), and `RefineAB` will not change B_k (since if $b \in F_{2k-1}$ with $S - A_{k-1} + B_k + b \in \mathcal{I}_1$ existed we would have entered the if-statement at line 13). We also remark that `RefinePath` ends with B_1 being a maximal subset of $D_1 \setminus R_1$, as otherwise some b would have been found in line 12. Hence Lemma 19 implies that $(B_1, A_1, \ldots, B_{\ell+1})$ now forms a *maximal* augmenting set.

Query complexity. The `RefineAB` and `RefineBA` calls will in total use $O(n)$ queries. The independence checks at Lines 7 and 12 happens at most once for each element, and thus use $O(n)$ queries in total. Lines 10 and 18 can be implemented using the binary-search-exchange-discovery Lemma 11. Hence Line 10 will use, in total, $O(n \log r)$ queries and Line 18 will use, in total, $O(n \log r)$ queries (since each $a \in Q$ will be discovered at most once). So we conclude that Algorithm 5 uses $O(n \log r)$ independence queries.

3.3 Hybrid Algorithm

Now we are finally ready to present the full algorithm of a phase, which is parameterized by a variable p. The following algorithm is similar to that of [3, Algorithm 12] but uses our improved `Refine` method and finds individual paths using the `RefinePath` method.

Algorithm 6 Phase ℓ.

1: Calculate the distance layers by a BFS.
2: Run `Refine` (Algorithm 4) until $|B_1| - |B_{\ell+1}| \leq p$, but at least once.
3: Run `RefinePath` (Algorithm 5) until $(B_1, A_1, \ldots B_{\ell+1})$ is maximal. Augment along it.

▶ **Lemma 35.** *Except for line 1, Algorithm 6 uses $O(nr/p + np \log r)$ queries.*[14]

Proof. Lemma 28 tells us that `Refine` changes types of at least p elements in even layers (i.e. elements in S) every time it is run, except maybe the last time. Thus we only run `Refine` $O(|S|/p + 1)$ times. Each call takes $O(n)$ queries (Lemma 29), for a total of $O(nr/p)$ queries in line 2 of the algorithm.

Now we argue that B_1 can never become larger than what it was just after line 2 was run. This is because `Refine` will run at least once, and ends with a `RefineABA`(0) call which in turn ends with a `RefineAB(0)` call – which extends B_1 to be a maximal set in $D_1 \setminus R_1$ for which $S + B_1 \subseteq \mathcal{I}_1$ holds.[15]

Lemma 30 tells us that each (except the last) time `RefinePath` is run, $B_{\ell+1}$ increases by 1. This can happen at most p times, so line 3 uses a total of $O(np \log r)$ queries. ◀

Now it is easy to prove Theorem 1, which we restate below.

[14] Compare this to $O(n^2/p + np\ell \log r)$ in [3]. The improvement from n^2/p to nr/p comes from the use of the new three-layer `RefineABA` method, and the (independent) improvement from $np\ell \log r$ to $np \log r$ comes from the use of the new `RefinePath` method.

[15] Indeed, since $\mathcal{M}_1$ is a matroid, all such maximal sets have the same size, so we can never obtain something larger later.

▶ **Theorem 1** (Approximation algorithm). *There is a deterministic algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ with $|S| \geq (1-\varepsilon)r$, using $O\left(\frac{n\sqrt{r \log r}}{\varepsilon}\right)$ independence queries.*

Proof. Pick $p = \sqrt{r/\log r}$.[16] Then each phase will use $O(n\sqrt{r \log r})$ independence queries (by Lemma 35), plus a total of $O(\frac{1}{\varepsilon} n \log r)$ to run the BFS's across all phases (see [3] for details on the BFS implementation). Since we need only run $O(\frac{1}{\varepsilon})$ phases (by Lemma 10 and Theorem 16), in total the algorithm will use $O(\frac{1}{\varepsilon} n\sqrt{r \log r})$ queries. ◀

4 Exact Matroid Intersection

In this section, we prove Theorem 2 (restated below) by showing how our improved approximation algorithm leads to an improved exact algorithm when combined with the algorithms of [2].

▶ **Theorem 2** (Exact algorithm). *There is a randomized algorithm which given two matroids $\mathcal{M}_1 = (V, \mathcal{I}_1)$ and $\mathcal{M}_2 = (V, \mathcal{I}_2)$ on the same ground set V, finds a common independent set $S \in \mathcal{I}_1 \cap \mathcal{I}_2$ of maximum cardinality r, and w.h.p.[17] uses $O(nr^{3/4} \log n)$ independence queries. There is also a deterministic exact algorithm using $O(nr^{5/6} \log n)$ queries.*

Approximation algorithms are great at finding the *many, very short* augmenting paths efficiently. Blikstad-v.d.Brand-Mukhopadhyay-Nanongkai [2, Algorithm 2] very recently showed how to efficiently find the remaining *few, very long* augmenting paths, with a randomized algorithm using $\tilde{O}(n\sqrt{r})$ queries per augmentation (or, with a slightly less efficient deterministic algorithm using $\tilde{O}(nr^{2/3})$ queries). In the randomized $\tilde{O}(n^{6/5}r^{3/5})$-query exact algorithm of [2, Algorithm 3], the current bottleneck is the approximation algorithm used. Replacing the use of the $\tilde{O}(n^{1.5}/\varepsilon^{1.5})$-query approximation algorithm from [3] with our improved version we obtain the more efficient randomized[18] $\tilde{O}(nr^{3/4})$-query Algorithm 7.

Algorithm 7 Exact Matroid Intersection. (Modified version of [2, Algorithm 3])

1: Run the approximation algorithm (Theorem 1) with $\varepsilon = r^{-1/4}$ to obtain a common independent set S of size at least $(1-\varepsilon)r = r - r^{3/4}$.
2: Starting with S, run Cunningham's algorithm (as implemented by [3]), until the distance between s and t becomes larger than $r^{3/4}$.
3: Keep finding augmenting paths – one at a time – to augment along, using the randomized $O(n\sqrt{r} \log n)$-query algorithm of [2, Algorithm 2]. When no (s,t)-path can be found in the exchange graph, S is a largest common independent set.

Query complexity. We analyse the individual lines of Algorithm 7.

Line 1. We see that the approximation algorithm uses $O(nr^{3/4} \log n)$ queries in line 1.

Line 2. One need to (i) compute distances up to $d = r^{3/4}$, and (ii) perform at most $O(r^{3/4})$ augmentations. [2, 3, 11] show how to do (i) in $O(nd \log n) = O(nr^{3/4} \log n)$ queries in total over all phases of Cunningham's algorithm, and how to do (ii) using $O(n \log n)$ queries per augmentation (for a total of $O(nr^{3/4} \log n)$ queries).

[16] Compare this to $p = \sqrt{n\varepsilon/\log r}$ in [3].
[17] *w.h.p. = with high probability* meaning with probability $1 - n^{-c}$ for some arbitrarily large constant c.
[18] The deterministic algorithm of Theorem 2 is obtained in the same fashion but by using the deterministic version of the augmenting path finding algorithm [2, Algorithm 2].

Line 3. By Lemma 10, line 3 runs $O(r^{1/4})$ times – each using $O(n\sqrt{r}\log n)$ queries – for a total of $O(nr^{3/4}\log n)$ queries.

▶ Remark 36. In Algorithm 7, the bottleneck between line 1-2 and line 2-3 now matches (which was not the case in [2]). This means that if one wants to improve the algorithm by replacing the subroutines in line 1 and 3, one need to **both** improve the approximation algorithm (line 1) and the method to find a single augmenting-path (line 3).

Graph Similarity and Homomorphism Densities

Jan Böker
RWTH Aachen University, Germany

Abstract

We introduce the tree distance, a new distance measure on graphs. The tree distance can be computed in polynomial time with standard methods from convex optimization. It is based on the notion of fractional isomorphism, a characterization based on a natural system of linear equations whose integer solutions correspond to graph isomorphism. By results of Tinhofer (1986, 1991) and Dvořák (2010), two graphs G and H are fractionally isomorphic if and only if, for every tree T, the number of homomorphisms from T to G equals the corresponding number from T to H, which means that the tree distance of G and H is zero. Our main result is that this correspondence between the equivalence relations "fractional isomorphism" and "equal tree homomorphism densities" can be extended to a correspondence between the associated distance measures. Our result is inspired by a similar result due to Lovász and Szegedy (2006) and Borgs, Chayes, Lovász, Sós, and Vesztergombi (2008) that connects the cut distance of graphs to their homomorphism densities (over all graphs), which is a fundamental theorem in the theory of graph limits. We also introduce the path distance of graphs and take the corresponding result of Dell, Grohe, and Rattan (2018) for exact path homomorphism counts to an approximate level. Our results answer an open question of Grohe (2020) and help to build a theoretical understanding of vector embeddings of graphs.

The distance measures we define turn out be closely related to the cut distance. We establish our main results by generalizing our definitions to graphons, which are limit objects of sequences of graphs, as this allows us to apply techniques from functional analysis. We prove the fairly general statement that, for every "reasonably" defined graphon pseudometric, an exact correspondence to homomorphism densities can be turned into an approximate one. We also provide an example of a distance measure that violates this reasonableness condition. This incidentally answers an open question of Grebík and Rocha (2021).

1 Introduction

Vector representations of graphs allow to apply standard machine learning techniques to graphs, and a variety of methods to generate such embeddings has been studied in the machine learning literature. However, from a theoretical point of view, these embeddings have not received much attention and are not well understood. Some machine learning methods only implicitly operate on such vector representations as they only access the inner products of these vectors. These methods are known as *kernel methods* and most graph kernels are based on counting occurrences of certain substructures, e.g., walks or trees. See [15] for a recent survey on vector embeddings.

Many kinds of substructure counts in a graph such as graph motifs are actually just *homomorphism* counts "in disguise", and hence, homomorphisms provide a formal and flexible framework for counting all kinds of substructures in graphs [5]; a homomorphism from a graph F to a graph G is a mapping from the vertices of F to the vertices of G such that every edge of F is mapped to an edge of G. A theorem of Lovász from 1967 [18], which states that two graphs G and H are isomorphic if and only if, for every graph F, the number $\mathsf{hom}(F,G)$ of homomorphisms from F to G equals the corresponding number $\mathsf{hom}(F,H)$ from F to H, led to the development of the theory of graph limits [2, 20], where one considers convergent sequences of graphs and their limit objects, graphons. In terms of the *homomorphism vector* $\mathsf{Hom}(G) \coloneqq (\mathsf{hom}(F,G))_{F \text{ graph}}$ of a graph G, the result of Lovász states that graphs are mapped to the same vector if and only if they are isomorphic.

Computing an entry of $\mathsf{Hom}(G)$ is $\#P$-complete and recent results have mostly focused on restrictions $\mathsf{Hom}_{\mathcal{F}}(G) \coloneqq (\mathsf{hom}(F,G))_{F \in \mathcal{F}}$ of these vectors to classes $\mathcal{F}$ for which computing these entries is actually tractable. Under a natural assumption from parameterized complexity theory, this is the case for precisely the classes $\mathcal{F}$ of bounded tree width [6]. This has led to various surprisingly clean results, e.g., for trees and, more general, graphs of bounded treewidth [10], cycles and paths [7], planar graphs [22], and, most recently, graphs of bounded tree-depth [14]. These results only show what it means for graphs to be mapped to the same homomorphism vector; they do not say anything about the similarity of two graphs if the homomorphism vectors are not exactly the same but *close*. Grohe formulated the vague hypothesis that, for suitable classes $\mathcal{F}$, the embedding $\mathsf{Hom}_{\mathcal{F}}$ combined with a suitable inner product on the latent space induces a natural similarity measure on graphs [15]. This is supported by initial experiments, which show that homomorphism vectors in combination with support vector machines perform well on standard graph classification. Our results further support this hypothesis from a theoretical standpoint by showing that tree homomorphism counts provide a robust similarity measure.

For the class $\mathcal{T}$ of trees and two graphs G and H, we have $\mathsf{Hom}_{\mathcal{T}}(G) = \mathsf{Hom}_{\mathcal{T}}(H)$ if and only if G and H are not distinguished by *color refinement* (also known as the 1-*dimensional Weisfeiler-Leman algorithm*) [10], a popular heuristic for graph isomorphism. Another characterization of this equivalence due to Tinhofer is that of *fractional isomorphism* [26, 27]. Let $A \in \mathbb{R}^{V(G)\times V(G)}$ and $B \in \mathbb{R}^{V(H)\times V(H)}$ be the adjacency matrices of G and H, respectively, and consider the following system $\mathsf{F}_{\text{iso}}(G,H)$ of linear equations:

$$\mathsf{F}_{\text{iso}}(G,H): \begin{cases} AX = XB \\ X\mathbf{1}_{V(H)} = \mathbf{1}_{V(G)} \\ \mathbf{1}_{V(G)}^T X = \mathbf{1}_{V(H)}^T \end{cases}$$

Here, X denotes a $(V(G) \times V(H))$-matrix of variables, and $\mathbf{1}_U$ denotes the all-1 vector over the index set U. The non-negative integer solutions to $\mathsf{F}_{\text{iso}}(G,H)$ are precisely the permutation matrices that describe isomorphisms between G and H. The non-negative real solutions are called *fractional isomorphisms* of G and H. Tinhofer proved that G and H are not distinguished by the color refinement algorithm if and only if there is a fractional isomorphism of G and H. Grohe proposed to define a similarity measure based on this characterization [15]: For a matrix norm $\|\cdot\|$ that is invariant under permutations of the rows and columns, consider

$$\operatorname{dist}_{\|\cdot\|}(G,H) \coloneqq \min_{\substack{X \in [0,1]^{V(G)\times V(H)}, \\ X \text{ doubly stochastic}}} \|AX - XB\|.$$

Most graph distance measures based on matrix norms are highly intractable as the problem of their computation is related to notoriously hard maximum quadratic assignment problem [23]. This hardness, which stems from the minimization over the set of all permutation matrices, motivated Grohe to propose $\mathrm{dist}_{\|\cdot\|}$, where the set of all permutation matrices is relaxed to the the convex set of doubly stochastic matrices, yielding a convex optimization problem. With the results of Tinhofer and Dvořák, we know that the graphs of distance zero w.r.t. $\mathrm{dist}_{\|\cdot\|}$ are precisely those that cannot be distinguished by tree homomorphism counts.

So far, the only known connection between a graph distance measure based on matrix norms and graph homomorphisms is between the *cut distance* and normalized homomorphism numbers (called *homomorphism densities*) [2]. Grohe asks whether a similar correspondence between $\mathrm{dist}_{\|\cdot\|}$ and restricted homomorphism vectors can be established, and we give a positive answer to this question. We introduce the *tree distance* $\delta^{\mathcal{T}}$ of graphs, which is a normalized variant of $\mathrm{dist}_{\|\cdot\|}$ and show the following theorem, which is stated here only informally. We also introduce the *path distance* $\delta^{\mathcal{P}}$ of graphs and prove the analogous theorem to Theorem 1 for $\delta^{\mathcal{P}}$ and normalized path homomorphism counts.

▶ **Theorem 1** (Informal Theorem 6 and Theorem 7). *Two graphs G and H are similar w.r.t. $\delta^{\mathcal{T}}$ if and only if the homomorphism densities $t(T,G)$ and $t(T,H)$ are close for trees T.*

In the theory of graph limits, *graphons* serve as limit objects for sequences of graphs. By defining distance measures on the more general graphons, we are able to use techniques from functional analysis to show that any "reasonably" defined pseudometric on graphons satisfying an exact correspondence to homomorphism densities also has to satisfy an approximate one. As an application, we get that both the tree and the path distance satisfy this correspondence to tree and path homomorphism densities, respectively. For the case of trees, we rely on a generalization of the notion of fractional isomorphism to graphons by Grebík and Rocha [13]. For the case of paths, we prove this generalization of the result of Dell, Grohe, and Rattan [7] by ourselves.

This paper is organized as follows. In the preliminaries, Section 2, we collect the definitions of graphs, the space $L_2[0,1]$, graphons, and the cut distance. In Section 3, we define the tree distance and the path distance for graphs and formally state Theorem 1 and its path counterpart. In Section 4, we state and prove the theorems that allow us to show these correspondences for graphon pseudometrics. Section 5 provides the first application of these tools for the tree distance: we first state the needed result of fractional isomorphism of graphons due to Grebík and Rocha and then use this to define the tree distance of graphons. These definitions and results specialize to the ones presented in Section 3 for graphs. The treatment of the path distance for graphons is similar to the one of the tree distance, except for the fact that we prove a characterization of graphons with the same path homomorphism densities ourselves, and can be found in Section 6. In Section 7, we define another distance measure on graphs based on the invariant computed by the color refinement algorithm and show that it only satisfies one direction of the approximate correspondence to tree homomorphism densities. Our counterexample incidentally answers an open question of Grebík and Rocha [13]. Section 8 poses some interesting open questions that come up during the study of these distance measures. All missing proofs can be found in the full version of the paper.

2 Preliminaries

2.1 Graphs

By the term graph, we refer to a simple, undirected, and finite graph. For a graph G, we denote its vertex set by $V(G)$ and its edge set by $E(G)$, and we let $\mathsf{v}(G) \coloneqq |V(G)|$ and $\mathsf{e}(G) \coloneqq |E(G)|$. We usually view the adjacency matrix A of a graph G as a matrix $A \in \mathbb{R}^{V(G)\times V(G)}$, i.e., it is indexed by the vertices of G. Sometimes, we assume without loss of generality that the vertex set of a graph is $[n] \coloneqq \{1, \dots, n\}$, where $n \in \mathbb{N}$ is a natural number. A homomorphism from a graph F to a graph G is a mapping $\varphi\colon V(F) \to V(G)$ such that $\varphi(u)\varphi(v) \in E(G)$ for every $uv \in E(F)$. We denote the number of homomorphisms from F to G by $\mathsf{hom}(F, G)$. The homomorphism density from F to G is given by $t(F, G) \coloneqq \mathsf{hom}(F, G)/\mathsf{v}(G)^{\mathsf{v}(F)}$.

A *weighted graph* $G = (V, a, B)$ consists of a vertex set V, a positive real vector $a = (\alpha_v)_{v\in V} \in \mathbb{R}^V$ of vertex weights and a real symmetric matrix $B = (\beta_{uv}) \in [0, 1]^{V\times V}$ of edge weights; that is, we restrict ourselves to edge weights from $[0, 1]$. We write $\mathsf{v}(G) = |V|$, $V(G) = V$, $\alpha_v(G) = \alpha_v$, $\alpha_G = \sum_{v\in V(G)} \alpha_v(G)$ and $\beta_{uv}(G) = \beta_{uv}$. A weighted graph is called *normalized* if $\alpha_G = 1$. For a simple graph F and a weighted graph G, we define the *homomorphism number*

$$\mathsf{hom}(F, G) = \sum_{\varphi\colon V(F)\to V(G)} \prod_{v\in V(F)} \alpha_{\varphi(v)}(G) \prod_{uv\in E(F)} \beta_{\varphi(u)\varphi(v)}(G)$$

and the *homomorphism density* $t(F, G) = \mathsf{hom}(F, G)/\alpha_G^{\mathsf{v}(F)}$. When viewing a graph as a weighted graph in the obvious way, these notions coincide with the ones for graphs.

2.2 The Space $L_2[0, 1]$ and Graphons

A detailed introduction to functional analysis can be found in [8]; here, we only repeat some notions we use throughout the main body of the paper. Let $L_2[0, 1]$ denote the space of $\mathbb{R}$-valued 2-integrable functions on $[0, 1]$ (modulo equality almost anywhere). We could consider consider a standard Borel space with a Borel probability measure, cf. [13], but for the sake of convenience, we stick to $[0, 1]$ with the Lebesgue measure just as [20]. The space $L_2[0, 1]$ is a Hilbert space with the inner product defined by $\langle f, g\rangle \coloneqq \int_{[0,1]} f(x)g(x)\,dx$ for functions $f, g \in L_2[0, 1]$. Let $T\colon L_2[0, 1] \to L_2[0, 1]$ be a bounded linear operator, or operator for short. We write $\|T\|_{2\to 2}$ for its operator norm, i.e., $\|T\|_{2\to 2} = \sup_{\|g\|_2\le 1}\|Tg\|_2$. The *Hilbert adjoint* of T is the unique operator $T^*\colon L_2[0, 1] \to L_2[0, 1]$ such that $\langle Tf, g\rangle = \langle f, T^*g\rangle$ for all $f, g \in L_2[0, 1]$, and T is called self-adjoint if $T^* = T$.

Let $\mathcal{W}$ denote the set of all bounded symmetric measurable functions $W\colon [0, 1]^2 \to \mathbb{R}$, called *kernels*. Let $\mathcal{W}_0 \subseteq \mathcal{W}$ denote all such W that satisfy $0 \le W \le 1$; such a W is called a *graphon*. Every kernel $W \in \mathcal{W}$ defines a self-adjoint operator $T_W\colon L_2[0, 1] \to L_2[0, 1]$ by setting $(T_W f)(x) = \int_{[0,1]} W(x, y)f(y)\,dy$ for every $x \in [0, 1]$, which then is a Hilbert-Schmidt operator, and in particular, compact [20].

A kernel $W \in \mathcal{W}$ is called a *step function* if there is a partition $S_1 \cup \dots \cup S_k$ of $[0, 1]$ such that W is constant on $S_i \times S_j$ for all $i, j \in [k]$. For a weighted graph H on $[n]$, one can define a step function $W_H \in \mathcal{W}$ by splitting $[0, 1]$ into n intervals $I_1, \dots, I_n$, where I_i has length $\lambda(I_i) = \alpha_i(H)/\alpha(H)$ for every $i \in [n]$, and letting $W_H(x, y) \coloneqq \beta_{ij}(H)$ for all $x \in I_i, y \in I_j$ and $i, j \in [n]$. Of course, W_H depends on the labeling of the vertices of H. Note that W_H is a graphon, and in particular, W_G is a graphon for every graph G.

2.3 The Cut Distance

See [20] for a thorough introduction to the cut distance. The usual definition of the cut distance involves the *blow-up* $G(k)$ of a graph G by $k \geq 0$, where every vertex of G is replaced by k identical copies, to get graphs on the same number of vertices. Going this route is rather cumbersome, and we directly define the cut distance for weighted graphs via *fractional overlays*; this definition also applies to graphs in the straightforward way. A *fractional overlay* of weighted graphs G and H is a matrix $X \in \mathbb{R}^{V(G)\times V(H)}$ such that $X_{uv} \geq 0$ for all $u \in V(G)$, $v \in V(H)$, $\sum_{v\in V(H)} X_{uv} = \alpha_u(G)/\alpha_G$ for every $u \in V(G)$, and $\sum_{u\in V(G)} X_{uv} = \alpha_v(H)/\alpha_H$ for every $v \in V(H)$. Let $\mathcal{X}(G,H)$ denote the set of all fractional overlays of G and H. Note that, for graphs G and H, the second and third condition just say that the row and column sums of X are $1/\mathsf{v}(G)$ and $1/\mathsf{v}(H)$, respectively. For weighted graphs G and H and a fractional overlay $X \in \mathcal{X}(G,H)$, let

$$d_\square(G,H,X) \coloneqq \max_{Q,R\subseteq V(G)\times V(H)} \Big| \sum_{\substack{iu\in Q,\\ jv\in R}} X_{iu}X_{jv}(\beta_{ij}(G) - \beta_{uv}(H))\Big|.$$

Then, define the *cut distance* $\delta_\square(G,H) \coloneqq \min_{X\in\mathcal{X}(G,H)} d_\square(G,H,X)$.

Defining the cut distance of graphons is actually much simpler. Define the *cut norm* on the linear space $\mathcal{W}$ of kernels by $\|W\|_\square \coloneqq \sup_{S,T\subseteq[0,1]} \left|\int_{S\times T} W(x,y)\,dx\,dy\right|$ for $W \in \mathcal{W}$; here, as in the whole of the paper, we tacitly assume sets (and functions) we take an infimum or supremum over to be measurable. Let $S_{[0,1]}$ denote the group of all invertible measure-preserving maps $\varphi\colon [0,1] \to [0,1]$. For a kernel $W \in \mathcal{W}$ and a $\varphi \in S_{[0,1]}$, let W^φ be the kernel defined by $W^\varphi(x,y) \coloneqq W(\varphi(x),\varphi(y))$. For kernels $U, W \in \mathcal{W}$, define their *cut distance* by setting $\delta_\square(U,W) \coloneqq \inf_{\varphi\in S_{[0,1]}} \|U - W^\varphi\|_\square$. This coincides with the previous definition when viewing weighted graphs as graphons [20, Lemma 8.9]. We can also express $\delta_\square(U,W)$ via the kernel operator as $\delta_\square(U,W) = \inf_{\varphi\in S_{[0,1]}} \sup_{f,g\colon [0,1]\to[0,1]} \left|\langle f, T_{U-W^\varphi} g\rangle\right|$ [20, Lemma 8.10]. The definition of the cut distance is quite robust. For example, allowing f and g in the previous definition to be complex-valued or choosing a different operator norm does not make a difference in most cases [16, Appendix E].

For a graph F and a kernel $W \in \mathcal{W}$, define the *homomorphism density*

$$t(F,W) \coloneqq \int_{[0,1]^{V(F)}} \prod_{ij\in E(F)} W(x_i,x_j) \prod_{i\in V(F)} dx_i,$$

which coincides with the previous definition when viewing weighted graphs as graphons [20, Equation (7.2)]. Lemma 2 and Lemma 3 state the connection between the cut distance and homomorphism densities: Informally, the Lemma 2 states that graphons that are close in the cut distance have similar homomorphism densities, while Lemma 3 states that graphs that have similar homomorphism densities are close in the cut distance. We refer to such statements as a *counting lemma* and an *inverse counting lemma*, respectively.

▶ **Lemma 2** (Counting Lemma [21]). *Let F be a simple graph, and let $U, W \in \mathcal{W}_0$ be graphons. Then, $|t(F,U) - t(F,W)| \leq \mathsf{e}(F)\cdot\delta_\square(U,W)$.*

▶ **Lemma 3** (Inverse Counting Lemma [3, 20]). *Let $k > 0$, let $U, W \in \mathcal{W}_0$ be graphons, and assume that, for every graph F on k vertices, we have $|t(F,U) - t(F,W)| \leq 2^{-k^2}$. Then, $\delta_\square(U,W) \leq 50/\sqrt{\log k}$.*

In particular, graphons U and W have cut distance zero if and only if, for every graph F, we have $t(F,U) = t(F,W)$. Call a sequence $(W_n)_{n\in\mathbb{N}}$ of graphons *convergent* if, for every

graph F, the sequence $(t(F, W_n))_{n\in\mathbb{N}}$ is Cauchy. The two theorems above yield that $(W_n)_{n\in\mathbb{N}}$ is convergent if and only if $(W_n)_{n\in\mathbb{N}}$ is Cauchy in $\delta_\square$. Let $\widetilde{\mathcal{W}_0}$ be obtained from $\mathcal{W}_0$ by identifying graphons with cut distance zero; such graphons are called *weakly isomorphic*. One of the main results from graph limit theory is the compactness of the space $(\widetilde{\mathcal{W}_0}, \delta_\square)$.

▶ **Theorem 4** ([19]). *The space $(\widetilde{\mathcal{W}_0}, \delta_\square)$ is compact.*

3 Similarity Measures of Graphs

In this section, we define the tree and path distances of graphs and formally state the correspondences to tree and path homomorphism densities, respectively. All presented results are specializations of the results for graphons proven in Section 5 and Section 6.

3.1 The Tree Distance of Graphs

Recall that two graphs G and H have the same tree homomorphism counts if and only if the system $\mathsf{F}_{\text{iso}}(G, H)$ of linear equations has a non-negative solution. Based on this, Grohe proposed $\text{dist}_{\|\cdot\|}$ as a similarity measure of graphs. This is nearly what we define as the tree distance of graphs. What is missing is, first, a more general definition for graphs with different numbers of vertices and, second, an appropriate choice of a matrix norm with an appropriate normalization factor; analogously to the cut distance, we normalize the tree distance to values in $[0, 1]$. As in the definition of the cut distance in the preliminaries, we handle graphs on different numbers of vertices by considering fractional overlays instead of blow-ups (and doubly stochastic matrices). Recall that a fractional overlay of graphs G and H is a matrix $X \in \mathbb{R}^{V(G)\times V(H)}$ such that $X_{uv} \geq 0$ for all $u \in V(G)$, $v \in V(H)$, $\sum_{v\in V(H)} X_{uv} = 1/\mathsf{v}(G)$ for every $u \in V(G)$, and $\sum_{u\in V(G)} X_{uv} = 1/\mathsf{v}(H)$ for every $v \in V(H)$. If $\mathsf{v}(G) = \mathsf{v}(H)$, then the difference between a fractional overlay and a doubly stochastic matrix is just a factor of $\mathsf{v}(G)$. Also recall that $\mathcal{X}(G, H)$ denotes the set of all fractional overlays of G and H.

We consider two matrix norms for the tree distance: First, just like in the definition of the cut distance, we use the *cut norm* for matrices, introduced by Frieze and Kannan [12], defined as $\|A\|_\square \coloneqq \max_{S\subseteq[m],T\subseteq[n]} |\sum_{i\in S, j\in T} A_{ij}|$ for $A \in \mathbb{R}^{m\times n}$. Second, we also consider the more standard spectral norm $\|A\|_2 \coloneqq \sup_{x\in\mathbb{R}^n, \|x\|_2\leq 1} \|Ax\|_2$ of a matrix $A \in \mathbb{R}^{m\times n}$. From a computational point of view, the Frobenius norm might also be appealing, but this would lead to a different topology, cf. [16, Appendix E].

▶ **Definition 5** (Tree Distance of Graphs). *Let G and H be graphs with adjacency matrices $A \in \mathbb{R}^{V(G)\times V(G)}$ and $B \in \mathbb{R}^{V(H)\times V(H)}$, respectively. Then, define*

$$\delta_\square^{\mathcal{T}}(G, H) \coloneqq \inf_{X\in\mathcal{X}(G,H)} \frac{1}{\mathsf{v}(G)\cdot\mathsf{v}(H)} \|\mathsf{v}(H)\cdot AX - \mathsf{v}(G)\cdot XB\|_\square \text{ and}$$

$$\delta_2^{\mathcal{T}}(G, H) \coloneqq \inf_{X\in\mathcal{X}(G,H)} \frac{1}{\sqrt{\mathsf{v}(G)\mathsf{v}(H)}} \|\mathsf{v}(H)\cdot AX - \mathsf{v}(G)\cdot XB\|_2.$$

Note that the spectral norm requires an adapted normalization factor in Definition 5. The advantage of $\delta_\square^{\mathcal{T}}$ is the close connection to the cut distance, which also utilizes the cut norm. However, the crucial advantage of the spectral norm is that minimization of the spectral norm of a matrix is a standard application of interior-point methods in convex optimization. In particular, an ε-solution to $\delta_2^{\mathcal{T}}$ can be computed in polynomial time [24, Section 6.3.3]. For $\delta_\square^{\mathcal{T}}$, it is not clear whether this is possible.

From the results of Section 5, we get that $\delta_\square^{\mathcal{T}}$ and $\delta_2^{\mathcal{T}}$ are pseudometrics (Lemma 16) and that two graphs have distance zero if and only if their tree homomorphism densities are the

same (Lemma 18). Moreover, we have $\delta_{\square}^{\mathcal{T}} \leq \delta_{\square}$ (Lemma 19), and these pseudometrics are invariant under blow-ups. Finally, we get the following counting lemma (Corollary 20) and inverse counting lemma (Corollary 21).

▶ **Theorem 6** (Counting Lemma for $\delta^{\mathcal{T}}$, Graphs). *Let $\delta^{\mathcal{T}} \in \{\delta_{\square}^{\mathcal{T}}, \delta_2^{\mathcal{T}}\}$. For every tree T and every $\varepsilon > 0$, there is an $\eta > 0$ such that, for all graphs G and H, if $\delta^{\mathcal{T}}(G,H) \leq \eta$, then $|t(T,G) - t(T,H)| \leq \varepsilon$.*

▶ **Theorem 7** (Inverse Counting Lemma for $\delta^{\mathcal{T}}$, Graphs). *Let $\delta^{\mathcal{T}} \in \{\delta_{\square}^{\mathcal{T}}, \delta_2^{\mathcal{T}}\}$. For every $\varepsilon > 0$, there are $k > 0$ and $\eta > 0$ such that, for all graphs G and H, if $|t(T,G) - t(T,H)| \leq \eta$ for every tree T on at most k vertices, then $\delta^{\mathcal{T}}(G,H) \leq \varepsilon$.*

3.2 The Path Distance of Graphs

Dell, Grohe, and Rattan proved that two graphs G and H have the same path homomorphism counts if and only if the system $\mathsf{F}_{\text{iso}}(G,H)$ of linear equations has a real solution [7]. This transfers to the definition of the path distance, i.e., we define the path distance analogously to the tree distance but relax the non-negativity condition of fractional overlays. For graphs G and H, we call a matrix $X \in \mathbb{R}^{V(G)\times V(H)}$ a *signed fractional overlay* of G and H if $\|Xy\|_2 \leq \|y\|_2/\sqrt{\mathsf{v}(G)\mathsf{v}(H)}$ for every $y \in \mathbb{R}^{V(H)}$, $\sum_{v\in V(H)} X_{uv} = 1/\mathsf{v}(G)$ for every $u \in V(G)$, and $\sum_{u\in V(G)} X_{uv} = 1/\mathsf{v}(H)$ for every $v \in V(H)$. Let $\mathcal{S}(G,H)$ denote the set of all signed fractional overlays of G and H. The first condition requires that X is a contraction (up to a scaling factor) in the spectral norm; we need this to guarantee that our definition of the path distance actually yields a pseudometric. This restriction to the spectral norm stems from the fact that the proof of Dell, Grohe, and Rattan [7] (and our generalization thereof to graphons) only guarantees that the constructed solution is a contraction in the spectral norm, cf. Section 6 for the details.

▶ **Definition 8** (Path Distance of Graphs). *Let G and H be graphs with adjacency matrices $A \in \mathbb{R}^{V(G)\times V(G)}$ and $B \in \mathbb{R}^{V(H)\times V(H)}$, respectively. Then, define*

$$\delta_2^{\mathcal{P}}(G,H) \coloneqq \inf_{X\in\mathcal{S}(G,H)} \frac{1}{\sqrt{\mathsf{v}(G)\mathsf{v}(H)}} \|\mathsf{v}(H)\cdot AX - \mathsf{v}(G)\cdot XB\|_2.$$

From Section 6, we get that $\delta_2^{\mathcal{P}}$ is a pseudometric (Lemma 25) that is invariant under blow-ups and that has as graphs of distance zero precisely these with the same path homomorphism densities. Moreover, we get the following (quantitative) counting lemma (Corollary 27) and inverse counting lemma (Corollary 30).

▶ **Theorem 9** (Counting Lemma for $\delta_2^{\mathcal{P}}$, Graphs). *Let P be a path, and let G and H be graphs. Then, $|t(P,G) - t(P,H)| \leq \mathsf{e}(P)\cdot\delta_2^{\mathcal{P}}(G,H)$.*

▶ **Theorem 10** (Inverse Counting Lemma for $\delta_2^{\mathcal{P}}$, Graphs). *For every $\varepsilon > 0$, there are $k > 0$ and $\eta > 0$ such that, for all graphs G and H, if $|t(P,G) - t(P,H)| \leq \eta$ for every path P on at most k vertices, then $\delta_2^{\mathcal{P}}(G,H) \leq \varepsilon$.*

4 Graphon Pseudometrics and Homomorphism Densities

In this section, we provide the main tools we need to prove the correspondences between the tree and path distances and tree and path homomorphism densities, respectively. Consider a pseudometric δ on graphons. We say that δ *is compatible with* $\delta_{\square}$ if, for every sequence of graphons $(U_n)_n$, $U_n \in \mathcal{W}_0$, and every graphon $\widetilde{U} \in \mathcal{W}_0$, $\delta_{\square}(U_n,\widetilde{U}) \xrightarrow{n\to\infty} 0$ implies

$\delta(U_n, \widetilde{U}) \xrightarrow{n\to\infty} 0$. For example, this is the case if $\delta \leq \delta_\square$, i.e., graphons only get closer if we consider δ instead of $\delta_\square$. We anticipate that the pseudometrics we are interested in, the tree distance and the path distance, are compatible with $\delta_\square$.

Together, the next two theorems state that every pseudometric that is compatible with $\delta_\square$ and whose graphons of distance zero can be characterized by homomorphism densities from a class of graphs $\mathcal{F}$ already has to satisfy both a counting lemma and an inverse counting lemma for this class $\mathcal{F}$. The proof of these theorems is a simple compactness argument, utilizing the compactness of the graphon space, Theorem 4, and the counting lemma for $\delta_\square$, Lemma 2. Therefore, it is absolutely crucial that we consider a pseudometric defined on graphons as the limit of a sequence of graphs may not be a graph.

▶ **Theorem 11** (Counting Lemma for $\mathcal{F}$)**.** *Let $\mathcal{F}$ be a class of graphs, and let $\delta^{\mathcal{F}}$ be a pseudometric on graphons such that (1) $\delta^{\mathcal{F}}$ is compatible with $\delta_\square$ and (2), for all graphons $U, W \in \mathcal{W}_0$, $\delta^{\mathcal{F}}(U, W) = 0$ implies $t(F, U) = t(F, W)$ for every graph $F \in \mathcal{F}$. Then, for every graph $F \in \mathcal{F}$ and every $\varepsilon > 0$, there is an $\eta > 0$ such that, for all graphons $U, W \in \mathcal{W}_0$, if $\delta^{\mathcal{F}}(U, W) \leq \eta$, then $|t(F, U) - t(F, W)| \leq \varepsilon$.*

Proof of Theorem 11. We proceed by contradiction and assume that the statement does not hold. Then, there is a graph $F \in \mathcal{F}$ and an $\varepsilon > 0$ such that, for every $\eta > 0$, there are graphons $U, W \in \mathcal{W}_0$ such that $\delta^{\mathcal{F}}(U, W) \leq \eta$ and $|t(F, U) - t(F, W)| > \varepsilon$.

Let $k > 0$. Then, by choosing $\eta = \frac{1}{k}$, we get that there are graphons $U_k, W_k \in \mathcal{W}_0$ such that $\delta^{\mathcal{F}}(U_k, W_k) \leq \frac{1}{k}$ and $|t(F, U_k) - t(F, W_k)| > \varepsilon$. By the compactness theorem, Theorem 4, we get that the sequence $(U_k)_k$ has a convergent subsequence $(U_{k_i})_i$ converging to a graphon $\widetilde{U}$ in the metric $\delta_\square$. By another application of that theorem, we get that $(W_{k_i})_i$ has a convergent subsequence $(W_{\ell_i})_i$ converging to a graphon $\widetilde{W}$ in the metric $\delta_\square$. Then, $(U_{\ell_i})_i$ and $(W_{\ell_i})_i$ are sequences converging to $\widetilde{U}$ and $\widetilde{W}$ in the metric $\delta_\square$, respectively.

Now, for every $i > 0$, we have

$$\delta^{\mathcal{F}}(\widetilde{U}, \widetilde{W}) \leq \delta^{\mathcal{F}}(\widetilde{U}, U_{\ell_i}) + \delta^{\mathcal{F}}(U_{\ell_i}, W_{\ell_i}) + \delta^{\mathcal{F}}(W_{\ell_i}, \widetilde{W}).$$

By assumption, we have $\delta^{\mathcal{F}}(U_{\ell_i}, W_{\ell_i}) \leq \frac{1}{\ell_i}$, which means that $\delta^{\mathcal{F}}(U_{\ell_i}, W_{\ell_i}) \xrightarrow{i\to\infty} 0$. Since $\delta_\square(U_{\ell_i}, \widetilde{U}) \xrightarrow{i\to\infty} 0$ and $\delta_\square(W_{\ell_i}, \widetilde{W}) \xrightarrow{i\to\infty} 0$, the first assumption about $\delta^{\mathcal{F}}$ yields that we also have $\delta^{\mathcal{F}}(U_{\ell_i}, \widetilde{U}) \xrightarrow{i\to\infty} 0$ and $\delta^{\mathcal{F}}(W_{\ell_i}, \widetilde{W}) \xrightarrow{i\to\infty} 0$. Hence, we must have $\delta^{\mathcal{F}}(\widetilde{U}, \widetilde{W}) = 0$.

Since $\delta^{\mathcal{F}}(\widetilde{U}, \widetilde{W}) = 0$, we have $t(F, \widetilde{U}) = t(F, \widetilde{W})$ by the second assumption about $\delta^{\mathcal{F}}$. By the Counting Lemma, Lemma 2, we get that $|t(F, U_{\ell_i}) - t(F, \widetilde{U})| \xrightarrow{i\to\infty} 0$ and $|t(F, \widetilde{W}) - t(F, W_{\ell_i})| \xrightarrow{i\to\infty} 0$. Now, for every $i > 0$, we have

$$|t(F, U_{\ell_i}) - t(F, W_{\ell_i})| \leq |t(F, U_{\ell_i}) - t(F, \widetilde{U})| + |t(F, \widetilde{U}) - t(F, \widetilde{W})| + |t(F, \widetilde{W}) - t(F, W_{\ell_i})|$$

Hence, $|t(F, U_{\ell_i}) - t(F, W_{\ell_i})| \xrightarrow{i\to\infty} 0$. This contradicts the fact that $|t(F, U_{\ell_i}) - t(F, W_{\ell_i})| > \varepsilon$ for every i. ◀

Just as the proof of Theorem 11, the proof of Theorem 12 only relies on the compactness of the graphon space and the counting lemma for $\delta_\square$, and not on a counting lemma for a specific class of graphs or the inverse counting lemma for $\delta_\square$.

▶ **Theorem 12** (Inverse Counting Lemma for $\mathcal{F}$)**.** *Let $\mathcal{F}$ be a class of graphs, and let $\delta^{\mathcal{F}}$ be a pseudometric on graphons such that (1) $\delta^{\mathcal{F}}$ is compatible with $\delta_\square$ and (2), for all graphons $U, W \in \mathcal{W}_0$, $t(F, U) = t(F, W)$ for every graph $F \in \mathcal{F}$ implies $\delta^{\mathcal{F}}(U, W) = 0$. Then, for every $\varepsilon > 0$, there are $k > 0$ and $\eta > 0$ such that, for all graphons $U, W \in \mathcal{W}_0$, if $|t(F, U) - t(F, W)| \leq \eta$ for every graph $F \in \mathcal{F}$ on at most k vertices, then $\delta^{\mathcal{F}}(U, W) \leq \varepsilon$.*

Proof. We proceed by contradiction and assume that the statement does not hold. Then, there is an $\varepsilon > 0$ such that, for every $k > 0$ and every $\eta > 0$, there are graphons $U, W \in \mathcal{W}_0$ such that $|t(F,U) - t(F,W)| \leq \eta$ for every graph $F \in \mathcal{F}$ on at most k vertices but $\delta^{\mathcal{F}}(U,W) > \varepsilon$.

Let $k > 0$. Then, by choosing $\eta = \frac{1}{k}$, we get that there are graphons $U_k, W_k \in \mathcal{W}_0$ such that $|t(F,U_k) - t(F,W_k)| \leq \frac{1}{k}$ for every graph $F \in \mathcal{F}$ on at most k vertices and $\delta^{\mathcal{F}}(U_k,W_k) > \varepsilon$. By the compactness theorem, Theorem 4, we get that the sequence $(U_k)_k$ has a convergent subsequence $(U_{k_i})_i$ converging to a graphon $\widetilde{U}$ in the metric $\delta_\square$. By another application of that theorem, we get that $(W_{k_i})_i$ has a convergent subsequence $(W_{\ell_i})_i$ converging to a graphon $\widetilde{W}$ in the metric $\delta_\square$. Then, $(U_{\ell_i})_i$ and $(W_{\ell_i})_i$ are sequences converging to $\widetilde{U}$ and $\widetilde{W}$ in the metric $\delta_\square$, respectively.

Let $F \in \mathcal{F}$ be a graph. Now, for every $i > 0$, we have

$$|t(F,\widetilde{U}) - t(F,\widetilde{W})| \leq |t(F,\widetilde{U}) - t(F,U_{\ell_i})| + |t(F,U_{\ell_i}) - t(F,W_{\ell_i})| + |t(F,W_{\ell_i}) - t(F,\widetilde{W})|$$

By the counting lemma for $\delta_\square$, Lemma 2, we get that $|t(F,\widetilde{U}) - t(F,U_{\ell_i})| \xrightarrow{i\to\infty} 0$ and $|t(F,W_{\ell_i}) - t(F,\widetilde{W})| \xrightarrow{i\to\infty} 0$. Moreover, by assumption, we have $|t(F,U_{\ell_i}) - t(F,W_{\ell_i})| \leq \frac{1}{\ell_i}$ for large enough i, which means that also $|t(F,U_{\ell_i}) - t(F,W_{\ell_i})| \xrightarrow{i\to\infty} 0$. Hence, we must have $t(F,\widetilde{U}) = t(F,\widetilde{W})$.

As we have $t(F,\widetilde{U}) = t(F,\widetilde{W})$ for every graph $F \in \mathcal{F}$, the second assumption about $\delta^{\mathcal{F}}$ yields that $\delta^{\mathcal{F}}(\widetilde{U},\widetilde{W}) = 0$. Since $\delta_\square(U_{\ell_i},\widetilde{U}) \xrightarrow{i\to\infty} 0$ and $\delta_\square(W_{\ell_i},\widetilde{W}) \xrightarrow{i\to\infty} 0$, we also have $\delta^{\mathcal{F}}(U_{\ell_i},\widetilde{U}) \xrightarrow{i\to\infty} 0$ and $\delta^{\mathcal{F}}(W_{\ell_i},\widetilde{W}) \xrightarrow{i\to\infty} 0$ by the first assumption about $\delta^{\mathcal{F}}$. Now, for every $i > 0$, we have

$$\delta^{\mathcal{F}}(U_{\ell_i},W_{\ell_i}) \leq \delta^{\mathcal{F}}(U_{\ell_i},\widetilde{U}) + \delta^{\mathcal{F}}(\widetilde{U},\widetilde{W}) + \delta^{\mathcal{F}}(\widetilde{W},W_{\ell_i}).$$

Hence, $\delta^{\mathcal{F}}(U_{\ell_i},W_{\ell_i}) \xrightarrow{i\to\infty} 0$. This contradicts the fact that $\delta^{\mathcal{F}}(U_{\ell_i},W_{\ell_i}) > \varepsilon$ for every i. ◀

5 Homomorphisms from Trees

In this section, we define the tree distance of graphons. To use the results from Section 4, we prove that the graphons of distance zero are precisely those with the same tree homomorphism densities (Lemma 18) and that the tree distance is compatible with the cut distance (Lemma 19). As for graphs, we define two variants of the tree distance, which yield the same topology (Lemma 17): one using the analogue of the cut norm and one using the analogue of the spectral norm.

5.1 Fractional Isomorphism of Graphons

Recall that two graphs G and H with adjacency matrices $A \in \mathbb{R}^{V(G)\times V(G)}$ and $B \in \mathbb{R}^{V(H)\times V(H)}$, respectively, are called fractionally isomorphic if there is a doubly stochastic matrix $X \in \mathbb{R}^{V(G)\times V(H)}$ such that $AX = XB$. Grebík and Rocha proved Theorem 13, which generalizes this to graphons [13]; doubly stochastic matrices become *Markov operators* [11]. An operator $S\colon L_2[0,1] \to L_2[0,1]$ is called a Markov operator if $S \geq 0$, i.e., $f \geq 0$ implies $S(f) \geq 0$, $S(\mathbf{1}) = \mathbf{1}$, and $S^*(\mathbf{1}) = \mathbf{1}$, where $\mathbf{1}$ is the all-one function on $[0,1]$. We denote the set of all Markov operators $S\colon L_2[0,1] \to L_2[0,1]$ by $\mathcal{M}$.

▶ **Theorem 13** ([13], Part of Theorem 1.2). *Let $U, W \in \mathcal{W}_0$ be graphons. There is a Markov operator $S\colon L_2[0,1] \to L_2[0,1]$ such that $T_U \circ S = S \circ T_W$ if and only if $t(T,U) = t(T,W)$ for every tree T.*

5.2 The Tree Distance

Recall that, for graphons $U, W \in \mathcal{W}_0$, the cut distance of U and W can be written as $\delta_\square(U,W) = \inf_{\varphi \in S_{[0,1]}} \sup_{f,g\colon [0,1]\to[0,1]} \left|\langle f, T_{U-W^\varphi} g\rangle\right|$. We obtain the tree distance of U and W by relaxing measure-preserving maps to Markov operators.

▶ **Definition 14** (Tree Distance). *Let $U, W \in \mathcal{W}_0$ be graphons. Then, define*

$$\delta^{\mathcal{T}}_\square(U,W) \coloneqq \inf_{S\in\mathcal{M}} \sup_{f,g\colon [0,1]\to[0,1]} |\langle f, (T_U \circ S - S \circ T_W) g\rangle| \text{ and}$$
$$\delta^{\mathcal{T}}_{2\to 2}(U,W) \coloneqq \inf_{S\in\mathcal{M}} \|T_U \circ S - S \circ T_W\|_{2\to 2}.$$

As the notation $\delta^{\mathcal{T}}_\square$ indicates, the definition of $\delta^{\mathcal{T}}_\square$ is based (although not explicitly) on the cut norm, while $\delta^{\mathcal{T}}_{2\to 2}$ is defined via the operator norm $\|\cdot\|_{2\to 2}$, which corresponds to the spectral norm for matrices. One can verify that these definitions specialize to the ones for graphs from Section 3.1.

▶ **Lemma 15.** *Let G and H be graphs. Then, $\delta^{\mathcal{T}}_\square(G,H) = \delta^{\mathcal{T}}_\square(W_G, W_H)$ and $\delta^{\mathcal{T}}_2(G,H) = \delta^{\mathcal{T}}_{2\to 2}(W_G, W_H)$.*

We verify that the tree distance actually is a pseudometric. To prove the triangle inequality for $\delta^{\mathcal{T}}_\square$ and $\delta^{\mathcal{T}}_{2\to 2}$, we use that a Markov operator is a contraction on $L_\infty[0,1]$ and $L_2[0,1]$, respectively [11, Theorem 13.2 b)].

▶ **Lemma 16.** *$\delta^{\mathcal{T}}_\square$ and $\delta^{\mathcal{T}}_{2\to 2}$ are pseudometrics on $\mathcal{W}_0$.*

The Riesz-Thorin Interpolation Theorem (see, e.g., [1, Theorem 1.1.1]) allows to prove that both variants of the tree distance define the same topology.

▶ **Lemma 17.** *Let $U, W \in \mathcal{W}_0$ be graphons. Then, $\delta^{\mathcal{T}}_\square(U,W) \le \delta^{\mathcal{T}}_{2\to 2}(U,W) \le 4\delta^{\mathcal{T}}_\square(U,W)^{1/2}$.*

To be able to apply the results from Section 4, we need that the tree distance of two graphons is zero if and only if their tree homomorphism densities are the same. Let $U, W \in \mathcal{W}_0$ be graphons. From the respective definitions, it is not immediately clear that $\delta^{\mathcal{T}}_\square(U,W) = 0$ or $\delta^{\mathcal{T}}_{2\to 2}(U,W) = 0$ implies $t(T,U) = t(T,W)$ for every tree T since the infimum over all Markov operators might not be attained. Here, we can use a continuity argument as the set of Markov operators is compact in the weak operator topology [11, Theorem 13.8]. However, we have to take a detour via a third variant of the tree distance where compactness in the weak operator topology suffices. All the details can be found in the full version of the paper.

▶ **Lemma 18.** *Let $U, W \in \mathcal{W}_0$ be graphons. Then, $\delta^{\mathcal{T}}_\square(U,W) = 0$ if and only if $t(T,U) = t(T,W)$ for every tree T.*

The *Koopman operator* $T_\varphi\colon f \mapsto f \circ \varphi$ of a measure-preserving map $\varphi\colon [0,1] \to [0,1]$ is a Markov operator [11, Example 13.1, 3)]. Hence, the tree distance can be seen as the relaxation of the cut distance obtained by relaxing measure-preserving maps to Markov operators. In particular, this means that the tree distance is compatible with the cut distance.

▶ **Lemma 19.** *Let $U, W \in \mathcal{W}_0$ be graphons. Then, $\delta^{\mathcal{T}}_\square(U,W) \le \delta_\square(U,W)$.*

With Lemma 18 and Lemma 19 we can apply the theorems of Section 4 and get both a counting lemma and an inverse counting lemma for the tree distance.

▶ **Corollary 20** (Counting Lemma for $\delta^{\mathcal{T}}$). *Let $\delta^{\mathcal{T}} \in \{\delta^{\mathcal{T}}_\square, \delta^{\mathcal{T}}_{2\to 2}\}$. For every tree T and every $\varepsilon > 0$, there is an $\eta > 0$ such that, for all graphons $U, W \in \mathcal{W}_0$, if $\delta^{\mathcal{T}}(U,W) \le \eta$, then $|t(T,U) - t(T,W)| \le \varepsilon$.*

▶ **Corollary 21** (Inverse Counting Lemma for $\delta^{\mathcal{T}}$). *Let $\delta^{\mathcal{T}} \in \{\delta^{\mathcal{T}}_{\square}, \delta^{\mathcal{T}}_{2\to 2}\}$. For every $\varepsilon > 0$, there are $k > 0$ and $\eta > 0$ such that, for all graphons $U, W \in \mathcal{W}_0$, if $|t(T,U) - t(T,W)| \leq \eta$ for every tree T on k vertices, then $\delta^{\mathcal{T}}(U,W) \leq \varepsilon$.*

6 Homomorphisms from Paths

In this section, we define the path distance of graphons. We prove a quantitative counting lemma for it (Corollary 27) and only rely on the results from Section 4 to obtain an inverse counting lemma. To this end, we we prove that the graphons of distance zero are precisely those with the same path homomorphism densities (Lemma 28) and that the path distance is compatible with the cut distance (Lemma 29). Since there is no existing characterization of graphons with the same path homomorphism densities that we can rely on, we first generalize the result of Dell, Grohe, and Rattan to graphons (Theorem 22).

6.1 Path Densities and Graphons

Dell, Grohe, and Rattan have shown the surprising fact that G and H have the same path homomorphism counts if and only if the system $\mathsf{F}_{\text{iso}}(G,H)$ has a real solution [7]. We need a generalization of their characterization to graphons in order to define the path distance of graphons and apply the results from Section 4. If two graphons $U, W \in \mathcal{W}_0$ have the same path homomorphism densities, the proof of Theorem 22 yields an operator $S\colon L_2[0,1] \to L_2[0,1]$ such that $S(\mathbf{1}) = \mathbf{1}$ and $S^*(\mathbf{1}) = \mathbf{1}$, which generalizes the result of [7] in a straight-forward fashion. An important detail is that the proof also yields that S is an L_2-contraction; this guarantees that the path distance satisfies the triangle inequality, i.e., that it is a pseudometric in the first place. For the sake of brevity, we call an operator $S\colon L_2[0,1] \to L_2[0,1]$ a *signed Markov operator* if S is an L_2-contraction, i.e., $\|Sf\|_2 \leq \|f\|_2$ for every $f \in L_2[0,1]$, $S(\mathbf{1}) = \mathbf{1}$, and $S^*(\mathbf{1}) = \mathbf{1}$. Let $\mathcal{S}$ denote the set of all signed Markov operators. It is easy to see that $\mathcal{S}$ is closed under composition and Hilbert adjoints.

▶ **Theorem 22.** *Let $U, W \in \mathcal{W}_0$. There is a signed Markov operator $S\colon L_2[0,1] \to L_2[0,1]$ such that $T_U \circ S = S \circ T_W$ if and only if $t(P,U) = t(P,W)$ for every path P.*

Homomorphism densities from paths can be expressed in terms of operator powers. For $\ell \geq 0$, let P_ℓ denote the path of length ℓ. Then, for a graphon U, we have

$$t(P_\ell, U) = \int_{[0,1]^{\ell+1}} \prod_{i\in[\ell]} U(x_i, x_{i+1}) \prod_{i\in[\ell+1]} dx_i = \langle \mathbf{1}, T_U^\ell \mathbf{1} \rangle$$

for every $\ell \geq 0$. The proof of Theorem 22 utilizes the Spectral Theorem for compact operators on Hilbert spaces to express $\mathbf{1}$ as a sum of orthogonal eigenfunctions. For a kernel $W \in \mathcal{W}$, $T_W\colon L_2[0,1] \to L_2[0,1]$ is a Hilbert-Schmidt operator and, hence, compact [20]. Since $L_2[0,1]$ is separable and T_W is compact and self-adjoint, the Spectral Theorem yields that there is a countably infinite orthonormal basis $\{f'_i\}$ of $L_2[0,1]$ consisting of eigenfunctions of T_W with the corresponding multiset of eigenvalues $\{\lambda_n\} \subseteq \mathbb{R}$ such that $\lambda_n \xrightarrow{n\to\infty} 0$ (see, e.g., [9]). If graphons U and W have the same path homomorphism densities, an interpolation argument yields that the lengths of the eigenvectors in the decomposition of $\mathbf{1}$ and their eigenvalues have to be the same. Then, one can define the operator S from these eigenfunctions of U and W. The detailed proof can be found in the full version of the paper.

6.2 The Path Distance

We define the *path distance* of graphons can analogously to the tree distance. However, as the proof Theorem 22 does not yield that the resulting operator is an L_∞-contraction, we are limited in our choice of norms.

▶ **Definition 23** (Path Distance). *Let $U, W \in \mathcal{W}_0$ be graphons. Then, define*

$$\delta^{\mathcal{P}}_{2\to 2}(U,W) \coloneqq \inf_{S\in\mathcal{S}} \|T_U \circ S - S \circ T_W\|_{2\to 2}.$$

One can verify that this defines a pseudometric that specializes to the one for graphs from Section 3.2.

▶ **Lemma 24.** *Let G and H be graphs. Then, $\delta^{\mathcal{P}}_2(G,H) = \delta^{\mathcal{P}}_{2\to 2}(W_G, W_H)$.*

▶ **Lemma 25.** *$\delta^{\mathcal{P}}_{2\to 2}$ is a pseudometric on $\mathcal{W}_0$.*

To apply the theorems of Section 4, we need that two graphons have distance zero in the path distance if and only if their path homomorphism densities are the same and that $\delta^{\mathcal{P}}_{2\to 2}$ is compatible with $\delta_\square$. For the former, we deviate from the way we proceeded for the tree distance as we actually can prove a quantitative counting lemma.

▶ **Theorem 26** (Counting Lemma for Paths). *Let P be a path, and let $U, W \in \mathcal{W}_0$ be graphons. Then, for every operator $S\colon L_2[0,1] \to L_2[0,1]$ with $S(\mathbf{1}) = \mathbf{1}$ and $S^*(\mathbf{1}) = \mathbf{1}$,*

$$|t(P,U) - t(P,W)| \leq \mathsf{e}(P) \cdot \sup_{f,g\colon [0,1]\to[0,1]} |\langle f, (T_U \circ S - S \circ T_W) g\rangle|.$$

Proof. Let $\ell \in \mathbb{N}$ and $S \in \mathcal{S}$. Then,

$$\begin{aligned}
|t(P_\ell,U) - t(P_\ell,W)| &= |\langle \mathbf{1}, T^\ell_U(S\mathbf{1})\rangle - \langle (S^*\mathbf{1}), T^\ell_W \mathbf{1}\rangle| \\
&= \Big| \sum_{i\in[\ell]} \big(\langle \mathbf{1}, (T^{\ell-i+1}_U \circ S \circ T^{i-1}_W)\mathbf{1}\rangle - \langle \mathbf{1}, (T^{\ell-i}_U \circ S \circ T^{i}_W)\mathbf{1}\rangle \big) \Big| \\
&= \Big| \sum_{i\in[\ell]} \langle T^{\ell-i}_U \mathbf{1}, (T_U \circ S - S \circ T_W)(T^{i-1}_W \mathbf{1})\rangle \Big| \\
&\leq \ell \cdot \sup_{f,g\colon [0,1]\to[0,1]} |\langle f, (T_U \circ S - S \circ T_W) g\rangle|. \qquad \blacktriangleleft
\end{aligned}$$

Theorem 26 suggests that, for graphons $U, W \in \mathcal{W}_0$, one should define

$$\delta^{\mathcal{P}}_\square(U,W) \coloneqq \inf_{S\in\mathcal{S}} \sup_{f,g\colon [0,1]\to[0,1]} |\langle f, (T_U \circ S - S \circ T_W) g\rangle|.$$

Then, we have $|t(P,U) - t(P,W)| \leq \mathsf{e}(P) \cdot \delta^{\mathcal{P}}_\square(U,W)$ for every path P. However, as mentioned before, we cannot verify that $\delta^{\mathcal{P}}_\square$ is a pseudometric as the operator S might not be an L_∞-contraction.

▶ **Corollary 27** (Counting Lemma for $\delta^{\mathcal{P}}_{2\to 2}$). *Let P be a path, and let $U, W \in \mathcal{W}_0$ be graphons. Then, $|t(P,U) - t(P,W)| \leq \mathsf{e}(P) \cdot \delta^{\mathcal{P}}_{2\to 2}(U,W)$.*

Proof. By the Cauchy-Schwarz inequality, we have

$$\begin{aligned}
\sup_{f,g\colon [0,1]\to[0,1]} |\langle f, (T_U \circ S - S \circ T_W) g\rangle| &\leq \sup_{f,g\colon [0,1]\to[0,1]} \|f\|_2 \|(T_U \circ S - S \circ T_W) g\|_2 \\
&\leq \sup_{g\colon [0,1]\to[0,1]} \|T_U \circ S - S \circ T_W\|_{2\to 2} \|g\|_2 \\
&\leq \|T_U \circ S - S \circ T_W\|_{2\to 2}
\end{aligned}$$

for every operator $S\colon L_2[0,1] \to L_2[0,1]$. Hence, the statement follows from Theorem 26. $\blacktriangleleft$

With this explicit counting lemma, we obtain that two graphons have distance zero in the path distance if and only if their path homomorphism densities are the same.

▶ **Lemma 28.** *Let $U, W \in \mathcal{W}_0$ be graphons. Then, $\delta^{\mathcal{P}}_{2\to 2}(U,W) = 0$ if and only if $t(P,U) = t(P,W)$ for every path P.*

Proof. If $\delta^{\mathcal{P}}_{2\to 2}(U,W) = 0$, then Corollary 27 yields that $t(P,U) = t(P,W)$ for every path P. On the other hand, if $t(P,U) = t(P,W)$ for every path P, then there is a signed Markov operator $S \in \mathcal{S}$ with $T_U \circ S = S \circ T_W$ by Theorem 22. Then, $\delta^{\mathcal{P}}_{2\to 2}(U,W) = 0$ follows immediately from the definition. ◀

By definition, the path distance is bounded from above by the tree distance (with the appropriate norm), which means that it also is compatible with the cut distance.

▶ **Lemma 29.** *Let $U, W \in \mathcal{W}_0$ be graphons. Then, $\delta^{\mathcal{P}}_{2\to 2}(U,W) \leq \delta^{\mathcal{T}}_{2\to 2}(U,W)$.*

With these lemmas, we can apply Theorem 12 and obtain the following inverse counting lemma for the path distance.

▶ **Corollary 30** (Inverse Counting Lemma for $\delta^{\mathcal{P}}_{2\to 2}$)**.** *For every $\varepsilon > 0$, there are $k > 0$ and $\eta > 0$ such that, for all graphons $U, W \in \mathcal{W}_0$, if $|t(P,U) - t(P,W)| \leq \eta$ for every path P on at most k vertices, then $\delta^{\mathcal{P}}_{2\to 2}(U,W) \leq \varepsilon$.*

7 The Color Distance

Color Refinement, also known as the *1-dimensional Weisfeiler-Leman algorithm*, is a heuristic graph isomorphism test. It computes a coloring of the vertices of a graph in a sequence of *refinement rounds*; we say that color refinement *distinguishes* two graphs if the computed color patterns differ. Formally, for a graph G, we let $C^G_0(u) = 1$ for every $u \in V(G)$ and $C^G_{i+1}(u) = \{\!\{C^G_i(v) \mid uv \in E(G)\}\!\}$ for every $i \geq 0$. Let $C^G_\infty = C^G_i$ for the smallest i such that $C^G_i(u) = C^G_i(v) \iff C^G_{i+1}(u) = C^G_{i+1}(v)$ for all $u, v \in G$ ("C_i is stable"). Then, color refinement distinguishes two graphs G and H if there is an $i \geq 0$ such that $\{\!\{C^G_i(v) \mid v \in V(G)\}\!\} \neq \{\!\{C^H_i(v) \mid v \in V(H)\}\!\}$. It is well-known that the partition $\{C^{-1}_\infty(i) \mid i \in C_\infty(V(G))\}$ is the *coarsest equitable partition* of $V(G)$, where a partition Π of $V(G)$ is called *equitable* if for all $P, Q \in \Pi$ and $u, v \in P$, the vertices u and v have the same number of neighbors in Q.

For a graph G, we can define a weighted graph G/C^G_∞ by letting $V(G/C^G_\infty) \coloneqq \{C^{-1}_\infty(i) \mid i \in C_\infty(V(G))\}$, $\alpha_C(G/C^G_\infty) \coloneqq |C|$ for $C \in V(G/C^G_\infty)$, and $\beta_{CD}(G/C^G_\infty) \coloneqq M^G_{CD}/|D|$ for all $C, D \in V(G/C^G_\infty)$, where M^G_{CD} is the number of neighbors a vertex from C has in D, which is the same for all vertices in C as the partition induced by the colors of C^G_∞ is equitable. Note that we have $|C|M^G_{CD} = |D|M^G_{DC}$ as both products describe the number of edges between C and D, i.e., G/C^G_∞ is well-defined. Usually, when talking about the invariant $\mathcal{I}^2_C$ computed by color refinement (see, e.g., [17]), one does not normalize M^G_{CD} by $|D|$. However, by doing so, we do not only get a weighted graph (with symmetric edge weights), but the graphs G and G/C^G_∞ actually have the same tree homomorphism counts. Grebík and Rocha already introduced the graphon analogue $U/\mathcal{C}(U)$ of G/C^G_∞ and proved the same fact for it [13, Corollary 4.3]; hence, we omit the proof.

▶ **Lemma 31.** *Let T be a tree, and let G be a graph. Then, $\mathsf{hom}(T,G) = \mathsf{hom}(T, G/C^G_\infty)$.*

By the result of Dvořák [10], G/C^G_∞ and H/C^H_∞ are isomorphic if and only if G and H have the same tree homomorphism counts. Hence, it is tempting to define a tree distance-like similarity measure on graphs by simply considering the cut distance of G/C^G_∞ and H/C^H_∞.

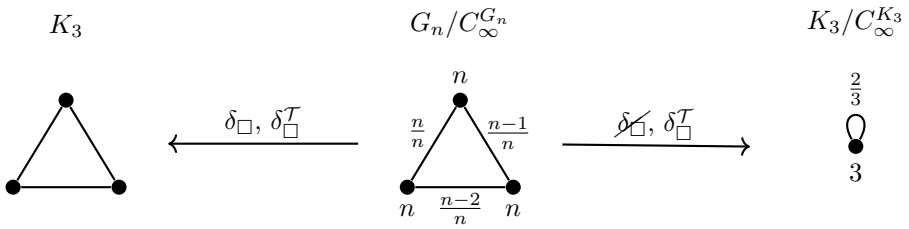

Figure 1 An example separating the color distance from the tree distance.

For graphs G and H, we call $\delta^{\mathcal{C}}_\square(G,H) \coloneqq \delta_\square(G/C^G_\infty, H/C^H_\infty)$ the *color distance* of G and H. As the cut distance $\delta_\square$ is a pseudometric on graphs, so is $\delta^{\mathcal{C}}_\square$. For $\delta^{\mathcal{C}}_\square$, we immediately obtain a quantitative counting lemma from Lemma 2 and Lemma 31.

▶ **Corollary 32** (Counting Lemma for $\delta^{\mathcal{C}}_\square$)**.** *Let T be a tree, and let G and H be graphs. Then, $|t(T,G) - t(T,H)| \leq |E(T)| \cdot \delta^{\mathcal{C}}_\square(G,H)$.*

Clearly, $\delta^{\mathcal{T}}_\square$ and $\delta^{\mathcal{C}}_\square$ have the same graphs of distance zero. Moreover, one can easily verify that the tree distance is bounded from above by the color distance.

▶ **Lemma 33.** *Let G and H be graphs. Then, $\delta^{\mathcal{T}}_\square(G,H) \leq \delta^{\mathcal{C}}_\square(G,H)$.*

Proof. We have $\delta^{\mathcal{T}}_\square(G,H) = \delta^{\mathcal{T}}_\square(G/C^G_\infty, H/C^H_\infty) \leq \delta_\square(G/C^G_\infty, H/C^H_\infty) = \delta^{\mathcal{C}}_\square(G,H)$ by Lemma 31 and Lemma 19. ◀

Now, the obvious question is whether these pseudometrics are the same or, at least, define the same topology. But it is not hard to find a counterexample; the color distance sees differences between graphs that the tree distance and tree homomorphisms do not see. In particular, an inverse counting lemma cannot hold for the color distance. See Figure 1, and for the moment, assume that we can construct a sequence $(G_n)_n$ of graphs such that $G_n/C^{G_n}_\infty$ is as depicted. It is easy to verify that $\delta_\square(G_n/C^{G_n}_\infty, K_3) \xrightarrow{n\to\infty} 0$, and thus, both $\delta^{\mathcal{T}}_\square(G_n,K_3) \xrightarrow{n\to\infty} 0$ and $|t(T,G_n) - t(T,K_3)| \xrightarrow{n\to\infty} 0$ for every tree T. But, $\delta^{\mathcal{C}}_\square(G_n,K_3) \geq \frac{1}{3}\cdot\frac{1}{3}\cdot\frac{2}{3}$ for every n since $G_n/C^{G_n}_\infty$ has a vertex without a loop.

The existence of graphs G_n such that $G_n/C^{G_n}_\infty$ is as depicted in Figure 1 follows easily from inversion results for the color refinement invariant $\mathcal{I}^2_C$. Otto first proved that $\mathcal{I}^2_C$ admits polynomial time inversion on structures [25], and Kiefer, Schweitzer, and Selman gave a simple construction to show that $\mathcal{I}^2_C$ admits linear-time inversion on the class of graphs [17]. Basically, we partition $3n$ vertices into three sets of size n and add edges between these partitions such that they induce n-, $(n-1)$-, and $(n-2)$-regular bipartite graphs.

The example in Figure 1 actually answers an open question of Grebík and Rocha [13, Question 3.1]. They ask whether the set $\{W/\mathcal{C}(W) \mid W \in \widetilde{\mathcal{W}_0}\}$ is closed in $\widetilde{\mathcal{W}_0}$: it is not. With a more refined argument, we can actually show that $\{W_{G/C^G_\infty} \mid G \text{ graph}\}$ is already dense in $\widetilde{\mathcal{W}_0}$. By properly rounding the weights of a given weighted graph, we can turn the inversion result of [17] into a statement about approximate inversion.

▶ **Theorem 34.** *Let H be a weighted graph. For every $n \geq 2\cdot \mathsf{v}(H)$, there is a graph G on n^2 vertices such that $\delta_\square(G/C^G_\infty, H) \leq 3\cdot\mathsf{v}(H)/n + \frac{1}{4}\cdot(\mathsf{v}(H)/n)^2$.*

In Theorem 34, the size of the resulting graph depends on how close we want it to be to the input graph. A simple consequence of the compactness of the graphon space is that, for $\varepsilon > 0$, we can approximate any graphon with an error of ε in $\delta_\square$ by a graph on $N(\varepsilon)$

vertices, where $N(\varepsilon)$ is independent of the graphon [20, Corollary 9.25]. With Theorem 34, this implies that the same is possible with the weighted graphs G/C^G_∞. This also means that the closure of the set $\{W_{G/C^G_\infty} \mid G \text{ graph}\}$ is already $\widetilde{\mathcal{W}_0}$.

8 Conclusions

We have introduced similarity measures for graphs that can be formulated as convex optimization problems and shown surprising correspondences to tree and path homomorphism densities. This takes previous results on the "expressiveness" of homomorphism counts from an exact to an approximate level. Moreover, it helps to give a theoretical understanding of kernel methods in machine learning, which are often based on counting certain substructures in graphs. Proving the correspondences to homomorphism densities was made possible by introducing our similarity measures for the more general case of graphons, where tools from functional analysis let us prove the general statement that every "reasonably defined" pseudometric has to satisfy a correspondence to homomorphism densities.

Various open questions remain. The compactness argument used in Section 4 only yields non-quantitative statements. Hence, we do not know how close the graphs have to be in the pseudometric for their homomorphism densities to be close and vice versa. Only for paths we were able to prove a quantitative counting lemma, which uses the same factor $\mathtt{e}(F)$ as the counting lemma for general graphs. It seems conceivable that a quantitative counting lemma for trees that uses the same factor $\mathtt{e}(T)$ also holds. As the proof of the quantitative inverse counting lemma is quite involved [3, 20], proving such statements for trees and paths should not be easy.

More in reach seems to be the question of how the tree distance generalizes to the class $\mathcal{T}_k$ of graphs of treewidth at most k. Homomorphism counts from graphs in $\mathcal{T}_k$ can also be characterized in terms of linear equations in the case of graphs [10] (see also [7]). How does such a characterization for graphons look like? And how does one define a distance measure from this?

Another open question concerns further characterizations of fractional isomorphism, e.g., the color refinement algorithm, which gives a characterization based on equitable partitions. Can one prove a correspondence between the tree distance and, say, ε-equitable partitions? It is not hard to come up with a definition for such partitions; the hard part is to prove that graphs that are similar in the tree distance possess such a partition.

Abstract

A function $f(x_1, \ldots, x_n)$ from a product domain $\mathcal{D}_1 \times \cdots \times \mathcal{D}_n$ to an abelian group $\mathcal{G}$ is a *direct sum* if it is of the form $f_1(x_1) + \cdots + f_n(x_n)$. We present a new 4-query direct sum test with optimal (up to constant factors) soundness error. This generalizes a result of Dinur and Golubev (RANDOM 2019) which is tailored to the target group $\mathcal{G} = \mathbb{Z}_2$. As a special case, we obtain an optimal *affinity test* for $\mathcal{G}$-valued functions on domain $\{0,1\}^n$ under product measure. Our analysis relies on the hypercontractivity of the binary erasure channel.

We also study the testability of *function partitionability* over product domains into disjoint components. A $\mathcal{G}$-valued $f(x_1, \ldots, x_n)$ is *k-direct sum partitionable* if it can be written as a sum of functions over k nonempty disjoint sets of inputs. A function $f(x_1, \ldots, x_n)$ with unstructured product range $\mathcal{R}^k$ is *direct product partitionable* if its outputs depend on disjoint sets of inputs.

We show that direct sum partitionability and direct product partitionability are one-sided error testable with $O((n-k)(\log n + 1/\epsilon) + 1/\epsilon)$ adaptive queries and $O((n/\epsilon)\log^2(n/\epsilon))$ nonadaptive queries, respectively. Both bounds are tight up to the logarithmic factors for constant ϵ even with respect to adaptive, two-sided error testers. We also give a non-adaptive one-sided error tester for direct sum partitionability with query complexity $O(kn^2(\log n)^2/\epsilon)$.

1 Introduction

In their seminal result, Blum, Luby and Rubinfeld [4] gave a four query test to determine whether a function $f : \mathbb{F}_2^n \to \mathbb{F}_2$ is affine. We consider a natural generalization of the notion of affinity to functions $f(x_1, \cdots, x_n)$ from $\{0,1\}^n$ to an arbitrary abelian group $\mathcal{G}$: Is f of the form $x_1 \cdot g_1 + \cdots + x_n \cdot g_n + g_0$ for some group elements $g_0, \ldots, g_n \in \mathcal{G}$? The analysis of Blum, Luby and Rubinfeld does not apply unless there is a group homomorphism from the domain to the range.

In this work we give an optimal four query affinity test for functions from $\{0,1\}^n$ to an arbitrary abelian group $\mathcal{G}$.

More generally, our test can be used to determine if a function $f(x_1,\ldots,x_n)$ from a finite product domain $\mathcal{D}_1 \times \cdots \times \mathcal{D}_n$ to an abelian group $\mathcal{G}$ is a *direct sum*, i.e., whether f is of the form $\sum f_i(x_i)$. This resolves a conjecture of Dinur and Golubev [9].

In contrast to the work of Blum, Luby, and Rubinfeld, which was primarily motivated by applications to probabilistically checkable proofs, direct sum testing over general groups arises in the context of testing *function partionability*: Can a multivariate function be decomposed into independent or loosely related components? Bogdanov and Wang [6] discuss the relevance of this question for real-valued functions to the problem of identifying decompositions of control variables in high-dimensional reinforcement learning. In that setting a direct sum decomposition of the advantage function f describes a system that can be partitioned into independent components, which are lower-dimensional and therefore typically easier to learn. An efficient testing algorithm can be used to probe the existence of such a decomposition before any effort is expended into learning it.

In this work we consider the following two natural partitioning problems for discrete functions over product domains $\mathcal{D}_1 \times \cdots \times \mathcal{D}_n$ (endowed with a product distribution):

- A *direct sum partition* ($\oplus$-partition) of f into k components is a representation of the form $f(x_1,\ldots,x_n) = f_1(x_{S_1}) + \cdots + f_k(x_{S_k})$, where $S_1,\ldots,S_k$ are disjoint nonempty sets of variables. Here, the range of f is an abelian group $(\mathcal{G},+)$.
- A *direct product partition* ($\otimes$-partition) of f is a representation of the form $f(x_1,\ldots,x_n) = (f_1(x_{S_1}),\ldots,f_k(x_{S_k}))$, where $S_1,\ldots,S_k$ are disjoint nonempty sets of variables. Here, the range of f is a k-product set $\mathcal{R}^k$.

We are interested in the query complexity of testing partitionability: Given oracle access to f and parameters k,ϵ, how many queries does it take to tell whether f is partitionable or ϵ-far from partitionable?

The related tasks of *direct product testing* and *direct sum testing* ask for the existence of such representations under a known (fixed) partition of inputs. Motivated by applications to probabilistically checkable proofs, Dinur and Steurer [10] and Dickstein and Dinur [8] analyze a 2-query direct product test of essentially optimal soundness.

The query complexity of direct sum testing for $\mathbb{Z}_2$-valued functions, that is of testing whether a function $f\colon \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathbb{Z}_2$ is of the form $f(x_1,\ldots,x_n) = f_1(x_1)+\cdots+f_n(x_n)$, was recently resolved by Dinur and Golubev [9]. They proposed and analysed a 4-query test of optimal (up to constant factors) soundness error. Their tester does not naturally extend to functions valued in arbitrary abelian groups.

Bogdanov and Wang [6] proposed an agnostic learning algorithm for unknown direct sum partitions. As a consequence of their analysis they concluded that $\oplus$-partitionability is testable with $O(kn^3/\epsilon)$ non-adaptive queries. They also showed that $\Omega(n-k+1)$ queries are necessary for constant ϵ. To the best of our knowledge $\otimes$-partitionability has not been studied before.

Our Results

We analyze a new 4-query direct sum test for functions valued over arbitrary abelian groups. The test is based on the following dual characterization: $f\colon \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{G}$ is a direct sum $f_1(x_1) + \cdots + f_n(x_n)$ if and only if $D_f(S,\overline{S};x,y) = 0$ for all pairs of inputs x,y and partitions $(S,\overline{S})$ of $[n]$, where

$$D_f(S,\overline{S};x,y) = f(x) - f(y_S x) - f(y_{\overline{S}} x) + f(y).$$

Here and in the rest of the manuscript, $y_S x$ is the string in $\mathcal{D}_1 \times \cdots \times \mathcal{D}_n$ that matches y in the S-coordinates and x in the other coordinates. We assume that the domain $\mathcal{D}_1 \times \cdots \times \mathcal{D}_n$ is furnished with a product distribution: For x chosen at random from $\mathcal{D}_1 \times \cdots, \times \mathcal{D}_n$, the coordinates $x_1, \ldots, x_n$ are independent.

The tester accepts if $D_f(S, \overline{S}; x, y) = 0$ for random independent inputs $x, y \in \mathcal{D}_1 \times \cdots \times \mathcal{D}_n$ and a uniformly random partition $(S, \overline{S})$ of $[n]$. Our main result is an optimal (up to constant factor) bound on the soundness error $\rho(f) = \Pr[D_f(S, \overline{S}; x, y) \neq 0]$ of this test in terms of the distance $\delta(f) = \min_g\{\Pr_x[f(x) \neq g(x)] \colon g \text{ is a direct sum}\}$.

▶ **Theorem 1.** *There is an absolute constant $c > 0$ such that for every collection of finite sets $\mathcal{D}_1, \ldots, \mathcal{D}_n$, every abelian group $\mathcal{G}$, and every $f \colon \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{G}$, $\rho(f) \geq c \cdot \delta(f)$.*

An important special case of the theorem concerns the Boolean domain $\mathcal{D}_1 = \cdots = \mathcal{D}_n = \{0, 1\}$ under the uniform distribution (Proposition 5). The class of direct sums from $\{0, 1\}^n$ to $\mathcal{G}$ is then precisely the class of affine functions $f(x) = x_1 g_1 + \cdots + x_n g_n + g_0$ for some group elements $g_0, g_1, \ldots, g_n \in \mathcal{G}$.

Using Theorem 1, we obtain the following upper bound on the query complexity of $\oplus$-partitionability.

▶ **Theorem 2.** *Direct sum partitionability over any abelian group is one-sided testable with $O((n-k)(\log n + 1/\epsilon) + 1/\epsilon)$-queries.*

We also prove an upper bound on the query complexity of $\otimes$-partitionability:

▶ **Theorem 3.** *Direct product partitionability is one-sided testable with $O((n/\epsilon)\log^2(n/\epsilon))$ non-adaptive queries.*

The testers in Theorem 2 and 3 are time-efficient.

By the lower bound of Bogdanov and Wang [6], the $\oplus$-partitionability tester is tight up to the $\log n$ factor for constant ϵ. In the special case when $k = n$, direct sum partitionability reduces to direct sum testing and the query complexity is the same as that of Theorem 1.

Our tester for $\oplus$-partitionability is adaptive. We also give a one-sided non-adaptive tester of query complexity $O(kn^2(\log n)^2/\epsilon)$. A non-adaptive lower bound of $\Omega((n-k+1)\,(\log(n-k+1)/\epsilon^c)\log(\log(n-k+1)/\epsilon^c))$ for any $c > 1$ follows from the work of Servedio et al. [13] on junta testing. As in the case of juntas, it follows that adaptivity helps in testing $\oplus$-partitionability for some settings of parameters.

The $\otimes$-partitionability tester is also nearly tight: We show that direct product partitionability requires $\Omega(n)$ queries for $\epsilon = 1/2$ for adaptive testers, and $\Omega(\frac{n}{\epsilon \log(1/\epsilon)})$ queries for non-adaptive testers, for every $k \geq 2$.

The non-adaptive test for $\oplus$-partitionability, and the lower bounds for $\oplus$-partitionability and $\otimes$-partitionability are deferred to the full version of this paper [5].

Ideas and Techniques

Direct sum testing over general groups

The main ingredient of Dinur and Golubev's direct sum tester for $\mathbb{Z}_2$-valued functions is an implicit reduction from general product domains to the Boolean domain $\{0, 1\}^n$ under the uniform distribution. We abstract and generalize their reduction. In interest of space we defer the details of this reduction to full version of this paper [5]. To complete their proof, Dinur and Golubev instantiate the reduction with the $\mathbb{Z}_2$-affinity test of Blum, Luby, and Rubinfeld [4].

Table 1 Summary of algorithmic results. All tests have one-sided error.

Property	Our Results	Prior Work
Direct Sum: $f : \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{G}$ s.t. $f(x) = f(x_1) + \cdots + f(x_n)$	4-query test for arbitrary abelian group $\mathcal{G}$ (Theorem 1)	4-query test for $\mathcal{G} = \mathbb{Z}_2$ [9]
k-$\oplus$-partitionability: $f : \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{G}$ s.t. $\exists S_1, \ldots, S_k \subseteq [n]$, $f(x) = f(x_{S_1}) + \cdots + f(x_{S_k})$	$O((n-k)(\log n + 1/\epsilon) + 1/\epsilon)$-query adaptive test (Theorem 2) $O(kn^2(\log n)^2/\epsilon)$-query non-adaptive test (See full version [5])	$O(kn^3/\epsilon)$-query non-adaptive test [6]
k-$\otimes$-partitionability: $f : \mathcal{D}_1 \times \cdots \times \mathcal{D}_n \to \mathcal{R}^k$ s.t. $\exists S_1, \ldots, S_k \subseteq [n]$, $f(x) = (f(x_{S_1}), \ldots, f(x_{S_k}))$	$O((n/\epsilon)\log^2(n/\epsilon))$-query non-adaptive test (Theorem 3)	

Our main technical contribution is a tight analysis of the affinity test D_f applied to functions $f\colon \{0,1\}^n \to \mathcal{G}$ valued in an arbitrary abelian group $\mathcal{G}$. To give a sense why the test is sound, let us argue that $\rho(f) = \Omega(\delta(f))$ under the additional assumption that f is close to a direct sum, say if $\delta = \delta(f) \leq 1/27$.

Let B be the set of measure at most $1/27$ on which f differs from its closest direct sum. We claim that conditioned on $x \in B$, the probability that any of the other test queries y, $y_S x$, $y_{\overline{S}} x$ land in B is at most $\delta + 2\delta^{1/3}$. By independence, the probability that $y \in B$ conditioned on $x \in B$ is exactly δ. In contrast, $y_S x$ and $y_{\overline{S}} x$ are not independent of x, but can be sampled by processing x through a binary symmetric channel with crossover probability $1/4$. The bound $\Pr[y_S x \in B | x \in B] \leq \delta^{1/3}$ follows from the small-set expansion of this channel [1], which is equivalent to the hypercontractivity of the corresponding Markov operator [7]. Since the event "$x \in B$ and $y_S x \notin B$ and $y_{\overline{S}} x \notin B$ and $y \notin B$" results in rejection, it follows that $\rho(f) \geq \delta \cdot (1 - \delta - 2\delta^{1/3})$, which is at least $\frac{8}{27}\delta$ by the closeness assumption on f.

For larger values of $\delta(f)$, our proof strategy is to argue that f can be *decoded* to a direct sum function by making at most $O(\rho(f))$ "changes" to the truth-table of f. The decoding algorithm we analyze in Lemma 6 is *iterative plurality* (i.e., iterative maximum likelihood). We show that the function

$$\phi(x) = \text{plurality}_{S,y}\ f(y_S x) + f(y_{\overline{S}} x) - f(y) \tag{1}$$

is, on the one hand, $2\delta(f)$-close to f, and on the other hand, has substantially smaller rejection probability of $\rho(\phi) \leq \rho(f)/2$. By iterating the decoding, i.e. applying the plurality to ϕ again, we arrive at a function that is $4\delta(f)$ close to f and passes the test with probability one, thus must equal a direct product.

This argument is inspired by the linearity test analysis of Blum, Ruby, and Rubinfeld (BLR), who also decode f to a function that is, on the one hand, close to f and, on the other hand, passes their test with probability 1. However, unlike the BLR decoder which yields a linear function after a single round of self-correction, ours inherently requires multiple iterations. For example, if f is a direct sum corrupted on all inputs with relative hamming weight around $1/4$, then $\phi(0)$ is unlikely to be correctly decoded (as $y_S 0$ and $y_{\overline{S}} 0$ will typically be corrupted) and so will typically be inconsistent with a direct sum.

Nevertheless, the high-level structure of our argument closely parallels the BLR analysis. First, in Claim 10 we show that for all but an $o(\rho)$-fraction of inputs x, the plurality in (1) is a strong majority consistent with 99% of the choices of $(S, \overline{S})$ and y. Second, we use the algebraic structure of our test (Claim 9) to show that if $D_\phi(S, \overline{S}; x, y) \neq 0$ then

$D_f(U, V; w, z) \neq 0$ for a substantially larger fraction of query sequences $(w, z_U w, z_{\overline{U}} w, z)$ that can be sampled by applying suitable "noise" to $(S, \overline{S}; x, y)$. If we represent the partition $(S, \overline{S})$ by a binary string $\sigma \in \{0,1\}^n$ (with 1 and 0 indicating memberships in S and $\overline{S}$, respectively), we show that the relevant noise can be modeled by independent fixed-probability *erasures* applied to the symbols of σ, x, and y. Using hypercontractivity bounds for the binary erasure channel [11], we conclude that ϕ fails the test on a significantly smaller fraction of queries than f does.

In the special case when the target group is $\mathbb{Z}_2$, the soundness error of D_f can be directly shown to be within a constant factor of the soundness error of the Dinur-Golubev tester (even though the two tests are different). The main motivating applications for function partitionability, however, concern real-valued functions [6]. The analysis of our $\oplus$-partionability testers for such functions relies on Theorem 1.

The idea of soundness analysis by iterative plurality decoding was introduced by Ben-Sasson et al. [2] and used by Shpilka and Wigderson [14] in the context of randomness-efficient linearity testing.

Testing partitionability

The main ingredient in our $\oplus$-partitionability algorithms is the direct 2-sum test D_f. The structure of this test allows us to efficiently detect a pair of variables x_s, x_t that must fall in the same component of the partition in any far from $\oplus$-partitionable function, effectively reducing the instance size by one variable.

Our $\otimes$-partitionability test looks for an input variable that is influential in at least two of the output coordinates of f. The analysis of this test is based on Lemma 24, which states that such a variable must exist in any far from partitionable function.

Organization

Section 2 outlines the proof of Theorem 1 in the case when the domain is the Boolean hypercube. The analysis is based on the convergence of the iterative decoder (Lemma 6), which is proved in Section 3. To prove Theorem 1 we use a reduction from testing functions over arbitrary product domains to testing functions on the hypercube (See the full version [5] for details of this reduction). Sections 4 and 5 describe and analyze the partitionability testers for direct sum and direct product, respectively.

Definitions and Notation

Let $\mathcal{D} \doteq \mathcal{D}_1 \times \ldots \times \mathcal{D}_n$ be a finite set. For strings $x, y \in \mathcal{D}$ and a set of indices $S \subseteq [n]$, let x_S to refer to the projection of x onto the coordinates in S. For strings $x^{(1)}, \ldots x^{(k)} \in \mathcal{D}$, and a partition $S_1, \ldots, S_k$ of $[n]$, let $x^{(1)}_{S_1} \ldots x^{(k)}_{S_k}$ be the string in $\mathcal{D}$ that is identical to $x^{(i)}$ on indices in S_i. For a bipartition $(S, \overline{S})$, we often write $x_S y$ instead of $x_S y_{\overline{S}}$.

In sections 2 and 3 we identify a bipartition $(S, \overline{S})$ of $[n]$ with its indicator vector $\sigma \in \{0,1\}^n$, and write $D_f(\sigma; x, y)$ instead of $D_f(S, \overline{S}; x, y)$, and x_σ instead of x_S.

We extend the definition of D_f to pairs of disjoint sets (S, T) that do not necessarily partition $[n]$ as

$$D_f(S, T; x, y) \doteq f(x) - f(y_S x) - f(y_T x) + f(y_{S \cup T} x).$$

2 Direct Sum Test for Functions on the Boolean Hypercube

The following dual characterization of direct sums motivates our test.

▶ **Fact 4.** *A function $f : \{0,1\}^n \to \mathcal{G}$ is a direct sum if and only if $D_f(\pi; x, y) = 0$ for every choice of $x, y, \pi \in \{0,1\}^n$.*

Proof of Fact 4. The "only if" direction is immediate from the definition of a direct sum. We prove the "if" direction. Let f be such that $D_f(\pi; x, y) = 0$ for every choice of $x, y, \pi \in \{0,1\}^n$. Fix $y \in \{0,1\}^n$. For every $x \in \{0,1\}^n$ we can write $f(x)$ as

$$\begin{aligned} f(x) &= f(x_{\{1\}}y) + f(y_{\{1\}}x) - f(y) \\ &= f(x_{\{1\}}y) + f(x_{\{2\}}y) + f(y_{\{1,2\}}x) - 2f(y) \\ &\vdots \\ &= f(x_{\{1\}}y) + f(x_{\{2\}}y) + \ldots + f(x_{\{n\}}y) - (n-1)f(y). \end{aligned}$$

Therefore, f is a direct sum. ◀

Algorithm 1 Direct sum test for functions over $\{0,1\}^n$.

Oracle : $f\colon \{0,1\}^n \to \mathcal{G}$

1 Sample $x, y, \pi \in \{0,1\}^n$ independently and uniformly at random.
2 If $f(x) + f(y) - f(x_\pi y) - f(y_\pi x) = 0$, **accept**.
3 Else, **reject**.

By Fact 4, the test accepts every direct sum with probability 1. The following proposition establishes soundness of the test. Let $\rho(f)$ denote the probability that Algorithm 1 rejects the function f. That is, $\rho(f) \doteq \Pr_{x,y,\pi}[D_f(\pi; x, y) \neq 0]$.

▶ **Proposition 5** (Soundness). *There exist a universal constant $\eta \in [0,1]$ such that for every function $f : \{0,1\}^n \to \mathcal{G}$,*

$$\rho(f) \geq \min(\delta/4, \eta),$$

where δ is the distance between f and the set of direct sums.

▶ **Lemma 6** (Iterative decoding). *There exists a universal constant $\eta \in [0,1]$ such that for every function $f : \{0,1\}^n \to \mathcal{G}$ with $\rho(f) < \eta$, there exists a function $\phi : \{0,1\}^n \to \mathcal{G}$ such that:*

(i) *the function ϕ is $2\rho(f)$-close to f, and*
(ii) $\rho(\phi) \leq \rho(f)/2$.

Proof of Proposition 5. Iteratively applying Lemma 6 results in a sequence of functions $f = f_0, f_1, \ldots$, such that for all $t \geq 1$, (i) the distance between f_t and f_{t-1} is at most $2\rho(f_{t-1})$, and (ii) $\rho(f_t) \leq \rho(f_{t-1})/2$. The probability that the test rejects a function is a discrete quantity. So, by (ii), there must exist an integer t such that $\rho(f_t) = 0$. That is, $D_{f_t}(\pi; x, y) = 0$ for every choice of $x, y, \pi \in \{0,1\}^n$. By Fact 4 this means f_t is a direct sum. The distance between f and the direct sum f_t at most

$$\sum_{i=0}^{t-1} 2\rho(f_i) \leq 2\sum_{i=0}^{t-1} \rho(f)/2^i \leq 4\rho(f).$$ ◀
